ARTICLE

Incorporation of Oleic Acid and Eicosapentaenoic Acid into Glycerolipids of Cultured Normal Human Fibroblasts

Michael Miller*, Mahnaz Motevalli, David Westphal and Peter O. Kwiterovich, Jr.
Lipid Research-Atherosclerosis Unit, Departments of Medicine and Pediatrics, Johns Hopkins Medical Institutions and The University of Maryland Medical Systems, Baltimore, Maryland 21205

Confluent skin fibroblasts from normal humans were incubated in serum free medium with up to 100 nmole/mL eicosapentaenoic acid (EPA; bound to albumin in a 4.6:1 ratio) and compared with cells incubated with oleic acid (OA) at similar concentrations. The rate of [^{14}C]OA incorporation into triacylglycerol (TG) (nmol/mg/h) was approximately 5-fold greater than that of [^{14}C]EPA. The mass of TG formed after incubation of fibroblasts with EPA was also significantly lower than that formed with OA (43.2 ± 9.3 *vs.* 59.5 ± 6.6 μg/mg cell protein, respectively, $P = 0.006$). The addition of excess, unlabeled EPA reduced the rate of incorporation of [^{14}C]OA into TG whereas unlabeled OA stimulated incorporation of [^{14}C]EPA into TG. When the cells were preincubated with human serum basic proteins (BP I, II and III), the mass of TG formed (compared to baseline) was significantly higher with the basic proteins whether OA or EPA was studied. Only BP I significantly stimulated the mass of cell phospholipids, an effect that occurred with either OA or EPA in the medium. The results suggest that in cultured normal human fibroblasts, OA is a better substrate for TG synthesis than EPA and that this effect may be accentuated by the presence of the basis proteins.
***Lipids* 28, 1-5 (1993).**

Long-chain n-3 polyunsaturated fatty acids have a number of beneficial effects including inhibition of hepatic very low density lipoprotein (VLDL) production (1). Inhibition reflects reduced lipogenesis and enhanced fatty acid oxidation (2). This results in decreased formation of triacylglycerols (TG) (3). In cultured Hep G-2 cells, for example, eicosapentaenoic acid (EPA), the archetype of the omega-3 fatty acids, inhibits TG synthesis as has been shown by reduced [^{3}H]triacylglycerol production from [^{3}H]glycerol (4). In mammalian cells such as fibroblasts, endothelial and intestinal cells, polyunsaturated fatty acids appear to be selectively incorporated into phospholipids (5-7).

In contrast to EPA, monounsaturated fatty acids, such as oleic acid (OA), are readily incorporated into TG. In cultured fibroblasts, OA comprises a substantially greater percentage of the fatty acid pool in total neutral lipid esters (8). The addition of EPA, however, inhibits the stimulation of hepatic TG secretion by OA (1,9). Taken together, these observations suggest that EPA and OA affect TG synthesis differently; EPA inhibits while OA stimulates the process.

Abbreviations: ASP, acylation stimulatory protein; BP, basic protein; DG, diacylglycerols; EPA, eicosapentaenoic acid; FCS, fetal calf serum; FFA, free fatty acids; GLC, gas-liquid chromatography; MEM, minimum essential medium; MG, monoacylglycerols; OA, oleic acid; PBS, phosphate buffered saline; TG, triacylglycerols; TLC, thin-layer chromatography; VLDL, very low density lipoprotein.

Recently, we and others reported a two- to threefold stimulation of [^{14}C]OA incorporation into cellular TG of normal human fibroblasts by a novel human serum basic protein, BP I, also termed acylation stimulatory protein (ASP) (10,11). Two other basic proteins (BP II and BP III) were also described, but their acylation stimulatory activity was less than that of BP I (11).

Our objectives here were to determine (i) whether the differential effects of OA and EPA on fatty acid incorporation into hepatocyte TG were also expressed in cultured normal human fibroblasts, and (ii) whether serum basic proteins affect incorporation of EPA into cellular glycerolipids in a similar manner as previously demonstrated with OA.

MATERIALS AND METHODS

Subjects. Skin biopsies were obtained from the forearms of six nonsmoking, non-obese, normolipidemic volunteers after informed consent. The mean age of the three male and three female donors was 24.2 yrs. The mean levels (mg/dL) of lipids and lipoproteins were: total cholesterol, 142, triglycerides, 43, low density lipoprotein cholesterol, 60, and high density lipoprotein cholesterol, 73 (11).

Cultured fibroblasts. To avoid experimentation with very young (*i.e.*, passage number <3) or senescent (*i.e.*, passage number >12) cells, passage numbers between 4-10 were used; during these passages, mitotic division is active. For each experiment, cells were plated on 35-mm or 60-mm Petri dishes in Eagle's minimal essential medium (MEM), containing 10% fetal calf serum (FCS), 1% nonessential amino acids and 1% penicillin-streptomycin. On day 6, FCS was replaced with serum-free medium, and the cells were incubated overnight prior to the experiment.

Fatty acid supplementation. [^{14}C]Oleic acid (specific activity, 57 mCi/mmol) and [^{14}C]EPA (specific activity, 52.2 mCi/mmol) were obtained from Amersham (Arlington, IL). Nonradiolabeled fatty acids were purchased from Sigma (St. Louis, MO) and pre-tested for purity (>95%) by gas-liquid chromatography (GLC) of the methyl ester. Unlabeled OA (90 mg) or unlabeled EPA (96 mg) were solubilized in 5 N NaOH (100 μL) and ethanol (2 mL). The solvent was evaporated to dryness with N_2, and 150 mM NaCl (10 mL) was then added to a final concentration of 31.9 mM and heated for 5 min at 60°C (12). Bovine serum albumin (24%, wt/vol, fatty acid free) in 150 mM NaCl (12.5 mL) was added and the solution stirred overnight. The solution was then adjusted with 150 mM NaCl to give a final concentration of 12.7 mM sodium oleate or 12.7 mM sodium eicosapentaenoate in 12% albumin (wt/vol). [^{14}C]OA/albumin and [^{14}C]OA/albumin and [^{14}C]EPA/albumin were then prepared to give preparations of 10 mM oleate or 10 mM eicosapentaenoate; specific activity, about 10,000 dpm/nmol, molar ratio of oleate or eicosapentaenoate to albumin (4.6:1) (11).

Free fatty acid (FFA) incorporation experiments. On day 7, dishes were incubated with increasing amounts of

[^{14}C]OA/albumin or [^{14}C]EPA/albumin (final concentration of fatty acid, 10 mM), for 1–2 h at 37°C. At the end of the incubation period, cells were placed on ice, and media removed. Cells were then washed thoroughly with phosphate buffered saline (PBS) and bovine serum albumin. Lipids were extracted with hexane/isopropranol (3:2, vol/vol), and the extract was taken to dryness with N_2. The lipids were then dissolved in hexane and subjected to thin-layer chromatography (TLC) employing hexane/diethyl ether/acetic acid (75:25:1, vol/vol/vol) as solvent. The incorporation of [^{14}C]OA or [^{14}C]EPA into cellular lipids was determined by scintillation counting and expressed as nmol incorporated/mg cell protein/h. In experiments designed to measure incorporation into monoylglycerols (MG) and diacylglycerols (DG), the TLC solvent system was ethylenedichloride/methanol (98:2, vol/vol) (13).

Competition experiments. Cell dishes were incubated with increasing amounts of [^{14}C]OA/albumin or [^{14}C]-EPA/albumin as described above in the absence or presence of unlabeled OA/albumin or unlabeled EPA/albumin (25 μg fatty acid/mL medium). Extraction of cellular lipids was done as described above.

Basic protein experiments. BP I, II and III were isolated from normal human serum as previously described (11). Cells were grown to near confluence, and on day 6 medium was changed from 10% FCS/MEM to delipidized MEM/F12 supplemented overnight with insulin, pantothenic acid and biotin. In fibroblasts grown in serum-deficient medium, the addition of these supplements maximizes cell viability (14). Subsequently, either OA or EPA, and BP I, II or III (6 μg/mL) were added to the media, and the cells incubated for 6 h (11). The medium was removed, cells were washed and lipids extracted.

Mass measurements. The amount of cellular TG was determined using an enzymatic assay (Boehringer Mannheim, Indianapolis, IN). The content of phosphorus in the cell lipid fraction was measured using the method of Bartlett and multiplied by 25 to express the total phospholipid content in mg% (15). Cellular protein content was determined using the method of Lowry *et al.* (16) with serum albumin as standard.

Statistical methods. Tests of significance were made using the paired *t*-test. In some cases, the Wilcoxon Rank Sum was used. The designated level of significance was $P < 0.05$.

RESULTS

The incorporation of OA into cell lipids was compared to that of EPA at increasing concentrations of the fatty acids (nmol/mL) in the culture medium (Fig. 1). The incorporation of [^{14}C]OA (nmol/mg/h) into triacylglycerols was significantly greater than that of EPA at each concentration tested (Fig. 1). In contrast, the pattern of incorporation for [^{14}C]EPA into cell phospholipids was greater than that of [^{14}C]OA, but this difference did not reach statistical significance (Fig. 1). For cellular cholesteryl esters, incorporation of [^{14}C]OA was greater than that of [^{14}C]EPA (Fig. 1).

We next compared the incorporation of [^{14}C]OA *vs.* [^{14}C]EPA into cellular MG, DG (both the 1,2-isomer and the 1,3-isomer), TG and phospholipids (Fig. 2). The incorporation of [^{14}C]OA was significantly greater than that of [^{14}C]EPA into cell 1,3-DG and TG (Fig. 2). No significant differences were observed for the incorporation of these two free fatty acids (FFA) into cell MG. In contrast, the incorporation of [^{14}C]EPA into cell phospholipids was significantly greater than that of OA (Fig. 2). The data confirmed the pattern of greater incorporation of OA into cell TG but higher incorporation of EPA into cell phospholipids.

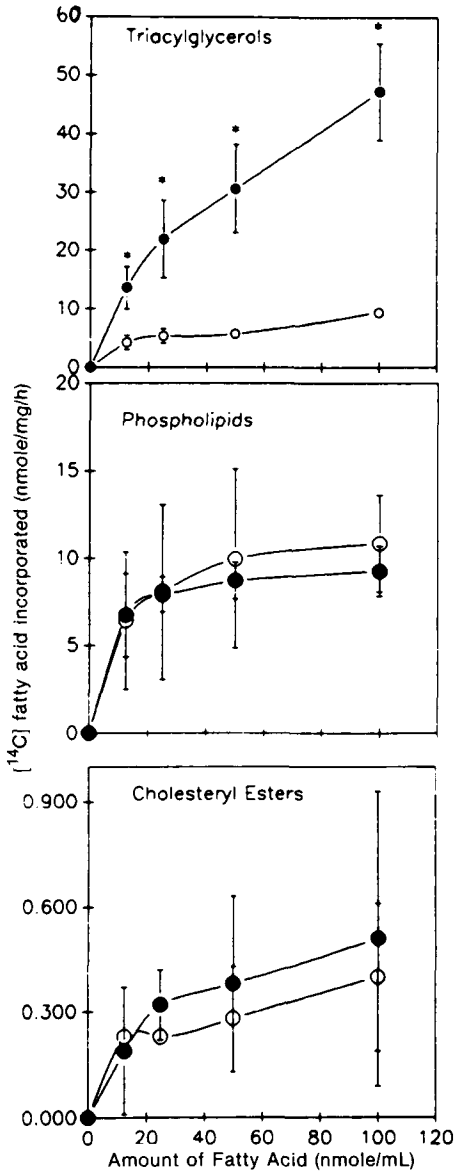

FIG. 1. Incorporation of [^{14}C]oleic acid (OA) and [^{14}C]eicosapentaenoic acid (EPA) into cellular triacylglycerols (top), phospholipids (middle) and cholesteryl esters (bottom) of normal human cultured fibroblasts. Cells were grown as described in Materials and Methods. On day 7, cells were incubated with increasing concentrations of [^{14}C]OA/albumin or [^{14}C]EPA/albumin (10 mM oleate or eicosapentaenoate, specific activity, 10,000 dpm/nmol) for 1 or 2 h at 37°C. Cells were then harvested and the incorporation of [^{14}C]OA (solid circles) and [^{14}C]EPA (open circles) into cell lipids was determined. The results represent the mean (±SD) of duplicate samples from two different cell lines. Those points that were significantly different between [^{14}C]OA and [^{14}C]EPA are designated with an asterisk.

Competition studies of OA and EPA. We next compared the effect of excess unlabeled OA or excess unlabeled EPA

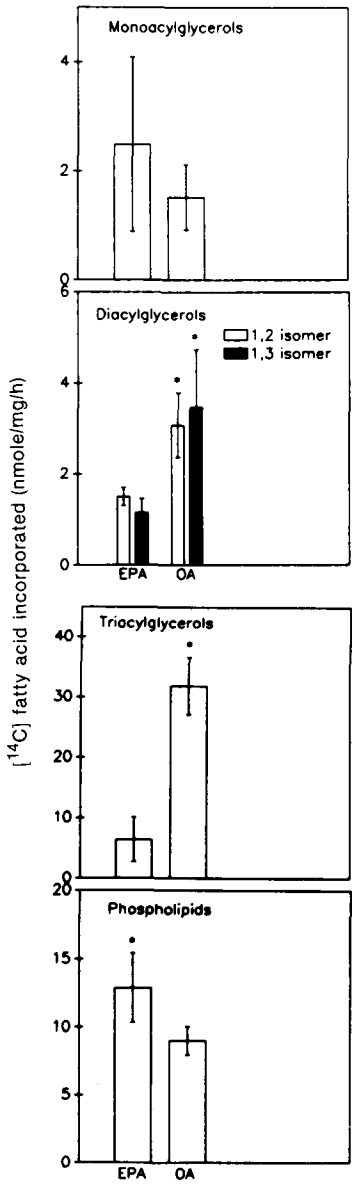

FIG. 2. Incorporation of [^{14}C]oleic acid (OA) and [^{14}C]eicosapentaenoic acid (EPA) into cellular monoacylglycerols, 1,2- and 1,3-diacylglycerols (upper two panels), triacylglycerols and phospholipids (lower two panels) of normal human cultured fibroblasts. Cells were grown as described in Materials and Methods. On day 7, cells were incubated with 50 nmol of either [^{14}C]OA/albumin or [^{14}C]-EPA/albumin (specific activity [^{14}C]OA, 11,128 dpm/nmol, [^{14}C]EPA, 11,765 dpm/nmol) for 1 h at 37°C. Cells were harvested and the incorporation of [^{14}C]OA and [^{14}C]EPA into cellular glycerolipids was determined (see Materials and Methods).

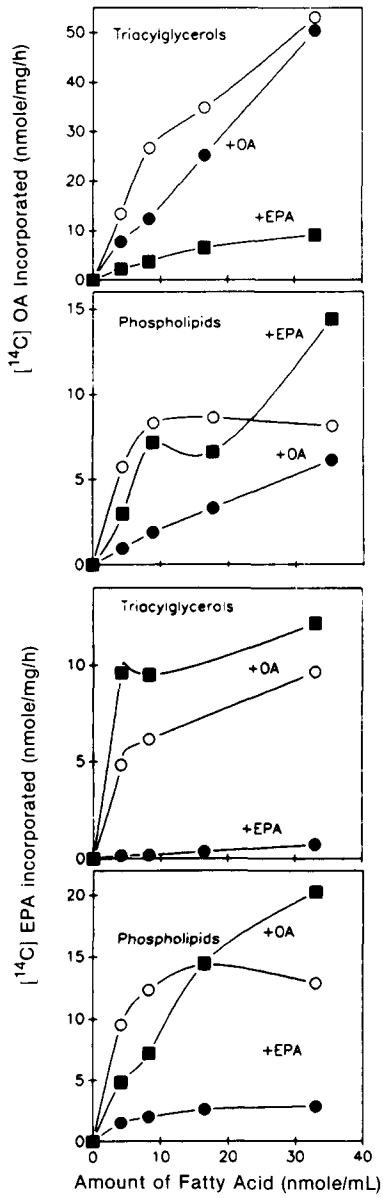

FIG. 3. Incorporation of [^{14}C]oleic acid (OA) (upper two panels) and [^{14}C]eicosapentaenoic acid (EPA) (lower two panels) into triacylglycerols and phospholipids in the absence (○) or presence (● and ■) of 25 μg/mL medium of unlabeled fatty acid. In the upper two panels, the effects of unlabeled OA (●) or EPA (■) on [^{14}C]OA (○) incorporation into triacylglycerols and phospholipids are shown. In the lower two panels, the effects of unlabeled EPA (●) or OA (■) on [^{14}C]EPA (○) incorporation into triacylglycerols and phospholipids are shown. Cells were grown as described in Materials and Methods. On day 7, cells were incubated with [^{14}C]OA/albumin or [^{14}C]EPA/albumin (10 mM oleate or eicosapentaenoate, specific activity, [^{14}C]OA, 11,128 dpm/nmol; [^{14}C]EPA, 10,203 dpm/nmol) for 1 h at 37°C. Extraction of cellular lipids was carried out as described in Materials and Methods.

on the rate of incorporation of either [^{14}C]OA or [^{14}C]EPA into cell TG and phospholipids (Fig. 3). Unlabeled EPA inhibited the incorporation of [^{14}C]OA into cellular TG to a markedly greater extent than unlabeled OA (Fig. 3). In contrast, the incorporation of [^{14}C]EPA into cellular TG was actually stimulated by unlabeled OA; unlabeled EPA markedly depressed the incorporation of [^{14}C]EPA into TG. The incorporation of [^{14}C]OA into cell phospholipids was inhibited by unlabeled OA but was somewhat stimulated by unlabeled EPA, particularly at higher concentration of [^{14}C]OA in the cell culture medium (Fig. 3). Incorporation of [^{14}C]EPA into cell phospholipids was inhibited by unlabeled EPA, while unlabeled OA decreased such incorporation at lower concentrations but increased it somewhat at higher concentrations.

Effect of preincubation with serum basic proteins. We next assessed the effect of normal human serum BP I, II and III on the mass of cellular TG and phospholipids in

TABLE 1

Cellular Mass of Triacylglycerol and Phospholipids (μg/mg cell protein) After Preincubation with Serum Basic Proteins in the Presence of Either Albumin/Oleic Acid (OA) or Albumin/Eicosapentaenoic Acid (EPA)[a]

	OA	*P* value	EPA	*P* value	OA *vs.* EPA *P* value
Triacylglycerol					
Without BP	59.5 ± 6.6[b]		43.2 ± 9.3		0.01
BP I	117.6 ± 30.8	0.007	78.2 ± 8.5	0.0001	0.15
BP II	76.2 ± 15.0	0.07	59.5 ± 10.5	0.02	0.97
BP III	69.3 ± 5.3	0.04	69.9 ± 13.9	0.02	0.13
Phospholipids					
Without BP	335.3 ± 103.4		244.6 ± 31.6		0.10
BP I	628.8 ± 222.7	0.05	556.2 ± 60.7	0.0001	0.90
BP II	440.0 ± 121.9	0.26	265.6 ± 66.5	0.58	0.41
BP III	352.4 ± 90.8	0.83	274.8 ± 98.0	0.48	0.74

[a]Confluent fibroblasts were incubated for 24 h in serum-free medium as described in Materials and Methods. The cells were then switched to medium containing albumin/OA or albumin/EPA with or without BP I, BP II or BP III (6 μg/mL) for 6 h. The cells were then harvested and the TG and phospholipid mass in cells were determined as described in Materials and Methods.

[b]Mean (one SD) in μg/mg cell protein from three normal cell lines studied in duplicate.

normal human fibroblasts, using either OA/albumin or EPA/albumin as the source of FFA in the cell culture medium. BP I, BP II and BP III each increased the cellular mass of TG over baseline; a similar pattern was found when either OA or EPA was used (Table 1). When the cell data on TG mass (OA *vs.* EPA) were compared, there was a significantly higher mass of TG formed at baseline (in the absence of BP I, II or III) with OA than with EPA, consistent with the previous patterns presented in Figures 1 and 2. When OA was compared with EPA in the presence of BP I, II or III, the baseline values were first subtracted from the values following incubation with BP I, II or III. After correction for baseline differences between OA and EPA, there were no significant differences between the effects of BP I, II or III on increasing the cell TG mass, when OA was compared with EPA as the source of fatty acid in the culture medium (Table 1).

Similar analyses were performed to assess the effect of serum basic proteins on the cellular mass of total phospholipids. BP I, but not BP II or BP III, significantly increased the mass of phospholipids compared to baseline, whether OA or EPA was used (Table 1). However, no significant differences were observed at baseline between the cell mass of phospholipids following incubation of the cells with either OA or EPA alone. Correcting for baseline, the extent of the stimulation of phospholipid mass by BP I was not significantly different when OA was compared with EPA (Table 1).

DISCUSSION

The most important observations were (i) that OA was preferentially incorporated into TG while EPA was preferentially incorporated into phospholipids of normal human fibroblasts; (ii) that EPA appeared to inhibit the synthesis of TG from OA, while OA stimulated the formation of TG from EPA; and (iii) that serum BP I, II and III increased the cell mass of TG when either OA or EPA was used (BP I also stimulated phospholipid mass). These observations were made under defined experimental conditions that were selected to produce maximal fatty acid modifications in human cultured fibroblasts (8) and which had previously been found to permit maximum acylation stimulatory activity of the serum (BP) (11).

Our studies with normal human fibroblasts support the findings of most (2-4,9,17,18), but not all (19), previous studies done on hepatocytes, which also showed preferential incorporation of OA into cellular TG, as judged by both mass measurements and by ^{14}C-incorporation into TG. In fibroblasts, we found here that incorporation of EPA into both DG (1,2- and 1,3-isomers) and TG was markedly reduced. Moreover, the presence of excess unlabeled EPA reduced [^{14}C]OA incorporation into TG. This supports previous studies done on hepatocytes where EPA was shown to reduce TG synthesis and to inhibit OA stimulation of TG secretion (1,9,17). However, we did not find any significant differences in the mass of cell phospholipids after incubation with EPA or OA. This was not unexpected, since we used experimental conditions similar to those of Spector *et al.* (8) in which the TG content of cells increased when grown in the presence of added fatty acids, but the phospholipid content remained unchanged.

Our results further suggest that EPA and OA may be metabolized differently in cultured mammalian cells. Previous studies have revealed preferential incorporation of OA over EPA in adipose cells and a preference for EPA over OA in other tissues (*i.e.*, platelet membranes) (20-23). While the mechanism(s) responsible for these differences are now known, it has been shown that activity of the enzymes regulating TG synthesis may be affected by external factors (24). Marsh *et al.* (25) and Wong and Marsh (26) reported a marked reduction in phosphatidate phosphohydrolase activity in rat hepatocytes following a diet rich in EPA, or after infusion of EPA into perfused rat livers. In our studies, EPA incorporation into both DG and TG was markedly reduced, compatible with an effect on phosphatidate phosphohydrolase which hydrolyzes phosphatidic acid to diacylglycerol, rather than an effect of EPA on 1,2-diacylglycerol acyltransferase (17).

We extended our previous studies where we found that BP I, II and III stimulated the incorporation of [^{14}C]OA

into TG of normal fibroblasts by showing here that preincubation of cells with normal human serum BP also increased the mass of TG. This effect was observed whether OA nor EPA was used as a source of fatty acids in the medium (Table 1). While the increase in the mass of TG with various BP was less with EPA than with OA, the differences were not statistically significant after correcting for baseline differences. Thus, we have no evidence for a greater avidity of BP to interact with OA as compared with EPA, or that their cellular effect is more specific for OA than EPA. Finally, we found evidence that BP I may also increase the mass of cell phospholipids. Since neither OA nor EPA alone stimulated phospholipid mass (as expected from the work of Spector *et al.*, ref. 8), this effect of BP I may be a specific one. Further work is indicated to determine whether BP I has any influence on membrane structure and function and what the underlying mechanism(s) may be.

In summary, the data suggest that the metabolic effects of EPA and OA in cultured normal human fibroblasts are different. Human skin fibroblasts from normal and dyslipidemic subjects may provide a useful system to further study glycerolipid metabolism, as we recently demonstrated for hyperapobetalipoproteinemia (27). The serum basic proteins may contribute further to understanding the metabolic processes underlying cellular free fatty acid uptake and utilization in this and other lipid disorders.

[Received December 26, 1991, and in final revised form November 3, 1992; Revision accepted November 4, 1992]

Influence of Dietary Egg and Soybean Phospholipids and Triacylglycerols on Human Serum Lipoproteins

Barbara C. O'Brien* and **Verona Gale Andrews**[1]
Department of Biochemistry and Biophysics, Texas Agricultural Experiment Station, Texas A&M University System, College Station, Texas 77843-2128

Human serum lipid and lipoprotein concentrations and compositions were compared in ten healthy middle-aged men consuming phospholipids from egg or from soybean or triacylglycerol mixtures with fatty acid compositions similar to those of the phospholipids. All subjects followed each of the four treatments: egg phospholipids (EP), soybean phospholipids (SP), an oil of fatty acid composition similar to that of EP, and an oil similar in fatty acid composition to SP for six weeks with "wash-out" periods of similar duration between treatment periods. The phospholipids, 15 g/d, and the oils, 12 g/d, which contained approximately equivalent quantities of fatty acids were provided to the subjects in gelatin capsules and were taken before meals. Diet intake was monitored by three-day food records. Serum lipoproteins (L_p) were separated by ultracentrifugation into very low density lipoproteins, low density lipoproteins (LDL), high density lipoproteins $(HDL)_2$ and HDL_3. L_p fractions and whole serum were analyzed for triacylglycerols, cholesterol (CH), phospholipids (PL), and protein. HDL cholesterol was determined in whole serum. Cholesteryl esters were determined in some L_p fractions. Lipid compositions of L_p were expressed in mmol/g protein. Apoprotein B was measured in whole serum and in LDL; apoprotein A-I in whole serum and in HDL_3. In whole serum, CH and PL were significantly lower after the SP compared to EP treatment periods. CH, but not PL, was lower after SPTG compared to EP. CH in HDL_2 was significantly higher after SP compared to SPTG. Also, PL in HDL_2 were significantly higher after SP compared to all other treatments and to baseline. Although human serum lipid responses to dietary phospholipids were generally the same as responses to ingested oils of comparable fatty acid composition, the data suggest the possibility that SP selectively increase HDL_2 cholesterol and phospholipids.
Lipids 28, 7-12 (1993).

Although "lecithin," primarily from soybeans, is widely used as a hypocholesterolemic and antiatherogenic agent, experimental tests of its effectiveness are inconsistent. Knuiman *et al.* (1) reviewed the literature to answer the question, Does ingested lecithin affect human serum cholesterol independent of its linoleic acid content? These authors found only four out of 24 studies in which human cholesterolemic responses to soybean lecithin were compared to polyunsaturated oils of similar linoleic acid content. They concluded that lecithin, phosphatidylcholine (PC), had no different effect on serum cholesterol than soybean oil. However, the issue concerning its effect on serum levels of high density lipoprotein cholesterol (HDLC) was not addressed by Knuiman and co-workers (1). HDLC is particularly important because of its inverse relationship to coronary heart disease (CHD) (2). Childs *et al.* (3) found a significant increase in HDLC in response to soybean lecithin compared to an equivalent amount of polyunsaturated fatty esters ingested as corn oil. Total serum cholesterol (TSC) levels were not significantly different between treatment groups. Galli *et al.* (4) administered 10 g/d of purified polyunsaturated phosphatidylcholine to male human volunteers for six weeks. They found no change in TSC but a significant increase in HDLC.

In a previously reported experiment with hypercholesterolemic guinea pigs, we compared cholesterolemic responses to soybean "lecithin" and to egg "lecithin," commercial preparations which were principally PC (5). Since the dietary "lecithins" used in that experiment with guinea pigs were mixtures and not lecithin, the term "phospholipids" will be used hereafter to refer to the polar lipid mixtures. Comparisons to oils of similar fatty acid compositions were not made. Soybean phospholipids resulted in a 50% reduction in TSC while HDLC increased 23%. When the guinea pigs were treated with egg phospholipids, we observed a dramatic increase of 177% in HDLC with no change in TSC. The ratio of TSC to HDLC in hypercholesterolemic guinea pigs that were not treated with phospholipids was 5.76. The groups of animals treated either with soybean phospholipids or with egg phospholipids had TSC/HDLC of 2.26 and 2.24, respectively. The egg phospholipids had a low ratio of polyunsaturated (P) to saturated (S) fatty acid composition (P/S = 0.38) compared to soybean phospholipids with a P/S of 3.5. These data suggested a cholesterolemic response to ingested phospholipids that was not totally dependent upon its fatty acid composition. The results of thisguinea pig experiment were inconclusive because we did not control the fatty acid compositions of the phospholipids nor could we extrapolate the results to responses in humans.

The present study was undertaken to evaluate human serum lipoprotein (L_p) responses to orally administered soybean and egg phospholipids relative to those responses to oils of similar fatty acid composition. In addition to determining serum concentrations of lipids, the lipid composition and the protein content of the major L_p fractions, very low density lipoproteins (VLDL), low density lipoproteins (LDL), high density lipoproteins (HDL_2) and HDL_3, were determined.

Abbreviations: apoA-I, apoprotein A-I; apoB, apoprotein B; BHT, butylated hydroxytoluene; CE, cholesteryl ester; CH, cholesterol; CM, chylomicrons; EP, egg phospholipid; EPTG, triacylglycerol mixture with a fatty acid composition similar to EP; GLC, gas-liquid chromatography; HDL, high density lipoproteins; HDLC, high density lipoprotein cholesterol; IDL, intermediate density lipoproteins; LCAT, lecithin:cholesterol acyltransferase; LDL, low density lipoproteins; L_p, serum lipoproteins; PBS, phosphate buffered 0.15 M NaCl, pH 7.40; PC, phosphatidylcholine; PE, phosphatidylethanolamine; PL, serum phospholipids; P/S, ratio (w/w) of polyunsaturated to saturated fatty acids; SP, soybean phospholipids; SPTG, triacylglycerol mixture with a fatty acid composition similar to SP; TG, serum triacylglycerols (triglycerides); TLC, thin-layer chromatography; TSC, total serum cholesterol; UC, unesterified cholesterol; VLDL, very low density lipoproteins.

MATERIALS AND METHODS

Subjects. The subjects were 10 normolipidemic men in the age range of 30 to 64 years with an average age (±SD) of 44.4 ± 10.3 y and without metabolic disease or obesity (BMI 25.2 ± 3.0 kg/m^2). None of the men were taking any medication known to alter blood lipids. The project was approved by the Institutional Review Board, Research with Human Subjects, and each subject gave his informed written consent. The subjects were Texas A&M University employees, predominantly scientists, who conscientiously adhered to the experimental protocol.

Test lipids. The test lipids were two phospholipid mixtures and two mixtures of triacylglycerols (triglycerides) with fatty acid compositions similar to those of the respective dietary phospholipids. The phospholipids were "soybean lecithin" (SP) provided by the American Lecithin Company (Atlanta, GA) and "egg lecithin" (EP) provided by the Asahi Chemical Industry Company (Tokyo, Japan). After determining the fatty acid compositions of SP and EP, mixtures of oils were prepared which had fatty acid compositions similar to those of the phospholipids. These triglyceride mixtures are referred to as soybean phospholipid triglycerides (SPTG) and egg phospholipid triglycerides (EPTG). To achieve the appropriate fatty acid compositions in readily absorbable oil mixtures, the following fats (oils) were used: edible beef tallow (compliments of Bunge Edible Oil Corp., Fort Worth, TX) which contained 116 mg cholesterol/100 g tallow (2.70 mmol/L), refined palm oil (compliments of Conway Oil Company, Denison, TX), edible linseed oil (Arista Industries, Darien, CT) and safflower oil (Hain Pure Food Co., Inc., Los Angles, CA). SPTG was 59% safflower oil, 29% palm oil and 12% linseed oil; and EPTG was 65% beef tallow, 31% palm oil, 4% safflower oil and 0.75% cholesterol. Antioxidant [0.01% butylated hydroxytoluene (BHT)] was included in each triglyceride mixture. The lipid and fatty acid compositions of the phospholipids and the triglycerides are shown in Table 1.

Experimental design. The duration of the experiment was divided into seven six-week periods. These included the four test lipid periods of six weeks each: SP, EP, SPTG, and EPTG, separated by six-week periods without supplementation, the "wash-out" periods. Each man followed each test period. In order to minimize bias associated with the order of the test lipids, the subjects were divided into four groups, and each group followed a different order, *i.e.,* Latin square. Initially, there were 12 subjects who were divided into four groups of three. After the first treatment period, two subjects from different groups withdrew from the study for personal reasons. Data resulting from those two subjects were not used.

The four test lipids were contained in opaque, color-coded gelatin capsules (SNAP-FIT capsules size 00, Capsugel, Greenwood, SC) and were taken by each subject as supplements to his habitual diet. The phospholipids were ingested at the level of 15 g/d; and the triglycerides, at the level comparable to the fatty acid content of the phospholipids, 12 g/d. Childs *et al.* (3) had found a significant increase in HDLC in response to 36 g/d SP that was 29% PC. The soybean phospholipid preparation that we used in this study was 69% PC (Table 1). Thus, 15 g SP was approximately equivalent in PC to the preparation used by Childs and co-workers (3) and by Galli *et al.* (4). The daily dose of 30 capsules was taken as 10 capsules before each meal. The subjects returned unused capsules at the end of each treatment period. One subject missed two days during one treatment period. Otherwise, adherence was 99% or better. In order to control for the effect of the capsules themselves on blood lipids and to allow the subjects to become accustomed to taking 30 capsules per day, the men took 30 empty capsules daily for two weeks before the baseline (initial) blood sample was taken.

Although no modification of the habitual diet of these subjects was planned, they were instructed to maintain their initial habitual diet for the duration of the experiment. In order to monitor their habitual diet, the subjects kept three-day diet records (a weekend day and two week days) during each test diet period. The subjects were instructed in the procedure for keeping a food record, and food scales were provided to aid in recording serving sizes.

TABLE 1

Lipid Compositions of Dietary Phospholipids and Oils (%)

Lipid component	Egg phospholipids	Egg phospholipid fatty acids	Soy phospholipids	Soy phospholipid fatty acids
Triglycerides	10.6	100	6.0	100
Phospholipids	73.0	0	68.8	0
Phosphatidylcholine (PC)	75.4		78.3	
Phosphatidylethanolamine	23.4		19.3	
Sphingomyelin	1.2			
LysoPC			2.3	
Fatty acids

18:0	17.4	8.2	3.3	1.8
18:1n-9	33.4	41.1	11.8	20.2
18:2n-6	14.2	13.7	62.8	52.1
18:3n-3	0.6		5.7	8.1
20:4n-6	3.0			
Polyunsaturated/saturated fatty acid ratio	0.35	0.34	3.5	3.1

These records were analyzed for energy and nutrient contents (Nutripractor 6000, Practocare, Inc., San Diego, CA). The subjects were cautioned to maintain a constant weight (±3 kg) by modifying serving sizes of diet ingredients.

Blood samples were taken at the Texas A&M University Health Center. When the subjects had their initial blood sample taken, measurements of resting blood pressure, body weight and height were also made. Body weight and height were measured with light clothing but without shoes. Blood (15 mL) was sampled at the beginning and end of each test period following a 12- to 14-h fast. The subjects were seated, and the blood samples were taken by venipuncture from an antecubital vein into separator vacutainer tubes containing clot-activating gel. The tubes were placed in wet ice. Within three hours the serum fraction was isolated by centrifugation at 2000 × *g* for 30 min at 4°C.

VLDL, LDL, HDL_2 and HDL_3 were separated from serum by ultracentrifugation and analyzed for lipid composition and protein content. The lipid composition of the unfractionated serum was also determined.

Analytical methods. The phospholipid-class compositions of the SP and EP were analyzed by determining the phosphorus content of the phospholipid (PL) fractions (6) which had been separated by thin-layer chromatography (TLC) (0.5 mm Adsorbosil-Plus, Alltech Associates, Inc., Applied Science Labs, Deerfield, IL) using the solvent system chloroform/methanol/water (65:25:4, vol/vol/vol). The fatty acid compositions of the phospholipids, component oils, oil mixtures and serum PL were determined by gas-liquid chromatography (GLC) of fatty acid methyl esters which were prepared by BF_3-catalyzed transesterification with methanol (7).

L_p were separated from a 4-mL aliquot of serum by ultracentrifugation according to the procedure of Havel *et al.* (8). The density ranges for the L_p fractions are: VLDL, d < 1.006 g/mL; LDL, d = 1.019–1.063 g/mL; HDL_2, d = 1.063–1.125 g/mL; HDL_3, d = 1.125–1.21 g/mL. The intermediate density lipoprotein (IDL) fraction, d = 1.006–1.019 g/mL, was separated, but it was not analyzed in this study. Briefly, each L_p fraction was separated sequentially from serum by flotation using a Ti 50 fixed-angle rotor in an ultracentrifuge (L2-65B, Beckman Instruments, Palo Alto, CA) at 110,000 × *g* for 22 h at 12°C. Density adjustments were made using either a stock salt solution; NaCl + KBr, d = 1.346 g/mL (8); or solid KBr (9). The L_p was withdrawn from the meniscus, overlaid with a salt solution of equilibrium density, recentrifuged as before, transferred to a 5-mL volumetric flask and diluted to mark with phosphate buffered 0.15 M NaCl, pH 7.40 (PBS). Purity was checked by electrophoresis (10).

Chemical, rather than enzymatic, methods of lipid analysis were used in order to avoid the need to dialyze the fractions which would result in substantial loss of material. It was determined that the salt concentration resulting when any L_p fraction was diluted to 5 mL with PBS did not interfere with electrophoresis, with the lipid extractions, nor with chemical analysis of the lipids and the proteins.

The cholesterol contents of the L_p fractions and of whole serum were determined chemically according to Searcy and Bergquist (11). Triglyceride concentrations were determined by the method of Foster and Dunn (12). For PL and cholesteryl ester (CE) analyses, lipids were extracted from serum and from L_p fractions as described by Kates (13). PL were determined as above (6). CE were separated by TLC using the adsorbent described above, but the solvent system was hexane/diethyl ether/acetic acid (80:20:1, vol/vol/vol). In addition to separating HDL subfractions by ultracentrifugation, a 1.0-mL aliquot of serum was used to separate HDL by precipitation with the heparin-$MnCl_2$ reagent described by Warnick and Albers (14). Protein in the L_p fractions was determined by the method of Lowry *et al.* (15). Bovine serum albumin was used as standard. Apoproteins A-I (apoA-I) and B (apoB) were determined in whole serum (16). ApoB was also determined in LDL, and apoA-I was determined in HDL_3.

Since enzymatic procedures are most frequently used for cholesterol analysis in aqueous media, we compared values of TSC and of HDLC which were obtained by the chemical method (11) and by an enzymatic procedure (Procedure No. 352, Sigma Diagnostics, St. Louis, MO). Fourteen human serum samples were used in which TSC ranged from 3.62 to 8.60 mmol/L; and HDLC, from 0.78 to 1.81 mmol/L. The chemically determined TSC was lower than the enzymatic by 0.13 ± 0.26 mmol/L. Chemically determined HDLC was lower by 0.11 ± 0.09 mmol/L.

Differences among treatment groups were assessed by one-way analysis of variance. Group means were considered to be significantly different at $P \leq 0.05$ as determined by the least significant difference technique (17).

RESULTS

In our experimental design, the test lipids were ingested as supplements to the habitual diet of the subjects. The subjects were instructed to keep their habitual (basal) diet relatively constant throughout the investigation. In order to monitor this instruction, each man kept a three-day diet record during each test period. These records were used to estimate the energy and nutrient compositions of the basal diets. The average daily energy intake for these subjects was 9123 ± 515 kJ (range: 73500–11,400 kJ). Their average fat consumption was 36 ± 2 en%, not including the test lipids. The test lipids contributed about 450 kJ to the daily energy consumption, approximately 5% of the daily average. Carbohydrate and protein contributed approximately 46 en% and 17 en%, respectively. Cholesterol intake for these subjects was about 300 mg/d. We found no significant interactions of habitual intakes of total energy and fat (not including lipid supplements), diet period and serum lipid concentrations.

The test lipids ingested by the subjects in this study were enclosed in opaque gelatin capsules. Using capsules as vehicles for these test materials had several advantages: (i) the subjects could not identify the particular preparation that they were taking, (ii) these free-living, active men were able to follow the treatment plan at home or while traveling, and (iii) the quantity of each test lipid taken by each man was defined by the number of capsules he took each day and not by measuring each daily dose individually.

The parameters measured in whole serum are shown in Table 2. These included the concentrations of total cholesterol, HDL cholesterol, triglycerides, phospholipids, apoB and apo A-I in blood obtained at baseline and at the

[a]Mean ± SD. Abbreviations: baseline, before treatment; EP, egg phospholipids; EPTG, triacylglycerol mixture with a fatty acid composition similar to EP; SP, soybean phospholipids; SPTG, triacylglycerol mixture with a fatty acid composition similar to SP; CH, cholesterol; CE, cholesteryl ester; PL, phospholipids; TG, triacylglycerol; apoB, apoprotein B; apoA-I, apoprotein A-I; LDL, low density lipoprotein; VLDL, very low density lipoprotein.

[b,c,d]Values not sharing a common superscript letter are significantly different, $P \leq 0.05$.

[e]Values were the result of determining the cholesterol content of the supernatant following precipitation of very low density lipoproteins and low density lipoproteins (14).

end of each treatment period. Total serum cholesterol was significantly lower after the SP treatment period compared to either the EP or the EPTG treatments. Total serum phospholipid concentration was significantly decreased after the SP treatment compared to treatment with EP or SPTG, but not EPTG.

The compositions of the lipoprotein fractions separated by ultracentrifugation are also presented in Table 2. Since the lipoproteins were not isolated quantitatively, the compositions are related to the protein mass of the isolated fraction rather than to serum volume. Recovery of the lipoproteins was estimated to be 71% which compares reasonably well with Meijer *et al.* (18). In an experiment with rabbits, these workers reported recoveries of 90 ± 15% (mean ± SD, n = 48) for total cholesterol in lipoprotein fractions. They used a similar isolation procedure, but they did not recentrifuge each L_p fraction through solvent of equilibrium density.

The VLDL at baseline contained significantly less cholesterol (CH) than at any of the treatment periods excepting the SPTG. Of course, triglycerides (TG) was the most abundant lipid in the very low density lipoprotein (VLDL), and the level of VLDL TG was not altered by the treatments used in this investigation. However, EP tended to have the lowest TG and the highest PL concentrations. The CH of VLDL combined free and esterified cholesterol.

LDL protein was significantly higher following EP treatment, compared to baseline and to SP. CH was the most abundant lipid in LDL. After the EP and SP treatment periods, the proportion of the total LDL CH that was esterified was substantially less (approx. 20%) than at baseline or after the other treatments. LDL PL were proportionally less abundant at the end of the SP treatment. The TG content of EP LDL tended to be less than for the other treatment groups or for baseline.

The mass of HDL_2 that was isolated was very small. Although HDL_2 is about 40% protein by mass, the protein concentrations of our HDL_2 preparations were in the range 15–26 mg/dL. Virtually all of the cholesterol was esterified, and the cholesterol content of SP HDL_2 was

significantly greater than for the SPTG HDL_2. This increase in HDL_2 CH was in conjunction with the significant decrease in TSC following the SP treatment. The PL content of HDL_2 was significantly higher for the SP treatment compared to all other treatment conditions. TG content of HDL_2 was not different among treatment groups.

The compositions of the HDL_3 subfractions showed little response to any of these dietary lipids. The only significant change was the increased level of PL in response to the SP and SPTG treatments compared to baseline.

The fatty acid compositions of the serum phospholipids for the various treatment groups and for baseline were similar. PL in baseline serum contained slightly more 18:1n-9 and slightly less 18:2n-6, 20:4n-6, and 22:6n-3. PL in serum after EP treatment contained significantly more 20:5n-3 than after SP treatment.

DISCUSSION

Relative to the effect of SP on the cholesterol concentration of whole serum, our data were consistent with the findings of Knuiman *et al.* (1). When these latter investigators examined the results of studies designed to test the effect of ingested soybean phospholipids on human cholesterolemia, they concluded that any hypocholesterolemic response to phospholipids could be attributed to its content of linoleic acid, 18:2n-6. In contrast with the responses of hypercholesterolemic guinea pigs (5), in this study we found that treatment with the relatively saturated dietary phospholipids EP provided no indication of improved blood lipid profile. TSC reflected the polyunsaturation of the lipid supplement. For this group of subjects, SP resulted in significantly lower average TSC than did EP. Treatment with SP did not significantly lower TSC, compared to SPTG, although the average tended to be lower. The only other significant effect of SP on total serum lipids was *ca.* 19% decrease in the concentration of PL compared to the effects of either SPTG or EP. The PL of hypercholesterolemic guinea pigs had the same qualitative response to SP compared to EP (5). Consistently, Beynen and Terpstra (19) showed a strong positive correlation between serum cholesterol and PL in humans, rabbits and calves.

Although the usefulness of SP specifically as a hypocholesterolemic agent is doubtful, SP may be antiatherogenic. In our experiment using guinea pigs (5), we found that the cholesterol content of aorta decreased in animals fed the SP-containing diet. The intravenous administration of PC has resulted in the regression of atherosclerosis in rabbits (20), in baboons (21) and in quail (22). In each case the regression of the disease state occurred despite continuation of the atherogenic diet. Free cholesterol is transferred from tissue to phosphatidylcholine-containing liposomes. *In vitro* experiments have shown the process to be more efficient in the presence of apoproteins, especially A-I and E. Even tissue cholesteryl esters appear to be mobilized by these apoproteins (23).

An antiatherogenic effect of dietary phospholipid could result from the relationship between PL and HDL. HDL is inversely related to risk of CHD (2). Recently, a prospective study using a large cohort of participants in the Physicians' Health Study demonstrated the power of HDLC and HDL_2 CH as predictors of myocardial infarction (24). Phospholipids from chylomicrons (CM) (25,26), along with apoproteins and unesterified cholesterol (UC), are precursors of HDL (27). Although dietary phospholipids are hydrolyzed to lysophosphatidylcholine and fatty acids for absorption, reesterification recaptures much of the original structures before PL are incorporated into CM (28).

In 1975 Miller and Miller (29) reported an increase in the body cholesterol pool with decreasing concentrations of plasma HDLC. The body cholesterol pool is strongly and positively associated with CHD. The mechanism which accounts for the antiatherogenicity of HDL is not clearly understood. However, the most widely accepted theory is "reverse cholesterol transport" which was proposed in 1968 by Glomset (30). Accordingly, HDL_3 accepts UC from peripheral tissue as the initial step in the "reverse cholesterol transport" theory (31). This step may involve HDL receptors (32) but more likely it is diffusion-controlled (31), and not mediated by HDL_3 cell-surface binding sites (33). HDL_3 is irreversibly converted to HDL_2 when UC is esterified to CE by lecithin:cholesterol acyltransferase (LCAT), a component of HDL_3 which is activated by apoA-I. LCAT uses PC as the acyl source in producing the larger, less dense HDL_2 particles (27). The transfer of HDL_2 CE to the liver for catabolism probably utilizes several pathways, but VLDL appears to be the preferential acceptor of CE. VLDL apoproteins B_{100} and E are able to interact with cell surface receptors for the transfer of CE into the cell (31).

Another possible relationship between dietary phospholipids and HDL_2 could involve cholesterol absorption. When Beil and Grundy (28) investigated the effect of infused PC on human plasma lipoproteins, they were surprised to find that PC blocked cholesterol absorption in the upper part of the small intestine. Other investigators have noted a relationship between cholesterol absorption and HDL metabolism. Shepherd *et al.* (34) reported an increase in the plasma HDL_2/HDL_3 ratio and an increase in apoA-I concentration in men treated with cholestyramine for four weeks. Childs *et al.* (35) observed consistent inverse relationships between consumption of certain shellfish (oysters and clams) which resulted in reduced cholesterol absorption and HDL_2/HDL_3 ratio.

Our data suggest a relationship between dietary polyunsaturated phospholipids (SP) and HDL metabolism. Although treatment with SP and SPTG did not result in significantly different TSC, the cholesterol determined in the HDL_2 fraction was significantly higher following SP treatment compared to treatment with SPTG. When we compared cholesteryl ester concentrations in HDL_2 isolated for all treatment groups, the CE for the SP group tended to be higher than for the other groups. Because of large standard deviations, however, these differences were not significant. A difficulty in determining these lipid concentrations, CH and CE, was that the CH concentration combined UC and CE and was determined in the aqueous medium of the isolated fraction. CE and PL were determined in the lipid extract of an aliquot of serum or L_p fraction. The determination of CE was preceded by its separation from the UC by TLC. These additional steps could easily account for the large standard deviations. Since by far the majority of cholesterol in the HDL_2 is esterified, the small differences between the CH and the

CE concentrations were buried in these deviations, Table 2.

Our data revealed no effect on HDL_2 of EP compared to EPTG. Apparently, the fatty acid composition of the dietary phospholipids was important for the HDL_2 response. EP and EPTG are relatively saturated compared to SP and SPTG with P/S ratios of 0.38 and 3.5, respectively. Dietary saturated triglycerides appear to suppress hepatic LDL receptor activity compared to dietary polyunsaturated fat by decreasing the number of hepatic LDL receptors (36,37). However, that would not explain the absence of an HDL_2 response to the EP treatment. Polyunsaturated PC may favor cholesterol esterification.

The possibility that dietary sources of phospholipids could induce increases in HDL_2 is provided by our experiments with men ingesting soybean and egg phospholipids. Further studies with an appropriate animal model should investigate the regulation of HDL metabolism by dietary phospholipids.

ACKNOWLEDGMENTS

We wish to thank the Wallace Genetic Foundation for financial support; the following companies for their generosity in providing the test lipids: American Lecithin Company, Asahi Chemical Industry Company, Bunge Edible Oil Corporation, and Conway Oil Company; Dr. Karen Kubena's staff for help with the diet analyses, Karen Troxler for help in preparing the filled capsules; and Michelle Harkin, Deaina Barry and Joseph Raya for providing technical assistance. Our special gratitude is extended to the volunteers for their participation.

Molecular Species Composition of Glycerophospholipids from White Matter of Human Brain

Robert Wilson[a,*] and **Michael V. Bell**[b]

[a]Department of Biological and Molecular Sciences and [b]NERC Unit of Aquatic Biochemistry, School of Natural Sciences, University of Stirling, Stirling FK9 4LA, Scotland

The molecular species composition of the major glycerophospholipids from white matter of human brain were determined by high-performance liquid chromatography of the 3,5-dinitrobenzoyl derivatives of the corresponding diradylglycerols. In phosphatidylcholine (PC) and phosphatidylserine (PS), molecular species containing only saturated fatty acids (SFA) and monounsaturated fatty acids (MUFA) comprised 85.7 and 82.4% of the respective totals, with 18:0/18:1 predominant in PS and 16:0/18:1 in PC. These molecular species were also abundant in phosphatidylethanolamine (PE), but in this phospholipid species containing polyunsaturated fatty acids (PUFA), largely 18:0/22:6n-3 and 18:0/20:4n-6, accounted for over half the total; 18:1/18:1 was also abundant in PE. In contrast, 1-*O*-alk-1′-enyl-2-acyl *sn*-glycero-3-phosphoethanolamine (GPE) had much more SFA- and MUFA-containing species, predominantly 16:0a/18:1, 18:0a/18:1 and 18:1a/18:1, with low amounts of species containing 20:4n-6 and 22:6n-3. In alkenylacyl GPE, 22:4n-6 was the major PUFA and 16:0a/22:4n-6 and 18:1a/22:4n-6 the main PUFA-containing species. There was six times more 22:6n-3, twice as much 20:4n-6 and half the amount of 22:4n-6 in PE as compared to alkenylacyl GPE.
Lipids 28, 13–17 (1993).

Nervous tissue contains large amounts of phospholipid with a distinctive fatty acid composition. In mammalian brain, 1-*O*-alk-1′-enyl-2-acyl-*sn*-glycero-3-phosphoethanolamine (plasmalogen) is especially abundant (1), and the glycerophospholipids overall have a fatty acid composition with characteristically high contents of arachidonic, 20:4n-6, docosatetraenoic, 22:4n-6 and docosahexaenoic, 22:6n-3, acids (2). Arachidonate and docosahexaenoate are selectively incorporated into brain tissue during development, but in humans after the age of two years changes in polyunsaturated fatty acids (PUFA) levels are slight (3,4). The rapid changes in brain fatty acid composition in early development are associated with the formation of dendrites and axons by neurons and myelination by oligodendrocytes (5). Neural tissue from adult mammals shows considerable resistance to dietary regimes deficient in PUFA, and depletion of 22:6n-3 in brain can often only be achieved after two generations (6–9). Dietary studies in rhesus monkeys (6) and rats (9) showed that depletion of 22:6n-3 in retina and brain impaired the visual and cognitive abilities of the offspring. Replacement of 22:6n-3 with n-6 PUFA may produce alterations in the biophysical properties of photoreceptor and neuronal membranes which may cause these functional abnormalities.

The fatty acid composition of individual brain glycerophospholipids from many species, including humans (2,3), has been studied; however, molecular species have only been determined in a few cases (10–12). The only information available on phospholipid molecular species of human brain is the presence of phosphatidylcholine (PC) species containing very long-chain fatty acids (13). The fatty acid composition of brain tissue differs markedly depending on the area in the brain sampled, which reflects the type of cell present. White matter largely consists of myelin membranes and oligodendrocyte cell bodies while gray matter contains astrocytes (3). The phospholipids from gray matter contain much more PUFA, especially in phosphatidylethanolamine (PE) and phosphatidylserine (PS), than those from white matter which show a fatty acid composition typical of myelin (2,3). The aim of the present study was to define the molecular species composition of the major glycerophospholipids in white matter from adult human brain.

MATERIALS AND METHODS

Materials. Phospholipase C from *Bacillus cereus* was purchased from Boehringer Corporation (London, U.K.). Butylated hydroxytoluene (BHT) was from Sigma Chemical Co. (Poole, Dorset, U.K.). 3,5-Dinitrobenzoyl chloride was from Aldrich Chemical Co. (Gillingham, Dorset, U.K.) and was recrystallized from carbon tetrachloride before use. Standard lipids were obtained from Sigma and from Nu-Chek Prep (Elysian, MN), as detailed earlier (14). Merck thin-layer chromatography (TLC) and high-performance TLC (HPTLC) plates coated with silica gel 60, Analar glacial acetic acid, carbon tetrachloride, propan-2-ol and pyridine were purchased from BDH Ltd. (Poole, Dorset, U.K.). All other solvents were from Rathburn Chemicals (Walkerburn, Peeblesshire, Scotland). Ultrasphere ODS and Ultrasphere C8 HPLC columns (25 ×0.46 cm, 5 μm particle size) were obtained from Altex/Beckman (Beckman Instruments U.K., High Wycombe, Bucks, U.K.).

Tissue samples. Samples of normal brain white matter were obtained from The Multiple Sclerosis Society Brain Bank, Institute of Neurology, London, U.K. White matter from the parietal ventricle was taken from three male patients, aged 53, 54 and 66 years, who had died from cardiac failure. All samples were collected and frozen at −70°C within 10–44 h after the death of the patient. The fatty acid composition of the phospholipid classes from these samples were published as part of a study comparing the lipid composition of white matter from multiple sclerosis and healthy brain (15).

*To whom correspondence should be addressed.

Abbreviations: BHT, butylated hydroxytoluene; GLC, gas-liquid chromatography; GPE, *sn*-glycero-3-phosphoethanolamine; HPLC, high-performance liquid chromatography; HPTLC, high-performance thin-layer chromatography; MUFA, monounsaturated fatty acid; PC, phosphatidylcholine; PE, phosphatidylethanolamine; PI, phosphatidylinositol; PS, phosphatidylserine; PUFA, polyunsaturated fatty acid; SFA, saturated fatty acid; TLC, thin-layer chromatography; UV, ultraviolet. Molecular species are abbreviated as follows: *e.g.*, 16:0/18:1 PE is 1-palmitoyl-2-oleoyl-*sn*-glycero-3-phosphoethanolamine; the corresponding alkenylacyl species, 1-*O*-hexadec-1′-enyl-2-oleoyl-*sn*-glycero-3-phosphoethanolamine is 16:0a/18:1.

Extraction and purification of lipids. All solvents apart from those used for TLC and HPLC (high-performance liquid chromatography) contained 0.01% (wt/vol) BHT. Samples were stored at −20°C under nitrogen between preparative procedures.

Total lipid was extracted from 200–250 mg of each brain sample according to the method of Folch *et al.* (16). Phospholipid classes were separated by TLC using methyl acetate/propan-2-ol/chloroform/methanol/0.25% aq.KCl (25:25:25:10:9, vol/vol/vol) as developing solvent (17). The lipids were visualized under ultraviolet (UV) light after spraying with a solution of 0.1% (wt/vol) 2′,7′-dichlorofluorescein in methanol. Phospholipid bands were scraped from the plate and eluted with chloroform/methanol/water (5:5:1, vol/vol/vol). Solvent was removed by rotary evaporation under vacuum at 35°C. Fatty acid methyl esters (FAME) of the phospholipids were prepared and analyzed using a Canberra Packard 436 gas chromatograph (Caversham, U.K.) equipped with either a CP Wax 52CB or CP Sil 5CB fused silica capillary column (both 50 m × 0.34 mm i.d., Chrompack U.K. Ltd., London, U.K.) as described previously (15).

The fatty acid compositions of individual phospholipid classes from each tissue sample were very similar. The individual classes from the three samples were therefore pooled prior to preparing derivatives for molecular species analysis.

Preparation of 3,5-dinitrobenzoyl derivatives. Two-mg portions of PC and PE and 1-mg portions of PS were hydrolyzed with phospholipase C from *B. cereus* using a two-phase system of 1 mL diethyl ether and 1 mL 0.01M Tris-SO_4, pH 7.4, at room temperature for 5 h (18). At the end of the incubations, 1,2-diradylglycerols were extracted and the diacyl and 1-alkenyl-2-acyl glycerols separated by TLC using hexane/diethyl ether/acetic acid (50:50:1, vol/vol/vol) (19). Modern precoated TLC plates separate these sub-classes without resorting to borate impregnated silica. Diradylglycerols were then derivatized in dry pyridine with 3,5-dinitrobenzoyl chloride at 60°C for 45 min under nitrogen, extracted and washed as described by Takamura *et al.* (20). The purity of the product was checked by HPTLC in hexane/diethyl ether/acetic acid (70:30:1, vol/vol/vol).

Separation of molecular species. The 1,2-diradyl-3-dinitrobenzoyl-*sn*-glycerols were separated by HPLC at 19–21°C on reverse phase columns using a Pye Unicam 4010 pump (Pye Unicam, Cambridge, U.K.) and three isocratic solvent systems. An ODS column was used with methanol/propan-2-ol (95:5, vol/vol) at a flow rate of 1.0 mL/min, and acetonitrile/propan-2-ol (80:20, vol/vol) at a flow rate of 1.0 mL/min (20); a C8 column was used with methanol/water/acetonitrile (93:5:2, vol/vol/vol) at a flow rate of 1.2 mL/min (19). Peaks were detected at 254 nm with a Pye Unicam 4020 detector and quantified using a Shimadzu C-R3A recording integrator (Anachem, Luton, Bedfordshire, U.K.).

Peaks were identified from plots of $\log_{10}$ (relative retention time) *vs.* the effective carbon number at the C-1 position of glycerol (20,21) by adding a 16:0/16:0 standard or by using 16:0/22:6 as a reference peak. Peaks on chromatograms were also identified by reference to the fatty acid composition of the samples and to molecular species identified in previous work (14,19). The major alkenyl acyl species were identified from a sample of bovine brain PE by collecting peaks and identifying component FAME and dimethylacetals by gas-liquid chromatography (GLC) following transesterification in 1% (vol/vol) sulfuric acid in methanol. Molecular species containing 20:2n-9, 20:3n-9, 22:3n-9 and 24:4n-6 gave relative retention times in each of the three solvent systems that were consistent with the identifications shown, but insufficient material was available to confirm these identifications directly by GLC analysis of individual molecular species. Each sample was chromatographed three times in each solvent system and the standard deviation calculated. Where final peak areas were calculated by subtraction, the standard deviations of the contributing peaks were added to give the final error. Results are presented to one decimal place for clarity.

RESULTS

The three main diacyl glycerophospholipid classes in human brain showed very different molecular species profiles (Table 1). In PC, saturated fatty acid/monounsaturated fatty acid (SFA/MUFA) species comprised two-thirds of the total with 16:0/18:1 (45.5%) and 18:0/18:1 (21.0%) being predominant. SFA/SFA and MUFA/MUFA species were also abundant with each category, making up almost 10% of PC; 16:0/16:0 and 18:1/18:1 were the main species in each category, respectively. Species containing PUFA were of minor importance. Arachidonic acid was the most abundant PUFA with smaller amounts of 18:2n-6, 22:6n-3, 22:4n-6 and 20:3n-6; 18:0/20:4n-6 was the only PUFA-containing species present at more than 1%.

In contrast, PUFA-containing species were much more abundant in diacyl PE, and the SFA/PUFA class was the largest component with over 40% of the total, mainly 18:0/22:6n-3 (19.3%) and 18:0/20:4n-6 (10.4%). The next most abundant species was 18:0/22:4n-6 (4.4%) with 16:0/22:6n-3, 16:0/20:4n-6, 16:0/22:4n-6 and 18:0/20:3n-9 all present at over 1%. MUFA/PUFA species totaled 9.2%, with 18:1/20:4n-6 contributing over half of this total. MUFA/MUFA species comprised almost a quarter of the total, with 18:1/18:1 contributing most of it (18.8%). SFA/MUFA species comprised almost 20%, but in contrast to PC, 18:0/18:1 (12.3%) was more abundant than 16:0/18:1 (5.5%). No SFA/SFA species were detected. PS was dominated by 18:0/18:1 which comprised 61.2% of the total molecular species. Another SFA/MUFA species, 18:0/20:1, was the next most abundant (9.2%), with 18:1/18:1 being almost equally abundant (8.5%). Only four other species contributed more than 1%, 18:0/22:6n-3, 18:0/20:4n-6, 18:0/22:4n-6 and the unresolved pair 18:1/20:1 + 20:1/18:1.

In plasmalogen PE, the 16:0, 18:1 and 18:0 alkenyl species were all of major importance, and 17:0 alkenyl species were minor components (Table 2). In decreasing order, 22:4n-6, 20:4n-6 and 22:6n-3 were the major PUFA, this being reflected in 16:0/22:4n-6, 18:1/22:4n-6 and 18:1/20:4n-6 being the main PUFA-containing species. Molecular species containing 18:2n-6, 20:3n-9, 22:3n-9, 20:2n-9 and 24:4n-6 were all found in small amounts. The MUFA/MUFA and SFA/MUFA classes both totaled about 29% with 18:1a/18:1 as the single most important species (22.9%). Also abundant were 16:0a/18:1 and 18:0a/18:1, being the only other species present at greater than 10%. SFA/SFA species totaled 5.7%, most of which was 16:0a/16:0.

[a]Values are means ±1 SD of three determinations of a pooled sample from three individuals, rounded to the nearest decimal place. Saturated fatty acid/monounsaturated fatty acid (SFA/MUFA) molecular species may contain small amounts of the reverse isomer, but for convenience the SFA is shown at the C-1 position of the glycerol; —, not detected; trace, <0.1%. The following fatty acid isomers were identified by gas-liquid chromatography: 16:1, n-7 and n-9; 18:1, n-7 and n-9; 20:1, n-7 and n-9; 24:1n-9; 18:2n-6; 20:2n-9; 20:3, n-6 and n-9; 20:4n-6; 22:4n-6; 22:6n-3 (ref. 15). PUFA, polyunsaturated fatty acid.

DISCUSSION

The glycerophospholipids from mature, adult human brain white matter contain more MUFA and less SFA and PUFA than do gray matter (2,3). It is therefore not surprising that the SFA/MUFA and MUFA/MUFA categories were major components in all three diacyl classes of phospholipid from white matter; there was also 9% of SFA/SFA in PC. There was only 5.9% of PUFA-containing species in PC and 10.2% in PS, the latter phospholipid class being dominated by 18:0/18:1 (61.2%). PC from rat cerebellum also contained low amounts of PUFA-containing molecular species and was dominated by 16:0/16:0, 16:0/18:1 and 18:0/18:1, which together totaled 67.5% (11). Earlier studies on human brain of different ages showed about twice as much PUFA in PC from gray matter than in PC from white matter (2,3). The fatty acids of myelin PC from ox brain and mouse brain also contained only 1.0% and 3.3% PUFA, respectively (22), while the fatty acids of PC from the cerebral cortex of rhesus monkeys contained 5.9% n-6 PUFA and 5.1% n-3 PUFA (23). These investigators also found low levels of PUFA in PS (22,23). In contrast, PC from fish brain contains much larger amounts of 22:6n-3, and 16:0/22:6n-3 was a major molecular species of brain PC from trout and cod (14,24). However, 16:0/18:1 and 18:0/18:1 were also abundant, whereas 18:1/24:1 + 24:1/18:1 comprised about 10% of fish brain PC (14,24). To our knowledge the latter molecular species has not been found in other animals. Brain PC, therefore, is much more saturated than PC from other tissues in terrestrial mammals or in fish. These differences in composition between animal species are even more marked in PS where 18:0/22:6n-3, 18:1/22:6n-3 and 22:6n-3/22:6n-3 are all abundant in brains of trout and cod

[a]Values are means ±1 SD of three determinations of a pooled sample from three individuals, rounded to the nearest decimal place. The following fatty acid and dimethyl acetal isomers were found by gas-liquid chromatography: 18:1, n-7 and n-9; 18:1a, n-7 and n-9; 20:1, n-7 and n-9; 22:1n-9; 18:2n-6; 20:2n-9; 20:3, n-6 and n-9; 20:4n-6; 22:3n-9; 22:4n-6; 22:6n-3; 24:4n-6 (ref. 15). It was not possible to separate 16:0 alkenyl and 18:1 alkenyl pairs containing 18:2, 20:2, 20:3, 22:3 and 24:4 because of the presence of 17:0 alkenyl species. SFA, saturated fatty acid; PUFA, polyunsaturated fatty acid; MUFA, monounsaturated fatty acid.

(14,24). Interestingly, Connor *et al.* (23) found PS (and PE) of brain of rhesus monkeys to be much more amenable to dietary perturbations than PC.

In the present study both PE and alkenylacyl *sn*-glycero-3-phosphoethanolamine (GPE) were much more unsaturated than were PC and PS, confirming earlier studies (2,3), but the PUFA compositions of the two subclasses of ethanolamine glycerophospholipid were markedly different. In the human brain PE samples analyzed here, 18:0/22:6n-3 and 18:0/20:4n-6 were major species, but there was a higher proportion of 18:1/18:1 and 18:0/18:1 and lower proportions of PUFA-containing species than in either ox or rat (10,11). In PE from bovine brain 18:0/22:4n-6 was also important and in rat brain 16:0/22:6n-3 comprised over 10% of the total (10,11). In trout and cod brain PE, di22:6n-3, 16:0/22:6n-3, 18:1/22:6n-3 and 18:0/22:6n-3 were the four main species, totaling 58–61% (14,24).

In the brains analyzed here, alkenylacyl GPE was more saturated than PE with PUFA-containing molecular species totaling 36.7% in the former *vs.* 51.9% in the latter; 18:1a/18:1, 16:0a/18:1 and 18:0a/18:1 were all major components of alkenylacyl PE. An early study of ox and mouse brain myelin had shown the preponderance of 22:4n-6 in PE relative to other glycerophospholipids (22), and in a later study the molecular species of PE subclasses in bovine brain showed a concentration of 22:4n-6 containing species in the alkenylacyl fraction (10), *i.e.*, the same as found here in humans. In juvenile rhesus monkeys a diet supplemented with safflower oil caused large increases in 22:4n-6 and 22:5n-6 in total PE at the expense of 22:6n-3 (23). An early study by O'Brien and Sampson (3) found more 22:5n-6 than 22:6n-3 in human brain white matter and myelin, with very small amounts of 22:4n-6. However, subsequent studies in a wide range of animal species found 22:4n-6 to be the major C_{22} n-6 PUFA with

little, if any, 22:5n-6 (2,4,5,6,15,22); it seems probable that 22:5n-6 was misidentified in the original work. It is possible that 22:4n-6 is a poor substrate for the Δ4 desaturase, or that 22:5n-6 is no better than 22:4n-6 or 22:6n-3 in fulfilling the role of these PUFA in brain cells. Alkenylacyl GPE also contained a number of minor PUFA, including 20:2n-9, 20:3n-9, 22:3n-9 and 24:4n-6. Some of these 16:0a/PUFA + 18:1a/PUFA pairs could not be resolved. There is, therefore, a marked concentration of n-6 PUFA in alkenylacyl GPE relative to PE, and the converse is true for 22:6n-3. The significance of this difference is not yet understood.

The presence of n-9 PUFA, albeit in small amounts, is intriguing since these fatty acids are usually taken to indicate essential fatty acid deficiency. Small amounts of 20:3n-9 were also reported in bovine brain (10,22). Neural fatty acid composition responds to changes in dietary fat in experimental animals even after the rapid accumulation of fatty acids during growth has ceased (23,25), and it is possible that there are differences in brain fatty acid composition in humans depending on dietary history. Dietary therapy to alleviate the symptoms of adrenoleukodystrophy is known to cause changes in brain fatty acid compositon (26).

ACKNOWLEDGMENTS

RW is supported by a Croda Chemicals Research Fellowship. We are grateful to Dr. J. Newcombe, The Multiple Sclerosis Society Laboratory, Department of Neurochemistry, Institute of Neurology, London, for providing brain samples, and to Prof. J. R. Sargent for constructive criticism of a draft of this paper.

1-*O*-Alk-1′-enyl-2-acyl-glycerophosphoethanolamine Content and Molecular Species Composition in Fish Brain

M.V. Bell* and **J.R. Dick**
NERC Unit of Aquatic Biochemistry, School of Natural Sciences, University of Stirling, Stirling FK9 4LA, Scotland

Ethanolamine glycerophospholipids from the brains of both trout and cod comprised 36–38% of 1-*O*-alk-1′-enyl-2-acyl-glycerophosphoethanolamine (GPE) determined using two methods. In 1-*O*-alk-1′-enyl-2-acyl-GPE from trout brain, the main molecular species were 18:1a/18:1, 18:0a/18:1 and 16:0a/18:1, which totalled 63.3%, while polyunsaturated fatty acid (PUFA) containing species totalled only 18.2%. 1-*O*-Alk-1′-enyl-2-acyl-GPE from cod brain was much more unsaturated with PUFA containing species totalling 52.6%, of which 18:0a/20:5n-3, 18:1a/20:5n-3 and 18:1a/22:6n-3 were predominant. In cod 18:1a/18:1, 18:0a/18:1 and 16:0a/18:1 were the only other species present at over 5% each, totalling 31.8%. In both cod and trout, small amounts of species containing 22:4n-6 were found. The results of this and earlier studies indicate that there is considerable specificity of composition at the level of molecular species between different lipid classes and subclasses.
Lipids 28, 19–22 (1993).

Molecular species determinations of glycerophospholipids have revealed the full complexity of the lipid constituents of the biomembrane at the molecular level. However, most analyses have been of the diacyl classes of the major glycerophospholipids, phosphatidylcholine (PC) and phosphatidylethanolamine (PE). Data for ethanolamine plasmalogens are more limited but have been obtained for bovine brain (1), rat brain (2) and monkey brain (3). Changes in molecular species composition during brain development (2) and the influence of diet on the lipid composition of brain (3) have also been investigated. Complete molecular species analyses of 1-*O*-alk-1′-enyl-2-acyl-glycerophosphoethanolamine (GPE) have been published for platelets (4), red blood cells (5) and umbilical vein and artery cells (6) from humans, neutrophils (7) and red blood cells (8) from rats, and macrophages from mice (9).

The 1-*O*-alk-1′-enyl-2-acyl-GPE fraction of ethanolamine glycerophospholipids (EGP) is a major component of mammalian brain (10). As part of a study investigating the role of polyunsaturated fatty acids (PUFA) in neural tissue, the subclass composition of EGP was determined in the brains of a freshwater fish, rainbow trout (*Salmo gairdneri*) and a marine fish, cod (*Gadus morhua*). The molecular species composition of the 1-*O*-alk-1′-enyl-2-acyl-GPE fractions were then analyzed. Previous studies had determined the molecular species composition of the diacyl classes of glycerophospholipids from the brains of these fish (11–13).

MATERIALS AND METHODS

Materials. Rainbow trout (400–600 g weight), obtained from a commercial fish farm, were maintained in a freshwater aquarium at 4–6°C on a standard diet (Ewos Ltd., Westfield, West Lothian, Scotland). Cod (300–600 g weight) were obtained from the Marine Station, Millport (Firth of Clyde, Scotland), maintained in a seawater aquarium at 10–14°C on a diet of chopped squid and used within two weeks of capture. Fish were killed by decapitation; the brains were removed and used immediately.

Phospholipase C from *Bacillus cereus* was obtained from Boehringer Corporation (London) Ltd. (Lewes, East Sussex, England). Butylated hydroxytoluene (BHT) was from Sigma Chemical Co. (Poole, Dorset, England). 3,5-Dinitrobenzoylchloride was from Aldrich Chemical Co. (Gillingham, Dorset, England) and was recrystallized from carbon tetrachloride before use. Standard lipids were obtained from Sigma and from Nu-Chek Prep (Elysian, MN), as detailed previously (11). Analar grade glacial acetic, carbon tetrachloride, propan-2-ol and pyridine were purchased from BDH Ltd. (Poole, Dorset, England). All other solvents of high-performance liquid chromatography (HPLC) grade were from Rathburn Chemicals (Walkerburn, Peeblesshire, Scotland). Thin-layer chromatography (TLC) and high-performance thin-layer chromatography (HPTLC) plates coated with silica gel 60 (Merck, Darmstadt, Germany) were also from BDH Ltd.

Ultrasphere ODS and Ultrasphere octyl HPLC columns (25 × 0.46 cm, 5 μm particle size) were obtained from Altex/Beckman (Beckman Instruments U.K. Ltd., High Wycombe, Bucks, England).

Extraction and purification of lipids. All solvents, apart from those used for TLC and HPLC, contained 0.01% (wt/vol) BHT. Samples were stored at −20°C under nitrogen between preparative procedures.

The brains were removed from 10 trout and 20 cod, the meninges separated and the remaining tissue homogenized in 30 mL of chloroform/methanol (2:1, vol/vol) using a polytron tissue disrupter. Total lipid was extracted essentially by the method of Folch *et al.* (14). Phospholipids were separated by TLC using methyl acetate/propan-2-ol/chloroform/methanol/0.25% (wt/vol) aq. KCl (25:25:25:10:9, by vol) (15) and fractions were made visible under ultraviolet (UV) light after spraying with 0.1% (wt/vol) 2′,7′-dichlorofluorescein in methanol containing 0.01% (wt/vol) BHT. Ethanolamine glycerophospholipids were eluted from the silica gel with three 40-mL washes of chloroform/methanol/water (5:5:1, vol/vol/vol), and the extract was rotary evaporated under vacuum at 35°C and dried under a stream of nitrogen. 2′,7′-Dichlorofluorescein was removed from lipid extracts by washing with a solution of 2% (wt/vol) $KHCO_3$.

Fatty acid methyl esters were prepared by esterification in 2 mL of 1% (vol/vol) H_2SO_4 in methanol at 50°C under nitrogen for 16 h and chromatographed on a Packard 436

Abbreviations: BHT, butylated hydroxytoluene; EGP, ethanolamine glycerophospholipids; GLC, gas-liquid chromatography; GPE, glycero-3-phosphoethanolamine; HPLC, high-performance liquid chromatography; HPTLC, high-performance thin-layer chromatography; PC, phosphatidylcholine; PE, phosphatidylethanolamine; PI, phosphatidylinositol; PUFA, polyunsaturated fatty acid; TLC, thin-layer chromatography; UV, ultraviolet. Molecular species of 1-*O*-alk-1′-enyl-2-acyl-GPE are abbreviated as follows: *e.g.*, 16:0a/18:1 GPE is 1-*O*-hexadec-1′-enyl-2-oleoyl-*sn*-glycero-3-phosphoethanolamine. The corresponding diacyl species, 1-palmitoyl-2-oleoyl-*sn*-glycero-3-phosphoethanolamine, is abbreviated as 16:0/18:1.

GLC fitted with a CP Wax 52CB fused-silica capillary column (50 m × 0.32 mm internal diameter) (Chrompack U.K. Ltd., London, England) using hydrogen as carrier gas (16).

Quantitation of alkenylacyl-GPE: Method 1. 1-*O*-Alk-1′-enyl-2-acyl-GPE was analyzed using a modification of the method by Touchstone *et al.* (17) which involves hydrolyzing the 1-*O*-alk-1′-enyl moiety with dilute acid on the origin of an HPTLC plate, separation of the 2-lyso-GPE and diacyl-GPE by chromatography, followed by detection using a phosphate stain and quantitation by densitometry. Eight μg of EGP was streaked on a 5 mm origin on an HPTLC plate, and before the solvent had completely evaporated 2.5 μL of 2.5% (wt/vol) trichloroacetic acid in 1 M HCl was applied over this, followed by a further 2.5 μL 10 min later. The HPTLC plate was air dried then desiccated for 4 h *in vacuo*. The plate was developed twice to 1 cm with methyl acetate/propan-2-ol/chloroform/methanol/0.25% (wt/vol) aq. KCl (25:25:25:10:9, by vol), air dried and then fully developed in this solvent. The plate was dried, lightly sprayed with a phosphate detection reagent (18) and peaks were quantitated by densitometry at 650 nm (Shimadzu CS9000 flying spot densitometer, V.A. Howe Ltd., Banbury, Oxon, England). This method gave a linear response up to 10 μg/component.

Method 2. The 3,5-dinitrobenzoyl derivatives of the total EGP fraction were separated into diradyl classes by HPTLC using hexane/diethyl ether (7:3, vol/vol) as developing solvent. Peaks were quantitated by densitometry at 254 nm. This method also gave a linear response up to at least 10 μg/component.

Preparation of 3,5-dinitrobenzoyl derivatives. Four-mg portions of total EGP were hydrolyzed with 200 units of phospholipase C using a two-phase system of 1 mL diethyl ether and 1 mL 0.1 M sodium borate buffer, pH 7.5, at room temperature for 3 h under nitrogen (19). At the end of the incubations, the 1,2-diradylglycerols were extracted and the 1-*O*-alk-1′-enyl-2-acyl fraction purified by TLC in hexane/diethyl ether/acetic acid (50:50:1, vol/vol/vol). Amounts of phospholipid remaining after phospholipase digestion were less than 2% of the starting material. 1-*O*-Alk-1′-enyl-2-acyl-glycerols were derivatized in dry pyridine with 3,5-dinitrobenzoyl chloride at 60°C for 45 min under nitrogen, extracted and washed as described by Takamura *et al.* (20). The purity of the product was checked by HPTLC in hexane/diethyl ether/acetic acid (70:30:1, vol/vol/vol).

Separation of molecular species. The 1-*O*-alk-1′-enyl-2-acyl-3-dinitrobenzoyl-*sn*-glycerols were separated by HPLC at 19–21°C on reverse phase columns using a Pye Unicam (Cambridge, England) 4010 pump and three isocratic solvent systems as described previously (21). An ODS column was used with methanol/propan-2-ol (95:5, vol/vol) at a flow rate of 1.0 mL/min and acetonitrile/propan-2-ol (80:20, vol/vol) at a flow rate of 1.0 mL/min; an octyl column was used with methanol/acetonitrile/water (93:5:2, vol/vol/vol) at a flow rate 1.2 of mL/min. Peaks were detected at 254 nm with a Pye Unicam 4020 detector and quantified uing a Shimadzu C-R6A recording integrator (Anachem, Luton, England).

Peaks were identified from plots of $\log_{10}$ (relative retention time, RRT) *vs.* the effective carbon number on the *sn*-1 position of the glycerol as described by Patton *et al.* (22) using 16:0/22:6 diacyl and 16:0/16:0 diacyl as reference peaks. The effective carbon numbers of the alkenyl moieties on these plots were found by chromatography of the 3,5-dinitrobenzoyl derivatives of bovine brain ethanolamine plasmalogen and by identifying the peaks by gas-liquid chromatography (GLC) of the dimethylacetals and fatty acid methyl esters. Each of the samples was chromatographed three times in each of the solvent systems and the standard deviations calculated. Where final peak areas were calculated by subtraction, the standard deviations of the contributing peaks were added to give the final error.

RESULTS AND DISCUSSION

Methods used to quantitate the subclass composition of EGP must depend on detecting a constituent which is common to each subclass such as the phosphate group. Alternatively they rely on modifying or replacing the head group with one which can easily be detected. Charring and densitometry of diradyl glycerols or their derivatives following HPTLC separations cannot be used since the subclasses of EGP have variable unsaturation which has a profound effect on staining and consequently quantitation; diacyl-GPE from fish brain contains large amounts of 22:6n-3 (11,13). The presence of dimethylacetals in GLC analyses of fatty acid methyl esters is only an indication of PE plasmalogen since the production of dimethylacetals is rarely quantitative (23).

The first method used in this study to quantitate the 1-*O*-alk-1′-enyl-2-acyl-GPE fraction from fish brain is a simple and quick procedure in which as little as 5 μg of material can be used if diacyl-GPE and 1-*O*-alk-1′-enyl-2-acyl-GPE are present in roughly similar amounts. However, none of the TLC solvents available for separating polar lipid classes can resolve EGP sub-classes and thus 1-*O*-alkyl-2-acyl-GPE cannot be separated from diacyl-GPE. The phosphate stain leaves a slightly blotchy background on the HPTLC plate which probably accounts for much of the error in quantitating the fractions.

The second method which was used to verify the validity of the approach described above utilizes the UV absorbing properties of the dinitrobenzoyl group to give quantitation independent of acyl unsaturation at the wavelength used. The preparation of dinitrobenzoyl derivatives is relatively time-consuming and also requires more material, but has the advantage that the diacyl and 1-*O*-alkyl-2-acyl subclasses can be resolved.

The two procedures outlined above gave identical results for the content of 1-*O*-alk-1′-enyl-2-acyl-GPE within the experimental error of the methods (Table 1). The values obtained for the two species were similar (Table 1) but substantially lower than the values reported for mammalian brain which typically contains over 50% of PE as plasmalogen (10). However, the different methodologies employed in many earlier studies may mean that such comparisons are not entirely valid. In addition, Method 2 shows 2–3% of 1-*O*-alkyl-2-acyl-GPE was present in the EGP fraction from both species (Table 1), slightly lower than the proportion found in mammalian brain (10).

The alkenyl moieties in 1-*O*-alk-1′-enyl-2-acyl-GPE from the brains of trout and cod were predominantly 16:0a, 18:0a and 18:1a with very small amounts of 17:0a present in trout and slightly more in cod (Table 2). The molecular species compositions showed some large differences be-

TABLE 1

Diradyl Class Composition of Ethanolamine Glycerophospholipids from the Brain of Trout and Cod

	Trout (mole %)		Cod (mole %)	
	Method 1[a]	Method 2[b]	Method 1[a]	Method 2[b]
1,2-Diacyl-GPE	63.9 ± 5.5	59.3 ± 0.9	61.4 ± 3.5	60.0 ± 1.2
1-*O*-Alk-1′-enyl-2-acyl-GPE	36.1 ± 5.5	38.5 ± 1.1	38.6 ± 3.5	37.2 ± 1.1
1-*O*-Alkyl-2-acyl-GPE	—[c]	2.1 ± 0.7	—[c]	2.8 ± 0.3

[a]1-*O*-Alk-1′-enyl-2-acyl-GPE was hydrolyzed with dilute acid on the origin of an high-performance thin-layer chromatography (HPTLC) plate, 2-lyso-glycero-3-phosphoethenolamine (GPE) was separated from phosphatidylethanolamine + 1-*O*-alkyl-2-acyl-GPE, the spots visualized with a phosphate stain and quantitated by densitometry as detailed in Materials and Methods.

[b]3,5-Dinitrobenzoyl derivatives of the total ethanolamine glycerophospholipids fraction were separated into classes by HPTLC and quantitated by densitometry as detailed in Materials and Methods.

[c]1,2-Diacyl-GPE includes 1-*O*-alkyl-2-acyl-GPE since Method 1 cannot separate these subclasses.

tween the two species of fish (Table 2) with that from cod brain being much more unsaturated. The saturated alkenyl/PUFA and monounsaturated alkenyl/PUFA subclasses were 18.2% and 16.2% more abundant, respectively, in cod than in trout with 18:0a/20:5n-3, 18:1a/20:5n-3 and 18:1a/22:6n-3 all present at over 5% in cod (Table 2). In contrast, molecular species containing only saturated or monounsaturated moieties comprised 75.8% in trout compared with 43.8% in cod (Table 2); 18:1a/18:1, 16:0a/18:1 and 18:0a/18:1 were the most abundant molecular species in both trout and cod.

In tissues from terrestrial animals the 1-*O*-alk-1′-enyl-2-acyl subclass of EGP is usually more polyunsaturated than the diacyl subclass *e.g.*, in mouse macrophage (9), rat neutrophil (7), rat erythrocyte (8), rat cerebellum (2), ox and mouse brain myelin (24), contrary to the case in fish brain, especially with respect to trout. The composition of 1-*O*-alk-1′-enyl-2-acyl-GPE is very different from that of PE in both trout and cod brain, where PE was very unsaturated, containing about 14% of di22:6n-3, and only 16–20% of molecular species comprised only saturated and monounsaturated moieties (11,13). In PE from fish brain, 22:6n-3 is by far the major PUFA, yet in 1-*O*-alk-1′-enyl-2-acyl-GPE from trout brain 22:6n-3, 20:4n-6, 22:5n-3 and 22:4n-6 are all of similar low abundance. In 1-*O*-alk-1′-enyl-2-acyl-GPE from cod brain, 20:5n-3 is the major PUFA with 18:0a/20:5n-3 (10.8%) and 18:1a/20:5n-3 (7.9%) being the two most important PUFA containing species (Table 2). Therefore, cod brain 1-*O*-alk-1′-enyl-2-acyl-GPE is similar to phosphatidylinositol (PI) from both trout and cod brains in that it is dominated by 18:0/20:5n-3 species (11,12). This selectivity may indicate a special role for 20:5n-3 in fish brain.

The presence of small amounts of molecular species containing 22:4n-6 in 1-*O*-alk-1′-enyl-2-acyl-GPE from both trout and cod brain is unexpected since this fatty acid was not found in any diacyl glycerophospholipid class in brain from either species (11–13). However, several studies in other organisms have found 22:4n-6 to be more abundant in the 1-*O*-alk-1′-enyl-2-acyl subclass of EGP than in diacyl-GPE, *e.g.*, in rat testes (25), rat brain (2,26), synaptosomal and myelin fractions from mouse brain (24), myelin from ox brain (27), and brain from monkeys (3) and humans (28). Sometimes the difference is an order of magnitude, *e.g.*, in rat erythrocyte (8) and mouse macrophage (9). This marked selectivity suggests that 22:4n-6 when paired with a 1-*O*-alk-1′-enyl group must be particularly suited for a specific role in membrane structure.

1-*O*-Alk-1′-enyl-2-acyl-GPE from both trout and cod brains has about three times more n-6 PUFA and 2.5 to 7 times less n-3 PUFA than the corresponding diacyl-GPE fraction (11,13). Consequently, the n-3/n-6 ratios of the diacyl- and 1-*O*-alk-1′-enyl-2-acyl-GPE subclasses are very different; 52.8 *vs.* 2.6 and 26.9 *vs.* 4.4 in trout and cod, respectively. It is well known that the high n-3/n-6 ratio found in fish lipids is a reflection of a high dietary input of n-3 PUFA, but it is clear from this study that 1-*O*-alk-1′-enyl-2-acyl-GPE is markedly depleted of n-3 PUFA and enriched in n-6 PUFA relative to diacyl-GPE; the selectivity for 22:4n-6 in 1-*O*-alk-1′-enyl-2-acyl-GPE is particularly impressive.

In a study of glycerophospholipid molecular speciation in human brain, which contains much more n-6 PUFA and less n-3 PUFA, the n-3/n-6 ratios of diacyl-GPE and 1-*O*-alk-1′-enyl-2-acyl-GPE were 0.96 and 0.13, respectively (28). However in brain from monkeys fed a control (soy oil) diet, the PUFA compositions of both EGP subclasses were similar and the n-3/n-6 ratios close to unity (3). In monkeys the PUFA composition of both EGP subclasses was easily perturbed by dietary manipulation; thus when monkeys were fed diets containing safflower oil or fish oil, the n-3/n-6 ratios of both subclasses changed by similar amounts to 0.12 and 2.4–3.1, respectively (3).

The compositional plasticity in response to dietary input can also be observed in blood cells from humans. The major molecular species of 1-*O*-alk-1′-enyl-2-acyl-GPE in human platelets are 18:0a/20:4n-6, 16:0a/20:4n-6 and 18:1a/20:4n-6 (4), but when subjects were fed a diet enriched in eicosapentaenoic acid, the 1-*O*-alk-1′-enyl-2-acyl subclass of EGP was found to be most enriched in this fatty acid and accounted for the largest reservoir of EPA in platelets (29). Some studies have also shown 1-*O*-alk-1′-enyl-2-acyl-GPE to be metabolically more active than other glycerophospholipids. In human platelets stimulated with thrombin and collagen, arachidonic acid-con-

[a]The following fatty acid and dimethylacetal isomers were identified by gas-liquid chromatography: 16:1, n-7 and n-9; 18:1, n-7 and n-9; 18:1a, n-7 and n-9; 20:1, n-7 and n-9; 18:2n-6; 20:4n-6; 20:5n-3; 22:4n-6; 22:5n-3; 22:6n-3. In 1-*O*-alk-1′enyl-2-acyl-glycero-3-phosphoethanolamine (GPE) from both trout and cod it was not possible to resolve 16:0a/22:4n-6 and 18:1a/22:4n-6, while in 1-*O*-alk-1′-enyl-2-acyl-GPE from trout it also proved impossible to satisfactorily resolve 16:0a/22:5n-3 and 18:1a/20:4n-6, and in cod, 18:1a/16:1 and 16:0a/16:1. Values are triplicate determinations of pooled samples from 10 trout and 20 cod brains rounded to the nearest decimal place. The errors are given as ±1 SD.

[b]Not detected.

[c]Trace, < 0.2%.

taining molecular species of 1-*O*-alk-1′-enyl-2-acyl-GPE and of phosphatidylserine were selectively degraded (30), and in human neutrophils 1-*O*-alk-1′-enyl-2-acyl-GPE was the major source of arachidonate liberated when the cells were challenged with ionophore A23187 (31). The large compositional differences between diacyl-GPE and 1-*O*-alk-1′-enyl-2-acyl-GPE in some tissues may thus reflect differences in both the structural and metabolic role of these subclasses.

ACKNOWLEDGMENTS

Phospholipids in *Drosophila* Heads: Effects of Visual Mutants and Phototransduction Manipulations

William S. Stark[a,*], Teng-Nan Lin[b,1], David Brackhahn[b], J. Scott Christianson[a,2] and Grace Y. Sun[b]

A procedure was developed to label phospholipids in *Drosophila* heads by feeding radioactive phosphate ($^{32}P_i$). High-performance thin-layer chromatography showed label incorporation into various phospholipids. After 24 h of feeding, major phospholipids labeled were phosphatidylethanolamine (PE), 47%; phosphatidylcholine (PC), 24%; and phosphatidylinositol (PI), 12%. *Drosophila* heads have virtually no sphingomyelin as compared with mammalian tissues. Notable label was in ethanolamine plasmalogen, lysophosphatidylethanolamine, lysophosphatidylcholine and lysophosphatidylinositol. Less than 1% of the total label was in phosphatidylinositol 4-phosphate and phosphatidylinositol 4,5-bisphosphate. Other lipids labeled included phosphatidylserine, phosphatidic acid and some unidentified lipids. A time course (3–36 h) study revealed a gradual decrease in proportion of labeled PI, an increase in proportion of labeled PC and no obvious change in labeled PE. There were no significant differences in phospholipid labeling comparing the *no* receptor *p*otential *(norpA)* visual mutant and wild type under light *vs.* dark conditions. However, overall ^{32}P labeling was higher in the wild type fed in the light as compared to the dark and to *norpA* either in light or dark. This suggests that functional vision facilitates incorporation of label. Differences in phospholipid labeling were observed between young and aged flies, particularly in lysophospholipids and poly-PI, implicating phospholipase A_2 function in recycling. Manipulations such as the *o*uter *r*habdomeres *a*bsent and *ey*es *a*bsent mutants and carotenoid deprivation failed to yield notable differences in phospholipid labeling pattern, suggesting that phospholipids important to vision may constitute only a minor portion of the total labeled pool in the head.
***Lipids 28,* 23–28 (1993).**

Photoreceptor membranes in *Drosophila* undergo constant turnover in order to reduce the hazards of light exposure (1–3). Such maintenance involves renewal of the major membrane protein, opsin (4), as well as lipids. In the fly, phospholipids in the photoreceptor membrane are known to play a role in signal transduction (5). In *Limulus,* receptor stimulation of hydrolysis of phosphatidylinositol 4,5-bisphosphate (PIP_2) by phospholipase C (PLC) was shown to result in the release of inositol trisphosphate (IP_3) which, in turn, serves as a second messenger for intracellular calcium mobilization (6–9). The *Drosophila* mutant *norpA* has *no* receptor *p*otential because of a defect in phospholipase C (10,11). *NorpA* is a PLC gene which has been cloned (12) and shows homologies to that in bovine brain (13).

Little is known regarding the distribution and metabolic activity of the phospholipids in *Drosophila* and variances in different mutants. This study describes a novel procedure for labeling the membrane phospholipids in the heads of normal, mutant and carotenoid deprived *Drosophila.* An improved high-performance thin-layer chromatography (HPTLC) procedure (14) allowed the analysis of the phospholipids that were labeled. The labeling protocol was used to study the effects of light and dark, mutants and carotenoid deprivation on membrane phospholipids. Brief reports of some of these findings have been published (15–17).

MATERIALS AND METHODS

Animals. Stocks of *Drosophila melanogaster* were raised at room temperature under cyclic lighting on a standard diet adequate for visual photoreceptor development (18). In the medium of agar, brewers yeast, molasses and cornmeal, the most relevant features were yellow cornmeal and a supplement of β-carotene (0.13 mg/mL) as sources of vitamin A. Carotenoid deprivation was achieved using a medium with defined components, Sang's medium (19), and the control here involved supplementing Sang's food with β-carotene at 0.13 mg/mL. Wild type (Oregon-R) and *w*hite *(w)* were used as normal (red-eyed) and white-eyed controls, respectively. Our red-eyed *norpA* was $norpA^{EE5}$, an effective allele (20) originally from Seymour Benzer at the California Institute of Technology (Pasadena, CA). For white-eyed *norpA,* and to provide a comparison allele also known to be effective (3,21), a stock of $norpA^{P24}$//C[1]Dx *y f; cn bw* (*c*in*n*abar *br*ow*n*) was constructed and supplied by Mitchell Dushay of Jeffrey Hall's laboratory at Brandeis University (Waltham, MA). Because only males had the *norpA* genotype, the females being heterozygous, only males were used for the mutant and control *(w)* flies in this experiment. We used the electroretinogram to verify our *norpA* stocks. An allele of *e*yes *a*bsent *(eya)* which lacks the compound eyes but not the simple eyes (ocelli) was obtained from Terry McGuire at Rutgers University (New Brunswick, NJ). The well studied *o*uter *r*habdomeres *a*bsent *(ora)* mutant (22,23) selectively deletes the outer rhabdomeres (R1-6), the predominant photoreceptor type in the compound eye. For *ora,* flies were aged in cyclic lighting one week or more because this manipulation insured a better deletion of the rhabdomeres

(23). The wild type controls in the *ora* experiments were similarly aged.

^{32}P incorporation and extraction. Flies were transferred into foam stoppered glass vials that contained three circles of filter paper (Whatman No. 3) soaked with 30–50 μCi of ^{32}P-inorganic phosphorus (P_i) in the form of Na_2HPO_4 (New England Nuclear, Wilmington, DE) added to 200 μL of 0.32 M sucrose solution. This amount was adequate for a 30-head sample when flies were fed for 24 h. Flies were fed either in the light or in the dark—dark vials were covered with black tape and light ones with translucent tape. Vials were placed near a fluorescent lamp under a humidified glass dish. Vials were plunged into liquid nitrogen and, when the flies were frozen, vials were shaken and rapped vigorously. By this procedure, heads were well separated from bodies and were sorted quickly with a brush at room temperature. These heads were then put into 1 mL of ice-cold 0.32 M sucrose with 50 mM Tris-HCl buffer (pH 7.4) and ethylenediaminetetraacetic acid (EDTA) (1 mM) and homogenized in a glass homogenizer tube fitted with a motor-driven teflon pestle. Lipids were extracted by adding 4 vol of chloroform/methanol (2:1, vol/vol), to the homogenate, followed by vortexing. After centrifugation at 1500 rpm for 5 min, the organic phase was removed and transferred into an evaporating cup. For more complete extraction of acidic phospholipids, a second extraction was performed with 2 vol of acidic chloroform/methanol/12 N HCl (2:1:0.0125, vol/vol/vol), and the organic phase was neutralized with one drop of 4 N NH_4OH before transferring to the evaporating cup. The extract was evaporated to dryness and resuspended in a small volume of chloroform/methanol (2:1, vol/vol). Aliquots were taken for counting of radioactivity using a Beckman LS5800 liquid scintillation counter (Beckman Instrument, Fullerton, CA).

High-performance thin-layer chromatography (HPTLC). For separation of phospholipids, samples were spotted onto 10 × 10 cm Silica gel 60 HPTLC plates (E. Merck, Darmstadt, Germany) which had previously been dipped in a solution containing 1% potassium oxalate and 2 mM EDTA and diluted with methanol in a ratio of 3:2 (vol/vol). The procedures for separation of phospholipids were described by Sun and Lin (14). Plates were developed in one dimension in a solvent system containing chloroform/methanol/acetone/29% ammonium hydroxide (70:40:10:10, by vol). After development, plates were dried and developed again in the same dimension with a solvent system containing chloroform/methanol/29% ammonium hydroxide/water (72:56:4:12, by vol). The second solvent system was specifically used to move PIP and PIP_2 from the origin. In some experiments, where poly-PI (phosphatidylinositol) separation was not deemed necessary, this solvent system was omitted. After development in the second solvent system, plates were exposed to HCl vapor for 3 min to hydrolyze the alkenyl groups of plasmalogen (24). After drying, plates were turned 90° and developed in a third solvent system containing chloroform/methanol/acetone/acetic acid/0.1 M ammonium acetate (70:30:27.5:2.25:5, by vol). After removal of organic solvent, plates were exposed to iodine vapor for visualization. Furthermore, plates were exposed to Kodak (Rochester, NY) X-omatic AR film for autoradiography of the samples. The phospholipid fractions were scraped into scintillation vials for measurement of radioactivity.

RESULTS

Figure 1 shows a typical autoradiogram and identifies the phospholipids extracted from 75 heads after exposure to $^{32}P_i$ for 26 h. The figure shows incorporation of $^{32}P_i$ into minor as well as major phospholipid components. We have consistently observed a spot to the right side of phosphatidylcholine (PC) on the TLC (thin-layer chromatography) plate (PC_r). Analysis of the fatty acid composition of this lipid fraction indicated a higher content of saturated fatty acids (14:0 and 16:0) and a lower content of 18:1 and 18:2 than in PC. Therefore, PC_r is probably a subspecies of PC. We also have observed two labeled lipid fractions to the right of phosphatidylethanolamine (PE). These spots seem to correspond to phosphatidylglycerol and cardiolipin, but the fractions were not firmly identified. Unlike mammalian tissues, practically no sphingomyelin, cerebrosides or ethanolamine plasmalogen (PE_{pl}) were detected in these samples. On the other hand, notable amounts of lysophospholipids were found.

Data in Figure 2 show the phospholipid labeling profiles in *norpA* and wild type, and compare feeding in light *vs.* dark for 24 h. Results showed no major differences in phospholipid distribution between *norpA* and wild type or between light and dark. The distributions of label in PE and PC, as determined from these and many other experiments, are around 47 and 24%, respectively. PC_r

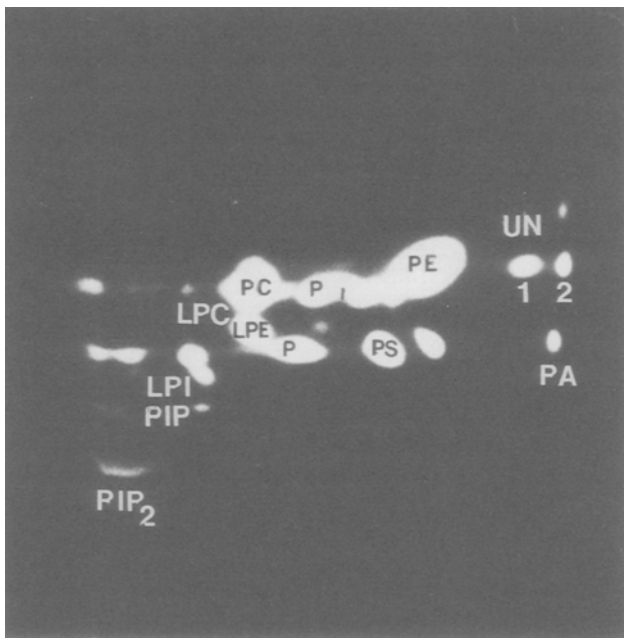

FIG. 1. Autoradiogram of a typical thin-layer chromatography separation of the lipids from *Drosophila melanogaster* heads developed in three solvent systems (ref. 14). The autoradiogram is slightly overexposed to reveal also those phospholipids which are present in small quantities. PIP_2, phosphatidylinositol 4,5-bisphosphate, PIP, phosphatidylinositol 4-phosphate; LPI, lysophosphatidylinositol; LPC, lysophosphatidylcholine; LPE, lysophosphatidylethanolamine; PI, phosphatidylinositol; PC, phosphatidylcholine; PC_r, spot to the right of phosphatidylcholine: PE, phosphatidylethanolamine; PS, phosphatidylserine; and PA, phosphatidic acid; UN 1 and 2 are unknown fractions also presented in Figures 2 and 4; they may correspond to the cardiolipins.

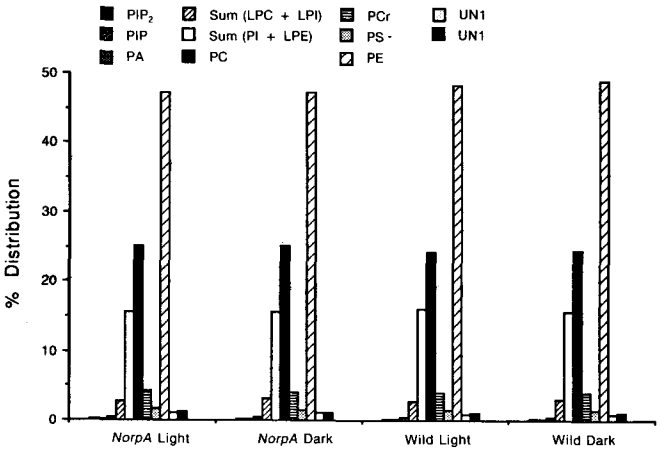

FIG. 2. The percentage distribution of ^{32}P radioactivity in major phospholipids in the heads of the flies studied (*norpA vs.* wild-type, light *vs.* dark reared). Data are pooled from 9 groups of samples (each consisting of 30 heads) in 4 experiments for *norpA* and 7 samples in 3 experiments for wild type. Variations within groups normally do not exceed 5%. Abbreviations as in Figure 1.

comprised 4% of the total radioactivity. In some experiments, the PI spot and the lysoPE (LPE) spot were not clearly separated, and the counts were combined. Nevertheless, on the basis of the plates with good separation, PI was found to comprise 11% and LPE only 2%. Other lysophospholipids, such as lysoPC (LPC) and lysoPI (LPI), comprised 1.6 and 1.4% of total radioactivity, respectively. Other minor phospholipids showing the label are: phosphatidic acid (PA), 0.4%; PIP_2, 0.2%; PIP, 0.2%; phosphatidylserine (PS), 1.6%; unknowns $(UN)_1$, 2.5% and UN_2, 1.1%. Although PS was only labeled sparingly, this phospholipid was a major phospholipid in mass.

We used information from seven experiments to assess incorporation of $^{32}P_i$ into the phospholipids of wild type and *norpA* under light and dark conditions (Fig. 3). Ratios

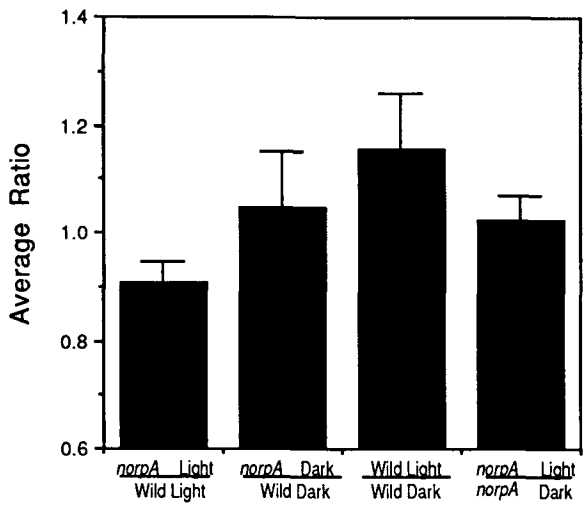

FIG. 3. Overall incorporation of ^{32}P into the phospholipids. Data are based on: (i) the overall counts from aliquots of sample; and (ii) the sum of radioactivity of the lipids on the plates. Data were normalized for the number of fly heads used and the amount of ^{32}P fed. Ratios were calculated using 17 values ± SE except for *norpA* light/*norpA* dark, which was from 19 values ± SE. *NorpA, no* receptor potential.

of about 1 are shown for *norpA*-dark over wild-dark and for *norpA*-light over *norpA*-dark, suggesting that the mutation has no effect in the dark and that the light/dark manipulation has no effect in the mutant. A ratio of about 1.15 was found for wild-light over wild-dark, and the ratio was about 0.9 for *norpA*-light over wild-light. These ratios tend to show that wild type flies have more feeding activity resulting in more labeling in the light, but no dark/light differences are shown for *norpA*, probably because these flies are blind.

When flies were presented with the $^{32}P_i$ for 4 d, rehydrating the filter paper with sucrose but not ^{32}P, the amount of radioactivity incorporated into the phospholipids was similar to that observed after 24-h exposure. However, differences in the phospholipid labeling profile were observed between the 24-h and the 4-d exposure. Data in Table 1 summarize the changes by expressing the ratio between the two data points. With the exception of PC, which did not change as a function of feeding time, substantial deviations from a ratio of 1.0 are evident for most of the lipids. For example, a ratio of less than 1 for PI indicated that the proportion of radioactivity in this phospholipid decreased during 4 d, and ratios greater than 1 for PS, PC_r and lysophospholipids indicate that the proportion of radioactivity of these phospholipids increased during 4 d of feeding. Interestingly, lysophospholipids tended to accumulate more in *norpA* than in wild type irrespective of lighting conditions. In this experiment, only 10 μCi/vial of ^{32}P was given, as it was expected that the 4 times longer feeding would balance the 5 times lower dose. However, incorporation was about 1/4, suggesting that most of the ^{32}P incorporation into phospholipids occurred during the first 24 h. On this basis, we conclude that this experiment simulates the pulse-chase type of study.

To further elaborate on these results, a time course experiment was carried out in which flies were analyzed at 3, 7, 16, 22 and 34 h after ^{32}P feeding. The data in Figure 4 show the distribution of radioactivity among the lipids for wild type (Fig. 4a) and *norpA* (Fig. 4b). In general, the phospholipid labeling patterns in *norpA* and wild type do not differ appreciably, but substantial changes in labeling pattern were observed with respect to time of ^{32}P feeding. For example, there is a time-dependent decrease

TABLE 1

Ratio of Chronic[a] over Acute[b] Incorporations into Selected Phospholipids of *Drosophila* Heads

Lipid[c]	*norpA* light	*norpA* dark	Wild light	Wild dark
PI	0.32575	0.40187	0.35354	0.38940
PS	2.10550	2.37810	3.15360	2.48900
PC	1.19600	1.07600	0.94984	0.92615
PCr	1.47800	1.60700	1.65740	2.25100
Sum LP	4.39600	4.03800	2.84500	3.36500
Sum PIP_2, PIP	1.27600	1.97200	2.20400	1.40000
PA	1.40000	0.89375	0.76000	0.92667

[a] Four-day feeding.

[b] One-day feeding.

[c] PI, phosphatidylinositol; PS, phosphatidylserine; PC, phosphatidylcholine; LP, lysophospholipids; PIP_2, PI 4,5-bisphosphate; PIP, PI 4-phosphate; PA, phosphatidic acid; *norpA, no* receptor potential.

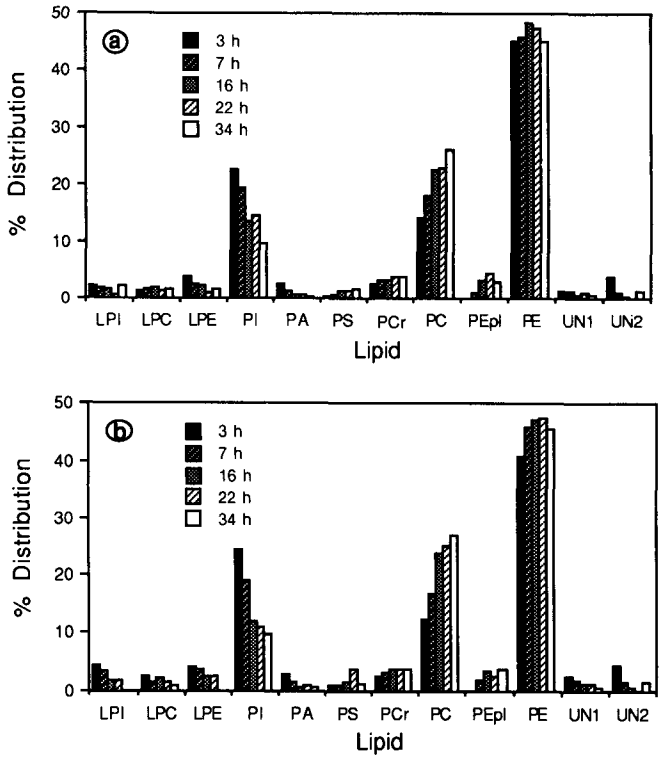

FIG. 4. Distribution of the radioactivity of phospholipids with respect to the duration of ^{32}P exposure: (a) for wild type; (b) for *norpA*. Abbreviations as in Figure 1.

in labeled PI, PA and lysophospholipids, and an increase in labeling of PC, PC_r and PS. Although label was highest in PE, the proportion of label associated with PE did not change greatly with time.

A study was performed to compare the phospholipid labeling pattern in aged *vs.* newly emerged flies. Although no profound changes were observed in the major phospholipids, aging may have increased the labeling of PIP and PIP_2 in wild type, but not in *norpA*, and decreased the labeling of LPC and LPI in all types (Fig. 5).

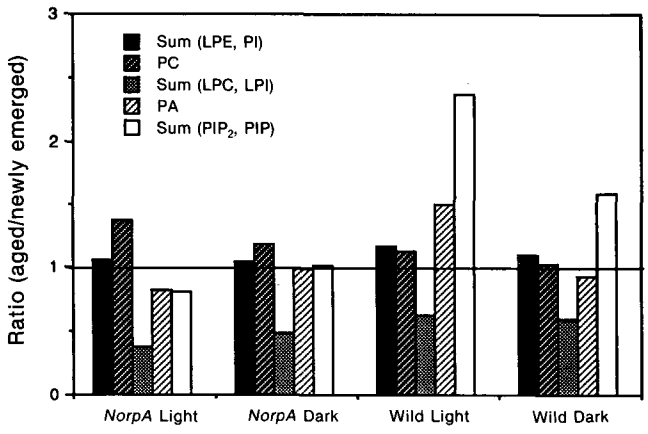

FIG. 5. Ratio of some representative phospholipids for flies aged one week compared with newly emerged flies. The ratio represents the percent distribution of lipids in the aged *vs.* newly emerged flies. Two plates each are pooled from one representative experiment for aged *vs.* newly emerged flies. Abbreviations as in Figure 1.

In pilot experiments, various time intervals were used for dissecting and sorting the heads, and we observed drastic differences in the labeling of lysophospholipids. For all of the data reported above, heads were more rapidly isolated by freezing in liquid nitrogen. When sample preparation was deliberately delayed, apparent lysophospholipid labeling was increased. These results seem to point at the presence of phospholipases in the head which would be responsible for the hydrolysis of the phospholipids.

Using the same feeding paradigm, *i.e.*, 24-h feeding of ^{32}P, labeling of major phospholipids (PA, PS, PI, LPE, PC and PE) was compared for the following groups: (i) wild type controls *vs. eya* (Fig. 6a); (ii) wild type controls *vs. ora* (aged, see methods) (Fig. 6b); (iii) β-carotene supplemented Sang's medium *vs.* Sang's medium which is deficient in carotenoid (Fig. 6c); and (iv) regular food (high carotenoid) controls with Sang's (high carotenoid) flies (Fig. 6d). This last comparison was important because the two diets differed in fatty acid composition (based on gas chromatography (GC) analysis, regular food has 16:0, 74.37%; 18:0, 13.61%; 18:1, 10.06%; and 18:2, 1.96%; whereas Sang's has 16:0, 61.13%; 18:0, 20.49%; 18.1, 18.38%; and 18:2, 0%). The data show that, despite the subtle differences that exist, the overall profiles for ^{32}P incorporation remain largely similar between the various groups.

DISCUSSION

Agonist stimulation of phosphoinositide hydrolysis by PLC is known to give rise to two second messengers, IP_3 and diacylglycerol (DG). The importance of IP_3 on Ca^{++} homeostasis (25) now explains the long realized importance of Ca^{++} on invertebrate photoreceptor function in transduction and/or adaptation. DG activates protein kinase C (PKC), two of which (one specific to the eye) have been cloned in *Drosophila* (26). DG can be converted to PA by DG kinase, an enzyme of interest in visual transduction as it is missing in the *rdgA* (retinal *d*egeneration) mutant (27). In this study, PA is consistently labeled after exposure of flies to ^{32}P, suggestive of its role as an intermediate for phospholipid biosynthesis.

PLC has been shown to play a role in photoreceptor function in *Drosophila* (5). The *norpA* mutant is interesting because it has rhodopsin but lacks the receptor potential (21). It was proposed that this mutant is like dominantly inherited night blindness in humans and the *rd* (retinal *d*ystrophic) chicken (for additional references, see ref. 20). *NorpA* loses rhodopsin as a function of age (3,28). It accumulates zipper-like membranes, suggested as a form of lipid storage abnormality (29). One of the original goals of this line of research was to design experiments to examine the phospholipids in this mutant and to understand how accumulation of lipids may occur during aging. As the data accumulated, it became obvious that it was also necessary to establish a method to label the membrane phospholipids and to present baseline data.

Our experiments revealed for the first time a novel method to label the phospholipids in *Drosophila* heads. By mixing $^{32}P_i$ with the food, effective labeling of the phospholipids in the heads can be achieved within a short time. Examination of the labeling pattern revealed high percentage of label distributed in PE (45%), followed by PC and PI. The ability to incorporate a large amount of

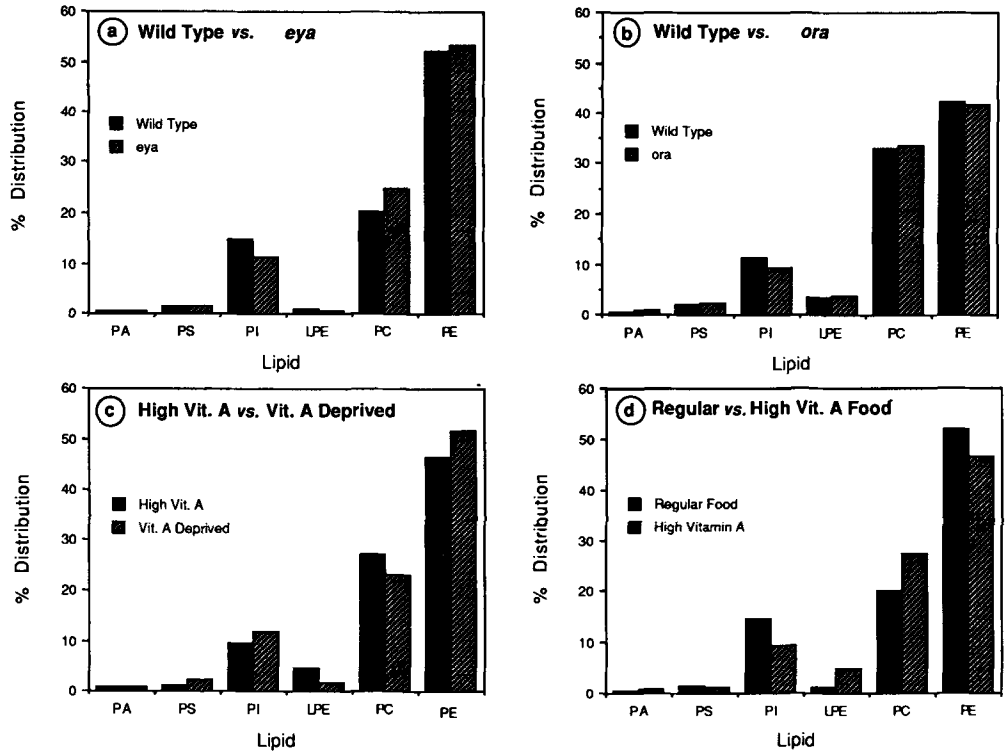

FIG. 6. The percentages of ^{32}P radioactivity in the major phospholipids (PA, PS, PI, LPE, PC and PE normalized to sum to 100%) from the heads of flies upon separation in two solvent systems. Fifty μCi of $^{32}P_i$ per vial was fed and 45 heads of deprived and 45 of the wild type were used. The sample was divided into three aliquots and spotted onto separate plates. The data from these plates were averaged. (a) Wild type *vs. eya*. All flies were newly emerged. (b) Wild type *vs. ora*. All flies were aged 11 d. (c) High β-carotene *vs.* β-carotene deprived flies. Heads were from flies of high β-carotene *vs.* deprived flies reared on Sang's medium. All flies were newly emerged. (d) Regular food *vs.* high Vitamin A food. The regular food control is the same as the *eya* control (Fig. 6a) while the Sang's is the high β-carotene for the vitamin A experiment (Fig. 6c). Abbreviations as in Figure 1. *Eya, eyes absent; ora, outer rhabdomeres absent.*

label into PE in the fly heads is interesting because PC is the predominant lipid in most mammalian tissues. The time course study revealed interesting differences in metabolism between PE *vs.* PI and PC, suggesting a role for PE in the structural make-up of the membrane. Unlike mammalian tissues, phospholipids in *Drosophila* heads are low in sphingomyelins and plasmalogens although the presence of various types of lysophospholipids is apparent. We were disappointed, though not surprised, that only trace amounts of label were incorporated into poly-PI, limiting the usefulness of our labeling procedure for further studies of the metabolism of inositol phospholipids.

Because $^{32}P_i$ is taken up by the flies as food, it is not possible to specifically address the labeling of phospholipids in the retina. In contrast, intracerebral injection of $^{32}P_i$ into mammalian brain can yield effective labeling of the poly-PI (14). Our inability to isolate retina from head, together with the fact that only trace amount of label is in poly-PI, may explain why we did not observe a difference in phospholipid labeling pattern between *norpA* and wild type, although it has clearly been established that the *norpA* mutant lacks PLC (10,11). Also, the *norpA* gene codes for PLC (12), which acts on the poly-PI as well as on PI (30). In the crab, an inositol trisphosphatase terminates the action of IP_3 in mediating visual transduction (31). In bovine brain, there are at least five different types of phospholipase C which are specific to inositol phospholipids (32).

We observed a difference in the overall labeling between *norpA* and wild type, likely attributable to a visually-mediated difference in the feeding behavior. Because *norpA* lacks the photoreceptor potential, these flies did not show a light-mediated increase in feeding. Another interesting observation is the comparison of phospholipid labeling between aged and newly emerged *norpA* and wild type flies. In both dark and light conditions, the aged wild type showed a ratio of greater than 1 for the labeling of poly-PI, whereas the ratios for *norpA* were not changed. The inability to show an age difference in the metabolism of poly-PI in *norpA* may reflect the defective metabolism of poly-PI turnover.

An interesting observation from this study is the presence of a significant amount of lysophospholipids in the heads, suggesting the presence of endogenous phospholipase A_2 (PLA_2) activity. In pilot experiments in which fly heads were not quickly broken off by freezing, we obtained evidence that varying amounts of lysophospholipids were released *post-mortem*. As the proportion of label of these lysophospholipids decreased in the chronic feeding (pulse chase) experiment (Table 1), it is reasonable to conclude that these compounds undergo metabolism and may form an integral part of the phospholipid

turnover cycle. Aging resulted in a decrease in the labeling of LPC and LPI, but there was no effect of mutant condition. We found that there was no effect of light on the appearance of lysophospholipids, though light seems to affect PLA_2 activity in vertebrate rods (33). In other systems, PLA_2 is known to serve as a direct source of arachidonate (34). However, analysis of the fatty acids of the phospholipids revealed no appreciable amount of arachidonic acid in *Drosophila* (data not shown). Zimmerman and Keys (35) characterized an enzymatic system responsible for the removal of LPC and suggested that the lysophospholipids generated by PLA_2 may be involved in the early stages of light-induced damage (35,36). In other studies, PLA_2 was shown to participate in "retailoring" of fatty acids in the 2-position (37). Thus, oxidized polyunsaturated fatty acids can be eliminated from the system through this mechanism. The lysophospholipid-acylCoA acyltransferases are important for recycling polyunsaturated fatty acids to the *sn*-2 position (38).

A comparison of the phospholipid labeling patterns was made among mutants including *norpA, ora* and *eya.* This type of "genetic dissection" is also underway in mouse (*rd* mutant) (39) and dog (*p*rogressive *r*od-*c*one *d*egeneration mutant) (40,41). We also dissected the system with carotenoid deprivation which selectively eliminates rhodopsin (42). This study suggests that the "annular lipids" are important for rhodopsin function (43).

Our results are consistent with the notion that $^{32}P_i$ is incorporated into phospholipids quickly and that some lipids do turnover more rapidly than others. Historically, in other systems, the fast turnover in membrane lipids heralded the discovery of lipid involvement in messenger systems. Our results provide the initial characterization of membrane phospholipids of *Drosophila* heads in wild type and vision mutants. This information will serve as an important base for understanding the mechanism of phototransduction. Future directions are likely to center around the functional role of lipids in visual receptors.

Stereospecificity of Monoacylglycerol and Diacylglycerol Acyltransferases from Rat Intestine as Determined by Chiral Phase High-Performance Liquid Chromatography

Richard Lehner, Arnis Kuksis* and **Yutaka Itabashi**[1]
Banting and Best Department of Medical Research, C.H. Best Institute, University of Toronto, Toronto, Canada M5G 1L6

Using chiral phase high-performance liquid chromatography of diacylglycerols, we have redetermined the ratios of 1,2-/2,3-diacyl-*sn*-glycerols resulting from acylation of 2-monoacylglycerols by membrane bound and solubilized triacylglycerol synthetase of rat intestinal mucosa. With 2-oleoyl[-^{3}H]glycerol as the acyl acceptor and oleoyl-CoA as the acyl donor, 97–98% of the diacylglycerol product was 1,2(2,3)-dioleoyl-*sn*-glycerol, 90% of which was the *sn*-1,2- and 10% the *sn*-2,3-enantiomer. The remaining diacylglycerol (less than 3%) was the *sn*-1,3-isomer. The overall yield of acylation products was 70%, of which 60% were diacylglycerols and 40% triacylglycerols. With 2-oleylglycerol ether as the acyl acceptor and [1-^{14}C]oleoyl-CoA as the acyl donor, 90% of the diradylglycerol was 1-oleoyl-2-oleyl-*sn*-glycerol and 10% was the 2-oleyl-3-oleoyl-*sn*-glycerol. The diradylglycerols made up 96% and the triradylglycerols 4% of the radioactive product. With 1-palmitoyl-*sn*-glycerol as the acyl acceptor and [1-^{14}C]oleoyl-CoA as the acyl donor, the predominant reaction product was 1-palmitoyl-3-oleoyl-*sn*-glycerol. The 3-palmitoyl-*sn*-glycerol was not a suitable acyl acceptor. Both 1,2- and 2,3-diacyl-*sn*-glycerols were substrates for diacylglycerol acyltransferase as neither isomer was favored when 1,2-dioleoyl-*rac*-[2-^{3}H]glycerol was used as the acyl acceptor. There was a marked decrease in the acylation of the 1(3)-oleoyl-2-oleyl-*sn*-glycerol to the 1,3-dioleoyl-2-oleyl-*sn*-glycerol. It is concluded that neither monoacylglycerol nor diacylglycerol acyltransferase exhibit absolute stereospecificity for acylglycerols as fatty acid acceptors.
Lipids 28, 29–34 (1993).

During fat absorption, triacylglycerol synthesis in the intestinal mucosa proceeds predominantly *via* acylation of lumenal 2-acylglycerols, although X-1(3)-acylglycerols are also absorbed. The enzymes catalyzing the reesterification of 2-acylglycerols with fatty acids reside together in the endoplasmic reticulum of the enterocyte (1) and are believed to form a triacylglycerol synthetase complex (2) composed of acyl-CoA ligase, monoacylglycerol acyltransferase (MGAT) and diacylglycerol acyltransferase (DGAT). Because the resynthesis of the higher acylglycerols involves acylation of prochiral and chiral esters, the reaction could theoretically proceed either *via* enantiomeric or racemic intermediates. Previous work with whole cells (3), homogenates (3), isolated microsomal membranes (4,5) or purified enzyme preparations (6,7) has led to inconsistent and contradictory conclusions, possibly due to inadequacies in the analytical methodology used for determination of the enantiomeric ratios of synthesized diacylglycerols.

In the present study we have taken advantage of the discovery of a chiral phase high-performance liquid chromatography (HPLC) method for the separation of enantiomeric diacylglycerols (8) and of its adoption for natural diacylglycerol analysis (9). This approach avoids the uncertainties of the past and provides direct and unambiguous information with regards to separation, identification and quantitation of the acylglycerol acylation intermediates, as well as the initial substrates and final products.

MATERIALS AND METHODS

Chemicals. [1-^{14}C]Oleoyl-CoA (specific activity 52 mCi/mmol) and Aquasol were purchased from New England Nuclear/Dupont Canada Inc. (Lachine, Quebec, Canada). [2-^{3}H]Glycerol trioleate (specific activity 2 Ci/mmol) was obtained from ICN Biochemicals Canada Ltd. (Montreal, Quebec, Canada). Oleoyl-CoA, trioleoylglycerol, oleic anhydride and phenylmethylsulfonyl fluoride (PMSF) were purchased from Sigma Chemical Co. (St. Louis, MO). Dithiothreitol (DTT) was from Bio-Rad Laboratories Canada Ltd. (Mississauga, Ontario, Canada). Silica gel H (Merck 60 H) and G (Merck 60 G) were obtained from Terochem Laboratories Ltd. (Mississauga, Ontario, Canada). Silica gel GF thin-layer chromatography (TLC) plates (20 × 20 cm, 0.25-mm thick) were purchased from Analtech Inc. (Newark, DE). 2-Oleylglycerol was from Serdary Research Laboratories (London, Ontario, Canada). The 1- and 3-palmitoyl-*sn*-glycerols were gifts from Dr. D. Buchnea (University of Toronto). All other chemicals and solvents were of reagent grade or better quality and were obtained from local suppliers.

Preparation of acyl acceptor substrates. 2-Oleoyl-[2-^{3}H]glycerol (specific activity 3.3 mCi/mmol) was prepared by digestion of [2-^{3}H]glycerol trioleate with porcine pancreatic lipase (10). The 1,2(2,3)-dioleoyl-*sn*-[2-^{3}H]-glycerol (specific activity 0.25 mCi/mmol) was prepared by Grignard degradation of [2-^{3}H]glycerol trioleate (10). 1,3-Dioleoyl-2-oleyl-*sn*-glycerol was prepared by chemical synthesis from 2-oleylglycerol and oleic anhydride as follows: four mg 4-dimethylaminopyridine and 90 μmol oleic anhydride were added to 90 μmol of 2-oleylglycerol in 150 μL dry toluene. After 5 min at room temperature the reaction mixture was dried under nitrogen, and the 1,3-dioleoyl-2-oleyl-*sn*-glycerol was recovered following

TLC on silica gel H developed in heptane/diisopropyl ether/acetic acid (60:40:4, vol/vol/vol). X-1(3)-oleoyl-2-oleylglycerol was prepared by digestion of the triradylglycerol with pancreatic lipase (10). The purities and concentrations of the radiolabeled and unlabeled substrates were assessed by boric acid TLC and by gas-liquid chromatography (GLC) on a polar capillary column.

Animals. Male Wistar rats weighing 250–300 g were purchased from Charles River Canada Inc. (La Salle, Quebec, Canada) and were housed for 1–3 wk with free access to Purina Rodent Chow and water before being used in these studies.

Preparation of subcellular fractions. The animals were anesthetized with diethyl ether and exsanguinated *via* their abdominal aortae. The mucosal scrapings of the upper two-thirds of the small intestine were isolated as described by Hoffman and Kuksis (11). Supernatant devoid of brush border membranes, obtained after homogenization of the scrapings and low-speed centrifugation (12), was spun at 25,000 × *g* for 10 min, and the postmitochondrial supernatant was further centrifuged at 106,000 × *g* for 60 min to pellet microsomal membranes. Microsomes were washed with 50 mM tris[hydroxymethyl]aminomethane (Tris)-HCl (pH 7.4), 0.5 M KCl, 1 mM ethylenediaminetetraacetate (EDTA), 2 mM DTT and sedimented by re-centrifugation at 106,000 × *g* for 60 min. All steps were carried out at 0–4°C. Washed microsomes were suspended in 50 mM K_2HPO_4 (pH 7.4), 1 mM EDTA, 1 mM DTT and 75 μg/mL PMSF to give a final concentration of protein between 7–8 mg/mL. Protein content was determined by bicinchonic acid (BCA) assay (Pierce Chemical Co., Rockford, IL.)

Preparation of triacylglycerol synthetase. Microsomes were solubilized with 0.6% 3-[(3-cholamidopropyl)dimethylammonio]-propanesulfonate (CHAPS) for 30 min on ice, and the solubilized extract was loaded on a Cibacron Blue 3GA agarose column (1 × 5 cm) preequilibrated with 20 mM K_2HPO_4 (pH 7.4), 2 mM DTT and 0.5% CHAPS (Buffer A). The column was washed with Buffer A, followed by Buffer A containing 10 mM ATP, and the triacylglycerol synthetase activity was subsequently eluted with Buffer A containing 0.8 M NaCl (13).

Enzyme assays. The activities of MGAT and DGAT were determined using acetone dispersed acylglycerols (14). The enzyme fractions (20–25 μg protein) were incubated at 37°C for 10 min in 0.5 mL of 20 mM K_2HPO_4, pH 7.4, 1 mM DTT, 1 mM EDTA containing [1-^{14}C]oleoyl-CoA (30 μM), and various monoradylglycerol isomers (60 μM) or 1,2(2,3)-dioleoyl-*sn*-glycerol (250 μM) supplied in acetone (final conc. 2.5%). The reaction was stopped by addition of 4 mL of $CHCl_3/CH_3OH$ (2:1, vol/vol) and lipids were analyzed as described by O'Doherty *et al.* (15). The lipid extracts were separated by TLC on silica gel H employing heptane/diisopropyl ether/acetic acid (60:40:4, vol/vol/vol) as the mobile phase, visualized with iodine vapor, and bands corresponding to 1,2(2,3)-diacyl-*sn*-glycerol, X-1(3)-diacylglycerol and triacylglycerol were scraped off and counted for radioactivity.

Stereospecific analysis. Following enzymatic assay, the 1,2(2,3)-diradyl-*sn*-glycerols formed were separated on boric acid impregnated TLC (silica gel G) plates using chloroform/acetone (96:4, vol/vol) as the mobile phase. The recovered 1,2(2,3)-diradyl-*sn*-glycerols were converted to the corresponding dinitrophenylurethane (DNPU) derivatives according to the procedure of Takagi and Itabashi (8). The crude urethane derivatives were purified by TLC (silica gel GF) using hexane/ethylene dichloride/ethanol (40:10:3, vol/vol/vol). The DNPU derivatives of the enantiomeric diradylglycerols were resolved by HPLC as previously described (8) using *N*-(*R*)-1-(α-naphthyl)ethylaminocarbonyl-(*S*)-valine as the chiral phase and hexane/ethylene dichloride/ethanol (150:20:1, vol/vol/vol) as the mobile phase. For chiral phase liquid chromatography/mass spectrometry (LC/MS) (Hewlett-Packard 5985B quadrupole mass spectrometer combined with a Hewlett-Packard direct liquid inlet interface, Palo Alto, CA), the original mobile phase was replaced with isooctane/*t*-butyl methyl ether/isopropyl alcohol/acetonitrile (80:10:5:5, vol/vol/vol) containing 1% ethylene dichloride to enhance the negative ion response (16).

RESULTS

Overall utilization of substrate. Table 1 compares the overall synthesis of diradyl- (DG) and triradylglycerols (TG) from various monoradylglycerols (MG) and radiolabeled oleoyl-CoA by the microsomes of rat intestinal mucosa. Starting with 2-oleoylglycerol (60 μM) and 25 μg microsomal protein, 70% of the 2-acylglycerol was incorporated into higher acylglycerols within a 10-min incubation (specific activity 23 ± 4 nmol/mg protein/min). The major acylation products were 1,2(2,3)-dioleoyl-*sn*-glycerols (61.6%) and trioleoylglycerols (35.4%). About 3% of the total was recovered as X-1,3-dioleoylglycerols, which apparently arose from acyl migration during the experimental manipulations.

With 2-oleylglycerol ether (60 μM) as the acyl acceptor and 25 μg microsomal protein, the acylation proceeded at about 80% of the rate seen for 2-oleoylglycerol ester. The main product (96.9%) was 1(3)-oleoyl-2-oleyl-*sn*-glycerol, with only about 3% of the total acylation product being recovered as the 1,3-dioleoyl-2-oleyl-*sn*-glycerol.

The 1-palmitoyl-*sn*-glycerol was utilized even less effectively (34.6% of the acylation rate observed for 2-oleoylglycerol). The major product (81.8%) was 1-palmitoyl-3-oleoyl-*sn*-glycerol with a smaller proportion (18.2%) of 1-palmitoyl-2,3-dioleoyl-*sn*-glycerol. Since X-1,3-diacylglycerols are not acylated at the 2-position, the formation of the triacylglycerols (4.9% of the final product) must be attributed to partial isomerization of the 1-palmitoyl-*sn*-glycerol to 2-palmitoylglycerol, formation of 1,2(2,3)-

TABLE 1

Synthesis of Di- and Triradylglycerols from Monoradylglycerols and [1-^{14}C]Oleoyl-CoA by Microsomes from Rat Intestinal Mucosa[a]

Substrate	Percentage of total product synthesized			Relative activity (%)

palmitoyl-*sn*-glycerols and their further acylation to 1,3-dioleoyl-2-palmitoyl-*sn*-glycerols. Under the same conditions, 3-palmitoyl-*sn*-glycerol was not acylated to the *sn*-1,3-isomer.

Table 2 shows the results obtained with the triacylglycerol synthetase complex purified from rat intestinal microsomes (MGAT specific activity 165 ± 23 nmol/mg protein/min).

Enantiomeric specificity. For this analysis, which represents mass ratios of formed diacylglycerols, lipid extracts from five incubations were combined and applied to a TLC plate in the absence of lipid carriers. The 1,2(2,3)-diacyl-*sn*-glycerols were eluted from the gel and converted to the DNPU derivatives. The incubation blank contained 1,2(2,3)-diacyl-*sn*-glycerol DNPU derivatives from five incubations performed in the absence of exogenous monoradylglycerols and oleoyl-CoA, and represent endogenous levels of microsomal diacylglycerols. Figure 1 shows the ultraviolet (UV) absorption profile of the DNPU derivatives of standard diacylglycerols (A) and of the diacylglycerols (B) recovered from incubation of the microsomes with radiolabeled 2-oleoylglycerol and oleoyl-CoA. The incubation products are seen to consist largely of the 1,2-diacyl-*sn*-glycerols with smaller, but clearly recognizable amounts, of the *sn*-2,3-enantiomers. The incubation blank (C) contains UV absorbing peaks that coincide with the 1,2-diacyl-*sn*-glycerol standards of other common diacylglycerol species. In parallel experiments carried out to assess the radioactivity of the diacylglycerol enantiomers formed by microsomal MGAT, the peaks corresponding to the 1,2- and 2,3-diacyl-*sn*-glycerols were collected and rechromatographed under identical conditions (Fig. 2). It can be seen that the collected *sn*-1,2-enantiomer does not contain any *sn*-2,3-isomer (B), whereas the *sn*-2,3-isomer is devoid of the *sn*-1,2-enantiomer (C). Similar enantiomeric separations were obtained for the acylation products of the 2-oleylglycerol ether, which, however, eluted earlier than the corresponding diacylglycerols under the same chiral phase HPLC conditions (Fig. 3). The isolation of these acylalkylglycerol peaks required co-chromatography with the corresponding non-radioactive 1-oleoyl-2-oleyl-*rac*-glycerols.

Table 3 shows that the 2-oleoylglycerol and its ether analog were preferentially esterified by the microsomal MGAT at the *sn*-1-position, giving an *sn*-1-/*sn*-3-acylation ratio of 9. Similar values were obtained for the acylation products of the solubilized triacylglycerol synthetase (Table 4). The radioactivity values are quite similar to those obtained by mass analysis (Figs. 1B and 2A).

The identity of the HPLC peaks was confirmed by chiral phase LC/MS (Fig. 4). The total negative ion current profiles of the incubation product (A) and standard (B) are identical to those of the UV profiles. The bottom part of Figure 4 (C and D) shows the full mass spectra recorded for the DNPU derivatives of the 1,2- and 2,3-dioleoyl-*sn*-glycerols obtained from acylation of 2-oleoylglycerol with oleoyl-CoA in the presence of microsomal MGAT. The 1,2- and 2,3-dioleoyl-*sn*-glycerols gave the $[M]^-$ molecular

(C) and (D), full spectra recorded for the 1,2- and 2,3-dioleoyl-*sn*-glycerol dinitrophenylurethane derivatives obtained by acylation of 2-oleoylglycerol with oleoyl-CoA and microsomal monoacylglycerol acyltransferase.

microsomes with racemic 1,2(2,3)-dioleoyl-*sn*-[2-^{3}H]-glycerol and oleoyl-CoA. Some 25–30% of the radiolabeled substrate was converted to triacylglycerols (30–40 nmoles). The substrate remaining after incubation was subjected again to chiral HPLC, and the residual *sn*-1,2- and *sn*-2,3-enantiomers resolved and the peaks collected for assay of radioactivity. There was no change in the relative proportions of the mass (Fig. 5) or in the radioactivity in the two enantiomers (Table 5).

DISCUSSION

The present study clearly demonstrated that membrane-bound, as well as solubilized, triacylglycerol synthetase of rat intestinal mucosa is capable of acylating both *sn*-1- and *sn*-3-positions of the 2-acylglycerols, although the *sn*-1-position is preferred. The *sn*-2-position of the 1- or 3-acyl-*sn*-glycerols or X-1,3-diacylglycerols is not acylated. The 1-acyl-*sn*-glycerol yielded exclusively 1,3-diacyl-*sn*-glycerol, and 3-acyl-*sn*-glycerol was not acylated. The above results, which were obtained with substrates and products of known enantiomeric composition and purity, allow critical comparisons with previous results. Thus, the studies confirmed the positional requirements established previously for rat intestine (17), which converts 2-acylglycerols to X-1,2-diacylglycerols and triacylglycerols, and 1-acyl-*sn*-glycerols to 1,3-diacyl-*sn*-glycerols, whereas 3-acyl-*sn*-glycerols are not acylated. Furthermore, the

[a]Numbers in parentheses refer to number of independent determinations performed in duplicates.

present study showed that X-1,3-diacylglycerols and X-1-acyl-2-alkylglycerols are not suitable substrates for DGAT. Previous work (17) had shown that DGAT of hamster microsomes utilizes X-1,3-diacylglycerols as well as acylalkylglycerols for triacylglycerol biosynthesis. However, more recent work has shown that the hamster also utilizes the 2-acylglycerols at similar rates as compared to the rat (18). Our microsomal preparations yielded closely similar MGAT specific activities (23 ± 4 nmol/mg protein/min) to those reported by Coleman and Haynes (14) in the absence of activating phospholipids and albumin (28–45 nmol/mg protein/min). Acylation of X-1-acylglycerols yields X-1,3-diacylglycerols which are not esterified further. The earlier studies (17,19) apparently did not eliminate all the uncertainties about the identity and composition of either substrates or products. The present results also differ from the findings in chicken embryos, where 1-oleoylglycerol and 2- and X-1-oleylglycerols and their amide analogs were much less efficiently utilized when compared to 2-oleoylglycerol (19). However, in all instances, a lower activity with 2-alkyl than found with 2-acylglycerol was observed in the present study, as reported previously (17,19).

The acylation of 2-acylglycerol yielded 90% *sn*-1,2- and 10% *sn*-2,3-enantiomers. The results obtained with solubilized MGAT indicate that the 2,3-diacyl-*sn*-glycerol formation cannot be attributed to the slower reaction rate of the microsomal preparations. A similar enantiomer proportion was observed for the acylation of 2-alkylglycerol, although the overall yield of the diacylglycerols was only about 80% of that obtained for the 2-acylglycerol. Furthermore, the 1-acyl-2-alkyl-*sn*-glycerol was only partly converted to the 1,3-diacyl-2-alkyl-*sn*-glycerol, which indicated that the DGAT discriminated more against the 2-alkylglycerol derivatives than did MGAT. The 90% yield of 1,2-diacyl-*sn*-glycerols is similar to the 85–90% originally reported by Johnston *et al.* (20), O'Doherty and Kuksis (4) and, more recently, by Coleman *et al.* (5), but the conclusions differed. Whereas Johnston *et al.* (20) and Coleman *et al.* (5) felt that the enzyme was completely stereospecific, O'Doherty and Kuksis (4) allowed for the possibility that the *sn*-2,3-enantiomers recovered were also products of direct acylation of 2-monoacylglycerols. All previous methods used for enantiomeric determinations employed indirect procedures that required 100% completion of enzymatic conversions of 1,2-diacyl-*sn*-glycerols to phosphatidic acid by diacylglycerol kinase (5) or hydrolysis of 1,2-diacyl-*sn*-glycerophosphophenols by phospholipase A_2 (4). The present study established by direct and unambiguous analysis that about 10% 2,3-diacyl-*sn*-glycerols occur as intermediates during triacylglycerol synthesis from 2-acylglycerols and 2-alkylglycerols. This is also the first instance where both products of enzymatic reaction have been directly measured, rather than estimated by difference from incomplete or partial reactions. The present finding is similar to the 15–19% 2,3-diacyl-*sn*-glycerol yield reported (4) for rat intestinal microsomes. The somewhat higher proportions of 2,3-diacyl-*sn*-glycerols recovered during biosynthesis in isolated cells and mucosal homogenates (3) also may have reflected partial lipolysis of the radioactive triacylglycerols by the endogenous lipases which participate in the lipolysis/reacylation cycle during lipoprotein secretion (21–23). The much higher yield (40%) of 2,3-diacyl-*sn*-glycerols obtained with the 37 kDa polypeptide of MGAT (7) was not confirmed in the present study. The acylation of 2-acylglycerols to 2,3-diacyl-*sn*-glycerols is supported by the isolation of 2-alkyl-3-acyl-*sn*-glycerols during the acylation of 2-alkylglycerols. Because the 2-alkylglycerol is not subject to acyl migration, the recovery of 2-alkyl-3-acyl-*sn*-glycerols cannot be attributed to X-1,3-alkylglycerols.

Finally, this study demonstrated that both 1,2- and 2,3-diacyl-*sn*-glycerols are acylated to triacylglycerols at comparable rates, which would explain why 2,3-diacyl-*sn*-glycerols did not accumulate during the acylation of 2-acylglycerols to triacylglycerols. Direct acylation of enantiomeric diacylglycerols was recognized in the early work of Weiss *et al.* (24), who noted greater than 50% utilization of 1,2-diacyl-*rac*-glycerols by chicken liver particles. As the acylation of 1,2(2,3)-alkylacyl-*sn*-glycerols to alkyldiacylglycerols is very slow, it was not possible to use this enantiomer mixture to confirm the utilization of the racemic diradylglycerols by DGAT. The present findings and the proposed interpretation of the data reconcile essentially all previous experimental findings and corrects earlier conclusions about the stereochemical course of acylation of 2-acylglycerols to triacylglycerols by rat intestinal mucosa.

Structural Analysis of Oxidation Products of Urofuran Acid by Hypochlorous Acid

Toyokazu Ohki[a,*], Kenji Maeda[b], Jinsaku Sakakibara[c], Eiji Suzuki[d] and Naoki Yamanaka[a]

[a]The Bio-Dynamics Research Institute, Nagoya Memorial Hospital, 4-305, Hirabari, Tenpaku-ku, Nagoya 468, [b]Nagoya University Branch Hospital, 1-20, Daiko-minami 1-chome, Higashi-ku, Nagoya 461, [c]Faculty of Pharmaceutical Sciences, Nagoya City University, 3-1, Tanabe-dori, Mizuho-ku, Nagoya 467 and [d]Faculty of Pharmacy, Meijo University, Yagoto, Tempaku-ku, Nagoya 468, Japan

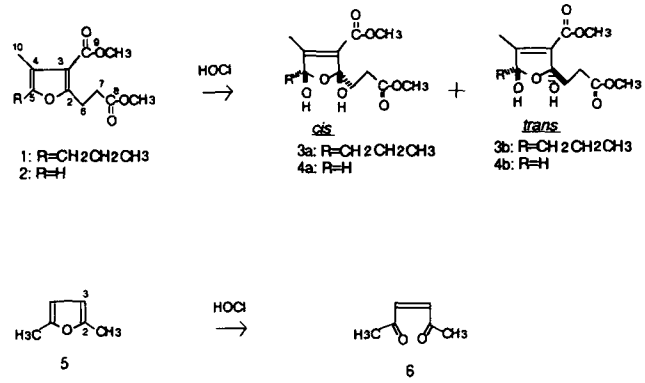
The oxidation of urofuran acid derivatives (1–2) by hypochlorous acid (HOCl) was investigated with the goal to possibly simplify the detection of their metabolites in biological materials. The oxidation products of 3-carboxy-4-methyl-5-propyl-2-furanpropionic acid (1) were obtained as an isomeric mixture and confirmed to exist as *cis* (3a) and *trans* (3b) isomers, based on their ^{13}C nuclear magnetic resonance (NMR) spectra. Similarly, the products of 5-H substituted acid 2 obtained by oxidation with HOCl were identified as 4a and 4b by ^{13}C and ^{1}H NMR which indicated the presence of *cis* and *trans* hemiacetal hydrogens at C-5 in a ratio of 2.11:1. The oxidation was found to proceed in a manner different from that of the F-acid, because of the presence of the electron withdrawing $COOCH_3$ group at C-3 which favored the nucleophilic attack on the carbonyl group to afford *cis*- and *trans*-2,5-dihydroxy-2,5-dihydrofurans (3a–b, 4a–b).
***Lipids* 28, 35–41 (1993).**

3-Carboxy-4-methyl-5-propyl-2-furanpropionic acid (1) (CMPF), known as urofuran acid, is found in human urine (1) and is retained in the blood of patients with chronic renal failure (2). CMPF inhibits the binding of methyl red to human albumin (3) and the binding of phenytoin and tryptophan to plasma protein (4). Although the 5-pentyl urofuran acid is known to be derived from 9-(3,4-dimethyl-5-pentyl-2-furyl)nonanoic acid (F-acid) present in food (5,6), the metabolic sequence leading to CMPF has not been fully elucidated.

It has been reported recently that various furan derivatives can be oxidized chemically or enzymatically. For example, 2,5-diphenylfuran can be converted to *cis*-1,2-dibenzoylethylene by hypochlorous acid (HOCl) *via* the intermediate 2-chloro-5-hydroxy-2,5-diphenyl-2,5-dihydrofuran (7), and F-acid, when treated with hydrogenperoxide/sodium hypochlorite, leads to methyl 11,12-dimethyl-10,13-dioxo-11-octadecenoate (8), which can also be obtained as an autoxidation product (9) or as an enzymatic oxidation product (10,11). These reports prompted us to investigate the oxidation of CMPF dimethyl ester (1) with HOCl with the goal to possibly simplify the detection of CMPF metabolites in biological materials.

In the present study, we found that the oxidation of 1 proceeded in a manner different from that of F-acid to afford an isomeric mixture of *cis*- and *trans*-2,5-dihydroxy-2,5-dihydrofurans (3a–b), which have not previously been described. The structural identification was confirmed by *spectral data, including* ^{13}C and ^{1}H nuclear magnetic resonance (NMR) and mass spectrometry (MS). To verify the *cis/trans* stereochemistry, the CMPF analogue (2), bearing a hydrogen substituent at C-5, was prepared and also subjected to HOCl oxidation under similar conditions. Based on ^{1}H NMR spectral analysis, the structure of the oxidation products (4a–b) was unequivocally confirmed to be the *cis* and *trans* hemiacetals.

In addition, an interesting effect of the electron withdrawing group $COOCH_3$ at C-3 was observed, and the results were compared with the oxidation of 2,5-dimethylfuran (5). The structural formulas and reaction sequences are given in Scheme 1.



SCHEME 1

RESULTS

Characterization of the oxidation products of 1 *by high-performance liquid chromatography (HPLC).* Figures 1A and 1B show the elution profiles of 1 and those of the reaction mixture obtained by oxidation of 1 with HOCl. Peaks 1 and 2 represent the oxidation products with retention times of 4.1 min and 4.6 min. We separated the effluents corresponding to peaks 1 and 2; however, the component ratios changed progressively with time (Fig. 1C). This pattern of behavior strongly suggested that the oxidation products existed as an equilibrium mixture of two tautomers.

Characterization of the oxidation products of 1 *by silica gel chromatography.* The oxidation products (peaks 1 and 2) were fractionated by silica gel column chromatography. The products were eluted with ethyl acetate/hexane (7:3, vol/vol) to give ten fractions. The fractions were analyzed by thin-layer chromatography (TLC) as shown in Figure 2. Fraction 5, combined fractions 6–8, and combined fractions 9–14 were further analyzed. Figures 3A, 3B and 3C

show the HPLC profiles of the fractions 5, 6–8 and 9–14, respectively. Fraction 5 was identified as 1 based on R_f value and electron impact ionization mass spectrum (EI-MS). Fractions 9–14 (Fig. 3C) consisted mainly of peaks 1 and 2, which are also seen in Figure 1B.

Structural analysis of the oxidation products (**3a–b** *and* **4a–b**). Although our efforts to isolate the two oxidation products in pure form were unsuccessful, structural assignments were carried out as follows. Fast atom bombardment mass spectrum (FAB-MS) showed an $[M - H]^-$ ion peak at *m/z* 301. This fragment indicated a molecular weight of 302, corresponding to 1 plus two hydroxy groups. The ^1H NMR spectrum showed four additional D_2O exchangeable singlets, attributable to four hydroxy protons in addition to the signals observed for 1. The ^{13}C NMR spectrum (Fig. 4) distortionless enhancement by polarization transfer (DEPT) showed paired singlets corresponding to two methyl, four methylene and six quarternary carbons in accordance with the multiplicity expected based on the parent structure of 1. The most characteristic signals were those that appeared as two sets of paired singlets at δ 106.74 (107.24) and δ 109.25 (110.42) (Fig. 4B). These signals were due to the two acetal carbons, whereas the remaining signals at δ 128.14 (129.49) and δ 154.66 (155.60) were assignable to the olefinic carbons. In GC/MS analysis, the trimethylsilyated derivatives could be separated into two components, and each component showed the $[M - 15]^+$ fragment at *m/z* 431. This fragment also provided further evidence that the oxidation products have two hydroxy groups per molecule.

From the spectral data, we deduced the structures of the oxidation products as methyl (±)-*cis*-2,5-dihydroxy-3-methoxycarbonyl-4-methyl-5-propyl-2,5-dihydro-2-furanpropionate (**3a**) and methyl (±)-*trans*-2,5-dihydroxy-3-methoxycarbonyl-4-methyl-5-propyl-2,5-dihydro-2-furanpropionate (**3b**), respectively (Scheme 1).

The relative ratio of the *cis* and *trans* isomers based on HPLC was 2:1. From molecular modelling, it appears most likely that the major isomer is the *cis*-2,5-dihydroxy-2,5-dihydrofuran (**3a**); the *cis* isomer (**3a**) seems to be favored over the *trans* isomer (**3b**) on account of the enhanced stability of **3a** due to intramolecular hydrogen bonding between the *cis* located dihydroxy groups at C-2 and C-5.

In order to provide further support for the stereochemical relationship between the C-2 and C-5 hydroxy groups, the oxidation reaction was applied to methyl 3-methoxy-

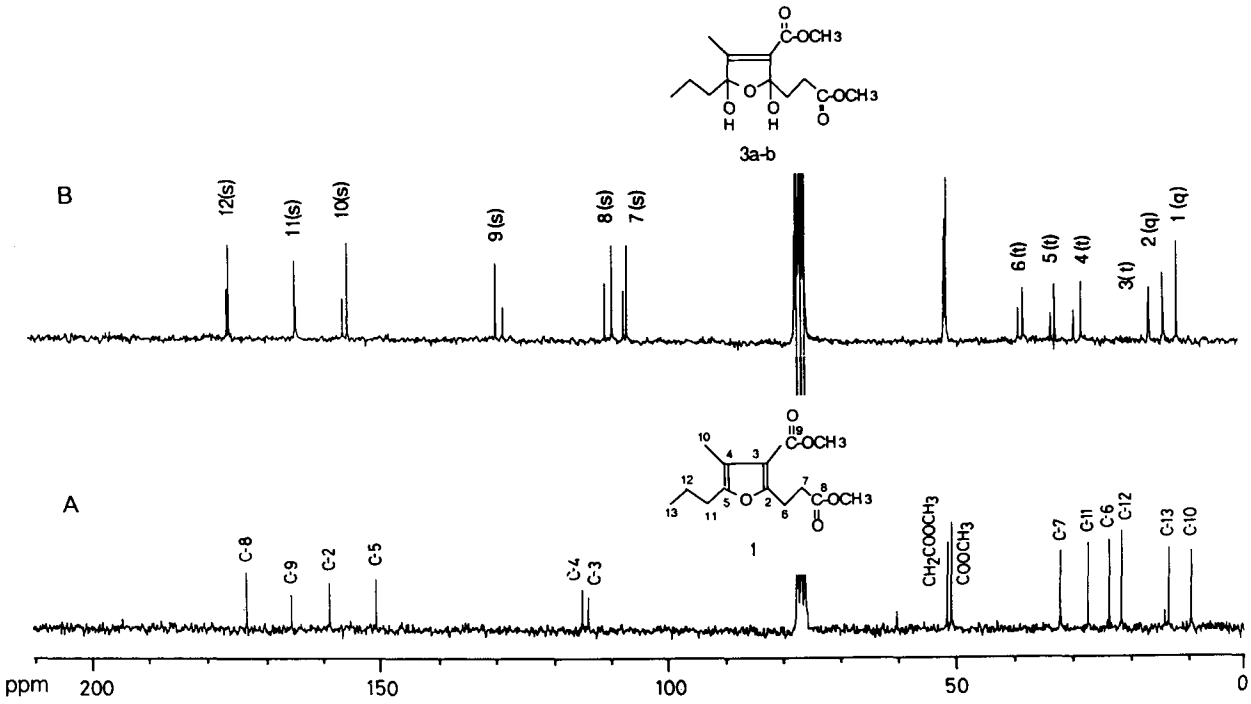

FIG. 4. ^{13}C nuclear magnetic resonance spectra (50.1 MHz, $CDCl_3$) of (A) 1 and (B) oxidation products.

carbonyl-4-methyl-2-furanpropionate (2) which does not bear a 5-alkyl substituent. After a similar workup as for 1, the oxidation products were obtained as an inseparable mixture of two isomers.

The ^1H NMR spectrum (Fig. 5) showed two pairs of doublets (δ 5.56 and δ 5.88) which could be attributed to the 5-hydrogens of the *cis* and *trans* isomers. The 5-hydrogens were coupled to the C-5 geminal hydroxy protons and they changed to singlets when treated with D_2O. The downfield doublet of δ 5.88 was assigned to the *trans* isomer (**4b**), because the 5-hydrogen of **4b** would be deshielded by hydrogen bonding to the C-2 hydroxy proton (Fig. 5). The upfield doublet at δ 5.56 was assigned to the 5-hydrogen of the *cis* isomer (**4a**). The two hydroxy protons at C-5 appeared as doublets at δ 4.09 and δ 4.44. One of hydroxyl protons at C-2 appeared as singlet at δ 4.91, the other C-2 hydroxy proton was absent probably due to overlapping with other signals.

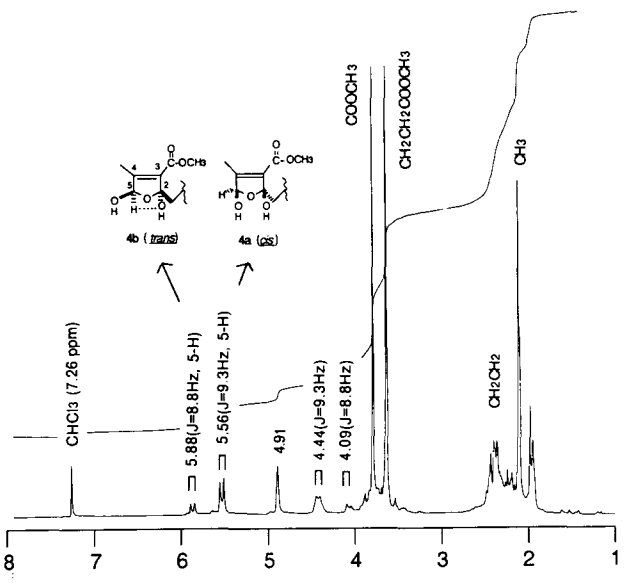

FIG. 5. ^1H nuclear magnetic resonance spectrum (199.5 MHz, $CDCl_3$) of the oxidation products of 2.

The FAB-MS of the mixture showed an $[M - H]^-$ peak at *m/z* 259, consistent with the molecular weight of 2 plus two hydroxy groups. The ^{13}C NMR spectrum was in full agreement with the proposed structures (**4a–b**) (Fig. 6 and Table 1).

Based on these data, the oxidation products were confirmed to be methyl (±)-*cis*-2,5-dihydroxy-3-methoxycarbonyl-4-methyl-2,5-dihydro-2-furanpropionate (**4a**) and methyl (±)-*trans*-2,5-dihydroxy-3-methoxycarbonyl-4-methyl-2,5-dihydro-2-furanpropionate (**4b**), respectively. This structural assignment is consistent with the earlier assignment of the *cis*- and *trans*-2,5-dihydroxy structures **3a** and **3b**.

The relative amounts of **4a** and **4b** based on ^1H NMR data, existed in a ratio of 1:2.11. The major isomer was assumed to be the *cis*-2,5-dihydroxy cmpound (**4a**) because of possible hydrogen bonding between the C-2 and C-5 hydroxy groups located *cis* to each other.

Reaction mechanisms. A reasonable mechanism to account for the formation of the diastereoisomeric 2,5-dihydroxyfuran derivatives is illustrated in Scheme 2. It is interesting to note that the electron withdrawing methoxycarbonyl group at C-3 seems to play an important role in the oxidation reactions. The elimination of hydrogen chloride from the 2-hydroxy-5-chloro intermediate (**7**)

[a]Carbon numbers as shown in Scheme 1. [b]Multiplicities were determined by DEPT spectra. [c,d]May be reversed.

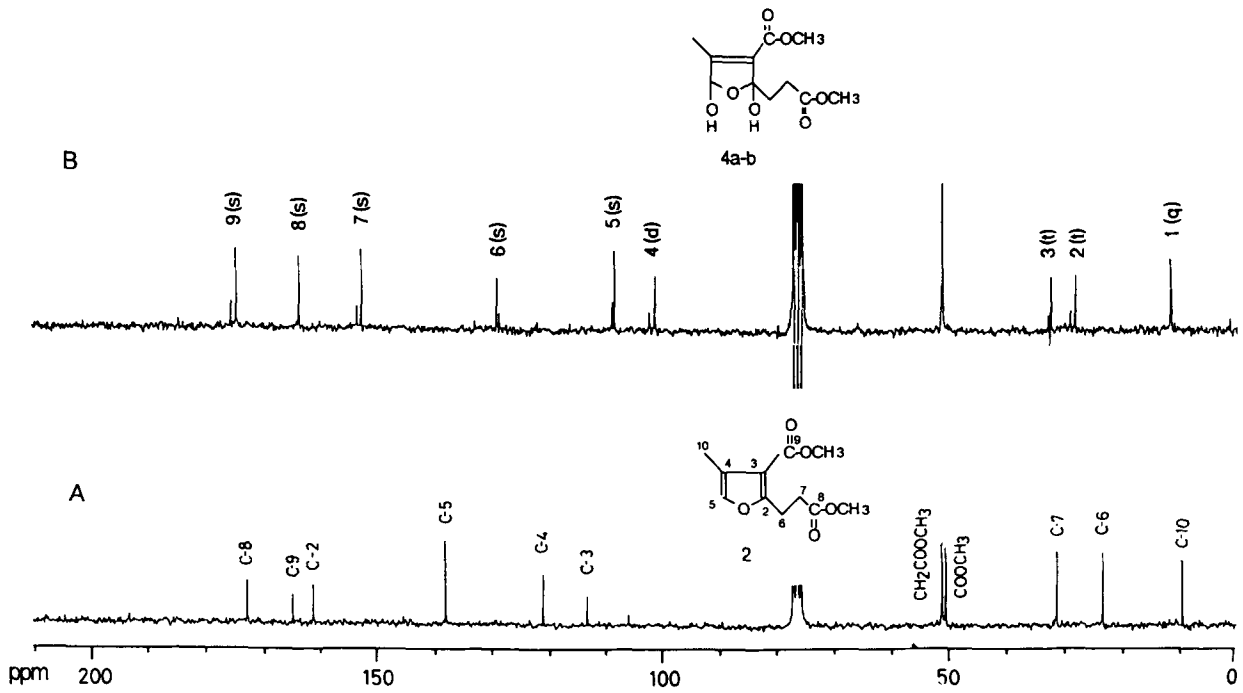

FIG. 6. ^{13}C nuclear magnetic resonance spectra (50.1 MHz, $CDCl_3$) of (A) 2 and (B) oxidation products.

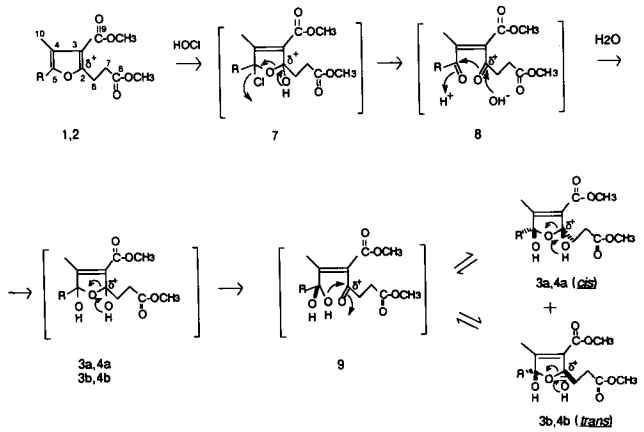
initially formed led to the dioxoene compound (8), consistent with the literature (7-11). The electron deficient carbonyl group of 8 subsequently underwent nucleophilic attack by the hydroxy anion to yield the racemic hemiacetal 3-4, which immediately produced the labile and transient intermediate (9) *via* the subtraction of the hydroxy protons of 3-4 followed by ring-opening. The succeeding reaction of one of the geminal hydroxy groups with the carbonyl group afforded a cyclic hemiacetal accompanied by creation of a new asymmetric center at C-2. This new asymmetric carbon can account for the equilibrium mixture of the *cis* and *trans* stereoisomers (3a-b and 4a-b) due to tautomeric interconversion between the *cis* and *trans* forms. To rationalize this mechanisms, 2,5-dimethylfuran (5) bearing no 3-electron withdrawing substituent was chosen as the model compound and similarly oxidized by HOCl. In this case only *cis*-1,2-diacetylethylene (6) was obtained as the sole product as shown in Scheme 1.

DISCUSSION

We have followed the oxidation of urofuran acid dimethyl esters (1-2) by HOCl; the oxidation was accomplished within 30 s at room temperature. Although we have not



SCHEME 2

been able to isolate the diastereomers, the structures of the oxidation products, **3a–b** and **4a–b** were established by detailed spectroscopic examination.

Initially, we expected that the oxidation would proceed in a fashion similar to that of F-acid to give the corresponding dicarbonyl compounds. However, the oxidation products were found to be very different. The ^{13}C NMR spectra showed no signal that would be attributable to a carbonyl carbon.

The most interesting feature of the reaction mechanism is that the multi-step reaction proceeds under the influence of the electron withdrawing methoxycarbonyl group in 3-position of the furan ring. If the electron withdrawing group is absent, the oxidation will be completed at the initial stage to give the dicarbonyl compound (**8**). It appears that the electron withdrawing effect of the $COOCH_3$ group enhances the nucleophilic attack at the carbonyl group leading to the formation of an equilibrium mixture of diastereoisomers (**3a–b, 4a–b**) after repeated enol-carbonyl nucleophilic additions as shown in **9**.

In summary, this study provides a first example for the effects of an electron withdrawing substituent on the oxidation of urofuran acid dimethyl ester by HOCl. The methodology is simple and accurate and may be useful for the detection of urofuran acid oxidation products.

EXPERIMENTAL PROCEDURES

Materials. Commercial grade solvents and reagents were used without further purification. $CDCl_3$ and silica gel 60 for column chromatography were purchased from E. Merck (Darmstadt, Germany); silica gel K5 for TLC was obtained from Whatman Industrial Ltd. (Maidstone, England).

NaOCl solution. A solution of $Na_2S_2O_3$ ($Na_2S_2O_3 \cdot 5H_2O$, 10 g) in distilled water (400 mL) was calibrated with KIO_3. For this purpose, KIO_3 (102.4 mg, 0.4785 mmol) was dissolved in distilled water (50 mL). KI (2 g) and 50% H_2SO_4 (5 mL) were added to the solution, and the mixture was titrated with $Na_2S_2O_3$ solution. When the color of the solution changed to yellow, 1% soluble starch (1 mL) was added, and the end-point of the titration was determined by disappearance of the blue color. As 1 mol of KIO_3 reacts with 6 mol of $Na_2S_2O_3$, the concentration of $Na_2S_2O_3$ was calculated to be 0.1002 M. Then 1 mL of NaOCl solution was added to 50 mL of distilled water, KI (2 g) and 6 M HCl (2 mL) were added to the solution, and the mixture was titrated with 0.1002 M $Na_2S_2O_3$. As 1 mol NaOCl reacts with 2 mol $Na_2S_2O_3$, the concentration of the NaOCl solution was found to be 1.54 M.

HPLC condition. A model LC-4A chromatograph (Shimadzu, Kyoto, Japan) with a SPD-2AS spectrophotometric detector was used together with an chromatopac C-R2AX integrator. Analyses were done on a TSK gel ODS 80TM (4.6 mm i.d. × 25 cm, particle size 5 μm) column. Acetonitrile/water (55:45, vol/vol) was used as mobile phase at a flow rate of 1.0 mL/min for the analysis of the oxidation products of **1** and **2**; detection wave length was 220 nm and the injection volume was 10 μL.

NMR. ^{13}C NMR and ^1H NMR spectra were recorded on a JNM FX-200 (JEOL, Tokyo, Japan) (50/200 MHz). Chemical shifts are expressed in parts per million (δ) downfield from tetramethylsilane (TMS) unless stated otherwise. DEPT was employed to assign carbon multiplicities (*s*,C; *d*,CH; *t*,CH_2; *q*,CH_3).

Mass spectrometry. Electron impact ionization mass spectra were recorded on a JMS D-300 mass spectrmeter (JEOL) under the following conditions: ionizing energy 70 eV, ionizing current 100 μA, ion source temperature 160°C, and accelerating voltage 3 kV. Chemical ionization mass spectra (CI-MS) using ammonia as a reactant gas were recorded under the same conditions as the EI-MS except for the ionizing energy (200 eV).

Fast atom bombardment mass spectra were recorded on a JMS DX-303 mass spectrometer (JEOL) using the negative ionization mode and a glycerol matrix.

Gas chromatography/mass spectrometry (GC/MS) was performed using a Hewlett-Packard 5710A instrument and a DB1 column (30 m × 0.25 mm i.d.) (Palo Alto, CA) with temperature programming (160°C–250°C at 3°C/min); helium was used as carrier gas at a flow rate of 0.9 mL/min. Oxidation products were trimethylsilylated at 110°C for 60 min with a mixture of TRI-SIL®Z, trimethylchlorosilane and *N,O-bis*-trimethylsilylacetamide in a ratio of 2:1:1 and subjected to GC/MS analysis.

Synthesis of methyl 3-methoxycarbonyl-4-methyl-5-propyl-2-furan propionate (1). CMPF was synthesized according to the method described by Spiteller *et al.* (12) using 3-ketoadipic acid diethyl ester instead of dimethyl ester. A solution of 3-hydroxy-2-hexanone (7.7 g, 66.4 mmol), 3-ketoadipic acid diethyl ester (19.8 g, 91.7 mmol), $ZnCl_2$ (7.0 g), and ethanol (16 mL) were refluxed for 20 h. After pouring into water (50 mL), the reaction mixture was extracted with benzene. The extract was washed successively with 30% $NaHSO_3$, 5% NaOH, and 0.1 M HCl. After dry over anhydrous Na_2SO_4, the extract was evaporated under reduced pressure to give an oil (18.4 g), which was chromatographed on silica gel. Elution with ethyl acetate/hexane (1:9, vol/vol) gave a mixture of ethyl 3-ethoxycarbonyl-4-propyl-5-methyl-2-furanpropionate and ethyl 3-ethoxycarbonyl-4-methyl-5-propyl-2-furanpropionate (9.5 g), which were hydrolyzed by refluxing with a mixture of 10% NaOH (32 mL) and ethanol (324 mL) for 6 h. The mixture acidified to pH 1 with 6 M HCl was extracted with diethyl ether and dried over anhydrous Na_2SO_4. The extract was evaporated to dryness to give a mixture of 3-carboxy-4-methyl-5-propyl-2-furanpropionic acid and 3-carboxy-4-propyl-5-methyl-2-furanpropionic acid (4.1 g). Two recrystallizations of the mixture from

chloroform gave 1.56 g (38.0%) of CMPF as a white powder; m.p. 180–182°C. ^{1}H NMR (D_2O, ppm from DSS) δ: 0.87 (3H, *t*, $J = 7.3$ Hz, $CH_2CH_2CH_3$), 1.57 (2H, *m*, $CH_2CH_2CH_3$), 1.98 (3H, *s*, Furan-CH_3), 2.46 (2H, *t*, $J = 7.9$ Hz, CH_2CH_2COOH), 2.52 (2H, *t*, $J = 7.3$ Hz, $CH_2CH_2CH_3$), 3.03 (2H, *t*, $J = 7.9$ Hz, CH_2CH_2COOH). EI-MS *m/z* (relative intensity): 240 (M^+, 10.8), 222(15.7), 211(17.6), 194(39.2), 193(27.5), 181(15.7), 165(100), 149(50.0), 147(11.8), 91(11.8), 77(21.6), 55(31.4).

A solution of CMPF (1.0 g, 4.17 mmol) in a mixture of methanol (12 mL) and benzene (40 mL), was treated with ethereal diazomethane prepared from *N*-methyl-*N*-nitrosourea. After removal of the solvent, the residue was chromatographed on silica gel. Elution with ethyl acetate/hexane (1:4, vol/vol) gave 0.88 g (78.7%) of **1** as a colorless oil. ^{1}H NMR (^{13}C-^{1}H correlation spectroscopy [COSY]) ($CDCl_3$) δ: 0.88 (3H, *t*, $J = 7.3$ Hz, $CH_2CH_2CH_3$), 1.57 (2H, *m*, $CH_2CH_2CH_3$), 2.05 (3H, *s*, Furan-CH_3), 2.45 (2H, *t*, $J = 7.3$ Hz, $CH_2CH_2CH_3$), 2.65 (2H, *t*, $J = 7.7$ Hz, $CH_2CH_2COOCH_3$), 3.24 (2H, *t*, $J = 7.7$ Hz, $CH_2CH_2COOCH_3$), 3.68 (3H, *s*, $CH_2CH_2COOCH_3$), 3.80 (3H, *s*, $COOCH_3$). ^{13}C NMR: see TAble 1. EI-MS *m/z* (relative intensity): 268 (M^+, 29.0), 239(18.8), 237(20.4), 209(19.4), 208(89.2), 207(17.7), 195(52.7), 179(100), 147(12.4), 55(12.9).

Synthesis of methyl 3-methoxycarbonyl-4-methyl-2-furanpropionate (2). 3-Carboxy-4-methyl-2-furan-propionic acid was synthesized by the procedure described by Pfordt *et al.* (13). The crystals appeared as colorless plates; m.p. 188–192°C, ^{1}H NMR (D_2O, ppm from DSS) δ: 2.02 (3H, *d*, $J = 1.2$ Hz, Furan-CH_3), 2.46 (2H, *t*, $J = 7.7$ Hz, CH_2CH_2COOH), 3.05 (2H, *t*, $J = 7.7$ Hz, CH_2CH_2COOH), 7.12 (1H, *q*, $J = 1.2$ Hz, Furan-*H*). EI-MS *m/z* (relative intensity): 198 (M^+, 19.4), 180(11.8), 152(100), 139(32.3), 138(9.7), 135(20.4), 121(7.5), 79(10.8), 77(8.6), 65(9.1).

A solution of 3-carboxy-4-methyl-2-furanpropionic acid (1.1 g, 5.56 mmol) in a mixture of methanol (12 mL) and benzene (40 mL) was treated with ethereal diazomethane prepared from *N*-methyl-*N*-nitrosourea, and evaporated under reduced pressure. The residue was purified by silica gel column chromatography to give 1.0 g (79.5%) of **2** as a colorless oil. ^{1}H NMR ($CDCl_3$) δ: 2.14 (3H, *d*, $J =$ 1.3 Hz, Furan-CH_3), 2.69 (2H, *t*, 7.7 Hz, $CH_2CH_2COOCH_3$), 3.29 (2H, *t*, 7.7 Hz, $CH_2CH_2COOCH_3$), 3.69 (3H, *s*, $CH_2CH_2COOCH_3$), 3.83 (3H, *s*, $COOCH_3$), 7.06 (1H, *q*, $J = 1.3$ Hz, Furan-*H*). ^{13}C NMR: see Table 1. EI-MS *m/z* (relative intensity): 226 (M^+, 24.6), 195(27.1), 194(25.4), 166(100), 153(45.8), 135(28.8), 134(9.3), 77(6.8), 59(6.8).

Reaction of **1** *with HOCl.* A solution of sodium hypochlorite (154 mM, 14.0 mL) was added with stirring to a mixture of **1** (310 mg, 1.16 mmol), acetone (85 mL) and sodium phosphate buffer (pH 7.40, 170 mL 0.15 M). After stirring for 30 s, the mixture was extracted with diethyl ether (3 × 500 mL). The extracts were dried over Na_2SO_4 and evaporated to dryness. The residual viscous oil was chromatographed on silica gel. Elution with ethyl acetate/hexane (7:3, vol/vol) gave three fractions: Fraction 5 (26.3 mg, 8.4%, R_f 0.97), Fractions 6–8 (172.0 mg, 54.8%, R_f 0.97, 0.91, 0.57) and Fractions 9–14 (115.5 mg, 36.8%, R_f 0.79 and 0.57). Effluents were gathered in a fraction collector in 9-mL volumes. One μL of each fraction was applied to a TLC plate which was developed with ethyl acetate/hexane (7:3, vol/vol). Fractions were detected by treatment with 50% H_2SO_4 and heating at 150°C for 3 min. Fractions 9–14: ^{1}H NMR ($CDCl_3$) δ: 0.90 (3H, *t*, $J = 7.0$ Hz, $CH_2CH_2CH_3$), 1.2–2.0 (4H, *m*, $CH_2CH_2CH_3$ and $CH_2CH_2CH_3$), 2.07 (3H, *s*, Furan-CH_3), 2.2–2.6 (4H, *m*, $CH_2CH_2COOCH_3$ and $CH_2CH_2COOCH_3$), 3.39 (1H, *s*, OH of **3b**, D_2O exchangeable), 3.63 (3H, *s*, $CH_2CH_2COOCH_3$ of **3b**), 3.67 (3H, *s*, $CH_2CH_2COOCH_3$ of **3a**), 3.80 (3H, *s*, $COOCH_3$), 3.95 (1H, *s*, OH of **3b**, D_2O exchangeable), 4.10 (1H, *s*, OH of **3a**, D_2O exchangeable), 5.18 (1H, *s*, OH of **3a**, D_2O exchangeable). ^{13}C NMR data are summarized in Table 1. Negative FAB-MS *m/z*: 301 ($[M - H]^-$), 284 ($[M - H]^- - OH$), 283 ($[M - H] - H_2O$), 269 ($[M - H]^- - CH_3OH$); CI-MS (ammonia) *m/z*: 302; EI-MS *m/z* (relative intensity): 284 ($M^+ - H_2O$, 5.0), 266(33.7), 253(19.1), 241(56.3), 237(12.6), 210(14.4), 209(29.4), 207(20.7), 206(28.9), 193(23.0), 181(100), 165(31.6), 149(19.0), 115(32.0), 71(15.2), 67(20.3), 59(17.5), 55(36.7). *anal.* Calcd for $C_{14}H_{22}O_7$: C, 55.62; H, 7.34. Found: C, 54.83; H, 7.29, GC/MS analysis of the trimethylsilylated derivatives showed two components in a ratio of 1:1.28 with retention times of 13.9 min and 15.3 min, respectively. Reaction of **2** *with HOCl.* A solution of sodium hypochlorite (1.54 M, 700 μL) was added with stirring to a mixture of **2** (230 mg, 1.02 mmol), acetone (16 mL), and sodium phosphate buffer (pH 7.40, 46 mL of 0.15 M). After stirring for 30 s, the reaction mixture was extracted with diethyl ether (150 mL × 3), and the extracts were dried over Na_2SO_4 and evaporated under reduced pressure at 10°C to give an oil, which was chromatographed on silica gel. Elution with ethyl acetate/hexane (7:3, vol/vol) gave a colorless viscous oil (97 mg). ^{1}H NMR ($CDCl_3$) δ: 2.13 (3H, *s*, Furan-CH_3), 2.2–2.5 (4H, *m*, CH_2CH_2 and CH_2CH_2), 3.66 (3H, *s*, $CH_2CH_2COOCH_3$), 3.81 (3H, *s*, $COOCH_3$), 4.09 (1H, *d*, $J = 8.8$ Hz, 5-OH of **4b**), 4.44 (1H, *d*, $J = 9.3$ Hz, 5-OH of **4a**), 4.91 (1H, *s*, 2-OH of **4a** or **4b**), 5.56 (1H, *d*, $J = 9.3$ Hz, 5-H of **4a**), 5.88 (1H, *d*, 8.8 Hz, 5-H of **4b**). ^{13}C NMR: see Table 1. Negative FAB-MS *m/z*: 259 ($[M - H]^-$), 242 ($[M - H]^- - OH$), 241 ($[M - H]^- - H_2O$), 227 ($[M - H]^- - CH_3OH$); CI-MS (ammonia) *m/z:* 260; EI-MS *m/z* (relative intensity): 242 ($M^+ - H_2O$, 25.5), 211 (38.6), 210(100), 183(33.7), 182(45.2), 173(21.7), 155(29.2), 151(20.0), 150(52.1), 127(60.2), 123(53.2), 122(21.1), 115(65.0), 95(22.1), 67(29.6), 59(46.1), 55(63.3). GC/MS analysis of the trimethylsilylated derivatives showed two components in a ratio of 1:2.20 with retention times of 10.2 min and 11.0 min, respectively. Component with retention time 10.2 min *(trans):* EI-MS *m/z* (relative intensity): 403 ($M^+ - H$, 1.0), 389 ($M^+ - 15$, 5.4), 317(91.7), 315(6.3), 299(7.3), 241(16.7), 193(6.3), 185(33.3), 169(12.5), 147(15.6), 127(12.5), 123(13.5), 89(16.7), 75(27.1), 73(100); CI-MS (ammonia) *m/z:* 422 (MNH_4^+), 322 ($MNH_4^+ - (CH_3)_3SiOH$), 315

$(MH^+ - (CH_3)_3SiOH)$, 260 $(242 + NH_4)$, 242 $(NH_4^+ - (CH_3)_3SiOH - (CH_3)_3SiOH)$. Component with retention time 11.0 min *(cis):* EI-MS *m/z* (relative intensity): 403 $(M^+ - H, 1.0)$, 389(6.0), 317(82.8), 315(10.9), 299(17.2), 241(11.2), 193(10.3), 185(32.8), 169(16.4), 147(30.2), 127(12.9), 123(20.7), 89(20.7), 75(30.2), 73(100); CI-MS (ammonia) *m/z*: 422 (MNH_4^+), 322 $(MNH_4^+ - (CH_3)_3SiOH)$, 315 $(MH^+ - (CH_3)_3SiOH)$, 260 $(242 + NH_4)$, 242 $(NH_4^+ - (CH_3)_3SiOH - (CH_3)_3SiOH)$.

Reaction of 5 *with HOCl.* A solution of sodium hypochlorite (0.154 M, 40.6 mL) was added with stirring to a mixture of 5 (610 mg, 6.35 mmol), acetone (255 mL), and sodium phosphate buffer (pH 7.40, 510 mL of 0.15 M). After 30 s, the mixture was extracted with diethyl ether (1 L × 3). The extracts were dried over Na_2SO_4 and concentrated under reduced pressure below 10°C to give a residue which was chromatographed on silica gel. Elution with ethyl acetate/hexane (4:6, vol/vol) gave 287 mg (40.3%) of *cis*-1,2-diacetylethylene (**6**) as a liquid (287 mg). ^1H NMR ($CDCl_3$) δ: 2.26 (6H, *s*, $2 \times CH_3$), 6.28 (2H, *s*, CH=CH). ^{13}C NMR ($CDCl_3$) δ: 29.57 (CH_3), 135.50 (CH=CH), 200.27 (C=O). EI-MS *m/z* (relative intensity): 112 (M^+, 20.5), 97 (54.0), 69 (14.2), 43 (100).

ACKNOWLEDGMENTS

We are grateful to Nanae Miyara for excellent technical assistance and Dr. Seiji Nagao for his help in the preparation of the manuscript. We thank Dr. Hideki Hattori for providing FAB-MS spectra (Aichi Medical University). We are indebted to Dr. Kazuhiro Ohta for his interest and encouragement.

Synthesis of Phenyl Substituted C_{18} Furanoid Fatty Esters

Marcel S.F. Lie Ken Jie* and **K.P. Wong**
Department of Chemistry, University of Hong Kong, Hong Kong

Methyl 9,12-epoxy-10-phenyl-9,11-octadecadienoate was prepared by acid catalyzed cyclization of methyl 9,12-dioxo-10-phenyloctadecanoate, which was derived from the oxidation of methyl 9-hydroxy-12-oxo-10-phenyloctadecanoate. The latter was exclusively obtained from methyl *cis*-9,10-epoxy-12-oxooctadecanoate with phenyllithium in the presence of copper (I) bromide. A mixture of positional isomers, methyl 9,12-epoxy-10(11)-phenyl-9,11-octadecadienoates, was also prepared by another route. The spectroscopic properties of the various intermediates and products were studied. The positional isomers of the phenyl substituted furanoid fatty esters were characterized by ^{13}C nuclear magnetic resonance spectrometry.
Lipids 28, 43–46 (1993).

Long-chain fatty acids containing a furan nucleus in the alkyl chain have been found in the lipid extracts of fish (1–5), plants (6–9), soft corals (10), crayfish (11), amphibians and reptiles (12) and in human and bovine blood plasma (13,14). Biosynthetic experiments by Sand *et al.* (15) have shown that furanoid fatty acids in fish are not produced from acetate by *de novo* synthesis, while Gorst-Allman *et al.* (16) have ruled out 10,13-nonadecadienoic acid as a possible precursor of furanoid fatty acids in animals.

In natural furanoid fatty acids, the only substituent found at the 3- and/or 4-position of the furan ring is a methyl group. We have reported the synthesis of the mono- and dimethyl substituted C_{18} furanoid fatty acid derivatives (17,18) and have recently extended this work to show the possible conversion of a malonic acid group to a methyl substituent (19). In the present paper, we describe the synthesis of a C_{18} furanoid fatty ester derivative containing a phenyl group in the 3-position of the furan ring (Scheme 1) and another procedure for the preparation of a mixture of positional isomers of C_{18} furanoid fatty esters containing a phenyl group at either the 3- or 4- position of the furan ring (Scheme 2).

MATERIALS AND METHODS

Thin-layer chromatography (TLC) was carried out on silica gel coated microscope slides (*ca.* 0.1 mm layers). Preparative TLC separations were done on glass plates (20 × 20 cm) coated with silica gel (0.7-mm layers). Column chromatographic purifications were done on silica gel, and mixtures of light petroleum (b.p. 60–80°C)/diethyl ether were used as eluent. Elemental analyses were carried out by Butterworth Laboratories Ltd. (Teddington, Middlesex, England, U.K.). Infrared spectra were obtained with a Perkin-Elmer 577 (Perkin-Elmer, Norwalk, CT) spectrophotometer. Nuclear magnetic resonance (NMR) spectra were recorded with a JEOL FX-90Q (90 MHz) (JEOL Ltd., Tokyo, Japan) Fourier transform spectrometer at 89.56 MHz for protons and at 22.5 MHz for carbon. Chemical shifts are expressed as ppm relative to tetramethylsilane used as an internal standard. Methyl ricinoleate (methyl 12-hydroxy-*cis*-9-octadecenoate) (1) was obtained from castor oil. Methyl 12-oxo-9-*cis*-octadecenoate (2), methyl *cis*-9,10-epoxy-12-oxooctadecanoate (3) and methyl 9,12-epoxy-9,11-octadecadienoate (7) were prepared by methods described elsewhere (18). Benzohydroxamic acid was prepared according to the procedure described by Hauser and Renfrow (20). Phenyllithium in

cyclohexane/ether was purchased from Aldrich Chemical Co. (Milwaukee, WI). All solvents were distilled and dried before use.

Preparation of methyl 9-hydroxy-12-oxo-10-phenyloctadecanoate (4). Phenyllithium in cyclohexane/ether (1.8 M, 6.4 mL) was added dropwise to a suspension of copper(I) bromide (0.83 g, 5.8 mmol) in diethyl ether (20 mL) at 0°C under nitrogen and stirred for 30 min. Methyl *cis*-9,10-epoxy-12-oxooctadecanoate (3, 1.5 g, 4.6 mmol) in anhydrous diethyl ether (30 mL) was added, and the reaction mixture stirred for a further 2 h at 0°C. Saturated aqueous ammonium chloride solution (50 mL) was added, and the reaction mixture was extracted with diethyl ether (3 × 50 mL). The organic extract was washed with brine (2 × 20 mL) and was dried over anhydrous sodium sulfate. The solvent was evaporated, and the residue was chromatographed on a silica column (100 g) using a mixture of light petroleum/diethyl ether (3:2, vol/vol) as eluant to give methyl 9-hydroxy-12-oxo-10-phenyloctadecanoate (4, 0.96 g, 52%) as an oil. Retardation factor (R_f) 0.3 (PE30); infrared (IR) (cm^{-1}) (film) 3400(*s*, O-H stretching), 1740(*s*, C=O stretching), 1580(*m*), 1450(*m*); ^1H NMR ($CDCl_3$, δ): 0.87 (*t*, 3H, CH_3), 1.2–1.8 (*m*, 18H, CH_2), 2.30 (*t*, $J = 7.5$ Hz, 2H, 2-*H*), 2.4–2.6 (*m*, 7H), 3.66 (*s*, 3H, $COOCH_3$), 4.05 (*q*, 1H, $J = 7.0$ Hz, *CH*OH), 6.7–6.9 (*m*, 3H, arom.) and 7.0–7.3 (*m*, 2H, arom.); ^{13}C NMR ($CDCl_3$, ppm): 14.0 (C-18), 22.5 (C-17), 23.6 (C-14), 24.9 (C-3), 25.6 (C-7), 29.0, 29.1, 29.3, 31.6 (C-16), 34.1 (C-2), 34.4 (C-8), 43.6 (C-13), 45.2 (C-11), 46.2 (C-10), 51.4 ($COOCH_3$), 60.3 (C-9), 128.4 (C-4′ arom.), 128.7 (C-2′ arom.), 129.0 (C-3′ arom.), 129.4 (C-1′ arom.), 174.5 (C-1) and 210.9 (C-12).

Preparation of methyl 9,12-dioxo-10-phenyloctadecanoate (5). Compound 4 (0.18 g, 0.44 mmol) was dissolved in diethyl ether (80 mL) and chromic acid (2.0 mL, prepared from 20 g of sodium dichromate, 28 g sulfuric acid and 65 mL water) was added over a period of 5 min at room temperature. The reaction mixture was stirred for a further 30 min. The ethereal solution was washed with water (20 mL) and then with sodium hydrogencarbonate (10%, 20 mL). The organic mixture was dried over anhydrous sodium sulfate. Silica column chromatographic purification gave methyl 9,12-dioxo-10-phenyloctadecanoate (5, 0.17 g, 95%) as an oil. R_f 0.5 (PE30); ^1H NMR ($CDCl_3$, δ): 0.87 (*t*, 3H, CH_3), 1.2–1.8 (*m*, 18 H, CH_2), 2.2–2.6 (*m*, 6H, CH_2), 3.39 (*d*, $J = 10.3$ Hz, 1H, CH_2CHPh), 3.43 (*d*, $J = 10.3$ Hz, 1H, CH_2CHPh), 3.66 (*s*, $COOCH_3$), 4.20, 4.23 (*d*, $J = 3.9$ Hz, 1H, *CH*Ph) and 7.1–7.5 (*m*, 5H, arom.); ^{13}C NMR ($CDCl_3$, ppm): 14.0 (C-18), 22.4 (C-17), 23.6 (C-14), 23.8 (C-7), 24.9 (C-3), 28.6, 28.7, 28.9, 31.5 (C-16), 34.3 (C-2), 41.6, 42.9 (C-8/C-13), 45.8 (C-11), 51.4 ($COOCH_3$), 53.3 (C-10), 127.4 (C-4′ arom.), 128.3 (C-2′ arom.), 129.0 (C-3′ arom.), 138.1 (C-1′ arom.), 174.4 (C-1), 209.8 and 210.0 (C-9/C-12).

Preparation of methyl 9,12-epoxy-10-phenyl-9,11-octadecadienoate (6). A mixture of compound 5 (0.15 g, 0.37 mmol), boron trifluoride etherate (0.2 mL) and chloroform (10 mL) was stirred at room temperature for 3 h. Water (20 mL) was added and the chloroform layer was isolated. The organic layer was then dried over anhydrous sodium sulfate. The solvent was evaporated under reduced pressure, and the residue was separated by preparative TLC using a mixture of light petroleum/diethyl ether, (95:5, vol/vol) as developing solvent to give methyl 9,12-epoxy-10-phenyl-9,11-octadecadienoate (6, 0.13 g, 93%). Elemental analysis: Calc. for $C_{25}H_{36}O_3$ (%), C, 78.08; H, 9.44; O, 12.48; found, C, 78.18; H, 9.41; O, 12.50. R_f 0.8 (PE20); IR (cm^{-1}) (film): 3100 (*w*, C-H furan and arom.), 1740 (*s*, C=O stretching), 1560, 1442, 1010 (*m*, C-O-C furan), 790 and 730; ^1H NMR ($CDCl_3$, δ): 0.88 (*t*, 3H, CH_3), 1.2–1.4 (*m*, 12H, CH_2), 1.4–1.8 (*m*, 6H, CH_2), 2.29 (*t*, 2H, 2-*H*), 2.60 (*t*, $J = 7.0$ Hz, 2H, 13-*H*), 2.73 (*t*, $J = 7.0$ Hz, 2H, 8-*H*), 3.65 (*s*, 3H, $COOCH_3$), 6.07 (*s*, 1H, furan *CH*) and 7.33 (*s*, 5H, arom.); ^{13}C NMR ($CDCl_3$, ppm): 14.1 (C-18), 22.6 (C-17), 24.9 (C-3), 27.0 (C-8), 28.0 (C-13), 28.1, 28.6, 29.0, 31.6 (C-16), 34.1 (C-2), 51.4 ($COOCH_3$), 106.2 (C-11), 121.2 (C-10), 126.0 (C-4′ arom.), 127.6 (C-2′ arom.), 128.4 (C-3′ arom.), 134.8 (C-1′ arom.), 149.8 (C-9), 154.3 (C-12) and 174.2 (C-1).

Preparation of methyl dioxazolyl C_{18}-enone esters (8a,8b). A mixture of methyl 9,12-epoxy-9,11-octadecadienoate (7, 14 g, 45.5 mmol), benzohydroxamic acid (9 g,

65 mmol), lead(IV) oxide (60 g, 0.25 mol) and ethyl acetate (150 mL) was stirred at room temperature for 24 h. The reaction mixture was filtered and the solvent was evaporated under reduced pressure. The residue was chromatographed on a silica column (200 g) using a mixture of light petroleum/diethyl ether (7:3, vol/vol) as eluant to give compounds **8a,8b** (14.7 g, 73%) as an oil. R_f 0.35 (PE40); IR (cm^{-1}) (film): 1735 (*s*, C=O stretching, ester), 1690 (*s*, C=O stretching, oxo), 1620 (m), 1450, 1360, 760, 690; ^1H NMR ($CDCl_3$, δ): 0.87 (*t*, 3H, CH_3), 1.2-1.4 (*m*, 12H, CH_2), 1.6-1.8 (*m*, 6H, CH_2), 2.20 (*t*, 2H, $J = 7.5$ Hz, $CH_2COOCNPh$), 2.30 (*t*, 2H, 2-*H*), 2.51 (*t*, $J = 7.5$ Hz, 2H, $COCH_2$), 3.66 (*s*, 3H, $COOCH_3$), 5.84, 6.18 (2*d*, $J = 12.8$ Hz, 2H, CH=CH), 7.3-7.5 (*m*, 3H, arom.) and 7.6-7.8 (*m*, 2H, arom.); ^{13}C NMR ($CDCl_3$, ppm): 14.0 (C-18), 22.5 (C-17), 23.4 (C-7 or C-14), 24.9 (C-3), 28.9, 29.0, 29.1, 29.3, 31.7 (C-16), 34.0 (C-2), 37.7, 37.8, ($CH_2COOCNPh$), 43.3, 43.5 ($COCH_2$), 51.2 ($COOCH_3$), 115.4 (COOCNPh), 123.4 (C-4′ arom.), 126.8 (C-2′ arom.), 128.7 (C-3′ arom.), 131.4 (C-1′ arom.), 132.4, 132.7 (C-10 or C-11), 158.1 (C=N), 173.8 (C-1) and 203.0 (C=O, oxo).

Preparation of phenyl substituted dioxazolyl C_{18}-keto esters (**9a,9b**). A mixture of freshly prepared copper(I) bromide (0.85 g, 5.9 mmol), phenyllithium (6.6 mL of a 1.8 *M solution) and anhydrous diethyl ether (150 mL)* was stirred at 0°C under nitrogen for 15 min. The mixture of compounds **8a,8b** (2.0 g, 4.5 mmol) was added and the temperature maintained at 0-5°C for 1 h. The reaction mixture was stirred for 10 h at room temperature and was then poured into cold aqueous ammonium chloride (2.0 M, 150 mL). The product was isolated by extraction with diethyl ether (2 × 100 mL) and was dried over anhydrous sodium sulfate. The solvent was evaporated, and silica gel column chromatography of the residue yielded a mixture of compounds **9a,9b** (1.8 g, 80%) as an oil. R_f 0.3 (PE40); IR (cm^{-1}) (film): 1734 (*s*), 1690 (*s*), 1615, 1570, 1440, 790, 720; ^1H NMR ($CDCl_3$, δ): 0.81 (*t*, 3H, CH_3), 1.2-1.8 (*m*, 20H, CH_2), 2.1-2.4 (*m*, 4H, CH_2), 2.90 (*m*, 2H, CH_2CHPh), 3.65 (*s*, 3H, $COOCH_3$), 3.78 (*dd*, $J = 4.0$, 9.0 Hz, 1H, CHPh) and 7.1-7.8 (*m*, 10H, arom.); ^{13}C NMR ($CDCl_3$, ppm): 13.9 (C-18), 22.4 (C-17), 23.5 (CH_2CH_2CO), 24.8 (C-3), 28.7, 28.8, 28.9, 29.1, 29.2, 31.5 (C-16), 34.1 (C-2), 36.4 (C-8 or C-13), 42.8 (CH_2CHPh), 43.4 (CH_2CO), 47.8 (CHPh), 51.4 ($COOCH_3$), 119.8 (COOCNPh), 123.1 (arom.), 126.7 (arom.), 127.3 (arom.), 128.4 (arom.), 128.7 (arom.), 129.1 (arom.), 131.4 (arom.), 138.9 (arom.), 158.6 (C=N) and 174.1 (C-1).

Preparation of methyl 9,12-dioxo-10(11)-phenyloctadecanoates (**5,5a**). A mixture of compounds **9a,9b** (1.5 g, 2.8 mmol and aqueous ethanol (50%, 60 mL) was refluxed for 20 h. Water (50 mL) was added, and the reaction mixture extracted with diethyl ether (2 × 50 mL). The ethereal extract was washed with water (20 mL) and was dried over anhydrous sodium sulfate. The solvent was evaporated, and the residue was chromatographed on a silica gel column using a mixture of petroleum ether/diethyl ether (4:1, vol/vol) as eluent to give a mixture of methyl 9,12-dioxo-10(11)-phenyloctadecanoates (**5,5a**) (0.97 g, 86%) as an oil. R_f 0.30 (PE40); IR (cm^{-1}) (film): 1740 (*s*, C=O stretching, ester), 1703 (*s*, C=O stretching, oxo), 1565, 1446, 790, 730. ^1H NMR ($CDCl_3$, δ): 0.87 (*t*, 3H, CH_3), 1.2-1.8 (*m*, 18H, CH_2), 2.2-2.6 (*m*, 6H, CH_2), 3.39 (*d*, $J = 10.3$ Hz, 1H, CH_2CHPh), 3.43 (*d*, $J = 10.3$ Hz, 1H, CH_2CHPh), 3.66 (*s*, 3H, $COOCH_3$), 4.20, 4.23 (*d*, $J = 3.9$ Hz, 1H, CHPh) and 7.1-7.5 (*m*, 5H, arom.); ^{13}C NMR ($CDCl_3$, ppm): 14.0 (C-18), 22.4 (C-17), 23.6, 23.8 (CH_2CO), 24.9 (C-3), 28.6, 28.7, 28.9, 31.5 (C-16), 34.3 (C-2), 41.6, 42.9 (CH_2CO), 45.8 ($COCH_2CHPh$), 51.4 ($COOCH_3$), 53.3 (CHPh), 127.4 (C-4′ arom.), 128.3 (C-2′ arom.), 129.0 (C-3′ arom.), 138.1 (C-1′ arom.), 174.4 (C-1), 209.8 and 210.0 (C=O, oxo).

Preparation of methyl 9,12-epoxy-10(11)-phenyl-9,11-octadecadienoates (**6,6a**). A mixture of methyl 9,12-dioxo-10(11)-phenyloctadecanoates (**5,5a**) (1.0 g, 2.6 mmol), boron trifluoride etherate (0.5 mL) and chloroform (20 mL) was stirred at room temperature for 3 h. Aqueous sodium carbonate (10%, 10 mL) was added, and the organic mixture was extracted with diethyl ether (2 × 20 mL). The solvent was evaporated and silica gel column chromatography of the residue gave compounds (**6,6a**) as an oil (0.96 g, 96%). R_f 0.8 (PE30); IR (cm^{-1}) (film): 1740 (*s*, C=O stretching), 1560 (*m*), 1142, 1010 (*w*), 790, 730; ^1H NMR ($CDCl_3$, δ): 0.88 (*t*, 3H, CH_3), 1.2-1.4 (*m*, 12H, CH_2), 1.4-1.8 (*m*, 6H, CH_2), 2.29 (*t*, 2H, 2-*H*), 2.60 (*t*, $J = 7.5$ Hz, 2H), 2.73 (*t*, $J = 6.8$ Hz, 2H), 3.65 (*s*, 3H, $COOCH_3$), 6.07 (*s*, 1H, furan CH) and 7.2-7.4 (*m*, 5H, arom.); ^{13}C NMR ($CDCl_3$, ppm): 14.1 (C-18), 22.6 (C-17), 24.9 (C-3), 26.9, 27.0 (α-CH_2 to furan), 28.0, 28.6, 29.0, 31.6 (C-17), 34.1 (C-2), 51.4 ($COOCH_3$), 106.0, 106.2 (CH furan), 121.2 (C-Ph), 126.0 (C-1′ arom.), 127.6 (C-2′ arom.), 128.4 (C-3′ arom.), 134.8 (C-4′ arom.), 149.8, 150.0, 154.1, 154.3 (C-2′ furan) and 174.1 (C-1).

RESULTS AND DISCUSSION

Following our earlier success in the regiospecific methylation of methyl *cis*-9,10-epoxy-12-oxooctadecanoate (**3**) (18), the latter compound was reacted with lithiumdiphenyl cuprate [generated *in situ* from phenyllithium and copper(I) bromide] to yield methyl 9-hydroxy-12-oxo-10-phenyloctadecanoate (**4**, 52%), exclusively. Two-phase oxidation of compound **4** gave methyl 9,12-dioxo-10-phenyloctadecanoate (**5**, 95%). Compound **5** was cyclized in the presence of boron trifluoride etherate to methyl 9,12-epoxy-10-phenyl-9,11-octadecadienoate (**6**, 93%).

The infrared spectrum of compound **6** showed a weak absorption band at 3100 cm^{-1}, while the ester carbonyl function absorbed at 1740 cm^{-1}. The presence of the phenyl system in methyl 9,12-epoxy-10-phenyl-9,11-octadecadienoate (**6**) was apparent from the appearance of the signal at δ 7.33 (*s*, 5H) arising from the shift of the aromatic protons in the ^1H NMR spectrum. The furan proton (11-*H*) appeared at δ 6.07 (*s*, 1H). The effect of the phenyl group at the C-10 position caused the protons of the methylene groups adjacent to the furan nucleus to be chemically nonequivalent. The shifts of the 8-*H* and 13-*H* protons were found at δ 2.73 and 2.60, respectively.

In the ^{13}C NMR spectral analysis of compound **6**, the monosubstituted phenyl system was confirmed by the appearance of four signals in the aromatic region, *viz.* 126.0 (C-4′ arom.), 127.6 (C-2′ arom.), 128.4 (C-3′ arom.) and 134.8 (C-1′ arom.). The effect of the phenyl ring on the chemical shifts of the furan carbon atoms was very significant. The carbon atoms of the furan nucleus were shifted to 149.8 (C-9), 121.2 (C-10) and 154.3 (C-12), while the methine carbon of the furan appeared at 106.2 (C-11) ppm. The shifts of the methylene carbon atoms (C-8, C-13) adjacent to the furan nucleus were also affected by the phenyl substituent in the furan nucleus. The chemical shifts for the C-8 and

C-13 carbon atoms were found at 27.0 and 28.0 ppm, respectively.

In the preparation of a mixture of positional isomers of furanoid fatty ester derivatives containing a phenyl group at the 3- or 4- position of the furan nucleus (**6,6a**), methyl 9,12-epoxy-9,11-octadecadienoate (**7**) was stirred with benzohydroxamic acid in the presence of lead(IV) oxide. Ring opening of the furan ring resulted in the formation of a mixture of conjugated dioxazolyl C_{18}-enone intermediates (**8a,8b**, 73%) (21). This reaction was nonregiospecific, and compounds **8a,8b** contain an oxo group at either the C-9 or C-12 position of the alkyl chain. Treatment of the mixture of compounds **8a,8b** with phenyllithium in the presence of copper(I) bromide furnished the corresponding 1,4-Michael addition products (**9a,9b**, 80%). The dioxazolyl function was subsequently removed by refluxing with aqueous ethanol to yield methyl 9,12-dioxo-10(11)-phenyloctadecanoates (**5,5a**, 86%). The latter mixture of compounds was treated with boron trifluoride etherate in chloroform to furnish a mixture of positional isomers of phenyl furanoid fatty esters, methyl 9,12-epoxy-10(11)-phenyl-9,11-octadecadienoates (**6,6a**, 96%).

In the analysis of the mixture of compounds **6,6a**, the infrared and ^{1}H NMR spectra were identical to those recorded for the single isomer **6**. However, the presence of the two positional isomers (**6,6a**) in the mixture was apparent from the ^{13}C NMR spectral analysis. The chemical shifts of the furan carbon nuclei were resolved into seven signals (106.0, 106.2, 121.2, 149.8, 150.0, 154.1 and 154.3 ppm). As the shift values of the furan carbon nuclei (106.2, 121.2, 149.8 and 154.3 ppm) for compound **6** were already established, it was therefore possible to assign unequivocally the shifts of the carbon nuclei of the furan nucleus of compound **6a**. Thus, the chemical shifts of the furan carbon atoms of compound **6a** (methyl 9,12-epoxy-11-phenyl-9,11-octadecadienoate) appeared at 154.1, 106.0, 121.2 and 150.0 ppm for C-9, C-10, C-11 and C-12, respectively. ^{13}C NMR spectrometry thus permitted the full characterization of C_{18} furanoid fatty ester derivatives containing a phenyl substituent at the 3- or 4-position of the furan nucleus.

Preparation of Methyl 5,11,14,17-Eicosatetraenoate-8,8,9,9-d_4

Henry Rakoff*

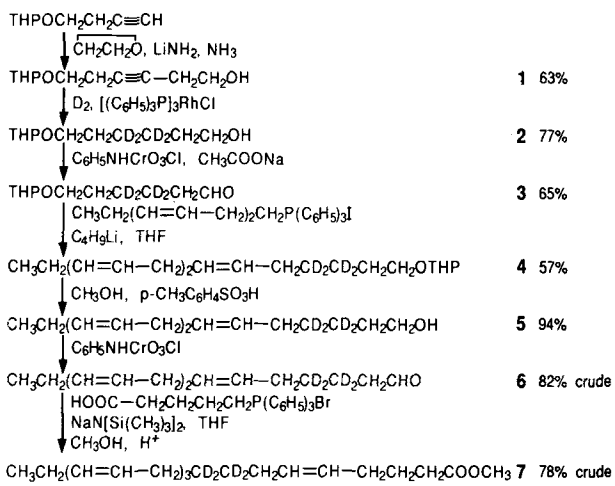
Food Quality and Safety Research, National Center for Agricultural Utilization Research, ARS, U.S. Department of Agriculture, Peoria, Illinois 61604

For studies of incorporation, elongation and desaturation of fats in humans and animals, methyl 5,11,14,17-eicosatetraenoate-8,8,9,9-d_4 was prepared by Wittig coupling, in the presence of sodium *bis*(trimethylsilyl) amide, of 6,9,12-pentadecatrienal-3,3,4,4-d_4 and 4-carboxybutyltriphenylphosphonium bromide. The all-*cis* isomer was separated from *trans* isomers and other impurities by silver resin chromatography. Location and configuration of the double bonds and deuterium atoms were affirmed by nuclear magnetic resonance and mass spectrometry.
***Lipids* 28, 47–50 (1993).**

For studies of incorporation, elongation and desaturation of fats in humans and animals (1,2), we have synthesized various monoenoic (3), dienoic (4) and tri- and tetraenoic (5–7) fatty acid esters labeled with deuterium in various positions. In this paper we describe the synthesis of methyl 5,11,14,17-eicosatetraenoate-8,8,9,9-d_4 (5,11,14,17-20:4-d_4) which is potentially an intermediate in the conversion of linolenate (9,12,15-18:3) to eicosapentaenoate (5,8,11,14,17-20:5). The 5,11,14,17-20:4-d_4 has been synthesized to study the proposed pathway (8) that involves the action of a Δ8 desaturase. The results of the biochemical investigation will be published separately.

RESULTS AND DISCUSSION

The original plan was to generate methyl 5,11,14,17-20:4-d_4 by Wittig coupling of 3,6-nonadienyltriphenylphosphonium iodide with methyl 11-oxo-5-undecenoate-8,8,9,9-d_4. The synthesis of the nine carbon phosphonium salt has been described previously (6,7). An improved preparation of 1-bromo-2-pentyne, the first intermediate in the synthesis of the phosphonium salt, is presented in this paper. The required aldehyde ester was to be obtained by oxidation of methyl 11-hydroxy-5-undecenoate-8,8,9,9-d_4. We thought this hydroxy ester should be accessible through Wittig reaction of 3,3,4,4-tetradeutero-6-hydroxyhexyltriphenylphosphonium iodide and methyl 5-oxopentanoate. However, the reaction did not yield the desired Wittig coupling product. A hydroxyphosphonium salt reacts with a simple aldehyde to give the expected Wittig coupling product but, according to Ohta *et al.* (9), the principal product (about 35% yield) of the reaction of a hydroxyphosphonium salt and an aldehyde ester is a macrocyclic lactone rather than the Wittig coupling product. In an effort to avoid this unwanted reaction, we prepared the tetrahydropyranyl (THP) ether of 6-hydroxyhexyltriphenylphosphonium bromide but were unable to obtain it in crystalline form. We were unsuccessful in our attempts to isolate a Wittig product from the reaction between the viscous phosphonium salt and the five-carbon aldehyde ester.



SCHEME 1

We then decided to approach the synthesis from the other end of the molecule (Scheme 1). This would involve coupling, *via* a Wittig reaction, 3,6-nonadienyltriphenylphosphonium iodide with the THP ether of 6-hydroxyhexanal-3,3,4,4-d_4, **3**, to yield, after hydrolysis, 6,9,12-pentadecatrienol-3,3,4,4-d_4, **5**.

For the synthesis of compound **3**, we condensed the THP ether of 3-butynol with ethylene oxide in the presence of lithium amide in liquid ammonia to give the mono-THP ether of 3-hexyne-1,6-diol, **1**. This compound was treated with deuterium gas in the presence of *tris*-(triphenylphosphine)chlororhodium to give the mono-THP ether of 1,6-hexanediol-3,3,4,4-d_4, **2**. Oxidation of this intermediate with pyridinium chlorochromate in the presence of sodium acetate (10) produced the THP ether of 6-hydroxyhexanal-3,3,4,4-d_4, **3**. Compound **3** was coupled with 3,6-nonadienyltriphenylphosphonium iodide and butyl lithium to give the THP ether of pentadecatrienol-3,3,4,4-d_4, **4**, which was then hydrolyzed to **5**. The pentadecatrienol-d_4, **5**, could be converted to the phosphonium iodide through the bromide. The phosphonium iodide could then be coupled with methyl 5-oxopentanoate to give 20:4-d_4. Alternatively, compound **5** could be oxidized to the corresponding aldehyde and coupled with 4-carboxybutyltriphenylphosphonium bromide (which is commercially available) to give 20:4-d_4. We chose the latter route. Accordingly, pentadecatrienol-d_4, **5**, was oxidized to pentadecatrienal-d_4, **6**, with pyridinium chlorochromate. With unsubstituted phosphonium salts, the Wittig reaction with butyl lithium as base yields about 10–15% *trans* in the coupled product. With carboxybutyltriphenylphosphonium bromide and nonanal we found that the Wittig reaction with butyl lithium gave about 30% *trans*

Abbreviations: DHP, dihydropyran; EE, diethyl ether; GC, gas chromatography; NMR, nuclear magnetic resonance; PE, petroleum ether (35–60°C); *p*-TSA, *p*-toluenesulfonic acid; THF, tetrahydrofuran; THP, tetrahydropyranyl.

isomer, and the yield was poor due to the formation of the aldol condensation product from the nonanal. We investigated other bases and settled on sodium *bis*(trimethylsilyl)amide (11) because it gave the desired product with only about 10% *trans*, and without the formation of the aldol product. Therefore we used sodium *bis*(trimethylsilyl)amide to condense pentadecatrienal-d_4, **6**, with 4-carboxybutyltriphenylphosphonium bromide to give compound **7**. The all-*cis* isomer of **7** was isolated on a 75% Ag/Na XN1010 column using 2–5% concentrations of acetonitrile in methanol as eluant.

EXPERIMENTAL PROCEDURES

Reagents. Butyl lithium, triphenylphosphine, dihydropyran, 4-carboxybutyltriphenylphosphonium bromide, 3-butynol, sodium *bis*(trimethylsilyl)amide and pyridinium chlorochromate were obtained from Aldrich Chemical Company (Milwaukee, WI). 2-Pentynol was purchased from Farchan Laboratories (Gainsville, FL), and *tris*(triphenylphosphine)chlororhodium was obtained from Strem Chemicals (Newburyport, MA). Silica gel (60–200 mesh) and Florisil (100–200 mesh) were purchased from J.T. Baker (Jackson, TN), and Silica Gel 60 A (70–230 mesh) was from American Scientific Products (McGaw Park, IL).

Methods. A 30 m × 0.25 mm SP2340 fused silica capillary column (Supelco, Inc., Bellefonte, PA) was used for analyzing binary mixtures of geometric isomers. For other analyses, a 6 ft × 4 mm column packed with 3% EGSS-X on 100/120 GasChrom Q or a 5 m × 0.53 mm HP-1 column (Hewlett-Packard Co., Avondale, PA) was employed.

^{13}C Nuclear magnetic resonance (NMR) spectra were recorded with a Bruker (Billerica, MA) WM 300 WB pulsed Fourier transform spectrometer operating at 75.5 MHz. Typically, 2500 transients were collected from solutions in $CDCl_3$, which served as both internal lock and secondary reference, using 5-mm tubes. Sweep widths of 200 ppm and 8 K real data points limited acquisition time to 0.54 s and were used to obtain chemical shift values within ± 1.85 Hz, *i.e.*, ±0.05 ppm. A pulse width of 3 μs (40°) was employed with no delay between pulses. Decoupling power was held to *ca.* 1 W to provide adequate broadband decoupling power while minimizing sample heating (27°C probe temperature). The signal from carbons bearing two deuterium atoms or one deuterium atom and a double bond is diminished to such an extent that it is usually not detected.

Mass spectra were obtained on a Finnigan (San Jose, CA) 4500 mass spectrometer using isobutane chemical ionization with data processing of the isotope distribution against standards (12).

The macroreticular resin used for the separations was Rohm and Haas (Philadelphia, PA) XN1010 sulfonic acid resin ground to the mesh size indicated. Preparation of the silvered columns has been described (13–15).

Improved preparation of 1-bromo-2pentyne. Triphenylphosphine (171.5 g, 655 mmol) was dissolved in methylene chloride (325 mL) in a 1-L, three-necked flask equipped with a mechanical stirrer, a low temperature thermometer and a burette or dropping funnel. A slow stream of N_2 was maintained through the apparatus as it was cooled in an ice bath. Bromine (102.8 g, 33.2 mL, 643 mmol) was added dropwise over 50 min while the temperature was kept between 3 and 15°C by intermittent cooling. 2-Pentynol (50.1 g, 595 mmol) in CH_2Cl_2 (50 mL) was added to the off-white slurry over 30 min at 4 to 8°C. The ice bath was removed and 15 min later petroleum ether (PE) (400 mL) was added. The mixture was filtered with suction and the precipitate was washed with PE (2 × 100 mL). A column (3 × 50 cm) was packed with Baker silica gel (100 g), and 900 mL of solution was passed through the dry column followed by two 250 mL portions of PE. Solvent was removed from the eluate on a rotary evaporator at about 15°C and about 100 torr to yield 103 g of residue. The residue was distilled through a jacketed Vigreux column to yield the title compound (77.59 g, 88.7% yield, 98% pure by gas chromatography (GC) b.p. 63–80°C at 90 torr). In contrast to previously described preparations, this sample of 1-bromo-2-pentyne was not a lachrymator.

Preparation of 6-(2-tetrahydropyranyloxy)-3-hexynol (**1**) (16). Liquid ammonia (*ca.* 400 mL) was charged to a 1-L, three-necked flask equipped with a mechanical stirrer and a dry ice-cooled condenser and surrounded by Vermiculite insulating material. Ferric nitrate (0.4 g) was added followed by the slow addition of metallic lithium (2.62 g, 328 mmol). After the slurry had turned gray, a solution of the THP ether of 3-butynol (45.5 g, 295 mmol) in diethyl ether (EE) (25 mL) was added. Liquid ethylene oxide (35.28 g, 40 mL, 802 mmol) was added in one portion and stirring was continued for 8 h. The Vermiculite insulating material was removed, and the ammonia was permitted to vent overnight through a tube containing KOH pellets. The next morning, aqueous NH_3 (5 mL) and water (100 mL) were added. The reaction mixture was extracted with EE (1 × 100, 2 × 50 mL), and the combined EE layers were washed with saturated NaCl solution (100 mL) and dried (Na_2SO_4). Distillation through a jacketed Vigreux column gave a forerun (5.12 g) b.p. 45–80°C at 0.35 torr containing principally unreacted THP ether of 3-butynol and then the title compound, **1**, (36.53 g, 62.6% yield, 94% pure by GC) b.p. 93–130°C at 0.3 to 0.5 torr. ^1H NMR ($CDCl_3$; ppm): δ 1.41–1.73 (*m*, 6H, $CH_2CH_2CH_2$), 2.28-2.40 (*m*, 4H, $CH_2C{\equiv}CCH_2$), 2.76 (*t*, 1H, OH), 3.39–3.48 (*m*, 2H, CH_2O), 3.53–3.60 (*m*, 2H, $THPOCH_2$), 3.66–3.78 (*m*, 2H, CH_2OH), 4.54 (*m*, 1H, OCHO). ^{13}C NMR (ppm): C-1, 61.0; C-2, 22.9; C-3, 77.7; C-4, 78.9; C-5, 20.0; C-6, 65.8; THP group: C-2, 98.6; C-3, 30.4; C-4, 19.3; C-5, 25.2; C-6, 62.1.

Preparation of 6-(2-tetrahydropyranyloxy)hexanol-3,3,4,4-d_4, (**2**). Compound **1** (26.1 g, 132 mmol) in benzene (1 L) was treated with deuterium gas in the presence of *tris*-(triphenylphosphine)chlororhodium (3 g) in the manner previously described (3). Benzene was removed on the rotary evaporator, and the red liquid remaining was diluted with PE (100 mL), filtered and passed through a column (3 × 50 cm) containing Silica Gel 60 (100 g) in PE. Elution with increasing concentrations of EE in PE (0 to 50%) yielded fractions which were combined (26 g) and distilled through a jacketed Vigreux column to yield a forerun (0.39 g), b.p. 50–100°C at 0.5 torr containing all the impurities and a main fraction (20.84 g, 76.8% yield), b.p. 120–123°C at 0.6 torr containing the title compound, **2**, (98% pure by GC). Deuterium distribution: 2.3% d_3, 96.7% d_4, 1.0% d_5, 0.1% d_6. ^1H NMR ($CDCl_3$; ppm): δ 1.44–1.76 (*m*, 10H, $CH_2CH_2CH_2$ and $CH_2CD_2CD_2CH_2$), 2.08 (*s*, 1H, OH), 3.30–3.37 (*m*, 2H, CH_2O), 3.54–3.58 (*m*,

2H, THPOCH_2), 3.64–3.72 (*m*, 2H, CH_2OH), 4.51 (*m*, 1H, OC*H*O). ^{13}C NMR (ppm): C-1, 62.6; C-2, 32.3; C-5, 29.3; C-6, 67.4; THP group: C-2, 98.7; C-3, 30.6; C-4, 19.6; C-5, 25.4; C-6, 62.3.

Preparation of 6-(2-tetrahydropyranyloxy)hexanal-3,3,4,4-d_4, (3). Pyridinium chlorochromate (38.9 g, 183 mmol) and sodium acetate (3 g, 36.6 mmol) were suspended in methylene chloride (170 mL) in a 500-mL, three-necked flask equipped with a mechanical stirrer and a thermometer. A stream of nitrogen was maintained through the apparatus. A solution of compound 2 (18.8 g, 91.3 mmol) in CH_2Cl_2 (10 mL) was added in one portion. The reaction mixture turned black, and the mildly exothermic reaction was maintained between 25 and 30°C by intermittent use of an ice bath. Ninety minutes later, EE was added to the stirred mixture. The EE layer was decanted, and the black residue was stirred with two fresh portions (100 mL each) of EE and decanted. The combined EE layers were passed through a column containing Florisil (40 g) to yield a pale green liquid (17.83 g). This material may be used without further purification or it may be passed through a column (3 × 50 cm) containing Silica Gel 60 (100 g) in PE. The title compound, 3, (12.13 g, 65% yield, 89% pure by GC) elutes with mixtures containing up to 15% EE in PE. ^{1}H NMR ($CDCl_3$; ppm): δ 1.43–1.78 (*m*, 8H, CH_2CH_2CH_2 and CH_2CD_2), 2.37 (*s*, 2H, CH_2CHO), 3.28–3.47 (*m*, 2H, CH_2O), 3.64–3.83 (*m*, 2H, THPOCH_2), 4.49–4.51 (*m*, 1H, OC*H*O), 9.70–9.71 (*t*, 1H, C*H*O). ^{13}C NMR (ppm): C-1, 202.5; C-2, 43.5; C-5, 29.1; C-6, 67.1; THP group: C-2, 98.9; C-3, 30.7; C-4, 19.6; C-5, 25.4; C-6, 62.3.

Preparation of 2-(3',3',4',4'-tetradeutero-6',9',12'-pentadecatrienyloxy)tetrahydropyran, (4). 3,6,-Nonadienyltriphenyl phosphonium iodide (33.5 g, 65.4 mmol) was slurried in tetrahydrofuran (150 mL) in a 500-mL, three-necked flask equipped with a mechanical stirrer, a thermometer and a $CaCl_2$ drying tube. While a stream of nitrogen was maintained through the apparatus, the slurry was cooled to 5°C, and butyl lithium (2.5 M, 30 mL, 75 mmol) was added. A dark red solution was formed. Fifteen minutes later, compound 3 (12.13 g, 59.5 mmol) in tetrahydrofuran (THF) (15 mL) was added. The color of the reaction remained red due to the presence of excess phosphonium salt. The ice bath was removed, and 1 h later GC analysis of a sample of the reaction mixture (after reaction with saturated NaCl solution) showed absence of aldehyde and presence of a new component. Thirty minutes later saturated NaCl solution (100 mL) was added and the layers were separated. Solvent was removed from the organic layer on the rotary evaporator to give a liquid and solid (38.7 g). This mixture was extracted with PE (4 × 50 mL), and the combined PE layers were dried (Na_2SO_4). After removal of the drying agent and solvent, the residue was placed on a column (3 × 50 cm) containing silica gel 60 (100 g) in PE. The title compound, 4, (13.44 g, 57% yield, 90% pure by GC) was obtained by elution with PE containing 2 or 5% diethyl ether. ^{1}H NMR ($CDCl_3$; ppm): δ 0.96 (*t*, 3H, CH_3), 1.49–1.80 (*m*, 6H, CH_2CH_2CH_2), 2.01–2.08 (*m*, 4H, C=CH-CH_2), 2.78 (*t*, 4H, C=CHCH_2CH=C), 3.32–3.39 (*m*, 2H, OCH_2), 3.68–3.75 (*m*, 2H, THPOCH_2), 4.54–4.56 (*m*, 1H, OC*H*O), 5.27–5.41 (*m*, 6H, *H*C=C*H*). ^{13}C NMR (ppm): C-1, 67.5; C-2, 29.4; C-5, 26.9; C-6, 130.1; C-7, 127.7; C-8, 25.6; C-9,10, 128.2; C-11, 25.5; C-12, 127.0; C-13, 131.9; C-14, 20.5; C-15, 14.2; THP group: C-2, 98.7; C-3, 30.7; C-4, 19.6; C-5, 25.5; C-6, 62.2.

Preparation of 6,9,12-pentadecatrienol-3,3,4,4-d_4, (5). Compound 4 (4.55 g, 14.7 mmol) was dissolved in methanol (125 mL). *p*-Tbluenesulfonic acid (0.5 g) was added, and the flask was flushed with nitrogen and capped. The next morning, solid $NaHCO_3$ was added, and the solvent was removed on the rotary evaporator. The residue was dissolved in saturated $NaHCO_3$ solution (25 mL) and extracted into EE (2 × 25 mL). The EE solution was dried (Na_2SO_4), and after removal of the drying agent, there was obtained the title compound, 5, (3.11 g, 94% yield, 87% pure by GC). Deuterium distribution: 0.1% d_0, 0.4% d_2, 3.9% d_3, 93.4% d_4, 1.6% d_5, 0.3% d_6. ^{1}H NMR ($CDCl_3$; ppm): δ 0.93–0.98 (*t*, 3H, CH_3), 1.45–1.65 (*m*, 3H, O*H*, CH_2CH_2OH), 2.05 (*m*, 4H, CH_2C=C), 2.77 (*m*, 4H, C=CCH_2C=C), 3.60 (*t*, 2H, CH_2OH), 5.35 (*m*, 6H, C*H*=C*H*). ^{13}C NMR (ppm): C-1, 62.8; C-2, 32.4; C-5, 26.9; C-6, 130.0; C-7, 127.8; C-8, 25.6; C-9,10, 128.2; C-11, 25.5; C-12, 127.0; C-13, 131.9; C-14, 20.5; C-15, 14.2.

Preparation of 6,9,12-pentadecatrienal-3,3,4,4-d_4, (6). Pyridinium chlorochromate (40.7 g, 189 mmol) was suspended in methylene chloride (170 mL) in a 500-mL, three-necked flask equipped with a mechanical stirrer and a thermometer. A flow of nitrogen was maintained through the apparatus and 6,9,12-pentadecatrienol-d_4, 5, (21.4 g, 94.7 mmol) was added in one portion. The mildly exothermic reaction was controlled by intermittent cooling with an ice bath. One hour later, EE (100 mL) was added to the black viscous reaction mixture and stirring was continued for 10 min. Liquid was decanted and two fresh portions of EE (100 mL each) were stirred with the tar for about 10 min each and liquid was decanted. The combined decantates were passed through a column (2 × 30 cm) containing dry Florisil (40 g). The column was flushed with EE (50 mL), and the combined eluates were concentrated on the rotary evaporator to yield a slightly colored liquid (17.4 g, 82% crude yield, 84% pure by GC on HP-1). This liquid was used without further purification in the Wittig reaction with carboxybutyltriphenylphosphonium bromide. An analytical sample was obtained by elution through a SepPak (Waters, Milford, MA). ^{1}H NMR ($CDCl_3$; ppm) : δ 0.93–0.99(*t*, 3H, CH_3), 2.01–2.10 (*m*, 4H, CH_2C=C), 2.40 (*s*, 2H, CH_2CHO), 2.80 (*m*, 4H, C=CCH_2C=C), 5.30–5.40 (*m*, 6H, C*H*=C*H*), 9.74 (*t*, 1H, C*H*O). ^{13}C NMR (ppm): C-1, 202.4; C-2, 43.5; C-5, 26.7; C-6, 129.4; C-7, 128.0; C-8, 25.6; C-9,10, 128.4; C-11, 25.5; C-12, 127.0; C-13, 131.9; C-14, 20.5; C-15, 14.2.

Preparation of methyl 5,11,14,17-eicosatetraenoate-8,8,9,9-d_4, (7). Carboxybutyltriphenylphosphonium bromide (29.36 g, 66 mmol) was slurried in THF (125 mL) in a 500-mL, three-necked flask equipped with a mechanical stirrer, a thermometer and a septum inlet. While a stream of nitrogen was passed through the apparatus, sodium *bis*(trimethylsilyl)amide (1M, 133/mL) was added over a period of about 10 min. The mildly exothermic reaction was kept at 23–30°C by intermittent use of an ice bath. The septum inlet was replaced with a reflux condenser, and the red-orange reaction mixture was heated at the reflux temperature for 1.5 h. The reaction mixture was cooled in an ice bath, and compound 6 (14.8 g, 66 mmol) in THF (10 mL) was added and the color changed to tannish-orange. One hour later, water (25 mL) was added to the slurry. The resulting cherry red solution was cooled

in an ice bath as it was acidified with 5N H_2SO_4 (70 mL). The organic layer was separated, washed with saturated NaCl solution and dried (Na_2SO_4). Removal of the drying agent and solvent left an amber liquid (43.67 g). Methanol (200 mL) and concentrated sulfuric acid (1 mL) were added, and the reaction mixture was heated at reflux temperature for 2 h. The acid was neutralized with solid $NaHCO_3$. Solvent was removed on the rotary evaporator to give a mixture of solid and liquid (47 g). This was extracted with hexane (2 × 50 mL and 1 × 25 mL), and the solvent was removed to give a residue (23.15 g). The title compound was obtained by purification on a column (3 × 45 cm) containing Baker silica gel (100 g) in PE. Elution with up to 5% EE in PE gave a product (16.81 g, 78% crude yield, about 70% pure by GC on SP2340). The all-*cis* isomer was isolated by silver resin chromatography on a 62% Ag/Na XN1010 resin column using 2% acetonitrile in methanol as eluant. Deuterium distribution. 0.3%d_1, 0.7%d_2, 2.8%d_3, 94.8%d_4, 1.3%d_5, 0.2%d_6, 0.1%d_8 (Ave. No. deuteriums=3.97). ^{1}H NMR ($CDCl_3$; ppm): δ 0.96 (*t*, 3, CH_3), 1.67 (*m*, 2H, CH_2CH_2COO), 1.91-2.1 (*m*, 8H, $C{=}CCH_2$), 2.3 (*t*, 2H, CH_2COO), 2.78 (*m*, 4H, $C{=}CCH_2C{=}C$), 3.65 (*s*, 3H, OCH_3), 5.32-5.36 (*m*, 8H, $CH{=}CH$). ^{13}C NMR (ppm): C-1, 174.0; C-2, 33.4; C-3, 24.9; C-4,7 and 10, 26.5 or 26.9; C-5, 130.9; C-6, 128.4; C-11, 130.1; C-12, 127.7; C-13, 25.6, C-14,15, 128.2; C-16, 25.5; C-17, 127.1; C-18, 131.9; C-19, 20.5; C-20, 14.3. Chemical shift assignments are consistent with data published by Gunstone *et al.* (17) and Gunstone (18) for similar compounds.

METHOD

The Enrichment of n-3 Polyunsaturated Fatty Acids Using Aminopropyl Solid Phase Extraction Columns

Robert Wilson[a,*], R. James Henderson[b], Ivan C. Burkow[c] and John R. Sargent[a]

[a]Department of Biological and Molecular Science and [b]NERC Unit of Aquatic Biochemistry, School of Natural Sciences, University of Stirling, Stirling FK9 4LA, Scotland, United Kingdom and [c]Norwegian Institute of Fisheries and Aquaculture, N-9001, Tromsø, Norway

A rapid, simple and reliable method is described for the preparation of concentrates of methyl or ethyl esters of n-3 polyunsaturated fatty acids by solid phase extraction using aminopropyl bonded silica columns. After applying mixtures of fatty acid esters in hexane, saturated and monounsaturated fatty acid esters are preferentially eluted with hexane whereas polyunsaturated fatty acids (PUFA) can subsequently be eluted with dichloromethane. Concentrates containing 80–90% n-3 PUFA can thus be obtained using fish oil fatty acids esters as a starting material.

Lipids 28, 51–54 (1993).

The concentration of polyunsaturated fatty acids (PUFA) can be achieved by utilizing differences in physical or chemical properties between saturated and unsaturated fatty acids. Low temperature crystallization, urea adduct fractionation and fractional distillation are all traditional methods used for the preparation of concentrates of n-3 PUFA from derivatives of fish oil fatty acids (1–4) and are best suited to large-scale preparations. Adsorption chromatography using layers or columns of silica gel impregnated with silver nitrate has been useful to isolate gram quantities of individual PUFA (5,6), whereas reversed-phase high-performance liquid chromatography (HPLC) has been applied for the same purpose on the milligram scale (7,8). More recently, planar thin-layer chromatography (TLC) using high-performance thin-layer silica gel has been used for the separation of C_{20} and C_{22} PUFA (9). The selective hydrolysis, by neutral lipases, of fish oil triacylglycerols, or of derivatives of their component fatty acids, has also been used to produce fractions enriched in n-3 PUFA (10). Used in conjunction with the above techniques, supercritical fluid carbon dioxide fractionation of esters of fish oil fatty acids has been utilized to produce highly enriched fraction of individual PUFA (11).

In the present report, a novel method is described for the isolation of PUFA concentrates from fish oil fatty acid methyl or ethyl esters by solid phase extraction using aminopropyl bonded silica.

MATERIALS AND METHODS

Materials. Aminopropyl columns (Bond-Elut) were purchased from Jones chromatography (Hengord, U.K.) and from J.T. Baker (Hayes, U.K.). Fish oil derived from sardines or anchovies was obtained from Seven Seas Ltd. (Hull, U.K.). All solvents were of HPLC grade and were purchased from Rathburn Chemicals (Walkerburn, U.K.). [1-^{14}C]18:0 (52.7mCi/mmol), [1-^{14}C]18:1n-9 (50.0mCi/mmol), [1-^{14}C]18:2n-6 (54.7mCi/mmol) and [1-^{14}C]18:3n-3 (53.9mCi/mmol), all as free acids, were purchased from Amersham International (Aylesbury, U.K.). Ecoscint A scintillation fluid was supplied by National Diagnostics (Manville, NJ).

Preparation of methyl and ethyl esters of fatty acids. Methyl esters of the fatty acids from fish oil were prepared by subjecting samples of the oil directly to acid-catalyzed transmethylation in methanol containing 1% sulfuric acid for 16 h at 50°C under nitrogen (12). Ethanol was substituted for methanol for the preparation of ethyl ester derivatives (12). [^{14}C]Fatty acid methyl esters (FAME) were prepared as described above by subjecting total lipid isolated from rat brain cell cultures that had been incubated with 1 μM/0.5 μCi of [1-^{14}C]18:0, [1-^{14}C]18:1n-9, [1-^{14}C]18:2n-6 or [1-^{14}C]18:3n-3 for 48h. Mixtures of saturated fatty acids (SFA) contained 85% 18:0, 7% 20:0 and 8% longer chain saturated fatty acids as [^{14}C]FAME. Mixtures of monounsaturated fatty acids (MUFA) contained 75% 18:1, 6% 20:1, 14% 24:1 and 5% > 24:1 as [^{14}C]FAME. Mixtures of n-6 PUFA contained 70% 18:2, 10% 20:3 and 20% 20:4 as [^{14}C]FAME, whereas n-3 PUFA contained 15% 18:3, 20% 20:5, 40% 22:5 and 25% 22:6 as [^{14}C]FAME.

Fatty acid methyl or ethyl esters were extracted from the reaction mixture using hexane/diethyl ether (1:1, vol/vol) containing 0.01% butylated hydroxytoluene (BHT) as antioxidant. After removal of the solvent by rotatory evaporation, the derivatives were redissolved in hexane containing 0.01% BHT and purified using 500 mg aminopropyl columns (Bond-Elut) (13). For this purpose, the columns were prewashed sequentially with 4 mL (7 bed volumes) hexane/glacial acetic acid (98:2, vol/vol) and 4 mL hexane before application of the fatty acid methyl or ethyl esters in hexane. Under these conditions the aminopropyl silica is protonated, and fatty acid esters are not retained on the column and are eluted using 4 mL hexane. Traces of free cholesterol, free fatty acids and triacylglycerols remain on the column (14) as do monohydroxy and monohydroperoxy fatty acids and polymeric material (unpublished results). To elute bound material, the columns were washed with 4 mL hexane/glacial acetic acid (98:2, vol/vol) followed by 4 mL hexane. The column could then be then be reused for the purification of fatty acid esters from the components described above.

Solid phase extraction. A 500 mg aminopropyl bonded silica column was prewashed using 4 mL dichloromethane and then 4 mL hexane. In these experiments, 5 mg of methyl or ethyl esters of fish oil fatty acids dissolved in 0.5 mL hexane were then applied to the column. Using a syringe attached to the column by an adapter, 4 mL of hexane (7 bed volumes) were slowly pushed through the column, and the eluting solvent collected in a test tube. Similarly, 4 mL of dichloromethane was applied to the

Abbreviations: BHT, butylated hydroxytoluene; FAME, fatty acid methyl ester; GLC, gas-liquid chromatography; HPLC, high-performance liquid chromatography; MUFA, monounsaturated fatty acids; PUFA, polyunsaturated fatty acids; SFA, saturated fatty acids; TLC, thin-layer chromatography.

column, and the eluting solvent collected in a tube. The solvent was evaporated under a stream of nitrogen; the components present in the hexane and dichloromethane fractions were redissolved in hexane containing 0.01% BHT and analyzed by capillary gas-liquid chromatography (GLC) as described below. After elution with hexane and dichloromethane, the column was washed with 4 mL hexane before loading the next sample.

Quantification of [^{14}C] fatty acid methyl esters. Saturated, monounsaturated and polyunsaturated [^{14}C]-FAME (0.1 μC_1) were mixed separately with 2.5 or 15 mg of fish oil FAME and applied to aminopropyl columns dissolved in hexane according to the solid phase extraction procedure described above. The hexane and dichloromethane fractions were collected directly into scintillation vials, and the solvent removed under nitrogen. Scintillation fluid (2.5 mL) was added and the level of radioactivity determined by liquid scintillation counting using a Canberra Packard (Pangbourne, U.K.) Tricarb 2000CA liquid scintillation analyzer.

Gas-liquid chromatography (GLC). Methyl and ethyl esters of fatty acids were analyzed on a chemically bonded CP Wax 52CB fused silica capillary column (50 m × 0.34 mm i.d.) (Chrompack, London, U.K.) contained in a Canberra Packard 436 gas chromatograph equipped with on-column injection and a flame ionization detector, using hydrogen as carrier gas and a thermal gradient from 50° to 225°C (15). Individual methyl and ethyl esters were identified by comparison with authentic standards and those prepared from a well-characterized fish oil. Values are recorded as means ± SD for three separate experiments.

RESULTS AND DISCUSSION

When mixtures of [^{14}C]FAME were combined with fish oil FAME and applied to aminopropyl columns as described in the Materials and Methods, all (99.5 ± 1.5%) the radioactivity applied to the column was recovered in the eluting solvents. The recoveries of the various types of [^{14}C]FAME in the hexane and dichloromethane fractions are shown in Table 1 as a function of the amount applied to the column. The distribution patterns of radioactivity from ^{14}C-labelled, saturated, monounsaturated and polyunsaturated FAME in the two eluants were markedly different and were dependent on column loading. In addition, it was noted that the proportion of radioactivity recovered in the dichloromethane fraction was related to the degree of unsaturation of the FAME. Thus, 83% of n-6 [^{14}C]PUFA and 95% of n-3 [^{14}C]PUFA were recovered in the dichloromethane fraction at a column loading of 0.5% (wt/wt), whereas only 33% of n-6 [^{14}C]PUFA and 79% of n-3 [^{14}C]PUFA were recovered in the dichloromethane fraction using a column loading of 3% (wt/wt). The difference in recovery between n-6 and n-3 [^{14}C]PUFA correlates with overall degree of unsaturation, an average of 2.5 and 5 double bonds for n-6 PUFA and n-3 PUFA, respectively.

The fatty acid composition of the fish oil employed in this study is typical of the starting material used in the preparation of PUFA concentrates or for the isolation of 20:5n-3 or 22:6n-3 as individual fatty acids (1). Of the total FAME, 41.3% were PUFA and 20:5n-3 and 22:6n-3 accounted for 20.4% and 8.9%, respectively. Saturated and monounsaturated fatty acids accounted for 29.1% and 29.6%, respectively, of total FAME with 14:0, 16:0, 16:1n-7 and 18:1n-9 being major components.

The maximum loading capacity of aminopropyl columns was found to be 1–4% by weight depending on the batch tested. When the basic solid phase extraction procedure was used at maximum loading capacity for the separation of the fish oil esters, the hexane and dichloromethane fractions contained 55 ± 3% and 45 ± 3%, respectively, of the fatty acid derivatives applied to the column. The fatty acid esters recovered in the two fractions were markedly different in composition (Table 2). SFA, MUFA and PUFA comprised 47.3, 42.7 and 10%, respectively, of the fatty acid esters in the hexane fraction. The corresponding values for the dichloromethane fraction were 2.6%, 8.7% and 88.7%, and this fraction contained almost all the 20:5n-3 and 22:6n-3 applied to the column. The proportions of individual PUFA, particularly those of the n-3 series, in the dichloromethane fraction were approximately double those in the original fish oil esters, and it was noted that the ratio of 20:5n-3 to 22:6n-3 was around 2 to 1 in both the original fish oil esters and the dichloromethane fraction. Fractions having the compositions presented in Table 2 could be obtained repeatedly using the same column up to 12 times without loss of function, and very similar results were found using four different batches of aminopropyl columns. Furthermore, no difference was observed between the methyl and ethyl ester derivatives of the fish oil fatty acids in terms of their chromatographic behavior in the procedures examined in this study.

A simple modification of the basic procedure using hexane/dichloromethane, (98:2, vol/vol) as an eluant and

Total PUFA	41.3 ± 1.3	10.0 ± 0.7	88.7 ± 1.8

[a]Values are means ± SD for three separate experiments. SFA, saturated fatty acids; MUFA, monounsaturated fatty acids; PUFA, polyunsaturated fatty acids.

[b]Includes all isomers; mainly 16:1n-7, 18:1n-9, 20:1n-9, 22:1n-11 and 24:1n-9. In these experiments 5 mg of fatty acid methyl ester was used, which represents a maximum column loading of 1% of aminopropyl weight.

subsequent elution of the column with dichloromethane yielded a fraction containing only PUFA but just 9 ± 2% of the fatty acid derivatives applied to the column. However, 20:5n-3 and 22:6n-3 each accounted for 45% of the total and 16:4n-1 (3%), 18:4n-3 (2.3%), 20:4n-3 (0.4%), 20:4n-6 (0.4%), 21:5n-3 (1.5%) and 22:5n-3 (2.4%) accounting for the remaining 10%. The presence of 22:6n-3 and 20:5n-3 in equal proportion reflects the stronger retention of 22:6n-3 than 20:5n-3 by the adsorbent since the ratio of 20:5n-3 to 22:6n-3 in the starting fish oil esters was approximately 2 to 1.

The above data show that aminopropyl columns are capable of concentrating PUFA from mixtures of fatty acid esters by retaining them on the adsorbent when the column is eluted with hexane. Aminopropyl bonded silica is an adsorbent that exhibits strong hydrogen bonding properties and functions also as a weak anion exchanger (13,16). PUFA exhibit strong dipoles at methylene-interrupted carbon atoms (17), and the formation of dipole-dipole interaction between the hydrogen atoms of these carbon atoms and aminopropyl bonded silica may form the basis of the interaction between PUFA and the aminopropyl groups. SFA and MUFA exhibit weaker dipoles than PUFA (17) and therefore are likely to bind to aminopropyl bonded silica to a lesser extent than PUFA. Since hexane is a nonpolar solvent and has an eluotropic strength of zero (16), it probably does not interfere with interactions based on dipole-dipole interaction between PUFA and the aminopropyl groups of the bonded silica, whereas saturated and monounsaturated fatty acids, being less strongly bonded to the adsorbent, can be eluted using hexane.

The capacity of the adsorbent is low under the conditions used here but the procedure can be easily scaled up by increasing the quantity of adsorbent used for extraction. Furthermore, the characteristics of the bonded silica permit rapid solvent flow through the adsorbent bed under conditions of minimal pressure (10-15 psi) (13). Although PUFA can be concentrated from fatty acid mixtures by other means, including low temperature crystallization, urea adduct fractionation and fractional distillation (1-4), these techniques usually have inherent disadvantages such as the requirement for sophisticated equipment, large volumes of solvent, or low yields. Furthermore, there is a risk of structural modification of PUFA during fractional distillation. Biotechnological procedures involving fungal lipases may be prohibitory in cost. Therefore, procedures based on the method described here, using large reusable columns packed with aminopropyl bonded silica, may provide an alternative to traditional methods for the preparation of PUFA concentrates. On a small scale, the method may prove most useful as a rapid method of enriching fatty acid mixtures in PUFA before further separation by other techniques such as silver nitrate chromatography or HPLC (5-8). Indeed, given further development, aminopropyl HPLC bonded silica (18) may ultimately provide analytical capabilities similar to silver nitrate chromatography or reversed-phase HPLC for the analysis of fatty acid derivatives.

In conclusion, the procedure described here allows the simple, rapid and reproducible concentration of methyl or ethyl esters of n-3 PUFA from natural mixtures of fatty acids. The procedure may lend itself to the large-scale preparation of high quality concentrates of n-3 PUFA for applications in human nutrition (19).

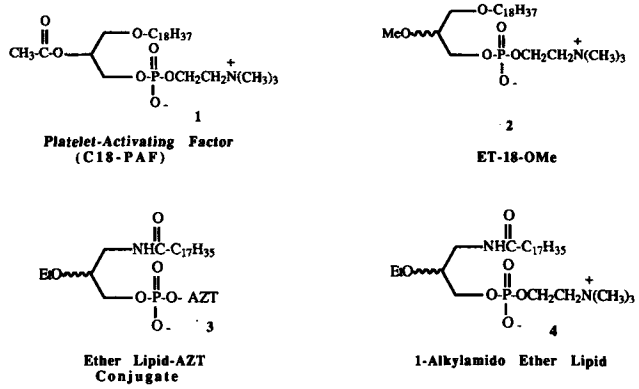
Phospholipids containing a 1-alkylamido linkage have shown promising *in vitro* neoplastic cell growth inhibitory properties and anti-human immunodeficiency viral activity. We have synthesized a series of alkylamido ether lipid analogues on a milligram scale for initial evaluation, but for further *in vivo* testing of these bioactive phospholipids, synthesis on a larger scale is required. The multigram synthesis of 1-alkylamido ether phospholipids was accomplished by modifying reaction conditions in the amidation step and changing reagents and solvent systems in both the detritylation and phosphorylation steps. This was most crucial in the phosphorylation step, where in the multigram synthesis 2-bromoethyl dichlorophosphate in diethyl ether/tetrahydrofuran (7:3, vol/vol) gave much improved yields as compared to the 2-chloro-2-oxo-1,3,2-dioxaphospholane reagent. The modifications also resulted in a product that could be more easily purified in sufficient quantities for use in *in vivo* inhibition studies.
Lipids 28, 55–57 (1993).

Over the past decade, it has become apparent that some classes of phospholipids may play a significant role in inflammatory processes, in cellular signalling events, in tumor growth inhibition, and in the processing of human immunodeficiency virus (HIV). For example, platelet-activating factor (1, Scheme 1) is a well-documented mediator of inflammatory processes and is involved in various other biological processes as well (1,2). Other alkyl ether lipids and their analogues (2–4, Scheme 1) have been shown to be potent, biologically active molecules (2–5) with the ability to modify biological responses through their action at the cell membrane level (3,4) or by modifying signal transduction pathways (5). The 1-alkylamido types of lipids (*e.g.*, 4, Scheme 1) have shown promise as neoplastic cell growth inhibitors (4) and anti-HIV agents (6,7) based on their *in vitro* activities. Further evaluation of these ether lipids required the preparation of the compounds in multigram quantities. As is often the case when scaling up a procedure that is adequate for synthesis on the milligram scale, problems arose in both the reaction and purification steps. Specific improvements were realized in the amidation reaction, in the detritylation of the 1-alkylamido-2-alkyl-3-tritylpropanediol intermediates, and in the subsequent phosphorylation step. The present paper describes the problems associated with and the alternative methods developed for the multigram synthesis of 1-alkylamido ether lipids.



SCHEME 1

RESULTS AND DISCUSSION

The multigram synthesis of four phospholipids containing 1-alkylamido linkages was completed as shown in Scheme 2. The synthesis of these compounds on a multigram scale required several modifications of our previously published procedure (4) for the synthesis of milligram quantities of these alkylamido lipids.

Using commercially available (±)-3-amino-1,2-propanediol 5 and the appropriate acid chloride (palmitoyl or stearoyl), the amidation reaction (4) was carried out in a larger volume of pyridine, omitting *N,N*-dimethylformamide. The amidation reaction thus proceeded smoothly, which appears to be an improvement over published procedures (8,9). Our previous method produced a significant amount of ester and ester/amide by-products that were difficult to remove during purification on the larger scale. A more dilute reaction solution resulted in a mixture that was more easily stirred, produced less ester by-product, and was easier to purify (one precipitation from isopropanol) than previously reported (4). The alkylamidopropanediol 6 formed by the new procedure was of higher purity, as judged by the 300 MHz ^1H nuclear magnetic resonance (NMR) data (*i.e.*, no signal was found that corresponded to ester α-methylene protons), and based on the higher melting point (106–107°C *vs.* 96–98°C, ref. 4). The tritylation was carried out using *N,N*-dimethylaminopyridine (DMAP) in CH_2Cl_2 to yield the desired product 7 which did not result in an improvement over the previously published procedure (4). The alkylation of the 2-hydroxyl group to produce 8 was performed as before using NaH and either methyl or ethyl iodide in tetrahydrofuran (THF).

Use of *p*-toluenesulfonic acid in CH_2Cl_2/CH_3OH (10) rather than BF_3/MeOH for removal of the trityl group also simplified the purification. The trityl methyl ether formed with the former reagent is more easily removed than the trityl alcohol produced by the latter, either by recrystallization of the product, alcohol 9, from hexane or by chromatography with the solvent CH_2Cl_2/MeOH (95:5, vol/vol) or hexane/ethyl acetate (2:1, vol/vol). The yields were also generally higher using the new reagent

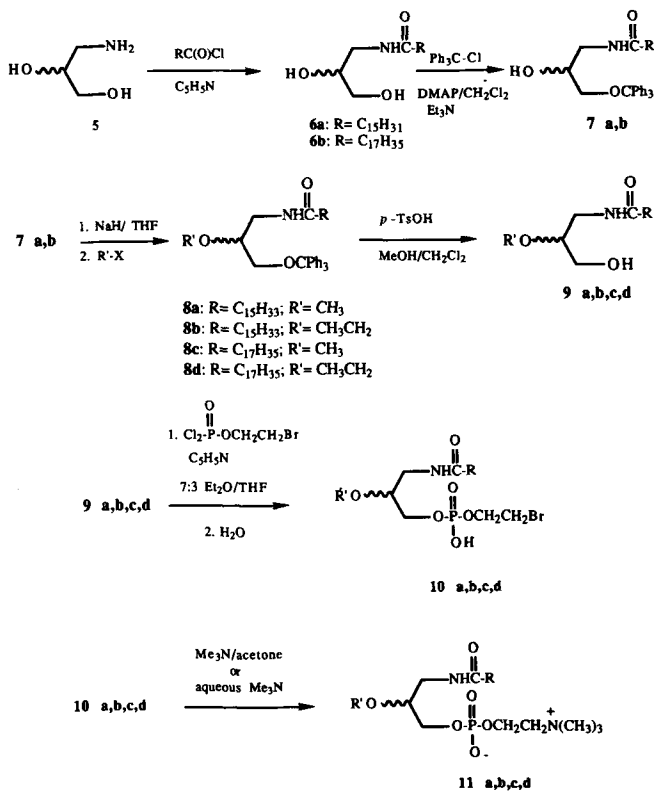
(90% *vs.* 50% for the 3-hexadecylamido-2-methoxypropanol).

A final major problem was the phosphorylation of the 1-alkylamido-2-alkylpropanol intermediate. Different phosphorylation reagents have been used in attempts to synthesize the alkylamidolipids: (i) $POCl_3$, (ii) 1,2-dimethylethenylene phosphochloridate (cyclic enediol phosphochloridate, CEP-Cl), (iii) 2-chloro-2-oxo-1,3,2-dioxaphospholane, or (iv) 2-bromoethyl dichlorophosphate. As noted previously (4,9,11), $POCl_3$ proved unsuitable in the presence of a variety of bases (Et_3N, C_5H_5N, or 2,6-lutidine) and resulted in polyphosphorylation and/or decomposition of the starting material. Previously, the appropriate phosphocholine **11** was synthesized on a milligram scale by treating the 3-alkylamidoether propanol intermediate **9** with 2-chloro-2-oxo-1,3,2-dioxaphospholane followed by treatment with condensed trimethylamine. However, in the multigram synthesis, this procedure gave poor results with milligram yields from 2–3 g of starting material.

Previous attempts to phosphorylate these 3-alkylamido ether lipids with 2-bromoethyl dichlorophosphate were unsuccessful due to difficulties in finding appropriate solvents (9,12–14). The alkylamido ether lipids are much less soluble in less polar solvents, as compared to the corresponding acyl, thioether or ether analogues. The starting material was not soluble in Et_2O, and solvents such as $CHCl_3$ have been shown to lead to chlorinated and polyphosphorylated by-products (14). However, the alcohol starting material was soluble in a mixture of Et_2O/THF (7:3, vol/vol), and the product (bromoethyl phosphochloridate **10**) precipitated out of the reaction mixture before further side reactions could occur, analogous to the approach described by Hansen *et al.* (14). It was absolutely critical to purify the intermediate bromoethyl phosphates to remove any traces of pyridine. The presence of pyridine in the amination reaction resulted in some pyridinium analogue formation, as indicated by ^1H NMR and the appearance of a fluorescent product peak in thin-layer chromatography (TLC). Therefore, all bromoethyl-phosphates were purified by chromatography prior to amination with either anhydrous or aqueous trimethylamine to produce the desired phosphocholine ether lipids **11** from the 3-alkylamido glycerols **9** in gram quantities in yields of 23–40%. The yields for the phosphorylation of multigram quantities using the bromoethyl dichlorophosphate/Me_3N procedure were similar to those reported for the milligram synthesis *via* 2-chloro-2-oxo-1,3,2-dioxaphospholane.



SCHEME 2

EXPERIMENTAL PROCEDURES

(±)-3-Amino-1,2-propanediol, palmitoyl chloride, stearoyl chloride, chlorotriphenylmethane (trityl chloride), 4-DMAP, 80% sodium hydride (oil dispersion), methyl iodide, ethyl iodide, *p*-toluenesulfonic acid monohydrate, and aqueous (40%) trimethylamine were used as obtained from the supplier (Aldrich, Milwaukee, WI). Anhydrous trimethylamine was condensed in a coldtrap (liquid nitrogen) immediately prior to use. Pyridine and triethylamine (Et_3N) were distilled from KOH, and THF was distilled from $LiAlH_4$. All reactions requiring anhydrous or inert conditions were performed under a positive pressure of dry nitrogen. 2-Chloro-2-oxo-1,3,2-dioxaphospholane (15,16) and 2-bromoethyl dichlorophosphate (12) were prepared according to literature procedures and freshly distilled before use. Chromatographic purifications were done using silica gel 60 (230–400 mesh; Merck, Darmstadt, Germany) and the indicated solvent systems. TLC was done on Whatman MK6F plates (Maidstone, England) and fractions were visualized by either spraying with sulfuric acid/dichromate or phosphomolybdate reagent followed by heating. Melting points were determined on a Thomas-Hoover capillary melting point apparatus and are uncorrected. ^1H NMR spectra were determined on a Bruker (Karlsruhe, Germany) AC-300 300-MHz spectrometer or a Varian (Palo Alto, CA) FT-80A spectrometer.

(±)-3-Hexadecanamido-1,2-propanediol (**6a**). To a mechanically stirred solution of (±)-3-amino-1,2-propanediol **5** (33.2 g, 0.36 mol) in 200 mL pyridine was added 100 g (0.36 mol) palmitoyl chloride over 1.5 h at room temperature. After addition, the reaction was stirred for three hours, and the mixture was poured onto an ice/water mixture with vigorous stirring. The solid crude product was filtered on a coarse sintered glass filter and the filtrate discarded. The precipitate was dissolved in 2 L of solvent ($CHCl_3$/MeOH, 2:1, vol/vol) and extracted successively with 2 × 200 mL 10% HCl, 3 × 200 mL 10% NaOH, and 2 × 200 mL 10% HCl, using MeOH to break the emulsions that formed. The nonaqueous layer was dried over anhydrous $MgSO_4$, filtered and solvents were removed with a rotary evaporator. The resulting solid was dissolved in 1.8 L of warm isopropanol, decanted from a small amount of insoluble material, and left at room temperature. The precipitated product was filtered and the filtrate placed in a −5° coldroom to precipitate a second crop of

product. The product **6a** was dried under vacuum over P_2O_5 to yield 85.3 g (72%) of a white powder (m.p. 106–107°C; lit. ref. 4, 96–98°C) that was pure by TLC (R_f 0.43, $CHCl_3$/MeOH, 9:1, vol/vol). The same procedure was followed to synthesize the octadecanamido analogue **6b** in 68% yield (m.p. 111.0–111.5°C; lit. ref. 4, 104–106°C).

(±)-3-Hexadecanamido-1-(triphenylmethoxy)-2-propanol (**7a**). To a slurry of the amidodiol **6a** (25 g, 0.076 mol) in 750 mL CH_2Cl_2 was added triethylamine (23 g, 0.228 mol) and 4-DMAP; 0.375 g, 3 mmol). The mixture was heated to 35°C, trityl chloride (23 g, 83.5 mmol) was added in one aliquot, and the reaction stirred overnight. TLC of an aliquot in hexane/ethyl acetate (2:1, vol/vol) showed the presence of starting material; so the reaction was heated at 60°C for 24 h. The reaction was cooled to room temperature and the solvents removed with a rotary evaporator, resulting in a viscous oil that solidified on standing. The residue was taken up in 1 L CH_2Cl_2 and extracted with 3 × 250 mL cold 10% HCl, 250 mL saturated NaCl, and dried over $MgSO_4$. The drying agent was filtered, the solvent removed on a rotary evaporator, the residue taken up in 800 mL MeOH and placed in a cold room at −5°C. The precipitate was filtered and dried as before to yield 54.2 g of product **7a** that was identical to the previously prepared material (4). The same procedure was utilized to synthesize the octadecanamido analogue **7a** in 72% yield, resulting in 43 g of product (m.p. 86–88°C).

(±)-3-Hexadecanamido-2-methoxy-1-(triphenylmethoxy)-propane (**8a**). The compound was synthesized as before (4) from 28.2 g (0.049 mol) of **7a** and purified by flash chromatography on 300 g silica gel (hexane/ethyl acetate, 2:1, vol/vol) to yield 18.5 g (65%) of product **8a**. The remaining intermediates were synthesized by the same procedure and were either used without further purification (**8b, 8c**) or purified by the same chromatographic procedure (**8d**, 78%).

(±)-3-Hexadecanamido-2-methoxy-1-propanol (**9a**). To 160 mL CH_2Cl_2/MeOH (5:1, vol/vol) was added 18.5 g (31.6 mmol) of the tritylated compound **8a** and 1.0 g of *p*-toluenesulfonic acid monohydrate. The reaction was stirred at room temperature for 15 h at which time TLC in hexane/ethyl acetate (2:1, vol/vol) showed no remaining starting material. The acid catalyst was neutralized with saturated sodium bicarbonate solution (~50 mL), and 50 mL H_2O was added. The nonaqueous layer was separated and extracted with 3 × 100 mL H_2O, the nonaqueous layers combined and extracted again with 100 mL H_2O and dried over anhydrous Na_2SO_4. Solvents were removed with a rotary evaporator and the crude solid residue was purified by flash chromatography on 300 g of silica gel in CH_2Cl_2/MeOH (95:5, vol/vol) to give 9.8 g (91%) of product **9a** (m.p. 67–68°C; lit. ref. 4, 61–62°C). The other analogues (**9b–9d**) were prepared in 45–63% yields using the same procedure.

(±)-3-Octadecanamido-2-methoxypropyl-1-phosphocholine (**11c**). To 150 mL anhydrous Et_2O/THF (7:3, vol/vol), cooled to 0°C in an ice bath under a positive atmosphere of dry nitrogen, were added 2.2 mL (0.016 mol) of freshly distilled 2-bromoethyl dichlorophosphate (12), followed by 6.5 mL pyridine. The alcohol **10c** (2.0 g, 0.0054 mol) was added to the reaction flask and the mixture warmed to room temperature and then heated to gentle reflux for 4 h. The solution was cooled to 4°C in an ice bath, 6 mL H_2O was added and stirred for 30 min. Solvents were removed with a rotary evaporator to give a semisolid that was dissolved in $CHCl_3$/MeOH (5:1, vol/vol). The solution was extracted with water, dried over sodium sulfate, filtered, and solvents were removed as before. Column chromatography on silica gel with a gradient of $CHCl_3$/MeOH (100:0 to 3:1, vol/vol) gave 600 mg of pure product and 1.6 g of impure product. The impure material was rechromatographed using $CHCl_3$/hexane (5:1, vol/vol), $CHCl_3$, and $CHCl_3$/MeOH (15:1 to 10:1, vol/vol) to give a further 1.0 g of pure bromoethylphosphate **10c**. The yield for **10c** was 52%, and the range for the other analogues was 37–47%.

The intermediate **10c** (1.4 g, 0.0025 mol) was dissolved in a solution of $CHCl_3$/*i*-PrOH/DMF (91 mL, 3:3:5, vol/vol/vol) and trimethylamine (18 mL, 40% aqueous) was added. The reaction mixture was heated to 65°C for 5 h and then cooled to room temperature before Ag_2CO_3 (1.2 g) was added. The mixture was heated for 1 h, cooled to room temperature, and filtered. Solvents were removed on a rotary evaporator, and the phospholipid was purified by column chromatography using $CHCl_3$/MeOH (10:1 to 3:1, vol/vol) followed by $CHCl_3$/MeOH/NH_4OH (75:25:5, vol/vol/vol) to give 1.0 g (76%) of pure product **11c**. The amination step for the other intermediates gave 47–63% yields. The overall yield of phospholipid **11c** from the alcohol **9c** was 40% and the range for the other compounds (**11a, 11b** and **11d**) was 23–26%.

COMMUNICATION

Release of Lipoprotein Lipase from Cardiac Myocytes by Low-Molecular Weight Heparin

J.E.A. Braun and **D.L. Severson***
MRC Signal Transduction Group, The University of Calgary, Faculty of Medicine, Calgary, Alberta T2N 4N1, Canada

Incubation of cardiac myocytes from rat heart with low-molecular weight heparin (LMWH; Mr approx. 3 kDa) for 30 min resulted in a concentration-dependent release of lipoprotein lipase (LPL) activity into the incubation medium. The release of lipoprotein lipase from cardiac myocytes isolated from both control and diabetic rat hearts induced by LMWH (10 μg/mL) following incubation times of 10 or 30 min was significantly greater than that produced by unfractionated heparin (10 and 30 μg/mL) or decavanadate (1 mM). Since LMWH released more LPL activity into the incubation medium than unfractionated heparin following a short (10 min) incubation time, LMWH is probably more effective in displacing LPL bound to heparan sulfate proteoglycan binding sites on the cell surface of cardiac myocytes.
Lipids 28, 59–61 (1993).

Lipoprotein lipase (LPL) catalyzes the hydrolysis of the triacylglycerol component of circulating lipoproteins at the luminal surface of the vascular endothelium (1). The enzyme is bound *via* electrostatic interactions to heparan sulfate proteoglycans on the surface of vascular endothelial cells (2,3). The *in vivo* administration of the anticoagulant heparin displaces LPL from its endothelial binding sites into the circulation as a lipase-heparin complex (post-heparin lipolytic activity). In the heart, LPL is synthesized in cardiac myocytes and then translocated to functional sites at the endothelium (4,5). LPL can be released into the medium of cardiac myocytes by short-term incubations with heparin (6,7), suggesting that the enzyme is also bound to heparan sulfate proteoglycans on the surface of parenchymal cells (8). The glycosaminoglycan specificity for the release of LPL from cardiac myocytes (6) was the same as observed for cultured endothelial cells (2).

Conventional (unfractionated) heparin is a heterogeneous polymer of repeating disaccharide sequences, with molecular weights ranging from 3–30 kDa (9). Low-molecular weight heparin (LMWH) subfractions are effective anticoagulants with improved pharmacokinetic properties and a reduced incidence of side effects (9). The intravenous administration of LMWH to rats or humans resulted in reduced plasma LPL activity compared to the administration of unfractionated heparin (10,11). Liu *et al.* (11) have recently demonstrated that LMWH was as effective as unfractionated heparin in releasing LPL from the capillary endothelium of perfused rat hearts and concluded that the lower plasma LPL activity measured after *in vivo* LMWH was due to the reduced ability of LMWH to prevent the rapid uptake of circulating LPL by the liver as compared to unfractionated heparin. The objective of our investigation was to compare the ability of LMWH and unfractionated heparin to displace LPL from the surface of cardiac myocytes.

MATERIALS AND METHODS

Preparation of cardiac myocytes. Calcium-tolerant cardiac myocytes were isolated from the hearts of male Sprague-Dawley (Charles River Canada Inc., St. Constant, Quebec, Canada) rats (200–300 g), essentially as described previously (12,13). The freshly isolated myocytes were resuspended in Joklik minimal essential medium supplemented with 1.2 mM $MgSO_4$ 1 mM carnitine, 1.5 mM $CaCl_2$ and 1% (wt/vol) defatted albumin (13) to a cell density of 4×10^5 cells/mL and were incubated for 10 or 30 min at 37°C with the indicated additions. The myocyte suspension was then centrifuged (10 s at 10,000 × *g* in a microcentrifuge), and the supernatant (medium) was removed for LPL assays (6). In some experiments, cardiac myocytes were isolated from rat hearts 3–4 d after the induction of diabetes by 100 mg/kg streptozotocin (13).

LPL assay. The activity of LPL in the post-heparin incubation medium was assayed with a sonicated [^{3}H]triolein (glycerol-[9,10-^{3}H]trioleate) substrate emulsion (12). The standard assay conditions were: 0.6 mM [^{3}H]triolein (1 mCi/mmol), 25 mM piperazine-N,N′-*bis*(2-ethanesulfonic acid) (PIPES), pH 7.5, 0.05% (wt/vol) defatted albumin, 50 mM $MgCl_2$, 2% (vol/vol) chicken serum as the LPL activator and 100 μL of post-heparin medium (13). After a 30-min incubation at 30°C, the release of [^{3}H]oleic acid was determined by liquid-liquid partitioning (12). All assays were performed in duplicate; LPL activity is routinely expressed as nmol oleate released per hour per 10^6 cells. LPL activity was linear with respect to the volume of post-heparin medium added to the assay, indicating that the introduction of different amounts of heparin into the assay had no effect on the determination of LPL activity.

Materials. Heparin (porcine intestinal mucosa) and LMWH (bovine intestinal mucosa; average molecular weight approx. 3 kDa) were obtained from Sigma Chemical Co. (St. Louis, MO) and were dissolved in water. Heparin was also obtained in solution (hepalean; 1000 U/mL) from Organon Teknika (Toronto, Ontario, Canada) (1 U/mL = 6 μg/mL). A 100 mM stock of decavanadate ($V_{10}O_{28}^{6-}$; yellow solution) was prepared by dissolving sodium orthovanadate (Na_3VO_4) in water and by adjusting the pH to 7.0 with concentrated HCl (14). [^{3}H]Triolein was purchased from Amersham Canada (Oakville, Ontario, Canada).

RESULTS AND DISCUSSION

Heparin produced a concentration-dependent increase in the release of LPL into the incubation medium of cardiac myocytes (Fig. 1). At every concentration (0.1–10 μg/mL) of

Abbreviations: DV, decavanadate; LMWH, low-molecular weight heparin; LPL, lipoprotein lipase; PIPES, piperazine-*N,N*′-bis(2-ethanesulfonic acid).

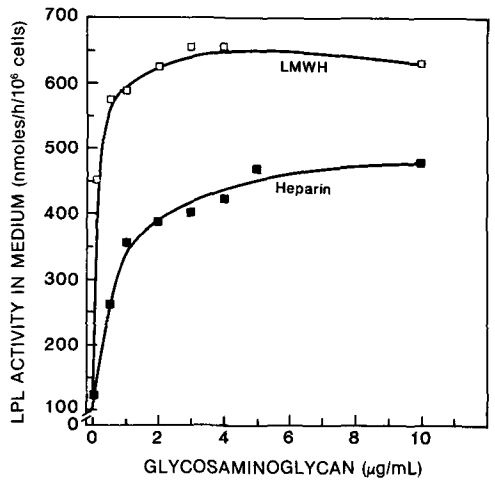

FIG. 1. Effect of heparin and low-molecular weight heparin (LMWH) concentrations on lipoprotein lipase (LPL) release from cardiac myocytes. LPL activity was determined in the incubation medium after cardiac myocytes were incubated for 30 min in the presence of the indicated concentrations of heparin (■) and LMWH (□).

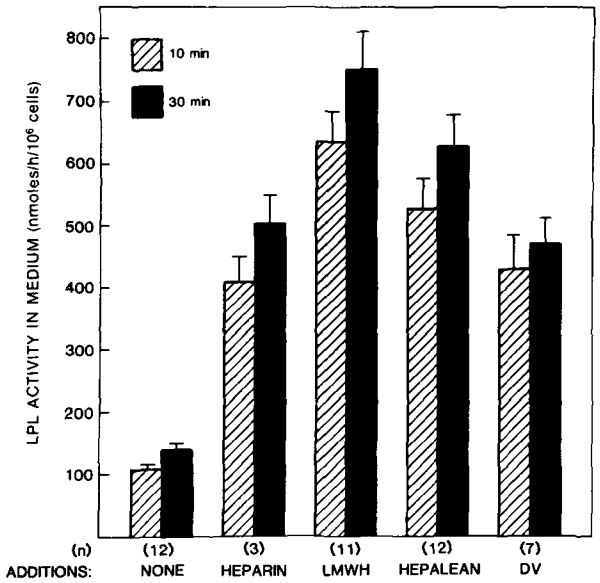

FIG. 2. Effect of heparin, low-molecular weight heparin (LMWH), and decavanadate (DV) on lipoprotein lipase (LPL) release from cardiac myocytes isolated from control rat hearts. Cardiac myocytes were incubated for 10 min (hatched bars) and 30 min (solid bars) with the following additions: heparin (10 μg/mL), heparin (hepalean; 5 U/mL or 30 μg/mL), LMWH (10 μg/mL) and DV (1 mM). LPL activity in the medium is presented as the mean ± SE for the number of experiments indicated in parentheses.

the glycosaminoglycans, incubation of cardiac myocytes with LMWH resulted in greater medium LPL activity than was measured after incubations with unfractionated heparin. Maximal LPL activity in the medium was observed at 3 μg/mL LMWH and 10 μg/mL heparin, suggesting that LMWH was more potent as well as being more effective in promoting the release of LPL into the medium of cardiac myocytes. On the other hand, if molar concentrations are calculated assuming Mr values of 3,000 and 12,000 (mean) for LMWH and heparin, respectively, then the optimal concentrations for LPL release (1.0 and 0.83 μM) were very similar. Interestingly, Liu *et al.* (15) have recently reported that a LMWH fraction (Mr 2,400–3,000) produced by enzymatic digestion was only one-tenth as potent by weight as a larger heparin fraction (Mr 12,700) in terms of release of LPL into plasma after intravenous injection into rats. Therefore, LMWH is much less effective (by weight) in displacing LPL from endothelial binding sites *in vivo* compared to the release of LPL from cardiac myocytes.

The heparin-induced release of LPL into the incubation medium of cardiac myocytes occurs in two phases: a rapid phase (5 to 10 min) followed by a slow phase (10 to 60 min) that is dependent on protein synthesis (6) and microtubular function (16). The rapid heparin-induced release of LPL was not decreased by cycloheximide or by a reduction in the incubation temperature from 37 to 23°C (6,16) and thus presumably reflects displacement of preformed enzyme from heparan sulfate proteoglycan binding sites on the myocardial cell surface (1,8,14). Incubation of cardiac myocytes with 10 μg/mL LMWH for 10 min (Fig. 2) resulted in a substantial release of LPL activity into the incubation medium (635 ± 52 nmol/h/10^6 cells) which was much greater than after incubation with unfractionated heparin (409 ± 41 nmoles/h/10^6 cells). Decavanadate (DV), a negatively charged polymerized vanadium compound, has recently been shown to mimic heparin and displace LPL from the surface of cardiac myocytes (14). As shown in Figure 2, medium LPL activity following incubations with 1 mM DV for 10 and 30 min was very similar to heparin-releasable LPL activity and thus substantially less than the LMWH-induced release of LPL.

Incubation of cardiac myocytes with a commercially available unfractionated heparin solution (hepalean; 5 U/mL or 30 μg/mL) resulted in slightly greater medium LPL activity than enzyme activity measured after incubation with the heparin solution prepared in our laboratory from the purchased powder (Fig. 2). Nevertheless, the net increment in medium LPL activity after incubation of control cardiac myocytes for 30 min with 10 μg/mL LMWH was 32 ± 4% greater ($P < 0.001$) than the heparin (hepalean)-induced release of LPL (Table 1). Braun and Severson (13) have reported that the heparin-induced release of LPL is reduced when cardiac myocytes are isolated from diabetic rat hearts. Incubation of diabetic cardiac myocytes with either heparin (hepalean) or LMWH resulted in lower LPL activity in the medium (Table 1) as compared to control myocytes, but the LMWH-induced release of LPL activity was still significantly greater (36 ± 7% increase) than the increment in medium LPL activity due to unfractionated heparin.

It is clear, therefore, that LMWH is significantly more effective than unfractionated heparin in displacing LPL from binding sites on the surface of cardiac myocytes; it follows that unfractionated heparin must not release the entire pool of LPL on the cell surface of cardiac myocytes. The observation by Rodrigues *et al.* (17) that preincubation of cardiac myocytes with unfractionated heparin reduced, but did not eliminate, the degradation of exogenous triolein in a subsequent incubation which is catalyzed by LPL bound to the surface of the myocardial cells (7) is consistent with this suggestion that the displace-

TABLE 1

Heparin- and Low-Molecular Weight Heparin (LMWH)-Induced Release of Lipoprotein Lipase (LPL) Activity into the Medium of Control and Diabetic Cardiac Myocytes[a]

Myocyte preparation	Net increment in medium LPL activity (nmoles/h/10^6 cells)		
	Heparin	LMWH	(%)[b]
Control (11)	470 ± 42	616 ± 50[c]	(32 ± 4%)
Diabetic (3)	325 ± 47	447 ± 84[c]	(36 ± 7%)

[a]Cardiac myocytes from either control or diabetic rat hearts were incubated for 30 min with no additions, 30 μg/mL heparin (5 U/mL hepalean), or 10 μg/mL LMWH, and the net increment of LPL activity in the incubation medium was measured (mean ± SEM) for the number of myocyte preparations indicated in parentheses.
[b]Percentage increase in the increment in medium LPL activity after LMWH compared to the heparin incubation.
[c]$P < 0.001$ (paired Student's t-test) relative to heparin.

ment of surface-bound LPL by unfractionated heparin is incomplete. The reduced mass of LMWH may permit a more effective interaction with endogenous heparan sulfate proteoglycans that are integrated into the glycocalyx on the plasma membrane so that the displacement of bound LPL is enhanced, although other factors must also play a role because LMWH was also more effective in releasing LPL than polymerized decavanadate which has an even lower molecular mass. LMWH may also complex differently with the dimeric LPL molecule (18). It must be acknowledged that unfractionated heparin and LMWH were isolated from porcine and bovine intestinal mucosa, respectively. Therefore, structural differences between two species, such as the degree of sulfation, may also contribute to the observed differences in promoting LPL release from cardiac myocytes. Previous experiments have shown that LPL activity released into the medium of cardiac myocytes was stable during incubation times up to 60 min (6). Therefore, the greater LPL activity in the medium after incubation with LMWH reflects enhanced release, not improved stability, of LPL in the medium of cardiac myocytes.

The increased effectiveness of LMWH to release LPL from isolated cardiac myocytes can be contrasted with results using other cell and tissue preparations. Unfractionated heparin and LMWH were not different with respect to their ability to release LPL from isolated adipocytes (10), whereas LMWH was slightly more effective than conventional heparin in promoting the release of LPL from the capillary endothelium of perfused hearts (11). These differences between the effectiveness of LMWH relative to unfractionated heparin will likely be a reflection of differences in the precise nature of the heparan sulfate proteoglycan binding sites for LPL on different cells. For example, LPL is bound to heparan sulfate proteoglycans that are covalently linked to the cell surface by a phosphatidylinositol-glycan membrane anchor in cardiac myocytes (13). In contrast, a similar pool of phosphatidylinositol-glycan-anchored heparan sulfate proteoglycans could not be detected on the surface of cultured aortic endothelial cells (3). Recently, Hoogewerf *et al.* (19) reported that the degree of sulfation of heparan sulfate proteoglycans influences the binding of LPL; cell-specific differences in the chemical composition of heparan sulfate proteoglycans could thus account for the observed variability in whether LMWH is more effective than unfractionated heparin in promoting the release of LPL from the surface of cells. Our results with cardiac myocytes reinforce the conclusion of Liu *et al.* (11) that lower plasma LPL activity following *in vivo* administration of LMWH is not due to a diminished ability to displace the enzyme from cellular binding sites, but rather is a consequence of more rapid hepatic clearance of circulating LPL released by LMWH as compared to unfractionated heparin.

Effect of Simvastatin on Desaturase Activities in Liver from Lean and Obese Zucker Rats

B. Georges, J.P. Blond*, C. Maniongui and J. Bézard
Unité de Recherche de Nutrition Cellulaire et Métabolique, Université de Bourgogne, 21004 Dijon Cedex, France

The effect of simvastatin, a hypocholesterolemic drug, on the biosynthesis of arachidonic acid was studied in obese and lean Zucker rats. After administration of 2 mg/kg body weight/d for 13 d, Δ6 and Δ5 desaturase activities were measured in liver microsomes at two substrate concentrations. In untreated rats, the Δ6 desaturation rate was similar in the obese and lean rats when measured at saturating substrate levels, whereas Δ5 desaturation was lower in the obese animals. Treatment with simvastatin did not change Δ6 desaturation in either phenotype but increased Δ5 desaturation in obese rats to reach the unchanged rate observed in lean animals. The changes were not reflected in the fatty acid composition of liver microsomal phospholipids when expressed as μg fatty acid/g of liver.
Lipids 28, 63-65 (1993).

Drugs such as resins or fibrates are commonly prescribed as therapeutic agents for the treatment of hypercholesterolemia. Simvastatin, also a hypocholesterolemic agent, belongs to a new series of competitive inhibitors of 3-hydroxy-3-methylglutaryl coenzyme A (CoA) reductase, the key regulatory enzyme of mammalian cholesterol biosynthesis (1-5). A recent study showed changes in fatty acid profiles of hepatic microsomal phospholipids from simvastatin treated Wistar rats, which suggested an effect of the drug on the activity of one or several desaturases involved in the biosynthesis of n-6 polyunsaturated fatty acids (6).

The genetic obesity of Zucker rats is often associated with hyperlipidemia. Increased rates of lipogenesis (7,8) and Δ9 desaturase activity (9) with concomitantly decreased activity of fatty acid (FA) oxidation (10) in the liver were the major abnormalities of the obese (fa/fa) animal as compared to its littermate (Fa/-). There was also an inhibition of linoleic acid (18:2n-6) conversion into arachidonic acid (20:4n-6), resulting from decreased Δ5 desaturation activity (11).

The purpose of the present study was to compare obese with lean Zucker rats with respect to the effect of simvastatin on the *in vitro* activities of hepatic Δ6 and Δ5 desaturases. The fatty acid composition of microsomal phospholipids was also studied in order to examine whether simvastatin treatment induced changes in the biosynthesis of n-6 and n-3 polyunsaturated fatty acids *in vivo*.

MATERIALS AND METHODS

[1-^{14}C]Linoleic acid and [2-^{14}C]dihomo-γ-linolenic acid (56 mCi/mmol, 97% radiochemical purity) were purchased from the Radiochemical Centre (Amersham, U.K.). The substrates were diluted with the corresponding unlabelled fatty acid using ethanol as solvent. Cofactors and biochemicals were from Sigma Chemical Co. (St. Louis, MO).

Male obese rats (fa/fa) of the Zucker strain were purchased from INSERM U177 (Paris, France). They were 12 weeks old on arrival at the laboratory and were given free access to a standard laboratory chow (A04 from UAR, Villemoisson sur Orge, France) and tap water. The animals were divided into four groups of six animals each; two groups of untreated (control), both obese and lean, and two groups of treated animals. From days 1 to 13 of the experiment, treated rats received a daily dose of 2 mg/kg body weight of simvastatin in 0.1 mL of corn oil by gastric intubation. For each phenotype, control rats received only the equivalent volume of excipient. On day 13, animals were treated as above, but they were kept fasting 16 h up to killing by decapitation on day 14. The liver of each rat was removed, weighed and perfused with ice-cold 0.154 M KCl solution and then homogenized in 5 vol of sucrose and 0.05 M phosphate (pH 7.4) solution using a Teflon Potter Elvejhelm homogenizer. The preparation of microsomal fractions from *ca.* 3 g of liver was done as described previously (11). The protein content of microsomal fractions was determined by the Biuret method (12).

Five mg microsomal protein was incubated in an open flask with [1-^{14}C]18:2n-6 or [2-^{14}C]20:3n-6. The substrate levels (60 nmol and 30 nmol, respectively) were nonsaturating so they would be close to physiological concentration. In addition, saturating levels, 120 and 60 nmol respectively, also were used to evaluate the Δ6 and Δ5 desaturation capacity of liver microsomes. Incubations were performed at 37°C in a shaking water bath for 15 min with a total volume of 2.1 mL incubation medium containing in mmol/L: phosphate buffer (pH 7.4) 72, $MgCl_2$ 4.8, CoA 0.5, adenosine 5′-triphosphate 3.6, and reduced nicotinamide adenine dinucleotide phosphate 1.2. Incubations were stopped by adding 15 mL of chloroform/methanol (1:1, vol/vol). The lipids were saponified, and the extracted fatty acids were methylated with methanol/boron trifluoride (13). The conversion of labelled substrates (linoleic and dihomo-γ-linolenic acids, respectively) into their Δ6 n-6 and Δ5 n-6 products (γ-linolenic and arachidonic acids, respectively) was determined after separation by reversed phase high-performance liquid chromatography as described by Narce *et al.* (14). Fractions corresponding to individual FA methyl ester were collected at the detector outlet (differential refractometer), and radioactivity was measured in the sample by liquid scintillation counting.

Lipids from aliquots of liver microsomes were extracted with dimethoxymethane/methanol (4:1, vol/vol) according to Delsal (15). Phospholipids were separated by silicic acid column chromatography (16). After heptadecanoic acid was added as internal standard, FA were transmethylated (13). Methyl esters were analyzed by gas-liquid chromatography using a Becker Packard Model 419 gas chromatograph (Packard Instruments, Rungis, France) equipped with a laboratory-made 30 m × 0.4 mm i.d. glass capillary

Abbreviations: CoA, coenzyme A; FA, fatty acid.

column coated with Carbowax 20 M (Applied Science, State College, PA). Peaks on the chromatograms were assigned based on their retention time relative to methyl heptadecanoate. Peak areas were measured using a Delsi Enica 21 integrator (Delsi Instruments, Suresnes, France).

Data presented are means ± SD. After analysis of variance using a Duncan's multiple range test, means were compared according to the least significant difference ($P < 0.01$) and classified in increasing order.

RESULTS AND DISCUSSION

In the untreated obese rats, the Δ6 desaturase activity at the saturating level of substrate was not significantly different from that observed in lean rats (Table 1). However, at half-saturating concentration, the Δ6 desaturation rate was higher in obese rats, contrary to what was observed previously in unfasted animals (11). The Δ6 desaturase affinity for the substrate might be slightly higher in the fasted obese rat, a condition which would not appear in the presence of a high level of substrate. In unfasted rats, the presence in microsomes of free unlabelled dietary linoleic acid from the blood, which are probably present in higher amounts in the hyperphagic obese rats, may decrease the apparent Δ6 desaturation rate in obese rats. The treatment with simvastatin did not induce any change in Δ6 desaturation in either phenotype or at either substrate concentration. On the contrary, the Δ5 desaturase activity was lower in untreated obese rats as compared to lean rats at both substrate concentrations (Table 1). This was probably due to a lower affinity of the enzyme for the substrate, as shown previously (11). Treatment by simvastatin restored the desaturation rate to the control level in obese rats, but had no significant effect on the lean animals. The same effect had been observed with fenofibrate, another hypolipidemic drug (17).

In liver microsomal phospholipids (Table 2) the amount of total FA per gram of liver was lower in untreated obese rats than in lean rats, contrary to what was previously observed in total microsomal liver lipids of 12-week-old rats (11). In obese rats, simvastatin treatment decreased the amount of 18:2n-6, 20:3n-6 and of total n-6 fatty acids, but not 20:4n-6. This effect was not observed in lean rats. The total n-6 plus n-3 FA from microsomal phospholipids

	Treated	2.0 ± 0.2[d]	3.7 ± 0.5[d]	11.2 ± 0.5[e]	15.2 ± 1.4[e]
Obese	Control	2.6 ± 0.2[e]	3.6 ± 0.2[d]	8.7 ± 0.5[d]	11.8 ± 1.9[d]
	Treated	2.5 ± 0.2[e]	3.5 ± 0.3[d]	10.6 ± 0.8[e]	15.1 ± 1.8[e]

[a] Desaturase activities are expressed as nmoles of substrate converted per 15 min per 5 mg microsomal protein. Results are means ± SD of six animals in each group. Means were compared in each column and classified according to increasing order. Means assigned different superscript letters were significantly different ($P < 0.01$).

[b] Nonsaturating substrate concentration (nmoles).

[c] Saturating substrate concentration (nmoles).

TABLE 2

Concentration (μg/g of liver) of Total and Polyunsaturated Fatty Acids in Liver Microsomal Phospholipids from Lean and Obese Zucker Rats[a]

	Phenotype			
	Lean		Obese	
Fatty acids	Control	Treated	Control	Treated
Total	2510 ± 400[e]	2500 ± 200[e]	1530 ± 100[d]	1300 ± 260[d]
18:2n-6	283 ± 30[f]	275 ± 10[f]	143 ± 14[e]	111 ± 12[d]
20:3n-6	19 ± 7[d,e]	16 ± 4[d]	37 ± 5[f]	25 ± 4[e]
20:4n-6	695 ± 55[e]	700 ± 20[e]	330 ± 11[d]	298 ± 20[d]
22:6n-3	258 ± 12[e]	270 ± 12[e]	226 ± 12[d]	200 ± 13[d]
Total n-6[b]	1013 ± 53[f]	1013 ± 13[f]	520 ± 11[e]	442 ± 9[d]
Total n-3[c]	310 ± 14[f]	315 ± 15[f]	283 ± 12[e]	240 ± 9[d]
n-6 plus n-3	1323 ± 50[f]	1328 ± 14[f]	803 ± 12[e]	682 ± 9[d]

[a] Results expressed as μg fatty acid/g of liver are means ± SD for n = 6 animals in each group. Within each line, means not showing a common superscript letter are significantly different ($P < 0.01$). They are classified according to increasing order.

[b] Total n-6 includes 18:3, 20:2, 22:4 and 22:5n-6, not listed individually.

[c] Total n-3 includes 18:3, 20:5 and 22:5n-3, not listed individually.

was 39% lower in untreated obese rats than in untreated lean animals. However, when expressed as a percentage of total fatty acids, there was no change, and the percentage (52.5% in both cases) was similar to that found in treated animals.

The mechanism by which simvastatin increases the Δ5 desaturation rate is unknown. Fibrates have been shown to exhibit the same effect (17,18). They are also proliferators of peroxisomes (19), and some desaturation activities have been observed in these organelles (20). This may explain the increased rate of Δ5 desaturation in fenofibrate treated obese rats (17). Because simvastatin is not a peroxisome proliferator (6), this mechanism cannot be evoked here. Alternatively, changes in the hormonal status of simvastatin-treated obese rats cannot be ignored as several hormones, such as insulin, increase the Δ5 desaturation rate (21). However, further studies are needed to test this hypothesis.

The increase in Δ5 desaturation rate in treated obese rats was not accompanied by an increase in the amount of arachidonic acid in liver microsomal phospholipids. Because of the relatively low turnover rate of these constituents, prolonged drug treatment may be necessary to restore a fatty acid profile in obese rats similar to that observed in lean rats.

ACKNOWLEDGMENTS

We wish to thank Dr. P. Gautheron, Merck-Sharp and Dohme, for financial aid. The authors are also greatly indebted to J. Gresti for technical help.

Composition of the Phospholipids and Their Fatty Acids in the ROC-1 Oligodendroglial Cell Line

Eric J. Murphy* and **Lloyd A. Horrocks**
Department of Medical Biochemistry and Neuroscience Program, The Ohio State University, Columbus, Ohio 43210

ROC-1 cells are a hybrid of C-6 rat glioma and rat oligodendroglia cells. Biochemically these cells resemble the oligodendroglia parent, but their lipid composition is unknown. The phospholipid composition in mole % was: cardiolipin, 1.0; phosphatidylglycerol, 1.2; ethanolamine glycerophospholipids, 27.6; phosphatidylinositol, 5.8; lysophosphatidylethanolamine, 0.8; phosphatidylserine, 5.6; choline glycerophospholipids, 43.7; sphingomyelin, 13.7; phosphatidylinositol-4-monophosphate, 0.8; and lysophosphatidylcholine, 0.6. The choline and ethanolamine plasmalogens made up 7.2 and 18.4% of the total phospholipids, respectively. The phospholipid composition reflects that of both parental cells. The cells had moderate to high levels of 20:3n-9 indicating n-6 series fatty acid deficiency. The phosphatidylinositol had very high 20:3n-9 levels with a 20:3n-9/20:4n-6 ratio of 2.1 compared to 0.44 and 0.58 for ethanolamine glycerophospholipids (EtnGpl) and choline glycerophospholipids (ChoGpl) respectively. The saturated/polyenoic fatty acid ratios were 0.40 for EtnGpl, 3.38 for ChoGpl and 1.48 for phosphatidylinositol.
Lipids 28, 67-71 (1993).

Phospholipids and their constituent fatty acids in the cell membrane have a major role in maintaining membrane structure, integrity and function including receptor-mediated signal transmission (1-8). Many different cell lines are used to study these areas, but for many of the cells the phospholipid and fatty acid compositions are unknown.

The partial phospholipid composition of oligodendroglia has been reported (9-12) as well as the composition of C-6 glioma cells (13). The fatty acid composition of oligodendroglia (14) and the fatty acid composition of oligodendroglia polar lipids (11) have also been reported.

In this communication, we report the phospholipid and fatty acid composition of ROC-1 cells. ROC-1 oligondendroglia cells are a hybrid between a C-6 rat glioma and a rat oligondendrocyte (15).

MATERIALS AND METHODS

ROC-1 cells were obtained from F.A. McMorris (Wistar Institute of Anatomy and Biology, Philadelphia, PA). The cells were maintained in modified Eagle's medium supplemented with 10% fetal calf serum, 100 μM hypoxanthine, 0.4 μM aminopterin and 16 μM thymidine. The cells were fed by removing half of the culture medium and replacing it with fresh culture medium. The cells were maintained in a 95% humidified air, 5% CO_2 atmosphere at a constant temperature of 37°C. Upon reaching confluency, medium was removed and cells were washed with phosphate-buffered saline (PBS) to remove any detached cells. Trypsin was added to remove attached cells and these cells were then suspended in medium. The cell suspensions were split and plated upon 100-mm polystyrene culture plates.

Confluent cells were extracted using *n*-hexane/2-propanol (3:2, vol/vol) (16). Compared with chloroform/methanol, this extraction method gives better recovery of lipids with less protein contamination. Prior to extraction, the medium was removed and the cells were washed with two 3-mL portions of cold PBS buffer to remove traces of medium. The plates were immediately placed upon dry ice and frozen to minimize acylhydrolase activity during extraction (17). Two 2-mL aliquots of 2-propanol were used to remove the cells from the cultured dishes. The initial aliquot was added to the frozen cells which were subsequently removed from the plate using a Teflon cell scraper. The second aliquot was used to rinse the plate. Both of these aliquots were added to a tube containing 6-mL of *n*-hexane for a final *n*-hexane/2-propanol ratio of 3:2 by volume. The extracts were kept under nitrogen to minimize autoxidation of lipids.

Prior to phospholipid separation. lipid extracts were ultrafiltered using a Rainin 0.2 μm nylon filter (Woburn, MA). The sample was dried under a stream of nitrogen and redissolved in a known volume of *n*-hexane/2-propanol/water (56.7:37.8:5.5, vol/vol/vol) before high-performance liquid chromatography (HPLC).

The cell lipid extracts were separated into major phospholipid classes by HPLC including the separation of the acidic phospholipids phosphatidylserine (PtdSer) and phosphatidylinositol (PtdIns), as well as lysophosphatidylethanolamine (lysoPtdEtn) (18). The lower limit of sensitivity was 100 nmol of injected phospholipid. Each phospholipid class was quantitated by measuring lipid phosphorus (19). The solvents, HPLC grade *n*-hexane and 2-propanol from E.M. Science (Cherry Hill, NJ), were filtered through a 0.5 μm Millipore FH-type nylon filter (Bedford, MA) and degassed. Solvent A was *n*-hexane/2-propanol (3:2, vol/vol) and solvent B was *n*-hexane/2-propanol/water (56.7:37.8:5.5, vol/vol/vol). Water was purified using a Millipore water purification system. The HPLC consisted of two Altex (Berkeley, CA) 100A pumps, an Altex 420/421 controller and an Altex model 210 injection port. The Dupont (Wilmington, DE) Zorbax Silica column (4.6 mm × 250 mm, 5-6 μm) was maintained at a constant temperature of 34°C with a Jones Chromatography (Lakewood, CO) heating block. An ISCO (Lincoln, NE) V4 ultraviolet (UV) variable wavelength detector was used to monitor absorption at 205 nm.

Plasmalogens were assayed by HPLC after mild acidic hydrolysis of the previously collected ethanolamine glycerophospholipid (EtnGpl) and choline glycerophospholipid (ChoGpl) fractions (20). This caused hydrolysis of the

Abbreviations: CerPCho, sphingomyelin; ChoGpl, choline glycerophospholipids; EtnGpl, ethanolamine glycerophospholipids; FA, fatty acid; FAME, fatty acid methyl ester; GLC, gas-liquid chromatography; Gpl, glycerophospholipid; HPLC, high-performance liquid chromatography; lysPtdEtn, lysophosphatidylethanolamine; PBS, phosphate-buffered saline; PlsCho, plasmenylcholine; PlsEtn, plasmenylethanolamine; PtdIns, phosphatidylinositol; PtdSer, phosphatidylserine; PUFA, polyunsaturated fatty acid; RCF, relative correction factors; TLC, thin-layer chromatography; UV, ultraviolet.

alkenyl ether bond of the plasmalogens while the alkylacyl and diacyl glycerophospholipids (Gpl) remained intact. The sample was reextracted and rechromatographed utilizing the same separation procedure as used in the initial separation. The lysophospholipid fractions were collected for phosphorus assay (19). The fraction containing the alkylacyl and diacyl Gpl was then collected and subjected to alkaline transmethylation in 2 mL of 0.1 M NaOH in methanol. After 15 min the reaction was terminated with addition of 1-mL ethyl formate (21). The two reaction products were separated by the addition of chloroform/isobutanol/water (4:2:3, vol/vol/vol) to the methanol followed by centrifugation to complete the phase separation. The top layer contained glycerophosphocholine or glycerophosphoethanolamine and the bottom layer contained the lysophospholipid. Aliquots were taken for phosphorus assay (19).

Phospholipid acyl chains were converted to fatty acid methyl esters (FAME) through base-catalyzed transesterification (22). This method, unlike BF_3-catalyzed transesterification, avoids oxidative side reactions and the formation of dimethylacetals from plasmalogens. FAME were extracted with 2-mL of hexane. The upper phase was pipetted off and the remaining methanol phase washed with two 2-mL aliquots of hexane. FAME were stored in a nitrogen atmosphere at −20°C.

FAME were separated and quantitated by gas-liquid chromatography (GLC). A set of standards (NuChek Prep, Elysian, MN) was used to establish relative retention times and relative correction factors (RCF) for each FAME. The internal standard was 17:0 methyl ester. The detector response was linear within the concentration range of the samples for all identified fatty acids of varying chain lengths and degrees of unsaturation with correlation coefficients of 0.985 or greater. This standard was used to establish standard curves and for each sample run.

The GLC system was comprised of a Shimadzu (Kyoto, Japan) GC-8A, a Supelco (Bellefonte, PA) SP-2330 capillary column (30 m long) and a flame-ionization detector. Column temperature was maintained at 190°C with nitrogen as the carrier gas at a pressure of 0.5 kg/cm^2. Detector and injector temperatures were maintained at 220°C. A split ratio of 100:1 was used. Peak area data were collected with a Nelson Analytical 760 series intelligent interface (Cupertino, CA) and computed with Nelson model 2600 software.

RESULTS

The ChoGpl comprise the largest proportion of the phospholipids in ROC-1 cells (Table 1). The order of the other phospholipids in decreasing proportions is EtnGpl > sphingomyelin (Cer*P*Cho) > PtdIns = PtdSer. The lysophospholipids make up a small portion of the total phospholipid.

The compositions of EtnGpl and ChoGpl subclasses are reported in Table 2. Ethanolamine plasmalogen (PlsEtn), the alkenylacyl subclass, accounted for 18.4 mol% of the total phospholipids. Of the ChoGpl subclasses, the diacyl subclass was the largest fraction making up 33.0 mol% of the total phospholipids. There was a large amount of choline plasmalogen (PlsCho), accounting for 7.2% of the phospholipids.

The fatty acid (FA) compositions of EtnGpl, ChoGpl and PtdIns are reported in Table 3. For EtnGpl the composition of the major FA in decreasing mole percent was: 20:4n-6 > 18:1n-9 > 18:0 > 20:3n-9 > 22:6n-3. There was a relatively large amount of the Mead acid, 20:3n-9. The 20:3n-9/20:4n-6 ratio was 0.43. For ChoGpl, the composition of the major FA in decreasing mole percent was: 18:1n-9 > 16:0 >> 18:0 > 20:4n-6. The 20:3n-9/20:4n-6 ratio was 0.58. The PtdIns FA composition in decreasing mole percent was: 18:0 > 18:1n-9 > 20:3n-9 > 16:0 >18:2n-6 = 20:4n-6. There was a large proportion of the Mead acid present, accounting for 12.6% of the total FA. The 20:3n-9/20:4n-6 ratio was 2.1.

The EtnGpl FA composition was the most unsaturated, with a saturated/unsaturated fatty acid ratio of 0.27. The unsaturation index for ChoGpl and PtdIns was 0.64 and 0.69, respectively. The saturated/monoenoic fatty acid ratios for ChoGpl and EtnGpl were essentially the same; however, this ratio was higher for PtdIns. There were large differences in the saturated/polyenoic fatty acid ratios for the phospholipid classes. These ratios were 0.40 for EtnGpl, 3.38 for ChoGpl and 1.48 for PtdIns.

TABLE 1

Phospholipid Composition of ROC-1 Cells[a]

Phospholipid	mol %
Cardiolipin	1.0 ± 0.4
Phosphatidylglycerol	1.2 ± 0.7
Ethanolamine glycerophospholipids	27.6 ± 3.3
Phosphatidylinositol	5.8 ± 1.4
Lysophosphatidylethanolamine	0.8 ± 0.8
Phosphatidylserine	5.6 ± 1.5
Choline glycerophospholipids	43.7 ± 5.1
Sphingomyelin	13.7 ± 2.8
Phosphatidylinositol 4-phosphate	0.8 ± 0.2
Lysophosphatidylcholine	0.6 ± 0.2

[a]The values are means ± SD and are expressed as mole percent of each phospholipid class. For each value n=5.

TABLE 2

Composition of Ethanolamine and Choline Glycerophospholipid (Gpl) Subclasses[a]

Phospholipid subclasses	Gpl (%)	Total phospholipid (%)
Ethanolamine glycerophospholipid (EtnGpl)		
Diacyl	25.6 ± 1.5	7.1
Alkylacyl	7.6 ± 0.9	2.1
Alkenylacyl	66.8 ± 1.9	18.4
Choline glycerophospholipid (ChoGpl)		
Diacyl	75.5 ± 1.8	33.0
Alkylacyl	8.1 ± 1.3	3.5
Alkenylacyl	16.4 ± 1.7	7.2

[a]Values are means ± SD and are expressed as mole percent of the individual glycerophospholipid class. The total % phospholipid represents the mole percentage of each subclass with respect to total phospholipid composition. For EtnGpl n=5 and for ChoGpl n=7.

DISCUSSION

One inherent problem of growing primary oligodendroglial cells in culture is the difficulty of isolating cells from

Saturated/polyenoic	0.40	3.38	1.48

[a]Values are mol% for each fatty acid for the respective phospholipid class. The values for PtdIns represent the means of two determinations. For ChoGpl and EtnGpl the values represent mean ± SD for 4 and 5 determinations, respectively.

tissue (23,24). Clonal cell lines are useful because large quantities can be grown with little or no difference between batches and no contamination from other cell types as commonly occur with primary cell cultures. The ROC-1 cell hybrid is the best oligodendroglia cell line now available and has morphological and biochemical characteristics that closely resemble those of the primary oligodendrocyte (25).

The ROC-1 oligodendroglial cell is a hybrid cell made from a rat oligodendrocyte and a C-6 rat glioma cell (15). Thus, the phospholipid composition should closely resemble one or both of the parent cell types. The Cer*P*Cho, EtnGpl, ChoGpl and cardiolipin mol% phospholipid composition of ROC-1 cells is similar to that of C-6 glioma cells (13). PtdIns and PtdSer levels reflect those in glial cells (9). These values are found in Table 4 for comparison. In the study using whole oligodendroglia, the PtdIns and PtdSer were not resolved from each other and the two classes made up 10.4% ± 0.6 of the total phospholipid composition (10). Our values for the phospholipid composition of ROC-1 cells agree with these reported values. Thus, the ROC-1 cell phospholipid composition is a hybrid, with a composition similar to the composition of both parent cells.

The ROC-1 cells had a lower ChoGpl content (43.7%) than reported for fresh oligodendroglia preparations 50.6% ± 4.8 (10) and 49.6% (12). Our lower value may reflect the complete separation of Cer*P*Cho from the ChoGpl which we achieve using HPLC. The EtnGpl composition (27.6%) was slightly higher than fresh oligodendroglia preparations 23.0% ± 2.6 (10) and 23.6% (12). Our values for PtdIns and PtdSer agree with those reported by other workers (10,12), suggesting the PtdIns and PtdSer composition closely resembled the oligodendroglial parent cell.

We report compositional values for the EtnGpl and ChoGpl subclasses. In freshly isolated glial cells from 14-day-old rat, the ethanolamine plasmalogen made up 7.5% of the total phospholipid compared to our value of 18.4%, but no choline plasmalogen was reported (9). ROC-1 cells contained a high proportion of choline plasmalogen (7.2% of the total phospholipid) and high proportions of 1-*O*-alkyl-2-acyl-glycerophosphoethanolamine and 1-*O*-alkyl-2-acyl-glycerophosphocholine. These two phospholipid classes made up 2.1 and 3.5% of the total phospholipids, respectively.

The fatty acid compositions of the EtnGpl, ChoGpl and PtdIns are reported in Table 3. The EtnGpl had a low saturated/unsaturated fatty acid ratio. This is partly due to the high ethanolamine plasmalogen proportion which contributes a large amount of 20:4n-6. There was a large proportion of 20:3n-9 (Mead acid) in the EtnGpl. Mead acid is thought to be increased in PUFA deficient cells in an attempt to maintain a normal saturated/unsatu-

TABLE 4

Comparison of Phospholipid Compositions of ROC-1, C-6 Glioma and Glial Cells[a]

Phospholipid	ROC-1 n=5	C-6 glioma[b] n=5	Mixed glial[c] n=9
Cardiolipin	1.0 ± 0.4	1.9 ± 0.7	2.5
Sphingomyelin	13.7 ± 2.8	8.1 ± 1.1	7.0
Ethanolamine glycerophospholipids	27.6 ± 3.3	28.5 ± 1.7	22.9
Choline glycerophospholipids	43.7 ± 5.1	52.2 ± 2.3	52.4
Phosphatidylinositol	5.8 ± 1.4	3.8 ± 0.5	5.8
Phosphatidylserine	5.6 ± 1.5	4.5 ± 0.5	6.2

[a]The values are mole percent of total phospholipid. ROC-1 phospholipids were separated by high-performance liquid chromatography and quantitated as lipid phosphorus. Values are means ± SD.
[b]The C-6 glioma cell phospholipids were separated by thin-layer chromatography (TLC) and quantitated as lipid phosphorus (13).
[c]The glial cell phospholipids were separated by two-dimensional TLC and quantitated as lipid phosphorus (9).

rated fatty acid index (26). The ChoGpl and PtdIns have even higher 20:3n-9/20:4n-6 ratios. This increase in 20:3n-9/20:4n-6 ratio indicates the apparent need to maintain a high level of PUFA in the cell through the increase in 20:3n-9 levels. Overall, the ROC-1 cells are deficient in the n-6 series, particularly in arachidonic acid as indicated by the higher 20:3n-9 proportions.

Cultured murine brain cells have a 20:3n-9/20:4n-6 ratio of 0.27 for cells grown in 10% fetal calf serum and 1.6 for cells grown in a chemically defined medium devoid of PUFA (14). We found a 20:3n-9/20:4n-6 ratio of 0.44 for EtnGpl, 0.58 for ChoGpl and 2.1 for PtdIns. These results indicate that the ROC-1 cells were in a state of PUFA deficiency. The two major phospholipid classes had moderate PUFA deficiency, while the PtdIns was severly PUFA deficient.

Oligodendrocytes in culture for 34 d have a saturated/polyenoic fatty acid ratio of 0.41 for fatty acids from polar lipids (11). Cells cultured for only 8 d have a saturated/polyenoic ratio in the total lipid extract of 1.29 for serum-supplemented cells, 1.86 for cells grown in a chemically defined medium deficient in PUFA and 0.84 for cells in culture for 34 d in a chemically defined medium supplemented with PUFA (26). Our cells were grown in medium supplemented with 10% fetal calf serum and were not supplemented with exogenously added PUFA. The saturated/monoenoic fatty acid ratio was essentially the same in EtnGpl and ChoGpl, *i.e.*, 0.81 and 0.80, respectively. The saturated/monoenoic ratio for PtdIns was 1.29. ChoGpl had a saturated/polyenoic fatty acid ratio of 3.38 compared to a ratio of 0.40 for EtnGpl and 1.48 for PtdIns. Clearly, the ChoGpl had a lower polyenoic fatty acid content, although this is generally the case for the more saturated ChoGpl. Regardless of the variation in the saturated/polyenoic fatty acid ratios, the values for ROC-1 cells indicate a decrease in PUFA compared to oligodendroglia cells grown under similar conditions. These differences cannot be explained due to medium conditions since the cells were grown in 10% fetal bovine serum. Further, the ROC-1 cells had a larger proportion of 20:3n-9 indicating that the cells were PUFA deficient, even though the culture conditions are known not to produce PUFA deficiency in other cells. The lower levels of PUFA in ROC-1 cells may be directly related to the tumor origin of the cell line. This deficiency may cause possible signal transduction problems and an interruption of normal cellular events.

A Simple and Efficient Synthesis of Fatty Thioacids

Hyeon-Cheol Shin and **Daniel M. Quinn***
Chemistry Department, University of Iowa, Iowa City, Iowa 52242

A rapid and high-yielding two-step synthesis of fatty thioacids from readily available starting materials has been devised. In the first step, an acid chloride is reacted with thioacetic acid at room temperature to produce a mixed thioanhydride, which in the second step is nucleophilically deacetylated with propylamine or butylamine at 5°C. Each step is complete in five minutes and proceeds in quantitative yield. The versatility of the procedure is demonstrated by the synthesis of fatty thioacids from six to sixteen carbons in length.
Lipids 28, 73-74 (1993).

Replacement of oxyester with thioester functions provides alternate lipolytic enzyme substrates that are close structural mimics of physiological lipid subtrates. Hydrolysis of thiolipid substrates can be followed in coupled spectroscopic assays and thus has analytical advantages over traditional radiochemical assays. For example, thiolipid assays for phospholipase A_1 (1,2) and phospholipase A_2 (3,4) have been described.

Hendrickson and colleagues (5,6) have devised synthetic methods for the preparation of racemic and enantiomeric thiophospholipid substrates of phospholipases A_1 and A_2. Their procedure uses $Na_2S{\cdot}9H_2O$ and the appropriate acid chloride to synthesize thioacids (6). However, the nonahydrate of Na_2S must be dehydrated, typically by drying *in vacuo* over P_2O_5 for two days, before reaction with the acid chloride, and yields are only ~50%. Residual water, or adventitious water contamination, promotes the formation of anhydrides and oxyacids as side products, and thus inert-atmosphere techniques are required to achieve maximal yields of thioacids. Moreover, the reaction mixture is a slurry because Na_2S is poorly soluble in the solvent, pyridine. An alternate method, reaction of H_2S with the appropriate acid chloride (7), has several disadvantages: extreme stench and toxicity of H_2S; a complicated experimental apparatus is required to contain H_2S; the reaction is conducted at −30°C, far from ambient temperature.

In this communication we describe a rapid, efficient and high-yielding synthesis of fatty thioacids that avoids these complications.

EXPERIMENTAL PROCEDURES

Materials. Thioacetic acid (TAA), hexanoyl chloride, decanoyl chloride, myristoyl chloride, palmitoyl chloride, propylamine (PA) and anhydrous pyridine were purchased from Aldrich Chemical Co. (Milwaukee, WI). TAA was usually distilled before use. Butylamine (BA) was purchased from Matheson, Coleman and Bell (Norwood, OH). Concentrated HCl was purchased from Fisher Scientific (Fair Lawn, NJ). High-performance liquid chromatography (HPLC)-grade hexane was from EM Science (Cherry Hill, NJ). Flexible plastic thin-layer chromatography (TLC) plates (Polygram SIL G/UV_{254}, silica gel with fluorescent indicator) were purchased from Brinkman Instruments, Inc. (Lauda-Königshofen, Germany) and were produced by Macherey-Nagel (Düren, Germany).

Synthesis and product characterization. Scheme 1 outlines the procedure for the thioacid synthesis; the preparation of thioadecanoic acid (TDA) is illustrative of the methods used. Except where specified, all manipulations were performed at room temperature. Reaction mixtures were analyzed by TLC, with hexane/diethyl ether (7:3, vol/vol) as the mobile phase. In a round-bottom flask (RBF) equipped with a magnetic stirrer, 4.2 mL of decanoyl chloride (0.02 mol) and 1.5 mL of TAA; (0.021 mol) were dissolved in 100 mL of hexane that contained 2.0 mL (0.025 mol) of pyridine, and the reaction mixture was stirred for 5 min. TLC of the reaction mixture showed a new spot at R_f 0.7 for the mixed acetic-decanoic thioanhydride. The reaction mixture was then cooled in an ice bath, 3.4 mL of propylamine (0.041 mol) was added and stirring was continued for 5 min. Use of an ice bath was necessary to moderate the exothermic reaction of the amine with the mixed anhydride. After these reactions, the acid chloride and mixed thioanhydride spots were no longer detected by TLC. The reaction mixture was washed with 6 N aqueous HCl to protonate the thioacid product and to remove pyridine and propylamine. A single trailing spot beginning at R_f 0.1 was detected that corresponded to thiodecanoic acid. The thioacid was isolated by drying the hexane phase with anhydrous Na_2SO_4, followed by solvent evaporation.

Thioacids products were characterized by Fourier transform infrared (FTIR) spectroscopy and electron impact mass spectrometry (EI-MS); the respective spectra were acquired on Mattson Instruments Cygnus 25 FTIR (Madison, WI) and VG-TRIO1 (VG Instruments Co., Altrincham, England) spectrometers. The melting point of thiopalmitic acid was measured on a Laboratory Devices Melt-temp melting point apparatus and was not corrected.

Abbreviations: BA, butylamine; EI-MS, electron impact mass spectrometry; FTIR, Fourier transform infrared; HPLC, high-performance liquid chromatography; PA, propylamine; RBF, round-bottom flask; TAA, thioacetic acid; TDA, thiodecanoic acid; THA, thiohexanoic acid; TLC, thin-layer chromatography; TMA, thiomyristic acid.

TABLE 1

Physical and Spectroscopic Data for Thioacid Products

Thioacid	Molecular formula	Formula weight	MS data[a]	Characteristic infrared frequencies
THA	$C_6H_{12}OS$	132.22		2563 cm^{-1} (SH) 1707 cm^{-1} (C=O)
TDA	$C_{10}H_{20}OS$	188.32	155 (−SH)	2561 cm^{-1} (SH) 1701 cm^{-1} (C=O)
TMA	$C_{14}H_{28}OS$	244.43	228 (−OH) 211 (−SH)	2564 cm^{-1} (SH) 1718 cm^{-1} (C=O)
TPA[b]	$C_{16}H_{32}OS$	272.49		2564 cm^{-1} (SH) 1716 cm^{-1} (C=O)

[a]Data are *m/e* values. Mass spectra (MS) were not acquired for thiohexanoic acid (THA) and thiopalmitic acid (TPA). TMA, thiomyristic acid; TDA, thiodecanoic acid.
[b]Melting point, 27–28°C. The other thioacids are colorless liquids.

RESULTS AND DISCUSSION

Table 1 lists spectroscopic data and other physical properties for the four fatty thioacids that were synthesized by the route shown in Scheme 1. Thiohexanoic (THA), TDA and thiomyristic acids (TMA) are liquids, and thiopalmitic acid is a low-melting solid. All the thioacids show C=O and S-H stretches in the FTIR spectra at 1700–1720 cm^{-1} and 2560–2565 cm^{-1}, respectively. These spectra lack the broad feature in the region 2500–3300 cm^{-1} expected for carboxylic acids, which demonstrates that the thioacids are not contaminated with the corresponding oxyacids. The EI-MS spectrum of TDA contains a peak at $m/e = 155$ for loss of SH, while the spectrum of TMA contains peaks at 211 and 228 for loss of SH and OH, respectively, from the parent ion.

The ease of the thioacid synthesis outlined herein is its greatest advantage. The use of highly toxic, foul-smelling reagents is avoided, and particular caution to exclude atmospheric moisture is not required. The synthesis is conducted at mild temperatures and takes only ten minutes. In addition, product workup is straightforward and quantitative yields are realized. Our procedure readily and inexpensively provides thioacid precursors for the enantiospecific synthesis of chiral sulfur-containing phospholipid, triacylglycerol and 1,2-diacylglycerol analogues (6).

Lipids from the Paracloacal Glands of the Chinese Alligator (*Alligator sinensis*)

B.S. Dunn, Jr.[a], P.J. Weldon[b,*], R.W. Howard[c] and C.A. McDaniel[a]

[a]Southern Forest Experiment Station, Forestry Sciences Laboratory, Gulfport, Mississippi 39505, [b]Department of Biology, Texas A&M University, College Station, Texas 77843 and Department of Herpetology, National Zoological Park, Smithsonian Institution, Washington, D.C. 20008 and [c]National Grain Marketing Research Laboratory, USDA-ARS, Manhattan, Kansas 66502

Lipids from the paracloacal glands of adult Chinese alligators (*Alligator sinensis*) were analyzed by gas chromatography/mass spectrometry. Acetates, aliphatic alcohols, free fatty acids and waxes consisting primarily of hexadecanoates were indicated in the secretions of males and females. Cholesterol, a diterpene hydrocarbon, and a diterpene ketone were detected in secretions of males but not in those of females. Lipids identified in the paracloacal secretions of *A. sinensis* are compared with those reported from the American alligator and other crocodilians.

Lipids 28, 75–78 (1993).

All extant crocodilians possess paired exocrine organs, known as paracloacal glands, embedded in the walls of the cloaca (1). Behavioral observations of free-ranging adult crocodilians suggest that secretions discharged from these glands contain pheromones used in mating and/or nesting activities (2). Laboratory studies show that immature American alligators (*Alligator mississippiensis*) detect airborne paracloacal gland chemicals (2), but no specific pheromonal function for these exudates has been demonstrated.

Comparative analyses of paracloacal gland secretions by thin-layer chromatography (TLC) indicate a variety of lipid classes, as well as taxonomic and other possible sources of variation in secretion composition (3,4). Analyses by gas chromatography/mass spectrometry (GC/MS) revealed terpenes, cholesterol, free fatty acids, acetates and other lipids among the paracloacal gland products of the American alligator (5) as well as in the dwarf (*Paleosuchus palpebrosus*) and the smooth-fronted caimans (*P. trigonatus*) (6,7).

We report here the results of GC/MS analyses of lipids from the paracloacal glands of the Chinese alligator (*A. sinensis*), an endangered species from the lower Yangtze Valley in the Anhui and Zhejiang Provinces of the People's Republic of China (8). TLC of the paracloacal gland secretions of this species has previously indicated the presence of bands that can be attributed to sterols, free fatty acids and other lipid classes (3), but structural details of the compounds in these exudates have not been reported.

MATERIALS AND METHODS

Secretions from the paracloacal glands of *A. sinensis* were obtained in September, 1989 from four 9-year-old females at the Houston Zoological Gardens (Houston, TX) and in November 1989 from seven 4-year-old and three 9-year-old females and one 5-year-old and two 10-year-old males at the New York Zoological Park (Bronx, NY). All animals were hatched at the Rockefeller Wildlife Refuge in Grand Chenier, LA, and raised in captivity.

Each gland was manually compressed while secretions were directed into a vial held next to the everted gland duct opening. Approximately 3–5 mL of dichloromethane were added to each vial, and the vials were stored on ice for 48 h or less before being shipped on dry ice. Samples were kept at −10°C prior to analysis.

The paracloacal secretions of each individual sampled were placed separately into a glass tissue grinder and extracted three times with 25-mL vol of pesticide-grade hexane while they were macerated with a pestle. The hexane extracts were decanted from insoluble materials and combined in a separatory funnel. Extracts were separated into free fatty acid (FFA) and neutral lipid fractions by partitioning them with 75 mL of a saturated solution of $NaHCO_3$. The lower aqueous layer, which contained FFA, was acidified with 10M H_3PO_4 to pH 1 and extracted with 75 mL of diethyl ether/hexane (50:50, vol/vol). The extract was rinsed with distilled water and dried over anhydrous sodium sulfate.

Neutral lipids in the hexane layer were dried over anhydrous sodium sulfate and separated by TLC on 0.75-mm silica gel layers developed in hexane/ethyl acetate (95:5, vol/vol). TLC bands were visualized by spraying with a solution of Rhodamine B and dichlorofluorescein (9) and viewed under ultraviolet light. Bands were scraped from the plate, extracted with diethyl ether and analyzed by GC/MS.

FFA in the residue were converted to methyl esters by reacting them with CH_2N_2 in diethyl ether (10). They were then separated by TLC, as described above. Alcohols were converted to acetates by placing microgram quantities into a vial with 0.2 mL of acetic anhydride/pyridine (2:1, vol/vol). Waxes in the lipid mixture were saponified with alcoholic KOH and separated into alcohol and fatty acid fractions. Alcohols formed by saponification were acetylated; ethyl esters of the fatty acids were prepared with Ethyl-8 (Pierce Chemical, Rockford, IL).

Portions of the unsaturated lipids were hydrogenated in ether solution in a 5-mL Reactivial (Wheaton Scientific, Millville, NJ) using 50 mg of PtO_2 as a catalyst (T. Jones, personal communication). Hydrogen gas was bubbled through the solution at approximately 0.5 mL/min for 30 min. Dimethyl disulfide (DMDS) derivatives were prepared by placing approximately 1 μg of unsaturated lipid in approximately 50 μL of DMDS, along with a crystal of iodine (11,12).

GC/MS analyses were performed on a Hewlett-Packard (Palo Alto, CA) 5890 gas chromatograph interfaced with a 5970 Mass Selective Detector (Hewlett-Packard). GC was done on a 30-m × 0.25-mm DB-1 fused silica column (J&W Scientific, Folsom, CA) using the following temperatures: injection port 250°C; transfer line, 280°C; oven, initially 50°C, then programmed to 150°C at 25°C/min, and then to 325°C at 4°C/min. The carrier gas was chromatog-

Abbreviations: DMDS, dimethyl disulfide; FFA, free fatty acid(s); FTIR, Fourier transform infrared; GC/MS, gas chromatography/mass spectrometry; TLC, thin-layer chromatography.

raphy-grade helium maintained at a head pressure of 105 kPa. All spectra were obtained at an ionizing voltage of 70 eV.

Fourier transform infrared (FTIR) vapor-phase spectra were obtained on a Hewlett-Packard 5890 GC with a 5965A FTIR detector and a 7958 data system. A 30-m × 0.32-mm DB-5 column (J&W Scientific) using chromatographic conditions identical to those described above was used.

RESULTS

C_{14}–C_{18} FFA, with a predominance of C_{16} and C_{18} compounds, were characterized as methyl esters in the secretions of *A. sinensis* (Table 1). Pentadecanoic, *Z*-9-hexadecenoic and *Z*-9-octadecenoic acids were indicated in the secretions of females but not in those of males; males possessed a small amount (1%) of heptadecanoic acid, which was not detected in females.

TLC separation of neutral lipids from female *A. sinensis* revealed three major bands. The eluants of Band I (R_f 0.37) displayed GC retention times and mass spectra consistent with primary aliphatic alcohols, as confirmed by comparisons with authentic alcohols (NuChek Prep, Elysian, MN). The identification of alcohols was further verified by derivatization of TLC eluates with acetic anhydride/pyridine to form acetates that were analyzed by GC/MS (Table 1). The mass spectra of DMDS derivatives of monounsaturated acetates displayed characteristic methyl thioether ions, thus allowing double-bond positions to be assigned. Some ambiguous spectra, likely representing heterocyclic adducts formed from diunsaturated alcohols, were observed; interpretation of these spectra was confounded by the co-elution of two or more compounds.

Band II (R_f 0.51) consisted of a series of acetates with alcohol moieties similar to those of the free alcohols eluted from Band I (Table 2). The double-bond positions of the acetates were determined by adding DMDS and analyzing the resulting vicinal dithiomethyl ethers by GC/MS, as described above.

Band III (R_f 0.81) consisted of a complex mixture of waxes, the major components of which were esters of hexadecanoic acid (percent compositions in parentheses): heptyl (7%), octyl (12%), nonyl (4%), decyl (4%), undecyl (3%), dodecyl (2%), tridecyl (3%), tetradecyl (13%), pentadecyl (11%), hexadecyl (28%) and octadecyl (11%). The mass spectrum of each of these compounds contained the protonated hexadecanoate ion ($C_{15}H_{33}CO_2^+$, *m/z* 257) and a corresponding hydrocarbon fragment. MS ions characteristic of dodecanoates ($C_{11}H_{25}CO_2^+$, *m/z* 201), tridecanoates ($C_{12}H_{27}CO_2^+$, *m/z* 215), tetradecanoates ($C_{13}H_{29}CO_2^+$, *m/z* 229), pentadecanoates ($C_{14}H_{31}CO_2^+$, *m/z* 243), hexadecenoates ($C_{15}H_{28}CO^+$, *m/z* 236), heptadecanoates ($C_{16}H_{35}CO_2^+$, *m/z* 271), octadecenoates ($C_{17}H_{32}CO^+$, *m/z* 264) and octadecanoates ($C_{17}H_{37}CO_2^+$, *m/z* 285) also were observed. Compounds of the same molecular weight co-eluted, even on capillary columns, thereby yielding complex mass spectra and frustrating our attempts to identify and quantify the percent compositions of many of these components.

The percent compositions of alcohols, acetates and waxes in the paracloacal gland secretions of female *A. sinensis*, calculated from the weights of residues eluted from TLC plates, were 19, 72 and 9%, respectively.

TABLE 1

Free Fatty Acids and Alcohols from the Paracloacal Gland Secretions of *Alligator sinensis* Showing Typical Percent Compositions Within Each Compound Class for Males and Females

11-Octadecen-1-ol	0	3
Octadecanol	7	5

TLC separation of neutral lipids in the paracloacal gland secretions of male *A. sinensis* yielded six major bands. Band I (R_f 0.03) contained a single compound, cholest-5-en-3-ol (cholesterol). Band II (R_f 0.28) consisted of a phthalate ester, a plasticizer that belongs to a class of ubiquitous environmental contaminants, readily classified by a base peak at *m/z* 149. The presence of this compound in the paracloacal glands is curious, but it was not characterized further because we assumed that it is not of biological origin.

Band III (R_f 0.38) consisted of a mixture of saturated and mono- and diunsaturated primary alcohols similar to, but not as complex, as that observed from female alligators (Table 1). These compounds were identified by forming acetate derivatives that were analyzed by GC/MS, as described above. Likewise, DMDS derivatives were made of the unsaturated acetate derivatives to determine double-bond positions.

Band IV (R_f 0.66) was shown by MS and FTIR to contain a diterpene ketone with a molecular weight of 288 and a molecular formula of $C_{20}H_{32}O$. Band VI (R_f 0.91)

[a]Trace amounts of pentadecenyl (10%), hexadecenyl (25%) and heptadecenyl acetates (65%) were detected in males.

contained a diterpene hydrocarbon that exhibited a molecular weight of 272 and a molecular formula of $C_{12}H_{32}$. Comparison of the FTIR spectra of the diterpene ketone and the diterpene hydrocarbon revealed identical absorbances, except for a carbonyl absorbance in the ketone at 1721 cm^{-1}.

Band V (R_f 0.81) consisted of a series of waxes that, as in females, was predominated by hexadecanoates (percent compositions in parentheses): dodecyl (2%), tridecyl (2%), tetradecyl (16%), pentadecyl (47%), hexadecyl (25%), heptadecyl (1%) and octadecyl (7%). MS ions characteristic of dodecanoates, tridecanoates, tetradecanoates, pentadecanoates, heptadecanoates, octadecenoates and octadecanoates also were observed; in contrast to the results with females, however, hexadecenoates were not detected in males.

The percent compositions of cholesterol, alcohols, the diterpene ketone, waxes and the diterpene hydrocarbon in the paracloacal gland secretions of male *A. sinensis*, calculated from the weights of residues eluted from TLC plates, were 1, 10, 15, 53 and 2%, respectively.

DISCUSSION

A TLC survey of 21 crocodilian species suggested the widespread occurrence of FFA in the paracloacal gland secretions (3). C_{16} and C_{18} FFA from the secretions of the American alligator and the dwarf caiman have been elucidated previously by GC/MS (5,7). Saturated and unsaturated C_{14}–C_{21} fatty acids also have been reported in the skin gland secretions of crocodiles (*Crocodylus* spp.), however, the exudates analyzed included secretions pooled from both the paracloacal glands and the gular glands (paired exocrine organs on the lower jaw) (13,14); thus, unfortunately, the source of the FFA is unclear. Our analysis indicates C_{14}–C_{18} FFA among the paracloacal products of *A. sinensis*. Cholesterol, another common tetrapod skin product, also was detected among the paracloacal gland secretions of male alligators.

A number of aliphatic alcohols have been documented among the paracloacal products of caimans (*Caiman* spp. and *Paleosuchus* spp.) (7,15,16), but these compounds were not reported for an analysis of the secetions of the American alligator (5). Our investigation indicates C_{12}–C_{18} saturated and unsaturated aliphatic alcohols in *A. sinensis*, thus establishing the presence of this compound class in the paracloacal secretions of the genus *Alligator*. 3-Dodecen-1-ol, dodecanol and an array of unsaturated C_{15}–C_{18} primary alcohols were detected in females, but not in males.

Acetates ranging in carbon-chain length from C_{10} to C_{18} were indicated in the paracloacal gland secretions of American alligators of both sexes and, to a lesser extent, in immature (unsexed) individuals (5). Our analysis of *A. sinensis* indicates C_{12}–C_{18} acetates primarily in females. C_{15}, C_{16} and C_{17} monounsaturated acetates in the total lipid mixture of some males were indicated by MS ions at *m/z* 61 and molecular ions 60 mass units less than the molecular weight (M−60); the unsaturation sites of these compounds were not determined because only trace amounts of these compounds were present and they were not detected by TLC. A number of mono- and diunsaturated compounds not detected in the American alligator were indicated in *A. sinensis*.

Dodecanoates, tetradecanoates and other waxes were observed in the paracloacal gland secretions of immature American alligators (5). Our results indicate a complex mixture of waxes in the secretions of adult *A. sinensis*, but detailed identifications were made only for hexadecanoates. The hexadecanoates indicated in female *A. sinensis* secretions range in carbon-chain length from C_7 to C_{18} whereas those of males range from C_{12} to C_{18}. Waxes comprised a larger percentage of the total lipids of the secretions of males than those of the females (53% *vs.* 9%, respectively).

A recent study of the smooth-fronted caiman indicates (*E,E*)-7,11,15-trimethyl-3-methylenehexadeca-1,6,10,14-tetraene (β-springene) in the paracloacal gland secretions (6). Traces of other diterpenes and β-farnesene also were detected. The diterpene hydrocarbon observed in male *A. sinensis* has the same molecular weight as β-springene, but the mass spectra of these two compounds are different. Carbon-13 and proton nuclear magnetic resonance data are needed to determine the structure of the compound in *A. sinensis* and that of an apparently related ketone.

ARTICLE

Overexpression of a *Rhizopus delemar* Lipase Gene in *Escherichia coli*[1]

Rolf D. Joerger* and **Michael J. Haas**
Eastern Regional Research Center, Agricultural Research Service, U.S. Department of Agriculture, Philadelphia, Pennsylvania 19118

A cloned complementary deoxyribonucleic acid encoding the precursor polypeptide of an extracellular lipase from the fungus *Rhizopus delemar* was altered by site-directed mutagenesis to generate deoxyribonucleic acid fragments that specifically code for the polypeptides of the proenzyme and the mature form of the lipase. Attempts to produce these polypeptides in enzymatically active form in *Escherichia coli* revealed toxic effects toward the host. Therefore the polypeptides were expressed as inactive and insoluble forms in the cytoplasm of *E. coli* BL21 (DE3) cells using plasmid vector pET11-d. With this tightly regulated high-level expression system, lipase and prolipase polypeptides were produced to estimated levels of up to 21% and 15%, respectively, of total cellular protein. The insoluble polypeptides were solubilized in 8 M urea. Refolding into active forms was achieved by treatment with the redox system cystine/cysteine and dilution. Refolded mature lipase was purified to homogeneity by affinity and ion exchange chromatography. The enzyme had a specific activity comparable to that of lipase from the fungal culture. The quantities of pure enzyme obtained from a 1-L culture of *E. coli* exceeded those obtained from the fungal culture by a factor of at least 100. Refolded recombinant prolipase was purified essentially to homogeneity and had a specific activity similar to that of the mature enzyme. Its pH optimum was 7.5, rather than the pH 8 determined for recombinant mature lipase and for the enzyme purified from the fungal culture. Recombinant prolipase retained activity after 15 min incubation at 65°C, while mature lipase retained activity only up to 45°C.
***Lipids* 28, 81-88 (1993).**

Lipases (acylglycerol acylhydrolases, EC 3.1.1.3) are enzymes capable of hydrolyzing ester bonds of water-insoluble substrates at the substrate-water interface. Lipolytic enzymes are ubiquitous and their physical and biochemical diversity provides the basis for many current and future biotechnological uses. In nature, the hydrolysis of acylglycerols is probably the main function of lipases. Under laboratory conditions, lipases are able to catalyze transesterification and ester synthesis reactions with alcohols other than glycerol and to hydrolyze a diversity of esters in nonaqueous solvent systems (1).

The fungus *Rhizopus delemar* (presently designated *R. oryzae*) produces extracellular lipases that hydrolyze the ester bonds at the *sn*-1 and *sn*-3, but not the *sn*-2 position, of a triacylglycerol (2). This pronounced positional specificity is one of the reasons for continued basic studies on the *R. delemar* lipases and for the use of partially purified *R. delemar* enzyme preparations in acylglycerol restructuring (3), the exchange of acyl groups of phospholipids (4) and ester and glyceride synthesis (5-7).

Industrial applications of lipases and basic scientific experiments are often hampered by the lack of sufficient enzyme or by the heterogeneity of the available preparations. The complete purification of the *R. delemar* lipase is time-consuming and yields only about 0.2-0.6 mg per liter of culture supernatant (8). Low purification yields have prompted researchers to employ molecular cloning techniques to improve the production of lipases. For example, the complementary DNA (cDNAs) for extracellular lipases from *Rhizomucor miehei* and *Humicola lanuginosa* were overexpressed in the fungus *Aspergillus oryzae*, and mature lipase was purified from the culture medium (9,10). The gene for a thermostable lipase from the bacterium *Pseudomonas fluorescens* was overexpressed in *Escherichia coli* to a level of 40% of the total protein (11).

The use of recombinant DNA techniques for the production of an *R. delemar* lipase became possible after a cDNA clone of the lipase was obtained and its nucleotide sequence was determined (12). The sequence data predict that the fungus produces a mRNA that is translated into a preproenzyme. The export signal peptide and the propeptide are then removed proteolytically to produce the mature lipase enzyme. Here we report on the cloning of DNAs encoding the prolipase and the mature lipase in *E. coli*, their expression in the bacterium in inactive form, their refolding *in vitro* to active lipolytic proteins, and their purification.

MATERIALS AND METHODS

DNA manipulations. Plasmid DNA and phage M13 RF DNA were isolated by an alkaline lysis procedure (13) followed by a phenol/chloroform extraction. Restriction enzyme digestions and ligation reactions were performed under conditions recommended by the suppliers. Transformation with plasmid DNA was accomplished using $CaCl_2$-treated *E. coli* cells as described by Sambrook *et al.* (14).

Construction of lipase expression plasmids. The previously cloned cDNA encoding the *R. delemar* lipase (12) was excised from plasmid pUC8-2.14 (12) as an *Eco*RI fragment and inserted into the *Eco*RI site of bacteriophage M13 mp18 (15). Site-directed mutagenesis of the insert DNA was carried out according to the method of Kunkel (16) using the MUTA-GENE M13 *IN VITRO* MUTAGENESIS KIT (Bio-Rad Laboratories, Richmond, CA). Mutagenic primers were obtained from the Department of Chemistry, University of Pennsylvania, Philadelphia, PA. A primer, 5'GGTTCATCCATGGTTCCTGT 3', was used to replace the codon for the C-terminal amino acid, alanine, of the predicted signal peptide of preprolipase with a codon representing methionine. This primer also changes the nucleotide sequence to introduce an *Nco*I

[1]Mention of brand or firm names does not constitute an endorsement by the U.S. Department of Agriculture over others of a similar nature not mentioned.

Abbreviations: bp, base pairs; cDNA, compementary deoxyribonucleic acid; CM-Sepharose, carboxymethyl Sepharose; DNA, deoxyribonucleic acid; DTT, diethiothreitol; EDTA, ethylenediaminetetraacetic acid; IPTG, isopropyl-β-D-thiogalactopyranoside; OA, oleic acid; PAGE, polyacrylamide gel electrophoresis; SDS, sodium dodecylsulfate; U, units of lipase activity.

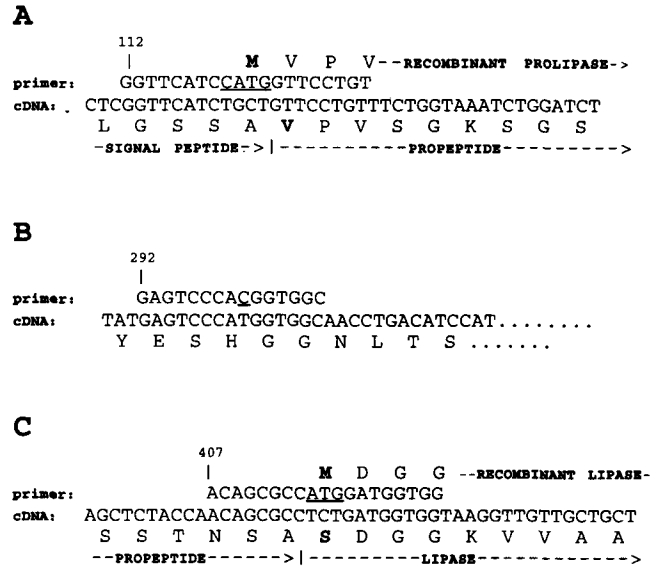

FIG. 1. Oligonucleotide primers used for mutagensis of the *R. delemar* lipase cDNA. A. Primer for the introduction of a methionine codon and an *Nco*I site at the position in the *R. delemar* lipase cDNA encoding the junction between signal peptide and propeptide. B. Primer for the removal of an *Nco*I site within the propeptide encoding region. C. Primer for the introduction of a methionine codon and an *Nco*I site at the position in the lipase cDNA encoding the junction between propetide and mature lipase. The amino acid sequence predicted from the cDNA is given below the nucleotide sequence. The amino acid sequence resulting from the oligonucleotide directed mutagenesis is given above the primer sequence. The numbers indicate positions of nucleotides in the published nucleotide sequence of the *R. delemar* cDNA (ref. 12).

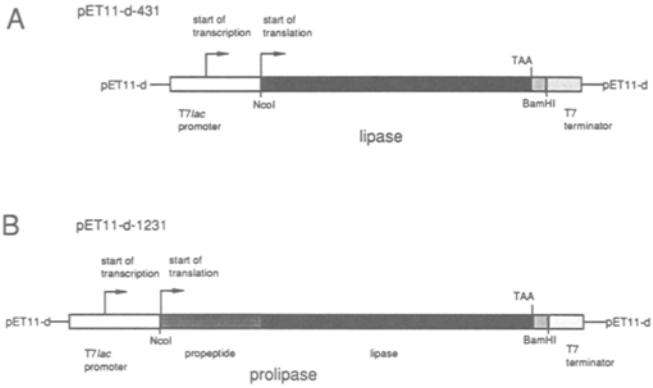

FIG. 2. Schematic representation of the lipase- and prolipase-encoding segments in the expression plasmid pET11-d (ref. 18). The lipase and prolipase genes were cloned as *Nco*I-*Bam*HI fragments between the T7*lac* promoter and T7 terminator sites in plasmid pET11-d. The termination codon for lipase and prolipase is indicated by the nucleotide triplet TAA.

site (Fig. 1A). An already existing *Nco*I site within the coding region was removed using a primer 5′GAGTCCCACGGTGGC 3′ (Fig. 1B). This base change did not alter the predicted amino acid sequence, but replaced the histidine codon, CAU, with the histidine codon, CAC, found considerably more frequently in mRNA from highly expressed genes of *E. coli* (17). Both primers were employed in a single mutagenesis experiment. In a second mutagenesis, a primer, 5′ACAGCGCCATGGATGGTGG 3′, was used to replace the codon for the *N*-terminal amino acid serine of the mature lipase enzyme (12) with the codon representing methionine (see Fig. 1C). This change also introduced an *Nco*I site. Phage carrying mutagenized cDNA inserts were identified by restriction enzyme cleavage of their double-stranded DNA. *Nco*I-*Bam*HI fragments, approximately 800 base pairs (bp) and 1100 bp in size, representing lipase- and prolipase-encoding DNA respectively, were isolated and ligated to vector pET11-d (18) that had been cleaved with *Nco*I and *Bam*HI (Fig. 2). The resulting plasmids, pET11-d-431 (Fig. 2A) and pET11-d-1231 (Fig. 2B), were introduced into *E. coli* BL21 (DE3) (18) by transformation.

Induction of lipase gene expression. E. coli BL21 (DE3) harboring the pET11-d recombinant plasmids were grown on solid LB agar medium (19) containing ampicillin (100 μg/mL). Cells from a single colony were inoculated into LB broth (19) containing ampicillin (100 μg/mL) and grown overnight at 30°C with light shaking. The culture was then diluted 100-fold into medium made up of the components of LB and of M9 minimal medium (19), pH 7.4, containing ampicillin (200 μg/mL). The cultures (500 mL of medium in 2 L baffled flasks) were shaken vigorously at 37°C until the optical density at 600 nm reached a value between 0.6 and 1.0. Isopropyl-β-D-thiogalactopyranoside (IPTG) was then added to a final concentration of 1 mM. Incubation was resumed, and the cells were harvested by centrifugation 3 to 4 h after the addition of IPTG. For experiments using lactose as inducer, the sugar was added to a final concentration of 10 mM.

Refolding of lipase. The cells obtained from a 1-L culture were resuspended in 50 mL of 50 mM Tris-HCl, pH 8, 5 mM ethylenediaminetetraacetic acid (EDTA), 10% sucrose. Lysozyme was added to a final concentration of 0.8 mg per mL. The mixture was incubated for 30 min at room temperature. Four-hundred mL of Triton buffer (10 mM Tris-HCl, pH 8, 1 mM EDTA, 0.5% Triton X-100) were added. After mixing, the lysate was sonicated to reduce viscosity and centrifuged at 15,000 × *g* for 30 min at 4°C. The insoluble pellet was resuspended in 400 mL of the Triton buffer and sonicated briefly. The resulting suspension was centrifuged at 15,000 × *g* for 20 min. The pellet was resuspended in 400 mL of 10 mM Tris-HCl, pH 8, 1 mM EDTA, and the suspension was centrifuged as above. The pellet was finally washed with distilled water and resuspended in 10 mL of distilled water. This suspension was added to 200 to 400 mL of 8 M urea [previously deionized by passage through mixed-bed resin AG 501-X8 (Bio-Rad Laboratories, Hercules, CA)] in 25 mM sodium phosphate, pH 7, 1 mM EDTA, 5 mM dithiothreitol (DTT). The solution was incubated at room temperature for 1 h, then centrifuged at 15,000 × *g* for 30 min at room temperature. Cystine (dissolved in 0.6 N NaOH) was added to a final concentration of 15 mM. The pH of the solution was maintained at 8.5 to 9 for 10 min. Then the solution was slowly added to 10 to 20 vol of cold (4–10°C) 50 mM sodium phoshate, pH 7.5–8, 1 mM EDTA, 5 mM cysteine. This solution was incubated for at least 48 h at 4°C to allow refolding of the denatured protein.

Purification of lipase and prolipase. The pH of the refolding solution was adjusted to 6.5 for lipase and 6.0 for prolipase by the dropwise addition of H_3PO_4. The solu-

tions were filtered through Whatman No. 1 paper (Whatman International Ltd, Maidstone, England) and concentrated in a stirred ultrafiltration cell using Diaflo ultrafiltration membranes YM10 or YM30 (Amicon, Beverly, MA) or by filtration through Minitan ultrafiltration filterplates type PLGC (Millipore, Bedford, MA).

The concentrated solution containing refolded lipase was filtered through Whatman No. 1 filter paper and loaded onto an oleic acid (OA) affinity chromatography column (16 × 250 mm) prepared as described previously (8). The column was washed with 200 mL 20 mM sodium phosphate, pH 6.5, 5% NaCl, followed by 200 mL 20 mM sodium phosphate, pH 6.5. The lipase was eluted with a gradient of Triton X-100 (0–0.5%) in 20 mM sodium phosphate, pH 6.5. For applications where the presence of detergent was not desirable, 60% ethyleneglycol in 20 mM sodium phosphate buffer, pH 6.5 was used for elution. Fractions containing lipase activity in excess of 200 U/mL were pooled and loaded onto a 12 × 200 mm column of carboxymethyl-sepharose (CM-Sepharose) CCL-6B-100 (Sigma, St. Louis, MO) equilibrated with 20 mM sodium phosphate, pH 6.5. The column was washed with 40 mL of the same buffer, and the lipase was eluted with 200 mL of an NaCl gradient (0–500 mM) in 20 mM sodium phosphate, pH 6.5.

Refolded prolipase did not bind to the oleic acid affinity gel. The buffer of the concentrated refolding solution was therefore exchanged for 20 mM sodium phosphate, pH 6, by diafiltration, and the solution was loaded onto a CM-Sepharose column (12 × 200 mm) equilibrated with 20 mM sodium phosphate, pH 6. The prolipase was eluted with a 0–500 mM NaCl gradient in the same buffer.

General protein techniques. Sodium dodecylsulfate (SDS)-12.5% polyacrylamide gel electrophoresis (PAGE) was performed as described by Laemmli (20). The molecular weight of proteins was estimated by comparison of their mobilities with those of protein standards (Dalton Mark VII-L, Sigma). Protein bands on gels were stained with Coomassie Brilliant Blue R. An estimate of the relative intensity of bands on dried Commassie Blue-stained gels was obtained by scanning with a Bio-Rad Model 620 Video Densitometer (Bio-Rad, Richmond, CA) and analysis of the scanning profile with the Bio-Rad 1-D Analyst II programs.

Protein concentrations were determined by the method of Bradford (21) using the Bio-Rad Protein Assay Kit (Bio-Rad Laboratories, Richmond, CA). Bovine-γ-globulin was used as the standard.

N-Terminal amino acid sequences of recombinant lipase and prolipase were determined by automated Edman degradation using an Applied Biosystem (Foster City, CA) 473A Protein Sequencer. Determinations were made from 300 pmoles of protein dissolved in 0.1% trifluoroacetic acid.

Determination of lipase activity. Activity was determined qualitatively by spotting samples onto solid media containing olive oil (25 mL/L) emulsified in 20 mM sodium phosphate, pH 7.5, 0.001% Rhodamine B (Sigma). Lipase activity was visualized under ultraviolet light (22). Quantitative activity determinations were carried out titrametrically as described previously (8) using a VIT 90 Video titrator (Radiometer, Copenhagen, Denmark). The pH of the reaction mixture was maintained by the continuous addition of 0.1 N NaOH. For routine activity measurements, the assays were conducted at 25 °C at pH of 7.5 using purified olive oil (Sigma) as substrate. A thermostatted, water-jacketed reaction chamber was used for the determination of the effect of temperature on the lipase activity. Lipase activity was calculated from the maximum rate of titrant addition using a lipase titrametric assay program (Cichowicz, D.J. *et al.*, unpublished). A unit (U) of activity released one μmole of fatty acid per minute.

RESULTS AND DISCUSSION

Expression of recombinant lipase and prolipase. Over the years, *E. coli* has proven to be a suitable and often preferable organism for the overexpression of both pro- and eukaryotic genes. The ability of this bacterium to synthesize lipolytic protein from *R. delemar* cDNA cloned in lambda gt11 was crucial in the original isolation of the lipase cDNA (12). This cDNA was subsequently cloned in plasmid pUC8-2 (23), and, after addition of IPTG, *E. coli* cells harboring the resulting recombinant plasmid pUC8.2-14 (12) produced lipolytic protein with the same positional specificity as that of lipase produced by the fungus (12). However, only small amounts of lipolytic protein were present in cell-free extracts from induced recombinant *E. coli*, and the protein species that cross-reacted with polyclonal antibody raised against the fungal lipase were all larger than the 30 kDa molecular mass of mature *R. delemar* lipase (8,12). This indicated that *E. coli* JM101 was unable to fully process precursor proteins. Therefore, to obtain recombinant lipase corresponding to the mature fungal enzyme, it was necessary to remove the portions of the *R. delemar* lipase cDNA that encode the pre- and propeptide fragments (Fig. 1C). A DNA fragment encoding prolipase was also generated by removal of the part of the cDNA encoding the fungal signal peptide (Fig. 1A). The availability of a prolipase clone was desirable, because it was unknown if the propeptide was required for or beneficial to obtaining active lipase.

Many factors are known to determine the ultimate level of expression of a cloned gene. Among those factors are transcription rate and stability of the mRNA, rate of translation and stability of the protein product and also the amount of protein that can be accumulated before toxic effects occur. Attempts to clone the *R. delemar* lipase cDNA, excised from pUC8-2.14, into expression vectors pRX-1 (24) allowing transcription from a *trp* promoter or into the pMAL vectors (New England Biolabs, Beverly, MA) allowing the production of MaLE fusion proteins after transcription from a *lac* promoter, demonstrated that the presence of the cDNA in the correct orientation with respect to the promoters lead to plasmid instability and impaired viability even in the absence of inducer substances (data not shown). Thus the protein species produced from the cDNA have toxic properties which could lead to the selection of recombinant strains with low expression levels. The toxicity might be caused by the presence of the fungal signal peptide in the recombinant polypeptides or by lipolytic activity of the protein species produced from the cDNA. As mentioned above, the mutagenesis outlined in Figure 1 allowed the isolation of lipase- and prolipase-encoding DNAs that lack the sequences coding for the fungal signal peptide. To further improve the chances for successful expression of these DNAs in

E. coli, an expression system was sought that would provide a tighter control over transcription than either *trp* or *lac* promoters could provide. Such a system should prevent the appearance of damaging levels of lipolytic recombinant protein during the growth phase of the cells in the absence of an inducing substance.

Studier *et al.* (18) developed an *E. coli* expression system that included an additional layer of gene control. The vector components (pET plasmid series) place the transcription of insert DNA under the control of a bacteriophage T7 gene 10 promoter. This promoter is recognized by T7 RNA polymerase, which is in turn regulated by a *lac* promoter in the host component of this expression system, *E. coli* BL21 (DES3) (18). The activity of low levels of T7 RNA polymerase synthesized under noninducing conditions is inhibited by the presence of intracellular lysozyme produced in strain *E. coli* BL21 (DE3)[pLysS] (18). Using a derivative of this system, Deng *et al.* (25) were able to overexpress bovine pancreatic phospholipase A_2, an enzyme toxic to *E. coli*. The phospholipase accumulated in the periplasm of *E. coli* since the phospholipase gene had been fused to DNA encoding the OmpA signal peptide from *E. coli*. We attempted to express the *R. delemar* lipase and prolipase genes using the system employed by Deng *et al.* (25). However, recombinant lipase and, to a lesser extent, recombinant prolipase were still toxic to *E. coli* BL21 (DE3)[pLysS].

The toxic effect of the expressed lipase, which manifested itself even under noninducing conditions, necessitated a more tightly controlled expression system for recombinant *R. delemar* lipase. Therefore plasmid pET11-d (18) was selected. It is similar to the vector of the expression system described above, but it contains, as additional control features, a *lac* operator site (required for *lac* repressor binding) located in the T7 promoter region and also the gene encoding the *lac* repressor. The lipase and prolipase genes, on their respective *Nco*I-*Eco*RI fragments, were cloned into one of these plasmids, vector pET11-d (18) (Fig. 2). *E. coli* BL21 (DE3) cells containing the recombinant plasmids were stable under noninducing conditions. Upon induction with IPTG, the cells accumulated protein that migrated to positions on SDS-PAGE corresponding to the predicted molecular weights of prolipase or lipase (Figs. 3 and 4). Scanning of gels indicated that recombinant lipase constituted between 15 and 21% of the total cellular protein. Extracts from cells producing recombinant prolipase contained between 9 and 15% prolipase.

Lactose can be used as a substitute for the relatively expensive inducer substance IPTG. As was observed earlier with *E. coli* HB101 harboring a recombinant plasmid containing a *tac* promoter (26) and with *E. coli* BL21 harboring a recombinant pET3 plasmid (27), the appearance of recombinant protein was delayed by approximately one hour when lactose was added instead of IPTG. However, Neubauer *et al.*(27) demonstrated that lactose can be as efficient an inducer as IPTG provided that the addition of lactose was timed with respect to the glucose level in the growth medium. Therefore, lactose might be a suitable inducer for lipase-producing *E. coli* strains grown in fermentors equipped with glucose biosensors.

Lysates of cells containing the pET11-d derivatives and expressing the recombinant lipase or prolipase exhibited very little, if any, lipase activity (Tables 1 and 2). After low-

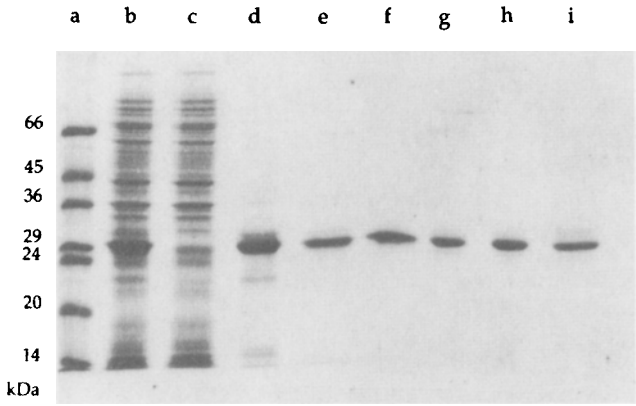

FIG. 3. Sodium dodecylsulfate-polyacrylamide gel electrophoresis of protein samples obtained during refolding and purification of recombinant *R. delemar* lipase. Lane a, molecular weight markers; lane b, lysate of *E. coli* BL21 (DE3) harboring pET11-d-431, induced for lipase expression; lane c, soluble fraction of lysate; lane d, buffer-insoluble fraction of lysate, dissolved in 8 M urea; lane e, concentrated refolding mixture to be subjected to affinity chromatography; lane f, combined fractions from affinity chromatography that exhibited significant lipase activity; lanes g and h, lipolytically active fractions eluted from CM-Sepharose column; lane i, *R. delemar* lipase purified from the fungal culture medium.

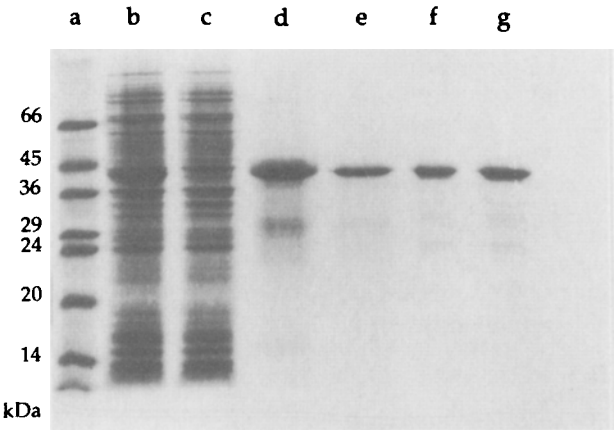

FIG. 4. Sodium dodecylsulfate-polyacrylamide gel electrophoresis of protein samples obtained during refolding and partial purification of recombinant *R. delemar* prolipase. Lane a, molecular weight markers; lane b, lysate of *E. coli* BL21 (DE3) harboring pET11-d-1231, induced for prolipase expression; lane c, soluble fraction of lysate; lane d, buffer-insoluble fraction of lysate, dissolved in 8 M urea; lane e, concentrated refolding mixture, to be subjected to ion exchange chromatography on CM-Sepharose; lanes f and g, lipolytically active fractions eluted from CM-Sepharose.

speed centrifugation of cell lysates, the supernatant appeared to be devoid of the IPTG-inducible protein (Fig. 3, lane c), which was now found in the pellet. This is indicative of protein that has aggregated as inclusion bodies, a phenomenon often encountered with high expression systems (28). The highly expressed polypeptides remain in unfolded or partially folded states, and their sulfhydryl groups are mostly reduced (29). In this inactive state, lipase and prolipase polypeptides did not appear to cause cell lysis during the three- to four-hour induction period.

Refolding of recombinant lipase. The appearance of pro-

TABLE 1

tein in insoluble form makes it necessary to devise a way to solubilize the polypeptides and to induce them to refold into an active form. The *R. delemar* lipase contains six cysteine residues which, based on amino acid sequence similarity with the lipase from *Rhizomucor miehei* (30,31), probably form three disulfide bridges. Therefore, refolding of recombinant *R. delemar* lipase has to include the formation of the proper disulfide bonds. The procedures necessary for successful refolding potentially add to the effort required for obtaining a pure protein, but there are advantages as well when protein is produced as inclusion bodies. First, a protein fraction highly enriched in the recombinant protein is obtained simply by separating the soluble from the insoluble fraction of a lysate. Second, recombinant protein is often synthesized in considerably higher amounts when deposited in inclusion bodies than when produced as soluble product. Thus, as shown for recombinant bovine interferon (32), the yield of active recombinant protein from cells producing inclusion bodies might be greater than that obtained from cells producing the recombinant protein in soluble form, even if only about 10% of the insoluble protein could be refolded properly.

The lipase-containing inclusion bodies were solubilized with 8 M urea, and unwanted inter- or intramolecular disulfide bonds that might have formed within the host cells or during isolation of the inclusion bodies were reduced with 5 mM DTT. In the resulting solution, 61 to 85% of the protein present co-migrated with purified *R. delemar* lipase on SDS-PAGE. Refolding was conducted on this solution of crude urea-solubilized inclusion bodies. The refolding procedure that gave the highest yield of refolded lipase was similar to that described for secretory leukocyte protease inhibitor (33). First, the urea-solubilized proteins were oxidized by the addition of cystine at a pH of 8.5 to 9. Then the urea concentration was reduced 10- to 20-fold by dilution to allow the folding process to commence. The dilution buffer contained cysteine to catalyze disulfide bond interchange. A pH of 7.5 to 8 in the dilution buffer gave the highest yield of active lipase.

During refolding, lipase displayed a tendency to aggregate and precipitate. Protein concentrations had to be kept below 100 μg/mL when diluting the urea-denatured protein in order to minimize this phenomenon. As was observed with other proteins (34,35), low temperatures during dilution also reduced the loss due to aggregation. The highest yield of active enzyme was achieved in refolding experiments conducted at 4 to 10°C. The yield was lower when the dilution buffer was at room temperature, and no active enzyme was obtained in experiments conducted at 37°C.

Refolding in buffer of pH 7.5 to 8 at 4°C was a relatively slow process and required several days for completion (Fig. 5). Some precipitate appeared during this time in the refolding solution. It was removed by filtration through Whatman No. 1 filter paper. In order to avoid strong precipitation during subsequent ultrafiltration and purification steps, the pH of the refolding solution was lowered to 6.5.

Purification of recombinant lipase. The mature recombinant lipase was purified by oleic acid affinity and ion

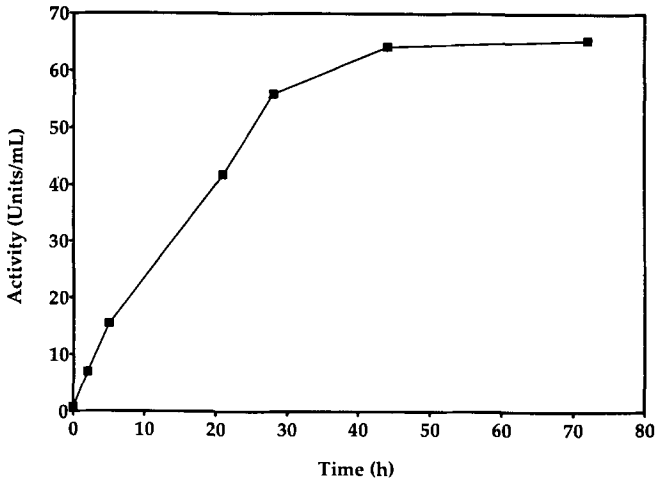

FIG. 5. Appearance of lipase activity after reduction of urea concentration from 8 M to 0.4 M. Samples were withdrawn from the refolding solution at the indicated time points and assayed for lipase activity as described in Materials and Methods.

exchange chromatography steps similar to those used for purification of the fungal enzyme (8). The activity recovered from 1 L of culture was almost completely retained by the 16 × 250 mm oleic acid affinity column. This activity was eluted virtually quantitatively as a single peak at a Triton X-100 concentration of approximately 0.25%. For purposes such as crystallization of the purified lipase, the presence of Triton X-100 might be undesirable due to its ability to bind to hydrophobic portions on proteins. Therefore an agent that presumably would not bind tightly to protein was sought to elute lipase from the OA affinity column. Ethylene glycol (60%) successfully eluted lipase from the column. The activity emerged in a broad peak, and trailing of activity was observed. Partially pure enzyme, recovered from the OA column either with Triton X-100 or ethylene glycol, was purified to apparent homogeneity by chromatography on CM-Sepharose at pH 6.5. (Fig. 3, lanes g–i). Migration of purified recombinant lipase on SDS-PAGE gels under reducing and nonreducing conditions was identical to that of lipase purified from *R. delemar*. The specific activity of fractions obtained after the ion exchange chromatography step was between 5000 and 8000 U per mg of protein. Similar specific activities were reported for purified lipase from *R. delemar* (8).

Amino acid sequence determination revealed that the *N*-terminal methionine was not removed post-translationally from the recombinant lipase. The second amino acid was predicted to be an aspartate (12); however, two sequencing runs failed to unambiguously discern between aspartate or asparagine as the identity of this residue. The sequence of the following 18 amino acids was identical to that determined for purified fungal-produced lipase and that predicted from the nucleotide sequence of the cDNA (12).

Refolding and partial purification of recombinant prolipase. Based on nucleotide sequence data (12), the *R. delemar* lipase was predicted to be synthesized as a proenzyme. The reason for the existence of the propeptide in lipase precursors is not known. Possibly, propeptides could be inhibitors of lipase, preventing membrane autolysis while the lipase is located inside the cell. This role for the propeptide was suggested for prophospholipase because the proenzyme did not exhibit interfacial activation and acted only on monomeric substrate (36). Thus prophospholipase might be unable to damage cellular phospholipid-containing structures.

It is also possible that the proregion is required for proper folding of the mature enzyme, as was observed for the *in vitro* and *in vivo* folding of some proteases (37,38). However, our data demonstrate that the propeptide is not required for *in vitro* refolding of mature recombinant *R. delemar* lipase. Whether or not the propeptide is involved in folding events *in vivo* or in some conformational changes during secretion from the fungal cell is unknown.

In vitro refolding of urea-denatured partially purified prolipase was conducted using the conditions used for the refolding of mature lipase. Yields from a refolding and purification experiment are shown in Table 2. The appearance of lipolytic activity measured titrametrically followed the same time course as that for lipase, and similar amounts of total activity were obtained from crude preparations of both proteins. Therefore the propeptide did not act as an inhibitor of recombinant lipase under the conditions employed. However, refolded recombinant prolipase behaved differently from recombinant mature lipase on solid media containing rhodamine B. Development of fluorescence was slower than was observed for the mature lipase, and fluorescent material was found in a diffuse zone around the site of sample application rather than only at the site of sample application. It is not known whether this was caused by physical differences, *e.g.*, mobility of the proteins in the agar medium, or by reactive differences that cause the differential removal of substrate or the generation of different products.

When purification was attempted in the same manner as for refolded recombinant lipase, recombinant prolipase did not bind to the oleic acid affinity column. This suggests that in the proenzyme the hydrophobic sites responsible for the binding of lipase to the affinity resin are obstructed or in some other manner unavailable for binding of the enzyme to the resin. Whether or not these differences between recombinant prolipase and lipase are important *in vivo* is unknown.

The refolded prolipase was purified only by ion exchange chromatography. The resulting preparations contained prolipase and a small amount of lower molecular weight proteins (Fig. 4, lanes f and g). The specific activities of such preparations ranged from 5000 to 8000 U/mg, comparable to those of purified fungal and recombinant mature lipase. The prolipase preparations were of sufficient purity to allow automated sequence determination of the first 20 amino acid residues. As was observed with recombinant lipase, the *N*-terminal methionine residue was still present. The sequence of the remaining 19 amino acid residues was as predicted from the nucleotide sequence of the cDNA (12).

Comparisons of physical properties of fungal lipase, recombinant lipase and recombinant prolipase. Haas *et al.* (8) have previously determined the influence of pH and temperature on the activity of purified fungal lipase. The lipase was most active at a pH around 8, near its predicted pI of 8.1, and the activity and stability were maximum at 30°C. The same characteristics were observed for the purified recombinant lipase (Fig. 6A–C). Recombinant prolipase was most active at pH 7.5, near its predicted pI

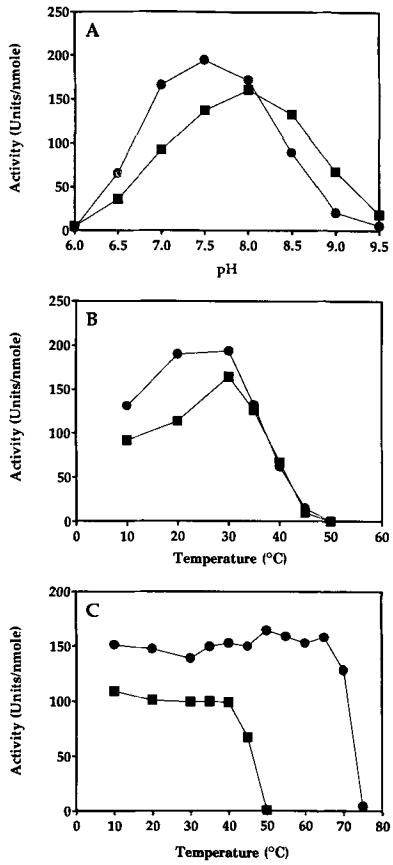

FIG. 6. A. Effect of pH on activity of lipase (—■—) and prolipase (—●—). Samples were assayed titrametrically as described in Materials and Methods. Activities were calculated based on the amount of protein used per assay and on molecular weights of 29,500 for lipase and 39,500 for prolipase. B. Effect of reaction temperature on activity of recombinant lipase and prolipase. Samples were assayed titrametrically in thermostatted reaction vessels as described in Materials and Methods. Activities were calculated as described for panel A. C. Thermal stability of lipase and prolipase. The enzyme samples were incubated at the indicated temperatures for 15 min and assayed at 25°C.

of 7.2 (Fig. 6A). The activity of prolipase was also maximum at 30°C (Fig. 6B). Thus, in their active conformation in the presence of substrate, both prolipase and lipase are equally susceptible to heat-induced denaturation. However, in the absence of substrate, prolipase, but not mature lipase, withstood exposure to temperatures as high as 70°C (Fig. 6C). Evidently, in the absence of an interface, the propeptide delays the onset of denaturation or promotes rapid renaturation of heat-exposed enzyme.

The similarities in the physical characteristics and the virtually identical specific activities suggest that the *R. delemar* lipase produced by *E. coli* and the lipase produced by the fungus could be of equivalent use for most applications. The yield of recombinant lipase after refolding and purification is about one-hundred times higher than that achieved by purification of the enzyme from fungal cultures. Thus a small culture provides sufficient enzyme material for most laboratory applications such as crystallography studies. It should be possible to increase the yield further simply by growing the recombinant *E. coli* in fermentors instead of the shaken flasks used in this study. Also, as our knowledge of protein refolding and appropriate refolding techniques advances, further yield increases should be possible.

ACKNOWLEDGMENTS

We would like to thank H. Farrell and H. Dower for performing the amino acid sequence analysis, J. Basch for help with the gel scanning and T. Deng for plasmids pTM-N and pTM2-2.

CDPcholine:1,2-Diacylglycerol Cholinephosphotransferase from Rat Liver Microsomes. I. Solubilization and Characterization of the Partially Purified Enzyme and the Possible Existence of an Endogenous Inhibitor

Kozo Ishidate*, Ritsuko Matsuo and **Yasuo Nakazawa**
The Department of Chemical Toxicology, Medical Research Institute, Tokyo Medical and Dental University, Chiyoda-ku, Tokyo 101, Japan

The solubilization and partial purification of cholinephosphotransferase (CDPcholine:1,2-diacylglycerol cholinephosphotransferase, EC 2.7.8.2) from rat liver microsomes were examined in the presence of ionic (sodium deoxycholate), nonionic (Triton X-100, *n*-octylglycoside), or zwitter ionic (CHAPS) detergents. Among the four detergents tested, only sodium deoxycholate was found to be an efficient solubilizer of cholinephosphotransferase activity from microsomal membranes, whereas the other three detergents caused irreversible inactivation of the enzyme at the solubilization step. Addition of phospholipids at the solubilization step, or after solubilization of the membrane proteins, could not preserve or reconstitute activity to any extent. The sodium deoxycholate-solubilized activity was partially purified by gel permeation chromatography (Superose 12HR). The partially purified preparation appeared to consist of a large aggregate containing phospholipids; further dissociation of the protein-phospholipid complex caused complete inactivation of the enzyme. The partially purified cholinephosphotransferase showed a specific activity of 100–130 nmol/min/mg protein, which is the highest activity reported to date from any tissue source; this amounts to a 4-fold enrichment of cholinephosphotransferase activity from the original KCl-washed rat liver microsomes. Ethanolaminephosphotransferase (CDPethanolamine:1,2-diacylglycerol ethanolaminephosphotransferase, EC 2.7.8.1) activity was copurified and 6-fold enriched with a total recovery of 60%. During the purification of cholinephosphotransferase activity, a putative endogenous inhibitor of cholinephosphotransferase was also solubilized and was isolated from the microsomal membranes. This heat-labile, nondialyzable inhibitor was shown to act specifically on cholinephosphotransferase and not on ethanolaminephosphotransferase. Further characterization of the inhibitory activity revealed that it may act at the binding step of the cholinephosphotransferase to its lipid substrate, diacylglycerol.

Lipids 28, 89–96 (1993).

Phosphatidylcholine and phosphatidylethanolamine are the two major membrane phospholipids in animal cells; together they typically constitute more than 80% of total phospholipids in most biomembranes. Beyond their apparent structural roles, both classes of phospholipid also appear to be involved in the modulation of certain membrane-bound enzymes (1). More recently, the participation of these phospholipids, and particularly of phosphatidylcholine, in signal transduction has also been implicated (2–6).

In most mammalian tissues, the CDPcholine (CDP ethanolamine) pathway is the major biosynthetic route for the formation of phosphatidylcholine (phosphatidylethanolamine). Either pathway involves three enzymatic steps *i.e.*, choline(ethanolamine) kinase, phosphocholine(phosphoethanolamine) cytidylyltransferase, and choline(ethanolamine)-phosphotransferase. In the past few years, enzymes of the first two steps have been purified from mammalian sources to apparent homogeneity. Choline kinase has been purifed from rat kidney (7), liver (8) and brain (9) cytosols and proven to be the same enzyme as ethanolamine kinase in these and other rat tissues (8,10). Phosphocholine cytidylyltransferase has been purified from rat liver cytosol (11,12), and this enzyme is distinct from the corresponding phosphoethanolamine cytidylyltransferase, which also had been purifed earlier from rat liver cytosol (13). The last two enzymes, cholinephosphotransferase (CPT) and ethanolaminephosphotransferase (EPT), which have been shown to be tightly membrane-bound, are so-called integral membrane proteins, and still have not been purified. These enzymes need to be purified to arrive at a better understanding of the molecular mechanisms involved in the regulation of phosphatidylcholine and/or phosphatidylethanolamine biosynthesis in animal cells.

A number of attempts have been made to solubilize CPT from several membrane sources by use of various detergents (14–16), but further efforts to purify the enzyme have not been successful mainly because of insufficient information about the nature of the enzyme and its susceptibility to detergents. EPT, on the other hand, was shown to be relatively stable in the presence of certain nonionic detergents; thus Roberti *et al.* (17) have recently succeeded in the 1200-fold purification of the enzyme upon solubilization from rat brain microsomes with Triton X-100 (TX-100), although their final preparation still showed several protein bands in sodium dodecylsulfate-polyacrylamide gel electrophoresis (SDS-PAGE).

In the present paper, we report (i) the selection of an effective detergent for solubilization of CPT from rat liver microsomes in intact form, (ii) the results of the partial purification of both the choline- and ethanolaminephosphotransferases, (iii) some characteristics of the solubilized, partially purified transferases and (iv) the possible existence of an endogenous inhibitor of CPT activity.

Abbreviations: CHAPS, 3-[(3-cholamidopropyl)dimethylamino]-1-propanesulfonate; CPT, cholinephosphotransferase; DOC, sodium deoxycholate; EGTA, ethyleneglycol-*bis*(β-aminoethylether)*N,N,N',N'*-tetraacetic acid; EPT, ethanolaminephosphotransferase; *n*-OG, *n*-octyl-β-D-glucopyranoside; PMSF, phenylmethylsulfonyl fluoride; SDS-PAGE, sodium dodecylsulfate-polyacrylamide gel electrophoresis; TLC, thin-layer chromatography; TX-100, Triton X-100.

MATERIALS AND METHODS

Chemicals. CDP[*methyl*-^{14}C]choline (ammonium salt) and CDP[1,2-^{14}C]ethanolamine were obtained from Amersham Japan Ltd. (Tokyo, Japan) and ICN Biochemicals Inc. (Costa Mesa, CA), respectively. The detergents used were sodium deoxycholate (DOC) and *n*-octyl-β-D-glucopyranoside (*n*-OG) from Sigma (St. Louis, MO), TX-100 from Nakalai Tesque (Kyoto, Japan) and Tween-20 and CHAPS from Bio-Rad (Richmond, CA). All other reagents were of analytical grade. 1,2-Diacylglycerol was prepared from egg yolk phosphatidylcholine by phospholipase C (*Clostridium welchii*) treatment and was purified by thin-layer chromatography (TLC) as described previously (18). The purified 1,2-diacylglycerol was dissolved in $CHCl_3$ at a concentration of 12 mg/mL and stored at −20°C until use.

Preparation of KCl-washed microsomes. Wistar rats of either sex, weighing 200–250 g, were killed by decapitation after overnight fasting. The livers were thoroughly rinsed with ice-cold saline and homogenized in 4 vol of 0.25 M sucrose, 3 mM Tris/HCl (pH 7.5) and 0.1 mM ethylenediaminetetraacetic acid using a Teflon-pestle glass homogenizer. The homogenates were centrifuged at 24,000 × *g* for 10 min, and the resulting supernatant was recentrifuged at 54,000 × *g* for 60 min. The pellet (microsomal fraction) was suspended in approximately 10 vol of 0.25 M sucrose, 10 mM Tris/HCl (pH 8.0), 1 mM histidine, and 0.1 mM phenylmethylsulfonyl fluoride (PMSF) (Buffer A), containing 0.6 M KCl, and stirred for 20 min at 0°C. The suspension was then centrifuged at 200,000 × *g* for 30 min. The resulting pellet (KCl-washed microsomes) was re-homogenized in a small amount of Buffer A (approximately 30 mg microsomal protein/mL) and stored at −20°C until use. Both choline- and ethanolaminephosphotransferase activities were found to be quite stable at this stage even after several thaw-freeze cycles.

Solubilization of CPT activity from KCl-washed microsomal membranes. Four typical detergents commonly used for solubilizing membrane proteins, TX-100, *n*-OG, CHAPS and DOC, were examined to check their efficiency in solubilizing CPT activity. The KCl-washed microsomal fraction (10 mg protein/mL) was incubated for 20 min to 21 h at 4°C in 0.25 M sucrose, 50 mM Tris/HCl (pH ranges of 6.0 to 9.0), 0.8 mM CDPcholine, 1 mM histidine, 0.3 mM PMSF, plus various amounts of the detergents (from 0.05 to 5.0 mg/mg microsomal protein). Detergent concentrations in the present investigation were measured in weight ratios of total detergent to membrane protein following the suggestion that this may be the best way to define the solubilizing power of a detergent (15,19). When DOC was used as solubilizing agent, 1 M KCl was added to the solubilization buffer. The mixture was centrifuged at 200,000 × *g* for 30 min, and the resulting supernatant was dialyzed overnight against 20% glycerol, 20 mM Tris/HCl (pH 8.5), 1 mM dithiothreitol (DTT), 0.5 mM ethyleneglycol-*bis*(aminoethylether)*N,N,N',N'*-tetraacetic acid (EGTA) and 0.3 mM PMSF (Buffer B) and then centrifuged at 200,000 × *g* for 30 min. After the pellet was re-homogenized in a small amount of Buffer B, an aliquot of both fractions was assayed for cholinephosphotransferase activity.

The pellet from the initial centrifugation step, *i.e.*, an unsolubilized microsomal membrane fraction, was also rehomogenized in a small amount of Buffer B and assayed to estimate unsolubilized CPT activity. For TX-100-solubilized preparations, Bio-beads SM-2 (Bio-Rad) was used to adsorb the detergent (15) from the solubilized sample after overnight dialysis against Buffer B.

Large-scale solubilization and gel permeation chromatography. KCl-washed rat liver microsomes (10 mg/mL) were solubilized in 0.25 M sucrose, 50 mM Tris/HCl (pH 7.5), 0.8 mM CDPcholine, 1 mM histidine, and 0.3 mM PMSF, containing 6 mM (0.25%) DOC and 1 M KCl, with moderate shaking for 20 min at 4°C; then the mixture was centrifuged at 200,000 × *g* for 30 min. In some experiments, 1,2-diacylglycerol (1.25 mg/mL), leupeptin (10 μg/mL) and aprotinin (10 μg/mL) were also included in the solubilization buffer. The high-speed supernatant was passed through a membrane filter (Millex-GS, 0.22 μm, from Japan Millipore Ltd. Tokyo, Japan), then the total filtrate was dialyzed overnight against Buffer B containing 2.4 mM (0.1%) DOC. The preparation at this stage could be stored at −20°C for at least 4 wk without loss of CPT activity. The solubilized preparation (0.5 mL each) was next applied onto a Superose 12HR column (Pharmacia Fine Chemicals, Uppsala, Sweden) and eluted with Buffer B containing 2.4 mM DOC and 0.15 M KCl at a flow rate of 0.3 mL/min. Fractions of 0.6 mL each were collected and assayed for both choline- and ethanolaminephosphotransferase activities. An aliquot of the fractions was also used for protein assay by the Lowry method (20) and for measuring lipid phosphorus after perchloric acid digestion (21). The fractions with high CPT activity were pooled and dialyzed for 16 h against Buffer B, then centrifuged at 200,000 × *g* for 30 min. The activity was recovered quantitatively in the high-speed pellet fraction, and the pellet was resuspended in a small amount of Buffer B by brief homogenization. At this stage the enzyme activity was stable when stored at −20°C.

Enzyme assay. CPT activity was assayed essentially as described before (18). The typical incubation mixture contained 75 mM Tris/HCl (pH 8.5), 10 mM $MgCl_2$, 5 mM EGTA, 3 mM DTT, 2 mM 1,2-di-acylglycerol (in final 0.02% Tween-20 emulsion), 0.5 mM CDP[*methyl*-^{14}C]-choline (specific activity, 0.1 Ci/mol) and an aliquot of enzyme preparation in a final volume of 0.2 mL. Incubations were started by addition of enzyme and carried out for 20 min at 37°C. The reaction was stopped by addition of 2 mL of $CHCl_3$/MeOH (2:1, vol/vol), followed by extraction of the reaction product, phosphatidylcholine, into $CHCl_3$. Blanks were usually done by stopping the reaction immediately after the addition of the enzyme. When appropriate, the activity without exogenous 1,2-diacylglycyerol (0.02% Tween-20 only) was subtracted as endogenous activity. The $CHCl_3$ layer was washed first with 2.5 mM cold CDPcholine (in 50% MeOH solution), then twice with 50% MeOH. The washed $CHCl_3$ layer was transferred into a liquid scintillation vial, dried under N_2 and counted for radioactivity in 10 mL ACS-II (Amersham) scintillation cocktail. The amount of phosphatidylcholine formed during the incubation was estimated from the specific radioactivity of CDP-[*methyl*-^{14}C]choline. The reaction was almost linear for 40 min (50 μg protein) and up to 100 μg protein (20-min

incubation) when the KCl-washed microsomal fraction was used as the enzyme source.

EPT activity was assayed in exactly the same manner as was CPT except that 10 mM $MgCl_2$ was replaced by 10 mM $MnCl_2$, and 0.5 mM CDP[1,2-^{14}C]ethanolamine (specific activity, 0.25 Ci/mol) was used instead for CDP-[*methyl*-^{14}C]choline. The specific activity of EPT in KCl-washed microsomes ranged around 4–5 nmol/min/mg protein; this value was one-fifth to one-seventh of that of CPT in the same enzyme preparation. The 1,2-diacylglycerol/Tween-20 emulsion (20 mM diacylglycerol) was prepared as follows: twelve milligram (20 μmoles) of dried 1,2-diacylglycerol was added in 1 mL of 0.2% Tween-20 solution and sonicated with a probe-type sonicator until no floating material remained. Usually three irradiation cycles of 30 s each were necessary (at 0°C). The emulsion could be stored at −20°C, but resonication just before use was necessary. For some experiments, 1,2-diacylglycerol (final 1.25 mM) was emulsified in 5 mM DOC and 0.25% Tween-20 mixtures according to the method of Kanoh and Ohno (14,22), and enzyme activities were compared for the two substrates in their different physical states.

In another experiment with the partially purified enzyme, total lipids from rat liver microsomes (extracted by the Folch method; ref. 23) were added to the incubation mixture as a 10 mM Tris/HCl (pH 7.5) dispersion to arrive at a final phospholipid concentration of 0.5 mM (estimated by lipid phosphorus).

Analysis of water-soluble products. After the reaction of CPT was stopped by the addition of 1.5 mL $CHCL_3$/MeOH (2:1, vol/vol), an aliquot of the resulting aqueous layer was applied to a TLC plate (Kiesel Gel 60 from Merck, Darmstadt, Germany) together with small amounts of carrier CDP—choline, phosphocholine and choline. The developing solvent system used was MeOH/0.6% NaCl/conc. NH_4OH (10:10:1, by vol). Fractions corresponding to each of the metabolites were detected by exposure to iodine vapor, scraped from the plate, transferred to a scintillation vial and counted using 1 mL H_2O plus 10 mL ACS-II.

RESULTS

Effect of detergents on CPT activity in rat liver microsomes. Before comparison of the solubilization efficiencies of the four detergents for CPT from liver microsomal membranes, the effect of the detergents on CPT activity was examined as a function of detergent concentration. As shown in Figure 1, all the detergents examined were found to inhibit CPT activity in a dose-dependent manner. When the dose was plotted as mg detergent per mg microsomal protein, the inhibition by TX-100 was most striking, followed by DOC, CHAPS and *n*-OG. The observations essentially agree with those reported by Cornell and MacLennan (15), who compared the effect of six different detergents on CPT activity from rabbit sarcoplasmic reticulum. The order of enzyme inhibition observed in the present investigation was essentially parallel to the detergents' capability to solubilize membranes (15), indicating that the inhibition of CPT activity was most likely due to the disruption of the membrane structure. Or conversely, the activity of CPT appeared to be very much dependent on its lipid environment, as was already suggested by Cornell and MacLennan (15). The possibility that the presence of detergent in the assay could also prevent the utilization of exogenous 1,2-diacylglycerol by the enzyme cannot be entirely ruled out.

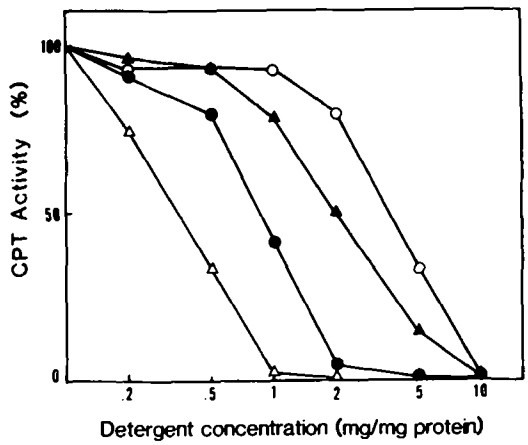

FIG. 1. Detergent sensitivity of cholinephosphotransferase activity from rat liver microsomes. Detergents were added directly to the cholinephosphotransferase assay mixtures at the indicated concentrations. The reaction was started with the addition of KCl-washed microsomes (50 μg protein) and continued for 20 min at 37°C. The specific activity in the absence of detergents ranged 30–35 nmol/min/mg protein. Data are averages of two separate experiments. △, TX-100; ●, DOC; ▲, CHAPS; ○, *n*-OG. CPT, cholinephosphotransferase.

Our results therefore indicate that, after solubilization of CPT from microsomal membranes by the detergents, the detergents must be removed from the solubilized preparation before enzyme activity is assayed.

In contrast to several reports which showed an activation of CPT by a low concentration of either TX-100 or DOC, we observed no stimulation of enzyme activity by these detergents. This may be due to differences in the physical state of the exogenously added lipid substrate. We used 1,2-diacylglycerol/Tween-20 emulsion, whereas phospholipid mixed micelles or ethanol dispersions were used in the earlier experiments (14, 15,24).

Solubilization of CPT from microsomal membranes. The solubilizing efficiency of the four detergents for CPT activity from KCl-washed rat liver microsomes was compared as a function of detergent concentration (from 0.05 to 5 mg/mg protein), incubation time (from 20 min to 21 h) and pH (from 6 to 9). Typical results are shown in Figure 2, in which CPT activities that were recovered in the solubilized fraction after the incubation with the detergents at various concentrations are compared. Both the total protein solubilized from the microsomal membranes and the unsolubilized CPT activity are given also as percentages of the values found in the initial microsomal membranes. The results suggest that, among the four detergents examined, only DOC effectively solubilized the microsomal CPT in active form. Other nonionic (TX-100 and *n*-OG) and zwitter ionic (CHAPS) detergents were found to cause irreversible inactivation

of the enzyme, which resulted in recovery of only 1 to 3% of the initial activity in the solubilized fraction. The inclusion of phospholipid dispersions (0.5 mM, isolated from rat liver microsomes) in the medium before or after the incubation with detergents did not significantly improve the recovery of enzyme activity.

Our result also showed that almost all of the CPT activity solubilized by DOC was recovered in the high-speed pellet when the detergent was removed by overnight dialysis against Buffer B. Prolonged incubation from 20 min to 2 h, 4 h or 21 h at pH 8.0 did not increase but actually did diminish the recovery of enzyme activity solubilized by the detergents (data not shown). Also a shift of pH between 6 and 9 did not significantly affect the solubilizing efficiency of DOC for CPT activity, but somewhat higher recoveries of both the enzyme activity and the protein were obtained at pH 9.0 with either CHAPS or TX-100; *i.e.*, 1% at pH 8.0 *vs.* 3.5% at pH 9.0 for CHAPS, and 2.5% at pH 8.0 *vs.* 6% at pH 9.0 for TX-100 (data not shown).

Cornell and MacLennan (15) had reported that inclusion of diacylglycerol at the solubilization step of the isolation of CPT from rabbit sarcoplasmic reticulum stabilized and partly protected enzyme activity from irreversible inhibition by detergents. We checked the effect of addition of diacylglycerol to the solubilizing medium with DOC and found that, if 0.8 mM CDPcholine, the other substrate of CPT, was included in the medium, there was no further stabilization or protection of enzyme activity by diacylglycerol. In addition, as mentioned in Materials and Methods, inclusion of diacylglycerol led to considerably higher endogenous activity values which could make it difficult to correctly estimate the enzyme activity during the subsequent enzyme purification. Thus, we decided not to include diacylglycerol at the solubilization step using DOC.

Partial purification of CPT. As DOC was the most effective agent for solubilizing CPT from rat liver microsomes, we next proceeded to purify the enzyme activity from the DOC-solubilized preparation by Superose 12HR column chromatography using a Pharmacia FPLC system. Figure 3 shows a typical elution pattern of CPT activity from the column together with the protein and lipid phosphorus values determined on the same run. The elution of EPT activity is also plotted in Figure 3. The results clearly show that both choline- and ethanolaminephosphotransferase activities are recovered in the fractions close to the void volume, suggesting that most of the activity is associated with large aggregates which still contain considerable amounts of phospholipids. Well-dissociated fractions of smaller molecular size were found not to exhibit any phosphotransferase activity with either CDPcholine or CDP—ethanolamine. CPT activity could be purified by gel permeation chromatography about four-fold with a recovery of approximately 40% when compared to the original microsomal activity (Table 1). EPT activity was purified 6-fold with 60% recovery, indicating that the latter activity remained relatively stable in the course of the solubilization-purification process. A number of reports had previously indicated that EPT, which is an enzyme distinct from CPT (25-28), is much more stable than CPT in the presence of various detergents, including DOC (14,29-31).

The SDS gel (Fig. 4) shows that the polypeptide pattern of the fraction with high choline- or ethanolaminephosphotransferase activity after gel permeation chromatography (lane C) was quite different from that of either the microsomes (lane A) or the DOC-solubilized fraction (lane B), indicating that the large aggregates in this fraction could not simply be fragments of microsomal membranes; however, it could be a complex of particular species of microsomal proteins which appear not easily dissociable in the presence of DOC.

Further attempts to purify CPT with a DEAE-Sepharose or hydroxyapatite column in the presence of DOC were not successful because of the extremely low recovery of enzyme activity.

It has been reported that Mn^{2+} is a preferable cation in the EPT reaction in most membrane systems (14,22,24, 31-33) whereas in certain mammalian systems Mg^{2+} is known to be more active in CPT reaction (14,22,31,34). Kanoh and Ohno (14) reported that, in rat liver microsomes, there might be two components contributing to

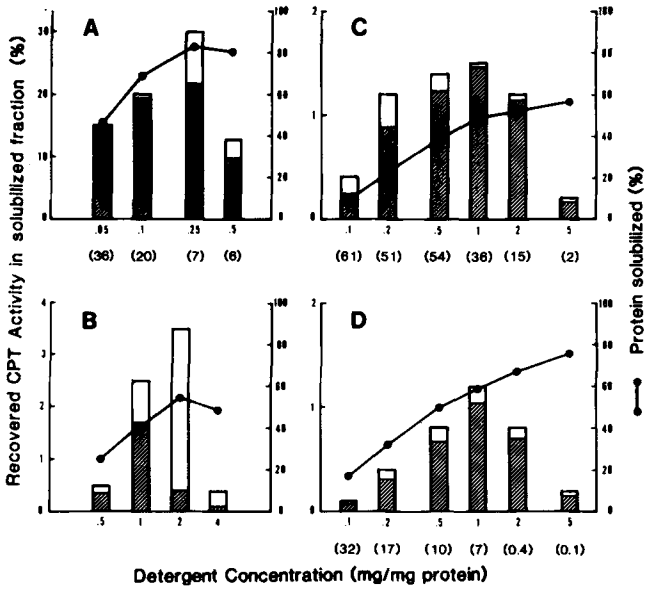

FIG. 2. Solubilization of cholinephosphotransferase activity from rat liver microsomes by detergents. The KCl-washed microsomes (10 mg protein/mL) were incubated for 20 min at 4°C in 0.25 M sucrose, 50 mM Tris/HCl (pH 8.0), 0.8 mM CDPcholine, 1 mM histidine, 0.3 mM PMSF and the indicated amounts of detergents in a final volume of 1.0 mL. 1 M KCl was also included in the case of DOC-solubilization, which resulted in a 25% increase in the total solubilized activity. The addition of KCl did not improve the recovery by other detergents. The contents were centrifuged at 200,000 × *g* for 30 min, and the resulting supernatant was dialyzed overnight against Buffer B, then recentrifuged at 200,000 × *g* for 30 min. The Triton-100-solubilized preparation was treated with Bio-beads SM-2 to adsorb the detergent (ref. 15) before the second centrifugation. Each column represents the total solubilized activity (as percentage of the initial microsomal activity) determined after removal of detergent, and the hatched portion represents the activity recovered in the pellet after the second high-speed centrifugation. The values in parentheses at the bottom represent the activity recovered in unsolubilized microsomal membrane remnants (as percentages of the initial microsomal activities). A, sodium deoxypanesulfonate; B, *n*-octyl-β-D-glucopyranoside; C, CHAPS; D, Triton-100. CPT, cholinephosphotransferase.

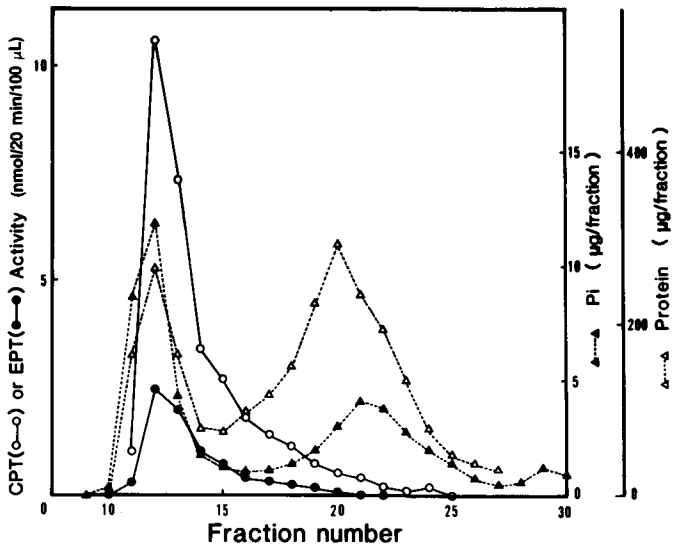

FIG. 3. Typical elution pattern of cholinephosphotransferase and ethanolaminephosphotransferase activities through a Superose 12HR column. An aliquot of the DOC-solubilized fraction (usually 0.5 mL, approx. 4 mg protein) was applied onto the column (1 × 30 cm) and eluted with Buffer B containing 2.4 mM (0.1%) DOC and 0.15 M KCl as described in Materials and Methods. Fractions of 0.6 mL each were collected and assayed for both choline (○)- and ethanolamine (●) phosphotransferase activities as well as for protein (△) and lipid phosphorus (▲) contents. Abbreviations used are: CPT, cholinephosphotransferase; EPT, ethanolaminephosphotransferase; DOC, sodium deoxycholate.

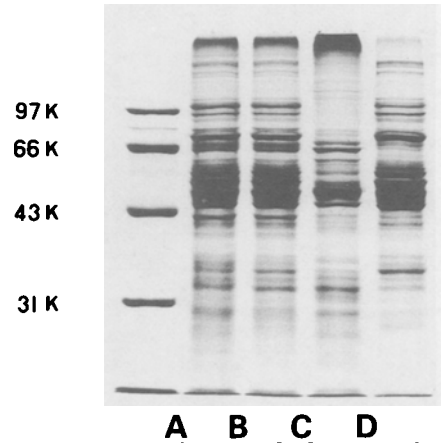

FIG. 4. Sodium dodecylsulfate (SDS)-polyacrylamide gel electrophoresis of rat liver choline(ethanolamine)phosphotransferase preparations. Each lane contained 50 μg protein from KCl-washed microsomes (A), sodium deoxycholate-solubilized fraction (B), partially purified enzyme preparation (C) and inhibitor Fraction 17 (D) obtained by Superose 12HR gel filtration. The left side lane shows molecular weight standards; rabbit muscle phosphorylase B (97 kDa), bovine serum albumin (66 kDa), ovalbumin (43 kDa), bovine carbonic anhydrase (31 kDa) and soybean trypsin inhibitor (22 kDa, bottom). A 10% SDS-polyacryalmide gel was run according to the method of Laemmli (ref. 40) and the protein was stained with Coomassie Brilliant Blue R-250.

CPT activity, one being Mg^{2+}-requiring and the other being Mn^{2+}-requiring; both could be partly separated from each other by sucrose density gradient centrifugation in the presence of 0.5% TX-100. We could not reconcile our results (Fig. 5) with those reported by Kanoh and Ohno (14,22) as well as others (35,36) working with rat tissue enzymes. Our preparations of either partially purified or microsomal phosphotransferases required Mg^{2+} rather than Mn^{2+}, particularly at physiological concentrations (less than 5 mM). when compared to the CPT, Mn^{2+} could more effectively replace Mg^{2+} in the EPT reaction but was never preferred over Mg^{2+} in either the microsomal preparation or the partially purified enzyme. These differences in cation requirements may partly be due to differences in the assay system, where a 0.02% Tween-20 emulsion of diacylglycerol was used in the present investigation. Alternatively, more than one species of both choline- or ethanolaminephosphotransferase could exist in rat tissues.

Possible existence of a CPT inhibitor protein in rat liver microsomes. During the process of CPT purification by gel permeation chromatography, we found that the DOC-solubilized preparation (after removal of DOC by overnight dialysis against Buffer B) gave a nonlinear, satur-

TABLE 1

Partial Purification of Cholinephosphotransferase (CPT) and Ethanolaminephosphotransferase (EPT) Activities from Rat Liver Microsomes[a]

Recovery (%)	—	38.4	—	59.1	—

[a]Purification was started with 265 mg KCl-washed microsomal protein. The activities in DOC-solubilized and Superose 12HR fractions were determined after the removal of DOC by overnight dialysis against Buffer B. DOC, sodium deoxycholate.
[b]S.A., specific activity.
[c]T.A., total activity.

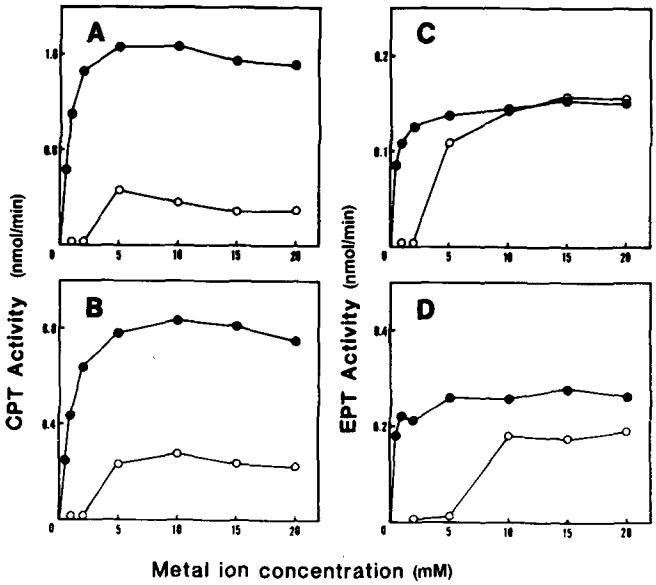

FIG. 5. Comparison of divalent cation dependency between cholinephosphotransferase and ethanolaminephosphotransferase in both microsomal and partially purified enzyme preparations. Each incubation contained 50 μg (microsomes) or 7 μg protein (partially purified enzyme) in a final volume of 0.2 mL. Other experimental details are those described in Materials and Methods. A and C, microsomal activity; B and D, partially purified enzyme activity. ●, activity with Mg^{2+}; ○, activity with Mn^{2+}. Abbreviations used are: CPT, cholinephosphotransferase; EPT, ethanolaminephosphotransferase.

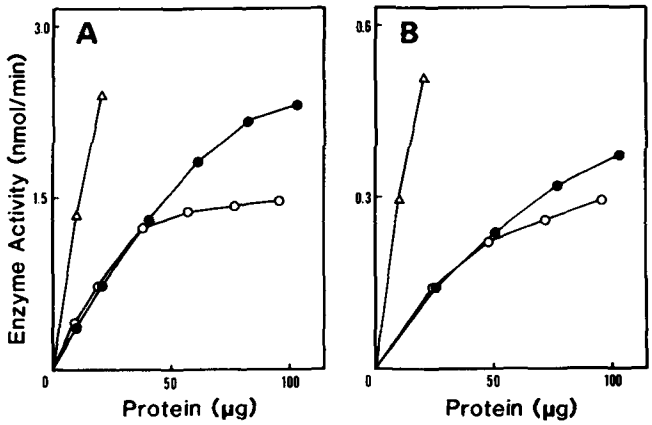

FIG. 6. Linearity of cholinephosphotransferase (A) and ethanolaminephosphotransferase (B) activities with microsomes, sodium deoxycholate (DOC)-solubilized, and partially purified enzyme preparations for increasing protein concentrations. The activity was determined after removal of DOC by overnight dialysis both for the DOC-solubilized and partially purified enzyme preparations. ●, microsomes; ○, DOC-solubilized enzyme; △, partially purified enzyme obtained with a Superose 12HR column.

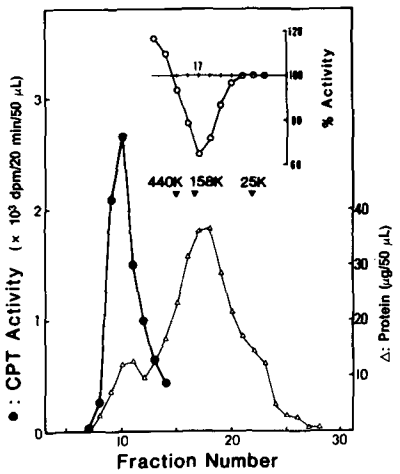

FIG. 7. The elution pattern of inhibitor activity obtained with a Superose 12HR gel filtration column. The fractions eluted after the peak of cholinephosphotransferase activity were dialyzed for 24 h against Buffer B and a 35-μL portion of each fraction was added to the assay mixture which contained the partially purified enzyme preparation (10 μg protein). The inhibitor activity was plotted (inset) as percent of the remaining cholinephosphotransferase activity, in which Fraction 17 showed the highest inhibition. Arrows indicate the elution peaks of the molecular weight standards from Pharmacia; ferritin (440 kDa, from horse spleen), aldolase (158 kDa, from rabbit muscle) and chymotrypsinogen A (25 kDa, from bovine pancreas). CPT, cholinephosphotransferase.

able curve when the enzyme activity was plotted as a function of protein content, as shown in Figure 6. This nonlinearity was not as pronounced when microsomal membranes were used as the enzyme source and was never detected with the partially purified CPT preparation from the Superose 12HR column. The effect was less pronounced when the relationship was plotted for EPT activity (Fig. 6B) using the same DOC-solubilized enzyme preparation.

It appears that the inhibition of CPT activity observed at higher protein concentrations may have been caused by the presence of an endogenous inhibitor that was solubilized together with the CPT by DOC and removed from the active enzyme fraction in the subsequent gel permeation step. In order to characterize the nature of the putative CPT inhibitor, samples of the partially purified enzyme preparation were mixed with aliquots of the fractions (after 24 h dialysis against Buffer B) eluted from the gel following the CPT activity peak and the activities were assayed. It is clear from Figure 7 that Fraction 17 contained the highest inhibitory activity. This fraction inhibited CPT activity in a dose-dependent manner (Fig. 8), and the inhibition appeared to be specific for CPT because the fraction did not significantly inhibit EPT activity. The inhibitory activity of Fraction 17 was completely abolished when the fraction was pre-heated for 2 min in a boiling water bath (data not shown).

The SDS-PAGE pattern of Fraction 17 (Fig. 4, lane D) was found to be quite different from that of the partially purified enzyme fraction (Fig. 4, lane C).

The inhibition of CPT was further characterized by measuring reaction kinetics. The partially purified preparation gave a saturation activity curve *vs.* CDPcholine and an apparent Km value for CDPcholine of 58 μM. This value became smaller in the presence of the inhibitor, and the inhibition appeared to be uncompetitive *vs.* CDPcholine (data not shown). An exact

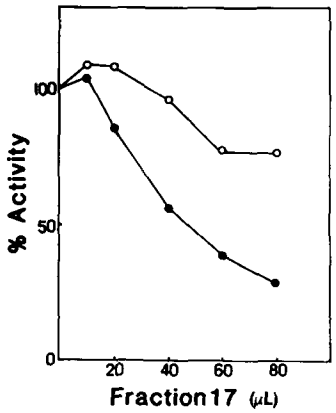

FIG. 8. The inhibition of cholinephosphotransferase and ethanolaminephosphotransferase activities by Fraction 17. An aliquot of the partially purified enzyme preparation (20 μg protein) was added by various amounts of Fraction 17 (DOC had been removed by 24-h dialysis against Buffer B); then the mixture was assayed for both choline- and ethanolaminephosphotransferase activities. The protein content of Fraction 17 was approx. 37 μg/50 μL; ●, cholinephosphotransferase; ○, ethanolaminephosphotransferase.

Km value for diacylglycerol could not be obtained because our assay system using exogenous diacylglycerol in Tween-20 emulsion gave a sigmoidal activity curve against diacylglycerol.

Next, the water-soluble choline metabolites of the CPT assay were analyzed in the absence or presence of the inhibitor protein to test the possibility that the apparent inhibition might be due to [^{14}C]CDPcholine hydrolytic activity. Although some hydrolyzing activity toward CDPcholine (or phosphatidylcholine) was observed in both the enzyme and inhibitor fractions, it seemed unlikely that the inhibition of CPT activity by Fraction 17 occurred at the level of CDPcholine hydrolysis, since more than 80% of [^{14}C]CDPcholine was recovered in its intact form after incubation in either the presence or absence of the inhibitor fraction (data not shown).

Finally, the inhibitory activity of Fraction 17 was tested in a different CPT assay system to check the possibility of whether the inhibitor might act on the diacylglycerol dispersion by rendering its physical state ineffective as substrate. We compared our assay method to that of Kanoh and Ohno (14,22), in which diacylglycerol (0.5 mM) was added in mixed micelles of phospholipids (0.5 mM)/Tween-20 (0.1%)/DOC (2 mM). While the specific CPT activity measured by this method was considerably lower (12–13 nmol/min/mg protein without phospholipids and 15–18 nmol/min/mg protein with 0.5 mM phospholipids) than when measured by ours (80–130 nmol/min/mg protein with or without added phospholipids), the activity measured essentially was not affected by the addition of the inhibitor fraction to the assay system (data not shown).

Thus, one could speculate that the putative endogenous inhibitor may act not only on the enzyme substrate (CDPcholine) complex, but also on the diacylglycerol/Tween-20 emulsion and may change its physical state in a way so it cannot be utilized effectively by the enzyme.

DISCUSSION

Recently, O and Choy (16) reported the partial purification of CPT solubilized from hamster liver microsomes with 3% Triton QS-15 using a DEAE-Sepharose column followed by Sepharose 6B gel filtration. The purified preparation had a specific activity of 3.68 nmol/min/mg protein; this value was approximately seven times that of the original microsomal preparation (0.5 nmol/min/mg protein). We applied this method to the isolation of CPT from rat liver microsomes and found that the enzyme solubilized with Triton QS-15 was extremely unstable when kept at 0°C in the presence of 1–3% Triton QS-15, and particularly in dilution (less than 1 mg protein/mL). In addition, the enzyme could not sustain most of its activity during a thaw freeze cycle.

Thus, in our system, DOC appeared to be a more effective detergent for solubilizing CPT. Subsequent purification of the DOC-solubilized enzyme through a Superose 12HR column in the presence of 0.1% DOC resulted in a 4-fold enrichment of activity with a 40% recovery in respect to the original microsomal activity. The result is similar to that reported by Kanoh and Ohno (14,22), who also achieved a 4-fold purification of CPT activity through differential pH treatment of rat liver microsomes in the presence of 16–20 mM DOC. The specific activity reported for their partially purified enzyme was 16–20 nmol/min/mg protein, which was less than the microsomal activity measured in our study (approx. 30 nmol/min/mg protein). This difference could be explained by the fact that we started the experiment with 0.6 M KCl-washed microsomes and that a considerable portion of the loosely attached, peripheral proteins had already been removed from the microsomal fraction. Furthermore, the specific activity measured using exogenously added diacylglycerol in Tween-20 emulsion, as we used in this study, was found to be much higher than that reported by Kanoh and Ohno (14,22) who used diacylglycerol in mixed micelles (phospholipid/Tween-20/DOC).

The partially purified enzyme obtained by gel filtration appeared to consist of a relatively large aggregate of particular microsomal proteins and phospholipids as it eluted near the void volume as a fairly milky dispersion. Further attempts to replace phospholipid by detergent were not successful. Thus, it appears that dissociation of the enzyme-phospholipid complex causes complete and irreversible inactivation of CPT activity. The results of our purification study thus would indicate that it may be extremely difficult to purify CPT from microsomal membranes by classical methods, as was also emphasized by Cornell in her recent review (37). Finally, it may be more effective to use affinity chromatography in the presence of DOC, in which CDPcholine would be coupled to either an epoxy-activated or a CH-activated Sepharose; such experiments are in progress in our laboratory.

The possible existence of an endogenous CPT inhibitor in rat liver microsomes was indicated in the present study. To our knowledge, this is the first description of such an inhibitor, which presumably is a protein, of the CPT reaction. The possible participation of a cytosolic phosphatidylcholine transfer protein in the regulation of CPT

activity in rat liver microsomes has been reported recently (38). Although the exact mechanism of the inhibition remains to be determined, the results of the present study suggest that the inhibition most likely occurs at or near the binding site between the enzyme and the lipid substrate. One could, thus, postulate that this inhibitory protein component regulates the availability of diacylglycerol to CPT (but not to EPT) in microsomal membranes. Metabolically, diacylglycerol is located at a branch point of the biosynthesis of phosphatidylcholine, phosphatidylethanolamine and triacylglycerol, and the mechanisms for the regulation of specific lipid pathways from diacylglycerol have not yet been identified (39). The actual involvement of a specific regulatory protein for each of the biosynthetic reaction, as may be suggested by this report, would offer an attractive and plausible mode of regulation.

Fatty Acid Synthesis from [2-^{14}C]Acetate in Normal and Peroxisome-Deficient (Zellweger) Fibroblasts

A. Poulos*, S. Usher and **B.C. Paton**
Department of Chemical Pathology, Women's and Children's Hospital, North Adelaide, South Australia 5006, Australia

The incorporation of [2-^{14}C]acetate into the lipids of normal and peroxisome-deficient (Zellweger's syndrome) skin fibroblasts was examined. Most of the label was incorporated into triacylglycerol fatty acids in normal as well as Zellweger's syndrome cells. Triacylglycerols and cholesteryl esters in Zellweger's syndrome cells contained increased levels of labelled saturated and monounsaturated very long-chain fatty acids (VLCFA, that is fatty acids with more than 22 carbon atoms), in particular hexacosanoic (26:0) and hexacosaenoic (26:1) acids. As traces of labelled VLCFA with up to 32 carbon atoms were detected in triacylglycerols even in control cells it is probable that these fatty acids are formed naturally during the elongation process. Our data suggest that peroxisomes are involved in the chain shortening of the saturated and monounsaturated VLCFA.
Lipids 28, 97-102 (1993).

It has become increasingly apparent that peroxisomes play an important role in a number of lipid metabolic pathways. While some of these pathways, for example fatty acid β-oxidation (1) and prostaglandin β-oxidation (2), are associated with catabolic processes, a number of biosynthetic pathways have also been reported. Thus, the biosynthesis of the 1-*O*-alkyl glyceryl ether bond is now believed to occur only in peroxisomes because the enzymes catalyzing the first two steps, namely dihydroxyacetonephosphate acyltransferase and alkyldihydroxyacetone phosphate synthase, are concentrated in this organelle (3-5). Similarly, the final step in the synthesis of bile acids, which involves an oxidative cleavage of 27-carbon bile acid precursors, is also thought to occur predominantly in peroxisomes (6).

As part of our ongoing interest in the role of peroxisomes in lipid metabolism, we have been investigating the metabolism of [1-^{14}C]-labelled long-chain and very long-chain (>22 carbon atoms, VLCFA) saturated and polyunsaturated fatty acids in normal cultured skin fibroblasts and fibroblasts from patients with Zellweger syndrome (7,8), a rare autosomal recessive disorder characterized ultrastructurally by a nearly complete deficiency of peroxisomes in all tissues thus far examined (9). We have found that labelled acetate, released from [1-^{14}C]-labelled VLCFA by normal cells in culture, is used for the biosynthesis of other fatty acids, presumably either by *de novo* synthesis or by elongation of existing fatty acids. In contrast, this process is impaired in Zellweger cells (7). While it is likely that the defect in [^{14}C]fatty acid synthesis from [1-^{14}C]VLCFA in Zellweger cells is due to the impaired β-oxidation activity and the concomitant reduction in [1-^{14}C]acetate release, it is not known whether lipid synthesis from acetate is also impaired in peroxisome-deficient cells.

Abbreviations: BHT, butylated hydroxytoluene; BMEM, basal modified Eagle's medium; VLCFA, very long-chain fatty acids; TLC, thin-layer chromatography.

In this study we have investigated the ability of normal and Zellweger cells to synthesize fatty acids from acetate. Our results indicate that the distribution of labelled acetate in VLCFA is abnormal in peroxisome-deficient cells. These findings confirm the importance of peroxisomal function in lipid metabolism.

MATERIALS AND METHODS

Materials. Reverse phase KC-18 thin-layer plates were purchased from Whatman Inc. (Clifton, NJ), and thin-layer silica gel plates were obtained from E. Merck (Darmstadt, Germany). Basal modified Eagle's medium (BMEM) and fetal calf serum were purchased from Flow Laboratories (North Ryde, N.S.W., Australia). Dulbecco's phosphate-buffered saline (Ca^{2+}- and Mg^{2+}-free) was from Commonwealth Serum Laboratories (Melbourne, Australia). Butylated hydroxytoluene (BHT) and the unlabelled lipid standards were obtained from Sigma Chemical Co. (St. Louis, MO). Bio-Rad protein assay dye reagent concentrate was from Bio-Rad Laboratories (Richmond, CA), and autoradiography film (Hyperfilm-^{3}H) from Amersham Australia Pty Ltd. (North Ryde, Australia). OptiPhase LKB scintillation solvent (HiSafe 3) was purchased from LKB-Produckter AB, (Bromma, Sweden). [2-^{14}C]Acetic acid, sodium salt (specific activity 57 mCi/mmol), [1-^{14}C]palmitic and [1-^{14}C]stearic acids were obtained from DuPont Company (Wilmington, DE). [1-^{14}C]Lignoceric(24:0) and [1-^{14}C]hexacosanoic (26:0) acids were synthesized as described by Singh and Poulos (10). The radiolabelled fatty acids were used as standards for reverse phase thin-layer chromatography (TLC). Unlabelled monoenoic fatty acid standards with 28 to 34 carbons were synthesized as described by Johnson (11).

Patients. Cultured skin fibroblasts from patients with Zellweger's syndrome were generously provided by Dr. L. Sheffield and Dr. G. Thompson (Royal Melbourne Children's Hospital), Dr. C. Oley (Mater Misericordiae Mothers' Hospital, Brisbane) and Dr. J. McGill (Royal Children's Hospital, Brisbane). The diagnosis of Zellweger's syndrome was based on clinical history and examination and confirmed by biochemical and, where possible, ultrastructural investigation (12).

Incubation of [2-^{14}C]acetate with fibroblasts in culture. Cultured skin fibroblasts from normal subjects and from Zellweger's syndrome patients were grown in tissue culture flasks (75 cm^2) in BMEM containing 10% fetal calf serum until confluent. One hundred μL of an ethanolic solution of [2-^{14}C]acetic acid (100 μCi) was added to individual culture flasks, and the flask tops were sealed tightly to prevent the escape of radioactive carbon dioxide into the atmosphere. For pulse labelling, incubations were carried out for 3 d prior to processing of the cells. Pulse-chase experiments were carried out using matched flasks of cells. For pulse-chase experiments the medium was removed after 3 d and replaced with fresh medium (without labelled acetate) and the incubation was continued for a further 7 d, with an additional medium change on day 4 of the chase period.

At the end of the incubation period the medium was removed and the cells were washed with Dulbecco's phosphate-buffered saline (Ca^{2+}- and Mg^{2+}-free) prior to harvesting by trypsinization. The harvested cells were washed a further three times with 10 mL of Dulbecco's phosphate-buffered saline (Ca^{2+}- and Mg^{2+}-free) and suspended in 450 μL Dulbecco's phosphate-buffer, Ca^{2+}-free but containing 4 mM magnesium chloride. The cells were disrupted by ultrasonication, and aliquots were removed for protein analysis (50 μL) and liquid scintillation counting (5 μL). Protein estimations were carried out as described by Bradford (13).

Lipid extraction and analysis. Lipids were extracted from the cell suspensions by the Bligh and Dyer method (14). BHT was added at all stages of extraction and analysis to minimize autoxidation of polyunsaturated fatty acids. For some experiments the delipidated cellular residue was treated with 4N HCl for 17 h at 100°C and the liberated fatty acids were extracted into hexane. Aliquots of lipid extracts were streaked as 1.5 cm-bands onto silica gel 60 thin-layer plates (20 × 20 cm) and developed about 7 cm with chloroform/methanol/water (65:25:4, by vol). After air drying, the plates were then run in the same direction in chloroform all the way to the top of the plate. This chromatographic system resolved the major phospholipid and neutral lipid classes but did not permit the separation of triacylglycerols and cholesteryl esters. Separation of these particular lipids was achieved by chromatographing lipid extracts in hexane/diethyl ether/glacial acetic acid (90:10:1, by vol). Tentative identification of the various lipid components was achieved by running appropriate standards. Individual zones were made visible by autoradiography. For some experiments the lipid extracts were saponified by treatment with 20% (wt/vol) potassium hydroxide in ethanol/water (67:33, vol/vol) for 3 h at 80°C prior to chromatography (15).

Lipid hydrolysis and methylation of the liberated fatty acids and purification of the fatty acid methyl esters was carried out as described earlier (7). Separation of the fatty acid methyl esters into saturated, monounsaturated and polyunsaturated fatty acid fractions was achieved by argentation TLC (7). Saturated and monounsaturated fatty acid methyl esters were separated according to carbon chain length by reverse phase TLC as described by Street *et al.* (7). Individual fatty acid zones were detected by autoradiography, scraped from the plate into glass scintillation vials and counted in 8 mL scintillation fluid. Where possible, tentative identification of the various saturated and monounsaturated fatty acids was based on a comparison of their mobilities on argentation and reverse phase TLC with those of authentic commercially available or specially synthesized standards. Unlabelled monounsaturated fatty acid standards (16:1-34:1) were detected on reverse phase TLC plates by exposure to iodine vapor. Labelled saturated fatty acid standards (16:0, 18:0, 24:0 and 26:0) were detected by autoradiography.

RESULTS

Approximately 3-4% of the label from [2-^{14}C]acetate was recovered in normal cells harvested 3 d after the addition of the label. About half of this radioactivity was recovered in the lipid fraction after extraction of the cells. Similar results were obtained with Zellweger's syndrome cells (Table 1). After removal of the radioactivity from the medium, the amount of label in the cellular lipids gradually decreased. After a 7-d chase, around 30 to 50% of the label remained within the lipid fraction in both control and Zellweger cells (Table 1).

[a]Control and Zellweger cells (four separate lines of each with each line taken from a different individual) were pulsed with [2-^{14}C]-acetate or pulse-chased as described in the text. The amount of label recovered in the lipid fraction of each cell line is tabulated.

Analysis of the lipid extracts revealed that the label was incorporated into all of the major phospholipid and neutral lipid species in normal cells. At least 95% of the label was recovered as fatty acid after alkaline hydrolysis, indicating that little was incorporated into the hydrophilic moieties of the various phospholipid molecules and most was associated with esterified fatty acids. Small amounts of label were detected in cholesterol, unesterified fatty acids, dolichol, squalene and ubiquinone. The major neutral lipid species labelled were triacylglycerols with up to 65% of the label appearing in these lipids. Cholesteryl esters were also labelled but the proportion of the total label rarely exceeded 2% in this period. After removal of the radioactivity from the medium, the amount of label in the various lipids, and in particular in the triacylglycerols, decreased markedly. After a 7-d chase, the amount of label in the latter dropped to a value of <5% of the total cellular lipid radioactivity (control mean 1.15, range 0.24-2.8 *vs.* Zellweger mean 1.7, range 0.7-2.5 nmol labelled acetate/mg protein).

An examination of chromatograms of lipid extracts revealed that Zellweger triacylglycerols and cholesteryl esters contained faster migrating (and hence more hydrophobic) molecular species than those observed in control cells indicating that the fatty acid labelling patterns were probably different in Zellweger cells (Fig. 1). Reverse phase TLC of the labelled fatty acids released from triglycerides and cholesteryl esters after the 3-d labeling period confirmed this. Most of the label in triacylglycerols (>75%) was recovered in saturated fatty acids, predominantly palmitic and stearic acids, with a lesser amount in monounsaturated fatty acids such as oleic acid. Polyunsaturated fatty acids were also labelled but these were not

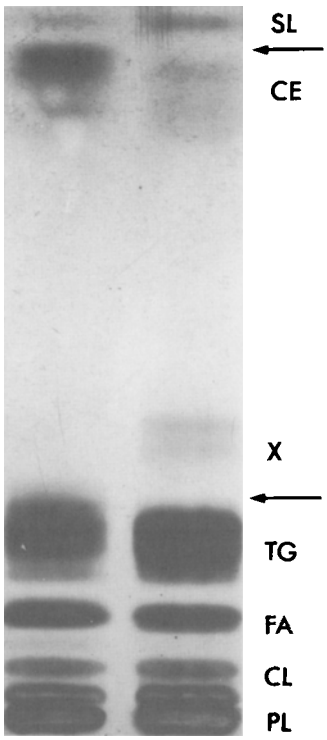

FIG. 1. Incorporation of [2-^{14}C]acetate into fibroblast neutral lipids. Fibroblast cultures were pulsed with [2-^{14}C]acetate as described in the text and the lipids extracted. The neutral (nonpolar) lipids were separated by thin-layer chromatography as described in the Materials and Methods section and the labelled products visualized by autoradiography. The amount of radioactivity applied to the different lanes was not the same. From left to right are a Zellweger then a control cell extract. X refers to an unidentified lipid; SL, to squalene; CE, to cholesteryl esters; TG, to triacylglycerol; FA, to unesterified fatty acids; CL, to cholesterol; and PL, to phospholipids. The arrows mark the position of the more hydrophobic molecular species of triacylglycerols and cholesteryl esters, which are evident in the Zellweger, but not the control, extract.

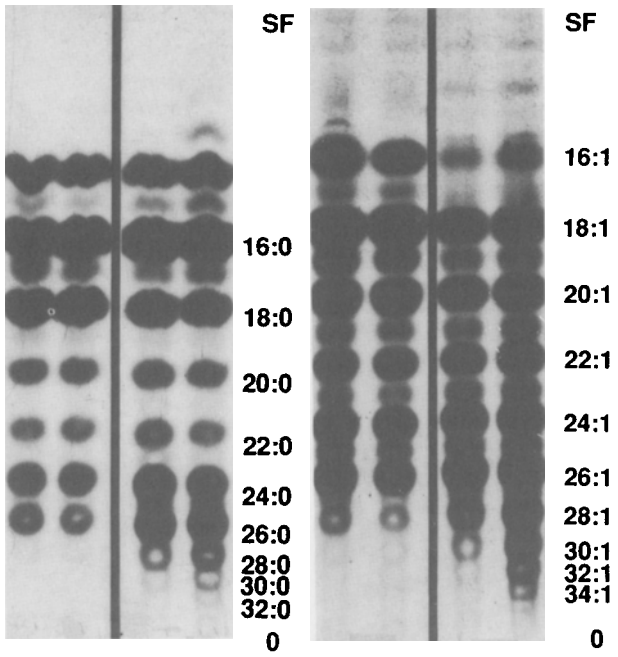

FIG. 2. Reverse phase thin-layer chromatography (TLC) of triacylglycerol-derived fatty acids. Fibroblasts were pulsed with labelled acetate as described in the text. Labelled saturated and monounsaturated fatty acids were isolated from triacylglycerols and chromatographed on reverse phase plates as described in the text. The amount of radioactivity applied to the different lanes was not the same. The figures show the autoradiographs produced after TLC. The figure on the left shows the labelled saturated fatty acids and the one on the right the labelled monounsaturated fatty acids. From the left to right of each figure are the triacylglycerol-derived fatty acids from two control then two Zellweger cell lines. The identity of the fatty acids is shown on the right of each figure, the origin on the TLC plate is indicated by an O and the solvent front by SF.

further characterized. The labelled fatty acids recovered also included a number of longer chain saturated and monounsaturated fatty acids with carbon chain lengths up to 32 (Fig. 2). The fatty acids recovered from Zellweger cells differed significantly from control cells in that they contained increased proportions of saturated and monounsaturated VLCFA with carbon chain lengths of at least up to 34 and a reduced proportion of label in stearic and oleic acids (Table 2, Fig. 2). Similar labelling patterns were observed after a 7-d chase (data not shown).

Labelled fatty acids incorporated into cholesteryl esters in control cells after a three-day incubation with labelled acetate also included a variety of products with palmitic acid predominating (Fig. 3, Table 3). Smaller amounts of saturated VLCFA were also present. Monounsaturated fatty acids were also detected, the main product being oleic acid. The labelling pattern for Zellweger cells differed primarily in that there was a greater proportion of label in monounsaturated VLCFA.

DISCUSSION

Our data demonstrate that human skin fibroblasts in culture actively incorporate the label from [2-^{14}C]acetate into a variety of neutral lipids and phospholipids with most of the label appearing in esterified fatty acids. Most of the label was incorporated into triacylglycerols with significant amounts in a variety of phospholipids and only minor amounts in free and esterified cholesterol. Our analysis of triacylglycerol and cholesteryl ester fatty acids was prompted by chromatographic evidence of the presence of more hydrophobic molecular species (and possibly VLCFA-containing molecular species of both of these lipid classes), in lipid extracts derived from Zellweger's syndrome cells grown in the presence of the label. The accumulation of labelled saturated and monounsaturated VLCFA in these two fractions in Zellweger cells almost certainly reflects the impairment in peroxisomal function reported in these cells (16). Cells from patients with X-linked ALD, a peroxisomal disorder characterized by a block in peroxisomal β-oxidation, have been reported to have increased 18:0 elongase activity (17,18), indicating that the increased microsomal elongation of fatty acids

[a]Fibroblast cultures were pulsed with [2-^{14}C]acetate as described in the text. The data are from two separate experiments (with different Zellweger and control lines for each experiment) and represent the percent distribution of recovered label in individual saturated and monounsaturated fatty acids isolated from cholesteryl esters. Small amounts of label were recovered in odd carbon chain length fatty acids and these are referred to as "other fatty acids." Amounts of less than 0.1% are indicated by a dash.

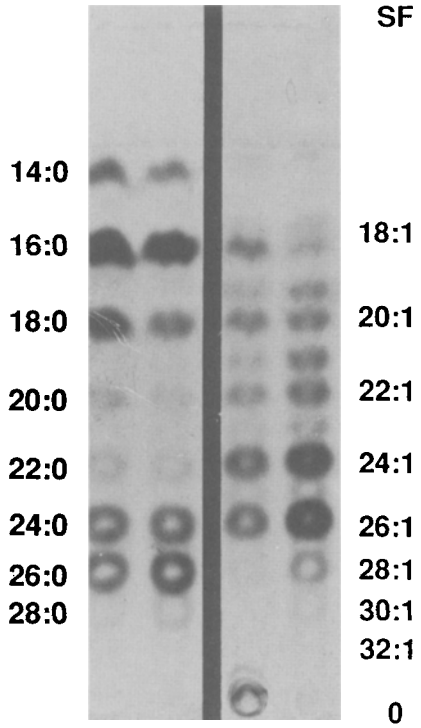

FIG. 3. Reverse phase thin-layer chromatography (TLC) of cholesteryl-ester derived fatty acids. Fibroblasts were pulsed with labelled acetate, and the saturated and monounsaturated fatty acids were isolated from the cholesteryl esters and subjected to reverse phase TLC as described in the text. The amount of radioactivity applied to the different lanes was not the same. The labelled fatty acids were visualized by autoradiography. The left panel shows the saturated fatty acids and the panel on the right the monounsaturated fatty acids. From the left to right of each panel are a control and then a Zellweger sample. The identity of the fatty acids is indicated as well as the origin (O) and solvent front (SF) on the TLC plate.

was in some way related to the peroxisomal defect. More recent studies have shown that there is an increased elongation of exogenous saturated VLCFA in Zellweger's syndrome and X-linked adrenoleukodystrophy fibroblasts (7,8,19). It has been postulated that the increased elongation of exogenous VLCFA may result as a consequence of its reduced breakdown (and therefore increased substrate availability). Our data demonstrate that there is also a greatly increased incorporation of labelled acetate into saturated and monounsaturated VLCFA. However, the identity of the endogenous fatty acids which are elongated to produce the labelled VLCFA and the elongases which catalyze these reactions are unknown.

Although saturated and monounsaturated VLCFA with up to 30 carbon atoms are important components of normal brain (20), VLCFA with more than 24 carbon atoms are only trace components of human skin fibroblasts with 26:0 comprising less than 0.1% while 28 and longer carbon chain length fatty acids are not detectable (21). We were surprised therefore to find some label associated with fatty acids with more than 26 and up to 32 carbon atoms even in normal fibroblasts (Fig. 2). The most likely explanation for the inability to detect endogenous levels of these fatty acids by the usual gas chromatographic procedures is that these longer chain fatty acids must turn over sufficiently rapidly to prevent any accumulation. They are probably synthesized *via* the sequential addition of 2-carbon units derived from acetate but their significance remains uncertain. They may simply represent secondary products of carbon chain elongation of shorter chain fatty acids although it is also possible that they may have some specific cellular function. Whether their function is the same or similar to that of the corresponding n-3 and n-6 polyenoic VLCFA found in brain (22), retina (23) and spermatozoa (24) remains to be determined.

The findings reported here provide further evidence for the importance of peroxisomal function in lipid metabolism. While it is clear that fatty acid oxidation represents a major function, it is perhaps not as well appreciated that the organelle plays a direct role in the synthesis of certain lipid classes, *e.g.*, ether lipids, as well as providing an important source of acetate for fatty acid synthesis occurring in other parts of the cell. The effect of the loss of this source of acetate, as occurs in peroxisomal-deficient cells, is not known, but it seems likely that the loss may be compensated for in other parts of the cell. It is possible that the disturbances in acetate metabolism we have observed are a reflection of these compensatory changes.

Docosahexaenoic Acid Increases Permeability of Lipid Vesicles and Tumor Cells

William Stillwell*, William Ehringer and **Laura J. Jenski**
Department of Biology, Indiana University-Purdue University at Indianapolis, Indianapolis, Indiana 46202-5132

Docosahexaenoic acid (DHA), a long-chain polyunsaturated ω3 fatty acid, is tested to determine its mode of action as an anti-cancer agent. We demonstrate that DHA can increase the permeability of phospholipid vesicles, as monitored by vesicle swelling in isomolar erythritol and leakage of sequestered carboxyfluorescein, and T27A tumor cells, as monitored by swelling in isomolar erythritol and release of sequestered ^{51}Cr. DHA was incorporated into lipid vesicles as either the free fatty acid or as 1-stearoyl-2-docosahexaenoyl-*sn*-glycero-3-phosphocholine. DHA was incorporated into the tumor cells by fusion with vesicles made from the mixed-chain phosphatidylcholines. DHA is demonstrated here to be much more effective in increasing permeability than is oleic acid, the major unsaturated fatty acid normally found in tumor plasma membranes. It is proposed that incorporation of DHA makes tumor plasma membranes substantially more permeable, which may explain, in part, its anti-tumor properties.
Lipids 28, 103-108 (1993).

Long-chain ω3 polyunsaturated fatty acids are believed to play a role in the prevention of a number of serious human afflictions (1) including cancer (2,3), heart disease (4) and arthritis (5). Their deficiency may also be involved in learning disabilities associated with early brain development (6,7) and may even play a role in multiple sclerosis (8). Involvement in such a broad spectrum of abnormal and pathological states implies a basic underlying molecular role for these fatty acids. Two fundamentally different nonexclusive roles have been proposed: ω3 fatty acids may affect membrane structure or they may serve as precursors to potent bioactive substances (*e.g.*, eicosanoid hormones). We have been investigating how one ω3 fatty acid, docosahexaenoic acid (DHA), may alter the physical structure of phospholipid bilayer membranes, producing changes in membrane environment and altering cell response.

Since the number and location of unsaturations are known to determine the conformation of the fatty acid chain, it would not be surprising if incorporation of a polyunsaturated fatty acid, such as DHA (22:6ω3), into membrane phospholipids might severely affect lipid packing and produce major changes in membrane function (9). However, by either monitoring the phase transition temperatures of mixed chain phosphatidylcholine (PC) molecules (10) or by using a variety of fluorescent membrane probes (11), no significant differences in membrane properties between α-linolenic acid (18:3ω3) and DHA could be detected. From these and other reports, it has become evident that while DHA significantly decreases the phase transition temperature and increases membrane fluidity of PC relative to saturated phospholipids, these properties are similar to membranes containing other, less unsaturated fatty acids. To understand why organisms would expend the energy required to produce a fatty acid that is so susceptible to oxidation, the effect of DHA on other membrane properties must be investigated. Here we report the effect of 18:0/22:6 PC on ion permeability of phospholipid vesicles and a living tumor cell (T27A).

EXPERIMENTAL PROCEDURES

Materials. 1,2-Dipalmitoyl-*sn*-glycero-3-phosphocholine (16:0/16:0 PC), 1,2-distearoyl-*sn*-glycero-3-phosphocholine (18:0/18:0 PC), 1-stearoyl-2-oleoyl-*sn*-glycero-3-phosphocholine (18:0/18:1 PC) and egg PC were purchased from Avanti Polar Lipids (Alabaster, AL). Oleic acid and DHA were purchased from Sigma Chemical Co. (St. Louis, MO). 1-Stearoyl-2-docosahexaenoyl-*sn*-glycero-3-phosphocholine (18:0/22:6 PC) was synthesized as described by Ehringer *et al.* (11). DHA anhydride was purchased from Nu-Chek-Prep (Elysian, MN), while carboxyfluorescein was from Molecular Probes (Eugene, OR).

Sample preparation. Lipids used in the preparation of vesicles were dissolved in chloroform and dried under a stream of nitrogen followed by vacuum pumping for a period of 10-12 h. Multilamellar vesicles (MLV) were made by hydrating the lipids in appropriate aqueous buffer and by vortexing the aqueous dispersion above the phase transition temperatures of the lipids for a period of 10 min. Small unilamellar vesicles (SUV) were prepared by sonication of the MLV on ice using a Heat Systems W-380 Cell Disruptor (level 5; Farmingdale, NY). All lipids were stored in the dark under an atmosphere of N_2 at −20°C prior to use. Lipids were occasionally analyzed before and after sonication by thin-layer chromatography (12) and gas chromatography (GC) (13) to determine if degradation of the lipids had occurred.

Erythritol permeability of MLV. The permeability of MLV to erythritol was followed spectrophotometrically with a Perkin-Elmer Lambda 4C ultraviolet (UV)/Visible Spectrophotometer interfaced with a Perkin-Elmer (Norwalk, CT) 7700 Professional Computer run by a PECUV program. MLV were hydrated in 40 mM glucose and 20 mM Na_2HPO_4 (pH 7.0) above the phase transition temperature of the lipid and equilibrated to the swelling temperature (25°C for the mixed chain PC or 47°C for the vesicles composed of 18:0/18:0 PC and free fatty acids). Approximately 200 μL of the lipid solution (10 mM) was rapidly injected into the swelling buffer (40 mM erythritol, 20 mM Na_2HPO_4, pH 7.0), and the swelling of the vesicles due to erythritol influx was monitored by measuring the absorbance at 350 nm. The initial swelling velocity

Abbreviations: CF, carboxyfluorescein; DHA, docosahexaenoic acid; GC, gas chromatography; MLV, multilamellar vesicles; PBS, phosphate buffered saline; PC, phosphatidylcholine; PE, phosphatidylethanolamine; SUV, small unilamellar vesicles; UV, ultraviolet; 16:0/16:0 PC, 1,2-dipalmitoyl-*sn*-glycero-3-phosphocholine; 18:0/18:0 PC, 1,2-distearoyl-*sn*-glycero-3-phosphocholine; 18:0/18:1 PC, 1-stearoyl-2-oleoyl-*sn*-glycero-3-phosphocholine; 18:0/22:6 PC, 1-stearoyl-2-docosahexaenoyl-*sn*-glycero-3-phosphocholine.

of the MLV (d(1/A)/dt%), measured for the first 20–30 s, is known to be directly proportional to erythritol permeability (14). Most permeability measurements were conducted in the liquid crystalline state of the lipids.

Carboxyfluorescein leakage from SUV. Measurements of ionic permeability of 18:0/18:1 PC and 18:0/22:6 PC SUV were followed by monitoring the increase in fluorescence intensity from carboxyfluorescein (CF) leakage (15). MLV were made by hydrating the lipids in 60 mM CF, 30 mM KCl, 10 mM Na_2HPO_4 (pH 7.0) above the phase transition temperature. SUV were made as described above. External nonsequestered CF was removed by passing the suspension down a column (1.5 cm × 30 cm) of Sephadex G-50 equilibrated with 90 mM KCl and 10 mM Na_2HPO_4 (pH 7.0). Aliquots of the vesicles (100 μL) were immediately mixed with 2.5 mL of 90 mM KCl/10 mM Na_2HPO_4, pH 7.0. Vesicles were kept on ice until the experiment was initiated to keep CF sequestered. The efflux of self-quenched CF from the SUV was monitored by an increase in fluorescence with excitation at 490 nm and emission at 520 nm using a Perkin-Elmer MPF-66 Fluorescence Spectrophotometer interfaced with a Perkin-Elmer 7700 Professional Computer. Temperature in the cuvettes was kept at 25°C with a circulating water bath. Maximum fluorescence was determined by addition of 100 μL of 5% Triton X-100, and subsequent CF leakage was calculated as follows:

$$\% \text{ CF leakage} = F - F_i/F_{max} (100) \quad [1]$$

where F is the fluorescence intensity at time t, F_i is the initial fluorescence at time zero, and F_{max} is the maximum fluorescence.

T27A cells. T27A is a non-T, non-B leukemia cell isolated from a BALB/c mouse infected with N-tropic murine leukemia virus (16). This cell line can be maintained both as an ascites tumor and in culture. To passage *in vivo*, each mouse was inoculated with 10^5 T27A cells i.p. 7 d before the ascites were harvested by peritoneal lavage. Ascitic tumor cells were freed of erythrocytes by lysis in 0.155 M NH_4Cl, 10 mM $KHCO_3$, 1 mM disodium ethylenediaminetetraacetic acid (pH 7.4) for 5 min at room temperature and were washed in Hanks' balanced salt solution. Cell lines were also maintained in culture in supplemented RPMI 1640 medium (plus antibiotics, 25 mM *N*-[2-hydroxyethyl] piperazine-*N'*-[2-ethanesulfonic acid] buffer and 2 mM glutamine) with 20% bovine calf serum (HyClone Laboratories, Logan, UT); under these conditions, the T27A line has a generation time of 12 to 15 h and grows to a maximum density of 1–2 × 10^6 cell/mL.

Vesicle fusion with T27A cells. SUV were made in phosphate buffered saline (PBS), pH 7.4, and fused with 1 × 10^7 T27A cells by incubation at room temperature for 10 min, 1 h or 2 h. Unfused vesicles were removed by one wash in cold 10% bovine serum albumin in PBS and three washes in PBS + 5% fetal bovine serum. Cell numbers were determined with a hemacytometer, and viability was checked by trypan blue exclusion.

Swelling of T27A cells. Cells fused with the vesicles were immediately subjected to isotonic swelling in erythritol. Briefly 3 × 10^6 cells of the fused T27A cells incubated at the swelling temperature (37°C) were injected into 3.0 mL of 175 mM sucrose/75 mM erythritol/20 mM Na_2HPO_4 (pH 7.4) at 37°C. The influx of erythritol and subsequent swelling of the cells was monitored at 420 nm with a Perkin-Elmer Lambda 4C UV/Visible Spectrophotometer. The results presented are the average of 20 experiments.

GC. Cells and vesicles to be analyzed by GC were placed in a separatory funnel, and the lipids were extracted three times with 80 mL of $CHCl_3/CH_3OH$ (2:1, vol/vol) along with 10 mL of a 0.5 N NaCl solution. The lipid extracts were combined and rotovaporated to a small volume. Saponification of the lipid material was accomplished by addition of 0.5 N NaOH in methanol and refluxing the mixture for 1 h. Fatty acids were esterified by addition of BF_3/methanol and refluxing again for an additional 30 min. Methyl esters were extracted three times by addition of 50 mL of hexane. The extracts were combined and rotovaporated to a small volume. A 2.0 μL sample of the methyl esters was then analyzed with an SRI Gas Chromatograph equipped with a flame ionization detector interfaced to a Micro Express 386 Computer (Santa Ana, CA). The 6′ × 1/8″ column was packed with 10% SP-2330 on 100/120 Chromosorb WAW. The initial oven temperature was 190°C while final oven temperature was 225°C after 25 min. Peaks were identified by direct comparison with the retention times of methyl ester standards (Nu-Chek-Prep, Elysian, MN).

^{51}Cr release. T27A cells (5 × 10^6) were incubated with 150 μCi of sodium [^{51}Cr]chromate (>500 mCi/mg; New England Nuclear, Boston, MA) in RPMI plus 5–10% serum and then washed three times in PBS + 5% serum. The cells were diluted to 5 × 10^4 cells/mL with RPMI + 5% serum, and 100 μL of the cell suspension was incubated in triplicate with 100 μL of medium (for spontaneous release) or detergent (for maximum release) for 4 h at 37°C in a humidified 7.5% CO_2 atmosphere.

RESULTS

Previous reports have indicated that DHA esterified to the *sn*-2 position of PC can increase bilayer permeability of nonelectrolytes (11,17). In Figure 1 we confirm these reports for the mixed chain 18:0/22:6 PC. The PC containing DHA is about 2.4 times more permeable to erythritol than is the corresponding PC containing oleic acid (18:0/18:1 PC). The disaturated PC (18:0/18:0 PC) which exists in the gel state at 25°C is almost impermeable. When DHA as the free fatty acid was incorporated at 20 membrane mol% into 16:0/16:0 PC bilayers, permeability to erythritol was dramatically increased (Fig. 2). Again oleic acid enhanced permeability but to a much lesser extent than did DHA (DHA/oleic acid permeability ratio = 3.0).

The effect of DHA on permeability to the anionic CF is shown in Figure 3. The lipid vesicles are composed of either egg PC (control) or of 80 mol% egg PC to which is added 20 mol% 18:0/18:1 PC or 18:0/22:6 PC. CF leakage is greater for the DHA-containing PC than it is for the oleic acid-containing PC. After 30 min the ratio of DHA/oleic acid permeability is about 2.0.

To assess the effect of DHA on the permeability of living T27A tumor cells, the tumor cells were modified by fusion with lipid vesicles composed of 18:0/22:6 PC and, for comparison, vesicles composed of 18:0/18:1 PC and the nonfusogenic control 16:0/16:0 PC. As shown in Figure 4 (insert), incorporation of DHA increases as a function of fusion time for 2 h at which time it comprises about 5% of the total membrane fatty acids. The cultured T27A cells

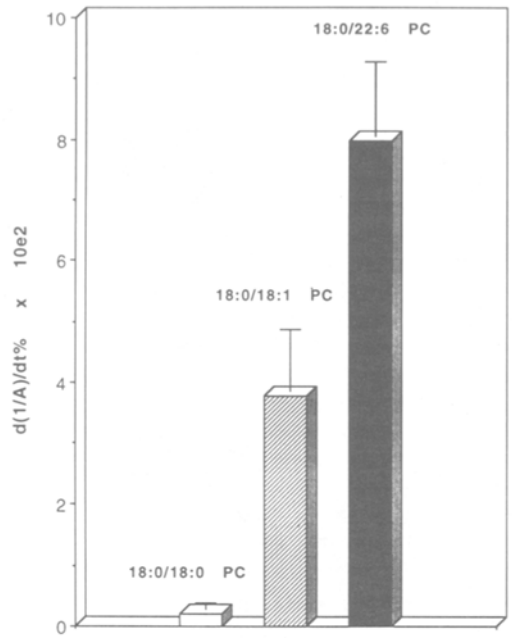

FIG. 1. Erythritol permeability for multilamellar vesicles (MLV) composed of 18:0/18:0 phosphatidylcholine (PC), 18:0/18:1 PC and 18:0/22:6 PC (25°C). MLV stock solutions (10 mM) were made in 40 mM glucose, 20 mM Na_2HPO_4, pH 7.0 and rapidly injected into 2.0 mL of the swelling buffer (40 mM erythritol, 20 mM Na_2HPO_4, pH 7.0). Lipid concentration was 1 mM, and vesicle swelling was followed at 25°C by absorbance at 350 nm. At this temperature 18:0/18:0 PC is in the gel state where its permeability is extremely low. Results are the mean of 20 experiments and are significant to the 0.001 level as determined by analysis of variance.

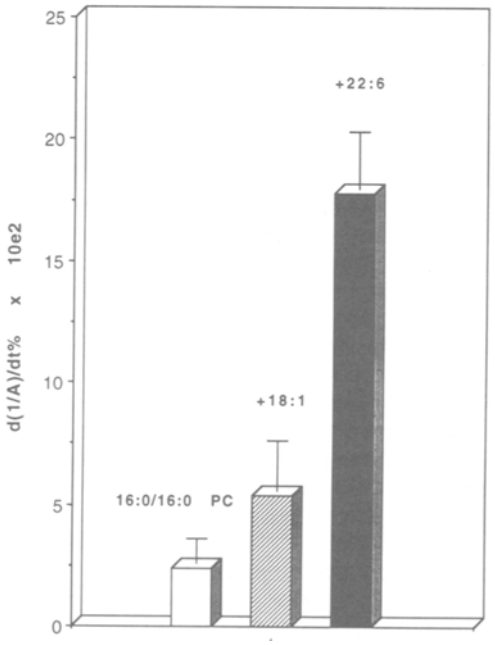

FIG. 2. Effect of oleic acid and docosahexaenoic acid as free acids on erythritol permeability of 18:0/18:0 phosphatidylcholine (PC) multilamellar vesicles (47°C). Experimental procedure is as outlined for Figure 1. At 47°C 18:0/18:0 PC is in the liquid crystal state. The fatty acids are incorporated at 20 membrane mol%. Results are the mean of 20 experiments and are significant to the 0.001 level as determined by analysis of variance.

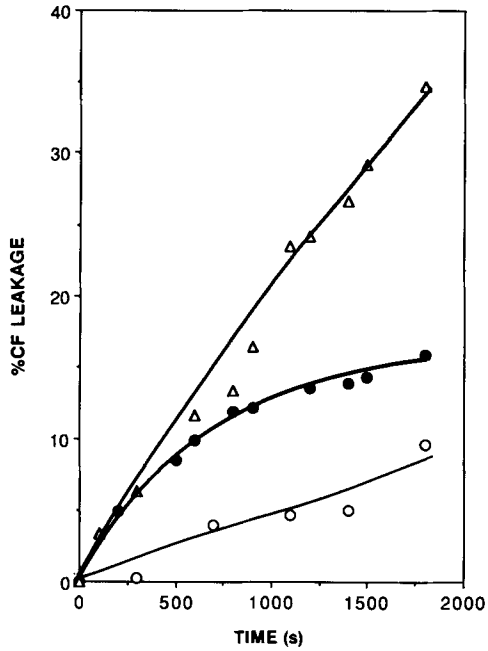

FIG. 3. Release of sequestered carboxyfluorescein (CF) from egg phosphatidylcholine (PC) small unilamellar vesicles (SUV) (30°C). Stock solutions of SUV composed of 100 mol% egg PC (open circles); 80 mol% egg PC, 20 mol% 18:0, 18:1 PC (closed circles); and 80 mol% egg PC, 20 mol% 18:0, 22:6 PC (open triangles) were made in 60 mM CF, 30 mM KCl, 10 mM Na_2HPO_4, pH 7.0. After nonsequestered CF was removed on a Sephadex G-50 column, aliquots of CF-loaded SUV were rapidly injected into 2.5 mL of 90 mM KCl/10 mM Na_2HPO_4, pH 7.0. Lipid concentration was between 200 to 400 μM, and the fluorescent intensity monitored at 520 nm (excitation 490 nm). Results are the average of three determinations and are significant to the 0.001 level by analysis of variance.

had essentially no DHA before fusion. As DHA accumulated in the tumor membranes, the cells became more permeable to erythritol (Fig. 4). When DHA represented 5% of the total fatty acids, T27A permeability was about triple that of the unaltered cells. By the first reported time period (10 min after fusion was initiated), it was clear that 18:0/22:6 PC fused much better with the T27A cells than did 18:0/18:1 PC (Fig. 5, insert). But even when incorporated at equivalent levels, DHA enhanced permeability to a much greater extent than did oleic acid (Fig. 5). For the permeability results presented in Figure 5, the T27A cells were fused with 18:0/18:1 PC vesicles at 2.0 mg/mL while incubation with the 18:0/22:6 PC vesicles was at 0.5 mg/mL. The insert of Figure 5 shows that fusion of 0.5 mg/mL of 18:0/22:6 PC produces an equivalent incorporation of lipid into T27A cells as does 2.0 mg/mL of 18:0/18:1 PC. The effect of 18:0/18:1 PC and 18:0/22:6 PC on membrane permeability was confirmed by monitoring the leakage of sequestered ^{51}Cr from T27A cells (Fig. 6). The DHA-containing cells were about 1.9 times more permeable to ^{51}Cr than the 16:0/16:0 PC (unaltered) controls and 1.5 times more permeable than the oleic acid-altered cells.

DISCUSSION

The fatty acids of phospholipids comprise the hydrophobic core of membranes and are known to affect a wide

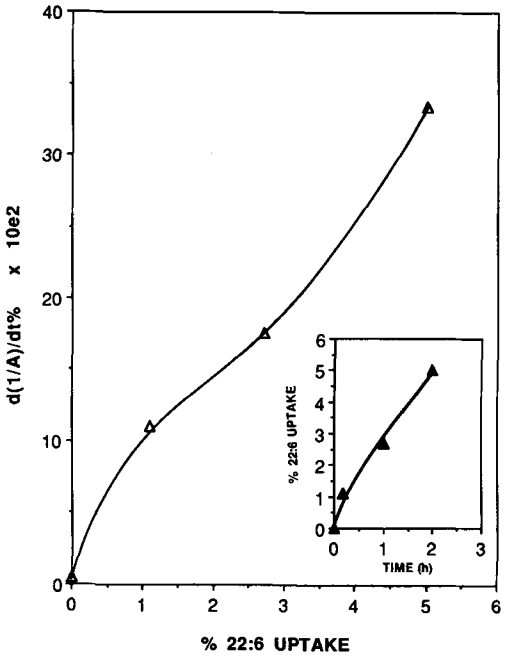

FIG. 4. Permeability of T27A cells fused with 0.5 mg/mL 18:0/22:6 phosphatidylcholine (PC) to erythritol, expressed as the rate of cell swelling (d(1/A)/dt%) as a function of docosahexaenoic acid (DHA) incorporation. 3×10^6 cells were injected into the swelling buffer (175 mM sucrose, 75 mM erythritol, 20 mM Na_2HPO_4, pH 7.4, 37°C). Erythritol-induced swelling was followed by absorbance at 420 nm. Insert: Uptake of DHA into T27A cells as a function of fusion time with 18:0/22:6 PC (0.5 mg/mL). Sample correlation coefficient for the swelling velocity *vs.* % 22:6 uptake is r = 0.988, while the insert is r = 0.991.

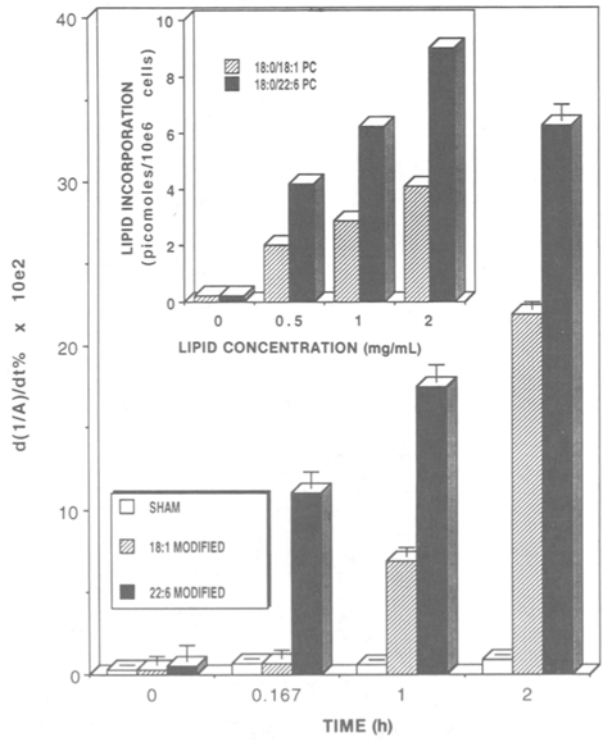

FIG. 5. Permeability of erythritol of T27A cells fused with 2.0 mg/mL 16:0/16:0 phosphatidylcholine (PC) (SHAM), 2.0 mg/mL 18:0/18:1 PC (18:1 MODIFIED) or 0.5 mg/mL 18:0/22:6 PC, 2.0 mg (22:6 MODIFIED) expressed as the rate of cell swelling (d(1/A)/dt%) *vs.* fusion time. Insert: Lipid incorporation as 18:0/18:1 PC vesicles or 18:0/22:6 PC vesicles are fused with T27A tumor cells. Permeability measurements are the average of 10 runs with $P < 0.001$ at all times tested.

variety of membrane properties. The extent of fatty acid unsaturation in particular has been shown to alter membrane order and fluidity, thickness, domain size and stability, permeability, lipid phase and, through interaction with membrane proteins, even biochemical activity (9,18–22). Of particular interest to us is the long-chain ω3 fatty acid DHA (DHA, 22:6), which is one of the most unsaturated lipids in biological systems and is mainly found at specialized locations where it probably provides specific, but as yet undefined, functions (9). Lower levels of DHA are found in most other membranes where its concentration may be further enhanced through diet (23–25). It appears that in membranes containing extremely high levels of DHA naturally, such as rod outer segment (26), sperm (27) and the gray matter of brain (28), DHA is found primarily in phosphatidylserine and phosphatidylethanolamine (PE) (1). In contrast, dietary supplementation produces increased levels of DHA in other membranes and mainly as a component of PC and PE.

The double bond effects, however, are not additive, and these changes may not necessarily be reflected in large alterations in general membrane "fluidity." Initially it was assumed that DHA-containing phospholipids would exhibit significantly decreased phase transition temperatures compared to the less unsaturated phospholipid homologs and so would impart to membranes a substantial increase in fluidity. Surprisingly this was not found to be true. Deese *et al.* (10) reported that 16:0/22:6 PC actually had a higher T_m (−3°C) than did 16:0/16:1 PC (−10°C). Recently we observed that "fluidity" of DHA-containing PC membranes, as monitored by fluorescence polarization of 1,6-diphenyl-1,3,5-hexatriene and a series of anthroloxy stearic acid probes, is increased relative to PC membranes composed of saturated acyl chains (11). However, bilayers composed of PC containing stearic acid (18:0) in the *sn*-1 position and either oleic (18:1), α-linolenic acid (18:3) or DHA (22:6) in the *sn*-2 position have very similar "fluidities." This is in agreement with several studies that showed that accumulation of DHA in biological membranes does not necessarily affect membrane fluidity (21). In contrast, Salem *et al.* (29) reported that DHA makes phosphatidylserine bilayers more "fluid" although other explanations for the results have been offered (9). The effect of DHA on membranes thus may be related to the polar head group of the phospholipid with which the fatty acid is associated. The results reported here involve membrane supplementation with DHA-containing PC and demonstrate that despite exhibiting fluidities typical of most unsaturated membranes, the DHA-enriched membranes have greatly enhanced permeabilities.

Here we have chosen 18:0/18:1 PC as a fusable control lipid to compare with 18:0/22:6 PC. Our analysis of T27A tumor cell plasma membranes (Ehringer, W., and Stillwell, W., unpublished results) show 11.7% oleic acid and only 0.4% linolenic acid. We reason, therefore, that addition of 18:0/18:1 PC will not severely alter the normal

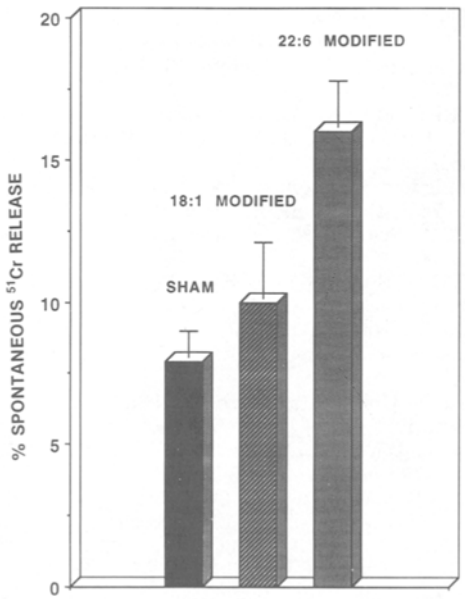

FIG. 6. Release of sequestered ^{51}Cr from lipid modified T27A cells. The cells (5×10^6) were incubated with 150 μCi of sodium (^{51}Cr) chromate and fused with either 18:0/22:6 phosphatidylcholine (PC) (22:6 MODIFIED), 18:0/18:1 PC (18:1 MODIFIED) or no lipid (SHAM). The percentage of spontaneous release was determined by addition of detergent. Results are the mean values of three experiments. Statistically significant differences were tested by analysis of variance for A) 22:6/18:1 modified cells and B) 18:1/sham: A) P, 0.0001; B) $P = 0.1119$.

composition of T27A plasma membranes but will indicate if the process of membrane fusion causes membrane damage resulting in enhanced permeability. Although the small amount of tumor cells used in the experiments presented here precluded us from performing a direct lipid analysis on the T27A plasma membranes, we nevertheless are convinced that the fused 18:0/22:6 PC resides at least in part with the cell surface (plasma) membrane. We have shown that treatment of murine T-cell leukemia cells with 18:0/22:6 PC lipid vesicles results in a dose-dependent change in epitope expression on a plasma membrane protein (30). The most reasonable explanation of these data is that 18:0/22:6 PC fused with the plasma membrane, altered membrane structure and affected the expression of membrane proteins. The monoclonal antibodies used to detect epitope expression monitor events only at the plasma membrane. Additionally, the increased expression of one epitope concurrently with decreased expression of another epitope on the same protein argues against an effect of 18:0/22:6 PC on protein synthesis.

Acyl chain composition of phospholipids has for years been known to greatly affect membrane permeability. In general, a direct relationship was found between the level of unsaturation and the magnitude of membrane permeability (17,31). If the studies on fatty acids with 1, 2 or 3 double bonds can be extrapolated to 6 double bonds, one would predict that DHA might produce extremely permeable membranes. In fact the rod outer segment membrane, which is known to be highly enriched in DHA (26), is also very permeable to Na^+ (32). However, only a few reports on the direct effect of DHA on membrane permeability have actually appeared. Chow and Jondal (33) showed that at high levels (50 μM or more in the bathing solution) free DHA increased cell permeability to ^{51}Cr. Since under normal physiological conditions free fatty acids are found only in trace amounts in membranes, this report does not address the role of DHA as it would normally be found in biological membranes. Burns and Spector (34-36) reported that dietary DHA make L1210 murine ascites lymphoblastic leukemia cells more permeable to the anti-cancer drugs mitoxantrone and doxorubicin. These drugs are thought to cross cell membranes by diffusion through the lipid phase (34). The biochemical species containing DHA was not reported for these experiments. In the experiments reported here, we use two very different techniques, cell swelling in isomolar erythritol and spontaneous release of sequestered ^{51}Cr to directly confirm that DHA esterified to the *sn*-2 position of PC enhances permeability of the tumor cell T27A.

DHA has also been shown to increase permeability of well-defined phospholipid vesicles. Demel *et al.* (17) reported that PC lipid vesicle permeability to glucose, erythritol and glycerol increased in proportion to the area/molecule of the membrane phospholipids. DHA in mixed chain PC produced a very permeable bilayer membrane in their system. Ehringer *et al.* (11) confirmed these finding showing that 18:0/22:6 PC-containing vesicles were far more permeable to erythritol than were 18:0/18:3 PC vesicles. The experiments reported here agree with the previous reports that DHA incorporated into PC bilayers increases permeability.

For several reasons we have chosen to add DHA as a mixed chain PC to tumor cells. Dietary DHA is known to readily accumulate in the *sn*-2 position of several phospholipids and mostly PC (23). The *sn*-1 chain of most PC is either palmitic acid (16:0) or stearic acid (18:0) (10). Therefore by fusing the tumor cell plasma membranes with 18:0/22:6 PC, we are enriching the cells with DHA acylated to PC, as it would be found in most biological membranes. Although there is a large body of evidence that DHA can have significant anti-tumor properties, there is little known about the possible mechanism of action. The experiments presented here indicate that the permeability of T27A cells can be substantially enhanced by accumulation of as little as 5% DHA into their membranes. It is also known that within a few weeks mice on dietary fish oils can increase the membrane levels of DHA to levels comparable to our permeability studies (34). Dietary experiments however can have serious interpretational drawbacks as the ratios of the various phospholipid types and other membrane components such as sterols may change as a function of the diet. Fusion experiments like those reported here alter the concentration of only a single membrane species and so data interpretation is more direct.

The increase in membrane permeability affected by DHA-containing PC reported here may be related to the well-documented anti-cancer properties of dietary fish oils. Kitada *et al.* (37) have reported that lipid mobilization in tumors is directed toward membrane synthesis and not energy production. We would therefore expect that DHA may accumulate faster in tumors than in the surrounding host tissues. The ensuing membrane perturbations caused by DHA could render the tumor more susceptible to anticancer drugs or to destruction by the immune system.

Hypertension in Rats Does Not Potentiate Hypercholesterolemia and Aortic Cholesterol Deposition Induced by a Hypercholesterolemic Diet

Hiromi Mori, Kyohko Ishiguro and **Harumi Okuyama***
Department of Biological Chemistry, Faculty of Pharmaceutical Sciences, Nagoya City University, Mizuhoku, Nagoya 467, Japan

The effect of a hypercholesterolemic diet (HCD) on hyperlipemia and atherogenesis was investigated using normotensive Wistar/Kyoto rats (WKY), spontaneously hypertensive rats (SHR) and stroke-prone SHR (SHRSP), with systolic blood pressures increasing in that order. Feeding an HCD diet containing cholesterol, cholate and suet induced hypercholesterolemia in all the strains examined as compared with a normal diet. The plasma cholesterol levels were significantly higher in WKY than in SHR and SHRSP fed the HCD diet. The HCD diet also induced hepatic fat deposition, particularly deposition of cholesteryl esters, a slight increase in aortic cholesterol deposition, and elevation of both monoenoic/saturated fatty acid ratios and linoleate/arachidonate ratios in tissue lipids. The changes induced in the three strains by the HCD diet were not positively correlated with blood pressures. The HCD diet affected hepatic acyl-CoA:cholesterol acyltransferase and plasma lecithin:cholesterol acyltransferase activities differently in WKY and SHR which, in addition to the induction of Δ9 desaturase, may partly account for the difference in the diet-induced changes in the fatty acid compositions of plasma cholesteryl esters. The results indicate that hypertension *per se* does not stimulate the development of hypercholesterolemia and arterial cholesterol deposition induced by an HCD diet, suggesting that other factors are involved.
***Lipids 28,* 109–113 (1993).**

Hypertension and hypercholesterolemia are generally recognized as risk factors for atherosclerosis. Accumulation of cholesteryl esters, particularly cholesteryl oleate, is a characteristic feature of atherosclerotic lesions (1–5). Monocyte-derived macrophages appear to play a key role in the atherogenic process (6), and most of the cellular cholesterol is assumed to be derived from plasma lipoproteins. In rabbits, hyperlipemia and atherosclerosis are easily induced by atherogenic diets (7–12), but normal rats rarely develop atherosclerosis or arterial fat deposition even after long-term feeding of atherogenic diets.

In contrast, spontaneously hypertensive rats (SHR) and stroke-prone spontaneously hypertensive rats (SHRSP) have been reported to rapidly develop hyperlipemia and ring-like arterial fat deposition when placed on an atherogenic diet (13–16). Therefore, it is widely accepted that hypertension is a risk factor which stimulates cholesterol infiltration into the arterial wall. However, our previous studies showed that plasma cholesterol levels were higher in normotensive Wistar/Kyoto rats (WKY) than in SHR fed a high cholesterol/cholate diet, and that arterial fat depositions were not detectable in either strain of rat (17). These discrepancies may have resulted from differences in the diets used. In the present study, we fed three strains (WKY, SHR, SHRSP) derived from Wistar rats the atherogenic diet reported to induce hypercholesterolemia and aortic fat deposition (13–16), and compared plasma, hepatic and aortic lipids. The systolic blood pressure decreased in the order SHRSP, SHR and WKY (18,19). Acyl-CoA:cholesterol acyltransferase (ACAT) and lecithin:cholesterol acyltransferase (LCAT) activities also were measured to gain some insight into the mechanism which lead to the production of different molecular species of cholesteryl esters in SHR and WKY.

MATERIALS AND METHODS

[1,2-^{3}H]Cholesterol and [9,10-^{3}H]oleic acid were purchased from New England Nuclear (Boston, MA). Radiolabeled and nonlabeled oleoyl-CoA were prepared by a modification of Seubert's procedure (20) as described elsewhere (21). Male SHR and WKY rats were obtained from Charles River of Japan (Kanagawa, Japan). SHRSP were kindly provided by Prof. Kozo Okamoto, Kinki University School of Medicine (Osaka, Japan). At 8 wk of age, these rats were fed *ad libitum* for up to 8 wk either a conventional diet (CE-2; Nippon Clea Co. Ltd., Tokyo, Japan) or a CE-2 diet supplemented with 5% cholesterol, 2% cholate, 20% suet and 1% mixed vitamins (hypercholesterolemic diet, HCD), which was prepared as described by Yamori *et al.* (14). The CE-2 diet contained (by weight): 24.9% protein, 4.5% fat, 7.5% minerals, 4.1% fiber and 50.2% non-nitrogenous compounds. The major fatty acid constituents of the CE-2 diet were linoleate (50.6%), oleate (21.9%), palmitate (14.9%) and α-linolenate (3.9%). Major fatty acids of the suet were oleate (46.5%), palmitate (23.2%), stearate (17.5%), palmitoleate (4.1%), linoleate (4.1%) and α-linolenate (0.3%).

Tail systolic blood pressure was measured at around 10:00 a.m. by the plethysmographic tail method with an apparatus produced by Natsume Co. (Tokyo, Japan). The rats were sacrificed after fasting for 17 h. Blood was sampled from the abdominal vein, and was centrifuged to separate plasma. Livers and aortas were excised. The attached fat tissues were removed from abdominal and thoracic aortas under a microscope. Samples were kept frozen at −80°C. Lipids were extracted with chloroform/methanol according to the method of Bligh and Dyer (22), and then chromatographically separated on silica gel plates (Merck 60, Merck, Darmstadt, Germany) which were prewashed with the developing solvent. Petroleum hydrocarbon (b.p. 35~60°C)/diethyl ether/acetic acid (80:30:1, by vol) was used as developing solvent for

Abbreviations: ACAT, acyl-CoA:cholesterol acyltransferase; Cho, cholesterol; ChoE, cholesteryl esters; FFA, free fatty acid; HCD, hypercholesterolemic diet; LCAT, lecithin: cholesterol acyltransferase; ND, normal diet; PL, phospholipid; SHR, spontaneously hypertensive rats; SHRSP, stroke-prone spontaneously hypertensive rats; TG, triacylglycerols; WKY, Wistar/Kyoto normotensive control rats.

separating neutral lipids from phospholipids. Fatty acids of the separated fractions were analyzed as methyl esters by gas-liquid chromatography using heptadecanoic acid as internal standard. Cholesterol was quantified by gas-liquid chromatography as trimethylsilyl ether using 5α-cholestane as internal standard (23).

Rats were fasted for 16 h before preparing subcellular fractions according to the method described by Eibl *et al.* (24). Protein was determined by the method of Lowry *et al.* (25). ACAT activity was determined essentially as described by Lichtenstein and Brecher (26). The assay mixture contained 2 mM dithiothreitol, 0.1 M sodium phosphate (pH 7.4), 60 μg of microsomal protein, 16.5 μM [^{3}H]oleoyl-CoA (100,000 cpm/nmol) and 16.5 μM bovine serum albumin, all in a total volume of 0.2 mL. The assay mixture was preincubated for 5 min without microsomal protein. Incubations were started by adding enzyme and were performed with vigorous shaking at 37°C for 2 min. ACAT activity was determined by following the production of cholesteryl [^{3}H]oleate. LCAT was assayed by the method of Albers *et al.* (27). Cholesterol and cholesteryl esters were separated by silica gel thin-layer chromatography using petroleum ether/diethyl ether/acetic acid (80:30:1, by vol) as solvent. Student's *t*-test was used for statistical analysis.

RESULTS

Body weights, liver weights and blood pressures are summarized in Table 1. Feeding the HCD for 8 wk induced slight weight losses, which were the largest in the SHR strain. The test diet did not affect the blood pressure of any of the strains. Liver weights were about twofold higher in the HCD groups than in the normal diet (ND) groups. In the HCD groups, the faded liver color was typical of that of fatty liver. Aortas were stained by oil red O, but no fat depositions were noted in all the strains fed the hypercholesterolemic diet (data not shown).

The plasma lipid levels are compared in Figure 1. In the ND groups, the plasma lipid levels, and particularly the phospholipid and cholesteryl ester levels, were the highest in WKY followed by SHR, and then by the SHRSP strain.

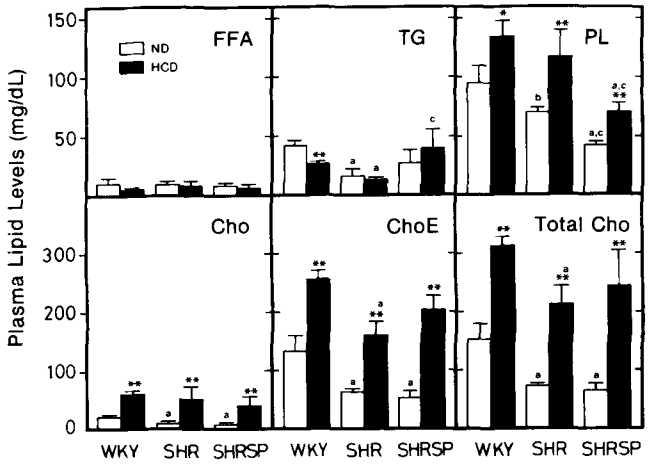

FIG. 1. Effect of a hypercholesterolemic diet on plasma lipid levels. Rats were fed the test diets for 8 wk from 8 wk of age. After fasting overnight, rats were sacrificed, and lipids were extracted from plasma with chloroform/methanol. Individual lipid classes were separated by a silica gel thin-layer chromatography and quantitated as described in the text. Cholesterol ester (ChoE), cholesterol (Cho), triacylglycerol (TG), free fatty acid (FFA) and phospholipid (PL) were determined. Normal diet group (ND, □) and hypercholesterolemic diet group (HCD, ■) in WKY, SHR and SHRSP were determined. Averages of determinations for three rats in each group (±SD) are presented. Statistical significance is shown as ** ($P < 0.01$) or * ($P < 0.05$) for the comparison of ND and hypercholesterolemic diet groups, a ($P < 0.01$) or b ($P < 0.05$) for the comparison of Wistar/Kyoto normotensive control rats (WKY) and other strains, and c ($P < 0.01$) or d ($P < 0.05$) for the comparison of spontaneously hypertensive rats (SHR) and stroke-prone SHR (SHRSP).

Plasma cholesterol, cholesteryl ester and phospholipid levels were elevated >3-fold, >1.9-fold and >1.4-fold, respectively, in the HCD groups as compared with the ND groups. The levels of total cholesterol in the HCD groups were 2.1-fold higher in WKY, 2.9-fold higher in SHR and 3.9-fold higher in SHRSP than in the ND groups. The difference between the ND groups and the HCD groups was the largest in SHRSP, but the total plasma cholesterol levels were the highest in WKY in both dietary groups.

TABLE 1

Effect of a Hypercholesterolemic Diet on Body Weight, Liver Weight, Blood Pressure, ACAT Activity and LCAT Activity[a]

Rat strain	Diet	Body weight (g)	Liver weight (g)	Blood pressure (mmHg)	ACAT (nmol/min/mg protein)	LCAT (nmol/h/mL)
WKY	ND	307 ± 9	10.5 ± 0.5	108 ± 2	0.16 ± 0.03	17.6 ± 0.4
	HCD	293 ± 9	19.3 ± 1.5^b	105 ± 10	0.84 ± 0.09^b	10.7 ± 1.0^b
SHR	ND	316 ± 4	12.0 ± 1.9	184 ± 6^c	0.27 ± 0.08	14.8 ± 1.0^c
	HCD	263 ± 10^{b,d}	20.5 ± 0.7^b	164 ± 16^c	0.84 ± 0.12^b	16.8 ± 2.2^c
SHRSP	ND	256 ± 10^{c,e}	10.6 ± 2.2	209 ± 12^{c,f}	n.d.	n.d.
	HCD	228 ± 11^{g,c,f}	20.1 ± 2.7^b	201 ± 17^{c,f}	n.d.	n.d.

[a]Male rats at 8 wk of age were fed a normal diet (ND) or a hypercholesterolemic diet (HCD) for 8 wk. Hepatic microsomal acyl-CoA:cholesterol acyltransferase (ACAT) activity was determined using [9,10-^{3}H]oleoyl-CoA, and plasma lecithin:cholesterol acyltransferase (LCAT) activity was assayed using [1,2-^{3}H]cholesterol. Averages of determinations (±SD) for 3 rats are presented. Statistical significance in Student's *t*-test is shown as superscript b ($P < 0.01$) or superscript g ($P < 0.05$) for the comparison of ND and HCD groups, superscript c ($P < 0.01$) or superscript d ($P < 0.05$) for the comparison of Wistar/Kyoto normotensive control rats (WKY) and other strains, and superscript e ($P < 0.01$) or superscript f ($P < 0.05$) for the comparison of spontaneously hypertensive rats (SHR) and stroke-prone spontaneously hypertensive rats (SHRSP); n.d., not determined.

Thus, the blood pressure and the total plasma cholesterol level were not positively correlated between the three strains of rats.

The amount of total cholesterol in whole plasma and whole liver were comparable in the ND groups (Fig. 2). Feeding HCD markedly increased total cholesterol in livers of all three strains; the increases were 120-fold in WKY, 150-fold in SHR and 160-fold in SHRSP. In spite of these tremendous increases in liver cholesterol, the total plasma cholesterol levels changed relatively little suggesting that secretion of hepatic cholesterol is suppressed in the HCD groups. The hepatic FFA and TG levels increased about twofold, but the PL levels were relatively unchanged in the HCD groups of the three strains (data not shown).

In the preparation of aortic tissues for lipid analysis, great care was taken to remove the surrounding fat tissues. Then, the levels of aortic phospholipid (PL), triacylglycerol (TG), free fatty acid (FFA), cholesterol and cholesteryl ester were determined. In the ND groups, the basal lipid levels were similar among the three strains. Feeding the HCD increased the aorta cholesterol levels slightly (Fig. 3); the level tended to be higher in WKY than in SHR and SHRSP. Again, the aortic cholesterol levels showed no positive correlations with the blood pressures in the three strains of rats.

Feeding the HCD induced a striking change in the fatty acid compositions of plasma and hepatic cholesteryl esters as noted previously (17). Fatty acid compositions of hepatic cholesteryl esters from WKY and SHR strains are shown in Figure 4A. The proportions of monoenoic fatty acids, especially octadecenoate, increased while those of saturated fatty acids, linoleate and arachidonate concomitantly decreased in both strains fed HCD. We previously reported that most of the octadecenoate was the Δ9 isomer, oleate (17). Similar changes induced by HCD

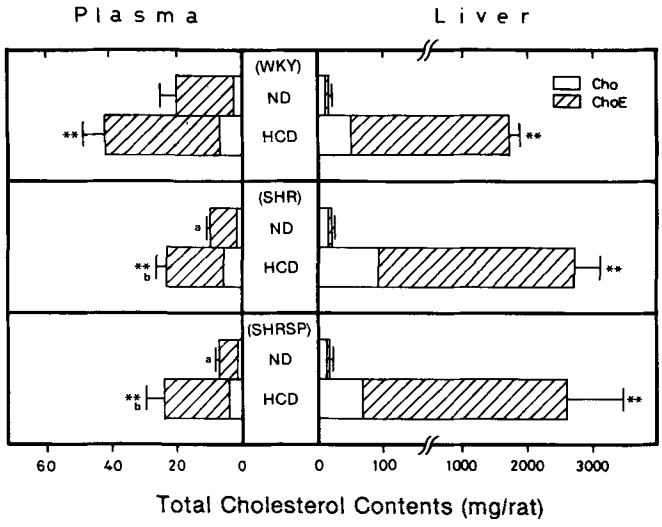

FIG. 2. Effect of a hypercholesterolemic diet on plasma and hepatic cholesterol contents. Cholesterol (Cho) and cholesteryl ester (ChoE) in plasma and liver were quantitated as described in the text. Plasma volume was assumed to be 4% of the body weight. Averages of determinations (±SD) for three rats are presented. Statistical significance is shown as ** ($P < 0.01$) or * ($P < 0.05$) for the comparison of WKY and other strains, and c ($P < 0.01$) or d ($P < 0.05$) for the comparison of SHR and SHRSP. Abbreviations as in Figure 1.

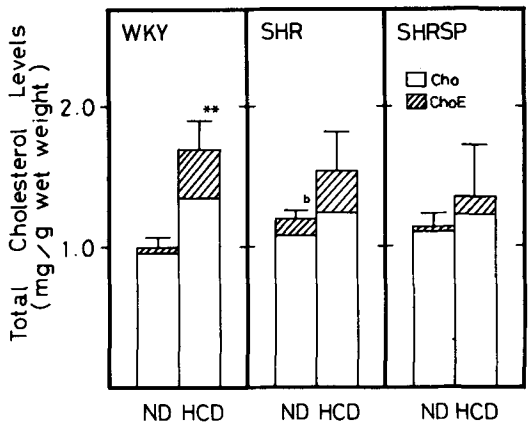

FIG. 3. Effect of a hypercholesterolemic diet on aortic cholesterol levels. Abdominal and thoracic aortas were freed of surrounding fat tissues under a microscope. Lipids were extracted and quantitated as described in the legend to Figure 1. Averages of determinations (±SD) for three rats are presented. Statistical significance is shown as ** ($P < 0.01$) for the comparison of ND and HCD groups, and b ($P < 0.05$) for the comparison of WKY and other strains. Abbreviations as in Figure 1.

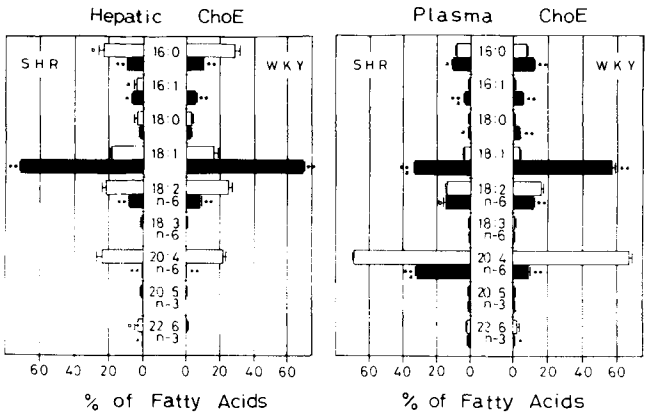

FIG. 4. Effect of a hypercholesterolemic diet on the fatty acid pattern of hepatic and plasma cholesteryl esters. Only the major fatty acids are presented. Fatty acids are designated by carbon chain length:number of double bond, and the n-6 or n-3 represents the position of the first double bond numbered from the methyl terminus. □, Normal diet group (ND); ■, hypercholesterolemic diet group (HCD). Averages of determinations (±SD) for three rats are presented. Statistical significance is shown as ** ($P < 0.01$) or * ($P < 0.05$) for the comparison of ND and HCD groups, and a ($P < 0.01$) or b ($P < 0.05$) for the comparison of WKY and SHR. Abbreviations as in Figure 1.

were also observed in other lipid classes, PL, TG and FFA. As a whole, the fatty acid patterns of hepatic cholesteryl esters were similar among the three strains of the ND groups, and HCD-induced changes also were similar among the three groups. These changes are possibly due to increased Δ9 desaturase activities (17,28) and to the impairment of elongation-desaturation activities in the formation of arachidonate from linoleate (17).

The major fatty acid compositions of plasma cholesteryl esters from WKY and SHR strains are shown in Figure 4B. Plasma cholesteryl esters contained relatively more arachidonate than did hepatic cholesteryl esters possibly

as a consequence of the LCAT reaction. The HCD feeding induced changes in the proportions of fatty acids qualitatively similar to those seen in hepatic cholesteryl esters; an increase in monoenoic fatty acids and a decrease in arachidonate were observed in both strains. Quantitatively, however, these changes were significantly less in SHR than in WKY. The fatty acid compositions of plasma lipids of SHRSP were similar to those of WKY (data not shown).

The molecular species of cholesteryl esters are thought to be produced mainly through the actions of LCAT in plasma and of ACAT in liver and intestine. Plasma LCAT and hepatic ACAT are considered to be particularly important in determining the molecular species of plasma cholesteryl esters in fasted rats. In the ND groups, the ACAT and LCAT activities were roughly similar in WKY and SHR. HCD-feeding increased the ACAT activities fivefold in WKY, and threefold in SHR. In contrast, different responses of LCAT activities to HCD-feeding were observed; LCAT activity significantly decreased to 60% in WKY, and increased in SHR (Table 1). These differences in the responses of ACAT and LCAT to the dietary changes appear to be consistent with the differences in the fatty acid patterns of plasma cholesteryl esters in WKY and SHR, because arachidonate is considered to be esterified preferentially *via* LCAT (32,36-39). The HCD-induced changes in the linoleate/arachidonate ratios of plasma and hepatic PL and cholesteryl esters (ChoE) were compared in the three strains (Fig. 5).

The increases in the linoleate/arachidonate ratios induced by HCD-feeding were seen in all strains, particularly in plasma and hepatic cholesteryl ester fractions, although the increase in the linoleate/arachidonate ratio of plasma cholesteryl esters was significantly less in SHR than in the other two strains.

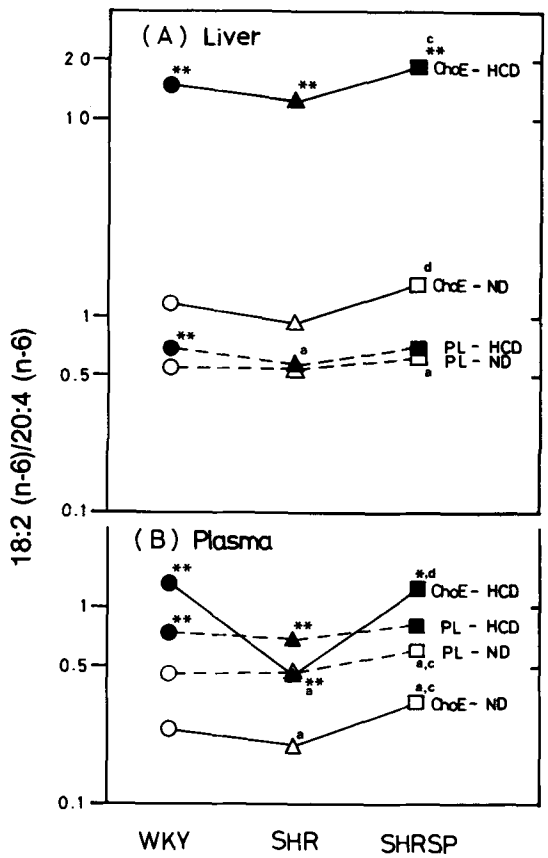

FIG. 5. Effect of a hypercholesterolemic diet on linoleate (18:2)/arachidonate (20:4) ratios of cholesterol esters and phospholipid in plasma and liver. Open symbols and closed symbols indicate the normal diet group (ND) and the hypercholesterolemic diet group (HCD), respectively. Averages of determinations (±SD) for three rats are presented. Statistical significance is shown as ** ($P < 0.01$) or * ($P < 0.05$) for the comparison of ND and HCD groups, a ($P < 0.01$) or b ($P < 0.05$) for the comparison of WKY and other strains, and c ($P < 0.01$) or d ($P < 0.05$) for the comparison of SHR and SHRSP. Abbreviations as in Figure 1.

DISCUSSION

SHR derived from the Wistar strain (WKY) are widely used as a model of hypertension. The SHRSP derived from SHR (29) have the highest blood pressure among rat strains and die mostly of cerebral bleeding (30). Some groups have reported that SHR develop hypercholesterolemia more easily than conventional strains when fed atherogenic diets (13,31); moreover, ring-like fat depositions were noted in SHR and SHRSP strains, but not in the normotensive WKY strain (15,16). However, the results obtained in the present experiments, as well as those of our previous study (17), are inconsistent with the results reported by others. Different methods used in different laboratories for the assay of cholesterol may be responsible for some of the inconsistent results. The plasma cholesterol and aortic cholesterol levels were the highest in WKY among the three strains fed the HCD. In contrast, the hepatic cholesterol contents were higher in SHR and SHRSP than in WKY. Therefore, there may be differences among WKY, SHR and SHRSP: (i) in the synthesis of lipoproteins and secretion from liver; (ii) in the synthesis of bile acid; and/or (iii) in the re-uptake of lipoproteins into liver. Although the enzymatic basis for inducing these differences in cholesterol metabolism remains to be elucidated, we conclude that hypertension does not stimulate hypercholesterolemia or fat deposition in the aorta induced by atherogenic diets.

The fatty acid compositions of hepatic and plasma cholesteryl esters changed substantially when rats were fed HCD. The increases in the proportions of oleate and in the linoleate/arachidonate ratios are interpreted to be due to elevated Δ9 desaturase activity to form oleate (32,33) and decreased elongation-desaturation activity (33). Although these changes in hepatic lipids were common to all the strains examined, the changes in plasma cholesteryl esters were significantly less in SHR than in WKY and SHRSP (Figs. 4 and 5). ACAT is known to be relatively specific for monoenoic, saturated and dienoic acyl-CoA (34-36), while LCAT is specific for arachidonate and linoleate, which are enriched in the 2-position of phosphatidylcholine (32,36-39). The relatively lower linoleate/arachidonate ratio of plasma cholesteryl esters observed in SHR, but not in WKY or SHRSP (Fig. 5), may be attributed to the difference in the relative activities of ACAT and LCAT, because the proportions of arachidonate in plasma phosphatidylcholine were very small among the three strains (Fig. 5, and data not shown). In fact, the LCAT/ACAT activity ratio was significantly lower in WKY than in SHR fed HCD diets, which could account

for part of the differences observed in the linoleate/arachidonate ratios of plasma cholesteryl esters in WKY and SHR.

Although SHRSP and SHR were derived from WKY, and the blood pressure decreases in the order of SHRSP > SHR > WKY, neither plasma lipid levels nor HCD-induced hyperlipidemia, nor aortic lipid deposition, nor the linoleate/arachidonate ratio of plasma cholesteryl esters paralleled the blood pressures measured in the three strains. Our data suggest that in rats hypertension *per se* does not promote the development of hyperlipemia or arterial fat deposition induced by the atherogenic diet.

The response of normal and transformed rat hepatocytes to oxidative stress was investigated. Isolated normal rat hepatocytes and differentiated hepatoma cells (the Fao cell line was derived from the Reuber H 35 rat hepatoma) in suspension were incubated with the ADP/Fe^{3+} chelate for 30 min at 37°C. Membrane lipid oxidation was assessed by measuring (i) free malondialdehyde (MDA) production by a high-performance liquid chromatography (HPLC) procedure, (ii) membrane fatty acid disappearance as judged by capillary gas chromatography, and (iii) α-tocopherol oxidation as determined by HPLC and electrochemical detection. The addition of iron led to increased MDA production in normal as well as in transformed cells, and to simultaneous consumption of polyunsaturated fatty acids (PUFA) and α-tocopherol. In addition, in Fao cells more α-tocopherol was consumed during lipid peroxidation while less PUFA was oxidized. Lipid peroxidation was lower in tumoral hepatocytes than in normal cells. This could be due to a difference in membrane lipid composition because of a lower PUFA content and a higher α-tocopherol level in Fao cells. During oxidation, Fao cells produced 1.5 to 2 times less MDA than normal cells, while in the tumoral cells the amount of oxidized PUFA having 3 or more double bonds was 7 to 8 times lower. Therefore, measuring MDA alone as an index of lipid peroxidation did not allow for proper comparison of the membrane lipid oxidizability of transformed cells *vs.* the membrane lipid oxidizability of normal cells.
***Lipids 28,* 115-119 (1993).**

Several disorders, including idiopathic hemochromatosis, can lead to excess iron deposition in tissues, especially in the liver (1,2). Excess hepatic iron causes cellular injury with resultant fibrosis and cirrhosis (3). In addition, chronic iron overloading causes an increased risk of hepatocellular carcinoma (4). The pathophysiological mechanisms of hepatocellular injury due to iron overloading are unknown. Free radical iron-induced oxidative stress resulting in membrane lipid peroxidation is a potential mechanism of cellular injury during an iron overload (5-8). *In vitro* studies have shown that iron can enter both normal and transformed hepatocytes (9). Generally, tumoral cells are highly resistant to lipid peroxidation, and their proliferation index correlates directly with their resistance to lipid peroxidation inducers (10). One of the possible reasons for the low level of lipid peroxidation is a decrease in unsaturated fatty acids, the main targets of lipid oxidation and an increase in lipid antioxidant content, particularly with regard to vitamin E (11,12). Lipid peroxidation is mainly estimated by measuring malondialdehyde (MDA), a by-product of polyunsaturated fatty acid (PUFA) peroxidation (13,14).

The aim of this study was to compare the response of normal rat hepatocytes and of a Fao cell line to oxidative stress induced by iron. Fao cells are derived from the Reuber H 35 rat hepatoma and are characterized by a slow rate of growth (15). They express most of the liver-specific functions. Lipid peroxidation was estimated by free MDA production. Furthermore, the disappearance of individual membrane fatty acids was followed as was simultaneous α-tocopherol oxidation.

MATERIALS AND METHODS

Reagents. Fatty acid methyl ester (FAME) standards and 1,1,3,3-tetramethoxypropane were purchased from the Sigma Chemical Company (St. Louis, MO). α-Tocopherol, tocol, sodium dodecyl sulfate (SDS) and butylated hydroxytoluene (BHT) were supplied by the Merck Chemical Company (Darmstadt, Germany) and adenosine diphosphate (ADP) by Boehringer Mannheim (Mannheim, Germany). Ferric sulfate, disodium hydrogen phosphate, chloroform, ethanol, acetic acid and methanol were obtained from Carlo Erba (Milan, Italy). *n*-Heptane [high-performance liquid chromatography (HPLC) grade] was provided by Rathburn Chemicals (Walkerburn, Scotland).

Isolation of hepatocytes. Normal rat hepatocytes were isolated from two-month-old Sprague-Dawley male adult rats by cannulating the portal vein and perfusing the liver with a collagenase solution, as previously described (16). The cells were collected in Leibovitz medium containing 1 mg bovine serum albumin and 5 μg bovine insulin per mL. The cell suspension was filtered through gauze and allowed to sediment for 20 min in order to eliminate cell debris, blood and sinusoïdal cells, and the cells were washed three times by centrifugation at 150 × *g*, and counted. The hepatocytes were then suspended for 15 min in a mixture composed of Eagle's minimum essential medium (75%) and medium 199 (25%) with Hank's salts; the mixture contained (per mL) kanamycin (50 μg), streptomycin (50 μg), penicillin (7.5 IU), bovine insulin (5 μg), bovine serum albumin (1 mg) and $NaHCO_3$ (2.2 mg). Viability was at least 90% as determined by trypan blue exclusion.

Fao cells were plated in 75-cm^2 Nunclon® flasks. The cells were grown at 37°C to confluency using the same medium as above but supplemented with fetal calf serum (10%).

Just before the experiment, the culture medium was discarded, and Fao cells were collected from the culture and suspended in phosphate buffer (0.01 M, pH 7.45). Similarly, in normal hepatocyte suspensions, the culture medium was replaced by the same phosphate buffer.

Abbreviations: ADP, adenosine diphosphate; BHT, butylated hydroxytoluene; FA, fatty acid; FAME, fatty acid methyl ester; GC, gas chromatography; HPLC, high-performance liquid chromatography; MDA, malondialdehyde; PUFA, polyunsaturated fatty acid; SDS, sodium dodecyl sulfate.

For experimental purposes, each cell suspension (30×10^6 hepatocytes or Fao cells) was maintained in the presence of an ADP/Fe^{3+} system in order to obtain final 20 mM ADP and 85 μM or 170 μM iron concentrations. Each sample with ADP/Fe^{3+} was compared to control suspensions without supplementation. Samples and controls were then incubated at 37°C for 30 min.

Estimation of free MDA. Lipid peroxidation was estimated by an increase in free MDA which was measured by HPLC according to an previously described method (17). The HPLC system (LDC, Milton Roy, Riviera Beach, FL) was equipped with a Spherogel-TSK G 1000 PW size exclusion column measuring 7.5 mm i.d. × 30 cm (Cluzeau, France). The eluant was composed of 0.1 M disodium phosphate buffer, pH 8, and was run at a flow rate of 1 mL/min at ambient temperature. Absorbance was monitored at 267 nm, and sensitivity was set at 0.05 AUFS. Samples were injected using an automatic injector (LDC Promis, Milton Roy) set at a volume of 250 μL. The data were recorded and integrated with a CI 3000 LDC integrator.

The free MDA standard solution was prepared by hydrolysis of 5 μL of 1,1,3,3-tetramethoxypropane in 5 mL of 0.1 N HCl for 5 min in a boiling water-bath. A one-to-thousand dilution of the solution was prepared in 0.01 M phosphate buffer, pH 7.45 corresponding to a 6 μM MDA solution. The MDA concentration in samples was calculated based on a standard free-MDA curve.

After the hepatocytes had been incubated with iron, the cells were lysed at 0°C using an ultrasonic homogenizer. An aliquot was filtered through a 500-dalton membrane ultrafilter (Millipore, Saint Quentin, France) in a 10-mL (Amicon, Lexington, MA) cell pressurized to four bars with nitrogen gas. Two-hundred fifty μL of the ultrafiltrate obtained was injected into the HPLC system. An aliquot of the lysed solution was used to determine protein content according to Bradford (18) using the Bio-Rad (Paris, France) protein assay reagents and bovine serum albumin as standard. A Cobasbio (Roche, Neuilly Seine, France) automatic analyzer was utilized for this purpose.

Lipid analysis. An aliquot of the lysed hepatocyte suspension was used for the extraction of lipids by the SDS method (19). Lipids were extracted with a mixture of heptane, ethanol and an aqueous SDS solution with a concentration of 100 μM (2:2:1, by vol). The upper layer (heptane) containing the lipids was used for fatty acid (FA) and α-tocopherol measurements.

Fatty acids were analyzed by capillary gas chromatography (GC) of the methyl esters. The transesterification reaction was carried out according to Christie (20). An aliquot of the lipid extract, which contained heptadecanoic acid as internal standard, was evaporated to dryness and redissolved in anhydrous methanolic 0.5 M sodium methoxide. The mixture was reflux-heated to 50°C for 20 min. FAME were then extracted and redissolved in ethanol.

FAME were analyzed on a Packard 439 GC instrument (Palo Alto, CA) equipped with a flame ionization detector using the on-column injection mode. The capillary column was a Carbowax 20 M (25 m × 0.25 mm i.d.) (Cluzeau, France). The carrier gas was hydrogen at a flow rate of 2 mL/min. The temperature was programmed from 60° to 214°C at 6°C/min for 20 min, 0°C/min for 10 min, 4°C/min for 10 min, 0°C/min for 5 min, then 4°C/min to 214°C. Samples of 0.3 μL of the ethanolic FAME solution were directly injected into the chromatograph. The FAME concentration in samples was calculated using standard curves obtained on standard solutions.

α-Tocopherol was measured by HPLC using electrochemical detection. An aliquot of the lipid extract, containing tocol (500 ng/mL) as an internal standard, was evaporated to dryness, redissolved in the mobile phase and injected into the HPLC instrument (LDC, Milton Roy) equipped with a 250 mm × 4.3 mm ODS C_{18} (5 μm) column (Sopares, France). The mobile phase consisted of methanol and a 6% aqueous potassium nitrate solution (2 g/L). The flow rate was 0.8 mL/min; α-tocopherol was detected with an electrochemical detector (ESA, Coulochem model 5100 A, Sopares, France) set at +0.4 V.

Statistics. All experiments were performed in triplicate. Results are expressed as mean ± SEM, and statistical differences were analyzed by Student's *t*-test.

RESULTS

Examination of fatty acids before and after lipid peroxidation. Before lipid peroxidation was induced, the membrane FA composition of normal hepatocytes and Fao cells were measured (Table 1). The FA profiles of normal rat hepatocytes were similar to those reported previously (21,22). A high percentage (14%) of 22:6 was found in our study, but variable values are reported in the literature (23). Fao cells showed a pronounced decrease (64%) in FA content, and a parallel decrease (70%) in PUFA level. The FA distribution of Fao cells was different from that of normal hepatocytes. The percentages of saturated FA, 16:0 and 18:0, were decreased, whereas 18:1 showed a 4-fold increase. A change in PUFA distribution was also noted, except for 20:4 the percentage of which remained unchanged. The 20:2 level was greatly increased, whereas 18:2 was detected only in trace amount, and the 22:6 level was reduced by half.

After 30 min of incubation in the presence of iron, a significant PUFA loss was noted in normal hepatocytes and a lesser loss in Fao cells (Table 2). PUFA oxidation was 7 to 8 times lower in Fao cells as compared to normal hepatocytes (Table 3). The extent of PUFA oxidation increased with the degree of FA unsaturation and the iron concentration (Table 2). No appreciable oxidation was detected in saturated and unsaturated FA in both normal and tumoral hepatocytes.

Free MDA as an index of membrane lipid peroxidation. In the absence of iron, both normal and tumoral cells (Fao) exhibited a basal level of free MDA (Table 3). Induction of lipid peroxidation by chelated iron brought about an increase of free MDA, depending on the iron concentration (Table 3). Fao cells produced 1.5 to 2 times less free MDA than did normal cells under the same conditions.

The ratio between the production of MDA and the consumption of PUFA (having three or more double bonds) was 11 and 44% for normal and tumoral cells, respectively, independent of the iron concentration. The ratio was therefore not linked to the degree of lipid peroxidation (Table 3). In normal cells, values of 8–12% in regard to MDA/PUFA ratio are common (14,23). This ratio was surprisingly high (44%) in Fao cells despite a low level of n-3 PUFA which are considered the major source of MDA production in the course of lipid peroxidation (24).

Measurement of α-tocopherol before and after lipid peroxidation. Fao cells contained a higher level of α-tocopherol

[a]Normal and transformed hepatocytes were incubated for 10 min at 37°C in the presence of ADP/Fe^{3+} (for details see Materials and Methods). Numbers for fatty acid (FA) (%) disappearance indicate the oxidized FA proportion as percentage relative to each FA.

[b]The results are given as the means of three independent experiments ± SEM; $P < 0.05$; PUFA, polyunsaturated fatty acids.

[c]Abbreviations used: N, normal hepatocytes; T, transformed hepatocytes (Fao cells); tr, trace amount; N.D., not detectable.

than did normal hepatocytes. Most workers have observed an increase in α-tocopherol content in tumor cells (25,26). The α-tocopherol/PUFA ratio was 10 times higher in Fao cells (1/300) than in normal hepatocytes (1/3000). PUFA peroxidation was accompanied by a rapid decrease in α-tocopherol content, especially in Fao cells which showed a disappearance of α-tocopherol of about 50% after 30 min of lipid peroxidation induced by both concentrations of iron (Table 2). In normal cells, α-tocopherol oxidation was lower than in Fao cells and increased with iron concentrations (Table 2).

DISCUSSION

The susceptibility to iron-induced lipid peroxidation in normal and transformed (Fao cell line) rat hepatocytes was investigated. Isolated hepatocytes in suspension proved to be a useful model for the study of cellular response to oxidative stress because the model allowed us to look into various events which influence lipid peroxidation, especially in regard to cell defense. *In vitro* studies of iron-induced lipid peroxidation have employed various iron complexes (27,28). In the present work the ADP/Fe^{3+} system was used because it is one of the iron complexes that most readily enters cells (29,30).

It is clear from the results reported in this study that there are marked differences in response to iron-induced lipid peroxidation between normal and transformed hepatocytes. Two indices of lipid peroxidation were used: oxidation of PUFA and free MDA production, the latter of which has been reported to be a more accurate index of lipid peroxidation than is the thiobarbituric acid reactive substance test (31). Yet, iron chelates catalyze the breakdown of PUFA hydroperoxides having three or more double bonds (14) and can also catalyze the degradation of amino acids, sugars and DNA to yield MDA (32). This latter oxidative degradation is not inhibited by antioxidants (33). Morel *et al.* (17) recently reported that, in the presence of iron, free MDA was completely reduced by the addition of α-tocopherol, a lipid antioxidant. Therefore, it is likely that under experimental conditions, free MDA resulted mainly from PUFA hydroperoxide breakdown.

Both lipid peroxidation indices were lowered in the Fao cells which exhibited greater resistance to lipid peroxidation compared to normal hepatocytes. Using the MDA index, lipid peroxidation could be estimated as 1.5 to 2 times lower in Fao cells. Using the other index, MDA-yielding oxidized PUFA, lipid peroxidation was 7 to 8 times lower in tumor cells. The MDA/oxidized PUFA ratio was abnormally high (44%) in Fao cells as compared to normal hepatocytes (11%). This difference may be explained by an increase in free MDA levels which could be due to: (i) changes in the breakdown pathways of lipid peroxides in Fao cells; the MDA production pathway may theoretically be increased compared to other aldehydic pathways; (ii) bound MDA to cellular materials, such as proteins (34), may possibly be decreased and the free MDA fraction measured in this study would increase; (iii) MDA metabolism may be reduced due to a decrease or a lack of activity in aldehyde dehydrogenases in tumoral cells (35). Thus, MDA as a marker of lipid peroxidation may lead to an overestimation of tumoral cell oxidizability.

Resistance to oxidative stress is a common feature of many tumoral cells (36–38). Among possible mechanisms

TABLE 3

Free MDA Production and PUFA[a] Disappearance in Normal and Tumoral Cells During Iron-Induced Lipid Peroxidation

Iron (μM)	Free MDA[b] (nmol/mg protein)		PUFA[a] disappearance[b] (nmol/mg protein)		MDA:PUFA[a] disappearance (%)

underlying this resistance, changes in lipid composition may be responsible; *i.e.*, a decrease in total lipid containing PUFA (39,40) and an increase in both cholesterol (41) and α-tocopherol (42), both of which stabilize lipid membranes. In addition, a rise in the level of cytosolic antioxidants and a reduction of cytochrome P450 activity (43) in the lipid peroxidation initiation phase were observed.

Fao cells showed similar changes: a decrease of about 65% in total FA content, including saturated and polyunsaturated fatty acids. An alteration in PUFA distribution was also observed. Also a net increase in the percentage of 18:1 was noted. Balasubramanian *et al.* (44,45) reported that oleic acid can assume the properties of an antioxidant. Moreover, no linoleic acid was detected in Fao cells, which could be related to the maintenance of Fao cells for a long time in culture. Pepin *et al.* (46) noted that normal hepatocytes, whenever cultured in a medium depleted in essential fatty acids, showed a rapid decline in linoleic acid content. Das *et al.* (47) also reported that tumor cells incorporated less linoleic acid than did normal cells in the cultured state.

Increased α-tocopherol levels are considered to be characteristics of tumor cells which may contribute to the resistance to oxidative stress. Yet some workers (48) have suggested that increased α-tocopherol may be associated with cell division. A high content of α-tocopherol, a lipid antioxidant, was also observed in Fao cells.

The oxidative stress triggered by iron caused a higher α-tocopherol consumption in Fao cells than in normal hepatocytes. The relationship between unsaturated fatty acids and α-tocopherol in membranes is complex (49). It is generally believed that α-tocopherol inhibits lipid peroxidation in biological membranes by scavenging the chain-propagating peroxyl radicals (50). Experiments have suggested that one mole of α-tocopherol completely protected *ca.* 220 moles of PUFA from autoxidation within microsomal fractions isolated from rat heart and lung (49). In our experiments, the α-tocopherol/PUFA ratio was 1/300 and 1/3000 in Fao cells and in normal hepatocytes, respectively. The high value for Fao cells could explain why PUFA oxidation was 7 to 8 times lower than in normal cells.

Reduction of Fatty Acid Hydroperoxides by Human Parotid Saliva

Junji Terao[a,*], Akihiko Nagao[a], Hiroko Yuki[b] and Yoshio Itoh[b]

[a]National Food Research Institute, Ministry of Agriculture, Forestry and Fisheries, Tsukuba, Ibaraki 305 and [b]Lotte Central Laboratory Co., Ltd., Urawa, Saitama 336, Japan

Arachidonic acid hydroperoxide (15-hydroperoxyeicosatetraenoic acid; 15-HPETE) was introduced into human parotid saliva and incubated at 37°C. Straight phase high-performance liquid chromatography analysis of the reaction mixture showed that 15-HPETE was detoxified to its reduced form, 15-hydroxyeicosatetraenoic acid, in the presence of glutathione. Therefore, it is concluded that human parotid saliva possesses fatty acid hydroperoxide-reducing ability. However, its effectiveness was found to be lower than that of blood plasma.

Lipids 28, 121–124 (1993).

Unsaturated fatty acids in foods are susceptible to enzymatic and nonenzymatic lipid peroxidation, resulting in a wide variety of oxidation products (1). Dietary intake of fatty acid hydroperoxides, primary products of lipid peroxidation, is of much concern because they are a potential source of free radicals leading to oxidative damage in the digestive tract and other tissues (2,3). Several studies on rodents have shown that dietary lipid hydroperoxides are largely metabolized before reaching the lymphatic circulation (4,5). It has also been implied that the small intestine possesses glutathione peroxidase activity to detoxify fatty acid hydroperoxides (6–8). However, little is known about the fate of dietary fatty acid hydroperoxides in the digestive tract.

Saliva is one of the digestive juices excreted from the digestive tract. Considerable amounts of saliva are excreted from the parotid, submandibular, sublingual and the large number of minor salivary glands (600 mL/day/person) (9). In an earlier paper (10), we reported that human parotid saliva has antioxidant effects on lipid peroxidation of liposomal phospholipids and fish meat. This prompted us to investigate whether human parotid saliva possesses the ability to detoxify dietary lipid hydroperoxides. We examined the behavior of arachidonic acid hydroperoxides in this extracellular fluid with or without the addition of a reducing agent. The results demonstrate that human parotid saliva possesses glutathione (GSH)-dependent fatty acid hydroperoxide-reducing ability.

MATERIALS AND METHODS

Materials. Arachidonic acid (99% grade) was obtained from Sigma Chemical Co. (St. Louis, MO). Reduced GSH and ascorbic acid were from Wako Pure Chemicals (Osaka, Japan). Oxidized glutathione (GSSG) and cysteine were provided by Nakarai Chemicals (Kyoto, Japan). α-Tocopherol was kindly supplied by Eisai Co. (Tokyo, Japan). 15-Hydroperoxyeicosa-5,8,11,13-tetraenoic acid (15-HPETE) was prepared by enzymatic oxidation of arachidonic acid using soybean lipoxygenase (Sigma Chemical Co.; Type I) (11). 15-Hydroxyeicosa-5,8,11,13-tetraenoic acid (15-HETE) was obtained by reducing 15-HPETE with $NaBH_4$ (12). The solvents for chromatography were of high-performance liquid chromatography (HPLC) grade and obtained from Nakarai Chemicals. Distilled water was further purified by the Mili-Q reagent system (Millipore Corp., Bedford, MA). The other reagents were of analytical grade and used without purification.

Preparation of human saliva and blood plasma. Parotid saliva was collected from healthy adult volunteers, the salivary flow being stimulated with citric acid troches before collecting directly with a Lashery's device (13). The collected saliva was immediately used for the experiments. Blood plasma was obtained from the same volunteers (12).

Incubation of 15-HPETE in saliva. A methanol solution of 15-HPETE (10–40 nmol in 10 μL) was added to 0.2 mL of the fluid and shaken in a water bath at 37°C. After incubation, total lipids were extracted from the fluid using chloroform and methanol (12).

HPLC analysis. HPLC was run on a YMC-packed A312 SIL column (6 × 150 mm, Yamamura Kagaku, Kyoto, Japan) with a Tosoh liquid chromatograph CCPD. A Shimadzu SPD-2A variable wavelength ultraviolet detector was used to monitor the effluent at 235 nm (0.01 AUFS). The lipid extracts were evaporated *in vacuo* and then redissolved in the eluting solvent. A Reodyne 7135 loop injector (20 μL) was used to inject the sample solution onto the column. The column was then developed with a mixture of hexane/isopropanol/acetic acid (97.3:2.5:0.2, by vol) at the flow rate of 1.0 mL/min.

Other procedures. To separate the high molecular weight (HMW) fraction (molecular weight > 5000) and the low molecular weight (LMW) fraction (molecular weight < 5000) of the parotid saliva, a Sephadex G25 column (PD-10, Pharmacia Co., Uppsala, Sweden) was equilibrated with 0.01 M Tris-HCl buffer (pH 7.4). Freshly collected saliva (10 mL) was applied to the column and eluted with the same buffer. The first eluate (1.5 mL) and second eluate (1.5 mL) were collected as an HMW fraction and an LMW fraction, respectively. Simulated gastric juice was prepared by diluting a solution of conc. HCl (0.82 mL, 12M) and 0.411 g NaCl in double distilled water to a total volume of 100 mL (pH 1.22) (14).

RESULTS

Figure 1 shows the results of straight phase HPLC of 15-HPETE, 15-HETE and the lipid extracts after incubation of 15-HPETE for 30 min with the saliva or normal saline. 15-HPETE and its reduced derivative, 15-HETE, were eluted separately in the chromatogram. The efficiency of extraction of 15-HPETE and 15-HETE from normal saline was reported to be nearly 100% (12). This analytical technique was therefore used to evaluate the conversion of 15-HPETE to 15-HETE in parotid saliva and in normal saline. 15-HETE appeared in the chromatograms of the extract after incubation of 15-HPETE in the saliva. The addition of GSH (200 μM) to the saliva significantly increased the level of 15-HETE, indicating

Abbreviations: GSH, glutathione; GSSG, oxidized form of glutathione; HMW, high molecular weight; 15-HPETE, 15-hydroperoxyeicosa-5,8,11,13-tetraenoic acid; 15-HETE, 15-hydroxyeicosa-5,8,11,13-tetraenoic acid; HPLC, high-performance liquid chromatography; LMW, low molecular weight.

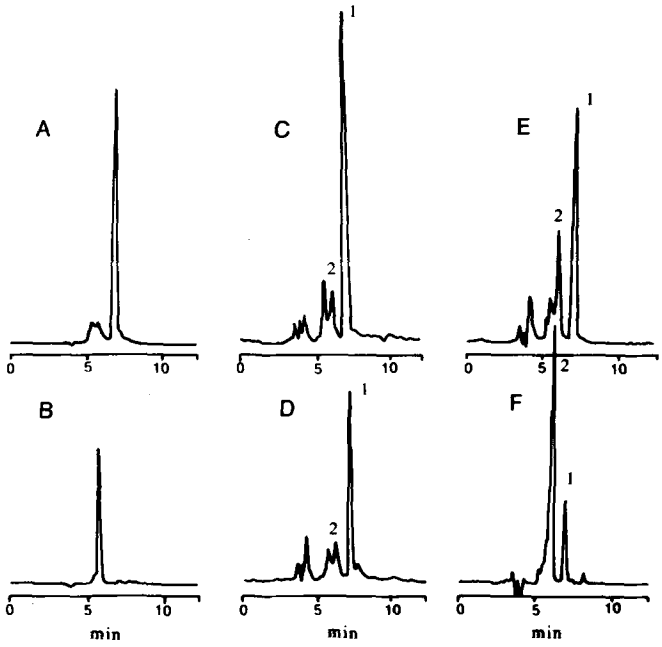

FIG. 1. High-performance liquid chromatography of 15-hydroperoxyeicosa-5,8,11,13-tetraenoic acid (15-HPETE) after incubation with normal saline or human parotid saliva. 15-HPETE (40 nmol) was added to normal saline or parotid saliva (0.2 mL) and incubated with or without glutathione (GSH) (200 μM) at 37°C for 30 min; (A), 15-HPETE standard; (B), 15-hydroxyeicosa-5,8,11,13-tetraenoic acid (15-HETE) standard; (C), the extract from normal saline without GSH; (D), the extract from normal saline with GSH; (E), the extract from parotid saliva without GSH; (F), the extract from parotid saliva with GSH. Peak 1 and peak 2 were identified as 15-HPETE and 15-HETE, respectively.

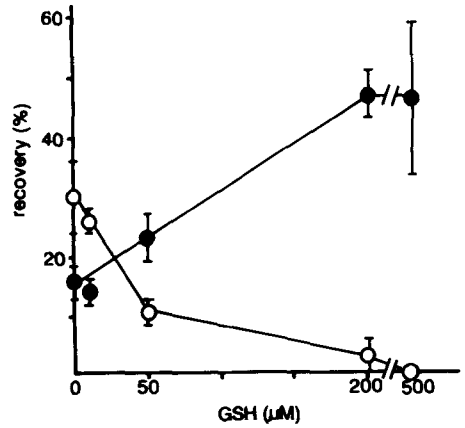

FIG. 2. Effect of GSH concentration on the reduction of 15-HPETE in parotid saliva. The reaction mixture containing 15-HPETE (10 nmol) in the saliva (0.2 mL) was incubated for 30 min at 37°C; ○, 15-HPETE; ●, 15-HETE. Abbreviations as in Figure 1.

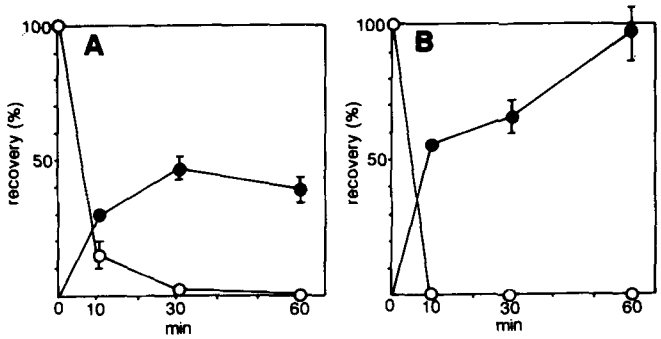

FIG. 3. Reduction of 15-HPETE to 15-HETE in parotid saliva (A) and blood plasma (B). The reaction mixture containing of 15-HPETE (10 nmol) and GSH (200 μM) in the fluid (0.2 mL) was incubated at 37°C; ○, 15-HPETE; ●, 15-HETE. Abbreviations as in Figure 1.

that GSH accelerated the conversion of 15-HPETE to 15-HETE. However, the level of 15-HETE was slightly increased after incubation of 15-HPETE with GSH in normal saline.

The effect of GSH concentration on the conversion of 15-HPETE in human saliva is shown in Figure 2. The conversion was enhanced with an increase in GSH concentration. However, the level of 15-HETE extracted from the saliva did not exceed half of the initial HPETE concentration (50 μM), even at 10 times the concentration of GSH (500 μM).

We have previously reported that human plasma has the ability to convert 15-HPETE to 15-HETE in the presence of GSH (12). Therefore, we compared the GSH-dependent reduction of 15-HPETE in the parotid saliva with that in the blood plasma from the same donor (Fig. 3). In the plasma, 15-HPETE disappeared with rapid formation of 15-HETE within the first 10-min, and all the 15-HPETE was converted to 15-HETE after 60 min. The level of 15-HETE obtained from the saliva did not exceed *ca.* 50% of the initial 15-HPETE during the incubation time. Thus, the HPETE-reducing ability of saliva was lower than that of blood plasma.

Ascorbic acid and α-tocopherol are other reducing substances of biological importance. However, the conversion was only slightly affected when GSH was replaced by these compounds (Table 1). While oxidized glutathione (GSSG) did not accelerate the formation of 15-HETE, cysteine exerted a moderate effect on the conversion of 15-HETE. The parotid saliva was separated into two fractions, an HMW fraction and an LMW fraction, by using gel-permeation chromatography. Both fractions yielded similar levels of 15-HETE after incubation for 30 min in the presence of GSH (23–27% of 15-HPETE). These levels were lower than that obtained from unseparated parotid saliva in the presence of the same concentration of GSH (45%). On the other hand, the recovery of 15-HPETE from the LMW fraction was significantly higher than that from the HMW fraction. Thus, it was apparent that the HMW fraction was responsible for the lower recovery of 15-HPETE from the parotid saliva.

Table 2 shows the effect of simulated gastric juice on the reduction of 15-HPETE in the saliva. This highly acidic juice did not accelerate the reduction regardless of the presence of GSH. However, significant conversion was observed when the juice was mixed with an equal amount of the parotid saliva. Moreover, the level of 15-HETE was higher in the mixture of saliva with simulated gastric juice than when a buffer at neutral pH was substituted for the simulated gastric juice. Thus, acidic pH, such as in the stomach environment, enhanced the hydroperoxide-reducing ability of the parotid saliva.

TABLE 1

Effect of Reducing Substances on the Recovery of 15-HPETE from Human Parotid Saliva[a]

Reducing substance	Fluid	HPETE + HETE (%)	HPETE (%)	HETE (%)
None	Saliva	23 ± 5	14 ± 3	9 ± 1
GSH	Saliva	45 ± 7	0	45 ± 7
GSH	HMW fraction	40 ± 7	12 ± 5	27 ± 2
GSH	LMW fraction	75 ± 12	55 ± 16	23 ± 2
GSSG	Saliva	31 ± 3	18 ± 3	12 ± 1
Cysteine	Saliva	25 ± 2	4 ± 3	22 ± 3
Ascorbic acid	Saliva	24 ± 4	13 ± 4	12 ± 1
α-Tocopherol	Saliva	26 ± 4	10 ± 1	11 ± 3

[a]Average value ± SD for three experiments. Reaction mixture containing 15-HPETE (10 nmol) in parotid saliva or its fraction (0.2 mL) was incubated for 30 min at 37°C. Reducing substances were added at the concentration of 200 μM. 15-HPETE, 15-hydroperoxyeicosa-5,8,11,13-tetraenoic acid; HETE, hydroxyeicosa-5,8,11,13-tetraenoic acid; GSH, glutathione; HMW, high molecular weight; LMW, low MW; GSSG, oxidized form of GSH.

TABLE 2

Effect of Simulated Gastric Juice on the Recovery of 15-HPETE[a]

System	HPETE + HETE (%)	HPETE (%)	HETE (%)
Simulated gastric juice (pH 1.2)	35 ± 9	23 ± 10	9 ± 3
Simulated gastric juice + GSH	35 ± 10	24 ± 10	7 ± 1
Simulated gastric juice + saliva + GSH	73 ± 7	21 ± 4	52 ± 3
Tris-HCl buffer (pH 7.4) + saliva + GSH	54 ± 4	21 ± 4	31 ± 4

[a]Average value ± SD for three experiments. 15-HPETE (20 nmol) was added to the stimulated gastric juice (0.2 mL) or the mixture of simulated gastric juice (0.2 mL) and parotid saliva (0.2 mL). Incubation was performed for 30 min at 37°C with or without addition of GSH (200 μM). Abbreviations as in Table 1.

DISCUSSION

Lipid hydroperoxides are mutagenic (15) and have been suspected to be carcinogenic (16). In addition, it was reported that linoleic acid hydroperoxides can induce oxidative damage in the epithelial cell of the gastrointestinal tract of rats (17). Recently, Oarada *et al.* (18) showed that dietary intake of peroxidized methyl linoleate impaired mouse lymphoid tissue, resulting in impaired immune response. Lipid hydroperoxides (LOOH) produce highly reactive alkoxyl radicals (LO•) by reacting with transition metal ions (M^{n+}) at their reduced state (19,20) (Equation 1).

$$LOOH + M^{n+} \rightarrow LO^{\cdot} + {}^{-}OH + M^{(n+1)+} \quad [1]$$

This one-electron transfer reaction may be responsible for the oxidative damage. Hydroxyl derivatives (LOH) are formed as minor products by radical combination (Equation 2) or hydrogen abstraction of alkoxyl radicals (Equation 3) (21,22).

$$H\text{-}C\text{-}O^{\cdot} + H\text{-}C\text{-}O^{\cdot} \rightarrow H\text{-}C\text{-}OH + \text{-}C{=}O \quad [2]$$

$$LO^{\cdot} + LH \rightarrow LOH + L^{\cdot} \quad [3]$$

On the other hand, detoxification of lipid hydroperoxides is a nonradical two-electron transfer reaction and thus requires electron donors (AH) [IV].

$$LOOH + 2AH \rightarrow LOH + H_2O + 2A \quad [4]$$

The conversion of lipid hydroperoxides to their hydroxyl derivatives by the reaction in Equation 4 is one of the defense systems against lipid peroxidation-induced oxygen toxicity (22–26).

We have previously found that human blood plasma possesses GSH-dependent fatty acid hydroperoxide-reducing ability as a defense against excessive accumulation of lipid hydroperoxides (12). The present study also demonstrates that human parotid saliva possesses this ability to detoxify peroxidized lipids in the diets. Thiol groups seem to be required as hydrogen donors for the reaction because cysteine also enhanced the formation of hydroxyl derivatives (Table 1). Both the LMW fraction and the HMW fraction were necessary for effective conversion (Table 1).

The conversion in saliva was not as effective as the conversion in blood plasma (Fig. 3). However, the hydroperoxide-reducing ability in parotid saliva seems to be of physiological importance. It was reported that total GSH level (GSH plus GSSG) in human saliva is 0.5–1.0 μg/mL (27). Dietary foods, such as fruits and vegetables, contain considerable amounts of GSH (28,29). Jones *et al.* (29) estimated that dietary intake of GSH varies between 10- to 40-fold from 2.9 mg to 131 mg/day/person. In addition, the hydroperoxide-reducing ability of parotid saliva was found to be more effective under highly acidic conditions

(Table 2). Thus, the hydroperoxide-reducing ability of parotid saliva may be favored in the environment of the stomach.

In conclusion, human parotid saliva is able to detoxify fatty acid hydroperoxides to alcohols in the presence of GSH. This extracellular fluid thus can participate in the defense against diet-induced oxidative damage.

ACKNOWLEDGMENTS

The authors are grateful to Dr. T. Matsukubo of Tokyo Dental College and Dr. T. Harada of Ajinomoto Co., Inc. for the device for saliva collection. The authors also thank Dr. P.L. Boey for help in the preparation of this manuscript.

The Identification of the Allylic Nitrite and Nitro Derivatives of Methyl Linoleate and Methyl Linolenate by Negative Chemical Ionization Mass Spectroscopy

Aris A. Gallon and **William A. Pryor***
Chemistry Department and the Biodynamics Institute, Louisiana State University, Baton Rouge, Louisiana 70803

The autoxidation of polyunsaturated fatty acids is initiated both *in vivo* and *in vitro* by nitrogen dioxide. The mechanism of the initiation process is believed to involve both addition reactions and hydrogen atom abstraction reactions, with hydrogen abstraction predominating at low levels of nitrogen dioxide. Therefore low levels of nitrogen dioxide should react with polyunsaturated fatty acids to give allylic derivatives; in an anaerobic system these derivations should be allylic nitro and nitrite compounds. Using negative methane chemical ionization mass spectrometry and other analytical techniques, we have identified these allylic nitrite and nitro compounds from the reactions of low levels of nitrogen dioxide with methyl linoleate and methyl linolenate in the absence of oxygen. *Lipids 28,* **125-133 (1993).**

Nitrogen dioxide, a toxin present in polluted air (1,2), has been reported to cause pulmonary edema, pulmonary fibrosis, bronchitis (1,2) and cancer (3-6). Low levels of nitrogen dioxide have been shown to cause the initiation of the autoxidation of polyunsaturated fatty acids both *in vivo* (7-11) and *in vitro* (10,12). Nitrogen dioxide-initiated autoxidation of polyunsaturated fatty acids in cell membranes can lead to membrane damage and eventually cell death (7-10,13).

We previously reported that low levels of nitrogen dioxide initiate the autoxidation of cyclohexene by a hydrogen-atom abstraction mechanism (14,15). Recently, Postlethwait and Bidani (11) have demonstrated that nitrogen dioxide in an isolated rat lung reacts by a H-atom abstraction mechanism.

In the H-abstraction mechanism (Schemes 1 and 2), nitrogen dioxide abstracts a hydrogen atom from the allylic position of an alkene forming a resonance-stabilized radical. In the absence of oxygen (Scheme 1), nitrogen dioxide combines with the resonance-stabilized radical forming an allylic nitro or nitrite compound; in the presence of oxygen (Scheme 2), the resonance-stabilized radical combines with oxygen forming a peroxyl radical that ultimately forms allylic hydroperoxides (14). Since allylic compounds are formed *via* a H-atom abstraction mechanism, the detection of these allylic nitro or nitrite compounds can be used as a marker for nitrogen dioxide-induced H-abstraction.

In this study, we used negative chemical ionization to identify the allylic nitrite and nitro compounds formed by the reaction of nitrogen dioxide with methyl linoleate and methyl linolenate in the absence of oxygen. The allylic nitrite and nitro isomers identified are similar to the geometrical and positional isomers of methyl linoleate and methyl linolenate hydroperoxides formed in autoxidation reactions (16). Analogous to the hydroperoxide isomers, not all possible diasteriomers are produced (17). The following system is used to abbreviate the allylic nitrite (nitro) and hydroperoxide isomers: The abbreviations for two typical compounds are shown in Figure 1. The letters *c* or *t* denote a *cis* or *trans* double bond. The position of the double bond is placed before the letter *c* or *t*. The

Abbreviations: AN, allylic nitro or nitrite compounds; *c*, *cis* double bond; DTPA, diethylenetriaminepentaacetic acid; GC, gas chromatography; HPLC, high-performance liquid chromatography; IR, infrared; M^-, parent ion; *m/z*, mass/charge; NCI, negative chemical ionization; NMR, nuclear magnetic resonance; HP, hydroperoxide; *t*, *trans* double bond; TLC, thin-layer chromatography; UV, ultraviolet; 9*c*,11*t*,15*c*-13AN, methyl 13-nitrito-*cis*-9,*trans*-11,*cis*-15-octadecatrienoate and methyl 13-nitro-*trans*-9,*trans*-11,*cis*-15-octadecatrienoate; 9*t*,11*t*,15*c*-13AN, methyl 13-nitrito-*trans*-9,*trans*-11,*cis*-15-octadecatrienoate and methyl 13-nitro-*trans*-9,*trans*-11,*cis*-15-octadecatrienoate; 9*c*,11*t*,15*c*-13HP, methyl 13-hydrperoxy-*cis*-9,*trans*-11*cis*-15-octadecatrienoate; 9*t*,11t,15*c*-13HP, methyl 13-hydroperoxy-*trans*-9,*trans*-11,*cis*-15-octadecatrienoate; 9*c*,12*c*,14*t*-16AN, methyl 16-nitrito-*cis*-9,*cis*-12,*trans*-14-octadecatrienoate and methyl 16-nitro-*cis*-9,*cis*-12,*trans*-14-octadecatrienoate; 9*c*,12*t*,14t-16AN, methyl 16-nitrito-*cis*-9,*trans*-12,*trans*-14-octadecatrienoate and methyl 16-nitro-*cis*-9,*trans*-12,*trans*-14-octadecadienoate; 9*c*,12*c*,14*t*-16HP, methyl 16-hydroperoxy-*cis*-9,*cis*-12,*trans*-14-octadecatrienoate; 9*c*,12*t*,14*t*-16HP, methyl 16-hydroperoxy-*cis*-9,*trans*-12,*trans*-14-octadecatrienoate; 9*c*,13*t*,15*c*-12AN, methyl 12-nitrito-*cis*-9,*trans*-13,*cis*-15-octadecatrienoate and methyl 12-nitro-*cis*-9,*trans*-13,*cis*-15-octadecatrienoate; 9*c*,13*t*,15*t*-12AN, methyl 12-nitrito-*cis*-9,*trans*-13,*trans*-15-octadecatrienoate and methyl 12-nitro-*cis*-9,*trans*-12,*trans*-15-octadecatrienoate; 9*c*,13t,15*c*-12HP, methyl 12-hydroperoxy-*cis*-9,*trans*-13,*cis*-15-octadecatrienoate; 9*c*,13*t*,15*t*-12HP, methyl 12-hydroperoxy-*cis*-9,*trans*-13,*trans*-15-octadecatrienoate 10*t*,12*c*,15*c*-9AN, methyl 9-nitrito-*trans*-10,*cis*-12,*cis*-15-octadecatrienoate and methyl 9-nitro-*trans*-10,*cis*-12,*cis*-15-octadecatrienoate; 10*t*,12t,15*c*-9AN, methyl 9-nitrito-*trans*-10,*trans*-12,*cis*-15-octadecatrienoate and methyl 9-nitro-*trans*-10,*trans*-12,*cis*-15-octadecatrienoate; 10*t*,12*c*,15*c*-9HP, methyl 9-hydroperoxy-*trans*-10,*cis*-12,*cis*-15-octadecatrienoate; 10*t*,12*t*,15*c*-9HP, methyl 9-hydroperoxy-*trans*-10,*trans*-12,*cis*-15-octadecatrienoate.

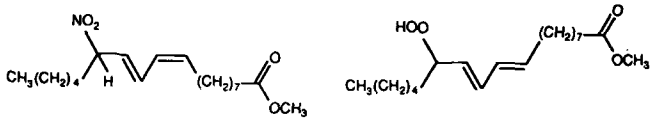

FIG. 1. Examples of the abbreviation systems used: Methyl 13-nitro-*cis*-9,*trans*-11-octadecadienoate and methyl 13-hydroperoxy-*cis*-9,*trans*-11-octadecadienoate are abbreviated as 9*c*,11*t*-13AN and 9*c*,11*t*-13HP.

letters "AN" are used to signify an allylic nitro or nitrite group and the letters "HP" denote a hydroperoxide functional group. The position of the functional group is placed before the letters AN or HP.

EXPERIMENTAL PROCEDURES

Materials. Methyl linoleate and methyl linolenate, 99% pure by gas chromatography (GC) (Sigma, St. Louis, MO), was purified by eluting the esters through four columns each of which contained 1.0 g of alumina (neutral, Aldrich, Milwaukee, WI), and the last of which also contained in the tip 0.02 g of diethylenetriaminepentaacetic acid (DTPA) to remove any trace metals. These purification steps were done in a glove bag under nitrogen.

Nitrogen dioxide was generated from dinitrogen tetroxide (99.5%, Matheson, Secaucus, NJ). Dinitrogen tetroxide was placed in a glass bulb with phosphorus pentoxide and purged of oxygen with argon by freezing and thawing the dinitrogen tetroxide three times. Isopentyl nitrite (97%, Aldrich), and nitrocyclohexane (97%, Aldrich) were used as infrared (IR) standards. Hexane, isopropanol and dichloromethane, all high-performance liquid chromatography (HPLC) grade (Mallinckrodt, St. Louis, MO), were purged of oxygen before use. Ultra pure helium (99.9999%, chromatographic grade, Air Products, Allentown, PA) was used as the carrier gas for the reaction. A thymol trap was made by dissolving 0.4 g of thymol (Sigma) and 4 g of sodium hydroxide (97%, EM Science, Gibbstown, NJ) in 1 L of deionized water.

Instrumentation. The Ultraviolet (UV) spectra were taken on a Hewlett-Packard (Avondale, PA) 8451A diode array spectrophotometer in hexane/isopropanol (99:1, vol/vol); the IR spectra were obtained on an IBM (Armonk, NY) IR/45 spectrometer. HPLC was done on a Varian (Palo Alto, CA) 5000 series instrument with a UV detector set at a 215 nm wavelength with a 16-nm slit width was used to separate the hydroperoxide and allylic nitro and nitrite isomers. A 25 × 0.46 cm silica column (Rainin, Woburn, MA; Microsorb) was used with hexane/isopropanol (99:1, vol/vol) at a flow rate of 1 mL/min. The nuclear magnetic resonance (NMR) spectra were recorded on a Bruker (Billerica, MA) 200 MHz instrument using deuterated chloroform as the solvent. Negative methane chemical ionization mass spectrometry was performed on a Finnigan MAT (San Jose, CA) TSQ 4500 mass spectrometer using a direct exposure probe ramped to 1 A at a rate of 10 mA/s. Methane gas at a pressure of 0.5 Torr was used for chemical ionization. The mass range scanned in the negative mode was 44–800 amu. The source temperature was 150°C and the manifold temperature was 100°C.

Methods. The hydroperoxides of methyl linoleate listed in Table 1 were formed by exposing methyl linoleate that was kept in a clear glass vial to air for one week at room temperature. The four hydroperoxides were separated from the starting material by thin-layer chromatography (TLC) using hexane/isopropanol (94:6, vol/vol). The mixture of hydroperoxide isomers was extracted from the silica gel with dichloromethane, concentrated and resuspended in hexane. The individual positional and geometrical hydroperoxide isomers were isolated from the mixture of hydroperoxides by HPLC and analyzed by UV spectrophotometry, NMR and negative methane chemical ionization (NCl) mass spectrometry.

The eight methyl linolenate hydroperoxide isomers listed in Table 2 were formed from methyl linolenate that

was kept in a clear glass vial and exposed to air for one week at room temperature. Mixtures of all eight of the hydroperoxide isomers were isolated by TLC from the methyl linolenate starting material. The individual hydroperoxide isomers are not resolved by adsorption phase HPLC and elute from the column as four groups of unresolved positional and geometrical isomers. Each group of unresolved hydroperoxides was isolated by HPLC and analyzed by NMR.

A sodium borohydride reduction (16) was used to reduce the four groups of unresolved geometrical and positional methyl linolenate hydroperoxide isomers eluting by HPLC as four peaks (I–IV) (Fig. 2). The eight isomeric alcohols formed by reduction are resolved by HPLC. Individual isomers were identified by their HPLC elution order, as given by Chan and Levett (16); the hydroperoxide assignments are given in Table 3.

The mixtures of allylic nitrite and nitro isomers (AN) of methyl linoleate listed in Table 1 were prepared by allowing 40 ppm of nitrogen dioxide in helium to react with purified methyl linoleate (neat, 3.4 mmole) for one hour. A bubbler apparatus similar to the one utilized in our earlier study (14) was used at a carrier gas flow rate of 60 mL/min at 25°C. The entire reaction was carried out in a glove bag under nitrogen. The nitrogen dioxide concentration in the carrier gas was determined by Saltzman analysis (18) of the thymol trap solution used in a run with no fatty acid in the apparatus. The mixture of allylic nitrite and nitro compounds was separated from the methyl linoleate starting material by TLC using hexane/isopropanol (94:6, vol/vol) that had been purged of oxygen in a glove bag under an atmosphere of nitrogen. The

[a]A 25 × 0.46 cm silica column with hexane/isopropanol (99:1, vol/vol) at a flow rate of 1 mL/min was used for high-performance liquid chromatography (HPLC) analysis. The four fractions refer to the four peaks shown in the HPLC chromatogram in Figure 4b.

positional and geometrical isomers, which contained unresolved nitrite and nitro isomers, were isolated by HPLC.

The allylic nitrite and nitro isomers (AN) of methyl linolenate that were identified are listed in Table 4. These isomers were prepared by allowing purified methyl linolenate to react with 3 ppm of nitrogen dioxide in ultrapure helium for one hour. The mixture of allylic nitrite and nitro isomers was isolated from the starting material by TLC. The allylic nitrite and nitro isomers of methyl linolenate elute in HPLC as four peaks containing mixtures of unresolved positional and geometrical nitrite and nitro isomers. The four groups of unresolved isomers were analyzed by NMR and negative methane chemical ionization.

RESULTS AND DISCUSSION

Methyl linoleate allylic nitrite (nitro) and hydroperoxide isomers. The HPLC trace of the allylic nitrite (nitro) and hydroperoxide isomers of methyl linoleate are presented in Figure 3. The comparable hydroperoxide and allylic nitrite and nitro compounds elute at similar retention times.

Negative chemical ionization (NCI) mass spectrometry was used to distinguish these two types of compounds. NCI has previously been used for the analysis of various types of nitro and chlorinated compounds and organophosphates (19–24). The NCI spectra for the allylic nitrite (nitro) isomers of methyl linoleate (Table 5) display a *m/z* 46 and *m/z* 62 ion that is not detected in the NCI spectra for the hydroperoxides (Table 5). The *m/z* 46 ion is formed by dissociative electron capture and is a characteristic ion for nitro-containing compounds (21,23,24). The *m/z* 62 ion is indicative of a nitrate function (21) and is though to originate from homolysis of the O–N bond of the allylic nitrite isomers (25). The formation of the alkoxyl radical in the source of the mass spectrometer is followed by the termination of the radical with NO_2 to form the allylic nitrate. The allylic nitrate then undergoes C–O bond scission in the source of the mass spectrometer to give the *m/z* 62 ion. The *m/z* 62 ion is believed to be formed in the source rather than to originate from an allylic nitrate present in the sample, because a *m/z* 355 ion indicative of the M^- molecular ion for the allylic nitrate was not detected.

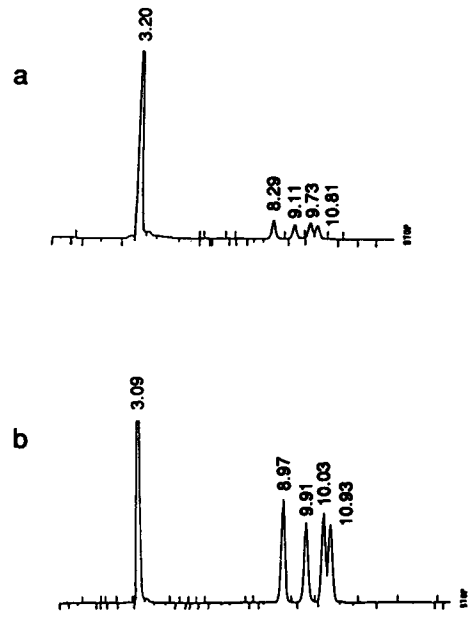

FIG. 3. High-performance liquid chromatographic chromatograms of the (a) allylic nitrite(nitro) isomers and (b) hydroperoxide isomers.

The *m/z* 339 M^- molecular ion of the allylic nitrite (nitro) isomers formed by resonance capture (23) (Table 5) reflects the ability of the compound to stabilize a negative charge (23). The *m/z* 326 molecular ion of the hydroperoxides (Table 5) was not detected. The $[M - H]^-$ ion of *m/z* 338 for the allylic nitrite (nitro) and *m/z* 325 ion for the hydroperoxides of methyl linoleate is caused by dissociative electron capture (23). The $[M + H]^-$ *m/z* 340 ion in the spectra of the allylic nitrites (nitro) is formed by H-abstraction reactions of the M^- ion (22). The Formation of $[M + H]^-$ ions also were reported by Dougherty and Dalton (22) for all chlorinated compounds that form a molecular ion. Consequently, the hydroperoxide isomers do not exhibit an M^- ion or an $[M + H]^-$ ion of *m/z* 327.

Determining the position of the hydroperoxide and nitrite functional groups. The positions of the nitrite group in the allylic nitrite isomers and of the HOO^- group in the hydroperoxide isomers were determined by the formation of an aldehyde produced from the thermal homolysis of the O-N and O-O bonds in the source of the mass spectrometer. The M^- ion of the aldehydes can be seen in the NCI spectra. Hydroperoxides have been reported to undergo thermal homolysis of the O-O bond to form an alkoxyl radical in the source of the mass spectrometer (26,27) which undergoes C-C bond cleavage to

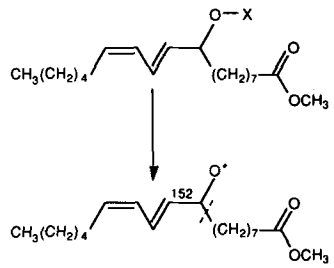
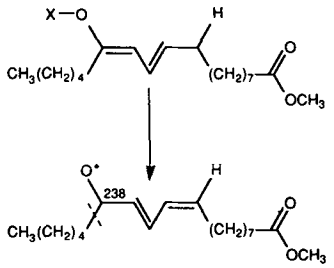
form an aldehyde (26). One of the major aldehydes reported to be formed by thermal homolysis of the 9-hydroperoxide isomers of methyl linoleate is 2,4-decadienal (26,27) (Scheme 3, where X = -OH, -NO). The major aldehyde formed by thermal homolysis of the 13-hydroperoxide of methyl linoleate is methyl 13-oxo-9,11-tridecadienoate (28,29) (Scheme 4, where X = -OH, -NO). The 9- and 13-positional allylic nitrite isomers also can form the same intermediate alkoxyl radicals that can undergo C-C bond scission to form 2,4-decadienal and methyl 13-oxo-9,11-tridecadienoate (Schemes 3 and 4).

In the NCI spectra for the 9- and 13-hydroperoxides (Table 5), a $[M - H]^-$ ion of *m/z* 151 for 2,4-decadienal is detected for the 9-hydroperoxides. Correspondingly, the $[M - H]^-$ ion of *m/z* 237 for methyl 13-oxo-9,11-tridecadienoate is seen in the NCI spectra for the 13-hydroperoxides (Table 5). The $[M - H]^-$ *m/z* 151 ion of 2,4-decadienal also is detected in the NCI spectra for the 9-allylic nitrite(nitro) isomers (Table 5). Similarly, the $[M - H]^-$ *m/z* 237 ion for methyl 13-oxo-9,11-tridecadienoate is detected in the NCI spectra for the 13-allylic nitrite(nitro) isomers. The detection of the *m/z* 151 ion and the *m/z* 237 ion in the NCI spectra of the 9- and 13-allylic nitrite(nitro) compounds, respectively, confirms the position of the functional group.

The presence of the nitro functional group. The coelution of the allylic nitro and nitrite isomers was determined by hydrolyzing the 13-*cis,trans*-allylic nitrite(nitro) compound; alkyl nitrites are known to hydrolyze to alcohols (30). The hydrolysis products of the 13-*cis,trans*-allylic nitrite(nitro) isomers display the *m/z* 46 and *m/z* 62 ions indicative of the nitro and nitrate groups by NCI. The $[M - H]^-$ *m/z* 338 and $[M + H]^-$ *m/z* 340 ions also are present. If the sample consisted of only the allylic nitrite isomer, the *m/z* 46, *m/z* 62, *m/z* 338 and *m/z* 340 ions would not have been detected in the hydrolyzed sample since alcohols do not give these ions.



SCHEME 3



SCHEME 4

IR spectral data. Table 6 displays IR data for isopentyl nitrite, nitrocyclohexane, a mixture of isopentyl nitrite and nitrocyclohexane, and our allylic nitrite(nitro) isomers. Stretching frequencies at 1603 cm^{-1} and 1587 cm^{-1} for the allylic nitrite(nitro) isomers may be caused by the presence of an oxime (31) formed by the decomposition of the allylic nitrite isomers. The stretching frequency for the nitro functional group is 1377 cm^{-1}. The stretching frequencies we observed diverge from the normal values, perhaps because of the electron-withdrawing effects of the double bonds (32).

Maximum UV absorptions. The UV maximum absorption wavelength of allylic nitrite(nitro) isomers isolated by HPLC using hexane/isopropanol (99:1, vol/vol) is 236 ± 2 nm for the *cis,trans* isomers and 234 ± 2 nm for the *trans,trans* isomers. The methyl linoleate hydroperoxides exhibit a UV maximum at 234 ± 2 nm for the *cis,trans* and 232 ± 2 nm for the *trans,trans* in hexane/isopropanol (99:1, vol/vol); these absorptions indicate that both isomers have conjugated double bonds (33).

Proton NMR data of the allylic nitrite(nitro) and hydroperoxide isomers. The proton NMR data for the 13-*cis,trans* and 13-*trans,trans* allylic nitrite(nitro) isomers are listed in Table 7. The 13-*cis,trans* and 13-*trans,trans* hydroperoxides reported by Gardner and Plattner (28) have similar chemical shifts and splitting patterns. The proton NMR data of the 9- and 13-allylic nitrite(nitro) isomers have the same chemical shifts and splitting patterns (Table 8). The 9- and 13-hydroperoxides of methyl linoleate also are reported to have identical proton NMR spectra (28). These similarities between the proton NMR data of the allylic nitrites and hydroperoxide isomers were used to confirm the structures assigned to the allylic nitrite(nitro) isomers.

NCI of the allylic nitrite(nitro) isomers of methyl linolenate. The allylic nitrite(nitro) isomers and hydroperoxides of methyl linolenate elute at similar retention times (Fig. 4), as do the allylic nitrite(nitro) isomers and hydroperoxides of methyl linoleate (Fig. 3). NCI mass spectrometry was used to identify the allylic nitrite(nitro) isomers of methyl linolenate that elute by HPLC as four groups (labeled "fraction I-IV") of mixtures of positional and geometrical isomers.

The NCI spectral data for the mixture of allylic nitrite (nitro) isomers in fraction I are shown in Table 9. The $[M + H]^-$ ion of *m/z* 338 and M^- ion of *m/z* 337 detected in this fraction confirm the molecular weight of the allylic nitrite(nitro) isomer. The *m/z* 46 ion, indicative of a nitro group, and the *m/z* 62 ion, indicative of a nitrate, also are

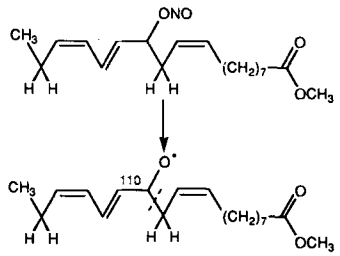
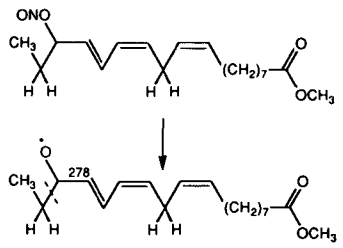


SCHEME 6

The NCI spectral data for the mixture of allylic nitrite(nitro) isomers in fraction III are shown in Table 9. The $[M + H]^-$ ion of *m/z* 338, M^- ion of *m/z* 337, NO_2^- ion *m/z* 46, and NO_3^- ion of *m/z* 62 are all observed. The *m/z* 237 ion for the 13-allylic nitrite isomer and the *m/z* 277 ion for the 16-allylic nitrite isomer were both detected.

The NCI spectral data of the mixture of allylic nitrite(nitro) isomers in fraction IV are shown in Table 9.



SCHEME 7

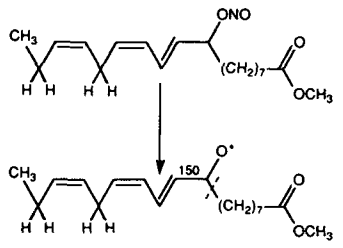
The $[M + H]^-$ ion of *m/z* 338, M^- ion of *m/z* 337, NO_2^- ion of *m/z* 46 and the NO_3^- ion of *m/z* 62 are detected. The *m/z* 149 ion is the $[M - H]^-$ ion of 2,4,7-decatrienal formed by thermal homolysis of the 9-allylic nitrite isomer (Scheme 8).

Proton NMR analysis of the hydroperoxide and allylic nitrite(nitro) fractions of methyl linolenate. The proton NMR chemical shifts and splitting patterns of the olefinic region of the hydroperoxide fractions of methyl linolenate are similar to those of the allylic nitrite(nitro) isomers (Table 10). The proton NMR of the methyl linoleate hydroperoxides and allylic nitrite(nitro) isomers also are very similar.

Assignments of the allylic nitrite(nitro) isomer fractions of methyl linolenate. The assignments of the allylic nitrite (nitro) isomers of methyl linolenate obtained from the NCI and NMR data presented above are listed in Table 11. Since the isomers of the methyl linoleate hydroperoxides and allylic nitrite isomers of methyl linoleate elute at similar retention times, the assigned *cis,trans* and *trans,trans* geometries of the allylic nitrite (nitro) isomers of methyl linolenate were based on the similar elution time profile of the hydroperoxide isomers.

We have shown that nitrogen dioxide reacts with methyl linoleate and linolenate in the absence of oxygen to give allylic nitro and nitrite isomers (34). Our data demonstrate that these isomers can be identified by NCI mass spectrometry. We have previously rationalized these products by a mechanism involving hydrogen atom abstraction by nitrogen dioxide (14,15).

The allylic nitrite(nitro) compounds and hydroperoxides elute at similar retention times by adsorption HPLC. The UV maximum absorption wavelengths and the proton NMR spectra of the allylic nitrite(nitro) and hydroperoxide compounds also are similar. These similarities were used to confirm the structure of the nitrite(nitro) compounds.



SCHEME 8

TABLE 10

Proton Nuclear Magnetic Resonance Data of the Hydroperoxide and Allylic Nitrite(nitro) Fractions of Methyl Linolenate[a]

Fraction II[b]		Fraction IV[c]

6.6 ppm *(m)*	6.6 ppm *(m)*	6.6 ppm *(m)*	6.6 ppm *(m)*
6.05 ppm *(t)*	6.05 ppm *(t)*	6.05 ppm *(t)*	6.05 ppm *(t)*
5.3-5.7 ppm *(br,m)*	5.3-5.65 ppm *(br,m)*	5.3-5.65 ppm *(br,m)*	5.3-5.65 ppm *(br,m)*
4.35 ppm *(br,m)*	4.35 ppm *(m)*	4.4 ppm *(m)*	4.38 *(m)*

[a] *br* = broad, *m* = multiplet and *t* = triplet. Since the fractions are a mixture of isomers, the coupling constants are not shown.

[b] Fraction II for the hydroperoxides and allylic nitrite(nitro) isomers was isolated using a silica column with hexane/isopropanol (99:1, vol/vol) at a flow rate of 1 mL/min. The retention time for the hydroperoxide in Figure 4b was 10.38 min and for the allylic nitrite(nitro) in Figure 4a was 10.16 min.

[c] The retention time of fraction IV is 11.49 min for the hydroperoxide and 11.26 min for the allylic nitrite(nitro) isomer.

TABLE 11

Allylic Nitrite(nitro) Isomers of Methyl Linolenate Contained in Isolated Fractions[a]

Fractions	Allylic nitrite(nitro) isomers
I	(9*c*,11*t*,15*c*-13AN)
II	(9*c*,13*t*,15*c*-12AN), (9*c*,13*t*,15*t*-12AN), and (9*c*,12*c*,14*t*-16AN)
III	(9*t*,11*t*,15*c*-13AN) and (9*c*,12*t*,14*t*-16AN)
IV	(10*t*,12*c*,15*c*-9AN) and (10*t*,12*t*,15*c*-9AN)

[a] A 25 × 0.46 cm silica column with hexane/isopropanol (99:1, vol/vol) at a flow rate of 1 mL/min was used for high-performance liquid chromatography (HPLC) analysis. The four peaks refer to the HPLC trace in Figure 4a.

Negative methane chemical ionization (NCI) was used to identify the presence of a nitrite and nitro group, to confirm the molecular weight and to locate the position of the functional group. The NCI spectra for the allylic nitrite(nitro) isomers of methyl linoleate (Table 5) and methyl linolenate (Table 9) display a *m/z* 46 and *m/z* 62 ion indicative of a nitro and nitrate functional group (20,22,23) and *m/z* 339 and *m/z* 337 molecular ions. These ions were not seen in the NCl spectra for the hydroperoxides of methyl linoleate (Table 5). The position of the functional group was determined by the aldehyde formed by thermal homolysis of the O-N bond of the nitrite group.

ACKNOWLEDGMENTS

We would like to thank Dr. S. Barker, Dr. R. Laine and T. Meyer for the use of their mass spectrometer and their assistance in analyzing the compounds. This work was supported in part by a MERIT Award from the National Institutes of Health, HL-16029.

The Effect of Incubation Temperature on Yolk Lipid Parameters During Embryonic Development of the Alligator (*Alligator mississippiensis*)

R.C. Noble[a,*], D.C. Deeming[b], M.W.J. Ferguson[b] and R. McCartney[a]

[a]Department of Biochemical Sciences, The Scottish Agricultural College (Auchincruive), AYR, KA6 5HW, Scotland, and [b]Department of Cell and Structural Biology, The University of Manchester, Stopford Building, Oxford Road, Manchester, M13 9PT, England

The effect of incubation temperature (30 and 33°C) on yolk lipid uptake and changes in the alligator has been studied. Notable changes occurred in the lipid and fatty acid compositions of the yolk. Triacylglycerols and phospholipids were the major lipid components of the yolk at the start of incubation. However, during incubation the level of cholesteryl esters increased considerably to become a major lipid component of the yolk at hatching. This increase in cholesteryl ester level occurred at a much earlier time in the eggs incubated at 33°C. The cholesteryl esters which accumulated within the yolk showed much higher levels of oleic acid. The triacylglycerols and phospholipids of the yolk both contained unusually high levels of palmitoleic acid. Their fatty acid compositions remained relatively unchanged during incubation. The lipid composition of the liver toward the end of the incubation period reflected the changes that occurred within the yolk. Thus the percentage of cholesteryl esters in the liver lipid of embryos incubated at 30 and 33°C were 7 and 40%, respectively. The accumulated cholesteryl esters also showed a significantly higher content of oleic acid. The differences in the yolk and tissue lipids during incubation at the two temperatures are discussed with reference to the respective rates of embryonic development but in particular with respect to the feature of temperature-dependent sex determination.

Lipids 28, 135–140 (1993).

Compared with the avian where the role of incubation temperature is almost wholly confined to being the final arbiter of survival, in the reptile the effects of incubation temperature are vividly manifested through a range of features. Thus in the crocodilians, the most extensively researched species to date, incubation temperature has been shown to control embryonic growth rate (1,2), the pigmentation pattern at hatching (3), post-hatching thermoregulation and growth (4,5) and, most importantly, the sex of the animal whereby at 30°C the hatchlings are all female, while at 33°C they are all male (1,6-9).

An extensive yolk mass to supply the developing embryo with a large proportion of its nutrients is common to all birds and reptiles (10–13). A major feature of the yolks is a high initial lipid content and rapid lipid utilization during the later stages of embryo development. Indeed, in the alligator there is a close similarity to the avian in the distinctive lipid compositional and metabolic events that accompany yolk uptake (11,12). The fact that temperature has an effect on overall yolk utilization has been shown in *Crocodylus johnstone* (10). Differences in lipid uptake at different incubation temperatures may be associated with or actually cause several of the events specified by incubation temperature in alligators. The present study reports on some of the major lipid changes occurring in the yolks of *Alligator mississippiensis* eggs during incubation at 30 and 33°C.

Abbreviations: CE, cholesteryl esters; FFA, free fatty acids; FC, free cholesterol; PL, phospholipids; TG, triacylglycerols; UV, ultraviolet.

MATERIALS AND METHODS

Eggs of *Alligator mississippiensis* were collected from nests of wild alligators at the Rockefeller Wildlife Refuge, Grand Chenier, LA, on the first or second day after laying and were immediately transported by air to Manchester, England. On arrival at the laboratory (day 3/4 depending on the clutch), the eggs were weighed and placed in incubators accurate to ±0.01°C (Vinden Scientific Ltd., Bolton, England) maintained at 30 and 33°C. The relative humidity in the incubator was maintained as close as possible to 100% relative humidity.

Embryos and yolk complexes were carefully excised from four fertile eggs at days 8, 16, 24, 32, 40, 48, 56, 64 (hatching at 33°C) and 75 (hatching at 30°C) of incubation. The embryos were staged (Table 1) according to the method of Ferguson (8). Following weighing, the yolk complexes were individually homogenized and a known weight of the homogenate was removed. Total lipid from the homogenized sample was extracted by refluxing in a suitable excess of chloroform/methanol (2:1, vol/vol) according to well established procedures (14). Total lipid concentration was determined gravimetrically. Livers were excised from embryos at each incubation temperature just prior to hatching and the lipid extracted as for the yolk samples. All lipid extracts were then stored in chloroform at −20°C until analyzed.

The lipids were fractionated into their classes on thin-layer chromatoplates of silica gel G, thickness 0.25 mm, using a solvent system of hexane/diethyl ether/formic acid (80:20:1, vol/vol/vol). Following visualization and identification of the separated bands under ultraviolet (UV) light after spraying with a 0.1% (wt/vol) solution of 2,7-dichlorofluorescein in methanol, the phospholipids were recovered from the silica gel with 3 × 5 mL of chloroform/methanol/water (5:5:1, vol/vol/vol); the remaining

TABLE 1

Ages and Stages of Alligator Embryos from Which the Yolk Complexes Were Excised at 30 and 33°C Incubation Temperatures

Embryo age (d)	Stage	
	30°C	33°C
8	8	8
32	19	22
40	21	23
48	23	24
56	24	26
64	25	28 (hatching)
75	28 (hatching)	—

lipid fractions were recovered with 3 × 5 mL of diethyl ether. The lipid fractions were then transmethylated by refluxing with methanol/toluene/sulfuric acid (20:10:1, vol/vol/vol) in the presence of a pentadecanoic acid standard (15). Gas-liquid chromatography of the fatty acid methyl esters on a packed column of 15% CP Sil 84 on Chromosorb WHP (Chrompak UK Ltd., Middleburg, The Netherlands) enabled quantification of both the relative proportions of the major long-chain fatty acids present and the absolute amounts of the lipids. Quantification of the fatty acid chromatograms was by integration. Free cholesterol was quantified by charring and subsequent densitometry using a liquid scintillation counter (16). Identification of lipid and fatty acid fractions was by comparison with known standards. All solvents were distilled before use and where appropriate, operations were performed under an atmosphere of nitrogen.

RESULTS

The initial whole weights (±SE) of the eggs incubated at the two temperatures were: 30°C, 69.9 ± 1.11 g and 33°C, 69.8 ± 0.53 g. The weights of all the eggs thus fell within the range expected for those from mature alligators. Figure 1 shows the changes observed in the total yolk weights, total lipid content of the yolks and the percentage of lipids within the yolks during the incubations at 30 and 33°C. As can be seen, total yolk weights at both incubation temperatures remained very similar over the first 32 d of incubation, both groups registering very small decreases. Eggs incubated at 30°C continued to show only a further slight decrease in yolk weight up to 56 d of incubation, but thereafter there was a rapid decline. By contrast, eggs incubated at 33°C showed a rapid decrease in total yolk weight following 32 d of incubation (Fig. 1a). Just prior to hatching at 30 and 33°C, total yolk weights were 9.8 and 10.1%, respectively, of initial values. This overall difference was evident macroscopically, free yolk being present within the thick yolk sac membrane at 33°C but sparse at 30°C. The changes in total yolk weights during incubation at the two temperatures were mirrored by similar relative changes in total lipid contents. Although lipid absorption was particularly extensive during the last third of incubation, in the eggs incubated at 33°C mobilization was already prominent from a much earlier stage of incubation (Fig. 1b). By the end of incubation, some 85% of the initial yolk lipids had been absorbed in the eggs incubated at 30°C, but only some 73% in eggs incubated at 33°C. As incubation proceeded, total lipids assumed an increasing proportion of the total yolk weight in both groups of eggs, rising from an initial level of 20% of the yolk weight to 31% just prior to hatching (Fig. 1c).

Table 2 shows the changes that occurred in yolk lipid composition (major classes, weight percentage of total lipids) during incubation at 30 and 33°C. The reduction in lipid levels in the yolk was accompanied by substantial changes in composition, particularly in the eggs incubated at 33°C. Initially and throughout incubation in both groups of eggs, triacylglycerols were the principal lipid components accompanied also by a large proportion of phospholipids. Incubation was characterized by a large increase in the proportion of cholesteryl esters (CE) within the remnant yolk lipids of both groups of eggs; as yolk mobilization occurred, the proportion of CE increased

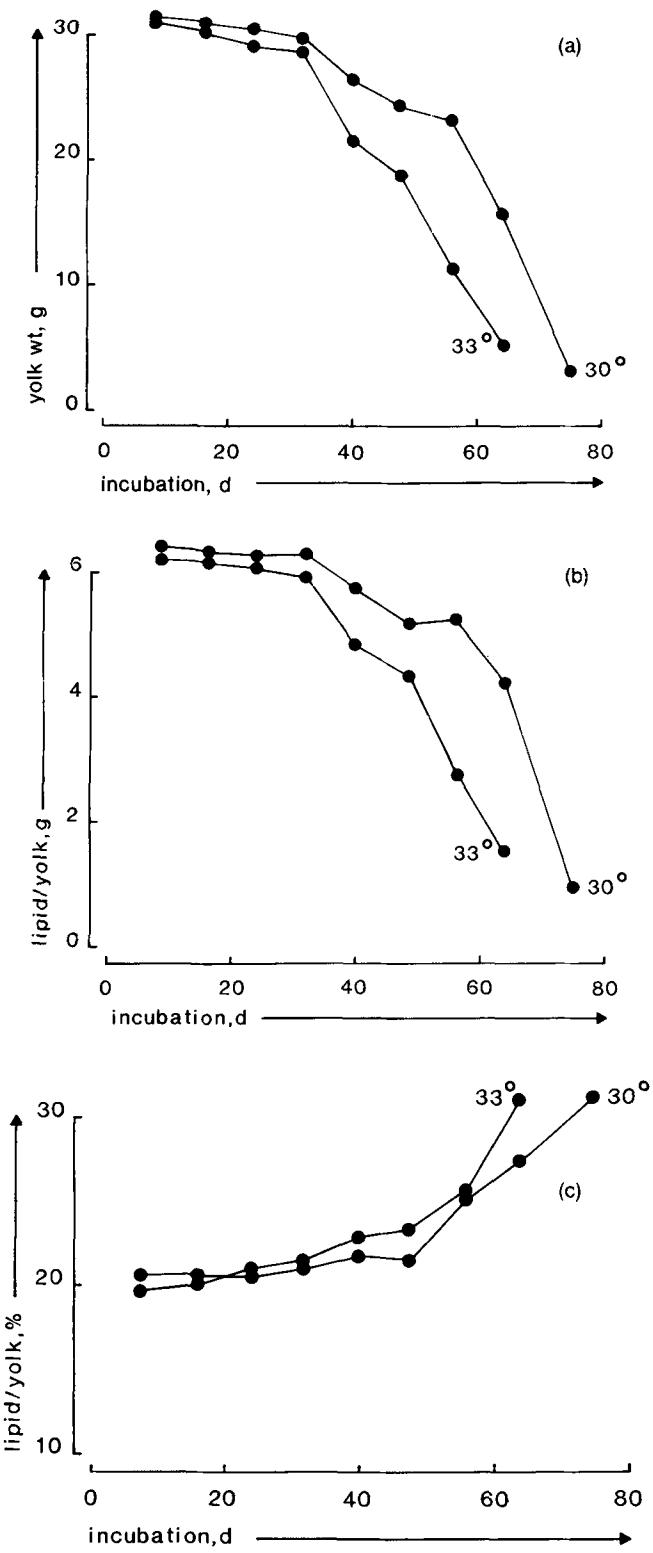

FIG. 1. Changes in total weight (a), total lipid content (b) and percentage of lipid (c) of the yolks during incubation at 30 and 33°C.

from a level of only about 1% in the yolk lipids initially to over 20% just prior to hatching. Proportions of free cholesterol were reduced. The increase in the level of CE was accompanied by a very large proportional decrease in phospholipids and also a decrease in triacylglycerols

(TG). At hatching the proportion of free fatty acids had shown an increase. Both groups of eggs showed similar yolk lipid compositions just prior to hatching. The changes in lipid composition of the yolk during incubation at 33°C were manifested at a very early stage; in particular the level of CE within the yolks had already shown a significant increase by day 32 of incubation. In general, if the data (Table 2) are compared by embryonic stage (Table 1), as opposed to embryonic age (days of incubation), then the changes in the lipid components are similar at equivalent embryonic stages regardless of incubation temperature, although some stage-independent changes exist.

Figure 2 shows the changes in the absolute amounts of CE, TG and phospholipids that occurred within the yolks during incubation at 30 and 33°C. As can be seen, in both groups of eggs a decrease in the amount of TG and phospholipids became increasingly obvious from around day 32 of incubation, but the reduction was particularly prominent in the yolks of the eggs incubated at 33°C. By contrast, absolute amounts of CE in the yolks of both groups of eggs increased over the incubation period with recognizable changes evident earlier in the eggs incubated at 33°C.

Table 3 shows the fatty acid compositions (major acids, weight percent of total) of the CE, TG and phospholipid fractions of the yolk at day 8 (beginning of incubation), day 64 (just prior to hatching at 33°C) and day 75 (just prior to hatching at 30°C) of incubation. In the triacylglycerol and phospholipid fractions, palmitic and oleic acids were the major constituent acids. Both fractions contained unusually high levels of palmitoleic acid. The high levels of polyunsaturated fatty acids in the phospholipids were characterized by levels of C_{20} and C_{22} acids that far exceeded those of the C_{18} precursors. In neither the TG nor the phospholipid fractions did the fatty acid compositions undergo any appreciable changes during the incubation period of the eggs. Although palmitic acid was the principal fatty acid present initially within the CE fraction, its level decreased markedly as incubation proceeded, and that of oleic acid increased. At day 64 of incubation there was a considerable difference in the oleic acid levels between the yolks of the two groups of eggs, but levels just prior to hatching were similar.

Table 4 shows the level and fatty acid composition of the CE found in the liver of the embryos at day 60 of incubation at 30 and 33°C. As can be seen, the concentration of CE within the lipids of the liver in embryos from the eggs incubated at 33°C was considerably elevated and showed a substantially different fatty acid composition, in particular much higher concentrations of palmitoleic, oleic and linolenic acids.

DISCUSSION

Yolk lipid uptake has been extensively studied in avian species, but particularly in the fowl (13,17). The patterns of events are similar throughout. A substantial reduction in egg yolk weight is associated with an extensive removal of lipids during the last third of the incubation period, the loss of lipids being particularly prominent in the last few days prior to hatching. Previous investigations (10,11) have already indicated that, in relative terms, yolk loss and lipid removal from the yolk of the alligator egg is

similar to that displayed by the fowl egg. Increasing the temperature of incubation of the alligator egg in the present investigations clearly resulted in a significant effect on both the rate and extent of overall yolk weight reduction and lipid uptake by the embryo. Thus, although by the end of the incubation period at both temperatures the amount of yolk material remaining unabsorbed was only some 10% of that initially present in the egg, the amounts of yolk lipid remaining unabsorbed were 15 and 27%, respectively, at 30 and 33°C. A similar effect of increased incubation temperature on overall yolk lipid uptake has been observed in other reptilian species (10).

In general terms, the lipid composition of the yolk of the alligator egg is similar to that of the fowl (18). However, the extent of lipid compositional changes as incubation proceeds is far more pronounced in the alligator egg. Thus although there is an accumulation of CE within the yolk complex of the fowl during incubation, its extent is considerably less than for the alligator (4% compared to 20% of total lipids). Furthermore, absorption of yolk lipids by the fowl embryo does not display any overall preferential uptake of phospholipids; any preference is confined to specific species comprising the individual phospholipid fractions (13,19,20). The major influence on yolk lipid composition, especially during the latter part of incubation, is undoubtedly the increasing development of the yolk sac membrane (13,19). Its extensive function with respect to absorption and synthesis of lipids dictates the extent of lipid changes. Synthesis of CE, in particular cholesteryl oleate, by the yolk sac membrane in order to facilitate efficient transfer of lipid into the embryo has been shown to be a major function of the membrane's metabolism (21). Although it is tempting to suggest that the much higher accumulation of cholesteryl esters within the yolk of the alligator during incubation, compared to the fowl, may be associated with higher lipid concentrations within the egg when laid (11), the extent of the differences in the accumulations indicates a more fundamental metabolic reason, presumably differential synthesis by the yolk sac membrane.

It is clear from the present investigations that the incubation of eggs at 33°C considerably accelerated the processes of lipid removal and uptake by the embryo when compared to incubation at 30°C. Thus at 33°C, changes in the total yolk and lipid weights became particularly evident from as early as day 32 of incubation, that is halfway through the incubation period. By comparison, at 30°C large-scale changes in yolk uptake became evident from about day 50 of incubation, that is the last third of the incubation period (*cf.* the fowl). More definitive parameters confirm the earlier and more active lipid metabolism in the yolks at 33°C. Cholesteryl ester accumulation within the lipid of the yolk is the most prominent feature. In spite of the extensive mobilization of yolk lipids into the embryo in association with the cholesteryl esters synthesized (12), absolute cholesteryl ester levels within the yolk increased throughout the incubation period, whereas absolute levels of other major lipid components dramatically decreased. The earlier (in terms of age) changes in yolk lipid metabolism in embryos incubated at 33°C correlate with the faster general development and growth of such embryos (2).

As a result of yolk lipid mobilization, the tissues of the alligator embryo are undoubtedly exposed to increasingly high levels of cholesterol; the change in lipid composition of the liver is only the most obvious case of cholesterol accumulation arising from yolk lipid absorption (12,13). Much has been said of the unique feature of temperature-dependent sex determination displayed by the alligator (1,9). A whole range of possible determining factors involved in the process has been noted. Among the several hypotheses suggested to operate at a cellular level is the involvement of steroid hormone and accelerated gonadal differentiation during development at differing incubation temperatures (1). Differential testicular and ovarian steroidgenic enzyme mRNA in tissues during gestation has been identified in mammalian and avian species (22,23). It is therefore tempting to suggest that, arising from the temperature of incubation, the unique set of metabolic circumstances whereby the alligator embryo is exposed to widely differing levels of cholesterol during its development may promote the synthesis of particular patterns of steroid hormones from cholesterol with subsequent effects on sexual differentiation. Interestingly the time of primary temperature sex determination in the alligator extends to about stage 21 (day 40 at 30°C), the time when major differences in yolk lipids are evident. It seems likely that these lipid changes are involved in stimulation of the primary sexual phenotype and the development of secondary sexual states by affecting steroid hormone biosynthesis.

ACKNOWLEDGMENTS

The authors thank Ted Joanen, Larry McNease and David Richard of the Rockefeller Wildlife Refuge, Louisiana Department of Wildlife and Fisheries, for their assistance over several years with the collection and transportation of eggs of *Alligator mississippiensis*.

METHOD

Determination of 4-Hydroxynonenal by High-Performance Liquid Chromatography with Electrochemical Detection

Christopher Goldring[1], Alessandro F. Casini, Emilia Maellaro, Barbara Del Bello and **Mario Comporti***
Istituto di Patologia Generale, Università di Siena, 53100 Siena, Italy

4-Hydroxy-*trans*-2-nonenal (HNE) is a highly reactive product of lipid peroxidation originating from the breakdown of phospholipid-bound polyunsaturated fatty acids of cellular membranes. Despite its biological relevance, this aldehyde is only occasionally determined due to the complexity of previously described procedures. Here we present a simple and very sensitive method for the detection of HNE in biological samples. The method is based on the measurement of the 2,4-dinitrophenylhydrazone (DNPH) of the aldehyde by electrochemical detection after separation by reverse-phase high-performance liquid chromatography (HPLC). The greater sensitivity of this procedure as compared to the ultraviolet detection method commonly employed to measure DNPH derivatives of aldehydes after HPLC will allow the detection of HNE below the pmol level. The detection of HNE is highly reproducible even in normal tissues and cells. Increased amounts of HNE were detected in the livers of animals intoxicated with prooxidant agents such as carbon tetrachloride, bromotrichloromethane or bromobenzene. An exponential increase in HNE (and in malondialdehyde) was measured in peroxidizing liver microsomes (in the NADPH/Fe-dependent system). The method is also suitable for the study of very small samples, since HNE could be detected in approximately 1 million cultured cells (polyoma virus-transformed baby hamster kidney fibroblasts); the level rose after exposure of the cells to a Fe^{3+}/ADP prooxidant system.
***Lipids* 28, 141-145 (1993).**

4-Hydroxy-*trans*-2-nonenal (HNE) is an α,β-unsaturated aldehyde which can be formed by peroxidation of ω6 unsaturated fatty acids, such as linoleic (18:2), γ-linolenic (18:3) and arachidonic (20:4) acid (1,2). In cellular membranes, however, HNE originates almost exclusively from phospholipid bound arachidonic acid (3) and can be considered as the most reliable index of free-radical stimulated lipid peroxidation. HNE exhibits a variety of cytopathological effects such as enzyme inactivation, inhibition of DNA and RNA synthesis, inhibition of protein synthesis and induction of heat shock protein (4-7). It is highly cytotoxic to many types of cells, such as hepatocytes, mammalian fibroblasts and Ehrlich ascites tumor cells (8-11); it shows inhibitory effects on cell proliferation as well as mutagenic effects (12,13). HNE may be one of the putative "second toxic messengers" (4,6) of peroxidation in cellular membranes, thereby providing the amplification that lipid peroxidation delivers for the initial free radical attack.

A number of methods have been applied to detect HNE in biological systems. The first to be developed (1,14) employed the commonly used aldehyde-derivatizing agent, 2,4-dinitrophenylhydrazine (DNPH) to stabilize the otherwise volatile HNE and to facilitate its detection both in a preliminary purification stage using thin-layer chromatography (TLC) and during its separation using high-performance liquid chromatography (HPLC) with ultraviolet (UV) detection at 378 nm (molar absorptivity of the DNPH derivative = 25000-28000, λ = 360-380 nm). A method for the HPLC determination of free HNE has also been described (15). The detection limit of standard HNE is approximately 2 pmol and that in biological samples is approximately 10 pmol/mg protein. Another HPLC method (16) employs derivatization with a fluorescent reagent (1,3-cyclohexanedione), but in our experience, the lack of a purification stage renders the HNE peak hardly distinguishable in chromatograms of biological samples. A very recent method (17) employing TLC densitometry to quantify aldehydes using the two derivatizing agents described above is limited by its low sensitivity. Various determinations of free HNE using gas chromatography/mass spectrometry (GC/MS) have also been reported (18-20). These are extremely sensitive and specific, but place a heavy burden on resources.

In order to overcome these problems of sensitivity or cost, we have modified the early DNPH derivatization method and employed electrochemical detection to improve the detection limit. This procedure has enabled us to measure HNE in very small biological samples, in both *in vivo* and *in vitro* experiments.

MATERIALS AND METHODS

Chemicals. Chemically synthesized 4-hydroxynonenal was a gift from H. Esterbauer, Department of Biochemistry, University of Graz, Graz, Austria. 2,4-Dinitrophenylhydrazine (analytical grade) was from Merck (Darmstadt, Germany). Dichloromethane, chloroform, benzene, *n*-hexane and methanol (all HPLC grade) were from Baker (Phillipsburg, NJ).

DNPH derivatization. DNPH derivatization of HNE essentially followed the procedure of Benedetti *et al.* (21). Samples obtained from *in vivo* and *in vitro* experiments were immediately reacted with an equal volume of DNPH reagent (pellets of approximately 10 million cells were derivatized with 2 mL of reagent). The reaction was carried out in the dark for 2 h at room temperature. The DNPH reagent was freshly prepared by dissolving 50 mg of DNPH in 100 mL of 1 N HCl, and the reagent was extracted twice with 50 mL of hexane to remove impurities. The reaction mixture (sample plus DNPH reagent) was

[1]During the course of these studies, Dr. Goldring was on leave from Division of Biochemistry, UMDS Guy's Hospital, London SE1 9RT, UK.

Abbreviations: DMEM, Dulbecco's Modified Eagle's Medium; DNPH, 2,4-dinitrophenylhydrazine; ED, electrochemical detection; EDTA, ethylenediaminetetraacetic acid; GC/MS, gas chromatography/mass spectrometry; HNE, 4-hydroxy-*trans*-2-nonenal; HNE-DNPH, 2,4-dinitrophenylhydrazone of 4-hydroxynonenal; HPLC, high-performance liquid chromatography; MDA, malondialdehyde; PBS, phosphate buffered saline; TBA, 2-thiobarbituric acid; TLC, thin-layer chromatography; UV, ultraviolet.

extracted three times with 3 vol of dichloromethane. The pooled extracts were dried under N_2 and redissolved in 200 μL of chloroform. The sample was then subjected to a purification procedure using either TLC or solid phase extraction. The DNPH derivatives (including the HNE-DNPH) were recognizable during these procedures because of their intense yellow color.

TLC purification. The sample was applied to a TLC plate (20 cm × 20 cm × 0.2 mm, silica gel pre-coated, obtained from Merck) and developed twice with dichloromethane (5 cm) and once with benzene (9 cm) (21). Standard HNE-DNPH was run along either end of the plate. The area corresponding to standard HNE-DNPH, together with material migrating at a higher R_f up to unreacted DNPH, was scraped off and eluted three times with 2 mL of methanol. The methanol extracts were pooled, dried under N_2 and redissolved in methanol (200 μL) prior to HPLC analysis.

Purification by solid phase extraction. The sample was applied to a disposable silica gel extraction column (3 mL vol, Baker) which had been preequilibrated with *n*-hexane/chloroform (2:1, vol/vol). The same solvent mixture (approximately 10 mL) was used to wash off the highly lipophilic DNPH derivatives in the sample in a discrete band. The remaining material (including the HNE-DNPH) was eluted using chloroform (approximately 6 mL). The chloroform extract was evaporated under N_2 and redissolved in methanol (200 μL) prior to HPLC analysis.

HPLC analysis. The separation of the HNE-DNPH derivative was performed using reverse-phase HPLC. A C18 column (5 nm Ultrasphere; 25 cm × 4.6 mm i.d.; Beckman Instruments Inc., San Ramon, CA), protected by a C18 precolumn (Guard-Pak, Millipore, Milano, Italy), was used. The mobile phase, a mixture of 30 mM sodium citrate/27.7 mM acetate buffer, pH 4.75, with three volumes of methanol, was delivered isocratically at 1.0 mL/min, using a Beckman (Palo Alto, CA) HPLC pump, model 114 M. Dinitrophenylhydrazones, including HNE-DNPH, were detected using an ESA model 5100A Coulochem detector linked to an ESA model 5011 analytical cell (ESA Inc., Bedford, MA). A potential of +0.3 V was used at the upstream (screening) electrode; the downstream (detecting) electrode was set at +0.8 V. These potentials were found in preliminary experiments as the most suitable conditions for maximal detector yield of HNE-DNPH together with maximal screening. Standards and samples were injected using a Rheodyne syringe loading injector model 7125 (Rheodyne, Cotati, CA) fitted with a 6-μL loop. The identification of HNE-DNPH was made on the basis of the retention time of standard HNE-DNPH, as well as on the basis of the coelution test performed by adding HNE-DNPH to biological samples. Quantitation of the HNE-DNPH derivative in standards and samples was done by measurement of peak height.

In vivo *experiments.* Male NMRI albino mice (Charles River, Como, Italy) weighing 20–30 g were used. The animals were maintained on a complete pellet diet (Altromin-Rieper, Bolzano, Italy). They were starved overnight before intoxication. CCl_4, $BrCCl_3$ or bromobenzene was administered intragastrically under light anesthesia, at the dose of 26, 26 and 15 mmol/kg body wt, respectively. Bromobenzene had been pre-mixed with two volumes of mineral oil. Control animals were given an equal volume of mineral oil. The animals were sacrificed 2, 3 and 12 h after intoxication, respectively. Liver homogenates (20%) were prepared in 0.154 M KCl/3 mM ethylenediaminetetraacetic acid (EDTA) (pH 7.4), and aliquots were taken for DNPH-derivatization, estimation of malondialdehyde (MDA) with 2-thiobarbituric acid (TBA; ref. 22), and protein determination (23).

In vitro *experiments.* Rat liver microsomes were prepared and allowed to peroxidize in a NADPH/Fe-dependent system as described by Benedetti *et al.* (24). Two concentrations (6 and 60 μM) of $FeSO_4$ were used to promote lipid peroxidation. At the times indicated, 1.5 mL of the mixture was removed for DNPH derivatization, and 1.0 mL was removed for MDA estimation. An aliquot was also removed for protein determination.

Baby hamster kidney fibroblasts transformed using polyoma virus (BHK-21/Py Y) (25) were routinely grown at 37°C in Dulbecco's modified Eagle's medium (DMEM) (Gibco Products Ltd., Uxbridge, United Kingdom), containing 10% (vol/vol) fetal calf serum (Flow Laboratories Ltd., Irvine, United Kingdom), under an atmosphere of air containing 5% CO_2. No evidence of mycoplasmal contamination was found by staining with bisbenzamide (Hoechst 33258, Sigma, Poole, United Kingdom). The cells were grown to near confluency in 80-cm^2 culture flasks (Nunc, Roskilde, Denmark) and washed twice with DMEM. Half were subjected to prooxidant stress, induced by a Fe^{3+}/ADP-containing medium (374 μM $FeCl_3$/10 mM ADP dissolved in DMEM) for two hours. DMEM alone was used as the medium for the remaining control monolayers. The prooxidant and the control media were then removed from the monolayers, which were washed twice with DMEM, trypsinized, washed once in phosphate buffered saline (PBS), suspended in PBS and counted using a Coulter counter (Coulter Electronics Ltd., Luton, United Kingdom). The cell suspension was then centrifuged, and the cell pellet was derivatized using the DNPH reagent.

RESULTS AND DISCUSSION

Figure 1 shows a typical chromatogram of standard HNE-DNPH revealed by electrochemical detection (ED). The detection limit for standard HNE-DNPH was 15 fmol (with a signal-to-noise ratio of 4). Thus the sensitivity of this method seems to be far greater than that of other methods (with the exception of GC/MS) employed to measure HNE. We found good proportionality between the amount of HNE-DNPH injected onto the column and the detector response. A typical calibration curve is shown in Figure 2.

We then applied this HPLC-ED method to biological samples obtained from *in vivo* and *in vitro* systems. The original method of Benedetti *et al.* (1) describes a sample purification using TLC. Because of the notoriously low recovery of analytes separated by TLC, we initially developed an alternative purification procedure for our *in vivo* samples, which utilized solid phase extraction with silica gel columns. This procedure was also considered to be more convenient and less time-consuming than TLC. Therefore, it was used for the determination of HNE in liver samples obtained from CCl_4, $BrCCl_3$ or bromobenzene intoxicated mice. Figure 3 shows representative chromatograms for control and CCl_4 intoxicated hepatic samples. As can be seen in Table 1, the highest levels of HNE were found in bromobenzene hepatotoxicity (in

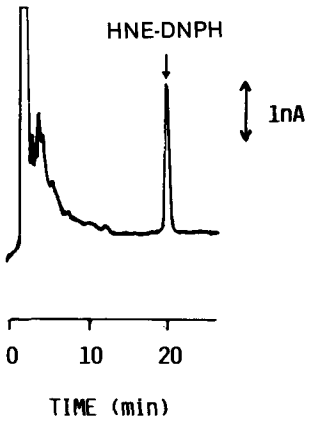

FIG. 1. High-performance liquid chromatography elution profile of standard 2,4-dinitrophenylhydrazone of 4-hydroxynonenal (HNE-DNPH) (0.5 pmol) with electrochemical detection. A C18 reverse phase column was used. Mobile phase, methanol/30 mM sodium citrate/27.7 mM acetate buffer, pH 4.75 (75:25, vol/vol) delivered isocratically at 1.0 mL/min. The HNE-DNPH was dissolved in methanol. A screening potential of +0.3 V and a detecting potential of +0.8 V were used.

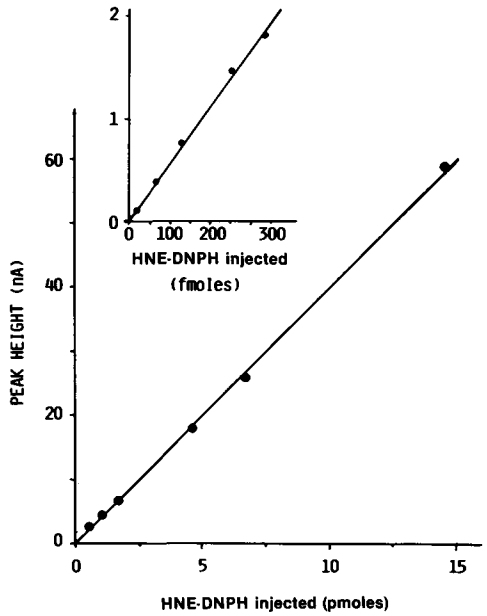

FIG. 2. Calibration curve of standard 2,4-dinitrophenylhydrazone of 4-hydroxynonenal (HNE-DNPH) by high-performance liquid chromatography (HPLC) with electrochemical detection. HPLC analysis was carried out as described in Figure 1.

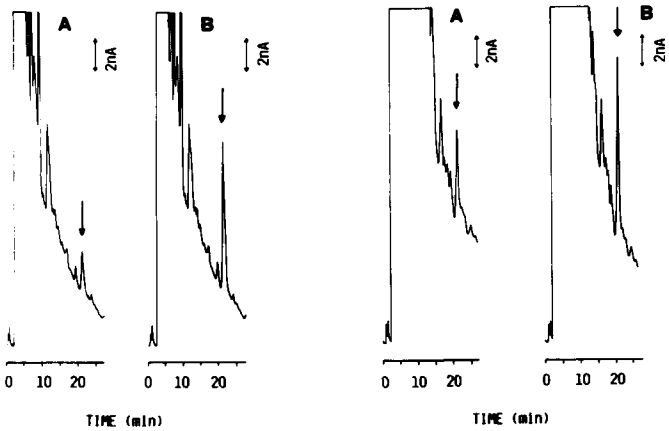

FIG. 3. Left: High-performance liquid chromatography (HPLC) analysis with electrochemical detection of (A) a liver extract from a control mouse (3.4 pmol 4-hydroxy-*trans*-2-nonenal (HNE)/mg protein), and (B) the same extract to which standard 2,4-dinitrophenylhydrazone (HNE-DNPH) had been added. Right: HPLC analysis with electrochemical detection of (A) a liver extract from a CCl_4 intoxicated mouse (7.8 pmol HNE/mg protein), and (B) the same extract to which standard HNE-DNPH was added. The HNE-DNPH peaks are indicated by arrows. Samples derived from a portion of liver corresponding to approximately 0.2 mg of protein were injected.

TABLE 1

Hepatic Concentrations of HNE and MDA in Control and CCl_4, $BrCCl_3$ or Bromobenzene Intoxicated Mice[a]

Treatment	(n)	HNE (pmol/mg protein)	MDA (pmol/mg protein)
Control	6	4.5 ± 0.7	18 ± 3
CCl_4	3	11.3 ± 0.7	33 ± 7
$BrCCl_3$	3	26.2 ± 3.8	40 ± 4
Bromobenzene	3	90.6 ± 19.3	1251 ± 420

[a]HNE was determined by high-performance liquid chromatography with electrochemical detection. MDA was determined with thiobarbituric acid. The animals were intoxicated and sacrificed at different times as described in Materials and Methods. Results are means ± SE. Abbreviations: HNE, 4-hydroxy-*trans*-2-nonenal; MDA, malondialdehyde.

agreement with our previous results; ref. 21) and the lowest in CCl_4 and $BrCCl_3$ hepatotoxicity. The basal levels of HNE measured by this method in normal livers are quite similar to that reported by others (20,26) and a little lower than that reported by Yoshino *et al.* (27). Data on the hepatic content of MDA are also reported here for comparison. Although the production of HNE is lower as compared to that of MDA, it must be considered, as is known, that HNE is a much more specific product of lipid peroxidation.

As stated in the Materials and Methods, the identification of the HNE-DNPH peak was done on the basis of the retention time of the standard (Fig. 4) and on the basis of the coelution test (Fig. 3). Further evidence for the identification of HNE-DNPH was obtained by comparing the modifications of the peak of standard HNE-DNPH (Table 2) and of putative HNE-DNPH in biological samples (Table 3), following changes in oxidative potential. Tables 2 and 3 show that the changes in the two peaks were very similar when the oxidative potential was varied.

Figure 5 shows the results of an *in vitro* experiment in which liver microsomes were allowed to peroxidize in a NADPH/Fe^{2+}-dependent system (with 6 or 60 μM $FeSO_4$). In both cases an exponential increase of HNE was observed during the incubation, and this was paralleled by an increase in MDA. The molar ratio of HNE/MDA was 1:5–10 in the system in which lipid peroxidation was induced by the lower amount of iron (6 μM), and 1:20–40 in the system in which lipid peroxidation was

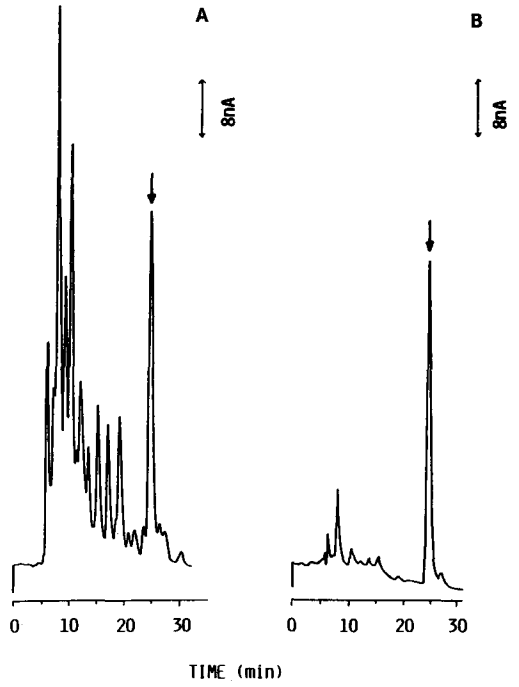

FIG. 4. High-performance liquid chromatography analysis with electrochemical detection of (A) a liver extract from a bromobenzene intoxicated mouse (66 pmol 4-hydroxy-*trans*-2-nonenal/mg protein). A sample derived from a portion of liver corresponding to approximately 0.2 mg of protein was injected. Standard 2,4-dinitrophenylhydrazone (HNE-DNPH) is shown in (B) for comparison of retention time. The HNE-DNPH peaks are indicated by arrows.

TABLE 2

Changes in the Response of the Electrochemical Detector with Changes in the Oxidative Potential Applied to Standard HNE-DNPH[a]

Detector potential	Detector response (nA) on injection of 20.6 pmol HNE	% of response at +0.8 V
+0.80	80	100
+0.75	73	91
+0.70	55	69

induced by the higher amount of iron (60 μM). Thus the ratio of HNE/MDA was higher when there was a lower degree of lipid peroxidation. The reason for such a difference is presently under investigation. Nevertheless, in the *in vivo* experiments too, a similar change in the ratio HNE/MDA was observed with different extents of lipid peroxidation (Table 1).

When very low levels of HNE were to be measured, in some samples the solid phase extraction for the purification step was found to be insufficient to remove material that interfered with the detection. Therefore it was considered necessary to revert to the TLC method to purify such samples. Using the procedure described in Materials and Methods (*i.e.*, scraping a broader area than that strictly corresponding to standard HNE-DNPH), we have obtained recoveries of HNE-DNPH added to rat liver

+0.70	52	63

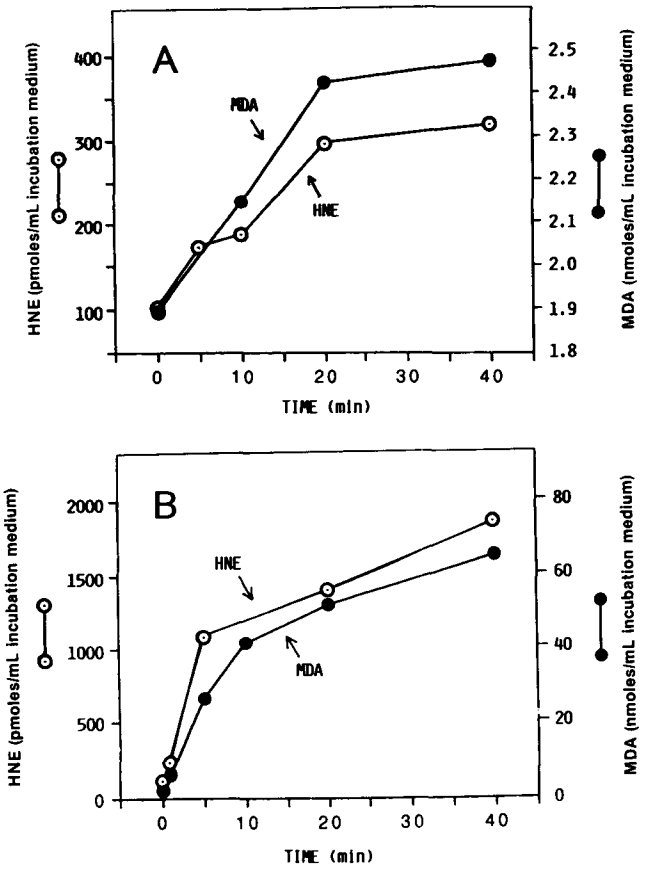

FIG. 5. Time-course of formation of 4-hydroxy-*trans*-2-nonenal (HNE) and concomitant evolution of malondialdehyde in liver microsomes peroxidized in the NADPH/Fe-dependent system. The incubation mixture was composed of microsomes derived from 250 mg liver (or 5 mg protein)/mL, 0.15 M KCl, 0.05 M tris-maleate buffer, pH 7.4, 6 or 60 μM $FeSO_4$, and an NADPH-generating system (0.1 mM NADP, 5 mM $MgCl_2$, 2.5 mM nicotinamide, 3 mM DL-isocitrate and 0.1 μM units/mL isocitrate dehydrogenase) (Boehringer Mannheim, Milano, Italy). (A), 6 μM $FeSO_4$; (B) 60 μM $FeSO_4$. MDA, malondialdehyde.

homogenates of 90 ± 8.5% (n = 6). This compares favorably with the usual virtually complete recoveries from solid phase extraction. The recovery of non-derivatized HNE added to the buffer alone (0.154 M KCl/3 mM EDTA, pH 7.4) and processed the same as liver homogenates or microsomal suspensions was 87 ± 2.8% (n = 4) when TLC purification was used, and almost complete (97%, mean of two samples) when the solid phase extraction was utilized. When HNE was added to liver

TABLE 4

Levels of HNE in Cultured BHK-21/PyY Cells Subjected to Oxidative Stress Induced by Fe^{3+}/ADP[a]

Treatment	HNE (pmol/million cells)
Control	1.96
$+Fe^{3+}$/ADP	7.84

[a]BHK-21/PyY cells were grown to near confluency in DMEM containing 10% fetal calf serum washed with DMEM, and then subjected to oxidative stress by adding DMEM containing 374 μM $FeCl_3$ and 10 mM ADP. DMEM alone was added to control cultures. Abbreviations: HNE, 4-hydroxy-*trans*-2-nonenal; DMEM, Dulbecco's Modified Eagle's Medium.

homogenates before the derivatization step, the recovery was much lower (nearly 40%), whatever purification procedure was used. This was very likely due to the quick binding of the aldehyde to biological components, as has also been noted by others (26).

TLC was used to purify samples obtained from cell culture experiments. The results of such measurements on control and oxidatively stressed fibroblasts are shown in Table 4. This indicates the suitability of the HPLC-ED method for the investigation of HNE in small *in vitro* samples such as are commonly obtained in cell culture work.

In summary, we have developed a sensitive method for the analysis of HNE in biological samples. The lowest amount of HNE which can be measured is 0.5–1 pmol per injected sample. In the *in vivo* studies, the injected samples were derived from a portion of liver corresponding to approximately 0.2 mg protein. Thus tissue samples much smaller than those used in our previous study (liver corresponding to 5 mg protein; ref. 21) can be analyzed. The method appears particularly suited, for example, to the measurement of endogenous levels of HNE under circumstances in which low levels of lipid peroxidation have occurred, or when the sample size is small (*e.g.*, in microassays, cell culture work or biopsy samples).

Regiospecific Analysis of Triacylglycerols Using Allyl Magnesium Bromide

Claus C. Becker*, Annemette Rosenquist and **Gunhild Hølmer**
Department of Biochemistry and Nutrition, Technical University of Denmark, DK-2800 Lyngby, Denmark

A method for the regiospecific analysis of triacylglycerols (TAG), using the Grignard reagent allyl magnesium bromide (AMB) to partially deacylate TAG, is described. 1,3-Distearoyl-2-oleoyl-glycerol (SOS) and 1,3-didecanoyl-2-palmitoyl-glycerol (CPC) were reacted with AMB. From the resulting mixture, the four different classes of partial acylglycerols and TAG were isolated, and the mole ratios between stearic acid and oleic acid, or decanoic acid and palmitic acid, respectively, were determined in each fraction. Different approaches of calculating the composition of the fatty acids in positions *sn*-1(3) and *sn*-2 of the original TAG were compared. For the *sn*-2 position, the best estimate was the direct determination of the fatty acid composition of 2-monoacylglycerol (MAG). Mole percentages of stearic acid and decanoic acid in the *sn*-1(*sn*-3) positions of SOS and CPC, respectively, were most accurately estimated from the fatty acid compositions of TAG and 2-MAG according to the formula: $1.5 \times \text{TAG} - 0.5 \times 2\text{-MAG}$. Using AMB and the present method of calculation, the results obtained were more accurate and showed smaller standard deviations than those obtained using other common deacylating agents, such as ethyl magnesium bromide or pancreatic lipase.
***Lipids* 28, 147-149 (1993).**

The distribution of fatty acids between the primary and secondary positions in triacylglycerols (TAG) can be determined either after pancreatic lipase degradation or after chemical degradation using a Grignard reagent (1,2). Both methods are based on the assumption that partial deacylation of TAG leads to representative mixtures of diacylglycerols (DAG) and monoacylglycerols (MAG), which can be characterized by chromatographic analysis. These methods, however, have certain limitations. The lipase assay is not reliable for TAG which contain significant amounts of short- or medium-chain fatty acids (C_{10} or less) or very long-chain polyunsaturated fatty acids (PUFA) (1). Milk fat, for instance, will not give representative acylglycerols as short- and medium-chain fatty acids are more readily hydrolyzed by the pancreatic lipase than are long-chain fatty acids (2). Some PUFA, on the other hand, have been reported to resist hydrolysis by lipase (3-5); therefore, marine oils should not be analyzed by the lipase assay either.

The reaction of TAG with ethyl magnesium bromide (EMB) can be used to obtain representative mixtures of DAG (6). However, the MAG are easily isomerized and cannot be used for regiospecific analysis of TAG. Therefore the mole percentages of the fatty acids in the *sn*-1(*sn*-3) and *sn*-2 positions are calculated from the composition of TAG and 1,2(2,3)-DAG. In the present communication it is shown that the more reactive Grignard reagent allyl magnesium bromide (AMB) yields representative 2-MAG, allowing the composition of the native TAG *sn*-2 position to be determined directly. The composition in the *sn*-1(*sn*-3) position can then be estimated from the composition of 2-MAG and TAG. The estimates obtained using AMB compare favorably to those found using EMB as they come closer to the theoretical value and have smaller standard deviations.

MATERIALS AND METHODS

1,3-Distearoyl-2-oleoyl-*sn*-glycerol (SOS) (99%+) was purchased from Sigma Chemical Company (St. Louis, MO). 1,3-Didecanoyl-2-palmitoyl-*sn*-glycerol (CPC) was synthesized according to Redgrave *et al.* (7). The structure of 1,3-didecanoyl-*sn*-glycerol was verified by ^{1}H nuclear magnetic resonance. Silicic acid 60G thin-layer chromatography (TLC) plates (Merck, Darmstadt, Germany) impregnated with boric acid were used for separation of the different acylglycerol species resulting from the action of AMB on TAG. The plates were prepared by spraying with a 0.4 M aqueous boric acid solution until saturated. Then, the plates were dried at room temperature overnight and kept in a desiccator over a drying agent. Diethyl ether, analytical grade, was redistilled immediately before use. During distillation, the ether was protected from the moisture by a $CaCl_2$-tube. AMB in diethyl ether (2M) was synthesized according to Gilman and McGlumphy (8). Methanol and hexane were high-performance liquid chromatography-grade and obtained from Rathburn Chemicals (Walkerburn, Scotland). Anhydrous Na_2SO_4, 37% HCl (aq.), and boric acid were purchased from Merck. Na_2SO_4 was dried at 130°C for at least 4 h before use. Dichlorofluorescein and tripalmitoylglycerol were from Sigma.

The TAG to be analyzed (6.0 to 6.5 mg) was dissolved in diethyl ether (5 mL) in a Teflon capped reaction tube with magnetic stirring. AMB (200 μL) was added with a pipette that had been flushed with nitrogen; the diethyl ether solution became opaque, indicating a spontaneous reaction. After one minute, additional diethyl ether (5.0 mL) was added. Then the organic phase was washed, first with an acidic buffer (4.0 mL) prepared by adding 37% HCl (1.0 vol) to a 0.4 M boric acid solution (36 vol) giving a final concentration of 0.27 M. This neutralized the $Mg(OH)_2$ formed in the reaction mixture upon addition of water. Additional washings (2×4.0 mL) with a 0.4 M boric acid solution removed excess HCl and remaining magnesium salts. The ether phase was dried briefly with about 2 g of anhydrous Na_2SO_4 before being decanted and evaporated *in vacuo*. The acylglycerol mixture was redissolved in chloroform (400 μL).

The chloroform solution was applied to a boric acid impregnated TLC plate which was developed in chloroform/acetone (96:4, vol/vol) in a saturated chamber. The fractions were visualized by spraying with 2,7-dichlorofluorescein (0.1% wt/vol) in anhydrous ethanol. The following bands were observed: 1,3-MAG ($R_f = 0.12$); 2-MAG ($R_f = 0.20$); 1,2(2,3)-DAG ($R_f = 0.50$); 1,3-DAG ($R_f = 0.62$);

Abbreviations: AMB, allyl magnesium bromide; CPC, 1,3-didecanoyl-2-palmitoyl-*sn*-glycerol (10:0/16:0/10:0); DAG, diacylglycerol; EMB, ethyl magnesium bromide; MAG, monoacylglycerol; PUFA, polyunsaturated fatty acid; SOS, 1,3-distearoyl-2-oleoyl-*sn*-glycerol (18:0/18:1/18:0); TA, tertiary alcohols; TAG, triacylglycerol, TLC, thin-layer chromatography.

tertiary alcohols of the deacylated fatty acids (TA) (R_f = 0.70); and TAG (R_f = 0.82). All bands except TA were scraped off. The acylglycerols were extracted from the silicic acid with diethyl ether (2 × 2 mL). After brief centrifugation, the ether was decanted and evaporated under a stream of N_2. The residue was methylated using the alkaline transesterification procedure described by Christie (9). The methyl esters from SOS were analyzed on a Hewlett-Packard (Palo Alto, CA) Gas Chromatograph HP 5890A, equipped with a flame-ionization detector, using a HP 7673A Automatic Sampler. The fused silica column (30 m in length and 0.32 mm i.d.) coated with SP2330 (film thickness 0.25 μm) was from Supelco (Bellefonte, PA). A helium flow rate of 34 mL/min and a split ratio of 1:20 were used. The temperature of the oven was initially 140°C and was increased at a rate of 3.0°C/min until the final temperature (200°C) was reached. The methyl esters from CPC were analyzed on a Hewlett-Packard Gas Chromatograph HP 5830A equipped with a flame-ionization detector and a column (2.75 m × 2 mm) containing 10% SP 2330 on 100/120 Chromosorb WAW (on column injection) using an HP 7671A automatic sampler. A flow rate of 40 mL helium/min was employed. After the injection of a sample, the column was maintained at 100°C for 4 min before the temperature was increased to 220°C at a rate of 8°C/min. In both gas chromatographs the detector and the injector were maintained at 250°C.

The composition of the partial acylglycerols was calculated based on relative integrated peak area obtained by gas chromatography for the pure triacylglycerols.

RESULTS AND DISCUSSION

The results of the analyses of the partial acylglycerols obtained after AMB degradation of SOS and CPC, respectively, are shown in Table 1.

For SOS, the stearic acid accounted for more than 98% of the total fatty acids in the 1,3-DAG and only 2.4% of the total fatty acids in the 2-MAG, showing that a representative mixture of partial acylglycerols was obtained. In the 1(3)-MAG from SOS, oleic acid originating from isomerized 2-MAG comprised 6.8% of the fatty acids. The presence of stearic acid (54%) in 1,2(2,3)-DAG may correspondingly be explained by minor isomerization of 1,3-DAG. The remaining TAG are still representative as shown by the presence of 66.7% stearic acid.

For CPC, the 2-MAG was only contaminated with decanoic acid to an extent of 1.2%. The 1(3)-MAG, on the other hand, contained 7.7% palmitic acid which had migrated from the 2-position. As found for SOS, the diglycerides of CPC were slightly less pure.

For other TAG species, such as 1,3-dipalmitoyl-2-oleoyl-glycerol and 1,3-didecanoyl-2-stearoyl-glycerol, comparably low degrees of migration for 2-MAG and 1,2(2,3)-DAG were observed (C.C. Becker, unpublished data).

The objective of a regiospecific analysis is to determine the fatty acid composition of positions *sn*-1(3) and *sn*-2 in the original TAG. This can be done by direct determination or by calculation based on the composition of the different acylglycerols, as demonstrated in Tables 2 and 3.

For both SOS and CPC the most accurate estimate for the composition of 1(3)-MAG was obtained by the formula: 1.5 × TAG − 0.5 × 2-MAG. The estimates were 98.8 ± 0.7 percent stearic acid in SOS and 99.4 ± 1.4 percent decanoic acid in CPC. For the 2-MAG obtained from the deacylation of TAG, only a low level of migration had occurred, and the composition of the 2-position could therefore be determined directly. During the synthesis of the TAG used in this investigation, a limited isomerization of the intermediate 1,3-DAG may have taken place. The values calculated for the *sn*-1(3) positions are therefore probably even less than one percent from the true value. For both 1(3)-MAG and 2-MAG it should be noted that the procedures giving the best estimates of the fatty acid composition in 1(3)-MAG and 2-MAG are also the procedures with the lowest standard deviation.

It is surprising that while the 1(3)-MAG resulting from the Grignard deacylation is slightly contaminated with former 2-MAG, the 2-MAG obtained appears to be almost completely representative. This could be explained by the greater stability of 1(3)-monoacylglycerols; thus an equilibrium mixture of monoolein in an aqueous system consists of about 90% of the 1-isomer and 10% of the 2-isomer (10).

When the EMB method is used, the composition of

[a]Abbreviations: See Table 1.
[b]Values are means ± SD for four experiments.
[c]The best estimate for the fatty acid composition of the *sn*-2 positions of the triacylglycerols.

sn-1(*sn*-3) and *sn*-2 is estimated from the composition of TAG and 1,2(2,3)-DAG. The equations employed are:

$$1(3)\text{-MAG} = 3 \times \text{TAG} - 2 \times 1,2(2,3)\text{-DAG} \quad [1]$$

$$2\text{-MAG} = 4 \times 1,2(2,3)\text{-DAG} - 3 \times \text{TAG (6)} \quad [2]$$

The results obtained with these equations are shown in Tables 2 and 3. The equations suggested for the EMB method showed larger standard deviations than the equations used with the AMB method due to larger factors and, in the case of 2-MAG, more terms. Furthermore, the results from the AMB method were closer to the theoretical value.

The possible discrimination between the primary and secondary positions in TAG by the present method was also examined, using 1,2,3-tripalmitoylglycerol. With 7% of the tripalmitin degraded, the ratio between 1(3)-MAG and 2-MAG, and between 1,2(2,3)-DAG and 1,3-DAG, respectively, approached the theoretical value of 2. This means that the positional discrimination was of minor importance, at least for palmitic acid. However, the calculations are based on mole% of fatty acid in each class of acylglycerol, and not the amount of these; therefore a certain positional discrimination will not influence the results obtained with the present method.

The amount of AMB added is theoretically enough to deacylate all ester bonds of about 250 mg of TAG. That only a minor proportion of the TAG was deacylated is partly due to the content of azeotropic water in ether. The amount of water should be minimized as it increases the polarity of the solvent, and hence, in principle, the rate of acyl migration. Therefore, an excess of AMB must be added to compensate for the reaction with the water present. This reaction produces magnesium salts which further increases the polarity of the solvent. In order to minimize isomerization, boric acid is added to the washing solutions (11).

In conclusion, the method presented offers a fast and simple way to carry out regiospecific analyses of triacylglycerols. Sample sizes of about 6 mg were used, but smaller amounts (2 mg) can also be analyzed. This makes the method well suited for biological samples. The method can be used for most fats, including those for which the pancreatic lipase assay is unreliable. The results obtained are also more accurate and have smaller standard deviations than when EMB is used. In our laboratory the AMB method has proven to be particularly useful for the analysis of triacylglycerols, such as marine oils, that contain long-chain polyunsaturated fatty acids and for seed oils that contain medium-chain fatty acids (C_8–C_{12}).

Microplate Methods for Determination of Serum Cholesterol, High Density Lipoprotein Cholesterol, Triglyceride and Apolipoproteins

Rachel B. Shireman* and **Janine Durieux**
Food Science and Human Nutrition Department, and Center for Nutritional Sciences, University of Florida, Gainesville, Florida 32611

Microtiter plate methods were developed for the enzymatic determination of serum total cholesterol (TC), high density lipoprotein cholesterol (HDL-C) and triglyceride (TG), and for the turbidometric determination of apolipoproteins. The micromethods resulted in accurate, precise values that were in good agreement with the conventional spectrophotometric assays. The coefficient of variation for TC determinations was 4.5% or less and bias was 5% or less. The lipid micromethod assays are sensitive to 10 mg/dL or less, and the apolipoprotein assay to 1 mg/dL. Less than 100 μL of serum suffices for TC, TG and apoprotein assays; HDL-C requires an additional 100 μL of serum. Advantages of the micromethods include reductions in assay time and in the amount of reagents required.
Lipids 28, 151-155 (1993).

In studies requiring large numbers of samples for assay of serum lipids and apoproteins in duplicate or triplicate, time and cost of the assays become significant factors. In both clinical and research laboratories, serum total cholesterol (TC), high density lipoprotein cholesterol (HDL-C) and triglyceride (TG) assays are most often performed using "test sets or kits" supplied by commercial sources. The methods recommended by the National Cholesterol Education Program (NCEP) (1) are enzymatic assays which may be done by either manual or autoanalyzer procedures (2,3). Apolipoprotein quantification usually involves either antibody-based or other types of precipitation assays (4,5), electroimmunoassay (6) or immunonepholometric assays (7).

The advantages of micromethods for determination of serum lipid levels include the small sample size required and a great savings in terms of time and cost of reagents and reference standards. This paper describes the adaption of enzymatic and turbidometric "test set" methods to microprocedures for determination of serum TC, HDL-C, TG and apolipoproteins A-I, A-II and B.

MATERIALS AND METHODS

Total serum cholesterol. The test set (Procedure No. 1010) was purchased from Stanbio Laboratory, Inc. (San Antonio, TX). It is based on the principles of the procedures defined by Allain *et al.* (2) and Trinder (3). The standard procedure using this commercial test set involves mixing 1.0 mL reagent with 10 μL standard supplied with the test set, 10 μL serum, or 10 μL phosphate-buffered saline (PBS) for the blank, and incubating for 15 min at room temperature before reading the absorbance against the blank in a Beckman (Palo Alto, CA) DU-40 spectrophotometer. For comparison to the plate reader in the microassay, absorbance was read at 490 nm. Calculations were performed as described in the test set. To determine the validity of the microtiter plate method, dilutions of serum and standard with PBS were assayed with both the spectrophotometer and the microtiter plate reader, using 50 μL of the 1:5 diluted sample and 1 mL reagent. The cholesterol standard (200 mg/dL) was diluted 1:5 with the same solvent (ethyleneglycol monomethyl ether) in which the original standard was dissolved.

For the micromethod, 100 μL of the Stanbio cholesterol reagent were added to wells containing 10 μL of PBS, 10 μL 1:5 diluted calibration standards, 10 μL 1:5 diluted reference sera or 10 μL 1:5 diluted fresh human serum in ELISA plates (Corning Co., Corning, NY). Samples were run in sets of 3-5 using 2 separate dilutions. Reference sera, including both normal and elevated lipid levels, were obtained from the National Bureau of Standards (NBS; Gaithersburg, MD) and Fisher Diagnostics (Orangeburg, NJ). After mixing by shaking the plate gently and incubating at room temperature for 15 min, bubbles were eliminated with a gentle stream of nitrogen. Absorbance was read at 490 nm in a microplate reader with an automix feature (UVmax™, Molecular Devices Corp., Menlo Park, CA). The mean absorbance from 5 PBS blanks was subtracted from each reading to provide the final reading.

To determine whether the use of a single standard concentration was as accurate as the use of a calibration curve, the latter was constructed by dilution of the cholesterol standard (200 mg/dL) to concentrations of 80, 60, 40, 30, 20 and 10 mg/dL. Absorbance values of samples were used to calculate and compare concentrations derived from the linear regression of the calibration line to those calculated by using only the 40 mg/dL concentration.

HDL-Cholesterol. The commercial method was performed as outlined in the brochure accompanying the test kit and compared to the micromethod. The reagent is the same as that used in the TC assay. Stanbio HDL-Cholesterol Procedure No. 0599 was used. Five minutes after mixing 0.5 mL serum with 50 μL precipitating reagent (1M $MgCl_2$ in aqueous 1% dextran sulfate, M_r = 500,000 D) (8), samples were centrifuged for 10 min in a microcentrifuge at 11000 rpm. Fifty μL of the clear supernatant were mixed with 1.0 mL cholesterol reagent and treated as described above for TC.

For the micromethod, 100 μL serum samples or reference sera were mixed with 10 μL precipitating reagent and centrifuged as described above; 100 μL enzymatic reagent were added to 5 μL aliquots of the supernatant in the plate wells and handled as described for TC. Two separate precipitations were done per serum sample. Five μL aliquots of the diluted standard cholesterol solution (40 mg/dL) were run in 5 wells and 5 μL PBS were used in each blank.

Triglycerides. The Stanbio Enzymatic Triglycerides Procedure No. 2000 is a colorimetric method based on a procedure (9) involving hydrolysis of triglyceride and subsequent enzymatic phosphorylation and oxidation of the

Abbreviations: apo, apolipoprotein; CV, coefficient of variation; ELISA, enzyme linked immunosorbent assay; HDL-C, high density lipoprotein cholesterol; NBS, National Bureau of Standards; NCEP, National Cholesterol Education Program; PBS, phosphate-buffered saline; std, standard; TC, total cholesterol; TG, triglyceride.

liberated glycerol. The method was performed as outlined in the brochure accompanying the test kit, except that absorbance was read at 490 rather than 500 nm. The procedure is essentially identical to that for TC, using 10 μL of the standard, reference or sample sera and 1 mL reagent. For the microprocedure, 100 μL reagent were mixed with 10 μL of PBS, diluted standard, diluted reference or diluted sample sera in the plate wells and absorbance was read at 490 nm after 15 min. Values for samples and references were compared using a single standard (40 mg/dL) with those calculated from the linear reqression of the calibration curve.

Apolipoproteins. Test sets for the turbidometric determination of apolipoproteins A-I, A-II and B (apo A-I, apo A-II, apo B) were purchased from Boehringer Mannheim Biochemica (Indianapolis, IN). The assay is based on the spectrophotometric determination of the turbidity of the antigen-antibody reaction. It is essentially the same for each apoprotein, except for the specific antiserum. Briefly, antiserum was diluted 10-fold with the antiserum diluent as specified by the manufacturer. Samples and calibration sera were diluted with PBS. In the conventional method, 50 μL diluted serum or standard were added to 1.0 mL diluted antiserum, mixed and incubated at 25°C for 2.5 h. The test set procedure specifies absorbance reading at 365 nm, but this wavelength was unavailable in the microplate reader. As the spectrophotometric absorbances of standards at 405 and 365 nm were essentially identical, microplate reader absorbance was read at 405 nm.

In the micromethod, 5 μL of diluted calibration serum, serum samples or PBS were each combined in plate wells with 100 μL diluted antiserum and incubated at 25°C for 2.5 h. The calibration serum was diluted 10- to 80-fold for construction of the apo A-I standard curve and 5- to 40-fold for apo A-II and apo B. Sample and reference sera were diluted 1:10 for apo B and apo A-II and 1:20 for apo A-I determinations. Absorbance was determined at 405 nm in the microplate reader; the mean absorbance of five blanks was subtracted from the sample values. The concentrations of diluted samples were determined from the calibration curves, and these values were multiplied by the dilution factor in the final calculation.

Statistical analyses on calibration curves and replicate comparisons were by analysis of variance using the procedures of Minitab (copyright, Penn State Univ., PA) in the VAX computer.

RESULTS

Absorbance readings for TC, HDL-C and TG resulted in very similar values for each comparison when samples were prepared by the conventional test set procedure and read first in the spectrophotometer and then in the microplate reader. Preliminary experiments showed that a total volume of 110 μL per well in the microtiter plate was sufficient for accuracy. A comparison of the same samples indicated that there were no significant differences between cholesterol values obtained using 220 μL total volume *vs.* 110 μL (97 ± 2 mg/dL *vs.* 93 ± 4, respectively, n = 6). Therefore, 100 μL reagent and 10 μL diluted serum were used in the final recommended procedure.

Calibration curves developed for total cholesterol from representative assays are shown in Figure 1. Essentially

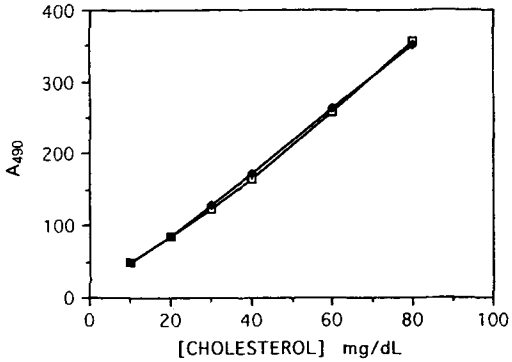

FIG. 1. Two typical cholesterol calibration curves. Two separate dilutions of a cholesterol standard were made as indicated in Materials and Methods and assayed by the micromethod. Absorbance was determined at 490 nm in a microplate reader. Five determinations provided the mean value for each point.

identical curves resulted from two replicates with five determinations each of a calibration standard (200 mg/dL) diluted on two separate occasions to 10, 20, 30, 40, 60 and 80 mg/dL. Precision was good as the intra-assay coefficient of variation (CV) for these values averaged 1.4% (range 1.0–1.6%), while the inter-assay CV was 2.8% (range 2.0–3.9%).

Similar values for each lipid class were obtained when comparing samples assayed by the conventional test set procedure to the same samples assayed by the micromethod (Table 1). The repeatability of the TC values from reference sera was good. The micromethod CV shown in Table 1 represents both inter- and intra-assay variation, as there were four determinations in each of two microassays; it ranged from 1–4.5%. The accuracy of the TC values, based on the "true" concentration given by the suppliers of the reference sera, ranged from 3.4–5%. In some assays, the conventional method provided slightly more accurate values; however, these were not significantly different from micromethod values ($P > 0.05$). Although there was good agreement between the values for HDL-C from both methods, the CV and bias for the micromethod were relatively large, up to 7.2 and 10.5%, respectively (Table 1). Likewise, there was no significant difference between the methods for TG, but deviations from the given "true" values ranged from 2–10%.

TC, HDL-C and TG values calculated from calibration curves were very similar to the values derived by using the absorbance of a single calibration standard (40 mg/dL) (Table 2). No significant differences were found between the mean values from the two methods. Because the calibration curve requires a number of plate wells, but offers no great advantage in accuracy of results, a single standard can be recommended.

The spectrophotometric assay for apoproteins resulted in the same value when the standard curve and sample were read at either 365 or 405 nm in the spectrophotometer. The values determined in the microplate reader at 405 nm for these conventional preparations were similar, and it was concluded that it was feasible to use the microplate reader (Table 3). Also, standards and samples prepared by the micromethod resulted in comparable values for apo B (Table 3), as well as for apo A-I and A-II (data

TABLE 1

Comparison of Conventional and Microplate Lipid Assays[a]

	Micromethod[b]	Conventional[c]	Reference[d]	CV (%)[e]	Bias (%)[f]
		Total cholesterol (mg/dl)[h]			
Serum[g]					
A	178 ± 3	179	172 ± 28	1.0	3.4
B	298 ± 8	304	309 ± 48	2.2	3.6
C	136 ± 8	140	141 ± 5	4.5	5.0
		HDL-C (mg/dL)[i]			
A	44 ± 4	41	48 ± 9	6.0	3.5
B	96 ± 8	91	87 ± 21	7.2	10.5
C	23 ± 2	22	—	7.0	—
		Triglyceride (mg/dL)[j]			
A	89 ± 4	92	100 ± 15	3.4	11.0
B	260 ± 7	253	261 ± 52	2.2	2.2
C	48 ± 2	53	—	3.7	—

[a]Each serum sample was diluted twice for two separate assays by each method.
[b]Values represent the mean ± SD of eight determinations by the microplate reader.
[c]Values represent the mean of four determinations (duplicates of two dilutions) in the spectrophotometer.
[d]Values were furnished by the suppliers of the reference sera.
[e]The coefficient of variation is a measure of the reproduciblity of the microassay.
[f]Bias is a measure of the accuracy of the microassay (variation from the true value).
[g]Serum A is a normal lipid level reference serum and serum B an elevated lipid level reference serum supplied by Fisher Diagnostics (Cinncinati, OH). Serum C is a normal level reference serum supplied by the National Bureau of Standards.
[h]For the microassay cholesterol concentration was calculated: Total Cholesterol (mg/dL) = $A_{sample}/A_{std} \times 40$ mg/dL $\times$ 5. The concentration of the diluted standard was 40 mg/dL; the factor 5 corrects for the 1:5 dilution of the serum sample. Concentration for the conventional method was calculated as specified in the test set: Total Cholesterol (mg/dL) = $A_{sample}/A_{std} \times$ [standard]. Std, standard.
[i]Microassay high density lipoprotein cholesterol = (HDL-C) values were calculated from the equation: HDL-C (mg/dL) = $A_{sample}/A_{std} \times 40$ mg/dL $\times$ 1.1, where 1.1 is the dilution factor for the precipitation step. Concentration for the conventional method was calculated as specified in the test set.
[j]Microassay TG values were calculated from the equation: Triglycerides (mg/dL) = $A_{sample}/A_{std} \times 40$ mg/dL $\times$ 5, where 40 is the concentration of the diluted standard and 5 is the factor for dilution of the sample. Concentration for the conventional method was calculated as specified in the test set.

not shown). Standard curves developed for the apoproteins are shown in Figure 2. Intra-assay variation was very small, but the inter-assay CV averaged approximately 4%. Values calculated from single standard determinations were not as satisfactory as those obtained from standard curves.

DISCUSSION

The TC, HDL-C, TG and apoprotein microassays described are sensitive, reliable, economical and rapid. The reagent for TC and HDL-C assays contains a combination of enzymes (peroxidase, cholesterol esterase and oxidase) and a chromogen. The intensity of the final color is proportional to the cholesterol concentration. The calibration curve was found to be linear to concentrations of 10 mg/dL for both cholesterol and TG. Even though a microplate reader is an expensive instrument, a 96 well plate can be read in approximately one minute. If three wells are used to provide the mean blank value, three for the standard, and three each for reference sera (normal and elevated lipids) for TC and HDL-C, the 78 remaining wells can accommodate 13 serum samples for TC and HDL-C in triplicate or 19 samples of each in duplicate. When large numbers of samples must be processed, it would be most economical to process TC and HDL-C together and triglycerides on a separate plate, as the blanks, standards and reference sera should be determined on each plate.

The dilution of standards and sera is the most critical part of the microassay as very small volumes are involved. The use of reference sera for TC and TG is strongly recommended for both research and clinical laboratories by the NCEP so that accuracy can be assessed (1). The NCEP has established criteria to minimize the CV and bias of TC assays with the hope that these can be reduced to 3% or less. In the present studies, the microassay values approached this goal with one set of reference standards, but we cannot explain why there was consistently greater bias (5%) with the reference serum from NBS. Interim recommendations of the NCEP Coordinating Committee have set bias for HDL-C at 10% or less and CV at 6% or less (10); these have been revised upwards from those criteria set in 1988 (1), because those goals were unrealistic given the current methods for HDL-C determinations. The CV and bias for HDL-C in the present study approached those now recommended. The NCEP

Conventional[a]		Microassay[b]	
A_{365}	78.0	A_{405} [1]	76 ± 3.4
A_{405}	78.5	A_{405} [2]	72 ± 2.5
		A_{405} [3]	75 ± 1.5

[a]Duplicate samples in a representative assay read in the spectrophotometer at both 365 and 405 nm.
[b]Mean ± SD of the same sample in a titer plate. Value for sample A_{405} [1] is the mean ± SD of values from four wells in which 5 μL diluted serum and 100 μL antiserum were mixed. A_{405} [2] represents the mean value of the conventional samples shown in the left column when the aliquots were dispensed into four wells. A_{405} [3] is the value obtained on four wells containing the same sample as [1] assayed on the following day with new dilutions of sample and standards.

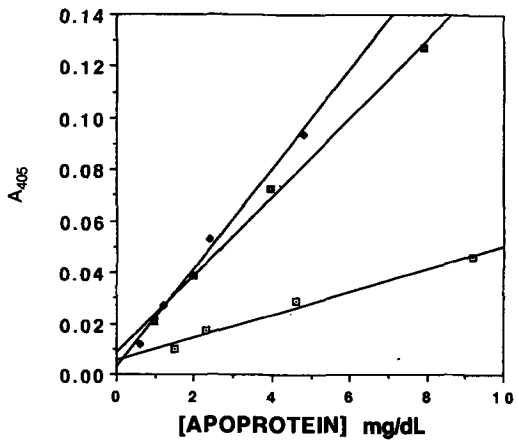

FIG. 2. Apoprotein calibration curves in a representative assay. The dilutions of both antisera and individual apoprotein calibration standards are described in Materials and Methods. Each point represents the mean of samples from duplicate microtiter plates: (open box with centered dot) apo A-II; (closed box) apo A-I; (closed box with centered dot) apo B.

has set 5% as the acceptable CV and bias for TG, thus our value of 11% bias using the Fisher Diagnostic normal reference does not meet the criterion. The values were well within the range of values stated by this supplier, however, and we attribute the large bias to the fact that the "true" value is based on a mean value determined from a number of different methods.

Several observations aided in developing these assays. Better results were obtained when the standard or serum sample was dispensed first on the bottom wall of the well before the addition of the 100 μL reagent. We did not find it necessary or more efficient to pretreat the wells with Tween 20, as reported by Belcher *et al.* (11) in their micromethod for lipid measurements in lipoprotein subfractions. The color of the TG sample is very stable and supplies identical values if read between 15 and 50 min. The TC and HDL-C microtiter plates should be read between 15 and 30 min. The micromethod using the turbidometric assay for apoproteins is not as sensitive as ELISA methods, but its sensitivity allows quantification in the range of a few mg per dL. Unlike the lipid assays, it seems advisable to use calibration curves for all apolipoprotein assays. The curve is not linear at concentrations higher than those used here; therefore if the absorbance of a sample is off the curve, the sample should be further diluted and reassayed. It is recommended by the manufacturer of the apoprotein test materials that each laboratory repeat the assay on two or more serum samples until a normal range of bias is established for the method.

COMMUNICATION

A Lack of Correlation Among Fatty Acids Associated with Different Lipid Classes in Human Milk

Richard M. Clark* and **Kenneth E. Hundrieser**
Department of Nutritional Sciences, University of Connecticut, Storrs, Connecticut 06269-4017

The fatty acids associated with triacylglycerol, cholesteryl ester, phosphatidylethanolamine, phosphatidylcholine and sphingomyelin in human milk were compared. Ten milk samples were selected for lipid class analysis based on their total lipid polyunsaturated/saturated fatty acid ratio (P/S ratio). The P/S ratio of the selected milk samples ranged from 0.3 to 0.8. Linoleic acid was the predominant fatty acid in milk to affect the P/S ratio. The percentage of linoleic acid in milk triacylglycerol was correlated ($r = 0.84$, $P < 0.05$) with the total milk lipid P/S ratio. Linoleic acid esterified to cholesterol was not correlated with total milk lipid P/S ratio but was correlated ($r = -0.66$, $P < 0.05$) with the quantity of lipid in the milk. Linoleic acid in the phospholipid classes did not correlate with shift in P/S ratio of the total milk lipid or linoleic acid content of other lipid classes.
Lipids 28, 157–159 (1993).

Lactating human mammary tissue secretes between 25 and 50 g of milk lipid per day. The major lipid classes in milk, which appear to remain proportionately constant, are the triacylglycerol (*ca.* 98%), phospholipids (*ca.* 1%) and cholesterol/cholesteryl esters (*ca.* 0.5%) (1). Although the phospholipids and cholesteryl esters are minor components of milk, they contain significant amounts of the long-chain unsaturated fatty acids required by the infant for synthesis of eicosanoids and structural lipids (2). These lipid classes are digested and absorbed differently than the milk triacylglycerols, and their fatty acids may have a different metabolic fate than the fatty acids from the triacylglycerols.

The purpose of this study was to make within-sample comparisons of the fatty acids associated with the major lipid classes in human milk. The fatty acids associated with the major lipid classes in breast milk have been identified and the literature recently reviewed by Jensen (3). Whereas most reports provide data on a limited number of lipid classes, a series of studies by Bitman *et al.* (4–6) provide information on fatty acids associated with the major lipid classes in breast milk from a group of mothers delivering prematurely and at full-term. From this literature it is known that there is a variation in fatty acids associated with all the lipid classes in breast milk. However, it is impossible to determine from the literature if there is any correlation between changes in fatty acids among the lipid classes. By comparing fatty acid composition of lipid classes within a milk sample, it is possible to determine how fatty acids associated with different lipid classes vary relative to each other.

Abbreviations: GLC, gas-liquid chromatography; P/S ratio, ratio of polyunsaturated to saturated fatty acids; PUFA, polyunsaturated fatty acid; TLC, thin-layer chromatography.

MATERIALS AND METHODS

Ten milk samples containing a wide range of unsaturated fatty acids were chosen for this study from an initial screening of approximately a hundred milk samples. The samples were complete breast expressions donated by mothers who had delivered full-term infants and had been lactating for at least a month. The general protocol for collection and subsequent handling of samples has been described (7).

On the day of analysis the milk samples were thawed to 38°C, homogenized, and a 15-mL aliquot was taken. The lipids then were extracted by a modified Folch procedure (8). Total lipid was determined by weighing the lipid extract. Preliminary separation of the polar and nonpolar milk lipids was on a column containing Unisil (Clarkson Chemical Co., Williamsport, PA) as recommended by Rouser *et al.* (9). The triacylglycerols and cholesteryl esters in the nonpolar fraction were isolated on silica gel G thin-layer chromatographic plates developed with hexane/diethyl ether/glacial acetic acid (90:30:2, by vol). When necessary, further purification of cholesteryl esters and triacylglycerols was achieved by a second plating on silica gel G plates developed with hexane/diethyl ether (95:5, vol/vol).

An aliquot of the triacylglycerols was used for structural analysis. The fatty acids esterified to the primary (*sn*-1,3) and secondary (*sn*-2) positions of the triacylglycerol were determined by digestion with pancreatic lipase (10). The residual triacylglycerols and *sn*-2 monoglycerols were isolated from the digestion mixture by thin-layer chromatography (TLC) on silica gel G plates containing 5% boric acid developed in chloroform/methanol (96:4, vol/vol).

The polar lipids were separated by the use of two TLC systems. First, the polar lipids were separated on silica gel G plates developed in chloroform/methanol/water (75:30:3, by vol). Phosphatidylcholine, phosphatidylethanolamine and sphingomyelin were eluted from the silica gel G and complete isolation obtained by a second plating on silica gel H. The second plating was developed in chloroform/methanol/acetic acid/water (25:15:4:2, by vol).

The fatty acids associated with triacylglycerol, *sn*-2 monoacylglycerol and cholesteryl esters were prepared for gas-liquid chromatography (GLC) by transmethylation with 2.5 N sodium methoxide (11). The fatty acids associated with the total polar lipids, sphingomyelin, phosphatidylcholine and phosphatidylethanolamine were transesterified in methanol/benzene (4:1, vol/vol) with acetyl chloride (12).

The methyl esters of fatty acids were separated by GLC on a Supelcowax 10 fused capillary column, 30 m × 0.53 mm i.d. (Supelco, Bellefonte, PA). Identification of fatty acids was based on the retention times of known fatty acids.

Statistical analyses included Pearson's correlation analysis and linear regression analysis among the fatty

acids in the different fractions and total milk polyunsaturated/saturated fatty acid ratio (P/S ratio) (13).

RESULTS AND DISCUSSION

The proportions of fatty acids in the three major phospholipid classes are shown in Table 1. There are relatively few values available on the fatty acid composition of phospholipids in breast milk, and the values in Table 1 are in general agreement with the literature (5,14). The range of unsaturated fatty acids in the total phospholipid fraction was 42–56%, with linoleic acid (*ca.* 22%) being the major polyunsaturated fatty acid (PUFA). A large proportion of the fatty acids were unsaturated in phosphatidylcholine (*ca.* 52%) and phosphatidylethanolamine (*ca.* 61%), and only 19% of the fatty acids in sphingomyelin were unsaturated. As previously reported, the major unsaturated fatty acid in sphingomyelin was nervonic acid (24:1), a fatty acid not observed in the other lipid classes (5). Linoleic acid was approximately 2% in sphingomyelin and arachidonic acid was not detected. The unsaturated fatty acids in the phospholipid classes were relatively constant and did not correlate with proportions of unsaturated fatty acids in the other major lipid classes in milk.

The total unsaturated fatty acids in the neutral lipid fraction containing cholesteryl esters and triacylglycerols had a range of 50–65%. The unsaturated fatty acids were 60% in triacylglycerols and 55% in cholesteryl esters (Table 2). Based on the literature, it appears that the fatty acids esterified to cholesterol in human milk are quite variable.

In previous reports, fatty acids of cholesteryl esters were reported to be more saturated (15,16), similar to (17,18) or less saturated (6) than the fatty acids of triacylglycerols. The primary difference in these reports was the values for linoleic acid esterified to cholesterol. Average

[a]Results are mean of 10 observations ± SD.
[b]Determined by digestion of triacylglycerol with pancreatic lipase.

cholesteryl linoleate in milk has been reported as 6.2% (16), 6.9% (15), 12.4% (17), 19.4% (18) and 30.6% (6). In this report, linoleic acid esterified to cholesterol ranged from approximately 9–30%, which encompasses most of the values from previous reports. The linoleic acid content of milk triacylglycerol ranged from 14 to 27%, which is not quite as great as that observed with the cholesteryl esters.

The fatty acids esterified to the *sn*-2 position of the milk triacylglycerol are presented in Table 2. Fatty acids are not randomly distributed among the positions of triacylglycerol. As observed in previous reports, 16:0 is found predominantly in the *sn*-2 position of the milk triacylglycerol, and the unsaturated fatty acids, 16:1, 18:1, 18:2 and 18:3, are found predominantly in the *sn*-1,3 position (14,19,20). Unlike the other unsaturated fatty acids, arachidonic acid and docosahexaenoic acid are also found predominantly in the *sn*-2 position. The predominance of arachidonic acid in the *sn*-2 position supports a previous report (20). The observation with docosahexaenoic acid, to our knowledge, has not been reported. However, this observation should be viewed with some caution as pancreatic lipase digestion was used for positional analysis and there is some debate about the relative activity of pancreatic lipase toward docosahexaenoic acid (21,22).

The total lipid in the milk samples used in this study ranged from 1.5 to 8.1 g/dL with a mean of 3.8 ± 2.4 g/dL SD. The samples had a P/S ratio that ranged from 0.3 to 0.8. Linoleic acid in the milk was the predominant fatty acid to affect the P/S ratio. When linoleic acid in the individual lipid classes is compared to the P/S ratio of the total milk lipid, different relationships are observed. As expected, linoleic acid content of milk triacylglycerol was correlated ($r = 0.84$, $P < 0.05$) with the P/S ratio of the total milk lipid. Linoleic acid content in both the primary and the *sn*-2 positions increase with the P/S ratio. The linoleic acid associated with the phospholipid [$r = -0.16$, (nonsignificant)] and cholesteryl ester ($r = 0.26$, ns) were not significantly correlated with whole milk P/S ratio. Rather than being related to the composition of fatty acids in the milk, the amount of linoleic acid esterified to cholesterol appears to be negatively correlated ($r = -0.66$, $P < 0.05$) with the quantity of lipid in the milk.

In this study, the milk phospholipids and cholesteryl esters contained substantial amounts of unsaturated fatty acids, but the fatty acids esterified to these lipid classes are not correlated with each other or with the amounts found in milk triacylglycerol. The phospholipids are part of the fat globule membranes in milk, and their composition appears to be closely maintained. The distribution of fatty acids esterified to cholesterol is more variable than observed with the phospholipids, and it may be affected by total milk lipid synthesis. The enzyme responsible for the esterification of fatty acids to cholesterol in milk has not been identified. The fatty acids esterified to the milk triacylglycerol make up the bulk of the fat globule core and may be most responsive to changes in the amounts of available fatty acids. This is supported by a previous observation that deuterium-labeled linoleic acid is incorporated into breast milk triacylglycerol, cholesteryl ester and phospholipid, but the influence of available linoleic acid on milk triacylglycerol is much greater than on milk cholesteryl esters and phospholipid (23).

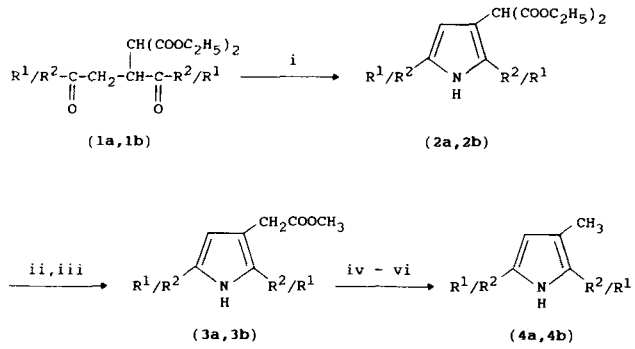
Synthesis of Trisubstituted C_{18} Pyrrole Fatty Ester Derivatives

Marcel S.F. Lie Ken Jie* and **K.P. Wong**
Department of Chemistry, University of Hong Kong, Hong Kong

Reaction of methyl 10(11)-dicarbethoxymethyl-9,12-dioxooctadecanoate (1a,1b) with ammonium acetate furnished a mixture of positional isomers of a pyrrole derivative, methyl 9,12-imino-10(11)-dicarbethoxymethyl-9,11-octadecadienoate (2a,2b). Decarboxylation of the mixture of compounds 2a,2b with sodium carbonate in aqueous methanol yielded a mixture of compounds 3a,3b containing a CH_2COOCH_3 group at the 3- or 4-position of the pyrrole ring after esterification. Heating of the hydrolyzed mixture of compounds 3a,3b at 180°C for 1 h gave the desired trisubstituted pyrrole derivatives, methyl 9,12-imino-10(11)-methyl-9,11-octadecadienoate (4a,4b), containing a methyl group at the 3- or 4-position of the pyrrole nucleus. The structures of the products and intermediates were confirmed by infrared, and by ^1H and ^{13}C nuclear magnetic resonance spectroscopy.
Lipids 28, 161–162 (1993).



where $R^1 = CH_3(CH_2)_5$; $R^2 = (CH_2)_7COOCH_3$; i) $(NH_4)_2CO_3$, AcOH; ii) Na_2CO_3, MeOH, H_2O; iii) BF_3/MeOH; iv) KOH, EtOH; v) HCl; vi) 180°C, 1 h.

SCHEME 1

We have recently reported a new synthetic approach for the introduction of a methyl group into the furan ring of a 2,5-disubstituted C_{18} furanoid fatty ester *via* a malonic acid function (1). The mechanism of the conversion of the CH_2COOCH_3 substituent to a CH_3 group, located at the 3- or 4-position of the furan ring in one of the intermediates, was postulated to be analogous to the decarboxylation process of α,β-unsaturated carboxylic acids (2). In continuing our study of this novel type of reaction, we have extended our investigation to include a pyrrole system. Fatty acid derivatives containing a pyrrole or *N*-methylpyrrole nucleus were obtained during the oxidative cleavage of the furan ring of furanoid fatty acids by lipoxygenase present in bovine liver homogenate when conducted at pH 7.5 and in using cofactors known to stimulate fatty acid oxidation (3). The synthetic route leading to the various trisubstituted pyrrole intermediates and products is presented in Scheme 1.

RESULTS AND DISCUSSION

As the primary objective was to study the feasibility of incorporating a methyl group into either the 3- or 4-position of a pyrrole ring *via* malonyl intermediates, no effort was made to develop synthetic methods to obtain regiospecific positional isomers. The synthesis of a regiospecific methyl substituted pyrrole fatty ester derivative was reported earlier by our group (4).

Treatment of methyl 10(11)-dicarbethoxymethyl-9,12-dioxooctadecanoate (**1a,1b**) with ammonium acetate yielded the pyrrole derivatives **2a,2b**, which contain a malonyl system at the 3- or 4-position of the pyrrole ring. The structure of the pyrrole system was characterized by the chemical shifts of the C-*H* and N-*H* protons of the *N*-heteroaromatic ring, which appeared at δ5.92 and 7.70, respectively.

Unlike the corresponding furan analogues, the ^{13}C nuclear magnetic resonance (NMR) chemical shifts of the ring C-2′ and C-5′ carbon nuclei of the pyrrole nucleus in compounds **2a,2b** were more shielded than those observed for the similarly positioned carbon nuclei in the furan. The shift of the C-2′ and C-5′ carbon atoms of the pyrrole ring appeared at the region of 127.9–130.8 ppm, while the shift of the C-2′ and C-5′ carbon atoms of the furan ring were found at 151.7–154.2 ppm.

Decarboxylation of one of the carboxylic acid groups in the malonyl moiety of compounds **2a,2b** was readily achieved when the mixture of compounds **2a,2b** was refluxed with sodium carbonate in methanol. Methylation of the decarboxylated product furnished compounds **3a,3b**. The presence of the CH_2COOCH_3 group in compounds **3a,3b** was confirmed by the singlet at δ3.38 for the shift of the methylene protons of the CH_2COOCH_3 substituent. When the hydrolyzed mixture of compounds **3a,3b** was heated at 180°C for 1 h, further decarboxylation took place to give the desired methyl substituted pyrrole derivatives (**4a,4b**). The methyl function attached to the pyrrole nucleus in compounds **4a,4b** was confirmed by the singlet at δ2.0 in the ^1H NMR spectrum and by the signal at 10.9 (pyrrole-CH_3) ppm in the ^{13}C NMR spectrum. The shift of the α-methylene carbon atoms located on either side of the pyrrole ring appeared at 25.8 and 27.7 ppm.

Pyrroles are generally more electrophilic than furans (5). This property of the *N*-heteroaromatic system appeared to accelerate the decarboxylation process during the conversion of the CH_2COOCH_3 substituent in compounds **3a,3b** to the CH_3 group in compounds **4a,4b**, which required heating at 180°C for only 1 h. In the case of the furan analogues of compounds **3a,3b**, conversion of the CH_2COOH to the CH_3 group required 4 h. From these results it can be concluded that the introduction of a methyl group into the ring of a pyrrole system *via* a malonyl group proceeds more readily than in the case of the corresponding furan analogue.

MATERIALS AND METHODS

Details of the chromatographic, analytical techniques and the method for the preparation of methyl 10(11)-dicarbethoxymethyl-9,12-dioxooctadecanoate (**1a,1b**) are described elsewhere (1).

*Synthesis of methyl 9,12-imino-10(11)-dicarbethoxymethyl-9,11-octadecadienoate (**2a,2b**).* A mixture of methyl 10(11)-dicarbethoxymethyl-9,12-dioxooctadecanoate (**1a,1b**, 1.0 g, 2.1 mmol), ammonium acetate (2.1 g, 27 mmol) and acetic acid (20 mL) was refluxed for 3 h. Water (50 mL) was added and the reaction mixture was extracted with diethyl ether (2 × 50 mL). The ethereal extract was washed with water (20 mL) and dried over anhydrous sodium sulfate. The mixture was filtered and the solvent was evaporated. Silica gel column chromatographic separation of the residue using a mixture of light petroleum/diethyl ether (7:3, vol/vol) as the eluant gave a mixture of methyl 9,12-imino-10(11)-dicarbethoxymethyl-9,11-octadecadienoate (**2a,2b**, 0.88 g, 90%) as an oil. Retardation factor (R_f) (light petroleum/diethyl ether, 3:2, vol/vol) 0.3; infrared (IR) (cm^{-1}) (film) 3387(*w*), 1738 (*s*), 1033(*m*); ^1H NMR ($CDCl_3$,) 0.88 (*t*, 3H, C*H*$_3$), 1.2–1.6 (*m*, 18H, C*H*$_2$), 2.31 (*t*, $J = 7$ Hz, 2H, 2-*H*), 2.52 (*t*, $J = 7.8$ Hz, 4H, C*H*$_2$-pyrrole), 3.66 (*s*, 3H, COOC*H*$_3$), 4.19 [*q*, $J = 7$ Hz, 4H, COOC*H*$_2$CH$_3$), 4.51 [*s*, 1H, C*H*(COOEt)$_2$], 5.92 (*s*, 1H, C*H* pyrrole) and 7.70 (*s*, 1H, N*H*); ^{13}C NMR ($CDCl_3$) 13.9 (C-18), 14.1 (2C, COOCH$_2$*C*H$_3$), 22.6 (C-17), 24.9 (C-3), 25.8, 27.8, 29.0, 29.1, 30.1, 31.6 (C-16), 34.0 (C-2), 49.9 [*C*H(COOEt)$_2$], 51.4 (COO*C*H$_3$), 61.3 (2C, 2 × COO*C*H$_2$CH$_3$), 105.3 (c-4′ of pyrrole, assuming malonate ester substituent at C-3′ of pyrrole ring), 110.0 (C-3′ of pyrrole), 128.9 (C-2′ of pyrrole), 130.8, 131.0 (C-5′ of pyrrole), 169.5 (2C, 2 × *C*OOEt) and 174.0 (C-1) ppm.

*Decarboxylation of compounds **2a,2b**.* A mixture of compounds **2a,2b** (0.8 g, 1.7 mmol), methanol (20 mL), water (7 mL) and sodium carbonate (5 g) was refluxed for 12 h. The reaction mixture was acidified with dilute HCl (2M, 25 mL) and extracted with diethyl ether (2 × 40 mL). The ethereal extract was washed with water (20 mL) and dried over anhydrous sodium sulfate. The solvent was evaporated, and the residue was refluxed with borontrifluoride methanol complex (15%, w/w, 5 mL) and methanol (20 mL) for 15 min. Water (40 mL) was added and the reaction mixture was extracted with diethyl ether (2 × 50 mL). The ethereal extract was washed with water and dried (Na_2SO_4). Silica gel column chromatographic separation of the residue gave compounds **3a,3b** (0.5 g, 78%) as an oil. R_f (light petroleum/diethyl ether, 3:2, vol/vol) 0.4; IR (cm^{-1}) (film) 3385(*w*), 1739(*s*), 1170(*m*), 1015(*m*); ^1H NMR ($CDCl_3$, δ) 0.88 (*t*, 3H, C*H*$_3$), 1.2–1.8 (*m*, 18H, C*H*$_2$), 2.30 (*t*, $J = 7$ Hz, 2H, 2-*H*), 2.52 (*t*, $J = 7.8$ Hz, 4H, C*H*$_2$-pyrrole), 3.38 (*s*, 2H, pyrrole-C*H*$_2$COOCH$_3$), 3.66 (*s*, 6H, 2 × COOC*H*$_3$), 5.76 (*s*, 1H, C*H* pyrrole) and 7.64 (*s*, 1H, N*H*); ^{13}C NMR ($CDCl_3$) 14.1 (C-18), 22.6 (C-17), 24.9 (C-3), 25.7, 27.7, 29.0, 29.2, 29.4, 29.5, 30.1, 31.7 (C-16), 32.1 (pyrrole-*C*H$_2$COOCH$_3$), 34.0 (C-2), 51.2 (COO*C*H$_3$), 51.8 (pyrrole-CH$_2$COO*C*H$_3$), 106.0 (C-4′ of pyrrole, assuming CH$_2$COOCH$_3$ substituent at C-3′ of pyrrole ring), 110.6 (C-3′ of pyrrole), 127.9, 128.1 (C-2′ of pyrrole), 130.6, 130.8 (C-5′ of pyrrole), 173.2 (pyrrole-CH$_2$-*C*OOCH$_3$) and 174.3 (C-1) ppm.

*Synthesis of methyl 9,12-imino-10(11)-methyl-9,11-octadecadienoate (**4a,4b**).* A mixture of compounds **3a,3b** (0.5 g, 1.3 mmol), potassium hydroxide (0.2 g) and aqueous ethanol (95%, 20 mL) was refluxed for 1 h. Dilute HCl (2M, 25 mL) was added, and the cooled reaction mixture was extracted with diethyl ether (2 × 20 mL). The ethereal extract was washed with water (20 mL) and dried (Na_2SO_4). The solvent was evaporated, and the residue was heated under nitrogen at 180°C for 1 h. The reaction product was refluxed with borontrifluoride methanol complex (15%, w/w, 5 mL) and methanol (20 mL) for 15 min. Water (30 mL) was added and the reaction mixture was extracted with diethyl ether (2 × 25 mL). Silica column chromatographic separation of the residue using a mixture of petroleum ether/diethyl ether, 7:3, vol/vol, as the eluant gave a mixture of compounds **4a,4b** (0.34 g, 82%) as an oil. R_f (light petroleum/diethyl ether, 3:2, vol/vol) 0.8; gas-liquid chromatography (SE-30) ECL = 20.4; ^1H NMR ($CDCl_3$, δ) 0.88 (*t*, 3H, C*H*$_3$), 1.2–1.8 (*m*, 18H, C*H*$_2$), 2.0 (*s*, 3H, pyrrole-C*H*$_3$), 2.30 (*t*, $J = 7$ Hz, 2H, 2-*H*), 2.47 (*t*, $J = 7.8$ Hz, 4H, pyrrole-C*H*$_2$), 3.66 (*s*, 3H, COOC*H*$_3$), 5.65 (*s*, 1H, C*H* pyrrole) and 7.3 (*s*, 1H, N*H*); ^{13}C NMR ($CDCl_3$) 10.9 (pyrrole-CH3), 14.1 (C-18), 22.6 (C-17), 24.9 (C-3), 25.8, 27.7, 29.3, 29.7, 30.1, 31.7 (C-16), 34.1 (C-2), 51.4 (COO*C*H$_3$), 106.5 (C-4′ of pyrrole, assuming CH$_3$ substituent at C-3′ of pyrrole ring), 113.4 (C-3′ of pyrrole), 126.5, 126.7 (C-2′ of pyrrole), 130.1, 130.2 (C-5′ of pyrrole) and 174.3 (C-1) ppm.

ARTICLE

Comparison of the Metabolism of α-Linolenic Acid and Its Δ6 Desaturation Product, Stearidonic Acid, in Cultured NIH-3T3 Cells

Richard C. Cantrill*, Yung-Sheng Huang, Gregory W. Ells and **David F. Horrobin**
EFAMOL Research Institute, Kentville, Nova Scotia, Canada, B4N 4H8

The incorporation and metabolism of α-linolenic acid (18:3n-3) and its Δ6 desaturase product, stearidonic acid (18:4n-3), were compared by NIH-3T3 cells. In the presence of fetal calf serum, cells accumulated exogenously added 18:3n-3 and 18:4n-3 apparently at the expense of oleic acid (18:1n-9). Both 18:3n-3 and 18:4n-3 were elongated and desaturated to eicosatetraenoic acid (20:4n-3), eicosapentaenoic acid (20:5n-3) and docosapentaenoic acid (22:5n-3), but not to docosahexaenoic acid (22:6n-3), and were incorporated into phospholipids and triacylglycerols. Over a 4-d period, the growth of NIH-3T3 cells was slightly stimulated in the presence of 18:3n-3 (20 μg/mL) but was strongly inhibited in the presence of 18:4n-3 at the same concentration. This inhibition may be caused by enhanced lipid peroxidation as a result of the high levels of 18:4n-3 present. *Lipids 28,* **163-166 (1993).**

In recent years an increased dietary intake of fish oils, rich in long-chain n-3 fatty acids, has been vigorously promoted for its possible medical benefits. For instance, eicosapentaenoic acid (20:5n-3) may reduce the risk of thrombosis and, consequently, the risk of coronary disease (1,2). However, there is increasing evidence that excessive fish oil intake may induce adverse side effects (3,4). Some researchers have suggested that increasing the intake of α-linolenic acid (18:3n-3), the precursor of long-chain n-3 fatty acids, may provide the same beneficial effects but minimize the adverse effects of fish oil supplementation (5,6). Unfortunately, the activity of Δ6 desaturase in humans is relatively low (7), thus limiting the formation of long-chain n-3 fatty acids and, consequently, their potential beneficial effects.

Stearidonic acid (18:4n-3), the Δ6 desaturation product of 18:3n-3, is found in small quantities in borage and blackcurrant oils (8-10) and certain fish oils (for a review, see ref. 11). It has previously been shown in experimental animals that stearidonic acid is a more effective dietary supplement than α-linolenic acid in the formation of long-chain n-3 fatty acids (12). In other words, supplementing the diet with stearidonic acid could compensate for the low activity of Δ6 desaturase and low availability of its products.

To date few studies have compared the metabolism of stearidonic acid and α-linolenic acid in cultured cells. Previous studies in our laboratory have shown that administration of certain n-6 polyunsaturated fatty acids (PUFA) in the concentration range of 5-60 μg/mL kills many tumor cell lines in culture (13-15). We (16) and others (17) have also shown that 18:4n-3 was toxic to tumor cells in culture; however, its effect on a normal cell line has not been reported. In the present study, stearidonic acid and its direct precursor, α-linolenic acid, were added individually, to cell culture medium, and their effects on NIH-3T3 cells, a nonmalignant cell line, were compared. Cell growth was determined by cell counting, and the extent of incorporation and modification of 18:3n-3 and 18:4n-3 was determined in lipid extracts of the cells.

Abbreviations: Chol, cholesterol; DMEM, Dulbecco's modified essential medium; HPLC, high-performance liquid chromatography; PC, phosphatidylcholine; PE, phosphatidylethanolamine; PI + PS, phosphatidylinositol and phosphatidylserine; PUFA, polyunsaturated fatty acids; TG, triacylglycerol.

MATERIALS AND METHODS

Cell culture. NIH-3T3 cells, obtained from Dr. R. Bassin (NIH, Bethesda, MD), were maintained in Dulbecco's modified essential medium (DMEM) (Flow Labs, Mississauga, Ontario, Canada) containing 10% fetal calf serum (Flow Labs), without the addition of antibiotics. The protocol for the examination of the effects of 18:3n-3 and 18:4n-3 on cell growth has been described previously (18). Cells were seeded in 24-well plates at a density of 10^4 cells per well (0.5 mL) and allowed to attach. Twenty-four hours later (Day 0), the medium was replaced with fresh medium containing 5% fetal calf serum (total fatty acid content = 12.5 μg/mL medium; major fatty acids in percent: 16:0, 21; 16:1, 5; 18:0, 12; 18:1, 24; 18:2n-6, 6; 20:3n-6, 3; 20:4n-6, 11; 20:5n-3, 1; 22:4n-6, 1; 22:5n-6, 2; 22:5n-3, 3; 22:6n-3, 4) and either 18:3n-3 or 18:4n-3. Solutions of each fatty acid in ethanol (40 mg/mL) were diluted with medium to give final concentrations between 5 and 30 μg/mL. The final ethanol concentration was maintained at 0.2%. Control wells received fresh medium containing 0.2% ethanol. Cells were observed daily by phase contrast microscopy. After an additional 4 d in culture, cells were detached with trypsin and counted in a haemocytometer counting chamber. The trypan blue exclusion technique was used to determine the number of dead cells (19). Some experiments were carried out in the presence of ferrous ions ($FeCl_2.4H_2O$ 10 μg/mL) or dl-α-tocopherol (Sigma, St. Louis, MO; 10 μM).

Determination of fatty acid profiles. For lipid analysis, cells were seeded in 5 mL medium at a density of 10^5 cells per 6-cm Petri dish and supplemented with either 18:3n-3 or 18:4n-3 according to the protocol described above. After 3 d cells were released from the dish with trypsin, pelleted at 900 × *g* and resuspended in phosphate buffered saline (pH 7.4, composition as in ref. 20). For fatty acid quantitation, 17:0 was added to each sample as internal standard. Lipids were extracted by the method of Folch *et al.* (21), and the lipid class distribution was determined by high-performance liquid chromatography (HPLC) (22). Data were expressed as area percentage and were taken directly from the HPLC/mass detector analysis. Different lipid classes were expressed as a ratio which was calculated from the area percentage data for individual samples. For fatty acid analysis, phospholipids and triacylglycerols (TGs) were first separated by thin-layer chromatography (23). After transmethylation of lipid extracts (24), the fatty acid composition of the growth

medium, cells and phospholipid and TG fractions was determined by gas-liquid chromatography as described elsewhere (12).

All data are presented as mean ± SD (n = 4). Statistical analysis was performed using one-way analysis of variance and the Student's *t*-test using the SPSS-PC+ software package (SPSS Inc., Chicago, IL).

RESULTS

Effects of 18:3n-3 and 18:4n-3 on cell growth. Supplementation with either fatty acid (20 μg/mL) led to the appearance of lipid droplets within 24 h. The number of droplets decreased as time progressed. This observation has also been made when NIH-3T3 cells were incubated with other exogenous fatty acids (16:0, 18:2n-6, 18:3n-6 and 20:4n-6; Cantrill, Ells and Horrobin, unpublished data). Phase contrast microscopy revealed no other changes in cell morphology in either control or supplemented media. Cell number was not affected by either fatty acid during the first two days after supplementation. Thereafter, cells grown in 18:4n-3 supplemented medium ceased to proliferate, whereas cells grown in the control medium and those treated with 18:3n-3 continued to divide (Fig. 1). On Day 4 the number of cells in the 18:3n-3 supplemented medium was greater than in the control medium.

The effects of 18:3n-3 and 18:4n-3 supplementation at different concentrations are shown in Figure 2. On Day 4, 18:4n-3 at concentrations greater than 10 μg/mL had significantly suppressed the proliferation of NIH-3T3 cells and few viable cells remained at concentrations above 25 μg/mL. On the other hand, 18:3n-3 caused a 25–50% increase in cell number above control levels. The effect of 18:4n-3 was exacerbated by the addition of ferrous ions ($FeCl_2.4H_2O$ 10 μg/mL) and reduced by the simultaneous addition of dl-α-tocopherol (10 μM) (Fig. 2).

Cellular lipid distribution. To compare the effect of 18:3n-3 and 18:4n-3 supplementation on cellular lipid class distribution, cells were harvested, and analyses were performed on Day 3, before any cytotoxic effects were evident. Table 1 shows that the presence of either fatty acid caused a marked increase in the relative amount of TG and phosphatidylethanolamine (PE) and a decrease in the proportions of free cholesterol (chol) and phosphatidylcholine (PC) in total cellular lipids. The ratios of different lipid classes were calculated in order to determine if these relative changes were solely a reflection of TG formation or were more complex. Cells treated with 18:4n-3, as compared with 18:3n-3, had a 40% increase in the chol/PC ratio, a 20% increase in the PE/PC ratio and a 33% increase in the TG/chol ratio (Table 1). These results indicate that the two fatty acids have different effects on lipid class distribution.

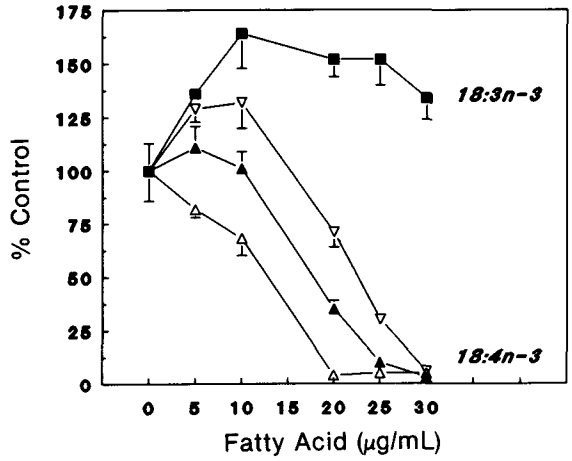

FIG. 2. Concentration-dependent effect of 18:3n-3 and 18:4n-3 on NIH-3T3 cells. Cells were cultured for four days in the presence of different concentrations of either 18:3n-3 (■) or 18:4n-3 (▲) between 0 and 30 μg/mL. 18:4n-3 treated cells were also grown in the presence of either ferrous ions ($FeCl_2.4H_2O$ 10 μg/mL) (△) or dl-α-tocopherol (10 μM) (▽). Data are presented as % control (total cell count at 0 μg/mL fatty acid) ± SD (n = 4).

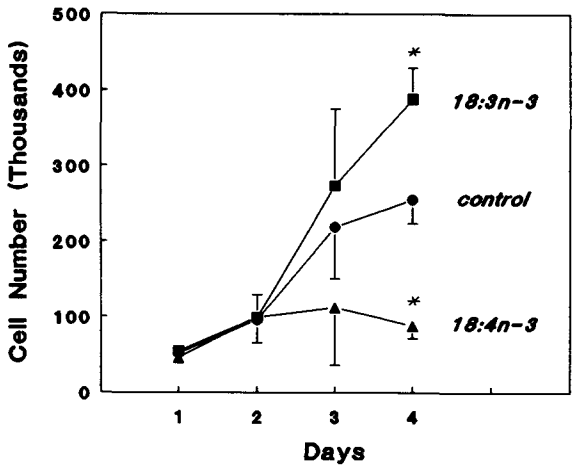

FIG. 1. Time-dependent effect of 18:3n-3 and 18:4n-3 on NIH-3T3 cells. Cells were cultured for four days in control medium (●), or in the presence of 20 μg/mL of either 18:3n-3 (■) or 18:4n-3 (▲). Data are presented as mean total cell count ± SD (n = 4). *Cell counts significantly different ($P < 0.05$) from control values on the same day.

[d]Significantly different from 18:3n-3 treated values ($P < 0.05$).

Cellular fatty acid composition. Incubation with either 18:4n-3 or 18:3n-3 significantly increased the amount of n-3 fatty acids in total cellular lipid extracts. The n-3 fatty acids increased at the expense of monounsaturated, especially 18:1n-9, and n-6 fatty acids (Table 2). On Day 1 only modest amounts of elongation and desaturation products of either 18:3n-3 or 18:4n-3 were present, and no increases in the amounts of 22:5n-3 and 22:6n-3 were seen. By Day 3, the amount of the products was increased above Day 1 values. The major metabolite of 18:3n-3 was 20:5n-3, and the major metabolites of 18:4n-3 were 20:4n-3 and 20:5n-3. The amount of 22:6n-3 was increased above control values only in 18:4n-3 supplemented cells (Table 2).

The cellular fatty acid content (μg/10^6 cells) in 18:3n-3 treated cells was slightly higher than in control or in 18:4n-3 treated cells on Day 1 (Table 2). This resulted from an increase in total cellular n-3 fatty acids. In 18:3n-3 and 18:4n-3 treated cells, the levels of n-3 fatty acids were 27.1 and 15.6 μg/10^6 cells, respectively, and constituted approximately 50% of the total fatty acids. This was more than a fourfold increase above the levels present in control cells.

On Day 3, the total fatty acid content of both control and 18:3n-3 treated cells was reduced by 30% with respect to Day 1 values. However, the fatty acid content of 18:3n-3 treated cells remained 50% higher than that of control cells on Day 3. The fatty acid content of 18:4n-3 treated cells on Day 3 was twice that measured on Day 1. This value was also 2- and 3-fold higher than that of the 18:3n-3 treated and of the control cells, respectively, on Day 3. At this time, the levels of n-3 fatty acids were 4% of the total fatty acid content in control cells and 44 and 50% in 18:3n-3 and 18:4n-3 treated cells, respectively.

Table 3 shows the distribution of 18:3n-3 and 18:4n-3 and their metabolites in the TG and phospholipid fractions on Day 3. In the TG fraction, most of the n-3 fatty acids in the 18:3n-3 treated cells were recovered as 18:3n-3. However, a significant proportion of 18:4n-3 had been elongated to 20:4n-3 and subsequently desaturated to 20:5n-3 in the 18:4n-3 treated cells. In the phospholipid fraction, 20:5n-3 was the major product in both 18:3n-3 and 18:4n-3 treated cells, and a substantial amount of 20:4n-3 was also observed in the 18:4n-3 treated cells. The results also show that the amount of 22:5n-3 or of 22:6n-3 did not depend on the precursor fatty acid.

TABLE 3

Percent Distribution of n-3 Fatty Acids in Triacylglycerol and Phospholipid Fractions of NIH-3T3 Cells Incubated for Three Days with Either 18:3n-3 or 18:4n-3 (20 μg/mL)[a]

[d]Significantly different from the 18:3n-3 values ($P < 0.05$).

DISCUSSION

Supplementation of growth medium with either 18:3n-3 or 18:4n-3 increased the quantities of n-3 fatty acids in NIH-3T3 cells. As shown in Table 2, however, the total fatty acid content on Day 3 was 30% lower than on Day 1 in both control and 18:3n-3 treated cells, whereas it was increased 2-fold in 18:4n-3 treated cells. The explanation for these differences is probably related to the rate of cell proliferation, since the number of 18:4n-3 treated cells had only doubled since Day 1, whereas the number of 18:3n-3 treated cells had increased 6-fold.

Treatment with 18:3n-3 increased the levels of the post Δ6 desaturase n-3 fatty acids (18:4n-3, 20:4n-3, 20:5n-3 and 22:5n-3) indicating that NIH-3T3 cells have an active Δ6 desaturase system (Table 2). In 18:4n-3 treated cells, there was an increase in 20:4n-3 levels but the level of 20:5n-3 was not affected. The data suggest that Δ5 desaturase activity was low in these cells and might have limited the production of 20:5n-3. Following either treatment, the amounts of 22:5n-3 and 22:6n-3 were similar on both Day 1 and Day 3.

It is also possible that the metabolism of n-3 fatty acids is not solely regulated by the activity of the desaturation and elongation enzymes but also by their incorporation into phospholipid and TG fractions. It has been proposed recently (25) that the distribution and metabolism of n-6 fatty acids is a consequence of the availability of acceptor molecules (PUFAs are predominantly found in the 2-position of phospholipids). There also exists the possibility of competition between n-3 fatty acids of different chain-length and degree of unsaturation for esterification into different positions of TG and phospholipid molcules.

An increased supply of n-3 fatty acids increased their incorporation into phospholipids and also led to the formation of TGs (Table 1). Acylation into TGs and the subsequent formation of intracellular perinuclear lipid droplets is evidence of another cellular response to excess PUFA intake. The formation of these lipid droplets was probably responsible for the changes in the lipid class ratios (Table 1). These changes could not be attributed solely to the increase in TG content since the proportions of different lipids were not reduced to the same extent. Thus, it is likely that the formation of the lipid droplet boundary membrane led to the alterations in the cholesterol/PC and the PE/PC ratios (Table 1). These shifts in the chol/phospholipid ratios may have also induced the incorporation of more PUFA into phospholipids.

If the incorporation of PUFA into phospholipid is restricted by the number of sites on suitable acceptor molecules, then excess fatty acid esterified into neutral lipids may be subsequently incorporated into phospholipid as cell number increases (26). In 18:3n-3 treated cells, the formation of long-chain metabolites and their accumulation in neutral lipid stores was lower than in 18:4n-3 treated cells (Table 3). This may have served to reduce the accumulation of substrates for lipid peroxidation since it has been shown previously that fatty acids with three and more double bonds are cytotoxic to many tumor cell lines in culture (14). This process is thought to be caused by the formation of lipid peroxides (27) since the cytotoxic effect of post Δ6 desaturase n-6 fatty acids cannot be prevented by certain cyclooxygenase or prostaglandin synthetase inhibitors (28). However, cell death may be accelerated by the addition of ferrous or copper ions and blocked by vitamin E and other antioxidants (18). Our observations support the involvement of lipid peroxidation in the lethal process (Fig. 2). The provision of 18:4n-3 to cells leads to the accumulation of substrates for lipid peroxidation, a process which is likely to cause cell death.

The Effects of Dietary Fish Oil on Alveolar Type II Cell Fatty Acids and Lung Surfactant Phospholipids

Richard Carleton Baybutt, John Edgar Smith and **Yu-Yan Yeh***
Nutrition Department, The Pennsylvania State University, University Park, Pennsylvania 16802

The purpose of this study was to determine the responsiveness of alveolar type II cells to dietary fish oil and the consequent effects on alveolar and lung surfactant. Rats were fed a corn oil or a fish oil diet for four weeks. Dietary n-3 fatty acids were readily incorporated into the type II cell phospholipids as indicated by higher levels of eicosapentaenoic acid (2.77 ± 0.10%) and docosahexaenoic acid (1.63 ± 0.10%) in the group receiving the fish oil diet. The elevated levels of n-3 fatty acids were accompanied by concomitant reduction in arachidonic acid and linoleic acid. Neither eicosapentaenoic acid nor docosahexaenoic acid was incorporated into type II cell triacylglycerols. Feeding a fish oil containing diet increased surfactant phospholipids, particularly 1,2-disaturated acyl phosphatidylcholines in whole lung compared to a corn oil diet. However, the amount of surfactant found in the alveolus was not different between the two diet treatment groups. The results suggest that dietary n-3 fatty acids stimulate synthesis and/or inhibit degradation of lung surfactant without altering surfactant secretion in alveoli.

Lipids 28, 167-172 (1993).

Surfactant is a lipoprotein complex that acts as a surface active agent to reduce the surface tension of the water lining the alveolar lumen for maintaining respiration (1). Also it plays an important role in the immune system by enhancing the activity of alveolar macrophages (2). Insufficiency of surfactant can cause respiratory distress syndrome in premature infants and adults (3,4). Surfactant is synthesized, stored and secreted by the alveolar type II cell, and all these processes regulate the availability of surfactant to alveoli (5,6). In an earlier study, we found that eicosapentaenoic acid stimulated surfactant secretion in cultured alveolar type II cells (Baybutt *et al.*, unpublished data). It is reasonable to assume that the stimulatory effect of eicosapentaenoic acid must be mediated first by its incorporation into tissue lipids.

The incorporation of dietary highly unsaturated long-chain fatty acids, eicosapentaenoic acid and docosahexaenoic acid has been demonstrated in humans (7,8) and animals (9-12). Specifically, these fatty acids are incorporated into various tissues such as kidney (11), liver (9-11,13) and brain (13) and different cell types such as macrophages (14), neutrophils (15), platelets (16) and erythrocytes (17,18). Little attention has been directed to the alveolar type II cell although some studies with lung tissue have been reported (9-11).

Abbreviations: CL, cardiolipin; C-DMEM, complete Dulbecco's modified Eagle's medium; DSPC, 1,2-disaturated acyl phosphatidylcholine; EDTA, ethylenediaminetetraacetic acid; LPC, lysophosphatidylcholine; P, phosphorus; PA, phosphatidic acid; PC, phosphatidylcholine; PE, phosphatidylethanolamine; PG, phosphatidylglycerol; PI, phosphatidylinositol; PL, phospholipid; PS, phosphatidylserine; Sph, sphingomyelin; TLC, thin-layer chromatography; USPC, unsaturated acyl phosphatidylcholine.

The present study was conducted to determine whether alveolar type II cells can be enriched by eicosapentaenoic acid and docosahexaenoic acid by feeding rats a diet containing fish oil. In addition, the effect of dietary n-3 fatty acids on surfactant content and phospholipid composition in lung lavage and lung tissue was investigated. The results showed that surfactant phospholipid and 1,2-disaturated acyl phosphatidylcholine (DSPC) content increased in whole lung but not in the alveolus in response to fish oil feeding. The alteration in the amount of surfactant was accompanied by an increase of eicosapentaenoic acid in phospholipids of alveolar type II cells.

MATERIALS AND METHODS

Animals and diet. Pathogen-free male Sprague-Dawley rats were purchased from Harlan Sprague-Dawley Co. (Indianapolis, IN) and housed in stainless steel cages at approximately 24°C and 50% relative humidity with a cycle of 12 h light and 12 h dark (0600-1800 h). The rats, weighing 130-190 g, were fed *ad libitum* a semi-purified diet containing 15% corn oil or 13% menhaden oil plus 2% corn oil for four weeks. Water was provided at all times. The complete composition of the diets was adapted from those of others (19,20) and is listed in Table 1. The diet containing corn oil was rich in n-6 fatty acids (*e.g.*, linoleic acid) while the fish oil diet was high in n-3 fatty acids (*e.g*, eicosapentaenoic acid and docosahexaenoic acid) (Fig. 1). To minimize oxidation, the diet was packaged in small plastic ziplock bags, purged with nitrogen and stored frozen (−20°C). Food intake was determined by measuring the difference in the preweighed and unconsumed amount of diet. The unconsumed portion was discarded and replaced. Every other day, the food was administered and food intake and body weight were measured.

Animal care complied with guidelines developed by the Pennsylvania State University, the federal and state governments, and the National Research Council's Institute of Laboratory Animal Resources.

Isolation of type II pneumocytes. The type II pneumocytes were isolated according to the procedure of Mason *et al.* (21) with minor modifications (22). The procedure followed closely the original method (21) except that the carotid artery was cut instead of the aorta during the lung perfusion, and that percoll was used for the discontinuous gradient cell purification by centrifugation. The cells were resuspended in complete Dulbecco's modified Eagles medium (C-DMEM) salt supplemented with 10% fetal bovine serum, penicillin (100 U/mL) and streptomycin (100 μg/mL) and immediately incubated under an atmosphere of 5% CO_2 and 95% air at 37°C. The nonadhering cells obtained after 3 h of incubation were further incubated for 20 h. The type II cells adhering to the culture plate, were washed to remove nontype II cells before being scraped and collected for lipid extraction. The purity of the adhering cells was determined microscopically after tannic acid staining (23).

Lung lavage and surfactant isolation. The lung lavage

Diet Composition[a]

Ingredients	Fish oil diet	Corn oil diet
	(g/100 g diet)	
Casein	20.0	20.0
Dextrose	27.4	27.4
Corn starch	27.5	27.5
Menhaden oil	13.0	0.0
Corn oil	2.0	15.0
Cellulose (amorphous)	5.0	5.0
Salt/mineral mix (AIN-76A)	3.5	3.5
Vitamin mix (AIN-76)	1.0	1.0
DL-Methionine	0.3	0.3
Choline bitartrate	0.2	0.2
α-Tocopherol	0.075	0.075
t-Butylhydroquinone	0.003	0.003
Cholesterol[b]	0.079	0.079

[a]The diets were adapted from those used by other investigators (19,20).

[b]Cholesterol was added to the corn oil diet at an amount equivalent to that contained in fish oil.

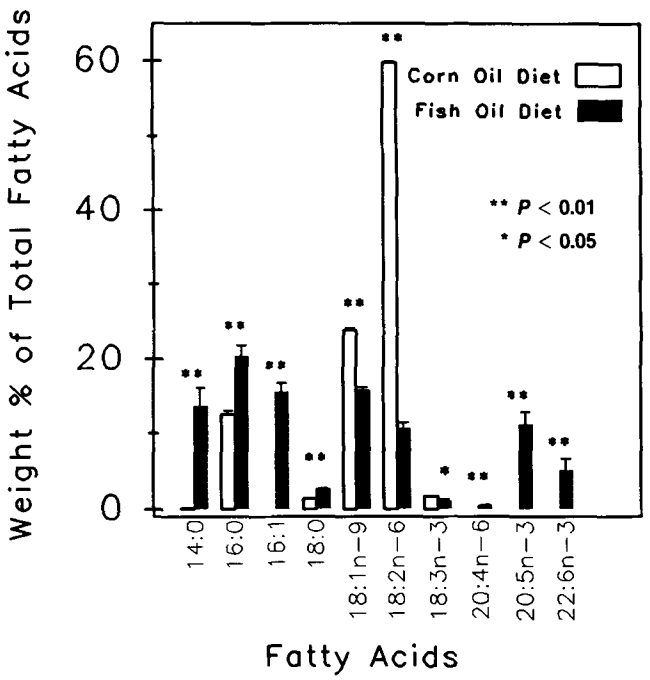

FIG. 1. The fatty acid compositon of the experimental diets is reported giving mean values with standard error for three samples. The wt% was calculated by dividing the weight of the fatty acid by the total fatty acid content and multiplying by 100. * and ** indicate significant difference between diets at $P < 0.05$ and $P < 0.01$, respectively.

was performed as previously described (24). Briefly, rats were anesthetized with sodium pentobarbital (50 mg/kg) by intraperitoneal injection. A cannula was placed in the trachea proceeding into the bronchi of the left lobe of the lung. The left lobe was chosen because it provided a manageable sample and was representative of whole lung (24). The lungs were removed from the animal, and the left lobe was instilled with approximately 6 mL of ice-cold 0.9% saline and lavaged. Three passes were made which has previously been shown to recover over 80% of the surfactant (24). The left lobe and whole lung of rats receiving similar dietary treatment were weighed for determining the weight proportion of the lavaged left lobe. This information was used to express the data relative to whole lung. The lavage fluid collected from three washes was pooled and centrifuged at 500 × *g* for 10 min to remove cells and cell debris. The supernatant was lyophilized and used for alveolar surfactant isolation. The lavaged lung (*i.e.*, left lobe) was dissected free of all connective and vascular tissue and homogenized in a medium consisting of 0.145 M NaCl in 0.01 M Tris buffer, pH 7.4, and 0.001 M ethylenediaminetetraacetic acid (EDTA), using a Ten Broeck homogenizer (Thomas Scientific, Philadelphia, PA) (25). The alveolar and tissue surfactants were isolated by the discontinuous sucrose gradient centrifugation procedure (26).

Lipid extraction and analysis. Alveolar type II cells, lung and lavage surfactant were extracted for lipids according to the method of Folch *et al.* (27). The extracted lipids were further separated into total phospholipid and triacylglycerol by thin-layer chromatography (TLC) using silica G plates, and the solvent system consisted of hexane/diethyl ether/acetic acid (80:20:1, by vol) (28). The phospholipids were visualized by exposing the plate to iodine vapor. The total phospholipid and triacylglycerol fatty acids of the type II cells were transmethylated with 14% boron trifluoride in methanol as described elsewhere (29). The methyl esters of fatty acids were analyzed by gas-light chromatography (Model 5880A, Hewlett-Packard, Palo Alto, CA) equipped with a hydrogen flame ionization detector using a glass column packed with 10% diethyleneglycol succinate + 1% phosphoric acid on 80/100 Chromosorb W AW (Supelco Co., Bellefonte, PA). The temperatures used were: injector, 200°C; column, 175°C; detector, 250°C. The flow rate of the carrier gas (helium) was 21.4 mL/min (30). Appropriate reference standards were used to determine retention times for identification of fatty acids. For quantification of the fatty acids, heptadecanoate was added as an internal standard at the methylation step (31). The mass was calculated as follows: fatty acid (wt) = {peak area of fatty acid/peak area of heptadecanoate} × weight of heptadecanoate added (32).

The individual phospholipids of lung tissue and lavage surfactant were separated by two-dimensional TLC on a Baker Si-250 silica gel plate (0.25 mm thick), with chloroform/methanol/petroleum ether (b.p. 60°C)/acetic acid/boric acid (40:20:30:10:1.8, vol/wt) as the developing solvent for the first dimension (33). Boric acid was dissolved in the methanol/acetic acid prior to combining with other solvents. The phospholipids were visualized by briefly exposing the plate to iodine vapor. Immediately after the removal of other phospholipids, phosphatidylcholine (PC) remaining on the plate was treated with 5% osmium tetroxide in carbon tetrachloride (33). The plate was developed in the second dimension for separation of DSPC using the developing solvent, chloroform/methanol/ammonium acetate (80:28:6, by vol). The individual phospholipids were quantified by determination of phosphorus content (34).

Data and statistical analysis. The phospholipid fatty acids of the alveolar type II cell are presented as weight

[a]Mean values are reported with standard error for four samples. Each sample was pooled from four culture wells.

[b]The wt% was calculated by dividing the weight of the fatty acid by the total fatty acid content and multiplying by 100. Within the lipid class, * and ** signify differences between diets at $P < 0.05$ and $P < 0.01$, respectively. nd, Not detectable.

percent or μg fatty acid/10^6 cells. The amount of surfactant found in alveoli and lavaged lung is reported as nmoles phosphorus of phospholipids/lung, whereas the distribution of individual phospholipids in surfactant is expressed as molar percent of total phospholipids. Data are presented as mean ± standard error. Differences between the two diet groups were determined by a two-tailed *t*-test.

RESULTS

Effects of diets on body and tissue weights. The initial body weights were 162 ± 8 g and 160 ± 9 g for the fish oil fed and corn oil fed rats, respectively. As a result of similar food intake and body weight gain, there was no significant difference in their respective final body weights (295 ± 10 g *vs.* 292 ± 7 g). In addition, lung weights were the same between the fish oil fed and corn oil fed rats at the end of the study (1.26 ± 0.07 *vs.* 1.31 ± 0.06 g).

Fatty acids of alveolar type II cell. As determined by the tannic acid staining procedure, the purity of the alveolar type II cells was 86 ± 2%. Fatty acid profiles of phospholipids and triacylglycerol were analyzed. As shown in Table 2, phospholipids of alveolar type II cells derived from the fish oil fed group were enriched with eicosapentaenoic acid (20:5n-3) and docosahexaenoic acid (22:6n-3) as compared to that of the corn oil group. The enrichment of eicosapentaenoic acid and docosahexaenoic acid was accompanied by reduction of arachidonic acid (20:4n-6), linoleic acid (18:2n-6) and stearic acid (18:0). Also, the contents of myristic acid (14:0) and palmitoleic acid (16:1n-7) in phospholipids were higher in the fish oil than corn oil fed groups. The dietary treatments had no effect on the content of palmitic acid, the predominant fatty acid of surfactant phospholipid.

The fatty acid distribution in triacylglycerol was essentially the same for both dietary groups (Table 2). However, palmitoleic acid was found only in the rats fed the fish oil diet. Fish oil feeding lowered palmitic acid content in triacylglycerols. Eicosapentaenoic acid and docosahexaenoic acid were not detected in triacylglycerol of the type II pneumocytes.

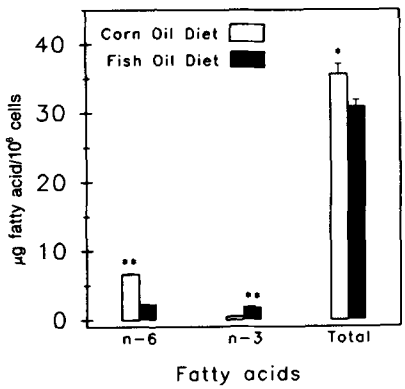

FIG. 2. The effects of dietary fats on n-6 and n-3 fatty acid mass of phospholipid in alveolar type II cells. Mean values are reported with standard error for four samples. Each sample was pooled from four culture wells. Data were derived from those shown in Table 2. * and ** indicate significant difference between diets at $P < 0.05$ and $P < 0.01$, respectively.

Consistent with the changes in wt% of phospholipid fatty acids, the mass of n-3 fatty acids (eicosapentaenoic acid and docosahexaenoic acid) was higher and n-6 fatty acid (arachidonic acid and linoleic acid) was lower in fish oil than corn oil fed animals (Fig. 2). The mass of total fatty acids of phospholipid was slightly but significantly higher in the corn oil than the fish oil group. This finding was most likely the result of a greater reduction of long-chain n-6 fatty acids relative to the increase in n-3 fatty acids in response to fish oil feeding.

Lung tissue and lavage surfactant. The effects of dietary fats on surfactant contents in lung tissue and alveolar lavage were determined by measuring the amount of sur-

[a]Mean values are reported with standard error for five samples.
[b]The individual phospholipids (PL) were separated by two-dimensional thin-layer chromatography (33). *and ** signify differences between diets at $P < 0.05$ and $P < 0.01$, respectively. nd, Not detectable. For abbreviations, see footnote to title.

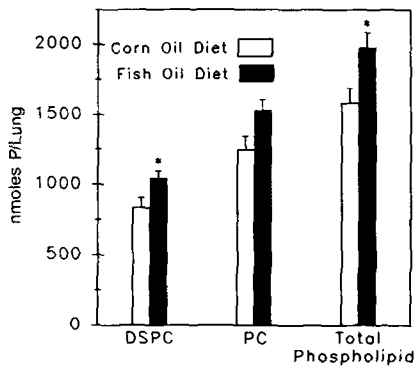

FIG. 3. The phospholipid content of whole lung surfactant. Mean values and standard error for five samples are presented. Data were obtained from Table 3 by combining the values for lavage surfactant and lavaged tissue surfactant. 1,2-Disaturated acyl phosphatidylcholine (DSPC) was separated from unsaturated acyl phosphatidylcholine (USPC) by two-dimensional thin-layer chromatography (33). Phosphatidylcholine was the sum of the DSPC and USPC. Total phospholipid was the sum of all individual phospholipid classes. *Indicates significant difference between diets at $P < 0.05$.

factant phospholipids. The amounts of lung tissue surfactant PC (1323 ± 75 nmoles P/lung) and total phospholipid (1768 ± 99 nmoles P/lung) measured in the fish oil fed animals were 34 and 36% higher than the corresponding values for the corn oil group. The mole% distribution of individual phospholipid was similar in the two dietary groups except for slightly higher phosphatidylinositol (PI) levels noted in the fish oil than in the corn oil group (data not shown).

However, when expressed as nmoles P/lung, there were apparent differences in the amounts of individual phospholipid classes resulting from the fats provided for the animals (Table 3). The fish oil feeding increased the amount of DSPC, PI, phosphatidylserine (PS) and phosphatidylethanolamine (PE) in lung tissue as compared to the corn oil feeding.

Unlike the alterations seen in lung tissue surfactant, the amounts of lavage surfactant PC (261 ± 18 nmoles P/lung) and total phospholipid (293 ± 17 nmoles P/lung) measured in the fish oil fed animals were not different from the corresponding values for the corn oil group. The contents of individual phospholipid classes in lavage surfactant were the same for both groups (Table 3).

When lung tissue and lavage surfactants were combined, the amount of DSPC (1046 ± 50 *vs.* 833 ± 73 nmols P/lung) and total phospholipid (1977 ± 109 *vs.* 1583 ± 110 nmoles P/lung) was again greater in the fish oil than in the corn oil fed animals (Fig. 3). This suggests an increase in total surfactant in the whole lung caused by fish oil.

DISCUSSION

Alveolar surfactant plays vital roles in pulmonary respiration and immune function. This together with the finding that eicosapentaenoic acid supplemented to tissue culture enhanced surfactant lipid secretion by alveolar type II cells prompted us to investigate the effect of dietary fish oil on surfactant availability in intact lung. In the present study, the amount of surfactant phospholipid (PL) was taken as a quantitative measure of surfactant because surfactant is composed of greater than 60% PL (35). As indicated by the increased amount of surfactant phospholipid in whole lung (*i.e.*, lavaged lung plus lavage surfactant), fish oil feeding can in fact augment the availability of surfactant. This finding suggests an overall increase in production and/or decrease in degradation of surfactant. It should be pointed out, however, that tissue associated surfactant is not as well characterized as alveolar surfactant and may not represent pure surfactant material (26). Thus the interpretation of the data must take into account these factors.

The reason for the observed increase of surfactant in

whole lung by fish oil is not known. Exogenous palmitic acid has been found to stimulate surfactant synthesis by alveolar type II cells (36,37). Also, maximal DSPC synthesis occurs when exogenous sources of palmitic acid are provided (38). This mechanism, however, may not explain the present observation since palmitic acid levels were either unaltered in phospholipids or decreased in triacylglycerol by fish oil feeding. Longmuir and Haynes (39) have suggested a cellular sorting mechanism favoring the incorporation of 14- and 16-carbon chain length fatty acids (including 16:1) into lamellar bodies in the alveolar type II cell. Therefore, the increased levels of 14:0 and 16:1n-7 in type II cell phospholipid and triacylglycerol of the fish oil fed rats may in part be responsible for the increased amount of surfactant in the lung.

In contrast to the stimulatory effect of eicosapentaenoic acid on surfactant secretion by cultured type II pneumocytes *in vitro* (Baybutt *et al.*, unpublished data), dietary fish oil rich in n-3 fatty acids did not alter the amount of surfactant found in the alveolus. However, this finding does not exclude the possibility that dietary n-3 fatty acid enhances surfactant secretion in intact lungs because the constant amount of surfactant found in alveoli could result from an increase in surfactant clearance.

In agreement with previous studies with whole lungs (10,11) and lung microsomes (9), the present study showed that dietary fish oil was effective in enriching eicosapentaenoic acid and docosahexaenoic acid in alveolar type II cell phospholipids. Not only did the relative proportion of eicosapentaenoic acid and docosahexaenoic acid to total fatty acids increase, the mass of these fatty acids was also higher in the fish oil fed than corn oil fed group. It should be noted that the increased n-3 fatty acid levels were accompanied by a reduction in arachidonic acid. There was little or no preformed arachidonic acid in the experimental diets containing either corn oil or fish oil (Fig. 1). Thus, the cellular content of arachidonic acid must be derived from its precursor, linoleic acid. It is then reasonable to speculate that the decreased content of arachidonic acid in type II cells of animals fed fish oil stems in part from the limited source of linoleic acid (Table 2) and from eicosapentaenoic acid inhibition on the conversion of dihomogamma linolenic acid to arachidonic acid (40). The low level of cellular linoleic acid in the fish oil fed group reflects a low content of the fatty acid in the diet (*i.e.*, 11%) as compared to 60% in the corn oil diet. A reduction of linoleic acid in whole lung has also been observed in rats fed a diet containing lard low in linoleic acid (10).

The failure to incorporate dietary eicosapentaenoic acid and docosahexaenoic acid into triacylglycerols of alveolar type II cell is in direct contrast to the significant accumulation of these long-chain n-3 fatty acids (9 and 11%, respectively) in liver triacylglycerols (12). Although the reason for the discrepancy observed between the type II cell and liver is not readily known, it may be related to the preferential incorporation of 14- and 16-carbon fatty acids into triacylglycerols *via* the lipid sorting mechanism within the alveolar type II cell (39), as mentioned above. The physiological significance of 14- and 16-carbon fatty acid enrichment in triacylglycerols is not known. It may be speculated that these fatty acids serve as a reserve for the synthesis of DSPC in the type II cells.

In summary, fish oil feeding modifies the lipid profile of the type II cell and increases whole lung surfactant.

ACKNOWLEDGMENTS

Turnover of Cholesterol and Dipalmitoyl Phosphatidylcholine in Surfactant of Adult Rat Lung

In order to compare the turnover of two major surfactant components, [1α,2α(n)-^{3}H]cholesterol and [*methyl*-^{14}*C choline*] dipalmitoyl phosphatidylcholine (DPPC) were introduced as lamellar bodies *via* the trachea into lightly anesthetized rats which were then allowed to recover. The radiotracers were assumed to have entered the alveolar surfactant pool and to have subsequently recycled in part into the lamellar bodies of alveolar type II cells. For DPPC, the specific activity *vs.* time curves of tubular myelin rich (alv-1) and tubular myelin poor (alv-2) alveolar lavage fractions were similar, and there was a plausible precursor-product relationship between lamellar bodies and either (or both) of these compartments. In contrast, however, the specific activities of alv-1 and alv-2 for cholesterol were quite different, allowing us to reject the hypothesis of a precursor-product relationship between classical lamellar bodies and alv-2. The estimated turnover time for DPPC in alv-1 was 240 or 206 min, depending on which subfraction of lamellar bodies one takes to be the precursor. For cholesterol it was 583 or 624 min. These longer turnover times for cholesterol should lead to a greater than twofold increase in the relative concentration of cholesterol in the putative product compartment. Such an increase was not found. We interpret this as reflecting either noncompartmental behavior of the alveolar surfactant pool, or multiple pools of lamellar bodies with different turnover times. We conclude that two major components of pulmonary surfactant, cholesterol and DPPC, are handled differently, and that for at least one of these substances, the widely accepted scenario of a compartmental precursor-product relationship between lamellar bodies and alveolar surfactant must be rejected.
***Lipids* 28, 173-179 (1993).**

The alveoli, and probably the distal airways, of the lungs would be mechanically unstable if the surface tension at the gas-liquid interface were the same as for saline or plasma. A mixture of phospholipids, neutral lipids and specific proteins, which can be recovered by lavage of lungs, is believed to supply the gas-liquid interface with a monolayer of surface-active material. The presence of this material, pulmonary surfactant, modifies the interface in at least two important ways: first, it reduces surface tension; second, it allows surface tension to vary between alveoli, permitting alveoli of different diameters to coexist.

The alveolar surfactant appears to be in a state of dynamic equilibrium, being replaced every few hours (1-3). This ongoing renewal raises a number of questions. Why is it necessary for there to be a turnover of surfactant? Could it not, like paint on a wall, be left to serve its purpose for many years? Does alveolar surfactant have a nominal life span analogous to the 120-d life of the red blood cell, or is it subject to a constant hazard such that its likelihood of being replaced is independent of the time already spent in the alveoli? Are the different components of surfactant replaced at different rates and, if so, does this reflect a multiplicity of turnover mechanisms?

Phospholipids make up about 77% of surfactant, with dipalmitoyl phosphatidylcholine (DPPC) being the most abundant. Phospholipids are found in alveolar surfactant in much the same proportion as found in the characteristic lamellar bodies of alveolar type II cells (4-6), and this has been taken as evidence that surfactant is synthesized in alveolar type II cells and stored and secreted as lamellar bodies. Electron microscopic evidence (7) suggests that lamellar bodies are precursors of alveolar surfactant, and this has been supported by radiotracer experiments (5).

If lamellar body DPPC is, indeed, the precursor for alveolar DPPC, then evidence from several laboratories points to there being substantial recycling of this component of surfactant (3,8). This argues that the impetus for surfactant turnover is not the destruction of individual molecules, for they could not then be recycled without modification. Several alternative reasons for recycling might be proposed, but it suffices to divide these into two broad categories: those which would necessarily involve all components (phospholipid, neutral lipid, protein) in the same turnover kinetics, and those in which similar kinetics would only occur as a matter of unlikely coincidence.

Tracer experiments depend in part on the fact that if two distinct molecular species enter a pool and exist within the pool in the same relative concentrations then they have the same residence time there. The early observation that lamellar bodies and alveolar surfactant yield the same relative concentrations of different phospholipids implied a similar turnover and was the early justification for studying phospholipid turnover as a whole without distinguishing between individual phospholipids (4). Individual phospholipids, however, have different physical and biochemical properties, and it would be a remarkable coincidence if, despite these differences, the independent and individual removal of phospholipid molecules were to result in identical mean residence times in the alveoli for distinct molecular species. If, however, the removal of molecules does not represent independent events, then similar turnover times might be not only possible but actually obligatory. If, for instance, local alveolar collapse were to lead to surfactant bilayer or vesicle formation and if the involved surfactant were then sufficiently stable that the original monolayer configuration could not be restored, then all components in the affected area might be destined for recycling. Baritussio *et al.* (1) note the logical nexus between bulk uptake processes and a lack of molecular specificity, and have demonstrated a remarkable constancy in phospholipid concentration

between nine phospholipids in two subfractions of alveolar lavage.

The similarity of residence times for different phospholipids suggested that bulk uptake might be a quantitatively dominant event in precipitating surfactant turnover. Not only would it dictate similar turnover times, but it would justify there being turnover when individual molecules, taken in isolation, were unchanged and seemingly in no need of being removed. Indeed, it would justify not only removal, but also the recycling of the individual molecules once repackaged into a physiologically useful configuration. Lamellar bodies once released into the alveolar hypophase release their contents in a morphologically distinct form called tubular myelin which may be the precursor of the more amorphous surfactant to be found at the gas-liquid interface. A plausible relationship between these pools is shown in Figure 1.

The distinct and structured architecture of tubular myelin lends support to the view that functioning surfactant depends on the well-ordered arrangement of the component molecules, and that a disturbance of this arrangement might necessitate recycling in order to restore a functioning architecture.

Appealing though such a conjecture might be for events precipitating surfactant removal, the evidence is based on the implied similar turnover times for relatively similar phospholipid molecules. We felt that the conjecture should be tested using dissimilar components such as cholesterol and DPPC which make up approximately 10 and 50%, respectively, of surfactant.

In these experiments we therefore introduced tracer amounts of radiolabelled DPPC and cholesterol *via* the trachea into the lungs of lightly anesthetized rats which were then allowed to recover. The tracers were introduced as lamellar bodies, the limiting membranes of which had been ruptured immediately prior to instillation. The disappearance of these tracers from the alveolar compartment of the recipient rats and the partial recycling of the tracers into the lamellar bodies of those rats were followed over the next 24 h. From these data the turnover times of the tracers in the alveolar compartment can be deduced and compared, as can the plausibility of a precursor-product relationship between lamellar bodies and the alveolar compartment. This experimental protocol, including the preliminary preparaton of radiolabelled lamellar bodies, is outlined in Figure 2.

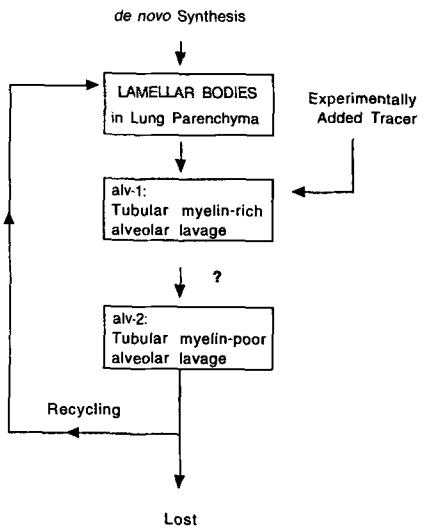

FIG. 1. The flow between proposed compartments may involve both *de novo* synthesis and recycling of surfactant components which are stored in lamellar bodies. These are released, or experimentally introduced, into the alveolar hypophase where we identify it as a tubular myelin-rich pool (alv-1). This may feed into a tubular myelin-poor pool (alv-2) before being either recycled or lost from the system.

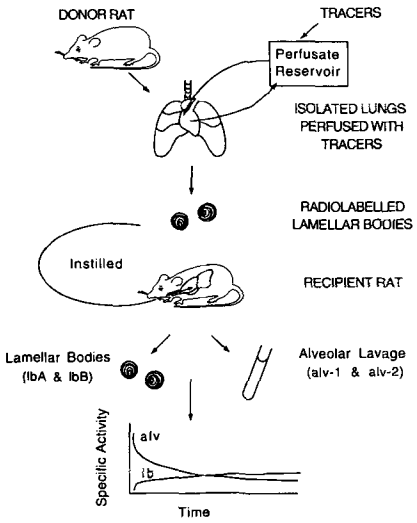

FIG. 2. The experimental protocol involves using an isolated perfused rat lung to prepare radiolabelled lamellar bodies (lbA and lbB). These are introduced *via* the trachea into the lungs of recipient rats and are assumed initially to enter the tubular myelin rich alevolar lavage fraction (alv-1) pool. The movement of the tracer molecules into other pools is followed over time, and from the specific activities of these pools, putative precursor-product relationships and turnover times can be inferred.

MATERIALS AND METHODS

All of the experiments were performed on specific pathogen-free male Porton rats (250–290 g) which were maintained in a positive pressure filtered environment and fed normal rat pellets (Milling Industries, Adelaide, Australia) and water *ad libitum.*

Preparation of radiolabeled lamellar bodies. Labeled lamellar bodies were prepared by reperfusing a reservoir containing radiolabeled precursor molecules through an isolated rat lung (3) which was set up as previously described (9). Briefly, the rat was heavily anesthetized with methohexital sodium (Eli Lilly, Sydney, Australia; 160 mg/kg i.p.) and ventilated with 5% CO_2/95% O_2 at 60 breathes/min, a tidal volume of 2.5 mL and end-expired pressure of 2 cm H_2O. The thorax was opened, and catheters were placed in the main pulmonary artery *via* the right ventricle and in the left atrium *via* the left ventricle. Without interruption of the circulation, the lungs were perfused at 10 mL/min with Krebs bicarbonate solution containing 4.5% bovine serum albumin (Cohn fraction V, Sigma, St. Louis, MO). Finally, the lungs were removed from the thorax and placed in a closed chamber saturated with water vapor at 37°C; the positive pressure ventilation continued. The perfusate was recirculated through a 25-mL reservoir which contained 100 μCi

[1α,2α(n)-^{3}H]cholesterol (46.2 Ci/mmol, Amersham, Sydney, Australia) and 10 μCi of [*methyl*-^{14}C]choline chloride (56.0 mCi/mmol, New England Nuclear, Boston, MA). The radiolabeled cholesterol in toluene was evaporated to dryness and then 25 mL of Krebs bicarbonate/albumin added. This was then warmed to 37°C, sonicated and stirred vigorously before the radiolabeled choline chloride was added. After 2 h of perfusion, the vascular bed was flushed free of radiolabel with 50 mL of unlabeled perfusate that was not recirculated.

Preparation of lamellar body fraction. We used a modification of the standard Duck-Chong method (10) and further fractionated this as previously described (11) to prepare fractions of greater uniformity. Briefly, the lungs were minced and then homogenized in 2 mL of 1.0 M sucrose. The homogenate was centrifuged at 1,000 × *g* (avg) for 5 min at 2°C, and the supernatant was aspirated and adjusted to 1.3 M with 2 M sucrose. Sucrose gradients were layered on the homogenate in 1 mL vol, each of 0.1 M, from 0.8 to 0.3 M (0.4 and 0.5 M were 0.5 mL vol) and the tubes were centrifuged at 80,000 × *g* (avg) for 2 h at 2°C. The band corresponding to lamellar bodies (between 0.4 and 0.5 M) was removed and diluted with an equal volume of cold distilled water, mixed gently, then centrifuged to prepare subfractions; lbA 8,000 × *g* (avg) for 30 min at 2°C; and lbB, 80,000 × *g* (avg) for 60 min at 2°C. Only the subfraction containing classical lamellar bodies as determined by transmission electron microscopy, and which we denote lbA, was used for tracheal instillation in the studies reported here.

Method of lung lavage. The lungs were degassed at 0.5 atm for 60 s and then lavaged at 2°C with three separate 10-mL vol (for a 250-g rat) of 0.15 M saline, each volume instilled and withdrawn three times (4). This recovered 73% of the phospholipids that could be recovered from ten triple lavages.

Analysis of phospholipids. Lipids were extracted in chloroform/methanol/water (1:2:0.8, by vol), the disaturated phospholipids were separated by the osmium tetroxide method, and the phospholipid content was determined by measuring inorganic phosphorus as described previously (4).

Analysis of cholesterol. Cholesterol was determined using high-performance liquid chromatography as previously described (12). Briefly, separation used prepacked μPorasil columns (15 cm × 3.9 mm) from Waters Associates (Milford, MA), a mobile phase consisting of hexane/isopropyl alcohol/acetic acid (750:10:0.1, by vol) and a variable wavelength detector (model 481, Waters Associates) at 206 nm.

Intratracheal instillation of lamellar bodies. The lbA fraction was instilled as previously described (3). Briefly, the limiting membranes were ruptured by incubation for 5 min at 37°C, and two separate 75-μL aliquots were rapidly instilled through a fine catheter inserted between cartilage rings of the trachea and advanced to the level of the carina, one into the left, and one into the right, bronchus. The amount of DPPC instilled was approximately 17 μg, containing 24,000 dpm, and the amount of cholesterol instilled was approximately 3 μg, containing 20,000 dpm per rat.

Statistical methods. Turnover time in the product compartment was estimated by a direct least squares fit to the untransformed data as outlined in the Appendix. We have previously shown (13) that this approach gives unbiased estimates of turnover time. Because the analysis depends on a comparison of the turnover times of two compounds, data was only included from experimental animals in which both compounds had been successfully assayed. The hypothesis of steady state compartmental precursor-product relationship may be tested using a test statistic analogous to a variance ratio (14). Because of the nonlinearity of the model and because the data from different times have different variances, the test statistic will vary from an F distribution. The distribution of the test statistic was therefore derived using a Monte-Carlo approach. Random number generation within the Monte-Carlo trials was carried out by applying a randomizing shuffle (15) to the sequence of random numbers generated by the Turbo Pascal subroutine *Random*.

RESULTS

The amount of DPPC and cholesterol in the tissue fractions lbA and lbB, and in the alveolar compartment fractions alv-1 and alv-2 are listed in Tables 1 and 2.

The ratios of cholesterol to DPPC (wt/wt) in lbA (0.077), lbB (0.17), alv-1 (0.11) and alv-2 (0.18) confirm that the two lamellar body compartments are biochemically dissimilar, as are the two alveolar subfractions. The rapid fall in

[a]Results are expressed as mean ± SEM. Rat numbers and abbreviations are identical to those in Table 1.

specific activity of both DPPC and cholesterol in the alveolar compartment was coincident with a rapid initial increase in specific activity of these two lipids in both of the lamellar body fractions, suggesting that there is considerable recycling of lipid from alveolus to lamellar bodies.

An example of the analysis of possible precursor-product relationships between these four fractions is illustrated in Figure 3, which addresses the relationship between the classical lamellar body compartment lbA and the tubular myelin rich alveolar subfraction alv-1, with DPPC as the tracer molecule. For DPPC it is widely held that lbA is the precursor of alv-1, that both pools act as homogeneous well mixed compartments and that both the turnover time of DPPC in alv-1 and that the extent of recycling into lbA can be calculated on the basis of those assumptions. Figure 3 illustrates the analysis of the experimental data on the basis of those assumptions. The observed decline

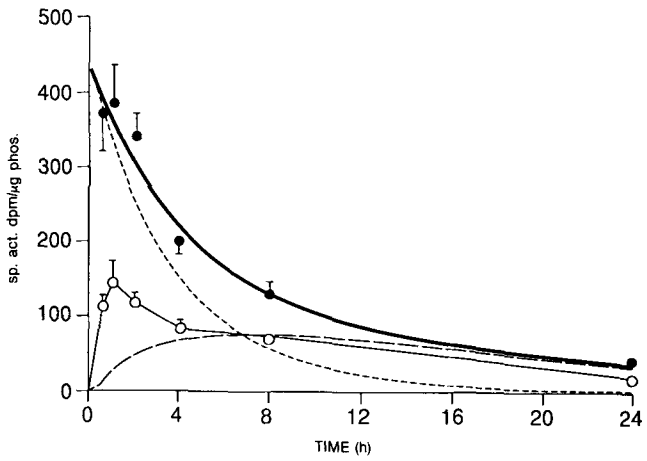

FIG. 3. Specific activities of dipalmitoyl phosphatidylcholine, measured as dpm per μg of phosphorus (sp. act. dpm/μg phos.) in the classical lamellar bodies from lung parenchyma (○), and in the tubular myelin-rich alveolar lavage (●) following intratracheal introduction of tracer is consistent with a turnover time of 240 min. The curve of best fit (weighted least squares) for the alveolar compartment (▬) is the sum of an exponential decay with 240 min time constant (- - -), and recycling from the newly synthesized lamellar bodies (— —) with the same time constant. Least squares estimates of the lamellar body specific activity is linearly interpolated (—) between sampling times.

TABLE 3

Analysis of Precursor-Product Relationships[a]

Tracer	Precursor	Product	Prob.	Turnover (min)	Recycle (%)
DPPC	lbA	alv-1	0.26	240 ± 38	46
	lbA	alv-2	0.29	206 ± 31	49
	lbB	alv-1	0.13	300 ± 47	36
	lbB	alv-2	0.17	254 ± 37	39
Cholesterol	lbA	alv-1	0.30	583 ± 55	24
	lbA	alv-2	0.02	180 ± 39	56
	lbB	alv-1	0.32	624 ± 52	18
	lbB	alv-2	0.14	198 ± 41	47

[a]The probability (Prob.) is the proportion of Monte-Carlo trials in which the trial test statistic exceeded that calculated from the real experiment. The turnover time is in minutes ± SD. For each precursor-product pair, 1000 simulations were carried out. The recycle % is the percentage of the product total radioactivity which can be attributed to recycling from lamellar bodies within the 24-h duration of the experiment. Abbreviations found in Table 1.

of the specific activity of DPPC in alv-1 represents the sum of two components. One component is an exponential decay, with time constant $\tau = 240$ min, of the initially introduced dose. This first component dominates the initial response. The second component represents recycled DPPC and is influenced by the appearance of tracer in the lbA compartment and the subsequent secretion of these labelled lamellar bodies into the alveolar compartment. This second component of alv-1 specific activity follows the lbA specific activity, approaching it always with the same time constant $\tau = 240$ min. Although its contribution is initially small, this second component dominates the latter part of the experiment.

Table 3 summarizes the result of such an analysis for both DPPC and cholesterol, taking either lbA or lbB as precursor and alv-1 or alv-2 as product.

DISCUSSION

The results for DPPC are broadly in line with the expectations. The widely accepted precursor-product relationship between lbA as precursor and alv-1 as product is not rejected by our statistical test, and the least-squares estimate of turnover time is close to our previous estimates (3). The specific activities in alv-1 and alv-2 are very similar. Our analysis accepts either lbA or lbB as precursor, and either alv-1 or alv-2 as product, deriving in each case similar time constants.

In constrast, the specific activities of alv-1 and alv-2 for cholesterol are quite different, suggesting that the alveolar kinetics of cholesterol differ from those of DPPC. The statistical analysis reflects this difference in specific activity and rejects the hypothesis that alv-2 is derived from lbA as sole precursor. There is a plausible precursor-product relationship ($P = 0.14$) between lbB and alv-2. The product alv-1 could be derived either from lbA or lbB as precursor. The time constants associated with these scenarios are, however, very much greater for cholesterol than for DPPC.

Were we to accept lbA as precursor, and alv-1 as product, then the 583 min time constant for cholesterol turnover in alv-1, taken in conjunction with the 240 min time constant for DPPC in alv-1, would lead us to expect that

the ratio of cholesterol to DPPC in alv-1 should be 583/240 = 2.4 times greater than the ratio of the two in lbA. This factor of 2.4 derives from the proposition that on average, cholesterol molecules reside in the alv-1 compartment 2.4 times longer than do DPPC molecules. The relative increase observed, however, was only 23%, and this is inconsistent with their having a common origin in lbA and the turnover times as calculated.

The alternative scenario of lbB as precursor and alv-1 as product is even less plausible. Not only does it involve a sequence of events which differs from accepted opinion, but it predicts by an argument analogous to that above, that in going from lbB to alv-1 there should be a relative *increase* in the cholesterol to DPPC ratio of more than twofold. Instead we note an observed *decrease* of 39%.

The precursor-product relationship which is plausible (although barely so) for both DPPC and for cholesterol, and for which the observed cholesterol/DPPC ratios are not in strong conflict with those predicted from the turnover times, is for lbB as precursor and alv-2 as product. Here, there is a decrease in cholesterol/DPPC ratio of 23% predicted from the turnover times against an observed increase of 3%. Perhaps the best one can say here is that the grounds for rejecting this scenario are not as strong as for the others discussed. Against this scenario, we note that lbB is the vesicular fraction and lacks the lamellae which are widely presumed to be 'packaged' surfactant. Further, alv-2 specifically lacks the tubular myelin which electron microscopic evidence argues to be the form taken by surfactant newly secreted from the alveolar type II cell.

The data therefore lead us to two tentative conclusions. First, that the apparent kinetics of cholesterol in lamellar bodies and alveolar surfactant under the experimental conditions described for the rats in this experiment, differ markedly from those of DPPC. In particular, if lbA is the sole precursor of alv-1 for DPPC, then this relationship cannot hold for cholesterol, and *vice versa*. Second, that if despite this evidence we persist in postulating that lbA is the common precursor for alveolar cholesterol and alveolar DPPC, then the differing turnover times precludes bulk uptake as the dominant mechanism of surfactant removal from the alveoli.

We can only speculate on the mechanism underlying these results. It is useful to consider our results in conjunction with those of Pettenazzo *et al.* (16) who have reported the results of similar experiments in the adult rabbit. In those experiments, the form in which the surfactant lipids were introduced had a profound effect on the turnover kinetics. When instilled as liposomes *via* the trachea, phosphatidylcholine and cholesterol had identical kinetics of removal from the alveolar compartment. However, the kinetics of liposome removal differed from those of a saline-suspended tubular-myelin-rich fraction, but again, for material instilled down the trachea as a tubular-myelin-rich fraction, the kinetics for phosphatidylcholine mirrored those for cholesterol. In the experiments of Petenazzo *et al.* (16), therefore, the form in which the tracer was instilled was pivotal, but the removal from alveoli did not distinguish between cholesterol and phosphatidylcholine.

In the present experiments, a clear difference exists between the behavior of cholesterol and that of DPPC in the rat. Although the difference may reflect the species, a more interesting possibility revolves around our introduction of the tracers within lamellar bodies. Removal of material from alveoli might well depend on whether it is recognized as a foreign body, as nonfunctioning surfactant or as physiologically functioning surfactant. We have introduced the surfactant in the form of lamellar bodies in the expectation that much of it will be treated as functionally normal surfactant. Consistent with this, we would interpret our results as suggesting that, in functionally normal rat surfactant, cholesterol and DPPC exhibit different kinetics of removal from the alveolar pool. We speculate that when these tracers are introduced as liposomes or as resuspended, processed lavage subfractions a significant proportion is treated either as foreign body or as nonfunctioning surfactant, and as such is subject to removal mechanisms which might not be expected to distinguish between the tracer molecules.

If we accept that the two tracers, when introduced as lamellar bodies intratracheally in the rat, differ in their kinetics, the question arises as to why cholesterol kinetics should differ from those of DPPC. Three interpretations suggest themselves.

First, cholesterol introduced as lamellar bodies *via* the trachea might not be acting as a tracer, and the aberrant behavior of alveolar cholesterol might be an artifact of the experiment. Against this, we note that DPPC introduced in the same lamellar bodies has behaved as expected and therefore presumably has acted as a tracer. Within the macrophages, the time course of the specific activity for DPPC and for cholesterol do not differ greatly. It is difficult to see why one substance would act as a tracer while another, introduced in the same lamellar body preparation, would not, but the possibility exists that DPPC might have dispersed from a local aggregation of introduced surfactant leaving a relatively immobile glob enriched in cholesterol.

A second possibility is that the introduced cholesterol acts as a tracer but that the alveolar pool is not a homogeneous compartment with respect to cholesterol. The experimental data is consistent with alveolar cholesterol existing as at least two compartments, one of which has a slow turnover. As a variation on this theme, alveolar cholesterol might be in rapid equilibrium with a poorly lavageable cholesterol compartment from which DPPC is excluded. While these scenarios are compatible with our results, we would not necessarily advocate them as the most likely explanations.

A third possibility is that alveolar cholesterol represents a single homogeneous compartment and that the apparent discrepancy in the results reflects recycling of cholesterol from a pool of higher specific activity than the lamellar bodies as analyzed. Either this is an entirely different source or the lamellar bodies themselves exist as distinct subpopulations of different composition, specific activity and turnover kinetics, as suggested by Young and Tierney (17). There is some support for this speculation in recent work from our laboratory concerning the effect of breathing pattern on alveolar and tissue surfactant (18).

Our working hypothesis is that the optimal physical characteristics of surfactant depend on the pattern of breathing. Reflecting this, the surfactant composition which is optimal in the resting individual might differ from that required during exercise. It is conceivable that the lipid composition of surfactant might change with activity in the mammal as it does with temperature in the

lizard *Ctenophorus nuchalis* (19). In fact, we have recently found that the ratio of cholesterol to DPPC in the alveolar compartment varies with exercise in both rats and humans, and this appears to reflect a differential release of these two components (20,21). The constant turnover of surfactant would then be a necessary consequence of matching surfactant composition to the activity of the mammal at the time. Changes on a short time scale might be accommodated by drawing on pools of lamellar bodies of different composition, and our results are consistent with there being within the surfactant precursor pool a subset of precursors with more rapid recycling. Such a subset would attain a higher than average specific activity following the tracheal instillation of tracer. The data is interpretable as evidence for the feeding of alveolar lavage cholesterol preferentially from a subset of precursors rich in cholesterol and with a rapid turnover.

APPENDIX

Turnover of surfactant components is difficult to quantify, even when seemingly drastic simplifying assumptions are made about the underlying mechanism. In the following we use a theoretical model in which lamellar bodies, or a subfraction of them, are the sole immediate precursors of alveolar surfactant. The assumptions underlying this model have been detailed elsewhere (22,23). Briefly they amount to there being a steady-state compartmental precursor-product relationship between the two pools (lamellar bodies as the sole precursor and lavagable alveolar surfactant as product) being examined.

Under those circumstances, the mean residence time τ, for a molecular species in the product compartment is given by $\tau = V/\dot{Q}$, where V is the volume of the product compartment (*i.e.*, mg DPPC per g dry lung) and $\dot{Q}$ the flux of the molecular species through the product compartment (*i.e.*, mg DPPC per g dry lung per min, being the rate at which DPPC enters and leaves the alveolar compartment at steady state). As $\dot{Q}$ is usually unknown, τ is determined experimentally in one of two ways.

In the first, radiotracer is introduced intravenously as a precursor (*e.g.*, as [^{14}C]choline *via* a caudal vein) and the specific activity of the substance of interest (*i.e.*, DPPC) determined in precursor and product compartments. If $s_a(T)$ and $s_b(T)$ are the specific activities in precursor A and product B compartments, respectively, then provided a steady state precursor-product relationship exists, we have

$$s_b(T) = \int_{t=0}^{T} s_a(t)e^{(T-t)/\tau}\, dt \qquad [1]$$

and a direct least-squares estimate of τ may be obtained using, for instance, the Marquardt-Levenberg algorithm to minimize the residual error, and we have shown (13) that this least squares approach to the estimation of turnover time can be very much more efficient than several other methods in common use. Where several animals are used to determine the specific activity at each time point and when the data is homoscedastic, deviations from the regression model closely follow an F distribution, notwithstanding that the regression is nonlinear (14). This provides an objective basis on which to decide whether a precursor-product relationship might be presumed to exist between two compartments. Where the data is heteroscedastic, the equivalent test statistic, even in a linear model, does not follow an F distribution. The problem of hypothesis testing then becomes an extension of the well known Behrens-Fisher problem (24). In practice, the distribution of the test statistic is then most easily derived empirically using a Monte-Carlo simulation, which is the approach we have adopted. Unless the data is at least consistent with a precursor-product relationship, then there is not a theoretical basis on which to proceed to determine a turnover time in the putative product compartment.

Where the turnover of two different substances is being compared, there are four specific-activity time curves, two for each substance, and the aim is to compare the time-constants derived from each pair. Although mathematically straightforward, the approach precludes any meaningful "eyeballing" of the data, and the validity of the results is strongly dependent on knowing the correct precursor compartment for each of the two molecular species.

A second experimental approach to estimating τ is to introduce the tracer directly into the product compartment and to examine the fall of specific activity with time. In a compartmental process without recycling of tracer, the specific activity would fall exponentially toward zero with time constant $\tau = V/\dot{Q}$.

In practice however, the recycling of tracer complicates the picture so that the specific activity in the precursor compartment still enters the calculations. Initially, however, precursor specific activity is zero, and its effect is not dominant. It enters the equations only as a correction, the importance of which increases with time. For tracer introduced as a bolus into the product compartment at time zero, the product specific activity $s_b(T)$ is given by

$$s_b(T) = s_0 e^{-T/\tau} + \int_{t=0}^{T} s_a(t)e^{(T-t)/\tau}\, dt \qquad [2]$$

where s_0 is the product specific activity at time zero after the introduction of the bolus. As before, $s_a(t)$ is the precursor specific activity at time t.

The experimental data comprise, for each molecular species, precursor specific activities $A_{i,j}$, $i = 1, 2, \ldots, n$, $j = 1, 2, \ldots, m_{ai}$ there being n times at which specific activities were determined, and m_{ai} rats from which precursor specific activities were obtained at the i^{th} sample time. $B_{i,j}$ and m_{bi} are defined analogously for product specific activities. The calculations assume a zero precursor specific activity at time zero and a linear interpolation of precursor specific activity between sample times. Given that both precursor and product specific activities are subject to random error, we introduce as nuisance parameters to be estimated θ_i, $i = 1, 2, \ldots, n$ being precursor specific activity at time T_i, $i = 1, 2, \ldots, n$, and θ_0 the product specific activity at time zero. For notational convenience let $\bar{\theta} = (\theta_0, \theta_1, \ldots, \theta_n)$. Then $\bar{\theta}$ and τ are the parameters to be estimated. Given $(\tau, \bar{\theta})$, equation 2 gives the predicted product specific activities $P_i(\tau,\bar{\theta})$. Then we define as the objective function to be minimized

$$\Omega(\tau,\bar{\theta}) = \sum_{i,j} w_{a,i}[A_{i,j} - \theta_i]^2 + \sum_{i,j} w_{b,i}[B_{i,j} - P_i(\tau,\bar{\theta})]^2 \qquad [3]$$

where $w_{a,i}$ and $w_{b,i}$ are weights determined by the assumed error structure of the data. In heteroscedastic data

such as found here, the weights are the reciprocals of the variances found in the compartment and, at the time, appropriate to the data being weighted.

The calculation of the extent of recycling depends on the parameters estimated above. The radioactivity, R_0, initially in the product compartment is given by $R_0 = \theta_0 V$. The radioactivity entering from the precursor compartment, all of which is "recycled," is denoted and defined

$$R_r = \dot{Q} \int s_a(t)\, dt, \qquad [4]$$

from which, using $V/\dot{Q} = \tau$, the ratio of the two becomes

$$R_r/R_0 = \int s_a(t)/(\theta_0 \tau)\, dt \qquad [5]$$

Hypolipidemic Effects of β-Cyclodextrin in the Hamster and in the Genetically Hypercholesterolemic Rico Rat

The effect of increasing amounts of a cyclic oligosaccharide, β-cyclodextrin (BCD), included in the diet on plasma cholesterol and triglycerides, was investigated in two animal models, namely in male genetically hypercholesterolemic Rico rats and in male Syrian hamsters. The distribution of bile acids in the gastrointestinal tract and in the feces of hamsters was also determined. In the Rico rats and hamsters, plasma cholesterol and triglycerides decreased linearly with increasing doses of BCD. In these two species, 20% BCD as compared to control diet lowered cholesterolemia (−35%) and triglyceridemia (−70%). In the hamster, the BCD diet caused a marked decrease in cholesterol and triglycerides in chylomicrons and very low density lipoprotein, and in high density lipoproteins cholesterol. Composition and amounts of bile acids were modified in the gastrointestinal tract of hamsters receiving 10% BCD as compared to the control group. The total bile acid content of the gallbladder of treated hamsters was fourfold higher than in the control group, and the bile contained a large amount of hydrophilic bile acids. This trend was also observed in the small intestine, in which percentages and total quantities of cholic plus deoxycholic acids (cholic pathway) were higher than those of chenodeoxycholic plus ursodeoxycholic plus lithocholic acids (chenodeoxycholic pathway). The bile acid contents of the cecum and colon of treated hamsters were 2.7-fold higher than those of control animals, but the bile acid composition was similar in the two groups of hamsters. Fecal excretion of bile acids was 3.3-fold higher in the treated group than in the control group, and the percentage of lithocholic acid was markedly increased and close to that observed in the colon. The turnover of the chenodeoxycholic pool was twice as fast in treated hamsters as in control hamsters, whereas that of cholic acid was not significantly modified. These results suggest that BCD does not alter the microbial degradation of bile acids, but rather stimulates their synthesis and increases their pool size. BCD prevents the intestinal absorption of lithocholic acid and washes this cytotoxic bile acid from the colon. The hypocholesterolemic effect of BCD appears to be due to stimulation of bile acid synthesis.
***Lipids* 28, 181-188 (1993).**

β-Cyclodextrin (BCD) is an enzymatically modified starch containing seven glucopyranose units all linked in a ring structure in α (1-4) position (1). BCD is cone-shaped with all of the secondary hydroxyl groups located at one end of the ring (the larger diameter end) and all of the primary hydroxyl groups at the other (2). The BCD cavity contains hydrogen and glycoside oxygen atoms and is therefore hydrophobic (3). BCD shows a remarkable ability to form inclusion complexes with various natural and synthetic molecules (4). In particular, BCD is able to encapsulate and solubilize cholesterol and bile acids to varying degrees *in vitro* (5-7). The inclusion process is influenced by the interactions between the guest molecules and the cavity of the host, and also by the shape and size of the guest. This can change the chemical and physical properties of the guest, such as stability, solubility and bioavailability.

When orally administered to animals for 13 weeks, BCD does not exert any toxic or genotoxic effects (8,9). BCD is not absorbed from the small intestine of rats (10). According to Gerloczi *et al.* (10), the cecum and colon of rats fed a BCD-containing diet contain large amounts of intact BCD, part of which is probably excreted in the feces. Whereas human salivary and pancreatic α-amylases do not hydrolyze this carbohydrate *in vitro* (11), it can be hydrolyzed by *Bacteroides* isolated from the human colon (12). BCD is slowly metabolized in the hindgut, probably by the microflora. The encapsulation of various molecules *in vivo* by BCD could modify the digestibility of the guest, but also of the host in the gastrointestinal tract.

In previous experiments we have observed that poorly digestible carbohydrates, such as lactose, amylomaize starch or pectin, modified bile acid metabolism and markedly reduced plasma cholesterol in germ-free or conventional rats (13-15). The mechanisms by which these carbohydrates exert their effects are poorly understood (16).

The purpose of the present study was to determine the effects of increasing levels of BCD, added to a semi-purified diet, on plasma cholesterol and triglyceride concentrations in genetically hypercholesterolemic Rico rats (17) and in Syrian golden hamsters. Subsequently, the effect of a diet containing 10% BCD on bile acid metabolism was analyzed in the male Syrian hamster which, like humans, possesses a gallbladder and shares a similar bile acid pattern (18).

MATERIALS AND METHODS

Animals and diets. The control semi-purified diet contained (g/kg): sucrose 625, lactic casein 200, lard 92, walnut oil 8, mineral mix 50, vitamin mix on cellulose 25, and cholesterol 0.5. In experimental diets, increasing amounts of BCD (Kleptose®, water content 12%, purity 99%, provided by Roquette Frères, Lestrem, France) were substituted for sucrose. The experimental diets contained 10, 50, 100 or 200 g of BCD/kg. Young male Syrian golden hamsters were purchased from the CNRS specialized breeding unit, Villejuif (France). Male hypercholesterolemic Rico rats were originally purchased from Ciba-Geigy (Basel, Switzerland).

Abbreviations: BCD, β-cyclodextrin; C, control hamsters; CA, cholic acid; EDTA, ethylenediaminetetraacetic acid; HDL, high density lipoprotein; HI, hydrophobicity index; K, chenodeoxycholic acid; LDL, low density lipoprotein; POPOP, 1,4-*bis*(5-phenyloxazol-2-yl)-benzene; PPO, 2,5-diphenyloxazole; T, 10% BCD treated hamsters; VLDL, very low density lipoprotein.

Experiment 1. Effect of BCD dose. Thirty hamsters and 18 Rico rats, 12-weeks-old at the beginning of the experiment, received food and water *ad libitum* throughout the 8 wk of the study. The room temperature was maintained at 23 ± 1°C and lighting conditions were controlled according to a 12-h cycle. Six hamsters per group were fed the control diet (C) or the experimental diet containing 1, 5, 10 or 20% BCD. Six rats per group were fed the control diet or this diet containing 10 or 20% BCD. During the last week of the experimental period, feces were collected for bile acid and neutral sterol analysis. At the end of the experiment, the hamsters and rats were killed at 10:00 a.m. by aortic puncture after Tiletamine-Zolazepam (Virbac, Paris, France) anesthesia. Plasma and liver were collected and immediately stored at −20°C. Two other groups of six hamsters each were used in order to determine lipoprotein composition. These hamsters, 12-weeks-old, received either the control diet or the experimental diet containing 20% BCD for 8 wk. After diethyl ether anesthesia, blood was collected over ethylenediaminetetraacetic acid (EDTA, 4%) and centrifuged at 3,000 × *g* for 15 min at 4°C. The plasma of two hamsters was pooled and 2 mL were used for lipoprotein isolation.

Experiment 2. Bile acid synthesis and distribution in the gastrointestinal tract and in the feces of hamsters. Two groups of four hamsters, 12-weeks-old, received either the control diet (C) or the experimental diet containing 10% BCD (T) for five weeks; thereafter they received these same diets containing 20,000 dpm/g of [24-^{14}C]chenodeoxycholic acid (CFA 533 batch 6, sp. act. 2,212 MBq/mmol, Amersham, Amersham, United Kingdom) for three weeks. Feces were collected from each hamster over two periods of four days during the last eight days of the experiment and were stored at −20°C. Finally, the hamsters were killed as previously described. Plasma, liver, gallbladder, small intestine, cecum and colon were collected and stored in ethanol prior to analysis.

Analysis of plasma cholesterol, triglycerides and lipoproteins. Total plasma cholesterol, triglycerides and phospholipids were determined enzymatically by using commercial reagent kits (Boehringer, Mannheim, Germany). For lipoprotein isolation, 2 mL of plasma was used and ultracentrifuged in a KBr density gradient at 105,000 × *g* for 24 h according to the method of Serougne *et al.* (19). Eighteen fractions were obtained, and cholesterol, triglycerides and phospholipids were determined in each fraction using commercial kits. Proteins were assayed by the method of Lowry *et al.* (20) using serum albumin as a standard.

Analysis of fecal sterols and bile acid distribution in the gastrointestinal tract. Lipids from the organs and feces were extracted with ethanol for 24 h in a Soxhlet apparatus. Lipid fractions were saponified in boiling ethanolic 2 M potassium hydroxide for 1 h. The sterols were extracted with hexane and bile acids were deconjugated by the method of Grundy *et al.* (21). Free bile acids were methylated with diazomethane, silylated with Deriva-sil (Chrompack, Middelburg, The Netherlands) and assayed on a Carlo Erba (Milano, Italy) HRGC 5160 gas chromatograph equipped with a standard fused silica WCOT capillary column cross-linked with OV1701 (Spiral, Dijon, France) or with CP Sil 5 CB (Chrompack) (length, 25 m; film thickness 0.2 μm; oven temperature, 240°C; flow-rate of hydrogen carrier gas, 2 mL/min).

For quantification of bile acids in the gastrointestinal tract and in the feces, an isotope equilibrium of [24-^{14}C]-chenodeoxycholic was used as described by Sacquet *et al.* (22). For three weeks, C and T hamsters received the radioactive diet. Dietary radioactive chenodeoxycholic acid absorbed daily in the intestine was diluted by newly synthesized or endogenous chenodeoxycholic acid until a constant dilution was obtained. When isotope equilibration was achieved, bile acids of the chenodeoxycholic pathway had the same specific activity. In particular, the specific activity of lithocholic acid (microbial metabolite of chenodeoxycholic), the most abundant fecal bile acid, became constant, and the input and output of the total radioactivity from the body were identical (see Results). The amounts of chenodeoxycholic acid and its metabolites in the gallbladder, small intestine, cecum, colon and feces were determined by dividing the radioactivities of the intestinal contents by the specific activity of lithocholic acid. These results and the percentages of chenodeoxycholic plus its microbial metabolites (chenodeoxycholic acid biosynthesis pathway, K) as determined by gas-liquid chromatography, allowed the calculation of the amounts of cholic acid plus its microbial metabolites (cholic acid biosynthesis pathway, CA) in the intestinal contents. The following equations were used:

$$\%\ \text{of CA} + \%\ \text{of K} = 100\% \quad [1]$$

$$\text{amount of K in } \mu\text{moles} = \frac{\text{radioactivity in the intestinal content}}{\text{specific activity of lithocholic acid in dpm} \times \mu\text{moles}^{-1}} \quad [2]$$

$$\text{amount of CA in } \mu\text{moles} = \frac{(\text{amount of K}}{\%\ \text{of K)}} \times (100 - \%\ \text{of K}) \quad [3]$$

Measurement of radioactivity. Radioactivities were measured in 2,5-diphenyloxazole (PPO)/1,4-*bis*(5-phenyloxazol-2-yl)benzene (POPOP) solution with a liquid scintillation spectrometer (MR 300 Kontron, Montigny le bretonneux, France).

Statistical analysis. Data are expressed as mean ± SEM and differences between groups were tested by ANOVA (Statview 512, Abacus Concepts Inc., Calabasas, CA).

RESULTS

When rats and hamsters received increasing doses of BCD up to 10% of the diet, body and liver weights, dietary intake and fecal excretion were no different from those of controls (Tables 1 and 2). With 20% BCD in the diet, liver weight was reduced by 22% and dietary intake increased by 15% in the hamster as compared to controls (Table 1). With this same diet, body weight was reduced by 12% in the rat as compared to controls (Table 2).

Concentrations of cholesterol and triglycerides. In the hamster, increasing doses of BCD in the diet decreased plasma cholesterol and triglyceride concentrations in a linear fashion. Regression lines were obtained; if y = plasma cholesterol concentration (mg/mL), or z = plasma triglyceride concentration (mg/mL), and x = % BCD in the diet, then $y = -0.028\ x + 1.583$ ($r = -0.811$, $P < 0.001$) and $z = -0.11\ x + 3.144$ ($r = -0.762$, $P < 0.001$).

These decreases were also observed in Experiment 2. In the Rico rats, the decrease in plasma cholesterol and triglycerides was similar to that observed in the hamsters. Plasma cholesterol and triglycerides in the hamsters fed 20% BCD were, respectively 33 and 66% lower than in the control group, and 40 and 55% lower in the treated Rico rats than in the control Rico rats (Table 3). In the hamsters receiving 20% BCD in the diet as compared to the control group, plasma concentrations of cholesterol, triglycerides, phospholipids and proteins in chylomicrons plus very low density lipoproteins (VLDL) decreased by 70, 59, 69 and 67%, respectively (Table 4). The concentrations of these compounds were slightly decreased in LDL_2 (low density lipoproteins). In high density lipoproteins (HDL), the concentrations of cholesterol and phospholipids were also reduced by 26 and 20%, respectively, but the protein and triglyceride concentrations were unchanged.

Variations of fecal sterols in the hamsters receiving increasing levels of BCD. In the feces of control hamsters, the level of microbial metabolites of cholesterol, including major metabolites (coprostanol and cholestanol) and minor

metabolites (epicoprostanol, cholestanone and cholestenone, called "other sterols" in Table 5), was ninefold higher than that of cholesterol itself. The addition of 1% BCD to the diet did not modify the sterol pattern, while 5, 10 or 20% BCD in the diet induced a much higher proportion of cholesterol and lowered the percentages of microbial sterols. The daily fecal elimination of neutral sterols was threefold higher in hamsters fed 20% BCD than in controls. Thus, BCD reduced microbial transformation of cholesterol and increased its fecal output and that of its by-products (Table 5).

The composition of bile acids in the feces was only slightly modified by increasing levels of BCD in the diet (Table 6). However, the percentages of lithocholic acid increased, while those of chenodeoxycholic acid decreased when the level of BCD in the diet was elevated. The increased proportion of lithocholic acid in the feces of hamsters receiving 10 or 20% BCD led us to compare the amount and nature of bile acids along the gastrointestinal tract and in the feces, in hamsters fed 10% BCD in the diet and in controls.

Distribution of bile acids in the gastrointestinal tract and in the feces of control hamsters (C) and treated hamsters (T) receiving 10% of BCD. In the gallbladder, bile acid content was 4.7-fold higher in the T group than in the C group (Table 7). In both groups, primary bile acids accounted for almost 75% of the total bile acids. The percentage of CA was increased, whereas the percentages of chenodeoxycholic acid and lithocholic acid were decreased in the T group as compared to the C group. In the small intestine, the bile acid content tended to be higher in the T than in the C group, but the bile acid composition was similar to that observed in the gallbladder, except for lithocholic acid and ketones which were increased in the two groups. In the cecum, bile acid content also tended to be higher in the T than in the C group. In both groups, the primary bile acids disappeared and microbial bile acids or secondary bile acids accounted for 95% of total bile acids. The compositions of these acids were similar and 7-oxolithocholic plus lithocholic acids accounted for 55–70% of total bile acids in the two hamster groups. In the colon, bile acid content was 2.7-fold higher in the T than in the C group, the bile acid composition being similar in these two groups. However, in comparison to what was observed in the cecum, 7-oxolithocholic acid had virtually disappeared, and the percentage of lithocholic acid in the colon corresponded to the sum of the percentages of 7-oxolithocholic and lithocholic acids in the cecum. Daily fecal elimination of bile acids was 3.3-fold higher in the T than in the C group. The fecal composition in both groups was virtually the same; 7-oxolithocholic acid was only present in trace amounts, but the percentage and mass of lithocholic acid were 1.6- and 5.3-fold higher, respectively, in the T than in the C group.

Pool sizes, biosynthesis and turnover of bile acids in the control and BCD treated hamsters. Bile acid pool sizes were calculated as the sum of bile acids in each part of the gastrointestinal tract, and the daily turnover of these acids was calculated as the ratio of bile acid pool size to daily fecal elimination of bile acids. When the isotope equilibrium of [24-^{14}C]chenodeoxycholic acid was achieved, the specific activity of lithocholic acid remained constant. It was determined in the extract of feces collected during two periods and corresponding to the 15–18th (a)

[d]$P < 0.01$.

and 19–22nd (b) days of the experiments. In the T group, this specific activity was (a) 17,290 ± 1,620 dpm/μmol and (b) 16,630 ± 900 dpm/μmol. In the C group, this specific activity was (a) 45,460 ± 3,560 dpm/μmol and (b) 38,709 ± 1,200 dpm/μmol. Moreover, the input and output of radioactivity in the two groups were almost identical. Under these conditions, the biosynthesis of bile acids was determined by the daily fecal elimination of the acids. The chenodeoxycholic acid and CA pool sizes were, respectively, 1.8- and 3.3-fold higher in the T than in the C group (Table 8). The pool size of chenodeoxycholic acid was greater than that of CA in the C group, whereas this difference disappeared in the T group. The biosynthesis of bile acids *via* the chenodeoxycholic pathway or the cholic pathway were, respectively, 3.8- and 2.6-fold higher in the T than in the C group. In the first group, the level of bile acids of the chenodeoxycholic acid synthesis pathway was twofold higher than that of the CA synthesis pathway; in contrast, these two pathways were almost identical in the C group. Thus, the turnover of bile acids of the chenodeoxycholic acid pathway in the T group was half that observed in the C group, whereas the turnover of bile acids of the CA pathway was not significantly altered.

DISCUSSION

BCD did not modify the physiological status (*i.e.*, growth, dietary intake, body and liver weights, etc.) of the hamsters and rats when it represented less than 10% of the diet. Similar results have been obtained with rats which ingested 1.25–10% BCD in the diet for 13 wk (9). When the BCD level reached 20%, the dietary intake of the hamster increased, but body weight was not changed; with rats body weight decreased slightly. A similar decrease in body weight in dogs and rats fed high levels of BCD in the diet has also been observed (23). The weight loss could be explained by the poor digestibility of this carbohydrate, which is not absorbed in the small intestine and only partially fermented by the intestinal microflora (10).

BCD induced a marked decline in plasma triglyceride and cholesterol levels in the hamster and in the genetically hypercholesterolemic rat, which reflected the decline in the triglyceride-rich particles and HDL. This hypolipidemic effect was linearly related to increased dietary BCD intakes. Several patents have claimed that the hypocholesterolemic effect of BCD and its chemical derivatives is "well-known" (24,25). However, the hypocholesterolemic effect of dietary BCD was first reported in 1990 by Pitha (26). The existence of an inclusion complex between cholesterol and BCD was indicated in 1982 (27); yet, tangible proof for the inclusion of cholesterol in BCD has only been obtained recently (6). Taken together, this suggests that the hypolipidemic effects of BCD are still poorly understood. In the present experiments, the BCD effects observed may have resulted from at least two changes that occurred in the metabolism of cholesterol and triglycerides, namely from a decrease in intestinal absorption of dietary cholesterol and triglycerides, and a stimulation of the catabolism of cholesterol into bile acids.

The decrease in the intestinal absorption of cholesterol by dietary BCD in hamsters is supported by two observations. Firstly, fecal elimination of cholesterol and its byproducts was 3.2-fold higher in the hamsters receiving 20% BCD in the diet than in the control group. Secondly, the dietary intake was only 15% higher in the first group than in the control; this small increase could not explain the stimulation of the fecal elimination of cholesterol. The decrease in cholesterol absorption was probably linked to the encapsulating capacity of BCD for cholesterol (6) and/or to disruption of intestinal bile salt mixed micelles following bile acid complexation. The complexation with BCD has been observed *in vitro* for various bile acids in aqueous medium (5,7). Moreover, the microbial transformation of cholesterol, which normally occurs in the cecum and colon, was markedly reduced by the diets containing 10 and 20% BCD. This also suggests that an intense cholesterol/BCD interaction occurs in these intestinal compartments. Such an interaction could be induced either by cholesterol encapsulation, which would prevent its microbial degradation, or by a change in the composition of the BCD fermenting microflora, which may eliminate the bacteria responsible. In the rats receiving poorly digestible carbohydrates (lactose, raw potato starch), a linear decrease of the transformation of cholesterol into coprostanol has also been observed (28).

In the hamsters, dietary BCD strongly stimulated bile acid synthesis, as determined by fecal excretion of the acids (+360%). The encapsulation of bile acids by BCD in the intestine probably prevents their reabsorption and

consequently interrupts their enterohepatic circulation, promoting their fecal elimination. When the enterohepatic circulation of bile acids is interrupted either by biliary bile diversion or by binding to a resin within the intestinal lumen, transport of bile acids to the hepatocyte is lowered and their synthesis *via* cholesterol 7α-hydroxylase is stimulated (29). These processes are altered due to the affinity of bile acids for BCD. The stimulation of biosynthesis is greater for the chenodeoxycholic acid pathway, expressed by formation of microbial metabolites (mainly lithocholic acid) in feces, than for the CA pathway. The encapsulation process is related to the hydrophobicity index (HI) of these bile acids. The HI of sodium glycochenodeoxycholate and glycolithocholate (+0.51 and 1.05, respectively) was higher than that of sodium glycocholate (+0.07) (30). *In vitro*, the affinity of free bile acid or glycine conjugate of chenodeoxycholic acid for BCD is higher than that of CA (5,7). The encapsulation of chenodeoxycholic acid in the small intestinal lumen probably increased its input into the cecum, where the bile acid can be degraded by the microflora to 7-oxolithocholic and lithocholic acids. The diet containing BCD, as compared to the control diet, did not modify the microbial pattern of bile acid degradation in the cecum and colon, but increased their intestinal contents. This microbial pattern was also observed in the hamster receiving chenodeoxycholic acid in its diet (31). The marked decrease of 7-oxolithocholic acid in the colon and its absence in the feces of the C and T hamsters suggests either its microbial transformation into lithocholic acid or its colonic reabsorption, the latter being supported by the observation reported in the literature of the absorption of 7-oxolithocholic acid through the rat colon (32). Furthermore, BCD prevented the absorption of lithocholic acid in the colon, the percentage and the amount of lithocholic acid in the feces as compared to those in the colon being significantly higher in the T than in the C group. This leads to the assumption that the very strongly hydrophobic lithocholic acid is still encapsulated in the unfermented colonic BCD (10). Under these conditions, BCD could prevent the cytotoxic effect and colonic mucosal damage induced by lithocholic acid (33).

BCD also increased the intestinal bile acid pool sizes. Previous work by Riottot and colleagues has shown that poorly digestible carbohydrates increase bile acid pool size in rats (14), and that this increase was correlated to a stimulation of bile acid absorption in the ileum (16). This process also could be modulated according to the bile acid affinity for BCD. Consequently, the turnover of chenodeoxycholic acid in the gastrointestinal tract was markedly decreased in the T group as compared to the C group of hamsters and the life-span of lithocholic acid in the colon was significantly reduced.

In the genetically hypercholesterolemic rats, the hypolipidemic action of BCD was also very pronounced and could have resulted from similar modifications as those observed in the BCD-treated hamsters. In genetically hyperlipidemic humans, the reduction in plasma cholesterol and triglycerides by dietary manipulation is generally moderate (34).

The effects of BCD were much more interesting than those induced by the classical bile acid binding resin cholestyramine. In contrast to this resin, BCD decreased plasma triglycerides, specifically stimulated the chenodeoxycholic acid pathway of biosynthesis, increased the bile acid pool (antilithiasic effect), eliminated a cytotoxic bile acid rapidly and specifically, eliminated dietary and endogenous cholesterol in feces, and was probably digested (energy production) by the microflora (35,36). Other poorly digestible carbohydrates, such as amylomaize starch, pectin or guar gum, also decreased plasma cholesterol (14,37,38), although their lipid lowering actions are poorly understood.

In conclusion, the hypolipidemic effect of BCD was shown to be due to the stimulation of bile acid biosynthesis and to the decrease of cholesterol absorption, the former being one of the most important mechanisms in the elimination of cholesterol from the plasma and, more generally from the body in the rat, hamster and humans (18,39,40). Given the efficacy of BCD observed in the two different species which we examined in the present series of experiments, it may be possible, and of interest, to carry out further studies on the hypolipidemic effects of BCD in humans.

The Effect of Culture Medium Composition on Ether Lipid Cytotoxic Activity

Luisa Diomede[a], Bianca Piovani[a], Edward J. Modest[b] and Mario Salmona[a,*]

[a]Istituto di Ricerche Farmacologiche "Mario Negri," 20157 Milan, Italy and [b]Department of Biochemistry, Boston University School of Medicine, Boston, Massachusetts 02118

The effect of a serum-free medium (TNB-100), compared to RPMI 1640 containing 10% fetal bovine serum (FBS), on the lipid composition of HL60 and K562 leukemic cells was investigated. The 10% FBS RPMI medium contained approximately three times more phospholipids (PL), about three times more protein and eight times more cholesterol (CHOL) than did the TNB-100 medium. Cells cultured in TNB-100 medium, referred to as HL60-TNB and K562-TNB cells, were significantly lower in PL and CHOL than 10% FBS RPMI cells, with about a threefold higher PL-to-CHOL ratio; however, these cells were significantly higher in protein content. Cells grown in TNB-100 were also significantly more fluid than 10% FBS RPMI cells and were more sensitive to the fluidizing action of the ether lipid 1-*O*-octadecyl-2-*O*-methyl-*rac*-glycero-3-phosphocholine. The 50% inhibitory dose of the drug was about 50% lower in TNB-grown cells than in 10% FBS RPMI cells.

***Lipids 28,* 189-192 (1993).**

Synthetic alkylglycerophospholipids, also known as ether lipids (EL), are a new class of agents that are used for the experimental therapy of cancer and leukemia (1-3). They are known to interact with the plasma membrane of neoplastic cells and to modify membrane biochemical (4-8) and biophysical properties (9-11). EL have been shown to exert a direct and specific effect on neoplastic cells; they cause preferential growth inhibition of both mouse and human leukemic cells as compared to normal bone marrow progenitor cells. These observations have led to clinical trials of EL as selective bone marrow purging agents (12,13). In addition, EL are cytotoxic, have antiinvasive capacity and induce malignant cell differentiation (1,3).

The molecular mechanisms leading to these direct effects are still not clear. Malewicz and Baumann (14) have shown first that membrane cholesterol (CHOL) levels affect the selective toxic action of EL. Recent data from our group (15,16) indicate that CHOL content modulates EL membrane effects and toxicity in leukemic cells. In fact, cells resistant to the toxic action of EL, such as K562 leukemic cells (17), are also richer in CHOL than sensitive HL60 cells (16). Moreover, by depriving K562 cells of their membrane CHOL content, it is possible to make them sensitive to originally nontoxic doses of EL (18).

The CHOL concentration in the culture medium is related to the cytotoxic action of EL, suggesting that the CHOL from serum added to the medium may modulate the biological activities of these drugs (16). This may be due, in part, to different growth conditions which may modify membrane lipid composition, or to a direct interaction of CHOL in the medium with EL resulting in reduced drug availability to the cells. We have suggested (18) that membrane CHOL levels should be considered when exposing cancer cells to EL *in vitro*, as for bone marrow purging, with the aim of optimizing the sensitivity of residual leukemic cells to EL. For this purpose we also investigated whether the use of a defined serum-free medium would affect CHOL levels in leukemic cells and consequently EL membrane effects and toxicity.

Abbreviations: CHOL, cholesterol; DPH, 1,6-diphenyl-1,3,5-hexatriene; EL, ether lipids; FBS, fetal bovine serum; ET-18-OMe, 1-*O*-octadecyl-2-*O*-methyl-*rac*-glycero-3-phosphocholine; ID_{50}, 50% inhibitory dose; PBS, phosphate buffered saline; PL, phospholipid(s).

MATERIALS AND METHODS

Chemicals. The ether lipid 1-*O*-octadecyl-2-*O*-methyl-*rac*-glycero-3-phosphocholine (ET-18-OMe) was provided by Dr. R. Nordstrom, Medmark Pharma (Munich, Germany). 1,6-Diphenyl-1,3,5-hexatriene (DPH) was purchased from Janssen (Beerse, Belgium). Erythrosin B (tetraiodofluorescein) was purchased from BDH (Poole, England). TNB basal medium with L-glutamine (2 mM) and lipid/protein complex were obtained from Seromed-Biochrom KG (Berlin, Germany). TNB-100 medium, obtained from 20 mL of lipid/protein complex and 980 mL of TNB basal medium, is defined as serum-free medium (19). The composition of the lipid/protein complex has been described (19). All other reagents were of analytical grade.

Cells. Human leukemia HL60 and K562 cells were obtained from Istituto Zooprofilattico Sperimentale (Brescia, Italy) and were free of mycoplasma contamination. Cells were cultured in RPMI 1640 medium containing 10% fetal bovine serum (FBS), 100 units/mL penicillin, 100 μg/mL streptomycin and 2mM L-glutamine, or in TNB-100 serum-free medium at 37°C in a humidified atmosphere containing 5% CO_2. Cells cultured in TNB-100 medium were defined as HL60-TNB and K562-TNB.

Phospholipid and cholesterol determinations. Lipids were extracted from 5 mL of 10% FBS RPMI or TNB-100 medium, or from the cell suspension (10×10^6 cells, total) according to Folch *et al.* (20). Phosphorus of total phospholipids (after acidic digestion) and cholesterol were determined according to Svanborg and Svennerholm (21).

Membrane fluidity. Membrane fluidity was assessed in cell suspension according to Shinitzky and Barenholz (22) using DPH as fluorescent probe. In order to measure the fluidizing effect of ET-18-OMe, cells cultured in 10% FBS RPMI or in TNB-100 medium were incubated with 10 μM ET-18-OMe for 2 h; cell viability was 100% at the end of the incubation. Control cells were incubated in the same volume of vehicle. Cells were then washed twice with Dulbecco's phosphate-buffered saline (PBS) and resuspended at $1\text{-}2 \times 10^5$/mL in PBS containing DPH (10^{-6} M). The mixture was incubated at 37°C for 30 min, and the fluorescence polarization (*P* values) were measured at 25°C using an MV-1 microviscosimeter (Elscint, Haifa, Israel). *P* values are a direct assessment of membrane fluidity as previously described (16). Arrhenius plots were

obtained for the cells with microviscosity (μ) being measured from 17 to 41°C. For each curve, the activation energy (ΔE) was determined according to Shinitzky and Barenholz (22) according to the equation: $\log \eta = \log A + \Delta E/RT$, where A is the value of the intercept of the curve with the ordinate, R is a rotational diffusion constant which was taken to be 0.362 (23) and T is the temperature expressed in degrees Kelvin.

Protein determination. Protein concentrations in 10% FBS RPMI and TNB-100 media or in the cells (after freezing and thawing) were measured according to Lowry *et al.* (24).

Cytotoxicity. EL cytotoxicity against HL60, HL60-TNB, K562 and K562-TNB cells was measured by erythrosin B dye exclusion. Different concentrations (0.5–40 μM) of ET-18-OMe were incubated with 5×10^5 cells/mL in 24-well culture dishes. After 2, 24 and 48 h at 37°C in the presence of 5% CO_2 and 95% humidified air, viable cells, *i.e.* those that retained a permeability barrier against erythrosin B, were counted.

Statistical analysis. Duncan's test for multiple comparisons was used.

RESULTS

Table 1 lists the phospholipid (PL), CHOL and protein content of the two media used for growing leukemic cells: RPMI 1640 containing 10% FBS and the serum-free TNB-100. The 10% FBS RPMI medium contained about three times more PL, three times more protein and 8 times more CHOL than TNB-100. We define cells cultured in normal 10% FBS RPMI medium as HL60 and K562 and cells grown in TNB-100 medium as HL60-TNB and K562-TNB.

TABLE 1

Phospholipids, Cholesterol and Protein Content of 10% Fetal Bovine Serum (FBS) RPMI 1640 and TNB-100 Media[a]

	Cholesterol (μg/mL)	Phospholipid (μg/mL)	Protein (mg/mL)
10% FBS RPMI	8.31 ± 0.1	0.99 ± 0.1	7.77 ± 0.3
TNB-100	1.10 ± 0.1[b]	0.31 ± 0.1[b]	2.62 ± 0.2[b]

[a] Each value is the mean ± SD of three different experimental values, obtained on three different samples.

[b] $P \leq 0.01$ according to Duncan's test for multiple comparisons.

Table 2 shows the protein content and the lipid composition of cells grown in the two media. The protein content was higher in leukemic cells cultured in TNB-100 medium (HL60-TNB and K562-TNB) than in HL60 and K562 cells cultured in 10% FBS RPMI. The TNB cells had significantly lower PL and CHOL contents, PL being 37% and CHOL being 81% lower in HL60-TNB than in HL60 cells. The reductions in K562-TNB cells were 63 and 88% respectively, compared with K562 cells. In both cell lines cultured in TNB-100 medium, there was a significant increase (about 3-fold) of the PL-to-CHOL ratio (PL/CHOL). As we have previously shown K562 cells are richer in CHOL than HL60 cells (16,18).

Figure 1 shows the relationship between the reciprocal temperature and the logarithm of microviscosity (η) for HL60 and HL60-TNB cells (Panel A) and for K562 and K562-TNB cells (Panel B). The cell microviscosity was measured in the range from 17 to 41°C. The equations describing each curve were: (i) for HL60 cells, $\log \eta = 0.917 - \log 2.834$ and the correlation coefficient was $r = 0.99$; (ii) for HL60-TNB cells, $\log \eta = 0.795 - \log 2.527$ and $r = 0.99$; (iii) for K562 cells, $\log \eta = 1.244 - \log 3.863$ and $r = 1.00$; (iv) for K562-TNB cells, $\log \eta = 1.269 - \log 4.044$ and $r = 0.99$. The temperature profiles of the four curves did not show any gel-to-liquid crystalline phase transition.

For each of these curves the activation energy (ΔE) was established at different temperatures (22). The ΔE values calculated at 25 and 37°C were: for HL60 cells, 2.73 and 2.85 Kcal/mol; for HL60-TNB cells, 2.37 and 2.46 Kcal/mol; for K562 cells, 3.71 and 3.82 Kcal/mol; for K562-TNB cells, 3.78 and 3.94 Kcal/mol.

Changes in EL toxicity related to lipid composition were investigated by incubating the cells with different doses of ET-18-OMe for 2, 24 and 48 h (Table 3). The 50% inhibitory doses (ID_{50}) were about 50% lower in HL60-TNB cells than in HL60 cells ($P \leq 0.01$). A similar enhancement of inhibition was seen for K562-TNB cells compared with K562 cells. Table 4 lists the fluorescence polarization data. Cells cultured in TNB-100 medium were significantly more fluid than cells cultured in 10% FBS RPMI. HL60 cells are known to be sensitive to the fluidizing action of EL, with an increase in fluidity of about 7% occurring after exposure to 5 μM EL for 2 h (16). In HL60-TNB cells the same dose of ET-18-OMe lowered the bulk fluidity by 14%. K562 cells, originally insensitive to the fluidizing action of EL (18), became sensitive when cultured in TNB-100 medium, showing a reduction in

fluorescent polarization of about 6% after exposure to 5 μM ET-18-OMe. Cell viability was 100% at the end of incubation.

DISCUSSION

Our recent data indicated that a correlation exists between the PL/CHOL ratio of the cell membrane and the cytotoxic effect of EL on leukemic cells (16). Modulation of the PL/CHOL ratio of leukemic cells, by extracting CHOL from the cell membrane, has been proposed as a method for enhancing the effectiveness of EL (18).

The PL/CHOL ratio of the cell membrane may also be changed by changing growth conditions, for example, by using media containing different percentages of serum and consequently of CHOL (16). We have here investigated whether the PL/CHOL ratio of HL60 and K562 leukemic cells which are, respectively, sensitive and quite resistant to EL toxic action (16,18), can be modified by culturing the cells in TNB-100 medium, a defined serum-free medium which contains about three times less PL and

TABLE 3

Effect of Culture Medium on ET-18-OMe 50% Inhibitory Doses (ID_{50})[a]

Cell type	ID_{50} (μM) 2 h	24 h	48 h
HL60	60.0 ± 4	4.1 ± 0.5	2.5 ± 0.5
HL60-TNB[b]	23.0 ± 5	2.4 ± 0.5	1.2 ± 0.5
K562	108.8 ± 5	36.4 ± 2	11.9 ± 0.7

K562	0.2045 ± 0.001
K562 + ET-18-OMe	0.2050 ± 0.001
K562-TNB	0.1960 ± 0.004[b]
K562-TNB + ET-18-OMe	0.1847 ± 0.001[c,d]

[a]Each value is the mean ± SD of at least six determinations. HL60 and K562, cells cultured in RPMI 10% fetal bovine serum (FBS) medium. HL60-TNB and K562-TNB, cells cultured in serum-free TNB-100 medium. ET-18-OMe, 5 μM ET-18-OMe for 2 h. Viability was 100% at the end of incubation.

[b]$P \leq 0.05$ and [c]$P \leq 0.01$ *vs.* HL60 or K562 cells cultured in 10% FBS RPMI; and [d]$P \leq 0.01$ *vs.* HL60-TNB or K562-TNB cells, according to Duncan's test for multiple comparisons.

protein and 8 times less CHOL than 10% FBS RPMI. The growth of leukemic cells in this medium, leading to HL60-TNB and K562-TNB cells, significantly modified the plasma membrane PL/CHOL ratio, increasing it by about three times compared to cells cultured in 10% FBS RPMI (Table 2). The cells grown in TNB-100 medium are also richer in protein relative to the cells cultured in 10% FBS RPMI (Table 2). Because the serum-free medium and the serum-containing medium have different compositions, the differences in sensitivity to the cytotoxic action of ET-18-OMe could not be attributed to the differences between PL/CHOL ratios alone. TNB-100 medium also contains 2 g/L of albumin which may bind lipids and thus modify the uptake of ether lipids (25). We measured the uptake of [^{3}H]ET-18-OMe in HL60 and K562 cells cultured in the two media (10% FBS RPMI and TNB-100) after 2 h of drug exposure, but no differences were observed (data not shown). One can exclude the possibility that the differences in sensitivity observed between the cell lines cultured in serum-free or serum-containing media can be attributed to differences in drug uptake, but it is not possible to exclude a possible effect of differences in cell protein content.

The temperature curves illustrate the substantial differences that exist between the overall lipid profile in 10% FBS RPMI and in TNB-100 cells. Also considered was the activation energy (ΔE), which represents the energy required to dissociate a molecule from the bulk phase. Under our experimental conditions, the cells cultured in TNB-100 medium were significantly more fluid than those cultured in 10% FBS RPMI; however the ΔE values were the same. The opposite pattern between fluorescence polarization and ΔE values in TNB-100 cells could be related to the higher protein concentration. Moreover, the increase in total PL and the decrease in CHOL content, with a consequent increase of the PL/CHOL ratio, is only one but a major factor responsible for the fluidization of cell membranes whereas the increase in protein concentrations may involve a reduction of the fluid phase of the lipids (25).

Extraction of CHOL from the cell membrane by the AL721 lipid mixture (26,27) has been proposed as a mean of enhancing the toxic action of EL. Under this condition, the culture medium composition stays constant, but the CHOL content is reduced (26,27). This approach modified the effect of the drug at 5 μM only at a very early stage of exposure (16,18). The TNB-100 medium may modulate the cytotoxic effects of EL at longer exposure times as well. In fact, the changes produced with the TNB-100 medium reduced the ID_{50} for ET-18-OMe by about 50% in HL60-TNB and K562-TNB cells compared with HL60 and K562 cells at 2, 24 and 48 h exposure times.

We conclude that the composition of the culture medium can modify the cell membrane PL/CHOL ratio and the protein content, thus modulating the biophysical and biochemical effects of EL. The possibility exists that a direct interaction between EL and CHOL or EL and albumin may reduce the availability of the drug. Nevertheless, for the purpose of *ex vivo* bone marrow purging, EL treatment, accompanied by the use of a serum-free TNB-100 medium combined with AL721 treatment, may offer a better therapeutic approach for a more effective elimination of residual myeloid leukemic cells.

Human Platelets Release a Paf-Acether: Acetylhydrolase Similar to That in Plasma[1]

Ruth Korth, Jocelyne Bidault, Remi Palmantier, Jacques Benveniste* and **Ewa Ninio**
INSERM U200, Université Paris Sud, 92140 Clamart, France

Intact washed human platelets aggregated in response to paf-acether (paf) and did not metabolize [^{3}H]paf at concentrations up to 10 nM. However, when platelets were lysed by exposure to pH 9.5, resulting in 37.5 ± 2.5% (mean ± SD, n = 3) lactic dehydrogenase (LDH) release, 20.5 ± 5.7% of the radioactivity was detected as labeled lyso paf and 5.7 ± 3.1% as labeled alkylacylglycerophosphocholine. When platelets were aggregated with 0.5 IU/mL thrombin or high concentrations of paf (100 nM), they released a part of their acetylhydrolase without releasing LDH. In supernatants obtained from aggregated platelets, 21 ± 2% or 10 ± 2% (n = 3), respectively, of the total platelet acetylhydrolase activity was detected *vs.* none in supernatants of resting cells. The release of acetylhydrolase was concentration- and time-dependent and paralleled the release of PF 4, a marker for α-granules. The acetylhydrolase affinity for paf (K_m) measured in sonicates of resting and thrombin-activated platelets was 8.3 ± 1.5 μM *vs.* 10.6 ± 1.5 μM, n = 5, n.s. in a "Mann Whitney" test. The latter K_m was slightly but significantly different ($P < 0.05$, n = 5) from that of the thrombin-released acetylhydrolase (7.9 ± 1.5 μM) and that of the latter was itself different from plasma acetylhydrolase (5.3 ± 0.5, $P < 0.05$, n = 5). Addition of plasma (acid-treated to inactivate acetylhydrolase) decreased the K_m value of supernatant acetylhydrolase to 6.1 ± 1.4 μM. All preparations of acetylhydrolase exhibited similar pH requirements and sensitivity to various inhibitors. Thus paf and thrombin cause release of acetylhydrolase from platelets in parallel with release of the α-granule marker PF4. This phenomenon might represent a protective mechanism against paf-mediated effects in thrombotic and cardiovascular diseases.
***Lipids* 28, 193-199 (1993).**

Paf-acether, first described as platelet-activating factor (paf) (2), with the structure of a 1-*O*-hexadecyl/octadecyl-2-acetyl-*sn*-glycero-3-phosphocholine (hexadecyl/octadecyl-acetyl-GPC; 3,4), is a biologically active ether phospholipid which is released from stimulated cells (for reviews, see Refs. 5,6). Paf is hydrolyzed into lyso paf by an acetylhydrolase (6-9), and in platelets an intracellular CoA-independent transacylase reacylates lyso paf to 1-*O*-alkyl-2-acyl-*sn*-glycero-3-phosphocholine (alkylacyl-GPC, 9,10). Both acetylhydrolase and transacylase metabolize paf in the absence of Ca^{2+} (7,9). The acetylhydrolase is active in a broad pH range (from 6.4 to 8.4) (7) and in plasma it is bound to lipoproteins (11,12).

When incubated under the same conditions as those of paf-induced aggregation, washed intact rabbit platelets metabolize paf (13) but washed intact human platelets do not (14). Many other cell types such as intact neutrophils, activated eosinophils, hepatocytes, macrophages and endothelial cells metabolize exogenous paf (6). Bovine platelets release acetylhydrolase in parallel with serotonin during platelet aggregation in response to paf, adenosine diphosphate and thrombin (15). Murine macrophages when maintained in culture (16) and human monocytes differentiated into macrophages by adherence (17) or incubated with low density lipoprotein (18) acquire the faculty to synthesize and/or to release acetylhydrolase.

In this study, we investigated the release of acetylhydrolase from human platelets. Our results led us to propose that activated platelets might be at least one of the sources of plasma acetylhydrolase.

MATERIALS AND METHODS

Reagents. Aspirin was used as lysine salt Aspegic^R and was obtained from Egic Laboratory (Amilly, France). Fatty acid-free bovine serum albumin (BSA), 5-hydroxytryptamine (serotonin) and β-glucuronidase were purchased from Sigma Chemical Co. (St. Louis, MO). Radiolabeled [^{3}H-*octadecyl*]paf (1-*O*-[^{3}H]octadecyl-2-acetyl-GPC, 80-120 Ci/mmol) and lyso paf (1-*O*-[^{3}H]octadecyl-GPC, 80-120 Ci/mmol) and the scintillation liquids Biodegradable Counting Scintillant (BCS) and Organic Counting Scintillant (OCS) were purchased from Amersham (Bucks, United Kingdom). [^{3}H-*acetyl*]Paf (1-*O*-octadecyl-2-[^{3}H]-acetyl-GPC, 10 Ci/mmol) was obtained from New England Nuclear (Boston, MA). Paf (1-*O*-octadecyl-2-acetyl-GPC), lyso paf (1-*O*-hexadecyl/octadecyl-GPC) and 1-*O*-hexadecyl-2-palmitoyl-GPC were purchased from Bachem (Bubendorf, Switzerland). GF/C filters were obtained from Whatman (Ferriére, France). Human fibrinogen (AB Kabi, Stockholm, Sweden, grade L, pretreated with diisopropyl-fluorophosphate and partially purified was a gift from B.B. Vargaftig, Institute Pasteur, Paris, France). Lactic dehydrogenase (LDH) was purchased from Boehringer (Mannheim, Germany) and platelet factor 4 (PF 4) was obtained from Abbott (Rungis, France). Thrombin was obtained from Hoffman-la-Roche (Basel, Switzerland). Zwittergent^R detergent 3.16 was purchased from Calbiochem (Frankfurt, Germany). Dextrose and citric acid were obtained from Merck (Darmstadt, Germany).

Aggregation of platelets. Washed platelets were prepared according to a method of Korth *et al.* (19). Briefly, human blood was collected in acid citrate dextrose (citric acid, 0.8%, trisodic citrate, 2.2% and 2.5% glucose, 2.45%) in a ratio 1:7 (vol/vol) and platelet rich plasma (PRP) was obtained after centrifugation at 100 × *g* for 15 min. PRP was centrifuged at 900 × *g* for 10 min. The supernatant plasma was centrifuged again to discard remaining platelets and was kept on ice for the acetylhydrolase assay.

[1]This study has been presented in part as a preliminary report at the 72nd Annual Meeting of the Federation of American Societies for Experimental Biology, Las Vegas, NV, May 1988 (1).

Abbreviations: Alkylacyl-GPC, 1-*O*-alkyl-2-acyl-*sn*-glycero-3-phosphocholine; BSA, fatty acid-free bovine serum albumin; EC_{50}, 50% maximal aggregation; LDH, lactic dehydrogenase; [^{3}H-*acetyl*]paf, 1-*O*-octadecyl-2-[^{3}H]acetyl-GPC; [^{3}H]paf, 1-*O*-[^{3}H]octadecyl-2-acetyl-GPC; lyso paf, 1-*O*-hexadecyl/octadecyl-GPC; paf, paf-acether, platelet-activating factor, 1-*O*-hexadecyl/octadecyl-2-acetyl-GPC; PF 4, platelet factor 4; PRP, platelet-rich plasma.

Platelets were washed twice in Tyrode's buffer containing (in mM) NaCl, 137; KCl, 2.68; $NaHCO_3$, 11.9; $MgCl_2$, 1.0; NaH_2PO_4, 0.41; dextrose, 0.5; HEPES, 5.0. After 30-min incubation with 0.1 mM aspirin (18), platelets were resuspended at the concentration of 2×10^9 cells per mL and were diluted to a final count of 3×10^8 cells per 300 μL Tyrode's buffer (pH 7.4) in the presence of 1.3 mM $CaCl_2$ and 0.16 mg/mL fibrinogen. Platelets were aggregated with either unlabeled paf (0.1 to 5 nM) or [^{3}H-*octadecyl*]paf (0.65 nM, 15 nCi) for 3 min under stirring at 20 or 37°C. Incubations were also performed in the presence of 0.25% BSA. The extent of platelet aggregation was calculated as percent of maximal light transmission.

*Metabolism of [^{3}-H-*octadecyl]paf in the presence of intact or damaged platelets.* Platelets (5×10^7 cells/500 μL) were incubated with [^{3}H-*octadecyl*]paf (0.65 nM, 15 nCi) without stirring at pH 7.4 for 30 min, 1 h and 2 h either at 20 or 37°C. Incubations were also performed in the presence of BSA. In some experiments, platelets were incubated at pH 9.5 for 30 min at 37°C either in the presence of BSA or in the absence of BSA. Platelet lysis was assessed by the amount of LDH in supernatants (20).

Extraction method and liquid chromatography. After incubation with labeled paf, platelet suspensions or corresponding supernatants were extracted as described (21). Dichloromethane/methanol (1:2, vol/vol) was added to platelet suspensions (0.5 mL) for 24 h at 4°C and then dichloromethane/water (1:1, vol/vol) containing 2% acetic acid was added. Organic phases were collected and water phases were washed three times with 1 vol of dichloromethane. The combined organic phases were brought to dryness under an air stream at 40°C. Dry residues were dissolved in small volumes of mobile phase (dichloromethane/methanol/water, 50:50:5, by vol) and then applied to a Microporasil column 3.9 mm i.d. × 300 mm length (Waters Associates, Milford, MA), which was eluted at a flow rate of 1 mL/min as described (22). Void volume was defined as 3–7 min, 11–13 min as alkylacyl-GPC, 18–21 min as paf and 28–31 min as lyso paf based on appropriate authentic standards. Radioactivity in the fractions was counted using OCS scintillation liquid and was expressed, after subtraction of background values, as percentage of the sum of radioactivity in all fractions. All water phases were also counted to monitor total radioactivity.

Release of acetylhydrolase and granular markers during platelet activation. Platelets were aggregated with thrombin (0.1 to 5 IU per mL) or paf (10 to 500 nM) for 15 s to 5 min. Platelets were centrifuged at 900 × *g* for 10 min at 4°C, and supernatants (5 μg protein) were tested for acetylhydrolase activity as described below. The acetylhydrolase activity in supernatants was expressed as percentage of the total acetylhydrolase activity of sonicated platelets. LDH and PF 4 were measured using commercial kits, and serotonin was measured by an electrochemical method (23) in supernatants and in corresponding pellets.

Acetylhydrolase assay. Acetylhydrolase activity was measured in lysates from resting or thrombin-aggregated platelets, in supernatants of stimulated platelets and in autologous plasma. Platelets were suspended in Tyrod's buffer (pH 6.4) without BSA at a concentration of 10^9 platelets per mL, platelet-free plasma (diluted 1:200, vol/vol in Tyrod's buffer) were added with Zwittergent detergent 3.16 (0.0015% wt/vol, final concentration) and were sonicated (6 pulses of 10 s, at 4°C, Bronson Sonic Power Co., Danbury, CT). Protein content was determined in cell lysates or plasma as described by Lowry *et al.* (24). Lysates from 5×10^7 platelets (50 μL containing 80 μg protein), supernatants from thrombin-activated platelets (50 μL, 5 μg protein) or diluted plasma (1/200, 50 μL, 20 μg protein) were added to 400 μL of a buffer (pH 8.0) containing HEPES 4.2 mM, NaCl 137 mM, KCl 2.6 mM, and EDTA 2 mM. After 5-min preincubation at 37°C, the reaction was initiated by addition of 10 μL [^{3}H-*acetyl*]paf (0.01 μCi, 0.5 to 35 μM final concentration). In some experiments hexadecylpalmitoyl-GPC (20 μM) was added to the assay mixture together with [^{3}H-*acetyl*]paf (10 μM) to determine the specificity of acetylhydrolase toward paf. Preparations containing acetylhydrolase were also treated for 30 min at 37°C with NaF (20 mM) or bromophenacylbromide (0.5 mM) as described by Stafforini *et al.* (25) prior to addition of [^{3}H-*acetyl*]paf for 10 min. In selected experiments, acid-treated plasma that was inactive in our acetylhydrolase assay was added together with platelets' lysate or supernatant obtained from thrombin-activated platelets. Assay mixtures were incubated for 10 min at 37°C unless stated otherwise and stopped by cooling in an ice bath. Two methods were used to separate [^{3}H]acetate from unreacted [^{3}H-*acetyl*]-paf. The first one, described by Palmantier *et al.* (16), was based on the extraction of [^{3}H-*acetyl*]paf in the organic phase by adding 2 mL methanol/dichloromethane (1:1, vol/vol) and 0.4 mL acetate (5%) solution containing [^{14}C]acetate (6000 dpm) as an internal standard. Mixtures were centrifuged at 5000 × *g* for 10 min to facilitate phase separation. The amount of [^{3}H]acetate in the aqueous phase resulting from the acetylhydrolase assay was determined by liquid scintillation counting using BCS as solvent. The second method used to separate [^{3}H]-acetate from unreacted [^{3}H-*acetyl*]paf described by Miwa *et al.* (26), that gave similar results as the former method (data not shown), was based on addition of an excess of BSA (16.7 mg/mL, final concentration) and subsequent precipitation of paf bound to added BSA by trichloroacetic acid (TCA) (7%, vol/vol, final concentration). Denatured proteins were centrifuged at 5000 × *g* for 15 min and the released [^{3}H]acetate was measured by liquid scintillation counting in BCS. Blanks performed using either heat-denatured (100°C for 10 min) or acid-treated (pH 2.0) enzyme were less than 20% of counts. Blanks were subtracted prior to calculations of enzyme activities. Results are expressed in pmol/min/mg protein after correction for extraction losses estimated using [^{14}C]acetate internal standard. The thermolability of acetylhydrolase of enzyme preparations was checked by heating for 30 min at 65°C before addition of [^{3}H-*acetyl*]paf as described (27). The optimal pH of acetylhydrolase using appropriate buffers (from pH 2 to pH 10) was also established.

Statistical analysis. Results are expressed as mean ± SD or SE as indicated. Statistical analysis was performed using the "Mann Whitney" test.

RESULTS

Lack of paf metabolism during platelet aggregation at low concentrations of paf. Paf was not metabolized during

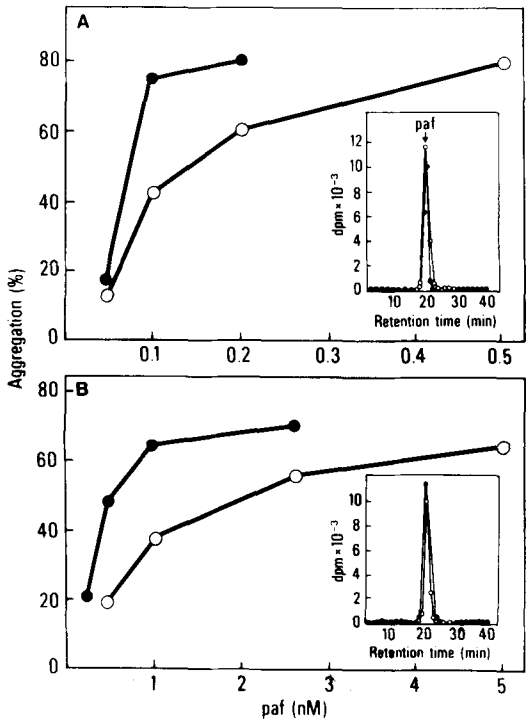

FIG. 1. Concentration-dependent platelet aggregation with paf-acether, platelet-activating factor (paf). Platelets ($3 \times 10^8 \times mL^{-1}$) were incubated with defined concentrations of paf in the absence (A) or in the presence of 0.25% bovine serum albumin (B) at 20°C (●) or 37°C (○) under stirring for 3 min. Values are calculated as percent of maximal light transmission. One experiment is representative of three (statistical analysis is given in the Results section). Insets: Lack of paf metabolism under conditions of platelet aggregation. Platelets were incubated with 15 nCi of 0.65 nM [^{3}H-*octadecyl*]paf at 20°C (●) or 37°C (○) under stirring for 3 min. Phospholipids were analyzed using liquid chromatography as described in Materials and Methods. [^{3}H-*octadecyl*]paf recovered corresponded to 21,279 ± 1369 dpm (mean ± SD, n = 4).

platelet aggregation in response to low concentrations of paf (0.1 to 5 nM) in the absence or presence of BSA and either at 20°C or at 37°C (Figs. 1A and and 1B). The paf concentration inducing 50% of the maximal aggregation (EC_{50}) in the absence of BSA was 0.07 ± 0.02 and 0.1 ± 0.02 nM at 20 and 37°C, respectively (mean ± SD, n = 3). Maximal aggregation was reached after 3 min at 0.2 ± 0.02 and 0.5 ± 0.02 nM paf at 20 and 37°C, respectively (Fig. 1A). BSA (0.25%) inhibited paf-mediated platelet aggregation; EC_{50} values increased to 0.4 ± 0.4 and 0.9 ± 0.2 nM paf after 3-min aggregation with a maximal aggregation at 2.6 ± 0.5 and 5.0 ± 0.5 nM paf at 20 and 27°C, respectively (Fig. 1B).

Stability of [^{3}*H-octadecyl*]*paf in the presence of intact platelets and its catabolism in the presence of damaged platelets.* When intact platelets were incubated with [^{3}H-*octadecyl*]paf (0.65 nM) without stirring either at 20°C (data not shown) or 37°C and either in the presence or in the absence of 0.25% BSA for 30 min, 1 h and 2 h, paf was not degraded (Table 1). Only 4.5% of the label was recovered as [^{3}H]alkylacyl-GPC and 3.5% as [^{3}H]lyso paf at 37°C in the absence of BSA (pH 7.4). Platelets were essentially undamaged since LDH release was less than 9% *vs.* 4.6 ± 0.7% in supernatants of control cells. However, when platelets were partially damaged by incubation at pH 9.5 in the absence of BSA (30 min, 37°C), 5.7 ± 6.2% of the [^{3}H-*octadecyl*]paf was recovered as [^{3}H]alkylacyl-GPC and 20.5 ± 11.4 as [^{3}H]lyso paf (mean ± SD, n = 3 or 4). Under these experimental conditions 14.7 ± 4.9%, 10.5 ± 3.0 and 37.5 ± 2.5% (n = 3) of acetylhydrolase, PF 4 and LDH were released, respectively.

Release of acetylhydrolase during platelet aggregation with thrombin or high concentrations of paf. Platelets released a fraction of their acetylhydrolase content during aggregation in response to thrombin or high concentrations of paf (Table 2). No increase in LDH release was observed after thrombin activation (Table 1) or in response to 100 nM paf (1.5%, n = 2). Unstimulated platelets did not release acetylhydrolase (Tables 2 and 3). The question arose whether acetylhydrolase was released from platelet granules together with one of markers that could help to locate this enzyme within the cell. Activation of platelets by thrombin promoted the release of all types of granule markers: β-glucuronidase (lysosome), serotonin (dense granules) and PF 4 (α-granules), in contrast to paf which only triggered PF 4 release (Table 2). The release of acetylhydrolase and PF 4 in response to thrombin or paf was time-dependent (Table 3). Whereas thrombin (0.5 IU/mL)

TABLE 1

Paf Metabolism by Resting, Damaged or Activated Platelets[a]

Treatment of platelets	LDH (% release)	Lyso paf (%)	Alkylacyl-GPC (%)
(1) 37°C, BSA	4.6 ± 0.7 [3]	0.7 ± 1.2	1.5 ± 1.4 [3]
(2) 37°C	9.0 [2]	3.5 ± 1.2	4.5 ± 3.6 [4]
(3) 30 min, 37°C, BSA, pH 9.5	13.0 [2]	10	0 [1]
(4) 30 min, 37°C, pH 9.5	37.5 ± 4.2 [3]	20.5 ± 11.4	5.7 ± 6.2 [4]
(5) Supernatant of (4)		20.1 ± 1.7	2.7 ± 2.2 [3]
(6) Supernatants of thrombin-activated platelets	6.5 ± 2.6 [3]	29.0	2.2 [2]

[a]Treated or untreated platelets [for (1) to (4) pooled results of 30, 60 and 120 min experiments were used] or their supernatants were incubated with [^{3}H-*octadecyl*]paf (15 nCi, 0.65 nM) for 30 min at 37°C. Labelled phospholipids were extracted, and analyzed as described in Materials and Methods. Results in percentages of the total counts (22,648 ± 1800 dpm) are means ± SD of [n] independent experiments. LDH, lactic dehydrogenase; lyso paf, 1-*O*-hexadecyl/octadecyl-GPC; alkylacyl-GPC, 1-*O*-alkyl-2-acyl-*sn*-glycero-3-phosphocholine; paf, paf-acether, platelet-activating factor; BSA, bovine serum albumin. Parentheses in Tables 1, 4 and 5 refer to in-table information, not References.

TABLE 2

Acetylhydrolase and Granular Content Release from Stimulated Human Platelets[a]

Stimulation		Acetylhydrolase	β-Glucuronidase	Serotonin	PF 4
Control		0	0	7 ± 3	2
Thrombin	0.2	15 ± 5	3 ± 2	43 ± 28	100
[IU/mL]	0.5	21 ± 3	10 ± 2	71	100
	5	19 ± 5	16 ± 7	80 ± 32	100
Paf	10	0	0	4 ± 2	20
[nM]	100	10 ± 1	0	3 ± 2	22
	500	8 ± 6	0	7 ± 2	27

[a]Platelets (10^8/mL) were incubated for 5 min at 37°C with given agonist and were centrifuged at 900 × *g* for 10 min at 4°C. Supernatants and pellets were tested for enzyme activities, serotonin content and PF 4 content. Results are in percentages of the total (mean ± SD, n = 3 to 5, when SD is omitted n = 2). 100% for acetylhydrolase was 182 pmol/min per mL, for β-glucuronidase 3.8 μg/mL, for serotonin 131 ng/mL, and for PF 4 4.8 μg/mL. Paf, paf-acether, platelet-activating factor; PF 4, platelet factor 4.

TABLE 3

Time-Course of Acetylhydrolase and PF 4 Release from Stimulated Platelets[a]

	Paf (500 nM)		Thrombin (0.5 IU/mL)	
Stimulation (s)	Acetylhydrolase	PF 4	Acetylhydrolase	PF 4
0	1.0 ± 1.7	0.8	2.2 ± 1.6	0.5 ± 0.1
15	8.2	10.2	8.5 ± 1.3	22.0 ± 1.6
30	7.8 ± 4.5	11.8	13.1 ± 6.8	36.1 ± 2.2
60	9.5 ± 6.7	28.5	12.8 ± 8.8	49.2 ± 6.7
120	10.0 ± 2.5	33.6	10.9 ± 5.3	67.9 ± 7.7
180	12.6 ± 6.5	27.5	17.9 ± 4.5	74.9 ± 4.6
300	10.3 ± 2.7	36.1	17.2 ± 5.3	87.7 ± 18.8

[a]Results are expressed as percentages of the total content of acetylhydrolase (mean ± SD, n = 3, when SD is omitted n = 2). For details see footnote to Table 2.

and paf (500 nM) triggered the release of 17.2 ± 5.3% and 10.3 ± 2.7% of the total acetylhydrolase, respectively, PF 4 increased to 87.7 ± 10.8% and 36.1 ± 14.8%, respectively (mean ± SD, n = 3). These data indicate that the releasable pool of the enzyme is limited.

Kinetic studies of acetylhydrolase. The acetylhydrolase activity was measured in plasma (Fig. 2A), in cell lysates (cells and supernatants) from nonactivated and thrombin-activated platelets (Fig. 2B) and in supernatants from thrombin-activated platelets (Fig. 2C). The acetylhydrolase activity in all preparations was linear with the incubation time up at least 10 min and with the protein concentration up to 100 μg/mL (data not shown). Under these conditions [^{3}H]acetate release from [^{3}H-*acetyl*]paf nearly reached a plateau at 20–40 μM (Fig. 2). The acetylhydrolase activity was independent of the presence of Ca^{2+} in the assay (data not shown) and was not inhibited by excess hexadecylpalmitoyl-GPC (Table 4), suggesting that the activity that we measured was not the classical phospholipase A_2. In addition treatment with bromophenacylbromide and NaF similarly affected acetylhydrolase in lysates from thrombin-activated platelets, in corresponding supernatants and in plasma (Table 4). All preparations exhibited similar pH optimum (data not shown).

The K_m values calculated from the Lineweaver-Burk plots are given in Table 5. The statistical analysis of the data showed a small but significant difference of the K_m values when measured in the supernatants as compared to lysates from thrombin-activated platelets and also when compared to autologous plasma enzyme (n = 5, $P < 0.05$). The addition of acid-treated plasma to supernatants decreased the K_m toward the plasma value although the change was not statistically significant. Thrombin stimulation of platelets did not change the affinity of the acetylhydrolase for paf as compared to unstimulated platelets. The V_{max} calculated for acetylhydrolase from Figure 2 are shown in Table 5. These values were calculated in relation to the total protein content of the assay and not to the pure acetylhydrolase protein. Thus they reflect the relative enrichment in acetylhydrolase of the supernatants obtained from the thrombin-stimulated platelets in comparison to the cell lysate.

DISCUSSION

Our data demonstrate the release of acetylhydrolase without release of LDH during platelet aggregation with thrombin or relatively high concentrations of paf. Our results are in good agreement with previous work showing the lack of paf metabolism by human platelets during paf binding (14,19) and/or aggregation (1). Kloprogge and Akkerman (28) found that gel-filtered human platelets may be slightly damaged or activated because they metabolized some of the added paf. In our experiments the presence of BSA either protected platelets against damage during incubation at pH 9.5 or indirectly inhibited acetylhydrolase by binding to the substate (29).

The amount of PF 4, a marker for α-granules, increased in parallel with the acetylhydrolase in supernatants

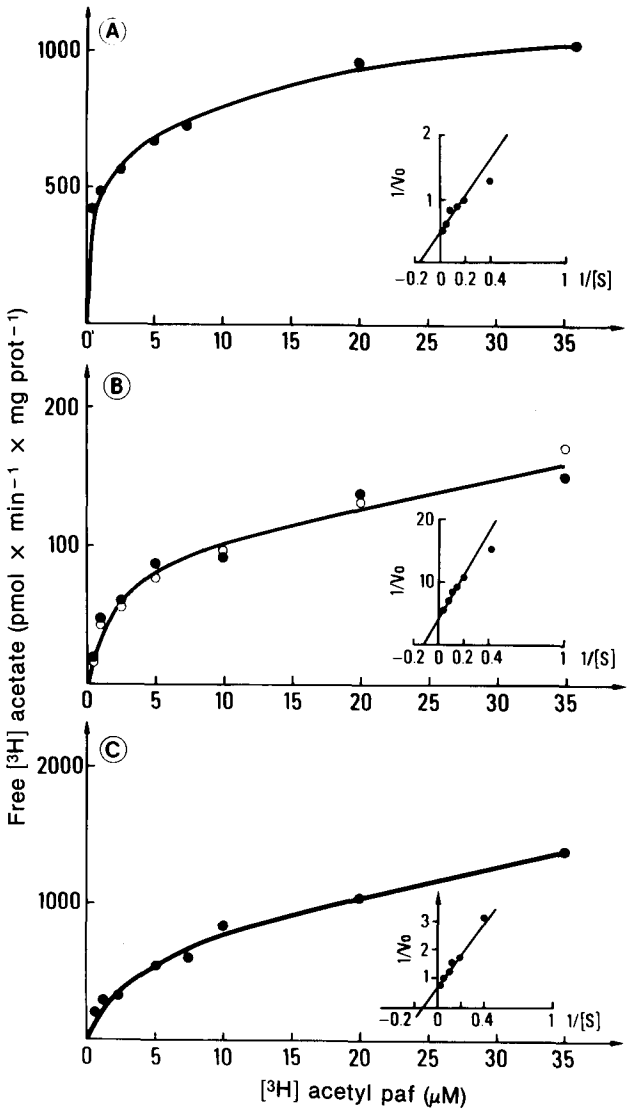

FIG. 2. Acetylhydrolase kinetic constants. The kinetic properties of acetylhydrolase were studied at 37°C for 10 min using 5 to 35 μM of acether, platelet-activating factor (paf) and 0.1 μCi/500 μCi/500 μL of [^{3}H-*acetyl*]paf. The Lineweaver-Burk plots of the data (using manual best fit analysis) are given in insets of each figure A, plasma (20 μg protein/mL); B, lysates (80 μg protein/mL) from resting (●) or thrombin (0.5 IU/mL)-activated (○) platelets; C, supernatants from thrombin-activated platelets (5 μg protein/mL).

of thrombin- and paf-activated platelets whereas it was not released from resting cells. In contrast to stimulation with thrombin, markers for dense granules (serotonin) and lysosomes (β-glucuronidase) were not released when platelets were stimulated with paf. The limited release of acetylhydrolase may either indicate that the major part of this enzyme is present in the cytosolic fraction of platelets or that its releasable pool is limited. It is interesting to note that murine phospholipase A_2 is similarly released from α-granules during platelet activation (30). The release of both hydrolytic enzymes may contribute to the control of the inflammatory process.

The K_m value for paf of acetylhydrolase released from thrombin-activated platelets was slightly but significantly different as compared to the enzyme contained in lyzates from the same cells and in autologous plasma. After addition of acid-treated plasma (inactivation of acetylhydrolase), the K_m of acetylhydrolase in supernatant moved toward that in plasma. Thus the differences in the K_m values for paf, observed for the released enzyme in comparison to that in platelet sonicates and plasma seem to be related to the enzyme protein environment. The treatment of enzyme preparations with various inhibitors indicated that all preparations were only slightly inhibited by NaF, in contrast they were affected up to 50% by bromophenacylbromide. The similarities of pH requirements and the lack of inhibition in the presence of an excess of alkylacyl-GPC let us postulate that platelets among other cells are one of the potential sources of plasmatic acetylhydrolase[2]. Our results are in agreement with those of earlier studies showing similar enzyme kinetics in the plasma (5.7 μM, in ref. 13) and in monocyte/macrophage-like cells (K_m 9.4 ± μM, in ref. 18). Similar results were also obtained using peripheral blood monocytes (17). In addition, after a 24-h culture period, murine peritoneal macrophages rapidly metabolized paf *via* induction of an acetylhydrolase indistinguishable from that in plasma (16).

What might be the biological relevance of the release of acetylhydrolase by platelets in response to paf and thrombin? This release (from platelets as well as, with other agonists, from other cells) may contribute to control the putative paf-mediated effects in (i) hypertensive rats (33), (ii) human Tangier disease (34), (iii) ischemic cerebrovascular diseases and platelet hypersensitivity (35) and (iv) may also be relevant to atherogenesis (36). Acetylhydrolase activity was decreased in rabbit plasma during the late phase of pregnancy in agreement with the important role of paf in enhancing myometrial contractions (27). A familial deficiency of the plasma acetylhydrolase was correlated with respiratory symptoms in asthmatic children (26). In the latter case, the acetylhydrolase level

TABLE 4

Treatment of Preparations Containing Acetylhydrolase with Various Inhibitors[a]

Source of acetylhydrolase	Alkylacyl-GPC (10 μM)	NaF (20 mM)	BPB (0.5 mM)
(1) Thrombin-activated platelets	105 ± 8	84 ± 9	64 ± 10
(2) Supernatant from (1)	115 ± 5	84 ± 8	50 ± 8
(3) Native plasma	115 ± 7	75 ± 3	82 ± 7

[a]Acetylhydrolase activity was measured in lysates of thrombin (0.5 IU/mL, 1 min, 37°C)-activated platelets, in supernatants of the latter, and in native plasma. Samples were preincubated 30 min at 37°C with given inhibitors and incubated further for 10 min at 37°C in the presence of 0.1 μCi [^{3}H-*acetyl*]paf (10 μM). Results in percentages of control (vehicle) are means ± SE of six experiments, except for experiments with alkylacyl-GPC that are means of 4. Values (1 *vs.* 2 *vs.* 3) showed no significant difference in a "Mann Whitney" test. Alkylacyl-GPC, hexadecylpalmitoylglycerophosphocholine; BPB, bromophenacylbromide.

[2]While this manuscript was in the reviewing process Satoh *et al.* (31) and Tarbet *et al.* (32) reported that Hep G2 secrete acetylhydrolase.

TABLE 5

Kinetic Constants of Acetylhydrolase[a]

Source of acetylhydrolase	K_m (μM)	V_{max} (nmol/min/mg protein)
(1) Platelets	8.3 ± 1.5	0.3
(2) Thrombin-activated platelets	10.6 ± 1.5	0.3
(3) Supernatant from (2)	7.9 ± 1.5	1.4
(4) Supernatant from (2) added with acid-treated plasma	6.1 ± 1.4	1.3
(5) Native plasma	5.3 ± 0.5	1.4

[a]Acetylhydrolase activity was measured in lysates of resting platelets or platelets stimulated with thrombin (0.5 IU/mL, 1 min, 37°C), in supernatants of thrombin-stimulated platelets with or without acid-treated (inactivated acetylhydrolase) plasma, and in native plasma. Samples were incubated for 10 min at 37°C in the presence of 0.1 μCi [^{3}H-acetyl]paf and concentrations of unlabeled paf varying from 5 to 35 μM. Results are means ± SD of five separate experiments. Values showed significant differences in "Mann Whitney" test (3 *vs.* 2 and 3 *vs.* 5: $P < 0.05$; 5 *vs.* 1 and 2: $P < 0.003$; n.s.: 2 *vs.* 1, 3 *vs.* 4 and 4 *vs.* 5).

in platelets remained normal although it was deficient in the plasma and the question arose whether the release of acetylhydrolase from platelets of asthmatic children was impaired. Finally, the accumulation of lyso paf was observed in rat alveoli following hypoxia and was attributed to the acetylhydrolase already present in alveolar fluid (37).

In this study we found that washed human platelets do not metabolize added paf. However, when platelets aggregate in response to thrombin or relatively high concentrations of paf, they release (independently of LDH) an acetylhydrolase which is similar to that detected in plasma. Acetylhydrolase may be released from α-granules, a platelet substructure containing other hydrolytic enzymes including phospholipase A_2. These results suggest that activated platelets may participate in the protection against paf-mediated effects in thrombotic and cardiovascular diseases.

ACKNOWLEDGMENTS

This study was supported by a grant from INSERM. We gratefully acknowledge the contribution of Martin Middeke, M.D. (Medizinische Poliklinik der Ludwig-Maximilians Universität München, Germany) to the statistical analysis of the data.

Reaction of α-Tocopherol with Alkyl and Alkylperoxyl Radicals of Methyl Linoleate

Ryo Yamauchi*, Nobuyuki Miyake, Koji Kato and **Yoshimitsu Ueno**
Department of Food Science, Faculty of Agriculture, Gifu University, Gifu 501-11, Japan

α-Tocopherol was reacted with alkyl and alkylperoxyl radicals at 37°C in bulk phase. The lipid-free radicals were generated by the reaction of methyl linoleate with the free radical initiator, 2,2′-azobis(2,4-dimethylvaleronitrile) (AMVN) under air-insufficient conditions. The products were isolated by high-performance liquid chromatography. Their structures were identified as 2-(α-tocopheroxy)-2,4-dimethylvaleronitrile (1), a mixture of methyl 9-(8a-peroxy-α-tocopherone)-10(*E*),12(*Z*)-octadecadienoate and methyl 13-(8a-peroxy-α-tocopherone)-9(*Z*),11(*E*)-octadecadienoate (2), methyl 9-(α-tocopheroxy)-10(*E*),12(*Z*)-octadecadienoate (3a), methyl 13-(α-tocopheroxy)-9(*Z*),11(*E*)-octadecadienoate (3b), α-tocopherol spirodiene dimer (4) and α-tocopherol trimer (5). When methyl linoleate containing α-tocopherol was oxidized with AMVN under air-sufficient conditions, the main products were 8a-alkylperoxy-α-tocopherones (2). In addition to these compounds, 6-*O*-alkyl-α-tocopherols (1, 3a and 3b) were formed when the reaction was carried out under air-insufficient conditions. The results indicate that α-tocopherol can react with both alkyl and alkylperoxyl radicals during the autoxidation of polyunsaturated lipids.
Lipids 28, 201–206 (1993).

α-Tocopherol, an antioxidant in foods and living cells, inhibits autoxidation of lipids by trapping lipid-peroxyl radicals in two ways (1,2): (i) lipid-peroxyl radicals can be trapped by hydrogen-atom transfer, giving hydroperoxides and α-tocopheroxy radicals; (ii) the resulting α-tocopheroxyl radicals can react with other lipid-peroxyl radicals, or each other, to form nonradical products. The products of the reaction of α-tocopherol with peroxyl radicals have previously been investigated to elucidate the mechanism of autoxidation inhibition by α-tocopherol (3–9).

Alkylperoxyl radicals generated in organic solvents from free radical initiators, such as 2,2′-azobis(2,4-dimethylvaleronitrile) (AMVN), oxidize α-tocopherol to 8a-alkylperoxy-α-tocopherones and other products (3–8). In our previous study (9), we isolated and characterized the primary products of the reaction of α-tocopherol with peroxyl radicals of methyl linoleate formed in the presence of molecular oxygen and initiated with AMVN. The products were isomeric 8a-(lipid-peroxy)-α-tocopherones. α-Tocopherol also traps alkyl and alkoxyl radicals to give alkylated products (10–13). If lipid peroxidation occurs under oxygen-insufficient conditions, lipid-alkyl radicals can be formed in addition to peroxyl radicals.

In the present study, the reaction products of α-tocopherol during the AMVN-induced oxidation of methyl linoleate under air-insufficient conditions have been isolated and characterized. The possible reaction mechanism of α-tocopherol with free radicals is discussed based on the reaction products observed.

Abbreviations: AMVN, 2,2′-azobis(2,4-dimethylvaleronitrile); HPLC, high-performance liquid chromatography; IR, infrared; NMR, nuclear magnetic resonance; MS, mass spectra; UV, ultraviolet.

MATERIALS AND METHODS

Materials. RRR-α-Tocopherol (Type V) was purchased from Sigma Chemical Co. (St. Louis, MO), and *RRR-γ*-tocopherol was prepared from mixed isomers of tocopherol (Hohnen Oil Co., Tokyo, Japan). Tocopherols were purified by Shephadex LH-20 (Pharmacia LKB, Uppsala, Sweden) column chromatography (14). Methyl linoleate (99%, Sigma) was purified and made peroxide-free by silica gel column chromatography (15). The free radical initiator, AMVN, was purchased from Wako Pure Chemical Industries (Osaka, Japan) and used without further purification. All solvents were distilled in an all-glass still before use.

High-performance liquid chromatography (HPLC). HPLC was performed using a Jasco Trirotar pump (Japan Spectroscopic Co., Tokyo, Japan) equipped with a Model GP-A40 gradient programmer. A Jasco Model 875-UV detector or a Model 820-FP spectrofluorometer was used as detector. Reversed-phase HPLC was done on a μBondasphere 5μC_8 100Å column (3.9 × 150 mm, Nihon Waters, Ltd., Tokyo, Japan). Preparative reversed-phase HPLC was done using a Wakosil 5C18 column (10 × 300 mm, Wako). Normal-phase HPLC was done on a Wakosil 5Sil column (10 × 300 mm).

Reaction procedure. A mixture of methyl linoleate (10 g, 34 mmol), α-tocopherol (0.20 g, 0.46 mmol) and AMVN (2.0 g, 8.1 mmol) was placed in a beaker (4.5 cm in diameter, specific surface area of 1.3 cm^2/g) and allowed to stand at 37°C for 30 h in the dark. The reaction mixture was concentrated by partitioning between hexane (150 mL) and methanol/water (97.5:2.5, vol/vol; 200 mL) (9). The concentrated products were isolated by preparative reversed-phase HPLC using methanol/ethanol (1:1, vol/vol) at a flow rate of 5.0 mL/min. The trimer in the column was eluted using 2-propanol as the solvent. The products were further purified by normal-phase HPLC using hexane/2-propanol (1000:3, vol/vol) at a flow rate of 4.0 mL/min. The eluent was monitored by measuring absorbance at 260 nm. The compounds isolated were dissolved in ethanol or hexane and stored at −20°C until analysis.

Methyl linoleate (0.20 g or 1.0 g) containing 0.1 or 1 mol% of α-tocopherol and 10 mol% of AMVN was placed in a glass vial (1.4 cm in diameter, specific surface areas of the 0.20-g and 1.0-g samples were 7.7 and 1.5 cm^2/g, respectively) to observe the course of the reaction. At regular intervals, aliquots of the sample were withdrawn, dissolved in ethanol and injected into the HPLC. The reversed-phase column was developed with a 15-min linear gradient of acetonitrile/methanol/water (60:35:5, by vol) to acetonitrile/2-propanol/hexane (35:50:15, by vol) at a flow rate of 1.0 mL/min. The amounts of α-tocopherol were calculated from the peak area by monitoring the fluorescence (ex. 295 nm, em. 340 nm). The amounts of reaction products were calculated from the peak areas by

monitoring elution at 240 nm. γ-Tocopherol was used as the internal standard.

Spectroscopy. ^1H (270.17 MHz) and ^{13}C (67.9 MHz) nuclear magnetic resonance (NMR) spectra were recorded at 25°C on a Jeol JNM-GX-270 FT NMR spectrometer using $CDCl_3$ as solvent and tetramethylsilane as internal standard. Mass spectra (MS) were obtained on a Shimadzu GCMS 9020DF instrument (Shimadzu Co., Kyoto, Japan) operated in the electron impact mode (70 eV). Samples were introduced *via* the direct inlet. Infrared (IR) spectra of samples in liquid film were measured on a Jasco A-302 IR spectrometer. Ultraviolet (UV) spectra were measured with a Jasco Ubest-30 spectrophotometer.

Derivatization. The positions of the double bonds in the reaction products were determined by the oxidative method described by Capella and Zorzut (16). The products were oxidized with osmium tetroxide and the osmates subsequently reduced with sodium sulfite. The hydroxylated products were converted to their corresponding trimethylsilyl ethers with *N,O-bis*(trimethylsilyl)trifluoroacetamide and then analyzed by mass spectrometry.

RESULTS

Characterization of reaction products. AMVN decomposes at 37°C to form alkyl radicals which, in turn, react with molecular oxygen to form alkylperoxyl radicals. The alkylperoxyl radicals attack methyl linoleate to generate the pentadienyl radicals, which react with oxygen to give the methyl linoleate-peroxyl radicals (2). If the supply of oxygen is insufficient, α-tocopherol may react with both the alkyl and the alkylperoxyl radicals.

The reaction products of α-tocopherol with the free radicals were analyzed by reversed-phase HPLC (Fig. 1). Five major peaks, **1, 2, 3, 4** and **5**, that appeared to be the reaction products of α-tocopherol were detected on the chromatogram. When the reaction was carried out under a nitrogen atmosphere, only peaks 1 and 3 in addition to peaks corresponding to methyl linoleate dimer were detected (data not shown). Therefore, peaks 1 and 3 were assumed to be the reaction products of α-tocopherol with

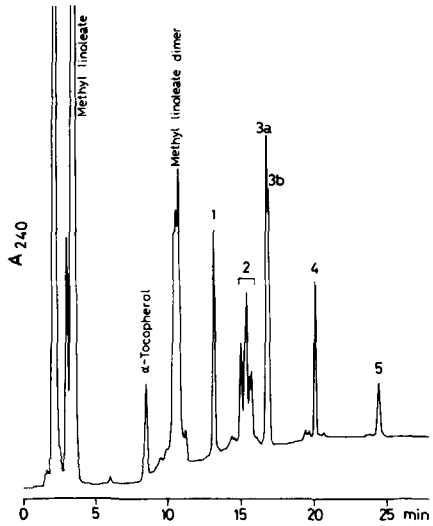

FIG. 1. Reversed-phase high-performance liquid chromatography (HPLC) of the products of the 2,2′-azo*bis*(2,4-dimethylvaleronitrile)-induced reaction of methyl linoleate and α-tocopherol for 30 h. HPLC was done on a μBondasphere 5μC_8 column which was developed with a 15-min linear gradient of acetonitrile/methanol/water (60:35:15, by vol) to acetonitrile/2-propanol/hexane (35:50:15, by vol) at a flow rate of 1.0 mL/min. The eluate was monitored by its absorbance at 240 nm.

alkyl radicals. Peaks corresponding to methyl linoleate dimer were collected by preparative reversed-phase HPLC and obtained as a colorless oil (10.1 mg yield). The structure was identified based on the MS spectrum; *m/z* 555 ($[M - 31]^+$, 1%), 293. (63), 261 (10), 243 (6), 137 (17), 123 (18), 109 (22), 95 (54), 81 (74), and 67 (100). The isomeric structures of the dimer were not investigated. Peaks **1, 2, 3, 4** and **5**, that appeared to be the reaction products of α-tocopherol, were collected by preparative reversed-phase HPLC. Peak **3** was further resolved into two peaks (**3a** and **3b**) by normal-phase HPLC. The structures of **1, 2, 3a, 3b, 4** and **5** were identified as follows (Fig. 2).

Compound **1** was obtained as a colorless oil (27.4 mg yield). Compound **1** was identified as 2-(α-tocopheroxy)-2,4-

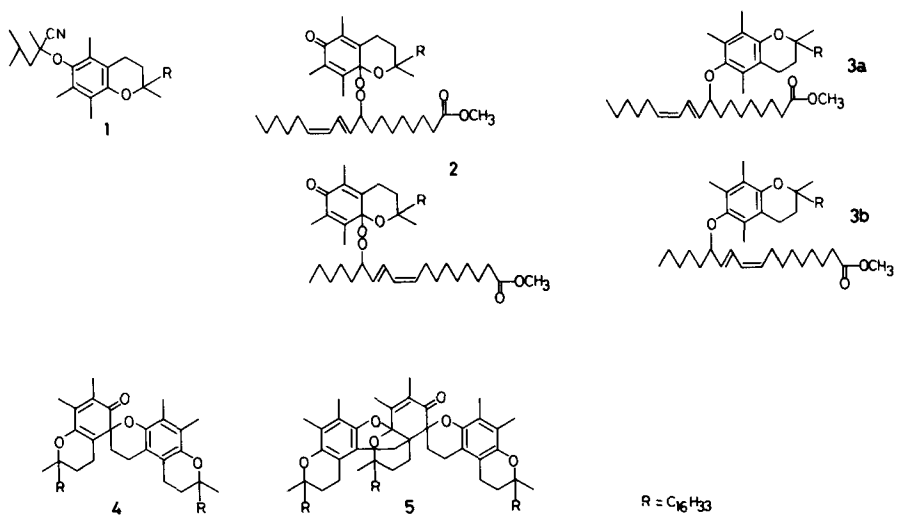

FIG. 2. Structures of compounds 1, 2, 3a, 3b, 4 and 5.

dimethylvaleronitrile: MS *m/z* 513 ([M − CN]$^+$, 6%), 430 (90), 205 (10), and 165 (100); UV (ethanol) λ 228 (ε 11000), 282 (shoulder), and 289 nm (ε 2070); IR (film) ν 2950, 1580, 1460, 1415, 1380, 1250, 1160, 1080, 940, and 920 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ 0.83–0.87 (*m*, 12H), 1.05–2.23 (*m*, 24H), 1.13 (*d*,*J* = 6.8 Hz, 6H), 1.23 (*s*, 3H), 1.46 (*s*, 3H), 1.80 (*m*, 2H), 2.08 (*s*, 3H), 2.19 (*s*, 3H), 2.20 (*s*, 3H), and 2.56 ppm (*dt*,*J* = 6.4 Hz, 2H); ^{13}C NMR ($CDCl_3$) δ 12.0, 14.7, 15.6, 19.7, 19.8, 20.8, 21.0, 22.7 (2 atoms), 24.0, 24.1, 24.5, 24.8 (2 atoms), 25.1, 25.6, 28.0, 31.4, 32.7, 32.8, 37.3, 37.5 (3 atoms), 39.4, 40.0, 50.3, 75.0, 76.8, 117.8, 121.5, 123.2, 128.1, 129.8, 143.7, and 148.5 ppm.

Compound 2 was obtained as a mixture (12.6 mg yield) that gave a positive peroxide test (17). The structures were identified by comparison of the HPLC behavior with that of authentic samples as reported previously (9). Compound 2 contained methyl (9*R*,8a*R*)-, (9*R*,8a*S*)-, (9*S*,8a*R*)- and (9*S*,8a*S*)-9-(8a-peroxy-α-tocopherone)-10(*E*),12(*Z*)-octadecadienoates and methyl (13*R*,8a*R*)-, (13*R*,8a*S*)-, (13*S*,8a*R*)- and (13*S*,8a*S*-13)-(8a-peroxy-α-tocopherone)-9(*Z*),11(*E*)-octadecadienoates.

Compounds **3a** and **3b** were obtained as colorless oils (**3a**, 9.3 mg yield; **3b**, 8.9 mg yield). UV spectra of these compounds were identical with absorption maxima at 228 nm (**3a**, ε 30700; **3b**, ε 30500), 282 (shoulder) and 289 nm (**3a**, ε 2500; **3b**, ε 2480) in ethanol. IR spectra of the compounds showed two absorption bands at 950 and 985 cm^{-1} suggesting the presence of *cis-trans* double bonds.

The ^{1}H NMR spectra of the compounds **3a** and **3b** were consistent with those expected for methyl 9-(α-tocopheroxy)-10(*E*),12(*Z*)-octadecadienoate and methyl 13-(α-tocopheroxy)-9(*Z*),11(*E*)-octadecadienoate (Table 1). The geometrical configuration of the conjugated diene system in each compound could be established (18). The *cis-trans* diene systems were present in both compounds, and both *cis* (*J* = 10.3–11.1 Hz) and *trans* (*J* = 14.5–15.4 Hz) coupling constants were observed.

Compounds **3a** and **3b** were oxidized with osmium tetroxide and the osmates were subsequently reduced with sodium sulfite (16). The resulting hydroxylated compounds were silylated and directly analyzed by MS (Fig. 3). The position of the α-tocopheroxy group attached to the fatty acid moiety could be determined from the fragment ion due to α-cleavage of the trimethylsilyloxy group of each derivative (*m/z* 173 for **3a** and *m/z* 259 for **3b**, respectively).

From these results and other spectral data, the structures of **3a** and **3b** were identified as follows. Compound **3a**, methyl 9-(α-tocopheroxy)-10(*E*),12(*Z*)-octadecadienoate: MS *m/z* 430 (64%), 293 (3), and 165 (100); IR (film) ν 2950, 1745, 1460, 1435, 1250, 985, and 950 cm^{-1}; ^{13}C NMR ($CDCl_3$) δ 11.9 (2 atoms), 13.1, 14.0, 19.7, 19.8, 20.8, 21.1, 22.5, 22.7 (2 atoms), 23.7, 24.5, 24.8, 25.0, 25.4, 27.7, 28.0, 29.1, 29.2 (2 atoms), 29.6, 31.4, 31.6, 32.8 (2 atoms), 34.1, 35.2, 37.3, 37.5 (2 atoms), 37.6, 39.4, 40.2, 51.4, 74.6, 83.9, 117.3, 122.6, 126.3, 127.9 (2 atoms), 128.4, 132.7, 132.9, 147.0, 147.4, and 174.3 ppm. Compound **3b**, methyl 13-(α-tocopheroxy)-9(*Z*),11(*E*)-octadecadienoate: MS *m/z* 430 (90%), 293 (3), and 165 (100); IR (film) ν 2950, 1745, 1460, 1435, 1250, 985, and 950 cm^{-1}; ^{13}C NMR ($CDCl_3$) δ 11.9 (2 atoms), 13.2, 14.1, 19.7, 19.8, 20.8, 21.1, 22.7 (3 atoms), 23.8, 24.5, 24.8, 25.0, 25.2, 27.7, 28.0, 29.0, 29.1 (2 atoms), 29.5, 31.6, 32.0, 32.8, 32.9, 34.1, 35.2, 37.3 (2 atoms), 37.5 (2 atoms), 39.4, 40.1, 51.4, 74.7, 84.0, 117.4, 122.6, 126.4, 127.8, 128.0, 128.4, 132.5, 133.1, 147.1, 147.4, and 174.3 ppm. Compounds **3a** and **3b** proved to be optically inactive each consisting of enantiomeric mixtures.

Compound 4 was obtained as a yellow oil (10.9 mg yield), and compound 5 was obtained as a pale yellow oil (8.4 mg yield). The structures were identified by comparison of the HPLC behavior with those of authentic samples as reported previously (19). Compound 4 was the spirodiene dimer of α-tocopherol and 5 was α-tocopherol trimer.

Reaction products of α-tocopherol in AMVN-induced oxidation of methyl linoleate. Methyl linoleate containing two different concentrations of α-tocopherol was oxidized with AMVN in bulk phase. The reaction was run on two different sample sizes (0.20 and 1.0 g). The exchange of oxygen between air and oil in the 0.20-g sample may be faster than that in the 1.0-g sample because of their different surface areas (the specific surface areas of the 0.20-g and 1.0-g samples were 7.7 and 1.5 cm^2/g, respectively).

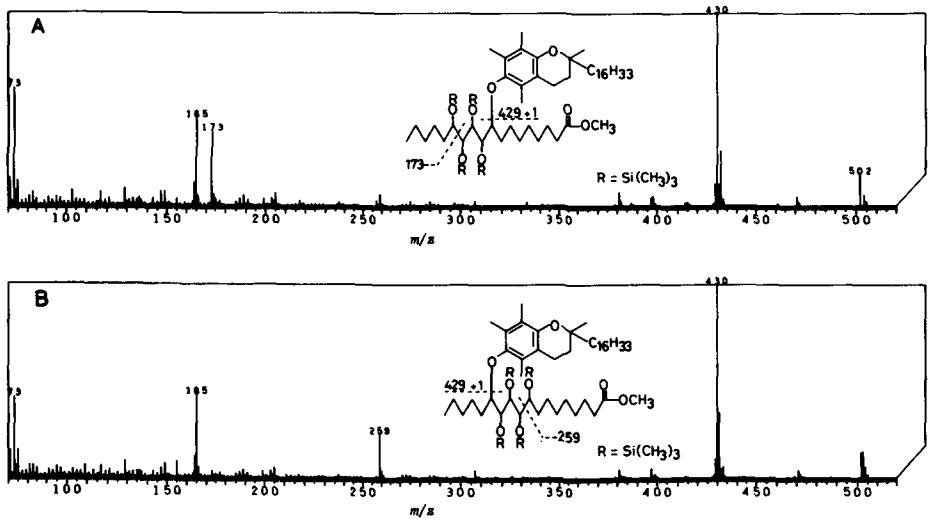

FIG. 3. Mass spectra of trimethylsilyl derivatives of compounds 3a (A) and 3b (B) after hydroxylation of the olefinic bonds by oxidation with OsO_4 and subsequent reduction of the osmates with Na_2SO_3.

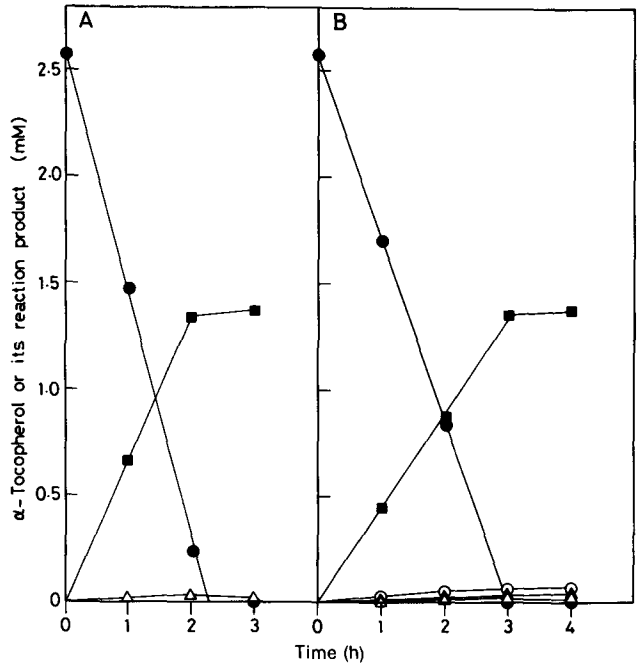

FIG. 4. Reaction of α-tocopherol during the 2,2′-azo*bis*(2,4-dimethylvaleronitrile) (AMVN)-induced oxidation of methyl linoleate containing 0.1 mol% α-tocopherol. Methyl linoleate containing 0.1 mol% α-tocopherol and 10 mol% AMVN was oxidized in two sample sizes in a glass vial; 0.20 g (A) and 1.0 g (B). Residual amounts of α-tocopherol (●) and the reaction products, compound 1 (▲), compound 2 (■), compound 3 (○) and compound 4 (△), in the reaction mixture are shown.

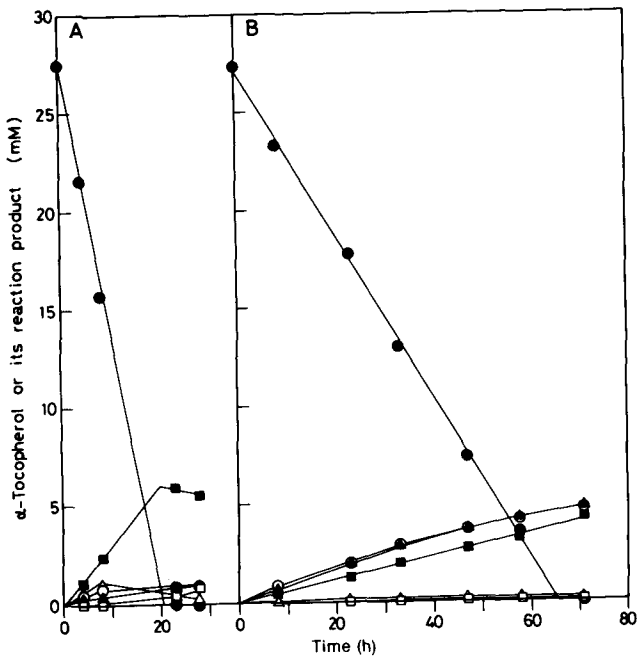

FIG. 5. Reaction of α-tocopherol during the 2,2′-azo*bis*(2,4-dimethylvaleronitrile) (AMVN)-induced oxidation of methyl linoleate containing 1 mol% α-tocopherol. Methyl linoleate containing 1 mol% α-tocopherol and 10 mol% AMVN was oxidized in two sample sizes, 0.20 g (A) and 1.0 g (B). Residual amounts of α-tocopherol (●) and the reaction products, compound 1 (▲), compound 2 (■), compound 3 (○), compound 4 (△) and compound 5 (□), in the reaction mixture are shown.

Figure 4 shows the results of α-tocopherol decay and the formation of the reaction products during the oxidation of methyl linoleate containing 0.1 mol% α-tocopherol. In both sample sizes of 0.20 and 1.0 g, the main reaction products were 8a-alkylperoxy-α-tocopherones (2). Besides a large amount of these compounds, a small amount of 6-*O*-alkyl-α-tocopherols (1, 3a and 3b) was formed in the 1.0-g sample (Fig. 4B).

Figure 5 shows the results of the oxidation of methyl linoleate containing 1 mol% α-tocopherol. The loss of α-tocopherol was affected by sample size. In the 0.20-g sample, α-tocopherol had disappeared by 20 h, and the main products were 8a-alkylperoxy-α-tocopherones (2) in addition to small amounts of 6-*O*-alkyl-α-tocopherols (1, 3a and 3b), dimer (4) and trimer (5) (Fig. 5A). On the other hand, the loss of α-tocopherol was slower in the 1.0-g sample,

and the main products were 8a-alkylperoxy-α-tocopherones (2) and 6-*O*-alkyl-α-tocopherols (1, 3a and 3b) (Fig. 5B). The 1.0-g sample also showed a larger proportion of methyl linoleate dimer; the concentration of methyl linoleate dimer in the reaction mixture after 23-h incubation was 0.84 mM for the 0.20-g sample and 1.71 mM for the 1.0-g sample, respectively.

DISCUSSION

α-Tocopherol is very reactive toward a variety of free radicals and active oxygen species. For example, α-tocopherol traps free radicals generated from certain free radical initiators such as 2,2′-azo*bis*(isobutylnitrile) (20), benzoyl peroxide (21), AMVN (3,6-8) and *tert*-butyl hydroperoxide (4,5,22-24), and it reacts with alkyl and alkoxyl radicals to give alkylated derivatives (10-13). In the present study, α-tocopherol trapped alkyl and alkylperoxyl radicals generated from the AMVN-induced oxidation of methyl linoleate to give 6-*O*-alkyl-α-tocopherols (1, 3a and 3b) and 8a-alkylperoxy-α-tocopherones (2), respectively. The 6-*O*-alkyl-α-tocopherols have been reported to be the reaction products of α-tocopherol with alkyl radicals (10,11,20). We have already reported the isolation and characterization of 8a-alkylperoxy-α-tocopherones as the primary products of α-tocopheroxyl radical with methyl linoleate-peroxyl radicals during autoxidation in bulk phase in the presence of AMVN (9). The dimer (4) and trimer (5) of α-tocopherol were also observed in this study. The dimers and trimers have previously been detected in the autoxidation of methyl linoleate (19).

The oxidation of methyl linoleate (LH) initiated with AMVN (A-N=N-A) and inhibited by α-tocopherol (TOH) in homogeneous solution at sufficient oxygen pressure proceeds by the following reaction sequence (1,2):

Initiation

$$\text{A-N=N-A} \rightarrow 2\text{A}^{\bullet} \quad [1]$$

$$\text{A}^{\bullet} + \text{O}_2 \rightarrow \text{AOO}^{\bullet} \quad [2]$$

$$\text{AOO}^{\bullet} + \text{LH} \rightarrow \text{AOOH} + \text{L}^{\bullet} \quad [3]$$

Propagation

$$\text{L}^{\bullet} + \text{O}_2 \rightarrow \text{LOO}^{\bullet} \quad [4]$$

$$\text{LOO}^{\bullet} + \text{LH} \rightarrow \text{LOOH} + \text{L}^{\bullet} \quad [5]$$

Termination

$$2\text{LOO}^{\bullet} \rightarrow \text{stable products} \quad [6]$$

$$\text{LOO}^{\bullet} + \text{TOH} \rightarrow \text{LOOH} + \text{TO}^{\bullet} \quad [7]$$

$$\text{LOO}^{\bullet} + \text{TO}^{\bullet} \rightarrow \text{stable products} \quad [8]$$

$$2\text{TO}^{\bullet} \rightarrow \text{dimer} \quad [9]$$

In the presence of α-tocopherol, Reaction 7 results in the formation of hydroperoxide (LOOH) and the α-tocopheroxyl radical (TO•); the latter reacts rapidly and irreversibly with a second peroxy radical (LOO•) to form stable products (Reaction 8) (25). Our results indicate that the reaction of peroxyl radicals with a low concentration of α-tocopherol under air-sufficient conditions proceeds by Reaction 8 to give the stable products (Fig. 4A). Alternatively, there may be other routes by which some of the tocopheroxyl radicals react, *e.g.*, a bimolecular self-reaction (Reaction 9). Although Reaction 9 is very slow (26,27), dimer and trimer could be formed in the reaction mixture containing a large amount of α-tocopherol (Fig. 5A).

All of the alkyl radicals produced are expected to react very rapidly with oxygen (Reactions 2 and 4); the rate constant of the pentadienyl radical with oxygen is 3.2×10^8 $M^{-1}s^{-1}$ (28). When the oxygen pressure is lowered, the produced alkyl radicals (A• and L•) can react with each other or with α-tocopherol as follows:

$$2\text{A}^{\bullet}(2\text{L}^{\bullet}) \rightarrow \text{dimer} \quad [10]$$

$$\text{A}^{\bullet}(\text{L}^{\bullet}) + \text{TOH} \rightarrow \text{AH(LH)} + \text{TO}^{\bullet} \quad [11]$$

$$\text{A}^{\bullet}(\text{L}^{\bullet}) + \text{TO}^{\bullet} \rightarrow \text{stable products} \quad [12]$$

The alkyl radicals produced from AMVN and methyl linoleate can attack the α-tocopheroxyl radical by Reaction 12 to form 6-*O*-alkyl-α-tocopherols under nitrogen atmosphere. The formation of 6-*O*-alkyl-α-tocopherols was also observed in the larger sample size reaction mixture (Figs. 4B and 5B). Therefore, the supply of oxygen may be dependent on the sample size in the reaction vessel. Reactions 10 and 11 are competing reactions. If Reaction 10 is faster, the α-tocopherol should take longer to be consumed. Our results indicate that the decay of α-tocopherol was lowered and more methyl linoleate dimer was formed under air-insufficient conditions (Fig. 5B). Thus, reactions of alkyl radicals with α-tocopherol may be slower than the reactions of the peroxyl radicals.

Analysis of Low Erucic Acid Turnip Rapeseed Oil (*Brassica campestris*) by Negative Ion Chemical Ionization Tandem Mass Spectrometry. A Method Giving Information on the Fatty Acid Composition in Positions *sn*-2 and *sn*-1/3 of Triacylglycerols

Heikki Kallio* and **Graeme Currie**[1]
Department of Chemistry and Biochemistry, Laboratory of Food Chemistry, University of Turku, SF-20500 Turku, Finland

A tandem mass spectrometric method is described for the rapid analysis of fatty acid combinations in mixtures of triacylglycerols. Triacylglycerols were introduced into a triple quadrupole mass spectrometer *via* a direct exposure probe and deprotonated using ammonia negative ion chemical ionization. Collisionally activated spectra were obtained and the resulting fragments used to identify the fatty acid constituents, and the fatty acids preferentially located at the *sn*-2 position of the triacylglycerols. Fourteen major molecular weight species of purified triacylglycerols of a supercritical fluid extract of low erucic acid turnip rapeseed oil (*Brassica campestris*) were analyzed. The five major combinations of fatty acids comprised two thirds of the total triacylglycerols and contained oleic, linoleic and α-linolenic acids with linoleic acid favoring the *sn*-2 position.
***Lipids* 28,** 207-215 (1993).

Mass spectrometry has been widely used to analyze the number of carbon atoms and double bonds of constituent fatty acids in natural mixtures of triacylglycerols (TAG). Electron impact-mass spectrometry (EI-MS) produces $M^{+\cdot}$ and $[M-18]^{+\cdot}$ ions, as well as many other characteristic fragment ions, *e.g.*, $[RCO]^+$, $[RCO + 74]^+$, $[RCO + 128]^+$, $[M - RCO_2H]^{+\cdot}$, $[M - RCO_2]^{+\cdot}$ (1,2) and $[RCO + 128 + 14n]^{+\cdot}$ (3). This latter ion series has been used with deuterium labelling of unsaturated linkages (4) in order to determine the position of double bonds in TAG (3). EI-MS has been used to determine the molecular weight distribution of TAG isolated from several edible fats and oils (5).

Murata and Takahashi (6) used positive ion chemical ionization-mass spectrometry (PICI-MS) to analyze several oils, including rapeseed. The intensity of the quasimolecular ion $[M + NH_4]^+$ was shown to be typically 20 times higher than that of the molecular ion in EI-MS. Schulte *et al.* (7) developed improvements for the analysis of solid fats by summing a number of mass spectra during the evaporation of the sample into mass spectrometer. This method corrected for the varying volatilities of the TAG. Field desorption (8) and fast atom bombardment (9) have also been applied to the analysis of TAG, but quantitative information was difficult to obtain and required rigorous calibration.

Various chromatographic interfaces have been used with mass spectrometers in the analysis of TAG mixtures, *e.g.*, gas chromatography (GC)/MS (10-13), reversed-phase liquid chromatography (LC)/CI-MS (14-19) and supercritical fluid chromatography (SFC)/MS (20-22).

In natural fats and oils, all three positions in TAG may be unique, which is of physiological importance. Therefore, in the analysis of TAG it is important to know the locations as well as the combinations of the fatty acids (FA). Ryhage and Stenhagen (1) showed that differentiation between the FA at positions *sn*-2 and *sn*-1/3 was possible in EI-MS by measuring the ions $[M - RCO_2CH_2]^{+\cdot}$. This method has been used in conjunction with on-line capillary SFC/MS (22).

The most common methods used for stereospecific analyses of triacyl-*sn*-glycerols (23) are still based on the principles developed by Brockerhoff (24,25). The methods allow the direct analysis of the fatty acids at positions *sn*-1 and *sn*-2. The fatty acid at position *sn*-3 is then calculated. Several useful modifications of this method have been developed, such as that of Lands *et al.* (26), who replaced the chemical phosphorylation step by specific enzymatic phosphorylation of the 1,2-diacyl-*sn*-glycerols. The methods and their applications have been extensively reviewed by several authors (25-28). There are, however, some difficulties in the stereospecific analyses using enzymes. For example, enzymatic hydrolysis is not always independent of the chain length and number of double bonds (28), and the possibility of acyl migration during the numerous analytical steps must also be taken into account. However, these limitations usually have to be accepted when the goal is to perform a stereospecific analysis of natural fats and oils. Nearly all the analyses over the last quarter of the century have been carried out either by analyzing the original TAG mixtures or simplified mixtures obtained by silver ion chromatography or other fractionation procedures. Only rarely have stereospecific analyses (28,29) been performed on pure "natural" TAG isolated by chromatographic methods. In the stereospecific analyses of TAG mixtures, enantiomer calculations are typically based on various random distribution assumptions. In oil seeds, a "1,3-random-2-random" distribution model has been commonly accepted since the studies of vander Wal (30) and Coleman (31). This distribution model assumes the positions *sn*-1 and *sn*-3 to be identical. However, such distribution models can only be considered as approximations.

Tandem mass spectrometry (MS/MS) is a useful technique for the characterization of individual components in mixtures of analytes. The combination of ammonia negative ion chemical ionization (NICI) and collisional activation (CA) of selected molecular ions is an effective MS/MS method for the analysis of TAG mixtures (32-33). Recently, the research group of Henion (34) has introduced an MS/MS method based on electrospray and $[M + NH_4]^+$ quasimolecular ions. This MS/MS method allowed the fatty acid combinations within a TAG to be identified.

Abbreviations: ACN, acyl carbon number; CA, collisional activation; DB, number of double bonds; EI-MS, electron impact-mass spectrometry; FA, fatty acid; GC, gas chromatography; GC/MS, gas chromatography/mass spectrometry; HPLC, high-performance liquid chromatography; LC/MS, liquid chromatography/mass spectrometry; LEAR, low erucic acid rape; MS/MS, tandem mass spectrometry; MW, molecular weight; NICI, negative ion chemical ionization; PICI, positive ion chemical ionization; SFC, supercritical fluid chromatography; TAG, triacylglycerols.

In this paper we describe details and applications of a sensitive ammonia NICI-MS/MS method to analyze TAG. This method allows the combinations of FA within a TAG to be determined and to distinguish between the fatty acids at positions *sn*-2 and *sn*-1/3. The method is applied to the characterization of TAG derived from low erucic acid turnip rapeseed oil (LEAR).

MATERIAL AND METHODS

Turnip rapeseed oil. LEAR (*Brassica campestris*, double zero-variety "Kova") was cultivated in Southwest Finland. Ripe seeds were dried to 5% moisture level and ground on a spice mill with cutting blades. Extraction of the seed oil was performed with chromatography-grade supercritical carbon dioxide at 60°C and 45 MPa (Suprex SFE/50, Suprex Corp., Pittsburgh, PA) (35). The extract was purified by silicic acid chromatography and the lipid fraction dissolved in chloroform (5 mg/mL) and sealed under nitrogen.

Triacylglycerol standards. Reference compounds purchased from Sigma (St. Louis, MO) included: tri-(*all-cis*-5,8,11,14-eicosatetraenoyl)glycerol (20:4-20:4-20:4), 1,2-dioctadecanoyl-3-hexadecanoyl-*rac*-glycerol (18:0-18:0-16:0), 1-hexadecanoyl-2-(*cis*-9-octadecenoyl)-3-octadecanoyl-*rac*-glycerol (16:0-18:1-18:0), 1,2-dioctadecanoyl-3-(*cis*-9-octadecenoyl)-*rac*-glycerol (18:0-18:0-18:1), 1,3-dioctadecanoyl-2-(*cis*-9-octadecenoyl)glycerol (18:0-18:1-18:0), 1,2-di-(*cis*-9-octadecenoyl)-3-hexadecanoyl-*rac*-glycerol (18:1-18:1-16:0), 1,3-di-(*cis*-9-octadecenoyl)-2-hexadecanoylglycerol (18:1-16:0-18:1), 1,2-di-(*cis*-9-octadecenoyl)-3-octadecanoyl-*rac*-glycerol (18:1-18:1-18:0) and 1,3-di-(*cis*-9-octadecenoyl)-2-octadecanoylglycerol (18:1-18:0-18:1). Pure TAG fractions (95–100%) from evening primrose oil had combinations 18:3-18:2-18:2, 18:3-18:3-18:2 and 16:0-18:3-18:2. These fractions were analyzed by MS/MS to determine correction factors for 18:2 and 18:3 FA. Correspondingly, the saturated human milk TAG fraction of molecular weight 806.7 consisted mainly of TAG 14:0/16:0/18:0 and 16:0/16:0/16:0, and was used to obtain the correction factor for the 14:0 fatty acid.

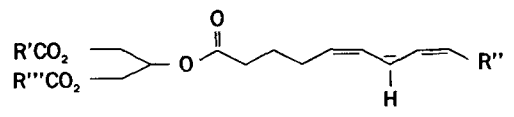
Fatty acid analysis. The fatty acid methyl esters were prepared by transesterification in BF_3/CH_3OH (36,37) and stored in dried hexane at −18°C under nitrogen. The methyl esters were analyzed by capillary gas chromatography/mass spectrometry (35).

Mass spectrometric analysis. Negative ion spectra and tandem mass spectra were obtained on a Finnigan MAT (San Jose, CA) TSQ-70 equipped with a combined EI/CI ion source with removable ion volumes. Negative ions were produced with ammonia CI. Ammonia was introduced into the ion source at an ion source pressure of approximately 8200 millitorr. The ion source temperature was 215°C; electron energy was 70 eV; emission current was 300 μA. Xenon was used as the collision gas in the collision quadrupole, at a pressure of approximately 1.5 millitorr. The offset for the collision quadrupole was 14 eV relative to the ion source. In a typical experiment, the TAG (1 μg) dissolved in dichloromethane (1 μL) was placed at the end of the standard direct exposure probe, the solvent was evaporated and the probe was introduced directly into the ion source. The analysis was started and the temperature of the probe was increased to 310°C at a rate of 300°C/min (the maximum heating rate of the probe). Daughter ion spectra were obtained by selecting the $[M - H]^-$ molecular ions with the first quadrupole mass spectrometer, collisionally activating these ions in the second quadrupole and scanning the third quadrupole from 50 amu to just above the $[M - H]^-$ ion. Spectra were acquired over a period of three minutes with a scan time of eight seconds. The first and last spectra were ignored and the remaining spectra were averaged and displayed. When the relative proportions of the $[M - H]^-$ ions were used for quantitative comparisons, corrections were made for the ^{13}C isotope content of the ions.

Combinations of FA in TAG. The type and ratio of FA within each molecular weight fraction of TAG were determined by obtaining daughter ion spectra of the corresponding $[M - H]^-$ ions. However, in order to analyze the proportions of the fatty acids within each molecular weight group, molar correction factors based on the abundances of the RCO_2^- ions were required. The correction factors for fatty acids were determined from the intensities of RCO_2^- ions of TAG standards. The factor 1.0 was given to octadecanoic acid and the other correction factors determined were: 14:0 = 1.3, 16:0 = 1.1, 16:1 = 1.5, 18:1 = 1.3, 18:2 = 1.6 and 18:3 = 1.9.

RESULTS AND DISCUSSION

MS analysis of reference compounds. Ammonia under chemical ionization conditions produces the reagent ion H_2N^- which is a powerful gas phase base (38,39) capable of deprotonating most organic substrates, including ketones and esters. TAG are deprotonated on the carbon α to the carbonyl group. Figure 1 and Table 1 list the partial, CA daughter spectra of $[M - H]^-$ ions derived from standard TAG. The most obvious feature of these spectra are their simplicity, with only four distinct groups of ions dominating the spectra, *i.e.*, $[M - H{-}RCO_2H]^-$ (very low intensity), $[M - H{-}RCO_2H{-}74]^-$, $[M - H{-}RCO_2H{-}100]^-$ and RCO_2^-. An exception was the spectrum of the dodeca-unsaturated tri-(all-*cis*-5,8,11,14-eicosatetraenoyl)-glycerol (triarachidonoylglycerol), which showed a number of additional fragmentations (Fig. 1c). This increase in fragmentations of triarachidonoylglycerol may be explained by the formation of a competing $[M - H]^-$ molecular ion. The competing ion is formed by deprotonation α to one of the double bonds on a fatty acid substituent, such as *a*.



a

CA of this ion results in additional fragmentations and increased complexity in the spectra of highly unsaturated TAG. Fortunately, in many edible fats and oils, most of these additional fragmentation processes are minor and do not seriously interfere with the sensitivity or the specificity of the technique.

Examination of the data presented in Table 1 reveals that the production of $[M - H{-}RCO_2H]^-$, $[M - H1{-}RCO_2H{-}74]^-$ and $[M - H{-}RCO_2{-}100]^-$ occurs primarily with the loss of the fatty acids from position *sn*-1/3.

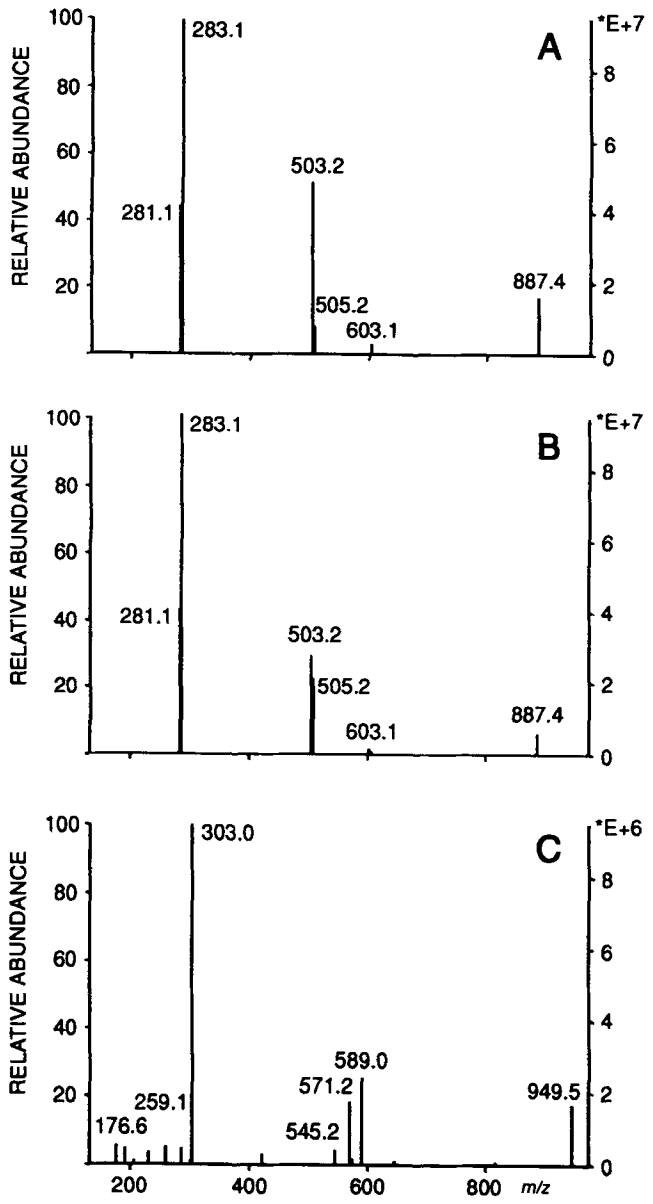


FIG. 1. Collisionally activated daughter spectra of the $[M-H]^-$ parent ions of A, 1,3-distearoyl-2-oleoylglycerol (18:0-18:1-18:0); B, 1,2-distearoyl-3-oleoyl-*rac*-glycerol (18:0-18:0-18:1); and C, triarachidonoylglycerol (20:4-20:4-20:4).

Again, as an exception, the $[M-H-RCO_2H-74]^-$ ion, which is a minor fragmentation in most spectra, is a major fragmentation in the spectrum of triarachidonoylglycerol.

The intensities of the RCO_2^- fragment ions also depend strongly on the composition of the TAG. Altogether, there are three compositional factors that affect the formation of RCO_2^-, namely (i) the number of double bonds on the FA substituent, (ii) the FA chain length and (iii) the regiospecific position of the fatty acid substituent. The formation of RCO_2^- seems to occur through a number of fragmentation mechanisms occurring at different rates. Some of these fragmentation processes are specific to the *sn*-1/3 carbons. This can be seen when the abundance of the RCO_2^- ions from the MS/MS spectrum of 1-palmi-

[a]FA, fatty acids. FA_2 is at the position *sn*-2; FA_1 and FA_3 randomly occupy the positions *sn*-1 and *sn*-3.

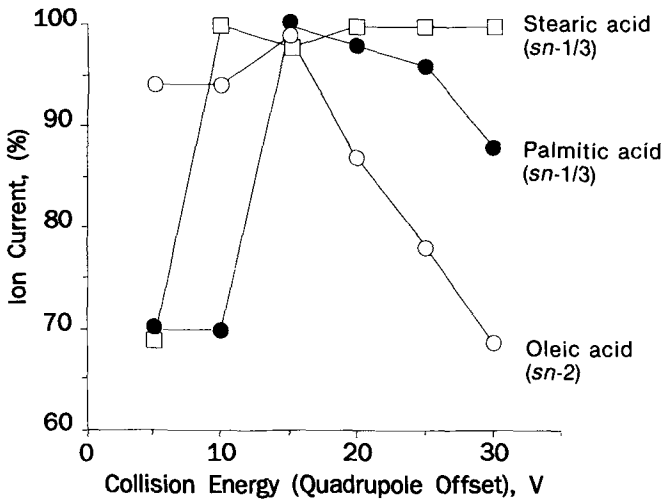

FIG. 2. Plot of RCO_2^- abundances from negative ion chemical ionization collisionally activated daughter spectra of 1-palmitoyl-2-oleoyl-3-stearoyl-*rac*-glycerol, showing variation in abundances with different collision energies.

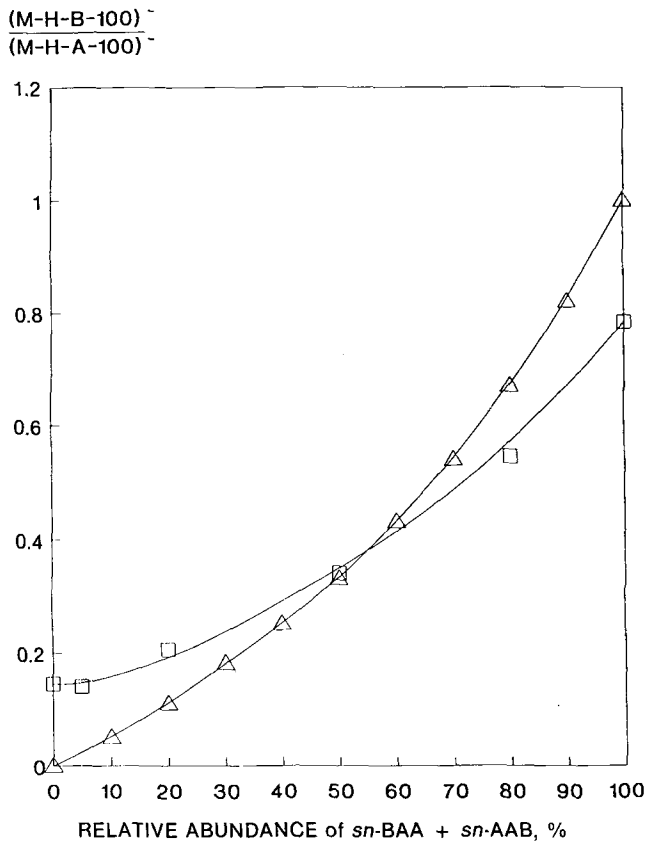

FIG. 3. Ratio of the ions $[M - H - B - 100]^-/[M - H - A - 100]^-$ in daughter spectra of binary mixtures of triacylglycerols of type A-A-B and A-B-A. A and B represent different fatty acids at regiospecific locations, *i.e.*, *sn*-1/3 and *sn*-2. Measurements were based on the intensities of the $[M - H - RCO_2H - 100]^-$ fragment ions. The squares represent the empirical correlation determined using mixtures of known ratios of reference compounds listed in Table 1. The triangles show the theoretical curve if no $[M - H - RCO_2H - 100]^-$ ions concerning the fatty acid at position *sn*-2 were formed.

toyl-2-oleoyl-3-stearoyl-*rac*-glycerol are plotted at different collision energy (Fig. 2). The results in Figure 2 indicate that the formation of RCO_2^- from position *sn*-2 has different energy requirements than the formation of RCO_2^- from position *sn*-1/3. Therefore, some or all of the RCO_2^- ions from the *sn*-2 position must be formed by a different fragmentation mechanism. In order to minimize this effect, it is essential to hold the collision energy at a fixed value that preferably does not discriminate against the *sn*-2 fragment. The other factor affecting the formation of RCO_2^- is the number of double bonds and the chain length. MS/MS results from racemic reference TAG compounds, and other TAG mixtures show that RCO_2^- ions with double bonds are consistently underestimated. The discrimination between unsaturated FA and FA of different chain lengths may be corrected by obtaining correction factors from reference TAG. It is also important to obtain the correction factors at the same collision energy with which the oil samples will be analyzed.

Information about regiospecific positions of fatty acids. The data in Table 1 and Figures 1a and 1b show that the formation of the ions $[M - H-RCO_2H]^-$, $[M - H-RCO_2H-74]^-$, and $[M - H-RCO_2H-100]^-$ in the MS/MS spectra of TAG occurs in from little to none of the *sn*-2 fatty acid. These ions can therefore be used to determine the fatty acid located at *sn*-2 position. It is convenient to use the $[M - H-RCO_2H-100]^-$ ion for this purpose, as it is the most abundant fragment, thus increasing the sensitivity of the technique.

In a simple, two FA system, the mixture of TAG may be considered to consist of TAG *rac*-A-A-B and A-B-A. A and B in these systems represent FA at different regiospecific locations; *e.g.*, in the system A-B-A, fatty acid B is at the *sn*-2 position. In order to determine the possibility of accurately calculating the regiospecificity in a TAG system of this type, the ratio of the MS/MS fragment ions $[M - H-B-100]^-/[M - H-A-100]^-$ from mixtures of TAG of the type A-A-B and A-B-A were compared. It was found in pure TAG systems of A-A-B and A-B-A that the ratio of the intensities $[M - H-B-100]^-/[M - H-A-100]^-$ were (A-A-B) 0.784 ± 0.015 and (A-B-A) 0.145 ± 0.016, respectively. These ratios were obtained regardless of the fatty acid combinations (Table 1). The different combinations of the binary mixture A-A-B and A-B-A showed an increase in the ratio of $[M - H-B-100]^-/[M - H-A-100]^-$ in going from 100% A-B-A to 100% A-A-B, as seen in Figure 3. This result indicates that in simple mixtures it is possible to determine not only whether the mixture consists of different regioisomeric TAG, but also the ratio of the isomers. There are a number of possibilities why some of the $[M - H-RCO_2H-100]^-$ is formed from the fatty acid at *sn*-2 position. These are: (i) rearrangement of the samples *via* acyl migration occurred during volatilization into the MS; (ii) the reference compounds were not pure isomers or; (iii) a small amount of $[M - H-RCO_2-100]^-$ is produced from the *sn*-2 fatty acid. Although we were unable to discount any one of these possibilities, experiments with different probe heating rates suggested that some acyl migration occurs during volatilization.

Analysis of turnip rapeseed oil. The fifteen major FA from the purified turnip rapeseed oil TAG analyzed as methyl esters by GC/MS are listed in Table 2. Only seven of the fatty acids exceeded 1% of the total fatty acids in

TABLE 2

[a]Represents TAG of the fourteen molecular weight species analyzed. Corrected due to ^{13}C species in NICI-MS and due to varying chain lengths and number of double bonds of the fatty acids in the collisionally activated daughter spectra. Abbreviations: GC, gas chromatography; NICI-MS, negative ion chemical ionization-mass spectrometry.

the TAG mixture. The most abundant were *cis*-9-octadecenoic (oleic, 18:1n-9), *cis,cis*-9,12-octadecadienoic (linoleic, 18:2n-6) and all-*cis*-9,12,15-octadecatrienoic (α-linolenic, 18:3n-3) acids. It is noteworthy that the content of *cis*-13-docosenoic (erucic, 22:1n-9) acid was below 1%. The major saturated fatty acids were palmitic (16:0), stearic (18:0) and eicosanoic (20:0) acids. Characterization of turnip rapeseed oil fatty acids, the acyl carbon number profile and the molecular weight distribution of TAG from the variety "Kova" during the growing period and maturation have been reported elsewhere (35). The major fatty acids in "Kova" have been shown to be practically identical with the LEAR cultivars "Janpol" (40) and "Candle" (41). The cultivar "Tower" contains more oleic (64%) and less erucic acid (0.08%) than the other varieties (41). Details of the minor fatty acids in the low erucic varieties "Span" and "Tower" have been extensively studied by Sebedio and Ackman (42).

An NICI mass spectrum of the TAG from turnip rapeseed oil ("Kova") is shown in Figure 4. The five clusters in the spectrum correspond to $[M - H]^-$ ions of ACN 50, 52, 54, 56 and 58. The major clusters were ACN 54 and ACN 52 and comprised 76 and 18% of the total ion count, respectively. Daughter spectra were obtained from the fourteen $[M - H]^-$ ions numbered in Figure 4. Results of the mass spectrometry analyses of turnip rapeseed oil are listed in Table 3.

The proportions of the MW fractions (878.7–884.7 Da) of ACN 54 were consistent with earlier results derived from ammonia PICI-MS (35). The deviations between the PICI results and the NICI results may occur as a result of the PICI data being corrected for ^{13}C isotope content, fatty acid chain lengths and the number of double bonds. In contrast, the NICI data were only corrected for the ^{13}C isotope content. The ratios of FA within an MW fraction were calculated directly from the abundances of the RCO_2^- ions in the daughter spectra. Quantitative correction factors were then applied to the RCO_2^- ion abundances to correct for the discrimination in the detection of the different FA (TAble 3). The total FA profile of the TAG analyzed by both GC/MS as methyl esters and directly by MS/MS is shown in Table 2. Only the most abundant MW species of the minor ACN clusters were ana-

[a]Ratios of the fourteen MW fractions of triacylglycerols (TAG) analyzed by NICI-MS. The values have been corrected for ^{13}C content.
[b]Ratios of the MW fractions of TAG analyzed by PICI-MS, values are corrected for ^{13}C content, the chain length and degree of unsaturation of FA (ref. 33).
[c]The slashes between FA do not indicate the regiospecific positions within the TAG.
[d]Proportions of FA were calculated by taking relative abundances of the $[FA-H]^-$ and multiplying by correction factors.
[e]FA preferentially (>67%) located at the *sn*-2 position.

Abbreviations as in Table 2 and MW, molecular weight; DB, double bond; PICI, positive ion chemical ionization; FA, fatty acid; ACN, acyl carbon number.

lyzed by MS/MS, whereas the GC/MS analysis represents the total oil. All the major fatty acids identified by GC/MS as their methyl esters (Table 2) are represented in the TAG combinations identified by MS/MS (Table 3). Discrepancies between the two methods of analysis are found for eicosatrienoic (20:3n-3) and tetracosanoic (24:0) acids, which are not detected in the MS/MS analysis. It is likely that these two fatty acids were present in the minor TAG of clusters ACN 56–60, which were not analyzed by MS/MS. Hexadecadienoic acid (16:2), which comprised less than 0.01% of the total FA, was found by MS/MS in the MW fraction 852.7 Da. Each of the 14 MW species of TAG fraction analyzed were composed of 3–10 FA of various MW and number of double bonds. The MS/MS method was not able to distinguish between the positional isomers of double bonds of unsaturated fatty acids. The GC/MS results from the rapeseed FA methyl esters indicate that the only two FA in which this would cause a practical problem were 18:1n-9 and 18:1n-7.

The MS/MS spectra showed that most MW fractions consisted of mixtures of TAG. This restricted the ability to evaluate the regiospecific positions of fatty acids in the triacylglycerols. Nevertheless, it was possible to determine that in many TAG certain FA were preferentially (>67%) located at the *sn*-2 position, and these are labelled with superscript e in Table 3.

The major ion in the cluster ACN 50 (Fig. 4) corresponded to TAG of molecular weight 830.7 Da and was a mixture of 16:0/16:0/18:2 (62%), 16:1/16:0/18:1 (24%) and 14:0/18:1/18:1 (14%). Linoleic acid occupied more than 75% of the *sn*-2 position of the major TAG 16:0/16:0/18:2. The second biggest $[M - H]^-$ cluster in the NICI spectrum was ACN 52, which accounted for 18% of the total ion current. Four MW fractions from this cluster were analyzed further by MS/MS. These MW fractions contained TAG with two to five double bonds and from four to six different fatty acids. Two abundant TAG, 16:0-18:3-18:2 and 16:0-18:2-18:1, had linoleic acid preferentially at position *sn*-2. The major TAG of MW 858.7 Da was 16:0-18:1-18:1 (91%) and had 18:1 preferentially at the *sn*-2 position. The most abundant TAG cluster was ACN 54 (Table 3 and Fig. 4), which comprised close to 80% of turnip rapeseed oil TAG. TAG 18:3/18:2/18:1 and 18:2/18:2/18:1 represented over 20% of all the TAG in the seed oil, and the regioisomers 18:3-18:2-18:1 and 18:2-18:2-18:1 containing linoleic acid at *sn*-2 position, clearly dominated. The TAG of molecular weight 886.7 Da (ACN 54, 2 DB) consisted predominantly of FA combinations 18:1-18:1-18:0 (94%) and 18:2-18:0-18:0 (6%). There appeared to be a preference for 18:0 at the *sn*-2 position in the combination 18:1-18:1-18:0, *i.e.*, TAG *sn*-18:1-18:0-18:1 dominated. This is an interesting detail from a nutritional point of view, as the saturated *sn*-2-monoacylglycerols derived from these TAG have special melting and solubility properties (43,44). The MW species of 910.8 Da (ACN 56, 4 DB) contained six fatty acids. The major TAG of this MW was 18:2-18:1-20:1, which mainly occurred as the regioisomer 18:1-18:2-20:1. The ACN cluster 58 was extremely small due to the low erucic acid (22:1n-9) content of the "Kova" seeds. The major TAG fraction of ACN 58 had MW 940.8 Da and three double bonds. The complexity of this fraction prevented any regiospecificity from being determined.

Altogether, 44 different FA combinations of TAG were identified in the "Kova" variety, of which more than half existed in trace amounts (<1%). Results of the LEAR variety "Janpol" (40) based on GC analysis of FA, silver ion thin-layer chromatographic analysis of TAG and pancreatic lipase hydrolysis of the FA at positions *sn*-1 and *sn*-3 showed that linoleic acid preferentially occupies position *sn*-2 in several major TAG species. The same trend was reported earlier by Sergiel (45), although his results lacked information on specific triacylglycerols. The current status of LEAR varieties is summarized in detail by Ackman (29). The results obtained by NICI MS/MS are consistent with those of Zadernowski and Sosulski (40) with a few minor exceptions; namely, the major TAG source of stearic acid in "Kova" was 18:1/18:1/18:0 in which the saturated stearic acid preferentially occupied the *sn*-2 position. The MS/MS method also identified the TAG 18:2/18:2/18:2 to be present as 2–3% of the total TAG in "Kova oil."

CONCLUSIONS

The MS/MS method applied in this paper gives the opportunity to separate triacylglycerols with one dalton (*m/z*) resolution at the first quadrupole mass analyzer. The $[M - H]^-$ molecular ions may then be structurally characterized by a second mass analyzer. The advantages of the method developed include: (1) the sensitivity of the method (typically at subnanogram range of an individual TAG molecule); (ii) the method is extremely fast, *e.g.*, the time to characterize one MW fraction takes 10–15 min; (iii) the different MW species of TAG may be separated without any chromatographic steps; and (iv) the fatty acid combinations of each TAG and their regiospecific locations can be identified. The method does not replace the commonly accepted stereospecific analyses based on enzymatic hydrolysis, nor does it make the current chromatographic methods less valuable than they are today. However, the method may supplement the common methods of analysis and may be used as the first step in the characterization of TAG mixtures. At its present stage of development there are some limitations in its use, including: (i) the isomers of fatty acids (positions of double bonds, branching) cannot be distinguished; (ii) discrimination between the FA at positions *sn*-1 and *sn*-3 is not possible; and (iii) in complex TAG mixtures extraction of the *sn*-2 information is difficult or perhaps even impossible.

In the future, some of these limitations, including the difficulty of the MS/MS method in determining the *sn*-2 fatty acid in complex MW fractions, may be overcome by interfacing chromatographic procedures to the MS/MS system, *e.g.*, argentation high-performance liquid chromatography (46,47) or SFC (22,48). Other areas in which the method may prove useful are in on-line process control in the edible oil, dairy and pharmaceutical industries (32,33). The method is also applicable in enzyme methodology, when studying the regiospecificity of enzymes or in research on human nutrition and clinical applications.

ACKNOWLEDGMENTS

We thank Professor Terry Lee and Dr. Pat Williams for access to the analytical facilities of The Australian Wine Research Institute, the Finnish Academy and the Foundation of the University of Turku, Finland, for financial support; and Anu Johansson for extraction and purification of the oil samples.

Triacylglycerols of Human Milk: Rapid Analysis by Ammonia Negative Ion Tandem Mass Spectrometry

Graeme J. Currie[1] and **Heikki Kallio***
Department of Chemistry and Biochemistry, Laboratory of Food Chemistry, University of Turku, SF-20500 Turku, Finland

Human milk triacylglycerols (TAG) were analyzed by ammonia negative ion chemical ionization tandem mass spectrometry. The deprotonated molecular ions of triacylglycerols were fractionated at the first mass spectrometry (MS) stage. Twenty-nine of the deprotonated TAG ions were further analyzed based on their collisionally activated (CA) spectra. The tandem MS analysis covered eleven major acyl carbon number fractions, two of which contained odd carbon number fatty acids. Fatty acids of 28 different molecular weights were recorded from the daughter spectra. Hexadecanoic acid was present in all CA spectra, octadecenoic acid in the CA spectra of all mono- and higher unsaturated TAG, and octadecadienoic acid in the CA spectra of all di- and higher unsaturated TAG. The major fatty acid combinations in triacylglycerols were: with 0 double bonds (DB), 12:0/12:0/16:0; with 1 DB, 12:0/16:0/18:1; with 2 DB, 16:0/18:1/18:1; with 3 DB, 16:0/18:2/18:1; with 4 DB, 18:2/18:1/18:1; and with 5 DB, 18:2/18:2/18:1; hexadecanoic acid typically occupied the *sn*-2 position. The most abundant TAG was shown to be *sn*-18:1-16:0-18:1, comprising about 10% of all triacylglycerols.
Lipids 28, 217-222 (1993).

Triacylglycerols (TAG) comprise 98% of the total lipids in both human and cow milk (1). A thorough investigation of the molecular structures in the highly complex pool of triacylglycerols of human milk requires stepwise application of analytical procedures: (i) for the separation according to molecular weights and acyl carbon numbers; (ii) for the fractionation of each molecular weight cluster according to different fatty acid combinations; and (iii) for the analysis of the fatty acids in individual stereospecific positions. Mass spectrometry (MS) to complement chromatographic and enzymatic methods has been applied successfully (2-5). Freeman *et al.* (2) and later Kuksis and colleagues (6-8), as well as Weber *et al.* (9), have used chromatographic and mass spectrometric techniques to determine in detail the compositional and structural characteristics of human milk triacylglycerols.

Studies on human milk lipids have been exhaustively reviewed by Lammi-Keefe and Jensen (10), Davies *et al.* (11) and Jensen (12). In 1965, Freeman *et al.* (2) showed that in the triacylglycerols of human milk, *n*-hexadecanoic acid is typically located at the *sn*-2 position. According to Breckenridge *et al.* (7) the major acyl carbon number (ACN) species of human milk are, in descending order of abundance, ACN 52, 50, 54, 48, 46, 44, 56 and 42, although abundances may vary slightly depending on the days *postpartum* (9,13-15). Close to 100 TAG species have been identified in human milk so far (9).

The aim of this work was to apply a rapid tandem mass spectrometric method using ammonia negative ion chemical ionization (16,17) to human milk triacylglycerols in order to identify the most abundant fatty acid combinations in TAG. Information concerning the fatty acyl groups located preferentially at the *sn*-2 position also was obtained using the tandem mass spectrometry (MS/MS) method.

MATERIALS AND METHODS

Human milk triacylglycerols. A sample of milk was obtained from a young Australian mother 1 day *postpartum*. Lipids were extracted according to the method of Bligh and Dyer (18) using $CHCl_3$/MeOH.

Tandem mass spectrometric analysis. The lipid fraction of human milk was dissolved in dichloromethane (*ca.* 1 mg/mL), and 1 μL of this mixture was placed in an aluminum crucible located at the end of the standard direct insertion probe of a Finnigan MAT (San Jose, CA) TSQ-70 triple quadrupole mass spectrometer. The negative ion chemical ionization mass spectra of TAG were acquired using ammonia as the reagent gas, and the collisionally activated (CA) daughter spectra of the deprotonated TAG were obtained using argon as the collision gas (17). The method, its mass spectral basis and its applicability have been described in more detail previously (17,19).

The CA daughter spectra of the $[M - H]^-$ ions consisted of two main fragment ion clusters, namely RCO_2^- and $[M - H - RCO_2H - 100]^-$ (17,19). These fragment ions were used to deduce the structure of the $[M - H]^-$ ion and thus of the TAG molecule(s). The proportions of fatty acids within the deprotonated TAG of each parent ion were calculated according to the intensities of the RCO_2^- ions corrected by empirical molar correction factors. The loss of the $(RCO_2H + 100)$ fragments from the $[M - H]^-$ ion in a CA daughter spectrum was used to obtain information regarding the fatty acyl groups at the *sn*-2 position, as shown previously (17,19).

RESULTS AND DISCUSSION

The triacylglycerols of human milk were deprotonated in the gas phase using ammonia negative ion chemical ionization (NICI). The individual deprotonated molecular weight fractions, $[M - H]^-$, were selected one by one using the first quadrupole mass spectrometer of the TSQ-70 instrument. This method allowed the separation of TAG species of human milk by mass with a practical resolution of 1 amu. The aim and goal of this NICI MS stage was analogous to currently available chromatographic techniques commonly used prior to single stage MS analysis. Mass spectral separation of the $[M - H]^-$ ions is, however, more efficient than is currently practical by chromatographic techniques. The $[M - H]^-$ ions chosen were then collisionally activated in the second quadrupole with argon, and the mass spectrum of the fraction was

obtained by scanning with the third quadrupole. No selectivity according to chemical or physical properties other than molecular weight was noted by MS.

Any signal corresponding to an $[M - H]^-$ ion would also contain some ions which originate from TAG having two ^{13}C atoms randomly distributed in their carbon skeleton but containing one additional double bond in their fatty acyl residues. The proportions of these isotopic contributions were subtracted from the $[M - H]^-$ parent ion. The corrected values for the even ACN TAG are summarized in Figure 1.

The major $[M - H]^-$ cluster in the NICI mass spectrum (Fig. 1) was ACN 52 (isotope-corrected proportion, 23%) followed by ACN 46–50 (*ca.* 16% each), ACN 44 (11%), ACN 42 (7%), ACN 40 (5%), ACN 54 (5%) and ACN 38 (3%). The corrected proportions of the saturated, monoenoic, dienoic, trienoic, tetraenoic and pentaenoic TAG were 14, 38, 30, 14, 4 and 1%, respectively (Fig. 1).

The specific responses of $[M - H]^-$ ions which varied according to their molecular weights were not taken into account in Figure 1 due to lack of proper correction factors. It was recognized that the lowest molecular weight areas were always overestimated in ammonia NICI MS when compared with the high mass range. The differing volatilities of triacylglycerols, which differ according to molecular weight, were therefore taken into account by acquiring the NICI spectra over a wide range and by averaging the spectra (17). Both the proportions of ACN species and of TAG with different degrees of unsaturation were close to earlier reports (12,15). Due to the effect of the mother's diet, especially in regard to the linoleic acid content of the milk, average values can only be indicative (20).

Examination of Figure 1 shows that the degree of unsaturation in TAG increases as the molecular weight of the TAG increases. This is in agreement with the earlier observations by Breckenridge *et al.* (7), who used a combination of chromatographic techniques in their studies. The majority of the TAG were mono- and diunsaturated, and the saturated TAG were not observed in notable quantities in ACN larger than 48. All ACN species with 48 or more acyl carbons contained tetraenoic TAG species. Pentaenoic TAG were found in all ACN groups with at least 52 acyl carbons. Those MW species with at least 0.5% relative abundance of total TAG (Fig. 1) were further analyzed by CA MS/MS. Although small traces of ACN species beyond 38–54 were observed, they were not analyzed. Several minor TAG with odd ACN could be observed between the major even-numbered TAG by NICI MS. However, only two of these odd-numbered species, 762.7 and 790.7, were further analyzed by tandem MS.

Table 1 lists the 28 fatty acid species identified based on both the RCO_2^- and $[M - H - RCO_2H - 100]^-$ ions in the CA daughter spectra of the $[M - H]^-$ ions. It is important to note that in these experiments no information other than the molecular weights of the fatty acids could be obtained, *i.e.*, information such as the positions and configurations of double bonds or possible branching could not be deduced. Thus, the minor TAG species containing *trans*-acids, such as 14:1, 16:1, 17:1 or 18:1, cannot be distinguished from the corresponding major *cis*-acids, nor can 18:3n-6 (γ-linolenic acid) and 18:3n-3 (α-linolenic acid) be separated without silver ion high-performance liquid chromatography (HPLC) (21) or an equivalent fractionation method. The fatty acid composition

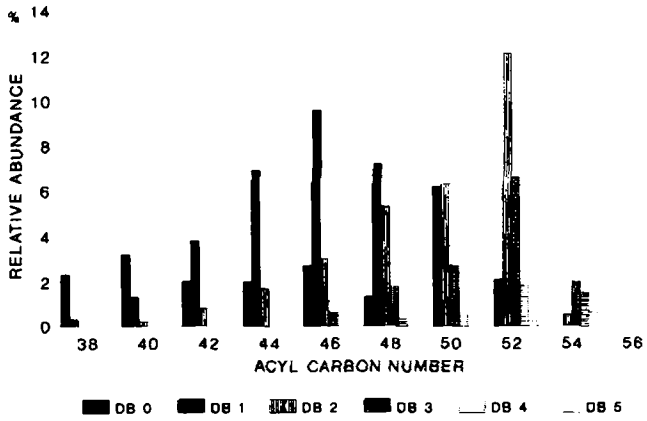

FIG. 1. Distribution of triacylglycerols in human milk according to the acyl carbon numbers and number of double bonds (DB). Calculations are based on the intensities of the ^{13}C isotope corrected $[M - H]^-$ ions of ammonia negative ion chemical ionization mass spectra.

of human milk is, however, well known (*e.g.*, 6,7,12,22, 23).

The daughter spectra of the $[M - H]^-$ ions revealed that hexadecanoic acid (16:0) was present in each molecular weight species of the TAG analyzed, octadecenoic acid (18:1) in each unsaturated species, and octadecadienoic acid (18:2) in each di- and higher unsaturated ones. Because of the lack of some response correction factors, the relative abundances of the fatty acids are not listed in Table 1.

Dodecanoic (12:0) and tetradecanoic (14:0) acids are typical constituents of human milk, and they were present in all TAG species up to MW 832.7 (ACN 50, 1 DB) and MW 860.7 (ACN 52, 1 DB), respectively. Octanoic acid (8:0) is not listed in Table 1 because the ion corresponding to the deprotonated fatty acid was not observed in the CA spectra, although the presence of this acid was indicated by the loss of $(RCO_2H + 100)$ of the $[M - H]^-$ ions. The absence of RCO_2^- ions derived from octanoic acid may be due to the larger potential energy loss in the fragmentation process; this could result in poor transmission through the third quadrupole and, hence, in a weak ion signal or no signal at all. Hexanoic (6:0) and butanoic (4:0) acids, which are known to be present in extremely small quantities in TAG evidently smaller than ACN 38, were not observed in the parent ions analyzed.

Long-chain fatty acids, such as 20:5, 22:4, 22:5, 22:6, 24:0 and 24:1, are typically present in TAG of ACN 56 and higher (6,22). However, the fatty acids were not found in the MW species analyzed by collisional activation. Yet, traces of the clusters ACN 56 and ACN 58 could be seen in the NICI mass spectrum of human milk TAG. The 29 MW species analyzed by MS/MS indicated that these MW fractions comprised 277 different TAG, even when the positional isomers and different fatty acid isomers are excluded. The two most abundant TAG of each MW fraction are listed in Table 2. Information concerning the number of various fatty acids and TAG within each MW species is also given. The fatty acids marked with a ^{c} were estimated, based on the relative abundances of the $[M - H - RCO_2H - 100]^-$ ions in the CA daughter spectra, to be preferentially located at position *sn*-2 (17). The

[a]Acyl carbon number.
[b]Molecular weight.
[c]Number of double bonds in triacylglycerols.
[d]Identifications are based on both RCO_2^- and $[M-H-RCO_2H-100]^-$ ions of collisionally activated daughter spectra of the deprotonated triacylglycerols. FA, fatty acid.
[e]The number of FA combinations in TAG.
[f]Preferentially at *sn*-2 position.

MS/MS results are consistent with the currently accepted concept that in human milk TAG hexadecanoic acid is typically located at position *sn*-2 (2,7,24,25). It could be seen from our data that in several instances where 16:0 acid was not present, 14:0, 15:0 and even 12:0 preferentially took the place of 16:0 and occupied the *sn*-2 position (Table 2). Although Freeman *et al.* (2) and Breckenridge *et al.* (7) observed the preference of 16:0 for *sn*-2 more than twenty years ago, they were not able to do this at the level of individual TAG species. The advantage of the MS/MS method is that direct information can be obtained on the regiospecific structure of individual TAG species (or small groups) instead of having to rely on averaged results of enzymatic analyses carried out on complex mixtures. In addition, the MS/MS method is more rapid.

A recent analysis of human milk by HPLC and gas chromatography (GC) reported by Weber *et al.* (9) identified and quantified 94 triacylglycerols in human milk, although no information regarding the stereospecific distribution of the fatty acids was given. All the TAG listed in Table 2, except for the two odd-numbered fatty acid TAG species and 12:0/12:0/18:2, also were reported by Weber *et al.* (9). For example, the typical CA daughter spectra of the two major MW species 858.7 (ACN 52, 2 DB) and MW 776.7 (ACN 46, 1 DB) are shown in Figures 2a and 2b, respectively. Examination of Figure 2a shows that the $[M-H]^-$ ion with the recorded *m/z* 857.4 in the NICI spectrum consisted of eight fatty acids (eight different MW species of fatty acids). The number of fatty acid combinations of the TAG was seven, based on the known number of carbons (ACN 52) and the degree of unsaturation (2 DB) in each TAG species (17).

According to the proportions of the RCO_2^- ions in Figure 2a, the order of abundances of the TAG in this MW fraction are 16:0/18:1/18:1, 16:0/18:2/18:0, 16:1/18:1/18:0, 16:1/16:0/20:1, 14:0/18:1/20:1, 16:0/16:0/20:2 and 14:0/18:0/20:2. The order of the fatty acids (separated by slashes) does not imply that the stereospecific positions of the fatty acyl groups are known. The two major TAG combinations of the MW fraction *m/z* 857.4 comprised more than 95% of the seven TAG species present, based on the relative counts of the RCO_2^- ions. From the abundances of the $[M-H-RCO_2H-100]^-$ fragment ions, it is clear (17,19) that hexadecanoic and tetradecanoic acids were preferentially located at the *sn*-2 position. Within the $[M-H-RCO_2H-100]^-$ cluster, the relative abundance of the signal originating from the 16:0

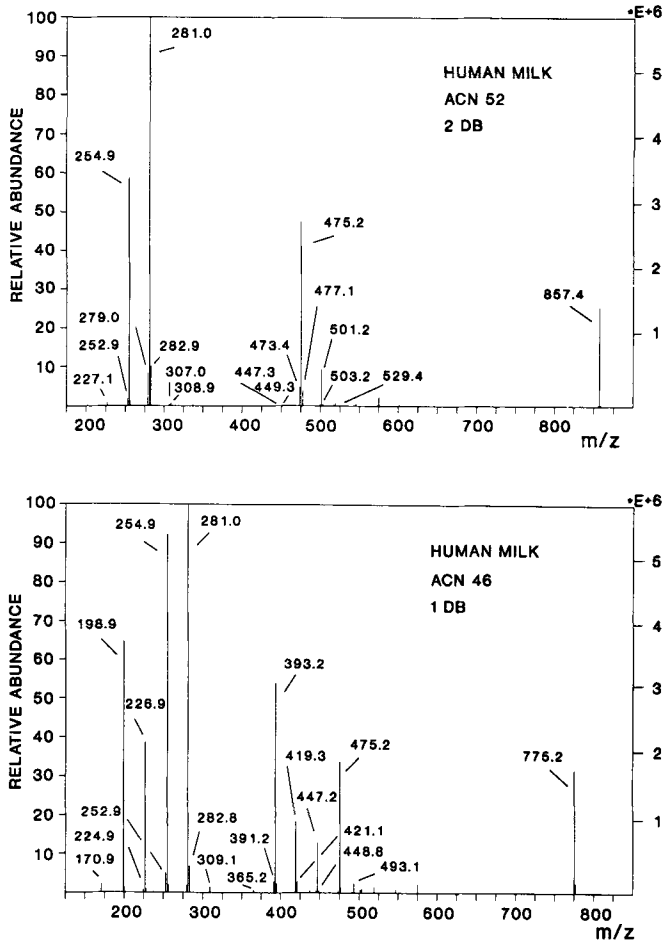

FIG. 2. Collisionally activated daughter spectra of the deprotonated molecular ions of triacylglycerols of molecular weights 858.7 (a) and 776.7 (b) from human milk.

fatty acid (recorded *m/z* 501.2) was only 14.2%, whereas within the RCO_2^- cluster the corresponding abundance of 16:0 (recorded *m/z* 254.9) was 32.3%.

To accurately calculate the proportions of fatty acids and their primary *vs.* secondary positions in the TAG species (*e.g.*, Fig. 2a), precise calibration for all the RCO_2^- ions is required. If just the three major TAG species—16:0/18:1/18:1, 16:0/18:2/18:0 and 16:1/18:1/18:0—were taken into account and the earlier defined correction factors (17) were applied ($k_{18:0} = 1.0$, $k_{18:1} = 1.3$, $k_{18:2} = 1.6$, $k_{16:0} = 1.1$ and $k_{16:1} = 1.5$), the relative proportions of the three TAG were 86, 12 and 2%, respectively. It could then be determined that 85% of 16:0 acid in the major TAG of human milk, 16:0/18:1/18:1, was located at position *sn*-2 (17). Thus the most abundant TAG in human milk, comprising 9% of all TAG species, was shown to be *sn*-18:1/16:0/18:1. The absolute error may not be very high, as the fatty acids excluded from the calculations above, 14:0, 20:1 and 20:2, comprised only 1-2% of the total fatty acid pool of the molecular weight 858.7 TAG.

The CA daughter spectrum of the MW fraction 776.7 (Fig. 2b, measured *m/z* $[M - H]^- = 775.2$) showed that this fraction consisted of nine different fatty acids, which again originated from nine different TAG species. The two most abundant TAG based on a relative ion count of the RCO_2^- ions were 12:0/16:0/18:1 and 14:0/14:0/18:1. The other TAG were 10:0/16:0/20:1, 10:0/18:1/18:0, 12:0/14:0/20:1, 12:0/16:1/18:0, 14:1/14:0/18:0, 14:0/16:1/16:0 and 14:1/16:0/16:0.

The list of the most abundant TAG species in each MW fraction (Table 2) and the distribution of TAG in Figure 1 are quite consistent with the results of Watts and Dils (14), as well as those of the Kuksis group (6-8). Their results, however, showed a slightly different order of relative abundances of the major TAG when compared with our data; *e.g.*, the total proportion of ACN 52 TAG, 23%, was lower than that reported by other authors. This discrepancy may suggest an underestimation of the abundances of the higher MW TAG by the ammonia NICI method. It is, however, quite possible that a number of natural factors may account for this difference, *e.g.*, randomization in human milk, which is known to occur as lactation proceeds (14), and the susceptibility of human milk TAG to dietary habits (7,26).

ACKNOWLEDGMENTS

We are grateful to Dr. Robert Gibson, Flinders medical Center, Adelaide (human milk triacylglycerol samples), and Professor Terry Lee and Dr. Pat Williams, the Australian Wine Research Institute, Adelaide, South Australia (MS facilities). We also thank the Finnish Academy and the Foundation of the University of Turku, Finland, for financial help.

Hypolipidemic Activity of 6-Alkoxycarbonyl-3-aryl-1,3,5-triazabicyclo[3.1.0]hexane-2,4-diones and 2-Alkoxycarbonyl-5-aryl-1,3,5-triazine-4,6(1H,5H)-diones in Rodents

Robert A. Izydore[a], O.T. Wong[b] and Iris H. Hall[b,*]

Significant hypolipidemic activity was demonstrated by 6-ethoxycarbonyl-3-phenyl-1,3,5-triazabicyclo[3.1.0]hexane-2,4-dione, 2-ethoxycarbonyl-5-phenyl-1,3,5-triazine-4,6(1H,5H)-dione and 2-ethoxycarbonyl-5-(4-chlorophenyl)-1,3,5-trizine-4,6(1H,5H)-dione in rodents at 20 mg/kg/day. These agents lowered serum cholesterol and triglyceride levels by approximately 40% in mice after 16 d. Tissue lipids in rat liver, small intestinal mucosa, aortic wall and feces were reduced by treatment with the agents. Very low density lipoprotein (VLDL) and low density lipoprotein (LDL) cholesterol levels were reduced in the rat; high density lipoprotein (HDL) cholesterol levels were elevated after 14 d of treatment. The activities of regulatory enzymes, *e.g.*, acetyl-CoA synthetase, acyl-CoA:cholesterol acyltransferase, cholesterol 7α-hydroxylase, *sn*-glycerol-3-phosphate acyltransferase, phosphatidylate phosphohydrolase and heparin-induced lipoprotein lipase, involved in *de novo* synthesis of hepatic lipids were affected by the agents. The new compounds may represent another class of potentially useful hypolipidemic agents for the treatment of atherosclerosis since HDL cholesterol levels were increased and VLDL and LDL cholesterol levels were lowered by some of the agents.

Lipids 28, 223–229 (1993).

We have previously reported that a number of low molecular weight compounds having different ring structures, *e.g.*, succinimides (1), dilantin (2), phenobarbital (3), terephthalic acid (4), 2-pyrrolidinones (5,6), 4-pyrimidinecarboxylic acids (7), 2-furoic acid (8) and 3,4-diphenylpiperidine-2,6-diones (9), have potent hypolipidemic activity in rodents. These agents were effective in lowering both serum cholesterol and triglyceride levels by 30–40% in rodents. Substitutions on the nitrogen atom of the ring, *e.g.*, cyclic imides with a bulky group [*N*-(4-methylphenyl)-diphenimide and *o*-(*N*-phthalimido)acetophenone], led to compounds which significantly lowered very low density lipoprotein (VLDL) and low density lipoprotein (LDL) cholesterol and elevated high density lipoprotein (HDL) cholesterol levels in rats at 10–20 mg/kg/d when administered orally. Subsequently, series of 1-acylated and 1,2-diacylated 4-substituted 1,2,4-triazolidine-3,5-dione and 2-benzoyl-4,4-dialkyl-3,5-isoxazolidinediones have demonstrated potent hypolipidemic activities in rodents (10,11). Since the earlier compounds have some structural similarities with 6-alkoxycarbonyl-3-aryl-1,3,5-triazabicyclo[3.1.0]hexane-2,4-diones and 2-alkoxycarbonyl-5-aryl-1,3,5-triazine-4,6(1H,5H)-diones, we tested the new derivatives for hypolipidemic activity in rodents. Results of these studies are reported here.

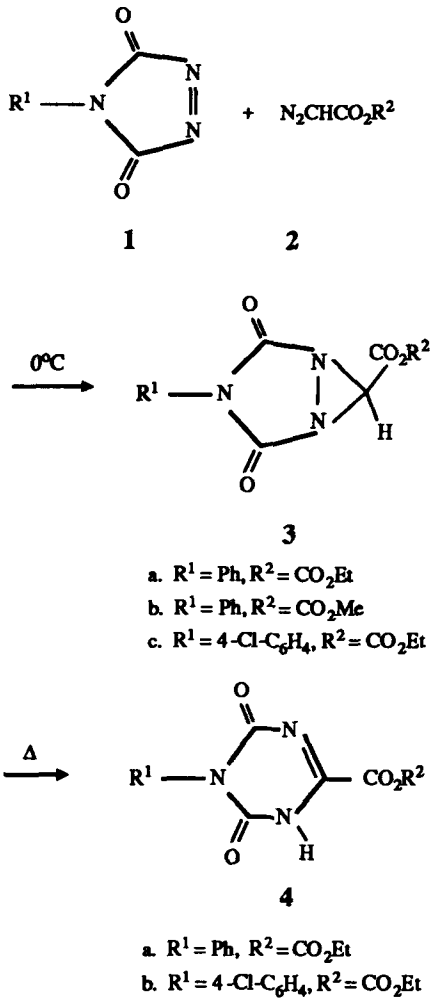
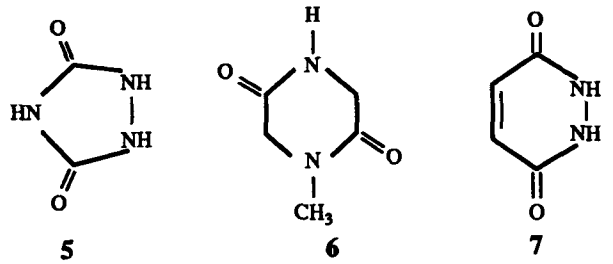
MATERIALS AND METHODS

The synthesis and the physical, chemical and spectral properties of 6-ethoxycarbonyl-3-phenyl-1,3,5-triazabicyclo[3.1.0]hexane-2,4-dione (**3a**), 6-methoxycarbonyl-3-phenyl-1,3,5-triazabicyclo[3.1.0]hexane-2,4-dione (**3b**), 6-ethoxycarbonyl-3-(4-chlorophenyl)-1,3,5-triazabicyclo-[3.1.0]hexane-2,4-dione (**3c**), 2-ethoxycarbonyl-5-phenyl-1,3,5-triazine-4,6(1H,5H)-dione (**4a**) and 2-ethoxycarbonyl-5-(4-chlorophenyl)-1,3,5-triazine-4,6(1H,5H)-dione (**4b**) have been described previously (Scheme 1) (10,11). Compounds **5**, **6** and **7** were purchased from Aldrich Chemical Co. (Milwaukee, WI) (Scheme 2). All radioactive compounds were purchased from New England Nuclear (DuPont, Boston, MA). Substrates and cofactors for the enzyme assays were obtained from Sigma Chemical Co. (St. Louis, MO).



SCHEME 1



5 6 7

SCHEME 2

Hypolipidemic screens in normal rodents. Test compounds **3a–c, 4a–b, 5, 6** and **7** were suspended in an aqueous 1% carboxymethylcellulose solution, homogenized and administered to CF_1 male mice (~25 g) at 20 mg/kg/d intraperitoneally for 16 d. Structure-activity relationship (SAR) studies were performed at 20 mg/kg/d for 16 d because this dose was optimal in activity for the succinimide, 2-furoic acid, dilantin, glutamide and phenobarbital studies in rodents (1–9). On days 9 and 16, blood was obtained from the tail vein, and serum was separated by centrifugation at 3500 × *g* for 3 min. Serum cholesterol levels were determined by a modification of the Liebermann-Burchard reaction (12). Serum was also analyzed for triglyceride content as determined by a commercial kit (BioDynamics/bmc single vial, triglycerides colorimetric method 348201, Boehringer Mannheim Diagnostics, Indianapolis, IN). Food and water were available *ad libitum.* The animals were maintained at 22°C on Rat, Mouse, Hamster 3000, Agway ProLab Animal Diets (Syracuse, NY) under a 12-h light/dark cycle.

Hyperlipidemic induced CF_1 mice. CF_1 male mice (~30 g) were fed a 1:1 mixture of basal atherogenic diet (U.S. Biochemical Corp., Cleveland, OH) with ground rodent chow (ProLab Animal Diet) for 14 d. In the diet-induced hyperlipidemic mice, serum cholesterol was elevated from normal levels of 121 mg% to 361 mg% whereas the serum triglyceride levels were elevated from normal levels of 137 mg% to 357 mg% over a two-week period. Drug administration was commenced at 20 mg/kg/d *i.p.* and continued for the next 14 d. Hyperlipidemic mice were bled and serum cholesterol and triglycerides were measured as previously described (3).

Sprague-Dawley rats. Selected compounds **3a, 4a, 4b** and **7** were tested in Sprague-Dawley male rats (~280 g) by oral administration at 20 mg/kg/d for 14 d maintained on ProLab Animal diet *ad libitum.* Serum cholesterol and triglyceride levels were measured as previously described.

Animal weights and food intake. Food consumption was determined daily as gram food/rat/d for control rats which were maintained on ProLab Animal diet and rats treated orally with compounds **3a, 4a, 4b** and **7** at 2 mg/kg/d. Body weights were obtained on days 7 and 14; they were expressed as percentage of the animal's weight on day 0. After dosing for 14 d with compounds, selected organs were excised, trimmed of fat and weighed (3).

Liver, small intestine, aorta and fecal lipid extraction. In Sprague-Dawley male rats on ProLab Animal diet receiving the test compounds **3a, 4a, 4b** and **7** at 20 mg/kg/d, orally for 14 d, the liver, small intestinal mucosa from duodenum to ileum, aorta and fecal materials (24-h collection) were removed and weighed. Homogenates (10%) (wt/vol) were prepared, extracted (13,14) and analyzed for cholesterol (12), triglyceride, neutral lipid (15) and phospholipid (16) contents. Protein content of the whole homogenate was also determined (17).

Enzymatic studies. Enzymatic assays were carried out using 10% homogenates of CF_1 male mouse liver prepared in 0.25M sucrose and 0.001M ethylenediaminetetraacetic acid (EDTA) (pH 7.2) with 25–100 μM concentrations of compounds **3a, 4a, 4b** and **7** *in vitro.* Activities of the following enzymes were determined by using established procedures: acetyl-coenzyme A synthetase (18); adenosine triphosphate dependent citrate lyase (19); mitochondrial citrate exchange (20,21); cholesterol 7α-hydroxylase (22); 3-hydroxy-3-methylglutaryl-coenzyme A reductase (23,24); acetyl-coenzyme A carboxylase (25); neutral cholesterol ester hydrolase (26); *sn*-glycerol-3-phosphate acyltransferase (27); phosphatidylate phosphohydrolase activity (28); acyl-CoA cholesterol acyltransferase (29) and heparin-activated hepatic lipoprotein lipase (30). Protein in the whole homogenates and in the mitochondrial and microsomal fractions was assayed according to Lowry *et al.* (17).

Serum lipoprotein fractionation. Sprague-Dawley male rats maintained on ProLab Animal diet (~340 g) were administered compounds **3a, 4a** and **4b** or **7** at 20 mg/kg/d orally. Blood was collected from the abdominal vein, and lipoprotein fractions were obtained by the methods of Hatch and Lees (31), and Havel *et al.* (32) as modified for the rat (33). Each fraction was analyzed for cholesterol (12), triglyceride, neutral lipids (15), phospholipids (16) and protein (17). LDL and HDL lipoprotein fractions were dialyzed, delipidated, and the apoproteins were separated by SDS-PAGE (5–15%) electrophoresis on 3% acrylamide gel which was stained with 0.5% coomassie blue (34).

RESULTS

We have recently described the synthesis of 6-alkoxycarbonyl-3-aryl-1,3,5-triazabicyclo[3.1.0]hexane-2,4-diones (**3**) and 2-alkoxycarbonyl-5-aryl-1,3,5-triazine-4,6(1H,5H)-diones (**4**) by the reaction sequence shown in Scheme 1 (10,11). This method was used to prepare compounds **3a–c** and **4a–b**. Compounds **3** were obtained by reaction of 4-substituted 1,2,4-triazole-3,5(4H)-diones (**1**) with alkyl diazoacetates (**2**) in dichloromethane at 0°C. These compounds are white amorphous solids composed of monomers which associate in solution. The extent of association increases as the temperature is lowered and as the (**3**) ⇌ $(3)_n$ ($n \geq 2$) concentration of the solutions is increased. Heating compounds **3** in chlorobenzene under reflux for two weeks resulted in ring-opening to give compound **4**.

Pharmacology. Compounds **3a, 3c, 4a** and **4b** tested in CF_1 mice at 20 mg/kg/d showed similar hypocholesterolemic activity, *i.e.,* a 43–46% reduction (Table 1). Compounds **3a, 4a** and **4b** demonstrated a 41–69% reduction of serum triglyceride levels. Compound **3b** caused only a 28% reduction of serum cholesterol and a 31% reduction of triglyceride levels. Compound **3c** was not as active showing only a 34% reduction of serum triglyceride levels. Compounds **5, 6** and **7** were not as effective as hypolipidemic agents in mice. Compounds **3a, 4a** and **4b** in hyperlipidemic diet induced mice successfully reduced elevated serum cholesterol levels by 51–56% (Table 2).

[a]$P \leq 0.001$. [b]362 mg%. [c]357 mg%.

Elevated serum triglycerides levels in these mice were reduced by 54–56% by these three compounds.

In Sprague-Dawley rats, **3a** at 20 mg/kg/d showed good activity, lowering serum cholesterol and serum triglycerides by 64 and 46%, respectively, by days 7 and 14 (Table 3). Compound **4a** (10 mg/kg/d) reduced serum cholesterol levels by 40%, but reduced serum triglyceride levels by only 23% by day 14. Compound **4b** (20 mg/kg/d) reduced serum cholesterol levels by 33% and serum triglyceride levels by 47% by day 14. Compound **7** caused a 24% reduction of serum cholesterol and a 32% reduction of serum triglyceride on day 14. In rats, none of the compounds suppressed food intake on a daily basis. The body weights did not differ from the control weights over 14 d. Organ weights of treated rats were not affected by the 14-d drug treatment.

Examination of tissue lipids showed that **4b** and **7** lowered liver and aorta wall cholesterol and neutral lipid levels. Compound **3a** lowered small intestinal mucosa cholesterol, triglyceride and protein contents (Table 4). Aorta cholesterol was reduced moderately by 18% by **3a**. Compound **4a** at 10 mg/kg/d elevated cholesterol levels in the liver and small intestinal mucosa, but lowered aorta wall cholesterol levels. The level of phospholipids was lowered in the small intestinal mucosa by **4a** and **4b**. Fecal lipids were increased by **3a** and **4b**. Treatment with **3a** resulted in significant increases in fecal cholesterol, triglyceride, phospholipid and protein contents. Treatment with **4b** resulted only in an increase in fecal cholesterol levels. Compound **7** caused moderate increases in fecal cholesterol, neutral lipid and phospholipid levels.

The serum lipoprotein lipid content was also modulated by the drugs (Table 5). Compounds **3a** and **4b** reduced

chylomicron cholesterol levels. Compounds **3a, 4a, 4b** and **7** reduced VLDL cholesterol levels by 29–73% and LDL cholesterol levels by 13–33%; nevertheless, HDL cholesterol levels were elevated by 13% by **4a** at 10 mg/kg/d and 240–309% by **3a** and **4b** at 20 mg/kg/d. Compound **7** increased HDL cholesterol levels by 52%. Triglyceride contents were reduced in the VLDL and LDL by **3a**. Neutral lipids were reduced in the VLDL by **4a, 4b** and **7**, in LDL by **3a** and in HDL by **3a**. Compound **7** caused a significant increase in HDL triglyceride levels. Chylomicron phospholipids were reduced by **4b** and **7**. VLDL and HDL phospholipids were reduced by **3a, 4a** and **4b** and LDL phospholipid levels by **3a**. VLDL protein content was reduced by **3a, 4b** and **7**, and LDL protein content was lowered by **3a**; nevertheless, **4a** and **7** caused elevations in LDL protein content. Electrophoresis of LDL and HDL apoproteins demonstrated that the drug treatment did not affect the apoprotein content of LDL. Only apo-B was present at what appeared to be normal concentrations. In the HDL fraction, apo-E and apo-A I bands were more dense suggesting a higher quantity of these apoproteins was induced by drug treatment.

Hepatic mouse enzyme activities were reduced by the drugs, *e.g.*, cytoplasmic acetyl-CoA synthetase activity was reduced in a concentration-dependent manner by **3a, 4a, 4b** and **7** (Table 6). HMG-CoA reductase activity was reduced in a concentration-dependent manner by **3a** and **4b** but was elevated by **7**. Acyl-CoA cholesterol acyltransferase activity was reduced by all the compounds in a concentration-dependent manner. Cholesterol ester hydrolase activity was elevated by **3a** but was reduced by **4a** and **7**. Cholesterol 7α-hydroxylase activity was inhibited by **4b** and by **7** at 100 μM. Acetyl-CoA carboxylase activity was inhibited by **4b** only at all concentrations. Compound **3a** was effective at 100 μM. *sn*-Glycerol-3-phosphate acyltransferase and phosphatidylate phosphohydrolase were

inhibited significantly by all four drugs in a concentration-dependent manner. Hepatic lipoprotein lipase activity was inhibited by **4b**, the only drug tested.

DISCUSSION

Selected derivatives of the 6-alkoxycarbonyl-3-aryl-1,3,5-triazabicyclo[3.1.0]hexane-2,4-diones and 2-alkoxycarbonyl-5-aryl-1,3,5-triazine-4,6(1H,5H)-diones proved to have effective hypolipidemic activity in rodents when administered either orally or intraperitoneally from 10–20 mg/kg/d. The drugs lowered both serum cholesterol and triglyceride levels effectively and were more effective than a number of commercially available agents. Selectivity derivatives were markedly effective in diet-induced hyperlipidemic mice. The effectiveness of the agents in lowering serum lipid levels was not due to a lower caloric intake. The compounds did cause an increase in lipid excretion by the fecal route. With the exception of **4a**, tissue lipids, *e.g.*, cholesterol and triglyceride, were generally reduced by the agents. Thus, the derivatives did not remove lipids from the blood and redistribute the lipids to the tissues.

The serum lipoprotein fractions appeared to be modulated in an effective manner, reducing VLDL and LDL cholesterol levels and elevating HDL cholesterol levels after only two weeks. The cyclic imides, *e.g.*, phthalimide and saccharin, in general, did not raise HDL cholesterol levels by 14 d. 4-Methylphenyl and acetophenone substitutions on the nitrogen atom of the cyclic imides did lead to elevated HDL cholesterol levels at 20 mg/kg/d (35,36). The current derivatives also have bulky substitution on the nitrogen of the ring, *e.g.*, phenyl or 4-chlorophenyl, suggesting that the pharmacoreceptor requires a certain length and bulk for the best fit. Modulation of VLDL cholesterol levels down and HDL cholesterol up by a therapeutic agent in man supposedly protects against myocardial infarction (4,37). The increased contents of apo-E and apo-AI may increase the receptor mediated uptake of HDL by liver receptors resulting in more excretion of cholesterol *via* the bile. These agents also afforded effects on hepatic regulatory lipid metabolizing enzymes. Suppression of cytoplasmic ATP-dependent citrate lyase, mitochondrial citrate exchange or acetyl-CoA synthetase activities reduced the available cytoplasmic acetyl-CoA for fatty acid and cholesterol synthesis. Only **4b** effectively inhibited the activity of HMG-CoA reductase, the rate-limiting enzyme in cholesterol synthesis. The agents were more potent in suppressing acyl-CoA cholesterol acyltransferase, thus reducing cholesterol ester formation and storage. There was an indication that the drug caused an increase in bile acids by stimulating cholesterol 7α-hydroxylase activity, the rate-limiting enzyme for cholesterol catabolism to bile acids. Neutral cholesterol ester

hydrolase activity was elevated by **3a**. This enzyme regulates the breakdown of cholesterol esters to free cholesterol. If a similar pattern existed in aorta plaque cells in that the cholesterol ester hydrolase activity was elevated and acyl-CoA cholesterol acyltransferase activity was inhibited by the drug, there would be a reduction in cholesterol ester accumulation as well as plaque growth in the aorta.

Inhibition of the present rate-limiting enzyme activities for *de novo* triglyceride synthesis, *i.e.*, by *sn*-glycerol-3-phosphatase acyltransferase and phosphatidylate phosphohydrolase, would significantly reduce triglyceride levels in tissues and in serum after drug treatment.

These studies suggest that 2-ethoxycarbonyl-3-(4-chlorophenyl)-1,3,5-triaze-4,6(1H,5H)-dione **4b** presented the best profile in reducing lipids and modulating serum lipoprotein lipids in favorable directions. Thus, these agents may have future clinical potential after further study.

Synthesis of Methyl 11,14,17-Eicosatrienoate-3,3,4,4,8,8,9,9-d_8

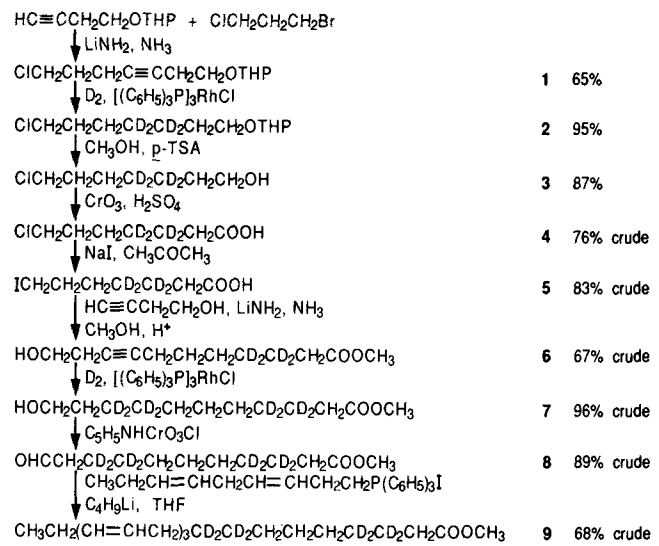
Henry Rakoff
Food Quality and Safety Research, National Center for Agricultural Utilization Research, ARS, U.S. Department of Agriculture, Peoria, Illinois 61604

For use in metabolic studies, methyl 11,14,17-eicosatrienoate-3,3,4,4,8,8,9,9-d_8 was prepared by Wittig coupling of 3,6-nonadienyltriphenylphosphonium iodide with methyl 11-oxoundecanoate-3,3,4,4,8,8,9,9-d_8 in the presence of butyl lithium. The *all cis* isomer was separated by high-pressure liquid chromatography using a reverse-phase column. An unexpected by-product, methyl 10,13,16-nonadecatrienoate-2,2,3,3,7,7,8,8-d_8, was also isolated. The structures and the configurations of the compounds were confirmed by nuclear magnetic resonance spectroscopy and mass spectrometry.
Lipids 28, 231–234 (1993).

In continuation of our studies on the metabolism of fats in humans (1,2) and animals, we have synthesized methyl *cis*-11,*cis*-14,*cis*-17-eiocosatrienoate-3,3,4,4,8,8,9,9-d_8 (20:3-d_8). This trienoate has recently been shown to be an intermediate in the conversion of linolenate (9,12,15-18:3) to eicosapentaenoate (5,8,11,14,17-20:5) *via* a nonclassical pathway (3) that utilizes Δ8 desaturation rather than the normal Δ6 desaturation to synthesize 20:5. The deuterated analog has been synthesized to investigate the contribution of this nonclassical pathway to the conversion of 18:3 to 20:5 and the retroconversion of 20:3 to 18:3.

RESULTS AND DISCUSSION

The synthetic steps which we followed are outlined in Scheme 1. The overall approach is similar to the sequence we used to synthesize tetradeuterated 11,14,17-20:3 (4).



SCHEME 1

Abbreviations: EE, diethyl ether; GC, gas chromatography; GC/MS, gas chromatography/mass spectrometry; NMR, nuclear magnetic resonance; PE, petroleum ether (35-60°C); THF, tetrahydrofuran; THP, tetrahydropyranyl.

The reaction sequence involves acetylenic couplings, catalytic deuterations, oxidations and a Wittig reaction.

The tetrahydropyranyl ether of 3-butynol was coupled with 1-bromo-3-chloropropane in the presence of lithium amide in liquid ammonia to give 1-(2-tetrahydropyranyloxy)-7-chloro-3-heptyne, 1, in 65% yield. Catalytic deuteration of 1 with deuterium gas in the presence of Wilkinson's catalyst, *tris*(triphenylphosphine)chlororhodium, gave the tetradeuterated product, 2, in 95% yield. The tetrahydropyranyl group was removed by reaction with methanol and *p*-toluenesulfonic acid to give 7-chloroheptanol-d_4, 3, in 87% yield. Addition of chromium trioxide in 10 N sulfuric acid to compound 3 or rapid addition of compound 3 to the oxidizing medium resulted in a low yield of the desired acid and a high yield of octadeuterated 7-chloroheptyl 7-chloroheptanoate. A 76% yield of the desired acid, 4, together with only a small amount of the ester was obtained by introducing a dilute solution of 3 in acetone under the surface of the rapidly stirred oxidizing medium by means of a syringe pump. If the addition is rapid or the solution is not dilute, the aldehyde formed initially in the oxidation reaction reacts with neighboring alcohol molecules to give a hemiacetal which is then oxidized to the ester (5). If a substantial amount of ester is inadvertently obtained, the acid and alcohol may be recovered. Hydrolysis with alcoholic KOH results in partial replacement of the chlorine by OC_2H_5. Interesterification with 96% formic acid and methanesulfonic acid (6) releases the tetradeuterated 7-chloroheptanoic acid and leaves the tetradeuterated chloroalcohol as the formate ester. The free alcohol may be obtained by interesterification with methanol and mineral acid.

The deuterated chloroacid, 4, was converted to the deuterated iodoacid, 5, in 83% crude yield by reaction with sodium iodide in acetone. Acetylenic coupling of 5 with 3-butynol in the presence of lithium amide in liquid ammonia (7) gave, after esterification, methyl 11-hydroxy-8-undecynoate-3,3,4,4-d_4, 6, in 67% crude yield. Compound 6 was reduced to the octadeuterated product with deuterium in the presence of Wilkinson's catalyst in 96% yield. The saturated hydroxyester 7 was oxidized to methyl 11-oxoundecanoate-3,3,4,4,8,8,9,9-d_8, 8, in 89% crude yield using pyridinium chlorochromate. Compound 8 was then coupled by a Wittig reaction with 3,6-nonadienyltriphenylphosphonium iodide (8,9) to give methyl 11,14,17-20:3-d_8 in 68% crude yield. Reverse-phase high-pressure liquid chromatography was used to isolate a 19% yield (based on the methyl 11-oxoundecanoate-d_8 used) of the all *cis*-20:3-d_8 and a 14% yield of a mixture of the mono-trans and *all cis* isomers. In addition, we obtained a 6% yield of a compound we identified by nuclear magnetic resonance (NMR) as methyl 10,13,16-nonadecatrienoate-2,2,3,3,7,7,8,8-d_8. We were also able to identify a very small amount of methyl octadecatrienoate-d_6 by gas chromatography/mass spectrometry (GC/MS).

Mention is made in the literature (10) of the fact that chromic acid oxidation of alcohols to acids gives poor yields due to the formation of shorter chain acids. The only detailed study reported was by Conant and Aston

(11) who demonstrated that oxidation of butyraldehyde by chromic acid yields some propanoic acid and carbon dioxide. Our analysis of the products formed by the oxidation of 7-chloroheptanol-d_4 with CrO_3 in H_2SO_4 showed the presence of 7-chloroheptanoic acid-d_4, 6-chlorohexanoic acid-d_4 and 5-chloropentanoic acid-d_2 in a ratio of 81:16:3. (We confirmed these observations by the oxidation of octanol which gave three acids and three esters. The esters were the octyl esters of octanoic, heptanoic and hexanoic acids.) Substitution of 6-chlorohexanoic acid-d_4 or 5-chloropentanoic acid-d_2 for 7-chloroheptanoic acid-d_4 in the reaction sequence would yield the 19:3-d_8 and 18:3-d_6 compounds obtained.

The structures and configurations of the final products and of the intermediates were confirmed by nuclear magnetic resonance spectroscopy. The signals for the carbons bearing deuterium atoms were essentially absent, and the chemical shifts for the allylic carbon atoms were consistent with an *all cis* configuration.

EXPERIMENTAL PROCEDURES

Reagents. Butyl lithium, dihydropyran, 3-butynol, 1-bromo-3-chloropropane and pyridinium chlorochromate were obtained from Aldrich Chemical Company (Milwaukee, WI); *tris*(triphenylphosphine)chlororhodium was purchased from Strem Chemicals (Newburyport,MA). Silica Gel (60–200 mesh) and Florisil (100–200 mesh) were obtained from J. T. Baker (Jackson, TN), Silica Gel 60 from American Scientific Products (McGaw Park, IL) and SEP PAK Silica cartridges from Waters Chromatography Division, Millipore Corporation (Milford, MA).

Analytic gas chromatography. A 30 m × 0.25 mm SP2340 or SP2330 fused silica capillary column (Supelco, Inc., Bellefonte, PA) was used for analysis of the binary mixtures of geometric isomers formed. For other analyses, a 6 ft × 4 mm column packed with 3% EGSS-X on 100/120 GasChrom Q or a 5 m × 0.53 mm HP-1 column (Hewlett-Packard, Avondale, PA) was employed. To separate the *trans,cis,cis* and *cis,cis,cis* isomers of 11,14,17-20:3-d_8, it was necessary to use a 100 m × 0.25 mm SP2560 capillary column.

^{13}C NMR. ^{13}C NMR spectra were recorded at ambient temperature with a Bruker (Billerica, MA) WM 300 WB pulse Fourier transform spectrometer operating at 75.5 MHz. Typically, 2500 transients were collected on $CDCl_3$ solutions using 5-mm tubes. $CDCl_3$ served as both the internal lock and secondary reference. Sweep widths of 200 ppm and 8 K real data points limited acquisition time to 0.54 s. Chemical shift values reported are within ±1.85 Hz, *i.e.*, ±0.05 ppm. A pulse width of 3 μs (40°) was employed with no delay between pulses. Decoupling power was held to *ca.* 1 Watt to provide adequate broadband decoupling while minimizing sample heating. The signal from carbons bearing two deuterium atoms or one deuterium atom and a double bond was diminished to such an extent that it was usually not detected.

Mass spectroscopy. Mass spectra were recorded on a Finnigan 4500 mass spectrometer (San Jose, CA) using isobutane chemical ionization and data processing of the isotope distribution against standards (12).

Preparation of 1-(2-tetrahydropyranyloxy)-7-chloro-3-heptyne, 1. Liquid ammonia (*ca.* 800 mL) was charged to a 2-L, three-necked flask equipped with a mechanical stirrer and a dry ice cooled condenser and surrounded by Vermiculite. Ferric nitrate (1 g) was added followed by lithium metal (5.6 g, 800 mmol) which was added in small pieces over 25 min. After the mixture turned grey, the tetrahydropyranyl (THP) ether of 3-butynol (115.5 g, 750 mmol) dissolved in tetrahydrofuran (THF) (100 mL) was added over 45 min. Then 1-bromo-3-chloropropane (59.1 g, 375 mmol) dissolved in THF (50 mL) was added over 15 min. Ten hours later stirring was stopped, the Vermiculite was removed and ammonia was allowed to evaporate overnight through a KOH trap. The next day the flask was immersed in a warm water bath and flushed with argon to remove residual ammonia. Water (300 mL) was added and the mixture was extracted with diethyl ether (EE) (4 × 100 mL). The combined EE layers were washed with saturated ammonium chloride solution (100 mL) and saturated sodium chloride solution (100 mL) and dried (Na_2SO_4). Removal of the drying agent and solvent left a product (138.2 g) which was distilled under reduced pressure to give a forerun containing the THP ether of 3-butynol (47.1 g) b.p. 50–75° at 0.5 torr and a main fraction containing **1** (56.1 g, 64.8% of theory, 90% pure by GC on HP-1) b.p. 112–120°C at 0.4 torr. ^{13}C NMR (ppm): C-1, 65.92; C-2, 20.07; C-3, 77.96; C-4, 78.98; C-5, 16.06; C-6, 31.53; C-7, 43.55. THP group: C-2′, 98.55; C-3′, 30.46; C-4′, 19.30; C-5′, 25.34; C-6′, 62.00.

Preparation of 1-(2-tetrahydropyranyloxy)-7-chloroheptane-3,3,4,4-d_4, 2. Compound 1 (53.2 g, 231 mmol) dissolved in benzene (1 L) was treated with deuterium gas in the presence of *tris*(triphenylphosphine)chlororhodium (4.2 g) in the manner previously described (13). The reduction took about 6 h. Benzene was removed on the rotary evaporator, petroleum ether (PE) was added and the mixture was filtered through a plug of glass wool onto a column (30 mm × 50 cm) containing Silica Gel 60 (120 g) in PE. Elution with 100% PE and PE/EE (90:10, vol/vol) gave the title compound, 2, (52 g, 95% of theory, about 95% pure by GC on HP-1). ^{13}C NMR (ppm): C-1, 67.44; C-2, 29.34; C-5, 26.52; C-6, 32.48; C-7, 45.03. THP group: C-2′, 98.78; C-3′, 30.73; C-4′, 19.65; C-5′, 25.45; C-6′, 62.27.

Preparation of 7-chloroheptanol-3,3,4,4-d_4, 3. Compound 2 (52 g, 218 mmol) was stirred overnight in methanol (500 mL) with *p*-toluenesulfonic acid (1 g). Solid sodium carbonate was added and methanol was removed on the rotary evaporator. Saturated sodium carbonate solution (50 mL) was added and the mixture was extracted with EE (4 × 50 mL) and dried (Na_2SO_4). The drying agent and solvent were removed, and the residue was distilled under reduced pressure to give the title compound, 3, (29.2 g, 87% of theory, 90% pure by GC on HP-1) b.p. 84–90°C at 0.4 torr. Deuterium analysis: 0.23% d_0, 1.12% d_1, 7.96% d_3, 88.76% d_4, 1.43% d_7, 0.12% d_{10}, 0.37% d_{11}. D average = 3.95. ^1H NMR ($CDCl_3$): δ 3.60 (*t*, 2H, CH_2OH); δ 3.50 (*t*, 2H, CH_2Cl); δ 1.69–1.79 (*m*, 3H, CH_2CH_2Cl and O*H*); δ 1.52 (*t*, 2H, CH_2CH_2OH); δ 1.39 (*t*, 2H, CH_2CD_2). ^{13}C NMR (ppm): C-1, 62.66; C-2, 32.22; C-5, 26.43; C-6, 32.36; C-7, 44.97.

Preparation of 3,3,4,4-tetradeutero-7-chloroheptanoic acid, 4. Chromium trioxide (24.05 g, 248 mmol) was dissolved in 10 N H_2SO_4 (250 mL) in a 1-L, three-necked flask equipped with a mechanical stirrer, a thermometer and a narrow plastic tube ending just below the surface of the liquid. The reaction vessel was cooled to about 3°C in an ice-salt bath, and a solution of compound **3** (19.05 g,

123 mmol) dissolved in acetone (250 mL) was added slowly, by means of a syringe pump, below the surface of the rapidly stirred solution at approximately 0.5 mL/min. The addition required about nine hours. Acetone was removed on the rotary evaporator, the residue was diluted with water (300 mL) and extracted with EE (5 × 100 mL). The combined EE extracts were washed with saturated NaCl solution (50 mL) and dried (Na_2SO_4). Removal of the drying agent and solvent left a product which was mostly the desired acid contaminated by only a small amount of ester. This residue was dissolved in EE (150 mL) and extracted with 10% NaOH (2 × 50 mL). The basic solution was washed with EE (25 mL) which was combined with the base extracted EE solution. The EE solution was washed with water (25 mL), dried (Na_2SO_4) and the solvent removed to yield impure tetradeutero-7-chloroheptyl tetradeutero-7-chloroheptanoate (1.23 g). The basic solution was acidified to Congo Red with 3 N HCl (*ca.* 180 mL) and the free acid was extracted into EE (4 × 50 mL). The combined EE extracts were washed with saturated sodium chloride solution (25 mL) and dried (Na_2SO_4). Removal of the drying agent and solvent yielded the desired product, **4**, (15.96 g, 76% crude yield, approximately 78% pure by GC on HP-1). An analytical sample was obtained by passage through a Waters SEP PAK silica cartridge with hexane (Milford, MA). ^{1}H NMR ($CDCl_3$): δ 3.51 (*t*, 2H, CH_2Cl); δ 2.33 (*s*, 2H, CH_2COOH); δ 1.73–1.78 (*m*, 2H, CH_2CH_2Cl); δ 1.42 (*t*, 2H, CH_2CH_2CH_2Cl). ^{13}C NMR (ppm): C-1, 180.3; C-2, 33.69; C-5, 26.20; C-6, 32.26; C-7, 44.90.

Preparation of 3,3,4,4-tetradeutero-7-iodoheptanoic acid, 5. Crude compound **4** (13.7 g, 81.3 mmol) was dissolved in acetone (250 mL). Sodium iodide (15.3 g) was added and the mixture was heated at reflux temperature for 60 h. The reaction mixture was cooled and the solvent was removed on the rotary evaporator. The reaction mixture was poured into EE and a precipitate formed. The mixture was washed with water to remove the solid. The EE solution was dried (Na_2SO_4) and the EE was removed to yield the desired product, **5**, (17.55 g, 83% crude yield, *ca.* 75% pure by GC on HP-1). An analytical sample was obtained by passage through a Waters SEP PAK silica cartridge with PE/EE (95:5, vol/vol); m.p. 42–44°C. ^{1}H NMR ($CDCl_3$): δ 3.16 (*t*, 2H, CH_2I); δ 2.32 (*s*, 2H, CH_2COO); δ 1.80 (*m*, 2H, CH_2CH_2I); δ 1.38 (*m*, 2H, CH_2CH_2CH_2I). ^{13}C NMR (ppm): C-1, 180.24; C-2, 33.69; C-5, 29.79; C-6, 33.12; C-7, 6.86.

Preparation of methyl 11-hydroxy-8-undecynoate-3,3,4,4-d_4, 6. Liquid ammonia (*ca.* 500 mL) was charged to a 1-L, three-necked flask equipped with a mechanical stirrer and a dry-ice cooled condenser and surrounded by Vermiculite insulation. Ferric nitrate (1 g) was added followed by slow addition of lithium metal (4.7 g, 673 mmol). After the reaction mixture assumed a grey color, a solution of 3-butynol (23.55 g, 336 mmol) in THF (50 mL) was added dropwise over 30 min. Then compound **5** (17.5 g, 67 mmol) in THF (50 mL) was added over 30 min. Eight hours later the Vermiculite insulation was removed, and ammonia was vented through a KOH trap. The next morning, the reaction vessel was immersed into a warm water bath and argon was passed through the flask to remove residual ammonia. The reaction mixture was cooled, diluted with water (200 mL) and acidified with 5 N H_2SO_4 (200 mL). The reaction mixture was extracted into EE (5 × 50 mL) and the EE solution was washed with saturated ammonium chloride solution (100 mL) and saturated sodium chloride solution (100 mL) and dried (Na_2SO_4). After removal of the drying agent and solvent, excess 3-butynol was removed by distillation under reduced pressure. Methanol (100 mL) and concentrated H_2SO_4 (1 mL) were added to the residue and the solution was heated under reflux for one hour. The reaction mixture was neutralized with solid sodium bicarbonate and solvent was removed on the rotary evaporator. The residue was diluted with water and extracted into EE (2 × 40 mL). The EE solution was dried (Na_2SO_4) and, after removal of the drying agent and solvent, distillation yielded the desired compound, **6** (9.72 g, 67% crude yield, about 85% pure by GC on HP-1) b.p. 112–120°C at 0.35 torr. ^{1}H NMR ($CDCl_3$): δ 3.58–3.62 (*m*, 5H, OCH_3, CH_2OH); δ 2.33–2.37 (*m*, 3H, CH_2CH_2OH, O*H*); δ 2.22 (*s*, 2H, CH_2COO); δ 2.06–2.11 (*m*, CH_2C=C); δ 1.30–1.44 (*m*, 4H, $CD_2CH_2CH_2$). ^{13}C NMR (ppm): C-1, 174.13; C-2, 33.62; C-5,6, 28.00,28.52; C-7, 18.51; C-8, 82.05; C-9, 76.44; C-10, 22.98; C-11, 61.22; OCH_3, 51.31.

Preparation of methyl 11-hydroxyundecanoate-3,3,4,4,8,8,9,9-d_8, 7. Compound **6** (3.63 g, 16.8 mmol) in benzene (100 mL) was treated with deuterium gas in the presence of *tris*(triphenylphosphine)chlororhodium as previously described (13). Benzene was removed on the rotary evaporator and the red residue was diluted with PE. The mixture was filtered onto a column (15 mm × 25 cm) containing Baker silica gel in PE. Elution with mixtures containing up to 75% EE in PE gave the desired product, **7** (3.62 g, 96% yield, 95% pure by GC on HP-1). Deuterium distribution: 0.03% d_0, 0.01% d_1, 0.01% d_2, 0.03% d_3, 0.22% d_4, 4.73% d_7, 92.97% d_8, 1.85% d_9, 0.15% d_{10}, 0.01% d_{11}. D average = 7.96. ^{1}H NMR ($CDCl_3$): δ 3.63 (*s*, 3H, OCH_3); δ 3.58 (*t*, 2H, CH_2OH); δ 2.25 (*s*, 2H, CD_2CH_2C=O); δ 1.51 (*t*, 2H, CH_2CH_2OH); δ 1.24 (*s*, 6H, (CH_2)$_3$). ^{13}C NMR (ppm): C-1, 174.32; C-2, 33.84; C-5,6,7, 28.92-29.21; C-10, 32.49; C-11, 62.93.

Preparation of methyl 11-oxoundecanoate-3,3,4,4,8,8,9,9-d_4, 8. Pyridinium chlorochromate (9.46 g, 43.8 mmol) was slurried in methylene chloride (100 mL) in a 250-mL, three-necked flask equipped with a mechanical stirrer and a thermometer. While a stream of nitrogen was passed through the apparatus, the reaction mixture was cooled to 10°C with an ice bath. Compound **7** (6.7 g, 30.2 mmol) dissolved in methylene chloride (15 mL) was added in one portion. The ice bath was removed, the reaction mixture turned black and the temperature rose to 19°C. Diethyl ether (50 mL) was added 1.5 h later to the tarry material and was decanted after 10 min of stirring. This was repeated twice with fresh portions (50 mL and 30 mL) of EE. The combined EE extracts were passed through a column (1.5 × 25 cm) containing dry Florisil (15 g) and the column was flushed with EE (50 mL). The solvent was removed on the rotary evaporator to yield compound **8**, (6 g, 89% crude yield, 74% pure by GC on HP-1). An analytical sample was obtained by passage through a Waters SEP PAK silica cartridge with hexane. ^{1}H NMR ($CDCl_3$): δ 9.74 (*t*, 1H, C*H*O), δ 3.64 (*s*, 3H, OCH_3), δ 2.38 (*s*, 2H, CH_2CHO), δ 2.25 (*s*, 2H, CD_2CH_2COO), δ 1.25 (*m*, 6H, (CH_2)$_3$). ^{13}C NMR (ppm): C-1, 174.23; C-2, 33.83; C-5,6,7, 29.0-29.7; C-10, 43.66; C-11, 202.78; methyl group, 51.39.

Preparation of methyl 11,14,17-eicosatrienoate-3,3,4,4,8,8,9,9-d_8, 9. Nonadienyltriphenylphosphonium

iodide (8,14) (29.12 g, 56.9 mmol) was slurried in THF (175 mL) in a 500-mL, three-necked flask equipped with a mechanical stirrer, a low temperature thermometer and a $CaCl_2$ drying tube. While a stream of nitrogen was passed through the apparatus immersed in an ice bath, butyl lithium (2.5M, 24 mL, 60 mmol) was added in portions over 10 min. The temperature achieved a maximum of 17°C and a very dark red solution formed. The ice bath was removed and compound 8 (10.98 g, 49.6 mmol) in THF (20 mL) was added in one portion and the temperature rose from 20–30°C. The color of the reaction mixture became a little lighter. About one hour later, saturated sodium chloride solution was added, and the organic layer was separated and dried (Na_2SO_4). Removal of the drying agent and solvent left a solid and a liquid (38.8 g). This was diluted with PE and filtered onto a column (22 mm × 35 cm) packed with Baker silica gel (40 g) in PE. Elution with PE and PE/EE (95:5, vol/vol) gave the desired compound, 9 (11.1 g, 68% of theory, 69% pure by GC on SP2330). Principal contaminant was 19:3-d_8.

The *all cis* isomer was separated by reverse phase chromatography on an HPLC column (Serva Feinbiochemica, Heidelberg, Germany) (5 × 25 cm) 5 micron Octadecyl Si 100 Polyol using 10% water in acetonitrile as eluant. From 9.9 g of reaction mixture, separated in approximately 1.4 g batches, there was obtained, after pooling similar fractions, 0.93 g of methyl nonadecatrienoate-d_8, 3.07 g of methyl *cis*-11, *cis*-14,*cis*-17-eicosatrienoate-3,3,4,4,7,7,8,8-d_8 and 2.28 g of a mixture of the mono-trans and *all cis* 20:3-d_8 isomers. The overall yield of 20:3-d_8 in the Wittig reaction was 33% and for the overall reaction sequence it was 6.4%.

Deuterium distribution: 0.01% d_0, 0.01% d_1, 0.02% d_2, 0.01% d_3, 0.09% d_4, 0.10% d_5, 4.98% d_7, 94.16% d_8, 0.48% d_9, 0.11% d_{10}, 0.02% d_{13}. D average = 7.95. ^{1}H NMR ($CDCl_3$): δ 5.28–5.42 (*m*, 6H, C*H*=C*H*); δ 3.65 (*s*, 3H, OCH_3); δ 2.77 (*t*, 4H, C=CCH_2C=C); δ 2.27 (*s*, 2H, CH_2COO); δ 2.01–2.12 (*m*, 4H, CH_2C=C); δ 1.25 (*m*, 6H, (CH_2)$_3$); δ 0.96 (*t*, 3H, CH_3). ^{13}C NMR (ppm): C-1, 174.3; C-2, 33.9; C-5,6,7, 29.0-29.3; C-10, 27.0; C-11, 130.3; C-12, 127.6; C-13,16, 25.6; C-14,15, 128.2; C-17, 127.1; C-18, 131.9; C-19, 20.5; C-20, 14.3; OCH3, 51.4.

The 19:3-d_8 was identified as methyl 10,13,16-nonadecatrienoate-2,2,3,3,7,7,8,8-d_8 by the fact that its NMR spectrum was identical to that of 20:3-d_8 with the sole exception of the absence of a chemical shift of δ 2.27 for CH_2COO in the ^{1}H NMR spectrum and of 33.9 for C-2 in the ^{13}C NMR.

METHOD

Antagonism of [^{3}H]Fatty Acid Incorporation into Vimentin by Sodium Pyruvate: Pitfalls of Protein Acylation

Richard J. Cenedella* and **Jeanne Mitchell**
Department of Biochemistry, Kirksville College of Osteopathic Medicine, Kirksville, Missouri 63501

In the course of studying possible fatty acid acylation of vimentin by cultured bovine lens epithelial cells, several potential pitfalls of protein-fatty acid acylation were recognized. Even exhaustive delipidation of vimentin with organic solvents failed to remove all noncovalently associated [^{3}H]palmitate and [^{3}H]myristate. Hydroxylamine treatment of vimentin, separated by sodium dodecylsulfate-polyacrylamide gel electrophoresis (SDS-PAGE), failed to remove either palmitate or myristate derived radiolabel. Hydroxylamine treatment did remove palmitate label from a group of lower molecular weight proteins. The myristate radiolabel associated with vimentin recovered after SDS-PAGE and subjected to acid hydrolysis was shown due to incorporated [^{3}H]amino acids, mainly glutamic acid, generated from the fatty acid. Adding excess sodium pyruvate to labeling media has been used by others to reduce the metabolic conversion of fatty acids to amino acids; however, no direct evidence in support of this antagonism was presented. We observed that inclusion of sodium pyruvate at between 5 and 20 mM in the labeling medium produced a dramatic decrease in incorporation of myristic acid radiolabel into vimentin. However, inclusion of even 20 mM pyruvate did not completely antagonize the metabolic conversion of fatty acid label to amino acids. Furthermore, the sodium pyruvate antagonism could be totally obscured if the exposure of X-ray film by fluorography was even slightly prolonged. The results illustrate the danger in assuming that solvent extraction totally delipidates proteins and that adding sodium pyruvate to labeling media prevents the transfer of fatty acid label to amino acids. Caution is necessary to conclude that radiolabel associated with specific proteins following incubation of cells with labeled fatty acid is due to covalent attachment of the fatty acid to the protein.
Lipids 28, 235–240 (1993).

The present study reexamines potential pitfalls of recognizing fatty acid acylation of cellular proteins. This could be worthwhile in view of the expanding interest in lipid-modifications of proteins. In the course of studying possible fatty acid acylation of vimentin, incorporation of radiolabel from [^{3}H]palmitic and [^{3}H]myristic acids that initially appeared to be due to covalent acylation of vimentin was ultimately shown to be due to incorporation of [^{3}H]labeled amino acids generated by fatty acid metabolism. Initial evidence that vimentin was covalently acylated by [^{3}H]palmitate and [^{3}H]myristate came from observing that [^{3}H]fatty acid was released from exhaustively delipidated vimentin by hydrolysis and from observing no inhibition by sodium pyruvate of [^{3}H]fatty acid incorporation into vimentin. Extensive extraction of cellular proteins with organic solvent is said to completely remove all noncovalently bound labeled lipid from proteins (1,2), and inclusion of 5 mM sodium pyruvate in the labeling media is said to block metabolic conversion of radiolabel from fatty acids into amino acids (3). We present here the first direct evidence that exhaustive delipidation of protein with organic solvents may not remove all noncovalently associated [^{3}H]fatty acid, and inclusion of even 20 mM sodium pyruvate in the labeling media may only partially block incorporation of [^{3}H]fatty acid into protein *via* amino acids, and even this block might be masked if the time used to detect labeled protein by fluorographic exposure of X-ray film is even slightly prolonged.

Vimentin, the single most abundant protein of bovine lens epithelial cells in culture (results of this study), is a cytoskeletal component which bridges nuclear and plasma membranes (4). The covalent attachment of fatty acid to other cytoskeletal proteins, such as actin (5), ankyrin (6) and vinculin (3), could contribute to their association with cellular membranes.

MATERIALS AND METHODS

Cell culture, labeling conditions and cell fractionation. Bovine lens epithelial cells were cultured and maintained in Dulbecco's modified Eagle's media (DMEM) supplemented with 10% calf serum as described previously in detail (7). At day 4 of subculture, medium on confluent cultures was replaced with serum-free DMEM containing 0.10 mCi/mL of [9,10-^{3}H]palmitic acid (60 Ci/mmol, New England Nuclear Corp., Boston, MA) or [9,10-^{3}H]myristic acid (39 Ci/mmol, New England Nuclear Corp.). In some experiments, the medium was supplemented with 5–20 mM sodium pyruvate. Cells were incubated for 4 h at 37°C in a 5% CO_2/95% air atmosphere.

After incubation, cells were washed four times in palmitate or myristate chase medium (8), twice with physiological buffered saline (PBS), pH = 7.4, scraped into PBS, centrifuged (1000 × *g* for 5 min) and washed once with 4 mL of PBS. The washed cells were hand homogenized in about 1.3 mL of 5 mM tris(hydroxymethyl)-aminomethane (Tris) buffer, pH = 8, containing 1 mM ethylenediaminetetraacetic acid (EDTA) plus 5 mM β-mercaptoethanol (Buffer A) using an Econo-Grind glass-glass mini-homogenizer (Radnoti Glass Tech Inc., Monrovia, CA). Water insoluble proteins were recovered by centrifugation (100,000 × *g* for 1 h, SW 60 rotor). Water soluble proteins were precipitated from the supernatant with 10% trichloroacetic acid (TCA), washed twice with 1% TCA and redissolved in Buffer A. Water insoluble proteins were suspended in about 0.5 mL of 55% (g sucrose/100 g solution) sucrose and overlayed with 0.4 mL of 45, 40, 30, 25 and 8% sucrose. All solutions were in Buffer A. The discontinuous gradient was spun at 100,000 × *g* for 2 h

Abbreviations: DMEM, Dulbecco's modified Eagle's media; EDTA, ethylenediaminetetraacetic acid; EGTA, ethyleneglycol-*bis*(β-aminoethyl ether)*N,N,N'N'*-tetraacetic acid; PBS, physiological buffered saline; P_y, pyruvate; SDS-PAGE, sodium dodecylsulfate-polyacrylamide gel electrophoresis; TCA, trichloroacetic acid; TLCK, *N*-α-*p*-tosyl-*l*-lysine chloromethyl ketone; Tris, tris(hydroxymethyl)aminomethane; V, vimentin; V_d, vimentin degradation products.

(SW 60 rotor); major fractions were seen at the 30/40% and 45/55% sucrose interfaces and in the pellet. Fractions were recovered and washed once in Buffer A. All solutions used in cell harvesting, homogenization and cell fractionation contained either no protease inhibitors or *N-α-p*-tosyl-*l*-lysine chloromethyl ketone, (TLCK; 1 mM, Sigma Chemical Co., St. Louis, MO) plus ethyleneglycol-*bis*(β-aminoethyl ether)*N,N,N'*,N'-tetraacetic acid (EGTA; 2 mM).

Isolation, recovery and identification of vimentin. Water soluble proteins and proteins from the sucrose gradient were separated by sodium dodecylsulfate-polyacrylamide gel electrophoresis (SDS-PAGE) under reducing conditions using 12% gels by the Laemmli method (9) and subjected to fluorography using EN^{3}HANCE (New England Nuclear Corp.) according to the manufacturer's instructions. Proteins also were electrotransferred from unstained SDS-PAGE gels to nitrocellulose membranes (Electro-Eluter, Bio-Rad, Richmond, CA), blotted with rabbit antichicken vimentin antiserum (1:1000 dilution) and detected using alkaline phosphatase conjugated goat antirabbit IgG (Sigma Chemical Co.). In some cases, the fixed gels were treated for 18 h with 1 M hydroxylamine at pH 7 or with 1 M Tris, pH 7 (control), prior to staining and fluorography (2). Water soluble proteins were also separated by combined electrophoresis and SDS-PAGE using the mini-Protean II, 2-dimensional cell of Bio-Rad. Proteins were electrotransferred to ProBlott membrane (Applied Biosystems, Foster City, CA) according to the manufacturer's instructions and stained and submitted for amino acid compositional analysis and sequence identification by the Edman degradation (Protein Structure Core Facility of the University of Nebraska Medical Center, Omaha, NE).

Vimentin delipidation, alkaline hydrolysis and acid methanolysis. The water insoluble fraction recovered from the 45/55% sucrose interface was extracted with 8 M urea and centrifuged (100,000 × *g* for 1 h). Vimentin is extractable from calf lens by concentrated urea (10). The supernatant was diluted to 1.6 M urea with water and brought to 10% TCA. The protein pellet was washed twice with 1% TCA, lyophilized and delipidated with the following series of organic solvent extractions: five extractions with ice cold chloroform/methanol (2:1, vol/vol), and one each with ice-cold methanol, chloroform/methanol (1:2, vol/vol), chloroform/methanol (1:1, vol/vol), chloroform/methanol/water (1:1:0.3, by vol) and methanol. This is similar to the protein-delipidation procedure used by Iozzo *et al.* (2). Delipidated protein was subjected to SDS-PAGE and fluorography.

Aliquots of the delipidated protein were suspended in 1.0 mL of either 0.67 N KOH in 67% ethanol/water (vol/vol) or 1 mL of 2 N HCl in methanol, heated at 110°C for 24 h or 72 h, respectively, and diluted with 1 mL of water. Unlabeled palmitate and myristate (25 to 100 μg) was added as carrier prior to heating. The alkaline hydrolysate was extracted with three 2-mL aliquots of hexane and the acid methanolysis mixture with three 2-mL aliquots of petroleum ether. Methyl palmitate and methyl myristate recovered from acid methanolysis were separated by thin-layer chromatography as described by James and Olson (8), and the distribution of radiolabel between methyl palmitate and methyl myristate in the excised spots was measured by scintillation counting.

Measurement of amino acid tritium in vimentin. Vimentin was electroeluted as the 59 kDa band excised from SDS-PAGE gels. The eluted protein fraction was dialyzed overnight against 5 mM ammonium bicarbonate containing 0.05% SDS (wt/vol). After adding 50 μg of albumin carrier, the protein suspension was SpeedVac-dried (SpeedVac Concentrator, Savant Inst., Farmingdale, NY), suspended in 50 μL of water and the protein precipitated at −20°C with 450 μL of acetone. The acetone washed pellet was air dried, suspended in 1.0 mL of 6 N HCl and hydrolyzed at 110°C for 18 h *in vacuo*. The hydrolysate was extracted three times with 1 mL of benzene. The aqueous phase was lyophilized, dissolved in a small volume of 10% isopropanol and the amino acids separated by two-dimensional thin-layer chromatography on Whatman No. 1 paper using *n*-butanol/acetic acid/water (1:0.25:0.42, by vol) in the first direction and phenol/water (1:0.25, wt/vol) in the second direction, and visualized by ninhydrin spray (11). The identity of amino acids was determined by comparison with standards. The excised amino acid spots were dissolved in 1 mL of water and the tritium content determined by liquid scintillation counting.

RESULTS

Radiolabeling of vimentin. When cultured bovine lens epithelial cells were homogenized and fractionated in the absence of calcium protease inhibitors, about 50% of the total cellular protein was water soluble and largely accounted for by several polypeptides of about 45–47 kDa (Fig. 1A). Insoluble protein fractions were recovered from a discontinuous sucrose gradient at the 30/40% and 45/55% sucrose interfaces and in a pellet fraction. In the presence of the protease inhibitors (TLCK plus EGTA), the soluble protein recovered from the cells decreased to about 15% of total and the protein recovered from the 45/55% sucrose interface fraction markedly increased, with a particular increase in the 59 kDa polypeptide component of this fraction.

Both the water soluble 45–47 kDa polypeptides and the water insoluble 59 kDa protein of the 45/55% sucrose fraction were labeled by [^{3}H]palmitic and [^{3}H]myristic acids (Fig. 1). The 59 kDa protein was immunostained with vimentin antiserum (Fig. 2). Water soluble polypeptides labeled from [^{3}H]palmitic acid were separated on two-dimensional gels and transferred to a ProBlott membrane (Fig. 3A). The two major components (Unknown 1 and 2) were excised and subjected to amino acid analysis, and Unknown 2 was sequenced. The amino acid composition of both was very similar to bovine vimentin (Fig. 3B), and the sequence of Unknown 2 corresponded to vimentin truncated by 72 amino acids from the amino terminal (Fig. 3C). Thus, the 59 kDa protein of the 45/55% sucrose interface fraction was vimentin and the 45–47 kDa water soluble polypeptides were vimentin degradation products. Nelson and Traub (15) and Ireland and Maisel (16) have shown that vimentin of both ascites tumor cells and lens cortical fiber cells is rapidly degraded by calcium activated proteases which can be inhibited by TLCK and EGTA.

Vimentin, like other cytoskeletal proteins, can be extracted from the cell's water insoluble fraction by 8 M urea (Fig. 4) (10). The urea extracted vimentin was precipitated with trichloroacetic acid after diluting the urea with water. The recovered vimentin was washed with 1% TCA, dried

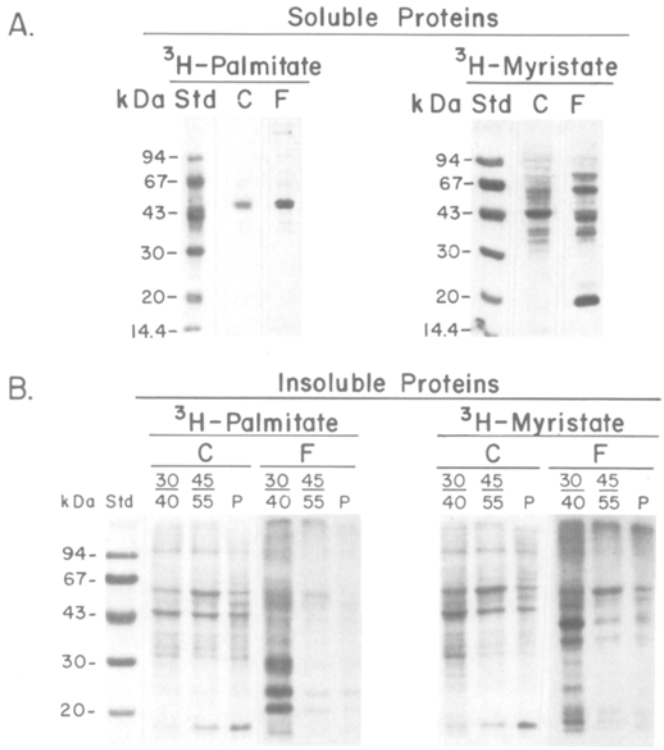

FIG. 1. Labeling of cultured bovine lens epithelial cell proteins with [^{3}H]palmitic acid and [^{3}H]myristic acid. Confluent dishes of cells at day 4 of culture were incubated for 4 h at 37°C in Dulbecco's modified Eagle's media containing 0.1 mCi/mL of either [^{3}H]palmitic or [^{3}H]myristic acid. Cells were separated into water soluble and insoluble fractions. The insoluble fraction was further fractionated on a discontinuous sucrose gradient. A. sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE) and fluorography (12–15 d) of soluble proteins. B. SDS-PAGE and fluorography (7 d) of insoluble proteins recovered from the 30/40% and 45/55% sucrose interface and pellet (P) fractions. C, Coomassie blue stained protein. F, fluorography.

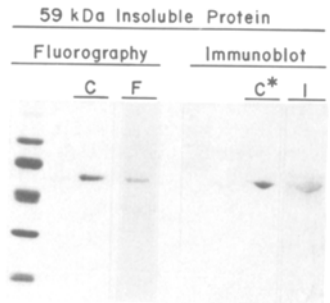

FIG. 2. Fluorography and western blot of the 59 kDa protein from the 45/55% sucrose interface fraction. The 59 kDa band from cells incubated with [^{3}H]palmitic acid was excised from SDS-PAGE gels and rerun in SDS-PAGE and either subjected to fluorography, F, (6 d) or immunostaining, I, with antichicken vimentin antiserum. C*, Coomassie blue staining protein which remained in the gel after transfer. Abbreviations as in Figure 1.

and exhaustively extracted with ice-cold organic solvents as described in Materials and Methods. The tritium content of the [^{3}H]palmitate labeled protein decreased from 35.7×10^6 dpm to 7.02×10^4 dpm (99.8% decrease) and the [^{3}H]myristate labeled protein decreased from 32.7×10^6 dpm to 7.1×10^4 dpm (99.8% decrease). Aliquots of the delipidated protein were subjected to acid methanolysis and alkaline hydrolysis. About 80% of the radiolabel was released from the [^{3}H]palmitate labeled vimentin into the lipid soluble phase following both alkaline hydrolysis and acid methanolysis. About 50% of the radioactivity was released from [^{3}H]myristate labeled vimentin into the lipid soluble phase following both alkaline hydrolysis and acid methanolysis. The release of myristate radioactivity by alkaline hydrolysis was unexpected as myristic acid attaches to protein by amide linkage (7). As discussed below, this observation likely reflects displacement by base of myristate which remained noncovalently associated with vimentin even after exhaustive extraction with organic solvents. Thin-layer chromatography of the recovered fatty acids showed methyl palmitate to account for about 93% of the label from the palmitoylated protein, and methyl myristate for about 73% of that from myristoylated vimentin; the remaining radiolabel comigrated with methyl palmitate.

The release of substantial radiolabel from both [^{3}H]palmitic and [^{3}H]myristic acid labeled vimentin by alkaline hydrolysis sharply contrasted with the apparent lack of effect of hydroxylamine treatment upon release of label from either palmitoylated or myristoylated vimentin separated by SDS-PAGE (Fig. 5). Hydroxylamine did release radioactivity from a group of palmitate labeled proteins between 20 and 30 kDa. This observation indicates that some lens epithelial cell proteins are acylated and that the conditions of hydroxylamine treatment were adequate to completely release fatty acid attached to the protein by an ester linkage.

From these observations, we considered the possibility that the lipid soluble radiolabel recovered following acid and base hydrolysis of delipidated vimentin represented trace amounts of noncovalently associated [^{3}H]fatty acid which was not removed by even exhaustive solvent extraction. We compared the release by acid methanolysis of lipid soluble myristate-radiolabel from vimentin, which was directly recovered from SDS-PAGE gels, with that from vimentin which was recovered by urea extraction and then delipidated. About 50% of the protein radiolabel was recovered in the organic solvent phase following direct acid methanolysis of the delipidated vimentin, but essentially none appeared as lipid-soluble radiolabel following acid-methanolysis of the protein recovered from the SDS-PAGE gel (Table 1).

Because we now suspected that the incorporation of fatty acid radiolabel into vimentin occurred through labeled amino acids generated from the fatty acids, the labeling studies were repeated with inclusion of excess sodium pyruvate in the incubation media. Increased pyruvate (P_y) is presumed to decrease the metabolic conversion of radiolabel from [^{3}H]fatty acids to amino acids by expanding the cellular acetate pool (2,3); however, data documenting this effect are not available. Adding 5 mM sodium P_y to the labeling media (which contains a basal level of 1 mM) produced no obvious decrease in the incorporation of either [^{3}H]palmitic or [^{3}H]myristic acid into vimentin or other cellular proteins (Fig. 6). This observation appeared to support the idea that vimentin was covalently labeled by these fatty acids. However, when the experiment was repeated using higher concentrations of

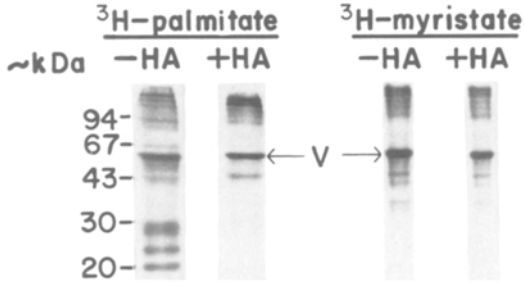

FIG. 5. Effect of hydroxylamine treatment on the release of label from [^{3}H]palmitate and [^{3}H]myristate labeled protein. Insoluble protein recovered from the 45/55% sucrose interface fraction was separated by SDS-PAGE. Gels were soaked in either 1 M Tris, pH 7, (−HA) or in 1 M hydroxylamine, pH 7, (+HA) for 18 h at room temperature prior to staining and fluorography (7 d). V, vimentin; abbreviations as in Figure 1.

sodium pyruvate, near complete inhibition of myristate labeling of vimentin could be observed depending upon the length of the fluorography exposure time. Following a six-day fluorography exposure, 5, 10 and 20 mM sodium pyruvate all produced similar decreases in the intensity of labeling of vimentin with [^{3}H]myristate (Fig. 7). When the fluorography exposure time was decreased to three days, near complete blockage of labeling of vimentin from [^{3}H]myristic acid was seen. Because blockage by sodium pyruvate of metabolic conversion of fatty acids into amino acids is incomplete, failure to initially recognize this antagonism by fluorography was likely due to exposing the X-ray film for too long (Fig. 6).

Final proof that the apparent incorporation of [^{3}H]myristic acid, and likely [^{3}H]palmitic acid, into vimentin was due to amino acids which were then used for protein synthesis was obtained by acid hydrolysis of labeled vimentin and measuring the radioactive content of the resulting amino acids. As seen before, over 90% of the tritium label in vimentin recovered from the SDS-PAGE gel remained in the water soluble phase following acid hydrolysis and solvent extraction. The essential absence of radiolabel in the organic solvent phase shows that the tritium incorporated into vimentin following incubation of the lens epithelial cells with [^{3}H]myristic acid was not due to acylation by fatty acid. Rather, aspartate, glutamate and serine accounted for essentially all of the radiolabel associated with vimentin, with glutamate alone accounting for about 50% of the total (Table 2).

[a]Vimentin from cells incubated with [^{3}H]myristic acid was recovered from sodium dodecylsulfate-polyacrylamide gel electrophoresis gels by electroelution. Albumin (50 μg) was added as carrier, and the recovered protein was hydrolyzed in 6N HCl (110°C, 18 h). More than 90% of the radiolabel in the hydrolysate remained in the aqueous phase following extraction with benzene. The aqueous phase was then lyophilized, the residue dissolved in 10% isopropanol and subjected to two-dimensional paper chromatography. Amino acids were visualized by ninhydrin spray and identified by comparison to standards. Spots were excised and counted.

[b]These amino acids accounted for 64% of the total [^{3}H]label theoretically applied to the paper. An additional 13% of the applied radiolabel was found outside of the areas of the identified amino acids.

DISCUSSION

In the process of investigating the possible fatty acid acylation of vimentin, we documented at least two potential pitfalls in detecting fatty acid acylation of cellular proteins. Following even exhaustive organic solvent extrac-

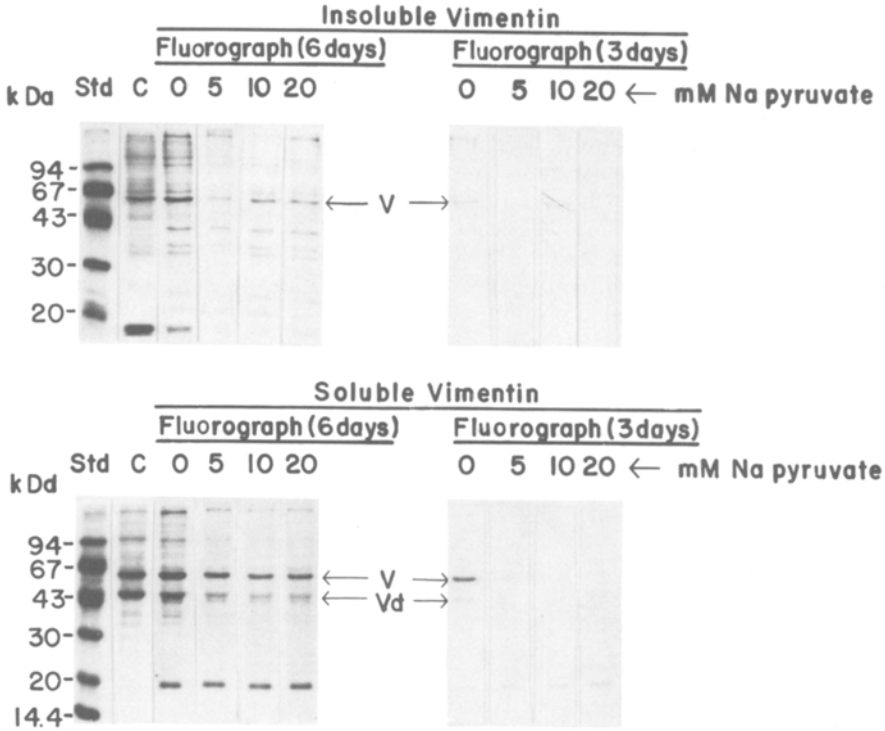

FIG. 7. Antagonism by sodium pyruvate of [^{3}H]myristic acid labeling of soluble and insoluble vimentin. Insoluble vimentin was from the cellular pellet fraction. Cells were incubated with [^{3}H]myristic acid in the absence or presence of excess sodium pyruvate (5, 10 or 20 mM). C, Coomassie stained, V, vimentin, Vd, vimentin degradation products.

tion, [^{3}H]labeled fatty acid can remain noncovalently associated with the protein. In the case of vimentin, 50 to 80% of the radiolabel associated with the protein after delipidation was likely free [^{3}H]palmitic or [^{3}H]myristic acid. By contrast, SDS-PAGE appeared to remove essentially all of noncovalently bound [^{3}H]fatty acid from vimentin. The difficulty in complete delipidation of proteins by solvent extraction is compounded by the high concentration and specific activity of radiolabeled substrates used in the fatty acid acylation of proteins and the low levels of incorporation typically obtained, usually requiring one or more weeks of fluorography exposure for detection. A second potential pitfall involves the use of sodium pyruvate to antagonize the metabolic conversion of fatty acid to amino acid. Because supplementing the labeling media with excess sodium pyruvate does not completely block incorporation of [^{3}H]fatty acid into protein *via* amino acids, careful attention must be given to the fluorography exposure times. Even slightly excessive times can mask the competitive effect of the pyruvate.

Olson *et al.* (1) stated that incorporation of [^{3}H]myristate into 3Ts mouse fibroblasts and PC12 cells occurred mainly due to generation of [^{3}H]amino acids, which were subsequently used for protein synthesis. However, specific proteins were not identified. The present study shows that the labeling of vimentin from either [^{3}H]palmitic or [^{3}H]myristic acid in cultured bovine lens epithelial cells during short-term incubation likely occurred solely by metabolic conversion of fatty acid to amino acids. This route of protein labeling would be greatest for actively synthesized proteins, and vimentin was the single most actively synthesized protein by these cells from [^{3}H]leucine (data not shown). An additional possible complication of protein-fatty acid acylation studies is that protein labeling might occur simultaneously by covalent acylation and amino acid incorporation. In fact, this possibility cannot be excluded in the case of the palmitate radiolabel associated with vimentin, as the SDS-PAGE separation of protein was performed in the presence of reducing agent which might cleave some palmitic acid attached to vimentin by thioester (18). However, retention of palmitic acid label in vimentin after treatment of gels with hydroxylamine supports incorporation of at least some palmitate radiolabel by way of amino acids. Proof of protein-fatty acid acylation can be obtained by showing that base and/or acid hydrolysis of labeled protein recovered from SDS-PAGE gels releases all of the radiolabel from the protein, the released label is soluble in organic solvent and it is shown to be in fatty acid. Recall that SDS-PAGE appeared to remove all noncovalently associated [^{3}H]fatty acid from protein, at least for vimentin.

ACKNOWLEDGMENTS

The authors thank Dr. Theodore A. Mahowald and Bruce Baggenstoss of the Protein Structure Core Facility of the University of Nebraska Medical Center (Omaha, NE) for performing the protein amino acid composition and sequence determinations. Dr. Mark Ireland, Department of Anatomy, Wayne State University (Detroit, MI) is thanked for the supply of rabbit antichicken vimentin antiserum. This work was supported by NIH grant EY02568.

An efficient three-step purification technique has been developed for the reticulocyte 15-lipoxygenase from rabbit. Ammonium sulfate fractionated reticulocyte lysate was purified by size exclusion chromatography and preparative scale isoelectric focusing. The entire procedure was complete in less than eight hours and was carried out in batches which typically yielded 10 mg of purified enzyme. The identity and purity of the enzyme were evaluated by *N*-terminal sequencing, sodium dodecylsulfate polyacrylamide gel electrophoresis and specific activity determinations. The enzyme contained approximately one g-atom iron per mole of protein. The iron was present in an electron paramagnetic spectroscopy (EPR) silent, presumably high spin iron(II), form in the isolated enzyme. Treatment with one equivalent of 13-hydroperoxy-9(*Z*),11(*E*)-octadecadienoic acid resulted in the appearance of an EPR signal around g6.

Lipids 28, 241–244 (1993).

Lipoxygenase occupies a key position in the metabolism of polyunsaturated fatty acids in both plants and animals. The products of lipoxygenase catalysis and subsequent metabolites are potent mediators of an array of biochemical events. For example, there is a substantial body of evidence indicating that rabbit 15-lipoxygenase plays a central role in the maturation of the red blood cell (1). The enzyme apparently catalyzes the peroxidation of mitochondrial lipids resulting in the destruction of the organelle, the inaugural step in the conversion of the reticulocyte into the mature erythrocyte. Like all lipoxygenases, the reticulocyte enzyme contains one non-heme iron atom per molecule of the protein (2). While the reticulocyte enzyme was by a wide margin the first mammalian lipoxygenase to be isolated, the non-heme iron site has not been characterized. By contrast the non-heme iron site of soybean lipoxygenase-1 has been a central focus of studies of that enzyme. Features of the iron have been probed by ultraviolet (UV) visible, electron paramagnetic resonance (EPR), magnetic circular dichroism (MCD), Mössbauer, X-ray absorption, paramagnetic nuclear magnetic resonance (NMR) spectroscopy and magnetic susceptibility measurements (3–5). These experiments demonstrated that the native soybean enzyme contained the metal in an EPR silent high-spin iron(II) form. Treatment of the native enzyme with the product of catalysis converted the metal to a high-spin iron(III) form with a characteristic EPR feature around g6. When the oxidized enzyme was treated with linoleic acid (substrate) in the absence of oxygen, the EPR signal was lost, and a new iron(II) species was detected. Therefore it has been concluded that the unique non-heme iron site plays a fundamental redox role in the catalytic mechanism of the enzyme. The non-heme iron sites in porcine leukocyte 5- and 12-lipoxygenases have been recently investigated and also found to be EPR active (6). However, the leukocyte enzymes as isolated displayed an EPR signal around g5.2 which did not require and was not affeced by the product of catalysis. Also the signal was not abolished by treatment with a reducing agent, nordihydroguaiaretic acid. Two purification procedures for rabbit 15-lipoxygenase have been published (2,7). While the procedures result in the isolation of homogeneous protein in good yields, there has been no apparent progress in the characterization of the non-heme iron site using spectroscopic probes. There is some indication that the purification scheme for the enzyme may need to be tailored to the specific application or investigation. For example, the purification procedure developed first was found not to provide protein samples suitable for crystallization. Initial experiments led us to believe that a critical element in the purification for the examination of the non-heme iron site might be speed. The previous procedures both involved multiple resolution steps with intervening concentration and dialysis manipulations spanning several days. Here we present a rapid purification procedure for the reticulocyte enzyme that provides samples of the enzyme suitable for undertaking the characterization of the non-heme iron site by EPR spectroscopy.

MATERIALS AND METHODS

Reticulocytes were obtained from New Zealand white rabbits injected (1.0–2.0 mL) daily for five days with a 1.2% aqueous solution of *N*-acetylphenylhydrazine adjusted to pH 6.8 using HEPES buffer (1 *M*, pH 7.0). The rabbits were bled daily from day 7 through day 12. The amount of blood collected was between 30 and 50 mL per day and was adjusted to maintain a hematocrit level between 18 and 22% cells.

The supernatant from lysed cells (2) was brought to 55% saturation with ammonium sulfate, and the mixture was centrifuged. The pellet was redissolved in potassium phosphate buffer (0.01 *M*, pH 6.0) and was dialyzed against the same buffer at 5°C. Precipitation was removed by centrifugation, and the supernatant was stored for future use in polypropylene tubes submerged in liquid nitrogen.

Samples (10–15 mL) of the thawed extracts were applied to a Sephacryl S200 HR column (2.5 × 40 cm) equilibrated with Tris buffer, 0.05 *M*, pH 7.2, containing 1 m*M* dithiothreitol (DTT) and 1 mM $MgCl_2$. Elution was carried out with the same buffer at a flow rate of 2 mL min^{-1}. During elution the buffer reservoir was purged continuously with nitrogen and was maintained at 5°C. Fractions (4 mL) were collected and stored under a nitrogen atmosphere on ice during subsequent analysis. Aliquots

Abbreviations: DTT, dithiothreitol; EDTA, ethylenediaminetetraacetic acid; EPR, electron paramagnetic spectroscopy; MCD, magnetic circular dichroism; NMR, nuclear magnetic resonance; PVDF, polyvinylidenedifluoride, SDS, sodium dodecylsulfate; UV, ultraviolet.

of the fractions were subjected to sodium dodecylsulfate (SDS) polyacrylamide determinations (8) and measurement of absorbance at 280 and 560 nm.

Pooled fractions (5, 20 mL) from the gel filtration experiment were combined with glycerol (5 mL), 5/7 ampholyte (3.0 mL, Biorad, Richmond, CA), and ice-cold deionized water to give a final volume of 50 mL. The sample was loaded into a preparative scale isoelectric focusing apparatus (Rotofor, Biorad), and a constant power (15 W) was applied for a period of four hours. The fractions were subjected to pH, activity (2) and SDS polyacrylamide gel electrophoresis determinations as well as measurement of absorbance at 280 and 560 nm. Fractions containing lipoxygenase were stored at −20°C without loss of activity for up to two weeks.

Protein sequence determination was carried out on an Applied Biosystems model 477A liquid-pulsed peptide protein sequencer. Samples were analyzed for iron content using flame atomization atomic absorption spectrometry. EPR measurements were made at 9 GHz using a Varian Century Line spectrometer (Palo Alto, CA) equipped with a liquid helium transfer line and a quartz dewar cavity insert. Spectra were recorded at 25 K using microwave power that avoided saturation. Running conditions were set at 5 mW power, 1 mT modulation amplitude, 4 min scan time and 0.128 s time constant. The samples were prepared for analysis by dialysis against Tris buffer, containing 0.1 *M* NaCl and 1 m*M* ethylenediaminetetraacetic acid (EDTA). The oxidized enzyme was obtained by treatment with 13-hydroperoxy-9*Z*,11*E*-octadecadienoic acid (9) in a 1:1.1 ratio. Final concentration of the samples for EPR was carried out in a centrifugal concentrator (Amicon Centricon 30, Lexington, MA).

RESULTS AND DISCUSSION

The mammalian lipoxygenases are susceptible to inactivation with loss of iron in the presence of oxygen (absence of reducing agents) (10,11). Therefore, a rapid purification procedure for rabbit 15-lipoxygenase which avoided exposure to oxygen was investigated. Attempted purification of the enzyme with a chromatofocusing procedure which has been successfully applied to the isolation of the soybean isoenzymes failed. A procedure based on size exclusion chromatography and preparative isoelectric focusing was developed.

The resolution of the proteins obtained from ammonium sulfate precipitated reticulocyte lysate by gel filtration chromatography is shown in Figure 1A. The applied sample was the result of a one-day collection of reticulocytes from two rabbits between day 7 and 14 of the protocol. The collected fractions were monitored for absorbance at 280 and 560 nm which allowed for detection of hemoglobin, a major protein component of the cells. The proteins were resolved between fractions 20 and 40. When fractions in this region were tested for lipoxygenase activity, it was found that the hemoglobin interfered with the assay showing quasi-lipoxygenase activity. SDS polyacrylamide gel electrophoresis (Fig. 1B) showed that a protein of about 75 kDa coeluted with hemoglobin. The only other candidate for the target enzyme in the elution profile was a protein of 70 kDa that was present in fractions 24–28. These samples, however, displayed no lipoxygenase activity. The identity of the 75 kDa protein as 15-lipoxygenase was confirmed by protein sequence analysis. The proteins in the gel were transferred electrophoretically to a polyvinylidenedifluoride (PVDF) membrane. After briefly staining and destaining the membrane containing the transferred proteins, the 75 kDa band was excised and subjected to sequence determination using automated Edman degradation chemistry. A clear amino acid sequence was obtained through 15 Edman cycles which matched exactly with the first 15 amino terminal residues for 15-lipoxygenase deduced from the corresponding c-DNA (12). These observations showed that a simple size exclusion chromatographic experiment was sufficient to provide samples of the enzyme with the only primary contaminant being hemoglobin.

Preparative scale isoelectric focusing was used to resolve the lipoxygenase from the hemoglobin. The result of a typical isoelectric focusing experiment is presented in Figure 2A. The apparatus separated the sample into 20 fractions upon focusing which were monitored for absorbance at 280 and 560 nm. The proteins were clearly resolved into two components one of which displayed

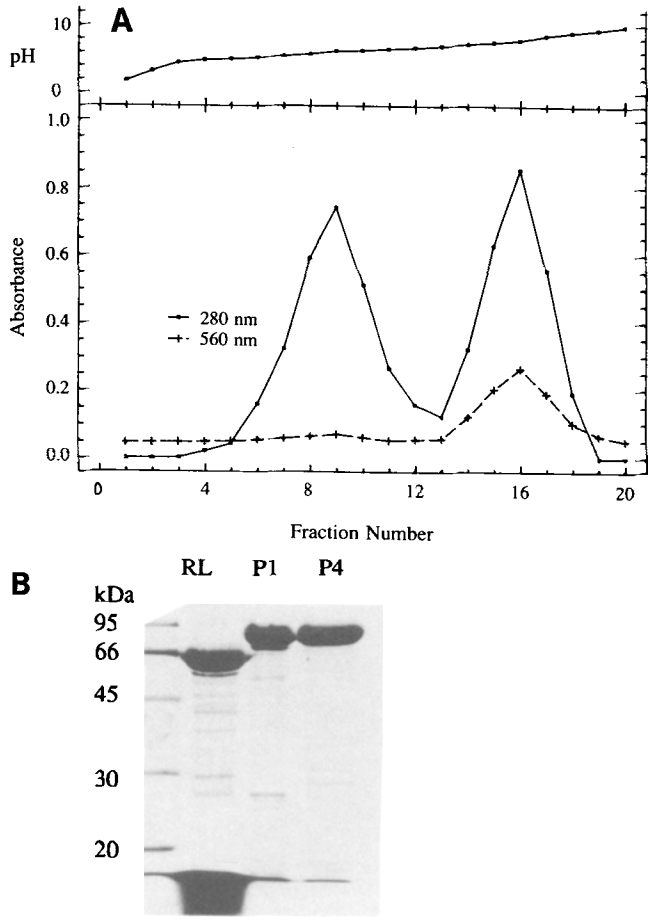

FIG. 2A. Preparative scale isoelectric focusing (pH 5–7) of fractions 30–34 from the size exclusion chromatography. B. Sodium dodecylsulfate polyacrylamide gel electrophoresis determination of fractions 8–10 (RL) from isoelectric focusing. Two isoenzymes of soybean lipoxygenase (P1, P4) were included for comparison.

significant absorbance at 560 nm due to the presence of hemoglobin. The other protein component was the 75 kDa protein previously identified as 15-lipoxygenase. The procedure typically yielded approximately 10 mg of the purified protein. The SDS polyacrylamide gel electrophoresis analysis of samples from fractions containing this protein (Fig. 2B; two isoenzymes of soybean lipoxygenase were run concurrently for comparison) showed the presence of only a single polypeptide and the ampholytes used in the separation procedure. This protein was found in a fraction with a measured pH of 5.5, consistent with the previously reported pI for the 15-lipoxygenase. The turnover number for lipoxygenase catalysis found for the fractions containing the 75 kDa protein was 30 s^{-1}, a value comparable to the reported 25 s^{-1} found previously for highly purified enzyme (2). The purified 15-lipoxygenase was also subjected to analytical isoelectric focusing determination in a polyacrylamide gel from pH 5 to 7 (13). A single band staining for protein and activity at pH 7 was detected in the experiment (data not shown). These experiments demonstrated that useful quantities of 15-lipoxygenase were obtained in an isolation procedure taking less than eight hours.

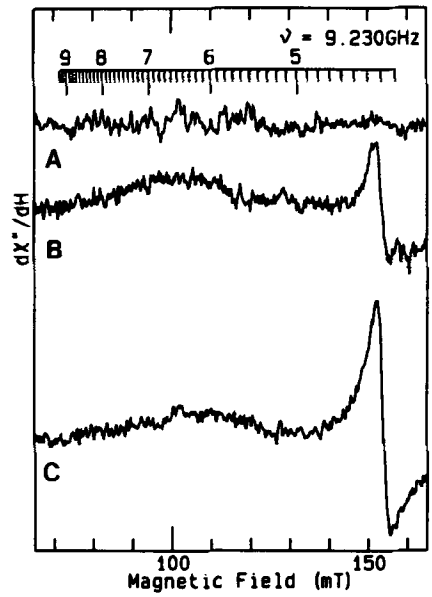

FIG. 3. Electron paramagnetic spectroscopy spectra for samples of purified reticulocyte lipoxygenase, Tris HCl (0.1 *M*, pH 7.4). (A) Spectrum of isolated enzyme, 200 μM. (B) Isolated enzyme, 165 μM, treated with 1.1X 13-hydroperoxy-9(*Z*),11(*E*)-octadecadienoic acid. (C) Oxidized enzyme, 200 μM purged with argon and treated with 1.2X linoleic acid.

For further experiments the enzyme solution was dialyzed in nitrogen purged Tris buffer (0.1 *M*, pH 7.4, 1 m*M* EDTA) at 5°C and concentrated in a centrifugal concentrator. These procedures were not accompanied by precipitation of protein. Solutions were obtained with concentrations of the enzyme around 0.20 m*M* displaying undiminished turnover number (30 s^{-1}). Samples of the purified and dialyzed enzyme contained 0.9 g-atom of iron per mole of enzyme using flame atomization atomic absorption spectrometry. The UV-visible spectrum of the purified enzyme contained only the absorbance maximum around 280 nm expected for the contribution of aromatic amino acids. Treatment of the enzyme solution with one equivalent of 13-hydroperoxy-9(*Z*),11(*E*)-octadecadienoic acid caused an increase in absorbance in the region 300–350 nm, but no new maximum was obtained. The UV-visible spectroscopy was, therefore, similar to observations on lipoxygenase-1 from soybeans (4). The enzyme as isolated had spectroscopic features consistent with a non-heme iron atom present in a high spin iron(II) form that was oxidized upon treatment with the product of catalysis to give a high spin iron(III) species.

The characterization of the non-heme iron site in the reticulocyte 15-lipoxygenase by EPR spectroscopy is presented in Figure 3. No signals were detected in the solution of the enzyme obtained from the isolation procedure (Trace A). This was consistent with the iron being present in the protein as high spin iron(II) as has been found and confirmed in other spectroscopic measurements for the soybean enzyme. Treatment of the enzyme with 13-hydroperoxy-9(*Z*),11(*E*)-octadecadienoic acid resulted in the appearance of two new signals in the EPR spectrum (Trace B), a sharp signal at g4.3 and a broad featureless signal around g6. The integrated intensity of the g6 signal accounted for 15–20% of the iron known to be in the sample.

When samples of the enzyme treated with product were made anaerobic by purging with argon and were subsequently treated with linoleic acid, the spectrum changed (Trace C). There was a diminution in the g6 signal and an increase in the signal at g4.3. The EPR observations were similar in nature to those for the soybean enzyme, but different in degree. The soybean enzyme was converted stoichiometrically into a high spin iron(III) species with the g6 EPR signal by oxidation with product, and the signal was abolished by treatment with substrate in the absence of oxygen (14). We conclude from the similarities in the UV-visible and EPR spectroscopy for the two enzymes that the non-heme iron sites in reticulocyte and soybean 15-lipoxygenase are similar. We speculate that aggregation of the reticulocyte enzyme in the concentrated solutions used in the spectroscopic studies resulted in diminished accessibility of reagents to the active/iron site resulting in incomplete reactions. The development of an efficient precedure for obtaining significant quantities of highly purified rabbit 15-lipoxygenase should facilitate the characterization of the physical and catalytic properties of this important enzyme.

Simultaneous Determination of the Main Molecular Species of Soybean Phosphatidylcholine or Phosphatidylethanolamine and Their Corresponding Hydroperoxides Obtained by Lipoxygenase Treatment

Patrice Therond[b], Martine Couturier[a], Jean-François Demelier[b] and Frédérique Lemonnier[a,*]
[a]Unité de Recherche d'Hépatologie Pédiatrique (INSERM U347), Hôpital Bicêtre, 94276 Le Kremlin Bicêtre and [b]Laboratoire de Biochimie, Hôpital R. Debré, 75019 Paris, France

A method for the simultaneous determination of the main molecular species of soybean phosphatidylcholine or phosphatidylethanolamine and their corresponding hydroperoxides is described. Hydroperoxides were formed by incubation of phospholipids with lipoxygenase at pH 9.2. Silicic acid column chromatography (silica Sep-Pak column) was used to separate the phospholipids into phosphatidylcholine and phosphatidylethanolamine. A single C-18 reverse-phase column was employed to separate the main molecular species of soybean phosphatidylcholine or phosphatidylethanolamine and their hydroperoxides by high-performance liquid chromatography. The mobile phase consisted of 5% 10 mM ammonium acetate at pH 5 and 95% methanol. The molecular species of phosphatidylcholine and phosphatidylethanolamine were detected at 205 nm; the eluate was mixed with a chemiluminescence reagent (isoluminol and microperoxidase) and monitored by fluorometry. Under the experimental conditions used, three individual molecular species of both soybean phosphatidylethanolamine and phosphatidylcholine (18:3/18:2, 18:2/18:2 and 16:0/18:2), together with their corresponding hydroperoxides, were identified and quantitated.
Lipids 28, 245–249 (1993).

The importance of free radicals in causing alterations in various biological systems has led to numerous attempts to determine lipid peroxides in tissues and biological fluids. The products generated by peroxidizing lipids are exceedingly complex, but considerable progress has been made in defining lipid oxidation at various stages of peroxide degradation. The most commonly used approach is the determination of an end-product of lipid peroxidation, namely malondialdehyde, based on its reaction with thiobarbituric acid. Assay is either by spectrophotometry, as initially described by Yagi (1), or by liquid chromatography (2–4). However, the specificity of this reaction has been questioned (5–7). Other techniques have subsequently been described based on other indices of lipid peroxidation, such as conjugated diene (8) or lipid hydroperoxide measurements (9,10). Progress has also been made in separating phospholipid hydroperoxides by high-performance liquid chromatography (HPLC). In this method, chemiluminescence (CL) detection with isoluminol in the presence of the heme fragment of cytochrome c (11) or with luminol in the presence of cytochrome c is usually used (12,13). Spectrophotometric detection of hydroperoxides, which is based on the formation of an iron thiocyanate complex, has also been described (14).

Several HPLC methods have been reported for separating the molecular species of phospholipids (15–17). However, to our knowledge, the simultaneous determination of phospholipid molecular species and of their hydroperoxides has not been described previously. We report here on an HPLC procedure, which combines the separation of the main molecular species of phosphatidylcholine (PC) or phosphatidylethanolamine (PE) and of their hydroperoxides produced after peroxidation by lipoxygenase. The phospholipid molecular species are detected by means of ultraviolet (UV) spectrophotometry and the hydroperoxides by means of CL. A single sample injection is sufficient for the separation and analysis of PC or PE and their hydroperoxides.

MATERIALS AND METHODS

Chromatographic equipment. Gas-liquid chromatography (GLC) was carried out on a Delsi (Puteaux, France) instrument equipped with a 25-m glass capillary column containing PEG-20 M (Supelco, Bellefonte, PA), and connected to a Delsi integrator. The HPLC system consisted of a Rheodyne injector (Pharmacia, Uppsala, Sweden) with a 50-μL sample loop, a 250 × 4.6 mm RP 18 Spherisorb 5 μm (SFCC/Shandon, Eragny, France) analytical column and a Pharmacia UV/visible light detector. The fluorometer (Spectroflow 980-fluorescence detector, Applied Biosystems, Ramsey, NJ) was equipped with a 5 μL flow cell.

Reagents and chemicals. HPLC-grade solvents and analytical-grade chemicals were obtained from Carlo Erba (Milano, Italy) or from Merck (Darmstadt, Germany). Microperoxidase (MP 11), isoluminol (6-amino-2,3-dihydro-1,4-phthalazinedione), soybean lipoxygenase (type IB, EC 1.13.11.12), soybean PC, soybean PE, 1,2-dilinoleoyl-*sn*-glycero-3-phosphocholine (18:2/18:2 PC), 1-palmitoyl-2-linoleoyl-*sn*-glycero-3-phosphocholine (16:0/18:2 PC) and 1-stearoyl-2-arachidonoyl-*sn*-glycero-3-phosphocholine (18:0/20:4 PC) and 15-hydroperoxyeicosatetraenoic acid (15-HPETE) were obtained from Sigma (St. Louis, MO).

Phospholipid peroxidation with lipoxygenase. Hydroperoxides were prepared from various molecular species of PE and PC and from soybean PE and PC, either separately or together (50 to 1000 nmol/mL of reaction mixture). Lipoxygenase (500 μg/mL) and 10 mM deoxycholic acid were added to 0.1 M borate buffer, pH 9.2 (18). The mixture (1 mL) was then incubated with gentle shaking at 30°C for 45 min. The reaction was stopped by adding

Abbreviations: CL, chemiluminescence; GLC, gas-liquid chromatography; 15-HPETE, 15-hydroperoxyeicosatetraenoic acid; HPLC, high-performance liquid chromatography; MTBE, methyl tertiary-butyl ether; PC, phosphatidylcholine; PCOOH, phosphatidylcholine hydroperoxides; 16:0/18:2 PC, 1-palmitoyl-2-linoleoyl-*sn*-glycero-3-phosphocholine; 18:0/20:4 PC, 1-stearoyl-2-arachidonoyl-*sn*-glycero-3-phosphocholine; 18:2/18:2 PC, 1,2-dilinoleoyl-*sn*-glycero-3-phosphocholine; 18:3/18:2 PC, 1-linolenoyl-2-linoleoyl-*sn*-glycero-3-phosphocholine; PE, phosphatidylethanolamine; PEOOH, phosphatidylethanolamine hydroperoxides; RP, reverse-phase; UV, ultraviolet.

100 μL of 1 M citric acid, and the tubes were placed on ice for 5 min.

Extraction and separation of phospholipids into PC and PE. Phospholipids were extracted with chloroform/methanol (2:1, vol/vol). The mixture was partitioned between the chloroform layer (lower organic phase) and the methanol/water layer (upper phase) by centrifugation at 1500 × *g* for 5 min. The extraction was repeated twice. The lower chloroform layer was collected and evaporated under a stream of nitrogen. The dried total lipids were then dissolved in methanol. For the separation of the soybean PC and PE mixture, the technique recently described by Hamilton and Comai (19) was adapted using Silica-Sep-Pak columns. After elution of neutral lipids with methyl *tertiary*-butyl ether (MTBE)/acetic acid (100:0.2, vol/vol), the polar lipids were separated using 8 mL of MTBE/methanol/10 mM ammonium acetate (10:4:1, by vol) for PE and 10 mL at a ratio of 5:8:2 (by vol) for PC. The various fractions were evaporated to dryness, dissolved in methanol and then each injected into the HPLC system.

Detection and identification of soybean molecular species and hydroperoxides. Separation was achieved by HPLC using an RP18 Spherisorb (250 mm × 4.6, 5 μm) analytical column maintained at 40°C. The mobile phase was composed of 5% 10 mM ammonium acetate, pH 5, and 95% methanol (flow rate, 1 mL/min) filtered through a 0.45 μm HV Millipore filter (Millipore Co., Bedford, MA). The CL reagent was prepared using a slight modification of the technique described by Yamamoto *et al.* (11). Isoluminol (55 mg) was dissolved in a mixture of methanol/borate buffer 0.1 M, pH 9.2, 300:700 (vol/vol); then 10 mg of microperoxidase was added. Under these conditions, the final concentration of isoluminol was 25 mg/L and that of microperoxidase was 5 mg/L. The hydroperoxides were first eluted and then detected in CL reagent at a flow rate of 1 mL/min using a fluorometer as photon detector with the excitation source turned off. The fatty acid molecular species were then eluted and detected at 205 nm. To identify the molecular species after HPLC separation, they were collected and transmethylated at 55°C with 0.5 M methanolic potassium hydroxide and BF_3/methanol (20) and injected into a GLC. Fatty acid methyl ester peaks were identified by their retention times relative to commercial standards (Nu-Chek-Prep, Elysian, MN). On the basis of the findings of Brash *et al.* (21), the intact phospholipids and not the hydrolyzed/reesterified fatty acids are the true substrates of the oxygenation reaction. Consequently, the hydroperoxides produced (specific for PC and PE) were identified using the peroxidation of the standard molecular species of phospholipids.

RESULTS AND DISCUSSION

Separation of phospholipid molecular species and hydroperoxides. Three main individual molecular species (18:3/18:2; 18:2/18:2 and 16:0/18:2) were separated from soybean PC and PE and identified. Each molecular species was quantified by comparing the integrated peak areas with a calibration curve obtained with commercial standards of soybean phospholipids (Fig. 1). The coefficient of variation of this method after extraction and separation was 3.5% for each molecular species (n = 3). The percentage recovery of molecular species was 100% for PE and 93% for PC.

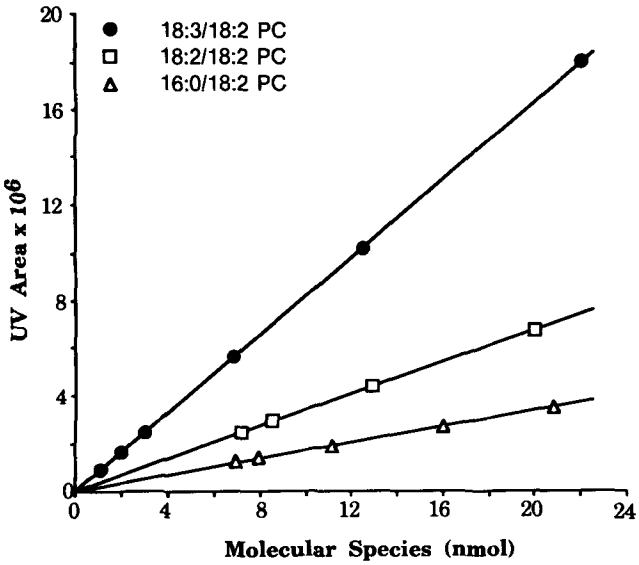

FIG. 1. Calibration curves obtained for soybean phospholipid molecular species detected at 205 nm including 18:3/18:2 PC, 18:2/18:2 PC and 16:0/18:2 PC. The high-performance liquid chromatography conditions used are those described in Materials and Methods. 18:3/18:2 PC, 1-linolenoyl-2-linoleoyl-*sn*-glycero-3-phosphocholine; 18:2/18:2 PC, 1,2-dilinoleoyl-*sn*-glycero-3-phosphocholine; 16:0/18:2 PC, 1-palmitoyl-2-linoleoyl-*sn*-glycero-3-phosphocholine.

The molecular species were detected at 205 nm both before (Fig. 2A) and after peroxidation (Fig. 2B). There was also a marked decrease in the three molecular species following peroxidation, particularly with 18:3/18:2 and 18:2/18:2. Hydroperoxides were not detected before peroxidation (Fig. 2C). Figure 2D shows the hydroperoxides produced after 45 min of incubation in the presence of lipoxygenase. The products were detected by CL and corresponded to the hydroperoxides derived from 18:3/18:2, 18:2/18:2 and 16:0/18:2, respectively, as identified by comparison with the peroxidation products of the standard molecular species. Each hydroperoxide was quantified on the basis of the relative sensitivity of the CL assay for 15-HPETE. Examples of such calibration curves are shown in Figure 3. A coefficient which took into account the sensitivity of detection of the various hydroperoxides relative to 15-HPETE was applied to determine the concentration of each molecular species (22). The sum of two hydroperoxide species of 18:2/18:2, corresponding to mono and bis hydroperoxides, was taken into account in expressing the results (23). Under these conditions, the correction coefficient was 0.8 for 18:3/18:2, 1.0 for 18:0/20:4, 1.0 for 18:2/18:2, and 3.5 for 16:0/18:2. The coefficient of variation for the hydroperoxide of each molecular species after extraction and separation was 9.8% for three determinations. The percentage recovery of the peroxidized molecular species was 93% ± 5 for PE and 80% ± 7 for PC.

The limit of hydroperoxide detection was 30 pmol when the CL signal was recorded at 0.01 μA and the supply voltage for the photomultiplier was 50% of full range (2000 V). Under our usual experimental conditions, 40% of full range was used to sustain a low background noise; under this condition the limit of detection was 100 pmol.

Optimization of the analytical procedure. The lipoxygenase assay was carried out as described above, at 30°C

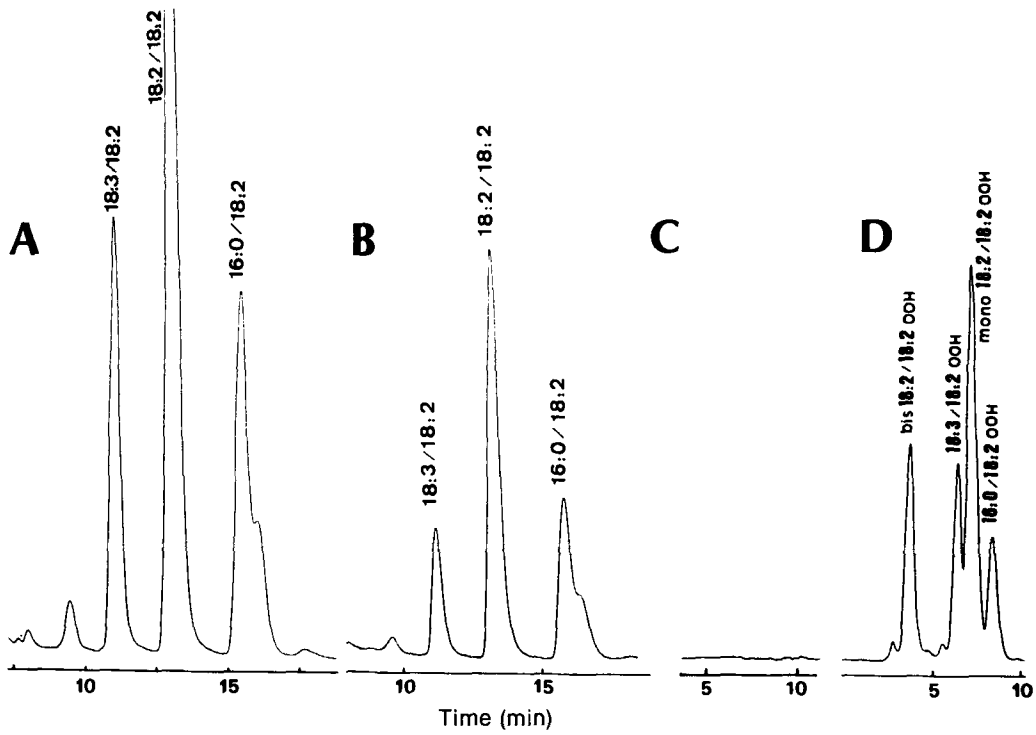

FIG. 2. Separation of molecular species of soybean phosphatidylethanolamine on an analytical RP18 Spherisorb column at 40°C. The mobile phase was methanol/0.01M ammonium acetate (95:5, vol/vol; pH 5.0) delivered isocratically at 1.0 mL/min. Fatty acid molecular species were detected at 205 nm, and the corresponding hydroperoxides were detected using the chemiluminescence reagent (isoluminol and microperoxidase; flow rate 1 mL/min). A, detection at 205 nm before peroxidation; B, detection at 205 nm after 45 min of incubation with lipoxygenase; C, chemiluminescence detection of hydroperoxides (PEOOH) before peroxidation; D, chemiluminescence detection of hydroperoxides (PEOOH) after 45 min of incubation with lipoxygenase.

in the presence of 340 nmol/mL of 18:2/18:2 PC or 18:0/20:4 PC, within a time range from 5 min and 120 min (Fig. 4). A slight decrease in hydroperoxide formation from 18:2/18:2 PC was observed after 45 min of incubation, whereas with 18:0/20:4 PC there was an increase in hydroperoxide formation up to 90 min and a drastic decrease thereafter. This was probably due to the degradation of hydroperoxide with longer incubation times. Thus, 45 min was selected as the incubation time in all the experiments.

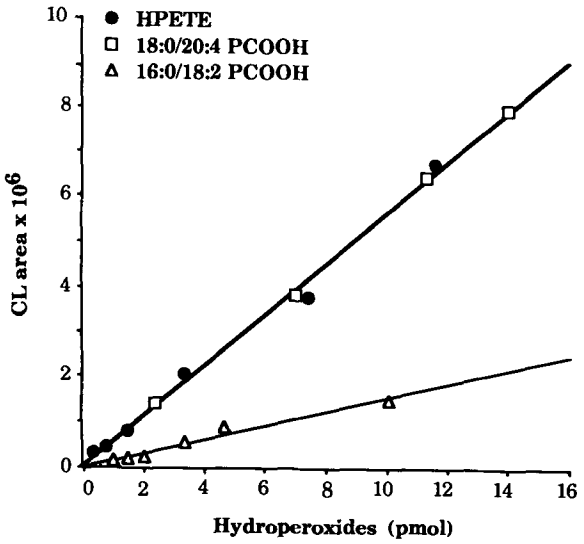

FIG. 3. Calibration curves for 15-*(S)*-HPETE, 18:0/20:4 PCOOH and 16:0/18:2 PCOOH. The separation and detection of hydroperoxides are described in the legend to Figure 2. Relative sensitivities of hydroperoxide detection relative to 15-*(S)*-HPETE (1.0) were for 18:0/20:4 PCOOH (1.0) and for 16:0/18:2 PCOOH (3.5). HPETE, hydroperoxyeicosatetraenoic acid; PCOOH, phosphatidylcholine hydroperoxides.

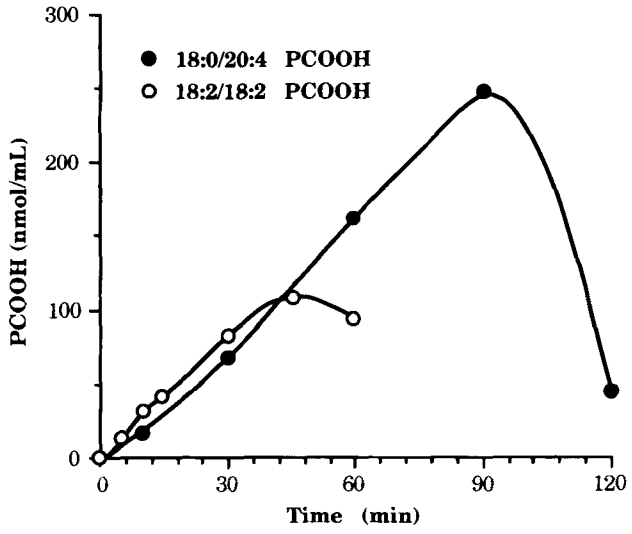

FIG. 4. Effect of incubation time with lipoxygenase on PCOOH production from 340 nmol of 18:2/18:2 PC (○) and 18:0/20:4 PC (●) per mL of incubation mixture. Abbreviations as in Figure 1.

Increasing concentrations (10–1000 nmol/mL of incubation mixture) of molecular species of standard or soybean PC and PE (18:2/18:2, 18:3/18:2, 18:0/20:4 and 16:0/18:2) were used to study the effect of phospholipid concentration on the rate of hydroperoxide production. Figure 5 shows the strong correlation between the amount of phospholipid present at T0 before peroxidation and that of the hydroperoxides detected after peroxidation. For a given concentration of 18:2/18:2 PC at T0, the concentration of hydroperoxides (Fig. 5A) was approximately twice that obtained with 16:0/18:2 PC (Fig. 5B), reflecting the importance of fatty acid unsaturation on hydroperoxide production.

The quantity of each molecular species transformed during 45 min of incubation was calculated as the difference between the concentration at T0 (start) and after 45 min of peroxidation (T45). This amount (T0–T45) was closely correlated to the concentration of the four molecular species at T0. Figure 6 shows the results obtained for 16:0/18:2 PC. Furthermore, the amount of phospholipid peroxidized was proportional to the number of double bonds in the constituent unsaturated fatty acids. For example, with 100 nmol of phospholipid at T0, 16.8 nmol of 16:0/18:2 PC was transformed, compared to 33.1 nmol of 18:2/18:2 PC (Table 1). We also assessed whether the amount of phospholipid transformed corresponded to the hydroperoxide concentrations determined by means of CL. Figure 7 shows, as an example, 16:0/18:2 PC, which was almost totally transformed into its hydroperoxide. Similar results were observed with 18:0/20:4 PC and 18:2/18:2 PC. However, this was only the case when the phospholipid concentrations at T0 were 50 nmol per mL or higher. At lower concentrations, the quantity of hydroperoxide produced was no longer related to the amount of molecular species transformed. Figure 7 shows that with 10–30 nmol/mL of phospholipid, similar amounts of hydroperoxide were detected. The procedure may not be suitable for

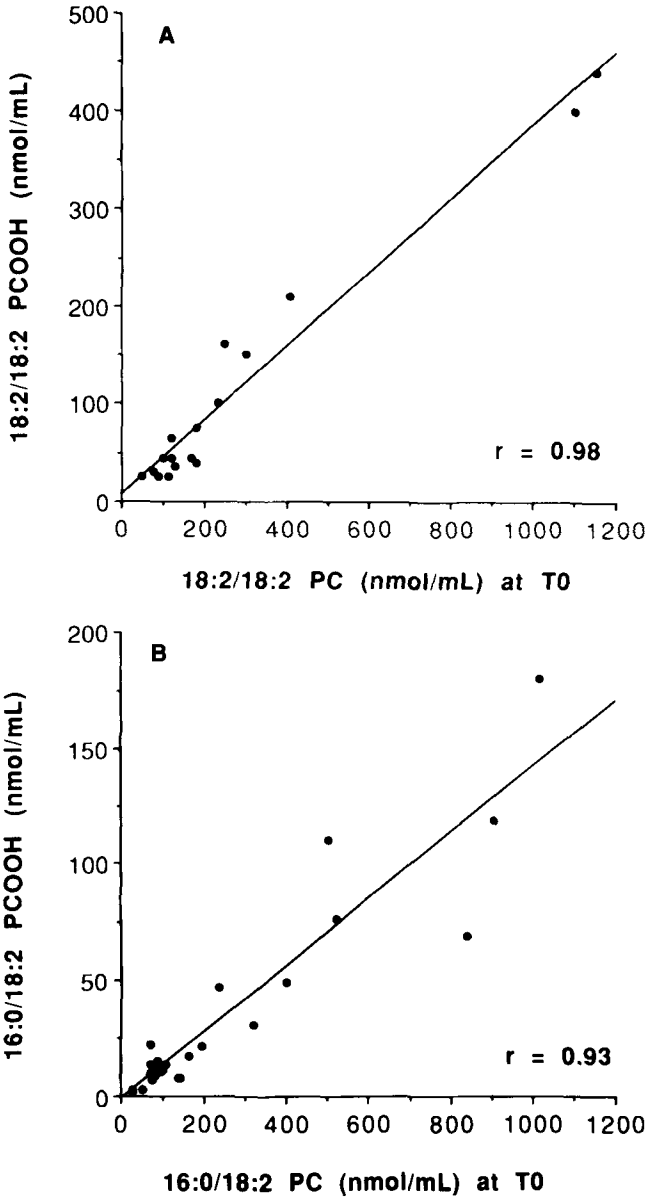

FIG. 5. Relationship between the concentration of 18:2/18:2 PC (A) and 16:0/18:2 (B) PC before peroxidation (T0) and the concentration of their corresponding PCOOH detected by chemiluminescence. Abbreviations as in Figure 1.

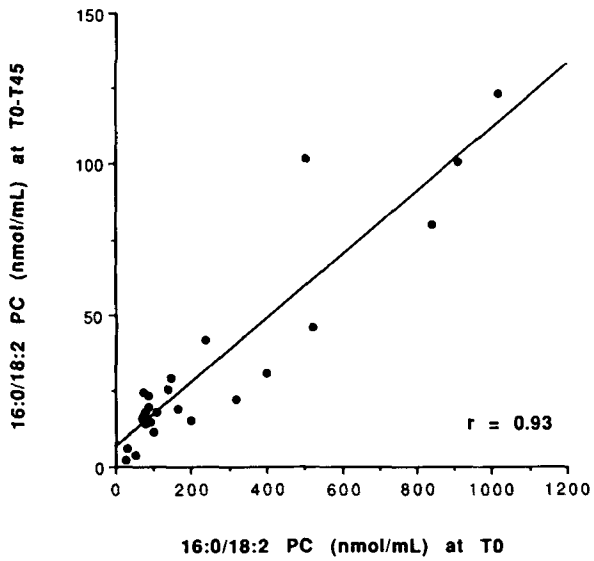

FIG. 6. Relationship between the concentration of 16:0/18:2 PC before (T0) and after peroxidation (T0–T45). Abbreviation as in Figure 1.

TABLE 1

Relationship Between the Amount of Phosphatidylcholine Molecular Species Transformed After Peroxidation and the Number of Double Bonds

Phospholipid molecular species (*sn*-1/*sn*-2)	Molecular species transformed[a] (nmol/mL)
18:3/18:2	42.3
18:2/18:2	33.1
18:0/20:4	30.5
16:0/18:2	16.8

[a]The concentrations of molecular species transformed were calculated from the regression line established for each molecular species, as shown in Figure 6, and expressed per 100 nmol of phosphatidylcholine per mL of incubation mixture.

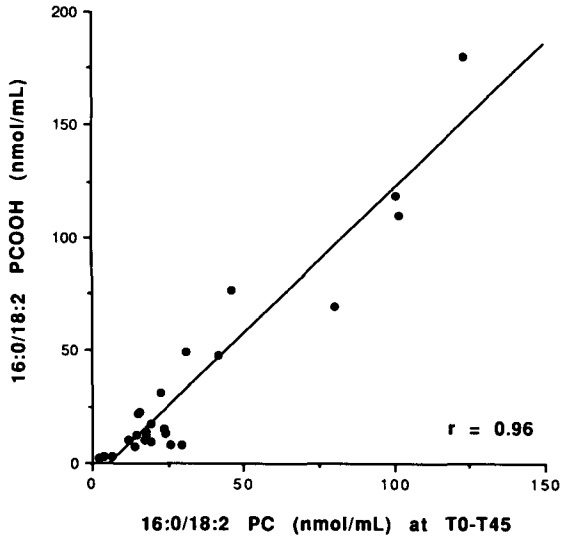

FIG. 7. Relationship between the concentration of transformed 16:0/18:2 PC after peroxidation (T0-T45) and the concentration of the corresponding PCOOH detected by means of chemiluminescence. Abbreviations as in Figures 1 and 2.

very low concentrations, possibly because the incubation time in the presence of lipoxygenase becomes too long, leading to degradation of the hydroperoxides produced.

In conclusion, the HPLC method described combines the separation of the main molecular species of phospholipids (PE, PC) and their corresponding hydroperoxides. The simultaneous determination of these products by spectrophotometry and CL allows quantification of both. The method should prove suitable for the analysis of molecular species in biological materials, such as in erythrocyte ghosts.

Enantiomeric Resolution of Diacylglycerol Derivatives by High-Performance Liquid Chromatography on a Chiral Stationary Phase at Low Temperatures

Toru Takagi* and **Toshiyuki Suzuki**
Department of Chemistry, Faculty of Fisheries, Hokkaido University, Hakodate, 041 Japan

Separation of 1,2-diacylglycerol (DG) enantiomers as their 3,5-dinitrophenylurethane derivatives by high-performance liquid chromatography on a chiral column (Sumichiral OA-4100) was significantly improved at low temperature, *e.g.*, at −30°C. A linear relationship between logarithmic retention volumes and the number of carbons and olefinic bonds of the DG enantiomers was obtained. The effects of temperature on the separation are discussed.
Lipids 28, 251–253 (1993).

We have recently been able to separate various 1,2-diacylglycerol (1,2-DG) enantiomers by high-performance liquid chromatography (HPLC) on chiral stationary phases (CSPs) as their 3,5-dinitrophenylurethane (3,5-DNPU) derivatives (1–3). These separations have proven very useful, but some problems remain. For example, improved enantioselectivity would often be desirable for the analysis of natural lipid mixtures.

In the present study, the effect of temperature on the enantiomer separation of 1,2-*rac*-DG was investigated with the goal to improve resolution. The CSP used in the present study also resolves DGs according to carbon number and the number of double bonds of the acyl groups. The effects of temperature are described.

MATERIALS AND METHODS

Samples. Enantiomers of 1,2- and 2,3-*sn*-DG were synthesized by the method of Howe and Malkin (4). DG racemates were obtained by interesterification of fatty acid methyl esters with glycerol in dimethylformamide. Separation of 1,2-*rac*-DG was carried out by thin-layer chromatography on silica gel G impregnated with boric acid, using hexane/diethyl ether (60:40, vol/vol) and chloroform/acetone (96:4, vol/vol) as developing solvents. Conversion of 1,2-*rac*-DG to the 3,5-DNPU derivatives was accomplished as described previously (5,6).

HPLC. HPLC separations were carried out using a Hitachi L-6200 instrument (Hitachi Ltd., Tokyo, Japan) equipped with a Shimadzu SPD-6A UV detector (Kyoto, Japan) and a chiral column (stainless-steel, 50 cm × 4 mm i.d.) packed with 5-μm particles of *N-(R)*-1-(α-naphthyl)-ethylaminocarbonyl-*(S)*-valine chemically bonded to γ-aminopropyl silanized silica (Sumichiral OA-4100, Sumitomo Chemical Co., Osaka, Japan). Analyses were done isocratically using a mixture of hexane/dichloroethane/ethanol as mobile phase at a constant flow rate. A Hitachi 638-0805 recycling valve (Hitachi Ltd.) was used (3). The column was put in a cylindrical tube (45 cm in height, 9 cm in diameter) along with an immersion cooler (Tokyo Rikakikai Co., Ltd., Tokyo, Japan). The temperature was maintained within about ±1.0°C. The solvent was not precooled before the injection system or before the column.

RESULTS AND DISCUSSION

Figure 1 shows the separation of a mixture of saturated 1,2-*rac*-DG homologues as 3,5-DNPU derivatives on Sumichiral OA-4100 at various temperatures. The homologue series was prepared by interesterification of a mixture of

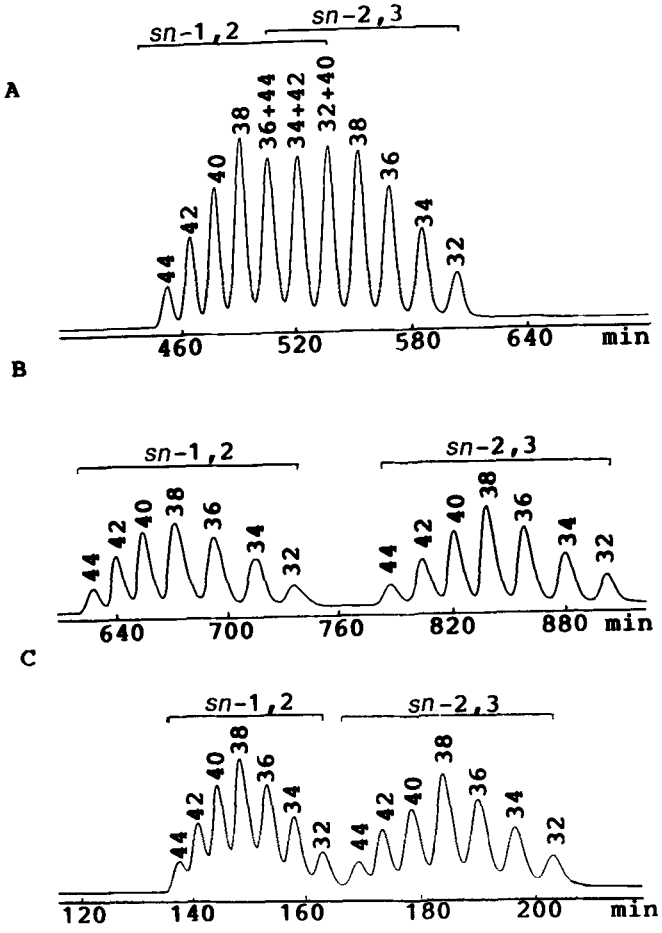

FIG. 1. Separation of saturated diacylglycerol (DG) enantiomers as 3,5-dinitrophenylurethane derivatives on an OA-4100 chiral column. A, temperature, 19.5°C; mobile phase, hexane/dichloroethane/ethanol (170:10:1, by vol); flow rate, 0.25 mL/min. B, temperature, −23.0°C; mobile phase, hexane/dichloroethane/ethanol (170:10:1, by vol); flow rate, 0.25 mL/min. C, temperature, −20.0°C; mobile phase, hexane/dichloroethane/ethanol (150:20:1, by vol); flow rate, 0.5 mL/min. Peaks were monitored at 254 nm after the first recycling. Above each peak the acyl carbon number of the DG is given.

four fatty acid methyl esters, namely 16:0, 18:0, 20:0 and 22:0, together with glycerol. The product therefore consisted of ten DG molecular species containing one or two of these four fatty acids. The mixture could be separated by HPLC on this CSP into seven DG homologues differing by two carbons in the acyl groups of each enantiomer because the CSP also provides for achiral separation according to carbon number and number of double bonds (3). Complete enantiomer separation of the seven DG homologues was obtained at −23°C (Fig. 1B), whereas the racemates were not separated on the same column at the higher temperature (19.5°C) (Fig. 1A). The separation factors (α) and peak resolutions (Rs) between the 1,2- and 2,3-enantiomers increased from 1.13–1.14 to 1.24–1.28, and from 4.33–5.07 to 9.64–11.13, respectively. For thermodynamic reasons (7), elution of the enantiomers was retarded by operating at the lower temperatures. We previously described (3) that the separation of enantiomeric 1,2-*rac*-DG homologues prepared from a mixture of those saturated fatty acids (16:0, 18:0, 20:0) required very long elution times (760 min) under the same chromatographic conditions as in Figure 1A.

In the present study, HPLC conditions were modified to accomplish a more rapid elution. This was done by selection of a more polar mobile phase and of a constant flow rate of 0.5 mL/min (Fig. 1C). The values of α and Rs of the enantiomers were 1.28–1.29 and 2.06–2.36, respectively.

Figure 2 shows the enantiomer separation by HPLC on the CSP as function of temperature of the 1,2-*rac*-DG prepared from 18:0 and 18:1 acids by transesterification with glycerol. Again, the better enantiomer resolution was obtained at the lower temperature (−10.5°C). The values of α and Rs for the enantiomers increased from 1.12 to 1.24, and from 3.41–3.44 to 6.05–6.28, respectively.

Very low HPLC column temperatures, *e.g.* −30°C as used in the separation shown in Figure 1B, often caused abnormal and sudden pressure increases, resulting in irregular chromatographic profiles and in peak deformations. These irregularities may in part be due to crystallization of the solutes and phase separation in the mobile phase consisting of a mixture of hexane, dichloroethane and ethanol. When these extra low temperatures were avoided, the retention times were reproducible and recoveries were quantitative.

Figure 3 shows the plots of the natural logarithm of retention volumes *vs.* acyl carbon numbers for the saturated DG. The two parallel lines are represented by the equations:

$$\ln \text{Vr}\ (sn\text{-}1,2) = h_c N + I \quad [1]$$

$$\ln \text{Vr}\ (sn\text{-}2,3) = h_c N + I + h_e \quad [2]$$

where corrected retention volume (Vr) (*sn*-1,2) and Vr (*sn*-2,3) are the retention volumes of 1,2- and 2,3-*sn*-DG enantiomers with the acyl carbon number N, respectively. The values of Vr were corrected by subtracting the column void volume; h_c (carbon number separation factor) and h_e (enantiomer separation factor) are the slopes of the lines and the distances between the two lines along the vertical axis, respectively. The value of I is a constant for the initial condition of Equation 1. This linear relationship between the logarithm of Vr and carbon numbers had also been found in the HPLC on CSP of a monoacylglycerol homologue mixture (8). The h_e value calculated from the linear relationship increased from 0.131 (24°C) to 0.230 (−12°C) by lowering the temperature. On the other hand, the value for h_c at 24°C and −12°C was 0.016. The results indicate that the separation of enantiomers is improved at lower temperature, while the resolution of DG molecular species according to carbon number is independent of temperature.

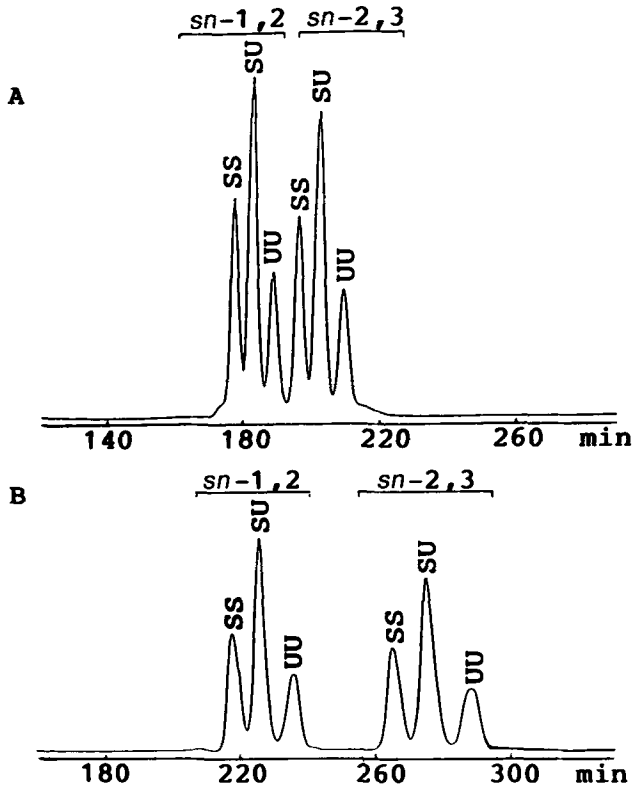

FIG. 2. Separation of diacylglycerol (DG) enantiomers prepared from stearic and oleic acids as 3,5-dinitrophenylurethane derivatives on an OA-4100 chiral column at different temperatures. A, 27.0°C. B, −10.5°C. Mobile phase, hexane/dichloroethane/ethanol (170:10:1, by vol); flow rate, 0.25 mL/min. SS, di-18:0-DG. SU, 18:0/18:1-DG. UU, di-18:1-DG. Peaks were monitored at 254 nm.

Figure 4 shows the plots of ln Vr *vs.* number of double bonds for DG prepared from 18:0 and 18:2 fatty acid mixtures. The linear relationships obey the equations:

$$h_d = \ln \text{Vr}\ (\text{SU-}sn\text{-}1,2) - \ln \text{Vr}\ (\text{SS-}sn\text{-}1,2)$$
$$= \ln \text{Vr}\ (\text{UU-}sn\text{-}1,2) - \ln \text{Vr}\ (\text{SU-}sn\text{-}1,2) \quad [3]$$

$$h_e = \ln \text{Vr}\ (sn\text{-}2,3) - \ln \text{Vr}\ (sn\text{-}1,2) \quad [4]$$

where S and U indicate saturated and unsaturated acyl groups, respectively; *e.g.*, SU stands for 18:0/18:2-DG. The h_e value is calculated from the distance between the two enantiomer lines, and the h_d value (double bond separation factor) is represented by the slope of the lines. Equation 3 was also applied to the *sn*-2,3-enantiomers, and the same h_d value can be expected for both antipodes as the lines for the two enantiomers are parallel. Higher values for h_e were obtained at lower temperature. The h_e value

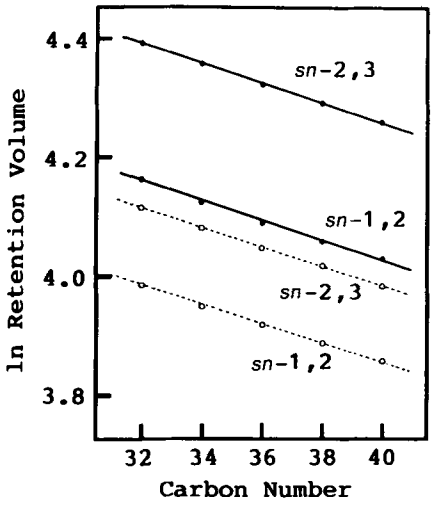

FIG. 3. Plots of ln retention volume *vs.* acyl carbon number for saturated diacylglycerol enantiomers as 3,5-dinitrophenylurethane derivatives on an OA-4100 chiral column at different temperatures. ●, −12.0°C. ○, 24.0°C. Mobile phase, hexane/dichloroethane/ethanol (170:10:1, by vol); flow rate, 0.25 mL/min.

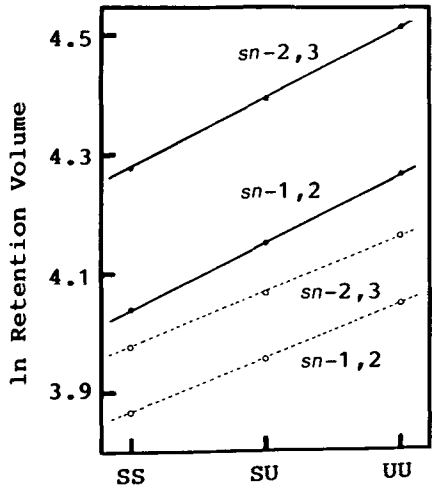

FIG. 4. Plots of retention volume *vs.* double bond number for diacylglycerol enantiomers prepared from stearic and linoleic acids as 3,5-dinitrophenylurethane derivatives on an OA-4100 chiral column at different temperatures. ●, −21.5°C. ○, 26.0°C. Mobile phase, hexane/dichloroethane/ethanol (170:10:1, by vol); flow rate, 0.25 mL/min.

of 0.245 obtained at −21.5°C is clearly much higher than that of 0.112 obtained at 26.0°C. In contrast, the h_d values increased from 0.092 (26°C) to 0.116 (−21.5°C) at lower temperature, that is, the slopes of the lines increased with decreasing temperature (Fig. 4). This trend was also noted for the other separations according to the number of double bonds, *e.g.*, for DG prepared from 18:0 and 18:3 acids. We found that the effect of temperature on the separation according to the number of double bonds increased with increase in the difference in number of olefinic bonds.

In present study we investigated the effects of temperature on the separations of DG according to enantiomeric configuration, carbon number and number of double bonds. We found that enantiomer separations were significantly improved by operating at low temperatures which give quantitatively correct and reproducible resolutions. Separation of DG molecular species according to carbon number was independent of temperature, whereas separation according to double bond was dependent on temperature.

On-Line Straight-Phase Liquid Chromatography/Plasmaspray Tandem Mass Spectrometry of Glycerolipids

Anders Valeur[a,*], **Peter Michelsen**[b] and **Göran Odham**[a]

[a]Division of Chemical Ecology, Lund University, Helgonavägen 5, S-223 62 Lund and [b]Hafslund Nycomed Innovation AB, Ideon, S-205 12 Malmö, Sweden

Class separation of common glycerolipids on a diol-phase liquid chromatography column with a gradient of the mixed solvents hexane/isopropanol/acetic acid/triethylamine is compatible with on-line plasmaspray ionization mass spectrometry. The positive ion mass spectra exhibit prominent diacylglycerol and monoacylglycerol derived fragments, which can be utilized for quantification. In the selected-ion monitoring mode, the detection limit for phospholipids is in the low nanogram range. The abundance of the diacylglycerol and monoacylglycerol fragments reflects the relative fatty acid composition of the phospholipid classes. Collision-induced decomposition of diacylglycerol fragments with argon as collision gas unambiguously reveals the chain length and degree of unsaturation of the esterified fatty acids in the native lipid. *Lipids 28,* 255–259 (1993).

Modern mass spectrometry (MS) with soft ionization techniques including true thermospray (TSP), "filament on" TSP, fast atom bombardment (FAB) and, most recently, discharge-assisted TSP (plasmaspray, PSP) have opened new possibilities for the characterization of glycerophospholipids with high sensitivity. The ionization techniques now available have permitted detailed investigations which were recently reviewed (1).

Among the soft ionization techniques used for phospholipids, FAB has become especially popular as it can usually provide information on molecular weight and partial fatty acid composition (2–5). Most FAB investigations, however, have been concerned with phospholipid classes isolated by thin-layer chromatography, for example, and not with on-line high-performance liquid chromatography/mass spectrometry (HPLC/MS). Although dynamic FAB is rapidly gaining widespread use and can be utilized in combination with HPLC, the chromatographic procedure is still inconvenient. For example, low solvent flows and ionization matrices, such as glycerol, must be used, calling for splitting of standard HPLC effluents or the use of microbore HPLC columns.

However, by using "filament on" TSP and conventional wide-bore HPLC/MS with ammonium acetate as electrolyte and a high percentage of hydrophobic solvents, Kim *et al.* (6–8) obtained detailed structural information on phospholipids, including the diacylglycerol/monoacylglycerol-derived fragments and acylium ions.

We recently showed (10) that the PSP ionization technique can provide significant advantages over "filament on" TSP as used by Kim and Salem (7) in regard to sensitivity and the range of HPLC mobile phases available. Our approach was to apply an HPLC procedure which would permit a class separation only. We examined two HPLC systems (11,12) of which we chose a cation exchange column and an acetonitrile/methanol/water mixture in an isocratic mode.

Quite recently, Herslöf *et al.* (13) have significantly improved class separations of a variety of glycerolipids, including the common intact glycerophospholipids, on a diol column with a gradient system involving hexane, isopropanol, acetic acid, triethylamine and water as mobile phase. The superiority of this separation procedure over that involving a cation-exchange column (10) led us to investigate its merits in combination with PSP ionization.

As previously pointed out (10), the TSP and PSP ionization methods frequently do not give the fatty acid composition of the intact glycerolipid unambiguously, based on the mass fragments formed. The number of combinations of fatty acids possible for a specific mass number of a diacylglycerol-derived fragment increases substantially with multiple unsaturation. The advantages of using on-line HPLC/MS/MS for the analysis of biological samples are presently being explored in our laboratories. To increase the structural information that can be obtained, we decided to study precursor/product relationships of glycerolipids upon collision of diacylglycerol-derived ions with certain reagent gases. The present paper describes experiments on the use of HPLC/MS/MS for structure determinations of intact glycerolipids.

MATERIALS AND METHODS

Chemicals and solvents. Triolein, 1,2-dilauroyl-3-stearoyl-*sn*-glycerol (12:0/12:0/18:0), 1-*O*-hexadecyl-2-3-dimyristoyl-*sn*-glycerol (16:0Et/14:0/14:0), 1,2-dipalmitoyl-*sn*-glycero-3-phosphate [16:0/16:0-phosphatidic acid (PA)], 1,2-distearoyl-*sn*-glycero-3-phosphocholine [18:0/18:0-phosphatidylcholine (PC)], 1-palmitoyl-2-linoleoyl-*sn*-glycero-3-phosphoethanolamine [16:0/18:2-phosphatidylethanolamine (PE)], 1,2-dioleoyl-*sn*-glycero-3-phosphoethanolamine (18:1/18:1-PE) and phosphatidylinositol [soybean phosphatidylinositol (PI)] were used as reference compounds.

1,2-Dipalmitoyl-*sn*-glycero-3-phosphate, 1,2-distearoyl-*sn*-glycero-3-phosphocholine and 1,2-dioleoyl-*sn*-glycero-3-phosphoethanolamine were from Serdary Ltd. (London, Ontario, Canada), triolein and PI were purchased from Larodan (Malmö, Sweden). 1-Palmitoyl-2-linoleoyl-*sn*-glycero-3-phosphoethanolamine were purchased from Sigma (St. Louis, MO). 1,2-Dilauroyl-3-stearoyl-*sn*-glycerol and 1-*O*-hexadecyl-2,3-dimyristoyl-*sn*-glycerol were prepared in the laboratory (14). All reference materials were stored under N_2 at −20°C until used.

The solvents used were from FSA Lab Supplier (Loughborough, England), or from May and Baker Ltd. (Dagenham, England). They were of HPLC grade and were used without further purification.

Bacterial samples. Pseudomonas fluorescens cells were grown, harvested and extracted for total lipids by Bligh

Abbreviations: CID, collision induced decomposition; FAB, fast atom bombardment; HPLC/MS, high-performance liquid chromatography/mass spectrometry; MS, mass spectrometry; PA, phosphatidic acid; PC, phosphatidylcholine; PE, phosphatidylethanolamine; PG, phosphatidylglycerol; PI, phosphatidylinositol; PSP, plasmaspray; TIC, total ion current; TSP, thermospray.

and Dyer (9) extraction as described previously (10). Freeze-dried cells (600 mg) yielded phospholipids which were dissolved in 1 mL of mobile phase (A) (see below).

Liquid chromatography. Class separations were performed by using a column packed with diol-modified silica (E. Merck, Darmstadt, Germany; Li-Chrosphere 100 Diol, 5 μm, 25 cm × 4 mm i.d.). The mobile phase was a modification of the method developed by Herslöf *et al.* (13) and consisted of (A) hexane/isopropanol/acetic acid/triethylamine (75:25:7.5:0.05, by vol) and (B) hexane/isopropanol/acetic acid/triethylamine (21:78:1.5:0.05, by vol) in a linear gradient from 100% of (A) to 100% of (B) during 25 min at a flow rate of 0.8 mL/min (13).

A Waters (Milford, MA) model 600-MS HPLC pump equipped with a variable-volume Waters model U6K injector was used. Samples injected were typically 10–20 μL from solutions containing 1 μg/μL of phospholipids.

MS. The effluent from the column was introduced into a Trio 3 (VG Masslab, Altrincham, United Kingdom) tandem quadrupole mass spectrometer through the standard liquid chromatography/MS thermospray/plasmaspray probe. The vaporizer capillary was at a temperature of 240–260°C, the ion source was at 280°C, the discharge current 500–700 μA and the repeller voltage typically between 95–110 V depending on source conditions. Collision-induced decomposition (CID) was achieved by using helium, argon or xenon at pressures between 1×10^{-4} to 5×10^{-2} mbar (measured in the collision cell) and at energies between 0-20 eV. A standard VG 11/253 data system configuration was employed for mass spectral data acquisition.

A cold trap (liquid nitrogen) was installed between the source diffusion pump and the backing rotary pump to prevent contamination of the pump oil by the hydrophobic HPLC solvents used.

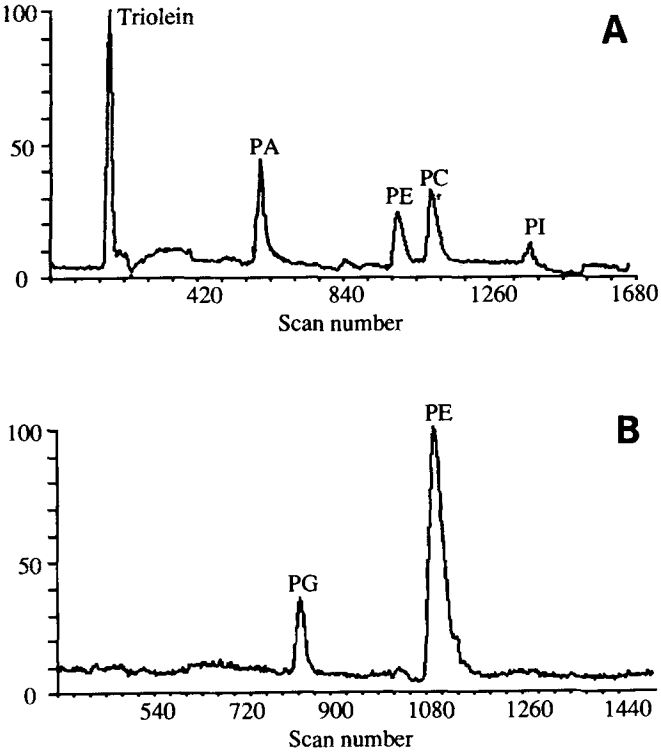

FIG. 1. A. Positive ion plasmaspray mass chromatogram of a mixture of glycerolipids consisting of: triolein, 1,2-dipalmitoyl-*sn*-glycero-3-phosphate (PA), 1,2-dioleoyl-*sn*-glycero-3-phosphoethanolamine (PE), 1,2-distearoyl-*sn*-glycero-3-phosphocholine (PC) and phosphatidylinositol (PI from soybean). B. Positive ion plasmaspray mass chromatogram of a total Bligh and Dyer (9) lipid extract from *Pseudomonas fluorescens* cells showing two peaks containing phosphatidylglycerol (PG) and PE species.

RESULTS AND DISCUSSION

Separation of glycerolipid classes. The positive ion mass chromatogram in PSP [total ion current (TIC) scanning over the range of *m/z* = 120–600] using the diol column and gradient mobile phase system as described above is shown in Figure 1A. The chromatographic peaks represent 76, 24, 25, 25 and 10 μg for triolein, PA, PE, PC and PI, respectively. Good chromatographic peak shape is obtained for all glycerolipid classes studied, including PI which is a natural complex species mixture (see below) isolated from soybeans. Moreover, the gradual change of solvent composition during the chromatographic run does not require modification of the ion source PSP parameters.

A phospholipid extract from bacterial cells *(P. fluorescens)* was also studied by PSP under the same chromatographic conditions (Fig. 1B). Only two glycerophospholipid classes are distinguishable, phosphatidylglycerol (PG) and PE, in agreement with the previously-reported phospholipid composition (15). As both mass chromatograms indicated excellent class separation characteristics with negligible or no apparent molecular species separation (that is PI in Fig. 1A, PG and PE in Fig. 1B), the ions forming the PE peak (Fig. 1B) from *P. fluorescens* (scan numbers 1100–1150) were studied in some detail. The abundances of the diacylglycerol-derived fragment cluster (*m/z* = 540–610) in all spectra within the PE peak were plotted three-dimensionally as a function of the scan numbers (Fig. 2). The diacylglycerol-related portion of the PSP mass spectrum averaged over the entire peak is shown on top. The results indicate a slightly shorter retention time of phospholipids with longer fatty acid chains (*i.e.*, *m/z* = 604 corresponding to 36 fatty acid carbon atoms) compared to phospholipids with shorter fatty acids (*m/z* = 550 corresponding to 32 fatty acid carbon atoms).

Relative fatty acid composition. The fatty acid composition of a PI from soybean was calculated by measuring the mean ion intensities of the monoacylglycerol and diacylglycerol related fragments from a series of full-scan spectra of variable amounts (5, 12.5, 25 and 32 μg) of phospholipid. In Figure 3, the amount of fatty acids present represented as wt% of the total fatty acids, has been reproduced as calculated either from the monoacylglycerol related ions or from the diacylglycerol related ions. For comparison, results from conventional gas chromatographic fatty acid analysis after transesterification (Larodan, Malmö, Sweden) have been incorporated in the figure. Apart from minor components (*i.e.*, 18:3) which fall below the detection limit in full-scan, there is a good agreement between MS measurements on intact phospholipids and gas chromatography measurements of total fatty acid methyl esters.

PSP spectra of triacylglycerol and 1-O-alkyl-2,3-diacyl-sn-glycerols. We have also studied the MS fragmentation of some nonphosphatidic glycerolipids using PSP

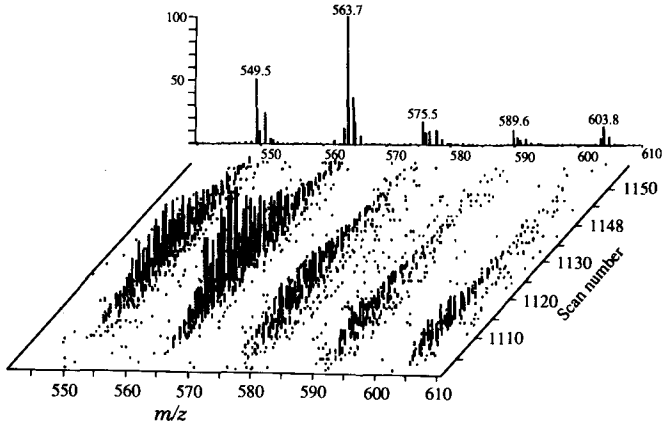

FIG. 2. Three-dimensional presentation of the diacylglycerol-derived fragments (m/z = 540–610) extracted from the phosphatidylethanolamine (PE) peak in Figure 1B. The upper spectrum shows the average intensities of the peak.

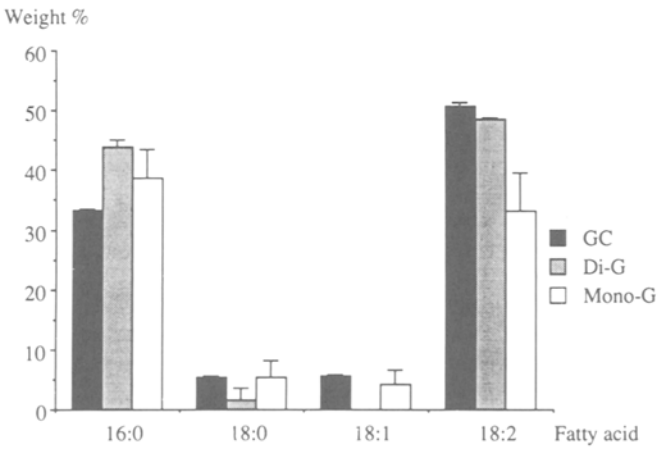

FIG. 3. Fatty acid composition of phosphatidylinositol from soybean determined by gas chromatography (GC) and by plasmaspray mass spectrometry calculated from the total counts of the intensities of the diacylglycerol-derived (Di-G) and the monoacylglycerol-derived (Mono-G) fragments.

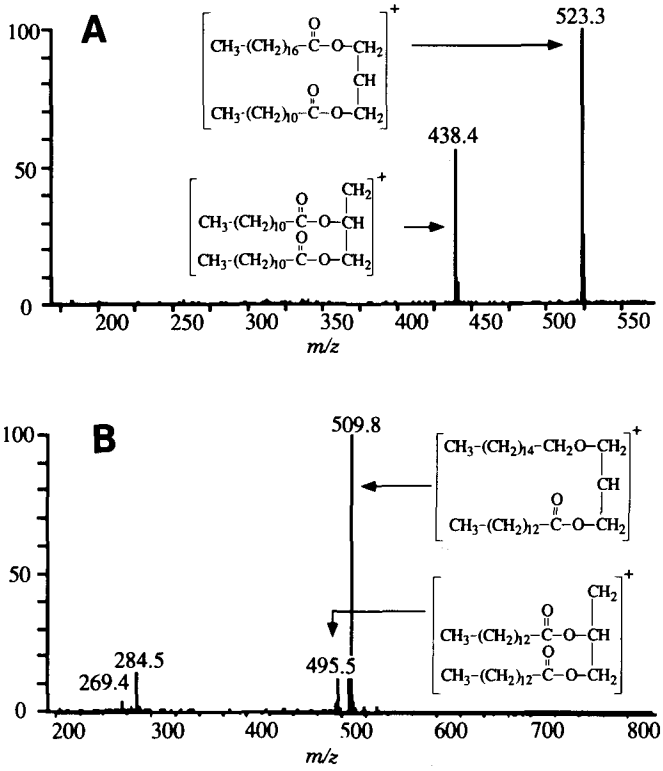

FIG. 4. Positive ion plasmaspray spectrum of A, 1,2-dilauroyl-3-stearoyl-*sn*-glycerol, and B, 1-*O*-hexadecyl-2-3-dimyristoyl-*sn*-glycerol.

ionization. Figure 4A shows the positive ion PSP spectrum of 10 μg of 1,2-dilauroyl-3-stearoyl-*sn*-glycerol. As for the phosphatides, no $(M + H)^{+1}$ ions are seen in PSP. The spectrum shows only the two possible diacylglycerol related fragments, formed by loss of a fatty acid from either position of the protonated molecule.

In Figure 4B, a spectrum of 1-*O*-hexadecyl-2-3-dimyristoyl-*sn*-glycerol has been reproduced. Similar cleavage mechanisms as operate for the triacylglycerol are seen. Notably, cleavage with loss of the carboxylic acid (α- and β-carbon atom) from the protonated molecule (m/z = 509) is a more prominent process than that involving formal loss of the alcohol group (m/z = 495).

Quantification. Previous preliminary studies on the quantification of phospholipids by using PSP and the cation HPLC column with an acetonitrile/methanol/water mixture indicate that straightforward procedures can be used to give linear dose-response curves. Such studies were repeated in some detail for several phospholipid classes by using the diol column and the hydrophobic solvent mixtures used in this work. Figure 5 shows dose response curves for PA, PC and PE (all dipalmitoyl substituted) measured by single ion monitoring of the m/z = 551 ion (diacylglycerol related fragments). The responses exhibit good linearity for all molecular species ($r^2 > 0.99$), and an intercept at the origin indicates negligible adsorption and/or breakdown in the chromatographic and interface system. At a signal-to-noise ratio of 3:1, the detection limit is approximately 3 ng. The ionization tendencies for the phospholipid classes investigated are in the same order of magnitude. Sensitivity in selected ion monitoring (SIM) is comparable with that obtained in the previously used liquid chromatographic system, providing a detection limit in the low nanogram range (10).

In another experiment, we compared the sensitivity of two PC molcules with different chain-lengths (dipalmitoyl and dioctanoyl PC). We found that the relative sensitivity between the long and short chain lengths is dependent on the experimental conditions, *i.e.*, tuning of the ion source, the cleanness of the source and the capillary vaporizer, but reproducibility under set conditions was found to be satisfactory.

CID measurements. PSP ionization of a phospholipid with a defined fatty acid composition was studied. Figure 6A shows the PSP positive ion mass spectrum of 1-palmitoyl-2-linoleoyl-*sn*-glycero-3-phosphoethanolamine. As expected, diacylglycerol related fragments are present at m/z = 575 (18:2 + 16:0). The spectrum further shows two monoacylglycerol related fragments at m/z = 337 (18:2) and m/z = 313 (16:0).

The mass spectrometer was arranged for MS/MS measurements in the precursor/product mode. A CID mass

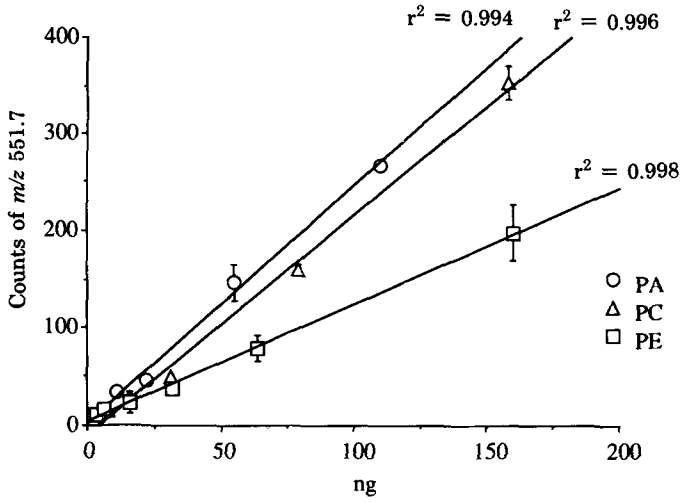

FIG. 5. Dose response curves of the diacylglycerol related fragments (*m/z* = 551) from 1,2-dipalmitoyl-*sn*-glycero-3-phosphate [16:0/16:0-phosphatidic acid (PA)], 1,2-dipalmitoyl-*sn*-glycero-3-phosphocholine [16:0/16:0-phosphatidylcholine (PC)], and 1,2-dipalmitoyl-*sn*-glycero-3-phosphoethanolamine [16:0/16:0-phosphatidylethanolamine (PE)] measured in single ion mode.

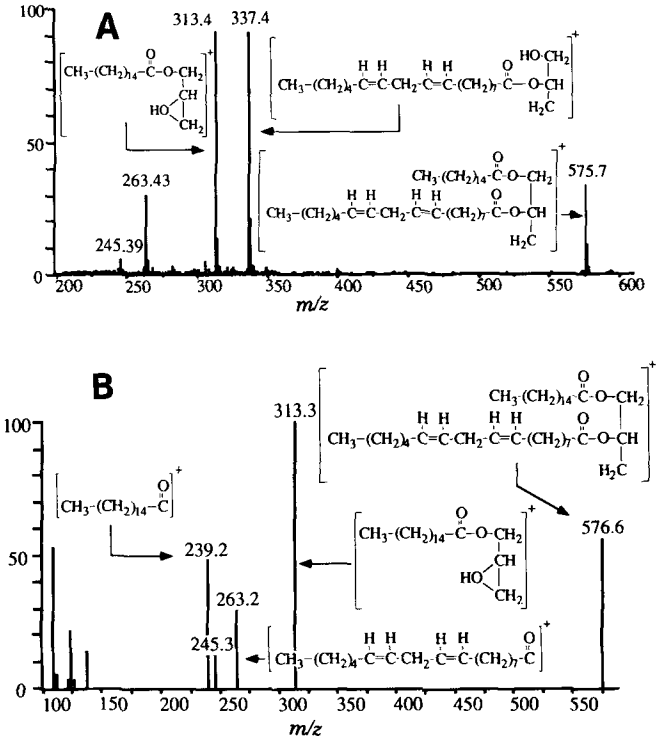

FIG. 6. A. Positive ion plasmaspray of 1-palmitoyl-2-linoleoyl-*sn*-glycero-3-phosphoethanolamine. B. Collision-induced decomposition of the diacylglycerol-derived fragment *m/z* = 575.5, showing the most abundant product ion, *m/z* = 313.3

spectrum of the diacylglycerol related fragments (*m/z* = 575) using argon as collision gas at a pressure of 10^{-3} torr, and a collision energy of 3 eV is shown in Figure 6B. The spectrum indicates in the high mass range the presence of undecomposed precursor ions at *m/z* = 575 and prominent monoacylglycerol related fragments at *m/z* = 313. Acylium ions at *m/z* = 263 and 239 of both fatty acids are observed in the spectrum corresponding to 18:2 and 16:0 fatty acids, respectively. The spectrum further indicates subsequent fragmentation of the fatty acid residues leading to a series of low mass fragments. The CID experiment thus unequivocally reveals fatty acid composition.

As an application, the fatty acid composition of PI from soybeans was examined. The three most abundant diacylglycerol related fragments as indicated from the full spectrum (Fig. 7) were analyzed by using precursor/product MS/MS as described above.

The three MS/MS product ion spectra of the precursor diacylglycerol related ions as shown in Figure 7 give information on the fatty acid species. The diacylglycerol related ions of *m/z* = 575.6 consist of an 18:2 fatty acid moiety (acylium ions of *m/z* = 263.3) and a 16:0 fatty acid (monoacylglycerol related ion of *m/z* = 313.3). Analogously, the H_2O adduct of the diacylglycerol related ions of *m/z* = 591.7 consists of an 18:3 acylium ion (*m/z* = 261.2) and a 16:0 acid (*m/z* = 313.3). The diacylglycerol-related ions of *m/z* = 603.3 have an 18:0 acid (*m/z* = 341) and a 18:2 acid (*m/z* = 263.3).

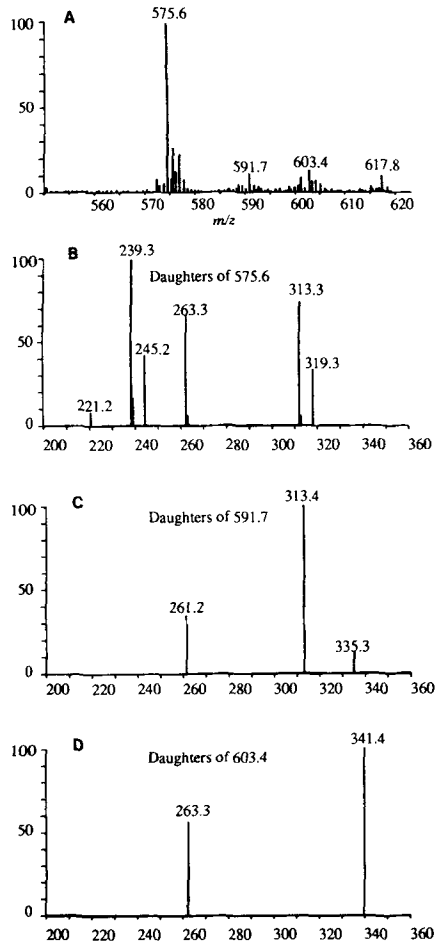

FIG. 7. A. Mass spectrum of phosphatidylinositol from soybean, and B, the collision-induced decomposition product ion spectra of the precursor ions of *m/z* = 575.6, C, of *m/z* = 591.7, and D, of *m/z* 603.4.

Changing the collision energy indicates that useful information was obtained only within a rather narrow ion energy range. For example, at 3 eV there is practically no decomposition of the precursor fragments whereas at 20 eV the CID spectrum only showed unspecific fragments of low mass. There are no major qualitative differences in the spectra when the collision gas Ar was replaced by He or Xe as long as the collision energy and pressure are adjusted accordingly for each. Argon was found to be the collision gas of choice, because adequate fragmentation was obtained at convenient gas pressures and collision energies.

CID after PSP ionization offers excellent possibilities to study glycerophospholipid molecules in detail. It is possible to obtain information on the fatty acid composition of individual species within phospholipid classes.

A Thermospray Mass Spectrometric Assay for Fe-Induced 4-Hydroxynonenal in Tissues

W. John Blanchflower*, Dominic M. Walsh[1], Seamus Kennedy and D. Glenn Kennedy
Veterinary Sciences Division, Department of Agriculture For Northern Ireland, Stormont, Belfast BT4 3SD, Northern Ireland, United Kingdom

A method is presented for the determination of 4-hydroxynonenal (HNE) in tissue homogenates following *in vitro* lipid peroxidation induced by iron (Fe^{++}). HNE is measured as the pentafluorobenzyl oxime derivative using liquid chromatography thermospray mass spectrometry. *In vitro* metabolism of HNE *via* the glutathione/glutathione-*S*-transferase pathway was inhibited using iodoacetic and iodobenzoic acids. The assay has been used as an indicator of the peroxidizability of tissue samples from animals both adequate in and depleted of α-tocopherol. The concentrations of HNE produced in tissues taken from animals depleted of α-tocopherol were found to be up to 8 times higher than those taken from animals supplemented with α-tocopherol.
***Lipids* 28, 261-264 (1993).**

Lipid peroxidation has been implicated in causing a wide range of biological effects (1,2) including heart disease, aging, retinal degeneration and cancer. Many tests have been proposed as indicators of lipid peroxidation in biological systems. Techniques for measuring primary lipid peroxidation products such as lipid hydroperoxides have included high-performance liquid chromatography (HPLC) with electrochemical (3) or chemiluminescent (4) detection and gas chromatography/mass spectrometry (GC/MS) of the methyl, trimethylsilyl and pentafluorobenzyl (PFB) esters of the hydroxy derivatives of the lipid hydroperoxides (5). Assays have also been developed to measure secondary lipid peroxidation products such as thiobarbituric acid reactive substances (TBARS; Ref. 6), conjugated dienes (7), alkanes such as ethane and pentane (8), and aldehydes such as hexanal (9) and 4-hydroxynonenal (HNE; Refs. 10,11).

The latter aldehyde is formed through the oxidation of linoleic or arachidonic acid (12,13) and has received much attention in the last few years. It has been shown to be cytotoxic and can exhibit a wide range of potent biological effects (14-17). It is also highly reactive toward molecules containing sulfhydryl groups such as reduced glutathione (GSH), cysteine and proteins in general (18,19).

Several techniques have been proposed for measuring HNE in biological samples. These methods have recently been reviewed (20) and include HPLC of the fluorescent decahydroacridine derivatives of HNE (21) and GC/MS of the butyldimethylsilyl (22) or PFB oxime derivatives (10,11). However, as mentioned above, HNE is highly reactive toward a wide range of cellular components. One study by Ishikawa *et al.* (23) showed that the half life of HNE in perfused rat heart was less than 4 s as a result of the conjugation of HNE to GSH, catalyzed by glutathione-*S*-transferase (GSHT) [E.C. 2.5.1.18]. Therefore it is unclear what proportion of the HNE originally present in the tissues can be recovered and measured by any of these procedures, since any free HNE may have been rapidly metabolized or irreversibly bound to cellular macromolecules. This problem is compounded by the possibility that some HNE may be formed during the work-up procedures. An alternative approach would be to analyze HNE in tissue samples in a way similar to that of measuring TBARS following ascorbate- or Fe^{++}-induced *in vitro* lipid peroxidation (24). This paper describes a method in which tissue homogenates are first treated with inhibitors of GSHT and then incubated with Fe^{++} to induce the production of HNE. This aldehyde is then measured using liquid chromatography/thermospray mass spectrometry (LC/MS) following derivatization with PFB hydroxylamine hydrochloride. The method has been used to measure the *in vitro* production of HNE following Fe^{++}-initiated peroxidation of muscle homogenates from cattle and pigs either supplemented with or depleted of α-tocopherol.

MATERIALS AND METHODS

Materials. HNE was kindly provided by Professor H. Esterbauer, Department of Biochemistry, University of Graz, Austria. It was supplied as a 50-60 mmol/L stock solution in dichloromethane and was stored at −20°C until required. An aliquot of this solution (500 μL) was evaporated to dryness under nitrogen at room temperature. The residue was dissolved in water (5 mL) by shaking. This solution was used as a stock standard and was stable for several months at 4°C. The exact concentration of HNE in this solution was determined by diluting 100 μL with 9.9 mL water and recording the ultraviolet spectrum in a 1-cm cuvette from 200-300 nm. The concentration was determined using the molar extinction coefficient of 13750 at 223 nm. Dilute standards (10 μM) were freshly prepared from the stock standard in water as required.

Piperazinediethanesulfonic acid (PIPES), PFB hydroxylamine hydrochloride, iodoacetic acid (IAA) and *o*-iodobenzoic acid (IBA) were obtained from Sigma Chemical Co. (St. Louis, MO). Acetonitrile, tetrahydrofuran, methanol and hexane were all HPLC-grade.

Tissue α-tocopherol concentrations. These were measured using HPLC with fluorescence detection, essentially as described by McMurray and Blanchflower (25).

Extraction of HNE from tissue and derivatization. Samples of tissue (0.5 g) were homogenized in ice-cold 25 mM PIPES buffer, pH 7.0 (9.5 mL), using a Silverson

Abbreviations: Fe^{++}, iron(II) ion; GC/MS, gas chromatography/mass spectrometry; GSH, reduced glutathione; GSHT, glutathione-*S*-transferase; HNE, 4-hydroxynonenal; HPLC, high-performance liquid chromatography; IAA, iodoacetic acid; IBA *o*-iodobenzoic acid; LC/MS, liquid chromatography/thermospray mass spectrometry; PFB, pentafluorobenzyl; PIPES, piperazinediethanesulfonic acid; SIM, selected ion monitoring; TBARS, thiobarbituric acid reactive substances.

homogenizer (Silverson Machines, Chesham, United Kingdom) for about 1 min, followed by 10 strokes in a Dounce homogenizer (Thomas Scientific, Swedesboro, NJ). Samples were freshly prepared and kept on ice at all times.

Aliquots of homogenate (1.0 mL) were transferred to test tubes to each of which was added mixed inhibitor solution (100 μL) containing 10 mM IAA and 10 mM IBA, dissolved in water. Following incubation for 10 min at 37°C in a shaking water bath, iron(II) sulfate (100 μL of a 7.2 mM aqueous solution) was added, and the samples were incubated for a further 45 min. Methanol (2 mL) was added, and the tubes were centrifuged at 2000 × *g* for 10 min at 4°C. Aliquots of supernatant (2.0 mL) were transferred to clean tubes. Standards (50 μL of 10 μM HNE) were also set up at this point, and the volumes of the tubes were adjusted to 2.0 mL using methanol/water (2:1, vol/vol). Aliquots of PIPES buffer (1.0 mL of a 25 mM aqueous solution, pH 7.0) and PFB hydroxylamine hydrochloride (100 μL of a 50 mg/mL freshly prepared solution in methanol) were added to all tubes. After standing at room temperature for 30 min, the mixtures were extracted with hexane (2 × 1 mL) by shaking for 30 s and centrifuging at 2000 × *g* at 4°C for 10 min. The hexane extracts were combined and evaporated to dryness under nitrogen at 50°C. The residues were dissolved in HPLC mobile phase (100 μL).

Analysis of HNE using thermospray LC/MS. The HPLC system consisted of a Merck-Hitachi (BDH Ltd., Dagenham, United Kingdom) model L-6000 pump, a Rheodyne (Rheodyne Inc., Cotati, CA) model 7125 injector fitted with a 50 μL sample loop and a Lichrosorb (BDH Ltd.) RP18, endcapped, 125 × 4 mm reverse-phase cartridge with holder. The mobile phase, acetonitrile/tetrahydrofuran/water (75:5:20, by vol), was pumped at a rate of 1.0 mL/min. This system was directly coupled to a Vestec model 201A thermospray LC/MS (Vestec Corporation, Houston, TX) complete with a Technivent workstation. The instrument was operated in the negative ion mode, using filament-initiated ionization with an electron beam current of 250 μA. The electron multiplier voltage was 1600 V. The temperatures of the source block, tip heater and lens assembly were 280, 250 and 150°C, respectively. The vaporizer probe was operated at about 15°C below the take-off point. This was optimized for each probe used but was typically in the region of 170°C. The instrument was operated either in the full scan mode to collect spectra, or in the selected ion monitoring (SIM) mode for maximum sensitivity.

Aliquots (25 μL) of the derivatized standards and sample extracts were injected into the LC/MS system. A standard was injected after every four samples to correct for drift, if any. SIM data were collected for the negative ion at *m/z* 331. The concentrations of HNE in samples were calculated from peak areas by comparison with standards.

Data. Where appropriate, data are presented as means ± SE. Comparisons between the α-tocopherol and HNE concentrations in tissue were by Student's *t*-test.

RESULTS AND DISCUSSION

The thermospray LC/MS negative ion spectrum for the PFB derivative of HNE is shown in Figure 1, together with the molecular structure of this derivative. This spectrum is unusual for thermospray LC/MS, when the base

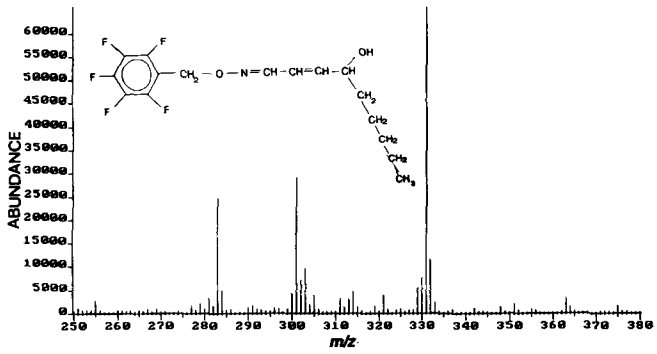

FIG. 1. Negative ion liquid chromatography/thermospray mass spectrometry spectrum and structure of the pentafluorobenzyl hydroxylamine derivative of 4-hydroxynonenal.

peak is normally the molecular ion (M), M + 1, or M − 1. In this case only a small molecular ion at *m/z* 351 is seen. The base peak fragment ion at *m/z* 331 probably results from the loss of hydrogen fluoride from the molecule and is the most sensitive ion to use for SIM. It is interesting to note that the best sensitivity is obtained without the addition of ammonium acetate to the HPLC mobile phase, a normal requirement of LC/MS.

Few authors have quoted recovery values for HNE from whole tissue homogenates. Norsten-Höög and Cronholm (22) reported a recovery of 84% from hepatocytes. They did not, however, quote a figure for liver homogenates, but gave a recovery value of 60% for their internal standard, cyclohexanone.

In the present study, initial attempts to measure analytical recoveries were disappointing. Therefore two approaches were attempted to improve the recovery of HNE from tissue homogenates, namely disruption of protein binding and inhibition of the GSH/GSHT conjugation pathway.

Hydroxylamine (22) or PFB hydroxylamine (11) have previously both been added to biological samples to recover HNE conjugated to protein, but the authors offered no evidence as to the efficacy of these procedures. We observed that HNE added to tissue homogenates disappears rapidly (80% in 5 min) and could not be recovered by these techniques (data not shown). It would therefore appear that protein conjugation is not the major problem causing poor recoveries, but that HNE is being rapidly metabolized *in vitro* by tissue homogenates.

Ishikawa *et al.* (23) have shown that HNE can react spontaneously with GSH, but that the rate of the reaction is increased 30-fold when catalyzed by GSHT. These workers estimated the half life of HNE in heart as less than 4 s, under the conditions used. Alin *et al.* (26) concluded that spontaneous reaction between GSH and HNE was negligible and that one of the major functions of GSHT was to protect the cell from the cytotoxic action of aldehydes such as HNE. However, Pabst *et al.* (27) showed that the GSHT-catalyzed conjugation of HNE to GSH could be inhibited by IAA and IBA. The effect of adding these substances to tissue homogenates carried through the described assay is shown in Figure 2. In the untreated homogenate, there was no increase in the HNE concentration for the first 30 min of incubation time, whereas in the inhibitor-treated homogenate there was a steady increase in HNE production. This showed that the

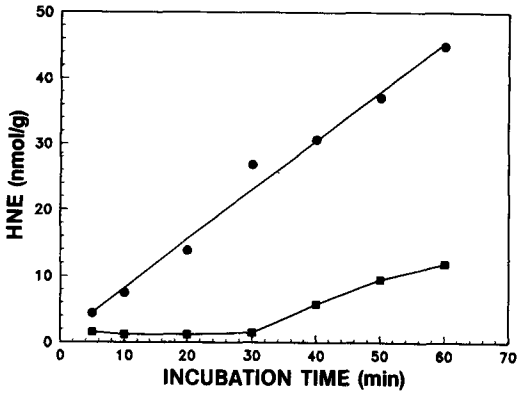

FIG. 2. Time course of the *in vitro* Fe^{++}-induced production of 4-hydroxynonenal by a tissue homogenate with (●) or without (■) incubation with iodoacetic and iodobenzoic acids as inhibitors of glutathione-*S*-transferase.

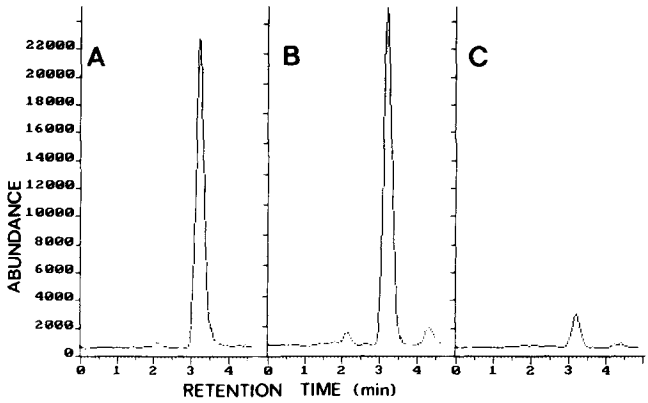

FIG. 3. Selected ion monitoring chromatograms of the negative ion at *m/z* 331 for the pentafluorobenzyl hydroxylamine derivative of 4-hydroxylnonenal from (A) a 10 μM standard solution, (B) a heart muscle homogenate from a α-tocopherol deficient pig and (C) a heart muscle homogenate from an α-tocopherol supplemented pig. The assays were performed as described in the text. 4-Hydroxylnonenal eluted from the column at a retention time of 3.2 min.

HNE produced in the untreated homogenate was being rapidly metabolized by the GSH/GSHT pathway; a rise only became apparent after 30 min, possibly as a result of GSH depletion. The inhibitors IAA and IBA therefore blocked this reaction in the treated homogenate which showed a 4-fold increase in HNE concentration after a 45-min incubation period, when compared with untreated homogenate.

In the described assay, recovery values were determined by spiking muscle homogenates with HNE, following treatment with IAA and IBA, incubation with Fe^{++} and then proceeding as described in the assay. The recovery values averaged 65% (Table 1), confirming that IAA and IBA had effectively blocked the reaction with GSH/GSHT. The losses of HNE (35%) may have been due to binding to other macromolecules, but this could not be confirmed.

Single ion chromatograms of the ion at *m/z* 331 are shown in Figure 3 for a standard and for heart muscle homogenates from α-tocopherol deficient and α-tocopherol supplemented pigs. The HNE derivative eluted from the column with a retention time of 3.2 min and was apparently free from interference by other compound eluting closely. The standard is equivalent to 16.1 nmol HNE/g sample. The concentrations of HNE induced in the muscle samples from the α-tocopherol deficient and α-tocopherol supplemented pigs were 17.8 and 1.9 nmol/g, respectively.

TABLE 1

Recovery of HNE from Muscle Homogenate[a]

HNE added (nmol)	HNE recovered (nmol)	Recovery (%)
0.00	0.10	—
0.32	0.32	66
0.64	0.51	64
1.28	0.93	65

[a]Aliquots (1.0 mL) of muscle homogenate, with added 4-hydroxynonenal (HNE) at the levels indicated, were carried through the described assay. Results are the mean of duplicate determinations.

The reproducibility of the assay was determined by analyzing six times two samples of masseter muscle and was found to produce relatively low and high concentrations of HNE following Fe^{++} stimulation. The values found for mean (SE) and coefficent of variation (CV) were 3.90 (0.16) nmol/g and 9.7% in the low sample and 51.3 (2.34) nmol/g and 11.1% in the high sample.

The assay has been used to measure "peroxidizability" of liver and various muscle samples from α-tocopherol deficient and supplemented pigs and cattle; the results of these studies will be published in full elsewhere. In brief, however, pigs fed a diet depleted of α-tocopherol for 7 mon had heart α-tocopherol and induced HNE concentrations of 7.7 (0.9) and 14.2 (1.5) nmol/g, respectively. These values were significantly different ($P < 0.001$) from those observed in control animals fed the same diet, but supplemented with α-tocopherol. In those animals the heart α-tocopherol and HNE concentrations were 32.5 (2.6) and 1.8 (0.2) nmol/g, respectively. The mean concentration of HNE induced in the homogenate from the deficient group was approximately 8 times higher than that from the sufficient group. This finding indicates that heart muscle from the α-tocopherol sufficient group was much better protected against possible free radical attack than that from the α-tocopherol deficient group.

We have also found that the differences in Fe^{++}-induced HNE have generally been greater than in ascorbate-induced TBARS between α-tocopherol deficient and sufficient tissues (data not shown), suggesting that HNE may be a better indicator of "peroxidizability" than TBARS. The assay using LC/MS is relatively simple to perform. Only one derivatization step is required, as opposed to two for the GC/MS assays (10,11) where a trimethylsilyl derivative is prepared after the PFB derivative. The detection limit of the LC/MS is about 6 pmol injected on-column. This equates to about 640 pmol/g for tissue samples. This is not as sensitive as GC/MS assays using GC with negative ion chemical ionization, with detection limits about 10 times higher. The sensitivity is, however, sufficient to measure the levels of induced HNE in tissue samples, and we have not found

it necessary to try to improve on this. Deuterated HNE could be used as an internal standard, if available. The synthesis of deuterated HNE has been described (10), and its use should further increase the reproducibility of the assay. However, we have already shown (28) that a dedicated LC/MS system, such as that used in this assay, is capable of good reproducibility with a typical coefficient of variation of 3.6% between standard injections, without the use of an internal standard.

ACKNOWLEDGMENTS

We wish to thank Professor H. Esterbauer for kindly supplying the HNE standard and M. Nolan for supplying tissues from α-tocopherol deficient and supplemented pigs for analysis.

LETTER TO THE EDITOR

Zinc and Red Cell Fatty Acid Composition

Dear Sir:

The paper by Driscoll and Bettger (1) on the effects of dietary zinc deficiency on red cell lipid and essential fatty acid (EFA) composition deserves comment with respect to extrapolation of the data to general concepts regarding the role of zinc in EFA metabolism. The dietary methodology and results in this paper agree quite closely with those of Kramer *et al.* (2) who also concluded that zinc deficiency *per se* has no significant effect on EFA composition beyond that caused by reduced food intake. The implication in both these papers is that zinc is probably not involved in Δ6 or Δ5 desaturation.

While the Δ6 desaturase is now known to be an iron-containing enzyme (3), zinc may be involved in determining overall desaturase activity by influencing electron availability from the electron donors NADH or NADPH (4). If zinc were to be involved in arachidonic acid synthesis, one would expect lower levels of arachidonic acid synthesis during zinc deficiency, as many studies have reported (5; reviewed in ref. 4), but higher arachidonic acid levels after zinc supplementation. In fact, this is the case both in animal models with normal food and nutrient intake (6,7) and in human disease; in acrodermatitis enteropathica (genetic defect impairing zinc absorption), dietary zinc supplementation significantly increases both arachidonic acid and docosahexaenoic acid in serum phospholipids (8,9). We have also recently shown that dietary zinc supplementation raises the mol% of arachidonic acid in serum phospholipids in Wilson's disease (controls, 12.6 ± 2.4%, n = 19; Wilson's disease before zinc, 10.9 ± 2.4%, n = 10; Wilson's disease after zinc, 12.7 ± 2.2%, n = 36; $P < 0.01$). Thus, the effect of zinc on arachidonic acid metabolism may be indirect, but becomes clearly apparent under a variety of circumstances.

Zinc deficiency studies in rats need not involve decreased food intake if the diet is not excessively deficient in zinc, *e.g.*, about 3 mg/kg in the diet *vs.* the < 0.3 mg/kg reported by Driscoll and Bettger (1) and Kramer *et al.* (2). Furthermore, if the low zinc diet is fed after the post-weaning growth spurt, the fatty acid changes induced by low zinc intake are still seen without any impairment in food intake (6).

The observation by Driscoll and Bettger (1) that free plasma arachidonic acid is normalized in food restricted rats refed zinc supports the majority of data which indicates a specific but undefined role of zinc in arachidonic acid synthesis. The fact that differences in red cell fatty acid composition between zinc deficient and zinc sufficient-restricted fed rats were for the most part minimal, appears to be more a function of the model than of the absence of a role of zinc in arachidonic acid synthesis.

ARTICLE

Elongation Predominates over Desaturation in the Metabolism of 18:3n-3 and 20:5n-3 in Turbot (*Scophthalmus maximus*) Brain Astroglial Cells in Primary Culture

Douglas R. Tocher
NERC Unit of Aquatic Biochemistry, School of Natural Sciences, University of Stirling, Stirling FK9 4LA, Scotland, United Kingdom

The origin of docosahexaenoic acid (DHA, 22:6n-3) that accumulates in turbot brain during development was investigated by studying the incorporation and metabolism *via* the desaturase/elongase pathways of [1-^{14}C]-labelled polyunsaturated fatty acids (PUFA) in primary cultures of brain astrocytic glial cells. There was little specificity evident in the total incorporation of PUFAs into the turbot astrocytes. However, specificity was apparent in the distribution of the various PUFAs among the individual lipid classes. In particular, there was very specific incorporation of [^{14}C]arachidonic acid (AA, 20:4n-6) into phosphatidylinositol balanced by a lower incorporation of this acid into total diradyl glycerophosphocholines. [^{14}C]-Linolenic acid (LNA, 18:3n-3) and [^{14}C]eicosapentaenoic acid (EPA, 20:5n-3) were metabolized *via* the desaturase/elongase pathways to a significantly greater extent than [^{14}C]linoleic acid (18:2n-6) and [^{14}C]AA. The turbot astrocytes expressed very little Δ5 desaturase activity and only low levels of Δ4 desaturation activity. Although the percentages were small, approximately 4–5 times as much labelled DHA was produced from [^{14}C]EPA compared with [^{14}C]LNA. However, it was concluded that very little DHA in the turbot brain could result from the metabolism of LNA and EPA in astrocytic glial cells.
***Lipids* 28, 267–272 (1993).**

During development, mammalian brains and retinas accumulate docosahexaenoic acid (22:6n-3, DHA) and arachidonic acid (20:4n-6, AA) (1) so that in adults neural tissues are characteristically rich in these specific polyunsaturated fatty acids (PUFA) (2). Studies with dietary deprivation of n-3 PUFA have shown that DHA is tenaciously retained in neural tissue (3), taking at least two generations to be significantly depleted (4–7). Reduced brain and retinal DHA content is associated with altered physiological parameters and functional defects, such as reduced visual acuity and impaired learning ability (4–7), suggesting a critical and probably essential role for DHA in neural tissue development and function (8,9).

Abbreviations: AA, 5,8,11,14-arachidonic acid (20:4n-6); ANOVA, analysis of variance; BHT, butylated hydroxytoluene; BSA, bovine serum albumin; CL, cardiolipin; CPL, total diradyl glycerophosphocholines; DHA, 4,7,10,13,16,19-docosahexaenoic acid (22:6n-3); DMEM, Dulbecco's modification of Eagle's medium; EDTA, ethylenediaminetetraacetic acid; EPA, 5,8,11,14,17-eicosapentaenoic acid (20:5n-3); EPL, total diradyl glycerophosphoethanolamines; GC, gas chromatography; HBSS, Hank's balanced salt solution; HPLC, high-performance liquid chromatography; HPTLC, high-performance thin-layer chromatography; LA, 9,12-linoleic acid (18:2n-6); LNA, 9,12,15-linolenic acid, α-linolenic acid (18:3n-3); PA, phosphatidic acid; PI, phosphatidylinositol; PS, phosphatidylserine; PUFA, polyunsaturated fatty acid; TLC, thin-layer chromatography; TN, total neutral lipids; TP, total polar lipids.

Fish neural tissues are also rich in DHA, with DHA to eicosapentaenoic acid (20:5n-3, EPA) ratios in the glycerophospholipids far exceeding those of most non-neural tissues (10,11). Although EPA levels are greater than those of AA in fish neural tissues (10), the selective location of AA in phosphatidylinositol (PI) combined with AA generally being the main eicosanoid precursor in many fish tissues, including brain cells (10–12), has implicated a similarly important role for AA in fish as in mammals. Recently, we have shown that DHA is rapidly and specifically accumulated in brains from post-larval turbot, *Scophthalmus maximus*, upon weaning from a diet low in DHA to one high in DHA (13,14). Prior to weaning, the turbot brains displayed low levels of DHA despite adequate dietary provision of both α-linolenic acid (18:3n-3, LNA) and EPA (13), suggesting that preformed DHA was required by turbot brains during development. However, biochemical studies on isolated mixed brain cells from juvenile turbot showed that there was no selectivity between [1-^{14}C]LNA and [1-^{14}C]DHA in the uptake into the cells (15). Furthermore, over 20% of [1-^{14}C]EPA incorporated into the mixed brain cells was chain elongated with up to 10% desaturated to DHA within 24 h (15).

The origin of neural tissue DHA during development in mammals is unclear. In rats, it has been shown that DHA was produced from intracranially-injected ^{14}C-labelled LNA (16), but other evidence has suggested that much of the DHA in mammalian brains results from accumulation of preformed DHA supplied by the liver (17,18). Studies using primary cultures of specific cell types from rat brain have recently shown that DHA and AA were produced from LNA and linoleic acid (18:2n-6, LA), respectively, in astrocytes, but not in neurons (19).

In the present study, we investigated the incorporation and metabolism *via* the desaturase/elongase pathways of [1-^{14}C]-labelled LA, LNA, AA and EPA in primary cultures of astrocytic glial cells from turbot. Our primary aim was to determine if astrocytes could contribute to the accumulation of DHA, particularly from EPA, during development in turbot brain. We have shown previously that an established turbot cell line, originally prepared from fin tissue, appeared to lack Δ5 desaturase activity (20–22). Therefore, we wished to determine if the primary cultures of brain astrocytes also had incomplete pathways for the desaturation and chain elongation of LA and LNA.

MATERIALS AND METHODS

Materials. Dulbecco's modification of Eagle's medium (DMEM), Hank's balanced salt solution (HBSS), glutamine, antibiotics, fetal calf serum and trypsin/ethylenediaminetetraacetic acid (EDTA) were all obtained from Northumbria Biologicals Ltd. (Northumberland, United

Kingdom). [1-^{14}C]PUFA (all 50–55 mCi/mmol and 99% pure) were obtained from NEN, DuPont (U.K.) Ltd. (Stevenage, United Kingdom). Sodium selenite, insulin, transferrin, triiodothyronine, poly-D-lysine, butylated hydroxy toluene (BHT), fatty acid-free bovine serum albumin (BSA) and silver nitrate were obtained from Sigma Chemical Co. Ltd. (Poole, Dorset, United Kingdom). Mouse monoclonal antiglial fibrillary acidic protein and F(ab')$_2$ rabbit anti-mouse IgG conjugated with fluorescein isothiocyanate were from Serotec (Oxford, United Kingdom). Rhodamine-phalloidin was a gift from Dr. R. Wilson (University of Stirling, Scotland, United Kingdom). Thin-layer chromatography (TLC) (20 × 20 cm × 0.25 mm) and high-performance thin-layer chromatography (HPTLC) (10 × 10 cm × 0.15 mm) plates, precoated with silica gel 60 (without fluorescent indicator), were obtained from Merck (Darmstadt, Germany). All solvents were high-performance liquid chromatography (HPLC) grade and were obtained from Rathburn Chemicals (Walkerburn, Scotland, United Kingdom).

Experimental animals. Turbot, *Scophthalmus maximus* (~500 g, and 7–8 mon old) were obtained from a commercial mariculture station (Golden Sea Produce, Hunterston, Scotland, United Kingdom). Fish were maintained in 2-m circular tanks supplied with recirculating, filtered sea water in the aquarium at Stirling University for between 2 and 4 wk during which period they were starved. Water temperature was 10 ± 2°C.

Preparation of primary cultures of turbot astroglial cells. Primary cultures of turbot astroglial cells were prepared by modification of methods used previously to prepare astrocytes from rainbow trout brain (23,24). Fish (four per experiment) were killed by severing the spinal cord immediately posterior to the brain. Entire brains were removed into ice-cold HBSS (Ca^{2+}- and Mg^{2+}-free) supplemented with 1.75% NaCl (HBSS/NaCl) and the meninges carefully dissected away. Brains were transferred into fresh, ice-cold HBSS/NaCl and were finely chopped. Brain cells were dissociated by sequential sieving through nylon gauzes of 190, 100 and 30 μm pore sizes essentially as described by McCarthy and de Vellis (25). The suspension was centrifuged at 300 × *g* for 10 min at 4°C and the pellet resuspended in DMEM containing 4 mM glutamine, antibiotics (50 IU/mL penicillin and 50 μg/mL streptomycin), 0.35% NaCl and further supplemented with 30 nM sodium selenite, 5 μg/mL of insulin, 50 μg/mL of transferrin, 30 nM triiodothyronine and 10% fetal calf serum. The cells were seeded into 75-cm^2 plastic tissue culture flasks (Gibco-Nunc) pretreated with polylysine. Cultures were incubated for four weeks at 22°C with the medium replaced on days 4, 14 and 24. After four weeks the cultures were well established and the incubation temperature was lowered to 15°C, which is approximately the upper limit of the ambient temperature range that turbot normally experience in United Kingdom waters, and incubation continued for a further two weeks without any medium change. The cells grow very slowly at 15°C, and therefore the cultures must be initially established at 22°C. Before use, the cultures were exposed to sheer forces to detach overlying cells (predominantly oligodendrocytes) and washed with HBSS/NaCl to remove these and dead cells (24). The resultant monolayer of cells was characterized as astrocyte-rich (~90%) by indirect immunofluorescence and dual-labelling using antiglial fibrillary acidic protein as an astrocyte marker and rhodamine-phalloidin as a general cell stain, as described in detail earlier (26).

Incubation of turbot astroglial cell cultures with [1-^{14}C]-labelled fatty acids. Medium was aspirated and the cultures washed with HBSS/NaCl. Fresh DMEM, used as above, except that it did not contain the supplements (selenite, insulin, transferrin and triiodothyronine) or serum that are required to establish the cultures, was added. Supplements are not required for the maintenance of the cell cultures and so were left out to remove their possible effects on PUFA uptake and metabolism. Serum was omitted so that the isotope was added undiluted by the fatty acids and lipids in serum. Triplicate flasks received 0.3 μCi each of either [1-^{14}C]18:2n-6, [1-^{14}C]18:3n-3, [1-^{14}C]20:4n-6 or [1-^{14}C]20:5n-3, added carrier-free in ethanol (final conc., fatty acid, 0.6 μM and ethanol, 0.25%). Cultures were incubated with the isotopes for 6 d at 15°C.

Harvesting of cells and lipid extraction. The medium was aspirated, and the cultures were washed twice with 20 mL of ice-cold HBSS/NaCl containing 1% fatty acid-free BSA. The cells were harvested by trypsinization and washed further twice with 10 mL of cold HBSS/NaCl, and lipid extracted essentially according to the procedure of Folch *et al.* (27) as detailed previously (28).

Incorporation of radioactivity into total lipid and glycerophospholipid classes. After weighing, the total lipid was resuspended in chloroform/methanol (2:1, vol/vol) containing 0.01% BHT as antioxidant at a concentration of 10 mg/mL. Samples of the total lipid were added to scintillation mini-vials, the solvent was evaporated under a stream of nitrogen, 2.5 mL of Ecoscint A (National Diagnostics, Manville, NJ) were added and radioactivity was determined using a Packard 2000CA TriCarb liquid scintillation analyzer (Downers Grove, IL). Samples of total lipid (50 μg) were applied in 1-cm streaks onto HPTLC plates, and the glycerophospholipid and other polar lipid classes were separated using methyl acetate/isopropanol/chloroform/methanol/0.25% aqueous KCl (25:25:25:10:9, by vol) (29). The lipid classes were vizualized by brief exposure to iodine vapor and marked, and the iodine removed under vacuum. Individual glycerophospholipid classes were scraped into scintillation mini-vials, and radioactivity was determined as above.

Incorporation of radioactivity into PUFAs. Fatty acid methyl esters were prepared from total lipid by acid catalyzed transmethylation at 50°C for 16 h (30) and were extracted and purified as described previously (10). Methyl esters were separated by a combination of argentation-TLC and radio-gas chromatography, and the identity of fatty acid methyl esters and the radioactivity in the individual methyl ester fractions determined as described previously in detail (22,24). The identity of 24:5n-3 was confirmed by gas chromatography/mass spectrometry. All solvents contained 0.01% BHT as antioxidant.

Statistical analysis. All results are presented as means ±SD (n = 3). The data were checked for homogeneity of the variances by the Bartlett test and, where necessary, the data were arcsin-transformed before further statistical analysis. Data for the incorporation of radioactivity into total lipid and individual lipid classes were analyzed by one-way analysis of variance (ANOVA) followed, where appropriate, by Tukey's multiple comparison test. Differences between the mean recoveries of radioactivity from

[^{14}C]18:3n-3 and [^{14}C]20:5n-3 in specific fatty acid fractions, compared with the recoveries of radioactivity from [^{14}C]18:2n-6 and [^{14}C]20:4n-6, respectively, in the homologous fatty acid fractions (*i.e*, recovery of radioactivity from [1-^{14}C]18:3n-3 and [1-^{14}C]20:5n-3 in the 22:6n-3 fraction was compared with the recovery of radioactivity from [^{14}C]18:2n-6 and [^{14}C]20:4n-6, respectively, in the 22:5n-6 fraction) were analyzed by the Student's *t*-test. Differences were reported as significant if $P < 0.05$.

RESULTS

The ^{14}C-labelled PUFAs were incorporated into the total lipid in amounts ranging from 4.10 to 4.77 pmol/μg total lipid (Table 1). The only significant difference between the four different PUFAs was that the incorporation of [^{14}C]AA was significantly less than the incorporation of [^{14}C]EPA (Table 1).

The incorporation of the C_{20} PUFA into total polar classes was generally greater than the incorporation of the C_{18} PUFA into total polar classes, although the difference between [^{14}C]LA and [14C]EPA was not statistically significant (Fig. 1). The percentage incorporation into polar lipid classes was lowest, and therefore the percentage incorporation into neutral lipids was highest, with [^{14}C]LNA. There were several significant differences between the [^{14}C]PUFA in their incorporation into the individual glycerophospholipid classes. The most striking was the significantly greater incorporation of [^{14}C]AA into PI balanced by significantly lower incorporation of this acid into diradyl glycerophosphocholines (CPL) (Fig. 1). Both ^{14}C-labelled C_{18} PUFA were incorporated into the phosphatidic acid/cardiolipin (PA/CL) fraction to a significantly greater extent than the ^{14}C-labelled C_{20} PUFA (Fig. 1).

Significantly more of the incorporated [^{14}C]LNA was metabolized *via* the desaturase/elongase pathway compared to [^{14}C]LA (Table 2). The majority of the metabolized [^{14}C]LNA was chain elongated to 20:3n-3, 22:3n-3 and 24:3n-3, whereas only 4.7% of the incorporated [^{14}C]LA was elongated to 20:2n-6, with no labelled 22:2n-6 and 24:2n-6 being detected (Table 2). Approximately equal amounts of radioactivity (~6–7%) from [^{14}C]LA and [^{14}C]LNA were found in the products of Δ6 desaturation. Radioactivity was detected in 22:4n-3, whereas no radioactivity was found in trienoic n-6 PUFA of chain length greater than C_{20}. Significantly more radioactivity from [^{14}C]LA, compared to [^{14}C]LNA, was found in the products of Δ5 desaturation, both 20:4n-6 and 22:4n-6. In contrast, a small percentage of radioactivity from [^{14}C]LNA was found in the DHA fraction, whereas no radioactivity from [^{14}C]LA was detected in 22:5n-6 (Table 2).

A significantly greater percentage of the incorporated [^{14}C]EPA was metabolized by chain elongation and desaturation compared to [^{14}C]AA (Table 3). The majority of the metabolized [^{14}C]EPA was chain elongated to 22:5n-3 (14.7%) and 24:5n-3 (8.7%) with less than 2% desaturated to DHA. The majority of the [^{14}C]AA metabolized was chain elongated to 22:4n-6 with only a trace desaturated to 22:5n-6 (Table 3). There was no labelling in elongation products of AA with chain length greater than C_{22}. In turbot astrocytes labelled with [^{14}C]EPA, small percentages of radioactivity were detected in less unsaturated fatty acid fractions. No labelling was detected in less unsaturated fatty acid fractions in turbot astrocytes labelled with [^{14}C]AA (Table 3).

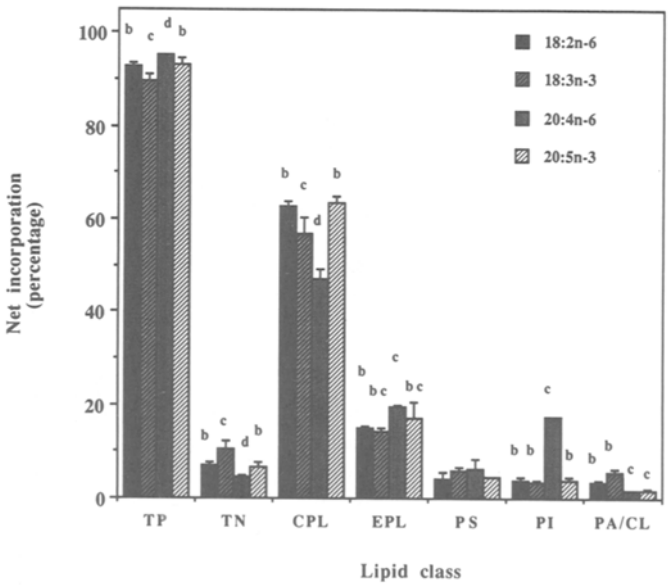

FIG. 1. Net incorporation of [1-^{14}C]-labelled fatty acids into lipid classes after 6 d incubation in turbot astroglial cells in primary culture. Results are means ± SD of three experiments. Statistical analysis is described in Materials and Methods. Values of columns within each grouping with different superscript letters are significantly different ($P < 0.05$). CPL, total diradyl glycerophosphocholines; EPL, total diradyl glycerophosphoethanolamines; PA/CL, phosphatidic acid/cardiolipin; PI, phosphatidylinositol; PS, phosphatidylserine; TN, total neutral lipid classes; TP, total polar lipid classes.

TABLE 1

Net Incorporation of [1-^{14}C]-Labelled Fatty Acids into Total Lipid from Turbot *(Scophthalmus maximus)* Astroglial Cells in Primary Culture[a]

[1-^{14}C]Fatty acid	Incorporation (pmol/μg total lipid)
[1-^{14}C]18:2n-6	4.77 ± 0.46^{bc}
[1-^{14}C]18:3n-3	4.34 ± 1.04^{bc}
[1-^{14}C]20:4n-6	4.10 ± 0.02^{b}
[1-^{14}C]20:5n-3	4.76 ± 0.15^{c}

[a]Results are means ± SD of three experiments. Cells were incubated with isotopes for 6 d at 15°C. Statistical analysis is described in Materials and Methods. Values with different superscript letters are significantly different ($P < 0.05$).

DISCUSSION

This paper is the first report of a primary culture of monolayers of any brain cell type from a marine fish. The methods used were modified from those used previously to culture astroglial cells from rainbow trout, *Oncorhynchus mykiss* (23,24). For the turbot astrocytes, all media and salt solutions were supplemented with NaCl. The main difference in the procedures was that the turbot astrocytes showed a much slower growth rate compared to the trout astrocytes, taking approximately twice as

TABLE 2

Metabolism of [1-^{14}C]18:2n-6 and [1-^{14}C]18:3n-3 by the Desaturase/Elongase Pathways in Turbot *(Scophthalmus maximus)* Astroglial Cells in Primary Culture[a]

Fatty acid fraction	Polyunsaturated fatty acid added	
	[1-^{14}C]18:2n-6	[1-^{14}C]18:3n-3
18:2n-6/18:3n-3	84.0 ± 2.0	71.1 ± 7.3[b]
20:2n-6/20:3n-3	4.7 ± 0.6	13.7 ± 1.3[b]
22:2n-6/20:3n-3	n.d.	6.6 ± 3.9[b]
24:2n-6/20:3n-3	n.d.	2.5 ± 1.5[b]

22:4n-6/22:5n-3	5.0 ± 1.1	14.7 ± 5.9[b]
24:4n-6/24:5n-3	n.d.	8.7 ± 0.8[b]
22:5n-6/22:6n-3	0.1 ± 0.1	1.9 ± 0.6[b]

[a]Results are expressed as percentages of total radioactivity recovered and are means ± SD of three experiments. Cells were incubated with isotopes for 6 d at 15°C. n.d., not detected. Values for the recovery of radioactivity from added [^{14}C]20:5n-3 in each fatty acid fraction were compared with the recovery of radioactivity from [^{14}C]20:4n-6 in the homologous fatty acid fractions.

[b]The differences were statistically significant ($P < 0.05$).

long to reach 75% confluence, the point at which the isotopes were added. With the longer growth period it was necessary to change the medium more often than was required with the trout astrocyte cultures.

The incorporation of [^{14}C]AA into the turbot astrocytes was significantly less than the incorporation of [^{14}C]EPA, but this was primarily due to the very low deviation (<0.5% of the mean) found in the AA data compared to the variances in the data for the other three PUFA, which ranged from 3 to 24% in the present study. A wide range of variances has consistently been observed in previous studies measuring the incorporation of radiolabelled PUFA into cultured fish cells, with reported variances ranging from 2.3 to 22.5% (24), 1 to 41.3% (22) and 15.3 to 39.3% (31). There was no difference in the incorporation into total lipid between [^{14}C]labelled LA, LNA, AA and EPA in trout astrocytes (24) or established cell cultures from trout, Atlantic salmon *(Salmo salar)* and turbot (22). In brain cell suspensions from turbot, there was no significant difference in the level of incorporation into total lipid between [^{14}C]LNA and [^{14}C]DHA (15). Therefore, the data in the present study are consistent with data obtained previously in fish astrocyte cultures and turbot cells generally. In contrast, in trout brain cell suspensions, the incorporation of ^{14}C-labelled C_{20} PUFA into total lipid tended to be lower than that of ^{14}C-labelled C_{18} PUFA, with the incorporation of [^{14}C)AA generally exceeding that of [^{14}C]EPA (31).

Between 90 and 95% of the total radioactivity from the four ^{14}C-labelled PUFAs incorporated into turbot astrocytes was esterified into polar lipid classes. An almost identical situation was found in trout astrocytes where 90 to 96% of the same four PUFAs were incorporated into total phospholipids (24). Similarly, between 83 and 95% of incorporated ^{14}C-labelled LA and LNA and between 95 and 98% of incorporated ^{14}C-labelled AA and EPA were esterified into phospholipids in trout, salmon and turbot cell lines (22). In contrast, in suspensions of isolated mixed brain cells from both trout and turbot, the greater percentages of the incorporated ^{14}C-labelled PUFA were generally found in the neutral lipid fractions, particularly with C_{20} and C_{22} PUFA (15,31). The distribution of radiolabel from [^{14}C]LA, LNA and EPA among the glycerophospholipid classes observed in the present study, with the rank order being CPL > EPL > PS and PI, has been observed in previous studies on fish brain cells and cell cultures (15,22,24,31), as has the specificity for incorporation of [^{14}C]AA into PI (22,24,31).

The n-3 PUFA, LNA and EPA were clearly preferred to the n-6 PUFA, LA and AA, as substrates for the desaturase/elongase pathways in turbot astrocytes. A similar preference was also observed in trout astrocyte cultures (24) and trout, salmon and turbot cell lines (22) in experiments of a similar duration (6–7 d incubation with isotope). In short-term experiments over 24 h in trout brain cell suspensions, there was no difference in the extent of metabolism between LA and LNA, although there was significantly more EPA metabolized *via* desaturation and elongation as compared to AA (31). The turbot astrocytes were unique in the extent to which elongation predominated over desaturation, particularly with LNA and EPA. The production of significant amounts of labelled 22:3n-3 and 24:3n-3, and some 22:4n-3 from [^{14}C]LNA and labelled 24:5n-3 from [^{14}C]EPA was not observed previously in studies in trout astrocytes (24) or mixed brain cells (31) or trout and salmon cell lines (22). However, radioactivity was detected in apparently longer chain metabolites, although at much lower levels than the

present study, in turbot fin cells incubated with labelled LNA and EPA for 7 d, but the identity of these was not confirmed in that study. In contrast, turbot brain cell suspensions incubated with LNA and EPA for 24 h showed only traces of radioactivity in the C_{22} and C_{24} PUFAs mentioned above (15). Therefore, the production of these longer-chain metabolites appears to be a characteristic of turbot cells, in particular astrocytes, but their biosynthesis may be more time-dependent than the normally observed desaturase products.

In mixed brain cell suspensions from trout and turbot, significant percentages of EPA were desaturated to DHA in 24 h. In trout brain cells, between 4.3 and 9.3% of label from [^{14}C]EPA was recovered in DHA, depending upon culture temperature (31), and for turbot mixed brain cells the equivalent figures were 7.1 to 10.0%, depending upon the age of the fish (15). In contrast, in the astrocyte cultures from turbot brain, less than 2% of the radioactivity from [^{14}C]EPA was recovered in DHA after 6 d incubation, and for trout astrocytes the corresponding figure was between 3.2 and 5.3%, depending upon culture temperature (24). Therefore in fish, particularly turbot, the enriched astrocyte cultures were less efficient in conversion of EPA to DHA as compared to mixed brain cell suspensions. This contrasts with the situation in neonatal rat brain astrocyte cultures which were very active in the production of DHA (19).

The above data indicate that fish astrocytes have rather low levels of Δ4 desaturation activity. This activity is often lost in cultured cells, apparently by the process of culturing itself (32). The elongation of LA to 20:2n-6 and LNA to 20:3n-3, the so-called "dead-end" pathway, is often increased in cells lacking Δ4 desaturation activity, and that is the case with the turbot astrocytes. However, recent evidence has suggested that there may not be an actual Δ4 desaturase enzyme, and that desaturation of 22:5n-3 to DHA may occur *via* elongation of 22:5n-3 to 24:5n-3, and Δ6 desaturation of 24:5n-3 to produce 24:6n-3 in the microsomes, followed by peroxisomal chain shortening of 24:6n-3 to DHA (33). Although a significant percentage of label from [^{14}C]EPA was recovered in 24:5n-3 in the turbot astrocytes, there was no evidence for labelled 24:6n-3, despite the presence of reasonable Δ6 desaturase activity toward LA and LNA.

Nutritional studies suggested that both turbot larvae and post-larvae (<1-mon-old) were unable to convert dietary EPA to DHA, in the brain at least (13,14). However, biochemical studies showed that mixed brain cells from older fish (1- and 4-mon-old) desaturated and elongated significant amounts of EPA to DHA (15). The activity was higher in the 4-mon-old fish, perhaps suggesting increasing Δ4 desaturation activity with age (15). In the present study, astrocytes from fish, approximately 8-mon-old, had very little Δ4 desaturation activity. Therefore, the data from the present study indicates that only a small percentage of the Δ4 desaturation activity observed in the mixed brain cell suspensions could be attributed to astroglial cells.

The turbot astrocytes lack, or express only very low, Δ5 desaturase activity. This is consistent with data obtained from *in vivo* injection studies (34,35) and *in vitro* cell studies (15,20,21). It was surprising that in the astrocytes significantly more label from [^{14}C]LA was recovered in n-6 tetraenes compared to the recovery of label from [^{14}C]-LNA in n-3 pentaenes (Table 2). This was not observed in the previous studies in turbot cells (15,20,21) and, in general, all the desaturase activities in fish cells are more active toward n-3 PUFA substrates (20,24,31,36,37), as previously reported for mammalian Δ6 desaturase activity (38).

In conclusion, astrocytic glial cells from turbot brain were similar to the other turbot tissues studied in that they expressed very little Δ5 desaturase activity. In addition, the cultured astrocytes had relatively low Δ4 desaturation activity. Consequently, we conclude that very little of the DHA that accumulates during development in the turbot brain could result from the metabolism of LNA and EPA in astrocytic glial cells.

A lack, or very low levels, of Δ5 desaturase activity appears to be a characteristic of marine fish species (11,15,20,34). Therefore, it is probable that DHA in the brains of marine fish in general cannot be derived from the metabolism of LNA *in situ*. In this respect, marine fish are similar to terrestrial carnivores such as the cat (39), and, in any case, like terrestrial carnivores, marine fish in the wild will probably have little dietary input of LNA. However, the turbot is also highly carnivorous (11,13,14), and so the study of a herbivorous marine fish is required to confirm the hypothesis for marine fish in general. How much DHA in the brains of marine fish is derived from the metabolism of EPA requires more extensive study of Δ4 desaturation in fish tissues, including the brain, particularly in light of the recent work suggesting that there may not be a specific Δ4 desaturase enzyme (33). Larval and early juvenile stages of marine fish should also be studied as the nutritional studies with cultured species suggest that it is at these times of rapid growth that dietary DHA may be limiting in live feed diets (13,14). However, the same situation may not apply to freshwater fish species which do not lack Δ5 desaturase and so are able to desaturate and elongate C_{18} essential fatty acids to EPA and DHA (11,34). Therefore, it is possible that the *in situ* metabolism of both LNA and EPA may contribute to brain DHA in freshwater fish. In some support of this we have shown that the production of [^{14}C]-labelled DHA from [^{14}C]LNA and [^{14}C]EPA in rainbow trout astrocytes (24) was at least twice the level of [^{14}C]-labelled DHA produced from [^{14}C]LNA and [^{14}C]EPA in the present study.

Fatty acid carbons are well-resolved in ^{13}C nuclear magnetic resonance (NMR) spectra of lipid extracts, but application of this methodology to the metabolism of ^{13}C-labelled fatty acids has not yet been reported. In the present study, ^{13}C NMR was used to monitor the presence of 98% [U-^{13}C]eicosapentaenoic acid (EPA) in liver and carcass lipids 24 h after it had been injected into the stomach of a rat. Natural abundance ^{13}C NMR spectra of liver total fatty acid extracts were obtained from four control rats for comparison. At 24 h post-injection, quantitative high resolution ^{13}C NMR showed ^{13}C enrichment in liver fatty acid extracts was present mainly at olefinic and at the n-1 to n-4 carbons, but ^{13}C signal intensities for C-1 to C-4 of [U-^{13}C]EPA were markedly reduced or absent. Small ^{13}C resonances, possibly indicative of some ^{13}C incorporation into docosahexaenoic acid and saturated or monounsaturated fatty acids, were present in spectra of liver fatty acids. Liver and carcass fatty acid composition was similar in both the controls and the EPA-injected rat, suggesting little accumulation of the injected [U-^{13}C]EPA after 24 h. We conclude that the carbon-specific data provided by ^{13}C NMR of lipid extracts may be useful in monitoring the fate of individual carbons during tracer studies using ^{13}C-labelled fatty acids.
***Lipids 28,* 273–277 (1993).**

^{13}C nuclear magnetic resonance spectroscopy (^{13}C NMR) is a useful technique for metabolic studies because of the wide spectral dispersion of ^{13}C signals (1–4) and because of the potential to monitor the metabolism of ^{13}C-labelled compounds as tracers in various biochemical pathways. The use of ^{13}C NMR to monitor incorporation of ^{13}C from [2-^{13}C]acetate into rat liver fatty acids has been reported (5), and fatty acid carbon assignments in ^{13}C NMR spectra are well-established (6–10), but this methodology has not yet been applied to tracer studies of ^{13}C-labelled fatty acids.

Eicosapentaenoic acid (20:5n-3; EPA) has a pivotal role in long-chain fatty acid metabolism as a precursor in the synthesis of its structurally more important homologue, docosahexaenoic acid (22:6n-3; DHA). It is also an important modulator of the synthesis and metabolism of eicosanoids derived from arachidonic acid (20:4n-6) (11,12). We have used high resolution ^{13}C NMR to detect [U-^{13}C]EPA in total lipid extracts of liver. [U-^{13}C]-labelled long chain fatty acids are not generally available, so the opportunity to study the metabolism of a single 89-mg sample of [U-^{13}C]EPA from an EPA-producing microalgae consuming ^{13}C-labelled glucose was unique. As the present results are based on only one experimental animal (and four controls), they must be considered as preliminary results.

Abbreviations: DHA, docosahexaenoic acid (22:6n-3); EPA, eicosapentaenoic acid (20:5n-3); GLC, gas-liquid chromatography; NMR, nuclear magnetic resonance; TMSS, tetrakis(trimethylsilyl)silane.

MATERIALS AND METHODS

Animals. Male Wistar rats (250–300 g) were housed individually and consumed rodent chow and tap water *ad libitum.* The rat receiving the [U-^{13}C]EPA was injected with the anesthetic, Inactin (100 mg/kg *i.p.*), and a nasogastric tube was inserted to inject the bolus of [U-^{13}C]-EPA directly into the stomach. Control rats (n = 4) were also anesthetized but received no injection. Only one rat was injected with [U-^{13}C]EPA because only a single 89-mg sample was available and no previous studies of this type have been reported from which the dose required for detection by ^{13}C NMR could have been determined.

Lipid extraction. To estimate the whole body fatty acid content of EPA and other n-3 fatty acids in the [U-^{13}C]-EPA-injected rat compared with uninjected controls, all the rats were killed and the liver and carcass (whole body − liver) were weighed and homogenized. The total liver and carcass lipids were extracted into chloroform/methanol (2:1, vol/vol) (13). Lipid extracts were saponified and the free fatty acids extracted. The total fatty acid extracts were dried under nitrogen and weighed. Aliquots (80–100 mg) of each were weighed, combined with 10 mg internal standard [tetrakis(trimethylsilyl)silane (TMSS); Aldrich Chemical Co., Milwaukee, WI] and dissolved in 500 μL of deuterated chloroform (Silanor; MSD Isotopes, Montreal, Quebec, Canada) in 5-mm NMR tubes (Wilmad Glass Co., Buena, NJ) for high resolution ^{13}C NMR (5). The resonance for TMSS is 2.67 ppm downfield relative to that of the usual chemical shift reference, tetramethylsilane at 0.00 ppm. TMSS was used as an internal standard because it is crystalline at room temperature and has a spin-lattice relaxation time of 2.56 s. Thus, with suitable NMR acquisition conditions (5) it could be used to obtain quantitative ^{13}C NMR data.

High resolution ^{13}C NMR. All high resolution ^{13}C NMR spectra were obtained using a broad band, 5-mm probe in an AM300 WB spectrometer operated at 75.4 MHz and 300 K (Bruker Canada, Milton, Ontario, Canada). Quantitative signal acquisition conditions were used, including long relaxation delay, inverse gated ^{1}H decoupling for suppression of nuclear Overhauser enhancement of ^{13}C resonances (see legend to Fig. 1 for details; also Refs. 5,10). Spectra were processed at the spectrometer or were down-loaded to an IBM AT-type computer for Fourier transformation, line-fitting of peaks (as required) and integration relative to the quantitative internal standard, TMSS (5). Peak integrals were determined using the Marquardt-Levenberg routine (NMR-286 program; Soft-Pulse Software, Guelph, Ontario, Canada).

Fatty acid analysis. Aliquots of the total fatty acid extracts of liver and carcass were methylated using 14% boron trifluoride in methanol (Sigma Chemical Co., St. Louis, MO) at 90°C for 30 min in screw-capped glass tubes under nitrogen (5). The resulting fatty acid methyl esters were separated by capillary gas-liquid chromatography (GLC) on a 30 m by 0.25 μm column (Durabond 23;

J&W Scientific, Folsom, CA) using Hewlett-Packard GLC equipment (5890A with automated sample delivery and injection; Palo Alto, CA).

Data presentation. Natural abundance ^{13}C NMR data for liver and carcass lipids from control rats have been expressed as μg ^{13}C/mg liver or carcass lipid. The lipid extracts contain mixtures of fatty acids, and ^{13}C NMR does not usually distinguish between different acyl chain lengths so carbon positions in the fatty acids have been designated from both ends of the molecule using the conventional abbreviations, "C" from the carboxyl end and "n" from the methyl end.

RESULTS

[U-^{13}C]Eicosapentaenoic acid. The main difference between ^{13}C NMR spectra of 95% pure EPA containing only natural abundance ^{13}C and 98% [U-^{13}C]-enriched EPA is the presence of multiplet peaks in the spectrum of [U-^{13}C]EPA caused by ^{13}C-^{13}C coupling due to the 90-fold ^{13}C enrichment at each carbon (Fig. 1). The ^{13}C-^{13}C splittings were either doublets (n-1 at 14.1 ppm) or mixed doublet pairs (n-2 carbon at 20.5 ppm; C-2 at 33.5 ppm; n-4 carbon at 127 ppm or n-3 carbon at 132 ppm). The multiplet at 20.5 ppm appears to be a triplet, but is actually two adjacent doublets. The ^{13}C resonance for C-2 of [U-^{13}C]EPA results in a doublet of doublets because it is split once by C-1 and is also split by C-3.

Resonances for several carbons with identical or nearly identical magnetic environments give larger, more complex peaks, *e.g.,* doubly allylic carbons at 25.5 ppm (which partially overlap with C-3 of EPA at 24.8 ppm and with C-4 of EPA at 26.5 ppm). If methylene-interrupted olefinic resonances are present (as in *cis*-polyunsaturated fatty acids), two envelope regions of olefinic resonances occur at about 128 ("inner" olefinic) and 130 ppm ("outer" olefinic). In the case of EPA and other n-3 fatty acids, the n-3 olefinic carbon resonance is affected by its close proximity to the n-1 carbon and, hence, this C=C resonance in EPA is shifted downfield from 130 to 132 ppm leaving the area at 130 ppm void of peaks (Fig. 1).

High resolution ^{13}C NMR. Part of the natural abundance ^{13}C NMR spectrum of rat liver fatty acids is shown in Figure 2B. ^{13}C spectra of the carcass extracts are not shown (the data are given later in Tables 2 and 3). For the most part, ^{13}C resonances in different n-3 fatty acids are the same or very close, but there are some unique resonances, *e.g.,* C-1 of DHA at 173.4 *vs.* 174 ppm, C-2 of EPA at 33.5 *vs.* 34 ppm and C-7 of DPA at 130.0 ppm (Table 1). Unfortunately, the C-2 resonance of EPA overlaps with C-2 of arachidonic acid, so unless arachidonic acid is present in very low amounts or EPA in high amounts, EPA itself cannot be readily distinguished in ^{13}C NMR spectra.

The peak areas in the ^{13}C natural abundance spectra of liver and carcass fatty acids have been quantitated against the integrated peak area of TMSS (Table 2). The natural abundance ^{13}C NMR spectra of liver and carcass fatty acids differed primarily at the olefinic carbons; the liver fatty acids were more polyunsaturated, hence the larger value for the ^{13}C/mg lipid at the "inner" olefinic resonances in the liver fatty acids. However, the carcass fatty acids were more monounsaturated, hence the larger value for ^{13}C content of the "outer" olefinic resonances

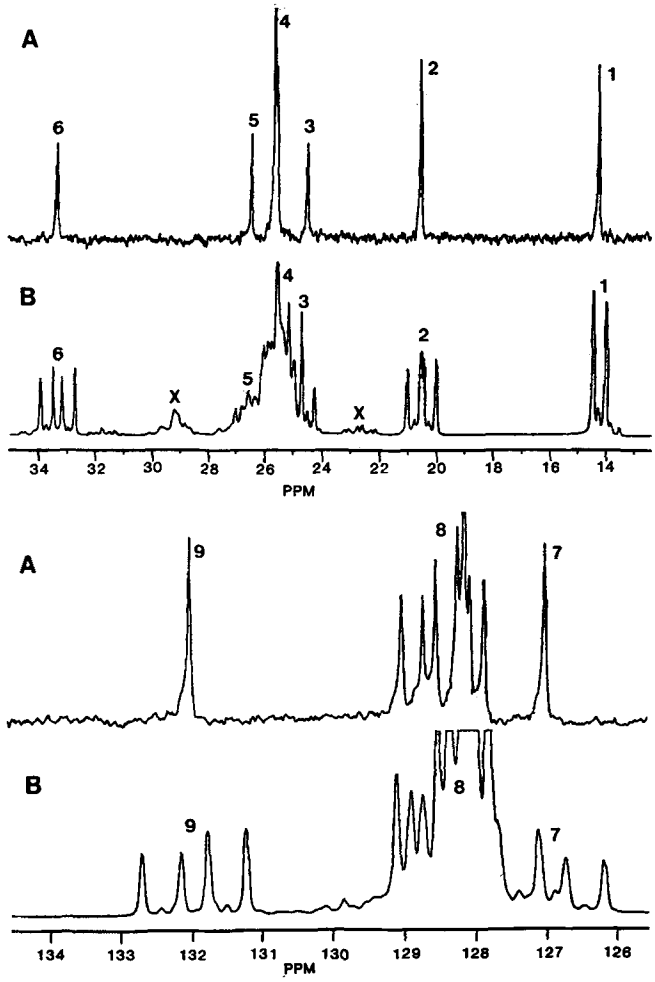

FIG. 1. Partial higher resolution ^{13}C nuclear magnetic resonance spectra of natural abundance (A), compared to 98% [U-^{13}C]eicosapentaenoic acid (B), showing the major regions of interest. Peak identification: 1, n-1 carbon; 2, n-2 carbon of n-3 fatty acids; 3, C-3 carbon; 4, doubly allylic carbons; 5, C-4 carbon; 6, C-2 carbon; 7, n-4 carbon of n-3 fatty acids; 8, "outer" olefinic carbons; 9, n-3 carbon of n-3 fatty acids; X, minor fatty acid impurities. Note that for [U-^{13}C]-eicosapentaenoic acid, most of the resonances are multiplets centered on the equivalent resonance of the natural abundance eicosapentaenoic acid. Each free induction decay comprised 1000 sequentially added scans. A sweep width of 17,281 Hz and 16K data points were used. Operating parameters were: acquisition time, 0.475 s; relaxation delay, 10.0 s; and excitation pulse width, 30°.

(Table 2). "Outer" olefinic carbon resonances occur at ~130 ppm and in rat liver are mainly from C-9 and C-10 of oleic acid and C-9 and C-13 of linoleic acid. "Inner" olefinic carbon resonances occur at about 128 ppm and are mainly from C-10 and C-12 of linoleic acid, as well as the 6 "inner" olefinic carbons of arachidonic acid and the 10 "inner" olefinic carbons from DHA; monounsaturated fatty acids have no "inner" olefinic carbons. These ^{13}C NMR data are confirmed by the fatty acid data obtained by GLC for liver and carcass, which shows 37% of liver total fatty acids were polyunsaturated compared to 30% in the carcass, but 35% were monounsaturated in the carcass compared to 16% in the liver (Table 3).

^{13}C spectra of the liver fatty acid extracts from a control rat (only natural abundance ^{13}C) and from the rat

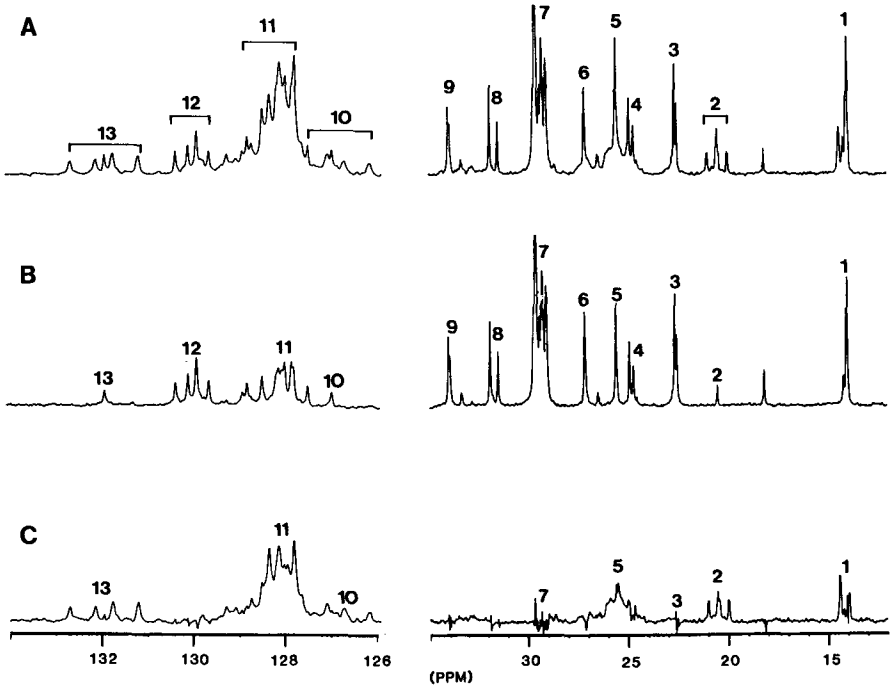

FIG. 2. Partial ^{13}C nuclear magnetic resonance (NMR) spectrum of liver total fatty acids extracted from a rat orally injected with a bolus of 98% [U-^{13}C]eicosapentaenoic acid 24 h previously (A), compared to a natural abundance ^{13}C NMR spectrum from an uninjected control rat (B), with the difference between A and B shown as C. Peak identification: 1, n-1 carbon; 2, n-2 carbon of n-3 fatty acids; 3, n-2 carbon plus C-3 of docosahexaenoic acid; 4, C-3 carbon; 5, doubly allylic carbons; 6, allylic carbons; 7, aliphatic carbons; 8, n-2 carbon; 9, C-2 carbon; 10, n-4 carbon of n-3 fatty acids; 11, "outer" olefinic carbons; 12, "inner" olefinic carbons; 13, n-3 carbon of n-3 fatty acids. Spectrometer operating conditions were as described in the legend to Figure 1, except that 5000 scans were obtained. Quantitative values shown in Table 4 are derived from Figures 2A and 2B; Figure 2C is for visual purposes only.

TABLE 1

^{13}C Nuclear Magnetic Resonances for Eicosapentaenoic Acid (EPA), Docosapentaenoic Acid (DPA) and Docosahexaenoic Acid (DHA) Relative to a Reference Standard at 0.00 ppm (adapted from Ref. 7)[a]

Carbon number	EPA	DPA	DHA
C-1	173.99	174.14	173.45
C-2	33.43	34.05	34.01
C-3	24.80	24.88	22.81
C-4	26.57	28.81	—
C-5	—	29.27	—
C-6	—	27.06	—
C-7	—	130.00	—
Doubly allylic	~25.6	~25.6	~25.6
Olefinic	128–129	128–129	128–129
n-4	127.03	127.04	127.02
n-3	132.02	132.02	132.00
n-2	20.57	20.57	20.57
n-1	14.29	14.27	14.28

[a]"C" carbons are those numbered from the carboxyl carbon; "n" carbons are those numbered from the terminal methyl carbon.

TABLE 2

Quantitative Analysis of Selected Carbons of Rat Liver and Carcass Total Fatty Acids by Natural Abundance ^{13}C Nuclear Magnetic Resonance Spectroscopy (n = 4; mean ± SD)[a]

Chemical shift (ppm)	Fatty acid carbon	μg ^{13}C/mg lipid	
		Liver	Carcass
14.1	n-1	36 ± 3	44 ± 2
25.6	Doubly allylic	22 ± 2	15 ± 2
31.5	n-3 (n-6)	9 ± 1	10 ± 2
31.9	n-3	17 ± 3	25 ± 4
34.0	C-2	20 ± 1	33 ± 4
~128	Olefinic ("inner")	58 ± 5	30 ± 7
~130	Olefinic ("outer")	23 ± 3	43 ± 5

[a]Determined relative to the peak area of a known amount of tetrakis-(trimethylsilyl)silane added as standard.

injected 24 h previously with [U-^{13}C]EPA were broadly similar as they both contained the ^{13}C signals of liver fatty acids (Fig. 2). The presence of a ^{13}C-labelled n-3 fatty acid(s) in the liver increased the ^{13}C signal intensity at several carbons of the liver, notably at the n-1 carbon (14.1 ppm), the n-2 carbon resonance of n-3 fatty acids (20.5 ppm) doubly allylic carbons (25.6 ppm) and at "inner" olefinic carbons (126–133 ppm; Fig. 2). From C-7 to the methyl terminal, the ^{13}C resonances of all n-3 fatty acids are virtually identical (Table 1) so the ^{13}C enrichment observed for these carbons does not distinguish EPA from other n-3 fatty acids which may have been synthesized from it in the 24 h after the [U-^{13}C]EPA was injected.

TABLE 3

Fatty Acid Composition (%) of the Liver and Carcass in Control Rats Compared to a Rat Orally Injected with a Bolus of [U-^{13}C]Eicosapentaenoic Acid (EPA)[a]

	Liver		Carcass	
	Control	EPA	Control	EPA
18:3n-3	0.4 ± 0.3	0.3	1.6 ± 0.3	1.0
20:5n-3	0.6 ± 0.1	0.7	0.2 ± 0.04	0.2
22:5n-3	1.1 ± 0.4	1.1	0.5 ± 0.1	0.4
22:6n-3	5.2 ± 0.4	6.2	1.1 ± 0.2	0.8
Sum n-3	7.3 ± 0.9	8.4	3.3 ± 0.3	2.4
Sum n-6	29.9 ± 2.1	29.7	27.1 ± 3.1	23.4
Sum mono	16.0 ± 2.3	15.3	34.8 ± 2.7	41.2
Sum sat	46.8 ± 3.7	46.9	34.9 ± 1.4	33.2

[a]Mean ± SD, n = 4 in controls; n = 1 in the EPA group. Sum n-3 = (18:3n-3 + 20:5n-3 + 22:5n-3 + 22:6n-3). Sum n-6 = (18:2n-6 + 20:3n-6 + 20:4n-6 + 22:4n-6 + 22:5n-6). Sum mono (monounsaturated) = (16:1n-7 + 18:1n-9 + 20:1n-9). Sum sat (saturated) = (14:0 + 16:0 + 18:0).

TABLE 4

Increase in ^{13}C Nuclear Magnetic Resonance Signal Intensity (%) at Selected Carbons in Total Fatty Acid Extracts of the Liver and Carcass of a Rat Orally Injected 24 h Previously with a Bolus of 98% [U-^{13}C]Eicosapentaenoic Acid[a]

Chemical shift (ppm)	Fatty acid carbon	^{13}C Signal intensity	
		Liver	Carcass
14.1	n-1	+83	+9
25.6	Doubly allylic	+45	−13
~128	Olefinic ("inner")	+245	+16
~130	Olefinic ("outer")	+17	+12

[a]Determined relative to the peak area of a known amount of tetrakis(trimethylsilyl)silane added as standard. Data are expressed as the increase above natural abundance ^{13}C values in control animals.

^{13}C enrichment at the C-1 to C-4 resonances of EPA were markedly reduced relative to those in the [U-^{13}C]-EPA itself (compare Figs. 1 and 2C). There were also three small ^{13}C resonances in the difference spectrum (Fig. 2C) which do not occur in [U-^{13}C]EPA itself: at 22.5 ppm, 29.5–30.0 ppm and 129.5–130.5 ppm. Combined with the marked reduction in the C-1 to C-4 resonances, these changes suggest there may have been some conversion of the [U-^{13}C]EPA to ^{13}C-enriched DPA (^{13}C enrichment at 29–30 ppm and 130 ppm) or DHA (^{13}C enrichment at 22.5 ppm). The loss of the C-1 to C-4 resonances is consistent with this possibility, but is also consistent with partial degradation of the [U-^{13}C]EPA to ^{13}C-enriched acetate from which saturated or monounsaturated fatty acids could be synthesized which also have signals at these chemical shifts. In contrast to the liver, ^{13}C signal intensities for fatty acid carbons of the carcass showed no consistent ^{13}C enrichment from the [U-^{13}C]EPA (Table 4).

DISCUSSION

Our aim in this study was to use high resolution ^{13}C NMR to monitor the presence of as many carbons of [U-^{13}C]EPA as possible in lipid extracts of liver and carcass so as to obtain information about possible oxidation compared with liver and carcass accumulation of EPA and its long chain metabolites, especially DHA. This is important because recent data suggest that >90% of dietary EPA is completely oxidized and therefore unavailable for metabolic or structural functions (13,14).

The high resolution ^{13}C NMR spectra showed that 24 h after injection, one or more ^{13}C-labelled n-3 fatty acids were present in the liver (Fig. 2). However, there was actually very low ^{13}C mass enrichment, and EPA-specific carboxyl terminal resonances virtually disappeared, which both agree with GLC data indicating minimal differences in EPA in the carcass or liver (Table 3). Thus, some of the weak ^{13}C enrichment may have been from DPA or DHA, *e.g.*, at C-3 of DHA (22.5 ppm), aliphatic carbons including C-5 of DPA (29–30 ppm) and at the "outer" olefinic carbons including C-7 of DPA (about 130 ppm). Some of the ^{13}C enrichment at 29–30 ppm and 130 ppm could also have arisen from a small amount of synthesis of monounsaturated fatty acids after degradation of [U-^{13}C]EPA. ^{13}C enrichment at these resonances was very weak, so basing net production of ^{13}C-enriched fatty acids on these data is speculative at this point. Nevertheless, high resolution ^{13}C NMR clearly has the potential to provide carbon-specific details of fatty acid synthesis and degradation.

Desaturation and elongation of EPA to DHA is dependent on the age of the animal and is influenced by fasting, anesthetic use, DHA and EPA level in the diet and the amount of substrate (EPA) given, so that the present data are subject to these constraints. When more [U-^{13}C]EPA or other [13C]-labelled fatty acids become available, several rats must be studied in each group so that more precise data about interanimal differences in metabolism of EPA and other fatty acids can be obtained. Nevertheless, we conclude that ^{13}C NMR may be able to assist in further investigation of these variables affecting metabolism and degradation of polyunsaturated fatty acids.

Positional Distribution of n-3 Fatty Acids in Triacylglycerols from Rat Adipose Tissue During Fish Oil Feeding

Claude Leray*, Thierry Raclot and **René Groscolas**
Centre d'Ecologie et de Physiologie Energétiques, CNRS, associé à l'Université Louis Pasteur, 67087 Strasbourg, France

The present study was designed to investigate the metabolism of the n-3 polyunsaturated fatty acids (PUFA) in adipose tissue and its dependence upon dietary factors. Changes in the positional distribution of the fatty acids in triacylglycerols from retroperitoneal adipose tissue were studied as a function of time on rats fed for 4 wk a diet enriched with fish oil. The stereospecific analysis of triacylglycerols was based on random formation of *rac*-1,2-diacylglycerols by Grignard degradation. This was followed by synthesis of *rac*-phosphatidic acids and treatment with phospholipase A_2. In the triacylglycerols of the fish oil diet, 57% of the total n-3 fatty acids were in position 3, *i.e.*, two-thirds of 20:5n-3 and 22:5n-3 were esterified in *sn*-3 position, whereas 22:6n-3 was equally distributed in positions 2 and 3. After 4 wk of feeding fish oil, the fatty acid composition of adipose tissue triacylglycerols reached a steady state. Half of the n-3 fatty acids were found in position 3, namely 75% of 22:5n-3, 50% of 20:5n-3 and 18:4n-3 and 45% of 22:6n-3, the latter being equally distributed in positions 2 and 3. This pattern of distribution resembled that found in triacylglycerols of the fish oil diet, except for a higher proportion of 20:5n-3 in adipose tissue in position 1 at the expense of position 3. Throughout the 4-wk period of fish oil feeding, the distribution pattern of minor n-3 fatty acids (18:4n-3 and 22:5n-3) in adipose tissue triacylglycerols remained unchanged. On the other hand, at the onset of fish oil feeding, 20:5n-3 and 22:6n-3 became concentrated in position 3, but thereafter 20:5n-3 was progressively incorporated into position 1 and 22:6n-3 into position 2. We thus conclude that n-3 fatty acids are differentially esterified in triacylglycerols of white adipose tissue. Despite the complex sequence of hydrolysis and acylation steps involved, the positional distribution of n-3 fatty acids was found to be similar in both the fish oil diet and the stored fat, in contrast to what was observed for nonessential fatty acids.
Lipids 28, 279–284 (1993).

The beneficial effects of dietary intake of marine polyunsaturated fatty acids (PUFA), especially 20:5n-3 and 22:6n-3 (1), have attracted considerable interest during the past 15 yr. The results of animal and clinical studies have suggested that n-3 fatty acids may prevent or improve various pathological conditions, including atherosclerotic vascular degeneration (2), hyperlipidemia and hypercholesterolemia (3), insulin-dependent diabetes (4) and endotoxic shock (5), as well as cancer (6). Adipose tissue is the reservoir of fatty acids, both nonessential and essential, including n-3 PUFA. However, the influence of n-3 PUFA on the overall metabolism of adipose tissues is poorly understood. Moreover, the specific mechanisms controlling the storage and the mobilization of n-3 PUFA are unknown. The regiospecific synthesis of triacylglycerols depends on the selectivity of the transacylases involved in the glycerophosphate pathway (7), but the fatty acid specificity of these enzymes is not well understood. The regiospecificity of hormone-sensitive lipase from rat adipose tissue has been documented (8), but the effect of fatty acid chain length and unsaturation is not known (9). The positional specificity of this enzyme together with a nonrandom distribution of n-3 fatty acids in adipose triacylglycerols may account for the differential mobilization of these fatty acids that has recently been observed (Raclot, T., and Groscolas R., unpublished data). A better understanding of the metabolism of n-3 PUFA in adipose tissue requires knowledge of the positional distribution of n-3 PUFA in triacylglycerols. The effect of the positional distribution of fatty acids in dietary triacylglycerols on the time dependency of their distribution in adipose tissue is also not known. To gain insight into the metabolism of n-3 PUFA in adipose tissue, we have studied the specific distribution of n-3 PUFA incorporated into triacylglycerols. The triacylglycerols were purified from retroperitoneal adipose tissue in rats that were shifted from a basal diet to a fish oil diet for 1–4 wk. The data were compared with those obtained on the distribution of these fatty acids in the dietary triacylglycerols.

MATERIALS AND METHODS

Animals and diets. From weaning up to 8 wk of age, 12 male Wistar rats were individually housed in a room having a 12 h light/dark cycle at a constant temperature of 25°C. The animals were kept on a basal diet (A04, UAR, Villemoisson, France) containing 3% lipids. When the animals reached a 227 ± 8 g body weight, 9 rats were shifted to a semi-synthetic diet containing (g/kg): 450 sucrose, 250 caseine, 45 agar-agar, 45 minerals (mix 205B, UAR), 10 vitamins (mix 200, UAR), 10 sunflower oil, 190 purified fish oil (MaxEPA, R.P. Scherer, Beinheim, France). The amount of sunflower oil was chosen to meet the daily requirement in essential 18:2n-6. The fish oil diet was prepared weekly in bulk and supplemented with α-tocopherol (300 mg/kg) as an antioxidant. The diet was divided into daily rations and kept at −20°C. The fatty acid composition of the triacylglycerols of the diets is shown in Table 1. The phospholipid fraction present in the basal diet (17% of its total lipid moiety) was shown to have the same fatty acid composition as the triacylglycerol fraction.

Extraction and separation of lipids. Animals were killed by cervical dislocation at 9 a.m. Three rats fed the basal diet were killed at the onset of the experiment. Animals fed the fish oil diet were killed after 1 wk (280 ± 3 g), 2 wk (331 ± 22 g) or 4 wk (388 ± 26 g) of feeding (three rats at a time). These time periods were chosen based on results of preliminary studies which showed that the n-3 PUFA content in triacylglycerols of adipose tissue reached a steady-state level after 2 wk of feeding the fish oil enriched diet. Adipose tissue samples from retroperitoneal fat depots were immediately excised, and their total

Abbreviations: DB, double bond index; EDTA, ethylenediaminetetraacetic acid; PUFA, polyunsaturated fatty acid(s); TLC, thin-layer chromatography; U/S, unsaturated/saturated fatty acid ratio.

lipids were extracted (10). Total lipids were similarly extracted from three pooled aliquots of the basal and the fish oil diets. The triacylglycerols were isolated by silicic acid column chromatography, using $CHCl_3$ for elution and were purified by thin-layer chromatography (TLC) on silica gel G (Merck, Darmstadt, Germany) using hexane/diethyl ether/acetic acid (70:30:1, by vol) as the developing solvent. Ethyl gallate was added to all solvents (25 mg/L) to minimize autoxidation, and reactions were carried out under nitrogen.

Generation of diacylglycerols. A procedure based on the Grignard degradation of about 10 mg of triacylglycerols was used as previously reported (11) without modification.

Preparation of phosphatidic acid. The first step of the diacylglycerol derivatization procedure (11) was performed with the following modifications. An ice-cooled solution of diacylglycerols (about 2 mg) in 0.2 mL of $CHCl_3$ was added slowly to 2 mL of a chilled phosphorus oxychloride solution ($CHCl_3$/pyridine/$POCl_3$; 9.5:9.5:1, by vol) with stirring, and the mixture was allowed to stand for 10 min at 0°C and for 50 min at 20°C. After the addition of 4 mL of $CHCl_3$, 2 mL of 0.5 M sodium hydrogen carbonate and 0.4 mL of 0.5 M ethylenediaminetetraacetic acid (EDTA), the mixture was vortexed for 2 h and then centrifuged. The lower phase was evaporated, and the dried product dissolved in a mixture of $CHCl_3$/methanol (1:1, vol/vol) and partitioned with one volume of water. After evaporation of the solvent under nitrogen, the phosphatidic acid was purified by TLC (12).

Hydrolysis of phosphatidic acid. A procedure using snake venom phospholipase A_2 (13) was used with the following modifications. Phosphatidic acid (1–1.5 mg) was vortexed for 2 h at 25°C with 2 mL of diethyl ether and 1 mL of Tris buffer (50 mM Tris, 4 mM $CaCl_2$, pH 7.5) containing 5 units of *Crotalus atrox* phospholipase A_2 (Sigma, St. Louis, MO) dissolved in 20 μL buffer. The hydrolysis products were isolated by TLC (12). Released fatty acids (R_f = 0.83) would then reflect the fatty acid composition at the *sn*-2 position and lysophosphatidic acid (R_f = 0.49) is representative of the fatty acid composition at the *sn*-1 position of the triacylglycerols. The composition of the *sn*-3 position was calculated as 3 × (triacyl) − (*sn*-1 + *sn*-2 position).

The accuracy of the method was checked by the analysis of synthetic 1,3-dioleoyl-2-palmitoyl-*rac*-glycerol. A contamination not exceeding 2% (absolute) by fatty acids migrating from positions 1 and 3 to position 2 was observed, which is consistent with other procedures reported (13,14). Reproducible results were obtained by the method described although there remain large relative errors for minor components in position 3. Therefore, mole percentages lower than 0.5 mol% in positional distribution were omitted.

Fatty acids analysis. Fatty acids were converted to methyl esters by BF_3-catalyzed transmethylation (15) and analyzed by gas-liquid chromatography using a Chrompack CP9000 chromatograph equipped with a polar capillary column (AT-WAX, 60 m, i.d. 0.25 mm, Alltech). All solvents and chemicals were of reagent grade as supplied by Merck or Sigma. Results are given as means ± SEM. The Student's *t*-test was used to compare significant differences among means.

RESULTS

Dietary triacylglycerols. The composition and positional distribution of fatty acids in the triacylglycerols of the basal and fish oil diets are given in Table 1. For the basal diet, it was observed that the major fatty acid, 18:2n-6, showed no marked preference for any of the three glycerol positions. A similar trend was also observed in the fish oil diet. In this diet, most of the n-3 PUFA (18:4, 20:5 and 22:5) were preferentially esterified (to the extent of 65%

for 20:5) in position 3. On the other hand, 22:6n-3 was bound almost exclusively in positions 2 and 3. Despite the low amount of n-3 PUFA in the basal diet, a trend toward preferential esterification of 20:5 and 22:6 in position 3 was observed.

Adipose tissue triacylglycerols. Feeding of the fish oil diet rapidly increased the concentration of the n-3 fatty acids in white adipose tissue (Table 2), except for 18:3n-3 whose concentration was significantly ($P < 0.02$) lowered after one week of feeding. The broad fatty acid composition of the adipose tissue triacylglycerols resembled that of the dietary triacylglycerols. Thus, after 4 wk, the high contents of the n-3 PUFA found typically in the fish oil diet were also observed in adipose tissue triacylglycerols. Similarly, the diet and the fat store shared low contents in n-9 monounsaturated fatty acids and in n-6 PUFA. The positional distribution of the main fatty acids in the triacylglycerols from the rat adipose tissues is given in Table 3. In rats fed the basal diet, each position of the triacylglycerols showed a discrete fatty acid pattern. Fatty acids at position 1 were highly saturated (unsaturated/saturated ratio, U/S = 0.8), about half of the 16:0 and 18:0 contents being found in this position. Fatty acids at position 3 were significantly ($P < 0.001$) more unsaturated (U/S = 2.4) than those at position 1; monoenoic acids (mainly 18:1n-9) and n-3 PUFA were preferentially esterified in this position. The highest degree of unsaturation (U/S = 4.6) was found at position 2, owing to a high concentration of 18:2n-6. A similar pattern was observed for the double bond index (DB), for which the order of increasing values corresponded to positions 1, 3 and 2, respectively. In rats fed the fish oil diet during 4 wk and having reached a steady-state fatty acid composition, the positional distribution of the saturated fatty acids remained closely similar to that observed in rats fed the basal diet. Of the monoenoic fatty acids, only 18:1n-9 was significantly affected; the amount of this acid at position 3 had decreased by one-half after 4 wk ($P < 0.01$ *vs.* basal diet). Although the 18:2n-6 content decreased more than twofold ($P < 0.001$ *vs.* basal diet) in triacylglycerols, the distribution pattern of this fatty acid remained unchanged with a high concentration in position 2 (between 50 and 70% of the total amount). Thus, despite the large increase in n-3 PUFA after 4 wk of feeding with the fish oil diet, the distribution of the other fatty acids at positions 1, 2 and 3 of glycerol was not markedly modified. The greatest extent of saturation was found at position 1 and the lowest at position 2. The main n-3 PUFA in adipose tissue triacylglycerols showed three different distribution patterns (Table 3, Fig. 1): (i) 22:5 was mainly concentrated at position 3 (75%), the remaining part being equally distributed between positions 1 and 2; (ii) 18:4 and 20:5 were found mainly at position 3 (50%), only 15% being found at position 2; (iii) 22:6 was equally distributed among positions 2 and 3 after 2 wk, with only 15% being found at position 1. In summary, when a steady fatty acid composition was reached, half of the total n-3 PUFA was found at position 3, the remaining part being equally distributed between positions 1 and 2. However, the proportion of each n-3 PUFA at position 3 decreased in the sequence 22:5 > 20:5 = 18:4 > 22:6 > 18:3, with only 18:3 and 22:6 showing a significant accumulation at position 2. From Table 4, it is evident that there is a close resemblance between triacylglycerols of the adipose tissue and those of the diet. Nevertheless, a higher esterification of 20:5 at position 1 was noted in adipose tissue, at the expense of position 3. It was observed that the time-dependent distribution of the minor n-3 PUFA of the fish oil diet (18:4 and 22:5) remained unchanged during the feeding period (Fig. 1). In contrast, the patterns displayed by the major n-3 PUFA (20:5 and 22:6) (Fig. 1) changed in the course of feeding from 1 to 4 wk. At the onset of feeding with fish oil, 20:5 and 22:6 accumulated preferentially in position 3. The final level of these n-3 fatty acids in position 3 was already reached one week after the diet was changed, thus leading to an increase in DB in this position reaching its highest value. Later, after 2 and 4 wk of feeding, 20:5 and 22:6 were progressively incorporated into positions 1 and 2, respectively.

DISCUSSION

Positional distribution of n-3 PUFA in adipose tissue triacylglycerols as a function of their distribution in the diet.

[a]Fatty acid composition in mol% in each position. Mean ± SEM of three experimental values.
[b]Less than 0.5 mol%. See legend of Table 1 for other explanations. U/S, unsaturated/saturated fatty acid ratio; DB, double bond index (number of double bonds per 100 mol fatty acids).

TABLE 4

Positional Distribution of Major n-3 Polyunsaturated Fatty Acids in Triacylglycerols from Fish Oil Diet (D) and White Adipose Tissue (WAT) of Rats Fed This Diet for Four Weeks[a]

Fatty acid	Position 1		Position 2		Position 3	
	D	WAT	D	WAT	D	WAT
20:5n-3	18	33	16	14	66	53
22:6n-3	7	15	48	40	45	45
18:4n-3	36	26	12	17	52	57
22:5n-3	12	11	20	14	68	75

[a]Mol% for each fatty acid, the sum of the three positions being 100. Fatty acids are arranged according to their decreasing content in the fish oil diet.

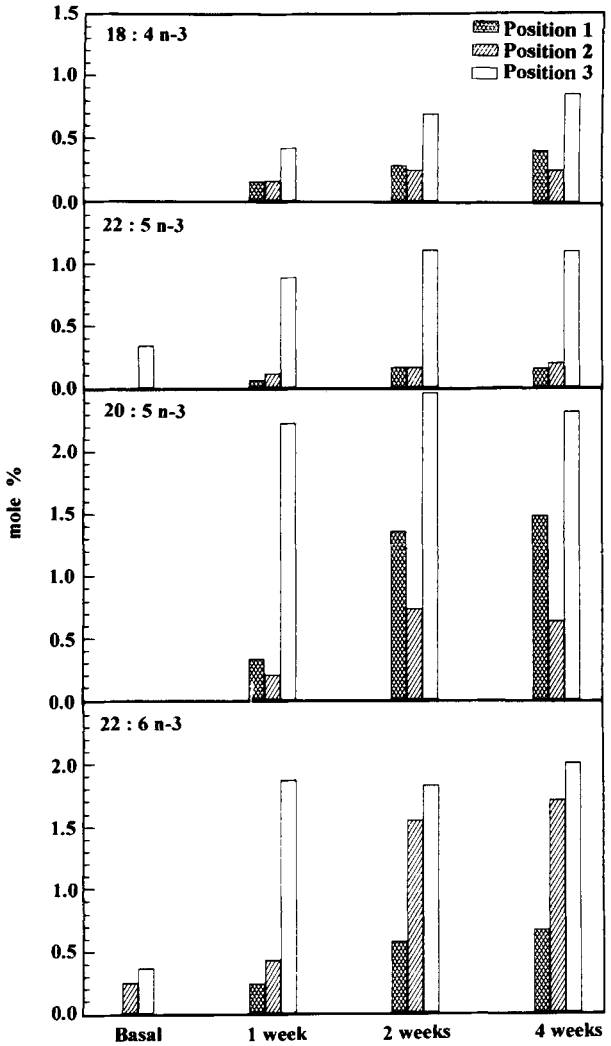

FIG. 1. Positional distribution as a function of time of n-3 fatty acids in retroperitoneal adipose tissue triacylglycerols from rats fed a fish oil diet. For each fatty acid, the sum of the three columns at each time represents its total amount (in mol%) in triacylglycerols (data recalculated from Table 3).

The incorporation of fatty acids into triacylglycerol stores is still poorly understood. Several factors may be involved in the control of the positional distribution of n-3 fatty acids in adipose tissue triacylglycerols, including their

immediate availability through intestinal absorption (16) and the specificity of acyltransferases (17) as well as of lipolytic enzymes (9,18). The structure of dietary triacylglycerols should also be taken into account. Recent studies (19,20) have demonstrated that fatty acids located at position 2 in dietary fish oil tend to remain in this position in circulating triacylglycerols. This is unexpected in view of the hydrolytic action of pancreatic lipase in the intestinal lumen and the complex processing of absorbed lipids in mucosal cells. The finding of a selective inhibitory action of 20:5n-3 on the rate of hydrolysis of triacylglycerols in fish oil chylomicron by lipoprotein lipase (21) suggests that fatty acids may be selectively directed toward the peripheral tissues. These observations may have important implications for the incorporation of n-3 fatty acids into adipose tissue stores. Several reports have been published on the positional distribution of fatty acids in fish oils (16,18,22–25). Only two of these studies were conducted with the Grignard reagent (16,22), which eliminates biases due to the well-known fatty acid specificity of pancreatic lipase (18). In 1963, a typical fish pattern with accumulation of polyenoic acids at position 2 of triacylglycerols was described (23), but this pattern would appear to be provisional rather than firmly established. The distribution of the two main n-3 fatty acids presented here for MaxEPA oil (20:5 mainly in position 3 and 22:6 in positions 2 and 3) is in marked contrast to that reported for menhaden oil (22) (20:5 mainly in positions 2 and 3, whereas 22:6 is principally located in position 2). This distribution is also different from that reported for a commercial preparation consisting largely of sardine oil (16) (20:5 evenly distributed among all three positions).

Previous studies on the distribution of n-3 fatty acids in triacylglycerol stores (23–27) have not involved defined diets. Hence, no information is available on the relationship between the structures of dietary n-3 enriched oils and those of the stored triacylglycerols. Animals fed the basal diet in the present study had adipose tissue triacylglycerols with the essential fatty acid 18:2n-6 mainly in position 2. The nonessential fatty acids of exogenous and endogenous origin were equally distributed between the two other positions, with 16:0 and 18:1n-9 being found mainly in positions 1 and 3, respectively. This distribution is similar to that previously reported for the rat and other mammals (25,28,29). After feeding fish oil, the triacylglycerol composition was profoundly modified, leading to a decrease in the 18:2n-6 content with compensation by an increase in the n-3 fatty acids. The distribution pattern of the n-3 fatty acids rapidly changed and thereafter remained stationary after a feeding period of two weeks. With respect to 20:5, 22:5 and 22:6, the resulting pattern was different from that reported in rat and mink fed with a mackerel diet (25) and from the pattern observed for wild polar bear and seal (25). No conclusion can be drawn from these differences since no information on the molecular structure of the dietary triacylglycerols was obtained in these studies. Our observation of a close resemblance between the position of n-3 fatty acids in triacylglycerols of the fish oil diet and those of the rat adipose tissue suggests that certain biosynthetic pathways in fish and rat may be similar. Unfortunately, no further light has been shed on this question by studies on mammals fed various marine oils (23,24,26). However, rat enterocytes purportedly transfer triacylglycerols to the lymph with a positional distribution of n-3 fatty acids similar to that of the consumed fish oil (20). Further studies of the metabolic chain following feeding with fish oil or fatty acid ethyl esters (19) are clearly necessary.

Incorporation of n-3 PUFA into adipose tissue triacylglycerols as a function of specific mechanisms. The rapid incorporation of the main n-3 fatty acids (20:5 and 22:6) observed in position 3 or adipose tissue triacylglycerols after feeding rats with the fish oil diet suggests that the enzyme diacylglycerol acyltransferase has a high selectivity for these fatty acids. This enzyme is known to play a key role in the final step of triacylglycerol synthesis (17). However, specific acylation in this position under our experimental conditions may also reflect in part the composition of the changing adipocyte acyl-CoA pool. The relative importance of enzyme properties *vs.* substrate availability remains to be determined. The observation of the delayed and concomitant channelling of 20:5 and 22:6 into positions 1 and 2 indicates that the two acylating enzymes along the glycerol-3-phosphate pathway have a much lower affinity for n-3 than for nonessential fatty acids. Nevertheless, our results suggest some specificity of the 1- and 2-acylglycerophosphate acyltransferases for 20:5 and 22:6, respectively. As was previously suggested for adipose tissue (7,17,25,30) and liver (31,32), the relative affinity and thus the competition of different polyunsaturated fatty acids for acylation into triacylglycerols may be an important factor for the asymmetric distribution. As for saturated fatty acids in rats fed coconut oil (33), it can be postulated that the delayed changes in 20:5 and 22:6 at positions 1 and 2 may also arise from an intermolecular rearrangement of triacylglycerol fatty acids. The extent of this intracellular remodelling is not yet certain, but the present results may be of help in designing future experiments on n-3 PUFA recycling in the pool of adipocyte triacylglycerols. The existence of a monoacylglycerol pathway in adipose tissue (34) and the recent demonstration of a partial retention of fish oil structure in chylomicron triacylglycerols (19) illustrate the diversity of mechanisms involved in depot fat remodelling.

Since interconversions of triacylglycerols and phospholipids through diacylglycerols are well documented, adipocyte membrane phospholipids are likely to contribute to the formation of diacylglycerols. These intermediates may be secondarily acylated to form highly unsaturated triacylglycerol species. The rapid incorporation of dietary n-3 PUFA into adipose tissue phospholipids (Leray *et al.*, unpublished data) is consistent with a contribution of membrane phospholipids in adipose triacylglycerol biosynthesis. From our observations and the reported similarity between the structures of the 1,2-diacylglycerol moiety in rat liver triacylglycerols and in phosphatidylcholine (32), one still needs to answer the question to what extent adipose lipid stores are influenced by cellular phospholipids. In conclusion, the present study has shown that considerable amounts of n-3 PUFA can be stored in rat adipose tissue and that these fatty acids are differentially esterified in triacylglycerols. Since the positional distribution of n-3 PUFA in the fish oil ingested is similar to that of the lipid stores, further information on their relationships would be desirable. It could be obtained through studies with natural and randomized fish oil or n-3 PUFA ethyl esters as the diet.

ACKNOWLEDGMENTS

The generous gift of MaxEPA oil by R.P. Scherer (Beinheim, France), the excellent technical assistance of Geneviève Gutbier, and the expert help of Dr. J. MacCordick in the preparation of the manuscript are gratefully acknowledged.

Relationship Between Mouse Liver Δ9 Desaturase Activity and Plasma Lipids

Roberto J. de Antueno*, Richard C. Cantrill, Yung-Sheng Huang, Michele Elliot and **David F. Horrobin**
Efamol Research Institute, Kentville, Nova Scotia, B4N 4H8 Canada

This study was undertaken to investigate the total plasma fatty acid composition and the relationship between plasma triacylglycerol (TG) levels and liver Δ9 desaturase activity in mice fed n-3 and/or n-6 fatty acid or hydrogenated coconut oil (HCO) (maximum 25 mg/g) supplemented diets. Generally, plasma TG levels and Δ9 desaturase activity were inversely correlated with the ratio of the sum of long chain n-6 fatty acids to 18:2n-6 and to the ratio of the sum of long chain n-3 fatty acids to 18:n-3, but they were positively correlated with the ratio of products and substrates (18:1/18:0) of the enzyme in plasma total lipids. The n-3 fatty acid (mainly 20:5n-3) enriched diet, when compared to the HCO diet at 21 d, caused a significant reduction in plasma TG levels but not in Δ9 desaturase activity. However, a marked reduction in plasma TG content (50–60%) and Δ9 desaturase activity (55–70%) was observed when both 20:5n-3 and 18:3n-6 were supplemented in the diet. The plasma TG levels and Δ9 desaturase activity rose again when the animals were fed the HCO diet or chow. The results suggest that low dose supplementation of a mixture of n-3 (mainly 20:5n-3) and n-6 (18:3n-6) fatty acids modified both plasma TG content and liver Δ9 desaturase activity, in parallel.
Lipids 28, 285–290 (1993).

Both n-3 and n-6 polyunsaturated fatty acids modulate plasma lipid composition and hepatic lipid metabolism. There also is considerable evidence that the n-3 fatty acids, present in fish oil, can reduce plasma triacylglycerol (TG) levels in normal and hyperlipidemic subjects (1,2) even with high linoleic acid intake (3). This effect has been attributed to the fact that n-3 fatty acids may inhibit very low density lipoprotein (VLDL) TG synthesis (2,4), promote the clearance of VLDL from the circulation (5) and reduce hepatic lipogenic enzyme activity (6). Moreover, it has been reported that n-3 fatty acids suppress fatty acid synthesis in isolated rat hepatocytes (7) and reduce Δ9 desaturase activity *in vivo* (8,9). In contrast, polyunsaturated fatty acids of the n-6 series, such as linoleic acid (18:2n-6) or its desaturation product γ-linolenic acid (18:3n-6), do no reduce plasma TG levels either in healthy or hypertriglyceridemic patients (3,10,11).

We have shown in a previous study that diets supplemented with 18:3n-6 together with n-3 fatty acids (mainly 20:5n-3) increase the levels of these fatty acids and their metabolites in liver microsomes (12). We have suggested that the increase in long chain n-3 and n-6 fatty acid metabolites might be responsible for the inhibition of microsomal Δ9 desaturase activity (12). However, the combined effect of a mixture of these n-3 and n-6 free fatty acids on plasma TG levels was not examined. The present paper describes the relationships between plasma TG levels and liver Δ9 desaturase activity and between plasma fatty acid composition and desaturase activity in mice fed n-3 and n-6 fatty acid supplemented diets.

MATERIALS AND METHODS

Chemicals. All organic solvents and chemicals were of reagent grade and obtained from British Drug House Inc. (Toronto, Ontario, Canada). Fatty acid standards were purchased from Nu-Chek-Prep (Elysian, MN). [1-^{14}C]Palmitic acid (more than 98% radiochemical purity; 9 mCi/mmol) was purchased from New England Nuclear (Boston, MA) and used without further purification. γ-Linolenic acid concentrate and fish oil concentrate were obtained from Callanish Ltd. (Isle of Lewis, Scotland). The free n-3 and n-6 fatty acids were prepared by urea inclusion, saponification and further purification by silicic acid chromatography following procedures described elsewhere (13).

Animals and diets. Female FVB mice (28-days-old) were obtained from Charles River Canada Breeding Laboratories (Montreal, Quebec, Canada). Animals were housed three per cage in a temperature-controlled environment (22 ± 2°C) with a 12 h light/dark cycle. All mice were adapted for 1 wk to Rodent Laboratory Chow No. 5001 diet (Ralston Purina Co., St. Louis, MO) and water *ad libitum*. Mice were then weighed and randomly allocated to one of the experimental groups. All diets were prepared using Rodent Laboratory Chow No. 5001 supplemented with 25 mg/g hydrogenated coconut oil (HCO) (Teklad Test Diets, Madison, WI) or replaced with mixtures of n-6 and n-3 free fatty acid concentrates. When diets were supplemented with 18:3n-6 and 20:5n-3 alone or in a mixture, these fatty acids were maintained at comparable levels. The saturated and other unsaturated fatty acids were also kept at similar levels. The final fatty acid composition of each of these diets is shown in Table 1.

Three different experimental feeding schedules were used. In Experiment 1, mice were fed a diet rich in both eicosapentaenoic acid (EPA) and γ-linolenic acid (GLA) (diet EPA/GLA), rich in EPA only (diet EPA), rich in GLA only (diet GLA) or supplemented with HCO in place of both n-3 and n-6 fatty acids (diet HCO) for 21 d. In Experiment 2, mice were fed either diet EPA/GLA or HCO for 7 d and then crossed over onto the other diet for 14 d. In Experiment 3, mice were fed diets EPA/GLA, EPA, GLA, or HCO for 7 d and then switched back to chow for a washout period of 14 d. All diets were fed *ad libitum*. Fresh diets were prepared every second day with free fatty acids that were kept under N_2 at −20°C.

Every 7 d, at least three mice from each experiment were put under ether anesthesia, and blood was drawn by cardiac puncture into heparinized syringes before sacrifice.

Isolation of hepatic microsomes. Nonfasted mice were sacrified at 9 a.m. to avoid circadian variations in enzyme activity (14) and to obtain the maximum activities of liver desaturases (14,15). Microsomes were isolated by differential ultracentrifugation as previously described (16). The

[a]Values shown are in mg/g diet calculated from gas chromatographic analysis. EPA, eicosapentaenoic acid; GLA, γ-linolenic acid; HCO, hydrogenated coconut oil; CHOW, Purina Rodent Chow, No. 500.

microsomal pellet was suspended in 0.25 M sucrose and 62 mM phosphate buffer solution and kept frozen at −80°C until used. The protein concentration was measured by the method of Lowry *et al.* (17) with bovine serum albumin as standard.

Desaturase assays. The activity of Δ9 desaturase was determined by measuring the conversion of [1-^{14}C]16:0 (palmitic acid) to [1-^{14}C] 16:1n-7 (palmitoleic acid). Reactions were started by adding microsomal protein (5 mg) to pre-incubated tubes containing 0.25 μCi of 16:0 (final concentration 53.3 μM) and ATP (1.30 mM), NADH (0.87 mM) and coenzyme A (0.06 mM) as described (18). After 15 min incubation in a shaking water bath (37°C), the reactions were stopped with 2 mL 10% (wt/vol) KOH in ethanol. Lipids in the incubation mixture were saponified at 80°C for 45 min under N_2. After acidification, fatty acids were extracted with hexane and then methylated with BF_3 in methanol at 90°C for 30 min (19).

Lipid analysis. Lipids were extracted from plasma with chloroform/methanol (2:1, vol/vol) according to the method of Folch *et al.* (20). The composition of fatty acid methyl esters (FAME) in plasma lipids was determined by gas-liquid chromatography as described previously (21). Radiolabelled FAME from the desaturase studies were analyzed by high-performance liquid chromatography (HPLC) essentially according to the method of Narce *et al.* (22). The HPLC equipment (Waters Associates, Milford, MA) included a variable wavelength UV-vis monitor (set at 205 nm), a radioisotope detector (model 171, Beckman, Fullerton, CA, with 96% efficiency for ^{14}C detection) and an ultrasphere ODS column 25 cm × 4.6 mm i.d. (5 μ particle size, Beckman). FAME were separated isocratically with acetonitrile/water (95:5, vol/vol) at a flow rate of 1 mL/min and were identified by comparison with authentic standards.

Plasma TGs were measured enzymatically on a Cobas-Bioanalyzer (Roche Analytical Instruments Inc., Nutley, NJ) using the La Roche MA-Kit.

Statistical analysis. The results are expressed as means ± SD. Significance was assessed by one-way analysis of variance and multiple range tests using the SPSS-PC+ software package (SPSS Inc., Chicago, IL). Regression analysis of desaturase activity and plasma TG content or fatty acid ratios was made using the least-square method.

RESULTS

Table 2 shows that mouse body weight, the liver weight/body weight × 100 ratio and food consumption were not affected by n-6 or n-3 long chain fatty acid enriched diets or the HCO diet at the end of the 3-week feeding period. These parameters were also not significantly different among different dietary groups at any other time of sacrifice. This indicated that the amounts and ratios of n-3 and n-6 fatty acids added to the diets were acceptable.

Figure 1, panel A shows the time-dependent changes in plasma TG from mice initially fed the HCO diet for 7 d and then changed to the EPA/GLA diet or to chow for a period of 14 d. Panel B shows the plasma TG levels in animals fed the EPA/GLA diet for either 21 d or for 7 d and then changed to either chow or HCO diet for 14 more days. The plasma TG content in all animals fed the EPA/GLA diet was reduced by 50-60% (Fig. 1, panels A and B). Replacing the EPA/GLA diet at day 7 with the HCO diet or chow for 14 more days led to a significant increase (maximum 81% from day 7 values) in plasma TG levels (Fig. 1, panel B). No significant changes in the plasma TG levels were observed in animals initially fed either the EPA or GLA diet or when replaced with chow (Fig. 1, panels C and D, respectively).

When the 18:1/18:0 ratios of plasma total lipids from all animals fed different diets were plotted against plasma TG content, a positive relationship was observed (Fig. 2, panel A). In contrast, plasma TG levels were negatively

TABLE 2

Effect of Different Diets on Food Intake, Body Weight and Liver Weight[a]

Diet	Food intake (g/d)	Body weight[b] (g)	Liver weight/body weight[b] × 100

EPA	3.12 ± 0.35	20.86 ± 2.34	6.30 ± 0.30
GLA	3.31 ± 0.20	21.37 ± 2.07	6.10 ± 0.40
Chow	3.67 ± 0.46	21.41 ± 1.41	6.00 ± 0.80

[a]Each value represents the mean ± SD from at least three mice fed the diets for 21 d. Differences were not significant among all diets. For abbreviations, see Table 1.
[b]At time zero, body weight: 19.66 ± 2.13 g, liver weight/body weight × 100: 6.10 ± 0.60.

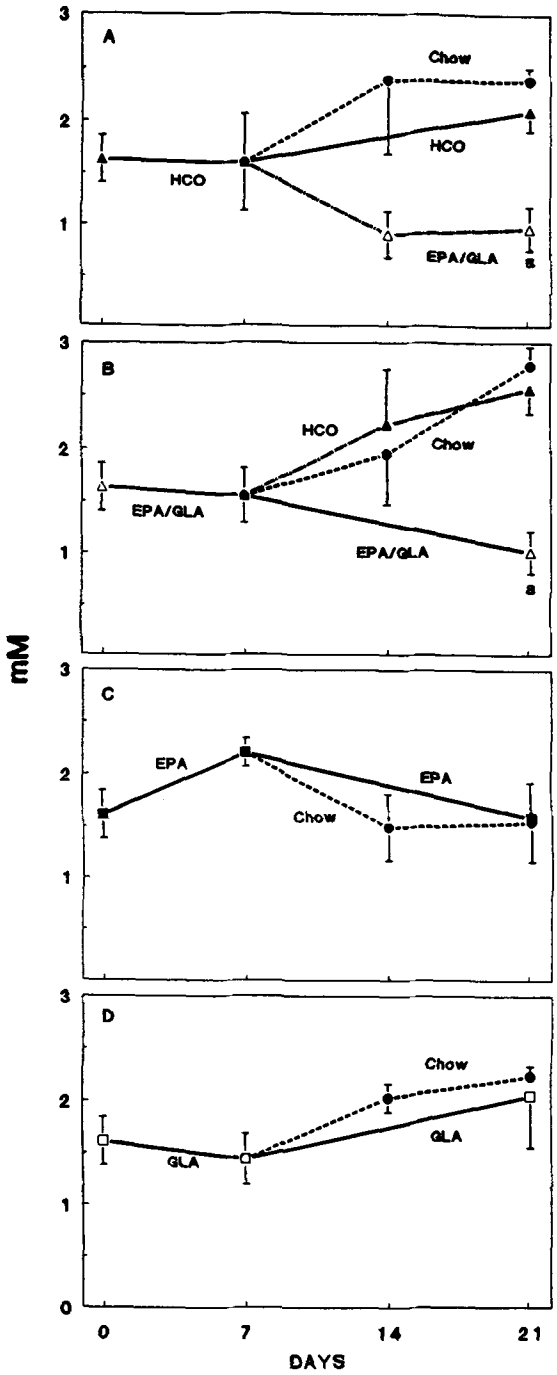

FIG. 1. Plasma triacylglycerol levels of mice fed n-3 and n-6 polyunsaturated fatty acid supplemented diets. Mice were fed one of the following diets as described in Material and Methods: ▲, hydrogenated coconut oil (HCO); △, eicosapentaenoic acid/γ-linolenic acid (EPA/GLA); ■, EPA; □, GLA; ●, Chow. Diets fed continuously throughout the experiment are denoted by solid lines. Diets changed on day 7 are indicated by dotted lines. Each value represents the mean ± SD of at least three mice. [a]Significantly different from 7-day values (panel A) or 0-day values (panel B) at $P < 0.01$.

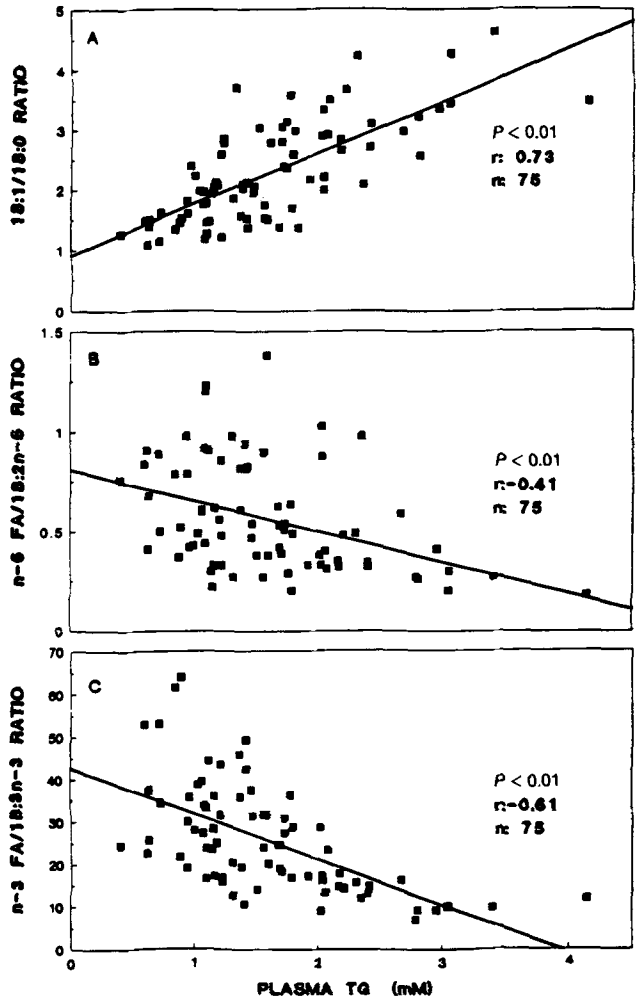

FIG. 2. Relationships between plasma fatty acids (FA) and triacylglycerols (TG). Correlations were calculated by linear regression analysis using data obtained from mice in all dietary groups at all times of sacrifice (n = 75). Total n-6 and n-3 fatty acids were related to their corresponding precursors 18:2n-6 and 18:3n-3, respectively, in order to normalize the differences found in plasma 18:2n-6 and 18:3n-3 content.

correlated to the ratio of the sum of long chain n-6 fatty acids/18:2n-6 or the ratio of the sum of long chain n-3 fatty acids/18:3n-3 (Fig. 2, panels B and C, respectively).

Liver Δ9 desaturase activity was readily affected by dietary modification. Feeding mice with the EPA/GLA diet for 7 to 21 d reduced Δ9 desaturase activity by 55 to 70% (Fig. 3, panels A and B). In mice previously fed the EPA/GLA diet, HCO feeding gradually increased the Δ9 desaturase activity; however, feeding chow for 14 d returned the Δ9 desaturase activity to day zero values. Feeding the HCO, EPA or GLA enriched diets throughout had no significant effect on Δ9 desaturase activity (Fig. 3, panels A, C and D, respectively).

Correlations between liver Δ9 desaturase activity and different fatty acids of plasma total lipids were also analyzed. Enzyme activity was positively correlated with the ratio of 18:1/18:0 (Fig. 4, panel A) whereas it was negatively correlated with the ratio of the sum of long chain n-6 fatty acids to 18:2n-6 or the ratio of the sum of long chain n-3 fatty acids to 18:3n-3 (Fig. 4, panels B and C, respectively).

DISCUSSION

Lawson and Hughes (23) have previously shown that free fatty acids were more efficiently absorbed than their re-

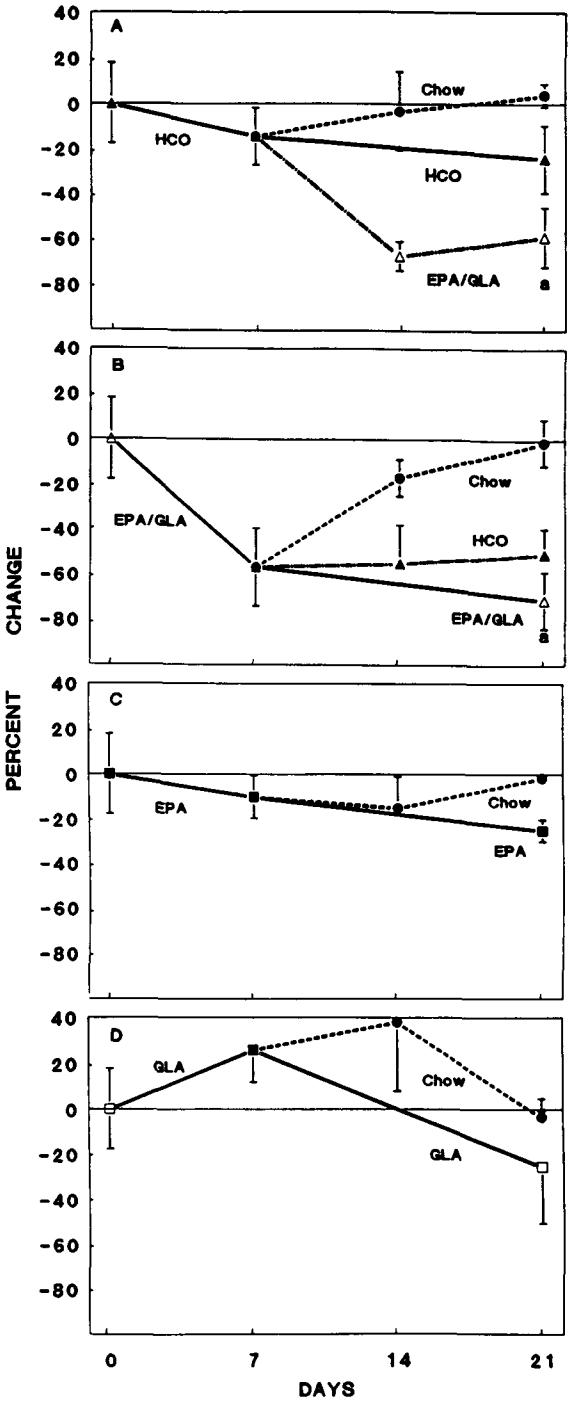

FIG. 3. Percent change of Δ9 desaturase activity of mice fed n-3 and n-6 polyunsaturated fatty acid supplemented diets. Mice were fed one of the following diets as described in Materials and Methods: ▲, hydrogenated coconut oil (HCO); △, eicosapentaenoic acid/γ-linolenic acid (EPA/GLA); ■, EPA; □, GLA; ●, Chow. Diets fed continuously throughout the experiment are denoted by solid lines. Diets changed on day 7 are indicated by dotted lines. Each value represents the mean ± SD of at least three mice. Δ9 Desaturase activity at day zero: 180 ± 30 pmol/min per mg of microsomal protein. [a]Significantly different from 7-day values (panel A) or 0-day values (panel B) at $P < 0.01$.

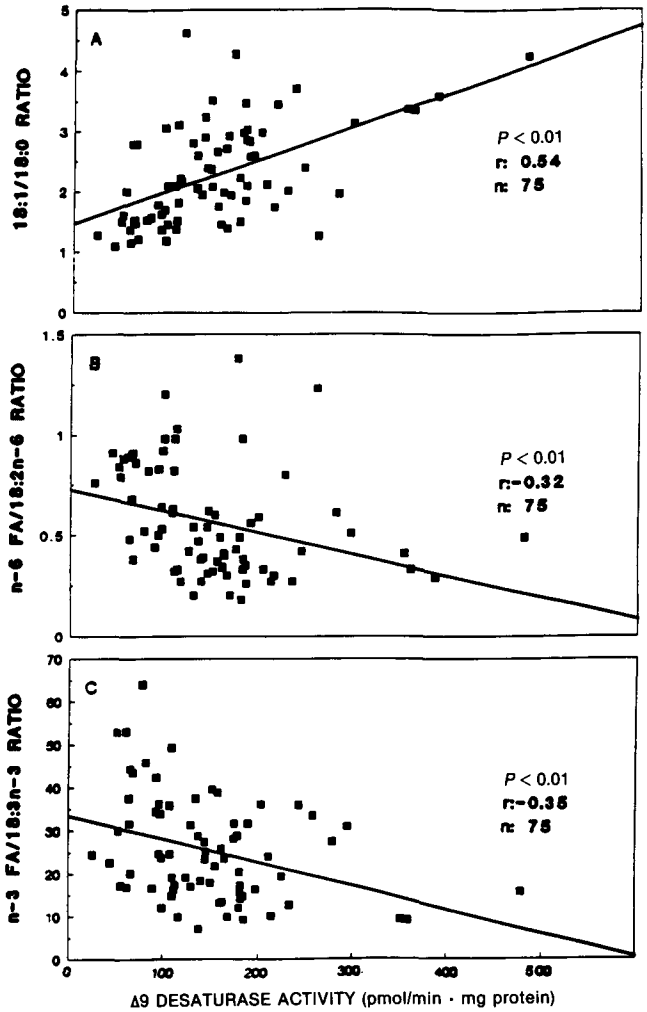

FIG. 4. Relationships between plasma fatty acids (FA) and hepatic Δ9 desaturase activity. Correlations were calculated by linear regression analysis as described in Figure 2. Δ9 Desaturase activity is expressed as pmol of substrate converted/min per mg of microsomal protein.

spective esters. Recently, Chautan *et al.* (24) have suggested that the plasma TG lowering effect of fish oil is partially due to incomplete hydrolysis of fish oil TGs by pancreatic lipase and reduced intestinal absorption of fatty acids. Therefore, we provided polyunsaturated n-3 and n-6 fatty acids in free fatty acid form in an attempt to maximize absorption. In the present study, the amounts of HCO or n-3/n-6 fatty acids added to the diets (2.5% by weight) were considerably lower than those used by other investigators (ranged from 8 to 20%) (9,25,26). Nevertheless, the dietary levels of n-3 and n-6 PUFAs were adequate to induce significant changes in the hepatic activity of Δ9 desaturase and several plasma lipid parameters (Figs. 1 and 3) without reducing the animals' body weight as reported elsewhere for higher fat intake (27).

The observed changes in plasma 18:1/18:0 ratio could not be attributed to differences in dietary 18:0 and 18:1 levels because the levels of 18:1 and 18:0 and the 18:1/18:0 ratios were similar in all diets tested (Table 1). Since the 18:1/18:0 ratio in plasma lipids was significantly and positively correlated with hepatic Δ9 desaturase activity (Fig. 4), it indicates that the plasma 18:1/18:0 ratio may reflect the liver Δ9 desaturase activity.

TABLE 3

Plasma TG Content and Liver Δ9 Desaturase Activity *vs.* Different Dietary PUFA Content[a]

	Dietary group			
	HCO	GLA	EPA	EPA/GLA
TG	2.0 ± 0.2	2.0 ± 0.5	1.5 ± 0.4[b]	0.9 ± 0.2[b,c]
Δ9	140.5 ± 27.5	139.0 ± 4.6	146.5 ± 10.6[b]	64.7 ± 4.1[b,c]
Dietary				
PUFA	29.2	57.8	54.9	61.2
P/S	0.6	2.8	2.9	3.4

[a]Each value represents the mean ± SD from three animals fed various supplemented diets for 21 d. TG, plasma triacylglycerol content, in mM. Δ9, Δ9 desaturase activity is expressed as pmol/min per mg microsomal protein. PUFA, percentage of total polyunsaturated fatty acids. P/S, polyunsaturated to saturated fatty acid ratio. For abbreviations, see Table 1.

[b,c]Significantly different ($P < 0.05$) from the HCO or EPA (or GLA) diet values, respectively.

It has been shown previously that dietary n-3 fatty acids can lower plasma TG levels and hepatic Δ9 desaturase activity (1,2,8). In the present study we observed that the ratios of post-Δ6 desaturation products to the parent acids in plasma lipids (n-3 fatty acids/18:3n-3 and n-6 fatty acids/18:2n-6) were negatively correlated with both plasma TG levels and Δ9 desaturase activity (Figs. 2 and 4). However, only the EPA/GLA diet was significantly effective in reducing both plasma TG levels and hepatic Δ9 desaturase activity when compared either to time zero values (Figs. 1 and 3) or to those from the HCO diet at the end of the study (Table 3). The EPA diet, when compared to the HCO diet at 21 d, caused a significant reduction in plasma TG levels but not in Δ9 desaturase activity (Table 3). These findings suggest that the TG and Δ9 desaturase activity-lowering effect of 20:5n-3, when given at low dose, requires the concomitant presence of n-6 PUFAs to be fully expressed.

These diet-induced differential effects may be related to the dietary PUFA levels and P/S ratio. Results shown in Table 3 indicated that increasing the PUFA content 2-fold and the P/S ratio 5-fold in the GLA diet, when compared to the HCO diet, did not affect plasma TG levels and Δ9 desaturase activities at the end of the study (21 d). These findings suggest that, under the experimental conditions used, the absolute PUFA levels or P/S ratios were not major factors in influencing plasma TG levels and Δ9 desaturase activity. On the other hand, the TG levels were reduced by 25% when animals were fed the EPA diet (Table 3) in spite of the fact that this diet had the same PUFA content and P/S ratio as the GLA diet. A further increase in PUFA content by only 11.5% and 17.2% in P/S ratio in the EPA/GLA diet significantly reduced both plasma TG and Δ9 desaturase activity by 55%. Again, this suggests that 20:5n-3 may lower TG levels and Δ9 desaturase activity only in combination with 18:3n-6. Whether these effects are confined to this strain of mouse or whether higher concentrations of 20:5n-3 in the diet could produce the changes documented here remains to be elucidated.

There are numerous mechanisms, such as modifications in peroxisomal and mitochondrial fatty acid oxidation (28,29) or in fatty acid and TG synthesis (30), that have been proposed to explain the effect of n-3 fatty acids on plasma TG levels. Insulin may also play a role in the TG-lowering effect of n-3 fatty acids. Otto *et al.* (25) have shown that n-3 fatty acid enriched diets decreased concomitantly both plasma insulin and TG levels. Insulin may also modify Δ9 desaturase activity and, consequently, the ratio of monoenoic to saturated fatty acids in the liver (31,32). In the present study, the levels of n-3 fatty acids were inversely related with the plasma TG levels as well as with the Δ9 desaturase activity (Figs. 2 and 4). These results are in agreement with the hypothesis that dietary n-3 fatty acids affect insulin levels or their receptors (25). However, it should be noted that the combined TG lowering and Δ9 desaturation suppressive effects of n-3 long chain fatty acids reported in this study were observed only in the presence of 18:3n-6. Since 18:3n-6 is an indirect precursor of eicosanoids (33), which are known to affect insulin secretion and binding (34–36), it is possible that this fatty acid may also contribute synergistically to the effects of n-3 fatty acids through insulin action. Additional investigations are needed to explore this possibility.

In summary, our data show that dietary supplementation with low doses of n-3 fatty acids (mainly 20:5n-3) and 18:3n-6 in combination, but not alone, caused a simultaneous reduction in plasma TG content and liver Δ9 desaturase activity. TG levels were positively correlated with the plasma 18:1/18:0 ratio but negatively correlated with the levels of n-6 and n-3 long chain PUFAs. It is suggested that these effects may be caused by a common factor (such as insulin) which is modulated by the presence of both 18:3n-6 and 20:5n-3 and/or their metabolites.

ACKNOWLEDGMENTS

We thank S. Churchill and M. Coldwell for their skillful assistance in the dietary treatment of the mice.

Age-Related Changes in Δ6 and Δ5 Desaturase Activities in Rat Liver Microsomes

C. Maniongui[a], J.P. Blond[a], L. Ulmann[a], G. Durand[b], J.P. Poisson[a] and J. Bézard[a,*]

[a]Unité de Recherche de Nutrition Cellulaire et Métabolique, Université de Bourgogne, 21000, Dijon and [b]Laboratoire de Nutrition et Sécurité Alimentaire, INRA, 78350 Jouy en Josas, France

Age-related changes in Δ6 desaturation of [1-^{14}C]α-linolenic acid and [1-^{14}C]linoleic acid and in Δ5 desaturation of [2-^{14}C]dihomo-γ-linolenic acid were studied in liver microsomes from Wistar male rats at various ages ranging from 1.5 to 24 mon. Desaturase activities were expressed both as specific activity of liver microsomes and as the capacity of whole liver to desaturate by taking into account the total amount of liver microsomal protein. Δ6 Desaturation of α-linolenic acid increased from 1.5 to 3 mon and then decreased linearly up to 24 mon to reach the same desaturation capacity of liver measured at 1.5 mon. The capacity of liver to desaturate linoleic acid increased up to 6 mon and then remained constant, whereas microsomal specific activity was equal at 1.5 and 24 mon of age. The capacity of liver to convert dihomo-γ-linolenic acid to arachidonic acid by Δ5 desaturation decreased markedly from 1.5 to 3 mon. It then increased to reach, at 24 mon, the same level as that observed at 1.5 mon. Age-related changes in the fatty acid composition of liver microsomal phospholipids at the seven time points studied and of erythrocyte lipids at 1.5 and 24 mon were consistent with the variations in desaturation capacity of liver. In particular, arachidonic acid content in old rats was slightly higher than in young rats whereas contents in linoleic and docosahexaenoic acids varied little throughout the life span. The results suggest that, in liver, the activity of desaturases may be regulated in the course of aging to maintain a constant level of polyunsaturated fatty acids in cellular membranes.
Lipids 28, 291-297 (1993).

Arachidonic acid (20:4n-6) and docosahexaenoic acid (22:6n-3), which are the major polyunsaturated fatty acids of phospholipids in mammalian cells, are formed, principally in liver, from the precursors linoleic acid (18:2n-6) and α-linolenic acid (18:3n-3), respectively. The essentiality of these precursors depends on their capacity to be Δ6 desaturated and then transformed to 20:4n-6 and 22:6n-3 by chain elongation and Δ5 desaturation (20:4n-6), and by another elongation and Δ4 desaturation (22:6n-3). Desaturation and elongation are alternative reactions, but the desaturation processes are rate-limiting whereas the elongation steps are rapid (1-3). The hepatic Δ6 desaturase, which is the regulatory enzyme in the pathway involved in the biosynthesis of polyunsaturated fatty acids of the n-6 and n-3 series, converts 18:2n-6 to γ-linolenic acid (18:3n-6) and 18:3n-3 to stearidonic acid (18:4n-3). Another important enzyme, the Δ5 desaturase, is responsible for the biosynthesis of the major precursors of eicosanoids of series 2 and 3, *i.e.*, 20:4n-6 from dihomo-γ-linolenic acid (20:3n-6) and eicosapentaenoic acid (20:5n-3) from eicosatetraenoic acid (20:4n-3). It also controls the balance between the precursors of eicosanoids of series 1 and 2 compounds (20:3n-6 and 20:4n-6, respectively), which have contrasting actions.

Several studies have shown that the *in vitro* fatty acid desaturase activities in liver microsomes are modified with aging. Peluffo and Brenner (4) showed that, in rat liver, Δ6 desaturation of 18:2n-6 and 18:3n-3 was decreased at 12 mon of age, when compared to desaturation at 3 mon. Bordoni *et al.* (5) demonstrated that the Δ6 desaturase activity toward 18:2n-6 decreased with the age of rats (between 1 and 22 mon). A linear correlation was proposed between activity and age. In another study, these authors showed that the decrease in the Δ6 desaturation of 18:3n-3 activity began later than did desaturation of 18:2n-6 (6). These results were obtained on Wistar rats fed a chow diet throughout their life. Choi *et al.* (7) found a significant age-dependent decrease in the Δ6 desaturation activity of 18:2n-6 between young (3-week-old) and adult (8-month-old) rats, but they did not confirm their results in a second study (8). Recently, Biagi *et al.* (9) showed that the Δ6 desaturation rate of 18:2n-6 in Wistar rats of 12 mon was only 44% of that found in young animals (3-month-old) after 1 mon of a semisynthetic diet containing soybean oil. The decrease with age in the rate of 18:3n-3 Δ6 desaturation was much less. Bourre *et al.* (10) found a 40% decrease in the Δ6 desaturation of 18:2n-6 in livers of mice between 4 and 17 mon. In studies using rat liver microsomes, the changes observed in the fatty acid compositions generally correlated with the impairment of Δ6 desaturation, suggesting a possible effect of age on the biosynthesis of prostaglandins and their metabolites.

These previous studies dealt only with Δ6 desaturation of 18:2n-6 or 18:3n-3 and often were limited to few time points. No study involved Δ5 desaturation. Moreover, results were expressed only as specific activity of Δ6 desaturation in liver microsomes. The Δ6 desaturation capacity of whole liver was not determined.

We therefore undertook a more complete survey of the evolution with age of Δ6 and Δ5 desaturation in rat liver. For this purpose, Wistar rats were fed the same balanced semisynthetic diet during their life span. The Δ6 desaturation of 18:2n-6 and of 18:3n-3 and the Δ5 desaturation of 20:3n-6 were determined in liver microsomes at seven time points ranging from 1.5 to 24 mon. Results were expressed both as specific activity and as total capacity of the liver to desaturate. The fatty acid composition of liver microsomal phospholipids was also determined to evaluate whether changes (if any) in the fatty acid profiles with age could be accounted for by modifications in desaturation specific activity or capacity. Data dealing with adult rats (3, 6, 9 mon of age) were reported in a preliminary study (11). The present paper describes the complete study carried out on young, adult and old rats.

MATERIALS AND METHODS

Animals and diet. Weanling male Wistar rats were randomized into groups of three rats and housed in stainless-steel cages in a well-ventilated room maintained at 22°C on a 12-h light/dark cycle. They were fed a balanced diet

Abbreviation: Prot, protein.

containing (g/kg): casein, 220; DL methionine, 1.6; cellulose, 20; starch, 440; sucrose, 218; mineral mixture, 40; vitamin mixture, 10; oil mixture (50% palm oil plus 50% rapeseed oil), 50. In 100 g of diet, linoleic acid (18:2n-6) and α-linolenic acid (18:3n-3) represented 945 and 188 mg, respectively (n-6/n-3 ratio, 5.0). The fatty acid composition of the diet lipids is shown in Table 1. The diet was stored at 4–6°C, and rats were fed *ad libitum*. Rats were maintained on this diet up to 1.5, 3, 6, 9, 12, 18 and 24 mon of age at the Laboratoire de Nutrition et Sécurité Alimentaire (INRA, Jouy en Josas, France). For the 1.5 mon study, only one group of six rats was used. For the other six ages (3 to 24 mon), two groups of three rats were used at two different periods (generally summer and winter) of the same year or of two different years in order to minimize the effect of season on the desaturation rate (4).

Chemicals. [1-^{14}C]Linoleic acid (58 mCi/mmol, 99% radiochemical purity) was purchased from CEA (Gif sur Yvette, France). [1-^{14}C]α-Linolenic acid and [2-^{14}C]dihomo-γ-linolenic acid (56 mCi/mmol, radiochemical purity, 96%) were purchased from the Amersham Radiochemical Centre (Amersham, United Kingdom). Each substrate was diluted in ethanol with unlabelled fatty acid to a specific activity of 10 mCi/mmol. Coenzymes, biochemicals and other chemicals were purchased from Sigma Chemical Co. (St. Louis, MO).

Preparation of microsomal fractions. All experiments were performed starting at 7:30 a.m. to avoid any circadian variation in desaturase activity (12) and on night-fed animals in order to obtain the maximum desaturation activity (2).

The rats were anesthetized with sodium pentobarbital (6 mg per 100 g of body weight). They were exsanguinated by drawing blood from the abdominal aorta. The liver was excised, rinsed with ice-cold saline solution and weighed. About 3.5 g of liver were homogenized at 4°C in a Potter-Elvejhem homogenizer with 6 vol of 0.25 M sucrose in 0.05 M buffer phosphate (pH 7.4). The homogenate was centrifuged at 13000 × *g* (Model J-21B centrifuge, J-21 rotor, Beckman, Lyon, France) for 20 min to sediment cell fragments, mitochondria and nuclei. The supernatant was recentrifuged (L8-55 Ultracentrifuge, Ti 60 rotor, Beckman) at 105000 × *g* for 60 min, and the microsomal pellet was resuspended in 0.4 mL of supernatant and 0.8 mL of sucrose buffer. The amount of microsomal protein was determined by the method of Layne (13).

Desaturation assays. Incubations were performed in open flasks at 37°C for 15 min using a shaker water bath with a total volume of 2.1 mL incubation medium containing 72 mM phosphate buffer, pH 7.4, 4.8 mM $MgCl_2$, 0.5 mM coenzyme A, 3.6 mM adenosine 5′-triphosphate, 1.2 mM reduced nicotinamide adenine dinucleotide phosphate and 120 nmol, 120 nmol and 80 nmol of labelled 18:3n-3, 18:2n-6 and 20:3n-6 (30 μL of ethanolic solution), *i.e.*, about 57, 57 and 38 μM, respectively. At time 0, 5 mg of microsomal protein was added to the incubation medium. Incubations were stopped after 15 min by adding 15 mL of chloroform/methanol (1:1, vol/vol). Lipids were transmethylated in methanolic BF_3 according to Slover and Lanza (14).

The substrate and desaturation product were separated by high-performance liquid chromatography as described by Narce *et al.* (15), using a Waters Chromatograph Model 6000A and a Model 401 differential refractometer (Waters Associates, Milford, MA). The 250 × 4 mm i.d. column packed with LiChrospher 100 RP-18 (4 μm particles), protected by a LiChrosorb RP-18 precolumn, was purchased from Merck (Darmstadt, Germany). The fatty acid methyl esters were collected at the detector outlet, and their radioactivity was measured directly in the solvent by liquid scintillation counting with a Packard Model A 3000CD spectrometer (Packard Instruments, Rungis, France). The conditions permitted a good separation of the different polyunsaturated fatty acid methyl esters, and the desaturation product was eluted before its substrate, avoiding its contamination by the highly radioactive substrate.

Specific activity was expressed as pmol of radioactive fatty acid converted to desaturation product per min and per mg microsomal protein. For each animal, the desaturation capacity of whole liver was calculated by taking into account the total amount of microsomal protein in liver. It was expressed as nmol of substrate converted per min and per whole liver.

Preparation of erythrocytes. Erythrocytes were isolated from blood according to Rao *et al.* (16). Blood was collected from the abdominal aorta using heparin mixed with buffered saline solution (NaCl, 141 mM; KCl, 10 mM; $MgCl_2$, 1 mM; $CaCl_2$, 1.3 mM; NaH_2PO_4, 5 mM) in the proportion 1:5 (vol/vol). The suspension was gently shaken and centrifuged at 2500–3000 × *g* for 7 min. The pellet was resuspended in the saline solution and recentrifuged. The operation was repeated three times.

Fatty acid analysis. Lipids from an aliquot of liver microsomes and from the remaining pellet containing erythrocytes were extracted with dimethoxymethane/methanol (4:1, vol/vol) according to Delsal (17). Microsomal phospholipids were obtained by silicic acid column chromatography according to Hirsch and Ahrens (18). Fatty acids were transmethylated (14), and the fatty acid methyl esters were analyzed by gas-liquid chromatography using a Packard Model 417 chromatograph equipped with a laboratory made 30 m × 0.3 mm i.d. glass capillary column coated with Carbowax 20M. Analyses

were carried out at 180°C at a nitrogen flow rate of 1 mL/min. The esters were detected with a flame-ionization detector. Peak areas were measured using a Delsi Model Enica 21 computing integrator (Delsi Instruments, Suresnes, France). Results are expressed as mole % of total fatty acids of the lipid fraction.

Statistical analysis. The results are expressed as means ±SD of six rats (1.5 mon) or of three rats in two different groups (3 to 24 mon). The graphs were traced using the means of the six rats for each age. After analysis of variance using the Fischer multiple range test, means were compared in the seven groups of age according to the least significant difference and classified in decreasing order. Means assigned different superscript letters were significantly different ($P < 0.05$). The fatty acid compositions of erythrocyte lipids and liver microsomal phospholipids were compared at 1.5 and 24 mon by means of Student's *t*-test.

RESULTS

Body weights, liver weights and liver microsomal protein concentrations at the seven time points studied are reported in Table 2. Body weight increased from 1.5 to 9 mon without any great difference between the two groups of three rats at 3, 6 and 9 mon of age. However, for the subsequent time points (12, 18 and 24 mon), body weight varied greatly between the two groups at each age. Liver weights also increased with age from 1.5 to 9 mon but more slowly than did body weights. As a consequence, the ratio of liver weight to body weight decreased from 1.5 to 6 mon. In the older rats, liver weight increased proportionally to body weight so that the liver weight/body weight ratio remained constant. The microsomal protein concentration was relatively constant, even in the two different groups (of the same age) of old rats so that the microsomal protein content of whole liver followed roughly the increase in liver weight.

The age-related specific activity of liver microsomes and capacity of whole liver to convert α-linolenic acid (18:3n-3) to stearidonic acid (18:4n-3) by Δ6 desaturation are reported in Figure 1. Both specific activity and liver capacity increased from 1.5 to 3 mon, but the latter increased more (2.8-fold) than did the former (1.3-fold). After 3 mon, the two parameters decreased with age but the specific activity decreased more rapidly than did liver capacity. At 24 mon, the specific activity of Δ6 desaturation of 18:3n-3 was 60% of that observed at 1.5 mon, while the liver capacity had returned to the initial level.

The parameters for the Δ6 desaturation of linoleic acid (18:2n-6) to γ-linolenic acid (18:3n-6) are reported in Figure 2. The specific activity of microsomes showed some variations with age, with relatively large differences occurring between groups at each age. However, the desaturation rate remained essentially constant between 1.5 and 24 mon. Paralleling the increase in total microsomal protein content, the liver capacity to desaturate linoleic acid increased from 1.5 to 6 mon, reaching a plateau between 6 and 24 mon. At 24 mon, the capacity was twice that measured at 1.5 mon.

The age-related specific activity of liver microsomes and the capacity of whole liver to convert dihomo-γ-linolenic acid (20:3n-6) to arachidonic acid (20:4n-6) by Δ5 desaturation are reported in Figure 3. The specific activity decreased markedly (6.5-fold) between 1.5 and 3 mon and then increased very slightly up to 24 mon to reach a value 2.5-fold lower than that at the earliest age studied. The capacity of the liver to desaturate also decreased between 1.5 and 3 mon but more slowly (2.4-fold) than did specific activity. From then on it increased, and, at 24 mon, the capacity of the liver to desaturate 20:3n-6 to 20:4n-6 was not significantly different from that found at 1.5 mon.

Figure 4 illustrates the age-related percentages of linoleic acid, of arachidonic acid, its product of Δ6 and Δ5 desaturations, and of docosahexaenoic acid in liver microsomal phospholipids. The percentage of 18:2n-6 did not change between 1.5 and 24 mon. The percentage of 20:4n-6 increased slightly, with some variations, reaching a higher value at 24 mon (32.2%) than at 1.5 mon (26.2%). Consequently, the 20:4/18:2 ratio increased from 3.4 (1.5

TABLE 2

Age-Related Changes in Body Weight, Liver Weight and Liver Microsomal Protein[a]

[a]Results are means ± SD for n = three or six animals in each group. After analysis of variance (Fisher multiple range test), means of the six rats per age were compared in each column according to the least significant difference and classified in decreasing order. Means assigned different superscript letters (b–f) were significantly different ($P < 0.05$).

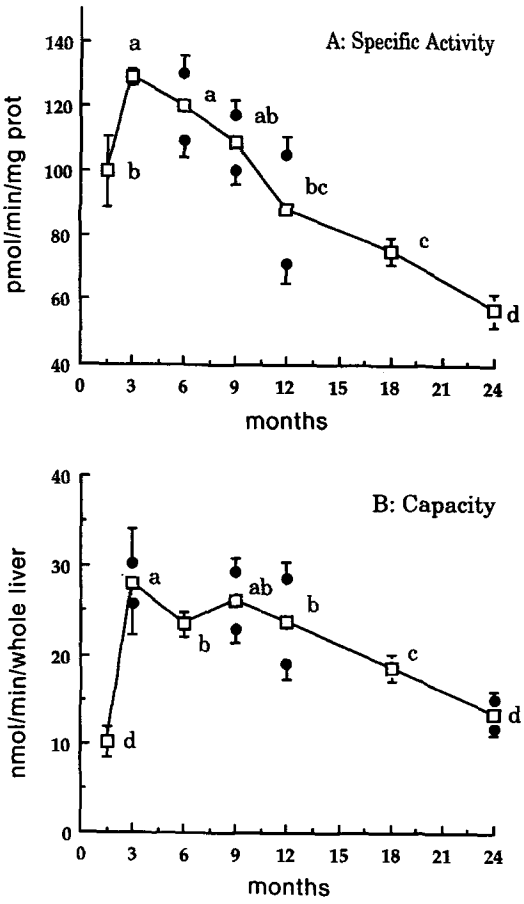

FIG. 1. Age-related changes in Δ6 desaturation of α-linolenic acid (18:3n-3) in liver microsomes expressed both as specific activity of liver microsomes (A) and activity of whole liver or capacity (B). Results are means ±SD obtained from one group of six rats (1.5 mon) or two groups of three rats at all other ages. After analysis of variance using the Fisher multiple range test, means of the six rats for each age were compared according to the least significant difference and classified in decreasing order. Means assigned different superscript letters were significantly different ($P < 0.05$). Prot, protein.

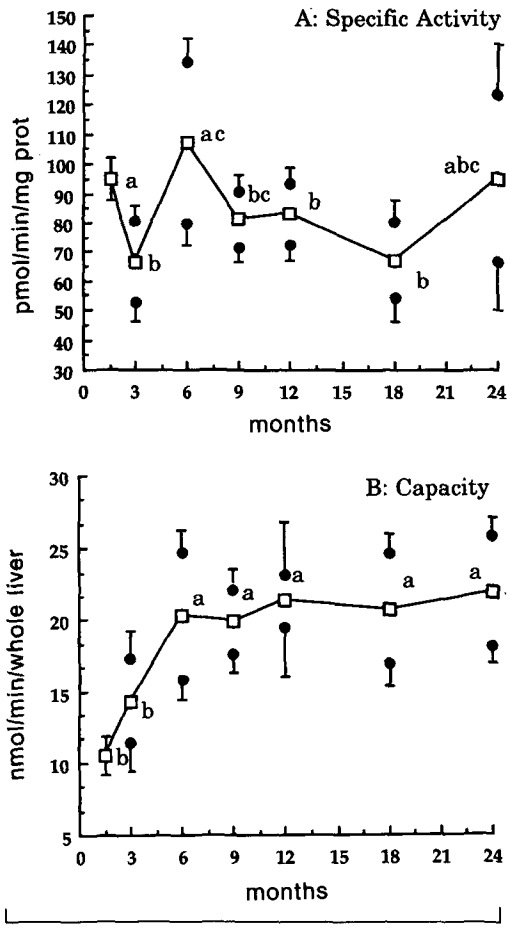

FIG. 2. Age-related changes in Δ6 desaturation of linoleic acid (18:2n-6) in liver microsomes expressed both as specific activity of liver microsomes (A) and activity of whole liver or capacity (B). Results are means ±SD obtained from one group of six rats (1.5 mon) or two groups of three rats at all other ages. After analysis of variance using the Fisher multiple range test, means of the six rats for each age were compared according to the least significant difference and classified in decreasing order. Means assigned different superscript letters were significantly different ($P < 0.05$). Prot, protein.

mon) to 3.8 (24 mon). The percentage of 18:3n-3 remained very low (*ca.* 0.3%) (unreported results) and constant, while that of 22:6n-3 decreased between 1.5 and 3 mon and then increased slightly to reach, at 24 mon, what had been the 1.5-mon value.

The fatty acid composition of erythrocyte lipids (mostly phospholipids) in 1.5- and 24-month-old rats is reported in Table 3, together with the composition of liver microsomal phospholipids at the same ages. The proportion of 18:2n-6 in erythrocytes was the same at the two ages studied, whereas the proportion of 20:4n-6 was higher in older rats. The percentage of 22:6n-3 in erythrocyte lipids was slightly lower in 24-month-old rats, but the level of total n-3 fatty acids was not significantly different at the two ages studied. The most striking difference in the fatty acid profiles of erythrocyte lipids and microsomal phospholipids is the higher percentage of 22:6n-3 and a lower percentage of palmitic acid (16:0) in the latter. Differences in the n-6 fatty acids were not pronounced.

DISCUSSION

The aims of this study were to investigate age-related changes in various desaturase activities of rat liver microsomes and to determine if these changes in turn induced alterations in the phospholipid fatty acid composition of erythrocytes and liver microsomes. The latter support the different desaturases and their associated proteins, and the former are rich in arachidonic acid.

Our data on the effects of age on Δ6 desaturation rates with 18:2n-6 and 18:3n-3 as substrates conflict with those reported by Hrelia *et al.* (6). These authors observed a decrease of 55% in the specific activity of Δ6 desaturase for 18:2n-6 between 1 mon and 22 or 25 mon. However, the Δ6 desaturation rate of 18:3n-3, much higher than that of 18:2n-6 at all ages, decreased from the end of 12 mon until 25 mon. We observed a pronounced decrease in the Δ6 desaturation of 18:3n-3 between 9 and 24 mon, whereas the Δ6 desaturation of 18:2n-6 was modified little through-

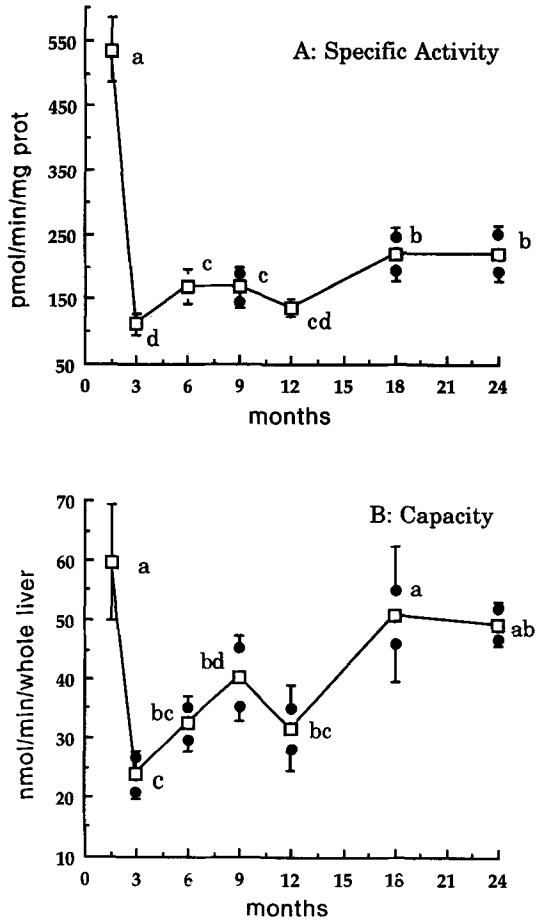

FIG. 3. Age-related changes in Δ5 desaturation of dihomo-γ-linolenic acid (20:3n-6) in liver microsomes expressed both as specific activity of liver microsomes (A) and activity of whole liver or capacity (B). Figures are means ±SD obtained from one group of six rats (1.5 mon) or two groups of three rats at all other ages. After analysis of variance using the Fisher multiple range test, means of the six rats for each age were compared to the least significant difference and classified in decreasing order. Means assigned different superscript letters were significantly different ($P < 0.05$). Prot, protein.

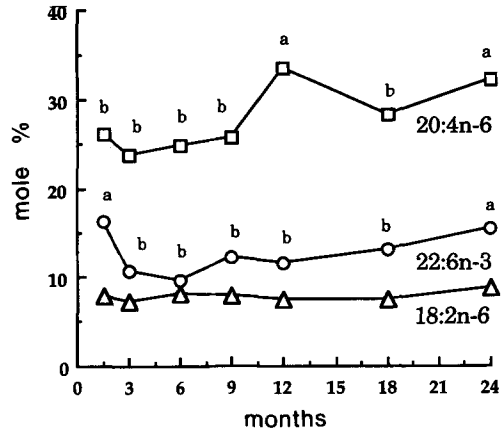

FIG. 4. Age-related changes in percentages of major polyunsaturated fatty acids in liver microsomal phospholipids. Results are means from six rats at each age. After analysis of variance using the Fisher multiple range test, the means were compared according to the least significant difference and classified in decreasing order. Means assigned different superscript letters were significantly different ($P < 0.05$).

out the life span. Moreover, the 18:2n-6 and 18:3n-3 Δ6 desaturation specific activities we observed at 1.5 mon (*ca.* 100 pmol/min/mg microsomal protein) were similar. Several differences between the experimental conditions used may in part explain these discrepancies. Hrelia *et al.* (6) used rats fed a chow diet throughout their life span and the liver microsomal preparations were frozen until use. Bourre *et al.* (10) also found a decrease with aging in Δ6 desaturation, but mice were used and desaturation measurements were done on liver homogenates. In our experiments, rats received a semisynthetic diet, and incubations were done immediately using fresh microsomes. In addition, we used a higher substrate concentration (57 μM instead of 40 μM used by Hrelia *et al.* (6)).

The differences in desaturation activities we observed between the two series of three animals, between 3 and 24 mon, were due in part to seasonal variations, as was previously shown for 6-month-old rats (11). To compensate for the seasonal variations of desaturation (4), we used two groups of animals at two different periods of the year. However, in the course of the experiment, another factor of variation appeared between the two groups: the liver weight in relation to the body weight. The desaturation rates varied in reverse order to the liver weight. So in 2-month-old rats, the amount of 18:2n-6 transformed by Δ6 desaturation was found equal to 71 ± 11 and 93 ± 4 pmol/min/mg microsomal protein in liver weighing 18.2 and 12.4 g, respectively. At certain ages, the effects of season and liver weight added and caused great variations between groups. At other ages, they compensated and the deviations were low. But within each group the variations between animals were not great.

No study has yet been reported on the age-related changes in Δ5 desaturase activity. Only data relative to the 20:3n-6/20:4n-6 ratio in liver lipids as a function of age have been reported, suggesting depressed Δ5 desaturase activity (19) or, on the contrary, a possible increase of this activity (20). Our results demonstrate that the specific Δ5 desaturase activity toward 20:3n-6 was 5.5 times higher than the Δ6 desaturase activity toward 18:2n-6 or 18:3n-3 at 1.5 mon.

The fatty acid composition of liver microsomal phospholipids and erythrocyte lipids reflected desaturation activities. The constant levels of 18:2n-6 and 20:4n-6 in liver microsomes after 3 mon are in agreement with the unchanged desaturation capacity of liver relative to 18:2n-6 and the increased capacity relative to 20:3n-6 in adult and aged animals. Despite some variations in desaturation activities, the 20:4n-6/18:2n-6 ratio varied little with age (3.4 to 3.8) except at 12 mon (4.5). These ratios were consistent with the observed changes in both Δ6 and Δ5 desaturation capacities. The changes in desaturation rates associated with the development of animals occur principally in the early stages of life.

The capacity of liver to convert 18:3n-3 to 18:4n-3 by Δ6 desaturation decreased with age, whereas the level of 22:6n-3 in microsomal phospholipids increased between 3 and 24 mon. An explanation for this may be that the decrease in Δ6 desaturase could be compensated for by

TABLE 3

Fatty Acid Composition (mole %) of Erythrocyte Lipids and Liver Microsomal Phospholipids at 1.5 and 24 Months of Age[a]

an increase in the Δ5 desaturation rate, as observed in the n-6 series, and/or by an increase in Δ4 desaturation and elongation rates, as reported recently by Mimouni *et al.* (21). On the other hand, an age-dependent decrease in the peroxisomal 22:6n-3 retroconversion, a decreased turnover rate and an increased incorporation into phospholipids may also explain that the 22:6n-3 levels in liver microsomes and in erythrocytes are maintained, despite a decrease in the Δ6 n-3 desaturation rate.

Although Δ6 and Δ5 desaturation activities are low in human liver (22–24), several studies indicated that few differences exist between elderly and young subjects with respect to the n-6 and n-3 fatty acid composition of serum (25,26), erythrocyte (27) and platelet (28) phospholipids. It can thus be assumed that in humans, as in rats, the desaturation activities are regulated to maintain constant the polyunsaturated fatty acid levels in membrane phospholipids. In particular, the desaturation rate could be increased to compensate for an increase, with aging, in peroxidation reactions in membranes. However, this compensation might disappear in different pathophysiological situations such as hypercholesterolemia or diabetes or modifications of nutritional conditions, leading to a decrease in polyunsaturated fatty acid content in tissue lipids and impairment of eicosanoid production.

Effect of Δ^9-Tetrahydrocannabinol and Merthiolate on Acyltransferase Activities in Guinea Pig Liver Microsomes

Ketan Badiani, Xiaoli Lu and **Gilbert Arthur***
Department of Biochemistry and Molecular Biology, Faculty of Medicine, University of Manitoba, Winnipeg, Manitoba, Canada R3E 0W3

Δ^9-Tetrahydrocannabinol (THC) and merthiolate have been utilized as lysophospholipid acyltransferase inhibitors in metabolic studies. However, their effects on acyltransferases other than lysophosphatidylcholine:acyl-CoA acyltransferase (LPCAT) are not known. We have therefore investigated the effectiveness of THC and merthiolate in inhibiting the acylation of lysophosphatidylcholine, lysophosphatidylethanolamine, lysophosphatidylserine, lysophosphatidylinositol (LPI) and lysophosphatidic acid (LPA) in guinea pig liver microsomes using oleoyl-CoA and arachidonoyl-CoA as acyl donors. THC inhibited LPCAT and lysophosphatidylethanolamine: acyl-CoA acyltransferase (LPEAT) by 40–50%, but had no effect or only slightly increased the activities of the other acyltransferases when assayed with oleoyl-CoA as the acyl donor. The results obtained with arachidonoyl-CoA were similar to those with oleoyl-CoA, with the exception of a 40% inhibition of lysophosphatidylserine:acyl-CoA acyltransferase (LPSAT) at concentrations of 50 μM or higher. At similar concentrations, merthiolate was more effective than THC in inhibiting the acyltransferases examined. Selective effects on the acyltransferases were observed at low concentrations of merthiolate (20 μM or less). Thus, LPCAT was most susceptible, followed by LPI acyltransferases, LPSAT, LPEAT and lysophosphatidic acid:acyl-CoA acyltransferases (LPAAT). The presence of LPA did not affect the inhibition of LPCAT by merthiolate. Thus the resilience of LPAAT to merthiolate inhibition was not due to chelation of the compound by the acidic lysolipid. Thiol reagents including *N*-ethylmaleiamide, 5,5′-dithio-*bis*-nitrobenzoic acid, iodoacetate, β-mercaptoethanol and dithiothreitol had little or no effect on the acyltransferases relative to equimolar concentrations of merthiolate. The above results indicate that merthiolate is a much more effective inhibitor of lysophospholipid:acyl-CoA acyltransferases than is THC, and that the selectivity exhibited by merthiolate may be due to direct and specific interaction with the acyltransferases. *Lipids 28,* 299–303 (1993).

A limiting step in the synthesis of eicosanoids and related compounds is the availability of unesterified fatty acids (1). Although these fatty acids are released from phospholipids by the action of phospholipases, increasing evidence suggests that acyltransferases play a key role in controlling the quantities of fatty acids available for eicosanoid synthesis (2–4). In order to investigate the effectiveness of agonists in stimulating the release of fatty acids or quantitation of fatty acids released, it is desirable to inhibit the enzymes that metabolize the released fatty acids, namely, the cyclooxygenases, lipoxygenases and acyltransferases. Inhibitors are available to block the cyclooxygenase and lipoxygenase pathways (5). A number of compounds, including some local anesthetics, have been shown to inhibit lysophosphatidylcholine:acyl-CoA acyltransferase (LPCAT) *in vitro* (6–8). Some of these also appear to inhibit LPCAT *in vivo* (6), but the effect of these inhibitors on the acylation of other lysophospholipids *in vitro* or *in vivo* is not known. A recent study reported the inhibition of LPCAT and lysophosphatidylethanolamine:acyl-CoA acyltransferase (LPEAT) by methyl lidocaine *in vitro* and in the isolated perfused hamster heart, but only moderate inhibition was obtained with a relatively high concentration (2 mM) of the local anaesthetic (8).

Agents generally regarded as acyltransferase inhibitors *in vivo* are Δ^9-tetrahydrocannabinol (THC) (9–12) and the thiol reagents merthiolate (thimerosal, 4) and *p*-hydroxymercuribenzoate (2,3). THC (10 μM) inhibited LPCAT activity by 80% in lymphocyte membranes (9). Merthiolate was equally effective in inhibiting LPCAT in macrophage membranes (4), but a higher concentration of *p*-mercuribenzoate (100 μM) was required to achieve a similar effect on the enzyme in macrophages, human lung fibroblasts or mouse liver membranes (2,3). Although these compounds may be effective inhibitors of LPCAT, this does not guarantee their effectiveness against other lysophospholipid:acyl-CoA acyltransferases. In the absence of such information, their utilization as general acyltransferase inhibitors may be inappropriate. Nevertheless, THC for example, is frequently cited as an acyltransferase inhibitor without mention of its possible limitations, despite conflicting reports on its effectiveness in inhibiting LPCAT *in vivo* (3,11,13). In view of this, the present study was undertaken to investigate the effect of THC and merthiolate on the acyltransferases involved in the acylation of lysophosphatidylcholine (LPC), lysophosphatidylethanolamine (LPE), lysophosphatidylinositol (LPI), lysophosphatidylserine (LPS) and lysophosphatidic acid (LPA) to form the parent phospholipids in guinea pig liver membranes. The specificity of merthiolate in inhibiting acylation processes was also investigated by comparing its effectiveness to that of other thiol reagents.

MATERIALS AND METHODS

Oleoyl-CoA, arachidonoyl-CoA, dimethylformamide (DMF), iodoacetate, *N*-ethylmaleiamide (NEM), 5,5′-dithio-*bis*-nitrobenzoic acid (DTNB), β-mercaptoethanol and merthiolate were obtained from Sigma Chemical Co. (St. Louis, MO). LPC (pig liver), LPE (pig liver), LPS (beef brain), LPI (pig liver) and LPA (egg lecithin) and

Abbreviations: DMF, dimethylformamide; DTNB, 5,5′-dithio-*bis*-nitrobenzoic acid; DTT, dithiothreitol; EDTA, ethylenediaminetetraacetic acid; LPA, lysophosphatidic acid; LPAAT, lysophosphatidic acid:acyl-CoA acyltransferase; LPC, lysophosphatidylcholine; LPCAT, lysophosphatidylcholine:acyl-CoA acyltransferase; LPE, lysophosphatidylethanolamine; LPEAT, lysophosphatidylethanolamine:acyl-CoA acyltransferase; LPI, lysophosphatidylinositol; LPIAT, lysophosphatidylinositol:acyl-CoA acyltransferase; LPS, lysophosphatidylserine; LPSAT lysophosphatidylserine:acyl-CoA acyltransferase; NEM, *N*-ethylmaleiamide; PA, phosphatidic acid; PC, phosphatidylcholine; PE, phosphatidylethanolamine; PI, phosphatidylinositol; PS, phosphatidylserine; THC, Δ^9-tetrahydrocannabinol; TLC, thin-layer chromatography.

phospholipid standards were purchased from Serdary Research Laboratories (London, Ontario, Canada). [1-^{14}C]-Oleoyl-CoA and [1-^{14}C]arachidonoyl-CoA were the products of Du Pont (Mississauga, Ontario, Canada). Tetrahydrocannabinol was generously provided by Health and Welfare Canada (Ottawa, Ontario, Canada). Guinea pigs (250–300 g) were obtained from Charles River Canada Inc. (St. Constant, Quebec, Canada). Dithiothreitol (DTT) was purchased from BDH (Toronto, Ontario, Canada). Whatman K6 thin-layer chromatographic (TLC) plates and all other chemicals and solvents (reagent grade) were obtained from Baxter Canlab (Winnipeg, Manitoba, Canada).

Preparation of microsomes. Microsomes were prepared from guinea pig liver by differential centrifugation (14) and the protein content was measured by the method of Lowry *et al.* (15).

Acyltransferase assays. LPCAT was assayed in a reaction mixture containing 100 mM Tris-HCl (pH 8.5), 92 μM acyl-CoA (specific radioactivity of oleoyl-CoA, 0.6 μCi/μmol; arachidonoyl-CoA, 1.5 μCi/μmol), 142 μM LPC and 50 μg guinea pig liver microsomal protein in a total volume of 500 μL. Microsomes in buffer and water were preincubated at room temperature for 20 min with the drugs prior to the addition of the lysophospholipid and radiolabelled acyl-CoA to initiate the reaction. THC was dissolved in DMF, and the required concentrations were added in a volume of 5 μL. Control tubes had 5 μL DMF. Incubation was for 20 min at 25°C. Lysophosphatidylinositol:acyl-CoA acyltransferase (LPIAT), lysophosphatidylserine:acyl-CoA acyltransferase (LPSAT) and lysophosphatidic acid:acyl-CoA acyltransferase (LPAAT) were assayed with 142 μM of the appropriate lysophospholipid in place of LPC above. The concentration of acyl-CoA required for optimal activity of LPIAT, LPSAT and LPAAT was 46 μM. LPEAT was assayed with 46 μM acyl-CoA and 214 μM LPE. These conditions were established as optimal for measuring this activity. In experiments to investigate the effect of LPA on LPCAT activity, the required quantity of LPA was added to the assay after the 20 min preincubation with merthiolate prior to the addition of LPC and initiation of the reaction by the addition of radiolabelled acyl-CoA. All reactions were stopped by the addition of 3 mL chloroform/methanol (2:1, vol/vol) followed by 1 mL KCl (0.9%). After mixing, the two phases were clarified by centrifugation. Aliquots of the lower phase were removed for TLC analysis. All phospholipids were separated on activated Whatman K6 plates with the solvent system chloroform/methanol/water/acetic acid (50:37.5:2:3.5, by vol; Ref. 16). The radioactivity associated with the phospholipid bands was measured by scintillation counting using a Beckman LS 3801 Scintillation Counter (Palo Alto, CA).

Statistics. Statistical significance of differences was assessed by comparing the means by Student's *t*-test. Differences were considered to be significant if $P < 0.01$.

RESULTS

The specific activities of the enzymes in guinea pig liver microsomes that catalyze the acylation of LPC, LPE, LPS, LPI and LPA were measured with optimal concentrations of oleoyl- or arachidonoyl-CoA as acyl donors (Table 1). All these enzyme activities were present in the microsomal fraction. The activities of LPCAT, LPEAT, LPSAT and LPIAT were higher with arachidonyl-CoA as the acyl donor than with oleoyl-CoA. The only exception was LPAAT, which was 1.3-fold higher with oleoyl-CoA than with arachidonoyl-CoA. This observation may reflect a functional difference between the LPAAT, which is involved in *de novo* phospholipid biosynthesis *vs.* the other activities which are involved in the remodelling pathways responsible for the asymmetric distribution of polyunsaturated fatty acids at the glycerol *sn*-2 position of phospholipids (17).

The effects of THC on the acyltransferase activities were assessed with oleoyl-CoA and arachidonoyl-CoA as acyl donors (Table 2). The activity of LPCAT assayed with oleoyl-CoA was not affected by up to 20 μM THC. At 50 μM THC the activity was inhibited 50% with no further decrease at 100 μM. The effect of THC on the acylation of LPC with arachidonoyl-CoA was similar to those obtained with oleoyl-CoA. The lack of inhibition of LPCAT activity at low concentration of THC (10 μM) is at odds with previous reports of severe inhibition of LPCAT by 10 μM THC (9,18). Therefore, we investigated whether this might be due to the different pre-incubation conditions used in the current and in previous (9,18) studies. The effect of 10 μM THC on guinea pig heart microsomal LPCAT was investigated by pre-incubating the microsomes for 30 min at 37°C with THC dissolved in dimethylsulfoxide. Under these conditions the LPCAT activity was till unaffected.

LPEAT activity assayed with oleoyl-CoA or arachidonoyl-CoA as the acyl donor was unaffected by 10 μM

TABLE 1

Specific Activities of Acyltransferases in Guinea Pig Liver Microsomes with Oleoyl-CoA or Arachidonoyl-CoA as Acyl Donors[a]

Acyl donor	Acyl acceptor				
	LPC	LPE	LPS	LPI	LPA
18:1-CoA	152 ± 23	302 ± 32	199 ± 29	244 ± 30	694 ± 82
20:4-CoA	1337 ± 92	598 ± 61	625 ± 123	613 ± 66	528 ± 48

[a]Acyltransferase activities were measured using acyl acceptors and acyl donors as indicated. The concentrations of substrates for each acyltransferase are indicated in the Materials and Methods section. The specific activities are expressed in nmol phospholipid formed/h/mg protein. The values represent the means ± SD of three experiments each carried out in duplicate. LPC, lysophosphatidylcholine; LPC, lysophosphatidylethanolamine; LPS, lysophosphatidylserine; LPI, lysophosphatidylinositol; LPA, lysophosphatidic acid.

THC, but increasing concentrations of the drug resulted in a progressive decrease in activity until, at a concentration of 100 μM, the activity was inhibited by 60% (Table 2). LPSAT activity was activated by approximately 30% at all concentrations of THC examined with oleoyl-CoA as the acyl donor. In contrast, LPSAT assayed with arachidonoyl-CoA was unaffected by 10 μM THC but was inhibited about 40% at concentrations of 50 μM or higher. Acylation of LPI was unaffected by the concentration range of THC used in our studies, irrespective of the acyl donor. LPAAT activity was either activated (10–50%) or not affected by THC with either oleoyl-CoA or arachidonoyl-CoA as acyl donor.

The effect of merthiolate on the acyltransferases was investigated in a fashion similar to that of THC using oleoyl-CoA or arachidonoyl-CoA as acyl donors (Table 3). The degree of inhibition of LPCAT by merthiolate was similar with either oleoyl- or arachidonoyl-CoA. At a concentration of 10 μM, about 90% of the activity was inhibited. LPIAT was also quite sensitive to the inhibitory effect of merthiolate irrespective of the acyl donor used in the assay. In contrast to LPCAT or LPIAT, acylation of LPS with both oleoyl- or arachidonoyl-CoA was relatively resilient to inhibition by merthiolate at low concentrations of the drug (<20 μM), but greater than 90% inhibition of LPSAT activity was observed in experiments with 100 μM merthiolate. LPEAT and LPAAT were also quite resistant to inhibition by merthiolate, especially the latter activity. A differential effect of merthiolate on LPEAT and LPAAT with different acyl donors was observed at the lower concentrations of the drug. LPEAT assayed with oleoyl-CoA was inhibited 30% by 10 μM merthiolate while acylation with arachidonoyl-CoA was inhibited 70% by the same concentration of merthiolate. The degree of inhibition obtained with both acyl donors was similar at higher concentrations of merthiolate. A modest activation of LPAAT (10–20%) was observed with merthiolate concentrations of 10 or 20 μM when arachidonoyl-CoA was used as the acyl donor. Acylation of LPA with oleoyl-CoA was inhibited about 15% at the same concentrations of merthiolate. LPAAT assayed with either acyl donor was inhibited between 60–70% by 100 μM merthiolate. One possible explanation for the inability of low concentrations of merthiolate to inhibit LPAAT could be the binding of the mercurial group of merthiolate to the negatively charged LPA. Such a reaction would decrease the effective concentration of merthiolate in the assay. To investigate this possibility, we examined the effect of varying concentrations of LPA on inhibition of LPCAT by merthiolate. The results which are displayed in Table 4 show no effect of LPA on the inhibition of LPCAT by merthiolate.

We also investigated the specificity of merthiolate in inhibition of the acyltransferases by comparing its effects with those of equimolar concentrations (20 μM) of the following thiol reagents: NEM, DTNB, iodoacetate, β-mercaptoethanol and DTT (Table 5). Merthiolate was clearly the most effective inhibitor of all the acyltransferase

reactions. Little inhibition of any acyltransferase activity was observed with the five compounds examined with the exception of a 24 and 37% decrease in LPCAT and LPSAT, respectively, by NEM and a 12–16% decrease in LPCAT and LPSAT by DTNB.

DISCUSSION

In this study we have examined the effectiveness of THC and merthiolate on the acylation of LPC, LPE, LPS, LPI and LPA in guinea pig liver microsomes. The results clearly demonstrate that THC does not inhibit all microsomal acyltransferases and even slightly activates some of the enzymes. Of those activities inhibited (LPCAT and LPEAT), high concentrations of 50 μM or more were required to achieve significant inhibition. The lack of inhibition of LPCAT at low concentrations of THC was surprising in view of the effectiveness of the drug in inhibiting the lymphocyte membrane enzyme (9). Although we cannot offer an explanation to account for the differences in effectiveness of THC in the present study and those of previous studies with lymphocyte membranes (9), the possibility that the LPCAT in different tissues may not be identical and may respond differently to the drug cannot be ruled out. Thus in rat islets, LPCAT activity was inhibited by only 20% after 30 min incubation with 20 μM THC (11). These values are in the range of those obtained in the present study rather than those reported for lymphocyte membrane (9).

It is also not clear why THC has a differential effect on the LPSAT activity assayed with oleoyl-CoA or arachidonoyl-CoA as acyl donors. Nevertheless, these results may be an indication that the drug may interact directly with the enzyme. If the effect was mediated through perturbation of the environment, one would not expect the effect of the drug to be dependent on the acyl donor. Another possible explanation is the existence of different enzymes that catalyze the acylation of LPS with different acyl donors (19).

Merthiolate proved to be a more effective inhibitor of acyltransferase reactions in the guinea pig liver microsomes than THC, resulting in greater inhibition of the enzyme activities at comparable concentrations of THC. At low concentrations (20 μM), merthiolate not only exhibited some specificity toward the different acyltransferases (LPCAT = LPIAT > LPSAT = LPEAT > LPAAT), but was also able to discriminate between the activities with different acyl donors for LPA and LPE. These observations were surprising as merthiolate is a sulfhydryl reagent and would be expected to react nonspecifically with the enzymes. The ineffectiveness of other sulfhydryl reagents in inhibiting the various acyltransferase activities suggests that the effectiveness of merthiolate may be unrelated to its reducing properties. In macrophages, *N*-ethylmaleiamide was unable to inhibit LPCAT under conditions where merthiolate (10 μM) inhibited the activity by 70% (4). The differential sensitivity of various acyltransferases to merthiolate and the demonstration that this cannot be attributed to chelation of the drug by acidic lysolipids suggest that merthiolate may interact directly and specifically with the enzymes.

The inability of THC to inhibit some acyltransferases and the moderate inhibition it had on other activities would suggest that if employed solely for the purpose of inhibiting the acylation of fatty acids released by agonists, a substantial amount of the released fatty acid could be reacylated in the presence of the drug, thereby resulting in an underestimation of the quantities of fatty acids released. On the other hand, low concentrations of

TABLE 5

Effect of Thiol Reagents on Acyltransferase Activities with Oleoyl-CoA as the Acyl Donor

Cholesterol Gallstone Induction in Hamsters Reflects Strain Differences in Plasma Lipoproteins and Bile Acid Profiles

Elke A. Trautwein, Jinsheng Liang and K.C. Hayes*
Foster Biomedical Research Laboratory, Brandeis University, Waltham, Massachusetts 02254

Because different strains of hamsters vary in their susceptibility to gallstones, the relationship between plasma lipoproteins, hepatic cholesterol, bile lipids and bile acid profile was examined during gallstone induction in strains of male Syrian hamsters from Charles River Lakeview (CHR), Biobreeder F_1B (BIO) and Harlan Sprague-Dawley (HAR). Gallstones were induced by feeding a purified diet containing 0.4 or 0.8% cholesterol for 5 wk. Basal plasma total cholesterol was similar, but the hypercholesterolemia induced by dietary challenge was significantly lower in CHR than in HAR and BIO hamsters. Cholesterol-fed CHR hamsters transported cholesterol mainly in HDL (47%), whereas VLDL-C + IDL-C predominated in BIO and HAR hamsters, and their HDL transported only 28 and 38%, respectively. HAR hamsters accumulated the most hepatic cholesterol, revealed the highest cholate/cheno ratio, the lowest glycine/taurine ratio and hydrophobicity index. HAR also developed the fewest cholesterol gallstones (23%), while 64% of CHR and 58% of BIO hamsters had cholesterol gallstones and 34% of BIO hamsters developed pigment stones. Doubling dietary cholesterol from 0.4 to 0.8% doubled the incidence of cholesterol gallstones but exerted minimal impact on other parameters compared to strain differences. Thus, different strains of hamsters vary considerably with respect to biliary cholesterol, bile acid profile and formation of cholesterol gallstones associated with differences in plasma lipoprotein profiles.
Lipids 28, 305-312 (1993).

Syrian hamsters are commonly used as a model for human lipid metabolism and cholelithiasis because hamster cholesterol and bile acid metabolism have certain similarities to humans (1,2). Furthermore, the hamster model is useful because cholesterol gallstones are readily induced by dietary manipulations (3-9). In the original studies by Dam (3), gallstones were induced most consistently by feeding hamsters a fat-free, glucose-rich diet. Other diet models have evolved that include a modest level of butterfat with or without dietary cholesterol (4-9). Whereas Dam's model is associated with essential fatty acid deficiency and results in abnormal physiology, other diet models are nutritionally more adequate. Our current purified diets are fomulated with a modest level of fat (5%) and a moderate amount of dietary cholesterol (0.4%) (8).

A complicating factor in hamster gallstone studies is the high incidence of pigment stones, which seem to be enhanced by feeding hamsters purified diets (3,8,10). Hamsters from different commercial sources also differ in their susceptibility to cholesterol gallstones (6), and differences in the metabolism of cholesterol, hepatic and biliary lipids as well as lipoprotein cholesterol distribution have been reported for different strains (11-15). For example, the hybrid F_1B hamster (Biobreeder) develops a unique cholesterolemic response to dietary cholesterol and saturated fat that renders it susceptible to fatty streak formation (16,17). In addition, a purified cholesterol-free diet containing 5% fat as a standard American fat blend (18) produced differences in plasma and biliary lipids, including the bile acid profile, in four strains of hamsters [Charles River Lakeview (CHR), Biobreeder F_1B (BIO), Harlan Sprague-Dawley (HAR) and Sasco] commonly used to study lipid metabolism.

In previous studies (7,8), hamsters fed a cholesterol-supplemented diet developed lithogenic bile and cholesterol gallstones in association with a lipoprotein profile that was characterized by an elevated very low density lipoprotein (VLDL)-cholesterol pool. Whether or how plasma lipoproteins modulate biliary cholesterol saturation and bile acid composition in the pathogenesis of cholesterol gallstones is poorly understood (19). Further, despite the importance of the hydrophobic/hydrophilic character of individual bile acids on cholesterol solubility (20), biliary cholesterol and phospholipid secretion (21) and bile acid synthesis (22), the impact of the physicochemical properties of dihydroxy *vs.* trihydroxy bile acids on bile lipid changes and cholesterol gallstone formation are not well defined *in vivo*.

To further examine this relationship and to identify the most susceptible model, we challenged three strains of hamsters (CHR, BIO and HAR) with a gallstone-inducing diet providing 0.4 or 0.8% dietary cholesterol while assessing plasma, hepatic and biliary lipids with particular emphasis on the individual bile acid profile. Our hypothesis was that the relationship between plasma lipoproteins, hepatic cholesterol and the bile acid profile would differ substantially during gallstone induction in hamsters reported to differ in their susceptibility to gallstones (6,7,13)

MATERIALS AND METHODS

Animals and diets. Thirty-six golden Syrian hamsters *(Mesocricetus auratus),* approximately 25-35 d old weighing 50-70 g were obtained from three different sources, namely Charles River Breeding Labs [Wilmington, MA (Lakeview strain)], Biobreeder Inc. [Watertown, MA (Hybrid F_1B hamster)] and Harlan Sprague-Dawley (Indianapolis, IN). Animals in each strain were randomly assigned to two groups (n = 5-7) and fed either of two purified diets containing 5% butter and either 0.4 or 0.8% cholesterol (Table 1) for 5 wk. The composition of the diet was in g/kg dry weight: casein 200, cornstarch 350, glucose 200, cellulose 100, wheat bran 50, fat 50, Ausman-Hayes mineral mix 6, Hayes-Cathcart vitamin mix 12, cholesterol 4 or 8, respectively, and choline chloride 3. The composition of the mineral and vitamin mix were detailed previously (10). Hamsters were housed in groups of 3-5

animals per cage with a bedding of wood chips kept in a temperature-controlled environment with a 12-h light/dark cycle (lights on 18:00 h). Hamsters were fed starch-gel diets *ad libitum* (25 g wet wt per hamster daily), and the food intake was monitored on a daily basis. Water was provided *ad libitum*. Body weights were monitored on a weekly basis. All protocols and procedures were approved by the Brandeis University Animal Care and Use Committee, Waltham, MA.

Plasma lipids and lipoprotein analysis. Blood was drawn upon arrival (baseline) and at the end of 5 wk. Prior to blood sampling, hamsters were fasted overnight (18 h) individually in wire-bottomed cages. Blood samples were collected under light anesthesia into an ethylenediaminetetraacetic acid wetted syringe by cardiac puncture, and plasma was separated immediately by centrifugation at 12,000 × *g* for 5 min. Total plasma cholesterol, high density lipoprotein (HDL)-cholesterol and triglycerides were determined by enzymatic assays (Sigma kit No. 352 for cholesterol and No. 336 for triglycerides, Sigma Chemical, St. Louis, MO). HDL-cholesterol was assayed following Mg^{2+}-phosphotungstate precipitation of lipoproteins containing apo B and apo E using HDL-cholesterol Reagent Set® (Boehringer Diagnostics, Indianapolis, IN) according to the procedure described by Weingard and Daggy (23). At 5 wk, plasma from 2-3 hamsters from each strain with similar cholesterol and triglyceride concentrations were pooled for plasma lipoprotein isolation. Lipoproteins were separated by density-gradient ultracentrifugation (24) in a Beckman L5-50 ultracentrifuge (Beckman Instruments, Palo Alto, CA) using a SW-41 rotor at 35,000 rpm and 15°C for 24 h with each tube stained with minimal Sudan Black to visualize lipoproteins (25). Three lipoprotein fractions were isolated, VLDL plus intermediate density lipoprotein (IDL) ($d < 1.019$ g/L), low density lipoprotein (LDL) ($1.019 < d < 1.055$ g/L) and HDL ($1.055 < d < 1.21$ g/L). Each lipoprotein fraction was dialyzed extensively against 0.15 M NaCl (pH 7.4) containing 100 mM butylated hydroxytoluene. Cholesterol, triglycerides and phospholipids were determined using enzymatic assays (Sigma kit No. 352 for cholesterol and No. 336 for triglycerides and Wako phospholipids B kit for phospholipids, Wako Chemicals, Richmond, VA). Protein concentration was determined according to the Lowry procedure (26).

Necropsy and gallstone evaluation. After 5 wk, hamsters were exsanguinated under anesthesia, and the liver, cecum and perirenal adipose fat excised, blotted and weighed. A portion of each liver was removed and frozen for hepatic cholesterol analysis. Gallbladder bile was aspirated for analysis of biliary lipids and bile acids prior to inspection for gallstones. The gallbladder was dissected from the liver, opened under a dissecting microscope and examined along with the remaining gallbladder bile for gallstones under regular and polarized light by light microscopy as previously described (10).

Bile analysis. Bile lipids were isolated using a modified Folch extraction (27). Ten μL of gallbladder bile was extracted with 3 mL chloroform/methanol (2:1, vol/vol) and 0.75 mL of 1.12% KCl solution. Biliary cholesterol was measured using an enzymatic assay (Wako free cholesterol C kit, Wako Chemicals) in an aliquot of the evaporated chloroform layer redissolved in 2-propanol. Biliary phospholipid concentration was determined in diluted gallbladder bile (1:10) by an enzymatic/colorimetric procedure using the Wako phospholipids B kit. Biliary bile acid concentration was determined as conjugated bile acids using an isocratic high-performance liquid chromatography (HPLC) procedure adapted from Rossi *et al.* (28). The mobile phase consisted of methanol/0.01 M KH_2PO_4 (75:25, vol/vol) to which 4.2 mL/L of 5 N NaOH was added before the pH was adjusted to pH 5.35 by adding about 1 mL of 85% H_3PO_4. The individual bile acid profile was analyzed using an aliquot of the methanol/KCl layer from the Folch extract, evaporated under a stream of nitrogen and redissolved in the mobile phase. A standard containing 60 mmol/L of taurine and glycine conjugates of cholic acid, chenodeoxycholic acid, deoxycholic acid and lithocholic acid (Sigma Chemical Co.) was used to calculate the individual bile acid concentrations. Total bile acid concentration was calculated as the sum of individual bile acids (taurine and glycine conjugates of cholate,

chenodeoxycholate and lithocholate) as determined by HPLC. Taurine and glycine conjugates of ursodeoxycholic acid were present only in trace amounts and therefore not included in the calculation.

The lithogenic index (LI) was calculated according to published procedures (29) based on the relative molar ratios of lipid components and total lipid concentration using a computerized version of cholesterol solubility (30,31). The bile acid hydrophobicity index (HI) for each bile sample was determined by multiplying hydrophobicity indices of individual bile acids (glycine and taurine conjugates) by the mol fraction of each bile acid and summing the products (32).

Hepatic cholesterol analysis. Hepatic cholesterol was extracted by grinding a 100-mg portion of liver with anhydrous sodium sulfate and extracting three times with chloroform/methanol (2:1, vol/vol). The liquid phase was evaporated to dryness and redissolved in chloroform. An aliquot was evaporated and redissolved in 2-propanol alcohol for analysis of free cholesterol by HPLC (33). Total cholesterol was determined enzymatically after hydrolysis with alcoholic KOH for 1 h as adapted from Tercyak (34), using the Wako free cholesterol C kit for cholesterol analysis.

Statistical analysis. Statistical differences between the three strains and the two diets were calculated using a two-factorial analysis of variance (ANOVA) followed by Scheffe's F-test utilizing a SuperANOVA statistical software package (Abacus Concepts, Inc., Berkeley, CA). When no significant diet effect was found, data from both diets were combined to evaluate strain differences.

RESULTS

Growth. All hamsters were healthy and showed normal daily weight gain. *Ad libitum* food consumption per hamster averaged 19.5 g per day (10.8 g dry weight) with no apparent difference between strains or the two diets. HAR hamsters began with a significantly lower body weight (Table 2), but final body weights were not different between the three strains and were not affected by the level of dietary cholesterol. Accordingly, HAR hamsters were considerably more feed-efficient and gained significantly more daily weight than CHR and BIO hamsters, but their perirenal fat weighed significantly less than that of the two other strains (Table 1).

Plasma lipids and lipoprotein profile. No apparent difference in plasma total cholesterol (TC) was found initially between the three hamster strains which had an average plasma cholesterol concentration of 149 ±32 mg/dL. However, BIO hamsters showed the lowest initial high density lipoprotein-cholesterol (HDL-C) (Table 2). Not surprisingly TC progressively increased in all hamsters fed the cholesterol-supplemented diets. After 5 wks, the TC differences between 0.4% *vs.* 0.8% dietary cholesterol was +18, +24, and −8%, respectively, for CHR, BIO and HAR. Since the dietary cholesterol effect was not significant, the cholesterol groups were combined to evaluate the strain effect. On this basis CHR hamsters revealed significantly lower TC and HDL-C concentrations. However, HDL-C expressed as percent of TC did not differ between strains.

Initial plasma triglyceride (TG) concentrations differed significantly between strains with the highest TG found in BIO hamsters, while HAR hamsters were intermediate and CHR hamsters were lowest (Table 2). After 5 wks, TG did not differ as a function of strain or level of dietary cholesterol, although CHR hamsters demonstrated somewhat lower values.

The distribution of cholesterol and TG in VLDL + IDL, LDL and HDL (pooled dietary data) revealed striking differences between strains (Table 3). Cholesterol-fed CHR hamsters transported most of their cholesterol in the HDL fraction (47 ± 3%), whereas BIO and HAR hamsters carried cholesterol mainly in the VLDL + IDL fraction (51 ± 3% and 46 ± 8%, respectively). The percent distribution of low density lipoprotein-cholesterol (LDL-C) did not differ significantly between the three strains (CHR, 18%; BIO, 21%; and HAR, 15%). The differences in the cholesterol distribution were further apparent in the LDL/HDL and the VLDL + IDL/HDL ratios (Table 3). BIO hamsters had a significantly higher LDL/HDL cholesterol ratio (1.9 times higher) than HAR and CHR hamsters and also had a significantly higher VLDL + IDL/HDL cholesterol ratio

which was 2.5 times higher than in CHR and 1.6 times higher than in HAR hamsters (Table 3).

Hepatic and biliary lipids. The level of added dietary cholesterol did not influence hepatic cholesterol accumulation, but total and esterified cholesterol concentrations in liver were significantly higher in HAR hamsters compared to CHR or BIO hamsters. Free cholesterol concentrations did not differ between the three strains of hamsters and accounted for 10-15% of the TC (Table 4).

The biliary lipid composition expressed as mol% of bile acids, phospholipids and cholesterol, was significantly affected by strain and level of dietary cholesterol (Table 5). Specifically, BIO hamsters had the highest mol% biliary cholesterol, and all hamsters fed 0.8% dietary cholesterol had approximately 30% more biliary cholesterol than hamsters fed 0.4% cholesterol. In like manner, HAR hamsters had the highest mol% bile acids when fed 0.4% dietary cholesterol, but this difference between strains disappeared at 0.8% dietary cholesterol. By contrast, mol% biliary phospholipids was only higher in CHR hamsters at 0.4% dietary cholesterol (Table 5). The LI was not affected by the level of dietary cholesterol, but BIO hamsters revealed the highest LI for both diets.

Bile acid profile. Total bile acid concentration (mM) was not affected by the level of dietary cholesterol, but at 0.4% cholesterol intake HAR hamsters had a significantly higher total bile acid concentration than either CHR or BIO hamsters (Table 5). The composition of individual bile acids expressed as percentage of the total bile acid concentration revealed considerable differences between the three hamster strains (Table 6) with HAR hamsters demonstrating the highest percentage of cholate (49 ± 8%) followed by BIO hamsters (40 ± 6%) and CHR hamsters (31 ± 7%). In contrast, total cheno was highest in CHR hamsters (61 ± 7%) but was similar (45 ± 7 and 42 ± 7%) in BIO and HAR hamsters. As a result, the cholate/cheno ratio was lowest in CHR hamsters and highest in the HAR hamsters. A significant strain effect existed also for taurocholate with the highest percentage in HAR hamsters, and lowest in CHR hamsters, whereas

[a]Statistical analysis (two-factorial ANOVA) revealed no effect of dietary cholesterol so data were combined. See Table 1 for abbreviations.

[b]Values are mean ± SD for 11-13 hamsters.

[c,d,e]Means sharing a common superscript are significantly different ($P < 0.05$).

glycocholate was not affected by strain. Taurocheno was the predominant bile acid and was unaffected between strains, whereas glycocheno was 5.2 times higher in CHR than in HAR hamsters and 1.7 times higher than in BIO hamsters. A higher percentage of taurodeoxycholate was observed in BIO and HAR hamsters compared to CHR hamsters. As a result, the ratio of primary to secondary bile acids was lower in BIO hamsters than in CHR or HAR hamsters.

A significant strain effect and a strain-diet interaction

were noted in the glycine/taurine conjugation pattern (Table 6). HAR hamsters had a significantly higher percentage of taurine-conjugated bile acids (78 ± 12%) than CHR and BIO hamsters (59 ± 6% and 63 ± 9%, respectively). Correspondingly, glycine conjugation was significantly lower in HAR hamsters (22 ± 12%) while CHR and BIO hamsters conjugated 41 ± 6% and 37 ± 9% of their bile acids with glycine. As a result, the glycine/taurine ratio was lowest in HAR hamsters, highest in CHR hamsters with BIO hamsters being intermediate.

The HI, a measure of the hydrophobic/hydrophilic balance of biliary bile acids, was lowest in HAR hamsters and significantly increased in both CHR and HAR hamsters.

Gallstone incidence. Examination of gallbladders after 5 wk revealed a striking difference in gallstone incidence attributed to both the strain of hamsters and the level of dietary cholesterol (Table 5). Overall, HAR hamsters proved least susceptible to cholesterol gallstones with only 3 of 13 hamsters (both diets combined) developing cholesterol stones and only when fed 0.8% dietary cholesterol. Two of 7 HAR hamsters fed 0.4% dietary cholesterol formed pigment gallstones. Cholesterol stones or crystals were present in 3 of 5 CHR hamsters fed 0.4% and in 4 of 6 CHR hamsters fed 0.8% dietary cholesterol. No pigment stones were found among CHR hamsters (Table 5). In BIO hamsters fed 0.4% cholesterol 2 of 6 hamsters developed pure cholesterol stones, whereas 3 of 6 hamsters formed pigment stones, two of which were mixed with cholesterol crystals. Feeding 0.8% dietary cholesterol increased the incidence of cholesterol stones among BIO hamsters with 5 of 6 hamsters developing cholesterol stones (in one case 3 small pigment stones were mixed with cholesterol stones and crystals) (Table 5).

DISCUSSION

Recently we described significant differences in plasma and biliary lipids and the bile acid profile in four strains of Syrian hamsters maintained on a similar, but cholesterol-free purified diet (18). For the current study three of these strains (CHR, BIO and HAR) were selected based on distinct differences in lipoprotein and biliary lipid composition detected during the previous study (18). Sasco hamsters, although susceptible to cholesterol gallstones (6,7), were not included because previous comparisons have found them to be slightly less susceptible than CHR hamsters under our conditions (7; unpublished observations). Challenges with a cholesterol-enriched diet have revealed differences in hepatic cholesterol accumulation and lipoprotein and bile acid profiles that appear to affect the incidence of cholesterol gallstones, with CHR hamsters being the most susceptible strain.

Liver cholesterol and gallstone incidence. Hepatic cholesterol accumulation was affected by strain. Surprisingly no substantial effect of dietary cholesterol (0.4 *vs.* 0.8%) was evident, suggesting that a plateau was reached with 0.4% dietary cholesterol or that the 5-wk period was too brief to allow a difference to develop. Although HAR hamsters accumulated significantly more hepatic cholesterol than BIO and CHR hamsters, the LI and incidence of cholesterol gallstones tended to be lowest in this strain. In contrast, CHR hamsters, with the lowest hepatic cholesterol concentration, developed the most cholesterol gallstones. Overall, no correlation existed between the hepatic cholesterol concentration (both free and total) and either the lithogenic index or the absolute (mM) or relative (mol%) biliary cholesterol concentrations. This corroborates previous findings (35–37) emphasizing the lack of relationship between hepatic cholesterol concentration and biliary cholesterol saturation. Thus, increased liver cholesterol accumulation can lead to supersaturated bile with minimal or no cholesterol gallstone formation, as demonstrated by HAR hamsters. On the other hand, the lack of hepatic cholesterol accumulation is typically found in the EFAD model where bile supersaturation and gallstone formation are prevalent (8).

Biliary lipids in relation to gallstones. Although all hamsters developed supersaturated bile and an LI exceeding 1.0, HAR hamsters maintained higher mol% bile acids and lower mol% biliary cholesterol resulting in the lowest LI. The LI of BIO hamsters was 1.5 times higher than HAR and 1.4 times higher than CHR hamsters, but the cholesterol gallstone incidence was practically equal for BIO and CHR hamsters (58% *vs.* 64% for the combined diets) and lowest for HAR hamsters (23%). When the same strains of hamsters were maintained on a purified cholesterol-free diet, CHR hamsters revealed significantly higher mol% biliary cholesterol and phospholipids and the lowest mol% bile acids with slightly supersaturated bile (LI of 1.0 ± 0.2) suggesting the onset of biliary cholesterol saturation even without dietary cholesterol (18). Thus, the LI *per se* is not necessarily a good predictor of cholesterol gallstone incidence. Factors such as antinucleating proteins (38), mucus production (39) or nucleation time presumably differ between hamster strains.

Lipoproteins and lithogenesis. Although all three strains of hamsters developed hyperlipemia in response to both levels of dietary cholesterol (0.4% *vs.* 0.8%), BIO and HAR hamsters had a markedly higher cholesterolemic and triglyceridemic response to the cholesterol-enriched diets than CHR hamsters. A similar sensitivity of the BIO hamster to dietary cholesterol and saturated fat was reported previously (16). Strain differences in the cholesterol lipoprotein distribution between CHR, BIO and HAR hamsters revealed that VLDL and IDL cholesterol were greatly expanded at the expense of HDL cholesterol (7,8). In the absence of dietary cholesterol the VLDL + LDL/HDL-cholesterol ratio was below 1.0 in all three strains (HAR, 0.4; CHR, 0.5; BIO, 0.8) (18), whereas this ratio increased after cholesterol feeding to 2.6 in BIO hamsters and to 1.5 and 1.6 in CHR and HAR hamsters, respectively.

Bile acid profile and gallstones. In the absence of dietary cholesterol, total cholate accounted for 50% of the total bile acids in CHR and 60% in BIO and HAR hamsters (18). Adding dietary cholesterol (this study) depressed the percent cholate to a different extent in the three hamster strains. Consequently, total cheno, normally representing 20% of the total bile acids in HAR, 30% in BIO and 46% in CHR hamsters, increased in all three hamster strains. In fact, cholesterol-fed CHR hamsters with the highest incidence of cholesterol gallstones demonstrated the highest percentage of cheno (61%) and the lowest percentage of cholate (31%), and the lowest cholate/cheno ratio (0.5), consistent with our previous results under the same dietary conditions (37). The shift in the bile acid profile was less pronounced in HAR hamsters, the only hamsters

with a cholate/cheno ratio that remained above 1.0 and which developed the least cholesterol gallstones. HAR hamsters fed a cholesterol-free diet maintained a cholate/cheno ratio of 3.3 (18).

The decline in the cholate/cheno ratio has been described previously under a variety of gallstone-inducing dietary conditions in hamsters (6,37,40,41). However, the striking strain differences in the cholate/cheno ratio and susceptibility to cholesterol gallstones emphasize the probable genetic influence on the relationship. Studies in rats (42) and hamsters (43) have led others to suggest that dietary cholesterol depresses 12α-hydroxylase activity, the key enzyme in cholate synthesis. However, extensive hepatic cholesterol accumulation does not necessarily depress cholate in hamster bile (37). In fact, HAR hamsters herein had the greatest cholate profile despite having the greatest hepatic cholesterol accumulation, providing further evidence that cholesterol feeding and liver cholesterol *per se* are not causally related to depressed 12-OHase activity. Differences in lipoprotein and bile acid distribution observed in the three hamster strains in this study support the hypothesis (19) that circulating lipoprotein cholesterol precursor pools, rather than hepatic cholesterol, exert the primary modulating effect over the bile acid profile.

Compared to a similar diet without cholesterol (18), the cholesterol content of the present diet increased the cheno pool, and taurochenodeoxycholic acid was the predominant bile acid. The glycine/taurine ratio did not differ between the three strains, and bile acids were equally conjugated with both amino acids. The cholesterol challenge decreased the glycine/taurine ratio in all three strains although to a different extent. HAR hamsters demonstrated the biggest shift in the conjugation pattern (from 1.1 to 0.3) whereas the change was less pronounced in CHR hamsters (from 1.0 to 0.7).

Our data suggest that the hydrophilic/hydrophobic balance between glycine and taurine-conjugated tri- and dihydroxy bile acids, calculated as the HI (32), was the best predictor of cholesterol gallstones. Usually, hamsters fed chow or a cholesterol-free purified diet have an HI between +0.22 and +0.27 (18,32,37), but this index has been depressed as low as +0.14 by cholestyramine, which totally prevented cholesterol gallstone formation (37). The HI increased in all our hamster strains during cholesterol feeding in parallel with gallstone induction. Thus, HAR hamsters with a high-normal HI (+0.27) had the lowest gallstone incidence, whereas the large number of cholesterol gallstones in CHR hamsters was associated with a 1.5-fold increase in HI to +0.37. BIO hamsters were intermediate, both for HI (+0.34) and cholesterol gallstones. Taken together, the results suggest a strong relationship between the cheno/cholate ratio, HI and cholesterol gallstone formation. It is noteworthy that the bile acid contributing most to the HI, *i.e.*, deoxycholic acid, has been associated with the pathogenesis of gallstones in humans (44).

In summary, differences in lipoprotein and biliary lipid composition, including the LI and HI, and cholesterol gallstone formation were observed during dietary cholesterol challenge of three strains of hamsters. Comparison of these parameters suggests that CHR hamsters are more prone to cholelithiasis under these dietary conditions than the two other strains examined, but a clear link between specific lipoproteins and gallstones was not obvious. Thus, the source (environmental and nutritional) and genetic background of the animals are important variables when cholesterol metabolism and cholelithiasis are evaluated in this species.

Fish oils containing different levels of polymers of triacylglycerols formed during autoxidation were incubated with pancreatic lipase to establish whether these polymers are substrates for lipase hydrolysis. With oils containing low amounts (less than 4%) of triacylglycerol polymers as substrates, both triacylglycerols and polymers of triacylglycerols were almost completely hydrolyzed, and fatty acid monomers and monoacylglycerols were the major lipid products. Under the same incubation conditions, some triacylglycerols remained intact when highly oxidized oils containing 20 or 30% triacylglycerol polymers were the substrate. The fatty acid composition of these residual triacylglycerols was almost identical to that of triacylglycerols present at the start of the assay. When fish oil containing 30% triacylglycerol polymers was incubated with the lipase, the component triacylglycerols and polymers of triacylglycerols were hydrolyzed at similar rates, and fatty acid dimers were detected as a product. It is concluded that the high molecular weight polymers of triacylglycerols present in oxidized fish oils can be hydrolyzed by pancreatic lipase *in vitro*.

Lipids 28, **313–319 (1993).**

There is currently much interest in fish oils in relation to human health, largely on account of their high content of n-3 polyunsaturated fatty acids (PUFA) (for reviews, see ref. 1). Although many studies have examined the effects of dietary fish oils on the lipid composition of blood and tissues in mammals (1–3), far less attention has been directed toward the initial digestion and absorption of the oils.

As with fats in general, the triacylglycerols which comprise the bulk of fish oils are hydrolyzed by pancreatic lipase in the intestinal lumen to free fatty acids and 2-monacylglycerols which are then absorbed by the enterocytes of the intestinal wall (4). Evidence from *in vitro* (5–7) and *in vivo* (8,9) studies suggests that long-chain PUFA characteristics of fish oils are more slowly liberated from triacylglycerol molecules than shorter chain, less unsaturated fatty acids. Possible bases for the discrimination of the digestive lipases against PUFA include chain length, degree of unsaturation and their distribution between the primary and secondary positions of the triacylglycerol molecule. Peroxidized PUFA, however, do not appear to be discriminated against during the hydrolysis of triacylglycerols by pancreatic lipase (10).

Commercial fish oils have recently been shown to contain small amounts of high molecular weight polymer material (11,12). These polymers most likely arise from the intermolecular linking of triacylglycerol molecules *via* peroxy bridges or other linkages formed during the autoxidation of their component PUFA. Studies on the enzymatic hydrolysis of thermally oxidized plant oils have shown that high molecular weight polymers of triacylglycerols are poor substrates for pancreatic lipase *in vitro* (13,14). No information, however, is available on the extent to which the polymers of triacylglycerols in oxidized fish oils can act as substrates for mammalian digestive lipases. In the present study, fish oils containing such polymers were subjected to hydrolysis with pancreatic lipase *in vitro* to establish whether these high molecular weight polymers are potential substrates for this enzyme *in vivo*.

MATERIALS AND METHODS

Fish oils. Cod liver oil (CLO) was obtained from Peter Moller A/S (Oslo, Norway). Chromatographically purified lipid (CPL) was the Fish Oil 30 manufactured by CPL Company AB (Karlshamn, Sweden). The oils contained no added antioxidant. To promote oxidation, 40 g samples of both oils were stirred for either 4 or 8 d in open beakers of 4.8 cm internal diameter at 35°C under irradiation from an artificial daylight fluorescent tube (1.1×1019 $Qm^{-2}s^{-1}$). CLOs subjected to these conditions for 4 and 8 d were designated CLO-4 and CLO-8, respectively. The corresponding CPL oils were refered to as CPL-4 and CPL-8. Peroxide values were measured by iodometric titration (15), and thiobarbituric acid values were determined as described by Ke and Woyewoda (16). Anisidine and iodine values were measured according to IUPAC 2.504 (17) and Wij's method (18), respectively. Polymer content was determined by size exclusion high-performance liquid chromatography (HPLC) as described previously (11).

Lipase hydrolysis. Purified porcine pancreatic lipases (triacylglycerol acylhydrolase, E.C. 3.1.1.3) were purchased from Sigma Chemical Co. Ltd. (Poole, United Kingdom) and was approximately 75% protein with 20,000 to 50,000 units per mg protein. Colipase purified from porcine pancreas was also obtained from Sigma. The standard assay system employed comprised $CaCl_2$ (0.18% wt/vol), sodium deoxycholate (0.01% wt/vol), lipase and fish oil (2% vol/vol) in 0.5 M Tris/HCl, pH 7.7 and total volume 5.0 mL. Each assay contained 10,000 units of purified lipase and 10 μg colipase. Assays were carried out in sealed tubes with stirring at 37°C in the dark. When required, aliquots were removed from incubations for lipid analysis.

Lipid analysis. Total lipid was extracted from whole assays or aliquots with chloroform/methanol (2:1, vol/vol) (19). The analysis of lipid extracts by size exclusoin HPLC was carried out as previously described using three columns connected in series (20). Values quoted are percentage of total area obtained for each analysis. When required, lipid class composition was also determined by high-performance thin-layer chromatography (HPTLC) using hexane/diethyl ether/glacial acetic acid (80:20:2, by

vol) as the developing solvent system. The copper acetate reagent of Fewster *et al.* (21) was used to visualize the separated components which were subsequently quantitated using a Shimadzu CS-930 dual wavelength thin-layer chromatography (TLC) scanner linked to a Shimadzu DR-2 data recorder (Tokyo, Japan). For confirmation of the identity of diacylglycerols, HPTLC plates were impregnated with boric acid by immersion in 1.2% (wt/vol) boric acid in ethanol/water (1:1, vol/vol) and dried at 105°C for 5 min. Samples and standards were then applied, and the plates developed in chloroform/acetone (96:4, vol/vol). Developed chromatograms were visualized as above.

To establish whether components containing intermolecular peroxy (C–OO–C) linkages were present, lipid recovered from lipase incubations with highly oxidized fish oil were treated with stannous chloride (22). Prior to its use for this purpose, the method was evaluated by applying it to methyl esters of cod roe total lipid, which had been oxidized under ultraviolet (UV) light for two days to produce polymers. Saponification of lipase products was performed using 1M KOH in 95% ethanol (19).

For fatty acid analysis, lipid classes were separated by TLC using 20 × 20 cm glass plates coated with silica gel G and the solvent system described above for HPTLC densitometry. The separated lipid classes were transesterified directly on the adsorbent with 1% H_2SO_4 in methanol to prepare methyl esters of the fatty acids (19). Fatty acid methyl esters were analyzed by capillary gas-liquid chromatography (GLC) using a 50 m × 0.32 mm i.d. CP Wax 51 fused silica column and on-column injection under conditions previously described (23).

RESULTS

Prior to the exposure of oils to oxidizing conditions, the initial peroxide, anisidine and thiobarbituric acid values of the cod liver oil (CLO-0) were all higher than those of the chromatographically purified fish oil, CPL-0 (Table 1). The triacylglycerol polymer content of the CLO-0 (1.6%) was also slightly higher than that of CPL-0 (1.3%). Conversely, the iodine value of CLO-0 (169) was lower than that of CPL-0 (222). The characteristics of both oils were changed markedly by exposure to oxidizing conditions. Peroxide, anisidine and thiobarbituric acid values and triacylglycerol polymer content were all related to the length of time exposed to the oxidizing conditions. The anisidine value of CLO-8 was double that of CPL-8, whereas the differences between these two oils in terms of peroxide and thiobarbituric acid values were not so great. Although little difference in iodine value was observed between starting oils and those oxidized for 4 d, the iodine values of CLO-8 and CPL-8 were substantially less than those of CLO-0 and CPL-0, respectively. The triacylglycerol polymer contents of CLO-4 and CPL-4 were more than double those of CLO-0 and CPL-0, respectively, as determined by HPLC analysis. In CLO-8, 30.3% of the oil was polymer material compared to only 20.4% in CPL-8. The polymers present in CLO-0 and CLO-4 consisted of only dimers of triacylglycerols whereas the polymers in CLO-8 were made up of 60% dimers, 24% trimers and 16% more highly polymerized forms of triacylglycerols. Similarly, only dimers of triacylglycerols were present in the CPL-0 and CPL-4 oils, but the polymer fraction of CPL-8 comprised 80% dimers, 18% trimers and 2% higher polymers.

TABLE 1

Characteristics of Fish Oils[a]

	PV (meq/kg)	AV	TBA (μmol/g)	IV	TAG Polymer (%)
CLO-0	4.3	23	0.7	169	1.6
CLO-4	82.0	38	5.4	169	3.7
CLO-8	940.0	360	39.0	139	30.3
CPL-0	3.0	2	0.3	222	1.3
CPL-4	130.0	20	6.6	220	3.4
CPL-8	740.0	180	33.0	206	20.4

[a]Abbreviations used are: CLO, cod liver oil; CPL, chromatographically purified lipid; PV, peroxide value; AV, anisidine value; TBA, thiobarbituric acid; IV, iodine value; TAG, triacylglycerol.

Analysis of the starting oils by HPLC showed that triacylglycerols were the major component of all oils (Table 2). A small amount of cholesterol was present in the cod liver oils but was absent from the CPL oils. Preliminary time course experiments in which HPTLC was used to follow the disappearance of triacylglycerols from CLO-0 and CPL-0 established that under the assay conditions employed triacylglycerols were almost entirely hydrolyzed by the lipase in 1 h. This incubation time was used in subsequent assays of lipase action on all oils.

The composition, as determined by HPLC, of total lipid extracted from assays after incubation of the oils with the purified pancreatic lipase is presented in Table 2. Polymers and dimers of fatty acids, if present, co-elute with triacylglycerols and diacylglycerols, respectively (14), when analyzed by size exclusion HPLC under conditions similar to those employed in this study. In all assays with CLO as substrate, monoacylglycerols and fatty acid monomers were the major lipid classes recovered at the end of the incubation period. Fatty acid monomers accounted for some 50% of the lipid from assays with CLO-0 and CLO-4 but only 34% of that from CLO-8. Monoacylglycerols were the second most abundant lipid class extracted from all assays with the exception of the CLO-8 assay in which the levels of fatty acid monomers and monoacylglycerols were equal. Higher proportions of components corresponding to triacylglycerols plus fatty acid polymers and diacylglycerols plus fatty acid dimers were present in the assays with CLO-8 than with CLO-4 or CLO-0. No polymers of triacylglycerols were recovered in the lipid extracted from assays with CLO-0 and CLO-4, but very small amounts were observed in the assays conducted with CLO-8.

The pattern observed with CPL oils as substrates (Table 2) was generally similar to that obtained with CLO oils. For CPL-0 and CPL-4, fatty acid monomers were the major lipid class recovered from each assay followed by monoacylglycerols. However, with CPL-8 as substrate, the proportion of fatty acid monomers present in the lipid extracted from assays was notably less than was observed when CPL-0 and CPL-4 were the substrate oils. The level of triacylglycerols plus fatty acid polymers recovered from assays with CPL-8 was higher than that observed with the other two oils. No polymers of triacylglycerols were recovered from assays with CPL-0 and CPL-4, whereas

[a]Values are means ± SD of three analyses or incubations. Abbreviations used are: CLO, cod liver oil; CPL, chromatographically purified lipid; FAP, fatty acid polymers; FAD, fatty acid dimers; HPLC, high-performance liquid chromatography.

TABLE 3

Effects of Saponification and Stannous Chloride ($SnCl_2$) Reduction on the Composition of the Products of Lipase Hydrolysis of CLO-8[a]

	Treatment			
Lipid class	None	Saponification	$SnCl_2$ reduction	$SnCl_2$ reduction + saponification
Triacylglycerol polymers	0.4	—	0.3	—
Triacylglycerol monomers	11.6	—	11.8	—
Diacylglycerols	19.5	—	14.6	—
Dimer fatty acids		3.3		4.0
Monoacylglycerols	34.4	—	35.0	—
Fatty acid monomers	33.9	95.8	38.0	95.0
Cholesterol	0.2	0.9	0.3	1.0

[a]Values are means of two experiments. CLO, cod liver oil.

some 1% of the lipid extracted from assays with CPL-8 was triacylglycerol polymeric material. The component corresponding to diacylglycerols plus fatty acid dimers was also a major lipid product of assays with CPL-8. Qualitative HPTLC analysis of the lipid extracted from assays generally agreed with the results of the HPLC analysis and, in the case of assays with CLO-8 and CPL-8 oils, showed the presence of a small amount of polar material which remained mostly at the origin but also ran as a diffuse band to just above the monoacylglycerols.

To establish whether polymer and dimer fatty acids were present as products of lipase hydrolysis, the lipids extracted from 1-h incubations of CLO-8 with lipase were subjected to saponification or stannous chloride reduction and analyzed by HPLC. In addition, samples which had been treated with stannous chloride were subsequently saponfied and re-analyzed. Of the saponified lipolysis products, 95.8% was monomeric fatty acids and 3.3% was fatty acid dimers which had the same retention time as the diacylglycerols in the original lipase products (Table 3).

Treatment of the lipolysis products with stannous chloride resulted in a decrease in the proportion of the component with retention time equal to that of diacylglycerols from 19.5 to 14.6%. At the same time the proportion of fatty acid monomers increased from 33.9 to 38.0%. Saponification of the CLO-8 after lipolysis and treatment with stannous chloride yielded 4% fatty acid dimers, the remainder being almost exclusively monomer fatty acids with 1% cholesterol. No fatty acid polymers were observed after any treatment.

The summarized fatty acid classes isolated by TLC from assays with the original oils and oils which had been oxidized for 8 d are compared in Tables 4 and 5 with those of the triacylglycerols present in these oils at the start of the assays. The triacylglycerols originally present in CLO-0 contained some 30% PUFA whereas only 18.8% of the fatty acids in CLO-8 triacylglycerols were polyunsaturated (Table 4). The ratio of 22:6n-3 to 20:5n-3 in CLO-0 triacylglycerols was 1.3 but only 1.1 in those of CLO-8. Residual triacylglycerols isolated from lipase incubations with CLO-8 were similar in fatty acid composition to those originally present before the initiation of lipolysis. PUFA accounted for 46.4% of fatty acids in CPL-0 triacylglycerols but only 38.7% in those of CPL-8 (Table 5). The ratios of 22:6n-3 to 20:5n-3 in CPL-0 and CPL-8 triacylglycerols were 0.9 and 0.7, respectively, and the fatty acid composition of the triacylglycerols remaining in assays with CPL-8 at the end of the incubation period was almost identical to that present at the start of the lipase digestion. With all substrate oils examined,

TABLE 4

Summarized Fatty Acid Compositon (wt%) of Original Triacylglycerols and Products of Lipolysis of Cod Liver Oils[a]

Fatty acids	Initial TAG	Final

[a]Footnote as in Table 3. CPL, chromatographically purified lipid.

the free fatty acid fraction after lipase hydrolysis contained a higher proportion of monenoic fatty acids than the starting triacylglycerols or partial acylglycerols. This was particularly true of assays with CLO-0 and CLO-8 whose triacylglycerols were initially richer in monoenoic acids than the equivalent CPL oils. Of the free fatty acids recovered from the assays with CLO-0 and CLO-8, 68 and 75%, respectively, were monounsaturated. With CLO-0 as substrate the content of PUFA in diacylglycerols and monoacylglycerols were similar and both higher than that of the starting triacylglycerols. However, it was notable that whereas the levels of 20:5n-3 and 22:6n-3 were similar at around 17% in the diacylglycerols, the level of 22:6n-3 in monoacylglycerols (22%) was almost twice that of 20:5n-3. With CLO-8 oil also, the diacylglycerols and monoacylglycerols were of similar PUFA content, and again the ratio of 22:6n-3 to 20:5n-3 in monoacylglycerols was almost double that in diacylglycerols. Similarly, with CPL-0 and CPL-8 as substrates, the ratio of 22:6n-3 to 20:5n-3 in monoacylglycerols was far greater than that of the starting triacylglycerols or the diacylglycerol and free fatty acid products.

To compare the rates of hydrolysis of triacylglycerol monomers and polymers, CLO-0 and CLO-8 were incubated with purified lipase and the lipid classes present in the assay examined by HPLC with respect to time (Fig. 1). With CLO-0 as substrate, the proportion of triacylglycerol monomers decreased rapidly over the initial 15 min and was balanced by increases in those of fatty acid monomers, monoacylglycerols and diacylglycerols plus fatty acid dimers. After 60 min, only 2% of the lipid present in the assay was triacylglycerol monomers, and fatty acid monomers closely followed by monoacylglycerols were the predominant lipids. Apart from the zero time point, polymers of triacylglycerols were not observed in samples taken at various times from the incubation.

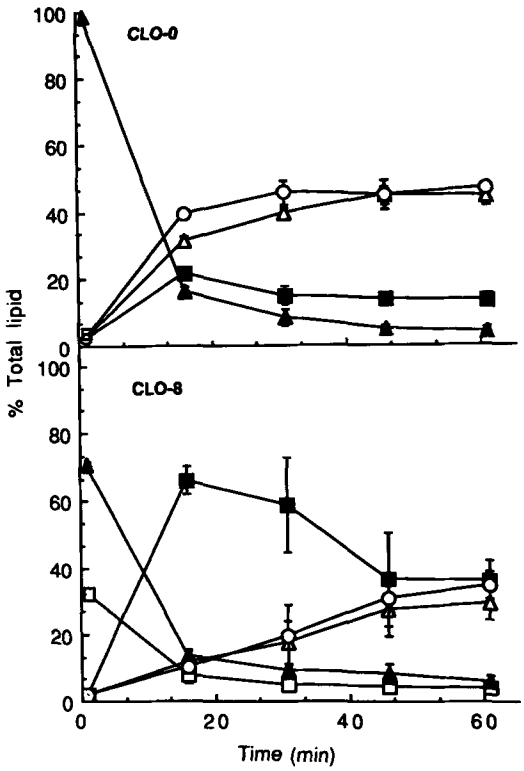

FIG. 1. Time course of hydrolysis of CLO-0 and CLO-8 with purified pancreatic lipase. Experimental conditions were as described in the text. Vertical bars represent SD obtained with three incubations. □—□, triacylglycerol polymers; ▲—▲, triacylglycerol monomers; ■—■, diacylglycerols + fatty acid dimers; △—△, monoacylglycerols; ○—○, fatty acid monomers. CLO, cod liver oil.

A different pattern of products was observed when CLO-8 was employed as substrate (Fig. 1). The proportions of triacylglycerol monomers and polymers in this oil decreased rapidly during the first 15 min. During this time the proportion of the component corresponding to diacylglycerols plus dimer fatty acids increased to 65% of the total lipid and decreased thereafter to a final value of 34% observed after 60 min. The levels of fatty acid monomers and monoacylglycerols increased almost equally with time of exposure of the oil to the lipase. The proportions of cholesterol remained constant at around 1.2 and 0.6% in assays with CLO-0 and CLO-8, respectively (data not shown). When the lipid extracted from the incubations with CLO-8 was analyzed by qualitative HPTLC, time-dependent changes similar to those observed with HPLC were discernable in the levels of triacylglycerols and free fatty acids. Apart from an initial increase over the first 15 min, no changes in the proportions of diacyl- and monoacylglycerols were obvious, and polar material was observed streaked above the origin at all time points. Analysis of lipid extracts using HPTLC plates impregnated with boric acid showed the diacylglycerols were always predominantly the 1,2-diacylglycerols. When the HPLC data obtained for triacylglycerols and triacylglycerol polymers were expressed as a percentage of their initial values in CLO-8, it was notable that these two lipid classes were hydrolyzed at similar rates. Thus, relative to their initial starting values, 80.9 and 83.2% of the triacylglycerol polymers and monomers, respectively, were hydrolyzed over the initial 15 min. The rate of hydrolysis over the subsequent 45 min was much less for each.

DISCUSSION

As found previously (11), the amount of polymer material of high molecular weight present in fish oils was directly related to the length of time the oils were exposed to conditions favoring the autoxidation of PUFA. A notable feature was that the formation of polymers in the CPL was less extensive than in the conventional CLO. This may be attributed to the virtual absence in the CPL (manufacturer's data sheet) of metal ions which can act as prooxidants.

The present results conform to the well established fact that fish oil triacylglycerols are efficiently hydrolyzed by mammalian pancreatic lipase *in vitro* (24). It was notable that monoacylglycerols accounted for around 33% of the final lipid product in incubations with original oils and oils which had been oxidized for 4 d. Since these oils originally comprised predominantly triacylglycerol monomers, this value is consistent with the purified lipase specifically hydrolyzing the fatty acids from the 1- and 3-position but not utilizing the resultant 2-monoacylglycerol as a substrate. This is in keeping with the known substrate specificity of the lipase (24).

The very high content of monoenoic acids in the free fatty acid fraction of all lipase-digested oils is consistent

with the lipase hydrolyzing the primary positions of the triacylglycerol molecules since monoenoic fatty acids are known to be preferentially esterified in position *sn*-3 of CLO triacylglycerols (25). Likewise, the high proportions of 22:6n-3 in monoacylglycerols suggest that, in keeping with its known stereospecific distribution in CLO triacylglycerols (25), this PUFA was concentrated in the *sn*-2 position of the original triacylglycerol molecules.

The lower ratio of 22:6n-3 to 20:5n-3 in the triacylglycerols of the heavily oxidized oils than in those of the original oils suggests that within triacylglycerols 22:6n-3 is more prone to autoxidation than 20:5n-3. The autoxidation of methyl ester derivative of 22:6n-3 is also known to be more extensive than that of 20:5n-3 (26). Given that 22:6n-3 is heavily oxidized during autoxidation of CLO, it might be expected that the position *sn*-2 of triacylglycerols will contain a higher proportion of autoxidized fatty acids than positions *sn*-1 and *sn*-3 simply on account of the high level of 22:6n-3 located in that position. It has been shown recently, however, that the oxidation of trilinoleoyl- and trilinolenoylglycerol is not selective toward either the 1(3)- or 2-position (27,28). A previous comparison of triacylglycerols in fresh sardine oil with that displaying moderate autoxidation as a result of freeze-thawing found no difference in the molecular species composition of the triacylglycerol present suggesting that autoxidation in fish oils is also a random process (29). Nevertheless, the highly unsaturated nature of the 2-position of fish oil triacylglycerols suggests that this position may be heavily involved in the formation of polymers of triacylglycerols by intermolecular condensation of peroxy radicals. The relative importance of PUFA situated in the different positions of triacylglycerols in intermolecular linking remains to be examined.

A recent study of the specificity of hydrolysis of triacylglycerols in menhaden oil by pancreatic lipase *in vitro* showed clearly that the triacylglycerols remaining after 70% hydrolysis of the oil were enriched in C_{20} and C_{22} fatty acids and that PUFAs were most resistant to hydrolysis (7). Although not studied in detail, no evidence for this specificity with fish oils was observed in the present study since residual triacylglycerols were almost identical to the original triacylglycerols in fatty acid composition. It was notable, however, that residual, nonhydrolyzed triacylglycerols were only present in assays with highly oxidized oils. Although this may imply that the presence of an autoxidized fatty acid in a triacylglycerol molecule slows its rate of hydrolysis by pancreatic lipase, it does not agree with a recent suggestion that triacylglycerols containing hydroperoxy linoleoyl and hydroperoxy linolenoyl groups are more hydrophilic in nature and may be more susceptible to hydrolysis by lipase (10). Nothing is known of the selectivity of lipase toward the peroxidized longer chain PUFA which will be present in highly oxidized fish oils. It is possible that the triacylglycerol monomers which remain after the incubation of highly-oxidized fish oils with lipase contain intramolecular linkages between component PUFA. Such linkages can be expected to be resistant to lipase hydrolysis and thus hinder the breakdown of the triacylglycerol. However, since any cross-linked fatty acids would not be detected by the procedure used for the comparison of relative fatty acid compositions, the present study does not provide definite evidence for the above situation.

Although the rates of hydrolysis of isolated triacylglycerol monomers and polymers were not compared in the present study, it was found that their rates of hydrolysis were very similar when presented simultaneously as components of a highly oxidized oil. This observation contrasts with the results of a similar previous study with thermally oxidized plant oils which showed that dimeric and polymeric acylglycerols were resistant to hydrolysis by pancreatic lipase *in vitro* (13). The authors of a more recent study in which triacylglycerol monomers and polymers isolated from heat-treated olive oil were exposed to pancreatic lipase *in vitro* also noted a slower rate of hydrolysis with the polymer fraction (14). It remains to be established whether similar differences in the rates of lipolysis exist between triacylglycerols monomers and polymers when they are isolated from autoxidized fish oils and presented separately to the lipase.

Peroxy bridges (C-OO-C) are known to be broken by reduction with stannous chloride, whereas carbon (C-C) and ether (C-O-C) linkages, as well as ester bonds, are resistant to this treatment (22). Alkaline hydrolysis, on the other hand, breaks both ester bonds and peroxy bridges but not C-C or C-O-C linkages (30). Consequently, the changes observed upon treatment of the CLO-8 lipolysis products with stannous chloride are consistent with the presence in the lipolysis products of peroxy-linked fatty acid dimers which co-elute with diacylglycerols under the HPLC conditions employed. The additional presence of fatty acid dimers containing ether or carbon linkages as products was revealed by saponification of the lipid products of lipase hydrolysis. Taken together, these observations provide evidence that the hydrolytic degradation of the triacylglycerol polymers of highly oxidized fish oils by pancreatic lipase gives rise to fatty acid dimers containing more than one type of linkage. A recent study has also demonstrated that fatty acid dimers are released from thermally oxidized olive oil when acted upon by pancreatic lipase *in vitro* (14).

With respect to the hydrolysis of triacylglycerol polymers by pancreatic lipase, extrapolation of the results obtained with thermally oxidized plant oils to air-oxidized fish oils is probably inaccurate although similarities are bound to exist. Apart from the obvious differences in fatty acid composition between plant oils and fish oils, the type of linkages present in triacylglycerol polymers may have an influence on the susceptibility of these compounds to lipase hydrolysis. Oxidation induced at the high temperatures used to produce thermally-oxidized oils is likely to generate a higher proportion of C-C linkages than autoxidation brought about by the passage of air or oxygen at moderate temperatures, a situation which favors the formation of peroxy linkages between PUFAs in their methyl ester form (31). Thus, the results of studies using thermally oxidized plant oils may differ considerably from those obtained with air-oxidized fish oils.

In summary, the present study shows that highly oxidized fish oils containing high levels of triacylglycerol polymers are hydrolyzed by pancreatic lipase *in vitro* less efficiently than fish oils which contain only moderate or low levels of these polymer compounds. Nevertheless, the high molecular weight polymers of oxidized fish oils can be degraded by lipase *in vitro* yielding fatty acid dimers as well as the normal products of triacylglycerol lipolysis. Further characterization of the nature of the

triacylglycerol polymers in autoxidized fish oils and the products of their lipolytic breakdown *in vitro* are merited before their digestion and absorption by mammals *in vivo* are considered.

Stearidonic Acid, an Inhibitor of the 5-Lipoxygenase Pathway. A Comparison with Timnodonic and Dihomogammalinolenic Acid

Michel Guichardant[a,*], Helmut Traitler[a], Danièle Spielmann[a], Howard Sprecher[b] and Paul-André Finot[a]
[a]Nestec Ltd., Nestle Research Centre, Vers-chez-les-Blanc, CH 1000 Lausanne 26, Switzerland and [b]Department of Physiological Chemistry, Ohio State University, Columbus, Ohio 43210

Leukotrienes have been shown to play an important role as mediators in various disease processes, including asthma and inflammation; thus, their synthesis is tightly regulated. The major precursor of leukotrienes is arachidonic acid (20:4n-6). Fatty acids which are structurally similar to 20:4n-6, such as eicosatrienoic acid (20:3n-6; dihomogammalinolenic acid) and eicosapentaenoic acid (20:5n-3; timnodonic acid) have been found to inhibit leukotriene biosynthesis. Because of the structural similarity of octadecatetraenoic acid (18:4n-3; stearidonic acid) with 20:4n-6, the present study was undertaken to determine whether stearidonic acid also exerts an inhibitory effect on the 5-lipoxygenase pathway. Human leukocytes were incubated with 18:4n-3 (20 μM or 10 μM), 20:5n-3 (20 μM) or 20:3n-6 (20 μM) and subsequently stimulated with 1 μM ionophore A23187 and 20:4n-6 (20 μM or 10 μM). The 5-lipoxygenase products were then measured by high-performance liquid chromatography. Leukotriene synthesis was reduced by 50% with 20 μM 18:4n-3 and by 35% with 10 μM 18:4n-3. Formation of 5S,12S-di-hydroxy-eicosatetraenoic acid and of 5-hydroxy-eicosatetraenoic acid was decreased by 25% with 20 μM 18:4n-3 and by 3% with 10 μM 18:4n-3. The inhibition observed with 20 μM 18:4n-3 appeared to be of the same order as that observed with 20 μM 20:5n-3; the inhibition observed with 18:4n-3 was shown to be dose-dependent. The inhibition produced by 20 μM 20:3n-6 was greater than that observed with either 20 μM 18:4n-3 or with 20 μM 20:5n-3. The results suggest that stearidonic acid, which is found, for example, in blackcurrant seed oil (which also contains the 20:3n-6 precursor), may play a role in suppressing inflammation.
Lipids 28, 321–324 (1993).

In stimulated human polymorphonuclear leukocytes (PMN), 5-lipoxygenase converts arachidonic acid to 5-hydroperoxy-eicosatetraenoic acid (5-HPETE). The 5-HPETE is then reduced to 5-HETE by glutathione peroxidase or transformed to a variety of leukotrienes (1–5) (Fig. 1). Leukotriene B_4 (LTB_4) possesses potent biological activities and is involved in leukocyte adhesion, aggregation and degranulation (6–10). Thus, because of their involvement in leukotriene synthesis, leukocytes play an important role in inflammatory processes (5,11,12). Inhibition of 5-lipoxygenase and hence leukotriene synthesis could therefore be a way of down-regulating inflammatory events.

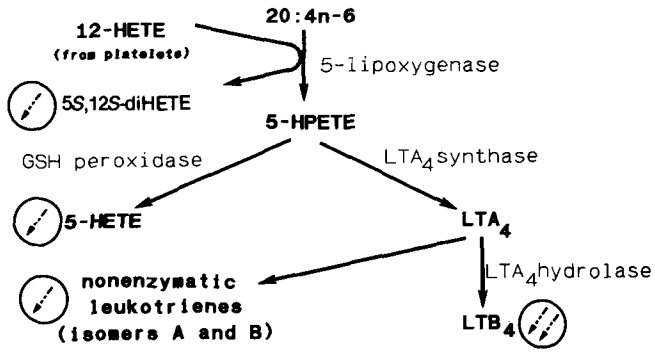

FIG. 1. Partial 5-lipoxygenase pathway in leukocytes. One circled slanted arrow indicates that less product was formed relative to the controls when the leukocytes were incubated with 18:4n-3, 20:5n-3 or 20:3n-6. Two circled slanted arrows indicate that much less product was formed. This suggests that the inhibition may have affected both 5-lipoxygenase and leukotriene A_4 (LTA_4) hydrolase. HETE, hydroxy-eicosapentaenoic acid; di-HETE, dihydroxylated eicosatetraenoic acid; HPETE, hydroperoxy-eicosatetraenoic acid; LTB_4, leukotriene B_4.

There is increasing evidence that certain polyunsaturated fatty acids (PUFA) of the n-3 series present in fish oil can, by modulating leukotriene synthesis, favorably affect inflammatory conditions (13–17).

In the present study, the effects of stearidonic acid (18:4n-3), which occurs, for example, in blackcurrant seed oil (18), were tested in comparison with other PUFA, namely eicosapentaenoic acid (20:5n-3) and dihomogammalinolenic acid (20:3n-6). Isolated human leukocytes were incubated together with these fatty acids, and the 5-lipoxygenase end-products were separated by thin-layer chromatography (TLC) and quantified by high-performance liquid chromatography (HPLC).

MATERIALS AND METHODS

Reagents. Calcium ionophore A23187, dextran 250, eicosatrienoic acid (20:3n-6), arachidonic acid, (20:4n-6), eicosapentaenoic acid, (20:5n-3), prostaglandin B_2 and soybean lipoxygenase type 1 (EC 1.13.11.12.) were obtained from Sigma Chemical Company (St. Louis, MO). 5-HETE and LTB_4 were purchased from Cayman Chemicals Company (Ann Arbor, MI). 12-HETE was prepared from arachidonic acid (19). [1-^{14}C]Arachidonic acid (20:4n-6) was obtained from Dupont-NEN Products (Zürich, Switzerland). Stearidonic acid was isolated from blackcurrant seed oil and purified as described (20,21). [1-^{14}C]Stearidonic acid was prepared by total synthesis using the general procedures previously described (22). The Nucleosil C18, 3 μm column was obtained from Macherey-Nagel (Düren, Germany). Silica gel G plates and organic solvents (analytical grade) were purchased from Merck (Darmstadt, Germany). The 13-hydroxy derivative of 18:2 [13-hydroxy-octadecadienoic acid (HODE)] was prepared by soybean lipoxygenase treatment according to the method of Funk *et al.* (23).

Abbreviations: di-HETE, dihydroxylated eicosatetraenoic acid; HEPES, *N*-2-hydroxyethylpiperazine-*N*'-2-ethanesulfonic acid; HETE, hydroxy-eicosatetraenoic acid; HHT, hydroxy-heptadecatrienoic acid; HODE, hydroxy-octadecadienoic acid; HPETE, hydroperoxy-eicosatetraenoic acid; HPLC, high-performance liquid chromatography; LTA_4, leukotriene A_4; LTB_4, leukotriene B_4; PGB_2, prostaglandin B_2; PUFA, polyunsaturated fatty acid; R_t, retention time.

Preparation of cell suspensions. Human leukocytes were prepared according to our published procedure (19). Blood was collected into acid citrate dextrose as anticoagulant from normal donors who had not been under medication for at least 10 d prior to venipuncture. After centrifugation at 200 × *g* for 15 min, platelet-rich plasma was removed, and dextran 500 (0.5 vol of 3% in 0.9% NaCl) was added to the pellet. Sedimentation of the red cells was achieved in about 90 min at room temperature, and the upper leukocyte phase was centrifuged for 15 min at 80 × *g*. The sediment (about 3×10^6 cells) was resuspended into 1 mL of distilled water for 15 s, and 1 mL of double strength Tyrode *N*-2-hydroxyethylpiperazine-*N'*-ethanesulfonic acid (HEPES) was added to restore the isoosmolarity of the leukocyte suspension. This suspension was centrifuged for 10 min at 60 × *g*, and the sedimented leukocytes were resuspended in Tyrode/HEPES containing 2 mM calcium chloride.

The leukocytes were incubated with either 10 μM or 20 μM 18:4n-3, 20 μM 20:5n-3, or 20 μM 20:3n-6 for 30 min at 37°C. They were then stimulated by 1 μM calcium ionophore A23187 and 20 μM 20:4n-6 for 10 min at 37°C. After acidification to pH 3 with 3N HCl, the lipids were extracted with cold ethanol/chloroform (3:6, vol/vol). Two nanomoles of 13-HODE and 2 nmol of prostaglandin B_2 (PGB_2) were added before extraction as internal standards to quantify the monohydroxylated fatty acids and the leukotrienes, respectively. The organic phase was immediately evaporated under nitrogen to avoid lactonization of the 5-hydroxy derivatives.

The 5-lipoxygenase response was also tested on 1 mL leukocytes (10^8 cells/mL) incubated with either 0, 10, 20, 40, 70 or 100 μM 18:4n-3 for 30 min at 37°C and were then stimulated by 1 μM ionophore A23187 and 10 μM 20:4n-6.

Analysis of monohydroxylated fatty acids. Lipid extracts were separated by two-dimensional TLC on silica gel G plates. In the first dimension, monohydroxylated fatty acids were separated with hexane/diethyl ether/acetic acid (60:40:1, by vol). The dihydroxylated fatty acids remained at the origin. The radiolabeled hydroxylated fatty acids were detected using a Berthold radioscanner, scraped off together with 13-HODE and extracted with diethyl ether, and the sample was then evaporated under nitrogen prior to analysis by HPLC. The hydroxy derivatives were then separated by reverse-phase HPLC, using a 4.6 mm by 250 mm column packed with Nucleosil C18 (3 μM). The eluent methanol/water (adjusted to pH 3 with acetic acid) (73:27, vol/vol) was pumped at a flow rate of 1 mL/min. The compounds were detected at λ = 234 nm and quantitated relative to the internal standard (2 nmol 13-HODE) assuming that all compounds had the same specific extinction ($\varepsilon = 3 \times 10^4$ M^{-1} cm^{-1}).

Analysis of dihydroxylated fatty acids. The dihydroxylated fatty acids which remained at the origin were eluted perpendicular to the first direction with hexane/diethyl ether/acetic acid (25:75:1, by vol). The dihydroxylated fatty acids were recovered by extraction with diethyl ether; the solvent was evaporated, and the metabolites were then separated by reverse-phase HPLC in the same way as described before except that the solvent was methanol/water (pH 3) (66:34, vol/vol). The internal standard PGB_2 was used to quantify the dihydroxylated fatty acids (λ = 270 nm, $\varepsilon = 2.8 \times 10^4$ and 5×10^4 M^{-1} cm^{-1} for PGB_2 and 5*S*,12*S* or *R*-dihydroxy derivatives, respectively) using a Hewlett-Packard diode array detector (model 1040A) (Basel, Switzerland).

Statistical analysis. Each data point represents the mean ± SEM of n determinations. The level of significance, P, was determined by a *t*-test against the corresponding control.

RESULTS

In the control group (Fig. 2), leukocytes were incubated with 1 μM ionophore A23187 and 20 μM arachidonic acid. The most prominent component observed was 5-HETE which had the same retention time (R_t = 42.69 min) as standard 5-HETE with a λ_{max} 234 nm. Hydroxyheptadecatrienoic acid (HHT) and 12-HETE was also detected by ultraviolet (UV) absorption (234 nm) at 15.42 and 36.14 min, respectively. HHT and 12-HETE are formed by platelet contamination. In this case the contamination was not more than 10 platelets per leukocyte.

In the presence of 18:4n-3 (Fig. 3), two compounds appeared with R_ts of 14.0 and 14.7 min, respectively. These components were also observed at a lower concentration, 10 μM of 18:4n-3, and were radioactive (results not shown). Their UV spectra (λ_{max} 234 nm) were similar to those

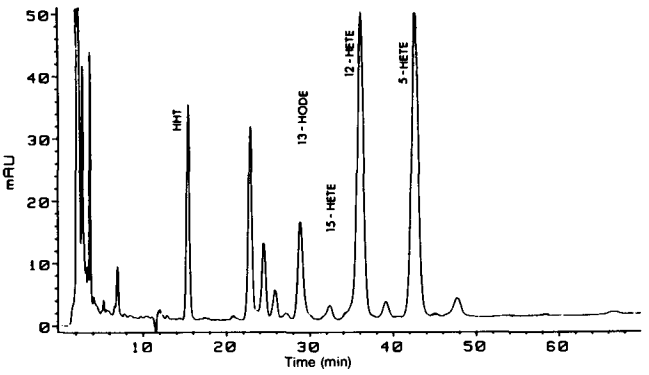

FIG. 2. Typical reverse-phase high-performance liquid chromatography profile of monohydroxylated fatty acids measured after triggering leukocytes with 20 μM arachidonic acid and 1 μM ionophore A23187. 13-hydroxy-octadecadienoic acid (HODE) was used as internal standard. Abbreviations as in Figure 1.

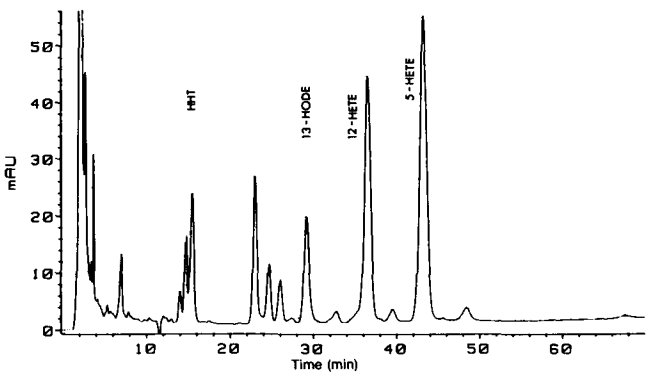

FIG. 3. Same profile as in Figure 2 but the leukocytes were preincubated for 30 min at 37°C with 20 μM stearidonic acid. See Figures 1 and 2 for abbreviations.

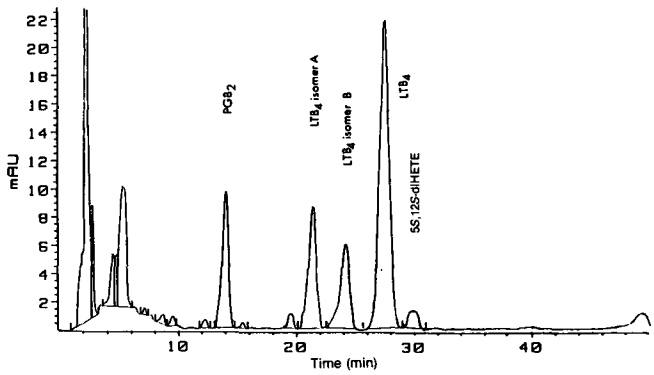

FIG. 4. Typical reverse-phase high-performance liquid chromatography (HPLC) profile of dihydroxylated fatty acids measured after stimulating leukocytes as described in Figure 2. Prostaglandin B_2 (PGB_2) was used as an internal standard. Abbreviations in Figure 1.

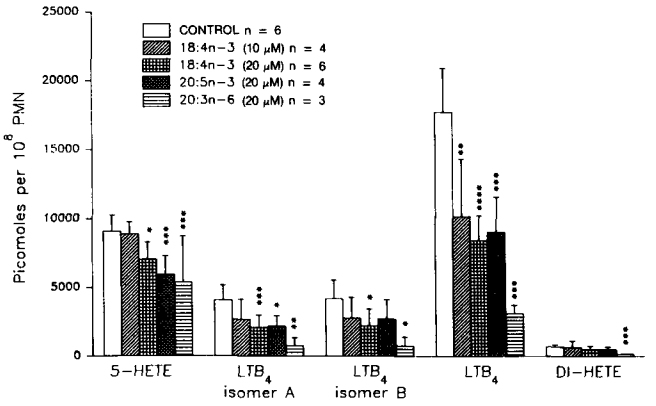

FIG. 5. Leukocytes (10^8 cells) were suspended in 1 mL of Tyrode *N*-2-hydroxyethylpiperazine-*N*'-2-ethanesulfonic acid (HEPES) and incubated in the presence or absence of different fatty acids at the indicated concentrations for 30 min at 37°C. Afterward the cells were stimulated with 20 μM arachidonic acid and 1 μM ionophore A23187 for 10 min at 37°C. The 5-lipoxygenase products were quantified as described in Materials and Methods. The results are expressed in picomoles per 10^8 cells and represent means ± SEM of the five separate experiments with n determination within each. The levels of significance, *P*, were determined by a *t*-test: *$P < 0.05$, **$P < 0.02$, ***$P < 0.01$, ****$P < 0.001$ when compared to the control. Abbreviations as in Figure 1.

obtained with standard monohydroxylated components but their levels were very low, with transformation of less than 2% of the radioactive substrate. Furthermore, the conversion of radiolabelled stearidonic acid to either 20:5n-3 or 22:6n-3 could not be detected in isolated leukocytes (results not shown).

The dihydroxylated fatty acids, isolated by TLC, were measured by HPLC using PGB_2 as internal standard (Fig. 4). Four main components were detected. The major metabolite was 5*S*,12*R*-[*Z*,*E*,*E*,*Z*]-LTB_4 since it had the same R_t(27.46 min) as did LTB_4. Its UV spectrum showed three λ_{max} at 261, 271 and 282 nm which is characteristic of compounds containing a conjugated triene. This compound was also radioactive when labelled arachidonic acid was the substrate. In addition two small more polar compounds with R_ts of 21.46 and 24.27 min, respectively, were detected, presumably corresponding to 5*S*,12*R*-[*E*,*E*,*E*,*Z*]-LTB_4 (LTB_4-isomer A) and 5*S*,12*S*-[*E*,*E*,*E*,*Z*]-LTB_4 (LTB_4-isomer B), as described previously

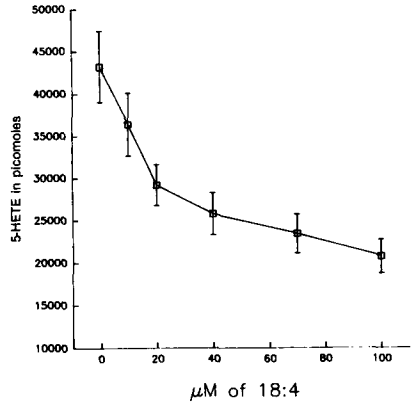

FIG. 6. Effect of 18:4n-3 on 5-hydroxy-eicosatetraenoic acid formation by human leukocytes. One mL leukocytes (10^8 cells/mL) were preincubated in Tyrode *N*-2-hydroxyethylpiperazine-*N*'-2-ethanesulfonic acid containing 2 mM $CaCl_2$ and different concentration of 18:4n-3 (0, 10, 20, 40, 70, 100 μM) for 30 min at 37°C and afterward stimulated with A23187 (1 μM) and 20:4n-6 (10 μM) for 10 min at 37°C. 5-HETE was quantified as described in Materials and Methods. The results are expressed in picomoles per 10^8 cells and represent means ± SEM of three determinations.

(19,24,25). A minor compound which eluted just after LTB_4 (R_t = 29.96 min) was identified as 5*S*,12*S*-[*E*,*Z*,*E*,*Z*-di-HETE. This compound with UV absorptions at λ_{max} 259, 268 and 279 nm has been reported previously (19,24-26).

The effects of the various fatty acids on the formation of metabolites by leukocytes are presented in Figure 5.

In the control, the formation of 5-HETE was maximal but decreased significantly ($P < 0.05$) by about 22% with 20 μM 18:4n-3. More pronounced inhibition was observed with 20 μM 20:5n-3 or 20 μM 20:3n-6, which amounted to 35 and 48%, respectively. Leukotriene formation was affected in a similar way.

Inhibition of LTB_4 was maximal (80%) when leukocytes were incubated with 20 μM 20:3n-6 ($P < 0.001$). LTB_4 formation fell by 50% ($P < 0.001$) in the presence of 20 μM 20:5n-3 or 20 μM 18:4n-3. Similar patterns of inhibition were observed with both of the LTB_4 isomers A and B, especially in the presence of 20:3n-6.

Furthermore, the production of 5*S*,12*S*-di-HETE, formed by synergy between platelets and leukocytes was also decreased but was only significant ($P < 0.001$) with 20 μM 20:3n-6 (75% inhibition).

Figure 6 shows the effect of different concentrations of 18:4n-3 on the formation of 5-HETE by leukocytes stimulated with 1 μM A23187 and 10 μM 20:4n-6. The data show that 18:4n-3 caused a dose-dependent inhibition of 5-HETE formation, and at the highest concentration of fatty acid used (100 μM) it resulted in an inhibition by about 45%.

DISCUSSION

Our results show that PUFAs modulate the level of leukotriene formed *in vitro* by activated leukocytes. Inhibition of leukotriene synthesis by 20:5n-3 and 22:6n-3 had previously been demonstrated (16,27-29), but not inhibition by 18:4n-3. Stearidonic acid is usually only a minor fatty acid in human plasma, and it is not found in many foods. However, after a 16 g/d supplementation with blackcurrant seed oil, which contains about 2 to 3%

18:4n-3, the level of 18:4n-3 can be increased to 0.3% in plasma and also in the blood cells (results not shown). In the present study stearidonic acid exerted an inhibitory effect on arachidonic acid metabolism similar to that observed with 20:5n-3. The production of 5*S*,12*S*-diHETE and 5-HETE were depressed by about 25% by 20 μM 18:4n-3 indicating inhibition of 5-lipoxygenase activity. The synthesis of the two nonenzymatic leukotrienes (isomers A and B) was also decreased to a similar extent. The inhibition of leukotriene B_4 formation was approximately twice that observed for 5-HETE production under the same conditions (Fig. 5). This is consistent with the suggestion that 18:4n-3 may inhibit both 5-lipoxygenase and epoxide hydrolase. Such a mechanism has already been reported for 20:5n-3 (30,31). The authors suggested that a metabolite of 20:5n-3 such as LTA_5 could down-regulate the conversion of LTA_4 to LTB_4 by LTA_4 hydrolase *via* a competitive process. A simplified diagram of the 5-lipoxygenase pathway is given in Figure 1. Moreover, 10 μM 18:4n-3 decreased formation of leukotriene by 35% but not that of 5-HETE (about 5%). Even with 10 μM 18:4n-3, oxygenated products are synthesized by leukocytes. Nevertheless, the metabolism of stearidonic acid appeared to be slower than that of arachidonic acid. Only 3% of the total radioactivity added as [1-^{14}C]stearidonic acid was recovered as hydroxylated compounds.

The inhibition of 5-lipoxygenase by 18:4n-3 was dose-dependent as shown in Figure 6. A similar inhibitory dose response was recently reported for 18:2n-6 and 20:3n-6 which both inhibited LTB_4 formation (32).

Among the fatty acids tested, the most potent inhibitor is 20:3n-6 which almost completely blocks the production of all 5-lipoxygenase products. The formation of LTB_4 and 5-HETE was reduced by 80 and 40%, respectively. This inhibitory effect has also been shown *in vivo* in different models of inflammation (33). Rats fed diets enriched with 18:3n-6, a precursor of 20:3n-6, showed as expected an increase in 20:3n-6 in their liver as well as a marked decrease in prostaglandin E_2 and LTB_4 synthesis (33). These two mediators have been shown to be formed during acute inflammation produced by monosodium urate crystals or subcutaneous air pouch models. Two mechanisms have been proposed to explain this inhibitory effect. When 20:3n-6 is metabolized to prostaglandin E_1, it has been shown to inhibit leukotrienes synthesized by activated human neutrophils (25,34) through an increase in cytosolic cAMP levels in human polymorphonuclear neutrophils (35). Secondly, 20:3n-6 could also be converted into 15-OH-20:3 by leukocyte 15-lipoxygenase and inhibit 5-lipoxygenase as has previously been described (32–36).

In conclusion it appears that stearidonic acid is a good 5-lipoxygenase inhibitor *in vitro* and its effect is comparable to that of timnodonic acid (20:5n-3) at the same concentration. The presence of both stearidonic (2–3%) and γ-linolenic acid (15–19%), a precursor of 20:3n-6 in blackcurrant seed oil (2–3%), suggests that this oil could become useful in the treatment of inflammatory diseases.

ACKNOWLEDGMENTS

We thank Dr. Gayle Crozier-Willi for helpful discussions and for reviewing this paper, Dr. R. Acheson for English translation and Isabelle Tavazzi-Schoenenberger for skillful technical help.

Conversion of 13(*S*)-Hydroperoxy-9(*Z*),11(*E*)-octadecadienoic Acid to the Corresponding Hydroxy Fatty Acid by KOH: A Kinetic Study

Thomas D. Simpson* and **Harold W. Gardner**
United States Department of Agriculture, Agricultural Research Service, National Center for Agricultural Utilization Research, Phytoproducts Research, Peoria, Illinois 61604

Transformation of 13(*S*)-hydroperoxy-9(*Z*),11(*E*)-octadecadienoic acid (13*S*-HPOD) to 13(*S*)-hydroxy-9(*Z*),11(*E*)-octadecadienoic acid (13*S*-HOD) under alkaline conditions (0.05 to 5 M KOH) occurred first-order with respect to 13*S*-HPOD concentration. Overall yield was about 80%. The energy of activation at higher concentrations (3.75 to 5 M KOH) was determined to be in the range of 15.3 to 15.6 kcal. Compared to the 13*S*-HPOD conversion, 13(*S*)-hydroperoxy-9(*Z*),11(*E*),15(*Z*)-octadecatrienoic acid (13*S*-HPOT) was converted at a faster rate to the corresponding hydroxy fatty acid (13*S*-HOT), with the reaction also being first-order. Chiral phase high-performance liquid chromatography demonstrated that in the transformation the stereochemistry of both the 13*S*-HPOD and 13*S*-HPOT reactants was preserved. Manometric analyses of the KOH/13*S*-HPOD reaction showed an uptake of gas, which amounted to 11% of the mols of reactant 13*S*-HPOD on the assumption that the gas was O_2. As there is a theoretical loss of 1 oxygen atom in the reaction, the fate of this oxygen (possibly *via* active oxygen species) may involve reaction with 13*S*-HPOD/13*S*HOD to form the 20% by-products.
***Lipids* 28,** 325–330 (1993).

The base-catalyzed conversion of organic hydroperoxides to alcohols has been known for over thirty years (1). Frankel *et al.* (2) first reported that saponification of methyl linoleate hydroperoxides resulted in formation of the corresponding hydroxy fatty acids. Subsequently, O'Brien (3) found that the conversion of linoleic acid hydroperoxide into the hydroxy fatty acid occurred in the presence of a number of "nucleophiles" other than hydroxide ion, such as dimercaptoethanol, cysteine, ascorbate, thiourea and sulfite. However, some of these reagents may actually serve as reductants. Although the thiolate anion of cysteine appears to be required to convert linoleic acid hydroperoxide to the hydroxy fatty acid, the fact that O_2 is also reduced to superoxide anion under these conditions may indicate the possibility of a hydroperoxide reduction by thiolate anion (4). Although the transformation by alkali has been known for many years, the specific details concerning overall yield, retention (or loss) of stereoconfiguration, mechanism of reaction and reaction kinetics remain little understood. Such information could be important when hydroxy fatty acid methyl esters are found in biological material after use of base in either saponification or transmethylation reactions of lipids (*e.g.*, see Ref. 5). The present communication reports an investigation of the reaction of two pure hydroperoxides, 13(*S*)-hydroperoxy-9(*Z*),11(*E*)-octadecadienoic acid (13*S*-HPOD) and 13(*S*)-hydroperoxy-9(*Z*),11(*E*),15(*Z*)-octadecatrienoic acid (13*S*-HPOT), with KOH at various concentrations.

MATERIALS AND METHODS

Materials. 13*S*-HPOD was prepared from linoleic acid (Nu-Chek-Prep, Inc., Elysian, MN) by oxidation with soybean lipoxygenase [EC 1.13.11.12] (Sigma Chemical Co., St. Louis, MO) using the method of Gardner (6). The 13*S*-HPOD product was isolated by column chromatography with SilicAr CC4 (Mallinkrodt, Inc., St. Louis, MO), and stepwise elution was performed with 5, 7.5 and 10% acetone in hexane (7). Fractions were monitored by absorption of the hydroperoxy diene at 234 nm. The initial 150 mL of absorbing eluent was collected. The solvent was removed on a rotary evaporator, and the reaction product redissolved in methanol. Concentration was determined on a DU-8B spectrophotometer (Beckman Instruments, Inc., Fullerton, CA). Maximum absorbance of the isolated hydroperoxide was at 233 nm, with an extinction coefficient of 26,800 $M^{-1}cm^{-1}$ (8). Purity was checked by thin-layer chromatography (TLC) and high-performance liquid chromatography (HPLC). A hydroxy standard, 13(*S*)-hydroxy-9(*Z*),11(*E*)-octadecadienoic acid (13*S*-HOD), was prepared by reducing 13*S*-HPOD in an excess of sodium borohydride in methanol for 0.5 h at 0°C.

13*S*-HPOT and 13(*S*)-hydroxy-9(*Z*),11(*E*),15(*Z*)-octadecatrienoic acid (13*S*-HOT) were prepared in the same manner as was done for 13*S*-HPOD and 13*S*-HOD. Racemic mixtures of methyl hydroxyoctadecadienoates, (*rac*-HOD), and methyl hydroxyoctadecatrienoates, (*rac*-HOT), were produced by sodium borohydride reduction of autooxidized linoleic and linolenic acids as previously described (8).

Kinetics. Stock solutions of fatty acid hydroperoxides in methanol were placed in diethyl ether and taken to near dryness with N_2 to remove methanol. KOH solution was added commencing the alkaline reaction. The system was vortexed 30 s and sonicated 60 s and then incubated in a temperature regulated bath. At intervals, 1-mL aliquots were removed to a separatory flask containing 3.5 mL H_2O, a measured quantity of internal standard, 9,11-octadecadienoic acid (Nu-Chek-Prep) and sufficient citric acid to result in a pH of 4–4.2. Extraction of the product and reactant was performed using 3 vol (based on acidified aqueous solution) of $CHCl_3$/MeOH (2:1, vol/vol). The $CHCl_3$ layer, containing the fatty acids, was evaporated under a stream of N_2 and the material redissolved in hexane/isopropanol (100:2, vol/vol) for HPLC analysis.

HPLC was used to determine the ratio of hydroxide to hydroperoxide fatty acid with a 4.6 × 250 mm Microsorb 5 μm silica column (Rainin Instrument Co., Inc., Woburn, MA). Isocratic runs were made with a Spectra-Physics

Abbreviations: E_a, energy of activation; EDTA, ethylenediaminetetraacetic acid; 13*S*-HPOD, 13(*S*)-hydroperoxy-9(*Z*),11(*E*)-octadecadienoic acid; 13*S*-HPOT, 13(*S*)-hydroperoxy-9(*Z*),11(*E*),15(*Z*)-octadecatrienoic acid; 13*S*-HOD, 13(*S*)-hydroxy-9(*Z*),11(*E*)-octadecadienoic acid; 13*S*-HOT, 13(*S*)-hydroxy-9(*Z*),11(*E*),15(*Z*)-octadecatrienoic acid; HPLC, high-performance liquid chromatography; *rac*-HOD, racemic mixture of 9(*R,S*)-hydroxy-10(*E*),12(*E,Z*)- and 13(*R,S*)-hydroxy-9(*E,Z*),11-(*E*)-octadecadienoic acids; *rac*-HOT, racemic mixture of 9(*R,S*)-hydroxy-10(*E*),12(*Z*),15(*Z*)-, 12(*R,S*)-hydroxy-9(*Z*),13(*E*),15(*Z*),13(*R,S*)-hydroxy-9(*Z*),11(*E*),15(*Z*)-, and 16(*R,S*)-hydroxy-9(*Z*),12(*Z*),14(*E*)-octadecatrienoic acids; TLC, thin-layer chromatography.

SP8800 pump (Spectra-Physics, San Jose, CA) using hexane/isopropanol/acetic acid (100:1.5:0.1, by vol) as solvent system. Absorption was monitored with a Spectra-Physics SP8490 detector at 235 nm. Quantities were determined using 9,11-octadecadienoic acid as an internal standard.

Chirality determination. Chirality of hydroxy fatty acids (as their methyl esters) was determined with a Bakerbond Chiral Phase DNBPG (ionic, 5 μm) 4.6 × 250 mm column (J.T. Baker, Phillipsburg, NJ) essentially as described previously (9). Analyses were performed isocratically using a Waters Model 6000A pump (Waters Associates, Inc., Milford, MA) with a solvent system consisting of hexane/isopropanol (99.5:0.5, vol/vol). Absorption was monitored at 235 nm using a Perkin-Elmer LC-75 spectrophotometric detector (Perkin-Elmer, Norwalk, CT). Fatty acids were esterified with diazomethane prior to analysis. Reactant hydroperoxides were examined after first reducing them with $NaBH_4$ (10) followed by esterification with diazomethane.

Respirometer study. A Gilson differential respirometer (Gilson Medical Electronics, Inc., Middleton, WI) was used to examine for gas evolution from mixtures of 13*S*-HPOD in KOH solution using general prescribed techniques (11). Two reaction flasks were used, one as a blank, the other for the reaction. Initially, 13*S*-HPOD was placed in the reaction vessel and the solvents removed. KOH solution was then placed in the vessel sidearm and the vessel fitted to the respirometer and submerged in the bath at 30°C. After temperature equilibration, the manometer was closed and the vessel was tipped, spilling the KOH solution into the vessel. The change in volume of gas was measured *vs.* time.

RESULTS AND DISCUSSION

Product analyses. Conversion of fatty acid hydroperoxides to hydroxide counterparts in alkaline media was noted previously (for a review, see Ref. 12), but neither the kinetics nor the mechanism has been examined. The investigation focused on the kinetics of the reaction and sought to identify its mechanism. Figure 1 shows TLC evidence of the hydroxy fatty acid produced from the reaction of 13*S*-HPOD with KOH. TLC further demonstrated that elevated reaction temperatures and the use of ethylenediaminetetraacetic acid (EDTA) to prevent interference from metal ions did not significantly alter the product composition. Using an internal standard, it was determined that there was an 80% conversion of 13*S*-HPOD into 13*S*-HOD, the remainder presumably consisting of other products.

Previous work has not shown if there is preservation of the stereochemistry in the transformation. Treatment of 13*S*-HPOD with 5 M KOH for 1.1 h at 35°C followed by chiral-phase HPLC of the methyl esters showed that the hydroxy fatty acid product was 96% 13*S*-HOD, with the remainder being 13(*S*)-hydroxy-9(*E*),11(*E*)-octadecadienoic acid (13*S*-*E*,*E*-HOD). This analysis is to be compared with $NaBH_4$-reduced 13*S*-HPOD starting material that was 96% 13*S*-HOD. Figure 2 shows a co-injection of KOH product with a racemic mixture of hydroxy fatty acids (*rac*-HOD) obtained by $NaBH_4$-reduction of autoxidized linoleic acid. The KOH product eluted with the peak obtained from autoxidation and earlier identified as 13*S*-HOD (8,9). Similarly, treatment of 13*S*-HPOT with KOH under the same conditions resulted in the formation of

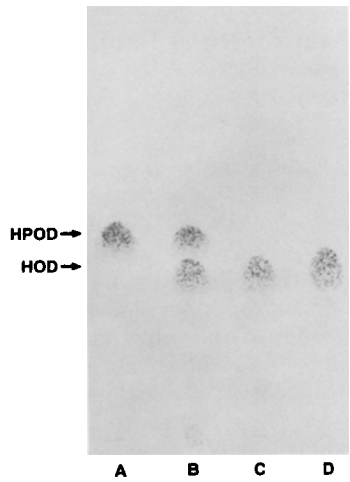

FIG. 1. Thin-layer chromatography separation of 13*S*-HPOD and 13*S*-HOD using a pre-coated Silica Gel 60-F-254 plate. Solvent system hexane/diethyl ether/HOAc (50:50:1, by vol): A, 13*S*-HPOD reactant; B, result of 2.3×10^{-3} M 13*S*-HPOD in 1 M KOH, 5 mM EDTA for 23 h at room temperature (ratio of HOD to HPOD, 83:17, by HPLC); C, result of 2.3×10^{-3} M 13*S*-HPOD in 5 M KOH, 5 mM EDTA for 5 h at 35°C (ratio of HOD to HPOD, 99:1, by HPLC); and D, 13*S*-HOD derived from 13*S*-HPOD by $NaBH_4$ reduction. 13*S*-HPOD, 13(*S*)-hydroperoxy-9(*Z*),11(*E*)-octadecadienoic acid; 13*S*-HOD, 13(*S*)-hydroxy-9(*Z*),11(*E*)-octadecadienoic acid; EDTA, ethylenediaminetetraacetic acid; HPLC, high-performance liquid chromatography.

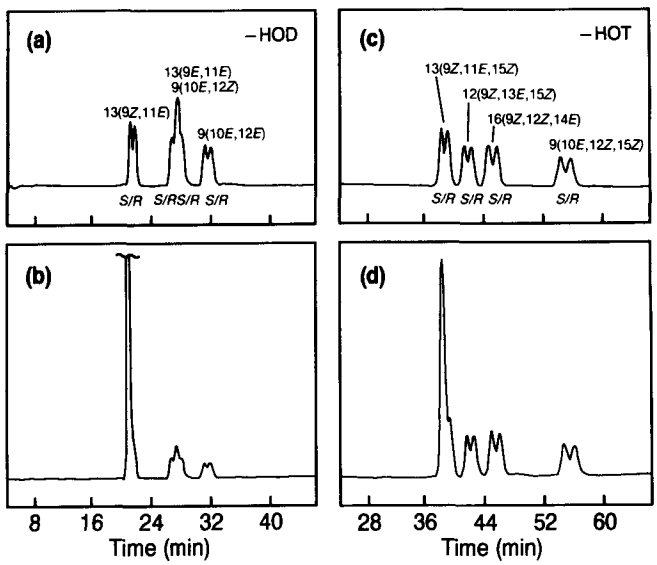

FIG. 2. HPLC separation of *rac*-HOD and *rac*-HOT and co-injection of racemic mixtures with 13*S*-HOD and 13*S*-HOT derived from KOH-treatment of 13*S*-HPOD and 13*S*-HPOT. Separations were performed on a chiral column (250 × 4.6 mm) at ambient temperature with a mobile phase of hexane/isopropanol (99.5:0.5, vol/vol) and a flow rate of 1 mL/min for (a) and (b) and 0.624 mL/min for (c) and (d); detection was by measuring absorbance at 234 nm. (a) Eight isomers of 9- and 13-hydroperoxides of *rac*-HOD with *R* and *S* stereoconfiguration [13*R*,*S*-HOD(9*E*,11*E*) and 9*R*,*S*-HOD (10*E*,12*Z*) peaks overlap]; (b) product of KOH treated 13*S*-HPOD co-injected with *rac*-HOD; (c) eight isomers of 9-, 12-, 13- and 16-hydroperoxides of *rac*-HOT with *R* and *S* stereoconfiguration (Ref. 9); and (d) product of KOH treated 13*S*-HPOT coinjected with *rac*-HOT. Abbreviations as in Figure 1. *rac*-HOD, racemic mixture of 9(*R*,*S*)-hydroxy-10(*E*),12(*E*,*Z*)- and 13(*R*,*S*)-hydroxy-9(*E*,*Z*),11(*E*)-octadecadienoic acids; *rac*-HOT, racemic mixture of 9(*R*,*S*)-hydroxy-10(*E*),12(*Z*),15(*Z*)-, 12(*R*,*S*)-hydroxy-9(*Z*),13(*E*),15(*Z*)-, 13(*R*,*S*)-hydroxy-9(*Z*),11(*E*),15(*Z*)- and 16(*R*,*S*)-hydroxy-9(*Z*),12(*Z*),14(*E*)-octadecatrienoic acids.

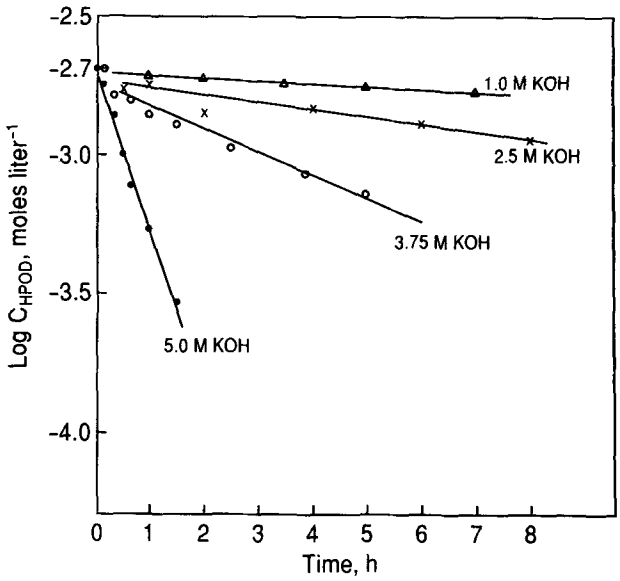

FIG. 3. First order plots of 13*S*-HPOD conversion (2.0×10^{-3} M starting concentration) at various concentrations of KOH at 35°C. Abbreviations as in Figure 1.

86% 13*S*-HOT as compared with 100% 13*S*-HOT obtained by $NaBH_4$-reduction of 13*S*-HPOT. The remaining 14% was an unidentified reaction product that did not correspond by chiral analysis to any of the racemic mixture of hydroxyoctadecatrienoic acid (*rac*-HOT) isomers. Figure 2 also reveals that a co-injection of the KOH-treated 13*S*-HPOT with *rac*-HOT showed the main product had the same retention time as 13*S*-HOT. These results lead to the important conclusion, regarding the mechanism, that the reaction does not proceed by nucleophilic substitution, which would either invert or randomize the stereoconfiguration.

Reaction kinetics. Examination of the reaction began by determining the reaction order for 13*S*-HPOD conversion at high KOH concentrations. The reaction was followed by plotting the log of the hydroperoxy concentration *vs.* time. Most of the kinetics were determined for 13*S*-HPOD and the data are presented in Figure 3. As seen in Table 1, four KOH concentrations were used at a fixed molarity of 2.3×10^{-3} 13*S*-HPOD. Three different temperatures were used, and the rate constants were calculated for a first-order reaction.

Plotting Arrhenius energies of activation in Figure 4 for the reactions provided evidence of the reaction difference between the 1.0 and 2.5 M KOH solutions *vs.* the higher KOH concentrations. Between 1.0 and 3.75 M KOH there was a decreasing energy of activation with increasing KOH concentration. In contrast, at either 3.75 or 5.0 M KOH, where much faster reaction rates occurred, the energy of activation (E_a) values were essentially the same.

The question whether KOH was participating in the reaction or acting as a catalyst needed to be determined. If KOH was involved in the reaction, the reaction would not be first-order. To examine for KOH involvement required that the alkali concentration be just above that of the fatty acid, because it must saponify the lipid and provide a basic medium, yet be of a low enough concentration to affect a change in KOH concentration with reaction time. The solution used to determine the KOH reaction order was 0.05 M KOH and 0.023 M 13*S*-HPOD. Assuming complete saponification, the remaining KOH concentration was 0.031 M, providing a pH of 12.5. Resultant conversion curves at 35 and 45°C are presented in Figure 5. For the purpose of comparison, curves representing the percent conversion of hydroperoxide material to its hydroxy form were plotted *vs.* time. Each reaction was

[a]The concentration of 13*S*-HPOD was 2.3×10^{-3} M, except for the 0.05 M KOH solution where it was 2.3×10^{-2} M.

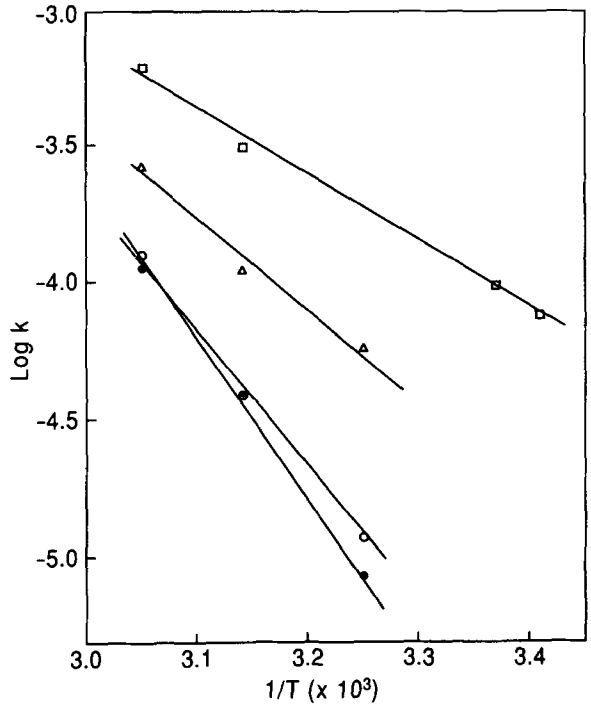

FIG. 4. Arrhenius plot of log reaction rates *vs.* reciprocal of temperature for 2.3×10^{-3} M 13*S*-HPOD in 1 M KOH, E_a (cal. $mole^{-1}$) = 26,000 (□); 2.5 M KOH, E_a = 23,500 (△); 3.75 M KOH, E_a = 15,300 (○); and 5.0 M KOH, E_a = 15,600 (●). E_a, energy of activation. Other abbreviations as in Figure 1.

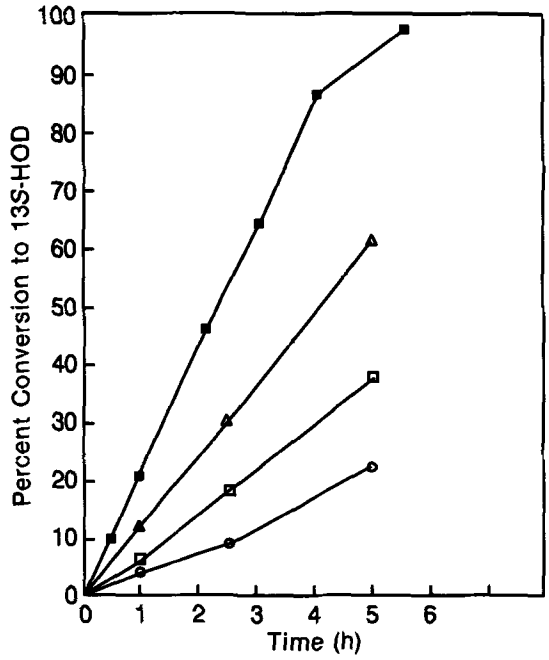

FIG. 5. Time course of 13S-HOD formation in 0.05 M KOH with varying starting concentrations of 13S-HPOD and temperatures. 13S-HPOD concentrations and incubation temperatures are 3.9×10^{-3} M, 35°C plus 1.8×10^{-2} M palmitic acid (total fatty acid, 2.2×10^{-2} M) (○); 3.9×10^{-3} M, 35°C (□); 2.3×10^{-2} M, 35°C (△); and 2.3×10^{-2} M, 45°C (■). Abbreviations as in Figure 1.

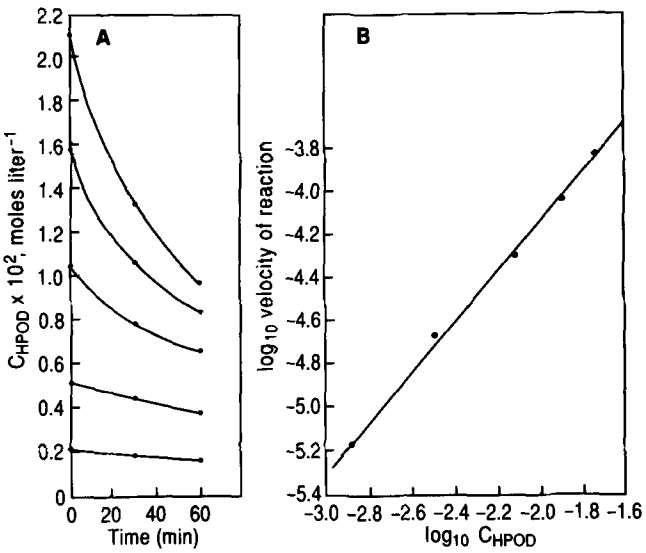

FIG. 6. A. Effect of 13S-HPOD concentration on the rate of conversion into 13S-HOD. Initial concentrations are 2.1, 1.58, 1.05, 0.52 and 0.21 M ($\times 10^{-2}$) 13S-HPOD. Reactions were by incubation for 1 h at 35°C in 2.0 M KOH. Rates of conversion determined tangentially at 30 min. B. Log-log plot of conversion rate *vs.* concentration. Abbreviations as in Figure 1.

first-order with respect to the hydroperoxide. Comparison of these rates to higher alkaline concentration runs are given in Table 1. The reaction rate at lower KOH concentration, 0.05 M, was proportional to the rates at the higher concentrations. A projected reaction rate of 0.64×10^{-5} s^{-1} was derived by extrapolating the reaction rates from Table 1 for 2.5 and 1.0 M KOH at 35°C and 2.3×10^{-3} M 13S-HPOD solutions to 0.05 M KOH. This value was then multiplied by a factor 10 to correct for the increase in hydroperoxide concentration to the 2.3×10^{-2} M 13S-HPOD at 0.05 M KOH. The value of 4.5×10^{-5} s^{-1} is close to the 5.6×10^{-5} s^{-1} value experimentally obtained under these conditions (Table 1). With the extrapolation yielding a slope of 1, the rate of hydroperoxide activity is directly proportional to OH^- concentration at KOH molarity up through 2.5. The conclusion is that KOH is not part of the reaction, but performs as a basic catalyst.

Rate dependence on 13S-HPOD concentration. The effect of hydroperoxide fatty acid concentration on the reaction rate was examined using varying concentrations of 13S-HPOD at constant KOH (2.0 M) at 35°C (Fig. 6). The lipid concentrations were 10^{-3} to 10^{-2} less than the KOH concentration. Reactions were examined at 30 and 60 min. The velocity of a reaction at 30 min was obtained from the slope of the tangent to the curve at 30 min. The reaction order was obtained by plotting the $\log_{10}$ velocity *vs.* $\log_{10}c_{HPOD}$. A linear regression analysis provided a line having a slope of 1.1, which is confirmatory of a first-order reaction.

The presence of nonhydroperoxy lipid material, such as palmitic acid, slowed the conversion of hydroperoxy compounds into their corresponding hydroxides (Fig. 5). Presumably, the addition of palmitic acid resulted in the formation of mixed micelles, thus masking the 13S-HPOD within a fatty acid micelle.

Temperature dependence. The initial rates approximately doubled for every ten degree increase in temperature. This observation was in keeping with reaction rate increase behavior for most chemical reactions near room temperature. There was no evidence that changing the incubation temperature altered the mechanism or the kinetic patterns at any of the KOH or hydroperoxide fatty acid concentrations tested.

Rate comparison of 13S-HPOD and 13S-HPOT. The rates of conversion of 13S-HPOD and 13S-HPOT to the corresponding hydroxy fatty acids were compared under two differing sets of conditions. The two trials differed in KOH concentration and incubation temperature (Fig. 7). Under both sets of conditions, the rate of product formation for the triene was greater than for the diene. 13S-HOT formation rates were first-order, although it was observed that in 5 M KOH the reaction rate decreased more rapidly after about 50% reaction completion than the rate for 13S-HPOD (data not shown). On the other hand, aliquots taken immediately after mixing of 13S-HPOT and KOH resulted in an unexplained rapid depletion of 13S-HPOT (Fig. 7), which was accounted for as conversion into 13S-HOT (data not shown). Other competing reactions may be the cause of the difference in 13S-HPOT kinetics, indicating the need for future work.

The hydroperoxide oxygen. The fate of the hydroperoxide oxygen is critical to determining the mechanism of the reaction. Formation of hydrogen peroxide as a possible reaction by-product was examined. The lack of peroxide formation was demonstrated using the AOCS method of peroxide value determination (13). A 13S-HPOD solution, 1.1×10^{-1} milliequivalents (meq)/mL 2 M KOH, was incubated at room temperature for 3 h. The resulting solu-

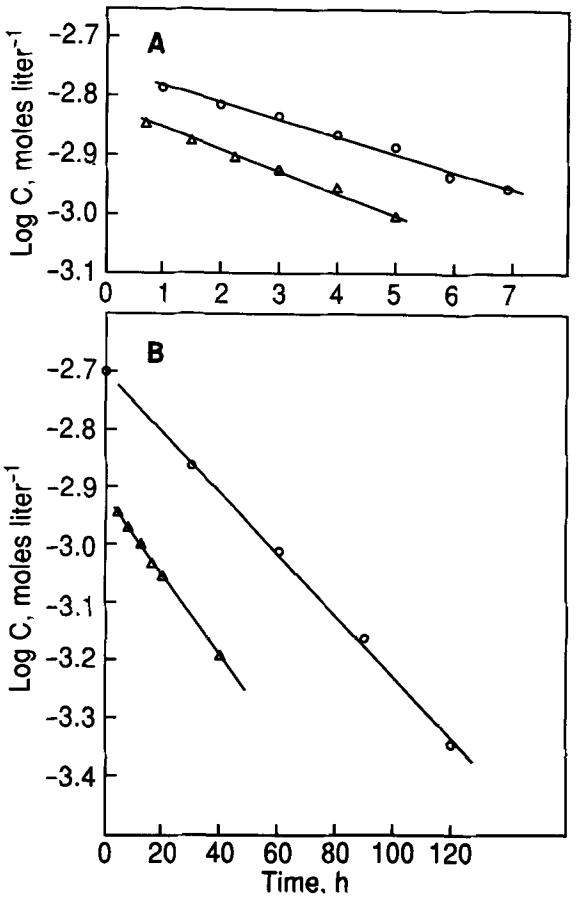

FIG. 7. Plot of log hydroperoxide concentration *vs.* incubation time for comparison of the conversion of 13*S*-HPOT (△) *vs.* 13*S*-HPOD (○). 13*S*-HPOT and 13*S*-HPOD starting concentrations were 2.0×10^{-3}. Incubation conditions: (A) 2.5 M KOH at 35°C; and (B) 5 M KOH at 25°C. Abbreviations as in Figure 1.

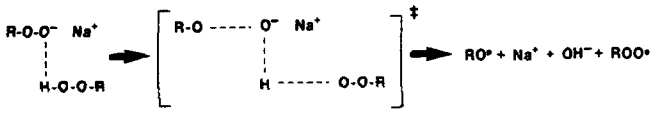
tion, following acidification, yielded a maximum peroxide value of 4×10^{-6} meq/mL. This is a factor of 10^{-4} times lower than the 5.5×10^{-2} meq/mL expected, further casting doubt on either a possible conversion of 13*S*-HPOD to H_2O_2 or its persistence in the alkaline medium. However, we cannot discount the possibility that H_2O_2 is a fleeting intermediate in the reaction.

Another possibility for the loss of oxygen in the hydroperoxide conversion to hydroxide is that the hydroperoxide oxygens could be released as molecular oxygen. A differential respirometer was used to examine for oxygen evolution during 13*S*-HPOD conversion to 13*S*-HOD. 13*S*-HPOD (33 μmol) was reacted with 0.5 mL of 5 M KOH in a respirometer reaction vessel, giving an uptake of 82 μL of gases during a 2-h period of incubation. In terms of oxygen (O_2), 3.6 μmol of gas was consumed. On a basis of reactivity of 1 O_2 per 13*S*-HPOD molecule, 11% of the hydroperoxide reacted with oxygen. This O_2 uptake may explain the 20% non13*S*-HOD by-products resulting from the reaction. Indeed, the by-products found arise from a dioxygenated intermediate (Gardner, H.W., and Hamberg, M., personal communication). However, these data do not explain the fate of one-half mol of O_2 expected to be produced from loss of one hydroperoxide oxygen in the reaction. Denny and Rosen (14) also observed oxygen consumption in treating 1,1,3,3,-tetramethylbutyl hydroperoxide in 10% NaOH.

The "Russell" mechanism for the reaction of secondary hydroperoxides by combination of peroxyl radicals was proposed in 1957 (15). Later, Howard and Ingold (16) and Nakano *et al.* (17,18) extended and further clarified this mechanism in the oxidation studies of *sec*-butyl hydroperoxide and linoleic acid hydroperoxide using ceric ion (Ce^{+4}). Of significance in this mechanism was the resultant production of an alcohol, a ketone and singlet oxygen. Denny and Rosen (14) also suggested a bimolecular reaction in the reduction of cumyl hydroperoxide:



However, it appears unlikely that the 13*S*-HPOD to 13*S*-HOD conversion reaction proceeds by a bimolecular reaction. In general, the order of a reaction is related to the sum of the exponentials of the reactant(s) in the rate equation. A bimolecular reaction would be expected to be second-order.

Accountability of the oxygen removed in the hydroperoxide conversion remains the puzzle. If one ignores the observed O_2 uptake data, the 20% by-products can only account for 20% of oxygen assuming each molecule reacts with one atomic oxygen plus retaining its own initial oxygen.

Simply put, we believe the conversion of 13*S*-HPOD to 13*S*-HOD in KOH does not proceed by a bimolecular reaction involving two hydroperoxide molecules nor does it proceed by a simple first-order reaction, although the kinetic results show the rate is proportional to the hydroperoxide concentration. The present inexplicability of the oxygen destination indicates a much more complex reaction mechanism, one which requires further investigation.

13*S*-HOD has been reported as a vessel wall chemorepellant factor (19) and as a factor in the self-defense mechanism in rice plants against rice blast disease (20). Because of its apparent active role in modulating cellular functions, two recent reports have dealt with the synthesis of 13*S*-HOD (coriolic acid) (21,22). Neither invoked use of the hydroperoxy precursor. It has been demonstrated here that an alkaline conversion of 13*S*-HPOD or 13*S*-HPOT can yield chirally pure 13*S*-HOD and 13*S*-HOT, respectively, in reasonably high yield. Optimum conditions for complete conversion have not yet been established.

ACKNOWLEDGMENTS

The authors thank Dr. Mats Hamberg for suggesting the use of conjugated octadecadienoic acid as an internal standard and McShell Hairston and Earl Nelson for technical assistance.

Identification of Core Aldehydes Among *in vitro* Peroxidation Products of Cholesteryl Esters

H. Kamido, A. Kuksis*, L. Marai and J.J. Myher
Banting and Best Department of Medical Research, University of Toronto, Toronto, Canada M5G 1L6

Synthetic cholesteryl 5-oxovalerate and 9-oxononanoate were used as reference standards for the isolation and identification of cholesteryl ester core aldehydes from *tert*-butyl hydroperoxide/Fe^{++} oxidation of synthetic and natural cholesteryl esters. The core aldehydes were recovered from the peroxidation products by thin-layer chromatography as the free aldehydes or the 2,4-dinitrophenylhydrazones and were identified, respectively, by gas-liquid chromatography (GLC) and by GLC combined with mass spectrometry (GC/MS) or by reverse-phase high-performance liquid chromatography (HPLC) and by HPLC with MS (LC/MS). The core aldehydes produced by peroxidation of cholesteryl linoleate were identified as mainly 9-oxononanoates of cholesterol and oxycholesterols, with smaller amounts of the 8-oxooctenoates, 10-oxodecenoates, 11-oxoundecenoates and 12-oxododecenoates. Peroxidation of cholesteryl arachidonate yielded 5-oxovalerates of cholesterol and the oxycholesterols as the main products with smaller amounts of the 4-oxobutyrates, 6-oxohexenoates, 7-oxoheptenoates, 8-oxooctenoates, 9-oxononenoates, 9-oxononadienoates and 10-oxodecadienotes. The oxycholesterols resulting from the peroxidation of the steroid ring were identified as mainly 7-keto-, 7α-hydroxy- and 7β-hydroxy-cholesterols and 5α,6α- and 5β,6β-epoxy-cholestanols. Cholesteryl palmitate and oleate did not yield core aldehydes in the present peroxidation system. In these esters, the sterol and linoleic acid moieties appeared to be oxygenated at about the same rate, while the arachidonic acid moiety reacted more rapidly than did the sterol moiety.
Lipids 28, 331-336 (1993).

There is extensive evidence that the autoxidation products of cholesterol and cholesteryl esters exert pronounced biological effects. Thus, the products of autoxidation of free cholesterol are well known inhibitors of the rate-limiting enzymes in cholesterol and bile acid biosynthesis (1). In addition, the cholesterol oxides possess carcinogenic (2) and atherogenic (3) properties. Among the major peroxidation products of cholesterol found in human plasma are the isomeric cholesterol 5α,6α- and 5β,6β-epoxides (4). The autoxidation products of cholesteryl esters have been less thoroughly investigated, and there is evidence that the fatty chain may exert a protective effect on the autoxidation of the steroid ring (5,6). Previous work has demonstrated the presence of cholesteryl ester hydroperoxides in fresh human blood plasma (7), but specific molecular species have not been identified. Stored human blood plasma has been shown to contain 9- and 13-hydroxylation products of cholesteryl linoleate and arachidonate (8), which presumably originated from a reduction of the corresponding hydroperoxides. In the present study, we have demonstrated the formation of cholesteryl ester core aldehydes during *in vitro* peroxidation of synthetic and natural cholesteryl esters with *tert*-butyl hydroperoxide in the presence of $FeSO_4$, which is believed to mimic lipid peroxidation in natural systems (9). This is the first report of the occurrence of lipid soluble core aldehydes among the peroxidation products of cholesteryl esters.

MATERIALS AND METHODS

Chemicals and reagents. Cholesteryl palmitate, oleate, linoleate and arachidonate, and *tert*-butyl hydroperoxide (*t*-BOOH) and cholesteryl ester hydrolase *(Pseudomonas)* were obtained from Sigma Chemical Co. (St. Louis, MO). Methoxylamine HCl (MOX reagent), trimethylchlorosilane and *bis*(trimethylsilyl)trifluoroacetamide were from Pierce Chemical Co. (Rockford, IL), while 2,4-dinitrophenylhydrazine was from Aldrich Chemical Co. (Milwaukee, WI). Acetonitrile and 2-propanol [high-performance liquid chromatography (HPLC) grade] were from Fisher Scientific Co. (Toronto, Ontario, Canada) or Caledon Laboratories Ltd. (Georgetown, Ontario, Canada), while propionitrile was from Romil Ltd. (Loughborough, England). All other chemicals and solvents were of reagent grade or better quality and were obtained from local suppliers. Standard 5-oxovalerate and 9-oxononanoate of cholesterol were previously synthesized in our laboratory (10). The cholesteryl esters of rat plasma were isolated by thin-layer chromatography (TLC) using the methods described below.

Peroxidation with t-BOOH/$FeSO_4$. The peroxidation routine was modeled after previous work of Borowitz and Montgomery (11). One to two mg of cholesteryl ester in 100 μL of chloroform/methanol (2:1, vol/vol) were placed in a 15-mL test tube, and the solvent was evaporated under nitrogen. To the dry sample was then added 1 mL of 70% aqueous *t*-BOOH and 100 μM $FeSO_4$ and the tube was mechanically shaken for 3 h at 37°C in the dark. The reaction was stopped by diluting the mixture with five volumes of chloroform/methanol (2:1, vol/vol) and washing with water to remove excess *t*-BOOH. The lower layer was collected, evaporated to dryness under nitrogen and taken up in chloroform for purification and identification of core aldehydes.

Isolation of core aldehydes. The chloroform extracts of the reaction mixture were resolved by TLC on silica gel H using heptane/isopropyl ether/glacial acetic acid (60:40:4, by vol) as the developing solvent. The location of the core aldehydes was revealed by spraying the plate with Schiff's reagent (10). The other lipids on the TLC plate were located under ultraviolet (UV) light by spraying the plate with 2,7-dichlorofluorescein. The aldehydes were recovered from the silica gel by extraction with chloroform/methanol (2:1, vol/vol). The core aldehydes and the derived oxycholesterols were reduced with sodium

borohydride to convert any 7-keto- to the 7-hydroxycholesterol derivatives (8).

Preparation of 2,4-dinitrophenylhydrazone (DNPH) derivatives. The cholesteryl ester core aldehydes were converted into the hydrazones using a modification of the method described by Esterbauer and Cheeseman (12) for water-soluble aldehydes. The chloroform extracts of the peroxidation products were treated with 0.5 mL of freshly prepared DNPH reagent (2,4-DNPH in 1 N HCl at a concentration of 0.5 mg/mL), mixed vigorously and kept in dark for 2 h at room temperature and then for 1 h at 4°C. The reaction mixture was extracted with chloroform/methanol (2:1, vol/vol), and the recovered hydrazones purified by TLC using a double development with dichloromethane (10 cm) and, after solvent evaporation, with toluene (17 cm). The yellow zones were scraped off and the gel extracted with methanol. The hydrazones could be purified further by reverse-phase HPLC and the UV absorbing fractions collected.

Enzymatic hydrolyses. The cholesteryl and oxycholesteryl esters were hydrolyzed with cholesteryl ester hydrolase using a method modified from Heider and Boyett (13). The esters (max. 1 mg) were dissolved in sodium taurocholate (25 mM final concentration) and incubated with cholesteryl ester hydrolase (0.5 U/mL) in sodium phosphate buffer (pH 7.4) (1 mL final volume) for 60 min at 37°C. The released sterols were extracted with chloroform/methanol (2:1, vol/vol) and backwashed with water to remove the bulk of the detergent. The oxysterols were purified by TLC using heptane/isopropyl ether/acetic acid (60:40:4, by vol) as solvent.

Gas-liquid chromatography (GLC) and gas chromatography/mass spectrometry (GC/MS). Intact cholesteryl esters, core aldehydes and their trimethylsilyl (TMS) and methoxime (MOX) derivatives were resolved on the basis of their molecular weights by GLC using an 8 m × 0.32 mm i.d. capillary column coated with DB-5 as previously described (10). The TMS derivatives of oxidized sterols were separated on 30 m × 0.32 mm i.d. capillary column coated with DB-5 according to the method of Maerker and Unruh (15). The sterols were injected on-column at 40°C, and after 0.5 min the oven temperature was first increased to 150°C at 30°C/min then to 230°C at 20°C/min, then to 260°C at 10°C/min and finally to 300°C at 0.5°C/min. The carrier gas was hydrogen at 6 psi and the flame-ionization detector was set at 325°C. The sterols were identified by means of standards and by GC/MS in the positive ion mode (16). The MOX derivatives were prepared and silylated as described by Horning *et al.* (17). The MOX derivatives of the core aldehydes were purified by TLC as previously described (10).

HPLC and liquid chromatography/mass spectrometry (LC/MS). Reverse-phase HPLC of the 2,4-DNPHs of the cholesteryl ester core aldehydes was performed on a Supelcosil LC-18 column (250 mm × 4.6 mm i.d.) (Supelco, Inc., Mississauga, Ontario, Canada) using acetonitrile/2-propanol (4:1, vol/vol) (1 mL/min) or a linear gradient of 30–90% propionitrile in acetonitrile (1.5 mL/min) as the eluting solvents as previously described (10). Earlier described methods were also used for reverse phase LC/MS of the DNPH derivatives of core aldehydes (14).

Quantitation. The relative proportions of the various oxidation products were estimated by high temperature GLC following preparation of the TMS-MOX derivatives or the TMS derivatives of the sodium borohydride reduction products of the total lipid extracts of the reaction mixtures (8).

RESULTS AND DISCUSSION

Identification of sterol ring oxidation products. Figure 1 shows the TLC resolution of the peroxidation products of free cholesterol and cholesteryl palmitate and oleate. The free sterol yields two bands, one of which corresponds to residual cholesterol (R_f 0.30) the other one to 7-ketocholesterol (R_f 0.10). Both cholesteryl palmitate and cholesteryl oleate give a band for residual esters (R_f 0.90) and a strong band for a polar product (R_f 0.72). Since the saturated fatty acid is inert to peroxidation, the oxidative transformation responsible for the slower migration must have taken place on the steroid ring. Likewise, the cholesteryl oleate appeared to be oxidized only in the ring, although a minor TLC band was seen corresponding to the 9-oxononanoate of 7-ketocholesterol. This conclusion was confirmed by hydrolysis of the *t*-BOOH oxidation products of cholesteryl oleate with cholesteryl ester hydrolase. The released free sterols gave two TLC fractions, one of which was due to unoxidized, the other to oxidized cholesterol as noted for the oxidation products of free cholesterol.

Figure 2 shows the GLC resolution of the oxycholesterols released by cholesteryl ester hydrolase from peroxidized cholesteryl oleate. These separations were carried out on a 30-m capillary column, which resolved close isomers of oxycholesterol. Specifically identified were 7-keto-, 7α- and 7β-hydroxy- and the 5α,6α- and 5β,6β-epoxy derivatives of cholesterol. The presence of 7-ketocholesterol was confirmed by sodium borohydride reduction, which yielded the 7α- and 7β-hydroxy cholesterols in equal

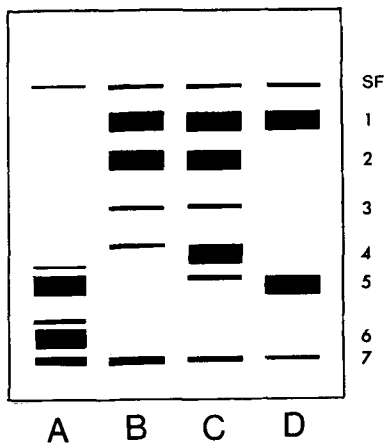

FIG. 1. Thin-layer chromatography resolution of *tert*-butyl hydroperoxide oxidation products of cholesterol, cholesteryl palmitate and cholesteryl oleate (in absence of $FeSO_4$). Lane A, oxidation products of free cholesterol; Lane B, oxidation products of cholesteryl palmitate; Lane C, oxidation products of cholesteryl oleate; Lane D, standard free cholesterol and cholesteryl oleate. Band 1, residual cholesteryl ester; Band 2, 7-ketocholesteryl esters; Band 3, unidentified; Band 4, 7-hydroxycholesteryl esters; Band 5, free cholesterol; Band 6, 7-ketocholesterol; Band 7, origin and 7-hydroxycholesterol. Solvent system: heptane/diisopropyl ether/glacial acetic acid (60:40:4, by vol). Lipid fractions were located by spraying with 2',7'-dichlorofluorescein and Schiff's reagent (10). SF, solvent front.

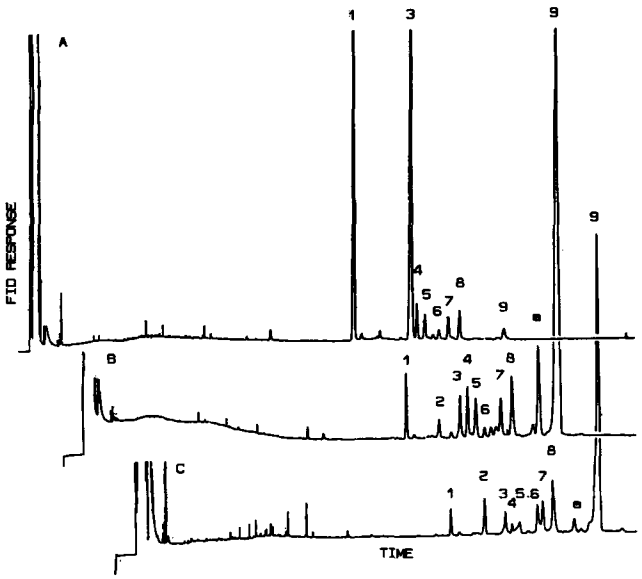

FIG. 2. Gas-liquid chromatography (GLC) resolution of the oxidation products of free cholesterol and cholesteryl oleate. A, oxidation products of free cholesterol after sodium borohydride reduction; B, oxidation products of free cholesterol; C, oxycholesterols released by cholesteryl ester hydrolase from oxidized cholesteryl oleate. Peak identification: 1, 7α-hydroxycholesterol; 2, 3,5-cholestadienol; 3, 7β-hydroxycholesterol; 4, cholesterol 5,6β-epoxide; 5, cholesterol 5,6α-epoxide; 6-8, unidentified oxysterols; 9, 7-ketocholesterol. GLC conditions: 30 m × 0.32 mm capillary coated with DB-5 (10); temperature programmed as given under Materials and Methods. Other GLC conditions, see also Materials and Methods. FID, flame-ionization detector.

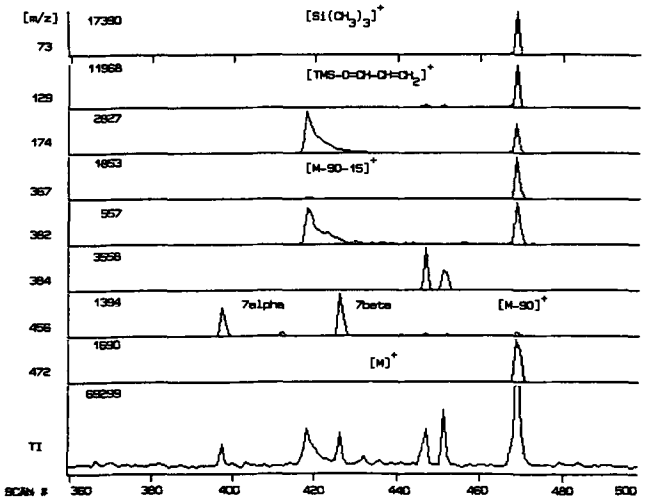

FIG. 3. Total ion current profile and single ion plots for major molecular species of ring oxidized cholesteryl oleate as obtained by gas-chromatography/mass spectrometry (GC/MS) of the oxysterols released by cholesteryl ester hydrolase digestion from oxidized cholesteryl oleate (trimethylsilyl ethers). Peak identification: TI, total positive ion current; *m/z*, fragment ions as identified in the figure. Numbers inside figure refer to the ion counts of the major single ion peak. GC/MS conditions as given under Materials and Methods.

proportions. These diols overlapped with the corresponding minor diol peaks in the original GLC profiles of each ester. Other minor peaks (Peaks 6-8) were attributed to mixed function derivatives but were not further identified. Addition of $FeSO_4$ to the peroxidation medium had no significant qualitative effect on the oxycholesterol composition.

Figure 3 shows the total ion current profile and the single ion plots for the major molecular species of the ring oxidized cholesterol moiety released by the enzyme from the oxidized cholesteryl oleate. The 7α- and 7β-hydroxy cholesterols gave strong $[M - 90]^+$, $[M - 90 - 15]^+$ as well as other minor ions characteristic of the TMS ether. An $[M]^+$ ion at *m/z* 382 was also obtained for cholesta-3,5-dien-7-one, which was assumed to be a minor product of dehydration of 7-ketocholesterol in the gas chromatograph (18). The unknown yielded strong ions corresponding to *m/z* 384, which suggested that they were isomeric dehydration products of oxycholesterol. The mass spectra of the oxysterols agreed with the corresponding spectra recorded in the literature for 7-ketocholesterol (19), 3,5-cholestadien-7-one (20), and the 7α- and 7β-hydroxy cholesterol di-TMS derivatives (21). The GC/MS profiles of the sterol moieties of peroxidized cholesteryl esters were similar to those of the oxysterols recovered from the peroxidation of free cholesterol.

The oxidized cholesteryl palmitate and oleate gave excellent GLC profiles (chromatograms not shown). The oxidized esters were eluted with retention times about one to two methylene units higher than the corresponding unoxidized esters. The overall elution patterns were similar for both esters as would be anticipated from the free oxysterol analyses. Reduction of the 7-ketocholesteryl oleate by sodium borohydride gave the corresponding 7α- and 7β-hydroxy cholesteryl stearates, which upon trimethylsilylation gave the anticipated decreases in the GLC retention times. The peak identity was confirmed by GC/MS, which yielded the correct molecular weights of the esters and fragment ions characteristic of the steroid ring.

TLC separation of the peroxidation products of cholesteryl linoleate gave several bands (chromatogram not shown). In addition to the residual ester (R_f 0.84), there was a band containing oxidized cholesterol in combination with unoxidized linoleic acid (R_f 0.72), a band containing mainly cholesteryl 9-oxononanoate (R_f 0.37) and a more diffuse band made up mainly of 9-oxononanoyl esters of various oxycholesterols (R_f 0.15-0.29). TLC separation of the peroxidized arachidonate failed to yield any of the original ester, but some oxycholesteryl arachidonate may have been present (see below). The identified peroxidation products of cholesteryl arachidonate were made up of mainly 5-oxovaleroyl colesterol (R_f 0.30) and 5-oxovaleroyl esters of the various oxycholesterols (R_f 0.10-0.20). The major steryl ester core aldehydes yielded GLC peaks which corresponded to standard 9-oxononanoyl and 5-oxovaleroyl esters of cholesterol when run as the MOX-TMS ethers or TMS ethers. The GLC peaks of the core aldehyde esters of the oxycholesterols gave much more complex profiles, although the 7-ketocholesterol and cholesteryl epoxide derivatives could be discerned. In all instances, characteristic peak shifts were seen in the GLC retention times when the MOX-TMS and TMS derivatives were analyzed (chromatograms not shown). However, many minor peaks remained unidentified in the mass profiles of the chromatograms, while the mass spectra of these derivatives were compromised by overlapping esters other than lipid ester core aldehydes.

This difficulty was largely overcome by the preparation of the DNPH derivatives of the steryl ester core aldehydes, which could be specifically detected as yellow bands on TLC, UV absorbing peaks on HPLC and negative ions on LC/MS.

Figure 4 shows the TLC separation of the yellow-colored DNPH derivatives of the core aldehydes derived by peroxidation of cholesteryl linoleate (Lane D) and cholesteryl arachidonate (Lane E). The peroxidation products of both esters gave four well-resolved bands (R_f values 0.20–0.40) migrating near the middle of the TLC plate along with less well-resolved yellow regions near the origin. The center bands corresponded in R_f values to the DNPH derivatives of standard 9-oxononanoyl and 5-oxovaleroyl esters of cholesterol. The region near the origin (R_f values 0.10 and 0.20) contained the DNPH derivatives of oxycholesteryl ester core aldehydes. The major TLC fractions were identified by LC/MS with NCI. Figure 5A gives the HPLC profiles of the core aldehydes recovered from the linoleate oxidation. Band 1 (Fig. 4, Lane D) contained mainly cholesteryl 12-oxododecenoate, 11-oxoundecenoate and 10-oxodecenoate. Band 2 (Fig. 4, Lane D) contained mainly cholesteryl 8-oxononanoate, while Band 3 (Fig. 4, Lane D) contained mainly cholesteryl 8-oxooctanoate, 10-oxodecenoate and 10-oxodecanoate. Band 4 (Fig. 4, Lane D) contained an unknown oxycholesteryl 9-oxononanoate, which gave the same molecular ion as 7-ketocholesteryl 9-oxononanoate. The bands near the origin (Fig. 4, Lane D) contained mainly 7-ketocholesteryl 9-oxononanoate and the 9-oxononanoate of 5,6-epoxycholestanol. Figure 5B gives the HPLC profiles of the core aldehydes derived from cholesteryl arachidonate and recovered from the four TLC bands (Fig. 4, Lane E) of the DNPH derivatives. The arachidonate yielded the corresponding

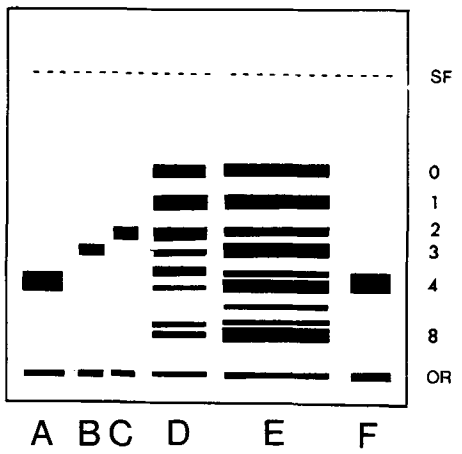

FIG. 4. Thin-layer chromatography (TLC) resolution of dinitrophenylhydrazone (DNPH) derivatives of *tert*-butyl hydroperoxide oxidation products of cholesteryl linoleate and cholesteryl arachidonate. Lane A, DNPH reagent; Lane B, DNPH derivative of cholesteryl 5-oxovalerate standard; Lane C, DNPH derivative of cholesteryl 9-oxononanoate standard; Lane D, DNPH derivatives of oxidized cholesteryl linoleate; Lane E, DNPH derivatives of oxidized cholesteryl arachidonate; Lane F, DNPH reagent. TLC Band identification: 0, original ester; 1, cholesteryl 12-oxododecenoate; 2, cholesteryl 9-oxononenoate; 3, cholesteryl 5-oxovalerate; 4, 7-ketocholesteryl 12-oxododecenoate; 8, 7-ketocholesteryl 5-oxovalerate. TLC conditions: double development as described under Materials and Methods. SF, solvent front; OR, origin.

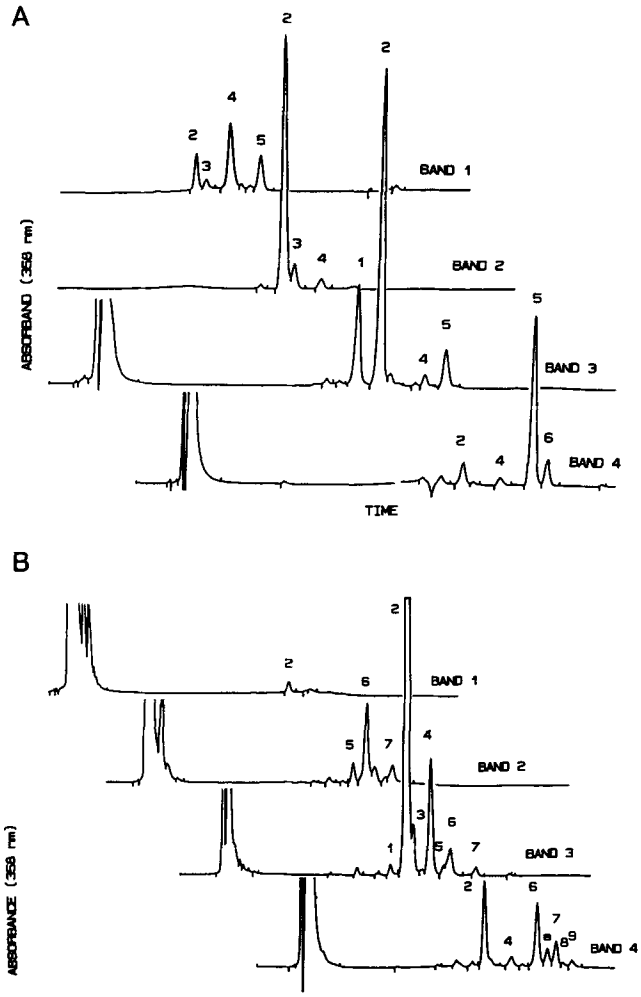

FIG. 5. Reverse-phase high-performance liquid chromatography (HPLC) resolution of dinitrophenylhydrazone derivatives of cholesteryl ester core aldehydes derived from peroxidation of cholesteryl linoleate (upper panel, Bands 1–4) and cholesteryl arachidonate (lower panel, Bands 1–4) following isolation by thin-layer chromatography (Fig. 4). Peak identification (upper panel): 1, cholesteryl 8-oxooctanoate; 2, cholesteryl 9-oxononananoate; 3, cholesteryl 10-oxodecenoate; 4, cholesteryl 11-oxoundecenoate; 5, cholesteryl 12-oxododecenoate; 6, cholesteryl 13-oxotridecadienoate. Peak identification (lower panel): 1, cholesteryl 4-oxobutyrate; 2, cholesteryl 5-oxovalerate; 3, cholesteryl 6-oxocaproate; 4, cholesteryl 7-oxoheptanoate; 5, cholesteryl 9-oxononadienoate; 6, cholesteryl 10-oxodecenoate; 9, cholesteryl 11-oxoundecenoate. HPLC conditions as given under Materials and Methods. Thin-layer chromatography conditions as given in Figure 4.

cholesteryl and oxycholesteryl esters of mainly 5-oxovalerate along with smaller amounts of 4-oxobutyrate, 6-oxohexenoate, 7-oxoheptenoate, 8-oxooctenoate, 9-oxononenoate and others. Band 1 (Fig. 4, Lane E) gave a small peak with a retention time similar to that of the major peak (9-oxononadienoate) in Band 2 (Fig. 4, Lane E). Band 2 (Fig. 4, Lane 4) contained mainly the 5-oxovalerate, along with minor peaks for 6-oxohexenoate, 7-oxoheptenoate, 8-oxooctenoate, 9-oxononadienoate and 10-oxodecadienoate. Band 4 (Fig. 4, Lane E) also contained the 5-oxovalerate of cholesterol on the basis of relative retention time, along with minor peaks corresponding to 7-oxoheptenoate and 9-oxononenoate.

Figure 6A shows the reverse-phase LC/MS profile of the total NCI current of the DNPH derivatives of the core aldehydes derived from the oxidation of cholesteryl linoleate, along with the single ion plots for the molecular weights of the species. These data establish the identities and the relative proportions of the various core aldehydes resolved by the TLC/HPLC combination. Thus, the major components in this fraction are cholesteryl 11-oxoundecenoate (*m/z* 746) and cholesteryl 12-oxododecenoate (*m/z* 780) and cholesteryl 9-oxononanoate (*m/z* 720), as indicated by the ion intensities listed on the left-hand side of the figure. Figure 6B shows the reverse-phase LC/MS total NCI current profile of the DNPH derivatives of the core aldehydes derived from the oxidation of cholesteryl arachidonate along with the molecular ion plots for the species. Here the major components by far are cholesteryl 5-oxovalerate (*m/z* 664) and cholesteryl 7-oxoheptenoate (*m/z* 690), with much smaller amounts of cholesteryl 4-oxobutyrate (*m/z* 650), cholesteryl 6-oxohexenoate (*m/z* 676), 9-oxononadienoate (*m/z* 716) and 10-oxodecadienoate (*m/z* 730), as indicated by the ion intensities listed on the left-hand side of the figure. Again, the LC/MS data establish the identification and proportionation of the core aldehyde species tentatively identified by the TLC/HPLC combination.

The mass spectra of the DPNH derivatives of cholesteryl 9-oxononanoate and cholesteryl 5-oxovalerate isolated from the peroxidation products of cholesteryl linoleate and arachidonate, respectively, corresponded exactly to those of synthetic standards (10). Only single ions corresponding to the molecular weight of these hydrazones were seen in the 500–800 mass range (figures not shown). Figure 7 shows the partial mass spectra of the DNPH derivative of 7-ketocholesteryl 9-oxononanoate (A) and 5,6-epoxycholestanyl 9-oxononanoate (B) recovered from oxidized cholesteryl linoleate and isolated from near the origin of the TLC plate (Fig. 4, Lane D). Again, only single ions corresponding to the molecular weights of the compounds are seen. The minor ion at *m/z* 580 in A is due to the DNPH derivative of 7-ketocholesterol, which overlapped with the 9-oxononanoate on the TLC plate. The minor masses at *m/z* 676 and 772 in B were due to the DNPH derivatives of unidentified components overlapping with the epoxy cholesteryl 9-oxononanoate on the TLC plate.

In addition, we investigated the peroxidation products of the mixed cholesteryl esters of rat plasma by exposing to the *t*-BOOH/$FeSO_4$ system: fresh rat plasma, total lipid extracts of rat plasma and purified cholesteryl esters of rat plasma. In all instances, we were able to demonstrate the formation of ring oxidized cholesteryl esters of palmitic, oleic and linoleic acids and the 5-oxovaleroyl and 9-oxononanoyl esters of cholesterol and oxycholesterol (chromatograms not shown). The various core aldehyde esters were found in proportions reflecting the composition of the fatty acids in the cholesteryl ester mixtures.

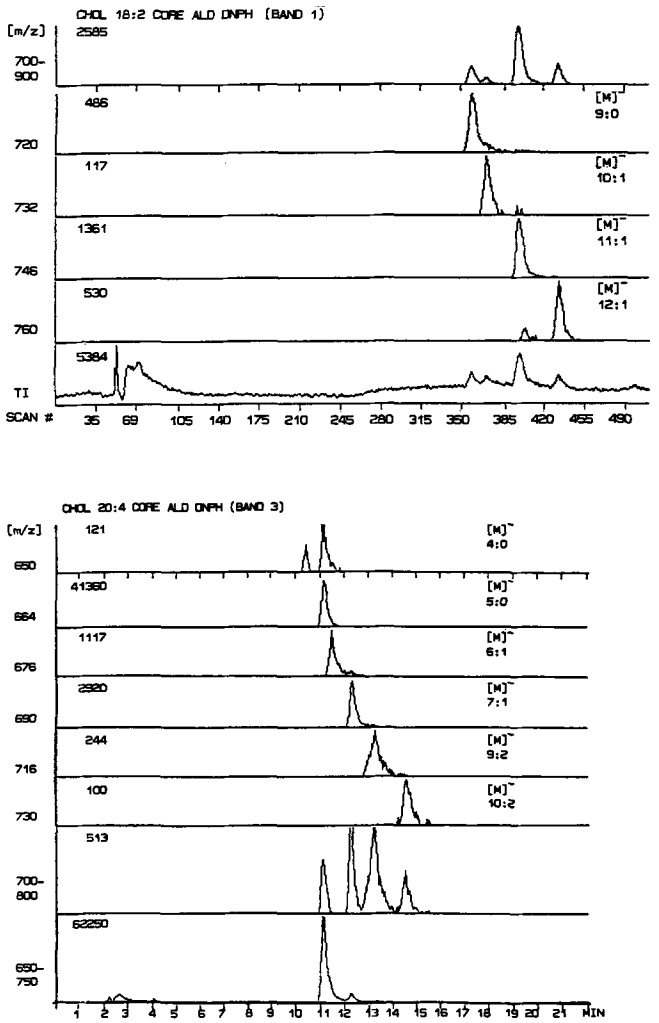

FIG. 6. Reverse-phase liquid chromatography/mass spectrometry (LC/MS) profile of total negative ion current along with molecular ion plots for dinitrophenylhydrazone (DNPH) of core aldehydes derived from oxidized cholesteryl linoleate (upper panel) and oxidized cholesteryl arachidonate (lower panel). Peak identification: as given in the figure (total carbon number:total number of double bonds in the aldehyde moiety). TI, total negative ion current. Other LC/MS conventions as in Figure 3. LC/MS conditions as given under Materials and Methods.

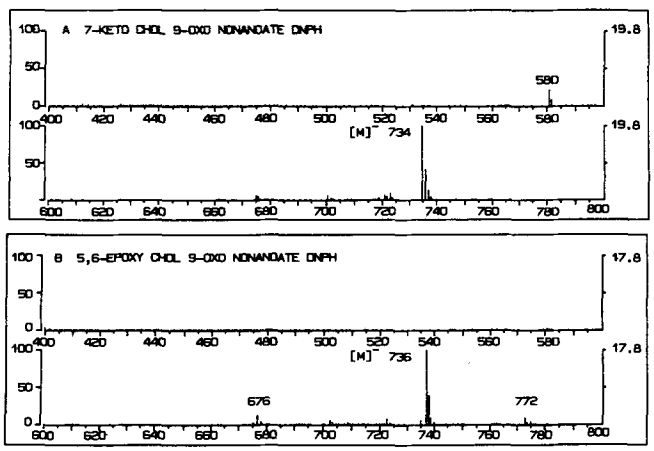

FIG. 7. Partial mass spectra of dinitrophenylhydrazone (DNPH) of 7-ketocholesteryl 9-oxononanoate (A) and DNPH of 5,6-epoxy cholestanyl 9-oxononanoate as obtained by reverse-phase liquid chromatography/mass spectrometry (LC/MS) with negative chemical ionization. LC/MS conditions are as given under Materials and Methods.

Mechanism of oxidation. The mechanism of oxidation of the steryl esters was not specifically investigated in this study, but the choice of the oxidant and the reference to peroxidation requires comment. The term "peroxidation" was adopted in keeping with previous usage. Halliwell and Gutteridge (9) had noted that addition of *tert*-butyl or cumene hydroperoxide along with Fe^{++} is an effective way to stimulate lipid peroxidation *in vitro*. Although free radicals and fatty acid peroxides or hydroperoxides were not identified as indicators of peroxidation in our experiments, conjugated dienes have been detected under comparable reaction conditions (11) suggesting that peroxidation of the polyunsaturated acids may have taken place. Furthermore, the steryl ester core aldehydes identified in this work appear to be of the type proposed for the peroxidation of linoleic and arachidonic acids by Esterbauer *et al.* (22), where a homolytic scission of the two C–C bonds on either side of the hydroperoxy group takes place. It should be noted, however, that the sterol ring oxidation products isolated and identified here are consistent with the mechanism proposed by Kimura and Muto (23) and discussed by Smith (1). These authors have pointed out that *tert*-butyl peroxyl radicals may epoxidize the Δ^5 double bond, and *tert*-butyl oxyl radicals may abstract the C_7 proton to yield C_7 alcohols and C_7 ketones without the generation of peroxides and hydroperoxides as intermediates. It is therefore possible that under the influence of the harsh reagent multiple oxidations may take place by several different pathways.

In summary, the present results demonstrate that polyunsaturated cholesteryl esters are subject to peroxidation in both sterol ring and in the fatty chain, while saturated and monounsaturated fatty acid esters are oxidized only in the ring, when exposed to *t*-BOOH in the presence of ferrous sulfate. The formation of the lipid-soluble core aldehydes from polyunsaturated fatty acid esters of cholesterol has not been previously reported, although it should have been anticipated in view of the known generation of the water-soluble low molecular weight aldehydes. The core aldehydes occur in combination with both unoxidized and oxidized cholesterols, although only the 7-keto cholesterol and the 5,6-epoxycholestanol core aldehydes were actually identified. The esterification of the 3β-hydroxyl group of cholesterol by the saturated or monounsaturated fatty acid had no significant qualitative effect upon the oxidation of the cholesterol ring, although quantitatively it may have provided some protection, as previously reported (1,5,6). The biological activity of the core aldehydes of normal or peroxidized cholesterol is not known. The present study shows that the core aldehyde esters of cholesterol and oxycholesterol are readily hydrolyzed by bacterial cholesteryl ester hydrolase.

Characteristics of the Thiobarbituric Acid Reactivity of Human Urine as a Possible Consequence of Lipid Peroxidation

Hiroko Kosugi[a,*], Takashi Kojima[b] and Kiyomi Kikugawa[b]

[a]Ferris University, 4-5-3 Ryokuen, Izumiku, Yokohama 245 and [b]Tokyo College of Pharmacy, 1432-1 Horinouchi, Hachioji, Tokyo 192-03, Japan

A 532 nm red pigment formed in the thiobarbituric acid (TBA) assay of human urine was characterized after separation of the pigment by high-performance liquid chromatography. The yield of the red pigment was somewhat higher at pH 2 than at pH 5; its development was not inhibited by ethylenediaminetetraacetic acid. The characteristics of the pigment were similar to those of the pigment derived from standard malonaldehyde. The amount of the pigment formed was roughly equal to the content of malonaldehyde derivatives estimated as 1-(2,4-dinitrophenyl)pyrazole. Pigment formation was significantly enhanced by *t*-butyl hydroperoxide (*t*-BuOOH) and ferric ions, which may be due to pigment formed from aldehydes other than malonaldehyde; the presence of these aldehydes was confirmed by the formation of the corresponding 2,4-dinitrophenylhydrazones. The amount of pigment produced from 24-h urine samples of 12 healthy subjects was estimated to be 26–95 nmol/kg, and 65–182 nmol/kg in the presence of *t*-BuOOH. These values are lower than those for urine of rabbit or rat. The TBA reactivity in the absence and presence of *t*-BuOOH of human urine was not related to age or sex. The TBA reactivity of human urine collected in the afternoon and in the evening was higher than that of urine collected in the morning. ***Lipids 28,*** **337–343 (1993).**

Lipid peroxidation has been implicated as being involved in various pathological conditions including aging, carcinogenesis, atherosclerosis, inflammation, ischemia and drug toxicities. Lipid peroxidation products excreted in human urine may thus reflect lipid peroxidation of the whole body. The thiobarbituric acid (TBA) assay (1) has previously been used for the measurement of lipid peroxidation products in rat and in human urine (2–5). Thus, heating of urine with TBA in acidic medium has been shown to give a red malonaldehyde TBA (1:2) adduct with a maximum absorption at 532 nm (6).

Although the red pigment had been assumed to be specific for malonaldehyde, other aldehydes generated during lipid peroxidation have been shown to produce the same pigment (1,7–14). Pigment formation from malonaldehyde is quantitative and is little affected by pH, added organic hydroperoxides or ferric ion. In contrast, pigment formation from alkadienals and alkenals is not quantitative, is highly pH-dependent (12,13) and is greatly enhanced by added organic hydroperoxides (8–14) and ferric ions (13,14). Our previous studies have shown that the pigment formed from oxidized fats and oils is due to alkadienals and/or alkenals (11,13), and that the pigment formed from rat liver and brain homogenate is due to both alkadienals and malonaldehyde (12,14).

In the present study, we characterized the red pigment formed in the TBA assay of human urine and determined which aldehydes generated during lipid peroxidation are responsible for pigment formation. We also determined the amounts of pigment formed from urine of healthy human subjects.

MATERIALS AND METHODS

Materials. TBA, 2,4-dinitrophenylhydrazine (DNPH), propanal, butanal, hexanal and 2,4-heptadienal were obtained from Wako Pure Chemical Industries (Osaka, Japan). 2-Butenal, 2-hexenal, 2,4-hexadienal and tetramethoxypropane (TMP) were obtained from Tokyo Kasei Kogyo Company (Tokyo, Japan). 2-Pentenal and 2-heptenal were obtained from Aldrich Chemical Company (Milwaukee, WI). *t*-Butyl hydroperoxide (*t*-BuOOH) (70% in water) was obtained from Sigma Chemical Company (St. Louis, MO); its concentration was determined to be 7.0 M by iodometric titration. Butylated hydroxytoluene (BHT) was obtained from Nikki Universal Company (Tokyo, Japan). *N*-(2-propenal)aminoacetic acid was prepared as described (15). Glacial acetic acid was a special reagent grade product of Wako Pure Chemical Industries.

Analysis. Absorption spectra were measured on a Hitachi U-2000 (Tokyo, Japan) or a Shimadzu UV-240-Visible (Osaka, Japan) spectrophotometer. High-performance liquid chromatography (HPLC) was carried out on a Hitachi L-600 or L-655-A11 liquid chromatograph equipped with a column (4.6 mm i.d. × 250 mm) of YMC A-303 ODS (Yamamura Chemical Laboratories, Kyoto, Japan). The fractions were detected with a Hitachi L-4200 UV-VIS or a Shimadzu SPD-6A detector.

Urine. Urine was collected from healthy human male and female subjects, Japanese White male rabbits and Wistar male rats and used for analysis within several hours. For determination of one-day amounts of the red pigment, 24-h urine was pooled for the assay.

Major TBA-reactive substances of human urine. The TBA-reactive substances of human urine were partially purified through an anion exchange column and by gel filtration according to the method of Hadley and Draper (16). Human urine (250 mL) was applied to a column (3 cm i.d. × 22 cm) of AG1-X8 (chloride form), the column was eluted with 1 L of linear gradient sodium chloride solution (0–1 M), and 5-mL fractions were collected. Most of the color of urine due to urobilin, and about 30% of the TBA-reactive substances were eluted in fractions (20–60) (200 mL) (shown later in Fig. 2). About 70 mL of the fractions were condensed into 6 mL and passed through a column (3 cm i.d. × 21 cm) of Sephadex G-10 equilibrated with water, and the column was eluted with 100 mL of water. The TBA-reactive substances loaded were completely eluted, and the eluate was condensed to 10 mL.

TBA assay. All TBA assays were performed by the two-step mode to obtain reproducible data for alkadienals (11).

*To whom correspondence should be addressed.

Abbreviations: BHT, butylated hydroxytoluene; DNPH, 2,4-dinitrophenylhydrazine; DNPP, 1-(2,4-dinitrophenyl)pyrazole; EDTA, ethylenediaminetetraacetic acid; HPLC, high-performance liquid chromatography; TBA, thiobarbituric acid; *t*-BuOOH, *tert*-butyl hydroperoxide; TMP, tetramethoxypropane.

The assays were performed with addition of BHT to avoid undesirable peroxidation during the assays (13,14).

Method A. Two mL of a solution containing 20 nmol TMP or urine (human urine 2.0 mL, rabbit and rat urine 0.5 mL) in water, 0.10 mL of 0.5% BHT solution in glacial acetic acid (the final concentration of acetic acid was 2%) and 3.0 mL of 0.5% TBA solution in water were placed in this order into a screw-cap test tube. For studying the effect of *t*-BuOOH, 10 μL of a 0.5–2 M *t*-BuOOH solution in acetic acid was added to the mixture. For studying the effect of ferric ion and ethylenediaminetetraacetic acid (EDTA), 0.5% TBA solution was replaced by 0.5% TBA/0.2–4 mM $FeCl_3$ (or EDTA disodium salt) in water. The mixture was kept at 5°C for 60 min and then was heated at 100°C for 20 min. After cooling, the mixture was extracted with 3 mL of chloroform and then centrifuged at 650 × *g* for 10 min. Absorbance at 532 nm of the aqueous phase was determined, and the amount of red pigment was calculated on the basis of the absorbance and the molecular extinction coefficient (156000) of red pigment (17). The aqueous phase was subjected to HPLC, and the column was eluted with 0.04 M acetate buffer (pH 5.5)/methanol (6:4 vol/vol) at a flow rate of 0.8 mL/min. A peak was detected at 532 nm. Red pigment from a standard TMP solution appeared at a retention time of 8.0 min. The amount of red pigment from urine was determined by comparing the peak area of red pigment with that of the standard TMP solution. The amounts of red pigment from human urine linearly increased with the volume up to 2.0 mL, and those from rabbit and rat urine linearly increased with the volume up to 0.5 mL.

Method B. Method B is a modification of the method of Ohkawa *et al.* (18). Two mL of a solution containing 20 nmol TMP in water or 2.0 mL of human urine, 1.50 mL of 20% acetic acid adjusted at the indicated pH value by addition of 10 N NaOH, 50 μL of 1% BHT solution in glacial acetic acid and 1.50 mL of 0.8% TBA solution in water were placed in this order into a test tube. For studying the effect of *t*-BuOOH, 10 μL of 1 M *t*-BuOOH solution in acetic acid was added. For studying the effect of ferric ions and EDTA, 0.1 mL of 100 mM $FeCl_3$ or EDTA disodium salt solution in water was added. The mixture was kept at 5°C for 60 min and was then heated at 100°C for 60 min. After cooling, the mixture was extracted with 3 mL of chloroform and centrifuged. The aqueous phase was subjected to HPLC as described.

Determination of malonaldehyde as DNPH derivative. Malonaldehyde was determined as 1-(2,4-dinitrophenyl)pyrazole (DNPP) by reaction with DNPH according to the established method (19,20) with slight modifications (14). Reference standard DNPP was prepared as described (14). Thus, a mixture of 1.5 mL of urine or an aqueous solution containing 30 nmol TMP, along with 1.2 mL of 0.25% (wt/vol) DNPH solution in 1 N HCl, was heated at 100°C for 30 min. The reaction mixture was extracted with chloroform as described (14), and the extract was subjected to HPLC. The column was eluted with acetonitrile/0.01 N HCl (45:55, vol/vol) at a flow rate of 1.5 mL/min. The peak due to DNPP appeared at a retention time of 7.0 min and was detected at 300 nm. Malonaldehyde content of urine was determined by comparing the peak height of DNPP from urine with that of DNPP from the TMP standard solution.

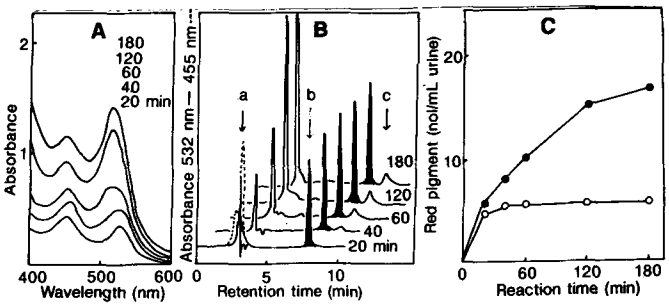

FIG. 1. Profiles of pigment formation in the thiobarbituric acid (TBA) assay of human urine. A: Absorption spectra of the TBA reaction mixture (method A) of human urine (2 mL) heated at 100°C for the indicated period. The reaction mixture of standard tetramethoxypropane (TMP) heated for 20–180 min showed the same absorbance with a single absorption maximum at 532 nm. B: High-performance liquid chromatography (HPLC) pattern of the TBA reaction mixture (method A) of human urine heated at 100°C for the indicated period. Three peaks, a, b and c, were detected. Red pigment (532 nm) from standard TMP eluted at a retention time of 8.0 min (peak b). C: Time course of 532 nm red pigment determined by absorbance (A) (●), and that determined by peak b in HPLC analysis (B) (○). The control reaction mixture without TMP and urine showed no significant coloration and HPLC peaks.

Determination of aldehydes with DNPH. Aldehydes other than malonaldehyde were determined as previously described (11). DNPH (50 mg) was dissolved in 100 mL of 1 N HCl, and the solution was extracted twice with 50 mL of *n*-hexane to remove impurities. Two mL of urine or an aqueous solution containing 5 μmol standard aldehyde was added to 2.0 mL of the solution. The mixture was vigorously shaken at room temperature for 5 min in the dark and extracted six times with 3 mL of benzene. The organic layers were combined and evaporated to dryness, and the residue was redissolved into 0.5 mL of benzene. The solution was applied to a column (1 cm i.d. × 3.5 cm) of silica gel, and the column was eluted with benzene. The hydrazone fractions (3–8 mL) and DNPH fractions (15–32 mL) were separated, the former being evaporated to dryness to be redissolved into 5.0 mL of methanol. Absorption spectra of the solution gave maxima at 360 nm. The amounts of aldehyde were calculated on the basis of the average molar extinction coefficient (26000) of the various hydrazones at 370 nm (21). The methanolic solution was evaporated to dryness and dissolved into 0.2 mL of acetonitrile for HPLC analysis. The column was eluted with acetonitrile/water (3:2, vol/vol) at a flow rate of 1.5 mL/min (14). The peaks were detected at 370 nm (shown later in Fig. 5).

RESULTS

The TBA reaction of the reference standard TMP and human urine was carried out by heating at 100°C for 20 min in 2% acetic acid containing 0.01% BHT (method A). While TMP produced 532 nm red malonaldehyde TBA (1:2) adduct quantitatively, human urine produced pigments with two absorption maxima at 455 and 532 nm (Fig. 1A). The absorbance was gradually increased by prolonged heating up to 180 min, and the maximum at 532 nm was shifted to 518 nm. The 532 nm red pigment could not be accurately determined by direct spectrophotometry

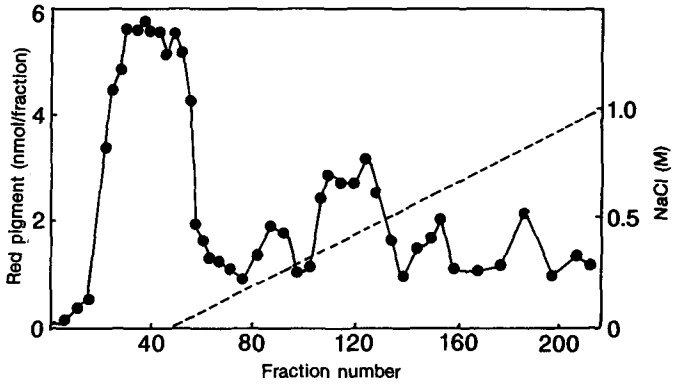

FIG. 2. Anion exchange column chromatography of the thiobarbituric acid (TBA)-reactive substance of human urine. Human urine (250 mL) containing the substances to produce 660 nmol 532 nm red pigment was applied to an AG1-X8 column (3 × 22 cm) with sodium chloride linear gradient elution, and 5-mL fractions were collected. The TBA-reactive substances were detected in the assay by their absorbance at 532 nm (method A).

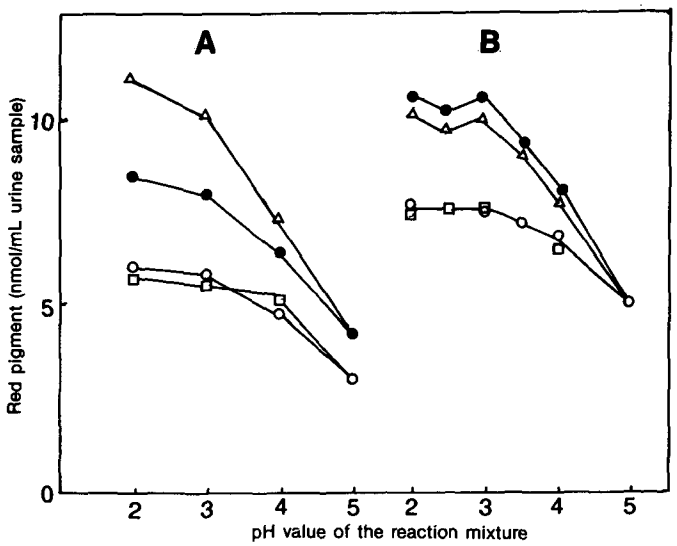

FIG. 3. Effect of pH, *t*-BuOOH, ferric ions and EDTA on the development of the red pigment in the TBA assay of human urine. Human urine (A) and the major TBA-reactive substances obtained by anion exchange column chromatography (see Fig. 2) (B) were subjected to the TBA assay (method B) in the absence (○) or presence of 2 mM *t*-BuOOH (●), 2 mM ferric ions (△) and 2 mM EDTA (□). The reaction mixture heated at 100°C for 20 min was subjected to HPLC analysis. Abbreviations as in Figure 1. *t*-BuOOH, *tert*-butyl hydroperoxide; EDTA, ethylenediaminetetraacetic acid.

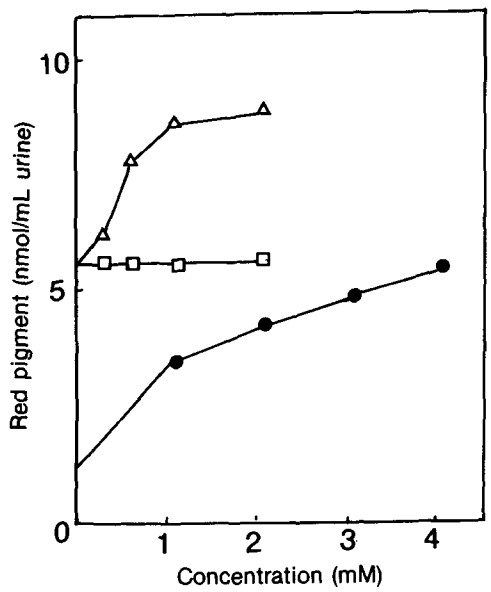

FIG. 4. Concentration-dependent effect of *t*-BuOOH, ferric ions and EDTA on the red pigment development in the TBA assay of human urine. Urine samples were subjected to the TBA assay (method A) in the presence of *t*-BuOOH (●), ferric ion (△) and EDTA (□) at the indicated final concentration. The reaction mixture heated at 100°C for 20 min was subjected to HPLC analysis. Abbreviations as in Figures 1 and 3.

owing to the production of the interfering pigments. In HPLC, the 532 nm red pigment was separated from the interfering pigments (peak a and peak c) and eluted at a retention time of 8.0 min (peak b) (Fig. 1B). The absorption spectrum of peak b showed a single maximum at 532 nm of red malonaldehyde TBA (1:2) adduct. The amount of the red pigment determined in peak b was constant during the heating periods from 20 to 180 min (Fig. 1C). The amount of the red pigment produced during 20 min as estimated by direct spectrophotometry was 20–30% higher than that measured by HPLC. Hence, HPLC separation was necessary for accurate quantitation of the red pigment from urine.

When human urine was dialyzed against water, about 90% of the TBA-reactive substances that produce the red pigment were removed (data not shown), indicating that most of the TBA-reactive substances were low molecular weight compounds. When human urine was passed through an anion exchange column according to the method of Hadley and Draper (16), the TBA reactive-substances were resolved into several peaks (Fig. 2). The chromatographic profile was similar to that of rat urine (16), and the TBA-reactive substances of human urine were not single. Major TBA-reactive substances (about 30%) of human urine were eluted in the first fraction. When the red pigment from human urine was determined by the methods of Ohkawa *et al.* (18), Buege and Aust (22) and Uchiyama and Mihara (23), similar results were obtained as long as the pigment was determined after HPLC separation (data not shown).

The effect of the pH of the TBA reaction mixture (method B) on the red pigment development from human urine (Fig. 3A) and from the major TBA-reactive substances separated by anion exchange column chromatography (Fig. 3B) was further investigated (open circles). Pigment formation was somewhat dependent on the pH value of the reaction mixture; it was maximal at pH 2, and 1.5-fold higher than at pH 5. Addition of 2 mM *t*-BuOOH (Fig. 3; closed circles) or ferric ions (Fig. 3; open triangles) increased pigment development in the pH ranges between 2 and 5, suggesting the presence of alkadienals and/or alkenals whose reactivity is known to be enhanced by these reagents (8–14). Addition of 2 mM EDTA (Fig. 3; open squares) did not affect the pigment development throughout the pH ranges, suggesting that a trace amount of contaminated ferric and ferrous ions had been already chelated and inactivated in the reaction mixtures containing urine samples so as not to enhance the TBA reactivity due to alkadienals and alkenals. Figure 4 shows

TABLE 1

Comparison of the Amount of Red Pigment Produced in the Thiobarbituric Acid (TBA) Assay of Human Urine Containing Malonaldehyde Derivatives and Other Aldehydes

Urine sample	532 nm Red pigment[a] (nmol/mL urine)			Malonaldehyde derivatives[b] (nmol/mL urine)	Other aldehydes[c] (nmol/mL urine)
	+ None	+ *t*-BuOOH	+ $FeCl_3$		
Urine					
1	10.6			15.3	
2	8.0			6.5

8	2.2	3.6	5.0		5.4
Major TBA-reactive substances of urine[d]					
9	19.2	20.9	24.1	24.2	24.2

[a]Red pigment (532 nm) was determined by high-performance liquid chromatography of the TBA reaction mixture (method A) heated at 100°C for 20 min in the absence or presence of 2 mM *tert*-butyl hydroperoxide (*t*-BuOOH) or $FeCl_3$.

[b]Malonaldehyde content was determined as 1-(2,4-dinitrophenyl)pyrazole by 2,4-dinitrophenylhydrazine (DNPH) method.

[c]Other aldehyde content was determined as hydrazones of DNPH by silica gel column chromatography.

[d]The major TBA-reactive substances were obtained by anion exchange column chromatography (see Fig. 2).

concentration-dependent enhancement of the red pigment development by *t*-BuOOH and ferric ions in the TBA assay (method A) of human urine samples. The pigment development from malonaldehyde derivatives, TMP and *N*-(2-propenal)aminoacetic acid was not enhanced by 2 mM ferric ions and not inhibited by 2 mM EDTA under the same conditions (data not shown).

The amounts of red pigment formed from human urine (Table 1, samples 1–4) and the major TBA-reactive substances obtained by anion exchange column chromatography (Table 1, sample 9) were compared with the contents of malonaldehyde derivatives determined as DNPP by the DNPH method (19,20). The amounts of red pigment obtained without added *t*-BuOOH and ferric ions were roughly equal to or even lower than the levels of malonaldehyde derivatives measured. Hence, the TBA reactivity of human urine without added *t*-BuOOH and ferric ions was ascribed to malonaldehyde derivatives.

The enhanced amounts of the red pigment that developed in the presence of *t*-BuOOH or ferric ions were compared with the levels of other aldehydes determined as the hydrazones of DNPH (Table 1, samples 5–8). The amounts of other aldehydes were high enough to account for the enhanced pigment formation. When the hydrazones from the major TBA-reactive substances obtained by anion exchange column chromatography (Table 1, sample 9) were analyzed by HPLC (Fig. 5), several peaks due to the hydrazones of aldehydes were detected. One of the hydrazones was identified as the hydrazone of 2,4-hexadienal by cochromatography with an authentic standard (data not shown). Hence, the red pigment development from urine enhanced by *t*-BuOOH and ferric ions may be due to alkadienals and/or alkenals.

One-day amounts of the red pigment from 24-h urine of 12 healthy subjects were determined and compared (Table 2, lane 1). The amounts of the pigment were 26–95 nmol/kg · day in the absence of *t*-BuOOH and 65–182 nmol/kg · day in the presence of *t*-BuOOH. All the subjects excreted both malonaldehyde derivatives and other aldehydes as TBA-reactive substances. However, the amount of pigment formed varied from subject to subject and also varied by the day of collection of urine from a specific subject. The TBA reactivity of urine with and without added *t*-BuOOH was not related to age or sex. One-day amounts of the pigment from rabbit urine (Table 2, lane 2) and rat urine (Table 2, lane 3) were similarly

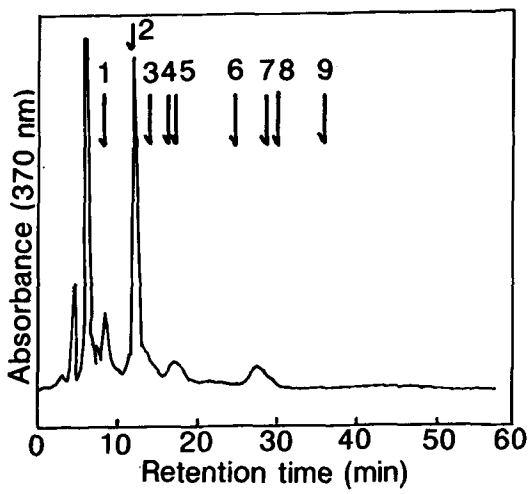

FIG. 5. HPLC chromatogram of the hydrazone fraction of silica gel column chromatography from the major TBA-reactive substances obtained by anion exchange column chromatography (see Fig. 2 and Table 1, lane 9). Hydrazones of standard aldehydes were eluted at the retention times indicated by arrows; 1, propanal; 2, butenal; 3, butanal; 4, pentenal; 5, hexadienal; 6, hexenal; 7, heptadienal; 8, hexanal; and 9, heptenal. The control reaction mixture without sample revealed no hydrazone fraction in silica gel column chromatography and no peaks in HPLC. Abbreviations as in Figure 1.

[a]24-h Urine was collected and subjected to the TBA assay (method A) heated at 100°C for 20 min in the absence or presence of 2 mM *t*-BuOOH. The red pigment was determined by high-performance liquid chromatography. The one-day amount of pigment (nmol ± SD/kg•day) was corrected for the volume of urine and the body weight. *t*-BuOOH, *tert*-butyl hydroperoxide.

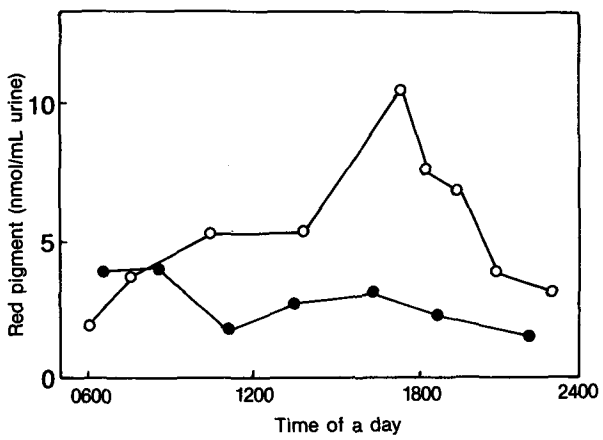

FIG. 6. The TBA reactivity of human urine collected at different times throughout a day. Two human urine samples were subjected to the TBA assay (method A), and the reaction mixture heated at 100°C for 20 min was subjected to HPLC analysis. Abbreviations as in Figure 1.

determined. The TBA reactivity of urine of these animals was much higher; thus humans excreted lower amounts of malonaldehyde derivatives and other aldehydes than did the animals.

Urine was collected from healthy human subjects at different times of the day, and the amounts of the pigment produced without *t*-BuOOH were determined and compared (Fig. 6). It was found that the TBA reactivity of urine collected in the afternoon or in the evening was higher than that collected in the morning.

DISCUSSION

The TBA reaction of human urine produced at least three pigments, namely 455 nm yellow, 532 nm red and 518 nm orange pigments, as shown in Figure 1. The yellow pigment may be derived from alkanals (24,25) and/or sugars (26) and cannot be regarded as an index of lipid peroxidation. The red pigment is only the pigment that appears to reflect lipid peroxidation. The orange pigment was produced when the reaction mixture was heated for prolonged periods. Bidder and Sipka (27) have demonstrated that the absorbance at 532 nm of the TBA reaction mixture of urine progressively increased with heating time, and they suggested that the abnormal increase is due to materials other than malonaldehyde derivatives. As alkadienals and alkenals produce 532 nm red pigment in a time course similar to that of malonaldehyde derivatives (7,8), the abnormal increase may be due to the development of

chromogens other than 532 nm red pigment. Several substances in urine have been shown to produce these different chromogens (1,28–31). HPLC separation of the pigment is necessary for accurate quantitation of the red pigment that appears to reflect lipid peroxidation products in urine.

The TBA reactivity of urine that produces the red pigment is barely dependent on the method used, whereas the reactivity of fats and oils (13) and rat liver and brain homogenate (12,14) have been shown to be greatly dependent on the method used. The yield of the red pigment from urine was somewhat higher at pH 2 than at pH 5, and its development was not inhibited by EDTA. The characteristics of the pigment development were similar to those of standard malonaldehyde derivatives. The amount of red pigment formed was roughly equal to the content of malonaldehyde derivatives estimated as DNPP. The TBA reactivity of urine thus appears to be due to malonaldehyde derivatives. However, the pigment development enhanced by *t*-BuOOH and ferric ions seem to be due to aldehydes other than malonaldehyde derivatives (13,14), whose presence was confirmed by hydrazone formation with DNPH.

The present results are consistent with earlier observations. Draper *et al.* (2–4) had demonstrated that the TBA reactivity of rat urine increased when supplemented with malonaldehyde derivatives, a vitamin E-deficient diet, iron or carbon tetrachloride, and that the TBA reactivity of human morning urine increased by consuming a supplement of n-3 fatty acids (5). They have identified malonaldehyde derivatives, such as *N*α-acetyl-ε-(2-propenal)lysine (32), *N*-(2-propenal)serine (16), *N*-ε-(2-propenal)lysine (33), *N*-(2-propenal)ethanolamine (34) and guanine-malonaldehyde adduct (35) as rat urinary metabolites. Ekstrom *et al.* (19,36) demonstrated that administration of chloroform or hydroquinone to rats resulted in high excretion of malonaldehyde derivatives as estimated by the DNPH method. Our results give additional evidence for the excretion of malonaldehyde derivatives in urine. Lee *et al.* (37) have recently demonstrated that HPLC separation of rat urine gives six TBA-reactive substances, including aldehydes other than malonaldehyde derivatives. Our results on the TBA reactivity of human unseparated urine in the presence of *t*-BuOOH or ferric ions clearly show the presence of aldehydes other than malonaldehyde derivatives.

It has been shown that the TBA reactivity of oxidized fats and oils is due to alkadienals and/or alkenals (11,13,14), and that the reactivity of tissue homogenate is mainly due to alkadienals and, to a lesser extent, to malonaldehyde derivatives (12,14). By contrast, the TBA reactivity of urine was found to be due mainly to malonaldehyde derivatives and, to a lesser extent, to other aldehydes only when the reaction was carried out in the presence of *t*-BuOOH or ferric ions. It is interesting to note that the TBA-reactive substances of urine were different from those of tissues. Nonpolar TBA-reactive substances composed of alkadienals generated in tissues may stay longer in tissues, and the polar TBA-reactive substances composed of malonaldehyde derivatives may be more readily excreted in urine.

The amounts of red pigment produced from 24-h urine of 12 healthy subjects were estimated to be 26–95 nmol/kg, and 65–182 nmol/kg in the presence of *t*-BuOOH, the values being lower than those from urine of rabbit or rat. Excretion of malonaldehyde derivatives and other aldehydes had no relationship to the age or sex of the subjects. TBA reactivity due to malonaldehyde derivatives was higher in the afternoon or in the evening than in the morning, suggesting that the physical activity of a subject during daytime may contribute to increased excretion. It has also been suggested that intake of polyunsaturated fatty acids leads to higher excretion of malonaldehyde derivatives in urine (5).

Fatty Acids in the Lipids of *Drosophila* Heads: Effects of Visual Mutants, Carotenoid Deprivation and Dietary Fatty Acids

William S. Stark[a,*], Teng-Nan Lin[b,1], David Brackhahn[b], J. Scott Christianson[a,2] and Grace Y. Sun[b]

Lipids of *Drosophila* heads were extracted and separated by high-performance thin-layer chromatography. Fatty acid compositions of major phospholipids as well as of triglycerides were analyzed by gas-liquid chromatography. Proportions of the major fatty acids (14:0, 16:0, 16:1, 18:0, 18:1, 18:2, 18:3) varied depending on the lipid analyzed. Docosahexaenoic acid (22:6), common in vertebrate photoreceptors and brain, and arachidonic acid (20:4), a precursor of eicosanoids, were lacking. A comparison of the fatty acid composition of the diet *vs.* the head suggested that *Drosophila* can desaturate but may not be able to elongate fatty acid carbon chains. Fatty acid analyses were carried out after the following visual system alterations: i) the transduction mutant where *no receptor potential* results from a deficit in phospholipase C; ii) an allele of *eyes absent*; iii) the mutant outer rhabdomeres absent which lacks visual pigment and rhabdomeres in the predominant type of compound eye receptor, rhabdomeres 1 through 6; and iv) carotenoid deprivation which reduces opsin and rhabdomere size. We also evaluated aging by comparing newly-emerged *vs.* aged wild-type flies. Alterations in fatty acid composition based on some of these manipulations were found. Based on comparisons between flies reared on media differing in C_{16} and C_{18}, there is an indication that diet readily affects tissue fatty acid composition.
***Lipids* 28, 345–350 (1993).**

In previous studies (1,2) we have quantified the fatty acids of phospholipids (PL) and triglycerides (TG) of *Drosophila* heads. Our primary interest in the fatty acids is based in their importance as structural components of the PL of visual membranes, which, in the fly, are tightly packed microvillar organelles called rhabdomeres. In addition, fatty acids are of interest in such membranes, whose main function is signal transduction, since they can serve as precursors of signalling molecules.

The strategy of genetic dissection (3), comparing strains with *vs.* without identified visual structures or processes in *Drosophila*, helped us to dissect the fatty acids of the visual system. In the present study, we analyzed: i) outer rhabdomeres absent *(ora)* an opsin mutant which selectively eliminates the predominant rhabdomeres, 1 through 6, (R1–6) of the compound eye (3); ii) *eyes absent (eya)* which eliminates the compound eyes and reduces the optic lobes; and iii) *no* receptor potential *(norpA)* whose phenotype results from a phospholipase C (PLC) deficiency (4,5). We also utilized carotenoid deprivation which lowers opsin in all receptors (6) and makes the rhabdomeres smaller (7). Moreover, we compared samples from aged *vs.* control heads and samples derived from animals reared on diets with different fatty acid compositions.

MATERIALS AND METHODS

Animals. Stocks of *Drosophila melanogaster* were raised at room temperature under cyclic lighting on a standard diet known to be adequate for visual receptor development (8). In the medium of agar, brewer's yeast, molasses and corn meal, the compounds most relevant to visual development were the yellow pigment (zeaxanthin) in corn meal and a supplement of β-carotene (0.13 mg/mL), both precursors of rhodopsin's chromophore. Flies were deprived of carotenoids by rearing on Sang's medium (9); replete controls were raised on Sang's medium supplemented with β-carotene at 0.13 mg/mL. Importantly, the diets differed in fatty acid composition (Table 1).

Wild type (Oregon-R) was used as the normal control fly. Our *norpA* stock was $norpA^{EE5}$, an effective allele (10), originally from Prof. Seymour Benzer's laboratory at the California Institute of Technology (Pasadena, CA). An allele of *eyes absent (eya)* was obtained from Prof. Terry McGuire at Rutgers University (New Brunswick, NJ); these flies lack the compound eyes but not the simple eyes (ocelli) (11). We used the well-studied outer rhabdomeres absent *(ora)* mutant allele of the R1–6 opsin gene in which the outer rhabdomeres (R1–6) are selectively deleted (12); R1–6 rhabdomeres comprise the predominant photoreceptive organelle in the compound eye. For *ora*, as well as the wild type controls in the *ora* experiments, flies were aged in cyclic lighting one week or more because this manipulation insured a better deletion of *ora*'s rhabdomeres (12). For all other types, flies were newly-eclosed, that is, newly emerged from the pupa case.

TABLE 1

Percentages of Fatty Acids in Medium

Fatty acid	Regular diet (mole %)	Sang's diet (mol %)
16:0	74.37	61.13
18:0	13.61	20.49
18:1	10.06	18.38
18:2	1.96	trace[a]
18:3	trace	trace

Abbreviations: DHA, docosahexaenoic acid; EDTA, ethylenediaminetetraacetic acid; EGTA, ethylene glycol-*bis*(β-aminoethyl ether) *N,N,N',N'*-tetraacetic acid; *eya*, eyes absent; GLC, gas-liquid chromatography; HPTLC, high-performance thin-layer chromatography; *norpA*, *no* receptor potential; *ora*, outer rhabdomeres absent; PC, phosphatidylcholine; PC_r, a likely PC analogue migrating to the right of PC in HPTLC; PE, phosphatidylethanolamine; PI, phosphatidylinositol; PL, phospholipids; PLC, phospholipase C; PS, phosphatidylserine; R1–6, rhabdomeres 1 through 6; TG, triglyceride; UV, ultraviolet.

Extractions. Glass vials with flies were plunged into liquid nitrogen. When flies were frozen, shaking vials vigorously separated heads from bodies, and 100 heads were sorted quickly with a brush at room temperature. Heads were then put into (usually) 1 mL of ice cold 0.32 M sucrose with 50 mM Tris-HCl buffer (pH = 7.4) and ethylenediaminetetraacetic acid (EDTA) (1 mM) and homogenized with a tightly fitted Teflon pestle. Then, 4 vols of chloroform/methanol (2:1, vol/vol) was added, followed by vortexing. In order to facilitate the recovery of the anionic PL, 50 μL of 40 mM ethylene glycol-*bis*(β-aminoethyl ether) *N,N,N',N'*-tetraacetic acid (EGTA) was added to the tube, followed by revortexing. The tubes were centrifuged at 1500 × *g* for 5 min, and the organic phase was recovered and passed through a mini-column containing anhydrous Na_2SO_4. For more complete extraction of the acidic PL, a second extraction with 2 vol of chloroform/methanol (2:1, vol/vol) with 0.4% HCl was performed. The second organic extract was neutralized with one drop of 4 N NH_4OH before combining with the first one, and the extract was then evaporated to dryness.

High-performance thin-layer chromatography (HPTLC) and gas-liquid chromatography (GLC). The lipids were resuspended in chloroform/methanol (2:1, vol/vol). Three separate aliquots of the samples were spotted onto 10 × 10 cm HPTLC plates (Silica gel, 60, E. Merck, Darmstadt, Germany). These plates had previously been dipped into a solution containing 1% potassium oxalate with 2 mM EDTA and then diluted with methanol in the ratio of 3:2 (vol/vol). Data from the three batches were averaged, and standard deviations were calculated.

The procedures for HPTLC separation of PL have been described (13). Briefly, plates were developed in the first solvent system containing chloroform/methanol/acetone/29% ammonium hydroxide (70:40:10:10, by vol). After drying, plates were exposed to HCl vapor for 3 min for hydrolysis of the alkenyl ether linkages and were further developed in a second dimension using a solvent system containing chloroform/methanol/acetone/acetic acid/0.1 M ammonium acetate (70:30:27.5:2.25:5, by vol). After development, the plates were sprayed with 2,7-dichlorofluorescein, and the lipid spots were identified under a ultraviolet (UV) lamp. Individual PL or TG (together with silica gel) were scraped into test tubes. Prior to transmethylation, a known amount of heptadecanoic acid (17:0) methyl ester was added to each sample as an internal standard and for quantification of the PL in the sample.

Conditions for the analysis have been described previously (13). Briefly, conversion of the glycerolipid acyl groups to their methyl esters was achieved by base-catalyzed methanolysis. We added 2 mL of 0.5 M NaOH in anhydrous methanol (sodium methoxide) to the sample. After incubation at room temperature for 10 min, the mixture was partitioned into two phases by adding 4 mL of chloroform and 1.5 mL of water. After phase separation, the organic layer was removed and filtered through a mini-column of anhydrous Na_2SO_4. The organic solvent was evaporated to dryness under nitrogen, and the fatty acid methyl esters were redissolved in hexane. Fatty acid methyl esters were separated using a Supelco (Bellefonte, PA) SP2330 0.2 μm capillary column, 30 m long and 0.25 mm inside diameter, with helium as the carrier gas. Column temperature was programmed from 140 to 195°C at 4°C/min. Analysis was with a HP 5890 gas-liquid chromatograph (Hewlett-Packard, Avondale, PA) equipped with a flame-ionization detector. Recoveries of fatty acids from phospholipids after methanolysis had been verified to be over 95% (13).

RESULTS

Experiments carried out in this study involved *Drosophila* that were reared either on a diet based on natural products such as yellow cornmeal, molasses and yeast, the regular diet (8), or a more defined medium which was useful for deprivation or supplementation with vitamin A, the Sang's diet (9). Importantly, the diets differed in fatty acid composition as shown in Table 1. For example, the Sang's diet had a considerably higher proportion of 18:1 and a slightly lower proportion of 18:2 as compared with the regular diet.

Figure 1 shows a typical GLC tracing depicting the fatty acids from phosphatidylethanolamine (PE) in *eya* together with the internal standard (17:0). The most conspicuous finding was the absence of polyunsaturated fatty acids with chain lengths longer than 18 carbons, an observation in good agreement with that reported by Yoshioka *et al.* (14). Despite the presence in the diets of trace amounts of the essential fatty acids with 18:2 and 18:3 acyl chains, substantial proportions of these fatty acids are present in the PL of *Drosophila* heads. Since the fatty acids of *Drosophila* heads showed a substantial proportion of 16:1 which was not found in either food, it is concluded that flies are capable of desaturating 16:0. When we omitted the 17:0 standard, our GLC tracings did not reveal detectable levels of odd-numbered fatty acids, which is in disagreement with the data of Yoshioka *et al.* (14).

During the analysis of PL and TG by GC, it is possible to quantify the mass of the lipids obtained. The relative

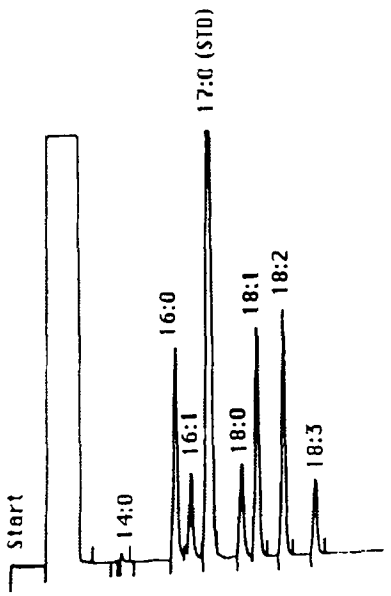

FIG. 1. A typical gas-liquid chromatogram, in this case from the *eyes absent* mutant for the phospholipid phosphatidylethanolamine. Fatty acid peaks at 14:0, 16:0, 16:1, 18:0, 18:1, 18:2 and 18:3 are labeled. The high peak at 17:0 is due to the standard (STD); when the STD is omitted (data not shown), there is virtually no reading at this location.

recovery of the standard (17:0 methyl ester), which had been added in known amount to samples from specified numbers of fly heads, should be inversely proportional to the quantity of each lipid in each strain. Data in Table 2 are calculated to represent the amount of each specified lipid for each experimental fly type studied (*eya*, *ora*, *norpA* and vitamin A deprived). PE, phosphatidylcholine (PC), a lipid which migrates to the right of PC on the HPTLC plate (PC_r), phosphatidylinositol (PI), phosphatidylserine (PS) and TG were analyzed. We divided the recovery of standard (averaged from the three samples partitioned from each 100-head batch) from each appropriate control strain by the recovery for each experimental strain. Lipid extracts were prepared with *eya* and *norpA* (*vs.* newly-eclosed wild-type controls), *ora* (aged to insure rhabdomere loss *vs.* aged wild-type controls) and carotenoid deprived and replete (control) wild-type reared on the same food (Sang's medium without *vs.* supplemented with β-carotene, respectively). As expected, *eya* shows the largest decrease in lipid content since the mutation eliminates the compound eyes entirely and reduces the optic lobes. Also, as expected, vitamin A deprived flies have lower PL since the rhabdomeres are reduced (7). We expected that *ora* would have lower PL since this mutant lacks the R1-6 rhabdomeres. Surprisingly, there were actually higher PL ratios in this mutant, suggesting that there may be a compensatory increase in PL in parts of the head other than the eyes. With the exception of a decrease in PC and PC_r, other membrane PL in *norpA* were not different from those of the wild type. This finding was expected because the *norpA* flies were newly emerged, while rhabdomere diminution is only realized in aged mutants (15). On the other hand, there was a large increase in TG in *norpA* as compared to controls. The cause for this increase is not clear.

The acyl group profiles of individual PL (PS, PI, PE, PC, PC_r) and TG in heads of newly-eclosed wild-type *Drosophila* reared on the regular diet are shown in Table 3. Although subtle differences could be found among the PL, the overall profiles were similar with high proportions of 18:1, 18:2 and, in some cases, 18:3, the latter two being very low in the regular food (Table 1). On the other hand, the acyl group profile of TG is in many ways different from that of PL. Similar to the TG acyl profiles of mammalian systems, the hallmark of the TG profile of *Drosophila* heads is the near absence of 18:0. On the other hand, the TG in *Drosophila* heads showed a high proportion of 14:0, a fatty acid which was below detection level in the food. An unknown lipid localized to the right of PC on the HPTLC plates (PC_r) has a greater proportion of the short chain saturated fatty acids (14:0 and 16:0) than PC. These data suggest that this newly resolved PL spot is part of the PC species. One conspicuous finding is that there are no fatty acid chains longer than 18 carbons in the PL and TG of *Drosophila* heads, confirming and extending the observations of Yoshioka *et al.* (14).

Since PE is the predominant PL present in the *Drosophila* head, we compared the acyl group profile of PE for different types of *Drosophila* (newly-eclosed wild-type, newly-eclosed *norpA*, newly-eclosed *eya*, aged wild-type, aged *ora*, and carotenoid replete and deprived wild-type, with only the latter two being reared on Sang's medium). As shown in Table 4, all types fed the regular diet showed similar fatty acid profiles. That is, aging and mutant condition did not change the profile of acyl groups in PE. Results from PI, not presented, are much like those for PE. The most striking diffrences result from comparing the flies fed the regular diet *vs.* the Sang's medium. Flies reared on Sang's medium showed significantly lower

proportions of 18:2 and 18:3 and higher proportions of 16:1 and 18:1 than those raised on the regular food; recall that the Sang's medium had higher 18:1 (Table 1).

The acyl group profiles for TG for the same fly types are presented in Table 5. In contrast with the acyl profile for PE, TG fatty acids tend to show large differences with age and mutant condition. The Sang's medium flies showed strikingly high 18:1. Interestingly, 18:1 was also very high in *eya* flies, which might imply that it is correspondingly low in the visual system which *eya* flies lack. Finally, the aged flies have a higher proportion of 18:1 and lower proportions of 16:0 and 16:1 in the TG (Table 5). Recall that we had originally decided to study aged wild-type flies as controls in the experiment with aged *ora* since *ora* loses its rhabdomeres as a function of age (12).

DISCUSSION

One of our primary findings is that the fatty acid content of *Drosophila* heads can readily be altered by the diet. Large differences in fatty acid composition for PL and TG were observed by comparing flies reared on the Sang's diet (for vitamin A manipulations) *vs.* the regular diet. Our data are in line with the statement by Turunen (16) that "the tissue fatty acid composition often is quite sensitive to dietary changes." A comparison of the fatty acids from the food *vs.* those from *Drosophila* suggests that the flies cannot elongate the fatty acids to make ≥20 carbon compounds but they can desaturate the fatty acids, *e.g.*, from 16:0 to 16:1.

Our results are in general agreement with those reported by Yoshioka *et al.* (14) who determined the fatty acid composition of PI and PC in *Drosophila*. Both studies concur in that there are no long chain polyunsaturated fatty acids in the tissue PL. The small discrepancies can well be attributed to differences in the diet since the diet used by Yoshioka *et al.* had less 16:0, did have 16:1 and had higher 18:0, 18:1 and 18:2. They obtained higher values of C_{16} fatty acids and lower values of C_{18} fatty acids in PI and the reverse for PC compared to ours. Their analysis showed the presence of small amounts of C_{15} and C_{17} fatty acids, but we did not find them in our study. On the other hand, we observed small amounts of 18:3 while they did not.

It would be interesting to determine whether dietary supplementation with long chain fatty acids may have any effects on the fatty acids of the visual system. In a preliminary study, R. Sapp and W. S. Stark (unpublished) found that supplementation of the regular food with menhaden oil (containing a high proportion of polyunsaturated fatty acids) had no obvious effect on visual receptor ultrastructure. On the other hand, D.-M. Chen and W. S. Stark (unpublished) showed a small increase in electroretinographic sensitivity of R1-6 from this supplementation, especially in the near UV region of the spectrum. These data suggest that the fly model will prove useful to elucidate the relationship between dietary fatty acids and visual function.

Vertebrate visual receptors contain high proportions of the long chain polyunsaturated fatty acids, especially 22:6 and 20:4 (17). Such high levels of long chain fatty acids in vertebrate visual receptors are of substantial interest (18). Although the function of 22:6 (DHA) in vertebrate photoreceptors is not known (19,20), the conventional wisdom is that unsaturated fatty acids contribute to membrane fluidity which could facilitate interactions of the molecules of the signal transduction cascade in the planar disk membranes of the rod outer segment. A defect in metabolism or transport of DHA in poodles afflicted with progressive rod-cone degeneration suggests that DHA is essential for visual receptor maintenance in vertebrates (21). *Drosophila* may prove helpful in determining the function of DHA since DHA is absent in the lipids of flies whose vision is intact. In contrast to the fly, the cabbage butterfly *Pieris brassicae* incorporates 20:5n-3 (eicosapentaenoic acid) into a variety of lipids including PI (22). Insects provide a wide natural diversity in diet potentially providing a wealth of comparative biochemistry. For instance, some insects are "phytophagous," meaning that they feed on plants, and, in many cases, the insect-host relationship is very specific, while others feed on meat or blood, which are rich sources of long chain fatty acids.

O-Alkyl Diol *O*-, *S*- and *Se*-Phosphoroamidates of DL-α-Tocopherol and Their Dimethylaminoalkyl Derivatives as Diester and Triester Models of Phospholipids

Stephan D. Stamatov[a,*] and **Salo Gronowitz**[b]

[a]Department of Organic Chemical Technology, University of Plovdiv, 4000 Plovdiv, Bulgaria and [b]Division of Organic Chemistry 1, University of Lund, Chemical Center, 221 00 Lund, Sweden

Hexamethyltriamide of phosphorous acid, activated by addition of iodine at an optimal molar ratio of 1.05:0.05, was used as a phosphorylating reagent to synthesize 1-hexadecyloxyethyl-2-*O*-, 1-hexadecyloxypropyl-3-*O*-, and 1-hexadecyloxybutyl-4-*O*-(DL-α-tocopheryl-6-*O*)-(*N*,*N*-dimethylamido)selenophosphate, -thiophosphate and -phosphate derivatives, and some of their 2-dimethyl-aminoethyl-1-*O*-, and 3-dimethylaminopropyl-1-*O*-triester analogues in a "one-pot procedure" in overall yields of 69–87%. Activation of the reaction with an equimolar mixture of imidazole and carbon disulfide at the triester formation step permits selective phosphorylation at room temperature. The compounds synthesized represent new diester and triester models containing alkyl ether diolphospholipid structures. *Lipids 28,* 351–354 (1993).

O-Alkyl diolphospholipids and polar lipids containing phosphate triester linkages are important mediators of a variety of biological activities (1–4). Diester types of naturally occurring and of model alkyl ether diolphospholipids have been obtained synthetically to elucidate their chemical and pharmacological properties (4–7). Triester derivatives, or thio- and selenophosphate analogues of alkyl ether diolphospholipids have not been reported to date. Thiophosphate model analogues of other naturally occurring phospholipids, however, are now well recognized as advantageous probes in biochemical and membrane studies (8,9).

Further developments in diolphospholipid research will be stimulated by the design of novel chemical structures that include (in addition to a diol moiety) a membrane active lipid (steroid, tocopherol, etc.) joined *via* a phosphate bridge. This new and challenging approach is expected to contribute to progress in biochemistry, pharmacology and membrane science (10,11).

In the present paper we describe the synthesis of alkyl esters of diol *O*-, *S*- and *Se*-phosphoroamidates of DL-α-tocopherol and some of their dimethylaminoalkyl triester analogues (Fig. 1). These compounds represent model types of ether diolphospholipids that have not been reported previously.

MATERIALS AND METHODS

The tris(*N*,*N*-dimethyl)amide of phosphorous acid (1) was prepared as described by Burg and Slota (12). 1-Hexadecyloxyethan-2-ol (a), 1-hexadecyloxy-propan-3-ol (b) and 1-hexadecyloxybutan-4-ol (c) were synthesized as described by Tsushima *et al.* (4). DL-α-Tocopherol (d), 2-dimethylaminoethanol (e), 1-dimethylamino-2-propanol (f) and 3-dimethylamino-1-propanol (g) (Fluka, Buchs, Switzerland; and Merck, Darmstadt, Germany) had a purity of more than 98%. All other reagents were purchased from Janssen (Stockholm, Sweden) and were better than 98% pure. Benzene (Merck) was dried over sodium and freshly distilled prior to use. Reaction conditions were kept strictly anhydrous.

Analytical thin-layer chromatography (TLC) on precoated aluminum sheets of Silica Gel 60 F_{254} (Merck) was routinely used for monitoring reactions. High-performance liquid chromatography (HPLC) was done (Gilson 305 System, equipped with a Gilson 131 refractive index detector; Medical Electronics, Middleton, WI) using a Polygosil 60-7 silica gel column (Scandinaviska Genetik AB, Sweden; 250 × 10 mm). Chloroform (System A), *n*-hexane/diethyl ether (20:80, vol/vol; System B), *n*-heptane/ethyl acetate (80:20, vol/vol; System C) and chloroform/methanol (90:10, vol/vol; System D) were used as mobile phases.

^{13}C Nuclear magnetic resonance (NMR) spectra were recorded on a Varian (Palo Alto, CA) XL-300 spectrometer at 75.43 MHz. ^{13}C Chemical shifts are reported in ppm relative to tetramethylsilane (TMS). ^{31}P NMR spectra were recorded on the same instrument at 121.42 MHz. ^{31}P Chemical shifts are reported in ppm relative to 85% phosphoric acid (external) where a positive sign is downfield from the standard. All ^{13}C and ^{31}P NMR data given refer to proton decoupled spectra. Infrared (IR) spectra were recorded on a Perkin-Elmer (Beaconsfield, England) FT-IR 1750 spectrometer. Peak positions are reported in cm^{-1}. Satisfactory microanalyses were obtained for **1adO, 1bdS, 1cdSe, 1adeS,** and **1cdgSe:** C, ±0.21; H, ±0.11; N, ±0.08; P, ±0.10; S, ±0.10.

dure. A mixture of iodine (0.025 g, 0.1 mmol) and the *tris* (*N,N*-dimethyl)amide of phosphorous acid (**1**; 0.343 g, 2.1 mmol) in benzene (50 mL) was heated at 70°C in a stream of argon for about 15 min until the precipitate dissolved. 1-Hexadecyloxyethan-2-ol (**a**; 0.576 g, 2.0 mmol) was added and the mixture was kept under these conditions for 5 min. Then DL-α-tocopherol (**d**; 0.861 g, 2.0 mmol) was added and the reaction mixture was heated at 70°C for 2 h. The resultant diester phosphite **1ad** was transformed to the phosphate **1adO** by reaction with benzoyl peroxide (with 20% water) (0.636 g, 2.1 mmol) at room temperature (20–25°C) for 10 min. The solvent was removed under vacuum, and the compounds was isolated by HPLC (System C) in pure form. Yield of **1adO**: 1.40 g (87%); $n_D^{40} = 1.4787$; R_f (System A), 0.11; Anal. Calcd. for $C_{49}H_{92}NO_5P$ (806.4): C, 72.98; H, 11.52; N, 1.74; P, 3.84. RESULTS AND DISCUSSION

As it has been shown, the acyclic triamides of phosphorous acid offer a number of advantages over conventional phosphorylating reagents (10,11). Moreover, these phosphamides, after appropriate activation, can also be subjected to stoichiometric alcoholysis under mild conditions to give mono-, di- and triester phosphites in high yields (13–15).

The *tris*(*N,N*-dimethyl)amide of phosphorous acid with iodine at the optimum molar ratio of 1.05:0.05 was used as base reagent, **1**. 1-Hexadecyloxyethan-2-ol **a**, 1-hexadecyloxypropan-3-ol **b**, 1-hexadecyloxybutan-4-ol **c**, DL-α-tocopherol **d**, 2-dimethylaminoethanol **e**, 1-dimethylamino-2-propanol **f** and 3-dimethylamino-1-propanol **g** were selected as substrates for phosphorylation. The synthesis was performed according to the method we recently proposed (13,14).

The diesters **1ad, 1bd, 1cd** were obtained in a "one-pot" procedure (Fig. 3) by consecutive treatment of the reagent **1** with equivalent quantities of the ether diols **a, b, c** and DL-α-tocopherol **d** at 70°C in high yields. This was proven by transformation of the phosphites to the corresponding phosphate **1adO**, thiophosphate **1bdS**, and selenophosphate **1cdSe** derivatives. The reverse phosphorylation sequence (DL-α-tocopherol first, and then an ether diol) led to transesterification, probably for both steric and chemical reasons. The reaction sequence established earlier for the synthesis of diol S- and O-phosphoroamidates of some sterols supports this explanation. The molecular masses of the diols chosen had no effect on the rates of phosphorylation.

The high selectivity of diester formation permits the direct synthesis of unsymmetrical triesters. Thus, an equimolar mixture of the third substrate, *e.g.*, imidazole and carbon disulfide, was treated in stoichiometric proportions with the crude diester intermediates **1ad, 1cd** at room temperature for 7 h (Fig. 4). Treating the reaction

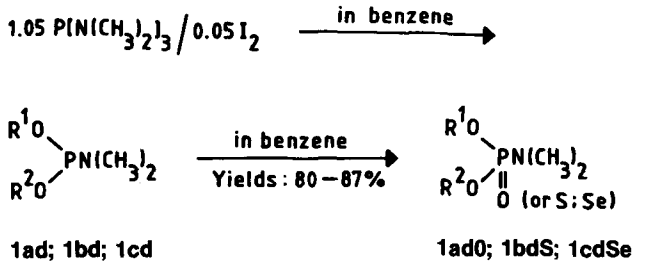

FIG. 3. For the synthesis of 1ad, 1bd, 1cd: 1.) R^1OH = a, b, or c (70°C/5 min); 2.) R^2OH = d (70°C/2 h); for the synthesis of 1adO: 3.) $(C_6H_5CO)_2O_2$ (20–25°C/10 min); or 1bdS: S_8 (70°C/3 min); or 1cdSe: Se (70°C/4 h). For a, 1ad, 1adO: R^1 = 1-hexadecyloxyethyl-; b, 1bd, 1bdS: R^1 = 1-hexadecyloxypropyl-; c, 1cd, 1cdSe: R^1 = 1-hexadecyloxybutyl-; d, 1ad, 1bd, 1cd, 1adO, 1bdS, 1cdSe: R^2 = DL-α-tocopheryl-.

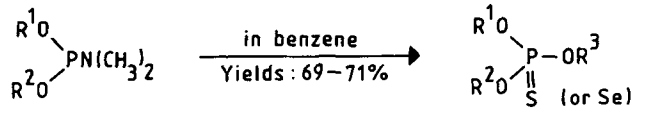

FIG. 4. For the synthesis of 1adeS, 1cdgSe: 1.) R^3OH = e, g/Im/CS_2 (20–25°C/7 h); 2.) S_8 (20–25°C/30 min); or Se (70°C/5 h). For 1ad, 1adeS: R^1 = 1-hexadecyloxyethyl-; R^2 = DL-α-tocopheryl-; 1cd, 1cdgSe: R^1 = 1-hexadecyloxybutyl-; R^2 = DL-α-tocopheryl-; e, 1adeS: R^3 = 2-dimethylaminoethyl-; g, 1cdgSe: R^3 = 3-dimethylamino-1-propyl-; Im = imidazole.

product then with sulfur, or selenium, generated the triester thiophosphate **1adeS**, or the selenophosphate **1cdgSe** (Fig. 2), in good overall yields.

Our attempts to obtain the 1-hexadecyloxypropyl-3-*O*-(1-dimethylaminopropyl-2-*O*) triester derivative of DL-α-tocopherol failed. Despite extended reaction times (up to one week), at the last synthetic step the third substrate **f** was not coupled with the activated diester intermediate **1bd**. The 1-dimethylamino-2-propanol **f** was not reactive either toward the other diester phosphites **1ad, 1cd**. This is probably due to the steric hindrance at the methyl substituted secondary hydroxyl function of **f**.

As a rule, reaction with selenium required relatively longer reaction times than oxidation or reaction with sulfur. No attempts were made to optimize this process.

Conclusions on the structures of the compounds synthesized were drawn on the basis of spectral and microanalytical data. ^{13}C NMR indicated that all characteristic signals present in the spectra of the starting substrates were also seen in the spectra of the corresponding target *O-*, *S-* and *Se*-phosphate derivatives. No chemical alterations in the alkyl ether diol (**a, b, c**), tocopheryl (**d**) and dimethylaminoalkyl (**e, g**) moieties were detected after oxidation, sulfurization or selenization. The ^{31}P NMR spectral analysis provided compelling evidence that the latter processes concerned the P^{III} atom, exclusively, under the specific experimental conditions selected. These results are in agreement with those reported in the literature for analogous systems (7,11,15).

ACKNOWLEDGMENTS

The authors thank J. Glans and K.E. Bergquist for recording the NMR spectra.

METHOD

Use of Acetyl Chloride/Methanol for Assumed Selective Methylation of Plasma Nonesterified Fatty Acids Results in Significant Methylation of Esterified Fatty Acids

The albumin-bound nonesterified fatty acid pool in plasma, which represents a very small percentage of total plasma fatty acids, has previously been quantitated by a variety of methods. In the present study we determined that the nonesterified fatty acid concentrations in the plasma, quantitated by a popular method using acetyl chloride and methanol which is reported to be specific for methylation of nonesterified fatty acids in the presence of esterified fatty acids (*i.e.*, without prior isolation of the plasma nonesterified fatty acids), were significantly overestimated due to cleavage and methylation of esterified fatty acids. Quantitation of the contaminating fatty acid from the esterified pool demonstrated that the amount of fatty acid cleaved from the esterified pool was enough to exceed the entire mass of nonesterified fatty acids. As an established method for comparison, we isolated nonesterified fatty acids from the plasma by thin-layer chromatography prior to methylation, using a number of simple precautions to limit oxidation. By performing all thin-layer chromatography steps in an atmosphere of nitrogen and by including fatty acid standards in the plasma with 0, 1, 2 or 4 double bonds, we were able to accurately and reproducibly determine the concentration of nonesterified fatty acids in the plasma, including arachidonate. We demonstrated that no oxidation occurred in the thin-layer chromatographic isolation of nonesterified fatty acids and that the coefficients of variation for repeat measurements of the same sample were <11% using our reference method. Our data indicate that the use of acetyl chloride and methanol for assumed selective methylation of plasma nonesterified fatty acids results in significant methylation of esterified fatty acids. *Lipids 28*, 355–360 (1993).

Nonesterified fatty acids (NEFA) bound to albumin comprise a very small percentage of the total plasma fatty acids. Although the size of this pool changes with diet, the percentage of the nonesterified fatty acids relative to total plasma fatty acids rarely exceeds 5% (1). The total nonesterified fatty acid pool has been quantitated by a variety of methods including colorimetric (2,3) and enzymatic (4–8) assays.

The quantitation of the small pool of plasma nonesterified fatty acids without contamination by the much larger pool of esterified fatty acids has led many investigators to isolate the plasma nonesterified fatty acids before quantitation. However, the isolation of nonesterified fatty acids by methods such as thin-layer chromatography (TLC) is time consuming and without special precautions being taken to minimize oxidation can result in significant loss of the polyunsaturated fatty acids, particularly arachidonate. To address this problem, a number of simple methods for measuring nonesterified fatty acids have been developed which do not involve prior nonesterified fatty acid isolation. One of these popular methods involving the use of acetyl chloride and methanol was developed by Lepage and Roy (7). In the present study we attempted to use that method to quantitate nonesterified arachidonate in the plasma. Although the method was very efficient in methylating nonesterified fatty acids and was easy to perform, we found that the plasma concentrations of nonesterified arachidonate, as well as the other fatty acids, were significantly overestimated using this approach. A similar observation has recently been made regarding a presumed selective method for nonesterified fatty acid methylation involving diazomethane, which was developed by Pace-Asciak (8). We therefore used TLC to first isolate plasma nonesterified fatty acids prior to methylation and employed simple precautions (i) to limit oxidation of polyunsaturated moieties by spotting and scraping the TLC plate in an atmosphere of nitrogen, and (ii) to account for all oxidation-induced polyunsaturated fatty acid losses by including a variety of polyunsaturated fatty acids as well as an odd-numbered saturated fatty acid as internal standards. Using this as a reference method, we were able to demonstrate that the acetyl chloride/methanol method developed for nonesterified fatty acid methylation also results in significant methylation of esterified fatty acids.

MATERIALS AND METHODS

Materials. Analytical grade solvents were used in all experiments. Acetyl chloride was purchased from Sigma (St. Louis, MO). Potassium carbonate (anhydrous) was obtained from Fisher (Pittsburgh, PA). Fatty acids, fatty acid methyl esters, triolein, triarachidonin, cholesteryl linoleate and cholesteryl heptadecanoate were purchased from Nu-Chek-Prep (Elysian, MN). Dipalmitoyl phosphatidylcholine and diarachidonoyl phosphatidylcholine were obtained from Avanti (Pelham, AL). Prostaglandin E_2 was a product of Caymen (Ann Arbor, MI). Bovine serum albumin was purchased from Sigma. TLC plates (silica gel 60) were products of E. Merck (Darmstadt, Germany).

Analysis of plasma nonesterified fatty acids. Blood samples were drawn from fasting (for at least 8 h) or nonfasting donors into ethylenediaminetetraacetic acid (EDTA) vacutainers and placed on ice until centrifuged at 4°C. Unless otherwise stated, donors were not fasting. All samples were centrifuged to obtain plasma, and the plasma from each sample was within 10 min after centrifugation frozen at −80°C for periods of up to 1 wk. In separate studies (data not shown), storage under these

conditions was found to have no effect on plasma nonesterified fatty acid concentrations. Plasma NEFA were quantitated in some experiments exactly according to the method of Lepage and Roy (see below) (7). In other experiments, NEFA analysis was performed using a modified Lepage and Roy method in which the temperature or the ratio of methanol to acetyl chloride was varied. Alternatively, NEFA were measured following extraction from plasma by a modified Folch method (9) after addition of known amounts of 17:0 (37 μM), 20:1n-9 (30 μM), 20:2n-6 (26.5 μM) and 22:4n-6 (15 μM) as internal standards. The fatty acids used as standards were not detected in the native plasma nonesterified fatty acid pool (data not shown). The inclusion of 22:4 as an internal standard permitted comparison of recoveries of fatty acids with 0, 1 and 2 double bonds with an internal standard fatty acid possessing 4 double bonds. In all studies, the recovery of the four internal standards was very similar. Thus, there is no reason to believe that arachidonate, isolated from the plasma with higher concentrations of other nonesterified fatty acids, should show a lower recovery than less unsaturated nonesterified fatty acids. In experiments involving NEFA isolation by TLC, lipid extracts were dried under nitrogen at room temperature, resuspended in 0.1 mL of chloroform and spotted onto silica gel 60 TLC plates. During spotting, a gentle stream of nitrogen was kept flowing over the lower half of the plate. The plates were developed in hexane/diethyl ether/acetic acid (70:30:1, by vol) which clearly separated plasma NEFA from other lipids, including phospholipids (PL), triacylglycerol (TG), and cholesteryl esters (CE). Nonesterified fatty acids, PL, TG and CE standards were simultaneously run as standards in parallel lanes on the sample plates. For visualization and scraping, TLC plates were first placed in a dry TLC tank which was continuously flushed with nitrogen. After 5–10 min, when the plate was dry, a glass pasteur pipette filled with iodine crystals connected by tygon tubing to a nitrogen source was inserted into the tank for another 2–5 min until all bands became visible. The iodine was allowed to sublime from the plate before the lipid bands were scraped off the plate. The tank was then tilted on its side, the pipette containing iodine crystals removed, and nitrogen was allowed to continue to flow through the tank. NEFA bands were scraped from the plates in an atmosphere of nitrogen, and the scrapings were immediately added to 5 mL of methanol/acetyl chloride. Excess silica in the mixture was found to reduce the efficiency of methylation. Because there were four internal standards in all test samples, differences in methylating efficiency between experiments had no effect on the final result. The tubes were vortexed for 1 min and then incubated for 45 min at room temperature. During incubation the tubes were vortexed twice for 1 min each time. The methylation reaction was stopped by adding 3 mL of 6% K_2CO_3. Fatty acid methyl esters were extracted into 0.2 mL hexane, dried under nitrogen and resuspended in 5 μL of hexane, from which one μL was injected into a Perkin-Elmer (Norwalk, CT) 8500 gas-liquid chromatograph equipped with a flame ionization detector. Individual fatty acid methyl esters were separated on a WCOT capillary column (Supelcowax 10; Supelco, Bellefonte, PA) using temperature programming from 150 to 250°C at a rate of 10°C/min. Peaks were identified by comparison with the retention times of known standards, and peak areas were integrated. Individual fatty acid masses were determined using internal standards possessing the same number of double bonds. However, in all experiments, because there was no loss of polyunsaturated fatty acids due to oxidation, masses determined for individual nonesterified fatty acids were the same when calculated based on any of the four internal standards.

Quantitation of hydrolysis of esterified fatty acids. Known amounts of dipalmitoyl phosphatidylcholine, diarachidonoyl phosphatidylcholine, tripentadecanoin, triarachidonin, cholesteryl heptadecanoate, cholesteryl linoleate and nonesterified 14:0 (43.8 nmol, 292 μM), 18:0 (35.2 nmol, 234 μM) and 22:4n-6 (15 nmol, 100 μM) were added to a test tube and dried to remove all solvents. Then 0.15 mL of distilled water was added to mimic the aqueous serum component, and the sample was processed using the method of Lepage and Roy (7) exactly as described. Samples of the same lipid mixture were analyzed in parallel for total fatty acid composition using the method of Turk *et al.* (10) to saponify and methylate the esterified fatty acids. For this purpose, the lipid extract was first dried under nitrogen and then resuspended in 0.6 mL of methylene chloride. After vortexing, 1.0 mL of 0.5 M KOH was added, and the mixture allowed to sit for 30 min. Then, 1.0 mL of 6 M HCl was added and, after vortexing, the sample was centrifuged at 100 × *g* for 50 min at room temperature to separate the two phases. The bottom organic layer was aspirated, dried under nitrogen and resuspended in a small volume of hexane for injection into the gas chromatograph. Percent hydrolysis of esterified fatty acids observed by the Lepage and Roy (7) method was calculated by dividing the concentration of methylated fatty acid generated by the Lepage and Roy (7) method by the total esterified fatty acid concentration in the sample for each of the individual lipids tested.

Total plasma fatty acid quantitation. Plasma fatty acids were extracted according to the method of Cohen *et al.* (9) and then methylated using the method of Turk *et al.* (10), followed by the esterification method of Lepage and Roy (7). Application of this sequence of fractions was found to methylate both esterified fatty acids and nonesterified fatty acids. In these experiments, 17:0 was used as an internal standard. Alternatively, tripentadecanoin or triheptadecanoin was used as an internal standard when only the method of Turk *et al.* (10) was employed as this method is more efficient for esterified than for nonesterified fatty acids.

RESULTS

We first performed a series of nonesterified fatty acid methylations using the method of Lepage and Roy (7) without modification (Table 1). We collected data from 34 nonfasting subjects and 5 fasting subjects. These data were compared with those generated by Lepage and Roy (7), which were from one plasma sample analyzed five times. Table 1 shows that the concentrations of various nonesterified fatty acids found in fasting plasma were slightly higher than those in nonfasting plasma. This is consistent with reports that TG hydrolysis in the fasting state elevates nonesterified fatty acid concentrations (11). The concentration of nonesterified arachidonate we obtained using the unmodified Lepage and Roy (7) method in five specimens from fasting subjects was 36 μM, which

was very similar to the arachidonate concentration in the sample analyzed by Lepage and Roy (35.5 μM), and not significantly different from the 25 μM value we obtained for a group of 34 nonfasting individuals. To test whether the concentration of nonesterified arachidonate we obtained in both cases could have been an overestimation, we pursued the possibility that the unmodified Lepage and Roy (7) method may also lead to some methylation of bound fatty acid in the plasma. The cleavage and methylation of only a few percent of esterified fatty acid would, of course, greatly confound the measurement of the much smaller pool of nonesterified fatty acid. Table 2 shows the results of experiments in which we determined the percent cleavage of esterified fatty acids using the unmodified Lepage and Roy method. In these experiments we used TG, PL and CE, the amounts of which were known from the amounts of TG, PL and CE delivered from gravimetrically prepared stock solutions. In addition, the amounts of TG, PL and CE shown in the middle column of Table 2 were confirmed by using 248 nmol of trimyristin as internal standard followed by alkaline hydrolysis, methylation of the fatty acids and quantitation by gas chromatography (10). We tested two TG, two PL and two CE standards, one of each containing only saturated and the other only polyunsaturated fatty acids, to determine whether the degree of fatty acid unsaturation had an effect on fatty acid analysis by the unmodified Lepage and Roy (7) method. There were no free fatty acids detected in the TG, PL and CE standards used in these studies. The data, however indicate that there was indeed cleavage and methylation of esterified fatty acids. In plasma, the concentration of esterified fatty acids is more than 100-fold greater than the concentration of nonesterified fatty acids. Therefore, the 1.2–6.8% cleavage of esterified fatty acids which we observed represents a substantial amount of contamination relative to the pool of nonesterified fatty acid. We also found that esterified polyunsaturated fatty acids were more readily cleaved from TG and CE than were saturated fatty acids, but from PL saturated fatty acids were cleaved as readily as polyunsaturated ones. The significantly higher rate of cleavage of polyunsaturated fatty acids *vs.* saturated fatty acids from TG and CE indicates that the Lepage and Roy (7) method results in greater overestimation of polyunsaturated fatty acid than saturated fatty acid, particularly as TG in the plasma occur at substantial concentrations. Thus, when assaying by the Lepage and Roy method, the amount of contaminating fatty acid measured may actually exceed the mass of true nonesterified fatty acid.

We observed similar problems when we attempted to use the method of Pace-Asciak (8) for methylation of plasma nonesterified fatty acids without prior isolation (data not shown). A report demonstrating that the Pace-Asciak method overestimates plasma nonesterified fatty acid concentrations has recently been published (12). The values for plasma nonesterified fatty acids (nonfasting

Total	606.5 ± 205.7	805.4 ± 134.8	709.4

[a]Nonesterified fatty acid concentrations in plasma samples from fasting and nonfasting subjects were determined using the unmodified method of Lepage and Roy (Ref. 7) (room temperature) as detailed in Materials and Methods. Values represent mean ± SD.
[b]The previously published values by Lepage and Roy are from one sample tested five times as reported in Reference 7.

TABLE 2

The Hydrolysis of Esterified Fatty Acids by the Unmodified Lepage and Roy Method[a]

Lipid	FA	Concentration of FA in solution (μM)	Concentration of FA methyl ester according to Ref. 7 (μM ± SEM)	% Ester cleavage
Triacylglycerol				
Tripentadecanoin	Saturated	6456	77.7 ± 5.5	1.2
Triarachidonin	Polyunsaturated	5192	218.5 ± 13.3	4.2
Phospholipid				
Dipalmitoyl PC	Saturated	4632	301.7 ± 10.3	6.5
Diarachidonoyl PC	Polyunsaturated	4095	231.7 ± 8.8	5.7
Cholesteryl ester				
Cholesteryl heptadecanoate	Saturated	2034	32.0 ± 2.1	1.6
Cholesteryl linoleate	Polyunsaturated	2005	135.4 ± 7.3	6.8

[a]Percent hydrolysis was calculated as 100 × (mean concentration of methylated fatty acids according to Lepage and Roy method, Ref. 7)/(concentration of esterified fatty acid in solution). FA, fatty acid; PC, phosphatidylcholine; n = 3 for all lipid moieties tested.

donors) obtained in our studies with the Pace-Asciak method (8) were: 16:0, 239 ± 7; 18:0, 113 ± 12; 18:1, 195 ± 26; 18:2, 153 ± 11; 20:4, 44 ± 4 (all values in μM; mean ± SEM, n=3). These values were very similar to those reported by Lepage and Roy and were also similar to our own results obtained by the Lepage and Roy (7) method (Table 1).

In an attempt to determine accurate and precise values for the individual nonesterified fatty acids in the plasma, including the polyunsaturated fatty acids, free of contamination from the esterified fatty acid pool, we compared the quantitation of nonesterified fatty acids by the Lepage and Roy method (at 0°C, which decreases cleavage of esterified fatty acid but does not eliminate it) with the quantitation of plasma nonesterified fatty acid following lipid extraction, isolation of NEFA by TLC, and methylation of NEFA using the procedure of Lepage and Roy (7) (Table 3). It is important to note that in these experiments, spotting of the lipid extract onto the TLC plate, drying of the developed TLC plate, identification of the bands on the plate and scraping the nonesterified fatty acid band from the TLC plate were all carried out in an atmosphere of nitrogen to prevent oxidation of polyunsaturated fatty acids. Also, to account for all losses of both saturated and unsaturated NEFA, due to oxidation and other causes, we used an internal standard mixture of four fatty acids with 0, 1, 2 or 4 double bonds (17:0, 20:1n-9, 20:2n-6 and 22:4n-6). Each of the internal standards, including the polyunsaturated ones, when used in the calculation of plasma nonesterified fatty acid concentrations yielded the same results, indicating that only an insignificant amount of polyunsaturated fatty acid oxidation, if any, occurred in our experiments. As shown in Table 3, the concentrations of the individual nonesterified fatty acids determined following isolation of plasma NEFA by TLC with precautions taken to avoid oxidation were significantly lower than the values obtained by Lepage and Roy (7). This was true not only for arachidonate, but also for the other plasma nonesterified fatty acids. A number of methods have been developed for the quantitation of plasma nonesterified fatty acids, most or all of which are less cumbersome than the reference method we used involving multiple internal standards and frequent use of nitrogen in isolation of the nonesterified fatty acids. However, these methods have generated values for plasma NEFA that vary over a very wide range. In view of the reproducibility of the method we used involving only conventional techniques, but avoiding shortcuts, and with the inclusion of multiple internal standards to account for various losses, it is likely that the data presented in Table 3 give the true NEFA concentrations in plasma. From the last column of Table 3, it can be seen that the concentrations of nonesterified fatty acids following isolation by TLC were 13–52% of the values obtained by the Lepage and Roy (7) method at 0°C. As suggested by our earlier results shown in Table 2, these data also show that the Lepage and Roy method overestimates polyunsaturated nonesterified fatty acids to a greater extent than nonpolyunsaturated fatty acids. The nonesterified arachidonic acid concentration measured following isolation by TLC was only 13% of the Lepage and Roy values. The concentration of nonesterified linoleic acid having two double bonds rather than four, was somewhat higher at 22%. Because the values for these two polyunsaturated fatty acids were lower relative to those for the more saturated fatty acids, the susceptibility of polyunsaturated fatty acid to oxidation during TLC was tested directly (Table 4). In the first two columns of Table 4, the plasma nonesterified fatty acid concentrations obtained by the unmodified Lepage and Roy (7) method on unfractionated plasma are shown. Only one μL of more than 100 μL of extracted plasma sample was injected into the gas chromatograph, and the remainder of the sample containing fatty acid methyl esters was subjected to TLC. The fatty acid methyl ester band was identified, and as in all other experiments, scraped from the plate in an atmosphere of nitrogen. The fatty acid methyl esters were then analyzed by gas chromatography. As noted by comparing the first and second columns of Table 4, the percentages for each individual fatty acids are essentially identical, for linoleic and arachidonic acid as well as for the other nonesterified fatty acids. This indicates that the additional thin-layer chromatographic step to separate the nonesterified fatty acids from TG, PL and CE did not result in oxidation of polyunsaturated fatty acids. We also performed other experiments to test for oxidation-induced

TABLE 3

Comparison of Nonesterified Plasma Fatty Acid Concentrations Determined by the Lepage and Roy Method on Unfractionated Plasma *vs.* Methylation of Isolated Nonesterified Fatty Acids[a]

NEFA source	Unfractionated plasma	Isolated from plasma by TLC	
MeOH/acetyl chloride	50:1	50:1	
Reaction temperature	0°C	RT

20:4n-6	14.0 ± 5.6	1.8 ± 0.4	13
Total	284.6 ± 58.6	92.3 ± 21.1	32

[a]Samples of unfractionated plasma were processed for nonesterified fatty acid (NEFA) quantitation using the Lepage and Roy (Ref. 7) method at 0°C. Nonesterified plasma fatty acids isolated by TLC were also quantitated. Values represent mean ± SD; TLC, thin-layer chromatography; RT, room temperature.

TABLE 4

Fatty Acid Concentration Determined by the Lepage and Roy Method with or Without Prior Isolation of Nonesterified Fatty Acids by Thin-Layer Chromatography[a]

Fatty acid	Source of fatty acids			
	Plasma without TLC	Plasma with TLC	Standard mixture without TLC	Standard mixture with TLC
	(% of total fatty acids)			
16:0	28.5	28.1	26.2	26.2
18:0	9.5	9.7	7.9	8.3
18:1n-9	32.0	30.8	24.7	24.9
18:2n-6	26.7	27.6	35.9	35.3
20:4n-6	3.3	3.8	5.3	5.3
Total	100.0	100.0	100.0	100.0

[a]Plasma nonesterified fatty acids were methylated by the Lepage and Roy (Ref. 7) method, and the resultant fatty acid methyl esters split into two fractions; one fraction was purified by TLC, one was injected directly into the gas chromatograph. A standard mixture of fatty acid methyl esters was also split into two fractions and processed similarly. Values represent the mean of two determinations for each sample. TLC, thin-layer chromatography.

loss of polyunsaturated nonesterified fatty acids following isolation by TLC, the data for which are shown in columns 3 and 4 of Table 4. For these studies, we injected one μL of a standard fatty acid methyl ester mixture directly into the gas chromatograph. We then chromatographed the same standard fatty acid methyl ester mix on a thin-layer plate, isolated the fatty acid methyl ester band, eluted it and injected the eluted fatty acid methyl esters into the gas chromatograph. As shown in Table 4, this did not result in oxidation of linoleate and arachidonate.

Collectively, the data in Table 4 indicate that as we performed the experiments, there was no preferential loss of linoleate and arachidonate due to oxidation. In additional studies on 10 samples in which we did not take precautions to limit polyunsaturated fatty acid oxidation, TLC plates were allowed to sit exposed to room air for up to 1 h, and then NEFA bands were scraped from the plate in room air over 5–10 min. In all the 10 samples tested, no arachidonate was detected, and linoleate (as percent of total fatty acid) decreased from 25–35% to 5–10%. This clearly shows that isolation of NEFA by TLC before quantitation will lead to spuriously low values, unless simple precautions are taken to limit oxidation-induced losses.

Table 5 shows the reproducibility of the nonesterified fatty acid measurements following NEFA isolation by TLC when using multiple internal standards. In this series of experiments, we used the plasma from one subject and analyzed seven separate aliquots of the same specimen identically. The coefficients of variation were not large for any of the fatty acids, with the highest values of 10.2 and 10.7 observed for palmitoleic acid (16:1n-7) and arachidonic acid (20:4n-6). These two particular nonesterified fatty acids, because they occur at the lowest concentrations, showed the greatest variability in the measurements.

TABLE 5

Reproducibility of Nonesterified Fatty Acid Measurements Following Isolation by Thin-Layer Chromatography[a]

Fatty acid	NEFA μM concentration		
	Mean	SD	CV
14:0	3.2	0.2	7.6
16:0	40.1	1.9	4.7
16:1n-7	3.3	0.3	10.2
18:0	17.7	0.6	3.4
18:1n-9	40.7	3.2	7.9
18:2n-6	22.9	1.1	5.0
20:4n-6	1.6	0.2	10.7
Total	129.5	7.1	5.5

[a]Values represent the mean ± SD and include the coefficient of variation (CV) for measurement of total NEFA and each individual fatty acid isolated from seven aliquots of the same plasma. NEFA, nonesterified fatty acids.

DISCUSSION

We have demonstrated that using the method of Lepage and Roy (7) to quantitate plasma nonesterified fatty acids leads to significant cleavage of esterified fatty acids, which contaminates the nonesterified fatty acid pool and makes accurate measurements impossible. In a recent report, Lin *et al.* (12) provided evidence for extensive phospholipid fatty acid methylation that occurred during the assumed selective methylation of plasma free fatty acids by diazomethane (8). In the present study, using a method for quantitating nonesterified fatty acid not involving diazomethane, cleavage and methylation of fatty acids esterified to phospholipids, as well as to triglycerides and CE, was observed. In the Discussion section, Lin *et al.* (12) stated that in the process of evaluating in detail the diazomethane method developed by Pace-Asciak they also observed that the acetyl chloride/methanol method developed by Lepage and Roy (7) overestimates plasma nonesterified fatty acid levels. Lin *et al.* (12) did not support this conclusion with data. Because of the reluctance of many investigators to work with diazomethane, we assessed the acetyl chloride/methanol method in some detail. In our evaluation, we quantitated the extent of overestimation for various types of plasma nonesterified fatty acids and demonstrated the preferential cleavage of esterified polyunsaturated fatty acids from TG and CE, but not from PL. Thus, this report and the one by Lin *et al.* (12) provide quantitative evidence that two popular methods for the assumed selective methyla-

tion of nonesterified fatty acids lead to overestimation of the small pool of plasma free fatty acids. The method we used for comparison with the Lepage and Roy (7) method involved isolation of the nonesterified fatty acids prior to methylation, with precautions being taken to limit fatty acid oxidation and to quantitate any losses due to any oxidation. The present method may be somewhat more cumbersome than the two direct methods, but it provides accurate and precise measurements of the free fatty acid concentrations in plasma.

Profiling of Arachidonic Acid Metabolites in Rabbit Platelets by Radio Gas Chromatography

Kazuki Akira, Tatsuji Nakamura, Yoshihiko Shinohara and **Shigeo Baba***
Tokyo College of Pharmacy, 1432-1 Horinouchi, Hachioji, Tokyo 192-03, Japan

A method for profiling arachidonic acid metabolites by radio gas chromatography (GC) is described. The incubation mixture of rabbit platelets with [^{14}C]arachidonic acid was purified on a Sep-Pak C_{18} cartridge and derivatized with diazomethane, *O*-methylhydroxylamine and dimethylisopropylsilylimidazole. The recovery of total ^{14}C-radioactivity was 93.1 ± 7.2%. Loss of radioactivity during derivatization was negligible. Baseline separations for [^{14}C]arachidonic acid and its metabolites were obtained in a single run within 45 min by GC using a synchronized accumulating radioisotope detector (GC/SARD). The recovery of radioactivity from the GC column was virtually 100%. The chemical structures of the metabolites were confirmed by GC/mass spectrometry; peaks of arachidonic acid metabolites were assigned by comparison of the methylene unit values with those of radioactive peaks in GC/SARD analyses. The intra-assay coefficients of variation in GC/SARD analyses were less than 10%. The method was used to map the profile of arachidonic acid metabolites formed by rabbit platelets in the presence of indomethacin, baicalein or glutathione.
Lipids 28, 361–364 (1993).

Arachidonic acid (AA) is enzymatically transformed into a variety of oxygenated products (eicosanoids) *via* two main pathways (1). The cyclooxygenase pathway leads to unstable endoperoxides that can be further converted to prostaglandins (PG) and thromboxanes (TX). The lipoxygenase pathway leads to hydroperoxyeicosatetraenoic acids (HPETE), hydroxyeicosatetraenoic acids (HETE) and leukotrienes (LT). Eicosanoids have a diverse range of physiological and pharmacological effects, and sometimes opposing effects; for example, TXA_2 stimulates (2), but PGD_2 (3), PGI_2 (4) and 12-HPETE (5) inhibit platelet aggregation.

Recently there have been numerous attempts to correlate the anti-inflammatory, antipyretic and analgesic effects of substances like aspirin, indomethacin and phenylpropionic acid derivatives with their ability to inhibit the production of AA metabolites in order to investigate the mechanism of action of these drugs (6–8). It is highly desirable to examine and quantitate as broad a band of AA metabolites as possible.

Radioisotope tracer techniques have been applied to investigate the profile of eicosanoids formed from AA. Thin-layer chromatography (TLC) (9–11) and high-performance liquid chromatography (HPLC) (12–16) with radiodetection have been used for the separation of radioisotopically labeled eicosanoids. The TLC methods do not provide sufficient resolution. The HPLC methods offer the advantage of high resolution and good reproducibility, but require long analysis times and a large amount of scintillation fluid. Although gas chromatography (GC) is generally accepted as one of the most effective methods for the separation of eicosanoids due to its excellent resolving power, GC combined with radiodetection (radio GC) has not been used previously for profiling complex mixtures of eicosanoids. Radio GC has the inherent drawback (17) that enhancement in detection sensitivity results in decreased resolution; this has lowered the usefulness of the technique. We have developed a radio GC system that utilizes a synchronized accumulating radioisotope detector (SARD) (18–20). In the SARD, seven identical counting tubes are connected in series so that signals from each counting tube are accumulated synchronously with the traveling radioactive gas particles. Moreover, the counting tubes are connected electrically by a mutual anti-coincidence circuit so that the background counts are effectively lowered and signal-to-noise ratios are improved tenfold without a loss in chromatographic resolution. SARD was successfully linked with capillary GC (21). The present paper describes a procedure for assessing the profile of eicosanoids formed from AA using [^{14}C]AA and capillary GC/SARD. Rabbit platelet homogenates were used as a model system for developing the procedure because they are readily harvested and they actively metabolize AA both through the cyclooxygenase and lipoxygenase pathways.

MATERIALS AND METHODS

Reagents. [1-^{14}C]AA (specific activity, 2.06 GBq/mmol; radiochemical purity, 99.2%) and 12-(*S*)-hydroxy[5,6,8,9,11,12,14,15(*n*)-[^{3}H]eicosatetraenoic acid ([^{3}H]12-HETE; specific activity, 5.29 TBq/mmol; radiochemical purity, 96.4%) were purchased from the Radiochemical Centre (Amersham, United Kingdom). Nonlabeled AA was purchased from Funakoshi (Tokyo, Japan). 12-HETE, 12-hydroxyheptadecatrienoic acid (12-HHT) were purchased from Sigma (St. Louis, MO). TXB_2 was kindly supplied by Upjohn Pharmaceutical Limited (Ibaraki, Japan). Dimethylisopropylsilyl(DMiPS)imidazole was purchased from Tokyo Kasei Kogyo (Tokyo, Japan). *O*-Methylhydroxylamine·HCl pyridine solution was purchased from Pierce (Rockford, IL). A Sep-Pak C_{18} cartridge was purchased from Waters Associates (Milford, MA). Indomethacin and baicalein were purchased from Wako (Tokyo, Japan). Glutathione (GSH) was purchased from Kanto Chemical (Tokyo, Japan).

Isolation of rabbit platelets. Fresh arterial blood (*ca.* 100 mL) was collected from a Japanese white rabbit into plastic tubes with 1/10 vol of 3.8% sodium citrate and centrifuged at 140 × *g* for 15 min to separate the platelet-rich plasma. The platelet-rich plasma was further centrifuged at 750 × *g* for an additional 15 min. The platelet pellet obtained from 50 mL of platelet-rich plasma was

Abbreviations: AA, arachidonic acid; DMiPS, dimethylisopropylsilyl; EDTA, ethylenediaminetetraacetic acid disodium salt; EPHETA, 11,12-epoxy-10-hydroxyeicosa-5,8,14-trienoic acid; FID, flame ionization detector; GC, gas chromatography; GC/MS, gas chromatography/mass spectrometry; GSH, glutathione; HETE, hydroxyeicosatetraenoic acid; 12-HHT, 12-hydroxyheptadecatrienoic acid; HPETE, hydroperoxyeicosatetraenoic acid; HPLC, high-performance liquid chromatography; LT, leukotriene; MU, methylene unit; PG, prostaglandin; SARD, synchronized accumulating radioisotope detector; TLC, thin-layer chromatography; TX, thromboxane; 8,9,12-THETE, 8,9,12-trihydroxyeicosa-5,10,14-trienoic acid; 8,11,12-THETE, 8,11,12-trihydroxyeicosa-5,9,14-trienoic acid.

washed in 100 mL of 12 mM Tris-HCl buffer (pH 7.4) containing 134 mM NaCl and 1.5 mM ethylenediaminetetraacetic acid disodium salt (EDTA), and centrifuged at 750 × *g* for 15 min. After a second wash in the same buffer, the final pellet was suspended in 15 mM Tris-HCl buffer (pH 7.4) containing 134 mM NaCl and 5 mM D-glucose at a concentration of 3–5 × 10^5 platelets/μL. The washed platelet suspension was stored at −80°C.

Sample preparation. Frozen platelets were thawed and homogenized by triplicate sonication at 27 kHz for 1 min. One mL of the homogenate (*ca.* 1 mg protein/mL) was incubated at 37°C for 5 min with [^{14}C]AA (10 nmol, 20 kBq). The reaction was terminated by the addition of 0.2 mL of 0.2 M citric acid (pH 3). The reaction mixture was applied to a Sep-Pak C_{18} cartridge which was washed with 5 mL each of methanol and water immediately before use. The cartridge was washed with 10 mL each of 5% ethanol/water, water, and petroleum ether and then eluted with 6 mL of methyl formate. The eluate was evaporated to dryness under a nitrogen stream. The residue was derivatized with diazomethane, *O*-methylhydroxylamine and DMiPS-imidazole as described previously (22). The derivatized sample was dissolved in 50 μL of 1% pyridine/hexane, and 1–3 μL was injected into the GC/SARD system.

Samples for measurements by GC/MS were prepared as follows. Five mL of the rabbit platelet homogenate was incubated with 50 nmole of unlabeled AA and the incubation products were purified and derivatized as described above. The derivatized sample was dissolved in 50 μL of 1% pyridine/hexane, and 0.5–1 μL was injected into the GC/mass spectrometry (MS) system.

Radio GC system. All radio GC analyses were performed on the GC/SARD system described previously (21). A wide-bore fused silica capillary column (12 m × 0.53 mm) coated with Shimadzu (Kyoto, Japan) nonpolar CBP-1 (1 μm film thickness) was used. The flow rates of helium were 5 mL/min for carrier gas and 50 mL/min for make-up gas. The column effluents were subjected to oxidation ($^{14}C \rightarrow {}^{14}CO_2$) or oxidation/reduction ($^{3}H \rightarrow {}^{3}H_2O \rightarrow {}^{3}H_2$) in the oxidation/reduction tube, and the resulting gas was introduced into the SARD after mixing with counting gas (methane). In the SARD, the seven gas flow proportional counting tubes (inner volume, 10 mL) are arranged in close packing and placed in a 30-mm thick cylindrical lead housing. The counting tubes are connected by a mutual anti-coincidence circuit. The total flow rates of methane and helium in the SARD were maintained at 200 mL/min. The sampling time (the transit time of the gas particles through one counting tube) (21) was set at 3 s, and the transit time of gas particles in the SARD system was 21 s (7 × 3 s). The column oven temperature was set at 180°C and increased at a rate of 2°C/min to 270°C.

Peak radioactivities, A (Bq), were calculated according to the following equation.

$$A\ (Bq) = \frac{\text{radioactive peak intensity (counts)} \times 100}{\text{transit time in the SARD (s)} \times \text{GC peak yield (\%)}} \quad [1]$$

GC peak yields (percentage of the amount of an injected substance that reaches the detector system) were calculated by analyzing authentic [^{14}C]AA (120 Bq) or [^{3}H]12-HETE (120 Bq), according to the method in our previous papers (22,23).

GC/MS. GC/MS analyses were performed on a Shamadzu gas chromatograph model GC-14A equipped with a capillary column (10 m × 0.25 mm) coated with Supelco (Bellefonte, PA) nonpolar SPB-1 (film thickness, 0.25 μm), coupled directly to the source of Shimadzu QP-1000 EX mass spectrometer. Helium was used as carrier gas at a pressure of 0.5 kg/cm^2. The column oven temperature was maintained at 100°C for 1 min after injection and then increased at a rate of 10°C/min to 270°C. The ion source temperature was set at 270°C. A splitless injection mode was used, and the vent was opened at 1 min after injection. Mass spectra were recorded in the electron impact mode at an electron energy of 70 eV and a trap current of 60 μA. The mass spectra were recorded, covering an *m/z* range of 50–800 every 2 s.

Liquid scintillation counter. The radioactivities were measured in 10 mL of toluene base scintillation cocktail with an Aloka (Tokyo, Japan) liquid scintillation counter (LSC, 903 or 1000).

RESULTS AND DISCUSSION

The gas chromatographic analysis of eicosanoids has been described in several papers (24–27). Maclouf and Rigaud (24) reported the complete resolution of some eicosanoids by capillary column GC using a flame ionization detector (FID). However, this method is not suitable for profiling AA metabolites in biological samples due to the presence of several peaks on the GC tracing other than those from the analytes. The radio GC approach described here provided much clearer profiling as radiodetection is not obstructed by endogenous compounds and derivatizing reagents.

Sep-Pak C_{18} cartridges have been extensively used to separate AA metabolites from biological samples. The separation with Sep-Pak C_{18} cartridges utilized in the present study was essentially the same as that proposed by Powell (28). [^{14}C]AA and its metabolites were eluted with methyl formate with a recovery of 93.1 ± 7.2% (n = 10). Loss of radioactivity during derivatization was negligible.

A typical radiochromatogram obtained by incubation of rabbit platelet homogenate with [^{14}C]AA is shown in Figure 1. The recovery of radioactivity from the GC column was virtually 100%. Baseline separations for all major products from platelets were obtained within 45 min under linear temperature programing conditions. The

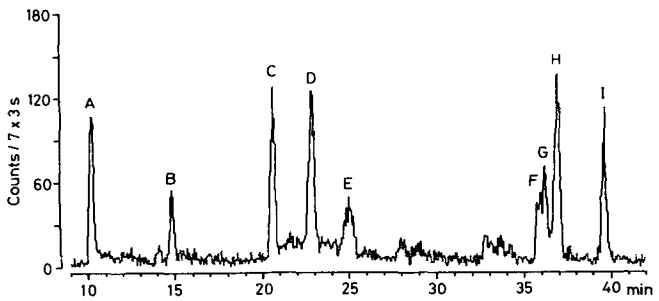

FIG. 1. Profile of [^{14}C]eicosanoids and its metabolites in rabbit platelets. Column, nonpolar fused silica capillary column (12 m × 0.53 mm); temperature programming, 180–270°C at 2°C/min; injected radioactivity, 514 Bq.

DMiPS derivatives were shown to be well separated and more stable than the corresponding trimethylsilyl derivatives.

Radioactive peaks in GC and HPLC are usually tentatively identified by comparing the retention times with those of reference standards. However, this approach is often ambiguous. In the present study, an attempt was made to directly confirm the structures of the metabolites by GC/MS analyses. The incubation mixture with unlabeled AA was extracted and derivatized in a procedure similar to that used for labeled AA and was analyzed by GC/MS. Each peak in GC/MS analysis was assigned by comparison of the methylene unit (MU) (29,30) values with those of the radioactive peaks in GC-SARD analysis. The metabolites in peaks A (MU; 22.2), B (MU; 24.0), C (MU; 26.0) and I (MU; 23.5) were identified as AA, 12-HHT, 12-HETE and TXB_2, respectively, by comparison with the mass spectra with those of authentic compounds. The metabolite in peak D (MU; 26.0) was identified as 11,12-epoxy-10-hydroxyeicosa-5,8,14-trienoic acid (EPHETA). Its mass spectrum showed the major fragment ions at *m/z*: 419[M − 31, loss of OCH_3], 407[M − 43, loss of $CH(CH_3)_2$], 310[M − 140, loss of $OHCCH_2CH{=}CH(CH_2)_4CH_3$], 297[M − 153, loss of $CH(O)CHCH_2CH{=}CH(CH_2)_4CH_3$], 279[M − (140 + 31)], 267[M − (140 + 43)], 265 [M − (111 + 31 + 43), loss of (C-13 to C-20), OCH_3 and $CH(CH_3)_2$], 221[M − (111 + 118), loss of (C-13 to C-20) and DMiPSOH]. The mass spectra of peaks F (MU; 31.2),

TABLE 1

Reproducibility of Analyses of [^{14}C]Arachidonic Acid (AA) and Its Metabolites

Peak[a]	Metabolite[b]	% of Injected radioactivity[c]	Coefficient of variation (%)
A	AA	7.1 ± 0.04	0.6
B	12-HHT	3.1 ± 0.26	8.4
C+E	12-HETE	18.4 ± 0.94	5.1
D	EPHETA	8.6 ± 0.02	0.2
F+G+H	THETEs	18.6 ± 0.34	1.8
I	TXB_2	6.6 ± 0.25	3.8

[a]Peaks designated by letter refer to Figure 1.
[b]12-HHT, 12-hydroxyheptadecatrienoic acid; 12-HETE, 12-hydroxyeicosatetraenoic acid; EPHETA, 11,12-epoxy-10-hydroxyeicosa-5,8,14-trienoic acid; THETE, trihydroxyeicosa-5,9,14-trienoic acid; TXB_2, thromboxane B_2.
[c]514 Bq (n = 3).

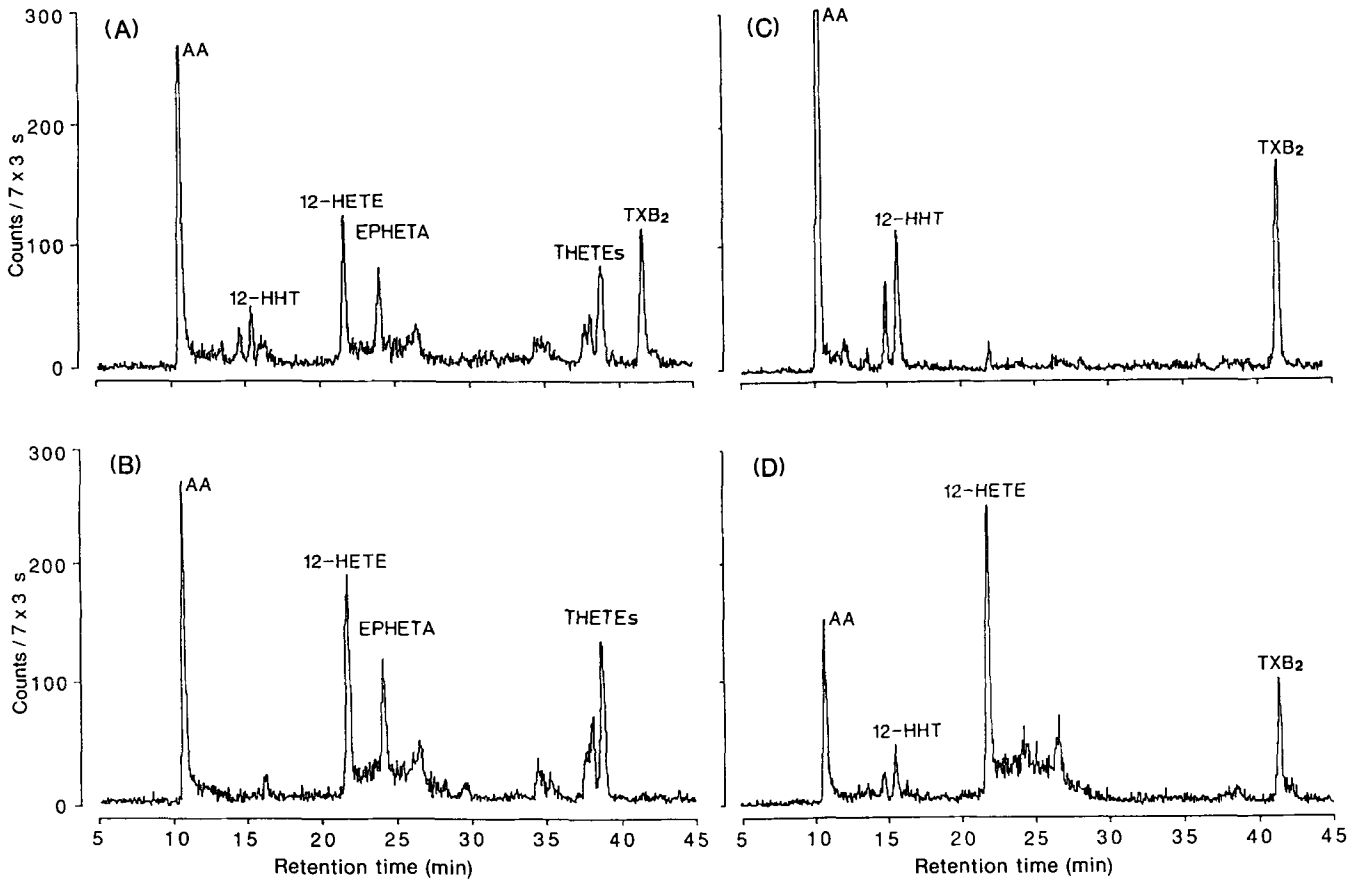

FIG. 3. Effects of inhibitors on [^{14}C]AA metabolism. One mL of platelets homogenate (*ca.* 1 mg protein/mL) was preincubated for 5 min with inhibitors (added in 1 μL ethanol) prior to addition of [^{14}C]AA (10 nmol, 8 kBq). Other procedures were as described in the Experimental section. Injected radioactivity, 300–500 Bq; (A), control; (B), indomethacin (56 μM); (C), baicalein (10 μM); (D), GSH (1 mM). Abbreviations as in Table 1.

G (MU; 31.3) and H (MU; 31.6) were almost identical. The metabolites reflected in these peaks were identified as a mixture of stereoisomers of 8,9,12-trihydroxyeicosa-5,10, 14-trienoic acid (8,9,12-THETE) and 8,11,12-THETE because the mass spectra showed the characteristic fragment ions at *m/z* 241 and 271 with similar intensity; this means preferential fragmentation occurs between the two adjacent DMiPS-substituted hydroxyl groups in 8,9,12- and 8,11,12-THETEs, respectively.

Thermal decomposition on a GC column has been noted in the analysis of HETEs (31,32). Some decomposition for 12-HETE was also observed in our investigation. Figure 2 shows a radiochromatogram of authentic [^{3}H]12-HETE after derivatization. The main peak (t_R 21.1 min; MU 26.1) is followed by a slightly elevated background and then by the second peak (t_R 25.5 min; MU 27.7). The MU value of the second peak was identical to that of peak E in Figure 1.

The counting reproducibility of the GC/SARD system was determined by repeated injections (n = 3). Each peak radioactivity was calculated based on the GC peak yields. The GC peak yields of the metabolites, except for 12-HETE, were assumed to be equal to that of AA (22). The GC peak yield of 12-HETE was 34.2% (coefficient of variation 5.7%, n = 3). The intra-assay coefficients of variation in GC/SARD analyses were less than 10% (Table 1).

Inhibition studies were performed in order to confirm the validity of the present method. [^{14}C]AA was incubated with platelets in the presence of indomethacin (56 μM), baicalein (10μM) or GSH (1 mM). Examples of the radiochromatograms obtained are shown in Figure 3. Indomethacin inhibited cyclooxygenase and eliminated 12-HHT and TXB_2. Baicalein, a selected inhibitor of 12-lipoxygenase, inhibited formation of 12-HETE, EPHETA, 8,9,12-THETE and 8,11,12-THETE. GSH inhibited formation of EPHETA, 8,9,12-THETE and 8,11,12-THETE but increased formation of 12-HETE by GSH-dependent peroxidase (33,34).

The present capillary GC/SARD approach provides a useful method for profiling AA metabolites and can also be used to detect inhibitors of AA metabolism.

ARTICLE

Dependence of the Bilayer Phase Transition Temperatures on the Structural Parameters of Phosphatidylcholines

C. Huang*, Shusen Li, Zhao-qing Wang and **Hai-nan Lin**
Department of Biochemistry, Health Sciences Center, University of Virginia, Charlottesville, Virginia 22908

Most saturated diacyl phosphatidylcholines C(X):C(Y)PC (saturated 1,2-diacyl-*sn*-glycero-3-phosphocholine with X carbons in the *sn*-1 acyl chain and Y carbons in the *sn*-2 acyl chain), in excess water, can self-assemble into lamellae which, upon heating, may undergo multiple thermotropic phase transitions at well-defined, discrete temperatures. The transition temperature corresponding to the main or the gel to liquid-crystalline phase transition (T_m) is known for many bilayers of fully hydrated phosphatidylcholines. In this study, we have analyzed the T_m values of 44 molecular species of phosphatidylcholines in terms of their structural and packing characteristics in the gel-state bilayer. Two general equations are thus derived: $T_m = 162.26 - 3651.71\ (1/N) - 88.42\ (\Delta C/N)$ for C(X):C(Y)PC with $X \geqslant Y$, and $T_m = 157.68 - 3525.44\ (1/N) - 93.28\ (\Delta C/N)$ for C(X):C(Y)PC with $X < Y$. Here, N is the minimal hydrophobic thickness of the dimeric C(X):C(Y)PC in the gel-state bilayer and ΔC is the effective chain length difference between the *sn*-1 and *sn*-2 acyl chains for the monomeric C(X):C(Y)PC in the gel-state bilayer. The advantage of these two equations in predicting the T_m values for phosphatidylcholines with ΔC/CL values in the range of 0.07 to 0.40 is their simplicity. A figure containing a total of 173 calculated T_m values is also presented.
Lipids 28, 365–370 (1993).

A fundamental and important concept of biochemistry is that the structural characteristics of biomolecules existing as either monomers or aggregated assemblies are ultimately responsible for their physical and chemical properties in the cell and in aqueous solution, under physiological conditions. Of the many physical properties associated with the main or the gel to liquid-crystalline phase transition for phospholipid bilayers in aqueous solution, the phase transition temperature (T_m) is the one that can be most accurately determined experimentally (1–3). The T_m values for aqueous lipid dispersions prepared from saturated, identical-chain phosphatidylcholines have been shown by several groups (4,5) to be related to certain structural features of the lipid molecules, such as the acyl chain length and the chain end perturbation (6,7). More recently, the structure-property relationship has been extended further (8) to include mixed-chain phosphatidylcholines, thus allowing the accurate prediction of T_m values from the structural characteristics expressed by a large number of phosphatidylcholines. The general equation of Huang (8), $T_m = 154.2 + 2.0\ (\Delta C) - 142.8\ (\Delta C/CL) - 1512.5\ (1/CL)$, has four terms with three variables (ΔC, ΔC/CL and 1/CL); moreover, these variables are related to two structural parameters (ΔC and CL) which are determined by the conformations of the two acyl chains of a monomeric phosphatidylcholine molecule in the gel-state bilayer. Here, the structural parameter ΔC denotes the effective chain length difference (in C-C bonds lengths along the chain) between the two acyl chains, and the other structural parameter, CL, is the effective length of the longer of the two acyl chain, also in C-C bonds (9,10), as shown in Figure 1A.

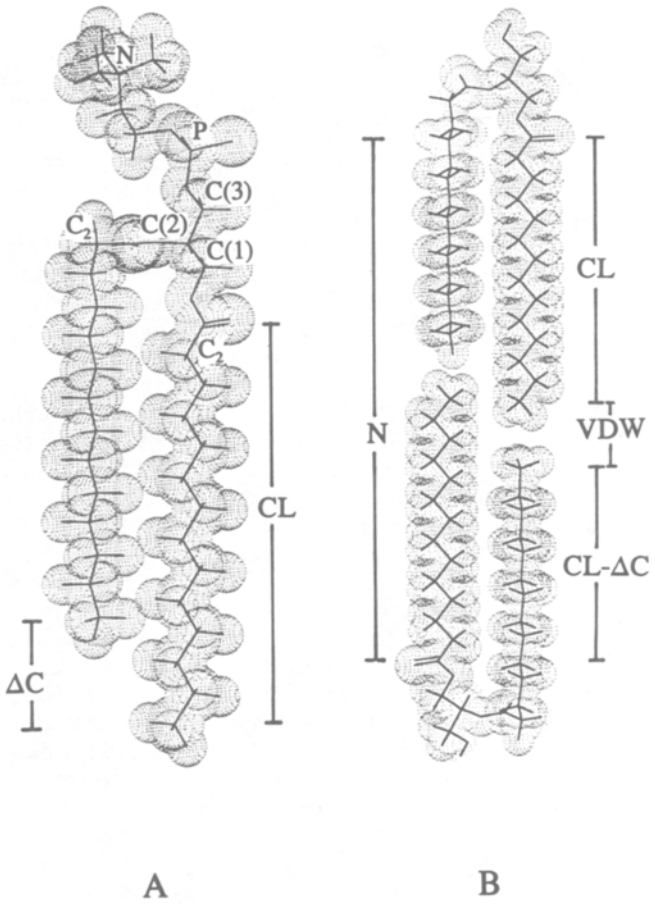

FIG. 1. Computer-generated diagrams to illustrate the acyl chain packing in (A) single crystal of C(14):C(14)PC, (B) a dimeric packing unit of C(X):C(Y)PC (saturated 1,2-diacyl-*sn*-glycero-3-phosphocholine with X carbons in the *sn*-1 acyl chain and Y carbons in the *sn*2 acyl chain) constructed based on the monomeric structure of (A). Only the diglyceride moiety of the lipid molecule is drawn in (B). ΔC is the effective chain length difference between the two chains in a monomeric lipid molecule. It equals 1.5 C-C bond lengths for C(14):C(14)PC in the gel-state bilayer. CL is the effective length of the longer of the two acyl chains. N is the distance separating the two carbonyl oxygens of the *sn*-1 acyl chains. VDW is the Van der Waals distance separating the two methyl termini.

Abbreviations: C(X):C(Y)PC, saturated 1,2-diacyl-*sn*-glycero-3-phosphocholine with X carbons in the *sn*-1 acyl chain and Y carbons in the *sn*-2 acyl chain; MW, molecular weight; RMSE, root mean square error; T_m, the phase transition temperature; VDW, Van der Waals distance.

The ratio of ΔC/CL is thus the normalized chain length difference for phosphatidylcholines in the highly ordered gel state.

In this communication, alternative equations are presented for predicting the T_m values for fully hydrated saturated phosphatidylcholines which can undergo the gel to liquid-crystalline phase transition upon heating. In this new approach, the transition temperature is also related to two structural parameters (N and ΔC). These equations, however, are simpler, having only three terms. Moreover, the predictive power is also improved in comparison with that of the general equation of Huang (8).

RESULTS

The structural parameters: ΔC, ΔC/CL and N. Prior to defining the various structural parameters, it is appropriate to briefly mention the structural characteristics of the two acyl chains in dimyristoyl phosphatidylcholine, C(14):C(14)PC. This is an identical-chain phosphatidylcholine whose crystal structure has been determined by X-ray diffraction technique (11). In single crystals, the C(1) and C(2) carbon atoms of the glycerol backbone and the fatty acyl chain ester-linked to the *sn*-1 position of the glycerol C(1) atom form an all *trans* zigzag chain (Fig. 1A). The initial segment of the *sn*-2 acyl chain, however, extends perpendicularly from the *sn*-1 acyl chain, but bends over at the second carbon atom, C_2, to become parallel to the *sn*-1 acyl chain, as schematically illustrated in Figure 1A. Moreover, the orientation of the two chain planes within each lipid molecule is alternately parallel and perpendicular to each other in the bilayer assembly. In Figure 1A, the two zigzag planes of the *sn*-1 and *sn*-2 acyl chains of a C(14):C(14)PC molecule are shown to be perpendicular to each other. Another structural feature of the two acyl chains, as illustrated in Figure 1A, is that the two terminal methyl groups are mismatched. This mismatch is defined as the effective chain length difference (ΔC) between the two acyl chains which, for C(14):C(14)PC in the crystalline state, is about 3.7 Å or 3.0 carbon-carbon bond lengths along the long chain axis. The two acyl chains are tilted with an angle of about 12°C relative to the axis perpendicular to the bilayer surface. For identical-chain C(14):C(14)PC in the gel-state bilayer, the structural features of the lipid acyl chains observed in the single crystals are essentially preserved; however, the chains are tilted more with an angle of about 30°C (12) and the axial displacement of the two methyl termini along the bilayer normal is about 1.5 carbon-carbon bond lengths (13).

The structural parameter ΔC is defined for a C(X):C(Y)PC (saturated 1,2-diacyl-*sn*-glycero-3-phosphocholine with X carbons in the *sn*-1 acyl chain and Y carbons in the *sn*-2 acyl chain) molecule in the gel-state bilayer based on the inherent mismatch of 1.5 C-C bond lengths between the two terminal methyl groups in the monomeric C(14):C(14)PC as follows: $\Delta C = |(X - 1) - (Y - 1 - 1.5)| = |X - Y + 1.5|$, where X and Y are the total numbers of carbon atoms in the saturated *sn*-1 and *sn*-2 acyl chains, respectively. The normalized chain length difference between the *sn*-1 and *sn*-2 acyl chain for a C(X):C(Y)PC molecule in the gel-state bilayer is expressed as ΔC/CL, where CL is the effective length of the longer of the two acyl chains in C-C distance along the chain.

When two phosphatidylcholine molecules are packed in the partially interdigitated mode, as shown in Figure 1B, a structural parameter, N, can be employed to specify the distance between the two carbonyl oxygens of the *sn*-1 acyl chains in the two opposing bilayer leaflets. This distance is tantamount to the minimal hydrophobic thickness of a dimeric unit of phosphatidylcholine molecules packed in the gel-state bilayer, and it can be expressed in C-C bond lengths along the long molecular axis of the lipid. As shown in Figure 1, the structural parameter, N, of the dimeric unit is related to the two structural parameters of the monomer (ΔC and CL) as follows: $N = 2CL - \Delta C + VDW$. For C(X):C(Y)PC with $X \geq Y$, it can easily be shown that the value of N is related to X and Y as follows: $N = 2(X\text{-}1) - (X\text{-}Y + 1.5) + VDW$ (Van der Waals distance) $= X + Y - 0.5$, where the VDW between the two opposing terminal methyl groups is assumed to be three C-C bond lengths along the chain. In fact, this equation of $N = X + Y - 0.5$ is general for all gel-state phosphatidylcholines, C(X):C(Y)PC, which are packed in the partially interdigitated mode.

The main phase transition temperature as a function of lipid structural parameters. In the past three years we have examined the thermotropic phase behavior of aqueous dispersions prepared from four series of saturated diacyl phosphatidylcholines by high-resolution differential scanning calorimetry (14-16). Within each series, all members have a common molecular weight (MW); however, the values of ΔC/CL are varied progressively from 0.05 to 0.67. When the T_m (or ΔH) values of these four series of lipids are plotted against the normalized acyl chain length difference, biphasic curves as shown in Figure 2 are observed. We find that in the T_m (or ΔH) *vs.* ΔC/CL plot, the T_m (or ΔH) value of the lipid dispersion within each of the four series decreases initially with increasing chain asymmetry. In fact, within the range of ΔC/CL values of 0.09–0.40, the experimental T_m values appear to fall on a linear curve. The minimum value of T_m within each lipid series corresponds to the phosphatidylcholine molecule with a ΔC/CL value of about 0.41. Beyond the minimum value, the T_m value increases with increasing value of ΔC/CL; moreover, the data fall on a bell-shaped curve with the maximum value of T_m at ΔC/CL of about 0.56. A detailed interpretation of the biphasic phenomenon is given elsewhere (15,16).

All the published calorimetric T_m values for saturated diacyl phosphatidylcholines with ΔC/CL values ranging from 0.07 to 0.40 are summarized in Table 1. There are 44 data points, 24 of them belong to the four homologous series of lipids labelled as the C(14):C(14)PC, C(15):C(15)PC, C(16):C(16)PC and C(17):C(17)PC series. The T_m values of these 24 lipids are plotted in Figure 3 against ΔC/N. Clearly, within each series, the T_m values of lipids with longer *sn*-2 acyl chains can fit into a curve which lies slightly but consistently below the T_m curve for lipids with longer *sn*-1 acyl chains. The difference in T_m, albeit small, can be assumed to arise from the possibility that the lipid-lipid interaction for C(X):C(Y)PC with $X > Y$, in the gel-state bilayer, is somewhat different from that for C(X):C(Y)PC with $Y > X$.

The dependence of T_m on structural parameters. An interesting feature of the experimental data shown in Figure 3 is that the T_m values for various C(X):C(Y)PC with constant values of MW are linear functions of ΔC/N.

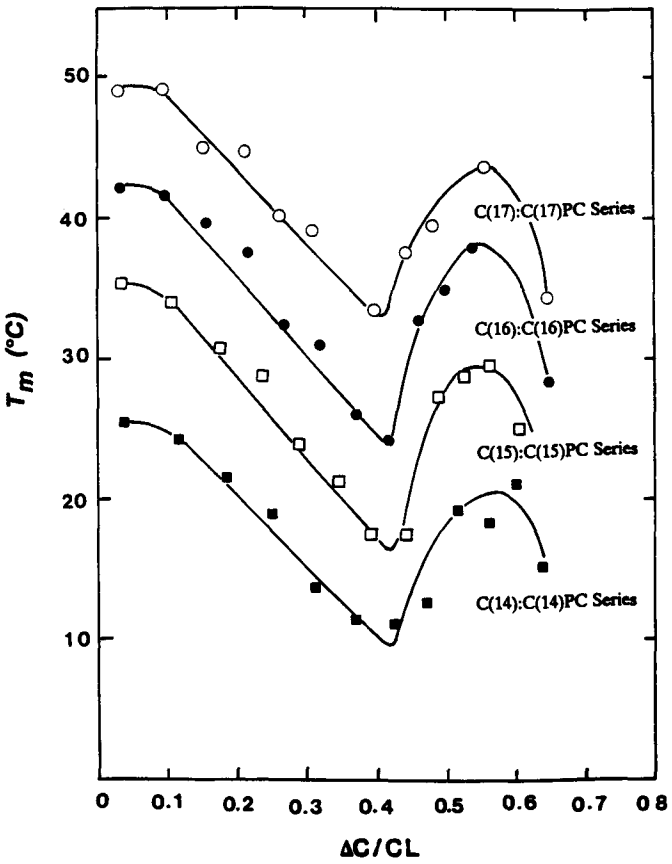

FIG. 2. Plot of the main phase-transition temperature (T_m) *vs.* the normalized chain length difference (ΔC/CL) between the two acyl chains of various phosphatidylcholines. The various phosphatidylcholines are grouped into four homologous series according to their molecular weight (MW), and the MW of the four series correspond to those of C(17):C(17)PC, C(16):C(16)PC, C(15):C(15)PC and C(14):C(14)PC, respectively.

Similarly, linear lines fitting T_m values are observed at constant ΔC values in the T_m *vs.* ΔC/N plot. These linear property-structure relationships suggest that the T_m value of the C(X):C(Y)PC bilayer may depend on the interplay of the two structural parameters ΔC and N. That is, $T_m = a_0 + a_1\,(1/N) + a_2\,(\Delta C/N) + \ldots$ might give a good fit to all T_m data obtained from aqueous dispersions of C(X):C(Y)PC with X > Y or with X < Y, where a_0, a_1 and a_2 are constants.

When the 22 experimentally observed T_m values of C(X):C(Y)PC with X ⩾ Y, shown in Table 1 (points Nos. 1-22), are subjected to statistical analysis using a multiple regression approach, a regression equation of $T_m = 162.26 - 3651.71\,(1/N) - 88.42\,(\Delta C/N)$ is obtained, with a correlation coefficient (σ) of 0.9996 and a root mean square error (RMSE) of 0.4791. Similarly, a regression equation of $T_m = 157.68 - 3525.44\,(1/N) - 93.28\,(\Delta C/N)$ with $\sigma = 0.9995$ and RMSE = 0.5332 is obtained for C(X):C(Y)PC with X < Y, when the other 22 T_m values from Table 1 (points Nos. 23-44) are subjected to multiple regression analysis.

The calculated and the experimental T_m values for all 44 molecular species of phosphatidylcholines are compared and the results are summarized in Table 1. Within each set of the data, only one lipid exhibits a deviation of greater than 1°C between the calculated and the observed T_m values (ΔT_m). The greatest deviation is observed for C(17):C(15)PC. This deviation, 1.2°C, corresponds to a relative error of 3.3% in °C or a relative error of 0.4% in absolute temperature. Because of the excellent agreement between the calculated and experimental T_m values, the two regression equations, $T_m = 162.26 - 3651.71\,(1/N) - 88.42\,(\Delta C/N)$ for C(X):C(Y)PC with X ⩾ Y and $T_m = 157.68 - 3525.44\,(1/N) - 93.28\,(\Delta C/N)$ for C(X):C(Y)PC with X < Y, can be used reliably to predict the T_m values for C(X):C(Y)PC with ΔC/CL values in the range of 0.07-0.40. Consequently, a table containing a total of 173 predicted T_m values is presented in Figure 4.

DISCUSSION

It has long been recognized that in excess water all saturated diacyl phosphatidylcholines with long acyl chains exhibit unique transition characteristics upon heating, and that the main phase transition temperature (T_m) increases with increasing chain length, all other things being equal (17,18). Recently we have examined and analyzed the structure-property relationship for a large number of saturated diacyl phosphatidylcholines C(X):C(Y)PC; we showed that the T_m values for various C(X):C(Y)PC with ΔC/CL values in the range of 0.09-0.40 can be related to the structural parameters ΔC and CL as follows (8): $T_m = 154.2 + 2.0\,(\Delta C) - 142.8\,(\Delta C/CL) - 1512.5\,(1/CL)$. This general equation of Huang's (8) was derived based on (i) the statistical analysis of T_m values obtained with 23 molecular species of C(X):C(Y)PC; and (ii) the structural parameters (ΔC and CL) associated with the monomeric unit of C(X):C(Y)PC in the gel-state bilayer. Although the predictive power of the general equation of Huang (8) is very high, this equation is cumbersome, having four terms and three variables (ΔC, ΔC/CL and 1/CL).

More experimental T_m values for fully hydrated C(X):C(Y)PC with ΔC/CL values in the range of 0.07-0.40 have been published (17,18); hence, the data base for our statistical analysis can be expanded to include 44 T_m values. Together with the knowledge of the proposed dimeric packing model for C(X):C(Y)PC in the gel-state bilayer as given in Figure 1B, we now derive the following two equations:

For C(X):C(Y)PC with X ⩾ Y

$$T_m = 162.26 - 3651.71\,(1/N) - 88.42\,(\Delta C/N) \quad [1]$$

with $\sigma = 0.99962$, RMSE = 0.47910

For C(X):C(Y)PC with X < Y

$$T_m = 157.68 - 3525.44\,(1/N) - 93.28\,(\Delta C/N) \quad [2]$$

with $\sigma = 0.99951$, RMSE = 0.53319

where σ is the correlation coefficient.

The major advantage of these two new equations is their simplicity. Each equation has only three terms with two variables (1/N and ΔC/N). A single equation can also be derived to fit all 44 data points. This equation, $T_m = 158.67 - 3532.18\,(1/N) - 94.99\,(\Delta C/N)$ with $\sigma = 0.99883$ and RMSE = 0.83735, is less accurate in predicting T_m due to its smaller value of σ and larger value of RMSE.

[a]Lipids from Nos. 1–22 are C(X):C(Y)PC with X ⩾ Y, and the calculated values of T_m^{cal} (column 6) are obtained from $T_m = 162.26 - 3651.71\ (1/N) - 88.42\ (\Delta C/N)$. Lipids from Nos. 23–44 are C(X):C(Y)PC with X < Y, and the calculated values of T_m^{cal} (column 6) are obtained from $T_m = 157.68 - 3525.44\ (1/N) - 93.28\ (\Delta C/N)$.

[b]Unpublished calorimetric results from this laboratory.

The general equation of Huang (8) also can be revised based on the available T_m values of 44 points, and the resulting equation is $T_m = 153.67 - 1.73\Delta C - 1498.03\ (1/CL) - 139.66\ (\Delta C/CL)$ with $\sigma = 0.9986$ and RMSE = 0.90878. Judging from the correlation coefficient and the RMSE, the accuracy of the revised equation is inferior in comparison with the two new equations presented in this paper. The general equation of Huang (8) also can be considered separately for C(X):C(Y)PC with longer or with shorter *sn*-1 acyl chain. The resulting equations are: $T_m = 154.86 + 1.75\Delta C - 1521.03\ (1/CL) - 136.97\ (\Delta C/CL)$ with $\sigma = 0.9989$ and RMSE = 0.81287 for C(X):C(Y)PC with longer *sn*-1 acyl chain (X ⩾ Y), and $T_m = 148.92 + 3.01\ \Delta C - 1406.26\ (1/CL) - 166.33\ (\Delta C/CL)$ with $\sigma = 0.9993$ and RMSE = 0.63108 for C(X):C(Y)PC with longer *sn*-2 acyl chain (X < Y). Again, the accuracy of predicting T_m values for these two equations can be compared with that of Equations 1 and 2 according to their σ and RMSE values. Clearly, Equations 1 and 2 are better in predicting the T_m values for C(X):C(Y)PC.

The fact that Equations 1 and 2 are simpler and better than the general equation of Huang (8) can be attributed to the different structural models employed in deriving the structure-property relationship. The basic structural model used in deriving Equation 1 or Equation 2 is a dimeric model (Fig. 1B), whereas the earlier equation of

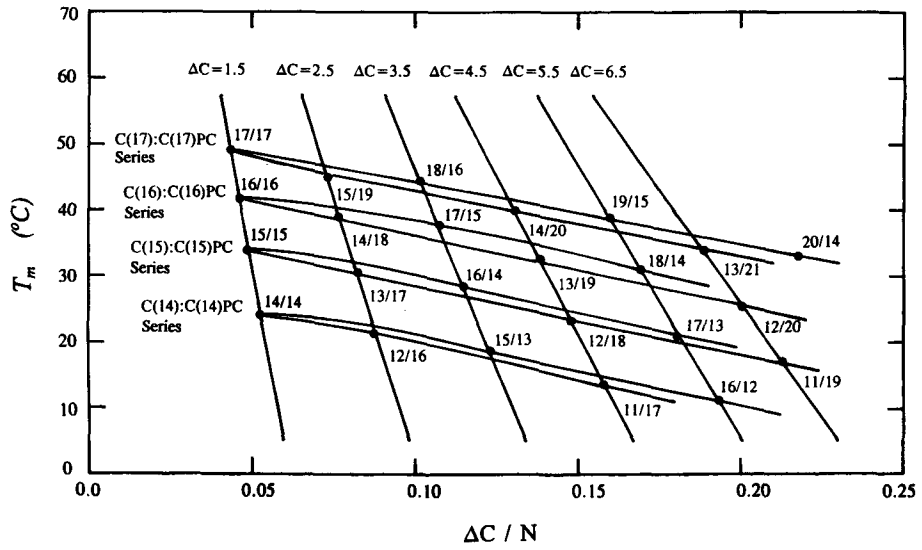

FIG. 3. The main phase transition temperature (T_m) *vs.* ΔC/N. The numeric ratio, X/Y, next to each data point is the ratio of the numbers of carbon atoms in the *sn*-1 and *sn*-2 acyl chains of the C(X):C(Y)PC molecular species, respectively. C(X):C(Y)PC as defined in Figure 1.

FIG. 4. Calculated T_m values for 173 molecular species of saturated diacyl phosphatidylcholines. The X and Y values in C(X):C(Y)PC are illustrated on the vertical and horizontal axes, respectively. The values of ΔC/N and T_m are shown in a square box which represents a defined molecular species of C(X):C(Y)PC. The ΔC/N and T_m values are printed in italic and boldface, respectively. Abbreviations as in Figure 3.

Huang (8) is based on a structural model of the monomer. Much structural information is inherently incorporated with a dimeric unit; consequently, a dimeric model ultimately leads to improved characterizations of the structure-property relationship for phospholipid bilayers.

Finally, we should comment on the physical meaning of the individual term in each of the two derived equations. The first term, a constant, corresponds to the maximal T_m value for the lipid bilayer comprised of phosphatidylcholine molecules with infinitely long acyl chains. The second term relates to the negative value of the inverse of the minimal hydrophobic thickness (N). As the minimal hydrophobic thickness becomes progressively larger, the T_m value correspondingly becomes higher. The third term can be regarded as a perturbation term. The close chain-chain interaction in the gel-state bilayer may be perturbed by the bulky chain terminal methyl groups and this perturbation is reflected by the negative value of ΔC (15,16). At a constant value of N, the ratio of $\Delta C/N$ in the third term is negative, thus making a negative contribution to the overall T_m value of the lipid system under study. Briefly, the equations derived in this paper emphasize that the T_m values of saturated diacyl phosphatidylcholines in excess water depend critically on the interplay of two structural parameters, ΔC and N, obtained from the dimeric lipid molecules in the gel-state bilayer.

Phosphatidylcholine as Substrate for Human Pancreatic Phospholipase A_2. Importance of the Physical State of the Substrate

Bengt Borgström*
Department of Physiological Chemistry, University of Lund, S-22100, Lund, Sweden

The long-chain phosphatidylcholine/sodium cholate aqueous system as substrate for human pancreatic phospholipase A_2 (PLA_2) was investigated. At a constant phosphatidylcholine (PC) concentration of 8 mM, the enzyme activity increased with a decrease in cholate (C) concentration up to a PC/C ratio of approximately 0.8 and then rather abruptly decreased to lower values at a ratio above 1.5. At ratios between 0.8 and 1.5, an increasing lag phase in the PLA_2 activity was seen, indicating a progressive decrease in substrate availability to the enzyme. Reaction mixtures with a PC/C ratio of up to 0.67 were optically clear solutions composed of mixed bile salt/PC micelles of increasing mixed micellar aggregate size. Ratios between 0.67 and 1.5 were characterized by an increase in turbidity (at 330 and 450 nm) due to increasing formation of vesicles or liposomes. Above a PC/C ratio of 1.5, a sharp increase in turbidity was seen due to increasing formation of bilayer structures other than vesicles. Pure vesicles obtained by dialysis of mixed micellar solutions were not hydrolyzed by the enzyme. Addition of bile salts reversed the inhibition which was accompanied by a decrease in turbidity. Phosphatidylcholine was preferred as substrate for human PLA_2 when present in large mixed disc-like bile salt micelles. Vesicular or other types of lamellar liquid-crystalline phases of long-chain phosphatidylcholine did not serve as substrate for PLA_2.
Lipids 28, 371-375 (1993).

The activity of pancreatic phospholipase A_2 (PLA_2) [EC 3.1.1.4] against long-chain unsaturated phosphatidylcholine (PC) dispersed in bile salt (BS) solution depends on the molar PC/BS ratio (1). Optimal activity has been reported to occur at a ratio of about 0.5, varying somewhat with the structure of the components. PLA_2 was found not to hydrolyze PC at a PC/BS molar ratio greater than 1 or less than 0.2 (1). With respect to the physical state of the substrate, it was observed that an optically clear micellar solution was obtained at a PC/BS molar ratio below 0.4. The substrates used were human bile, intralipid emulsions or PC from egg yolk dispersed in a mixed trihydroxy-dihydroxy-conjugated bile salt solution; the physical state of the substrates was not further characterized. Hoffman *et al.* (2) studied the activity of porcine PLA_2 on egg PC/cholate (C) mixed micellar solutions at 5 mM PC. They found that the enzyme activity was related to the molar PC/C ratio within the mixed micelle rather than to the bulk concentration of PC. When the ratio of micellar PC to C within the micelle was varied from 0.2 to 2.0, the enzyme activity was increased 10-fold. Long-chain unsaturated PC, which forms bilayer structures (vesicles) in water, has generally been found to be a poor substrate for PLA_2 (3,4). PC/BS mixed micellar aggregates are thus good substrates for PLA_2 but it is unclear to what extent other types of PC aggregates will function as substrates. In view of the increase in knowledge that has been gained in recent years on the physical state of the aqueous long-chain PC/BS system (5-7), it seemed of interest to further characterize the interaction of PLA_2 with experimentally defined physical substrate structures. A study with a partially similar objective was published (8) when the present work was well under way.

Abbreviations: BS, bile salt; C, cholate; IMC, intermicellar concentration; MW, molecular weight; PC, phosphatidylcholine; PLA_2, phospholipase A_2; SDS, sodium dodecylsulfate; TLC, thin-layer chromatography.

MATERIALS AND METHODS

Materials. PC, prepared from soybean (Epikuron 200), was kindly supplied by Lucas Meyer (Hamburg, Germany), it was better than 95% pure as confirmed by thin-layer chromatography (TLC). The main fatty acid components were: saturated fatty acids, 18%; 18:1, 12%; 18:2, 65%; and 18:3, 5%. Sodium cholate (C) was purchased from Serva (Heidelberg, Germany) and was better than 99% pure as judged by TLC. Human PLA_2 was prepared from pancreatic juice essentially according to Grataroli *et al.* (9). The enzyme was pure according to sodium dodecyl sulfate (SDS)/polyacrylamide gel electrophoresis. A preparation with an optical density of 1.46 at 280 nm was used. Centricon-10 [10,000 molecular weight (MW) cutoff] and Centricon-100 (100,000 MW cutoff) filters were products of Amicon (Amicon Division, W.R. Grace and Co., Danvers, MA). The filters were used as described in the manufacturer's manual. The radioactive products 1-palmitoyl-2-[9,10-^{3}H]oleoyl PC and [^{14}C]cholate were from Amersham (Buckinghamshire, England).

Determination of PLA_2 activity. The availability of substrate for the enzyme was measured titrimetrically using a Mettler pH stat assembly (Mettler Instruments A.G., Zürich, Switzerland). Ten mL portions of the PC/C dispersions were pipetted into glass vials, the pH was adjusted to 8.0 and 10-20 μL of the enzyme solution was added. The pH was maintained at 8 for at least 10 min, and the activity was calculated from the slope of the titration curve in μmole/min. With samples with a PC/C ratio of 0.8 to 1.5, a latency period was initially seen before the steady state was reached. This type of titration curve is often observed with PLA_2, and initial rates as well as steady state rates have been calculated. By extrapolating the steady state curve to the time axis, the lag time (in min) was calculated.

Preparation of micellar solutions and vesicles. PC in aqueous C solution was dispersed as described by Almog *et al.* (6) either by hydration of lipid films in 135 mM NaCl or by rapid dilution of concentrated mixed micellar dispersions into 135 mM NaCl solutions. In the former case, PC and NaC were weighed into glass flasks and dissolved in chloroform/methanol (1:1, vol/vol). The solvent was

evaporated to form a thin film, and the flasks were kept under vacuum overnight to remove residual solvent. The lipids were then dispersed by adding the appropriate volume of buffer that was 135 mM in NaCl, 1 mM in Ca^{2+} and 0.5 mM in Tris/HCl, pH 8.0. Equilibration was rapid and the dispersions were used 1–2 h after preparation.

In the dilution experiments, aqueous solutions were prepared which were 100 mM in PC and 50–100 mM in NaC. These were clear micellar solutions, except for the PC/C solutions of ratios 100:62.5 and 100:50, which were turbid. Dilutions were then made by mixing 8 mL of the above solutions with 92 mL of the above buffers, or buffers with NaC when appropriate, under constant stirring. This way, dilutions of PC were obtained in the PC/C range from 8:32 to 8:4, which all contained a dilution of PC of 1:12.5. The rate of vesiculation was fast and maximum turbidity, when present, was reached after 1–2 h; this was followed by a steady state over 24 h. The solutions were in general allowed to "age" at room temperature overnight before being used as substrates. Turbidity of the dispersions was measured at 330 and 450 nm using a Hitachi U-1 100 spectrophotometer (Tokyo, Japan).

Filtration of PC dispersions using Centricon filters. Generally clear filtrates were obtained. The filtration rates were slow in some cases with dispersions of high turbidity. In such cases better filtration rates were obtained with the Centricon-10 filters if the dispersion were pre-filtered through a Centricon-100 filter. In the filtration studies, radioactively-labeled PC and C were used to calculate concentrations in the filtrates. Appropriate amounts of PC and C were mixed in a glass flask with 1-palmitoyl-2-[9,10-^{3}H]oleoyl PC and [^{14}C]cholate in chloroform/methanol solution. The solvent was evaporated after the solutions became clear. The dried films were dispersed in buffer under constant stirring. Samples were taken for determination of radioactivity before filtration and from the filtrates.

RESULTS

The importance of the PC/C ratio for the activity of PLA_2. The PC concentration in the bulk phase was kept constant at 8 mM and the C concentration was varied from 4 to 32 mM. In the experiments, the results of which are given in Figure 1, the dispersions were prepared by hydrating the dry PC/C film in buffer. The films were dispersed by the use of a magnetic stirrer. At low PC/C ratio the solutions were clear and the optical density at 330 and 450 nm low until a PC/C ratio of 0.67. At this point the values started to increase more sharply at 330 than at 450 nm, with a discontinuity at a molar ratio of PC/C of 1.5. Increasing turbidity of the solutions above a ratio of 0.67 was also observable in normal light. The activity of PLA_2 increased from the PC/C of 0.25 up to approximately 0.8 and then dropped abruptly. At PC/C ratios of 0.89 to 1.14, a lag phase was seen before a constant rate of hydrolysis was attained. The lag time increased with increasing PC/C ratio and became very long; for a PC/C ratio of 1.6 a constant and low rate of hydrolysis could only be seen after 90 min of incubation. At even higher ratios the lag time became too long to be experimentally measured.

Vesicles (or liposomes) as substrate for PLA_2 and the effect of adding C. Liposomes were prepared by diluting

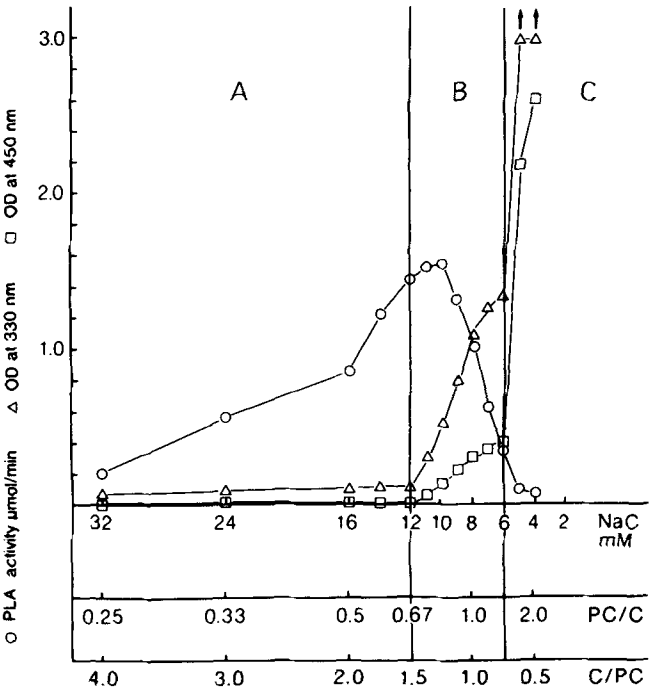

FIG. 1. Plots of phospholipase A_2 (PLA_2) activity (○), optical density (OD) at 330 nm (△) and 450 nm (□) over concentration of cholate (C), the phosphatidylcholine (PC)/C ratio, and C/PC ratio. The dispersions were 8 mM in soybean PC, 135 mM in NaCl and 1 mM in CaCl. NaC, sodium cholate.

a micellar solution of PC/C, 100 mM of each, 12.5 times in 135 mM NaCl and by leaving it overnight. This dispersion had an optical density at 450 nm of 0.33 and was dialyzed against two changes of 10 times the volume of the sodium chloride buffer. During the dialysis the optical density increased to 0.49. The liposome suspension was not hydrolyzed by PLA_2. When C was added back to the liposomal dispersions, they cleared and became substrates for the enzyme. Such an experiment is seen in Figure 2. Turbidity of the liposomal dispersions decreased after adding C. PLA_2 activity was measured 2 h after the addition of C. At low cholate and high turbidity a lag time was seen; at a concentration of 3.8 mM (PC/C 2.0) the lag time was 47 min, at 7.4 mM C (PC/C 1.0) no lag time was seen.

After diluting PC/C (100:100) 12.5 times in 135 mM NaCl, maximal turbidity was reached after 1–2 h, followed by a steady state for at least 24 h. The PLA_2 activity followed the same pattern with a tendency to a slow decrease over time (not shown). The results indicate that formation of liposomes (vesiculation) is a fast process and that the liposomes are rather stable. They also show that dissolution of vesicles by bile salt is a fast process.

Filtration of PC/C dispersions of different ratios through Centricon filters. The results of these experiments are seen in Figures 3 and 4. No PC passed the Centricon-10 filter with a molecular cutoff of MW 10,000 at any BS concentration (Fig. 3). This means that no mixed micelles passed this filter. The C concentration in the filtrates increased linearly with total C concentration, and thus represents the intermicellar concentration of C (monomers + simple C micelles) (10). From these figures the PC/C ratio in aggregated form in the bulk phase can be calculated and

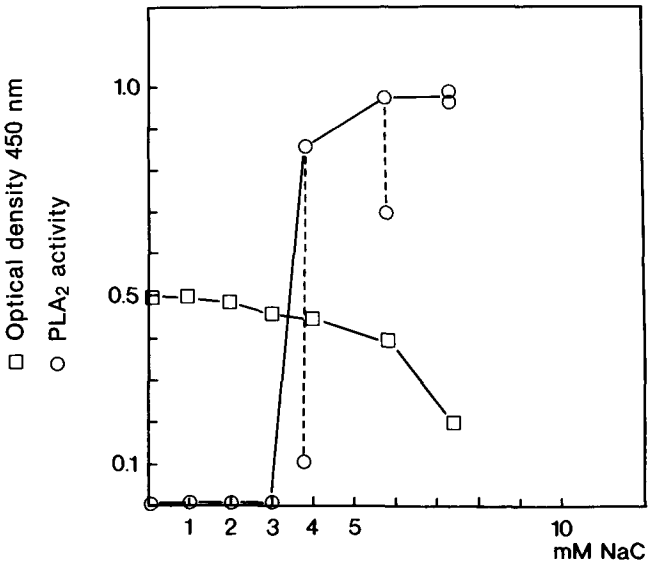

FIG. 2. Phospholipase A_2 (PLA_2) activity (μmol/min) (○) and optical density at 450 nm (□) of liposomal dispersions of 8 mM PC 2 h after the addition of sodium cholate (NaC) to obtain different final concentrations of cholate. At intermediate bile salt concentrations there was a lag phase before PLA_2 activity reached a steady state. In the figure the initial rates are connected by a broken line with the corresponding final steady state rates. At low cholate concentrations, no PLA_2 activity was seen.

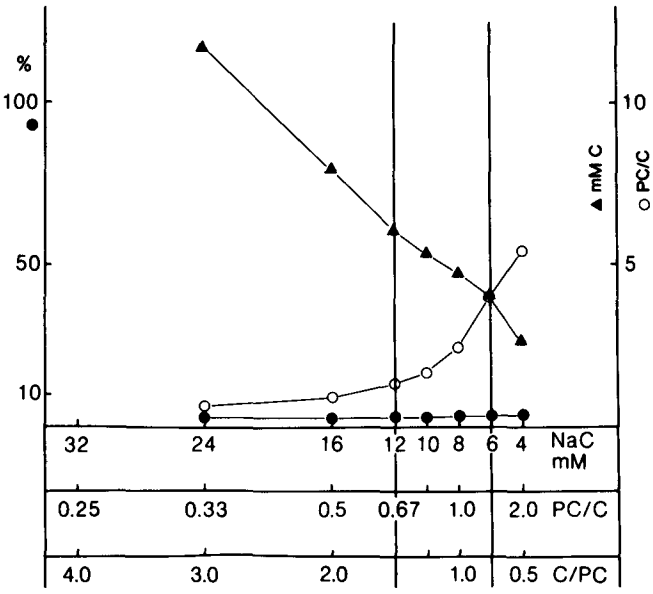

FIG. 3. Results obtained in the Centricon-10 filtration experiments of dispersions of 8 mM phosphatidylcholine (PC) in cholate (C) solutions at different PC/C ratios. The symbols indicate: percent of PC in the filtrate (●); concentration of cholate (mM) in the filtrate (▲) which equals the intermicellar concentration (monomers + simple micelles), PC/C ratio in the aggregated form at different cholate concentrations (○). NaC, sodium cholate.

is given in Figure 3. It increases from 0.64 at a PC/C ratio of 0.33 in the bulk phase to 5.49 at a PC/C ratio of 2.

When filtered through Centricon-100 filters, the filtrates were, in principle, clear (some filters were leaking and the

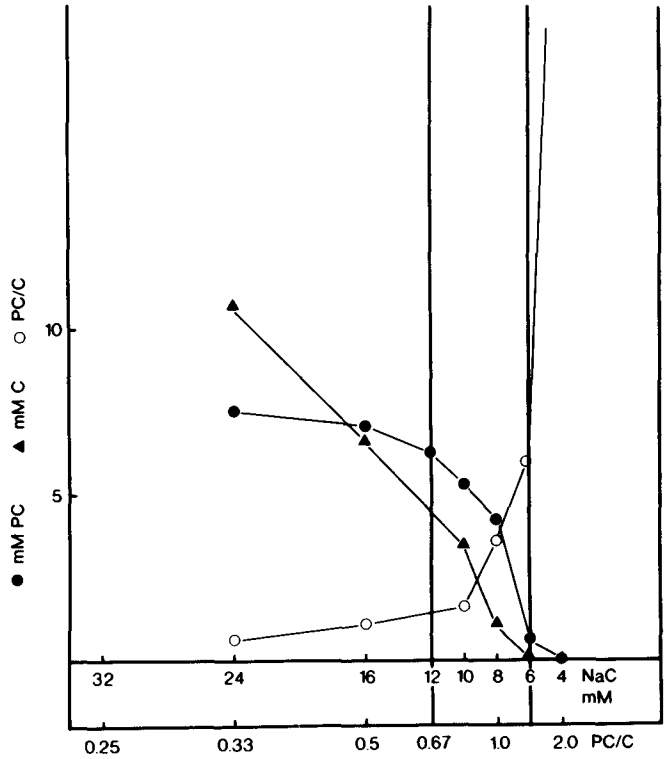

FIG. 4. Results obtained in the Centricon-100 filtration experiments of dispersions of 8 mM phosphatidylcholine (PC) in cholate (C) solutions at different PC/C ratios. The symbols indicate concentrations of PC (mM) in the filtrates out of a total of 8 mM (●); concentration of C in aggregate form in the filtrates (mM) (△). PC/C ratio in aggregated form at different PC/C ratios in the bulk dispersion (○). NaC, sodium cholate.

filtrates were discarded). Figure 4 shows the concentration of PC in mM (total PC 8 mM) in the filtrates as a function of the PC/C ratio. PC passed through the filters and therefore was in mixed micellar solution. With increasing PC/C ratio, the concentration of PC in the filtrates decreased steeply after a PC/C ratio of 0.67, and PC was absent from the filtrate at a ratio of 2. This indicates that with a decrease in C, vesicles and other aggregated forms of PC were formed that were not able to pass through the Centricon-100 filter. The concentration of C in the filtrate fell sharply with decreasing total concentration of C. The C found in the filtrates was in intermicellar and mixed micellar form. As the intermicellar concentration of C was obtained from the Centricon-10 experiments, these figures together can be used to calculate the amount of C in aggregated form in the Centricon-100 experiments, as well as the PC/C ratios. The latter figures from the Centricon-10 and Centricon-100 experiments were similar.

DISCUSSION

The physiological substrate for pancreatic PLA_2 in the small intestinal content is long-chain PC in BS dispersions. Although such systems have been studied *in vitro* (1,2) as substrate for PLA_2, no systematic determination of the enzyme activity in relation to the physical state of the substrate had been done until recently (8). In the present work, the studies were done at a constant PC concentration of 8 mM and at varying concentrations of sodium

C. The solutions were used as substrate for human pancreatic PLA_2, and the enzyme activity measured was correlated with the PC/C ratio. The physical state of the dispersions was defined by measuring the optical density at 330 and 450 nm and by filtering through synthetic filters with defined MW cutoffs. The interpretation of the data was aided based on studies on aqueous BS/lecithin systems that have been published in recent years. Mazer *et al.* (5) have shown that at low PC/C ratios, simple BS micelles coexist with small-size mixed BS lecithin micelles. As the PC/C ratio increases, the number of simple micelles decreases to furnish BS for the formation of mixed micelles. The solubilization of further PC at an increased PC/C ratio leads to a reorganization of mixed micellar size and structure. The data of Mazer *et al.* (5) seem to indicate that disk-shaped mixed micelles are formed which grow in size up to the mixed micellar phase limit. Above this limit bilayer structures in the form of unilamellar vesicles or liposomes appear; these are metastable and precipitate as bilayered structures other than vesicles. Almog *et al.* (6) have reported that for equal total concentration of PC and C, any mixture with a concentration of 8 mM or less was vesicular. The size of the vesicles was dependent on the dilution, and for the 12.5 times dilution used here the hydrodynamic radius was around 500Å. The turbidity at a given dilution thus depends on the vesicular size and the number of vesicles. If the results of our experiments are interpreted against the background discussed above, it appears that in Figure 1, the mixed micellar phase boundary can be located by the appearance of turbidity that occurs at a PC/C ratio of 0.67. The turbidity is due to the formation of vesicles. The abrupt increase in the turbidity at a PC/C ratio of 1.5 represents a transition of vesicles to precipitated bilayer structures (5). Figure 1 thus can be divided into three zones marked A, B and C. Zone A contains monomeric C in equilibrium with simple micelles and mixed PC/C micelles. The coexistence boundary, defined by Mazer *et al.* (5), separates regions in which both simple and mixed micelles exist from the region in which only mixed micelles are present, and is indicated by an increase in the hydrodynamic radii but cannot be located in our experiments. In zone A, PLA_2 activity increases linearly up to a PC/C ratio of 0.5 and thereafter shows a steeper increase in activity into Zone B, where vesicles start to form. In our experiments the total concentration of PC is constant at 8 mM; hence increase in PLA_2 activity must be due to increased availability of PC to the enzyme. Therefore, it appears that the large-size, mixed disk-like micelles are the preferred substrate for PLA_2. Zone B contains large mixed PC/C micelles coexisting with an increasing number of unilamellar vesicles, which is reflected in a sharp decrease in enzyme activity. When the relative C concentration is too low, the vesicles aggregate to form precipitated bilayer structures which are essentially unavailable as substrate. This transition starts at a PC/C ratio of 1.5 and is indicated by a sharp increase in turbidity.

Inside Zone B, starting at a PC/C ratio of 0.89, a lag phase in the PLA_2 activity begins to appear, which increases to 90 min at a ratio of 1.6. The lag phase, which increases with the PC/C ratio, can likely be explained by decreasing availability of PC in the vesicular structures to the enzyme. The fact that the activity starts after a lag phase is probably due to product activation, as fatty acids and lysoPC affect the bilayer structure (10,11). By removing C from vesicles by dialysis, pure metastable vesicles are obtained (6). Such vesicles are not a substrate for PLA_2. Adding C back to the system resulted in a decrease in the turbidity and appearance of enzyme activity after the addition of PLA_2 (see Fig. 2). At low cholate concentration, a long lag phase occurred. The presence of cholate in the bilayer is therefore important for the activity of PLA_2. The studies with Centricon filters allowed the calculation of the PC/C ratio in the aggregated form and showed an increase from 1.2 to 4 in Zone B. For optimal activity, the PC/C ratio in the aggregates should be around 2. It has previously been shown that in bilayer structures of PC within a limited temperature region just above the transition temperature (in the absence of bile salts), the PLA_2 activity increases at a gradually increasing rate due to a change in the transition temperature because of the appearance of products of the enzyme reaction (3,4). Structural defects in the substrate bilayer introduced by sonication have also been shown to facilitate the hydrolysis by PLA_2, and this has led to the conclusion "that structural irregularities in the packing of the substrate molecules facilitate the action of PLA_2 on bilayers" (4). In an analogous way it appears that such irregularities can be induced by BS, thus affecting the activity of PLA_2. The presence of low PC/BS molar ratios (0.17–0.28) in native human bile (1) explains why this substrate is almost unavailable to PLA_2. Figures obtained on human duodenal contents, however, indicate PC/BS molar ratios of around 0.6, which should be optimal for attack by human PLA_2 (12).

The results of the present study are, in many respects, confirmatory of those of a previous report (8) which was published when the present study was essentially finished. In the work by Gheriani-Gruszka *et al.* (8), the hydrolysis of egg PC in mixtures with C by porcine pancreatic PLA_2 was studied. It was found that increasing the C/PC ratio (decreasing the PC/C ratio) in the micelle resulted in a decreased (increased) initial velocity of hydrolysis. Special attention was given to the hydrolysis of C containing unilamellar vesicles. These were found sensitive to the ratio of C/PC in the vesicles, and it was concluded that large structural fluctuations are introduced into the vesicles by the presence of C, thus promoting the activation of the enzyme. In the present study, C was added back to the vesicles obtained by dialysis, and the results were also interpreted to indicate that the presence of C in the bilayer is important for the activity of PLA_2. Another interpretation of the results would be that adding C to the vesicles results in the formation of mixed micelles which are substrates for the enzyme.

Purification and Properties of an Extracellular Lipase from *Pythium ultimum*[1]

Zahid Mozaffar and **John D. Weete***
Department of Botany and Microbiology, Alabama Agricultural Experiment Station, Auburn University, Alabama 36849

An extracellular triacylglycerol lipase (EC 3.1.1.3) from *Pythium ultimum* strain No. 144 was purified by ammonium sulfate precipitation, and by diethylaminoethyl Sepharose CL-6B and Sephacryl S-200 chromatography. The purified enzyme preparation showed a prominent polypeptide band in polyacrylamide gel electrophoresis, associated with esterase activity according to activity staining. Molecular weight of the protein was estimated at 270 kD using gel filtration on Sephacryl S-200, and 68 kD by sodium dodecyl sulfate-polyacrylamide gel electrophoresis indicating that the enzyme may be a tetramer. The optimum pH and temperature for activity of the enzyme were 8.0 and 30°C, respectively. Activity was reduced by Co^{2+}, Fe^{2+}, Sn^{2+} and Mn^{2+} and stimulated by Ca^{2+}, Mg^{2+}, Na^{+}, K^{+} and surfactants such as taurocholic acid, Triton X-100, *n*-octyl glucoside, *n*-dodecyl-β-D-maltoside, 3-[(3-cholamidopropyl) dimethylammonio]-1-propanesulfonate(CHAPS), and 3-[-cholamidopropyl)dimethylammonio]-2-hydroxy-1-propanesulfonate. The apparent maximum specific activity was 42 μmole/min/mg in the absence of CHAPS and 77 μmole/min/mg in its presence. The reaction rate was progressively higher with increasing number of double bonds in the substrate, and the enzyme showed a preference for triacylglycerols containing fatty acids having the *cis* double bond configuration.
***Lipids* 28, 377–382 (1993).**

Lipases (EC 3.1.1.3, glycerol ester hydrolases) mainly catalyze the hydrolysis of triacylglycerols to diacylglycerols and free fatty acids, but some lipases are also known to catalyze the hydrolysis of mono- and diacylglycerols, and the interesterification of oils (1,2). Lipases are produced by a wide variety of organisms, including fungi (3). Lipases from several fungi representing mostly the *Ascomycotina*, *Deuteromycotina* and *Zygomycotina* have been isolated and partially characterized. Microbial lipases have become industrially important in the modification of fats and oils (4).

Extracellular lipase production by the filamentous fungus *Pythium ultimum* strain No. 144, which belongs to the primitive fungal class Oomycetes, was suggested in our previous studies on the production of fungal oil enriched in arachidonic and eicosapentaenoic acids; *i.e.*, cultures readily utilized soybean oil as a co-carbon substrate for growth (5,6). This report describes the isolation, purification and properties of an extracellular lipase from this fungus.

MATERIALS AND METHODS

Materials. Trizma maleate (Tris maleate), lipase substrate (50%, vol/vol olive oil emulsion), tristearin, triolein, trilinolein, trilinolenin, trielaidin, taurocholic acid, 3-[(3-cholamidopropyl)dimethylammonio]-1-propanesulfonate (CHAPS), 3-[(3-cholamidopropyl)dimethylammonio]-2-hydroxy-1-propanesulfonate (CHAPSO), Fast blue RR salt, α-naphthyl acetate, bovine serum albumin (BSA), ovalbumin, carbonic anhydrase, α-lactalbumin, diethylaminoethyl (DEAE) Sepharose CL-6B, Sephacryl S-200 and reagents for polyacrylamide gel electrophoresis were from the Sigma Chemical Co. (St. Louis, MO). Dye reagent for protein assays was purchased from Bio-Rad Laboratories (Richmond, CA), and molecular weight standards for gel chromatography were obtained from Boehringer Mannheim (Mannheim, Germany). All other reagents were of the highest purity available.

Fungus. Pythium ultimum strain No. 144, obtained from D.J.S. Barr of the Biosystematic Research Center, Central Experimental Farm (Ottawa, Canada), was maintained in Vogel's medium (5) at 18°C with rotary shaking at 120 rpm. The fungus was transferred to new medium at approximately 6-d intervals.

Lipase production. The fungus was cultivated for 6 d at 18°C in 250-mL Erlenmeyer flasks containing 100 mL Vogel's medium and 2 mL soybean oil in a Lab-line rotary incubator shaker at 120 rpm. Inoculations were made with 5 mL of blended mycelium from a 6-day-old culture grown as described above. Mycelia were separated from the medium by suction filtration in a Buchner funnel, and the lipases were then isolated from the medium.

Lipase purification. Proteins were precipitated from the culture medium with ammonium sulfate (85% saturation). After standing in the ammonium sulfate solution for 16 h at 4°C, the precipitate was collected by centrifugation at 15,000 rpm for 30 min and then dissolved in 50 mM sodium phosphate buffer pH 7.5 containing 10% glycerol (buffer A). Undissolved materials were removed by centrifugation as before, and the solution was dialyzed against the same buffer overnight. The dialyzate was placed on a DEAE-Sepharose CL-6B column (25 mm × 100 mm) which had been equilibrated with Buffer A. The column was washed sequentially with 100 mL each of Buffer A containing 0.05, 0.1, 0.2, 0.3 and 0.5 M NaCl and finally with 50 mM sodium phosphate buffer pH 7.5 (Buffer B) containing 1.0 M NaCl. The highest lipase activity was found in the fraction eluted with Buffer B containing 1.0 M NaCl. This fraction was dialyzed against Buffer A and concentrated by passage through a DEAE-Sepharose CL-6B column (10 mm × 20 mm). Lipase was eluted with a minimal volume of Buffer B containing 1.0 M NaCl, and the eluate was dialyzed against Buffer A and then placed onto a Sephacryl S-200 column (15 mm × 400 mm) previously equilibrated with Buffer A. The active fractions were concentrated by DEAE column chromatography as before. Glycerol (10%) was added to the buffer during purification and long term storage (4–6 mon) to

prevent the loss of enzyme activity. All procedures were carried out at 0–4°C.

Assay of lipase activity. Lipase activity was measured by the method of Ota *et al.* (7). Composition of the reaction mixture was 2 mL 0.2 M Tris maleate-NaOH buffer pH 8.0, 1 mL 0.06 M $CaCl_2$, 5 mL deionized water, 1 mL olive oil emulsion (50% vol/vol olive oil) and 1 mL of the enzyme preparation appropriately diluted with Buffer A. When substrates other than olive oil were used, they were emulsified in 5 mL deionized water with or without CHAPS (1.6 mM), but otherwise the reaction mixture was the same as described above. The emulsion was made using a Ross micro-mixture emulsifier (Charles Ross & Son Co., New York, NY). The reaction mixture was incubated at 30°C with constant reciprocal shaking (45 cycles/min). After 60 min, 20 mL of an acetone/ethanol (1:1, vol/vol) solution were added to stop the reaction, and the free fatty acid content was determined by titration with 0.05N aqueous NaOH. The reaction mixture without enzyme (blank) was also incubated as described above, but the enzyme was added prior to titration. The amount of product formed during incubation was calculated by subtracting the amount of free fatty acid in the blank from that of the reaction mixture after incubation with the enzyme. One unit of lipase was defined as the amount of enzyme required to liberate 1 μmol of fatty acid per min under the conditions specified. The assay method for the *P. ultimum* lipase was standardized using the olive oil emulsion as the source of substrate. The time course of hydrolysis was measured at various enzyme dilutions at constant substrate concentrations to establish the incubation time for the assay. The reaction was linear over time for 60–120 min at enzyme/substrate ratios where fatty acid release was between 35 to 70 μmol. Thus, 60 min was selected as the incubation time.

Values for the apparent K_m and V_{max} (maximum specific activity) were determined from reciprocal plots of substrate (triolein) concentrations *vs.* initial reaction rates (8). Initial reaction rates for all substrate concentrations were determined by appropriately diluting the enzyme preparation. Optimum temperature for the reaction was determined by measuring activity after incubation for 60 min at temperatures between 20 to 60°C. Tris maleate/NaOH (0.2 M) buffer at different pH values (4 to 10) was used to determine pH dependence of the enzyme at 30°C.

Treatments within each experiment were done in triplicate, and each experiment was done at least twice.

Positional specificity determination. The course of triolein (0.1 mL triolein in 10 mL reaction mixture as described above) hydrolysis by the lipase was followed by thin-layer chromatography (TLC). Small portions of the reaction mixture were removed at 0, 1, 3 and 5 h of incubation period. Diethyl ether was added to stop the reaction and to extract the products. The extraction was done at 4°C, and the extract was kept at 4°C prior to analysis. Samples were applied to silica gel layers (250 μm thick) on 20 cm × 20 cm glass plates, and the plates were developed in chloroform/acetone (96:4, vol/vol) as the solvent system. Components of the reaction mixture were visualized with iodine vapor and identified by comparison of their migration rates with those of known standards (Sigma).

Effects of temperature, metal ions, chelators and surfactants on lipase activity. The effect of temperature on lipase activity was determined by measuring the activity remaining after exposing the enzyme for 60 min to various temperatures (20–60°C), after which time the enzyme activity was determined under the assay condition described above.

To determine the effects of metal ions and various surfactants and chelators on lipase activity, the enzyme was incubated for 10 min at 20°C, in 0.2 M Tris-maleate-NaOH buffer, pH 8.0, containing the agents to be tested, and then enzyme activity was determined as before.

Molecular weight determination. Molecular weight of the purified lipase was determined by SDS-PAGE using 7.5% slab gels (9) and by gel filtration on a Sephacryl S-200 column (15 mm × 400 mm). In the case of sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE), BSA, ovalbumin, carbonic anhydrase and α-lactalbumin were used as standards. Proteins were stained on the gels with Coomassie blue. For gel chromatography, the column was calibrated using the Boehringer kit for molecular weight determination.

Activity staining. Native PAGE was performed on a 7.5% slab gel, and the enzymatically active (esterase) zone was identified by staining with 0.03% Fast blue RR salt, 0.05% α-naphthyl acetate and 1% acetone in 25 mL Tris-HCL at pH 7.4 (10).

Protein determination. Protein was determined colorimetrically at 595 nm using the Bio-Rad protein reagent according to the Bradford method with BSA as the standard.

RESULTS AND DISCUSSION

Enzyme purification. Most of the proteins in the medium were precipitated by ammonium sulfate. In the case of DEAE-chromatography, most of the proteins having essentially no lipase activity were removed from the column with a stepwise gradient of NaCl solution up to 0.5 M. Most of the lipase activity was eluted as a single peak with 1.0 M NaCl; the specific activity of the enzyme was increased 3.5-fold by this chromatographic step (Table 1). The specific activity was increased only slightly with the final purification step using Sephacryl S-200 gel chromatography. Total recovery of lipase activity was 22%. The active fraction was relatively pure according to native PAGE and activity staining (Fig. 1). However, minor proteins with relatively low molecular weights were also observed when the active fraction was subjected to SDS-PAGE (Fig. 2). Further purification was not achieved using DEAE-Cibacron blue 3GA-agarose or CM cellulose chromatography, both of which resulted in low recovery (less than 5%). The final specific activity of the lipase, after DEAE and Sephacryl chromatography, was about 63 units/mg protein which is relatively low compared to some of the fungal extracellular lipases reported previously, *e.g.*, 447 U/mg protein for *Goetrichum candidum* (11), 331 for *Aspergillus niger* (12), 3485 for *Mucor miehei* Lipase A (13) and 7638 for *Rhizopus delemar* (14). Clearly the activities of lipases from different fungal sources vary considerably. We have observed that the addition of surfactants to the incubation mixture increased activity of the *P. ultimum* lipase up to 161 units/mg protein (see below). Further studies have indicated that the amount and type of surfactant plays an important role in the activity of the *Pythium* lipase and that the activity could be increased

TABLE 1

Purification of an Extracellular Lipase from *Pythium ultimum* strain No. 144[a]

Steps	Volume (mL)	Protein (mg)	Specific activity[b] (units/mg protein)	Yield (%)
Media	1000	134	17.4	100
$(NH_4)_2SO_4$ precipitation	100	91	16.8	66

tenfold over that of the control without surfactant (Mozaffar, Z., and J.D. Weete).

The enzyme preparation contained a prominent polypeptide possessing esterase activity according to activity staining on PAGE (Fig. 1), but there were also several minor polypeptides on the gel showing activity (Fig. 1A). The production of multiple lipases seems to be typical of fungi such as *A. niger* (12), *Saccharomycopsis lipolytica* (7), *G. candidum* NRRL Y-553 (15) and *Penicillium cyclopium* (16). It is not known whether the different *P. ultimum* lipases are the result of post-synthesis modifications of single gene products, such as proteolytic breakdown as suggested for lipases from *S. lipolytica* (7), of *N*-glycosylation as for the lipases from *G. candidum* (15) or of more than one lipase gene as suggested for the lipases from *P. cyclopium* (16). The prominent lipase from *P. ultimum*, which had the slowest mobility in the gel, was separated from the others by ammonium sulfate precipitation and DEAE chromatography, and it is this lipase that was further characterized.

Molecular weight. The estimated molecular weight of the major polypeptide in the purified extracellular lipase preparation from *P. ultimum* was 68 kD according to SDS-PAGE (Fig. 2). However, chromatography under nondenaturing conditions indicated that the molecular weight of the lipase was 270 kD, suggesting that the enzyme exists as a tetramer. Most fungal extracellular lipases are monomers having molecular weights ranging from 19 to 64 kD. Exceptions are a 207 kD lipase from *Candida deformans* (17) and that from *Neurospora crassa* which exists as a dimer with 27 kD molecular weight subunits (18).

Effect of temperature and pH. Hydrolytic activity was detected between 20 and 60°C, but optimum activity was at 30°C. The enzyme retained full activity when exposed to 20–40°C for 60 min prior to assay. However, activity decreased substantially when exposed to temperatures above 40°C and disappeared completely on treatment for 60 min at 60°C. This appears to be typical of most fungal lipases except for those from *R. delemar* (19) and *Humicola lanuginosa* No. 3 which exhibited activity at 60°C (20).

Activity of the *P. ultimum* lipase was observed over the range pH 4–10, but the pH optimum was 8. Most extracellular fungal lipases have acid or neutral pH optima, and very few are alkaline lipases.

Effects of metal ions, chelators and surfactants on lipase activity. The effects of various metal ions, chelators and surface active reagents on the activity of the extracellular lipase from *P. ultimum* were also investigated. Na^+, K^+, Ca^{2+} and Mg^{2+} enhanced activity by 56 to 150%, with the monovalent cations giving the strongest stimulatory activity (Table 2). Fe^{2+}, Co^{2+}, Sn^{2+} and Mn^{2+} reduced activity by 14 to 86% (Table 2). Perhaps the reduction in activity by the latter cations was due to their catalytic effects on oxidation, *i.e.*, their presence promoted the oxidation of unsaturated fatty acids. Similar results have been reported by others for lipases from different sources (17,20).

Six surfactants were tested for their effects on lipase activity by adding them to the reaction mixture containing the proprietary emulsified olive oil (Sigma) as the substrate. Whereas the surfactants were added to the reaction mixtures at concentrations below their critical micelle concentrations, some of their concentrations differed such that it was not possible to make direct comparisons of their effects on lipase activity in all cases. However, the surfactants generally stimulated lipase activity by 117 to 300% (Table 2). Triton X-100, CHAPS and CHAPSO were all added to the reaction mixture at a final concentration of 0.8 mM and exhibited the greatest stimulation of activity at 317, 367 and 400%, respectively (Table 2). Whether the stimulation of lipase activity was due to a direct interaction of the surfactant with the enzyme or to an alteration of emulsion properties which in turn affected activity is not known. However, different surfactants affect fungal lipases differently. For example, Triton X-100 and *n*-octyl glycopyranoside inhibited lipases from *Candida rugosa* and *G. candidum*, but Triton X-100 stimulated the lipase from *Rhizopus arrhizus* (21).

Kinetic parameters. Apparent K_m and V_{max} values obtained for lipase with triolein as the substrate in the absence of CHAPS were 25 mM and 42 μmol/min/mg protein, respectively. These values were 20 mM (K_m) and 77 μmol/min/mg protein (V_{max}), respectively, when CHAPS was added to the reaction mixture. The apparent K_m values with and without CHAPS were not significantly different, but the apparent V_{max} values for the reaction in the presence of the surfactant was significantly higher than without it ($P < 0.001$). The increased V_{max} is probably due to an improvement in emulsion properties of the reaction mixture which favor more enzyme molecules becoming active. Only up to 30 mM triolein could be emulsified in the absence of CHAPS. Above this concentration, dispersibility of the oil in aqueous solutions decreased, and a thick cream was formed. On the other hand, 60 mM triolein was readily emulsified in the presence of CHAPS.

Activity as a function of substrate unsaturation. The lipase from *P. ultimum* has marked preference for substrates containing *cis*-unsaturated fatty acids (Table 3). For example, the rate of hydrolysis of trielaidin (18:1 *trans*-9) was 82% less than that for triolein (18:1 *cis*-9). There was no detectable hydrolysis of tristearin by this enzyme. Since tristearin and trielaidin are solid at room temperature, the poor lipase activity toward these substrates may have been due to poor emulsification, although an emulsifier was used to disperse the substrates in water.

TABLE 2

Effects of Cations, Chelators and Surface Active Agents on the Activity of the Extracellular Lipase from *Pythium ultimum* strain No. 144

Substances[a]	Activity[b] (μmol/min/mg protein)	Relative activities[c]
Control (none)	40.4 ± 0.8[d]	100
Sodium chloride (500 mM)	101.0 ± 3.2[f]	250

CHAPSO (0.8 mM)	161.6 ± 4.8[f]	400

[a]EDTA, ethylenediaminetetraacetic acid; EGTA, ethyleneglycol-*bis*-(β-aminoethyl-ether)*N,N,N',N'*-tetraacetic acid; CHAPS, 3-[(3-cholamidopropyl)dimethylammonio]-1-propanesulfonate; CHAPSO, 3-[C3-cholomidopropyl)dimethylamonio]-2-hydroxy-1-propanesulfonate. Concentrations of the additives in the reaction mixture during activity determination are shown in parentheses.

[b]Each value is the mean ± SD of three determinations. Statistical significance was assessed by Student's *t*-test. The significance of differences between respective values is shown as *P*; $P < 0.01$ between d and e; and $P < 0.001$ between d and f. Details regarding the activity determinations are given in Materials and Methods.

[c]Values were calculated relative to the control (without additives) using mean values.

TABLE 3

Substrate Specificity of Lipase Activity

Substrate[a]	Activity[b] (μmol/min/mg protein)	Relative activities (%)[c]
Triolein (18:1*cis*-9)	37.5 ± 1.0[e]	100
Trilinolein (18:2*cis*-9,12)	41.7 ± 0.6[f]	111
Trilinolenin (18:3*cis*-9,12,15)	45.8 ± 1.5[g]	122
Trielaidin (18:1*trans*-9)	6.8 ± 0.8[g]	18
Tristearin (18:0)[d]	0	0

[a]Triacylglycerols were emulsified in 5 mL deionized water with CHAPS (for abbreviation, see Table 2) (1.6 mM). Substrate concentration in the 10 mL reaction mixture was 20 mM for triolein, trilinolein, trilinolenin and trielaidin; and 5 to 10 mM for tristearin. CHAPS concentration in the reaction mixture was 0.8 mM. The reaction mixture (pH 8.0) was incubated at 30°C for 60 min, and the free fatty acids were titrated with 0.05 N NaOH as described in Materials and Methods.

[b]Each value is the mean ± SD of three determinations. Significance was assessed by Student's *t*-test; $P < 0.01$ between e and f, and $P < 0.001$ for e and g and f and g.

[c]Values were calculated relative to triolein using only the mean values.

[d]No titrable fatty acid was detected when either taurocholic acid (4 mM) or CHAPS (0.8 mM) were used as surfactants.

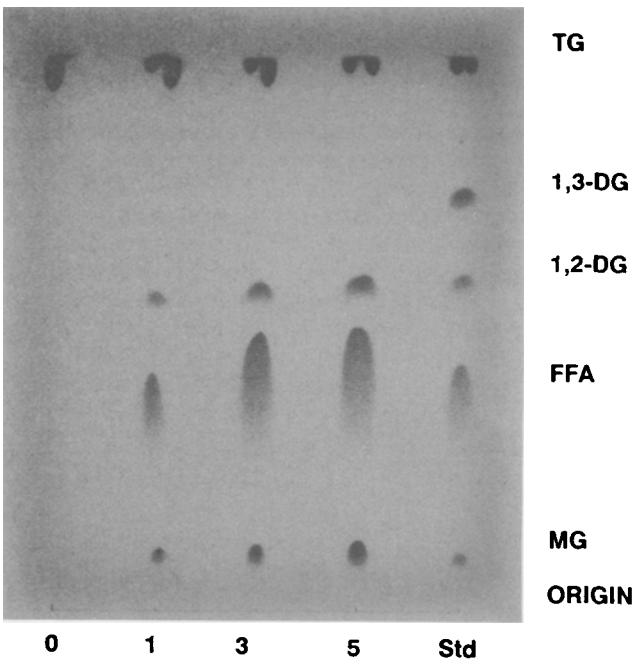

FIG. 3. Thin-layer chromatography of products of triolein hydrolysis by extracellular lipase from *Pythium ultimum*. The reaction conditions are given in the Materials and Methods section. TG, triacylglycerol; 1,3-DG, 1,3-diacylglycerol; 1,2-DG, 1,2-diacylglycerol; FFA, free fatty acid; MG, monoacylglycerol.

The rate of triacylglycerol hydrolysis increased with increasing number of double bonds per molecule. This result is unlike those reported previously with lipases from *C. deformans* and *H. lanuginosa* No. 3 for which the presence of two and especially three double bonds in the C_{18} fatty acid chains reduced the rate of hydrolysis (17,20). In contrast, an extracellular lipase from the fungus *G. candidum* can hydrolyze triacylglycerol containing 18:1 *cis*-9 and 18:2 *cis* 9,12 unsaturated fatty acids from natural and synthetic substrates regardless of their position within the substrate molecule (22). We cannot say unequivocally whether the differences in *Pythium* lipase activity with different substrates were due to differences in emulsion properties of substrates, or the substrate structure *per se*, but lipases isolated from various sources have been shown to exhibit different substrate preferences. For example, lipases from *N. crassa* readily hydrolyzed triacylglycerols with C_{16} and C_{18} fatty acids, hydrolyzed equally saturated and unsaturated substrates (18), but hydrolyzed triacylglycerols with short chain fatty acids (C_4-C_{10}) at a very slow rate. A lipase from *S. lipolytica* preferred substrates with short chain fatty acids and required oleic acid as an activator (7). Furthermore, multiple forms of lipases from the same fungus have been shown to exhibit different substrate preferences on the basis of either acyl chain length (12) or degree of unsaturation (16).

Positional specificity. Figure 3 shows the course of triolein hydrolysis by the lipase from *P. ultimum*. 1,2-Diolein was produced along with monoolein and oleic acid. 1,3-Diolein was not detected by TLC. It is clear from the TLC analysis of the reaction mixture that the lipase did not hydrolyze the ester bond at position 2 of triolein, indicating that the enzyme has 1,3-positional specificity which has been typical of the fungal lipases studied previously.

Purification and Characterization of a Fatty Acid Binding Protein from Human Prostatic Tissue[1]

Aziz A. Chaudry[a] and **Asim K. Dutta-Roy**[b,*]

[a]Department of Urology, Aberdeen Royal Infirmary, Aberdeen AB9 2ZD and [b]Receptor Research Laboratory, Division of Biochemical Sciences, Rowett Research Institute, Aberdeen, AB2 9SB, Scotland, United Kingdom

Epidemiological studies suggest the existence of a strong relationship between the incidence of prostatic cancer and the intake of dietary lipids in humans. However, very little information is available on intracellular fatty acid metabolism in human prostatic tissue. The objective of this study was to identify and subsequently characterize a fatty acid binding protein of human prostatic tissue. A fatty acid binding protein (FABP) was purified and characterized from human prostatic tissue. The purified FABP had an apparent molecular mass of 15.0 ± 1.0 kDa as averaged from three different methods, sodium dodecylsulfate-polyacrylamide gel electrophoresis (SDS-PAGE), gel filtration and amino acid analysis. The pI value of the protein was determined to be 6.8. Scatchard analysis of fatty acid binding to the purified FABP from malignant prostatic tissue showed a Kd value of 0.53 ± 0.02 μM for arachidonic acid (n = 5). The Kd values of FABP purified from benign prostatic tissue were 0.57 ± 0.02 μM for oleic acid and 0.51± 0.04 μM for arachidonic acid (n = 5). Fatty acid analysis revealed that the level of endogenously bound arachidonic acid was about 2.5-fold higher in FABP from malignant than from benign tissue. In addition, both malignant and benign tissues contained the same concentration of FABP. The concentrations of FABP in malignant and benign tissues were 19.2 ± 1.8 and 21.4 ± 2.1 μg per mg of total cytosolic protein, respectively. Characterization based on amino acid composition, isoelectric point and fluorescence with dansyl undecanoic acid suggests that the FABP may not be of the heart type, but is rather more closely related to the liver type. As malignant prostatic tissue produces more PGE_2 compared to benign tissue, our data suggest that FABP may help enhancing the synthesis of the prostaglandin in malignant tissue by facilitating arachidonic acid transport.

Lipids 28, 383-388 (1993).

Fatty acid binding proteins (FABP) belong to a family of small molecular weight cytosolic proteins (14–15 kDa) which are found in abundance in a number of tissues of mammals, birds, fish and insects (2,3). Intracellular fatty acids are critical molecules for energy delivery and for the synthesis of membrane lipids and lipid mediators. Thus FABP may have regulatory functions in energy production as well as in the synthesis of membrane lipids and lipid mediators (prostaglandins, leukotrienes and thromboxanes). The significance of FABP in intracellular fatty acid metabolism has been demonstrated in several studies (2,3). FABP are also associated with cell growth and regulation by virtue of binding various growth inhibitory and stimulatory compounds (4). Liver-type FABP binds various eicosanoids such as prostaglandin E_1 (PGE_1) (5), the lipoxygenase metabolites of arachidonic acid (6) and growth inhibitory cyclopentenone prostaglandins such as $^{\Delta 12}$-PGJ_2 (9-deoxy $^{\Delta 9,12}$-13,14-dihydro-prostaglandin D_2) and prostaglandin A_2 (PGA_2) (7). FABP binds these cyclopentenone prostaglandins avidly and apparently transports them to the nuclear membrane (7,8). These prostaglandins induce *gadd* 153 mRNA, a member of a novel class of genes associated with growth arrest and DNA damage (9). In the phospholipids of malignant human prostatic tissue, only the arachidonic acid (20:4n-6) level was significantly lower compared to the level in benign tissue; no difference was observed in the levels of linoleic acid (18:2n-6) or dihomogammalinolenic acid (20:3n-6) (10). The reduced arachidonic acid level in phospholipids of malignant tissue may be due to increased synthesis of prostaglandin E_2 (PGE_2), which is reported to be a tumor promoter in prostatic tissue (11–13). FABP have been implicated in prostaglandin metabolism as well as in cell growth and regulation (4,14); however, no information is available on FABP in human prostatic tissue. Here we report the purification and characterization of a FABP from human prostatic tissue.

MATERIALS AND METHODS

Materials. [1-^{14}C]Oleic acid (53 mCi/mmol) and [5,6,8,9,11,12,14,15-^{3}H(n)]arachidonic acid (83.6 mCi/mmol) were obtained from New England Nuclear (Hertfordshire, United Kingdom). Sepharoses CL-4B, rabbit anti-human albumin IgG and unlabelled fatty acids were obtained from Sigma Chemicals (Poole, United Kingdom). The molecular weight protein standard kit, and pI marker proteins (pI 3.5 to 9.3) were obtained from Pharmacia-LKB Biotechnology (Uppsala, Sweden). 11-(Dansylamino)undecanoic acid (dansyl undecanoic acid) was obtained from Molecular Probes (Junction City, OR), and Lipidex-1000 was obtained from United Technologies Packard (Downers Grove, IL). All other reagents used were of analytical grade quality. Prostatic tissue was obtained from Aberdeen Royal Infirmary, Aberdeen, Scotland.

Preparation of FABP. Prostatic tissue was obtained from patients undergoing surgical removal of the prostate gland with a provisional diagnosis of benign or malignant prostatic disease. Prostatic tissue was collected fresh at operation and was immediately frozen in liquid nitrogen

[1]A preliminary account of this work was presented at the Biochemical Society Meeting, London, December 16-18, 1991, and published as an abstract (Ref. 1).

Abbreviations: Dansyl undecanoic acid, 11-(dansylamino)undecanoic acid; DTT, dithiothreitol; EDTA, ethylenediaminetetraacetic acid; EFA, essential fatty acid; FABP, fatty acid binding protein(s); FPLC, fast protein liquid chromatography; 15-HPETE, 15-hydroperoxyeicosatetraenoic acid; 5-HPETE, 5-hydroperoxyeicosatetraenoic acd; 5-HETE, 5-hydroxyeicosatetraenoic acid, PITC, phenylisothiocyanate; PMSF, phenylmethylsulfonyl fluoride; PGE_1, prostaglandin E_1; PGE_2, prostaglandin E_2; PGD_2; prostaglandin D_2; PGA_1, prostaglandin A_1; PGA_2, prostaglandin A_2; $^{\Delta 12}$-PGJ_2, 9-deoxy$^{\Delta 9,12}$-13,14-dihydro-prostaglandin D_2; SDS-PAGE, sodium dodecyl sulfate-polyacrylamide gel electrophoresis.

and then stored at −70°C until required. Samples were classified as benign or malignant by histological examination. FABP was purified separately from malignant and benign prostatic tissues following the procedures as described previously with slight modifications (5). Typically, 20 g prostatic tissue (pooled tissues either from benign or malignant samples) was washed twice with ice-cold saline to remove blood. The tissue was then blotted and weighed. After chopping, the tissue was homogenized in 70% (wt/vol) 20 mM Tris-Hcl buffer, pH 7.4, containing 1 mM ethylenediaminetetraacetic acid (EDTA), 1 mM phenylmethylsulfonyl fluoride (PMSF) and 0.25 mM sucrose. After centrifugation at 5000 × *g* for 15 min, the pellet was discarded and the supernatant was then centrifuged at 110,000 × *g* for 1 h 20 min at 4°C. The supernatant obtained after the second centrifugation was subjected to 70% ammonium sulfate saturation, then centrifuged at 10,000 × *g* for 20 min. The supernatant was dialyzed against 10 mM Tris-HCl buffer containing 1 mM dithiothreitol (DTT), 1 mM EDTA and 0.002% sodium azide at 4°C for 24 h and concentrated by ultrafiltration using a filter with a molecular weight cut-off of 3,500 daltons (Amicon Diaflow, Glucocestershire, United Kingdom). The dialyzed and concentrated fraction was termed fraction "A". FABP was then finally purified to homogeneity from fraction "A" by fast protein liquid chromatography (FPLC) (Pharmacia-LKB Biotechnology, Uppsala, Sweden) using Sephacryl S-300 and Superose 12 columns, respectively. The presence of FABP in protein samples at different stages of purification was monitored using the radiochemical binding assay as described elsewhere. Protein was detected in column fractions by measuring absorption at 280 nm.

The protein concentrations in the tissue homogenate or in the pooled column fractions were determined according to the Bradford method using bovine serum albumin as standard (15). The FABP concentrations calculated from quantitative amino acid analysis were used only for determination of B_{max} and K_d values of fatty acid binding. In some cases, it was necessary to delipidize the FABP preparation. Delipidation of protein was done by passing through a Lipidex-1000 column (0.5 × 8 cm) at 37°C, as described previously (16).

Sephacryl S-300 chromatography. All the chromatographic procedures described below were carried out at 4°C. Approximately 30 mg of proteins from de-albuminized fraction "A" were applied to an FPLC Sephacryl S-300 column (2.6 × 60 cm) which had previously been equilibrated with 10 mM Tris-HCl buffer, pH 8.2 containing 0.1 mM PMSF, 1 mM DTT, 1 mM EDTA and 0.002% sodium azide. The fractions containing FABP were eluted with the same buffer at a flow rate of 1 mL/min. The FABP fractions were then pooled (300–350 mL) and concentrated for further purification.

Superose 12 column chromatography. The FABP fractions eluted from the Sephacryl S-300 column still contained some high molecular weight proteins. Further purification was achieved by applying 5 mg of the eluted FABP to an FPLC Superose 12 column (26 × 1.6 cm) which had previously been equilibrated with the same buffer used in the Sephacryl S-300 column. The fractions containing fatty acid binding activity were eluted at 40–65 mL. They were pooled and concentrated for further studies.

Polyacrylamide gel electrophoresis and molecular mass determination. The purity of the FABP preparation at each step was assessed by sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE) under reducing conditions on SDS Phast gel homogeneous 20 (Phast System, Pharmacia-LKB Biotechnology). The relative molecular mass of FABP was determined with the aid of marker proteins. The purified protein was kept at −70°C for further study.

Isoelectrofocusing of FABP. Isoelectric focusing of the delipidized FABP was performed in the Phast system (Pharmacia-LKB Biotechnology) on a Phastgel IEF 3-9, exactly as described in the instrument manual.

Amino acid analysis. Amino acid analysis of the purified FABP was carried out using a Waters Pico-Tag Amino Acid Analyser (Millipore, Edinburgh, United Kingdom). Protein (100 μL) was hydrolyzed with 6.0 N HCl at 110°C for 18 h. The phenylisothiocyanate (PITC)-amino acids generated were identified using a C_{18} reverse-phase narrow bore cartridge. Norleucine was used as an internal standard (200 nmol/mL). Cysteine and methionine were analyzed as cysteic acid and methionine sulfone, respectively.

The amino acid composition of proteins constitutes a set of integral residue numbers, whereas amino acid analysis gives nonintegral numbers. However, a minimum can be obtained in the function

$$y = \left[\sum_{i=1}^{n} \frac{|x_i - \text{nearest integer}|}{\text{nearest integer}} \cdot 100 \; \frac{1}{n} \right] \qquad [1]$$

which allows us to find the appropriate integers for each amino acid and to calculate the corresponding relative molecular mass (17). In the above equation, y (in %) represents the average deviation from the nearest integer of n different amino acids present in the protein, x_i is the non-integral residue number of amino acid i, calculated in relation to an arbitrary 'key' amino acid. To cover the prospective range of the relative molecular mass, a set of integer values is chosen for the key amino acid.

Fatty acid binding assay. The fatty acid binding assay was performed as described previously using the Lipidex method (5). Typically, 10–20 μg of protein in 50 mM Tris-HCl buffer, pH 7.4, was incubated with 1 μM [^{14}C]oleic acid, or [^{3}H]arachidonic acid, for 20 min at 37°C in a total volume of 200 μL. After incubation, the assay mixture was cooled and 100 μL of Lipidex-1000 suspension was added to remove the unbound radioligand. After further incubation for 10 min at 4°C, it was centrifuged. Radioactivity was determined in 100 μL of supernatant by liquid scintillation counting. Non-specific binding was determined in the presence of a 1000-fold excess of unlabelled fatty acids. For accurate determination of binding kinetics, Scatchard analysis was performed by incubating 15 μg of delipidated FABP in the presence of 100 μM Triton X-100 (18) in the above assay mixture with various concentrations of oleic acid or arachidonic acid (0.1–1 μM).

Cytosolic protein samples or column fractions were routinely tested for FABP contents at 1 μM [^{14}C]oleic acid concentration.

Fatty acid analysis. Endogenous fatty acids from FABP were extracted according to the method of Folch *et al.* (19). The fatty acid composition was then analyzed in a

Hewlett-Packard gas chromatograph (Hewlett-Packard, Geneva, Switzerland), after methylation of fatty acids by methanolic HCl as described previously (20).

Fluorescence assay. For the determination of FABP concentrations in benign and malignant prostatic tissue by the fluorescence method, tissues (average weight 2.23 g, n = 5) were separately processed and fraction "A" was prepared as described above. As albumin also binds dansyl undecanoic acid, albumin was removed by passing the samples through an affinity column of rabbit anti-human albumin IgG bound to Sepharose CL-4B after activation with tresyl chloride. Concentrations of FABP in these samples were measured by a fluorescence assay described previously (21). Dansyl undecanoic acid (0.1 mM) solution was prepared in 20 mM Tris-HCl buffer, pH 7.8. Fluorescence measurements were carried out in a Perkin-Elmer Luminescence spectrophotometer LS-5B (Perkin-Elmer, Buckinghamshire, United Kingdom) at 22°C. Fluorescence intensity was measured at 500 nm after excitation at 350 nm, with a slit width of 10 nm for both excitation and emission. Small aliquots (5 μL) of dansyl undecanoic acid stock solution (0.1 mM) were added by a micro syringe to the cuvettes containing either buffer or protein sample (3 mL). Maximum fluorescence enhancement for aliquots of de-albuminized fraction "A" was then determined. FABP concentration was estimated in these samples by using a standard curve prepared with purified FABP from prostate tissue, as described earlier (21,22).

Statistical analysis. Differences between the benign and malignant prostatic tissues were assessed by means of Student's unpaired *t*-test. Differences were considered significant when the *P* value was less than 0.05. Results are expressed as means ± SD.

RESULTS

Identification and purification of FABP from human prostatic tissue. The purification protocol of prostatic FABP is summarized in Table 1. FABP was purified to homogeneity both from benign and malignant human prostatic tissue as described in the Methods section. Figure 1 shows the elution profile of de-albuminized fraction "A" from Sephacryl S-300 column. FABP fractions emerged around 300–350 mL. Figure 2 shows an SDS-PAGE (15%) of the 70% ammonium sulfate fraction (supernatant) and FABP fractions obtained from the Superose 12 column. SDS-PAGE of the purified FABP protein showed a single band with a mobility that corresponded to a M_r 14,400. FABP was purified from both malignant or benign prostatic tissues, as described in the Methods section, yielding 0.51 ± 0.02 mg FABP/g wet tissue (n = 5).

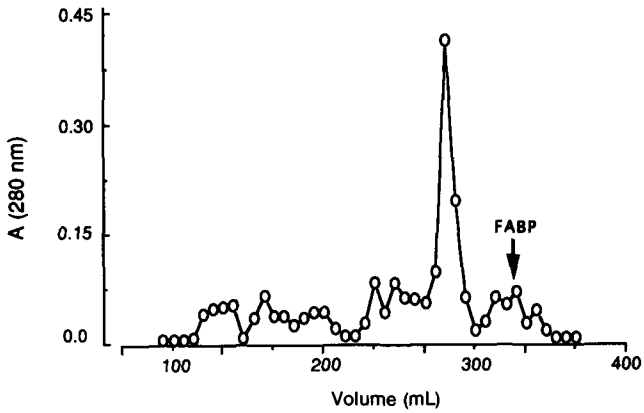

FIG. 1. Chromatography of prostate supernatant on a fast protein liquid chromatography (FPLC) Sephacryl S-300 column. De-albuminized fraction "A" (30 mg) was loaded onto an FPLC Sephacryl S-300 column equilibrated with 10 mM Tris-HCl, pH 8.2, containing 0.002% sodium azide and 1 mM dithiothreitol and 1 mM ethylenediaminetetraacetic acid. The proteins were eluted with the same buffer. The trace is representative of approximately 8 separations carried out. The fractions containing fatty acid binding activity are marked by fatty acid binding protein (FABP). FABP fractions were then pooled and purified further using a Superose 12 column.

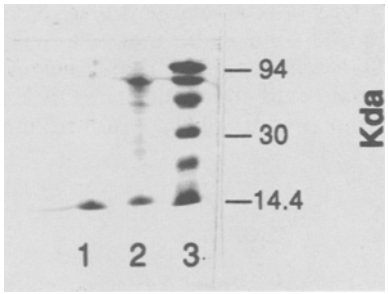

FIG. 2. Sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE) of proteins. Fractions were separated in an SDS-PAGE gel (20%) and stained for protein with coomassie blue. Lane 1, purified fatty acid binding protein eluted from Superose 12 column; Lane 2, 70% ammonium sulfate fraction; Lane 3, the molecular mass markers, phosphorylase b (94 kDa), bovine serum albumin (67 kDa), ovalbumin, (43 kDa), carbonic anhydrase (30 kDa), soybean trypsin inhibitor (20.1 kDa), lactalbumin (14.4 kDa).

Amino acid composition and molecular mass determination. The amino acid composition of FABP by individual determinations is given in Table 2. In this protein, 2 Cys,

TABLE 1

Summary of FABP Purification from Human Prostatic Tissues[a]

Purification step	Protein (mg)	Specific binding activity (nmol/mg)	Purification (fold)	Yield (%)
110,000 × *g* supernatant	538.8	0.3	1.0	100.0
70% $(NH_4)_2$ SO_4 fraction	145.7	0.8	2.5	69.2
Sephacryl S-300 column	21.6	5.8	16.8	67.9
Superose 12 column	10.1	12.9	37.5	70.3

[a]Protein was determined by the Bradford method (15). FABP, fatty acid binding protein(s).

TABLE 2

Amino Acid Composition of FABP from Malignant Prostate Tissue[a]

Amino acid residues	Number of residues
Asx	15
Glx	9
Ser	9
Gly	18
His	10
Arg	7
Thr	6
Ala	10
Pro	4
Tyr	5
Val	10
Met	1
Cys	2
Ile	7
Phe	6
Trp	n.d.
Lys	7

[a]n.d., Not determined. See Table 1 for abbreviation.

1 Met, 6 Phe, 7 Arg and large numbers of Lys, Leu, Val and Pro residues were present (Table 2). Trp was not determined. An estimation of the M_r value of FABP from amino acid analysis by reduction of the residues using Leu, Thr, Gly and Asx as key amino acids gave average value of 14,895. The molecular mass was calculated to be 15.0 ± 1.0 kDa when averaged from three different determinations (amino acid composition, SDS-PAGE and gel filtration). The procedure of the Bradford method gave a value of protein mass which was 1.4- to 1.6-fold lower than that determined by quantitative amino acid analysis. Isoelectric focusing of the purified FABP also revealed a single band with a pI value of 6.85 (results not shown).

Fatty acid binding activity. Prufied FABP from malignant and benign tissues showed similar binding kinetics toward arachidonic and oleic acids. Scatchard analysis showed a Kd value, for FABP from benign prostate tissue, of 0.57 ± 0.01 μM for oleic acid and 0.51 ± 0.04 μM for arachidonic acid (n = 5), whereas the Kd values for FABP from malignant tissue were 0.53 ± 0.02 μM for oleic acid and 0.44 ± 0.01 μM for arachidonic acid (n = 5) (Table 3). The maximal binding capacities (B_{max}) for oleic acid and arachidonic acid were 1.4 and 1.7 mol per mol of FABP, respectively.

Fatty acid analysis. The composition of endogenously bound fatty acids from purified FABP from malignant and benign tissues is shown in Table 4. No significant difference was observed in the levels of individual fatty acids except the level of arachidonic acid which was 2.5-fold greater in FABP of malignant tissue compared to that of benign tissue. Malignant prostatic tissue FABP contained 4.6 nmoles of arachidonic acid per mg of protein as compared to 1.8 nmoles arachidonic acid per mg of protein in FABP of benign tissue ($P < 0.05$, *t*-test). However, the total endogenous fatty acid bound to FABP in these two tissues did not differ significantly, 78.1 and 76.0 nmoles per mg FABP ($P > 0.623$, *t*-test, n = 5) in malignant and benign tissues, respectively.

Quantitation of FABP in benign and malignant human prostatic tissue. Dansyl undecanoic acid was used as a fluorescence probe to determine FABP levels in the fraction "A". Interaction of dansyl undecanoic acid with

TABLE 3

Scatchard Analysis of Fatty Acid Binding to Prostatic FABP[a]

	FABP (malignant tissue)		FABP (benigh tissue)	
Fatty acids	Kd (μM)	B_{max} (mol/mol)	Kd (μM)	B_{max} (mol/mol)
Oleic acid	0.53 ± 0.02	1.42 ± 0.34	0.57 ± 0.01	1.52 ± 0.23
Arachidonic acid	0.44 ± 0.01	1.65 ± 0.39	0.51 ± 0.04	1.72 ± 0.27

[a]The binding values were determined from Scatchard individual isotherms. The amount of prostatic FABP used was approximately 15 μg (n = 5). See Table 1 for abbreviation.

TABLE 4

Endogenous Fatty Acids Associated with FABP Purified from Benign and Malignant Human Prostatic Tissues[a]

	(nmol per mg of protein)	
Fatty acid	FABP (malignant tissue)	FABP (benign tissue)
16:0	18.4 ± 2.4	17.4 ± 1.7
18:0	7.1 ± 1.4	6.5 ± 1.2
18:1n-9	20.4 ± 3.2	24.8 ± 2.9
18:2n-6	26.8 ± 4.0	24.4 ± 3.4
18:3n-6	0.6 ± 0.0	0.7 ± 0.0
20:3n-6	0.2 ± 0.0	0.1 ± 0.0
20:4n-6	4.6 ± 0.9	1.8 ± 0.0[b]

[b]Significantly different from the malignant, $P < 0.05$, Student's *t*-test.

prostate FABP caused a large fluorescence enhancement and a considerable shift both in the excitation maxima (from 330 to 350 nm) and emission maxima (550 to 500 nm) wavelength (data not shown). FABP concentrations in benign and malignant prostatic tissues were estimated to be 19 ± 1.8 and 21 ± 2.1 μg per mg of cytosolic protein ($P > 0.534$, n = 5), respectively, as measured in "fraction A" of these samples using the fluorescence assay described in the Methods section. The validity of this method was confirmed by measuring the total FABP content in fraction "A" after adding known amounts of pure FABP. The accuracy of quantitation of FABP by this method was found to be within 95-97%.

DISCUSSION

Our data demonstrate for the first time the presence of an FABP in human prostatic tissue. The FABP was purified and characterized from both benign and malignant prostatic tissue. The relative molecular mass of the purified FABP was calculated to be 15.0 ± 1.0 kDa as derived from three independent methods (SDS-PAGE, gel filtration and from amino acid analysis). The average molecular mass of prostate FABP is similar to the size of FABP types from other species (2,3). No significant difference was observed in FABP concentrations between malignant and benign prostatic tissue. The *N*-terminal of this protein was found to be blocked; therefore sequencing was precluded. The relative excitation maxima at 274 nm and emission maxima at 309 nm are due to tyrosine residues, while the small peak at 258 nm reflects the presence of phenylalanine residues (data not shown). The fluorescence analysis revealed that FABP does not have a tryptophan moiety as is also the case for liver FABP (2). Amino acid analysis of the FABP revealed the presence of one Met, two Cys, six residues of Phe and a large number of His and Arg residues.

So far, three different FABP types have been identified and characterized in man: liver, heart and intestinal FABP (23-25). The FABP types are reported to differ markedly in their isoelectric point, amino acid composition, fluorescence with dansyl undecanoic acid and immunological cross-reactivities (3). Our data on amino acid composition, pI value and the fluorescence with dansyl undecanoic acid suggest that prostatic FABP may not be of the heart type. The pI value of prostate FABP is 6.85 which is similar to liver-type FABP (neutral pI value), whereas heart-type FABP are acidic proteins (pI about 5.0) (2). The amino acid composition of prostatic FABP also clearly differs from the heart-type FABP, the major differences being the presence of two Cys residues in prostate FABP, which are absent in heart-type FABP (2). Furthermore, the absence of Trp in prostate FABP suggests that it may be more related to liver-type, which is devoid of Trp residue (3). Fluorescence data on the interaction of prostatic FABP with dansyl undecanoic acid showed a marked shift of both excitation and emission wavelength and a large fluorescence enhancement which are similar to those observed with liver-type FABP but not with heart-type FABP (21,22). However, further work on immunochemical reactivities of prostatic FABP against anti-sera of known human FABP types, as well as amino acid/cDNA sequence analysis of the protein or Northern blotting of mRNA, is required for definitive conclusions.

The binding kinetics showed no difference in the Kd values of FABP of malignant and benign prostatic tissues for oleic acid and arachidonic acid. The values of the same order of magnitudes as the Kd are described for other FABP types (2). A discrepancy is usually observed with the stoichiometry of ligand binding by FABP. In our experiments, prostate FABP appears to bind more than one mole of oleic or arachidonic acid (1.4 to 1.7 mol fatty acid per mol FABP). It has been generally accepted that FABP bind one mole of fatty acid per mol of protein (2). Liver-type FABP has a binding stoichiometry which appears to vary between 1 and 3 (23,26-28). The differences in B_{max} value may be due to variations in procedures employed for the radiochemical binding assay, preparations of FABP, as well as for the ligand preparation.

Prostate FABP endogenously bound 76 to 78 nmoles fatty acids per mg of protein which is equivalent to 1 mol fatty acid bound per mol FABP. *In vivo*, the protein would be fully loaded with ligands only if the B_{max} is around one mole fatty acid per mol of FABP. However, the B_{max} of the prostate FABP appears to be 1.4 to 1.7 mol per mol protein. The molar ratio of endogenously bound fatty acids is reported to vary between 0.4 and 1.3 mol per mol of FABP (2). The isolation procedures for FABP may also have effects on the quantity of endogenously bound fatty acids. This variation could also be due to the results of lipolysis before or during the homogenization of tissue. Although the prostatic tissue used for FABP preparation was immediately frozen after surgical removal, it is very unlikely that freezing will stop tissue lipolysis completely. Despite the similar affinity for arachidonate, the endogenous level of this fatty acid in FABP of malignant tissue was found to be 2.5-fold higher than that of benign tissue, possibly indicating an increased level of free arachidonic acid in the cytoplasm of malignant tissue compared to benign tissue. FABP isolated from various tissues differ both qualitatively and quantitatively in bound long-chain fatty acids. In the present case, differences may be the result of higher activity of phospholipase(s) in malignant prostatic tissue compared to benign tissue. Alterations of essential fatty acid (EFA) and prostaglandin metabolism in malignant human tissues have been reported (10,29,30). Whether profiles of endogenously bound fatty acids to FABP reflect the status of intracellular fatty acid and prostaglandin metabolism in malignant and benign tissues remains to be established. In any event, our data show that more arachidonic acid is endogenously bound to FABP of malignant tissue compared to benign tissue. The increased arachidonic acid bound to FABP of malignant prostate tissue and the reduced arachidonic acid levels in phospholipids of malignant tissue compared to benign tissue (10) may suggest a difference in the degree of phospholipase activity in these tissues. Increased prostaglandin synthesis in the kidney of genetically hypertensive rats is thought to be facilitated by increased levels of arachidonic acid bound to FABP (14). The synthesis of prostaglandins depends on the availability of substrate. However, it is tempting to speculate that FABP in malignant prostatic tissue may help to enhance prostaglandin synthesis by transporting more arachidonic acid to the cyclooxygenase in the endoplasmic reticulum. Whether FABP enhance prostaglandin synthesis by increasing arachidonic acid transport needs further investigation. Preliminary studies showed that malignant prostatic

tissue produced 12-fold more PGE_2 than the benign tissue when these tissues were incubated with radiolabelled arachidonic acid (31).

In addition to fatty acid binding, liver-type FABP also binds PGE_1, growth inhibitory cyclopentenone prostaglandins (Δ^{12}-PGJ_2, PGA_1 and PGA_2) and growth stimulatory lipoxygenase metabolites (15-HPETE, 15-hydroperoxyeicosatetraenoic acid; 5-HPETE, 5-hydroperoxyeicosatetrenoic acid, 5-HETE, 5-hydroxyeicosatetraenoic acid), with similar affinities (Kd in nanomolar range) (5-7). However, the implication of these observations in cell growth and regulation is not yet elucidated. Since prostate FABP appears to be closely related to the liver-type FABP, future studies on its role in intracellular eicosanoid metabolism and transport in prostate tissue should give us a better understanding of the precise function of FABP in cellular growth and regulation.

In conclusion, we have identified and purified FABP from benign and malignant human prostatic tissue. The prostatic FABP seem to be more related to liver-type FABP with respect to amino acid composition, electrophoretic behavior and fluorescence data, but its precise role remains to be established.

ACKNOWLEDGMENTS

We thank Dave Brown for amino acid analysis. We also thank L.E.F. Moffat and S. McClinton of Aberdeen Royal Infirmary, for supplying the prostate tissue. This work was supported in part by the Scottish Office Agriculture and Fisheries Department and a grant from the Grampian Health Board, Scotland (grant no. MB/IAA 1991/92/21).

Trans-Monoenoic and Polyunsaturated Fatty Acids in Phospholipids of a *Vibrio* Species of Bacterium in Relation to Growth Conditions

R.J. Henderson[a,*], R.-M. Millar[a], J.R. Sargent[a] and J.-P. Jostensen[b]

[a]N.E.R.C. Unit of Aquatic Biochemistry, Department of Biological and Molecular Sciences, University of Stirling, Stirling FK9 4LA, Scotland and [b]The Norwegian College of Fishery Science, University of Tromsø, N-9037 Tromsø, Norway

A *Vibrio* species of bacterium known to contain the polyunsaturated fatty acid 20:5n-3 was grown in both freshwater and seawater media at 5 and 20°C and examined for adaptive changes in lipid composition. Phosphatidylethanolamine (PE) and phosphatidylglycerol (PG), together with a smaller proportion of nonesterified fatty acids (NEFA), comprised almost all the lipid under all growth conditions examined. Temperature had a more pronounced effect than the salinity of the medium on lipid composition. The proportion of PE in total lipid was always higher at 5 than at 20°C. Conversely, the proportion of NEFA was lower at 5 than 20°C whereas that of PG was not altered. The levels of saturated fatty acids in total lipid, PE and PG were all decreased by growth at 5°C. No differences were observed with respect to growth temperature in the levels of *cis* 16:1n-7, the principal monoenoic fatty acid in both PE and PG. *Trans* 16:1n-7 was found to comprise 12.8–15.2% of fatty acids in PE and PG of bacteria grown at 5°C but only 4.4–8.5% of phospholipid fatty acids in bacteria cultured at 20°C. Regardless of medium composition, a reduction in growth temperature from 20 to 5°C also caused the proportions of 20:5n-3 to increase from around 0.8 to 4.4% in PE and from around 4 to 20% in PG. The simultaneous occurrence of *trans* 16:1n-7 and 20:5n-3 is unique to this *Vibrio* species of bacterium. The increased proportions of both these fatty acids with decreasing temperature suggest that they have a role in retailoring biomembrane phospholipids during temperature acclimation of the bacterium.

***Lipids 28,* 389–396 (1993).**

In general, the lipids of bacteria do not contain polyunsaturated fatty acids (1). An exception to this rule is the occurrence of polyunsaturated fatty acids in a few species of marine bacteria (2–5) isolated from diverse sources including seawater, deep sea sediments and the intestines of fish. These bacteria are invariably motile and Gram-negative, with *Vibrio* species being the most common (4,5).

Studies to date on the lipids of these bacteria which contain polyunsaturated fatty acids have examined only their total lipid and have not reported the distribution of individual fatty acids in the component lipid classes. Furthermore, although the biosynthesis of monounsaturated fatty acids has been well studied in bacteria (1), nothing is known of the mechanisms of bacterial synthesis of polyunsaturated fatty acids.

An increase in the level of unsaturated fatty acids in phospholipids of eukaryotic poikilotherms, both invertebrate and vertebrate, has been shown frequently to occur as an adaptation to a decrease in environmental temperature (6–8). In contrast, the effect of changes in environmental temperature on the detailed lipid composition of bacteria has been less well studied. The few studies that have been carried out show that there is no uniformity between different bacterial species in the changes that occur in lipid composition in response to changes in growth temperature. For example, in marine *Vibrios*, increases in the proportion of monounsaturated fatty acids, or increased synthesis of shorter chain fatty acids or no changes at all have all been observed as responses to reduced growth temperature (9). Most recently, the interconversion of *cis* and *trans* isomers of 16:1n-7 has been implicated in the thermal adaptation of a psychrophilic species of *Vibrio* (10,11).

In addition to growth temperature, the salt concentration of the medium may also influence the lipid composition of bacteria. This aspect has been studied in several species of bacteria including species of *Paracoccus* (12), *Staphylococcus* (13,14), *Vibrio* (15) and *Pseudomonas* (16). With Gram-negative bacteria in general, the proportions of phosphatidylglycerol (PG) and phosphatidylethanolamine (PE) increase and decrease, respectively, with increasing salt concentration in the growth medium (12,15, 16). However, the effect is somewhat different with the Gram-positive *Staphylococcus* species in that the PG decreases with increasing salinity while cardiolipin increases (13,14). Changes in fatty acid composition of total lipid are also observed in relation to the salinity of the growth medium. Thus, the level of monounsaturated fatty acids in total lipid has been shown to decrease significantly when marine species of *Vibrio* are grown in medium of reduced salinity (17) whereas with the moderate halophile *Vibrio costicola* the relationship between salt concentration and the proportion of monounsaturated fatty acids is parabolic with a maximum at 1.0 M (18).

To establish whether adaptive changes occur in the lipid composition of bacteria which are capable of producing polyunsaturated fatty acids, the lipids synthesized by a *Vibrio* species known to contain 20:5n-3 were examined in relation to growth conditions.

MATERIALS AND METHODS

Chemicals. Lipid standards were purchased from Sigma Chemical Co. Ltd. (Poole, Dorset, United Kingdom) and Supelchem U.K. Ltd. (Saffron Walden, United Kingdom). Solvents were of glass distilled or high-performance liquid chromatography (HPLC) grade and were supplied by Rathburn Chemicals (Walkerburn, United Kingdom).

Organism and growth conditions. The *Vibrio* species used in the study was originally isolated as described elsewhere (19) from the gut of Arctic char (*Salvelinus alpinus* L.) maintained in freshwater. To remove lipid from growth media, Oxoid general purpose nutrient broth powder (Unipath Ltd., Basingstoke, United Kingdom) was extracted with chloroform/methanol (2:1, vol/vol), filtered and air dried before being used for the preparation of the

Abbreviations: GC/MS, gas chromatography/mass spectrometry; HPLC, high-performance liquid chromatography; HPTLC, high-performance thin-layer chromatography; NEFA, nonesterified fatty acids; PE, phosphatidylethanolamine; PG, phosphatidylglycerol; R_f, retardation factor; Tris, tris(hydroxymethyl)aminomethane.

media. The defatted nutrient broth was made up at a concentration of 13 g/L either in distilled water or artificial seawater (approximately 0.4M NaCl) buffered with 1.6 mM Tris HCl to produce freshwater and seawater medium, respectively. The pH of both media was 7.2. Cultures were grown in the dark under sterile conditions in glass conical flasks in temperature-controlled shaking incubators at either 5 or 20°C. Growth rates were assessed by measurement of absorbance at 600 nm against non-inoculated medium as the blank. Bacterial cells were harvested from cultures grown at 20 and 5°C after 24 h and 5 d, respectively, by centrifugation at 7,000 × *g* for 10 min. The resulting pellet was resuspended in the washing buffer of Hanna *et al.* (18) and the centrifugation repeated. Pellets of cells were lyophilized and weighed prior to lipid extraction.

Lipid analysis. Lipid was extracted by blending pelleted cells with chloroform/propan-2-ol (2:1, vol/vol) in a glass/Teflon homogenizer. The organic phase was then filtered and washed with one-quarter its volume of 0.88% (wt/vol) KCl. After removal of the solvent by evaporation under nitrogen, the lipid extract was desiccated overnight *in vacuo.* After weighing, the lipid extract was redissolved in a known volume of chloroform/methanol (2:1, vol/vol) and stored at −70°C until analyzed further.

Lipid class analyses were performed by high-performance thin-layer chromatography (HPTLC) using various solvent systems. Separated lipid classes were identified by reference to authentic standards and by the staining of chromatograms with reagents specific for functional groups (20). Two-dimensional HPTLC was performed using methyl acetate/propan-2-ol/chloroform/methanol/0.25% KCl (25:25:25:10:9, by vol) and chloroform/methanol/7M aqueous ammonia (65:35:5, by vol) for development in the first and second dimensions, respectively. For quantitation of lipid classes, plates were developed to two-thirds of their length in chloroform/methanol/water (65:25:4, by vol) followed, after drying of the plate, by development to full distance with hexane/diethyl ether/acetic acid (90:10:1, by vol). Developed chromatograms were sprayed with 3% (wt/vol) copper acetate in 8% (vol/vol) phosphoric acid and the stained classes quantitated by scanning densitometry using a Shimadzu (Kyoto, Japan) CS9000 dual wavelength scanner attached to a Shimadzu DR-13 data recorder as described elsewhere (21).

For analysis of their constituent fatty acids, lipid classes were separated by HPTLC using the double development solvent system described above. Developed chromatograms were sprayed lightly with (0.01% wt/vol) 2′,7′-dichlorofluorescein in methanol and viewed under ultraviolet light. Bands of adsorbent containing the required classes were scraped from the plates and subjected to acid-catalyzed transesterification to produce the methyl ester derivatives of the constituent fatty acids (20). Fatty acid methyl esters were purified by HPTLC on silica gel plates using hexane/diethyl ether/glacial acetic acid (85:15:1, by vol) as developing solvent and recovered from the adsorbent by elution with hexane/diethyl ether (1:1, vol/vol). Aliquots of total lipid were also subjected directly to the acid-catalyzed transesterification procedure.

The analyses of fatty acid methyl esters of total lipid were performed using a Packard (Pangbourne, Berks., United Kingdom) 436 gas chromatograph equipped with a CP Wax 51 fused silica capillary column (50 m × 0.34 mm i.d.) (Chrompack UK Ltd., Milharbour, London, United Kingdom), on-column injection and H_2 as carrier gas. The oven temperature was programmed to increase from 50 to 225°C during the course of an analysis. For the analysis of fatty acid methyl esters of individual phospholipid classes, a fused silica capillary column coated with BPX 70 (25 m × 0.32 mm i.d.) was used, and the oven temperature was programmed to rise from 50 to 180°C. These samples were further analyzed using a chemically bonded CP Sil 5CB fused silica capillary column (50 m × 0.34 mm i.d.) with a single step thermal gradient from 50 to 260°C at 4°/min.

Separated methyl esters were identified by comparison with known standards and were quantitated using a Shimadzu CR-3A recording integrator attached to the gas chromatograph. The unsaturated nature of component methyl esters was confirmed by hydrogenation using PtO_2 followed by re-analysis. Identities were confirmed by gas chromatography/mass spectrometry (GC/MS) of selected samples by Dr. W.W. Christie, Hannah Research Institute, Ayr, United Kingdom, using conditions described elsewhere (22).

To confirm the identity of *trans* 16:1n-7, the fatty acid methyl esters of representative samples were separated on HPTLC plates impregnated with silver nitrate using hexane/diethyl ether/glacial acetic (94:4:2, by vol) as the developing solvent system (23). Components corresponding to saturated, *cis*-monounsaturated and *trans*-monounsaturated fatty acid methyl esters [identified by comparison of retardation factor (R_f) values with those of authentic standards run on the same chromatogram] were recovered from the adsorbent and analyzed by GC using the BPX70 phase as described above. The methyl ester of *trans* 16:1 was isolated as a component having an R_f value between that of saturated and *cis*-monounsaturated fatty acids.

Further confirmation of the identity of *trans* 16:1n-7 was obtained by stereospecific epoxidation with peracetic acid of fatty acid methyl esters separated by argentation chromatography (24). The epoxy derivatives were analyzed by GC using the BPX70 capillary column described above. The oven temperature was programmed to increase from the injection temperature of 50 to 150°C over 2.4 min and then after 18 min to increase to 220°C at 3 min. The separated epoxy derivatives of the methyl esters of the *cis* and *trans* isomers of 16:1n-7 in samples were identified by comparison of retention times of derivatives synthesized using standards of these fatty acids.

Student's *t*-test was used to determine the significance of differences between pairs of particular means (25), and differences were considered significant when $P < 0.05$. For the sake of clarity, values which are significantly different are not denoted in tables but are referred to in the text. The effects of the two factors (temperature and medium composition) were assessed by means of a two-way analysis of variance at a confidence level of 95% ($P < 0.05$) (25).

RESULTS

Growth characteristics. The *Vibrio* was capable of growing in both freshwater and seawater media. Growth rates, as assessed by absorbance measurements, were much higher at 20 than 5°C (Fig. 1) in both types of media. At 20°C the growth rates of bacteria grown in freshwater and

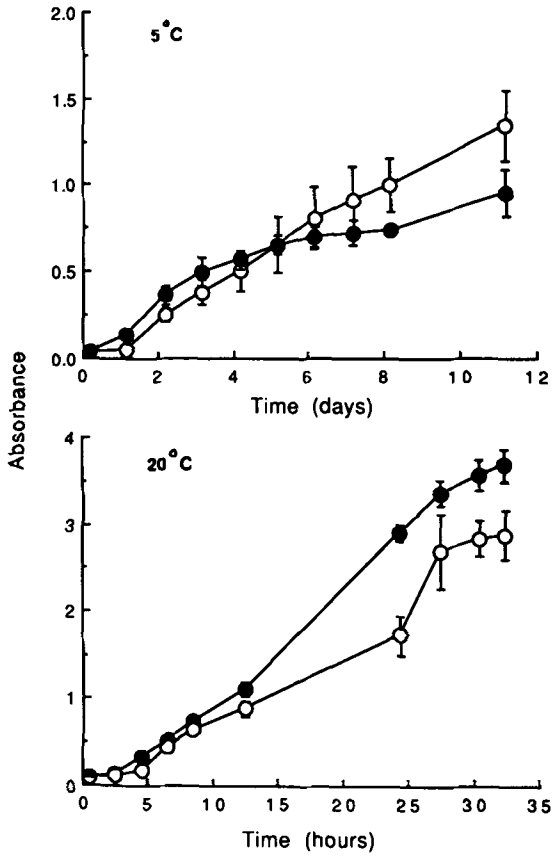

FIG. 1. Growth rates of *Vibrio* sp. cultured at 5 and 20°C in freshwater and seawater media. O, Seawater medium; ●, freshwater medium. Note different scales on x-axis.

seawater media were initially similar but diverged as the culture aged so that cultures grown in seawater medium finally contained fewer cells. The growth rate of bacteria at 5°C was higher in the freshwater medium than seawater medium over the initial 4 d of culture; but thereafter a higher biomass was observed in the seawater medium. Nevertheless, the influence of media composition on bacterial growth in Figure 1 was not marked. In contrast, further experiments showed that the *Vibrio* had poor growth rates in media containing 1M or 1.5M NaCl (data not shown).

Lipid content. Bacteria growth in seawater medium at 20°C contained only 4.5% of their dry weight as lipid whereas this component accounted for 7.4–7.9% of the dry weight of bacteria cultured under the other three conditions examined (Table 1). However, the only significant difference in lipid content was that observed between bacteria grown in seawater medium and bacteria grown in freshwater medium at 20°C. No statistically significant differences in lipid content existed between bacterial cultures in relation to growth temperature.

Lipid class composition. The lipid of the bacteria in all cultures was composed mainly of PE and PG (Table 1). At a given temperature (5 or 20°C) the lipid class composition was very similar for cells grown either in freshwater or seawater media. In bacteria grown at 5°C, more than 50% of the total lipid was PE, with PG and nonesterified fatty acids comprising around 31 and 12%, respectively, while at 20°C in both media the percentage of PE was substantially lower, and that of nonesterified fatty acids much higher, than at 5°C. The proportion of PG was only slightly higher in cells grown at 20°C than in those grown at 5°C in either medium. Overall, temperature affected lipid class composition more than the nature of the medium. LysoPE was present in trace amounts in lipid extracted from all cultures. When, in preliminary studies, chloroform/methanol (2:1, vol/vol) was used as extraction solvent, the levels of nonesterified fatty acids in the total lipid were notably higher, and those of PE and PG correspondingly lower (data not shown), than the values presented in Table 1. No components were observed in the total lipid extract which gave a positive stain for carbohydrate moieties.

Fatty acid composition of total lipid. The fatty acid compositions of total lipid from the *Vibrio* grown at 5 and 20°C in freshwater and seawater media are presented in Table 2. The major fatty acid component of total lipid was always the monounsaturated 16:1, but under the conditions employed complete resolution of the component *cis* and *trans* isomers of 16:1 was not attainable using the CP Wax 51 column. Overall, monounsaturated fatty acids accounted for just over half of the total fatty acids present

in the bacterial lipid regardless of growth conditions. An increase in the level of 16:1 with the lowering of growth temperature was largely balanced by reductions in the proportions of 17:1n-8 and 18:1n-9, and consequently the overall proportion of monounsaturated fatty acids in total lipid was not greatly affected by growth temperature. The proportions of saturated fatty acids in total lipid were significantly higher in bacteria grown in seawater and freshwater medium at 20°C than in those grown at 5°C. Palmitic acid (16:0) and *iso*-15:0 were the predominant saturated components present although smaller proportions of other saturated fatty acids, both with even and odd numbered chains, were also present. Under the conditions employed for the analysis of total lipid fatty acid methyl esters, any 13:0 and *iso*-13:0 present in the total lipid were obscured by the butylated hydroxytoluene added as antioxidant. The only polyunsaturated fatty acid present in the bacteria was 20:5n-3 which accounted for 9% of the fatty acids of total lipid from cultures grown at 5°C and around 2% of those from cultures grown at 20°C in either medium.

In contrast to temperature, the salt content of the medium had only a small effect on the fatty acid composition of total lipid at both temperatures examined. Small but significant differences in the levels of several fatty acids were notable between bacteria grown at 5°C in seawater and freshwater, with the overall result being higher and lower proportions of monounsaturated and saturated fatty acids, respectively, in the total lipid of bacteria grown in seawater medium. At 20°C, however, there were no overall changes in the levels of total saturated, monounsaturated or polyunsaturated fatty acids in the total lipids in relation to the salinity of the medium. Two-way analysis of variance with pooled means showed that, overall, temperatures had a greater effect on the fatty acid composition of total lipid than medium composition. The levels of 14:0, 15:1, 16:0, 16:1, 17:1n-8 and 17:1n-6 were also influenced significantly by the interaction of temperature and medium composition. That is to say, changing temperature and medium composition simultaneously brought about a significant change in the proportions of these components.

Fatty acid composition of lipid classes. The use of two columns for the analysis of fatty acid methyl esters of phospholipid classes allowed the resolution of more components than were obtained for total lipid samples. Thus 13:0 and *iso*-13:0, as well as the various isomers of 16:1, were discernable.

Although the fatty acid composition of PE (Table 3) showed general similarities with that of total lipid, it was notable that the proportions of polyunsaturated fatty acids in the phospholipid were only half those present in total lipid (Table 2) while those of total saturated fatty acids were higher under all growth conditions examined. The overall levels of monoenoic fatty acids in PE were only slightly lower than those observed in total lipid. *Iso*-15:0 and 16:0 were always the major saturated fatty acids in PE. Although the proportion of *iso*-15:0 in bacteria grown

in the seawater medium was not affected by temperature, that in freshwater bacteria was significantly higher at 20 than 5°C (19.1 *vs.* 15.7%). A different effect was noted in the proportions of 16:0, in that temperature did not affect its level in bacteria grown in freshwater, but its proportion in seawater bacteria was significantly higher at 20°C (14.6%) than at 5°C (10.5%). Overall, the PE of *Vibrio* grown at 20°C in both seawater and freshwater media had a significantly higher proportion of saturated fatty acids than that of bacteria grown at 5°C. However, only at 5°C was there a significant difference between bacteria grown in seawater and freshwater in terms of the total level of saturated fatty acids in the PE.

The predominant isomer of 16:1 in PE was *cis* 16:1n-7 which accounted for 18–23% of the total PE fatty acids. Growth conditions had no major effect on the level of this fatty acid in PE although its level was slightly, but significantly, lower in freshwater than seawater at 5°C. The only *trans*-monoenoic fatty acid detected was *trans* 16:1n-7 which comprised 12.8 and 15.4% of the total PE fatty acids in *Vibrio* grown at 5°C in seawater and freshwater medium, respectively. The level of this *trans*-monoenoic fatty acid was markedly lower in the corresponding cultures grown at 20°C, *i.e.,* 4.4 and 6.3% in seawater and freshwater, respectively. The proportions of 20:5n-3 in PE in bacteria grown at 5°C in seawater and freshwater were very similar at around 4.3%. Likewise there was no difference between bacteria grown in seawater and freshwater medium at 20°C in terms of the percentage of 20:5n-3 in PE but the percentage (around 0.9%) was significantly lower than were those of the 5°C cultures. As a consequence of temperature-related changes in the contents of monoenoic and polyunsaturated fatty acids, the PE of bacteria grown at 5°C was more unsaturated overall than that of bacteria grown at 20°C. As with total lipid, analysis of variance of the pooled mass for individual fatty acids showed that the effect of temperature was generally more significant than that of medium composition and that significant interaction between these two factors occurred with only a few fatty acids.

The overall fatty acid composition of PG (Table 4) was notably different from that of PE in that it contained higher proportions of unsaturated fatty acids. Conversely, the overall proportion of saturated fatty acids was lower in PG than PE. Bacteria grown in either freshwater or seawater medium at 20°C contained higher proportions of saturated fatty acids in this phospholipid than those cultured at 5°C.

The levels of monoenoic fatty acids in PG were significantly reduced by growth at 5°C regardless of whether the bacteria were cultured in freshwater or seawater media. Thus, for seawater medium, monoenoic fatty acids comprised 60.2 and 66.2% of total PG fatty acids at 5 and

20°C respectively, with the corresponding values for freshwater medium being 55.0 and 65.9%. The only monounsaturated fatty acid which did not decrease or stayed constant in proportion between 20 and 5°C was *trans* 16:1n-7, which exhibited a marked increase in proportion at the lower growth temperature with both media. As with total lipid and PE, the only polyunsaturated fatty acid present in PG of the *Vibrio* was 20:5n-3 which accounted for 16.2% of the total fatty acids present in PG of bacteria grown at 5°C in seawater and 20.2% in the same phospholipid of bacteria grown at the same temperature in freshwater medium. The proportion of 20:5n-3 was very notably and significantly ($P < 0.001$) lower in the PG from bacteria grown in either medium at 20°C. As with total lipid and PE, the fatty acid composition of PG was apparently more influenced by the temperature at which the *Vibrio* was grown than whether seawater or freshwater medium was employed. The significant interactions between the effects of temperatures and medium composition on fatty acid composition occurred mainly with monoenoic fatty acids.

DISCUSSION

The lipid class composition of the *Vibrio* species examined in the present study is relatively simple with PE and PG predominating and is typical of Gram-negative bacteria in general (1). However, the bacterium apparently lacks the phosphatidylserine and cardiolipin which have been reported for psychrophilic *Vibrio* isolated from marine sediments (9).

The bacterium possessed two types of fatty acids which are not typical of bacteria in general, namely, polyunsaturated fatty acids and *trans*-monoenoic fatty acids. Although these fatty acids have been reported as occurring independently in *Vibrio* (2,10,11,26), as far as we are aware this is the first report of their simultaneous presence in the lipids of a single bacterial species. Since the nutrient was defatted before its incorporation into the growth media, all the fatty acids extracted from the bacteria must have been synthesized *de novo* and not taken up preformed from the medium. The level of 20:5n-3 in the total lipid of the *Vibrio* examined here, however, is considerably less than that observed for bacteria isolated from deep-sea sources (2) where this polyunsaturated acid can account for up to 36.7% of the total fatty acids. As with *Vibrio* species in general (9,17), 16:1 was a major fatty acid of the *Vibrio* species examined in the present study. However, the levels of *iso*-13:0 and *iso*-15:0, particularly the latter, were much higher than have previously been reported for *Vibrio* and other marine species of bacteria (2,9,17,27). It is notable that the reported fatty acid compositions of *Vibrio* bacteria do vary widely (2,9).

Despite their overall rarity in bacteria, *trans* fatty acids have been found in some strains of marine bacteria including *Pseudomonas atlantica* (28) and an unidentified *Vibrio* sp. grown in seawater (11). The levels of *trans*

16:1n-7 in both the PG and PE of the *Vibrio* employed in this study were notably higher, especially at 5°C, than those observed by Okuyama *et al.* (10) in another *Vibrio* species. Furthermore, in the *Vibrio* studied here, the proportions of the *trans*-monoenoic fatty acid in PE and PG were similar, whereas in the bacteria studied by Okuyama *et al.* (10) the *trans* 16:1n-7 was present in higher concentration in PE than PG. The biological significance of *trans* fatty acids in bacteria remains to be established.

Given the relatively high levels of 18:1n-9 present in the lipids of the *Vibrio*, it seems likely that, in addition to the enzymes of the so-called anaerobic pathway of desaturation (1), the bacterium also possesses the aerobic Δ9 desaturase of eukaryotic cells. The wide spectrum of monounsaturated fatty acids present also indicates that the inferred Δ9 desaturase can act on a wide range of both odd- and even-numbered saturated fatty acids and that the *Vibrio* contains an active system for the elongation of acyl chains. Although the profile of monounsaturated fatty acids can be explained by the existence in the *Vibrio* of a single desaturase, the Δ9 desaturase, the synthesis of 20:5n-3 requires the bacterium to possess Δ12, Δ15, Δ6 and Δ5 desaturases if its formation proceeds *via* conventional pathways found in eukaryotes. It is notable that intermediates between monounsaturated and the pentaenoic fatty acid product are not found, even in trace amounts, in the *Vibrio* lipid. Although uncommon, this situation is similar to that found with the dinoflagellate *Crypthecodinium cohnii* in which 22:6n-3 is a major fatty acid and no other polyunsaturated fatty acid comprises more than 0.1% of the total fatty acids (29). It remains to be established whether the desaturations leading to the formation of 20:5n-3 in the *Vibrio* involve acyl carrier protein derivatives or fatty acids esterified in phospholipids, as substrates.

The effects of temperatures on lipid composition were far more pronounced than those of the salinity of the medium. The increased proportions of PE in lipid at low growth temperature is in keeping with the situation observed with poikilothermic animals (7). It is notable, however, that the increase in the proportion of PE was balanced by reductions in those of NEFA rather than those of PG. This lack of change in the proportion of PG is consistent with the fact that significant alterations in the level of this phospholipid in the halophilic *Vibrio costicola* occur only when the salt concentration of the medium is increased to values far in excess of those employed here (30).

Temperature effects on *Vibrio* fatty acid compositions have been reported previously with the actual effect varying with species (9). The present study showed a definite increase in the proportion of polyunsaturated fatty acids in the bacterial lipid as temperature decreased. This is in keeping with the situation reported for many poikilothermic vertebrate and invertebrate animals (7). The increase in the level of 20:5n-3 in the *Vibrio* by lowering growth temperature from 20 to 5°C was slightly less than the sixfold increase in the proportion of 22:6n-3 which occurs when *Vibrio marinus* is subjected to a decrease in environmental temperature from 20 to 2°C (2).

Also very notable was the increase in the content of *trans* fatty acids as the growth temperature decreased. This is in marked contrast to the report of Okuyama *et al.* (10) who found that the *trans*-monoenoic fatty acid content of the lipid from *Vibrio* sp. strain ABE-1 was higher at 20 than 5°C. Previously, increases in the proportion of *trans* 16:1n-7 with increasing growth temperature have been explained in terms of the *trans* fatty acid increasing the phase transition temperature of the membrane phospholipid as an adaptation to changes in the ambient temperature (10). However, this explanation is not applicable to the situation observed in the present study where the level of *trans* 16:1n-7 was higher at 5 than 20°C. Since the proportions of *trans* 16:1n-7 and 20:5n-3 both increased with decreasing temperature, it is possible that the net effect is a cooperative response between two fatty acids in the same phospholipid molecule which ensures molecular packing compatible with membrane bilayer properties required at lower temperature.

In summary, the present study demonstrates that 20:5n-3 and *trans* 16:1n-7 occur simultaneously in both PG and PE of a *Vibrio* species of bacterium and that a reduction in growth temperature significantly increases the proportions of both fatty acids in these lipids. Studies are continuing with the *Vibrio* to establish the pathways of 20:5n-3 biosynthesis. In addition, the positional distribution of *trans* 16:1n-7 and 20:5n-3 in PG and PE and how this is influenced by growth temperature, is under examination.

ACKNOWLEDGMENTS

The authors gratefully acknowledge the assistance of Dr. W.W. Christie, Hannah Research Institute, Ayr, Scotland, in the identification of fatty acids by GC/MS. They also thank Einar Ringø, Foundation for Applied Research, Tromsø, Norway, for making the *Vibrio* available for use in this study.

2-Hydroxyhexadecanoic and 8,9,13-Trihydroxydocosanoic Acid Accumulation by Yeasts Treated with Fumonisin B_1

Tsuneo Kaneshiro[a,*], Ronald F. Vesonder[b], Robert E. Peterson[c] and Marvin O. Bagby[a]

[a]Oil Chemical Research, [b]Mycotoxin Research and [c]Bioactive Constituents, National Center for Agricultural Utilization Research, Agricultural Research Service, U.S. Department of Agriculture, Peoria, Illinois 61604

Fumonisin B_1 is a sphingolipid-like compound that enhances the accumulation of yeast sphingolipids and 2-hydroxy fatty acids. These lipids occur both as freely extractable and cell bound components in yeast fermentations. Both free and bound 2-hydroxy fatty acids produced by *Pichia sydowiorum* NRRL Y-7130 were increased when fumonisin B_1 (50 mg/L) was added to the usual growth medium containing yeast extract/malt extract/peptone/glucose. Fumonisin-treated cultures contained 38 mg/L more 2-hydroxyhexadecanoic and 15 mg/L more 2-hydroxyoctadecanoic acids than did untreated cultures. By contrast, fumonisin inhibited the accumulation of free 8,9,13-trihydroxydocosanoic acid in *Rhodotorula* sp. YB-2501 cultures, leading to 240 mg/L lower trihydroxy acid production than by untreated cultures.
***Lipids 28,* 397-401 (1993).**

Water-soluble fumonisin B_1, a propane-1,2,3-tricarboxylic acid 14,15-diester of the 2-amino-12,16-dimethyl-3,5,10,14,15-pentahydroxyicosane base (1), is a sphingolipid-like compound (Fig. 1). It has been shown to cause, in the presence of [^{14}C]serine, labeled sphinganine (D-*erythro*-2-amino-1,3-octadecanediol) accumulation in rat hepatocytes (2). Fumonisin B_1 is a cerebral toxin (3) and phytotoxin (4) produced by the mold *Fusarium moniliforme.* However, the effect of fumonisin on microorganisms and their lipid composition has not yet been determined.

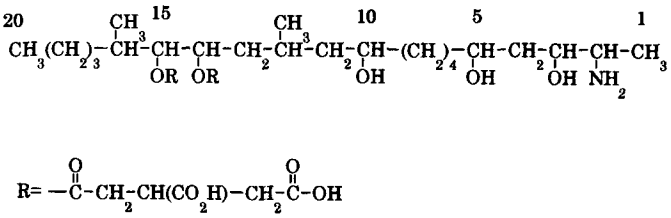

FIG. 1. Structure of fumonisin B_1.

The yeast *Pichia (Hansenula) ciferri* NRRL Y-1031 is known for both its extracellular production of triacetylsphinganine and tetracetyl-4-oxysphinganine (5) and its ability to synthesize sphingolipid bases (6,7). When *P. ciferri* Y-1031 is treated with fumonisin, accumulation of sphinganine, 4-D-hydroxysphinganine and other polar lipids (8) is increased in both the free and bound lipid fractions.

As microbial cultures produce sphingolipids and polar hydroxy fatty acids in freely extractable and bound glycolipid form (5,9,10), specific yeast strains that produce either a 2-hydroxy (11) or 8,9,13-trihydroxy (12) fatty acid extracellularly were studied to assess the effects of fumonisin. In order to detail the lipid changes that occur in fumonisin-treated cultures, both free and bound forms of the hydroxy acids were determined.

P. sydowiorum NRRL Y-7130 produces aerobically an extracellular 2-D-hydroxyhexadecanoic acid in growth-limiting glucose/malt extract medium (11). *Rhodotorula* sp. YB-2501 produces extracellular *erythro*-8,9,13-triacetoxydocosanoic (12) acid under similar restricted growth conditions. For direct comparison of yeast hydroxy acids with sphingolipid (8) accumulation, culture broths were separated by centrifugation into supernatant and particulate (cell/particle) fractions. Each fraction contained freely extractable lipids. From the defatted cells, a bound lipid fraction was extracted after saponification (8,9). The effect of fumonisin B_1 on yeast hydroxy fatty acid production is discussed in respect to the free and bound lipid composition determined.

MATERIALS AND METHODS

Materials and biologicals. 2-DL-Hydroxypalmitic and 2-DL-hydroxystearic acids were purchased from Sigma Chemical Co. (St. Louis, MO). Standard 2-D-hydroxystearic, 3-D-hydroxypalmitic and *erythro*-8,9,13-trihydroxydocosanoic acids were obtained from the NRRL chemical collection of Stodola and Vesonder (5,11,12). Fumonisin B_1 was produced by a *Fusarium moniliforme* fermentation of corn (13) and purified by XAD-2 anion exchange column chromatography in sequence with high-performance liquid chromatography (HPLC).

P. sydowiorum Y-7130 and *Rhodotorula* sp. YB-2501, obtained from the ARS Culture Collection (Peoria, IL), were maintained on 1.6% (wt/vol) agar slants containing 0.3% yeast extract, 0.3% malt extract, 0.5% peptone and 2.7% glucose medium (11) adjusted to pH 6.5. Growth of the yeasts in liquid medium (g wet wt/L) was compared with aerobic cultures grown on 1% (wt/vol) glucose and 5% malt extract medium (12). Because the latter medium increased extracellular accumulation of both 2-hydroxy (11) and trihydroxy (12) fatty acids, but lowered cell yields, the two different media served as useful monitors to relate cellular growth to accumulated fatty products. When yeast cells were dried at 70°C to constant weight, a mean value of 0.28 g dry wt was obtained per g wet weight.

Media (100 mL medium per 300-mL Erlenmeyer flask) containing either 5 mg or no (control) exogenous fumonisin B_1 were inoculated with 3-d cultures (1 mL) of fully grown yeasts. After 5-7 d of aerobic (180 rpm, rotary shaker) incubation at 25°C, fermentation broths were centrifuged.

Lipid and fatty acid extraction. Extracellular fatty acids were extracted as described (11,12). After centrifugation, supernatants were acidified to pH 3 and extracted (Fraction 1). *Pichia* Y-7130 supernatant was extracted with diethyl ether (3 × 50 mL), and *Rhodotorula* YB-2501 supernatant was extracted with ethyl acetate (2 × 50 mL).

Abbreviations: GC, gas chromatography; HPLC, high-performance liquid chromatography; MS, mass spectrometry; TLC, thin-layer chromatography.

Centrifuged pellets containing cells and lipid particles were extracted by a modified Folch procedure (14,15) using two 15-mL portions of warm chloroform/methanol (2:1, vol/vol) (Fraction 2). The respective extracts were combined and concentrated to dryness with a rotary evaporator. Fraction 2 lipids were resuspended in 8 mL chloroform/methanol (2:1, vol/vol), washed with water (0.5 mL) and dried over anhydrous Na_2SO_4. The drying agent was removed by decanting and the solvents were removed *in vacuo*.

Lipids bound to defatted cells (8–10), most likely glycolipids (5,16,17), were saponified with excess 1 N KOH (70% methanol; vol/vol) for 2 h at 70°C. The reaction mixture was acidified with H_2SO_4, mixed with 1 vol of chloroform and filtered through 5 g Celite. The Celite was extracted twice with 50-mL portions of chloroform/methanol (2:1, vol/vol), and the combined extracts were concentrated to dryness (Fraction 3). The yield of each fraction was determined by weighing.

Ester preparation. Lipids in Fractions 1–3 were not analyzed specifically for triacylglycerols, phospholipids and glycolipids, as has been done in other studies (18–22). Instead, a portion of each fraction (5 mg) was saponified with excess 0.5 N KOH (1 mL) in aqueous ethanol (6% water, vol/vol) (12) for 30 min at 70°C. Hydrolysates were then cooled, acidified and extracted with warm chloroform/methanol. Each dried sample was suspended in a few drops of methanol, and the fatty acids were esterified with diazomethane.

Silicic acid chromatography. The methyl esters were separated over a Unisil (100–200 mesh; Clarkson Chemical Co., Williamsport, PA) silicic acid column using 3 g of silicic acid for up to 60 mg of lipids. The 2-hydroxy fatty esters of strain Y-7130 were separated by sequential elution (8 column volumes for each solvent): (i) 20% chloroform in petroleum ether (vol/vol); (ii) 100% chloroform; and (iii) 20% methanol in chloroform. The more polar trihydroxy fatty esters were eluted with (i) chloroform, and solvent mixtures containing (ii) 5%, and (iii) 30% methanol. Selected samples were also analyzed by thin-layer chromatography (TLC). Fractions were separated on silica gel G plates using toluene/dioxane/acetic acid (79:14:17, by vol) as solvent system. The fractions were made visible by acid-charring (23). Authentic methyl esters had the following R_f values: 2-hydroxyhexadecanoate (0.80), 3-hydroxyhexadecanoate (0.67), 2-hydroxyoctadecanoate (0.80), 9,10-dihydroxyoctadecanoate (0.53) and 8,9,13-trihydroxydocosanoate (0.30).

Gas chromatography (GC) and mass spectrometry (MS). Methyl esters of 2-hydroxy fatty acids were dissolved in chloroform/methanol and analyzed immediately by capillary GC. The 2-hydroxy esters were separated isothermally at 230°C using a 15-m SE-30 column (SPB-1; Supelco Inc., Bellefonte, PA) and were quantified by calculating peak areas relative to authentic standards. Authentic 2-DL-hydroxypalmitate and 2-DL-hydroxystearate gave mean values of 36.2 and 33.3×10^6 unit areas per mg, respectively, using a Hewlett-Packard 5890 instrument (Avondale, PA). The less-volatile trihydroxy fatty ester was analyzed at 270°C as trimethylsilyl derivative that was generated with Tri-Sil TBT reagent (Pierce Chemical Co., Rockford, IL). Authentic methyl 8,9,13-tri(trimethylsiloxy)-docosanoate gave a mean peak area of 57.7×10^6 units per mg of free acid.

Structures were confirmed by GC/MS using a fused silica, 25-m capillary column coated with methyl silicone in tandem with a Hewlett-Packard 5970 Mass Selective Detector (70 eV; Palo Alto, CA). Methyl esters were separated on the GC column by temperature programming from 160–250°C at an 8°C increase per min and holding at 250°C for 10 min. Authentic methyl 2-DL-hydroxyhexadecanoate (molecular weight 286) gave characteristic molecular ion and mass ion fragments of *m/z* 227, 208, 182, 159, 127, 97 and 83. Authentic methyl 8,9,13-tri(trimethylsiloxy)docosanoate (molecular weight) 618) gave characteristic ions of *m/z* 401, 373, 318, 283, 245, 229, 147 and 129. The mass spectra of these compounds have been characterized earlier by others (24,25).

RESULTS

Fumonisin B_1 did not significantly affect the cell yield of the yeasts. *Rhodotorula* sp. YB-2501 cultures produced 33 g wet wt/L of cells when grown on yeast extract/malt extract/peptone/glucose medium containing either 50 mg/L or no fumonisin B_1. In the same medium, growth of fumonisin-treated *P. sydowiorum* Y-7130 was retarded slightly by 10%, yielding 41 g wet wt/L without (control) and 36 g with fumonisin treatment. With the restrictive growth medium of glucose/malt extract, cell yields averaged 8 g wet wt/L for strain YB-2501 and 21 g/L for strain Y-7130, regardless of fumonisin treatment. Thus cellular yields were affected more by the nutrients than by fumonisin.

Fumonisin effect on 2-hydroxy fatty acid accumulation. With *P. sydowiorum* Y-7130, which is known to produce extracellular accumulation of 2-D-hydroxyhexadecanoic (hydroxy C_{16}) and 2-hydroxyoctadecanoic (hydroxy C_{18}) acids (11), fumonisin B_1 supplementation was found to increase 2-hydroxy fatty acid production. Yeast hydroxy fatty acids are extractable in both free and bound forms and accumulate more readily in a glucose/malt extract (11, 12) rather than in yeast extract/malt extract/peptone/glucose fermentation broths. The data in Table 1 are therefore presented separately to allow detailed assessment. Cellular 2-hydroxy fatty acid accumulation was significantly affected by fumonisin in vigorously growing cultures using a yeast extract/malt extract/peptone glucose medium. However, when grown in the restrictive glucose/malt extract medium, the fumonisin effect on 2-hydroxy acid accumulation was less noticeable.

In yeast extract/malt extract/peptone/glucose medium, fumonisin-treated strain Y-7130 cultures accumulated 38 mg/L more free 2-hydroxy C_{16} and 15 mg/L more free 2-hydroxy C_{18} acids (Table 1; combining Fractions 1 and 2) than did untreated control cultures. The fumonisin-treated cultures accumulated increasing amounts of hydroxy C_{18} (14% increased to 19% of total peak areas by GC) rather than hydroxy C_{16} (75% decreased to 50%) esters. Bound hydroxy C_{16} and C_{18} acids in Fraction 3 (total of 24 mg/L) also increased in fumonisin-treated cells. In addition, 2-hydroxy fatty acids bound to fumonisin-treated cells appeared to be a larger portion (2.4/25) of the total, bound polar lipids than those from untreated cells (0.04/44).

Large amounts of cell bound lipids (0.3 to 1.1 g/L) were recovered in saponified Fraction 3. Fumonisin-treatment caused a decrease in bound, nonpolar lipids (1.1 g

[a] Abbreviations: C_{16}, methyl 2-hydroxyhexadecanoate; C_{18}, methyl 2-hydroxyoctadecanoate; GM, growth medium of glucose/malt extract; nonpolar, methyl ester of nonpolar lipid fraction recovered from silicic acid column; polar, methyl ester of polar lipid fraction recovered from silicic acid column; YMP, growth medium of yeast extract/malt extract/peptone/glucose.

[b] Liquid cultures of the yeast were separated by centrifugation. Supernatant, cell/particle and saponified residue (bound) fractions were subsequently extracted with solvents.

[c] Lipid fractions were saponified and methyl esters prepared before partition by silicic acid chromatography. Nonpolar lipids were eluted with 20% chloroform/petroleum ether (vol/vol), and polar lipids were eluted with chloroform.

[d] Determined by capillary gas chromatographic peak areas relative to standard C_{16} and C_{18} compounds, 36.2 and 33.3 $\times$ 10^6 unit area per mg free acid, respectively.

decreased to 0.7 g/L), whereas polar lipids were not affected (0.4 g to 0.3 g/L).

TLC analysis of the methylated polar lipids showed four prominent fractions at R_f 0.65, 0.75, 0.95 and 1.0, one of which was similar to authentic 2-hydroxy C_{16}–C_{18} methyl esters (R_f 0.80 $\pm$ 0.05). Analyses in combination with GC indicated that the 2-hydroxy acids of fumonisin-treated cells were a significant portion of the total, bound polar lipids (16.1/44 or 37%). GC/MS of selected samples confirmed the presence of 2-hydroxy C_{15}–C_{18} methyl ester homologues (23,24). In addition to the expected molecular ions, fragment ions $[M-59]^+$ were most prominent. For example, authentic methyl 2-hydroxyhexadecanoate and samples from the yeast fractions (Table 1) gave identical retention times and MS fragment ions.

Decrease in 8,9,13-trihydroxydocosanoic acid accumulation. Table 2 contains data for *Rhodotorula* sp. YB-2501 which is known to produce extracellular, freely extractable *erythro*-8,9,13-triacetoxydocosanoic acid (12). In contrast to strain Y-7130 (Table 1), the fumonisin-treated strain YB-2501 accumulated approximately 240 mg/L less free trihydroxy acid in Fraction 2 than did the untreated controls (Table 2). Also, fumonisin B_1 was found to inhibit free trihydroxy fatty acid formation (combined Fractions 1 and 2) in both media. Because both free nonpolar and polar lipids decreased in fumonisin-treated cultures, fumonisin appears to nonspecifically inhibit accumulation of free cellular lipids of the strain YB-2501. However, bound trihydroxy acid of cells grown on yeast extract/malt extract/peptone/glucose medium was not appreciably affected by fumonisin (0.27 g/L for treated culture and 0.24 g/L for control). Thus, the trihydroxy acid represented a major portion of the free polar (25/26) rather than the bound polar (1.9/24) lipids.

The trihydroxy fatty ester was characterized by TLC (R_f 0.30), and the structure was confirmed by GC/MS as that of a 8,9,13-trihydroxydocosanoic acid.

DISCUSSION

Fumonisin B_1 in animal cells and tissues (2,26) inhibits a cellular ceramide synthase; whereby, sphinganine accumulates while sphingenine synthesis is inhibited. Unlike animal cells, *P. ciferri* Y-1031 produce extracellular tetraacetyl-4-oxysphinganine and triacetylsphinganine (5) and may synthesize free sphinglipid bases by an alternate pathway (6,7). Because fumonisin B_1 enhances the accumulation of unknown polar lipids as well as sphingolipids (8) in strain Y-1031 cultures, polar lipid changes need to be considered when other yeast strains are treated with fumonisin (Table 1).

In our studies, both 2-hydroxy fatty acids of *P. sydowiorum* H-7130 (Table 1) and sphingolipids of strain Y-1031 accumulated in fumonisin-treated cultures. Fumonisin B_1 was not particularly toxic to the yeast cells as judged by cell yields. As expected, fumonisin increased both types of polar lipids when growth occurred in a restrictive glucose/malt extract medium. Nonpolar lipids bound in cells (Fraction 3) decreased significantly from 1.1 g/L to 0.72 g/L upon fumonisin treatment. The

	GM	50	2.5	4.8	0.2

[a] Abbreviations: C_{22}, trimethylsilylated derivative of methyl trihydroxydocosanoate; GM, growth medium of glucose/malt extract; nonpolar, methyl ester of nonpolar lipid fraction from silicic acid column; polar, methyl ester of polar lipid fraction recovered from silicic acid column; YMP, growth medium of yeast extract/malt extract/peptone/glucose.

[b] Liquid cultures of the yeast were separated by centrifugation. Supernatant, cell/particle and saponified residue (bound) fractions were subsequently extracted.

[c] Lipid fractions were saponified and methyl esters prepared before partition over silicic acid column. Nonpolar lipids were eluted with chloroform, and polar lipids were eluted with 5% methanol/chloroform (vol/vol).

[d] Trimethylsilylated C_{22} determined by capillary gas chromatographic peak areas relative to standard 8,9,13-trihydroxydocosanoate (57.7×10^6 unit area per mg free acid).

lipid changes caused by exogenous fumonisin were similar in respect to 2-hydroxy acids and sphingolipids. Whether other bound polar lipids (Fraction 3) functioned interchangeably with either 2-hydroxy fatty acids or sphingolipids was not determined. However, fumonisin appeared to stimulate the release and turnover of lipids bound to glycolipids and glycosphingolipids (5,17).

The free and bound hydroxy fatty acids of *P. sydowiorum* Y-7130 were found to be mainly 2-hydroxy C_{15}–C_{18} acids, suggesting a prominent C-2 rather than a C-3 hydroxylating system. Thus, analogous to the 2-hydroxy C_{20}–C_{25} fatty acid synthesis by Caribbean sponges (27), a 2-oxidation system involving 2-peroxylactone intermediates (28,29) may be expressed by strain Y-7130.

In contrast, fumonisin B_1 inhibited free 8,9,13-trihydroxydocosanoic acid accumulation (combined Fractions 1 and 2). Moreover, the trihydroxy acid in the bound form (Fraction 3) was not affected by fumonisin. This implies that fumonisin B_1 affects accumulation of trihydroxy fatty acid in yeast in a different way than either 2-hydroxy acid (Table 1) or sphingolipids (8).

ACKNOWLEDGMENTS

We thank Dr. M.E. Slodki (ARS, retired) for helpful suggestions concerning the manuscript and J.J. Nicholson for GC/MS of the fatty acid samples. D.W. Ehmke assisted in the TLC of samples.

Effect of Cell Density on Cytotoxicity of Ether Lipid Analogues in Variants of B16 Murine Melanoma

Luis Lligona Trulla, Armondo Magistrelli, Mario Salmona and **Maria Teresa Tacconi***
Istituto di Ricerche Farmacologiche "Mario Negri", Milano, Italy

Ether lipids are defined here as analogues of naturally occurring lysophosphatidylcholines with cytotoxic activity against neoplastic cells. The activity of 1-*O*-octadecyl-2-*O*-methyl-*rac*-glycero-3-phosphocholine (ET18OMe) and 3-hexadecylmercapto-2-methoxymethyl-propyl-1-phosphocholine (Ilmofosine®) (BM 41.440) was tested in variants of B16 murine melanoma, grown in adhesion cultures (B16F1 with low metastatic potential; B16F10 and B16BL6 with high metastatic potential). Cytotoxicity was evaluated by counting the cells that survived after 24 h of drug exposure. Cholesterol, sphingomyelin, total phospholipid and phosphatidylcholine levels were determined. After 24 h of drug exposure, cultures of the B16BL6 variant contained a larger number of cells, especially when high drug concentrations (100–250 μM) were used, than cultures of the B16F1 and B16F10 variants. The sensitivity to ET18OMe of the three variants was evaluated at different cell densities (at each density the dose was equalized per number of cells/well; 0.1 μmol/10^6 cells/well). In B16F1 and B16F10 cultures the dose-response curve was not affected by the number of cells/well, while in B16BL6 no more than 20% of the cells were killed at all cell densities measured. A linear relationship was noted between cell density and cholesterol/phospholipid and sphingomyelin/phosphatidylcholine ratios in the resistant variant B16BL6, confirming that lipid composition modulates the cytotoxic activity of ether lipids.
Lipids 28, 403–406 (1993).

Ether lipids (EL) constitute a class of biological response modifiers that are cytotoxic to neoplastic cells *in vitro* (1) and protect animals from proliferative metastasis by a number of primary tumors (2). Their mechanism of action and the reasons for their selective action are still to be clarified. EL do not affect DNA metabolism (3), but affect plasma membrane biochemical and biophysical properties (1,4–7).

Two main biochemical parameters have been recognized to affect EL cytotoxic activity, namely membrane cholesterol (CHOL) and endogenous EL levels. CHOL affects the susceptibility of tumor cells to EL either when incorporated into neoplastic cells in culture (8,9), or when variants of leukemic cells rich in CHOL were exposed to EL (10), or when cell membrane cholesterol was depleted by incubating the cells with AL 721 (a mixture of phospholipids, PL) (11). As the metabolism of natural ether lipids appears to be impaired in some tumors (12), EL metabolism may also be affected in these tumors. However, this has not yet been fully clarified (13,14).

Abbreviations: BM 41.440, 3-hexadecylmercapto-2-methoxymethyl-propyl-1-phosphocholine (Ilmofosine®); CHOL, cholesterol; EDTA, ethylenediaminetetraacetic acid; EL, ether lipids; ET18OMe, 1-*O*-octadecyl-2-*O*-methyl-*rac*-glycero-3-phosphocholine; FBS, fetal bovine serum; i.v., intravenous; PC, phosphatidylcholine; PL, phospholipids; s.c., subcutaneous; SPH, sphingomyelin.

Few data are available in regard to the cytotoxic activity of EL on cells grown in adhesion; however, melanomas seem less sensitive to EL than are other tumors (15). In the present study, the cytotoxic activity of 1-*O*-octadecyl-2-*O*-methyl-*rac*-glycero-3-phosphocholine (ET18OMe) and 3-hexadecylmercapto-2-methoxymethyl-propyl-1-phosphocholine (BM 41.440, Ilmofosine) was tested on three variants of the B16 murine melanoma cell line with different metastatic capacity cultured in adhesion.

MATERIALS AND METHODS

ET18OMe was provided by Dr. R. Nordstrom (Medmark Pharma, Munich, Germany) (16). BM 41.440 was provided by Boehringer (Mannheim, Germany) (17). Medium and culture flasks and wells were supplied by Flow Laboratories (Irvine, United Kingdom). Sodium pyruvate, glutamine, nonessential amino acids, vitamins, antibiotics, fetal bovine serum (FBS) and fungizone were obtained from Gibco (Parsley, United Kingdom). All reagents were of analytical grade.

F1, F10 and BL6 variants of the B16 murine melanoma cell line were supplied by Dr. J. Fidler (NCI, Frederick, MD). The metastatic capacity of the three clones as shown by Talmadge and Fidler (18) and tested at semiconfluence was as follows: B16F1, parental B16 melanoma, metastasizes poorly when tumors are implanted intravenous (i.v.) (experimental metastasis) or subcutaneous (s.c.) (spontaneous metastasis); B16F10 is highly metastatic after i.v. injection; B16BL6 is highly metastatic after i.v. and s.c. administration.

Cells were stored at −180°C in flasks containing 2×10^6 cells. Cells for experiments were taken from the frozen stock and used for not more than three passages. Cultures were shown to be mycoplasm-free.

Cells were grown in Eagle's minimal essential medium (with 2 g/L sodium bicarbonate and 20% FBS), supplemented with penicillin (0.02 IU/mL), streptomycin (0.1 mg/mL) and fungizone (0.5 mg/mL) and containing vitamins, nonessential amino acids, 1 mM sodium pyruvate and 4 mM glutamine, in a humidified atmosphere containing 5% CO_2 at 37°C. After five to six days, cells were detached by incubating at 37°C for 1 min with 0.25% trypsin in phosphate buffered saline containing 2 mM ethylenediaminetetraacetic acid (EDTA), and counted with a Coulter Counter (Coulter Electronics Ltd., Hapenden, Herts, United Kingdom) and a cell analyzer (Coulter Channalyzer C-1000).

Approximately 50,000 cells, in triplicate, were placed in 9-cm^2 wells with 2 mL of medium. When the cell number reached $40–50 \times 10^3/cm^2$, the medium was replaced with media containing different concentrations of ET18OMe or BM 41.440, and the cells were incubated for 24 h. To estimate cell density at the beginning of an experiment, additional control wells, also in triplicate, were run in parallel; cells were detached as described above at the time when drugs were added to the experimental groups, and counted.

Stock solutions containing 50–100 mg/mL ET18OMe or BM 41.440 in ethanol were prepared and stored in small aliquots. Immediately before each experiment, stock solutions were diluted with the medium used for growing cells to obtain final concentrations of 20, 40, 100, 150 and 250 μM. Final ethanol content was less than 0.1%. Control media contained similar concentrations of ethanol.

To study the relationship between cytotoxicity and cell density, treatment was started using cultures with various cell densities (25 to 250 × 10^3 cells/cm^2). The dose was adjusted according to the number of cells in the well at the beginning of the treatment (ET18OMe concentration was 0.1 μmol/10^6 cells/well).

Cytotoxic activity in cells detached as described above was measured by erythrosin B dye exclusion. Cytotoxicity test results were expressed as a percentage of viable cells (*i.e.*, cells that retained a permeability barrier against erythrosin B) after 24 h of incubation with EL *vs.* viable cells after 24 h incubation without EL.

For lipid analysis, 0.3 × 10^6 cells were seeded and grown at different densities in T75 cm^2 flasks for 48 to 72 h. Cells were detached as described above and counted, then washed, resuspended in 5 mL of 0.05% hydroquinone-containing methanol and sonicated. Cell lipids were extracted according to Folch *et al.* (19). Aliquots of the resulting chloroform phases were used to measure total CHOL, using the Lieberman-Burchard reaction and, after acidic digestion, Pi in total PL (20). Sphingomyelin (SPH) and phosphatidylcholine (PC) were separated by thin-layer chromatography (21) and their Pi content measured as described above.

Duncan's new multiple range test for multiple comparisons was used for statistical analysis.

RESULTS

B16 murine melanoma variants with different metastatic capacity, grown in adhesion cultures to reach approximately 40 × 10^3 cells/cm^2, were exposed for 24 h to a range of concentrations of ET18OMe and BM 41.440. Toxicity was dose-related in all variants, though more BL6 cells survived than in the other variants, after concentrations of 100 μM or more of ET18OMe (Fig. 1, panel A) and BM 41.440 (Fig. 1, panel B). For both drugs the approximate ID_{50} concentrations were 85 μM in F1, 106 μM in F10 and 150 μM in BL6.

In various neoplastic cells the cytotoxic effect of EL can be modulated by other lipids (8–11). In order to test whether the lower sensitivity of the BL6 variant was related to some intrinsic difference in lipid composition, CHOL and PL were measured in the three variants. CHOL and PL levels of murine melanoma variants were affected differently by cell density: PL tended to decrease in all variants with increasing cell number, whereas CHOL decreased only in F1 and F10, while in BL6 it was low at low cell density and rose gradually with cell number (Table 1).

SPH and PC levels were also measured under these conditions: as with CHOL, SPH levels dropped as cell density increased in F1 and F10, but increased slightly in BL6; PC remained unchanged. Thus SPH/PC ratios fell with increasing cell density in F1 and F10 (Table 2) ($P < 0.05$ in low compared to high density), while the ratio increased with cell density in BL6. SPH/PC ratios of the

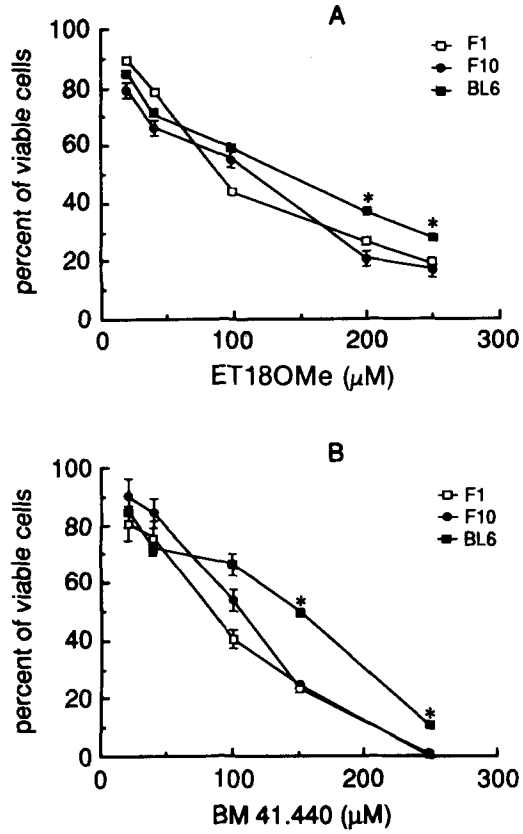

FIG. 1. Effect of 24-h exposure to ET18OMe (panel A) and BM 41.440 (panel B) on cytotoxicity in variants of B16 murine melanoma. 1-*O*-octadecyl-2-*O*-methyl-*rac*-glycerol-3-phosphocholine (ET18OMe) and 3-hexadecyl-mercapto-2-methoxymethyl-propyl-1-phosphocholine (Ilmofosine®) (BM 41.440) were added when cell density was 50 × 10^3 cells/cm^2. Results are the percentages of viable cells after 24-h incubation with ether lipids (EL)/viable cells after 24-h incubation without EL. Each point is the mean ± SEM of 3–4 determinations. The asterisk designates $P < 0.01$ in comparison to F1 at similar drug concentration.

BL6 variant were significantly different ($P < 0.05$) from F1 at low density and from F1 and F10 at high density.

The data indicated that BL6 membranes differed in lipid content from those of the two other variants, especially when cultures were dense. This difference may have influenced the sensitivity to EL. The effect of cell density on the sensitivity of the cells to EL was therefore studied in all variants, using ET18OMe as the representative EL (Fig. 2). Cultures were grown for different time periods to obtain cell numbers per well ranging from 25 to 250 × 10^3 cells/cm^2 (densities at which lipid changes were observed), then ET18OMe was added. The doses were proportional to the number of cells/well (0.1 μmol/10^6 cells). In F1 and F10, cytotoxicity was dose related, rising with the number of cells in the well at the time of addition of the drug (for example, when cell density was 250 × 10^3 cells/cm^2 and the drug concentration 0.22 μmol/10^6 cells, only 10–20% of cells survived) (Fig. 2). In BL6, instead, as many as 70–80% of cells survived at all cell densities (and drug concentrations) tested, suggesting that a high percentage of BL6 cells was resistant to EL. This could be observed when cultures were dense and it correlated with high relative amounts of CHOL and SPH.

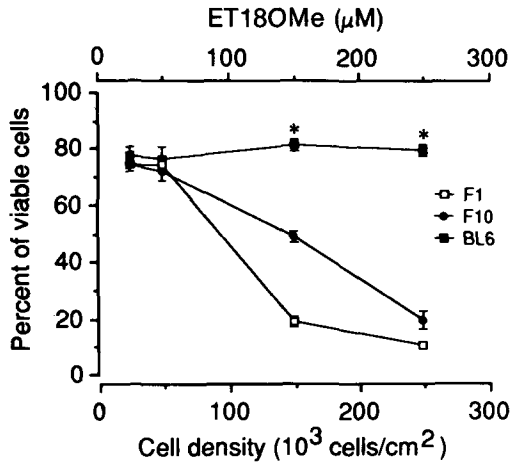

FIG. 2. Relationship between cell number and 1-*O*-octadecyl-2-*O*-methyl-*rac*-glycerol-3-phosphocholine (ET18OMe) cytotoxicity. The dose used (0.1 μmol/10^6 cells/well) was proportional to the number of cells before addition of the drug. Results are the percentages of viable cells after 24-h incubation with ether lipids (EL)/viable cells after 24-h incubation without EL. Each point is the mean ± SEM of 3–4 determinations. The asterisk designates $P < 0.01$ compared to B16F1 and B16F10.

DISCUSSION

The data confirm previous observations on the critical role of certain lipids on EL activity (8–11), but also demonstrate that endogenous conditions affecting lipid composition (in this case, cell density) can influence the effect of EL even within the same cell line. CHOL/PL and SPH/PC ratios are often taken as indices of membrane fluidity: the higher these ratios, the lower membrane fluidity (21). This could be an important factor since EL are known to exert their cytotoxic activity on the membrane. Blebs and holes have been observed in plasma membranes upon ET18OMe treatment of HL60 cells (17,23). Membrane lipids may affect EL sensitivity, for example, by reducing EL binding to cell membranes or by modifying drug permeability. This latter mechanism was proposed by Ramu *et al.* (24) to explain how tamoxifen and other drugs circumvent multidrug resistance. In fact, they found an increase in PC and a reduction in SPH in multidrug resistant cells after treatment with tamoxifen and other compounds with similar activity.

Of course, there may be other explanations for the different sensitivities of the BL6 variant to EL. For example, other PL, like phosphatidylserine or the fraction containing phosphatidylglycerol and cardiolipid, are also

changed in BL6, in comparison to both F1 and F10 (25), while phosphatidylinositol contents were similar to those of the other high metastatic variant, F10.

It is not clear at present why the contents of certain lipids differ so much in BL6 and the other variants; BL6 growth rate and cell volume were not different from those of F1 and F10 (25). One possibility is that, as BL6 is highly malignant (it retains metastatic capacity after s.c. injection and growth of a primary tumor) it may have developed altered metabolic pathways affecting membrane functions, which may be essential for it to spread and adhere to other tissues.

Endogenous EL have been suggested to play a role in EL cytotoxicity (13,26), but no data are available on their levels in the BL6 variant. A difference in the rate of uptake of EL (by endocytosis) has also been proposed to explain resistance of certain tumor lines (27).

The data confirm that membrane lipids can modulate EL activity. Further studies should give interesting clues as to the relationship between EL cytotoxicity and lipid make up, and may suggest strategies for improving therapeutic efficacy. For example, it may become possible to improve the effectiveness of EL (which at present is very low, at least *in vivo*), by manipulating the lipid composition of target cells. For example, in bone marrow purging, a treatment in which these drugs are currently being tested (28), reducing the CHOL content might increase the sensitivity of leukemic cells to EL. Another possibility, which needs further study with a larger number of tumors, is that by knowing the lipid content of a certain tumor, one could predict whether EL treatment has any likelihood of success. Taking into consideration the observations of Ramu *et al.* (24) and a previous observation by Tsuruo and Fidler (29), who found that among other B16 melanoma variants BL6 was more resistant to conventional antitumor drugs, we suggest that lipid composition-induced modulation of drug sensitivity may be a more general phenomenon that could be exploited to improve antitumor drug efficacy.

Modulation of Phorbol Ester-Associated Events in Epidermal Cells by Linoleate and Arachidonate

Martha A. Belury[a], **Mary Locniskar**[a] and **Susan M. Fischer**[b,*]

[a]The University of Texas at Austin, Division of Nutrition, Austin, Texas 78712 and [b]The University of Texas M.D. Anderson Cancer Center, Science Park, Research Division, Smithville, TX 78957

To elucidate the events elicited by the skin tumor promoter 12-*O*-tetradecanoylphorbol-13-acetate (TPA), which are modulated by linoleic acid (LA) and arachidonic acid (AA), the activity of these fatty acids in cultured mouse epidermal cells was compared. Approximately 94% of either exogenous radiolabelled fatty acid was incorporated into the total phospholipid pool over 15 h. The relative distribution among the phospholipid classes differed, however, such that approximately 70% of phospholipid-associated [^{14}C]-LA was found in phosphatidylcholine, compared to approximately 30% for [^{14}C]AA. Phosphatidylethanolamine and phosphatidylinositol/phosphatidylserine contained 17 and 13% of the phospholipid [^{14}C]LA, and 34 and 30% of [^{14}C]AA, respectively. Prostaglandin (PG) E_2 production was low but similar in unstimulated cultures prelabelled with either [^{14}C]LA or [^{14}C]AA. However, in cultures treated with TPA (1.6 μM), [^{14}C]AA-prelabelling resulted in approximately three times the amount of [^{14}C]PGE_2 compared with cultures prelabelled with [^{14}C]LA. Cultured cells were found to contain significant Δ6 desaturase activity, which may enable conversion of LA to AA, and thus may account for the observed PGE_2 production from [^{14}C]LA treated cells. AA-Supplemented (1.6 μM) cultures supported approximately twice the induction of ornithine decarboxylase activity by TPA compared with cultures treated with 1.8 μM LA. Activation of partially purified protein kinase C was similar for either fatty acid tested over a 10–300 μM dose range. Overall, the results suggest that LA does not have the same biological activity as AA with regard to several TPA-associated events known to be important in skin tumor promotion. This reduced biological activity of LA may be partly responsible for the known inhibition of mouse skin tumor promotion by high dietary levels of LA [Leyton, J., Lee, M.L., Locniskar, M.F., Belury, M.A., Slaga, T.J., Bechtel, D., and Fischer, S.M. (1991) *Cancer Res. 51*, 907–915].

***Lipids 28*, 407–413 (1993).**

Different types of dietary fatty acids can modulate tumor development in several organ models (1–4). In particular, diets rich in the n-6 fatty acid linoleate (LA; 18:2n-6), have been associated with increased tumor incidence in the pancreas (5), colon (6) and mammary gland (7) of the rat. Additionally, dietary fats containing n-3 fatty acids, such as eicosapentaenoate (20:5n-3) and docosahexaenoate (22:6n-3), have exhibited tumor inhibiting properties in these organs (8–10). In studies of the modulatory effects of dietary lipids on the tumor promotion stage of multistage skin carcinogenesis, we found different effects of n-6 and n-3 fatty acids; increasing the amount of the dietary n-6 fatty acid LA in 15% (w/w) total fat diets correlated with inhibition of tumor promotion (1). In a separate study, a 10% (w/w) fat diet containing n-3 fatty acids in the form of fish oil was shown to not have a significant effect on phorbol ester skin tumor promotion, as compared to an n-6 rich diet (11). With this latter diet LA accumulated in epidermal phospholipids while arachidonic acid (AA; 20:4n-6) decreased slightly, although the ratio of unsaturated to saturated fatty acids did not change appreciably (1). This was somewhat unexpected as LA can be converted to AA in the liver through a series of reactions limited by the first step, Δ6 desaturation. LA and AA can be further metabolized to eicosanoids in the epidermis, including lipoxygenase products of LA and AA (12) and cyclooxygenase products of AA (13).

The metabolites of arachidonate have been shown previously to modulate tumor development in several organs, including the mammary gland (14,15) and skin (reviewed in Ref. 13). Specifically, in multistage skin carcinogenesis in mice, the AA-derived eicosanoid, prostaglandin (PG) E_2 has been found to be required for the induction of ornithine decarboxylase activity (ODC) and epidermal hyperproliferation, events essential to tumor promotion by the phorbol ester, 12-*O*-tetradecanoylphorbol-13-acetate (TPA) (13,16). We have previously shown that TPA-induced PGE_2 production *in vivo* in the epidermis can be modulated by the level of dietary LA (1). However, unlike mammary tumors where increased dietary LA correlated with increased PGE_2 production (10), we found decreased PGE_2 production in the epidermis of animals fed high levels of LA. The diet-induced decrease in PGE_2 correlated with decreased TPA-induced skin papilloma formation (1).

One concept of multistage carcinogenesis is that it represents a progressive disorder of signal transduction pathways that control gene expression (17). TPA may accomplish this through its action as a highly active analog of the endogenous ligand, diacylglycerol, for protein kinase C (PKC). Fatty acids, including LA and AA, have also been shown to activate specific isozymes of PKC *in vitro* (18–20), and thus may contribute to an altered cell behavior mediated by this signal transduction pathway.

The study reported here was concerned with determining whether the correlation between high dietary LA and decreased skin tumor development correlated with reduced biological activity of LA, as compared to AA, in several TPA-induced responses in epidermal cells. We report here on (i) the rate of incorporation into, and release of these fatty acids from, epidermal membranes; (ii) the amount of PGE produced by cells prelabelled with each fatty acid; (iii) the effect of LA and AA on TPA-induced ODC activity; and (iv) the fatty acid activation of PKC *in vitro*. Understanding the differences in the disposition and activity of LA and AA should contribute to our understanding of the effects of specific dietary fats on skin tumor development.

Abbreviations: AA, arachidonic acid; ATP, adenosine triphosphate; DTT, dithiothreitol; EDTA, ethylenediaminetetraacetic acid; EGTA, ethylureglycol-*bis*(β-aminoethyl ether)*N,N,N',N'*-tetraacetic acid; HODE, hydroxyoctadecadienoic acid; LA, linoleic acid; γ-LN, γ-linolenic acid; ODC, ornithine decarboxylase; PC, phosphatidylcholine; PE, phosphatidylethanolamine; PI, phosphatidylinositol; PKC, protein kinase C; PMSF, phenylmethylsulfonyl fluoride; PS, phosphatidylserine; TLC, thin-layer chromatography; TPA, 12-*O*-tetradecanoyl-phorbol-13-acetate.

MATERIALS AND METHODS

Chemicals. TPA was purchased from Life Systems (Newton, MA) and diluted in acetone. [1-^{14}C]AA, [1-^{14}C]LA (specific activities, 55.7 mCi/mmol and 54.6 mCi/mmol, respectively) and γ-[^{32}P]ATP (23 Ci/mmol) were purchased from Amersham Corp. (Arlington Heights, IL). Fatty acid methyl esters, adenosine triphosphate (ATP), phenyl methyl sulfonyl fluoride (PMSF), histone, authentic PG and phospholipid standards were purchased from Sigma Chemical Co. (St. Louis, MO). AA, LA and γ-linolenate (γ-LN) standards were obtained from Cayman Chemical Co. (Ann Arbor, MI). Normal phase, Silica Gel 60-254 thin-layer chromatography (TLC) plates (0.25 mm) were obtained from Merck (Darmstadt, Germany); reverse-phase TLC plates were from Analtech (Newark, DE). Solvents and other chemicals were of the highest quality commercially available.

Epidermal cell isolation. Inbred SENCAR (SSIN) mice (21) were obtained from the Science Park Veterinary Division breeding colony (UTMDACC, Smithville, TX). Epidermal cells were isolated from one-day-old newborn mice by the trypsinization procedure of Yuspa and Harris (22). For culture experiments, basal-like cells were plated at densities of 2×10^6 per 35 mm dish, 5×10^6 per 60 mm dish or 15×10^6 per 100 mm dish. The plating medium was an enriched Waymouth's containing 10% fetal bovine serum; the growth medium was an enriched MCDB 151 (referred to as SPRD-111) containing 0.1% fatty acid-free bovine serum albumin but no serum, as described by Morris *et al.* (23). Following plating, the cultures were incubated at 37°C in 5% CO_2 for 24–48 h prior to use in the assays described below.

Phospholipid extraction and analysis. The extent of incorporation of labelled fatty acids was determined by replacing the plating medium with SPRD-111 medium containing radiolabelled LA or AA (0.1 μCi/mL media). At designated times, the medium was aspirated from cultures which were then washed once with cold saline and frozen at −20°C. The thawed cells were scraped into 1.0 mL methanol and a 100-μL aliquot of the cell mixture was counted directly by liquid scintillation. Phospholipids were extracted from the remaining cell mixture with 3.0 mL chloroform/methanol (3:1, vol/vol) and 1.0 mL 2M KCl, and the extracts were dried under nitrogen. Reconstituted extracts as well as authentic standards were separated into phospholipid classes by normal-phase TLC using a solvent system of chloroform/methanol/acetic acid (65:25:4, by vol). Standards were identified with iodine vapors, and corresponding sample phospholipid bands were then scraped and quantitated by liquid scintillation.

Δ6 Desaturase activity. For the analysis of Δ6 desaturase activity in cultured epidermal cells, confluent cultures were grown in serum free SPRD-111 media for 12 to 24 h, after which time cells were scraped and homogenized in ice-cold buffer adjusted to pH 7.0 (24) with 100 mM PMSF, and microsomes were prepared according to the method of Marcel *et al.* (25). Microsomal pellets were resuspended in ice-cold sucrose buffer (0.25 M) with 0.15 M KCl adjusted to pH 7.2. Protein concentrations were determined by the bicinchoninic acid assay (26) system obtained from Pierce Chemicals (Rockford, IL).

Δ6 Desaturase activity was determined in microsomal preparations of cultured cells and adult mouse liver homogenates by measuring the percent conversion of [^{14}C]LA to [^{14}C]γ-LN, according to Chapkin and Ziboh (24). In brief, 2.0 mg microsomal protein was suspended in a potassium phosphate buffer (80 μM, pH 7.2). A duplicate set of microsomal preparations was boiled for 30 min to destroy desaturase activity in order to determine the rate of nonenzymatic conversion of [^{14}C]LA to [^{14}C]γ-LN. [^{14}C]LA was diluted with unlabelled LA to a specific activity of 6.6 mCi/mmole, incubated with the microsomal preparations for 30 min at 37°C and the reaction stopped by the addition of 10.0 mL chloroform/methanol (2:1, vol/vol). Fatty acids were extracted twice, dried under nitrogen and methylated with 6% HCl/methanol (2.0 mL) at 60°C for 2 h. Fatty acid methyl esters were extracted with water/1.0 M aqueous KCl/hexane (1:1:1, by vol) and separated by reverse-phase TLC in a solvent system of acetonitrile/water (90:10, vol/vol) at 40°C. [^{14}C]Fatty acid methyl esters, which co-migrated with authentic standards as identified by autoradiography and staining with iodine vapor, were scraped and quantitated by liquid scintillation counting. The activity of Δ6 desaturase was expressed as percent conversion of [^{14}C]LA to [^{14}C]γ-LN.

TPA-stimulated fatty acid release and PGE synthesis. Release of fatty acids from phospholipids was determined by labelling cultures with either [^{14}C]LA or [^{14}C]AA in SPRD-111 (0.1 μCi/mL medium) for 15 h. The labelled medium was replaced with fresh SPRD-111 containing either acetone or TPA (1.6 μM), and medium was collected at 4 h and quantitated by liquid scintillation counting.

To determine prostaglandin synthesis in viable epidermal cells, cultures were labelled with either fatty acid (0.1 μCi/mL media) for 15 h, washed, then treated with acetone or TPA (1.6 μM) for 4 h. Media were collected and acidified to pH 3 with 1 N HCl and eicosanoids were extracted twice with 3 mL ethyl acetate with extraction efficiencies usually greater than 90%. Extracts were dried under vacuum, redissolved in ethyl acetate and applied with standards to normal-phase silica G TLC plates. Plates were developed with the organic phase of ethyl acetate/isooctane/acetic acid/water (28:13:5:25, by vol) (27). The band which co-migrated with the PGE_2 standard was identified with iodine vapors, scraped and counted. The sample band is referred to as PGE because in the case of [^{14}C]LA labelled cultures this PG may be either PGE_2 or PGE_1.

ODC activity. ODC activity was assessed in cultures pretreated with cold LA or AA (free fatty acid; 1.8 and 1.6 μM, respectively) for 15 h followed by treatment with acetone (1 μL/mL) or TPA (1.6 μM) for 6 h. The concentration of TPA and fatty acid are based on previous studies with this culture system (28). Homogenized scraped cells were centrifuged (12,000 × *g*) in an Na/K-phosphate buffer containing pyridoxal phosphate. ODC activity was determined in the supernatant as described by Weeks and Slaga (29) and total protein was measured by the Coomassie blue reaction (Bio-Rad, Richmond, CA). Results are expressed as nmol CO_2/mg protein/h.

PKC activation in vitro. To determine the relative ability of LA and AA to activate partially purifed epidermal PKC, cells cultured for 24 h were scraped into buffer [pH 7.6; 20 mM Tris-HCl, 2 mM ethylenediaminetetraacetic acid (EDTA), and 2 mM ethyleneglycol-*bis*(β-aminoethyl ether)*N,N,N′,N′*-tetraacetic acid (EGTA), 1 mM dithio-

threitol (DTT), 1 mM PMSF, 0.5% Triton-X, 10 μg/mL pepstatin A, 20 μg/mL aprotinin, and 50 μg/mL leupeptin], homogenized and centrifuged for 10 min in a Beckman TL-100 ultracentrifuge at 541,000 × *g*. After the supernatant, which represents the total cellular extract, was applied to a 1-mL DEAE-cellulose column, the column was washed with 2 column volumes of buffer (without Triton-X 100) and eluted with buffer containing 0.12 M NaCl. The eluate was collected in tubes containing protease inhibitors. The assay used is that described by Ashendel *et al.* (30). Total protein kinase, as well as non-C kinase activity, was determined by comparing the transfer of ^{32}P from γ-[^{32}P]ATP to histone type IIIs in both the presence and the absence of phosphatidylserine (PS) (100 μg/mL) and 2 mM $CaCl_2$. All reaction mixtures contained 20 mM Tris-HCl, pH 7.6, 10 mM $MgCl_2$, 0.5 mM EDTA, 0.5 mM EGTA, 375 μg/mL histone and 20 μM ATP, along with 0.5–1 × 10^6 dpm γ[^{32}P]ATP. A 75-μL aliquot of the reaction mixture was added to 25 μL of column eluate and allowed to incubate at 30°C for 10 min, after which 50 μL was spotted onto small squares of P81 phosphocellulose paper, immersed in 75 mM phosphoric acid, washed with water, allowed to air dry, and radioactivity was counted. Total counts present in the reaction mixture were determined by counting unwashed paper spotted with 25 μL of reaction mixture. Protein content was also assayed using the Coomassie blue protein assay. From these data, specific activity of PKC was calculated as pmol of phosphate incorporated per min per mg protein. Results are expressed as percent increase in the specific activity of PKC as compared to reactions containing no fatty acid.

Statistical analyses. Data from the above studies were analyzed by the ANOVA Fisher Protected Least Squares Difference test using Statview 512+Software, 1986 (Brain-Power Inc., Calabasas, CA).

RESULTS

Disposition of LA and AA. Because fatty acids are normally found esterified in phospholipids prior to hydrolysis and further metabolism, the equal availability of free LA and AA after agonist activation of cells is dependent on similar patterns of both esterification and hydrolysis. Thus, the extent of incorporation of LA and AA was compared in our serum-free epidermal cell culture system. When confluent cultured epidermal cells were labelled with [^{14}C]LA or [^{14}C]AA, fatty acid uptake was found to increase at the same rate for either fatty acid for up to 15 h ($P > 0.05$) (Fig. 1). Incorporation was nearly maximal by 9 h; for convenience, all further experiments used a 15 h incorporation time.

Comparison of the extent of esterification of the labelled fatty acids into the different lipid classes showed that approximately 94% of either [^{14}C]LA and [^{14}C]AA was incorporated into phospholipids, compared with 6% incorporation into other glycerides for either fatty acid (Fig. 2A). However, the distribution of incorporated LA and AA differed across the phospholipid classes. Of the phospholipid-associated fatty acid, 70% of [^{14}C]LA was incorporated into phosphatidylcholine (PC), and 17 and 13% were in phosphatidylethanolamine (PE) or phosphatidylinositol (PI)/PS (Fig. 2B). [^{14}C]AA was more evenly incorporated into PC, PE or PI/PS (36, 34 and 30%, respectively).

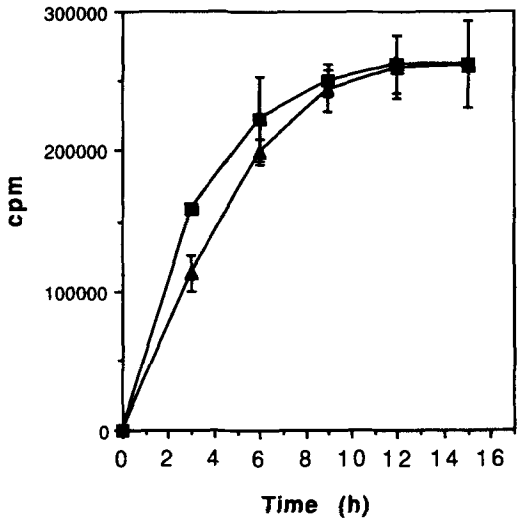

FIG. 1. Rate of incorporation of [^{14}C]arachidonic acid (AA) or [^{14}C]linoleic acid (LA) into total lipids of cultured mouse epidermal cells. Each time point represents cultures (n = 3 or 4) of 2 × 10^6 cells grown for up to 15 h in serum free medium containing 0.1 μCi of [^{14}C]LA (open triangle) or [^{14}C]AA (closed square). Total lipids were extracted and counted. Results are expressed as the mean (n = 3) ± SD of labelled fatty acid incorporated into 2 × 10^6 cells from a representative experiment. Three separate experiments were performed.

As TPA treatment of cultured epidermal cells has been shown to stimulate release of fatty acids from phospholipids *via* phospholipase A_2 activation (31), release of incorporated labelled fatty acids was assessed 4 h after acetone or TPA treatment of cultures (Fig. 3A). Within either the acetone or TPA treatment groups, there was no difference between the amount of radiolabelled LA or AA released. TPA treatment significantly increased ($P < 0.05$) the release of either LA or AA (as fatty acid or metabolites), compared to acetone-treated cultures.

TPA-induced synthesis of radiolabelled PGE was increased significantly ($P < 0.01$) for both fatty acids compared to acetone-treated cultures (Fig. 3B). In AA-prelabelled cultures synthesis of radiolabelled PGE in acetone-treated cultures was significantly higher ($P < 0.01$) at 4 h than synthesis in LA-prelabelled cultures. Within the TPA treatment group, [^{14}C]PGE synthesis was three times greater in [^{14}C]AA-prelabelled cultures than in cultures prelabelled with [^{14}C]LA ($P < 0.01$).

The possibility of LA conversion to AA *via* desaturation-elongation-desaturation was examined by determining Δ6 desaturase activity in cultured epidermal cells. Compared to microsomal preparations from freshmouse liver, cultured epidermal cell microsomes exhibited similar Δ6 desaturase activity measured as the conversion of radiolabelled LA to γ-LN (Table 1). For liver microsomes, an average 10% conversion of LA to γ-LN was observed while microsomes from epidermal cultures supported a 16% conversion.

Biological activity of LA and AA. We have previously shown that AA enhances TPA-induced ODC activity (28); the purpose of this experiment was to determine whether

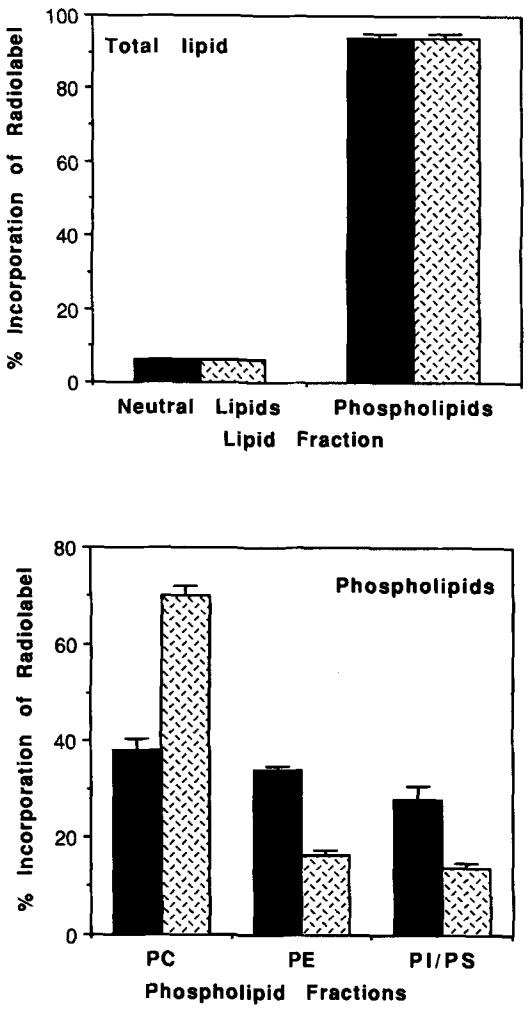

FIG. 2. Incorporation of [^{14}C]arachidonic acid (AA) and [^{14}C]linoleic acid (LA) into epidermal total glycerides and phospholipids. Panel A, following labelling for 15 h with either [^{14}C]AA (solid bars) or [^{14}C]LA (hatched bars) for 15 h, glycerides were separated from phospholipids by thin-layer chromatography (TLC) and counted. Glycerides were tentatively identified as tri-, di- and monoglycerides; sphingomyelin was also identified by co-chromatography with standards. Panel B, phospholipid classes were separated by TLC, identified with authentic standards and counted by liquid scintillation. Values represent the mean cpm ± SD from two separate experiments containing triplicate samples. PC, phosphatidylcholine; PE, phosphatidylethanolamine; PI, phosphatidylinositol; PS, phosphatidylserine.

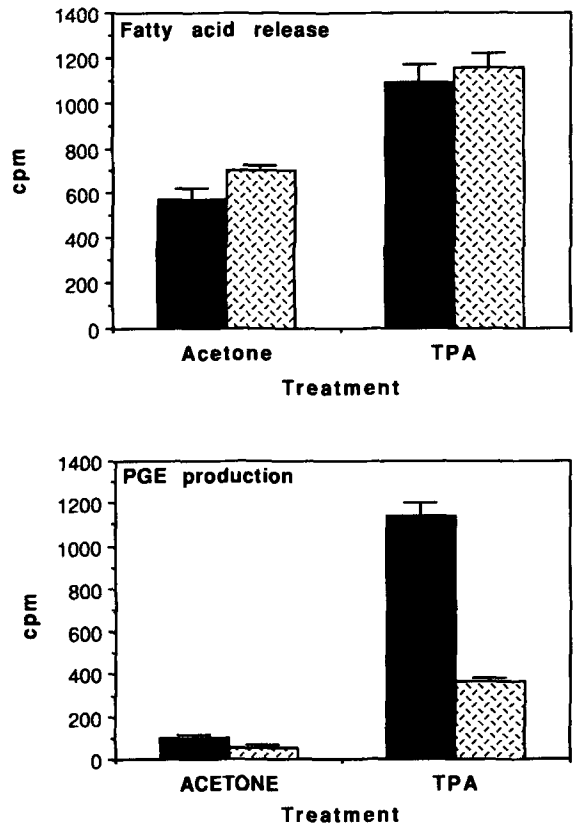

FIG. 3. TPA-Stimulated fatty acid release and PGE production in epidermal cells. After labelling cultures with [^{14}C]AA (solid bars) or [^{14}C]LA (hatched bars) for 15 h, cultures were treated for an additional 4 h with solvent (acetone at 1 μL/mL) or TPA (1.6 μM). Panel A, media was removed and a 100-μL aliquot was counted to determine release of radiolabel. Panel B, PGE production was determined by extraction from 1 mL medium, separation by TLC and counting bands co-migrating with authentic PGE_2 standard. Values represent the mean cpm ± SD from two separate experiments containing triplicate dishes. Abbreviations as in Figure 2; TPA, 12-*O*-tetradecanoyl-phorbol-13-acetate; PG, prostaglandin.

LA supported TPA-induced ODC activity to a greater or a lesser extent than AA. Thus, ODC activity was assessed in cultures supplemented with either cold LA or AA for 15 h followed by treatment with either acetone or TPA for 6 h (Fig. 4). Acetone-treated cultures exhibited very little ODC activity when either fatty acid was present as compared to cultures treated with TPA. Between TPA-treated cultures, AA supported approximately twice the induction of ODC activity compared to cultures grown in LA supplemented media ($P < 0.01$).

Compared to reactions containing no fatty acid, LA and AA activated PKC to a significantly greater extent ($P < 0.01$) (Fig. 5) at concentrations ranging from 10 to 300 μM. Maximal activation of PKC occurred near 100 μM. No difference was observed between the abilities of LA and AA to activate PKC over the dose range tested.

TABLE 1

Δ6 Desaturase Activity in Liver and Cultured Epidermal Cells[a]

Tissue	% Conversion
Liver	10 (9-11)
Epidermal cells	16 (10-22)

[a]Microsomal pellets were prepared from fresh murine liver or epidermal cells grown in serum free media for at least 12 h as described in Materials and Methods. Resuspended microsomal pellets were aerobically incubated at 37°C for 30 min with [^{14}C](linoleic acid). Reactions were stopped by the addition of chloroform/methanol (2:1), fatty acids were extracted, converted to fatty acid methyl esters and separated by reverse-phase thin-layer chromatography. Bands were identified by co-chromatography with authentic fatty acid methyl ester standards, scraped and counted by liquid scintillation. Results are expressed as the average percent conversion (range of three experiments) of [^{14}C]LA to [^{14}C]γ-linolenate.

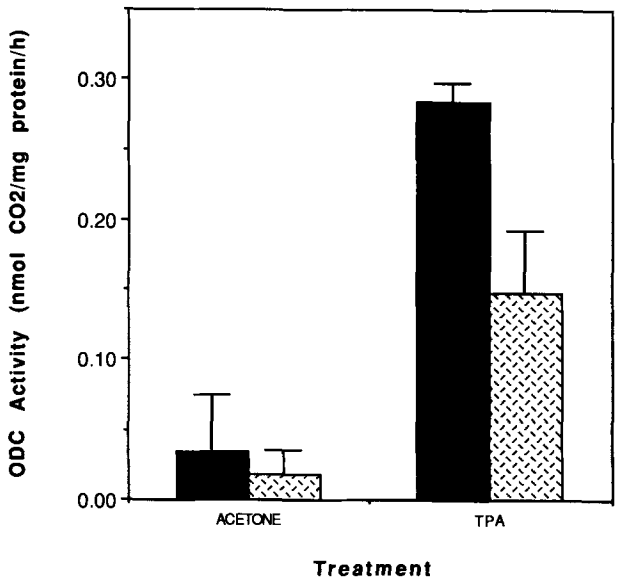

FIG. 4. AA and LA modulation of TPA-induced ornithine decarboxylase (ODC) activity in epidermal cells. Cultures were pretreated with either 1.6 μM AA (solid bars) or 1.8 μM LA (hatched bars) for 15 h followed by treatment with acetone (1 μL/mL) or TPA (1.6 μM) for 6 h. Values represent the mean ± SE for triplicates in two separate experiments. Abbreviations as in Figure 3.

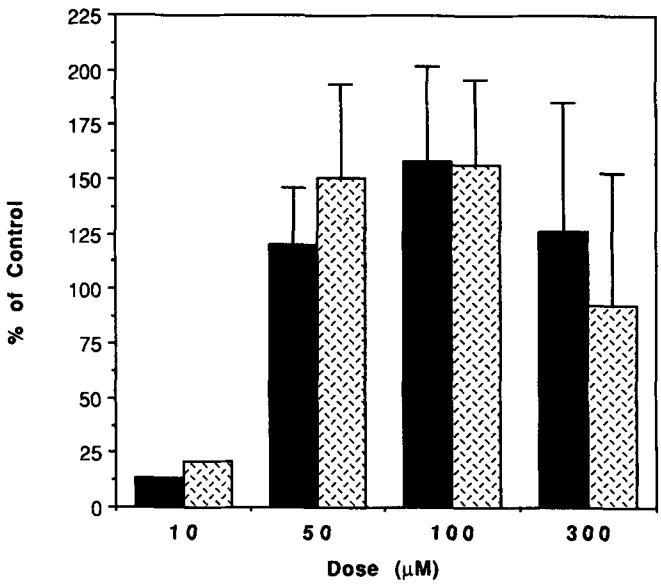

FIG. 5. Protein kinase C (PKC) activation by arachidonic acid or linoleic acid. After partially purifying PKC isolated from cultured epidermal cells, *in vitro* activation by 10, 50, 100, 150 and 300 μM fatty acid was determined. Results are expressed as percent increase in PKC specific activity as compared to assays containing no fatty acid. These data represent the average ± SE of three separate experiments each containing triplicate samples.

DISCUSSION

We have shown that LA, in the form of highly polyunsaturated corn oil, modulates tumor promotion differently in mouse skin (1) compared to mammary tumor development (2). Because fatty acid modulation of mouse tumor development is organ-site specific, we wanted to determine the modulatory roles of the n-6 fatty acids, LA and AA, on specific TPA-elicited events in epidermal cells. In order to answer this question, we traced the rate and lipid class of incorporation and release of radiolabelled fatty acids from cultured epidermal cell phospholipids in cells grown in a serum-free tissue culture system. Where cultured epidermal cells incorporated either exogenously-added fatty acid to the same extent over time, LA was preferentially incorporated into PC while the remainder was incorporated into PE, and PS/PI. Incorporation of AA was more equitably distributed among the four phospholipid classes, the preferential incorporation of labelled LA into epidermal PC is important as this is the major phospholipid which turns over after TPA application to the skin *via* phospholipase A_2 activation (32). Therefore, PC serves as the principal source of free LA available for several metabolic pathways, including lipoxygenase pathways, which have been shown to convert LA to hydroxyoctadecadienoic acids (HODE) in several tissues (33–35), including skin (36). On the other hand, with an elevated pool of free LA, less free AA is available for metabolism to the pro-inflammatory cyclooxygenase and lipoxygenase products known to modulate TPA tumor promotion in mouse skin (13). Hence, LA and its metabolites may have the potential to modulate the TPA-elicited inflammation response which occurs during skin tumor promotion (13).

The rate-limiting step in the conversion of LA to AA, Δ6 desaturase, was found to be active in our cultures to at least the same extent as Δ6 desaturase activity in adult mouse liver. Thus, some of the [^{14}C]LA taken up by the cells in these experiments may have been converted to [^{14}C]AA, although this was not experimentally determined. Conversion of LA to γ-LN by Δ6 desaturation has been previously reported to occur in cultured epidermal cells from neonatal mice and humans (12), but not *in vivo* in guinea pig or mouse epidermis (24,37). This difference between epidermal preparations derived from *in vitro* and *in vivo* sources has important ramifications, especially in the interpretation of these data and in the extrapolation of our findings to *in vivo* fatty acid metabolism and modulation of tumorigenesis in the skin.

The AA-derived prostaglandin, PGE_2, has been shown to modulate several events associated with TPA tumor promotion in mouse skin (13,16,38) including ODC activity, vascular permeability and hyperplasia. We report here that cultures labelled with [^{14}C]LA and treated with TPA supported significantly less radiolabelled PGE production compared with TPA-treated [^{14}C]AA-labelled cells. Because cyclooxygenase, the enzyme involved in the conversion of AA to prostaglandins, has not been shown to use LA as a substrate to form prostaglandins in the skin (36), the small amount of [^{14}C]PGE detected in [^{14}C]LA-supplemented cultures is most likely derived from labelled LA which had been metabolized to either γ-dihomolinolenic acid or AA.

Treatment of the epidermis with TPA has been reported to result in elevated PGE_2 production prior to induction of ODC and epidermal cell hyperproliferation (39,40). Pretreatment of mouse skin with indomethacin inhibited cyclooxygenase activity and thus resulted in inhibition of PGE_2 formation and reduced TPA-induced ODC activity. Induction of ODC was restored if PGE_2 was topically applied to mouse skin with TPA (16). Our studies indicated that *in vitro*, LA supported significantly less

TPA-induced ODC activity compared with AA-supplemented cultures which may be partly due to reduced PGE_2 synthesis. In *in vivo* dietary studies using n-3 rich oils, a reduction in PGE was observed in rat mammary tumors, which correlated with a concurrent reduction in ODC activity (10,41). Reddy and Sugie (42) have also reported a correlation between n-3 rich diets and reduced ODC activity in the colonic mucosa. Similar findings have been reported in the skin (43) where, compared to mice fed corn oil diets, mice fed n-3 fatty acid-rich diets exhibited reduced ultraviolet-induced ODC activity. Although we have previously shown that reduced PGE_2, associated with the synthesis of PGE_3 from eicosapentaenoate, correlated with reduced TPA-induced ODC activity in cultured epidermal cells (29), we did not observe a correlation between dietary n-3 fatty acid reduction of PGE_2 and inhibition of TPA-induced ODC activity in epidermis *in vivo* (11). We are currently investigating the possible modulatory role of high dietary levels of LA on reduced PGE_2 and its relationship to TPA-induction of ODC's activity in mouse skin *in vivo*.

TPA-induced ODC mRNA expression, activity and tumor promotion in mouse epidermis are thought to be mediated by the activation of PKC, the plasma membrane receptor for TPA (29,44). Because fatty acids have been shown to modulate protein kinase activity in several *in vitro* systems (18-20,45), we also investigated the relative abilities of AA or LA to activate PKC isolated from cultured epidermal cells. Both LA and AA were shown to activate PKC equally at all concentrations of fatty acid tested. The similar ability of LA and AA to activate PKC in epidermal cells has been shown in several (45,46), but not all (47) other cell types, probably due to differences in isozyme profiles in different cell types. The ability of LA and AA to equally activate partially purified PKC from cultured epidermal cells suggests that these fatty acids probably do not differentially affect PKC-mediated events by this mechanism in this model system.

In summary, the incorporation of tracer amounts of radiolabelled LA or AA into the phospholipids of cultured epidermal cells was quantitatively similar although LA was preferentially incorporated into PC. With regard to the modulation of two events elicited by phorbol esters, our results indicate that LA is less efficient at supporting PGE production and induction of ODC activity than AA. However, the activation of PKC isolated from cultured epidermal cells was equal for either fatty acid. The reduction of TPA-induced PGE production and ODC activity by LA *in vitro* may at least partially explain the previously observed inhibition by dietary LA of TPA tumor promotion in mouse skin *in vivo* (1).

Agents which prime the neutrophil NADPH oxidase develop during routine storage of whole blood and packed red blood cells. This plasma priming activity can be inhibited by bepafant (WEB 2170), a specific platelet activating factor (PAF) receptor antagonist. Quantitation of the priming agent(s), by a commercially available radioimmunoassay for PAF, reproducibly demonstrated high levels of PAF activity. However, analysis of these plasma samples from stored blood components by gas chromatography/mass spectroscopy did not reveal any 1-*O*-alkyl-2-acetyl-*sn*-glycero-3-phosphocholine. We conclude that the polyclonal antibody to PAF used in these studies may have recognized different epitopes of a family of heterogeneous, biologically active lipids that manifest their effects through the PAF receptor.

Lipids 28, 415–418 (1993).

Platelet activating factor (PAF) is a biologically active lipid which has been implicated as an etiologic agent in a number of clinical conditions which include necrotizing enterocolitis, asthma and the adult respiratory distress syndrome (ARDS) (1–4). PAF also causes a number of biologic effects on blood cells including both platelet aggregation and polymorphonuclear leukocyte (PMN) priming (5,6). Priming is a process by which an agent augments a response to a subsequent agonist but does not itself activate this response (5,7). PAF not only primes the PMN NADPH oxidase but also augments other PMN functions including adherence, chemotaxis and degranulation (5,7,8). Intracellular synthesis of PAF is upregulated by lipopolysaccharide (LPS) priming of PMN (9). PAF is also thought to be a mediator of inflammation, although its precise role in inflammation is not clear (5,7–9). There are specific PAF receptors on the PMN membrane through which PAF manifests its biologic activity including its own synthesis (6,9). These receptors can be blocked by a number of synthetic molecules in a competitive fashion (10). PAF is rapidly metabolized *in vivo* to form inactive lysoPAF by a plasma acetylhydrolase (11). Recent studies in our laboratory have documented the presence of oxidase priming activity in the plasma from stored blood components (12,13). Developing during storage, this plasma priming capacity of whole blood and packed red blood cells enhanced the NADPH oxidase activity in response to formyl-methionyl-leucyl-phenylalanine (fMLP) 2.2–2.8-fold by the time the components outdated (12,13). Priming was inhibited by bepafant (WEB 2170), a specific PAF receptor antagonist (12,13). In addition, the priming activity was extractable into chloroform which confirmed the lipid nature of this priming substance and suggested that this priming agent was PAF (12,13).

In an effort to quantitate the lipid(s) from stored blood, radioimmunoassays for PAF were performed using a commercially available polyclonal sheep antibody, an antibody which has been previously shown not to react with other acyl or alkyl PAF-like lipids except for C_{16} or C_{18} PAF (14). Gas chromatographic/mass spectrometric (GC/MS) measurements demonstrated that the immunoreactivity was not due to PAF or its 1-*O*-acyl analogue. The results suggested that a number of lipids rapidly prime PMN through the PAF receptor, and also showed PAF immunoreactivity.

MATERIALS AND METHODS

Plasma isolation. Ten healthy volunteers each donated one unit of whole blood: five were left as whole blood (WB) and five were separated into packed red blood cells (PRBC) by standard centrifugation procedures (13). WB and PRBC were stored at 4°C under standard protocols (13). Sterile couplers were inserted into the storage containers, and samples were obtained weekly until outdate of the component, 35 d for WB and 42 d for PRBC. These samples were centrifuged at 7,000 × *g* for 7 min to remove cells followed by a second spin at 12,500 × *g* for 5 min to remove acellular debris. Plasma samples were divided into 1-mL aliquots and stored at −70°C.

Neutrophil priming. PMN were isolated by standard techniques including dextran sedimentation, ficoll-hypaque gradient centrifugation and hypotonic lysis (12). The isolated PMN were pre-incubated for 5 min at 37°C with 400 μM WEB 2170 to block the PAF-receptor. Plasma from the stored components was added so that the final plasma concentration was 10% (by vol). The maximal rate of O_2^- formation was measured in response to fMLP by the superoxide dismutase (SOD) inhibitable reduction of cytochrome c at 550 nm as previously described (12).

Lipid extraction and radioimmunoassay (RIA). The samples were extracted with a chloroform/methanol-0.2% acetic acid/water mixture (1:1:1, by vol), and the chloroform phase was taken to dryness in a rotary evaporator (15). An RIA (New England Nuclear, E.I. Du Pont, Boston, MA) was performed three times on each sample. Briefly, the dried lipids were resolubilized in Tween 20 and incubated with a primary sheep polyclonal antibody to PAF for 15 min at room temperature. The secondary anti-sheep antibody together with ^{125}I-labelled PAF was then added, and the reaction mixture was incubated overnight. The samples were centrifuged at 1000 × *g* for 30 min,

TABLE 1

Priming of the Neutrophil Oxidase by Whole Blood (WB) and Packed Red Blood Cells (PRBC) During Storage

Storage time	O_2^- Production[a]			
	WB	WB + WEB 2170 (400 μM)	PRBC	PRBC + WEB 2170 (400 μM)
Control (Buffer)	2.4 ± 0.2[b]	1.9 ± 0.1	2.7 ± 0.5	2.5 ± 0.4
Day 0	1.9 ± 0.1	1.5 ± 0.2	2.9 ± 0.5	2.8 ± 0.3
Day 7	2.1 ± 0.1	1.5 ± 0.1	2.8 ± 0.8	2.6 ± 0.6
Day 14	2.8 ± 0.6	1.7 ± 0.2	3.2 ± 0.9	2.5 ± 0.7
Day 21	4.1 ± 0.5	2.4 ± 0.3	4.7 ± 1.3	2.8 ± 0.8
Day 28	4.7 ± 0.9	1.8 ± 0.3	6.9 ± 1.3	3.2 ± 1.0
Day 35	5.5 ± 0.6	2.0 ± 0.1	9.0 ± 2.0	3.7 ± 1.2
Day 42	–	–	10.7 ± 1.8	4.5 ± 1.8

[a]Priming activity measured as the maximal rate of O_2^- in response to formyl-methioninyl-leucinyl-phenylalanine as described in Materials and Methods. WEB 2170, bepafant.

[b]Results are nmol/3.75 × 10^5 cells/min and numbers are the means ± the SE of the mean of two units of both WB and PRBC.

the supernatant removed and the pellets counted in a gamma counter. The quantitation of PAF was completed by interpolation from a standard curve of known PAF concentrations quantitated simultaneously by the same RIA procedure. As controls, solutions with either [^{3}H]PAF (1-*O*-alkyl-2-[^{3}H]acetyl-*sn*-glycero-3-phosphocholine; NEN, Du Pont, Boston, MA; specific activity 10Ci/mmol) or known concentrations of PAF were extracted and quantitated by RIA. Quantitation of both sets of controls demonstrated a recovery greater than 90%.

GC/MS. A second aliquot from each specimen was analyzed by GC/MS as previously described in detail (16). Briefly, the isolation procedure involved addition of [D_3]PAF (1-*O*-alkyl-2-[$^2H_3$]-acetyl-*sn*-glycero-3-phosphocholine) and [D_3]PAPC (1-*O*-palmitoyl-2-[$^3H_2$]acetyl-*sn*-glycero-3-phosphocholine) for use as internal standards followed by extraction of the sample with ethanol. The lipid components were then adsorbed on an octadecylsilica (ODS) solid phase extractor cartridge (Bond-Elut, 100 mg, Analytichem, Harbor City, CA). The ODS column was eluted with ethanol, and the extract was put directly on a silica solid phase extractor cartridge (Supelco, Bellefonte, PA). An enriched PAF fraction was eluted, hydrolyzed to diradylglycerol by phospholipase C (Sigma, St. Louis, MO) and derivatized with pentafluorobenzoyl chloride (Aldrich, Milwaukee, WI). The samples were taken to dryness and re-dissolved in 10 μL of decane for injection onto the GC/MS.

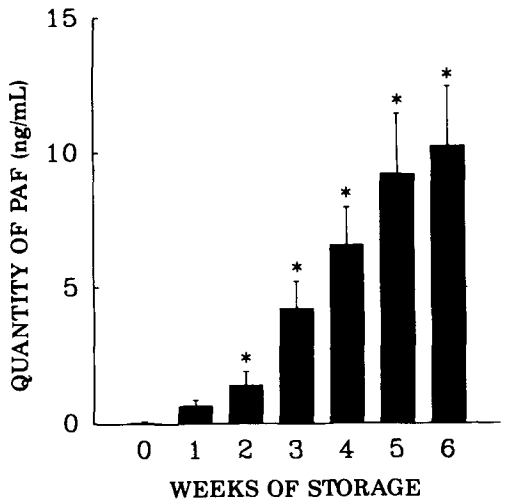

FIG. 1. Quantitation by radioimmunoassay of the amount of platelet activating factor (PAF)-like lipid(s) in plasma samples from stored whole blood. Controls consisting of [^{3}H]PAF and known concentrations of PAF dissolved in fat free albumin prior to lipid extraction demonstrated yields of greater than 90% as described in Materials and Methods. The asterisk denotes statistical significance as compared to the amount of PAF-like lipid quantitated on the day of component collection (day 0, $P < 0.05$).

RESULTS

The PMN priming activity from two units each of both WB and PRBC is shown in Table 1. During routine storage the amount of PMN priming increased dramatically. The maximal plasma priming activity at component outdate was completely inhibited by 40 μM WEB 2170 in samples from WB and by 80 ± 12% in plasma samples from PRBC. Previous results have demonstrated that 400 μM WEB 2170 inhibited purified PAF priming of PMN by 80% in similar experiments (12).

The RIA quantitation of this PAF-like agent that developed over routine storage of all PRBC units is shown in Figure 1. On the day of phlebotomy, the amount of PAF-like lipid estimated by RIA was approximately 50 pg/mL. The amount of this immunoreactive lipid increased with storage to a level equivalent to 10 ng/mL of PAF by the time of product outdate. The amount of lipid became significant following two weeks of storage ($P \leq 0.05$).

Analogous quantitation of the PAF-like lipid was completed for plasma from WB, and the results are shown in Figure 2. As with PRBC, approximately 50 pg/mL of PAF-like lipid was present on the day of isolation. The amount of lipid increased with storage to a maximum amount equivalent to 2 ng/mL of PAF becoming significant by four weeks of storage ($P \leq 0.05$). The PAF immunoreactivity at outdate from PRBC is about 5-fold higher than the corresponding amount of PAF-like lipid from WB.

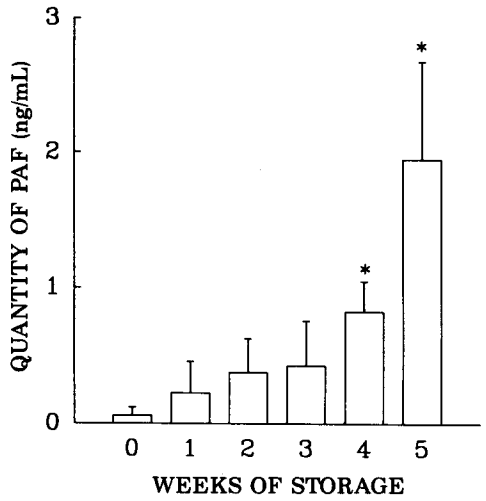

FIG. 2. Quantitation by radioimmunoassay of the amount of platelet activating factor (PAF)-like lipid(s) in plasma samples from stored packed red blood cells. Controls consisting of [^{3}H]PAF and known concentrations of PAF dissolved in fat free albumin prior to lipid extraction demonstrated yields of greater than 90% as described in Materials and Methods. The asterisk denotes statistical significance as compared to the amount of PAF-like lipid quantitated on the day of component collection (day 0, $P < 0.05$).

TABLE 2

Analysis of Plasma Samples from Stored Packed Red Blood Cells (PRBC) and Whole Blood (WB) (at 42 and 35 d, respectively) by Gas Chromatography/Mass Spectroscopy (GC/MS)[a]

Sample	Quantity of lipid	
	PAPC (ng/mL)	PAF (ng/mL)
PRBC1	7.13	<0.1
PRBC2	5.73	<0.1
PRBC3	5.78	<0.1
PRBC4	4.27	<0.1
PRBC5	4.67	<0.1
WB1	9.42	<0.1
WB2	11.90	<0.1
WB3	15.40	<0.1
WB4	14.10	<0.1
WB5	10.40	<0.1

[a]WB and PRBC were collected by phlebotomy, separated and stored by standard techniques. The numbers represent the relative amounts of platelet activating factor (PAF) and PAPC at outdate of the blood products when polymorphonuclear leukocyte priming is maximal. Analysis by GC/MS was completed as described in Materials and Methods. PAPC is 1-*O*-palmitoyl-2-acetyl-*sn*-glycero-3-phosphocholine.

No hexadecyl or octadecyl PAF was detected by GC/MS in any of the plasma samples from either WB or PRBC on the day of collection or the day of component outdate (35 and 42 d, respectively). The result of GC/MS analysis for the day of outdate of the blood component is presented in Table 2. A PAPC analogue of PAF was present in these plasma samples. Although PAPC has the ability to prime PMN, concentrations 100-fold greater than found in stored PRBC and WB were required to produce PMN effects similar to PAF (16). Moreover, the relative amounts of PAPC on the day of collection of the components were similar to the amounts at component outdate. Since the relative amount of PAPC by GC/MS did not increase over storage while the PMN priming activity did, there was no correspondence between PMN priming activity and PAPC concentrations. Neither PAF nor its 1-*O*-acyl analogue increased with storage of either PRBC or WB (Table 2). Previous results have demonstrated that PAPC has some minor cross-reactivity with the PAF antibody, but the increased immunoreactivity observed in samples from stored blood could not be ascribed to PAPC.

DISCUSSION

PAF is a polar lipid that mediates its actions through a specific receptor in the cell membrane (6,9,17). Several biologic and chemical characteristics of this compound have been utilized to define its presence. Both platelet aggregation and PMN priming by activation of the PAF receptor have been attributed to PAF alone (5,6). This receptor can be competitively blocked by heterazepines, a family of compounds which include WEB 2170 (10). Commercially available polyclonal antibodies to PAF have been reported to be specific for C_{16} or C_{18} PAF (14). PAF behaves chromatographically as a polar phosphatidylcholine and has distinctive mass spectroscopic characteristics (18,19).

PMN priming agents have been implicated in the complications of burns and trauma, including ARDS and multiple organ failure (3,4). These agents prime PMN through the PAF receptor as shown by their inhibition by WEB 2170, a specific PAF receptor antagonist (3,4). Furthermore, blood transfusions, especially massive transfusions (equal to the replacement of the total blood volume), or anaphylactic reactions to blood products, in these patients may be associated with the development of ARDS (19,20). Both PRBC and WB contain a PMN priming activity which can be extracted into lipid solvents and which manifested its activity through the PAF receptor (12–14). It appears likely that this biologically active lipid could play an etiologic role in the clinical complications previously noted.

The data presented here demonstrated production by stored blood of a factor or a class of factors with PAF biologic activity and immunoreactivity. Chemical analysis has shown, however, that the factor is not PAF, which is chemically defined as 1-*O*-alkyl-2-acetyl-*sn*-glycero-3-phosphocholine. The exact chemical nature of the compound(s) with PAF-like bioactivity is unknown, but the high degree of specificity of both the receptor and antibody binding would imply structural similarities to PAF. The lipids may be generated in stored cellular blood components by metabolic pathways in individual cell types, by cellular interactions or by peroxidation of membrane lipids during blood storage.

It should be noted that many studies have attributed biological activities to PAF on the basis of inhibition of those biologic responses by compounds which are described to be specific PAF receptor antagonists (1,3,4, 8,10,12–14). Such interpretation should be re-examined in the light of this demonstration that compounds which interact with both the neutrophil PAF receptor and a polyclonal antibody to PAF are not necessarily identical to PAF.

The effects of increasing concentrations of eicosapentaenoic acid (20:5n-3; EPA) and oleic acid (18:1n-9; OA) on esterification to triacylglycerols (TG) and phospholipids (PL), and the relationship to formation and secretion of the very low density lipoproteins (VLDL) were compared in the isolated perfused rat liver. Mixtures of EPA and OA were also studied to determine whether substrate levels of one fatty acid might influence the metabolism of the other. The basal perfusion medium, which contained 30% (vol/vol) washed bovine erythrocytes, 6% (wt/vol) bovine serum albumin (BSA), and 100 mg glucose/dL in Krebs-Henseleit bicarbonate buffer (pH 7.4) was recycled through the liver for 2 h. EPA or OA, as a complex with 6% BSA, was infused at rates of 70, 105, 140 and 210 μmol/h. In other experiments, mixtures of EPA and oleic acid (70 μmol total), with molar percentages of 100, 75, 50, 25 and 0% of each fatty acid were infused per hour. BSA (6%) in the buffer was infused alone and served as the control. At an infusion rate of 70 μmol EPA per hour, hepatic VLDL lipid output was not different from that when fatty acid was not infused (approximately half that when 70 μmol OA/h was infused). However, when larger amounts of EPA and OA were infused individually, rates of VLDL secretion were stimulated to a similar extent with either fatty acid. The apparent inhibitory influence of EPA on TG synthesis and VLDL lipid output when 70 μmol EPA were infused per hour could also be overcome by the presence of as little as 25 mol% OA in a mixture. Furthermore, the presence of EPA in the infused fatty acid mixture stimulated the incorporation of OA into TG, enhancing VLDL secretion. When EPA or OA was infused at rates exceeding 70 μmol/h, a constant amount of endogenously-derived fatty acids was incorporated into VLDL-TG, similar in amount to that when exogenous fatty acid was not supplied. However, when EPA was infused at a rate of 70 μmol/h, incorporation of endogenous fatty acids was depressed. At this low rate of EPA infusion, esterification of EPA and endogenous fatty acid was inhibited. Conceivably, this may reflect the existence of independently-regulated pools of fatty acid (exogenous and endogenous), in that only exogenously available fatty acid preferentially enrich the secreted TG. Enrichment of PL by the infused fatty acid at the higher rates of fatty acid infusion showed similar, but much less pronounced, differences between VLDL and liver, compared to that for TG, providing additional evidence for a distinct metabolic pool of PL used for VLDL fabrication. It now appears that when EPA is available to the liver in high enough concentrations, or when OA (or other fatty acids?) is present in substrate amounts along with EPA, competing reactions and/or specific inhibitory influences of EPA on enzymatic reactions are overcome, and EPA can be utilized in a manner similar to OA for esterification to TG with subsequent enhanced VLDL formation and secretion.

Lipids 28, 419–425 (1993).

We reported recently that the utilization of eicosapentaenoic acid (EPA) for synthesis of triacylglycerols (TG) and formation and secretion of very low density lipoprotein (VLDL), by perfused livers from normal male rats was reduced when compared to oleic acid (OA) (1). These animals had been maintained on standard laboratory chow. Generally, similar findings have been reported for studies with rat (2–4) and rabbit (5) hepatocytes in culture, HepG2 cells (6) and isolated perfused rat (7,8) and monkey livers (9,10). Similar data have been obtained with CaCo2 cells (11). Additional studies with animals fed fish oil, a common source of the n-3 fatty acids, suggested that EPA and docosahexaenoic acid (DHA) are poorer substrates for TG synthesis and VLDL formation and secretion than are the more common fatty acids of the n-9 and n-6 series, and may, in fact, be inhibitory to these processes (8). Our observation (1) that DHA was as effective in stimulating TG synthesis and VLDL TG secretion as was OA, however, is, in general, in conflict with the results of other studies carried out in hepatocytes or perfused liver preparations, which indicated (2,9) that both DHA and EPA were poor substrates for esterification to TG secreted in VLDL. Since we had shown that DHA, one of the common n-3 fatty acids, was not inhibitory to VLDL secretion, but that EPA was at a similar concentration, it was of interest to determine if such inhibiting influence was also evident when greater amounts of EPA were available to the liver. In the present study, therefore, we compared the effects of increasing concentration of EPA alone and OA alone, and mixtures of the two fatty acids on TG synthesis and VLDL secretion. It was observed that the apparent inhibition of VLDL secretion, previously reported with EPA, could be overcome when sufficient fatty acid was provided, or when OA was also supplied to the liver for TG synthesis.

MATERIALS AND METHODS

Materials. EPA (>99% purity) was obtained from Cayman Chemical Co. (Ann Arbor, MI); and oleic acid (>99% purity) from Nu-Chek-Prep, Inc. (Elysian, MN). Purity was confirmed by gas chromatography (GC) of the methyl esters (see below). Bovine serum albumin (BSA) (fraction

Abbreviations: BSA, bovine serum albumin; C, cholesterol; CE, cholesteryl esters; DHA, docosahexaenoic acid; EPA, eicosapentaenoic acid; FFA, free fatty acids; GC, gas chromatography; OA, oleic acid; PL, phospholipids; TG, triacylglycerols; VLDL, very low density lipoprotein.

V) was purchased from Sigma Chemical Co. (St. Louis, MO). The BSA was delipidated with methanol as described previously (12). All other chemicals were reagent grade.

Liver perfusions. Male Sprague-Dawley rats were obtained from Harlan, Inc. (Indianapolis, IN). Animals (225–250 g) were housed for 1–3 wk with free access to Purina Rodent Chow and water before being used in these studies. Livers from fed animals were perfused *in vitro* as described previously (1) in a recycling system with a medium (80 mL) consisting of washed bovine erythrocytes (30% vol/vol) and purified BSA (3% wt/vol) in Krebs-Henseleit bicarbonate buffer, pH 7.4, gassed continuously with 95/5%-O_2/CO_2. After 20 min equilibration, a pulse of 12, 18, 24 or 36 μmol fatty acid, as a complex with albumin (or albumin in buffer only), was added. During the two-hour perfusion, the complex of fatty acid (OA or EPA) with BSA (6%), or albumin alone, in Mg^{++} and Ca^{++} free buffer was infused at a rate of 11.7 mL/h (1) (70, 105, 140 or 210 μmol fatty acid/hour). These infusion rates permitted us to maintain relatively constant concentrations of free fatty acids (FFA), and yet supply the liver with a threefold range in the amount of OA and EPA. The molar ratios of fatty acid to albumin in the infused complexes ranged from 6.9 to 20.7 with the various rates of fatty acid infusion. However, the actual ratio in the perfusion medium was in the range of 0.8 to 1.5, the result of hepatic uptake of the infused fatty acids. In other experiments, mixtures of 20:5 and 18:1 were infused at 70 μmol/h. A 10-mL sample of the perfusate was removed after 1 h for chemical analysis. At the termination of the experiment, a 60-mL sample was obtained for isolation of the VLDL (13), after sedimentation of the erythrocytes. Lipids were extracted from aliquots of perfusate plasma and VLDL with chloroform/methanol (2:1, vol/vol) using 20 mL/mL plasma (12). At the end of each perfusion experiment, the liver was flushed with 60 mL ice-cold 0.9% NaCl, blotted and weighed. One gram samples were minced and homogenized with a Polytron homogenizer (Brinkmann Instruments, Inc., Westbury, NY) in 20 vol of chloroform/methanol (2:1, vol/vol). Individual lipid classes were separated on silica gel thin-layer plates, and assays for TG, phospholipids (PL), cholesterol (C), FFA and cholesteryl esters (CE) were carried out (1).

Analysis of fatty acids by GC was carried out with a Varian 3300 System (Sunnyvale, CA) using an SP2340 column (Supelco, Inc., Bellefonte, PA) (12). Methanolic BF_3 was used to prepare the methyl esters (14).

The rate of hepatic uptake of OA or EPA is expressed as disappearance from the circulating medium and was calculated from the difference between the amount infused and the amount of OA or EPA (GC and mass analyses) remaining at the end of the liver perfusion.

Statistics. All data are presented as means ±SE. The statistical analysis was by a one-way analysis of variance and significance reported for levels of $P < 0.05$. Differences between means were identified using a protected Fisher least significant difference test.

RESULTS

The hepatic uptake of OA and EPA, infused at rates of 70–210 μmol/h for 2 h, is shown in Table 1. No significant differences in uptake between the two fatty acids were observed at any level of infusion. The average concentration of FFA in the perfusate is also presented. Net hepatic secretion of VLDL lipids (Fig. 1) was not statistically different at rates of 70–210 μmol oleic acid/hour during the 2-h perfusion experiment. Although there was a distinct trend indicating an increase in VLDL TG secretion as uptake of oleic acid increased, an apparent maximal output of TG was also evident. We reported previously that with the infusion of OA during 4-h liver perfusions TG secretion positively correlated with the rate of uptake of fatty acid. A maximal output of TG, however, did occur at a rate of OA uptake of about 10 μmol/g liver/h (15). This rate of uptake corresponds to an infusion rate of about 110–120 μmol fatty acid/hour and is approximately the rate at which the maximal output of TG seems to have occurred in the present 2-h liver perfusion studies.

TABLE 1

Uptake by the Perfused Liver and Concentration of OA and EPA in the Medium[a]

Infused fatty acid	Rate of FFA infusion (μmol/h)			
	70	105	140	210
	μmol FFA/mL[b]			
Concentration				
OA (3)	0.47 ± 0.04 (11)	0.55 ± 0.05	0.58 ± 0.07	0.97 ± 0.08
EPA (3)	0.33 ± 0.03 (9)[c]	0.39 ± 0.06	0.53 ± 0.12	0.68 ± 0.07
	μmol/g liver/h			
Hepatic uptake				
OA (3)	5.5 ± 0.6 (11)	8.9 ± 1.8	11.4 ± 1.5	16.4 ± 1.4
EPA (3)	5.9 ± 0.6 (9)	8.9 ± 1.3	12.0 ± 3.0	17.9 ± 2.7

[a]Data are means ±SEM. Numbers of observations are indicated in parentheses. Perfusion conditions are as described in the legend to Figure 1 and the Materials and Methods section.

[b]Average concentration of the infused free fatty acids (FFA) was essentially constant during the two-hour experiment. When exogenous fatty acid was not infused, the average concentration of perfusate total FFA was 0.16 ± 0.02 μmol/mL of which 0.052/μmol/mL was oleic acid (OA) and 0.001 μmol/mL was eicosapentaenoic acid (EPA).

[c]$P < 0.05$ *vs.* OA.

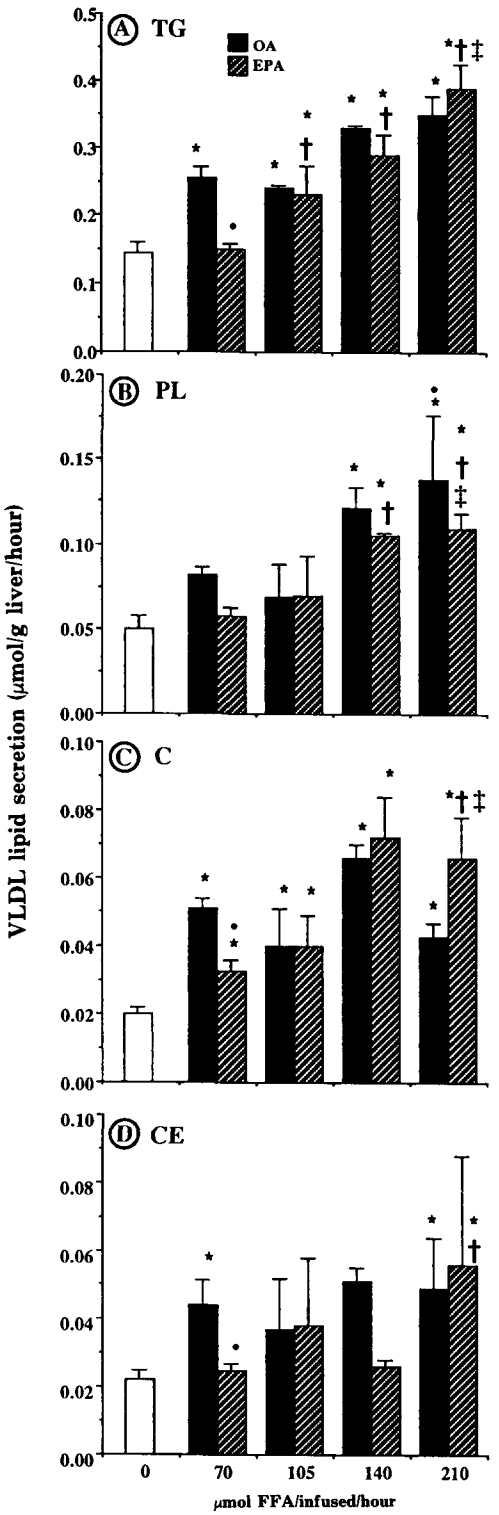

FIG. 1. Effects of eicosapentaenoic acid (EPA) and oleic acid (OA) on secretion of very low density lipoprotein (VLDL) lipids. Liver perfusions were carried out for two hours with a medium containing erythrocytes, as described in the Materials and Methods section. Data are means ±SEM, derived from 3–11 experiments (see Table 1). The symbols indicate: * $P < 0.05$ compared to experiments in which fatty acid was not infused; • $P < 0.05$ compared to infusion of 70 μmol OA/h; † $P < 0.05$ compared to infusion of 70 μmol EPA/h; ‡ $P < 0.05$ compared to infusion of 105 μmol EPA/h. Abbreviations: TG, triacylglycerols; PL, phospholipids; C, cholesterol; CE, cholesteryl esters; FFA, free fatty acids.

With increased infusion of EPA, however, a proportional increase in hepatic output of VLDL lipids was observed (Fig. 1). When EPA was infused at 70 μmol/h, VLDL output was significantly less than that observed with OA and was not different from that when fatty acid was not infused (Fig. 1), as reported previously (1). At higher infusion rates, however, both fatty acids stimulated VLDL output to similar degrees.

Hepatic PL, C and CE concentrations were not significantly affected by the rate of infusion of either fatty acid (24 ± 1, 4.1 ± 0.2 and 0.81 ± 0.05 μmol/g, respectively; $n = 50$). However, after infusion of either fatty acid, hepatic TG concentration was significantly higher (2.73 ± 0.10 μmol/g ($n = 44$) than when exogenous fatty acid was not supplied [1.99 ± 0.15 ($n = 6$)] ($P < 0.05$).

As we reported earlier (12), infused exogenous fatty acid was incorporated preferentially into VLDL-TG and secreted, rather than equilibrating with the large pool of hepatic TG. Table 2 illustrates the enrichment by the infused fatty acid of VLDL and hepatic TG, as infusion rates of OA and EPA were increased. In all cases, incorporation of either EPA or OA into VLDL-TG exceeded that of hepatic TG, indicating the separation of a newly formed metabolic pool and a storage pool, as we have reported for a variety of FFA (12). When the net mass of either infused fatty acid incorporated into the secreted TG was calculated, linearity as a function of infusion rate was evident (Fig. 2). It can also be seen from this figure that the amount of other major fatty acids, linoleate and palmitate (and OA when EPA was infused), present in the TG was similar, regardless of the amount of OA or EPA infused, suggesting a constant synthesis of TG from an endogenous pool, but enriched by additional exogenous fatty acid. The incorporation of infused fatty acid, EPA or OA, into TG, relative to hepatic uptake of fatty acid, is shown in Table 3. It was observed that incorporation of EPA and OA into TG was similar when rates of infusion of FFA were greater than 70 μmol/h; only when infused at a rate of 70 μmol/h was incorporation of EPA less than that of OA in the VLDL, liver or the sum total. Table 4 indicates the similar amounts of endogenously-derived fatty acids (those not infused) which were incorporated into the VLDL-TG with infusion of either exogenous fatty acid; only when EPA was infused at a rate of 70 μmol/h was incorporation of endogenous fatty acid reduced. Infusion of either OA or EPA enriched VLDL and hepatic PL with the infused fatty acid, although much more modestly than it did TG (Table 5).

When various mixtures of OA and EPA were infused (total of 70 μmol/h), secretion of VLDL was stimulated compared to infusion of EPA alone (Fig. 3 and Table 6). With molar ratios for 18:1/20:5 of 75:25 or 50:50, VLDL secretion was stimulated over that when OA was infused alone (Fig. 3). This is evident from incorporation of the fatty acid into the secreted TG. Even with 25% OA, the secretion of TG (Fig. 3) and the incorporation of EPA (Fig. 4) into VLDL-TG (but not liver TG) was enhanced over that when EPA alone was infused. The presence of 25 mol% EPA in the mixture seemed to stimulate the incorporation of OA into TG over that when 70 μmol OA/h (100 mol% OA) was infused (Fig. 4 and Table 6), but statistical significance was not obtained with the smaller number of observations.

TABLE 2

Incorporation of Infused Fatty Acid into VLDL and Hepatic Triacylglycerol[a]

Infused fatty acid	Rate of FFA infusion (μmol/h)				
	0	70	105	140	210
	Total TG fatty acid as OA (%)

VLDL	24.3 ± 1.0(5)	46.7 ± 0.8(8)	51.2 ± 4.4(3)	61.9 ± 1.3(3)	63.2 ± 1.1(3)
Liver	26.0 ± 0.4(5)	38.8 ± 0.9(8)[b]	35.0 ± 4.5(3)[b]	49.5 ± 1.0(3)[b]	39.1 ± 3.5(3)[b]
	Total TG fatty acid as EPA (%)				
EPA					
VLDL	3.1 ± 0.1(5)	26.4 ± 1.7(10)	39.2 ± 2.8(3)	46.4 ± 2.0(3)	57.9 ± 0.6(3)
Liver	3.2 ± 0.6(5)	12.3 ± 1.1(10)[b]	12.1 ± 3.3(3)[b]	33.4 ± 6.8(3)[b]	37.9 ± 9.4(3)[b]

[a]Data are means ±SEM and represent percentage of oleic acid (OA) (18:1) or eicosapentaenoic acid (EPA) (20:5). Abbreviations: FFA, free fatty acid; TG, triacylglycerol.
[b]$P < 0.05$ *vs.* corresponding value for very low density lipoprotein (VLDL).

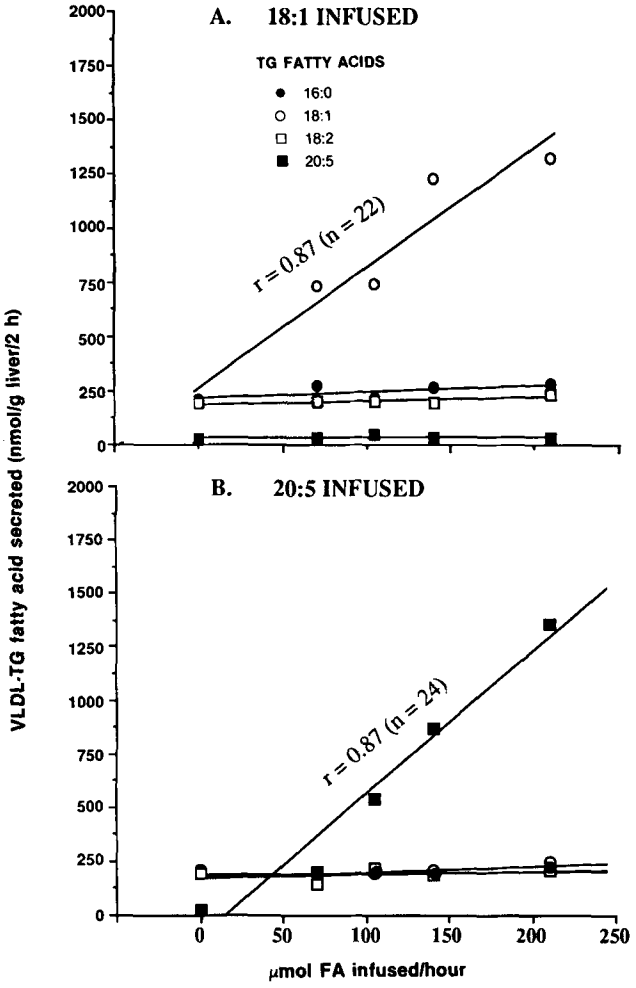

FIG. 2. Effect of infusion rate of oleic acid and eicosapentaenoic acid on secretion of very low density lipoprotein-triacylglycerols (VLDL-TG) fatty acids. The TG fatty acids secreted in the VLDL/g liver/2 hour were calculated as the product of the mean value for TG mass output (Fig. 1) and the percentage of fatty acid in TG for the infused fatty acid (Table 3). Abbreviation: FA, fatty acid.

TABLE 3

Incorporation of Infused Oleic Acid (OA) and EPA into Hepatic and VLDL Triacylglycerol (TG), Relative to Hepatic Uptake of Fatty Acid[a]

Infused fatty acid (n)	VLDL-TG	Liver TG	Total TG
	nmol FFA incorporated/1000 nmol FFA taken up		
OA			
70 μmol/h (8)	71.3 ± 5.1	134.2 ± 31.0	205.4 ± 28.5
>70 μmol/h (9)	54.4 ± 5.8	84.3 ± 14.9	138.6 ± 19.4
EPA			
70 μmol/h (10)	17.9 ± 2.1[b]	50.7 ± 8.4[b]	68.6 ± 10.7[b]
>70 μmol/h (9)	41.3 ± 5.2[c]	76.8 ± 15.3	118.2 ± 19.4[c]

[a]Data are means ±SEM. The values were derived from individual perfusions with the number of experiments given in parentheses. Data points for very low density lipoprotein (VLDL) were calculated from the output of VLDL TG, the percentage composition of the infused fatty acid in the TG (Table 2), and rate at which the fatty acid was taken up (Table 1). For the liver, the calculation was made from hepatic concentration of TG at the end of the 2-h perfusion, the percentage of the infused fatty acid and the rate of which the fatty acid was taken up (Table 1). For liver, the mean (n = 5) amount of each of the infused fatty acids present in TG when fatty acid was not infused was subtracted. Data from experiments in which 105, 140 and 210 μmol fatty acid/h were infused were grouped together since no differences among "groups" were seen (>70 μmol/h). Abbreviations: EPA, eicosapentaenoic acid; FFA, free fatty acids.
[b]$P < 0.05$ *vs.* oleate 70 μmol/h.
[c]$P < 0.05$ *vs.* EPA 70 μmol/h.

DISCUSSION

Our previous report (1) of reduction in utilization of EPA for hepatic TG synthesis, and consequent effects on TG transport in the VLDL, has been reevaluated, using larger amounts of EPA. These current observations indicate a substantial incorporation of EPA into TG similar to that of the reference fatty acid substrate, oleic acid, when EPA becomes available at concentrations greater than examined previously. Generally, our previous data showing re-

TABLE 4

Incorporation of Endogenous Hepatic Fatty Acids into the Secreted VLDL Triacylglycerol (TG) During Infusion of Either OA or EPA[a]

Rate of FFA infusion μmol/h	FA infused	
	OA	EPA
	μmol endogenous FA/g2 h	
None (5)	0.708 ± 0.075	0.904 ± 0.089
70 (8)	0.889 ± 0.053	0.573 ± 0.068(10)[b]
105 (3)	0.771 ± 0.148	0.948 ± 0.293
140 (3)	1.020 ± 0.133	1.388 ± 0.295
210 (3)	0.879 ± 0.070	1.029 ± 0.092

[a]Data are means ±SEM with the number of observations (n) in parentheses. Data were calculated from percentage composition of the total very low density lipoprotein (VLDL) fatty acid (FA) excluding infused oleic acid (OA) or eicosapentaenoic acid (EPA) (Table 2) and the μmol TG FA secreted/2 h (Fig. 1). FFA, free FA.
[b]$P < 0.05$ *vs.* all other groups.

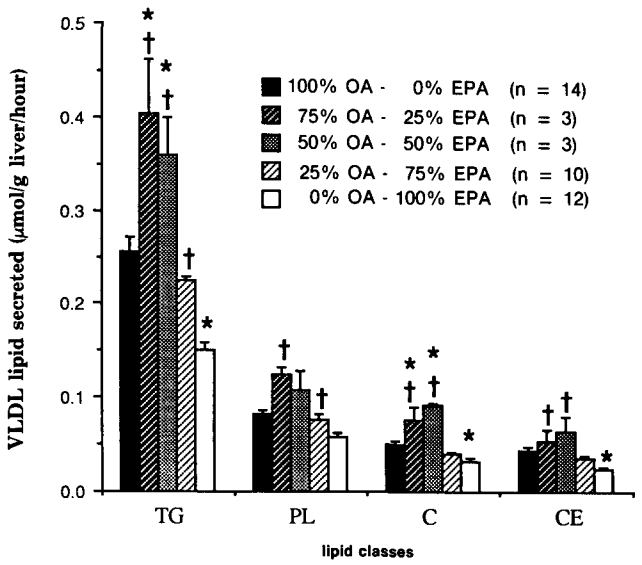

FIG. 3. Effect of oleic acid (OA)/eicosapentaenoic acid (EPA) molar ratio on very low density lipoprotein (VLDL) lipid secretion. Liver perfusions were carried out for two hours with a medium containing erythrocytes, as described in the Materials and Methods section. Seventy μmol of total free fatty acid were infused per hour at the indicated molar percentages. The symbols indicate. *$P < 0.05$ compared to 100% OA; + $P < 0.05$ compared to 100% EPA.

duced secretion of VLDL and TG by EPA are in agreement with those obtained with rat hepatocytes (2–4). Our present data, however, seem to be in conflict with these studies and with those carried out in Hep G2 cells (6,16) and the perfused liver (7) in which EPA was reported to be inhibitory to TG synthesis, expressed in lower rates of esterification to TG, compared to OA. Recently, Lang and Davis (3) reported that synthesis of TG from [^{3}H]glycerol in hepatocytes, in the presence of 1 mM EPA or DHA, was similar to that from OA. The secretion of TG mass, however, was depressed in response to the two n-3 fatty acids as compared to OA. Furthermore, ^{35}S apoB secretion was also impaired. This finding, along with accumulation of hepatic TG, and a similar increase in hepatic apoB content, lead them to conclude that the n-3 fatty acids impair VLDL assembly and secretion, but this did not result from altered rates of synthesis of TG from these fatty acids.

Our data demonstrate that incorporation of either OA or EPA into secreted TG, and accumulation in hepatic TG, can occur at similar rates (Table 3), *i.e.*, total TG synthesis is similar. This observation is therefore in agreement with the data of Lang and Davis (3) which indicated that TG synthesis was the same for OA and EPA except that VLDL secretion in our study was not diminished, as noted in this report. Nevertheless, at the lowest infusion rate we studied, EPA was distinctly inhibitory to TG synthesis and to VLDL secretion, the latter presumably being a consequence of the former.

Previous reports on studies with cultured hepatocytes (5,6) or CaCo2 cells (11) have also emphasized a preferential utilization of EPA over OA in PL formation. Even in perfused liver studies (7) the incorporation of EPA and DHA into hepatic PL has been reported to be quite significant. We did not directly measure PL synthesis; however, the enrichment of hepatic PL content of EPA at the highest rate of infusion was similar to that of OA (Table 5) which would not seem to suggest a preferential utilization pathway for EPA over that of OA. The composition of the pool of secreted PL (VLDL), however, might be indicative of a higher rate of incorporation of EPA, than OA, into newly formed PL since the enrichment noted at the highest rate of fatty acid infusion was indeed greater. The VLDL pool is quite small, however, and more direct measurement needs to be made to establish the signifi-

TABLE 5

[a]Data are means ±SEM. Mixtures of oleic acid (OA) and eicosapentaenoic acid (EPA) were infused at a total of 70 μmol/h. For comparison purposes, data from experiments in which fatty acid was not infused, as well as those for 100% EPA or 100% oleate, are included (Table 2). Abbreviations: VLDL, very low density lipoprotein; TG, triacylglycerols.

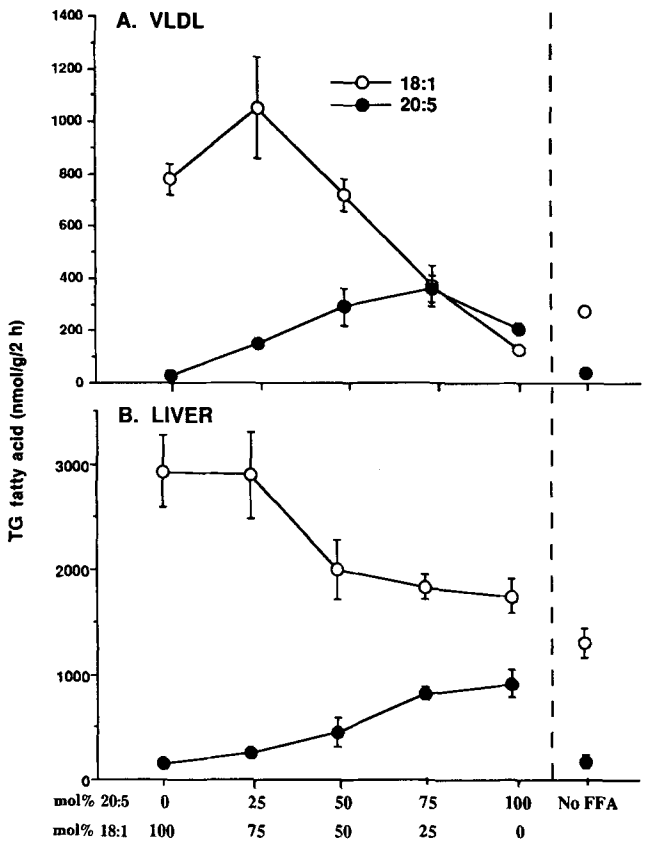

FIG. 4. Effect of oleic acid/eicosapentaenoic acid molar ratio on hepatic and very low density lipoprotein-triacylglycerols (VLDL-TG) fatty acids. Experiments were carried out as indicated in the legend to Figure 3 and the Materials and Methods section. Values were calculated as the product of the individual values for TG mass output (Fig. 3) and the percentage of fatty acid composition of the infused fatty acid in TG. Abbreviation: FFA, free fatty acids.

cance of this observation. Earlier (1) we reported that PL synthesis from [1-^{14}C]EPA and [1-^{14}C]OA was similar, whereas incorporation of OA into TG was greater than was that of EPA, indicating that utilization of EPA for PL synthesis was preferred over that for TG synthesis.

The dilemma surrounding data on the effects of n-3 fatty acids on hepatic VLDL secretion from whole liver and from hepatocytes (HepG2 cells) remains. Consider that the work of Lang and Davis (3), carried out at 1 mM EPA or OA, showed inhibition of VLDL secretion (but not TG synthesis), whereas in the present report, perfusate levels of EPA approaching 1 mM stimulated VLDL secretion, as was observed for OA. Perhaps, the constant supply of the fatty acid as obtained in our perfusion experiments is critical, since in the hepatocyte studies the free fatty acid level would be expected to decrease during incubation. It is also puzzling that we were able to demonstrate that EPA and OA were equally stimulating to TG synthesis and VLDL secretion in the studies with the perfused rat liver model, with amounts of EPA which Wong and Marsh (7) in their liver perfusion studies found inhibitory. Although there were a number of differences in the experimental designs between the two studies, it is not apparent how any of these might be responsible for the difference in results. In general, however, Wong and Marsh (7) found a much greater enrichment of PL and less of TG than we did, which could account for the difference in VLDL synthesis and output. Resolution of the difference must await other unifying evidence not presently available.

In the present liver perfusion studies, as in our previous report (1), there is definite evidence for a persistent secretion of TG derived from endogenous hepatic fatty acids, in agreement with the persistent secretion of endogenous free fatty acids (1). Data in Figure 2 illustrate that a constant amount of two common fatty acids, linoleate and palmitate, are present in secreted TG. As TG secretion increased with infusion of EPA, a constant secretion of OA in TG was also observed. The presence of a constant amount of endogenously-derived fatty acid in the VLDL-TG, regardless of the amount of exogenous fatty acid infused (compared to experiments when FFA was not infused), suggests that the utilization of endogenous and exogenous fatty acid for TG synthesis is independently regulated. This endogenous fatty acid pool presumably is derived from lipolysis (turnover of esterified lipid) and *de novo* synthesis. This consistency in the presence of these two common fatty acids (and small amounts of others) in TG may reflect some restriction in positional

configuration of the fatty acids in the TG, *i.e.*, the liver may be able to produce only TG which contains up to 67% of the individual fatty acid. At the highest rate of OA infusion, a maximum of 63% OA in the TG was obtained, while for EPA the value was similar, 58%, which would seem to support this possibility. Support is also evident in our previous studies with several common long-chain fatty acids in which the greatest enrichment of VLDL-TG was 65% (12).

The mechanisms by which esterification of EPA and secretion of TG in VLDL is enhanced when exogenous OA (at amounts as low as 25 mol% of the 70 μmol of fatty acid mixture infused/hour), or whereby EPA at 25 mol% seemed to enhance OA esterification and TG secretion, are unknown. The observation may reflect the existence of some permissive effect of one fatty acid on another in the process of esterification. Whether this is quite specific, (*e.g.*, for OA and EPA) or is a more general phenomenon is not known, but may relate to limitations on TG structure, as mentioned above.

It is probable that the VLDL particles secreted in response to the infusion of OA or EPA do not differ in size, as indicated by the similarities in ratios (PL + C/TG + CE) of the surface to core lipids (primarily TG) which can be calculated from the data in Figure 1. The overall grouped average of the molar ratios (0.47 ± 0.03; $n = 66$) was not different from that of VLDL produced by the livers of the various individual experimental groups, including that when fatty acid was not provided (0.42 ± 0.06; $n = 6$). This finding suggests that, in these experiments, over the range of TG synthesis and secretion, VLDL fabrication was not curtailed by availability of surface constituents, and that any differences in TG structure (fatty acid composition, up to 63% OA and 59% EPA) do not contribute appreciably to apparent differences in the volume of the secreted particle. The liver will produce and secrete larger VLDL particles, and TG will accumulate in the liver with increasing availability of FFA, perhaps because lipid surface components are not readily available, *i.e.*, PL and/or C (15). We have suggested that C may become limiting (17), resulting in reduced VLDL formation and secretion, and accumulation of TG in the liver. The apparent similarities in particle size as reflected by the lipid ratios in the present study might be predicted, perhaps, because the rate of TG synthesis, reflecting the availability of FFA, seems to be more of a determinant of size (based on these ratios) than is fatty acid structure *per se*, as we suggested previously (12). As we noted previously (12), the molar ratio of the major surface lipids (PL/C) seems to be invariate for the VLDL secreted by the liver. In the present study, the mean value of 66 experiments was 1.98 ± 0.19.

In summary, regardless of the mechanism(s), the inhibition of VLDL secretion observed at low perfusate concentrations of EPA appears to be overcome when increased quantities of EPA are available to the liver, *i.e.*, formation and secretion of VLDL do not differ from that obtained with OA. Furthermore, addition of OA to the medium leads to higher rates of incorporation of EPA into TG. The mechanism(s) which may be involved must be sorted out, whether a reflection of the inhibitory effect on acyl-coenzyme A:1,2-diacylglycerol acyltransferase (18) or phosphatidate phosphohydrolase (6), related to diversion of n-3 fatty acids to PL formation (5,6,11) attended by significant PL compositional differences and related membrane structural modifications; inhibition of lipogenesis (19) or increased oxidation (8), decreased TG transport secondary to defects in VLDL assembly and apoB availability (3,4), or some combination peculiar to species differences or model or experimental design. It is perhaps significant that, only at the lower experimental concentrations of EPA, was VLDL secretion diminished, since it is unlikely that levels of n-3 fatty acid derived from the diet would reach the concentrations seen at the higher infusion rates in our studies.

Involvement of Vitamin E and Protein Thiols in the Inhibition of Microsomal Lipid Peroxidation by Glutathione

Jairam R. Palamanda and **James P. Kehrer***
Division of Pharmacology and Toxicology, College of Pharmacy, The University of Texas at Austin, Austin, Texas 78712-1074

Iron-ascorbate stimulated lipid peroxidation in rat liver microsomes can be inhibited by glutathione (GSH). The role of protein thiols and vitamin E in this process was studied in liver microsomes isolated from rats fed diets either sufficient or deficient in vitamin E and incubated at 37°C under 100% O_2. Lipid peroxidation was induced by adding 400 μM adenosine 5′-triphosphate, 2.5 to 20 μM $FeCl_3$, and 450 μM ascorbic acid. One mL of the incubation mixture was removed at defined intervals for the measurement of thiobarbituric acid reactive substances (TBARS), protein thiols and vitamin E. In vitamin E sufficient microsomes, the addition of GSH enhanced the lag time prior to the onset of maximal TBARS accumulation and inhibited the loss of vitamin E. Treatment of these microsomes with the protein thiol oxidant diamide resulted in a 56% loss of protein thiols, but did not significantly change vitamin E levels. However, diamide treatment abolished the GSH-mediated protection against TBARS formation and loss of vitamin E during ascorbate-induced peroxidation. Liver microsomes isolated from rats fed a vitamin E deficient diet contained 40-fold less vitamin E and generated levels of TBARS similar to vitamin E sufficient microsomes at a 4-fold lower concentration of iron. GSH did not affect the lag time prior to the onset of maximal TBARS formation in vitamin E deficient microsomes although total TBARS accumulation was inhibited. Similar to what was previously found in vitamin E sufficient microsomes [Palamanda and Kehrer, (1992) *Arch. Biochem. Biophys. 293,* 103-109], GSH prevented the loss of protein thiols in vitamin E deficient microsomes. However, GSH did not protect efficiently against the loss of residual vitamin E in deficient microsomes. These data provide support for the concept that GSH protects against microsomal lipid peroxidation by maintaining protein thiols, and consequently vitamin E, in the reduced state. The lack of protection in vitamin E deficient microsomes may be related to the inability of such low levels of vitamin E to inhibit peroxidation.
***Lipids 28,* 427-431 (1993).**

The oxidation of the polyunsaturated fatty acids associated with membranes can result in the disruption of various cellular functions and cause leakage of intracellular contents. This process, termed lipid peroxidation, is believed to be a major factor in causing various toxicities. The susceptibility of polyunsaturated fatty acids to lipid peroxidation is countered in biological systems by various endogenous antioxidant enzyme systems and antioxidants. Vitamin E is a potent chain breaking antioxidant which inhibits lipid peroxidation in membranes (1). However, since the fully oxidized form of vitamin E is inactive and cannot be used to regenerate the parent molecule, vitamin E turnover is relatively slow, and there is only approximately one molecule of vitamin E per 1200 polyunsaturated fatty acids in membranes (2), it is believed that the partially oxidized tocopherol is reduced to vitamin E in some sort of recycling reaction.

The source of the reducing equivalents which might regenerate vitamin E is unknown. A number of researchers have focused on glutathione (GSH) which is capable of inhibiting lipid peroxidation in rat liver microsomes with the help of a putative heat- and trypsin-labile microsomal "factor" (3-6). This factor appears to exist primarily in rat liver microsomes (7), and there is evidence regarding a soluble factor which may perform a similar or related function (8). The protective effect of GSH against microsomal lipid peroxidation is diminished (9,10) and even abolished (11,12) in microsomes from vitamin E deficient rats indicating a requirement for this vitamin. The microsomal factor also appears to require thiol groups for activity since either *N*-ethyl maleimide or hydroxynonenal treatment of the membrane results in its inactivation (13). However, it is also possible that the protective effects of GSH are related to its direct interaction with protein thiols leading to protection or regeneration of vitamin E.

A time course of the effect of GSH on the loss of vitamin E and protein thiols, and on the formation of thiobarbituric acid reactive substances (TBARS) in vitamin E deficient microsomes undergoing iron-ascorbate stimulated lipid peroxidation, has not been studied in detail. The role of protein thiols is of increasing interest because of the lability of the GSH protective effect to thiol oxidants and recent data indicating the importance of protein thiols in controlling lipid peroxidation (14,15). Furthermore, we have recently shown that heating or trypsinizing microsomes abolishes the GSH-dependent protective effect against protein carbonyl group formation, and this is accompanied by a 60% loss of free protein thiol groups (6).

The present study examined the time course of the effect of GSH on vitamin E oxidation and TBARS formation in hepatic microsomes isolated from vitamin E sufficient and deficient rats. The effect of GSH on vitamin E oxidation during peroxidation in vitamin E sufficient liver microsomes was compared to microsomes pretreated with the thiol oxidant diamide. In addition, the time course of the effect of GSH on the loss of protein thiol groups during peroxidation in vitamin E deficient membranes was studied. The results support the concept that both vitamin E and protein thiols are involved in GSH-mediated protection against lipid peroxidation.

MATERIALS AND METHODS

Materials. Adenosine diphosphate (ADP), butylated hydroxytoluene, *N*-ethylmaleimide, thiobarbituric acid, diamide and 5,5′-dithio*bis*(2-nitrobenzoic acid) (DTNB) were

*To whom correspondence should be addressed.

Abbreviations: ADP, adenosine 5′ triphosphate; DTNB, 5,5′-dithio*bis*(2-nitrobenzoic acid); GSH, glutathione; TBARS, thiobarbituric acid reactive substances.

obtained from Sigma Chemical Co. (St. Louis, MO). Ferric chloride, trichloroacetic acid, guanidinium HCl and 2,2′-dipyridyl were obtained from Aldrich Chemical Company (Milwaukee, WI). L(+)-ascorbic acid was obtained from MCS Manufacturing Chemists Inc. (Cincinnati, OH). Oxygen was obtained from Big Three Industries Inc. (Laporte, TX). All other chemicals were of reagent grade.

Animals and diets. Two groups of nine rats were maintained for 9 wk on vitamin E sufficient (500 U of vitamin E acetate/g) and vitamin E deficient (0 U of vitamin E acetate/g) AIN-76A diets obtained from Dyets Corporation (Bethlehem, PA). All studies were done in liver microsomes isolated from rats fed these diets. The body weights of rats were monitored during the 9-wk study, and both groups gained weight similarly.

Preparation of microsomes. Microsomal membranes were isolated by differential centrifugation in a 50 mM potassium phosphate buffer (6). Protein was determined by the microbiuret method (16) using bovine serum albumin as the standard. The protein concentration of the final incubation mixture was adjusted to 2.5 mg/mL. Diamide-treated microsomes were prepared by mixing 1 mL of diamide solution (1 mM in 50 mM potassium phosphate, pH 7.4) with 10 mg of microsomal protein in 1 mL. After incubating on ice for 15 min, this mixture was diluted with 15 mL of cold 50 mM potassium phosphate buffer, pH 7.4 and centrifuged at 101,000 × *g* for 60 min. The supernatant was discarded, the pellet gently washed and finally resuspended in 10 mL of the same buffer (1 mg protein/mL). Control microsomes were treated similarly except that diamide was omitted.

Lipid peroxidation assay. Twenty-five mg of microsomal protein was placed in a 25-mL flask in 10 mL of 50 mM potassium phosphate buffer (6). ADP (400 μM) plus 2.5, 10 or 20 μM ferric chloride and 450 μM ascorbic acid (final concentrations) were then added to initiate lipid peroxidation. The mixture was gassed with 100% O_2, stoppered and incubated at 37°C. Lipid peroxidation was quantitated as TBARS, and the lag time prior to the onset of maximal TBARS formation was measured as described before (6).

Protein sulfhydryl (thiol) and vitamin E assays. Protein thiols were determined according to the method of Boyne and Ellman (17). Briefly, 1 mL of the microsomal incubation mixture was precipitated with 0.3 M perchloric acid. After centrifugation, the pellet was washed with 2 mL of 0.3 M perchloric acid, extracted with 8 mL of ethanol/ethyl acetate (1:1, vol/vol) and dried. The lyophilized pellet was dissolved in 6M guanidinium HCl and the absorbance at 412 nm quantitated after adding 1 mL of 2 mM DTNB solution in the presence and absence of 10 μM *N*-ethylmaleimide (6,18).

Vitamin E was extracted from microsomal membranes with heptane, separated on a C_{18} reversed-phase column by high-performance liquid chromatography and measured electrochemically as described previously (19).

Statistics. Results are expressed as the mean ±SE of three separate determinations. Multiple comparisons between groups were done using the Student-Newman-Keuls test (20) after analysis of variance was performed. A paired *t*-test was used to compare mean values at individual time points with and without GSH treatment. A *P* value less than 0.05 was considered significant.

RESULTS

Vitamin E sufficient microsomes subjected to iron (10 μM)-ascorbate stimulated lipid peroxidation showed a rapid time-dependent accumulation in TBARS formation after a 32-min lag period (Fig. 1A). The addition of GSH inhibited TBARS by 84% at the end of the 60 min of incubation in this system. Increasing the iron concentration to 20 μM decreased the lag time before peroxidation in vitamin E sufficient microsomes to 21 min and increased the amount of TBARS formed after 60 min (Fig. 1B). GSH increased the lag time to 26 min in the presence of 20 μM iron and inhibited the maximal rate of TBARS accumulation.

There was a 56% loss of protein thiols in vitamin E sufficient microsomes treated with the thiol oxidant diamide (Table 1). Although diamide treatment had no effect on microsomal vitamin E content (Table 1), the GSH-mediated protection against TBARS formation was abolished (Table 2).

An iron concentration of only 2.5 μM in the presence of vitamin E deficient rat liver microsomes was sufficient

TABLE 2

Effect of Diamide Treatment on GSH-Mediated Protection Against TBARS Formation[a]

Treatment	TBARS (% of control)
Untreated microsomes + GSH	26.3 ± 9.5[b]
Diamide-treated microsomes + GSH	100 ± 9.3

[a]Data are expressed as mean ± SE of three separate determinations. Thiobarbituric acid reactive substances (TBARS) formation was determined in untreated and diamide-treated vitamin E sufficient microsomes incubated at 1 mg protein/mL with 450 μM ascorbate and 10 μM iron for 30 min. TBARS formation in untreated or diamide-treated microsomes in the absence of glutathione (GSH) were not significantly different and represent control values.

[b]Significantly different from respective control ($P < 0.05$).

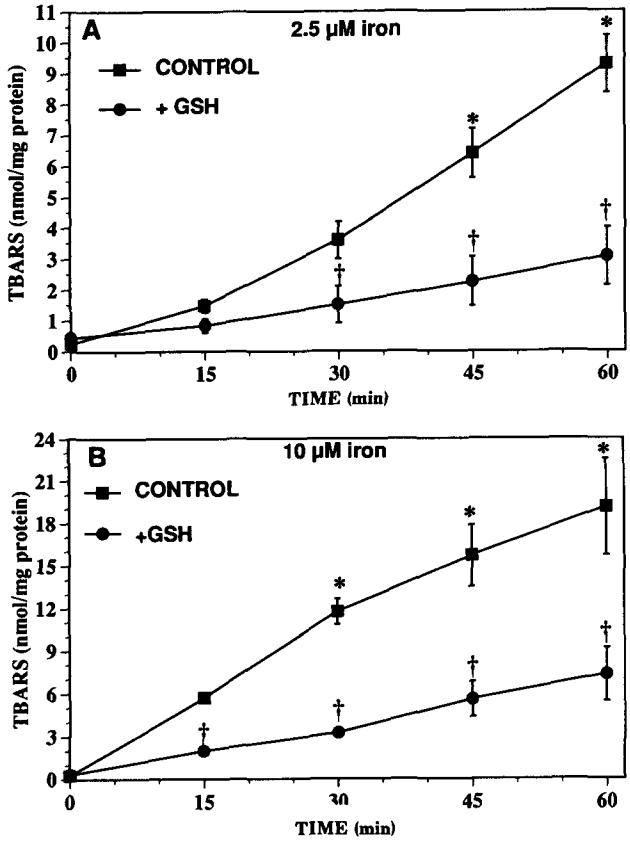

FIG. 2. Time course of thiobarbituric acid reactive substances (TBARS) formation in vitamin E deficient microsomes incubated with 450 μM ascorbate in the presence or absence of 1 mM glutathione (GSH) and either (A) 2.5 μM or (B) 10 μM iron. GSH did not affect the lag time before TBARS formation but inhibited total TBARS accumulation at both doses of iron tested. Each result is the mean ±SE of three separate determinations. †Significantly different from corresponding time point lacking GSH. *Significantly different from time 0 ($P < 0.05$).

to stimulate the formation of the same amount of TBARS (Fig. 2A) as 10 μM iron produced in vitamin E sufficient microsomes (Fig. 1A). In the presence of 10 μM iron, vitamin E deficient microsomes produced about three times as much TBARS (Fig. 2B) as similarly treated vitamin E sufficient microsomes (Fig. 1A). TBARS accumulated in vitamin E deficient microsomes without a distinct lag time prior to the onset of TBARS formation at both doses of iron tested, an effect in contrast to the vitamin E sufficient microsomes. However, GSH significantly inhibited TBARS accumulation in vitamin E deficient microsomes. At the end of 60 min, this inhibition was 67 and 62% compared to control preparations lacking GSH at iron doses of 2.5 and 10 μM, respectively (Fig. 2).

The loss of GSH-mediated inhibition against lipid peroxidation in diamide-treated vitamin E sufficient microsomes was accompanied by the failure of GSH to prevent the loss of vitamin E (Fig. 3A). These results contrast with control microsomes where the addition of GSH resulted in complete protection against the loss of vitamin E throughout the 60 min of incubation.

There was 40-fold less vitamin E present in deficient microsomes as compared to vitamin E sufficient microsomes (Fig. 3B). Although the addition of GSH protected against vitamin E loss at 30 and 45 min of incubation even in vitamin E depleted microsomes, GSH did not completely prevent vitamin E from oxidizing as was the case in the vitamin E sufficient microsomes. In the absence of GSH, approximately 90% of the vitamin E present at time zero was lost by 60 min in both sufficient and deficient microsomes.

Protein thiol groups were gradually lost during peroxidation of vitamin E deficient microsomes at both doses of iron tested (Fig. 4). The addition of GSH prevented the loss of thiol groups throughout the 60 min of incubation with 2.5 μM iron. In contrast, thiol loss was delayed, but not prevented by GSH in the presence of 10 μM iron. Surprisingly, the extent of protein thiol loss was not different at any time point in control microsomes peroxidized with iron-ascorbate and either 2.5 or 10 μM iron.

DISCUSSION

The ability of GSH to inhibit rat liver microsomal lipid peroxidation has been extensively documented (3–7,9–14, 21). GSH appears to require vitamin E to be present in the microsomal membranes since the absence of sufficient vitamin E abolishes GSH-dependent protection against iron-NADPH stimulated lipid peroxidation (11,12). Various reported differences in the effects of GSH on peroxidation may be due to differences in the peroxidation systems employed. It is also possible that other factors

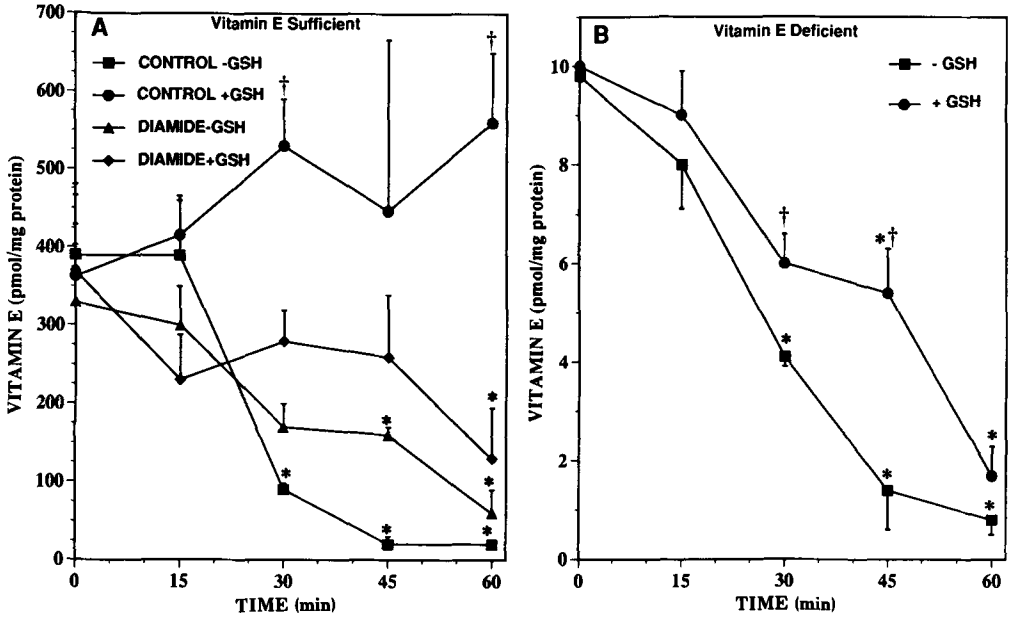

FIG. 3. The time course of the loss of vitamin E in (A) vitamin E sufficient microsomes incubated with 450 μM ascorbate and 10 μM iron in the presence or absence of 1 μM glutathione (GSH) in either control or diamide pretreated microsomes, or (B) vitamin E deficient microsomes incubated with 450 μM ascorbate and 10 μM iron in the presence or absence of 1 mM GSH. GSH inhibited thiobarbituric acid reactive substances formation in control but not in diamide-pretreated microsomes. GSH did not provide complete protection against loss of vitamin E in vitamin E deficient microsomes. Each result is the mean ± SE of three separate determinations. †Significantly different from the corresponding time point lacking GSH. *Significantly different from time 0 ($P < 0.05$).

FIG. 4. Each result is the mean ± SE of three separate determinations. †Significantly different from the corresponding time point lacking GSH. *Significantly different from time 0 ($P < 0.05$).

such as the level of E deficiency attained play a role. In addition, while ascorbate exerts prooxidant effect in the presence of a metal (1), it can also scavenge oxygen radicals and regenerate α-tocopherol from the α-tocopheroxy radical (22).

GSH both enhanced the lag time preceding rapid TBARS accumulation and inhibited total TBARS accumulation in vitamin E sufficient rat liver microsomes subjected to iron-ascorbate stimulated peroxidation, in agreement with previous findings (3-7,9-11,13,23). However, when vitamin E sufficient microsomes were pretreated with the protein thiol oxidant diamide, the protective effect of GSH against loss of vitamin E was reduced and against TBARS formation was completely abolished. This indicated that protein thiols play an important role in mediating the GSH-dependent inhibition of lipid peroxidation and in preventing oxidation of vitamin E. These data are consistent with the finding that pretreatment of microsomes with either *N*-ethylmaleimide, 4-hydroxynonenal or glutathione disulfide also compromised GSH-dependent protection against lipid peroxidation (13,24).

Vitamin E deficient microsomes peroxidized without a lag time and at fourfold lower concentrations of iron as compared to vitamin E sufficient microsomes. Furthermore, in contrast to vitamin E sufficient microsomes, the addition of GSH to the vitamin E deficient system did not maintain vitamin E during the incubation period. These data indicate that the level of vitamin E remaining in deficient microsomes was below the threshold required for protection against lipid peroxidation, even for brief periods of time. Alternately, because of accelerated peroxidative damage to these microsomes, the hypothetical microsomal factor could also be destroyed quickly, especially considering its presumed lability to free radicals (21).

Despite the lack of effect of GSH on the lag time prior to the onset of lipid peroxidation, total TBARS accumulation was inhibited by this thiol in vitamin E deficient microsomes. This suggests that GSH was inhibiting lipid peroxidation independent of its effects on vitamin E. Recently, Scholz *et al.* (25) reported that there may be two factors mediating the effect of GSH against lipid peroxidation. One of the factors is vitamin E dependent and the other is vitamin E independent. The exact mechanism by which the second factor interacts with GSH to inhibit peroxidation is unknown. Using an iron-ascorbate system, Hill and Burk (23) demonstrated that GSH could inhibit lipid peroxidation in vitamin E deficient microsomes and have suggested a vitamin E-independent, GSH-dependent radical scavenging activity that could inhibit lipid peroxidation. Reddy *et al.* (9) also observed that GSH inhibited iron-ascorbate stimulated lipid peroxidation in vitamin E deficient microsomes, albeit less efficiently. These findings indicate that the loss of vitamin E can be partially compensated for by the presence of GSH. The mechanism of this effect can be explained by the maintenance of protein thiols in the reduced form by GSH. Our data are consistent with the conclusion that this occurs without the intervention of any undefined factor.

Preservation of reduced protein thiols seems unlikely to account fully for GSH-mediated protection against lipid peroxidation since other thiol agents such as cysteine and mercaptoethanol do not substitute for this protective effect (26). The combination of a protein thiol sparing effect along with the reduction of vitamin E radicals would make GSH a very potent antioxidant molecule against lipid peroxidation in vitamin E sufficient microsomal membranes. The finding that GSH inhibits the peroxidation associated loss of protein thiols, even in vitamin E deficient microsomes, suggests that effects on protein thiols independent of vitamin E content are important in the mechanism by which GSH inhibits microsomal lipid peroxidation.

Takenaka *et al.* (15) have recently examined the relationship between membrane protein thiols and vitamin E. They reported that protein thiols are unable to directly reduce the vitamin E radical to vitamin E. However, protein thiols facing the aqueous cytosol could potentially compete with vitamin E for free radicals formed in an aqueous environment thereby sparing vitamin E from attack and consumption. The same study reported that generation of free radicals in a lipid environment would first cause consumption of vitamin E followed by consumption of protein thiols. In an *in vitro* system, free radicals are generated by the addition of water soluble components such as ascorbic acid and ADP-chelated iron. It is possible that under these conditions protein thiols could effectively compete with vitamin E for free radicals. GSH-dependent protection of protein thiols could thus spare the protein thiols and either prevent vitamin E consumption or perhaps facilitate the transfer of reducing equivalents among GSH, protein thiols and vitamin E.

The data have shown that GSH inhibited lipid peroxidation in liver microsomes from vitamin E sufficient rats more effectively than in liver microsomes from vitamin E deficient rats. The lesser protection in vitamin E deficient microsomes may be related to the inability of residual levels of vitamin E, which were consumed rapidly during peroxidation, to inhibit initiation. In contrast, GSH prevented peroxidation and vitamin E oxidation very effectively in vitamin E sufficient rat liver microsomes. Protein thiols were partially spared by GSH in both vitamin E sufficient (6) and deficient microsomes while destruction of protein thiol groups by diamide abolished GSH-dependent protection against vitamin E oxidation and also lipid peroxidation. The mechanism by which GSH inhibits lipid peroxidation in rat liver microsomes may involve the maintenance of protein thiols, and consequently vitamin E, in the reduced state.

ACKNOWLEDGMENTS

The purpose of this study was to investigate the roles of decreased synthesis and increased consumption in the depression of arachidonic acid levels in renal cortex and glomeruli of rats with streptozotocin-induced diabetes mellitus. In diabetic rats, arachidonic acid was depressed 33.2% in renal cortex, 47.4% in liver and 66.1% in heart compared to values of control rats. Δ6 Desaturase activity was depressed in renal cortex, liver and heart of diabetic rats to 53.3, 55.5 and 63.7%, respectively, of control values. Δ5 Desaturase activity was also depressed 43.7, 55.5 and 47.6% in renal cortex, liver and heart of diabetic rats, respectively. In other rats the activities of five enzymes involved in the synthesis and esterification of arachidonic acid were measured in renal cortex and in isolated glomeruli. Both tissues from diabetic rats showed depressed activities of Δ5 and Δ6 desaturases, increased activities of long-chain acyl-CoA synthetase and 1-acyl-*sn*-glycero-3-phosphocholine acyltransferase and no change in the activity of elongase as compared to those in control tissues. Malondialdehyde, an end product of lipid peroxidation, was lower in the renal cortex of diabetic rats than in control rats, whereas β-oxidation of linoleic acid and arachidonic acid were similar in diabetic and in control rats. Basal and stimulated prostaglandin E^2 synthesis were significantly higher in isolated glomeruli from diabetic rats compared to those in control rats. In isolated tubules, prostaglandin E_2 synthesis was similarly low in both groups. From these data we conclude that the reduced level of arachidonic acid esterified in lipids of the kidney cortex is caused principally by depressed synthesis of arachidonic acid secondary to decreased activity of Δ5 and Δ6 desaturases. Increased consumption of arachidonic acid to support prostaglandin synthesis may have contributed to the depression of arachidonic acid in glomeruli but not in tubules.
Lipids 28, **433-439 (1993).**

Arachidonic acid, the most abundant constituent polyunsaturated fattty acid in lipids of mammalian cells, has been found to be greatly depressed in a number of organs of humans and animals with diabetes mellitus (1-13). Recent studies in our laboratory have confirmed that arachidonic acid esterified in lipids is depressed in renal cortex of rats with streptozotocin-induced diabetes mellitus (14). Several investigators have shown that the activities of Δ6 and Δ5 desaturases are decreased in the liver of diabetic animals (4,15-18). These observations, together with the demonstration that the rate of conversion of linoleic acid to arachidonic acid is reduced in diabetes mellitus (1,18,19), provide strong support for the hypothesis that the low level of arachidonic acid in complex lipids found in diabetes mellitus is caused, at least in part, by decreased synthesis. In the renal cortex of diabetic rats, however, increasesd activity of Δ6 desaturase activity has been reported (20). This observation implicates a different mechanism underlying the depression of arachidonic acid levels in the kidney.

Arachidonic acid is synthesized from linoleic acid, an essential fatty acid. The five enzymes involved in the synthetic pathway include long-chain acyl-CoA synthetase, which is required for the activation of linoleic and arachidonic acids; Δ6 desaturase, which converts linoleoyl-CoA to γ-linolenoyl-CoA; elongase, which converts γ-linolenoyl-CoA to dihomo-γ-linolenoyl-CoA; Δ5 desaturase, which converts dihomo-γ-linolenoyl-CoA to arachidonoyl-CoA; and acyltransferase, which mediates arachidonoyl-CoA acylation of phospholipids (21). Increased activity of acyl-CoA synthetase has been reported in renal cortex of diabetic rats in one study (20), and increased activity of both acyl-CoA synthetase and acyltransferase has been observed in isolated glomeruli of diabetic rats in another study (22). However, in no single study have the activities of all five enzymes been systematically examined. Thus, no firm conclusions can be drawn about the contributions of decreased arachidonic acid synthesis and/or esterification to the depressed level of arachidonic acid in renal cortical lipids in diabetes mellitus. Furthermore, the possibility that increased consumption contributes to the depression of arachidonic acid in diabetes mellitus has been neglected. The major pathways of arachidonic acid consumption include synthesis of prostaglandins, β-oxidation and free radical mediated lipid peroxidation. The purpose of the current study was to investigate whether the depression of arachidonic acid in the renal cortex of diabetic rats is caused by decreased synthesis or increased consumption of arachidonic acid.

MATERIALS AND METHODS

Diabetes mellitus was induced in male Sprague Dawley rats, weighing 200-250 g, by intravenously injecting streptozotocin at a dose of 65 mg/kg body weight. The rats were studied 4-6 wk thereafter, at which time they manifested hyperglycemia (>500 mg/dL), 4+ glucosuria and polyuria. Three groups of rats were studied. In one group the composition of esterified fatty acids and the activities of Δ6 and Δ5 desaturases were measured in renal cortex, heart and liver of 12 control and of 12 diabetic rats. In a second group the activities of five enzymes involved in the synthesis and esterification of arachidonic acid in lipids and the consumption of arachidonic acid by β-oxidation and lipid peroxidation were measured in the renal cortex of 17 control and 17 diabetic rats. In a third group the above measurements were performed in isolated glomeruli from 6 control and 6 diabetic rats. Rats were anesthetized with 50 mg of pentobarbital, after which
