Conjugated bile acids, namely glyco- and tauro-3α,6α-dihydroxy-5β-cholanoic acid (hyodeoxycholic acid), 3α,7α-dihydroxy-5β-cholanoic acid (chenodeoxycholic acid), 3α,6α,7α-trihydroxy-5β-cholanoic acid (hyocholic acid) and 3α-hydroxy-6-oxo-5β-cholanoic acid (6-keto-litocholic acid) were isolated from pig bile, and subsequently transformed into the corresponding methyl esters. Separation of the methyl esters of the isolated bile acids by high-performance liquid chromatography (HPLC) was accomplished on a ZORBAX-CN column (Dupont, Boston, MA) with *n*-hexane/2-propanol/methylene chloride (89:6:5, by vol) as the mobile phase containing traces (≈1%) of amyl alcohol and water as moderators. HPLC analysis of the methyl esters also showed the presence of methyl 3α-hydroxy-6-oxo-5α-cholanoate, which was probably produced in the course of alkaline hydrolysis of the conjugated bile acids. ***Lipids 28,*** **863–865 (1993).**

3α,6α-Dihydroxy-5β-cholanoic acid, which makes up about 50% of pig bile, is often used as starting material for the synthesis of progesterone (1–3). Isolation of 3α,6α-dihydroxy-5β-chlanoic acid from pig bile is based on the crystallization of the adduct between methyl 3α,6α-dihydroxy-5β-cholanoate and benzene (4). To monitor the course of isolation of methyl 3α,6α-dihydroxy-5β-cholanoate, a procedure was developed for the separation of the mixtures of methyl esters of bile acids present in pig bile.

There have been a number of papers (5–7) dealing with the separation and analysis of methyl esters of bile acids by high-performance liquid chromatography (HPLC). Jefferson and Chang (5) and Iida *et al.* (6) described in detail both qualitative and quantitative analyses of some synthetic methyl esters of mono-, di- and trihydroxy-cholanoic acids, as well as of keto-cholanoic acids. Tint *et al.* (7) reported a method for the separation methyl esters of the bile acids from the *Alligator mississippiensis.* Scheme 1 shows the structures of the various bile acid methyl esters obtained from pig bile.

MATERIALS AND METHODS

Equipment. Methyl esters of pig bile acids were separated on a Dupont (Boston, MA) ZORBAX-CN column (25 cm × 4.6 mm i.d.) using a Waters Associates (Milford, MA) HPLC Model 6000 A, and a Waters Model IR 401 differential refractometer for detection (sensitivity: ×8), and a Kipp & Zonen (Delft, Holland) recorder (1 and 2 mm/min).

Synthesis of standard methyl esters of bile acids. Methyl 3α,6α-dihydroxy-5β-cholanoate, methyl 3α,7α-dihydroxy-5β-cholanoate, 3α,6α,7α-trihydroxy-5β-cholanoate, 3α-hydroxy-6-oxo-5β-cholanoate and 3α-hydroxy-6-oxo-5α-cholanoate were prepared from free bile acids, purchased from Sigma Chemical Co. (St. Louis, MO), by treatment with diazomethane.

Isolation of a mixture of conjugated bile acids from pig bile and their conversion to methyl esters. Sodium salts of the conjugated bile acids were precipitated from fresh pig bile with saturated aqueous sodium chloride (8). Conjugated bile acids (200 g) were hydrolyzed with KOH (100 g) in a mixture of ethyleneglycol (1000 mL) and water (500 mL) at 140°C for 10 h. After acidification with HCl (1:1) to pH 1, an oily product was obtained which, after solidification, was separated by filtration, air-dried and finally ground with mortar and pestle. The product (130 g) thus obtained was a mixture of free bile acids.

Free bile acids (90 g) were esterified with methanol (700 mL) in the presence of perchloric acid (10 mL) at room temperature for 12 h. The course of esterification was followed by thin-layer chromatography using benzene/isopropanol (85:15, vol/vol) as developing solvent. After the reaction was completed, the solution was neutralized, diluted with water and the methyl esters were extracted with diethyl ether. Yield of the mixture of crude methyl esters was 90 g.

Preparation of methyl 3α,6α-dihydroxy-5β-cholanoate. A mixture of crude methyl esters of pig bile acids (90 g) was refluxed in benzene (300 mL) for 1 h. The clear reaction mixture was left at room temperature, and after 3 d methyl 3α,6α-dihydroxy-5β-cholanoate was crystallized as a benzene adduct. The crystals were separated by filtration, and the filtrate was evaporated to dryness. The oily residue was again dissolved in benzene, and methyl 3α,6α-

Abbreviation: HPLC, high-performance liquid chromatography.

dihydroxy-5β-cholanoate was crystallized. After removal of the crystals, the procedure was repeated. Pure methyl 3α,6α-dihydroxy-5β-cholanoate was obtained in a yield of 32.6% (calculated based on the mixture of crude methyl esters of pig bile acids); m.p. 114°C. *All procedures involving benzene were carried out in a well-ventilated hood.*

RESULTS AND DISCUSSION

A procedure for the separation of the methyl esters of crude pig bile acids has been developed to follow the course of the isolation of methyl 3α,6α-dihydroxy-5β-cholanoate from this mixture.

To optimize conditions for HPLC analysis, experiments were first carried out with mixtures of standard synthetic methyl esters, which included methyl 3α-hydroxy-6-oxo-5α-cholanoate, methyl 3α,7α-dihydroxy-5β-cholanoate, methyl 3α-hydroxy-6-oxo-5β-cholanoate, methyl 3α,6α-dihydroxy-5β-cholanoate and methyl 3α,6α,7α-trihydroxy-5β-cholanoate. Figure 1 shows the chromatogram of this mixture on a ZORBAX-CN column, using *n*-hexane/2-propanol/methylene chloride (89:6:5, by vol) as mobile phase with traces of water and amyl alcohol (≈1%) as moderators. Under these conditions, an efficient separation of these methyl esters was achieved in less than 30 min.

Methyl 3α-hydroxy-6-oxo-5α-cholanoate had a retention time of 7.52 min, followed by methyl 3α,7α-dihydroxy-5β-cholanoate (9.17 min) and methyl 3α-hydroxy-6-oxo-5β-cholanoate (12.16 min). Further elution at an isobaric flow rate of 1.5 mL/min resulted in the appearance of methyl 3α,6α-dihydroxy-5β-cholanoate and methyl 3α,6α,7α-trihydroxy-5β-cholanoate at the retention times of 16.59 and 21.30 min, respectively.

The elution profile of a mixture of crude methyl esters of pig bile acids is presented in Figure 2 (left panel). Figure 2 (center and right panels) shows the elution profiles of the filtrates from the first and second recrystallization of methyl 3α,6α-dihydroxy-5β-cholanoate. The relative

FIG. 1. Peak designations and chromatographic conditions are as in Figure 1.

TABLE 1

Relative Percentage of Methyl Esters of Bile Acids in Pig Bile Fractions

Methyl ester	Crude mixture	Filtrate after first crystallization	Filtrate after second crystallization
Methyl 3α-hydroxy-6-oxo-5α-cholanoate	10.53	15.76	17.95
Methyl 3α,7α-dihydroxy-5β-cholanoate	26.85	32.23	43.21
Methyl 3α-hydroxy-6-oxo-5β-cholanoate	6.54	8.94	10.46
Methyl 3α,6α-dihydroxy-5β-cholanoate	48.25	28.23	19.07
Methyl 3α,6α,7a-trihydroxy-5β-cholanoate	5.82	8.82	9.30

percentages of individual methyl esters of bile acids in the mixture of methyl esters of crude pig bile acids and in the filtrates from first and second recrystallization are given in Table 1.

Application of HPLC under the conditions described resulted in a good separation of methyl 3α-hydroxy-6-oxo-5α-cholanoate, methyl 3α,7α-dihydroxy-5β-cholanoate, methyl 3α-hydroxy-6-oxo-5β-cholanoate, methyl 3α,6α-dihydroxy-5β-cholanoate and methyl 3α,6α,7α-trihydroxy-5β-cholanoate. Because of its accuracy and simplicity, the method has been proven useful in monitoring the preparative isolation of 3α,6α-dihydroxy-5β-cholanoic acid from pig bile.

ARTICLE

Modulation by Sphingosine of Substrate Phosphorylation by Protein Kinase C in Bovine Mammary Gland

Norio Katoh*
National Institute of Animal Health, Hokkaido Branch Laboratory, Sapporo 062, Japan

The effect of sphingosine on the phosphorylation of endogenous proteins by protein kinase C (PKC) was investigated in bovine mammary gland. Several proteins were shown to be substrates for PKC in both cytosolic and total particulate fractions by phosphorylation in the absence or presence of 1-oleoyl-2-acetyl-*sn*-glycerol, phosphatidylserine (PS) and Ca^{2+}. At concentrations of 83 μM or less, sphingosine inhibited phosphorylation of several substrates for PKC in both fractions. Phosphorylation of cytosolic 36 kDa, 21 kDa and particulate 36 kDa proteins was particularly sensitive to sphingosine. Cytosolic 97 kDa phosphorylation (which was enhanced by Ca^{2+} alone) was also sensitive to sphingosine. The inhibition was reversed by excess addition of lipid cofactors, particularly PS, but not by Ca^{2+}. At higher concentrations (167 and 417 μM), in addition to the inhibition seen at lower concentrations, sphingosine stimulated phosphorylation of several proteins, including cytosolic 19 kDa and particulate 53 kDa, which were not detected in the absence of sphingosine. The sphingosine-induced phosphorylation disappeared with excess addition of PS, but not with addition of Ca^{2+}. The results point toward the importance of the interaction of sphingosine with membrane phospholipids in the signal transduction pathway mediated by PKC-dependent phosphorylation in bovine mammary gland.
Lipids 28, 867–871 (1993).

Mammary gland is a tissue rich in glycosphingolipids, and bovine milk is known to be rich in the gangliosides GD3 and GM3, as constituents of the milk fat globule membrane derived from the plasma membrane of secretory epithelial cells (1,2). Glycosphingolipids are located at the cell surface and are believed to be important as recognition sites for mediating extracellular signals to intracellular second messengers such as diacylglycerols.

Protein kinase C (PKC) is a key enzyme in the signal transduction pathway, which is activated by the combined action of diacylglycerols, phospholipids and Ca^{2+} (3). Mammary gland PKC is suggested to be important in the gland's function. For example, mouse mammary gland PKC activity is regulated by steroid hormones (4) and is depressed during pregnancy and lactation (5). It also has been reported that mouse mammary gland PKC is translocated by prolactin from cytosol to the particulate fraction (6). Sphingosine, a constituent of glycosphingolipids, inhibits PKC (7), and the inhibition is reversed by phospholipids and diacylglycerols (7,8). The increase in sphingosine concentrations in canine kidney cells induced by the addition of a glucosylceramide synthase inhibitor resulted in reduced PKC activity, as well as in inhibition of cell growth and DNA synthesis (9), suggesting an intimate relationship between endogenous sphingosine concentrations and PKC activity. Phenotypic changes in 3T3 cells are also suggested to be associated with accumulation of sphingosine induced by a ceramide analogue (10).

PKC is thought to function by phosphorylating its intracellular substrate proteins after activation by diacylglycerols which are transiently produced by extracellular signals and translocation from the cytosol to particulate fractions. In bovine mammary gland, several proteins have been identified as substrates for PKC in both cytosolic and total particulate fractions (11). The purpose of the present study was to define the effect of sphingosine on PKC-dependent endogenous protein phosphorylation in bovine mammary gland.

MATERIALS AND METHODS

Materials. D-sphingosine from bovine brain cerebrosides, 1-oleoyl-2-acetyl-*sn*-glycerol (OAG), phosphatidylserine (PS), histone H1 (type III-S) and leupeptin were purchased from Sigma Chemical Co. (St. Louis, MO). Phenylmethylsulfonyl fluoride (PMSF) was from Boehringer (Mannheim, Germany). [γ-^{32}P]adenosine triphosphate (ATP) was from New England Nuclear-DuPont (Wilmington, DE). Cow mammary glands in the lactating state were obtained from a local slaughterhouse. The *pars glandularis* was cut into small blocks and frozen at −80°C until use.

Preparation of subcellular fractions. The tissue was thawed, cut into small pieces and homogenized in 9 vol of 0.25 M sucrose containing 20 mM *tris*(hydroxymethyl)-aminomethane (Tris)-HCl, pH 7.5, 2.5 mM ethyleneglycol *bis*(2-aminoethylether)tetraacetic acid (EGTA), 10 mM 2-mercaptoethanol, 0.5 mM PMSF and 10 μg/mL leupeptin, using a Polytron (Kinematica, Littau, Switzerland). The homogenate was centrifuged at 38,000 × *g* for 60 min; the resultant supernatant is being referred to as cytosol. The pellet was treated with 0.3% Triton X-100 for 60 min on ice, then centrifuged at 38,000 × *g* for 60 min, and the supernatant obtained was used as (solubilized) total particulate fraction.

PKC assay. The standard assay mixture (0.2 mL) contained 25 mM Tris-HCl, pH 7.5, 10 mM $MgCl_2$, 40 μg of histone, 50 μM [γ-^{32}P]ATP and appropriate amounts of the subcellular proteins, in the absence or presence of OAG (1 μg), PS (5 μg) and Ca^{2+} (1 μM). Ca^{2+}–EGTA buffer was prepared in the presence of 250 μM EGTA (from the enzyme solution) (12). The cofactor concentrations were similar to those used by other investigators (13,14). In particular, the 1 μM Ca^{2+} was physiological, because the intracellular Ca^{2+} concentration was in the micromolar range. Sphingosine suspended in 20 mM Tris-HCl, pH 7.5, was sonicated and added to the mixture at different concentrations as indicated in the figures and tables. The reaction was initiated by the addition of ATP and continued

Abbreviations: ATP, adenosine triphosphate; DEAE, diethylaminoethyl; EGTA, ethyleneglycol *bis*(2-aminoethylether)tetraacetic acid; OAG, 1-oleoyl-2-acetyl-*sn*-glycerol; PKC, protein kinase C; PMSF, phenylmethylsulfonyl fluoride; PS, phosphatidylserine; SDS, sodium dodecyl sulfate; Tris, *tris*(hydroxymethyl)aminomethane.

for 5 min at 30°C. PKC activity was determined by subtracting basal activity in the absence of cofactors.

Endogenous protein phosphorylation. The reaction conditions for phosphorylation were the same as those described for the PKC assay except for the deletion of histone from the mixture. Sodium dodecyl sulfate (SDS)-polyacrylamide gel electrophoresis was done using a 12% gel. After electrophoresis, gels were stained with Coomassie brilliant blue, destained, dried and exposed to Kodak X-omat AR film (Rochester, NY) for 5–7 d at −80°C with the aid of a Kodak Hi-Plus intensifying screen (Rochester, NY).

Other methods. PKC from mammary gland cytosol was partially purified by diethylaminoethyl (DEAE)-cellulose (DE-52) chromatography (11). PKC from pig spleen was highly purified using ammoniumsulfate fractionation, DE-52, Sephacryl S-200 and protamine-Sepharose 4B chromatography (15). Protein was determined by the method of Bradford (16).

RESULTS

Sphingosine dose-dependently inhibited the activity of PKC obtained by DEAE-cellulose chromatography of mammary gland cytosol (Fig. 1). The IC_{50} value was estimated to be 32 μM, which was similar to the reported value (17). At a higher concentration (417 μM), sphingosine slightly increased both the basal and cofactor-dependent activities. The sphingosine inhibition of PKC was reversed by the addition of higher concentrations of OAG or PS (Fig. 2). Tenfold excess addition of OAG (50 μg/mL) and PS (250 μg/mL) was enough to reverse the inhibition of PKC activity in the presence of 83 μM sphingosine. Reversal by higher concentrations of cofactors of sphingosine inhibition was seen using PKC from different sources and of different purities (Table 1). In the absence of sphingosine, addition of a higher concentration of OAG (50 μg/mL) enhanced PKC activity in both cytosol and the DEAE-cellulose fraction, whereas higher concentrations of PS (250 μg/mL) and Ca^{2+} (250/μM) had little effect on PKC activity. Sphingosine at a concentration of 83 μM was less effective in inhibiting PKC activity in the cytosol than in the DEAE-cellulose fraction. The excess addition of both OAG and PS reversed PKC inhibition in the two fractions, whereas Ca^{2+} was without effect. With 417 μM sphingosine, PKC activity in the two fractions was completely inhibited. However, basal activity was increased, particularly in the cytosol. This increase in basal activity was not observed when highly purified PKC from pig spleen was used in the assay. The increased basal activity of cytosol was restored nearly to the control level by PS, but not by OAG or Ca^{2+}.

The cytosolic and total particulate proteins were phosphorylated in the absence or presence of 10 μM Ca^{2+} and 25 μg/mL PS (Fig. 3). The higher Ca^{2+} concentration was used to fully activate PKC and calmodulin-dependent protein kinase(s). OAG was not included because it was not required for PKC activation at the high Ca^{2+} concentration. Of the phosphoproteins detected, cytosolic 97 kDa phosphorylation was dependent on Ca^{2+}, but not on PS. Its electrophoretic mobility was the same as that of the phosphorylase b used as the marker protein, suggesting that this was phosphorylase b (the substrate for phosphorylase kinase). By comparison, cytosolic 91 kDa, 56 kDa and 38-36 kDa phosphorylation was stimulated by Ca^{2+}, but was more enhanced by the combination with PS. Phosphorylation of cytosolic 72 kDa, 21 kDa and a high molecular weight protein (indicated by the arrow; heavier than myosin heavy chain, 205 kDa), as well as of particulate 91 kDa, 43 kDa, 38 kDa and 36 kDa proteins, showed a more distinct dependency on the two cofactors. Phosphorylation of cytosolic 89 kDa and particulate 56 kDa proteins was considerably enhanced by PS alone. Cytosolic 27 kDa protein was phosphorylated in the absence of the cofactors, but sometimes acted as the PKC substrate (see Figs. 4 and 5). Collectively, these phosphoproteins, except for cytosolic 97 kDa, appeared to be the substrates for PKC. Casein (30 kDa) phosphorylation was independent of the cofactors in the cytosol, but in the particulate fraction were enhanced by PS. The reason for this is unknown at present (the PS-dependency of casein is not apparent in Fig. 6). As described in Materials and

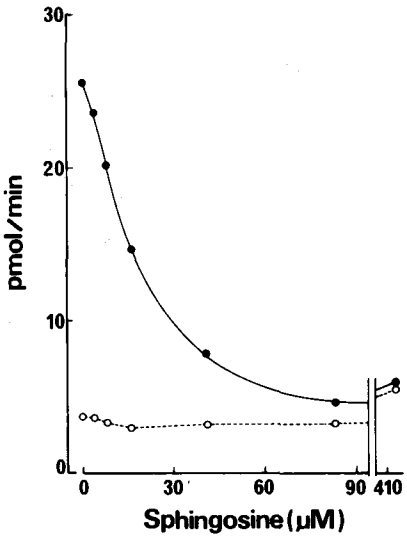

FIG. 1. Dose-dependent inhibition by sphingosine of the activity of protein kinase C partially purified by diethylaminoethyl-cellulose chromatography of the cytosol from bovine mammary gland. The eluant (0.02 mL containing 0.031 mg protein) was assayed in the absence (○) or presence (●) of 5 μg/mL 1-oleoyl-2-acetyl-*sn*-glycerol, 25 μg/mL phosphatidylserine and 1 μM Ca^{2+}.

[a]PKC, protein kinase C.
[b]OAG, 1-oleoyl-2-acetyl-*sn*-glycerol.
[c]PS, phosphatidylserine.
[d]n.d., Not determined.

Methods, the homogenate was centrifuged at 38,000 × *g*, instead of 105,000 × *g*. The centrifugation at 38,000 × *g* seemed to reduce the casein contamination of the particulate fraction. Phosphorylation patterns of the 105,000 × *g* supernatant and pellet were essentially the same as those obtained with the 38,000 × *g* fractions (data not shown).

Figure 4 shows the effect of sphingosine on the phosphorylation of the cytosolic proteins in the absence or presence of 5 μg/mL OAG, 25 μg/mL PS and 1 μM Ca^{2+}. Sphingosine inhibited phosphorylation of several proteins. Of the PKC substrates, phosphorylation of the high molecular weight 89, 36 and 21 kDa proteins was inhibited by 83 μM sphingosine. By comparison, 91, 41 and 38 kDa

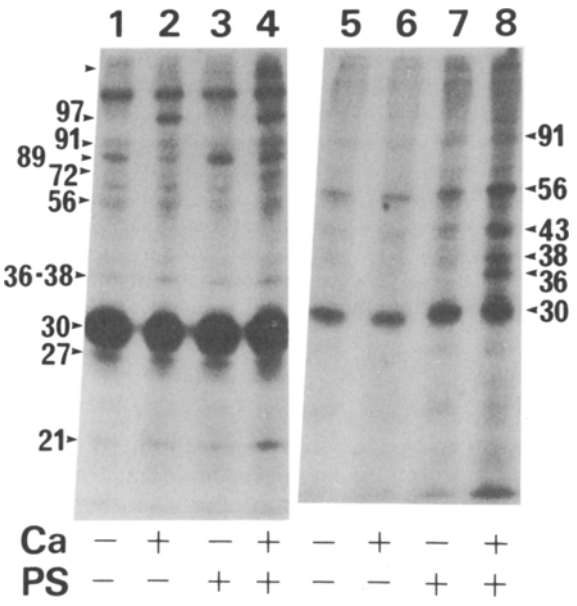

FIG. 3. Phosphorylation of cytosolic (1–4) and total particulate proteins (5–8) of bovine mammary gland in the absence or presence of Ca^{2+} (10 μM) and phosphatidylserine (PS, 25 μg/mL). Endogenous protein kinases in the subcellular fractions were used as the enzyme source.

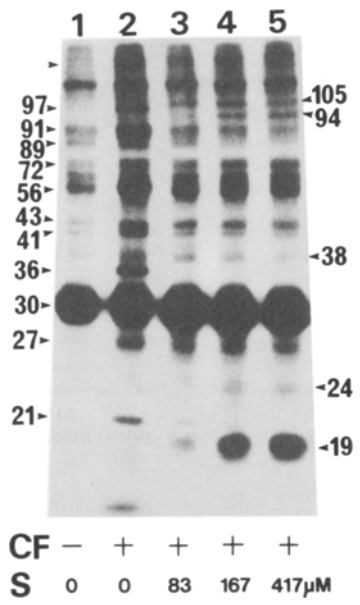

FIG. 4. Autoradiogram showing the effect of sphingosine on the phosphorylation of the cytosolic proteins by protein kinase C. CF, cofactors (5 μg/mL 1-oleoyl-2-acetyl-*sn*-glycerol, 25 μg/mL phosphatidylserine and 1 μM Ca^{2+}); S, sphingosine.

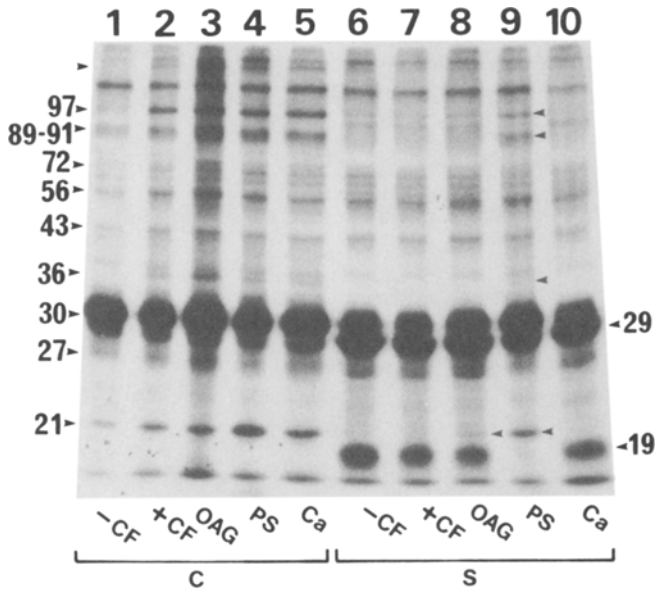

FIG. 5. Reversal by excess addition of the protein kinase C (PKC) cofactors of the cytosolic protein phosphorylation by PKC in the presence of 417 μM sphingosine. C, control (without sphingosine); S, sphingosine; CF, cofactors [5 μg/mL 1-oleoyl-2-acetyl-*sn*-glycerol (OAG), 25 μg/mL phosphatidylserine (PS) and 1 μM Ca^{2+}]; OAG, (50 μg/mL OAG, 25 μg/mL PS and 1 μM Ca^{2+}); PS, (250 μg/mL PS, 5 μg/mL OAG and 1 μM Ca^{2+}); Ca, (250 μM Ca^{2+}, 5 μg/mL OAG and 25 μg/mL PS).

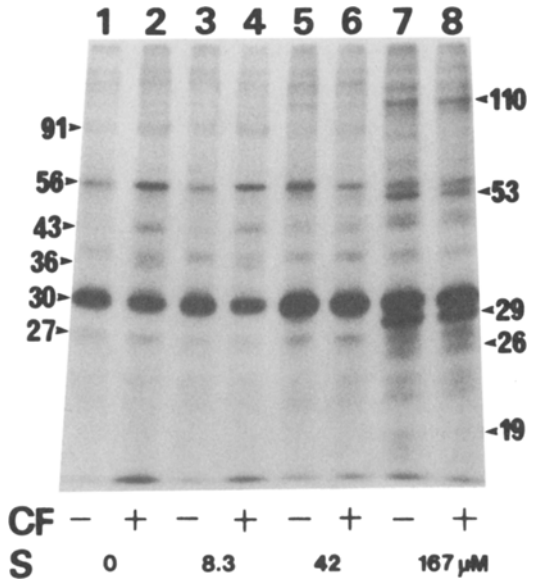

FIG. 6. Effect of sphingosine on total particulate protein phosphorylation by protein kinase C. CF, cofactors (5 μg/mL 1-oleoyl-2-acetyl-*sn*-glycerol, 25 μg/mL phosphatidylserine and 1 μM a^{2+}); S, sphingosine.

phosphorylation was relatively unaffected by sphingosine, because these protein bands were detected, although faintly, even with 417 μM sphingosine. The 72, 56, 43 kDa and 27 kDa phosphorylations appeared to be resistant to sphingosine. The 97 kDa phosphorylation (which was enhanced by Ca^{2+} alone) was effectively inhibited by 83 μM sphingosine. Casein and 135 kDa protein (between the arrow and 97 kDa), whose phosphorylation was independent of the cofactors, were not affected by sphingosine. At higher concentrations of sphingosine (167 and 417 μM), several phosphorylated bands (105, 94, 24 and 19 kDa), which were not detected in the absence of sphingosine (Lane 2), appeared. The bands were not seen when proteins were not included in the reaction mixture, indicating that these bands were not due to artifacts.

The inhibition of the phosphorylation in the cytosol by sphingosine was reversed by excess addition of lipid cofactors (Fig. 5). PS (250 μg/mL) effectively reversed the phosphorylation of 97, 91-89, 36 and 21 kDa proteins (Lane 9). OAG (Lane 8) was less effective in doing so under the conditions used (50 μg/mL in the presence of 417 μM sphingosine), although it enhanced phosphorylation in the absence of sphingosine (Lane 3). Ca^{2+} (250 μM) was without effect (Lane 10). Phosphorylation of 72, 56, 43 and 27 kDa proteins was enhanced by 417 μM sphingosine (compare Lanes 1 and 6). In the presence of cofactors, the effect of sphingosine on 72, 56 and 43 kDa phosphorylation was unclear, irrespective of the cofactor concentrations. However, PS reversed the enhanced 27 kDa phosphorylation nearly to the level seen in Lane 2.

Phosphorylated bands detected at higher concentrations of sphingosine (Fig. 4) can also be seen in Figure 5. Although the 105 kDa band is not clear, 94 kDa (between 97 kDa and 91-89 kDa), 24 kDa (between 27 kDa and 21 kDa) and 19 kDa bands can be seen in the autoradiogram. The appearance of these bands was independent of the cofactors (Lane 6), as in the case of the PKC assay (Table 1). These bands disappeared almost completely upon excess addition of PS (Lane 9), but not upon excess addition of OAG or Ca^{2+}.

In the total particulate fraction, sphingosine suppressed 91 and 36 kDa phosphorylation (Fig. 6). The effect of sphingosine on 56, 43, 38 (between 43 and 36 kDa) and 27 kDa phosphorylation was unclear. Phosphorylated bands that were not detected in the absence of sphingosine were seen with higher concentrations of sphingosine. The 19 kDa band, which was distinct for the cytosol, was faintly seen in the particulate fraction. A 53 kDa band not present in the cytosol, was seen in the particulate fraction, indicating that the band pattern due to sphingosine was different in the cytosol and the particulate fraction. These bands disappeared when excess PS (250 μg/mL) was included (not shown). Phosphorylation of 91 and 36 kDa proteins was also reversed by excess addition of PS, but not by excess addition of OAG or Ca^{2+}.

DISCUSSION

The present study has shown that sphingosine inhibits endogenous protein phosphorylation catalyzed by PKC, as well as PKC activity using histone as the substrate, in bovine mammary gland. The inhibition was overcome by excess addition of lipid cofactors for PKC, particularly PS. To measure PKC activity, the lipid/vesicle assay was used instead of Triton X-100/lipid micellar assay (17). The results obtained with the lipid/vesicle assay were consistent with the phosphorylation patterns shown in autoradiography. For example, the higher basal activity in the cytosol with 417 μM sphingosine (Table 1) was

consistent with the appearance of phosphorylated bands such as the 19 kDa band (Figs. 4 and 5).

The 19 kDa band is similar to that of the 18 kDa protein which is phosphorylated in the presence of 0.4 mM sphingosine in Jurkat T cells (18). The 19 kDa phosphorylation, however, was induced only by pharmacological doses of sphingosine [the band was detected faintly with 83 μM sphingosine (Fig. 4), but not at 42 μM (data not shown)]. Because cellular sphingosine levels in the resting state are in the micromolar range (19), the physiologic significance of the 19 kDa phosphorylation is presently not clear. However, the pathologic importance of the phosphorylation cannot be ruled out, because tumor necrosis factor α, which is increased in inflammation such as mastitis, is known to increase the cellular sphingosine levels (20).

Sphingosine also effectively inhibited phosphorylation of cytosolic 97 kDa protein, and the inhibition was reversed by excess addition of PS. This protein is suggested to be phosphorylase b, because it was phosphorylated by Ca^{2+} alone. The reversal of inhibition by excess PS may be explained by reduced sphingosine binding with the calmodulin subunit of phosphorylase kinase. The inhibition by sphingosine of calmodulin-dependent phosphorylation has already been reported (21). In rat mammary gland, acetyl-CoA carboxylase (240 kDa) and ATP-citrate lyase (116 kDa) have been identified as substrates for PKC (22). The two enzymes are also substrates for calmodulin-dependent multiprotein kinase (22). The high molecular weight substrate (Figs. 3–5) seems to be different from acetyl-CoA carboxylase, because its phosphorylation was not enhanced by Ca^{2+} alone.

PKC substrates can be classified into two groups with respect to the mode of modulation by sphingosine: one is inhibited at both lower and higher concentrations and includes the 36 kDa protein in both the cytosolic and particulate fractions; the other group containing cytosolic 72 kDa protein is resistant to inhibition by sphingosine at lower concentrations, and its phosphorylation is enhanced at higher concentrations in the absence of the cofactors. The different sensitivity may be explained by the assumption that the substrates in the two groups are catalyzed by different PKC isozymes. Another possibility is that sphingosine directly interacts with the substrate proteins. Since sphingosine interacts with phospholipids (7,8) and inhibition of substrate phosphorylation by sphingosine is overcome by PS, it is conceivable that sphingosine binds to phospholipid-binding and Ca^{2+}-binding proteins such as annexins (23). Mammary gland contains proteins of the annexin family, including calelectrin (70 kDa) and calpactin (36 kDa) (24). Our preliminary study suggests that the 36 kDa protein in both fractions is annexin I because the protein reacted with anti-annexin I as shown by immunoblot analysis. Identification of substrates for PKC as well as for calmodulin-dependent protein kinase(s) is required for further study of the physiologic and pathologic importance of sphingosine in bovine mammary gland function.

ACKNOWLEDGMENTS

I am grateful to M.K. Barrymore for his critical reading of the manuscript. This study was supported in part by a Grant-in-Aid (Glycotechnology Program) from the Ministry of Agriculture, Forestry and Fisheries of Japan.

Intravenous Injection of Tridihomo-γ-linolenoyl-glycerol into Mice and Its Effects on Delayed-Type Hypersensitivity

Hirofumi Taki, Norio Nakamura, Tomohito Hamazaki* and Masashi Kobayashi
The First Department of Internal Medicine, Toyama Medical and Pharmaceutical University, Toyama 930-01, Japan

Highly purified tridihomo-γ-linolenoyl-glycerol (DGLA-TG) was emulsified with egg yolk lecithin as a 10% (wt/vol) DGLA-TG emulsion. We injected 0.05 or 0.5 mL of the emulsion into mice through the tail vein and investigated its effects on the fatty acid composition of spleen cells and on delayed-type hypersensitivity (DTH) response. At 1 h after the injection, dihomo-γ-linolenic acid (DGLA) concentrations were increased significantly in the total phospholipid fraction of spleen cells from 1.21 ± 0.13 mol% to 2.09 ± 0.74 mol% ($P < 0.02$) and 7.95 ± 1.25 mol% ($P < 0.001$) in the 0.05-mL and 0.5-mL groups, respectively. Mice, which had already been immunized with sheep red blood cells (SRBC), were challenged by the injection of SRBC into the right-hind footpad. Intravenous injection into mice with 0.5 mL of the emulsion immediately before the challenge almost completely suppressed DTH response measured by the swelling of the right-hind footpads 24 h thereafter. This inhibitory effect on the DTH response was significant with as little as 0.05 mL of the emulsion, whereas a soybean oil emulsion was not effective at all. In conclusion, intravenous injection of a DGLA emulsion increased DGLA concentrations in immune cells within 1 h and suppressed the DTH reaction.
Lipids 28, 873–876 (1993).

Dihomo-γ-linolenic acid (20:3n-6, DGLA) is an elongation product of γ-linolenic acid (18:3n-6, GLA). DGLA is further converted to arachidonic acid (20:4n-6, AA) through Δ5 desaturation. DGLA is also the precursor fatty acid of prostaglandin E_1 (PGE_1), which has immunosuppressive effects through increase in intracellular cyclic adenosine monophosphate (AMP) levels (1). *In vitro* administration of DGLA depresses interleukin-2 (IL-2) production by human peripheral mononuclear lymphocytes (2) and the proliferation of human synovial cells also by increasing their cytosolic cyclic AMP levels (3). In addition, oral administration of DGLA has been shown to depress human platelet aggregation (4–6).

Delayed-type hypersensitivity (DTH) response is one of the T cell-mediated immune responses (7) and is probably related to allograft rejection. In the present study we formulated an injectable emulsion of DGLA and examined the effect of its injection on DTH response. We also checked how quickly injection of the emulsion changed the fatty acid composition of mouse spleen cells and plasma.

MATERIALS AND METHODS

Materials. Female BALB/c mice (6–8 wk of age) were purchased from Sankyo Labo Service (Tokyo, Japan). They were housed in groups of five in a temperature-, light- and humidity-controlled room. They were fed standard chow and tap water *ad libitum* throughout the experiments. Tridihomo-γ-linolenoyl-glycerol (DGLA-TG) (purity >95%) was kindly donated by Idemitsu Petrochemical Co. (Tokyo, Japan) and emulsified according to the method of Geyer *et al.* (8). One hundred mL of the emulsion contained 10 g of DGLA-TG, 1.2 g egg yolk lecithin (Asahi Chemicals, Tokyo, Japan) as an emulsifier and 2.5 g glycerol. A 10% soybean oil emulsion (Intralipid) was generously donated by Otsuka Pharmaceuticals (Tokyo, Japan). Sheep red blood cells (SRBC) purchased from Nippon Bio-Sup Center (Tokyo, Japan) were washed three times and resuspended in sterilized saline just before use.

Measurement of DTH response. Mice were primed by subcutaneous injection of 0.1 mL of a 10% SRBC suspension. Six days later, 50 μL of a 20% SRBC suspension was injected into the right-hind footpad. Mice were injected with 0.05 or 0.5 mL of the DGLA-TG emulsion, 0.5 mL of Intralipid, or 0.5 mL of a 2.5% glycerol solution through the tail vein, immediately before the second injection of SRBC. In order to inject 0.05 mL of the emulsion, 0.5 mL was injected after the emulsion had been diluted 10 times with the glycerol solution.

Twenty-four hours after the second injection of SRBC, the dorsoventral thickness of the right- and left-hind footpads of each mouse was measured three times with a vernier caliper. The mean difference between both footpads was taken as the DTH response for each mouse.

Fatty acid analysis. A separate set of experiments was used for fatty acid analysis. Mice were injected similarly with 0.05 or 0.5 mL of the DGLA-TG emulsion without any SRBC injection. The fatty acid composition of the spleen cell phospholipid (PL) and plasma free fatty acid (FFA) fractions was analyzed before the injection (0 h), and 1 and 6 h thereafter. Five mice were used at each time point and for each dose.

Ethylenediaminetetraacetic acid-anticoagulated blood samples were taken from the retroorbital plexus under diethyl ether anesthesia, and plasma was obtained by centrifugation. Spleens were also obtained immediately after the blood sampling. Each spleen was minced through a stainless steel mesh and suspended in cold Hank's balanced salt solution without phenol red (HBSS; Whittaker Bioproducts, Walkersville, MD). Contaminating red blood cells were lysed with a 34 mM *tris*(hydroxymethyl)aminomethane-NH_4Cl buffer (pH 7.4), and spleen cells were washed three times with HBSS. Plasma and spleen cells were stored at −80°C until fatty acids were analyzed.

The fatty acid composition of spleen cells and plasma was analyzed as follows: The total PL fraction of spleen cells and the FFA fraction of plasma were separated by thin-layer chromatography (TLC) on Silica Gel 60 plates (5 × 20 cm, 0.25 mm thick; Merck, Darmstadt, Germany) after total lipid extraction with chloroform/methanol (2:1, vol/vol). After transmethylation with 6% sulfuric acid/methanol, fatty acid methyl esters of each fraction were analyzed using a GC-14A gas chromatograph (Shimadzu, Kyoto, Japan) equipped with an SP-2330 capillary

Abbreviations: AA, arachidonic acid; AMP, adenosine monophosphate; ANOVA, analysis of variance; DGLA-TG, tridihomo-γ-linolenoyl-glycerol; DGLA, dihomo-γ-linolenic acid; DTH, delayed-type hypersensitivity; FFA, free fatty acid; GLA, γ-linolenic acid; HBSS, Hank's balanced salt solution; IL-2, interleukin-2; LT, leukotriene; PL, phospholipid; PG, prostaglandin; SRBC, sheep red blood cell; TLC, thin-layer chromatography.

column (30 m × 0.32 mm i.d.; Supelco, Bellefonte, PA). The temperature of the injection port was 250°C. Column temperature was kept at 160°C for 10 min, then raised from 160 to 200°C at 4°C/min and then held at 200°C. The detection was done by flame-ionization. Helium was used as a carrier gas at an inlet pressure of 0.56 kg/cm^2. Peaks were identified by comparison of retention times with those of authentic fatty acid standards (Sigma Chemical Co., St. Louis, MO).

Statistics. The results are expressed as means ± SD. The DTH response of the emulsion-injected groups was compared with that of the vehicle-injected group by an unpaired *t*-test with Bonferroni's adjustment after analysis of variance (ANOVA). Fatty acid concentrations after DGLA injection were similarly compared with those before the injection. In the case of spleen cells, Wilcoxon 2-sample test was also performed with Bonferroni's adjustment. In the case of plasma-free DGLA concentrations, data were log-transformed and compared using the unpaired *t*-test with Bonferroni's adjustment after ANOVA. $P < 0.05$ was taken as significant.

RESULTS

As shown in Figure 1, the injection of the DGLA-TG emulsion immediately before the second injection of SRBC markedly suppressed DTH response as compared with vehicle injection, whereas Intralipid injection did not alter the response at all. The effect of the DGLA-TG emulsion was dose-dependent, and the DTH response was significantly inhibited, even with 0.05 mL of the DGLA-TG emulsion (Fig. 1).

Vehicle injection did not change the fatty acid composition of either spleen cells or plasma (data not shown); therefore, for simplicity's sake, we compared the fatty acid composition before and after DGLA injection instead of comparing data after DGLA and vehicle injection at each time point and at each dose. Changes in the fatty acid composition of the spleen cell PL fraction after DGLA injection are shown in Table 1. DGLA concentrations were significantly increased both 1 and 6 h after the injection at either dose. AA concentrations were slightly, but significantly, decreased 1 h after the injection in the 0.5-mL group only.

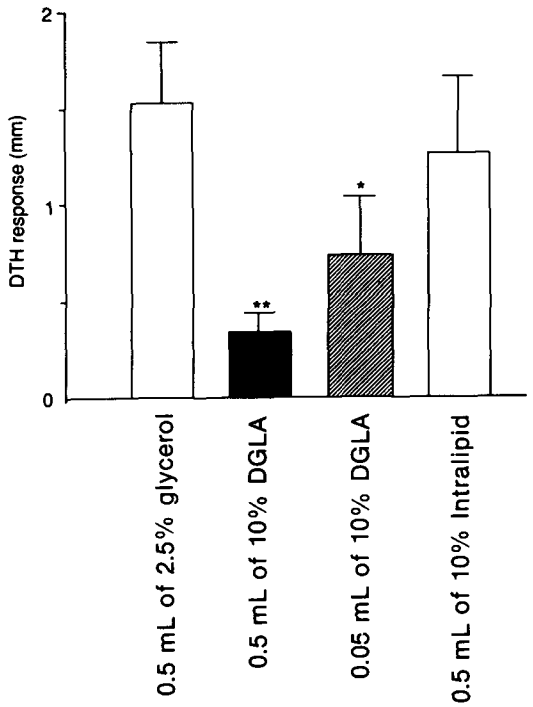

FIG. 1. The effect of a dihomo-γ-linolenic acid (DGLA) emulsion and a soybean oil emulsion (Intralipid) on delayed-type hypersensitivity (DTH) response. The effect of intravenous administration of a 10% tridihomo-γ-linolenoyl-glycerol emulsion on DTH response to sheep red blood cells (SRBC) was compared with that of a 2.5% glycerol solution. For this purpose, 0.05 mL or 0.5 mL of the DGLA emulsion, 0.5 mL of 10% Intralipid, or 0.5 mL of the glycerol solution was injected through the tail vein immediately before the second challenge of SRBC into the right-hind footpad. Twenty-four hours later the thickness of both hind footpads was measured three times. A mean difference (in mm) between the right and left footpad thickness was regarded as the DTH response. The DTH response of each group is expressed as mean ± SD from five mice. Significant differences from the control group injected with 0.5 mL of the glycerol solution are shown by *$P < 0.01$ and **$P < 0.001$.

Changes in DGLA concentrations in the plasma FFA

TABLE 1

Changes in Fatty Acid Composition (mol %) of the Spleen Cell PL Fraction after DGLA Injection[a]

	0 h	0.05-mL injection		0.5-mL injection	
	(n = 5)	1 h (n = 5)	6 h (n = 5)	1 h (n = 5)	6 h (n = 5)
16:0	26.94 ± 0.76	27.68 ± 2.54	24.91 ± 0.53	26.55 ± 3.79	28.52 ± 5.05
18:0	15.60 ± 0.72	17.10 ± 0.30[e]	15.33 ± 0.49	14.44 ± 1.65	16.10 ± 1.03
18:1n-9	6.30 ± 0.49	6.50 ± 0.56	6.77 ± 0.35	6.52 ± 0.45	6.52 ± 0.32
18:1n-7	2.87 ± 0.15	2.98 ± 0.12	2.83 ± 0.24	2.76 ± 0.22	3.01 ± 0.18
18:2n-6	7.69 ± 0.39	7.99 ± 0.12	7.99 ± 0.37	7.74 ± 0.57	8.11 ± 0.45

20:4n-6	17.42 ± 0.60	16.55 ± 0.48	17.51 ± 0.80	15.69 ± 0.49[d]	16.86 ± 1.08
22:4n-6	1.71 ± 0.10	1.66 ± 0.08	1.75 ± 0.12	1.30 ± 0.73	1.60 ± 0.24
22:5n-3	1.84 ± 0.10	1.90 ± 0.23	1.94 ± 0.13	1.57 ± 0.26	1.80 ± 0.34
22:6n-3	7.29 ± 0.44	6.89 ± 0.31	7.36 ± 0.54	6.56 ± 0.47	6.56 ± 0.87

[a]Mice were injected with 0.05 or 0.5 mL of a 10% dihomo-γ-linolenic acid (DGLA) emulsion through the tail vein. Spleen cells were obtained 1 or 6 h after the injection and analyzed for fatty acid composition of their total phospholipid (PL) fraction by gas chromatography. Fatty acids, which comprised more than 1%, are listed. [b-f]Data were compared with the 0-h group; [b]$P < 0.02$; [c]$P < 0.01$; [d]$P < 0.005$; [e]$P < 0.001$ by unpaired *t*-test with Bonferroni's adjustment; and [f]$P < 0.05$ by Wilcoxon 2-sample test with Bonferroni's adjustment.

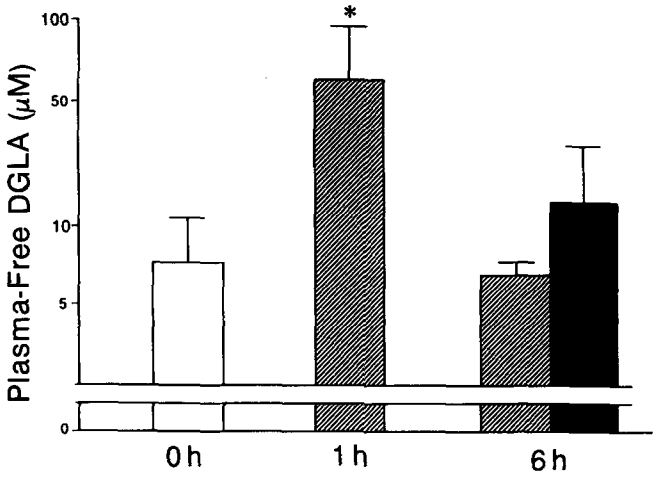

FIG. 2. Comparison of plasma free dihomo-γ-linolenic acid (DGLA) concentrations before (the 0-h group, white column) and after the injection of 0.05 mL (grey columns) or 0.5 mL (black column) of a 10% tridihomo-γ-linolenoyl-glycerol emulsion. Data were log-transformed. Significant difference from the 0-h group is indicated by *$P < 0.01$.

fraction are shown in Figure 2. The concentrations were significantly increased 1 h after the injection in the 0.05-mL group. We could not successfully analyze the plasma FFA fraction 1 h after the injection in the 0.5-mL group because the excessive amount of DGLA-TG present in plasma samples made it difficult to separate FFA from DGLA-TG by TLC.

DISCUSSION

A number of studies have been concerned with the effects of orally administered DGLA in animals (4,6) and in humans (4,5,9). However, the effect of intravenously injected DGLA, except for our recent work (10), had not been studied previously.

As shown in Figure 1, DTH response was suppressed by a single injection of a DGLA emulsion immediately before the second SRBC injection. The mechanism of action of DGLA is not clear at present, although conceivable mechanisms are discussed below.

The plasma-free DGLA concentrations were drastically increased to about 50 μM at 1 h after the injection of 0.05 mL of the DGLA emulsion. Taking into account that the ID_{50} concentrations of DGLA for IL-2 production are about 30 μm (2), IL-2 production around the SRBC-injected footpad appears to be reduced in the 0.05-mL group. The rate of reduction in IL-2 production may be even greater in the 0.5-mL group than in the 0.05-mL group. Because Th1 clones, which are significantly involved in DTH in mice (7), proliferate in response to IL-2 (11), the reduction in IL-2 may be at least partly involved in the anti-inflammatory action of DGLA.

DGLA is a substrate of cyclooxygenase, and the rate of conversion of DGLA to E-series PG (PGE_1) is greater than that of AA to PGE_2 (12). Actually, oral administration of DGLA resulted in increased PGE_1 output by a renal papilla preparation of rabbits (13) and human platelet-rich plasma (5). PGE_1 is a well-known immunosuppressant (1) and depresses the expression of the class II histocompatibility complex (Ia molecules) (14). On the other hand, the conversion of DGLA to thromboxane (TX), which is an antagonist of PGE_1 in terms of immune response (14), was reported to be negligible (15,16). Also, the effect of TXA_1 synthesized from DGLA was reported to be much less pronounced than that of TXA_2 (15). Moreover, *in vivo* DGLA administration inhibits TXA_2 production (17). Taken together, DGLA appears to be a potent immunosuppressive fatty acid.

In addition to cyclooxygenase products, lipoxygenase products are also involved in immune response (18). Due to the absence of a double bond at C-5, DGLA is not a substrate of 5-lipoxygenase (19), and thus leukotrienes (LT) are not synthesized from DGLA except for the isomer of LTC_3 that is oxygenated at C-8 (20). We recently observed that the intravenous administration of the same DGLA emulsion used in the present study reduced LTB_4 production by rat peritoneal resident macrophages within 6 h by one-half (10). Guichardant *et al.* (21) also observed that supplementation with DGLA inhibited LTB_4 production by human leukocytes *in vitro*. Because LTB_4 augments IL-1 production (22) and complements IL-2 activity (23), it is conceivable that the inhibitory effect on LTB_4 production is one of the mechanisms for suppression of DTH response. LTB_4 may be involved in any of the steps of DTH response with or without intervening in cytokine production.

The increased free DGLA levels in plasma after DGLA injection probably affect the PL fatty acid composition of local lymph nodes near footpads. In preliminary experiments we tried to determine the fatty acid composition of local lymph nodes. However, the nodes were too small to yield reliable fatty acid compositional data. Instead of measuring the fatty acid composition of lymphocytes of the local lymph nodes, we determined the fatty acid composition of the PL fraction of spleen cells. As shown in Table 1, DGLA was quickly increased in both the 0.05-mL and 0.5-mL groups. It is likely that similar changes took place in local lymphocytes affecting lymphocyte function.

Horrobin (24) has reported the effects of evening primrose oil containing GLA. The mechanism of the effect of GLA administration is probably through the elongation of GLA to DGLA. It also takes a few weeks upon oral administration of GLA to observe an effect (24). In this case, intravenous injection of DGLA seems superior to that of primrose oil. Emulsified lipids are also taken up preferentially by inflammatory tissues (25), which helps in the accumulation of DGLA in those tissues in which DGLA takes effect.

If in the future DGLA emulsions should clinically be applied to patients that require a rapid correction of DTH response, as is the case in allograft rejection, the present observations could provide basic information about the doses required and the pharmacokinetics of such emulsions.

ACKNOWLEDGMENTS

We are grateful to Mariko Tabayashi and Akimi Takashima for technical and editorial help, respectively, and Fumio Ibuki (Nihon Pharmaceutical Co., Osaka, Japan) for preparing the emulsion.

Cardiolipin (CL) is found in inner mitochondrial membranes and the plasma membrane of aerobic prokaryotes. CL is tightly bound to those transmembrane enzymes associated with oxidative phosphorylation. CL has earlier been reported to have a single pK at low pH. We have titrated CL in aqueous suspension (bilayers) and in solution in methanol/water (1:1, vol/vol) and found it to display two different pK values, pK_1 at 2.8 and pK_2 initially at 7.5 but shifting upwards to 9.5 as the titration proceeds. The unusually high pK_2 might be explained by the formation of a unique hydrogen bond in which the free hydroxyl on the central glycerol forms a cyclic intramolecular hydrogen-bonded structure with one protonated phosphate (P-OH group). We have therefore chemically synthesized the 2′-deoxycardiolipin analogue, which lacks the central free hydroxyl group, and measured its pH-dissociation behavior by potentiometric titration, under the same conditions as those for CL. The absence of the hydroxyl group changes the titration dramatically so that the deoxy analogue displays two closely spaced low pK values (pK_1 = 1.8; pK_2 = 4.0). The anomalous titration behavior of the second dissociation constant of CL may be attributed to the participation of the central glycerol OH group in stabilizing the formation of a cyclic hydrogen-bonded monoprotonated form of CL, which may function as a reservoir of protons at relatively high pH. This function may have an important bearing on proton pumping in biological membranes.

Lipids 28, 877-882 (1993).

Almost a century ago, Wasserman *et al.* (1) reported the finding of "specific" antibodies in the sera of syphilitic patients by using the antigen in alcohol extracts from the spleen of a syphilitic fetus. Within a few years, Browning *et al.* (2) established that the antigen could be extracted from a variety of tissues, and Noguchi (3) discovered that the ether-soluble antigen was precipitable by acetone, a characteristic of phospholipids. The latter observation provoked Pangborn (4) to isolate and purify the antigen from beef heart by means of the Wasserman antibody assay. She named the isolated antigen "cardiolipin" (CL) and subsequently chemically characterized it as an acylated polyglycerolphosphate complex (5). CL was soon found to be present not only in mammals but in bacteria and plants (6-8).

Although CL was one of the first membrane lipids to be isolated in pure form, its structure proof and synthesis were not achieved until the 1960s. Le Cocq and Ballou (9) established its structure and configuration as di-*O*-(*sn*-3-phosphatidyl)-*sn*-1′,3′-glycerol (Fig. 1). The total synthesis of CL was soon achieved by de Haas *et al.* (10).

Few *et al.* (11), in a classic paper in which they measured pK values of surface charges of suspensions of bacterial cells and cell lipid extracts by microelectrophoresis, determined the pK_a of a sample of CL obtained from Pangborn. The pK_a of CL they reported was 1.05. They also found that the lipids of *Micrococcus lysodeikticus* displayed a pK_a of 0.4. A curious feature of the titration curves obtained by Few *et al.* (11) was that unlike those of the *M. lysodeikticus* cells and the lipids, the CL titration continued to rise after the observed endpoint.

Shortly thereafter, Coulon-Morelec *et al.* (12) also reported a single pK below pH 4.0 for CL based on titration in ethanol solution using indicator dyes. In a more recent study, Seddon *et al.* (13) reported a pK of 2.8 based on the pH dependence of phase changes. In all three measurements, it was assumed that there is only one pK for the two phosphate protons, presumably because the molecule is symmetrical. This view is widely held in the literature (14-16).

CL has a variety of unique physical and chemical properties. Unlike most phospholipids, it readily forms a hexagonal II(H_{II}) phase (17), which is easily characterized by ^{31}P nuclear magnetic resonance (NMR) (18). This

Abbreviations: BH, beef heart; CL, cardiolipin (diphosphatidylglycerol); CL-BH, cardiolipin from beef heart; 18:0-CL (H_2-CL-BH), hydrogenated beef heart cardiolipin; H_2-CL-EC, hydrogenated cardiolipin from *E. coli; cy*-17:0 and *cy*-19:0, 9,10-methylenehexadecanoic and octadecanoic acid, respectively; DAG, diacylglycerols; dCL, 2′-deoxycardiolipin (diphosphatidyl-1,3-propanediol); 16:0-dCL, synthetic deoxycardiolipin with palmitoyl (16:0) as acyl groups; DPG, dipalmitoylglycerol; DPPA, dipalmitoyl phosphatidic acid; FAB-MS, fast-atom bombardment mass spectrometry; FTIR, Fourier transform infrared spectroscopy; GLC, gas-liquid chromatography; NMR, nuclear magnetic resonance; PA, phosphatidic acid; PPD, phosphatidylpropanediol; PPOP, phosphatidylpropanediol-phosphate; TLC, thin-layer chromatography.

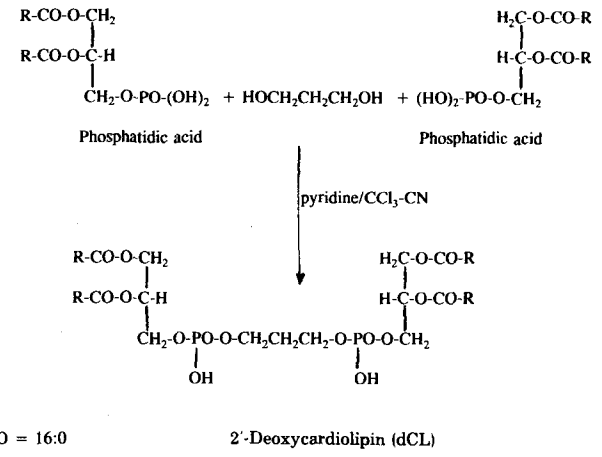

FIG. 2. Scheme for the synthesis of 2'-deoxycardiolipin.

characteristic is promoted by a fatty acid chain composition rich in polyunsaturated fatty acids, as is found in mitochondrial CL. A lesser known and more poorly understood chemical quality is the low degree of accessibility of the free hydroxyl group to acetylation in pyridine using vigorous conditions (19,20). In this connection, recent Fourier transform infrared (FTIR) studies of CL have shown (21) that the central free hydroxyl group can form intramolecular hydrogen bonds with the phosphate groups, which might explain the difficulty in acetylating the C-OH group.

In mitochondria, CL is located largely on the matrix side of the inner membrane (for a review, see Ref. 22). CL is known to bind tightly to inner mitochondrial membrane-bound enzymes, such as cytochrome oxidase (23), the F_0F_1ATPase (24), and the ADP/ATP exchange protein (25), and to play an essential role in the optimal functioning of cytochrome c oxidase (26) and F_0F_1-ATPase (27,28). Nonetheless, the specific role of this lipid still requires clarification.

Knowledge of the pH-dissociation characteristics of CL may be of interest in connection with its biological structure-function relationships, particularly that of a proton reservoir in energy transducing membranes. We therefore examined the pH potentiometric titration of CL and found that, instead of titrating as a simple dibasic acid, it displayed two widely separated pK values, one at 2.8 and a second, anomalous pK above physiological pH. In order to explain the existence of the second pK, we synthesized 2'-deoxycardiolipin (dCL) (Figs. 1 and 2). This permitted us to examine the role of the central free hydroxyl group of the connecting glycerol in the anomalous CL titration. The dCL titrated as a typical dibasic acid with two closely spaced pK values below pH 4. Comparison of the titration behavior of dCL and CL suggests that the free hydroxyl of the connecting glycerol in CL participates in stabilizing the monoprotonated form of the CL molecule, thus enabling it to function as a proton reservoir at high pH (see Discussion section).

MATERIALS AND METHODS

Chemicals. All solvents were glass distilled prior to use, except for pyridine and triethylamine, which were dried over fresh potassium hydroxide pellets and used without distillation. Dipalmitoyl phosphatidic acid (DPPA, disodium salt) and *Escherichia coli* CL [Na salt; fatty acid analysis by gas-liquid chromatography (GLC): 16:0, 43.0%; *cy*-17:0, 24.2%; *cy*-19:0, 20.6%; 14:0, 1.4%; 16:1, 1.6%; 18:0, 1.6%; 18:1, 5.2%] were purchased from Sigma Chemical Co. (St. Louis, MO); beef heart (BH) CL (Na salt) was purchased from Sigma (fatty acid analysis by GLC: 18:1, 6.7%; 18:2, 92.2%; 16:0, 0.5%; 16:1, 0.4%; 18:0, 0.2%) or from Avanti (Pelham, AL). Adams' catalyst ($PtO_2 \cdot xH_2O$, Gold label), 1,3-dibromopropane and trichloroacetonitrile were purchased from Aldrich Chemical Co. (Milwaukee, WI).

Hydrogenation of CL. CL-BH (*ca.* 25 mg) or *E. coli* CL (*ca.* 13 mg) were hydrogenated in methanol (10 or 5 mL, respectively) in the presence of 170 or 100 mg, respectively, of Adams' catalyst in an all-glass hydrogenator by stirring in an atmosphere of hydrogen gas at room temperature (22-24°C) until uptake of hydrogen ceased (*ca.* 2-3 h). The mixture was centrifuged, and the platinum catalyst washed twice with 1 mL of chloroform/methanol (1:1, vol/vol). The combined supernatants were diluted with the appropriate amounts of chloroform and 0.2N HCl (final ratio, chloroform/methanol/water, 1:2:0.8, by vol) to form a biphasic system (29); the chloroform layer was removed, neutralized by addition of 1 N ammonium hydroxide in methanol, diluted with benzene and concentrated to a small volume under a stream of nitrogen. The ammonium salt of hydrogenated CL was then precipitated by the addition of 10 vol of acetone and cooling at −10°C; it was collected by centrifugation, reprecipitated from chloroform by addition of acetone, washed with cold acetone and finally dried *in vacuo;* the yield of hydrogenated CL was 80-85%; thin-layer chromatography (TLC) R_f, 0.48 in solvent A (R_f of unhydrogenated CL, 0.48). Fatty acid analysis by GLC: BH hydrogenated CL (H_2-CL-BH): 14:0, 1.0%; 16:0, 9.3%; 16:1, 2.5%; 18:0, 76.6%; 18:1(*t*), 9.4%. *E. coli* hydrogenated CL (H_2-CL-EC): 14:0, 2.8%; 16:0, 50.5%; *cy*-17:0, 19.1%; 18:0, 8.9%; *cy*-19:0, 12.9%. Positive fast-atom bombardment mass spectrometry (FAB-MS) of H_2-CL-EC showed major ion peaks at 523, 551, 563, 579, 591 and 607 *m/z,* corresponding, respectively, to 14:0/14:0, 16:0/16:0, 16:0/*cy*-17:0, 16:0/18:0, 16:0/*cy*-19:0 and 18:0/18:0 molecular species of diacylglycerols (DAG), consistent with the fatty acid analytical data. Negative FAB-MS did not yield any diagnostic ion peaks.

Chromatography. TLC of CLs and the deoxy analogue was carried out on 20 × 20 cm plates coated with silica gel 60A K6 (0.25 mm thick; Whatman International Co., Maidstone, England) using chloroform/methanol/conc. (14M) ammonium hydroxide (65:35:5, by vol) as solvent (Solvent A). GLC of fatty acid methyl esters, prepared by methanolysis of CL or dCL samples in methanolic HCl (30), was carried out on a column of SP-2330 (Supelco, Inc., Bellefonte, PA) at 185°C on a PYE Unicam (Cambridge, England) gas chromatograph.

Physical measurements. ^1H and ^{13}C NMR spectra were measured in $CDCl_3$ on a Bruker (Karlsruhe, Germany) CXP-300 spectrometer. FAB-MS was carried out on a VG-7070E (Vacuum Generators, Inc., Manchester, England) mass spectrometer with digital RL 02 data system and printonic printer.

Potentiometric titration. Samples (6-15 mg, 4-11 μmoles) of H_2-CL-BH, H_2-CL-EC, or 16:0-dCL, were converted to their respective protonated form using an

acidified Bligh and Dyer (29) procedure (see Ref. 30) and suspended in 2 mL of 0.05 M KCl by vortexing and sonication with a needle tip sonicator (Sonic Dismembranator, Quigley-Rochester, Inc., Rochester, NY). The samples of free acids formed milky-to-translucent dispersions in 0.05 M KCl, which were titrated with 0.05N KOH in 0.05 M KCl using a glass electrode, accurate over the pH range 2-12, and a pH meter (Radiometer, Copenhagen, Denmark). The KOH solution was delivered in increments with a syringe microburet (1 mL; Micro-Metric Instrument Co., Cleveland, OH). In some experiments, samples were sonicated in a cup horn type sonicator (Ultrasonics, Inc., Model W-385, Plainview, NY), with a Lauda K-2/R water circulator (Brinkmann Instruments, Westbury, NY), and titrated with an Orion digital pH meter (Model 601A) with a microelectrode (Microelectrodes Inc., Model No. MI-410, Londondery, NH), using a Hamilton syringe (2 mL) and a syringe pump (Razel Scientific Instruments, Stamford, CT) for constant delivery of the aqueous 0.05M KOH.

Titrations were also done on solutions of the protonated forms of CL or dCL (4-9 μmoles) in 2 mL of methanol/aqueous 0.05 M KCl (1:1, vol/vol). It was difficult to suspend the free acid form of the natural, unsaturated BH-CL in water by sonication and vortexing. This lipid was therefore titrated only in methanol/0.05 M KCl (1:1, vol/vol).

All titrations were done at room temperature (22-24°C) and care was taken to minimize exposure of samples to pH conditions above 8. Total consumption of alkali was in the range of 95-105 and 85-100% of the theoretical values calculated for CL and dCL, respectively. Immediately after titration, samples were recovered (85-100%, depending on the fatty acid composition) by acetone precipitation of the ammonium salt form (30); little or no degradation was observed by TLC using Solvent A.

Titration curves were computer-simulated using the general equation (31) for either monoprotic or diprotic systems. For the CL titrations, the curve after the first endpoint was calculated according to the approximation:

$$pH = pK_a(eff) + \log\{[A^-]/[HA]\} \quad [1]$$

where $pK_a(eff)$, the effective pK_a, varies as the titration of CL proceeds. In this case, it is not a constant as it is in the general equation (31). The theoretical curve for dCL was calculated on the basis of the equation:

$$V_b = \frac{V_a\,\alpha\gamma - V_b\,\beta F_a + F_a V_a \alpha}{\alpha(F_b\gamma)} \quad [2]$$

where V_b = volume of base added; V_a = initial volume of acid; F_a = initial formality of the acid; F_b = normality of base; $\alpha = (H^2)/(K_1K_2) + (H)/(K_2) + 1$; $\beta = (H^2)/(K_1K_2) - 1$; and $\gamma = (K_W)/(H) - H$; $H = [H^+]$ and K_1 and K_2 = the first and second dissociation constants of a diprotic acid.

The water-soluble phosphate esters, glycerol-1,3-diphosphate and 1,3-propanediol-1,3-diphosphate, were titrated in water as described for CL and dCL.

Syntheses of glycerol-1,3-diphosphate. Glycerol-1,3-diphosphate was synthesized as described previously (32) by condensation of 1,3-dibromo-2-palmitoyloxypropane with silver dibenzylphosphate (33) followed by removal of the benzyl groups by catalytic hydrogenolysis (Pd/C) and the palmitoyl group by mild alkaline hydrolysis; the product was isolated as the dibarium salt and converted to the free acid by treatment with Dowex-50 (H^+) ion-exchange resin and to various salt forms by neutralization with the appropriate base (32).

Synthesis of 1,3-propandiol-1,3-diphosphate. 1,3-Propandiol-1,3-diphosphate was synthesized by a procedure analogous to that for glycerol-1,3-diphosphate, in which 1,3-dibromopropane (0.377 g, 1.87 mmol) was condensed with silver dibenzylphosphate (1.4 g, 3.6 mmol) in anhydrous benzene (13.5 mL) under reflux with stirring for 24 h, followed by hydrogenolysis of the benzyl groups of the blocked product in ethanol (4 mL) with Pd/C catalyst (200 mg). The final product was isolated as the dibarium salt (28.4 mg, 0.055 mmol; 3% yield) and converted to the free acid form and to other salt forms as described for glycerol-1,3-diphosphate (32).

Synthesis of 2'-deoxy-cardiolipin (16:0-dCL). The synthesis of 16:0-dCL was carried out as summarized in Figure 2. DPPA disodium salt (67 mg, 0.1 mmol) was converted to the free acid form (30), dried in a desiccator over KOH pellets, mixed with an excess of 1,3-propanediol (140 mg, 1.84 mmol) and dissolved in dry pyridine or triethylamine (10 mL) at 50°C. The condensation was then brought about by adding trichloroacetonitrile (4 mL) to the clear tan solution and stirring in a nitrogen atmosphere at 50°C for 20 h (34). The dark brown mixture was diluted with an equal volume of benzene, concentrated in a rotary evaporator at 40-50°C and dried in a desiccator over concentrated sulfuric acid and then KOH pellets. The black residue was dissolved in 12 mL of chloroform/methanol (1:1, vol/vol), diluted with 5.4 mL of 1 N HCl and the mixture was centrifuged. The chloroform layer was removed, washed with an equal volume of methanol/water (10:9, vol/vol), made alkaline with 0.2 N ammonium hydroxide in methanol and concentrated to dryness *in vacuo*. The residue was dissolved in 0.5 mL of chloroform, diluted with 5 mL of acetone, and cooled on ice. The black precipitate of crude product, 16:0-dCL, was centrifuged, washed with cold acetone and reprecipitated from a small volume of chloroform (0.5 mL) by the addition of 10 vol of cold acetone. The combined acetone supernatants were concentrated to a small volume and diluted with acetone to yield a second crop (yield of combined crops, 36.5 mg).

This crude 16:0-dCL, containing unreactied DPPA, was purified by preparative TLC using Solvent A, eluted from the silica with chloroform/methanol/water (1:2:0.8, by vol) and isolated as the ammonium salt as described above. The yield of TLC-pure 16:0-dCL ammonium salt was 14 mg (0.01 mmol, 10% from DPPA); R_f 0.60 in Solvent A. Fatty acid analysis by GLC: 14:0, 1%; 16:0, 95.5%; 16:1, 1%; 18:0, 1.6%; 18:1, 0.9%. ^1H NMR ($CDCl_3$): 0.86 (*t*, terminal CH_3, 12H), 1.23 [acyl CH_2, C-4 to C-(ω - 1), 96H], 1.55 (acyl C-3, 8H), 1.77 (*s*, unidentified, 4H), 2.08 (broad single peak, HOH), 2.28 (*t*, acyl C-2, 8H), 3.67 (*s*, unidentified, 3H), 3.9 (*m*, CH_2-O-P, 8H), 4.13 (*t*, P-O-C-CH_2-C-O-P, 2H), 4.33 (*d*, CH_2-O-acyl, *sn*-1-glycerol, 4H), 5.18 (*t*, CH-O-acyl, *sn*-2-glycerol, 2H). Negative FAB-MS: 811 (unidentified, possibly [M - dipalmitoylglycerol (DPG) + OH + Na - H]$^-$ or [phosphatidylpropanediol phosphate (PPDP) + Na - H]$^-$); (base peak) 705 [M - H -

DPPA + H_2O]$^-$ or [phosphatidylpropanediol (PPD) − H]$^-$; 647 [M − PPD + OH]$^-$ or [DPPA − H]$^-$; Positive FAB-MS: 707 [M − DPPA + H_3O]$^+$; 551 [M − PPDP + H]$^+$ or [DPG − OH]$^+$; calcd. for 16:0-dCL (free acid), $C_{73}H_{142}O_{16}P_2$, M = 1336; PPDP, $C_{38}H_{76}O_{12}P_2$, M = 786; PPD, $C_{38}H_{75}O_9P$, M = 706; DPPA, $C_{35}H_{69}O_8P$, M = 648; DPG, $C_{35}H_{68}O_5$, M = 568. No parent ion peak for 16:0-dCL was detected by negative or positive FAB-MS.

The free acid form of 16:0-dCL was prepared by the acidified Bligh and Dyer (29) procedure (see Ref. 30). The sodium salt was prepared by titration of the free acid form of 16:0-dCL0 with 0.05N NaOH in methanol to pH 7.5, followed by precipitation from chloroform solution with acetone.

Synthesis of the unsaturated deoxy analogue of CL. A synthesis of the unsaturated deoxy analogue of CL was carried out as described above for 16:0-dCL, but starting with commercial phosphatidic acid (PA) (0.08 mmole) derived from egg lecithin (Serdary, London, Ontario, Canada). The yield and TLC R_f values of the unsaturated dCL (yellow oil) were the same as for 16:0-dCL. Fatty acid composition: 14:0, 0.4%; 16:0, 39.2%; 16.1, 1.9%; 18:0, 10.9%; 18:1, 36.2%; 18.2, 9.8%; 18:3, 0.2%. ^{1}H NMR: 0.86 (*t*, terminal CH_3, 12 H), 1.23 (acyl-CH_2, C-4 to C-(ω − 1), 92 H), 1.56 (acyl C-3, 8 H), 1.75 (*s*, unidentified, 4 H), 2.00 (*q*, allylic methylene, 8 H), 2.28 (*q*, acyl C-2, 8 H), 2.76 (*t*, diallylic methylene, 2 H), 3.70 (*s*, unidentified, 4 H), 3.96 (*m*, CH_2-O-P, 8 H), 4.17 (*q*, PO-C-CH_2-C-OP, 2 H), 4.39 (*d*, CH_2-O-acyl, *sn*-1-glycerol, 4 H), 5.21 (*t*, H-C-O-acyl, *sn*-2-glycerol, 2 H), 5.32 (*m*, olefinic C-H, 5 H).

RESULTS

Syntheses. Because of the symmetry of the 2′-deoxy analogue of CL (16:0-dCL), its synthesis could be achieved by a single-step condensation of di-16:0-PA with 1,3-propanediol in the presence of pyridine or triethylamine and trichloroacetonitrile (Fig. 2). The 16:0-dCL was obtained in about a 10% overall yield but was contaminated with a black substance that co-precipitated with it and could only be removed by preparative TLC in Solvent A. The 16:0-dCL had a much higher mobility on TLC (R_f 0.60) in Solvent A than either natural CL or the hydrogenated CL (R_f 0.48), which can be attributed to the absence of the central OH group. Both the ^{1}H NMR and the FAB-MS spectra were consistent with the expected chemical structure of the dCL (Fig. 1). Under the conditions used here for FAB-MS, 16:0-dCL did not show a parent ion peak, the only negative ion peaks observed being those for the cleavage products, DPPA, PPD and possibly PPDP.

Potentiometric titration. H_2-CL-BH (18:0-CL) formed bilayer phases in either sonicated aqueous dispersion or in methanol/water (1:1, vol/vol) (21). On titration (Fig. 3), 18:0-CL showed the presence of one strong acid group, with apparent pK = 3.2, accounting for one equivalent of acid per mole, and a weak acid group with a surprisingly high pK accounting for a second equivalent of acid. The titration curve of the unhydrogenated BH-CL in methanol/water (1:1, vol/vol) was virtually superimposable on that of the 18:0-CL in water. Titration of the former in aqueous medium was not possible because this phospholipid forms hexagonal II phased dispersions in water (21), in which the polar head groups are not available for titration. In contrast, 16:0-dCL titrated as a normal dibasic acid in either sonicated aqueous dispersion (Fig. 3) or in methanol/water (1:1, vol/vol) (data not shown). It titrates two equivalents of base with an apparent pK of about 3.

Computer-simulated titration curves. An attempt was made to obtain more precisely the pK values of 18:0-CL (Fig. 3) by computer simulation assuming reasonable values for both the lower pK and the upper pK. It was apparent that this was not possible since a single value for pK_2 could not be obtained. As is shown in Figure 4, the experimental data crossed through a family of theoretical curves corresponding to pK_2 values varying from 7.5 to 9.5. Furthermore these values fit the lower portion of the curve best when pK_1 was assumed to be 2.8. It can be seen that the experimental curve differs from the theoretical curves by a "flattening" that is expected for titrations at polyanionic surfaces, on the basis of the calculations made by Tanford and Kirkwood (35) from Gouy-Chapman considerations. The second pK of CL appears to follow the formula: pK_2 = 7.5 + (fractional equivalent/2), approximating a linear increase in its pK value between 7.5 and about 9. CL thus "buffers" the protons throughout this range, entrapping protons up to a pH of 9.0 or greater.

In contrast, the titration of 16:0-dCL (Fig. 3) can be computer-stimulated (Fig. 5) by a theoretical curve for a typical dibasic acid having two strongly acidic groups with a pK_1 of 1.8 and pK_2 of 4.0. The "flattening" of the experimental curve here can also be accounted for by the surface charge effects desribed by Tanford and Kirkwood (35). Unlike the CL titration which displays an actual shift in the pK_2, dCL exhibits only a slight flattening of its titration curve (Fig. 5). This shows that the Gouy-Chapman effects are insufficient to provoke the dramatic pK_2 shift observed with CL (Fig. 4). It should also be noted that the results of Few *et al.* (11) show an upward drift after the pK_1 not unlike the titration reported here. Few *et al.* (11) obtained BH mitochondrial CL from Pangborn (5). Since there is no mention of hydrogenation, we must assume the CL was polyunsaturated and hence, we cannot be certain of the state of the CL (H_{II}, bilayer, *etc.*). Nevertheless, the upward drift of the titration curve obtained by Few *et al.* (11) appears to be consistent with our results.

Two other "titrations" have been reported in the literature for cardiolipin. Seddon *et al.* (13) reported a pK below 2.8 based upon the pH dependence of phase changes. This measurement could not be expected to detect a second pK unless there was a discrete phase change associated with it. These investigators assumed at the outset that there was only one pK and that CL is dibasic (16). The other attempt to measure the pK of CL (12) was made by titration in ethanol solution using indicator dyes. In this case a single pK was reported to be below 4.0 although a precise number could not be assigned.

Finally, the glycerol-1,3-diphosphate and 1,3-propanediol-1,3-diphosphate, model compounds for the polar headgroups of 18:0-CL and 16:0-dCL, respectively, both titrated as tetrabasic acids having two strong acid groups with pK 2.25 or 2.35, respectively, and two weak acid groups with pK 6.3 or 7.1, respectively (data not shown). The free hydroxyl on the glycerol-1,3-diphosphate does not appear to alter significantly the titration characteristics of the

phosphate groups since the propanediol-1,3-diphosphate displays essentially the same titration curve. However, see the discussion that follows.

DISCUSSION

The titration of the 18:0-CL presented in this paper is apparently the first electrometric titration of CL. Unlike previous attempts to titrate CL (11–13), the present measurements specifically examine the number of equivalents titrated at each pK. Our titration yielded two significant and surprising results. The first is that there are two pK values, the second pK (pK_2) being above physiological pH even at its lowest value. The second unexpected result is that the pK_2 itself changes rather dramatically as the titration proceeds. Furthermore, we have shown that in view of the comparison of the titration of CL to that of the dCL both of these unexpected results are due to the presence of the free hydroxyl on the connecting glycerol in CL.

The fact that dCL has two strong acid groups while CL has only one strong acid group may be attributed to the absence of the central OH in dCL, and to the presence of the central C-OH group in CL. The most likely way that this hydroxyl group can so significantly affect the pK of the phosphate groups is to form an intramolecular hydrogen bond with one of the P-OH groups (Fig. 6), analogous to the lipid acid anions described by Haines (36). The existence of such an intramolecular hydrogen bond has been demonstrated (37,38) by FTIR spectroscopy in phosphatidylglycerophosphate (now identified as phosphatidylglyceromethylphosphate, Ref. 39), as well as in CL (21).

The water-soluble headgroup moieties, glycerol-1,3-diphosphate and propanediol-1,3-diphosphate, do not display a significant difference in titration, as described in the Results section. This suggests that the difference between titrations of 18:0-CL and 16:0-dCL are due to the conformation of the headgroup of CL allowing the alignment of the C-OH and P-OH groups under constraint by the presence of the acyl groups (Fig. 6). It is this latter

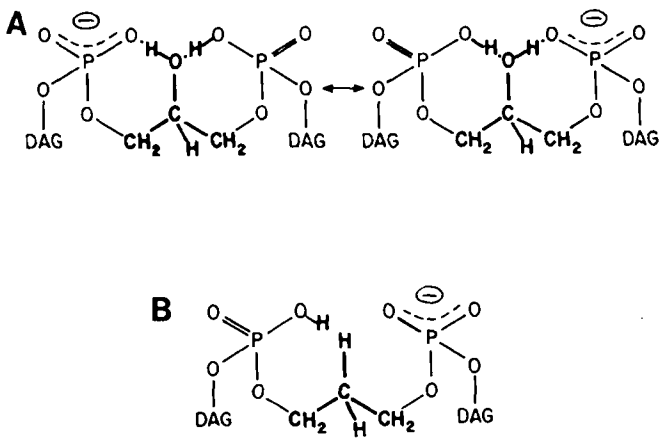

FIG. 6. A, proposed intramolecular hydrogen bonded acid-anion structure of cardiolipin at pH 7.5–9.5; and B, the structure of deoxycardiolipin at pH 2.0 (DAG, diacylglycerol). Note that structure A can trap a proton above pH 7.5 by forming an acid ion, while structure B cannot trap a proton, *i.e.*, cannot form an acid anion.

feature that also provides a mechanism to explain how the pK_2 of CL increases during the titration from 7.5 to 9.5 (Fig. 4).

The titration of dCL displays a pK_2 somewhat higher than its pK_1, presumably due to the suppression of ionization by the increased charge density on the surface as can be predicted from the work of Tanford and Kirkwood (35). In contrast, CL displays a shifting pK_2 as the titration proceeds. This suggests that the pK_2 of CL is sensitive to the charge density in two ways, first in the same way that dCL is, and second by a tightening of the H-bonded ring (Fig. 6). Presumably the second effect is significantly greater than the first; not only does a small increase in charge density provide a large increase in pK_2 but as the titration proceeds and the charge density increases, the pK shifts.

The biological significance of these observations pertains primarily to the capacity of CL to bind protons at relatively high pH. This might allow CL to buffer protons and provide a proton reservoir at high pH for participation in proton conduction in energy-transducing membranes as discussed by Haines and Kates (manuscript in preparation). These statements run counter to the suggestion that CL might provide protons at low pH (13).

ACKNOWLEDGMENTS

This work was supported in part by a grant from the Natural Sciences and Engineering Research Council of Canada (to M.K.), and by a grant from CUNY FRAP (to T.H.H.). The assistance of S. Desilva and B. Bhullar in the synthesis of the deoxycardiolipins is gratefully acknowledged. Appreciation is also extended to Dr. N. Moldoveanu for help in preparation of the hydrogenated cardiolipins, to C. Kazakoff for the mass spectra and to R. Capoor for the NMR spectra.

Bile lipids are secreted in association with a newly identified major apoprotein called anionic polypeptide fraction-calcium binding protein (APF-CBP), which is synthesized in the hepatocytes and has been detected in both bile and plasma and characterized. The secretion of the lipids in bile depends both on the concentration and the hydrophobicity of the bile salts (BS) secreted. The present study was undertaken to determine whether the synthesis and the secretion of APF-CBP are similarly regulated by BS, using two methods. The synthesis and secretion of labelled, newly synthesized APF-CBP by isolated rat hepatocytes were monitored by solid-phase immunoassay. For this purpose, hepatocytes were incubated with either glycodeoxycholate (GDC) or taurocholate (TC). The synthesis and secretion of labelled, newly synthesized APF-CBP by perfused rat liver were measured by immunological enzyme-linked assay (ELISA) upon perfusing the liver with either GDC or TC. We found that (i) the synthesis and the secretion of APF-CBP were increased during either TC or GDC perfusion, but the increase was more pronounced with TC; (ii) in GDC perfusion the APF-CBP levels measured were more closely related to the levels of bile salts and not to phospholipid levels, (iii) when the two bile salts were perfused in reverse order, *i.e.*, first GDC and then TC, the secretion of APF-CBP in bile decreased when GDC was perfused, but increased when TC was perfused. Similar results were obtained in experiments with isolated hepatocytes. The data suggest that the hydrophobicity of the BS used in the infusion modulates the synthesis and secretion of APF-CBP. In the liver, the pool of APF-CBP can be modified by BS and responds rapidly to BS stimulation.
Lipids 28, 883-887 (1993).

The relationship between biliary phospholipid (PL) secretion and bile acid levels suggests that the hydrophobic/hydrophilic balance of the bile salts (BS) (1) is an important aspect of bile regulation.

Until a decade ago, bile lipids were generally considered to be exclusively organized as mixed micelles (2). However, more recently, evidence of a far more complex organization has been emerging (3-5). Various structures have been implicated in the cholesterol transport in bile, including mixed micelles and large vesicles (3), as well as bile lipoprotein complexes (BLC) (4,5). BLC consist mainly of biliary lipids and a major apoprotein designated as anionic polypeptide fraction (APF).

APF has been isolated from human bile by zonal ultracentrifugation, and polyclonal and monoclonal antibodies have been obtained (6,7). APF has recently been identified as an apolipoprotein associated with bile lipids (5% of total PL weight) and serum high density lipoprotein (HDL_3) (0.6-1% of human apo HDL_3) (7). By weight, APF is the third most abundant protein in human (5) and rat bile (8). In cholesterol gallstones, APF has been detected at the pigment-cholesterol interface (6). Recently, another laboratory has independently isolated a 7 kDa amphipathic from bile (9) and various types of gallstones (9,10). It is a highly acidic polypeptide that contains covalently-bound bilirubin and shows a strong tendency to self-aggregate. The immunologic and functional identity of the polypeptide isolated from bile, APF, and gallstone calcium binding protein (CBP) has been established by collaboration between two laboratories (7) who have recommended the common designation APF-CBP. APF-CBP is the first bile-gallstone protein that has been shown to inhibit calcium carbonate precipitation and was also found to promote aggregation and fusion of biliary vesicles and crystallization of cholesterol therefrom (11).

APF-CBP was shown to be synthesized by both isolated and cultured rat hepatocytes (8) which have saturable and specific recognition sites for APF-CBP (12). APF-CBP has also been shown to be involved in the regulation of cholesterol uptake and cholesterol metabolism in the liver (13). In the rat, APF-CBP levels in bile are controlled by the nature of the bile acids (14), with cholic acid and dehydrocholic acid showing opposite effects. APF-CBP is associated with PL and cholesterol in bile, and the secretion of both these lipids depends on BS. Hence, it is important to determine whether APF-CBP secretion is directly modulated by BS and whether this modulation is a function of the hydrophobicity of the BS or whether it is under the control of other lipids, such as PL or cholesterol.

In the present study, we have compared the effects of two natural BS, namely taurocholate (TC) and glycodeoxycholate (GDC), on the synthesis and the secretion of APF-CBP in isolated perfused rat liver and in isolated hepatocytes. Using a relatively highly hydrophylic BS (TC) and a very hydrophobic BS (GDC) (15), we have also studied the effect of insulin, a hormone known to stimulate the synthesis of proteins in the liver (16).

MATERIALS AND METHODS

Liver perfusion. Male Sprague-Dawley rats weighing 250-300 g (IFFA Credo, l'Arbresle, France) with free access to food and water were used in all experiments. Animals were anesthetized by intraperitoneal sodium pentobarbital injection (60 mg/kg), and isolated liver was perfused in a single-pass system according to a slightly modified version of the technique described by Brauer *et al.* (17). First, the liver was exposed by abdominal incision and, after cannulation of the common bile duct, a 20-gauge intravenous Teflon catheter was immediately

Abbreviations: ALT, alanine aminotransferase; APF-CBP, anionic polypeptide fraction-calcium binding protein; BLC, bile lipoprotein complex; BS, bile salts; GDC, glycodeoxycholate; HDL, high density lipoprotein; PL, phospholipid; TC, taurocholate.

placed in the portal vein, and perfusion was initiated at 37.0 ± 0.5°C. As soon as the liver turned white, the diaphragm was opened and the suprahepatic *vena cava* was cannulated with a 14-gauge Teflon catheter.

The perfusion medium was Krebs-Henseleit bicarbonate buffer (119 mM NaCl, 25 mM $NaHCO_3$, 4.7 mM KCl, 1.2 mM $MgSO_4$, 1.2 mM KH_2PO_4 and 2.5 mM $CaCl_2$) at pH 7.4 containing 10 mM glucose. Insulin at 5 U/100 mL (8), 0.6 mCi [^{14}C]leucine (specific activity 322 mCi/mmol or 11.8 GBq/mmol; CEA, Saclay, France) and 6 mL/100 mL RPMI 1640 (Flow Laboratories, Paris, France) were added to the medium. The complete medium was filtered through a 80-μm millipore filter using a peristaltic pump, and gassed to equilibrium with O_2/CO_2 (95:5, vol/vol). During perfusion, hydrostatic portal pressure was maintained constant at an average flow rate of 2.50 mL/min/g liver.

The experimental procedure involved a nonrecirculating system. After a 20-min equilibration period, during which the perfusion medium was infused at 12.5 nmol/min/g liver, the effect of the two BS upon bile lipid secretion was tested by infusing either 12.5 nmol/min/g liver TC or GDC over a 90-min period. When the rate of APF synthesis was assessed, [^{14}C]leucine (0.05 μmol/g liver) was infused with TC or GDC during the first 20 min.

In all experiments, bile was collected at 10-min intervals for 110 min in preweighed tubes. The perfusate was collected simultaneously from the supra-hepatic *vena cava*. Oxygen consumption by the liver was determined by measuring the oxygen saturation of the entering and exiting perfusate.

Preparation of isolated hepatocytes. The surgical procedure, as well as the purity and viability of the hepatocytes, were assessed as described previously (8). Hepatocytes were isolated according to the method of Berry and Friend (18) as modified by Seglen (19).

For incubations, hepatocytes 8–10 × 10^6 cells/mL were suspended in an incubation medium composed of fetal bovine serum (40 mL/L) supplemented with gentamycin (8 mg/L) and insulin (0.05 IU/mL). Ten-mL samples of medium were placed in 20-mL round glass flasks and incubated at 37°C under slow stirring with 95:5% O_2/CO_2. TC or GDC were added at concentrations of 0.2 μmol/mL and 0.17 μmol/mL, respectively.

Polyclonal (8) or monoclonal (7) antibodies against APF were prepared as previously described. APF synthesis was assessed by measuring the incorporation for 5 h of [^{14}C]-leucine, which was added to the incubation medium at a concentration of 5.4 μCi/mL. APF content was determined in supernatant samples by solid-phase radioimmunoassay (20) using a specific monoclonal mouse anti-human APF and a polyclonal rabbit anti-human APF reacting against rat APF (4). APF was bound to solid-phase CNBr-activated Sepharose 4B (Pharmacia, Saint Quentin, Yvelines, France) coupled with specific anti APF serum.

A-200 μL sample of supernatant from the incubation medium containing radiolabelled APF was mixed with a buffer composed of 0.05 M Na_2HPO_4, 0.35 M KCl, and 0.05 M DL-leucine at pH 7.2 to a final volume of 1.84 mL. A 100-μL sample was used with an excess of whole rat anti-serum (200 μL) in the same buffer to determine the nonspecific binding of radiolabelled leucine (21). A 200-μL sample of Sepharose coupled with specific antibodies was added to all the samples and incubated under continuous rotation for 3 h at room temperature. The resulting suspension was centrifuged at 200 × *g* for 5 min, and the pellet was washed three times in 5 mL of 0.05 M Na_2HPO_4 and 0.085 M KCl buffer (pH 7.2). The final pellet was suspended in 1 mL of a tissue solvent (Soluène 350; Packard, Rungis, France). After adding 0.1 mL of 30% H_2O_2 and incubating for 30 min at 50°C, the samples, upon cooling and solubilization, were counted after adding 10 mL of scintillation fluid (Instafluor; Packard). The radioactivity incorporated into APF was calculated for each sample by subtracting the nonspecific binding of other radioactive-labelled proteins as determined above.

Assays of bile and perfusate. BS concentrations were measured using the 3α-hydroxysteroid dehydrogenase assays (22). Radioactivity in bile and perfusate was measured by liquid scintillation counting as mentioned above. PL were determined by a semi-automatic colorimetric method (23). APF was detected and quantified by direct antigen binding enzyme-linked sandwich assay using polyclonal and monoclonal antibodies as described elsewhere (7).

Statistics. All data were statistically analyzed as the means ± SE, and the significance of the difference was determined using the unpaired Student's *t*-test. Probability values less than 0.05 were considered significant.

RESULTS

Bile flow. During the infusion with TC alone, the bile flow remained constant for 110 min. The bile flow of perfused rat liver stabilized at 18.8 ± 1.9 μL/min during TC infusion then decreased from 13.8 ± 1.3 μL/min to 9.5 ± 0.9 μL/min during GDC perfusion (Table 1). There was no difference between the two BS with regard to hepatic O_2 consumption, which was taken as a criterion of viability. Mean O_2 consumption was 2.5 ± 0.3 μmol/min/g liver for both groups, suggesting that no toxicity of BS was observed (24). Also, no elevation of bilirubin was noted. Alanine aminotransferase (ALT) elevation was observed with some BS, but no correlation was noted between

[a]Data are means ± SE (n = 5). For the conditions of bile salt infusion, see the Materials and Methods section.

enzyme activity and hydrophobicity index. The only significant effect noted by us was a bile flow decrease.

Effects of TC and GDC on the secretion of lipids and APF-CBP into the bile of perfused rat liver. TC infused at 12.5 nmol/min/g liver induced physiological rates of lipid secretion (BS and PL) which remained stable throughout the experiment (BS range, 503-606 nmol/min; PL range, 71-79 nmol/min) (Fig. 1). The molar APF-CBP/BS and APF-CBP/PL ratios remained constant. The two curves (Fig. 1) showed a plateau at a mean of 1.7 for APF-CBP/BS and a mean of 12.7 for APF-CBP/PL.

GDC infused at 121.5 nmol/min/g liver induced a rapid decrease in PL secretion between 20 min and 110 min (Fig. 1). The secretion of APF-CBP also decreased, but not to the same extent as did PL. Thus, the molar APF-CBP/PL ratio varied from 25 to 5. By contrast, the decrease in APF-CBP and BS was the same, so the APF-CBP/BS molar ratio remained constant. During the experiment, the oxygen consumption did not change, and ALT activity remained in the physiological range of 3.2-23 IU/L.

Two procedures were used to study the effect of inverting the sequence of perfusion of BS on the APF-CBP secretion (Fig. 2): (i) TC (12.5 nmol/min/g liver) was infused for 30 min; then GDC (12.5 nmol/min/g liver) was infused for 60 min. The infusion of GDC after TC induced a dramatic decrease in APF-CBP secretion (Fig. 2A). (ii) GDC (12.5 nmol/min/g liver) was infused for 30 min and then TC for 60 min (Fig. 2B). The infusion of TC after GDC restored APF-CBP secretion in bile to near that observed with the TC perfusion (Fig. 2A).

Effect of TC and GDC on secretion of newly synthesized APF-CBP. The quantity of [^{14}C]leucine-labelled APF-CBP recovered from the bile of isolated perfused liver was the same after a 90-min perfusion with either TC or GDC, *i.e.*, 2.4 and 2.5 μg/whole liver (Fig. 3). However, the kinetics of the secretion changed. With TC infusion

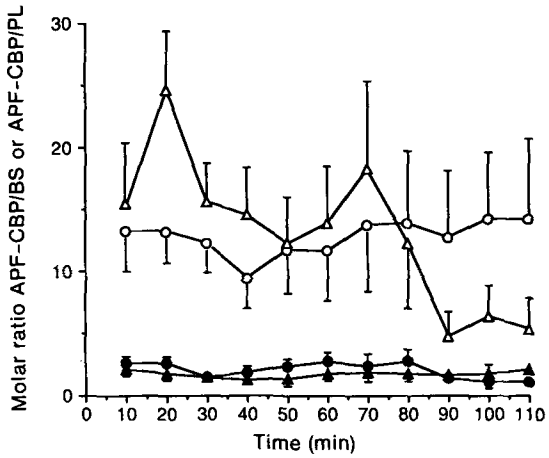

FIG. 1. Molar ratios of the secretion of bile lipids and anionic polypeptide fraction-calcium binding protein (APF-CBP) are shown as a function of time. Different components are expressed in nmol/min secreted from perfused rat liver during infusion of taurocholate (TC) or glycodeoxycholate (GDC) after a 20-min stabilization period with TC. Each point represents the mean ± SE (n = 5). The symbols used are APF-CBP/BS with TC (●), APF-CBP/PL with TC (○), APF-CBP/BS with GDC (▲), and APF-CBP/PL with GDC (△). BS, bile salts; PL, phospholipids.

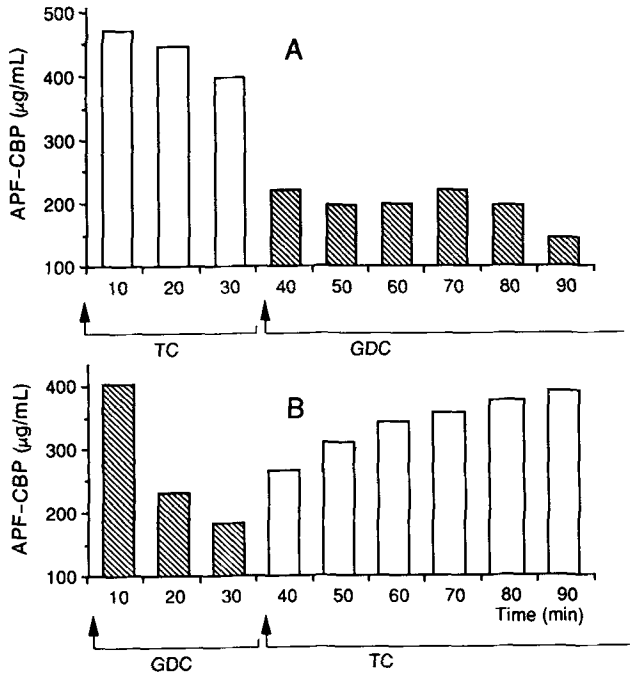

FIG. 2. Effect of inverting the sequence of perfusion of bile salts on the quantitative APF-CBP secretion in bile. A, APF-CBP secretion in bile from perfused rat liver after infusion of TC (30 min), followed by GDC (90 min) at a concentration of 12.5 nmol/min/g liver. B, APF-CBP secretion in bile from perfused rat liver after infusion of GDC (30 min) followed by TC (90 min) infusion. Output of APF-CBP is expressed in μg/mL (n = 2). The hatched bars represent the APF-CBP values with GDC infusion, the open bars after TC infusion. Abbreviations as in Figure 1.

(Fig. 3B), the maximum secretion of the labelled, newly synthesized protein was noted 40 min after perfusion of the labelled amino acid. With GDC infusion, the maximum secretion was noted 50 and 60 min after perfusion of amino acid (Fig. 3A). [^{14}C]Leucine in biliary APF-CBP represented 0.1% of the dose in the medium, and 1% of the [^{14}C]leucine was recovered in the liver.

No significant difference was noted in the effects of TC or GDC on APF-CBP synthesis by freshly isolated hepatocytes for 4 h (Table 2). With TC, the mean APF-CBP synthesis for this period was 0.819 μg/g of cells in the medium, and with GDC it was 0.693 μg/g cells. In both experiments, cell viability after 4 h of incubation was 85%. APF-CBP secretion was dependent on the addition of BS to the medium. The quantity of BS added to the medium was 0.20 μmol/mL for TC and 0.17 μmol/mL for GDC.

Effect of insulin on APF-CBP synthesis by isolated perfused liver. In the bile, the secretion of the labelled, newly synthesized APF-CBP in the presence of TC (12.5 nmol/min/g liver) is shown in Figure 3. When insulin was added at a dose of 5 IU/100 mL (Fig. 3B), the quantity of secreted protein doubled compared to the quantity obtained without insulin (Fig. 3C).

DISCUSSION

The results from the two experimental models used in this study demonstrate that APF-CBP secretion into bile is dependent on the presence of BS. APF-CBP secretion increased after either TC or GDC infusion, but GDC was

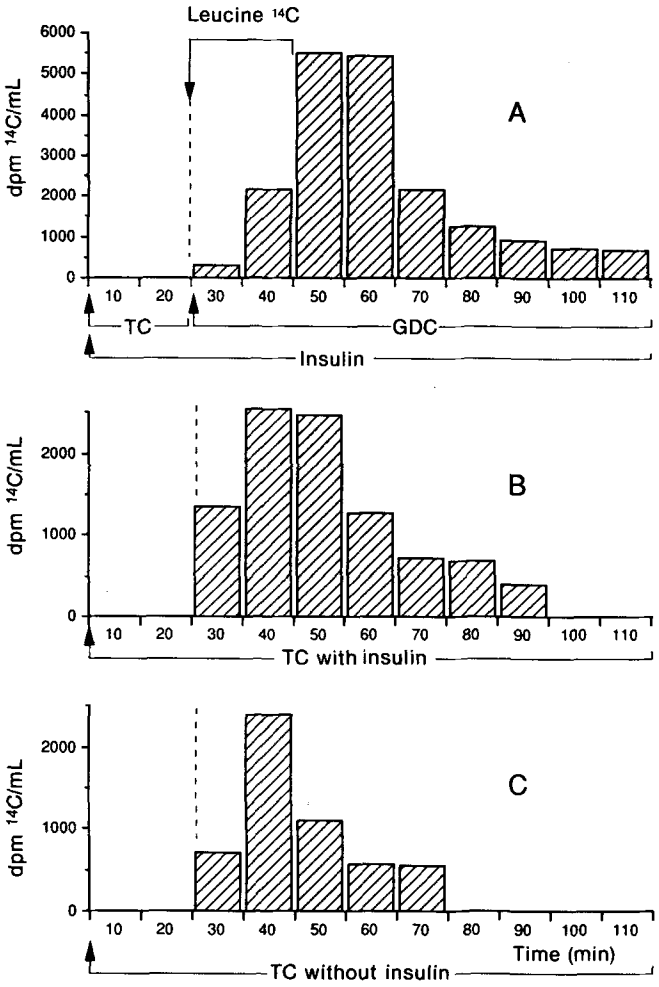

FIG. 3. Secretion of labelled APF-CBP by perfused rat liver. A, with GDC infusion at 12.5 nmol/min/g liver with insulin. B, with TC infusion at 12.5 nmol/min/g liver with insulin. C, with TC infusion at the same concentration without insulin. [^{14}C]leucine was infused for 20 min after TC equilibration. The values are expressed in dpm of [^{14}C]leucine quantified on APF-CBP secreted in bile (n = 3). Abbreviations as in Figure 1.

[a]The cells were incubated in the presence of insulin and fetal calf serum. Samples were tested as described in the Materials and Methods section. Values are means ± SE of two determinations of anionic polypeptide fraction-calcium binding protein (APF-CBP) synthesized from cells prepared from four rat livers. APF-CBP determined in the supernatant is expressed in mg of APF-CBP/g of cells in the medium. The BS were added to the incubation medium at concentrations of 0.2 μmol/mL for TC and 0.17 μmol/mL for GDC. Abbreviations as in Table 1.

more effective in stimulating APF-CBP synthesis and secretion.

The results obtained on isolated perfused rat liver and isolated hepatocytes indicate that BS regulate the synthesis and secretion of APF-CBP. In contrast, insulin clearly enhanced only APF-CBP synthesis. The constant molar ratio of APF-CBP and BS furthermore emphasized the importance of BS in modulating this protein. Previous studies had focused on the binding of APF-CBP to biliary lipids. This association was especially strong with bile PL. For example, APF-CBP provoked a negative electrophoretic behavior of BLC depleted in BS and dissolved together with biliary lecithin in organic solvents (4).

Biliary secretion of PL and cholesterol depends strongly on the hydrophobicity of BS (24). Crawford *et al.* (25) have shown that bile flow, as well as PL and cholesterol levels in bile, were significantly correlated with TC secretion and that bile lipid secretion seemed to be related to the hydrophobicity of the BS.

Phosphatidylcholine in bile can originate from either the canalicular membranes (26), lysosomes (27) or microsomes (26) of liver. However, most likely, it originates from the microsomal membranes and our preliminary data indicate that APF-CBP most likely arises from microsomes as well (12). BS can have a detergent effect on microsomes, and several investigators have shown that the quantity of cholesterol and PL that was solubilized from these membranes increased with the hydrophobicity of the BS (15, 24); secretion of cholesterol and PL increased up to 50% depending on the degree of hydrophobicity of BS varying from 1.7 to 4.5 on the Bilhartz and Dietschy scale (1).

Although TC infusion induced a correlated, steady secretion of APF-CBP in bile, the levels of APF-CBP and PL in bile secretion varied independently when GDC was infused. Our data suggest that the BS could act as the initial modulator of APF-CBP secretion in bile.

The present study clearly showed that BS modulate the synthesis and secretion of APF-CBP and that, unlike other proteins, APF-CBP levels correlate with bile lipid secretion (28). Other studies in the rat had shown that albumin remained constant during BS infusion although APF-CBP was modulated by cholic acid and dehydrocholic acid (14). Furthermore, BS hydrophobicity was shown to determine how cholesterol is distributed between bile and plasma (15). A similar mechanism may also be operative with APF-CBP and could explain the distribution of APF-CBP in bile and plasma. The hydrophobicity of the BS may similarly affect phosphatidylcholine recruitment. When TC was infused after GDC, PL increased in bile suggesting that TC may mobilize a different pool of PL than the one mobilized by GDC.

The bipolar secretion of albumin has recently been demonstrated in hepatocytes (29); however, its BS dependence was not tested. The effect of BS upon APF-CBP secretion appears to be of considerable physiological relevance in regulating biliary secretion.

ACKNOWLEDGMENTS

We wish to thank Dr. J. Grosclaude and S. Labiau (INRA, Laboratoire de Virologie, Jouy-en-Josas) for their helpful collaboration and Dr. Groen (Amsterdam) and Dr. Ostrow (Chicago) for fruitful discussions during the preparation of this manuscript.

On the Syntheses of Branched Saturated Fatty Acids

Salo Gronowitz[a,*], Tomas Klingstedt[a,1], Leif Svensson[b] and Ulf Hansson[b]
[a]Organic Chemistry 1, Chemical Center, University of Lund, Lund, Sweden and [b]Karlshamns AB, S-374 82 Karlshamn, Sweden

In order to investigate the relation between the structure of mono-branched saturated fatty acids and their physical properties, a three-factor central composite design was constructed. For this purpose sixteen different fatty acids were prepared. The synthetic strategy was to use, if possible, a few common starting materials for the preparation of most of the acids. Thus alkylation and hydrolysis of oxazolines were used for the preparation of 2-butylhexanoic acid, 2-methyloctadecanoic acid, 2-hexadecyloctadecanoic acid and 2-pentyloctadecanoic acid. A number of acids were prepared from thiophene derivatives followed by desulfurization with Raney-Nickel alloy under alkaline conditions. Thus, starting from 3-ethylthiophene, 4-ethyl-2-thiophenecarboxylic acid and 4-ethyl-2-methyl-5-thiophenecarboxylic acid were prepared, which upon desulfurization gave the desired 4-methylhexanoic acid. From 3-bromo-2-methylthiophene, 3-ethyl-2-methyl-5-thiophenecarboxylic acid was prepared *via* 3-acetyl-2-methylthiophene and 3-ethyl-2-methylthiophene. Desulfurization gave 4-ethylhexanoic acid. Another approach started with 2-acylthiophenes, which were reacted with Grignard reagent to yield the appropriate olefins. By metalation and reaction with carbon dioxide, these were transformed to the corresponding 2-thiophenecarboxylic acids. Upon desulfurization, the desired fatty acids were obtained. In this way 6-propyldecanoic acid, 6-hexyldodecanoic acid, 6-methyldodecanoic acid and 6-pentylpentadecanoic acid were prepared. The remaining four acids were prepared from some of the branched acids described above through Kolbe reactions of dioic acids. Thus 16-methyloctadecanoic acid and 10-methyl-dodecanoic acid were obtained from 4-methylhexanoic acid, 16-ethyloctadecanoic acid from 4-ethylhexanoic acid and 9-pentyloctadecanoic acid from 6-pentylpentadecanoic acid.
***Lipids* 28, 889–897 (1993).**

Branched-chain fatty acids can be found in nature in many oils, fats and waxes, although in most cases the levels are very low. They also are minor components of many bacterial lipids, animal fats and marine oils (1). Bird waxes (from the preen gland) and lipids of gram-positive bacteria are important exceptions, where branched acids predominate (2,3). The preen gland wax of the Shanghai duck has a mono- and dimethyl-substituted fatty acid content of more than 85%. A total of 66 different methyl-branched saturated fatty acids have been identified from this species (4).

The industrial use of branched acids is very limited; only a few branched acids are produced today. The branching is almost exclusively either adjacent to the carboxyl group (α-branched) or near the end of the alkyl chain (*iso* or *anteiso* compounds). The α-branched compounds can be obtained by way of the Koch reaction, the oxo reaction or *via* aldol condensation followed by an oxidation of the aldehyde formed (5,6). Isostearic acid is a by-product in the dimerization process of unsaturated C_{18} fatty acids (7). 2-Ethyl-hexanoic acid, *iso*-stearic acid and the various *neo*-acids (formed in the Koch process from terminal olefins) are among the most important commercial branched-chain fatty acids (8,9).

The physical properties of branched-chain fatty acids are very different from straight-chain acids. The introduction of a branch alters many properties such as the melting point, the surface tension and the viscosity. The low pour point, low surface tension and the excellent oxidative stability of the acids and their derivatives make them useful in many applications. They have found use in cosmetics, lubricants, fabric softeners, etc. (5).

In order to investigate the relation between the structure of mono-branched saturated acids and their physical properties, a three-factor central composite design was constructed (10). The three factors involved are the length of the main chain, the length of the side chain and the branching position. This design required the preparation of fifteen different fatty acids. The results of this investigation are published in the following paper together with a more detailed discussion of the experimental design.

RESULTS AND DISCUSSION

According to the design discussed, the branched fatty acids 1–16 given in Table 1 were needed. Many of these acids have been described in the literature. However, we wanted to prepare these acids from as few starting materials as possible.

Therefore two main synthetic strategies were adopted. The α-branched acids were synthesized by alkylation of the lithium enolate of the dimethyl oxazolidines from the

proper unbranched acid (11), while the ω-2 and the internally substituted acids were synthesized *via* Raney-Nickel desulfurization of suitably substituted thiophenecarboxylic acids (12). In some cases the branched acids obtained upon desulfurization were chain-extended by use of an asymmetrical Kolbe synthesis (13,14).

Thus, **1** and **5** were prepared by alkylation of the enolate from 2-ethyl-4,5-dihydro-4,4-dimethyloxazole (propionic acid oxazoline) with butyl bromide and hexadecyl bromide, respectively (Scheme 1). The choice of propionic acid instead of hexanoic and octadecanoic acid as starting material for the oxazolidine synthesis could be motivated by the fact that both **1** and **5** might be synthesized from the same oxazoline.

However, a more important factor for the choice of the short acid is the simplicity gain in the purification of the branched oxazolines, especially in the case of **5** where the similarity of the product and the starting material would make the purification almost impossible. Similarly, heptanoic acid oxazoline and decyl bromide were used for the preparation of **13** and not dodecanoic acid oxazoline and pentyl bromide. Acid **2** was obtained *via* butylation of the hexanoic acid oxazoline, and **6** *via* octadecanoic acid oxazoline and hexadecyl bromide (Scheme 1).

SCHEME 1

Acid **1** is commercially available. There are also a number of methods for the preparation of **1**. Dialkylation of malonic ester followed by decarboxylation has been used (15). Acid **1** has been prepared by treating an oxazoline with lithium diisopropylamide (LDA) and alkylating the anion formed (16). Hexanol treated with a nickel catalyst and carbon monoxide gives **1** (17). Alkylation of the dianion of propionic acid also gives **1** (18). A common route is to add carbon monoxide to 1-hexene in the presence of a catalyst (19–21).

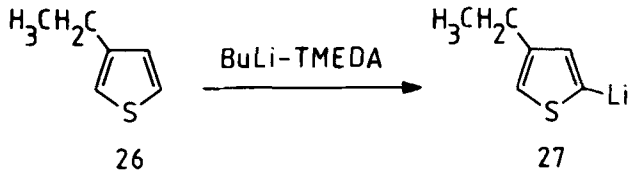
Acid **2** has been synthesized by treating the dianion of hexanoic acid with butyl bromide (18). It has also been prepared by decarboxylation of dibutylated malonic acid (22).

Several methods are available for the preparation of acid **5**. It has been prepared by reacting α-bromooctadecanoic acid with methylmagnesium iodide (23), and it has also been synthesized by a Kolbe electrolysis of hexadecanoic acid and 3-cyanobutanoic acid, followed by hydrolysis (24). A third alternative has been reported by Reppe and Kröper (25). They reacted octadecene with carbon monoxide in water in the presence of nickel carbonyl. Acid **5** has also been prepared by a dialkylation of diethyl malonate, followed by decarboxylation (26).

Acid **6** has been prepared by a malonic ester synthesis (27,28). It has also been synthesized from 1-hexadecene and octadecanoic acid in the presence of *t*-butyl peroxide (29). The method which we have adopted, converting the acid to its oxazoline and treating this with butyllithium followed by hexadecyl bromide, has been used before (30).

Acid **13** has been prepared by dialkylation of ethyl malonate followed by decarboxylation (31), and it was also synthesized from dodecanoic acid upon heating with *t*-butyl peroxide in the presence of 1-pentene (32).

It is well known that substituents can be selectively introduced in the thiophene ring when proper reaction conditions and reagents are used (33). This in combination with Raney-Nickel desulfurization, when the sulfur and the double bonds are removed, gives a saturated carbon skeleton. In organic synthesis, thiophene can therefore be used as a synthon for both straight and branched 4-carbon chains. Both of these possibilities have been exploited in this work.



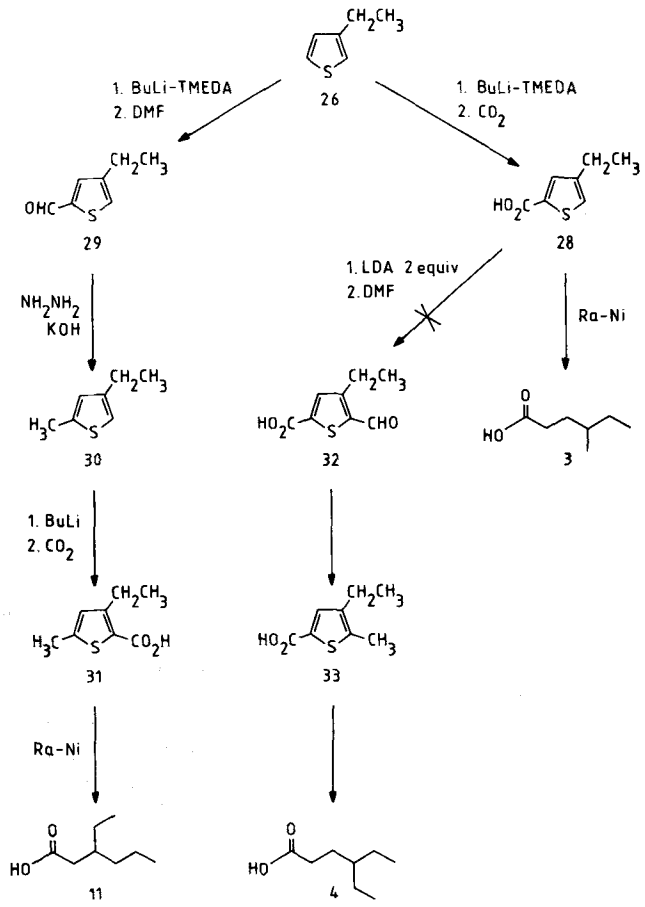
26 27

SCHEME 2

Our approach for the syntheses of the acid **11** and the (ω-2)-branched fatty acids was to use 3-ethylthiophene (**26**) as a key substance. If **26** is treated with one equivalent of the butyllithium-*N,N,N,N*-tetramethylethylenediamine (TMEDA) complex at room temperature, 4-ethyl-2-thienyllithium (**27**) will selectively be formed (Scheme 2) (33).

In the synthesis of 4-methylhexanoic acid (**3**), the lithiated 3-ethylthiophene (**27**) was treated with carbon dioxide to give 4-ethyl-2-thiophenecarboxylic acid (**28**) in 69% yield, which, upon Raney-Nickel desulfurization, gave **3** in 71–89% yield (Scheme 3).

Acid **3** has previously been synthesized in a number of ways. Wolff-Kishner reduction of the unsaturated aldehyde, citronellal yields 2,6-dimethyl-2-octene, which can be oxidatively cleaved by potassium permanganate (34) or ozone (35) to give **3**. This compound was also prepared from 1-bromo-2-methylbutane, formed from the corresponding alcohol, by treatment with diethyl malonate in the presence of sodium ethoxide, followed by decarboxylation (36). A third option is to use the reaction of succinic acid anhydride with ethyl- and methylaluminium chloride reagents to form a tertiary lactone, which can be



SCHEME 3

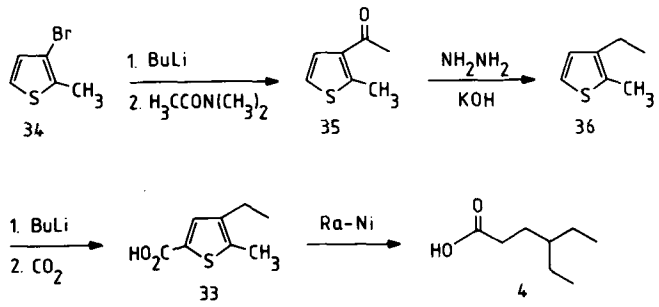
reductively opened by treatment with an organoaluminum halide reagent (37–39).

3-Ethylhexanoic acid (11) was also synthesized from 26, the lithiated derivative 27 reacted with *N,N*-dimethylformamide to give 4-ethyl-2-thiophene aldehyde (29), which was reduced to 4-ethyl-2-methylthiophene (30). Metalation of 30 with butyllithium followed by reaction with carbon dioxide gave 3-ethyl-5-methyl-2-thiophenecarboxylic acid (31) in 67–76% yield. After Raney-Nickel desulfurization, 11 was obtained in 73% yield (Scheme 3).

Acid 11 has previously been synthesized by reacting 3-bromohexane, synthesized from the corresponding alcohol, with either diethyl malonate (40), or acetic acid oxazoline (41).

Attempts to use 26 for the synthesis of 4-ethylhexanoic acid (4) *via* desulfurization of 3-ethyl-2-methyl-5-thiophenecarboxylic acid (33) were not successful. A direct lithiation of 28 with two equivalents of LDA followed by reaction with *N,N*-dimethylformamide failed to give 3-ethyl-2-formyl-5-thiophenecarboxylic acid (32), which we planned to reduce to 33. We then tried to prepare 2-iodo-4-ethylthiophene *via* metalation of 3-ethylthiophene followed by addition of iodine. The purpose of this approach was to use the iodine substituent as a protecting group, and then to be able to selectively introduce a formyl group to the 5-position by lithiation of the 2-iodo-4-ethylthiophene using one equivalent of LDA, followed by the addition of *N,N*-dimethylformamide. However, 2-iodo-4-ethylthiophene was formed in a mixture with 3-ethyl-2-iodothiophene.

We therefore prepared 33 from 3-bromo-2-methylthiophene (34) by converting it *via* halogen-metal exchange and reaction with *N,N*-dimethylacetamide to 3-acetyl-2-methylthiophene (35), which through Wolff-Kishner reduction was transformed to 3-ethyl-2-methylthiophene (36). Metalation followed by reaction with carbon dioxide gave 33, which upon Raney-Nickel desulfurization formed 4 in 77% yield (Scheme 4).



SCHEME 4

Acid 4 has previously been synthesized by reacting 2-ethyl butyraldehyde with malonic acid. The unsaturated acid was then hydrogenated using platinum oxide as catalyst (42). It has also been synthesized from succinic acid anhydride following the procedure described for acid 3 (37–39).

Another very useful starting material for several of the desired acids was 2-heptanoylthiophene (37) prepared by Friedel-Crafts acylation of thiophene with heptanoyl chloride using tin tetrachloride as catalyst (*cf.* Scheme 5). Reaction of this ketone with propyl magnesium bromide followed by dehydration gave a mixture of the isomeric olefins 38 and 39 in 73% yield. The mixture was metalated with butyllithium and reacted with carbon dioxide to give a mixture of the acids 40 and 41 in 78% yield, which was desulfurized to give 6-propyldodecanoic acid (9). The crude product obtained in 79% yield contained small amounts of unsaturated product, and was therefore hydrogenated over Pd on carbon using ethanol as solvent. As partial esterification occurred during the hydrogenation, the product was completely esterified, distilled and then hydrolyzed with sodium hydroxide to give pure 9 in an overall yield of 50%.

The acids 6-hexyldodecanoic acid (14) and 6-methyldodecanoic acid (15) were prepared in a similar way by treating the 2-heptanoylthiophene (37) with hexylmagnesium bromide and methylmagnesium iodide, respectively. The reaction of 2-heptanoylthiophene with methylmagnesium iodide gave, as in the first case, a mixture of the two olefines 44 and 45 in 64% yield. The isomeric distribution of this mixture could be determined by ^1H nuclear magnetic resonance spectroscopy (NMR). It was found that the least substituted olefin dominated, contrary to what might be expected. The overall yields of 6-hexyldodecanoic acid (14) and 6-methyldodecanoic acid (15) from heptanoylthiophene were 59 and 78%, respectively.

SCHEME 6

Acid 15 has been synthesized by Weitzel and Wojahn (43) using the same strategy as they used in the synthesis of 12, *i.e.*, repeated malonic ester syntheses. An alternative treatment of 4-methyl-1-decene with diethyl malonate in the presence of *t*-butyl peroxide gave 4-methyldecyl malonate, which upon decarboxylation yielded 15 (44). A third approach to 15 has been published by Asano *et al.* (45) in which hexyl zinc iodide and adipic acid chloride monoethyl ester were reacted to form ethyl 6-keto dodecanoate. The barium salt of the corresponding acid was treated with methylmagnesium iodide, and the product was dehydrated and reduced to give 15.

In order to obtain 6-pentylpentadecanoic acid (16), which was needed for the prepration of 9-pentyloctadecanoic acid (10), thiophene was acylated with decanoyl chloride to give 2-decanoylthiophene (48), which upon reaction with pentyl-magnesium bromide and dehydration in the same way as described above gave a mixture of the olefinic thiophenes 49 and 50. After metalation, treatment with carbon dioxide and desulfurization, 16 was obtained in 32% yield.

The remaining acids, 7, 8, 10, 12, were prepared by Kolbe syntheses (Scheme 6). The acids 7 and 12 were prepared by coupling of 3 with the monomethyl esters of tetradecanedioic acid and octadecanedioic acid, and the acid 8 by coupling of 4 with tetradecanedioic acid monomethyl ester. Finally acid 10 was obtained from 16 and the monomethyl ester of glutaric acid. Due to the formation of symmetrical coupling products, the yields obtained were only about 30%.

Acid 7 has been prepared in a multistep synthesis starting from 1-bromo-2-methylbutane. By extending the chain by repeatedly reacting the organocadmium compounds, synthesized from the corresponding halide, with mono acid chlorides to form keto esters, which could be reduced and converted to new saturated halides, which finally gave 7 (46). Milburn and Truter (47) have, in an approach similar to ours, used Kolbe syntheses for the preparation of 7. However, in their case 4-methyl hexanoic acid was coupled with two diacids in two consecutive steps to give 7.

Milburn and Truter (47) have also synthesized 12 by a Kolbe synthesis from 3-methylpentanoic acid and methyl hydrogen azelate. The 3-methylpentanoic acid was synthesized in three steps from 2-methyl-1-butanol. In another route, 12 has been prepared by repeated malonic ester synthesis, where the acids formed were reduced and halogenated and used again in new malonic ester syntheses (43).

MATERIALS AND METHODS

^{1}H NMR spectra were recorded on a Varian XL-300 spectrometer (Palo Alto, CA). The infrared (IR) spectrometer used was a Perkin-Elmer Model 298 (Norwalk, CT). Mass spectra were recorded on a Finnigan 4021 (San Jose, CA) and a Jeol JMS-SX 102 spectrometer (Tokyo, Japan). Gas chromatograms were obtained using Varian gas chromatographs models 1400 and 3300. Glass columns (length 2.0 m, i.d. 2 mm) were used with 10% SP-2340 and 3% OV 101 on Chromosorb Q 100/120. Careful analyses of the acids showed that they were of high purity (>98%).

2-Methylhexanoic acid (1) was prepared as described by Herslöf and Gronowitz (30). A 250-mL round-bottom flask equipped with reflux condenser was charged with 2-methylhexanoic acid oxazoline (10.0 g, 55 mmol) and 6M hydrochloric acid (55 mL). The reaction mixture was heated to reflux and kept at this temperature for 24 h. A hydrolyzed sample from the reaction mixture was analyzed by gas chromatography (GC), which showed no starting material. The reaction mixture was cooled and then poured into dichloromethane (50 mL). The organic phase was separated and the water phase was extracted twice with dichloromethane. The combined organic phases

were washed three times with 2M sodium hydroxide solution, after which the alkaline solution was acidified with concentrated hydrochloric acid under cooling. The product was dissolved in dichloromethane, and this solution was washed with water and dried over magnesium sulfate. Upon removal of the solvent, compound 1 (6.3 g, 88%) was obtained. ^{1}H NMR ($CDCl_3$) δ 0.9 (*t*, 3H, CH_3), 1.2 (*d*, 3H, CH_3), 1.25–1.35 (*m*, 4H, CH_2), 1.35–1.50 (*m*, 1H, CHH), 1.65–1.75 (*m*, 1H, CHH), 2.45 (*sext.* 1H, CHCO). Mass spectroscopy (MS) [electron impact (EI)] *m/e* (rel. int.): 115(0.7), 101(3), 87(21), 74(100). Known compound (15–21).

2-Butylhexanoic acid (2) was prepared as described above from 2-butylhexanoic acid oxazoline (10.0 g, 44 mmol) and 6M hydrochloric acid (44 mL). Evaporation of the solvent gave compound 2 (6.7 g, 88%). ^{1}H NMR ($CDCl_3$) δ 0.9 (*t*, 6H, CH_3), 1.25–1.40 (*m*, 8H, CH_3), 1.40–1.55 (*m*, 2H, CHH), 1.55–1.70 (*m*, 2H, CHH), 2.30–2.40 (*m*, 1H, CHCO). MS (EI) *m/e* (rel. int.): 173(1), 155(0.4), 143(2), 129(7), 116(45), 87(48), 73(100). Known compound (18,22).

4-Methylhexanoic acid (3). A 5-L three-necked round-bottom flask was equipped with a mechanical air-driven stirrer, the side-necks were equipped with two-necked adapters on one side for nitrogen and a funnel with a cork. The cork could be removed by pulling an iron wire attached to the cork. The two-necked adapter on the other side was equipped with a thermometer and two consecutive condensers. After sweeping the flask for 15 min with a strong stream of nitrogen, the flow was reduced and the flask was charged with 10% sodium hydroxide solution (2300 mL). During stirring, 4-ethyl-2-thiophenecarboxylic acid (28) (48) (30.0 g, 0.19 mol) was added. When 28 was dissolved, the solution was heated to 90°C, whereupon Raney-Nickel (240 g) was slowly added by means of a spoon through the funnel. It was important to add the alloy at a very moderate rate to avoid a too vigorous reaction. The temperature of the reaction mixture was kept at 90–100°C. When addition was completed, the reaction mixture was stirred at 90°C overnight. The hot reaction mixture was filtered through a glass filter, and the Raney-Nickel was washed twice with 150 mL of water. *It is important that the Raney-Nickel be kept wet, since it is pyrophoric.* The Raney-Nickel residue was then transferred to a glass bottle and covered with water. The combined alkaline water phases were cooled in an ice-bath, after which they were poured into ice-cooled concentrated hydrochloric acid (1500 mL). The acidic water solution was divided into two parts, and each part was extracted with three 500-mL portions of diethyl ether. The combined ether phases were washed with water and dried over magnesium sulfate. After evaporation of the solvent and distillation (b.p. 109–116°C/15 mm Hg), compound 3 (14.7 g, 89%) was obtained. ^{1}H NMR ($CDCl_3$) δ 0.87 (*t*, 3H, CH_3), 0.89 (*d*, 3H, CH_3), 1.10–1.25 (*m*, 1H, CHH), 1.30–1.55 (*m*, 3H, CHH, CHH), 1.65–1.75 (*m*, 1H, CHH), 2.25–2.45 (*m*, 2H, CH_2CO). MS (EI) *m/e* (rel. int.): 131(3), 113(2), 101(10), 83(15), 73(46), 71(76), 55(82), 41(100). Known compound (34,37).

4-Ethylhexanoic acid (4) was prepared analogously to 3 from 4-ethyl-5-methyl-2-thiophenecarboxylic acid (33) (25.0 g, 0.15 mol), Raney-Nickel (250 g) and 10% sodium hydroxide solution (2400 mL). After distillation (b.p. 126–131°C/15 mm Hg), compound 4 (16.4 g, 77%) was obtained. ^{1}H NMR ($CDCl_3$) δ 0.85 (*t*, 6H, CH_3), 1.20–1.35 (*m*, 5H, CH, CH_2), 1.55–1.65 (*m*, 2H, CH_2), 2.30 (*t*, 2H, CH_2CO). MS (EI) *m/e* (rel. int.): 145(1), 115(6), 97(12), 85(42), 73(51), 69(47), 60(22), 55(49), 43(100). Known compound (42).

2-Methyloctadecanoic acid (5) was prepared analogously to 1 from 2-methyloctadecanoic acid oxazoline (10.0 g, 28 mmol) and 6M hydrochloric acid (29 mL). As 5 is a solid compound, the reaction mixture was transferred to a beaker and cooled in an ice-bath, whereupon the product separated as a solid phase, which was collected on a glass filter and washed twice with water. After recrystallization from ethanol (m.p. 54.5–56.0°C), pure 5 (5.7 g, 68%) was obtained. ^{1}H NMR ($CDCl_3$) δ 0.88 (*t*, 3H, CH_3), 1.18 (*d*, 3H, CH_3), 1.20–1.35 (*m*, 28H, CH_2), 1.35–1.50 (*m*, 1H, CHH), 1.60–1.75 (*m*, 1H, CHH), 2.40–2.50 (*m*, 1H, CHCO). MS (EI) *m/e* (rel. int.): 298(5), 255(3), 241(4), 227(2), 199(4), 185(4), 143(7), 129(7), 87(33), 74(86), 43(100). Known compound (23–26).

2-Hexadecyloctadecanoic acid (6) was prepared analogously to 5 from 2-hexadecyloctadecanoic acid oxazoline (30) (10.0 g, 18 mmol) and 6M hydrochloric acid (17 mL). After recrystallization from ethanol (m.p. 74.0–76.5°C), compound 6 (7.5 g, 82%) was obtained. ^{1}H NMR ($CDCl_3$) δ 0.88 (*t*, 6H, CH_3), 1.15–1.35 (*m*, 56H, CH_2), 1.40–1.55 (*m*, 2H, CHH), 1.55–1m70 (*m*, 2H, CHH), 2.30–2.40 (*m*, 1H, CHCO). MS (EI) *m/e* (rel. int.): 508(6), 409(1), 395(1), 381(1), 297(7), 284(20), 241(6), 185(8), 129(16), 57(98), 43(100). Known compound (27–29).

16-Methyloctadecanoic acid (7). A 500-mL flask, equipped with a thermometer and a magnetic stirring bar, was charged with 4-methylhexanoic acid (3) (5.0 g, 38 mmol), monomethyl ester of tetradecanedioic acid (21.0 g, 77 mmol) and potassium hydroxide (0.6 g, 11.5 mmol) in methanol (400 mL). A platinum electrode (12 cm^2, as anode) and an iron electrode (as cathode) were inserted into the solution, which was electrolyzed using a constant voltage. The initial current density was 175 mA/cm^2, and the temperature of the reaction mixture was kept at 40–55°C. The volume of the reaction mixture was kept constant by adding methanol during the reaction. When 1.1 F/mol had passed through the cell, the reaction was stopped. The reaction mixture was treated with a mixture of diethyl ether, dichloromethane and 1M hydrochloric acid. The phases were separated and the organic phase washed with sodium carbonate solution and water, dried over magnesium sulfate and evaporated. The residue was distilled (b.p. 136–142°C/0.05 mm Hg), and methyl ester of 16-methyloctadecanoic acid (3.0 g, 26%) was obtained.

In order to hydrolyze the ester, a mixture of ester (3.0 g, 10 mmol) and sodium hydroxide (3.0 g, 77 mmol) in ethanol (2 mL) and water (20 mL) was refluxed for 5 h. The reaction mixture was poured into a beaker and cooled to room temperature. The precipitate formed was treated with concentrated hydrochloric acid (7.5 mL) and diethyl ether/dichloromethane (1:1, vol/vol). The phases were separated and the organic phase washed with water, dried over magnesium sulfate and evaporated, giving pure 7 (2.9 g, 93%) with m.p. 49.0–50.5°C. ^{1}H NMR ($CDCl_3$) δ 0.85 (*t*, 3H, CH_3), 0.84 (*d*, 3H, CH_3), 1.05–1.20 (*m*, 1H, CHH), 1.20–1.40 (*m*, 26H, CHH, CH, CH_2), 1.58–1.70 (*m*, 2H, CH_2), 2.35 (*t*, 2H, CH_2CO). MS (EI) *m/e* (rel. int.): 298(6), 281(2), 269(3), 251(4), 199(5), 185(5), 129(10), 71(39), 43(100). Known compound (46,47).

16-Ethyloctadecanoic acid (8) was prepared analogously to 7 from 4-ethylhexanoic acid (4) (5.0 g, 35 mmol), monomethyl ester of tetradecanedioic acid (19 g, 70 mmol) and potassium hydroxide (0.6 g, 11.5 mmol) in methanol (400 mL). Distillation (b.p. 187–189°C/2 mm Hg) gave the ester (3.5 g, 31%), which upon hydrolysis gave 8 (3.2 g, 96%) with m.p. 51.0–54.0°C. ^{1}H NMR ($CDCl_3$) δ 0.78 (*t*, 6H, CH_3), 1.10–1.35 (*m*, 29H, CH_2, CH), 1.50–1.65 (*m*, 2H, CH_2), 2.20 (*t*, 2H, CH_2CO). MS (EI) *m/e* (rel. int.): 312(6), 294(3), 283(6), 256(6), 242(4), 111(9), 98(13), 84(26), 71(31), 55(55), 43(100). Calc. for $C_{20}H_{40}O_2$: C, 76.86; H, 12.90; MW 312.54. Found: C, 74.89; H, 12.60.

6-Propyldodecanoic acid (9). The first attempt was analogous to the preparation of 3 from a 10% sodium hydroxide solution (2500 mL), ethanol (1000 mL), a mixture of 4-(5′-carboxy-2′-thienyl)-3-decene (31) and 4-(5′-carboxy-2′-thienyl)-4-decene (32) and Raney-Nickel (200 g). GC analysis of the crude product showed that 38% of the starting material was left. The crude product was therefore desulfurized twice, each time using 10% sodium hydroxide solution (830 mL), ethanol (330 mL) and Raney-Nickel (67.0 g). After this procedure, GC analysis showed that the starting material was consumed. However, traces of unsaturated compounds were detected. The product (17.0 g) was therefore hydrogenated in ethanol (100 mL) with hydrochloric acid (3 drops) over palladium on charcoal (0.5 g) at 50°C and a hydrogen pressure of 50 psi. After 72 h, the reaction was interrupted and the catalyst was removed by filtration through celite. The filtrate was treated with concentrated hydrochloric acid (2 mL) and refluxed for 4 h. The reaction mixture was cooled, poured into brine (50 mL), and the product was taken up in diethyl ether (3 × 150 mL). The combined ether phases were dried over magnesium sulfate and evaporated, whereupon the residue was distilled (b.p. 103–108°C/0.25 mm Hg) giving ethyl 6-propyl dodecanoate (12.2 g, 60%).

The ester was mixed with water (65 mL), ethanol (13 mL) and sodium hydroxide (11.0 g, 0.26 mol), and the reaction mixture was refluxed for 5 h. After cooling and acidification with concentrated hydrochloric acid, the product was taken up in diethyl ether, and the ether solution was dried over magnesium sulfate. Evaporation gave pure 9 (10.2 g, 93%). ^{1}H NMR ($CDCl_3$) δ 0.87 (*t*, 3H, CH_3), 0.88 (*t*, 3H, CH_3), 1.15–1.35 (*m*, 19H, CH_2, CH), 1.55–1.70 (*m*, 2H, CH_2), 2.36 (*t*, 2H, CH_2CO). MS (EI) *m/e* (rel. int.) $Si(CH_3)_3$ derivative: 314(4), 299(20), 285(2), 271(5), 299(5), 180(14), 145(36), 132(45), 117(70), 73(100). Calc. for $C_{15}H_{30}O_2$: C, 74.32; H, 12.47; MW 242.41. Found: C, 74.95; H, 12.56.

9-Pentyloctadecanoic acid (10) was prepared analogously to 7 from 6-pentylpentadecanoic acid (16), monomethyl ester of pentanedioic acid (37.4 g, 26 mmol) (49), potassium hydroxide (0.90 g, 16 mmol) and methanol (400 mL). After work-up and distillation (184–191°C/0.7 mm Hg), methyl 9-pentyloctadecanoate (5.9 g, 25%) was obtained. The ester was hydrolyzed using water (60 mL), ethanol (10 mL) and sodium hydroxide (5.0 g, 125 mmol). After work-up, compound 10 (5.0 g, 89%) was obtained. ^{1}H NMR ($CDCl_3$) δ 0.88 (, 6H, CH_3), 1.20–1.40 (*m*, 35H, CH_2, CH), 1.57–1.70 (*m*, 2H, CH_2), 2.35 (*t*, 2H, CH_2CO). MS (EI) *m/e* (rel. int.): 355(1), 283(2), 260(2), 227(4), 209(4), 111(8), 97(13), 85(18), 71(35), 57(75), 43(100). Calc. for $C_{23}H_{46}O_2$: C, 78.02; H, 13.00; MW 356.62. Found: C, 78.14; H, 13.19.

3-Ethylhexanoic acid (11) was prepared analogously to 3 from 10% sodium hydroxide solution (2400 mL), 3-ethyl-5-methyl-2-thiophenecarboxylic acid (31) (25.0 g, 0.15 mol), and Raney-Nickel (250 g). After work-up and distillation (b.p. 120°C/13 mm Hg) 11 (14.8 g, 73%) was obtained. ^{1}H NMR ($CDCl_3$) δ 0.88 (*t*, 6H, CH_3), 1.20–1.50 (*m*, 6H, CH_2), 1.75–1.90 (*m*, 1H, CH), 2.28 (*d*, 2H, CH_2). MS (EI) *m/e* (rel. int.): 145(1), 115(5), 101(7), 84(30), 60(90), 43(100). Known compound (40,41).

10-Methyldodecanoic acid (12) was prepared analogously to 7 from 4-methylhexanoic acid (3) (10.0 g, 76.9 mmol), monoethyl ester of octanedioic acid (50) (31.1 g, 154 mmol), potassium hydroxide (1.3 g, 23 mmol) and methanol (450 mL). Work-up and distillation (b.p. 105–110°C/1 mm Hg) gave ethyl 10-methyl dodecanoate (7.6 g, 1 mm Hg). The ester was hydrolyzed using water (50 mL), ethanol (5 mL) and sodium hydroxide 3.8 g, 95 mmol). Work-up and evaporation gave 12 (6.0 g, 84%). ^{1}H NMR ($CDCl_3$) δ 0.88 (*d*, 3H, CH_3), 0.89 (*t*, 3H, CH_3), 1.05–1.20 (*m*, 1H, CHH), 1.20–1.45 (*m*, 14H, CH, CHH, CH_2), 1.55–1.70 (*m*, 2H, CH_2), 2.30 (*t*, 2H, CH_2CO). MS (EI) *m/e* (rel. int.) ($Si(CH_3)_3$ derivative: 286(3), 271(16), 257(3), 243(3), 227(3), 201(5), 145(4), 132(22), 117(50), 75(70), 73(100). Known compound (46,47).

2-Pentyldodecanoic acid (13) was prepared analogously to compound 5 from 2-pentyldodecanoic acid oxazoline (105.3 g, 0.33 mol) and 6M hydrochloric acid (330 mL). After 96 h the reaction mixture was worked up and 13 (59.4 g, 67%) was obtained. ^{1}H NMR ($CDCl_3$) δ 0.88 (*t*, 6H, CH_3), 1.20–1.40 (*m*, 24H, CH_2), 1.40–1.55 (*m*, 2H, CHH), 1.55–1.70 (*m*, 2H, CHH), 2.35 (*m*, 1H, $CHCO$). MS (EI) *m/e* (rel. int.): 270(4), 213(6), 143(15), 130(62), 87(71), 73(100), 43(90). Known compound (31,32).

6-Hexyldodecanoic acid (14) was prepared analogously to 9 from 10% sodium hydroxide solution (2460 mL), ethanol (990 mL), 7-(5′-carboxy-2′-thenyl)-6-tridecene (43) (20.0 g, 65 mmol) and Raney-Nickel (197 g). After work-up pure 14 (10.9 g, 59%) was obtained. ^{1}H NMR ($CDCl_3$) δ 0.88 (*t*, 6H, CH_3), 1.15–1.35 (*m*, 25H, CH_2, CH), 1.55–1.70 (*m*, 2H, CH_2), 2.36 (*t*, 2H, CH_2). MS (EI) *m/e* (rel. int.): 285(4), 266(3)m, 248(5), 222(22), 199(9), 181(11), 163(10), 102(25), 57(79), 43(100). Calc. for $C_{18}H_{36}O_2$: C, 75.99; H, 12.76; MW, 284.49. Found: C, 76.19; H, 13.12.

6-Methyldodecanoic acid (15) was prepared analogously to 9 from 10% sodium hydroxide solution (2500 mL), ethanol (1000 mL), the mixture of 2-(5′-carboxy-2′-thienyl)-1-octen (46) and 2-(5′-carboxy-2′-thienyl)-2-octene (47) (20.0 g, 84 mmol) and Raney-Nickel (200 g). After work-up and distillation (b.p. 131–136°C/1.1 mm Hg) 15 (14.2 g, 78%) was obtained. ^{1}H NMR ($CDCl_3$) δ 0.84 (*d*, 3H, CH_3), 1.05–1.15 (*m*, 1H, CHH), 1.20–1.40 (*m*, 14H, CH_2, CH), 1.55–1.65 (*m*, 2H, CH_2), 2.36 (*t*, 2H, CH_2CO). MS (EI) *m/e* (rel. int.): 215(9), 197(7), 179(6), 152(29), 129(8), 111(7), 83(39), 55(65), 43(100). Known compound (43–45).

6-Pentylpentadecanoic acid (16) was prepared analogously to 9 from 10% sodium hydroxide solution (1500 mL), ethanol (1000 mL), the mixture of 6-(5′-carboxy-2′-thienyl)-6-pentadecene (51) and 6-(5′-carboxy-2′-thienyl)-6-pentadecene (52) (30.0 g, 89 mmol) and Raney-Nickel (120 g). The crude product (17 g) was hydrogenated and esterified giving upon distillation (b.p. 177–180°C/0.40 mm Hg) ethyl 6-pentylpentadecanoate (11.6 g, 99%). ^{1}H NMR ($CDCl_3$) δ 0.88 (*t*, 6H, CH_3), 1.15–1.35 (*m*, 29H, CH_2, CH), 1.55–1.65 (*m*, 2H, CH_2), 2.36 (*t*, 2H, CH_2CO).

MS (EI) *m/e* (rel. int.) 312(0), 294(6), 276(10), 250(100), 241(13), 223(15), 185(20), 167(28). Calc. for $C_{20}H_{40}O_2$: C, 76.86; H, 12.90; MW, 312.54. Found: C, 76.64; H, 13.08.

Propionic acid oxazoline (**17**) (51) was prepared analogously to acetic acid oxazoline (52). A 500-mL round-bottom flask equipped with a thermometer, magnetic bar and reflux condenser was charged with freshly distilled 2-amino-2-methyl-1-propanol (178 g, 2.0 mol), and propionic acid was added. With stirring the reaction mixture was refluxed until the reflux temperature dropped from 165 to 142°C. The oxazoline was distilled azeotropically at 95–125°C through a Vigreux column. The distillate was collected in a receiver containing 300 mL of hexane, in which the water separated as a lower layer. The water layer was extracted three times with hexane, and the combined organic phases were dried over magnesium sulfate. After evaporation and distillation (b.p. 130–131°C) compound **17** (177.4 g, 70%) was obtained.

Hexanoic acid oxazoline (**18**) was prepared according to (30) from hexanoic acid (116 g, 1.0 mol) and 2-amino-2-methyl-1-propanol (116 g, 1.3 mol) in xylene (100 mL). The flask was equipped with a water estimator and the reaction mixture was refluxed for 2 h, whereupon the xylene was distilled off. The residue was chromatographed on neutral alumina (Merck, Darmstadt, Germany) using diethyl ether as eluent. After evaporation and distillation (b.p. 83–85°C/19 mm Hg) **18** (105 g, 62%) was obtained. Lit. value (30) b.p. 90–92°C/25 mm Hg.

Octadecanoic acid oxazoline (**19**) was prepared analogously to **18** from octadecanoic acid (284 g, 1.0 mol) and 2-amino-2-methyl-1-propanol (116 g, 1.3 mol). Distillation (138–143°C/0.025 mm Hg) gave compound **19** (275 g, 82%). Lit. value (30) b.p. 90–92°C/0.01 mm Hg.

Heptanoic acid oxazoline (**20**) was prepared analogously to **18** from heptanoic acid (130 g, 1.0 mol) and 2-amino-2-methyl-1-propanol (116 g, 1.3 mol). After reflux for 36 h at 180–190°C and work-up followed by distillation (b.p. 98°C/18 mm Hg), compound **20** (122.6 g, 67%) was obtained. Lit. value (53) b.p. 96–98°C/15 mm Hg.

2-Methylhexanoic acid oxazoline (**21**). A 500-mL round-bottom flask equipped with a nitrogen inlet, dropping funnel and magnetic bar was charged with propionic acid oxazoline (**17**) (10.0 g, 79 mmol) in tetrahydrofuran (200 mL) and cooled to −78°C. Butyllithium (58 mL, 1.50 M) in hexane was added dropwise, and the reaction mixture was stirred for 1.5 h. Butyl bromide (10 mL, 94 mmol) in tetrahydrofuran (120 mL) was then added. One hour later the cooling bath was removed, and the reaction mixture was allowed to reach room temperature overnight. The mixture was poured into saturated ammonium chloride solution, diethyl ether was added and the phases were separated. The water phase was extracted twice with ether, and the combined organic phases were washed with saturated sodium chloride solution and dried over magnesium sulfate. After evaporation and distillation (b.p. 110–114°C/53 mm Hg) compound **21** (11.0 g, 76%) was obtained. ^{1}H NMR ($CDCl_3$) δ 0.90 (*t*, 3H, terminal CH_3), 1.10 (*d*, 3H, terminal CH_3), 1.20–1.35 (*m*, 10H, CH_2, ring CH_3), 1.40–1.50 (*m*, 1H, CHH), 1.55–1.70 (*m*, 1H, CHH), 2.43 (*sext.*, 1H, CH), 3.90 (*s*, 2H, ring CH_2). MS (EI) *m/e* (rel. int.) 183(2), 168(13), 154(6), 140(34), 127(100). 112(18).

2-Butylhexanoic acid oxazoline (**22**) was prepared as described for **21** from hexanoic acid oxazoline (**18**) (10.0 g, 59 mmol) in tetrahydrofuran (150 mL), butyllithium (45 mL, 1.44 mol) in hexane and butyl bromide (7.7 mL, 71 mmol) in tetrahydrofuran (90 mL). After evaporation, the residue was flash-chromatographed on silica using hexane/diethyl ether (9:1, vol/vol) as eluent, and compound **22** (7.7 g, 58%) was obtained pure. ^{1}H NMR ($CDCl_3$) δ 0.87 (*t*, 6H, terminal CH_3), 1.20–1.35 (*m*, 14H, CH_2, ring CH_3), 1.40–1.60 (*m*, 4H, CH_2), 2.30–2.40 (*m*, 1H, CH), 3.90 (*s*, 2H, ring CH_2). MS (EI) *m/e* (rel. int.) 225(0.4), 210(3), 196(1), 182(16), 169 (14), 140(24), 126(100).

2-Methyloctadecanoic acid oxazoline (**23**) was prepared as described for **21** from propionic acid oxazoline (**17**) (10.0 g, 79 mmol) in tetrahydrofuran (200 mL), butyllithium in hexane (58 mL, 1.50 M) and hexadecyl bromide (29.0 g, 94 mL) in tetrahydrofuran (300 mL). After work up and distillation (b.p. 136–144°C/0.03 mm Hg) compound **23** (17.0 g, 62%) was obtained. ^{1}H NMR ($CDCl_3$) δ 0.88 (*t*, 3H, CH_3), 1.15 (*d*, 3H, CH_3), 1.20–1.35 (*m*, 36H, ring CH_3, CH_2), 2.37–2.50 (*sext.*, 1H, CH), 3.88 (*s*, 2H, ring CH_2). MS (EI) *m/e* (rel. int.) 351(3), 336(2), 322(1), 308(3), 294(2), 182(6), 140(31), 127(100).

2-Hexadecyloctadecanoic acid oxazoline (**24**) was prepared (30) from octadecanoic acid oxazoline (**19**) (10.0 g, 30 mmol) in tetrahydrofuran (350 mL), butyllithium in hexane (20 mL, 1.50 M) and hexadecyl bromide (11.0 g, 36 mmol) in tetrahydrofuran (120 mL). Work-up and distillation (b.p. 240–275°C/0.04 mm Hg) gave compound **24** (12.0 g, 70%). Lit. value (30) m.p. 76.5–78.0°C.

2-Pentyldodecanoic acid oxazoline (**25**) was prepared as described for **21** from heptanoic acid oxazoline (**20**) (120.0 g, 0.65 mol) in tetrahydrofuran (325 mL), butyllithium in hexane (473 mL, 1.51 M) and decyl bromide (161.0 g, 0.73 mol) in tetrahydrofuran (200 mL). Work-up and distillation (b.p. 128–142°C/0.05 mm Hg) gave compound **25** pure (105.0 g, 50%). ^{1}H NMR ($CDCl_3$) δ 0.83–0.90 (*dt*, 6H, termal CH_3), 1.20–1.35 (*m*, 28H, ring CH_3, CH_2), 1.38–1.61 (*m*, 4H, CH_2), 2.23–2.29 (*m*, 1H, CH), 3.90 (*s*, 2H, ring CH_2). *MS (EI) m/e* (rel. int.) 323(5), 308(4), 226(8), 196(18), 183(20), 126(100), 43(75).

3-Ethyl-5-methyl-2-thiophenecarboxylic acid (**31**). A 500-mL three-necked flask was equipped with a two-necked adapter, stirrer, condenser with drying tube, nitrogen inlet and dropping funnel. After flushing with nitrogen, the apparatus was charged with 2-methyl-4-ethylthiophene (33) (11.9 g, 94 mmol) in anhydrous diethyl ether (100 mL). Butyllithium in hexane (68.2 mL, 1.51 M), diluted with dry ether (100 mL), was added dropwise at room temperature. When the addition was complete, the reaction mixture was refluxed for 15 min, after which it was poured onto solid carbon dioxide covered with dry ether. At 0°C, water (200 mL) was added, the phases were separated and the ether phase was extracted twice with 2M sodium hydroxide solution. The combined aqueous phases were acidified with 1M sulfuric acid, and the precipitate was filtered off. Recrystallization from ethanol/water gave compound **31** (10.7 g, 67%) with m.p. 128.0–129.0°C. Calc. for $C_8H_{10}O_2S$: C, 56.46; H, 5.92; MW, 170.23. Found: C, 56.31; H, 5.91; MW, 170.

4-Ethyl-5-methyl-2-thiophenecarboxylic acid (**33**) was prepared analogously to **31** from 3-ethyl-2-methylthiophene (**36**) (33) (19.3 g, 153 mmol) in dry diethyl ether (100 mL) and butyllithium in hexane (112 mL, 1.50 M) diluted with dry ether (100 mL). Recrystallization from ethanol/water gave compound **33** (17.7 g, 68%) with m.p.

106–108°C. Calc. for $C_8H_{10}O_2S$: C, 56.46; H, 5.92; MW, 170.23. Found: C, 56.49; H, 5.94; MW, 170.

2-Heptanoylthiophene (**37**) was prepared according to Reference 54 from heptanoyl chloride (55) (14.9 g, 0.10 mol), thiophene (8.40 g, 0.10 mol), toluene (100 mL) and stannic chloride (10.4 g, 40 mmol). Distillation (b.p. 110°C/1 mm Hg) gave compound **37** (10.7 g, 55%) [Lit. value (54) 170–171°C/22 mm Hg, 84%].

7-(2′-Thienyl)-6-tridecene (**42**). A three-necked flask (1000 mL) was equipped with a dropping funnel, reflux condenser, thermometer and magnetic bar. The flask was charged with magnesium (14.9 g, 0.61 mol), a small amount of iodine and dry diethyl ether (60 mL). Hexyl bromide (100.9 g, 0.61 mol) in dry ether (130 mL) was added under stirring at such a rate that gentle reflux was maintained. When the addition was complete, the reaction mixture was refluxed for 20 min, dry ether (100 mL) was added and the reaction mixture was cooled in an ice bath. 2-Heptanoylthiophene (80.0 g, 0.41 mol) was added dropwise for 10 min, and the reaction mixture was refluxed for another 15 min, after which it was poured into a mixture of saturated ammonium chloride solution (800 mL) and ice (500 g) and stirred for 15 min. The product was extracted with ether (2 × 400 mL), and the combined ether phases were washed with water and dried over magnesium sulfate. After removal of the ether, the residue was treated with oxalic acid (4.0 g) and a small amount of hydroquinone (to avoid polymerization) and heated at 90°C for 30 min. The product was taken up in ether, and the ether solution was washed with water and sodium carbonate solution. After drying over magnesium sulfate and evaporation, the residue was distilled in an apparatus powdered with hydroquinone (b.p. 122°C/0.5 mm Hg) giving compound **42** (54.5 g, 42.5%). ^{1}H NMR ($CDCl_3$) δ 0.89 (*m*, 6H, CH_3), 1.20–1.38 (*m*, 14H, CH_2), 2.17 (*q*, 2H, CH_2), 2.45 (*t*, 2H, CH_2), 5.90 (*t*, 1H, C*H*), 6.95 (*m*, 2H), 7.08) *q*, 1H, J = 4.55 and 1.77 Hz). MS (EI) *m/e* (rel. int.) 264(8), 207(13), 179(22), 124(100), 97(57), 41(48).

7-(5′-Carboxy-2′-thienyl)-6-tridecene (**43**). Butyllithium (116 mL, 1.48 N) was added at room temperature under nitrogen and with magnetic stirring to 7-(2′-thienyl)-6-tridecene (**42**) in dry diethyl ether (350 mL). When the addition was complete, the reaction mixture was refluxed for 20 min, after which it was poured onto dry ice covered with dry ether. Water (560 mL) was added at 0°C, the phases were separated and the ether phase was extracted with sodium hydroxide solution (40 mL, 2N). The combined alkaline phases were acidified with sulfuric acid (2N) while cooling with ice. The product was dissolved in ether, the ether phase dried over magnesium sulfate and the ether evaporated to give compound **43** as an oil (44.0 g, 83%). MS after silylation (EI) *m/e* (rel. int.) 380(3), 295(7), 240(17), 193(8), 73(100), 43(10).

4-(2′-Thienyl)-3-decene (**38**) and 4-(2′-thienyl)-4-decene (**39**) were prepared analogously to **42** from magnesium (6.38 g, 0.26 mol) in dry diethyl ether (60 mL), propyl bromide (32.2 g, 0.27 mol) in dry ether (100 mL) and heptanoylthiophene (34.3 g, 0.175 mol). Distillation (b.p. 108–110°C/1.0 mm Hg) gave compounds **38** and **39** (24.7 g, 63%).

4-(5′-Carboxy-2′-thienyl)-3-decene (**40**) and 4-(5′-carboxy-2′-thienyl)-4-decene (**41**) were prepared analogously to **43** from **38** and **39** (24.7 g, 0.11 mol) in anhydrous diethyl ether (200 mL) and butyllithium (73.5 mL, 1.51 N). After evaporation, compounds **40** and **41** were obtained as an oil (23.2 g, 78%).

2-(2′-Thienyl)-1-octene (**44**) and 2-(2′-thienyl)-2-octene (**45**) were prepared analogously to **42** from magnesium (1.86 g, 76.4 mmol) in dry diethyl ether (20 mL), methyl iodide (10.8 g, 76.4 mmol) in dry ether (30 mL) and heptanoylthiophene (10.0 g, 50.9 mmol) in anhydrous ether (30 mL). Distillation (b.p. 92–96°C/1.5 mm Hg) gave compounds **44** and **45** (6.90 g, 70%).

2-(5′-Carboxy-2′-thienyl)-1-octene (**46**) and 2-(5′-carboxy-2′-thienyl)-2-octene (**47**) were prepared analogously to **43** from **44** and **45** (8.5 g, 43.5 mmol) in anhydrous diethyl ether (80 mL) and butyllithium (28.8 mL, 1.51 N). Upon acidification, one of the isomers, **46**, precipitated as yellow crystals (m.pl 65–68°C). After evaporation compounds **46** and **47** were obtained as an oil (5.85 g, 56%).

Decanoylthiophene (**48**) was prepared analogously to **37** from decanoyl chloride (56) (76.3 g, 0.40 mol), thiophene (33.6 g, 0.40 mol) in anhydrous toluene (400 mL) and stannic chloride (41.7 g, 0.16 mol). Distillation (b.p. 123°C/0.4 mm Hg) gave compound **48** (61.7 g, 64%) [Lit. value (57) b.p. 205°C/22 mm Hg].

6-(2′-Thienyl)-5-pentadecene (**49**) and 6-(2′-thienyl)-6-pentadecene (**50**) were prepared analogously to **42** from magnesium (15.7 g, 0.64 mol) in anhydrous diethyl ether (100 mL), pentyl bromide (97.0 g, 0.64 mol) in dry ether (120 mL) and decanoylthiophene 102.9 g, 0.43 mol) in anhydrous ether (300 mL). Distillation (b.p. 168°C/1.5 mm Hg) gave compound **49** and **50** (70.8 g, 56%).

6-(5′-Carboxy-2′-thienyl)-5-pentadecene (**51**) and 6-(5′-carboxy-2′-thienyl)-6-pentadecene (**52**) were prepared analogously to **43** from **49** and **50** (70.8 g, 0.25 mol) in anhydrous diethyl ether (400 mL) from butyllithium (193 mL, 1.42N). Upon evaporation, compounds **51** and **52** were obtained as an oil (78.1 g, 94%).

ACKNOWLEDGMENTS

This work was financially supported by a grant from Karlshamns AB's Research Foundation. The authors are very much indebted to Kerstin Pettersson and Ann Carlstein for their help with the syntheses.

[Received October 25, 1991, and in final revised form March 22, 1993; Revision accepted July 5, 1993]

The Relationship Between the Structure of Monoalkyl Branched Saturated Fatty Acids and Some Physical Properties

Leif Svensson[a,*], **Ulf Hansson**[a], **Salo Gronowitz**[b] and **Tomas Klingstedt**[b,1]
[a]Karlshamns AB, S-374 82 Karlshamn, Sweden and [b]Organic Chemistry 1, Chemical Center, University of Lund, Lund, Sweden

The gel point and the refractive index of monoalkyl branched saturated fatty acids were determined and related to the structure of the acids. A three-factor central composite face-centered design was constructed where the three variables were the length of the main chain, the branching position and the length of the side chain. Second-order models were calculated in which the two properties were related to the structure. In order to confirm the validity of the models, two additional fatty acids were analyzed. The gel point was found to be proportional to the length of the main chain and the square of the branching position whereas the refractive index was proportional to the length of both the main and the side chain and also to the square of the main chain.
Lipids 28, 899-902 (1993).

It has long been known that the introduction of a branch into fatty acids and their derivatives alters their physical properties, *e.g.*, the melting point, the density, the refractive index and the viscosity (1-10). Many branched fatty acids, most of which are methyl branched, are found in nature (11-16).

In spite of the commercial interest in branched fatty acids there has, to our knowledge, only been one previous study in which the relationship between the structure of branched fatty acids and their physical properties has been systematically investigated. This is the study by Cason and Winans (9) in which all methyl branched octadecanoic acids, from 2-methyloctadecanoic acid to 17-methyloctadecanoic acid, were synthesized. The melting points were studied, and it was found that the melting points were all lower than for octadecanoic acid itself. The lowering effect was largest when the methyl group was attached to carbon number 10 or 11.

In the present study, two physical properties, the gel point ("solidification point") and the refractive index (at 80°C), of monoalkyl branched saturated fatty acids were related to the structure. A chemometrical approach was used. Polymorphic properties, if any, have not been considered.

MATERIALS AND METHODS

Materials. 2-Ethylhexanoic acid was purchased from E. Merck (Darmstadt, Germany). All other fatty acids were synthesized (17). The purity of the acids were found to be >98% by gas-liquid chromatography (GLC) and/or high-performance liquid chromatography (HPLC).

Measurements. The gel points were determined on a Bohlin VOR Rheometer (Lund, Sweden) used in the oscillation mode. The samples were placed between a cone and a plate with diameters of 25 mm and a gap size of 0.15 mm. The gap was adjusted at 0°C for the samples with high gel points (> −10°C) and at −25°C for the samples with low gel points (< −10°C). The torsion bar used had a torque constant of 92.3 gcm. The samples were subjected to an oscillation (frequency 0.500 s^{-1}) in the autostrain mode. This means that the strain was adjusted according to the measured torque in such a way that increased torque led to a decrease in strain. The strain amplitude varied between 0.002 and 0.2. The measurements were performed in a standard low temperature cell cooled by liquid nitrogen. The samples were cooled from −10 to −100°C (10 to −10°C for the acids with high gel points) with a temperature gradient of −0.5°C/15 s. The results were recorded every 6 s.

The gel points were determined by means of the tangent to the sharply increasing storage modulus (G′, the elastic component of a viscoelastic material). This indicates an increase in the elastic component of the sample (a solidification). The results are strongly dependent on the temperature gradient chosen, due to the fact that the acids show different polymorphic behavior. This method of determining the gel point is a modification of the method of Bohlin *et al.* (8).

The gel points of the acids with very high gel points (>10°C) were determined simply by agitating 2 g of the acid contained in a small bottle with a thermometer using the same frequency as in the rheometer. The samples were cooled by the surrounding air and, when necessary, with an ice-water mixture. The cooling was carried out in such a way as to achieve the same gradient as with the rheometer (−2°C/min).

The refractive indices were determined at 80°C with an Abbé refractometer, Carl Zeiss (Jena, Germany), model A.

Experimental design. The structures of the monoalkyl branched saturated fatty acids were chosen according to a three-factor central composite design (18). The three factors are the length of the main chain (X_1), the branching position (X_2) and the length of the side chain (X_3). As can be seen in Table 1, the different levels of variable X_2 are defined as functions of variable X_1. In a similiar way the levels of variable X_3 are defined as functions of variables X_1 and X_2. This is due to the fact that, *e.g.*, in the case of the branching position, level +1 represents a carbon atom near the end of the main chain. Depending on the length of the main chain, the number of the carbon atom to which

TABLE 1

Factor Levels of the Experimental Design

Control acids			
6-Pentylpentadecanoic	+0.5	−0.273	0
2-Ethylhexanoic	−1	−1	−0.333

the branch is affixed will vary. In the same way the length of the branch has an upper limit. If this limit is passed, the branch has become the main chain. In the case of the branching position, level +1 has been chosen as a position two carbons away from the end of the main chain to be able to vary the length of the branch.

The complete experimental design, including two control substances, is shown in Table 2. As can be seen, the axial points have been placed one unit away from the center instead of the ideal distance of 1.682 units. This variant of the central composite design is called central composite face-centered design (CCF).

Statistical analyses. The evaluation of the results was made with the help of the software MODDE (MODeling and DEsign) version 1.2 (Umetri AB, Umeå, Sweden). All measurements were done in a randomized order. Measurements in the center point of the design were repeated twice. MODDE uses multiple linear regression to calculate a prediction equation for each response (Equation 1):

$$Y_p = b_0 + b_1X_1 + b_2X_2 + b_3X_3 + b_{12}X_1X_2 + b_{13}X_1X_3 + b_{23}X_2X_3 + b_{11}X_1^2 + b_{22}X_2^2 + b_{33}X_3^2 \quad [1]$$

The estimated coefficients are then rejected or retained depending on their probability. The test is performed at a significance level of $\alpha = 0.05$. The significant coefficients are then reestimated to give the final prediction equation. Outliers, identified by normal probability plots of the residuals (19), are excluded from the multiple linear regression.

RESULTS AND DISCUSSION

Gel point. The coefficients of the final prediction equation of the gel point are shown in Table 3 with corresponding probabilities and 95% confidence intervals. 9-Pentyloctadecanoic acid and 3-ethylhexanoic acid have been identified as outliers (by the technique of normal probability plots) and are consequently excluded from the regression calculations. The resulting equation is Equation 2.

TABLE 3

Coefficients from the Final Prediction Equations of the Gel Point and the Refractive Index

Term	Coefficient[a]	Probability[b]
Gel point		
Constant	−79 ± 13	0.00
Main chain (X_1)	68 ± 10	0.00
Branching position (X_2	0.5 ± 9	0.91
(Branching position)^2 (X_2^2)	69 ± 16	0.00
Refractive index		
Constant	1.4271 ± 0.0018	0.00
Main chain (X_1)	0.0146 ± 0.0015	0.00
Side chain (X_3)	0.0037 ± 0.0015	0.02
Main chain^2 (X_1^2)	−0.0075 ± 0.0024	0.00

[a]Values are given with 95% confidence intervals.
[b]The probability that a coefficient is equal to zero.

$$Y_{p,\ \text{gel point}} = -79 + 68X_1 + 0.5X_2 + 69X_2^2 \quad [2]$$

According to the prediction equation, the gel point is proportional to the length of the main chain (X_1) and to the square of the branching position (X_2^2). Any polymorphic properties, if present, have not been considered. Figure 1 shows a three-dimensional picture of the response surface, which has the shape of a long and rising valley.

The observed and the predicted gel points are compared in Table 4. An analysis of variance (ANOVA) scheme is shown in Table 5. The coefficient of multiple determination is $R^2 = 0.964$. The test for lack of fit indicates a high probability (40%) that the lack of fit is due to pure experimental error.

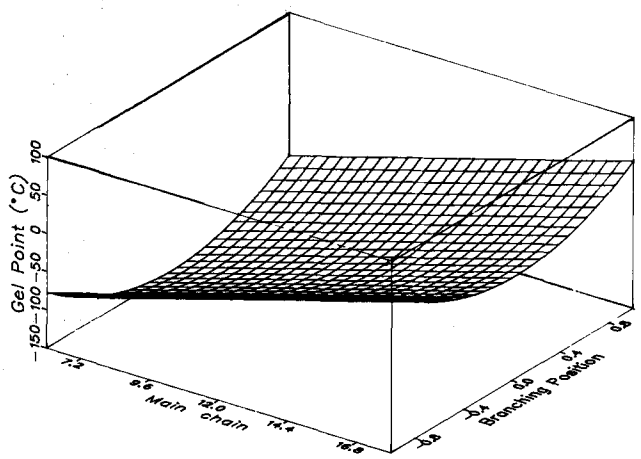

FIG. 1. Three-dimensional response surface showing the gel point as a function of the structure for monoalkyl branched saturated fatty acids. The length of the main chain (X_1) is given as the number of carbons (6 to 18) while the branching position (X_2) is given as coded values (−1 to +1).

TABLE 5

ANOVA Scheme and Residual Sum of Squares Breakdown for the Gel Point Prediction Equation[a]

Source of variation	ANOVA scheme: Sum of squares	Degrees of freedom	Mean square
Constant	16 138	1	16 138
Model terms	52 320	3	17 440
Residuals	1 956	11	178
Total	70 414	15	4 694
Residual sum of squares breakdown			
Pure error	1 463	8	183
Lack of fit	494	3	165

[a]P (lack of fit = pure error) = 0.400. ANOVA, analysis of variance.

The compounds for which the difference between the predicted and the observed gel point is largest have in common that they are branched near the middle ($X_2 \approx 0$) and that they, at the same time, have main chains which are not twelve carbons long. In other words the second order model does not give good predictions of the gel points of long or short fatty acids branched near the middle of the main chain. The lowering effect on the gel point achieved by putting a branch near the middle seems to be more pronounced the longer the main chain. This effect cannot be explained by the model. However, all other types of branched fatty acids, within the experimental domain, are satisfactorily explained.

The fact that the length of the branch does not influence the gel point came as a surprise. This is probably due to the fact that earlier investigations had been focused on methyl branched acids. Almost all naturally occurring branched fatty acids found up to now are methyl branched ones (2,3,11,14). On the other hand, the influence of the square of the branching position is a confirmation and extension of the results of the study on methyl branched octadecanoic acids by Cason and Winans (9).

Refractive index (80°C). The final prediction equation of the refractive index resulted in the coefficients shown

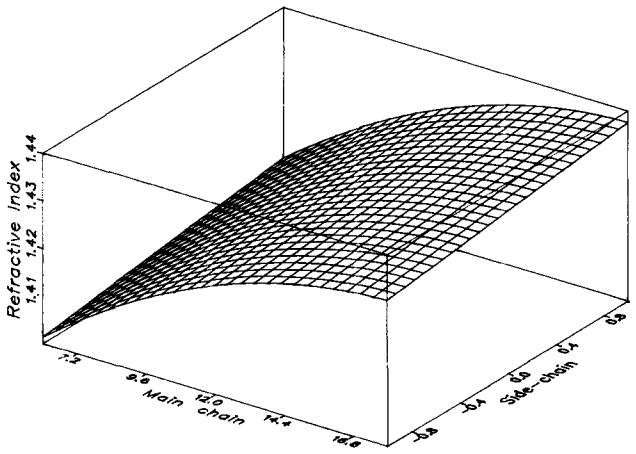

FIG. 2. Three-dimensional response surface showing the refractive index (at 80°C) as a function of the structure for monoalkyl branched saturated fatty acids. The length of the main chain (X_1) is given as the number of carbons (6 to 18) and the length of the side chain (X_3) is given as coded values (−1 to +1).

in Table 3 (with corresponding probabilities and 95% confidence intervals). The equation is Equation 3.

$$Y_{p,\ \text{refractive index (80°C)}} = 1.4271 + 0.0146X_1 + 0.0037X_3 - 0.0075X_1^2 \quad [3]$$

In this case the branching position does not influence the response. The refractive index is instead proportional to the length of both the main and the side chain and to the square of the length of the main chain.

Figure 2 shows a three-dimensional picture of the response surface. The conclusion is that the larger the molecule, the higher the refractive index. The observed and the predicted values are compared in Table 4. An ANOVA scheme is shown in Table 6. The coefficient of multiple determination is $R^2 = 0.980$, which is even better than in the gel point case. The test for lack of fit shows a high probability (44%) that the lack of fit is due to pure experimental error.

ACKNOWLEDGMENT

This work was financially supported by a grant from Karlshamns AB's Research Foundation.

3-Carboxy-4-nitrophenyl-dithio-1,1′,2-*tris*norsqualene: A Site-Directed Inactivator of Yeast Oxidosqualene Cyclase

Gianni Balliano, Giorgio Grosa, Paola Milla, Franca Viola and **Luigi Cattel***
Istituto di Chimica Farmaceutica Applicata, 10125 Torino, Italy

The role and location of essential thiol groups in 2,3-oxidosqualene cyclase from *Saccharomyces cerevisiae* was examined (i) by comparing inactivation properties of two known thiol reagents, 5,5′-dithio*bis*(2-nitrobenzoic acid) (DTNB) and 2-nitro-5-thiocyanobenzoic acid (NTCB), with 3-carboxy-4-nitrophenyl-dithio-1,1′,2-*tris*norsqualene (CNDT-squalene), a new thiol reagent designed as a site-directed inactivator of oxidosqualene cyclase and (ii) by testing the ability of the substrate to protect the enzyme against inactivation by the reagents. All reagents gave a time-dependent inactivation following pseudo-first order kinetics. DTNB and CNDT-squalene showed comparable inactivation ability (K_i = 0.67 and 1.21 mM), whereas NTCB was less effective (K_i = 15.6 mM). Strong differences between the two most active inhibitors, DTNB and CNDT-squalene, were observed when the enzyme was saturated with substrate prior to incubation with the thiol reagent. While substrate did not protect the enzyme against the inactivation caused by DTNB, a reduction in the inactivation ability of CNDT-squalene was observed under protection conditions. The data suggest that the squalene-like inactivator modifies a thiol group located at the active site of the enzyme.
***Lipids* 28, 903–906 (1993).**

Squalene and oxidosqualene cyclizing enzymes play a central role in the biosynthesis of steroid-like molecules, as they catalyze the conversion of acyclic precursors into tetra- or pentacyclic compounds (1,2). In recent years, several research groups have focused their efforts on the characterization and purification of these cyclizing enzymes from both prokaryotic and eukaryotic organisms (3–11). The evolutionary connection between these two classes of enzymes has been hypothesized on the basis of the ability of prokaryotic squalene cyclases to cyclize 3*R*- and 3*S*-2,3-oxidosqualene, in addition to their natural substrate, squalene (12). An important property shared by prokaryotic and eukaryotic cyclizing enzymes is their sensitivity to thiol reagents. *p*-Chloromercuribenzenesulfonic acid and *N*-ethyl maleimide strongly inhibit squalene-hopene cyclase from *Bacillus acidocaldarius* (13) and oxidosqualene-lanosterol cyclase from yeast (9) and hog liver (6). In the latter work cited, the authors demonstrated that a sulfhydryl group is essential for the activity of mammalian liver cyclase, using inactivation experiments with *N*-ethyl maleimide as a modifying agent. However, the presence of a reactive thiol group at the active site of the enzyme could not be proven, as no protection against inactivation was observed when experiments were repeated in the presence of a competitive inhibitor as a protecting agent (6).

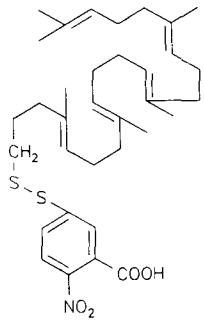
Abbreviations: CNDT-squalene, 3-carboxy-4-nitrophenyl-dithio-1,1′,2-*tris*norsqualene; DTNB, 5,5′-dithio*bis*(2-nitrobenzoic acid); NTCB, 2-nitro-5-thiocyanobenzoic acid; TNB, thionitrobenzoate.

The search for more specific inactivators of yeast oxidosqualene cyclase, which would be able to enter and modify the active site of the enzyme, led us to design new thiol modifying agents with squalene-type substituents. In the present paper we desdribe a chemical modification of yeast oxidosqualene cyclase by 3-carboxy-4-nitrophenyl-dithio-1,1′,2-*tris*norsqualene (CNDT-squalene) (Scheme 1), a new thiol reagent designed as a site-directed inactivator. Properties of the new reagent were compared with those of the two known thiol reagents, 5,5′-dithio*bis*(2-nitrobenzoic acid) (DTNB), the Ellman's reagent and 2-nitro-5-thiocyanobenzoic acid (NTCB), which inactivates proteins by cyanylating thiol groups (14). Protection experiments, performed with the new reagent, provided the first evidence of the existence of an essential thiol group within the active site of the enzyme.



SCHEME 1

MATERIALS AND METHODS

Chemicals. Nonidet P-40, Tween 80, NTCB and DTNB were obtained from Sigma Chimica (Milan, Italy). 2,3-Oxidosqualene and [3-^{3}H]2,3-oxidosqualene (44 × 10^6 dpm/μmol) were synthesized as reported (15). CNDT-squalene was synthesized (16) by an exchange reaction between 5,5′-dithio*bis*(2-nitrobenzoic acid) and 1,1′,2-*tris*norsqualene thiol (17).

Solubilization of 2,3-oxidosqualene cyclase from yeast microsomes. Saccharomyces cerevisiae (ATCC 12341) was cultured as previously described (18). The yeast homogenate, obtained by sonication of washed cells in 1 vol of 0.1 M Na/K phosphate buffer (pH 7.1) (10,18), was cleared up by low-speed centrifugation (10,000 × *g* for 15 min) and then centrifuged at 150,000 × *g* for 90 min. The pellet was resuspended in 0.1 M phosphate buffer (pH 7.1) at 4°C, and a solution of Nonidet P-40 in the same buffer was added dropwise to arrive at a final concentration of protein and detergent of 2 and 1 mg/mL, respectively. The solution was gently stirred for 60 min at 4°C and then centrifuged at 150,000 × *g* for 60 min. Solubilized proteins (0.25 to 0.35 mg/mL) had a specific activity ranging from 40 to 60 nmol lanosterol/h/mg protein. At 35°C, spontaneous decay of enzyme activity from different preparations

ranged from 80 to 60% of the original activity within 30 min.

2,3-Oxidosqualene cyclase assay. The assay procedure used was essentially as previously reported (10). Briefly, the reaction mixture containing [^{3}H]2,3-oxidosqualene (70,000 dpm), Tween 80 0.2 mg/mL and solubilized microsomes (0.3 mg prot/mL) in 0.1 M Na/K phosphate buffer (pH 7.1), was incubated for 30 min at 35°C. The nonsaponifiable extract was separated by thin-layer chromatography, and bands co-migrating with 2,3-oxidosqualene and lanosterol were monitored by liquid scintillation counting.

Time-dependent inactivation; general procedure. The enzyme solubilized from microsomes with detergent in 0.1 M phosphate buffer, pH 7.1, was incubated at 35°C with different concentrations of reagent. After the preincubation period, the inactivator was removed by 10-fold dilution of the enzyme preparation or by direct neutralization of the thiol reagent with dithiothreitol or mercaptoethanol (both ineffective on oxidosqualene cyclase at up to 20 mM). Enzyme activity was then assayed as described above. Either way of removing the inactivator after the preincubation gave similar results. Differences in the spontaneous decay of the enzyme activity can be observed dependent on the conditions under which the inhibitors were solubilized.

Protein determination. Proteins were determined by the method of Lowry, as modified by Peterson, using bovine serum albumin as a standard (19).

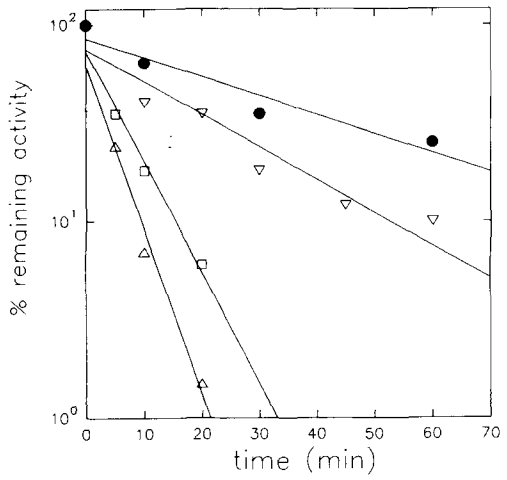


FIG. 1. Time-dependent inactivation of yeast oxidosqualene cyclase by 3-carboxy-4-nitrophenyl-dithio-1,1′,2-*tris*norsqualene. The enzyme solubilized from microsomes with Nonidet P-40 was incubated (0.3 mg protein/mL, 0.1 M K/Na phosphate buffer, pH 7.1, containing 1 mg/mL Nonidet P-40) at 35°C with 0.0 (●), 0.1 (▽), 0.5 (□) and 1 mM (△) reagent. At time intervals, 50 μL-aliquots were withdrawn and diluted with 450 μL 0.1 M K/Na phosphate buffer, pH 7.1, containing 0.5 mg/mL Nonidet P-40, 0.2 mg/mL Tween 80, [^{3}H]2,3-oxidosqualene (50,000 dpm) and 2,3-oxidosqualene (25 μM). The mixture was then incubated for 30 min at 35°C to determine the residual activity, which is expressed as percentage of control (no reagent).

RESULTS AND DISCUSSION

Inactivation of yeast oxidosqualene cyclase by CNDT-squalene, NTCB and DTNB. The ability of CNDT-squalene, NTCB and DTNB to inactivate yeast oxidosqualene cyclase was evaluated by measuring the enzyme activity solubilized from microsomes after exposure to each of the thiol reagent at different concentrations. In all cases, a time-dependent inactivation following pseudo-first order kinetics was observed (Figs. 1 and 2). The similarity of the kinetic patterns was also apparent by comparison of the reciprocal plots of the pseudo-first order rate constants *vs.* the reagent concentratons (Figs. 3 and 4). All reagents showed saturation kinetics indicating that an enzyme/reagent reversible complex is formed prior to the inactivation event (20). Apparent binding constants, K_i (mM), and inactivation rate constants at saturation, $kapp_{max}$ (min^{-1}), for each reagent were calculated from the slope and intercept of the linear plot, respectively (Table 1). CNDT-squalene and DTNB inactivated oxidosqualene cyclase faster than did NTCB (Table 1).

Effect of the substrate on the rate of inactivation by CNDT-squalene, NTCB and DTNB. In order to localize the thiol groups involved in the inactivation of oxidosqualene cyclase, substrate protection experiments were performed in the presence of the three inactivators of the enzyme. In the only reported attempt to protect an oxidosqualene cyclizing enzyme against thiol reagents, no protection was observed (6). In the cited work, the authors reacted the pig liver enzyme with *N*-ethyl maleimide in the presence of a competitive inhibitor of oxidosqualene cyclase. The lack of protection suggested that the sulfhydryl group modified by the inactivator was not directy involved in the catalytic process, but played a role in the maintenance

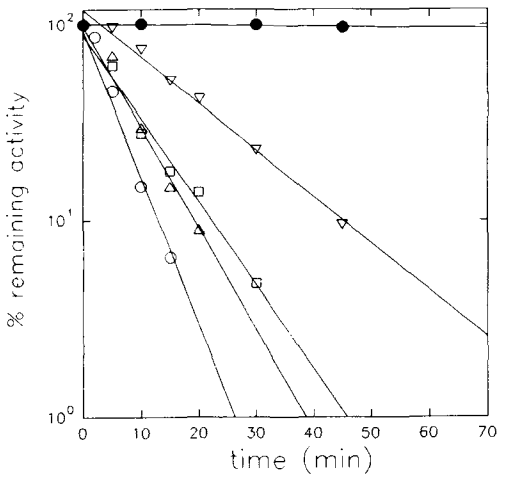

FIG. 2. Time-dependent inactivation of yeast oxidosqualene cyclase by 5,5′-dithio*bis*(2-nitrobenzoic acid) (DTNB). Treatment of the enzyme and incubation conditions were as described in the legend for Figure 1. DTNB concentrations during inactivation time: 0.0 (●), 0.1 (▽), 0.3 (□), 0.5 (△) and 0.6 mM (○).

of an active enzyme conformation. In our experiments, done with substrate as protecting agent, considerable differences were observed among the three inactivators. The substrate did not protect at all against inactivation caused by DTNB (Fig. 5), whereas a weak protection seemed to be detectable in experiments with the less powerful inhibitor NTCB. So far, however, data obtained with this weak inhibitor are not sufficient to conclude that the small and uncharged cyanogroup of the reagent modifies a thiol group within the active site of the enzyme. Better evidence

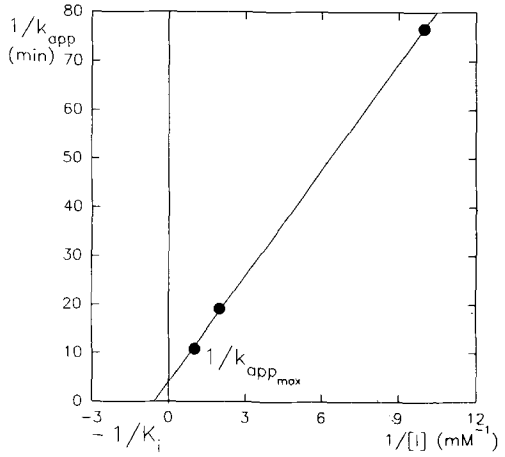

FIG. 3. Double reciprocal plot of the apparent pseudo-first-order rate constants (kapp) of inactivation *vs.* 3-carboxy-4-nitrophenyl-dithio-1,1′,2-*tris*norsqualene concentrations; kapp were obtained from graph in Figure 1.

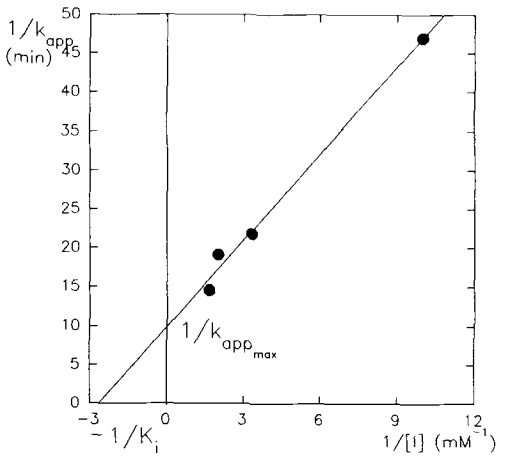

FIG. 4. Double reciprocal plot of the apparent pseudo-first-order rate constants (kapp) of inactivation *vs.* 5,5′-dithio*bis*(2-nitrobenzoic acid) concentrations; kapp were obtained from graph in Figure 2.

for the existence of a thiol group directly involved in the catalytic process came from protection experiments in the presence of CNDT-squalene: substrate, at a saturating concentration, clearly protected the enzyme against inactivation (Fig. 6). As CNDT-squalene molecules differ from the Ellman's reagent (DTNB) by a squalenoid residue in place of a nitrobenzoic residue, we suggest that the squalene moiety of the CNDT-squalene acted as a "delivery moiety," able to lead the modifying agent into the active site of the enzyme. The results were confirmed by following photometrically the release of TNB during the inactivation of the enzyme by DTNB and CNDT-squalene (21). While the release of TNB from DTNB was not affected by saturating substrate concentrations, there was a significant reduction of release of TNB from CNDT-squalene under the same conditions (Fig. 7). Other CNDT-derivatives, bearing different alkyl (aliphatic or isoprenic) moieties are at the moment under investigation for their inactivation properties. Preliminary results indicate that replacement of a squalene residue by a dodecane residue

TABLE 1

Inactivation of Yeast Oxidosqualene Cyclase by CNDT-squalene, DTNB and NTCB

Inactivator	Apparent binding constant[a] K_i (mM)	Inactivation rate constant[a] at [I] = ∞ $kapp_{max}$ (min^{-1})
CNDT-squalene	1.21	0.220
DTNB	0.67	0.093
NTCB	15.60	0.067

[a]K_i and $kapp_{max}$ were calculated from graphs similar to those shown in Figures 3 and 4. Values were corrected for the spontaneous decay of the enzyme. Abbreviations: CNDT-squalene, 3-carboxy-4-nitrophenyl-dithio-1,1′,2-*tris*norsqualene; DTNB, 5,5′-dithio*bis*(2-nitrobenzoic acid); NTCB, 2-nitro-5-thiocyanobenzoic acid.

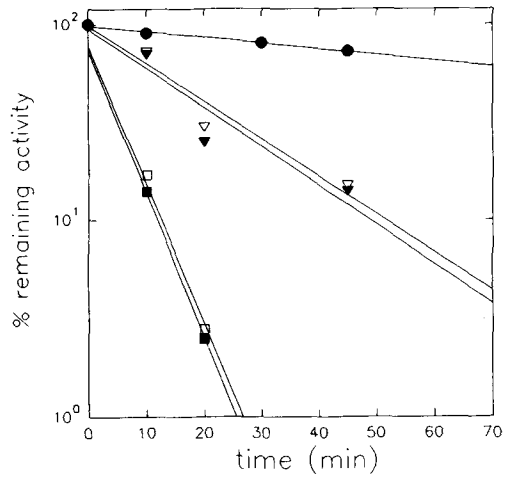

FIG. 5. Lack of protection by oxidosqualene (substrate) against 5,5′-dithio*bis*(2-nitrobenzoic acid) (DTNB) inactivation of yeast oxidosqualene cyclase. The enzyme solubilized from microsomes with Nonidet P-40 was pre-equilibrated (0.3 mg protein/mL, 0.1 M K/Na phosphate buffer, pH 7.1, containing 1 mg/mL Nonidet P-40 and 0.2 mg/mL Tween 80) at 35°C with substrate at a saturating concentration (0.5 mM) for 15 min. After addition of 0.0 (●), 0.1 (▼) and 0.5 mM (■) DTNB in ethanol solution, the experiment proceeded under conditions similar to those described for a normal inactivation experiment (see legend to Fig. 1). The residual activity was determined at 50 μM substrate. In control experiments performed without protection [inactivator concentrations: 0.1 (▽) and 0.5 mM (□)], substrate (50 μM) was added just before determination of the residual activity.

makes the inhibitor less specific and less active (G. Balliano, personal communication).

Results obtained with CNDT-squalene are consistent with the hypothesis of the existence of a cysteinyl residue essential for catalysis at the active site of yeast oxidosqualene cyclase. This residue could act as a protonating group in the acid-catalyzed opening of the oxirane ring of squalene-oxide. Further insights in the different classes of thiol groups of the yeast oxidosqualene cyclase should be achieved when it will be possible to repeat inactivation experiments with the enzyme purified to homogeneity.

General Resistance to Sterol Biosynthesis Inhibitors in *Saccharomyces cerevisiae*

Véronique Ladevèze, Christophe Marcireau, Didier Delourme and **Francis Karst***
Laboratoire de Biochimie et Génétique des Microorganismes, Institut de Biologie Moléculaire et d'Ingéniérie Génétique, Université de Poitiers, 86022 Poitiers Cedex, France

Screening for resistance to fenpropimorph was undertaken in order to isolate yeast mutants affected in the regulation of the ergosterol pathway. Among the mutants isolated, one bearing the recessive *fen1-1* mutation was characterized by a 1.5-fold increase in the ergosterol level and a general resistance to sterol biosynthesis inhibitors. The *fen1-1* mutation was linked to *MAT* locus on chromosome III. The measurement of enzyme activities involved in the ergosterol pathway revealed that isopentenyl diphosphate (IPP) isomerase activity was specifically increased 1.5-fold as compared to the wild type strain. However, overexpression of IPP isomerase in the wild type strain was not by itself sufficient to lead to sterol increase or resistance to sterol biosynthesis inhibitors, showing that IPP isomerase is not a limiting step in the pathway. The *fen1-1* mutation permits viability in aerobiosis of yeast disrupted for sterol-14 reductase in absence of exogenous ergosterol supplementation, whereas the corresponding strain bearing the wild type *FEN1* allele grows only in anaerobiosis. This result shows that ignosterol is able to efficiently replace ergosterol as bulk membrane component and that the *fen1-1* mutation eliminates the specific ergosterol requirement in yeast.
***Lipids* 28, 907-912 (1993).**

The sterol biosynthetic pathway is the target of powerful fungicides. Among them, the most commonly used against pathogenic fungi are azoles and morpholine derivatives. Azoles, such as ketoconazole, flusilazol or LAB 170250 F, inhibit the C-14 lanosterol demethylase step (1-3) through the binding of the fungicide's heterocyclic nitrogen atom to the protohaem iron of cytochrome P450 lanosterol demethylase (4). Morpholines block two later steps downstream in the ergosterol pathway, Δ^{14} sterol reductase and Δ^{8}-Δ^{7} sterol isomerase (5). These compounds, which are likely to be protonated at physiological pH, share some structural and electronic similarities with the sterol carbocationic high energy intermediates involved in the Δ^{14} sterol reductase and Δ^{8}-Δ^{7} sterol isomerase reactions (6).

Ergosterol plays a specific role in yeast which has been described as regulatory (7), synergistic (8) or as sparking effect (9). In addition to ergosterol, a few ergosterol precursors have also been described to fullfil the sparking function (10). We have shown recently that fenpropimorph inhibits cell growth by leading to a specific drop in ergosterol level below the level required for the sparking function (11).

Regulation mechanisms of ergosterol biosynthesis in yeast are not well understood. Although hydroxymethylglutaryl-coenzyme A (HMG-CoA) reductase is probably implicated in the regulation (12), there is no definitive evidence that this enzyme is regulated by the ergosterol level. Specific activities of acetoacetyl-CoA thiolase, HMG-CoA synthase, squalene synthase and squalene epoxidase have been shown to be dependent on the sterol needs of the cells (13,14), but it is unlikely that ergosterol itself is the regulatory molecule (13). An approach to find out the limiting step or the key regulatory step in a pathway is the isolation and the characterization of mutant strains that overproduce the end product. The isolation of mutants resistant to an inhibitor specific for the pathway studied has been shown to be a valuable approach (15). In this report, we describe a mutant strain of *Saccharomyces cerevisiae* that was isolated and shown to be resistant to fenpropimorph. The main features of this strain are an overproduction of ergosterol and a strong resistance to a large number of sterol biosynthesis inhibitors. This paper describes a study on the mechanism of resistance displayed by this strain and its relation to ergosterol biosynthesis.

EXPERIMENTAL PROCEDURES

Strains and growth conditions. The strains used were derived from *S. cerevisiae* FL100 (ATCC 28383) haploid, a mating type, or from an isogenic strain FL200 (ATCC 32119) haploid, α mating type. *Saccharomyces cerevisiae* strain DD21 is a derivative of the Gal^{+} strain (16) W303-1B (*a* mating type, *leu2-3, 112, his3-11, 15, trp1-1, ura3-52, ade2-1, can1-100*).

Culture conditions and media were those previously described (11).

Stock solutions of fungicides were prepared as follows: fenpropimorph and fenpropidin (BASF, Agrochemical Station, Limburgerhof, Germany) and SF 86327 (Sandoz Forschungsinstitut, Wien, Austria), in ethanol (the final solvent concentration in the culture medium did not exceed 1%, vol/vol), ketoconazole (Janssen Pharmaceutica Bersee, Belgium), fluzilasol (Du Pont de Nemours and Co., Wilmington, DE) and LAB 170250 (BASF, Agrochemical Station) in sterile water. Amphotericin B and nystatin (Laboratoires Squibb, Paris, France) in sterile water containing 20% (vol/vol) dimethylformamide (DMF).

For the determination of MIC values (minimum inhibitory concentration inhibiting growth completely after 48 h incubation at 28°C) of drugs, approximatively 10^{6} cells were spotted on solid media which contained varying concentrations of the drug being tested.

Strain DD21 construction. A polymerase chain reaction (PCR) was carried out on yeast genomic DNA with two

Abbreviations: ATP, adenosine triphosphate; cM, centimorgan (unit of map distance for gene-gene linkage); DMF, dimethyl formamide; HMG-CoA, hydroxymethylglutaryl-coenzyme A; IPP, isopentenyl diphosphate; FAD, flavine adenine dinucleotide; FPP, farnesyl diphosphate; GC, gas chromatography; GPP, geranyl diphosphate; MIC, minimal inhibitory concentration; MVA, mevalonic acid; PCR, polymerase chain reaction; pDD1 plasmid carrying yeast IPP isomerase gene; SBI, sterol biosynthesis inhibitor(s).

oligonucleotide primers derived from the yeast isopentenyl diphosphate (IPP) isomerase gene sequence (17). The PCR product was purified, digested with *Eco*RI and *Bam*HI and ligated into the *Eco*RI/*Bam*HI site of pYeDP1/8-2 (yeast replicative vector carrying p*GAL10-CYC1* promoter/*PGK* terminator 16). The resulting IPP isomerase expression vector (pDD1), recovered after propagation in *E. coli* strain 71/18, was used to transform yeast strain W303-1B giving DD21.

Total sterol extraction and analysis. Freeze-dried cells were saponified by the method of Molzahn and Woods (18). Sterols were extracted and analyzed by gas chromatography (GC) as described (11). Sterols with 5,7-diene system and 8.14-diene system were identified and quantified by their specific absorption spectra (19).

Separation of free and esterified sterols. The free sterol and steryl ester fractions were extracted from freeze-dried cells by a procedure adapted from Taylor and Parks (20). Free sterols and steryl esters were separated on a column of alumina (neutral, grade 1; Sigma Chimie, L'Isle D'Abeau, France) washed with *n*-hexane. Steryl esters were eluted with dichloromethane, then free sterols with ethanol.

Determination of radioactive [^{14}C-methyl] *methionine incorporation into sterols.* Cells (logarithmic growth phase) were cultured in minimum medium; aliquots (0.2 mL, approximately 3×10^7 cells) of the cultures were incubated with [^{14}C-*methyl*]methionine (0.15 mCi/mmol, 0.67 mM final concentration; Amersham, Les Ulis, France). Incubation was stopped by addition of 1 mL of 40% KOH (wt/vol). This mixture was heated at 60°C for 1 h. Nonsaponifiable lipids were extracted with *n*-heptane. After concentration under nitrogen, an aliquot was assayed for radioactivity by liquid scintillation counting. Incorporation of radioactivity was linear during 1 h.

Incorporation of [^{14}C]*mevalonic acid (MVA) or* [^{14}C]*IPP* in vitro. Cells were harvested during the exponential growth phase and washed thrice in ice-cold 0.05M Tris-HCl, pH 7.4, and then disrupted in the same buffer containing 1 mM dithiothreitol. The standard mixture contained in a final volume of 0.2 mL 10 mM $MgCl_2$, 20 mM adenosine triphosphate (ATP), 0.5 mM NADPH, 1 mM glucose-6-phosphate, 2 units glucose-6-phosphate dehydrogenase, and [2-^{14}C](R)MVA (37.5 μM, 66.6 μCi/mmol; Amersham) or [1-^{14}C]IPP (40 μM; 1 mCi/mmol, Amersham); ATP was omitted in the incubation with IPP. Incubation temperature was 37°C. One volume of methanol was then added. Proteins were precipitated by heating at 65°C for 5 min and separated from the supernatant by centrifugation. Radioactivity in the supernatant [MVA to farnesyl diphosphate (FPP)] and in the pellet (nonsaponifiable fraction) was measured on aliquots. Reaction products in the pellet were identified by thin-layer chromatography using silica gel G plates developed with dichloromethane. The major compound was squalene, as expected, since flavine adenine dinucleotide (FAD) required for squalene epoxidase reaction was omitted. Incorporations were linear for 1 h in the range of protein concentration used (100–400 μg).

Enzyme preparation. Cells were harvested during the exponential phase of growth and washed with ice-cold 0.1M Tris-HCl buffer, pH 7.4. Cells were disrupted in the same buffer containing 5 mM dithiothreitol for IPP isomerase and squalene synthease, or 5 mM iodoacetamide for FPP synthase. A 12,000 × *g* supernatant was used as a crude extract. In studies of squalene synthase, we used a 105,000 × *g* microsomal fraction.

Protein concentration was determined by the biuret procedure using crystalline bovine serum albumin as a standard.

IPP isomerase assay. The standard mixture (21) contained in a final volume of 0.2 mL 100 mM Tris-HCl, pH 7.4, 2 mM $MgCl_2$, and crude extract. The assay was initiated with 60 μM [1-^{14}C]IPP (1 mCi/mmol) and incubated for 5 min at 37°C. The sample was chilled on ice and 1 mL pentane was added, followed by 0.6 mL HCl, 0.33N. The mixture was shaken during 15 min at 37°C. After vigorous mixing, the two phases were allowed to separate. An aliquot (0.1 mL) of the pentane layer was assayed for radioactivity by liquid scintillation counting. Specific activity was expressed in nmoles IPP incorporated into acid-labile products per min per mg protein. Product formation at 37°C was proportional to protein amounts within 20–200 μg and to time within 2–8 min.

FPP synthase assay. The enzyme activity was assayed as previously described (22) with geranyl diphosphate (GPP) as the second substrate. Specific activity was expressed in nmol IPP incorporated into acid-labile products per min per mg protein.

Squalene synthease assay. The standard assay was the same as described by M'Baya *et al.* (14). Squalene synthase activity was determined as the radioactivity in the squalene fraction and expressed in nmol of FPP converted per min per mg protein.

RESULTS

Isolation of the fen1-1 *mutation.* We isolated one spontaneous and seven ultraviolet (UV)-induced mutants resistant to fenpropimorph. Genetic analysis showed that all mutations were recessive and belonged to seven complementation groups. Among them we studied the mutant strain FD49, bearing the *fen1-1* mutation, which showed a strong fenpropimorph resistance and an increased ergosterol level. On the contrary, all the other mutants showed a sterol composition similar to that of the wild type strain.

Phenotypic analysis. The MIC of different drugs was determined for the wild type strain and the mutant strain FD49. Table 1 shows that the mutant strain FD49 resists up to 66 μM fenpropimorph, while the wild type strain is inhibited by 0.3 μM fenpropimorph. A strong resistance to fenpropidin (piperidine), to SF 86327 (allylamine), to Lab 170250F, to ketoconazole and to flusilazol (azoles) was also observed. Nevertheless the FD49 mutant strain exhibited the same sensitivity as the wild type strain to various growth inhibitors such as polyene antibiotics (nystatin and amphotericin B), allylic alcohol, copper and cycloheximide. This result strongly suggests that the cross resistance of FD49 is specific to ergosterol biosynthesis inhibitors and therefore is not the result of a decrease in membrane permeability.

Genetic analysis. The heterozygous diploid obtained by crossing FD49 with the wild type strain was sensitive to fenpropimorph showing that the *fen1-1* mutation is recessive. Tetrad analysis showed a 2:2 segregation of resistance to sensitivity. The two resistant spores always showed a 40% increase in the level of sterols with a

TABLE 1

Effects of Growth Inhibitors on the Wild Type Strain and the Mutant Strain FD49[a]

Inhibitor	Strains	
	FL100	FD49

[b]Glycerol is the carbon source instead of glucose.

5,7-diene system (Table 2). These results show that a single mutation confers at the same time resistance to fenpropimorph and an increase in the sterol level.

Furthermore, it should be noted that recombinants bearing the *fen1-1* mutation exhibited, as did FD49, a 66% increase in generation time as compared to the wild type strain (Table 2). Tetrad analysis revealed that the *fen1-1* mutation was linked to the *MAT* locus (Table 3). To establish a genetic map, crosses were made with a strain bearing a *thr4* mutation localized at 22 cM from *MAT* locus (23). Results (Table 3) showed that the *fen1-1* mutation is located on chromosome III, at 6.6 cM from *MAT*, and 30 cM from *thr4*.

Sterol analysis. Sterols from both the FD49 mutant and the wild type strain were analyzed by GC to assess the

effect of the *fen1* allele on sterol synthesis in the absence and presence of fenpropimorph. First we studied the sterol composition of both strains in the absence of the sterol biosynthesis inhibitor (SBI). The results showed (Tables 4 and 5) that the high level of sterols with a 5,7-diene system in FD49 is due to a specific increase in the ergosterol level. Treatment of wild type cells with increasing concentrations of fenpropimorph induced a modification of the sterol profile (Table 4) consisting in a progressive

[a]Cells were cultured for 15 h in complete medium containing different concentrations of fenpropimorph.
[b]The sterols were quantified by gas chromatography using the area method and expressed as % of total sterols. Cholesterol was used as internal standard.
[c]—, Not detected.

disappearance of ergosterol and in an accumulation of unusual sterols, such as ergost-8-enol and ergosta-8,14-dienol (ignosterol). At a 0.066 μM fenpropimorph concentration, which does not inhibit cell growth, the ergosterol content in cells was lowered by about 75%, and the major sterols were ergost-8-enol and fecosterol. At a concentration of 0.660 μM, cell growth was strongly inhibited, ergosterol was no longer detected and ignosterol accumulated in addition to ergost-8-enol (Table 4). The same progressive inhibition of ergosterol formation was observed in FD49 (Table 5), but, surprisingly, ignosterol levels increased simultaneously with ergost-8-enol levels at a fenpropimorph concentration as low as 0.066 μM. In contrast, the wild type strain accumulated ignosterol only at a much higher drug concentration (*i.e.*, 0.660 μM). Treatment with fenpropimorph induces an accumulation of the same sterols in FD49 and the wild type strain. Therefore, resistance mechanisms, such as failure in drug uptake, drug expulsion, detoxification, or a decrease in affinity of the target enzymes for the inhibitor, can be ruled out. It has been suggested (24,25) that antifungal activity of morpholines and piperidines is directly related to the accumulation of ignosterol; its integration into membranes is thought to disorganize membrane structure due to the presence of the 8,14-diene system. Since only free sterols are incorporated into membranes while esterified sterols are largely stored as lipid droplets (20,26), an increased degree of esterification of unnatural sterols could result in resistance to fenpropimorph. We measured free and esterified sterol levels in FD49 and FL100 in order to check this hypothesis. The results (Table 6) showed that both strains displayed the same strong degree of esterification of the atypical sterols, ergosta-8-enol and ergosta-8,14-dienol, while ergosterol essentially existed in the free state. Therefore, esterification does not explain the resistance properties of FD49. Moreover, since the levels of free ignosterol and ergost-8-enol are similar in both strains, the toxicity of fenpropimorph could not be due to the presence of these sterols in membranes. This also agrees with the hypothesis (11) that specific ergosterol starvation is at the basis of cell growth inhibition by morpholines. Consequently, the resistance mechanism might be directly related to the increase of ergosterol observed in FD49.

Ergosterol metabolism in FD49 and wild type strains. *In vivo* measurement of ergosterol biosynthesis using [^{14}C-*methyl*]methionine showed, as expected, that the rate of sterol biosynthesis is increased about 1.6-fold in the mutant strain FD49 in comparison with the wild type strain (Table 7). In order to identify enzymatic steps responsible for this increase, we measured the *in vitro* transformation of both MVA and IPP into nonsaponifiable lipids; transformations of the two intermediates were again increased 1.5-fold in FD49 in terms of specific activity as shown in Table 6. This result clearly shows that a specific enzyme activity, downstream from IPP formation, is increased in FD49, as compared to the wild type strain. We measured the specific activities of IPP isomerase, FPP synthase and squalene synthase. Table 8 shows that IPP isomerase specific activity is enhanced 1.5-fold in FD49 when compared with the wild type strain, whereas FPP synthase and squalene synthase specific activities were similar in both strains. Therefore the increase in the ergosterol level observed in FD49 could be specifically related to the enhancement of IPP isomerase specific activity, suggesting that IPP isomerase is a limiting step in the ergosterol pathway in yeast.

The IPP isomerase gene (17) was amplified by PCR and inserted in an expression vector under the control of

TABLE 6

Analysis of Free and Esterified Sterols in the Mutant Strain FD49 and in the Wild Type Strain as Function of Fenpropimorph Concentration[a]

[a]The cells were grown for 48 h (complete medium) in the presence of different concentrations of fenpropimorph. The free sterols were separated from the esters as described in the Experimental Procedures section. The results are expressed for each sterol in % of the total sterols.
[b]Fenpropimorph concentration is expressed in μM.
[c]—, Not detected.

TABLE 7

Rate of Sterol Biosynthesis in the Wild Type Strain and in the Mutant Strain FD49

Substrate	FL100	FD49
[^{14}C-methyl]methionine[a]	0.34 ± 0.03 (3)	0.57 ± 0.03 (2)
[^{14}C]MVA[b]	0.20 ± 0.01 (3)	0.32 ± 0.01 (3)
[^{14}C]IPP[b]	0.14 ± 0.02 (5)	0.22 ± 0.01 (2)

[a]Cells were grown in minimum medium in the presence of radioactive methionine. Incorporation of radioactivity into nonsaponifiable lipids was determined. Results are expressed in μmoles per min per mg protein ± SD (number of independent experiments).
[b]*In vitro* transformation of labelled substrates into nonsaponifiable lipids. Results are expressed in nmoles squalene per min per mg protein ± SD (number of independent experiments). MVA, mevalonic acid; IPP, isopentenyl diphosphate.

TABLE 8

Enzyme Specific Activities in the Mutant Strain FD49 and in the Wild Type Strain[a]

	IPP[b] isomerase	FPP[b] synthase	Squalene[c] synthase
FL100	4.4 ± 0.7 (7)	5.0 ± 0.1 (3)	0.58 ± 0.02 (2)
FD49	6.4 ± 0.4 (3)	5.0 ± 0.1 (2)	0.57 ± 0.02 (2)

[a]Growth medium was complete medium.
[b]Specific activity is expressed as nmoles [^{14}C]isopentenyl diphosphate (IPP) incorporated per min per mg protein ± SD (number of independent experiments).
[c]Specific activity is expressed as nanomoles [^{14}C]farnesyl diphosphate (FPP) converted into squalene per min per mg protein ± SD (number of independent experiments).

GAL10-CYC1 inducible promoter (16). The transformed strain DD21 grown on galactose as carbon source showed a tenfold increase in IPP isomerase (23.3 nmol min^{-1} mg $prot.^{-1}$) specific activity when compared with glucose grown cells (2.4 nmol min^{-1} mg $prot.^{-1}$). In spite of this tenfold increase, no apparent increase in ergosterol level was noted (data not shown). In addition the strain DD21 did not show any increased resistance to fenpropimorph on galactose medium (data not shown). Thus, it can be concluded that the increase in IPP isomerase activity in FD49 is not, in itself, cause of both ergosterol enhancement and general resistance to inhibitors.

The fen1-1 *mutation suppresses the specific ergosterol requirement of yeast.* If one assumes that the toxic effect of the SBI is directly related to the starvation in "sparking" ergosterol, some mutations could by-pass this ergosterol requirement. We have shown that strains bearing a disrupted allele of sterol 14-reductase are unable to grow in aerobiosis unless they carry mutations such as *erg12-2* or *aux30* (27) allowing sterol uptake. In either case they are able to grow in the presence of a sparking ergosterol supplement (27). In order to check whether *fen1* allele relieves the specific ergosterol requirement, we constructed the recombinant strain, CM59, bearing the *fen1* allele in addition to a disrupted sterol 14-reductase allele.

Strain CM59 *(14str::TRP1, fen1)* was able to grow in aerobiosis, without the need of exogenous ergosterol (Fig. 1), unlike the parent strain defective in sterol 14-reductase. The nonsaponifiable lipid fraction of CM59 analyzed by GC contained ignosterol (70%), lanosterol (19%), squalene (10%) and zymosterol (1%), but ergosterol was not detected. These results show that ignosterol can efficiently replace ergosterol as a bulk membrane component and that the *fen1-1* mutation can overcome the specific ergosterol need of yeast cells.

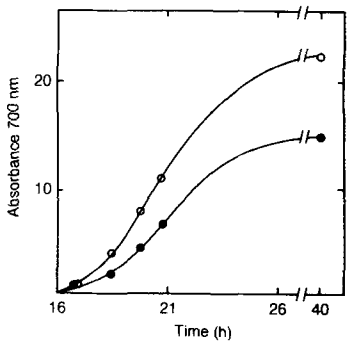

FIG. 1. Growth curves of FD49 *(fen1-1)*, and CM59 *(14str::TRP1, fen1-1)*. Cells were inoculated in complete medium at 28°C. The absorbance of the culture was measured after overnight growth; ○, FD49 *(fen1-1)*; ●, CM59 *(14str::TRP1, fen1-1)*.

DISCUSSION

The screening for fenpropimorph resistance allowed us to isolate a yeast mutant showing a pleiotropic phenotype, consisting of an enhancement of the ergosterol content and cross-resistance to numerous SBI.

The genetic analysis showed that this phenotype is linked to a unique recessive mutation, located on chromosome III, that we named *fen1-1*. The general resistance to SBI strongly suggests a mechanism of resistance linked to a common feature of the SBI, that is the generation of ergosterol starvation. The accumulation of the same intermediate sterols (ergost-8-enol and ignosterol) in the presence of fenpropimorph in *fen1-1* mutant and in the wild type strains excludes mechanisms of resistance such as loss of sensitivity of the target enzymes (28), diminution of drug concentration inside the cells related either to increased excretion of the fungicide (29) or reduced uptake of fungicide by the mutant strain (30), or a detoxication of products accumulated by fungicide treatment as it has been reported for azole-resistant mutants defective in sterol 5(6)-desaturation (31). We show here that there is no detoxication of the atypical sterols by esterification in FD49. Moreover the mutant strain remains sensitive to growth inhibitors independent of the sterol pathway (*e.g.*, cycloheximide, allyl alcohol, or copper) allowing one to exclude resistance due to a general loss of membrane permeability.

The increased ergosterol level in FD49, however, suggested another mechanism of resistance linked to the ergosterol overproduction. The 1.5-fold specific increase in IPP isomerase specific activity observed *in vitro* may by itself explain the ergosterol enhancement. However this hypothesis was ruled out since a high level of IPP isomerase in a wild type strain, obtained by gene overexpression, did not increase the amount of cellular ergosterol and the resistance to SBI.

An alternate explanation for the general resistance to SBI is that the *fen1-1* mutation exempts the cells from the need of the sparking ergosterol. This hypothesis could be tested by the construction of strains disrupted in sterol 14-reductase. Such strains require a sparking ergosterol amount for aerobic growth, but if in addition they carry the *fen1* allele, the need for ergosterol is no longer observed.

Dahl *et al.* (32) reported that a protein kinase, probably involved in the exit from the G1 phase, is stimulated by very low levels of ergosterol. The functional product of the *FEN1* gene could correspond to a protein linking ergosterol to cell proliferation, but since the *fen1* allele is recessive, it cannot correspond to the structural gene of this protein kinase. In fact a mutant gene encoding a constitutively-stimulated protein kinase would be dominant. This leads us to assume that the functional *FEN1* allele most likely encodes a negative transcriptional regulator of a gene, the product of which is involved in the control of the G1 phase exit; transcription of this gene could take place if ergosterol binds to the *FEN1* gene product. The *fen1* allele might encode a defective protein leading to constitutive expression of the hypothetical gene involved in G1 phase exit; in this case ergosterol would no longer be required. In addition, the *fen1* allele would lead to an increased flux in sterol biosynthesis suggesting that the protein encoded by *FEN1* is also implicated in the regulation of the ergosterol pathway.

ACKNOWLEDGMENTS

We thank Professor Benveniste for stimulating discussions during the course of this work, Dr. D. Pompon for the gift of the yeast

expression vector, and Dr. M. Servouse, Dr. M. Guilloton and Dr. F. Nau for help in editing this manuscript. Part of this work was supported by a Grant from Ministère de la Recherche et de la Technologie.

Effect of Lipid Content of Diet on Cholesterol Content and Cholesterogenic Enzymes of European Eel Liver

C. Burgos, M.F. Zafra, M. Castillo and **E. Garcia-Peregrin***
Department of Biochemistry and Molecular Biology, University of Granada, 18071 Granada, Spain

The effect of dietary lipid levels on the levels of cholesterol and the activities of the major cholesterogenic enzymes of the liver has been studied in the European eel. An increase in hepatic total cholesterol was observed when the dietary lipid levels increased from 12 to 20%, while protein levels were maintained at 30%. This change paralleled an increase in mevalonate 5-pyrophosphate decarboxylase activity, while 3-hydroxy-3-methylglutaryl-CoA reductase, mevalonate kinase and mevalonate 5-phosphate kinase were not affected by changes in diet composition. These results suggest that the decarboxylase may be a rate-limiting enzyme in cholesterogenesis in eel liver.
Lipids 28, 913–916 (1993).

Little is known about cholesterol metabolism in freshwater fish. In studies with northern pike (1) and carp (2), a small portion of radioactivity recovered in tissue lipids after injection of [^{14}C]acetate was associated with steryl esters. It also has been reported that the nutritional state of the animals did not affect the incorporation of [^{14}C]acetate into sterols by liver slices from European eel (3). More recently, it has been shown that the rate of cholesterol synthesis in trout hepatocytes is related to the glycogen content of the liver from which the hepatocytes were prepared (4).

Although the pathway of cholesterol synthesis in fish has not been examined in great detail, it can be assumed that the conventional mammalian route *via* 3-hydroxy-3-methylglutaryl-CoA (HMG-CoA) is operative (5). In mammalian liver and other tissues, HMG-CoA reductase is the rate-limiting enzyme in cholesterogenesis (6). Changes in the activity of this enzyme correlate with changes in cholesterol synthesis in response to different experimental conditions (7,8). Nevertheless, the existence of secondary regulatory sites in cholesterol biosynthesis after HMG-CoA reductase has also been proposed (9–11). Results from our laboratory on the evolvement of chick mevalonate 5-pyrophosphate (MVAPP) decarboxylase during embryonic (12) and postnatal (13) stages, as well as the MVAPP decarboxylase changes in response to changing nutritional conditions (14,15), may suggest the importance of this enzyme in the regulation of cholesterol biosynthesis.

Until now, the enzymes responsible for cholesterogenesis in fish had not been characterized. In the present study we have investigated the effect of the lipid content of the diet on the main cholesterogenic enzymes in eel liver. Our results show that HMG-CoA reductase, mevalonate (MVA) kinase and mevalonate 5-phosphate (MVAP) kinase were not affected by changes in dietary lipid composition, while MVAPP decarboxylase activity was increased when dietary lipid content was increased from 12 to 20%. Thus, MVAPP decarboxylase activity may be related to the increases in hepatic cholesterol levels observed after such dietary manipulation.

MATERIALS AND METHODS

3-Hydroxy-3-methyl[3-^{14}C]glutaryl-CoA and [1-^{14}C]- and [2-^{3}H]mevalonic acid lactone were supplied by Amersham International (Amersham, United Kingdom). All other reagents were analytical grade. Fish oil was supplied by Afansa (Vigo, Spain).

Wild European eels *(Anguilla anguilla)* from the coastal marshes in southwest Spain were weight-selected and acclimated to fresh water for at least 3 wk by keeping them in 350-L fiber-glass tanks at a constant photoperiod (12 h light/12 h dark) prior to the experiments. Temperature was maintained at 25°C to obtain a faster growth (16). Aeration was continuously provided and water flow was maintained at about 1 L/min. Each experiment was comprised of 50 young fish in the fattening stage with an initial weight of about 50 g each.

Experimental diets were prepared as shown in Table 1 using three lipid levels (12, 16 and 20% per dry matter) and 30% of protein. The amount of herring meal used in all diets contained 4.91 g of lipid and 30 g of protein. Because of this, fish oil was added in the amounts necessary to reach the desired levels (7.5, 10.0 and 12.5 g).

Abbreviations: CoA, coenzyme A; HMG-CoA, 3-hydroxy-3-methylglutaryl-CoA; MVA, mevalonate; MVAP, mevalonate 5-phosphate; MVAPP, mevalonate 5-pyrophosphate.

Corn oil was added in the amounts necessary to reach a fish oil/corn oil ratio of 1.66 in all diets. Fish were fed twice a day by placing the diets in submerged baskets with free access to the fish for 15 min. Each diet was fed to two groups during the experimental period of 60 d. Each group consumed a similar amount of each diet. Weight gain was maximal in the animals fed the 30% protein/20% fat (30/20) diet.

At the end of the experimental period, the fish were weighed, killed, and the livers excised. The weighed livers were homogenized in 4 vol of 50 mM phosphate buffer (pH 7.4) containing 30 mM ethylenediaminetetraacetic acid, 250 mM NaCl and 1 mM dithiothreitol. The broken cell preparation was centrifuged at 5,000 × *g* for 15 min to remove nuclei and cell debris. The resulting supernatant was centrifuged at 15,000 × *g* for 15 min to sediment mitochondria. Microsomes were obtained by centrifugation of the 15,000 × *g* supernatant fraction for 60 min at 105,000 × *g*. All operations were done at 4°C.

HMG-CoA reductase activity was measured essentially as described by Shapiro *et al.* (17), with the modifications described by Alejandre *et al.* (18). Reductase activity was expressed as pmol of MVA synthesized per min per mg protein. MVA phosphorylation and decarboxylation was measured as previously described (11) using the 105,000 × *g* supernatant and [1-^{14}C]MVA as substrate. Total MVA kinase activity was measured by adding the MVAP and MVAPP formed during the reaction to the CO_2 formed. Similarly, MVAP kinase activity was measured by adding MVAPP and CO_2 formed. MVAPP decarboxylase activity was considered as the CO_2 formed. Specific activities were expressed as pmol per min per mg protein. Protein contents were determined by the method of Lowry *et al.* (19) using bovine serum albumin as standard.

Lipids were extracted with chloroform/methanol (2:1, vol/vol) as described by Folch *et al.* (20). Total and free cholesterol contents were determined by enzymatic/colorimetric methods using the "Test-Combination Cholesterol" or the "Test-Combination Free Cholesterol" kits from Boehringer Mannheim GmbH (Mannheim, Germany). The fatty acid composition of the different diets was determined according to Morrison and Smith (21) using gas chromatography as previously described (22). Methyl esters were analyzed using a Hewlett-Packard (Palo Alto, CA) 5880 A gas chromatograph equipped with a flame-ionization detector and a glass column (4 m × 2 mm) containing 12% SP 2340 on chromosorb WAW (100–120 mesh). The column temperature was kept at 180°C for 8 min and then raised by 5°C per min to a final temperature of 260°C. The nitrogen carrier gas flow rate was 30 mL/min. The column was standardized by injection of a standard mixture of fatty acid methyl esters, and unknown fatty acid methyl esters were identified by comparing their retention times with those of standards. Peak areas were determined by electronic integration and expressed as relative percentage of total fatty acids.

RESULTS

The effect of different experimental diets on the cholesterol content of eel liver was measured after 60 d of treatment. As can be seen in Table 2, feeding a 30% protein/20% fat (30/20) diet increased total hepatic cholesterol when compared with the 30/12 and 30/16 diets. This increase was mainly due to an increase in free cholesterol, a fraction that represented about 80–85% of liver cholesterol in all the experimental treatments.

In order to investigate the relationship between the changes in cholesterol content and the major regulatory enzymes in cholesterogenesis, we measured the effect of the diets on the specific activities of hepatic HMG-CoA reductase, MVA kinase, MVAP kinase and MVAPP decarboxylase. The results in Table 3 show that no significant differences were observed in HMG-CoA reductase specific activities upon any of the dietary manipulations. Similarly, MVA kinase and MVAP kinase did not change when the fat content of the diet was altered. Differences observed in $^{14}CO_2$ production from [1-^{14}C]MVA could be related only with MVAPP decarboxylase. Feeding the 30/20 diet produced a large increase in decarboxylase activity which was correlated with the total and free cholesterol content measured in the same tissue.

In order to correlate the changes in hepatic cholesterol content and enzyme activities with the different experimental diets, we analyzed the fatty acid compositions of these diets. Table 4 shows that no major differences were observed in the percentages of total saturated and unsaturated fatty acids. No significant differences were found in the levels of total polyunsaturated fatty acids in each diet, as well as in the percentages of ω3 and ω6 fatty acids. The saturated/unsaturated and saturated/polyunsaturated fatty acid ratios were essentially the same in the diets assayed. Similarly, no significant differences were observed in the ω3/ω6 ratio.

TABLE 2

Effect of Experimental Diets on Cholesterol Content (mg/g wet tissue) of Eel Liver[a]

	Diets[b]		
	30/12	30/16	30/20

DISCUSSION

In a previous study, we have shown that the dietary protein content (35–55%) did not affect the triglyceride and phospholipid content of eel liver when the lipid level of the diet was maintained at about 12% (23). However, feeding a herring meal 55% diet increased the total cholesterol content in eel liver, while feeding a white fish meal 55% diet did not cause significant changes in hepatic cholesterol (24). Given that the ω3/ω6 fatty acid ratio was manifestly lower in herring meal 55% diet, differences in the hepatic cholesterol content may have been related to the fatty acid composition and not the protein content of the diet. In the present study, we observed a substantial increase in hepatic cholesterol content when the lipid level of the diets was increased from 12 to 20%, while the protein level was maintained at 30%.

It is generally accepted that the relationship between cholesterol content and the activities of cholesterogenic enzymes can be used as a measure to assess the importance of a given enzyme in cholesterol metabolism. However, no significant differences were observed in HMG-CoA reductase activity after any of the dietary treatments. By contrast, hepatic MVAPP decarboxylase drastically increased with increasing lipid content of the diet parallelling the increase in liver cholesterol content. This suggests that decarboxylase may be the rate-limiting enzyme in cholesterogenesis in eel liver, as it has been

reported in other animal species under various physiological conditions (9-15). Since the fatty acid composition was essentially the same in all the diets assayed, the increased cholesterol content and increased MVAPP decarboxylase activity appear to be related to the increased fat content of these diets.

Parameters Influencing Cholesterol Oxidation

S.K. Kim and **W.W. Nawar***
Department of Food Science, University of Massachusetts, Amherst, MA 01003

The purpose of this study was to investigate the effects of temperature, oxidation time, presence of water, pH, type of buffer and form of substrate used on cholesterol oxidation. Microcrystalline cholesterol films, both solid and melted, and aqueous suspensions of film fragments were used as substrates. Use of dispersing agents was avoided. Quantitative analysis of the unaltered substrate and the products of its autoxidation was carried out by gas chromatography over the course of oxidation. Solid cholesterol films were found to be resistant to autoxidation in the dry state. However, when heated at 125°C, a sudden increase in oxidation rate occurred at a point coinciding with the visible melting followed by a plateau of the oxidation rate. All of the autoxidation products formed underwent further decomposition. Film fragments of cholesterol oxidized at a faster rate in aqueous suspensions than when oxidized in the dry state. In aqueous suspensions, the differences in the resistance of cholesterol to oxidation were not significant within the pH range 6.0–7.4, except for the early stages of oxidation. The 7-ketocholesterol/7-hydroxycholesterol ratio dropped significantly with increasing pH. However, at all pH levels tested, this ratio remained relatively constant during the 6 h of heating. While the 7β-hydroxycholesterol/7α-hydroxycholesterol ratio was not affected by pH in the range of 6.0–7.4, at pH 7.4 a high preference was observed for the cholesterol β-epoxide over its α-isomer. The β/α-epoxide ratio decreased with time of heating and with decreasing pH. The data show that the physical state of the substrate exerts a major influence on the oxidative behavior of cholesterol.
Lipids 28, 917–922 (1993).

The products of cholesterol oxidation and the mechanisms for their formation have been reviewed (1–3). In general, the epimeric 3β-hydroxycholest-5-en-7α- and 7β-hydroperoxides (7α- and 7β-hydroperoxides) are recognized as the initial products, with the 7β-hydroperoxides being produced more abundantly than the α-isomers (1,4–6). Thermal decomposition of the hydroperoxides gives rise to the isomeric cholest-5-ene-3β,7α-diol(7α-hydroxycholesterol) and cholest-5-ene-3β,7β-diol(7β-hydroxycholesterol), the 5,6α- and the 5,6β-epoxy-5α-cholestan-3β-ols (cholesterol α-epoxide and cholesterol β-epoxide) and 3β-hydroxycholest-5-en-7-one (7-ketocholesterol), with the latter being a major product.

Studies on cholesterol oxidation that have been reported differed with regard to the form of the substrate used, with sample preparation, with oxidants and with the methods of analysis. Only few studies have been reported in which the oxidizing systems were examined over the entire course of the autoxidation process. Consequently results varied, qualitatively and quantitatively, and the effects of various treatment conditions on cholesterol oxidation were often ill-defined. Oxidation products were also different when colloidal dispersions of cholesterol were used rather than when solid cholesterol was oxidized, and in suspensions dispersed with sodium stearate rather than when other dispersing agents were used (1,4,7–9). The dispersing agent itself can influence the course of oxidation or the profile of oxidation products.

The purpose of the present work was to study the effects of temperature, oxidation time, presence of water, pH and type of buffer on oxidizing cholesterol in different physical states (dried film, melted form, aqueous suspensions of film fragments) without the interference of dispersing agents.

EXPERIMENTAL PROCEDURES

Materials. Cholesterol, *tris*(hydroxymethyl)aminomethane (Tris) and triethanolamine (TEA) were purchased from Sigma Chemical Co. (St. Louis, MO). Cholesterol contained less than 0.9% contaminants including 7-ketocholesterol, 7β-hydroxycholesterol, cholesterol α- and β-epoxides and cholesta-3,5-dien-7-one. Other steroid standards [7-ketocholesterol, 7-hydroxycholesterols, cholesterol epoxides, 20- and 25-hydroxycholesterols, 5α-cholestane-3β,5,6β-triol (3β,5α,6β-triol), cholesta-3,5-diene, cholesta-3,5-dien-7-one, etc.] were from Steraloids Inc. (Wilton, NH). *N,O-bis*(trimethylsilyl)trifluoroacetamide (BSTFA) plus 1% trimethylchlorosilane (TMCS) was obtained from Pierce Chemical Co. (Rockford, IL). Solvents including water were high-performance liquid chromatography (HPLC) grade from various sources.

Sample treatment. Solutions of cholesterol in chloroform (1 mg in 100 μL) were pipetted into vials (15 mm diameter, 45 mm long), and the solvent evaporated on a rotary evaporator. This resulted in the formation of a thin film on the bottom of each vial. Under the microscope, these preparations appeared as thin films of needle-shaped microcrystals, 10–40 μm in length. Some more dense regions appeared to consist of several such layers while other regions appeared amorphous. For studies with dry cholesterol, the vials containing 1 mg of the cholesterol film were placed in an oven at preset temperature and heated for specified periods of time. For the aqueous samples, 1 mL of water or buffer solution was added to test tubes (16 mm diameter, 125 mm long), containing 1 mg of cholesterol film, prepared as described above, and sonicated (Branson Ultrasonic Co., Danbury, CT) for 1 min to detach and break the cholesterol film into suspended small fragments. Under the microscope these fragments appeared as multilamellar structures suspended throughout the aqueous medium. Preliminary tests by gas chromatography (GC) showed that sonication did not generate detectable amounts of cholesterol oxides. The aqueous samples were incubated with shaking at 75°C for up to 6 d or at 37°C up to 30 d.

Cholesterol analysis. Analyses of cholesterol and its oxidation products were carried out as described previously (10). Dry samples were silylated with 0.5 mL BSTFA plus 1% TMCS at 80°C for 1 h. For aqueous samples,

Abbreviations: BSTFA, *N,O-bis*(trimethylsilyl)trifluoroacetamide; GC, gas chromatography; HPLC, high-performance liquid chromatography; TEA, triethanolamine; TMCS, trimethylchlorosilane; Tris, *tris*(hydroxymethyl)aminoethane.

cholesterol and its oxidation products were extracted once with 3.5 mL of $CHCl_3$/MeOH solvent mixture (2:1, vol/vol). The extraction yields (relative to the internal standard) of cholesterol, 7-hydroxycholesterols, 5,6-epoxides, 7-ketocholesterol and 3β,5α,6β-triol were 98.3% (SD = 3.4%), 99.3% (SD = 4.3%), 105.5% (SD = 14.7%), 95.8% (SD = 5.0%) and 99.0% (SD = 4.2%), respectively. The extract was dried under a nitrogen stream and silylated. The silylated samples were analyzed by GC (Varian 3700; Palo Alto, CA) using an Ultra-1 capillary column (50 m × 0.2 mm × 0.33 μm, Hewlett-Packard, Avondale, PA). GC parameters were as follows: sample size, 0.2 μL; concentration, 0.5% (wt/vol); split ratio, 30:1; carrier gas flow rate, 0.3 mL He/min at 305°C. Oven temperature was programmed from 105 to 305°C at 10°C/min. 3β-Acetoxy-5α-androstan-17-one was used as an internal standard. GC peaks were identified by their retention times and by comparison of their mass spectra with those of authentic compounds. A Hewlett-Packard Model 5985 B gas chromatoaph/mass spectrometer system was used.

RESULTS AND DISCUSSION

Effect of temperature. In general, solid cholesterol showed high resistance to oxidation. At 110 and 120°C, where cholesterol remained solid, less than 10% was oxidized after 80 h of heating (Fig. 1). At 125°C, a temperature approximately 20°C below the melting point, cholesterol remained in the solid state for 20 h during which oxidation was slow. Beyond this point, melting became visible and a sudden increase in oxidation rate occurred. The melting of heated cholesterol below its melting point probably reflects the effect of trace amounts of oxidation products formed on the melting point. After approximately 40 h of heating, the sample was completely melted and the rate of oxidation decreased. It is not clear why such a decrease in the oxidation rate occurred, although the accumulation of oxidation products may have an inhibitory effect on the oxidation rate (1,5). The same phenomenon was also observed at 130°C and to a lesser degree at 135°C. At higher temperatures, *e.g.*, 150 and 180°C, cholesterol was in the liquid state from the beginning of heating, and more than 80% of the initial cholesterol disappeared within 1 h of heating. The remaining cholesterol levels after 30 min at 150°C and after 20 min and 40 min at 180°C were 24.4, 28.3 and 16.4%, respectively.

The oxidation products that were detected in the present study were those known to result from cholesterol oxidation: for example, 7-ketocholesterol, and 7α- and 7β-hydroxycholesterols from 7-derivatization; cholesterol α- and β-epoxides and 3β, 5α, 6β- triol from epoxidation; 20- and 25-hydroxycholesterol from side-chain derivatizations; and cholesta-3,5-diene, cholesta-3,5-dien-7-one and several other ketones from elimination reactions. Other products, *e.g.*, volatiles (1), relatively high molecular weight compounds (Vajdi, M., and Nawar, W.W., unpublished data) and other minor oxides, may have also been formed but could not be detected by the methods used in this study. Only traces of side-chain derivatives, *i.e.*, 20- and 25-hyoxycholesterols, and triols were detected in the dry-state oxidation.

Figure 2 shows the relationship between heating time and amounts of cholesterol decomposition products formed. The top line represents the total amounts of

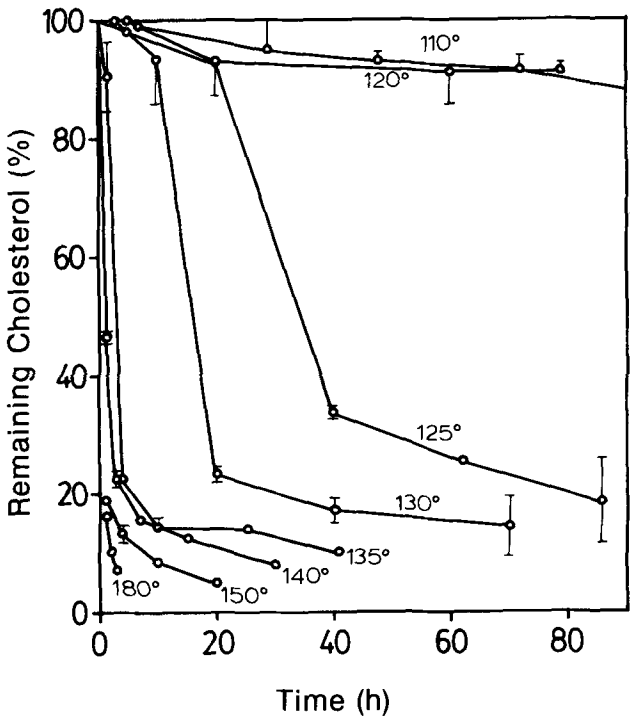

FIG. 1. Effect of temperature (average of two determinations) on the oxidation of dry cholesterol films, 1 mg each, prepared by placing chloroform solutions of cholesterol into vials (15 mm diameter, 45 mm long) and evaporating the solvent. Samples were heated in air in an oven at preset temperatures. Remaining unaltered cholesterol was determined by gas chromatography and is expressed as percent of initial substrate.

altered cholesterol. The bottom line represents that portion of the altered cholesterol which was observed as specific products, *i.e.*, 7-ketocholesterol, the 7-hydroxycholesterols, the cholesterol epoxides, cholesta-3,5-diene and cholesta-3,5-dien-7-one. The region d, which is the difference between total altered cholesterol and the sum of the 7-derivatives, epoxides and elimination products, represents other compounds not detected and measured in this study. Polymers and/or other compounds of relatively high molecular weight may constitute a major portion of such compounds. When cholesterol heated for 1 h at 180°C was subjected to size exclusion chromatography, a fraction amounting to 21.1% of the initial cholesterol represented material of higher molecular weight than the substrate (Vajdi, M. and Nawar, W.W., unpublished data).

Figure 3 illustrates the relationship between heating time and amounts of 7-ketocholesterol formed, one of the major products detected in the early stage of cholesterol oxidation. Obviously, 7-ketocholesterol, and other products as well, undergo further decomposition during heating; the amount of 7-ketocholesterol at any given time represents the net balance between formation and decomposition. As expected, the higher the temperature, the faster the production and decomposition of the oxides. The amounts of 7-ketocholesterol produced in the course of heating at different temperatures (Fig. 3) are consistent with the oxidative behavior of cholesterol discussed

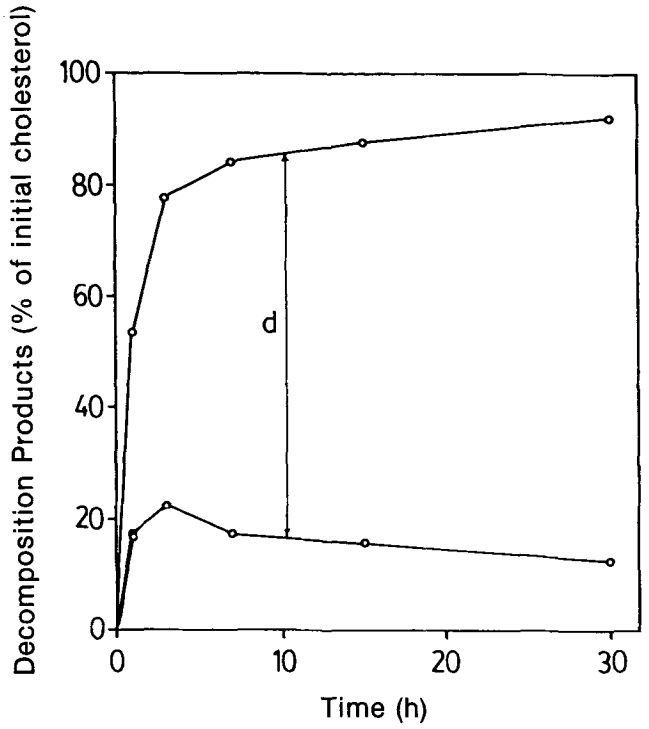

FIG. 2. Production of cholesterol decomposition products in dry cholesterol films heated in air at 140°C (average of two determinations). Samples, 1 mg each, were prepared by placing chloroform solutions of cholesterol into vials, 15 mm diameter × 45 mm long, and evaporating the solvent. Remaining unaltered cholesterol and decomposition products were determined by gas chromatography; ○—○, total amount of altered cholesterol; ●—●, sum of oxidation products detected; region d, sum of undetected products.

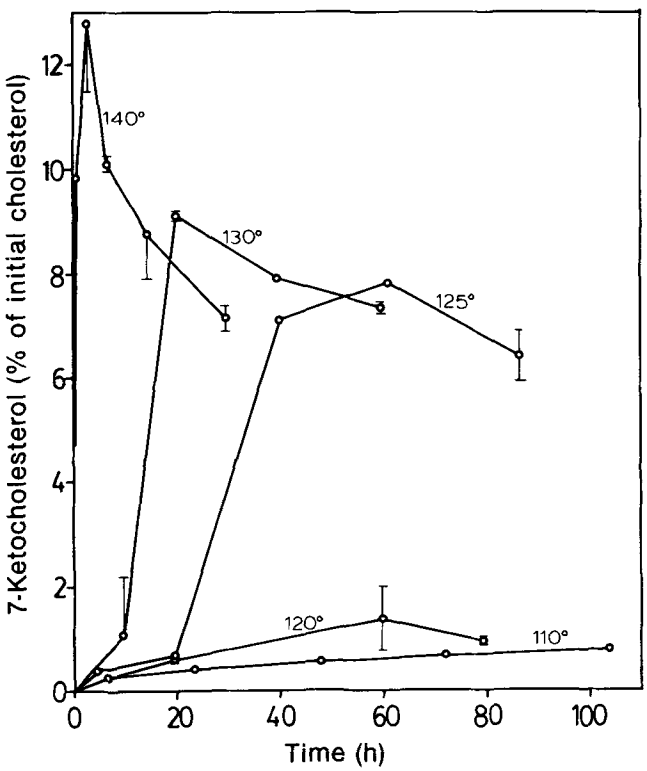

FIG. 3. Effect of temperature on the production of 7-ketocholesterol in dry cholesterol films (average of two determinations). Samples, 1 mg each, were prepared by placing chloroform solutions of cholesterol into vials, 15 mm diameter × 45 mm long, and evaporating the solvent. Samples were heated in air in an oven at preset temperatures, and 7-ketocholesterol was monitored by gas chromatography of their silyl derivatives.

previously (Fig. 1). At 110 and 120°C, the rates of 7-ketocholesterol production were slow and not too different from each other. However, 7-ketocholesterol formation was markedly increased at 125°C when cholesterol melting was seen.

To illustrate the effect of heating on the products of cholesterol oxidation, and the effect of these on cholesterol oxidation, several heating experiments were carried out with pure compounds. When dry film of 7-ketocholesterol, prepared in the same manner as described above for cholesterol, was heated alone at 150°C, after 10 h of heating 83% of the initial amount remained unchanged. However when mixed with pure cholesterol before heating, 64% of the initial 7-ketocholesterol and 33% of the initial cholesterol remained. When a mixture containing equal amounts, 1 mg each, of 7-ketocholesterol, 7β-hydroxycholesterol, cholesterol β-epoxide and 3β, 5α,5α,6β-tril were similarly heated, the amounts found after 10 h heating were 53, 6, 5 and 16%, respectively. These results confirm the decomposition of 7-ketocholesterol upon heating and the difference in stability of the various oxidation products when heated while exposed to air. Not only do these products influence the oxidation of cholesterol, but also the oxidation of each other.

Figure 4 shows formation of the 7-hydroxycholesterols in the dry system during autoxidation for 30 h at 140°C. While most studies show approximately equal yields of the 7α- and the 7β-hydroxycholesterol isomers (4,5,11), the reported β/α ratios of the epoxides varied widely

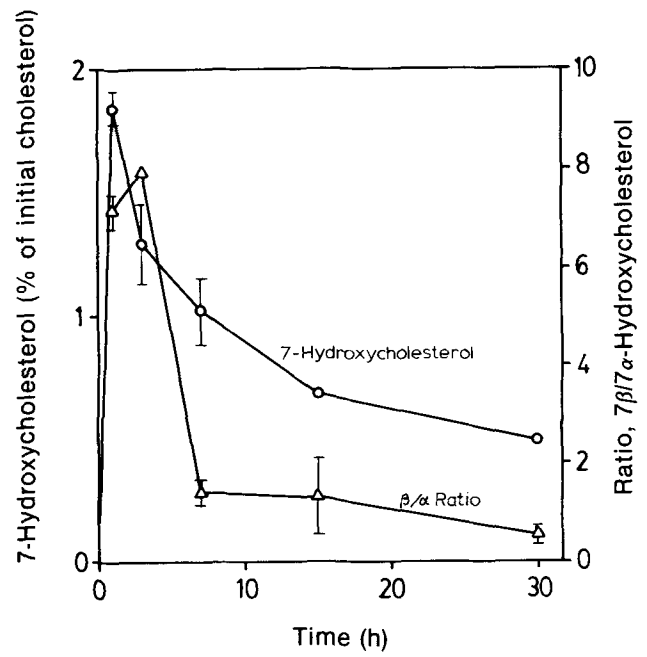

FIG. 4. Effect of heating time on the levels of 7-hydroxycholesterols in dry film fragments at 140°C (average of two determinations). Samples, 1 mg each, were prepared by placing chloroform solutions of cholesterol into vials, 15 mm diameter × 45 mm long, and evaporating the solvent. The 7α- and 7β-hydroxycholesterols were monitored by gas chromatography of their silyl derivatives.

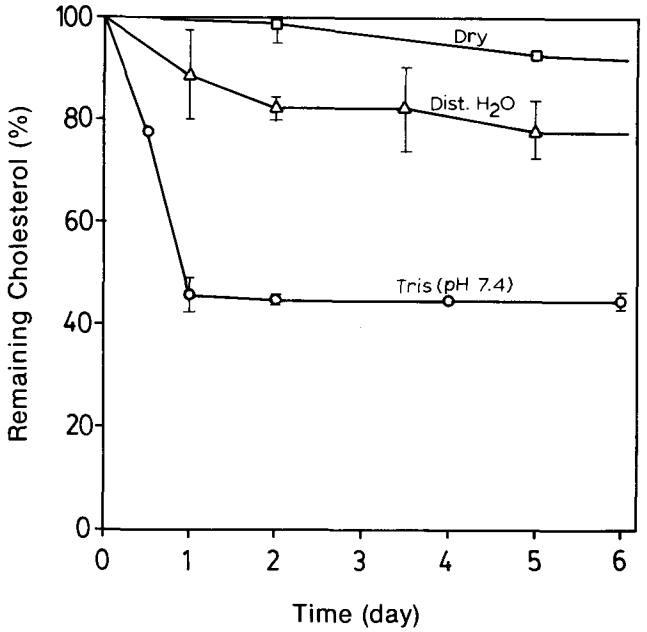

FIG. 5. Effect of medium on cholesterol oxidation at 75°C (average of three determinations). Samples were prepared by adding 1 mL of water or buffer to test tubes, 16 mm diameter × 125 mm long, contianing 1 mg of cholesterol film and sonicating for 1 min. Remaining unaltered cholesterol was determined by gas chromatography of its silyl derivative and is expressed as percent of initial substrate. Tris; *tris*(hydroxymethyl)aminoethane; Dist., distilled.

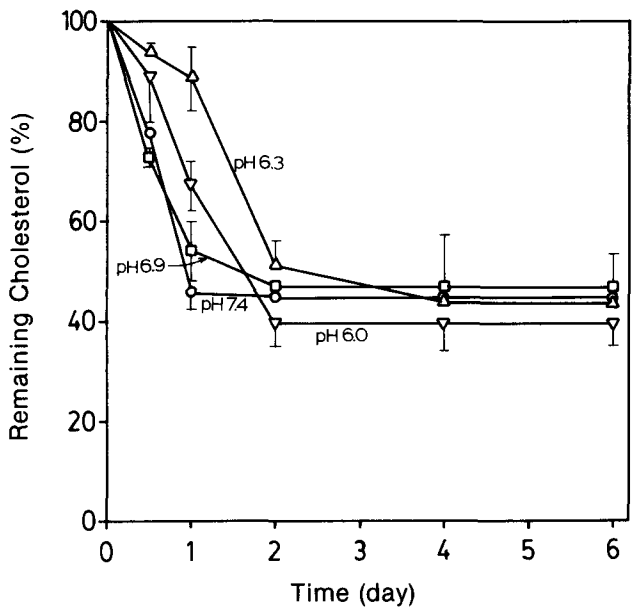

FIG. 6. Effect of pH on cholesterol oxidation in film fragments suspended in tris buffer, 75°C (average of three determinations). Samples were prepared by adding 1 mL of buffer solution to test tubes, 16 mm diameter × 125 mm long, containing 1 mg of cholesterol film and sonicating for 1 min. Remaining unaltered cholesterol was determined by gas chromatography of its silyl derivative and expressed as percent of initial substrate.

depending on conditions (4,12-14). In our work with dry films, the level of 7-hydroxycholesterols reached 1.8% of the initial amount of cholesterol after 3 h heating, then decreased to 0.5% after 30 h (Fig. 4). The β/α-hydroxycholesterol ratio reached a maximum of 8 at the early stage of heating then dropped rapidly and leveled at a ratio of approximately 1 as has been reported for studies with colloidal dispersions. Formation of the 5,6-epoxides was similar (data not shown). Their level reached about 7% of initial cholesterol after 3 h then decreased to 3% after 30 h of heating. The β/α ratio of the epoxides was 1.3 after 3 h, then dropped to a relatively constant ratio of around 0.3 after 6 h. This decrease in β/α ratios during heating probably reflects a faster degradation of the β-epoxides than of their α-isomers. Below 130°C, the β/α-epoxide ratio did not exceed 1.0 (data not shown),. At lower temperature, the overall rate of formation was reduced, but degradation of β-epoxide may not be as sensitive to temperature change as degradation of the α-form.

Effect of water. Cholesterol oxidation was faster in the presence of water than in the dry state, and faster in Tris buffer (10 mM) than in distilled water (Fig. 5). Several workers have reported that in aqueous dispersion the oxidation of cholesterol occurred in the early stage of incubation with no further change after 70-75% substrate had been consumed. Smith *et al.* (7) defined this phenomenon as the apparent product inhibition of the cholesterol oxidation reaction, while Maerker (3) suggested that this plateau may be caused by changes in micelle structure due to the presence of the oxidation products. In the present study, such a plateau was also observed. The phenomenon, however, may be due to factors other than those in aqueous dispersions. Since dispersing agents were not used, cholesterol existed not in micellar structure but as film fragments suspended in the aqueous medium. Cholesterol oxidation is likely to occur on the surface of these fragments (15) whereas their inside may remain inert causing the plateau. Any treatment which influences the structure of the fragments may thus have a significant effect on the oxidation in the latter stages.

The profiles of cholesterol oxidation products formed at 75°C in the absence and presence of water were compared (data not shown). Because of the slow oxidation at 75°C, the dry cholesterol film did not accumulate high amounts of oxidation products even after 40 d, but a number of products were detected. In contrast, in the presence of water the products were relatively few, *i.e.*, the 7-derivatives and the epoxides were the only major products detected. The levels of detectable oxidation products were much higher in the presence of water than those observed in the dry state. Therefore, in aqueous systems, 7-peroxidation and 5,6-epoxidation showed greater effects on cholesterol decomposition than in the dry state.

Effect of pH and buffer. Significant differences in cholesterol stability were observed within the pH range of 6.0-7.4, but only in the early stages of incubation (Fig. 6). After one day in 10 mM Tris-HCl buffer at 75°C, the remaining unaltered cholesterol amounted to 90% of the initial cholesterol at pH 6.3, 55% at pH 6.9 and 43% at pH 7.4. Between the second and sixth day, the remaining cholesterol was about the same for all pH values showing a plateau at 40-50%.

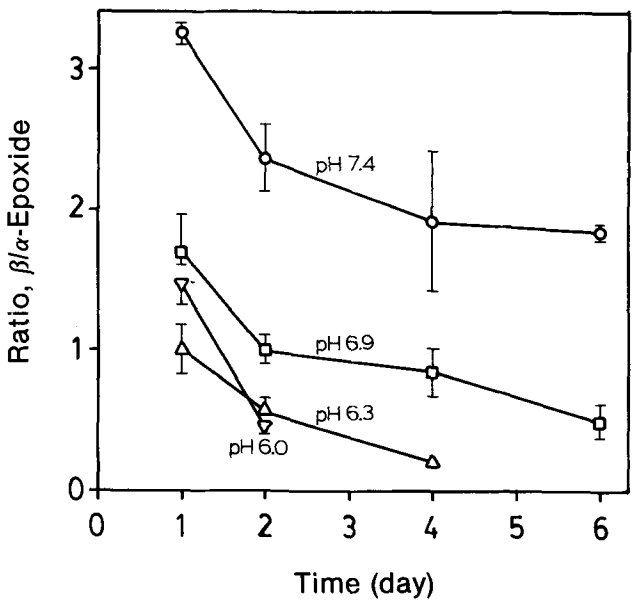

FIG. 7. Effect of pH on β/α-epoxide ratio in cholesterol film fragemts suspended in tris buffer, 75°C (average of three determinations). Samples were prepared by adding 1 mL of buffer solution to test tubes, 16 mm diameter × 45 mm long, containing 1 mg of cholesterol film and sonicating for 1 min. The α- and β-epoxycholesterols were monitored by gas chromatography of their silyl derivatives.

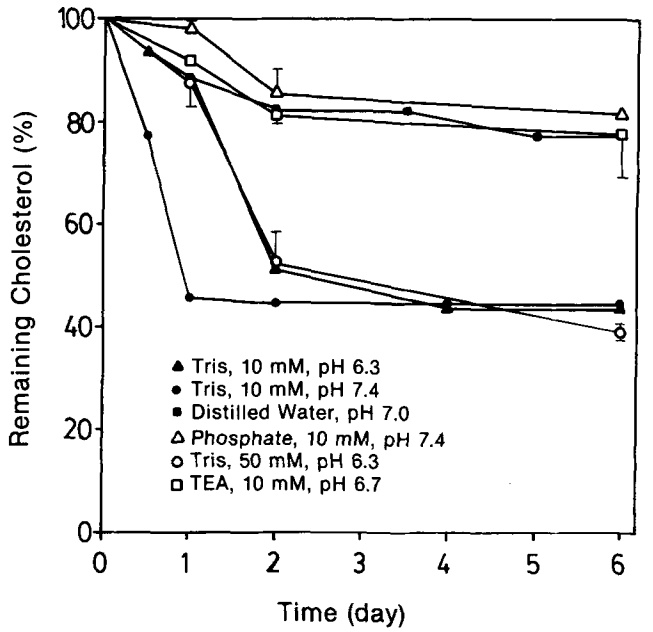

FIG. 8. Effect of different buffer systems on cholesterol oxidation in aqueous suspension of film fragments at 75°C (average of three determinations). Samples were prepared by adding 1 mL of water or buffer solution to test tubes, 16 mm × 45 mm long, containing 1 mg of cholesterol film and sonicating for 1 min. Remaining unaltered cholesterol was determined by gas chromatography of its silyl derivative and expressed as percent of initial substrate. TEA, triethanolamine. See Figure 5 for other abbreviation.

Ratios of 7-keto/7-hydroxycholesterol have been reported to be around 2 in aqueous media (6,5,10,13). In the present work the 7-keto/7-hydroxycholesterol ratio was approximately 7 at pH 6 and dropped with increasing pH reaching about 3 at pH 7.4. This trend was expected. Dehydration of the 7-hydroperoxide to yield 7-ketocholesterol occurs readily at lower pH, whereas the latter is particularly sensitive to alkaline conditions (3,16–18). At all pH levels tested, the 7-ketocholesterol/7-hydroxycholesterol ratios remained relatively constant during the 6-h heating period.

The stereoselectivity in 7-hydroxylation was not affected by pH in the range of 6.0–7.4, but as shown in Figure 7 higher β/α-epoxide ratios were observed at pH 7.4. Maerker and Bunick (4) found no significant change in the β/α-epoxide ratio 3–5 during the oxidation of cholesterol in aqueous dispersions at pH 8 and 12. However at pH 5.5, large changes in the α/β ratio were observed, and the β-epoxide was more labile than its α-isomer by a factor of 2.5.

Figure 7 shows that at all pH levels tested, the β/α-epoxide ratios were highest after one day of heating (the point where the total epoxide level reached a maximum) and then decreased with time of heating. It is also clear that the β/α-epoxide ratios were markedly decreased as the pH was reduced, reflecting the instability of the β-isomer in acidic media (4).

The effects of various buffer systems, 10 mM tris-HCl pH 6.0–7.4, 50 mM tris-HCl pH 6.3, 10 mM potassium phospshate pH 7.4, and 10 mM triethanolamine (TEA) HCl-NaOH pH 6.7, on cholesterol oxidation are shown in Figure 8. Phosphate and TEA buffers did not show any difference from the distilled water control, while tris buffer showed a destructive effect within the pH range of 6.0–7.4. The concentration of tris buffer (10 mM and 50 mM) did not influence cholesterol oxidation. Tsai and Smith (19) reported that the phosphate group and quaternary amine showed no effect on the oxidation of methyl linoleate while protonated primary amines accelerated lipid oxidation. In this study, TEA buffer, which has a quaternary amine and phosphate buffer, did not show any difference from the distilled water control while tris buffer, which has a protonated primary amine, accelerated cholesterol oxidation. The effect of such ionic species on free radical reactions remains unclear. Since the pH of tris buffer was adjusted with HCl, there was a possibility of a higher level of iron contamination than in other media. This possibility, however, is unlikely in view of the fact that the lower pH buffers, which would provide more Fe contamination, showed less cholesterol oxidation at the early stage of incubation. Also, increasing concentration of the tris buffer did not show a significant effect.

Distilled water, phosphate and TEA buffer produced similar product profiles and β/α ratios of epoxides and 7-hydroxycholesterols. Only in tris buffer, the β/α-epoxide ratio was higher than 1, and hydroxylated side-chain products, *e.g.*, 20-hydroxycholesterol and 25-hydroxycholesterol, were observed.

At 37°C, the variation among observations was very high (SD = 0.17–22%, average SD = 8%). The difference between the effects of tris and phosphate buffers at pH 7.4 was not as pronounced as that observed at 75°C. As

in the case of tris buffer in the early stage of incubation at 75°C (Fig. 6), cholesterol was more stable at pH 6.3 than at pH 7.4 in phosphate buffer at 37°C.

The experimental work detailed above was designed to provide basic information as part of an ongoing study on oxidation interactions of cholesterol with other components in more complex systems. For example, the approach used here allows the study of cholesterol/phospholipid co-oxidation without interference from dispersing agents. Such interactions will be discussed in a later report.

Cholesterol oxidation is system dependent. The products of cholesterol oxidation and their relative amounts vary depending on temperature, oxidation time, presence of water, pH, type of buffer and form of substrate. The effects of these parameters on the rate and products of oxidation appear to be largely manifested through their effects on the physical state of the substrate.

Cholesterol and 25-Hydroxycholesterol Retention in Specimens of Liver and Aorta Prepared for Electron Microscopy. I. Standard Fixation Methods and Metabolism of the Labeled Sterols

E. Fornas*, J. Renau-Piqueras, A. Fortea, F. Mayordomo and **E. Alborch**
Centro de Investigación, Hospital "La Fe", 46009 Valencia, Spain

In the present work, several preparatory procedures commonly used for electron microscopy (EM) were evaluated as to their ability to preserve cholesterol (CHO) and CHO derivatives in tissue. We also determined in several rat tissues to what extent the sterols used as tracers are metabolized. Sprague-Dawley rats were injected intraperitoneally with [1α,2α(n)-^{3}H]cholesterol ([^{3}H]CHO) and 25-hydroxy-[26,27-^{3}H]cholesterol ([^{3}H]25-OH-CHO). Lipids of the liver, aorta and brain were extracted one and five days after injection, and the distribution of the labeled lipids was followed by thin-layer chromatography. When labeled CHO was injected as tracer, most of the radioactivity remained associated with the CHO fraction. When 25-hydroxycholesterol (25-OH-CHO) was used, we found that it was mostly metabolized to yield more polar compounds. Our results show that the loss of CHO and CHO derivatives from tissues depends not only on the preparatory procedure used for EM, but also on the type of tissue studied. ***Lipids 28,*** **923–928 (1993).**

Lipids usually constitute about half of the membrane mass, and in most mammalian plasma membranes cholesterol (CHO) is present at an about equimolar ratio with phospholipids. Changes in CHO content affect membrane fluidity, permeability, electrical resistance, integral functions and hydration properties (1).

Conventional procedures used for the preparation of biological specimens for electron microscopy (EM) involve extensive loss of lipids from the specimens. Several approaches have been proposed to minimize this loss (2). Most previous studies have mainly been concerned with the fate of total lipids, and little information is available on how EM preparatory procedures affect the CHO content of plasma membranes (2). The retention of CHO as cell membrane component is desirable both to preserve membrane structural integrity and for the ultrastructural localization of these components.

Controversy also exists in regard to the types of lipid losses that occur during conventional EM preparatory procedures (2–4), and differences exist between the type of lipid losses that occur after fixation with aldehydes as compared to OsO_4, the two fixatives most commonly used. Whereas aldehydes do not prevent lipid loss in most tissues, there is evidence that OsO_4 may minimize the loss of some types of lipids (2). It is also not clear how CHO metabolites are affected.

In the present study we determined to what extent various labeled tracers are metabolized, and we followed the loss of the labeled lipids during the fixation procedures. The radioactive components present in the tissues before fixation were extracted and analyzed. We also determined the extent to which CHO and 25-hydroxycholesterol (25-OH-CHO) were lost from rat aorta and liver in the course of various standard procedures used for the preparation of animal tissues for conventional EM and CHO cytochemistry.

MATERIALS AND METHODS

Animals and tracers. Sprague-Dawley rats weighing 150–200 g were used. Animals were injected intraperitoneally (i.p.) with 1 mCi of [^{3}H]CHO, 40–60 Ci/mmol (Amersham International, Amersham, England), or [^{3}H]25-OH-CHO, 75–87 Ci/mmol (New England Nuclear, Boston, MA) 1 and 5 d prior to being sacrificed. Both products were prepared for injection by the method described by Baranowsky *et al.* (5). After evaporation of the toluene from the original vial containing the tracer, the labeled sterol was redissolved in 0.5 mL of ethanol. One mL of saline was added and most of the ethanol was evaporated by a stream of nitrogen. The resulting sterol suspension was injected i.p..

The optimum sampling time for fixation and for thin-layer chromatography (TLC) of the lipid extracts was determined by measuring the specific activity [disintegrations per minute (dpm)/g] in aortic tissue of rats 1, 2, 5, 7 and 13 d after i.p. injection of 0.125 Ci of [^{3}H]CHO or [^{3}H]25-OH-CHO per 100 g of animal weight. Maximum activity (dpm/g) was found at 5–7 d when [^{3}H]CHO was injected, and at 5 d when the tracer was [^{3}H]25-OH-CHO (Table 1). A sampling time of 5 d was therefore used for the present study. An additional sample was taken on the first day for TLC analysis to document the metabolic changes with time.

Rats were kept under pentobarbital anesthesia when removing tissue. After cannulating the aorta, saline was

Abbreviations: CHO, cholesterol; [^{3}H]CHO, [1,α2α(n)-^{3}H]cholesterol; EM, electron microscopy; F, formaldehyde; G, glutaraldehyde; 25-OH-CHO, 25-hydroxycholesterol; [^{3}H]25-OH-CHO, 25-hydroxy-[26,27-^{3}H]cholesterol; dpm, disintegrations per minute; i.p., intraperitoneal; PB, 0.1 M phosphate buffer (pH 7.3, 2 mM $MgCl_2$); TA, tannic acid; TLC, thin-layer chromatography.

infused for one min at 100 mm Hg pressure. Immediately thereafter, aliquots of tissue from aorta and liver were taken for each of the fixation procedures. Samples of aorta, liver and brain were also taken to measure radioactivity and to extract lipids.

Lipid extraction and chromatography. Liver homogenates (2 g liver and 5 mL saline) and aortas were extracted with chloroform/methanol (2:1, vol/vol) by the Folch method (6). After evaporation of the chloroform phase, lipids were separated by TLC on a Kieselgel 60 plate (Merck, Darmstadt, Germany) with two developments in *n*-heptane/ethyl acetate (1:1, vol/vol). On the same plate and in parallel chromatograms, the following standards were used: CHO linoleate (Sigma, St. Louis, MO); CHO (Sigma); 5-cholestene-3β, 25-diol (Steraloids, Wilton, NH) and cholestane-3β, 5α, 6β-triol (Steraloids). The standards were made visible with iodine vapor, and the chromatograms were divided into nine areas, one containing the origin and four others containing the areas corresponding to the standards. The scraped areas were extracted with chloroform/methanol (2:1, vol/vol) and radioactivity logs counted after evaporation of the solvent.

Counting techniques. Radioactivity of the residual liquids of the individual steps of the fixative procedures was measured. As the chemical composition of the different samples varied greatly, the counting efficiency of the samples was determined using an internal standardization method, and the counts were converted into dpm. Special care was required to measure the samples containing osmium because of especially low counting efficiencies. The original dpm of the tissues to be fixed was determined by dissolving aliquots of the same type of tissue in Nuclear Chicago Solubilizer (Chicago, IL) and counting as described before. A toluene/Triton X-100 liquid scintillator (Scharlau, Barcelona, Spain) and LKB 1219 Rackbeta counter (LKB, Turku, Finland) were used. Results are the mean of three experiments; three animals were injected with each tracer, and two samples of tissue per animal were fixed independently in each of the fixative procedures studied.

Preparation of tissues for EM by Procedure G + Os. Aliquots of tissue from aorta and liver (1 mm^3) were immersed (7) in 1% glutaraldehyde (G) in 0.1 M phosphate buffer (PB) (pH 7.3, 2 mM $MgCl_2$) for 24 h at room temperature in the dark. Effective osmolarity of the fixative solution (300 mOsm) was determined as described (8,9). Purity of G (Merck) was determined by measuring the relative values of ultraviolet absorbance between 210 and 310 nm (8,10,11). The ultraviolet absorbance spectra showed a peak only at 280 nm. After a brief washing in PB, the tissues were postfixed with 2% OsO_4 containing 1.8% potassium ferrocyanide in PB for 2 h in the dark at room temperature (296 K).

Samples were dehydrated by 5-min immersions into ethanol (60, 80 and 95%)/water (vol/vol), and by two 5-min immersions into 100% ethanol; all immersions were at 273 K.

Epon 812 (Polysciences, Warrington, PA) consisted of 21 mL Poly/Bed 812, 13 mL dodecenyl succinic anhydride, 11 mL nadic methyl anhydride and 0.7 mL DMP-30, which was added just before use. Samples were placed in mixtures of Epon 812 and ethanol at concentrations of 25, 50 and 75% (60 min, room temperature). Then the samples were placed in 100% Epon 812 overnight at 277 K, and cured during a second night at 333 K.

Both $CaCl_2$ and $MgCl_2$ are known to decrease the loss of lipid during fixation of a variety of tissues (12). In the present work, $MgCl_2$ was chosen instead of $CaCl_2$ to avoid the formation of calcium phosphate precipitates. Osmium potassium ferrocyanide mixtures are increasingly popular as a secondary fixative in both conventional EM and in several cytochemical procedures because they combine selective fixation and enhance staining of membrane systems, glycocalix and glycogen (13–15).

Preparation of tissues by Procedure G + F. Samples were place in 0.8% formaldehyde (F) and 0.8% G in 0.075 M phosphate buffer, pH 7.2, for 1 h in darkness at 277 K. Samples were then washed for 2 h in PB at 277 K, which was followed by the dehydration and embedding procedures described in Procedure G + Os.

Preparation of tissues by Procedure G + TA + Os. Tissues were fixed in 1% G and 2 mg/ml tannic acid (TA) in PB for 30 min at room temperature in darkness. A brief washing in PB and 20-min post-fixation in 1% osmium tetroxide in PB at room temperature in the dark were followed by the same dehydration and embedding processes described in Procedure G + Os.

RESULTS

In our experiments, rats were injected i.p. with [^{3}H]CHO or [^{3}H]25-OH-CHO and the total radioactivity in the tissue and the fluids of the various steps of the different preparatory procedures was measured by liquid scintillation counting.

G, F and OsO_4 were used as fixatives and were applied according to standard procedures. However, our interest was mainly focused on the OsO_4 procedure, because OsO_4 or osmium, in combination with other agents such as TA or ferrocyanide, can reduce loss of some lipids in the course of dehydration and embedding steps.

Lipid metabolism. Lipid extracts of the liver and brain were analyzed by TLC one and five days after i.p. injection of [^{3}H]CHO. Most radioactivity was found in the TLC area corresponding to CHO (Figs. 1 and 2); between 6 and 10% was found in the area corresponding to sterol esters.

Nevertheless when the tracer injected was [^{3}H]25-OH-CHO, little radioactivity was found in TLC in the area corresponding to this compound (Figs. 1 and 2). One day after i.p. injection, radioactivity was found in all the scraped TLC areas and particularly in the region corresponding to the CHO standard (more than 20% in both aorta and brain). However, in the area corresponding to the labeled compound injected, less than 5% radioactivity was observed. When lipids were extracted five days after i.p. injection, practically all the radioactivity was at the origin in TLC. Evidently, the injected compound was converted into more polar products.

The percentage of tritium in the aqueous phase of the lipid extracts was also determined. In animals injected with [^{3}H]CHO, the percentage of tritium in liver and brain was 6 and 9%, respectively. When the tracer [^{3}H]25-OH-CHO was used, 53 and 43% of tritium was found in liver and brain, respectively, which suggests that [^{3}H]25-OH-CHO was metabolized to more polar compounds.

Radioactivity loss in the fixation procedures: [^{3}H]CHO. The total radioactivity loss in the procedures studied are summarized in Figures 3–6.

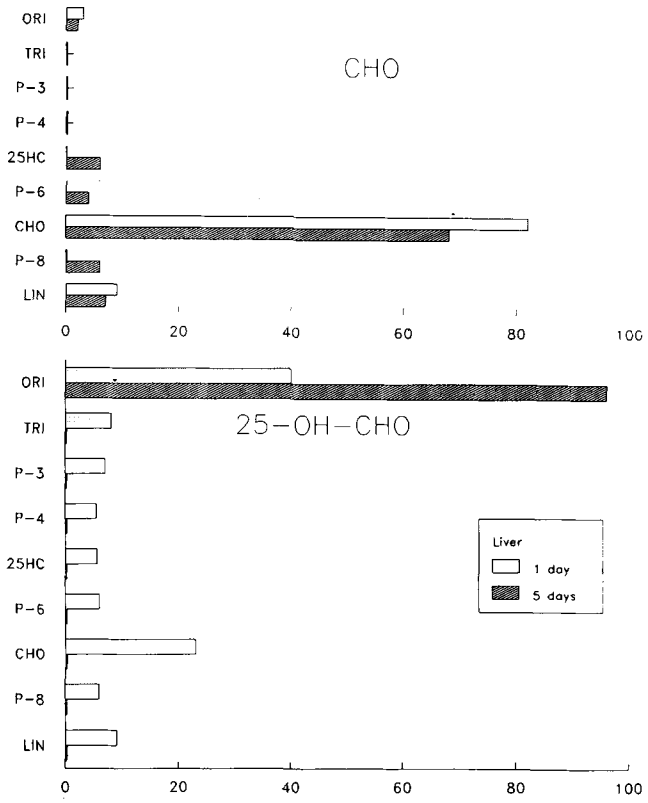

FIG. 1. Thin-layer chromatography profile of lipid extracts of liver one and five days after intraperitoneal injection with [1α,2α(n)-^{3}H]-cholesterol ([^{3}H]CHO) or 25-hydroxy[26,27-^{3}H]cholesterol ([^{3}H]25-OH-CHO). Values are percent of total radioactivity. The scraped areas corresponding to the four standards used are indicated as: TRI (cholestane-3β,5α,6β-triol), 25HC (cholestene-3β,25-diol), CHO (cholesterol) and LIN (cholesteryl linoleate); the areas corresponding to the origin and other positions are indicated as ORI and P-3 to P-8. Results are given as percentage of radioactivity found in each of the scraped areas, when the sum of all is taken to be 100%.

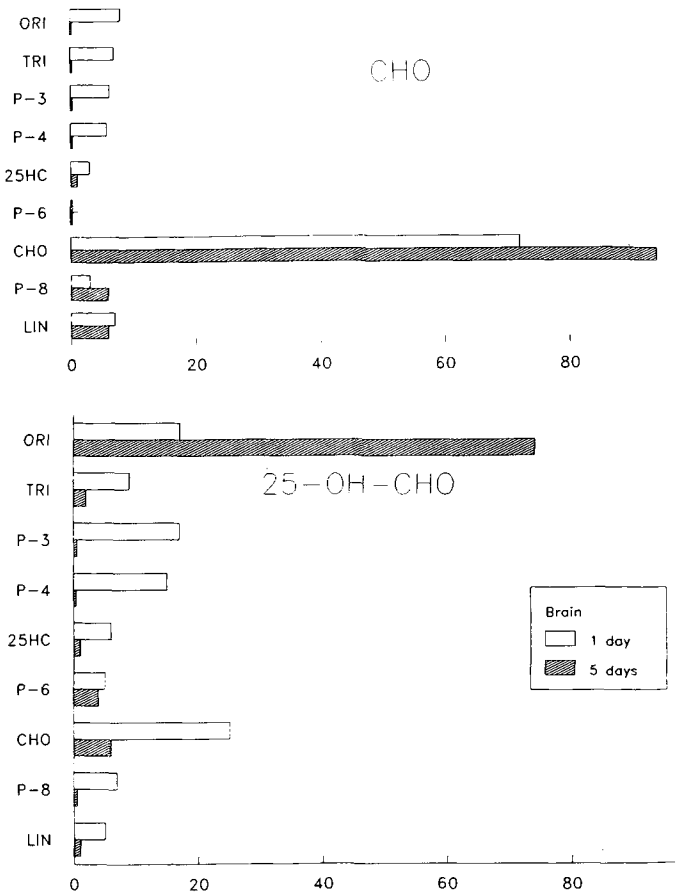

FIG. 2. Thin-layer chromatography of lipid extracts of brain one and five days after intraperitoneal injection with [^{3}H]CHO or [^{3}H]25-OH-CHO. Values are percent of total radioactivity. The scraped areas corresponding to the four standards used are indicated as: TRI (cholestane-3β,5α,6β-triol), 25HC (cholestene-3β,25-diol), CHO (cholesterol) and LIN (cholesteryl linoleate); the areas corresponding to the origin and other positions are indicated as ORI and P-3 to P-8. Results are given as percentage of radioactivity found in each of the scraped areas, when the sum of all is taken to be 100%. Abbreviations as in Figure 1.

To simplify the charts, the radioactivity loss measured in the pre-fixation, fixation, post-fixation and washing liquids are given in bulk as FIXAT; the sum of radioactivity losses in the dehydration fluids is given as DEHYD; and the losses for the different embedding steps are given together as EMBED.

None of the procedures studied prevented radioactivity loss in the liver (Figs. 3-6). The minimum loss observed was approximately 65% in the first two procedures, and essentially 100% in the third one. Radioactivity was lost mainly during the dehydration and embedding steps (k), while there was almost no loss of radioactivity during fixation.

By comparison, when aortic tissue was used, the percentage of radioactivity lost was 24 and 16% in the first two procedures, respectively, and 45% in the third one. Thus, there was a big difference between the results obtained for the liver (all procedures over 60% loss) and those obtained for the aorta (one of the procedures showed more than 80% retention of radioactivity).

Radioactivity loss in the fixation procedures: [^{3}H]25-OH-CHO. When [^{3}H]25-OH-CHO was used, the total loss of radioactivity in the three procedures was less than 20%; the results for the two types of tissue did not vary greatly. The loss of radioactivity in the fixation steps was much higher than with CHO, which is consistent with the conversion of the tracer into more polar compounds. The low loss of the polar radioactive metabolites during the dehydration and embedding steps is also consistent with the detected increase in polarity of the tritiated molecules.

DISCUSSION

During the last few years, special emphasis has been placed on EM preparatory procedures which retain functional properties of proteins throughout the fixation, dehydration and embedding steps (16). Conservation of protein functional features is particularly important in postembedding immunocytochemistry, which makes possible the analysis of the distribution, and in some cases the amount, of antigenic sites in tissues (17). Although the loss of lipids during preparatory procedures has been found not to affect the immunochemical technique, several functional properties of proteins depend on their lipid environment (18,19). In addition, loss of lipids, including

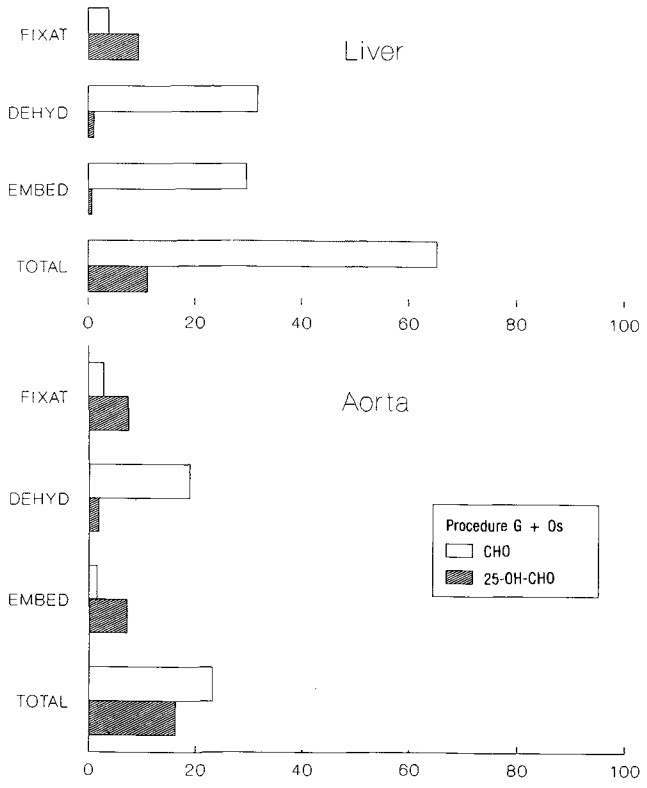

FIG. 3. Fixation procedure G + Os. Loss of radioactivity percentage during fixation of liver and aortic tissues five days after intraperitoneal injection with [^{3}H]cholesterol (CHO) or [^{3}H]25-OH-CHO. The radioactivity losses during pre-fixation, fixation, post-fixation and washing are given in bulk as FIXAT; the losses in the dehydration fluids are given as DEHYD; the losses in the embedding steps are given as EMBED, and the sum of the radioactivity losses are given as TOTAL. Abbreviations as in Figure 1.

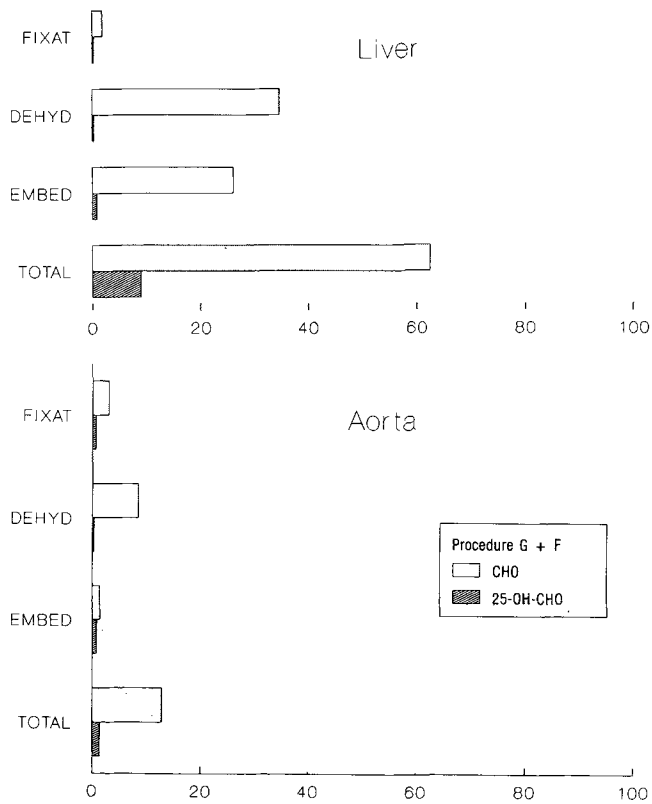

FIG. 4. Fixation procedure G + F. Loss of radioactivity percentage during fixation of liver and aortic tissues five days after intraperitoneal injection with[^{3}H]cholesterol (CHO) or [^{3}H]25-OH-CHO. The radioactivity losses during pre-fixation, fixation, post-fixation and washing are given in bulk as FIXAT; the losses in the dehydration fluids are given as DEHYD; the losses in the embedding steps are given as EMBED, and the sum of the radioactivity losses are given as TOTAL. CHO and CHO metabolites, during these preparatory procedures constitutes a disadvantage in studies on cell structures containing these molecules, such as plasma membranes. However, there are additional problems of CHO localization due to the ubiquitous presence of different chemical forms or the sterols in the cells. Free CHO forms part of the plasma membrane structure in mammalian cells, but CHO is typically stored as its ester and, finally is converted from its free form to other steroids. Our results indicating that both CHO and 25-OH-CHO are metabolized in tissues including liver and brain agree with those reported by Taylor and Kandutsch (20).

Most of the CHO loss from liver tissue occurred during the dehydration and embedding steps, whereas in aortic tissue the losses took place mainly during dehydration; very little radioactivity was lost in either tissue during the embedding steps. In contrast, the loss of 25-OH-CHO took place during fixation, which reflects the higher polarity of the tritium labeled metabolites of 25-OH-CHO as compared to those of CHO, as was demonstrated by TLC. The results suggest the need for alternative procedures to minimize the loss of both sterols.

Since dehydration at 277 K or partial dehydration was reported to reduce lipid loss (21,22), we analyzed in a preliminary study the effect of low temperature dehydration and embedding procedures on [^{3}H]CHO and [^{3}H]25-OH-CHO loss in liver and aortic tissues five days after i.p. injection of the tracers. The hydrophilic embedding medium Lowicryl K4M (Polysciences, Inc., Warrington, PA) was used for this purpose. The results show that this technique, used widely for immunocytochemistry, also significantly reduces the loss of both sterols. The total loss of CHO in liver and aortic tissues was 23 and 7%, respectively, while 6 and 4% of 25-OH-CHO metabolites were lost in liver and aortic tissues, respectively. Therefore, low temperature procedures recommend themselves as superior alternatives to standard EM procedures. However, other more recent techniques, such as cryofixation, also need to be investigated.

Our results further show that the loss of CHO differs from that of CHO derivatives, such as 25-OH-CHO. For this reason, the results obtained for CHO fixation cannot be extrapolated for other steroids. Moreover, there is no standard procedure for preventing the loss of CHO from different mammalian tissues during EM preparation. The loss of CHO appears to depend on several factors, including its chemical form in which it is present in these tissues.

The role of OsO_4 in the retention of lipids during fixation remains unclear. Whereas in some studies it has been

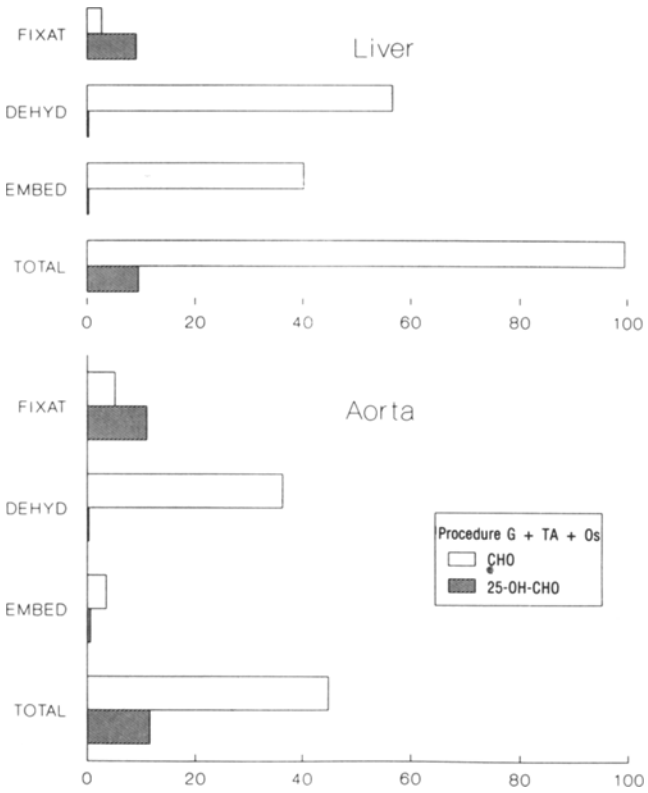

FIG. 5. Fixation procedure G + TA + Os. Loss of radioactivity percentage during fixation of liver and aortic tissues five days after intraperitoneal injection with [^{3}H]cholesterol (CHO) or [^{3}H]25-OH-CHO. FIG. 6. Total losses of radioactivity percentage during fixation of liver and aortic tissues by Procedures G + Os, G + F and G + TA + Os, five days after intraperitoneal injections with [^{3}H]cholesterol (CHO) or [^{3}H]25-OH-CHO. Other abbreviations as in Figure 1.

shown that this fixative minimizes lipid loss (2), x-ray diffraction analyses indicate that fixation with this compound is not enough to prevent the loss of CHO during dehydration (23).

The staining system osmium ferrocyanide is widely used to enhance staining of membranes and the sarcoplasmic reticulum. There is an equilibrium between the different oxidation states, Os(VII) and Os(VI), where Os is immobilized at the chelation sites of the macromolecular matrix of the substrate (13). Little is known about this process, but it seems that while the bilayer lipids disappear, remnants of the former structure (probably denatured proteins) remain, although much of the protein is also lost (24).

Inclusion of osmium in the fixation process does not affect the structures visualized, and the effect on proteins is the same whether there has been prefixation or not. Making proteins insoluble with TA also does not significantly prevent protein loss (24). In fact, there seems to be no relationship between the proposed mechanisms for osmium staining and the loss of CHO in the fixation procedures studied. Our data on CHO retention in liver tissue show that the use of $OsO_4/K_4Fe(CN)_6$ (Procedure G + Os) gave the same result as Procedure G + F (0.8% F + 0.8% G, without osmium treatment). The best results with aortic tissue were obtained with Procedure G + F. The loss of CHO was the highest in both liver and aortic tissues with Procedure G + TA + Os (TA in the fixative solution and OsO_4 treatment), even though TA is a chelating agent for osmium (13).

When 25-OH-CHO was used as tracer, the loss of tritium was lower than when CHO was used, and the use of osmium did not increase metabolite retention.

In summary, our results show that the degree of CHO and 25-OH-CHO loss does not depend only on the procedures used for EM but also on the type of tissue. This is in substantial agreement with previous studies that have focused on total lipids (2,21).

Cholesterol and 25-Hydroxycholesterol Retention in Specimens of Liver and Aorta Prepared for Electron Microscopy. II. Effect of Filipin, Osmium, Digitonin and Saponin

E. Fornas*, J. Renau-Piqueras, A. Fortea, F. Mayordomo and **E. Alborch**
Centro de Investigación, Hospital "La Fe," 46009 Valencia, Spain

Sprague-Dawley rats were injected intraperitoneally with [1α,2α(n)-^{3}H]cholesterol or 25-hydroxy-[26,27-^{3}H]cholesterol, and one and five days later liver and aortic tissues were fixed. The extent to which these sterols were lost from the tissues during preparation for electron microscopy (EM) was examined utilizing different fixation procedures and various protective agents. Radioactive tracers, scintillation counting and standard EM techniques were used. Although most of the procedures examined caused major lipid losses, useful fixation procedures that allow retention of cholesterol or 25-hydroxycholesterol in liver and aortic tissues were found and are described here.
Lipids 28, 929–935 (1993).

Lipids usually constitute one of the major components of cell membranes, and in most mammalian membranes cholesterol (CHO) is present at an about equimolar ratio with phospholipids. One of the limiting factors in plasma membrane studies using electron microscopy (EM) is that the conventional procedures for preparing biological material for EM lead to extensive loss of lipids (1). In the preceding paper we examined the loss of CHO and of 25-hydroxy-cholesterol (25-OH-CHO) from rat aorta and liver tissues during conventional EM preparatory procedures (2). The procedures included aldehyde fixation with or without osmium tetroxide postfixation, dehydration in ethanol, and embedding in Epon 812. We found that the radioactive tracer 25-hydroxy-[26,27-^{3}H]cholesterol ([^{3}H]25-OH-CHO), when injected intraperitoneally (i.p.), was metabolized to more polar compounds. When the tracer injected was [1α,2α(n)-^{3}H]cholesterol ([^{3}H]CHO), about 90% of the radioactivity of the lipid extracts was associated with the CHO fraction, and about 10% was converted to steryl esters. The calculated increases in CHO present in liver and aortic tissues upon injection of the tracer were 5.3×10^{-4} and 3.6×10^{-4}%, respectively. Under these conditions loss of CHO significantly differs from that of its derivatives. Our results showed, moreover, that CHO loss from mammalian tissues cannot be avoided when conventional EM procedures are used. This appears to be due to several factors, including the different chemical forms into which CHO is converted in a particular tissue. Our results also pointed out the importance of finding alternative procedures which would make it possible to analyze by EM cell structures containing CHO.

The aim of the present work was to compare various procedures used in CHO cytochemistry and to examine how CHO and 25-OH-CHO loss and total lipid loss can be prevented during the preparation of the biological specimens for EM. The procedures we examined include addition of digitonin, saponin or filipin to the fixative solutions in an attempt to preserve CHO in its native location. The experiments were carried out by giving rats i.p. injections of [^{3}H]CHO and [^{3}H]25-OH-CHO and by measuring the radioactivity present in the residual fluids of the various steps of the preparatory process.

Abbreviations: CB, cacodylate buffer; CHO, cholesterol; [^{3}H]CHO, [1α,2α(n)-^{3}H]cholesterol; EM, electron microscopy; F, formaldehyde; G, glutaraldehyde; i.p., intraperitoneal(ly); 25-OH-CHO, 25-hydroxycholesterol; [^{3}H]25-OH-CHO, 25-hydroxy-[26,27-^{3}H]cholesterol; PB, 0.1 M phosphate buffer (pH 7.3, 2 mM $MgCl_2$).

MATERIALS AND METHODS

Animals and tracers. Sprague-Dawley rats weighing 150–200 g were used. One and five days prior to being sacrificed, animals were injected intraperitoneally with 5 mCi of [^{3}H]CHO, 40–60 Ci/mmol (Amersham International, Amersham, England), or 2 mCi of [^{3}H]25-OH-CHO, 75–87 Ci/mmol (New England Nuclear, Boston, MA). Both products were prepared for injection as described by Baranowsky *et al.* (3). After evaporation of the toluene from the original vial containing the tracer, the labeled sterol was redissolved in 0.5 mL of ethanol, 1 mL of saline was added to this solution and most of the ethanol was evaporated in a stream of nitrogen. The resulting sterol suspension was injected i.p.

For removal of the tissues, the rats were kept under pentobarbital anesthesia, and after cannulating the aorta, saline was infused at 100 mm Hg for one minute. Immediately thereafter, aliquots of tissue from aorta and liver were taken for each of the fixation procedures, which were started immediately. Aliquots of aorta and liver were also taken to measure radioactivity per tissue.

Counting techniques. Radioactivity of the residual liquids of the individual steps of the fixative procedures was measured. As the chemical composition of the samples varied greatly, the counting efficiency for each type of sample was determined based on internal standards, and the counts were converted into disintegrations per min (dpm). Special care was required to measure the samples containing osmium, which had especially low counting efficiencies. The original dpm of the tissues to be fixed was determined by dissolving aliquots of the same type of tissue in Nuclear Chicago Solubilizer (Chicago, IL) and counting as described before. A toluene/Triton X-100 liquid scintillator (Scharlau, Barcelona, Spain) and LKB 1219 Rackbeta counter (LKB, Turku, Finland) were used. Results are the mean of three experiments; three animals were injected with each tracer, and two samples of tissue per animal were fixed independently for each of the fixative procedures studied.

Radioactivity was measured in each of the fluids used in all the processes, but in order to simplify the charts, the radioactivity losses measured in the pre-fixation, fixation, post-fixation and washing liquids are given in bulk as FIXATION, the sum of radioactivity losses in the

dehydration fluids is given as DEHYDRATION, and the losses in the different embedding steps are given together as EMBEDDING.

Radioactivity calculations. Since the weight of the aliquots of tissue to be fixed (and consequently their total radioactivity) was not uniform, they were weighed and their radioactivities calculated using the values given in Table 1. The radioactivity losses are given in percentages to facilitate comparison of the different fixation processes.

The radioactivity remaining in the fixed aliquots of tissue is taken to be the difference between the total radioactivity of the aliquot (calculated) and the sum of radioactivity losses measured in the fluids. The embedded aliquots were then used to obtain representative electron micrographs.

Preparation of tissues for EM. General procedure. Aliquots of tissue from aorta (3–4 mg) and liver (1–4 mg) were immersed for different periods of time (4) into 0.1 M phosphate buffer (PB) (pH 7.3, 2 mM $MgCl_2$) or in cacodylate buffer (CB) (pH 7.3, 2 mM $MgCl_2$) containing 1% glutaraldehyde (G) following the specific procedures described below. Effective osmolarity of the fixative solution (300 mOsm) was determined as described in the literature (5,6). The purity of G (Merck, Darmstadt, Germany) was determined by measuring the relative ultraviolet absorbances between 210 and 310 nm (5,7,8); the spectra showed a peak only at 280 nm. After brief washing in PB, the tissues were postfixed with 2% OsO_4 containing 1.8% potassium ferrocyanide in PB for 2 h in the dark at room temperature (296 K).

Samples were dehydrated by 5-min immersions into ethanol (60, 80 and 95%)/water (vol/vol), and by two 5-min immersions into 100% ethanol; all immersions were at 273 K. Use of propylene oxide was not considered necessary.

Epon 812 (Polysciences, Warrington, PA) consisted of 21 mL Poly/Bed 812, 13 mL dodecenyl succinic anhydride, 11 mL nadic methyl anhydride and 0.7 mL DMP-30, which was added just before use. Samples were placed into mixtures of Epon 812 and ethanol at concentrations of 25, 50 and 75% (60 min, room temperature). Then the samples were placed in 100% Epon 812 overnight at 277 K, and cured during a second night at 333 K.

Both $CaCl_2$ and $MgCl_2$ are known to decrease the loss of lipid during fixaton of various tissues (9). In the present work, $MgCl_2$ was used instead of $CaCl_2$ to avoid formation of calcium phosphate precipitates. Osmium/potassium ferrocyanide mixtures are increasingly popular as a secondary fixative in both conventional EM and in various cytochemical procedures because they combine selective fixation and enhanced staining of membrane systems, glycocalix and glycogen (10–12).

Preparation of tissues for EM. Specific procedure. CHO was localized in membranes by using saponin, digitonin or polyene antibiotics such as filipin (13,14). The latter reagent forms large complexes with CHO that are visible in freeze-fracture replicas as distinct ondulations in thin sections or protuberances. Use of filipin is the method of choice for cytochemical localization of sterols (14) and is also used in studies that require blocking of membrane steroids (15,16).

We therefore examined the ability of these substances to retain CHO or 25-OH-CHO in the course of the EM preparatory procedures in the tissues. The G fixation step is the only one studied here that is relevant to freeze-fracture preparations (14). The other steps are required in the preparation for thin-sectioning.

Filipin treatment (Procedures 1 and 2). Unfractionated filipin (Upjohn Co., Kalamazoo, MI) was added to the G-based fixatives in CB (see general procedure section) at concentrations of 0, 2, 5, 10, 20, 60 and 100 μg/mL. Filipin was first dissolved in dimethyl sulfoxide and then added to the fixative (final concentration of dimethyl sulfoxide was 1% in all solutions). Fixation was for 24 h at room temperature in the dark. Samples were then processed for EM as described in the general procedure. In the pre-treatment with filipin (Procedure 2), tissues were incubated before fixation for 2 h at room temperature and in the dark in CB containing filipin at concentrations of 100, 10 and 0 μg/mL. Thereafter, the general procedure was followed.

The ability of filipin to form complexes with β-hydroxysterols had been tested in a previous study (17) using freeze-fracture on synaptosomes isolated from cerebral cortex of rats.

Osmium tetroxide treatment (Procedure 3). Since mixtures of aldehydes and Os have been recommended for different types of tissues, isolated cells and cells in monolayers (2,18,19), samples were fixed in 1% osmium tetroxide, 0.8% formaldehyde (F) and 0.8% G in 0.075 M PB, pH 7.2 for 1 h in the dark at 277 K. A similar fixative but without osmium tetroxide was used in parallel, and the

5	1 082	813				
6	1 128	890				

[a]Values of [1α,2α(n)-^{3}H]cholesterol ([^{3}H]CHO) in mmol/mg of tissue and the cholesterol (CHO) increases were estimated as described in Counting Techniques. 25-Hydroxy-[26,27-^{3}H]cholesterol ([^{3}H]25-OH-CHO) values were not calculated, as this tracer is rapidly metabolized. i.p., intraperitoneal.

two procedures are identified as 3-Osmium and 3-Osmium Blank. Samples were then washed for 2 h in PB at 277 K, and dehydrated and embedded as described in the general procedure.

Digitonin treatment (Procedure 4). A partial dehydration method, similar to the one described by Darrah *et al.* (20), was followed. Samples were fixed for 1 h in 2.5% G and 0.2% digitonin in PB at 277 K, and in the corresponding fixative without digitonin. The two procedures are identified as 4-Digitonin and 4-Digitonin Blank. After one-hour post-fixation in Dalton's chrome/osmium tetroxide, the tissues were dehydrated at 273 K, 5 min each step, in two 70% ethanol steps, and in two 95% ethanol steps. This was followed by four embedding steps with 100% Epon 812 at 277 K. The first three were for one hour each and the last one continued overnight. Finally the sample was embedded in Epon 812 for 90 min at 310 K and cured at 333 K overnight.

Saponin treatment (Procedure 5). Tissues were fixed in 1% G, 2 mg/mL tannic acid and 0.5 mg/mL saponin in PB for 30 min in the dark at 293 K. A corresponding control without saponin was also used. The two procedures are identified as 5-Saponin and 5-Saponin Blank. A brief washing in PB and 20-min post-fixation in 1% osmium tetroxide in PB at room temperature in the dark were followed by dehydration and embedding as described in the general procedure.

RESULTS

Table 1 gives the radioactivities found in liver and aortic tissues, the values in mmol of the tracer [^{3}H]CHO and the estimated CHO increase due to the tracer. CHO increases (5.3×10^{-4}% for liver and 3.6×10^{-3}% for aorta) were calculated using 3.9 g/kg and 1.0 g/kg for the CHO contents of liver and aortic tissues, respectively (21). Increases in [^{3}H]25-OH-CHO were not evaluated, as this tracer is rapidly metabolized and the radioactivity found in the tissues corresponds to other, more polar compounds (2).

Treatment of tissue with osmium tetroxide (Procedure 3 and the corresponding blank procedure) resulted in protection against loss of CHO (13 and 14%, respectively) and 25-OH-CHO and its metabolites (1 and 1.4%, respectively) from aortic tissue (Figs. 1 and 2). However, in the liver only 25-OH-CHO and its metabolites (9.2 and 9.0% radioactivity loss, respectively) were preserved when this treatment was used (Figs. 3 and 4).

When the specific cytochemical procedures were used, *i.e.*, with inclusion of filipin, digitonin or saponin, the results varied greatly. None of the filipin procedures prevented CHO loss from the liver, and in all cases losses were over 60% (Fig. 5). In all the filipin procedures, in fact, the results were quite similar to those of the controls, which shows that filipin provides little protection. When filipin was used in the first step (but without G) to fix CHO or 25-OH-CHO in the liver, the radioactivity loss was as high as in the standard filipin procedures (over 60% loss for CHO and between 7 and 12% for 25-OH-CHO and its metabolites). The results of the control procedure were also quite similar to the results of the filipin procedures (Figs. 6 and 8). The results, however, were clearly different when CHO was fixed with filipin in the aortic tissue, where the total radioactivity loss was reduced (Fig. 7), but still was more than 15%.

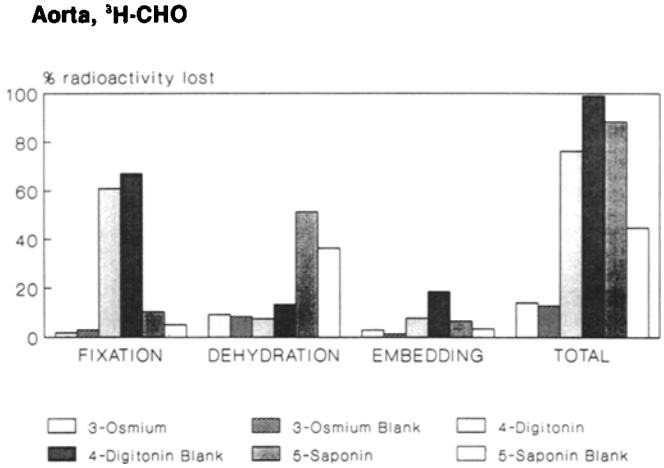

FIG. 1. Fixation Procedures 3, 4 and 5 (treatments with osmium tetroxide, digitonin and saponin). Loss of radioactivity during fixation of aortic tissue five days after intraperitoneal injection of [^{3}H]cholesterol (CHO). Radioactivity losses during pre-fixation, fixation, post-fixation and washing are given in bulk as FIXATION; losses in all the dehydration fluids are given as DEHYDRATION; losses in all the embedding steps are given as EMBEDDING; and the sum of all the radioactivity losses are given as TOTAL.

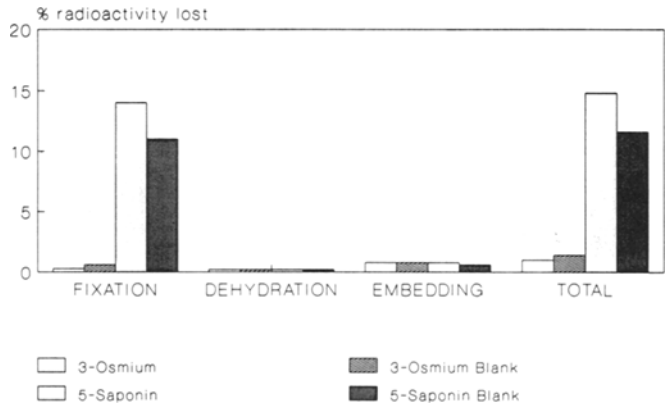

FIG. 2. Fixation Procedures 3 and 5 (treatments with osmium tetroxide and saponin). Loss of radioactivity during fixation of aortic tissue five days after intraperitoneal injection of [^{3}H]25-OH-cholesterol (CHO). Radioactivity losses during pre-fixation, fixation, post-fixation and washing are given in bulk as FIXATION; losses in all the dehydration fluids are given as DEHYDRATION; losses in all the embedding steps are given as EMBEDDING; and the sum of all the radioactivity losses are given as TOTAL.

All the filipin procedures tested on liver tissue resulted in a smaller radioactivity loss in the case of 25-OH-CHO (between 7 and 12%) than for CHO (over 60%; Figs. 5, 6 and 8), and similar results were obtained in aortic tissue (losses close to 20% for CHO and close to 15% for 25-OH-CHO and its metabolites; Figs. 7 and 9). The total loss, however, was high in all the procedures, and again control and filipin procedures gave similar results. Results obtained in pre-treatment with filipin were good in the case of 25-OH-CHO and its metabolites showing close to 7% retention in liver (Fig. 6), and, again, the blank procedure gave results similar to those obtained with filipin.

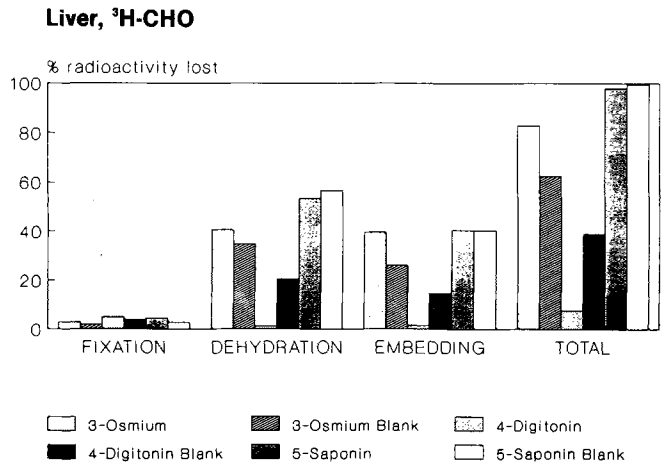

FIG. 3. Fixation Procedures 3, 4 and 5 (treatments with osmium tetroxide, digitonin and saponin). Loss of radioactivity during fixation of liver tissue five days after intraperitoneal injection of [^{3}H]cholesterol (CHO). Radioactivity losses during pre-fixation, fixation, post-fixation and washing are given in bulk as FIXATION; losses in all the dehydration fluids are given as DEHYDRATION; losses in all the embedding steps are given as EMBEDDING; and the sum of all the radioactivity losses are given as TOTAL.

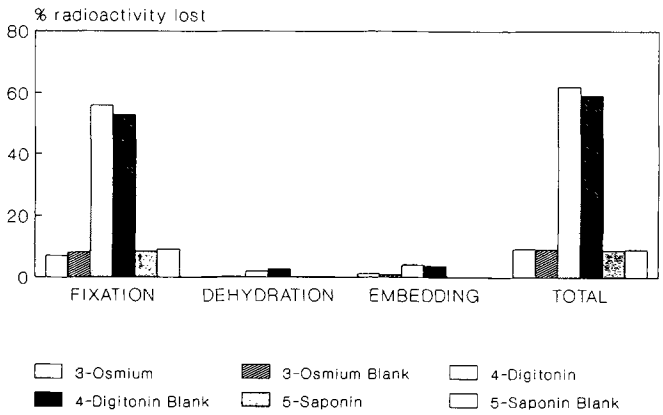

FIG. 4. Fixation Procedures 3, 4 and 5 (treatments with osmium tetroxide, digitonin and saponin). Loss of radioactivity during fixation of liver tissue five days after intraperitoneal injection of [^{3}H]25-OH-cholesterol (CHO). Radioactivity losses during pre-fixation, fixation, post-fixation and washing are given in bulk as FIXATION; losses in all the dehydration fluids are given as DEHYDRATION; losses in all the embedding steps are given as EMBEDDING; and the sum of all the radioactivity losses are given as TOTAL.

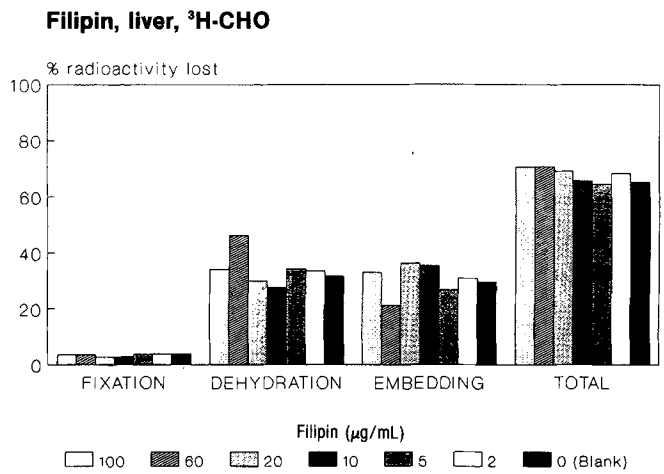

FIG. 5. Fixation Procedure 1 (treatment with filipin). Radioactivity loss in liver tissue fixation five days after intraperitoneal injection of [^{3}H]cholesterol (CHO). Radioactivity losses during pre-fixation, fixation, post-fixation and washing are given in bulk as FIXATION; losses in all the dehydration fluids are given as DEHYDRATION; losses in all the embedding steps are given as EMBEDDING; and the sum of all the radioactivity losses are given as TOTAL.

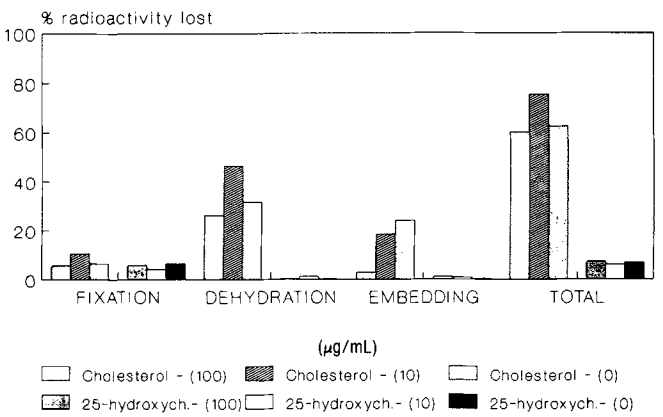

FIG. 6. Fixation Procedure 2 (pre-treatment with filipin). Radioactivity losses in liver tissue fixation five days after intraperitoneal injection of [^{3}H]cholesterol (CHO) and [^{3}H]25-OH-CHO. Radioactivity losses during pre-fixation, fixation, post-fixation and washing are given in bulk as FIXATION; losses in all the dehydration fluids are given as DEHYDRATION; losses in all the embedding steps are given as EMBEDDING; and the sum of all the radioactivity losses are given as TOTAL. Abbreviation: 25-hydroxych., 25-hydroxycholesterol.

Digitonin, which has been described as a good tool for avoiding lipid losses, protected liver against CHO loss (7.5% loss *vs.* 39% with the corresponding blank procedure, Fig. 3). However, in aorta tissue more than 75% of CHO was lost using the digitonin procedure and its blank (Fig. 1). Digitonin does not prevent 25-OH-CHO loss from liver (losses of more than 60% for the procedure and its blank, Fig. 4).

In contrast, saponin treatment and the corresponding blank procedure prevented losses of 25-OH-CHO and its metabolites in both aorta and liver tissues (12 and 9% loss, respectively, Figs. 2 and 4).

DISCUSSION

In recent years many attempts have been made to develop EM preparatory procedures which minimize the loss of molecules from the specimens and preserve structural integrity and functional properties (2,9,20,22). Special emphasis has been placed on procedures which retain the antigenicity and/or enzymatic activity of a variety of proteins (20,22,23). Although it has been claimed that the loss of lipids is not a serious problem (22), it constitutes an important disadvantage in studies on the ultrastructural

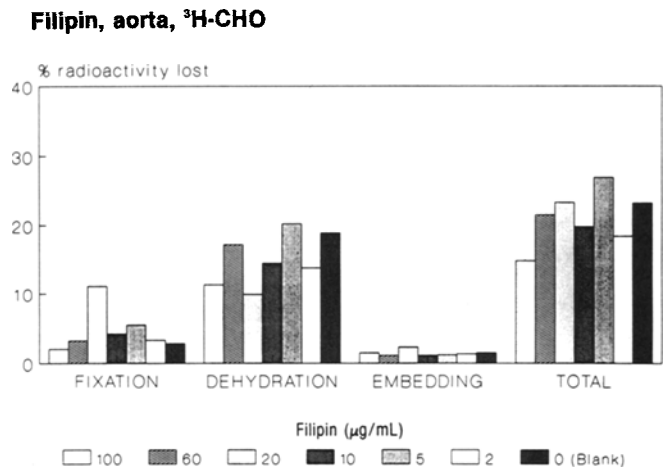

FIG. 7. Fixation Procedure 1 (treatment with filipin). Loss of radioactivity during fixation of aortic tissue five days after intraperitoneal injection of [^{3}H]cholesterol (CHO). Radioactivity losses during pre-fixation, fixation, post-fixation and washing are given in bulk as FIXATION; losses in all the dehydration fluids are given as DEHYDRATION; losses in all the embedding steps are given as EMBEDDING; and the sum of all the radioactivity losses are given as TOTAL.

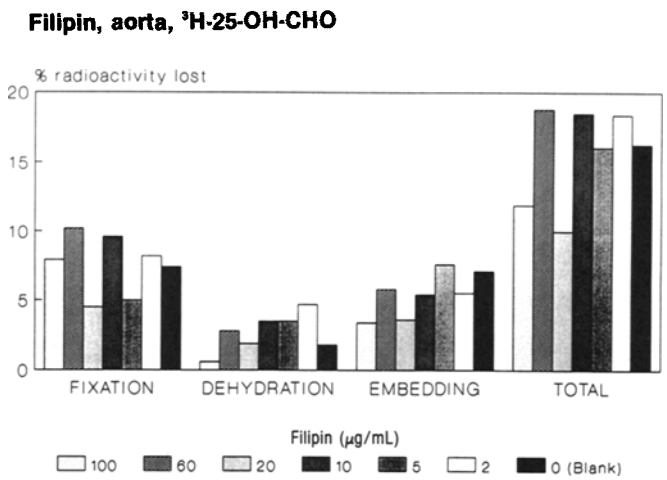

FIG. 9. Fixation Procedure 1 (treatment with filipin). Loss of radioactivity during fixation of aortic tissue five days after intraperitoneal injection of [^{3}H]25-OH-cholesterol (CHO). Radioactivity losses during pre-fixation, fixation, post-fixation and washing are given in bulk as FIXATION; losses in all the dehydration fluids are given as DEHYDRATION; losses in all the embedding steps are given as EMBEDDING; and the sum of all the radioactivity losses are given as TOTAL.

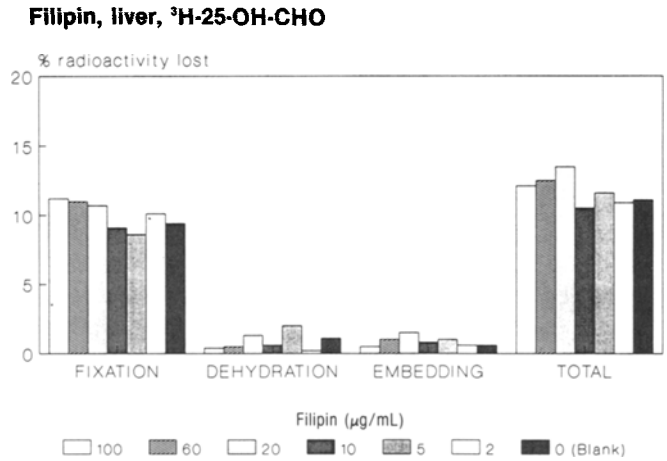

FIG. 8. Fixation Procedure 1 (treatment with filipin). Loss of radioactivity during fixation of liver tissue five days after intraperitoneal injection of [^{3}H]25-OH-cholesterol (CHO). Radioactivity losses during pre-fixation, fixation, post-fixation and washing are given in bulk as FIXATION; losses in all the dehydration fluids are given as DEHYDRATION; losses in all the embedding steps are given as EMBEDDING; and the sum of all the radioactivity losses are given as TOTAL.

localization of CHO. Moreover, there are important additional problems of CHO localization due to the ubiquitous presence of different sterol forms in the cells. Free CHO forms part of the plasma membrane structure in mammalian cells, CHO is stored as steryl ester, and, finally, it is metabolized to other steroids.

The losses of [^{3}H]CHO introduced in the tissues (estimated CHO increases of 5.3×10^{-4}% for liver and 3.6×10^{-3}% for aorta) are used to evaluate CHO retention. We assumed that the tracer is uniformly distributed in the tissues and that its loss corresponds to the loss of native CHO, although this has not been proven. It also must be taken into account that the radioactivity losses from tissues of animals injected with [^{3}H]25-OH-CHO largely correspond to 25-OH-CHO metabolites and not to native 25-OH-CHO, if present at all.

The staining system osmium/ferrocyanide is widely used for enhanced staining of membranes and of the sarcoplasmic reticulum. There is an equilibrium between the different oxidation states, Os(VII) and Os(VI), that are immobilized at the chelation sites of the macromolecular matrix of the substrate (9). Little is known about this process, but it seems that while the lipid bilayers disappear, remnants of the former structure (probably denatured proteins) remain, although much of the protein is lost (24). Our results confirm that osmium does not retain CHO in the tissues studied, where the same results were obtained for osmium containing fixative and the corresponding blank (Figs. 1–4).

When digitonin was used as a protective agent (19) our results for CHO retention in liver coincided with those reported by Scallen and Dietert (25) for this tissue and by Darrah *et al.* (20) for the lung. Moreover, thin sections obtained from liver tissue fixed in the presence of digitonin revealed good ultrastructural preservation of hepatocyte components (Fig. 10A). By contrast, digitonin treatment does not prevent 25-OH-CHO metabolite loss from the liver. Also, a significant loss of CHO was observed in aortic tissue when digitonin was used during aldehyde fixation. This suggests that digitonin does not stabilize CHO in this tissue, although the ratio of free CHO *vs.* esterified CHO is similar to that observed in the liver. The results obtained with [^{3}H]25-OH-CHO in the liver very much depend on the type of fixative and buffer used.

Pretreatment of tissue with filipin before fixation and the corresponding blank procedure retain about 90% of the 25-OH-CHO metabolites. However, filipin treatment of unfixed tissue causes extensive alterations in cell ultrastructure, including mitochondrial disorganization

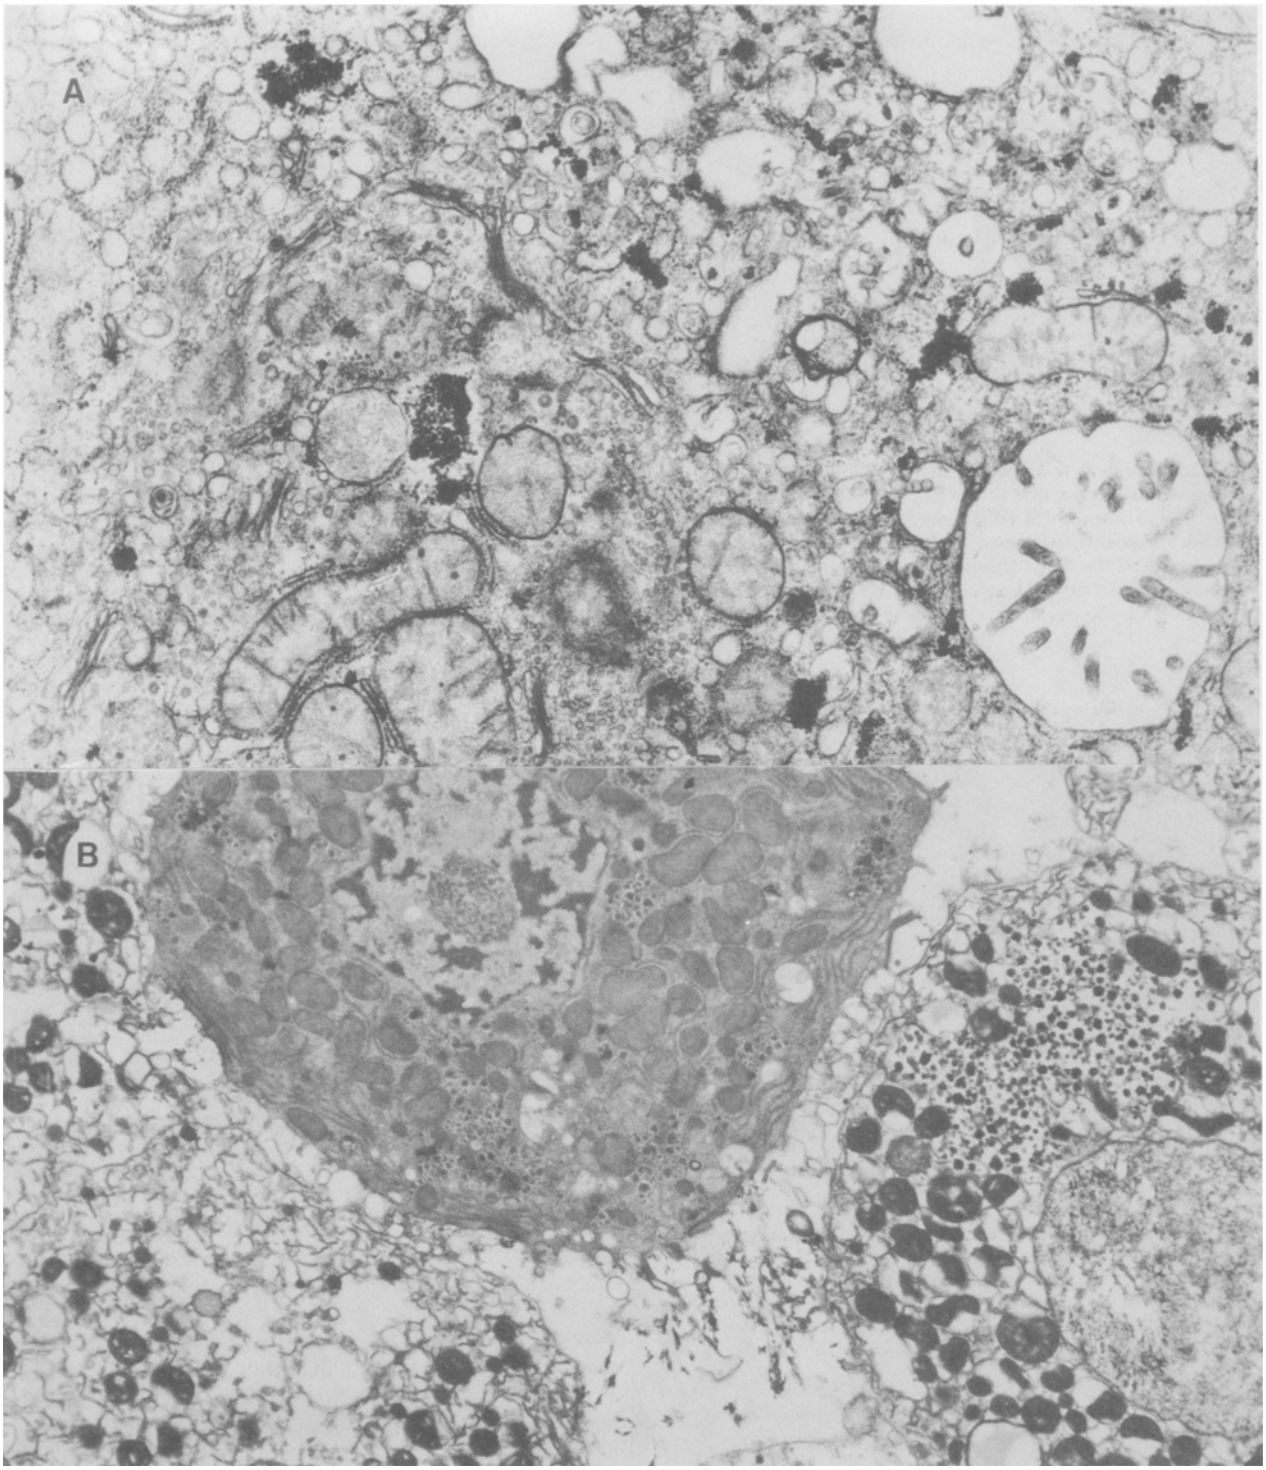

FIG. 10. (A) Details of a rat hepatocyte processed for electron microscopy using digitonin as a protective agent (Procedure 4). There is a good preservation of the ultrastructure of most of the cell components, including mitochondria, endoplasmic reticulum, glycogen and small vesicles. Some specific alterations induced by this treatment are a collapsed Golgi apparatus and the presence of some clear vacuoles. (B) Micrograph showing the effect of pretreatment of rat liver with filipin before fixation. As shown, this treatment induces an extensive alteration of hepatocyte ultrastructure, including mitochondrial disorganization. (A, ×8585.60; B, ×28981.60.)

and swelling (Fig. 10B). This finding is consistent with reported results (12).

Some of the procedures tested here could be used in conventional EM, and in cytochemical or autoradiographic studies on the ultrastructural localization of CHO or CHO derivatives. Thus, the combination of G and F significantly reduces CHO and 25-OH-CHO loss in liver and in aortic tissue. Moreover, this procedure results in a good ultrastructural preservation of cell components (18) and can be used in ultrastructural studies concerned with CHO distribution by freeze-fracture techniques using filipin as marker.

Although the procedures described here and in the preceding paper (2) are widely used in conventional EM as well as in cytochemistry, various procedures have been developed during the last few years that would avoid problems such as loss of antigenicity and functional activities and also just loss of mass. These procedures include cryofixation and the use of low temperature embedding resins. Although the cryofixation techniques appear to be a good alternative to standard techniques, technical problems still prevent their routine use. In contrast, low temperature embedding appears to become an established method facilitating cytochemical and immunochemical procedures. Moreover, these latter methods result in good ultrastructural resolution as well as provide suitable contrast. Preliminary results obtained in our laboratory have shown that low temperature embedding resins, such as Lowicril K4M, are a good tool and minimize sterol loss in the preparatory procedures for thin sectioning.

The Effect of Lyophilization on the Solvent Extraction of Lipid Classes, Fatty Acids and Sterols from the Oyster *Crassostrea gigas*

Graeme A. Dunstan*, John K. Volkman and **Stephanie M. Barrett**
CSIRO Division of Oceanography, Hobart, Tasmania 7001, Australia

The lipid class compositions of adult Pacific oysters [*Crassostrea gigas* (Thunberg)] were examined using latroscan thin-layer chromatography/flame-ionization detection (TLC/FID), and fatty acid compositions determined by capillary gas chromatography and gas chromatography/mass spectrometry (GC/MS). The fatty acid methyl esters were separated using argentation TLC and also analyzed as their 4,4-dimethyloxazoline derivatives using GC/MS. Major esterified fatty acids in *C. gigas* were 16:0, 20:5n-3, and 22:6n-3. C_{20} and C_{22} nonmethylene interrupted (NMI) fatty acids comprised 4.5 to 5.9% of the total fatty acids. The NMI trienoic fatty acid 22:3(*7,13,16*) was also identified. Very little difference was found in the proportions of the various lipid classes, fatty acids or sterols between samples of adult oysters of two different sizes. However, significant differences in some of the lipid components were evident according to the method of sample preparation used prior to lipid extraction with solvents. Lyophilization (freeze drying) of samples led to a significant reduction in the amounts of triacylglycerols (TG) extracted by solvents in two separate experiments (7.0 and 52.5% extracted). Extracts from lyophilized samples had less 16:0, C_{18} unsaturated fatty acids, and 24-ethylcholest-5-en-3β-ol, while C_{20} and C_{22} unsaturated fatty acids comprised a higher proportion of the total fatty acids. There was no significant change in the amounts of polar lipids, total sterols, free fatty acids or hydrocarbons observed in extracts from lyophilized samples relative to extracts from nonlyophilized samples. Addition of water to the freeze-dried samples prior to lipid extraction greatly improved lipid yields and resulted in most of the TG being extracted.
***Lipids* 28, 937-944 (1993).**

Species of true oyster (family Ostreidae), primarily of the genera *Crassostrea* and *Ostrea* are intensively grown in mariculture farms for human consumption worldwide. The economic value of these bivalve molluscs has resulted in considerable efforts to improve production by increasing survival and growth rates, especially of the larval stages. Insufficient quantities of the long-chain polyunsaturated fatty acids (PUFA) 20:5n-3 and 22:6n-3 in the diet can lead to reduced growth rates and increased mortality in larval and juvenile bivalve molluscs (*e.g.*, 1-3). Larval viability has also been related to the total lipid content of oyster eggs and larvae (4,5), and variations in total lipid with age and season in adult oysters can give a measure of the mollusc's nutritional and reproductive status (6,7). As in most marine animals, the polar lipids (PL) in species of *Crassostrea* contain relatively more PUFA than neutral lipids [primarily triacylglycerols (TG)] (2,8,9). Because these lipid classes are not homogeneous with respect to fatty acid composition, incomplete lipid extraction would result in incorrect estimates of total lipid content and PUFA composition and also of larval condition and adult reproductive status where such lipid indices are used (5).

One of the most widely used techniques for solvent extraction of lipid from animal tissues is the method of Bligh and Dyer (10). This rapid method was developed for the extraction of lipids from fresh and frozen fish flesh, yielding approximately 94% of the total lipid or even more if the residue is reextracted. The authors suggested it could be used for many other tissues, and over the years this technique has been adapted successfully for the extraction of lipids from a wide range of terrestrial and aquatic samples. Variable results for lipid extraction using alternative solvent systems have been reported and appear to be highly tissue dependent (*e.g.*, 11-13).

The lyophilization or freeze drying of samples is a common technique employed as a form of preservation of animal tissues prior to analysis, and is useful in sample preparation as it makes tissues brittle and easily homogenizable and can be beneficial by denaturing enzymes (14). It has long been recognized that lyophilization increases the difficulty with which lipids can be extracted with solvents (*e.g.*, 14,15), and even though it is a widely used technique, the effect of this form of preservation on the efficiency of solvent extraction of lipids from tissues is rarely established. Lyophilization can also lead to the loss of certain compounds (16) and to artifact formation (17). Many schemes have been proposed involving lyophilization of samples prior to analysis of lipids as well as cellular protein, carbohydrate and nucleic acids (18-20), where lyophilization presumably does not affect the extraction of these components.

This study examined the effect of lyophilization on the solvent extraction of lipids from adult Pacific oysters (*Crassostrea gigas*) using a modification of the method of Bligh and Dyer (10). Also described is a modification of the method of Fay and Richli (21) for 4,4-dimethyloxazoline (DMOX) derivatization, which permits the rapid identification of double-bond positions in PUFA without loss of unsaturated fatty acids.

MATERIALS AND METHODS

Samples and lipid extraction. Lipids were extracted using a modification of the method of Bligh and Dyer (10). Solvent ratios from the original method were retained, *i.e.*, monophasic extraction with chloroform/methanol/water (1:2:0.8, by vol), followed by partition of aqueous and organic phases by solvent ratio adjustment to

chloroform/methanol/water (1:1:0.9, by vol). Significant changes to the original method were the increased solvent–residue contact time (from 10 min to overnight; Experiment 1), or increasing the number of solvent washes of the residue (from 2 to 4) and incorporating ultrasonication to aid in cell membrane disruption at each solvent–residue stage (Experiment 2). The Bligh and Dyer method (10) with either modification yielded the same total lipid and lipid class composition for duplicate samples of wet tissue of adult *C. gigas* (Dunstan, G.A., and Volkman, J.K., unpublished data). All organic solvents used were Nanograde® (Mallinckrodt, Paris, KY). All water used in these and subsequent steps was purified using a Milli-Q® Type I Reagent Water System (Millipore®, Bedford, MA) which removes dissolved inorganic electrolytes, particles (<0.22 μm) and organic compounds. Blank extractions were also performed to establish the lack of contaminants.

Experiment 1. Oysters of similar genetic stock and exposed to similar environmental conditions were collected out of breeding season (winter) from Pipe Clay Lagoon, Tasmania, Australia. Twelve adult oysters each of two size classes, large (average soft tissue weight 8.9 ± 0.5 g) and small (average soft tissue weight 5.8 ± 0.4 g), were divided into two replicate batches of six oysters each and frozen in liquid nitrogen prior to analysis. One batch of the large oysters and one batch of the small oysters were chopped and then homogenized in solvent separately with a Ystral® (Döttingen, Germany) homogenizer. These "control" samples (solvent extracted nonlyophilized wet tissue) were left to extract overnight in chloroform/methanol/water (1:2:0.8, by vol; 250 mL), then partitioned against chloroform/water (1:1, vol/vol) (taking tissue water content into account) to give a final solvent ratio of chloroform/methanol/water of 1:1:0.9, by vol (10).

The remaining batch of large oysters and batch of small oysters were separately lyophilized prior to solvent extraction using a Javac SB9 (Knoxfield, Victoria, Australia) centrifugal freeze drier, model C.T. 1000. When completely dry (42 h), each sample was homogenized with a mortar and pestle and placed in the freeze drier for a further 2 h. A subsample of known weight (0.6 g dry weight) was taken and extracted with chloroform/methanol/water (1:2:0.8, by vol; 4 × 15 mL), ultrasonicated and centrifuged between extractions, until the last extract was colorless. Chloroform and water were added to the combined extracts from these lyophilized samples to give a final solvent ratio of chloroform/methanol/water (1:1:0.9, by vol) (10). At this stage, the same amount of water that had been removed from the tissues by lyophilization was added back in order to maintain this ratio.

The lower chloroform phase from each of the four samples (large and small "control" samples and large and small lyophilized samples) was reduced *in vacuo* to recover the lipids. These lipid extracts were then stored in chloroform under nitrogen at −20°C until further analysis.

Experiment 2. To verify the results from the first experiment, a further six fresh oysters (of larger size; mean soft tissue weight 9.8 ± 1.1 g) were harvested from the same location during the same season of the following year. The combined soft tissues of these oysters were frozen in liquid nitrogen, sliced finely, homogenized and the homogenate stored in liquid nitrogen prior to analysis. Six subsamples (1 g wet wt) of the homogenate were accurately weighed and four of these were lyophilized for 24 h. Two of the lyophilized subsamples were rehydrated prior to extraction by adding an amount of water equivalent to that removed by lyophilization, shaken and allowed to stand for 5 min. All samples, *i.e.*, the lyophilized duplicates, rehydrated-lyophilized duplicates and remaining "control" (nonlyophilized) duplicates were extracted according to the method outlined in Experiment 1 for lyophilized samples except that enough NaCl to make a 0.9% (wt/vol) solution was added to the aqueous phase to aid in phase separation (14,22).

Analyses of lipid classes and fatty acids. The lipid class compositions (Table 1) were determined by analyzing a portion of the total lipid extract with an Iatroscan Mk III TH-10 thin-layer chromatography/flame-ionization detector (TLC/FID) analyzer (Iatron Laboratories, Tokyo, Japan) as described by Volkman *et al.* (23), except that S-III silica rods were used and the TG standard curve was calibrated using a preparation of Atlantic salmon oil (99.4% TG). The solvent system used for the lipid class separation was hexane/diethyl ether/acetic acid (60:17:0.2, by vol), which separates most of the major nonpolar lipid classes found in oysters (23). Results (Table 1) are the average of three replicate rods (within ± 5% for each component), and Experiment 2 data are the average for duplicate extractions with standard deviation in parentheses showing the small variations associated with this method.

Aliquots of lipid extracts from Experiment 1 were transesterified to form fatty acid methyl esters (FAME) from esterified and free fatty acids (FFA) using methanol/chloroform/HCl (10:1:1, by vol; 3 mL) at 80°C for 2 h under high purity nitrogen. After cooling, 1 mL of water was added, and the FAME were extracted with hexane/chloroform (4:1, vol/vol; 3 × 3 mL). Another aliquot was saponified with 5% KOH (wt/vol) in methanol/water (4:1, vol/vol) at 80°C for 2 h. Sterols were extracted with hexane/chloroform (4:1, vol/vol) and derivatized with *bis*-(trimethylsilyl)trifluoroacetamide. FAME samples were analyzed with a Hewlett-Packard 5890 (Avondale, PA) GC equipped with an FID at a temperature of 280°C. FAME samples containing a known amount of methyl heptadecanoate (17:0 FAME) internal standard were injected using an air-cooled OCI-3 on-column injector (SGE, Ringwood, Victoria, Australia) onto a polar Supelcowax™ 10 fused-silica column (60 m × 0.32 mm i.d.; Supelco, Bellefonte, PA). The carrier gas was high purity hydrogen. Initially the GC oven was held at 45°C; 2 min after injection the temperature was increased at 30°C/min to 120°C then at 3°C/min to 250°C and held isothermal for 15 min. FAME and OTMS-sterols were analyzed using a Shimadzu GC-9A (Kyoto, Japan) GC also fitted with an air-cooled OCI-3 on-column injector, but with a nonpolar methylsilicone (HP-1) fused-silica capillary column (50 m × 0.32 mm i.d., Hewlett-Packard, Avondale, PA). GC conditions were identical to those of the polar column GC except that the FID temperature was 310°C, and the final oven temperature was held isothermal at 300°C for 25 min. Analyzing FAME on columns of two different polarities enabled identification and quantitation of coeluting components. Peak areas were quantified with Shimadzu CR-2A and CR-3A integrator/plotters.

Identification of fatty acids. Fatty acids were identified from retention index data on both polar and nonpolar columns and confirmed by interpretation of mass spectra

[e]Each data series is the average (SD in parentheses) of duplicate analyses of samples taken from the homogenate of six oysters of average soft tissue weight 9.8 ± 1.1 g; "control"-average solvent extracted lipids from nonlyophilized wet tissue samples; lyophilized-average solvent extracted lipids from freeze-dried samples; lyophilized and rehydrated-solvent extracted lipids from freeze-dried samples after rehydration with water for 5 min before extraction; times (h) refer to duration of lyophilization.

obtained with a Hewlett-Packard 5970B gas chromatography/mass spectrometry (GC/MS) system. GC/MS operating conditions were: electron multiplier, 2200 V; transfer line, 310°C; electron impact energy, 70 eV; 0.8 scan/s; mass range, 40–600 dalton. The dimethyldisulfide (DMDS) reaction (24) in conjunction with GC/MS was used to identify monoenoic fatty acid double-bond positions and geometries.

Fatty acid identifications were confirmed by argentation TLC using cleaned Macherey-Nagel (Düren, Germany) SIL G-100 UV_{254} TLC plates which had been impregnated with silver nitrate. Methyl esters were separated by double development in a single solvent system (hexane/diethyl ether/acetic acid, 94:4:2, by vol; Ref. 25). After development, each band (containing FAME of the same degree of unsaturation) was scraped from the plates, extracted and analyzed on polar and nonpolar capillary columns by GC and GC/MS. This enabled the degree of unsaturation of each fatty acid and the geometry of the double bond in *trans*-16:1n-10 to be determined, since the *trans*-monoenoic FAME characteristically elute in the band between the saturated and *cis*-monoenoic fatty acids. The unusual odd chain fatty acid 21:5n-3 eluted with other pentaenoic FAME. The nonmethylene interrupted dienoic (NMID) fatty acids eluted between the methylene interrupted dienoic and the trienoic fatty acids, the nonmethylene interrupted trienoic (NMIT) fatty acid co-eluted with the methylene interrupted trienoic fatty acids (the separation between trienoic and tetraenoic methylene interrupted fatty acids was insufficient to permit analysis of a band between them).

Samples of oyster FAME and FAME standards (Nu-Chek-Prep Inc., Elysian, MN) were analyzed to determine the double-bond positions in all PUFA including verification of the NMID and NMIT fatty acids using a modification of Fay and Richli's (21) procedure for the formation of DMOX derivatives. Solvent was removed from the FAME under nitrogen; they were then reacted with 500 μL of 2-amino-2-methylpropanol under nitrogen overnight at 140°C instead of 180°C (to reduce the loss of unsaturated fatty acids). To reduce time, solvent usage and loss of sample, smaller volumes of washing and extraction solvent were used according to the following method. After the 2.5 mL vials containing the samples were allowed to cool, 1 mL of dichloromethane and 1 mL of water were added. After shaking and allowing the phases to settle, the upper aqueous layer was discarded, and each sample was washed a further three times prior to being dried with anhydrous sodium sulfate. The solvent in each vial was transferred to a clean vial and evaporated under nitrogen. The residue consisting of DMOX derivatives of FAME was made up in chloroform and analyzed by GC/MS.

RESULTS AND DISCUSSION

Lipid classes extracted from C. gigas *and the effect of lyophilization on composition.* The solvent extracted lipids of the "control" (nonlyophilized) samples of *C. gigas* were composed mostly of PL and TG with low contents of sterols and FFA (Table 1). These "control" samples provide accurate data against which results for lipid extracts from lyophilized samples could be compared. There was no

obvious difference between the lipid classes extracted from oysters of different sizes (large *cf.* small, Experiment 1).

Extracts from samples which had been lyophilized prior to analysis had similar contents of polar lipids, sterols and FFA to extracts from "control" samples, but there were markedly reduced levels of triacylglycerols extracted (Table 1). There was no increase in the amount of other lipid classes so the loss of TG was not due to degradation to form mono- and diacylglycerols (DG) and FFA since these would have been detected (Table 1). In the first experiment only 7% of the TG were extracted compared with the nonlyophilized "control" samples. In Experiment 2, 52.5% of the TG were extracted relative to the "control" samples. The reasons for the different extents of extraction are unclear, although the higher initial contents of TG in the oysters of Experiment 1 compared to those in the second experiment may have been a factor. Also, because of different sample weights, oyster samples from Experiment 1 were lyophilized for longer than samples in Experiment 2 (42 *vs.* 24 h). A further experiment showed that there was no further decrease in the efficiency of extraction of the TG after 8 h in the freeze drier, with the same amount of TG being extracted from samples lyophilized for 8, 16 and 24 h (Dunstan, G.A., and Volkman, J.K., unpublished data). Perhaps more significantly, the samples in Experiment 1 were lyophilized prior to homogenization, whereas in Experiment 2 the samples were homogenized first.

Rehydration prior to solvent extraction, as recommended by Christie (15), significantly increased the amount of TG extracted from lyophilized samples (Table 1). Therefore if lyophilization must be used prior to solvent extraction of lipids from adult oysters, it is recommended that the tissues be rehydrated prior to extraction. The original schemes of Holland and Gabbott (18) and Mann and Gallager (26) incorporate rehydration of the sample prior to analysis, whereas the scheme of Whyte *et al.* (20) does not.

The reasons for the reduced extraction of TG from lyophilized tissues are unclear, although Nelson (14) has suggested that extraction of hydrophobically bound lipids from lyophilized tissues is more difficult because proteins provide an ionic barrier to nonpolar solvents. However, it should be noted that the Bligh and Dyer (10) solvent system is a mixture of both polar and nonpolar solvents. Reduced extraction of lipids from freeze-dried samples may be associated with the high concentration of glycogen in molluscs (Ackman, R.G., personal communication), or due to lyophilization possibly altering the solubility of macromolecules (22).

Significant reductions in the amounts of *n*-alkanes, cycloalkanes and polyaromatic hydrocarbons as well as reduced recoveries of added internal standards from lyophilized mussel homogenate relative to nonlyophilized homogenate have been demonstrated by Farrington *et al.* (27). They suggested that the losses may have been due in part to volatilization, but also possibly to removal of some hydrocarbons from the extraction solution by absorption or adsorption. Interestingly, the greatest losses of *n*-alkanes were between *n*-C_{19} and *n*-C_{25}; lighter and heavier molecules were relatively unaffected. Other potential problems associated with lyophilization are the formation of artifacts, particularly in sediment samples (17), and loss of organic molecules of low to intermediate molecular weight due to the high vacuum of a freeze drier (16).

Fatty acids extracted from C. gigas *and the effect of lyophilization on composition.* Sixty-four fatty acids were identified in the samples of *C. gigas* analyzed. The fatty acid compositions of the "control" group (Table 2) are typical for adult oysters of *C. gigas* (6) and provide accurate data against which results for lipid extracts from lyophilized samples can be compared. All samples had high proportions of PUFA (51.1–55.5% of total fatty acids), the most abundant being 20:5n-3 (15.3–17.0%) and 22:6n-3 (20.2–25.0%), which is typical of most marine invertebrates (28). In *C. virginica* the proportions of these long-chain n-3 PUFA vary seasonally with diet and reproduction (29). There was very little difference between the amounts and distribution of fatty acids in oysters of different sizes (Table 2).

The major saturated fatty acid in all samples of *C. gigas* was 16:0 (15.4–18.6%), and the most abundant monoenoic fatty acids were 18:1n-9 (2.4–4.5%), 18:1n-7 (2.8–3.4%) and 20:1n-7 (2.7–3.9%; Table 2). The saturated and monoenoic fatty acids present in this species are partly of dietary origin although they may also be formed *de novo* by the animal (30). Small contents of branched-chain (mostly *iso*- and *anteiso*-) fatty acids (2.3–3.0%) were detected in *C. gigas*, with little difference between extracts from "control" and lyophilized samples (Table 2). Although the main source of monomethyl branched-chain fatty acids is probably bacteria in the gut and tissues of the animal, some of these fatty acids may also be normal minor metabolites derived from amino acid precursors (30). The isoprenoid fatty acids 4,8,12 TMTD (trimethyltridecanoic acid), pristanic and phytanic acids are derived from the isoprenoid moiety (phytol) in chlorophylls present in the microalgal diet (30).

The fatty acid composition of the TG generally reflects the animal's diet (because TG are the major storage lipid for dietary fatty acids as well as those synthesized *de novo*), whereas the PL fatty acid composition is selectively modified by the oyster according to cellular membrane requirements (2,9). Relative to the PL, the TG generally contain higher proportions of 16:0 and C_{18} unsaturated fatty acids but lower proportions of C_{20} and C_{22} unsaturated fatty acids (2,8). Extracts from lyophilized samples had very different fatty acid distributions relative to the extracts from "control" samples with less 16:0 and C_{18} unsaturated fatty acids resulting in artificially high proportions of C_{20} and C_{22} unsaturated fatty acids (Table 2). These variations in fatty acid distributions in oysters from different treatments were probably the result of the reduced extraction of TG from lyophilized samples. Ackman (30) has suggested that dietary 18:4n-3 (stored in the TG) after chain elongation is desaturated by a Δ5 desaturase to form 20:5n-3 and incorporated into the PL, explaining the reduced contents of 18:4n-3 in extracts from lyophilized samples.

Although the importance of dietary long-chain PUFA is relatively well established, the functions of the unusual odd-chain 21:5n-3 is unclear. This PUFA has been found in molluscs, rotifers, fish and marine mammals (6,31,32). Ackman (32) has proposed that 21:5n-3 is formed by α-oxidation of 22:5n-3, and it may be that this system is common in invertebrates.

Many authors have used lyophilization prior to lipid

analysis (33,34), but very few direct comparisons have been made with solvent extraction of fresh tissue. Although such methods are fast and convenient, our data suggest that direct comparisons with solvent extraction of fresh or frozen samples should be performed to validate data obtained from lyophilized samples. In our experience, lyophilizaton does not affect the solvent extraction of lipids from fish flesh and prawn larvae (Dunstan, G.A., and Volkman, J.K., unpublished data). Interestingly, others have found little difference in the FAME distribution of saponified then methylated lyophilized oyster and scallop eggs and larvae, a diatom, rotifers and certain fish tissues compared with the FAME distribution of solvent extracted lipids from lyophilized samples of the same tissues (31). However, significant differences between FAME distributions of directly saponified then methylated and solvent extracted lipids from lyophilized fish faeces have been noted (35), whereas in the same study such differences were not observed in analyses of nonlyophilized fish diets. Lyophilization apparently did not affect the amount of lipid extracted from adult *C. madrasensis*, although lipid determinations were made on extracts after acid hydrolysis and not solvent extraction of native tissues (36).

It is not only lyophilization which reduces solvent extraction of lipids from certain samples. For example, we have observed that solvent extraction of lipids from steam-pelleted fish feeds was also significantly reduced (Dunstan, G.A., and Volkman, J.K., unpublished data). Rehydration did not increase extraction efficiency from these dried samples, but increasing the solvent contact time greatly increased the yield. Reduced extraction of lipids by a modified Bligh and Dyer method has also been observed with vacuum or hot air dried (but not lyophilized) brine shrimp *Artemia* (37).

Most comparative work has been performed with microalgae, but the results are often divergent making it difficult to draw significant conclusions. Guckert *et al.* (13) showed that Soxhlet extraction significantly increases the extraction of neutral lipids relative to Bligh and Dyer solvent extraction from lyophilized cells of the green microalga *Chlorella*. These authors suggested that this increase was due to transesterification of fatty acids even though there was no corresponding decrease in the PL classes from which these FAME were presumably derived. Alternatively, Soxhlet extraction may free the fatty acids from those TG which were not extracted by the Bligh and Dyer solvent system. However, the possible loss of the more labile PUFA during prolonged Soxhlet extraction also needs to be considered (13).

NMI fatty acids in C. gigas. The NMI FAME were tentatively identified based on their mass spectra. The mass spectra of NMID resembled those of monoenoic methylene interrupted fatty acids, with a base peak at *m/z* 55. Other major ions were *m/z* 67 and *m/z* 81 both of which are indicative of dienoic methylene interrupted fatty acids (*e.g.*, Fig. 1). The mass spectra of the C_{20} and C_{22} NMID had molecular ions at *m/z* 322 and *m/z* 350 (Fig. 1) respectively, establishing the presence of two double bonds. The mass spectrum of the NMIT resembled that of a dienoic methylene interrupted fatty acid (due to the methylene interrupted double bonds), with a base peak at *m/z* 67 and strong *m/z* 81, other major ions were *m/z* 79 and *m/z* 91,

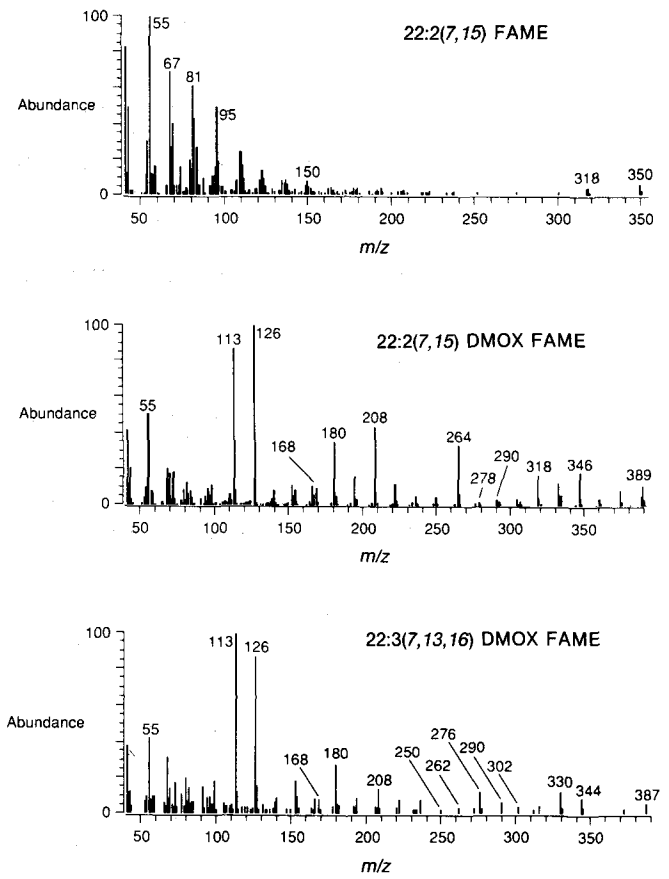

FIG. 1. Selected mass spectra of nonmethylene interrupted fatty acid methyl esters (FAME) from *Crassostrea gigas*. Top, mass spectrum of 22:2(*7,15*) nonmethylene interrupted diene (NMID) FAME, with a base peak at *m/z* 55, other major ions were *m/z* 67 and *m/z* 81 and molecular ion of *m/z* 350. Middle, mass spectrum of 22:2(*7,15*) NMID FAME 4,4-dimethyloxazoline (DMOX) derivative with 12 dalton between *m/z* 168 and *m/z* 180 (double bond at Δ7) and between *m/z* 278 and *m/z* 290 (double bond at Δ15) and a molecular ion at *m/z* 389 (C_{22} FAME DMOX derivative with two double bonds). Bottom, mass spectrum of 22:3(*7,13,16*) NMIT FAME DMOX derivative with 12 dalton between *m/z* 168 and *m/z* 180 (double bond at Δ7), *m/z* 250 and *m/z* 262 (double bond at Δ13) and *m/z* 290 and *m/z* 302 (double bond at Δ16) and a molecular ion at *m/z* 387 (C_{22} FAME DMOX derivative with three double bonds).

which are indicative of three or more double bonds, but the M^+ was not detected in the mass spectrum of the C_{22} NMIT FAME.

The modified method of DMOX derivatization resulted in reduced loss of PUFA, while still ensuring complete reaction of the FAME. Double-bond positions were readily identified according to the criteria outlined in Fay and Richli (21) with distinctive ion abundance patterns being evident for monoenoic, polyenoic FAME, terminal ω end double bonds and NMI and conjugated PUFA. Figure 1B shows the mass spectrum of the DMOX derivative of the NMID FAME 22:2(*7,15*) with 12 dalton between *m/z* 168 and *m/z* 180 (Δ7) and between *m/z* 278 and *m/z* 290 (Δ15) and a molecular ion at *m/z* 389 establishing the presence of two double bonds in a C_{22} FAME DMOX derivative. Figure 1C shows the mass spectrum of the DMOX derivative of the NMIT FAME 22:3(*7,13,16*) with 12 dalton between *m/z* 168 and *m/z* 180 (Δ7), *m/z* 250 and *m/z* 262 (Δ13) and *m/z* 290 and *m/z* 302 (Δ16) and a molecular ion at *m/z* 387 clearly establishing the presence of three double bonds in the C_{22} FAME DMOX derivative. These fragments are the same as those for the equivalent bond positions using pyrrolidine derivatization (38). The DMOX derivatization of FAME enabled positive identification of the double-bond positions in the 21:5n-3, NMID, NMIT and the more common unsaturated FAME.

Organisms known to contain NMI fatty acids include species of bacteria, macroalgae and marine invertebrates (39; reviewed in Refs. 28,32). The presence of both 18:1n-13 and 20:1n-15 suggested the existence of a Δ5 desaturase in those molluscs which produce NMID fatty acids (40). In the present study these monoenoic fatty acids as well as 16:1n-11 were detected in small amounts (<1%, Table 2). Ackman and Hooper (40) proposed a biosynthetic pathway for the formation of NMID in molluscs which involves a Δ5 desaturase acting on 20:1n-7 and 20:1n-9 to form 20:2(*5,13*) and 20:2(*5,11*), respectively. Chain elongation of these two C_{20} NMID produces 22:2(*7,15*) and 22:2(*7,13*), respectively. The presence and abundance of these isomers suggests that the same or a similar pathway is acting in *C. gigas* (Table 2). The synthesis of these NMID *via* these pathways in bivalve molluscs has been verified using [^{14}C]acetate (41, and references therein), although it is not known whether bacteria present in the tissues of *C. gigas* play a role in NMI fatty acid formation by Δ5 desaturation. The 22:3(*7,13,16*) NMIT is most likely the result of the Δ5 desaturation and subsequent elongation of 20:2n-6. Although a candidate for the intermediate C_{20} trienoic NMI was detected, its abundance was too low for positive identification. Interestingly, desaturation of the 22:3(*7,13,16*) NMIT at the Δ10 carbon would yield 22:4n-6 which is the shortest methylene interrupted C_{22} PUFA detected in *C. gigas* (Table 2). The NMIT fatty acid 22:3(*7,13,16*) was originally identified from a sponge extract (38), but to our knowledge has not been recorded in oysters, although the unusual NMIT 22:3(*7,11,15*) was recently detected in hydrocarbon seep mussels (42). In *C. virginica* the 22:2 NMI fatty acids are abundant in PL (8,39), whereas the 20:2 NMI are primarily resident in the TG (8). This possibly explains the enhanced proportions of 22:2 NMID fatty acids and reduced 20:2 NMID fatty acids in the extracts from lyophilized samples of *C. gigas* with reduced contents of TG (Table 2).

The effect of lyophilization on sterols. C. gigas contained a complex sterol distribution with no significant difference between the two size classes (Table 3). However, extracts from lyophilized samples had significantly lower amounts of 24-ethylcholest-5-en-3β-ol (0.8 and 0.9%) compared with extracts from "control" samples (6.0 and 5.7%; Table 3), implying that lyophilization also affects the extraction efficiency of this sterol. Most of the sterols listed in Table 3 were probably derived from a diet rich in microalgae although 24-ethylcholest-5-en-3β-ol can also be indicative of terrestrial plant matter and sea-grasses, and it is common in marine sediments (43). Data on the ability of bivalve molluscs to synthesize sterols *de novo* is often contradictory, but these molluscs have the ability to form cholesterol from dietary phytosterols, albeit at a reduced level (44).

TABLE 3

ACKNOWLEDGMENTS

We thank Shellfish Culture Pty. Ltd. Pipe Clay Lagoon, Tasmania, Australia, for supplying oysters for the first experiment, and G. Thayer of Mures fish restaurant for supplying oysters for the second experiment. Also Dr. C. Garland and Dr. M. Brown, for help in preparing the oysters for the first experiment and M. Bessell for preparing the figure. We thank A. Murray, P. Nichols, and D. Nichols and two anonymous reviewers for valuable comments on the manuscript, and also Professor R.G. Ackman for useful discussions and additional literature. This work was funded by FIRDC grants 1988/69 and 1991/59 and ARC grant A18831836.

[Received April 24, 1992, and in final revised form July 15, 1993; Revision accepted July 27, 1993]

METHOD

Rapid Separation of the Major Phospholipid Classes on a Single Aminopropyl Cartridge

Angelika Pietsch and Reinhard L. Lorenz*
Institute for Prophylaxis of Cardiovascular Disease, University of Munich, D-80336 Munich, Germany

A rapid method for the separation of the individual phospholipid classes phosphatidylcholine (PC), phosphatidylethanolamine (PE), phosphatidylserine (PS) and phosphatidylinositol (PI) by a single solid-phase extraction was developed. PC, PE, PS and PI were sequentially eluted from aminopropyl bonded silica with acetonitrile/*n*-propanol (2:1, vol/vol), methanol, isopropanol/methanolic HCl (4:1, vol/vol) and methanol/methanolic HCl (9:1, vol/vol). Standard recoveries were over 95% for PC and PE and over 85% for PS and PI with undistorted fatty acid composition. The separation of complex lipid mixtures on aminopropyl minicolumns can be refined to the level of individual phospholipid classes.
***Lipids 28,* 945–947 (1993).**

The rapid group separation of complex lipid mixtures by solid-phase extraction on an aminopropyl bonded phase was introduced by Kaluzny *et al.* (1) in 1985. This convenient method was extended by Kim and Salem (2) in 1990 to allow the separation of neutral from acidic phospholipids (PL) using an additional acidic eluent. The separation of individual PL classes, however, still required thin-layer chromatography (TLC) or high-performance liquid chromatography (HPLC) (3), which are much more laborious and have several drawbacks. We therefore developed a new system of eluents to further refine the separation of lipids on a single aminopropyl bonded minicolumn to the further level of individual PL classes.

MATERIALS AND METHODS

Materials. Egg yolk phosphatidylcholine (PC), egg yolk phosphatidylethanolamine (PE), bovine brain phosphatidylserine (PS), soybean phosphatidylinositol (PI) (all of >98% purity) and *all-cis*-eicosadienoic acid (20:2n-6) were from Sigma (St. Louis, MO). 1,2-Di-[1′-^{14}C]palmitoyl PC (112 mCi/mmol), 1-palmitoyl-2-[(1′-^{14}C]linoleoyl PE (53 mCi/mmol), 1,2-dioleoyl phosphatidyl-[3′-^{14}C]serine (53 mCi/mmol), 1,2-diacyl-*sn*-glycero-3-phospho-[2′-^{3}H]inositol (18.2 Ci/mmol) and (*N-methyl*-^{14}C)sphingomyelin (SM; 52 mCi/mmol) prepared from bovine brain were from Amersham (Little Chalfont, Amersham, United Kingdom). Butylated hydroxytoluene (BHT) was obtained from Serva (New York, NY). Aminopropyl bonded silica minicolumns (100 and 500 mg) and silica minicolumns (100 mg) were from J.T. Baker (Deventer, The Netherlands). Water-free 3N methanolic HCl was from Supelco (Bellefonte, PA). All other solvents (analytical grade), molybdatophosphoric acid hydrate and silica G60 plates for TLC were purchased from Merck AG (Darmstadt, Germany). A "Vac Elut" apparatus from Analytichem International (Harbour City, CA) was used for flushing the cartridges. Screw-capped glass reaction vials were from Schott (Jena, Germany). Plasma lipid extracts were prepared by the method of Folch *et al.* (4) in the presence of BHT.

TLC. PL classes were separated on G60 silica plates developed in chloroform/methanol/acetic acid/water (100:75:7:4, by vol) (5). For visualization of the lipid fractions, the plates were sprayed with a 10% solution of molybdatophosphoric acid hydrate in ethanol and heated at 120°C for 5 min. Approximate R_f values in this systems are 0.7 for PE, 0.4 for PI, 0.3 for PS and 0.15 for PC.

Solid-phase extraction procedure. The 100-mg (500-mg) aminopropyl cartridges were preconditioned with 1 mL (3 mL) hexane. Then the sample was applied to the 100-mg (500-mg) cartridge in 100 μL (300 μL) chloroform and left to sink into the solid phase. Solvents were then completely sucked through the solid phase under slight vacuum, but then the vacuum was released to avoid prolonged air passage and drying of the solid phase. The sequence of solvents and the optimized solvent volumes used for 100-mg and 500-mg cartridges, respectively, are listed in Table 1.

First, the neutral lipids and then the free fatty acids were eluted with chloroform/isopropanol (2:1, vol/vol) and diethyl ether/acetic acid (98:2, vol/vol), respectively. These

Abbreviations: BHT, butylated hydroxytoluene; HPLC, high-performance liquid chromatography; PA, phosphatidic acid; PC, phosphatidylcholine; PE, phosphatidylethanolamine; PI, phosphatidylinositol; PL, phospholipid; PS, phosphatidylserine; SM, sphingomyelin; TLC, thin-layer chromatography.

first two steps were done with all samples as described by Kaluzny *et al.* (1). Then individual PL classes were sequentially eluted using our newly developed solvent systems as follows: PC was eluted with acetonitrile/*n*-propanol (2:1, vol/vol) (Solvent 3, A), PE was eluted with methanol (Solvent 4, B), then PS was eluted with isopropanol/methanolic HCl (4:1, vol/vol) (Solvent 5, C) and finally PI was eluted with methanol/methanolic HCl (9:1, vol/vol) (Solvent 6, D).

Quantification. Aliquots of about 5000 cpm of each of the phospholipids were either directly transferred to a scintillation vial or applied to aminopropyl cartridges. Each fraction eluted from the cartridge was transferred to a scintillation vial, brought to dryness under nitrogen and taken up again in 0.5 mL ethanol. All vials were filled with 5 mL "Aquasafe 300" scintillation solution (Zinsser Analytik, Frankfurt, Germany) and counted for 2 min on a Beckman LS 5801 liquid scintillation system (Munich, Germany). Recoveries in each fraction are expressed as percentage of the total counts applied to the cartridge.

Transmethylation and gas chromatography. Samples were taken up in 1 mL of methanol and 2 mL of methanolic HCl (3N). Forty μg of 20:2n-6 was added as internal standard. The vials were sealed, heated to 90°C for one hour and then cooled in water. After adding 2 mL of distilled water the fatty acid methyl esters were extracted twice with 2 mL of petroleum hydrocarbon (b.p. 40–60°C), dried and stored in 40 μL hexane. A 4 μL aliquot of the sample was injected onto a Hewlett-Packard 5890 gas chromatograph equipped with a capillary column of 0.25 mm i.d. and 30-m length coated with DB 225 0.15μ from ICT (Frankfurt, Germany). The injector temperature was set at 200°C, helium flow was 1 mL/min and the column temperature was linearly increased from 90°C at the start at 70°C/min and then held at 200°C. The detector temperature was 250°C.

RESULTS AND DISCUSSION

Kim and Salem (2) had reported partial resolution of PL on an aminopropyl cartridge by eluting PC and PE with methanol, and PS and PI with hexane/isopropanol/ethanol/0.1 M ammonium acetate in water/formic acid (420:350:100:50:0.5, by vol) with 5 mL phosphoric acid added per 100 mL. We tried to further refine the resolution to the level of individual PL classes. First, a series of solvents of increasing polarity was tested for differential PL elution of PC and PE from the aminopropyl matrix. Acetonitrile partially eluted PC, but not PE. *n*-Propanol and all solvents more polar than acetonitrile eluted both PC and PE, whereas solvents less polar than acetonitrile eluted neither compound. A mixture of acetonitrile and *n*-propanol (2:1, vol/vol) quantitatively eluted PC, whereas PE was completely retained. PE could subsequently be eluted with methanol (Fig. 1).

Second, methanolic HCl was found to be the simplest acidic solvent to elute both PS and PI from the aminopropyl matrix. Therefore, mixtures of less polar solvents with methanolic HCl were tested for differential elution of PS and PI. Isopropanol/methanolic HCl (4:1, vol/vol) was found to elute PS, whereas PI was retained. PI could subsequently be eluted with methanol/methanolic HCl (9:1, vol/vol) (Fig. 1).

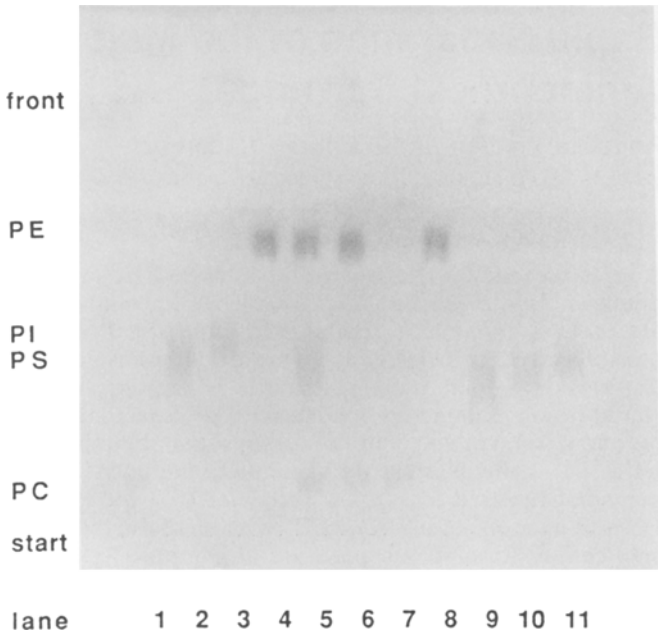

FIG. 1. Verification by thin-layer chromatography (TLC) of the separation of lipid mixtures by sequential elution from a single aminopropyl minicolumn. TLC and staining was as described in the Materials and Methods section. Lanes 1 to 4: reference standards of phosphatidylcholine (PC), phosphatidylserine (PS), phosphatidyinositol (PI) and phosphatidylethanolamine (PE). Lane 5: Standard mixture as applied to the minicolumn. Lane 6: Phospholipids fraction eluted according to Reference 1 contains PC and PE. Lane 7: Eluent A contains PC only. Lane 8: Eluent B contains PE. Lane 9: Acidic eluent according to Reference 2 contains PS and PI. Lane 10: Eluent C contains only PS. Lane 11: Eluent D contains PI.

Labeled standards were used to confirm and to optimize the elution volumes for cartridges filled with 100 and 500 mg sorbent, and the results obtained were verified by TLC. The eluents and volumes established for the definitive procedure are listed in Table 1. Recoveries in each fraction for pure standards and standards added to plasma extracts were determined for each PL class. The results are summarized in Table 2.

Changes in fatty acid composition due to preferential retention of specific molecular species during the separation procedure could be excluded. Relative amounts of fatty acid methyl esters prepared from each PL standard were found unchanged after the samples had been carried through the separation procedure twice (Table 3).

With 100-mg cartridges, the binding and separation of labeled standard PL was unchanged by the presence of cold PL in the mass range from 1 to 500 μg. At higher concentrations PC was not completely retained and was partially eluted in the neutral lipid fraction.

Two other PL classes, SM and phosphatidic acid (PA), can be present in biological samples. SM was eluted with acetonitrile/*n*-propanol (2:1, vol/vol), and PA was eluted with isopropanol/methanolic HCl (4:1, vol/vol). Attempts to separate SM from PC and to separate PA from PS on the same cartridge were not successful. The contamination of PC with SM and PS with PA is even a problem with sophisticated gradient HPLC methods (6) and should not compromise this method for many applications. SM will not interfere with fatty acid analyses of PC, as the

22:5n-6	0.9	0.9	2.3	2.3	4.1	3.9	—	—
22:5n-3	—	—	0.2	0.1	0.4	0.2	—	—
22:6n-3	0.7	0.7	2.3	1.5	10.1	10.4	—	—

[a]Abbreviations: PL, phospholipid; PC, phosphatidylcholine; PE, phosphatidylethanolamine; PS, phosphatidylserine; PI, phosphatidylinositol.
[b]Nonradioactive PL standards were either directly (1) transmethylated and analyzed by gas chromatography as described in Methods, or first carried twice through the whole procedure (2).
[c]Percent recovery.

N-acyl bonds in SM are stable under the mild conditions used for transmethylation. Furthermore, if a pure preparation of PC is needed, the fraction A can be loaded in 100 μL of chloroform onto a 100-mg silica cartridge preconditioned with hexane. About 80.6% of PC can be eluted with the first 2 mL of acetonitrile/methylacetate/methanolic HCl (130:30:18, by vol), whereas more than 98.6% of SM are retained.

In summary, we further extended a widely used solid-phase extraction method for the separation of the major lipid classes (1,2,7). Making use of differences in polarity, pKa and solvent strength, the separation of PL on the same aminopropyl matrix was refined to the level of individual PL classes. No expensive equipment is needed, and very low solvent volumes suffice. The method considerably simplifies and speeds up the purification of PL in large numbers of sample.

A Micro Enzymic Method for Determination of Choline-Containing Phospholipids in Serum and High Density Lipoproteins

Ying Nie[a,b], **Jin Lin He**[a,b] and **S.L. Hsia**[a,b,c*]

[a]Lipid Profile Evaluation Laboratory, [b]Department of Dermatology and Cutaneous Surgery and [c]Department of Biochemistry and Molecular Biology, University of Miami School of Medicine, Miami, Florida 33136

A micro method is described for the assay of choline-containing phospholipids in serum and high density lipoproteins (HDL) using an automated microtiter plate reader. The method is adapted from the enzymic method of Takayama, Itoh, Nagasaki, and Tanimuzu (*Clin. Chim. Acta 79*, 93–98, 1977) using phospholipase D, choline oxidase, and peroxidase coupled with the color generating system phenol and 4-amino-antipyrine. The micro method requires 5 μL of serum or HDL sample, and 42 samples can be assayed in duplicate in one run using a 96-well flat-bottom microtiter plate. The reaction is linear up to 400 mg/dL and the lower limit of detection is 0.25 mg of choline-containing phospholipids per assay. The coefficient of variation within an assay is 0.86–0.79%, and day-to-day variation is 0.9–1.5%. Results obtained by the micro method are in excellent agreement with those obtained by the procedure of Takayama *et al.* (r = 0.997). The supernatant left after removal of low density lipoproteins and very low density lipoproteins from serum and precipitation with heparin/manganese chloride reagent can thus be conveniently used for the micro assay of choline phospholipids in HDL.
***Lipids* 28, 949–951 (1993).**

It has been shown that choline-containing phospholipids, including phosphatidylcholine, lysophosphatidylcholine and sphingomyelin, make up 91–97% of serum phospholipids (1,2). For practical purposes, their measurement is therefore a close approximation of total serum phospholipids. To meet the need for routine assays, an enzymic method for measuring choline-containing phospholipids was developed by Takayama *et al.* (1). The method utilizes phospholipase D to release the choline moiety, and the released choline is subsequently oxidized by choline oxidase to form equimolar amounts of betaine and hydrogen peroxide, which in the presence of peroxidase coupled with phenol and 4-aminoantipyrine generates a red color which is amenable to spectrophotometric measurement. This method and its modifications have been used in a number of studies to determine phospholipids in serum and high density lipoproteins (HDL) (2–4).

In the present paper we describe a micro enzymic method adapted from the method of Takayama *et al.* (1) using a microtiter plate reader for the measurement of choline-containing phospholipids in serum and HDL. It uses 5 μL of serum or HDL sample for each determination, and the results are in close agreement with those obtained by the original method (r = 0.997).

In clinical laboratories, a commonly used procedure for measuring HDL cholesterol requires the precipitation of low density lipoproteins (LDL) and very low density lipoproteins (VLDL) from serum with heparin/manganese chloride reagent (H-M reagent) (5). It would be convenient if the same HDL preparation could be used for measurement of phospholipids. However, it has been reported that the H-M reagent interferes with the enzymic assay of cholesterol (6). Since the enzymic assay of choline-containing phospholipids and the assay of cholesterol are based on the same principle, namely the color generated by H_2O_2, we investigated the possible interference of the H-M reagent with phospholipid measurements in HDL by the micro method. Our results show that the interference can be readily overcome, and that it is practical and convenient to use the micro method for measuring choline phospholipids in HDL prepared with the H-M reagent.

MATERIALS AND METHODS

Serum samples. The serum samples used were routine clinical test samples. For developing the micro method, we utilized the supernatant solution that is obtained after precipitation of LDL and VLDL with the H-M reagent for HDL cholesterol measurements. The supernatant was stored in a 4°C refrigerator for at least 24 h after measurement of cholesterol before the fine precipitate was removed by centrifugation at 2000 × *g* for 30 min. The clear supernatant was used for the assay of choline phospholipids in HDL.

Apparatus. The micro enzymic assay utilized a Thermomax Microplate Reader (Molecular Devices, Menlo Park, CA) linked to an IBM-compatible computer with a 386 microprocessor and a Panasonic KX-P1124 multimode printer. The software, SoftMax, was supplied by the manufacturer of the Microplate Reader. For comparison of the results obtained by the micro method and by the procedure of Takayama *et al.* (1), we tested the same serum samples using the Microplate Reader and a Spectronic 1201 instrument (Milton Roy Co., Rochester, NY).

Chemicals and reagents. All enzymes and chemicals were purchased from Sigma Chemical Company (St. Louis, MO) except that phenol and $CaCl_2 \cdot 2H_2O$ were purchased from Malinckrodt (St. Louis, MO).

A 50 mM Tris/HCl buffer, pH 7.8, solution was prepared that contained 5 g Triton X-100 and 73.51 mg $CaCl_2 \cdot 2H_2O$. A single reagent containing the enzymes and color generating system was prepared fresh each day by dissolving 44 units phospholipase D (from *Streptomyces chromofuscus*), 94 units choline oxidase (from *Arthrobacter globiformis*) and 204 units peroxidase (from horseradish), 5 mg phenol and 14.7 mg 4-aminoantipyrine in 25 mL of the above described buffer.

For the preparation of H-M reagent, 5 g of $MnCl_2 \cdot 4H_2O$ and 1.3×10^5 units of heparin were dissolved in 50 mL of distilled water, and 100 μL of this solution was used for each one mL of serum for precipitation of VLDL and LDL at room temperature for 45 min. The supernatant after centrifugation at 2000 × *g* for 45 min was used for routine measurement of HDL cholesterol.

Abbreviations: CV, coefficient of variation; HDL, high density lipoproteins; H-M reagent, heparin/manganese chloride reagent; LDL, low density lipoproteins; VLDL, very low density lipoproteins.

The same supernatant was used for developing the micro enzymic method as described under Assay Procedure.

Standard solutions. A standard solution containing 500 mg/dL of 1,2-dipalmitoyl-*sn*-glycero-3-phosphocholine was prepared by dissolving 10.0 mg of the phospholipid in 2 mL of a 5% solution of Triton X-100. Aliquots of this solution were diluted with 5% Triton X-100 solution, to make standard solutions containing 100, 200, 300 and 400 mg/dL of the phospholipid.

Assay procedure. To each well of the microtiter plate (Bio-Rad Laboratories, Richmond, CA) is added with a Hamilton syringe (Baxter Co., McGaw Park, IL) 5 μL of serum, or the HDL supernatant after precipitation of VLDL and LDL, or the standard solution, and then with a Labysystems Multistepper pipet (Baxter Co.) is added 200 μL of the enzyme reagent. All samples, standards and reagent blanks are determined in duplicates. The plate is agitated and incubated at 37°C for 20 min, then read using a 505-nm filter in the Microplate Reader. The results are printed out as directed by the SoftMax program. The average of duplicate measurements is recorded. The duplicates usually differ less than 1%. Duplicates that differ more than 3% are rejected, and the test is repeated.

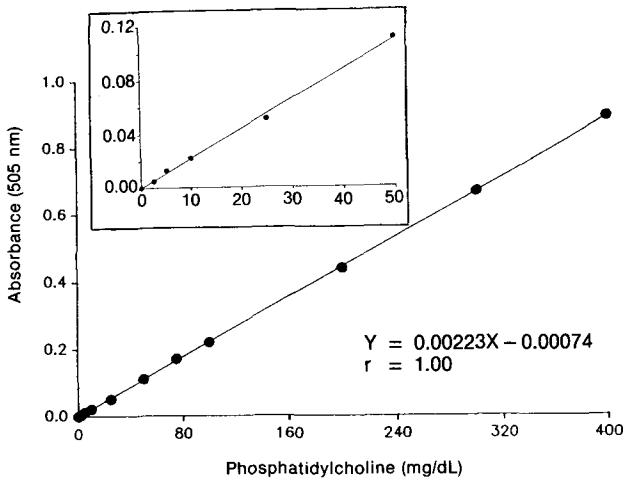

FIG. 2. Standard curve of (A) at 505 nm *vs.* concentration of dipalmitoyl-*sn*-glycero-3-phosphocholine. Reaction time was 20 min at 37°C. The inset is an enlargement of the curve at phosphatidylcholine concentrations below 50 mg/dL.

RESULTS AND DISCUSSION

To select optimal conditions for the micro assay, we varied sample size, the amount of reagent used, incubation time, etc. The assay procedure given above was established on the results of many of such tests.

The time course for the reaction is shown in Figure 1. At a substrate concentration of 400 mg/dL, a plateau of absorbance (A) at 505 nm was reached between 20 to 25 min. At lower substrate concentrations, the plateau was reached within 15 to 20 min. The color was stable for over 1 h, with a slight decline in A after 30 min. For routine assays, we allowed 25-min incubation time before reading.

The results obtained on four standard solutions are shown in Figure 2. Absorbance (A) was linear with substrate concentrations from 2.5 mg/dL up to 400 mg/dL, with the regression line passing through the zero point of both axes ($P < 0.001$). The lower limit of detection was 0.25 mg of choline-containing phospholipids per assay.

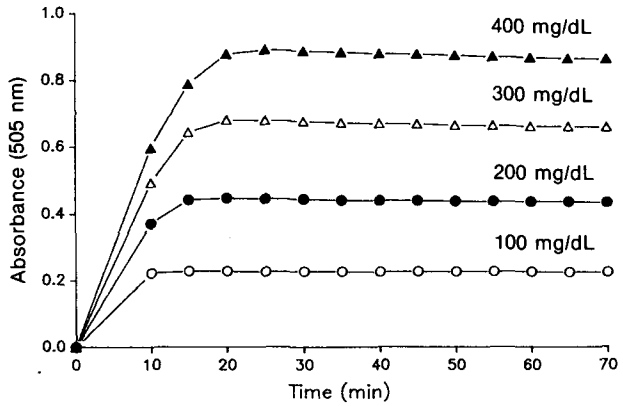

FIG. 1. Time course of the reaction at four concentrations of dipalmitoyl-*sn*-glycero-3-phosphocholine. The phospholipid was dissolved in 5% Triton X-100 and allowed to react with the enzyme reagent at 37°C. Absorbance at 505 nm was read using a Thermomax Microplate Reader.

The coefficient of variation (CV) (standard deviation/mean × 100%) within the assay of 10 determinations for three serum samples was between 0.79 and 0.86%. CV for day-to-day variation for three samples over 12 d was between 0.9 and 1.5% (Table 1).

Figure 3 shows the excellent correlation between the results for 48 serum and samples assayed using Thermomax Microplate Reader the Spectronic 1201 spectrophotometer. The range of values was from 56 to 298 mg/dL; r = 0.997.

SD	0.8	1.7	2.5	1.6	2.6	3.5
CV (%)	0.79	0.86	0.84	1.5	1.3	0.9

[a]All values are in mg/dL and are the average of duplicate measurements. Serum samples 1-3 were each measured 10 times successively on the same day, and serum samples 4-6 were measured each day for 12 d; CV, coefficient of variation.

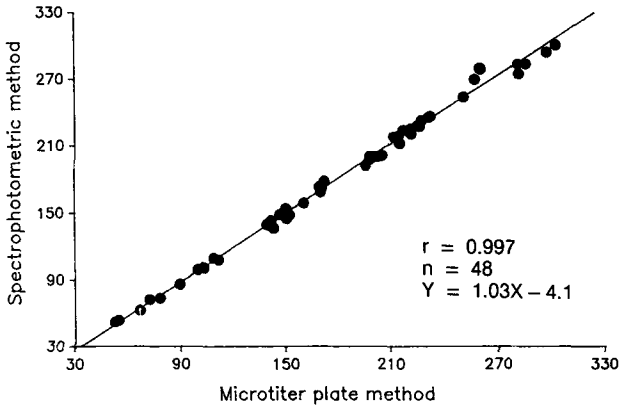

FIG. 3. Correlation between results obtained by the microtiter plate method and the spectrophotometric method. A Thermax Microplate Reader and a Spectronic 1201 spectrophotometer were used.

Two problems were encountered in the determination of choline-containing phospholipids in HDL prepared using the H-M reagent. One was the fine precipitate that continued to form after removal of the precipitates of VLDL and LDL, which caused turbidity and interfered with the readings of the Microplate Reader and led to erratically high results. We solved this problem by storing the HDL preparation in the refrigerator at 4°C for at least 24 h to allow complete precipitation before removal of the fine precipitate by centrifugation at 2000 × *g* for 30 min. The clear supernatant was then used for the measurement of choline phospholipids. Determination of phospholipids by the chemical method based on measuring inorganic phosphorus (7) showed that removal of the fine precipitates did not change the phospholipid content of the HDL preparation (Table 2). It has been reported previously that after removal of apo B-containing lipoproteins from serum by precipitation with the H-M reagent, the supernatant continues to become turbid due to formation of manganese oxide (5). The turbidity eventually turns into the fine precipitate described here.

The other problem in measuring HDL phospholipids was the interference of the H-M reagent with the color generated by H_2O_2 which is the end product of the enzymic reactions for both the measurement of cholesterol and of choline-containing phospholipids. Previously, McGowan *et al.* (6) had shown that the H-M reagent caused the values of HDL cholesterol measured by the enzymic method to be somewhat high. In our experiments, we also found the H-M reagent to cause slightly higher absorbance readings, which were equivalent to less than 3% of the phospholipids. This difference was corrected by adding 7 μL of H-M reagent to 3 mL of the enzyme mixture to simulate the concentration of H-M reagent in the HDL supernatant. This modified enzyme mixture was used for the standard assay, so that the effect of the H-M reagent could be canceled automatically in the calculations using the SoftMax computer program.

The micro method described here is simple and expedient, and is suited for the routine measurement of choline-containing phospholipids in serum and HDL. It can easily be adapted to measure other lipoprotein fractions and body fluids as well. The method offers a number of advantages over the original enzymic method of Takayama *et al.* (1). The sample size required for each determination is reduced from 20 to 5 μL, and the amount of enzyme reagent required is about one-fourth. An important advantage is also the expedience gained by use of the microtiter plate reader. In seconds, 42 serum samples in duplicates besides standards and blanks can be read in a single 96-well microtiter plate. Interfacing of the instrument with a computer and printer eliminates much of the tedium of routine operations.

Another micro method for the quantitation of phospholipids that uses a microtiter plate fluorometer has recently been reported (8). This method is highly sensitive and requires dilution of the serum before the measurements. The micro method described here is less sensitive and uses serum directly without dilution.

Phospholipids, especially choline phospholipids, are major components of lipoproteins, and of cellular membranes and organelles. Although the relevance of serum choline phospholipid levels to disease is largely unknown, it deserves further investigation. The micro enzymic method described here may expedite such investigations.

TABLE 2

Concentrations of HDL Phospholipids Before and After Removal of the "Fine Precipitate"[a]

Sample	Before	After	Difference
1	94.7	93.5	1.2

Microwave-Mediated Methanolysis of Lipids and Activation of Thin-Layer Chromatographic Plates

Mobashsher U. Khan and **John P. Williams***
Department of Botany and Centre for Plant Biotechnology, University of Toronto, Toronto, Ontario, M5S 3B2 Canada

A technique is described for the methanolysis of fatty acids from acylglycerols with HCl/CH_3OH or $NaOH/CH_3OH$ using a microwave oven. The esterification is rapid and complete and does not result in significant degradation of polyunsaturated fatty acids, even in the presence of oxygen. The fatty acid compositions of intact tissues were also determined using this technique. The microwave oven has also been used to condition normal silica gel and argentation thin-layer chromatographic plates in a fraction of the time normally required.
Lipids 28, 953–955 (1993).

In our work on the effect of environmental and genetic factors on glycerolipid metabolism in higher plants, we routinely analyze large numbers of samples of lipids and their fatty acids. Existing methods of lipid analysis are often time-consuming, especially if thin-layer chromatographic (TLC) plates are prepared in the laboratory. Results obtained are also often inconsistent and unreliable because of the oxidation of unsaturated fatty acid that can occur. Activation of TLC plates by standard techniques may take 1–4 h (1,2) and the preparation of fatty acid methyl esters (FAME) from lipids 1–8 h at 80°C in H_2SO_4/CH_3OH or HCl/CH_3OH (1,3,4).

The microwave oven has been used in the past in the laboratory to speed up synthetic reactions in the preparation of various organic compounds (5). Recently, it has also been used to reduce the reaction time for the hydrolysis of triacylglycerols, the esterification of free fatty acids and for other chemical transformations of long-chain fatty acid esters (6). We have investigated the routine use of microwaves to speed up the esterification of fatty acids from plant tissue. The technique described here ensures complete esterification of acylglycerols in a short period of time without oxidation using lower concentrations of reagents.

We have also found that microwaves can be used to reduce the time required for the activation of TLC plates as compared to using a conventional oven.

MATERIALS AND METHODS

Lipid separation by TLC. Lipids were extracted from leaf tissues, seeds and cyanobacterial cell cultures with chloroform/methanol (2:1, vol/vol), and the nonlipid contaminants were removed from the total lipid extract as described previously (7). Silica gel G (E. Merck, Darmstadt, Germany) plates were prepared in the laboratory with ammonium sulfate (1.5 M) (2) using an applicator from Desaga (Heidelberg, Germany). The plates were activated for 10 min in a microwave oven (Toshiba, Toronto, Canada, Model ERX-8900) at full power or, for comparison, for 4 h in a conventional oven at 110°C. Plates were cooled to room temperature and used immediately or stored for later use.

For molecular species analysis of the lipids separated, silica gel plates were impregnated with 10% $AgNO_3$ (w/w) and activated in the microwave oven for 10 min. The chromatoplate was developed with chloroform/methanol/water (65:25:4, by vol), the silica gel bands containing the lipid fractions were then scraped from the plate directly into glass tubes and the samples were methanolyzed with 0.5 mL $NaOH/CH_3OH$ (0.1 M).

Methanolysis of lipids and methylation of fatty acids. Aliquots of lipid or fatty acid samples were methanolyzed or methylated in thick glass tubes (20 × 150 mm with Teflon-lined screw caps; Pyrex, Corning, NY) with freshly prepared HCl/CH_3OH or $NaOH/CH_3OH$. The samples were exposed to the maximum power of the microwave oven for 1 min. For safety, the glass tubes containing lipid samples were encased in a large microwave-safe plastic container. The volume of HCl/CH_3OH *must not* exceed 0.5 mL because excess reagent and rapid heating may lead to the explosion of the tubes. After methanolysis, the samples are cooled to room temperature inside the microwave oven; the hot tubes should *not* be removed from the microwave oven immediately after heating. We have experienced no explosions of tubes using these simple precautions. Identical samples were methanolyzed in a conventional oven at 80°C for 6–8 h comparison. Whole *Brassica napus* seeds were directly methanolyzed after being crushed with a smooth glass rod in the glass tube with HCl/CH_3OH. The resulting FAME were extracted with hexane and quantified by gas–liquid chromatography (GLC) using a fused silica capillary column (DB 225, 30 m × 0.25 mm; J & W Scientific, Folsom, CA) programmed with an initial hold for 2 min at 180°C, and then temperature was increased to 220°C at the rate of 4°C/min (Hewlett-Packard GLC, Model 5890A; Mississauga, Ontario, Canada). Pentadecanoate (15:0) was used as internal standard.

Chemicals. All solvents were obtained from Fisher Scientific Co. (Unionville, Ontario, Canada) and were glass distilled before use. A model mixture of free fatty acids (Sigma Chemical Co., St. Louis, MO) ranging from C_{12} to C_{20} was prepared in the laboratory, HCl/CH_3OH was prepared in the laboratory by passing dry HCl gas through dry, distilled CH_3OH.

RESULTS AND DISCUSSION

TLC plate activation. Our objective was to minimize the time required for TLC plate activation without reducing the quality of lipid separation. Activation of 0.5-mm thick silica gel TLC plates for 10 min at full power in the microwave oven resulted in a quality of separation of individual lipids equal to that occurring with at least 4 h at 110°C in a conventional oven (2). TLC plates impregnated with 10% $AgNO_3$ were also activated for 10 min in the microwave oven; the separation of lipid molecular species on these plates was identical to that obtained by the

4.5	4.2 ± 0.2	4.4 ± 0.3
5.0	4.7 ± 0.1	4.8 ± 0.3

[a]Different volumes of a fatty acid mixture were analyzed by gas-liquid chromatography (GLC) after methanolysis in HCl/CH_3OH as described in Materials and Methods; the added quantities are compared to the values determined by GLC. The complete fatty acid analyses are contained in Table 2.
[b]Mean ± SD, n = 5.

conventional method and the rapid procedure resulted in less discoloration of the chromatoplates.

Preparation of FAME. Different concentrations of a mixture of fatty acids, ranging in carbon chain length from C_{12} to C_{20}, were methylated with HCl/CH_3OH (1.5 M) for 1 min in the microwave oven and 6-8 h in a conventional oven (Table 1). Higher concentrations of fatty acids were shown to require up to 2 min for maximum yield (data not shown). There was no significant change in the quantity of the fatty acids between mixtures methylated in a microwave and in a conventional oven although the mean values of the microwave method were closer to the added values at higher concentrations.

The yield of FAME by the microwave method was examined at various concentrations of HCl/CH_3OH in order to determine the optimal concentration of the reagent (Table 2). The quantities of FAME produced at different concentrations of HCl/CH_3OH reagent, ranging from 0.025 to 2.0 M, were quite similar. Higher concentrations of HCl/CH_3OH appeared to cause some loss of FAME (data not shown) while the low yield of FAME at concentrations of HCl/CH_3OH at 0.00625 M was probably due to incomplete methylation. Our results suggest that 0.5 M HCl/CH_3OH is a suitable concentration which yields optimum levels of FAME from lipids without loss of unsaturated fatty acids.

Analysis of whole plant tissue. The analyses of the fatty acid content of *B. napus* seeds did not require prior lipid extraction and purification. The seeds were methanolyzed directly with 1.5 M HCl/CH_3OH or 0.1 M $NaOH/CH_3OH$ in the microwave oven. The results of GLC analyses (Table 3) showed no significant differences in the fatty acid composition of seed lipids methanolyzed by these reagents. There was a small difference in quantity, probably due to the inability of $NaOH/CH_3OH$ to methylate free fatty acids (unpublished data).

Loss of unsaturated fatty acids by oxidation. The model fatty acid mixture was esterified using the microwave method and in a conventional oven in tubes that were incompletely closed (unsealed). In unsealed tubes from the microwave oven, the analyses revealed no significant oxidation of unsaturated fatty acids, while methylation of fatty acids by the conventional method in unsealed tubes caused severe loss of unsaturated fatty acids due to oxidation (data not shown). In the microwave method, the duration of heating is only 1 min and therefore, there is less chance of evaporation of the regent and subsequent oxidation of unsaturated fatty acids should this occur.

Methanolysis of molecular species in the presence of $AgNO_3$. The molecular species of galactosyldiacylglycerols and phospholipids are routinely analyzed in our laboratory using sodium methoxide (8,9) (which does not react with $AgNO_3$). This technique is time-consuming and sometimes results in the appearance of false peaks due to impurities in the prepared sodium methoxide reagent. The use of $NaOH/CH_3OH$ in the analysis of lipid molecular species using the microwave oven was faster,

more reliable and the GLC analyses of FAME were free from contamination (data not shown).

In conclusion, the microwave method of lipid analysis has proven to be very efficient, fast and reliable. The technique requires very little reagent to esterify lipids and free fatty acids in a short period of time. We have also successfully employed the method to analyze fatty acid contents of intact seeds, whole leaves and cyanobacterial cells in fresh sedimented pellets from liquid cultures.

LETTER TO THE EDITOR

Comments on Erythrocyte Membrane Phospholipid Fatty Acid Changes in Cerebral Palsy Patients During Nutritional Rehabilitation

Dear Sir:

When Harper *et al.* (1) reported on the fatty acid profile of erythrocyte membrane phospholipids in cerebral palsy, they showed that although a soy oil-based nasogastric formula resulted in an increased proportion of linoleic acid in the erythrocyte phospholipids, α-linolenic acid and 20 and 22 carbon polyunsaturated fatty acids were unchanged over a period of at least 25 d on this regimen. It was suggested that the high linoleic acid in the formula may have inhibited the desaturases, causing the observed lack of change in the longer chain metabolites.

Two other factors may also have contributed to the increase in linoleic acid, but lack of change in α-linolenic acid and in 20 and 22 carbon ω6 and ω3 fatty acids. First, as these children were gaining weight and body fat during this phase of nutritional rehabilitation, they were not in a steady-state. In humans in the steady-state, dietary linoleic acid is more readily oxidized than are saturated fatty acids (2). Although not studied in humans, α-linolenic acid is also more readily oxidized than are saturated acids (3). A greater demand in these patients to oxidize dietary linoleic and α-linolenic acids, as provided in the soy oil-based formula, might contribute to a lack of change in both α-linolenic acid and longer chain metabolites of both linoleic and α-linolenic acid during nutritional rehabilitation in cerebral palsy.

Second, various vitamins and trace elements are required in linoleic acid desaturation. Notable among these is zinc, the deficiency of which has a clear inhibitory effect on the synthesis of both arachidonic and docosahexaenoic acids in animals and in humans (4,5). Although the cerebral palsy patients reported by Harper *et al.* (1) may not have been zinc deficient, their weight gain during the period of the study again points to a nonsteady-state for zinc which could influence the availability of zinc needed in desaturation. This could also contribute to the lack of change in longer chain metabolites of both linoleic and α-linolenic acid in the presence of adequate amounts of these precursors in the diet.

Erythrocyte Membrane Phospholipid Fatty Acid Changes in Cerebral Palsy Patients During Nutritional Rehabilitation—A Response

Dear Sir:

We are very interested in the suggestions of Dr. Cunnane (1). The whole issue of nutrient supply in relation to growth rate is very important and often misunderstood, so we welcome the opportunity to clarify this point.

Although our patients were all very deficient in body mass before treatment, unlike children in the developing world, there was no clinical evidence of deficiency of minor components; in particular, hair, skin and mucous membranes were all healthy.

Our treatment regime did not lead to extremely rapid weight gain (30 g/kg/d, or more) but was usually around 10 g/kg/d. At that rate, the enteral feed used, Isocal™ (Mead Johnson, Evansville, IN), provides sufficient trace and minor nutrients to synthesize lean tissue. On average, the children studied were consuming 15.7 mg Zn per day. Isocal™ provides 10 mg Zn per 1000 kcal; the mixed Canadian diet contains approximately 5 mg Zn per 1000 kcal (2), and in a study involving Canadian preschool children, aged 4–5 y, the average Zn intake was 4.6 ± 1.0 mg per 1000 kcal (3). In addition, we do not base our prescription of nutrient intake on recommended intakes (which are designed to supply average, normal requirements plus two SD), but on calculations based upon data describing tissue composition and percent absorption from the gut. We are therefore confident that there were no minor nutrient deficiences.

Isocal™ provides 37.4% of energy as fat. Of the fatty acids therein, 18:2n-6 and 18:3n-3 comprise 45.6 and 6.7%, respectively (4). There does not seem much likelihood that there was a limitation in the supply of these fatty acids.

We thank Dr. Cunnane for his comments and hope that our response makes it clear that the provision of micronutrients is important and needs careful control in refeeding protocols.

Effect of Dietary α-Linolenic Acid on n-3 Fatty Acids of Rainbow Trout Lipids
Karen C. Sowizral, Gary L. Rumsey and John E. Kinsella
Lipids 25, 246-253 (1990)

In the Results and Discussion section of this paper, part of the third paragraph on page 249 and part of the first paragraph on page 250 were inadvertently deleted. The third and fourth paragraphs of the Results and Discussion section should read:

The mean weights of the fish on the four diets were similar, and all fish showed comparable weight gains (76 g) during the study period. Feed conversion (weight food fed/weight gain) for fish on the four diets was not statistically significant between treatments and averaged 1.30. There was no significant effect of diet on the proximate composition (Table 4).

There were no significant differences in the lipid content of muscle from fish fed different diets though lipid content of the flesh increased from 4.3 ± 0.14% to 6.95 ± 0.21% over the 64-day feeding period. The lipid content was within the range reported by this and other laboratories (22,23).

The identification of the precise structural features of yeast sterol molecules required for the essential "sparking" function has been a controversial area of research. Recent cloning and gene disruption studies in *Saccharomyces cerevisiae* have shown that C-24 methylation (*ERG6*), C-5 desaturation (*ERG3*) and Δ^8-Δ^7 isomerization (*ERG2*) are not required, while C-14 demethylation (*ERG11*) and C-14 reduction (*ERG24*) are each required for aerobic viability. Earlier observations had indicated that C-14 demethylase deficient strains could be restored to aerobic growth by suppressor mutations that caused a deficiency in C-5 desaturase. These strains were reported to synthesize some ergosterol, indicating that they contained leaky mutations in both *ERG11* and *ERG3*, thereby making it impossible to determine whether the removal of the C-14 methyl group was required for aerobic viability. The availability of the *ERG11* and *ERG3* genes has been used in this study to construct strains that contain null mutants in both *ERG11* and *ERG3*. Results show that these double disruption strains are viable and that spontaneously arising suppressors of the *ERG11* disruption are *erg3* mutants. The *erg11* mutants of *S. cerevisiae* are compared to similar mutants of *Candida albicans* that are viable in the absence of the *erg3* lesion.
***Lipids* 28, 963-967 (1993).**

The ergosterol biosynthetic pathway of yeast has been a focus of study for several decades. Initial interest resulted from the fact that several antifungal agents target this pathway or its end product, ergosterol. This is particularly true of the portion of the pathway beginning with the formation of the first sterol molecule, lanosterol. Although research on the mechanisms of action and resistance for antifungals and the development of new agents is still pursued, additional fundamental questions related to sterol function in membranes are being addressed.

Sterols play critical bulk roles in eucaryotic membranes providing the appropriate membrane fluidity to allow for normal functions such as membrane permeability (1,2), the activity of membrane-bound enzymes (3) and cellular growth rates (4). Beyond the bulk function, sterol has been implicated in providing an essential component required for completion of the cell cycle. Studies using a sterol auxotroph have indicated that yeast cells were unable to exit the G1 phase of the cell cycle unless a specific sterol molecule was present (5). This specific sterol was required in hormonal amounts and allowed resumption of the cell cycle provided that sufficient nonspecific bulk sterol was also present. Ergosterol could satisfy both the bulk function and the specific, or "sparking" function (6,7).

Several sterol structural features have been suggested as essential for sparking activity. One group proposed that methylation of the C-24 position (*ERG6* gene) was essential (8,9) while a second proposed that desaturation of the C-5(6) position (*ERG3* gene) was required for sparking (6,7,10). Recently the *ERG6* and *ERG3* genes have been cloned and used to obtain gene-disrupted haploid strains (11,12). In both cases, cells carrying the null allele were viable, indicating the nonessentiality of each gene. A similar result has also been reported for gene *ERG2* encoding the Δ^8-Δ^7 isomerase activity (13). More recent reports (14,15) describe the cloning and disruption of the C-14 sterol reductase gene (*ERG24*). In one of these studies (14), cells containing the C-14 reductase gene disruption were shown to be nonviable under aerobic conditions, indicating that this gene contributes an essential structural feature to the sparking function.

Moreover, the C-14 demethylase (*ERG11*), has been cloned and sequenced (16). Haploid strains disrupted for this gene are nonviable under aerobic conditions (16). Although this result established an essential role for this gene, prior studies using several aerobically viable *erg11* mutant strains (17,18) indicated that these mutants also carried a mutation in *ERG3*, the gene for C-5(6) desaturase. An explanation for this situation has been proposed based on the isolation and identification of a novel sterol, 14α-methyl-ergosta-8,24(28)-dien-3β,6α-diol (19), found in *erg11* mutants of *Candida albicans* (20,21). Although not a problem for *C. albicans*, production of this sterol in *erg11* mutants of *Saccharomyces cerevisiae* is suggested to result in loss of viability due to the sterol's interference with normal membrane function. Its formation in *erg11* strains presumably arises from the action of C-5(6) desaturase on C-14 methyl fecosterol rather than its normal substrate, fecosterol, with the resulting formation of the diol. Indeed, this diol has been found in a wild type *Saccharomyces* strain treated with the 14α-demethylase inhibitor, fluconazole (19). The presence of an *erg3* mutation that prevents the formation of the diol in *S. cerevisiae erg11* mutants thus allows viability of the cell.

One of the features of the double mutants used in prior studies (17,18) is that they were reported to continue to produce some ergosterol, indicating that both the *erg11* and *erg3* mutations were leaky. This presents a difficulty in interpretation since sparking sterol is required in such small amounts and also presents a problem in determining the level of diol required to render the cell inviable. To clarify such questions we have (i) constructed *S. cerevisiae*

erg11 erg3 double disruptions (nonleaky null mutants) and various combinations of the disruptions and point mutations, (ii) isolated and investigated the nature of suppressors of the *erg11* disruption and (iii) re-examined the sterol profiles of a *C. albicans erg11* mutant. Our results confirm the aerobic viability of *erg11 erg3* null mutant strains and present a new array of accumulated sterol intermediates which is compatible with growth.

MATERIALS AND METHODS

Strains. The strains used in this study and the sterol biosynthetic lesions they contain are listed in Table 1. Strain *erg3Δ::LEU2 erg11::URA3* was created by disruption of the *ERG11* gene site in strain *erg3Δ::LEU2* (see below). Strain *erg3 erg11::URA3* was created by crossing *erg3-2c* (12) and the *erg11:URA3* strain. Spontaneous revertants of *erg11::URA3* to aerobic viability were isolated by collecting anaerobically-grown cells and plating them on yeast minimal medium (YMM) under aerobic conditions. After 5–7 d colonies emerged from the nongrowing lawn. The variants were confirmed to retain the *erg11::URA3* genotype and were designated *s*uppressors of *l*anosterol *d*emethylase *d*eficiency (*sld*) strains.

Growth. Strains of *S. cerevisiae* were grown aerobically on 1% yeast extract, 2% peptone and 2% dextrose (YPD) or 0.67% yeast nitrogen base and 2% dextrose (YMM) or 2% galactose (YMG) at 30°C. For anaerobic growth, YMM medium was boiled, degassed and then supplemented with ergosterol and Tween 80 added from a 2% ergosterol solution in ethanol/Tween 80 (1:1, vol/vol) to a final ergosterol concentration of 35 mg/L, giving a final Tween 80 concentration of 0.0875% (22). Media were supplemented with the appropriate nutritional supplements when selection protocols were employed. Strain D10 of *C. albicans* (23) was maintained on YPD supplemented with 45 mg/mL nystatin to prevent reversion of the *erg11* lesion.

Gene disruption. Disruption of the *ERG11* gene in *erg3Δ::LEU2* was accomplished as previously described (16) using a modification of a previously described electroporation procedure for the transformation step (24). Briefly, a 1.1 kb fragment of the *URA3* gene from YEp24 was inserted into the coding sequence of *ERG11* (LB4-3A). A linear *Bam*HI-*Hind*III fragment from this construct was used to transform yeasts to uracil prototrophy. The *ERG3* gene was also disrupted as previously described (12). A 1.1 kb *SAl*I-*Xho*I fragment spanning the *ERG3* gene was deleted, the *Xho*I site was filled in and in its place was inserted a 2.0 kb *Sal*I-*Hpa*I fragment containing the *LEU2* gene. Cells were grown aerobically to late log phase at 30°C, pelleted and suspended in 0.3 mM Na_2HPO_4, 0.2 mM KH_2PO_4, 10% glycerol for transformation (25). Selection of the uracil prototrophs was done aerobically. Gene disruption was confirmed using polymerase chain reaction (PCR; results not shown).

PCR. PCR procedures were carried out in a Perkin Elmer (Norwalk, CT) Cetus DNA Thermal Cycler. Amplimers based upon the published *ERG3* sequence (12) were chosen to yield a 2.2 kb amplification product. The *Kpn*I and *Sph*I restriction enzyme sites were included in the amplimers to facilitate proper orientation upon cloning into an expression vector. These primers were used to amplify *sld1*-1 genomic DNA.

Analysis of amplified alleles. Following amplification of the wild-type *ERG3* and *sld1*-1 from the respective strains, the products were inserted into a galactose inducible plasmid, pYES2.0 (Invitrogen). Ten of 12 *ERG3* and nine of 12 *sld1-1 Escherichia coli* transformants were shown to contain PCR products in the correct orientation. From these, six of each were transformed into a *erg3Δ::LEU2 ura3* Gal^+ host. The presence of a functional *ERG3* allele was established based upon the restoration of cycloheximide resistance. Minimum inhibitory concentration values of the transformants were obtained using YMM or YMG as growth media.

Sterol analysis. Cells for sterol analysis were grown to stationary phase in YPD medium. After harvesting by centrifugation, the cells were subjected to saponification as previously described (26). Gas chromatographic (GC) separation and mass spectral (MS) analysis of sterols were done on a Finnigan MAT TSQ 700 (San Jose, CA) GC/MS. GC separations were carried out on a 15 m × 0.32 mm Durabond DB-5 column with a 0.25-mm thickness. The oven temperature was programmed from 50–260°C at 25°C per min and held at 260°C for 20 min. The carrier gas was helium at a linear velocity of 60 cm/s. The capillary column was interfaced directly into the mass spectrometer ion source. The indicated ion source temperature was 150°C. The MS was operated in the electron impact mode at 70 eV and was scanned from *m/z* 50 to *m/z* 650 at a 0.5 s/scan rate. The resulting spectra were enhanced by subtraction when necessary. The chromatographic peaks were quantitated based on area percent. Derivatizations were done with *N, O-bis*(trimethylsilyl)-

trifluoroacetamide (BSTFA) containing 1% trimethylchlorosilane (TMCS) purchased from Pierce (Rockford, IL). Fifty mL of BSTFA containing 1% TMCS was added to the dry sample followed by 50 mL of pyridine. Solutions were heated for 5 min at 45°C on a heating block. The sample was cooled to room temperature before analysis.

RESULTS AND DISCUSSION

Previously isolated lanosterol demethylase mutants of *S. cerevisiae* (17,18) have been reported to be leaky and to contain a second leaky mutation in the C-5(6) desaturase (*erg3*). The resulting formation of low levels of ergosterol makes conclusions regarding the essential sterol structure provided by the *ERG11* and *ERG3* genes problematic. Single disruptions of these genes result in aerobic viability for *erg3* (12) and aerobic nonviability for *erg11* (16). The combination of these two disruptions would clarify the proposed *erg3* suppression of *erg11* mutants and could help test the hypothesis that the *erg11* mutation results in nonviability due to the accumulation of a sterol diol (19). To that end, several combinations of *ERG11* disruptions and *ERG3* disruptions and point mutations as well as a suppressor of the *erg11::URA3* aerobic lethality were generated and characterized as to sterol content and aerobic viability. In addition, a lanosterol demethylase mutant of *C. albicans* was analyzed to ascertain how closely sterol metabolism and requirements are related in the two species.

Table 2 shows the sterol profiles of the strains used in this study. The *erg11::URA3* strain is not included since it is not viable under the aerobic conditions required for sterol synthesis. Strains bearing the *erg3* mutation or the disrupted *ERG3* gene copy produce similar typical sterol profiles. Strain JR4 accumulated exclusively 14-methylsterols indicative of a block in lanosterol demethylation. Trace amounts of ergosterol were also detected confirming that the mutation is leaky (18). No evidence of the presence of a sterol diol was observed. The *erg3 erg11* strains produced for this study, one containing the *erg3* point mutation and the *ERG11* disruption (*erg3-2c erg11::URA3*) and one containing disruptions of both genes (*erg3Δ::LEU2 erg11::URA3*), produced the same

[a]Cells were grown in yeast extract for 48 h, centrifuged and saponified as described previously (26). Gas chromatography and mass spectrometry analysis were performed as described in Materials and Methods. See Table 1 for abbreviation. Trace, much less than 1%.

sterol profile as that of JR4, with the exception that no ergosterol was detected. Thus, viability of JR4 is not the result of leakiness of the individual point mutations. Strain SG1, which has been previously identified as containing point mutations in the *ERG3* and *ERG11* genes (17), produced a sterol profile consistent with that of an *erg3* strain. Our isolate must have resulted from a spontaneous revertant of the *erg11* lesion.

Table 2 also shows the sterol profile of strain *sld1-1*, a strain which contains a wild-type copy of *ERG11*. This *sld1-1* marker originally arose in an aerobically growing variant of the *ERG11* disrupted strain, strain *erg11::URA3 sld1*. Since *erg11::URA3 sld1* was shown to retain its original *erg11::URA3* disruption based on uracil prototrophy, its ability to grow aerobically was attributed to a suppressor mutation at a different locus. The strain was mated to *erg11::URA3*, an obligate anaerobe, in order to determine whether the suppressor mutation was dominant or recessive. The resulting diploid was found to be also an obligate anaerobe, indicating that the *sld* mutation is recessive. Mating of *erg11::URA3 sld1* with an *ERG11 ura3-52* strain yielded a diploid for which sporulation resulted in a high percentage of incomplete tetrads. This may be due to the accumulation of decreased sterol levels or aberrant sterols in the developing asci. Of the four intact tetrads recovered, one (nonparental ditype) yielded 2:2 segregation for uracil prototrophs that were obligate anaerobes and uracil auxotrophs that were capable of aerobic growth. Thus, the *erg11* marker and the *sld1* marker are not linked. This aerobically competent *sld1* segregant was named *sld1-1* (Table 1). Sterol analysis of *sld1-1* yielded a spectrum that was consistent with that of an *erg3* strain (Table 2). Strain *sld1-1* was then mated separately with known *erg3* strains. The resulting diploids remained nystatin resistant, indicating that *erg3* and *sld1-1* are allelic (27).

PCR primers chosen for amplification of *ERG3* gave a single product of the predicted size using *ERG3* genomic DNA. When these identical amplimers were used with *sld1-1* genomic DNA as the template, a single band of the same 2.2 kb size was produced. Since this *sld1-1* strain was never shown to revert (27), it is of interest that *sld1* yielded a product that is the same as wild-type product, indicating no gross insertion or deletion has occurred.

As is the case with many of the *erg* mutants (11-13), *erg3* and *sld1-1* are cycloheximide sensitive, apparently due to the increased permeability of the cytoplasmic membrane. To further examine the *erg3* nature of *sld1-1*, we examined the capacity of the amplified gene sequence for either *ERG3* or *sld1-1* to restore cycloheximide resistance to an *erg3* null mutant. Plasmids were prepared containing either the amplified *ERG3* or *sld1-1* sequence under regulation of the galactose promoter and were transformed into strain *erg3Δ::LEU2*. The results are shown in Table 3. When the *ERG3* plasmid was present, cycloheximide resistance returned in the cells grown on YMG, but not in cells grown in YMM. However, addition of the *sld1-1* containing plasmid had no effect on cycloheximide sensitivity of cells grown on either medium. These patterns are consistent with *sld1* being a nonfunctional *erg3* allele.

The demonstration that the *erg11* lesion is not aerobically viable in *S. cerevisiae* (16), coupled with the results showing that azole-resistant mutants of this organism were *erg3* mutants, led to the hypothesis that the *erg11* mutation was lethal due to the formation of a sterol diol (19). Since azoles are inhibitors of C-14 demethylation (28), they are mimics for the *erg11* mutation. Thus, the *erg3* mutation would allow aerobic survival in the presence of azole *via* the same mechanism that allows survival of the *erg11* mutation when accompanied by the *erg3* mutation. The situation in the pathogenic fungus *C. albicans*, appears different in that *erg11* mutants are capable of aerobic growth. These mutants showed decreased growth rates (29), altered membrane properties (30) and defective hyphae formation (29). Coupled with recent results (31) indicating the increased active oxygen sensitivity of azole-treated cells, the mode of efficacy of these drugs appears quite complex.

TABLE 3

Cycloheximide Sensitivity of Strain LB4-3A *(erg3Δ::LEU2)* Transformed with Polymorase Chain Reaction Products Under the Galactose Promoter

Growth conditions[a]	Cycloheximide [Minimal inhibitory concentration (ng/mL)[b]					
Galactose	0	10	20	40	80	160
pGal (control)	+	+	+	−	−	−
pGal-*sld1*	+	+	+	−	−	−
pGal-ERG3	+	+	+	+	+	+
Glucose	0	10	20	40	80	160
pGal (control)	+	+	+	−	−	−
pGal-*sld1*	+	+	+	−	−	−
pGal-*ERG3*	+	+	+	+	−	−

[a]Cells were grown on yeast extract peptone media containing either 2% galactose plus 0.1% glucose, or 2% glucose.
[b]Results presented are a compilation of six independent clones of either *ERG3* or *sld1* gene sequences transformed into *erg3Δ::LEU2*; +, growth at 48 h; −, no growth at 48 h.

We previously reported the sterol profile of an *erg11* mutant (strain D10) of *C. albicans* (32). The sterols identified for D10 were 14-methylfecosterol, obtusifoliol, lanosterol, 24-methylene-24,25-dihydrolanosterol and 24,25-dihydrolanosterol. In view of the identification of a sterol diol in another *C. albicans* strain (20) and in the context of this study, the sterol content of D10 was reexamined. The sterol profile of D10 along with that of the *S. cerevisiae* strain *erg3Δ::LEU2 erg11::URA3* are shown in Figure 1. The *S. cerevisiae* strain shows the profile of C-14 methylsterols typically found in *erg11* strains in an *erg3* background. In the *C. albicans erg11* strain, a somewhat different array of C-14 methylsterols is seen to accumulate. The peak eluting at 18:03 has now been identified as 14α-methylergosta-8,24(28)-dien-3β,6α-diol rather than 24,25 dihydrolanosterol.

The MS analysis of the strain D10 diol yielded results similar to those reported in the identification of the diol in another *erg11* of this organism (20). The electron impact mass spectrum of this sterol showed the following ions: *m/z* 428, $M^{+\cdot}$; *m/z* 413, $M^{+\cdot} - \cdot CH_3$; *m/z* 395, $M^{+\cdot} - \cdot CH_3 - H_2O$; and *m/z* 377, $M^{+\cdot} - \cdot CH_3 - 2\ H_2O$. The formation of the trimethylsilyl derivatives using BSTFA (1% TMCS) resulted in a *bis*-trimethylsilyl derivative, which is consistent with the presence of a diol. The electron impact spectrum of this derivative yielded the following ions: *m/z* 572, $M^{+\cdot}$; *m/z* 557, $M^{+\cdot} - \cdot CH_3$; *m/z* 467, $M^{+\cdot} - \cdot CH_3 - HOSiMe_3$; and *m/z* 377, $M^{+\cdot} - \cdot CH_3 - 2\ HOSiMe_3$.

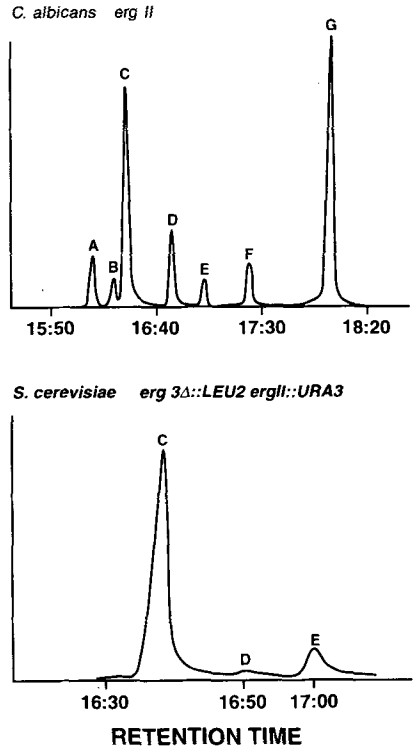

FIG. 1. Sterol profiles of *Candida albicans* strain D10 and *Saccharomycea cerevisiae* strain *erg11::URA3 erg3Δ::LEU2*. A, unidentified sterol of *m/z* 408; B, unidentified sterol of *m/z* 410; C, 14-methylfecosterol; D, obtusifoliol; E, lanosterol; F, 24-methylene lanosterol; G, 14-methylergosta-8,24(28)-dien-3β,6α-diol.

The results presented here indicate conclusively that, in the absence of ergosterol (detection level much less than 1%), removal of the methyl group from the C-14 position is not required for the aerobic growth of *S. cerevisiae*. Previous reports using leaky strains (JR4 and SG1) that produced low levels of ergosterol made a definitive determination regarding the requirement for C-14 demethylation impossible. This conclusion is clearly evident by the aerobic growth of *erg3Δ::LEU2 erg11::URA3*, a strain that produces 14-methylsterols exclusively. The results using *erg3* disrupted strains, and *erg11* suppressor strains (*sld1*) also confirm the necessity of an *erg3* mutation for the aerobic growth of *erg11* mutants of this organism. This confirmation supports the hypothesis that the *erg11* mutation is lethal due to the accumulation of sterol diol. The viability of *erg11* isolates from *C. albicans* and the detection of significant levels of diol indicate either that the two organisms produce differing amounts of diol or that they vary in their sensitivity to the lethal effects of the diol. In addition, the possibility exists that *C. albicans* may be spared the lethal effects of the diol by sequestering this compound in an esterified form.

ACKNOWLEDGMENTS

This project was supported in part by NIH grant IR15 GM45959-01 to M.B. and NIH grant ES 04908 to J.L. We thank Dr. Leo Parks for providing *S. cerevisiae* strain JR4. Our special thanks to Dr. Ralph I. Murray for the initial sterol analyses of the *sld1* strains.

Farnesylamine: An Inhibitor of Farnesylation and Growth of *Ras*-Transformed Cells

Ravi Kothapalli[a], Najla Guthrie[a], Ann F. Chambers[b,1] and Kenneth K. Carroll[a,*,2]

[a]Department of Biochemistry, University of Western Ontario, London, Ontario N6A 5C1 and [b]Department of Oncology, London Regional Cancer Centre, London, Ontario, N6A 4L6 Canada

Farnesylamine, an analogue of farnesol, was shown to inhibit growth of PAP2 cells (*ras*-transformed NIH 3T3 cells) in a dose-dependent manner. This inhibition was overcome by adding farnesol to the culture medium, but not by adding geranylgeraniol, squalene, cholesterol, dolichol, myristic acid or palmitic acid. Farnesylamine inhibited both farnesyl/protein transferase and geranylgeranyl/protein transferase in whole cell extracts and also inhibited the prenylation of proteins, particularly *ras* p21, in PAP2 cells. Inhibition of prenylation was associated with increased biosynthesis of other products of the mevalonate biosynthetic pathway. These observations suggest that inhibition of the growth of PAP2 cells by farnesylamine may be due to blocking of *ras*-mediated signal transduction. This offers a means of investigating mechanisms involved in *ras* action and raises the possibility of developing novel strategies for anticancer therapy.

***Lipids* 28, 969-973 (1993).**

Recently it has been established that polyisoprenoid compounds such as farnesol and geranylgeraniol are attached posttranslationally to a small group of proteins (1-4). Some of these proteins, such as *ras* proteins, are biologically active only when they are associated with the inner surface of plasma membranes (5-8). Several posttranslational modifications are required for interaction of these proteins with the plasma membrane. These include addition of a farnesyl group to the C-terminal cysteine residue by a thioether linkage (9,10), proteolytic cleavage of three amino acids at the C-terminal end, methylation of the carboxyl group of cysteine (11,12) and palmitoylation (13-15). A list of well-characterized farnesylated and geranylgeranylated proteins is included in recent reviews (7,16). Among these prenylated proteins, much attention has been focused on *ras* proteins, because of their involvement in many types of cancer (7,17-19).

Several reports suggest that both membrane association and biological activity of *ras* proteins are abolished by blocking farnesylation of these proteins. For example, altering the amino acid sequence at the C-terminal end of the *ras* protein to prevent farnesylation abolishes its cell transforming activity (20-22). The growth of *ras*-transformed cells and other cells can also be prevented by 3-hydroxy-3-methylglutaryl coenzyme A (HMG-CoA) reductase inhibitors, which block the synthesis of mevalonic acid, a precursor of farnesyl pyrophosphate (FPP) (17,23,24). However, it was recently shown that inhibition of cell growth by lovastatin (an HMG-CoA reductase inhibitor) is independent of *ras* function (25), and the concentrations of such inhibitors required to prevent the prenylation of *ras* proteins in cell culture are approximately 100 times higher than the concentrations required to inhibit cholesterol biosynthesis (26). Similarly, high concentrations (1 mM) of *d*-limonene and its metabolites are required to prevent *ras* prenylation (27).

The enzymes involved in the transfer of farnesol and geranylgeraniol moieties from their pyrophosphate forms to protein have been identified in several mammalian cells and tissues (28-35). Farnesyl/protein transferase has been purified from rat brain (30), and a number of synthetic tetrapeptides were found to be good inhibitors of this enzyme *in vitro* (36). Biological activity of *ras* proteins has been inhibited in *Xenopus* oocytes by microinjection of an octapeptide with sequences similar to the C-terminal end of *ras* p21 protein (37). However, doubts were expressed about the use of these peptides as anticancer drugs, because their delivery to intracellular targets may present problems (19). Therefore, compounds that specifically inhibit farnesylation at low concentrations without affecting the biosynthesis of other compounds may be useful in controlling malignancies.

In this paper, we describe the synthesis of farnesylamine, a derivative of farnesol, and its use an inhibitor of cell growth and farnesylation of proteins in *ras*-transformed PAP2 (*ras*-transformed NIH 3T3) cells. In these cells, p21 *ras* levels are expressed about 100 times higher than in the NIH 3T3 cells from which they are derived (38).

MATERIALS AND METHODS

Materials. Mevinolin was a gift from Murray Huff (Department of Medicine, University of Western Ontario, London, Ontario, Canada). The lactone form of mevinolin was converted to its sodium salt as described by Habenicht *et al.* (39). (*RS*)[5-^{3}H]Mevalonolactone (MVA) (27.5 Ci/mmol) was obtained from New England Nuclear, Dupont Canada Inc. (Markham, Ontario, Canada). [^{3}H]-Thymidine (6.7 Ci/mmol) was from ICN (Irvine, CA). [1(n)-^{3}H]FPP (15 Ci/mmol) and [1(n)-^{3}H]geranylgeranyl pyrophosphate (GPP) (15 Ci/mmol) were purchased from Amersham Life Sciences (Oakville, Ontario, Canada). Farnesol was purchased from Sigma Chemical Co. (St. Louis, MO), and farnesyl bromide from Aldrich Chemical Co., Inc. (Milwaukee, WI). Tissue culture medium and fetal calf serum were purchased from GIBCO (Burlington, Ontario, Canada). X-Omat AR film was obtained from Eastman Kodak Co. (Rochester, NY). Electrophoresis reagents were from Bio-Rad (Richmond, CA). All other chemicals were purchased from Sigma.

Synthesis of farnesylamine. All-*trans* farnesylamine was synthesized from all-*trans* farnesol by the Gabriel synthesis (40). Farnesol was first converted to farnesyl tosylate and then to farnesylphthalamide, which was subjected to hydrazinolysis to yield the amine. Farnesylamine

Abbreviations: DNA, deoxyribonucleic acid; FPP, farnesylpyrophosphate; GPP, geranylgeranyl pyrophosphate; HMG-CoA, 3-hydroxy-3-methyl-glutaryl coenzyme A; MTT, 3-[4,5-dimethylthiazole]-2,5-diphenyltetrazolium bromide; MVA, mevalonic acid; PAP2 cells, *ras*-transformed NIH 3T3 cells; PBS, phosphate buffered saline; PMSF, phenylmethylsulfonyl fluoride; SDS-PAGE, sodium dodecyl sulfate-polyacrylamide gel electrophoresis; TCA, trichloroacetic acid; TLC, thin-layer chromatography.

was separated from the reaction mixture and purified by silica gel 60 H thin-layer chromatography (TLC). Chloroform/acetone/methanol/acetic acid/water (10:4:2:2:1, by vol) was used as developing solvent, and the farnesylamine was detected by spraying with ninhydrin. Farnesylamine has an R_f of 0.58. The structure was confirmed by mass spectroscopy and nuclear magnetic resonance spectroscopy. All-*trans* farnesylamine was also synthesized in better yield from all-*trans* farnesyl bromide according to Galat and Elion (41).

Cell culture. PAP2 cells (malignant, T24 H-*ras*-transformed NIH 3T3 cells) (42,43) were maintained at 37°C in Dulbecco's modified Eagle medium containing 3.7 g of $NaHCO_3$ per liter, supplemented with 10% (vol/vol) fetal bovine serum. The medium was equilibrated with a humidified atmosphere of 5% CO_2. Stock cultures were seeded at a density of 2×10^5 cells/mL and allowed to multiply for 48 to 72 h. Viability of the cells was measured before and after treating with farnesylamine, using the 3-[4,5-dimethylthiazole]-2,5-diphenyltetrazolium bromide method as described by Hansen *et al.* (44). Cell proliferation was measured by plating cells in plastic dishes, allowing cell growth for the times specified, trypsinizing the cells and counting them with a hemacytometer.

Incorporation of [^{3}H]thymidine into DNA. PAP2 cells were plated at 1×10^4 cells/well in 96-well, flat-bottomed culture plates in a total volume of 200 μL of medium and incubated at 37°C for 24 h with or without various test compounds. [^{3}H]Thymidine (0.5 μCi/well) was then added, and after 4 h the cells were harvested onto a glass fiber filter paper using a semiautomatic 12-well cell harvester (Skatron Inc., Sterling, VA). Radioactivity on the filter paper was counted using ScintiVerse (Fisher Scientific, Napean, Ontario, Canada) in a liquid scintillation counter.

Incorporation of [^{3}H]MVA into proteins. Cells were cultured for 48 h, and 30 μM mevinolin, 100 μM unlabelled MVA and 50 to 100 μCi/mL (*RS*) [5-^{3}H]MVA (27.5 Ci/mmol) were added. Farnesylamine (20 μM when used) was also added at this time. After 24 h, the cells were trypsinized and collected by centrifugation at 500 × *g* for 5 min. They were washed with citrate saline or phosphate buffered saline (PBS) and used for different experiments.

For electrophoresis, cell pellets were dispersed in Tris-HCl, pH 7.4, and homogenized in the same buffer. The protein was precipitated with cold 10% trichloroacetic acid (TCA), and the precipitate was collected by centrifugation. It was washed twice with cold 10% TCA, then delipidated by extracting twice with diethyl ether. The precipitate was dissolved by heating at 100°C for 5 min in a sample buffer containing 8M urea, 2% sodium dodecyl sulfate (SDS), 5% 2-mercaptoethanol, 10% glycerol, 0.0625 M Tris-HCl, pH 6.8. Proteins were subjected to SDS-polyacrylamide gel electrophoresis (SDS-PAGE) (45). After staining with Coomassie Blue, the gels were treated with fluorographic enhancer, En^{3}Hance, dried and exposed to X-OMAT AR film for 20 d at −80°C.

TCA precipitation. After labelling the cells with [^{3}H]MVA, they were washed with PBS and homogenized in a buffer containing 0.02 M Tris-HCl, pH 7.4, 5 mM $MgCl_2$, 0.1 M NaCl, 1% vol/vol Triton X-100, 0.5% SDS and 3 mM phenylmethylsulfonylfluoride (PMSF), and centrifuged at 100,000 × *g* for 30 min at 4°C. The supernatant was used for TCA precipitation and immunoprecipitation. Equal amounts of protein were taken and precipitated with 30% TCA and 4% SDS and filtered through micro-glass filters as described by Reiss *et al.* (30).

Immunoprecipitation. To 800 μg of protein in 1-mL buffered solution, were added 10 μL of an anti-v-H-*ras* monoclonal antibody (Ab-1; clone Y13-259) (Oncogene Science, Manhasset, NY) and 15 μL goat anti-rat IgG/protein A *Staphylococcus* complex. The mixture was incubated at 4°C for 24 h with a rocking device. The precipitate was collected by centrifugation in a microcentrifuge at 2500 rpm for 15 min and washed four times with PBS, ph 7.25, containing 1% Triton X-100, 0.5% deoxycholate and 0.1% SDS, dissolved in ScintiVerse (Fisher Scientific) and counted in a liquid scintillation counter.

Farnesyl/protein and geranylgeranyl/protein transferase assays. Farnesyl/protein transferase assay was carried out essentially as described by Reiss *et al.* (30). [^{3}H]FPP (300,000 dpm) and various amounts of farnesylamine were mixed and dried under nitrogen. PAP2 cells (at about 80% confluency) were treated with 30 μM mevinolin for 3 h and harvested. The cells were washed with PBS several times and homogenized in a buffer containing 50 mM Tris-HCl pH 7.4, 100 mM NaCl, 0.2% β-octaloglucoside, 2 mM dithiothreitol, 5 mM $MgCl_2$ and 100 mM NaF. Cell debris was pelleted by low-speed centrifugation. The supernatant was used as enzyme source. Cell extract (100 μL; 40 μg of protein) was added to the mixture of labelled FPP and farnesylamine and incubated for 1 h at 30°C. The reaction was stopped by adding 0.5 mL of 30% TCA and 0.5 mL of 4% SDS and processed as described by Reiss *et al.* (30). Similarly, geranylgeranyl/protein transferase assays were carried out by using [^{3}H]GPP instead of [^{3}H]FPP.

Biosynthesis of other isoprenoid compounds in presence of farnesylamine. After labelling the cells with [^{3}H]MVA as described above, they were washed with PBS several times and homogenized in a glass homogenizer with acetone. The resulting mixture was centrifuged, and the pellet was washed three times with chloroform/methanol (2:1, vol/vol), three times with chloroform/methanol/water (10:10:3, by vol) and finally three times with diethyl ether. All the washings were pooled, dried and saponified for 6 h with NaOH in presence of methanol. The nonsaponified lipids were extracted with ether and washed with water, and the lipids were applied on reverse-phase TLC and developed with acetonitrile/water (9:1, vol/vol). Areas corresponding to geraniol, farnesol and geranylgeraniol were scraped off and counted. The radioactive material at the origin was scraped off, extracted and applied onto a silica gel 60H TLC and developed with *n*-hexane/diethyl ether/acetic acid (65:35:1, by vol). The areas corresponding to cholesterol, dolichol and coenzyme Q were scraped off and counted.

RESULTS

Effects of farnesylamine and other compounds on the growth of PAP2 cells in culture. Proliferation of PAP2 cells was significantly inhibited by farnesylamine at a concentration of 7.5 μM, as measured by incorporation of thymidine into DNA (Fig. 1A) as well as by cell growth studies (Fig. 1B). Cells were viable at concentrations of farnesylamine up to 50 μM. Farnesol and farnesyl bromide

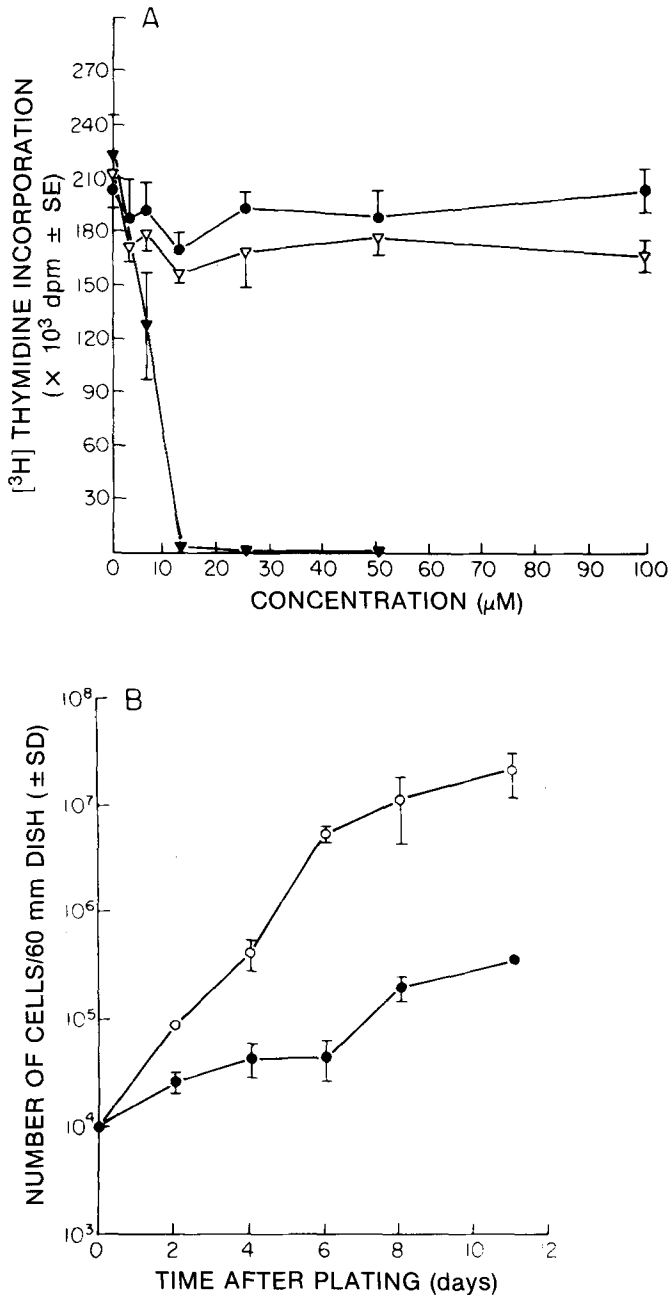

FIG. 1. A: Effects of farnesol, farnesyl bromide and farnesylamine on *ras*-transformed NIH 3T3 (PAP2) cells. Cells were plated in triplicate at 2 × 10^4 cells/well in 96-well, flat-bottomed, culture plates. Different concentrations of farnesol (●), farnesyl bromide (▽) or farnesylamine (▼) were added as indicated in the figure, and the incorporation of [^{3}H]thymidine was measured. Points are the average of mean values from three experiments ± SE. B: Growth of PAP2 cells in presence (●) or absence (○) of 7.5 μM farnesylamine. Cells were plated in triplicate in 60-mm^2 culture dishes. Cells were removed by trypsinization at specified times and were counted by a hemocytometer. Points are mean values ± SD.

did not inhibit cell growth at concentrations up to 100 μM (Fig. 1A). Various straight-chain, saturated amines-(C_6-C_{18}) were also tested with PAP2 cells. Short-chain amines (C_6, C_8) did not inhibit cell growth, whereas longer-chain amines inhibited at higher concentrations (IC_{50} 12.5 to 50 μM) (Kothapalli, R., Lui, E.M.K., Guthrie, N., Chambers, A.F., and Carroll, K.K., unpublished data).

TABLE 1

Effect of Various Compounds on the Growth of Farnesylamine Treated Cells[a]

Compounds added	[^{3}H]Thymidine incorporation into DNA (× 10^3 dpm ± SD)
Control	227.7 ± 23
Farnesylamine	4.2 ± 0.9
+ Farnesol	215.8 ± 26
+ Geranylgeraniol	3.1 ± 0.6
+ Squalene	5.2 ± 0.8
+ Cholesterol	4.7 ± 0.4
+ Dolichol	4.3 ± 0.5
+ Myristic acid	4.5 ± 0.3
+ Palmitic acid	5.8 ± 0.7

[a]*ras*-Transformed NIH 3T3 cells were cultured with or without 10 μM farnesylamine for 24 h. Other compounds (20 μM) were added to the cells treated with farnesylamine, and the incorporation of [^{3}H]thymidine into DNA was measured after 14 h.

The growth inhibition of PAP2 cells by farnesylamine was overcome by adding farnesol to the culture medium, but not by adding various other isoprenoids or fatty acids (Table 1). Inhibition of cell proliferation by various other long-chain amines was not overcome by adding farnesol (Table 2).

Mechanism of action of farnesylamine. The mechanism by which farnesylamine inhibits cell growth was investigated by labelling PAP2 cells with [^{3}H]MVA in the presence or absence of farnesylamine. Proteins were extracted, subjected to SDS-PAGE and exposed to x-ray film. Inhibition of prenylation of proteins was observed in cells treated with farnesylamine (Fig. 2).

In order to determine whether farnesylamine inhibits the transfer of farnesyl moieties from FPP to protein, extracts of PAP2 cells were prepared and incubated with [^{3}H]FPP plus different concentrations of farnesylamine. Assays for farnesyl/protein transferase activity showed

TABLE 2

Inability of Farnesol to Reverse Inhibition of Cell Proliferation by Long-Chain Fatty Amines[a]

Amines added	[^{3}H]Thymidine incorporation into DNA (× 10^3 dpm ± SD)
Control (without any fatty amines)	125.7 ± 13.8[b]
Dodecylamine (25 μM)	29.7 ± 2.1
Dodecylamine + farnesol	28.2 ± 2.8
Tridecylamine (12.5 μM)	20.5 ± 1.8
Tridecylamine + farnesol	21.2 ± 1.3
Tetradecylamine (12.5 μM)	30.1 ± 4.3
Tetradecylamine + farnesol	25.4 ± 0.52
Hexadecylamine (25 μM)	25.3 ± 1.3
Hexadecylamine + farnesol	27.1 ± 2.8
Octadecylamine (50 μM)	48.1 ± 1.2
Octadecylamine + farnesol	47.0 ± 5.6

[a]*ras*-Transformed NIH 3T3 cells were cultured with or without various long-chain amines (dissolved in dimethyl sulfoxide) for 24 h. Farnesol (20 μM) was added to the cells at that time, and the incorporation of [^{3}H]thymidine into the DNA was measured after 14 h.
[b]This value is dpm ± SE rather than SD.

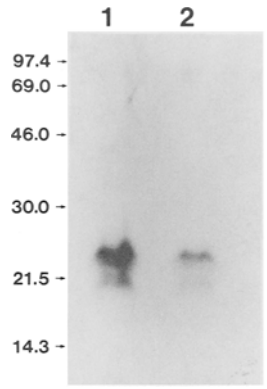

FIG. 2. Electrophoretic profiles of farnesylated proteins in *ras*-transformed NIH 3T3 cells. Lane 1: 160 μg of total protein obtained from control cells (without farnesylamine). Lane 2: 130 μg of total protein obtained from cells treated with 20 μM of farnesylamine.

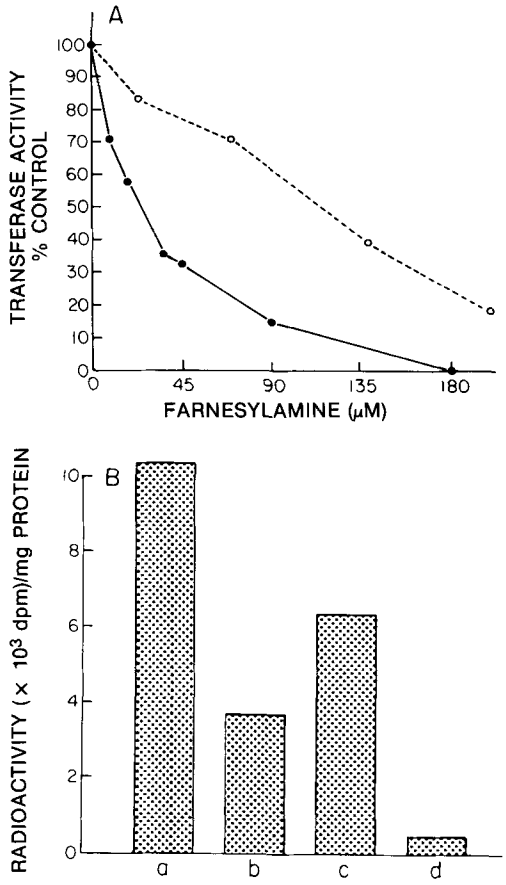

FIG. 3. A: Inhibition of farnesyl/protein transferase and geranylgeranyl/protein transferase in cell extracts by farnesylamine. Details of the assays are given in the text. B: Effect of farnesylamine on the synthesis of farnesylated proteins in intact cells. *ras*-Transformed NIH 3T3 cells were labelled with [^{3}H]mevalonic acid, and total proteins were extracted and precipitated with trichloroacetic acid (TCA) or with antibodies raised against *ras* protein. a, Total TCA precipitable protein in control; b, total TCA precipitable protein in farnesylamine-treated cells; c, immunoprecipitable protein in control cells; d, immunoprecipitable protein in farnesylamine-treated cells.

TABLE 3

Biosynthesis of Other Isoprenoid Compounds in Presence or Absence of Farnesylamine in the Medium[a]

Compound	Control (dpm/100 mg of cells)	Farnesylamine treated (dpm/100 mg of cells)
Cholesterol	26,501	37,792
Dolichol	1,387	1,841
Coenzyme Q	1,095	1,291

[a]*ras*-Transformed NIH 3T3 cells were labelled with [^{3}H]mevalonic acid. After 16 h, total lipids were extracted and saponified. The non-saponified lipids were extracted, and the amount of radioactivity incorporated into various compounds was measured as indicated in the Materials and Methods section.

that the farnesyl moiety was transferred from FPP to proteins and that the transfer was inhibited by farnesylamine. Farnesylamine was similarly shown to inhibit geranylgeranyl/protein transferase activity (Fig. 3A).

To confirm that farnesylamine affects the formulation of farnesylated proteins in intact cells, particularly *ras* proteins, PAP2 cells were labelled with [^{3}H]MVA in the presence or absence of farnesylamine, and total proteins were extracted. A portion of the extracted proteins was precipitated with TCA and filtered through a glass fiber filter. The remaining portion was immunoprecipitated by anti-v-H-*ras* monoclonal antibody (Ab-1, clone Y13-259). The amount of radioactivity incorporated into total protein and *ras* proteins was determined. Prenylation of total proteins was inhibited by 60% and prenylation of *ras* protein by 90% in farnesylamine-treated cells (Fig. 3b).

Effect of farnesylamine on biosynthesis of other isoprenoid compounds. Increased synthesis of cholesterol, dolichol and coenzyme Q was observed in cells treated with farnesylamine compared to untreated cells (Table 3).

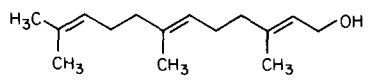
DISCUSSION

Analogues of purines have been prepared and successfully used as anticancer drugs (46). As part of a similar strategy, we synthesized and tested farnesylamine, an amino analogue of farnesol (Scheme 1).

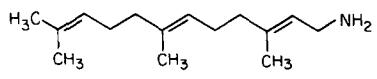
Farnesylamine inhibited the growth of PAP2 cells more effectively than various straight-chain, saturated fatty amines. The inhibition by farnesylamine could be overcome by farnesol, but not by other isoprenoids or fatty acids (Table 1). This suggested that farnesylamine was acting by specifically interfering with farnesylation of proteins, particularly *ras* protein. The inhibition of cell growth by other amines could not be overcome by farnesol, and they may be acting by some other mechanism, such as inhibition of protein kinase C (47).

Our experiments showed that farnesylamine inhibits farnesyl/protein transferase, which catalyzes the transfer of farnesol from FPP to the protein (Fig. 3A). Further experiments also showed that prenylation of *ras* protein by PAP2 cells was inhibited to a greater extent than prenylation of the cellular proteins as a whole (Fig. 3B).

Farnesylamine also inhibited geranylgeranyl/protein transferase *in vitro* (Fig. 3A). Farnesyl and geranylgeranyl transferases have a common α-subunit for substrate binding (48), so farnesylamine may be inhibiting both enzyme activities by interacting with that subunit. It is possible that inhibition of geranylgeranylation of proteins may be



FARNESOL



FARNESYLAMINE

SCHEME 1

partly responsible for the growth inhibition by farnesylamine. However, the fact that the inhibition could be overcome by farnesol and not by geranylgeraniol suggests that inhibition of farnesylation may be a more important factor. It should also be noted that *ras* protein is greatly overexpressed in PAP2 and is probably largely responsible for the increased growth potential of these cells.

The FPP that serves as a substrate for farnesylation of proteins by farnesyl/protein transferase is most probably derived from the mevalonate biosynthetic pathway. If less of it is utilized for farnesylation, more will be available for conversion to other products of the pathway. This could account for the increased biosynthesis of cholesterol, dolichol and coenzyme Q in PAP2 cells treated with farnesylamine compared to controls (Table 3).

Overall, these results suggest that inhibition of the growth of PAP2 cells by farnesylamine is due primarily to inhibition of farnesylation of proteins, particularly *ras* p21, with farnesylamine acting as an inhibitor of farnesyl/protein transferase. This provides a means of investigating the role of *ras* in cellular metabolism and suggests a novel approach to controlling *ras*-mediated malignant cell growth.

ACKNOWLEDGEMENTS

We thank V. Kuikuero and D.H. Hunter for their advice and for NMR analysis of farnesylamine; S.M. Wilson and F.N. Ali for assistance with the growth curve; D.T. Denhardt and W.C. McMurray for critical reading of the manuscript; and Charlotte Harman for typing the manuscript. This work was supported by the Medical Research Council of Canada and the National Cancer Institute of Canada.

The phospholipid and associated fatty acid compositions of the bacterial symbiont of clover, *Rhizobium leguminosarum* biovar *trifolii* wild-type ANU843, was analyzed by two-dimensional silica thin-layer chromatography, fast atom bombardment–mass spectrometry, flame-ionization detection gas–liquid chromatography and combined gas–liquid chromatography/mass spectrometry. The phospholipid composition included phosphatidylethanolamine (15%), *N*-methylphosphatidylethanolamine (47%), *N,N*-dimethylphosphatidylethanolamine (9%), phosphatidylglycerol (19%), cardiolipin (5%) and phosphatidylcholine (2%). Fatty acid composition included predominantly *cis*-11-octadecenoic acid, lower levels of *cis*-9-hexadecenoic acid, hexadecanoic acid, 11-methyl-11-octadecenoic acid, octadecanoic acid, 11,12-methyleneoctadecanoic acid, eicosanoic acid and traces of branched, and di- and triunsaturated fatty acids. The influence of expression of the "nodulation" genes encoding symbiotic functions on the composition of these membrane lipids was examined in wild-type cells grown with or without the flavone inducer, 4′,7-dihydroxyflavone and in mutated cells lacking the entire symbiotic plasmid where these genes reside, or containing single transposon insertions in selected nodulation genes. No significant changes in phospholipid or associated fatty acid compositions were detected by the above methods of analysis.

Lipids 28, 975–979 (1993).

The initiation of the nitrogen-fixing root-nodule symbiosis between *Rhizobium* and its legume host involves extensive bilateral signaling. In response to plant-excreted flavonoids, several nodulation (*nod*) genes residing on the large symbiotic plasmid (pSym) of *Rhizobium* are expressed, and their action fulfills pivotal roles in the establishment of the bacteria-plant symbiotic program. Several pSym Nod proteins are membrane-associated and are proposed to be involved in the synthesis of a family of acylated chitooligosaccharides (1–3). Although these glycolipids were initially isolated from culture supernatants and thus considered extracellular, their amphiphilic character argues that they reside primarily in bacterial membranes. Recently, we obtained evidence of the membrane association of such acylated glucosaminoglycans (Orgambide, G.G., Hollingsworth, R.I., and Dazzo, F.B., unpublished data). Furthermore, we previously reported the characterization of a membrane-associated diglycosyl diacylglycerol (BF-7) from *Rhizobium leguminosarum* biovar *trifolii* (*R. trifolii*) ANU843 (4), a wild-type strain used extensively in studies of the *Rhizobium*-clover symbiosis. In subsequent studies, we found that cellular accumulation of BF-7 was increased when ANU843 was grown in the presence of the *nod* gene inducer 4′,7-dihydroxyflavone (DHF) and reduced in a *nodA*::Tn*5* mutant derivative (5). Since the above *nod*-influenced glycolipids are all minor membrane components, we wondered whether flavone-activated expression of *nod* genes also affects the composition of the major class of membrane lipids, namely the phospholipids. An earlier study addressing this question concluded that *nod* gene expression does not influence the phospholipid composition of the alfalfa symbiont, *R. meliloti* (6). However, a recent preliminary report suggested that induction of *nodFE* gene expression in the pea symbiont, *R. leguminosarum* bv. *viciae*, resulted in *de novo* synthesis of phospholipids with specific polyunsaturated fatty acids (7).

In the present study, we examined the phospholipid and associated fatty acid compositions of *R. trifolii* ANU843 grown in defined medium, and evaluated the effect of alterations in pSym *nod* composition and of the *nod* gene inducer DHF on this major class of membrane lipids.

MATERIALS AND METHODS

Bacterial cultures and preparation of the lipid extract. Strains of *R. trifolii* used were wild-type ANU843, its pSym-cured derivative ANU845 and transposon insertion *nod* mutant derivatives of ANU843, including strains ANU851 (*nodD*::Tn*5*), ANU252 (*nodA*::Tn*5*), ANU258 (*nodE*::Tn*5*), ANU251 (*nodL*::Tn*5*), ANU896 (*nodM*::mud*lacZ*) and ANU895 (*nodN*::mud*lacZ*), all kindly provided by B. Rolfe, Australian National University, Canberra, Australia (see Ref. 8 for strain characteristics). Bacteria were grown aerobically at 30°C in defined BIII broth (9), with or without 4 μM DHF, and harvested by centrifugation in late exponential phase at a density of 7.5×10^8 cells/mL. The cell pellet was washed twice with water, extracted by stirring with 100 mL chloroform/methanol/water (2:1:0.5, by vol), for 20 h at 25°C under a nitrogen atmosphere, and the organic extract was then filtered through a Millipore GVWP04700 (0.22 μm) membrane (Milford, MA). In comparison with a Bligh and Dyer extraction (10) from the same batch of ANU843 cells, this extraction procedure yielded the same pattern of phospholipids in silica thin-layer chromatography (TLC) but with a slightly higher recovery. The phospholipid extract represented approximately 10% (w/w) of the dry cell residue for all cultures. Phospholipid composition of transposon-insertion *nod* mutants was compared to ANU843 and ANU845 based on silica TLC of lipid extracts from

Abbreviations: CL, cardiolipin; DHF, 4′,7-dihydroxyflavone; DMPE, *N,N*-dimethylphosphatidylethanolamine; FAB-MS, fast atom bombardment–mass spectrometry; FID-GLC, flame-ionization detection gas–liquid chromatography; GLC/MS, gas–liquid chromatography/mass spectrometry; MPE, *N*-methylphosphatidylethanolamine; PC, phosphatidylcholine; PE, phosphatidylethanolamine; PG, phosphatidylglycerol; pSym, symbiotic plasmid; TLC, thin-layer chromatography.

cells grown at 30°C for 5 d on BIII plates containing 4 μM DHF and solidified with 1% purified agar.

Characterization of the phospholipid components. Phospholipid extracts were analyzed by fast atom bombardment-mass spectrometry (FAB-MS) using a JEOL HX-110 mass spectrometer (JEOL USA, Peabody, MA) at an accelerating voltage of 10 kV, and *m*-nitrobenzyl alcohol and triethanolamine as matrices for positive and negative mode analyses, respectively. Individual phospholipid classes were purified from the lipid extract of ANU843 cells by two-dimensional TLC on silica plates (Whatman, Hillsboro, OR), preactivated for 1 h at 100°C, with chloroform/methanol/ammonia (70:35:5, by vol) as solvent for dimension I and chloroform/acetone/methanol/acetic acid/water (10:4:2:2:1, by vol) for dimension II and characterized by FAB-MS. Fatty acid methyl ester derivatives were prepared by alkaline methanolysis (11) of an aliquot of the phospholipid extracts. Fatty acid derivatives were identified by gas-liquid chromatography/mass spectrometry (GLC/MS), using a Hewlett-Packard 5890 gas chromatograph (Palo Alto, CA) fitted with a DB-1 column and coupled to a JEOL AX505H mass spectrometer (JEOL USA), by matching both their retention times and mass spectra to those of authentic standards. Quantification was by flame-ionization detection gas-liquid chromatography (FID-GLC), using a Hewlett-Packard 5890 instrument fitted with a DB-1 column.

Phospholipid quantitation. Silica TLC plates of phospholipid extracts were sprayed with either phosphomolybdic acid (phospholipid stain) or sulfuric acid/methanol (25:75, vol/vol, universal stain), followed by heating at 150°C. Densitometry was performed using a high-resolution charge-coupled device camera and an Ambis Optical Imaging System (San Diego, CA) with individual background subtraction for each spot. The relative abundance of each phospholipid class was calculated from densitometry values obtained from phosphomolybdic acid- and H_2SO_4-stained plates, corrected for the specific staining response of phospholipid standards. Values reported are an average from two independent batch cultures of ANU843 − DHF, ANU843 + DHF, and ANU845 + DHF.

RESULTS AND DISCUSSION

Phospholipid and fatty acid composition of R. trifolii *ANU843 grown without DHF.* Two-dimensional silica TLC of the phospholipid extract obtained from ANU843 separated several classes of phospholipid components (Fig. 1A). Negative mode FAB-MS analysis of each isolated lipid class led to the identification of *N*-methylphosphatidylethanolamine (MPE) (yielding quasimolecular ions $[M-H]^-$ at *m/z* 756 [predominant], 758, 770, 784, 798, daughter ion fragments formed by elimination of *N*-methyl-vinylamine [−57 amu], and low-mass diagnostic ions at *m/z* 154 and 194), and *N,N*-dimethylphosphatidylethanolamine (DMPE) (quasimolecular ions at *m/z* 744, 770 [predominant], 772, 784, daughter ion fragments formed by elimination of *N,N*-dimethyl-vinylamine [−71 amu] and low-mass diagnostic ions at *m/z* 168 and 208) (12). The analysis also revealed the presence of phosphatidylglycerol (PG) (quasimolecular ions at *m/z* 747, 773 [predominant], 775, 787, 789, 845, daughter ion fragments formed by elimination of dehydrated glycerol [−74 amu],

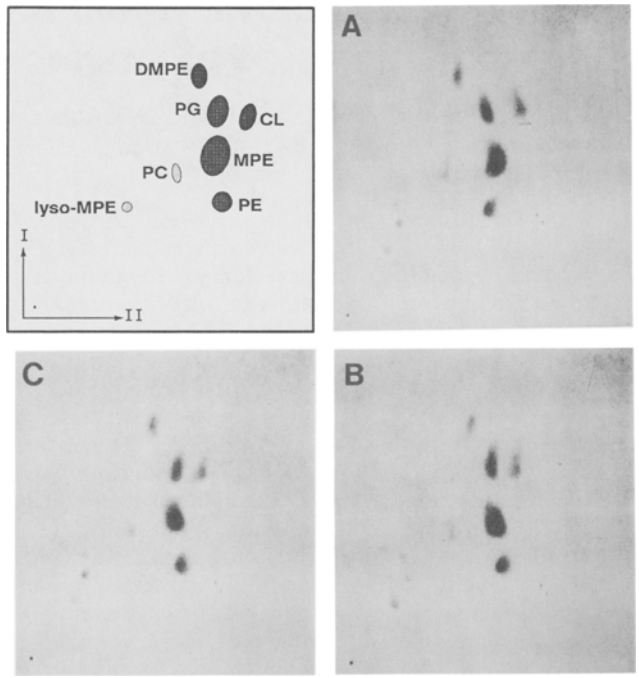

FIG. 1. Two-dimensional silica thin-layer chromatography analysis of phospholipid extracts from: (A) ANU843 wild-type grown without 4′,7-dihydroxyflavone (DHF), (B) ANU843 grown in presence of 4 μM DHF, (C) symbiotic plasmid-cured derivative ANU845 grown with 4 μM DHF (staining: 25% H_2SO_4 in methanol, 150°C). Abbreviations: DMPE, *N,N*-dimethylphosphatidylethanolamine; PG, phosphatidylglycerol; PC, phosphatidylcholine; CL, cardiolipin; MPE, *N*-methylphosphatidylethanolamine; PE, phosphatidylethanolamine.

and low-mass diagnostic ions at *m/z* 153, 171 and 211), and cardiolipin (CL) (quasimolecular ions at *m/z* 1453, 1455, 1457, 1459, 1479, 1481, 1483, 1493, 1495, 1497, fragment ions produced by loss of the acyl glycerol portion of one phosphatidic acid group and/or elimination of fatty acyl residues, and prominent low-mass ions at *m/z* 137 [glycidol phosphate] and 153 [allyl phosphate]) (13). The identity of PG and CL was further verified by cochromatography on silica TLC of the phospholipid extract with PG or CL authentic standards. Phosphatidylethanolamine (PE) was identified as a fifth phospholipid in the extract based on a mass spectrum showing quasimolecular ions at *m/z* 676, 690, 702, 716, 718, 732, positive reaction to ninhydrin staining, and cochromatography with a standard. Only minute amounts of product were recovered from two minor TLC fractions, and their mass spectra yielded tentative assignments to phosphatidylcholine (PC) (also supported by cochromatography with a PC standard), and lyso-MPE. Upon positive mode FAB-MS analysis of the phospholipid extract, PE, MPE and DMPE species provided prominent molecular ions $[(M + H)^+$ and $(M + Na)^+]$, high-mass fragments and low-mass diagnostic ions consistent with the molecular species identified in negative mode, and with literature data (12,13), whereas the acidic species PG and CL were barely detected. The occurrence of PC (primarily as dioleoyl species) was confirmed by this positive mode FAB-MS analysis showing pseudomolecular ions $(M + H)^+$ and $(M + Na)^+$ at *m/z* 786 and 808, a fragment ion generated by loss of phosphocholine from $(M + H)^+$ at

m/z 603 (this connection between the two ions was verified by mass spectrometry/mass spectrometry analysis), and low-mass diagnostic ions at *m/z* 184 and 224 (12,13). Based on densitometry of the digitized TLC plate, the relative abundance of the different phospholipids in the ANU843 cell extract were: PC 2%, DMPE 9%, MPE 47%, PE 15%, PG 19%, CL 5.0%, and lyso-MPE 3%.

Alkaline methanolysis of the ANU843 phospholipid extract, followed by GLC/MS characterization and FID-GLC quantitation of the fatty acid methyl esters, revealed the large predominance of *cis*-11-octadecenoic acid (18:1), together with low levels of *cis*-9-hexadecenoic acid (16:1), hexadecanoic acid (16:0), 11-methyl-11-octadecenoic acid (11-Me-18:1; Ref. 14), octadecanoic acid (18:0), 11,12-methyleneoctadecanoic acid (19:0Δ) and eicosanoic acid (20:0) (Table 1). Minute amounts (<0.1%) of tetradecanoic acid (14:0), *iso*-pentadecanoic acid (*i*-15:0), *iso*-hexadecanoic acid (*i*-16:0), *anteiso*-heptadecanoic acid (*a*-17:0), *iso*-heptadecanoic acid (*i*-17:0), 9,10-methylenehexadecanoic acid (17:0Δ) and heptadecanoic acid (17:0) fatty acid methyl esters were also detected by FID-GLC. Negative mode FAB-MS analysis of the phospholipid samples also suggested the presence of trace amounts of several unusual fatty acids detected by their carboxylate anion at *m/z* 279 (18:2), 297 (19:0 or hydroxy-18:1), 305 (20:3), 307 (20:2), 309 (20:1), 325 (21:0 or hydroxy-20:1), 337 (22:1), and 339 (22:0 or hydroxy-21:1).

Effect of DHF and pSym on growth rate of R. trifolii *ANU843.* Previous studies showed that 4 μM DHF supplement to BIII broth activates the expression of pSym *nod* genes at least 10-fold higher than the constitutive background level in ANU843 (8,15). The exponential growth rates of ANU843 grown in BIII broth with or without 4 μM DHF, and the pSym-cured derivative ANU845 grown with 4 μM DHF, were 0.29, 0.36 and 0.46 generation/hour, respectively. These results indicate that DHF at 4 μM partially inhibits growth of ANU843 and that this inhibition is pSym-dependent.

Evaluation of the influence of DHF and pSym nod *genes on phospholipid and associated fatty acid compositions of* R. trifolii *ANU843.* The phospholipid extracts obtained from cells of standardized broth cultures of ANU843 grown with or without DHF, and from the pSym-cured derivative ANU845 grown with DHF, were compared by FAB-MS analysis, two-dimensional silica TLC with video densitometry quantitation and FID-GLC analysis of fatty acid methyl esters. These analyses did not reveal major changes in phospholipid or associated fatty acid composition of these three cultures (Figs. 1-3, Table 1), including the fatty acids detected in trace amounts by negative mode FAB-MS analysis as described above. A silica TLC survey of the polar lipid composition of mutant derivatives of ANU843 containing transposon insertions in selected *nod* genes (*nodD, nodA, nodE, nodL, nodM* or *nodN*) from the four operons in the 14 Kb *Hind*III pSym *nod* region (15) was also performed. When phosphomolybdic acid was used to detect phospholipids, all strains displayed the same qualitative and quantitative pattern (data not shown). However, a universal stain (25% H_2SO_4 in methanol, 150°C) revealed slight differences among minor lipids in the extracts from wild-type and *nod* mutants (Fig. 4). Since these minor lipids did not stain with phosphomolybdic acid (thus were unlikely to be phospholipid components), and were below detection by two-dimensional TLC, they were not investigated further in this study.

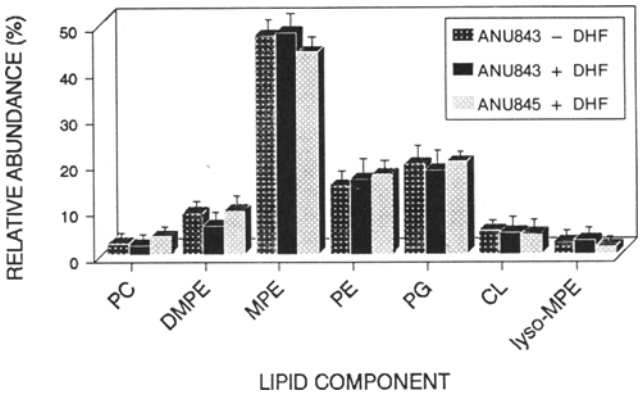

FIG. 2. Relative abundance of individual phospholipid classes in the lipid extracts from *R. trifolii* wild-type ANU843 grown without DHF (ANU843 − DHF), ANU843 grown in presence of 4 μM DHF (ANU843 + DHF), and pSym-cured derivative ANU845 grown with 4 μM DHF (ANU845 + DHF). The minor components from both ANU843 and ANU845 present in the lower left quadrant of the thin-layer chromatography plates (Fig. 1) were not included in this quantitative evaluation since the subtle variations in their relative intensity were not reproducible. See Figure 1 for abbreviations.

TABLE 1

Relative Abundance of Individual Fatty Acid Species in the Phospholipid Extracts from *R. trifolii* Wild-Type ANU843 Grown Without DHF (843-DHF), ANU843 Grown in Presence of 4 μM DHF (843 + DHF), and pSym-cured Derivative ANU845 Grown with 4 μM DHF (845 + DHF)

Phospholipid extract	Fatty acid (%)[a]						
	16:1	16:0	18:1	18:0	11-Me-18:1	19:0Δ	20:0
843 − DHF	1.0 (0.05)	3.3 (0.30)	81.0 (0.95)	11.0 (0.60)	1.1 (0.35)	2.4 (0.20)	0.2 (0.04)
843 + DHF	0.9 (0.25)	3.2 (0.30)	81.5 (1.15)	10.7 (0.35)	1.0 (0.05)	2.5 (1.10)	0.2 (0.07)
845 + DHF	0.9 (0.05)	3.2 (0.30)	82.1 (0.80)	10.4 (0.50)	1.1 (0.20)	2.0 (0.35)	0.3 (0.11)

[a]% of total fatty acids. Values in parentheses correspond to the standard error of the means. See text for full definition of each fatty acid. DHF, 4',7-dihydroxyflavone; pSym, symbiotic plasmid.

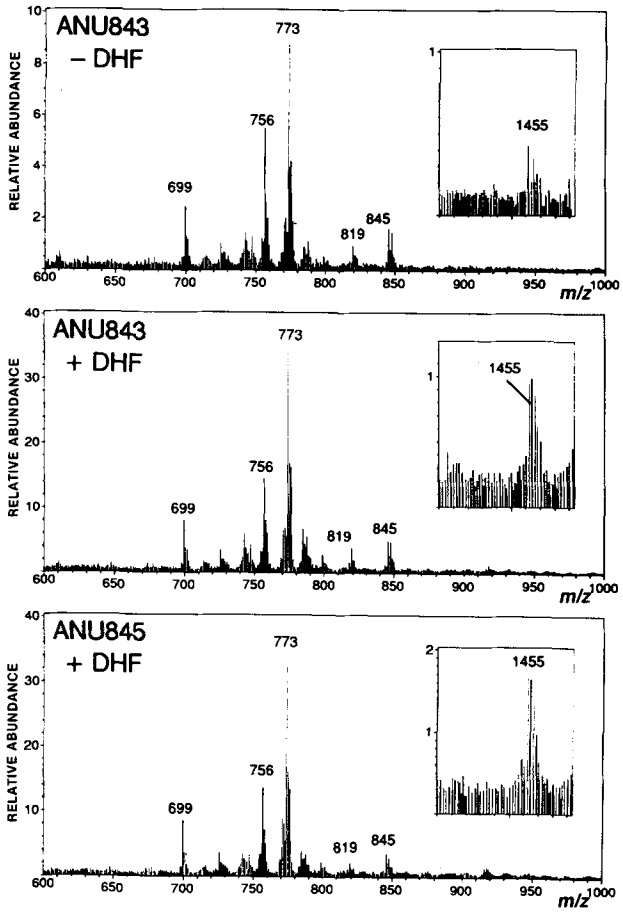

FIG. 3. Negative mode fast atom bombardment-mass spectrometry spectra of phospholipid extracts from ANU843 wild-type grown without DHF, ANU843 grown in presence of 4 μM DHF, and pSym-cured derivative ANU845 grown with 4 μM DHF (see text for ion assignments). See Figure 1 for abbreviations.

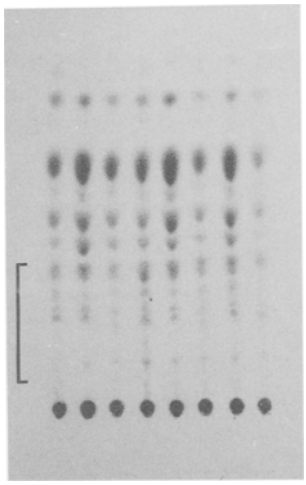

FIG. 4. One-dimensional thin-layer chromatography (TLC) analysis of phospholipid extracts from: (1) ANU843 wild-type, and various mutant derivatives (2) *nodD*::Tn*5*, (3) *nodA*::Tn*5*, (4) *nodE*::Tn*5*, (5) *nodL*::Tn*5*, (6) *nodM*::mud*lacZ*, (7) *nodN*::mud*lacZ*, (8) pSym-cured ANU845 (solvent: chloroform/methanol/ammonia, 70:35:5, by vol; staining: 25% H_2SO_4 in methanol, 150°C). Bracket indicates the area of the TLC where minor changes are observed.

The predominance of components of the PE series (PE, MPE, DMPE), together with significant amounts of PG and CL in *R. trifolii* ANU843, is consistent with data reported for certain other *Rhizobiaceae* isolates, including *R. meliloti* (6,16), the soybean symbiont *Bradyrhizobium japonicum* (17,18) and species of the plant pathogen *Agrobacterium* (19). In contrast, *R. loti* contained high amounts of phosphatidylserine and phosphatidylinositol (20), and an isolate of *R. leguminosarum* (bv. *viciae*) lacked MPE (21). A major difference in phospholipid composition between ANU843 and the other isolates of *Rhizobiaceae* reported is the level of PC (2% in ANU843, whereas it exceeds 20% in the other isolates). The relative level of PC in *A. tumefaciens*, as well as in *R. meliloti*, has been shown to increase with progression of cultures from exponential to stationary phase (16). The fact that *R. trifolii* ANU843 cells in the present study were harvested while in exponential rather than stationary phase might explain why they contained a low proportion of PC.

Several previous lines of evidence suggested that flavone-induced pSym *nod* expression modulates the accumulation of membrane-associated Nod proteins and minor membrane glycolipids. In the present study we addressed whether the phospholipids and their associated fatty acids were also altered when *Rhizobium* was grown to express its pSym *nod* genes. A second reason to test this possibility was our finding that ANU843 exhibits a pSym-dependent inhibition of growth in defined medium when DHF is added to activate *nod* expression. A combination of one- and two-dimensional TLC, FAB-MS, FID-GLC and GLC/MS analyses detected no significant difference in these membrane components between cultures of wild type *R. trifolii* ANU843 and its pSym-cured derivative ANU845 after at least seven generations in flavone induction medium. Thus, in wild-type ANU843, minor membrane glycolipids appear to be more central than phospholipids to the *nod*-encoded metabolism that enables the development of the *Rhizobium*-clover symbiosis.

ACKNOWLEDGMENTS

The authors thank R.N. Reusch, R.I. Hollingsworth and B. D. Jarvis for valuable discussions, and B.A. Chamberlin for skillful assistance with the GLC/MS analysis of the fatty acids. In the present study, we examined the effect of the following factors on a hamster model of cholesterol cholelithiasis: (i) the source of the golden Syrian hamsters (Sasco, Omaha, NE or Charles River, Wilmington, MA), (ii) the sex of the experimental animals and (iii) their age (4 wk *vs.* 8 wk of age). All hamsters were fed a semipurified diet which contained cholesterol (0.3%) and palmitic acid (1.2%). No cholesterol gallstones formed in any of the female hamsters regardless of age or source. The 4-week-old male hamsters from Sasco had the greatest incidence of gallstones (93%). The 8-week-old male hamsters tended to have a lower incidence of cholesterol gallstones than the younger ones, regardless of the commercial supplier (67 *vs.* 93% for Sasco and 27 *vs.* 40% for Charles River). Female hamsters had higher liver and serum cholesterol levels than the male hamsters; Charles River hamsters had lower serum cholesterol concentrations than the Sasco animals. Total biliary lipid concentrations were highest in Sasco male hamsters, but biliary cholesterol (mol%) was lower in the males than in the females (4.2–4.5% *vs.* 6.1–7.1%) regardless of age. The cholesterol saturation indices were higher in the Sasco females than the corresponding males; these values were lower in the Sasco hamsters than the Charles River animals, regardless of age or sex. The male Sasco hamsters had a higher total biliary bile acid concentration (98.9 mg/mL) than the Sasco females (58.9 mg/mL) and the Charles River animals (24.6 mg/mL for males and 38.2 mg/mL for females). The percentage of chenodeoxycholic acid in bile was significantly lower, and the percentage of cholic acid was higher in all females as compared to males. We conclude that there is a sex, age and "strain" difference in cholesterol cholelithiasis in hamsters; it is important to consider these factors when working with the hamster model of gallstone disease. All female hamsters were markedly resistant to the induction of cholesterol gallstone disease.

Lipids 28, 981–986 (1993).

A number of hamster models has been used to study cholesterol cholelithiasis (1–5). In our laboratory, hamsters are fed a nutritionally adequate semipurified diet (SPD) containing cholesterol (0.3%) and butterfat (4.0%) to produce cholesterol gallstones in 50–60% of the animals (6). When palmitic acid, a major fatty acid component of butterfat, was substituted for butterfat, gallstone incidence increased to 90% or higher (7). These earlier studies used young (4-week-old) male golden Syrian hamsters from Sasco Inc. (Omaha, NE), since these animals gave the best and most reproducible incidence of cholesterol stones. Hamsters from other commercial suppliers (such as, Charles River Breeding Labs, Wilmington, MA) were significantly less susceptible to the development of gallstones (5,6).

We have now examined the effect of age (4-week-old *vs.* 8-week-old hamsters), sex (male *vs.* female animals) and commercial source of hamster (Sasco *vs.* Charles River) on the incidence of cholelithiasis. All animals were fed a lithogenic diet containing 0.3% cholesterol and 1.2% palmitic acid. Our results showed that male Sasco hamsters, 4 wk of age, had the greatest incidence of gallstones. Gallstone incidence tended to decrease in the older, 8-wk, animals. Interestingly, no cholesterol gallstones formed in any female hamsters, regardless of age or source.

MATERIALS AND METHODS

Animals. Male and female, golden Syrian hamsters (*Mesocricetus auratus*), 4-week-old (48–62 g) and 8-week-old (93–111 g), were obtained from two different suppliers, namely, Sasco and Charles River. The animals were maintained with water and Purina rodent chow *ad libitum* for a 1-wk quarantine period prior to the start of the experiment. All hamsters were fed the following pelleted, color-coded lithogenic diet (Dyets, Inc., Bethlehem, PA): 46.2% corn starch, 20.0% casein, 14.6% dyetrose (soluble starch), 10.0% fiber (cellulose), 5.0% salt mix (modified U.S.P. XIV salt mix, no. 200951), 2.0% corn oil, 1.2% palmitic acid, 0.5% vitamin mix (no. 300000), 0.3% cholesterol, 0.2% choline chloride. The hamsters were randomly divided into eight groups as follows: group 1, 4-week-old Sasco males; group 2, 4-week-old Sasco females; group 3, 4-week-old Charles River males; group 4, 4-week-old Charles River females; group 5, 8-week-old Sasco males; group 6, 8-week-old Sasco females; group 7, 8-week-old Charles River males; group 8, 8-week-old Charles River females. At the end of the 6-wk feeding period, the hamsters were fasted for 24 h and then anesthetized with 20 mg of ketamine hydrochloride (Aveco Co., Inc., Fort Dodge, IA). Blood was withdrawn by cardiac puncture for the determination of serum cholesterol. The gallbladder was examined for the presence of gallstones. Bile was removed with a syringe and examined under a polarizing light microscope (Olympus MCHAP microscope; Olympus Corp., Lake Success, NY) for the presence of cholesterol crystals or liquid crystals. The remaining bile was aliquoted for the determination of biliary lipids. The liver was excised and weighed, and portions were taken for cholesterol analysis. Liver segments from hamsters in the 4-week-old categories were fixed in Millonig's buffered formalin, then embedded in paraffin, sectioned and stained with hematoxylin and eosin. Using a grade scale of 0 to ++++, the pathologist

Abbreviations: CA, cholic acid; CDCA, chenodeoxycholic acid; CSI, cholesterol saturation index (indices); DCA, deoxycholic acid; 7-keto-DCA, 3α,12α-dihydroxy-7-keto-5β-cholenic acid; FT-IR, Fourier transform infrared; SPD, semipurified diet.

evaluated the sections without knowledge of the treatment category of the hamsters. This procedure was similar to that used in a prior study (8).

Analytical procedures. Biliary bile acids were determined as the methyl ester acetates using a SPB-5 15 m capillary column (Supelco, Bellefonte, PA) attached to a Hewlett-Packard 5890 gas chromatograph (Hewlett-Packard, Palo Alto, CA); 3α, 7α-dihydroxy-12-keto-5β-cholanoic acid was used as an internal standard (8). Biliary phospholipids were determined by an enzymatic-colorimetric procedure using the Wako phospholipid B kit (Wako Pure Chemical Industries, Ltd., Osaka, Japan). Cholesterol concentrations of bile, liver and serum were determined by gas–liquid chromatography on a 0.5% OV-210 packed column, using 5α-cholestane as an internal standard as described previously (9).

Gallstones were analyzed by diffuse reflectance Fourier transform infrared (FT-IR) spectroscopy, using a Perkin-Elmer 1710 spectrometer (Perkin-Elmer Corp., Norwalk, CT) attached to a Perkin-Elmer 7500 laboratory computer (10).

Calculations and statistics. The cholesterol saturation indices (CSI) were determined using published methods (11,12). The data were reported as the mean ± SD. Differences between the various experimental groups were calculated using ANOVA to determine the F statistic; Student's *t*-test was applied to those values for which the F statistic was significant ($P < 0.05$) (13,14).

RESULTS

All hamsters were fed the experimental diets for a 6-wk period. The animals remained healthy throughout the experiment. The 4-week-old males, from either Sasco or Charles River, gained more weight than the corresponding female hamsters (Table 1); 44 *vs.* 32 g for Sasco and 50 *vs.* 34 g for Charles River. The 8-week-old hamsters maintained the same weight or gained less weight than the corresponding 4-week-old animals. There were no significant differences in food intake (10–11 g/d) for all eight groups. On the average, liver weights of female hamsters were larger than males for both Sasco (groups 2 and 6 *vs.* groups 1 and 5; 6.8 and 8.3 *vs.* 6.2 and 6.1 g) and Charles River (groups 4 and 8 *vs.* groups 3 and 7; 5.4 and 7.5 *vs.* 5.6 and 6.0 g).

In all hamsters from the 4-week-old categories, the liver sections revealed minimal (+) bile duct proliferation in the portal tracts. In the livers of the Sasco hamsters, both male and female, the bile duct proliferation was accompanied by a mild (+) infiltration of mononuclear cells, mostly small lymphocytes. This was conspicuously absent from the portal tracts of the Charles River animals. Microvesicular parenchymal steatosis was evident in all of the 4-week-old hamsters, generally graded as ++ to +++, except for the Sasco males wherein the steatosis was often minimal (+). The 4-week-old Sasco females also exhibited multiple fatty cysts, a phenomenon that was less prevalent or absent from the livers of hamsters in the other 4-week-old categories. Focal infiltrates of mononuclear cells in the lobular parenchyma were noted in all of the 4-week-old hamster livers, generally graded as +, except for the Sasco females which frequently displayed more prominent parenchymal infiltrates (++ to +++).

Gallstone incidence was determined at sacrifice (Table 2). No cholesterol gallstones formed in any of the female hamsters, regardless of age or source. Cholesterol cholelithiasis in the males showed marked variability. In all cases, the male Sasco hamsters had a greater incidence of cholesterol gallstones than the male Charles River hamsters: group 1 *vs.* group 3, 14/15 *vs.* 6/15 for 4-week-old, and group 5 *vs.* group 7, 10/15 *vs.* 4/15 for 8-week-old animals. The older hamsters tended to have a lower incidence of cholesterol gallstones than the younger animals. Some 8-week-old male Sasco hamsters had pigment stones in the gallbladder (group 5, 4/15). The pigment stones consisted mainly of calcium phosphate, protein and calcium bilirubinate. In the 4-week-old and 8-week-old Charles River animals, females had more pigment stones than the males. A few of the Sasco females had pigment stones but there were no significant differences among the groups.

Table 3 summarizes the cholesterol concentrations in liver, serum and bile. In all cases, regardless of source or age, female hamsters had higher liver cholesterol levels than males: groups 2 and 6 *vs.* groups 1 and 5; 64.30 and 60.52 *vs.* 34.99 and 43.68 mg/g in Sasco hamsters, and groups 4 and 8 *vs.* groups 3 and 7; 60.10 and 57.31 *vs.*

TABLE 1

Body Weight, Food Intake and Liver Weight of Sasco and Charles River Hamsters on the Palmitic Acid Diet[a]

Group	Source	Age/sex	Number of animals	Initital weight (g)	Final weight (g)	Food intake (g/d)	Liver weight (g)
1	Sasco	4 wk-M	15	61 ± 2	105 ± 8[b]	10 ± 1	6.2 ± 0.6[c]
2	Sasco	4 wk-F	13	62 ± 3	94 ± 7	11 ± 1	6.8 ± 0.9
3	Charles River	4 wk-M	15	53 ± 4	103 ± 12[d]	10 ± 1	5.6 ± 0.7

42.02 and 44.51 mg/g in Charles River hamsters. Serum cholesterol in Sasco males (groups 1 and 5, 311 and 326 mg/dL) was lower than in the corresponding female hamsters (groups 2 and 6, 491 and 552 mg/dL) regardless of age. The male Charles River hamsters also had lower serum cholesterol (groups 3 and 7, 294 and 262 mg/dL) compared to the females (groups 4 and 8, 308 and 376 mg/dL); in all cases, Charles River hamsters had lower serum cholesterol than the Sasco animals. Biliary cholesterol was higher in 4-week-old male Sasco hamsters compared to the corresponding Charles River animals (group 1 *vs.* group 3, 4.46 *vs.* 2.36 mg/mL). Four-week-old Charles River males had lower biliary cholesterol levels than 8-week-old males (group 3 *vs.* group 7, 2.36 *vs.* 3.75 mg/mL). Interestingly, 8-week-old Charles River males had significantly higher bile cholesterol than the females (group 7 *vs.* group 8, 3.75 *vs.* 2.56 mg/mL).

Biliary lipids and cholesterol saturation indices are summarized in Table 4. In Sasco hamsters, the mol% biliary cholesterol was lowest in the males (groups 1 and 5, 4.2 and 4.5%) as compared to females (groups 2 and 6, 6.1 and 7.1%) regardless of age. In the Charles River groups, the mol% cholesterol was higher in the 8-week-old *vs.* the 4-week-old animals regardless of sex (groups 7 *vs.* 3, 9.5 *vs.* 7.8% and groups 8 *vs.* 4, 8.7 *vs.* 7.1%). Charles River males had a higher mol% phospholipid than the corresponding Sasco males (groups 3 and 7 *vs.* groups 1 and 5; 14.1 and 17.7 *vs.* 10.9 and 9.9%). The total lipids were higher in Sasco males than the corresponding females (groups 1 and 5 *vs.* groups 2 and 6; 14.9 and 14.6 *vs.* 9.4 and

6.6 g/dL). On the average, the Sasco males had higher total lipids (groups 1 and 5, 14.9 and 14.6 g/dL) than the corresponding Charles River males (groups 3 and 7, 4.1 and 5.2 g/dL); a similar result was observed for the female hamsters (groups 2 and 6 *vs.* groups 4 and 8; 9.4 and 6.6 *vs.* 6.8 and 3.9 g/dL). The CSI were higher in the Sasco females than the males (groups 2 and 6 *vs.* groups 1 and 5; 1.43 and 1.82 *vs.* 0.87 and 1.00). On the average, the Sasco males had lower CSI than the Charles River males (groups 1 and 5 *vs.* groups 3 and 7; 0.87 and 1.00 *vs.* 1.67 and 1.72); similar results were found in female hamsters (groups 2 and 6 *vs.* groups 4 and 8; 1.43 and 1.82 *vs.* 1.36 and 2.49).

Table 5 summarizes the biliary bile acid composition in the gallbladder at the time of sacrifice. Male Sasco hamsters of both ages had a higher total bile acid concentration as compared to the corresponding females (groups 1 and 5 *vs.* groups 2 and 6; 98.9 and 97.0 *vs.* 58.9 and 41.0 mg/mL). The total bile acid concentration did not differ significantly within all four groups of Charles River hamsters. Overall, Charles River animals had lower total bile acid concentrations compared to Sasco hamsters: groups 3 and 7 *vs.* groups 1 and 5; 24.6 and 30.0 *vs.* 98.9 and 97.0 mg/mL for males, and groups 4 and 8 *vs.* groups 2 and 6; 38.2 and 24.4 *vs.* 58.9 and 41.0 mg/mL for females. The female Charles River hamsters tended to have a higher percentage of deoxycholic acid (DCA) than the males (groups 4 and 8 *vs.* groups 3 and 7; 12.7 and 10.8 *vs.* 5.3 and 5.4%). Chenodeoxycholic acid (CDCA) was significantly lower in all Sasco females compared to the males (groups 2 and 6 *vs.* groups 1 and 5; 22.6 and 21.3 *vs.* 38.4 and 36.0%). Similar results were observed for the Charles River hamsters: groups 4 and 8, 27.6 and 25.7% for females *vs.* groups 3 and 7, 40.8 and 43.3% for males. The percentage of cholic acid (CA) was higher for females from either Sasco or Charles River: for Sasco animals, groups 2 and 6 *vs.* groups 1 and 5, 42.9 and 44.9 *vs.* 23.4 and 20.7%; for Charles River animals, groups 4 and 8 *vs.* groups 3 and 7, 46.7 and 46.5 *vs.* 34.7 and 34.4% for females *vs.* males, respectively. The keto bile acid, 3α,12α-dihydroxy-7-keto-5β-cholanoic acid (7-keto-DCA acid), was present in smaller amounts in male Sasco hamsters (groups 1 and 5) 0.3 and 0.5% as compared to the females (groups 2 and 6) 2.9 and 2.8%. The proportion of this bile acid was higher in the Charles River hamsters: groups 3 and 7, 6.6 and 4.8% in males, and groups 4 and 8, 4.4 and 8.3% in females, than in the Sasco hamsters.

DISCUSSION

Attempts to induce cholesterol cholelithiasis in hamsters have given variable results. These differences can be attributed to changes in dietary components (6,15–17) and the source of the hamsters (5,6,18). Our laboratory has spent the last decade studying hamster models of cholelithiasis in an attempt to make them reliable and reproducible. We have now studied the effect of age, sex and source of hamsters on gallstone incidence.

Male and female hamsters, 4-week-old and 8-week-old from Sasco or Charles River, were fed nutritionally adequate SPDs containing 0.3% cholesterol and 1.2% palmitic acid for a 6-wk period. We have previously reported that the substitution of palmitic acid for butterfat in a lithogenic diet enhanced cholesterol gallstone

incidence in the 4-week-old male golden Syrian hamster from Sasco (7). The 8-week-old animals had initial weights similar to the final weights of the 4-week-old animals (groups 1–4). In the present study, palmitic acid did not enhance cholelithiasis in female hamsters as it did in males; no cholesterol gallstones formed in any of the females. Male Sasco hamsters had the greatest incidence of stones. In general, the cholelithiasis was more severe in young (4-week-old) hamsters than in the older (8-week-old) animals. The opposite effect has been found in humans, where gallstone incidence is more prevalent in females with increasing age (19). Dam (16), who studied hamsters many years ago, had shown that young hamsters tended to have more cholesterol gallstones than older animals. In addition, male hamsters tended to have a higher incidence of cholesterol stones than females. However, under the conditions employed, females, too, formed cholesterol gallstones (16). This is different from our results with female hamsters who had no stones. It should be noted that Dam's hamsters were of a different source, frequently became ill and died prematurely on the fatty acid-deficient diet. Hikasa *et al.* (20) also demonstrated the influence of age on the production of gallstones in the hamster, with the younger hamsters having a higher incidence. Trautwein *et al.* (21) recently published a comparison of gallstone incidence in three strains of hamsters: Charles River, Biobreeder (Ottawa, Canada) and Harlan Sprague-Dawley (Indianapolis, IN). Their study was not strictly comparable to the present experiments, since they used a "Dam-type" diet which contained 5% butter as fat, but very little essential fatty acids (21). A strain difference for gallstone incidence was observed, but the number, 5–7, of animals used was too small for statistical comparison.

Although female hamsters did not form cholesterol stones, they had high CSI. Cholesterol saturation of bile is a necessary, but obviously not the only, determinant of cholesterol stone formation (22). Our previous study and those of others have shown that there is an increase in cholesterol saturation of bile with advancing age in both sexes (23). However, total biliary lipid concentrations were significantly lower in female hamsters than in males. Studies in humans showed that nucleation times were prolonged in dilute gallbladder bile despite a very high CSI; concentrated bile had short nucleation times despite a relatively low CSI (24,25). In addition, individuals with a supersaturated bile may not form stones because the time required for cholesterol to nucleate may be longer than the residence time of the bile in the gallbladder (26). In our experiment, since female hamsters from both sources had more dilute bile than males, the nucleation time might have been prolonged, and gallstones did not form.

Cholesterol is solubilized in bile in two different forms: (i) vesicles composed mainly of cholesterol and phospholipid and (ii) micelles composed of cholesterol, phospholipid and bile salt (27–29). Cholesterol is known to nucleate from the vesicles; vesicles with a high cholesterol/phospholipid ratio are more prone to nucleation (30–33). Dilute bile may have a smaller amount of cholesterol in the vesicular form and therefore does not nucleate. In our experiments, the male Sasco hamsters have a twofold higher bile acid concentration in the gallbladder than the female hamsters from Sasco or the Charles River hamsters of either sex. Hamsters from Charles River have very dilute bile; the males have even more dilute bile than the females from Sasco, yet a small percentage of these hamsters formed gallstones. There must be other factor(s) besides biliary total lipid concentration that make female hamsters resistant to cholesterol gallstone formation; a hormonal effect should be considered. It is also reported that bile contains nucleating or antinucleating agents, presumably proteins, that play a role in cholesterol nucleation or lack thereof (34–37).

It has been shown that administration of estrogens to animals and humans decreased bile acid secretion, which would result in a rise in biliary cholesterol saturation (38–47). Estrogen prevents the stimulation of cholesterol 7α-hydroxylase by dietary cholesterol in the hamster (38,39,41). This may explain the lower bile acid concentration observed in female hamsters. A lower bile salt concentration reduces the number of micelles. It has been observed that as the number of micelles decreases, the cholesterol/phospholipid ratio of vesicles decreases, and nucleation time increases (48).

Biliary bile acid composition was markedly different among the various groups. The female hamsters had a lower CDCA concentration than the males. Hormones could be responsible for this effect, since the administration of estrogen has been found to reduce CDCA in bile (44,49). Sasco males had a higher percentage of hyodeoxycholic acid and murideoxycholic acid, but a lower percentage of 7-keto-DCA than the Sasco females or the Charles River hamsters of both sexes. These three bile acids are bacterial in origin. The formation of cholesterol gallstones could conceivably be affected by bacterial alteration of the biliary bile acid composition as some earlier investigators have indicated (50–52). The liver normally biotransforms ketonic secondary bile acids, such as 7-keto-DCA to hydroxy acids (*e.g.*, CA) by reduction of the keto group. Keto bile acids are more common in patients with liver disease (53). Female hamsters may conceivably have some liver injury as a result of the cholesterol diet, but a possible role of the 7-keto bile acid, in particular, and bile acid composition, in general, in lithogenesis remains unknown.

Female hamsters had larger livers and higher liver cholesterol levels than the males, regardless of age or source. Females store more cholesterol esters in the liver than males (54). The accumulation of the cholesterol ester in the liver is associated with suppression of cholesterol synthesis (54). This difference between male and female hamsters might also be hormonal in origin. Coyne *et al.* (38) reported that estrogen-treated hamsters on a high cholesterol diet had increased liver weights, which may be explained in part by an impaired ability to excrete the high exogenous cholesterol load in the form of bile acids. The fatty cysts and parenchymal infiltrates in the 4-week-old Sasco females may reflect this impairment; however, similar changes were either less prevalent or absent from the livers of hamsters in the other 4-week-old categories, including the Charles River females. While none of the observed morphologic changes should be construed as reflecting substantial or irreversible liver damage, still it is useful to know that the same diet can elicit different morphologic alterations in the livers of hamsters, depending on sex and source.

Our studies show that the "best" model for gallstone formation is the 4-week-old Sasco male hamster fed

palmitic acid. Although our animal model is not identical to human cholelithiasis, it should enable us to systematically examine how certain dietary components (fat, fiber), hormones and synthetic cholelitholytic agents affect stone incidence. In addition, because experiments (stone formation) can be completed in only 6 wk, and bile can easily be obtained, this model is clearly superior to studies in humans.

In conclusion, sex, age and source are important when working with the hamster model of cholesterol cholelithiasis. Our results show for the first time that age and sex may affect cholesterol cholelithiasis in hamsters fed nutritionally adequate diets.

[Received May 17, 1993 and in revised form August 19, 1993; Revision accepted August 20, 1993]

Preferential Reduction in Adipose Tissue α-Linolenic Acid (18:3ω3) During Very Low Calorie Dieting Despite Supplementation with 18:3ω3[1]

Anna B. Tang[a], Karen Y. Nishimura[b] and Stephen D. Phinney[a,*]
[a]Division of Clinical Nutrition and Metabolism, Department of Medicine and [b]School of Medicine, University of California at Davis, Davis, California 95616

We have previously reported that the relative content of 18:3ω3 in adipose triglyceride (TG) of women was reduced following major weight loss while on a very low calorie diet (VLCD). In an attempt to prevent this loss of 18:3ω3 reserves, we have tested two VLCD supplemented with varying amounts of 18:3ω3. The formula (FORM) and food VLCD (2.1–3.0 MJ or 500–700 kcal/d) contained 20 g/d of fat and provided the recommended dietary allowance for minerals and vitamins. FORM subjects (Group 1) were 5 women [initial body mass index (BMI) of 36.8, 168% ideal body weight (IBW) who received 20 g/d of canola oil (1.6 g 18:3ω3). Their mean weight loss was 23.9 kg in a 4–5 mon period. Food VLCD subjects (Group 2) were 6 women (BMI 33.9, 155% IBW) supplemented with 2 g/d of linseed oil (1.1 g 18:3ω3). Their mean weight loss was 17.4 kg in a 2–3 mon period. Needle biopsies of adipose tissue were obtained from Group 1 before, at midpoint and after weight loss; and from Group 2 before and after weight loss. The adipose TG and serum (Group 1) were separated and their fatty acid composition determined by thin-layer and gas chromatography. In Group 1, adipose 18:3ω3 fell from 0.65 to 0.59 wt%, then to 0.52 wt% during weight loss. In Group 2, it fell from 0.77 to 0.64 wt%. The fall in adipose 18:3ω3 with weight loss was significant at $P = 0.01$ (Group 1) and $P < 0.01$ (Group 2). There were no differences between responses to the 1.1 g/d or 1.6 g/d 18:3ω3 supplements. The relative content of 18:3ω3 in serum free fatty acids from Group 1 was reduced after major weight loss. Thus, in both groups the ω3 supplementation did not help to maintain adipose tissue 18:3ω3 during rapid weight loss, and its decrement may affect circulating lipid pools. As adipose 18:2ω6 did not change with weight loss, this reduction in the ratio of ω6 precursor to ω3 precursor could eventually alter the balance of their products as well.
Lipids 28, 987-993 (1993).

Very low calorie diets (VLCD; less than 3.3 MJ/d or 800 kcal/d) have been used extensively to achieve rapid weight loss. Many concerns regarding the safety of VLCD in treating moderate to severe obesity have been addressed in the past two decades (1,2), but the issue concerning the degree to which functional tissue is preserved during and after major weight loss remains. Thus, attention has been focused on nutrient composition, especially high quality proteins and supplements, and their relation to preserving lean tissue and vital organ function (3–6). However, limited studies have been done to examine the effects of VLCD with varying fat composition on adipose essential fatty acid (EFA) reserves and their content in serum lipid fractions (7,8).

Humans undergoing rapid weight loss during a VLCD derive a majority of their daily energy needs from adipose tissue. In addition to the oxidation of fatty acids from adipose triglycerides (TG) to meet energy needs, EFA are mobilized to meet other physiological and metabolic needs. The effect of weight loss on adipose tissue composition has received little attention since the pioneering work of Hirsch (9) over 30 years ago. Given a 2.5 MJ (600 kcal) per day fat-free diet for up to 150 d, Hirsch (9) reported that obese humans showed no change in the proportion of palmitic (16:0), oleic (18:1ω9) and linoleic acids (18:2ω6) in adipose tissue, despite over 30 kg of weight loss. The response of the lesser components, such as arachidonic acid (20:4ω6), α-linolenic acid (18:3ω3), eicosapentaenoic acid (20:5ω3; EPA) and docosahexaenoic acid (22:6ω3; DHA), to weight loss was not reported in those studies. However, the fate of these minor components of adipose tissue are of increasing interest in view of their important roles in membrane function, where they do exist in greater concentration, and from which substrates for eicosanoid synthesis are derived. Furthermore, the relative homogeneity of adipose tissue composition among people of diverse ethnic backgrounds and diets (10–12) suggests that its composition is regulated to some degree, possibly to fulfill some metabolic or physiological need.

In a previous study (13) we examined adipose fatty acid composition of two groups of obese women on VLCD before and after undergoing 15–30 kg of weight loss. Neither diet group received ω3 fatty acid supplements, and the daily intake of this class of fatty acid was estimated at <200 mg. Following weight loss, their remaining body adipose tissue content of 18:1ω9, 18:2ω6 and 20:4ω6 had not changed, but 18:3ω3 fell significantly in the first group (0.67 to 0.56 wt%, $P < 0.001$) and similarly in the second (0.71 to 0.59 wt%, $P = 0.03$).

α-Linolenic acid cannot be synthesized endogenously by humans and must be obtained through their diet. It is also the metabolic precursor for the elongation and desaturation products 20:5ω3 and 22:6ω3. Dietary intake of 20:5ω3 and 22:6ω3 has been associated with reduced risk for atherosclerosis (14–16). Repeated weight loss in adults has been found to predispose them to early atherosclerosis (17,18), perhaps due to the depletion of ω3 fatty acid stores. Although the essentiality of the ω3 family remains a topic of debate, the two case reports in the literature of symptomatic human deficiency (19,20) suggest that the minimum maintenance ω3 fatty acid intake should be 0.5–1.0% of calories. A recent study of young adults reported the intake of 18:3ω3 at 0.3% of total energy (21). This implies that the ω3 nutriture of much of the population may be marginal. Seen from

this perspective, the loss of 18:3ω3 from adipose TG during rapid weight loss may have important health implications.

Due to our previous findings (13) and the evidence discussed now on the importance of ω3 fatty acids in metabolism, we have conducted a follow-up study. We have assessed whether additional supplementation of VLCD with 1.1 or 1.6 g/d of 18:3ω3 helps to maintain 18:3ω3 levels in adipose and serum during prolonged dieting (for up to six months) in obese females.

MATERIALS AND METHODS

This project was conducted with two separate groups of subjects. Both groups were studied in a multidisciplinary weight management clinic at the University of California at Davis. The subjects received one of two VLCD providing between 1.9–3.0 MJ (450–700 kcal) daily with different protein, carbohydrate and fat contents. The study protocols were approved by the Human Subjects Review Committee at the University of California at Davis. Written informed consent was obtained from each subject prior to participation.

Subjects. Volunteers for this study were recruited from a group of subjects who responded to newspaper advertisements. Preselection criteria included normal medical history, physical examination, electrocardiogram and routine hematological and serum biochemical studies to rule out cardiac, hepatic, renal, thyroid and pancreatic beta-cell dysfunction. All subjects were weight stable within a 3 kg range for the month prior to the study. An initial diet history indicated no restriction of animal products or vegetable fats in their habitual diets. Group 1 contained 5 obese females ages 38 to 44. They were from 25 to 76 kg above ideal body weight [IBW; taken as the median value of the medium frame range from the Metropolitan Life Insurance Tables (22)]. The subjects were given a formula VLCD containing canola oil. Group 2 contained 6 obese females ages 37 to 44. They were from 15 to 64 kg above their IBW. These subjects were assigned to a common food VLCD and supplemented with linseed oil capsules. The characteristics of Group 1 and Group 2 subjects are shown in the Results section in Table 1.

Diets. During the first two weeks of the outpatient protocol, all subjects were prescribed a 4.1 MJ/d (1000 kcal/d diet) common food diet containing 90 g of protein. Following the two-week adaptation period, subjects were assigned to one of two VLCD.

The formula diet (Sandoz, Minneapolis, MN) provided a daily intake of 2.8 MJ (660 kcal) with 90 g protein, 30 g carbohydrate and 20 g of fat. The protein source for this formula was pasteurized egg albumin and casein, and the fat source was canola oil (11% saturated, 58% monounsaturated, 23% 18:2ω6 and 8% 18:3ω3). The mineral and vitamin content of the formula met or exceeded the recommended dietary allowances (RDA) (23) for minerals, trace minerals and vitamins. Subjects in both groups were also prescribed 1.5–2.0 L of noncaloric fluids and up to 3 g of sodium daily with bouillon to maintain euvolemia despite the nutritional ketosis induced by the VLCD.

The common food VLCD consisted of three daily portions of lean meat, low-fat fish or poultry providing less than 10 g of carbohydrate and 1.5 g protein per kg IBW in 1.9–2.5 MJ (450–600 kcal) daily. The lipid content of this diet consisted of those fats inherent in the foods selected, and was judged by diet history to range from 15–20 g/d. Based upon the diet histories of the subjects and published tables for the fatty acid contents of these animal fats, approximately 10% of this dietary fat was 18:2ω6 and 1% 18:3ω3 (for estimated daily intakes of 2 g and 0.2 g, respectively). The mean ω3 fatty acid intake from fish as 20:5ω3 and 22:6ω3 was estimated at less than 100 mg/d. This diet was supplemented daily with 2 linseed oil capsules (1.1 g/d 18:3ω3), 25 mEq of potassium bicarbonate (K-Lyte, Bristol, Evansville, IN), 4 tablets of calcium/magnesium antacid (Calcitrel, Sterling, New York) providing 800 mg and 200 mg of these minerals, respectively, and a multivitamin with minerals (Centrum, Lederle). In total, the food portions plus supplements provided at least 100% of the RDA (23) for the major and trace minerals and vitamins. The calories given to all subjects on the formula diet were fixed; whereas the common food VLCD intake was variable, depending upon stature. The range of energy intakes between groups during the VLCD varied from 660 kcal/d for the former to 450–600 kcal/d for the latter. Thus, the diets were similar in energy content but were neither precisely isocaloric nor isonitrogenous. Their total ω3 contents from all sources were 1.6 g/d and 1.4 g/d, respectively.

Monitoring. Body weight and breath acetone (by gas chromatography; Caldetect Inc., Richmond, CA) were measured weekly. The weekly weights and breath ketones effectively monitored for subject adherence to the diets during the outpatient protocol.

Body composition analysis. Body composition of Group 1 was determined by hydrostatic weighing, as previously published (13), before dieting, at approximately 12–15 kg of weight loss, and following 17–30 kg of weight loss; while body composition of Group 2 was done before dieting and following 7–26 kg of weight loss. Body density and percent body fat were calculated using the Siri formula (24) and Brozek equation (25), respectively. Fat-free mass (FFM) was calculated as body weight minus total body fat.

Serum sampling and analysis. Fasting blood was drawn by venipuncture with minimal hemostasis from Group 1 subjects before the initial diet, early in the diet (month 2) and late in the diet (month 4 to month 6). Lipids were extracted from 2 mL of serum using 6 mL of chloroform/methanol (2:1, vol/vol) (26). The phospholipid, free fatty acid, TG and cholesteryl ester fractions were separated by thin-layer chromatography (TLC), transesterified using 5% methanolic HCl, and their fatty acid composition was determined by capillary gas chromatography (GC) (13,27). The serum cholesteryl ester data are not reported, due to difficulties with sample recovery following the TLC step.

Adipose tissue sampling and analysis. Subcutaneous adipose tissue was obtained by biopsy with a 14-gauge needle following local anesthesia. Group 1 subjects were biopsied from the lateral thigh before and after a mean of 14 kg of weight loss, and after a mean of 24 kg lost. The initial and final serum samples coincided with the initial and final adipose biopsies. Group 2 subjects were biopsied from the lateral thigh before and after a mean of 17 kg weight loss. After careful washing in saline solution and blotting, the adipose tissue was extracted in a ground glass homogenizer (26), the triglyceride fraction

was separated by TLC and its fatty acid composition was determined by capillary GC. The specific details of this procedure have recently been published in detail (13).

Statistical analysis. Data analysis was performed using the PC-SAS (28) package on a microcomputer. Changes in the level of each specific fatty acid were assessed in Group 1 by repeated measures analysis of variance (ANOVA), and in Group 2 by paired *t*-test. Due to the number of individual tests done with each diet group, the threshold for significance was $P < 0.01$. Data are reported as means (SEM).

RESULTS

The characteristics of the two groups of subjects participating in this study are shown in Table 1. The two groups had similar age, height, initial body weight, %IBW, and body mass index (BMI). All the subjects exceeded the standards for obesity as determined by percent IBW and BMI, and all lost at least 0.9 kg per week. The mean rates of weight loss for the Group 1 and 2 subjects are shown in Table 1, and each subject's cumulative loss in Figure 1.

The data for Figure 1 are calculated as percent loss from initial weight, and this figure illustrates the consistent rate of loss within and between diet groups. These results indicate that little, if any, additional fat calories were consumed during the VLCD by our subjects. Adherence to the VLCD was further supported by breath acetone determinations. The subjects achieved and sustained values exceeding the equivalent of 0.4 mM β-hydroxybutyrate during the VLCD. This increase over baseline values (less than 0.05 mM in the pre-weight loss phase) indicated consistent avoidance of unprescribed dietary carbohydrate.

Body composition data for Group 1 and Group 2 are shown in Table 2. Total adipose weights are provided at each time point, plus total change for these parameters and FFM across weight loss. The changes in body composition were similar for both diets. There were no significant differences between the diets for total weight loss, fat loss or loss of FFM. A mean weight loss of 23.9 ± 2.4 kg was observed in the Group 1 and 17.4 ± 3.0 kg in the Group 2 subjects, corresponding to 22.8 and 18.2% reduction in initial body weight. The weight loss as fat was 87% for Group 1 and 70% for Group 2 subjects.

The fatty acid contents of adipose tissue from the lateral thigh regions of Group 1 and Group 2 subjects are shown in Table 3. For Group 1, α-linolenic acid declined significantly with weight loss from 0.65 to 0.52 wt% (20%, $P = 0.01$). Using the body composition data, the loss of 18:3ω3 from adipose stores was 1.2 g/d. Oleic acid and 22:5ω3 both showed slight rises after weight loss ($P = 0.007$ and $P = 0.003$, respectively), and 18:3ω6 showed a slight decline ($P = 0.006$). For Group 2, the only significant change with weight loss occurred in 18:3ω3, which fell from 0.77 to 0.64 wt% (17%, $P < 0.01$). Again from the body composition data, the rate of 18:3ω3 loss from adipose stores was 1.6 g/d.

The fatty acid constituents of the serum phospholipid (PL) fraction of Group 1 at three time points before and during the rapid weight loss phase are shown in Table 4. There were no significant changes in the PL ω6 or ω3 fatty acids. The serum free fatty acids for Group 1 subjects are shown in Table 5. Among the nonessential fatty acids, 14:0 declined ($P = 0.003$) with the VLCD, and 18:1ω9 rose ($P = 0.005$). Among the ω6 family, the only change was a fall in 18:3ω6 ($P = 0.01$). In the ω3 class, 18:3ω3 sustained a significant ($P < 0.01$) decline. Neither 20:5ω3 nor 22:6ω3 underwent significant change. The serum TGs for the Group 1 subjects are shown in Table 6. There were no

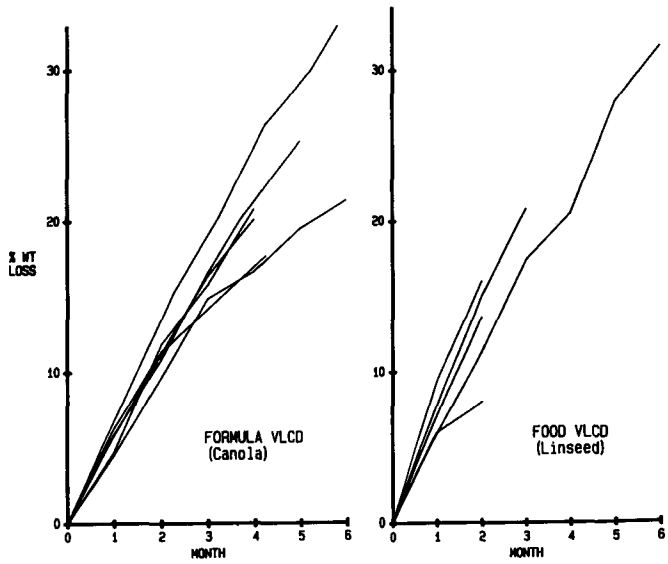

FIG. 1. Rates of weight loss for formula (Group 1) and common food very low calorie diets) (VLCD) (Group 2) subjects, calculated as percent of initial weight, and indicating uniform adherence to the VLCD.

significant changes among the nonessential fatty acids. In the ω6 family, 18:3ω6 fell ($P < 0.01$ for both). There were no significant changes in the ω3 family with the VLCD.

DISCUSSION

Our previous study had shown that VLCD employed for rapid weight loss in humans selectively reduce the content of α-linolenic acid in the remaining body adipose pool (13). This finding was consistent across two separate groups of subjects experiencing 15–25 kg of weight loss and was independent of the type of VLCD (food or formula) employed. It also implied a need for ω3 fatty acid supplementation to avoid tissue reduction of this nutrient. In the present study, we assessed two VLCD providing 1.6 g/d of 18:3ω3 (formula diet containing canola oil) or 1.4 g/d (common food plus linseed oil capsules). The diet-induced reduction of 18:3ω3 in adipose TG was similar in the two groups and was comparable to that found in the previous study (in which the diets provided < 0.2 g ω3 daily). There were no other consistent changes in the adipose fatty acid composition in either diet group. Thus, the 18:3ω3 supplementation did not prevent the loss of 18:3ω3 from adipose stores during the VLCD.

The 18:3ω3 supplement dose used in this study was determined using the data from the body composition studies of our previous work (13). Assuming uniform loss from different anatomic sites, total α-linolenic acid disappearance from adipose TG was determined to be 171 g in 140 d, or 1.2 g/d. This amount represented about 0.5% of daily energy expenditure and is very close to the estimates of minimum human need determined in two case studies describing overt deficiency of this required nutrient (19,20). We decided on supplement doses for the present study that would equal (linseed) or exceed (canola) the projected minimum need, hoping that this would protect the relative content of 18:3ω3 in adipose triglyceride. Despite the supplements, however, the calculated rates of 18:3ω3 loss from adipose triglyceride were 1.2 and 1.6 g/d for Groups 1 and 2, respectively. Clearly these 18:3ω3 supplements did not protect adipose reserves. Linoleic acid mobilization, on the other hand, was determined to be 22 g/d, providing more than 10% of total energy needs. This

[e]$P \leq 0.05$ by ANOVA.

was 5- to 20-fold in excess of the minimum amount to avoid EFA deficiency in rats (29) and in humans (30-32). Given this degree of excess provision, there was no decrease in adipose TG 18:2ω6 relative content.

Among the serum fractions, the most notable observation was the decline in free fatty acid 18:3ω3 during the VLCD. Unlike the precursor 18:3ω3, the ω3 product fatty acids EPA and DHA in serum showed no consistent change with the diet. As 18:3ω3 has no known essential functions in its own right other than as a precursor for EPA and DHA, this decline in its level in adipose and in circulatory pools carries no immediate risk. Nonetheless, there could be late sequelae if the 18:3ω3 were not replaced in the post-weight loss phase, as slow equilibration with the hepatic 18:3ω3 substrate pool may impact production of 20:5ω3 or 22:6ω3, allowing their contents in serum or tissues to eventually decline.

Another interesting observation from the serum lipid fraction fatty acid profiles is the low level of 18:2ω6 at all time points as compared to previously published values for lean adults using the same analytical methodology (33). Jones and Schoeller (34) have shown that humans preferentially oxidized polyunsaturated compared to saturated and monounsaturated fatty acids, and that lean and obese subjects differ in their responses to diets varying in polyunsaturated to saturated fatty acid ratio (35). These observations, along with our data suggesting low 18:2ω6 in serum fractions at baseline and during the VLCD, suggest an abnormality in the regulation of 18:2ω6 content in the various serum lipid fractions in obesity. This is consistent with our observations in the obese Zucker rat (36), in nondieting obese humans (37) and in obese humans prior to major weight loss (38). It is clear that the low 18:2ω6 in the three serum fractions did not represent overt EFA deficiency, as PL 20:3ω9 was not elevated.

The mechanism for the selective loss of 18:3ω3 from adipose TG and serum free fatty acids remains unclear. Raclot and Groscolas (39) have shown that 18:3ω3 is preferentially released from stimulated adipocytes, and Clouet *et al.* (40) reported preferential *in vitro* mitochondrial oxidation of α-linolenic acid in the nonesterified form. As the subjects in our study were in marked negative energy balance, dietary 18:3ω3 would be presented to muscle in free fatty acid form, predisposing it to preferential β-oxidation in the mitochondria. This may partially explain the significant reduction in 18:3ω3 in the serum free fatty acid fraction.

The health significance of the reduction in adipose 18:3ω3 with rapid weight loss remains to be determined. One determinant of the physiologic importance of the decline in adipose 18:3ω3 is the extent to which it interacts with other tissue fatty acid pools. Due to the higher rate of adipose fatty acid turnover than oxidation, a reduction in adipose 18:3ω3 will eventually reduce its content in other tissue pools.

Another potential consequence of reduced body ω3 fatty acid stores would be a decrease in the production of EPA and DHA from 18:3ω3. Although this conversion has been reported to be so slow as to be inconsequential (41), other studies indicate that anabolic conversion occurs at a meaningful rate in humans. For example, dietary 18:3ω3 supplementation increases 20:5ω3 content (42-45), and vegan vegetarians do not show depletion of EPA and DHA from serum PL (33). These products of 18:3ω3 modulate cellular response to injury and infection (46,47) and reduce atherosclerosis in an animal model (16) and its manifestations in humans (14,48,49). This participation

of ω3 fatty acids in the pathogenesis of coronary occlusion offers a potential explanation for the findings of Hamm *et al.* (17) and Lissner *et al.* (18), who observed that repeated weight loss in adults predisposed them to early atherosclerosis. If weight loss reduces body ω3 stores independent of the type of fat intake, this may not be subsequently replaced during weight regain if dietary ω3 intake is marginal. Barr *et al.* (21) recently reported that 18:3ω3 constituted 0.3% of calories in a group of young adults given a free choice diet. Thus, a subtle but chronic risk state could be established if recurrent dieting depletes ω3 reserves and intake during maintenance or weight gain does not allow effective repletion. In view of the observation that as few as three fish meals per week (providing a mean of 0.5 g/d of ω3 fatty acids) can reduce atherosclerosis risk (14), this possible explanation for the increased coronary risk with repeated weight loss is not beyond reason.

In conclusion, we have observed a consistent decline in adipose 18:3ω3 content with major weight loss induced by very low calorie dieting. This change occurred independent of the type of VLCD (food or formula) and despite moderate supplementation with 18:3ω3. Both the mechanism through which this fatty acid is selectively removed from adipose tissue and the health implications of this finding deserve further study.

ACKNOWLEDGMENTS

We wish to thank Carolyn Waggoner for assistance in patient management and Diane Hardy and Robert Lipman for administrative assistance. We thank Dr. Francis Peterson of Sandoz Nutrition for donation of the formula diet used in this study.

An Increased Incidence of Apolipoprotein E2/E2 and E4/E4 in Retinitis Pigmentosa

Previous studies from our laboratory have shown that retinitis pigmentosa (RP), a family of hereditary retinal degenerations, is often accompanied by abnormal levels of cholesterol or polyunsaturated fatty acids. The requirement of the retina for n-3 fatty acids is well known, and a defect in the supply of these lipids (*e.g.*, by apolipoproteins) could affect the course of the disease. The present study confirms and extends a report on apolipoprotein E (apo E) isoforms in German RP patients [Jahn, Oette, Esser, Bergmann, and Leiss, (1987) *Ophthalmic Res. 19*, 285–288] which showed a tenfold increased frequency of the E2/E2 phenotype compared to the average German population. In our study, apo E phenotypes were determined in the probands of 100 Scottish RP families. The findings revealed a 4-fold increase in the incidence of E2/E2 and an 8-fold increase in E4/E4 compared to a Scottish control population. These increases were statistically significant at the $P < 0.05$ and $P < 0.01$ levels, respectively. To investigate the possibility that some of these apparent E2/E2 or E4/E4 phenotypes might actually be new apo E mutations, we examined the behavior of the apo E on sodium dodecyl sulfate–polyacrylamide gels (E2 migrates anomalously) and on isoelectric focusing gels following cysteamine modification of cysteines. These studies showed that two RP patients possibly had new apo E mutations, though amino-terminal sequence analysis revealed no changes in the sequence of the first 19 residues; further sequence analysis is obviously warranted.
***Lipids* 28, 995–998 (1993).**

Retinitis pigmentosa (RP) is a family of hereditary retinal degenerations characterized by tunnel vision and night blindness, characteristics which are consistent with the deterioration of rod photoreceptor cells.

Photoreceptor outer segments are highly enriched in polyunsaturated fatty acids and especially in docosahexaenoic acid (22:6n-3, DHA), which comprises as much as 50% of the total fatty acids (1). The continual process of outer segment renewal requires the supply of n-3 fatty acids, in particular DHA, and thus any imbalance might lead to their degeneration. This is supported by evidence from dietary studies on rats and rhesus monkeys where animals deprived of dietary DHA developed visual defects similar to RP (2–5). Therefore it seems possible that the photoreceptor degeneration seen in RP may be due to a defective supply of the appropriate lipids to the retina.

Various lipid defects have been observed in different types of RP. Converse and colleagues (6,7) first reported a trend of hyperlipidemia in RP patients when compared to controls. This was especially noted in men over 35 years of age and hemizygotes of X-linked families. Factors such as diet and lifestyle, which might influence lipid levels, did not differ between the affected and control groups (8). An increase in total serum cholesterol was also noted in a German study of RP subjects, and this was found especially in individuals with autosomal dominant (AD), autosomal recessive (AR) and simplex RP (9). In contrast, hypolipidemia was observed in a number of RP families with AD inheritance (6,10).

In another study, low levels of DHA were found in the plasma of affected X-linked and ADRP patients, compared to their unaffected relatives (6,8,11,12); however, in one AD family, high levels of DHA were reported in the plasma of affected ADRP subjects compared to their unaffected relatives (13). Thus, the pattern of lipid abnormalities appears to vary from one type of RP to another, and this is consistent with the heterogeneity of the disease. However, the question is whether such defects in lipid metabolism play a role in the pathogenesis of some forms of RP.

An investigation of specific categories of lipids may hold the answer. For example, apolipoproteins (apo) play a pivotal role in lipoprotein transportation and metabolism (14–16). Genetic variations of apo E have been shown to be associated with lipid abnormalities; in particular there is an association between the phenotype E2/E2 and type III hyperlipidemia (17). In view of this, Jahn and co-workers (18,19) conducted a survey of apo E phenotypes in the German RP population. A 10-fold increase in the prevalence of E2/E2 was observed in the RP population, in addition to an increase in the heterozygotes E3/E2 and E4/E3, when compared to German controls. This was statistically significant at the $P < 0.001$ level for the E2/E2 homozygote and at $P < 0.05$ for the heterozygote phenotypes, respectively. As apo E2 is a primary gene product, it seems unlikely that its high incidence is secondary to the RP in these patients. The data suggest that the effect on lipid metabolism caused by apo E2 may play a role in the pathogenesis of RP in these patients.

In view of these findings, we investigated the incidence of apo E phenotypes in the Scottish RP population and also the contribution that apo E may have in the etiology of RP.

METHODS

Blood samples were collected in potassium ethylenediaminetetraacetic acid tubes and plasma separated by centrifugation. Apo E phenotyping was performed using the conventional isoelectric focusing of delipidated very low density lipoproteins (VLDL) as described by Wardell *et al.* (20). During the later stages of this study, a recently developed, rapid micromethod by Menzel and Utermann (21) was adopted. This method, based on isoelectric

Abbreviations: AD, autosomal dominant; AR, autosomal recessive; apo, apolipoprotein; DHA, docosahexaenoic acid (22:6n-3); RP, retinitis pigmentosa; SDS-PAGE, sodium dodecyl sulfate–polyacrylamide gel electrophoresis; VLDL, very low density lipoproteins.

focusing of delipidated plasma followed by immunoblotting using polyclonal anti-apo E antibody, has the additional advantage that fresh plasma is not required; it can be performed on stored, frozen plasma.

For the chemical modification studies, the plasma was first treated with cysteamine as described by Weisgraber *et al.* (22). The samples were then subjected to immunoblotting as before.

To determine the apparent molecular weight of apo E, electrophoresis on sodium dodecyl sulfate-polyacrylamide gels (SDS-PAGE) was performed. This method of identifying apo E variants by difference in molecular weight was initially described by Utermann and colleagues (23) who used the SDS-PAGE method of Neville (24). This method was adopted as well as the SDS-PAGE system developed by Laemmli (25).

The amino-terminal sequencing studies were performed as described by Matsudaira (26). This involved directly sequencing proteins that were blotted onto polyvinylidene difluoride membranes which were stained in 0.1% Coomassie blue R250 in 50% methanol. The apo E band was identified, cut out and directly sequenced using the Edman method (27).

RESULTS AND DISCUSSION

The survey of the incidence of apo E phenotypes in the Scottish RP population (Table 1) reveals significant differences when the percentages of the phenotypes are compared to a control Scottish population (taken from a study by Cumming and Robertson, Ref. 28). There is a 4-fold increase in the E2/E2 phenotype but even more striking is the 8-fold increase in the incidence of E4/E4 in the RP population when compared to the controls. The increases in the E2 and E4 homozygotes compared to the other phenotypes were statistically significant at the $P < 0.05$ and $P < 0.001$ levels, respectively, as analyzed by 2×2 Chi-squared tests. This finding is interesting in that the increase in E4/E4 was not previously observed in the German study (18,19). There is very little difference among (control) European populations in the frequencies of the various apo E phenotypes (18-20,28,29).

The significance of this finding to RP is of interest. It is known that both E2 and E4 are "dysfunctional" isoforms in their binding to receptors and catabolism (14,30); the increased prevalence of these isoforms in RP may have some significance in the pathogenesis of the disease.

There are several possible explanations for the above findings. The first is that E2 or E4 might cause some types of RP. This is very unlikely, as the incidence of these isoforms is much greater than the incidence of RP (1 in 2000 or more) (31,32). Secondly, RP might be polygenic or multifactorial, at least in the RP patients who are homozygous for either E2 or E4. That is, the patient would inherit the RP gene, but the disease would only be expressed if they also inherited a "dysfunctional" apo E phenotype such as E2/E2 or E4/E4. This possibility is perhaps consistent with the occurrence of E2/E2 and E4/E4 in simplex cases of RP in both the study by Jahn *et al.* (18,19) and in our study (Table 2).

Another possibility is that there is a new variant of apo E in these RP patients that resembles E2 or E4 but is in fact directly involved either alone or with another gene or factor in the pathogenesis of RP in these patients. This last hypothesis was investigated further.

First, to determine whether the E2 and E4 isoforms from the selected E2/E2 and E4/E4 patients had the predicted number of cysteine residues in their sequence, chemical modification using cysteamine was performed (22). In this method, E2 with two cysteine residues moves to the E4 position (in IEF gels); E3, with one cysteine, also moves to the E4 position, and E4, with no cysteines, does not react with cysteamine and so does not move at all. The isoelectric focusing patterns of the eight E4 homozygotes were the same before and after treatment with cysteamine, indicating that they had no cysteamine residues, as predicted (22). The E2 band in three out of four E2/E2 subjects behaved as expected (Fig. 1), that is, the E2 band moved up two positive charge units to the E4 position, indicating the presence of two cysteine residues. However, in one of the E2 homozygotes (IC) the "E2" band moved up only one charge unit, indicating that this isoform has only one cysteine residue instead of the predicted two residues. The cysteamine result for IC suggests that perhaps this is a variant of the E3 isoform (which has one cysteine residue) and that perhaps there is a substitution elsewhere in the sequence causing the charge difference, thus causing it to focus at the E2 position. This possibility was further investigated by measuring the mobility of the apo E isoforms on SDS-PAGE. The E2 isoform can be distinguished from E3 and E4 by its slower mobility (*i.e.*, higher apparent molecular weight) on SDS-PAGE (23). Figure 2 (method of Laemmli, Ref. 25) shows that two subjects (BH & IC)(lanes c and d)

[a]Apo E phenotypes were determined by isoelectric focusing and immunoblotting (21).
[b]The types of RP are: X-L: X-linked; AD: autosomal dominant; AR: autosomal recessive; Mult.: multiplex; Simp.: simplex; Usher: Usher Syndrome; LMBB: Laurence-Moon-Bardet-Biedl Syndrome.

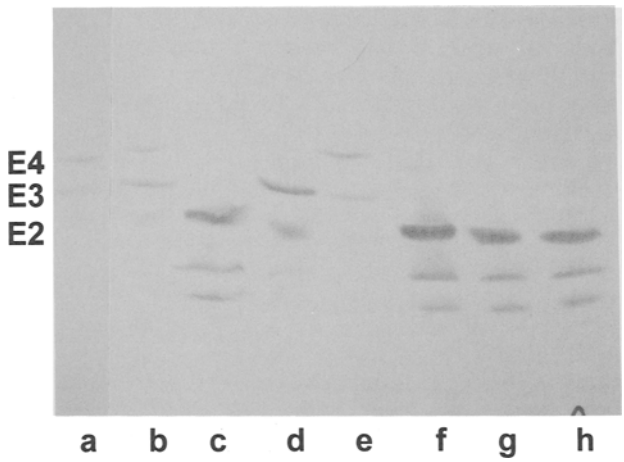

FIG. 1. Immunoblot of delipidated plasma, separated on an isoelectric focusing gel (21), depicting the apolipoprotein E isoforms of four E2/E2 retinitis pigmentosa patients and the effect of cysteamine treatment. The positions of the normal E4, E3 and E2 isoforms are indicated. The vertical lanes contain the following samples: lanes a, f: patient BH, treated (a) and untreated (f), respectively; b, c: patient WA, treated (b) and untreated (c); d, g: patient IC, treated (d) and untreated (g); e, h: patient AP, treated (e) and untreated (h).

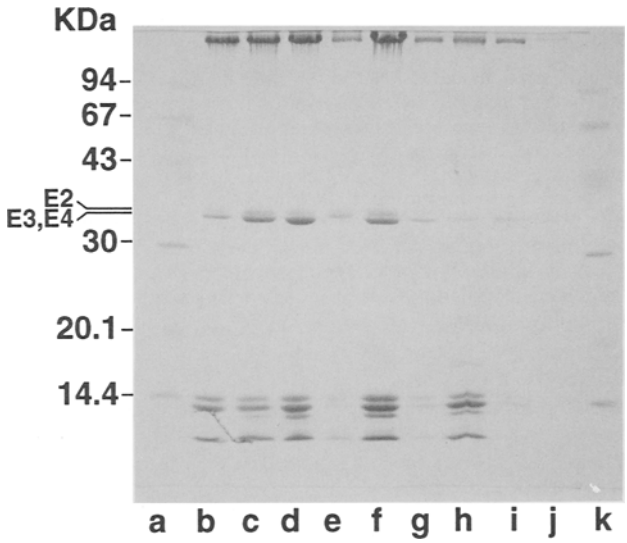

FIG. 2. Sodium dodecyl sulfate-polyacrylamide gel (according to Laemmli, Ref. 25) of delipidated very low density lipoprotein (VLDL) from selected retinitis pigmentosa patients, illustrating the mobility of their apo E. Lanes a and k contain low molecular weight protein markers, whose molecular weights in kDa are shown on the y axis. E2, E3 and E4 designate the position of these isoforms. The other lanes are as follows: b: pooled VLDL; c: patient IC (E2/E2); d: patient BH (E2/E2); e: patient AP (E2/E2); f: E3/E2 standard; g: patient LG (E4/E4); h: patient JB (E4/E4); i: patient MS (E4/E4); j: patient HM (E4/E4).

displayed two distinct bands; one band corresponded to the position of E2 and the other to the position of E3 and E4 (which have identical positions). Gels of patients AP and WA (not shown) showed a single band at the E2 position. Similar results were obtained with SDS-PAGE by the method of Neville (24)(data not shown). It is possible that the lower band seen in lanes c and d could be the result of proteolysis; however it is perhaps unusual to get such a strong, distinct band formed by proteolysis, and no such effect was seen in any of the other lanes or in previous studies (23).

The SDS-PAGE results for IC are consistent with the cysteamine modification result that indicated an apo E variant similar to E3. However, BH had two cysteine residues as determined by cysteamine modification (Fig. 1, lane h). It is therefore possible that these two patients have different apo E variants. It has been shown that the E2 variants E2 (Lys 146→Gln) and E2 (Arg 145→Cys) migrate on SDS-PAGE to the positions of E3 and E4 (23), as in our two patients. Therefore, these two patients could have substitutions similar to these variants or could have new variants altogether. The amino-terminal sequences

(up to 19 residues) of these two patients (IC & BH) and two E4 homozygote patients revealed no differences when compared to the predicted amino-terminal sequence (33). Therefore, it seems that if variants exist, the substitutions are further along in the sequence.

The evidence so far points toward two individuals having apo E variants, but the exact positions of the substitutions have yet to be determined.

Apo E has also been found to be synthesized and secreted in other tissues such as kidney, adrenal gland, brain and retina (34,35). Its role in lipid uptake has been demonstrated in photoreceptor cells (36). Growing evidence suggests that apo E plays an important role within the nervous system, for example, in nerve regeneration (16). Although the function of apo E in the retina is still unclear, it is possible that apo E may be involved in the maintenance and repair of the photoreceptor membranes and, if defective, may lead to their degeneration.

In conclusion, if a variant of apo E exists in these patients, it is reasonable to postulate that a defect in lipid metabolism (caused by defective binding of the variant to the receptors) could diminish the supply of lipid to the retina, and this may eventually lead to their retinal dystrophy. Further investigation is warranted to establish the role of apo E in RP.

ACKNOWLEDGMENTS

We would like to thank the following: M.F. Collins, A. Bow, E. Alvarez and C. Brogan for their help in obtaining blood samples, T. Demant for useful discussions and B. Dunbar and J. Fothergill for assistance in the sequencing studies. We are grateful to the British Retinitis Pigmentosa Society, the National Retinitis Pigmentosa Foundation, the George Gund Foundation, the Royal National Institute for the Blind and the W.H. Ross Foundation (Scotland) for the Study of Prevention of Blindness for financial support. Thanks are also due to N. Savage and B. Aitken for typing the manuscript, S. Lucas for skilled technical assistance and the many RP patients and relatives who willingly donated blood samples.

Different Resistance of Mammalian Red Blood Cells to Hemolysis by Bile Salts

G. Salvioli*, E. Gaetti, R. Panini, R. Lugli and J.M. Pradelli
Geriatrics and Gerontology, University of Modena, Ospedale Estense, 41100 Modena, Italy

To evaluate why hemolysis of red blood cells (RBC) by bile acids varies in different mammalian species, we determined the mean corpuscular volume (MCV), lipid content and the concentrations of the conjugates of deoxycholate and of NaCl inducing 50% hemolysis of RBC from healthy humans, pigs, horses, cows, sheep and jaundiced humans. A volume of 0.05 mL of washed RBC at 1% hematocrit, which has the same lipid content but different phospholipid composition and number of erythrocytes (owing to the variable MCV), was incubated in taurodeoxycholate (TDC) solution (0–5 mM) to determine the TDC concentration inducing 50% hemolysis (TDC_{50}). The TDC_{50} was highest in RBC of sheep and decreased within the series sheep > pig > cow > horse > healthy human > jaundiced human, which have generally increasing MCV. The osmotic resistance followed an inverse order, with jaundiced human > healthy human > horse > cow > pig > sheep. Although we found no correlation between the TDC_{50} and phospholipid composition of the erythrocytes tested, the extent of bile salt-induced hemolysis seemed to depend on both the MCV and the number of erythrocytes in the incubation medium.
Lipids 28, 999–1003 (1993).

Red blood cells (RBC) from different mammalian species have a remarkably similar lipid content per milliliter of packed cells (1), but their phospholipid composition (1–3), mean corpuscular volume (MCV) (2) and osmotic resistance (4) vary widely. Sphingomyelin (SM) and phosphatidylcholine (PC) are preferentially located in the outer leaflet of the RBC membrane and represent about 45–60% of total phospholipids (PL) (5); their proportions vary in RBC from different animal species (1). Furthermore, the lipid composition of RBC membranes has been considered an important factor influencing the susceptibility to damage from bile salts. Coleman *et al.* (6) have shown that cow and sheep RBC, whose PC content is very low and is replaced by SM, are more resistant to glycocholate-induced hemolysis than human erythrocytes.

In this study we evaluated whether criteria, besides RBC membrane composition, were correlated with bile salt-induced hemolysis of RBC from different species. Variations in the MCV of mammalian erythrocytes may contribute to the different hemolytic effects observed with detergent bile salts.

MATERIALS AND METHODS

Taurodeoxycholate (TDC) and glycodeoxycholate (GDC) (Na^+ salt, grade A) were purchased from Calbiochem (Milan, Italy) and were more than 96% pure as judged by thin-layer chromatography (TLC). Blood from healthy human subjects and from humans with obstructive jaundice, which have large RBC (7), was drawn into heparinized vacutainer tubes. Blood from pigs, cows, sheep and horses was obtained from local slaughterhouses. Cell indices (MCV and mean cell hemoglobin) were evaluated in an S-plus Coulter Counter Analyzer (Coulter, Hialeah, FL). Blood samples were centrifuged and the plasma buffy coat was removed. Then the RBC were washed three times with 15 mM *tris*(hydroxymethyl)aminomethane buffer (pH 7.4) containing 145 mM NaCl and 5 mM glucose. The lipid content of RBC was determined after extracting 1 mL of packed RBC according to Rose and Oklander (8); PL (9) and cholesterol (Biochemia kit no. 676535, Boehringer Mannheim, Mannheim, Germany) were determined on the chloroform extracts. The PL classes contained in RBC membranes were separated by two-dimensional TLC on silica gel G plates (Merck, Darmstadt, Germany), using chloroform/methanol/aqueous ammonia (65:35:5, by vol) as the first solvent and chloroform/acetone/methanol/acetic acid/water (50:20:10:10:5, by vol) as the second (10). The fractions were located with iodine vapor and scraped off the silica gel plates; PL were measured after digestion with perchloric acid (9). Fractions were identified by comparison with standards (Supelco, Milan, Italy).

The hemolytic effect of TDC and GDC was evaluated as follows: Washed RBC at 1% hematocrit were incubated in TDC and GDC solutions (0–5 mM) in 15 mM of the abovementioned TRIS buffer, pH 7.4, for 45 min, at a final volume of 5 mL. Afterwards, the samples were centrifuged at 5,000 rpm for 4 min (model 153, Microfuge; Beckman Instruments, Fullerton, CA), and the extent of hemolysis was evaluated by comparing absorbance at 546 nm of 100-fold serial dilutions of the supernatant with that of RBC totally lysed in distilled water.

Osmotic fragility of the different RBC was evaluated according to Parpart *et al.* (11). The mean cell fragility was taken as the NaCl concentration (g/dL) at which 50% of the RBC were hemolyzed (12).

RESULTS

Table 1 reports the cell parameters of the RBC tested. The MCV increased along the order sheep, cow, horse, pig and human; the largest RBC came from jaundiced humans (MCV 115 μm^3). Cholesterol and phospholipid content (mg/mL) of the packed RBC was relatively constant in all species, as previously reported by Nelson (1). Even though the lipid content per RBC was greater in humans than in pigs, horses, cows and sheep, the lipid content of RBC from cholestatic humans was even higher (Table 1).

The same volume of packed RBC (0.05 mL) from the various species tested in the hemolysis experiments contained different numbers of cells, even though the total lipid content and the cholesterol to PL molar ratio were roughly the same (Table 2).

Figure 1 shows the hemolysis induced by increasing concentrations of TDC. RBC from sheep, pig and cow were

much more resistant to TDC than healthy human erythrocytes; the latter cells were less prone to TDC-induced hemolysis than the larger ones that were obtained from jaundiced humans. Horse RBC showed an intermediate behavior. Because the GDC concentrations causing 50% hemolysis overlapped the values reported for TDC, these have not been reported.

At a constant volume of incubated RBC, the TDC concentration causing 50% hemolysis (TDC_{50}) increased in the order sheep > pig > cow > horse > healthy human > jaundiced human (Table 2). The plot of TDC_{50} *vs.* erythrocyte MCV gave a strong negative correlation, which reached statistical significance ($r = -0.83$)($P < 0.02$) (Fig. 2).

At TDC_{50}, the number of bile salt molecules per RBC in the incubation tubes was lowest for horse and highest for pig (Table 2); no correlation was found between this ratio and TDC_{50} ($r = 0.5$; P = not significant).

Sheep (n = 3)	0.63 ± 0.07	25 ± 3

[a]The values indicate means ± SD. MCV, mean corpuscular volume.

Hemolytic behavior also seems to be correlated with the physical characteristics of the erythrocytes studied. The osmotic resistance of RBC from different mammalian species decreased with MCV (Table 3). The correlations between the NaCl concentration inducing 50% hemolysis and both MCV ($r = -0.86$) ($P < 0.001$) and TDC_{50} ($r = 0.95$, $P < 0.003$) were statistically significant.

The RBC of the species studied had variable amounts of choline-containing PL (Table 4), as reported by Nelson (1,3). In particular, SM accounted for more than 50% of total PL in cow and sheep RBC, whereas PC content was near zero in these species. In contrast, SM proportions are similar in human, pig and horse RBC, even though the latter two have smaller MCV and a higher resistance to TDC than human RBC. The correlation between SM content of RBC membranes (expressed as percent of total PL) and the TDC_{50} was not statistically significant (Fig. 3).

DISCUSSION

Previous studies have indicated that RBC containing SM are more resistant to bile salt-induced hemolysis (6). Several hematological parameters, such as MCV, surface area and surface-to-volume ratio differentiate erythrocytes from different mammalian species (12–17); surface area is negatively correlated with the volume of the RBC (18). Hypotonic stress reduces the surface-to-volume ratio, and hemolysis occurs after the cells have become spherical and have reached a critical volume. Osmotic resistance is strongly correlated to the surface-to-volume ratio of the RBC (7,18), and it increases with MCV (4,12) (Table 3). An increment of both the surface area and the surface-to-volume ratio, as occurs in cholesterol-enriched RBC of cholestatic humans, enhances osmotic resistance (7) (Table 3); these erythrocytes are resistant to hemolysis from hypotonic stress but are susceptible to the action of deoxycholic acid conjugates. By contrast, erythrocytes with

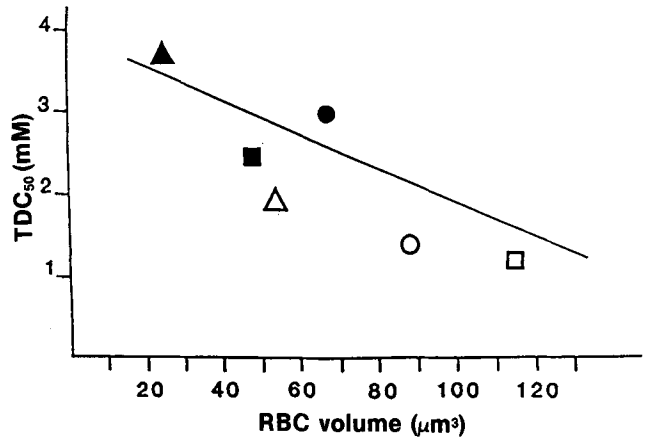

FIG. 2. Correlation between taurodeoxycholate (TDC) concentrations able to induce 50% hemolysis (TDC_{50}) and mean corpuscular volume of the red blood cells (RBC) tested (μm^3) ($r = -0.83$, $P < 0.02$). Symbols indicate RBC from healthy human (○), cholestatic human (□), cow (■), sheep (▲), pig (●) and horse (△).

TABLE 4

Phospholipid Composition of Red Blood Cells from Various Animal Species[a]

	(% of total phospholipids)						
	LPC	PI	PS	SM	PC	PE	Other
Healthy humans	1.6	1.8	12.9	25.7	39.5	26.2	3.1
Obstructive jaundice	1.3	1.8	12.6	23.4	32.4	26.1	2.2
Cow	—[b]	2.1	15.9	50.8	1.5	26.8	2.7
Pig	0.9	2.7	16.1	20.1	30.3	28.2	1.6

Sheep	—[b]	1.8	14.2	56.2	1.6	24.4	1.6

[a]The data were taken from three healthy humans, two humans with obstructive jaundice and three animals each for cow, pig, horse and sheep. LPC, lysophosphatidylcholine; PI, phosphatidylinositol; PS, phosphatidylserine; SM, sphingomyelin; PC, phosphatidylcholine; PE, phosphatidylethanolamine.
[b]—, Not detected.

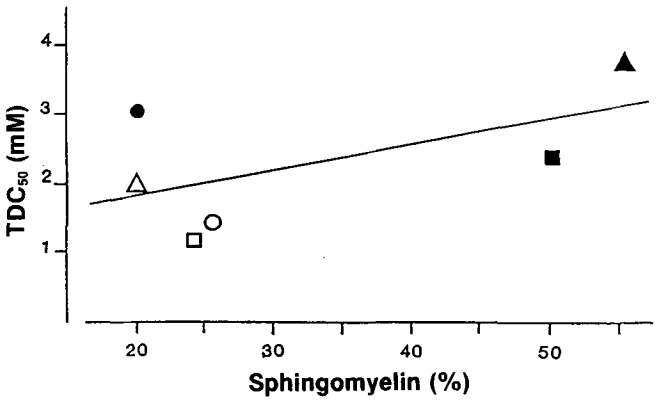

FIG. 3. Correlation between taurodeoxycholate (TDC) concentration inducing 50% hemolysis (TDC_{50}) and the percentage of sphingomyelin in red blood cell (RBC) membranes (r = 0.60; P = N.S.). Symbols indicate RBC from healthy human (○), cholestatic patient (□), cow (■), sheep (▲), pig (●) and horse (△).

small surface-to-volume ratio, such as those from sheep and cow, are osmotically fragile but resistant to bile salts (19). Erythrocytes with small MCV would lyse at lower bile salt concentrations if cell swelling alone were responsible for breaking down the cell membrane. Instead, the smaller cells are more resistant to the detergent effect of tauroconjugates of deoxycholic acid (Table 2) (Fig. 2), even if the number of TDC molecules per erythrocyte required to obtain 50% hemolysis does not vary accordingly (Table 2).

Few data are available on the mechanisms underlying hemolysis induced by bile salts; at appropriate concentrations bile salts solubilize RBC membrane constituents (20), but like other anionic drugs, sublytic concentrations of bile salts actually protect against hypotonic stress (21). Hypotonic hemolysis and hemolysis induced by bile salts thus occur *via* different mechanisms.

Bile salt hemolysis is traditionally evaluated by incubating packed RBC with serial concentrations of bile salts (6). In our hemolysis experiments, 0.05 mL of packed RBC contained a variable number of cells but the same amount of lipids (Table 2); therefore the volume of packed erythrocytes used in the hemolysis experiments contained more cells when these had a small MCV, as for sheep, pig and cow.

As the concentration of TDC required to determine 50% hemolysis was inversely correlated with the volume of the erythrocytes tested (r = −0.83; see Fig. 2), it seems that some physical characteristics of the single erythrocyte play a role in determining the extent of hemolysis in the presence of TDC.

The variable resistance to damage by bile salts has been attributed to the peculiar PL composition of RBC from some animal species (2,6). In fact, SM largely replaces phosphatidylcholine in cow and sheep RBC (1) (Table 4). SM-rich membranes are typically less fluid and are lysed more slowly by bile salts than are more fluid membranes (19). Moreover, SM reduces the permeability to water (22) and phosphates (23). The influx of glycerol, phosphate and urea decreases when the ratio of poly- to monounsaturated fatty acids in the membrane decreases (4,5), as is the case in pig and sheep RBC (23,24).

The correlation between TDC-induced hemolysis and SM percentage in RBC membranes was not statistically significant (Fig. 3). Schubert and Schmidt (25) demonstrated *in vitro* that SM does not stabilize membranes against bile salt damage, as suggested by Lowe and Coleman (19) for erythrocytes. The latter authors incubated RBC at a concentration of 2% (by vol), so that the number of cells changed widely for the different animal species tested. Support for the importance of additional factors besides lipid composition comes from the hemolytic behavior of RBC from pig and horse; the erythrocyte PL composition in these species compares well with that in humans, but pig and horse RBC are smaller and have a TDC-resistance similar to those rich in SM.

In conclusion, several factors, including membrane characteristics and PL composition (6), influence the resistance of RBC to bile salts. In this study we have shown that both the MCV and the number of erythrocytes present strongly influence the extent of bile salt-induced hemolysis.

ACKNOWLEDGMENT

This study was carried out with the financial support of MURST (40 and 60%) grants.

Fatty Acid Content and Composition of *Oenothera hookeri* Seeds Containing Mutant Plastids

Melvin D. Epp and **Michael R. Pollard***
The Plant Cell Research Institute, Inc., Dublin, California 94568

The effects of plastid mutations on seed oil content and fatty acid composition are of considerable interest. Seeds of a number of plastome mutants produced by the *pm* plastome mutator line of *Oenothera hookeri* were therefore harvested to investigate these effects. The mutants were altered solely in their plastome: each seed lot had the same nuclear background. To facilitate the study, a rapid single-step method was developed to simultaneously assay both oil content and fatty acid composition of small quantities of *Oenothera* seed. The lipid analyses showed that the mutated plastome often changed the oil content of the seeds, and that such changes always reduced oil content. Strong negative correlations were observed between oil content and palmitate or γ-linolenate, and a strong positive correlation was observed between oil content and linoleate. This is the first instance to our knowledge in which plastid mutations have been unequivocally demonstrated to affect seed oil content and composition. Such effects would be indirect, since the mutated plastid genes would not be the structural genes for enzymes on the pathway of oil biosynthesis. The plastid mutations demonstrate another layer of potential complexity in understanding oilseed genetics.
***Lipids* 28, 1005–1009 (1993).**

Analysis of the inheritance of oil content in seeds of diverse species, such as rapeseed (1), soybean (2,3), sunflower (4) and lupin (5), has shown that seed oil content is determined largely by the genotype of the maternal parent and that the effect of the genotype of the seed embryo is small. By contrast, seed oil composition is largely under the control of the genotype of the developing embryo with smaller and variable maternal influences. For example, in soybean, maternal influences have been reported to influence oleate and linoleate levels (3), but not linolenate (3,6) or stearate levels (7). Maternal control of seed oil content in rapeseed does not persist into the F2 generation and appears not to be under cytoplasmic control (1). It was therefore reasoned that maternal control of oil content was mediated by a metabolic dependence of the developing embryo on the seed-bearing plant (8). However, it has been suggested that other factors, such as genetic cytoplasmic elements or even endosperm tissue, might play a role in seed oil biosynthesis (5). The effects of cytoplasmic inheritance on fatty acid composition and content are documented for corn (9). Sixteen male sterile cytoplasms (presumably mutations in the mitochondrial genome) were examined in two nuclear backgrounds. The oleate and linoleate levels were similar in the different cytoplasms, while oil content varied considerably.

Oenothera has recently received considerable attention as a producer of γ-linolenic acid (10–12). *Oenothera biennis* is grown commercially for seed production. Another facet of the genus *Oenothera* is the availability of plastome mutants generated by plants homozygous for the recessive gene *pm*, plastome mutator (13). This gene functions similar to other nuclear gene-induced plastid mutator systems (14) and includes the induction of plastid mutations with many different phenotypes (13,15). The precise function of *pm* is not known, but it is believed to be involved in chloroplast DNA replication or repair (16).

Chloroplast mutants are maintained as mosaics on plants with normal green plastids. *Oenothera* has biparental transmission of plastids, and mutant plastids can be transmitted sexually if flowers develop on stems which have mutant plastids in the subepidermal histogenic tissue layer LII, since the pollen and egg cells are derived from this tissue (17). When a flower which derives from LII with mutant plastids is self-pollinated, all the seeds are composed of tissues with mutant plastids only. By identifying variegation on sibling plants within a population derived from the self-pollination of a single inbred plant, the nuclear genetic influences can be kept constant, and one can study the differences generated by the plastid mutations.

Most, if not all, of the genes coding for the enzymes of fatty acid and lipid synthesis are nuclear encoded (18). Also, it is known that the site of *de novo* fatty acid biosynthesis in plants is the plastid (19). Thus, it is of interest to see how plastid mutations would affect seed oil content and composition in *Oenothera*, since the mutations would not directly affect enzymes on the pathway. To facilitate this study, a rapid, single-step method was developed to simultaneously assay the oil content and fatty acid composition of small quantities of *Oenothera* seeds.

MATERIALS AND METHODS

Plant material. Plants of an inbred line (84007) of *O. hookeri* strain Johansen with plastome I were used as the control for this study. Plants of an inbred line (84009) of *O. hookeri* strain Johansen with plastome I and homozygous for the gene *pm* were used as the source of plastome mutations. During the course of the growing season, over 100 of the 411 sibling plants within 84009 developed variegated sectors. Once a mutational sector was evident, the sector remained stable in color and enlarged in a manner consistent with the patterns of growth and development characteristic of *Oenothera*. A sample of sectors was selected for analysis, which typified the range of possible mutant phenotypic colors. The photosynthetic lesions of these mutant chloroplasts were not determined. All experimental plants were grown together in a greenhouse to minimize environmental factors that might alter oilseed content and composition. Seed from self-pollinated flowers originating from 17 different sectors that included mutant subepidermal histogenic layer II were harvested. Additionally, the seeds of two green plants were harvested individually for use as controls. Paired comparisons were made with two plants where seeds were produced both on an all-green branch and on a mutant sector. Also compared were two mutants on a single plant. For both types of paired comparisons, analyses will reflect plastid differences, because the nuclear contribution is identical.

Abbreviation: GC, gas chromatography.

For the analysis of tissues with plastome mutations, the seeds were from individual plants or from individual sectors on single plants. Because the nuclear genetic background of these sibling inbred plants were similar, the differences between mutants is thought to reflect the influence of the chloroplastic mutants themselves.

Lipid analysis. Seeds were weighed into 50–100 mg lots, dried to constant weight at 80°C and reweighed. The seeds were transferred to glass reaction tubes with Teflon-lined screw caps, and the derivatization reagent was added. This reagent was composed of 2.0 mL of 5% sulfuric acid in methanol and 1.0 mL of either benzene or toluene containing a triheptadecanoin internal standard at a concentration of 0.5 mg/mL. The seeds plus reagent were heated at 90–100°C for 4 h, cooled, and 3 mL of water added. The tubes were shaken vigorously and then centrifuged to break the emulsion and give phase separation. An aliquot of the upper phase was injected directly onto the gas chromatography (GC) column.

GC analysis was performed using a 30 m × 0.25 mm fused silica column coated with Supelcowax 10 (Supelco, Bellefonte, PA) stationary phase, run isothermally at 245°C, with injector and flame-ionization detector temperatures set at 250°C, using a "splitless" injection mode. Peak areas were measured with an electronic integrator. Because the variation in fatty acid chain length is very limited, fatty acid quantitation used peak areas without applying any corrections.

Multiple Soxhlet extractions of ground seeds with hexane were used to determine seed oil content. Linear regression analyses were performed on the seed oil content and fatty acid composition data set to determine r^2 values.

RESULTS AND DISCUSSION

Determination of fatty acid content and composition. Because of the limited amount of seed tissue available from the *pm* mutants, in some cases between 0.1–0.2 g, routine methods of oil content analysis (by nuclear magnetic resonance and gravimetrically by oil extraction with organic solvents) were considered inappropriate for accurate and quantitative measurements. However, it seemed reasonable that the small seeds of *O. hookeri* (*ca.* 0.45 mg each) could be derivatized directly in the presence of an internal standard, allowing the derivatization reagent to also perform the organic extraction. A similar approach was used to rapidly screen leaf lipids for fatty acid composition (20). Although the use of such direct derivatization methods on plant tissue to determine fatty acid composition is well known, their use to determine fatty acid content has only recently been demonstrated (21).

Soxhlet extraction of control seeds gave 0.247 mg oil per mg seed. Transmethylation of this oil in the presence of an internal standard gave 0.214 mg fatty acids per mg seed. For crushed seeds, the derivatization/extraction was rapid (< 30 min), but for whole seeds it was also complete within two hours. The final values for the extraction/derivatization protocol with crushed or whole seeds were slightly higher than for the extracted oil. Six independent determinations of fatty acid content gave 0.217 ± 0.003 mg fatty acids per mg seed (Table 1, Experiment 1). This indicated that a high degree of reproducibility is possible for this type of analysis. Fatty acid composition of the extracted oil differed only marginally from that obtained by the derivatization/extraction protocol. The comparison was repeated in a second experiment (Table 1, Experiment 2). The slightly higher fatty acid contents compared to Experiment 1 may have resulted from a new batch of triheptadecanoin internal standard being made up, the quality of the internal standard being a potential source of error between experiments.

The results reported from Experiments 1 and 2 (Table 1) are in general agreement with those reported in the literature for *O. hookeri* (10). The small differences could easily be due to either genotypic differences within the species, or environmental differences during plant growth and seed set (22). The method can thus be used to accurately, rapidly and simultaneously screen for both fatty acid composition and oil content in small batches of dried seeds.

Analysis of the fatty acid content and composition of Oenothera *seeds.* Table 2 shows the seed weights and seed lipid analyses for 17 different mutants and five controls ("normal green") of *O. hookeri.* The sectors producing these seeds were considered independent plastome mutational events, because the sectors were not evident in the cotyledonary tissues and, in most cases, not in the first few leaves of the maternal plants. The colors of the sectors ranged from "white" to "yellow" to "light green" and "yellow green". The frequency of the mutational events,

[a]Number of seed batches analyzed for fatty acid composition and content. For each seed batch, duplicate gas chromatography runs were made.
[b]Total fatty acid or γ-linolenic acid contents are expressed as mg fatty acids per mg dry seed weight × 100.
[c]18:3 is solely γ-linolenic acid.

the spectrum of phenotypic differences and the cytoplasmic transmission of the variegation were consistent with published data (13). Although the mutational frequency of plants homozygous for *pm* is approximately 1,000 times higher than spontaneous rates (13), the rate is still sufficiently low that only rarely do two mutations occur on a single plant within a single growing season. Thus the sectors were expected to give results that would be consistent even when sexually transmitted to subsequent generations. In Table 2, oil content is reported on a dry weight basis. The seed weights ranged from 0.36 to 0.50 mg per seed, indicating good seed fill in all cases except for 84009-139. In 84009-139, the seeds were uniformly smaller and had much lighter colored seed coats. The sector for this mutant involved a whole branch and also showed reduced seed weight. The other mutants were maintained as periclinal chimeras in which LII had the mutant plastids, and LIII was normal green. The tissues with mutant plastids derived their energy from the normal green portions of the plant. This juxtaposition of mutant and green tissues may influence the response of the mutants. Some examples of the influence of adjacent tissue have been described in *Oenothera* (23) involving nuclear-plastome incompatibilities. However, since the seeds with mutant plastids differ from the seeds with wild-type plastids, this influence may cause some modulation in response but the influence was insufficient to compensate for the defects in the mutant plastids.

The oil content of the bulked seeds was 22.7%, and the range for seeds from individual normal green plants was 20.4 to 26.1%. The range of oil content values for the seeds with mutant plastids was 6.2 to 25.6% with 10 of the 17 seed lots from mutant plastid sectors falling within the wild-type range. No plastid mutations were observed which increased oil content.

The results of three paired analyses are presented in Table 2. In two comparisons, seeds from both the normal green portion of the plant and seeds from a mutant sector on the same plant were analyzed. In both single plant comparisons, the seeds in the green portion were a little heavier. In the 84009-213 comparison, the fatty acid content of the seeds from the green tissue exceeded the content of the seeds from mutant tissue, but in the other example (84009-20) the fatty acid content was equivalent. Mutant seeds from 84009-213 had a significantly higher percentage of γ-linolenic acid than seeds from the "normal green" sector control. The third paired analysis involved two different plastid mutations on one plant, 84009-389. Both mutations had average seed weights below 0.4 mg/seed, with fatty acid contents below 20%, and both had γ-linolenic acid above 13%. Overall, the paired analyses show the uniqueness of each plastome mutation when the environmental factors and the nuclear genetic influences are kept constant.

Seeds from 13 additional mutant sectors were analyzed without a green paired control. The results of these analyses are listed in Table 2 in order of decreasing oil content. There was a strong inverse correlation between palmitate and oil content ($r^2 = 0.926$). Seeds from green control tissues had a palmitate range of 5.6–6.2%, while seeds from mutant tissues ranged from 5.9 to 10.3%. The inverse relationship between palmitate and oil content is interesting in the light of the current emphasis on breeding oilseeds for reduced saturated fatty acid levels. Other significant trends were an increase in γ-linolenate ($r^2 = 0.629$) and a decrease in linoleate ($r^2 = 0.781$) as the fatty acid content decreased, and an inverse relationship between linoleate and γ-linolenate ($r^2 = 0.700$). For linoleate, seeds of control tissues ranged from 73.4 to 75.9%, and the seeds with mutant plastids ranged from 65.3 to 74.7%. The ranges for γ-linolenate were 9.5 to 10.6% for the controls and 10.8 to 15.9% for the seeds from mutants. The changes in fatty acid composition are a reflection of the fatty acid composition of the triacylglycerol fraction (data not shown), which is the dominant lipid in the seed oils of all the mutants.

The changes in the level of γ-linolenic acid are of particular interest because, in *Oenothera*, γ-linolenic acid is a seed-specific fatty acid. It is reported to be absent in leaves (12). The biosynthesis of γ-linolenic acid is believed to occur by the cytoplasmic desaturation of *sn*-2-linoleoyl phosphatidylcholine and has been most extensively studied on *Borago officinalis* (24). The Δ6 desaturase is presumably coded by a nuclear gene, as plastid-encoded gene products are not exported to the cytoplasm. We can speculate that the plastome-mutant modulation in the relative amount of γ-linolenic acid might be controlled by the flux through the lipid biosynthetic pathway, since there appears to be an inverse relationship between the amounts of linoleic and γ-linolenic acid. A reduced flux would result in a longer residence time for linoleoyl moieties in phosphatidylcholine molecules, increasing their availability for Δ6 desaturation. In some of the mutants, not only does the percentage of γ-linolenic acid in the oil increase, but the actual content of γ-linolenic acid on a percentage of seed weight basis also increases. Clearly, further experiments to test lines such as 84009-389, -348 or -353 for the inheritance of increased γ-linolenate and for seed yield would be worthwhile. Conversely, breeders selecting for higher γ-linolenate in *Oenothera* seed oils should be aware of the inverse linkage between γ-linolenate and oil content, and the potential influence of cytoplasmic (plastid) genetics; they may prefer to make selections to break this linkage and to look for nuclear-encoded traits.

The implication is that in some general way these mutant plastids have a genetic defect which prevents the plastids from developing into fully functional, photosynthetically active chloroplasts. This represents the visual basis upon which the mutants were identified and selected. The results in Table 2 would indicate that these lesions appear also to affect the accumulation and processing of fatty acids in seeds. The plastid mutations involved in this study have not been analyzed for their fine structure using electron microscopy. However, four other *pm*-induced mutants have been analyzed (15). In these four mutants, the internal membranes were reduced in quantity in phenotypes with less color. In particular, mottled mutants had developed disorganized membranes, yellow had a few too many abnormal thylakoids, and white had little to no internal membranes. A recent analysis of leaf tissues from a specific *O. hookeri* plastome mutant, *pm7*, showed that approximately equal amounts of plastid membrane components (fatty acids, acyl lipids and carotenoids) were present in both mutant and wild-type (25). Instead, there appeared to be a defect in chloroplast protein processing, which resulted in a lack of photosynthetic electron transport chain activity, thylakoid membrane

structures and chlorophyll biosynthesis. Fatty acid biosynthesis was not affected and was apparently not tightly linked to the development of a functional photosynthetic apparatus.

For fatty acid synthesis in seeds, the *pm*-induced mutations involve biosynthetic activity, which precedes the need for fully developed chloroplasts since only leucoplasts (proplastids) exist in developing seeds during the time when the seeds oils are synthesized. However, the present study has demonstrated that it is possible for mutations in the plastid genome to significantly alter seed oil content and modulate seed oil composition. This is not a surprising result, but we believe that this is the first time such a phenomenon has been directly demonstrated. It is not clear exactly what the influence of pigment-deficient maternal tissue is on the change in oil accumulation in the developing embryo and whether or not the plant adjusts its seed set to compensate for the reduced photosynthate. Indeed, the simplest explanation is that the changes in oil composition and content are mediated through reduced photosynthate availability in the supporting maternal tissues. However, the paired comparisons do strongly suggest that the mutants themselves are a major determinant in both accumulation and composition.

The effects of these plastome mutations on seed oil content and composition are almost certainly indirect; that is, the mutated genes do not code for enzymes directly involved in lipid biosynthesis. However, these results highlight the effect of an additional genetic component, the plastid, which can bring additional complexity to our understanding of seed oil genetics. Whether the observation that plastid mutations only decrease oil content, and the relationships between oil content and palmitate or linoleate are universally applicable to all oilseeds, remain to be determined, as do the mechanisms underlying these effects.

ACKNOWLEDGMENTS

We wish to thank our colleagues J.B. Mudd, L. Sernyk and J. Romero-Severson for critical comments on the manuscript, and Sue Colson and Ann Hefner for their technical assistance in running the GC assays.

Isolation of Brominated Long-Chain Fatty Acids from the Phospholipids of the Tropical Marine Sponge *Amphimedon terpenensis*

Mary J. Garson[a,*], Mary P. Zimmermann[b], Max Hoberg[b], Rundi M. Larsen[c], Christopher N. Battershill[d] and Peter T. Murphy[d]

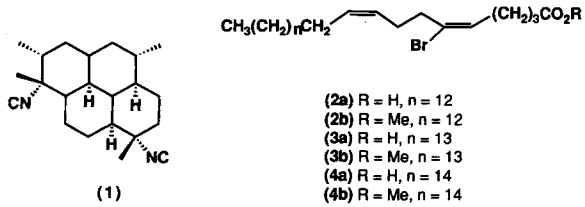
[a]Department of Chemistry, The University of Queensland, Brisbane, Queensland 4072 and Department of Chemistry, University of Wollongong NSW 2500 Australia, [b]Department of Chemistry, Stanford University, Stanford, California 94305, [c]Sir George Fisher Centre for Tropical Marine Studies, James Cook University of North Queensland, Townsville, Queensland 4811 Australia and [d]Australian Institute of Marine Science, Townsville MC Queensland 4810 Australia

Preliminary investigation of the phospholipid fatty acid composition of the tropical marine sponge *Amphimedon terpenensis* by gas chromatography/mass spectrometry revealed the presence of some novel brominated fatty acids. Two new brominated fatty acids, (5*E*, 9*Z*)-6-bromo-5,9-tetracosadienoic acid (2a) and (5*E*, 9*Z*)-6-bromo-5,9-pentacosadienoic acid (3a) were subsequently isolated from a chloroform/methanol (3:1, vol/vol) extract of the sponge and characterized as their methyl esters 2b and 3b. The known brominated fatty acid (5*E*, 9*Z*)-6-bromo-5,9-hexacosadienoic acid (4a) was also isolated. The new fatty acid methyl esters were confirmed as brominated Δ5,9 acid derivatives by chemical ionization mass spectrometry. The position of the bromine substituent was determined to be C-6 by nuclear magnetic resonance techniques while the stereochemistry of the two double bonds was deduced by nuclear Overhauser enhancement difference spectroscopy. The biosynthetic implications of the co-occurrence of the three brominated acids are discussed.

Lipids 28, 1011-1014 (1993).

Marine sponges (Phylum porifera) are characterized by wide variation in sterol composition and by the presence of nuclear-modified or side chain alkylated sterols (1,2), some of which are cell membrane components (3,4). The unusual composition of marine sterols is frequently complemented by the presence of unusual phospholipid fatty acids (1,5), and is presumed to result in a unique membrane structure which may be an important factor in the survival of this "dead end" phylum. Characteristics of the fatty acids isolated from sponges include long carbon chains (C_{24}-C_{34} very long chain fatty acids, VLFA) with novel branching and unsaturation patterns or substituents (1,6,7).

The tropical marine sponge *Amphimedon terpenensis* contains low levels of Δ5,7 sterols with conventional side chains (8), together with large quantities of a tetracyclic diterpene, diisocyanoadociane **1** (Scheme 1), recently shown by us to be associated with the sponge cell membranes (9). This raised the intriguing possibility that the phospholipid components of this sponge might be modified in order to accommodate the terpene within a stable lipid bilayer, which prompted us to analyze the fatty acids present in *A. terpenensis;* we now report the structures of two new brominated fatty acids characterized as their methyl esters using nuclear magnetic resonance (NMR) and mass spectrometric (MS) analysis.



SCHEME 1

EXPERIMENTAL PROCEDURES

Sponge samples. Specimens of *A. terpenensis* (Australian Museum No. 4978) were collected near Townsville using scuba, specifically from John Brewer Reef at −15 m in November 1987 and at −10 m from Davies Reef in December 1989.

Extraction and isolation of phospholipids. A. terpenensis (10 g) collected in November 1989 was extracted with $CHCl_3$/methanol (1:1, vol/vol) to yield total lipids (350 mg). The neutral lipids, glycolipids and phospholipids were separated according to the procedure of Privett *et al.* (10). A portion of the phospholipid extract (50 mg) was transmethylated with 1.4 M HCl in methanol and the resulting fatty acid methyl esters (FAME) purified by passage through a short plug of florisil (200 mesh; Aldrich, Milwaukee, WI) using toluene as eluant. After solvent removal, the residue was dissolved in hexane and analyzed by capillary gas chromatography (GC) using a Hewlett-Packard (Palo Alto, CA) 5790A series gas chromatograph equipped with a 25-m (0.3 mm i.d.) SE-54 coated, fused silica column programmed at 170–320°C, and an automatic injector system (sampler model 7672A), injector (model 3392A) sampler/event control module (model 19405A), together with a computerized fatty acid library (software S/N 2614R100027, version 1.2) previously used for the fatty acid analysis of *Pseudaxinyssa* sp. (11), *Tethya* sp. (12) and a hymeniacidonid sponge (13).

Isolation and identification of fatty acids. A specimen of *A. terpenensis* (380 g wet weight) collected in November 1989 was washed in sea water and carefully cleaned of all non-sponge debris and chopped into small pieces. After freeze-drying, the sponge was extracted with $CHCl_3$/methanol (1:1, vol/vol) yielding a total of 15.6 g of lipids (4.1%). A portion (3.12 g) was transmethylated with 14% BF_3/MeOH under N_2, and the FAME were purified by silica column chromatography using hexane/diethyl ether

*To whom correspondence should be addressed.

Abbreviations: CIMS, chemical ionization mass spectrometry; COSY, correlation spectroscopy; ECL, equivalent chain length; EIMS, electron impact mass spectrometry; FAME, fatty acid methyl ester; FTIR, Fourier transform infrared; GC, gas chromatography; HMQC, heteronuclear multiple quantum coherence; HPLC, high-performance liquid chromatography; MS, mass spectrometry; NMR, nuclear magnetic resonance; NOE, nuclear Overhauser enhancement; VLFA, very long chain fatty acid.

(19:1, vol/vol) as eluant to give 50 mg of FAME extract. A 1-mg portion of FAME was dissolved in 0.25 mL hexane and passed through a short silica column (thin-layer chromatography grade, 5 cm height silica) eluting with hexane (10 mL). After solvent concentration, the resulting hexane extract (1 mL) was analyzed by GC. For the isolation and characterization of individual FAME, the remaining extract (49 mg) was first purified by reverse-phase high-performance liquid chromatography (HPLC) (Waters Millipore, Bedford, MA; M6000 pump, U6K injector, R401 differential refractometer) using two Altex Ultrasphere ODS columns (10 mm i.d. × 25 cm) in series and absolute methanol as the mobile phase at 3 mL/min. Fractions identified by GC as containing brominated FAME were further purified by reverse-phase HPLC using two Altex Ultrasphere ODS columns (10 mm i.d. × 25 cm) and acetonitrile/methanol/ethyl acetate (11:4:4, by vol) as mobile phase at 2 mL/min to give methyl (5*E*, 9*Z*)-6-bromo-5,9-tetracosadienoate (**2b**; HPLC retention time in MeOH relative to methyl palmitate, 1.97; 0.50 mg, 1.0%), methyl (5*E*,9*Z*)-6-bromo-5,9-pentacosadienoate (**3b**; HPLC retention time in MeOH relative to methyl palmitate, 2.29; 1.75 mg, 3.5%), and methyl (5*E*,9*Z*)-6-bromo-5,9-hexacosadienoate (**4b**; HPLC retention time relative to methyl palmitate 2.70; 0.65 mg, 1.3%), respectively. Further processing of the crude extract provided 2.1 mg of **2b**, 10.6 mg of **3b** and 2.7 mg of **4b**. *N*-Acyl pyrrolidide derivatives were prepared by direct treatment of methyl esters with pyrrolidine/acetic anhydride (10:1, vol/vol) in capped vials at 100°C for 1 h, followed by ethereal extraction from the acidified solution and purification by short column chromatography using hexane/diethyl ether (8:2, vol/vol) as eluant. Samples for ^{1}H NMR were run as solutions in $CDCl_3$ on a Varian XL-400 (Palo Alto, CA), JEOL GX-400 (Tokyo, Japan) or a Bruker AMX-500 spectrometer (Karlsruhe, Germany), referenced to $CHCl_3$ at δ 7.25. Samples for ^{13}C NMR were run as solutions in $CDCl_3$ on a Bruker AMX-500 spectrometer with Waltz decoupling referenced to $CDCl_3$ at 77.0 ppm. A 2D COSY (correlation spectroscopy)-45 spectrum was run on a Varian XL-400 spectrometer using a spectral width of 2946 Hz, an acquisition time of 0.17 s and a pulse delay of 1.0 s. Sixteen scans were accumulated for each of 256 increments into each of 1024 data points. The spectrum was zero-filled before Fourier transformation. Nuclear Overhauser enhancement (NOE) difference spectra were obtained on a JEOL GX-400 spectrometer using a 90° pulse and a 20 s pulse delay. A heteronuclear multiple quantum coherence (HMQC) experiment was run on a Bruker AMX-500 spectrometer using 8 scans for each of 512 increments accumulated into 2048 data points, with a 0.6 s delay for the Bird Sequence, and 3 s recycle delay (14). The experiment was optimized for a ^{13}C-^{1}H one-bond coupling constant of 135 Hz. The phase cycling program TPPI was used. Prior to Fourier transformation, the initial data matrix was zero-filled in each dimension and multiplied by a sine-squared bell function in both the t_1 and t_2 dimensions. The spectrum was not symmetrized, but the T_1 noise was eliminated using the program *Aurelia*. Samples for electron impact mass spectrometry (EIMS) were dissolved in hexane and run on a Hewlett-Packard HP 5995 GC/MS instrument in the direct insertion mode while samples for chemical ionization mass spectrometry (CIMS) were run on a Ribermag R-10-10 quadrupole mass spectrometer with ammonia as reagent gas. GC/MS samples were analyzed using a Ribermag GC/MS/DS system which combines a Ribermag R-10-10 quadrupole mass spectrometer with a Carlo Erba series 4160 Fractionvap chromatograph (Carlo Erba, Milano, Italy) containing a fused silica column (28 m × 0.32 mm) with SE-54 (J&W Scientific Inc., Folsom, CA). Samples for Fourier transform infrared (FTIR) spectrometry were run on a Bomen DA3.26 spectrometer (Bomen, Quebec, Canada) as solutions in $CHCl_3$.

A FAME extract of a hymeniacidonid sponge was prepared by $CHCl_3$/MeOH treatment of wet tissue (21.2 g) followed by methylation as described above.

RESULTS

The major fatty acids of *A. terpenensis* were identified in standard fashion from GC equivalent chain length (ECL) values and EIMS of methyl esters and *N*-acyl pyrrolidides. As shown in Table 1, the most abundant phospholipid fatty acids were generally 16:0 and 18:0 together with 3,7,11,15-tetramethylhexadecanoic acid (phytanic acid); however, the three brominated acids, initially detected by GC/MS, were also present in significant quantity. Complete phospholipid fatty acid analyses of *A. terpenensis* will be presented in a separate paper (15).

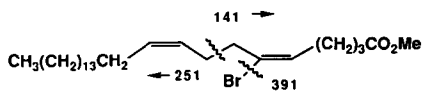
Samples of each new brominated FAME were purified by reverse-phase HPLC and their structures elucidated by NMR and MS. Under CIMS conditions, the major brominated FAME, **3b**, had strong peaks due to ($M + NH_4^+$) adduct ions with the 51:49 ratio characteristic of a single bromine substituent. The molecular ion (*m/z* 472, 470) corresponded to a molecular formula of $C_{26}H_{47}O_2Br$, confirming a C_{25} acid, while major peaks at 391, 251 and 141 were assigned as shown in Scheme 2. Under EIMS conditions, **3b** showed a major peak at *m/z* 74 (McLafferty rearrangement) together with a series of peaks at *m/z* 391, 359, 341 and 317, closely corresponding to those for a C_{26} monobrominated FAME **4b** recently reported from

TABLE 1

Major Phospholipid Fatty Acids of *Amphimedon terpenensis* by Analytical GC[a]

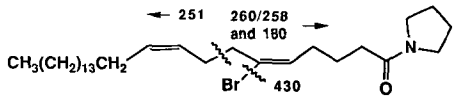
FAME	ECL	%
16:0	16.00	13.5
18:0	18.00	2.6
Phytanic acid	17.74	10.0
24:2 + Br (**2b**)	26.24	0.7
25:2 + Br (**3b**)	27.28	2.5
26:2 + Br (**4b**)	28.31	1.1
18:1	17.76	2.1

[a]Normalized to phytanic acid, average of three values. Other fatty acids present in *A. terpenensis* are identified in Reference 15. Abbreviations: GC, gas chromatography; FAME, fatty acid methyl esters; ECL, equivalent chain length; Br, brominated.



SCHEME 2

a hymeniacidonid sponge (13), except for the 14 amu mass difference. EIMS of the pyrrolidide derivative of **3b** gave weak molecular ions at 511 and 509 in the expected ratio, together with ions at 430, 260, 258, 180 (assigned as in Scheme 3) and 113 (McLafferty rearrangement). This mass spectrum corresponded to that reported for the pyrrolidide of **4b** apart from the 14 amu difference.



SCHEME 3

The structure of **3b** was unambiguously elucidated by 400 MHz NMR in $CDCl_3$. Downfield signals in the spectrum were a triplet (1H) at δ 5.85 together with a complex 2H multiplet at δ 5.31–5.41. The methylene envelope at δ 1.25–1.40 integrated for 26 protons while the presence of a triplet integrating for 3H at δ 0.87 ruled out chain branching. The connectivity from $(H\text{-}2)_2$ at δ 2.32 (*t*) to H-5 at δ 5.85 was deduced from a COSY-45 spectrum as was that from $(H\text{-}7)_2$ at δ 2.45 (*t*) to $(H\text{-}11)_2$ at δ 2.06 (*m*). In particular, $(H\text{-}7)_2$ and H-5 showed only one cross peak each in the COSY-45; therefore, the bromine substituent was located at C-6, consistent with the downfield shift of the adjacent H-5 relative to H-9 and H-10. Full ^1H and ^{13}C assignments are given in Table 2.

The absence of prominent bands between 960–980 cm^{-1} in the FTIR spectrum of **3b** suggested a *Z* configuration for the Δ9 double bond (13,16). This stereochemistry, together with the *E* stereochemistry for the Δ5 double bond, were confirmed by the observation of NOE effects between H-4 and H-7 and between H-8 and H-11. The 5*E*, 9*Z* stereochemistry has been found previously in brominated fatty acids (13,16).

The second new brominated FAME was suggested by its GC and HPLC characteristics to be the C_{24} acid **2b**, and this identification was confirmed by NMR, MS and HPLC. Under EI conditions, **2b** showed the expected series of peaks at 377, 345, 327, 303, 236, 141 and 74. The *N*-acyl pyrrolidide showed weak molecular ions at 497 and 495 together with ions at 416, 260, 250, 180 and 113. The proton NMR spectrum was identical to that of **3b** except that the methylene envelope integrated for 24 protons. The lack of prominent IR bands between 960–980 cm^{-1} suggested a *Z* configuration for the Δ9 double bond.

The remaining brominated FAME **4b** was identified as the C_{26} acid by comparison of its GC, MS and NMR data with the compound reported recently by Lam *et al.* (13). The stereochemistry of the two double bonds of **4b** was confirmed as 5*E*, 9*Z* by co-injection of a purified sample of **4b** from *A. terpenensis* with a crude extract prepared from a hymeniacidonid sponge.

DISCUSSION

Litchfield and Morales (17) reported high levels of long-chain fatty acids in sponges of the class Demospongiae, and furthermore suggested that these "demospongic" fatty acids might be membrane components. Bergquist and colleagues (18,19) reported on the fatty acid composition of 85 species of Porifera and noted that seasonal and geographic variations occur, restricting the chemotaxonomic relevance of fatty acid data. Brominated fatty acids have to date been found in *Xestospongia* spp. (C_9, C_{16} and C_{18} acids), in *Petrosia* spp (C_{18}, C_{27} and C_{28} acids) and in a sponge tentatively identified as belonging to the family Hymeniacidonidae (C_{26} acid) (13,16,20–27). *Xestospongia* and *Petrosia* represent very closely related genera with similar skeletal morphology, internal structure, growth form and ecology. It is now agreed that both genera belong within the family Nepheliospongidae (order Nepheliospongida). The precise taxonomic status of the sponge used in this study is unclear; it may prove to be a new genus, certainly within the order Haplosclerida, but the presence of isonitrile metabolites is reminiscent of some Axinellida. Until further electron microscopy can be done on cell structure, the sponge is referred to the genus *Amphimedon* (family Niphatidae, order Haplosclerida) (28). It is possible that the presence of brominated fatty acids may represent a useful taxonomic characteristic with which to position sponges in the Nepheliospongida and Haplosclerida. The species sample is too small at the present to make any strong suggestion on that matter.

Fatty acids with a Δ5,9 substitution pattern are characteristic of marine sponges (2,5,7,8,13,16). The VLFA isolated in this study have exclusively Δ5,9 unsaturation. There is no evidence for the presence of trienoic acids such as 24:3 or 26:3 (2,13) or the corresponding monoenoic acids 24:1, 25:1 and 26:1 (2,11–13) in *A. terpenensis*. Although Carballeira and Shalabi (27) recently reported the isolation of C_{27} and C_{28} brominated fatty acids from a Petrosiid sponge, the isolation of 24:2 brominated, 25:2 (brominated)

and 26:2 (brominated) represents an interesting example of such homology in a marine sponge.

The biosynthesis of brominated fatty acids has been evaluated by Lam *et al.* (13) and was found to conform to the currently accepted mode of fatty acid biosynthesis in marine sponges (1). The bromine substituent is introduced following chain elongation and desaturation of a 16:0 precursor. In this manner, the formation of 24:2 brominated and 26:2 brominated acids may be explained, but our isolation of a 25:2 brominated acid suggests that sponges may additionally have the capacity to chain extend, desaturate and functionalize an odd carbon chain length fatty acid also. Odd carbon chain fatty acids, such as 15:0 and 17:0, generally have a branched structure rather than straight chain structure and are usually found in bacteria. *A. terpenensis* contains both bacterial and cyanobacterial symbionts (10), thus an additional consideration is which of the three cell types, sponge, bacteria or cyanobacteria contains the brominated fatty acids. This question is being addressed in another report from our group (15).

ACKNOWLEDGMENTS

This work was supported by grants from the Australian Research Council (to MJG and PTM), the Royal Society (to MJG) and NIH grants GMO6840 and AM094257 to Professor Carl Djerassi. We also thank the University of Wollongong for financial support. MJG thanks Professor Carl Djerassi for his generous hospitality during a short study leave spent at Stanford University, and Professor Pat Bergquist and Drs. John Hooper and Jane Fromont for taxonomic discussions.

Overoxidation of α-tocopherol (1a) by silver nitrate produces tocored (9a) as a major product. The aim of the present work was to elucidate the pathway of formation of tocored using the α-tocopherol model compound, 2,2,5,7,8-pentamethyl-6-chromanol (1b). Oxidation of 1b by silver nitrate in ethanol produces 2-(3-hydroxy-3-methylbutyl)-3,5,6-trimethyl-1,4-benzoquinone (6b) and 2,2,7,8-tetramethylchroman-5,6-dione (9b, the model compound of tocored) as major products. Formation of 6b is rapid and is accompanied by an equally rapid fall in pH. Formation of 9b only occurs after 6b has reached maximum concentration and has begun to decline. It appears that acid promotes the dehydration and recyclization of 6b into a quinone methide (2b), which is then rehydrated into 5-hydroxymethyl-2,2,7,8-tetramethyl-6-chromanol (5b), the phenolic isomer of the quinone 6b. Oxidative deformylation of 5b leads to 9b. It is also demonstrated that 6b, heated in ethanol in the presence of acid and in the absence of any oxidizing agent, is converted into 9b, 1b, 5-ethoxymethyl-2,2,7,8-tetramethyl-6-chromanol (4b) and 2-(3-hydroxy-3-methylbutyl)-3-ethoxymethyl-5,6-dimethyl-1,4-benzoquinone (7b). It seems that dehydration and recyclization of 6b into 5b occurs as above and that 6b then oxidizes 5b into 9b, while being reduced into the hydroquinone of 6b (6bH_2). Compound 6bH_2 then cyclizes in acid to 1b. A possible alternative pathway from 6b to 9b that does not involve 5b is also discussed. These results suggest that 6b and, by implication, α-tocopheryl quinone (6a), is not a stable compound and, in the presence of acid, is readily oxidized to 9b.

Lipids 28, 1015–1020 (1993).

There has been much discussion in the literature as to whether α- or γ-tocopherol is the better antioxidant. Much of the early work suggested that γ-tocopherol (**10a**) was a better antioxidant than α-tocopherol (**1a**) (1–4), whereas more recent work has suggested the reverse (5–8). It has been proposed that antioxidant activity may be best assessed in an initiated autoxidation system and that, in such a system, **1a** is better than **10a** (9). Using an uninitiated autoxidation system, we have found that 2,2,7,8-tetramethyl-6-chromanol (**10b**), the model compound of **10a**, was a far superior antioxidant to 2,2,5,7,8-pentamethyl-6-chromanol (**1b**), the model compound of **1a** (10). Thus our results agree with those in the early literature.

We have suggested that the superior performance of **10b** over **1b** in the uninitiated system may be due to oxidation products of **10b** rather than to **10b** itself (10). Thus 2,2,7,8-tetramethylchroman-5,6-dione (**9b**), which is a major oxidation product of **10b** (Kohar, I., and Southwell-Keely, P.T., unpublished results) has antioxidant activity and may extend the activity of **10b**, whereas 2-(3-hydroxy-3-methylbutyl)-3,5,6-trimethyl-1,4-benzoquinone (**6b**), which is the major oxidation product of **1b**, has no antioxidant activity (10).

Compound **9b**, in addition to being a major oxidation product of **10b**, can also be formed by overoxidation of **1b** (11). Treatment of **1b** with silver nitrate at 65°C in absolute ethanol for 2 h gave **9b** (40%) and 5-ethoxymethyl-2,2,7,8-tetramethyl-6-chromanol (**4b**, 30%) as the major products (12). Formation of both these compounds is believed to occur through an intermediate quinone methide (**2b**) (Scheme 1). Addition of ethanol to **2b** would form **4b**, whereas addition of water to **2b**, followed successively by oxidation, further addition of water, deformylation and further oxidation would form **9b** (12). Although this reaction was performed in absolute ethanol, there was sufficient water (0.5%) in the solvent to account for formation of compound **9b** by this pathway. Nonetheless, there was an overwhelming excess of ethanol in the reaction, and this led to the thought that compound **4b** might also be an intermediate in the formation of **9b**. The earliest report of compound **9b**, which did not include characterization of its structure, indicated that it could be formed from **1b** and also from **6b** by silver nitrate oxidation (11). Although **6b** was not a significant product

of our silver nitrate oxidation of **1b**, it was decided to follow the rate of oxidation of compounds **4b**, **5b** and **6b** in turn with silver nitrate to determine the most probable pathway to **9b**.

MATERIALS AND METHODS

Infrared (IR) spectra were determined on a Perkin Elmer (Norwalk, CT) 580B spectrometer, ultraviolet (UV) spectra on a Perkin Elmer 124 double beam spectrophotometer. ^{1}H and ^{13}C nuclear magnetic resonance (NMR) spectra were recorded on a Bruker (Karlsruhe, Germany) AM 500 spectrometer and were taken in $CDCl_3$ and are reported in parts per million downfield from tetramethylsilane as internal standard. Electron impact (EI) mass spectra were determined at 70 eV on an AEI (Manchester, England) MS 12 spectrometer. pH Measurements were made on a Crison micropH 2001 pH meter (Crison Instruments, Barcelona, Spain).

Compound **1b** (13), together with its spirodimer (14) and spirotrimer (14), 5-ethoxymethyl-2,2,7,8-tetramethyl-6-chromanol (**4b**) (15), 5-hydroxymethyl-2,2,7,8-tetramethyl-6-chromanol (**5b**) (16), 2-(3-hydroxy-3-methylbutyl)-3,5,6-trimethyl-1,4-benzoquinone (**6b**) (11), 5-formyl-2,2,7,8-tetramethyl-6-chromanol (17), 1H-2,3-dihydro-3,3,5,6,9,10,11a(*R*)-heptamethyl-7a(*S*)-(3-hydroxy-3-methylbutyl)pyrano[2,3-a]xanthene-8(7aH),11(11aH)dione (18), 2-(3-hydroxy-3-methylbutyl)-3-hydroxymethyl-5,6-dimethyl-1,4-benzoquinone (**8b**) (16) and 2,2,7,8-tetramethylchroman-5,6-dione (**9b**) (12), were prepared as reference compounds by known methods.

Hexane (Ajax Chemicals, Auburn, Australia) and isopropanol (BDH Chemicals, Poole, England) for high-performance liquid chromatography (HPLC) were passed through an Activon (Sydney, Australia) 0.45-μm filter, degassed (Waters Associates pump, Waters Associates, Milford, MA) and sonicated (Branasonic 12, Branson, Danbury, CT) before use. HPLC employed a Waters Associates M-45 solvent delivery system, U6K injector, with a 2-mL loop, a model 440 fixed wavelength (280 nm) detector, a National Pen Recorder (Matsushita, Yokohama, Japan) VP-6513A and an SIC Chromatocorder 12 (Alphatech, Tokyo, Japan) integrator. All compounds other than **5b** were separated isocratically using hexane/isopropanol (95:5, vol/vol) on a Waters μPorasil column (10 μm; 300 × 3.9 mm) at a flow rate of 1.1 mL/min. Separated compounds had the following retention times (min): **4b**, 3.0; **1b**, 3.4; **6b**, 5.1; **7b**, 6.3; **9b**, 7.2; and **8b** 14.0. For reasons that are not clear, but have to do with the lability of the compound, **5b** could not be detected with this system or in other normal phase systems (19), but was detected using methanol/water (92.5:7.5, vol/vol) as eluent on a Lichrosorb C_{18} column (10 μm; 250 × 4.6 mm) (Alltech Associates, Deerfield, IL). Compounds **5b**, **6b** and **9b** have the same retention time (3.7 min) in this reverse-phase system. Therefore, in order to determine the concentration of **5b**, duplicate samples were analyzed by normal- and reverse-phase HPLC, as above. The concentrations of **6b** and **9b**, determined by normal-phase HPLC, were converted into the corresponding areas for the reverse-phase system, and these were subtracted from the reverse-phase peak, which contained all three compounds.

Oxidation procedure. The following oxidation procedure was applied to compounds **1b**, **4b**, **5b** and **6b** and is illustrated for compound **1b**.

Oxidation of **1b** *by silver nitrate in absolute ethanol.* Compound **1b** (50 mg) was dissolved in absolute ethanol (45 mL) and heated to 60°C. An aliquot (2 mL) was taken as a control, then silver nitrate (500 mg) and absolute ethanol (5 mL) were added. The solution was stirred at 60°C for 3 h, during which it became orange-red and silver precipitated. Aliquots (2 mL) were taken for analysis at the following intervals (2, 5, 10, 15, 30, 60, 120 and 180 min). Each aliquot was diluted with water (5 mL) and extracted with diethyl ether (3 × 5 mL). The combined ether extracts were washed with water (2 × 5 mL), dried (Na_2SO_4) and the solvent removed *in vacuo.* The dry residue was dissolved in a little light petroleum and dried again under nitrogen. All fractions were analyzed quantitatively by HPLC.

pH of the reaction between **1b** *and silver nitrate.* Compound **1b** (25 mg) was dissolved in absolute ethanol (25 mL) and an aliquot (3 mL) taken immediately, diluted with distilled water (7 mL), and the pH determined. Silver nitrate (250 mg) was added to the remaining solution (22 mL), and the solution was heated at 60°C. Aliquots (3 mL) of the reaction mixture were taken at various intervals (1, 2, 5, 10, 20, 30 and 45 min) and added to cold distilled water (7 mL) to slow the reaction. The solutions were allowed to come to room temperature for pH determination. The pH values shown in Figure 1 are those of the diluted solutions. No attempt was made to correct the pH for dilution as the nature of the acidic material was unknown.

pH of the reaction between **4b** *and silver nitrate.* The protocol for this reaction was exactly the same as for the reaction between **1b** and silver nitrate.

Oxidation of **6b** *by silver nitrate in absolute ethanol.* Compound **6b** (100 mg) was dissolved in absolute ethanol

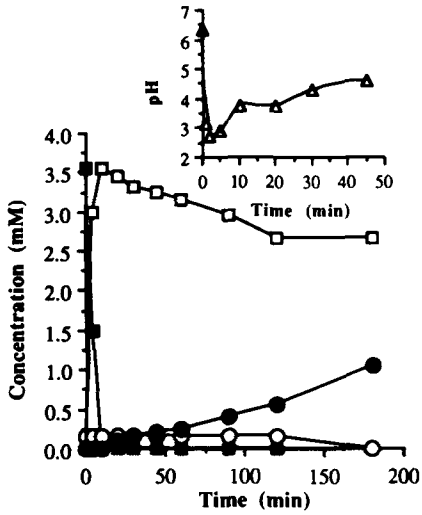

FIG. 1. Formation of products in the reaction between silver nitrate and 2,2,5,7,8-pentamethyl-6-chromanol (1b) in absolute ethanol at 60°C; ■, 1b; ○, 5-ethoxymethyl-2,2,7,8-tetramethyl-6-chromanol (4b); □, 2-(3-hydroxy-3-methylbutyl)-3,5,6-trimethyl-1,4-benzoquinone (6b); ●, 2,2,7,8-tetramethylchroman-5,6-dione (9b). Insert shows the change in pH during the course of reaction.

(20 mL), heated to boiling and an aliquot (1 mL) was taken as a control. Silver nitrate (1 g) was added, and the solution was stirred under reflux for 3 h. After 50 min the color turned orange, and after 60 min red crystals appeared on the wall of the flask. Aliquots (1 mL) of the reaction mixture were taken for HPLC analysis at the following intervals (5, 10, 15, 30, 60, 90, 120 and 180 min). The aliquots were diluted with water, extracted with diethyl ether and analyzed by HPLC as described previously.

Reaction of **6b** *with 0.03M sulfuric acid in absolute ethanol.* Fifty mg of **6b** was added to a 0.03-M solution of sulfuric acid in absolute ethanol (10 mL), and the solution heated at 60°C under nitrogen. Aliquots (1 mL) of the reaction mixture were taken for HPLC analysis at the following intervals (10, 20, 30, 45, 60 and 90 min). One mL of brine was added to each aliquot, and the solution extracted with diethyl ether (3 × 1 mL). The combined ether extracts were washed with brine (5 × 1 mL) and distilled water (1 mL), dried (Na_2SO_4) and the solvent removed *in vacuo*.

Reaction of **6b** *with* **5b** *in absolute ethanol containing 0.001 M sulfuric acid.* To a 0.001 M solution of sulfuric acid in absolute ethanol (5 mL) was added **5b** (25 mg) and **6b** (25 mg), and the solution heated at 60°C. Aliquots (0.5 mL) of the reaction mixture were taken for HPLC analysis at the following intervals (3, 5, 15, 30, 45 and 60 min). One mL of brine was added to each aliquot, and the solution extracted with diethyl ether (3 × 1 mL). The combined ether extracts were washed with brine (5 × 1 mL) and distilled water (1 mL), dried (Na_2SO_4) and the solvent removed *in vacuo*.

*Isolation of 2-(3-hydroxy-3-methylbutyl)-3-ethoxymethyl-5,6-dimethyl-1,4-benzoquinone (***7b***).* Compound **4b** (50 mg) and silver nitrate (500 mg) were added to absolute ethanol (50 mL), and the solution heated at 60°C for 3 h during which time the solution changed to blood red and silver precipitated. Water (25 mL) was added, and the solution was extracted with diethyl ether (3 × 25 mL). The combined ether extracts were washed with water (3 × 25 mL), dried (Na_2SO_4) and the solvent removed *in vacuo*. The residue was chromatographed on thin layers of silica gel GF_{254} [solvent, petroleum hydrocarbon (b.p. 60-80°C)/ethyl acetate, 1:1, vol/vol]. The fractions were located under UV light and eluted with distilled chloroform. The solvent was removed under a stream of nitrogen. Major bands with the following R_f values were isolated: 0.26 (yellow, 13.4 mg), 0.39 (yellow, **6b**, 12.6 mg), 0.51 (**9b**, 15.7 mg), 0.65 (colorless, changing to yellow-orange on thin-layer chromatography; unidentified, 5.5 mg), 0.82 (yellow; unidentified, 1.2 mg). The yellow band with R_f 0.26 was identified as 2-(3-hydroxy-3-methylbutyl)-3-ethoxymethyl-5,6-dimethyl-1,4-benzoquinone (**7b**) and had the following spectral data: UV (λ_{max}, hexane) 260, 265 (sh) nm; IR(KBr) (cm^{-1}): 3437 (OH), 2975, 2932, 2875, 1648 (C=O), 1467, 1449, 1379, 1304, 1279, 1237, 1219, 1153, 1124, 1099 (C-O-C), 1030, 937, 910, 877, 761, 727. MS (EI) *m/z* (rel. intensity): 280 (M^+) (2), 262 (7), 234 (33), 221 (50), 176 (100). ^1H NMR ($CDCl_3$): δ 1.20 (*t*, 3H, J = 7.0 Hz, -O-CH_2-CH_3), 1.25 (*s*, 6H, 2 × CH_3), 1.62 (*m*, 2H, =C-CH_2-CH_2), 2.01 (*s*, 6H, 2 × =C-CH_3), 2.67 (*m*, 2H, =C-CH_2-), 3.55 (*q*, 2H, J = 7.0 Hz, -O-CH_2-CH_3), 4.40 (*s*, 2H, =C-CH_2-O-); ^{13}C NMR ($CDCl_3$): δ 187.77, 186.72, 148.48, 140.88, 140.69, 138.32, 70.84, 66.81, 62.60, 43.17, 29.18 (2 peaks), 21.98, 15.25, 12.45, 12.36.

RESULTS

Figure 1 shows that compound **1b** was oxidized completely to **6b** in 10 min, after which the concentration of **6b** fell gradually, but it was still the major product (70 mole %) after 180 min. Compound **9b** did not appear until 10 min and then rose gradually to 28% at 180 min. Compound **4b** rose rapidly to 5% within 5 min and then fell very slowly to zero at 180 min. The product distribution in this present silver nitrate oxidation of **1b** differed a great deal from that observed previously (12). The major product by far in the present reaction was compound **6b**, which was only observed in very small amounts in the previous reaction (12). By contrast compound **4b**, which had been one of the major products in the previous reaction (12), was only a very minor product in the present reaction. The reason for this product reversal may be the amount of water in the reaction. Thus the molar ratio of water/**1b** in the present reaction (16:1) was much greater than in the previous study (3:1). It has been shown that a relatively low concentration of water in the presence of a large excess of ethanol favors the formation of **6b** rather than **4b** (20).

The fact that compound **9b** did not appear until **1b** had disappeared completely suggests that **9b** was a secondary product. Also, compound **9b** only began to form after **6b** had reached a maximum and was beginning to decline. This suggested that **9b** was being formed from **6b**. In order to test this theory, **6b** was heated at 60°C and, subsequently, at 78°C in ethanol in the presence of silver nitrate, but was found to be stable and unchanged after several hours. The original report of the formation of **9b** indicated that it could be formed from **6b**, as well as from **1b** (11). The lack of reactivity of **6b** in our reaction was in conflict with the original report until it was realized that the original authors had used a much more concentrated solution of **6b** (13 mg/mL) than we had used (1 mg/mL). On changing to a more concentrated solution (5 mg/mL) and heating at 78°C, we observed the results shown in Figure 2. The reaction showed a lag period of almost one hour before any change occurred, after which **6b** was converted fairly rapidly into **9b**. The reason for this lag period is unknown. As **6b** at a concentration of 1 mg/mL was

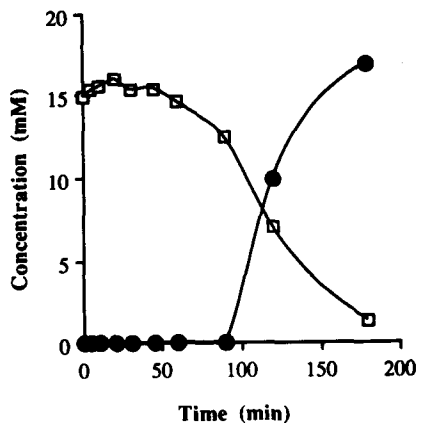

FIG. 2. Formation of 2,2,7,8-tetramethylchroman-5,6-dione (9b) from the reaction of silver nitrate with 2-(3-hydroxy-3-methylbutyl)-3,5,6-trimethyl-1,4-benzoquinone (6b) in absolute ethanol at 78°C; □, 6b; ●, 9b.

stable when heated directly with silver nitrate at 78°C, but decomposed steadily at 60°C after it was formed in the **1b** oxidation (Fig. 1), it appeared that another product of the **1b** oxidation might be promoting the decomposition of **6b**. A study of pH change during **1b** oxidation revealed an initial, rapid drop to pH 2.7, followed by a much slower rise (insert, Fig. 1). A pH of 2.7 corresponds closely to that which would have been obtained if **1b** had dissociated completely. However, as **1b** is a very weak acid, these results suggest that silver nitrate reacts with **1b** to liberate a proton as follows:

$$Ag^+ + ArOH \rightarrow Ag + ArOH^{+\bullet} \rightarrow ArO\bullet + H^+ \qquad [1]$$

This pH drop was definitely due to reaction between silver nitrate and **1b**, because a solution of silver nitrate in ethanol had a pH of 6.5.

In order to determine the effect of acid on the course of reaction, **6b** was heated at 60°C under nitrogen in the presence of 0.03 M sulfuric acid and in the absence of silver nitrate. Figure 3 shows that the concentration of **6b** fell by 40% within 2 min and then by a further 30% in the next 88 min. Compound **6b** was converted into **4b**, **1b**, **7b** and **9b**. When this reaction was repeated using 0.03 M hydrochloric instead of sulfuric acid, the rate was faster and the same products were formed (results not shown). One may conclude that, in the presence of acid, **6b** is readily dehydrated to **2b**, which can then add ethanol to form **4b** (Scheme 1). Alternatively, **2b** can add water to form **5b** (16), which may react with ethanol in acid solution to form **4b**. Formation of **9b**, and particularly **1b**, in this reaction is more difficult to explain. Compound **9b** is believed to be formed by the oxidative deformylation of **5b** (12) (see Equation 4). However, as the reaction of **6b** with sulfuric acid was performed under nitrogen, the only oxidant present was **6b** itself. A possible explanation is that **6b** was dehydrated by acid to **2b**, which then added water to form **5b**. Compound **5b** is a phenol (reducing agent) that may be able to react with **6b** (oxidizing agent) to form **9b** (oxidation product) and the hydroquinone of **6b** (**6bH$_2$**; reduction product). In acid solution, **6bH$_2$** would cyclize to **1b** (11). To test this hypothesis, compound **6b** was reacted with **5b** at 60°C in the presence of 0.001 M sulfuric acid (to simulate the approximate pH of the **1b** oxidation) (Fig. 4). Compound **4b** was the major product, and **9b**, **7b** and **1b** were formed in smaller amounts. Although initially there were equal amounts of **6b** and **5b** in the reaction mixture, it appears that the first step involves the effective isomerization of **6b** into more **5b**, and thus the concentration of **5b** rises as that of **6b** falls.

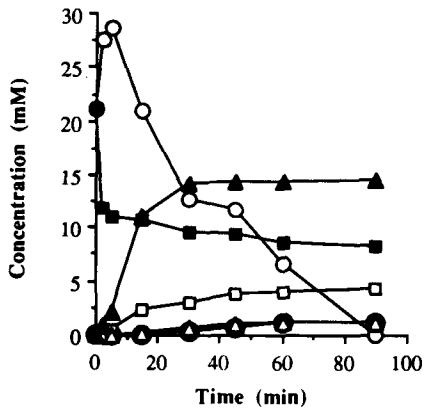

FIG. 4. Formation of products in the reaction of 2-(3-hydroxy-3-methylbutyl)-3,5,6-trimethyl-1,4-benzoquinone (6b) with 5-hydroxymethyl-2,2,7,8-tetramethyl-6-chromanol (5b) in the presence of 0.001 M sulfuric acid in absolute ethanol at 60°C under nitrogen; □, 2,2,5,7,8-pentamethyl-6-chromanol (1b); ▲, 5-ethoxymethyl-2,2,7,8-tetramethyl-6-chromanol (4b); ○, 5b; ■, 6b; ●, 2-(3-hydroxy-3-methylbutyl)-3-ethoxymethyl-5,6-dimethyl-1,4-benzoquinone (7b); △, 2,2,7,8-tetramethylchroman-5,6-dione (9b).

$$\mathbf{6b} \xrightarrow{H^+,\ -H_2O,\ +H_2O} \mathbf{5b} \qquad [2]$$

A number of reactions then follow. Compound **5b** reacts very readily with ethanol in the presence of acid to form **4b** (Eq. 3; Fig. 5), and the reaction does not require **6b**.

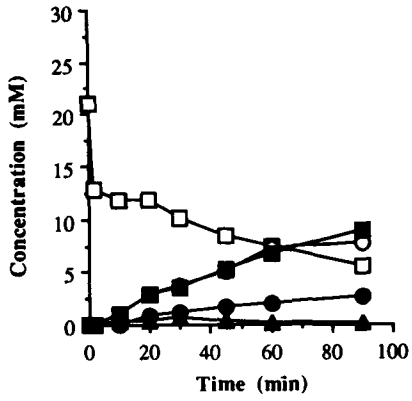

FIG. 3. Formation of products in the reaction of 2-(3-hydroxy-3-methylbutyl)-3,5,6-trimethyl-1,4-benzoquinone (6b) with 0.03 M sulfuric acid in absolute ethanol at 60°C under nitrogen; ■, 2,2,5,7,8-pentamethyl-6-chromanol (1b); ○, 5-ethoxymethyl-2,2,7,8-tetramethyl-6-chromanol (4b); □, 6b; ▲, 2-(3-hydroxy-3-methylbutyl)-3-ethoxymethyl-5,6-dimethyl-1,4-benzoquinone (7b); ●, 2,2,7,8-tetramethylchroman-5,6-dione (9b).

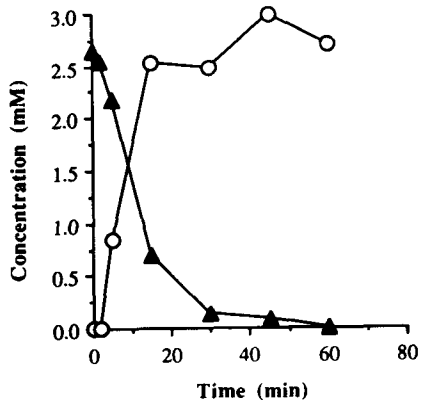

FIG. 5. Formation of 5-ethoxymethyl-2,2,7,8-tetramethyl-6-chromanol (4b) from the reaction of 5-hydroxymethyl-2,2,7,8-tetramethyl-6-chromanol (5b) in the presence of 0.001 M sulfuric acid in absolute ethanol at 60°C; ○, 4b; ▲, 5b.

$$5b + EtOH \xrightarrow{H^+} 4b \quad [3]$$

Compound **6b** reacts with **5b** in the presence of acid (but not in its absence) to form **9b** and **1b** (Fig. 4). The conversion of **5b** into **9b** is a four-electron oxidation, and, therefore, the production of one mole of **9b** would require two additional moles of **6b** and lead to the formation of two moles of **1b** (Eqs. 4 and 5)

$$2 \times 6b + 5b + H_2O \xrightarrow{H^+} 2 \times 6bH_2 + 9b + HCHO \quad [4]$$

$$2 \times 6bH_2 \xrightarrow{2H^+} 2 \times 1b + 2H_2O \quad [5]$$

In summary, Equations 2, 4 and 5 give:

$$3 \times 6b \rightarrow 9b + 2 \times 1b + H_2O + HCHO \quad [6]$$

It is possible to conceive of an additional pathway from **6b** to **9b**, which does not involve the intermediacy of **5b** (Scheme 2). Thus, enolization of **6b**, followed by the addition of water, would yield 1,4-dihydroxy-2,3-dimethyl-5-(3-hydroxy-3-methylbutyl)-6-hydroxymethylbenzene (**8bH$_2$**), the hydroquinone of **8b**.

$$6b + H_2O \rightarrow 8bH_2 \quad [7]$$

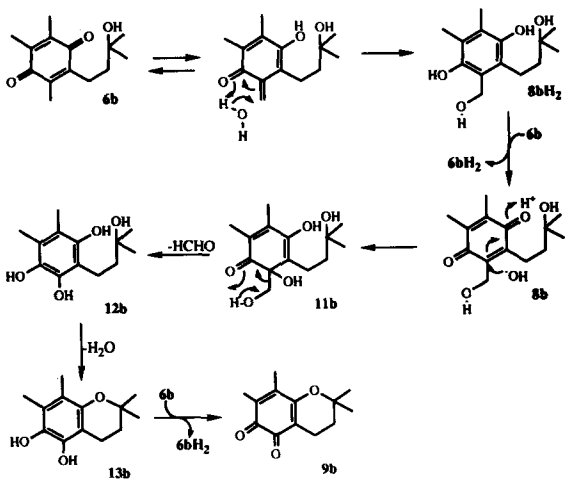
A second molecule of **6b** could then oxidize **8bH$_2$** to **8b** and be reduced to **6bH$_2$**:

$$6b + 8bH_2 \rightarrow 8b + 6bH_2 \quad [8]$$

Addition of water to **8b** would form 4,6-dihydroxy-2,3-dimethyl-5-(3-hydroxy-3-methylbutyl)-6-hydroxymethylcyclohexa-2,4-dienone (**11b**), which could deformylate to 1,2,4-trihydroxy-5,6-dimethyl-3-(3-hydroxy-3-methylbutyl)benzene (**12b**).

$$8b + H_2O \rightarrow 11b \quad [9]$$

$$11b \rightarrow 12b + HCHO \quad [10]$$



SCHEME 2

As discussed previously (12), the deformylation is a typical retro-aldol type of reaction whose driving force is the establishment of aromaticity in **12b**. Cyclization of **12b** would produce 2,2,7,8-tetramethyl-5,6-dihydroxychroman (**13b**), which could be oxidized by a third molecule of **6b** to form **9b**.

$$12b \rightarrow 13b + H_2O \quad [11]$$

$$6b + 13b \rightarrow 9b + 6bH_2 \quad [12]$$

Cyclization of **6bH$_2$** in acid conditions would yield **1b**:

$$2 \times 6bH_2 \rightarrow 2 \times 1b + 2H_2O \quad [13]$$

The sum of Equations 7–13 is Equation 6.

In order to determine whether **4b** could be converted into **9b**, it was oxidized with silver nitrate. Figure 6 shows that oxidation of **4b**, although relatively rapid, is much slower than that of **1b** and appears to go through a 20-min lag period before commencing. During the lag period the pH dropped from 6.2 to 4.2 (insert, Fig. 6), so that acid appears to play a role in this reaction also. Compound **9b** was a major product of the reaction, but it did not appear until after 30 min and was, therefore, a secondary product. The first-formed product was again compound **6b**, which reached a maximum in 90 min and then began to decline. Thus it appeared that **4b** was being converted *via* **2b** into **6b** and then into **9b** as before. Although compound **9b** formed more slowly than **6b**, it reached a higher concentration at 240 min and was formed more rapidly than in the oxidation of **1b**.

Compound **5b**, which was believed to be a key intermediate in the formation of **9b** from **1b** (12), was oxidized completely by silver nitrate within 20 min (Fig. 7). Although **9b** was the major product of the reaction (90%

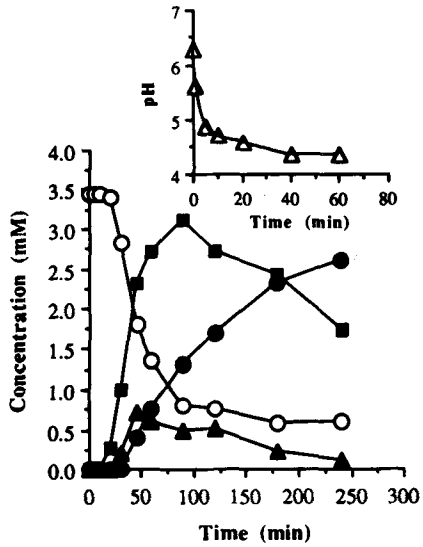


FIG. 6. Formation of products in the reaction between silver nitrate and 5-ethoxymethyl-2,2,7,8-tetramethyl-6-chromanol (4b) in absolute ethanol at 60°C; ○, 4b; ■, 2-(3-hydroxy-3-methylbutyl)-3,5,6-trimethyl-1,4-benzoquinone (6b); ▲, 2-(3-hydroxy-3-methylbutyl)-3-ethoxymethyl-5,6-dimethyl-1,4-benzoquinone (7b); ●, 2,2,7,8-tetramethylchroman-5,6-dione (9b). Insert shows the change in pH during the course of reaction.

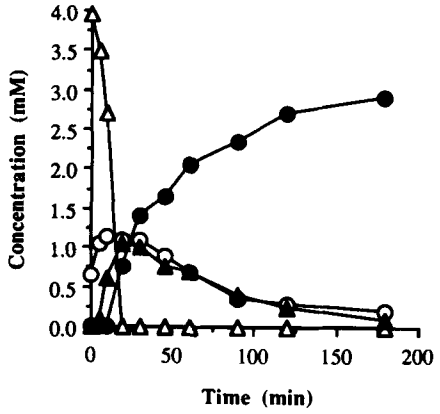

FIG. 7. Formation of products in the reaction between silver nitrate and 5-hydroxymethyl-2,2,7,8-tetramethyl-6-chromanol (5b) in absolute ethanol at 60°C; ○, 5-ethoxymethyl-2,2,7,8-tetramethyl-6-chromanol (4b); △, 5b; ▲, 2-(3-hydroxy-3-methylbutyl)-3-hydroxymethyl-5,6-dimethyl-1,4-benzoquinone (8b); ●, 2,2,7,8-tetramethylchroman-5,6-dione (9b).

after 180 min) and was formed faster in this reaction than in any other reaction, it was formed predominantly after **5b** had disappeared. Thus it must be concluded that **9b** was, at least in part, a secondary product of this reaction as well. Compounds **4b** and **8b** were formed more rapidly than **9b** early in the reaction and subsequently declined. Thus, it would appear that **5b** undergoes three separate reactions simultaneously, oxidative deformylation to **9b**, oxidation to **8b** and reaction with ethanol to form **4b**. Again it appeared that **4b** and **8b** were being converted into **9b**. A possible pathway from **4b** to **9b** would be protonation of the ethoxy oxygen of **4b**, followed by loss of ethanol to form the quinone methide **2b**. Addition of water to **2b** would form **5b**, oxidative deformylation of which would yield **9b**. The pathway by which **8b** is converted into **9b** is not clear but may involve acid-catalyzed cyclization to the enol of 5-formyl-2,2,7,8-tetramethyl-6-chromanol followed by oxidative loss of formic acid to form **9b**.

DISCUSSION

Compound **9b** can be formed from **1b**, **4b**, **5b** and **6b** and is formed most rapidly from **5b**, suggesting that **5b** is the immediate precursor of **9b**. In all oxidations except that of **6b**, compound **9b** was a secondary product. Conversion of **1b** into **9b** may be explained as in Scheme 1. Reaction of silver ion with **1b** produces silver metal and the radical cation of **1b** (Eq. 1). Dissociation of the radical cation liberates the chromanoxyl radical of **1b** and a proton which causes an immediate drop in pH (Eq. 1). Two molecules of the chromanoxyl radical disproportionate to give one molecule of the unstable intermediate quinone methide **2b** and one molecule of **1b** (21-23). Compound **2b** can react immediately with ethanol to form **4b**. Alternatively, **2b** may react with a proton to form **3b**, which can then react with water to form **6b** and regenerate a proton. Compound **6b** is unstable in the presence of acid and undergoes dehydration and recyclization into **2b**. Compound **2b** then undergoes hydration to **5b** and oxidative deformylation to **9b**. Although silver nitrate is the oxidant for the deformylation of **5b**, it is interesting to note that **6b** is also capable of bringing about the deformylation of **5b** with the concomitant formation of **1b** in mild acid conditions. It is also possible that **6b** may be converted into **9b** without the intermediacy of **5b** as shown in Scheme 2.

Acid also promotes the loss of ethanol from **4b** and its conversion into **2b**. Surprisingly, in this reaction **2b** does not proceed directly to **5b** and **9b** but rather to **6b**. Then as the acid increases further, **6b** is recyclized to **2b** and then to **5b** and **9b**. Thus the oxidation of **1b** is under the control of the equilibria **4b** ↔ **2b** ↔ **3b** ↔ **6b** (Scheme 1). In the absence of water, the major product is **4b** (20). In the presence of water, the equilibria shift to the right and a mixture of **4b** and **6b** will be formed, with **6b** dominating as the concentration of water rises. Then as the acid increases, the equilibria shift to the left and to the key intermediate **2b**, which undergoes hydration and further oxidation.

It is worth noting that the spirodimer and spirotrimer of **1b** were not observed in any of the reactions. This confirms previous observations that **2b** shows a much greater tendency to react with nucleophiles, such as water and alcohols, than it does to polymerize (20).

ACKNOWLEDGMENTS

Thanks are due to N. Juranario for running the IR spectra, to H. Stender for the NMR spectra and to Dr. J. Brophy for the mass spectra.

Synthesis and Antitumor Activity of 1-β-D-Arabinofuranosylcytosine Conjugates of Optical Isomers of Ether and Thioether Lipids[1]

Chung Il Hong*, Seung-Ho An[2], Alexander Nechaev, Alan J. Kirisits, Rakesh Vig and Charles R. West
Department of Neurosurgery, Roswell Park Cancer Institute, Buffalo, New York 14263

Four 1-β-D-arabinofuranosylcytosine conjugates (ara-C) (1a, b and 2a, b) of *sn*-1 and *sn*-3 isomers of 1-*O*-octadecyl-2-*O*-palmitoylglycerol and its 1-*S*-alkyl analogue have been synthesized, and their antitumor activity against L1210 lymphoid leukemia in mice were compared with those of the previous conjugates (3a, b) of racemates in order to determine the significance of chirality of the glycerol moieties for activity. Administration (i.p.) of a single dose (300 mg/kg) of conjugates of *sn*-1 (1a), *sn*-3 (2a) and *rac* (3a) isomers of the ether lipid increased lifespan of i.p. implanted L1210 lymphoid leukemic DBA/2J mice by 169, 175 and 236%, respectively. The *sn*-1 (1b), *sn*-3 (2b), and *rac* (3b) isomers of the thioether lipid with a single dose of 300 mg/kg produced an increase in lifespan values of 238, 263 and 250%, respectively. The results indicate that chirality of the glycerol moieties appears not to be critical for the activity, and racemates 3a and 3b are promising prodrugs of ara-C for further clinical investigations.
Lipids 28, 1021-1026 (1993).

1-β-D-Arabinofuranosylcytosine (ara-C) conjugates of the racemic mixtures of 1-*O*-alkyl (ether) and 1-*S*-alkyl (thioether) phospholipids (1-10) have demonstrated a superior antitumor activity against animal tumor models *in vivo*. The rationale is that the conjugates are not only new prodrugs of ara-C, but also may generate two cytotoxic groups, the nucleoside and the ether or thioether lipid analogue, with different target sites in tumor cells. Among them, ara-CDP-*rac*-1-*S*-octa-decyl-2-*O*-palmitoyl-1-thioglycerol (ara-CDP-DL-PTBA, Cytoros, **3b**) (Fig. 1) showed significant therapeutic effects on human colorectal (11) and PSN-1 pancreatic cancer xenografts in nude mice (12). In order to determine the stereochemical significance of the ether and thioether moieties, we have now synthesized the ara-C conjugates of the *sn*-1 (**1a, b**) and *sn*-3 (**2a, b**) isomers of 1-*O*-octadecyl-2-*O*-palmitoylglycerol and its 1-thioglycerol isomer (Fig. 1). This paper described the synthetic procedures for the preparation of these conjugates and the comparison of their antitumor effects with those of the previous conjugates (**3a** and **3b**) of the racemates of ether and thioether lipids against L1210 lymphoid leukemia in mice.

EXPERIMENTAL PROCEDURES

Melting points were taken on a Mel-Temp capillary melting point apparatus (Cambridge, MA) and are uncorrected. ^1H nuclear magnetic resonance (NMR) spectra were recorded on a Varian Associate (Sunnyvale, CA) EM-390 spectrometer. Chemical shifts are expressed as δ values (ppm) relative to tetramethylsilane as internal standard. The optical rotations were measured on a Perkin-Elmer 241 polarimeter (Norwalk, CT). An AG1-X8 (Bio-Rad, Hercules, CA), [(diethylamino)ethyl]cellulose (DE-52) (Whatman, Clifton, NJ) and a CG-50 (Sigma, St. Louis, MO) were used for column chromatography. Evaporations were carried out on a rotary evaporator under reduced pressure applied by an Aspirator A-3S (Wheaton, Millville, NJ) or a vacuum pump with a bath temperature of under 30°C. Thin-layer chromatography (TLC) was performed on glass plates coated with a 0.25-mm layer of silica gel PF-254 (Brinkman, Westbury, NY) with use of the following solvent systems: (A) $CHCl_3$, (B) $CHCl_3$/MeOH (95:5, vol/vol), (C) $CHCl_3$/MeOH/H_2O/HOAc (25:15:4:2, by vol), and *i*-PrOH/H_2O/concentrated NH_4OH (7:2:1, by vol). Ultraviolet (UV)-absorbing compounds were detected by visualization under a UV lamp (254 nm), and phosphorus-containing compounds were detected with a modified Dittmer-Lester spray (13). Elemental analyses were performed by Galbraith Laboratories (Knoxville, TN) and Robertson Microlit Laboratories (Madison, NJ).

Abbreviations: ara-C, 1-β-D-arabinofuranosylcytosine; ara-CDP, ara-C 5′-diphosphate; ara-CDP-DL-PTBA (Cytoros), ara-CDP-*rac*-1-*S*-octadecyl-2-*O*-palmitoyl-1-thioglycerol; ara-CMP, ara-C 5′-monophosphate; ILS, increase in life span; NMR, nuclear magnetic resonance; TBDMS, *tert*-butyldimethylsilyl; THF, tetrahydrofuran; TLC, thin-layer chromatography; UV, ultraviolet.

Ara-C 5′-monophosphate (ara-CMP) (14), ara-CMP morpholidate (15), 1,2-*O*-isopropylidene-*sn*-glycerol (16), 2,3-*O*-isopropylidene-*sn*-glycerol (17), 1,2-*O*-isopropylidene-3-thio-*sn*-glycerol (18) and racemic compounds **3a, 3b, 6a, 6b, 9a** and **9b**) were prepared by procedures in the literature (1,7) .

2,3-*O*-Isopropylidene-1-thio-*sn*-glycerol was prepared from 2,3-*O*-isopropylidene-*sn*-glycerol in an analogous manner for 1,2-*O*-isopropylidene-3-thio-*sn*-glycerol (18), and was used for the next step without distillation.

1-O-Octadecyl-sn-*glycerol* and *3-O-Octadecyl*-sn-*glycerol.* These compounds were prepared following literature procedures (19,20).

1-O-Octadecyl-2-O-palmitoyl-sn-*glycerol (4a).* Palmitoyl chloride (6.95 g, 25 mmol) in toluene (20 mL) was added dropwise to a mixture of 1-*O*-octadecyl-3-*O*-benzyl-*sn*-glycerol (21) (10 g, 23 mmol), pyridine (1.76 g, 23 mmol) and toluene (50 mL) at room temperature. The mixture was heated at 60°C overnight and then cooled to room temperature. The mixture was partitioned between Et_2O (150 mL) and H_2O (150 mL), and the organic layer was washed with H_2O (2 × 150 mL) and evaporated to dryness. The residue was dissolved in boiling 95% EtOH (1500 mL), and the solution was cooled to room temperature overnight. The solid, 1-*O*-octadecyl-2-*O*-palmitoyl-3-*O*-benzyl-*sn*-glycerol, was filtered, washed with cold 95% EtOH and dried *in vacuo*; yield, 13.1 g (84.6%); m.p., 43–44.5°C; $[\alpha]_D^{25}$ +1.4° (c 8.0, $CHCl_3$); ^1H NMR ($CDCl_3$) δ 0.9 (6, *t*, J = 6 Hz, 2 CH_3), 1.18–1.74 (58, *m*, $(CH_2)_{16}$, $(CH_2)_{13}$), 2.35 (2, *t*, J = 6 Hz, CH_2CO), 3.44 (2, *t*, J = 6 Hz, OCH_2), 3.56 (2, *d*, J = 5 Hz, 1-CH_2), 3.63 (2, *d*, J = 5 Hz, 3-CH_2), 4.52 (2, *s*, benzyl CH_2), 5.16 (1, *quintet*, J = 5 Hz, 2-CH), 7.26 (5,*s*, C_6H_5). The compound (12.5 g, 18.6 mmol) was hydrogenated with 10% Pd/C (1 g) in tetrahydrofuran (THF) (100 mL) and HOAc (50 mL) at 50 psi for three days. After removal of the catalyst, the filtrate was evaporated to dryness, and the residue was crystallized from $CHCl_3$-petroleum ether 30–60°C; yield, 9.8 g (74.9%); m.p., 70–71°C; $[\alpha]_D^{25}$ −0.15° (c 8.0, $CHCl_3$). *Anal.*: Calcd. for $C_{37}H_{74}O_4$: C, 76.23; H.12.79. Found: C, 76.00; H.12.76.

3-O-Octadecyl-2-O-palmitoyl-sn-*glycerol (5a).* 3-*O*-Octadecyl-2-*O*-palmitoyl-1-*O*-trityl-*sn*-glycerol (17.7 g, 21.4 mmol), prepared by the procedure in the literature (1), was dissolved in HOAc (200 mL) and toluene (50 mL) and hydrogenated in the presence of PtO_2 (500 mg) and PdO (700 mg) at 50 psi for five days. The catalysts were removed by filtration, the filtrate was evaporated to dryness and the residue was crystallized from 95% EtOH/hexanes (5:1, vol/vol); yield, 10.5 g (84.2%); m.p., 51–52°C; $[\alpha]_D^{22}$ +2.0° (c 1, $CHCl_3$); ^1H NMR ($CDCl_3$) δ 0.85 (6, *t*, J = 5 Hz, 2 CH_3), 1.27–1.65 (58, *m*, $(CH_2)_{16}$, $(CH_2)_{13}$), 2.30 (2, *m*, CH_2CO), 3.42 (2, *t*, J = 6 Hz, OCH_2), 3.58 (2, *d*, J = 5 Hz, 1-CH_2), 3.77 (2, *d*, J = 5 Hz, 3-CH_2), 4.97 (1, *quintet*, J = 5 Hz, 2-CH). The product was also prepared in 46% yield by using the method for **4b**. *Anal.*: Calcd. for $C_{37}H_{74}O_4$: C, 76.23; H, 12.79. Found: C, 76.26; H, 12.33.

3-S-Octadecyl-3-thio-sn-*glycerol.* Two hundred mL of 1 N KOH in MeOH was added dropwise to a mixture of 1,2-*O*-isopropylidene-3-thio-*sn*-glycerol (29.6 g, 0.2 mol) in 100 mL of MeOH and 1-bromooctadecane (60.1 g, 0.18 mol) in 200 mL of hexanes, at room temperature for a period of 1 h, and then the mixture was stirred at room temperature for 1 d. The mixture was evaporated to dryness, and the residue was partitioned between hexanes (800 mL) and H_2O (300 mL). The organic layer was evaporated to dryness, and the residue was refluxed with 10% HCl in aqueous MeOH (125 mL concentrated HCl and 280 mL MeOH) for 30 min and decolorized with Norit A (Fisher Scientific, Pittsburgh, PA). After being left to stand at room temperature overnight, the solid in the mixture was filtered off, washed with 50% MeOH and then MeOH (50 mL each), and then dried *in vacuo.* The crude product was recrystallized from hot MeOH; yield, 49.2 g (75.8%); m.p., 67–68°C; $[\alpha]_D^{22}$ +22.1° (c 1.0, $CHCl_3$); ^1H NMR ($CDCl_3$) δ 0.83 (3, *t*, J = 6 Hz, CH_3), 1.27–1.65 (32, *m*, $(CH_2)_{16}$), 2.40–2.63 (4, *m*, CH_2SCH_2), 3.33 (2, *t*, J = 6 Hz, 1-CH_2), 3.63 (1, *m*, 2-CH). *Anal.*: Calcd. for $C_{21}H_{44}O_2S{\cdot}0.1H_2O$: C, 69.59; H, 12.26. Found: C, 69.49; H, 12.48.

1-*S*-Octadecyl-1-thio-*sn*-glycerol was prepared from 2,3-*O*-isopropylidene-1-thio-*sn*-glycerol in an analogous manner; yield, 52.9%; m.p., 66–67°C; $[\alpha]_D^{22}$ +9.0° (c 1.0, $CHCl_3$); ^1H NMR ($CDCl_3$) δ 0.87 (3, *t*, J = 6 Hz, CH_3), 1.27–1.57 (32, *m*, $(CH_2)_{16}$), 2.43–2.68 (4, *m*, CH_2SCH_2), 3.35 (2, *t*, J = 6 Hz, 3-CH_2), 3.77 (1, *m*, 2-CH). *Anal.*: Calcd. for $C_{21}H_{44}O_2S{\cdot}0.75H_2O$: C, 67.42; H, 12.26. Found: C, 67.25; H, 11.63.

1-S-Octadecyl-3-O-(tert-butyldimethylsilyl)-1-thio-sn-*glycerol.* A mixture of 1-*S*-octadecyl-1-thio-*sn*-glycerol (9.15 g, 25 mmol), *tert*-butyldimethylsilyl chloride (4.66 g, 30 mmol), imidazole (4.13 g, 60 mmol) and *N,N*-dimethylformamide (DMF) (50 mL) was stirred at room temperature for one day. The solvent was evaporated to dryness *in vacuo* at 70°C, and the residue was partitioned between H_2O and Et_2O (50 mL each). The organic layer was dried over Na_2SO_4 and then evaporated to dryness. The oily residue was further evaporated by using a high vacuum at 70°C. The crude product, essentially homogeneous by TLC, weighed 10.4 g (87.6%) and was used for the next step without further purification.

1-*O*-(*tert*-Butyldimethylsilyl)-3-*S*-octadecyl-3-thio-*sn*-glycerol was prepared by using an analogous procedure; yield, 85.7%.

1-S-Octadecyl-2-O-palmitoyl-1-thio-sn-*glycerol (4b).* Palmitoyl chloride (7.01 g, 25 mmol) was added dropwise to a mixture of the above product (10.4 g, 22 mmol) in anhydrous pyridine (10 mL) and toluene (400 mL) at room temperature, and the mixture was stirred at room temperature for one day. The mixture was then partitioned between Et_2O and H_2O (100 mL each). The organic layer was washed with 0.5 N H_2SO_4, saturated $NaHCO_3$ and H_2O (50 mL each), and then evaporated to dryness. The residue was crystallized from 95% EtOH at 10–15°C. The solid was filtered and washed with 95% EtOH. The soft solid, 1-*S*-octadecyl-2-*O*-palmitoyl-3-*O*-(*tert*-butyldimethylsilyl)-1-thio-*sn*-glycerol, weighed 13.0 g (81.8% yield). To a mixture of this product (13.0 g, 18 mmol) in HOAc (3.5 mL) and THF (100 mL) was added dropwise 1 M tetrabutylammonium fluoride in THF (35 mL) for a period of 1 h at 5–10°C, and the mixture was stirred at room temperature for 6 h. After cooling at 0–5°C overnight, the solid was filtered and washed with ice-cold 95% EtOH. The filtrate was evaporated to dryness, and the residue was treated with ice-cold 95% EtOH. The combined solids were dissolved in boiling 95% EtOH, and the solution was cooled to room temperature overnight, which resulted in an isomer of **4b**, 1-*S*-octadecyl-3-*O*-palmitoyl-1-thio-*sn*-

glycerol. After filtration, the filtrate was cooled at 0–5°C overnight, and the white solid (**4b**) was filtered and washed with cold 95% EtOH. Repeated recrystallization of the crude products in this manner gave 6.7 g (50.0% yield); m.p., 44–45°C; $[\alpha]_D^{22}$ +0.6° (c 1.0, $CHCl_3$); ^1H NMR δ 0.87 (6, *m*, $2CH_3$), 1.27–1.60 (58, *m*, $(CH_2)_{16}$, $(CH_2)_{13}$), 2.32 (2, *t*, J = 7 Hz CH_2CO), 2.47–2.73 (4, *m*, CH_2SCH_2), 3.80 (2, *m*, 3-CH_2), 4.97 (1, *m*, 2-CH). *Anal.*: Calcd. for $C_{37}H_{74}O_3S$: C, 74.18; H, 12.45. Found: C, 74.24; 12.78.

3-*S*-Octadecyl-2-*O*-palmitoyl-3-thio-*sn*-glycerol (**5b**) was prepared in an analogous manner; yield, 28.8%; m.p., 45–46°C; $[\alpha]_D^{22}$ +1.0° (c 1.0, $CHCl_3$); ^1H NMR ($CDCl_3$) δ 4.93 (1, *m*, 2-CH). *Anal.*: Calcd. for $C_{37}H_{74}O_3S$: C, 74.18; H, 12.45. Found: C, 73.99; H, 11.79.

3-O-Octadecyl-2-O-palmitoyl-sn-*glycerol-1-phosphate (8a).* Phenyl dichlorophosphate (1.45 g, 6.8 mmol) in toluene (30 mL) was added dropwise at room temperature to a solution of **4b** (2.0 g, 3.4 mmol), pyridine (1 mL) and toluene (30 mL), and the mixture was stirred first at 60°C for 6 h and then at room temperature for 1 d. Water (1 mL) was added to the mixture, and the suspension was stirred at room temperature for 1 h. The mixture was then partitioned between Et_2O and H_2O (40 mL each). The organic layer was washed with H_2O (40 mL × 3), dried over Na_2SO_4 and evaporated to dryness. The residue was crystallized from 95% EtOH at −20°C, and the solid was quickly filtered and washed with cold 95% EtOH; yield, 2.0 g (79.6%). The phenyl-protected phosphate was then hydrogenated with PtO_2 (400 mg) and PdO (400 mg) in AcOH (50 mL) and toluene (50 mL) at 50 psi for 2 d. The mixture was diluted with toluene (30 mL) and filtered through a Celite bed. The filtrate was evaporated to dryness, and the residue was dried by coevaporating with toluene (10 mL × 2). The crude product was dissolved in $CHCl_3$ (20 mL), and the solution was applied to a silica gel column (3 × 30 cm). The column was eluted with $CHCl_3$ (400 mL) and then with $CHCl_3$/MeOH/H_2O (10:10:1, by vol) (250 mL). The eluate with the latter was evaporated to dryness and the residue weighed 1.8 g (100%, 79.6% overall); m.p., 49–51°C; $[\alpha]_D^{22}$ +5.55° (c 1.0, $CHCl_3$); ^1H NMR δ 0.83 (6, *m*, $2CH_3$), 1.23–1.56 (58, *m*, $(CH_2)_{16}$, $(CH_2)_{13}$), 2.26 (2, *t*, J = 6 Hz, CH_2CO), 3.33–3.43 (4, *m*, OCH_2, 3-CH_2), 4.08 (2, *d*, J = 4.5 Hz, 1-CH_2), 5.12 (1, *m*, 2-CH). *Anal.*: Calcd. for $C_{37}H_{75}O_7P{\cdot}4.5H_2O$: C, 59.72; H, 10.56. Found: C, 59.37; H, 11.38.

1-S-Octadecyl-2-O-palmitoyl-1-thio-sn-*glycerol-3-phosphate (7b).* Triethylamine (7.08 g, 70 mmol) in hexanes (20 mL) was added dropwise to an ice-cold mixture of $POCl_3$ (9.96 g, 70 mmol) and hexanes (20 mL). To this mixture a solution of dried **4b** (32.1 g, 50 mmol) in toluene (250 mL) was added dropwise at 0–5°C over a period of 1.5 h, and the mixture was stirred at room temperature overnight. Water (25 mL) was added to the mixture followed by stirring at room temperature for 1 h. The mixture was partitioned between Et_2O (250 mL) and H_2O (125 mL). The organic layer was dried over Na_2SO_4 and evaporated to dryness. The residue was crystallized from hexanes at 0–5°C and then recrystallized from Et_2O at room temperature; yield, 21.4 g (45%); m.p., 65–70°C; $[\alpha]_D^{22}$ +3.6° (c 1.0, $CHCl_3$); ^1H NMR δ 0.85 (6, *t*, J = 7 Hz, $2CH_3$), 1.27–1.53 (58, *m*, $(CH_2)_{16}$, $(CH_2)_{13}$), 2.20–2.73 (6, *m*, CH_2CO, CH_2SCH_2), 4.03 (2, *m*, 3-CH_2), 5.03 (1, *m*, 2-CH). *Anal.*: Calcd. for $C_{37}H_{75}O_6SP{\cdot}0.5H_2O$: C, 64.59; H, 11.13. Found: C, 64.26; H, 11.34. Phosphatidic acids **7a** and **8b** were prepared in an analogous manner.

1-O-Octadecyl-2-O-palmitoyl-sn-*glycerol-3-phosphate (7a).* Yield, 74.0%; m.p., 58–60°C; $[\alpha]_D^{22}$ +1.1° (c, 3.55, $CHCl_3$). *Anal.*: Calcd. for $C_{37}H_{75}O_7P$: C, 67.03; H, 11.40; P, 4.67. Found: C, 66.83; H, 11.45; P, 4.32.

3-S-Octadecyl-2-O-palmitoyl-3-thio-sn-*glycerol 1-phosphate (8b).* Yield, 50.0%; m.p., 60–70°C; $[\alpha]_D^{22}$ +1.5° (c 1.0, $CHCl_3$); ^1H NMR 5.03 (1, *m*, 2-CH). The product was used for the condensation with ara-CMP morpholidate without chemical analysis.

ara-C-5-diphosphate-(ara-CDP)-1-S-octadecyl-2-O-palmitoyl-1-thio-sn-*glycerol (1b).* Phosphate **7b** (3.40 g, 5 mmol) was dried azeotropically with pyridine twice and mixed with ara-CMP morpholidate (2.75 g, 4 mmol), followed by co-evaporation with pyridine three times. The dried mixture was then mixed with anhydrous pyridine (300 mL) and stirred at room temperature for five days. The solvent was evaporated to dryness, and the residue was co-evaporated with toluene to remove the residual pyridine. The residue was dissolved in 300 mL of $CHCl_3$/MeOH/H_2O (2:3:1, by vol) and then mixed with 1 N HCl (11 mL) and H_2O (26 mL). The organic layer was separated, and the aqueous layer was extracted with $CHCl_3$ (2 × 50 mL). The combined organic layers were evaporated to dryness, and the residue was dissolved in 400 mL of $CHCl_3$/MeOH/H_2O (2:3:1, by vol). The solution was applied to a DE-52 (AcO^-) column (5 × 30 cm) prepacked with the solvent. The column was eluted with $CHCl_3$/MeOH/H_2O (2:3:1, by vol) (1000 mL) and then with 0.04 M NH_4OAc in the same solvent. The 0.04 M NH_4OAc fractions between 2100–4700 mL were evaporated to a small volume, and the solid was collected on a filter, followed by washing with 50% aqueous Me_2CO and then Me_2CO. The solid (NH_4 salt of 1b) was dissolved in $CHCl_3$/MeOH/H_2O (2:3:1, by vol), and the solution was passed through a CG-50 (Na^+) column (2 × 10 cm). The column was washed further with the same solvent until no UV-absorbing material was detected. The combined eluate was cooled at 0–5°C overnight, and the solid was filtered off. The filtrate was evaporated to a small volume and the product (Na salt) was filtered, washed with acetone and dried *in vacuo*; yield, 2.44 g (59.3%); m.p., 200–201°C; $[\alpha]_D^{22}$ +31.0° (c 1, $CHCl_3$-MeOH-H_2O 2:3:1, by vol); ^1H NMR ($CDCl_3$-CD_3OD-D_2O, 2:3:1, by vol) δ 0.83 (6, *t*, J = 6 Hz, $2CH_3$), 1.27–1.73 (58, *m*, $(CH_2)_{16}$, $(CH_2)_{13}$), 2.32 (2, *t*, J = 7 Hz, CH_2CO), 2.50 (2, t, J = 7 Hz, SCH_2), 2.76 (2, *t*, J = 7 Hz, 1-CH_2), 3.97–4.73 (7, *m*, 3-CH_2, H-2′, H-3′, H-4′, H-5′), 5.07 (1, *m*, 2-CH), 5.92 (1, *d*, J = 7.5 Hz, cytosine H-5), 6.08 (1, *d*, J = 5 Hz, H-1′), 7.80 (1, *d*, J = 7.5 Hz, cytosine H-6). *Anal.*: Calcd. for $C_{46}H_{85}N_3O_{13}SP_2{\cdot}2Na{\cdot}H_2O$: C, 52.81; H, 8.38; N, 4.01. Found: C, 52.97; H, 8.44; N, 3.61. The conjugates **1a**, **2a** and **2b** were prepared in an analogous manner.

ara-CDP1-O-octadecyl-2-O-palmitoyl-sn-*glycerol (1a).* Yield, 24.4%; m.p., 156–164°C; $[\alpha]_D^{22}$ +33.5° (c, 0.23, $CHCl_3$/MeOH/H_2O, 2:3:1, by vol); ^1H NMR ($CDCl_3$/CD_3OD/D_2O, 2:3:1, by vol) δ0.87 (6, *m*, $2CH_3$), 1.25–1.80 (58, *m*, $(CH_2)_{16}$, $(CH_2)_{13}$), 2.33 (2, *m*, CH_2CO), 3.36–4.13 (11, *m*, 1-CH_2, 3-CH_2, OCH_2, H-2′, H-3′, H-4′, H-5′), 4.97 (1, *m*, 2-CH), 5.92 (1, *d*, J = 7.5 Hz, cytosine H-5), 6.14 (1, *d*, J = 5 Hz, H-1′), 7.88 (1, *d*, J = 7.5 Hz, cytosine H-6). *Anal.*: Calcd. for $C_{46}H_{87}N_3O_{14}P_2 3CH_3OH$: C, 56.42; H, 9.06; N, 3.95; P, 5.82. Found: C, 56.82; H, 9.27; N, 3.69; P, 5.87.

ara-CDP3-O-octadecyl-2-O-palmitoyl-sn-glycerol (2a). Yield, 26.2%; m.p., 200–205°C; $[\alpha]_D^{22}$ +25.6° (c, 0.39, $CHCl_3$/MeOH/H_2O, 2:3:1, by vol); ^1H NMR ($CDCl_3$/CD_3OD/D_2O, 2:3:1, by vol) δ0.94 (6, *m*, $2CH_3$), 1.15–1.85 (58, *m*, $(CH_2)_{16}$, $(CH_2)_{13}$), 2.37 (2, *t*, *J* = 7 Hz, CH_2CO), 3.25–4.40 (11, *m*, 1-CH_2, 3-CH_2, OCH_2, H-2′, H-3′, H-4′, H-5′), 5.16 (1, *m*, 2-CH), 5.97 (1, *d*, *J* = 7.5 Hz, cytosine H-5), 6.16 (1, *d*, *J* = 5 Hz, H-1′), 7.82 (1, *d*, *J* = 7.5 Hz, cytosine H-6). *Anal.*: Calcd. for $C_{46}H_{85}N_3O_{14}P{\cdot}2Na{\cdot}0.5(CH_3)_2CO$: C, 55.05; H, 8.66; N, 4.01; P, 5.92. Found: C, 54.84; H, 9.16; N, 3.55; P, 6.12.

ara-CDP3-S-octadecyl-2-O-palmitoyl-3-thio-sn-glycerol (2b). Yield 20.4%; m.p., 198–200°C; $[\alpha]_D^{22}$ +18.4° (c 1.0, $CHCl_3$/MeOH/H_2O, 2:3:1, by vol); ^1H NMR ($CDCl_3$/CD_3OD/D_2O, 2:3:1, by vol) δ0.88 (6, *t*, *J* = 6 Hz, $2CH_3$), 1.24–1.71 (58, *m*, $(CH_2)_{16}$, $(CH_2)_{13}$), 2.38 (2, *t*, *J* = 7 Hz, CH_2CO), 2.59 (2, *t*, *J* = 7 Hz, SCH_2), 2.79 (2, *m*, 3-CH_2), 4.12–4.80 (7, *m*, 1-CH_2, H-2′, H-3′, H-4′, H-5′), 4.93 (1, *m*, 2-CH), 6.02 (1, *d*, *J* = 7.5 Hz, cytosine H-5), 6.21 (1, *d*, *J* = 5 Hz, H-1′), 7.94 (1, *d*, *J* = 7.5 Hz, cytosine H-6). *Anal.*: Calcd. for $C_{46}H_{85}N_3O_{13}SP_2{\cdot}2Na$: C, 53.73; H, 8.33; N, 4.09. Found: C, 54.07; H, 8.37; N, 3.54.

Antitumor activity in vivo. DBA/2J male mice in groups of 5–8 (wt: 20–29 g) were inoculated i.p. with 1 × 10^6 L1210 lymphoid leukemia cells (22), and a sonicated solution of the conjugates was given i.p. once daily a single or multiple injections, starting at day 1, as outlined previously (8). Survival time and animal weights were recorded and the % increase in life span (%ILS) was compared with the median survival of the untreated mice. The results are shown in Table 1.

RESULTS

The synthetic route used to prepare ara-C conjugates **1a, b** and **2a, b** was analogous to that of our earlier work in this series with conjugates **3a** (1) and **3b** (7). Optically pure 1,2-*O*-isopropylidene-*sn*-glycerol (16), 2,3-*O*-isopropylidene-*sn*-glycerol (17) and the respective *O*-alkylated products 1-*O*-octadecyl-*sn*-glycerol (19) and 3-*O*-octadecylglycerol (19) were prepared by literature procedures (20). The 1-thioglycerol analogue, 1,2-*O*-isopropylidene-3-thio-*sn*-glycerol (18), was prepared by the procedure in the literature and its optical isomer, 2,3-*O*-isopropylidene-1-thio-*sn*-glycerol, was prepared from 2,3-*O*-isopropylidene-*sn*-glycerol in an analogous manner. Alkylation and subsequent removal of the isopropylidene group of these 1-thioglycerol derivatives gave 1-*S*-octadecyl-1-thio-*sn*-glycerol and 3-*S*-octadecyl-3-thio-*sn*-glycerol. After protecting the 1- or 3-OH group of the *O*-octadecyl-*sn*-glycerols with a benzyl or trityl, the 2-OH was acylated with palmitoyl chloride in the presence of pyridine, and subsequent removal of the benzyl or trityl protective group by catalytic hydrogenolysis with 10% Pd/C or PtO/PdO gave **4a** and **5a** in 46–84% yield (Fig. 2). The benzyl or trityl group of the *sn*-1 (or *sn*-3) *O*-octadecyl-2-*O*-palmitoylglycerol was removed with minimal acyl migration to form 1-*O*-octadecyl-3-*O*-palmitoyl-*sn*-glycerol or 3-*O*-octadecyl-2-*O*-palmitoyl-*sn*-glycerol. The 1- or 3-OH group of the *S*-octadecyl-thio-*sn*-glycerols was protected with *tert*-butyldimethylsilyl (TBDMS) group, and the 2-OH was acylated with palmitoyl chloride in the presence of pyridine. The TBDMS group was removed by treatment with tetrabutylammonium fluoride in THF and HOAc at 5–10°C and then at room temperature (7), resulting in **4b** and **5b** in 29–50% yield. The acyl migration during the deblocking was also minimal. However, the acyl migration occurred even during the crystallization in 95% EtOH. Structure assignments of **4a, b** and **5a, b** were confirmed by ^1H NMR spectrometry. The *sn*-2 methine proton of the above compounds gave a first-order quintet at 4.93–5.16 ppm, as demonstrated previously (1,7).

TABLE 1

Antitumor Activity Against i.p. Implanted L1210 Lymphoid Leukemia in Mice[a]

Compound	Treatment schedule, qd	Dose, mg (μmol)/kg per day	Survival days			45-Day survivors
			Range	Median T/C[b]	% ILS[c]	
ara-C.HCl	1	55 (196)	8–9	9.0/8.0	13	0/5
		81 (290)	9–10	9.0/9.0	0	0/6
	1–5	230 (822)	14–15	15.0/7.5	100	0/6
1a	1	100 (98)	11–21	14.5/8.0	81	0/6
		200 (196)	17–22	19.5/8.0	144	0/6
		300 (294)	18–25	21.5/8.0	169	0/6
2a	1	100 (98)	15–17	16.0/8.0	100	0/6
		200 (196)	16–23	21.0/8.0	163	0/6
		300 (294)	15–>45	22.0/8.0	175	1/6

[a]Each group of 5–8 DBA/2J mice (male, 20–29 g) received i.p. inoculation of 1 × 10^6 cells on day 0. Treatments (i.p.) were initiated on day 1. Ara-C, 1-β-D-arabinofuranosylcytosine.
[b]Calculated based on survivors according to the NCI protocols (22). T/C, treated/control (untreated).
[c]Increase in life span: (T/C − 1) × 100.

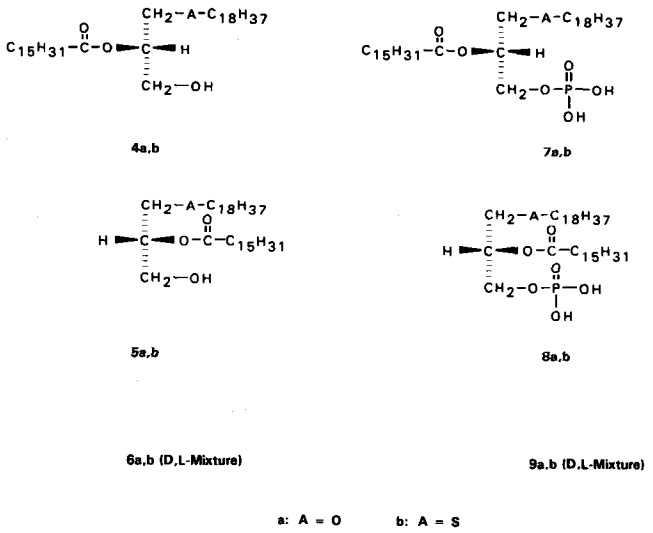

FIG. 2. Structures of ether and thioether lipids.

Compounds **4a, b** and **5a, b** were phosphorylated with $POCl_3$ and Et_3N at 0–5°C, as outlined previously (1), and the resulting phosphates, **7a, b** and **8a, b**, were purified by successive crystallization from hexanes and Et_2O, to obtain a final yield of 45–74%. Phosphate **8a** was also prepared in 80% yield by phosphorylation of **5a** with phenyl dichlorophosphate in the presence of pyridine and subsequent removal of the phenyl group by catalytic hydrogenolysis with PtO_2/PdO. Condensation of **7a, b** and **8a, b** with ara-CMP morpholidate (15) in pyridine gave conjugates **1a, b** and **2a, b** in overall yields of 20–59%, and their structures were verified by elemental analysis and ^1H NMR spectroscopy.

Antitumor activity. Conjugates **1a–3a** and **1b–3b** were compared for their *in vivo* antitumor activity against i.p. implanted L1210 lymphoid leukemia in DBA/2J mice, according to the procedures outlined in the NCI protocols (22), with some modifications, such as inoculation of 1×10^6 cells and 45-day observation. In Table 1, the untreated animals died on days 6–8 after tumor implantation. Conjugates of *sn*-1 (**1a**) and *sn*-3 (**2a**) isomers of the ether lipid injected i.p. as a single dose produced comparable ILS values among the isomers at each of three dose levels: 81 *vs.* 100% at 100 mg (98 μmol)/kg, 144 *vs.* 163% at 200 mg (196 μmol) and 169 *vs.* 175% at 300 mg (294 μmol)/kg on day 1. The racemic mixture (**3a**) at the same doses gave somewhat higher ILS values (157–286%) than the *sn*-1 and *sn*-3 isomers. However, a single i.p. injection of equimolar doses (196 and 290 μmol/kg) of ara-C failed to increase survival of the leukemic mice. Multiple high doses of ara-C (230 mg, 822 μmol/kg per day × 5) produced 100% ILS. Administration (i.p.) of a single dose (300 mg, 292 μmol/kg) of conjugates of *sn*-1 (**1b**), *sn*-3 (**2b**), and racemic mixture (**3b**) of the thioether lipid produced ILS values of 238, 263 and 250%, respectively, with 1–2 long-term survivors (<45 d) out of five animals. When a total 300 mg/kg of the conjugates was administered i.p. in three or five divided doses, the ILS values obtained were 175–288%.

DISCUSSION

Results obtained in this study demonstrated again that ara-C conjugates of ether and thioether lipids are highly effective against L1210 lymphoid leukemia in mice regardless of chirality at the glycerol, exceeding the activity of ara-C. Both racemic mixtures **3a** and **3b** showed a comparable activity to the *sn*-1 isomers **1a** and **1b**, as previously reported for the *sn*-1 isomer and racemic mixture of ara-CDP-dipalmitin (23). These conjugates contain both ara-C and an ether or thioether lipid in place of the cytidine and diacylglycerol, which are present in natural cytidine diphosphate diglyceride, a precursor for membrane phosphatidylinositol and cardiolipin (24). Thus, the conjugates may produce two cytotoxic groups, ara-C 5′-triphosphate (ara-CTP) and alkyllysophospholipid or 1-*S*-thioether lysophospholipid after biotransformation (1,8). Synthetic analogues of the latter lipids are membrane-active antitumor agents (25,26) and 1-*O*-octadecyl-2-*O*-methyl-*rac*-glycero-3-phosphocholine (ET-18-OCH_3) and 1-hexadecylmercapto-2-methoxymethyl-*rac*-propane-3-phosphocholine (BM 41.440, Ilmofosine) are in clinical trials (27,28). These compounds are also racemic mixture. Thus, conjugates **3a** and **3b** (Cytoros) of a racemic mixture of the thioether lipid are good candidate drugs for the clinical trials. In fact, **3b** (Cytoros) is highly active in both human colorectal cancer xenografts (11) and PSN-1 human pancreatic cancer xenograft in nude mice (12), in addition to the broad spectrum of antitumor activity against *in vivo* animal solid tumor models (4,5,8,9). Furthermore, this compound inhibited liver metastases of M5076 sarcoma (8) and lung metastases of 3-Lewis lung carcinoma in mice (4,5). With regard to its action as prodrug of ara-C, Cytoros (**3b**) and its analogues are resistant to hydrolysis by cytidine deaminase (29), are taken up rapidly by tumor cells (30), give a greater intracellular retention of ara-CTP than that resulting from ara-C (8,12) and interact extensively with serum lipoproteins (31). In addition, superior antitumor activity of Cytoros as compared to *sn*-1 isomer of ara-CDP-dipalmitin, a diacylglycerol conjugate (6), could possibly be due, in part, to the release of two cytotoxic groups, ara-CTP and 1-*S*-thioether lysophospholipid after biotransformation (32,33). A preclinical toxicology study of Cytoros is now in progress.

ACKNOWLEDGMENT

We are very grateful to Roswell Park Cancer Institute for providing us with DBA/2J mice.

Synthesis of Oxygenated Fatty Acid Esters from Santalbic Acid Ester

Mohammed Khysar Pasha[a] and **Fasih Ahmad**[b,*]

[a]Section of Oils and Fats, Department of Chemistry, Faculty of Science and [b]Department of Biochemistry, Faculty of Life Sciences, Aligarh Muslim University, Aligarh-202 002, India

The reaction of methyl octadec-*trans*-11-en-9-ynoate (1) with mercuric sulfate in the presence or absence of sulfuric acid is described. Treatment of 1 with mercuric sulfate in absolute methanol yielded methyl 9(10)-oxooctadec-*trans*-11-enoates (Product A). This product, upon treatment with *m*-chloroperbenzoic acid, afforded methyl *trans*-11,12-epoxy-9-oxooctadecanoate (4) and methyl 10-oxooctadec-*trans*-11-enoate (2). Sodium borohydride reduction of A furnished the corresponding hydroxy esters. The treatment of 1 with mercuric sulfate in the presence of sulfuric acid gave as major product methyl 9(10)-oxo-11(12)-methoxyoctadecanoates and methyl 9(10)-oxooctadec-*trans*-11-enoates as a minor product. When methyl 11,12-epoxyoctadec-9-ynoate was reacted with acid in methanol, methyl 12-hydroxy-11-methoxyoctadec-9-ynoate was formed, which on treatment with zinc chloride in CCl_4 yielded methyl 9,12-epoxyoctadec-9,11-dienoate exclusively. The preparation of oxo fatty esters from the total methyl esters of *Santalum album* was also demonstrated. The structures of the products were established by chemical derivatization and spectral characterization. *Lipids 28,* 1027–1031 (1993).

Santalbic (octadec-*trans*-11-en-9-ynoic) acid, a conjugated enynoic fatty acid, is a major component of *Santalum album* (Linn.) seed oil. The seeds from *S. album* contain about 50–60% drying oil, which is 74% santalbic acid (1). The seeds can be collected in quantity from sandal wood plantations. Santalbic acid can be readily isolated in high yield by crystallization from mixed fatty acids of *S. album* seed oil. Although large amounts of santalbic acid are produced naturally, few studies (1–5) have been undertaken on the chemistry of this fatty acid.

The chemistry of conjugated enynes is of current interest for the synthesis of biologically active compounds such as pheromones, leukotrienes and prostaglandins (6–8). Lam and Lie Ken Jie (9,10) have synthesized methyl 5(6)-oxooctadec-*cis*-10-enoates and 5(6)-hydroxy-10(11)-methoxyoctadecanoates by oxymercuration and demercuration reactions of a nonconjugated enynoic fatty ester (methyl octadec-*cis*-10-3-en-5-ynoate). Earlier workers have reported the hydration of nonconjugated enynic compounds with sulfuric acid and mercuric sulfate (11).

To the best of our knowledge, no such work has been carried out on long-chain fatty acids containing conjugated enynic chromophores. To explore the utility of santalbic acid, we have carried out some studies on its oxidation reactions. Santalbic acid esters were modified to α- and β-enoates, 9(10)-oxo-11(12)-methoxy fatty esters, 11,12-epoxy-9-oxo fatty ester, 11,12-epoxy-9-ynoate, 12-hydroxy-11-methoxy-9-ynoate and a furanoid fatty acid ester.

Abbreviations: GLC, gas-liquid chromatography; IR, infrared; MS, mass spectrometry; NMR, nuclear magnetic resonance; TLC, thin-layer chromatography.

EXPERIMENTAL PROCEDURES

Thin-layer chromatography (TLC) was done on microscope glass plates coated with silica gel G (about 0.1 mm thick), and a mixture of petroleum ether (40–60°C)/diethyl ether in various proportions was used as developing solvent. Perchloric acid (40% in water) was used as spray reagent to visualize fractions on the plates. Column chromatography was performed on silica (60–120 mesh) using gradient elution with a mixture of petroleum ether/diethyl ether. Collected fractions were checked by TLC to ascertain their purity. Adsorbents for TLC and column chromatography were obtained from E. Merck Limited (Bombay, India). All reagents and solvents were of analytical grade; solvents were distilled and dried before use. Sulfuric acid (95–98%), sodium borohydride, sodium bicarbonate, perchloric acid and zinc chloride were purchased from E. Merck, and *m*-chloroperbenzoic acid was from Fluka (Buchs, Switzerland). Mercuric sulfate was obtained from E. Merck (Darmstadt, Germany).

S. album seeds were obtained from Sandal Research Centre (Bangalore, India). Infrared (IR) spectra were measured on a Shimadzu IR-408 Spectrometer (Tokyo, Japan). Mass spectroscopy (MS) was done on a JEOL JMS-D3000 instrument (Tokyo, Japan) at 70 eV. Nuclear magnetic resonance (NMR) spectra were recorded on a Varian (Palo Alto, CA) A 60D spectrometer. NMR spectra were measured on $CDCl_3$ solutions and chemical shifts are reported in parts per million downfield from tetramethylsilane as internal standard.

Extraction of the oil from S. album *seeds, isolation of santalbic acid and preparation of its methyl ester. S. album* seeds were crushed in a mortar to separate kernels from the pericarp. The kernels and sodium sulfuate (20 g/50 g of kernels) were then finely crushed, and oil was extracted by repeated addition of petroleum ether (40–60°C) in a Soxhlet apparatus on a waterbath for 3 h. The petroleum ether extract obtained from the kernels was kept on anhydrous sodium sulfate overnight and was then filtered. The removal of petroleum ether under reduced pressure yielded 60% of a lightly yellowish oil. The oil (32.7 g) was hydrolyzed by refluxing with 120 mL of ethanolic potassium hydroxide (6.54 g/130.8 mL) solution for 1 h. During this saponification process, a gummy substance was separated from the reaction mixture. Ethanol was then evaporated *in vacuo* at 60°C. The potassium salts of the mixed fatty acids were dissolved in excess water and acidified with 1N HCl. The liberated free fatty acids were extracted repeatedly with diethyl ether. The combined extract was dried over anhydrous sodium sulfate, and the solvent was evaporated, yielding 30.0 g of mixed free fatty acids.

The mixed fatty acids (30.0 g) of *S. album* seed oil upon crystallization from hexane at −10°C yielded crude santalbic acid (22.4 g; m.p. 36–38°C), which upon recrystallization from hexane at −10°C, gave the pure product [×9.7 g; m.p. 39°C; m.p. reported (2) 38.5°C]. Methyl santalbate (1) was prepared by treating the santalbic acid (4 g) overnight with a 50-mL mixture of methanol/benzene/sulfuric

acid (21:2.5:1, by vol) at room temperature. Water (approximately 100 mL) was added to the reaction mixture to reach the cloud point. The methyl ester was extracted repeatedly with diethyl ether, and the ethereal layer was washed twice with exceses 5% (wt/vol) sodium bicarbonate solution, then twice with water. The ethereal layer was dried over anhydrous sodium sulfate and the diethyl ether was evaporated yielding methyl santalbate. The purity of methyl santalbate was verified by TLC and gas-liquid chromatography (GLC) (99% pure).

Reaction of 1 *with mercuric sulfate and absolute methanol.* Compound 1 (1.15 g) was added to a well-stirred solution of mercuric sulfate (0.227 g) in absolute methanol (30 mL) at room temperature. The reaction was complete within 30 min. The reaction mixture was diluted by adding excess water (about 100 mL) and then extracted with diethyl ether (3 × 20 mL). The ethereal layer was dried over anhydrous sodium sulfate, filtered and the solvent was evaporated to yield a lightly yellowish oily product which on silica gel column chromatography afforded Product A in 95% yield. ^{1}H NMR spectrum ($CDCl_3$) δ 6.46-7.0 ppm (*m*, C*H*=C*H*CO), 5.5-5.83 (*m*, C*H*=C*H*CH$_2$CO), 3.0 (*d*, CH=CHC*H*$_2$CO), 3.58 (*s*, COOC*H*$_3$) 2.1-2.45 (*m*, methylene protons α to ester carbonyl, free carbonyl and double bond). IR spectrum (film) 1740 (s, ester carbonyl), 1710 (s, C=O stretching), 1670 and 1630 (s, CH=CHCO), 950 (s, *trans*-unsaturation) cm^{-1}; mass spectrum (*m/z*, rel intensity) 310 (M^+, absent), 225 ($M^+ - R^1$, 52.3), 185 ($M^+ - R^1CH{=}CHCH_2$, 57.1), 125 ($M^+ - R^2CO$, 38.09), 199 ($M^+ - R^1CH{=}CH$, 21.4), 153 ($M^+ - R^2$, 26.1), 139 ($M^+ - R^2CH_2$, 52.3), 280 (9.52), 279 (45.2), 278 (4.76), 267 (2.3), 226 (0.7), 211 (9.5), 200 (4.7), 55 (base peak, 100).

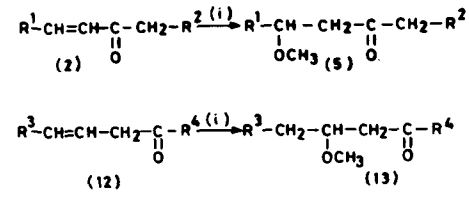
Reaction of Product A *with* m-*chloroperbenzoic acid.* Product A (0.2 g) was dissolved in chloroform (50 mL), and *m*-chloro-perbenzoic acid (0.71 g) was added in portions. The reaction was allowed to run for 24 h at 5°C. Chloroform was removed from the reaction mixture under reduced pressure, and the reaction products were extracted with diethyl ether (3 × 20 mL). Removal of diethyl ether and subsequent silica gel column chromatography of the reaction product yielded about 70% of methyl 10-oxo-octadec-*trans*-11-enoate (2) and 25% of methyl 9-oxo-*trans*-11,12-epoxyoctadecanoate (4). Product 2: R_f, 0.69; ^{1}H NMR spectrum ($CDCl_3$) δ 6.46-7.0 ppm (*m*, 2H, C*H*=C*H*CO), 3.6 (*s*, 3H, COOC*H*$_3$), 2.0-2.6 (*m*, 6H, methylene protons α to ester carbonyl, free carbonyl and double bond); IR spectrum (film) 1740 (s, ester carbonyl), 1670 and 1630 (s, CH=CHCO) cm^{-1}. Product 4: R_f, 0.53; ^{1}H NMR spectrum ($CDCl_3$) 2.9-3.0 (*m*, 2H, epoxide protons), 3.6 (*s*, 3H, COOC*H*$_3$), 2.2-2.6 (*m*, 6H, methylene protons α to ester carbonyl, free carbonyl and epoxy ring), 1.3 (*m*, chain methylene protons) and 0.9 (*t*, 3H, terminal methyl protons). IR spectrum (film) 1740 (s, ester carbonyl), 890 (s, 1,2-epoxide stretching), 1710 (s, C=O stretching).

Reaction of 1 *with mercuric sulfate and methanol containing sulfuric acid.* Methyl santalbate (1) (1.15 g) was added to a well-stirred solution of mercuric sulfate (0.227 g), sulfuric acid (1.55 g) and absolute methanol (30 mL). The reaction mixture was stirred for 90 min at room temperature. After completion of the reaction, water (100 mL) was added to the reaction mixture, and the mixture was extracted with diethyl ether (3 × 20 mL). The ethereal layer was successively washed with dilute $NaHCO_3$ (10%, 40 mL) and water (2 × 40 mL). The organic layer was dried over anhydrous sodium sulfate, filtered and evaporated. Silica gel column chromatography of the reaction mixture yielded two products, D as the major (70%) and C as the minor product (25%). The major Product D gave the following spectral data: ^{1}H NMR spectrum ($CDCl_3$) δ 3.7 ppm (*s*, 3H, COOC*H*$_3$), 3.3 (*s*, 3H, HC-OC*H*$_3$), 2.16-2.6 (*m*, 6H, methylene protons α to ester carbonyl and free carbonyl), 3.6 (*m*, 1H, methine); IR spectrum (film) 1740 (s, ester carbonyl), 1710 (s, C=O stretching), 1160 (m, ether linkage) cm^{-1}; mass spectrum (*m/z*, rel intensity) 342 ($M^+ - R^1CH_2CHOCH_3$, 92.8), 143 ($M^+ - CH_2COR^2$, 15.47), 243 ($M^+ - R^1CH_2$, 32.14), 171 ($M^+ - R^1CH(OCH_3)CH_2CO$, 44.04), 257 ($M^+ - R^1$, 100), 295 (11.9), 296 (14.2), 280 (4.7), 279 (27.3), 258 (14.2), 227 (52.3), 228 (8.3), 200 (13.0), 183 (2.3), 139 (38.09), 129 (67.85), 55 (base peak, 100). The minor Product C was identical with Product A.

Sodium borohydride reduction of Product A. Sodium borohydride (0.025 g) was added in portions within 10 min at 0°C to a well-stirred solution of A (mixture of 2 and 3) in methanol (0.2 g in 25 mL). Monitoring of the reaction mixture by TLC indicated the completion of the reaction within 15 min. The reaction mixture was diluted immediately by adding excess water, acidified with 1N HCl and extracted with diethyl ether. Evaporation of diethyl ether gave the oily Product E (a mixture of 7 and 8), which was purified by silica gel column chromatography. ^{1}H NMR spectrum ($CDCl_3$) δ 5.33-5.5 ppm (*m*, olefinic protons), 3.9-4.38 (*m*, methine protons), 3.6 (*s*, 3H, COOC*H*$_3$), 1.93 (*s*, -O*H*, D_2O exchangeable); IR spectrum (film) 1740 (s, ester carbonyl), 3350 (broad, -OH), 965 (*m*, *trans*-unsaturation) cm^{-1}. Interconversion of Product E into Product A was achieved by chromic acid oxidation (12); Product A was identified as a mixture of 2 and 3 by spectral analysis.

Reaction of 2 *and* 12 *with methanol containing sulfuric acid.* Methyl 12-oxo-octadec-9-enoate (9) was prepared from methyl 12-hydroxy-octadec-9-enoate (12).

The compounds 2 and 12 (0.5 g each) were each dissolved separately in 30 mL of methanol containing sulfuric acid (1.55 g) and stirred for 90 min at room temperature. The reaction mixture was diluted by adding 100 mL of water, and the reaction products were extracted with diethyl ether. The products were purified by silica gel column chromatography using petroleum ether/diethyl ether (85:15, vol/vol) as eluent. Compound 2 furnished Product 5 (70%), and 12 afforded Product 13 (70%) (Scheme 1).



SCHEME 1

Product 5: ^{1}H NMR spectrum ($CDCl_3$) δ 3.7 ppm (*s*, 3H, $COOCH_3$), 3.3 (*s*, 3H, $CH-OCH_3$), 2.16-2.6 (*m*, 6H, methylene protons α to ester carbonyl and free carbonyl) 3.6 (*m*, 1H, methine); IR spectrum (film) 1740 (s, ester carbonyl), 1710 (s, C=O stretching), 1160 (*m*, ether linkage) cm^{-1}; mass spectrum (*m/z*, rel intensity) 257 ($M^+ - R^1$, 100), 129 ($M^+ - R^2CH_2COCH_2$, 99), 199 ($M^+ - R^1CH(OCH_3)CH_2$, 93), 171 ($M^+ - R_2CH_2$, 49), 185 ($M^+ - R^2$, 98), 327 (3.7), 311 (5.8), 295 (6.4), 279 (7.1), 258 (3.9), 244 (6.4), 243 (19.0), 225 (14.9), 212 (3.6), 200 (14.5), 186 (17.0), 172 (5.7), 168 (10.4), 154 (21.0), 153 (18.6), 149 (21.7), 143 (42.4), 139 (60.5), 130 (10.5), 127 (19.6), 125 (50.4), 121 (23.3), 55 (base peak, 100). Product 13: ^{1}H NMR spectrum ($CDCl_3$) δ 3.7 ppm (*s*, 3H, $COOCH_3$), 3.3 (*s*, 3H, $HC-OCH_3$), 2.16-2.6 (*m*, 6H, methylene protons α to ester carbonyl and free carbonyl), 3.6 (*m*, 1H, methine); IR spectrum (film) 1740 (s, ester carbonyl), 1710 (s, C=O stretching), 1160 (m, ether linkage) cm^{-1}; mass spectrum (*m/z*, rel intensity) 342 (M^+, absent), 257 ($M^+ - R^4$, 95), 113 ($M^+ - R^3CH_2CH(OCH_3)CH_2$, 80), 229 ($M^+ - R^4CO$, 84), 127 ($M^+ - R^3CH_2CH(OCH_3)$, 30.7), 183 ($R^3CH_2CH(OCH_3) - CH_3OH$, 10.1), 171 ($M^+ - R^3CH_2$, 11.9), 283 (5.1), 264 (12.6), 230 (13.4), 205 (2.2), 202 (4.8), 199 (6.6), 195 (2.2), 185 (4.6), 180 (4.4), 179 (8.9), 161 (11.2), 158 (5.9), 143 (14.4), 137 (11.3), 115 (33.1), 109 (32.3), 101 (28.0), 55 (base peak, 100).

Preparation of oxo fatty esters from total methyl esters of S. album *seed lipids.* Total methyl esters of *S. album* seed lipids (1.15 g) were added to a well-stirred solution of mercuric sulfate (0.167 g) in absolute methanol (30 mL). After half an hour, the reaction was stopped by adding excess water (about 100 mL), and the reaction products were extracted (3 × 20 mL) with diethyl ether. The combined ethereal layer was dried over anhydrous sodium sulfate. Solvent was evaporated, and the oxygenated fatty esters were separated from nonoxygenated fatty esters by silica gel column chromatography to afford 72% of Product A.

Reaction of methyl 11,12-epoxyoctadec-9-ynoate (9) with acidic methanol. Methyl 11,12-epoxy-octadec-9-ynoate (9) was synthesized by the procedure of Abbot and Gunstone (13). The compound 9 (1 g) was stirred vigorously with 15 mL of 10% aqueous sulfuric acid in methanol. After 5 min, TLC of the reaction mixture showed the complete conversion of epoxide into a more polar compound. The reaction mixture was diluted by adding excess water (100 mL), and the product was extracted with diethyl ether. The organic layer was washed twice with $NaHCO_3$ (10%, 40 mL) and then with water (2 × 40 mL) and dried over anhydrous sodium sulfate. Evaporation of the solvent yielded an oily product, which was purified over a silica gel column to remove some minor contaminants. The isolated compound (95%) was identified as methyl 12-hydroxy-11-methoxy-octadec-9-ynoate (10) on the basis of the following spectral data: ^{1}H NMR spectrum ($CDCl_3$) δ 3.88 ppm (*m*, 2H, methine), 3.66 (*s*, 3H, $COOCH_3$), 3.43 (*s*, 3H, OCH_3), 2.63 (*s*, 1H, $-OH$, D_2O exchangeable), 2.3 (*m*, 4H, methylene protons α to ester carbonyl and triple bond); IR spectrum (film) 1740 (s, ester carbonyl), 3350 (broad, -OH), 1160 (*m*, ether linkage) cm^{-1}.

Reaction of methyl 12-hydroxy-11-methoxy-octadec-9-ynoate (10) with zinc chloride. Compound 10 (1 g), carbon tetrachloride (30 mL) and zinc chloride (0.4 g) were refluxed for 2 h. TLC of the reaction mixture revealed the formation of only one product. Carbon tetrachloride was removed under reduced pressure, and the product was extracted with diethyl ether (3 × 20 mL). The combined ethereal layers were washed twice with water. Diethyl ether was evaporated, and the product was purified by column chromatography. Based on spectral data, the product (90%) was confirmed to be methyl 9,12-epoxyoctadec-9,11-dienoate (11). ^{1}H NMR spectrum ($CDCl_3$) δ 5.78 ppm (*s*, 2H, ethylenic), 3.6 (*s*, 3H, $COOCH_3$), 2.08-2.66 (*m*, 6H, methylene protons α to ester carbonyl and furan ring); IR spectrum (film) 1740 (s, ester carbonyl), 1555 (s, $\nu_{C=C}$, furan stretching), 1015 (furan ring breathing) cm^{-1}.

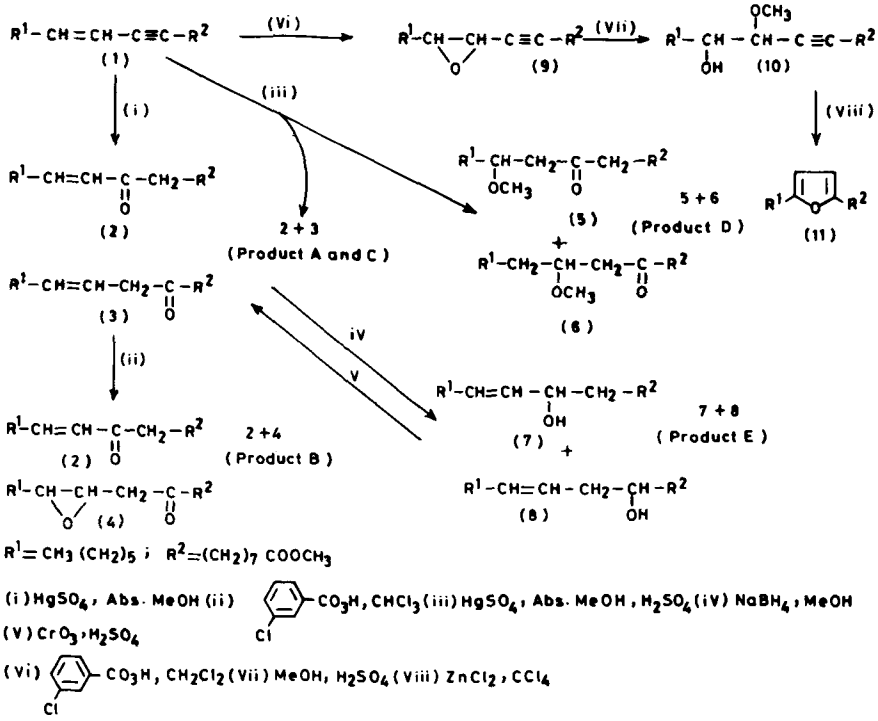
RESULTS AND DISCUSSION

Reaction of 1 with mercuric sulfate in absolute methanol (Scheme 2) gave Product A, which is a mixture of methyl 10-oxo-octadec-*trans*-11-enoate (2) and methyl 9-oxo-octadec-11-enoate (3). The same reaction in the presence of sulfuric acid (Scheme 2) resulted in the formation of 2 and 3 in minor amounts (Product C) and 5 and 6 (methyl 9(10)-oxo-11(12)-methoxy-octadecanoates) in major amounts (Product D). The hydration of 1 in the presence of sulfuric acid yielded, initially 2 and 3. Compound 2, an α,β-unsaturated oxo fatty ester, was readily converted to methyl 10-oxo-12-methoxy octadecanoate (5) by sulfuric acid catalyzed methoxylation. The β,γ-unsaturated oxo fatty ester (3) was first converted to α,β-unsaturated oxo fatty ester (methyl 9-oxooctadec-10-enoate), which on further acid-catalyzed methoxylation yielded methyl 9-oxo-11-methoxy-octadecanoate (6). These observations were supported by the acid-catalyzed methoxylation of pure α,β-unsaturated oxo fatty ester (2) and β,γ-unsaturated oxo fatty ester (12), which afforded β-methoxy ketones (5 and 13), respectively (Scheme 1).

Although compounds 2 and 3 of Product A were not separable by TLC, their identity was established by spectral characterization. The NMR spectrum of the mixture exhibited a complex multiplet at δ 6.46-7.0, which is characteristic of the α- and β-protons of α,β-unsaturated keto moiety. A broad multiplet at δ 5.5-5.83 for two protons (β and γ) and a doublet at δ 3.0 for two methylene protons of C-10 suggested the presence of a β,γ-unsaturated carbonyl system. The IR spectrum displayed characteristic bands at 1670 and 1630 cm^{-1}, which are due to the presence of an α,β-unsaturated carbonyl group, and at 1710 cm^{-1} indicating the presence of a β,γ-unsaturated carbonyl function. The mass spectral fragmentation pattern of Product A was in good agreement with the structures unveiled by IR and NMR spectra, which exhibited the structure identifying fragment ions at *m/z* 185 ($M^+ - R^1CH{=}CHCH_2$, 57.1) and *m/z* 139 ($M^+ - R^2CH_2$, 52.3), suggesting that Product A was a mixture of 2 and 3.

Compounds 2 and 3 of reaction Product A were separated when the mixture was treated with *m*-chloroperbenzoic acid at 5°C. Compound 3 readily formed an epoxide (4) while 2 remained unchanged, which greatly facilitated their separation by chromatography.

In the presence of sulfuric acid, the reaction of 1 with methanolic mercuric sulfate yielded C as the minor product and D as the major product. Product D was identified by IR, ^{1}H NMR and MS as a mixture of methyl 10-oxo-12-methoxy-octadecanoate (5) and methyl 9-oxo-11-methoxy-octadecanoate (6).



SCHEME 2

Sodium borohydride reduction of Product A (Scheme 2) at 0°C afforded methyl (9)10-hydroxy-octadec-11-enoates (7 and 8), which could find importance in the preparation of low-temperature plasticizers. It has been reported (14) that superior low-temperature plasticizing properties can be obtained with fatty acids having a hydroxyl group at C-9 or C-10 rather than C-12 position as in ricinoleic acid.

The mercuric sulfate-catalyzed reaction of santalbic acid is a useful method for the preparation of oxo fatty esters (2 and 3) in high yield. These oxo fatty esters can also be obtained directly from the mixed fatty acid methyl esters of *S. album* seed oil in 70% yield.

Lie Ken Jie and Lam (15) described the synthesis of isomeric furanoid C_{18} acids from furan and furfural or appropriate octadecadiynoates. Alternatively, furanoid acids have been prepared from appropriate C_{18} compounds by reactions which include Pd(II)-catalyzed cyclodehydration of unsaturated oxygenated acids and rearrangement of unsaturated oxygenated acids (16). The present study describes a new method for synthesizing methyl 9,12-epoxy-octadec-9,11-dienoate (**11**), a substance found naturally in fish and other lipids (17). The furanoid ester (**11**) has been synthesized from the α,β-acetylenic epoxide (**9**) in two steps (Scheme 2). The acid-catalyzed ring opening reaction of **9** yielded, exclusively, 11-methoxy-12-hydroxy-ynoate (**10**), which on subsequent cyclization under the influence of zinc chloride afforded methyl 9,12-epoxy-octadec-9,11-dienoate (**11**). The sharp NMR signal exhibited by this compound at δ 5.78 (two ethylenic protons) and characteristic IR bands at 1555 and 1015 cm^{-1} suggested it to be a furanoid fatty ester. This furanoid fatty ester was earlier prepared from α,β-epoxy acetylenic ester by mercuric sulfate catalyzed cyclization (13).

The ring opening reaction of epoxide (**9**) with acidic methanol may yield an isomeric mixture of 11(12)-hydroxy-12(11)-methoxy-ynoates. We observed the formation of the 12-hydroxy-11-methoxy-ynoate (**10**) but not of 11-hydroxy-12-methoxy-ynoate isomer. This was confirmed by the ready formation of furanoid fatty ester (**11**) on treatment of compound **10** with zinc chloride. The reason for the exclusive formation of isomer **10** could also be explained on the basis of the stabilities of the intermediate carbocations. Isomer **10** was formed by the intermediacy of propargylic cation (-CH(OH)$\overset{+}{C}$HC≡C-), which is much more stable (18) as compared to the other expected cation (-$\overset{+}{C}$HCH(OH)C≡C-).

ACKNOWLEDGMENTS

We thank S.A.A. Zaidi, the chairman of the Chemistry Department at AMU, Aligarh, for providing research facilities. B.N. Dhawan, the director of Central Drug Research Institute, Lucknow, is acknowledged for mass spectral analysis. S.N. Rai, the conservator of forests, Sandal Research Centre, Bangalore, supplied sandal seeds. This research was financed by a grant from USDA under PL-480 research project. The Council of Scientific and Industrial Research, New Delhi, India, provided a senior research fellowship to M. Khysar Pasha.

METHOD

Application of Paired-Ion High-Performance Liquid Chromatography to the Separation of Molecular Species of Phosphatidylinositol

Yasuhito Nakagawa
School of Pharmaceutical Sciences, Kitasato University, 5-9-1 Shirokane, Minato-ku, Tokyo 108, Japan

A paired-ion high-performance liquid chromatographic (HPLC) procedure was developed for the separation of individual molecular species of phosphatidylinositol (PI) without prior derivatization. The separation is accomplished on a reverse-phase column using acetonitrile, methanol and 10 mM tetrabutylammonium phosphate as mobile phase. Separation of the major molecular species of soybean PI by HPLC is achieved within 60 min. The method is applicable to analytical and metabolic studies on PI and has the advantage that the entire PI structure is preserved, as no degradation or derivatization procedures are involved.
Lipids 28, 1033–1035 (1993).

Phospholipids consist of populations of well-defined molecular species that contain various fatty acyl chains at both the 1- and 2-position of the glycerol backbone (1,2). The molecular species composition of phosphatidylinositol (PI) in mammalian tissues is quite different from that of other phospholipids, as there is a great abundance of the 1-stearoyl-2-arachidonoyl (18:0/20:4) species in PI (1). The rapid turnover of PI and of polyphosphoinositides in response to extracellular stimuli is believed to be part of the signal transduction system in various mammalian tissues (3,4).

The metabolic heterogeneity of PI molecular species has been studied in liver and brain using radiolabeled precursors, such as [^{3}H]glycerol and [^{32}P]phosphate (5,6), and preferential degradation of the arachidonoyl species of phospholipids, including those of PI, in response to extracellular stimuli has been reported in collagen-stimulated platelets (7) and in concanavalin A-stimulated lymphocytes (8). These studies have reemphasized the importance of monitoring the metabolism of PI at the molecular species level. However, little information is available about PI molecular species in mammalian tissues as the separation of phospholipid species with uniform structure is difficult to achieve.

Reverse-phase high-performance liquid chromatography (HPLC) is a useful method for the separation of phospholipid molecular species. We have previously developed an HPLC method for the separation of diradylglycerol derivatives from phospholipids, after derivatization to 1,2-diacyl-3-acetylglycerols (9), and several methods are available for the separation of molecular species after modification at the 3-position of the glycerol backbone (10–12). However, these methods are typically less suited for studies in which metabolic changes in phospholipid polar head groups occur because the polar heads are removed prior to analysis. Patton *et al.* (13) developed an HPLC method for the separation of phospholipid molecular species without modification of polar head groups; however, this method is time-consuming. It is also generally difficult to achieve a clear separation of intact phospholipids by reverse-phase HPLC because of the presence of the free polar head groups. Thus a reduction in the polarity of the polar head group is desirable to achieve a better separation.

Ion-pair reverse-phase HPLC has been successfully employed for the separation of both cationic and anionic compounds, such as barbiturates, sulfonamides and 5-fluorouracil (14–16). PI is an anionic hydrophobic compound, and cationic ion-pair reagents, such as tetrabutylammonium (TBA) or hexadecyltrimethylammonium ions, can counter the charge of the PI phosphate groups through the formation of ion-pairs with PI. Counter ions thus can enhance nonpolar interactions of the PI moiety in the reverse-phase system, leading to increased selectivity and improved separation.

The present report describes the first application of an ion-pair reagent to the separation of the molecular species of PI by reverse-phase HPLC.

EXPERIMENTAL PROCEDURES

Materials. TBA phosphate was obtained from Kodak (Rochester, NY). Soybean PI was purchased from Sigma (St. Louis, MO) and purified by thin-layer chromatography using chloroform/methanol/acetone/acetic acid/water (5:1:2:1:0.5, by vol) as developing solvent. HPLC-grade organic solvents were purchased from Wako Pure Chemical Co. (Osaka, Japan).

Apparatus. The chromatographic system included a model 6-A pump (Shimadzu Co., Kyoto, Japan) and a model SPD-6A ultraviolet (UV) absorbance detector (Shimadzu Co.). PI was dissolved in chloroform/methanol (1:1, vol/vol), and a glass syringe with a 0.45-μm membrane filter (type HV; Nihon Millipore Kogyo K.K., Tokyo, Japan) was used to clean the samples prior to injection. PI was loaded onto the reverse-phase column (LiChrosorb RP-18; 25 × 0.4 cm i.d.; particle size, 5 μm; Merck, Darmstadt, Germany) and eluted with an isocratic mobile phase (acetonitrile/methanol/10 mM TBA phosphate, 51:35:14, by vol) at a flow rate of 0.5 mL/min. The column temperature was kept at 35°C using a heating box (model CTO-6A; Shimadzu Co.). The eluate was monitored by measuring the UV absorbance at 205 nm; absorbance was recorded with an integrator (model C-R 3A; Shimadzu Co.).

Fatty acid analysis. Fractions containing PI molecular species after elution from the reverse-phase column were transmethylated by treatment with 0.5 M sodium methoxide; fatty acyl moieties were identified as their methyl-esters by gas chromatography (GC) on a GC-14A instrument (Shimadzu Co.) using a capillary column (30 m × 0.53 mm i.d.; Supercowax X1; Supelco Japan, Tokyo,

Abbreviations: GC, gas chromatography; HPLC, high-performance liquid chromatography; PI, phosphatidylinositol; TBA, tetrabutylammonium, UV, ultraviolet.

Japan). Molecular species were quantified relative to heptadecanoic acid methyl ester, which was used as an internal standard.

RESULTS AND DISCUSSION

Soybean PI are particularly suited to demonstrate the analysis of molecular species because, unlike mammalian PI, they contain a variety of fatty acids. Soybean PI was separated into individual molecular species by paired-ion HPLC within 60 min. The solvent system, based on acetonitrile, methanol and TBA phosphate, proved useful for the separation of molecular species by reverse-phase without any prior modification. Although isopropyl alcohol is commonly added to solvent systems in reverse-phase HPLC, it did not improve the separation in our situation. TBA phosphate markedly enhanced the interaction of PI with the particle surface of reverse-phase column and increased observed retention times. Soybean PI was resolved into several fractions under the present isocratic conditions (Fig. 1). Analysis by gas–liquid chromatography of individual peaks revealed that seven different constituents of soybean PI were separated from each other (Table 1). The composition of soybean PI was quite different from that of PI from mammalian tissues in that the 18:0/20:4 species was only a minor component of soybean PI. The predominant molecular species of soybean PI were 16:0/18:2 (55.4%) and 18:0/18:2 (15.2%). The retention time of the molecular species increased with increasing chainlength and decreased with increasing degree of unsaturation of the fatty acids. The 18:0/18:1 species was expected to occur as a constituent of soybean PI, but was not found under the present conditions. This could be due to the low levels present and the long elution time of this species.

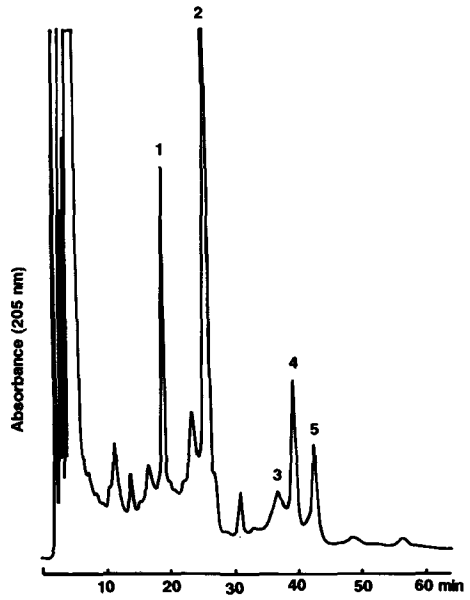

FIG. 1. Separation of the molecular species of soybean phosphatidylinositol (PI) by paired-ion high-performance liquid chromatography. Soybean PI, dissolved in 20 μL of chloroform/methanol (1:1 vol/vol), was chromatographed on a LiChrosorb RP-18 column (Merck, Darmstadt, Germany) at a flow rate of 0.5 mL/min. The mobile phase was acetonitrile/methanol/10 mM tetrabutylammonium phosphate (51:35:14, by vol). Eluates were monitored at 205 nm. The peak numbers correspond to those listed in Table 1.

TABLE 1

Relative Levels of the Individual Molecular Species of Soybean Phosphatidylinositol

Peak number[a]	Molecular species	Composition[b] (%)
1	16:0/18:3	7.1 ± 0.6
	18:2/18:2	7.0 ± 0.9
2	16:0/18:2	55.4 ± 3.6
3	16:0/18:1	6.0 ± 0.7
4	18:0/20:4	7.5 ± 0.4
	18:1/18:1	1.7 ± 0.1
5	18:0/18:2	15.2 ± 1.2

[a]Peak numbers correspond to the peaks in Figure 1.
[b]Values are expressed as the mean percentage ± SD (n = 3).

The fatty acid composition of PI, calculated from the molecular species composition as shown in Table 1, was similar to that of the original unfractionated sample, although the relative proportion of 18:1 was slightly lower after reverse-phase HPLC (Table 2). The results indicate that no significant losses of individual PI molecular species occurred during passage through the reverse-phase column.

The use of a TBA-containing eluent allowed the separation of PI molecular species in a manner that was not dependent, to any great extent, on the polarity of the head group. The method for the separation of the individual PI molecular species, as described here, will be valuable in studies on the metabolism of individual PI species. For example, the rates of turnover of the polar head group, of the acyl moieties and of the glycerol backbone of individual PI molecular species can be compared simultaneously by triple labelling, using [^{32}P]phosphate, [^{14}C]-glycerol and [^{3}H]fatty acid. In addition, the present method should also prove useful for the separation of the molecular species of polyphosphoinositides.

[Received February 9, 1993; Revision accepted September 7, 1993]

Separation and Identification of Isomeric Conjugated Fatty Acids by High-Performance Liquid Chromatography with Photodiode Array Detection

Sajid Husain* and **K. Sita Devi**
Analytical Division, Indian Institute of Chemical Technology, (CSIR), Hyderabad—500 007, India

A simple, high-performance liquid chromatographic method is described for the separation of tetraenoic, trienoic and dienoic conjugated fatty acids on a Zorbax ODS reversed-phase column using acetonitrile/tetrahydrofuran (95:5, vol/vol) at a flow rate of 1.2 mL/min as mobile phase. Also described is the separation of the isomeric conjugated fatty acids with acetonitrile/water/tetrahydrofuran (90:90:1, by vol) as mobile phase. The simultaneous detection and identification of the separated geometrical isomers in the eluant was accomplished using photodiode array detection. *Lipids 28*, **1037–1040 (1993).**

Conjugated fatty acids are an important class of compounds present in seed oils (1), and their separation, identification and quantitation is essential. Existing analytical methods are often tedious and time-consuming and usually involve a combination of procedures. High-performance liquid chromatography (HPLC) is commonly used to resolve fatty acids. However, only nonconjugated fatty acids have previously been analyzed by HPLC (for a review, see Ref. 2). The separation of positional and geometrical isomers can be accomplished by HPLC using the silver ion mode (3). The characterization of hydroxy/eicosatetraenoic acids and their conjugated dienes has been reported using ultraviolet (UV) spectroscopic detection (4). Tan (5) reported on a method for the analysis of carotenoids using nonaqueous reversed-phase HPLC and photodiode array (PDA) detection. The PDA detector has an advantage over other modes of HPLC detection, as it can selectively monitor UV chromophores of conjugated systems in mixtures. As each geometrical isomer has its characteristic λ_{max} value, PDA detection provides a convenient and reliable method for the identification of such isomers.

The conjugated fatty acids have distinct λ_{max} values in different regions of the spectrum, which are characteristic for their UV chromophores and facilitate identification. The conjugated tetraenoic acids (6–8) absorb in the range of 278–320 nm, whereas trienoic (9,10) and dienoic (11) fatty acids absorb around 260–285 nm and 225–245 nm, respectively. The purpose of the present study was to separate and identify isomeric conjugated tetraenoic, trienoic and dienoic fatty acids and to characterize the individual fatty acid isomers based on their geometrical configuration using HPLC and PDA detection.

MATERIALS AND METHODS

Materials. Garden balsum (*Impatiens balsamina*), bitter gourd (*Momordica charantia*) and snake gourd (*Trichosanthes anguina*) were obtained from the Seed Corporation (Hyderabad, India). Dehydrated castor oil (DCO) fatty acids were obtained from the Division of Oils and Fats (IICT, Hyderabad, India). All solvents were of HPLC grade (Spectrochem, Hyderabad, India).

Extraction procedure. The kernels of *I. balsamina*, *M. charantia* and *T. anguina* seeds were each ground with anhydrous Na_2SO_4 and were extracted three times with *n*-hexane (40–60°C) at room temperature. The combined extracts of each lipid sample were passed through anhydrous Na_2SO_4 and concentrated in a rotary evaporator at 40°C. The extracted oils were stored under nitrogen at −15°C.

Esterification. The fatty acid methyl esters from the oils were prepared by transesterification. The oil sample (100 mg) was dissolved in hexane (3 mL) in a round-bottom flask. Sodium methoxide in anhydrous methanol (5 mL) was added, the flask was flushed with nitrogen and the solution was shaken on a Griffin flask shaker for 30 min. Water (10 mL) was added, and the content was transferred into a separatory funnel and extracted with hexane (10 mL). The hexane layer was filtered through anhydrous Na_2SO_4. The methyl esters of DCO fatty acids were prepared by reaction with diazomethane (12). The methyl esters were purified by thin-layer chromatography (TLC) on Silica Gel G plates, using hexane/diethyl ether (90:10, vol/vol) as developing solvent, and stored under nitrogen at −15°C.

Preparation of standard samples. Methyl parinarate, methyl α-eleostearate and methyl punicate were isolated from the total methyl esters of *I. balsamina*, *M. charantia* and *T. anguina*, respectively. The total methyl esters of these oils were spotted onto Silica Gel G plates, and the plates were developed twice with hexane/diethyl ether (94:6, vol/vol) (13). The conjugated fatty esters were separated well from the nonconjugated ones, and the bands could be seen under UV light after spraying the plates with 2′,7′-dichlorofluorescein. The separated band of conjugated fatty acid esters was scraped off and extracted with diethyl ether by passing through a small column. The excess solvent was removed under vacuum, and the samples were stored under nitrogen at −15°C.

Isomerization of total methyl esters. An iodine solution (0.2 mL) was prepared by dissolving iodine in pure *n*-hexane (0.65 g/100 mL hexane) and was then added to the methyl esters (50 mg) dissolved in 3 mL of *n*-hexane. The reaction mixture was shaken well and left overnight at ambient temperature (14). The isomerized product was extracted with *n*-hexane and purified by passing through a small column of silica gel. β-Eleostearic acid was isolated from the isomerized methyl esters of *M. charantia* by preparative TLC using hexane/diethyl ether (94:6, vol/vol). β-Parinaric acid could not be isolated in pure form from the isomerized methyl esters of *I. balsamina*. Therefore, the isomerized methyl esters of *I. balsamina* were used as such for HPLC analysis. However, this did not affect the analysis, as the PDA detector facilitated the selective identification of the conjugated components, either from pure fatty acid esters or from total methyl esters at the

*To whom correspondence should be addressed.

wavelength corresponding to the conjugated tetraenoic fatty acids (278–320 nm).

UV spectroscopy. The λ_{max} values of pure fatty acid methyl esters were measured on 4.5 μg/mL solutions using a Shimadzu (Kyoto, Japan) UV-240 model recording double-beam spectrophotometer fitted with a deuterium lamp. The solvent used was cyclohexane. The λ_{max} values measured are given in Table 1.

HPLC equipment and conditions. HPLC separations were carried out using a Shimadzu LC-6A instrument with a single piston pump, a CDQR (Constant Displacement with Quick Return) system (Shimadzu, Tokyo, Japan) and a 7125 injector valve. The instrument was linked to MIA photodiode array UV-visible spectrophotometric detector (PDA detector) (Shimadzu) and a WX 4421 XYT C-R_3A data processor chromatopac recorder (Shimadzu). For all chromatographic separations, a 5-μm pore size 4.6 mm i.d. × 25 cm Zorbax ODS reversed-phase column from DuPont Instruments (Barley Mill Plaza, Wilmington, DE) connected to a Shimadzu 10-μm ODS guard column was used.

Sample preparation. To illustrate the separation and identification of individual conjugated tetraenoic and trienoic fatty acids, the methyl esters of *I. balsamina*, *M. charantia* and *T. anguina* oils were used. The isomerized methyl esters of *I. balsamina* oil were used to show the separation and identification of the geometrical isomers of conjugated tetraenoic acids. The methyl esters of DCO fatty acids were used for the separation and identification of the geometrical isomers of conjugated dienoic acids.

In all of the above cases, 5 mg of the sample was dissolved in 10 mL of the mobile phase (acetonitrile/tetrahydrofuran, 95:5, vol/vol) and used for analysis. However, for the separation and identification of the geometrical isomers of the conjugated trienoic acids, 2 mg each of the methyl esters obtained from *M. charantia* and *T. anguina* and the isomerized methyl esters of *M. charantia* oils were dissolved in 10 mL of the same mobile phase as above and used for the analysis.

Pure samples. One mg of each standard sample, *i.e.*, methyl parinarate, methyl α-eleostearate, methyl punicate

and methyl β-eleostearate, was dissolved in 10 mL of the mobile phase and used for analysis.

Twenty μL of these solutions were injected using a 20-μL loop in the injector port. The conjugated fatty acids were eluted using a binary mobile phase consisting of acetonitrile/tetrahydrofuran (95:5, vol/vol) at a flow rate of 1.2 mL/min. The geometrical isomers were separated using the same column, but a more polar tertiary mobile phase consisting of acetonitrile/water/tetrahydrofuran (90:9:1, by vol), at a flow rate of 1.2 mL/min.

RESULTS AND DISCUSSION

Table 1 gives the λ_{max} values of the tetraenoic, trienoic and dienoic conjugated fatty acids and of their geometrical isomers as measured by PDA detection and conventional UV spectroscopy. The HPLC column clearly separated the conjugated tetraenoic and trienoic fatty acid analogues, but only partially resolved the dienoic fatty acid analogues. A small bathochromic shift was observed, which was thought to be a solvent effect.

Tetraenes. Figure 1 shows the three-dimensional spectrochromatogram of the conjugated tetraenoate, methyl parinarate, present in the methyl esters of *I. balsamina* oil (7,15). The mobile phase was acetonitrile/tetrahydrofuran (95:5, vol/vol), and the flow rate was 1.2 mL/min. Methyl esters of *I. balsamina* oil were injected onto the HPLC column at ambient temperature, and the eluant was monitored with the PDA detector at the fixed wavelength of 320 nm. The eluant was scanned over the 200–400 nm range. The resulting spectrochromatogram is shown in Figure 1. The λ_{max} at 304.5 nm (Fig. 1, inset) compared well with that of the conventional UV spectrum (λ_{max} 303 nm) and with the spectrochromatogram (304.5 nm) of pure methyl parinarate (methyl 9-*cis*,11-*trans*,13-*trans*,15-*cis*-octadecatetraenoate).

Figure 2 shows the spectrochromatogram of the isomers of methyl parinarate found in the eluant of the isomerized methyl esters derived from *I. balsamina* oil. The mobile

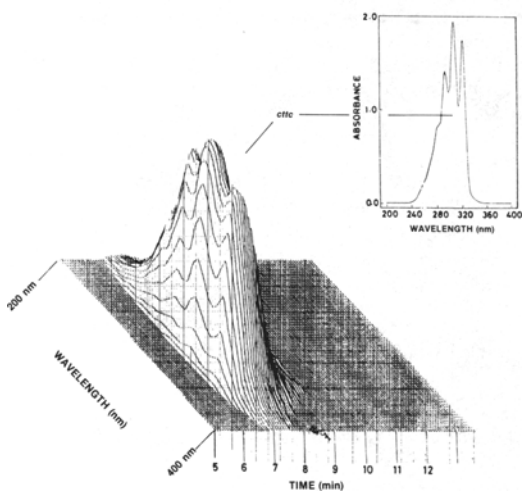

FIG. 1. Three-dimensional spectrochromatogram of tetraenoic fatty acid as seen by photodiode array detection. The inset shows the broad absorption band. A Zorbax ODS column and acetonitrile/tetrahydrofuran (95:5, vol/vol) as the mobile phase were used. The flow rate was 1.2 mL/min.

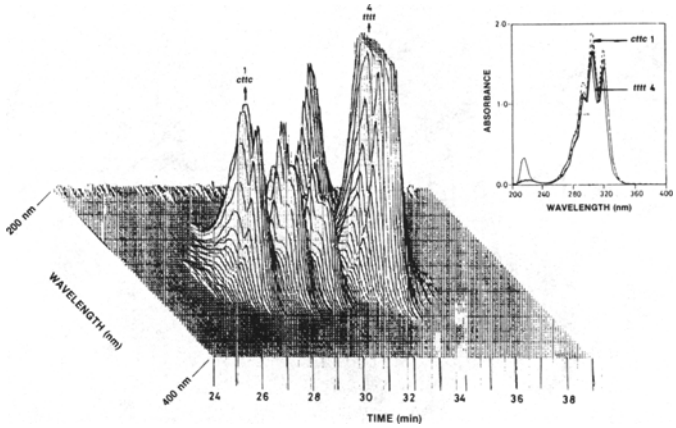

FIG. 2. Three-dimensional spectrochromatogram of the isomers of parinaric acid as seen by photodiode array detection. The inset shows the absorption spectra of the geometrical isomers. The mobile phase was acetonitrile/water/tetrahydrofuran (90:9:1, by vol) using the same column and flow rate as in Figure 1.

phase used here was acetonitrile/water/tetrahydrofuran (90:9:1, by vol), and the flow rate was 1.2 mL/min. Twenty μL of the sample was injected onto the HPLC column, and the eluant was monitored by PDA detection at an absorbance of 320 nm. Four isomers of parinaric acid can be seen in the broad absorption band in the range of 278–320 nm (Fig. 2, inset). The peak at λ_{max} 304.5 nm (peak 1) was identified as methyl parinarate (Fig. 1, inset). A similar spectrochromatogram with a λ_{max} 2.3 nm lower (302.2 nm) was assigned to the all-*trans* analogue, namely methyl β-parinarate, *i.e.*, methyl 9-*trans*,11-*trans*,13-*trans*,15-*trans*-octadecatetraenoate (peak 4). This assignment was confirmed by the relative retention times of methyl parinarate and β-parinarate in a separate analysis, where the isomerized methyl esters of *I. balsamina* oil were monitored using a UV detector and the column and conditions mentioned in Figure 2. The other two peaks seen in the center may be due to the other geometrical isomers of parinarate, as implied from their absorption profile (Fig. 2, inset), but their exact geometrical configuration could not be established.

Trienoates. The methyl esters of *M. charantia* and *T. anguina* were also subjected to HPLC separation at 270 nm using conditions similar to those given in Figure 1. The conjugated trienoate from *M. charantia* (13,16) was identified as methyl α-eleostearate. The UV spectrum (273 nm) and the spectrochromatogram (274.5 nm) of pure methyl α-eleostearate were used to further confirm methyl 9-*cis*,11-*trans*,13-*trans*-octadecatrienoate. Methyl punicate, namely methyl 9-*cis*,11-*trans*,13-*cis*-octadecatrienoate, from the methyl esters of *T. anguina* (13) oil had spectrum similar to that of methyl α-eleostearate with a λ_{max} 2 nm higher (at 276.5 nm). The results compared well with those obtained for pure methyl punicate by conventional UV and PDA detection. Figure 3 shows the spectrochromatogram of the three isomers, methyl punicate (peak 1), α-eleostearate (peak 2) and β-eleostearate (peak 3). The conditions were the same as those used in the separation illustrated in Figure 2. The three peaks corresponding to the *cis*,*trans*,*cis*(*ctc*),*cis*,*trans*,*trans*(*ctt*) and *trans*,*trans*,*trans*(*ttt*) analogues could be easily distinguished from

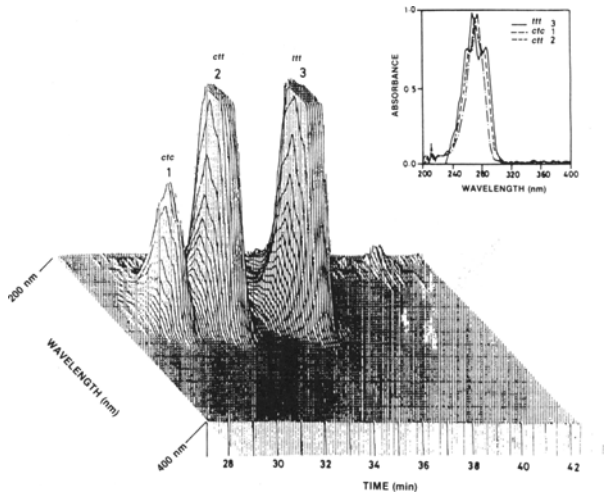

FIG. 3. Three-dimensional spectrochromatogram of the isomers of punicic acid as seen by photodiode array detection. The inset shows the absorption spectra of the isomers. Conditions are the same as in Figure 2.

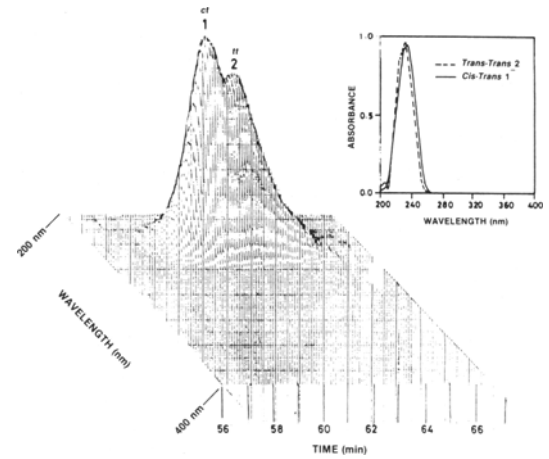

FIG. 4. Three-dimensional spectrochromatogram of the conjugated dienoic fatty acids as seen by photodiode array detection. The inset shows the absorption spectra. Conditions are the same as in Fig. 2.

each other. There were subtle, but noticeable differences in the chromophores of the individual isomers; and λ_{max} at 276.5, 274.5 and 270 nm confirmed the presence of all three geometrical isomers, methyl punicate, α-eleostearate and β-eleostearate, respectively, as shown in Figure 3. The all-*trans* analogue, β-eleostearate, had a similar spectrum with a λ_{max} 4.5 nm lower than that of its *ctt* analogue, α-eleostearate. The λ_{max} of methyl punicate was 2 nm higher than that of its *ctt* analogue, α-eleostearate (λ_{max} at 274.5 nm), and 6.5 nm higher than that of its all-*trans* analogue, β-eleostearate (λ_{max} 270 nm).

Dienes. Figure 4 presents the spectrochromatogram of the conjugated dienoates present in the methyl esters derived from DCO. The resolution was not quite satisfactory in this instance, as the retention times of the conjugated diene isomers were very close as seen from the spectrochromatogram obtained by PDA detection. However, under the experimental conditions employed for tetraenoic and trienoic acid isomers, only a partial separation of methyl 9-*cis*,11-*trans*-octadecanoate and 9-*trans*, 11-*trans*-octadecanoate analogues was possible. *cis*,*trans*-Dienoate had a λ_{max} 2 nm higher (λ_{max} 234 nm) than its *trans*,*trans* analogue (λ_{max} 232 nm. The HPLC method described, employing a PDA detector, is simple, rapid and sensitive. It permits the separation and simultaneous characterization of conjugated fatty acid isomers present in mixtures in a single analytical run.

COMMUNICATION

Reevaluation of the Neutral Lipids of *Tilletia controversa* and *Tilletia tritici*

S.E. Beattie*, A.E. Stafford and **A.D. King, Jr.**
Western Regional Research Center, USDA, ARS, Albany, California 94710

Differential scanning calorimetry of whole teliospores and lipid extracts of *Tilletia controversa* Kühn and *T. tritica* Tul. indicated that the lipid composition of teliospores was different than earlier reported. An exothermic peak at −40 to −45°C and an endotherm at −25 to −15°C indicated that the majority of lipids were triacylglycerols (TAG). Hot isopropanol was used to inactivate lipases during lipid extraction. Thin-layer chromatographic analysis of extracted lipids showed that free fatty acids (FFA) were not present in great quantities unless water was present during lipid extraction. As measured by gas chromatography, FFA accounted for 1–5% of the lipid content in teliospores of *Tilletia* spp. The TAG content of teliospores was 60–80% of total lipids.
***Lipids* 28, 1041–1043 (1993).**

Tilletia controversa Kühn (TCK) and *T. tritici* Tul. (TCT) are the fungi that cause dwarf and common bunts of wheat, respectively. A major difference between TCK and TCT is the germination of their teliospores. Teliospores of TCK take 4–6 wk to germinate while those of TCT require only 4–7 d (1). Additionally, TCK will only germinate at temperatures less than 7°C while TCT has an optimum germination temperature of 15°C. The cause of the dormancy of TCK has been elusive (1–3), but one theory has evolved around the high (30–35%) lipid content of teliospores (4,5). Gardner *et al.* (4) and others (5) reported that the predominant lipid class of these organisms was free fatty acids (FFA). It was postulated that FFA, in particular linoleic acid, and oxidation products from FFA, were the cause of dormancy of TCK and TCT (6).

Because the dwarf bunt mold is under quarantine regulations in several countries (7), this organism is important to wheat-exporting and -importing countries. Based on morphological characteristics, teliospores of TCK are difficult to differentiate from those of TCT (8). Our initial goal was to differentiate TCK from TCT by the use of differential scanning calorimetry (DSC) and supposed differences in lipid composition of teliospores. Preliminary DSC data indicated that the lipid profiles of these organisms were different than those reported. We report here on a reevaluation of the neutral lipids of TCK and TCT.

MATERIALS AND METHODS

Source of teliospores. Wheat spikelets infected by TCK or TCT were obtained from Blair Goates at the USDA, ARS, National Small Grains Germplasm Research Facility (Aberdeen, ID). Sori were separated from spikelets and crushed through a 90-nm sieve after outer plant material was removed. Lipids were extracted from a mixture of TCK races and two races of TCT (T-19 and T-4).

Lipid extraction. Throughout lipid extraction, great care was taken not to activate endogenous lipase. Dormant, dry teliospores were ground under a nitrogen atmosphere with glass beads agitated by a vortex mixer. Boiling isopropanol (9) was added before grinding to inactivate lipases. During homogenization, the mixture was periodically reheated to 85°C. Generally, it took 15–30 min of vortex mixing to achieve over 95% teliospore breakage using 50 to 100 mg of teliospores. After the isopropanol was evaporated from the homogenate, lipids were extracted with chloroform/methanol (1:2, vol/vol) by a modification of the method of Bligh and Dyer, as found in Kates (10). In all extractions, the aqueous phase was acidified to ensure complete extraction of FFA. Lipids were stored under nitrogen in either hexane or chloroform at −20°C. Three separate extractions were analyzed in duplicate.

DSC. A Thermal Analysis 2910 (TA Instruments, Groton, CT) equipped with a Liquid Nitrogen Cooling Accessory was used to determine crystallization and melting temperatures *in vivo* and of extracted lipids. Data were collected using a TA 2100 computer work station. Nitrogen gas was used to flush the cell during scans. Samples of teliospores or isolated lipids were held at 40°C for 20 min and then cooled at 5°/min to −90°C, held at this temperature for 10 min, and then heated at 5°C/min to 70°C. Scans were calibrated to 1 mg sample weight.

Thin-layer chromatography (TLC). Lipids were separated on silica gel TLC plates (Silica gel 60, 250 μm; E. Merck, Darmstadt, Germany). The mobile phase used was hexane/diethyl ether/glacial acetic acid (80:20:1, by vol; Ref. 10). This allowed separation of total lipids into 6–8 distinct bands with triacylglycerols (TAG) migrating at $R_i = 0.6$. Iodine vapor was used for visualization of lipid fractions. Lipid standards were obtained from Sigma (St. Louis, MO), Alltech Associates (Deerfield, IL), and Nu-Chek-Prep (Elysian, MN). Peanut, corn and olive oil were purchased locally.

Internal standards (IS). Margaric acid (17:0) was used as an IS for high-performance liquid chromatography (HPLC) and gas chromatography (GC). Total saponifiable lipids were quantified based on the IS added before saponification. To quantitate FFA, the IS was added to total lipids before HPLC injection. For TAG, IS was added after elution of TAG from the HPLC column. Different quantities of IS were added depending upon the lipid component being analyzed.

HPLC. Two silica-based C_{18} columns (15 cm, 5 μm particle size; Shodex/Waters, Milford, MA) in series and connected to a Waters HPLC instrument were used to separate TAG from FFA and fatty acid methyl esters (FAME). The mobile phase used in the isocratic mode was acetonitrile/isopropanol/methanol/hexane (8:5:3:1, by vol) at

Abbreviations: DSC, differential scanning calorimetry; FAME, fatty acid methyl ester(s); FFA, free fatty acid(s); GC, gas chromatography; HPLC, high-performance liquid chromatography; ME, methyl esters; IS, internal standard; MSD, mass selective detector; TAG, triacylglycerol(s), triglyceride(s); TCK, *Tilletia controversa* Kühn; TCT, *T. tritici* Tul.; TLC, thin-layer chromatography; TSL, totalsaponifiable lipids.

room temperature. All solvents were HPLC-grade and from either Burdick and Jackson (Muskegon, MI) or Fisher (Fair Lawn, NJ). A flow program was used to optimize separation, *i.e.*, 1.5 mL/min initially, decreasing to 1.2 mL/min at 0.07 mL/min, then increasing to 2.0 mL/min at 0.07 mL/min. Eluting lipids were monitored by ultraviolet detector (Perkin-Elmer, Mountain View, CA) at 220 nm. The injection volume for optimum peak separation of individual TAG was 20 to 40 μg/μL lipid in 10 μL hexane. For quantitation of lipid classes, up to 400 μg of lipid was injected. Larger amounts of lipid caused retention time alterations and poor resolution of peaks, but allowed separation of FFA from TAG.

Derivatization of lipids. FAME from total lipids and TAG were made by heating with methanolic KOH. After neutralization and extraction with hexane, the dried extracts were heated with 14% (wt/vol) boron trifluoride (Alltech Associates) to ensure complete methylation (11). FAME were extracted and stored in isooctane. The FFA fraction collected by HPLC was directly methylated with boron trifluoride (11).

Identification of FAME. FAME were identified and quantitated using a Hewlett-Packard 5880 gas chromatograph equipped with a flame-ionization detector and capillary injection system (Palo Alto, CA; Model 18835B, HP). A fused silica capillary column (30 m × 0.25 mm) coated with Stabilwax CW20M (df = 0.25 μm; Restek, Bellefonte, PA) was used. Detector and injector temperatures were 280 and 260°C, respectively. Initial oven temperature was 60°C and was increased to 110°C at 25°C/min. The temperature program was slowed to 5°C/min until 250°C and held for 10 min. Helium was the carrier gas, and splitless injection was used.

All FAME were identified by retention time comparisons and mass spectrometry. An HP 5790 gas chromatograph was used and was coupled to an HP 5970 quadrapole-based mass selective detector (MSD). A fused silica capillary column (25 m × 0.2 μm) coated with dimethyl silicone (df = 0.1 μm; HP-1) was used to separate FAME before introduction into the MSD through a direct capillary interface. Helium was used as carrier gas (1 mL/min) with splitless injection. The oven temperature was initially held at 60°C for 1 min, then increased to 140°C at 25°C/min, then to 220°C at 3°C/min, and finally to 280°C at 5°C/min. Injector temperature was 260°C and the MSD interface was held at 280°C. The MSD was operated mainly in the scan mode with the selected ion monitoring mode reserved to measure trace amounts of FAME. Ionization voltage was 70 eV with the ion source being operated at the fixed nominal temperature of 250°C. Identification of peaks was based on comparison with known spectra and retention times.

RESULTS AND DISCUSSION

Past research on teliospores of TCT and TCK indicated that FFA were the major lipid components (4,5). Examination of teliospores by light (6,12) and electron microscopy (13) showed numerous lipid droplets within the endospore. DSC analysis of whole teliospores and of lipid extracts from teliospores showed an endothermic peak at −25 to −15°C and an exothermic peak at −40 to −45°C (Fig. 1). This peak was in the temperature range expected for unsaturated TAG rather than FFA (14).

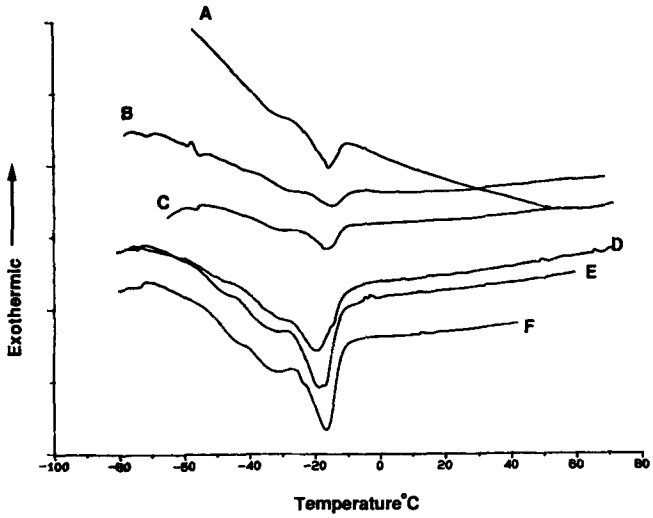

FIG. 1. Differential scanning calorimetry thermograms of whole teliospores of *Tilletia controversa* (A), *T. tritici* (TCT) 19 (B), TCT 4 (C), and lipid extracts from same (D), (E) and (F), respectively. For experimental details, see Materials and Methods.

TLC analysis of lipids (Fig. 2) showed that the FFA content of TCK and TCT was dependent upon the method of lipid extraction. Fishwick and Wright (9) showed that use of boiling isopropanol during extraction prevented enzymatic lipid degradation. The lipid profiles of TCK and TCT were altered dramatically when endogenous lipases were inactivated by boiling isopropanol. It is clear that when teliospores are ground in water or exposed to water (6), a substantial amount of FFA appear. Additionally, when teliospore homogenates were left in water for longer periods of time, the FFA spot in TLC increased in density (not shown), most likely due to the hydrolysis of TAG

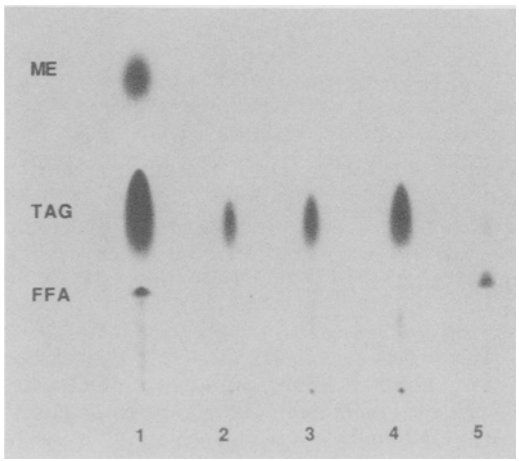

FIG. 2. Thin-layer chromatography of total lipids extracted from teliospores of *Tilletia* spp. Lane 1, standards; lane 2, *T. controversa* (TCK), homogenized in hot isopropanol; lane 3, *T. tritici* (TCT) 19, homogenized in hot isopropanol; lane 4, TCT 4, homogenized in hot isopropanol; lane 5, TCK, homogenized in water. Hexane/diethyl ether/glacialacetic acid (80:20:1, by vol) was used as mobile phase. FFA, free fatty acids; TAG, triacylglycerols; ME, methyl esters (FAME).

TABLE 1

Fatty Acid Profiles of Lipid Classes of *Tilletia tritici* and *T. controversa*

Organism	Lipid class[b]	% Total lipids (SEM)	Relative % FAME[a]								
			14:0	16:0	16:1	18:0	18:1[c]	18:2	24:0	24:1	24:2
Tilletia tritici (T19)	FFA	1.0 (0.1)	<0.5	33.0	7.8	8.7	13.1	39.1	<0.5	6.1	<0.5
	TAG	64.8 (5.9)	<0.5	13.3	1.1	1.4	11.5	61.5	1.6	5.2	0.7
	TSL	92.6 (3.9)	<0.5	13.0	1.1	1.1	11.3	61.3	1.6	5.3	0.7
T. tritici (T4)	FFA	2.0 (0.1)	2.0	21.4	5.6	11.6	12.5	44.4	<0.5	2.1	<0.5
	TAG	65.6 (3.8)	0.8	15.8	3.7	1.8	10.1	60.4	0.8	6.0	<0.5
	TSL	92.4 (4.6)	0.7	14.5	3.6	0.9	9.8	59.3	0.8	6.8	<0.5
T. controversa	FFA	1.1 (0.0)	<0.5	26.1	3.8	5.8	14.8	42.8	2.6	5.7	<0.5
	TAG	78.5 (0.7)	<0.5	14.2	2.4	1.0	8.4	64.6	0.8	5.2	0.6
	TSL	87.4 (1.4)	<0.5	13.9	2.3	0.8	8.3	64.5	0.9	5.5	0.7

[a]Other fatty acids found at less than 0.5% include 20:0, 20:1, 20:2, 22:0, 22:1, 22:2, and 18:3; FAME, fatty acid methyl esters.
[b]Abbreviations: FFA, free fatty acids; TAG, triacylglycerols; TSL, total saponifiable lipids.
[c]Δ9 and Δ11 isomers.

and/or phospholipids by lipases. The activities of endogenous lipases are actually the basis of a rapid viability test used for teliospores of TCK (15).

Because DSC and TLC indicated that TAG were the major lipid class, we quantitated the major lipid components by use of an internal standard. When the internal standard was injected into the HPLC, it eluted within the first 4 min along with all other FFA with a recovery exceeding 90%. Under the HPLC conditions used, all pure FFA and FAME eluted within 4 min.

The FFA content of TCK or TCT was determined to be 1–5% of the total lipid extracted (Table 1). Most fungal spores and mycelia have FFA contents within this range (16). The total lipid content of teliospores was found to be 30–35% (by weight) of which over 80% was saponifiable. The fatty acid compositions of the lipid components are given in Table 1. The FAME profile of TCK is similar to that reported by Trione and Ching (5), although the amount of FFA found in the current study (Table 1) was ten times less. Palmitic acid was reported to be the most abundant FFA found in dormant teliospores of TCT (17). This is in agreement with the data shown in Table 1 for TCT races 19 and 4. However, the amount of FFA found in the current study is again about ten times less than that found by others (4).

Total lipid and TAG FAME profiles were very similar (Table 1). Linoleic acid was the most common fatty acid, followed by palmitic acid. The FAME profile of FFA showed more of the saturated and monounsaturated fatty acids. The low amounts of FFA found suggest that there was little lipase activity during extraction. The presence of large amounts of linoleic acid in TAG of TCT and TCK might be expected, considering the fact that these teliospores must survive cold winter conditions (1,2), and crystallization could rupture storage vesicles. Additionally, TCK must maintain fluid lipid reserves, since the germination temperature is 4–7°C, and the fungus uses lipids as an energy source during germination. Finally, the host lipid composition may affect the composition of the lipids stored during sporogenesis of TCK and TCT.

Lipids, in particular FFA and oxidation products of FFA, have been suggested as the cause of dormancy of TCK (6). Earlier findings had indicated that lipids of TCT and TCK were composed mainly of FFA (4,5). When techniques that reduced degradation of TAG to FFA were employed, we found that 60–80% of the lipid component of *Tilletia* spp. was TAG. The amount of FFA in teliospores of TCT and TCK is closer to the amount of FFA found in other biological systems (*e.g.*, less than 5%). The remaining lipid components of teliospores are probably sterols and small amounts of phospholipids (16). These lipid components may play a more direct role in germination than the neutral lipids examined here. Based on these findings, the role of lipids as inhibitors of germination should be reevaluated.

ACKNOWLEDGMENTS

We thank Blair Goates for providing bunted wheat spikelets and advice. David Ruch is thanked for isolating teliospores.

The Excretion and Characterization of Intravenously Administered Olestra
R.J. Jandacek and B.N. Holcombe
Lipids 26, 754–758 (1991)

In this paper, the panels of Figure 1 (p. 757) were inadvertently transposed; 1a is the bottom panel, 1b is the top panel. The legend should read:

FIG. 1. Bottom (1a). Two-dimensional TLC autoradiogram of the [^{14}C]olestra used in Studies 2 and 3. A denotes the octaester; B, hepta- and hexaesters; C, unknown species. Top (1b). Two-dimensional TLC autoradiogram of the chloroform-soluble ^{14}C extracted from bile in Study 3. A and B are as in 1a; traces of radioactivity in area D may reflect lower esters.

Characterization of Triacylglycerols in the Seeds of *Aquilegia vulgaris* by Chromatographic and Mass Spectrometric Methods
Mustafa Demirbüker, Lars G. Blomberg, N. Urban Olsson, Magnus Bergqvist, Bengt G. Herslöf and Fernando Alvarado Jacobs
Lipids 27, 436–441 (1992)

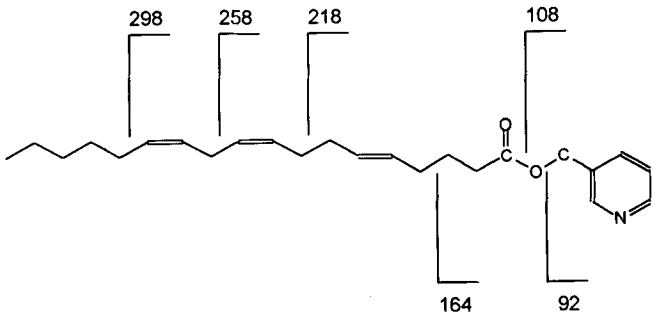
In this paper, fatty acids were numbered from the methyl terminus rather than starting from the carboxyl group. To translate the n-x terminology used into internationally accepted n nomenclature, the following changes are required:

Page 436, sixth line of Introduction section: "Columbinic acid (Cb), 6*c*,9*c*,13*t*-18:3" should read "5*t*,9*c*,12*c*-18:3 . . ."

Page 436, first line of Abbreviations section: ". . .9*c*,13*t*-18:2 . . ." should read ". . . 5*t*,9*c*-18:2 . . ."

Page 439, Table 1: "7*c*-18:1" should read "11*c*-18:1"; "11*c*-20:1" should read "9*c*-20:1"; "9*c*,13*t*-18:2" should read "5*t*,9*c*-18:2"; "6*c*,9*c*-18:2" should read "9*c*,12*c*-18:2"; "6*c*,9*c*,13*t*-18:3" should read "5*t*,9*c*,12*c*-18:3"; "3*c*,6*c*,9*c*-18:3" should read "9*c*,12*c*,15*c*-18:3"; "3*c*,6*c*,9*c*,12*c*-18:4" should read "6*c*,9*c*,12*c*,15*c*-18:4." The fatty acid nomenclature used throughout in the right column on page 439 should be changed accordingly.

Page 439, Scheme 1 should be:



The Editor-in-Chief wishes to thank Drs. Klaus Vosmann and Kurt Aitzetmüller, Institute for Chemistry and Physics of Lipids, Münster, Germany, for calling these errors to his attention.

Nonessential Fatty Acids in Formula Fat Blends Influence Essential Fatty Acid Metabolism and Composition in Plasma and Organ Lipid Classes in Piglets
Katharine M. Wall, Deborah Diersen-Schade and Sheila M. Innis
Lipids 27, 1024–1031 (1992)

The following changes should be made:

In Table 1 (p. 1025), the fatty acids listed as "20:0 + 14:0" should be "12:0 + 14:0"; the fatty acid composition of the diet is explained correctly in the text.

The second error occurred in the description of the homogenizing buffer used for brain and liver samples (p. 1025). This buffer contained 500 ng/mL leupeptin and 2 ng/mL aprotinen, not 500 mg/mL leupeptin and 2 μg/mL aprotinen.

Influence of Dietary Egg and Soybean Phospholipids and Triacylglycerols on Human Serum Lipoproteins
Barbara C. O'Brien and Verona Gale Andrews
Lipids 28, 7–12 (1993)

In Table 2 (p. 10), the values in the last two columns for HDL_2 PL should read 0.80 ± 0.19^c (instead of 0.36 ± 0.08) for SP treatment and 0.63 ± 0.15^b (instead of 0.35 ± 0.09) for SPTG treatment.

Lipoxin A_4 (LXA_4) possesses potent bioactions. To facilitate its detection, an enzyme-linked immunosorbent assay (ELISA) was developed that proved sensitive and selective. Quantitation by ELISA of LXA_4 generated from cellular sources strongly correlated ($r = 0.99$) with values obtained by high-pressure liquid chromatography (HPLC). We used this LXA_4-ELISA to examine parameters influencing LXA_4 generation from endogenous substrates during human platelet-neutrophil (PLT-PMN) interactions *in vitro*. Agonist-induced LXA_4 production was clearly evident at a PLT-PMN ratio of 10:1, and recombinant human granulocyte/monocyte colony stimulating factor-priming of PMN augmented LXA_4 generation 5–6 fold. The chemotactic peptide formylmethionyl-leucyl-phenylalanine, platelet-derived growth factor and arachidonic acid (20:4n-6) each stimulated formation of immunoreactive LXA_4 ($iLXA_4$) in these co-incubations. The presence of $iLXA_4$ was also evaluated *in vivo* in aspirin-sensitive asthmatic patients who, in a randomized, double-blind crossover design, underwent nasal lavage after they each ingested a predetermined threshold dose of aspirin or placebo. Aspirin challenge provoked statistically significant increases in $iLXA_4$ in each patient ($P < 0.005$). These results validate the use of a solid-phase ELISA for detection of LXA_4. Furthermore, the use of this ELISA has allowed the first documentation of $iLXA_4$ formation in human subjects with aspirin-sensitive asthma following specific antigenic challenge.

***Lipids* 28, 1047–1053 (1993).**

Lipoxins (LX) are bioactive eicosanoids generated by the interaction of individual lipoxygenases (LO) (reviewed in Ref. 1). These compounds can be produced by single cell types from endogenous sources of 20:4n-6 (2) or by cell-cell interactions that initiate transcellular pathways for their biosynthesis (3). Multiple biosynthetic routes can lead to LX generation (1). In human cell types, two main pathways have been demonstrated: one involves the transcellular metabolism of (15*S*)-hydroxy-(5*Z*,8*Z*,11*Z*,13*E*)-eicosatetraenoic acid (15-HETE) by 5-LO (4), and the other utilizes (5*S*)-(*E*)-5(6)-oxido-(7*E*,9*E*,11*Z*,14*Z*)-eicosatetraenoic acid (LTA_4) that is converted by either 12-LO (3) or 15-LO (5,6). Using physical methods, (5*S*),(6*R*),(15*S*)-trihydroxy-(7*E*,9*E*,11*Z*,13*E*)-eicosatetraenoic acid (LXA_4) has been identified *in vivo* in two different pathophysiologic settings—after percutaneous transluminal coronary angioplasty (PTCA) (7) and in bronchoalveolar lavage samples from patients with respiratory diseases (8).

LX possess biological activity in subnanomolar quantities in experimental models (reviewed in Ref. 1). Evidence is accumulating that LXA_4 may play a role as an endogenous regulator of inflammation (4,9–11). As is the case with other bioactive eicosanoids, it is critical to have a rapid and sensitive means for the detection of LXA_4 to assess the role of LXs in both physiological and pathophysiological events. To this end, we developed a solid-phase, enzyme-linked immunosorbent assay (ELISA), and here report its validation and utility in detecting LXA_4 in biological fluids both *in vitro* and *in vivo*.

MATERIALS AND METHODS

Materials. Formylmethionyl-leucyl-phenylalanine (fMLP), A23187, nordihydroguaiaretic acid (NDGA) and natural human platelet-derived growth factor (PDGF)-AB were purchased from Sigma Chemical Co. (St. Louis, MO); thrombin and leukocyte separation media were from Enzyme Research Laboratories (South Bend, IN). Recombinant human granulocyte/monocyte colony stimulating factor (GM-CSFrh) was purchased from Boehringer Mannheim (Indianapolis, IN). Synthetic LXA_4 (molecular weight 352.5 and extinction coefficient 50,000) was obtained from Cascade Biochem Limited (Reading, Berkshire, England), (5*S*),(14*R*),(15*S*)-trihydroxy-(6*E*,8*Z*,10*E*,12*E*)-eicosatetraenoic acid (LXB_4) was from Biomol Research Laboratories (Plymouth Meeting, PA), and (5*S*),(6*R*)-dihydroxy-(7*E*,9*E*,11*Z*,14*Z*)-eicosatetraenoic acid [(5*S*),(6*R*)-DiHETE] was from Cayman Chemical Co. (Ann Arbor, MI). High-pressure liquid chromatography (HPLC) grade solvents were purchased from Doe and Ingalls (Medford, MA), methyl formate was from Eastman Kodak Co. (Rochester, NY) and Sep-Pak C_{18} cartridges were from Waters Associates (Milford, MA).

Cell suspensions. Using acid citrate dextrose as an anticoagulant, fresh peripheral blood was obtained by

venipuncture from healthy donors who had not taken aspirin or other medication for at least seven days. After the platelet-rich plasma was obtained, platelets (PLT) were washed in *N*-2-hydroxyethyl-piperazine-*N'*-2-ethanesulfonic acid-Tyrode buffer (pH 7.4) in the presence of ethylenediaminetetraacetic acid disodium dihydrate (EDTA; 7 mM), and then enumerated using a Coulter Counter (model ZBI; Coulter Electronics, Inc., Hialeah, FL). Neutrophils (PMN) were isolated from the remaining blood by Ficoll-Hypaque gradient centrifugation and dextran sedimentation (3). Suspensions contained 98 ± 1% PMN when enumerated by light microscopy.

PLT-PMN Incubations. Freshly isolated PMN were incubated in Dulbecco's phosphate-buffered saline containing both $CaCl_2$ (0.6 mM) and $MgCl_2$ (1.0 mM; pH 7.4) for 90 min at 37°C in the presence or absence of GM-CSFrh (200 pM). Aliquots (0.5 mL) of each cell suspension (8–30 × 10^6 PMN/mL) were combined with aliquots (0.5 mL) of isolated PLT suspensions with the cell ratio adjusted from 0:1 to 100:1 (PLT-PMN). PMN and PLT were warmed (5 min, 37°C) before exposure to soluble stimuli (20 min, 37°C). Incubations were stopped by the addition of 1 vol of 0.05 M Tris-HCl (pH 8.0) and vigorous mixing. Materials were kept at −30°C for at least 30 min prior to analysis to facilitate protein precipitation, as well as to retard autooxidation.

Nasal lavage fluid. After written informed consent to a protocol approved by the Beth Israel Hospital Committee on Clinical Investigations, subjects with aspirin-sensitive asthma were identified, and a threshold dose of aspirin (ASA) was determined that would elicit, 1–3 h after ingestion, a ≥ 15% decline in the FEV_1; in these subjects bronchospasm was often accompanied by oculo-nasal symptoms. In a randomized, double-blind, crossover design, nasal lavages were performed as previously described (12) with 0.9% saline (8 mL) two and three hours after ingestion of either placebo (lactose) or the threshold dose of aspirin (60–100 mg). Patients were 32–42-years-old, without a history of recent illness or tobacco use for ≥10 yr, and had normal baseline spirometry with an FEV_1 that decreased 16–25% with ASA challenge. Subjects were allowed to use inhaled steroids; however, theophylline was discontinued for 48 h prior to provocation and inhaled β-agonists and nasal steroids were withheld for at least 8 h prior to challenge. All lavage fluids were stored at −70°C.

LXA_4-ELISA. LXA_4 antiserum was produced in a similar manner to that described for TxB_2 antiserum (13). Briefly, LXA_4 was conjugated to keyhole limpets hemocyanin through succinimide ester of LXA_4. Rabbits were immunized initially with 100 μg of LXA_4-hemocyanin conjugate per rabbit. Booster injections were carried out on a monthly basis with half of the initial conjugate. The rabbits were bled through ear veins and the antisera were collected by centrifugation of the blood and stored at −20°C. The antiserum was diluted (1:200) in ELISA buffer to a concentration optimized for assay conditions (*vide infra*). LXA_4 was labeled with horseradish peroxidase through succinimide ester of LXA_4 as described above. The enzyme-labeled LXA_4 and the antisera were used to develop an ELISA for LXA_4.

The ELISA buffer containing 0.1% bovine serum albumin and 0.9% NaCl in 0.1 M potassium phosphate buffer, pH 7.4, was used for diluting antisera, standard or sample, and enzyme conjugate. Prior to assay, methanol and ethanol were eliminated from all samples, as traces of organic solvent interfered with ligand-antibody binding. The 96-well plate was precoated with 1 μg of affinity-purified goat anti-rabbit IgG per well. The assay was initiated by adding appropriately diluted antisera (50 μL), LXA_4 standard or samples (50 μL) and enzyme-labeled LXA_4 (50 μL) into each well. Plates were gently shaken for 1 h at room temperature. After three washings with wash buffer (0.01 M potassium phosphate, pH 7.5 containing 0.05% Tween 20), the enzyme reaction was carried out by adding 150 μL of K-Blue substrate at room temperature for approximately 15 min and stopped by the addition of 100 μL of 1N H_2SO_4. The absorbance at 450 nm was read using a Dynatech Plate Reader (model No. MR 700; Alexandria, VA). Serial dilutions of unlabeled synthetic LXA_4 (0.20–2.00 ng LXA_4/mL) were assayed and included within each 96-well plate to generate calibration curves for quantitation of immunoreactive LXA_4 ($iLXA_4$) (ng/mL) present in samples; all samples were assayed in duplicate.

Quantitation of LXA_4 by electrochemical detection-ultraviolet (ED-UV) reverse phase (RP) HPLC. Prostaglandin B_2 (25 ng) was added, as an internal standard, to materials to be analyzed by HPLC. Samples were extracted and eluted from Sep-Pak C_{18} cartridges, and methyl formate fractions were concentrated under a stream of N_2 as in (3). This RP-HPLC system was equipped with both a Lambda-Max UV detector, model 481, and an on-line Electro Chemical detector (ED), model M 460, operated with a $Ag/AgCl_2$ reference electrode (Waters Associates) that permitted detection of LXs in the picogram range (3). The electrode potential was set at 1.345 V, and the UV detector was set at 300 nm to monitor the LX tetraene chromophore. LXA_4 was identified by comparison of its retention time with those of synthetic and authentic LXA_4 standards, and quantities were determined by comparison to areas beneath the peaks obtained for UV-calibrated authentic LXA_4 after adjustment for recovery of internal standard.

All data are expressed as the mean ± SE of the mean (SEM). The Student's *t*-test was used for statistical calculations on the naturally paired *in vitro* cell suspensions reported later and the self-paired patient samples in Table 1. *P* values <0.05 were considered significant. All analyses were performed on a Macintosh computer (Apple Computer, Inc., Cupertino, CA) with the use of Statworks (Cricket Software, Inc., Philadelphia, PA).

RESULTS

ELISA sensitivity and selectivity. After conditions for the enzyme immunoassay of LXA_4 were optimized, calibrated dose-response curves were obtained using serial dilutions of competing unlabeled synthetic LXA_4 (Fig. 1A). Inhibition of 50% of the maximal binding (IC_{50}) observed with enzyme-labeled LXA_4 occurred with 0.45 pmol LXA_4/mL, and the minimum detectable amount (80% of maximal binding) was 90.8 fmol LXA_4/mL. This IC_{50} is comparable to those obtained by ELISA for other eicosanoids: 0.4 pmol (14) and 0.2 pmol/mL for (5*S*)-hydroxy-(6*R*)-*S*-glutathionyl-(7*E*,9*E*,11*Z*,14*Z*)-eicosatetraenoic acid (LTC_4) (15), 0.49 pmol/mL for 6-keto-$PGF_{1\alpha}$ (16), 1 pmol/mL for 13,14-dihydro-15-keto-$PGF_{2\alpha}$ (17) and

0.54 (18) and 0.4 pmol/mL for TxB_2 (15). Crossreactivity of the antibody for related compounds was 0.1% for 15-HETE, and <0.1% for (5*S*)-hydroxy-(6*E*,8*Z*,11*Z*,14*Z*)-eicosatetraenoic acid (5-HETE), (12*S*)-hydroxy-(5*Z*,8*Z*,10*E*,14*Z*)-eicosatetraenoic acid (12-HETE), (5*S*),(12*R*)-dihydroxy-(6*Z*,8*E*,10*E*,14*Z*)-eicosatetraenoic acid (LTB_4), LTC_4, (5*S*)-hydroxy-(6*R*)-*S*-cysteinylglycyl-(7*E*,9*E*,11*Z*,14*Z*)-eicosatetraenoic acid (LTD_4), (5*S*)-hydroxy-6(*R*)-*S*-cysteinyl-(7*E*,9*E*,11*Z*,14*Z*)-eicosatetraenoic acid (LTE_4) and 20:4n-6 (Fig. 1A, insert). Further experiments on the stereoselectivity of antibody binding employed lipoxygenase products with structures identical to portions of native LXA_4, namely (5*S*),(6*R*)-DiHETE (C-1 to C-6) and LXB_4 (C-1 to C-5 and C-15 to C-20). Crossreactivity for these closely related eicosanoids was <5% for 5(*S*),6(*R*)-DiHETE and between 1–7.5% for LXB_4 (Fig. 1A). These results indicate that the antiserum is both sensitive and selective for LXA_4.

Co-incubations of autologous human PLT and PMN in the presence of stimuli have been demonstrated by both HPLC and gas chromatography/mass spectrometry (GC/MS) to generate LXA_4 from endogenous sources (3, 19). For purposes of direct comparison to prior results and to evaluate the ELISA's use in the determination of LXA_4 generation by cellular sources, GM-CSFrh-primed PMN (15×10^6) were co-incubated with PLT (150×10^6) in the presence of A23187 (10^{-7} M) and thrombin (1 U/mL). After the co-incubations, serial dilutions of the materials generated were performed, and the quantities of LXA_4 present were determined using both ELISA and ED-UV RP-HPLC. Figure 1B shows results representative for PLT-PMN co-incubations that gave a correlation coefficient of 0.99. Together, these results demonstrate that quantitation by ELISA of biologically-derived LXA_4 correlates with values obtained following HPLC. In addition, the quantities of $iLXA_4$ identified are in good agreement with those reported using HPLC-based quantitation (3,19), and indicate that lower cell numbers than those required for analysis by HPLC and GC/MS can be used in each incubation.

Characteristics of $iLXA_4$ generation during PLT-PMN interactions. We used this assay to examine factors regulating LXA_4 generation by suspensions of human PMN co-incubated with increasing numbers of autologous PLT (Fig. 2). As GM-CSFrh is known to increase arachidonic acid availability and LXA_4 generation (3), the impact of adding this cytokine on LXA_4 generation was examined at different ratios of PLT-PMN. At each cell ratio examined (Fig. 2), PMN primed with GM-CSFrh (200 pM) generated higher levels of $iLXA_4$ when exposed (20 min, 37°C) to A23187 (10^{-7} M) and thrombin (1 U/mL). As the PLT-PMN ratio was increased to 10:1, GM-CSFrh-primed PMN led to generation of 5–6 times more LXA_4 than activated PMN that were not primed. At higher PLT number, homotypic PLT-PLT interactions led to decreased LXA_4 generation. Also, in the presence of stimuli (A23187 or fMLP plus thrombin), neither PMN alone nor isolated PLT (data not shown) generated $iLXA_4$ in statistically significant amounts greater than incubations performed in the absence of stimuli. Primed PMN in the presence of stimuli, but without deliberate addition of PLT, generated nanomolar quantities (≈3 nM $iLXA_4$/incubation) of $iLXA_4$. Because limitations in the isolation of PMN resulted in ≈1–2 PLT per PMN contaminating

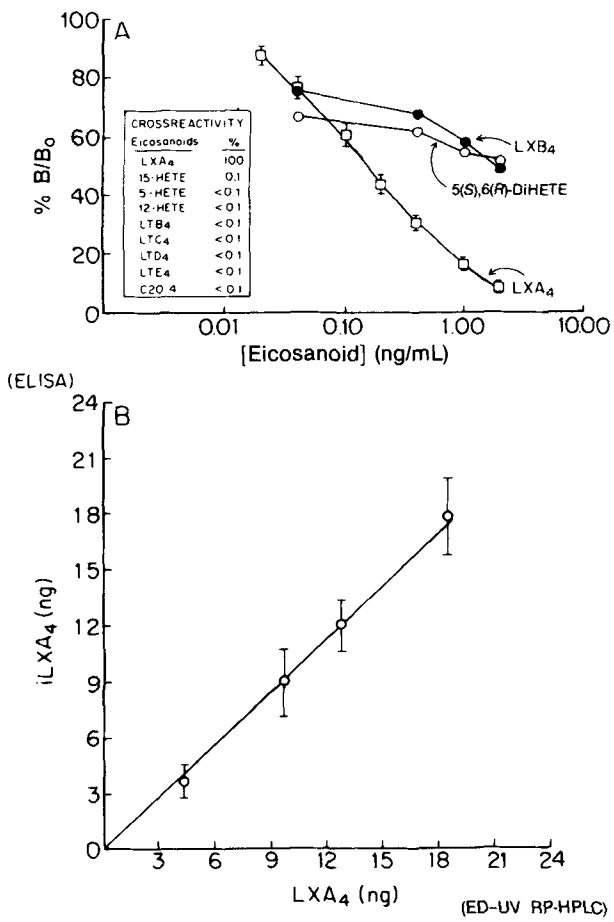

FIG. 1. Quantitation of lipoxin A_4 by enzyme-linked immunosorbent assay (ELISA): crossreactivity with related eicosanoids and correlation with high-pressure liquid chromatography (HPLC). A: Unlabeled (5*S*),(6*R*),(15*S*)-trihydroxy-(7*E*,9*E*,11*Z*,13*E*)-eicosatetraenoic acid (LXA_4) (0.02 to 2.00 ng/mL), (□) was added to a standard amount of enzyme-labeled LXA_4 and incubated (60 min, 23°C) with the antibody (n = 15, mean ± SEM). On the vertical axis, % B/B_0 represents the bound enzymatic activity in the presence (B) of unlabeled LXA_4 relative to its absence (B_0). To examine the antibody's stereoselectivity, 0.04 to 2.00 ng/mL of (5*S*),(6*R*)-dihydroxy-(7*E*,9*E*,11*Z*,14*Z*)-eicosatetraenoic acid [(5*S*),(6*R*)-DiHETE] (○) and (5*S*),(14*R*),(15*S*)-trihydroxy-(6*E*,8*Z*,10*E*,12*E*)-eicosatetraenoic acid (LXB_4) (●) were added to enzyme-labeled LXA_4 and incubated in parallel (n = 3, mean). The insert reports the crossreactivity of related compounds when identical quantities of unlabeled material were added in place of LXA_4. B: Freshly isolated human neutrophils (15×10^6) were exposed to 200 pM recombinant human granulocyte/monocyte colony stimulating factor (90 min, 37°C) prior to incubation (20 min, 37°C) with autologous platelets (150×10^6) in the presence of A23187 (10^{-7} M) and thrombin (1 U/mL). Incubations were stopped with 1 vol of ice-cold, 0.05 M Tris-HCl (pH 8.0). Serial dilutions of the products generated were assayed by both ELISA and electrochemical detection-ultraviolet (ED-UV) reverse-phase (RP) HPLC. Prior to RP-HPLC, the materials were purified by extraction with Sep-Pak C_{18} cartridges in the presence of an internal standard (see Materials and Methods section). These results were plotted from a representative incubation (cells from two separate donors, four determinations for each concentration) for regression analysis (r = 0.99, y = 0.98x − 0.19). ELISA values represent the mean of two separate assays. $iLXA_4$, immunoreactive LXA_4.

these suspensions, we were unable to determine the amount of $iLXA_4$ produced by PMN alone. Intentional addition of PLT dramatically increased formation of $iLXA_4$ (Fig. 2) to levels with a range of bioactions

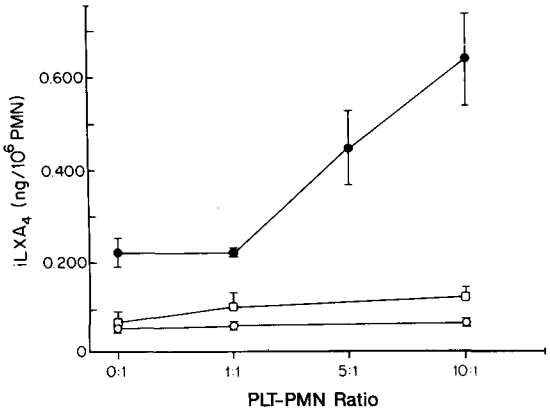

FIG. 2. Generation of iLXA$_4$ from endogenous sources during co-incubations of platelet-neutrophil (PLT-PMN): effect of cell ratio (PLT-PMN) and recombinant human granulocyte/monocyte colony stimulating factor (GM-CSFrh) priming of PMN. PMN (8–10 × 10^6) were incubated in the presence of GM-CSFrh (200 pM) for 90 min at 37°C, and then combined with autologous PLT. After warming (5 min, 37°C), cells were exposed to either A23187 (10^{-7} M) and thrombin (1 U/mL) (●) or vehicle control (○) for 20 min at 37°C. In parallel, PMN, not primed with GM-CSFrh, were co-incubated with PLT and exposed to the soluble stimuli (□). Incubations were stopped with 1 vol of cold 0.05 M Tris-HCl (pH 8.0). ELISA was performed without further purification of products, (n = 3 separate donors, mean ± SEM). Abbreviations as in Figure 1.

(reviewed in Ref. 1), including the stimulation of myelopoiesis (20). These findings are consistent with production of leukotriene A$_4$ by activated PMN that is released and transformed to LXA$_4$ by platelet 12-lipoxygenase (1). Additionally, stimulus-induced formation of iLXA$_4$ was maximal during co-incubations that were held motionless; shaking the co-incubations inhibited iLXA$_4$ formation (>83%, data not shown). This finding suggests that interference with PLT-PMN interactions impairs the transcellular exchanges of biosynthetic intermediates, such as LTA$_4$. Thus, taken together, these results obtained using independent methodologies both confirm and extend the findings that activated cytokine-primed PMN interacting with PLT have the potential to generate biologically relevant quantities of LXA$_4$ (3).

PDGF is also known to promote activation of PMN (21,22). To determine if this cytokine also stimulates LXA$_4$ generation, GM-CSFrh-primed PMN were co-incubated with autologous PLT in the presence of PDGF and the chemotactic peptide, fMLP, which has been previously shown to activate PMN for transcellular biosynthetic generation of LXA$_4$ (3). Indeed, cells exposed to either fMLP (10^{-7} M) or PDGF-AB (10 ng/mL) generated more iLXA$_4$ from endogenous sources of substrates than from unstimulated cells (Fig. 3A). When exogenous arachidonic acid was added to these incubations, increases in iLXA$_4$ levels were obtained upon exposure to fMLP (410%, $P < 0.02$) or PDGF (381%, $P < 0.09$). Moreover, arachidonic acid itself may be a second messenger (23), as it is known to activate both PMN and PLT (24), and PLT can contribute their 20:4n-6 to be transformed by PMN in a bidirectional route to LXA$_4$ (3). In these experiments, exogenous 20:4n-6 also stimulated LXA$_4$ generation (Fig. 3A). Agonist-induced formation of iLXA$_4$ from endogenous sources of sub-

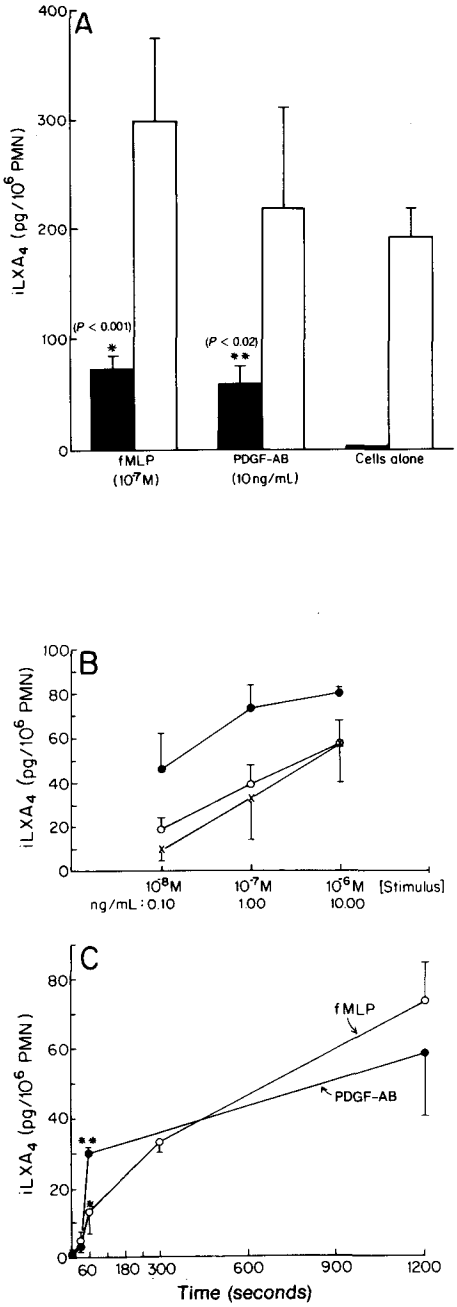

FIG. 3. Generation of iLXA$_4$ from endogenous and exogenous arachidonic acid during co-incubations of GM-CSFrh-primed PMN with autologous PLT. PMN (10 × 10^6) were exposed (90 min, 37°C) to 200 pM GM-CSFrh and then incubated (20 min, 37°C) with autologous PLT (100 × 10^6) in the presence of stimuli. Incubations were terminated and assayed as described in Materials and Methods. Values are expressed in pg/10^6 PMN (mean ± SEM, n = 3) minus values obtained without stimuli present in parallel incubations. A: Exogenous arachidonic acid. Parallel incubations were performed in the presence (open bars) or absence (solid bars) of exogenous arachidonic acid (10 μM) during simultaneous exposure to either formylmethionyl-leucine-phenylalanine (fMLP) (10^{-7} M), PDGF-AB (10 ng/mL), or vehicle control, (*, $P < 0.001$; ** $P < 0.02$). B: Concentration response. Incubations were carried out in the presence of PDGF-AB reported in ng/mL (x), fMLP alone (●) or fMLP and thrombin (1 U/mL) (○). C: Time course. Incubations were terminated at the indicated time points after exposure to either 10^{-7} M fMLP (○) or 10 ng/mL PDGF-AB (●) (* $P < 0.05$; ** $P < 0.01$). Abbreviations as in Figures 1 and 2.

TABLE 1

Elevated $iLXA_4$ in Nasal Lavage Fluid After Aspirin Challenge in Aspirin-Sensitive Asthmatics[a]

Subject	Determinations	Placebo (pg $iLXA_4$/mL)	Aspirin (pg $iLXA_4$/mL)
1	2	Not detected	47.5 ± 3.5
2	8	61.0 ± 13.8[b]	318.9 ± 8.0 (523%)[b]
3	4	Not detected	47.7 ± 6.3
4	4	Not detected	41.7 ± 3.9
5	2	47.5 ± 0.5[b]	312.5 ± 9.5 (658%)[b]

[a]Subjects were lavaged with 0.9% saline 2 and 3 h after ingestion of either a placebo or a threshold dose of aspirin. Levels of $iLXA_4$ were determined by enzyme-linked immunosorbent assay (see Materials and Methods). Results represent the mean ± SEM of these two lavages. The percent increase in levels of $iLXA_4$ in lavage fluid after aspirin challenge compared with placebo is parenthetically displayed for patients 2 and 5. $iLXA_4$, immunoreactive (5*S*), (6*R*), (15*S*)-trihydroxy-(7*E*,9*E*,11*Z*,13*E*) eicosatetraenoic acid.
[b]$P < 0.005$.

strate proved to be both concentration- and time-dependent (Fig. 3B and C). PDGF (10 ng/mL) and fMLP (10^{-6} M) plus thrombin (1 U/mL) led to approximately equivalent levels of $iLXA_4$ (Fig. 3B). In addition, the divalent cation ionophore A23187 led to a concentration-dependent (10^{-8}–10^{-5} M) increase in $iLXA_4$ (0.004–2.340 ng $iLXA_4/10^6$ PMN). With each stimulus examined, $iLXA_4$ generation was rapid in onset and statistically significant ($P < 0.05$) within 60 s (Fig. 3C). Exposure to NDGA (100 μM), a nonselective LO inhibitor that blocks 5-, 12- and 15-LO, led to complete inhibition of $iLXA_4$ formation during co-incubations (cells from two separate donors with four determinations). Together, these findings confirm that $iLXA_4$ is derived from arachidonic acid and demonstrate that its formation is triggered by either fMLP or PDGF.

Aspirin challenge in sensitive asthmatics provokes $iLXA_4$ formation. When challenged with a dose of ASA sufficient to lead to airflow obstruction, ASA-sensitive asthmatics generate cysteinylpeptide leukotrienes in amounts substantially higher [in nasal lavage (25) and urine (26)] than ASA-insensitive individuals. Since LXA_4 could also be formed with 5-LO activation (1,8), we next evaluated LXA_4 formation in ASA-sensitive patients using the ELISA to determine if LXA_4 is generated *in vivo* after challenge. In a randomized, double-blind, crossover design, subjects were lavaged with normal saline after ingestion of either placebo or a predetermined threshold dose of ASA (see Materials and Methods section). Each subject thus served as their own "control." Quantities of LXA_4 added to nasal lavage fluid ("spiking samples") were quantitatively recovered by ELISA ($r = 0.95$, $n = 3$), indicating the absence of significant amounts of interfering substances. After ingestion of placebo, patients were asymptomatic, and $iLXA_4$ was not detected in lavages from three of five patients (Table 1). In sharp contrast, following aspirin challenge, $iLXA_4$ was present in significant quantities in lavages obtained from each patient. In those individuals where $iLXA_4$ was found after placebo challenge (Nos. 2 and 4), 5–6-fold increments in $iLXA_4$ were obtained after challenge with ASA. Hence, the presence of $iLXA_4$ after placebo that is significantly elevated after challenge with ASA may reflect, in part, their heightened sensitivity. These results demonstrate appearance of $iLXA_4$ after a specific challenge.

DISCUSSION

To explore the role of LXA_4 in human pathobiology requires a method to reliably detect it in subnanomolar amounts *in vitro* and pathologically-derived materials. To this end, we report on the validation of an ELISA for LXA_4 and its utility in examining the formation and presence of this eicosanoid. The developed assay proved both sensitive and selective for synthetic LXA_4 (Fig. 1A) with characteristics comparable to ELISA tests constructed for other eicosanoids (14–18). Authentic LXA_4 production from cellular sources was confirmed by ED-UV RP-HPLC (Fig. 1B), and parameters for agonist-induced generation of LXA_4 from endogenous substrates *in vitro* were determined (Fig. 2). fMLP and PDGF each triggered concentration- and time-dependent formation of $iLXA_4$ from endogenous stores of 20:4n-6 (Fig. 3), and patients with ASA-sensitive asthma had $iLXA_4$ in nasal lavage after ASA provocation (Table 1). Given the ELISA's ability to detect both synthetic and authentic LXA_4 from cellular sources (Figs. 1–3) and pathologic fluids (Table 1), it appears well-suited for use in exploring this eicosanoid's role in physiologic and pathophysiologic processes.

Enzyme immunoassays have been developed for many other eicosanoids, such as prostaglandins, LTB_4 and LTC_4 (cf. Refs. 14 and 15). Their use minimizes the time and extensive sample preparation required for physical methods of detection, like HPLC and GC/MS. Because of this ELISA's sensitivity (90.8 fmol LXA_4/mL) and selectivity (Fig. 1), it also permits efficient utilization of material. Using this method, we were able to detect LXA_4 after ASA provocation in aliquots (50 μL) of nasal secretions from asthmatic patients. To ensure the accuracy of the ELISA, nonspecific binding was routinely assayed on the 96-well plates as an internal control. In addition, a clear correlation between ELISA and ED-UV RP-HPLC in the generation of LXA_4 (Fig. 1) indicated the presence of insignificant amounts of crossreacting compounds in this system, and the accurate detection of known quantities of LXA_4 added to nasal lavage fluid demonstrated the absence of interfering substances in this biological matrix (see Results section). Therefore, this ELISA proved to be a sensitive and reliable technique for the detection of LXA_4.

Enabled by this new method, human PLT and PMN interactions were examined as an established *in vitro* model for LXA_4 production in the presence of stimuli that activate cells by receptor-mediated signals. These cell types were selected because together they possess the three major mammalian LO (5-, 12- and 15-LO) and can be readily obtained as freshly isolated cell suspensions. Human platelets possess high levels of 12-LO, and leukocytes possess both 5- and 15-LO. Interactions between these enzymes with 20:4n-6 as the substrate give rise to LXs (1). The generation of LXA_4 during co-incubations of PLT and PMN in the presence of increased numbers of PLT or with GM-CSFrh-priming of PMN (Fig. 2) not only confirmed previous reports using these combined cell suspensions (3,19), but also demonstrates LXA_4

formation from endogenous sources when PMN and autologous PLT are exposed to stimuli. Agonist-induced generation of $iLXA_4$ was rapid and concentration-dependent (Fig. 3B and C) with the reactions producing levels detectable by ELISA in the pico- to nanomolar range. It is important to point out that these levels of LXA_4 were achieved without the addition of exogenous 20:4n-6. Pico- to nanomolar quantities of LXA_4 have been demonstrated to elicit a range of bioactions in experimental models, including arteriolar dilatation and antagonism of LTB_4-induced PMN activation (reviewed in Ref. 1). In addition, PDGF was recently demonstrated to lead to the accumulation of neointimal smooth muscle after balloon-catheter deendothelialization of rat carotid arteries (27). This potent mitogen for smooth muscle is found in PLT and can activate many cell types, including PMN, leading to a chemotactic response (21,22). Similar to PDGF, LXA_4 is released intravascularly after balloon angioplasty in human coronary arteries (7). PDGF increases 20:4n-6 availability (28) and, in the present experiments, at biologically relevant concentrations led to the formation of $iLXA_4$ (Fig. 3). Thus, our findings suggest a potential link in PDGF and LXA_4 generation. Cytokine-primed PMN and PLT are likely to interact at sites of inflammation or vascular damage; thus, stimulus-induced LXA_4 generation may be relevant in these processes.

In humans, LXA_4 has been demonstrated in bronchoalveolar lavage fluid from asthmatics using HPLC and GC/MS (8). Aspirin-sensitive asthmatics are a select group of patients characterized by bronchospasm after ingestion of ASA (29). This cyclooxygenase inhibitor leads to higher levels of LO-derived products, including LXA_4, *in vivo* after PTCA (7) and, *in vitro*, does not inhibit lipoxin generation (1). Compared with ASA-insensitive individuals, sensitive asthmatics often have nasal polyps, which, *in vitro*, generate LXA_4 when incubated in the presence of either LTA_4 or activated neutrophils (6). Moreover, PLTs from these patients demonstrate abnormal responsiveness upon exposure to ASA (30). Results in Table 1 clearly indicate the presence of LXA_4 in nasal lavages after ASA ingestion. Although the present data do not permit an evaluation of the cellular source of LXA_4, there are several cell types present in these patients, such as eosinophils, cytokine-primed PMN, PLT, mast cells and nasal polyps, which are known to generate LX either individually or by transcellular biosynthesis *in vitro* that could have contributed to LXA_4 generation (reviewed in Ref. 1). Enabled by the ELISA's sensitivity and accuracy, these findings are the first to demonstrate the appearance of LXA_4 after a specific provocation *in vivo*, and indicate a potential role for LXA_4 in the airway. Recently, LXA_4 administered by nebulizer to humans has been shown to attenuate LTC_4-induced bronchoconstriction in asthmatic patients (10). Also, LXA_4 is further metabolized by phorbol myristate acetate-treated HL-60 cells and human monocytes to several major products including 15-oxo-LXA_4, 13,14-dihydro-15-oxo-LXA_4 and 13,14-dihydro-LXA_4 *in vitro* (31). It is not presently known if these metabolites represent the major route of LX metabolism *in vivo* and whether this ELISA can also be used to detect the metabolites. Thus, the present results indicate that further investigation is warranted in evaluating the role of LXA_4 in ASA-sensitive asthma and airway disease.

In conclusion, we present evidence for a new, sensitive and selective ELISA for LXA_4 and demonstrate its utility to detect LXA_4 *in vitro* and in pathologic fluids. Moreover, the availability of this assay enabled the demonstration of PMN and platelet agonists, such as PDGF, in the generation of LXA_4 during cell-cell interactions *in vitro* and documentation of the appearance of LXA_4 in humans after given an inflammatory stimulus.

[a]Department of Food Science and Human Nutrition and Center for Crops Utilization Research and [b]Department of Mathematics, Iowa State University, Ames, Iowa 50011

To observe how the stereospecific distribution of acyl groups in triglycerides is affected by the composition of fatty acids available for esterification, the oleaginous yeast *Apiotrichum curvatum* was grown on various binary mixtures of palmitic, stearic, oleic and linoleic acids as carbon sources, and the yeast triglycerides were analyzed. When oleic acid–linoleic acid mixtures in various ratios were used as substrates, the yeast grew well, and the composition of the intracellular triglycerides reflected the substrate composition, but more linoleate than oleate was deposited in the triglycerides. Oleate was favored over linoleate at the *sn*-2 position of the glycerol. With substrates containing palmitic and stearic acids, the yeast accumulated less oil, and incorporation of stearic acid into the triglycerides also was very limited. When mixtures of palmitic acid–oleic acid and palmitic acid–linoleic acid were used as substrates, the yeast triglyceride composition did not reflect that of the substrate, and the accumulation in the yeast of the unsaturated acid in the substrate was favored. Possibly, the yeast had more limited access to solid than to liquid substrates. For oleic acid–linoleic acid substrates, when the percentages of oleate and linoleate at the three glycerol positions were plotted *vs.* the percentage of these acyl groups in the total triglyceride, apparent linear relations were observed for most of the range, and the sums of the intercepts and slopes of the three lines for each acyl group were 0 and 3, respectively. Two mathematical models of triglyceride assembly are proposed, both of which fit the experimental data. One model assumes that for a certain proportion of the glycerol molecules, the acyl composition of the three *sn* positions is rigidly controlled independently of the substrate concentration. The other assumes that the various acyl groups are distributed on the three *sn* positions of glycerol with different affinities.

***Lipids* 28, 1055–1061 (1993).**

Triglyceride structure affects the consistency, stability and nutritional value of fats and oils (1–3), but because of the complexity of triglyceride mixtures, a complete analysis of triglycerides is seldom achieved. Stereospecific analysis of the acyl composition on the three positions of glycerol has revealed that the distribution of acyl groups is not random (3,4). It has been suggested that the restraints manifest in the stereospecific distribution account for the triglyceride structure, but analyses of olive oil suggest that other restrictions on the distribution also occur (5). Various proposals have been made to account for the distribution of acyl groups on the positions of glycerol, especially in oilseed, where the triglyceride supposedly is simply deposited during seed development. The distribution should reflect the biosynthetic pathways resulting in triglycerides and the specificity of the enzymes involved in the various steps, but the process is complicated by changes with time in the proportions of the acyl groups being deposited and by exchange reactions among the various lipid classes involved in the biosynthesis (6). Studies with labeled precursors and intermediates have led to helpful insights into triglyceride synthesis, but such studies often are limited by the insolubility of lipid substrates in water and the nonphysiological conditions sometimes required for the experiments.

A number of generalizations can be made about the observed distribution of acyl groups on glycerol, and these have been reviewed by Litchfield (3). One of these generalizations notes that, for a group of individual plants or animals with different acyl group compositions, there are linear relations between the percentages of a particular acyl group on the three glycerol positions and the percentage of that acyl group in the whole triglyceride mixture. Such linear relations have been reported in corn (7), soybean (4,8), oat (8), cruciferae (9) and peanut (10,11) oils.

The oleaginous yeast *Apiotrichum curvatum* ATCC 20509 (formerly known as *Candida curvata D*) will accumulate oil when grown on sugar or fat substrates if nitrogen for growth is limiting (12). It also will grow on fatty acids with 14–20 carbon chain lengths and accumulate triglycerides, but it grows best on palmitic, oleic or linoleic acid (13). It tends to deposit the same acyl groups that are in its substrate with minor modifications. In the yeast triglycerides, oleate tends to be favored on the *sn*-2 position of the glycerol, and saturated fatty acids are strongly favored on the *sn*-1 and *sn*-3 positions.

The characteristics of this yeast make it possible to study the effect of a wide range of oleate/linoleate ratios on the stereospecific distribution in the triglycerides, and the results of such a study are reported in this paper. From a few simple assumptions about triglyceride assembly, two models were derived that account for many of the relations observed in yeast and oilseeds.

MATERIALS AND METHODS

Apiotrichum curvatum was maintained as refrigerated slant cultures on yeast extract/dextrose/peptone/agar (1:2:2:1.5, by wt) and transferred monthly. The constituents of the basal medium were (g/L): KH_2PO_4, 2.5; $MgSO_4 \cdot 7H_2O$, 1.0; asparagine, 0.8; $CaCl_2 \cdot 2H_2O$, 0.2; NaCl, 0.06; $FeCl_3 \cdot 6H_2O$, 0.02; $MnSO_4 \cdot H_2O$, 0.002; $ZnSO_4 \cdot 7H_2O$, 0.001; thiamine-HCl, 0.001; and $CuSO_4 \cdot 5H_2O$, 0.0001 (12). The basal medium was adjusted to pH 5.5 and supplemented with 18 g/L of fatty acids purchased from Sigma Chemical Co. (St. Louis, MO). When linoleic acid was used as a carbon source, it was supplemented with 1,000 ppm of butylated hydroxyanisole to prevent oxidation during incubation.

A seed culture was prepared by inoculating about 5×10^5 cells from a slant culture into 100 mL of heat-

*To whom correspondence should be addressed at Department of Food Science and Human Nutrition, Food Sciences Building, Iowa State University, Ames, IA 50011.

sterilized basal medium with the fatty acids isolated from saponified corn oil as a carbon source. The culture was grown in 250-mL flasks in a Labline orbital shaker (Melrose Park, IL) at 32°C and 180 rpm. The seed culture was in late logarithmic growth after about 2 d, at which time its optical density at 440 nm was normally 9 to 10. One milliliter of 48-h seed culture was inoculated into 100 mL of medium containing the substrate lipid to be tested. The test cultures were grown for 7 d under the same conditions used for the seed culture.

Residual oleic or linoleic acid was separated from the culture, and the yeast oil was extracted according to Hammond *et al.* (12) by sequential extraction with ethanol, hexane and benzene. Fatty acid mixtures having palmitic and stearic acid were emulsified with 5 g/L gum acacia by blending after sterilization, and agitation was decreased to 140 rpm. When emulsified substrates were used, the yeast cell mass could not be separated completely; so after removal of as much of the cell mass as possible by centrifugation, the supernatant was evaporated in a rotary evaporator, and the residue was pooled with the cell mass recovered by centrifugation. Extraction of lipid in the pooled cel mass was accomplished as before.

The amount of triglyceride in yeast oil was determined by thin-layer chromatography (13). Aliquots of the ethanol extract and pooled hexane and benzene extracts were applied to layers 1.0 mm thick. The plates were developed in hexane/diethyl ether/acetic acid (50:50:1, by vol), and bands were visualized by spraying with 0.2% dichlorofluorescein in ethanol and viewed under ultraviolet light. The triglyceride bands were scraped from the plates and eluted with diethyl ether, and the residue was weighed after evaporation of the ether under nitrogen.

Stereospecific analysis was done according to Christie and Moore (14). For fatty acid analysis, glycerides were transesterified by the method of Frey and Hammond (15), and the methyl esters were analyzed on a Varian Model 3700 Gas Chromatograph (Sugarland, TX) equipped with a 1.8 m × 3.3 mm column of 10% SP-2330 on Chromosorb WAW (Supelco, Bellefonte, PA) and a flame-ionization detector.

RESULTS AND DISCUSSION

Structure of triglycerides from A. curvatum *grown on oleic acid–linoleic acid mixtures.* Table 1 shows the fatty acid composition and stereospecific distribution of the acyl groups in triglycerides from *A. curvatum* grown on pure oleic acid or linoleic acid and on mixtures of oleic and linoleic acids as carbon sources. Saturated acyl groups in the yeast triglycerides amounted to <6% in all instances. Figure 1 shows the percentages of oleate and linoleate in the yeast triglycerides plotted *vs.* the percentages of these fatty acids in the substrate. The intercept of the oleate line is very near zero, but that of the linoleate line is about +8%. Seemingly, linoleate is accumulated in slightly greater amounts than oleate from binary mixtures of the acids, and when one of the pure acids was the substrate, there was greater conversion of oleate to linoleate than of linoleate to oleate by the yeast. The plots had almost the same slopes and correlation coefficients (0.892 and 0.9988 for oleate and 0.900 and 0.9984 for linoleate, respectively).

[a]Triglyceride. [b]Not detected. [c]Data not available.

In the triglycerides from the yeast grown on oleic acid–linoleic acid mixtures, oleate was favored at the *sn*-2 position compared with linoleate. The same trend was reported in oat oil (8), but in many seed oils, linoleate is favored in the *sn*-2 position (3). The percentages of oleate and linoleate in the *sn*-1, *sn*-2 and *sn*-3 positions were linearly related to the total percentages of these acyl groups in the triglyceride over a certain range. For oleate, the range was approximately 15–70%, and for linoleate it was approximately 25–80%. The slopes, intercepts and correlation coefficients for the linear ranges of oleate and linoleate are given in Table 2. The sign of the intercepts (positive or negative) in Table 2 indicates whether the placement of an acyl group in a certain position is favored or not. Slopes greater than 1 indicate that, as the amount of an acyl group in the whole oil increases, there is a tendency

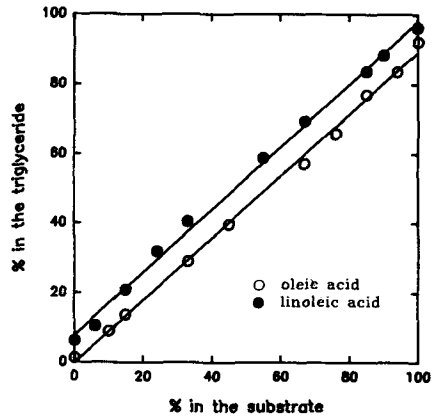

FIG. 1. The percentage of oleate and linoleate in the *Apiotrichum curvatum* triglycerides *vs.* their percentage in the substrates on which the yeast was grown. Standard linear regression lines are shown.

to place more of it in a particular glycerol position than is present in the whole oil. A slope less than 1 indicates the opposite. The slopes in Table 2 are close to 1, but slopes that deviate significantly from 1 are not unusual in vegetable oils (4,8).

Theoretical treatment of glyceride distribution. Fatemi and Hammond (4) observed that, if the slopes and intercepts of plots, such as those described in the preceding paragraph, were determined for soybean oil, the slopes for a particular acyl group for the three positions would total 3 and the intercepts would total 0. The use of plant varieties for such plots limits the range of the data to the range of fatty acid compositions that are available. Pan and Hammond (8) pointed out that, although these plots were linear over the range that could be observed, it was impossible for them to be linear over their entire range and that the lines must bend toward 0,0 and 1,1 at their extremes. The data obtained with *A. curvatum* have made it possible to examine a much longer range and to verify this prediction.

Two models are proposed to account for the data shown in Tables 1 and 2 and Figure 1. Model 1 can be used to explain the apparently linear relations, with slopes of the lines in Table 2 adding to 3.0 and intercepts adding to 0.0. The derivation is based on the simple hypothesis (Model 1) that, for some fraction of the glycerol molecules, there are enzymes that determine which acyl groups appear at the *sn*-1, *sn*-2 and *sn*-3 positions independently of the substrate concentration. This might be accomplished either by controlling which acyl group gets attached or by possible conversion of acyl groups from one form to another after attachment to the glycerol backbone. An alternate, simple model (Model 2) derived from basic chemical kinetics assumes that the glycerol positions are filled in proportion to substrate concentration but that the three *sn* positions of glycerol have different affinities for the various acyl groups. Model 2 leads to nonlinear relations, all of which pass through 0,0 and 1,1; however, Model 2 fits the seemingly linear data rather well. Both models assume that there are just two acyl groups, A and B, and that they are present in the substrate in the proportions α:β, respectively, with $\alpha + \beta = 1$. However, as a first approximation, the models can be used when more than two acyl groups are being studied, by letting A denote one specific acyl group and B denote all of the remaining acyl groups collectively. For the data in Table 1, A is identified with oleate and B with linoleate. B is favored at positions *sn*-1 and *sn*-3, and A is favored at position *sn*-2. The models can be easily adapted to other positional preferences.

TABLE 2

Linear Regression of the Percentage of an Acyl Group at the *sn* Positions of Glycerol *vs.* the Percentage of the Acyl Group in the Total Triglyceride[a]

Fatty acid	Position	Intercept	Slope	r^b
Oleate	*sn*-1	−4.76	0.94	0.9986
	sn-2	14.05	1.03	0.9992
	sn-3	−9.30	1.03	0.9991
	Sum	−0.01	3.00	
Linoleate	*sn*-1	10.02	0.93	0.9966
	sn-2	−14.04	1.01	0.9984
	sn-3	4.02	1.06	0.9994
	Sum	0.00	3.00	

[a]Ranges used for this linear regression were 13.8–65.7% for oleate and 31.9–83.6% for linoleate in the total triglyceride.
[b]Correlation coefficient.

Model 1. Assume that there are enzymes, E_1, E_2 and E_3, that control the character of the acyl groups attached to, respectively, the *sn*-1, *sn*-2 and *sn*-3 positions on certain fractions of the glycerol molecules. Assume that E_1 affects a proportion, p_1, of the glycerol molecules and ensures that acyl group B is attached to position *sn*-1. The action could be accomplished by selecting B and attaching it to *sn*-1, by blocking the attachment of A to *sn*-1, or by converting to B all acyl groups A at *sn*-1 in the fraction affected by E_1. The fraction, $1 - p_1$, of the glycerol molecules that is not affected by E_1 has A and B attached to *sn*-1 in the substrate proportions α:β. Enzyme E_2 acts at position *sn*-2 to ensure acyl group A is attached to *sn*-2 on a fraction p_2 of the glycerol molecules, and enzyme E_3 ensures that B appears at position *sn*-3 on a fraction p_3 of the glycerol molecules. It is not necessary to assume that the enzymes act independently, so that, for example, the fraction of the glycerol acted on by both E_1 and E_3 may be different from the fraction $p_1 \cdot p_3$ that would be expected from independence.

Analysis of Model 1. At position *sn*-1, the fraction p_1 of the glyceride molecules has acyl group B, and $1 - p_1$ of the molecules has acyl groups A and B distributed according to the ratio α:β. Therefore, the fraction, A_1, of glyceride molecules with acyl group A at *sn*-1 is $(1 - p_1)\alpha$. At position *sn*-2, the fraction p_2 of the molecules has A, and $1 - p_2$ of the molecules has A and B in the proportions α:β, so that the fraction A_2 of glyceride molecules with acyl group A at *sn*-2 is $p_2 + (1 - p_2)\alpha$. Analysis of position *sn*-3 is similar to *sn*-1, and the fraction, A_3, of glyceride molecules with acyl group A at *sn*-3 is $(1 - p_3)\alpha$. The fraction, A_*, of the total positions on the glyceride molecules on which fatty acid A appears is $(A_1 + A_2 + A_3)/3$. This yields Equations 1 and 2.

$$A_1 = (1 - p_1)\,\alpha$$

$$A_2 = (1 - p_2)\,\alpha + p_2$$

$$A_3 = (1 - p_3)\,\alpha \qquad [1]$$

$$A_* = \left(1 - \frac{p_1 + p_2 + p_3}{3}\right)\alpha + \frac{p_2}{3} \quad [2]$$

Because $A_* + B_* = 1$, one obtains from Equation 2:

$$B_* = \left(1 - \frac{p_1 + p_2 + p_3}{3}\right)\beta + \frac{p_1}{3} + \frac{p_3}{3} \quad [3]$$

and in a similar way one can obtain equations for B_1, B_2 and B_3 from Equations 1. Equations 2 and 3 describe linear relations as illustrated in Figure 1, in which the fraction of an acyl group in the triglyceride appears to be linearly related to the fraction of the acyl group in the substrate. Note that the slopes are equal, consistent with the observed slopes shown in Figure 1 of 0.90 and 0.892. Both intercepts are positive in Equations 2 and 3 at zero substrate concentrations, due to the hypothesized enzymatic specificity for the fatty acids. Only one intercept is positive in Figure 1, but it is this positive intercept that motivates a model in which an acyl group of a certain type is placed on the glyceride molecule independently of the amount in the substrate. The linear Equations 1 can be fit by the method of least squares to oleate data in Table 1 to get estimates of p_1, p_2 and p_3 for use in Equation 2. In a similar way, linoleate data from Table 2 can be used to get estimates of p_1, p_2 and p_3 for use in Equation 3. With these values, the graphs of Equations 2 and 3 are almost indistinguishable from the regression lines shown in Figure 1. The two sets of estimates are similar, (0.1994,0.0972,0.1672) and (0.1490,0.1001,0.1350), with the two estimates for p_2 being very close, since nearly all the acyl groups at *sn*-2 are either oleate or linoleate.

To get equations descriptive of the linear relations found in Table 2, one eliminates α between the expressions for A_i, i = 1, 2 and 3, in Equations 1 and A_* in Equation 2, and obtains Equations 4.

$$A_1 = \frac{3(1 - p_1)}{3 - p_1 - p_2 - p_3}A_* - \frac{(1 - p_1)p_2}{3 - p_1 - p_2 - p_3}$$

$$A_2 = \frac{3(1 - p_2)}{3 - p_1 - p_2 - p_3}A_* + \frac{(2 - p_1 - p_3)p_2}{3 - p_1 - p_2 - p_3}$$

$$A_3 = \frac{3(1 - p_3)}{3 - p_1 - p_2 - p_3}A_* - \frac{(1 - p_3)p_2}{3 - p_1 - p_2 - p_3} \quad [4]$$

Observe that the sum of the slopes is 3 and that the intercepts sum to 0, as is true of the data shown in Table 2. Equations 4 yield values of A_i between 0 and 1 when $p_2/3 < A_* < 1 - p_1/3 - p_3/3$. Figure 2 is a plot of the oleate on the three *sn* positions of glycerol *vs.* the oleate in the total triglyceride with the linear Equations 4 fit to the data. The lines correspond to, and are almost exactly the same as, those in Table 2. Because the equations are not linear in p_1, p_2 and p_3, nonlinear least squares fitting procedures are required.

Model 2. Assume that the affinities for A and B at the *sn*-1 position are, respectively, K(1,A) and K(1,B). The number of A acyl groups that attach to *sn*-1 will depend on the substrate fraction α and the ratio of K(1,A) to K(1,B). The fraction of A on *sn*-1 is assumed to be Equation 5.

$$\frac{K(1,A)\alpha}{K(1,A)\alpha + K(1,B)\beta} = \frac{K(1,A)\alpha}{K(1,A)\alpha + K(1,B)(1 - \alpha)} = \frac{r_1\alpha}{r_1\alpha + 1 - \alpha} \quad [5]$$

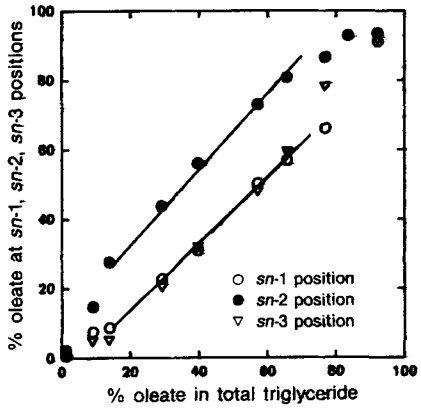

FIG. 2. The percentage of oleate in the *sn*-1, *sn*-2 and *sn*-3 positions of glycerol *vs.* the percentage of oleate in the total triglyceride fitted with Equations 4 with $p_1 = 0.2673$, $p_2 = 0.1657$, $p_3 = 0.2715$. The range of 13.8–65.7% oleate in the total triglyceride was used, as in Table 2.

where

$$r_1 = \frac{K(1,A)}{K(1,B)} \quad [6]$$

Assuming that B is preferred at *sn*-1 (meaning that the binding affinity for B at *sn*-1 is higher than for A), one would have $r_1 < 1.0$. Similar notation is assumed for *sn*-2 and *sn*-3, with $r_2 > 1.0$ and $r_3 < 1.0$.

Analysis of Model 2. From the definitions in Model 2 and of A_*, A_1, A_2 and A_3, one immediately obtains Equations 7–9.

$$A_1 = \frac{r_1\alpha}{r_1\alpha + 1 - \alpha}$$

$$A_2 = \frac{r_2\alpha}{r_2\alpha + 1 - \alpha}$$

$$A_3 = \frac{r_3\alpha}{r_3\alpha + 1 - \alpha} \quad [7]$$

$$A_* = \frac{1}{3}\left[\frac{r_1\alpha}{r_1\alpha + 1 - \alpha} + \frac{r_2\alpha}{r_2\alpha + 1 - \alpha} + \frac{r_3\alpha}{r_3\alpha + 1 - \alpha}\right] \quad [8]$$

As in Model 1, From $A_* + B_* = 1$, one obtains an expression:

$$B_* = \frac{1}{3}\left[\frac{\beta}{r_1(1 - \beta) + \beta} + \frac{\beta}{r_2(1 - \beta) + \beta} + \frac{\beta}{r_3(1 - \beta) + \beta}\right] \quad [9]$$

and in a similar way one can get equations for B_1, B_2 and B_3. In Equation 8, the relation between A_* and α is not linear, and the graph passes through 0,0 and 1,1. One can use a nonlinear minimization computer code to do a least squares fit of Equations 7 to the oleate data of Table 1 in order to get estimates for r_1, r_2 and r_3 for use in Equation 8, and a fit of a similar set of equations to the linoleate data and for use in Equation 9. Doing so, we obtain a figure analogous to Figure 1, shown in Figure 3. It is apparent from the graphs that the relations are not linear and that the intercepts are all at 0,0 and at 1,1.

One can eliminate α between Equations 7 and Equation 8 and obtain the following equations analogous to

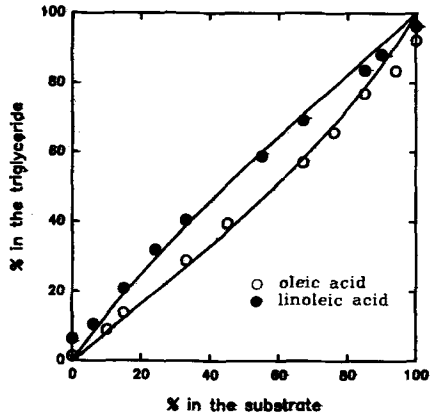

FIG. 3. The percentage of oleate and linoleate in yeast triglycerides *vs.* their percentage in the substrate with the graphs of Equations 8 and 9. The values of $r_{1,A} = 0.4651$, $r_{2,A} = 1.5460$, $r_{3,A} = 0.5041$ were obtained from fitting Equations 7 to oleate data in Table 1 and used in Equation 8. A similar procedure was used to obtain $r_{r,B} = 0.6468$, $r_{2,B} = 1.5689$, $r_{3,B} = 0.5768$ for use in Equation 9.

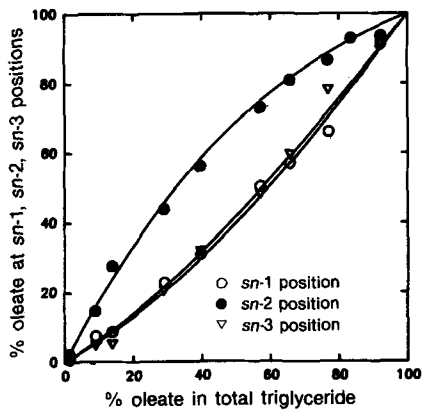

FIG. 4. The percentage of oleate in the *sn*-1, *sn*-2 and *sn*-3 positions of glycerol *vs.* the percentage of oleate in the total triglyceride fitted with Equations 10; $r_1 = 0.3146$, $r_2 = 1.0$ and $r_3 = 0.3380$.

Equations 4 and descriptive of the relations shown in Figure 2 (see Equations 10).

$$3A_* = A_1 + \frac{A_1 r_2}{(r_2 - r_1)A_1 + r_1} + \frac{A_1 r_3}{(r_3 - r_1)A_1 + r_1}$$

$$3A_* = \frac{A_2 r_1}{(r_1 - r_2)A_2 + r_2} + A_2 + \frac{A_2 r_3}{(r_3 - r_2)A_2 + r_2}$$

$$3A_* = \frac{A_3 r_1}{(r_1 - r_3)A_3 + r_3} + \frac{A_3 r_2}{(r_2 - r_3)A_3 + r_3} + A_3 \qquad [10]$$

To write A_i in terms of A_* requires computing the root of a cubic, and it is better to use a root-solving routine to compute the value of A_i, given A_*, as needed. These equations are homogeneous in the values r_1, r_2 and r_3; the relations defined for one set of values r_1, r_2 and r_3 will be exactly the same for another set of values Cr_1, Cr_2 and Cr_3 for any nonzero number C. Therefore, in fitting these equations to data, such as that represented in Figure 2, only the relative values of r_1, r_2 and r_3 will be obtained. We normalized the three equations by dividing by r_2, (equivalent to restricting r_2 to be 1.0), fit the equations to the data in the oleate column of Table 1 and obtained $r_1 = 0.3146$ and $r_3 = 0.3308$. These compare with the values in Figure 3, $r_{1,A}/r_{2,A} = 0.3008$ and $r_{3,A}/r_{2,A} = 0.3261$. The resulting curves are shown in Figure 4, where it can be seen that these curved lines fit the data very well.

In plots analogous to Figure 2, the slopes add to 3, and the intercepts add to 0. The data for Figure 2 are based on N measurements $\{A_{i,j}\}_{j=1,N}$ of oleate percentages at each position, *sn*-i, i = 1, 2 and 3, and computation of $A_{*,j} = (A_{1,j} + A_{2,j} + A_{3,j})/3$, j = 1, N. Similar plots are shown in (4,8,10,11) in which straight lines $A_i = m_i A_* + b_i$ are fit by the method of least squares to the data $\{A_{i,j}, A_{*,j}\}_{j=1,N}$ for i = 1, 2 and 3. We will show that for all such regressions, there is an algebraic identity that $m_1 + m_2 + m_3 = 3$ and $b_1 + b_2 + b_3 = 0$. From the method of least squares, the "normal equations" (16) used to obtain m_i and b_i (for i = 1, 2 or 3) are represented by the matrix equation, Equation 11.

$$\begin{bmatrix} \sum_{j=1}^{N} A_{*,j}^2 & \sum_{j=1}^{N} A_{*,j} \\ \sum_{j=1}^{N} A_{*,j} & \sum_{j=1}^{N} 1 \end{bmatrix} \begin{bmatrix} m_i \\ b_i \end{bmatrix} = \begin{bmatrix} \sum_{j=1}^{N} A_{*,j} A_{i,j} \\ \sum_{j=1}^{N} A_{i,j} \end{bmatrix} \qquad [11]$$

The matrix on the left is indepdent of i and is invertible. Adding the three equations for i = 1, 2 and 3, one obtains Equation 12.

$$\begin{bmatrix} \sum_{j=1}^{N} A_{*,j}^2 & \sum_{j=1}^{N} A_{*,j} \\ \sum_{j=1}^{N} A_{*,j} & \sum_{j=1}^{N} 1 \end{bmatrix} \begin{bmatrix} m_1 + m_2 + m_3 \\ b_1 + b_2 + b_3 \end{bmatrix} = \begin{bmatrix} \sum_{j=1}^{N} A_{*,j}(A_{1,j} + A_{2,j} + A_{3,j}) \\ \sum_{j=1}^{N} (A_{1,j} + A_{2,j} + A_{3,j}) \end{bmatrix} \qquad [12]$$

Using the definition of $A_{*,j} = (A_{1,j} + A_{2,j} + A_{3,j})/3$, one obtains Equation 13.

$$\begin{bmatrix} \sum_{j=1}^{N} A_{*,j}^2 & \sum_{j=1}^{N} A_{*,j} \\ \sum_{j=1}^{N} A_{*,j} & \sum_{j=1}^{N} 1 \end{bmatrix} \begin{bmatrix} m_1 + m_2 + m_3 \\ b_1 + b_2 + b_3 \end{bmatrix} = \begin{bmatrix} 3\sum_{j=1}^{N} A_{*,j}^2 \\ 3\sum_{j=1}^{N} A_{*,j} \end{bmatrix} \qquad [13]$$

This last matrix equation has the solution $m_1 + m_2 + m_3 = 3$ and $b_1 + b_2 + b_3 = 0$, which is unique because the matrix on the left is invertible.

Biological significance of the models. The biased distribution of acyl groups at the *sn* positions of glycerol has mostly been attributed to biases in the specificity of the enzymes involved (6). Model 2 shows that if these biases are the only factors operating, plots such as those in Figures 2 and 4 cannot be linear; however, the curvature

of the plot may be slight enough to appear linear over a short range of variation. The yeast data reported here are the only data available with enough range to demonstrate such curvature, and their fit, illustrated in Figure 4, support this model. Model 2 is also supported by reports that the amounts of individual triglycerides in seed fats agree fairly well with the amounts predicted by stereospecific analysis and 1-random-2-random-3-random distribution Equations 4.

For a truly linear outcome of plots, such as those in Figures 2 and 4, Model 1 teaches that a fixed fraction of the triglycerides must have a particular acyl group distribution that is uninfluenced by the amounts of fatty acids available for esterification. Such a distribution might occur, for example, if a fraction of the triglycerides is always formed from a certain pool of phosphatides with rigid acyl group compositions. This sort of assumption is supported by plots (*e.g.*, Fig. 1) that show a fixed bias in the incorporation of linoleate regardless of the amount available in the medium. This assumption also is supported by the seeming linearity of plots (*e.g.*, Fig. 2) for many seed oils. This model also might account for nonrandom biases in acyl group distribution that cannot be attributed to stereospecific distributions, such as those reported for olive oil (5).

Effect of substrate mixtures containing saturated fatty acid on the composition of yeast triglycerides. The other binary mixtures of fatty acids could not be studied over the wide range used for oleic acid–linoleic acid mixtures because the acyl group composition of *A. curvatum* triglycerides varied over a relatively narrow range, regardless of the ratios of fatty acids in the substrate. Also the emulsions of solid, saturated, high-melting acids used as substrates made it difficult to isolate the yeast triglyceride for stereospecific analysis. Table 3 shows the fatty acid composition of triglycerides isolated from *A. curvatum* grown on various binary combinations that included saturated fatty acids as carbon sources. When large proportions of stearic acid were present in the medium, the amount of accumulated yeast oil decreased (data not shown) in agreement with the previous observations by Lee *et al.* (13). Less than 10% stearic acid was observed in the yeast triglycerides even from a substrate with 75% stearic acid. Seemingly, the yeast reluctantly used and incorporated stearic acid into its triglycerides. In a study using cell-free extracts and spheroplasts, Holdsworth and Ratledge (17) reported that the activity of fatty acyl coenzyme A (CoA) synthetase in *A. curvatum* was some 6- to 8-fold lower with stearic acid than with palmitic, oleic and linoleic acids. The apparently poor substrate activity of this enzyme with stearic acid might account for the very limited utilization of stearic acid and its low incorporation into the triglyceride. In the stearic acid–oleic acid and palmitic acid–oleic acid mixtures, the presence of saturated acids seemed to decrease by 2–4% the linoleate found in the yeast triglyceride compared with that found for pure oleic acid as a substrate.

Although Holdsworth and Ratledge (17) reported that the activities of fatty acyl CoA synthetase for palmitic and linoleic acids were similar, our microscopic observation of the yeast showed that they accumulated less lipid as the proportion of palmitic acid increased in the substrate. In palmitic acid–stearic acid mixtures, the yeast seemed to prefer palmitic over stearic acid because the yeast triglyceride contained much more palmitate than stearate. With palmitic acid–oleic acid or palmitic acid–linoleic acid substrates, the yeast contained only 15–18% palmitate when the proportion of palmitic acid was 25–50%. It is suggestive that the 15–18% palmitate found in these triglycerides corresponded to the solubility of palmitic acid in oleic acid at 33°C, namely, 15.7% (18). It appears likely that the access of the yeast to solid lipid substrate is less than for liquid fatty acids, and this influences the proportions of the acyl groups in the yeast triglyceride. The percentage of palmitate in the triglyceride increased to 25–40% when the proportion of palmitic acid in the substrate was 75%. Much more palmitate was found in combination with oleate than with linoleate.

Table 4 shows the stereospecific analyses of three triglycerides that we were able to isolate from yeast grown on mixtures containing palmitic acid and an unsaturated acid. The palmitate accumulated in the *sn*-1 and *sn*-3 positions, and the amounts of unsaturated acyl groups in these positions decreased relative to the amounts found for substrates of pure oleate or linoleate.

Different Mechanisms of Uptake of Stearic Acid and Cholesterol into Rabbit Jejunal Brush Border Membrane Vesicles

S. Burdick, M. Keelan and **A.B.R. Thomson***
Nutrition and Metabolism Research Group, Division of Gastroenterology, University of Alberta, Edmonton, T6G 2C2 Canada

The rate of uptake of stearic acid and cholesterol solubilized in taurocholic acid (TC) was examined in rabbit jejunal brush border membrane vesicles (BBMV). For stearic acid (18:0) or cholesterol there was an initial rapid rate of uptake, which reached a plateau within approximately 1 min and remained stable thereafter. At low concentrations of 18:0 and 20 mM, but not 2 mM, TC, there was a curvilinear relationship between the concentration of 18:0 and uptake, whereas the relationship between cholesterol uptake and concentration was linear over a wide range of values. When the concentration of TC was held constant at increasing concentrations of 18:0 or cholesterol, there was a linear increase in the rate of uptake. When the concentration of 18:0 or cholesterol was held constant and the concentration of TC was increased from 2 to 20 mM, the uptake of 18:0 declined, but the rate of uptake of cholesterol increased. When the concentrations of 18:0 plus TC, or cholesterol plus TC, were both increased in unison and their ratio was held constant, their rate of uptake increased. Thus, (i) BBMV may be used to assess the rate of uptake of lipids; (ii) the partitioning of cholesterol from bile acid micelles into the BBMV appears to be by way of "collision" of the cholesterol with the membrane. In contrast, the uptake of 18:0 from the micelle into the membrane vesicles may be by both the collision and the aqueous/dissociation models; and (iii) 18:0 uptake may be mediated by both a concentration-dependent and a concentration-independent component. Thus, stearic acid and cholesterol seem to be taken up from bile acid micelles into rabbit BBMV by different mechanisms.
Lipids 28, 1063–1067 (1993).

The intestinal uptake of lipids involves a variety of mechanisms by which lipids interact with the brush border membrane (BBM) of the small intestine (1–4). Uptake of lipids is thought to occur passively *via* an energy-independent diffusion process (5,6). A membrane fatty acid binding protein may be involved in fatty acid absorption in the intestine (7), and the uptake of both cholesterol and phosphatidylcholine may also be protein-mediated in rabbit small intestine (8,9).

The mechanism by which lipid is transferred from the bile acid micelle to the BBM has been studied using *in vitro* experiments. These studies have provided evidence for the movement of lipid from the micelle into the aqueous phase, with the lipid then permeating into the BBM (10,11). Studies using intestinal BBM vesicles (BBMV) have suggested that some portion of the uptake of lipids results from collision of micelles with the BBMV (8,12,13). BBMV are a useful model to study the uptake of lipid in the absence of an unstirred water layer and of cytosolic fatty acid binding proteins.

The aim of this study was to examine the uptake of stearic acid and cholesterol into jejunal BBMV of rabbits under conditions of varying concentrations of bile acid, and varying ratios of bile acid to stearic acid or cholesterol. The results suggest that stearic acid and cholesterol may be taken up from bile acid micelles into intestinal BBMV by different mechanisms.

MATERIALS AND METHODS

Chemicals. [1-^{14}C]Stearic acid (55.3 mCi/mmol) and [^{14}C]cholesterol (55 mCi/mmol) were purchased from ICN Radiochemicals (Irvine, CA). Phloretin, *N*-(2-hydroxyethyl)piperazine-*N'*-ethanesulfonic acid (HEPES), Tris-HCl and taurocholic acid (TC) were obtained from Sigma Chemical Co (St. Louis, MO). All other chemicals were reagent grade.

Isolation of BBMV. BBMV were prepared at 4°C using a modification (14) of the method described by Ling *et al.* (15). Female New Zealand white rabbits weighing 2.0–2.5 kg were given an injection of sodium pentobarbital (240 mg/kg) into the marginal ear vein.

Approximately 80 cm of jejunum distal to the ligament of Treitz was removed and flushed three times with 60 mL of 0.9% ice cold saline. The tissue was then placed on a pre-chilled glass slide and moistened with a small volume of Tris-mannitol buffer (50 mM mannitol, 2 mM Tris, pH 7.1). The mesenteric border was removed and the intestine was opened, exposing the mucosal surface. The mucosa was removed by gently scraping with two glass slides and placing the scrapings into a vial containing 5 mL isolation buffer (300 mM D-mannitol, 10 mM HEPES-Tris, pH 7.0). All steps were done at 4°C. The scrapings were transferred to a 250-mL polypropylene bottle with an additional 110 mL of isolation buffer homogenized using a Polytron® (Brinkman Instruments, Westbury, NY) at setting "9" for 30 s. The homogenate was centrifuged at 500 × *g* for 15 min (Beckman J2-21, JA-14 rotor, Beckman Instruments, Fullerton, CA). Sufficient 1M $CaCl_2$ was added to the supernatant to yield a 10 mM concentration; the mixture was then stirred on ice for 10 min. Following precipitation, the solution was centrifuged at 7500 × *g* for 20 min (JA-14 rotor). The supernatant was decanted into 50-mL polypropylene tubes and centrifuged at 28000 × *g* for 20 min (JA-20 rotor). The supernatant was then discarded, and the pellet was resuspended in vesicle resuspension buffer (300 mM D-mannitol, 10 mM HEPES-Tris, pH 7.4) and homogenized at setting "8" for 30 s. The homogenate was centrifuged at 30000 × *g* for 20 min (JA-20 rotor). The supernatant was discarded and the pellet resuspended in an appropriate volume of resuspension buffer and homogenized at setting "6" for 15 s. BBMV were incubated at 4°C for 90 min before uptake studies were done. The protein concentrations were determined using Hartree's modification (16) of the Lowry method (17) using bovine serum albumin as standard.

Abbreviations: BBM, brush border membrane; BBMV, brush border membrane vesicles; HEPES, *N*-(2-hydroxyethyl)piperazine-*N'*-2-ethanesulfonic acid; TC, taurocholic acid.

The purity of the BBMV was examined measuring sucrase and alkaline phosphatase activities (18,19). The final BBMV were enriched 10- to 15-fold.

Preparation of the stearic acid probe. [^{14}C]Stearic acid was combined with unlabelled stearic acid, dried down under a stream of nitrogen and reconstituted in lipid transport buffer (1 mM $MgCl_2$, 2 mM $CaCl_2$, 100 mM D-mannitol, 10 mM HEPES-Tris, 20 mM TC, pH 7.4) such that the final concentration of 18:0 was 50 or 200 μM, and the final specific activities were 8.8 and 9.8 Ci/mol, respectively. The final probes were sonicated for 15 min in a water-bath sonicator (Branson 1200; Branson Ultrasonic, Danbury, CT) at 37°C.

Preparation of the cholesterol probe. [^{14}C]Cholesterol was combined with unlabelled cholesterol and dried down under a stream of nitrogen and reconstituted in lipid transport buffer, yielding a final concentration of 50 μM and a final specific activity of 20.8 Ci/mol. The probe was sonicated for 15 min in a water-bath sonicator.

Preparation of filter prewash. Stearic acid (300 μM) was solubilized in stock stop buffer (0.15 M KCl, 2 mM HEPES-Tris, pH 7.4) containing 30 mM TC. Similarly, cholesterol (300 μM) was solubilized in stock stop buffer containing 20 mM TC. All filter prewash solutions were stirred at 48°C until the solutions cleared.

Uptake studies. Transport studies were performed using a method of rapid filtration as described by Hopfer *et al.* (20). All incubations were done at room temperature (20°C). For incubation times less than 1 min, 20 μL (60 μg) vesicles and 20 μL probe were pipetted into a polystyrene tube without the two drops touching. The reaction was initiated by mixing the two drops, maintained by continuous vortexing, and stopped by adding 1.25 mL of ice cold stop buffer (0.15 mM KCl, 2 mM HEPES-Tris, pH 7.4).

For incubation times greater than 1 min, 50 μL of vesicles (150 μg) was added to a polystyrene tube containing 50 μL of labelled substrate. The mixture was vortexed and allowed to stand for the duration of the incubation. To stop the reaction, 40 μL of the incubation mixture was added to 1.25 mL of ice-cold stop buffer. One mL of the stopped mixture was filtered through prewashed 0.45 μM cellulose filters (Millipore, Bedford, MA; Micron Sep, Fisher E04WPO2500, Cincinnati, OH) under vacuum on an Amicon (Danvers, MA) filtration manifold VFMI. Similarly, blanks were prepared by adding 20 μL of probe and 20 μL of vesicle resuspension buffer followed by 1.25 mL ice cold stop buffer.

Standards were prepared by aliquoting 50 μL of incubation mixture that was pooled from the experiment onto a pre-washed filter. The filters were placed in vials and then dried at 55°C for 10 min, followed by the addition of 7 mL scintillation fluid (Beckman scintillation cocktail).

Radioactivity was determined using a Beckman LS 9000 liquid scintillation counter.

Experimental procedures. Stearic acid (25 or 100 μM) or cholesterol (25 μM) uptake was studied as a function of time. The lipids were solubilized in 20 mM TC and were incubated with BBMV suspension for 5-s to 16 min. Stearic acid was examined at concentrations of 1 to 200 μM, and cholesterol was studied at increasing concentrations of 1 to 50 μM.

Stearic acid (25 or 100 μM) and cholesterol (25 μM) were examined at 5 s incubation periods with TC concentrations ranging from 2 to 20 mM. Stearic acid uptake with TC at fixed ratios of 12.5:1 or 1.25:1 (μM 18:0 mM TC) and cholesterol (1.25:1) were examined at initial rates of 5-s incubation periods. Stearic acid (25 μM) and cholesterol (25 μM) uptake was studied when the pH of the vesicle resuspension buffer and lipid probe were maintained at pH 4.0, 6.0 and 7.4; the concentration of TC was 20 mM, and the duration of incubations was 5 s.

The data for each point on the subsequent graphs represent the mean value ± standard error of four experimental days on which four replicates were performed. Uptake in the time-course experiments was expressed as nmol/mg BBMV protein; it represents the total radioactivity of the sample minus the nonspecific binding of labelled lipid to the filter. To determine the best curve fit, Sigmaplot (4.1) graphics program (Jandel Scientific, San Rafael, CA) was used for the time-course experiments. For the concentration curves, lipid/TC ratio (constant ratio of lipid/TC with increasing concentrations of both) and constant concentration of lipid with increasing TC, the uptake is presented as nmol per mg BBMV protein per second. First-order regressions and regression coefficients were calculated for experiments done under initial rate conditions (5 s).

RESULTS

Time course of stearic acid and cholesterol. Studies of 100 μM stearic acid (18:0) uptake as a function of time showed an initial rate of uptake that plateaued within 2 min at a value of approximately 35 nmol per mg BBMV protein (Fig. 1A). Similarly, 25 μM 18:0 (Fig. 1B) and 25 μM cholesterol (Fig. 1C) showed a rapid initial rate of uptake, equilibrating within 2 min at values of 3 and 4 nmol per mg protein, respectively.

Lipid concentration curve. The uptake of 18:0 was greater from low (2 mM) than from high (20 mM) concentrations of TC (Fig. 2A and 2B). The relationship between the concentration of 18:0 and uptake was linear when the 18:0 was solubilized with 2 mM TC (Fig. 2A), but a curvilinear relationship was noted at low concentrations of 18:0 when the fatty acid was solubilized with 20 mM TC (Fig. 2B). For cholesterol, there was a linear relationship between concentration and uptake (Fig. 2C).

Lipid and TC varied to maintain constant ratio. The concentrations of 18:0 and TC were both increased in unison, maintaining a constant ratio of 12.5 μM/1 mM (Fig. 3A) or 1.25 μM/1 mM (Fig. 3B); there was a linear increase in 18:0 uptake. Similarly, cholesterol uptake increased at a linear rate as both cholesterol and TC concentrations were increased at a constant ratio of 1.25 μM/1 mM (Fig. 3C).

Constant lipid concentration with increasing TC. The uptake of 100 or 25 μM 18:0 decreased as the concentration of TC was increased from 2 to 20 mM (Fig. 4A and 4B), whereas cholesterol uptake increased as the TC concentration was increased (Fig. 4C).

DISCUSSION

Several mechanisms have been postulated to explain the sequence of events occurring when lipid is transferred from bile salt micelles in the intestinal lumen into the BBM. Uptake of the entire micelle is not supported by experimental data (21). The second model involves a "collision" between the micelle and the BBM whereby the solubilized lipid moves directly from the micelle into the BBM. In the third model, the movement of lipid occurs

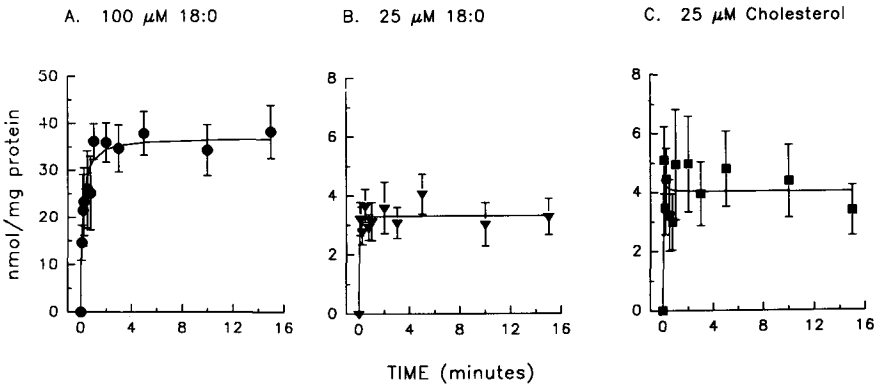

FIG. 1. Rate of uptake (mean ± SEM) of stearic acid and cholesterol into brush border membrane (BBM) vesicles. The concentration of stearic acid was 100 μM (panel A) or 25 μM (panel B), and the concentration of cholesterol was 25 μM (panel C). The lipids were solubilized in 20 mM taurocholic acid. BBM vesicles were equilibrated with vesicle resuspension buffer for 90 min prior to experimentation. BBM vesicles were incubated with labelled stearic acid or cholesterol at room temperature (20°C). Assays were performed in quadruplicate on BBM vesicles from four rabbits in each group.

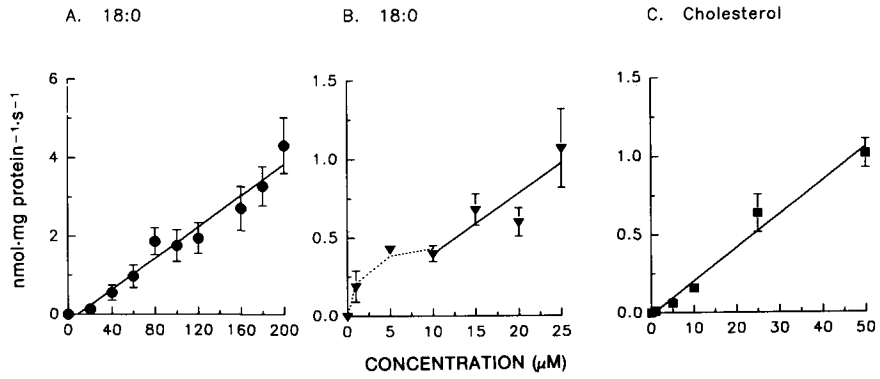

FIG. 2. Effect of varying concentration of 18:0 and cholesterol on uptake into brush border membrane (BBM) vesicles. The concentration of stearic acid (18:0) or cholesterol was varied, and the concentration of taurocholic acid was 2 mM (panel A) or 20 mM (panels B and C). The duration of incubation was 5 s. Each point represents the mean ± SEM of the results of quadruplicate measurements on BBM vesicles obtained from four rabbits in panels A and B and five rabbits in panel C.

via transfer from the micelle to the aqueous phase followed by permeation into the BBM. This "monomer" or "aqueous" hypothesis is based on an equilibrium between fatty acids that exist in monomeric form and in a micellar form (10). In solution there is a maximum concentration of monomers and a finite amount of lipid that can be solubilized into the micellar form. When the solubilizing agent has reached the total carrying capacity for the lipid, any further increase in the lipid concentration will result in the formation of an emulsion (22,23). The monomeric and micellar forms are present in the bulk phase in the intestinal lumen and in the unstirred water layer. As the monomeric form of the lipid permeates into the membrane, there is further partitioning of lipid from the micelle into the water phase.

A variation of the aqueous model, the "dissociation" model, suggests that fatty acids in a low pH microclimate just external to the BBM will be protonated, resulting in increased permeation through the lipid membrane (24). The presence of an acid microclimate has been demonstrated *in vitro* and *in vivo* (25,26). Stremmel *et al.* (7) showed that binding of oleate to rat jejunal microvillus membranes increased at pH values below 6.8 with a maximum at pH 4.0; at pH values above 8.0, there was a decrease in binding. Shiau (27) studied fatty acid uptake in everted rat jejunal sacs and demonstrated increased fatty acid uptake at lower pH values. He interpreted this data to suggest that the pH microclimate provides an environment in which fatty acid preferentially partitions from the micelle. Stearic acid is protonated in a low-pH environment and becomes more lipid soluble, whereas cholesterol is not protonated. Thus, the "dissociation" model may explain the uptake of stearic acid but not of cholesterol.

In addition to the passive permeation of lipids through the BBM, there may be a mediated component of this

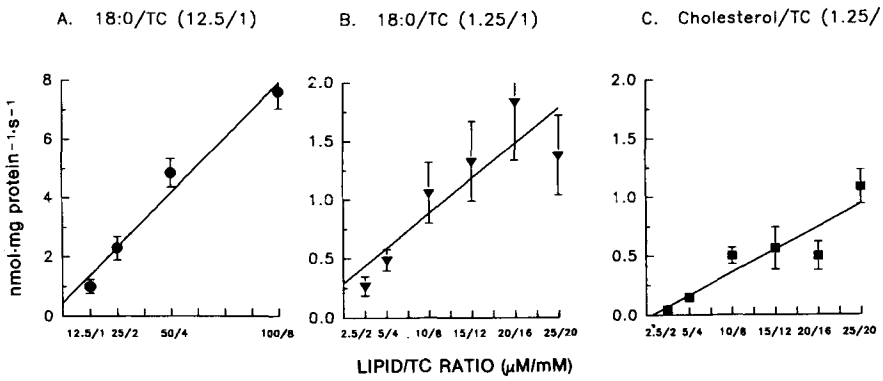

FIG. 3. Effect of increasing concentrations of both stearic acid (18:0) and taurocholic acid (TC), or cholesterol and TC, with constant ratio of stearic acid/TC or cholesterol/TC, on uptake of 18:0 or cholesterol into brush border membrane (BBM) vesicles. The duration of incubation was 5 s. The ratio of probe to TC was 12.5 μM/1 mM for 18:0 (panel A), or 1.25 μM/1 mM for 18:0 or cholesterol (panels B and C). Each point represents the mean ± SEM of the results of quadruplicate measurements on BBM vesicles obtained from four rabbits in panel A and eight rabbits in each of panels B and C.

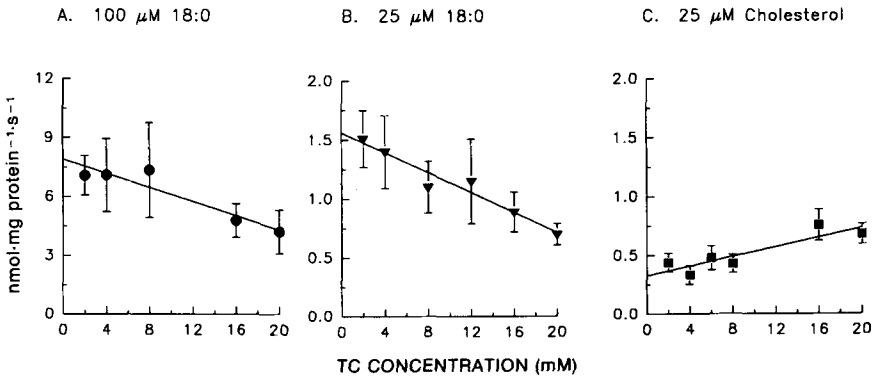

FIG. 4. Effect of varying concentrations of taurocholic acid (TC) on the uptake of 100 μM (A) or 25 μM (B) stearic acid or 25 μM cholesterol into brush border membrane (BBM) vesicles. The duration of incubation was 5 s. Each point represents the mean ± SEM of the results of quadruplicate measures on BBM vesicles obtained from five rabbits in panel A, six rabbits in panel B, and eight rabbits in panel C. The slope and correlation coefficient for panesl A, B, and C are −0.018, 0.937; −0.042, 0.972; and 0.020, 0.884, respectively.

process. Recent findings with linolenic acid uptake into rabbit jejunal BBMV demonstrated an uptake with a sodium-dependent "overshoot", suggesting that there may be a protein-mediated component involved in fatty acid uptake (15). This overshoot has not been confirmed (14), but this may be due to technical difficulties between the two studies. The use of the BBMV overcomes an effect of cytosolic fatty acid binding proteins (7) and of unstirred layers, and allows the comparison of the collision *vs.* the aqueous/dissociation models of lipid uptake. Under the conditions of low concentration of 18:0 and 20 mM TC, but not 2 mM TC, a curvilinear relationship was noted between 18:0 concentration and uptake (Fig. 2B). This suggests that under certain experimental conditions there may be a linear and a nonlinear component describing fatty acid uptake, in contrast to the single component describing cholesterol uptake under the same conditions (Fig. 2C). Caution must be used with this interpretation, however, since the regression line between 10–25 μM 18:0 intersects with the origin and since this curvilinear relationship was not obtained at equilibration (4 min or beyond).

The increasing uptake of 18:0 and cholesterol with increasing concentrations of both lipid and solubilizing TC (but with a constant ratio of lipid/TC) (Fig. 3) is suggestive of partitioning of fatty acid or cholesterol from the micelle directly into the BBMV (28), the so-called "collision" model. This same lipid/lipid model is supported by the finding of an increasing uptake of cholesterol with increasing concentrations of TC (Fig. 4C). In contrast, the reduction in the intake of 100 or 25 μM 18:0 with increasing concentrations of TC (Fig. 4A and 4B) supports, but does not prove the model of partitioning of the fatty acid from the micelle into an aqueous phase, and then into the BBM (28), the so-called aqueous/partitioning model. Again, one must be cautious with these interpretations, since the increasing cholesterol uptake with increasing concentrations of TC (Fig. 4C) may reflect increasing amounts of TC enhancing the solubility of cholesterol in the micelles; the fact that there is no derivation from the linear relation-

ship in the uptake of cholesterol above and below the critical micellar concentration of TC suggests that cholesterol solubility is present over the concentration range tested. On the other hand, the effect of increasing the amount of TC *vs.* 18:0 (Fig. 4A and 4B) might be explained by increasing competition of TC micelles for 18:0 *vs.* the BBMV. We do not have data on the activity or solubility of 18:0 in the different solutions, so that our data supports, but does not prove one or the other model. Notwithstanding, there appeared to be qualitative differences in the uptake of stearic acid and cholesterol (Figs. 3 and 4): the partitioning of cholesterol from the bile acid micelle into the BBM appears to be by way of the "collision" of the cholesterol into the membrane. In contrast, the uptake of stearic acid from the micelle into the BBM may be by both the collision and the aqueous/dissociation models, in which the acid microclimate may play an additional role. Furthermore, the curvilinear relationship between concentration and uptake of low concentrations of 18:0 solubilized in 20 mM TC, but a linear relationship for cholesterol under the same conditions further suggests that stearic acid and cholesterol may be taken up by different mechanisms from bile acid micelles into the intestinal BBM.

The uptake of D-glucose into BBMV is not affected by 2 mM TC, but is reduced by 20 mM TC (14,15). We were aware, therefore, of the possibility that the higher concentrations of TC might open the sealed vesicles and dissipate the sodium gradient. This might be one of several possible explanations for our not demonstrating an "overshoot" in the uptake of 18:0 or cholesterol (Fig. 1). However, it was at the condition of 20 mM TC that there was a curvilinear relationship between concentration and uptake of 18:0 (Fig. 2A), so that a possible leakiness of the vesicles due to TC could not explain the lack of a curvilinear concentration/uptake curve for cholesterol, or 18:0 at a lower concentration of 18:0 (Fig. 2A and 2C). Furthermore, any possible effect of TC on BBMV integrity did not produce a break in the linear relationship between the ratio of lipid/TC and uptake (Fig. 3), nor could the possibility of leakiness explain the qualitatively different relationship between the uptake of 18:0 or cholesterol when the concentration of TC is increased (Fig. 4). We recognize, of course, that the data suggesting different mechanisms for the uptake of stearic acid and cholesterol apply only to the special conditions of BBMV and may not necessarily apply to the intact intestine *in vivo*.

Effects of *trans* Fatty Acids on Lipid Accumulation in 3T3-L1 Cells

Kalpana Panigrahi[1] and **Joseph Sampugna***
Department of Chemistry and Biochemistry, University of Maryland, College Park, Maryland 20742

Previous work had shown that dietary *trans* fatty acids (*t*FA) resulted in decreased fat deposition in adipose tissue. This study was conducted to see if *t*FA influence lipid accumulation in Swiss mouse fibroblast 3T3-L1 cells, which are widely used as an adipocyte model. Cells were cultured in the presence of experimental or control growth media supplemented with fatty acids complexed to bovine serum albumin. Fatty acid compositions of experimental and control growth media were similar except that the octadecenoates in the control growth media were *cis* fatty acids, whereas those in the experimental media contained both *cis* and *trans* fatty acids. Cell-conditioned media and cellular lipids at the preadipocyte and differentiating adipocyte stages were analyzed. At both stages of development, less fat accumulated in cells cultured in the presence of *t*FA, due primarily to a decrease in the nonpolar lipid content of cells exposed to *t*FA, and linoleate to arachidonate ratios were higher in cells supplemented with *t*FA. Calculations comparing sums of saturated and monounsaturated fatty acids in cells at the differentiating adipocyte stage suggested that *t*FA may have replaced monounsaturated fatty acids in the nonpolar lipid fraction and saturated fatty acids in the polar lipid fraction. The results of these studies are in good agreement with the *in vivo* effects of *t*FA seen in previous work with mouse adipose tissue. It was concluded that the 3T3-L1 *in vitro* model is an appropriate system for further studies of *t*FA and lipid metabolism in adipose tissue.
***Lipids* 28, 1069–1074 (1993).**

Partially hydrogenated fats are widely used in processed food and constitute a significant proportion of dietary lipid (1–4). These fats contain a broad range of positional isomers (5) of *trans* fatty acids (*t*FA), whose average dietary intake in the United States has been estimated to be anywhere between 7.6 to 13.3 g per capita per day (6,7).

Considerable attention has been focused on *t*FA as they are not the normal end products of lipid metabolism in animal tissues (8,9). Despite the large number of studies that have been undertaken, questions regarding the nutritional significance (10–12) and the metabolic fate and effects of *t*FA remain to be answered. It is clear, however, that some of the physiological properties of *t*FA are substantially different from those of the corresponding *cis*-unsaturated isomers. Recent dietary studies (13–16) have demonstrated that in contrast to *cis*-monounsaturated FA, *t*FA raise low density lipoprotein (LDL) cholesterol, lower high density lipoprotein (HDL) cholesterol and raise levels of plasma lipoprotein (a). *In vitro* studies (17) have provided evidence that *cis*- and *trans*- octadecenoates have opposite effects on cholesteryl ester transfer protein activity. As a consequence of these recent studies, there is renewed interest in the possible role of *t*FA in health and disease.

Most studies involving metabolism of *t*FA have employed laboratory animals. In our laboratory, we have used the C57Bl/6J mouse as a model for dietary studies of *t*FA. Work with this model has demonstrated an ability of diets containing *t*FA to affect lipid accumulation in milk fat (18) and in adipose tissue (19). In these studies, diets containing *t*FA depressed the percentage of fat in mouse milk (18) and decreased epididymal fat pad weight, perirenal fat weight, epididymal fat cell size and the triacylglycerol-to-polar-lipid ratio in epididymal fat pads (19).

The present study was conducted to see if *t*FA affect lipid accumulation in 3T3-L1 cells, a subclone of Swiss mouse embryo 3T3 fibroblasts. The 3T3-L1 cell line was selected for study because it has been reported to differentiate into cells with biochemical and morphological characteristics of adipocytes (20–23), and it has been widely studied as a model for adipocyte differentiation (24–26) and the regulation of lipid metabolism (27–33).

MATERIALS AND METHODS

Materials. The 3T3-L1 cells were generously provided by Dr. Juan Calvo (National Institute of Health, Bethesda, MD). Low protein serum replacement (LPSR-1) (serum supplement), essentially FA-free bovine serum albumin (BSA), fetal calf serum (FCS), 3-isobutyl-1-methyl xanthine (MIX) and dexamethasone (DEX) were purchased from Sigma Chemical Co. (St. Louis, MO). Dulbecco's modified Eagle medium (DMEM) was purchased from Life Technologies (Gaithersburg, MD). Trypsin-Versene mixture, L-glutamine, penicillin–streptomycin–fungizone mixture, sodium pyruvate and nonessential amino acid mixture (NEAA) were purchased from Whittaker M.A. Bioproducts (Columbia, MD). All fats (cocoa butter, corn oil, olive oil and margarine) for the experiments were obtained locally. Authentic FA methyl ester (FAME) standards were purchased from Nu-Chek-Prep (Elysian, MN).

Preparation of FA-supplemented media. DMEM supplemented with 2 mM glutamine, 0.1 mM of each NEAA, 1 mM sodium pyruvate, 100 units of potassium penicillin G/mL, 100 μg streptomycin sulfate/mL and 0.25 μg fungizone/mL, 3% FCS and 2% LPSR-1 was designated as growth medium (GM). FA-supplemented media were prepared as described by Grunfled *et al.* (34). FA were derived by saponification of an experimental fat (which was obtained by decanting a melted corn oil margarine) and a control fat (which was made from a mixture of corn oil, olive oil and cocoa butter). After saponifying the fats in 0.6 N NaOH in methanol at 37°C for 1 h and removing the nonsaponifiable material by extracting the reaction mixture with 3 × 1 vol of hexane, the FA were obtained by acidifying the FA sodium salts with 6N HCl and extracting the mixture with hexane. Hexane was removed

Abbreviations: BSA, bovine serum albumin; cAMP, 3′,5′-cyclic adenosine monophosphate; CGM, control growth medium; DA, differentiating adipocytes; DEX, dexamethasone; DMEM, Dulbecco's modified Eagle medium; EGM, experimental growth medium; FAME, fatty acid methyl esters; FCS, fetal calf serum; GM, growth medium; HDL, high density lipoprotein; LDL, low density lipoprotein; LPSR-1, low protein serum replacement; MIX, 3-isobutyl-1-methyl xanthine; NEAA, nonessential amino acids; PA, preadipocytes; PBS, phosphate buffered saline; *t*FA, *trans* fatty acids; TLC, thin-layer chromatography; 3T3-L1, subclone of Swiss mouse embryo 3T3 fibroblasts.

by vacuum evaporation, and the FA were dissolved in ethanol. FA (0.2M) in ethanol were diluted 1:25 with phosphate buffered saline (PBS), pH 7.4, containing 20% BSA, and heated at 55°C for 45 min. The mixture was gently agitated until the solution was clear. The pH of the FA-albumin solution was then adjusted to 7.4 with NaOH. This procedure resulted in a noncovalent complex of FA to BSA in an FA/BSA molar ratio of no greater than 3:1. The FA-albumin complex was then diluted 1:10 with GM and then filter-sterilized. GM supplemented with control or experimental FA are referred to as control growth medium (CGM) and experimental growth medium (EGM), respectively.

Cell culture. Stock cultures of 3T3-L1 cells were maintained in 75-cm^2 culture flasks in GM. Cultures were maintained in an atmosphere of 5% CO_2, 95% air at 37°C and were fed with 12 mL of medium every four days. Cell monolayers at near confluence were trypsinized (1% Trypsin-Versin at 37°C for 30 s), split 1:4, supplemented with 12 mL of either CGM or EGM, and allowed to grow for 96 h to reach confluence. Confluent cells cultured in the presence of CGM and EGM were designated as preadipocytes (PA). The day cells reached confluence in the presence of CGM and EGM was referred to as Day 0, with respect to differentiating adipocytes (DA). On Day 0, cell-conditioned media were removed, and 12 mL of CGM or EGM containing 0.5 mM MIX and 0.25 μM DEX was added to stimulate differentiation as described by Rubin *et al.* (35). After 48 h (Day 2), cell-conditioned media were removed, and the cells were allowed to grow in 12 mL of fresh CGM or EGM for an additional 3 d (Day 5). The Day 5 cells are referred to as DA.

Lipid extraction and FA analysis. Cell-conditioned media on Days 0, 2 and 5 were cleared of cells by centrifugation at 200 × *g* for 3 min and lyophilized. Media were extracted with chloroform/methanol as described below. Cell monolayers were washed three times with cold PBS, pH 7.4, and harvested by centrifugation, after using a rubber policeman to help detach them from the culture flask. Each cell pellet was resuspended in 1 mL of PBS and extracted with chloroform/methanol (2:1, vol/vol) containing butylated hydroxytoluene (36). Prior to analysis the total cellular lipid was separated into a nonpolar and polar lipid fraction by thin-layer chromatography (TLC) on Silica Gel G plates using diethyl ether as the mobile phase. After adding triheptadecanoin as an internal standard, the FA and fatty acyl groups in the media and cellular polar and nonpolar lipids were converted to FAME and analyzed by gas-liquid chromatography, using a glass capillary column coated with SP-2340 in a Hewlett-Packard (Avondale, PA) model 5840 chromatograph essentially as described previously (37). This involved transesterification with methanolic HCl, purification of the FAME on silicic acid TLC plates, identification of FAME by comparison of retention times with those of known standards and quantification of FAME, using appropriate response and correction factors as described elsewhere (37). The *t*-test was used to analyze the results using the Statworks (Macintosh) programs.

RESULTS

In preliminary work, cells grown in the presence of CGM and EGM were analyzed for protein by the method of Lowry *et al.* (38) and counted in a hemocytometer. Regardless of whether cells were grown in the presence of CGM or EGM, they contained similar amounts of protein and yielded similar cell counts. The protein values ranged from 2250 to 2575 μg/flask, and cell numbers were between 12 × 10^5 and 14 × 10^5 per flask.

The FA contents and compositions, as FAME, of 12 mL each of the CGM and EGM are given in Table 1. In general, the values in experimental and control media were similar, except that all of the octadecenoate fraction was *cis* in the CGM whereas about 40% of this fraction was *t*FA in the EGM. Compared to the CGM, the EGM contained significantly ($P < 0.05$) more 18:0 and slightly more total FA per mL of growth medium.

The content and composition of FA, as FAME, in polar lipids of control and experimental cells at the PA and the DA stages are summarized in Table 2. Similar data for nonpolar lipid are shown in Table 3. The *trans*-18:1 isomers (18:1*t*) were readily incorporated from the EGM into the nonpolar and polar lipid fractions isolated from the experimental cells at both the PA and DA stages of development. Small amounts of *trans* 16:1 (16:1*t*) were also observed in the cells exposed to the EGM, providing evidence that these cells were capable of at least partial oxidation of 18:1*t*. The total content of *t*FA, as well as that of other FA, was higher in the DA compared to the PA.

Compared to control cells, there was less arachidonic acid (20:4n-6) in experimental cells on either an absolute or relative basis. This was observed in both polar (Table 2) and nonpolar lipids (Table 3) and at both stages of development. Ratios of 18:2n-6/20:4n-6 were calculated, and are included in Tables 2 and 3. The ratios were significantly higher ($P < 0.05$) in experimental cells in both lipid classes for both PA and DA.

Although the EGM contained more 18:0 than CGM (Table 1), cells grown in the presence of EGM did not contain more 18:0 than the cells grown in the presence of CGM. In fact, in experimental cells, less 18:0 was observed in polar lipids of DA (Table 2) as well as in nonpolar lipids of both PA and DA (Table 3). To a certain extent, the lower amount of 18:0 in the experimental cells appeared to be compensated for by the presence of *t*FA. The extent to which *t*FA may have replaced 18:0 was evaluated by comparing the sums of saturated and monounsaturated FA

Sums of Saturated and Monounsaturated Fatty Acids in Polar and Nonpolar Lipid[a]

Fatty acids	Polar				Nonpolar			
	CPA	EPA	CDA	EDA	CPA	EPA	CDA	EDA
Total saturated	42 ± 3	40 ± 5	47 ± 6	36 ± 4[b]	35 ± 3	34 ± 5	31 ± 5	29 ± 4
Total saturated + *t*FA	42 ± 3	49 ± 5	47 ± 6	46 ± 4	35 ± 3	46 ± 4[c]	31 ± 5	48 ± 6[d]
Total monounsaturated	23 ± 6	19 ± 5	18 ± 3	18 ± 3	36 ± 4	21 ± 3[e]	32 ± 6	21 ± 4[f]
Total monounsaturated + *t*FA	23 ± 6	28 ± 4	18 ± 3	28 ± 4[g]	36 ± 4	33 ± 5	32 ± 6	40 ± 2

[a]Values are means ± SEM of wt% values for fatty acids given in Tables 2 and 3; CPA, control preadipocytes; EPA, experimental preadipocytes; CDA, control differentiating adipocytes; EDA, experimental differentiating adipocytes; *t*FA, *trans* fatty acids.
[b-g]Denote statistically significant differences between control and experimental cells at $P < 0.05$ when comparisons were made between CPA and EPA and between CDA and EDA.

in control and experimental cells, alternatively including the *t*FA as either saturated or monounsaturated FA (Table 4). The weight percent data were used to calculate these values because the contents of FA in control and experimental cells were significantly different in the nonpolar lipid fractions (see Fig. 1, discussed later). In the polar lipids of DA, but not of PA, similar levels of saturated and monounsaturated FA were found in control and experimental cells when *t*FA were included as saturated FA. However, this was not seen in nonpolar lipids, in which case the differences in the sums of saturated and monounsaturated FA became significantly different ($P < 0.05$) when *t*FA were included as saturated FA.

Except for *t*FA, and possibly 18:2n-6 in polar lipids, there was a tendency for all FA to be present in lower amounts in experimental cells. Comparisons of the sums of FA found in PA and DA cultured in the presence of EGM and CGM (Fig. 1) clearly revealed that, compared to control cells, experimental cells contained significantly ($P < 0.05$) lower amounts of nonpolar lipid. Although the polar lipid contents of control and experimental cells were similar, the total lipid obtained by adding the nonpolar and polar lipid contents remained significantly ($P < 0.05$) different in both the PA (178 μg *vs.* 155 μg for control and experimental cells, respectively) and the DA (271 μg *vs.* 212 μg in control and experimental cells, respectively).

The contents and compositions of FA, as FAME, in control and experimental conditioned media on Days 0, 2 and 5 were determined and summed to obtain information on the FA remaining in the media from the 36 mL of original CGM and EGM used to culture the DA in these studies. These data are summarized in Table 5. As was observed for the original media, there were slightly more total FA in the experimental conditioned media. On a weight percent basis the distribution among the major FA was generally similar to that observed in the original growth media (Table 1). However, the conditioned media contained some FA that were not observed or were present in much lower proportions in the original growth media. These included 16:1*t* in the experimental conditioned

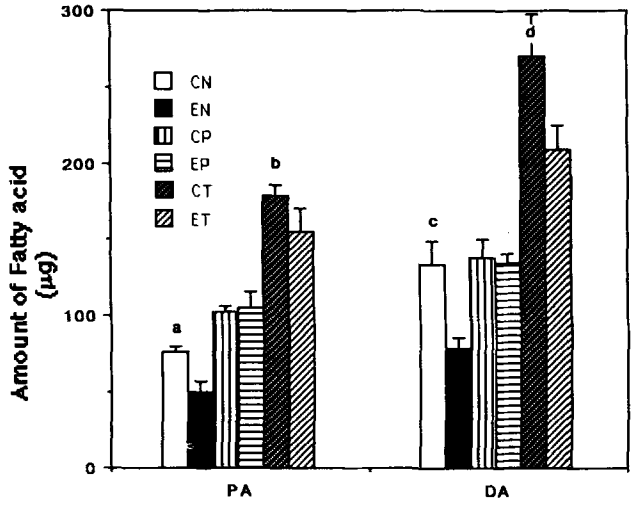

FIG. 1. Total fatty acids in polar and nonpolar lipids of 3T3-L1 cells cultured in the presence or absence of *trans* fatty acids. Bars represent means ± SEM for three independent determinations of total fatty acids/flask in polar, nonpolar and total lipids of preadipocytes (PA) and differentiating adipocytes (DA). CN, control nonpolar lipid; EN, experimental nonpolar lipid; CP, control polar lipid; EP, experimental polar lipid; CT, control total lipid = CN + CP; and ET, experimental total lipid = EN + EP. Significant differences ($P < 0.05$) between control and experimental cells are indicated by the letters a, b, c and d.

TABLE 5

Fatty Acid Content and Composition of Conditioned Media[a]

medium and 14:0 as well as 16:1*c* in both control and experimental conditioned media. Interestingly, these FA were observed in conditioned media in greater amounts than were found in the cultured cells. The presence of significant amounts of cellular FA in the conditioned media may have resulted from efflux of cellular lipids.

DISCUSSION

The 3T3-L1 cells readily incorporated exogenous FA, including *t*FA. Compared to PA, more *t*FA were incorporated in the polar and nonpolar lipids of DA, reflecting the longer contact of DA with the growth media. In polar lipids, *t*FA appeared to be incorporated at the expense of saturated FA. In particular, *t*FA tended to replace 18:0. This inverse relationship between *t*FA and saturated FA may be related to the similarity of their properties. Compared to *cis* FA, both *t*FA and saturated FA are linear molecules with relatively high melting points. Other similarities between *t*FA and saturated FA have been reported. These include the preferential incorporation of both types of FA into the 1-acyl position of phospholipids *in vivo* (8), the similar reactivities of these FA in acyl transferase reactions *in vitro* (9) and the similar responses to dietary intake of *t*FA or of saturated FA in raising the plasma level of LDL cholesterol (13,14) in humans.

Nevertheless, *t*FA have unique properties and should not be arbitrarily categorized together with saturated FA. Despite the apparently similar effects of *t*FA and saturated FA on LDL cholesterol, their effects on HDL cholesterol were reported (13) to be different. Unlike dietary *t*FA which decreased HDL cholesterol, saturated FA increased the level of this lipoprotein fraction. In our studies (Table 4), whereas *t*FA replaced saturated FA in the polar lipid fraction, this was not the case for the nonpolar lipid fraction, in which case *t*FA appeared to replace monounsaturated FA. A similar behavior of *t*FA was observed in studies of epididymal fat pads in C57Bl/6J mice (19). However, the functional significance, if any, of these biochemical observations cannot be ascertained from these studies.

Comparisons of FA in control and experimental cells suggested that *t*FA may have altered the metabolism of n-6 FA in experimental cells. The lower content of 20:4n-6 and higher ratio of 18:2n-6/20:4n-6 observed in the experimental cells is consistent with an effect of *t*FA on the conversion of 18:2n-6 to 20:4n-6; however, differences in the uptake of these FA or preferential catabolism or efflux of 20:4n-6 could also account for these observations. We are not aware of any reports of preferential uptake, catabolism or efflux of n-6 FA in tissues exposed to *t*FA. In contrast, *t*FA have been reported to inhibit desaturases in liver tissue (39) as well as in cell culture (40,41). In the cell culture studies with human skin fibroblasts, Δ9-18:1*t* was reported to be a potent inhibitor of Δ6 (40) and Δ5 (41) desaturase activities, both of which are important in the conversion of 18:2n-6 to 20:4n-6.

One of the most striking observations in this study was that, compared to cells exposed to CGM, 3T3-L1 cells exposed to EGM contained less total FA in the nonpolar lipid fraction. In contrast, the total FA level in the polar lipid fraction was similar in control and experimental cells. The similarity in polar lipid content and the difference in nonpolar lipid content suggested that fat accumulation, rather than the number of cells, may have been affected by the *t*FA in the EGM. This was further supported by the finding, in preliminary studies, that there were comparable numbers of cells and amounts of protein in both control and experimental flasks. The reason for the difference in fat accumulation is not known, but a lower availability of FA for experimental cells compared to control cells seems unlikely as a comparison of total FA values for CGM and EGM (Table 1) suggests that the experimental cells were exposed to a slightly higher concentration of FA in the growth medium than were the control cells.

It can be calculated that the experimental cells should have incorporated more FA than the control cells by comparing the data in Tables 1 and 5. The DA were exposed to the levels of FA shown in Table 1 on three occasions. Thus, on the average, control cells were exposed to 7356 μg, and experimental cells were exposed to 8556 μg of total FA. Since the average values for the total FA in the total conditioned media (Table 5) were 5766 and 6057 μg for control and experimental cells, respectively, the average amount taken up by control and experimental cells should have been 1590 and 2499 μg, respectively. These calculations suggest that uptake of FA was actually more, rather than less, in the experimental cells compared to the control cells, even though the resulting lipid of cells cultured in EGM was less than that of cells grown in CGM. Considering the total lipid available in the growth media, the lipid remaining in the conditioned media and the lipid accumulated in control DA (271 μg) and experimental DA (212 μg), more total lipid was unaccounted for in experimental cells (27%) than in the control cells (18%). These findings suggest that there was greater catabolism of FA in cells exposed to the EGM.

Compared to *cis* FA, many *t*FA have been reported to be less well oxidized by mitochondria (42–44). Nevertheless, the presence of significant amounts of 16:1*t* in the experimental conditioned media (Table 5) and in the experimental cells (Tables 2 and 3) provides evidence that these cells were capable of at least partially oxidizing 18:1*t*. Chain shortening of FA that are poorly oxidized by mitochondria has been postulated (42,45,46) to be an important function of the β-oxidation pathway in peroxisomes. Moreover, *t*FA appear to be capable of inducing peroxisomal proliferation. In studies with liver tissue isolated from C57Bl/6J mice (47), it was found that the number of peroxisomes and the level of cyanide-insensitive β-oxidation activity could be increased by dietary *t*FA. Others (42,48–50) have reported that a variety of dietary fats can cause induction of peroxisomal β-oxidation. It is possible that the decreased accumulation of lipid observed in the experimental cells in this study may have resulted from induction of peroxisomal β-oxidation by the *t*FA in the EGM.

Decreased accumulation of lipid in 3T3-L1 cells has been observed previously (20). In that study (20), the cells were treated with dibutyryl cAMP and epinephrine over a period of two weeks, and the reduction in lipid accumulation was attributed to increased activity of hormone sensitive lipase. Hormone sensitive lipase is unique to adipose tissue where stored triacylglycerols are degraded to glycerol and free fatty acids by this enzyme (51). If *t*FA increase peroxisomal β-oxidation activity in 3T3-L1 cells, it is likely that hormone-sensitive lipase may also be affected.

Effect of Propylthiouracil-Induced Hypothyroidism on Membranes of Adult Rat Brain

S. Salvati*, L. Malvezzi Campeggi, M. Sorcini, A. Olivieri and **A. Di Biase**
Istituto Superiore di Sanità, Rome, Italy

The effect of hypothyroidism on the lipid composition of myelin and synaptosomes isolated from adult rat brain was investigated. The animals were made hypothyroid by adding 0.05% propyl-2-thiouracil to their drinking water for four weeks. This pathological state resulted in a significant increase in the relative percentage of choline glycerophospholipids in synaptosomes with a concomitant decrease in ethanolamine glycerophospholipids as compared to controls. In myelin, hypothyroidism significantly influenced only the relative percentage of sulfatides. The effect of the hypothyroid state on mature brain was also reflected in changes in the membrane fatty acid composition. Myelin and synaptosomes showed an increase in arachidonic (20:4) and eicosatrienoic (20:3) acids and an increase in the fatty acid unsaturation index. Furthermore, the 20:4/20:3 and 20:3/18:2 ratios were lower and higher, respectively, in treated animals. The data indicate that hypothyroidism affects the lipid composition of synaptosomes and myelin even though the effects were less pronounced in myelin. The lipid changes observed in hypothyroidism may be of physiological significance, as it is well known that lipid composition modulates various membrane-bound enzymes, transporters and receptors. *Lipids 28,* **1075–1078 (1993).**

That a relationship exists between lipid metabolism and the thyroid state was first noted in 1931 by Wesson and Burr (1). Since then, many investigators have reported that hypothyroidism affects lipid content and composition of membranes isolated from different rat tissues and subcellular fractions (2–5). The fatty acid changes observed were interpreted as being consistent with a modulation of the activity of enzymes involved in their synthesis, desaturation and elongation (6–10). The mechanism responsible for producing the changes in membrane phospholipid (PL) composition is still not known.

Brain is an important target of thyroid hormones, with striking effects occurring during the development of the central nervous system (CNS). Hypothyroidism induced during the pre- and postnatal periods causes biochemical, morphological and behavioral changes (11,12). Alterations in brain lipid composition could be responsible for the observed changes in the activity of several synthesizing and degrading neurotransmitter enzymes (11).

The effect of hypothyroidism on mature brain is not well understood. A number of reports have recently indicated that thyroid hormone deficiency affects brain function in the adult rat (13–15), but data on biochemical changes were not reported.

In order to elucidate the effects of hypothyroidism on brain membranes, we studied the lipid composition of CNS myelin and of synaptosomes in adult rats with hypothyroidism induced by propylthiouracil (PTU).

MATERIALS AND METHODS

Animals. Male Sprague-Dawley rats (Charles River, Wilmington, MA), weighing 200–210 g at the beginning of the experiments, were used. They were fed a standard diet *ad libitum.* The animals were made hypothyroid (HO) by adding PTU (0.05% wt/vol) to their drinking water for four weeks (16). They were then sacrificed, and the brains were quickly removed. Adequacy of HO state was assessed by measuring serum 3,3′,5,5′-tetraiodothyronine (T4) and 3,3′,5-triiodothyronine (T3) levels by radioimmunoassay (Serono Biodata, Milano, Italy). The PTU treatment led to a decrease in circulating mean T4 levels (21.6 ± 2.9 ng/mL), as compared with mean T4 value in euthyroid (EU) rats (88.5 ± 17.9 ng/mL; $P < 0.001$). A similar tendency was observed for the serum T3 levels. The respective mean values for T4 and T3 for six independent experiments were: 0.41 ± 0.06 ng/mL in HO and 0.95 ± 0.16 ng/mL in EU animals ($P < 0.01$).

Subcellular fractions. The brains were homogenized with a Dounce homogenizer in 0.32 M sucrose (5% wt/vol), and myelin was isolated by sucrose density gradient centrifugation according to Norton and Poduslo (17). Synaptosomes were prepared using a Percoll density gradient as suggested by Nagy and Delgado-Escuanta (18). The purity of both subcellular fractions was checked by electron microscopy. The membranes were submitted to osmotic shock with distilled water, pelleted by centrifugation, lyophilized and stored at −20°C.

Lipid analysis. Lipids were extracted from membranes with 20 vol of chloroform/methanol (2:1, vol/vol) according to Folch *et al.* (19). Lipids were separated into classes by one-dimensional high-performance thin-layer chromatography. In our solvent system, plasmalogens are not separated from the corresponding diacylglycerophospholipids. Lipids were quantified by *in situ* laser densitometry (model XL; Produckker, Bromma, Sweden) after staining with specific reagents for PL, cholesterol and galactolipids, as previously described (20). Peak areas were measured with an internal digital integrator. Lipids were analyzed for fatty acid composition by gas–liquid chromatography (GLC). The fatty acid methyl esters (FAME) were prepared by transmethylation with methanolic HCl (Supelco, Inc., Bellefonte, PA) at 70°C for 2 h and analyzed using a Hewlett-Packard HP 5890A gas chromatograph (Hewlett-Packard, Palo Alto, CA) equipped with a flame-ionization detector. Dimethylacetals derived from plasmalogens during the transmethylation procedure did not interfere with fatty acid analysis. This was ascertained on some samples when the fatty acid composition obtained was the same whether dimethylacetals were

Abbreviations: CB, cerebrosides not containing hydroxy fatty acids; CBOH, cerebrosides containing hydroxy fatty acids; CPL, choline glycerophospholipids; CNS, central nervous system; EPL, ethanolamine glycerophospholipids; EU, euthyroid; FAME, fatty acid methyl ester; GLC, gas–liquid chromatography; HO, hypothyroid; PL, phospholipids; PTU, propylthiouracil; PUFA, polyunsaturated fatty acids; T3, triiodothyronine; T4, tetraiodothyronine.

removed or not. Fatty acid composition was analyzed by GLC of the FAME at 260°C on a fused silica capillary column of Supelcowax 30 m × 0.53 mm i.d. (Supelco) using helium as carrier gas (flow rate 1.3 mL/min). Fatty acids were identified by comparison with commercial standards [polyunsaturated fatty acids (PUFA) 1 and PUFA 2; Supelco]. Quantitative data were derived using an integrator (Hewlett-Packard 3396A) and a standard mixture of FAME to establish the response factors for the components identified.

Statistical analysis. All results are expressed as means with standard deviations (SD). The statistical significance of mean differences was determined by Student's *t*-test.

RESULTS

The effect of PTU-induced hypothyroidism on the lipid composition of myelin is shown in Table 1. The relative percentage of each class of glycolipids was lower in the treated rats than in the controls. However, only the decrease in sulfatides was statistically significant. The ratio of hydroxy fatty acid containing cerebrosides (CBOH) to hydroxy fatty acid-free cerebrosides (CB) was increased in hypothyroidism (20%), mainly as the result of a more pronounced decrease in CB as compared to CBOH.

Table 2 shows the effect of thyroid hormone deficiency on the lipid composition of synaptosomes. A significant increase in the percentage of the choline glycerophospholipids (CPL) with a concomitant decrease in the ethanolamine glycerophospholipids (EPL) was observed in treated animals compared with controls. No differences were observed between the two groups in the other lipid classes.

The effect of PTU-induced hypothyroidism was also reflected in changes in myelin fatty acid composition. As shown in Table 3, the percentage of total monounsaturated fatty acids, which are characteristic fatty acids of myelin, is significantly lower in HO than in EU rats, mainly due to the decrease in 24:1 and 20:1. Total saturated fatty acids were not affected by the treatment, even though a significant decrease in 20:0 and 24:0 was observed. PUFA increased in both types of membranes of the treated rats. This increase was more pronounced in synaptosomes with a consequent elevation of the unsaturation index (Table 4). Because 20:3 increased more in synaptosomal membranes than did the other PUFA (50%), the 20:4/20:3 ratio decreased while the 20:3/18:2 ratio increased.

DISCUSSION

PTU-induced hypothyroidism affects the lipid composition both in myelin and synaptosomes from adult rat brain, even though the changes are more pronounced in the synaptosomes than in myelin. Synaptosomes of the HO rats show a significant increase in CPL with a concomitant decrease in EPL. Similar changes were shown to occur in heart mitochondria by Paradies and Ruggiero

[b]$P < 0.005$.
[c]$P < 0.05$.
[d]UI, unsaturation index, which is the sum of the percentage of each unsaturated fatty acid multiplied by the number of double bonds.

(3). By contrast, the PL composition of colonic apical plasma and erythrocyte membranes (2) were not significantly altered in the HO state. As the changes vary widely between cells and subfractions from various tissues, this may suggest that different membranes respond to thyroid hormone deficiency differently, depending on their function.

CPL can be synthesized by methylation of EPL (21,22), as well as by the cytidine diphosphocholine pathway (23). In brain the major route is the latter (*de novo* route); nevertheless, an increase in methyltransferase activity was observed in membranes rich in PUFA (24). Because a significant increase of PUFA is observed in synaptosomes of HO rats, we could suggest that this route could be operative in treated animals, resulting in an increase in CPL. Moreover, a higher percentage of PUFA may increase membrane fluidity. It is known that the successive methylation of EPL increases membrane fluidity, reducing its viscosity (21). On the other hand, modulation of insulin receptors and catecholamine has been shown to occur in hypo- and hyperthyroid rats (15). Recently, some changes in neurotransmitter metabolic activity were also observed in brain of hypothyroid adult rat (25,26). Therefore, it is tempting to suggest that one of the factors responsible for these changes could be the changes that occur in the lipid environment.

Our data show that in adult brain the thyroid hormones are also involved in PUFA metabolism, probably by modulating desaturase activities, as is known for other tissues (9). In synaptosomes the relative percentages of 20:3 and 20:4 are higher in HO than in EU rats; the increase in the 20:3/18:2 ratio and the decrease in the 20:4/20:3 ratio would indicate that Δ6 and Δ5 desaturases are affected differently by thyroid hormone deficiency. However, some factors other than desaturation activities may influence the fatty acid composition of HO rats, such as fatty acid synthesis, membrane lipid degradation and transport of fatty acids from one site to another.

The myelin membrane is more affected by thyroid hormone deficiency in the developmental period than at adult age. This different response could be due to regional differences in the distribution of receptors in adult brain. Their highest concentration was found in neuronal cell-rich regions, such as the amygdala, the hippocampus and the cortex, whereas the lowest concentration was found in the brain stem and in the cerebellum, which are myelin and oligodendroglial cell-rich regions (27–29). However, the decrease in relative monoenoic acid and sulfatide levels could affect membrane structural integrity and stability because these lipid components play an important role in maintaining myelin packing (30).

In conclusion, our data indicate that hypothyroidism affects the lipid composition of membranes isolated from adult rat brain, with synaptosomes being more susceptible than myelin.

Action of the New Hypolipidemic Agent Lifibrol (K12.148) on Lipid Homeostasis in Normal Rats: Plasma Lipids, Hepatic Sterologenesis, and the Fate of Injected [^{14}C]Acetate

Frank P. Bell* and **Lori C. St. John**
Upjohn Laboratories, Kalamazoo, Michigan 49001

Lifibrol, a new hypocholesterolemic agent with activity in humans, was examined in normal rats for its short-term and long-term effects on lipid homeostasis. Cholesterol (Chol) synthesis inhibition by lifibrol was demonstrated *in vitro* in liver minces from normal rats by following [1-^{14}C]acetate ([^{14}C]Ac) and DL-[2-^{14}C]mevalonate ([^{14}C]-MVA) incorporation into [^{14}C]Chol. When administered at 50 mg/kg/d, lifibrol reduced plasma total Chol and triglycerides (TG) ($P < 0.001$) within 24 h. The Chol reduction was largely a result of reduction of low density and very low density lipoprotein cholesterol (LDL + VLDL-chol) and a smaller decrease in high density lipoprotein cholesterol (HDL-chol). After 10 d, however, a rebound effect emerged, and after 41 d, plasma Chol, LDL + VLDL-chol, and HDL-chol were restored. In contrast, plasma TG remained at reduced levels ($P < 0.01$). The rebound is attributed to counter-regulation of hepatic sterologenesis that was assessed both *ex vivo* and *in vivo*. The *ex vivo* incorporation of [^{14}C]MVA and [^{14}C]octanoate into [^{14}C]Chol and total digitonin-precipitable [^{14}C]sterols ([^{14}C]DPS) in liver minces was increased 2- and 6-fold, respectively, in rats treated 6 d at 50 mg/kg. Similarly, *in vivo* incorporation of intraperitoneally injected [^{14}C]Ac into hepatic [^{14}C]DPS (2 h post-injection) was increased 2- to 5-fold at 50 mg/kg, and evidence for increased sterologenesis in nonhepatic tissue was also obtained. The increased hepatic sterologenesis, evident within 48 h, persisted out to 41 d of treatment by which time increases ($P < 0.002$) in hepatic Chol and carcass total sterols were observed. Additionally, incorporation of injected [^{14}C]Ac into hepatic [^{14}C]TG was inhibited 60% by lifibrol ($P < 0.001$), and the appearance of [^{14}C]TG in plasma was reduced. Circulating free [^{14}C]fatty acids ([^{14}C]FFA) were also reduced, but hepatic [^{14}C]FFA synthesis was unaffected, thus suggesting either a lesser release of newly formed FFA from liver or an enhanced removal from plasma.
***Lipids* 28, 1079–1085 (1993).**

Lifibrol is a new hypolipidemic agent that reduces plasma total cholesterol (Chol) and low density lipoprotein cholesterol (LDL-chol) in experimental animals and humans (1–4), and in some species reduces plasma triglyceride (TG) levels also (1,3). Based upon *in vitro* studies in supernatants of rat liver homogenates, the putative mechanism of the Chol-lowering action of lifibrol is considered to be inhibition of hepatic Chol biosynthesis between acetate and β-hydroxy-β-methylglutaryl-CoA (HMG-CoA) (1,2,5). In marmosets (1) and pigs (3) treated with lifibrol for 3 (40 and 100 mg/kg) or 6 (12.5, 25, 50 and 100 mg/kg) mon, respectively, dose-related plasma Chol reductions were sustained with no evidence for any development of counter-regulatory responses. Likewise, no indication of plasma Chol rebound was observed in human volunteers (mean % change from baseline) treated for 2 wk at up to 900 mg/d (4). However, in rats whose plasma Chol was lowered during a three-day treatment at 100 mg/kg (2), the incorporation of [1-^{14}C]acetate ([^{14}C]Ac) into digitonin-precipitable sterols was increased 3.7 times in homogenates of their livers. Since the stimulation of sterol synthesis could alter the long-range response, the experiments presented here were designed to provide a comprehensive examination of the response of rats to lifibrol over a time-course that extended to 41 d. Measurements were made of plasma lipid/lipoprotein levels [TG, total Chol, high density lipoprotein cholesterol (HDL-chol), and low density plus very low density lipoprotein cholesterol (LDL + VLDL-chol)], and hepatic sterologenesis was evaluated in liver minces *in vitro* and *ex vivo* using DL-[2-^{14}C]mevalonic acid ([^{14}C]MVA) and [^{14}C]Ac or [1-^{14}C]octanoate as precursors. Additionally, *in vivo* sterologenesis and other aspects of lipogenesis in liver and other organs were evaluated by following the fate of intraperitoneally injected [^{14}C]Ac 2h post-injection in 6 and 41 day-treated rats. The results indicate that lifibrol at 50 mg/kg significantly reduces plasma Chol and TG within 24 h of initiating treatment. However, counter-regulation sets in by 2 to 3 d as evidenced by 4-fold increases in hepatic sterologenesis that eventually lead to rebound of plasma Chol to normal levels or above. By contrast, plasma TG levels remain suppressed as long as drug is provided and are paralleled by decreased incorporation of [^{14}C]Ac into hepatic TG2h after intraperitoneal injection of the tracer. Evidence is also presented that liver and carcass sterol concentrations are significantly elevated in rats receiving 50 mg/kg/d for 41 d.

MATERIALS AND METHODS

Chemicals and supplies. The following materials were purchased from New England Research Products (Boston, MA): [^{14}C]Ac, sodium salt, sp. act. 56.0 Ci/mol; DL-[^{14}C]MVA, DBED salt, sp. act. 48.6 Ci/mol; [1-^{14}C]octanoic acid, sodium salt, 58.0 Ci/mol; Protosol tissue and gel solubilizer (NEF-935); and Liquefluor liquid scintillation counting cocktail (NEF-903). Caprylic acid, sodium salt (sodium octanoate) and digitonin were purchased from Sigma Chemical Company (St. Louis, MO). Silica Gel G-coated glass plates used for thin-layer chromatography (Sil G-25, 20 × 20 cm) were obtained from Brinkman Instruments Co. (Westbury, NY). Lifibrol (K12.148, 4-[4′-*tert*-butylphenyl]-1-[4′-carboxyphenoxy]-2-

Abbreviations: ACAT, acyl-CoA:cholesterol acyltransferase (EC 2.3.1.26); Chol, cholesterol; HDL, high density lipoprotein; HMG-CoA, β-hydroxy-β-methylglutaryl-CoA; LCAT, lecithin:cholesterol acyltransferase (EC 2.3.1.42); LDL, low density lipoprotein, TG, triglyceride; VLDL, very low density lipoprotein; [^{14}C]Ac, [1-^{14}C]acetic acid, sodium salt; [^{14}C]DPS, digitonin-precipitable [^{14}C]sterols; [^{14}C]FFA, free [^{14}C]fatty acid, [^{14}C]MVA, DL-[2-^{14}C]mevalonic acid, DBED salt.

butanol) was obtained from Klinge Pharma (Munich, Germany).

Animals and diets. Male TUC-Sprague-Dawley rats (Charles River Laboratories, Kalamazoo, MI) were used throughout the studies. The rats were individually housed in wire-bottom cages with free access to water and feed. All rats received Purina Rodent Chow No. 5002 (Purina Mills, St. Louis, MO) during a 7-d acclimation and were then continued on the diet or the diet admixed with lifibrol at a level calculated to provide the desired dose of drug based upon average daily feed consumption. Lifibrol administration had no negative effects on growth of the animals. In the longest study (41 d), terminal weights in the control group and 10 and 50 mg/kg lifibrol-treated groups were 391 ± 28, 390 ± 33 and 383 ± 25 g, respectively.

Injection and blood sampling procedures. All intraperitoneal injections and blood sampling were performed under diethyl ether anesthesia. Blood was drawn *via* cardiac puncture into heparinized syringes and placed on crushed ice for approximately 1 h until centrifugation at 10°C to separate the plasma.

Plasma lipid measurements. Plasma lipid measurements (total Chol, TG and HDL-chol) were performed with an Ektachem DT60 analyzer (Eastman Kodak, Rochester, NY) (6,7) and were completed within 2 h of plasma preparation. LDL + VLDL-chol was determined as the difference between total Chol and HDL-chol.

Lipid extraction from plasma and tissue samples. Plasma and tissue total lipid extracts were prepared by the method of Folch *et al.* (8) employing chloroform/methanol mixtures. The nonsaponifiable lipid fractions from liver and other tissues were obtained by *n*-hexane extraction following digestion/saponification of the samples for 45 min at 60°C in the presence of alcoholic KOH as detailed previously (9). Digitonin-precipitable sterols were obtained by redissolving nonsaponifiable lipid extracts in acetone/ethanol (1:1, vol/vol) and treating with digitonin for 18 h (10).

Thin-layer chromatography of total lipid extracts and nonsaponifiable lipid extracts. All thin-layer chromatography employed silica Gel G-coated glass plates that were developed with a running solvent consisting of *n*-hexane/diethyl ether/glacial acetic acid (146:50:4, by vol). This system was used to fractionate total lipid extracts into the various lipid classes (11) and to isolate Chol, lanosterol and squalene from nonsaponifiable lipid extracts (11).

Assay of sample radioactivity. In all instances, radioactivity was assayed in a liquid scintillation spectrometer (Beckman Instruments Inc., Irvine, CA; Model LS9800) in glass vials using 15 mL of Liquefluor (toluene-based) counting cocktail. Lipids isolated by thin-layer chromatography were scraped directly from the chromatoplates into the fluid-filled vials for assay (11). Digitonin-precipitable sterols were dissolved in pyridine prior to the addition of counting cocktail (12). Quench corrections were made using the external standardization method and counting efficiency for ^{14}C averaged 94%.

In vitro *and* ex vivo *hepatic sterologenesis studies.* The effect of lifibrol on hepatic sterologenesis was evaluated in liver minces from chow-fed rats (average weight 215 g) in the presence of exogenous lifibrol (*in vitro* studies) and in liver minces from rats (average weight 175 g) pretreated with the drug (50 mg/kg/d) for 6 d (*ex vivo* studies). Liver minces (500 mg) were prepared from samples of the central region of the large hepatic lobe as described previously (7,11) and were incubated at 37°C in 3.5 mL of Krebs-Ringer bicarbonate buffer, pH 7.4 (7,11) in the presence of appropriate ^{14}C-labeled substrates. In the *in vitro* studies, the incubations contained 2 μCi of either [^{14}C]MVA (DBED salt) or sodium [^{14}C]Ac. Lifibrol was added to the incubations, at the outset, dissolved in 12 μL of dimethylsulfoxide; control incubations received the vehicle alone. In the *ex vivo* experiments, the [^{14}C]MVA was present at 1 μCi/mL. Sodium [1-^{14}C]octanoate substituted for [^{14}C]Ac in order to avoid any probability of [^{14}C]Ac dilution resulting from possible alterations in the endogenous acetate pool size arising from drug treatment (13). The [^{14}C]octanoate was present at a level of 3 μCi/mL in the presence of 1 mM unlabelled sodium octanoate (13). After incubation, all samples were digested/saponified and their *n*-hexane extracts used for isolation of Chol on thin layers of Silica Gel G and total sterols by digitonin-precipitation as described above.

Intraperitoneal injections of [^{14}C]Ac. Rats (average weight 150 g) were randomly assigned into groups of 3 to 8 and treated with lifibrol for up to 41 d. In Study I (Table 2, shown later), the rats were treated for 0 (Controls), 1, 2, 3, 4 and 10 d (n = 3/group) at 50 mg/kg/d. Initiation of the drug was staged so that all groups were evaluated concurrently. In Study II (Table 2, shown later), the rats were treated for 41 d (Controls, n = 8; 10 mg/kg, n = 7; 50 mg/kg, n = 7) and were also evaluated concurrently. At the end of their treatment period, body weights were recorded (to be used in expressing whole body sterol estimates), and the rats were injected intraperitoneally with 20 μCi sodium [^{14}C]Ac. Two hours post-injection, 4.0 mL of blood was taken under ether anesthesia for plasma lipid analysis, and the rats were sacrificed by ether overdose. The carcasses and samples of liver from the large lobe were frozen at −20°C until processed further. In all of the rats, digitonin-precipitable [^{14}C]sterols ([^{14}C]DPS) were measured in the nonsaponifiable lipid extracts from liver. Additionally, in rats from the 41-day study, the incorporation of [^{14}C]Ac into the individual lipid classes was measured in total lipid extracts from plasma and liver.

Incorporation of intraperitoneally injected [^{14}C]Ac into Chol intermediates in nonhepatic tissue was also investigated 2 h post-injection in rats (average weight 150 g) that received lifibrol for 6 d (50 mg/kg/d). Squalene and lanosterol were isolated from the nonsaponifiable lipid fraction from kidney, spleen, testes and adrenal gland.

Carcass sterol analysis. All rats from the 41-day study were taken from the storage freezer, and the brains and brain stems were removed without thawing the carcasses. The carcasses were next placed into 2-L screw-cap polypropylene bottles that contained 1200 mL of 15% alcoholic KOH. The carcasses were permitted to digest for 5 d at room temperature and were shaken several times per day to facilitate tissue dissolution and dispersion. On the fifth day, the digests were placed on a magnetic mixer, and a large stirring bar was placed into each bottle. The digests were stirred for approximately 30 min; this permitted the final disintegration of the delipidized, decalcified bone residues. The digests were next transferred into 2-L volumetric flasks. The digestion bottles were rinsed clean by multiple washings with ethyl alcohol and the washings were transferred to the volumetric flask. The

samples were next filled up to the 2.0-L mark with ethyl alcohol. All steps beyond this point utilized standard quantitative analysis techniques employing volumetric glassware at all stages. Five-mL aliquots of the digests were extracted with *n*-hexane to recover the total sterol fraction. The extracts were evaporated to dryness under N_2, suspended in acetone/ethanol (1:1, vol/vol) and the sterols were precipitated with digitonin as above (10). The washed digitonide precipitates were assayed using the Lieberman-Burchard reaction (10). Digitonin-precipitable sterols in the carcasses were corrected upward by the sterol content of the 4.0-mL of blood drawn and the sample of liver that was removed for analysis prior to carcass digestion. This correction permitted calculation of total carcass digitonin-precipitable sterols (minus brain and brain stem, which were discarded). Digitonin-precipitation of sterols and their assay by color development with Lieberman-Burchard reagent (10) provides a quantitative measure of Chol in plasma, liver and most other tissues where all but traces of the total sterol are Chol. Skin, however, has numerous other sterols that would not be quantitatively measured by this methodology. Therefore, the presence of skin in the carcass analysis will result in a degree of underestimation of total carcass sterols.

Statistical analyses. All data are presented as mean ± SD. Statistical analyses were performed by one-way analysis of variance. Comparisons between groups were made using Student's *t*-test for unpaired variates. Differences were considered to be significant when P was equal to, or less than, 0.05.

RESULTS

In vitro *and* ex vivo *hepatic sterologenesis.* Confirmation of *in vitro* Chol synthesis inhibition by lifibrol was documented in normal rat liver minces as a prerequisite to undertaking the present studies. Exogenous lifibrol present at 10^{-4} and 10^{-3} M in the incubations reduced [^{14}C]Ac incorporation into [^{14}C]Chol by 23 ± 3% (n = 4) and 43 ± 18% (n = 4), respectively; the differences in the percentage inhibition between 10^{-3} and 10^{-4}, however, were not statistically different ($P > 0.05$). Lifibrol also inhibited the incorporation of [^{14}C]MVA into [^{14}C]Chol by 37% at 10^{-4}M (mean of n = 2; 46 and 28) and 64% at 10^{-3}M (mean of 2; 65 and 63).

The effect of lifibrol on sterologenesis was also evaluated *ex vivo* in liver minces from rats that were fed lifibrol in the diet for 6 d at doses of 15 and 50 mg/kg/d (Table 1); [1-^{14}C]octanoate and [^{14}C]MVA were used as precursors. No inhibition of sterologenesis was observed in either of the two treatment groups. To the contrary, the incorporation of both precursors into [^{14}C]DPS and [^{14}C]Chol was increased significantly ($P \leq 0.04$) in the 50 mg/kg group. This group also displayed a significant reduction in plasma Chol relative to the control group (64 ± 24 *vs.* 24 ± 3 mg/dL, $P < 0.04$). In contrast, rats that received the lower dose (15 mg/kg) registered no significant change in plasma Chol or in the incorporation of either precursor into [^{14}C]DPS or [^{14}C]Chol.

Effects of lifibrol on in vivo *hepatic lipogenesis, plasma lipids, and liver and carcass sterol content.* The *ex vivo* sterologenesis experiments described in Table 1 were followed up by studies of *in vivo* sterologenesis in rats that received lifibrol in the diet for 1, 2, 3, 4, 10 and 41 d at a dose of 50 mg/kg/d (Table 2). A 10 mg/kg dose was also included in the 41-day treatment. All rats received an intraperitoneal injection of [^{14}C]Ac and were killed 2 h post-injection.

The incorporation of [^{14}C]Ac into hepatic [^{14}C]DPS was increased significantly ($P < 0.05$) by 48 h after initiation of the 50 mg/kg dose. The increased incorporation persisted out to 41 d, at which time it exceeded the control values by greater than 4-fold; this would appear to be a maximal response since a similar increase was observed at 41 d in the 10-mg/kg group. Plasma lipid concentrations were also measured in the rats and demonstrated a rapid response to the hypolipidemic action of lifibrol (Study I, Table 2). Within the first 24 h after initiating treatment at 50 mg/kg, there were significant reductions ($P < 0.001$) of 60–70% in plasma total Chol and TG concentrations. HDL-chol was also reduced 37% ($P < 0.01$) during the same period. The plasma lipid fraction experiencing the greatest change, however, was the combined fraction of LDL + VLDL-chol, which was reduced by about 80% in 24 h. The plasma lipid-lowering effects of lifibrol were maximal at 4 d. Between 4 and 10 d, HDL-chol returned to control values; the other parameters stayed significantly below the control values but did show a definite "up-trend" toward control values. After 41 d of treatment at doses of 10 and 50 mg/kg (Table 2, Study

[a]Rats receiving lifibrol in the diet for up to 41 d were killed 2 h after an intraperitoneal injection of 20 μCi sodium [1-^{14}C]acetate in 0.5 mL physiologic saline/ethanol (24:1, vol/vol). Plasma lipids were measured, hepatic nonsaponifiable lipids were obtained, and total digitonin-precipitable sterols were isolated as detailed under Materials and Methods. Values are means ± SD of the number of rats indicated by N. Abbreviations: Chol, cholesterol; HDL, high density lipoprotein; VLDL, very low density lipoprotein; LDL, low density lipoprotein. [b-e]Statistically significantly different from the respective control mean ([b]$P < 0.001$; [c]$P < 0.01$; [d]$P < 0.02$, [e]$P < 0.05$).

II), no hypocholesterolemic action was evident and VLDL + LDL-chol returned to control levels; the hypolipidemic action of lifibrol observed at this time was limited solely to its hypotriglyceridemic action (50% decrease in plasma TG, $P < 0.01$).

Hepatic total Chol and carcass total digitonin-precipitable sterols were also measured in the rats treated for 41 d with 10 and 50 mg/kg of lifibrol. Hepatic total Chol was increased significantly from a control mean of 1.97 ± 0.20 mg/g wet wt to 2.42 ± 0.20 ($P < 0.002$) and 2.31 ± 0.15 ($P < 0.002$) mg/g wet wt in the 10- and 50-mg/kg dose groups, respectively. Carcass total sterol (DPS) was also increased by lifibrol. Carcass DPS in the control group measured 1665 ± 103 mg/kg body weight compared with 1735 ± 96 and 1845 ± 100 mg/kg body wt in the 10- and 50-mg/kg groups, respectively. The increase at 50, but not at 10, mg/kg was significant ($P < 0.002$).

Injected [^{14}C]Ac was used not only to monitor sterol synthesis in liver (Table 2) but the synthesis of other major lipid classes as well [*i.e.*, free fatty acids (FFA), glycerolipids and cholesteryl esters] (Table 3). The hepatic synthesis of ^{14}C-labeled cholesteryl esters was increased two to three times in the treated rats. In contrast, synthesis of labeled TG was reduced about 60% ($P < 0.02$) by lifibrol

TABLE 3

Effect of Lifibrol on the *in vivo* Incorporation of Intraperitoneally Injected [1-^{14}C]Acetate into Hepatic and Plasma Free Fatty Acids and Esterified Lipids in Normal Rats After 41 Days of Treatment (10 and 50 mg/kg/d)[a]

Lifibrol daily dosage	N	Phospholipid	Triglyceride	Free fatty acid	Esterified cholesterol
		dpm/g liver wet wt			
Control	8	7764 ± 2728	2445 ± 1077	856 ± 293	161 ± 77
10 mg/kg	7	5042 ± 1436[b]	945 ± 312[c]	786 ± 340	532 ± 206[b]
50 mg/kg	7	5202 ± 1082[b]	961 ± 577[c]	663 ± 222	374 ± 292[d]
		dpm/mL plasma			
Control	8	2565 ± 497	326 ± 186	126 ± 55	165 ± 24
10 mg/kg	7	2487 ± 447	111 ± 86[e]	58 ± 21[e]	563 ± 292[c]
50 mg/kg	7	2437 ± 362	39 ± 29[f]	29 ± 21[f]	449 ± 195[d]

[a]Samples of liver and plasma from the 41-day rats described in Table 2 were extracted and fractionated by thin-layer chromatography as detailed under Materials and Methods. Values are means ± SD of the number of rats, indicated by N.
[b-f]Statistically significantly different from the control mean ([b]$P < 0.03$; [c]$P < 0.001$; [d]$P < 0.02$; [e]$P < 0.001$; [f]$P < 0.003$).

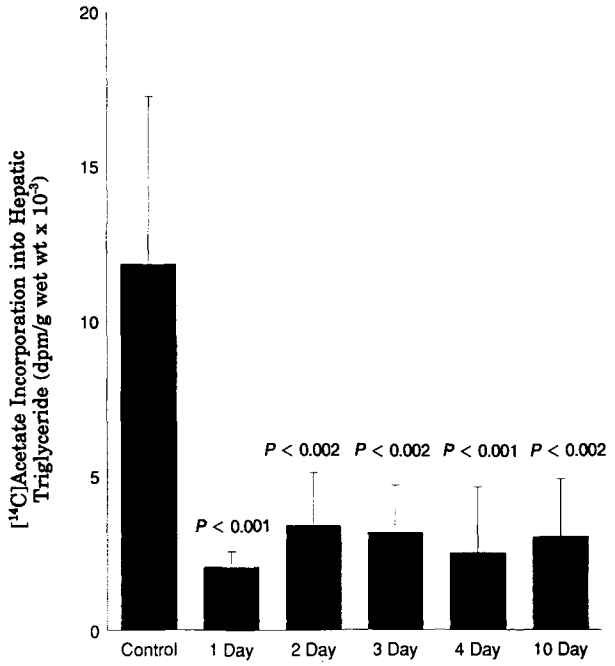

FIG. 1. Effect of lifibrol on the incorporation of intraperitoneally injected [1-^{14}C]acetate into hepatic triglycerides in normal rats. Rats (initial average weight 150 g) which received lifibrol (50 mg/kg/d) in the diet for up to 10 d were injected intraperitoneally with 20 μCi [1-^{14}C]acetate 2 h prior to killing. Samples of liver were extracted and fractionated by thin-layer chromatography to obtain the triglyceride fractions that were assayed for radioactivity as detailed under Materials and Methods. Values shown are means ± SD of three rats per group.

treatment. A smaller but significant reduction (approximately 35%, $P < 0.02$) in labeled phospholipid synthesis also occurred with both doses of lifibrol. These changes occurred in the absence of any significant differences in the amount of ^{14}C-labeled FFA recovered from the livers. The impact of lifibrol on hepatic TG synthesis has a rapid onset as shown by the data in Figure 1. Rats that received 50 mg/kg showed an 80% decrease in hepatic TG synthesis within 24 h of receiving treatment with lifibrol. The data of Figure 1 and Table 3 give no indication that the rats become refractory to the hypotriglyceridemic action.

Lipid newly synthesized from [^{14}C]Ac was also present in the plasma of the rats (Table 3). The profile of the labeled plasma lipid in the lifibrol-treated rats differed from the controls in two major respects. The first of these was a significant ($P < 0.003$) dose-related lowering of circulating ^{14}C-labeled TG and FFA; these changes occurred in the absence of any drug-related effect on the levels of circulating ^{14}C-labeled phospholipids. The second relates to the cholesteryl esters. Just as with liver, the plasma from treated rats had higher levels of ^{14}C-labeled cholesteryl esters (dpm/mL).

Relative sterologenesis activity in nonhepatic tissues. Evidence for an effect of lifibrol on *in vivo* sterologenesis in nonhepatic tissue (kidney, spleen, testes and adrenal glands) was investigated 2 h after intraperitoneal injection of [^{14}C]Ac into untreated rats (control, n = 6) and rats treated with lifibrol for 6 d (50 mg/kg, n = 6) (Table 4). Although [^{14}C]Chol was found in each of the tissues, its presence in the plasma (1814 ± 747 and 538 ± 286 dpm/mL in the lifibrol *vs.* control group, respectively, $P < 0.003$) precluded any attempt to relate tissue [^{14}C]Chol to *in situ* synthesis. However, no [^{14}C]squalene or [^{14}C]-lanosterol could be detected in the plasmas from either group. It was considered, therefore, that the presence of these Chol intermediates in nonhepatic tissues could be taken as an indication of *in situ* sterologenesis. The ratio of [^{14}C]squalene or [^{14}C]lanosterol recovered (dpm/g) in treated *vs.* control rat tissues provides an index of relative differences in sterologenesis activity. On this basis, the data indicate that lifibrol treatment increased the relative rate of synthesis about 2-fold (Table 4).

DISCUSSION

The studies presented here clearly demonstrate that the hypocholesterolemic effects of lifibrol in normal rats are

TABLE 4

Estimated Relative Rates of Sterol Synthesis in Nonhepatic Tissues from Rats Receiving Lifibrol (50 mg/kg/d) for Six Days[a]

	[^{14}C]Squalene			[^{14}C]Lanosterol		
	Lifibrol	Control	Ratio	Lifibrol	Control	Ratio
	(dpm/g wet wt)			(dpm/g wet wt)		
Kidney	148 ± 109	68 ± 12	2.2	188 ± 77[b]	67 ± 17	2.8
Spleen	35 ± 34[c]	49 ± 82	0.7	188 ± 86[c]	103 ± 61	1.8

Adrenal gland	45 ± 29[f]	17 ± 10	2.6	14 ± 14[c]	4 ± 7	3.5

[a]Rats (average weight 150 g) that received lifibrol in the diet (50 mg/kg) for 6 d were killed 2 h after intraperitoneal injection with 20 μCi sodium [1-^{14}C]acetate in 0.5 mL physiologic saline/ethanol (3:2, vol/vol). The organs were removed and fractionated by thin-layer chromatography to obtain the cholesterol intermediates, [^{14}C]squalene and [^{14}C]lanosterol, as detailed under Materials and Methods. The mean ± SD recovery of labeled lanosterol and squalene (dpm/g wet wt) in each tissue (n = 6 per group) was expressed as a ratio of lifibrol *vs.* control. Since these labeled intermediates of cholesterol were not detected in plasma, their presence in the tissues was taken as evidence for active *in situ* sterologenesis. The assumption is that their amount recovered from the tissues is proportional to the rate of sterologenesis extant.

[b-e]Statistically significantly different from the corresponding control mean ([b]$P < 0.004$; [c]not significant; [d]$P < 0.04$; [e]$P < 0.003$, [f]$P < 0.05$). Plasma total cholesterol was 47 ± 9 and 25 ± 4 mg/dL ($P < 0.0001$) in the lifibrol *vs.* control group, respectively, and [^{14}C]acetate incorporation into hepatic [^{14}C]cholesterol was 38232 ± 23843 *vs.* 6710 ± 2398 dpm/g ($P < 0.009$), respectively.

transient and not sustainable with extended treatment (Table 2). This differs from the experiences in marmosets and pigs where the hypocholesterolemic effect of the drug persists throughout treatment periods of 3 to 6 mon (1,3). Analysis of lipoproteins in pigs receiving 50 mg/kg lifibrol yielded results similar to the rats studied here (Ref. 3; Table 2). The overall lowering of plasma Chol involved reductions in HDL-chol in both species but was largely accounted for by lowering of the LDL + VLDL-chol. In the case of pigs, it has been proposed that lifibrol lowers the LDL through increased hepatic LDL-receptor activity which is the response to reduced hepatic Chol synthesis (2,3). Inasmuch as this is a reasonable hypothesis for the pig, the response of rats would appear to be more complicated since reduced plasma LDL + VLDL-chol and increased hepatic sterologenesis are observed concurrently during the hypocholesterolemia phase in the rat (Tables 1 and 2).

The stimulation of hepatic sterologenesis in the rat begins within 48 h of lifibrol treatment and persists as long as drug is administered (Table 2). This increased synthesis likely accounts for the frank rebound in plasma Chol observed at 41 d and indicated as early as 10 d (Table 2). Data from the *ex vivo* liver mince studies in lifibrol-treated rats (Table 1) and *in vivo*-treated rats injected with [1-^{14}C]acetate (Table 2) suggest that the increased hepatic sterologenesis is a function of dose and time. Doses of 50 mg/kg, but not 15 mg/kg, increased *ex vivo* hepatic sterologenesis in 6-day treated rats, whereas treatment for 41 d at similar or higher doses (10 and 50 mg/kg) yielded equivalent increases in sterologenesis (4.5-fold, Table 2).

Clearly, the intrinsic ability of lifibrol to inhibit sterologenesis as demonstrated here, using [^{14}C]Ac and [^{14}C]-MVA, and elsewhere (1) is readily neutralized in normal rats over time. The species difference in tolerance to lifibrol may be related to differences in the degree of counter-regulation achievable or to differences in the site(s) of drug action. In this regard, Schliak *et al.* (2) have proposed that the sustained hypocholesterolemia induced by lifibrol in pigs argues for inhibition of sterol synthesis prior to the rate-limiting, HMG-CoA reductase (14) step, whereas inhibition of [^{14}C]MVA incorporation into hepatic sterols *in vitro* in rat liver minces in the presence of exogenous lifibrol described here suggests that post-reductase site(s) of inhibition also exist (*i.e.*, assuming no drug-induced changes in substrate access). The reductions in sterol synthesis in liver minces cannot be attributed to an overall inhibition of lipogenesis since [^{14}C]Ac incorporation into total saponifiable lipid (dpm/g wet wt) is either unchanged or slightly increased in the presence of drug (9480 $\pm$ 1942, 11866 $\pm$ 2770, and 15648 $\pm$ 3544 at 0, 10^{-4} and 10^{-3} M lifibrol respectively, n = 3/group). More definitive studies will be necessary to more specifically characterize the inhibitory sites of lifibrol in the liver and the actions which determine counter-regulation. The relatively small increases in inhibition of sterol synthesis from [^{14}C]Ac and [^{14}C]MVA that we observed in going from 10^{-4} to 10^{-3} M lifibrol in liver minces suggests that factors such as drug solubility and tissue uptake may be limiting in some *in vitro* systems.

Another important observation made in these studies relates to the effect of lifibrol on tissue sterol concentration. In the 41-day rat study, hepatic Chol concentration was increased significantly at 10 and 50 mg/kg; carcass total sterols were also increased significantly at 50 mg/kg. The accumulation of body sterol may be a direct consequence of overproduction of sterol not only by the liver, but by certain nonhepatic tissues as well (Table 4).

Apart from increased sterologenesis, the most steadfast response of the normal rat to lifibrol was the hypotriglyceridemic response. A 24-hour treatment period at 50 mg/kg was sufficient to significantly lower plasma TG by 76% (Table 2). At the same dose, Schliak *et al.* (3) reported plasma TG lowering in male (but not female) pigs. However, the onset of the reduction was much slower to develop and was not statistically significant until some time between 2 and 12 wk. Unlike the situation with plasma Chol, there is no strong indication that plasma TG lowering in the rat is transient in nature. Quite to the contrary, it is a direct reflection of the reduced TG synthesis in the liver (Table 3 and Fig. 1) and the subsequent reduced appearance of newly synthesized TG in plasma (Table 3) that was demonstrated in the [^{14}C]Ac injection studies. The fact that the 41-day treated rats maintained significant reduction in plasma TG even though VLDL + LDL-chol were not significantly different from control levels (Table 2) suggests that the hypotriglyceridemia is not secondary to problems in LDL production and/or secretion. Future studies of VLDL secretion and turnover will more specifically address this issue.

The inhibition of TG synthesis appers to be relatively specific in that phospholipid synthesis was only modestly affected and fatty acid synthesis was not significantly affected (Table 3). It was observed, however, that newly formed ^{14}C-labeled FFA circulating in plasma were significantly lower in 41-day lifibrol-treated rats (Table 3). Whether or not this effect, which seems to be dose-dependent, represents a lesser release from liver (or other tissues) or a drug-enhanced clearance by peripheral tissues is not known. In the studies presented here, we did not assay directly the activity of plasma LCAT (lecithin/Chol acyltransferase; EC 2.3.1.42) or hepatic ACAT (acylCoA/Chol acyltransferase; EC 2.3.1.26), which are the main determinants of the status of plasma and hepatic cholesteryl esters (15). It is therefore possible that the higher levels of ^{14}C-labeled cholesteryl esters found in plasma and liver of the 41-day treated rats reflect lifibrol-induced increases in the activity of these enzymes. Alternately, the increase may reflect the availability of higher specific radioactivity Chol in both compartments as a result of increased synthesis of hepatic [^{14}C]Chol.

At the time of this writing, it is not known to what extent the long-term response of animals to lifibrol will be reflective of the long-term response in humans. In a 14-day human volunteer trial, lifibrol at 300, 600 and 900 mg/d significantly decreased plasma total Chol and LDL-chol by up to 30% or more without significantly affecting plasma HDL-chol and TG (4). These results, which were similar to the response in pigs given somewhat higher doses for 6 mon (3), gave no indication of an impending rebound in plasma Chol. In fact, plasma Chol and LDL-chol were still in a definite downslope after 2 wk, indicating that maximal lowering, at the doses provided, had not been reached. Provided that long-term safety and efficacy of lifibrol can be demonstrated clinically, the drug may be useful in the management of hypercholesterolemia.

Effects of Lovastatin on Hepatic Fatty Acid Metabolism

Manuel Guzmán, Josefa P. Cortés and **José Castro***
Department of Biochemistry and Molecular Biology I, Faculty of Chemistry, Complutense University, 28040 Madrid, Spain

The *in vitro* and *in vivo* effects of lovastatin on fatty acid metabolism were studied in isolated rat hepatocytes. When added *in vitro* to cell incubations, lovastatin stimulated *de novo* fatty acid synthesis and acetyl-CoA carboxylase activity, whereas fatty acid synthase activity was unaffected. Lovastatin depressed palmitate, but not octanoate, oxidation. This may be attributed to the lovastatin-induced increase in intracellular malonyl-CoA levels, as no concomitant change of carnitine palmitoyltransferase I (CPT-I) specific activity was detected. Lovastatin had no effect on the synthesis and secretion of triacylglycerols and phospholipids in the form of very low density lipoproteins (VLDL). When rats were fed a diet supplemented with 0.1% (w/w) lovastatin for one week, both acetyl-CoA carboxylase activity and *de novo* fatty acid synthesis were reduced compared to pair-fed controls, whereas fatty acid synthase activity was unaffected. Palmitate oxidation was enhanced in the lovastatin-fed group. There was an increase in CPT-I activity but no change in intracellular concentration of malonyl-CoA. Lovastatin feeding had no significant effect either on the esterification of exogenous palmitic acid into both cellular and VLDL triacylglycerols and phospholipids or on hepatic lipid accumulation. The *in vitro* and *in vivo* effects of lovastatin were not significantly different between periportal and perivenous hepatocytes. The results indicate that: (i) the administration of lovastatin increased the fatty acid-oxidative capacity of the liver at the expense of its lipogenic capacity, (ii) the rate of *de novo* cholesterol synthesis did not seem to be a limiting factor in the synthesis and secretion of VLDL and (iii) lovastatin produced opposite effects on hepatic fatty acid metabolism *in vitro* and *in vivo*.
***Lipids* 28, 1087-1093 (1993).**

The liver plays a central role in the synthesis and redistribution of cholesterol (1,2), and 3-hydroxy-3-methylglutaryl-CoA (HMG-CoA) reductase catalyzes the rate-limiting step in hepatic *de novo* cholesterol synthesis (3-5). The amounts and activities of hepatic HMG-CoA reductase are controlled very closely by a series of mechanisms acting at the transcriptional, translational and post-translational levels (3-5).

Increased plasma low density lipoprotein (LDL)-cholesterol levels are recognized as a major risk factor in the development of atherosclerosis and coronary heart disease (6,7). With the design of nontoxic inhibitors of HMG-CoA reductase, and therefore of cholesterol biosynthesis, treatment of hypercholesterolemic patients has become more effective (8-10). Among the different inhibitors of HMG-CoA reductase, lovastatin (mevinolin) is one of the most widely used agents, owing to its high efficacy and low toxicity (8-10). Inhibition of liver cholesterol biosynthesis increases the number of apo B/apo E (LDL) receptors on the hepatocyte surface, and this in turn causes lower plasma concentrations of LDL-cholesterol (8-12). By contrast, plasma levels of anti-atherogenic high density lipoprotein-cholesterol are unaffected or even raised by lovastatin treatment (8-10). Administration of lovastatin to animals and humans has been shown to affect bile acid metabolism as well (13,14).

Much less is known about the effects of lovastatin on hepatic fatty acid metabolism. It is well recognized that the regulation of cholesterol and fatty acid biosynthesis appear intertwined; *i.e.*, in physiopathological situations in which cholesterol biosynthesis is increased, fatty acid biosynthesis seems also to be enhanced, and *vice versa* (5,15,16). HMG-CoA reductase and acetyl-CoA carboxylase, the rate-limiting enzyme of *de novo* fatty acid synthesis, are phosphorylated, and thus inactivated, by the same protein kinase, namely the adenosine monophosphate-activated protein kinase (5,17). Treatment of rats with lovastatin leads to an induction of hepatic phosphatidate phosphohydrolase, one of the putative regulatory enzymes of triacylglycerol synthesis (18). In addition, a close relationship exists in rat liver between HMG-CoA reductase and the key regulatory enzyme of long-chain fatty acid oxidation, *viz.* carnitine palmitoyltransferase I (CPT-I) (19,20). Thus, inhibition of CPT-I leads to an induction of HMG-CoA reductase (19), whereas prolonged lovastatin feeding increases CPT-I activity (20). Hence, it is likely that lovastatin administration may induce important changes in hepatic fatty acid metabolism. In addition, by inhibiting cholesterol synthesis in the liver and/or by acting on fatty acid-metabolizing pathways, lovastatin has been shown to interfere with hepatic synthesis of lipoproteins. Thus, it has been reported that chronic treatment with lovastatin decreases very low density lipoprotein (VLDL) secretion in perfused rat liver (21), as well as in the intact animal (22,23). More recently, a similar effect of lovastatin administration has been shown to occur in humans (24). In addition, treatment with lovastatin and other HMG-CoA reductase inhibitors resulted in reduced plasma VLDL levels (8-10,22-24).

In the present article we report on the *in vitro* and *in vivo* effects of lovastatin on fatty acid metabolism in rat hepatocytes. Because different pathways of lipid metabolism are operative at different rates in the periportal and perivenous zones of the liver acinus (25), we also looked at possible differences in the observed effects of lovastatin on periportal and perivenous hepatocytes.

MATERIALS AND METHODS

Materials. ^3H_2O (5 Ci/mol), [1-^{14}C]acetyl-CoA (54 Ci/mol), [U-^{14}C]palmitic acid (403 Ci/mol), [1-^{14}C]palmitic acid (58 Ci/mol), [1-^{14}C]octanoic acid (32 Ci/mol) and L-[*methyl*-^{14}C]carnitine (54 Ci/mol) were supplied by Amersham International (Amersham, Bucks, United Kingdom). Lovastatin was kindly furnished by Dr. J. González Esteban (Merck, Sharp & Dohme, Madrid, Spain). Digitonin, bovine serum albumin (fraction V; essentially fatty acid-free) and collagenase (type I) were purchased from Sigma Chemical Co. (St. Louis, MO). All other reagents and solvents were analytical reagent grade from Sigma, Boehringer (Mannheim, Germany), Merck (Darmstadt, Germany) and Aldrich (Steinheim, Germany).

*To whom correspondence should be addressed.

Abbreviations: ATP, adenosine triphosphate; CPT-I, carnitine palmitoyltransferase I; HMG-CoA, 3-hydroxy-3-methylglutaryl-coenzyme A; LDL, low density lipoproteins; TLC, thin-layer chromatography; VLDL, very low density lipoproteins.

Animals. Male Wistar rats (225–275 g body weight) were used in all experiments. The *in vitro* effects of lovastatin were studied in hepatocytes isolated from rats fed a standard, stock-pelleted diet (21% of total calories as protein, 15% as fat and 64% as carbohydrates). The *in vivo* effects of lovastatin were studied in hepatocytes isolated from rats pair-fed, for one week, the same standard diet either supplemented (lovastatin group) or not (control group) with 0.1% (w/w) lovastatin. Animals were housed individually and kept in a constant-temperature room with a 12-h light–dark cycle (light, 6 a.m. to 6 p.m.; dark, 6 p.m. to 6 a.m.) Hepatocytes were isolated at 9 a.m. Food intake and body weight gain were not significantly different in lovastatin-fed and control animals (results not shown).

Isolation of hepatocytes. Hepatocytes from the whole liver were isolated as described by Beynen *et al.* (26), whereas periportal and perivenous hepatocytes were isolated by the digitonin/collagenase perfusion technique of Chen and Katz (27), and further characterized based on several marker enzyme activities (25,28). As lipogenesis is markedly depressed just after the isolation procedure, hepatocytes were incubated for 20 min at 37°C in a metabolic gyratory shaker and then filtered through nylon mesh (25,26). The final hepatocyte preparation was suspended in Krebs-Henseleit bicarbonate buffer (pH 7.4) supplemented with 10 mM glucose. Cell viability, as determined by Trypan Blue exclusion, always exceeded 85% in the final hepatocyte suspension.

Hepatocyte incubations. Hepatocytes were incubated in Krebs-Henseleit bicarbonate buffer (pH 7.4) supplemented with 10 mM glucose and 2% (wt/vol) defatted and dialyzed bovine serum albumin. Incubations were carried out in a metabolic gyratory shaker (85 rpm) in a total volume of 2 mL at 37°C in an O_2/CO_2 (19:1) atmosphere. Cell concentration was adjusted to 4–6 mg of cellular protein per mL (1.3–2.1 $\times$ 10^6 cells/mL) in order to obtain comparable rates of fatty acid metabolism independent of cell density (25,28). For the study of the *in vitro* effects of lovastatin, stock solutions of lovastatin were prepared in dimethylsulfoxide. Control incubations contained corresponding dimethylsulfoxide levels; no significant effect of dimethylsulfoxide on fatty acid metabolism was observed at the concentrations used (0.2%, vol/vol).

Rates of fatty acid metabolism and cholesterol synthesis. Hepatocytes were incubated as described earlier to monitor the rates of *de novo* fatty acid and cholesterol synthesis, fatty acid esterification and fatty acid oxidation. The three parameters were determined at time points when reaction rates were linear (results not shown).

The rates of *de novo* fatty acid and cholesterol synthesis were determined by following the incorporation of ^3H_2O into total fatty acids and total cholesterol, respectively. Reactions were initiated by the addition of ^3H_2O (0.4 mCi/mL) to the hepatocyte incubations. After 60 min, the reactions were stopped, and lipids were extracted as described previously (29). Total lipids were saponified at 75°C with 0.3 M NaOH in 90% (vol/vol) methanol. After acidification of the samples, fatty acids and cholesterol were extracted with petroleum ether (b.p. 40–60°C) (30). Cholesterol was separated from the other lipid fractions by thin-layer chromatography (TLC) on silica gel G plates using hexane/diethyl ether/formic acid (40:20:1, by vol) as the developing system.

The rates of fatty acid esterification were monitored by following the incorporation of [U-^{14}C]palmitic acid into major lipid classes. Hepatocytes were incubated in the presence of 0.4 mM albumin-bound [U-^{14}C]palmitic acid (0.05 Ci/mol), and after 60 min, cells were transferred into centrifuge tubes and separated from the medium (31) from which VLDL were isolated by gradient ultracentrifugation (32). The appearance of VLDL in the incubation medium showed a lag phase of *ca.* 20 min. Therefore, rates of VLDL secretion were calculated between 30 and 60 min of cell incubation. Cellular and VLDL lipids were extracted (29) and subsequently separated by TLC on silica gel G plates using hexane/diethyl ether/formic acid (40:20:1, by vol) as the developing system. Individual bands were scraped off for determination of radioactivity.

The rates of fatty acid oxidation were measured by following the formation of oxidation products from either [1-^{14}C]palmitate or [1-^{14}C]octanoate. Hepatocytes were incubated in the presence of 0.4 mM albumin-bound [1-^{14}C]fatty acid (0.05 Ci/mol), and after 30 min, the reactions were stopped by addition of 0.5 mL of 2 M perchloric acid. At the same time, 0.1 mL of 6 M KOH was injected into a center well containing filter paper. Samples were allowed to equilibrate for an additional 60 min, and the content of the center well (with the $^{14}CO_2$ fixed as bicarbonate) was transferred to vials for radioactivity counting. Ketone bodies were determined as the nonvolatile, acid-soluble oxidation products (33). Total oxidation products were calculated as the sum of CO_2 plus ketone bodies.

Acetyl-CoA carboxylase assay. The activity of acetyl-CoA carboxylase was determined by following the incorporation of radiolabelled acetyl-CoA into fatty acids in a reaction coupled to the fatty acid synthase reaction, both in the 12000 $\times$ *g* supernatant (29) and in digitonin-treated hepatocytes (30). This method does not suffer from interferences, as does the classical bicarbonate-fixation assay of acetyl-CoA carboxylase activity (30). In order to measure enzyme activity in digitonin-treated hepatocytes, 100 μL of hepatocyte suspension were added to 100 μL of digitonin-containing assay medium. The final assay mixture contained 63 mM *N*-(2-hydroxyethyl)piperazine-*N'*-(2-ethanesulfonic acid) (pH 7.5), 1.5 mM $MgCl_2$, 0.5 mM citrate, 2.5 mM ethyleneglycol-*bis*(β-aminoethyl ether) *N,N,N',N'*-tetraacetic acid, 22.5 mM $NaHCO_3$, 70.5 mM NaCl, 5 mM glucose, 0.5 mM $MgSO_4$, 1.25 mM $CaCl_2$, 2 mM adenosine triphosphate (ATP), 0.5 mM NADPH, 0.44 mM dithioerythrol, 0.93% bovine serum albumin (defatted and dialyzed), 0.062 mM [1-^{14}C]acetyl-CoA (4 Ci/mol), 0.062 mM butyryl-CoA, 64 μg of digitonin/mg of cellular protein and 3.2 milliunits of rat liver fatty acid synthase. After 4 min, reactions were stopped with 0.1 mL of 10 M NaOH and fatty acids were extracted and radioactivity was measured (30).

Fatty acid synthase assay. The activity of fatty acid synthase was determined using digitonin-treated hepatocytes and by following the incorporation of radiolabelled acetyl-CoA into fatty acids under conditions in which acetyl-CoA carboxylase remains inactive (30). One hundred μL of hepatocyte suspension were added to 100 μL of digitonin-containing assay medium. The final assay mixture contained the same components as the acetyl-CoA carboxylase assay, except that butyryl-CoA was replaced by malonyl-CoA and ATP; citrate and purified fatty acid synthase were omitted. After 8 min, reactions

were stopped with 0.1 mL of 10 M NaOH, and fatty acids were extracted and radioactivity measured (30).

CPT-I assay. The activity of CPT-I was determined by following the malonyl-CoA-sensitive incorporation of radiolabelled L-carnitine into palmitoylcarnitine, both in isolated mitochondria and in digitonin-treated hepatocytes. In the first case, mitochondria were isolated from intact hepatocytes, and CPT-I activity was measured as described previously (34). Preparations of mitochondria were practically devoid of peroxisomes, as judged by measuring catalase activity (results not shown).

In order to determine CPT-I activity in digitonin-treated hepatocytes (35), 100 μL of hepatocyte suspension were added to 100 μL of digitonin-containing assay medium. The final assay mixture contained 12.5 mM Tris-HCl (pH 7.4), 70 mM sucrose, 5 mM glucose, 32.5 mM KCl, 12.5 mM $NaHCO_3$, 60 mM NaCl, 0.5 mM KH_2PO_4, 0.5 mM $MgSO_4$, 1.25 mM $CaCl_2$, 1 mM ethylenediaminetetraacetic acid, 1 mM dithioerythrol, 50 μM palmitoyl-CoA, 0.5 mM L-[*methyl*-^{14}C]carnitine (1 Ci/mol), 0.5% bovine serum albumin (defatted and dialyzed) and 40 μg of digitonin/mg of cellular protein. After 1 min, reactions were stopped with 0.3 mL of 1 M HCl and [^{14}C]palmitoylcarnitine product was extracted with *n*-butanol as described before (33).

In both the isolated mitochondria and the digitonin-treated hepatocyte assays, malonyl-CoA-insensitive CPT activity, representing the latent form of mitochondrial CPT activity (CPT-II), was always subtracted from the total CPT activity that was experimentally determined. CPT-I activity always accounted for more than 90% of this total CPT activity. Furthermore, the degree of inhibition of hepatocellular CPT activity by 100 μM malonyl-CoA was similar within a wide range of palmitoyl-CoA concentrations (20-200 μM) (results not shown).

Other analytical procedures. Intracellular levels of malonyl-CoA were determined in neutralized perchloric acid cell extracts by a radioenzymatic method using purified rat liver fatty acid synthase (26). Kits from Boehringer were used for the determination of cellular cholesterol and triacylglycerols.

Statistical analysis. Results shown represent the means ± SD of the number of animals indicated. Cell incubations and/or enzyme assays were carried out in triplicate. Statistical analysis was performed by the Student's *t*-test.

RESULTS

In vitro *effects of lovastatin.* The *in vitro* effects of lovastatin on fatty acid metabolism were studied in isolated rat hepatocytes. In preliminary experiments, lovastatin was shown to decrease *de novo* cholesterol synthesis in a dose-dependent manner (Fig. 1). A similar trend was observed with regard to the appearance of labelled VLDL cholesterol in the extracellular medium (93 ± 5% inhibition in the presence of 0.1 mM lovastatin). A lovastatin concentration of 0.1 mM was chosen as standard condition.

Addition of lovastatin to the hepatocyte incubation increased the rate of *de novo* fatty acid synthesis by 35% (Table 1). This increase correlated well with the lovastatin-mediated stimulation of acetyl-CoA carboxylase activity, as measured in digitonin-treated cells (Table 1). No

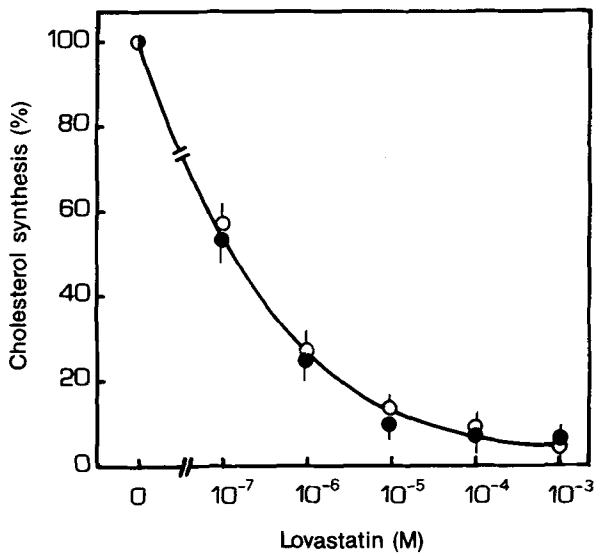

FIG. 1. ***In vitro*** **effect of lovastatin on hepatic** ***de novo*** **cholesterol synthesis. Periportal (○) and perivenous (●) hepatocytes were preincubated for 30 min in the presence of different concentrations of lovastatin and** ***de novo*** **cholesterol synthesis was followed. Results represent the means ± SD of three different preparations of periportal and perivenous hepatocytes. The 100% level for the rate of cholesterol synthesis (in nmol acetyl units/h × mg cell protein) was 10.54 ± 2.31 and 6.47 ± 1.26 in periportal and perivenous hepatocytes, respectively.**

direct effect of lovastatin was observed on acetyl-CoA carboxylase activity, as measured in the 12000 × *g* supernatant (results not shown). In addition, lovastatin showed no effect on fatty acid synthase activity (Table 1).

In cell incubations, lovastatin had no significant effect on the rate of fatty acid esterification from exogenous palmitate into the major glycerolipid fractions, namely triacylglycerols and phospholipids (Table 1). Isolated hepatocytes have previously been used to study the secretions of newly synthesized VLDL lipids (1,28,36). Thus, we monitored the rate of VLDL lipid secretion into the incubation medium by following incorporation of exogenous palmitic acid into the VLDL fraction. This approach is valid as long as changes in fatty acid incorporation into cellular lipids are also considered. When cells were incubated with [^{14}C]palmitic acid, no effect of lovastatin was observed on the appearance of labelled VLDL triacylglycerols and VLDL phospholipids in the extracellular medium (Table 1).

The rate of palmitate oxidation was depressed by the addition of lovastatin to the incubation medium; the decrease was seen in both the CO_2 and the acid-soluble component of total oxidation products (Table 1). However, lovastatin had no significant effect on hepatic octanoate oxidation (Table 1). As can be seen in Table 1, CPT-I activity was not changed when hepatocytes were incubated with lovastatin. In addition, no direct effect of lovastatin was observed on CPT-I activity measured in isolated mitochondria (results not shown).

Inhibition of CPT-I activity by malonyl-CoA is a well-described property of the enzyme (16,37-39). Hence, we determined the effects of lovastatin on hepatic malonyl-CoA levels. In line with the lovastatin-mediated stimulation of acetyl-CoA carboxylase activity previously

Fatty acid synthase	1.65 ± 0.20	1.68 ± 0.07
CPT-I	1.53 ± 0.18	1.62 ± 0.32

[a]Hepatocytes were isolated from whole liver and preincubated in the absence or in the presence of 0.1 mM lovastatin. After 30 min, part of the cells was used for determination of the rates of fatty acid synthesis, esterification [in both cell and very low density lipoproteins (VLDL) lipids] and oxidation in intact hepatocytes. The rest of the cells were used for measurement of enzyme activities in digitonin-treated hepatocytes. Rates of fatty acid synthesis are expressed as nmol acetyl units/h × mg cell protein. Rates of fatty acid esterification and oxidation are expressed as nmol fatty acid into product/h × mg cell protein. Enzyme activities are expressed as nmol product/min × mg cell protein. Results represent the means ± SD of six hepatocyte preparations. CoA, coenzyme A; CPT-I, carnitine palmitoyltransferase I.

[b]$P < 0.05$ between incubations with no additions and lovastatin-containing incubations.

[c]$P < 0.01$ between incubations with no additions and lovastatin-containing incubations.

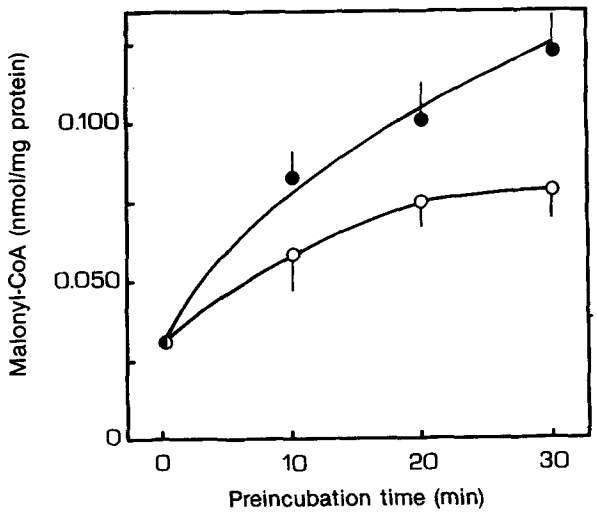

FIG. 2. *In vitro* effect of lovastatin on hepatocyte levels of malonyl-CoA. Hepatocytes isolated from whole liver were preincubated for 30 min in the absence (○) or in the presence (●) of 0.1 mM lovastatin, and intracellular levels of malonyl-CoA were subsequently determined. Results represent the means ± SD of three different hepatocyte preparations. CoA, coenzyme A.

mentioned here, lovastatin induced a significant increase in the intracellular concentration of malonyl-CoA in intact hepatocytes (Fig. 2).

Because HMG-CoA reductase is predominantly located in the periportal zone of the liver (40), the aforementioned *in vitro* effects of lovastatin on hepatic fatty acid metabolism were studied in periportal and in perivenous hepatocytes. However, no significant differences between the two hepatocyte subpopulations were found with regard to the effects of lovastatin on fatty acid synthesis and oxidation. Thus, lovastatin stimulated *de novo* fatty acid synthesis by 42 ± 10% in periportal hepatocytes and by 31 ± 11% in perivenous hepatocytes, whereas lovastatin increased acetyl-CoA carboxylase activity by 24 ± 4% in periportal hepatocytes and by 27 ± 5% in perivenous hepatocytes. In addition, lovastatin depressed palmitate oxidation to CO_2 by 30 ± 8% in periportal hepatocytes and by 47 ± 7% in perivenous hepatocytes.

In vivo *effects of lovastatin.* The *in vivo* effects of lovastatin on fatty acid metabolism were studied in hepatocytes isolated from rats that had been pair-fed a standard diet either supplemented (lovastatin group) or not (control group) with 0.1% (w/w) lovastatin. In preliminary experiments, we observed that the rate of *de novo* cholesterol synthesis in hepatocytes isolated from lovastatin-treated animals was 8.4 ± 2.1-fold higher than in control cells. This may be due to the well-described induction of HMG-CoA reductase upon prolonged lovastatin administration (3,40).

Both the activity of acetyl-CoA carboxylase and the rate of *de novo* fatty acid synthesis were depressed in cells from lovastatin-fed animals, whereas fatty acid synthase activity was not significantly changed (Table 2).

Lovastatin administration had no significant effect on the esterification of exogenous [^{14}C]palmitic acid into cellular triacylglycerols and phospholipids (Table 2). In addition, the rate of appearance of labelled VLDL triacylglycerols and VLDL phospholipids into the extracellular medium was not affected by lovastatin administration (Table 2). The lipid content of hepatocytes isolated from lovastatin-fed animals was similar to that of pair-fed controls (Table 3).

The rates of hepatic palmitate oxidation to both CO_2 and acid-soluble products were increased in hepatocytes isolated from lovastatin-treated animals as compared to control cells (Table 2). A similar trend was observed with regard to CPT-I activity (Table 2). As most of the long-term variations of hepatic long-chain fatty acid oxidation are accompanied by changes in malonyl-CoA levels (16,37-39), hepatocytes were isolated from the two animal groups and the intracellular concentration of malonyl-CoA was determined. However, no significant differences in malonyl-CoA concentrations were detected. The resulting values (in nmol/mg cell protein) were 0.038 ± 0.016, 0.036 ± 0.009, 0.048 ± 0.013 and 0.038 ± 0.007 for the control group periportal zone, control group perivenous zone, lovastatin group periportal zone and lovastatin group perivenous zone, respectively.

Induction of HMG-CoA reductase by administration of lovastatin or cholestyramine appears to occur

TABLE 2

In vivo Effects of Lovastatin on Hepatic Fatty Acid Metabolism[a]

Metabolic parameter	Animal group	
	Control	Lovastatin-fed
Fatty acid synthesis	27.0 ± 3.5	13.1 ± 2.3[b]
Palmitate esterification		
Cell lipids		
Triacylglycerols	7.92 ± 1.78	8.05 ± 2.67
Phospholipids	7.41 ± 1.35	8.39 ± 1.80
VLDL lipids		
Triacylglycerols	0.85 ± 0.27	0.67 ± 0.21
Phospholipids	0.25 ± 0.07	0.25 ± 0.09
Palmitate oxidation		
Acid-soluble product	44.3 ± 7.9	62.1 ± 9.6[b]
CO_2	5.8 ± 2.8	8.2 ± 1.4[c]
Total product	50.1 ± 8.2	70.3 ± 10.8[b]
Enzyme activities		
Acetyl-CoA carboxylase	0.48 ± 0.07	0.17 ± 0.05[b]
Fatty acid synthase	1.26 ± 0.68	1.46 ± 0.71
CPT-I	1.31 ± 0.17	1.82 ± 0.16[b]

[a]Hepatocytes from whole liver were isolated from animals fed either the control or the lovastatin-containing diet for one week. Part of the cells were used for determination of the rates of fatty acid synthesis, esterification (into both cell and VLDL lipids) and oxidation in intact hepatocytes. The rest of the cells were used for measurement of enzyme activities in digitonin-treated hepatocytes. Rates of fatty acid synthesis are expressed as nmol acetyl units/h × mg cell protein. Rates of palmitate esterification and oxidation are expressed as nmol palmitate into product/h × mg cell protein. Enzyme activities are expressed as nmol product/min × mg cell protein. Results represent the means ± SD of eight different animals of each group. Abbreviations as in Table 1.
[b]$P < 0.01$ between control and lovastatin-fed animals.
[c]$P < 0.05$ between control and lovastatin-fed animals.

predominantly in the perivenous zone of the liver (40). Hence, we determined whether the effects of lovastatin feeding on hepatic fatty acid synthesis and oxidation differed between periportal and perivenous hepatocytes. The lovastatin-induced reduction of fatty acid synthesis (and of acetyl-CoA carboxylase activity), and the lovastatin-induced increase in palmitate oxidation (and CPT-I activity) were seen equally in both liver zones. Thus, lovastatin administration depressed *de novo* fatty acid synthesis by 55 ± 8% in periportal hepatocytes and by 47 ± 9% in perivenous hepatocytes, whereas it reduced acetyl-CoA carboxylase activity by 56 ± 11% in periportal hepatocytes and by 65 ± 8% in perivenous hepatocytes. In addition, lovastatin administration enhanced palmitate oxidation to CO_2 by 39 ± 14% in periportal hepatocytes and by 45 ± 18% in perivenous hepatocytes. It also increased palmitate oxidation to acid-soluble products by 32 ± 13% in periportal hepatocytes and by 48 ± 15 in perivenous hepatocytes, and enhanced CPT-I activity by 41 ± 17% in periportal hepatocytes and by 37 ± 13% in perivenous hepatocytes.

DISCUSSION

The *in vitro* and *in vivo* effects of lovastatin on fatty acid metabolism were studied in rat hepatocytes with a twofold goal. On the one hand, lovastatin is known to be useful in modulating the rates of hepatocellular cholesterol synthesis, thus allowing study of the relationship between cholesterol synthesis and fatty acid metabolism both *in vitro* and *in vivo*. On the other hand, lovastatin is widely used in clinical practice and, hence, we considered it of interest to investigate both the rapid response (*in vitro* studies) and the prolonged effects (*in vivo* studies) of administering to animals.

The parallel *in vitro* stimulation of acetyl-CoA carboxylase activity and *de novo* fatty acid synthesis by lovastatin supports the general view that acetyl-CoA carboxylase is a key regulatory point in the fatty acid-synthesizing process (5,15). Malonyl-CoA, the product of the reaction catalyzed by acetyl-CoA carboxylase, is a physiological inhibitor of CPT-I and plays an essential role in the coordinate control of fatty acid synthesis and oxidation in the liver (37-39). It is well established that palmitate is transported into the mitochondria by a carnitine-dependent process, whereas octanoate may enter mitochondria independently of carnitine (16,37-39). Therefore, the lovastatin-induced increase of malonyl-CoA levels, together with the differential effects of lovastatin on palmitate and octanoate oxidation in intact hepatocytes, indicates that decreased CPT-I activity might be involved in the lovastatin-mediated inhibition of long-chain fatty acid oxidation. Other components of the fatty acid-translocation system, namely acyl-CoA synthetase, carnitine:acylcarnitine translocase and CPT-II, are generally not considered to play a significant regulatory role in the transport of long-chain fatty acids into the mitochondrial matrix (16,37-39). Although we were not able to detect any rapid effect of lovastatin on CPT-I activity, it should be pointed out that, in order to measure

TABLE 3

Lipid Content of Hepatocytes Isolated from Control and Lovastatin-Fed Rats[a]

Lipid fraction	Control group		Lovastatin-fed group	
	PP (n = 4)	PV (n = 5)	PP (n = 5)	PV (n = 4)
Triacylglycerols	57.0 ± 8.4	63.7 ± 14.0	63.2 ± 9.0	60.8 ± 14.8
Cholesterol				
Free	42.9 ± 13.2	49.3 ± 10.5	46.1 ± 10.0	39.4 ± 3.9
Esterified	53.4 ± 7.8	52.5 ± 9.8	60.2 ± 12.1	56.5 ± 8.7
Total	96.3 ± 18.7	101.8 ± 12.1	106.3 ± 21.8	95.9 ± 8.9

[a]Cellular levels of triacylglycerols, free cholesterol and esterified cholesterol were determined in periportal (PP) and perivenous (PV) hepatocytes isolated from control and lovastatin-fed animals. Lipid content is expressed as nmol lipid/mg cell protein. Results represent the means ± SD of the number of hepatocyte preparations indicated in parentheses.

enzyme activity, we had to make the plasma membrane permeable. This may have caused the cytosol to leak out of the cell, leading to a substantial dilution of cytosolic components, including malonyl-CoA. Lovastatin is not expected to induce an irreversible, *e.g.*, covalent, modification of CPT-I protein. Conformational constraints exerted by malonyl-CoA on CPT-I disappear almost immediately at the temperature at which the assay is carried out (37°C) (37). Therefore, if lovastatin exerts rapid changes in CPT-I activity, they will probably not be preserved in digitonin-treated hepatocytes. It is thus possible that increased malonyl-CoA levels would inhibit CPT-I activity in intact hepatocytes, but not in digitonin-treated hepatocytes. As a matter of fact, short-term changes in CPT-I activity induced by a number of agonists, such as hormones and phorbol esters, seem to involve changes in the phosphorylation state of the enzyme, which may be preserved upon digitonin treatment of the plasma membrane (35,41,42).

We realize that the *in vitro* effects of lovastatin on fatty acid synthesis, oxidation and esterification seem somewhat contradictory. Thus, if fatty acid synthesis is increased and oxidation is reduced, there should be an increase in the incorporation of labelled palmitate into lipids. Reduced oxidation of the tracer might be balanced by additional synthesis of unlabeled palmitate. However, in palmitate-containing incubations, the fatty acid oxidized or esterified is mostly of exogenous origin. We have observed that addition of 0.5 mM palmitic acid to the hepatocyte incubations strongly blunts fatty acid synthesis through inhibition of acetyl-CoA carboxylase, as determined in digitonin-treated hepatocytes. Although hepatic lipogenesis and long-chain fatty acid oxidation usually change in concert (*i.e.*, higher rates of lipogenesis are accompanied by lower rates of oxidation, and *vice versa*), there are situations in which this relationship is not seen (see Ref. 39). The reasons for these discrepancies are not known.

Changes in hepatic acetyl-CoA carboxylase activity observed in lovastatin-fed animals did not parallel changes in malonyl-CoA content. However, this is not the only case where this occurs. For example, during lactation (43), or after prolonged ethanol feeding (29,44), acetyl-CoA carboxylase activity decreases but malonyl-CoA levels remain unaltered. This may be due to the fact that malonyl-CoA levels depend not only on changes in the activity of acetyl-CoA carboxylase, but also on variations in the activity of a number of malonyl-CoA consuming enzymes, such as fatty acid synthase, malonyl-CoA decarboxylase and the microsomal fatty acid elongation/desaturation system (30,37). Because the rate of palmitate oxidation was enhanced in the lovastatin-fed group, this would indicate that the intracellular concentration of malonyl-CoA, the physiological inhibitor of CPT-I activity, is not the factor responsible for the regulation of hepatic long-chain fatty acid oxidation under these conditions. Increased long-chain fatty acid oxidation after lovastatin administration seems to involve, at least in part, an increase in CPT-I activity (see also Ref. 20). Other examples of malonyl-CoA independent control of hepatic long-chain fatty acid oxidation have been described previously (41,43-46). Although changes in rat liver CPT-I activity usually occur in concert with changes in enzyme sensitivity to inhibition by malonyl-CoA (37-39), the latter parameter has been shown to remain unaltered by lovastatin treatment (20). Something similar is known to occur after prolonged treatment of rats with other drugs, such as anabolic steroids (47).

It is worth noting that lovastatin caused opposite effects *in vitro* and *in vivo* on hepatic fatty acid synthesis and oxidation. Upon addition of lovastatin to the incubation medium, *de novo* cholesterol synthesis was blocked, and cytosolic acetyls may be diverted into fatty acid synthesis at the expense of cholesterol synthesis. However, in the long term it is well known that lovastatin produces a very strong induction of the HMG-CoA reductase enzyme (3,40). In the whole animal the continuous presence of lovastatin in the diet ensures that hepatic HMG-CoA reductase activity (and thus cholesterol biosynthesis) is permanently blunted in spite of the increase in enzyme concentration (9,10). By contrast, in hepatocytes isolated from lovastatin-fed animals, *de novo* cholesterol synthesis is markedly enhanced because of the induction of HMG-CoA reductase and the absence of lovastatin in the extracellular medium (3,40). Therefore, cytosolic acetyls would preferentially be used for cholesterol synthesis at the expense of fatty acid synthesis. Hence it seems that fatty acid and cholesterol synthesis compete for the same cytosolic acetyl-CoA pool.

On the basis of *in vitro* and *in vivo* studies, Khan *et al.* (21,22) have suggested that cholesterol availability is a regulatory factor for the secretion of VLDL by the liver. In our system, addition of lovastatin to the hepatocyte incubation medium strongly decreased both cholesterol synthesis *de novo* and the secretion of newly synthesized cholesterol as VLDL. However, lovastatin had no effect on the secretion of newly synthesized VLDL triacylglycerols and VLDL phospholipids. Likewise, Khan *et al.* (21) did not observe any significant effect of lovastatin on VLDL output by perfused rat liver when the drug was directly added to the perfusion medium, although lovastatin strongly decreased *de novo* cholesterol synthesis from [^{14}C]acetate when either control or lovastatin-fed animals were used as liver donors. Moreover, in the present study, we showed that hepatocytes isolated from lovastatin-fed rats displayed an enhanced capacity for *de novo* cholesterol synthesis and for secretion of this newly synthesized cholesterol, but they secreted VLDL triacylglycerols and VLDL phospholipids at the same rate as cells isolated from control animals. Therefore, the rate of *de novo* cholesterol synthesis did not seem to be a limiting factor for VLDL secretion by the liver, at least in the experimental system employed herein. This does not seem surprising, as the total pool of hepatic cholesterol (free plus esterified) would be very large compared to the metabolic pool required for the formation and secretion of VLDL (21).

Intermediary metabolism, including fatty acid metabolism, is asymmetrically distributed within the liver acinus (25,27,48-50). However, no differences between periportal and perivenous hepatocytes have been noted in the short-term modulation by cellular effectors of lipid (25) and carbohydrate (51) metabolism. This was also the case in short-term incubations with lovastatin. In addition, the zonal heterogeneity of hepatic intermediary metabolism is flexible and may change during the development of the animal and upon physiopathological changes, including starvation, diabetes and alcohol ingestion (28,48-50,52).

By contrast, the distribution of fatty acid metabolism within the liver acinus remains unchanged after lovastatin administration. The situation *in vivo*, of course, must be more complicated due to the existence of concentration gradients for nutrients, hormones and oxygen, as well as due to the particular innervation of the two domains of the liver acinus (48–50). Ongoing studies are directed toward defining the effects of lovastatin on fatty acid metabolism in the whole animal.

[a]Scott-Ritchey Research Center, College of Veterinary Medicine, Auburn University, Auburn, Alabama 36849 and [b]Department of Medicine, New York University School of Medicine, New York, New York 10016

To assess the relationship between tissue α-tocopherol depletion and histopathologic or functional changes in nervous tissue, a longitudinal study of male 1-year-old beagle dogs, two fed a vitamin E-deficient diet (0.05 ± 0.02 mg α-tocopherol/kg; −E dogs) and two fed a vitamin E-supplemented diet (114 ± 14 mg α-tocopherol/kg; +E dogs), was carried out. Plasma and adipose tissue α-tocopherol concentrations, neurological examinations, and sensory and motor nerve conduction velocities were determined at approximately 8-wk intervals over 109 wk. Tibial nerve α-tocopherol concentrations were measured at 65 and 109 wk; adjacent sections were examined for histologic changes. In the two −E dogs, plasma α-tocopherols declined linearly on a semilog plot to < 0.1 μg/mL by 109 wk. Plasma α-tocopherol concentrations were depleted to half of the initial concentrations in approximately 87 d. Adipose tissue α-tocopherol concentrations (based on wet weight, cholesterol or triglyceride) also declined linearly on semilog plots, and were depleted to half of the initial concentrations in approximately 120 d. Tibial nerve α-tocopherols (ng/μg cholesterol) in −E dogs decreased to 16% of average +E at 65 wk, and to 2% at 109 wk. Neurologic examinations, histologies and nerve conduction velocities were normal in all dogs throughout the study. Our results demonstrate in dogs that depletion of plasma, adipose tissue and nerve α-tocopherol precedes histologic and functional changes in peripheral nerves during vitamin E deficiency.

Lipids 28, 1095–1099 (1993).

Symptoms of vitamin E deficiency in humans and experimental animals include spinocerebellar ataxia and peripheral neuropathy (for review, see Ref. 1); therefore, vitamin E deficiency should be considered in the diagnosis of patients with neurological disease. Measurements of plasma α-tocopherol (α-T) concentrations have been widely used for assessment of vitamin E status, but are not necessarily the most reliable indicator because plasma α-T values vary with lipid levels (2).

Adipose tissue α-T can be a more reliable indicator of vitamin E status than plasma concentrations. For example, adipose tissue α-T levels are depleted in vitamin E-deficient humans (3), while normal adipose tissue α-T levels are associated with the prevention of neurologic dysfunction in patients at risk for vitamin E deficiency, consuming adequate levels of vitamin E supplements (4). In response to supplementation with vitamin E, adipose tissue α-T in most species do increase (5–10). Further, adipose tissue α-T concentrations are correlated with sural nerve α-T concentrations in humans (3).

*To whom correspondence should be addressed.

Abbreviations: α-T, α-tocopherol; −E, dogs fed a vitamin E-deficient diet, +E, dogs fed a vitamin E-supplemented diet; i.m., intramuscularly; NCV, nerve conduction velocity; SD, standard deviation; $t_{1/2}$, time to deplete half of initial concentrations; TG, triglycerides.

Longitudinal studies in rodents demonstrated that, in response to a vitamin E-deficient diet, adipose tissue α-T is conserved compared with that in other tissues (5,6). However, rodents may not be accurate models of human vitamin E deficiency because they develop clinical signs of the deficiency within months, as opposed to humans, in whom clinical signs can take several years to decades to develop (1).

The purpose of this study was to compare tissue α-T depletion with functional and histopathologic changes in nervous tissue. Beagle dogs were chosen as an alternative animal model of experimental vitamin E deficiency because they have a longer life span than rodents. Vitamin E deficiency in dogs has been documented to cause pathologic changes in smooth and skeletal muscles, central nervous system and retina, as well as hematologic changes (11,12). The dogs were fed semi-purified casein-based diets with or without (−E, dogs fed a vitamin E-deficient diet; +E, dogs fed a vitamin E-supplemented diet) added vitamin E for 109 wk. At approximately 8-wk intervals, we performed physical and neurologic examinations, measured plasma and adipose tissue α-T, and sensory and motor nerve conduction velocities (NCV). We collected biopsy (65 wk) and necropsy (109 wk) samples of the tibial nerve to determine the depletion of α-T from nerves in comparison with adipose tissue, and to evaluate histopathologic changes.

MATERIALS AND METHODS

Protocol. All procedures were approved by the Auburn University Institutional Animal Care and Use Committee (Auburn, AL). Four 1-year-old male beagle dogs (Marshall Farms, North Rose, NY), weighing 18 kg, were fed a purified diet containing *all-rac*-α-tocopheryl acetate (TD No. 87238; Teklad Laboratories, Madison, WI; α-tocopherol, 114 ± 14 mg/kg) for an adjustment period of 4 wk. Then, two dogs (−E1 and −E2) were selected randomly to receive the same diet without vitamin E (TD No. 87237, α-tocopherol 0.05 ± 0.02 mg/kg) and two dogs (+E1 and +E2) continued on the supplemented diet. The detailed composition of the diet has been reported elsewhere (13). Diets were ordered in batches of 50 kg and stored at 4°C for a maximum of 8 wk. Samples from each shipment were collected toward the end of the storage period for measurement of α-T to verify that the supplemented diet contained approximately 120 IU vitamin E/kg, the manufacturer's added vitamin E content prior to mixing.

At the end of the 4-wk adjustment period, blood was collected by jugular venipuncture into heparinized 10-mL Vacutainer tubes (143 USP units of heparin; Becton-Dickinson Co., Rutherford, NJ) and immediately placed on ice. The tubes were centrifuged (Model CRU-5000, rotor No. 269; IEC, Needham Heights, MA) at 1500 × *g* for 10 min, and 1-mL aliquots of plasma were removed and stored at −80°C for α-T analysis (see below). The following day, physical and neurologic examinations were

conducted. Then, the dogs were premedicated with acepromazine maleate (0.5 mg/kg body weight, i.m., Atravet; Ayerst Laboratories, Montreal, Quebec, Canada) and atropine (0.05 mg/kg i.m., Fort Dodge Laboratories, Fort Dodge, IA) and anesthetized with Pentothal (18 mg/kg body weight, IV; Abbott Laboratories, North Chicago, IL). Sensory NCV of the superficial radial and peroneal nerves and motor NCV of the ulnar and tibial nerves were determined, as described (14).

Bleeding and electrodiagnostics were repeated at approximately 8-wk intervals for 109 wk. From 24 wk onward, adipose tissue samples were biopsied from subcutaneous fat in the popliteal fossa; samples were wrapped in aluminum foil, immediately frozen on dry ice and stored at −80°C for α-T analysis. At 65 wk, fascicular biopsies of the tibial nerve from the left side (just proximal to the calcaneal tuber) were obtained under anesthesia.

Half of the nerve biopsy specimen was wrapped in foil, frozen on dry ice and stored at −80°C for α-T analysis, as described below. The other half was stretched on a wooden tongue depressor and fixed in 3% glutaraldehyde (4°C) for a week, followed by osmication, dehydration and embedding in epon. Semithin (1 μm) sections of epon embedded nerves were cut, stained with *p*-phenylenediamine and examined by light microscopy (15). Stained sections of nerves were projected onto a monitor, using a computerized video-display image analysis system (Optomax semiautomatic image analysis system; Optomax, Hollis, NH), and mean external diameters of 500 randomly selected fibers were measured (15).

At 109 wk, the dogs were euthanized by an overdose of Pentothal, and 2-cm sections of the tibial nerve from the right side (same location as the biopsy) were collected and processed as described for the biopsies.

α-Tocopherol, triglyceride and cholesterol analyses. Samples of diet, plasma, adipose tissue and nerves were shipped on dry ice, within 7 d of collection, to New York University School of Medicine for analysis of α-T within 1 mon of receipt. Plasma α-T levels were analyzed, as described (16). Adipose tissue α-T, cholesterol and triglycerides (TG) and nerve α-T and cholesterol were analyzed, as described (3,7,17). Data are reported as the mean ± standard deviation (SD).

Semilog plots depicting plasma and adipose tissue α-T concentrations over time were constructed, and linear regression analysis was used to determine depletion rates (Delta Graph Professional, Delta Point, Monterey, CA). Because the decay curves were exponential functions following first-order kinetics, the time to deplete half of the α-T was calculated from the equation: $t_{1/2} = \ln(2)/\beta$, where β is the elimination rate constant (given by the slope) for each curve (18).

RESULTS

Physical and neurologic examination. No abnormalities (rough skin coat, hind limb ataxia or depressed tendon reflexes) were detected in the dogs during physical and neurologic examinations. All dogs maintained their body weights throughout the study (−E1, 18 ± 4 kg; −E2, 19 ± 6; +E1, 18 ± 5; +E2, 19 ± 6).

Plasma and adipose tissue α-T. Baseline plasma α-T concentrations of the four dogs were 25 ± 6 μg/mL (range, 18.4 to 31.3 μg/mL). Throughout the study (14 measurements), plasma α-T values in +E1 were 24 ± 3 μg/mL and in +E2 were 28 ± 5 μg/mL. In −E dogs, semilog plots showed a linear decline in plasma α-T concentrations (Fig. 1); values were <1.0 μg/mL by 65 wk (455 d) and <0.1 μg/mL by 109 wk (763 d). The times to deplete half of the plasma tocopherol ($t_{1/2}$), estimated from the slopes of the plasma α-T concentration curves, were 90 d for −E1 and 85 d for −E2 (Fig. 1).

Shown in Figure 2 are the α-T contents (ng) of adipose tissue expressed per mg wet weight, per mg TG and per μg cholesterol. These three denominators were chosen because (i) wet weight can vary if the specimen becomes dried, (ii) TG have been used as the denominator for measurements of needle biopsies in humans where wet weights are not available and (iii) cholesterol is extracted during α-T isolation and can be conveniently measured. Cholesterol/TG ratios were calculated and found to be relatively constant throughout the study, thereby demonstrating the relative uniformity of the biopsy specimens (−E1, 2.3 ± 1.3 μg/mg; −E2, 1.8 ± 0.6; +E1, 2.4 ± 2.1; +E2, 2.1 ± 1.3).

In +E dogs, adipose tissue α-T concentrations remained high throughout the study (+E1, 450 ± 110 μg/g wet weight; +E2, 320 ± 180) (Fig. 2). Adipose tissue α-T/TG in +E dogs (730 ± 280 μg/mg and 470 ± 250, for +E1 and 2, respectively) are somewhat higher than those obtained by needle biopsies of subcutaneous adipose tissue from nine healthy adult humans (402 ± 154 μg/mg) (19).

Semilog plots of adipose tissue α-T concentrations in −E dogs decreased linearly, and were similar in both −E dogs, whether expressed per wet weight (Fig. 2A), TG (Fig. 2B) or cholesterol (Fig. 2C). The $t_{1/2}$ estimated from Figures 2A, B and C for −E1 were 103, 91 and 104 d and for −E2 were 133, 121 and 165 d; the overall mean was 120 d.

Nerve α-T concentrations, NCV and histopathology. At 65 wk, α-T/cholesterol in tibial nerves of −E dogs were reduced to about 16% of +E values, and by 109 wk, had decreased to about 2% (Table 1).

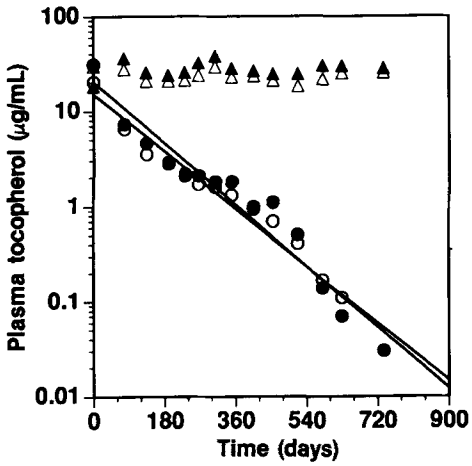

FIG. 1. The semilog plots of plasma α-tocopherol (α-T) in dogs fed a vitamin E-supplemented diet (+E dogs) (△, +E1, ▲, +E2) are relatively constant, while in dogs fed a vitamin E-deficient diet (−E dogs) (○, −E1; ●, −E2) concentrations decline linearly on the semilog plot (−E1, $r^2 = 0.97$; −E2, $r^2 = 0.94$). The half-life of plasma α-T in −E dogs, given by the equation $t_{1/2} = \ln(2)/\beta$ where β is the elimination rate constant of the exponential function (−0.0077 and −0.0082 in −E1 and 2, respectively) is 90 d for −E1 and 85 d for −E2.

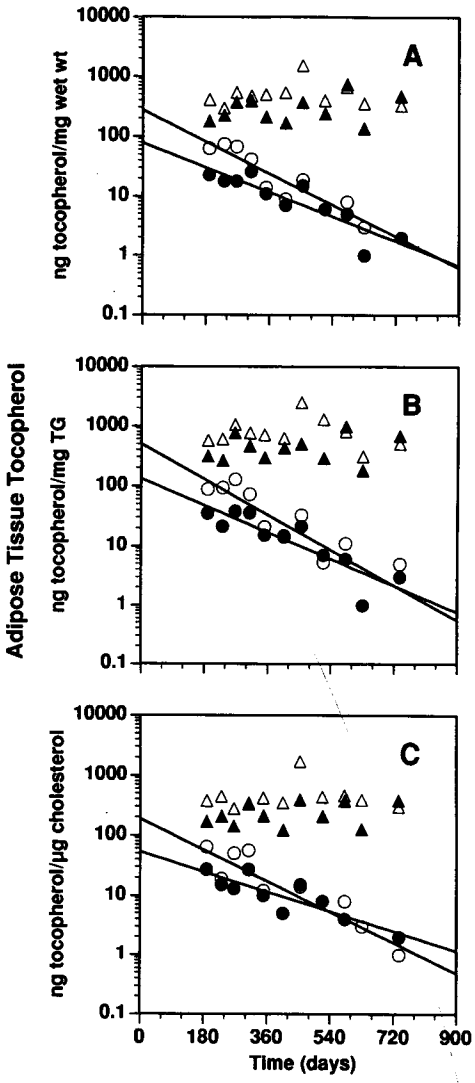

FIG. 2. Semilog plots of adipose tissue α-T concentrations (A) per wet weight, (B) per triglycerides (TG), and (C) per cholesterol are shown. In +E dogs (△, +E1; ▲, +E2), the values remained relatively constant throughout the study. In −E dogs (○, −E1; ●, −E2), the declines in adipose tissue α-T concentrations were linear on a semilog plot for each of the denominators (wet wt, r^2 = 0.90, 0.79; TG, r^2 = 0.77, 0.77; cholesterol, r^2 = 0.80, 0.75, for −E1 and −E2, respectively). The time to deplete half of initial concentrations ($t_{1/2}$) values were calculated as described in Figure 1. The β values were similar for each of the denominators (in −E1, β = −0.0067, −0.0076, −0.0066; in −E2, β = −0.0052, −0.0057, −0.0042; from A, B and C, respectively). The $t_{1/2}$ values calculated from A, B and C for −E1 were 103, 91 and 104 d and for −E2 were 133, 121 and 165 d, respectively. See Figure 1 for other abbreviations.

The sensory and motor NCV values were similar in all dogs throughout the study (Fig. 3). Sensory action potential amplitudes were also measured and were similar in all dogs throughout the study (data not shown).

At 65 and 109 wk, no detectable differences between −E and +E nerves were apparent by light microscopy. Electron microscopic examination of semithin sections of the tibial nerve did not reveal any abnormalities (such as loss of large-diameter myelinated fibers) at either 65 or 109 wk. By 109 wk, mean external diameters of myelinated nerve fibers were not different between the two groups (Table 1).

TABLE 1

α-T/Cholesterol Ratios and Diameters of Tibial Nerves from Dogs Fed Vitamin E-Deficient (−E) or Supplemented (+E) Diets

Time (wk)	Dog	Nerve composition (μg α-T/mg cholesterol)	Nerve diameter (μm ± SD)
65	+E1	6.3	na[a]
	+E2	5.6	na
	−E1	0.4	na
	−E2	1.5	na
109	+E1	3.6	5.1 ± 2.6
	+E2	6.7	4.1 ± 2.0
	−E1	0.04	3.8 ± 1.6
	−E2	0.09	4.8 ± 2.6

[a]na, Not analyzed; abbreviations: α-T, α-tocopherol; SD, standard deviation.

DISCUSSION

This is the first longitudinal study measuring plasma and adipose tissue α-T concentrations in dogs fed vitamin E-supplemented or -deficient diets over 109 wk. In −E dogs, both plasma and adipose tissue α-T concentrations decreased with first-order kinetics. Estimated values of the $t_{1/2}$ for depletion of α-T from plasma were 87 d and from adipose tissue were 120 d. These data suggest that dog adipose tissue α-T stores are utilized for the maintenance of plasma α-T. Plasma and adipose tissue α-T concentrations in −E dogs were correlated (−E1, r^2 = 0.7942, $P < 0.0003$; −E2, r^2 = 0.7930, $P < 0.0003$), giving further support to this hypothesis.

Plasma α-T concentrations also decrease with first-order kinetics in response to a vitamin E-deficient diet in other species, such as rats (6,20), guinea pigs (5), monkeys (6) and humans (for a review, see 21). Adipose tissue α-T also decreases with first-order kinetics in rodents. We have estimated, using previously reported data, that the $t_{1/2}$ of α-T in adipose tissue of mature rats was 70 d (20), and of mature guinea pigs was 600 d (5). Thus, the $t_{1/2}$ of α-T in adipose tissue is longer in the dog compared to the rat, but much shorter than the guinea pig.

By 65 wk, −E dogs had tibial nerve concentrations (Table 1), which were comparable to those from sural nerves of vitamin E-deficient humans (1.8 ± 1.2 ng/μg cholesterol) (3). By 109 wk, α-T concentrations of tibial nerves in −E dogs were well below deficient human sural nerve levels. By contrast, weanling rats fed vitamin E-deficient diets had a faster decline of α-T from nerve (4–7% of control sciatic-tibial nerve values by 36 wk) compared to −E dogs (16% of control tibial nerve values by 65 wk). Furthermore, vitamin E-deficient rats had decreased tibial NCV by 8 mon (22) and axonal swelling in sural nerves by 12 mon (23). The earlier onset of changes in rats may be attributed to the younger age when vitamin E-deficient diets were initiated and to species differences.

The −E dogs did not develop neurologic abnormalities, and electrophysiologic tests remained normal (Table 1). The lack of slowing in nerve conduction velocities in our study is similar to findings in vitamin E-deficient humans with subclinical disease (24). In nine patients with serum

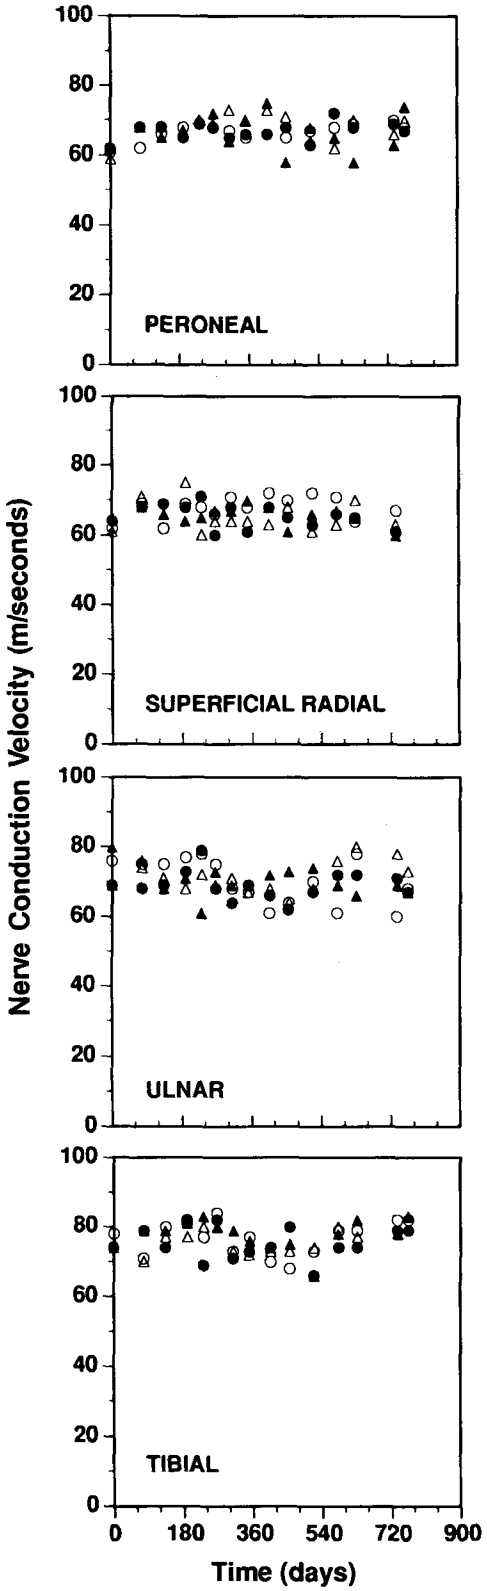

FIG. 3. Sensory nerve conduction velocity (NCV) of the peroneal and superficial radial nerves, and motor NCV of the ulnar and tibial nerves in dogs fed vitamin E-deficient (○, −E1; ●, −E2) or control diets (△, +E1; ▲, +E2) were similar in both groups at all times.

α-T < 5 μg/mL, three were clinically asymptomatic and did not show any electrophysiologic abnormalities. The remaining six patients had varying degrees of neurologic abnormalities including weakness, proprioceptive deficits and ataxia, and had delayed central conduction measured by somatosensory evoked potentials (24). These findings and a previous report in humans (3) suggest that nerves must be depleted of α-T for years before histologic changes occur.

In conclusion, plasma α-T in adult dogs fed vitamin E-deficient diets declines in parallel with adipose tissue α-T. The correlation of plasma α-T with adipose tissue α-T suggests that the adipose tissue α-T can be taken up by plasma lipoproteins for delivery to other tissues in the body (as reviewed in Ref. 25). The development of vitamin E deficiency in adult dogs resembles that in humans more closely than in rodents in terms of tissue α-T depletion, and the relatively prolonged duration of the deficient state before development of clinical, electrophysiologic and/or histopathologic signs.

ACKNOWLEDGMENTS

The research was supported in part by funds from the Scott-Ritchey Research Center. MGT and HJK were supported in part by grants from the U.S. Public Health Service, Grant No. HL 30842, and from the Natural Source Vitamin E Association. The authors acknowledge the excellent technical assistance provided by Nora Lagmay (New York University School of Medicine) for vitamin E analyses and Dr. Maria Tolvio-Kinnucan for processing of tibial nerve sections.

The effects of dietary vitamin E levels on tissue α-tocopherol (α-T) concentrations in different parts of the nervous system are largely unknown. Therefore, we measured the α-T contents of nervous and other tissues obtained from beagle dogs fed for two years a vitamin E-deficient diet (−E, 0.05 ± 0.02 mg vitamin E/kg diet, n = 2), a vitamin E-supplemented diet (+E, 114 ± 14 mg/kg, n = 2), or a standard chow diet (E_n, 74 ± 6 mg/kg, n = 3). Brain regions and spinal cords of +E dogs contained about double the α-T concentrations of E_n dogs, and about 10-fold those of −E dogs. The various brain regions of −E dogs, compared with E_n dogs, retained 12-18% of the α-T concentrations, with the exception of the caudal colliculus, which retained 48%. Peripheral nerve α-T concentrations in +E dogs (67 ng/mg wet weight) were nearly 5-fold higher than in E_n dogs (13.4 ± 5.9 ng/mg) and 80-fold higher than in −E dogs (0.8 ng/mg). Within each dietary group, the lowest α-T concentrations in the central nervous system (CNS) were in the spinal cord. Peripheral nerves were the most susceptible to vitamin E repletion or depletion: in +E dogs, nerves contained higher concentrations of α-T than most brain regions; in E_n dogs, they contained similar concentrations; but in −E dogs, they contained less α-T than most brain regions. Muscles and other tissues of −E dogs retained from 1 to 10% of E_n values. The studies demonstrate that the CNS conserved α-T compared to peripheral nerves and nonnervous tissues in adult dogs, but contained lower absolute concentrations of α-T compare with most other tissues.

***Lipids* 28, 1101-1105 (1993).**

Vitamin E deficiency symptoms in humans and in experimental animals include a progressive peripheral neuropathy (1). Our hypothesis is that the development of pathological changes resulting from vitamin E deficiency depends upon the tissue concentrations of α-tocopherol (α-T), which reflect the storage capacity of the tissue (*i.e.*, the lipid content of the tissue), α-T utilization rates and α-T replacement rates. For example, in rodents the nervous system conserves α-T compared to liver, heart and muscle (2,3). However, the cerebellum of rodents is particularly susceptible to vitamin E deficiency, presumably because the low α-T concentrations reflect high utilization despite a high uptake of α-T, as measured with radioactive α-T (4).

To investigate the effects of vitamin E deficiency on nervous tissue concentrations of α-T in adult dogs, four male 1-year-old beagle dogs were evaluated; two were fed a vitamin E-deficient diet (−E), and two were fed the same diet supplemented with vitamin E (+E) for two years. Additionally, tissues from three female 5-year-old beagles that were fed a standard chow diet were analyzed. Concentrations of α-T in the central nervous system (CNS), peripheral nerves, skeletal muscles and selected tissues were determined.

MATERIALS AND METHODS

Protocol. All procedures were approved by the Auburn University Institutional Animal Care and Use Committee (Auburn, AL). As described in other works (5,6), four 1-year-old male beagle dogs (Marshall Farms, North Rose, NY), weighing about 18 kg, were fed a purified diet containing *all-rac*-α-tocopheryl acetate (TD No. 87238; Teklad Laboratories, Madison, WI; α-T, 114 ± 14 mg/kg) for an adjustment period of 4 wk. Then, two dogs (−E1 and −E2) were selected randomly to receive the same diet without vitamin E (TD No. 87237, α-T 0.05 ± 0.02 mg/kg), and two dogs (+E1 and +E2) continued on the supplemented diet.

The dogs (3-years-old), following maintenance on the diets for two years, were euthanized by an overdose of intravenous barbiturate (Pentothal; Abbott Lab; North Chicago, IL); tissues were collected for measurement of α-T as described below. Additional tissues from three healthy female 5-year-old beagles maintained for two years in the same facility were collected. These dogs (designated E_n) had received a standard laboratory diet (Dog Chow; Purina Mills, St. Louis, MO) containing added *all-rac*-α-tocopheryl acetate (measured α-T content, 74 ± 6 mg/kg).

Tissue collection. Immediately after euthanasia, the cranium was opened and the entire brain was removed and placed on ice. The left half was used to dissect out 500-mg pieces of frontal, parietal, temporal and occipital cortex, caudate nucleus, hippocampus, amygdala, rostral and caudal colliculus, cerebellum, pons and medulla. The spinal cord was dissected into cervical (C 1), thoracic (T 6-7) and lumbar (L 5-6) segments, and 500-mg pieces from the dorsal columns were collected. Samples (1 cm) of the sciatic (at the coxo-femoral joint), tibial (proximal to the tarsus) and superficial radial (at the elbow joint) nerves, and the rectus femoris and extensor carpi radialis muscles were excised. Pieces (1 g) of liver, cardiac muscle (left ventricle), adrenal gland, renal cortex and medulla, and testicles were collected also. All tissue samples were stripped of connective tissue and fat, immediately wrapped in aluminum foil and frozen on dry ice. The samples were stored at −80°C until shipment, within 1 wk of collection, to New York University School of Medicine for α-T analysis. The α-T and cholesterol contents of all samples were analyzed, as previously reported (7,8), within two months of receipt.

Statistical analysis. Average α-T concentrations of tissues for +E and −E dogs, and means ± standard deviations for E_n dogs were calculated [Super ANOVA; Abacus Concepts, Berkeley, CA). For E_n dogs, one-way analysis of variance and comparisons of least square means were used to determine differences in α-T concentrations in the brain and spinal cord samples, and peripheral nerves. A value of $P < 0.05$ was considered significant.

Abbreviations: α-T, α-tocopherol; ANOVA, analysis of variance; CNS, central nervous system; +E, dogs fed vitamin E-supplemented diet; −E, dogs fed vitamin E-deficient diet; E_n, dogs fed standard chow diet; SD, standard deviation.

RESULTS

Brain regions. The α-T contents of various anatomical sites from the brains of the three groups of dogs fed different dietary levels of vitamin E are shown in Table 1. Because α-T concentrations in specific neuroanatomic areas of the brain did not differ markedly, brain regions were grouped according to embryological divisions, *viz.*, telencephalon (frontal, parietal, occipital and temporal cortices, caudate nucleus, hippocampus and amygdala), diencephalon (thalamus and hypothalamus), mesencephalon (rostral and caudal colliculus), metencephalon (cerebellum and pons) and myelencephalon (medulla oblongata). Mean α-T concentrations for these regions and the statistical significance between regions in E_n dogs are also shown in Table 1.

In E_n dogs, α-T concentrations in the telencephalon were significantly greater than those of the medulla oblongata. Furthermore, the rostral brain regions (telencephalon, diencephalon), irrespective of diet group, contained higher α-T concentrations than the caudal areas (mesencephalon, metencephalon, myelencephalon).

On an α-T/cholesterol basis, the telencephalon in E_n dogs contained significantly greater concentrations ($P < 0.05$) than the other brain regions. Indeed, the α-T/cholesterol ratios were markedly higher in the telencephalon compared with the myelencephalon in all dogs. The α-T/cholesterol ratios were high in the telencephalon because this region contained the lowest cholesterol concentrations, while the myelencephalon contained the highest. It should be noted that the cholesterol concentrations of each of the brain regions were similar between the three dietary groups (Table 1).

In −E dogs, α-T concentrations of the brain regions were minimal, ranging from 0.7 to 3.8 ng/mg wet wt (Table 1), about 12–18% of those of E_n dogs, with the exception of the mesencephalon (Fig. 1). In the mesencephalon, the caudal colliculus of −E dogs contained 48% of α-T concentrations in E_n dogs. However, the caudal colliculus in −E dogs did not contain high concentrations of α-T, nor was it particularly enriched with α-T in either +E or E_n dogs (Table 1).

Spinal cord. The spinal cord α-T/wet weight ratios were significantly lower than in the telencephalon and the peripheral nerve in E_n dogs (Table 1). Again the high cholesterol content of the spinal cord caused the α-T/cholesterol ratio to be one of the lowest in the nervous system. In E_n dogs, the spinal cord α-T/cholesterol ration was 1/8 of that of the telencephalon ($P < 0.05$).

Spinal cord α-T contents (expressed per weight or per cholesterol) in +E dogs were double those in E_n dogs, and more than 10-fold those in −E dogs (Table 1).

Peripheral nerves. Of all nervous tissues, peripheral nerves were the most susceptible to vitamin E repletion or depletion (Table 1 and Fig. 1). In +E dogs, nerve α-T concentrations were more than double those of most brain regions, or spinal cord. In E_n dogs, nerve α-T concentrations were significantly greater than in the mesencephalon, metencephalon, myelencephalon or the spinal cord. However, in −E dogs, nerve α-T concentrations were about half of most other brain regions. Peripheral nerves of −E dogs contained about 6% of those of E_n nerves, the lowest percentage retained of all the nervous tissues (Fig. 1), but comparable to α-T retention in nonnervous tissues (see below).

[a–l]Regions of E_n dogs in each column bearing the same superscript letter are significantly different ($P < 0.05$) by least squares means comparisons.

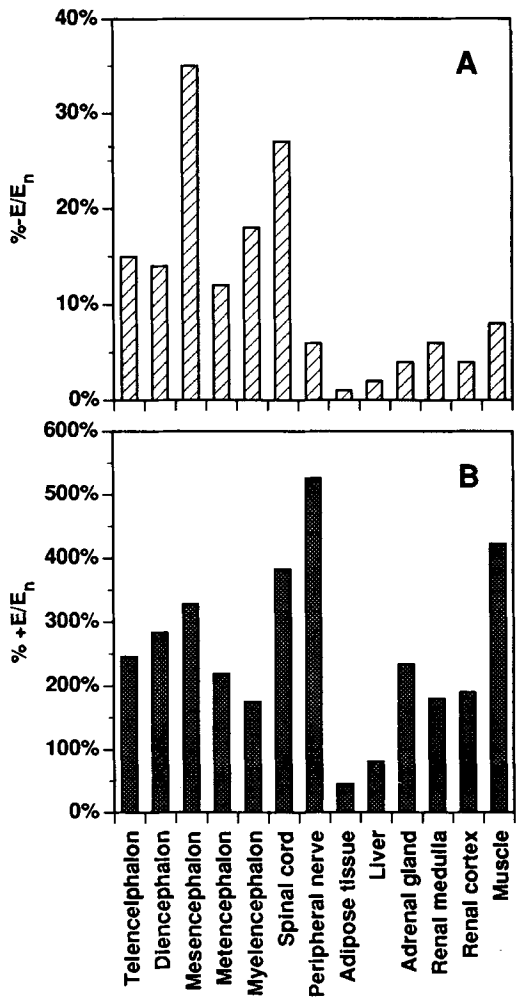

FIG. 1. A. α-Tocopherol (α-T) concentrations of tissues from two dogs fed vitamin E-deficient diets (−E), expressed as a % of mean E_n dog α-T concentrations, *i.e.*, % = $-E/E_n \times 100$. B. α-T concentrations of tissue from two dogs fed vitamin E-supplemented diets (+E), expressed as a % of E_n dog α-T concentrations, *i.e.*, % = $+E/E_n \times 100$.

Because of their relatively low cholesterol contents compared with other parts of the CNS (except telencephalon and diencephalon), α-T/cholesterol ratios were significantly ($P < 0.05$) higher in E_n peripheral nerves than in mesencephalon, metencephalon, myelencephalon and spinal cord.

Other tissues. α-T concentrations were followed longitudinally in −E and +E dogs, as reported in the preceding paper (6). In +E dogs, adipose tissue α-T concentrations remained high throughout the study [450 ± 110 μg/g wet weight and 320 ± 180 for +E 1 and 2, respectively (6)], and were similar to those in E_n dogs (376 μg/g) (Table 2).

In −E dogs, α-T was depleted from adipose tissue with first order kinetics to 1.6 ng/mg wet wt in −E1 and 1.9 in −E2 (6). However, 1 wk prior to sacrifice, these dogs were given a dose of deuterated α-tocopherol [4 mg/kg body weight each of *RRR-* and *all rac-α*-tocopheryl acetates, 142 mg total (9)], which apparently raised the adipose tissue values to 7.9 ng/mg wet weight in −E1 and 2.6 in −E2, as shown in Table 2.

The liver contained similarly high α-T concentrations in both +E dogs and in E_n dogs (Table 2). Thus, the liver did not store additional α-T in response to supplementation. The liver in −E dogs contained 3.2 ng/mg, only 1.6% of that in E_n liver (Fig. 1).

High α-T concentrations were found in the adrenal glands of both +E and E_n dogs, but were depleted in −E dogs to 3.5% of E_n values (Table 2 and Fig. 1). The high cholesterol contents of the adrenal glands (20–30 μg/mg wet weight) decreased the ratios of α-T/cholesterol to values lower than those in most other nonnervous tissues (Table 2).

Irrespective of diet, the renal medulla contained 8–10 times more α-T than did the cortex on a wet weight basis and 4–5 times more on a cholesterol basis (Table 2). The higher α-T contents of the medulla can be explained by differences in lipid contents. On histologic examination of fixed tissue, the medulla was observed to have more lipid than the cortex. The cholesterol contents confirm this observation; the medulla contained roughly double the cholesterol concentration of the cortex.

Within each dietary group, α-T concentrations (either per wet weight or per cholesterol) of the three different muscles (cardiac and the two skeletal muscles) were similar (Table 2). The average α-T concentration of muscles from +E dogs were approximately 4-fold greater than those of E_n and 50-fold greater than those of −E dogs.

Testicles of +E dogs contained about 50 times more α-T than those of −E dogs (Table 2).

DISCUSSION

The distribution of α-T in brain regions of dogs fed three dietary levels of vitamin E was measured in an effort to

assess which brain regions are responsive to changes in dietary α-T. In response to vitamin E deficiency, the lowest concentrations of α-T in −E dogs were found in the cerebellum (0.7 ng/mg) and the myelencephalon (medulla oblongata) (0.7 ng/mg); the cerebellum retained the lowest percentage of α-T (9%). Previous studies in rats (2,3) and mice (10) have shown that the cerebellum is readily depleted of α-T, and is an active site of uptake of radioactive vitamin E. Typically, axonal dystrophy occurs in the cerebellum and brainstem in experimental vitamin E deficiency in rodents and monkeys (11), and immature dogs (12). Dystrophic changes were also seen in the brainstem nuclei of −E dogs (Pillai, S.R., and Steiss, J.E., unpublished observations).

In −E dogs, the brain region which retained the largest percentage of α-T (48%) was the caudal colliculus, part of the auditory pathway. Apparently, the auditory pathway is more resistant to vitamin E depletion than the visual and somatosensory tracts. Consistent with our study are findings in vitamin E-deficient humans. No changes in brainstem auditory-evoked potentials were reported, although these patients had delayed somatosensory-evoked potentials, abnormal electroretinograms and delayed visual-evoked potentials (13). Similarly, in vitamin E-deficient rats, brainstem auditory-evoked potentials are normal (14), while somatosensory-evoked potentials (14,15), electroretinograms and visual-evoked potentials (14) are abnormal.

Brain regions of dogs and rodents appear to respond somewhat differently to vitamin E supplementation. In +E dogs, the highest increase of α-T occurred in the mesencephalon, while in vitamin E-supplemented rats, maximum increases have been reported in the medulla oblongata and pons (2), and the cerebellum (16). By contrast, the medulla in +E dogs was the brain region with the smallest increase in α-T concentrations (Table 1).

Peripheral nerves were remarkable in having the highest α-T concentration of all nervous tissue in +E dogs, as previously observed in rats (4,17). Furthermore, in +E dogs, the increases in nerve α-T concentrations were about double those of the CNS. Correspondingly, in −E dogs, the nerves retained lower percentages (6%) of α-T than other portions of the nervous system. The ease with which peripheral nerves are depleted may explain why humans (18), monkeys (11) and rats (19) develop a peripheral neuropathy associated with vitamin E deficiency. However, in the present study, −E dogs did not develop clinical, electrophysiological or histologic evidence of peripheral neuropathy (Pillai, S.R., and Steiss, J.E., unpublished data).

Of other tissues examined, the highest α-T concentrations in response to vitamin E supplementation were in adipose tissue, liver, adrenal gland and kidney (Table 2). Adipose tissue is a major α-T storage site in humans (7), rats (20), guinea pigs (21), mink (22) and horses (23). The liver also accumulates α-T with vitamin E supplementation in most species (20–25). The accumulation of α-T by the adrenal gland in +E dogs is in agreement with studies in humans (26), rats (27) and cattle (28,29). These high α-T concentrations may be related to the high cholesterol contents of the adrenal gland, or higher antioxidant levels may be required to protect the tissue during steroid hormone synthesis (26). We found higher α-T concentrations in the renal medulla compared with the cortex, which are likely due to the higher lipid contents of the medulla.

In dogs, irrespective of diet, cardiac and skeletal muscle contained similar α-T concentrations, but in pigs (25), cattle (28) and sheep (30), cardiac muscles contained higher α-T concentrations than skeletal muscles. These may represent species differences.

In conclusion, the present study demonstrates in dogs that of all nervous tissues, peripheral nerves were most responsive to vitamin E supplementation and deficiency. In −E dogs, the CNS retained higher percentages of α-T than either peripheral nerves or non-nervous tissues; however, the absolute α-T concentrations in nervous tissues were lower than in most other tissues. Considering vitamin E functions as an antioxidant, and that tissues depleted of α-T are susceptible to free radical damage, it is therefore not surprising that vitamin E-deficient dogs display neuromuscular abnormalities (12,31).

ACKNOWLEDGMENTS

The research was supported in part by funds from the Scott-Ritchey Research Center. MGT and HJK were supported in part by grants from the U.S. Public Health Service, Grant No. HL 30842 and from the Natural Source Vitamin E Association. The authors acknowledge the excellent technical assistance provided by Nora Lagmay (New York University School of Medicine) for vitamin E analyses.

Vitamin E Deficiency in Dogs Does Not Alter Preferential Incorporation of *RRR*-α-Tocopherol Compared with *all rac*-α-Tocopherol into Plasma

Maret G. Traber[a,*], Shreekumar R. Pillai[b], Herbert J. Kayden[a] and Janet E. Steiss[b]

[a]Department of Medicine, New York University School of Medicine, New York, New York 10016 and the [b]Scott-Ritchey Research Center, College of Veterinary Medicine, Auburn University, Auburn, Alabama 36849

The plasma and lipoprotein transport of *RRR* and *all rac*-α-tocopherols, labeled with different amounts of deuterium [2*R*,4′*R*,8′*R*-α-[5-C^2H_3]tocopheryl acetate (*d_3RRR*-α-tocopheryl acetate] and 2*RS*, 4′*RS*, 8′*RS*-α-[5,7-$(C^2H_3)_2$]tocopheryl acetate (*$d_6$all rac*-α-tocopheryl acetate), was studied in adult beagle dogs that had been fed a vitamin E-deficient (−E; two dogs) or supplemented (+E; two dogs) diet for two years. We set out to test the hypothesis that the activity of the hepatic tocopherol binding protein (which is thought to preferentially incorporate *RRR*-α-tocopherol into the plasma) is up-regulated by vitamin E deficiency. Labeled α-tocopherols increased and decreased similarly in plasma of both −E and +E dogs. Irrespective of diet, *d_3RRR*-α-tocopherol was preferentially secreted in plasma. Thus, vitamin E deficiency in dogs does not markedly increase the apparent function of the hepatic tocopherol binding protein. We also studied vitamin E transport in a German Shepherd dog with degenerative myelopathy (DM). Based on the coincident appearance of *d_3RRR*-α-tocopherol in plasma and chylomicrons, we suggest that the abnormality in DM may be associated with abnormal vitamin E transport resulting from an impaired function of the hepatic tocopherol binding protein.
***Lipids* 28, 1107–1112 (1993).**

Vitamin E, a fat-soluble vitamin, is transported in the plasma lipoproteins (for reviews, see Refs. 1 and 2). Vitamin E is absorbed by the intestine and secreted in chylomicrons (3), which are catabolized in the circulation. Chylomicron remnants are then taken up by the liver. Of the various forms of dietary vitamin E, *RRR*-α-tocopherol is preferentially secreted by the liver into the plasma in very low density lipoproteins (VLDL) (3–6). This phenomenon was demonstrated directly using perfused monkey livers from animals fed deuterium-labeled tocopherols (5). The nascent VLDL secreted by the livers were preferentially enriched with *RRR*-, as compared with *SRR*-α-tocopherol or γ-tocopherol (5).

Catabolism of circulating VLDL maintains plasma *RRR*-α-tocopherol concentrations, as shown in studies using deuterated stereoisomers of α-tocopherol (*RRR*- and *SRR*-) or naturally occurring, deuterated forms of vitamin E (α- and γ-tocopherols) in healthy subjects (4), patients with familial, isolated vitamin E deficiency (7,8) and patients with genetic abnormalities of lipoprotein metabolism (6,9). Further, we have proposed that incorporation of *RRR*-α-tocopherol in nascent VLDL requires the action of the hepatic tocopherol binding protein. Such a protein has been purified from rat liver (10,11) and shown to transfer α-tocopherol (in preference to other tocopherols) between liposomes and microsomes (10).

Because of its putative role in maintaining plasma vitamin E levels (2), the tocopherol binding protein or its activity might be increased in response to vitamin E deficiency. However, there are conflicting reports in the literature as to whether its activity is increased (12) or unchanged (11) in response to vitamin E deficiency in rats. In addition, because this protein likely differentiates between forms of vitamin E, secretion of *RRR*-α-tocopherol into the plasma might be enhanced by vitamin E deficiency. Therefore, to test the hypothesis that the activity of the tocopherol binding protein is up-regulated by vitamin E deficiency, we studied the transport of *RRR*- and *all rac*-α-tocopherol labeled with different amounts of deuterium in adult beagle dogs that had been fed a vitamin E-deficient or vitamin E-supplemented diet for two years (−E, +E, respectively).

We also studied vitamin E transport in a German Shepherd dog diagnosed to have degenerative myelopathy (DM) (13). This disease (13–15) has several similarities to vitamin E deficiency in other species (16,17), namely, degenerative changes in the spinal cord, pelvic limb ataxia and paresis, hyporeflexia or areflexia, impaired cellular immunity, and low serum vitamin E levels. Furthermore, a preliminary report suggests that progression of the disease is slowed by the administration of large doses of vitamin E to affected dogs (14). Familial isolated vitamin E deficiency in humans is an inherited disease (18), and DM in dogs primarily affects the German Shepherd breed, suggesting a genetic predisposition. Based on the possibility that DM might be the result of an impaired transport of vitamin E due to a defective hepatic tocopherol binding protein, we tested the ability of this dog to transport deuterated α-tocopherols.

MATERIALS AND METHODS

Animals. All procedures were approved by the Auburn University Institutional Animal Care and Use Committee (Auburn, AL). As described previously (19,20), four one-year-old male beagle dogs (Marshall Farms, North Rose, NY), weighing about 18 kg each, were fed a purified diet containing *all rac*-α-tocopheryl acetate (TD No. 87238; Teklad Laboratories, Madison, WI; α-tocopherol, 114 ± 14 mg/kg) for an adjustment period of 4 wk. Then, two dogs (−E1 and −E2) were selected randomly to receive the same diet without vitamin E (TD No. 87237, α-tocopherol 0.05 ± 0.02 mg/kg) and two dogs (+E1 and +E2) continued on the supplemented diet. The dogs were maintained on the diets for two years. At the time of this study, −E dogs were clinically healthy, but their plasma, red blood cells and tissues were depleted of vitamin E (19–21).

The dog diagnosed to have DM was a nine-year-old male, purebred German Shepherd. His diet consisted primarily of commercial dog food. Ataxia and paresis involving

Abbreviations: c_{max}, Maximum observed concentrations; DM, degenerative myelopathy; −E, dogs fed a vitamin E-deficient diet; +E, dogs fed a vitamin E-supplemented diet; HDL, high density lipoproteins; LDL, low density lipoproteins; t_{moc}, time of maximum observed concentration; VLDL, very low density lipoproteins.

the pelvic limbs were first noted in March 1991. Three months later, a subcutaneous adipose tissue biopsy from the popliteal fossa and a plasma sample were collected, and the deuterated tocopherol study was performed. At this time, the dog had patellar hyperreflexia, a decreased lymphocyte blastogenesis test to three test antigens, normal findings on cerebrospinal fluid analysis, negative tiers for canine distemper virus (<1:2 for IgG and IgM) and no evidence of a compressive lesion on myelogram. Six months later, the dog was re-admitted for peripheral nerve biopsy for vitamin E analysis. At that time, the dog was paraplegic, and the patellar reflexes were depressed bilaterally. The dog was not receiving any vitamin E supplementation during the time of this study.

Deuterated tocopherols. Deuterated forms of vitamin E [2*R*,4′*R*,8′*R*-α-[5-C^2H_3]tocopheryl acetate (d_3*RRR*-α-tocopheryl acetate] and 2*RS*, 4′*RS*, 8′*RS*-α-[5,7-$(C^2H_3)_2$]tocopheryl acetate (d_6*all rac*-α-tocopheryl acetate) were synthesized by Eastman Chemical Products, Inc. (Kingsport, TN) and were a generous gift from Eastman Chemical Products and the Natural Source Vitamin E Association (Washington, D.C.). Tocopherols were analyzed by gas chromatography/mass spectrometry after conversion to their trimethylsilyl ethers with quantitation by comparison to an added internal standard, 2-*ambo*-α-[5,7,8-$(C^2H_3)_3$]tocopherol, as described previously (3,8,22-24).

Experimental protocols. Following an overnight fast, +E and −E dogs consumed a dose containing 71 mg each of d_3*RRR*- and d_6*all rac*-α-tocopheryl acetates (4.0 mg/kg body weight) dissolved in 1 mL vegetable oil (94 ng unlabeled α-tocopherol/mL and 396 ng γ-tocopherol/mL), and then were given their daily ration of food. Due to a calculation error, the DM dog was given a smaller dose, 63 mg of each isotope (2.1 mg/kg body weight) in 1 mL vegetable oil. Blood samples were obtained at 0, 3, 6, 9, 12, 24, 36, 48 and 72 h. Lipoproteins were isolated from the plasma, as described previously (4), at densities used for human lipoproteins [VLDL, d < 1.006 g/mL; low density lipoprotein (LDL), 1.006 < d < 1.063; and high density lipoprotein (HDL) d > 1.063]. These densities have been used previously to characterize dog plasma lipoproteins (25). The areas under the curves for the plasma and the lipoproteins were calculated using Kaleida Graph (Synergy Software, Reading, PA).

RESULTS

Plasma and lipoprotein α-tocopherols in +E and −E dogs. Plasma concentrations of unlabeled (d_0) and labeled α-tocopherols following oral administration of d_3*RRR*- and d_6*all rac*-α-tocopheryl acetates are shown in Figure 1. At 0 h, plasma d_0-α-tocopherol concentrations in −E dogs were <0.2 nmol/mL; these increased and decreased similarly to the labeled α-tocopherols, but were always less than the deuterated α-tocopherol concentrations. Likely this represents the 200 nmol d_0-α-tocopherol present in the vegetable oil given with the dose of labeled α-tocopherols. By contrast, in +E dogs, d_0-α-tocopherol concentrations were relatively constant throughout the experiment and did not mimic that of the labeled α-tocopherols (Fig. 1).

Plasma-deuterated α-tocopherol concentrations were lower in −E dogs compared with +E dogs. Although the

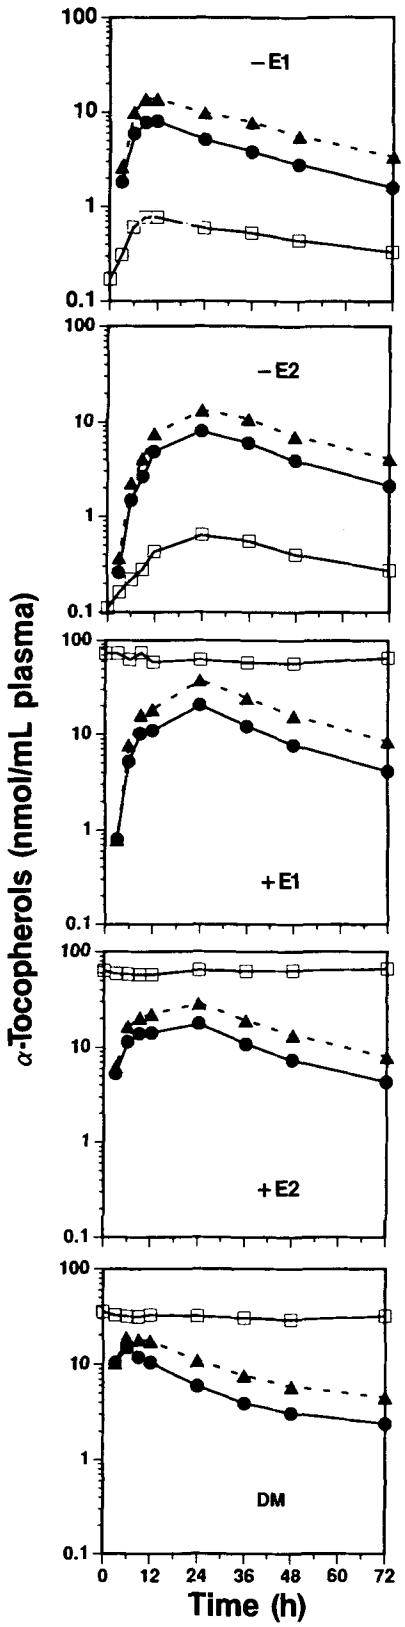

FIG. 1. Plasma concentrations (nmol/mL) of unlabeled (d_0, □), d_3*RRR*-(▲) and d_6*all rac*-α-tocopherols (●) in dogs fed vitamin E-deficient (−E) or vitamin E-supplemented (+E) diets, or in a German Shepherd with degenerative myelopathy (DM) following oral administration of d_3*RRR*- and d_6*all rac*-α-tocopheryl acetates.

shapes of the plasma-deuterated α-tocopherol disappearance curves in the two groups were similar, the areas under the curve of the −E dogs were 42% of those in +E dogs (Table 1). Slopes of the disappearance of portion of plasma *d₃RRR*-α-tocopherol were similar in all dogs (−E1, −0.0234; −E2, −0.0249; +E1, −0.0289; +E2, −0.0256), but maximum observed concentrations (c_{max}) of *d₃RRR* in −E dogs were less than half of those in +E dogs (−E1, 13.8 nmol/mL; −E2, 13.3; +E1, 38.1; +E2, 28.8). The times of maximum observed concentration (t_{moc}) in the plasma were 12 h in −E1 and 24 h in −E2, +E1 and +E2.

Comparison of plasma concentrations of *d₃RRR*- with *d₆all rac*-α-tocopherol in −E and +E dogs shows that vitamin E deficiency did not further enhance the preferential secretion of *RRR*-α-tocopherol into plasma. By 24 h, the plasma in all dogs was preferentially enriched with *d₃RRR*-α-tocopherol; the ratios of *d₃RRR*-/*d₆all rac*-α-tocopherol concentrations at 24 h were 1.88 mol/mol in −E1; 1.63 in −E2; 1.82 in +E1; and 1.61 in +E2. Furthermore, the ratios of the areas under the plasma curves of *d₃RRR*-/*d₆all rac*-α-tocopherol concentrations were also similar in both groups (1.90 in −E1; 1.73 in −E2; 1.90 in +E1; and 1.67 in +E2).

Labeled and unlabeled α-tocopherol contents of the lipoproteins were determined, and representative data are illustrated in Figures 2 and 3 (+E2 and −E2, respectively). (The complete data set is available from the corresponding author upon request.) Unlike human chylomicrons, which contain proportions of tocopherols similar to the administered dose (4,6,7), dog chylomicrons were somewhat enriched in *RRR*- relative to *all rac*-α-tocopherol. The ratios of chylomicron areas under the curves were greater than 1, and in each of the dogs, the c_{max} of chylomicron *d₃RRR*-α-tocopherol was greater than that of *d₆all rac*-α-tocopherol (Figs. 2 and 3). This preferential enrichment of chylomicrons with *RRR*-α-tocopherol could have arisen if dogs have an intestinal tocopherol binding protein, which would function in an analogous manner to the hepatic protein. More likely, dogs may have a faster turnover of chylomicrons with a more rapid VLDL secretion than humans and, therefore, the chylomicrons were contaminated with VLDL. The t_{moc} and c_{max} of the chylomicrons and VLDL support this possibility; in +E1, VLDL t_{moc} (9 h) occurred prior to chylomicron t_{moc} (12 h), and in all dogs, VLDL c_{max} was smaller than chylomicron c_{max} (data not shown).

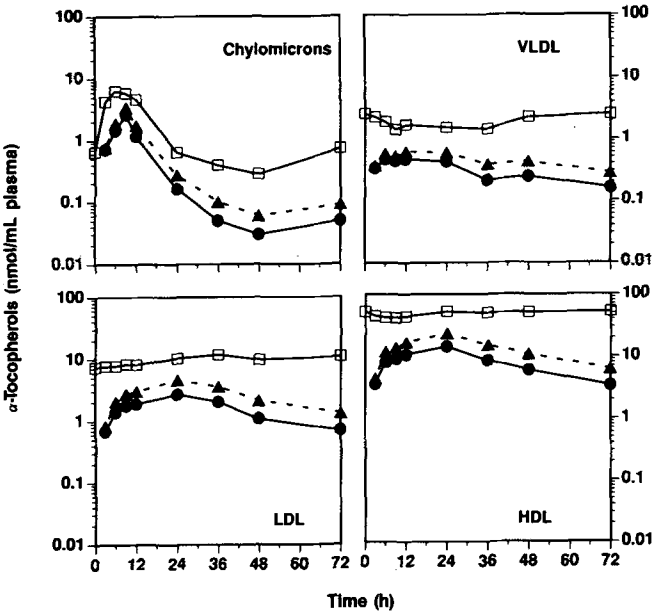

FIG. 2. Lipoprotein concentrations (nmol/mL plasma) of d_0 (□), *d₃RRR*-(▲) and *d₆all rac*-α-tocopherols (●) in dog +E2. Chylomicrons, very low density lipoprotein (VLDL) (d < 1.006 g/mL), low density lipoprotein (LDL) (1.006 < d < 1.063 g/mL) and high density lipoprotein (HDL) (d > 1.063 g/mL) were isolated as described previously (Ref. 4).

It is likely that the preferential enrichment of nascent VLDL with *RRR*-α-tocopherol causes the preferential enrichment of plasma with *RRR*-α-tocopherol because in all dogs (i) the earliest time point (3 h) showed the least enrichment of lipoproteins with *d₃RRR*- compared with *d₆all rac*-α-tocopherol (Figs. 2 and 3); (ii) compared with chylomicrons, other lipoproteins were more dramatically

TABLE 1

Areas Under the Curves (nmol/mL • h) of Deuterated α-Tocopherol Concentrations in Dogs Fed Vitamin E-Deficient (−E) or Vitamin E-Supplemented (+E) Diets, or in a German Shepherd with Degenerative Myelopathy (DM)

[a]VLDL, very low density lipoprotein; LDL, low density lipoprotein; HDL, high density lipoprotein.

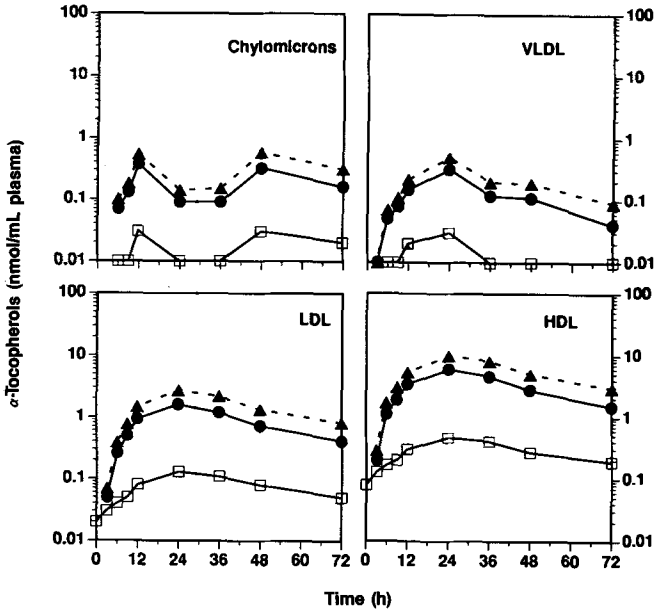

FIG. 3. Lipoprotein concentrations (nmol/mL plasma) of d_0 (□), d_3RRR-(▲) and d_6all *rac*-α-tocopherols (●) in dog −E2. Chylomicrons, VLDL (d < 1.006 g/mL), LDL (1.006 < d < 1.063 g/mL) and HDL (d > 1.063 g/mL) were isolated as described previously (Ref. 4). Abbreviations as in Figure 2.

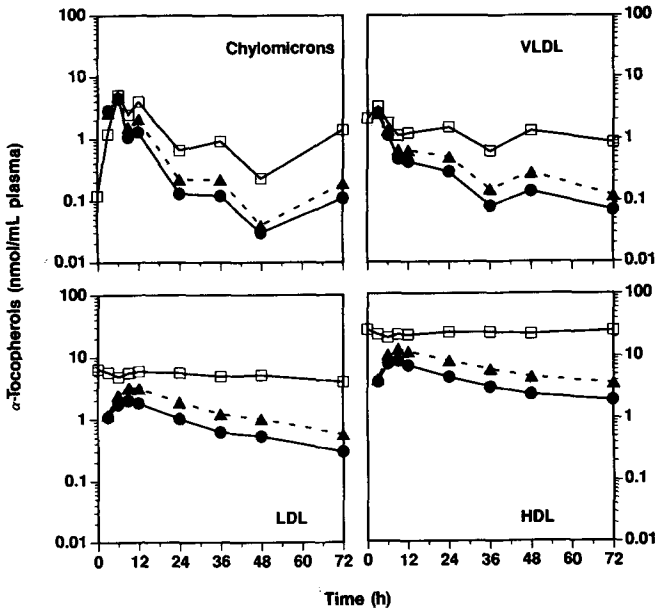

FIG. 4. Lipoprotein concentrations (nmol/mL plasma) of d_0 (□), d_3RRR-(▲) and d_6all *rac*-α-tocopherols (●) in the German Shepherd with degenerative myelopathy. Chylomicrons, VLDL (d < 1.006 g/mL), LDL (1.006 < d < 1.063 g/mL) and HDL (d > 1.063 g/mL) were isolated as described previously (Ref. 4). Abbreviations as in Figure 2.

enriched with *RRR*-α-tocopherol (Figs. 2 and 3 and Table 1); and (iii) VLDL t_{moc} (14 ± 7 h) occurred nearly simultaneously with that of chylomicrons (11 ± 2), but prior to, or simultaneously with, t_{moc} in plasma (21 ± 6 h), LDL (20 ± 8 h) and HDL (21 ± 6).

As might be expected from the plasma data, none of the −E dogs' lipoproteins contained more deuterated tocopherols than did those of the +E dogs (Table 1). The areas under the curves of −E chylomicron d_3RRR-α-tocopherol were about 33% of +E. These areas do not include the second peak in the chylomicron fraction observed in both −E dogs because this peak likely represents enterohepatic circulation and reabsorption of the dose. The areas under the curves of d_3RRR-α-tocopherol in −E dogs' VLDL, LDL and HDL were about 55, 58 and 37% of those of +E dogs, respectively.

Plasma and lipoprotein α-tocopherols in a German Shepherd with DM. Like +E dogs, DM plasma d_0α-tocopherol concentrations following the dose of labeled α-tocopherols were relatively constant throughout the experiment (from 29 to 35 nmol/mL) (Fig. 1). Plasma-deuterated tocopherols in the DM dog peaked earlier than in +E dogs (6 h compared with 21 ± 6, respectively), while the area under the curve of d_3RRR-α-tocopherol was half of that in +E dogs (Table 1). This could be the result of the smaller dose of deuterated tocopherols that was inadvertently administered; however, the kinetic data suggest otherwise. The slope of the disappearance portion of the DM plasma d_3RRR-α-tocopherol curve (−0.0300) was slightly faster than in the other four dogs (−0.0259 ± 0.0024). Furthermore, DM plasma d_3RRR-α-tocopherol peaked at 6 h, earlier than in −E1 (12 h) or −E2, +E1 and +E2 (24 h). Importantly, DM plasma peaked coincident with the DM chylomicron t_{moc} (6 h).

Defective transport of α-tocopherol by DM is also suggested by comparison of the areas under the lipoprotein α-tocopherol curves. The area under the d_3RRR-α-tocopherol curve in DM chylomicrons was 145% of that of +E dogs, and in DM VLDL was about 100%, yet those of DM LDL and HDL were markedly smaller, 52 and 45%, respectively. Despite the reduced incorporation of α-tocopherol into lipoproteins, the ratio of d_3RRR/d_6all *rac* in the plasma at 24 h was 1.91 mol/mol, and the ratio of the plasma areas under the curves was 1.68. The ability to differentiate between α-tocopherols does not necessarily indicate normal function of the tocopherol binding protein because some patients with familial isolated vitamin E deficiency also differentiate between α-tocopherols (7).

DISCUSSION

Vitamin E deficiency in adult beagle dogs in response to a single oral dose of deuterated α-tocopherols did not increase plasma-labeled α-tocopherol concentrations higher than in controls (Fig. 1), did not alter rates of disappearance of plasma labeled α-tocopherols, and did not enhance discrimination between *RRR*- and *all rac*-α-tocopherols (Table 1). Although studies in humans indicate that the tocopherol binding protein is apparently responsible for the discrimination between tocopherols and for the regulation of plasma α-tocopherol (4,6–8), the activity of this protein does not appear to be up-regulated in response to vitamin E deficiency in dogs. This finding may not be as surprising as it first appears. The putative role of the protein is to discriminate between the different forms of dietary vitamin E; therefore, it may already be optimized for recognizing low levels of α-tocopherol. Furthermore, because it is virtually impossible for natural

diets to be vitamin E-deficient, there would have been no evolutionary pressure for the tocopherol binding protein to be responsive to a vitamin E-deficient diet.

Contrary to our expectations, −E dogs had lower plasma-deuterated α-tocopherol concentrations than did +E dogs. If α-tocopherol is readily transferred to vitamin E-depleted tissues, then plasma concentrations may be low. Although measurements of tissue-deuterated α-tocopherols were not carried out, adipose tissue α-tocopherol levels were measured at intervals throughout the two-year vitamin E depletion (20). At 1 and 3 mon prior to sacrifice, adipose tissue α-tocopherol levels were 2.3 ng/mg and 1.6, respectively, in −E1; and 0.6 and 1.0, respectively, in −E2. At autopsy, 1 wk following the deuterated tocopherol study, where a total of 142 mg of α-tocopheryl acetates were consumed, adipose tissue α-tocopherol concentrations had increased to 7.9 ng/mg in −E1 and 2.6 in −E2 (21), suggesting that deuterated tocopherols were transferred from plasma to −E tissues.

From our study, it appears that HDL delivers α-tocopherol to dog tissues. The HDL area under the curve in −E dogs were only 37% of those of +E dogs, while the areas under the curve of −E dog VLDL and LDL were >50% of +E values (Table 1), suggesting that −E HDL readily donated α-tocopherol. This is likely because HDL α-tocopherol readily exchanges to other lipoproteins and to tissues (26–29).

All dogs preferred *RRR*-α-tocopherol compared with *all rac*-α-tocopherol, apparently the result of the preferential secretion of *RRR*-α-tocopherol in VLDL. Unlike humans, dogs have relatively low amounts of apolipoprotein B-containing lipoproteins (25,30–33); therefore, most of the plasma α-tocopherol is in HDL. Nonetheless, enrichment of HDL with *RRR*-α-tocopherol took place after the peak in VLDL d_3*RRR*-α-tocopherol, demonstrating that VLDL enriched with d_3*RRR*-α-tocopherol is the source of HDL d_3*RRR*-α-tocopherol.

We also investigated a German Shepherd dog diagnosed to have DM, in an effort to determine if it had a defective tocopherol binding protein. Dogs afflicted with DM have some, but not all, of the characteristics of familial isolated vitamin E deficiency, a human genetic disorder in vitamin E transport thought to result from a defect in the tocopherol binding protein (7,8,18). Like these patients, this dog did have low adipose tissue α-tocopherol (14 ng/mg wet wt) and peripheral nerve α-tocopherol (13 ng/mg wet wt), but, unlike the patients, the DM plasma vitamin E levels were not markedly reduced, nor did they rapidly decrease (Fig. 4). The labeled vitamin E appeared in the DM plasma apparently as a result of chylomicron, not VLDL catabolism (Fig. 4). However, because both chylomicrons and VLDL turn over rapidly in dogs (30), and because we did not study a control German Shepherd, it is not clear whether or not this dog had an abnormality in vitamin E transport. We had anticipated a much more rapid decline in plasma-deuterated tocopherol concentrations based on studies in humans with familial isolated vitamin E deficiency (7,8,18); however, the relatively low incorporation of α-tocopherol into LDL and HDL is suggestive of a defect in α-tocopherol transport in VLDL. This question must remain unanswered until more dogs with this disorder are studied.

In conclusion, our studies of the transport of vitamin E in dogs have demonstrated that dogs discriminate between *RRR*- and *all rac*-α-tocopherol with a preference for the natural, *RRR*-α-tocopherol form. This differentiation results from the preferential secretion of *RRR*-α-tocopherol in VLDL. Catabolism of VLDL labels the plasma with *RRR*-α-tocopherol, despite the limited amount of apolipoprotein B-containing lipoproteins in dog plasma (25, 30–33). Vitamin E deficiency in dogs does not appear to markedly alter the function of the tocopherol binding protein.

ACKNOWLEDGMENTS

Nora Lagmay provided excellent technical assistance. The authors thank Drs. Keith U. Ingold and Graham W. Burton and their staff (especially Ewa Lusztyk and Malgorzata Daroszewska) at the National Research Council in Ottawa, Ontario, Canada for measuring the deuterated tocopherol contents of the samples. The research was supported in part by funds from the Morris Animal Foundation and the Scott-Ritchey Research Center. MGT and HJK were supported in part by grants from the U.S. Public Health Service, Grant No. HL 30842, and from the Natural Source Vitamin E Association.

This study was designed to determine whether incorporation of γ-tocotrienol or α-tocopherol in an atherogenic diet would reduce the concentration of plasma cholesterol, triglycerides and fatty acid peroxides, and attenuate platelet aggregability in rats. For six weeks, male Wistar rats (n = 90) were fed AIN76A semisynthetic test diets containing cholesterol (2% by weight), providing fat as partially hydrogenated soybean oil (20% by weight), menhaden oil (20%) or corn oil (2%). Feeding the ration with menhaden oil resulted in the highest concentrations of plasma cholesterol, low and very low density lipoprotein cholesterol, triglycerides, thiobarbituric acid reactive substances and fatty acid hydroperoxides. Consumption of the ration containing γ-tocotrienol (50 mg/kg) and α-tocopherol (500 mg/kg) for six weeks led to decreased plasma lipid concentrations. Plasma cholesterol, low and very low density lipoprotein cholesterol, and triglycerides each decreased significantly ($P < 0.001$). Plasma thiobarbituric acid reactive substances decreased significantly ($P < 0.01$), as did the fatty acid hydroperoxides ($P < 0.05$), when the diet contained both chromanols. Supplementation with γ-tocotrienol resulted in similar, though quantitatively smaller, decrements in these plasma values. Plasma α-tocopherol concentrations were lowest in rats fed menhaden oil without either chromanol. Though plasma α-tocopherol did not rise with γ-tocotrienol supplementation at 50 mg/kg, γ-tocotrienol at 100 mg/kg of ration spared plasma α-tocopherol, which rose from 0.60 ± 0.2 to 1.34 ± 0.4 mg/dL ($P < 0.05$). The highest concentration of α-tocopherol was measured in plasma of animals fed a ration supplemented with α-tocopherol at 500 mg/kg. In response to added collagen, the partially hydrogenated soybean oil diet without supplementary cholesterol led to reduced platelet aggregation as compared with the cholesterol-supplemented diet. However, γ-tocotrienol at a level of 50 mg/kg in the cholesterol-supplemented diet did not significantly reduce platelet aggregation. Platelets from animals fed the menhaden oil diet released less adenosine triphosphate than the ones from any other diet group. The data suggest that the combination of γ-tocotrienol and α-tocopherol, as present in palm oil distillates, deserves further evaluation as a potential hypolipemic agent in hyperlipemic humans at atherogenic risk. *Lipids 28,* 1113–1118 (1993).

That diets rich in polyunsaturated fatty acids lead to reduced plasma cholesterol concentrations and lower atherogenic risk has been well documented (1–7). Studies reported by this laboratory have shown that though menhaden oil (MO) is efficacious in lowering plasma triglycerides (TG), it is also associated with significant increases in plasma fatty acid hydroperoxides (LOPS) and malondialdehyde equivalent substances. Furthermore, such highly polyunsaturated oils lead to depletion of plasma α-tocopherol and other antioxidants. Supplementation of the diet with α-tocopherol significantly increases plasma α-tocopherol concentrations and results in significantly less accumulation of peroxides in the plasma (8). Both epidemiological and clinical data have implicated peroxidized plasma lipid in atherogenesis (9,10). γ-Tocotrienol by itself has been shown in short-term feeding studies to lower total low density lipoprotein (LDL) cholesterol and TGs in both pigs (11) and in humans (12); however, when tested in combination with α-tocopherol, it showed no such effect (13). Neither thiobarbituric acid reactive substances (TBARS) nor LOPS were tested in these trials. Should γ-tocotrienol effectively lower plasma cholesterol or reduce plasma lipid peroxidation, or both, it would be a prime candidate for further testing in humans.

In the present study, γ-tocotrienol alone, or together with α-tocopherol, was tested as a potential hypocholesterolemic agent and also as an antioxidant. For this purpose, γ-tocotrienol, α-tocopherol, or both, were incorporated along with cholesterol into rations fed to rats that provided MO, partially hydrogenated soybean (SO) or corn oil (CO) to test the purported hypocholesterolemic and antithrombotic potential of γ-tocotrienol.

MATERIALS AND METHODS

Ninety male Wistar rats (Hilltop Laboratory Animals, Scottdale, PA) were weighed and divided into nine groups. All rats were fed standard, defined (AIN76A; American Institute of Nutrition) semisynthetic ration (Dyets, Bethlehem, PA) with indicated oils. Commercially available CO and SO were used; MO was obtained from a processor (specially Processed Menhaden Oil; Zapata Haynie Corp., Reedville, VA). After a two-week adaptation period on a chow diet (Ralston-Purina, St. Louis, MO), the animals were fed the semisynthetic rations with the diet treatments for six weeks as described in Table 1. Rats were housed in groups of two or three in plastic cages with access to ration and water *ad libitum*. Room temperature was maintained at 25 ± 2°C. A biphasic lighting cycle, with alternating 12-h light and dark phases, started with the light phase at 7:00 a.m.

The fatty acid composition of the commercial oils used is shown in Table 2. Diets 1–7 provided 18% protein, 42% carbohydrate and 40% fat. The CO ration without added cholesterol (CO − chol; Diet 8) delivered 22% protein, 73% carbohydrate and 5% fat. The SO ration without added cholesterol (SO − chol; Diet 9) contained 17% protein, 43% carbohydrate and 40% fat. Supplemental vitamin E

22:5			2.4
22:6			9.1

[a]Soy oil was partially hydrogenated soybean oil containing vitamin E, 200 mg/kg (Procter & Gamble, Cincinnati, OH). Corn oil contained vitamin E, 112 mg/kg (CPC International, Elizabeth, NJ). Menhaden oil contained vitamin E, 50 mg/kg (Zapata Haynie Corp., Reedville, VA).

(>96% dl-α-tocopherol; Roche, Nutley, NJ) and γ-tocotrienol (>88% pure by reverse-phase chromatography; PORIM, Kuala Lumpur, Malaysia) were mixed with the dietary oil before being added to the diet. Diets were made fresh weekly and were flushed with nitrogen and stored in daily allotments in "zip-loc" polethylene bags at −20 ± 2°C.

Diets provided adequate levels of vitamins. Calculations indicated that the diets provided ample thiamin and riboflavin (1.3 mg/1000 kcal each) for the dietary energy load, pyridoxine for the protein load (7.0 mg/4 g protein/d) and vitamin E for the fat load, there being more than 0.4 IU of α-tocopherol per g linoleic acid equivalent in all diets.

At the end of the study, the rats were fasted overnight (18 h). The animals were weighed, then euthanized with carbon dioxide. All animals were bled by syringe from the dorsal aorta. Two and one-half mL of blood was transferred to a sterile, citrate-containing Vacutainer tube (0.105 M buffered sodium citrate; Becton-Dickinson, Rutherford, NJ). The remaining 4.5 mL of blood was transferred to an ethylenediaminetetraacetic acid (EDTA)-containing Vacutainer tube (0.05 mL of 0.34 M tripotassium EDTA; Becton-Dickinson) for lipid analysis. After centrifugation to pellet the red cells, the plasma was transferred to a screw-cap polyethylene tube, flushed with nitrogen and frozen until analysis.

Plasma cholesterol, high-density lipoprotein (HDL) cholesterol and TGs were determined using a dry film kit (Eastman Kodak, Rochester, NY; C303-C341). The kits were used according to the manufacturer's instructions. Plasma oxidation products were measured spectrophotometrically as TBARS by the method of Mihara *et al.* (14) against 1,1,3,3-tetramethoxypropane as reference. Plasma LOPS were measured spectrophotometrically with a kit (LPO; Kamiya Biomedical, Thousand Oaks, CA), according to the manufacturer's instructions. The sample LOPS convert 10-*N*-methylcarbamoyl-3,7-dimethylamino-10H-phenothiazine to methylene blue in equimolar quantity. They were assayed with cumene hydroperoxides as reference as described by Ohishi *et al.* (15). Absorbance data were obtained with a UV-vis spectrophotometer (Milton Roy Company, Rochester, NY). Plasma retinol and α-tocopherol were separated on a C18 column by the high-performance liquid chromatography (HPLC) method of Bieri *et al.* (16), which was modified to detect analytes near their absorbance maxima—retinol at 325 nm, α-tocopherol at 300 nm and tocopheryl acetate (the internal standard) at 286 nm. All manipulations were done under amber light to reduce photo-induced oxidation. Solvents (HPLC grade) were obtained from EM Separations (Gibbstown, NJ).

Platelet response was measured with an impedance aggregometer (Chronolog, Havertown, PA) by the method of Galvez *et al.* (17) and Mackie *et al.* (18). Whole blood was incubated with the agonist for 6 min, at which time the response was recorded. Reagents were obtained from Sigma Chemical Company (St. Louis, MO), except for luciferin-luciferase and collagen for platelet studies (Chronolog, Havertown, PA) and dl-α-tocopheryl acetate (Roche), unless indicated otherwise.

Group means and standard errors were analyzed by Student's *t*-test. Past studies had shown that at n = 10, statistical significance at $P < 0.05$ can be achieved with 95% confidence.

RESULTS

At the start of the feeding trials, the mean body weights of the animals in all nine groups was 173 ± 2.7 g, and after six weeks of feeding, the average body weights for each group ranged from 416–473 g. All diets were well accepted; no significant difference was observed in mean body weights between groups, except for a borderline increase in the SO − chol group (Diet 9). No signs of vitamin deficiency on snout, paws or tail were observed; no hemolysis or xerophthalmia was seen. Growth rates and coat sheen and quality suggested that the diets were adequate for maintaining normal growth and vigor.

Plasma lipid data that was measured after the animals were kept on the test diets for six weeks are shown in Table 3. Animals given 20% MO with 2% cholesterol (MO/chol; Diet 3) had the highest total cholesterol levels when compared to all other groups, including controls and Diets 8 and 9. In animals fed the MO/chol diet with α-tocopherol and γ-tocotrienol (Diet 6), the lowest cholesterol levels were observed, which were significantly lower than those of animals fed the MO/chol diet with α-tocopherol (Diet 5). They were also somewhat lower than those of the group fed MO/chol with γ-tocotrienol (Diet 4). Diet 4 also resulted in a plasma cholesterol concentration that was significantly lower than that of the CO control without added cholesterol (Diet 8), 53.5 ± 4.4 *vs.* 72.8 ± 5.1, $P < 0.01$. In the 20% SO groups with 2% cholesterol (SO/chol; Diets 1 and 2), plasma cholesterol concentrations did not decrease significantly with γ-tocotrienol supplement, 75.7 *vs.* 66.9, although plasma cholesterol decreased without the 2% cholesterol supplement in the diet, SO/chol *vs.* SO − chol, 75.7 *vs.* 57.2 (Diet 1 *vs.* 9).

Plasma combined LDL and very low density lipoprotein (VLDL) cholesterol concentrations approximated the values found for total cholesterol (Table 3). The MO/chol group (Diet 3) had the highest total and LDL + VLDL cholesterol levels; the lowest LDL + VLDL concentrations were measured in the groups fed γ-tocotrienol supplement (Diets 4 and 7). No dosage effect was observed (Diets 4 and 7). The addition of α-tocopherol did not further enhance the hypocholesterolemic effect of γ-tocotrienol. No dietary supplement resulted in total or LDL + VLDL cholesterol levels as low as those in the group not given cholesterol, which was also reflected in the higher HDL cholesterol found in this group (SO − chol, Diet 9). Incorporation of γ-tocotrienol in the SO/chol ration resulted in a lower LDL + VLDL cholesterol concentration (Diet 1 *vs.* 2); however, omission of the dietary cholesterol was of a much larger effect (Diet 1 *vs.* 9).

Supplementary γ-tocotrienol did not result in increased HDL cholesterol concentrations (Table 3). Plasma HDL cholesterol concentrations were lower in animals fed the 2% cholesterol supplement, compared with both the CO − chol group (Diet 8) and the SO − chol (Diet 9) group. The group fed MO/chol had a mean HDL cholesterol concentration statistically higher than all of the other groups, except those fed added α-tocopherol (Diet 5). γ-Tocotrienol had a negligible effect when added to the MO/chol groups; the combined α-tocopherol (500 mg/kg) with γ-tocotrienol group (Diet 6), and 100 mg/kg γ-tocotrienol group (Diet 7) had statistically lower values than Diets 3 or 8. In general, higher plasma HDL cholesterol was associated with lower LDL + VLDL cholesterol concentrations.

In the case of plasma TGs, the SO/chol groups (Diets 1 and 2) and MO/chol (Diet 3) group produced concentrations similar to the CO − chol (Diet 8) and the SO − chol groups (Diet 9). In the SO/chol groups, γ-tocotrienol supplementation did not attenuate the plasma TG concentration (Diet 1 *vs.* 2); the cholesterol supplementation masked a γ-tocotrienol effect, if any. In contrast, the MO/chol groups inclusion of γ-tocotrienol or α-tocopherol resulted in significantly improved plasma TG clearance, or decreased synthesis, or both (Diets 3, 4, 5, 6 and 7). A combination of α-tocopherol and γ-tocotrienol was not better than either alone (Diet 3 *vs.* 4, 5 or 6). γ-Tocotrienol at 100 mg/kg was no more effective than at 50 mg/kg in influencing plasma TG concentrations (Diet 4 *vs.* 7). The groups fed MO/chol with or without α-tocopherol or γ-tocotrienol (Diets 4, 5, 6 and 7) had lower TG concentrations than the other groups, pointing to an effect of the acyl composition in addition to the γ-tocotrienol effect.

Oxidation product levels measured as TBARS or LOPS varied both with the dietary oil fed and the antioxidant supplement (Table 4). As expected, the TBARS were

TABLE 3

Plasma Cholesterol and Triglycerides (TG) Concentrations of Rats Fed Atherogenic Diets for Six Weeks with or without Tocotrienol or Tocopherol[a]

greatest in the MO/chol group without α-tocopherol or γ-tocotrienol supplement (Diet 3), presumably because of the high level of unsaturation in the MO-rich diet. γ-Tocotrienol inclusion in the SO/chol ration had no measurable effect on either TBARS or LOPS (Diet 1 *vs.* 2). α-Tocopherol supplementation (Diet 5) resulted in moderately decreased TBARS concentrations, but when γ-tocotrienol was included, either alone (Diets 4 or 7) or combined with α-tocopherol (Diet 6), TBARS values decreased significantly as compared with the MO/chol group lacking a supplement of either antioxidant (Diet 3). α-Tocopherol in combination with γ-tocotrienol was no more effective than the latter alone in keeping TBARS concentrations down (Diet 3 *vs.* 4, 5 and 6). Twice the amount of γ-tocotrienol did not reduce TBARS levels any further (Diet 4 *vs.* 7); no dose-response effect was apparent. The lowest TBARS concentrations were measured in the groups without the 2% cholesterol supplement (Diets 8 and 9). Although TBARS levels were lower in the SO and CO than the MO/chol groups (Diets 1, 2, 8 and 9 *vs.* Diets 3, 4, 5, 6 and 7), the SO/chol group with γ-tocotrienol was somewhat higher than SO − chol (Diet 2 *vs.* 9). This occurred in spite of the inclusion of 50 ppm of α-tocopherol in the MO. The CO group (Diet 8) contained the least TBARS; it also contained the least fat, 2% rather than 20%, and 112 ppm of α-tocopherol.

Some oxidation to hydroperoxides occurred for each oil fed, even for the CO − chol group as seen in the LOPS data (Diets 1, 3 and 8; Table 4). The LOPS concentrations were similar in groups with or without the 2% cholesterol supplementation (Diet 1 *vs.* 9). Although γ-tocotrienol was not effective in protecting the SO/chol groups (Diet 1 *vs.* 2), it effectively protected the MO/chol groups (Diets 3, 4, 6 and 7), and α-tocopherol did not afford such protection in these trials (Diet 3 *vs.* 5). No dose-response effect was seen under these conditions for γ-tocotrienol (Diet 4 *vs.* 7). Also, in the case of LOPS, as for TBARS, no apparent synergism of α-tocopherol with γ-tocotrienol was observed (Diets 3 *vs.* 4, 5 or 6), the combination being no better than γ-tocotrienol alone at 50 mg/kg.

Supplementation of the SO/chol group with γ-tocotrienol at 50 mg/kg (Diet 1 *vs.* 2) did not result in increased plasma α-tocopherol concentrations (Table 5). The lowest plasma concentration of α-tocopherol was measured in the MO/chol group (Diet 3) fed very polyunsaturated oil. Inclusion of 50 mg/kg of γ-tocotrienol had no effect on plasma α-tocopherol (Diet 4), but when that amount was doubled (Diet 7), the α-tocopherol concentration increased significantly, $P < 0.05$. Yet this level was still lower than when α-tocopherol was added alone or in combination with γ-tocotrienol at 50 mg/kg (Diets 5 and 6 *vs.* Diet 7). Plasma α-tocopherol was highest in the CO − chol group (Diet 8), being comparable to the SO groups (Diets 1, 2 and 9).

Plasma retinol concentrations were the lowest in the MO/chol group supplemented with α-tocopherol (Diet 5) (Table 5). The highest levels of plasma retinol measured occurred in groups not given cholesterol (Diets 8 and 9). In the SO/chol groups, γ-tocotrienol apparently spared plasma retinol (Diet 1 *vs.* 2). In the MO/chol groups, γ-tocotrienol at 100 mg/kg or α-tocopherol combined with γ-tocotrienol at 50 mg/kg resulted in higher retinol concentrations (Diet 3 *vs.* 6 and 7).

Using collagen as agonist, the only significant difference observed in platelet aggregation responses occurred between the α-tocopherol-supplemented group (Diet 5) and the SO − chol group (Diet 9), as compared with the CO − chol group (Diet 8) (Table 6). Inclusion of cholesterol supplement resulted in hyperaggregable platelets, as seen in the SO/chol and SO − chol groups (Diet 1 *vs.* 9). Neither γ-tocotrienol nor α-tocopherol at the levels fed significantly decreased platelet aggregation in the SO/chol or the MO/chol groups (Diet 1 *vs.* 2, and Diet 3 *vs.* 4, 5, 6 and 7).

Neither γ-tocotrienol nor α-tocopherol supplementation decreased platelet adenosine triphosphate (ATP) release with thrombin as agonist (Diet 1 *vs.* 2 and Diet 3 *vs.* 4, 5, 6 or 7; Table 5). However, the acyl composition, particularly the ω3 content, resulted in reduced platelet ATP charge. The MO/chol group without α-tocopherol or γ-tocotrienol showed significantly less ATP release, presumably indicative of less ATP platelet charge. ATP release of the other groups were virtually identical and greater than Diet 3. Supplementation with either α-tocopherol or γ-tocotrienol resulted in increased ATP release in the MO/chol groups (Diet 3 *vs.* 4, 5, 6 and 7),

possibly related to lower plasma hydroperoxide levels (Table 4).

DISCUSSION

Incorporation of dietary cholesterol in these test rations (Diets 1-7) was expected to result in elevated plasma cholesterol; such was observed in the SO/chol groups (Diet 1 *vs.* 9); Table 3). It is presumed that the presence of *trans*-fatty acid in the SO groups led to elevated plasma cholesterol. Lichtenstein *et al.* (19) have observed this when feeding human subjects partially hydrogenated CO *vs.* CO. Our data confirmed that as dietary fatty acid unsaturation increased, plasma cholesterol decreased (Diet 8 *vs.* 9); however, the MO/chol group without chromanol supplement (Diet 3) had the highest plasma cholesterol. Though dietary MO has been reported by Haglund *et al.* (20) to attenuate plasma TG levels, its hypocholesterolemic effect, if any, was marginal.

Supplementation of these test diets with 50 mg/kg of γ-tocotrienol resulted in reduced total and LDL + VLDL cholesterol (Table 3). Marked decreases were measured in the MO/chol groups when either γ-tocotrienol or α-tocopherol was added (Diets 2, 4 and 5 *vs.* 3). γTbcotrienol at 100 mg/kg of diet spared α-tocopherol, but no further decrease in total or LDL + VLDL cholesterol occurred. That no further decrease in plasma cholesterol occurred at this higher dosage suggested that key 3-hydroxy-3-methyl-glutaryl coenzyme A (HMG-CoA) reductase sites were approaching saturation at the lower dosage. No significant decrease of plasma cholesterol was observed in the SO/chol groups with supplementation of γ-tocotrienol, 50 mg/kg (Diet 1 *vs.* 2). The *trans*-fatty acid content of the SO/chol and SO − chol diets likely introduced matrix ordering incompatible with access to HMG-CoA reductase by γ-tocotrienol. As in previous rat studies done in this laboratory (8,21), supplementation of rat diets with 20% MO and 2% cholesterol produced the highest total and LDL + VLDL cholesterol concentrations.

The finding that the combination of α-tocopherol and γ-tocotrienol produced further decreases over γ-tocotrienol alone was somewhat unexpected, as in an earlier human study, Qureshi *et al.* (11) had found a subgroup which did not respond to a mixture of tocopherols and tocotrienols (although the majority did). Only when they were supplemented with 200 mg/d of γ-tocotrienol for an additional 14-28 d did their total and LDL cholesterol decrease. Wahlquist *et al.* (13) has also reported a similar failure of human subjects to respond to a mixture of tocopherols and γ-tocotrienol (obtained from the γ-tocotrienol-rich fraction of palm oil). The lower dosage used by Qureshi *et al.* (12) may have explained the different response. In those studies the maximal dosage fed was about 2.5 mg/kg/d as mixed tocotrienols; in this study we fed γ-tocotrienol at a level of about 2.5 mg/kg/d. Hence, γ-tocotrienol may be a more efficacious hypocholesterolemic agent than the mixed tocotrienols. If future studies show the combination of γ-tocotrienol and α-tocopherol to be as effective, or more effective than γ-tocotrienol alone, then supplying a naturally occurring mixture would be easier and more cost-effective.

As to the method of action of γ-tocotrienol, animal and tissue culture studies (22,23) have shown that γ-tocotrienol derived from barley or palm oil lowers serum cholesterol concentrations by inhibiting enzymes of the cholesterol biosynthetic pathway, including HMG-CoA reductase and cholesterol-7-hydroxylase. The currently widely used HMG-CoA reductase inhibitors of the lovastatin family are effective in similarly reducing serum lipids percentagewise (24,25), but they have no activity against free radicals and are quite expensive on a long-term basis.

Neither γ-tocotrienol nor α-tocopherol supplementation altered HDL cholesterol concentrations. HDL concentrations were higher in groups not given exogenous cholesterol (Diets 8 and 9) as compared with each of the other groups (Diets 1-7) fed rations with cholesterol (2%) along with SO, CO, or low erucic acid rapeseed oil (8,21). The apparent lack of a chromanol effect on HDL cholesterol levels suggests that the effect observed was related more directly to LDL and/or VLDL clearance, *i.e.*, membrane dynamics dependent upon acyl composition or stacking order, because in groups with higher LDL + VLDL concentrations, HDL cholesterol levels were lower (Diets 1, 2, 3 and 5 *vs.* 4, 6, 7, 8 and 9).

Supplementation with γ-tocotrienol did not result in decreased plasma TGs in the SO/chol groups (Diet 1 *vs.* 2), presumably a reflection of higher melting points, hence order, in the membranes of these groups, as also seen by the addition of the cholesterol supplement (Diet 1 *vs.* 9). In contrast, in MO/chol groups given γ-tocotrienol or α-tocopherol (Diets 4-7), the plasma TG concentrations decreased significantly; whether this reflected altered synthesis or clearance because of altered membrane dynamics is unclear.

As increased unsaturation of lipid increases susceptibility to oxidation of lipid *ex vivo*, so plasma lipid peroxidation increased with increasing dietary lipid unsaturation (Table 4). Plasma TBARS and LOPS accumulated at higher concentrations in groups fed more highly unsaturated lipid, as expected: CO, SO and MO. Supplementation with α-tocopherol (500 mg/kg) was accompanied by a decrease in malondialdehyde equivalent material. However, γ-tocotrienol supplementation (50 mg/kg) netted the

lowest concentrations of hydroperoxides and substances reactive with TBA. The trend observed in each diet for LOPS was similar, though greater quantitatively, for each group. The hydroperoxides level for CO − chol was distinctly greater than the TBA adducts concentration. These data suggest that γ-tocotrienol may be a more efficient antioxidant than α-tocopherol on a molar basis.

Much work in recent years has suggested an important inverse relationship between the development of arteriosclerosis and plasma antioxidant concentrations. This was well stated by Riemersma *et al.* (26), who showed a clear, inverse relation between the incidence of angina pectoris in men with low serum vitamin E levels. They also demonstrated that this relationship was a better predictor of disease development than serum cholesterol, hypertension or smoking. In this study, the addition of α-tocopherol improved the plasma malondialdehyde equivalent material concentrations, and in combination with γ-tocotrienol, these levels were decreased to levels similar to the SO groups, which were fed lower levels of unsaturated fat. The plasma LOPS concentrations followed a similar trend, though the significant decreases were observed in the groups with γ-tocotrienol supplementation. It appears, therefore, that a dual benefit, lowering of plasma cholesterol and TG as well as peroxides, may be achieved by supplementation with γ-tocotrienol in combination with α-tocopherol.

Further, as in previous studies (8,21), plasma α-tocopherol concentrations decreased when highly unsaturated oils, such as MO, were fed (Table 5). With a dietary fat load of 20% MO, γ-tocotrienol at 50 mg/kg did not improve the plasma α-tocopherol economy. However, if incorporated at a level of 100 mg/kg, γ-tocotrienol spared plasma α-tocopherol. With the combination of supplementary γ-tocotrienol and α-tocopherol, the highest plasma levels of α-tocopherol were measured.

In spite of significant hypocholesterolemic and hypotriglyceridemic effects of γ-tocotrienol, no significant antiaggregation effect of this tocotrienol on platelets was measured at either supplementation level. The attenuation of platelet aggregation to collagen agonist in the group supplemented with α-tocopherol (Diet 5) was similar to that seen in human feeding studies in this laboratory (27). The platelet effect of γ-tocotrienol would be expected to be similar to that of α-tocopherol; however, neither of the two levels of γ-tocotrienol tested was sufficient to reduce the platelet response to collagen in these short-term trials. The geometry of the unsaturated side chain of γ-tocotrienol may restrict its partitioning into platelet membranes compared with α-tocopherol. ATP release after thrombin stimulation of the MO/chol group without chromanol supplement (Diet 3) was of the same order of response as seen in another study from this laboratory (21); it showed no further improvement with either γ-tocotrienol or α-tocopherol supplementation.

In summary, supplementation with γ-tocotrienol alone or in combination with α-tocopherol resulted in decreased concentrations of plasma total and LDL + VLDL cholesterol, TG, TBARS and LOPS, and raised plasma α-tocopherol concentrations in these feeding studies with semisynthetic, hypercholesterolemic diets. Platelet hyperaggregability was decreased by α-tocopherol supplementation. No noxious effect was observed in any of the groups supplemented with γ-tocotrienol. The combination of γ-tocotrienol with α-tocopherol was better, in general, than either supplement alone; hence, the combination of α-tocopherol with γ- (or other) tocotrienols deserves further evaluation as a potential antiatherogenic agent.

Inhibition by Cardiolipins of Platelet-Activating Factor-Induced Rabbit Platelet Activation

Demokritos Tsoukatos[a,b,*], Constantinos A. Demopoulos[c], Alexandros D. Tselepis[a], Michael C. Moschidis[c], Andreas Donos[d], Angelos Evangelou[b,d] and Jaques Benveniste[b]

[a]Department of Chemistry, School of Science, University of Ioannina, 451 10 Ioannina, Greece, [b]INSERM U200, 921 40 Clamart, France, [c]Department of Food Chemistry, School of Science, University of Athens, 106 80 Athens, Greece and [d]Laboratory of Experimental Physiology, Medical School, University of Ioannina, 451 10 Ioannina, Greece

Evidence is presented that cardiolipin, a naturally occurring phospholipid, inhibits the aggregatory effect of platelet-activating factor (paf) on rabbit platelets *in vitro*. Bovine heart cardiolipin was shown to inhibit the aggregation of washed rabbit platelets induced by 1×10^{-10} M and 2×10^{-10} M paf with IC_{50} values (doses for half-maximal inhibition) of $8.4 \pm 0.8 \times 10^{-7}$ M and $2.6 \pm 0.6 \times 10^{-6}$ M, respectively. Phosphonocardiolipin was also able to inhibit platelet aggregation induced by 1×10^{-10} M paf with an IC_{50} value of $3 \pm 1 \times 10^{-7}$ M. Both compounds, in concentrations up to 1×10^{-5} M, were unable to aggregate washed rabbit platelets and failed to inhibit the aggregation induced by 0.9 and 1.8 μM adenosine diphosphate or 0.2–1.0 μM arachidonic acid. By contrast, the acetylated derivative of cardiolipin exerted an aggregatory effect on aspirin-treated rabbit platelets in the presence of creatine phosphate/creatine phosphokinase. This aggregation was inhibited by the specific paf antagonists BN 52021 and WEB 2086. Also, platelets treated with acetyl-cardiolipin were insensitive to the aggregatory effect of paf. Phosphatidic acid, phosphatidylglycerol, *bis*(dipalmitoylglycero)phosphate and their phosphono analogues were totally inactive. Similar data were obtained when platelet-rich plasma was used instead of washed rabbit platelets. Our results support the hypothesis that the effect of cardiolipin is mediated through specific paf receptors that act on the rabbit platelet membrane. *Lipids 28,* 1119–1124 (1993).

Platelet-activating factor (paf), 1-*O*-alkyl-2-acetyl-*sn*-glycero-3-phosphocholine (1–3), is a naturally occurring lipid mediator with a wide range of effects *in vivo* and *in vitro*. These effects include vasodilation and hypotension (3–5), increased vascular permeability (4,6), a negative inotropic effect, coronary vasoconstriction, reduced coronary blood flow (7–11), cardiac arrhythmias (11) and bronchoconstriction (12,13). In addition, paf can stimulate various cells, such as platelets, neutrophils, macrophages, endothelial cells and protozoan cells (14–16). It has also been suggested that paf is involved in the pathogenesis of various diseases, such as bronchial asthma (17), endotoxemia (18), acute serum sickness (19,20), ischemic bowel necrosis (21), gastro-intestinal ulceration (22), cold urticaria (23) and psoriasis (24).

Over the last few years, various synthetic and naturally occurring compounds have been identified that act as specific paf antagonists (25). These include compounds that are structural analogs of paf and others with no structural resemblance. Endogenous lipid inhibitors of paf have been found in various mammalian tissues and organs (26–28). Phospholipids with a chromatographic behavior similar to that of cardiolipins and phosphatidylglycerols, which specifically inhibit rabbit platelet aggregation induced by paf *in vitro*, have been isolated from perfusates of guinea pig heart (Tsoukatos, D., Chignard, M., Boullet, C., LeCoedic, J.P., and Benveniste, J., unpublished data).

In the present study, we examined the effect of bovine heart cardiolipin, phosphatidylglycerol and of some structural analogues, on rabbit platelet aggregation induced by paf and other agonists *in vitro*.

MATERIALS AND METHODS

Bovine heart cardiolipin sodium salt, 1,2-dipalmitoyl-*sn*-glycero-phosphoric acid sodium salt (phosphatidic acid), 1,2-dipalmitoyl-*sn*-glycero-3-phosphoglycerol sodium salt (phosphatidylglycerol), 1,2-dipalmitoyl-*sn*-glycerol, 1,2-dipalmitoyl-*sn*-glycero-3-phosphocholine (PC), 1,2-dipalmitoyl-*sn*-glycero-3-phosphoethanolamine (PE), 2,4,6-triisopropylbenzenesulfonyl chloride (TPS), trimethylchlorosilane, creatine phosphate (CP), creatine phosphokinase (CPK), arachidonic acid (AA), adenosine diphosphate (ADP) and bovine serum albumin (BSA) were purchased from Sigma (St. Louis, MO). Tris-HCl was from Fluka (Buchs, Switzerland), 1-*O*-hexadecyl-2-acetyl-*sn*-glycero-3-phosphocholine (paf) was a product of Bachem (Bubendorf, Switzerland); and aspirin as a lysine soluble salt (Aspergic) was obtained from Egic Laboratory (Amilly, France). Trimethyl phosphite, purchased from lancaster synthesis Ltd. (East Gate Lancaster, England) was redistilled and kept over molecular sieve (5Å). BN 52021 [3-(1,1-dimethylethyl)hexahydro-1,4,7b-trihydroxy-8-methyl-9H-1,7a-(epoxymethano)-1H,6aH-cyclopenta[c]furo(2,3b)-[3′2′3,4]cyclopenta[1,2-d]furan-5,9,12(4H)-trione] was a gift from Dr. Braquet (Institute Henri Beaufour, Paris, France); WEB 2086 [3-[4-(2-chlorophenyl)-9-methyl-6H-thieno[3,2-f][1,2,4]triazolo[4,3-a][1,4]diazepine-2-yl]-1-(4-morpholinyl)-1-propanone] was a gift from Dr. Weber (Boehringer-Ingelheim, Ingelheim, Germany).

Animals. Male New Zealand white rabbits were used as the platelet source.

Buffers and reagents. The following buffers and reagents were used: Tyrode's-gelatin-ethylene-glycoltetraacetic acid (EGTA) buffer solution (Tg-EGTA), pH 6.5 that consisted of KCl, 2.6 mM; $MgCl_2$, 1.0 mM; NaCl,

*To whom correspondence should be addressed.

Abbreviations: AA, arachidonic acid; ADP, adenosine diphosphate; BN 52021, 3-(1,1-dimethylethyl)hexahydro-1,4,7b-trihydroxy-8-methyl-9H-1,7a-(epoxymethano)-1H,6aH-cyclopenta[c]furo(2,3b)-[3′2′3,4]cyclopenta[1,2-d]furan-5,9,12(4H)-trione; BSA, bovine serum albumin; CP, creatine phosphate; CPK, creatine phosphokinase; EDTA, ethylenediaminetetraacetic acid; EGTA, ethyleneglycoltetraacetic acid; IR, infrared; paf, platelet-activating factor, 1-*O*-alkyl-2-acetyl-*sn*-glycero-3-phosphocholine; PC, phosphatidylcholine; PE, phosphatidylethanolamine; PPP, platelet-poor plasma; PRP, platelet-rich plasma; Tg-EGTA, Tyrode's-gelatin-EGTA buffer; Tg-Ca^{2+} buffer; TLC, thin-layer chromatography; TPS, 2,4,6-triisopropylbenzenesulfonyl chloride; WEB 2086, 3-[4-(2-chlorophenyl)-9-methyl-6H-thieno[3,2-f][1,2,4]triazolo[4,3-a][1,4]diazepine-2-yl]-1-(4-morpholinyl)-1-propanone.

137 mM; $NaHCO_3$, 12 mM; glucose, 1.0 g/L; EGTA, 0.2 mM; and gelatin, 0.25% (by vol). Tg-Ca^{2+}, pH 7.4, was the Tg-EGTA buffer that contained $CaCl_2$, 12 mM, and Tris-HCl, 10 mM, but no $NaHCO_3$ or EGTA. Ethylenediaminetetraacetic acid (EDTA) solution in saline, 0.2 M, pH 7.2, and ACD solution (citric acid, trisodium citrate and glucose, 0.1 M each), were used as anticoagulants. Paf solutions in BSA saline (2.5 mg/mL) were prepared as previously described (29).

Synthesis and identification of the compounds tested. The structures of cardiolipin, phosphatidic acid, phosphatidylglycerol, and of their analogues are shown in Table 1. The chemical purity of the commercial products (cardiolipin, phosphatidic acid and phosphatidylglycerol) was confirmed by thin-layer chromatography (TLC) on silica gel G plates (0.25-mm thick) using (i) acetone/petroleum ether (1:3, vol/vol) followed by chloroform/methanol/acetic acid/water (80:13:8:0.3, by vol) and (ii) chloroform/methanol/water/ammonium hydroxide (65:35:5:2, by vol) as solvent systems. TLC of the compounds developed either way showed a single fraction with R_f values of 0.36 and 0.46 for cardiolipin, 0.44 and 0.15 for phosphatidic acid and 0.22 and 0.39 for phosphatidylglycerol, respectively, in the two systems. The fatty acid composition of cardiolipin was determined by gas–liquid chromatography. The main constituent fatty acid was linoleic, 87%, and oleic and linolenic acids amounted to 7.2 and 3.1%, respectively. The optical rotation of cardiolipin was $[\alpha]_D^{20} = +5.4°$ (c = 2.55, in chloroform), and the melting point (m.p.) was in the range of 206–208°C.

*1,2-Dipalmitoyloxypropyl-3-(1',2'-dipalmitoyl-*sn*-glycero)phosphate,* [bis*(dipalmitoylglycero)phosphate*]. Dry 1,2-dipalmitoyl-*sn*-glycero-3-phosphate (105 mg, 0.162 mmol) and dry 1,2-dipalmitoyl-*sn*-glycerol (191.6 mg, 0.326 mmol) were dissolved in 1.0 mL anhydrous pyridine, and a solution of TPS (123 mg, 0.492 mmol) in anhydrous pyridine (2.0 mL) was added. The reaction mixture was kept at room temperature for 6–8 h. After completion of the reaction, excess TPS was hydrolyzed by addition of water (1.5 mL), the solvents were evaporated under reduced pressure and the residue was extracted twice with diethyl ether (5 mL).

The product was purified by preparative TLC on silica gel H plates (0.55-mm thick) chloroform/methanol/water (65:25:4, by vol) using as solvent system. The band with R_f 0.72 was scraped off, and the adsorbent was eluted with chloroform/methanol (2:1, vol/vol). The yield of the pure product was 34.5 mg (50.6%) (30).

*1,2-Dipalmitoyloxypropyl-3-(1',2'-dipalmitoyl-*sn*-glycero)phosphonate,* [*phosphono analogue of* bis*(dipalmitoylglycero)phosphate*]. Dry 1,2-dipalmitoyloxypropyl-3-phosphonic acid (300 mg, 0.46 mmol) and 1,2-dipalmitoyl-*sn*-glycerol (547 mg, 0.93 mmol) were dissolved in 2.5 mL of anhydrous pyridine (31,32). A solution of TPS (350 mg, 1.4 mmole) in anhydrous pyridine (4.0 mL) was added to this, and the reaction mixture was kept at room temperature for 8 h. Then water was added (3.0 mL), and the solvents were evaporated under reduced pressure. The residue was extracted twice with diethyl ether (10 mL), and chromatographically pure *bis*(1,2-dipalmitoyl-*sn*-glycero)phosphonate was obtained by preparative TLC on silica gel H plates (0.75-mm thick). The band with an R_f of 0.72 was scraped off the plate, and the adsorbent was eluted with chloroform/methanol (2:1, vol/vol). The yield was 334.9 mg (59.7%), and the m.p. was 59.5°C.

Elemental analysis. Found: C, 69.98%; H, 11.81%; O, 14.98%; P, 2.64%. Calculated: C, 71.06%; H, 11.42%; O, 14.90%; P, 2.62%.

Phosphorus determinations confirmed that the compound was a phosphonolipid because it did not release inorganic phosphorus when subjected to hydrolysis with 6N HCl for 48 h at 110°C. Infrared (IR) spectrum: carbonyl of ester, C=O, at 1,740 cm^{-1}; P=O, at 1,320 and 1,245 cm^{-1}; O=P-OH, at about 2,300 cm^{-1}; P-C, at 1,000, 1,040 and 1,180 cm^{-1}; and C-P stretching at 725 cm^{-1}. Optical rotation $[\alpha]_D^{24} = +7.2°$ (c = 3.6, in benzene).

*1,2-Dipalmitoyloxypropyl-3-(1',2'-diacyl-*sn*-glycero-3-phosphoryl-1,3-*sn*-glycero)phosphonate* [*phosphono analogue of cardiolipin*]. Phosphatidylglycerol (100 mg) was mixed with 1,2-dipalmitoyloxypropyl-3-phosphonic acid (500 mg, 0.077 mmol) in 5.0 mL of anhydrous pyridine (31,32). Then, 230 mg (0.90 mmol) of TPS in 5.0 mL of pyridine was added, and the reaction mixture was kept at room temperature for 8 h. After the completion of the reaction, 2 mL of water was added and the product was extracted with chloroform. The product was purified by preparative TLC on silica gel H plates with chloroform/methanol/water (65:25:4, by vol) as solvent system (R_f 0.96). The yield of the pure product was 63 mg (60%), and the m.p. was 174–175°C.

Elemental analysis. Found: C, 64.90%; H, 10.10%; P, 4.22%. Calculated: C, 65.80%; H, 10.40%; P, 4.40%. The IR spectrum was similar to that reported previously (33). The optical rotation of the compound was $[\alpha]_D^{24} = +6.4°$ (c = 2.4, in chloroform).

1,2-Dipalmitoyloxypropyl-3-(glycerol-1)phosphonate [*phosphono analogue of phosphatidylglycerol*]. Trimethylchlorosilane (7 mg, 0.065 mmol) was mixed with LiBr (5 mg, 0.052 mmol) in 3.0 mL of CH_3CN. A solution of phosphatidylglycerol (20 mg, 0.026 mmol) in 2.0 mL of CH_3CN was added to this, and the reaction was completed within 20 h. The reaction mixture was taken up in diethyl ether (40 mL) and washed successively with H_2O, then with $NaHCO_3$ solution (10% wt/vol), and finally with NaCl solution (5% wt/vol), and the ether layer was dried over anhydrous Na_2SO_4. Evaporation of the solvent afforded the bromohydrin. The dry bromohydrin was reacted at 120°C for 24 h with trimethylphosphite according to the procedure of Kosolapoff (33). The crude product was hydrolyzed with trimethylchlorosilane/NaI in CH_3CN at room temperature for 15 min, and the final product was purified by preparative TLC on silica gel G plates (0.75-mm thick) using chloroform/methanol/water (65:25:4, by vol). The R_f value was 0.57, and the optical rotation of the compound was $[\alpha]_D^{24} = +1.8°$ (c = 9, in chloroform). The m.p. was 57–59°C (uncorrected), and the IR spectrum in the region 900–1,400 cm^{-1} was similar to that reported previously (31,32).

Acetyl-cardiolipin. Bovine heart cardiolipin was acetylated with acetic anhydride at 65°C for 3 h. The product was purified by preparative TLC on silica gel plates (0.55-mm thick) using the solvent system chloroform/methanol/water (80:20:2, by vol). The R_f of acetyl-cardiolipin was 0.8, and the R_f of cardiolipin was 0.72.

Platelet-rich plasma (PRP) preparation. Whole blood from rabbits was mixed with ACD (9:1, vol/vol) in polyethylene tubes and centrifuged at 375 × *g* for 20 min at

TABLE 1

Structure and Biological Activity of Cardiolipin, Phosphatidic Acid, Phosphatidylglycerol and Some Structural Analogues

No.	Name/activity	Structure
1	Cardiolipin/inhibition	2	Phosphonocardiolipin/inhibition	3	Acetyl-cardiolipin/aggregation	4	Phosphatidic acid/inactive	5	Phosphatidylglycerol/inactive	6	Phosphonophosphatidylglycerol/inactive	7	*bis*(Dipalmitoylglycero)phosphate/inactive	8	Phosphono analogue of 7/inactive	
room temperature. The PRP was collected and centrifuged at 1,400 × *g* for 15 min at room temperature to obtain platelet-poor plasma (PPP). Platelets were counted on a hematocytometer according to the method of Brecher and Cronkite (34), and PRP was diluted with homologous PPP to yield a concentration of 3.0 ± 0.2 × 10^8 cells/mL.

Washed rabbit platelet preparation. Platelets were prepared from whole blood (collected in EDTA, 1:40, vol/vol) by successive centrifugations and dilutions in Tg-EGTA buffer according to the method of Ardlie *et al.* (35) as modified by Benveniste *et al.* (29). The washed platelets were suspended in an appropriate volume of Tg-EGTA to give a concentration of 2.5 × 10^9 cells/mL.

Platelet aggregometry. Platelet aggregation was monitored with a single channel aggregometer (ChronoLog Corp., Havertown, PA) under constant sitrring (1,200 rpm at 37°C). PRP was treated with aspirin (1 mM), and with CP (5 mM) and CPK (40 U/mL), for 15 min and 1 min, respectively, before aggregation was measured. Cardiolipin solutions in ethanol/water (60%, vol/vol) were added to 500 μL of PRP, in volumes of 1-5 μL. In inhibition studies, PRP was incubated with cardiolipin for 30 s and 10 min before the paf addition. Aggregation measurements with washed rabbit platelets were done as follows: 100 μL of platelet suspension pre-incubated with aspirin (1 mM) for 15 min was transferred into the cuvette of the aggregometer in which 400 μL of Tg-Ca^{2+} buffer containing CP/CPK (5 mM/40 U/mL, respectively) was added. Antagonist solutions in ethanol/water (60%, vol/vol), in volumes of 1-5 μL were added to paf, 30 s before the platelet suspension. In other experiments, the platelet suspension was incubated in the cuvette with the antagonist for 10 min prior to paf addition. For the aggregation studies with ADP or AA, CP/CPK or aspirin (respectively) was omitted. Inhibition studies with the specific paf inhibitors, BN 52021 (solubilized in dimethylsulfoxide) and WEB 2086 (solubilized in Sorenson's phosphate buffered saline, pH 7.4) were performed as previously described (36,37).

RESULTS

General comments. The structures of the compounds tested as possible paf inhibitors as well as their biological activities are shown in Table 1. The compounds were chosen with the aim of elucidating the possible relationship between cardiolipin structure and biological activity.

Experiments with washed rabbit platelets. The EC_{50} value for paf (dose for half-maximal aggregation) was 1 × 10^{-10} M, while at a dose of 2 × 10^{-10} M paf caused submaximal aggregation. The possible inhibitory effect of cardiolipin and of its analogues and derivatives was tested at the above paf concentrations. As shown in Figure 1, cardiolipin inhibited platelet aggregation induced by paf at 1 × 10^{-10} M and 2 × 10^{-10} M in a concentration-dependent manner with an IC_{50} value of 8.4 ± 0.8 × 10^{-7} M and 2.6 ± 0.6 × 10^{-6} M, respectively. In contrast, cardiolipin in concentrations ranging from 1 × 10^{-7} to 1 × 10^{-5} either failed to inhibit or only slightly inhibited platelet aggregation induced by 0.2-1.0 μM AA or 0.9-1.8 μM ADP. Under the same experimental conditions, the phosphono analogue of cardiolipin showed a more potent inhibitory effect than cardiolipin itself against the aggregation induced by paf (1 × 10^{-10} M); the IC_{50} value was 3 × 10^{-7} M. Also, phosphonocardio-

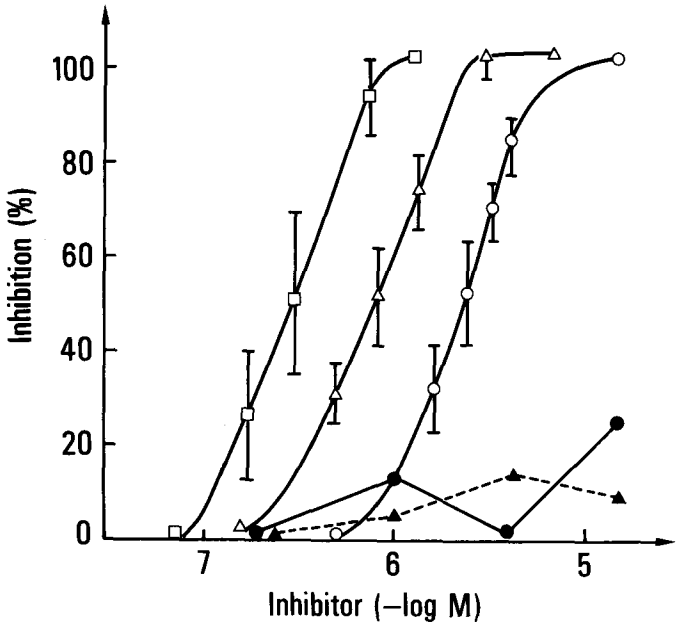

FIG. 1. The inhibitory effects of cardiolipin and phosphonocardiolipin on platelet-activating factor, 1-*O*-alkyl-2-acetyl-*sn*-glycero-3-phosphocholine (paf)-, arachidonic acid (AA)- and adenosine diphosphate (ADP)-induced washed rabbit platelet aggregation. ○, Cardiolipin against 2×10^{-10} M paf; △, cardiolipin against 1×10^{-10} M paf; ●, cardiolipin against 1 μM AA; ▲, cardiolipin against 0.9 μ M ADP; and □, phosphonocardiolipin against 1×10^{-10} M paf. Each point represents the mean ± 1 SD of ten experiments.

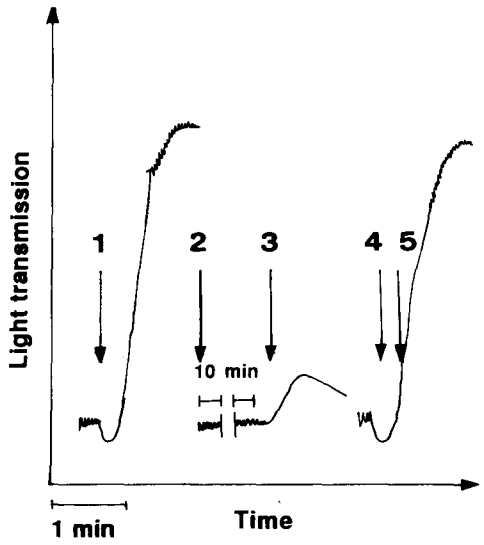

FIG. 2. Representative tracings of the inhibitory effect of cardiolipin on washed rabbit platelets. 2×10^{-10} M (1); 7×10^{-6} M cardiolipin (2); 2×10^{-10} M paf (3); 2×10^{-10} M paf (4); 7×10^{-6} M cardiolipin (5). Abbreviation as in Figure 1.

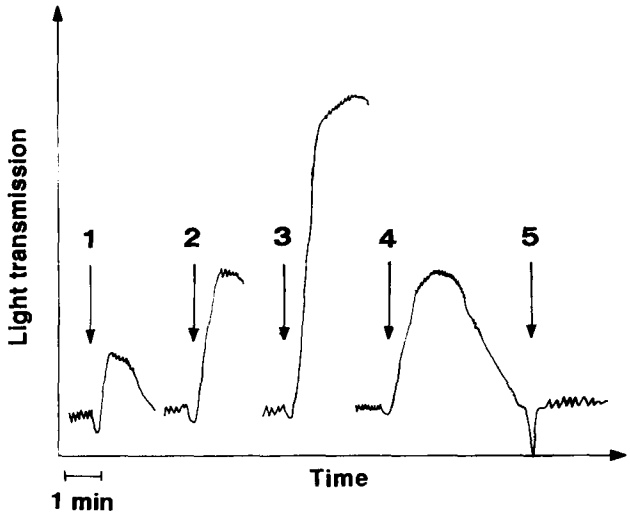

FIG. 3. Representative tracings of the aggregatory effect of acetyl-cardiolipin. 8×10^{-6} M acetyl-cardiolipin (1); 1.5×10^{-5} M acetyl-cardiolipin (2); 2×10^{-10} M paf (3); 1.5×10^{-5} M acetyl-cardiolipin (4); 2×10^{-10} M paf (5). Abbreviation as in Figure 1.

lipin in concentrations up to 1×10^{-5} M failed to inhibit platelet aggregation induced by AA (0.2-1.0 μM) or ADP (0.9-1.8 μM) (Fig. 1). Phosphatidic acid, phosphatidylglycerol, *bis*(dipalmitoylglycero)phosphate and their phosphono analogues at concentrations up to 1×10^{-5} M were ineffective in inhibiting platelet aggregation induced by paf, AA or ADP (results not shown). Similar results were obtained when PC and PE were tested as possible paf inhibitors at the above concentrations. In some experiments, platelets were preincubated with cardiolipin for 10 min prior to paf addition. As shown in Figure 2, the inhibitory effect of cardiolipin was preserved even after a 10-min incubation with platelets. In contrast, cardiolipin added to the platelets after paf failed to reverse the aggregation (Fig. 2).

In contrast to other compounds tested, which failed to induce platelet aggregation or lysis even at concentrations up to 1×10^{-5} M, acetyl-cardiolipin at concentrations higher than 1×10^{-6} M exerted a weak aggregatory effect on washed rabbit platelets that reached a maximum (%) at a concentration of 1.7×10^{-5} M (Fig. 3). This maximal aggregation was totally inhibited by 1×10^{-5} M BN 52021 or 1×10^{-6} M WEB 2086. Also, platelets treated with acetyl-cardiolipin were insensitive to the aggregatory effect of paf (Fig. 3).

Experiments with rabbit PRP. The purpose of these experiments was to study the effect of plasma on the activity of cardiolipin as a paf inhibitor. The inhibitory effect of cardiolipin was examined in respect to platelet aggregation induced by paf, 6×10^{-8} M, which resulted in a submaximal response. As shown in Figures 4 and 5, cardiolipin added 30 s prior to paf addition inhibited platelet aggregation in a dose-dependent manner up to a concentration of $1.5 \pm 0.3 \times 10^{-5}$ M, at which 50% inhibition was observed. This inhibitory effect decreased with higher cardiolipin concentrations, and was completely lost at a concentration of $1 \pm 0.5 \times 10^{-4}$ M. Incubation of PRP with cardiolipin at 1.5×10^{-5} M for 10 min at room temperature caused a complete loss of inhibition. Finally, acetyl-cardiolipin at concentrations higher than 1×10^{-5} M exhibited a weak aggregatory effect (Fig. 5).

DISCUSSION

The existence of endogenous paf inhibitors in various mammalian cells and tissues has been described previously (26-28), but the chemical structures of these inhibitors are still unknown. Also, little is known about their

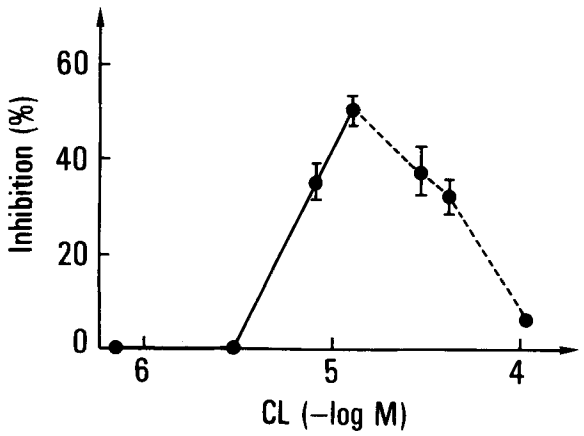

FIG. 4. The inhibitory effect of cardiolipin (CL) on rabbit platelet-rich plasma aggregation induced by 6×10^{-8} M paf. Each point is the mean ± 1 SD of four experiments. Abbreviation as in Figure 1.

biological role as anti-paf agents under normal conditions or in various diseases in which paf is thought to be involved. In the present study we demonstrated that cardiolipin, a phospholipid that is a normal constituent of mammalian tissues, specifically inhibits rabbit platelet aggregation induced by paf *in vitro*.

Cardiolipin can constitute 2-10% of the total phospholipids of various mammalian tissues and is characteristically associated with subcellular membranous particles, particularly mitochondria; it is thought to play an important role as a structural component in the respiratory chain (38). As far as we are aware, little research has been done on the relationship between cardiolipin and platelets, although cardiolipin is a minor constituent of platelet phospholipids (39). In high concentrations (10-100-fold greater than those employed in this study), cardiolipin exhibits a significant Ca^{2+} ionophoretic activity on washed human platelets and also enhances platelet aggregation caused by ADP and epinephrine in human PRP (40). Clinical interest in the possible involvement of anti-cardiolipin antibodies in thrombocytopenia observed in Lupus erythematosus and related auto-immune disorders has been increasing, although little is known about the mode of action (41,42).

Our results show that cardiolipin is a specific inhibitor of paf in washed rabbit platelet aggregation *in vitro* because it failed to inhibit the aggregation induced by AA and ADP. Of particular interest is the observation that cardiolipin exhibits its inhibitory effect at concentrations similar to those of known, specific paf antagonists (25). These concentrations were lower than those reported for other endogenous paf inhibitors (28) and lower than the concentrations at which various phospholipids cause nonspecific paf inhibition, possibly due to general disturbance of the platelet membrane structure (43). It is unknown whether or not within our range of concentrations, and under our experimental conditions, cardiolipin forms micelles with paf which could explain inhibition. Nevertheless, when cardiolipin is incubated with washed rabbit platelets 10 min prior to paf addition, it preserves its inhibitory effect. A decrease in cardiolipin inhibitory effect would be expected if paf molecules were sequestered in micelles under our experimental conditions. Our study also demonstrates that the cardiolipin molecule must be intact to exhibit its specific anti-paf action. Any alteration of the structure of the molecule results in a complete loss of observed biological activity; also, lyso-monocardiolipin has been reported to be inactive (27).

Of particular interest is the observation that acetyl-cardiolipin exhibits a paf-like aggregatory effect on platelets because it aggregates platelets in the presence of aspirin and CP/CPK, while its aggregatory effect is completely inhibited by the paf receptor antagonists, BN 52021 and WEB 2086. Also, platelets treated with acetyl-cardiolipin are desensitized to the aggregatory effect of paf. This observation supports the hypothesis that the acetyl-cardiolipin aggregatory effect and the cardiolipin inhibitory effect on washed rabbit platelets are paf receptor-mediated phenomena, although both compounds are not structural analogues of paf.

The complicated behavior of cardiolipin in PRP is possibly due to its binding to various plasma constituents, such as enzymes, proteins and ions leading to configurational changes (38). These interactions may be responsible for the loss of biological activity, particularly at high cardiolipin concentrations or after a prolonged incubation with PRP.

Our study has provided evidence that cardiolipin is a specific paf inhibitor. Cardiolipin may play an anti-paf role, *in vivo*, in cell-to-cell interactions in which paf is involved. In plasma and in other biological fluids, it may have a special pathophysiological significance through its anti-paf action.

To develop a synthesis of tritiated cyclopropene fatty acids (CPFA), compounds that should prove useful for affinity labeling of desaturases in insect pheromone biosynthetic studies, a series of novel, selectively deuterated CPFA analogues was prepared and characterized. In methyl [16-^{2}H]12,13-methylene-12-hexadecenoate, the incorporation of deuterium was achieved by treatment of the corresponding ω-chloro derivative with sodium borodeuteride in dimethylsulfoxide at 70°C for 24 h (67% yield) following conventional procedures. Alkylation of the tetrahydropyranyl derivative of 13-tridecynol in the presence of lithium diisopropylamide in tetrahydrofuran at −20°C with 1-chloro-3-iodopropane in hexamethylphosphoramide, followed by Jones oxidation of the crude product, yielded 16-chloro-12-hexadecynoic acid (54%), which was esterified to the corresponding methyl ester by treatment with potassium carbonate and methyl iodide in dimethylformamide. Treatment of this acetylenic ester with ethyldiazoacetate in the presence of activated copper-bronze as catalyst followed by hydrolysis in KOH solution at room temperature yielded 16-chloro-12,13-(carboxymethylene)-12-hexadecenoic acid. This diacid was treated with excess oxalyl chloride to give the corresponding diacyl chloride, which was decarbonylated in a diethyl ether solution with zinc chloride, and the cyclopropenium ions thus formed were added at −40°C to a methanolic sodium hydroxide solution of sodium borohydride to give methyl 16-chloro-12,13-methylene-12-hexadecenoate. Analogous procedures were followed to prepare methyl [17-^{2}H]10,11-methylene-10-hexadecenoate, methyl [17-^{2}H]11,12-methylene-11-hexadecenoate and methyl [17-^{2}H]12,13-methylene-12-hexadecenoate from the corresponding diacids using sodium borodeuteride in the reduction of the cyclopropenium ions. Alternatively, methyl [2,2,3,3-$^2H_4$]hexadecynoate, prepared by reaction of methyl 2,11-hexadecadiynoate with magnesium in deuterated methanol at room temperature, was submitted to the above cyclopropenylation and reductive decarbonylation sequence to give methyl [2,2,3,3,17-$^2H_5$]-11,12-methylene-11-hexadecenoate. In summary, complementary methods for the selective incorporation of one to five deuterium atoms into cyclopropene fatty acids, at different sites, in moderate to high yields have been developed. The methods should easily be applicable to the preparation of the corresponding tritiated analogues.
Lipids 28, 1125–1130 (1993).

Desaturases are key enzymes in the biosynthesis of lepidopteran sex pheromones (1). Our interest in these unique enzymes led us to the search for specific and irreversible desaturase inhibitors that would be useful for affinity labeling. We had previously found (2,3) that certain cyclopropene fatty acids (CPFA) are potent and presumably irreversible inhibitors of *Z*(11) and *Z*(9) desaturation of palmitic and *E*(11)-tetradecenoic acids, respectively, in *Spodoptera littoralis* pheromone glands. We thought that these compounds, conveniently radiolabeled, might be suitable affinity labels for these enzymes. Additional bioassays indicated that compounds **1b**, **3b**, **4b** and **5b** would label both the *Z*(11) and the *Z*(9) desaturase, whereas **2b** and **6b** would be specific for the *Z*(9) and the *Z*(11) enzymes, respectively. As a pilot study to the synthesis of tritiated cyclopropene fatty acids, we describe in this paper the preparation of the deuterated cyclopropene fatty esters **1a**–**6a**. In most cases, deuterium was introduced in the last step of the synthesis to optimize the procedures for the preparation of the corresponding radioactive materials.

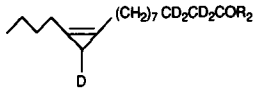
5a: R_1=C_5H_{11}, R_2=OCH_3, n=8
5b: R_1=C_5H_{11}, R_2=OH, n=8



6a: R=OCH_3
6b: R=OH

RESULTS AND DISCUSSION

Cyclopropene fatty ester **1a**, in which deuterium is placed at the ω-position, was prepared as illustrated in Scheme 1. A chlorine atom was selected as precursor of deuterium. Alkylation of **7a** with 1-chloro-3-iodopropane, followed by Jones oxidation and methylation of the resulting fatty acid **8b**, afforded **8a** in 45% overall yield. The cyclopropene ring in **10b** was formed by reaction of alkyne **8a** with ethyldiazoacetate in the presence of activated Cu-bronze as catalyst (4), and the resulting diester **10a** was hydrolyzed at room temperature. Decarbonylation of diacyl

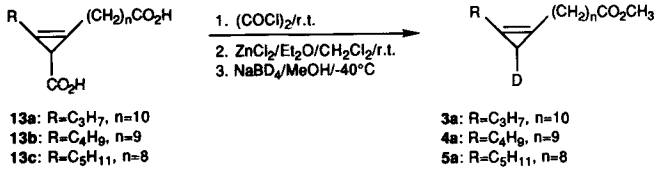


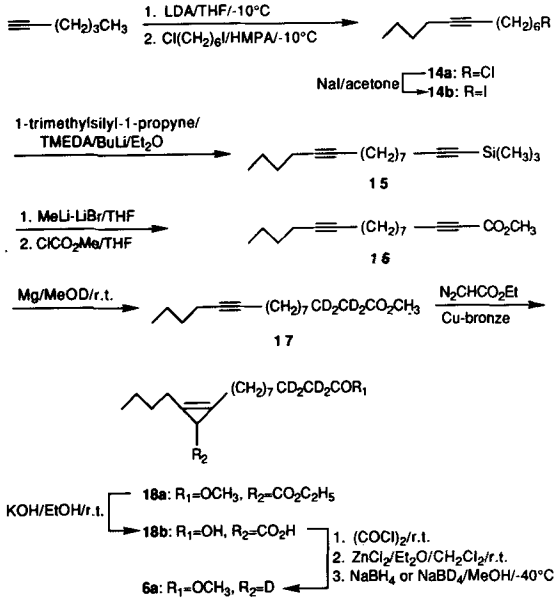
SCHEME 2

chloride of **10b** was accomplished with $ZnCl_2$. Although solid $ZnCl_2$ had been used in previous studies (4,5), we found that the reaction proceeded more rapidly when $ZnCl_2$ was used as diethyl ether solution, which is commercially available. Reduction of the cyclopropenium ions thus formed was accomplished with $NaBH_4$ in NaOH/MeOH at low temperature. Although a molar cation/hydride ratio of 1:4 was used in previous syntheses (4,5), we found that the ratio could be lowered to 1:2 without significant decrease in yield. This modification was particularly important in the case of the ring-deuterated compounds as it allowed less labeling reagent to be used. The chlorine atom remained unaffected under these reduction conditions, but chlorine was successfully reduced by $NaBD_4$ in dimethylsulfoxide (DMSO) at 70°C (6). It should be noted that in the ^1H nuclear magnetic resonance (NMR) spectra of both diester **10a** and diacid **10b**, signals corresponding to the methylenes C-11, C-14 and C-16 revealed the diastereotopic nature of the protons at these positions. Assignment of ^{13}C signals in the different cyclopropenes was carried out on the basis of distortionless enhancement by polarization transfer (DEPT), heteronuclear correlation (HECTOR) and double quantum filtered correlation spectroscopy (DQ-COSY) experiments, with some compounds.

Cyclopropene fatty ester **2a** was prepared as shown in Scheme 1. Alkylation of acetylene **7b** with 1-bromopropane, followed by Jones oxidation and methylation of acid **9b** produced **9a**. Transformation of **9a** into the final product was accomplished as described above for the C_{16} compounds.

The synthesis of ring-labeled cyclopropene fatty esters **3a–5a** (Scheme 2) was accomplished by decarbonylation, followed by reduction of diacyl chlorides of **13a–c**, which were prepared as previously described (5). Both decarbonylation and cyclopropenium ion reduction were carried out as previously indicated, although $NaBD_4$ was used as reducing agent.

The pentadeuterated cyclopropene **6a** was also prepared. Additional deuterium atoms were introduced at $\alpha,\alpha,\beta,\beta$-positions to avoid chain-shortening of the inhibitor in the gland and thus increase its specificity toward the *Z*(11) desaturase (3). The synthesis of **6a** was carried out as shown in Scheme 3. Alkylation of 1-hexynyllithium with 1-chloro-6-iodohexane yielded the chloroalkyne **14a**, which was transformed into **14b** by treatment with NaI in acetone. Propargylation was achieved in high yields by alkylation of **14b** with lithio-1-trimethylsilylpropyne (7,8) which, in turn, was readily obtained by reaction of 1-trimethylsilyl-1-propyne with tetramethylethylenediamine and an equivalent amount of *n*-butyllithium (8). The presence of a trimethylsilyl group was very convenient as it replaced the acidic acetylenic proton in propyne, allowing metallation of the methyl group for the propargylation reaction to take place. Metallation at C-1 in the resulting diyne **15** was achieved by direct treatment with MeLi-LiBr complex (9). Quenching of the acetylide thus formed with methyl chloroformate afforded the expected ester **16**. Deuterium atoms were introduced by reduction with Mg/CH_3OD (10). This reaction proceeded by selective reduction of the conjugated triple bond at C-2, leaving the isolated triple bond at C-11 intact. Transformation of tetradeuterated ester **17** into the cyclopropene **6a** was accomplished as indicated, following the general sequence of reactions.



SCHEME 3

EXPERIMENTAL PROCEDURES

Commercial-grade reagents and solvents were directly used as supplied, with the following exceptions: Diethyl ether and tetrahydrofuran (THF) (SDS, Barberá del Vallés, Spain) were distilled over Na/benzophenone under N_2, diisopropylamine (Fluka, Buchs, Switzerland) over KOH pellets and CH_2Cl_2 (SDS) over P_2O_5. Dimethylformamide (DMF) (Panreac, Montcada i Reixac, Spain), hexamethylphosphoramide (HMPA) (Fluka) and tetramethylethylenediamine (TMEDA) (Fluka) were distilled and kept over molecular sieves (3Å). Reactions sensitive to oxygen and moisture were carried out under an argon atmosphere. Purification of products by column chromatography was done using Merck (Darmstadt, Germany) 70-230 mesh silica gel deactivated with 10% water. Thin-layer chromatography (TLC) was carried out using Merck $60F_{254}$ (0.25-mm) sheets. Products were generally isolated by pouring the reaction mixture onto ice, and by extracting with solvent, washing with brine and drying over $MgSO_4$. Elemental analyses were performed on a Carlo Erba (Milano, Italy) elemental analyzer model 1106. Fourier transform infrared spectra were recorded on films using a Michelson Bomem (Montreal, Quebec, Canada) MB-120 spectrometer. ^1H and ^{13}C NMR spectra were obtained on $CDCl_3$ solutions with either a Bruker (Karlsruhe, Germany) WP80SY, a Varian (Palo Alto, CA) XL200 or a Varian Unity-300 spectrometer at 80, 200 or 300 MHz, respectively, for ^1H, and at 20, 50 or 75 MHz for ^{13}C. Low-resolution mass spectra were measured on a Hewlett-Packard (Palo Alto, CA) HP 5995 mass spectrometer coupled to a gas chromatograph equipped with a fused silica capillary column (30 m × 0.32 mm i.d.) SPB-5 from Supelco (Bellefonte, PA). High-resolution mass spectra (HRMS) were measured on an Autospec-Q (VG Analytical, Fisons, Rodano, Italy) mass spectrometer.

10-Tetradecynoic acid (**9b**) *(Ref. 11).* Under argon, 4.8 mL (34 mmol) of diisopropylamine in 34 mL of dry THF was placed in a three-neck, round-bottom flask. The solution was stirred at −10°C, and 29 mL (35 mmol) of a 1.2 M solution of BuLi in hexane was added. The mixture was stirred for 2 h at 0°C, and then 7.8 g (31 mmol) of **7b** in 89 mL of THF was added at the same temperature. Stirring was continued for 1 h, and then the acetylide was treated with a solution of 3.5 mL (35 mmol) of 3-bromopropane in 80 mL of HMPA. After stirring for a further 18 h, 8.1 g of an oil was isolated using hexane for extraction. Jones oxidation of 0.706 g of the oil under standard conditions (5) afforded **9b** in 78% yield from **7b** after column chromatography using CH_2Cl_2/MeOH (97:3, vol/vol) as eluent. Infrared (IR): 3550-2500, 2930, 2860, 1710, 1460 cm^{-1}. ^1H NMR (80 MHz); δ 9.75 (*s*, 1H, COOH), 2.13 (*c*, 6H, CH_2CO and $CH_2C{\equiv}$), 1.10-1.60 (*b*, 14H, $\equiv CC(CH_2)_6$ and CH_2CH_3), 0.89 (*t*, J = 7.0 Hz, 3H, CH_3).

16-Chloro-12-hexadecynoic acid (**8b**). The procedure for the synthesis of **9b** was applied to the alkylation of **7a** (1.2 g, 4.25 mmol). Jones oxidation of the crude tetrahydropyranyl derivative (1.0 g, 2.8 mmol) afforded **8b** in 54% yield after purification by column chromatography and elution with CH_2Cl_2/MeOH (97:3, vol/vol). Anal: Calcd. for $C_{16}H_{27}O_2Cl$: C, 67.01; H, 9.42. Found: C, 67.08; H, 9.36. IR: 3500-2500, 2927, 2854, 1708, 1288 cm^{-1}. ^1H NMR (200 MHz): δ 3.64 (*t*, J = 6.4 Hz, 2H, CH_2Cl), 2.38-2.28 (*c*, 4H, CH_2CO and $ClCCCH_2C{\equiv}$), 2.12 (*tt*, J = 6.8 and 2.4 Hz, 2H, $CCCCH_2C{\equiv}$), 1.92 (*m*, J = 6.4 Hz, 2H, $ClCCH_2$), 1.62 (*c*), 1.42 (*c*) and 1.27 (*b*, 16H, $\equiv CC(CH_2)_8$). ^{13}C NMR (50 MHz): 180.23 (C-1), 81.41 (C-12), 77.99 (C-13), 43.78 (C-16), 34.06 (C-2), 31.79 (C-15), 29.42, 29.34, 29.19, 29.08, 29.03 and 28.81 (C-4 to C-10), 24.64 (C-3), 18.68 (C-11), 16.20 (C-14).

Methyl 16-chloro-12-hexadecynoate (**8a**). Esterification of **8b** (0.65 g, 2 mmol) with K_2CO_3 (1.1 g, 7.9 mmol) and CH_3I (0.5 mL, 8 mmol) in DMF (10 mL) afforded **8a** in 95% yield after column chromatography and elution with hexane/diethyl ether (10:1, vol/vol). Anal: Calcd. for $C_{17}H_{29}ClO_2$: C, 67.89; H, 9.65. Found: C, 67.93; H, 9.71. IR: 2927, 2854, 1739, 1434, 1170 cm^{-1}. ^1H NMR (200 MHz): δ 3.65 (*s*, 3H, OCH_3), 3.64 (*t*, J = 6.4 Hz, 2H, CH_2Cl), 2.38-2.25 (*c*, 4H, CH_2CO and $ClCCCH_2C{\equiv}$), 2.12 (*tt*, J = 6.8 and 2.4 Hz, 2H, $CCCCH_2C{\equiv}$), 1.91 (*m*, J = 6.6 Hz, 2H, $ClCCH_2$), 1.60 (*c*), 1.42 (*c*) and 1.27 (*b*, 16H, $\equiv CC(CH_2)_8$). ^{13}C NMR (50 MHz): 174.26 (C-1), 81.39 (C-12), 77.95 (C-13), 51.39 (OCH_3), 43.76 (C-16), 34.06 (C-1), 31.77 (C-15), 29.41, 29.34, 29.19, 29.10, 29.06, 28.97, 28.80 (C-4 to C-10), 24.90 (C-3), 18.65 (C-11), 16.18 (C-14). MS: *m/z* 300 (5%), 130 (50%), 116 (51%), 81 (100%).

Methyl 10-tetradecynoate (**9a**). The same esterification and purification procedures applied to **8b** (0.380 *g*, 1.60 mmol) furnished **9a** in 70% yield. Anal: Calcd. for $C_{15}H_{26}O_2$: C, 75.63; H, 10.92. Found: C, 75.59; H, 10.88. IR: 2930, 2860, 1750, 1465, 1440, 1170 cm^{-1}. ^1H NMR (80 MHz): δ 3.66 (*s* 3H CH_3O), 2.12 (*c*, 6H, CH_2CO and $CH_2C{\equiv}$), 1.20-1.80 (*b*, 14H, $\equiv CC(CH_2)_6$ and CH_2CH_3), 0.86 (*t*, J = 7.4 Hz, 3H, CH_3C).

1-Iodo-7-dodecyne (**14b**). The alkylation procedure described for the synthesis of **9b** applied to 2.5 g (40.3 mmol) of 1-hexyne and 7.8 g (31.7 mmol) of 1-chloro-6-iodohexane afforded 5.8 g of **14a**, which was directly treated with 9 g (60 mmol) of NaI in 30 mL of dry acetone under reflux for 36 h. Extraction with diethyl ether followed by column chromatography and elution with hexane/diethyl ether (5:1, vol/vol) yielded 5 g (17 mmol, 63%) of pure **14b**. Anal: Calcd. for $C_{12}H_{21}I$: C, 49.31; H, 7.19. Found: C, 49.43; H, 7.24. IR: 2956, 2935, 2856, 2219, 1461, 1433, 1197, 727 cm^{-1}. ^1H NMR (200 MHz): δ 3.17 (*t*, J = 7.0 Hz, 2H, CH_2I), 2.13 (*c*, 4H, $CH_2C{\equiv}$), 1.82 (*c*, 2H, $ICCH_2$), 1.40 (*c*, 10H, $\equiv CC(CH_2)_3$ and $(CH_2)_2CH_3$), 0.89 (*t*, J = 7.2 Hz, 3H, CH_3). ^{13}C NMR (50 MHz): δ 80.31 and 79.72 (C-7 and C-8), 33.34 (C-2), 31.17 (C-10), 29.95 (C-3), 28.77 (C-5), 27.59 (C-4), 21.85 (C-11), 18.58 (C-9), 18.36 (C-6), 13.57 (C-12) and 6.95 (C-1).

1-Trimethylsilyl-1,10-pentadecadiyne (**15**). Into a three-neck, round-bottomed flask was placed (under argon) 1.5 mL (10 mmol) of dry TMEDA, and 6.4 mL (10 mmol) of a 1.6 M solution of BuLi was slowly added at −5°C. After 2.5 h of stirring, 1.5 mL (10 mmol) of 1-trimethylsilyl-1-propyne in 10 mL of dry diethyl ether was added. This mixture was stirred at −5°C for 30 min and was reacted with 3 g (10 mmol) of iodoalkyne **14b** in 10 mL of dry diethyl ether. The ice bath was removed, and the mixture stirred at room temperature for 12 h. Extraction with hexane afforded 2.6 g (9.5 mmol, 92%) of diyne **15**. A small sample was purified by bulb-to-bulb distillation (170°C/1 Torr) for characterization. Anal: Calcd. for $C_{18}H_{32}Si$: C, 78.26; H, 11.59. Found: C, 78.15; H, 11.43. IR: 2483, 2433, 2089, 1933, 1464, 1245, 845 cm^{-1}. ^1H NMR (200 MHz): δ 2.21 (*t*, J = 7.2 Hz, 2H, $CH_2C{\equiv}CSi$), 2.14 (*t*, J = 6.6 Hz,

4H, $CH_2C{\equiv}CC$), 1.42 (*c*, 14H, $\equiv CC(CH_2)_5$ and $(CH_2)_2CH_3$), 0.90 (*t*, J = 7.4 Hz, 3H, CH_3C), 0.14 (*s*, 9H, CH_3Si). ^{13}C NMR (20 MHz): δ 107.47 (C-2), 84.15 (C-1), 79.97 (C-10 and C-11), 31.26 (C-13), 29.02 and 28.59 (C-4 to C-8), 21.87 (C-14), 19.75 (C-3), 18.66 and 18.35 (C-9 and C-12), 13.57 (C-15), 0.12 (CSi). MS: *m/z* 203 (10%), 73 (100%).

Methyl 2,11-hexadecadiynoate (**16**). A solution of 0.5 g (1.8 mmol) of **15** in 10 mL of THF was treated at 0°C with 1.2 mL (1.8 mmol) of a 1.5 M solution of MeLi/LiBr in diethyl ether, and the mixture was stirred for 3 h. The resulting acetylide was transferred to a solution of methyl chloroformate (0.155 mL, 2 mmol) in 3 mL of THF at −30°C. Stirring was continued for 40 min, and the reaction mixture was treated with a saturated aqueous solution of NH_4Cl and extracted with diethyl ether, affording 350 mg of an oil that was purified by column chromatography using hexane/diethyl ether (5:1, vol/vol) to obtain 230 mg (0.88 mmol, 49%) of pure **16**. Anal: Calcd. for $C_{17}H_{26}O_2$: C, 77.86; H, 9.92. Found: C, 77.94; H, 10.03. IR: 2931, 2858, 1749, 1718, 1434, 1253 cm^{-1}. ^1H NMR (200 MHz): δ 3.74 (*s*, 3H, CH_3O), 2.31 (*t*, J = 7.0 Hz, 2H, $CH_2C{\equiv}CCO$), 2.12 (*c*, 4H, $CCH_2C{\equiv}CCH_2$), 1.40 (*c*, 14H, $\equiv CC(CH_2)_5$ and (CH_2CH_3), 0.88 (*t*, J = 7.0 Hz, 3H, CH_3C). ^{13}C NMR: δ 154.11 (C-1), 89.81 (C-3), 80.24 and 79.93 (C-11 and C-12), 72.80 (C-2), 52.49 (CH_3O), 31.20 (C-14), 28.98, 28.65, 28.50, 27.39 (C-5 to C-9), 21.88 (C-15), 18.64, 18.57 and 18.37 (C-4, C-10 and C-13), 13.58 (C-16). MS: *m/z* 262 (8%), 231 (20%), 205 (25%), 67 (100%).

Methyl [2,2,3,3-$^2H_4$]11-hexadecynoate (**17**). A mixture of ester **16** (0.922 g, 3.52 mmol) and Mg (0.422 g, 17.6 mmol) in 26 mL of CH_3OD was stirred at room temperature for 20 h. After this time, the mixture was poured onto ice and acidified with 0.1 N HCl. Extraction with hexane yielded 0.720 g of a material that was purified by column chromatography and elution with hexane/diethyl ether (5:1, vol/vol) to afford 590 mg (2.2 mmol, 62%) of pure **17**. HRMS: Calcd. for $C_{17}H_{26}D_4O_2$: 270.249687. Found: 270.248833. IR: 2929, 2856, 1739, 1267 cm^{-1}. ^1H NMR: δ 3.65 (*s*, 3H, CH_3O), 2.12 (*c*, 4H, $CH_2C{\equiv}$), 1.47-1.27 (*c*, 16H, $\equiv CC(CH_2)_6$ and $(CH_2)_2CH_3$), 0.87 (*t*, J = 8.8 Hz, 3H, CH_3C). ^{13}C NMR: δ 80.15 (C-11 and C-12), 51.41 (CH_3O), 31.27 (C-14), 29.33, 28.14, 29.08, 28.81, 28.37 (C-4 to C-9), 21.93 (C-15), 18.74 and 18.44 (C-10 and C-13), 13.63 (C-16). MS: *m/z* 270 (3%), 96 (100%).

Methyl 16-chloro-12,13-(ethoxycarbonylmethylene)-12-hexadecenoate (**10a**). Into a two-neck, round-bottomed flask, 0.51 g (1.7 mmol) of **8a** and 40 mg (0.63 matg) of activated Cu-bronze were placed under argon. The mixture was heated at 135°C for 15 min, and 0.350 mL (3.4 mmol) of ethyl diazoacetate was slowly added. After 15 min of stirring at this temperature, the mixture was cooled to room temperature, hexane was added and the crude mixture filtered through celite. Removal of solvent gave an oil that was submitted to bulb-to-bulb distillation at 120°C/20 Torr to remove ethyl maleate and ethyl fumarate. The resulting residue was purified by column chromatography with hexane/diethyl ether (9:1, vol/vol), affording 0.3 g (0.78 mmol, 46%) of **10a**. HRMS: Calcd. for $C_{21}H_{35}O_4Cl$: 386.222388. Found: 386.223434. IR: 2927, 2854, 1737, 1722, 1178 cm^{-1}. ^1H NMR (300 MHz) δ 4.10 (*q*, J = 6.8 Hz, 2H, CH_2O), 3.66 (*s*, 3H, CH_3O), 3.57 (*c*, 2H, CH_2Cl), 2.58 (*c*, 2H, $ClCCCH_2C{=}$), 2.40 (*tt*, J = 7.2 and 1.5 Hz, 2H, $CCCCH_2C{=}$), 2.29 (*t*, J = 7.4 Hz, 2H, CH_2CO), 2.04 (*s*, 1H, CH), 2.01 (*m*, J = 6.9 Hz, 2H, $ClCCH_2$), 1.57 (*c*, 4H, $CH_2CC{=}$ and CH_2CCO), 1.26 (*b*, 12H, $=CCC(CH_2)_6$), 1.23 (*t*, J = 7.2 Hz, 3H, CH_3C). ^{13}C NMR (50 MHz): δ 176.63 (CHCO), 174.21 (C-1), 107.38 (C-13), 103.98 (C-12), 59.82 (CH_2O), 51.34 (CH_3O), 44.00 (C-16), 34.01 (C-2), 29.83 (C-15), 29.37, 29.30, 29.18 and 29.05 (C-4 to C-9), 26.88 (C-10), 24.86 (C-3), 24.43 (C-11), 22.13 (CH), 21.83 (C-14), 14.33 (CH_3C). MS: *m/z* 386 (6%), 315 (100%), 201 (56%), 173 (50%).

Methyl 10,11-(ethoxycarbonylmethylene)-10-tetradecenoate (**11a**). The procedure described above afforded **11a** in 42% yield from **9a** (0.454 g, 1.9 mmol). HRMS: Calcd. for $C_{19}H_{32}O_4$: 324.230060. Found: 324.229995. IR: 2969, 2925, 1739, 1722, 1176 cm^{-1}. ^1H NMR (200 MHz): δ 4.10 (*q*, J = 7.2 Hz, 2H, CH_2O), 3.67 (*s*, 3H, CH_3O), 2.38 (*c*, 4H, $CH_2C{=}$), 2.29 (*t*, J = 7.6 Hz, 2H, CH_2CO), 2.02 (*s*, 1H, CH), 1.58 (*c*, 6H, $CH_2CC{=}$ and CH_2CCO), 1.29 (*b*, 10H, $=CCC(CH_2)_4$ and CH_2CH_3), 1.23 (*t*, J = 7.2 Hz, 3H, CH_3CH_2O), 0.95 (*t*, J = 7.4 Hz, 3H CH_3CH_2C). ^{13}C NMR (50 MHz): δ 177.05 (CHCO), 174.26 (C-1), 105.76 and 105.51 (C-10 and C-11), 59.72 (CH_2O), 51.42 (CH_3O), 34.06 (C-2), 29.15, 29.12 and 29.08 (C-4 to C-7), 26.92 (C-8) 26.51 (C-12), 24.89 (C-3), 24.47 (C-9), 22.24 (CH), 20.38 (C-13), 14.40 (CH_3CH_2O), 13.84 (C-14). MS: *m/z* 293 (10%), 251 (100%).

Methyl [2,2,3,3,-$^2H_4$]11,12-(ethoxycarbonylmethylene)-11-hexadecynoate (**18a**). The procedure applied to **17** (0.48 g, 3.57 mmol) gave **18a** in 83% yield. HRMS: Calcd. for $C_{21}H_{32}D_4O_4$: 356.286467. Found: 356.285461. IR: 2954, 2929, 2856, 1731, 1724, 1176 cm^{-1}. ^1H NMR (200 MHz): δ 4.08 (*q*, J = 7.2 Hz, 2H, CH_2O), 3.64 (*s*, 3H, CH_3O), 2.37 (*t*, J = 7.2 Hz, 4H, $CH_2C{=}$), 2.00 (*s*, 1H, CH), 1.51 (*c*, 4H, $CH_2CC{=}$), 1.29-1.39 (*c*, 12H, $=CC(CH_2)_5$ and CH_2CH_3), 1.21 (*t*, J = 6.2 Hz, 3H, CH_3CH_2O), 0.89 (*t*, J = 7.4 Hz, 3H, CH_3CH_2C). ^{13}C NMR (50 MHz): δ 177.02 (CHCO), 174.29 (C-1), 105.59 (C-11 and C-12), 59.70 (CH_2O), 51.36 (CH_3O), 29.30, 29.17, 29.03 and 28.82 (C-4 to C-8 and C-14), 26.93 (C-9), 24.45 (C-10), 24.17 (C-13), 22.29 and 22.24 (CH and C-15), 14.38 (CH_3CH_2O), 13.71 (C-16). MS: *m/z* 356 (7%), 297 (30%), 284 (100%).

16-Chloro-12,13-(carboxymethylene)-12-hexadecenoic acid (**10b**). A solution of 0.15 g (0.39 mmol) of **10a** in 2 mL of 20% KOH in 98% EtOH was stirred at room temperature under argon. Disappearance of the starting material was followed by TLC. After completion of the reaction (10–18 h), 130 mg (0.34 mmol) of pure **10b** was obtained by extraction with CH_2Cl_2. A small sample was purified by column chromatography and elution with CH_2Cl_2/MeOH (90:10, vol/vol) for characterization. HRMS: Calcd. for $C_{18}H_{29}O_4Cl$: 344.439888. Found: 344.439876. IR: 3500–2200, 2927, 2854, 1703, 1697, 1417, 1282, 1232 cm^{-1}. ^1H NMR (300 MHz): δ 3.59 (*c*, 2H, CH_2Cl), 2.61 (*c*, 2H, $ClCCCH_2C{=}$), 2.43 (*c*, 2H, $CCCCH_2C{=}$), 2.34 (*t*, J = 6.9 Hz, 2H, CH_2CO), 2.04 (*s*, 1H, CH), 2.03 (*m*, J = 6.9 Hz, 2H, $ClCCH_2$), 1.58 (*c*, 4H, $CH_2CC{=}$ and CH_2CCO), 1.26 (*b*, 12H, $=CCC(CH_2)_6$). ^{13}C NMR (50 MHz): δ 183.61 (CHCO), 180.30 (C-1), 107.06 (C-13), 103.49 (C-12), 44.04 (C-16), 34.11 (C-2), 29.77 (C-15), 29.16, 29.07, 28.94 (C-4 to C-9), 26.77 (C-10), 24.58 (C-3), 24.47 (C-11), 21.96 (CH), 21.88 (C-14).

10,11-(Carboxymethylene)-10-tetradecenoic acid (**11b**). Using the same hydrolysis and purification procedures gave **11b** in 70% yield from **11a** (0.600 g, 2.12 mmol). HRMS: Calcd. for $C_{16}H_{26}O_4$: 282.183110. Found: 282.180732. IR: 3600–2200, 2929, 2856, 1703, 1226 cm^{-1}.

^{1}H NMR (200 MHz): δ 10.41 (*b*, 2H, COOH), 2.38 (*c*, 4H, CH_2C=), 2.32 (*t*, *J* = 7.4 Hz, 2H, CH_2CO), 2.01 (*s*, 1H, CH), 1.57 (*m*, 6H, CH_2CC= and CH_2CCO), 1.29 (*b*, 8H, =CCC$(CH_2)_4$), 0.94 (*t*, *J* = 7.2 Hz, 3H, CH_3). ^{13}C NMR (50 MHz): δ 183.91 (CHCO), 180.16 (C-1), 105.39 and 105.13 (C-10 and C-11), 34.15, (C-2), 28.99 and 28.89 (C-4 to C-7), 26.79 (C-8), 26.47 (C-12), 24.61 (C-3), 24.41 (C-9), 22.04 (CH) 20.32 (C-13), 13.82 (C-14).

[2,2,3,3-$^2H_4$]11,12-(Carboxymethylene)-11-hexadecynoic acid (**18b**). Using the same hydrolysis procedure furnished **18b** in 86% yield from **18a** (528 mg, 1.47 mmol). HRMS: Calcd. for $C_{18}H_{26}D_4O_4$: 314.239517. Found: 314.237953. IR: 3000–2500, 2956, 2929, 2856, 1693, 1420, 1265, 740 cm^{-1}. ^{1}H NMR: δ 11.70 (*b*, 2H, COOH), 2.33 (*t*, *J* = 6.8 Hz, 4H, CH_2C=), 1.94 (*s*, 1H, CH), 1.55–1.05 (*c*, 16H, =CC$(CH_2)_6$ and C$H_2)_2CH_3$), 0.83 (*t*, *J* = 7.2 Hz, 3H, CH_3). ^{13}C NMR: δ 184.21 (CHCO), 180.61 (C-1), 105.24 (C-11 and C-12), 29.28, 29.18, 29.11, 28.948, 28.76 (C-4 to C-8 and C-14), 26.89 (C-9), 24.45 (C-10), 24.17 (C-13), 22.34 (C-15), 22.10 (CH), 13.74 (C-16).

Methyl 16-chloro-12,13-methylene-12-hexadecenoate (**12**). A modification of previously reported procedures (4,5) was followed. Diacid **10b** (100 mg, 0.29 mmol) was treated with three equivalents of $(COCl)_2$, and the mixture was stirred at room temperature for 1 h. Excess $(COCl)_2$ was removed with a stream of argon, and the residue thoroughly dried at 0.1 Torr for 2 h. After this time, dry CH_2Cl_2 (1 mL) and 0.3 mL (0.3 mmol) of a 1 M solution of $ZnCl_2$ in diethyl ether was added and the mixture stirred at room temperature for 10 min under argon. The resulting cyclopropenium ion solution was added, at −40°C under argon, to 0.6 mL of a 1 M solution of $NaBH_4$ (0.6 mmol) in 0.5 M NaOH in dry MeOH. Stirring was continued for 30 min at this temperature, and the suspension was warmed to room temperature and treated with 0.1 N HCl. Extraction with CH_2Cl_2 gave an oil that was purified by column chromatography using hexane to furnish 15 mg (0.05 mmol, 17%) of ester **12**. HRMS: Calcd. for $C_{18}H_{31}O_2Cl$: 314.530507. Found: 314.530456. IR: 2925, 2854, 1739, 1434, 1170, 1008 cm^{-1}. ^{1}H NMR (200 MHz): δ 3.66 (*s*, 3H, CH_3O), 3.56 (*t*, *J* = 6.6 Hz, 2H, CH_2Cl), 2.56 (*tt*, *J* = 7.0 and 1.3 Hz, 2H, $ClCCCH_2C$=), 2.38 (*tt*, *J* = 7.2 and 1.8 Hz, 2H, $CCCCH_2C$=), 2.31 (*t*, *J* = 7.6 Hz, 2H, CH_2CO), 2.03 (*m*, *J* = 6.8 Hz, 2H, $ClCCH_2$), 1.28 and 1.58 (*c*, 16H, =CC$(CH_2)_8$), 0.79 (*s*, 2H, ring CH_2). ^{13}C NMR (50 MHz): δ 174.33 (C-1), 110.94 (C-13), 107.61 (C-12), 51.43 (CH_3O), 44.48 (C-16), 34.09 (C-2), 30.39 (C-15), 29.47, 29.35, 29.23, 29.12 (C-4 to C9), 27.28 (C-10), 25.97 (C-11), 24.97 (C-3), 23.27 (C-14), 7.34 (C-17). MS: *m/z* 314 (1%), 283 (17%), 130 (18%), 95 (100%).

Methyl [17-H_2]12,13-methylene-12-hexadecenoate (**3a**). The same procedure was followed to prepare **3a** in 18% yield from **13a** (21 mg, 0.068 mmol). HRMS: Calcd. for $C_{18}H_{31}DO_2$: 281.246507. Found: 281.246629. COMMUNICATION

Synthesis of Arachidonic Acid Metabolites by Syrian Hamster Platelets and Peritoneal Cells

Marc E. Surette*, Jay Whelan[1], G.-P. Lu[2] and John E. Kinsella[3]
Lipids Research Laboratory, Institute of Food Science, Cornell University, Ithaca, New York 14853

In this study, the metabolism of arachidonic acid by hamster platelets and peritoneal macrophages was assessed. Peritoneal macrophages stimulated *in vitro* with the calcium ionophore A23187 or stimulated *in vivo* by intraperitoneal injections of opsonized zymosan produced prostaglandin E_2, thromboxane B_2 (TxB_2) and 6-keto-prostaglandin $F_{1\alpha}$, as determined by radioimmuno assays. Leukotriene B_4 (LTB_4), and 11- and 15-hydroxyeicosatetraenoic acids (HETE), which were identified by reverse-phase high-performance liquid chromatography coupled with diode array detection, were produced by peritoneal cells stimulated *in vitro* with A23187 but were not found in the peritoneal exudate following *in vivo* stimulation with opsonized zymosan. Synthesis of 11- and 15-HETE, but not LTB_4, was inhibited by 1 μM indomethacin but not by 10 μM nordihydroguaiaretic acid, which did inhibit LTB_4 synthesis. Washed hamster platelets were prepared and shown to synthesize TxB_2, 12-HETE and 12-hydroxyheptadecatrienoic acid following stimulation with thrombin. This paper is the first to report on eicosanoid metabolism in tissues related to atherosclerosis, thrombosis and inflammation in hamsters.
Lipids 28, 1131-1134 (1993).

The Syrian hamster has become a model of choice for the study of the effects of dietary lipids on circulating plasma lipoprotein concentrations due to similarities in cholesterol metabolism in hamsters and humans (1-3). While the concentration of circulating lipids is an important risk factor for the development of cardiovascular disease (CVD), atherosclerosis is being recognized as a chronic inflammatory disease in arteries, which is similar to inflammatory events in other tissues (4,5).

Platelets, neutrophils, monocytes, macrophages and smooth muscle cells produce cytokines and other inflammatory mediators involved in the progression of atherosclerotic lesions (4). One class of inflammatory compounds susceptible to dietary or pharmaceutical modulation are the products of the arachidonic acid (AA) cascade. Prostaglandins, which are products of the cyclooxygenase (CO) pathway, are largely immunomodulatory and directly affect platelet function (6). The 5-lipoxygenase product leukotriene B_4 (LTB_4) is one of the most potent chemotactic agents (7); leukotrienes C_4, D_4 and E_4 (LTC_4, LTD_4 and LTE_4) induce smooth muscle cell contraction and can increase post-capillary venule permeability (8,9); and hydroxyeicosatetraenoic acids (HETE) have been implicated in the regulation of several cellular capacities such as phospholipase A_2 activity (10) and calcium mobilization (11).

Dietary lipids can have a profound effect on tissue AA levels and eicosanoid production (12-14). Consequently, the basis for dietary lipid-induced changes in CVD risk may be considered to be a function of changes in the capacity for lipid mediator synthesis in addition to changes in circulating plasma lipid levels (15,16). In order to more thoroughly characterize the hamster as a model for the evaluation of CVD risk, changes in potential risk factors other than plasma lipid levels must be examined, especially when considering the effects of dietary lipids of the n-3 class whose antiatherogenic effects have been linked to altered eicosanoid production (15,16). However, no information exists on AA metabolism in hamster cells. Therefore, in this study, platelets and macrophages were prepared from Syrian hamsters in order to characterize their formation of CO and lipoxygenase (LO) products.

MATERIALS AND METHODS

Materials. AA metabolites were purchased from Cayman Chemical Co. (Ann Arbor, MI). Male Syrian hamsters (90-110 g) were purchased from Charles River Laboratories (Wilmington, MA).

Stimulation of peritoneal cells in vitro. Peritoneal cells were harvested by washing the peritoneal cavity twice with 5 mL of physiologically buffered saline (PBS) and were washed twice by centrifugation. The peritoneal exudate population consisted mainly of macrophages (90%) as determined by standard morphological criteria using cytospin preparations stained with May-Grünwald-Giesma stain. Pooled cell suspensions (10^6 cells per mL) were incubated in RPMI medium (Hazelton Biologics Inc., Lenexa, KS) in 3-mL aliquots for one hour at 37°C in a humidified atmosphere of 5% CO_2 and 95% air. The adherent cells (> 98% macrophages) were washed and stimulated for 15 min at 37°C with 5 μM calcium ionophore A23187, and the culture media were collected for eicosanoid analysis. In inhibition studies, the adherent cells were preincubated for 15 min with either 1 μM indomethacin or 10 μM nordihydroguaiaretic acid (NDGA) prior to stimulation with A23187 as above.

Eicosanoid production in vivo. Opsonized zymosan was prepared as previously described (17). Opsonized zymosan (2 mg in 1 mL saline) was injected intraperitoneally (18), and after 30 min the animals were killed and the peritoneal

Abbreviations: AA, arachidonic acid; CO, cyclooxygenase; CVD, cardiovascular disease; HETE, hydroxyeicosatetraenoic acid; HHT, hydroxyheptadecatrienoic acid; RP-HPLC, reverse-phase high-performance liquid chromatography; 6-keto-$PGF_{1\alpha}$, 6-keto-prostaglandin $F_{1\alpha}$; LTB_4, leukotriene B_4; LTC_4, leukotriene C_4; LTD_4, leukotriene D_4; LTE_4 leukotriene E_4; LO, lipoxygenase; NDGA, nordihydroguaiaretic acid; PBS, physiologically buffered saline; PGB_1, prostaglandin B_1; PGE_2, prostaglandin E_2; PRP, platelet-rich plasma; RIA, radioimmunoassay; TxB_2, thromboxane B_2; UV, ultraviolet.

cavity was washed twice with 5 mL of PBS. The peritoneal wash was centrifuged (700 × *g* for 10 min at 4°C), and the supernatant was removed for eicosanoid analysis.

Preparation and stimulation of washed platelets. Platelet-rich plasma (PRP) was prepared by centrifugation (650 × *g*, 10 min) of citrated blood (0.38% citrate) collected from hamsters anesthetized with metafane. The centrifugation was repeated two more times, and the PRP was pooled and acidified with citric acid (pH 6.4). The PRP was then centrifuged (900 × *g*, 10 min), and the pellet was washed once with calcium-free modified tyrode's buffer (19). Aggregation studies were carried out using a Payton aggregometer (Payton Instruments, Buffalo, NY) with 6 × 10^5 platelets per μL at 37°C. Platelets were preincubated at 37°C for 15 min, and $CaCl_2$ (0.1 mM) was added to the suspension before the addition of agonist. Platelets were stimulated with thrombin (0.4 U/mL), which was the concentration that caused 75% platelet aggregation, and the reaction was stopped after 4 min by the addition of acetic acid (0.4% final) prior to eicosanoid analysis.

Sample extraction and analysis. Samples were extracted and analyzed for eicosanoids by radioimmunoassay (RIA) or reverse-phase high-performance liquid chromatography (RP-HPLC) as previously described (13). Separation by RP-HPLC of compounds produced by peritoneal cells was accomplished using a methanol/water (68:32, vol/vol) mobile phase, and for platelet products using methanol/water (72:28, vol/vol).

RESULTS

Eicosanoid production by peritoneal cells. Three peaks were identified in HPLC of the supernatant of A23187-stimulated peritoneal cells that had the characteristic ultraviolet (UV) absorption spectra of known LO products (Fig. 1). Compound C1 co-eluted with LTB_4 and possessed a UV absorption spectrum identical to that of authentic LTB_4, with a λ max at 270 nm (Fig. 2). The identity of LTB_4 was further confirmed by enzyme-linked immunosorbant assay (Cayman Chemical Co., Ann Arbor, MI), which shows little cross-reactivity (0.3%) with isomers of LTB_4 (data not shown). Compounds C2 and C3 co-eluted with 15- and 11-HETE, respectively, and possessed UV absorption spectra (Fig. 3) characteristic of conjugated dienes with distinctively different λ max at 236 nm and 234.5 nm corresponding to the λ maxima of 15-HETE and 11-HETE, respectively (20). No peaks co-

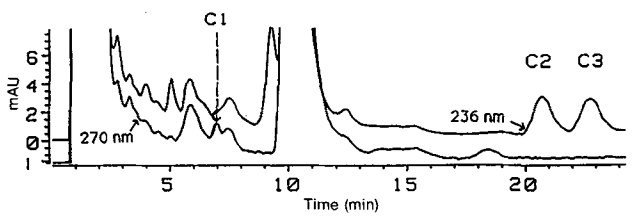

FIG. 1. Reversed-phase high-performance liquid chromatography (RP-HPLC) of supernatant of hamster peritoneal cells stimulated with calcium ionophore A23187. Adherent hamster peritoneal cells were stimulated with 5 μM A23187 for 15 min at 37°C. Separation was accomplished by RP-HPLC on a Whatman (Maidstone, England) Partisphere C-18 column (6 mm × 12.5 cm) using a methanol/water (68:32, vol/vol) mobile phase containing 5 mM ammonium acetate and 1 mM ethylenediaminetetraacetic acid, pH 5.6 and a flow rate of 0.9 mL/min. Absorbance of the eluate was monitored at 270 nm and 236 nm.

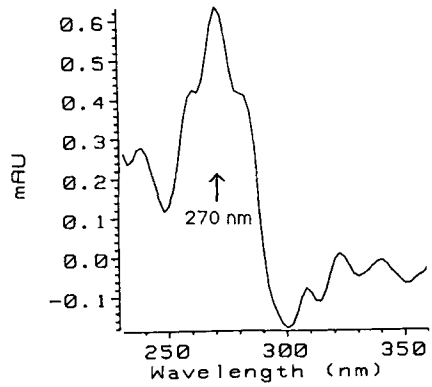

FIG. 2. Ultraviolet absorption spectrum (λ max 270 nm) of compound 1 (see Fig. 1) produced by peritoneal cells stimulated with 5 μM calcium ionophore A23187 for 15 min at 37°C.

eluting with LTB_4, C_4, D_4 or E_4, nor with 5-, 8-, 11-, 12- or 15-HETE were observed following analysis of the peritoneal exudate by RP-HPLC after *in vivo* stimulation with opsonized zymosan (data not shown).

Cells stimulated *in vitro* with A23187 or *in vivo* with opsonized zymosan produced prostaglandin E_2 (PGE_2), 6-keto-prostaglandin $F_{1\alpha}$ (6-keto-$PGF_{1\alpha}$) (the stable metabolite of prostacyclin) and thromboxane B_2 (TxB_2) (the stable metabolite of thromboxane A_2) as determined by RIA (Table 1).

Incubation of cells with 1 μM indomethacin before stimulation with ionophore resulted in a 70% decrease in HETE production, but did not affect LTB_4 production compared to untreated cells (Table 2). Incubation of cells with 10 μM NDGA prior to stimulation with ionophore only resulted in a 27% decrease in HETE synthesis but decreased LTB_4 synthesis to levels below limits of detection.

Eicosanoid production by washed platelets. Three AA metabolites were identified in extracts of stimulated platelets; TxB_2, 120 ± 10 ng per 10^9 platelets; 12-hydroxyheptadecatrienoic acid (HHT), 85 ± 15 ng per 10^9 platelets; and 12-HETE , 70 ± 14 ng per 10^9 platelets (means ± SEM, n = 5). HHT and 12-HETE were identified by HPLC by comparing their retention times to those of

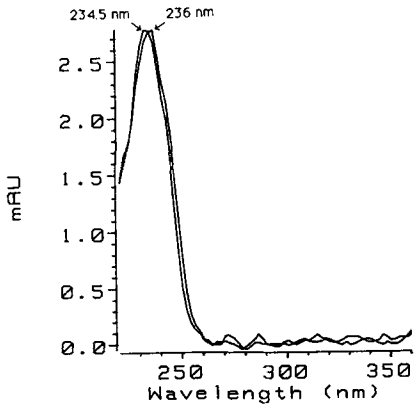

FIG. 3. Ultraviolet absorption spectra of compounds 2 (λ max 236) and 3 (λ max 234.5) (see Fig. 1) produced by peritoneal cells stimulated with 5 μM calcium ionophore A23187 for 15 min at 37°C.

TABLE 1

Synthesis of Eicosanoids by Hamster Peritoneal Cells Stimulated *in vitro* with the Ionophore A23187 or *in vivo* by Peritoneal Injections of Opsonized Zymosan[a]

Stimulus	Eicosanoids (ng/10^6 cells)					
	PGE_2	6-k-$PGF_{1\alpha}$	TxB_2	LTB_4	11-HETE	15-HETE
A23187	0.25 ± 0.09	11.6 ± 4.7	0.39 ± 0.09	5.5 ± 1.3	14.1 ± 3.0	12.4 ± 2.8
Zymosan	2.01 ± 0.3	141 ± 45	0.75 ± 0.23	ND[b]	ND	ND

[a]Adherent hamster peritoneal cells were stimulated *in vitro* for 15 min with 5 μM A23187 prior to extraction and analysis of arachidonic acid metabolites. Peritoneal cells were stimulated *in vivo* by intraperitoneal injections of 2 mg opsonized zymosan for 30 min (means ± SD, n = 8). $P6E_2$, prostaglandin E_2; 6-k-$PGF_{1\alpha}$, 6-keto-prostaglandin $F_{1\alpha}$; TxB_2, thromboxane B_2; LTB_4, leukotriene B_4; HETE, hydroxyeicosatetraenoic. [b]ND, not detected.

TABLE 2

Effect of Inhibitors on Calcium Ionophore-Induced Production of LTB_4, 15-HETE and 11-HETE by Peritoneal Cells[a]

Treatment	ng per million cells		
	11-HETE	15-HETE	LTB_4
Control	11.5 ± 2.0	9.8 ± 1.4	5.0 ± 0.3
Indomethacin	3.3[b] ± 0.4	3.7[b] ± 0.2	4.9 ± 0.4
NDGA	8.1 ± 1.0	7.4 ± 0.9	ND[b,c]

[a]Peritoneal cells were pre-incubated without inhibitors (control), with indomethacin (1 μM) or with NDGA (10 μM) for 15 min prior to stimulation with 5 μM A23187 for 15 min. Means ± SD (n = 3). Abbreviations: LTB_4, leukotriene B_4; HETE, hydroxyeicosatetraenoic acid; NDGA, nordihydroguaiaretic acid.
[b]Significantly different from control, $P < 0.01$.
[c]ND, not detected.

authentic standards and by their characteristic UV absorption spectra (data not shown).

DISCUSSION

The hamster has been a valuable model for understanding the metabolism of circulating lipoproteins and their regulation by factors such as dietary lipids (1–3,21). However, little has been reported on the production of AA metabolites in hamster even though these compounds are believed to be involved in the development of atherosclerosis, and their synthesis is susceptible to dietary as well as pharmaceutical modulation.

The hamster peritoneal cells examined in this study, like those of the rat, mouse and guinea pig, consist mostly of macrophages (> 90%). However, the AA metabolites produced in response to stimuli by this cell population differed from those produced in similar cell populations from other species (17,22–25). Stimulation of the adherent peritoneal cell population with the ionophore, A23187 resulted in the detection by RP-HPLC of three AA metabolites, LTB_4, 11-HETE and 15-HETE. In comparison, mouse peritoneal cells stimulated *in vitro* have been reported to produce LTB_4, LTC_4, LTE_4 and 5-, 12- or 15-HETE (25–27) and rat cells LTB_4, C_4 and D_4 (23). Adherent hamster peritoneal macrophages, like mouse peritoneal macrophages, also produced the CO-derived PGE_2, 6-keto-$PGF_{1\alpha}$ and TxB_2, following ionophore stimulation as determined by RIA.

The treatment of cells with the CO inhibitor indomethacin, at concentrations which do not affect LO activity (28), as expected did not affect LTB_4 production, but resulted in a 70% decrease in HETE synthesis. Cells treated with the nonspecific LO inhibitor NDGA inhibited the synthesis of LTB_4, but not of 11- and 15-HETE. This suggests that the 11- and 15-HETE are synthesized *via* the CO pathway as has been previously reported in human umbilical arteries (29) and endothelial cells (30), fetal calf aorta (31) and cultured rat aorta smooth muscle cells (32).

In vivo stimulation of hamster peritoneal cells with opsonized zymosan resulted in the synthesis of greater amounts of PGE_2, 6-keto-$PGF_{1\alpha}$ and TxB_2 than were observed in cells stimulated *in vitro* (Table 1). This may be due to the potential contribution of other cells in the peritoneal cavity to the synthesis of prostaglandins. However, the production of hydroxy fatty acids or leukotrienes by as many as 1.5×10^7 cells was not detected following *in vivo* stimulation. In contrast, the mouse peritoneum subjected to the same stimulus produces in addition to the prostanoids, the cysteinyl-leukotrienes LTC_4 and LTE_4 in concentrations of 16 and 78 ng per 10^6 cells, respectively (17). Thus, the profile of AA-derived compounds produced by peritoneal cells shows species variations and, as with mouse peritoneal cells (22), is stimulus-dependent.

Washed hamster platelets produced the same major AA metabolites as platelets from other species, including humans, following stimulation with agonist (33). 12-HETE, a product of the 12-LO pathway, and the CO-derived HHT as well as TxB_2, were identified in supernatants of platelets stimulated with thrombin. The preparation of platelets for the determination of aggregability and eicosanoid production could be of value in the determination of the potential anti-atherogenic or anti-thrombotic effects of drugs or special diets in this species.

Differences in eicosanoid metabolism between different species underscore the need to determine AA metabolites produced in animal models used for the study of lipid metabolism and its relationship to diseases such as atherosclerosis. The identification, in this study, of AA metabolites synthesized by hamster cells should enable, in the future, a more thorough evaluation of the potential anti-atherogenic effects of dietary or pharmaceutical interventions in this species.
