they were sacrificed by exsanguination from the aorta. The kidneys were removed and the renal cortex was dissected free. Glomeruli and tubules were isolated by a sieving technique (23). Lipids were extracted from known quantities of tissue by homogenizing first in 5 mL methanol containing 2% HCl. Chloroform was then added to achieve a final concentration of chloroform/methanol/HCl (100:50:1, by vol). All organic solvents contained the antioxidant 2,6-di-*tert*-butyl-4-methyl-phenol at 1.5 mg/100 mL. The homogenate was mixed by vortexing, shaken for 5 min in a water bath at room temperature and filtered over a Whatman glass-fiber filter, model GF/C. The filter was washed with chloroform/methanol (2:1, vol/vol) and the combined filtrates were centrifuged to achieve phase separation. The organic phase was removed and dried under N_2; the residue was re-dissolved in 4 mL of chloroform/methanol (2:1, vol/vol) and stored at −70°C until lipids were analyzed. To determine the fatty acid composition, an aliquot of lipid solution was evaporated to dryness under N_2. Fatty acids were liberated by hydrolysis with formation of methyl esters in the presence of sodium methoxide and methanol. The resulting fatty acid methyl esters were analyzed by gas-liquid chromatography, as previously reported (24).

Enzyme assays. Tissue was homogenized in ice-cold 0.25 M sucrose, 62 mM potassium phosphate, 0.15M KCl, 5 mM $MgCl_2$ and 0.1 mM ethylenediaminetetraacetate (EDTA) at pH 7.0. The homogenate was centrifuged at 16,000 × *g* for 10 min at 4°C, following which the supernatant was centrifuged at 100,000 × *g* for 60 min at 4°C. The microsomal pellet was resuspended in the homogenizing buffer at a final protein concentration of 10 mg/mL and assayed for enzyme activity. The activities of Δ6 desaturase, Δ5 desaturase and elongase were assayed by adding 0.1 mL of the microsomal suspension (1 mg of protein) to 0.75 mL of buffer composed of 0.25 M sucrose, 0.15 M KCl and 62 mM potassium phosphate (pH 7.4) and containing in micromoles: ATP 10, NADH 26, CoA 1.0, $MgCl_2$ 7.5, glutathione 1.5, NaF 62.5 and NAD 0.5. This assay mixture represents a slight modification of that used by Mandon *et al.* (25). The appropriate [^{14}C]acyl-CoA substrate (50 nmoles) (radiochemical purity 99%, New England Nuclear, Boston, MA) dispersed in 0.15 mL of buffer was added to the above reaction mixture, and the mixture was incubated for 30 min in a shaking water bath maintained at 37°C. The reaction was saponified under N_2 by adding 10% KOH in ethanol and boiling in a water bath for 1 h. After the reaction mixture cooled to room temperature, it was acidified with HCl. The fatty acids were extracted in hexane and then converted to methyl esters with 14% boron trifluoride in methanol (26). The fatty acid methyl esters were separated on 15% $AgNO_3$ thin-layer chromatography plates using hexane/diethyl ether (40:60, vol/vol) as solvent system. The [^{14}C]fatty acid methyl esters were identified by cochromatography with authentic standards and assayed directly on the plate using a radioscanner (Vanguard, Hartford, CT). In pilot experiments, we established that the recovery of fatty acids as methyl esters using this procedure was 94.0 ± 0.7% (n = 4). The data were not corrected to a recovery of 100%. In other pilot experiments we established that under these assay conditions product formation by each enzyme was linear during the 30-min incubation period using samples containing up to 1.5 mg of protein.

Acyl-CoA synthetase activity in the homogenate of renal cortex and of glomeruli was determined as reported by Morisaki *et al.* (27). The homogenate was centrifuged at 800 × *g* for 5 min, and the supernatant was used for enzyme assay. An aliquot of homogenate supernatant containing 10 μg of protein was added to the reaction mixture containing 0.15 M Tris HCl (pH 7.4), 0.1% Triton X-100, 50 mM $MgCl_2$, 20 mM ATP, 0.2 mM [1-^{14}C]fatty acid (radiochemical purity 99%, New England Nuclear), 0.2 mM CoASH and 2.5 mM glutathione in a final volume of 0.25 mL; the mixture was incubated for 10 min at 37°C. The reaction was terminated by the addition of 2.5 mL of isopropanol/heptane/1N H_2SO_4 (40:10:1, by vol) and the precipitate was removed by centrifugation. Water and heptane were added to the supernatant. The aqueous phase was removed and assayed for [1-^{14}C]acyl-CoA in a liquid scintillation spectrometer. In pilot studies we established that under these assay conditions product formation was linear over 10 min.

1-Acyl-*sn*-glycero-3-phosphocholine acyltransferase (GPCAT) activity was measured in the microsomal fraction of renal cortex and of isolated glomeruli using a spectrophotometric assay as described by Dang *et al.* (28). The method involves the reduction of 5,5-dithio*bis*-2-nitrobenzoic acid (DTNB) by the thio group of free CoASH released from acyl-CoA. An aliquot of the microsomal fraction containing 0.1 mg of protein was added to the reaction mixture composed of 0.1 M Tris HCl (pH 7.4), 0.33 mM DTNB, 0.1 mM 1-acyl-*sn*-glycero-3-phosphocholine (Avanti Polar Lipids, Birmingham, AL) and 25 μM acyl-CoA. In pilot experiments we established that under these assay conditions product formation was linear for 15 min when samples containing up to 0.15 mg of protein were added.

β-Oxidation was determined by measuring acyloxidase activity in renal cortex homogenized in buffer composed of 0.25 M sucrose, 62 mM potassium phosphate, 0.15 M KCl, 5 mM $MgCl_2$, 0.1 M EDTA and 3 mM imidazole (29). An aliquot (100 μL) of homogenate was added to 1 mL of a reaction mixture composed of 0.25 M sucrose, 0.1 M potassium phosphate, 0.15 M KCl, 5 mM $MgCl_2$, 5 mM ATP, 1 mM NADH, 0.5 mM NAD, 1.5 mM glutathione and 45 mM NaF at pH 7.4 and 37°C. The reaction was initiated by the addition of 100 nmol [1-^{14}C]acyl-CoA dispersed in homogenizing buffer and was terminated after 10 min by the addition of acid. The reaction product, $^{14}CO_2$, was trapped in hyamine hydroxide contained in a center well and subsequently assayed in a liquid scintillation spectrometer.

Lipid peroxidation in renal cortex and in glomeruli was estimated by measuring malondialdehyde by the thiobarbituric acid method as previously reported (30).

For determination of prostaglandin E_2 (PGE_2), isolated glomeruli and isolated renal cortical tubules were homogenized in 50 mM phosphate buffer containing 0.01 M EDTA, 0.05% Triton X-100, 0.05% sodium azide and 0.1 mM $CaCl_2$. Aliquots of homogenate were incubated in a water bath at 37°C for 10 min and then assayed for basal PGE_2 synthesis by radioimmunoassay (23). A23187 at 10^{-6}M was added to parallel samples and 10 min later stimulated PGE_2 synthesis was measured.

The data in the text, tables and figures are expressed as the mean ± SE. Differences between groups were assessed by Student's *t*-test. A P value ⩽ 0.05 was considered statistically significant.

RESULTS

The composition of fatty acids esterified in total lipids of renal cortex, liver and heart is summarized in Table 1. Arachidonic acid comprised 28.0 ± 1.1, 21.2 ± 1.0 and 27.0 ± 1.1 mol% of the fatty acids extracted from the renal cortex, liver and heart, respectively, of nondiabetic control rats. In diabetic rats arachidonic acid was significantly reduced by 33.2% in renal cortex, by 47.2% in liver and by 66.7% in heart as compared to the respective control values ($P < 0.01$). The depression of arachidonic acid was accompanied by significant increases of fatty acids that serve as precursors for the synthesis of arachidonic acid. These included dihomo-γ-linolenic acid and γ-linolenic acid in renal cortex and heart, and linoleic acid in renal cortex, liver and heart (Table 1). Isolated glomeruli and isolated renal cortical tubules of diabetic rats showed changes in fatty acid composition similar to those observed for the whole renal cortex (data not shown).

The activities of Δ6 and Δ5 desaturases in renal cortex, liver and heart of control and diabetic rats are summarized in Table 2. In control rats Δ6 desaturase activity in the liver was 5.5-fold higher than in renal cortex and 6.5-fold higher than in heart. In diabetic rats, Δ6 desaturase activity was significantly reduced in all three tissues ($P < 0.01$): −46.7% in renal cortex; −44.5% in liver; −36.3% in heart (Table 2). Δ5 Desaturase activity in the liver of control rats was fourfold higher than in renal cortex and fivefold higher than in heart. In diabetic rats the activity of Δ5 desaturase activity was significantly reduced by 56.2% in renal cortex, by 44.5% in liver and by 52.4% in heart as compared to the respective control values ($P < 0.01$).

In a second group of rats the activities of five enzymes involved in the synthesis and esterification of arachidonic acid in lipids, as well as the consumption of arachidonic acid by β-oxidation and by lipid peroxidation, were measured in renal cortex. The activity of long-chain acyl-CoA synthetase was significantly higher in the renal cortex of diabetic rats than in that of control rats (Table 3). With linoleic acid as substrate, acyl-CoA synthetase activity was 158.4% of that of control ($P < 0.01$); with arachidonic acid as substrate, acyl-CoA synthetase activity was 139.2% of that of controls ($P < 0.01$). The activities of Δ6 and Δ5 desaturases in diabetic rats were depressed 80.2 and 66.7%, respectively, below the desaturase activities of control rats (Table 3). The activity of elongase, which catalyzes the elongation of γ-linolenic acid to dihomo-γ-linolenic acid, was slightly higher in diabetic rats compared to that in control rats, but the difference did not reach statistical significance ($0.05 < P < 0.1$). The activity of 1-acyl-GPCAT in diabetic rats was increased to 161.6% of that of control rats with linoleoyl-CoA as substrate ($P < 0.01$) and to 149.7% of that of control rats with

[a]Data represent mean ± SE in units of nmol/mg protein, except for acyl-CoA oxidase for which the unit is pmol CO_2/mg protein. Assays for desaturases, elongase and 1-acyl-GPCAT were performed using the microsomal fraction, and assays for acyl-CoA synthetase and acyl-CoA oxidase using homogenate of renal cortex and glomeruli; C, control; D, diabetic. Numbers in parentheses denote n. GPCAT, *sn*-glycero-3-phosphocholine acyltransferase.

[b]Significantly different from control, $P < 0.01$.

arachidonyl-CoA as substrate ($P < 0.01$). Thus, of the five enzymes examined, only Δ6 and δ5 desaturase activities were found to be depressed in the renal cortex of diabetic rats. Similar directional changes in the activities of these five enzymes were found in isolated glomeruli of diabetic rats (Table 3).

β-Oxidation of fatty acids by acyl-CoA oxidase is illustrated in Figure 1. Acyl-CoA oxidase activity in the renal cortex of diabetic rats was significantly higher than that of control rats when palmitoyl-CoA or oleoyl-CoA were the substrates; however, acyl-CoA oxidase activity in diabetic rats was not different from control when linoleoyl-CoA or arachidonoyl-CoA was the substrate. The latter findings were confirmed in isolated glomeruli (Table 3). Malondialdehyde, an end product of lipid peroxidation, was significantly lower in the renal cortex of diabetic rats compared to that of control rats (0.63 ± 0.02 *vs.* 0.77 ± 0.02 nmol/mg protein, n = 17, $P < 0.01$). In isolated glomeruli of diabetic rats, malondialdehyde was not significantly different from that of controls (1.05 ± 0.07 *vs.* 0.98 ± 0.06 nmol/mg protein, n = 6, $P > 0.2$).

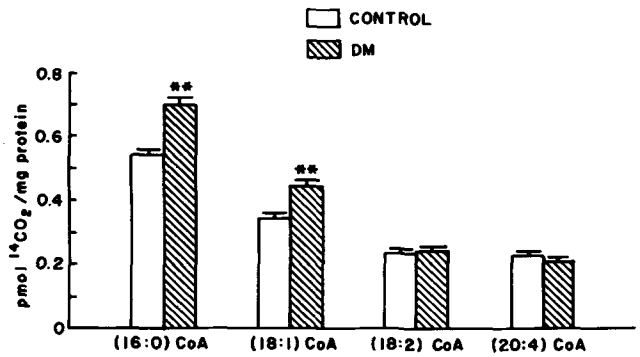

FIG. 1. β-Oxidation rates of palmitoyl-CoA, oleoyl-CoA, linoleoyl-CoA and arachidonoyl-CoA by acyl-CoA oxidase in renal cortical homogenate of control and diabetic rats. Bars denote mean ± SE, n = 17. Asterisks denote that data are significantly different from control, $P < 0.01$.

Basal PGE_2 production by glomeruli of diabetic rats was significantly greater than that of control glomeruli (1,423 ± 79 *vs.* 1,002 ± 44 pg/mg protein, n = 12, $P < 0.01$). The calcium ionophore A23187 augmented PGE_2 production to 1,960 ± 91 pg/mg protein in glomeruli of diabetic rats ($P < 0.01$) and to 1,371 ± 66 pg/mg protein in glomeruli of control rats ($P < 0.01$). The fractional increase of PGE_2 in response to A23187 was 38% in glomeruli of diabetic rats and 37% in glomeruli of control rats. Basal PGE_2 production by isolated renal cortical tubules of diabetic rats (125 ± 15 pg/mg protein) was not different from that of control rats (130 ± 7 pg/mg protein, $P > 0.2$). These values are less than 10 percent of the respective basal glomerular PGE_2 synthesis. Furthermore, no increased PGE_2 production was detected in isolated tubules in response to A23187 (data not shown).

DISCUSSION

This study confirms our previous observation (14) that the amount of arachidonic acid esterified in renal cortical lipids of rats with streptozotocin-induced diabetes mellitus is greatly reduced, and that the reduction of arachidonic acid is accompanied by significant increases of precursor fatty acids involved in the arachidonic acid synthetic pathway. The present study extends our earlier observation by demonstrating that the reduction of esterified arachidonic acid occurs both in renal cortical tubular cells and in renal glomerular cells. The latter observation in glomeruli confirms the earlier report of Clark *et al.* (8). We have also confirmed the work of other investigators who showed that the depression of esterified arachidonic acid occurs in the liver (1-5) and in the heart (5,10) of diabetic rats. Thus, our results add to a growing body of data derived from human and animal studies (1-13), indicating that diabetes mellitus is complicated by a general disturbance of arachidonic acid metabolism and is characterized by a depression of arachidonic acid esterified in the lipids of most, if not all, organs and tissues.

The main objective of our study was to elucidate the major mechanism(s) responsible for the depression of

arachidonic acid in the renal cortex of diabetic rats. We investigated, therefore, the possible roles of decreased synthesis and increased consumption of arachidonic acid. Linoleic acid, the starting substrate for the synthesis of arachidonic acid, is not synthesized in mammalian cells and must be supplied by dietary intake. The observation that linoleic acid was higher in tissues from diabetic rats than in tissues from control rats eliminates the possibility that the low level of arachidonic acid is a consequence of an inadequate supply of substrate. The data are consistent with decreased utilization of linoleic acid for the synthesis of arachidonic acid. Strong support for this conclusion is provided by the data on the activities of the five enzymes involved in the synthesis of arachidonic acid from linoleic acid and the subsequent esterification of arachidonic acid in phospholipids. Of the five enzymes involved in these processes, we found that the activities of two enzymes, Δ6 and Δ5 desaturase, were significantly depressed, whereas the activities of the three remaining enzymes, acyl-CoA synthetase, γ-linolenoyl-CoA elongase and 1-acyl-GPCAT, were either increased or unchanged in renal cortex and in glomeruli of diabetic rats. Decreased activities of Δ6 and Δ5 desaturases were also found in liver and in myocardium of diabetic rats. Thus, our results are internally consistent in that the renal cortex, the liver and the heart exhibited depressed levels of arachidonic acid esterified in lipids and also exhibited depressed activities of Δ6 and Δ5 desaturases. These data, taken together with the evidence that arachidonic acid consumption in the renal cortex of diabetic rats was not appreciably increased *(vide infra)*, provide strong support for the conclusion that the depression of arachidonic acid is caused almost entirely by decreased synthesis.

Decreased Δ5 desaturase activity appears to be more important than decreased Δ6 desaturase in causing decreased synthesis of arachidonic acid (at least in the renal cortex and glomeruli of diabetic rats). Dihomo-γ-linolenic acid, the substrate for Δ5 desaturase, was increased in these tissues. This finding implicates decreased enzyme activity rather than inadequate substrate availability as the mechanism responsible for decreased synthesis of arachidonic acid. By contrast, γ-linolenic acid, the product generated by the action of Δ6 desaturase on linoleic acid, was increased in renal cortex and in glomeruli of diabetic rats despite the fact that Δ6 desaturase activity was depressed. This finding implies that the conversion of linoleic acid to γ-linolenic acid was not the rate limiting step for arachidonic acid synthesis in these tissues. Δ5 Desaturase activity is probably also the major factor responsible for decreased synthesis of arachidonic acid in the heart of diabetic rats in view of the findings that the changes in Δ5 and Δ6 desaturase activities and in fatty acid composition of lipids in the heart were directionally similar to those observed in the renal cortex. Because no significant differences were detected between the levels of γ-linolenic acid or between the levels of dihomo-γ-linolenic acid in the livers of control and diabetic rats, no conclusion can be drawn concerning the relative importance of decreased Δ5 and Δ6 desaturase activities in the depression of arachidonic acid synthesis in the liver of diabetic rats.

Our enzyme data are in agreement with the results of other investigators who have demonstrated decreased activities of Δ6 and Δ5 desaturase in various organs and tissues of diabetic animals (1,4,15–19). By contrast, in the only study of desaturase activity in the kidney of diabetic rats, Clark and Queener (20) reported that Δ6 desaturase pathway activity was increased in renal cortex but was unchanged in liver of alloxan-induced diabetic rats. Although no data were provided, the authors stated that they obtained similar results in rats with streptozotocin-induced diabetes mellitus. The reason for the discrepancy between the results of Clark and Queener (20) and our study on Δ6 desaturase activity in the renal cortex and between the results of Clark and Queener (20) and those of other investigators (4,15,16,18) (including our own) on Δ6 desaturase activity in the liver most likely relates to significant differences in methodology. Clark and Queener (20) used unesterified arachidonic acid or linoleic acid as substrate and added CoASH, whereas we used the CoA esters of these fatty acids as substrates. Clark and Queener (20) also used a crude enzyme preparation that included soluble factors, whereas we used a traditional microsomal preparation. The investigators showed that the desaturase pathway activity in their experiments was influenced by long chain acyl-CoA synthetase activity as they detected no difference between the Δ6 desaturase pathway activities in renal cortex of normal and diabetic rats when exogenous long-chain acyl-CoA synthetase was included in the assay reaction. Clark and Queener (20) suggested that previous studies in which Δ6 desaturase activity was reported to be depressed were open to question because the investigators had failed to document that the enzymatic reaction was linear under the assay conditions employed. That criticism, however, does not pertain to our study.

No disagreement exists with respect to our findings of increased activities of linoleoyl-CoA synthetase and of arachidonoyl-CoA synthetase in renal cortex and in glomeruli of diabetic rats, as similar results were obtained for the renal cortex of diabetic rats by Clark and Queener (20) and in glomeruli of diabetic rats by Kanzaki *et al.* (22). Our observation that 1-acyl-GPCAT activity was increased in renal cortex and in glomeruli of diabetic rats is in agreement with similar findings in glomeruli of diabetic rats by Kanzaki *et al.* (22) and in liver of diabetic rats by Dang *et al.* (28).

Insulin-dependent diabetes mellitus is complicated by a shift in metabolism from carbohydrates to fatty acids as a source of fuel (31,32). Moreover, it is well established that renal proximal tubular cells have the capacity to transport and metabolize fatty acids (33,34). Therefore, we assessed the possibility that increased β-oxidation of fatty acids might contribute to the pathogenesis of low arachidonate levels in the renal cortex of diabetic rats. Although β-oxidation of palmitoyl-CoA and of oleoyl-CoA was significantly higher in the renal cortex of diabetic rats compared to that of control rats, no difference was detected between the acyl-CoA oxidase activities of renal cortex or glomeruli of diabetic and control rats when linoleoyl-CoA and arachidonyl-CoA were the substrates. Thus, increased consumption of arachidonic acid or its precursor by β-oxidation cannot be implicated as a cause of the reduced level of arachidonic acid in the renal cortex or in glomeruli of diabetic rats.

Arachidonic acid is the most abundant polyunsaturated fatty acid in mammalian tissue and is highly susceptible to free radical attack (35,36). Increased lipid peroxidation and increased activities of enzymes involved in peroxide

metabolism have been observed in diabetes mellitus (37). In the renal cortex, peroxisomal β-oxidation is stimulated in diabetes mellitus (32) and this metabolic pathway generates hydroxyl radicals (38,39). Therefore, we considered the possibility that consumption secondary to increased lipid peroxidation might contribute to the depression of arachidonic acid in the renal cortex of diabetic rats. For this purpose we measured malondialdehyde, an end product of lipid peroxidation (35). However, the level of malondialdehyde in the renal cortex of diabetic rats was significantly lower than that of control rats, a finding more consistent with a reduced rate of lipid peroxidation, possibly due to the reduced quantity of arachidonic acid present.

Finally, we considered the possibility that increased consumption of arachidonic acid in support of eicosanoid synthesis might contribute to the depression of this fatty acid in the renal cortex of diabetic rats. In agreement with the results of other investigators (40), we found that basal and stimulated PGE_2 synthesis were higher in glomeruli from diabetic rats when compared to PGE_2 synthesis in glomeruli from control rats. Thus, increased consumption of arachidonic acid to support prostaglandin synthesis may contribute to the depression of arachidonic acid in glomeruli of diabetic rats. In renal cortical tubules, however, basal PGE_2 synthesis was similarly low in both groups and did not increase in response to stimulation with A23187. It remains uncertain whether the trivial level of PGE_2 synthesis in renal cortical tubules reflects the presence of contaminating glomeruli or is derived from cells of the cortical collecting tubule. As tubules comprise the vast bulk of the renal cortex, the low rate of PGE_2 synthesis detected in renal cortical tubules argues against increased consumption of arachidonic acid in support of prostaglandin synthesis as a significant factor contributing to the depression of arachidonic acid.

Arachidonic acid may also be metabolized by the lipoxygenase pathway which, in the kidney, is found primarily in glomeruli (40,41), with little or no activity detectable in renal cortical tubules (41–43). Arachidonic acid can also be metabolized by cytochrome P-450 dependent monooxygenases (44,45) and this enzyme system is present in renal proximal tubules. We did not measure the metabolism of arachidonic acid by the lipoxygenase pathway and the P-450 pathway in our study, and no information is available in the literature concerning the activities of these pathways in the renal cortex of diabetic rats. Although unlikely to be a major factor, we cannot exclude the possibility that increased activity of these pathways may contribute to the depression of arachidonic acid in the renal cortex of diabetic rats.

In summary, the results of our experiments support the conclusion that the depression of arachidonic acid esterified in lipids of the renal cortex and glomeruli of rats with diabetes mellitus is principally due to decreased synthesis of arachidonic acid consequent to depression of Δ6 and Δ5 desaturases. No evidence was found to implicate increased consumption of arachidonic acid secondary to accelerated lipid peroxidation or to β-oxidation. Increased consumption of arachidonic acid to support prostaglandin synthesis may contribute to the depression of arachidonic acid in glomeruli, but not in renal cortical tubules of diabetic rats. The possible role of increased consumption of arachidonic acid by the lipoxygenase and cytochrome P-450 pathways remains to be assessed.

Effect of High Fat Corn Oil, Olive Oil and Fish Oil on Phospholipid Fatty Acid Composition in Male F344 Rats

Chinthalapally V. Rao, Edith Zang and **Bandaru S. Reddy***
Division of Nutritional Carcinogenesis, American Health Foundation, Valhalla, New York 10595

Epidemiological and laboratory animal model studies have provided evidence that the effect of dietary fat on colon tumorigenesis depends on the amount of fat and its composition. Because of the importance of the composition of dietary fat and of tissue membrane fatty acid composition in tumor promotion, experiments were designed to investigate the relative effects of high fat diets rich in ω3, ω6 and ω9 fatty acids and colon carcinogen on the phospholipid fatty acid composition of liver, colon, small intestine, erythrocytes and blood plasma. At 6 wk of age, groups of animals were fed diets containing 5% corn oil (LFCO), 23.5% corn oil (HFCO), 23.5% olive oil (HFOO), and 20.5% fish oil plus 3% corn oil (HFFO). Two weeks later all the animals except the vehicle-treated animals received azoxymethane s.c. once weekly for 2 wk at a dose rate of 15 mg/kg body weight. Animals were sacrificed 5 d later and liver, colon, small intestine and erythrocytes and blood plasma were analyzed for phospholipid fatty acids. The results indicate that the phospholipid fatty acid composition of liver, colon and small intestine of HFCO diet fed animals, were not significantly different from those fed the LFCO diet. The levels of palmitoleic acid and linoleic acid were increased in erythrocytes and blood plasma of the animals fed the HFCO diet compared to those fed the LFCO diet. Feeding the HFOO diet significantly increased the oleic acid content and decreased the linoleic acid and arachidonic acid levels in various organs when compared to the HFCO diet. Animals fed the HFFO diet showed a marked increase in eicosapentaenoic acid and docosahexaenoic acid and a decrease in linoleic acid and arachidonic acid levels as compared to those fed the HFCO diet. The results also indicate that carcinogen treatment had only a minimal effect on the phospholipid fatty acid composition.
Lipids 28, 441–447 (1993).

Several epidemiological studies have demonstrated that diets particularly high in total fat generally correlate with an increased risk for the development of colon cancer in humans (1–4). Laboratory animal model studies have provided evidence that the effect of dietary fat on colon tumorigenesis depends on the amount and types of fat consumed. For example, high fat diets containing corn oil, safflower oil, beef fat or lard increased the chemically-induced colon tumors when compared to the respective low fat diets, whereas the diets containing high levels of coconut oil, olive oil or fish oil had no effect on colon tumor promotion (4–10). One study showed that even at a low dietary fat level, rats fed the diet containing 5% linoleate showed a greater tumorigenesis than did rats fed 0.3% linoleate and 4.7% stearate (7). These studies suggest that the differential effect of various high fat diets on colon tumorigenesis, at least in part, depends on the fatty acid composition of the diets consumed.

Dietary lipids have been shown to induce extensive modification in the fatty acid composition of cell membranes which in turn affects various cellular functions (11–14). Modifications in the fatty acid composition can influence the activities of various membrane-bound enzymes and carriers (15,16). For example, phospholipids composed of mainly essential fatty acids are required for optimal mixed function oxidase activities (17). Diets containing corn oil increase the mixed function oxidase activity and cytochrome P_{450} levels in rat liver (18). Many carcinogens require metabolic activation in liver and other organs, including colon, to exert their carcinogenic effect (19). These activating enzymes have been shown to be influenced by dietary fats (18,20). In addition, several xenobiotics and other environmental and dietary carcinogens alter the lipid metabolism through modulation of these enzymes (20,21).

In view of significance of both amount and types of dietary fat and membrane fatty acid composition in tumor promotion, experiments were designed to assess the relative effect of high fat diets rich in ω3 (fish oil), ω6 (corn oil) and ω9 (olive oil) fatty acids on phospholipid fatty acid composition of the liver, colon, small intestine, erythrocytes and plasma. Also the effect of carcinogen on the phospholipid fatty acid composition of these organs was investigated.

MATERIALS AND METHODS

Animals, diets and carcinogen. Weanling male F344 rats were purchased from Charles River Breeding Laboratories (Kingston, NY). Cold pressed extra virgin olive oil was obtained from a supermarket. Fish oil was supplied by the National Institutes of Health through the National Marine Fisheries Service (Charleston, SC). The ingredients of semipurified diets were purchased from Dyets, Inc. (Bethlehem, PA) and azoxymethane (AOM) was from Ash-Stevens (Detroit, MI). A total of 64 male F344 rats received at weaning were quarantined for 7 d and then randomly assigned to one of four dietary groups of 16 animals each. Each dietary group was then divided equally into vehicle-treated and AOM-treated subgroups. They were housed three to a plastic cage with filter tops and maintained under controlled conditions of 21°C, 50% humidity and 12-h light/dark cycle. All animals were fed *ad libitum*. The food cups were replenished every day.

The compositions of the experimental diets were based on modified AIN-76A diets (22,23) and are shown in Table 1. The percent composition of all experimental diets was adjusted so that the animals in all dietary groups would consume the same amount of calories, protein, vitamins, minerals and fiber. All the diets were prepared in our laboratory three times weekly and stored in a cold room at 4°C in the dark in air-tight containers filled with nitrogen. Aliquots of experimental diets were analyzed for their fatty acid composition.

Experimental procedure. Beginning at 5 wk of age, all animals were fed the control diet containing 5% low fat corn oil (LFCO). At 6 wk of age, *i.e.*, two weeks before AOM

or saline (vehicle) treatment, groups of animals were placed on experimental diets containing 5% low fat corn oil (LFCO), 23.5% high fat corn oil (HFCO), 23.5% high fat olive oil (HFOO) or 20.5% high fat fish oil plus 3% corn oil (HFFO). At the beginning of 8 and 9 wk of age, all animals except the vehicle-treated animals received AOM subcutaneously once weekly at a dose rate of 15/mg/kg body wt/wk. Five days after the last AOM injection, all the animals were bled by heart puncture under CO_2 anesthesia. They were then killed and livers were excised and frozen in liquid nitrogen. The colon and small intestine were rapidly removed and rinsed in ice-cold normal saline. They were slit open longitudinally and freed from all contents. They were laid flat on a glass plate, and mucosa scraped with a microscopic glass slide. The samples were quickly frozen in liquid nitrogen and stored at −80°C.

Analytical methods. Blood samples were centrifuged at 3,000 × *g* for 10 min at 4°C to separate plasma from cells. Erythrocyte ghosts were obtained according to the method described by Hanahan and Ekholm (24). Liver and colonic and small intestinal mucosal samples were homogenized in 0.15 M KCl using a polytron homogenizer. Debris and nuclei were removed by centrifugation at 1500 × *g* for 10 min at 4°C. Microsomes were pelleted by centrifuging the supernatant at 105,000 × *g* for 1 h at 4°C. Methods for isolation of phospholipids from erythrocytes, plasma and from microsomal fractions of liver, colon and small intestine were as described by Bligh and Dyer (25) using chloroform/methanol (2:1, vol/vol) containing butylated hydroxytoluene (0.005%). Fatty acid phenacyl esters from phospholipids were prepared according to the method of Borch (26). The fatty acid derivatives were analyzed by high-performance liquid chromatography (HPLC) using a Waters HPLC system driven by model 510 system controller (Waters Associates, Milford, MA). Briefly, the fatty acid derivatives were separated on a Waters μ Bond pack C_{18} column (30 cm length × 4 mm diameter) using a step-wise gradient of acetonitrile and water at a flow rate of 1.5 mL/min. Elutions of fatty acid phenacyl esters were monitored at 240 nm wavelength in a Waters 990 Photodiode Array Detector (Waters Associates). Individual fatty acids were identified by comparing to authentic standards derivatized and analyzed under the same conditions and by the comparison of retention times.

Statistical analysis. Data are presented as means ± SD. Significant difference in values of fatty acids between various dietary groups was analyzed by analysis of variance and Student *t*-test. The data were analyzed routinely using both the log transformed and arithmetic values of the dependent variables (in the case of percentage composition of fatty acids) in view of the assumption of normality proscribed by parametric tests, such as the *t*-test. When the results were similar, we assumed that there was no significant departure from normality and reported only the *P*-values based on the arithmetic comparison. Furthermore, our *P*-values were based on the Student's *t*-distribution rather than normal distribution to further account for deviations from the standard normal curve.

The conventional method of adjusting for the critical *P*-values (α error) is by dividing the usual probability (*e.g.*, $P = 0.05$) by the number of comparisons made (α/k). Thus, while the *P*-values listed in the tables that are below 0.01 remain significant even after adjustment, those values between 0.05 and 0.01 lose their significance and should, therefore, be interpreted with caution. The potential interactions between the diet and carcinogen with regard to fatty acid composition have been evaluated using a factorial analysis of variance model with diet, carcinogen and diet *vs.* carcinogen interactions.

RESULTS

The fatty acid composition of the experimental diets is summarized in Table 2. As expected, corn oil, olive oil and fish oil diets contain high levels of linoleic acid, oleic acid and ω3 fatty acids (eicosapentaenoic acid and docosa-

hexaenoic acid), respectively. The body weights and the weights of colonic and small intestinal mucosa and liver were similar among the dietary groups (Table 3).

The fatty acid composition of plasma phospholipids in animals fed various experimental diets and treated with AOM is shown in Table 4. In animals fed the HFCO, a slight but significant increase in the plasma palmitoleic acid, linoleic acid and eicosapentaenoic acid were observed when compared to those fed the LFCO diet. When compared to HFCO, HFOO-fed animals showed a significant increase in the plasma oleic acid and a decrease in linoleic acid. Feeding of HFCO or HFOO diets had no measurable effect on the palmitic acid and stearic acid content of plasma. The plasma eicosapentaenoic acid and docosahexanoic acid were significantly increased, and stearic, linoleic and arachidonic (20:4n-6) acids were decreased in the animals fed the HFFO diet compared to those fed the HFCO diet. The results also indicate that carcinogen treatment did not significantly alter the plasma fatty acid composition irrespective of the type of fat in the diet.

The fatty acid composition of erythrocyte phospholipids is shown in Table 5. Dietary HFCO caused a slight increase in palmitoleic acid and linoleic acid as compared to LFCO. Oleic acid was significantly higher and stearic acid, linoleic acid and arachidonic acids were lower in animals fed the HFOO diet as compared to those fed the HFCO diet. Animals fed the HFFO diet showed a marked increase in eicosapentaenoic acid and docosahexaenoic acid, the two major ω3 fatty acids, and a signifi-

[a]Values are means ± SD (n = 6); animals were treated with azoxymethane (AOM).
[b]LFCO, low fat corn oil; HFCO, high fat corn oil; HFOO, high fat olive oil, HFFO, high fat fish oil.
[c]SFA, saturated fatty acids.
[d]Significantly different from animals fed LFCO and treated with AOM; [f]$P < 0.05$, [g]$P < 0.01$.
[e]Significantly different from animals fed HFCO and treated with AOM: [f]$P < 0.05$, [g]$P < 0.01$, [h]$P < 0.001$, [i]$P < 0.0001$.

cant decrease of stearic acid, linoleic acid and arachidonic acid, as compared to those fed the HFCO diet. AOM treatment had a minimal effect on fatty acid composition of erythrocyte phospholipids.

The percentage composition of fatty acids of colon and small intestine and liver phospholipids are shown in Tables 6, 7 and 8, respectively. Dietary HFCO had no effect on the levels of fatty acids of colon, small intestine and liver as compared to the LFCO group. In the olive oil (HFOO) group, there was a marked increase in oleic acid and a slight increase in ω3 fatty acids and a decrease in linoleic acid and arachidonic acid content of all three organs. In contrast, the HFFO diet increased the eicosapentaenoic acid and docosahexaenoic acid levels and decreased the oleic acid, linoleic acid and arachidonic acid in the colon, small intestine and liver. AOM-treatment had no effect on the fatty acid profile of all three organs.

DISCUSSION

The results of the present study are of considerable interest because they demonstrate that the types of fat in

the diet affect the fatty acid composition of blood plasma, and of the phospholipids of erythrocytes, liver, colon and small intestine in rats. In general, high dietary olive oil increased the oleic acid content of plasma, erythrocytes, liver and intestines and decreased the linoleic acid content of these tissues and of plasma. These results are in agreement with published reports from other laboratories (27-29). Furthermore, in the olive oil-fed animals, the arachidonic acid content was decreased in plasma, erythrocytes and other tissue phospholipids. The inverse relationship between the arachidonic acid and oleic acid of phospholipids suggests that increasing the ratio of dietary ω9/ω6 fatty acids enhances the availability of ω9 fatty acids for incorporation into membrane phospholipids relative to ω6 fatty acids. Also the slightly higher content of ω3 fatty acids observed in phospholipids of the olive oil group as compared to the corn oil group may be related to the lower linoleic acid and linolenic acid ratio

in olive oil. It is well known that competition exists between oleate, linoleate and α-linolenate for the Δ6 desaturase enzyme system. Enzyme affinity decreases in the order linolenic acid (ω3), linoleic acid (ω6) and oleic acid (ω9) (30). Thus, the lower linoleate content of olive oil could enhance α-linolenate desaturation, thereby increasing the ω3 fatty acid in phospholipids of olive oil-fed animals.

This study also demonstrates that high dietary fish oil significantly increased the eicosapentaenoic acid and docosahexaenoic acid levels with a concomitant decrease of linoleic acid and arachidonic acid in phospholipids of various organs. These results are in general agreement with those of studies in which decreased levels of linoleic acid and arachidonic acid were found in plasma, platelets, heart, lung and kidney in animals fed cod liver oil or concentrates of other marine oils (12,27,31-33). It has also been reported that dietary fish oil significantly decreases liver, plasma and platelet arachidonic acid levels (11). Previously, our laboratory had shown a dose-related increase in the incorporation of ω3 fatty acids into the microsomes of colonic mucosal cells when feeding increasing levels of menhaden oil to F344 rats (34).

The fatty acid changes that occur following supplementation of various high fat diets appear to be facilitated through competition among individual saturated, monounsaturated, polyunsaturated and highly polyunsaturated fatty acids for the enzyme system that synthesizes long-chain fatty acids through a sequence of elongation and desaturation reactions (35). Although in our study, the fatty acid composition of various organs was not affected by AOM-treatment factors such as modulation of the ongoing dynamic acyl exchange and transfer, and remodeling involved in the modification of membrane lipid fatty acid composition were affected by AOM-treatment (35,36). In this regard we are not aware of any previous studies on the modulating effect of carcinogens on membrane phospholipids. Our recent study indicates that AOM-treatment significantly enhances plasma, liver and colonic mucosal synthetic activity of prostaglandins, such as PGE_2 and 6-keto $PGF_{1\alpha}$, when compared to saline-treated animals fed similar diets (37). This may be due to increased turnover of membrane arachidonic acid as a consequence of AOM-treatment.

The role of diets containing olive oil and diets high in fish in coronary heart disease and cancer is currently of great interest. There is evidence indicating that populations consuming large amounts of olive oil or marine animals have a decreased incidence of heart disease (38-41). Laboratory animal model studies conducted in our laboratory indicated that high dietary olive oil or fish oil had no colon tumor promoting effect when compared to diets high in corn oil or safflower oil (34,42). Similar results were observed with olive oil on the 7,12-dimethylbenz[a]anthracene and *N*-methyl-*N*-nitrosourea induced mammary tumorigenesis (43-45) and fish oil on AOM induced colon tumorigenesis (34,42,46). Recently, Laseken *et al.* (47) showed that animals fed olive oil and treated with 7,12-dimethylbenz[a]anthracene had a longer latency period, fewer tumors per rat and lower tumor incidence as compared to those fed safflower oil or olive oil plus linoleic acid. This may be partly due to an increase in oleic acid content with an associated decrease in linoleic and arachidonic acid in membrane phospholipids. Whether this altered composition of oleic acid and linoleic acid content of phospholipids has any significant effect on tumorigenesis remains to be established. Previously, several studies have shown a positive correlation between the amount of ω3 fatty acids in the microsomes of colon tumors (34) or mammary tumors (48) and the amount in the fish oil diet. Also, the results of earlier studies indicate that the diets containing high levels of beef fat, lard, corn oil or safflower oil increase the incidence of colon tumors when compared to a low fat diet (4-9). Thus, the results of the present study and of a previous investigation (34) suggest that high fat intake is a necessary but not a sufficient condition for colon tumor promotion and that the fatty acid composition of the dietary fat is one of the determinants of the tumor promoting effect of a high fat diet.

ACKNOWLEDGMENTS

We thank Donna Virgil for help in the preparation of the manuscript and the National Marine Fisheries Service, Charleston, SC, for donating the fish oil. This investigation was supported by USPHS Grants CA-17613 and CA-37663 from the National Cancer Institute.

[Received May 4, 1992; Revision accepted January 30, 1993]

Effect of Varying Proportions of Dietary Menhaden and Corn Oil on Experimental Rat Mammary Tumor Promotion[1]

Leonard A. Cohen*, Jye-Yu Chen-Backlund, Daniel W. Sepkovic[2] and Shigeyuki Sugie[3]
Division of Nutrition and Endocrinology, Naylor Dana Institute for Disease Prevention, American Health Foundation, Valhalla, New York 10595

Dose-related effects of long-chain highly unsaturated n-3 fatty acids on the development of *N*-nitrosomethylurea (NMU)-induced rat mammary tumors were assessed in female F344 rats. Four test groups (36 rats/group) were fed the following high-fat (HF) diets (23% fat, w/w): Group 1, 18% menhaden oil (MO) and 5% corn oil (CO); Group 2, 11% MO and 11.8% CO; Group 3, 5% MO and 18% CO; Group 4, CO alone. A fifth group, serving as an internal control, was fed a low-fat diet containing 5% CO alone. Experimental diets were begun after initiation with NMU, and the experiment was terminated 31 wk later. Total tumor numbers in the five groups were 28, 16, 32, 26 and 11, respectively, indicating that the promotion phase of NMU-induced carcinogenesis was significantly suppressed only when equal parts of CO and MO (Group 2) were fed or when CO alone was fed at 5% (w/w). At high (Group 1) or low (Group 3) levels of MO, tumor numbers were indistinguishable from the HF CO group (Group 4). The same pattern was observed when assessed in terms of cumulative tumor incidence and multiplicity. However, when expressed in terms of final tumor incidence, dietary MO did not suppress tumor promotion in a statistically significant fashion at any concentration. Animals fed MO gained weight at the same rate as those fed CO, indicating that the presence of MO in the diet did not result in food avoidance behavior. Measurement of total serum cholesterol indicated an inverse trend with respect to the MO content of the diet. Analysis of serum fatty acid profiles indicated that the proportion of n-3 and n-6 polyunsaturated fatty acids (PUFA) in the serum reflected that of the diet. These results support the hypothesis that the relative proportions of dietary n-3/n-6 fatty acids play an important role in the suppression of experimental mammary tumorigenesis and suggest that changes in circulating cholesterol or n-3 PUFA levels, induced by dietary MO, are not directly related to tumor development.
***Lipids* 28, 449-456 (1993).**

It is well established that the development of carcinogen-induced, transplantable and virus-induced mammary tumors is enhanced by high-fat (HF) diets (1). In addition, it has been shown that diets containing high levels of the n-6 diunsaturated fatty acid linoleic acid (LA) stimulate the promotion phase of experimental mammary carcinogenesis (2,3) as well as metastasis to distant organs (4,5), whereas diets containing high levels of medium-chain saturated fatty acids (FA) or monounsaturated FA such as oleic acid (18:1n-9), do not (6).

A fourth class of fatty acids, the n-3 polyunsaturated fatty acids (PUFA) has been shown to exhibit protective effects, in most but not all cases, in primary tumor models including mammary (7-19), colon (20,23), prostate (24,25) and pancreas (26), and in one metastasizing mammary tumor model (27). The majority of studies on n-3 PUFA have used menhaden oil (MO) as the source of n-3 PUFA and have focused on mammary cancer. However, many inconsistencies appear in the literature. In some cases, fish oil suppressed tumorigenesis (8,19); while in others it had little effect (7,9). Still in others, fish oil at certain concentrations actually enhanced tumor development (10,17,23). Also of concern is the lack of any consistent dose-response effects of n-3 PUFA on mammary tumorigenesis (8,9,14-16). The reasons for these inconsistencies are unclear but may involve (i) variations in diet composition, (ii) the use of undeodorized MO which reduces diet palatability, (iii) the use of MO, which is LA deficient, as the sole source of fat, (iv) small numbers of animals and (v) differences inherent in the models being used (transplantable *vs.* chemically induced).

The present study was designed to assess whether increasing amounts of dietary n-3 PUFA inhibit the promotion phase of *N*-nitrosomethylurea (NMU)-induced mammary carcinogenesis in a dose-related manner. Three HF groups containing blends of MO and corn oil (CO) were formulated to obtain n-3/n-6 ratios of 1.51, 0.55 and 0.19 (Groups 1-3, respectively). They were compared with HF and low-fat diet (LF) groups (Groups 4 and 5) containing CO only (n-3/n-6 ratio, 0.007) (Fig. 1). To gain insight into possible mechanisms, the effect of feeding these diets on the cholesterol content and FA composition of serum was also examined.

MATERIALS AND METHODS

Experimental protocol. One-hundred and eighty virgin female inbred F344 rats, 28 d of age (Charles River Breeding Laboratories, North Wilmington, MA), were maintained on the standard NIH-07 diet (Zeigler Bros., Gardners, PA) until 50 d of age. All animals were then assigned into groups of 36 animals each by recognized randomization procedures (27) to equalize initial weight. On day 50 of age, all animals received a single dose (37.5 mg/kg body wt) of NMU (CAS:684-93-5) (Ash Stevens Inc., Detroit, MI) by tail vein injection. NMU was dissolved in a few drops of 3% acetic acid and diluted with distilled H_2O to give a stock solution of 10 mg NMU/mL, which was administered within 2 h of formulation (28). At weekly intervals beginning 4 wks after NMU injection, each rat was weighed and the position and date of palpable tumors recorded.

Two days after NMU administration, animals were randomly allocated to one of five different experimental diets. Groups of thirty-six animals each were placed on diets

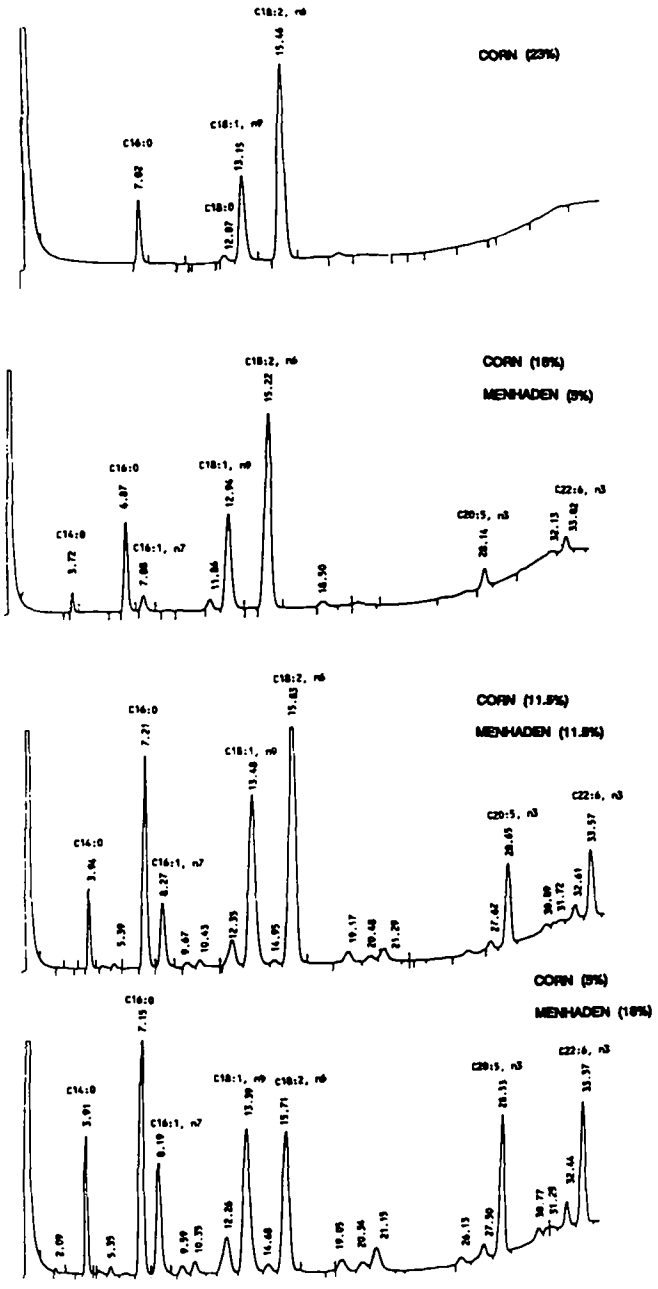

FIG. 1. Comparative fatty acid profiles of corn oil and corn oil/menhaden oil blends. Gas-liquid chromatography (GLC) traces depict the relative area percentages of fatty acids as a function of retention time (numbered vertically). Total lipids were extracted from diets 1-4 and processed for GLC analysis as described in Materials and Methods. Only the major peaks were identified using authentic standards.

containing: 18% MO, 5% CO (Group 1); 11.8% MO, 11.8% CO (Group 2); 5% MO, 18% CO (Group 3); 23% CO (Group 4); and 5% CO (Group 5). The animals remained on the diets for the duration of the experiment (31 wks). Animals were housed three to a polyethylene cage containing hardwood shavings and covered with a filter top. The animal room was controlled for temperature (24 ± 2°C), light (12-h cycle) and humidity (50%). Diets were administered

[a]High- and low-fat diets based on Newberne *et al.* (31) with replacement of starch/dextrose for sucrose as carbohydrate source.

in powdered form and tap water was provided *ad libitum*. Stainless steel "J" type powder feeders were used to prevent scattering of food. Animals were maintained according to the revised *Guide for the Care and Use of Laboratory Animals* (Department of Health, Education, and Welfare Publications, NIH 85-23, Bethesda, revised 1985) (29).

HF and LF diets. The HF and LF diets used in these experiments were based on the recommendations of the Committee on Laboratory Animal Diets of the National Academy of Sciences (30,31) with slight modifications (Table 1). Because the HF diet is more calorie-dense than the LF diet, less is eaten. The adjusted formulation accounts for this, ensuring that all animals consume the same amount of vitamins, minerals and fiber. The increase in fat in the HF diet was at the expense of starch-dextrose. The HF and LF diets consisted of 23 and 5% fat by weight, respectively. The LF diet was designed to provide approximately 5-6 calories/d of fat, based on an estimated consumption of 45 calories/d (≈12% of total calories). The HF diet provided approximately 20-21 calories/d of fat (≈45% of total calories). The LF and HF diets were designed to mimic the Japanese diet of the 1950s and the U.S. diet during the 1970s (32,33).

Bulk vacuum-deodorized menhaden oil (Lot No. L89195BB) was obtained *gratis* from the Fish Oils Test Materials Program (DOC/NOAA/NIH/ADAMHA) (Southeast Fisheries Center, Charleston, SC). The MO contained 1 g/kg α-tocopherol and 1 g/kg γ-tocopherol and 0.2 g/kg *t*-butyl hydroquinone (TBHQ) as added antioxidants. Food-grade corn oil, provided by BioServ Inc. (Frenchtown, NJ) which contains some α- and γ-tocopherol, was supplemented further with α- and γ-tocopherol and TBHQ to yield an amount of total antioxidants equal to that in MO. Cholesterol was added to the corn oil at 2.0 g cholesterol/kg oil in order to equalize the cholesterol in all five diets.

All dietary ingredients, other than MO, were obtained and diets were prepared by BioServ Inc. In order to prevent the formation of oxidized lipids, diets were formulated and stored undeer the following conditions: both MO and CO were stored under a blanket of N_2 in the dark at 4°C. Batches of diet were mixed and placed in 2- or 4-kg plastic bags, flushed with N_2 and heat-sealed. Upon receipt, aliquots of the diets were rebagged in amounts sufficient for a single feeding per group. The

[a]Data for corn oil were obtained as previously described (34); data for menhaden oil were provided by Southeast Fisheries Center, Charleston Laboratory. Values are area percentage of total methyl esters.

[b]Percentage of fatty acids adds up to 72%; these represent the major fatty acid species in menhaden oil. In total, menhaden oil contains 11 saturated, 21 monounsaturated, 9 unsaturated and 19 other fatty acids containing from 3 to 6 double bonds.

[c]— = value <0.05%. PUFA, polyunsaturated fatty acids.

bags were flushed with N_2 and heat sealed. All diets were stored at 4°C. Once opened and animals fed, the remaining diet was discarded. Animals were fed three times per week and feeders removed and washed after each feeding.

Quality controls for experimental diets. The fatty acid profile of the MO was provided by the National Marine Fisheries Service (Charleston Laboratory) (Table 2). Fatty acid analyses were conducted in our laboratory as described previously (34). The fatty acid profiles of formulated diets were determined as follows: One gram of diet 1–4 was placed in a pre-weighed 25-mL glass conical test tube, and lipids were extracted with 18 mL of a hexane/isopropyl alcohol (HIP) mixture (3:2). The mixture was then vortexed and the organic layer decanted following centrifugation. After a second extraction with 10 mL HIP, the two organic phases were pooled and evaporated to dryness under a stream of N_2. The conical tube containing the dried residue was weighed to confirm that approximately 0.23 g of lipid was present. Methanolysis was then performed by addition of methanol containing 5% HCl (80°C for 2 h) under N_2. A known amount of pentadecanoic acid was added as an internal standard to the extract prior to methanolysis. The fatty acid methyl esters were extracted with *n*-hexane and quantitatively analyzed by gas-liquid chromatography (Hewlett-Packard 5890, Palo, Alto, CA) using a column packed with 10% DEGS-PS adsorbed on 80–100 mesh Supelcoport (Supelco, Bellefonte, PA). The oven temperature was programmed at 24°C/min from 160 to 225°C. Individual fatty acids were identified by comparison with authentic standard mixtures. All standards were from Nu-Chek-Prep (Elysian, MN). Thiobarbituric acid tests for lipid oxidation products were conducted on formulated diets (35).

Necropsy, serum collection and histopathology. Approximately 31 wk after NMU administration, the experiment was terminated. Blood was drawn by heart puncture under ketamine anaesthesia, collected in evacuated, sterile autosep tubes (Terumo Med., Elkton, MD) and serum separated by centrifugation. Serum was stored at 20°C until use. Animals were then sacrificed by CO_2 euthanasia, and mammary tumors, classified as palpable or nonpalpable but grossly visible, were excised, fixed in 10% buffered formalin, blocked in paraffin and stained with hematoxylin and eosin for histological examination. Histologic diagnosis of mammary tumors was based on criteria outlined by Young and Hallowes (36).

Serum lipid analysis. Total serum cholesterol content in aliquots of serum were determined enzymatically using a DT-60 Clinical Chemistry Analyzer (Kodak Inc., Rochester, NY). The limit of detection of this assay is 30 mg/100 mL and the coefficient of variance is 5%. The method is based on a layered coating dry-slide technique (37,38). Serum fatty acid profiles were determined in the laboratory of Dr. M.T. Clandinin (University of Alberta, Edmonton, Alberta, Canada) using methods described in Reference 39.

Statistical analysis. A tumor-free survival function was estimated separately for each experimental group by the Kaplan-Meier product limit method (40). The survival functions for the different dietary groups were then compared by Gehan's generalized Wilcoxon (41,42). The purpose of this method was to test the null hypothesis that all five survival functions were identical. Differences in the overall frequency of tumor/animal (including tumor-free animals) and in the number of tumors/tumor-bearing animal were assessed by the *Chi* Square test (43). Weight gain over time and the latency of tumors were compared by analysis of variance with multiple comparison procedures (44,45). Trends in serum cholesterol levels as a function of diet were tested by multiple regression analysis (44). Pairwise comparisons of cholesterol levels were performed by analysis of covariance, the covariates being weight gain and latency. The relationship between the presence (or absence) of a tumor and serum cholesterol levels was assessed by the two-tailed *t*-test.

RESULTS

Animal weight gains (Fig. 2) were similar in Groups 1–4, suggesting that differences in dietary MO content did not alter food consumption patterns. It was not possible to measure food consumption accurately because of diet scattering. Group 5, however, exhibited a lower body weight gain when compared to Groups 1–4 which was of borderline significance ($P > 0.10$).

With the exception of mammary tumors, no gross changes in the major organs or organ systems were seen. Mammary tumors were either adenocarcinomas or fibroadenomas, with the fibroadenomas varying in frequency from 0 to 11%. There were 0, 1, 2, 2, 0 unscheduled terminations in Groups 1–5, respectively, due to necrotizing tumors. No animals died of extraneous causes. Tumor incidence data, presented as either total tumor incidence or incidence of adenocarcinoma alone, can be seen in Table 3. Tests for overall trend were nonsignificant for the four HF groups. Pairwise comparisons indicated that Group 1 *vs.* Group 3, Group 2 *vs.* Group 3 and Group 5 *vs.*

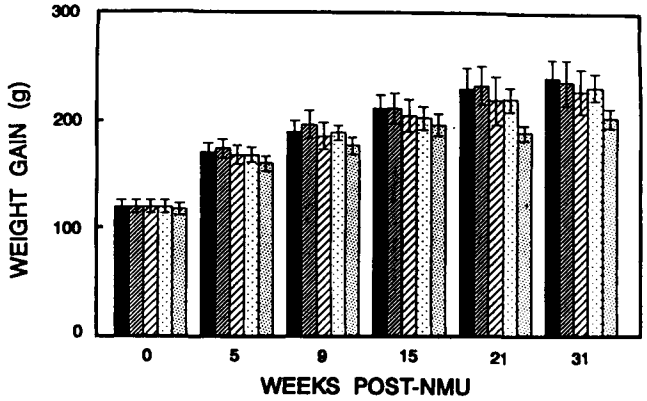

FIG. 2. Mean (± SD) weight gains for Groups 1–5 at selected time points. CO-5/MO-18 Group, solid bars; CO-11.5/MO-11.5 Group, narrow-hatched bars; CO-18/MO-5 Group, broad-hatched bars; CO-23 Group, dotted bars; CO-5 Group, densely dotted bars. Overall comparison is based on analysis of variance, $P < 0.001$. Differences in mean weights for Groups 1–4 *vs.* 5, $P < 0.10$ are by one-tailed *t*-test. Abbreviations: NMU, *N*-nitrosomethylurea; CO, corn oil; MO, menhaden oil.

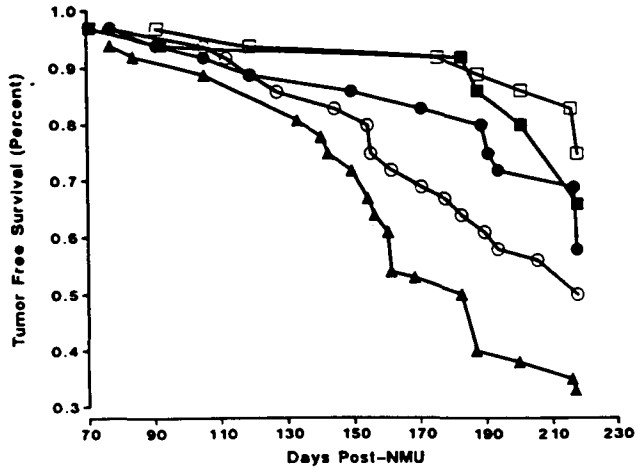

FIG. 3. Kaplan-Meier life table curves for cumulative mammary tumor incidence for Groups 1–5. □, Corn oil (CO) 5%; ■, menhaden oil (MO) 11.5%/CO 5%; ●, MO 18%/CO 5%; ○, CO 5%; ▲, MO 5%/CO 18%. Life table data include all palpable tumors (adenocarcinoma and fibroadenoma). The proportion of animals surviving per unit time-without-tumor (1.0 represents 100% tumor-free animals) plotted as a function of days post-*N*-nitrosomethylurea (NMU) treatment. Tests for overall trend: Cox's test for adjusted trends and generalized Kruskal-Wallis analysis, not significant. Pairwise comparisons: Cox's test, Groups 3 and 4 *vs.* Groups 1, 2 and 5 ($P < 0.05$).

Groups 3 and 4 exhibited significant differences in tumor incidence, respectively.

Analysis of time-to-first-tumor curves for each of the five experimental groups (Fig. 3) indicated that mammary tumors appeared most rapidly in Group 3 (5% MO + 18% CO) and Group 4 (23% CO), less rapidly in Group 1 (15% MO + 18% CO) and least rapidly in Groups 2 (11.8% MO + 11.8% CO) and 5 (5% CO). Tests for overall trend were not significant, indicating that there was no direct (or indirect) relationship between the amount of MO in the diet and average time to first tumor in Groups 1–3. Pairwise comparisons by Wilcoxon's Rank test among the five experimental groups revealed that tumors appeared significantly more rapidly in Group 3 *vs.* Group 5 ($P < 0.001$), Group 2 *vs.* Group 3 ($P < 0.01$), and Group 2 *vs.* Group 4 ($P < 0.05$). Pairwise comparisons between Groups 1, 2 and 5 were nonsignificant. During the course of the experiment, palpable tumors occasionally appeared and then disappeared. The number of such animals in each group exhibiting such transient tumors were 4, 0, 4, 3, 2, respectively, in Groups 1–5.

The frequency distribution of tumors can be seen in Tables 4 and 5. Examination of the patterns of distribution of tumors/rat among the various groups reveals distinct differences. The three high incidence groups (1, 3 and 4) exhibited a pattern characterized by a higher frequency of animals bearing either one or two tumors than zero tumors. The two low-incidence groups (2 and 5) exhibited the opposite pattern. In terms of total tumor number, Groups 1, 3 and 4 exhibited significantly higher tumor yield compared to Groups 2 and 5 (Table 4). A similar pattern was found when only histologically verified adenocarcinomas (Table 5) were evaluated with the exception that total tumor yields in Group 4 were not significantly greater than in Group 2. When tumor multiplicity was assessed in terms of mean number of

4. Corn oil (23%)	19	12	4	0	1	0	24	0.67 ± 0.89
5. Corn oil (5%)	27	8	1	0	0	0	10	0.28 ± 0.51

[a]Pairwise comparisons. Differences between Group 3 *vs.* Group 5, Group 3 *vs.* Group 2, and Group 4 *vs.* Group 5 are statistically significant ($P < 0.05$-0.01) by *Chi* Square test.
[b]Number of rats.
[c]Mean ± SD. Group 3 *vs.* Group 5 ($P < 0.01$), Group 3 *vs.* Group 2 ($P < 0.0125$). All other pairwise comparisons, not significant (analysis of variance).

tumors/total animals at risk, or mean number of tumors/tumor bearing animal, no overall trends among the five treatment groups were observed. Rats in Group 3 exhibited higher multiplicities than Groups 2 and 5 ($P < 0.004$ and $P < 0.01$, respectively); all other pairwise comparisons were nonsignificant (Table 4). Similar results were obtained when only adenocarcinomas were compared. When assessed using only tumor bearing animals, Group 1, containing the highest levels of n-3 PUFA, exhibited greater tumor multiplicity than Groups 2-5 ($P < 0.001$) (Table 4).

Mean serum cholesterol levels (Table 6) were significantly suppressed in the high MO Groups (1 and 2) compared to the CO Groups (4 and 5). When assessed in terms of median levels, a similar pattern was observed (30, 36, 53, 58, 64 mg cholesterol/100 mL for Groups 1-5, respectively). Tests for trend indicated a strong inverse association between the proportion of MO in the diet and total serum cholesterol levels. No association was found between animal weight (at termination) or latency and serum cholesterol, nor was there any association between the presence or absence of a mammary tumor and serum cho-

[a]Percent total fatty acids (SD). Rows do not necessarily add up to 100% since only the even major fatty acids in serum are shown. A total of 19 to 21 fatty acids were detected in groups 2, 3, 4 and 5. Group 1 exhibited 27 different fatty acids. In the majority of cases these minor fatty acids were present at <1% of the total.
[b]N = 3.

lesterol levels in individual animals. The results remained unchanged after adjustment for differences in weight gain and/or presence of a tumor or after segregation of cholesterol data into tertiles (30, 30–50, >50 mg/100 mL) followed by evaluation of the association between cholesterol and tumorigenesis by the Mantel-Haenszel *Chi* Square test and logistic regression.

Analysis of serum fatty acid profiles (Table 7) indicated that when dietary MO was increased at the expense of CO, keeping total lipid content constant, there was a stepwise decrement in the major n-6 serum fatty acids, linoleic (LA) and arachidonic (AA) and a concomitant stepwise increase in the major n-3 fatty acids, eicosapentaenoic (EPA) and docosohexaenoic (DHA). In contrast, lowering CO intake from 23 to 5% resulted in a 50% decrease in serum LA but no change in AA. No trend was found between the amount of EPA or DHA in serum and overall tumor yield in the five experimental groups. Interestingly, the levels of n-3 PUFA in serum never rose above 9% of total serum FA, despite levels of dietary n-3 intake as high as 4 g/100 g diet (Group 1).

DISCUSSION

In the present study, significant inhibition of mammary tumor promotion was seen only when MO and CO were fed in equal proportions (n-3/n-6 ratio = 0.55). Moreover, at the lowest MO/CO ratio (0.19) a nonsignificant enhancement of tumor numbers and incidence was seen. An HF diet containing a n-3/n-6 ratio of 0.55 resulted in a tumor yield (Tables 4 and 5) and latency (Fig. 3) similar to that of animals fed a LF CO diet indicating the importance of the type as well as the amount of dietary fat in affecting mammary tumor promotion.

Previous attempts at demonstrating linear dose-related effects of n-3 PUFA have been largely unsuccessful. Using a transplantable mouse mammary tumor model, Gabor and Abraham (16) examined the effects of various combinations of MO and CO fed at 10% (w/w) on tumor growth rates, and reported no dose-related changes when MO was increased from 25 to 75% of total fat. These authors did report, however, that growth of the tumor implant was inhibited at a MO/CO ratio of 9:1 or when MO alone was fed. In another study, using a transplantable rat mammary tumor model, Karmali *et al.* (8) fed F-344 rats (15/group) a 5% chow diet supplemented with Max EPA, a fish oil concentrate containing 17% EPA and 16% DHA (MO contains 16% EPA and 11% DHA and a far greater spectrum of other fatty acids), at 100, 200 and 400 μL rat/day. Growth of the tumor implant was inhibited equally in all three supplemented diets. Direct comparison of these studies with ours is difficult due to differences in (i) the resolving power of the models used, (ii) the small numbers of animals used in the transplant studies (5–15/group) and (iii) differences in the fat content and composition of the diets employed.

In the only study directly comparable to ours, Jurkowski and Cave (15) fed HF diets containing MO alone and MO/CO ratios of 3:1 and 1:3 to Buffalo rats initiated with NMU. No differences in tumor yields were found between the MO-containing groups and CO controls with the exception of the group fed MO alone which did suppress tumor development. Unfortunately, the authors did not include a group fed MO and CO in equal proportions. The results of the Jurkowski and Cave (15) study are consistent with our findings as are two other reports in the 7,12-dimethylbenz(a)anthracene (DMBA) model (10,17): low levels of MO in a CO-based diet either had no effect or enhanced mammary tumor development compared to CO alone. Also concordant with our findings is the study by Ip *et al.* (14) which reported that DMBA-tumor suppression occurred in rats fed almost equal levels of MO and CO (12% MO + 8% CO), but not in rats fed high levels of MO (19% MO + 1% CO). Interestingly, the tumor-enhancing effects of low levels of menhaden oil have also been observed in the neoplastic pancreatic foci model (26), the two-stage skin papilloma model (46) and the azoxymethanol-induced colon cancer model (23).

Various mechanisms have been proposed to explain the putative beneficial effects of n-3 PUFA. These include effects on eicosanoid metabolism (8,26,47–50), immune functions (50), cell membrane structure and function (50,51), free radical activity (9) and oncogene activity (47). Clearly, any mechanism proposed must be able to account or the nonlinear dose-response effect of n-3 PUFA in the mammary tumor model. In this regard, an eicosanoid-based mechanism seems plausible since eicosanoids have been shown to exhibit opposed biological effects based on their relative concentrations in specific tissues (52).

Most biochemical studies on n-3 PUFA have focused

on their effects on lipid metabolism and particularly serum triglyceride and cholesterol levels (39,53,54). In humans, n-3 PUFA suppress serum triglycerides and inconsistently suppress serum cholesterol (54), while in rodents both lipid classes are suppressed (39,53). Total serum cholesterol was examined in the present study because of the known link between high cholesterol and HF intake (55) and a reported epidemiological association between elevated serum cholesterol levels and (i) increased risk for breast cancer (56,57) and (ii) decreased survival among breast cancer patients (58,59). Our studies show clearly that serum cholesterol levels are inversely related to the amount of n-3 PUFA in the diet but are unrelated to mammary tumorigenesis.

Examination of serum FA profiles indicated that, in general, the serum profiles of the various treatment groups reflected the n-3/n-6 content of the diet, and because the levels of AA in the high MO groups were decreased, support the idea that increased n-3 PUFA suppresses elongation and desaturation of LA to AA. However, since we did not examine tissue PUFA profiles, it is not possible to know whether or not similar changes took place at the phospholipid or neutral lipid level. Two studies (8,15) have examined changes in mammary tumor membrane lipids induced by n-3 PUFA, and these suggest that n-3 PUFA can displace n-6 PUFA from membrane phospholipid and may thereby alter eicosanoid metabolism (8,18). It is of interest that despite the fact that the Group 1 diet provided twice as much n-3 PUFA as LA, serum levels of n-3 PUFA in Group 1 were lower (9%) than those of LA (12%). These results imply that dietary n-3 PUFA were preferentially oxidized or sequestered in a manner different than dietary LA.

It is noteworthy that the blended oils differed in a number of ways other than the relative amounts of n-3 and n-6 PUFA (Fig. 1). Fish oil, in contrast to corn oil, contains a wide variety of minor fatty acids, hence blends of CO and MO result in markedly different overall FA profiles. For example, 14:0 increased incrementally along with EFA and DHA, and the ratio of 18:0 to 18:2n-6 changed dramatically as the proportion of MO increased relative to CO. The possibility must therefore be considered that the effects of these diets on mammary tumorigenesis may not be due solely to n-3 PUFA or their n-3/n-6 ratios. To resolve this methodological problem future studies may require use of the nontriglyceride forms of n-3 PUFA as recently suggested by Ackman (60).

Several authors have drawn attention to the present dietary imbalance of n-3 and n-6 PUFA in Western countries and have attributed the high prevalence of chronic diseases such as coronary heart disease, cancer and arthritis in these societies specifically to this imbalance (66). With regard to breast cancer, this notion has received partial support from epidemiological studies (67-69). For example, special populations such as rural Japanese (70) and Greenland Eskomos (71), which exhibit low breast cancer rates, consume n-3/n-6 PUFA at ratios of 0.365 and >1, respectively, compared to high-risk Americans who consume a n-3/n-6 PUFA ratio of approximately 0.060 (71). Moreover, in a cross-country comparison, a positive association was demonstrated between breast cancer mortality and fish consumption (67), and Hislop *et al.* (68) reported similar results in a case/control study. In contrast, however, no association between risk for breast cancer and fish consumption was found in a recent large-scale prospective study (69).

In summary, the results of our study suggest that, with regard to the NMU-tumor inhibition, a n-3/n-6 ratio of 0.55 was the most effective and that raising or lowering the ratio above or below that point offered no beneficial effects. The implications of these experimental findings to human breast cancer remain to be determined.

ACKNOWLEDGMENTS

This work was supported by NIH/DHHS grant CA-47326 from the Division of Extramural Activities, National Cancer Institute, Bethesda, MD. We thank Dr. M.T. Clandinin. University of Alberta. Edmonton, for conducting the serum fatty acid analyses. We also thank J. Reinhardt for supervising the feeding study, M. Epstein and R. Bland for expert technical assistance, and A. Banow for preparation of the manuscript.

Effects of Dietary Proteins on Linoleic Acid Desaturation and Membrane Fluidity in Rat Liver Microsomes

Kazunori Koba[a], Kosaburo Wakamatsu[a], Keisuke Obata[a] and Michihiro Sugano[b,*]
[a]Laboratory of Nutrition Chemistry and [b]Laboratory of Food Science, Kyushu University School of Agriculture 46-09, Fukuoka, Japan

The effect of dietary protein, casein (CAS) and soybean protein (SOY), on linoleic acid desaturation in liver microsomes was studied in rats. The activity of Δ6 desaturase in total and rough endoplasmic reticula (ER and RER) was significantly higher in the CAS group than in the SOY group. In ER and smooth endoplasmic reticulum, the steady-state fluorescence anisotropy of 1,6-diphenyl-1,3,5-hexatriene, when incorporated into the membrane, was decreased in the SOY group and accompanied by a reduction in the cholesterol/phospholipid (CHOL/PL) ratio, consistent with an increase in membrane fluidity. In a separate study, the effect of varying dietary proteins, CAS, milk whey protein, egg albumin, SOY, potato protein and wheat gluten, on the relationship between the Δ6 desaturase activity and microsomal membrane fluidity was also examined. The results indicated that the dietary protein-dependent change in the liver microsomal CHOL/PL ratio affected membrane fluidity, and subsequently the activity of Δ6 desaturase in liver microsomes. However, since dietary protein influenced the Δ6 desaturase activity in RER without influencing membrane fluidity, it is possible that some regulation might have taken place at the level of enzyme synthesis.
Lipids 28, 457-464 (1993).

Dietary protein influences not only the serum cholesterol level (1,2) but also the metabolism of linoleic acid (3,4). It has been observed in rats that casein (CAS) not only increases the concentrations of serum and liver cholesterol, but also promotes the metabolism of linoleic acid to arachidonic acid more than does soybean protein (SOY) (3-8). These protein-dependent effects may result, at least in part, from the arginine content of the two dietary proteins (6,7). However, the exact mechanism as to how dietary protein affects linoleic acid metabolism is not clear. Since both Δ5 and Δ6 desaturases, two rate-limiting enzymes of linoleic acid metabolism, are bound to the microsomal membrane (9), it is possible that desaturase activity may be affected by changes in the liver microsomal membrane architecture. Microsomes (endoplasmic reticulum; ER) are composed of rough endoplasmic reticulum (RER), with ribosomal particles attached on the outer surface, and smooth endoplasmic reticulum (SER), which has no ribosomes attached (10). To elucidate the mechanism of the protein-dependent effect on the metabolism of linoleic acid, we invstigated the protein-effect at the level of RER and SER of rat liver. We also studied the relationship between membrane fluidity and Δ6 desaturase activity and between membrane fluidity and the relative distribution of liver microsomal lipids [cholesterol/phospholipid (CHOL/PL) ratio and phospholipid subclasses] using various dietary proteins.

Abbreviations: CAS, casein; CHOL, cholesterol; DPH, 1,6-diphenyl-1,3,5-hexatriene; EAL egg albumin; EDTA, ethylenediaminetetraacetic acid; ER, endoplasmic reticulum; GLC, gas-liquid chromatography; PC, phosphatidylcholine; PE, phosphatidylethanolamine; PL, phospholipids; POT, potato protein; RER, rough endoplasmic reticulum; SER, smooth endoplasmic reticulum; SOY, soybean protein; TLC, thin-layer chromatography; WGL, wheat gluten; WHY, milk whey protein.

MATERIALS AND METHODS

Animals and diets. Male Sprague-Dawley rats (four-weeks-old) were purchased from Seiwa Experimental Animals (Fukuoka, Japan) and acclimated for four days (Experiment 1) or three days (Experiment 2) in a room maintained at 20-23°C with a 12-h light-dark cycle (lights on 8 a.m. to 8 p.m.). During this period, rats were allowed free access to commercial rat chow (Type NMF, Oriental Yeast Co., Tokyo, Japan). Then rats were divided into two groups (Experiment 1) and six groups (Experiment 2) of six animals each according to the source of the dietary protein. In Experiment 1, the dietary proteins used were CAS (Wako Pure Chemical Industries Ltd., Osaka, Japan) and SOY (Fujipro R, Fuji Oil Co., Osaka, Japan). In Experiment 2, CAS, milk whey protein (WHY; Meiji Milk Co., Tokyo, Japan), egg albumin (EAL; Wako Pure Chemical Industries Ltd.), SOY, potato protein (POT; protamyl PF; Avebe Holland, provided by Ajinomoto Co., Tokyo, Japan) and wheat gluten (WGL; Nisshin Flour Milling Co., Tokyo, Japan) were used. The diets were prepared according to recommendations of the American Institute of Nutrition (11) and contained (by wt%) protein (CAS or SOY) 20, corn oil (Ajinomoto Co.) 5.0, vitamin mixture (AIN-76™) 1.0, mineral mixture (AIN-76™) 3.5, choline bitartrate 0.2, DL-methionine 0.3, cellulose 5.0, corn starch 15 and sucrose 50 for Experiment 1. In Experiment 2, the dietary protein level (wt%) was adjusted to be isonitrogenous as follows: CAS 20, WHY 20, EAL 21.8, SOY 20, POT 20, WGL 25.7 + 0.7% L-lysine·HCl + 0.32% $NaHCO_3$. The diets were adjusted to 100% at the expense of corn starch. In both experiments, the rats were fed these diets *ad libitum* for 21 d. At the end of the feeding period, they were killed by decapitation, and liver was excised immediately.

Preparation of liver microsomes (total ER fraction). According to the method of Svensson (12), a piece of liver (approximately 2 g) was homogenized in 10 vol of 0.25 M sucrose solution containing 0.05 M potassium phosphate buffer (pH 7.0), 0.15 M KCl, 5 mM $MgCl_2$, 1 mM ethylenediaminetetraacetic acid (EDTA) and 1.5 mM reduced glutathione. The homogenate was centrifuged at 10,000 × *g* for 20 min at 4°C. The supernatant was recentrifuged at 105,000 × *g* for 60 min to sediment microsomes. The microsomal pellet was resuspended in potassium phosphate buffer (pH 7.0) (approximately 10 mg protein/mL).

Separation of liver RER and SER fractions. According to the method of Dallner (13), a piece of liver (approximately 2 g) was homogenized in 12 mL of 0.25 M sucrose buffer containing 0.05 M potassium phosphate buffer (pH 7.0), 0.15 M KCl, 5 mM $MgCl_2$, 1 mM EDTA and 1.5 mM

reduced glutathione. The homogenate was centrifuged at 10,000 × *g* for 20 min at 4°C, and the supernatant was harvested. Then 0.15 mL of 1 M CsCl was added to 9.85 mL of this supernatant giving a final CsCl concentration of 15 mM. The supernatant (7 mL) was layered over 4.5 mL of the buffer containing 1.30 M sucrose and 15 mM CsCl (pH 7.0). After centrifugation at 165,000 × *g* for 180 min at 4°C, a fluffy double-layered fraction appearing around the gradient boundary and a tight pellet at the bottom (RER fraction) were separated. The upper 7.5 mL including the fluffy double-layer was diluted with 4 mL 0.25 M sucrose buffer (pH 7.0) and recentrifuged at 165,000 × *g* for 60 min at 4°C to yield a tight pellet (SER fraction). Each pellet was resuspended with 0.25 M sucrose buffer (pH 7.0). We confirmed that CsCl that may be contaminating the RER fraction does not influence the enzymatic activity.

Measurement of the desaturase activity of liver microsomes. [1-^{14}C]Linoleic acid (51.7 mCi/mmol, New England Nuclear, Boston, MA) and [1-^{14}C]dihomo-γ-linolenic acid (47.0 mCi/mmol, New England Nuclear) were used as substrates to determine the activities of the Δ6 and Δ5 desaturase, respectively. Enzyme activity measurements were based on the method of Svensson (12). Microsomal protein (approximately 1 mg) was incubated at 37°C for 20 min together with 100 nmol 0.1 μCi radiolabelled fatty acid in 1 mL (final volume) 0.25 M sucrose buffer containing 0.1 M KCl, 5 mM ATP, 0.25 mM CoA, 0.25 mM NADH, 5 mM $MgCl_2$, 1.5 mM reduced glutathione, 45 mM NaF and 0.5 mM nicotinamide. In a preliminary study, we found that under these conditions the enzymes were saturated with substrate and the reactions proceeded linearly with microsomal protein concentration and incubation time (12). The reaction was terminated by adding 5 mL of ethanol, and lipids were extracted. Fatty acids were separated by argentation thin-layer chromatography (TLC) (14) using petroleum ether/diethyl ether (70:30 and 30:70, vol/vol, for Δ6 and Δ5 desaturase, respectively) as a developing solvent. The fractions corresponding to fatty acids with 2 and 3 double bonds were scraped for the measurement of Δ6 desaturase activity, whereas those with 3 and 4 double bonds were scraped for the measurement of Δ5 desaturase activity. Each fraction dissolved in a toluene scintillation fluid (2 g of 2,5-diphenyloxazole and 50 mg of 2,2′-*p*-phenylene-*bis*[5-phenyloxazole]/liter toluene), and radioactivity was determined using a liquid scintillation spectrometer (Aloka LSC-1000, Aloka, Tokyo, Japan). Microsomal protein was measured by the method of Lowry *et al.* (15).

Lipid analyses. Liver microsomal lipids were extracted by the method of Folch *et al.* (16). CHOL was assayed by gas-liquid chromatography (GLC) on a OV-17 column (17). Microsomal PLs were resolved by TLC (18). The concentration of total PL as well as of individual PL classes was measured using the method of Rouser *et al.* (19). Fatty acid compositions were analyzed by GLC of the methyl esters using a SILAR 10C (Chromatotec, Tokyo, Japan) column (20).

Fluorescence anisotropy measurements. According to the method of Leikin and Brenner (21), one volume of 2 μM 1,6-diphenyl-1,3,5-hexatriene (DPH; Nacalai Tesque, Kyoto, Japan) was mixed with a volume of a microsomal suspension diluted with 0.25 M sucrose buffer (pH 7.0) (approximately 50 μM phospholipid). Then the mixture was incubated for 1 h at 25°C. A reference blank was prepared without the fluorescence probe. The fluorescence anisotropy measurements (352 nm excitation and 435 nm emission) were made at 37°C in a spectrofluorometer equipped with two polarizers (Hitachi 650-10S, Tokyo, Japan) with a HP-85F computer (Yokogawa Hewlet-Packard, Tokyo, Japan). They were corrected by subtraction of the corresponding blank values. The steady-state fluorescence anisotropy (r_s) was calculated using the equation: $r_s = (I_\parallel - GI_\perp)/(I_\parallel + 2GI_\perp)$ where $I_\parallel$ and $I_\perp$ are the fluorescence intensities detected with the excitation polarizer in vertical position and with the analyzer in vertical and horizontal position, respectively. $G = i_\perp/i_\parallel$ is a correction factor arising from instrumental factors. The fluorescence intensities are $i_\perp$ and $i_\parallel$ detected with the excitation polarizer in horizontal position and the analyzer in vertical and horizontal position, respectively.

Statistical analyses. Data were analyzed by Student's *t*-test (22) or Duncan's new multiple-range test (23) preceded by analysis of variance.

RESULTS

Growth and liver weight. In Experiment 1, no statistically significant differences were found in body weight gain and food consumption between the groups (Table 1). Relative liver weight (g/100 g body weight) was higher in rats fed the CAS diet than in those fed the SOY diet. In Experiment 2, body weight gain was lower in the EAL group than in the SOY group, although food consumption was comparable among the groups (Table 1). Relative liver weight was significantly higher in rats fed the CAS diet than in those fed the EAL, SOY, POT and WGL diets and was lowest in the SOY group. When the effects of animal proteins were compared to those of vegetable protein, relative liver weight was significantly higher in the former than in the latter (5.80 ± 0.12 *vs.* 5.20 ± 0.07, $P < 0.05$).

Desaturase activity in liver microsomes. In Experiment 1, the Δ6 desaturase activity in total ER and RER fractions was significantly higher in the CAS group than in the SOY group (Fig. 1). The Δ5 desaturase activity of total ER and SER was also higher in the CAS group than in the SOY group, but differences were not statistically significant. The Δ5 desaturase activity of RER was comparable between the groups. In Experiment 2, the activity of Δ6 desaturase was significantly higher in rats fed CAS, EAL or POT diets than in those fed the SOY diet (Fig. 2). The activities of the WHY and WGL groups also tended to be lower than that of the CAS, EAL and POT groups, although the difference was not statistically significant. However, no effect was found in the activity between animal and vegetable proteins.

The activity of Δ6 desaturase measured in Experiments 1 and 2 was different (231 *vs.* 80 nmol/min·mg protein for CAS and 112 *vs.* 56 nmol/min·mg protein for SOY). In Experiment 1, the activity of total endoplasmic reticulum (microsomes) was measured after storage for about 6 h at 4°C until RER and SER were available. In Experiment 2, on the other hand, the enzymatic activity was measured immediately after separation of microsomes. These differences may influence the activity of desaturase. Nevertheless a dietary protein-dependent effect on the desaturase activity was observed in both experiments.

TABLE 1

Effects of Dietary Protein on Growth Parameters and Liver Weight[a]

Group	Body weight (g)		Food intake (g/d)	Liver weight (g/100 g body wt)
	Initial	Gain		
Experiment 1				
CAS	114 ± 2	185 ± 9	21.7 ± 0.8	6.18 ± 0.14[b]
SOY	114 ± 2	178 ± 10	20.7 ± 0.7	5.08 ± 0.05[b]
Experiment 2				
CAS	108 ± 4	179 ± 5[b,c]	21.5 ± 0.4	6.16 ± 0.22[b]
WHY	108 ± 3	169 ± 7[b,c]	20.4 ± 0.8	5.74 ± 0.22[b,e]
EAL	108 ± 3	160 ± 11[b]	19.4 ± 0.9	5.51 ± 0.14[c,e]
SOY	108 ± 3	188 ± 8[c]	21.5 ± 0.7	4.91 ± 0.05[d]
POT	108 ± 3	175 ± 11[b,c]	20.7 ± 1.0	5.25 ± 0.06[c,d]
WGL	108 ± 3	167 ± 8[b,c]	20.0 ± 0.8	5.45 ± 0.10[c,e]

[a]Mean ± SE of six rats. CAS, casein; SOY, soybean protein; WHY, milk whey protein; EAL, egg albumin; POT, potato protein; WGL, wheat gluten. Values in each experiment without a common superscript (b-e) are significantly different at $P < 0.05$.

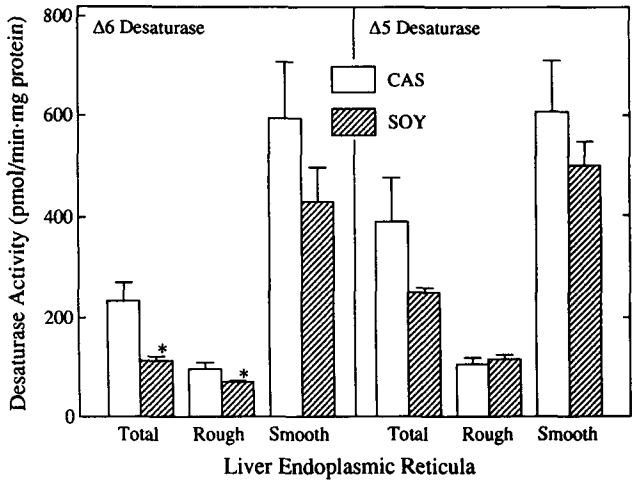

FIG. 1. Effects of dietary protein on Δ6 and Δ5 desaturase activities of liver endoplasmic reticula (Experiment 1). Values are expressed as mean ± SE of six rats. CAS, casein; SOY, soybean protein. *Significantly different from the corresponding CAS group at $P < 0.05$.

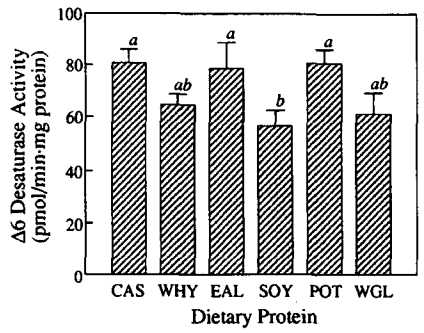

FIG. 2. Effects of dietary protein on Δ6 desaturase activity of liver microsomes (Experiment 2). Values are expressed as mean ± SE of six rats. CAS, casein; WHY, milk whey protein; EAL, egg albumin; SOY, soybean protein; POT, potato protein; WGL, wheat gluten. *a,b*Values without a common superscript are significantly different at $P < 0.05$.

Lipid composition of liver microsomes. The lipid composition of hepatic ER (Experiment 1) is shown in Table 2. The concentration of CHOL in SER was significantly lower in the SOY group than in the CAS group. RER contained approximately one-fifth to one-sixth as much CHOL as SER, but no protein-dependent difference was observed. Similarly, the PL concentration in ER was approximately one-third of that seen in SER. No protein effect on the PL concentration was observed in all fractions. The CHOL/PL ratio of total ER and SER was significantly higher in the CAS group than in the SOY group, whereas the CHOL/PL ratios of the RER were comparable between the groups. In Experiment 2, the concentration of CHOL was significantly higher in the CAS, EAL and POT groups than in the WHY, SOY and WGL groups (Table 2). The PL concentration was significantly higher in the CAS, EAL and POT groups than in the WGL group, whereas the PL levels in the WHY and SOY groups were comparable. As a result, the CHOL/PL ratio of the CAS group was significantly higher than that of the SOY and WGL groups. When the effects of animal proteins were compared to those of vegetable proteins, the concentration of CHOL (39.4 ± 0.6 *vs.* 37.2 ± 0.7, $P < 0.05$) and the CHOL/PL ratio (9.22 ± 0.11 *vs.* 8.81 ± 10, $P < 0.05$) were significantly higher in the former than in the latter. Although it is difficult to explain the reason why the lipid concentrations observed in Experiment 1 were higher than those in Experiment 2, the ratio of CHOL/PL was comparable, and the same protein-dependent difference was observed in both experiments.

Fatty acid composition of liver microsomal lipids. The fatty acid composition of total lipids in hepatic ER (Experiment 1) is shown in Table 3. The proportion of linoleic acid was significantly lower in the CAS group than in the SOY group in all ER fractions. The proportion of arachidonic acid in total ER was significantly higher in the CAS group than in the SOY group, whereas those in RER and SER were comparable between the groups. Consequently, the desaturation index for linoleic acid expressed as (20:3n-6 + 20:4n-6)/18:2n-6 was significantly higher in the CAS group than in the SOY group in all ER fractions. Interestingly, the RER fraction in both dietary protein groups, contained more n-3 highly polyunsaturated fatty

CAS	145 ± 21	1147 ± 203	12.9 ± 1.1[b]
SOY	95.5 ± 7.8	969 ± 73	9.99 ± 0.36[c]
Rough endoplasmic reticulum			
CAS	27.8 ± 1.5	340 ± 30	8.31 ± 0.39
SOY	30.2 ± 2.4	359 ± 19	8.43 ± 0.44
Smooth endoplasmic reticulum			
CAS	180 ± 6[b]	1187 ± 23	15.2 ± 0.6[b]
SOY	162 ± 4[c]	1196 ± 17	13.5 ± 0.4[c]
Experiment 2			
Liver microsomes			
CAS	40.8 ± 0.7[b]	435 ± 10[b]	9.38 ± 0.16[b]
WHY	37.3 ± 1.1[c,d]	413 ± 7[b,c]	9.03 ± 0.19[b,c]
EAL	40.1 ± 0.8[b,d]	434 ± 5[b]	9.24 ± 0.24[b,c]
SOY	36.5 ± 1.1[c,e]	418 ± 7[b,c]	8.73 ± 0.21[c]
POT	39.2 ± 1.2[b,d,e]	436 ± 11[b]	8.99 ± 0.08[b,c]
WGL	35.4 ± 1.0[c]	407 ± 6[c]	8.69 ± 0.20[c]

[a]Mean ± SE of five or six rats. CHOL, cholesterol; PL, phospholipid; CAS, casein; SOY, soybean protein; WHY, milk whey protein; EAL, egg albumin; POT, potato protein; WGL, wheat gluten. Values in each experiment without a common superscript (b-e) are significantly different at $P < 0.05$.

acids, in particular docosapentaenoic acid (22:5n-3) than did the SER fraction.

In Experiment 2, the proportion of linoleic acid in liver microsomal phosphatidylcholine (PC) was significantly lower in rats fed the CAS, EAL and POT diets than in those fed the SOY and WGL diets (Table 3). Conversely, the proportion of arachidonic acid was significantly higher in rats fed the WHY, EAL and POT diets than in those fed the SOY diet. Consequently, the desaturation index, (20:3n-6 + 20:4n-6)/18:2n-6, was significantly higher in the CAS, WHY, EAL and POT groups than in the SOY and WGL groups. In rats fed WGL, all responses resembled those in rats fed SOY. When comparisons were made between animal and vegetable proteins, the proportion of linoleic acid (8.0 ± 0.2 *vs.* 9.0 ± 0.3, $P < 0.05$) was significantly lower whereas that of arachidonic acid (31.1 ± 0.3 *vs.* 29.9 ± 0.3, $P < 0.05$) was significantly higher in the former than in the latter. Consequently, the desaturation index was significantly higher in rats fed animal proteins than in those fed vegetable proteins (4.2 ± 0.1 *vs.* 3.7 ± 0.2, $P < 0.05$).

Distribution of PL subclasses in liver microsomes. The PL compositions are shown in Table 4. In Experiment 1, the protein-effect was observed only in the proportion of lysophosphatidylcholine and phosphatidylinositol, and no effect was seen in the main components, PC and phosphatidylethanolamine (PE) in all fractions except PC in SER. The ratio of PC/PE was therefore similar in all fractions.

In Experiment 2, the proportion of liver microsomal PC was significantly higher ($P < 0.05$) in the animal proteins (57.2 ± 0.5%) than in the vegetable protein group (55.4 ± 0.5%), whereas the proportion of PE was significantly lower ($P < 0.05$) in the animal protein groups (9.6 ± 0.2%) than in the vegetable protein group (10.7 ± 0.3%). Thus, the PC/PE ratio was significantly higher ($P < 0.05$) for animal protein fed rats (6.0 ± 0.2%) than for vegetable protein fed rats (5.3 ± 0.2%). The difference was most evident in the CAS and WHY groups in comparison with the WGL group (Table 4). The proportion of PC was significantly higher (57.2 ± 0.5 *vs.* 55.4 ± 0.5, $P < 0.05$) whereas that of PE was significantly lower (9.6 ± 0.2 *vs.* 10.7 ± 0.3, $P < 0.05$) in rats fed animal proteins than in those fed vegetable proteins.

Membrane fluidity measured by fluorescence anisotropy. In Experiment 1, the DPH-fluorescence anisotropy in total ER and SER was significantly higher in the CAS group than in the SOY group, but that in RER was comparable between the groups (Fig. 3). In Experiment 2, the fluorescence anisotropy of the CAS group was significantly higher than that of the SOY and WGL groups (Fig. 4). When the effect of animal proteins was compared to vegetable proteins, the fluorescence anisotropy was significantly higher in the former than in the latter (0.099 ± 0.003 *vs.* 0.089 ± 0.002, $P < 0.05$).

Correlations between lipid parameters, Δ6 desaturase activity and membrane fluidity. As shown in Figure 5, the fluorescence anisotropy was highly correlated with the CHOL/PL ratio (r = +0.941) (Fig. 5A). Significant correlation was also observed between the CHOL/PL ratio *vs.* Δ6 desaturase activity (r = +0.832) (Fig. 5B). The anisotropy *vs.* Δ6 desaturase activity (r = +0.804) was not correlated significantly ($0.05 < P < 0.1$) (Fig. 5C). The correlations between the anisotropy *vs.* the PC/PE ratio (r = +0.800) (Fig. 6A) and PC/PE ratio *vs.* the Δ6 desaturase activity (r = +0.420) were also not significant (Fig. 6B).

DISCUSSION

The present study showed a characteristic effect of dietary protein on the metabolism of linoleic acid. The results in

[a]Mean ± SE of six rats, except for pooled values from six samples for rough endoplasmic reticulum. SPH, sphingolipids; LPC, lysophosphatidylcholine; PC, phosphatidylcholine; PE, phosphatidylethanolamine; PI, phosphatidylinositol; PA, phosphatidic acid; PS, phosphatidylserine; CAS, casein; SOY, soybean protein; WHY, milk whey protein; EAL, egg albumin; POT, potato protein; WGL, wheat gluten. Values in each experiment without a common superscript (b-d) are significantly different at $P < 0.05$.

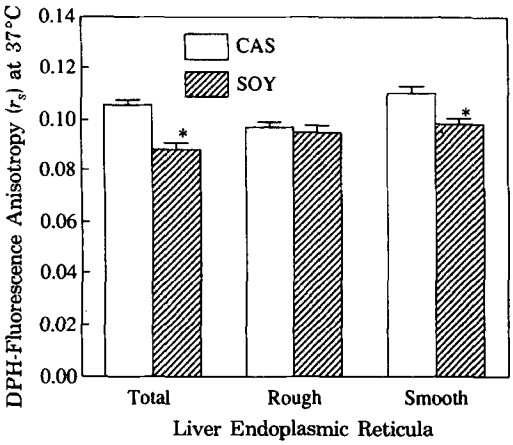

FIG. 3. Effects of dietary protein on fluorescence anisotropy of liver endoplasmic reticula (Experiment 1). Values are expressed as mean ± SE of six rats. CAS, casein; DPH, 1,6-diphenyl-1,3,5-hexatriene; SOY, soybean protein. *Significantly different from the corresponding CAS group at $P < 0.05$.

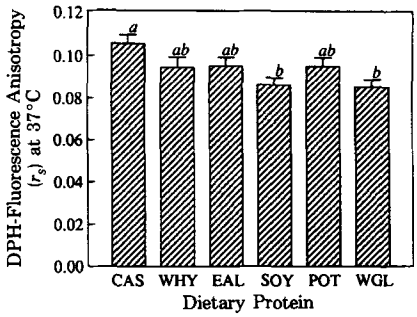

FIG. 4. Effects of dietary protein on fluorescence anisotropy of liver microsomes (Experiment 2). Values are expressed as mean ± SE of six rats. CAS, casein; WHY, milk whey protein; EAL, egg albumin; SOY, soybean protein; POT, potato protein; WGL, wheat gluten; DPH, 1,6-diphenyl-1,3,5-hexatriene. ^{a,b}Values without a common superscript are significantly different at $P < 0.05$.

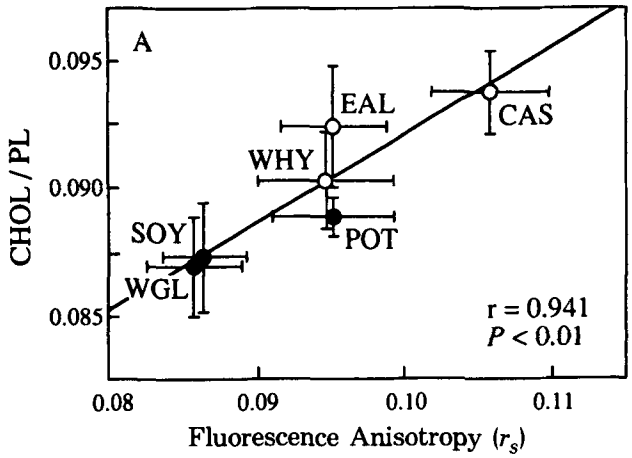

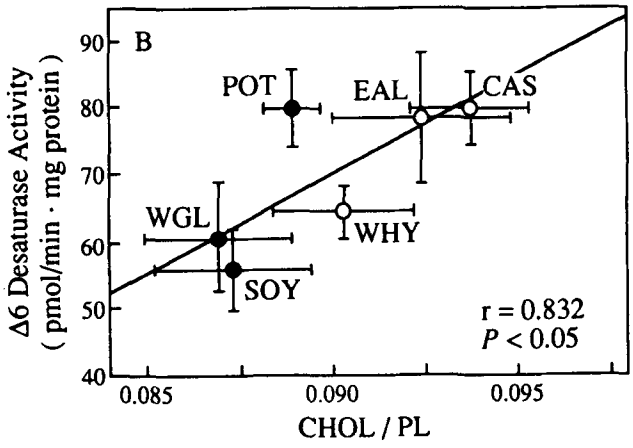

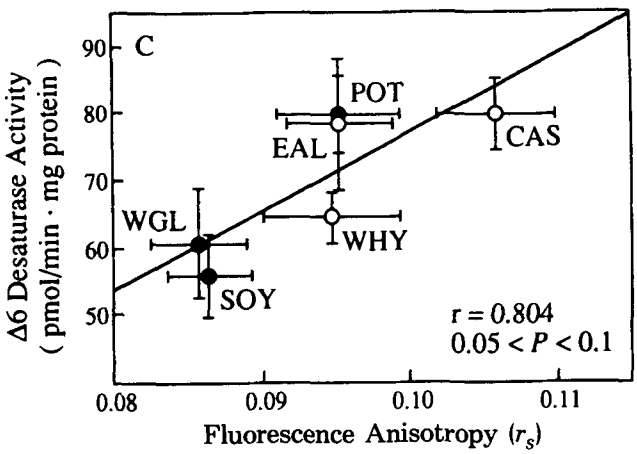

FIG. 5. Correlation between Δ6 desaturase activity, fluorescence anisotropy and microsomal lipids (Experiment 2). Values are expressed as mean ± SE of six rats. CAS, casein; WHY, milk whey protein; EAL, egg albumin; SOY, soybean protein; POT, potato protein; WGL, wheat gluten. CHOL/PL, cholesterol/phospholipid ratio; PC/PE, phosphatidylcholine/phosphatidylethanolamine ratio.

Experiment 1 showed that the Δ6 desaturase activity in total ER and RER in the CAS group was higher than that in the SOY group. This protein-dependent difference was also reflected in the fatty acid profiles of total PL in microsomal preparations; the Δ6 desaturation index expressed as (20:3n-6 + 20:4n-6)/18:2n-6 was significantly higher in ER, RER and SER in rats fed the CAS diet than in those fed the SOY diet. The results in Experiment 2 with various dietary proteins also indicated that microsomal membrane fluidity plays an important role in the regulation of the Δ6 desaturase activity of liver microsomes. Since the Δ5 desaturase activity in total ER and SER was also higher in the CAS group than in the SOY group, it is possible that dietary protein exerted a similar mode of the action on both desaturase activities, even though the response seemed to be less marked with Δ5 than with Δ6 desaturase.

The exact mechanism as to how dietary protein affects microsomal membrane properties is not clear. Previously, we (5–8) and others (24) have reported that CAS-feeding as compared with SOY-feeding stimulated the Δ6 desaturase activity of liver microsomes. Garda and Brenner (25) have shown in an *in vitro* study that a decrease in the fluoescence anisotropy (increased membrane fluidity) caused a decrease in the activity of Δ6 desaturase and that an increase in the fluorescence anisotropy (decreased membrane fluidity) induced an increase in Δ6 desaturase

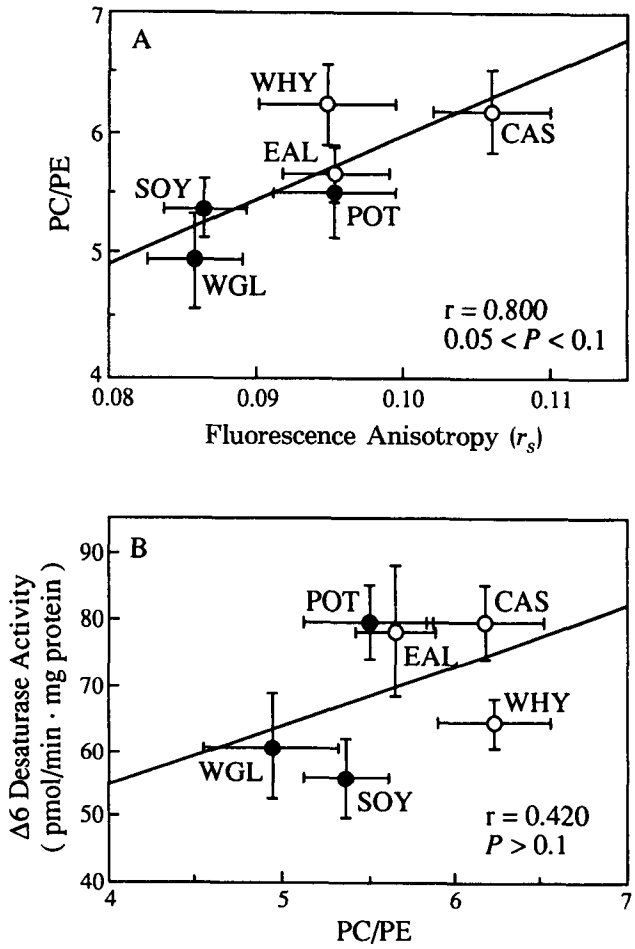

FIG. 6. Correlation between Δ6 desaturase activity, fluorescence anisotropy and microsomal lipids (Experiment 2). Values are expressed as mean ± SE of six rats. CAS, casein; WHY, milk whey protein; EAL, egg albumin; SOY, soybean protein; POT, potato protein; WGL, wheat gluten. CHOL/PL, cholesterol/phospholipid ratio; PC/PE, phosphatidylcholine/phosphatidylethanolamine ratio.

activity in liver microsomes (26). These findings suggest that the activity of desaturases is closely associated with membrane fluidity. Since the steady-state fluorescence anisotropy in the total ER was significantly higher in the CAS group than in the SOY group (Fig. 3), membrane fluidity was lower in the CAS than in the SOY groups. Furthermore, fluorescence anisotropy was correlated significantly with Δ6 desaturase activity (r = 0.804), indicating that an increase in the fluorescence anisotropy (decreased membrane fluidity) is associated with an increase in the total Δ6 desaturase activity (Fig. 5). Thus, our finding is consistent with the *in vitro* studies by Garda and Brenner (25,26). It is concluded that dietary protein modulates desaturase activity through its effect on membrane fluidity.

To examine how dietary protein affects membrane fluidity, we have also analyzed the microsomal lipid profiles. Results in Table 2 show that dietary protein modulated the lipid composition of liver ER; the ratio of CHOL/PL of total ER was significantly higher in the CAS group than in the SOY group. The evidence that the CHOL/PL ratio directly influences the microsomal membrane fluidity is further illustrated by the results shown in Figure 5, which illustrate that fluorescence anisotropy correlated significantly with the CHOL/PL ratio. Therefore, it is confirmed that dietary protein changes the microsomal CHOL/PL ratio, which in turn modulates membrane fluidity. Hence, Δ6 desaturase activity reflects changes in the fluidity of the microsomal membrane consistent with the "self-regulatory function" of liver microsomes proposed by Garda and Brenner (25,26). Since these protein-dependent differences in the CHOL/PL ratio and membrane fluidity were detected only in SER, but not in RER, it seems that the above mechanism operates only in SER. However, the results have shown that dietary protein also modulated Δ6 desaturase activity in RER, even though the CHOL/PL ratio and the membrane fluidity of RER were not affected. Since the microsomal desaturase enzyme is considered to be synthesized on the RER (27), it is speculated that CAS, in comparison with SOY, might have stimulated the synthesis of the Δ6 desaturase enzyme protein, which then exhibited its activity after being transferred to the SER.

The difference in the microsomal PC/PE ratio could also be a factor influencing membrane fluidity (28). It has been shown that increasing the PC/PE ratio, through an increase in the transformation of PE to PC by methyltransferase, increases membrane fluidity (28). Results in Figure 6A show that the fluorescence anisotropy is correlated, to a certain extent, with the PC/PE ratio (r = 0.800, $0.05 < P < 0.1$), suggesting that decreased microsomal membrane fluidity might be associated with an increase in the PC/PE ratio. This finding is apparently opposite to what has been reported (28). In our study, however, the dietary protein source affected liver microsomal properties in a manner similar to that reported by Garda and Brenner (26) in an *in vitro* CHOL-supplementation study. In this case, it was suggested that CHOL-supplementation had no effect on the PC/PE ratio (9,29,30), but increased the CHOL-content, the CHOL/PL ratio and Δ6 desaturase activity in the microsomal preparation (26,31). Since our results did not show any correlation between the PC/PE ratio and Δ6 desaturase activity (Fig. 6B), we conclude that the change in the PC/PE ratio is not associated with the change in desaturase activity.

In summary, our results suggest that dietary protein modulates microsomal CHOL levels, the CHOL/PL ratio and membrane fluidity, and subsequently the activity of Δ6 desaturase (and possibly Δ5 desaturase) in liver microsomes.

ACKNOWLEDGMENTS

We thank Drs. S. Iwanaga, S. Kawabata and F. Tokunaga for use of their spectrofluorometer, and Drs. Y. S. Huang, C. Cantrill and S. Samman for their most valuable help and advice in the preparation of this manuscript.

COMMUNICATION

Sterols of *Chaetoceros* and *Skeletonema*[1]

E. Tsitsa-Tzardis[a,2], G.W. Patterson[a,*], G.H. Wikfors[b], P.K. Gladu[c] and D. Harrison[d]

[a]Department of Botany, University of Maryland, College Park, Maryland 20742, [b]NOAA, National Marine Fisheries Service, Northeast Fisheries Science Center, Milford, Connecticut 06460, [c]Department of Biology, Lindsey Wilson College, Columbia, Kentucky 42728 and [d]Insect Neurobiology and Hormone Laboratory, USDA, Beltsville, Maryland 20705

Dietary sterol is required by the oyster for growth, and sterol is believed to be obtained primarily from dietary phytoplankton. Seven isolates of *Chaetoceros* and one of *Skeletonema*, which are of potential use as oyster food, were analyzed for sterol composition using gas chromatography, high-performance liquid chromatography and gas chromatography/mass spectrometry. *Skeletonema* and five isolates of *Chaetoceros* contained cholesterol as their major sterol. Two other isolates of *Chaetoceros* also contained cholesterol, but 24-methylenecholesterol was the principal sterol. Cholesterol has rarely been reported as the major sterol from phytoplankton. In view of the widespread occurrence of *Skeletonema* and *Chaetoceros* in the marine environment, these algae could be an important source of the oyster's cholesterol.
***Lipids* 28, 465–467 (1993).**

The American oyster *Crassostrea virginica* has a complex sterol composition of some forty compounds (1–3). This complexity has been attributed to dietary sterols that are accumulated due to the oyster's inability to synthesize sterols from simple precursors (4–7). Oysters must therefore obtain sterols from their diet of phytoplankton. In carefully controlled studies, the growth rates of oysters have been correlated with several dietary factors, one of which is sterol composition (8). The principal sterol of the oyster is cholesterol (1,9); however, cholesterol is rarely found in phytoplankton species, which are used in the laboratory or in commercial hatcheries to feed oysters or clams (10). This leads to the conclusion that other as yet unexamined phytoplankton must provide the oyster's cholesterol. In studies designed to evaluate phytoplankton as food for juvenile oysters, Enright *et al.* (11,12) listed three species of *Chaetoceros* and *Skeletonema costatum* as the most effective phytoplankton for promoting growth of the juvenile oyster, *Ostrea edulis*. *S. costatum* was reported by Ballantine *et al.* (13) to contain 24-methylenecholesterol as the principal sterol, and it also contained cholesterol, 24-methylcholesterol and 24-ethylcholesterol in amounts greater than 10% of total sterol. In *Chaetoceros simplex calcitrans* the principal sterols were cholesterol and 24-methylenecholesterol (14), but in an unidentified *Chaetoceros* sp., 24-methylcholesterol and 24-ethylcholesterol were the principal sterols (15). In view of the importance of sterols to the oyster, and the reports of cholesterol in some isolates of the cosmopolitan marine genera *Chaetoceros* and *Skeletonema*, the present study was undertaken to quantitatively determine the sterol composition of all *Chaetoceros* and *Skeletonema* isolates available to us.

Abbreviations: GC, gas chromatography; GC/MS, gas chromatography/mass spectrometry; HPLC, high-performance liquid chromatography.

MATERIALS AND METHODS

Phytoplankton strains were obtained from the Milford Culture Collection (Strain number is listed in parenthesis in Table 1.). Five of the eight strains were bacterized, and three were axenic. Of the seven *Chaetoceros* isolates analyzed, only B-13 forms short chains (*ca.* 4 cells); the others grow as essentially solitary unicells with sizes easily consumed by post-set oysters (<10 μm). The *Skeletonema* strain produced only short chains (*ca.* 3–4 cells). Algae were cultured in enriched natural seawater medium "E" formulation (16) under aseptic conditions (17). Algae from the stationary phase were centrifuged, lyophilized and stored in a freezer before analysis. Cells from the centrifuged concentrate were diluted and counted in an Improved Neubauer Hemocytometer (American Optical Co., Buffalo, NY) with a microscope. Dry weights were determined by weighing a known number of cells collected on a glass fiber filter (Whatman, GF/F, Whatman Labsales, Hillsboro, OR), washed with ammonium formate isotonic to the growth medium and dried in an oven at 80°C. Means of two dry weight determinations were calculated for each species, ranges never exceeded 5% of the mean.

Lyophilized samples were extracted overnight in a Soxhlet apparatus with $CHCl_3$/methanol (2:1, vol/vol) and sterol ester, sterol glycoside and free sterol fractions were isolated by Biosil A column chromatography and analyzed by capillary gas chromatography (GC), as described previously (17). Sterols were identified by capillary GC and gas chromatography/mass spectrometry (GC/MS) (17). High-performance liquid chromatography (HPLC) was employed to assign C-24 stereoconfiguration.

RESULTS AND DISCUSSION

Cholesterol, desmosterol, 24-methylenecholesterol, 24-methylcholesterol, 24-ethylcholesterol, fucosterol and isofucosterol were significant components in the sterol fractions of the isolates studied. They were identified on the basis of their relative retention times in capillary GC as compared to authentic compounds and by analysis with capillary GC/MS (21).

Table 1 shows the free sterol composition of the phytoplankton examined. Ester sterol and glycoside sterol each made up less than 2% of the free sterol and were not examined further.

The sterol composition of *C. gracile* (isolates Chaet B and ARC-11), *C. muelleri* and *C. sp.* (NRAC-Chaet) were essentially identical, with cholesterol being slightly more

TABLE 1

Sterols of *Chaetoceros* and *Skeletonema*

Isolate	Dry wt μg/g	fg/cell	Sterol composition[a] (% of total sterol)						
			CHOL	DES	24MEC	24MC	24EC	FUCO	ISOFUCO
Chaetoceros gracile (Chaet B)	9.9	41	47		9			39	1
C. gracile (ARC-11)	10.1	40	49		6			33	3
C. muelleri (CHGRA)	14.4	69	48	9				41	1
C. sp. (NRAC-Chaet)	27.7	84	47		7	3		37	3
C. simplex (Chaet-G)	3.8	104	40	1	24	1		31	1
C. sp. (B-13)	3.7	51	1		35	20	23		10
C. calcitrans (Chaet-cal)	0.3	3	39	3	56				
Skeletonema costatum (NRAC-Skel)	2.0	16	71		8	3	12		1

[a]Abbreviations: CHOL, cholesterol; DES, desmosterol; 24MEC, 24-methylenecholesterol; 24MC, 24-methylcholesterol; 24EC, 24-ethylcholesterol; FUCO, fucosterol; ISOFUCO, isofucosterol.

abundant than fucosterol. Small amounts of 24-methylenecholesterol and isofucosterol were also present. The amount of sterol in three of these isolates on a per cell basis (40–84 fg/cell) was also similar, although NRAC Chaet contained appreciably more sterol on a dry weight basis (27.7 μg/g) than the other strains in this group. Cholesterol made up 40% of the sterols of *C. simplex*, but substantial quantities of both 24-methylenecholesterol and fucosterol were also present. The amount of sterol per cell in *C. simplex* (104 fg/cell) was slightly greater than in the other isolates examined (Table 1); however, cells of this strain were much larger than the others, resulting in % dry weight values less than those of the *C. gracile/muelleri* group. *Chaetoceros* sp. (B-13) is the only isolate examined that had large amounts of 24-ethylcholesterol and 24-methylcholesterol occurring. The latter sterol was examined by HPLC (18), which separates most 24α from 24β sterols. It revealed that the 24-methylcholesterol of *Chaetoceros* sp. (B-13) was all 24β-methylcholesterol (5-ergostenol). This system does not resolve 24-ethylcholesterol isomers. In each previous case where a member of the diatom order centrales was examined for stereochemistry at C-24, the β isomer was also reported (10). The sterols of *C. calcitrans* (Chaet-cal) differed from those in the other isolates in two respects. The total sterol was at least an order of magnitude less (3 fg/cell or 0.31 μg/g dry wt) in this isolate than in any other *Chaetoceros* isolate examined. Chaet-cal was the only isolate examined that did not contain C_{29} sterols. This isolate contained a small amount (3% total sterol) of desmosterol and the remaining sterol consisted only of cholesterol and 24-methylenecholesterol, with the latter sterol being most abundant. Cholesterol was prevalent in *S. costatum*, with the overall sterol content (16 fg/cell or 2.0 μg/g dry wt) being less than all *Chaetoceros* isolates except *C. calcitrans*. However, the second most abundant sterol in *Skeletonema* was the 24-ethylcholesterol and not fucosterol, as was the case in most *Chaetoceros* isolates (Table 1).

Previous indications (10) were that most algae in the families Chaetoceraceae and Thalassiosiraceae, to which *Chaetoceros* and *Skeletonema* belong, contain 24-methylenecholesterol as a principal sterol. The presence of 24-methylenecholesterol was demonstrated in each isolate examined in this study. The seven isolates of *Chaetoceros* examined showed four distinct compositional patterns. With the exception of *Chaetoceros* sp. (B-13), cholesterol was a substantial component, and was the prevalent component of six of these sterol mixtures. Cholesterol was also most abundant in *Skeletonema*. With the exception of the red algae (10), the prevalence of cholesterol in sterol mixtures is rare in most plant groups (22). Until now few phytoplankton were known to contain cholesterol, and it appeared that cholesterol in natural populations of oysters must come from dealkylation of dietary phytoplankton sterols. Rapid growth of oysters on cultured phytoplankton species that contain no cholesterol (8) suggests that dealkylation of certain phytosterols to cholesterol is likely to occur. Nevertheless, the discovery of the prevalence of cholesterol in these widely occurring marine phytoplankton isolates could point the way to locating direct phytoplankton sources of cholesterol for the oyster and other marine invertebrates in nature.

Pollen Sterols from Three Species of Sonoran Cacti

W.R. Lusby[a,*], **S.L. Buchmann**[b] and **M.F. Feldlaufer**[a]

[a]Insect Neurobiology and Hormone Laboratory and [b]Honey Bee and Insect Biological Control Research Laboratory, Agricultural Research Service, USDA, Beltsville, Maryland 20705

Cactus bees are important pollinators that contribute to the long-term stability of arid regions in the United States. Since all insects are dependent upon a dietary source of sterol for normal growth, development and reproduction, a study was undertaken to determine neutral sterols available to cactus bees. The total neutral sterol composition of hand-collected pollen was determined for three species of Sonoran cacti by gas-liquid chromatography and mass spectrometry. 24-Methylenecholesterol was the predominant pollen sterol in Engelmann's prickly pear, *Opuntia phaeacantha*, cholla, *O. versicolor*, and cardon, *Pachycereus pringlei*. Two pentacyclic triterpene alcohols, lupeol and moretenol, were also isolated. Since no cholesterol was detected in any of the pollen samples, cactus bees would have to utilize the 24-alkyl sterols unchanged or convert these sterols to cholesterol *via* dealkylation.
***Lipids 28,* 469–470 (1993).**

Insects, unlike mammals and plants, are unable to synthesize sterols and therefore require a dietary source of sterol for normal growth and development (1). Many species of insects are capable of converting dietary C_{28} and C_{29} phytosterols to cholesterol, while other species lack this capability (2–4). Amongst the Hymenoptera, it appears that the phytophagous members of this group lack the ability to dealkylate plant sterols since the body sterols of these species examined contain little or no cholesterol (4–8). *Diadesai rinconis* Cockerell is a solitary cactus bee that feeds primarily on the pollen of *Opuntia* (9) and is therefore considered an important pollinator of these Sonoran cacti. The purpose of this investigation was to examine the neutral sterol content of several species of Sonoran cacti to determine the dietary sterols available to *Diadasia* bees.

MATERIALS AND METHODS

Isolation of sterols. Pollen from Engelmann's Prickly Pear cactus, *Opuntia phaeacantha*, from Cholla cactus, *O. versicolor*, and from Cardon cactus, *Pachycereus pringlei*, were hand-collected near Tucson, AZ, and stored in methanol at −20°C until workup. Each sample (2–10 g) was saponified under reflux using 4% KOH in a solution of ethanol/benzene/water (10:1:1, by vol). After 5 h, the solution was allowed to cool, acidified with 6N HCl, and subsequently extracted with hexane (3×) and diethyl ether (1×). The combined organic phases were dried *in vacuo* and fractionated over Florisil (Fisher Scientific, Fair Lawn, NJ) in a diethyl ether/hexane system as previously described (10). Fractions were monitored by thin-layer chromatography (TLC) and capillary gas-liquid chromatography (GLC). Sterols were purified prior to mass spectrometry by reversed-phase high-performance liquid chromatography (HPLC).

Analyses and instrumentation. All solvents for extraction and purification were reagent grade, redistilled. Solvents for HPLC were obtained from Burdick & Jackson (Baxter Scientific, Columbia, MD). TLC was done on high-performance silica gel 60 F_{254} plates developed in hexane/diethyl ether/acetic acid (60:40:1, by vol). Reversed-phase HPLC was performed on a Shandon ODS Hypersil column (4.6 × 250 mm, 5 μm particle size; Shandon Scientific, Runcorn, Chesire, United Kingdom) eluted with 98% aqueous methanol at 1 mL/min. Effluent was monitored at 200 and 215 nm using a Waters 991 photodiode array detector (Milford, MA). Capillary GLC was performed at 245°C on a Shimadzu GC-9A gas chromatograph (Columbia, MD) equipped with a J&W DB-1 fused silica column (15 m × 0.25 mm; 0.25 μm film; J&W Scientific, Folsom, CA) and a recording integrator. Mass spectra were obtained on a Finnigan 4500 gas chromatograph/mass spectrometer fitted with a J&W DB-1 fused silica column (30 m × 0.32 mm; 0.25 μm film) and temperature programmed (230°C for 2 min, then increased 5°C/min to 255°C and held). Electron impact spectra were collected at 70eV and a source block temperature of 150°C. All sterol identifications were based on relative retention time (to cholesterol) and mass spectra.

RESULTS

The predominant pollen sterol in all three cactus samples was 24-methylenecholesterol, with additional C_{28}, C_{29} and C_{30} sterols comprising the remainder. 24-Methylenecholesterol accounted for 80.3% of the neutral sterols in Prickly Pear to over 90% in Cardon (Table 1). The next most prevalent sterols were 24-ethylcholesterol (7.3%) and cycloartenol (7.2%) in Prickly Pear, fucosterol (6.6%) and 24-ethylcholesterol (5.6%) in Cholla, and 31-norcycloartenol (3.8%) and fucosterol (2.0%) in Cardon. Seven sterols, ranging in concentration from 0.4–2.2%, were found in only a single pollen source (Table 1). In addition, two pentacyclic triterpene alcohols were identified during this study. Lupeol was found in both the Prickly Pear and Cardon pollens, and mortenol [a'-neogammacer-22(29)-en-3β-ol] was isolated from Prickly Pear. No cholesterol was detected in any of the cactus pollens examined.

DISCUSSION

One species of cactus, the saguaro, *Cereus giganteus* (=*Carnegiea giganteus*) was included in the survey of pollen sterols by Standifer and collaborators (11) and was shown to contain predominantly (94%) 24-methylenecholesterol. The preponderance of 24-methylenecholesterol in saguaro pollen was later confirmed by Nes and Schmidt (12), who reported several additional sterols including 24-dehydropollinasterol and a new sterol, 25(27)-dehydrolanost-8-enol. The only parallels we can perhaps draw between these two as well as our present study are with a close relative of saguaro, cardon (*Pachycereus pringlei*), where we found the pollen to contain more than 90% 24-methylenecholesterol.

Abbreviations: GC/MS, gas chromatography/mass spectrometry; GLC, gas-liquid chromatography; HPLC, high-performance liquid chromatography; TLC, thin-layer chromatography.

TABLE 1

Relative Percentages of Neutral Sterols from Sonoran Cactus Pollen[a]

	Prickly Pear *(Opuntia phaeacantha)*	Cholla *(Opuntia versicolor)*	Cardon *(Pachycereus pringlei)*
Pollinastanol	—	0.7	—
24-Dehydropollinastanol	0.8	—	—
24-Methylenecholesterol	80.3	81.2	90.3
24-Methylcholesterol	0.4	1.1	—
Ergosta-8(9),24(28)-dienol	—	—	1.3
24-Ethylcholesta-5,22-dienol	—	—	1.1
31-Norcycloartenol	1.8	—	3.8
24-Ethylcholesta-8,24(28)-dienol	—	—	0.4
24-Methylenepollinastanol	—	1.0	—
24-Ethylcholesterol	7.3	5.6	0.3
Fucosterol	—	6.6	2.0
Cycloeucalenol	2.2	—	—
Cycloartenol	7.2	2.0	0.4
Unknown	—	1.8	0.4

[a]Sterols were identified by a combination of capillary gas-liquid chromatography (GLC) and capillary gas chromatography/mass spectrometer. Relative percentages were determined by integration of the flame-ionization detector signal from capillary GLC.

Though no literature appears to exist on sterols from *Opuntia* pollen, several studies involving other plant parts from this genus are interesting. Examination of mature photosynthetic tissue of *O. comoduensis* and *O. humifusa*, two nonsonoran species, indicated that sitosterol was the primary sterol, accounting for 86.7 and 87.0%, respectively (13). The sterol composition of the fruits of seven species of *Opuntia*, including *O. phaeacantha*, indicated that sitosterol comprised anywhere from 50.7 to 87.7%. In Engelmann's Prickly Pear, 81% of the neutral sterols consisted of sitosterol (14). Based on our results, it is apparent that the sterol content of pollen can be markedly different from that of the tissue since 24-ethylcholesterol (presumably sitosterol) accounted for only 7.3% of the sterols in prickly pear pollen, and only 5.6% in the pollen of cholla (*O. versicolor*).

It will be of great interest to examine the sterol content of the solitary bees that frequent specific pollen sources, given none of the pollen sources in the present study contain even trace amounts of cholesterol. The role of plant sterols in determining how different species of *Drosophila* utilize different species of cacti for feeding and breeding is well documented (15,16, and references therein). It remains to be determined if cactus bees exhibit a similar dependence on specific, dietary sterols.

[Received August 18, 1992, and in revised form February 10, 1993; Revision accepted March 1, 1993]

Changes in Fatty Acid Desaturation in Hepatic and Intestinal Tissues Induced by Intestinal Resection

C.M. Vázquez[a,*], F.J.G. Muriana[b] and V. Ruiz-Gutierrez[b]

[a]Departamento de Fisiología y Biología Animal, Facultad de Farmacia and [b]Instituto de la Grasa y sus Derivados (C.S.I.C.), 41012 Sevilla, Spain

We have studied the activities of Δ9, Δ6 and Δ5 desaturases in rat liver and jejunum when the entero-hepatic circulation was interrupted by either 50 or 75% intestinal resection. Desaturase activities in caecal mucosa were also determined in control and operated rats. Distal small bowel resection significantly altered the activities of desaturase enzymes in liver, jejunum and caecum. Thus, the Δ9 desaturase activity was lower in hepatic microsomes from operated animals, and this decrease was not related to the extent by which the intestine was removed. However, a significant increase in both Δ6 and Δ5 desaturases was found in these animals compared to sham-operated rats, the increase in both desaturases being higher after 75% than after 50% intestinal resection. The activities of Δ9 and Δ5 desaturases were significantly increased in jejunal mucosa of resected rats. The activity of Δ6 desaturase was increased only in 50% resected-animals. An increase in Δ6 desaturase activity was observed in caecal mucosa after resection, together with a decrease in Δ9 desaturase and no change in Δ5 desaturase activities. Enzyme activities were highest in the liver relative to the activity in jejunal and caecal homogenates. In sham rats, the caecal mucosa showed higher Δ9 and Δ6 but lower Δ5 desaturase activities than in jejunal mucosa.

Lipids 28, 471-473 (1993).

It is well known that intestinal resection, by altering the entero-hepatic circulation (EHC), decreases the input of bile acids into the liver, leading to changes in both hepatic (1) and intestinal (2) lipid metabolism. Thus, the hepatic and intestinal activities of 3-hydroxy-3-methylglutaryl-coenzyme A (HMG-CoA) reductase and acyl-CoA:cholesterol acyltransferase (ACAT), the major rate-controlling enzymes in cholesterol biosynthesis and conversion of cholesterol into cholesteryl esters, respectively, are modified after the interruption of the EHC (3-5). The relative availability of saturated and unsaturated fatty acids for phospholipid synthesis is determined by the diet and the activity of elongase and desaturase enzymes (6). Since changes in both lipid composition and the fatty acid profiles of hepatic and intestinal phospholipid fractions are also observed after the interruption of the EHC (2,5), it is quite likely that changes in desaturase activities might occur after this operation.

*To whom correspondence should be addressed.

Abbreviations: ACAT, acyl-coenzyme A:cholesterol acyltransferase; ANOVA, analysis of variance; ATP, adenosine 5'-triphosphate; DSBR, distal small bowel resection; DTT, dithiothreitol; EDTA, ethylenediaminetetraacetic acid; EGTA, ethylene glycol-*bis*(β-aminoethyl ether)*N,N,N',N'*-tetraacetic acid; EHC, entero-hepatic circulation; HEPES, *N*-2-hydroxyethylpiperazine-*N'*-2-ethanesulfonic acid; HMG-CoA, hydroxymethylglutaryl-coenzyme A; NADH, nicotinamide adenine dinucleotide (reduced form); TLC, thin-layer chromatography.

Δ9, Δ6 and Δ5 desaturase enzymes have been well documented in liver microsomes of several mammalian species (7) and, recently, they have been found in the mucosa of jejunum and ileum (8). However, as far as we are aware, desaturase activities in the caecal mucosa have not been previously identified. Our study was undertaken in order to determine the activities of desaturase enzymes bringing about the conversion of fatty acids in rat liver and jejunum when the EHC was interrupted by either 50 or 75% distal small bowel resection (DSBR). In addition, desaturase activities in caecal mucosa were determined in control and operated rats.

MATERIALS AND METHODS

Animals. Male Wistar-strain rats, purchased from Iffa-Credo (Lyon, France) and weighing 300 g each, were used. The animals were given food (Panlab A-04, Barcelona, Spain) and water *ad libitum* and housed in a room maintained at 21 ± 2°C with lights on from 0800 to 2000. The composition of the diet was as follows: lipids, 3.5%; protein, 19.0%; starch, 66.0%; non-nutritive cellulose, 5.0%; mineral mix, 5.5%; and vitamin mix, 1.0%. The fatty acid composition of the diet is shown in Table 1. The rats were randomly assigned to one of three groups: sham operated, 50 and 75% DSBR. Operative details have been previously described (9). Briefly, the rats were anesthetized with an intraperitoneal injection of sodium pentobarbitone (4.5 mg/100 g body weight) after a 24-h fasting period, laparotomy was performed and rats assigned for DSBR underwent either 50 or 75% DSBR by excision of the distal small intestine beginning 1 cm proximal to the ileocaecal junction. Before DSBR, the blood vessels of the resected intestinal segment were tied and sectioned, and the blood supply and the innervation of the remaining intestine were carefully maintained. Intestinal continuity

was re-established by an end-to-end anastomosis. Finally, both muscle and cutaneous layers were sutured separately with appropriate thread. Rats from the sham-operated group underwent simple mid-small intestinal transection, without removal of any tissue, followed by re-anastomosis. After the surgical operation, the rats were housed in a temperature-controlled laboratory with a strict 0400–1600/1600–0400 dark/light cycle. At 6 wk after DSBR, the rats were fasted overnight (with access to water only) and killed by stunning and cervical dislocation.

Sample preparation procedure. After the animals were killed, the abdomen was opened and livers, jejunum and caecum were removed from each rat and placed in ice-cold physiological saline. All subsequent operations were done at 4°C. Livers were homogenized in a Potter-Elvehjem homogenizer with ice-cold homogenization medium containing 0.25 M sucrose, 10 mM *N*-2-hydroxyethylpiperazine-*N'*-2-ethanesulfonic acid (HEPES) (pH 7.4), 20 mM ethylenediaminetetraacetic acid (EDTA), 2 mM ethyleneglycol-*bis*(β-aminoethyl ether)*N,N,N',N'*-tetraacetic acid (EGTA) and 5 mM dithiothreitol (DTT). Each homogenate was centrifuged for 20 min at 15,000 × *g*. The supernatant was collected and centrifugation (15,000 × *g*) was repeated. The 15,000 × *g* supernatant was centrifuged at 105,000 × *g* for 60 min in a Sorvall (Newton, MA) ultracentrifuge, model OTD 50B. The resulting microsomal pellets were immediately frozen in liquid N_2 and stored at −70°C until assayed. The mucosal surface of jejunum and caecum was removed by gently scraping with a microscope slide and stored at −70°C until further use. Jejunal and caecal mucosal scrapings were homogenized in 0.25 M sucrose buffer containing 10 mM HEPES (pH 7.4), 20 mM EDTA, 2 mM EGTA and 5 mM DTT. Portions of jejunal and caecal homogenates were used for desaturase assays. Desaturase activities of both liver microsomes and intestinal mucosas were not affected by the storage time (results not shown).

Assay of desaturases. The hepatic microsomes and jejunum and caecum mucosas were assayed for Δ9, Δ6 and Δ5 desaturase activities as previously described (10), with minor modifications. The assay mixture contained, in a final volume of 1 mL, 1.25 mM NADH, 1.5 mM reduced glutathione, 5 mM ATP, 5 mM $MgCl_2$, 0.3 mM coenzyme A and 75 μM [1-^{14}C]palmitic, 75 μM [1-^{14}C]linoleic or 75 μM [1-^{14}C]eicosa-8,11,14-trienoic acid in the form of the sodium salt-albumin complex (1 μg free fatty acid/11.5 μg bovine serum albumin). Incubations were done at 37°C for 20 min in a metabolic shaker. Enzyme assays were terminated by addition of 1 mL of 10% (wt/vol) KOH in ethanol, followed by saponification at 100°C for 30 min and addition of 1 mL of 4 N H_2SO_4 under nitrogen atmosphere to avoid oxidation of fatty acids. Lipids were extracted twice with 5 mL chloroform/methanol (2:1, vol/vol). The organic phases were combined and evaporated under nitrogen. Fatty acids were methylated using 14% boron trifluoride in methanol. Fatty acid methyl esters were separated on commercial silica gel G-60 thin-layer chromatography (TLC) plates containing 5% (wt/vol) $AgNO_3$. Plates were developed three times at 4°C in benzene, and radioactivity was analyzed in a Berthold (Nashua, NH) Automatic TLC-Linear Analyzer with the aid of a computer program.

Protein assay. Microsomal and mucosal proteins were determined by the method of Lowry *et al.* (11) with bovine serum albumin as the standard. Enzyme activities were expressed as pmol of desaturated product formed per min per mg of either microsomal (liver) or mucosal (jejunum and caecum) protein.

Statistical analysis. Results are presented as the mean ± standard deviation. An analysis of variance as a first step prior to the use of *t*-test was used to test the significance of the difference between the means for sham-operated and resected animals.

RESULTS AND DISCUSSION

A significant decrease in the hepatic activity of Δ9 desaturase was observed after the interruption of the EHC. However, an increase in both Δ6 and Δ5 desaturase activities was found in these animals compared to sham rats (Table 2). Δ6 Desaturase converts 18:2n-6 into 18:3n-6 fatty acid. Increased Δ6 desaturase activity in rat liver microsomes of operated rats should increase the conversion of 18:2n-6 to 18:3n-6. We have previously reported that γ-linolenic acid (18:3n-6) levels were increased in hepatic microsomes of resected rats and that the increase was higher after 75% than after 50% DSBR (5). Thus, the relatively high content of 18:3n-6 in operated rats might be related to enhanced Δ6 desaturase. Similarly, the levels of 20:3n-6, the substrate for Δ5 desaturase, increased in hepatic microsomes of 75%-resected rats (5). The elevation in 20:3n-6 together with a subsequent decrease in arachidonic acid observed after massive resection (75%) suggests an inhibition of Δ5 desaturase activity. However,

75%-DSBR	18.5 ± 0.58[d,e]	41.2 ± 1.83[d,e]	14.5 ± 1.33
Results of ANOVA ($P <$)	0.0001	0.0001	0.1896

[a]The data (expressed as pmol/min/mg mucosal protein) are presented as the mean ± SD of five animals. Abbreviations as in Table 2.

[b]$P < 0.05$, [c]$P < 0.01$, [d]$P < 0.001$ 50 or 75% resected rats *vs.* sham animals.

[e]$P < 0.001$ 75% resected rats *vs.* 50% resected animals.

our *in vitro* results for Δ5 desaturase activity showed an increase in 75%-resected animals (Table 2). No significant changes in the levels of both 20:3n-6 and 20:4n-6 had previously been observed in 50%-resected rats (5), although an increase in Δ5 desaturase was found in hepatic microsomes of these animals (Table 2). Therefore, *in vivo* metabolism cannot always be surmised from *in vitro* observations, since there are many factors *in vivo* that would not be operative under *in vitro* conditions.

Consistent with previous reports (8,12), the present study shows that the intestinal mucosa is capable of desaturating palmitic acid (16:0), linoleic acid (18:2n-6) and eicosatrienoic acid (20:3n-6) and that this desaturation is affected by the interruption of the EHC. Thus, the activities of the Δ9 and Δ5 desaturase enzymes were significantly increased in jejunal mucosa as a consequence of the interruption of the EHC, the increase in Δ5 desaturase activity being related to the extent of the EHC interrupted. However, the activity of Δ6 desaturase was increased only after 50% DSBR (Table 3).

As far as we are aware, desaturase activities of caecal mucosa have not been previously determined. Table 3 shows the activities of Δ9, Δ6 and Δ5 desaturases in caecal mucosa of sham-operated and resected rats. The intestinal resection produced in caecal mucosa a decrease in Δ9, an increase in Δ6 and no change in Δ5 desaturase activities (Table 3).

In sham rats the caecal mucosa showed higher Δ9 and Δ6 desaturase activities than jejunal mucosa. Δ5 Desaturase activity was, however, lower in caecal mucosa (Table 3). The observation that the levels of all three desaturase enzymes were higher in liver than in intestine is consistent with previous results (8). However, the differences in enzymatic activities between liver and intestine might be due, in part, to the different preparations used, microsomes for liver and mucosal homogenates for intestine.

The results of this study show that DSBR significantly altered the activities of Δ9, Δ6 and Δ5 desaturase enzymes in liver, jejunum and caecum but in different ways. Several factors could explain the current observations. Thus, it is well known that the interruption of the EHC causes lipid malabsorption (13). This malabsorption is due to an effective loss of absorptive surface area together with a defect in the EHC of bile salts. Therefore, an effect of intestinal resection on the dietary source of liver fatty acids cannot be ruled out. In addition, if the intestinal mucosa is capable of desaturating fatty acids, then loss of intestinal tissue by DSBR might also produce changes in fatty acid metabolism.

ACKNOWLEDGMENT

We are grateful to Instituto de la Grasa y sus Derivados (C.S.I.C.) for the use of their laboratories and for supplies used in this study.

Garlic Supplementation and Lipoprotein Oxidation Susceptibility

Stacy Phelps and **William S. Harris***
Lipid and Arteriosclerosis Prevention Clinic, Division of Clinical Pharmacology, Department of Medicine, University of Kansas Medical Center, Kansas City, Kansas 66160

Interventions which make serum lipoproteins less susceptible to oxidation may be antiatherogenic. The antioxidant properties of garlic which have been demonstrated *in vitro* led us to investigate the effects of garlic supplements on lipoprotein oxidation susceptibility in humans. Ten healthy volunteers were given 600 mg/d of garlic powder (6 tablets of Kwai®) for two weeks in a placebo-controlled, randomized, double-blind crossover trial. We found that although serum lipid and lipoprotein levels were not lowered in this short time period, the *ex vivo* susceptibility of apolipoprotein B-containing lipoproteins to oxidation was significantly decreased (−34%). Because garlic has been reported to beneficially affect serum lipid levels, platelet function, fibrinolysis and blood pressure, this additional effect of retarding lipoprotein oxidation may contribute to the potential antiatherosclerotic effect of garlic.
Lipids 28, 475–477 (1993).

There is growing evidence that the oxidation of low density lipoproteins (LDL) may play a significant role in the development of atherosclerosis (for a review, see Ref. 1). Accordingly, interventions which can prevent the oxidation of LDL may be expected to slow atherogenesis, reducing the incidence of coronary heart disease, possibly even without lowering serum LDL levels.

There are currently three nutrients (ascorbic acid, α-tocopherol, monounsaturated fatty acids, Refs. 2–4), one food preservative (butylated hydroxytoluene, Ref. 5) and one drug (probucol, Ref. 6) that function as *in vivo* antioxidants. The latter two have also been shown to be antiatherosclerotic in animal models (5,6). Garlic is a food which has has been reported to lower cholesterol levels (7), and in addition, to have a beneficial effect on a number of other physiological disorders contributing to heightened cardiovascular risk, *e.g.,* high blood pressure (8), enhanced platelet aggregation (9–11), delayed fibrinolysis (9) and vasoconstriction (9). A recent report suggested that garlic powder extracts also act as antioxidants *in vitro* (12). Therefore, we conducted a trial in humans to determine the effects of short-term garlic supplementation on plasma lipid levels and on lipoprotein oxidation susceptibility (LOS).

MATERIALS AND METHODS

Ten healthy, normolipidemic subjects, five males and five females (mean age 32 ± 10 years) volunteered for the study. The subjects were taking no medications known to affect serum lipids, and none were taking garlic or significant quantities of antioxidants (vitamins C or E or β-carotene) in their background diets. Subjects were asked to keep their smoking and exercise patterns constant throughout the study. Informed consent was obtained from each subject prior to beginning the study, which had been approved by the Human Subjects Committee of the University of Kansas Medical Center (Kansas City, KS).

The subjects were instructed to take six 100-mg tablets of garlic powder a day for two weeks (Kwai®, Lichtwer Pharma GmbH, Berlin, Germany) or placebo. The study had a randomized, placebo controlled, double-blind crossover design. There was a one-week washout period between the two treatment periods.

Maintaining dietary stability was highly stressed throughout the study, and subjects were advised to avoid any foods containing significant amounts of garlic. Diets were monitored by having the subjects complete two three-day diet diaries (one during each treatment period) which were analyzed by Professional Nutrition Systems, Inc. (Kansas City, KS). This was done to determine whether the changes in plasma lipid levels, if any, were due to the garlic or to a change in diet. Results of these analyses were expressed as the RISCC rating (ratio of ingested saturated fat and cholesterol to calories) which summarizes the major cholesterol raising nutrients in the diet as a single numerical score. An RISCC rating of 20–24 is typical of the American diet (13).

Blood samples were drawn (always after a 12-h overnight fast) at the beginning and the end of each test period. Lipids and lipoproteins in plasma containing ethylenediaminetetracetic acid (1 mg/mL) were analyzed for cholesterol and triglycerides using enzymatic methods on a Cobas Mira (Roche Diagnostics, Belleville, NJ). The plasma high density lipoprotein (HDL) cholesterol levels were measured following precipitation of the apoprotein B (apoB)-containing lipoproteins with heparin/manganese chloride. LDL cholesterol was estimated by the Friedwald equation (14). These methods have been described in detail elsewhere (15), and were carried out in our laboratory which participates in the Lipid Standardization Program of the Centers for Disease Control (16).

LDL phospholipid and cholesteryl ester fatty acid composition. Lipids were extracted from LDL isolated from plasma by sequential ultracentrifugation between densities 1.019 and 1.063 kg/L. Thin-layer chromatography was used to separate the various lipid classes, and the cholesteryl ester and phospholipid bands were obtained. The lipids were transmethylated with boron trifluoride and analyzed by gas-liquid chromatography in a GC9A Gas Chromatograph (Shimadzu Corp., Columbia, MD), equipped with a 30-m, 0.32 mm i.d., SP2330 capillary column. These methods were described in detail previously (15).

LOS test. A 500-μL plasma sample was treated with 50 μL of a solution containing 0.2 mM dextran sulfate (MW 50,000; Genzyme, Cambridge, MA) and 0.5 M $MgCl_2 \cdot 6H_2O$ to precipitate the apoB-containing lipoproteins [LDL and very low density lipoproteins (VLDL)]

*To whom correspondence should be addressed at Lipid Laboratory, 3800 Cambridge St., KU Medical Center, Kansas City, KS 66160.

Abbreviations: apoB, apolipoprotein B-100; HDL, high density lipoproteins; LDL, low density lipoproteins; LOS, lipoprotein oxidation susceptibility; MDA, malondialdehyde; RISCC, ratio of ingested saturated fat and cholesterol to calories; TBA, thiobarbituric acid; TBARS, TBA reactive substances; TCA, trichloroacetic acid; VLDL, very low density lipoproteins.

according to Bachorik and Albers (17). After centrifugation at 3,000 rpm at 20°C for 10 min, the supernatant was removed, and 1 mL of 6% bovine serum albumin and another 50 μL of the dextran sulfate magnesium solution was added. The solution was briefly vortexed and recentrifuged as above to wash away any HDL or residual serum proteins (except, of course, albumin). The supernatant was removed and the washed precipitate (containing LDL and VLDL) was dissolved in 2.5 mL of 4% NaCl. A volume of redissolved precipitate containing 100 μg of non-HDL cholesterol was combined with sufficient 4% NaCl to give a total volume of 500 μL (approximately a 1:5 dilution). Fifty μL of a 0.5 mM $CuCl_2 \cdot 2H_2O$ solution was added (final copper concentration was 46 μM), and then the samples were incubated at 37°C in a shaking water bath for 3 h. Next, thiobarbituric acid reactive substances (TBARS) were measured (18) by adding 2 mL of the TBARS reagent to each tube. [This reagent contained 26 mM thiobarbituric acid (TBA) and 0.92 M trichloroacetic acid (TCA) in 0.25 N HCl. The TBA was added first, heated and stirred. After it was dissolved, the TCA was added, and the solution brought to volume with 0.25 N HCl. The reagent was stored in a dark bottle at room temperature.] The mixture was heated at 100°C in a waterbath for 15 min. After removing and cooling the tubes, 2.5 mL *n*-butanol was added, the tubes were vortexed, and then centrifuged for 15 min at 3,000 rpm at room temperature. The pink upper layer was removed and the optical density was determined in a spectrophotometer at 532 nm. A standard curve was constructed with malondialdehyde (MDA, 0.5–16 nmol/mL), and the results were expressed as nmol of MDA produced per mg of non-HDL cholesterol. The coefficient of variation of the method was 4% intraassay and 9% interassay. The mean LOS value for 20 normal subjects was 66 ± 22 nmol MDA/mg non-HDL cholesterol. Using this assay, we have shown that probucol treatment reduced LOS by 95%, while fish oil supplementation (high in polyunsaturated fatty acids) raised LOS by 45% (Harris, W.S., unpublished data).

Statistical evaluation. As the subjects served as their own control for four observations (pre and post, garlic and placebo), the data were analyzed by ANOVA with repeated measures followed by the Neuman-Kuels *post-hoc* test. A P value of <0.05 was required for statistical significance.

RESULTS AND DISCUSSION

Two weeks of garlic supplementation did not alter plasma total, LDL or HDL, cholesterol or triglyceride levels (Table 1). This was not a wholly unexpected finding as previous investigators had reported only small decreases in lipid levels after 4 wks, with maximum effects noted at 16 wks (7). Thus, longer periods of supplementation would probably be needed to change these parameters.

On the other hand, garlic supplementation significantly reduced the susceptibility of the apoB-containing lipoproteins to copper-induced oxidation (Fig. 1). LOS values went from 80 ± 25 to 53 ± 32 nmol MDA/mg non-HDL cholesterol, a 34% decrease ($P < 0.05$). Values after two weeks of placebo were unchanged at 72 ± 19 *vs.* 73 ± 16 nmol MDA/mg non-HDL cholesterol. Only about half of the subjects actually experienced decreases in LOS, and two showed remarkable reductions. The relative non-responsiveness of the other half of the subjects suggests that other factors (dose, duration, endogenous antioxidants) may modulate the effectiveness of garlic.

Dietary stability was confirmed in this study by analysis of diet diaries during both phases. RISCC ratings were identical (23 ± 5) in both phases, indicating that the subjects were consuming a typical American diet, and that there was no change in background diets between periods which would be expected to alter plasma lipid levels. Because the diets were stable, the effects observed on LOS were likely to be due to the garlic powder supplements.

A change in LDL fatty acid composition (*i.e.*, a reduced amount of polyunsaturated fatty acids) could have been responsible for the reduced susceptibility of lipoproteins to oxidative stress during the garlic period. However, we found no change whatever in LDL phospholipid or cholesteryl ester fatty acid patterns (Table 2). Data on LDL vitamin E levels are not available, but because garlic powder contains no vitamin E, it seems unlikely that changes in α-tocopherol status would explain these findings.

Kourounakis and Rekka (12) recently tested the antioxidant properties of garlic powder, Kwai and alliin (the odorless precursor which is converted to odoriferous allicin when exposed to alliinase, an enzyme released when the

garlic clove is crushed). They reported that both the garlic powder and Kwai were effective antioxidants when tested against rat hepatic microsomes stressed by ascorbic acid/Fe^{2+} and evaluated by TBARS generation. The garlic powder and alliin were also tested for their ability to scavenge hydroxyl radicals. Only the powder was effective at concentrations between 0.8 and 3.3 mM.

The application of these results to the *in vivo* situation is unclear, at best, as blood levels of garlic powder constituents (alliin or allicin) in subjects taking the products have eluded quantitation. Garlic is rich in a variety of sulfur-containing compounds (diallyldisulfide, vinyldithiines, ajoene), which are all potential antioxidants, but finding the putative *in vivo* antioxidant may be difficult.

In view of these considerations, it was with some skepticism that we evaluated the antioxidant effects of Kwai in healthy volunteers, and it was also with some surprise that we discovered that some component of this garlic preparation appeared to retain its antioxidant effect *in vivo*, even protecting isolated lipoproteins from oxidative stress. Future studies will be needed to determine exactly which component is responsible.

We conclude that 600 mg of Kwai taken for only two weeks significantly decreased the lipoprotein oxidation susceptibility without altering serum cholesterol levels in normal adults. If confirmed, such an effect may be considered to be potentially antiatherogenic. Trials should be undertaken to examine this effect in larger groups, for longer periods of supplementation, and in patients at increased risk for heart disease. In addition, the effects of garlic on atherosclerosis-prone animal models should be evaluated.

ACKNOWLEDGMENTS

The authors wish to thank David Sternshein, Sumner Academy of Arts and Science, for his guidance and encouragement, Alayne Ward for technical assistance and the volunteers for making this study possible.

ARTICLE

Protein Kinase C-Dependent Stimulation of Phospholipase D in Phospholipase C-Treated Fibroblasts

Zoltan Kiss* and **Nandor Garamszegi**
The Hormel Institute, University of Minnesota, Austin, Minnesota 55912

Treatment of [^{14}C]choline- or [^{14}C]ethanolamine-labeled NIH 3T3 fibroblasts with *Bacillus cereus* phosphatidylcholine-specific phospholipase C (PLC) enhanced phospholipase D (PLD)-mediated hydrolysis of the respective ^{14}C-labeled phospholipids. PLD activity was stimulated by 1.5 U/mL of PLC and by 100 nM of the protein kinase C (PKC) activator phorbol 12-myristate 13-acetate (PMA) to similar extents. Treatment of [^{14}C]palmitic acid-labeled fibroblasts with PLC in the presence of ethanol also enhanced PLD-mediated formation of phosphatidylethanol; the effects of PLC and PMA were nonadditive. PLC had no effect on PLD activity in fibroblasts in which PKC was down-regulated by prolonged (24 h) treatment with 300 nM PMA. These data indicate that treatment of fibroblasts with exogenous PLC results in PKC-dependent activation of PLD.
Lipids 28, 479–481 (1993).

Recent evidence suggests that phospholipase C [EC 3.1.4.3] (PLC)-mediated hydrolysis of phosphatidylcholine (PtdCho) may be involved in the regulation of cell growth by platelet-derived growth factor (1), *ras* proteins (2–4), insulin (2), colony stimulating factor (5), epidermal growth factor (6) and hepatocyte growth factor (7). In agreement with the proposed role of cellular PLC as a cell growth regulator, exogenous addition of *Bacillus cereus* PtdCho-hydrolyzing PLC to fibroblasts was found to elicit a potent mitogenic response (1).

The mechanism by which the action of PLC leads to increased cell growth is not known. The primary products of PtdCho hydrolysis are 1,2-diacylglycerol and choline phosphate. While choline phosphate is not known to be part of the cellular signalling system, 1,2-diacylglycerol is an activator of protein kinase C (PKC) (8,9). However, in fibroblasts in which PKC-α was down-regulated by prolonged treatment with phorbol 12-myristate 13-acetate (PMA), exogenous PLC remained mitogenic (1). On this basis, PKC is not presently thought to serve as a mediator of the growth regulatory effect of PLC (1).

In most cell types examined so far, activated PKC is a major regulator of phospholipase D [EC 3.1.4.4] (PLD) (10–12). This enzyme is capable of rapidly generating phosphatidic acid, a potent mitogen in fibroblasts and several other cell lines (13–19). Thus, in principle, activation of PLD could be a requirement for the growth stimulatory action of PLC.

Although exogenous PtdCho-hydrolyzing PLC is known to stimulate the phosphorylating activity of cellular PKC (20), this may not automatically lead to the activation of PLD because regulation of this latter enzyme by PKC appears to involve a nonphosphorylating mechanism (21). Furthermore, regulation of PtdCho synthesis by exogenous PLC, which is mediated by 1,2-diacylglycerol, was shown to occur by a PKC-independent mechanism (22). Here, we show that exposure of NIH 3T3 fibroblasts to PLC leads to enhanced, PKC-dependent hydrolysis of phospholipids by PLD.

MATERIALS AND METHODS

Materials. PLC from *B. cereus*, PMA and Dowex-50-W(H^+ form) were purchased from Sigma Chemical Co. (St. Louis, MO); [*methyl*-^{14}C]choline chloride (50 mCi/mmol), [2-^{14}C]ethanolamine (50 mCi/mmol) and [1-^{14}C]palmitic acid (60 mCi/mmol) were from Amersham (Arlington Heights, IL); and tissue culture reagents were bought from Gibco (Grand Island, NY). Phosphatidylethanol (PtdEtOH) was prepared by PLD-catalyzed reaction from PtdCho and ethanol as described earlier (23).

Treatment of [^{14}C]choline-prelabeled fibroblasts. NIH 3T3 fibroblasts were grown to ≈80–90% confluency in 12-well culture dishes in the presence of [*methyl*-^{14}C]choline (0.5 μCi/mL) for 48 h. Fibroblasts were washed twice and then incubated in fresh medium for another 3-h period (needed to lower intracellular levels of free [^{14}C]choline). Fibroblasts were then treated with PLC and/or PMA in the presence of 20 mM unlabeled choline (final vol, 0.3 mL) for 5–20 min as indicated. After treatments with 0.75 or 1.5 U/mL of PLC or 100 nM PMA for 20 min, 95–98% of cells were viable, determined by the Trypan Blue dye exclusion assay. Incubations were terminated by adding 1 mL of ice-cold methanol to the wells. The methanol extracts were transferred to tubes containing 2 mL chloroform. The wells were washed twice with 0.5 mL of methanol.

Treatment of [^{14}C]ethanolamine- or [^{14}C]palmitic acid-labeled fibroblasts. Fibroblasts were grown in 150 mm-diameter plastic dishes for 48 h in the presence of [2-^{14}C]ethanolamine (0.25 μCi/mL), or for 24 h in the presence of [1-^{14}C]palmitic acid (0.25 μCi/mL). Fibroblasts were washed and then incubated in fresh medium for 3 h (to decrease the cellular level of unincorporated radiolabeled precursors; see Refs. 23–25). Fibroblasts were harvested by gentle scraping from 2 to 4 dishes. Washed fibroblasts (0.9–1.1 × 10^6 cells/mL) were incubated (final vol 0.25 mL) in an incubator at 37°C in the presence of agents as indicated. In the case of [^{14}C]ethanolamine-labeled fibroblasts, the incubation medium contained 2 mM unlabeled ethanolamine to prevent metabolism of newly formed [^{14}C]ethanolamine (24,25). Incubations were terminated by the addition of 4 mL of chloroform/methanol (1:1, vol/vol).

Separation of ^{14}C-labeled hydrolytic products. PtdEtOH was separated from other phospholipids on

Abbreviations: PLC, phosholipase C; PLD, phospholipase D; PtdCho, phosphatidylcholine; PtdEtn, phosphatidylethanolamine; PtdEtOH, phosphatidylethanol; PKC, protein kinase C; PMA, phorbol 12-myristate 13-acetate.

potassium oxalate (1%)-impregnated silica gel H plates (Analtech, Newark, DE) by using the solvent system of chloroform/methanol/acetone/acetic acid/water (50:10:15:10:2, by vol). The choline and ethanolamine metabolites were fractionated on Dowex-50-W(H^+)-packed columns (Bio-Rad Econo columns, Richmond, CA; 1-mL bed volume) as described by Cook and Wakelham (26) with the modifications described previously (27). The metabolites of [^{14}C]-ethanolamine and [^{14}C]choline were further identified by thin-layer chromatography (28). Contamination of the [^{14}C]ethanolamine fraction by [^{14}C]choline was less than 1%.

RESULTS

Concentration-dependent effects of PLC on the formation of choline and choline phosphate. We have shown (28) that in NIH 3T3 fibroblasts, labeled with [^{14}C]choline until radioisotopic equilibrium was achieved (48 h), PMA-induced formation of [^{14}C]choline from the prelabeled cellular PtdCho occurs by a PLD-mediated mechanism. In addition, we have demonstrated (23) that treatment of fibroblasts with PLC results in a significant increase in 1,2-diacylglycerol. As shown in Figure 1a, 0.25–1.5 U/mL concentrations of *B. cereus* PLC enhanced the formation of [^{14}C]choline from [^{14}C]PtdCho in a concentration-dependent manner. At an optimal stimulatory concentration of PMA (100 nM), the stimulatory effects of PLC were nonadditive with that of PMA, suggesting that these agents were acting through the same mechanism (Fig. 1a).

NIH 3T3 fibroblasts contain the α-, δ-, ε- and ζ-PKC isozymes. Treatment of fibroblasts with 300 nM PMA for 24 h almost completely down-regulates PKC-α (29), and also decreases the cellular levels of PKC-δ and PKC-ε by 75–90% (data not shown). In contrast, prolonged (24 h) PMA-treatment had no effect on the cellular level of PKC-ζ (N. Garamszegi and Z. Kiss, unpublished data). Prolonged (24 h) treatment of fibroblasts with PMA (300 nM) significantly enhanced the formation of [^{14}C]choline from labeled PtdCho, indicating partial activation of PLD (Fig. 1a). After chronic (24 h) treatment with PMA, neither newly added PMA (not shown) nor PLC (Fig. 1a) had any further effect on PtdCho hydrolysis.

Treatment of fibroblasts with PMA for 20 min or 24 h caused only little, if any, changes in PLC-catalyzed formation of choline phosphate (Fig. 1b). Thus, the inability of PLC to enhance [^{14}C]choline formation in the presence of PMA was not due to PMA-induced inactivation of PLC.

In the presence of ethanol, activated PLD catalyzes the formation of the metabolically more stable PtdEtOH. As shown in Figure 2, 0.75–1.5 U/mL concentrations of exogenous PLC greatly enhanced the formation of PtdEtOH in the presence of 200 mM ethanol. In agreement with the data in Figure 1, PLC failed to enhance PtdEtOH synthesis in the presence of PMA (Fig. 2).

In NIH 3T3 fibroblasts, activated PLD was shown to hydrolyze PtdEtn in addition to PtdCho (24,25,28–30). Thus, it was of interest to examine possible stimulation of PtdEtn hydrolysis by exogenous PLC. For this study, suspended [^{14}C]ethanolamine-labeled fibroblasts were used, because they were found to contain much lower background levels of unincorporated [^{14}C]ethanolamine compared to attached fibroblasts (24,27). Both in [^{14}C]-choline-labeled attached fibroblasts (Fig. 3a) and [^{14}C]-ethanolamine-labeled suspended fibroblasts (Fig. 3b), 0.75–1.5 U/mL concentrations of PLC rapidly, and to a similar extent, stimulated PLD-mediated hydrolysis of the respective labeled phospholipids. However, the stimula-

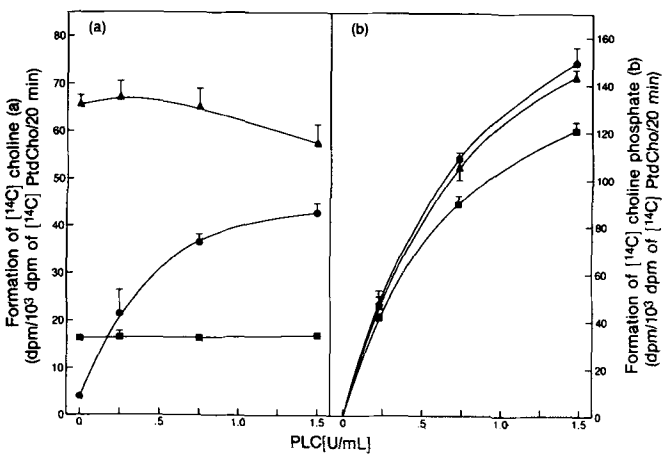

FIG. 1. Concentration-dependent effects of phospholipase C (PLC) on phosphatidylcholine (PtdCho) hydrolysis in NIH 3T3 fibroblasts. Fibroblasts were labeled with [^{14}C]choline for 48 h, followed by incubation of labeled fibroblasts for 20 min in the absence (●) or presence of 100 nM phorbol 12-myristate 13-acetate (PMA) (▲). In one set of experiments (■), cells were treated with 300 nM PMA for the last 24 h of the labeling period. [^{14}C]Choline (a) and [^{14}C]choline phosphate (b) were separated by ion-exchange chromatography. The ^{14}C content of PtdCho was 883000 and 819000 dpm/10^6 cells in the untreated and PMA-pretreated fibroblasts, respectively. Each point represents the mean ± SE of three incubations. Similar results were obtained in two other experiments.

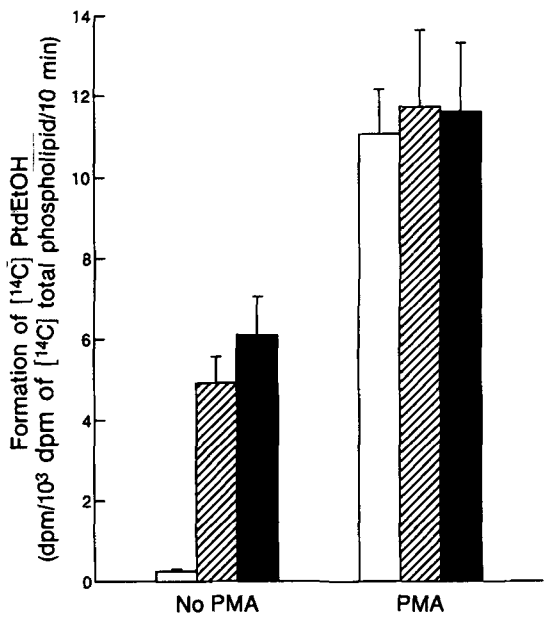

FIG. 2. Stimulatory effects of PLC and PMA on the formation of phosphatidylethanol (PtdEtOH) in [^{14}C]palmitate-labeled NIH 3T3 fibroblasts. Suspended [^{14}C]palmitate-labeled NIH 3T3 fibroblasts were incubated in the presence of 200 mM ethanol for 10 min. PLC was absent (open bar) or present at a concentration of 0.75 U/mL (hatched bar) or 1.5 U/mL (closed bar). When present, the concentration of PMA was 100 nM. Data are the mean ± SE of four incubations. Similar results were obtained in two other experiments. Abbreviations as in Figure 1.

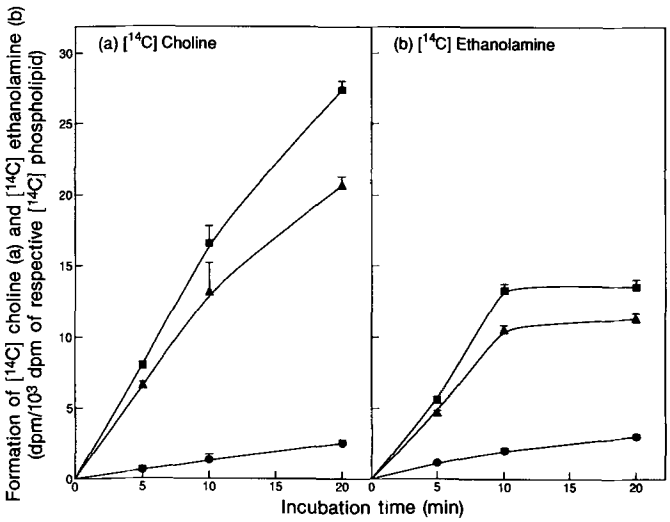

FIG. 3. Comparison of the time-dependent effects of PLC on the hydrolysis of PtdCho and PtdEtn in NIH 3T3 fibroblasts. Fibroblasts were labeled with [^{14}C]choline (a) or [^{14}C]ethanolamine (b) for 48 h. Attached [^{14}C]choline-labeled and suspended [^{14}C]ethanolamine-labeled fibroblasts were incubated for 5–20 min in the absence (●) or presence of 0.75 U/mL of PLC (▲), or 1.5 U/mL of PLC (■). The [^{14}C]content of PtdCho and PtdEtn was 0.966×10^6 and 1.29×10^6 dpm/10^6 cells, respectively. Each point represents the mean ± SE of three incubations. Similar results were obtained in three other experiments. Abbreviations as in Figure 1.

tory effect of PLC on PtdEtn hydrolysis appeared to be rather transient (lasting only for 10 min) compared to PLC-induced PtdCho hydrolysis. One possible, and the most likely, explanation for this difference is that scraping decreased the sensitivity of fibroblasts to PLC. In support of this possibility, the stimulatory effects of PLC on PtdCho hydrolysis in [^{14}C]choline-labeled suspended fibroblasts also lasted for only 10–15 min (data not shown).

In NIH 3T3 fibroblasts, the methylation process is a relatively minor pathway. Thus, after labeling of fibroblasts with [^{14}C]ethanolamine for 48 h, only 3% of total phospholipid-associated ^{14}C-activity was present in PtdCho (data not shown). This, coupled with efficient separation of ^{14}C-labeled metabolites, ensured that contamination of the [^{14}C]ethanolamine fraction by [^{14}C]choline was minimal (less than 1%).

DISCUSSION

We have shown that treatment of NIH 3T3 fibroblasts with exogenous PLC leads to PKC-dependent activation of PLD. This indicates that 1,2-diacylglycerol, generated through the action of exogenous PLC, can stimulate not only the phosphorylating activity of PKC (20), but it can also enhance the ability of PKC to activate PLD by a non-phosphorylating mechanism (21). Because activated PLD generates the potent mitogen phosphatidic acid (13–19), this phospholipid product could be involved, at least in principle, in the mediation of mitogenic effects of PLC.

While chronic treatment of cells with PMA completely abolished the stimulatory effect of PLC on PLD activity (this work), such treatment failed to prevent the mitogenic effect of PLC (1). Therefore, a direct role of phosphatidic acid in the mediation of mitogenic effect of PLC is unlikely. However, in view of the present finding that prolonged treatment of fibroblasts with PMA results in permanent partial activation of PLD, the possibility that increased formation of phosphatidic acid by PLD is a prerequisite for the mitogenic action of PLC cannot be excluded. Further experiments are required to distinguish between these possibilities.

Effect of Clofibric Acid on the Turnover of the Fatty Acid-Binding Protein Identified in Cultured Endothelial Cells from Bovine Aorta

Markus Robers[a], Brigitte Loddenkötter[a], Hans Kresse[b] and Friedrich Spener[a,*]

Several types of fatty acid-binding proteins are found in mammalian cells. Cultured endothelial cells from bovine aorta were shown to contain exclusively the cardiac-type fatty acid-binding protein (cFABP) with a mean concentration of 90 ng cFABP/mg extract protein. Only small variations were observed from passage to passage. In pulse-chase labeling experiments with L-[^{35}S]methionine, a half-life of 4.0 d was measured for cFABP which is about two times longer than the average half-life of the extracted proteins. These data imply that in aortic endothelial cells cFABP is not subject to short-term regulation. However, addition of clofibric acid to the culture medium led to a shortening of the half-life of cFABP, which was compensated for by an increase in its biosynthesis. The turnover of the bulk of extract proteins remained unchanged when the cells were challenged with clofibric acid.
Lipids 28, 483–486 (1993).

The fatty acid-binding proteins of the hepatic (hFABP), intestinal (iFABP) and cardiac (cFABP) type belong to a group of structurally well, but functionally ill-defined 14–15 kDa proteins that are variably expressed in mammalian cells. To date, hFABP expression appears to be limited to liver and intestinal cells, iFABP expression to the epithelial cells that line the intestinal tract, whereas cFABP is expressed in a broad range of tissues including heart, skeletal muscle, kidney, brain, stomach and placenta (1). Immunoblotting techniques and protein A-gold labeling revealed a complex distribution pattern for cFABP in the heart. The protein was detected in the cytosol of heart muscle cells where it associates with myofibrils, and in the mitochondrial matrix and in the nucleus (2,3). It is also present in heart capillary endothelium (3), in cultured endothelial cells of humans and rats (4) and in rat aortic tissue where its expression is specifically suppressed within 3 wk by experimentally induced hypertension (5). The cFABP contents of rat heart as well as the hFABP contents of rat liver are augmented by long-term feeding of high-fat diets (6). In response to clofibrate and other lipid-lowering drugs, however, the cFABP level in rat heart is not affected (7) which is in contrast to the elevated levels observed for hFABP in liver and intestinal cells (1). The data suggest that FABP are not rapidly regulated and, indeed, the half-life of hFABP in rat liver was found to be 3.1 d (8), and the half-life of cFABP in cultured neonatal cardiomyocytes was 2.5 d (9).

The occurrence of FABP types in cells of the vascular system and the strategic position of the endothelium at the interface between blood and tissue argue for a transporter function of this protein for fatty acids. With this in mind, we investigated the regulation of FABP in cultured endothelial cells from bovine aorta. We report here data on the half-life of FABP of the cardiac type and on the turnover of cFABP in endothelial cells that were treated with clofibric acid.

Abbreviations: ELISA, enzyme-linked immunosorbent assay; cFABP, hFABP, iFABP, cardiac, hepatic and intestinal fatty acid-binding protein, respectively; SDS-PAGE, sodium dodecyl sulfate-polyacrylamide gel electrophoresis; TCA, trichloroacetic acid.

MATERIALS AND METHODS

Materials. L-[^{35}S]Methionine (1100 Ci/mmole) was purchased from Amersham-Buchler (Braunschweig, Germany); Eagle's minimum essential medium and Hanks' salt solution were from Seromed (Munich, Germany). Penicillin and streptomycin were from Boehringer (Mannheim, Germany), protein A-Sepharose and clofibric acid (2-(*p*-chlorophenoxy)-2-methyl-propionic acid) from Sigma (Deisenhofen, Germany) and nitrocellulose paper (0.1 μm) from Schleicher and Schuell (Dasseln, Germany).

Cell cultures, conditions of preincubation and protein labeling. Endothelial cells were derived from bovine aorta, cultured and passaged in Eagle's minimum essential medium supplemented with 10% of fetal calf serum (Conco, Wiesbaden, Germany) in 25-cm^2 Nunc plastic flasks as outlined earlier (10). After cultures reached confluency, the medium was removed and cells were washed two times with 2 mL Hanks' salt solution. Preincubation with methionine-free Waymouth's MAB 87/3 medium (Gibco, Eggenstein, Germany) and labeling with L-[^{35}S]methionine were carried out in a manner analogous to that described (11). Per 25-cm^2 flask, 100–150 μCi were applied in a total volume of 1.9 mL. The pulse was terminated after 5 h either by harvesting or by feeding the cultures with complete tissue culture medium. Clofibric acid was solubilized in Eagle's minimum essential medium, and preincubation was carried out as described in the legends to Tables 1 and 2.

Immunoprecipitation. At the end of the incubation time, the cell layer was washed two times with 2 mL Hanks' salt solution and extracted with 0.4 mL detergent buffer [0.5% (wt/vol) sodium deoxycholate, 0.5% (vol/vol) Triton X-100, 1 M NaCl and proteinase inhibitors in 0.1 M Tris-HCl (pH 7.4)] for 90 min at room temperature and centrifuged (10 min, 10,000 × *g*). An aliquot of the resulting supernatant was treated with 12.5% (wt/vol) trichloroacetic acid (TCA) overnight at 4°C, the precipitate was washed twice with 10% (wt/vol) TCA and finally dissolved in 0.2 mL of 2.5 M NaOH ("extract proteins"). After neutralization, the radioactivity incorporated into extract proteins was measured by liquid scintillation counting. The remaining supernatant was shaken end over end with preimmune IgG-coated protein A-Sepharose (3 mg/25-cm^2 flask) at 4°C for 12–24 h. This step was repeated five times to remove unspecifically bound proteins. Sepharose was spun down, and the supernatant was transferred to a tube containing the same amount of protein A-Sepharose coated with affinity purified anti-cFABP-IgG or anti-Cathepsin D-IgG, respectively. After shaking for 20–24 h, the mixture was washed three times with 1 mL detergent buffer (see above) and two times with 1 mL of 10 mM sodium phosphate (pH 7.4) containing 0.15 M NaCl. The pellet was solubilized in sodium dodecyl sulfate

(SDS) sample buffer as described (11). Sepharose was removed by centrifugation and the immunoprecipitate was subjected to SDS-polyacrylamide gel electrophoresis (SDS-PAGE).

Other methods. SDS-PAGE was performed in slab gels (12.5 cm long and 1.5 mm thick, separating gel 15% and stacking gel 5.85% acrylamide) (12), and the gels were then prepared for fluorography (13). For quantitative determinations, appropriate gel areas were cut out, swollen in water and treated with dimethyl sulfoxide to remove 2,5-diphenyloxazole. There was no loss in radioactivity during these procedures. Before determination of radioactivity, samples were dissolved in 2.2 M *ortho*-periodic acid for 5–10 min at 80–90°C, and after cooling the radioactivity was counted in 10 mL Instagel (Packard, Frankfurt, Germany). Antibodies against various FABP types were raised, purified and used in Western blots in a manner outlined earlier (2). cFABP was quantitated with the aid of a specific enzyme-linked immunosorbent assay (ELISA) (2) and protein by the bicinchoninic acid assay (14) with ovalbumin as standard.

Statistical analysis. Data are presented as means ± SD of n determinations. The significance of differences was evaluated by Student's *t*-test.

RESULTS

Characterization and quantitation of FABP. With all types of FABP known to occur in bovine tissue as well as respective antibodies on hand, SDS-PAGE and Western immunoblotting defined the FABP present in the extract of cultured bovine aortic cells as a cardiac-type protein (Fig. 1). The sensitivity of the sandwich-ELISA employed for quantitation was in the range of 0.05 to 1.0 ng cFABP per mL and allowed the determination of the minute amounts present in the extract. The content was ~90 ng cFABP/mg extract protein with variations of up to ±20% being observed from passage to passage.

Determination of cFABP half-life. Endothelial cells were pulse-labeled for 5 h with [^{35}S]methionine and chased for up to 12 d. [^{35}S]Methionine could be used as radioactive precursor, because bovine cFABP contains three methionine residues (15,16). The immunoprecipitation of [^{35}S]cFABP was of sufficient quality (Fig. 2) and was quantitative, as less than 5% of the total cFABP were found by the ELISA technique in the supernatant after immunoprecipitation. The band appearing around 30 kDa on gels after SDS-PAGE could only be detected after immunoprecipitation, but not in Western blots and it could be quenched by unlabeled cFABP. The radioactivity found in this band was about 68% of that in cFABP. Small molecular mass bands indicate the gel front. For the determination of cFABP half-life a log cpm *vs.* time plot was constructed which yielded straight lines with correlation coefficients from 0.97 to 0.99 (Fig. 3). From the decay curve, a half-life of 4.0 d was calculated for cFABP (15 kDa protein) and of 1.8 d for total extract proteins. Interestingly, the ~30 kDa cross-reactive protein also exhibited a half-life of 4.0 d. The sequence of the bovine cDNA for cFABP (15) excludes the possibility of the expression of a higher molecular mass precursor of cFABP and hence, the nature of this cross-reacting protein remains to be determined.

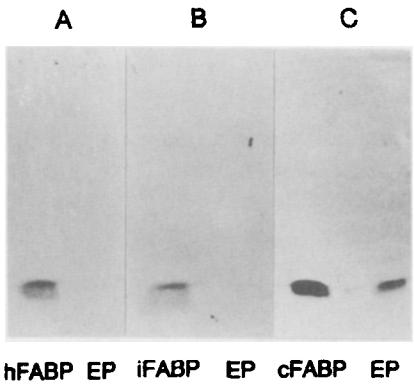

FIG. 1. Determination of fatty acid-binding protein (FABP) type expressed in aortic endothelial cells. Western blots after 15% sodium dodecyl sulfate-polyacrylamide gel electrophoresis of 20 μg extract proteins (EP) and of 100 ng FABP, each. Immunostaining was carried out with anti-hepatic (h)FABP antibodies (A), anti-intestinal (i)FABP antibodies (B), and anti-cardiac (c)FABP antibodies (C).

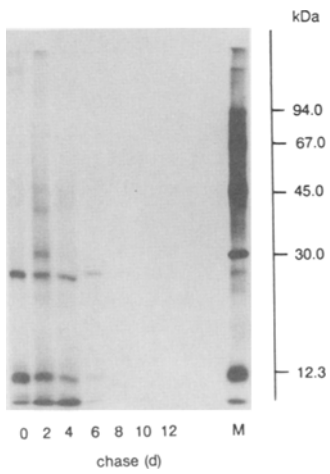

FIG. 2. Determination of cardiac fatty acid-binding protein half-life. After a 5-h pulse with 120 μCi of [^{35}S]methionine, cultures were chased for the times indicated. Autoradiogram after 15% sodium dodecyl sulfate-polyacrylamide gel electrophoresis of immunoprecipitated proteins; M, marker proteins (phosphorylase b, bovine serum albumin; ovalbumin; carbonic anhydrase; cytochrome c, migrates as 14–15 kDa protein).

Influence of clofibric acid on cFABP metabolism. Clofibric acid was admixed to the culture medium in the concentrations shown in Tables 1 and 2. After administration for 3 to 5 d (order of cFABP half-life), the concentrations of cFABP and of extract proteins were determined. Compared with untreated controls, the values remained constant within the margin of error (Table 1). At a concentration of 5 mM clofibric acid, toxic effects were observed as some of the endothelial cells became detached from the dishes and, therefore, only concentrations up to 1 mM were used in subsequent experiments. Interestingly, clofibric acid did influence the *de novo* synthesis of cFABP. After preincubation of the cells for 2 d with this drug and a subsequent 5-h pulse with [^{35}S]methionine, a dose-dependent increase of up to 50% of the radioactivity

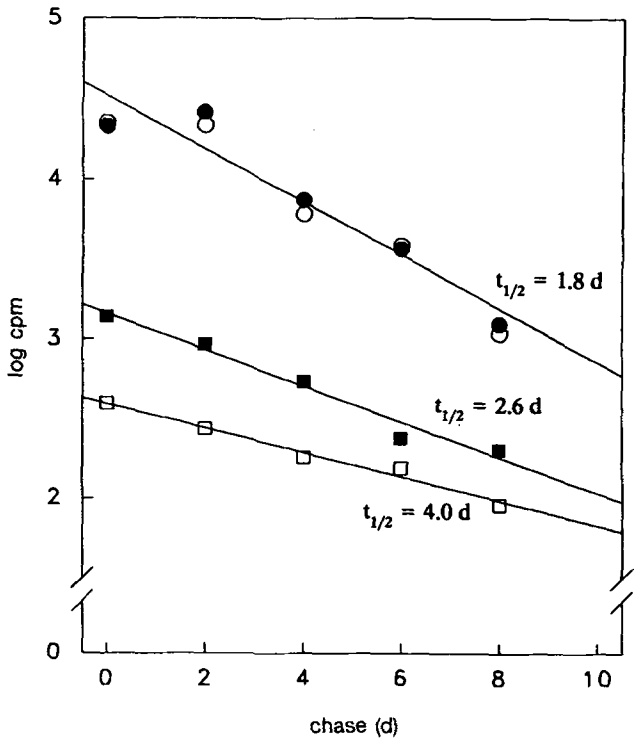

FIG. 3. Decay of radioactivity in cardiac fatty acid-binding protein (cFABP) and extract proteins following pulse labeling with [^{35}S]methionine in the presence or absence of clofibric acid. From experiments as shown in Figure 2, bands with cFABP (15 kDa protein) were excised from the gel and subjected to scintillation counting. Radioactivity in extract proteins was determined after precipitation with trichloroacetic acid. ●, Extract proteins + clofibric acid; ○, extract proteins − clofibric acid; ■, cFABP + clofibric acid; □, cFABP − clofibric acid.

TABLE 1

Effect of Clofibric Acid on the Concentration of cFABP[a]

Clofibric acid	cFABP	Extract proteins
mM	ng/mg protein (n = 18)	μg/culture flask (n = 18)
0.0	90 ± 20	268 ± 22
0.2	100 ± 20	265 ± 40
1.0	80 ± 40	261 ± 62
5.0	70 ± 40	221 ± 49

[a]Prior to harvesting, endothelial cell cultures were treated with the drug for 3–5 d. Proteins were determined as described under Materials and Methods. Values represent means ± SD of n determinations. cFABP, cardiac fatty acid-binding protein.

incorporated into cFABP was observed as compared to untreated controls (Table 2). This increase was detected in four independent experiments whereas the incorporation of the radioactivity into extract proteins was not significantly affected by clofibric acid. Moreover, in additional immunoprecipitation experiments with treated (1 mM clofibric acid) and untreated cells we determined the half-life of cathepsin D, a lysosomal protein structurally and functionally unrelated to cFABP, and could not find any difference (data not shown). Taking all controls together, we concluded that clofibric acid did not affect the [^{35}S]-methionine pool, and consequently we studied the cFABP turnover in the presence of 1 mM clofibric acid analogously as described above, except that the chase was shortened to 8 d. From the decay curves (Fig. 3), a half-life of 2.6 d was calculated for cFABP and of 1.8 d for extract proteins. The shorter half-life corresponded to the increase in cFABP synthesis since cellular cFABP levels were not altered. On the other hand, clofibric acid had no effect on the half-life of extract proteins or cathepsin D (see above).

TABLE 2

Effect of Clofibric Acid on the *de novo* Synthesis of cFABP[a]

Clofibric acid	Radioactivity in cFABP	Radioactivity in extract proteins
mM	(%) n = 4	(%) n = 4
0.0	100 ± 10	100 ± 11
0.2	129 ± 17[b]	97 ± 17
1.0	152 ± 17[c,d]	79 ± 26

[a]Endothelial cell cultures were pretreated with the drug for 2 d and then pulsed with 120 μCi [^{35}S]methionine. After 5 h, cells were lysed and proteins analyzed as described under Materials and Methods. Values represent means ± SD of n determinations. cFABP, cardiac fatty acid-binding protein.
[b]Significantly different ($P < 0.025$) from untreated cells.
[c]Significantly different ($P < 0.0025$) from untreated cells.
[d]Significantly different ($P < 0.05$) from cells treated with 0.2 mM clofibric acid.

DISCUSSION

Aortic endothelial cells, as shown here, and heart endothelium (3,4) express FABP of the cardiac type. The identifications are based on SDS-PAGE and immunological cross-reactivity, the latter requiring at least a 70–80% homology in primary structures of FABP when polyclonal antibodies are used (17). The cross-reacting endothelial protein with ~30 kDa may be related to cFABP; however, it was found only after biosynthetic labeling and not in Western blots of cell extracts. This suggests either a high [^{35}S]methionine content of the cross-reacting species or the formation of a dimer of newly synthesized cFABP. Previously the existence of a disulfide-linked dimer of cFABP has been shown, whose formation was facilitated under denaturing conditions due to the exposure of the protein's single cysteine residue (18). Such dimerization seems to be unlikely because the immunoprecipitate was treated with 10 mM dithiothreitol in SDS sample buffer for 6 min at 95°C but cannot be excluded.

The concentration of cFABP in aortic endothelial cells is 90 ± 20 ng/mg extract protein and stays within this range from passage to passage (data not shown). It is much smaller than that of cFABP in the capillary endothelium of rat heart muscle as calculated by the protein A-gold method (3) as well as the 3.18 ± 0.651 μg/mg protein of bovine heart cytosol determined by the cFABP-specific ELISA (2). The small amount of cFABP in the aortic endothelial cells could be due to the fact that in cultured cells the expression is lower than *in vivo*. It could also reflect the different functions of heart aorta and heart muscle. The half-life of 4.0 d for cFABP was calculated from a representative experiment, variations were from

3.6 to 4.6 d possibly due to the biological variability in different cell strains. These half-lives are longer than the 3.1 d determined for hFABP half-life in rat liver (8) and the 2.5 d found for cFABP half-life in cultured neonatal cardiomyocytes (9). Although the functional role(s) of cFABP in endothelial cells remain(s) to be defined, the data elaborated here imply that cFABP plays a housekeeping role and is not subject to short-term regulation. It may thus sustain the intracellular flux of fatty acids under fast changes of nutritional states and may provide a pool of fatty acids available for membrane biosynthesis and production of metabolites of the arachidonic acid cascade.

For the studies on the effect of clofibrate, clofibric acid was used instead of its ethyl ester, because of its better solubility in the culture medium. The drug did not affect the concentration of cFABP in endothelial cells. Our data are consistent with the observation that hypolipidemic drugs of this type do not enhance the cFABP content in rat heart (7). The concentration of hFABP in liver, on the other hand, is increased by clofibrate proportional to the effect of this drug on peroxisomal proliferation without being necessarily linked to the latter (19,20). The mechanism by which hypolipidemic drugs influence the concentration of hFABP is still unknown. Our findings reveal an increased *de novo* synthesis of cFABP in endothelial cells following clofibric acid treatment, while the cFABP content remains unchanged. In contrast to Bass *et al.* (21), who have found that the hFABP concentration was increased in clofibrate-treated rats without changes in the turnover, cFABP turnover was accelerated in endothelial cells after clofibric acid treatment. These observations suggest different roles of liver and heart FABP types in cellular lipid metabolism. Their specific tissue distribution is another important indication in this respect (22). The fact that in clofibrate-treated rats the hFABP mRNA concentration is increased in parallel with the hFABP concentration indicates a pretranslational regulation of hFABP (21). The markedly reduced expression of cFABP mRNA in aorta during hypertension, concomitant with a reduction of immunologically detectable protein, suggests transcriptional regulation of cFABP synthesis (5). In further studies the isolation of total cellular RNA and Northern blot analysis may give an insight into cFABP mRNA concentration and its response to clofibric acid treatment of endothelial cells.

ACKNOWLEDGMENTS

This study was supported by a grant from the Deutsche Forschungsgemeinschaft (SFB 310) and the Fonds der Chemischen Industrie. We thank T. Börchers for helpful discussions and Dr. A. Hasilik for providing antibodies against cathepsin D.

[Received November 14, 1992, and in revised form April 7, 1993; Revision accepted April 7, 1993]

Transformation of Fatty Acid Hydroperoxides by Alkali and Characterization of Products

Harold W. Gardner[a,1,*], **Thomas D. Simpson**[a] and **Mats Hamberg**[b]
[a]NCAUR, ARS, USDA, Peoria, Illinois 61604 and [b]Department of Physiological Chemistry, Karolinska Institutet, S-104 01 Stockholm, Sweden

It has previously been determined that (13*S*,9*Z*,11*E*)-13-hydroperoxy-9,11-octadecadienoic acid was mainly converted into (13*S*,9*Z*,11*E*)-13-hydroxy-9,11-octadecadienoic acid by 5 N KOH with preservation of the stereochemistry of the reactant [Simpson, T.D., and Gardner, H.W. (1993) *Lipids 28,* 325–330]. In addition, about 20–25% of the reactant was converted into several unknown by-products. In the present work it was confirmed that the stereochemistry was conserved during the hydroperoxy-diene to hydroxy-diene transformation, but also, novel by-products were identified. It was found that after only 40 min reaction (9*Z*)-13-oxo-*trans*-11,12-epoxy-9-octadecenoic acid accumulated to as much as 7% of the total. Later, (9*Z*)-13-oxo-*trans*-11,12-epoxy-9-octadecenoic acid began to disappear, and several other compounds continued to increase in yield. Two of these compounds, 2-butyl-3,5-tetradecadienedioic acid and 2-butyl-4-hydroxy-5-tetradecenedioic acid, were shown to originate from (9*Z*)-13-oxo-*trans*-11,12-epoxy-9-octadecenoic acid, and they accumulated up to 2–3% each after 4 to 6 h. Some other lesser products included 11-hydroxy-9,12-heptadecadienoic acid, 3-hydroxy-4-tridecenedioic acid, 13-oxo-9,11-octadecadienoic acid and 12,13-epoxy-11-hydroxy-9-octadecenoic acid. Except for the latter two, most or all of the compounds could have originated from Favorskii rearrangement of the early product, (9*Z*)-13-oxo-*trans*-11,12-epoxy-9-octadecenoic acid, through a cyclopropanone intermediate.
***Lipids 28,* 487–495 (1993).**

It is known that organic hydroperoxides are converted into the corresponding hydroxy compounds by alkali (for a review, see Ref. 1). As a result of saponification of autoxidized fatty acid methyl esters, such a conversion of fatty ester hydroperoxide to fatty acid hydroxide was first reported in 1961 (2). A number of other "nucleophiles" also converted linoleic acid hydroperoxide into the corresponding hydroxy fatty acid (3), but the earlier reports included few details on the mechanism or the structure of the product(s). Recently, the kinetics of the KOH-catalyzed transformation of (13*S*,9*Z*,11*E*)-13-hydroperoxy-9,11-octadecadienoic acid (13*S*-HPOD) and (13*S*,9*Z*,11*E*,15*Z*)-13-hydroperoxy-9,11,15-octadecatrienoic acid (13*S*-HPOT) have been reported, including the observation that the stereoconfiguration of the reactant hydroperoxides is preserved in the product hydroxy fatty acid (4).

In this communication we not only confirm that the alkali-promoted hydroperoxide-to-hydroxide transformation proceeds without change of the stereoconfiguration, but also describe the isolation and structure determination of several novel oxylipins which are formed from fatty acid hydroperoxides in the presence of alkali. At least two of the novel compounds appear to be derived from an intermediate fatty acid, (9*Z*)-13-oxo-*trans*-11,12-epoxy-9-octadecenoic acid.

MATERIALS AND METHODS

13S-HPOD preparation. [1-^{14}C]- and [U-^{14}C]linoleic acids (Amersham, United Kingdom) were diluted with unlabeled linoleic acid (Nu-Chek-Prep, Elysian, MN) and purified by silicic acid chromatography. Labeled and unlabeled 13*S*-HPOD (chemical and radiochemical purity in excess of 95%) were prepared from the linoleic acid samples as described previously (5). For time-course experiments [1-^{14}C]-labeled 13*S*-HPOD was utilized (specific radioact., 1.9 kBq/μmol); [U-^{14}C]-labeled 13*S*-HPOD (specific radioactivity, 0.2 kBq/μmol) was used for product isolation.

Reactant conditions. ^{14}C-labeled 13*S*-HPOD (2.3 mM) was reacted in 5 N KOH (Elektrokemiska Aktiebolaget, Bohus, Sweden) at 35°C with periodic vigorous agitation. Products were recovered by rapid neutralization to pH 4.0 with 1 M oxalic acid (about 3 vol), and the fatty acids were immediately partitioned into $CHCl_3$ by addition of 3 vol of $CHCl_3/CH_3OH$ (2:1, vol/vol) based on the volume of the neutralized reaction mixture. The $CHCl_3$ layer was washed twice with H_2O, and the recovered product mixture was esterified with CH_2N_2 in diethyl ether/CH_3OH (9:1, vol/vol).

Chromatographic methods. The esterified products were preparatively separated into fractions by low-pressure liquid chromatography (LPLC). In a typical isolation, 98 mg of product was applied to a column (1.5 cm i.d.) packed with 9 g SilicAR CC4 (Mallinckrodt, Paris, KY) in hexane. Elution was sequentially done with 150 mL each of 3.5, 7.5 and 15% diethyl ether in hexane followed by 100 mL of diethyl ether. The eluent was collected in 30-mL fractions. The first 210 mL contained methyl (9*Z*)-13-oxo-*trans*-11,12-epoxy-9-octadecenoate, dimethyl 2-butyl-3,5-tetradecadienedioate, and some 13*S*-HPOD (methyl ester), and the fraction collected between 210 and 300 mL consisted mainly of 13*S*-HPOD (methyl ester) and small amounts of methyl (9*Z*)-13-oxo-*trans*-11,12-epoxy-9-octadecenoate and (13*S*,9*Z*,11*E*)-13-hydroxy-9,11-octadecadienoic acid (13*S*-HOD) as its methyl ester. Material eluting between 300 and 390 mL was comprised of 13*S*-HOD (methyl ester). Some 13*S*-HOD (methyl ester), other fatty ester dienols and dimethyl 2-butyl-4-hydroxy-5-tetradecenedioate were obtained in the final elution between 390 and 540 mL.

Thin-layer chromatography (TLC) was done on precoated plates (Kieselgel 60, 0.25 mm thickness) obtained

Abbreviations: GC/MS, gas chromatography/mass spectrometry; GLC, gas-liquid chromatography; 13*S*-HOD, (13*S*,9*Z*,11*E*)-13-hydroxy-9,11-octadecadienoic acid; 13*S*-HOT, (13*S*,9*Z*,11*E*,15*Z*)-13-hydroxy-9,11,15-octadecatrienoic acid; 13*S*-HPOD, (13*S*,9*Z*,11*E*)-13-hydroperoxy-9,11-octadecadienoic acid; 13*S*-HPOT, (13*S*,9*Z*,11*E*,15*Z*)-13-hydroperoxy-9,11,15-octadecatrienoic acid; IR, infrared; LPLC, low-pressure liquid chromatography; MC, (−)-menthoxycarbonyl derivative; NMR, nuclear magnetic resonance; OTMS (or TMSO), trimethylsilyloxy derivative; R_f, migration relative to the solvent front; TLC, thin-layer chromatography; TMS, trimethylsilyl cation; UV, ultraviolet.

from E. Merck (Darmstadt, Germany). Solvent A, comprised of hexane/ethyl acetate (4:1, vol/vol), was used for general separation of samples. Solvents B, C and D, hexane/ethyl acetate (85:15, vol/vol 93:7, vol/vol and 7:3, vol/vol, respectively), were utilized for additional purification of methyl (9*Z*)-13-oxo-*trans*-11,12-epoxy-9-octadecenoate (Solvent B, $R_f = 0.51$), dimethyl 2-butyl-3,5-tetradecadienedioate (Solvent C, $R_f = 0.33$), and dimethyl 2-butyl-4-hydroxy-5-tetradecenedioate (Solvent D, $R_f = 0.51$). Other TLC separations employed hexane/ethyl acetate (3:1, vol/vol, Solvent E), hexane/diethyl ether (3:2, vol/vol, Solvent F), hexane/acetone (7:1, vol/vol, Solvent G). Separated components were localized by spraying with aqueous 0.1% 8-anilino-1-naphthalenesulfonic acid (Na salt) from Aldrich Chemical (Milwaukee, WI) and viewing under ultraviolet (UV) light. Radioactivity on TLC plates was measured by a Berthold Dünnschichtscanner II (Wildbad, Germany) interfaced with a Macintosh SE/30 PC.

Spectral and instrumental analyses. Gas chromatography/mass spectrometry (GC/MS) was done with a Hewlett-Packard Model 5970B mass selective detector connected to a Hewlett-Packard Model 5890 gas chromatograph (Avondale, PA) equipped with a methyl silicone capillary column (length, 11 m; film thickness, 0.33 μm). Usually, the temperature was increased from 120 to 200°C at 10°C/min and then held isothermally at 200°C. For the derivative obtained by reaction of dimethyl 2-butyl-4-hydroxy-5-tetradecenedioate with $LiAlH_4$ followed with treatment by menthoxycarbonyl chloride, oxidative ozonolysis and methyl ester formation, the temperature was increased to 240°C and held.

Gas-liquid chromatography (GLC) of (−)-menthoxycarbonyl (MC) derivatives was done with a Hewlett-Packard Model 5890 gas chromatograph equipped with a methyl silicone capillary column (length, 25 m; film thickness, 0.33 μm); separation of methyl MC-2-hydroxyheptanoates required that the temperature was increased from 190 to 260°C at 2°C/min (*S*- and *R*-2-hydroxy-isomers eluted at 10.38 and 10.51 min, respectively). Dimethyl MC-malate derived from (13*S*,9*Z*,11*E*,15*Z*)-13-hydroxy-9,11,15-octadecatrienoic acid (13*S*-HOT) was separated by a DB-210 capillary column (length 15 m; film thickness, 0.25 μm; J & W Scientific, Folsom, CA) by temperature programming from 160 to 210°C at 2°C/min (*S*- and *R*-malate isomers eluted at 11.72 and 12.15 min, respectively). Infrared (IR) spectra were recorded with a Perkin-Elmer Model 257 IR spectrophotometer (Norwalk, CT), and UV spectra were obtained on a Hewlett-Packard Model 8450A UV/VIS spectrophotometer. Nuclear magnetic resonance (NMR) spectra were recorded on a Bruker Model WM-300 spectrometer (Karlsruhe, Germany) with samples dissolved in C^2HCl_3. Radioactivity was measured with a Packard Tricarb Model 4450 liquid scintillation counter (Downers Grove, IL).

Chemical methods. The stereochemistry of hydroxydiene and hydroxytriene fatty esters was determined by GLC separation of MC derivatives obtained after oxidative ozonolysis (6) using a recently modified procedure for analysis of dienols (7). Hydrogenation of samples dissolved in CH_3OH was completed under H_2 for 1 h with 5% Pd on $CaCO_3$.

Trimethylsilyloxy (OTMS) derivatives were prepared with trimethylchlorosilane/hexamethyldisilazane/pyridine (3:2:2, by vol). Methyl esters (0.5 mg) were transesterified with 50 μL of 0.17 M Na ethoxide overnight at 23°C, and the ethyl esters were recovered by $CHCl_3$ extraction after acidification. Epoxides (0.5 mg) dissolved in 1.5 mL H_2O/1,2-dimethoxyethane (2:1, vol/vol) were hydrolyzed by addition of 50 μL of 70% $HClO_4$ and incubation for 10 min at 23°C. Samples (1 mg or less) were reduced with 20 mg $LiAlH_4$ in 2 mL diethyl ether overnight at 23°C. Ketones (1 mg or less) were reduced with 5 mg NaB^2H_4 (Merck Sharp and Dohme, Montreal, Canada) in 1 mL CH_3OH for 30 min at 0°C.

RESULTS

Formation of the principal product, 13S-HOD. A 2.3 mM solution of ^{14}C-labeled 13*S*-HPOD in 5 N KOH was held at 35°C for several hours. Aliquots taken at various time points revealed that after acidification to pH 4, the ^{14}C-label was quantitatively extracted into $CHCl_3$ up to at least 2.5 h of reaction. Thereafter, there was a small decline of extractable label to 91% after 17 h of incubation.

As we previously reported (4), the principal product of the reaction was 13*S*-HOD. Although there were several minor products, 72–75% of the initial ^{14}C-label was recovered as 13*S*-HOD when the reaction was essentially complete after 4 h (Figs. 1 and 2). As seen in Figure 1, at least one of the minor products was transiently formed, and two others became more prominent later in the reaction.

We confirmed by spectral methods that the major product was 13*S*-HOD. The IR spectrum showed absorptions at 984 and 948 cm^{-1} consistent with the *E,Z*-configuration of a dienol (8). GC/MS of the OTMS-methyl ester revealed one major peak corresponding to the *E,Z*-dienol isomer containing a trace of the *E,E*-dienol. The main peak afforded a characteristic spectrum for this compound and localized the dienol moiety between C-9 and C-13 as follows: [*m/z* (percentage relative intensity, ion structure)] 382 (31, M^+); 367 (2, $[M - CH_3]^+$); 351 (2, $[M - CH_3O]^+$); 311 (59, $[M - CH_3(CH_2)_4]^+$; 225 (24, $[M - (CH_2)_7COOCH_3]^+$); 130 (58); 73 [100, trimethylsilyl cation (TMS)]. The 13-hydroxyl was localized by hydrogenation of 13*S*-HOD and GC/MS of the corresponding OTMS-methyl ester giving the following characteristic ions: 371 (3, $[M - CH_3]^+$); 355 (7, $[M - CH_3O]^+$); 339 (20, $[M - CH_3OH - CH_3]^+$); 315 (100, $[M - CH_3(CH_2)_4]^+$); 286 (18, $[M - CH_3(CH_2)_4CHO]^+$); 173 (90, $[M - (CH_2)_{11}COOCH_3]^+$); 73 (54, TMS).

It was previously shown by chiral-phase high-performance liquid chromatography that the stereoconfiguration of 13*S*-HPOD was conserved in the KOH reaction product, 13*S*-HOD (4). As shown in Table 1, we confirmed the previous result by an independent method employing GLC separation of MC derivatives (6,7). In addition, it was confirmed (Table 1) that 5 N KOH treatment of 13*S*-HPOT resulted in preservation of the stereoconfiguration of the corresponding product, 13*S*-HOT.

13*S*-HOD isolated from a reaction with KOH was reincubated with 5 N KOH for 4 h at 35°C, and the resulting material was examined by TLC as its methyl ester. One radio-labeled peak corresponding to 13*S*-HOD indicated that this compound is surprisingly stable to strong alkali treatment. Subsequent isolation of the methyl ester from

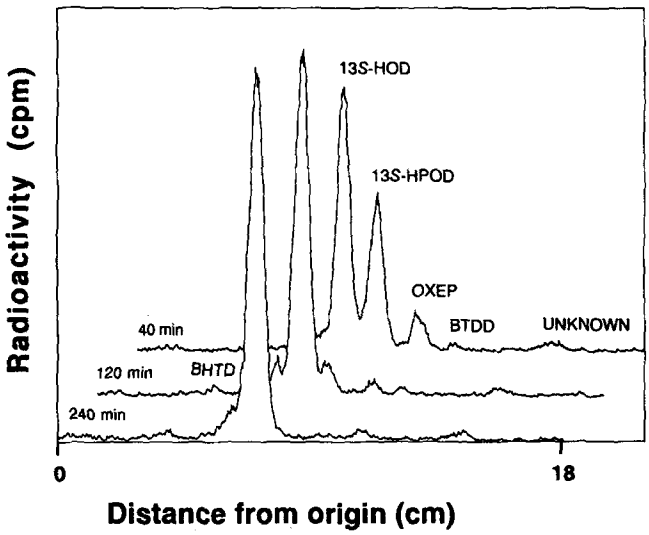

FIG. 1. Thin-layer chromatography (TLC) radiograms of products (as methyl esters) sampled at 40, 120 and 240 min from 5 N KOH treatment of 13*S*-HPOD at 35°C. TLC plates were developed with Solvent A, hexane/ethyl acetate (4:1, vol/vol). BHTD, 2-butyl-4-hydroxy-5-tetradecenedioic acid; BTDD, 2-butyl-3,5-tetradecadienedioic acid; 13*S*-HOD, (13*S*,9*Z*,11*E*)-13-hydroxy-9,11-octadecadienoic acid; 13*S*-HPOD, (13*S*,9*Z*,11*E*)-13-hydroperoxy-9,11-octadecadienoic acid; OXEP, (9*Z*)-13-oxo-*trans*-11,12-epoxy-9-octadecenoic acid.

TLC and GC/MS of the OTMS ether confirmed that 13*S*-HOD was unchanged.

Other significant products. The time course of appearance of three of the most significant of the minor products, analyzed as their methyl esters, is plotted in Figure 2. The most transient of these was (9*Z*)-13-oxo-*trans*-11,12-epoxy-9-octadecenoic acid which amounted to as much as 7% of the total products at its peak accumulation after 40 min. The two other products, 2-butyl-3,5-tetradecadienedioic acid and 2-butyl-4-hydroxy-5-tetradecenedioic acid, slowly accumulated for 4 h after which they reached a maximum of 2–3% of the total.

(9*Z*)-13-Oxo-*trans*-11,12-epoxy-9-octadecenoic acid, a novel product of 13*S*-HPOD, was isolated as its methyl ester by sequential LPLC and TLC. After a 40-min reaction of 13*S*-HPOD with 5 N KOH, a 6.6% yield was obtained (Table 2). Subsequently, the isolated methyl (9*Z*)-13-oxo-*trans*-11,12-epoxy-9-octadecenoate was subjected to spectral analyses. GC/MS afforded the mass spectrum shown in Figure 3, consistent with its proposed structure. An IR spectrum gave the following absorptions in wave number, intensity and assignment, respectively: 1743 cm^{-1}, strong, ester CO; 1714 cm^{-1}, medium, ketone CO; 880 cm^{-1}, weak, *trans*-epoxide; 835 cm^{-1}, weak, *cis*-epoxide. The ambiguity left in assigning the configuration of the epoxide based on the IR spectrum was clarified by the ^1H NMR spectrum which furnished a $J_{11,12}$ of 2.0 Hz, typical of *trans*-epoxides. Other ^1H NMR data are given as follows in chemical shifts, ppm and followed in parentheses by the number of protons, multiplicity, coupling constants and carbon assignments: 2.18 (2H, *m*, C-8); 5.79 (1H, *dt*, $J_{8,9} = 7.7$ Hz, $J_{9,10} = 10.9$ Hz, C-9); 5.03 (1H, *ddt*, $J_{9,10} = 10.9$ Hz, $J_{10,11} = 9.0$ Hz, $J_{8,10} = 1.4$ Hz, C-10); ~3.67 (partly obscured, apparent *dd*, C-11); 3.36 (1H, *d*,$J_{11,12} = 2.0$ Hz, C-12); 2.41 (2H, *m*, C-14); 3.66 (3H, *s*, ester methyl). The $J_{9,10} = 10.9$ Hz established that the 9,10-olefin had a *Z* configuration. The spin system was confirmed by correlative spectroscopy.

A number of derivatives of methyl (9*Z*)-13-oxo-*trans*-11,12-epoxy-9-octadecenoate were examined by GC/MS. The most informative of these were from (i) solvolysis of the epoxide, (ii) hydrogenation, and (iii) hydrogenation followed by NaB^2H_4 reduction of the C-13 ketone. First, methyl (9*Z*)-13-oxo-*trans*-11,12-epoxy-9-octadecenoate was treated by $HClO_4/H_2O$ to solvolyze the allylic epoxide. Two components were observed upon GC/MS analysis of the silylated solvolysis product. The early eluting peak accounted for about one-third of the total ion intensity

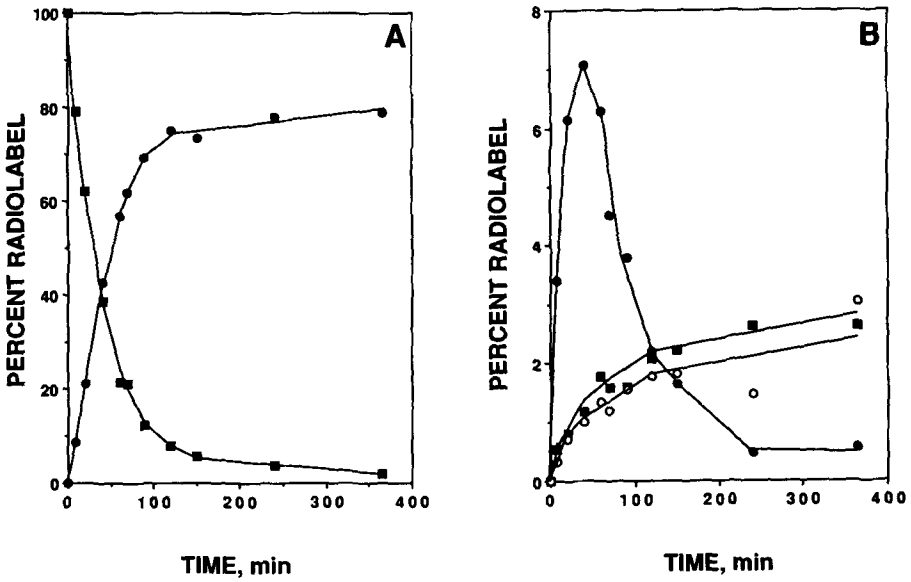

FIG. 2. Time course analysis of products from 5 N KOH treatment of 13*S*-HPOD at 35°C. TLC radiochromatograms of methyl esters were developed using Solvent A, and component peaks were integrated. [f]Product may have been obscured by close migration of a major component.

and was consistent with methyl 13-oxo-11,12-*bis*(trimethylsilyloxy)-9-octadecenoate as follows: 455 (2, $[M - CH_3O]^+$); 387 (1.5, $[M - CH_3(CH_2)_4CO]^+$); 285 (77, $^+CHOTMSCH{=}CH(CH_2)_7COOCH_3$); 274 (100 TMS + $^+CHOTMSCO(CH_2)_4CH_3$); 259 (7, 274 − CH_3); 129 (24); 99 (7, $^+CO(CH_2)_4CH_3$); 73 (72, TMS). The later-eluting peak accounting for two-thirds of the total ion intensity had ions consistent with methyl 13-oxo-9,12-*bis*(trimethylsilyloxy)-10-octadecenoate as follows: 455 (4, $[M - CH_3O]^+$); 387 (95, $[M - CH_3(CH_2)_4CO]^+$); 300 (27, TMS + $CH_3(CH_2)_4COCHOTMSCH{=}CH^+$); 297 (64, 387-TMSOH); 259 (8); 99 (10, $^+CO(CH_2)_4CH_3$); 73 (100, TMS). As expected, solvolysis of the allylic epoxide gave products that could be explained by formation of the C-11 carbocation. Delocalization of the carbocation caused hydroxyl substitution at both C-11 and C-9. Next, hydro-

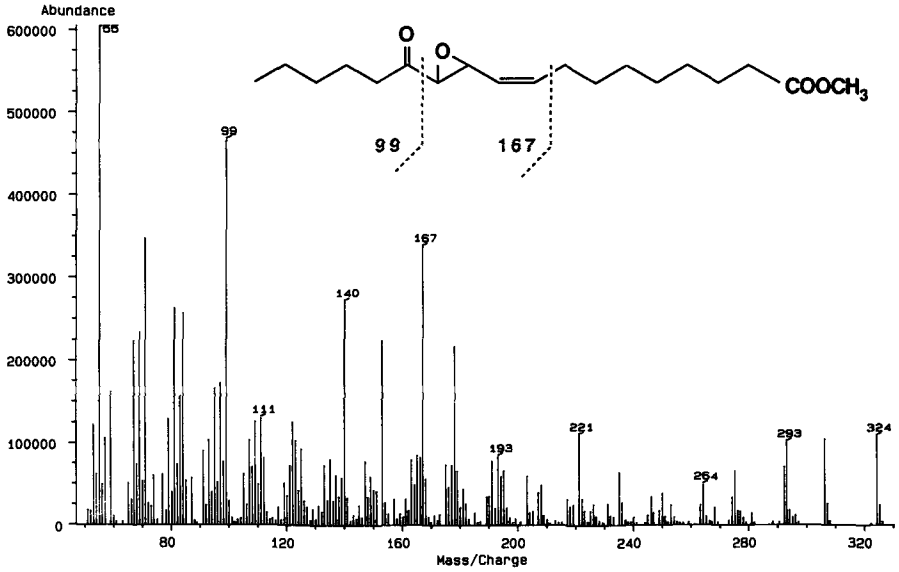

FIG. 3. Mass spectrum of methyl (9*Z*)-13-oxo-*trans*-11,12-epoxy-9-octadecenoate.

genation of methyl (9*Z*)-13-oxo-*trans*-11,12-epoxy-9-octadecenoate followed by OTMS derivatization afforded one GC/MS peak with ions indicative of methyl 13-oxo-12-trimethylsilyloxyoctadecanoate from hydrogenation of both the double bond and the allylic carbon at C-11 as follows: 385 (5, $[M - CH_3]^+$); 301 (100, $[M - CO(CH_2)_4CH_3]^+$); 73 (34, TMS). The C-13 ketone was localized by NaB^2H_4 reduction and OTMS derivatization of the hydrogenation product furnishing two separable isomers by GC/MS in approximately 3:2 ratio (presumably from *erythro* and *threo* diols). These two peaks gave essentially identical mass spectra; the first-eluting and largest of the two afforded the following ions: 444 (4, $[M - CH_3O]^+$); 374 (13); 301 (100, $^+CHOTMS(CH_2)_{10}COOCH_3$); 174 (51, $CH_3(CH_2)_4C^2HOTMS^+$); 73 (70, TMS). The *m/z* 174 ion showed that the ketone was located at C-13.

The (9*Z*)-13-oxo-*trans*-11,12-epoxy-9-octadecenoic acid structure was also proven by synthesis. Reaction of 13*S*-HPOD with vanadium oxyacetylacetonate followed by methyl ester formation afforded *erythro* and *threo* isomers of methyl (9*Z*)-13-hydroxy-*trans*-11,12-epoxy-9-octadecenoate as previously described (9). Reduction of methyl (9*Z*)-13-oxo-*trans*-11,12-epoxy-9-octadecenoate with $NaBH_4$ afforded two isomers that migrated at the same R_f with three different solvent systems (Solvents E–G) as the methyl esters of *erythro* and *threo* isomers synthesized by vanadium oxyacetylacetonate oxidation of 13*S*-HPOD. As estimated by spot intensity, $NaBH_4$ reduction of methyl (9*Z*)-13-oxo-*trans*-11,12-epoxy-9-octadecenoate resulted in the formation of *erythro/threo* isomeric ratio of about 3:1. Oxidation by CrO_3 of the vanadium oxyacetylacetonate synthesized isomers resulted in the formation of methyl (9*Z*)-13-oxo-*trans*-11,12-epoxy-9-octadecenoate that was identical to the KOH-produced compound as shown by its GC/MS, TLC, IR spectrum and ^1H NMR spectrum.

2-Butyl-3,5-tetradecadienedioic acid, another novel product of 13*S*-HPOD, was produced by reaction of 13*S*-HPOD for 4 h with 5 N KOH, and this compound was isolated as its dimethyl ester in 2.0% yield by LPLC followed by TLC (Table 2). Dimethyl 2-butyl-3,5-tetradecadienedioate was characterized by its GC/MS, UV spectrum and GC/MS of its derivatives. The GC/MS (Fig. 4) showed the molecular ion at *m/z* 338, a strong $[M - CH_3OH]^+$ ion indicative of methyl ester(s), an *m/z* ion at 274 indicative of the loss of two CH_3OH molecules and two ions at *m/z* 279 and 278 indicative of a labile carboxylic ester function, $[M - 59]^+$ and $[M - 60]^+$. The absence of carbonyl and hydroxyl groups was demonstrated by lack of change in the GC/MS after treatment with $NaBH_4$ and silylating reagent. That this product was a dimethyl dicarboxylate was shown by transesterification with Na ethoxide followed by GC/MS of the product. The molecular ion increased as expected to *m/z* 366, and strong ions (>50% relative intensity) were observed at *m/z* 321, 320 and 274 due to loss from M^+ of ethoxide radical, ethanol and two ethanols, respectively. $LiAlH_4$ reduction followed by formation of the OTMS derivative for GC/MS demonstrated that the dicarboxylate function was converted into two OTMS-substituted alcohols as indicated by the following mass spectrum: 426 (2, M^+); 411 (1, $[M - CH_3]^+$); 369 (1, $[M - CH_3(CH_2)_3]^+$); 336 (49, $[M - TMSOH]^+$); 323 (7); 147 (23); 103 (99, $^+CH_2OTMS$); 73 (100, TMS).

A conjugated diene moiety was indicated in the dimethyl 2-butyl-3,5-tetradecadienedioate structure by its UV spectrum which showed a smooth-featureless spectrum typical of conjugated dienes at λ_{max} 235 *nm* ($\varepsilon = 25{,}800$). The diene was also demonstrated by hydrogenation of dimethyl 2-butyl-3,5-tetradecadienedioate which also confirmed the position of the butyl group as follows: 311 (5, $[M - CH_3O]^+$); 286 (9, $[M - (CH_2)_3CH_3 + H]^+$); 283 (24, $[M - COOCH_3]^+$); 269 (9); 254 (23); 222 (8); 154 (18); 130 (100, $[M - (CH_2)_{11}COOCH_3 + H]^+$); 98 (63); 87 (83); 55 (68). The strong McLafferty rearrangement ions at *m/z* 286 and 130 placed the butyl group at C-2. Further confirmation of the structure, particularly of the McLafferty rearrangement ions, was obtained by transesterification of the hydrogenation product by Na ethoxide which gave the following ions: 370 (0.3, M^+);

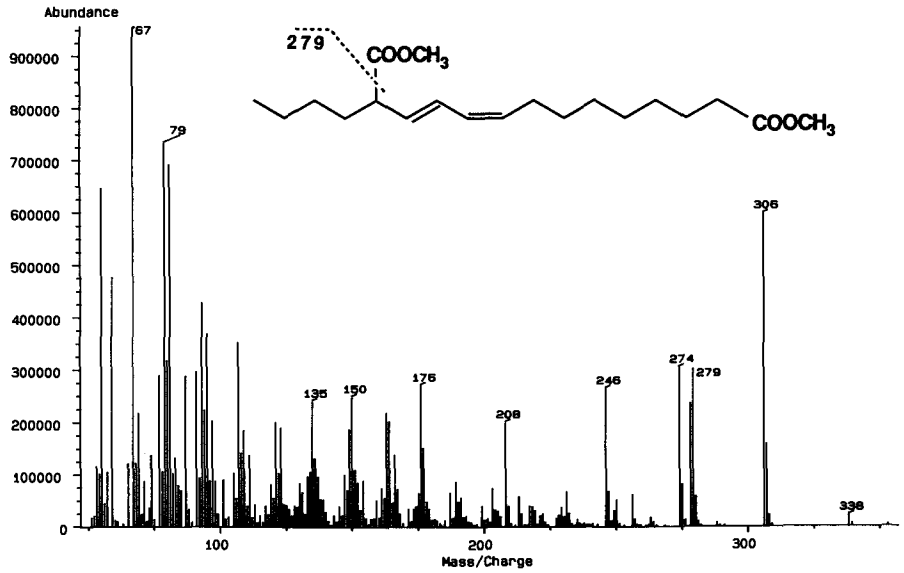

FIG. 4. Mass spectrum of dimethyl 2-butyl-3,5-tetradecadienedioate.

325 (11, $[M - CH_3CH_2O]^+$); 314 (12, $[M - (CH_2)_3CH_3 + H]^+$); 298 (12); 297 (56, $[M - COOCH_2CH_3]^+$); 283 (14); 268 (18); 227 (13, $^+(CH_2)_{11}COOCH_2CH_3$); 144 (100, $[M - (CH_2)_{11}COOCH_2CH_3 + H]^+$); 101 (70); 98 (59); 55 (65).

Dimethyl 2-butyl-3,5-tetradecadienedioate was subjected to ozonolysis, followed by $LiAlH_4$-reduction and formation of the OTMS ether. This treatment afforded two major peaks by GC/MS. The early eluting peak gave mass spectrum consistent with the *bis*-trimethylsilyloxy ether of 2-butyl-1,3-propanediol as follows: 261 (2, $[M - CH_3]^+$); 186 (17, $[M - TMSOH]^+$); 171 (39, $[M - TMSOH - CH_3]^+$); 147 (100, $TMSO^+=Si(CH_3)_2$); 143 (36); 133 (21); 129 (69); 103 (13, $^+CH_2OTMS$); 73 (90, TMS). The later eluting peak was identified as the *bis*-trimethylsilyloxy ether of 1,9-nonanediol from the following mass spectrum: 289 (1, $[M - CH_3]^+$); 214 (2, $[M - TMSOH]^+$); 199 (7, $[M - TMSOH - CH_3]^+$); 177 (10); 149 (36); 147 (89, $TMSO^+=Si(CH_3)_2$); 103 (33, $^+CH_2OTMS$); 83 (77); 75 (89); 73 (81, TMS); 69 (100); 55 (69). These fragmentation data placed the diene moiety of 2-butyl-3,5-tetradecadienedioic acid between C-3 and C-6. This result was confirmed by formation of a different derivative of the ozonolysis products; essentially, dimethyl 2-butyl-3,5-tetradecadienedioate was reduced by $LiAlH_4$, derivatized by MC chloride, ozonized and then methyl esterified for GC/MS (data not shown).

2-Butyl-4-hydroxy-5-tetradecenedioic acid, a third novel product of 13*S*-HPOD, was obtained by reaction of 13*S*-HPOD with 5 N KOH for 4 h. The compound was isolated as its dimethyl ester in 2.0% yield by LPLC followed by TLC purification (Table 2). Dimethyl 2-butyl-4-hydroxy-5-tetradecenedioate was characterized by GC/MS of its OTMS ether and other chemically transformed derivatives. As shown in Figure 5, the GC/MS of the dimethyl 2-butyl-4-hydroxy-5-tetradecenedioate OTMS ether afforded characteristic fragmentation ions of straightforward interpretation, but also the McLafferty rearrangement ion at *m/z* 130 $[129 + H]^+$ was observed. Rather strong ions at *m/z* 396 $[M - CH_3OH]^+$ and 369 $[M - COOCH_3]^+$ were also obtained.

$LiAlH_4$ reduction of dimethyl 2-butyl-4-hydroxy-5-tetradecenedioate followed by GC/MS of the OTMS ether furnished the following characteristic ions indicating the possibility of three OTMS ether moieties: 516 (0.1 M^+); 501 (0.2, $[M - CH_3]^+$); 426 (1, $[M - TMSOH]^+$); 413 (3, $[M - CH_2OTMS]^+$); 403 (4); 345 (4); 329 (100, $^+CHOTMSCH=CH(CH_2)_7CH_2OTMS$); 172 (19); 157 (13); 147 (14); 129 (24); 103 (10, $^+CH_2OTMS$); 73 (55, TMS). Further structural information was obtained by hydrogenation of dimethyl 2-butyl-4-hydroxy-5-tetradecenedioate followed by GC/MS of the OTMS ether. As can be seen by the following ions, the most prominent were from fragmentation vicinal to the C-11 OTMS ether: 415 (10, $[M - CH_3]^+$); 399 (9, $[M - CH_3O]^+$); 301 (25, $^+CH_2CHOTMS(CH_2)_9COOCH_3$); 287 (60, $^+CHOTMS(CH_2)_9COOCH_3$); 277 (12); 245 (100, $[M - (CH_2)_9COOCH_3]^+$); 185 (44, $^+(CH_2)_9COOCH_3$); 129 (12, $CH_3(CH_2)_3CH^+(COOCH_3)$); 127 (15); 73 (39, TMS).

Dimethyl 2-butyl-4-hydroxy-5-tetradecenedioate was reduced by $LiAlH_4$, converted into an MC derivative, subjected to oxidative ozonolysis, and then methyl esters were formed. One fragmentation product, the MC derivative of methyl 9-hydroxynonanoate (retention time of 11.9 min), was identified by its *m/z* of 339 (0.8, $[M - CH_3O]^+$) and 233 (18), the latter ion, $[M - 137]^+$, being a characteristic of MC derivatives. The other fragment, a *bis*-MC derivative $CH_3(CH_2)_3CH(CH_2OMC)CH_2CHOMCCOOCH_3$, separated as diastereomers at 27.8 and 28.4 min, and both peaks, as expected, gave a small ion at *m/z* 431 (0.4 and 1, $[M - 137]^+$) as well as an intense one at *m/z* 293 (40 and 41, $[M - 137 - 137]^+$). These data placed the double bond of 2-butyl-4-hydroxy-5-tetradecenedioic acid at Δ9.

It was envisioned that 2-butyl-4-hydroxy-5-tetradecenedioic acid or its dimethyl ester could be converted by 5 N KOH into 2-butyl-3,5-tetradecadienedioic acid *via* elimination of the 11-hydroxyl group. However, after a 4 h incubation of dimethyl 2-butyl-4-hydroxy-5-tetradecenedioate at 35°C in 5 N KOH and separation of the methyl esterified products by TLC using Solvent A, it was

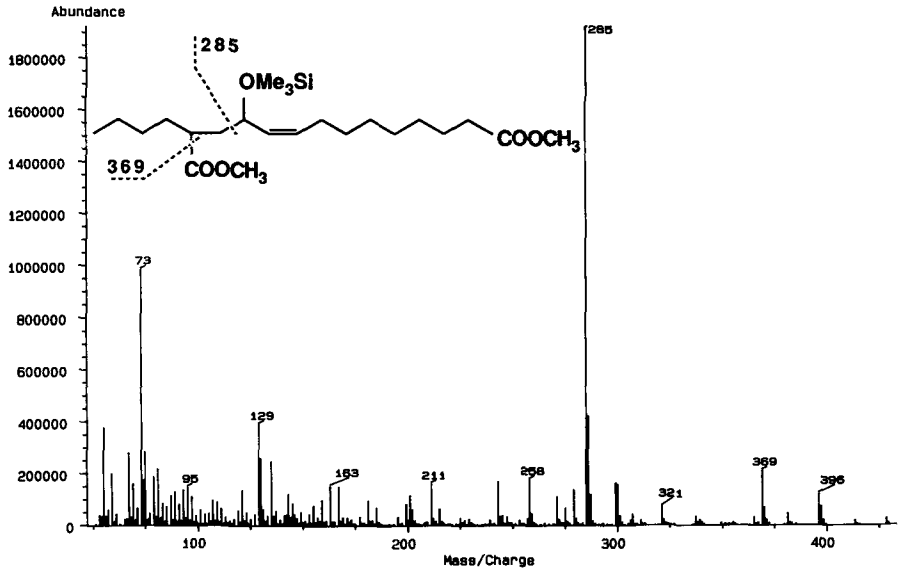

FIG. 5. Mass spectrum of dimethyl 2-butyl-4-hydroxy-5-tetradecenedioate, 11-trimethylsilyloxy ether.

determined that about two-thirds of dimethyl 2-butyl-4-hydroxy-5-tetradecenedioate ($R_f = 0.25$) was converted into a less polar product consistent with formation of a γ-lactone ($R_f = 0.48$). No evidence for dimethyl 2-butyl-3,5-tetradecadienedioate was found. That methyl 2-butyl-4-hydroxy-5-tetradecenedioate γ-lactone was the principal compound isolated from the incubation mixture was shown by GC/MS as follows: 324 (4, M^+); 306 (11, $[M - H_2O]^+$); 293 (18, $[M - CH_3O]^+$); 292 (48, $[M - CH_3OH]^+$); 278 (17); 265 (11); 264 (13); 208 (20); 167 (29, $[M - (CH_2)_7COOCH_3]^+$); 139 (30); 95 (39); 81 (48); 67 (65); 55 (100). The γ-lactone methyl ester was hydrogenated and examined by GC/MS giving the following diagnostic ions: 295 (39, $[M - CH_3O]^+$); 294 (25, $[M - CH_3OH]^+$); 280 (9); 270 (21, $[M - CH_3(CH_2)_3 + H]^+$, McLafferty rearrangement); 266 (10); 251 (13); 238 (14); 235 (15); 197 (19); 141 (100, $[M - (CH_2)_9COOCH_3]^+$); 98 (52); 95 (71); 69 (77); 55 (97). Methyl ester formation of the hydrogenated γ-lactone reaction mixture revealed that the main component was a hydrogenolysis product (from elimination of the 11-hydroxyl) which afforded a GC/MS virtually identical to that of hydrogenated dimethyl 2-butyl-3,5-tetradecadienedioate, that is, dimethyl 2-butyl-tetradecanedioate. Finally, isolated methyl 2-butyl-4-hydroxy-5-tetradecenedioate γ-lactone was reconverted to dimethyl 2-butyl-4-hydroxy-5-tetradecenedioate by treatment with 5 N KOH for 3.5 h at 35°C followed by reesterification. Conversion to the OTMS ether followed by GC/MS afforded virtually the same spectrum as shown in Figure 5. Also, evidence was obtained that a portion of 2-butyl-4-hydroxy-5-tetradecenedioic acid (free dioic acid) was partially converted into γ-lactone after normal work-up in the absence of KOH.

Conversion of the oxoepoxyoctadecenoic acid. About 175 μg methyl (9*Z*)-13-oxo-*trans*-11,12-epoxy-9-octadecenoate was treated with 1 mL 5 N KOH at 35°C taking aliquots at 30, 60, 120 and 240 min. Very little, if any, conversion of this compound occurred in the samples taken at early times. However, at 240 min, methyl (9*Z*)-13-oxo-*trans*-11,12-epoxy-9-octadecenoate was almost completely converted into roughly equivalent amounts of 2-butyl-3,5-tetradecadienedioic acid and 2-butyl-4-hydroxy-5-tetradecenedioic acid as determined by TLC of their dimethyl esters after treatment with diazomethane. The esters isolated from the TLC plates were examined by GC/MS (dimethyl 2-butyl-4-hydroxy-5-tetradecenedioate as the OTMS ether), and these spectra afforded data virtually identical to those compounds obtained directly from KOH treatment of 13*S*-HPOD.

The data shown in Figure 2 implies that in KOH-13*S*-HPOD reactions, the intermediate (9*Z*)-13-oxo-*trans*-11,12-epoxy-9-octadecenoic acid was converted into 2-butyl-3,5-tetradecadienedioic acid and 2-butyl-4-hydroxy-5-tetradecenedioic acid with greater ease than by the direct incubation of its methyl ester. This may be due to the insolubility of the methyl ester in aqueous KOH. Methyl esters are often remarkably resistant to saponification, because of the absence of a less polar solvent, like ethanol, to effect solvation.

Minor products. Other minor products were examined by GC/MS after TLC isolation from LPLC fractions (Table 2). These minor products were considerably different in both structure and polarity.

Of the minor products, mixed isomeric dienols other than 13*S*-HOD comprised about 2% of the total after 4 h reaction (Table 2), and these compounds were seen by TLC as a more polar shoulder of the main 13*S*-HOD peak (Fig. 1). As determined by GC/MS ion intensity, about half to less than half of this fraction was comprised of methyl (10*E*,12*Z*)-9-hydroxy-10,12-octadecadienoate (OTMS ether) judging from its retention time by GC/MS (11.8 min) and its mass spectrum: 382 (38, M^+); 311 (25); 225 (100). Since the minor isomer obtained by oxidation of linoleic acid by soybean lipoxygenase is (10*E*,12*Z*)-9-hydroperoxy-10,12-octadecadienoic acid (1-5%), the corresponding hydroxy fatty acid probably originated from the hydroperoxide present as a minor component in the 13*S*-HPOD used as a reactant. The next most abundant component

(ranging from about 25% to almost half of the dienols) proved to be an unusual product giving a retention time (9.8 min) and mass spectral data (as its methyl ester, OTMS ether) consistent with hydroxyheptadecadienoic acid with the dienol located between C-9 and C-13 as follows: 368 (40, M^+), 311 (36, $[M - CH_3(CH_2)_3]^+$); 211 (75, $[M - (CH_2)_7COOCH_3]^+$); 130 (33); 73 (100, TMS). Hydrogenation gave, not only a significant amount of its hydrogenolysis product, methyl heptadecanoate (data not shown), but a product shown by GC/MS of its OTMS ether to be methyl 11-hydroxyheptadecanoate as follows: 357 (3, $[M - CH_3]^+$); 341 (6, $[M - CH_3O]^+$); 325 (19, $[M - CH_3OH - CH_3]^+$); 287 (100, $[M - CH_3(CH_2)_5]^+$); 258 (13); 187 (71, $[M - (CH_2)_9COOCH_3]^+$); 73 (50, TMS). Therefore, the GC/MS data of both the hydrogenated and the unhydrogenated compound together showed that the product was 11-hydroxy-9,12-heptadecadienoic acid, a nonconjugated dienol. These data were consistent with the mass spectra of OTMS ethers of a similar nonconjugated dienol, methyl 11-hydroxy-9,12-octadecadienoate and its product of hydrogenation (10). The remainder of the dienols, methyl (*E,E*)-9- or (*E,E*)-13-hydroxyoctadecadienoates, were present in very minor amounts. Their mass spectra were similar to the corresponding (*E,Z*)-dienols with retention times of 12.8 and 13.2 min for the 9- and 13-OTMS ethers, respectively.

A minor product, isolated by TLC with the fraction containing dimethyl 2-butyl-4-hydroxy-5-tetradecenedioate, was identified as methyl 11-hydroxy-12,13-epoxy-9-octadecenoate by GC/MS of its OTMS ether. This compound, a commonly observed decomposition product of 13*S*-HPOD, eluted after 13.5 min, compared to 13.8 min for dimethyl 2-butyl-4-hydroxy-5-tetradecenedioate (OTMS ether), and gave a mass spectrum consistent with published data (5).

A number of minor polar compounds were present (Table 2). The weak TLC band immediately below dimethyl 2-butyl-4-hydroxy-5-tetradecenedioate ($R_f = 0.20$) appeared to be its isomer with a similar mass spectrum of its OTMS ether and with a slightly longer GC/MS retention time (14.4 min *vs.* 13.8 min for dimethyl 2-butyl-4-hydroxy-5-tetradecenedioate, OTMS ether). More polar than the aforementioned compound was a weak TLC band ($R_f = 0.15$) that appeared to be dimethyl 3-hydroxy-4-tridecenedioate by GC/MS of its OTMS ether (GC/MS retention time of 8.8 min) as follows: 358 (1, M^+); 343 (13, $[M - CH_3]^+$); 326 (4, $[M - CH_3OH]^+$); 311 (18, $[M - CH_3OH - CH_3]^+$; 298 (7); 285 (55, $[M - CH_2COOCH_3]^+$); 237 (19); 236 (15); 201 (31, $[M - (CH_2)_7COOCH_3]^+$); 135 (30); 89 (81); 73 (100, TMS). $LiAlH_4$ reduction of dimethyl 3-hydroxy-4-tridecenedioate followed by formation of the *tris*-OTMS ether gave the mass spectrum: 446 (0.3, M^+); 403 (5); 356 (6, $[M - TMSOH]^+$); 329 (100, $[M - (CH_2)_2$-OTMS$]^+$); 217 (13, $TMSO^+{=}CHCH{=}CHOTMS$); 155 (75); 147 (46, $TMSO^+{=}Si(CH_3)_2$); 129 (33); 103 (36, $^+CH_2OTMS$); 73 (95, TMS). The latter derivative was further hydrogenated and examined by GC/MS as the *tris*-OTMS ether affording diagnostic fragment ions as follows: 433 (5, $[M - CH_3]^+$); 331 (31, $[M - (CH_2)_2OTMS]^+$); 219 (89, $[M - (CH_2)_{10}OTMS]^+$); 177 (7); 147 (65, $TMSO^+{=}Si(CH_3)_2$); 103 (99, $^+CH_2OTMS$); 73 (100, TMS). The most polar of the TLC fractions obtained near the origin contained a small quantity of methyl trihydroxyoctadecenoate as identified by GC/MS of its *tris*-OTMS ether (data not shown) as well as other unidentified compounds.

Several minor products were isolated from TLC fractions less polar than 13*S*-HPOD (Table 2). One of these, methyl 13-oxo-9,11-octadecadienoate, was found as a minor component of fractions containing methyl (9*Z*)-13-oxo-*trans*-11,12-epoxy-9-octadecenoate and dimethyl 2-butyl-3,5-tetradecadienedioate, apparently migrating with intermediate or similar polarity to the former two compounds. The amount of ketodiene appeared to be variable in these fractions; the GC/MS peak(s) attributed to the ketodiene isomers were usually nearly absent but could occasionally amount to 25% of the total ion intensity. The ketodiene was identified by its characteristic *m/z* ions at 308, M^+, 277 $[M - CH_3O]^+$, 237 $[M - CH_3(CH_2)_4]^+$, and 151 $[M - (CH_2)_7COOCH_3]^+$.

The least polar compound migrating near the front in TLC (Fig. 1) could not be identified as it would not elute by GC/MS. Another minor component eluting between the unknown and dimethyl 2-butyl-3,5-tetradecadienedioate gave a mass spectrum consistent with methyl 13-methoxy-9,11-octadecadienoate, which undoubtedly originated as an artifact by etherification during the diazomethane treatment and/or the extraction using aqueous methanol.

A TLC fraction migrating immediately below the methyl (9*Z*)-13-oxo-*trans*-11,12-epoxy-9-octadecenoate fraction contained several short-chain compounds which had GC/MS retention times between 6 and 8 min. These compounds gave mass spectra consistent with dimethyl dienedioates of 10-, 12- and 13-carbon chain lengths (Table 2). These compounds were not examined further to confirm their putative structures.

DISCUSSION

It has been known for many years that organic hydroperoxides (1), including lipid hydroperoxides (2), are converted into the corresponding alcohols by alkali treatment. Recently, the alkali conversion of 13*S*-HPOD and 13*S*-HPOT has been studied in more detail revealing that the conversion resulted in retention of the stereochemistry of the reactant hydroperoxide (4). In this study we confirm that the stereoconfiguration is conserved by a completely independent method based on GLC separation of MC derivatives. We also show by GC/MS and IR spectra that the main product is identical to $NaBH_4$-reduced 13*S*-HPOD, that is, 13*S*-HOD. By the use of ^{14}C-tracer, it was found that the overall conversion of 13*S*-HPOD to 13*S*-HOD is close to 75%.

The origin of the remaining 25% of products was investigated. (9*Z*)-13-Oxo-*trans*-11,12-epoxy-9-octadecenoic acid was the most abundant of these by-products, but it was formed to a maximum of about 7% after a 40-min reaction. It was demonstrated that (9*Z*)-13-oxo-*trans*-11,12-epoxy-9-octadecenoic acid could be further converted into 2-butyl-3,5-tetradecadienedioic acid and 2-butyl-4-hydroxy-5-tetradecenedioic acid accounting for the transient appearance of the former. This latter transformation is fully consistent with the known Favorskii rearrangement (11,12), which proceeds through a cyclopropanone intermediate. In the base-catalyzed rearrangement of 2,3-epoxycyclohexanones, such as piperitone oxide and isophorone oxide, transformations occurred that

were analogous to those giving rise to 2-butyl-3,5-tetradecadienedioic acid, 2-butyl-4-hydroxy-5-tetradecenedioic acid, and the γ-lactone of the latter (12). In the previous study it was postulated that the γ-lactone eliminated to form the product analogous to 2-butyl-3,5-tetradecadienedioic acid (12); however, in the present work this conversion was not observed. The data are consistent with the formation of 2-butyl-3,5-tetradecadienedioic acid directly from the cyclopropanone intermediate. Thus, the formation of products can be largely explained as shown in Figure 6.

The γ-lactone of 2-butyl-4-hydroxy-5-tetradecenedioic acid (methyl ester) was only observed after dimethyl 2-butyl-4-hydroxy-5-tetradecenedioate was incubated with KOH; however, a small amount of the γ-lactone was detected after work-up of the free dioic acid. A minor amount of the γ-lactone could have escaped observation after incubation of 13*S*-HPOD with KOH, but it would not be expected to be formed in KOH solution. It is possible the formation of γ-lactone could have been favored by transesterification of the dimethyl ester in KOH.

Several of the other minor products could also originate from Favorskii rearrangement of (9*Z*)-13-oxo-*trans*-11,12-epoxy-9-octadecenoic acid. For example, 11-hydroxy-9,12-heptadecadienoic acid could arise from the cyclopropanone intermediate by elimination of the carbonyl group as CO_2 after oxidation. Previously, the decarbonylation of cyclopropanones into olefins has been observed to occur in the presence of basic H_2O_2 (13). Also, the lack of a 2-butyl group and one additional carbon is the only structural feature that distinguishes 3-hydroxy-4-tridecenedioic acid from 2-butyl-4-hydroxy-5-tetradecenedioic acid implying the elimination of the butyl group plus a carbonyl from the intermediate. Several other short-chain dioic acids could arise from the Favorskii rearrangement, but their mechanism of formation is less obvious.

The stability of 13*S*-HOD to exposure to 5 N KOH for rather long periods is remarkable, but even more surprising was the survival of the nonconjugated, double allylic hydroxy fatty acid, 11-hydroxy-9,12-heptadecadienoic acid, in alkali. Similar fatty acids are notably unstable to acid treatment, but are stable in the absence of acids (10).

The mechanism by which KOH replaces hydroperoxide with hydroxyl without affecting the stereochemistry should be considered. It seems unlikely that the mechanism would involve homolytic cleavage of the hydroperoxide oxygens as the alkoxyl radical derived from 13*S*-HPOD is known to largely rearrange into the 12,13-epoxyallylic radical which then combines with O_2 at C-9 and C-11 (14). 12,13-Epoxy-11-hydroxy-octadecenoic acid was found, but it was quantitatively insignificant. As suggested previously (3), one possibility is the nucleophilic displacement from the distal OH of the hydroperoxide by hydroxide anion affording 13*S*-HOD anion and H_2O_2; however, in this very alkaline medium one would surmise that the hydroperoxide group would exist principally as an anion which would repulse approach of the hydroxide anion. Perhaps this could explain why the KOH reaction is relatively slow when compared to a more rapid conversion of 13*S*-HPOD to the corresponding dienol by thiolate anion under mildly alkaline conditions (15). Previous work (4) showed total loss of peroxide oxygen when the conversion was complete after 3 h, but H_2O_2 may have a transient existence during the first 60–100 min of hydroperoxide decomposition by KOH. This H_2O_2 may be the active oxygen species responsible for formation of the epoxide group of (9*Z*)-13-oxo-*trans*-11,12-epoxy-9-octadecenoic acid.

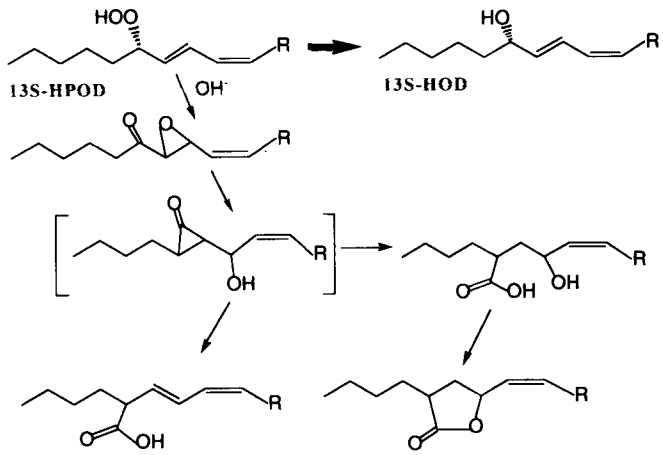

FIG. 6. Proposed pathway to 13*S*-HOD, as well as other products *via* Favorskii rearrangement; R = $-(CH_2)_7COOH$. The cyclopropanone fatty acid within brackets is proposed as an intermediate, but it was not directly observed. Abbreviations as in legend of Figure 1.

Peroxidation of egg yolk phosphatidylcholine (egg PC) liposomes was induced by addition of ascorbic acid (AsA) and Fe(II) in the presence of a trace of autoxidized egg PC (PC-OOH), but not in the absence of PC-OOH. PC-OOH was degraded upon addition of AsA and Fe(II) but not of either one alone. The results suggest that PC-OOH is necessary to initiate lipid peroxidation by AsA/Fe(II). AsA oxidation in the bulk water phase was also associated with an increase in lipid peroxidation by AsA/Fe(II) in the presence of PC-OOH, but not in the absence of PC-OOH. Furthermore, the spin probe 12-NS [12-(*N*-oxyl-4,4′-dimethyloxazolidin-2-yl)stearic acid], which labels the hydrophobic region of dimyristoyl phosphatidylcholine (DMPC) liposomal membranes, was degraded upon addition of AsA and Fe(II) in the presence of PC-OOH, but not in the absence of PC-OOH. These results indicate that the "induction message" that is associated with decreases of PC-OOH and AsA in the initiation step of lipid peroxidation must be transferred from the membrane surface to the inner hydrophobic membrane region. AsA in the bulk phase was oxidized faster and more extensively upon its addition together with Fe(II) to egg PC liposomes than to DMPC liposomes, though the initial content of PC-OOH in the former was 5–10 times lower than in the latter. This suggests that, in egg PC liposomes, the OOH-groups of new PC-OOH generated in the inner membrane regions must become accessible from the surface, enabling reaction with AsA/Fe(II) which in turn would result in an extensive decrease in AsA. By contrast, in DMPC liposomes, that do not generate PC-OOH, AsA is only oxidized slightly in connection with the degradation of the PC-OOH initially present. The effect of surface charges on the membrane surface was also studied to obtain further information on the initiation step of lipid peroxidation. The rate of lipid peroxidation by AsA/Fe(II) or Fe(III) decreased in the order, egg PC liposomes ≫ negatively charged egg PC liposomes containing dicetylphosphate > positively charged egg PC liposomes containing stearylamine. The rate of associated AsA oxidation was in the order, egg PC liposomes ≫ egg PC/stearylamine liposomes > egg PC/dicetylphosphate liposomes. However, in DMPC liposomes that do not generate PC-OOH, the rates of AsA oxidation associated with the reductive cleavage of PC-OOH by AsA/Fe(II) and coupled with the reduction of Fe(III) to Fe(II) were in the order, DMPC liposomes = DMPC/stearylamine liposomes ≫ DMPC/dicetylphosphate liposomes. These differences in the rates of lipid peroxidation, depending on differences in membrane charge, are discussed in relation to two properties of AsA: (i) its antioxidant property through trapping of lipid radicals and (ii) its prooxidant properties (a) by being an effective iron chelator thus altering the reactivity of iron with oxygen and peroxides and (b) by being an iron reductant and providing a source of Fe(II).

***Lipids* 28, 497–503 (1993).**

Lipid peroxidation has received much attention both as it relates to pathological events in biological systems and to food deterioration (1–5). Peroxidation usually proceeds by the following free-radical chain reactions:

$$LH \rightarrow L\cdot \quad \text{(initiation reactions)}$$

$$L\cdot + O_2 \rightarrow LOO\cdot \quad \text{(propagation reaction)}$$

$$LOO\cdot + LH \rightarrow LOOH + L\cdot \quad \text{(propagation reaction)}$$

where LOO· is the lipid peroxy radical and LOOH is the lipid hydroperoxide. Iron is supposed to be the catalyst of the initiation reaction. Iron and ascorbic acid (AsA) are well known to initiate lipid peroxidation, and indeed they are often used for this purpose in model experiments (6–9). However, it is unknown how these water-soluble substances can initiate the reactions occurring in the inner hydrophobic membrane core. Furthermore, AsA action appears to be a complex process as AsA can act on lipid oxidation both as prooxidant and antioxidant. Its antioxidant effect is supposed to scavenge lipid free radicals formed during lipid peroxidation. It is also not clear how water-soluble AsA can reduce radicals generated in the inner hydrophobic membrane core.

Recently, Thomas *et al.* (10) reported that the removal of LOOH from membranes by treatment with phospholipid hydroperoxide glutathione peroxidase effectively inhibited lipid peroxidation by xanthine-xanthine oxidase plus Fe(III) or AsA plus Fe(III). We (11) also observed that a trace of preformed LOOH played an important role in iron-induced lipid peroxidation and proposed a site-specific initiation mechanism in which the binding of iron to the membrane surface is a prerequisite for its reaction with the hydroperoxy group of LOOH. The alkoxyl radical (LO·) formed by a Fenton-like reaction [LOOH + Fe(II) → LO· + Fe(III) + OH^-] at the surface may penetrate into the hydrophobic region and trigger the initiation reaction:

$$LOOH + Fe(II) \rightarrow LO\cdot + Fe(III) + OH^-$$

$$LO\cdot + LH \rightarrow LOH + L\cdot \quad \text{(initiation reaction)}$$

In this paper, we report studies on the requirement of LOOH for initiation of lipid peroxidation induced by AsA and Fe(II) and discuss the dynamics of peroxidation of phospholipids in bilayer membranes.

Abbreviations: AsA, ascorbic acid; DMPC, dimyristoyl phosphatidylcholine; ESR, electron spin resonance; egg PC, egg yolk phosphatidylcholine; HEPES, 2-hydroxyethylpiperazine-*N*′-2-ethanesulfonic acid; HPLC, high-performance liquid chromatography; 12-NS, 12(*N*-oxyl-4,4′-dimethyloxazolidin-2-yl)stearic acid; MDA, malondialdehyde; PC-OOH, hydroperoxide of egg PC; TBA, thiobarbituric acid.

MATERIALS AND METHODS

Materials. Egg yolk phosphatidylcholine (egg PC) was obtained from Nippon Oil and Fats Co. (Tokyo, Japan). The preparation was contaminated with 3.8 μmol of hydroperoxide of egg PC (PC-OOH)/mmol egg PC, as determined iodometrically by the method of Buege and Aust (12). Dimyristoyl phosphatidylcholine (DMPC), *N*-2-hydroxyethylpiperazine-*N'*-ethanesulfonic acid (HEPES), dicetylphosphate, superoxide dismutase (from bovine erythrocytes) and catalase (from bovine liver) were purchased from Sigma Chemical Co. (St. Louis, MO). 12-(*N*-Oxyl-4,4'-dimethyloxazolidin-2-yl)stearic acid (12-NS) was from Aldrich Chemical Co. (Milwaukee, WI). α,α'-Dipyridyl and triphenylphosphine were obtained from Wako Pure Chemical Industries (Tokyo, Japan). Ascorbyl-6-palmitate, L-AsA, $FeSO_4$ and $FeNH_4(SO_4)_2$ were purchased from Nacalai Tesque (Kyoto, Japan). All other reagents were of analytical grade.

Preparation of hydroperoxides. PC-OOHs were prepared as described previously (13). Briefly, a sample of 100 mg of PC dissolved in 5 mL of methanol containing 0.1 mM methylene blue was shaken continuously under illumination from a 30-W tungsten projection lamp at room temperature for 12 h. The PC-OOH obtained was purified by high-performance liquid chromatography (HPLC) on a reverse-phase glass column (240 × 10 mm) prepacked with Lichloprep RP-8 (Merck, Darmstadt, Germany; silica gel powder binding octane, 40–63 mm size) using chloroform/methanol/water (1:10:0.5, by vol) as eluant. The PC-OOH obtained was a mixture of conjugated and non-conjugated isomers. The purity of the PC-OOH, as determined iodometrically (12), was 98.2 mol%.

Preparation of liposomes. Liposomes were prepared as described previously (7) with a minor modification. Stock solutions of egg PC and DMPC in chloroform with or without stearylamine or dicetylphosphate were evaporated under nitrogen. The thin lipid film was dispersed in 10 mM HEPES buffer, pH 7.0, and then subjected to ultrasonic irradiation in a Bransonic-12 sonic bath (Yamato, Tokyo, Japan) at 40°C. When necessary, egg PC was freed of contaminating PC-OOH by treatment with triphenylphosphine in chloroform (11) just before preparation of liposomes. Residual triphenylphosphine was not removed because PC-OOH was produced again during the processes of its removal and during liposome preparation. For preparation of 12-NS-labeled DMPC liposomes, a solution of 3.6 μmol of DMPC, 0.1 μmol of 12-NS and 0 or 0.4 μmol of PC-OOH in chloroform was evaporated under nitrogen, and the resulting film was dispersed in 1.0 mL of 10 mM HEPES buffer (pH 7.0) and sonicated (14).

Lipid peroxidation assay. Lipid peroxidation was measured by monitoring oxygen consumption with a Clark-type oxygen electrode as described previously (15). Oxygen consumption was calculated assuming an oxygen concentration of 217 nmol/mL in the initial incubation mixture at 37°C. Lipid peroxides formed during incubation were also measured by the thiobarbituric acid (TBA) method as described previously (7) and expressed as TBA-reactive substances as equivalents in nmol of malondialdehyde/μmol egg PC. The incubation conditions and the concentrations of constituents in reaction mixtures are given in the legends of the figures and tables.

Measurement of oxidation of ascorbic acid. Oxidation of AsA was measured at 37°C by monitoring the decrease in absorbance at 265 nm as described by Buettner (16). The molar absorption of AsA at pH 6.1 is reported to be 14,500 $M^{-1} \cdot cm^{-1}$ at 265 nm (16). The colorimetric method of Murata *et al.* (17) with slight modification was used to determine the concentration of AsA.

Electron spin resonance (ESR) measurement. 12-NS, an *N*-oxyl-4,4'-dimethyloxazolidine derivative of stearic acid, was used as a spin probe to label the hydrophobic region of liposomal membranes as described above. The reaction was started by addition of 5 μL of 20 mM AsA and then 5 μL of 2 mM $FeSO_4$ to 1 mL of 12-NS-labeled liposomes. After incubation at 25°C, the reaction mixture was transferred to a flat rectangular ESR cell. The ESR spectra of 12-NS were recorded under the following conditions (11): microwave power, 8 mW; magnetic field, 3374 G; scanning range, 25 G; modulation width, 1.0 G.

RESULTS

As shown in Figure 1, addition of AsA plus Fe(II) [AsA/Fe(II)] to liposomes prepared from egg PC contaminated with a trace of PC-OOH (0.38 mol%, measured before preparation of liposomes) induced lipid peroxidation (line 1). Lipid peroxidation induced by AsA/Fe(II) was slightly suppressed in liposomes prepared from egg PC pretreated with 5 μM triphenylphosphine (18) to reduce PC-OOH to the corresponding alcohol (PC-OH) (line 2), and was completely suppressed in liposomes prepared from egg PC pretreated with 8 μM triphenylphosphine (line 3). This suppression was reversed by addition of 3 μM PC-OOH to egg PC pretreated with 8 μM triphenylphosphine (line 4). Addition of ferrous ions alone did not promote lipid peroxidation (line 5), though a high concentration of ferrous ions induced slight peroxidation (line 6). TBA-reactive substances were also measured to confirm the formation of lipid peroxides (see legend to Fig. 1). The amounts of TBA-reactive substances formed and oxygen consumed (lines 1–5) were well correlated. Fenton reagent [Fe(II) and H_2O_2] did not induce peroxidation of egg PC. The addition of α-tocopherol, ascorbyl palmitate, a lipid-soluble analog of AsA, or a high concentration (>1 mM) of AsA completely inhibited oxygen consumption associated with lipid peroxidation by AsA/Fe(II), but superoxide dismutase, catalase or OH-radical scavengers such as thiourea and mannitol were not inhibitory (data not shown), as reported by Bachowski *et al.* (19).

We measured AsA oxidation associated with lipid peroxidation induced by AsA/Fe(II) in the presence and absence of PC-OOH. As shown in Figure 2 (line 1), AsA was rapidly oxidized upon its addition together with Fe(II) to egg PC liposomes not treated with triphenylphosphine, as measured by a decrease in absorbance at 265 nm (16). The ultraviolet-absorbance of AsA could not be measured in triphenylphosphine-treated egg PC liposomes, because triphenylphosphine has a strong absorbance at 265 nm. So oxidation of AsA in egg PC liposomes treated with triphenylphosphine to remove PC-OOH was measured colorimetrically with α,α-dipyridyl (17). Table 1 shows that AsA was not oxidized in egg PC liposomes from which PC-OOH had been removed by treatment with triphenylphosphine, but was oxidized extensively in egg PC liposomes not treated with triphenylphosphine. We compared

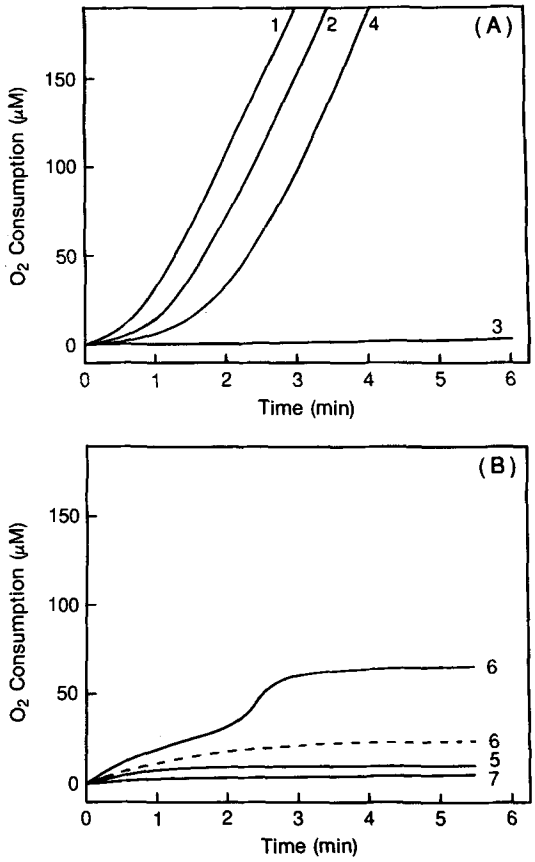

FIG. 1. Hydroperoxide of egg PC (PC-OOH)-dependent peroxidation in egg yolk phosphatidylcholine (egg PC) liposomes induced by ascorbic acid (AsA) and Fe(II), and its inhibition by antioxidants. Reaction 1—egg PC (not treated with triphenylphosphine, contaminated with 5–8 μM PC-OOH/mM egg PC), AsA and Fe(II); Reaction 2—egg PC (treated with 5 μM triphenylphosphine), AsA and Fe(II); Reaction 3—egg PC (treated with 8 μM triphenylphosphine), AsA and Fe(II); Reaction 4—egg PC (treated with 8 μM triphenylphosphine), PC-OOH (3 μM), AsA and Fe(II); Reaction 5—egg PC (not treated with triphenylphosphine) and Fe(II); Reaction 6—egg PC (not treated with triphenylphosphine) (continuous line) or dimyristoyl phosphatidylcholine (DMPC) (dotted line) and Fe(II) (110 μM) and Reaction 7—egg PC (not treated with triphenylphosphine), AsA, Fe(II) and α-tocopherol (6 μM) or ascorbyl palmitate (20 μM). The increases of thiobarbituric acid-reactive substances after incubation for 10 min were: Reaction 1—133.9, Reaction 2—128.4, Reaction 3—0.1, Reaction 4—120.0 and Reaction 5—6.6 nmol malondialdehyde/mL reaction mixture. The concentrations of reactants were 1 mM egg PC or DMPC, 100 μM AsA, 10 μM $FeSO_4$ and 10 mM 2-hydroxyethylpiperazine-*N*'-2-ethanesulfonic acid buffer (pH 7.0). Reactions were started by addition of $FeSO_4$ to the reaction mixtures at 37°C.

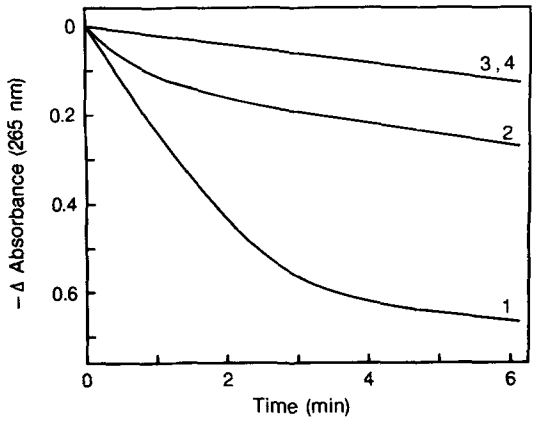

FIG. 2. Oxidation of ascorbic acid (AsA) in the presence of Fe(II) in egg yolk phosphatidylcholine (egg PC) and dimyristoyl phosphatidylcholine (DMPC) liposomes with and without hydroperoxide of egg PC (PC-OOH). Reaction 1—egg PC liposomes not treated with triphenylphosphine, Reaction 2—DMPC liposomes containing PC-OOH, Reaction 3—DMPC liposomes, Reaction 4—liposome-free system. Reaction mixtures contained 1 mM egg PC (contaminated with 5–8 μM PC-OOH) or DMPC with or without 50 μM PC-OOH, 100 μM AsA, 10 μM $FeSO_4$ and 10 mM 2-hydroxyethylpiperazine-*N*'-2-ethanesulfonic acid buffer (pH 7.0). Incubation conditions were as for Figure 1.

the oxidation rates of AsA in egg PC liposomes that generate lipid peroxides and in DMPC liposomes that do not. AsA was oxidized more rapidly upon addition of AsA/Fe(II) to egg PC liposomes contaminated with less than 10 μM PC-OOH than upon addition of AsA/Fe(II) to DMPC liposomes containing 50 μM PC-OOH. Moreover, oxidation of AsA was higher in DMPC liposomes with PC-OOH than in those without PC-OOH (Fig. 2 and Table 1).

Table 2 shows the effects of Fe(II), AsA, and of both on the degradation of PC-OOH in DMPC liposomes.

TABLE 1

Oxidation of AsA by Fe(II) in Liposomes with Different Charges with and without PC-OOH

Liposome system[a]	Decrease of AsA (μM/5 min)
DMPC (without PC-OOH)	6.6
DMPC (with 10 μM PC-OOH)	14.4
DMPC (with 50 μM PC-OOH)	25.0
Egg PC	50.1
Egg PC (with 0.2 mM dicetylphosphate)	7.5
Egg PC (with 0.2 mM stearylamine)	10.6
Egg PC (pretreated with 10 μM triphenylphosphine)	4.5

[a]System contained 1 mM dimyristoyl phosphatidylcholine (DMPC) or 1 mM egg yolk phosphatidylcholine (egg PC) with or without indicated additions or pretreatments, and 100 μM ascorbic acid (AsA), 10 μM $FeSO_4$ and 10 mM 2-hydroxyethylpiperazine-*N*'-2-ethanesulfonic acid buffer (pH 7.0). Reactions were carried out for 5 min at 37°C. Egg PC not treated with triphenylphosphine was contaminated with 0.38 mol% of hydroperoxide of egg PC (PC-OOH).

TABLE 2

Degradation of PC-OOH in DMPC Liposomes by AsA/Fe(II)

Incubation system[a]	Degradation of PC-OOH[b] (%)
AsA	4.9
Fe(II)	5.3
AsA/Fe(II)	60.5

[a]The concentration of hydroperoxide of egg yolk phosphatidylcholine (PC-OOH) was 100 μM. The concentrations of other reactants were as for Figure 2. Incubations were carried out at 37°C for 5 min. AsA, ascorbic acid.

[b]Degradation of PC-OOH was determined by high-performance liquid chromatography. DMPC, dimyristoyl phosphatidylcholine.

PC-OOH was degraded only in the presence of both AsA and Fe(II).

Next, we investigated how the prooxidant effect of water-soluble AsA/Fe(II) is transmitted to the hydrophobic initiation site of lipid peroxidation within the membrane. Labeled nitroxide radicals in liposomal (14) or micellar (11) lipid aggregates have been reported to be lost by reacting with radicals formed during membrane lipid peroxidation. The spectrum of 5-NS exhibits wide, highly anisotropic bands, whereas that of 12-NS shows a set of three symmetrical peaks (Fig. 3) indicating a higher fluidity of its environment deep within the membrane in which 12-NS is located. Table 3 shows the consumption of 12-NS, possibly due to reaction with radicals generated deep within the membrane. The ESR signals of 12-NS were decreased by AsA/Fe(II) in DMPC liposomes with PC-OOH, but not appreciably in those without PC-OOH. The addition of AsA or Fe(II) individually did not cause any decrease in the intensity of the ESR spectrum of 12-NS in DMPC liposomes containing PC-OOH (Table 3).

As shown above, PC-OOH was necessary to initiate lipid peroxidation by AsA/Fe(II). The hydroperoxy (OOH) group has been reported (20,21) to have a large dipole moment and thus to be likely to be close to the membrane surface where it can react with water-soluble AsA/Fe(II). Hence, we next investigated the effects of different surface charges of liposomes on lipid peroxidation by AsA/Fe(II) and the associated oxidation of AsA, degradation of PC-OOH and reduction of Fe(III) to Fe(II) by AsA.

Figure 4(A) shows that lipid peroxidation by AsA/Fe(II) was induced markedly in uncharged egg PC liposomes, weakly in negatively charged liposomes containing dicetylphosphate, and not appreciably in positively charged liposomes containing stearylamine. Addition of AsA plus Fe(III) also initiated lipid peroxidation, but AsA/Fe(III) had a lower initiation ability than AsA/Fe(II). The data in Figure 4B and Table 1 illustrate the oxidation of AsA associated with lipid peroxidation by AsA/Fe(II) in differently charged liposomes. AsA was oxidized rapidly in uncharged egg PC liposomes, but not oxidized appreciably

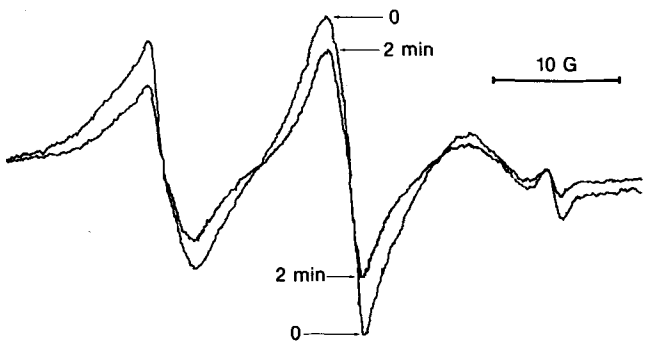

FIG. 3. Decrease of electron spin resonance signal of 12-(*N*-oxyl-4,4′dimethyloxazolidin-2-yl)stearic acid (12-NS) by ascorbic acid (AsA)/Fe(II) in dimyristoyl phosphatidylcholine (DMPC) liposomes with hydroperoxide of egg yolk phosphatidylcholine (PC-OOH). The figure shows the 12-NS spectra before and 2 min after addition of AsA and Fe(II) to DMPC liposomes containing PC-OOH (see also Table 3).

TABLE 3

Decrease of Electron Spin Resonance Signal of 12-NS by AsA/Fe(II) in DMPC Liposomes with or without PC-OOH (see Fig. 3)[a]

	Decrease of 12-NS signal (%)
PC-OOH + AsA/Fe(II)	28.4
PC-OOH + Fe(II)	3.8
PC-OOH + AsA	3.2
AsA/Fe(II)	6.6
Fe(II)	2.5
AsA	1.8

[a]The concentrations of reactants were 0.1 mM 12-(*N*-oxyl-4,4′-dimethyloxazolidin-2-yl)stearic acid (12-NS), 0.4 mM hydroperoxide of egg yolk phosphatidylcholine (PC-OOH), 3.6 mM dimyristoyl phosphatidylcholine (DMPC), 100 μM ascorbic acid (AsA) and 10 μM $FeSO_4$ in 10 mM 2-hydroxyethylpiperazine-*N*′-2-ethanesulfonic acid buffer (pH 7.0). Incubations were carried out for 2 min at 37°C.

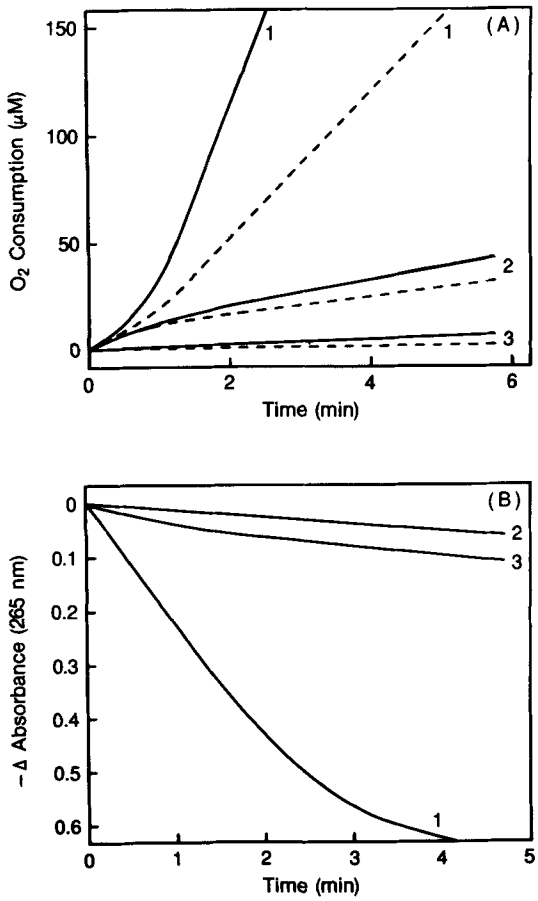

FIG. 4. (A) Lipid peroxidation by ascorbic acid (AsA) with Fe(II) or Fe(III) and (B) associated oxidation of AsA in uncharged egg yolk phosphatidylcholine (egg PC) liposomes, and liposomes negatively charged with dicetylphosphate, or positively charged with stearylamine. Reaction 1—egg PC liposomes, Reaction 2—egg PC/dicetylphosphate liposomes, Reaction 3—egg PC/stearylamine liposomes. The reaction mixtures contained 1 mM egg PC, 0.2 mM dicetylphosphate or stearylamine, 100 μM AsA, 10 μM $FeSO_4$ (solid lines) or $FeNH_4(SO_4)_2$ (dotted lines) and 10 mM 2-hydroxyethylpiperazine-*N*′-2-ethanesulfonic acid buffer (pH 7.0). Other experimental conditions were as for Figure 1.

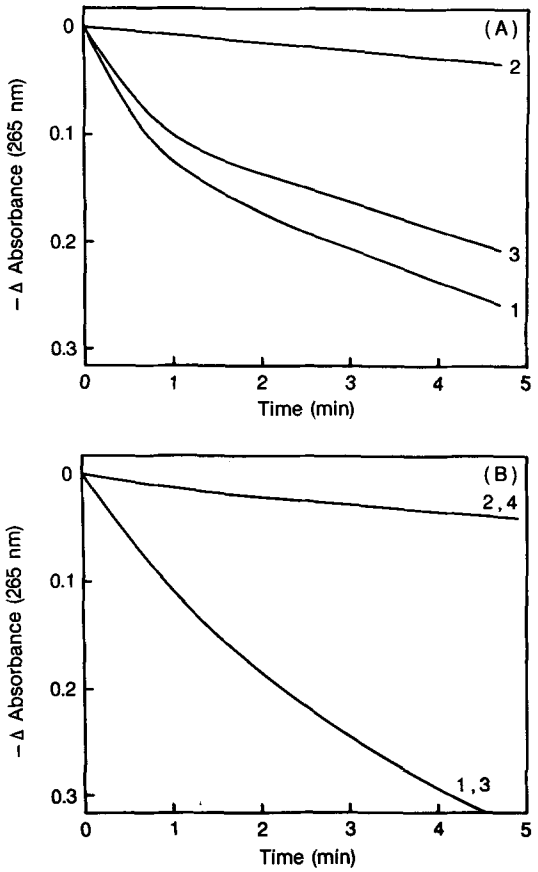

FIG. 5. Oxidation of ascorbic acid (AsA) (A) associated with reductive cleavage of hydroperoxide of egg PC (PC-OOH) by AsA/Fe(II) and (B) coupled with reduction of Fe(III) to Fe(II) in dimyristoyl phosphatidylcholine (DMPC) liposomes with and without dicetylphosphate or stearylamine. Reaction 1—DMPC liposomes, Reaction 2—DMPC/dicetylphosphate liposomes, Reaction 3—DMPC/stearylamine liposomes, Reaction 4—liposome-free system. The concentrations of PC-OOH were 50 and 0 μM in Experiments (A) and (B), respectively. The concentrations of other components were 1 mM DMPC, 0.2 mM dicetylphosphate or stearylamine, 100 μM AsA, 10 mM 2-hydroxyethylpiperazine-*N*'-2-ethanesulfonic acid buffer (pH 7.0) and 10 μM $FeSO_4$ (Experiment A) or 25 μM $FeNH_4(SO_4)_2$ (Experiment B). Incubation conditions were as for Figure 1.

in egg PC liposomes charged by stearylamine or dicetylphosphate.

Next we investigated the effect of membrane charge on the ability of AsA/Fe(II) to initiate lipid peroxidation by measuring the rate of AsA oxidation associated with PC-OOH cleavage. For study of the initiation step of lipid peroxidation only, we used DMPC liposomes to avoid complications from PC-OOH generation during incubation. We found that the oxidation rate of AsA in the reaction of AsA with PC-OOH in the presence of Fe(II) in DMPC liposomes was almost the same as in DMPC/stearylamine liposomes, but faster than in DMPC/dicetylphosphate liposomes (Fig. 5A). We also examined the effect of membrane charges on the reduction of Fe(III) to Fe(II) by AsA. The relative rates of AsA oxidation in the liposomes were also in the order, DMPC liposomes = DMPC/stearylamine liposomes ≫ DMPC/dicetylphosphate liposomes (Fig. 5B).

DISCUSSION

We found that AsA/Fe(II) induced lipid peroxidation in liposomes prepared from fresh egg PC that was contaminated with a trace of PC-OOH. However, addition of AsA/Fe(II) did not induce lipid peroxidation in liposomes prepared from egg PC after removal of contaminated PC-OOH by pretreatment with triphenylphosphine. Moreover, AsA was oxidized only slightly by Fe(II) in the system with liposomes prepared from DMPC or egg PC treated with triphenylphosphine, but was appreciably oxidized in the system with DMPC liposomes containing PC-OOH and was markedly oxidized in the system with liposomes of egg PC not treated with triphenylphosphine (Table 1 and Fig. 2). These results suggest that PC-OOH is necessary to initiate lipid peroxidation by AsA/Fe(II).

In systems without PC-OOH, AsA was autoxidized slightly but significantly (1.4 μM/min) (Fig. 2, lines 3 and 4) associated with a slight oxygen consumption (0.5 μM/min). Iron-catalyzed autoxidation of AsA in a system of this type is reported to give rise to $O_2^{\cdot-}$ and ·OH (22,23). However, addition of AsA plus Fe(II) did not initiate lipid peroxidation in the absence of PC-OOH (Fig. 1, line 3), indicating that ·OH and $O_2^{\cdot-}$ generated during autoxidation of AsA/Fe(II) are not involved in the process of lipid peroxidation. This was supported by the findings that superoxide dismutase, catalase and ·OH scavengers did not inhibit lipid peroxidation by AsA/Fe(II).

Addition of AsA/Fe(II) to DMPC liposomes containing PC-OOH resulted in a decrease in the intensity of the spectrum of 12-NS, a spin probe monitoring the inner hydrophobic membrane region. However, the intensity of the 12-NS spectrum decreased only slightly upon omission of AsA, Fe(II) or PC-OOH from this system (Table 3 and Fig. 3). These results indicate that the alkoxy radical (PC-O·) generated from PC-OOH near the membrane surface by a Fenton-like reaction triggers the hydrophobic initiation reaction of lipid peroxidation. Lipid peroxidation was induced by AsA/Fe(II) much faster in uncharged egg PC liposomes than in negatively charged egg PC/dicetylphosphate liposomes (Fig. 4), indicating that the cleavage of PC-OOH by a Fenton-like reaction is catalyzed by the weakly charged Fe(II)-AsA complex, not by positively charged free Fe(II).

From these results, we propose a possible site-specific mechanism of lipid peroxidation in liposomes induced by the addition of AsA and Fe(II) (Fig. 6, where PC is a phosphatidylcholine with unsaturated fatty acid, and PC· is phosphatidylcholine with a fatty acid radical). The OOH-group of PC-OOH may be cleaved near the membrane surface by the Fe(II)-AsA complex (Reaction 1), and the resulting PC-O· may penetrate into the hydrophobic region of the membranes (2 in Fig. 6) and react with the unsaturated moieties of fatty acids of egg PC (Reaction 3) resulting in a chain reaction (Reaction 4). We found that the oxidation rate was much greater upon addition of AsA/Fe(II) to egg PC liposomes containing less than 10 μM PC-OOH (not treated with triphenylphosphine) than upon addition to DMPC liposomes containing 50 μM PC-OOH (Fig. 2 and Table 1). These results indicate that a lipid hydroperoxide is generated by the radical chain reaction in the inner hydrophobic regions of egg PC membranes (Reactions 3 and 4), and the polar OOH-group of new PC-OOH then moves towards the surface (5 in Fig. 6)

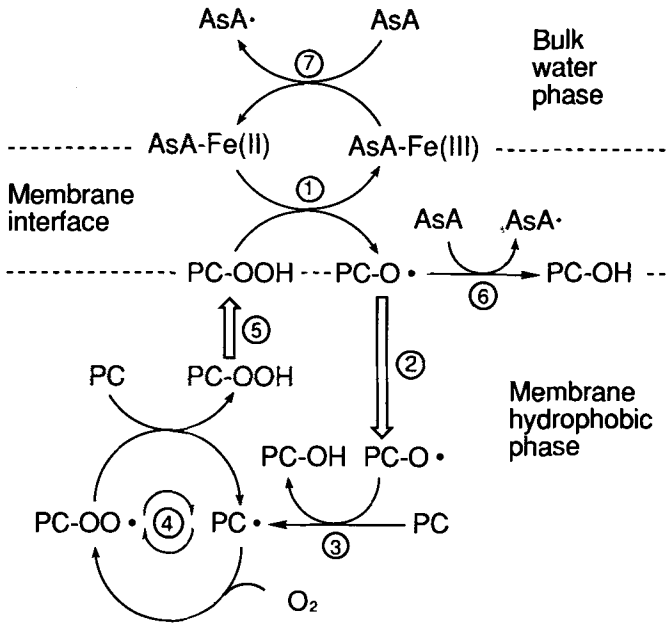

FIG. 6. Proposed mechanism of lipid peroxidation induced by ascorbic acid (AsA)/Fe(II) in liposomal membranes. PC-OOH, hydroperoxide of egg yolk phosphatidylcholine; AsA·, ascorbyl radical.

and reacts with the Fe(II)-AsA complex (Reaction 1). The resulting Fe(III) complex is then reduced by AsA to regenerate the Fe(II) complex (Reaction 7) resulting in further degradation of AsA.

Lipid peroxidation by AsA/Fe(II) was much slower in negatively charged liposomes containing dicetylphosphate than in uncharged liposomes (Fig. 4A, solid line 2). Moreover, we recently observed slow lipid peroxidation by AsA/Fe(II) in negatively charged egg PC liposomes containing phosphatidylserine (24). Slow oxidation of AsA associated with reductive cleavage of PC-OOH by AsA/Fe(II) (Figs. 4B and 5A, line 2) and with reduction of Fe(III) to Fe(II) (Fig. 5B, line 2) were also observed in dicetylphosphate-containing liposomes. A probable explanation for these findings is that positively charged Fe(II) or Fe(III) may interact with negatively charged dicetylphosphate and so react less with negatively charged AsA, thus reducing the formation of an AsA/Fe complex and initiation of lipid peroxidation.

By contrast, in positively charged liposomes containing stearylamine, the oxidation rates of AsA associated with reductive cleavage of PC-OOH by AsA/Fe(II) and coupled with reduction of Fe(III) to Fe(II) were high and almost the same as those in uncharged DMPC liposomes (Figs. 5A and B, line 3), but the rates of O_2 consumption associated with lipid peroxidation by AsA/Fe(II) and associated oxidation of AsA were much lower than those in uncharged egg PC liposomes (Figs. 4A and B, line 3). These results indicate that, in positively charged stearylamine liposomes, Reactions 1 and 2 both progress smoothly, but that the propagation step (Reaction 4) in lipid peroxidation does not progress, resulting in decreased formation of PC-OOH and consequently reduced oxidation of AsA (Reaction 1). Since negatively charged AsA was reported (25) to be present at the positively charged surface of egg PC/stearylamine liposomes and in the bulk water phase in uncharged egg PC or negatively charged egg PC/dicetylphosphate liposomes, it should effectively scavenge PC-O· (Reaction 6) at the membrane surface before the latter penetrates into the membrane resulting in a decrease in Reactions 3 and 4. Reaction 4 may also be reduced by scavenging of PC-OO· by AsA, because we recently observed that PC-OO· "floated up" from the hydrophobic region and was scavenged effectively by AsA at the surface of positively charged stearylamine liposomes but not of negatively charged dicetylphosphate liposomes. This idea is supported by the finding that ascorbyl palmitate, a lipid-soluble analog of AsA, strongly inhibited AsA/Fe(II)-induced lipid peroxidation in egg PC liposomes (Fig. 1), as its antioxidant polar group is located in the uncharged membrane surface (26).

Lipid peroxide and iron may play important roles in the initiation of lipid peroxidation *in vivo*. Recently, new types of antioxidants, such as a LOOH breakdown seleno compound (27) and an iron-inactivating chelator (28), were reported to prevent the pathological states induced by LOOH-linked and iron-dependent lipid peroxidation and free radical generation. The development of antioxidants other than radical scavenging types and studies on their effects seem important.

The time course of hydrolysis of a mixed phospholipid substrate containing bovine liver 1,2-diacyl-*sn*-glycero-3-phosphocholine (PC) and 1,2-diacyl-*sn*-glycero-3-phosphoethanolamine (PE) catalyzed by *Crotalus adamanteus* phospholipase A_2 was measured before and after peroxidation of the lipid substrate. The rate of hydrolysis was increased after peroxidation by an iron/adenosine diphosphate (ADP) system; the presence of iron/ADP in the assay had a minimal inhibitory effect. The rate of lipid hydrolysis was also increased after the substrate was peroxidized by heat and O_2. Similarly, peroxidation increased the rate of hydrolysis of soy PC liposomes that did not contain PE. In order to minimize interfacial factors that may result in an increase in rate, the lipids were solubilized in Triton X-100. In mixtures of Triton with soy PC in the absence of PE, peroxidation dramatically increased the rate of lipid hydrolysis. In addition, the rate of hydrolysis of the unoxidizable lipid 1-palmitoyl-2-[1-^{14}C]oleoyl PC incorporated into PC/PE liposomes was unaffected by peroxidation of the host lipid. These data are consistent with the notions that the increase in rate of hydrolysis of peroxidized PC substrates catalyzed by phospholipase A_2 is due largely to a preference for peroxidized phospholipid molecules as substrates and that peroxidation of host lipid does not significantly increase the rate of hydrolysis of nonoxidized lipids.
***Lipids* 28, 505–509 (1993).**

The activity of phospholipase A_2 is increased in a number of tissues subjected to free-radical damage as a consequence of oxidative stress. Phospholipase inhibitors, such as chlorpromazine (1,2), inhibit the loss of phospholipid which is associated with peroxidative damage in cells. Extensive hydrolysis of cell membrane or lipoprotein phospholipids in the absence of adequate means for repair may lead to serious adverse consequences. For example, peroxidation of low density lipoproteins (LDL) and the associated hydrolysis of LDL phospholipids may play a role in the development of atherosclerosis (3). In addition, the structural reorganization of cell membranes consequent to lipid peroxidation and phospholipid hydrolysis may lead to edema (4), cell death and myocardial injury. Products of phospholipid hydrolysis, such as lysophospholipids (5), may also disrupt normal regulatory mechanisms that depend upon maintenance of the integrity of cell membrane structure. Adverse consequences of fatty acid and lysophospholipid accumulation have been demonstrated in brain and cardiac tissue in which the detergent effects of these molecules alter membrane function (5). In addition, release of arachidonic acid may produce eicosanoids that alter cardiovascular function, and phospholipid degradation has been observed in ischemia-reperfusion injury (6). However, control of lysolipid concentrations in membranes may be regulated by deacylation and reacylation of lipids. Accumulation of low concentrations of lysolipids has been shown to lead to increases in membrane permeability (7), activation of membrane-bound enzymes (8) and the activation of macrophages (9).

Preferential hydrolysis of peroxidized lipids has been observed in isolated brain capillaries (10), hepatic lysosomes (11), mitochondria (12) and microsomes (13) and in purified lipid mixtures (14,15). The rate of hydrolysis of these peroxidized lipids by phospholipase A_2 is some 2–3 times the rate of that of the unoxidized lipids in lipid mixtures that have been systematically examined (14). A repair mechanism based on this preference for peroxidized lipids has been proposed by van Kuijk *et al.* (16). The hydrolysis of peroxidized lipids results in excision of the peroxidized fatty acyl chains which are reduced, repaired and reesterified. This proposal is supported by several reports that demonstrate that phospholipase A_2 activity is required to release peroxidized fatty acids for subsequent detoxification by glutathione peroxidase (7,8, 17,18).

It is also conceivable that peroxidized lipids may promote the hydrolysis of neighboring unoxidized lipids, locally altering the membrane structure and possibly leading to cellular degeneration. Such a mechanism would suppose that peroxidation results in physical alterations in the substrate structure that lead to an increased rate of hydrolysis of the unoxidized lipids. A possible structural relationship between peroxidized lipids and increased activity of phospholipase A_2 was suggested by experiments of Sevanian *et al.* (19) who correlated an increase in microviscosity of diphenylhexatriene in liposomes following peroxidation with an increase in enzyme activity. In addition, an increase in the susceptibility of the lipids to fusion was observed following peroxidation suggesting a decrease in the stability of the liposomes.

In order to explore mechanisms that might explain the increase in rate of hydrolysis of peroxidized phospholipids by phospholipase A_2, the effect of lipid peroxidation on the rate of lipolysis in detergent-dispersed lipid and of a nonoxidizable radiolabeled substrate incorporated into liposomes comprising a host peroxidizable lipid were measured. The addition of detergent is expected to minimize differences in the surface structure of the substrates that may be due to lipid peroxidation. The host lipid experiments were designed to test whether the rate of hydrolysis of an unoxidized lipid increases when the host lipid is peroxidized.

MATERIALS AND METHODS

Lipid vesicles. To prepare lipid vesicles, bovine liver 1,2-diacyl-*sn*-glycero-3-phosphocholine (PC; Type II-B, Sigma

*To whom correspondence should be addressed at Marion Merrell Dow Research Institute, 2110 East Galbraith Road, Cincinnati, OH 45215.

[1]Present address: Department of Biochemistry, The Medical College of Pennsylvania, 2900 Queen Lane, Philadelphia, PA 19129.

Abbreviations: ADP, adenosine diphosphate; LDL, low-density lipoproteins; PC, 1,2-diacyl-*sn*-glycero-3-phosphocholine; PE, 1,2-diacyl-*sn*-glycero-3-phosphoethanolamine; TBARS, thiobarbituric acid reactive substances.

Chemical Company, St. Louis, MO) or soy phosphatidylcholine (Type III-S; Sigma) and bovine liver 1,2-diacyl-*sn*-glycero-3-phosphoethanolamine (PE; Type VII; Sigma) were mixed in chloroform at a 4:1 molar ratio. In some experiments, 5 mole% 1-palmitoyl-2-oleoyl PC (Avanti Polar Lipids, Birmingham, AL) or a trace quantity (0.1 μCi/mL of liposomes) of 1-palmitoyl-2-[1-^{14}C]oleoyl PC (58.0 mCi/mmol; New England Nuclear, Boston, MA) was included. The organic solvent was first dried with N_2, then under vacuum. The lipids were dispersed in 0.1 M KCl, 10 mM Tris-HCl, pH 7.6 at a concentration of 2.5 mM by incubating at 37°C with occasional vortexing for 1 h. The resulting liposomes were sonicated to clarity [15 min at setting 4 with a Branson (Branson Ultrasonic, Danbury, CT) 350 Sonifier operating on a 50% duty cycle] on ice under an argon atmosphere. These clear vesicles were stored at room temperature overnight to anneal (20). To prepare Triton/phospholipid mixtures (21), liposomes were prepared as described above without sonication at a concentration of 2.5 mM in 0.1 M KCl, 10 mM Tris-HCl, pH 7.6 containing 10 mM Triton X-100 (Ultragrade, LKB, Stockholm, Sweden). In some experiments additional Triton X-100 was added. The lipids were then suspended in the detergent-containing buffer by vortexing for 10 min.

The vesicles were peroxidized by one of three methods: (i) *Peroxidation by iron/adenosine diphosphate (ADP).* Vesicles (2.5 mM) were mixed with a fresh solution of 1.2 mM ADP and 0.2 mM $FeSO_4$ in water to attain a final concentration of either 20 μM $FeSO_4$ and 120 μM ADP or 10 μM $FeSO_4$ and 60 μM ADP. The vesicles were then incubated at 37°C for 30 min under air. (ii) *Peroxidation by iron (II)/iron (III).* A solution of 10 mM $FeCl_3$ and 11 mM ethylenediaminetetraacetic acid prepared in N_2-purged water was added to the vesicles to attain a concentration of 0.1 mM $FeCl_3$. Then a fresh solution of $FeSO_4$ (1 mg/mL water) was added to attain a concentration of 0.1 mM. (iii) *Peroxidation by heat and oxygen.* Prior to swelling the lipids in buffer, the tubes were flushed with oxygen, capped and heated at 60°C for up to 4 h. These peroxidized samples were stored at −20°C for up to 24 h. Then, buffer was added to the lipids and vesicles were prepared as described above. Prior to phospholipase measurements, aliquots were taken for measurement of thiobarbituric acid reactive substances (TBARS).

The rate of hydrolysis of lipids catalyzed by phospholipase was measured directly following peroxidation by the pH-stat technique or by measurements of released [^{14}C]oleic acid as described in detail by McLean *et al.* (21). The vesicles were diluted after peroxidation to 0.5 mM in 5 mL of 0.5 mM bicine, 0.1 M KCl, 10 mM $CaCl_2$, pH 8.0. The assay temperature was 37°C. Hydrolysis was initiated by addition of 3 μL of a 0.3 mg/mL solution of *Crotalus admanteus* phospholipase A_2 (Sigma) in standard buffer without calcium.

TBARS were measured by addition of 0.5 mL of sample to 0.1 mL of butylated hydroxytoluene (2%), followed by 1.5 mL each of 20% trichloroacetic acid and 0.67% thiobarbituric acid/0.05 N NaOH. Reaction proceeded for 30 min at 100°C. The tubes were then cooled, centrifuged for 15 min at 3000 rpm and transferred to plastic semimicro cuvettes. The difference in absorbance at 532 nm and 580 nm (to correct for light scattering) was measured in a Beckman DU-7 spectrophotometer (Fullerton, CA). The TBARS were calculated in units of malondialdehyde equivalents using a molar extinction coefficient of 1.56×10^5 M^{-1} cm^{-1}.

RESULTS

Mixtures of PC and PE were chosen for evaluation of the effects of peroxidation on the rate of hydrolysis of phospholipids because of their abundance in biological membranes and the availability of previous data on similar mixtures (16). Unoxidized mixtures of bovine liver phosphatidylcholine (PC) and phosphatidylethanolamine (PE) are hydrolyzed at a relatively slow rate by *Crotalus adamanteus* phospholipase A_2 at 37°C (Fig. 1). The rate is increased dramatically after peroxidation with iron and ADP. Because iron and ADP were not removed prior to assay, it is possible that the iron/ADP mixture directly affects the enzyme. Addition of iron and ADP to the assay mixture at the concentration at which it is present in the peroxidized samples inhibits the rate of hydrolysis slightly, so that the increased rate of hydrolysis observed in Figure 1 is not the result of a direct interaction of the iron and ADP with the enzyme. In a second set of experiments, dry lipids were peroxidized by heat and oxygen, to eliminate the presence of peroxidizing agents during the assay. This resulted in a slightly lower TBARS than with iron peroxidation, but peroxidation of the lipids by heat and oxygen increases the rate of lipid hydrolysis (Fig. 2), and the rate of hydrolysis increases progressively with time of incubation under oxygen at elevated temperature. The rate of hydrolysis of mixed PC/PE liposomes also depends upon the extent of lipid peroxidation and peaks after a time that depends on the particular substrate and experimental conditions under which it is examined (data not shown). With 10 μM $FeSO_4$ and 60 μM ADP at 37°C, the maximal rate occurs when the TBARS

The rates of hydrolysis were measured by pH-stat (○) before incubation [thiobarbituric acid reactive substances (TBARS) of <0.2 nmol malondialdehyde (MDA)/μmole lipid]; (●) after incubation with 20 μM $FeSO_4$ and 120 μM ADP for 30 min at 37°C (TBARS of 7.9 ± 0.8 nmol MDA/μmole lipid); and (□) in the presence of 2 μM $FeSO_4$ and 12 μM ADP. Data are averages ± SEM of 3–4 experiments.

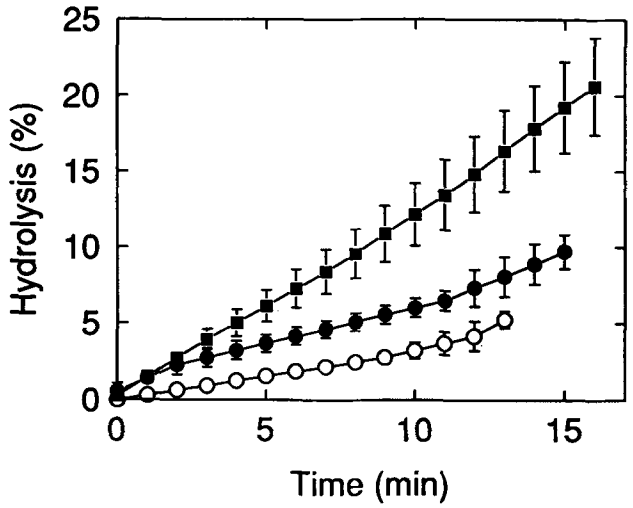

FIG. 2. Effect of incubation at elevated temperature under oxygen on the rate of hydrolysis of PC/PE vesicles by phospholipase A_2. Dry mixtures of PC/PE were incubated at 60°C for (○) 0 h (TBARS of <0.2 nmol MDA/μmole lipid), (●) 1 h (TBARS of 1.1 nmol MDA/μmole lipid) and (■) 4 h (TBARS of 2.1 nmol MDA/μmole lipid) prior to formation of vesicles and measurements of rates of hydrolysis. Abbreviations as in Figure 1.

reach ≈8 nmol/μmole lipid (Fig. 3). Further peroxidation of liposomal lipids as measured by TBARS formation results in slower rates of hydrolysis. Thus, the rate measured may depend critically on the extent of peroxidation. It is not possible to directly equate the TBARS results with the number of peroxidized lipid molecules.

One explanation for the increased rate of hydrolysis of peroxidized lipids in PC/PE mixtures is that the presence of the peroxidized lipids alters the structure of the vesicle in a manner that promotes interaction of the enzyme with substrate. One approach to test this hypothesis is to compare the rates of hydrolysis in the presence of a detergent which minimizes possible effects of substrate structure and physical form on the rates of hydrolysis. However, the presence of two types of phospholipids in the PC/PE mixture complicates interpretation of the data due to potential effects of the interface between the two lipids and the complications inherent in assessing experiments with more complex lipid mixtures. Thus, PC in the absence of PE was further investigated. Although more variability was observed in experiments with pure PC liposomes, the rate of hydrolysis of peroxidized PC liposomes exceeded that of the unoxidized liposomes (Fig. 4A) in a manner similar to that observed with the PC/PE mixtures. To minimize interfacial effects, samples were mixed with Triton X-100 at a molar ratio of 4:1 (Triton X-100 to lipid) and assayed. This addition of Triton to the peroxidized phospholipids resulted in a far more rapid rate of hydrolysis than with unoxidized PC mixtures. In the

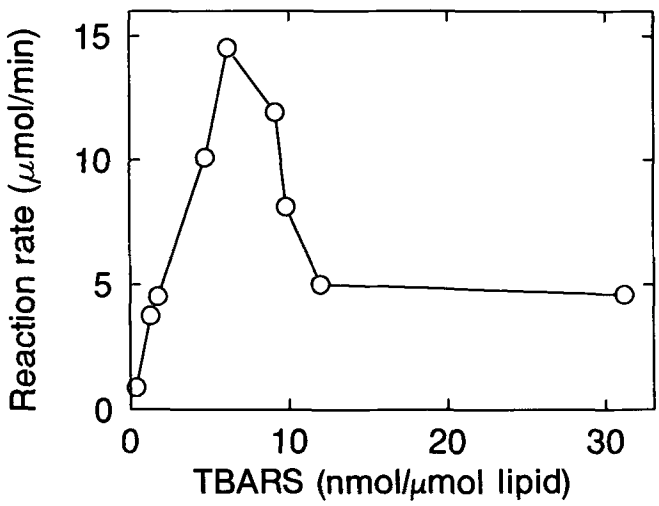

FIG. 3. Dependence of reaction rate on the extent of peroxidation as measured by TBARS. PC/PE (4:1) vesicles were peroxidized for various periods of time at 37°C with 10 μM $FeSO_4$ and 60 μM ADP. The rates were calculated from the initial linear portion of the kinetic course. Abbreviations as in Figure 1.

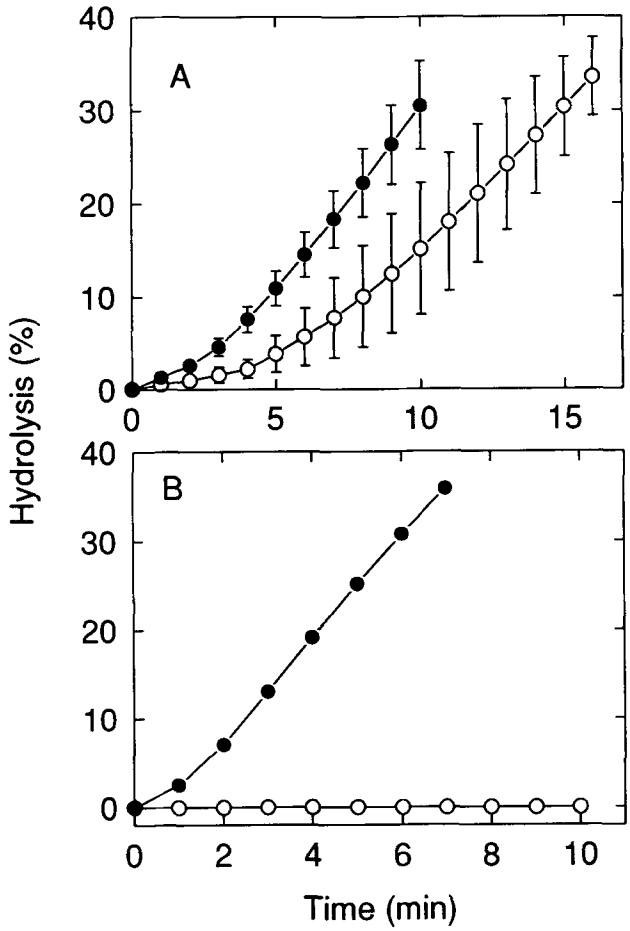

FIG. 4. Effect of peroxidation on hydrolysis of soy PC vesicles with and without Triton by phospholipase A_2. (A) Rates of hydrolysis of soy PC vesicles measured by pH-stat (○) before incubation (TBARS of 1.0 ± 0.1 nmol MDA/μmol lipid) and (●) after incubation with 100 μM Fe(II) and 100 μM Fe(III)/ethylenediaminetetraacetic acid for 30 min at 37°C (TBARS of 1.8 ± 0.2 nmol MDA/μmole lipid). Each curve is the average of two experiments. (B) Effect of peroxidation on rate of hydrolysis of soy PC in Triton X-100 micelles. Incubated (●) and unincubated (○) lipids from A were mixed with Triton X-100 (4:1 Triton/phospholipid mole/mole) and rates of hydrolysis were measured following addition of 3 μL (0.18 μg/mL) of enzyme. Abbreviations as in Figure 1.

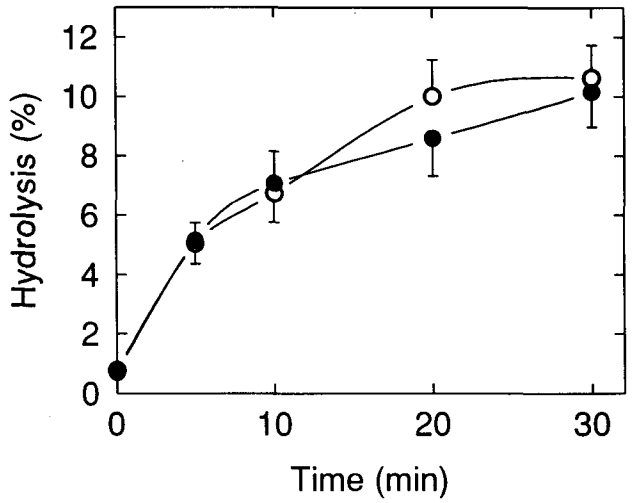

FIG. 5. Effect of peroxidation of host lipid on the rate of hydrolysis of 1-palmitoyl-2-[1-^{14}C]oleoyl PC by phospholipase A_2. PC/PE vesicles containing a trace amount of 1-palmitoyl-2-[1-^{14}C]oleoyl PC were peroxidized with iron/ADP as described in the legend to Figure 1. The rate of hydrolysis was measured by counting the released [^{14}C]oleic acid. (○) Unincubated vesicles (TBARS of 1.4 nmol MDA/μmol lipid), (●) incubated vesicles (TBARS of 8.7 nmol MDA/μmol lipid). Abbreviations as in Figure 1.

latter, no hydrolysis was measurable over a period of >60 min with a 4:1 ratio of Triton/PC (Fig. 4B). Higher ratios of Triton/PC were required to elicit measurable rates of hydrolysis in the unoxidized lipids, but peroxidized lipid/Triton mixtures were always more rapidly hydrolyzed (data not shown).

To test more directly whether peroxidation of the host lipid has any effect on the rate of hydrolysis of unoxidized lipids, the rate of hydrolysis of palmitoyl-[^{14}C]oleoyl PC in soy PC/soy PE vesicles before and after peroxidation was examined. Because palmitoyl-oleoyl PC is not readily peroxidized, it served as a marker for host lipid effects. The experiment described under Figure 1 was repeated with 1-palmitoyl-2-[1-^{14}C]oleoyl PC present in the liposomes, and the released fatty acids were assayed to determine the rate of hydrolysis of the radioactive palmitoyl-oleoyl PC tracer. In these experiments, peroxidation of the host lipid had no effect on the rate of hydrolysis of the palmitoyl-oleoyl PC (Fig. 5).

DISCUSSION

The present set of experiments demonstrates that peroxidation of mixed PC/PE vesicles by either iron/ADP or oxygen/heat results in a marked increase in the rate of phospholipase A_2-catalyzed hydrolysis that is not the result of a direct effect of peroxidizers on the enzyme. This supports the notion that phospholipase A_2 prefers peroxidized substrates (18,22). The dramatic increase in the overall rate of hydrolysis of PC/PE mixtures with peroxidation may be due to either a preference for phospholipid molecules with peroxidized acyl chains or a preference for structurally altered liposomes containing peroxidized lipids. It is difficult to distinguish between these two mechanisms in PC/PE mixtures because of potential differences in the rate of hydrolysis of the two components. The inability to make mechanistic conclusions with the mixed PC/PE mixture led us to study simple PC vesicles in more detail. To minimize interfacial interactions that may complicate interpretation of the effects of peroxidation of lipids on phospholipase activity, a detergent was included in some experiments. These experiments could not be interpreted at a molecular level with the PC/PE mixtures as addition of detergent may alter the substrate head-group preference of the enzyme (23,24).

In the simpler system containing PC in the absence of PE, the increase in rate of hydrolysis of lipids after peroxidation was relatively small. Addition of detergent increased the rate of hydrolysis of the lipids that had been incubated under peroxidizing conditions and reduced the rate of hydrolysis of unoxidized lipids. These data suggest that the peroxidized lipids are better substrates for the enzyme. An alternative explanation is that Triton enhances structural differences between the oxidized and peroxidized substrates. However, peroxidized lipids were still hydrolyzed more rapidly when the ratio of Triton to PC was increased. Consistent with this apparent substrate preference is the observation that the rate of hydrolysis of the nonoxidizable lipid, palmitoyl-[^{14}C]oleoyl PC, incorporated into a peroxidizable liposome was not influenced by peroxidation of host lipid.

These data suggest that in pure PC vesicles the primary effect of lipid peroxidation is to provide a phospholipid substrate with acyl chains that are preferentially hydrolyzed by the phospholipase. It does not appear that peroxidation of host lipid results in dramatic increases in the rate of hydrolysis of nonoxidized phospholipids. In terms of the proposed protective role of phospholipase A_2 in the repair of peroxidative membrane damage (16), the model provided by adding a trace of palmitoyl-oleoyl PC to peroxidizable lipids indicates that even in the case of transfer of nonoxidized lipids into regions of the membrane that have been damaged by peroxidation, the nonoxidized lipids may not be more rapidly hydrolyzed. However, the likelihood for peroxidation of lipid which diffuses into a region of peroxidized lipid is increased by its potential interaction with free radicals formed by peroxidative mechanisms at the site of injury. Such lipids would then be rapidly hydrolyzed in an attempt to minimize membrane damage.

No repair mechanism is available, to our knowledge, for the phospholipid hydrolysis associated with lipoproteins (25). We suggest that in cases of free-radical damage to lipoproteins or cells, in which the repair mechanism is unable to keep up with lipid hydrolysis, unchecked damage may occur that would lead to severe disruption of membrane or lipoprotein integrity and function. Part of this damage in LDL may be the result of transfer of liberated fatty acids from either the phospholipids or cholesteryl esters to amino groups on the surface of the lipoprotein (3). Recent experiments indicated that probucol prevents modification of the lipoprotein surface under conditions in which lipid peroxidation is observed, possibly by limiting transfer of fatty acids to the surface of the particle (26). These principles, when applied to the design of an antioxidant, suggest that one would need not only an effective free radical scavenger, but also a molecule that alters the structure of the membrane or lipoprotein surface in such a way that the transfer of nonoxidized lipids into the region of membrane peroxidative damage is limited. The possibility that other antioxidants may

exert their effects in a similar beneficial manner is currently under investigation.

Structure-Function Relationships of Alkyl-Lysophospholipid Analogs in Selective Antitumor Activity

William R. Vogler[a], Anita C. Olson[a], Joseph Hajdu[c], Mamoru Shoji[a], Robert Raynor[b] and J.F. Kuo[b]
[a]Department of Medicine, Leukemia Research Laboratory and [b]Department of Pharmacology, Emory University, Atlanta, Georgia 30322 and [c]California State University-Northridge, Northridge, California 91330

This investigation was initiated in order to delineate the structure-function relationship of the anticancer alkyl-lysophospholipids and assess their degree of selective cytotoxicity toward neoplastic cells. A series of glycerol phosphocholine analogs with varying substitutions in the *sn*-1 and *sn*-2 position were tested for their inhibitory activity as measured by thymidine incorporation, clonogenic assays and effects on protein kinase C activity against a series of human leukemic cell lines and healthy bone marrow progenitor cells. The IC_{50} was determined for each of the compounds in each cell line and healthy bone marrow cells following a 4-h incubation. The data indicated that a 16–18 carbon chain at the *sn*-1 coupled with a short substitution at *sn*-2 had the broadest antitumor activity and was the least toxic to normal bone marrow cells. The results provide a number of useful leads toward the design and development of potentially more active phospholipid compounds.
Lipids 28, 511–516 (1993).

Since the discovery by Munder *et al.* (1) that synthetic analogs of naturally occurring lysophosphatidylcholine (LPC) had antitumor activity, considerable interest has focused on this new family of compounds which mediate their effects through cell surface events. Andreesen *et al.* (2), Modolell *et al.* (3) and others (4,5) stressed the selective cytotoxicity aspects. We have shown that there is a selective cytotoxic effect of synthetic alkyl-lysophospholipids (ALP) on neoplastic tissues and a sparing of normal marrow progenitor cells (NMPC) (6,7), and have begun clinical studies using one of these compounds as an *in vitro* purging agent to eliminate any residual leukemic cells from marrow obtained from patients in remission prior to autologous bone marrow transplantation (8).

A series of analogs have been synthesized, and from earlier studies it is evident that specific structural configurations are important for antitumor activity. Munder *et al.* (9) found that longer hydrocarbon chains (18 carbons) were more active than shorter (12 carbon) chains. Andreesen *et al.* (2) reported that an ether linkage of the aliphatic side chain in *sn*-1 of the glycerol molecule and substitution of the hydroxy group in the *sn*-2 position were essential for antitumor activity. Stereoisomers were also active, and greater growth inhibition was observed with choline phospholipid analogs than the ethanolamine phospholipid analogs (10). Replacement of oxygen with sulfur in *sn*-1 has yielded essentially an equally active product (11,12).

Abbreviations: ALP, alkyl-lysophospholipid; BCS, bovine calf serum; BFU-E, erythroid bursts; CFU-E, erythroid colonies; ET-18-OCH_3, 1-*O*-octadecyl-2-*O*-methyl-*rac*-glycero-3-phosphocholine; GEMM, mixed colonies; GM-CFU, granulocyte-macrophage colonies; LP, lysophosphatidylcholine; NMPC, normal marrow progenitor cells; PHA-LCM, phytohemagglutinin-lymphocyte conditioned medium; PKC, protein kinase C.

The mechanism of action of ALP is not completely understood. The site of action appears to be the cell membrane. Evidence for this is the membrane damage seen with electron microscopy (13), inhibition of phosphatidylcholine synthesis (14), inhibition of protein kinase C (PKC) activity (15) and inhibition of Na, K-ATPase activity (16). In addition, DNA synthesis is indirectly inhibited (17). It is not known whether or not this is a direct effect or a result of cell surface modification induced by these compounds. Furthermore, it is not clear how these compounds are relatively selectively toxic to neoplastic tissues and spare healthy cells. It has been assumed that healthy cells are capable of metabolizing the compound, whereas neoplastic cells are not. It has been shown that healthy tissues contain an enzyme which cleaves the alkyl group in the *sn*-1 position, and tumor tissues lack this cleavage enzyme (18–20). However, one of the most active compounds, 1-*O*-octadecyl-2-*O*-methyl-*rac*-glycero-3-phosphocholine (ET-18-OCH_3) is not a substrate for the cleavage enzyme (21,22).

In order to gain further insight into structure-function relationships, we have tested a series of glycerophospholipid analogs for cytotoxicity against leukemic cell lines, effects on PKC activity and DNA synthesis. We chose a 4-h incubation time as preliminary studies with ET-18-OCH_3 indicated an anti-leukemic effect on the clonogenicity and thymidine incorporation of fresh leukemic cells, with little activity against clonogenic bone marrow cells. In addition, such a time interval would serve as practical methods for a clinical marrow purging procedure.

MATERIALS AND METHODS

Compounds. Figure 1 lists the compounds tested. Compounds A (ET-18-OCH_3) and L (BM 41.440, Boehringer Mannheim, Mannheim, Germany) were obtained from Dr. Wolfgang Berdel (Freie Universität Berlin, Berlin, Germany). The other compounds were synthesized by one of us (J.H.) as described previously (23,24). Synthesis of compounds C, D, G_1 and G_2 will be reported separately. All compounds were fully characterized, including satisfactory elemental analyses (within 0.3% of the calculated values). The compounds were stored at −20°C. Prior to testing for their cellular effects, stock solutions were prepared by dissolving the compounds in the appropriate medium, usually RPMI 1640, at a concentration of 1 mg/mL. The solutions could be frozen without loss of activity.

Human cell lines. The myeloid leukemic cell line HL60 was obtained from Dr. Robert Gallo (NIH, Bethesda, MD) (25); K562 was obtained from Bismark Lozzio (University of Tennessee, Knoxville, TN) (26); B-cell leukemic cell lines, Daudi and U-937 (human histiocytic lymphoma) with monocyte-like characteristics were obtained from American Type Culture Collection (Rockville, MD) (27). Cells were continuously cultured in RPMI 1640 medium and 10% bovine calf serum (BCS) (Hyclone, Logan, UT). Studies were conducted with cells during log-phase growth.

FIG. 1. Structure of alkyl-lysophospholipid analogs. R_1 substitutions have either oxygen or sulfur linked to a 16 or 18 carbon chain. R_2 substitutions include methoxy (compounds A & I) acetamide (B, H & K), methoxycarbonylamino group (C), methansulfonamide group (D), a carbonyl group with a long carbon chain (E), 2-deoxy analogs (G_1 & G_2), which are chiral, G_1 is the *sn*-3 phosphocholine derivative and G_2 is the *sn*-1 phosphocholine, a thiomethyl group (J), methoxymethyl (L) and trifluoroacetyl group (N).

NMPC. Cells were obtained from donors for allogeneic bone marrow transplants (having given informed consent) by aspirate from posterior iliac crests or from bone marrow fragments following orthopedic procedures. Mononuclear cells were separated by Ficoll-Hypaque (Histopaque-1077, Sigma Chemical Co., St. Louis, MO) and the interphase cells were used in the assay.

Cytotoxicity assays. Varying concentrations of the compounds were incubated with 1×10^6 cells in 1 mL in RPMI 1640, 10% BCS (except for NMPC, where 10% fetal bovine serum, FBS, with 2×10^6 cells is used), 1% PS antibiotic mixture and 1% glutamine (Gibco, Grand Island, NY) (RPMI-C) at 37°C for 4 h. Following incubation, the cell line cells were diluted with RPMI-C to provide a suitable plating cell number and thereby diluting the drug at least 250-fold. For NMPC, the drug was effectively diluted by adding 4 mL of RPMI-C, pelleting, removing 4.8 mL media and resuspending to 1×10^6/mL with RPMI-C. Viability was determined by trypan blue dye exclusion at the end of the 4-h incubation.

Tritiated thymidine incorporation. For this assay, 4×10^5 cells in 200 μL of medium containing 10% BCS were incubated in triplicate with 0.4 μCi of methyl-[^{3}H]thymidine (spec. act. 80–90 Ci/mmol) for 1 h in 5% CO_2 at 37°C. Following incubation, the cells were harvested in a cell harvester (Brandel, Gaithersburg, MD), dried, scintillation fluid was added and the mixture was counted in a scintillation counter (17). The results were expressed as cpm/4×10^5 cells.

Clonogenic assays of leukemic cells. Assays for the clonogenic potential of the leukemic cell lines were carried out as previously described (7). Briefly, 500 cells (or 333 for K562) in RPMI-C were plated in triplicate in alpha MEM medium containing 0.8% methylcellulose, 30% BCS, 0.3% bovine serum albumin, 5×10^{-5}M mercaptoethanol and 5.6×10^{-8}M selenium. The plates were incubated in moist 5% CO_2 at 37°C for 7–14 d and colonies (>40 cells) scored.

Clonogenic assays for NMPC. Progenitor cells were assayed in triplicate by a modification of the method of Fauser and Messner (28) as previously described (7). Briefly, culture conditions were similar to the clonogenic assay for leukemic cells with the exception that both phytohemagglutinin stimulated lymphocyte conditioned media (PHA-LCMK) and human placental conditioned medium and 1 unit/mL erythropoietin (Step III Connaught Laboratories, Willowdale, Ontario, Canada) were added. Later, NMPC assays were done with 1% methylcellulose in Iscove's modified Dulbecco's medium, 30% FBS, 5×10^{-5}M mercaptoethanol, 5% PHA-LCM and 2 units/mL Epotin Alpha (Amgen, Inc., Thousand Oaks, CA) with comparable results. The plates were scored on day 14. The total number of progenitors was defined as the sum of mixed colonies (GEMM), erythroid colonies (CFU-E), erythroid bursts (BFU-E), granulocyte-macrophage colonies (GM-CFU) (>40 cells) and GM clusters (<40 cells).

PKC assay. PKC activity was assayed as previously described (29,30). Briefly, partially purified PKC from pig brain or purified PKC from rat brain was used. The reaction mixture (0.2 mL) contained 5 μmol of piperazine-*N,N'-bis*(2-ethanesulfonic acid) (pH 6.5), 2 μmol $MgCl_2$, 5 μg of phosphatidylserine, 40 μg of histone H1, 0.06 μmol of ethyleneglycol-*bis*(β-aminoethyl ether)*N,N,N'N'*-tetraacetic acid, with or without 0.1 μmol of $CaCl_2$, 1.0 nmol of [γ-^{32}P]ATP (containing about 1×10^6 cpm) and varying concentrations of glycerophospholipid analogs dissolved in water by sonication. The reaction was carried out at 30°C for 5 min.

Statistical methods. The IC_{50} was defined as the concentration of compound which caused a 50% inhibition of the control value for any given assay. Repeated experiments were performed and the means used for comparisons of compounds using standard *t*-tests. Where the inhibition appeared linear, the IC_{50} was calculated using the least-squares method. Nonlinear inhibitions were graphed and IC_{50} determined by inspection. A therapeutic index was calculated by dividing the IC_{50} for NMPC by the IC_{50} for the clonogenic leukemic cells.

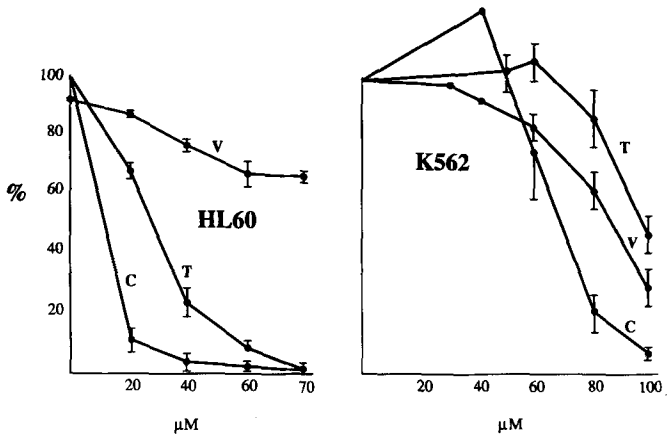

FIG. 2. Effect of a 4 h incubation of ET-18-OCH_3 on colony formation, [^{3}H]thymidine incorporation and viability in HL60 and K562 cells. Colony formation (C) and [^{3}H]thymidine (T) incorporation are expressed as percent of controls. The plating efficiency of K562 cells varies between 36 and 49% in controls, and in HL60 controls vary 13–36%. Average cpm uptake of T for 4×10^5 control for K562 and HL60 cells is in excess of 10^4. Viability (V) is the percentage of cells excluding trypan blue. Bars are standard errors of means of a minimum of three separate experiments.

RESULTS

Figure 1 gives the structure of the compounds investigated. In the *sn*-1 position, variations in chain length (16 or 18 carbons) and the substitution of sulfur for oxygen were the modifications tested. In the *sn*-2 position, a series of substitutions of varying composition, as indicated in Figure 1, were tested.

We observed two types of cytotoxicity. At high doses (>60 μM) cells were lysed, presumably because of a detergent effect of the phospholipids. Lower doses demonstrated no effect or, in some instances, an increase in colony formation and thymidine incorporation. The other type of cytotoxicity noted was a dose-related near linear reduction in colony formation and thymidine incorporation. These types of cytotoxicity are illustrated in Figure 2. In the HL60 cell line, which is sensitive to ET-18-OCH_3, there is a marked reduction in colony formation and [^{3}H]thymidine incorporation with no major change in cell viability. In contrast, in K562 cells which are relatively resistant to ET-18-OCH_3, there is an initial increase in colony formation and [^{3}H]thymidine incorporation at lower doses followed by a decrease at higher doses which parallels the decrease in the percentage of viable cells.

Table 1 gives the IC_{50} for each of the compounds with respect to colony formation for each of the cell lines tested. Because compound A has been the most widely studied and is active against a variety of human tumors (31), all of the others were compared to A. Except in the Daudi cell line, where compounds C and I were significantly more active than compound A, none were more active. On the other hand, several compounds were significantly less active than compound A. In HL60 cells, compounds C, D, K and N were less active and compound E, which has a long chain substitution at *sn*-2, was inactive. In K562, compounds G_2, I and K were inactive and compounds D and G_1 were less active than compound A. The IC_{50} values for NMPC were somewhat similar and did not vary significantly from compound A, except for compound G_1, which was more active.

Table 2 gives the data and the effects of the compounds upon DNA synthesis. Except for compound H in the Daudi cell line, none were significantly more active than compound A. In HL60, compounds C, K and N were significantly less active. In K562, compounds G_1, G_2, H, I, J and K had no inhibitory effect and compounds C and D were less effective. In Daudi, compounds C, G_1, J and K had low activity, whereas in U-937 compounds D, G_1, G_2, H, J and K were less active.

Table 3 shows the calculated therapeutic indices for the compounds obtained by dividing the IC_{50} for the NMPC by the IC_{50} for each of the cell lines. As can be seen, compounds A, H, I and J showed the highest values, indicat-

[a]The data presented are means of two experiments with experimental errors being less than ±5%. ET-18-OCH_3, 1-*O*-octadecyl-2-*O*-methyl-*rac*-glycero-3-phosphocholine.
[b]NI, no inhibition up to 500 μM.

ing a higher degree of selectivity. Table 4 gives the IC_{50} values for the various compounds on PKC activity. Compounds A, B, H and L proved to be the most active inhibitors.

DISCUSSION

Various substitutions at the *sn*-1 and *sn*-2 positions of glycerophosphocholine were tested to determine what structural changes influenced the selective antitumor activity of these ether lipids. The *sn*-3 substitutions were identical. All of the compounds had either a 16 or 18 carbon chain at *sn*-1. This difference in chain length appeared to make no difference (*i.e.*, compare compounds A and I as well as B and H) as long as the substitution at *sn*-2 was a methoxy group. Substitution of a sulfur for an oxygen linkage at *sn*-1 resulted in less activity (compare compounds B and K) when the *sn*-2 substitution was an acetamide. However, this did not prove to be true when the substitution at *sn*-2 was a methoxymethyl group (compare compounds K and L). In fact, compound L was quite similar to compound A in cytotoxicity.

sn-2 Substitution had a greater impact on activity. A long chain substitution (compound E) at *sn*-2 eliminated any cytotoxic activity and had no effect on PKC. The introduction of a trifluoroacetyl group in compound N (which is less hydrophobic than the acetyl group in compound H) reduced the activity significantly. The methoxy substitution at *sn*-2 was somewhat more cytotoxic than the thiomethyl moiety (compare compounds I and J) although the PKC inhibitory activity was similar.

The chiral *sn*-2 deoxy analogs (compounds G_1 and G_2) had similar activities, although substantially lower than those exhibited by compound A, and appeared to be more toxic to the NMPC. They had the lowest therapeutic index and were inactive toward PKC.

Other substitutions at *sn*-2 did not enhance cytotoxicity over that observed in compound A. The methoxycarbonyl-

amino substitution (compound C) had an effect similar to that of the methyl carbonyl substitution (compound B). Introducing a methanesulfonamide moiety (compound D) which adds an additional oxygen did not increase potency (compound B).

These ALP analogs differ from the naturally occurring acetyl derivative, platelet-activating factors (PAF), in that they have antitumor activity, but have little or no PAF-like activity (32,33). Lai *et al.* (34) synthesized a spin label derivative of ET-18-OCH_3. They also synthesized a derivative of PAF (an ester linkage at *sn*-2) and another compound with ester linkages at *sn*-1 and *sn*-2. Neither inhibited thymidine incorporation. Electron spin resonance indicated that the ether chains were less mobile than the ester chains. Also, the former, being more hydrophobic, appeared to promote packing of the two *O*-alkyl chains.

It has been suggested that the cytotoxicity of ALP may result from ALP's combined effects on certain membrane targets (such as PKC, Na, K-ATPase, Na pump and certain phospholipid-metabolizing enzymes) whose synergism may result in cell damage or death (35). The effects of ALP analogs on cells (Tables 1 and 2) are likely to be specific and do not seem to be due to a general membrane perturbation brought about by the ALPs. We reported previously that compound A (ET-18-OCH_3) inhibited TPA-induced differentiation (a PKC-mediated process) and ^{86}Rb uptake (an indicator of Na pump activity) of HL60 cells, both with an IC_{50} of 9 μM (35), a value identical to that for its inhibition of PKC (35; also see Table 4). Taking into consideration factors such as binding of ALP to serum in the medium and uptake of the agent into the cell membrane, the ratio of the agent to total membrane phospholipid was estimated to be about 0.036 mol%, assuming that 7×10^5 cells contained 1,250 nmol of membrane phospholipids (35). Chabot *et al.* (36) and Diomede *et al.* (37) have determined the phospholipid content to be 9.1 and 27.0 nmol, respectively, for the same number of cells. The ratios of compound A to total membrane phospholipid, accordingly, were much higher (4.9 and 1.7 mol%, respectively) when their values for phospholipid were used. The IC_{50} values of compound A for clonogenicity (Table 1) and thymidine uptake (Table 2) for various leukemia cell lines and NMPC from the present studies ranged from 24.5 to 142.2 μM. The mol% of the agent to total cell membrane phospholipid was estimated accordingly, to be about from 13.3 to 26.9, respectively, using the phospholipid content reported by Chabot *et al.* (36). It is thus conceivable that incorporation of compound A into a biomembrane will have a profound effect on a number of enzymes, including PKC, which could contribute to the cytotoxicity of the ether lipids.

Additional studies of ALP derivatives will be necessary to further assess the structural requirements of antitumor active PAF analogs. Nevertheless, the present series of tumor-cytotoxicity studies and determination of therapeutic indices in comparison of healthy bone marrow progenitor cells provide a number of ueful leads toward the design and development of more potent antitumor active phospholipids. Demonstrating selective and specific tumor cytotoxicity of either 16 or 18 carbon chain *sn*-1-alkyl ether and thioether analogs containing short-chain *sn*-2-alkyl- or acetamido-deoxy- as well as an alkoxymethyl-substituted phospholipid confirms and expands the earlier attempts to delineate structural requirements of antitumor active phospholipids and provides an additional set of criteria (38). The functional role of the *sn*-3-phosphodiester substitution can now be addressed further, as it has been shown that PAF analogs containing headgroup bases other than choline exhibited significant antitumor activity (39).

Effect of Age and α-Linolenic Acid Deficiency on Δ6 Desaturase Activity and Liver Lipids in Rats

T.K.L. Dinh[a], J.M. Bourre[b] and G. Durand[a,*]

[a]Laboratoire de Nutrition et de Sécurité Alimentaire, INRA 78352 Jouy-en-Josas Cédex and [b]Laboratoire de Neurotoxicologie, INSERM U26, 75010 Paris, France

The combined effects of age and of diet deficient in n-3 fatty acids on Δ6 desaturation of linoleic acid and on lipid fatty acid composition were studied in the liver of the rat at 2, 6, 12, 18 and 24 mon of age. The profiles of Δ6 desaturase activity and fatty acid composition were studied in the deficient rats refed, at these different ages, either with 18:3n-3 (mixture of peanut and rapeseed oils) or with 20:5n-3 + 22:6n-3 (fish oil) diets for 2, 4, 8 or 12 wk. Results showed that the liver Δ6 desaturation activity in the control rats remained high at 2 and 6 mon, decreased by 30% from 6 to 12 mon, and then remained stable from 12 to 24 mon. In the deficient rats, this activity remained high during the entire period studied. Thus, the profile of liver Δ6 desaturase activity after puberty was not related to age only; it also depended on the polyunsaturated fatty acid (PUFA) n-6 and n-3 balance in the diet. In the controls, in parallel with the Δ6 desaturase activity, PUFA metabolism could be divided into three periods: a "young" period, and "old age" period, separated by a period of transition between 6 and 12 mon. Recovery from PUFA n-3 deficiency occurred at all ages but in a different manner depending on whether the rats were "young" or "old." Recovery was faster if long-chain n-3 PUFA rather than α-linolenic acid were supplied in the diet.

***Lipids* 28, 517–523 (1993).**

Some long-chain polyunsaturated fatty acids (PUFA) of tissue and serum lipids are supplied directly by the diet, but most are derived by desaturation and elongation of their precursors, linoleic and α-linolenic acids. The first step in this process is catalyzed by a microsomal enzyme, Δ6 desaturase. The two precursor fatty acids compete for this enzyme (1,2); 18:3n-3 is desaturated at a higher rate than 18:2n-6. In the presence of the two dietary fatty acids and at equal concentrations, 18:3n-3 effectively inhibits the desaturation of 18:2n-6 (3). Δ6 Desaturase activity is also inhibited by the products of the desaturation-elongation process due to feedback inhibition by 20- and 22-carbon fatty acids (4,5). Studies on rats after puberty have shown that age affects Δ6 desaturase activity (6–8). Some investigators showed that this activity decreased progressively with age (6,7), others that it fluctuated (8). These variations in enzyme activity were reported to be either accompanied by changes in tissue lipid composition (6,7), or not (8). Other authors have studied the fatty acid profile in the liver of rats ranging in age from 1.5 to 40 mon; only the proportion of 20:4n-6 was shown to decrease with age (9). When animals given an α-linolenic acid-deficient diet were refed a balanced PUFA diet, the composition of tissue phospholipids returned to normal within variable times depending on the organ studied. However, these studies were carried out only on young animals, and the n-3 PUFA used in refeeding was derived from vegetable oil (10,11).

The aim of the present work was to study (i) the combined effects of age and dietary n-3 PUFA deficiency on changes in the activity of Δ6 desaturase on 18:2n-6 and changes in the fatty acid composition of liver total lipids in male rats between 2 and 24 mon of age, and (ii) the combined effects of age and of refeeding with α-linolenic acid or its long-chain derivatives on the two parameters.

MATERIALS AND METHODS

Animals and diets. Two generations of female Wistar rats were given a diet containing lipids in the form of African peanut oil (5%, w/w) low in α-linolenic acid; this diet (deficient) supplied about 900 mg of linoleic acid but only 5 mg of α-linolenic acid/100 g of diet. Two weeks before mating, the deficient second-generation females were divided into two groups. The first group continued to receive the deficient diet while the second group was given a diet in which the peanut oil was replaced by a mixture of peanut and rapeseed oils (50:50). This diet (control) supplied the same amount of linoleic acid as the deficient diet but also about 200 mg of α-linolenic acid/100 g of diet (n-6/n-3 = 5). At weaning, the male progeny of these two female groups were given the same diet as their respective dam, and animals were killed when 2, 6, 12, 18 or 24 mon old. At each of these ages some deficient animals were refed with n-3 PUFA, one-half with the control diet described above and the other half with a diet containing a mixture of peanut oil and cod liver oil (92.5–7.2%, respectively); thus, the first half was refed with n-3 PUFA with α-linolenic acid and the other with a mixture of eicosapentaenoic and docosahexaenoic acids (EPA plus DHA). The latter diet supplied about 900 mg of n-6 PUFA (like the other diets) and 100 mg of long-chain n-3 PUFA/100 g of diet. This amount of long-chain n-3 PUFA was chosen because of a preliminary study had shown that it was equivalent to 200 mg of α-linolenic acid, which is sufficient to satisfy the n-3 PUFA requirement (11). Some animals were killed at 2, 4, 8 or 12 wk (T2, T4, T8 and T12) after refeeding with n-3 PUFA. The composition of the diets and the fatty acid composition of the lipids are given in Tables 1 and 2.

Measurements of Δ6 desaturase activity. Non-fasted animals were killed between 8:00 and 9:00 a.m. to ensure optimal conditions for Δ6 desaturase measurement (12) and to avoid any variation in Δ6 desaturase activity due to circadian rhythm (13). The liver was rapidly excised and weighed. One part was used to measure enzyme activity and the rest for fatty acid analysis.

Specific Δ6 desaturase activity was assayed using the method of Blond and Lemarchal (14) as modified by Bourre *et al.* (15). The liver was homogenized at 4°C in 0.25 M saccharose buffer containing 0.05 M Na_2HPO_4, 2 mM glutathione, pH 7.4 (5 mL of buffer/2 g fresh tissue). The homogenate was centrifuged at 12,000 × *g* for 15 min

[c]Control diet consists of a mixture of peanut oil and rapeseed oil (50:50), deficient diet consists of peanut oil, refeeding diets consist of a mixture of peanut oil and rapeseed oil (50:50) or a mixture of peanut oil and cod liver oil (92.5:7.5).

to precipitate cell debris, mitochondria and nuclei. The supernatant contained both microsomes and cytosol. The latter increased the activity of acyl-CoA synthetase activity, thus favoring the formation of acyl-CoA (14) serving as substrates of desaturases. The supernatant was diluted twice with the same buffer before the protein content was determined by the method of Lowry *et al.* (16). Five mg of protein and 100 nmol of [1-^{14}C]18:2n-6 (2 μCi, 20 μL) were added. A final volume of 2 mL was obtained using the same buffer as before containing the following cofactors: Na_2HPO_4 (50 mM) ATP (7.5 mM), $MgCl_2$ (3.8 mM), NADPH (0.2 mM), NADH (0.5 mM) and CoA (0.2 mM). The tubes were incubated for 30 min with shaking. The reaction was stopped by the addition of 1 mL of KOH in 12% ethanol. Thirty μg each of several standard commercial fatty acids (18:2n-6, 18:3n-6, 20:3n-6, 20:4n-6, 20:5n-3, 22:6n-3) were added to facilitate identification of chromatographic fractions. After saponification at 100°C for 30 min, 0.4 mL of 10 N HCl was added, the fatty acids were extracted using hexane, followed by methylation with 1 mL of 14% boron trifluoride for 1 h at 100°C. The fatty acid methyl esters were extracted with hexane, purified by thin-layer chromatography using a mixture of petroleum ether/diethyl ether (80:20, vol/vol), and then were localized by autoradiography. The methyl ester band was scraped from the plate and extracted successively with hexane (2 times 3 mL) and diethyl ether (2 times 3 mL). The methyl esters were finally separated according to their degree of unsaturation by $AgNO_3$ thin-layer chromatography. Plates were impregnated with 10% $AgNO_3$ in acetonitrile for 15 min, then dried at 100°C for 20 min.

[a]Abbreviations: SFA, saturated fatty acid; MUFA, monounsaturated fatty acid; PUFA, polyunsaturated fatty acid.

The mobile phase was a mixture of petroleum ether/diethyl ether (50:50, vol/vol). The fractions were localized by autoradiography, and the radioactive distribution was determined using a plate reader (Automatic TLC Linear Analyzer Berthold, La Garenne Colombes, France). Results were expressed in pmol of 18:3n-6 formed/mg protein/min incubation.

Fatty acid composition of liver total lipids. Liver lipids were extracted from frozen dried liver with a chloroform/methanol mixture (2:1, vol/vol) using the method of Folch *et al.* (17) as modified by Pollet *et al.* (18). The lipid extracts were then transmethylated (19). After extraction with hexane, the methyl esters were analyzed by gas chromatography, using a Carlo Erba (Rueil Malmaison, France) chromatograph with an automatic on-column injector, a flame-ionization detector and capillary-type Carbowax C.P. Wax 52 C.B. column. Data were processed using a Stang microcomputer (Pavillon sous Bois, France) and Nelson software (Cupertino, CA).

Analysis of results. This study required a large number of animals: 144 male rats were killed at various ages. Nevertheless, only a small number of animals could be studied at each time point (3 or 2 rats). Liver total lipid fatty acid composition was analyzed for only two rats per time period; thus common statistical procedures could not be applied. High mortality in the groups of rats 24 mon of age or older did not permit measurements at 12 wk of refeeding.

RESULTS

Effect of age and dietary α-linolenic acid deficiency. In control rats, the specific Δ6 desaturase activity (Fig. 1) remained constant at 2 and 6 mon; it decreased by about 30% between 6 and 12 mon and then did not change between 12 and 24 mon. Enzyme activity in α-linolenic acid-deficient animals was comparable to that in controls at 2 and 6 mon, but instead of decreasing thereafter it remained high during the entire period studied; thus, from 12 to 24 mon, enzyme activity was 50% higher than in controls.

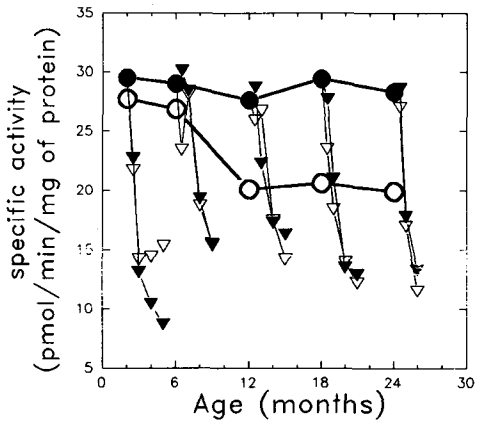

FIG. 1. Effect of age and α-linolenic acid deficiency on Δ6 desaturase activity in the rat. Effect of refeeding n-3 polyunsaturated fatty acids (PUFA) according to age and nature of n-3 PUFA (α-linolenic acid or long-chain n-3 PUFA). Assays of Δ6 desaturase were carried out as described in Materials and Methods; ○, control rats; ●, deficient rats; ▽, 18:3n-3 refed rats; ▼, 20:5n-3 + 22:6n-3 refed rats. Values are the mean of three or two rats/diet.

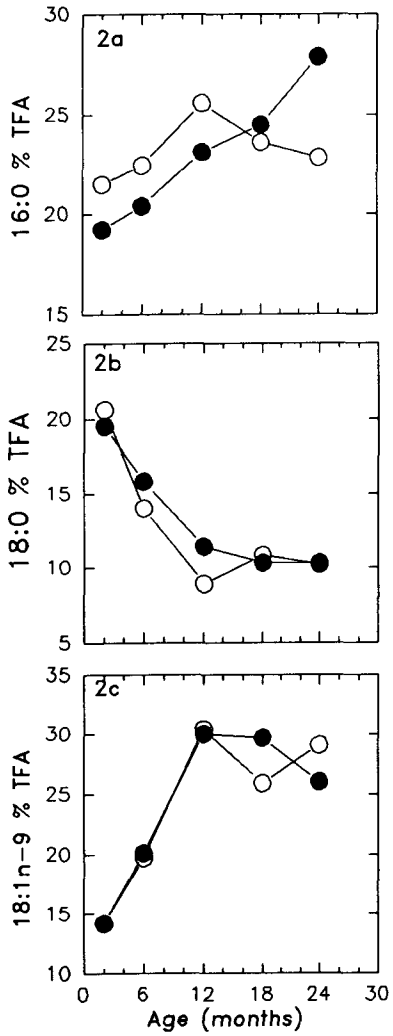

FIG. 2. Effect of age and α-linolenic acid deficiency on levels of the main saturated fatty acids and monounsaturated fatty acids of liver total lipids in the rat. Only values for the major fatty acids are reported. Experimental details are given in Materials and Methods. Data were derived from the percent of total fatty acids (TFA); ○, control rats; ●, deficient rats. Values are the mean of two rats/diet.

Fatty acid composition was also affected by the diet. Palmitic (16:0) and stearic (18:0) acids were the major saturated fatty acids (SFA). In controls, the proportion of palmitic acid was unchanged (21 to 23%) between 2 and 24 mon (Fig. 2a), but stearic acid levels decreased by half between 2 and 12 mon and then remained constant up to 24 mon (Fig. 2b). The 18:0 profile affected the proportion of total SFA which decreased from 44 to 36% between 2 and 12 mon and then remained stable until 24 mon (Table 3). Generally, an n-3 PUFA deficient diet had very little influence on the proportions of liver lipid SFA and monounsaturated fatty acids (MUFA). However, in the deficient rats, 18:0 decreased with age, as in the controls, and 16:0 increased regularly so that, as the decrease of one compensated the increase of the other, the level of total SFA remained almost constant from 2 to 24 mon (between 36 and 40% of total fatty acids). The MUFA time course was similar in control and deficient animals: their proportions doubled between 2 and 12 mon (from 20 to 40%) at

[b]Number in parentheses is age in months.

the same time as oleic acid increased from 14 to 28% (Fig. 2c); between 12 and 24 mon there was no change.

As expected, the n-6 PUFA profiles were different in control and deficient animals: in the former the proportion of total n-6 PUFA decreased from 30 to 23% between 2 and 12 mon and then stabilized. This overall relatively moderate decrease was due entirely to arachidonic acid (20:4n-6) which decreased from 18 to 11% between 2 and 12 mon (Fig. 3b), while the proportion of linoleic acid was constant (about 10%) (Fig. 3a). In deficient animals, the proportion of 18:2n-6 (which did not vary with age) was systematically lower than in controls. On the other hand, 20:4n-6 and especially 22:5n-6 levels were higher (Fig. 3c). However, the level of 22:5n-6, higher from 2 to 6 mon, diminished considerably between 6 and 12 mon. After 12 mon, the higher values of 20:4n-6 and 22:5n-6 just compensated for the lower value of 18:2n-6, so that total n-6 PUFA became similar in control and deficient rats after 12 mon (about 23%). The level of 20:3n-6 did not vary with either age or diet. DHA (22:6n-3) was the main n-3 PUFA in controls. It represented 5–6% of n-3 PUFA up to 6 mon, dropped between 6 and 12 mon to about 3.4% and then remained at that level until 24 mon (Fig. 3d). The total n-3 PUFA profile was comparable. In deficient rats, n-3 PUFA were represented only by 22:6n-3, and it proportion remained at about 1% during the whole period studied. Total n-6 + n-3 PUFA in controls remained at the same level from 2 to 6 mon, decreased by about 20% between 6 and 12 mon and then stabilized; in deficient animals, the same pattern was seen but the plateau reached at 12 mon was lower due to a lower proportion of n-3 PUFA which was no longer compensated for by a high n-6 PUFA level (Fig. 3e). If only long-chain PUFA (⩾20 C) are considered instead of total PUFA, there was overcompensation for the n-3 PUFA deficiency by n-6 PUFA at 2 mon but not at other time points. In controls, the n-6/n-3 ratio remained about 5 throughout the period studied; it was 6 to 7 times higher in deficient rats (Fig. 3f). The 22:5n-6/22:6n-3 ratio, which may be considered an index of dietary n-3 PUFA deficiency (20), did not change in controls. It was high in deficient rats but decreased progressively with age. In controls the 20:4n-6/18:2n-6 ratio, an index of total Δ6 and Δ5 desaturase activities (21), remained high and stable from 2 to 6 mon, dropped by one-half between 6 and 12 mon and then remained stable until 24 mon. The profile of the deficient rats was comparable but the ratio was higher.

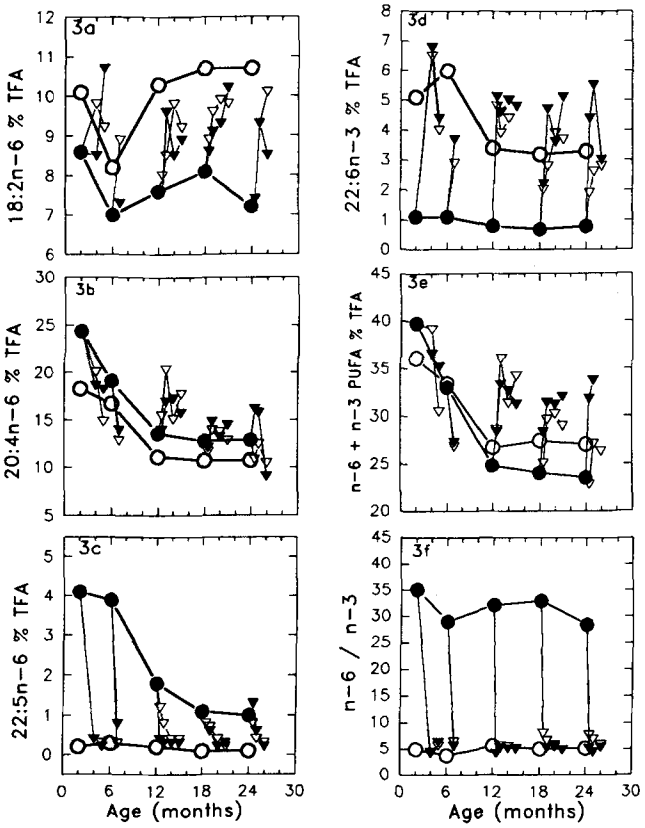

FIG. 3. Effect of age and α-linolenic acid deficiency on the levels of the main polyunsaturated fatty acids (PUFA) of liver total lipids in the rat. Effect of refeeding n-3 PUFA according to age and nature of n-3 PUFA (α-linolenic acid or long-chain n-3 PUFA). Experimental details are given in Materials and Methods. Data were derived from the percent of total fatty acids (TFA); ○, control rats; ●, deficient rats; ▽, 18:3n-3 refed rats; ▼, 20:5n-3 + 22:6n-3 refed rats. Values are the mean of two rats/diet.

Effect of PUFA n-3 refeeding in deficient rats. Generally, the addition of n-3 PUFA to the diet, whether in the form of 18:3n-3 or of 20:5n-3 + 22:6n-3, caused the Δ6 desaturase activity to drop by one-half to a level lower than that in controls of the same age (Fig. 1). The inhibition appeared much sooner in 2-month-old animals, independent of the nature of the PUFA n-3 in the diet. In older animals there was a latency period of about 2 wk before the inhibition became evident, especially when the rats received long-chain n-3 PUFA. Maximal inhibition was obtained only after 8 wk of refeeding.

The addition of 18:3n-3 to the diet of deficient rats modified the fatty acid composition of liver total lipid with a decrease in n-6 PUFA level between 2 and 6 mon. At these two ages, the values obtained at T8 for 2-month-old rats and at T4 for 6-month-old ones were very close to those of controls. This decrease was accompanied by a new balance between the 18:2n-6 on one hand and the 20:4n-6 and the 22:5n-6 fatty acids on the other. At the end of the first two wk of refeeding (T2), the level of 18:2n-6 increased and that of 22:5n-6 decreased; thus, there was a return to normal values (Figs. 3a,3c). The level of 20:4n-6 decreased to a level lower than that of controls (Fig. 3b). There were no differences between the levels of total n-6 PUFA in 12-, 18- and 24-month-old controls and deficient animals, and refeeding α-linolenic acid did not cause an overall change. However, refeeding did promote an increase in the level of 18:2n-6, which reached a plateau at the end of 4 wk but did not return to normal values. The levels of 20:4n-6 returned to normal only at 24 mon; it was practically stable at 18 mon and increased at 12 mon. The level of 22:5n-6 returned to normal values, but only after 8 wk of refeeding. The addition of 18:3n-3 to the diet of n-3 PUFA deficient animals caused an increase in liver 22:6n-3 (Fig. 3d). With the exception of 24-month-old rats, all the age groups returned to control values and even exceeded them. In 6-month-old rats, the values reached after 4 wk of refeeding showed that these rats were recovering, whereas in 24-month-old animals the level of 22:6n-3 remained lower than that in controls of the same age. Due to variations in the levels of different PUFA, total (n-6 + n-3) PUFA decreased in rats refed 18:3n-3 at 2 and 6 mon (Fig. 3e) because n-6 PUFA decreased more than n-3 PUFA increased. However, total PUFA were appreciably higher when rats were refed at 12 mon; this overcompensation disappeared with age, and at 2 yr total (n-6 + n-3) PUFA was the same as in controls. Refeeding 18:3n-3 returned the n-6/n-3 ratio and the 22:5n-6/22:6n-3 ratio to normal values within 4 wk (5 and 0.05, respectively) (Fig. 3f).

Refeeding fish oil had almost the same effect on liver n-6 PUFA as refeeding 18:3n-3. After refeeding long-chain n-3 PUFA, 18:3n-3 was not detected in liver lipids; 20:5n-3 and 22:5n-3 levels were lower than or equal to 0.5% (results not shown). Refeeding with 100 mg of 20:5n-3 + 22:6n-3/100 g of diet resulted in an increase in 22:6n-3 comparable to a supply of 200 mg of 18:3n-3/100 g of diet in 2-, 6- and 12-month-old rats. But in rats of 18 and 24 mon of age, the fish oil diet raised the level of 22:6n-3 more quickly than the rapeseed oil diet. After 2 wk of refeeding, the level was much higher than that seen in control rats of the same age. After this increase the values stabilized. In 12- and 18-month-old rats, the values remained higher than normal but in 24-month animals they returned to control values as observed after 8 wk of refeeding.

DISCUSSION

Effect of age. We found a decrease of 18:0 between 2 and 12 mon and an increase of 18:1n-9 during the same period, corroborating the results of Ulmann *et al.* (8) who found a slight decrease in the sum of 16:0 + 18:0 together with an increase of 16:1n-7 + 18:1n-9 in the liver microsomal phospholipids of rats 3-, 6- and 9-months old. In regard to the PUFA composition of liver total lipids, our study showed that the postpuberty period can be divided into three parts: (i) a period of stability between 2 and 6 mon; (ii) a transition period between 6 and 12 mon during which levels of 20:4n-6, 22:5n-6 and 22:6n-3 decrease; and (iii) another period of stability from 12 to 24 mon. Thus, the PUFA level was lower in old than in young rats. However, our results do not show whether the transition period extends over the whole 6 to 12 mon interval or whether it is shorter. Murawski *et al.* (9) also observed a decrease in the level of total liver lipid 20:4n-6 in rats receiving a standard diet and with ages ranging from 1.5 to 40 mon. But these authors found no variation in the proportions of other PUFA. In contrast to these results, Bordoni *et al.* (6) found that total liver lipid 20:4n-6 levels were not different in rats 4- and 22-months-old.

Our study shows that in animals receiving a balanced PUFA diet the variations in PUFA composition correspond to variations in specific Δ6 desaturase activity which, like total liver lipids, was similar at 2 and 6 mon, decreased between 6 and 12 mon and was stable thereafter. The 20:4n-6/18:2n-6 ratio also fell during this period. However, the 20:3n-6 level did not change. Thus, it seems that only Δ6 desaturase should be involved in the decrease of the 20:4n-6/18:2n-6 ratio; otherwise, we likely would have observed an increase in 20:3n-6 level if Δ5 desaturase was also involved (22). Peluffo and Brenner (23) showed that Δ6 desaturase activity tends to decrease with age in rats receiving a standard diet; but their experiment only concerned rats aged 3 mon and 1 yr and, therefore, any intermediate fluctuations would have been missed. Recently, Ulmann *et al.* (8) studying rats aged 3, 6 and 9 mon receiving a control diet similar to the ones in our study also showed that Δ6 desaturase activity decreased from 6 to 9 mon. However, other authors have not observed the same trend of Δ6 desaturase activity with age; Bordoni *et al.* (6) using liver microsomes of rats at 13 d and 1, 4, 14 and 22 mon which had received a standard diet noted that enzyme activity decreased progressively from 4 to 22 mon. In a similar study on rats aged 1, 6, 10 and 25 mon, Hrelia *et al.* (7) also found a linear decrease in Δ6 desaturase activity with age; in mice, Bourre *et al.* (15) noted that liver Δ6 desaturase activity did not change between 3 wks and 4 mon but progressively decreased between 4 and 17 mon. The discrepancy between the results of our study and those of Ulmann *et al.* (8) on one hand, and those of Bordoni *et al.* (6) and Hrelia *et al.* (7) on the other, could be due to different diet compositions since this, as we have shown, determines the profile of enzyme activity during postpubertal development.

Effect of dietary n-3 PUFA deficiency. The previous studies on dietary n-3 PUFA deficiency have shown that the deficiency causes an increase in 20:4n-6 and 22:4n-6 levels, and especially in 22:5n-6 levels, to compensate for the decrease in 18:2n-6, 22:5n-3 and especially 22:6n-3 (24–28). Other studies have shown that n-6 PUFA can

completely compensate for n-3 PUFA (22, 29–31) and that total PUFA (n-6 + n-3) remains constant. These studies on n-3 PUFA deficiency were done on 15-day-old and 60-day-old rats. Our results showed that this was not the case in animals from 12 mon of age, and that compensation was not adequate so that the sum of PUFA was lower in n-3 PUFA-deficient animals than in controls. However, if only fatty acids with at least 20 carbon atoms are considered, n-3 PUFA were exactly compensated for by n-6 PUFA. In other words, in the old, deficient animals, increases in 20:4n-6 and 22:5n-6 did not compensate for the decrease in 18:2n-6 but only for the decrease in 22:5n-3, and especially 22:6n-3. Moreover, in n-3 PUFA-deficient rats, results are remarkably consistent in regard to the lower level of 18:2n-6 and the higher level of 20:4n-6 and 22:5n-6 on one hand, and the higher level of Δ6 desaturase activity on the other, as compared to controls. In the deficient animals, specific enzyme activity did not change with age as it did in controls. Thus, it is evident that changes in Δ6 desaturase activity were not related solely to age but were also a function of diet. It is known that the desaturase activities, and especially the Δ6 desaturase activity, also depend on non-lipid dietary factors. These activities moreover depend on hormonal factors, the effects of which being obvious in some pathological conditions, such as diabetes. At last, if the influence of desaturases on the lipid composition of tissue lipids, and in particular that of microsomal phospholipids, is generally assumed, it should be observed that this composition also results from many other metabolic factors (for a review, see Ref. 32).

Effect of n-3 PUFA refeeding. Our results showed that, independent of the nature of dietary n-3 PUFA, the modalities of recovery in young animals (2- and 6-months-old) were clearly different from those in old animals (12-, 18- and 24-months-old). Refeeding tended to decrease the level of total liver lipid PUFA in the young, while this level was markedly increased in old animals so that it reached the level in young controls. Moreover, a supply of long-chain n-3 PUFA permitted a more rapid and more complete recovery than a supply of 18:3n-3, the difference being more evident in older animals. In this study, EPA plus DHA supplementation did not increase the level of 20:5n-3 to the detriment of 20:4n-6, as occurred when a larger amount of these fatty acids was supplied in the diet (33,34). It is likely that, because of the moderate supply of EPA plus DHA (100 mg/100 g of diet), 20:5n-3 was completely transformed into 22:6n-3 to cover the requirements for phospholipid 22:6n-3. The persistently low activity of Δ6 desaturase in refed rats compared to that in controls of the same age could be due to the fact that 22:5n-6 progressively released from phospholipids decreased Δ6 desaturase activity by feedback inhibition. This fatty acid may then be eliminated either by mitochondrial and/or peroxisomal oxidation, or by retroconversion into 20:4n-6. If in old rats the retroconversion is the usual pathway, this would explain why the high 20:4n-6 levels found in n-3 PUFA-deficient rats was maintained or even increased when the animals were refed with n-3 PUFA. This high 20:4n-6 level could in itself contribute to maintaining Δ6 desaturase activity at the low level seen after n-3 PUFA refeeding. In any case, Δ 6 desaturase activity at a given age may depend not only on the relative proportions of n-6 and n-3 PUFA in the current diet but also on the relative proportions in the diet eaten over a longer period of time.

In conclusion, this study shows for the first time that during adult rat life (puberty to old age), PUFA metabolism can be divided into three periods: two of stability ("young" and "old" ages), separated by a transition period. The latter occurs between 6 and 12 mon and its duration remains to be determined. In rats given a balanced PUFA diet, the transition period is characterized by a decrease in liver long-chain PUFA, in particular 22:6n-3 and 20:4n-6. Our results show that the profile of Δ6 desaturase activity as a function of age cannot be dissociated from the n-6 and n-3 PUFA ratio in dietary lipids. Thus, an n-3 PUFA-deficient diet maintains specific Δ6 desaturase activity at a high, constant level throughout adult life, from puberty to old age. Finally, it is possible to recover from multi-generational n-3 PUFA deficiency at all ages but the pattern of recovery is different, depending on whether the animal is in the "young" or the "old age" period. During the "old age" period, recovery is quicker if the diet directly supplies long-chain n-3 PUFA.

Differential Utilization of Eicosapentaenoic Acid and Docosahexaenoic Acid in Human Plasma

Jason Hodge[a], **Kerrie Sanders**[a] and **Andrew J. Sinclair**[b,*]
[a]Department of Human Nutrition, Deakin University, Geelong 3217 and [b]Department of Applied Biology, Royal Melbourne Institute of Technology, Melbourne 3001, Victoria, Australia

It has recently been shown that the ω3 fatty acid status in humans can be predicted by the concentration of eicosapentaenoic (EPA) and docosahexaenoic (DHA) acids in plasma phospholipids [Bjerve, K.S., Brubakk, A.M., Fougner, K.J., Johnsen, H., Midjthell, K., and Vik, T. (1993) *Am. J. Clin. Nutr.*, in press]. In countries with low intake of ω3 fatty acids, the level of EPA in plasma phospholipids is often only about one-fifth the concentration of DHA. The purpose of this study was to investigate whether this difference in the concentration of these two fatty acids was due to a selective loss of EPA relative to DHA or to a lower dietary intake of EPA. Seven female volunteers ingested four grams of MaxEPA daily for 2 wk and in the following 4 wk they ate a diet almost completely devoid of the long-chain ω3 fatty acids. The concentrations of the ω3 fatty acids in the plasma cholesteryl esters, triglycerides and phospholipids and the high density lipoprotein phospholipids were examined at weekly intervals throughout the study. There was a more rapid rise in the concentration of EPA than in DHA levels in the supplementation period in all lipid fractions, but there was a disproportionate rise in DHA relative to EPA in the plasma lipids compared with the ratio in the supplement. In the depletion phase there was a rapid disappearance of EPA from all fractions, such that pre-trial levels were reached by one week post-supplementation. The disappearance of DHA was slower, particularly for the plasma phospholipids: at 4 wk post-supplementation, the DHA concentration in this fraction was still 40% above the pre-trial value. It is suggested that the low plasma EPA values relative to DHA are the result of increased β-oxidation of EPA and/or low dietary intake, rather than a rapid conversion of EPA to DHA. One practical result of this experiment is that, compared with DHA, the maintenance of increased EPA levels in plasma (and therefore tissues) would require constant inputs of EPA due to its more rapid loss from the plasma. *Lipids 28,* 525–531 (1993).

The ω3 fatty acids are now recognized as important components of the human diet. Following intense investigations during the last two decades, their role as modulators of the metabolism of arachidonic acid to eicosanoids (1), their importance in protecting against cardiovascular disease by a variety of actions (2) and their potential significance for the development of normal function of the retina and brain (3) has been established.

The main ω3 polyunsaturated fatty acids (PUFA) from the food chain are α-linolenic acid (from plant sources), eicosapentaenoic acid (20:5ω3 or EPA), docosapentaenoic acid (22:5ω3 or DPA) and docosahexaenoic acid (22:6ω3 or DHA). These latter three fatty acids, which can be found in high concentrations in marine foods, are often referred to as ω3 long-chain PUFAs (LCP). The interest in these PUFA was stimulated by the observations on the low incidence of cardiovascular disease in Greenland Eskimos despite the high fat content of their diet (4).

There is general agreement that the level of ω3 PUFA should be increased in the Western diet, and various suggestions have been made regarding an appropriate level of ω3 fatty acids in our current diet (5). In most Western countries the level of ω3 PUFA in the diet is low relative to the ω6 PUFA [estimated at 1:11 based on world production figures (6), and a similar ratio for the United States, based on consumption figures, (7)] and this is reflected in the balance of these fatty acids in plasma and certain tissues. The ratio of ω3 to ω6 PUFA in the diet in Australia is likely to be lower than that in the United States since many common vegetable oils used in this country are low in α-linolenic acid (*e.g.*, significant sources of α-linolenic acid such as soybean oil and rapeseed oil have not been commonly used in the margarine and vegetable oil industry).

Bjerve *et al.* (8) recently showed that plasma phospholipid (PL) concentrations of EPA and DHA can be used to assess the ω3 PUFA status. Within the dietary range of 0.1 to 0.6% of energy of total ω3 PUFA (0.05 to 0.5 g per day of EPA and 0.1 to 0.8 g per day of DHA), there was a rectilinear association between plasma PL EPA and DHA levels and the dietary intake. Previously, plasma fatty acid levels have only been considered as a short-term indicator of dietary intake, whereas long-term intake was thought to be better judged from the fatty acid pattern of tissues or cells such as erythrocytes or white blood cells (9).

The level of ω3 PUFA in tissues such as plasma, white cells and erythrocytes is low relative to the ω6 PUFA in people on typical Western diets (10–13). In addition, the EPA level is substantially lower than that of DHA and, in the case of the plasma PL, it is of the order of 0.2 × the DHA value (10,13). From these data, the following conclusions can be drawn: (i) intake or absorption of EPA is substantially lower than that of DHA, (ii) there is a selective utilization of EPA and/or (iii) there is a selective retention of DHA.

Although it is recognized that dietary change can be associated with rapid changes in the fatty acid composition of plasma lipids (13), the study of plasma lipids can provide useful information about fatty acid dynamics in the body since all dietary lipids pass through the plasma pool(s) before being incorporated in tissue lipids. The purpose of this investigation was to study the accumulation and loss of EPA and DHA in human plasma since it was believed that this might help explain why there was such a difference between the levels of these fatty acids in plasma in subjects on typical Western diets containing low levels of ω3 PUFA.

The design of this experiment was to increase the levels of EPA and DHA in plasma over a two-week period, then

Abbreviations: CE, cholesteryl esters; DHA, docosahexaenoic acid (22:6ω3); DPA, docosapentaenoic acid (22:5ω3); EPA, eicosapentaenoic acid (20:5ω3); GLC, gas-liquid chromatography; HDL, high density lipoproteins; LCP, long-chain polyunsaturated fatty acids; LDL, low density lipoproteins; PL, phospholipid; PUFA, polyunsaturated fatty acids; TG, triglycerides.

to follow the washout of these PUFA from plasma during the next 4 wk when the subjects were on a diet with very low levels of LCP ω3, thus ensuring that the disappearance from plasma was not confounded by an influx of ω3 LCP from the diet. The fractions chosen for study were the plasma PL, triglycerides (TG) and cholesteryl esters (CE) and the high density lipoprotein (HDL) PL.

MATERIALS AND METHODS

Subjects. Seven healthy, female volunteers (mean age, 30.6 yrs; mean body mass index, 21.4) participated in the study. The protocol for this study was approved by the Deakin University Ethical Review Committee (Geelong, Australia) and informed consent was obtained from the volunteers, all of whom were staff members of the Department of Human Nutrition, Deakin University.

Experimental protocol. The study ran for six weeks. In the first two weeks (ω3 supplementation phase) the subjects consumed their normal diet plus four 1-g capsules daily of MaxEPA (Nature's Way®, Nature's Way Health Products, Chadstone, Australia). Analysis of the oil by capillary gas-liquid chromatography (GLC) using an internal standard of triheptadecanoin (Nu-Chek-Prep, Elysian, MN) established that the concentrations of EPA, DPA and DHA were 137, 21 and 98 mg/g oil, respectively (16.3, 2.5 and 12.1% of total fatty acids); thus the 4 g of fish oil provided 548 mg EPA and 392 mg DHA daily. In the remaining four weeks (ω3 depletion phase), the subjects were advised to reduce the ω3 PUFA content of their diet to a minimum by avoiding fish and other marine products, and vegetable oils and margarines containing α-linolenic acid such as canola oil, and walnuts, red meat and offal meats. They were allowed to consume one egg/week, three meals of lean pork and/or chicken (<100 g/serve) per week and were provided with four vegetarian meals weekly, consisting mainly of lentils and vegetables. The estimated maximum intakes of EPA, DPA and DHA in this latter phase were less than seven mg/d for each ω3 LCP. These figures were calculated from our own data on the PUFA content of Australian foods (14,15). Blood samples were taken before the study began and at weekly intervals between 08:00 and 09:00 following a 10-h overnight fast.

Fatty acid analysis of plasma and HDL lipids. Fasting blood samples were collected in heparinized tubes, stored in ice immediately after collection and centrifuged at 3000 rpm (1700 × *g*, 15 min, 4°C) in a Beckman TJ-6 centrifuge (Beckman Instruments Australia, P/L., Melbourne, Victoria, Australia). Plasma was collected for cholesterol and TG analysis, and aliquots were stored for subsequent lipid extraction. The HDL were separated from a 1.0 mL aliquot of plasma within 2 h of blood collection from other plasma lipoproteins by precipitation with dextran sulfate (Dextralip 50, Sochibo, Velizy Villacoublay, France).

Lipids of whole plasma and the HDL fraction were extracted with chloroform/methanol (2:1, vol/vol) containing 10 mg/L of butylated hydroxytoluene (16). Internal standards of diheptadecanoyl phosphatidylcholine (Sigma, St. Louis, MO), cholesteryl heptadecanoate and triheptadecanoin (Nu-Chek-Prep) were added to the plasma samples and HDL samples prior to lipid extraction. The lipid extracts were separated by thin-layer chromatography (16), and the fatty acid methyl esters of the PL, CE and TG fractions were formed as described previously (16). The fatty acid methyl esters were analyzed by flame-ionization capillary GLC (model GC-9A, Shimadzu, Kyoto, Japan) using a 50 m × 0.32 mm i.d. fused silica (CPSil 88) capillary column (Chrompack, Middelburg, The Netherlands), programmed from 110°C for 3 min to 190°C at 8°C/min with helium as carrier gas at a flow rate of 5 mL/min. Fatty acids were identified by comparison with standard mixtures of fatty acid methyl esters, and the results were calculated using response factors derived from chromatography standards of known composition (GLC-68A and 63B, Nu-Chek-Prep).

Lipoprotein lipid analysis. Concentrations of cholesterol and triglyceride in fasting plasma were measured enzymatically on an autoanalyzer (Hitachi Automatic Analyzer 705, Nissei Sangyo Co. Ltd., Tokyo, Japan) using commercially available kits (Cholesterol CHOD-PAP; Triglyceride GPO-PAP; Boehringer Mannheim, Germany).

Statistical analyses. The results are presented as mean ± SD. The experiment was designed to compare the increase in the ω3 LCP values at week 2, achieved using the MaxEPA supplement, with the initial levels of these PUFA, and to compare the values at the end of the depletion phase (week 6) with the initial values. The statistical significances between means (week 2 *vs.* week 0, and week 6 *vs.* week 0) were analyzed using a paired *t*-test; significant results were taken as $P < 0.05$.

RESULTS

Plasma cholesterol and TG levels. There were no significant changes in the total plasma cholesterol and TG levels during the course of the experiment (Table 1), which is consistent with the results of a 20-wk study using similar low doses of ω3 LCP (17).

Initial fatty acid data. The pre-trial plasma PL fatty acid concentrations of the seven subjects were within the normal range established in this laboratory (Table 2). The mean values for the plasma PL arachidonic acid, EPA and DHA were 9.3, 0.6 and 3.0 (as percent of phospholipid fatty acids), respectively; however, there was a spread of the values for the ω3 LCP, indicating a variation in ω3 intake of the seven subjects prior to the start of this experiment. The EPA values ranged from 0.3 to 1.0 mg/100 mL and the DHA concentrations from 2.0 to 4.5 mg/100 mL. There was no significant correlation between the EPA and DHA values ($r^2 = 0.045$), and the EPA-to-DHA ratio in the plasma PL varied from 0.11 to 0.38 (mean 0.22).

TABLE 1

Mean Concentration of Plasma Cholesterol and Triglyceride During Supplementation and Depletion of Diet with ω3 PUFA

Week	Plasma cholesterol	Plasma *triglyceride*
0	4.50 ± 0.93[b]	0.95 ± 0.25
2	4.37 ± 1.00	0.84 ± 0.49
6	4.40 ± 0.93	1.03 ± 0.47

[a]Results are expressed as mean ± SD deviation. ω3 Polyunsaturated fatty acid (PUFA) supplementation period during weeks 0 to 2; ω3 PUFA depletion period, weeks 3 to 6.

[a]Results are expressed as mean ± SD. ω3 Polyunsaturated fatty acid (PUFA) supplementation period during weeks 0 to 2; ω3 PUFA depletion period, weeks 3 to 6. Normal values (in 39 females) for 20:5, 1.5 ± 1.0; 22:5, 1.4 ± 0.5; 22:6, 5.8 ± 2.9 (mean ± SD). HDL, high density lipoprotein.
[b]mg/100 mL.

ω3 Supplementation phase. With all fractions studied, there was a consistent and rapid rise in the EPA concentration after supplementation started and, in most fractions, the maximum increase had occurred by week 1. There was a less consistent response in the increase in DHA in the different fractions (Figs. 1-4). The increases in the EPA and DHA concentrations between the start and week 2 were not related to the initial EPA and DHA values in the plasma lipid fractions.

The results for the plasma PL showed that the maximum values for EPA, DPA and DHA were reached at 2 wk after supplementation commenced (Fig. 1); the increases in the concentration of these fatty acids relative to the pre-trial values were 2.2, 0.6 and 3.0 mg/100 mL plasma for EPA, DPA and DHA, respectively. These values represented increases of 4.1, 1.7, 1.9× the initial values, respectively ($P < 0.0001$, 0.019, 0.0024, respectively). There was a stepwise increase in the DHA level from week 1 to week 2 of the supplementation phase compared with the rise in EPA which had plateaued by the end of week 1 of the supplementation.

Similar results were seen for the plasma CE EPA concentration where there was a rapid rise by week 1 (Fig. 2); the increase in EPA in this fraction was by a factor of 3.4 (an increase of 1.3 mg/100 mL) ($P < 0.0003$). The DHA in the CE fraction also rose significantly ($P < 0.019$)

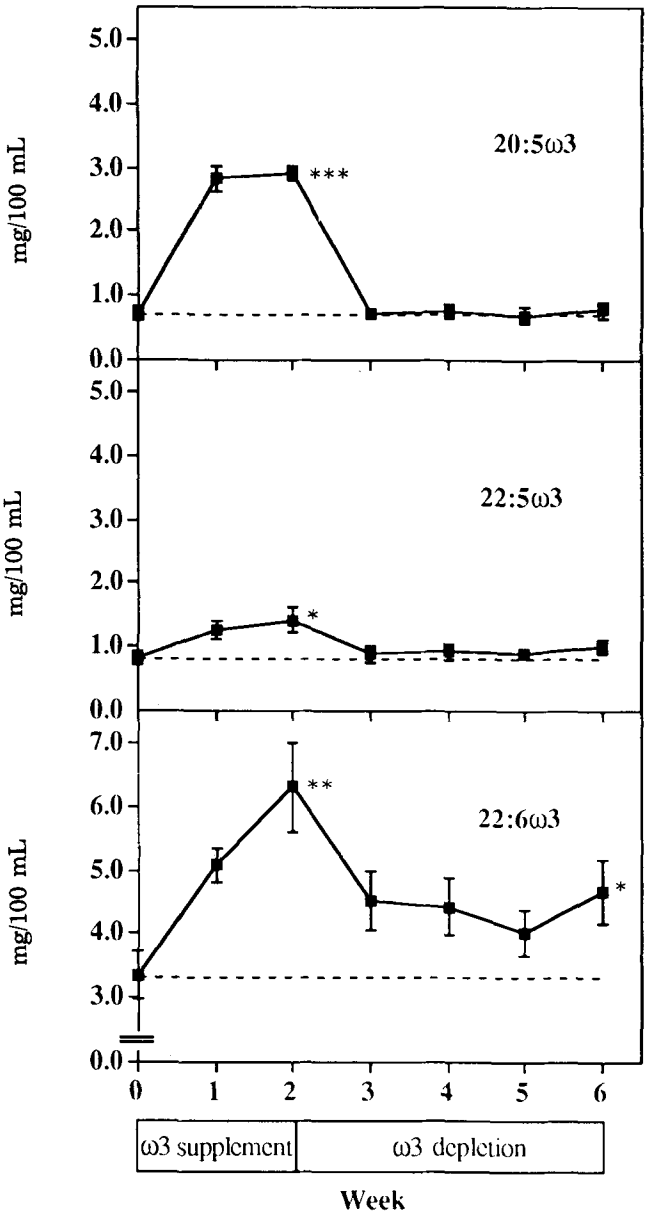

FIG. 1. The concentration (mean ± SD) of ω3 long-chain polyunsaturated fatty acids (PUFA) in plasma phospholipids during supplementation and depletion of diet with ω3 PUFA. Paired *t*-tests were conducted between the week 2 and week 0 samples, and between the week 6 and week 0 samples (*$P < 0.05$, **$P < 0.01$, ***$P < 0.001$).

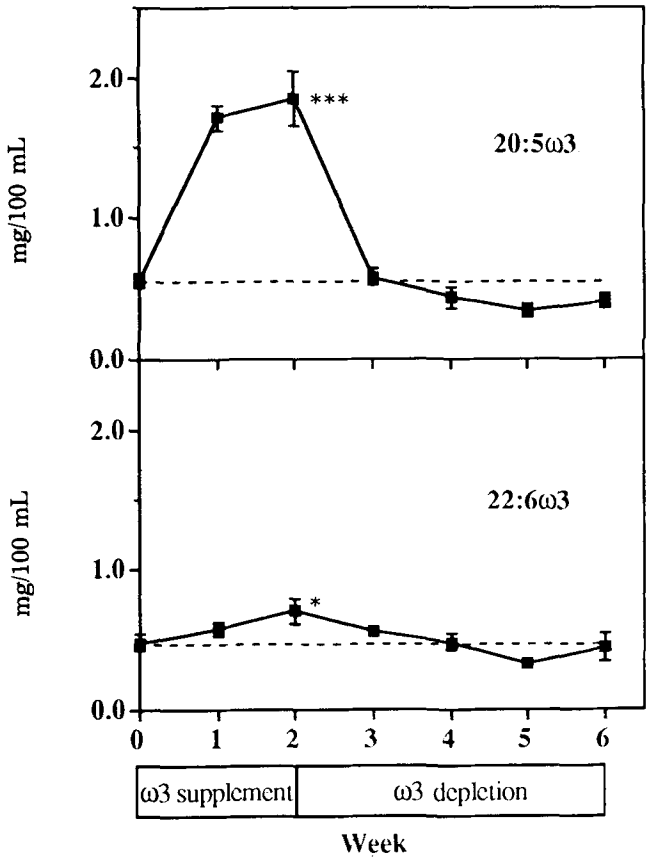

FIG. 2. The concentration (mean ± SD) of ω3 long-chain polyunsaturated fatty acids (PUFA) in plasma cholesteryl esters during supplementation and depletion of diet with ω3 PUFA. Paired *t*-tests were conducted between the week 2 and week 0 samples, and between the week 6 and week 0 samples (*$P < 0.05$, ***$P < 0.001$).

by 0.5 mg/100 mL, a factor of 1.5. There was no detectable DPA in the CE fraction.

In the plasma TG fraction, only the 22 carbon ω3 LCP were evident and only at a low concentration (Table 2); the increases in these fatty acids during the supplementation period were not significant (Fig. 3).

The concentration of ω3 LCP in the HDL PL was about 70% of the total plasma PL ω3 LCP concentration (Table 2). In contrast to the total plasma PL, the rise in all three ω3 LCP in this fraction was maximal after 1 wk of supplementation (Fig. 4). The maximum increases in the concentration of the ω3 LCP relative to the pre-trial values were: EPA 1.3 mg/100 mL ($P < 0.003$), DPA 0.3 mg/100 mL ($P < 0.0083$), DHA 0.8 mg/100 mL ($P < 0.0024$).

ω3 Depletion phase. There was a rapid depletion of EPA and DPA in all of the total plasma and HDL fractions (Figs. 1-4), with the values returning to pre-trial levels within 1 wk.

In the case of DHA, there was a slower depletion than for the other two ω3 LCP, particularly in the total plasma PL (Fig. 1). The DHA concentration had returned to pre-trial values by week 4 for the plasma CE and HDL PL and by week 5 for plasma TG. For the plasma PL there was a substantial drop in the DHA concentration in the first week of depletion (week 3), but no further fall in the remaining 3 wks. For six of the seven subjects examined, the DHA values did not return to the baseline values during the depletion phase. In one subject it reached baseline in weeks 5 and 6. At the end of the experiment, the mean plasma PL DHA concentration was still 40% above the baseline figure ($P < 0.02$) (Fig. 1).

DISCUSSION

The results of this experiment indicate that there were differences in the rate of accumulation and decay of the

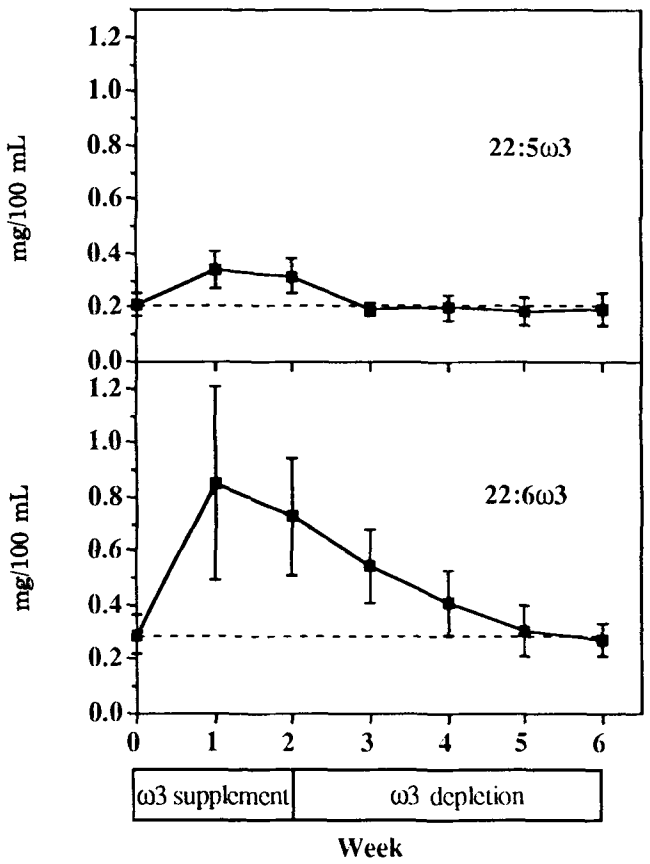

FIG. 3. The concentration (mean ± SD) of ω3 long-chain polyunsaturated fatty acids (PUFA) in plasma triglycerides during supplementation and depletion of diet with ω3 PUFA. Paired *t*-tests were conducted between the week 2 and week 0 samples, and between the week 6 and week 0 samples.

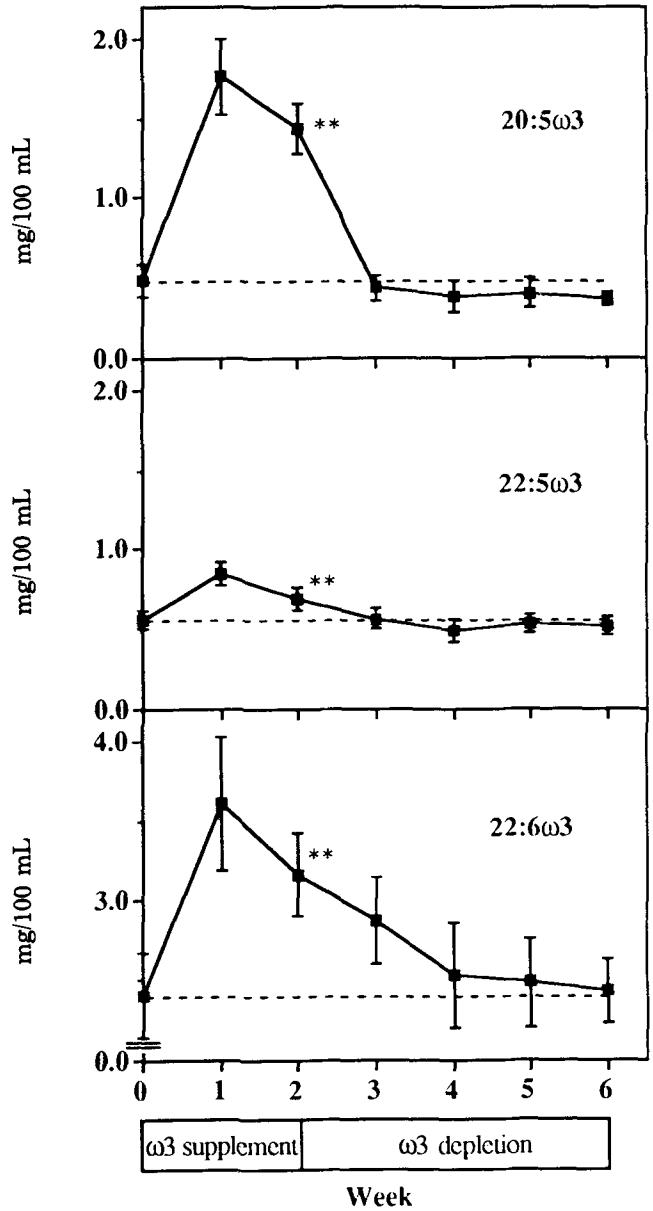

FIG. 4. The concentration (mean ± SD) of ω3 long-chain polyunsaturated fatty acids (PUFA) in high-density lipoprotein plasma phospholipids during supplementation and depletion of diet with ω3 PUFA. Paired *t*-tests were conducted between the week 2 and week 0 samples, and between the week 6 and week 0 samples $^{**}P < 0.01$.

three ω3 LCP in the plasma lipids during the supplementation and depletion phases, respectively. The EPA accumulated in the plasma PL and CE more rapidly than DPA and DHA, and in the depletion phase the EPA and DPA decayed more rapidly compared with DHA, particularly in the plasma PL. The EPA and DPA had returned to pre-trial values within one week in all plasma fractions whereas there was a slower decrease in the DHA concentrations and, in the case of the plasma PL, the DHA still remained above the pre-trial concentration 4 wk after the supplementation had finished.

These results are consistent with those reported by Bronsgeest-Schoute *et al.* (18), where volunteers were given different doses of fish oils (1.4–8.2 g/d of ω3 fatty acids) for 4 wk, and the effects of the plasma lipids were monitored during this period and for a further 2 wk after supplementation ceased. At the completion of the experiment for the three highest dose levels, the EPA, but not the DHA values, had returned to their pre-trail levels in the plasma CE, TG and phosphatidylcholine fractions. Similar results have been reported by others for erythrocytes and platelets (12,19). The slow return of erythrocyte DHA to baseline by comparison with EPA has been noted in particular by Brown *et al.* (20). They reported that 12 wk after fish plus fish oil supplementation had finished in eight volunteers, the degree of retention of erythrocyte EPA was 16% compared with a 44% retention of DHA (values expressed as a percent of the maximum increase on the fish plus fish oil diet). The present study differs from those discussed above, since in none of the previous studies was there a specific reduction in the dietary intake of ω3 LCP during the "washout" phase, thus confounding the possible interpretation of the results for the decay of the ω3 fatty acids.

There was an interesting difference between the disappearance of the ω3 fatty acids from HDL PL and total

plasma PL: in the former case, the DHA values returned to baseline within 2 wk whereas the disappearance from the total plasma was much slower. Although the interrelationships between the PLs in the different plasma lipoproteins are a poorly understood area of study, these results suggest there may be different rates of metabolism for the acyl chains in the PLs of the plasma lipoproteins.

These results also showed differences in the distribution of ω3 LCP in the lipid classes of the plasma and a disproportional accumulation of DHA. Most of the EPA was incorporated into both the PL and CE fractions (44% in PL, 48% in CE), whereas DPA and DHA were mainly found in the PL fraction (86 and 83%, respectively). This partitioning of EPA and DHA into different plasma lipids has been noted previously (18) and might be explained by differences in the positional specificity of EPA and DHA in the chylomicron TG (21,22). There was also a disproportional increase in the DHA in the plasma lipids. For example, at the end of the supplementation phase, the DHA-to-EPA ratio in the plasma lipids was 1.0 (expressed as the increase in DHA in the plasma lipid fractions, PL plus CE plus TG, over the 2-wk supplementation period/increase in EPA) compared with a ratio of 0.7 (DHA-to-EPA) in the supplementary fish oil. The DPA-to-EPA ratio in the plasma lipids was 0.19 compared with 0.15 in the supplement, and the DPA-to-DHA ratio was 0.20 in both the plasma and the supplement. These calculations assume that most of the LCPω3 in the supplementation phase was derived from the fish oil supplement and not from other dietary sources such as fish. A disproportional increase in DHA into various tissues relative to EPA has been reported for rabbits and rats fed fish oils (23,24). In the former article, it was estimated that DHA was three times more likely to be incorporated into adipose tissue than was EPA: the authors speculated that EPA was diverted into alternative metabolic pathways such as oxidation or deposition in other tissues.

The results from this and other studies showing marked differences in the fate of EPA and DHA following ingestion may allow an explanation of the low EPA levels in plasma lipids relative to the DHA levels. These data are consistent with the following possibilities: (i) that EPA is absorbed less effectively than DHA. This is not consistent with the data on the absorption of EPA and DHA from MaxEPA in the rat (22). (ii) That EPA is rapidly removed from the plasma pools to other tissues. This is not consistent with data showing disproportional increases in DHA relative to EPA in a variety of tissues (liver, muscle, adipose) (23,24). (iii) That EPA is β-oxidized faster than DHA. This is consistent with a preliminary report which indicated a more rapid *in vitro* β-oxidation of EPA compared with DHA in rat liver and muscle (25), a significantly greater rate of acylcarnitine synthesis of EPA compared with DHA in rat liver mitochondria (26) and an accelerated loss of α-linolenic acid and EPA compared with DHA in adipose tissue of human subjects undergoing weight loss (27). Gronn *et al.* (28) have indicated that the feeding of fish oil or purified ω3 PUFA to rats stimulates fatty acid oxidation in both mitochondria and peroxisomes and leads to an increased peroxisomal oxidation of ω3 PUFA. This report did not indicate whether there was any difference between the rate of oxidation of EPA and DHA. Zhang *et al.* (29) have reported that in the perfused rat liver, there is significantly less EPA compared with DHA incorporated into very low density lipoprotein lipids which is consistent with a greater of oxidation of EPA in the liver. (iv) That there is a rapid conversion of EPA to DHA. There have been no experiments conducted in humans which have directly addressed this issue. Indirect evidence from experiments of several weeks' duration does not support the view that EPA is rapidly transformed to DPA and DHA in humans. These experiments involved a variety of dietary changes, such as feeding canola oil or lean meat, which induced increases in EPA or EPA and DPA, respectively, in plasma or white cell lipids (13,30). These data do not rule out the possibility of slow conversion or the possibility of any DPA and DHA formed being transferred from the plasma to a tissue such as adipose (27). There must be some conversion of α-linolenic acid to DHA in humans since vegan vegetarians have normal levels of EPA and DHA in their plasma lipids (10), although the direct measurement of metabolism of deuterated α-linolenic acid suggests that the process is very slow (31). (v) That there is a lower intake of EPA than DHA in typical Western diets. Dietary sources of EPA and DHA in typical Western diets such as those consumed in Australia would include fish (EPA-rich for fatty fish and DHA-rich for lean fish, Ref. 32), lean red meat (which contains EPA plus DPA, Ref. 15), offal (which contains EPA, DPA, DHA) and eggs (which contain DHA) (14). Furthermore some EPA and DPA may be produced by the slow conversion of dietary α-linolenic acid to EPA (30,31). It is possible that the dietary intake of EPA is lower than that of DHA in some individuals (*e.g.*, diets containing fish low in fat and therefore DHA-rich, and eggs, which contain DHA but no EPA), but in general the EPA intake on a diet containing a variety of foods should be of the same order as that of DHA, as we have shown previously (13).

In conclusion, the relatively low levels of EPA compared with DHA in human plasma may be the result of a lower intake of EPA and an increased β-oxidation of EPA relative to DHA. One practical outcome of this data, especially for those with low levels of ω3 LCP, is that maintenance of increased EPA levels in plasma (and therefore tissues) would require constant inputs of EPA due to the relatively rapid loss of EPA from tissues.

ACKNOWLEDGMENTS

The willing participation of the subjects is gratefully acknowledged. The authors also thank Miranda Hughes and Dr. Bob Gibson for constructive criticism of the manuscript.

Dietary α-Linolenic Acid Alters Tissue Fatty Acid Composition, but Not Blood Lipids, Lipoproteins or Coagulation Status in Humans[1]

Darshan S. Kelley[a,*], Gary J. Nelson[a], James E. Love[b], Leslie B. Branch[b], Peter C. Taylor[a], Perla C. Schmidt[a], Bruce E. Mackey[c] and James M. Iacono[a]

[a]USDA, ARS, WHNRC, Presidio of San Francisco, California 94129, [b]Department of Pathology and Allergy Clinic, Letterman Army Medical Center, Presidio of San Francisco, California 94129 and [c]USDA, ARS, WRRC, Albany, California 94710

We examined the effect of dietary α-linolenic acid (ALA) on the indices of lipid and coagulation status and on the fatty acid composition of serum and peripheral blood mononuclear cell (PBMNC) lipids in ten healthy men (age 21–37 yr) who consumed all their meals at the Western Human Nutrition Research Center for 126 d. There was a stabilization period of 14 d at the start when all 10 subjects consumed the basal diet (BD) containing 23.4 energy percent (en%) fat and two intervention periods of 56 d each. During the first intervention period, 5 subjects consumed the BD containing 23.4 en% fat, and 5 subjects consumed a diet providing 6.3% calories from α-linolenic acid [flaxseed oil (FSO) diet containing 28.8 en% fat]. Diets were crossed over between the two groups during the second intervention period. Feeding the FSO diet did not significantly alter serum triglycerides, cholesterol, high-density lipoproteins, low-density lipoproteins, apoprotein A-I and apoprotein B when compared to the corresponding values in the subjects fed the BD, nor was there any effect of the FSO diet on the bleeding time, prothrombin time and partial prothrombin time for these subjects. Feeding the ALA-containing diet did cause a significant increase in ALA concentration in serum ($P < 0.001$) and PBMNC lipids ($P < 0.05$). It also caused a significant increase ($P < 0.05$) in the eicosapentaenoic and docosapentaenoic acid contents of PBMNC lipids, and a decrease ($P < 0.01$) in linoleic and eicosatrienoic acid contents of serum lipids. Thus, dietary ALA, fed for 56 d at 6.3% of calories, had no effect on plasma triglyceride or very low density lipoprotein levels or the common risk factors associated with atherosclerosis, although these parameters have been reported by others to be influenced by fatty acids, such as palmitic or linoleic acids, in the diet. Dietary ALA did significantly alter the fatty acid composition of plasma and PBMNC.

Lipids 28, 533–537 (1993).

Several studies have examined the effects of oils, usually of marine origin, rich in n-3 fatty acids on the concentration and composition of serum lipids (1,2). Most of these studies have indicated a reduction in serum triglycerides and very low density lipoprotein (VLDL) cholesterol with fish oil feeding. The results of these studies in regard to total serum cholesterol and low-density lipoprotein (LDL) cholesterol have been variable. Some of these inconsistencies may have resulted from differences in the level and duration of fish oil consumption, cholesterol and total fat, as well as the fatty acid composition of the diet. Fish oil consumption also has been reported to increase the bleeding time in human subjects (3,4). In contrast to the many studies conducted with marine oils, only limited studies have been conducted to examine the effects of n-3 fatty acids of plant origin on serum lipids and bleeding time in humans. Flaxseed oil (FSO) is free of cholesterol and contains about 60% α-linolenic acid (ALA, 18:3n-3). Thus, it is the richest source of n-3 fatty acids among plant oils. However, it does not contain any C_{20} or C_{22} n-3 fatty acids usually found in fish oils. Previous studies that have examined the effects of ALA-containing diets on the serum fatty acid composition have shown that humans have a limited capacity to convert ALA to eicosapentaenoic acid (EPA, 20:5n-3) and docosahexaenoic acid (DHA, 22:6n-3) (5–7). In the study reported here, we examined the effects of FSO-containing diets on serum lipids and indices of coagulation in ten healthy men. We also examined the effects of FSO-containing diets on the serum and peripheral blood mononuclear cell (PBMNC) fatty acid composition.

MATERIALS AND METHODS

Subjects. Sixteen men were selected to participate in the study. All had a complete physical examination by a physician to rule out any underlying disease. Data regarding only ten of the men who completed the entire study are included in this report. Partial results obtained from the six subjects who dropped from the study were comparable to those obtained from subjects who completed the entire study. Their ethnic backgrounds were as follows: one African-American, one Hispanic, one Filipino, one Iranian and six Caucasians. Nine of these men were soldiers assigned to the Letterman Army Medical Center and the Letterman Army Institute for Research, and the tenth was a civilian working at the Western Human Nutrition Research Center (WHNRC). They ranged in age from 21–37 (mean ± SEM, 27.3 ± 1.9 yr), in weight from 62.7–81.8 (74.6 ± 2.4 kg) and in height from 1.63–1.88 (1.74 ± 0.03 m). The study was approved by the institutional review boards of the U.S. Department of Agriculture and the Letterman Army Medical Center. Informed consent was obtained from all subjects before participation in the study.

Experimental design. The study consisted of an initial 14-d stabilization period and two intervention periods of 56 d each. During the stabilization period, all subjects consumed the basal diet (BD). For intervention period 1 (study days 15–70), five of the subjects continued to

consume the BD while the other five were fed an FSO (Omega Nutrition, Inc., Vancouver, British Columbia, Canada) supplemented diet. Subjects in the two groups were matched for age and weight; however, as each subject was fed both diets, the basis used for their distribution into two groups was not critical. The FSO was stored at −20°C and served cold mixed with yogurts, salads, sandwich spreads and vegetables. The diets were crossed over between the two groups for study days 71–126 (intervention period 2). All meals were prepared and consumed at the WHNRC on a 7-d rotating menu for 126 d under the supervision of the dietary staff. The subjects engaged in their normal activities and resided at their own homes. Body weights were maintained constant throughout the study by caloric adjustments and by maintaining the physical activities at the pre-study level.

Diets. Both diets consisted of natural foods except that 100 international units of α-tocopherol was supplemented twice a week to both dietary groups. The mean daily nutrient intake from the BD and FSO diets during the two intervention periods is shown in Table 1. Nutrient intake from the BD was similar for both the stabilization and intervention periods. The BD provided 23.4% energy (en%) as fat, 60.1% as carbohydrates and 16.5% as proteins. The mean daily intake of fat from the basal diet was 77.5 g, of which sunflower oil provided 11.0 g and safflower oil 4.3 g. In the BD, the saturated, monounsaturated and polyunsaturated fatty acids provided 7, 8.6 and 6.3 en%, respectively. The flax diet provided 28.8% energy as fat, 55.0% as carbohydrates and 16.2% as proteins. The mean daily intake of fat in the flax diet was 96.8 g, of which linseed oil provided 31.7 g and safflower oil 4.3 g. Energy from saturated, monounsaturated and polyunsaturated fats in the linseed oil diet was 7.0, 9.6 and 10.6%, respectively. The polyunsaturated/saturated fatty acids ratio of the two diets differed markedly with 0.89 for the basal diet and 1.50 for the linseed oil diet.

The fatty acid composition of the basal and linseed oil diets, in weight percent, are shown in Table 2. The amounts (g) of each fatty acid consumed from the two diets can be calculated from the data presented in Tables 1 and 2. The differences in individual fatty acids consumed each day between the basal and the linseed oil diets were minor, except for ALA. The percentages of energy from ALA, calculated from Tables 1 and 2, are 0.3% for the BD and 6.3% for the flax diet. All other nutrients in both diets were provided at or above the recommended daily allowance.

Laboratory methods. The proximate analysis of the diets was performed by Curtis and Tompkin Ltd. (Berkeley, CA) using standard procedures (8). Fatty acid composition of the diets was determined using capillary gas-liquid chromatography (GLC) (9). Composition of all other nutrients in the diets were calculated from the USDA Handbooks No. 8 and No. 456 (10,11).

Blood from overnight fasting subjects was collected by antecubital venipuncture into vacutainer tubes containing ethylenediaminetetracetate for lipid determinations and no anticoagulant for apolipoprotein determinations. Samples were drawn from subjects in both dietary groups at study days 1, 14, 42, 56, 70, 98, 112 and 126. Samples were always drawn between 7:00 a.m. and 8:00 a.m. and the plasma or serum separated from the cells within 1 h after collection. Specimens that could not be analyzed immediately were stored at 4°C or in accordance with reagent kit manufacturer's instructions. Total cholesterol, triglycerides and high-density lipoprotein (HDL) cholesterol were analyzed by enzymatic methods (12,13) adapted to the Cobas Fara Centrifugal Analyzer (Roche Diagnostic Systems, Nutley, NJ) (14) using Boehringer-Mannheim reagents (BMC, Indianapolis, IN). HDL cholesterol was

determined after precipitating LDL and VLDL with phosphotungstate and manganese (15). LDL was calculated using Friedewald's formula (16). Apolipoprotein A-I and B (apo A-I and apo B) were measured by nephelometry using the Beckman Immunochemistry System (Beckman Instruments, Brea, CA) (17). PBMNC were isolated using histopaque-1077 (Sigma Chemical Co., St. Louis, MO) (18), washed three times with phosphate buffered saline and stored at −20°C until direct transmethylation without prior solvent extraction (19). The impurities extracted into the hexane phase after transmethylation were removed by thin-layer chromatography as described by Nelson (20). Fatty acid compositions of the sera were determined by capillary GLC as previously described (21). The column used for serum and PBMNC fatty acid analysis was a 30 m × 0.025 mm fused quartz column coated with SP-2340 (Supelco, Bellefonte, PA). All GLC data were processed with an Perkin-Elmer (Norwalk, CT) model 7500 data station using Perkin-Elmer Chrom 3 software. Bleeding time, prothrombin time and partial prothrombin time were determined at the end of stabilization, and 21 and 56 d after the start of feeding each diet. The bleeding time was determined using a well-established laboratory procedure (22). The prothrombin and partial prothrombin times were measured by a photo optical method using the MLA Electro 700 Coagulation Analyzer (Medical Laboratory Automation, Inc., Pleasantville, NY) (23).

Data analysis. The data were analyzed by analysis of variance using SAS/STAT PROC GLM (24). The cross over design model included effects of order, subject (order), period, diet, time and diet × time using subject (order) as an error term for order. Single degree of freedom, orthogonal polynomial contrast for the time effects were partitioned out of the time and diet × time sources. The significance of the differences between the effects of the two diets were assessed from the P values for the main effect. The diet × time interaction was not significant for any of the measured responses ($P > 0.16$). Changes in the variables examined are considered significant for $P < 0.05$ or otherwise stated. Because the effect of order in which the two diets were fed in the two intervention periods was nonsignificant for all the variables included in this report, the data from the two intervention periods for each diet were pooled. The diet effects were determined analyzing all of the data collected during the study; however, for the ease of presentation, pooled data from all subjects collected at the end of each diet are shown in the Results and Discussion section.

RESULTS AND DISCUSSION

Data regarding the effects of basal and FSO diets on serum concentrations of cholesterol, triglycerides, HDL, LDL, apo A-I and apo B are given in Table 3. None of the response variables were altered by either of the two diets fed to the subjects included in this study. These results differ from those obtained in fish oil studies showing reduction in serum triglycerides and VLDL cholesterol (25–27). This suggests that EPA and DHA are more effective in lowering serum lipids than is ALA. However, the subjects and diets used in our study may also be partly responsible for the lack of effects. The subjects in our study were young and active soldiers whose serum lipids base line values were lower than those of the average public. To exclude the possibility that the low values we measured were in error, we had the cholesterol and triglyceride levels checked in an independent laboratory. The results from the two laboratories were within 5% of each other. The BD used in our study contained very low levels of saturated (7 en%) and total fat (23 en%). Thus, it may not be feasible to lower the serum lipids with the FSO diet or even with fish oils when switching from the type of low-fat diet used in our study. It should also be noted that the FSO diet contained 6 en% extra fat (total 29 en%) above the level of the BD; yet this did not cause an increase in the concentration of any of the serum lipids tested. Although there were minor differences in the concentration of several fatty acids between the two diets, the major difference was in the concentration of ALA (0.3% in BD, and 6.3 en% in FSO diet). It remains possible that the FSO diet would lower serum lipids in hyperlipidemic subjects. The diets and subjects in our study were selected primarily to examine the effects of an FSO diet on the immune response, which was suppressed (18).

TABLE 3

Effects of Basal and Flaxseed Oil Diets on Serum Lipids (mg/dL)[a]

Serum fraction	End stabilization	End flaxseed oil diet	End basal diet
Cholesterol	149.3 ± 8.6	147.0 ± 11.4	153.0 ± 14.1
Triglycerides	79.5 ± 21.3	60.2 ± 14.8	66.1 ± 13.3
HDL	46.1 ± 4.7	48.0 ± 5.8	47.1 ± 4.1
LDL	84.2 ± 12.6	87.2 ± 13.1	90.7 ± 12.4
Apo A-I	118.4 ± 9.1	117.6 ± 9.6	115.9 ± 7.5
Apo B	67.1 ± 11.2	58.9 ± 8.5	68.1 ± 10.6

[a]Data shown are the mean ± SEM (n = 10). During the stabilization period all ten subjects were fed the basal diet. For the next 56 d, five subjects were fed the flaxseed oil diet, and the other five remained on the basal diet. Diets between the two groups were crossed over for the next 56 d. Data were also collected after feeding the two diets for 28 and 42 d and used for analysis of variance. None of the serum lipids were altered by either diet. HDL, high-density lipoproteins; LDL, low-density lipoproteins; apo A-I, apoprotein A-I; apo B, apoprotein B.

The fatty acid compositions of the serum and PBMNC lipids are shown in Tables 4 and 5, respectively. Data presented in Table 4 show that the concentrations of ALA, linolenic acid (LA, 18:2n-6) and eicosatrienoic acid (ETA, 20:3n-3) were significantly ($P < 0.05$) different when the subjects were fed FSO or the BD. With the feeding of the FSO diet, the concentration of ALA in serum lipids increased and that of LA and ETA decreased ($P < 0.05$). The data also show that the levels of other fatty acids including EPA, DHA, and arachidonic acid (AA, 20:4n-6) in serum lipids were not altered by the FSO diet. The data in Table 5 show that the concentration of ALA in PBMNC lipids increased threefold, and that of EPA and docosapentaenoic acid (DPA, 22:5n-3) increased twofold ($P < 0.05$) with the feeding of the FSO diet. In PMBNC lipids, the concentrations of DHA, AA and other fatty acids were not different between the two dietary groups. In serum lipids, an increase in ALA concentration was accompanied by a decrease in the LA and ETA concentrations, while in PBMNC lipids no single fatty acid could be identified whose concentrations decreased when the concentrations of ALA, EPA and DPA increased. This may be because the total concentration of these three fatty acids, even in

the FSO groups, was less than 3%. The fact that the FSO diet contained 21% ALA (Table 2), yet the ALA contents of PBMNC and serum lipids were only 0.6 and 3.2%, respectively, suggests that diet plays only a minor role in determining the ALA concentration of these tissues and that genetic factors have a major regulatory effect.

[a]Data shown are the mean ± SEM (n = 10). For other details see footnote to Table 3. Data were also collected at 28 and 42 d after the start of feeding flaxseed oil and basal diets and used for analysis of variance.

[b]Significantly different between flaxseed oil and basal diet ($P < 0.05$).

The increase in the serum concentration of ALA with the FSO diet is in agreement with previous reports (5,6) showing an increase in plasma ALA concentration when diets were supplemented with this fatty acid. We did not find an increase in EPA and DPA content in serum lipids with the FSO diet, whereas the concentrations of these two fatty acids in PBMNC lipids were increased. This may reflect the fact that triglycerides make up the major portion of the serum lipids, while membrane phospholipids comprise the major part of PBMNC lipids. Previous studies (5–7) on plasma phospholipids, in contrast to our data on total serum lipids, did find an increase in plasma EPA and DHA contents with the feeding of ALA-containing diets. Regardless, whether the total lipids or the phospholipids are analyzed, the conversion of ALA to EPA and DHA appears limited. In our study, we did not find an increase in DHA concentration of PBMNC lipids, even when the EPA and DPA contents were significantly elevated (Table 5). These results suggest that the conversion of ALA to DHA in humans may be restricted at the conversion step from DPA to DHA.

A comparison of the data in Tables 4 and 5 shows minor differences in the concentrations of several fatty acids between serum and PBMNC lipids; however, major differences were observed in the concentrations of AA and LA. The concentration of LA in serum lipids is about 25%, and in the PBMNC lipids it is only about 6%. The AA content of the serum lipids was about 6% and that of the PBMNC lipids was about 24%.

Data regarding bleeding times, prothrombin times and partial prothrombin times are given in Table 6. None of these response variables was altered by either diet. Again these findings are at variance with the results obtained upon feeding of fish oil which caused an increase in bleeding times (3,4). The reasons for the lack of an effect of the FSO diet on these indices of coagulation may be similar to those already discussed for serum lipids.

In conclusion our results show that in the young soldiers studied, the FSO diet did not alter indices of serum lipids or of blood coagulation even when the FSO diet contained 6 en% more fat, which came from ALA. Because this study was done with young subjects on very low-fat diets, it does not rule out the possibility of a serum lipid lowering effect of an FSO diet in hyperlipidemic subjects or in subjects eating high-fat diets. This should be examined in future studies. We did, however, find significant changes in the fatty acid composition of serum and PBMNC lipids in subjects on the FSO diet.

TABLE 6

Effects of Basal and Flaxseed Oil Diets on Bleeding, Prothrombin and Partial Prothrombin Times (min)[a]

Response variable	End stabilization	End flaxseed oil diet	End basal diet
Bleeding time	5.0 ± 0.4	4.5 ± 0.4	4.6 ± 0.4
Prothrombin time	12.2 ± 0.1	12.0 ± 0.2	12.0 ± 0.1
Partial prothrombin time	29.0 ± 0.5	28.9 ± 0.3	28.9 ± 0.6

[a]Data shown are the mean ± SEM (n = 10). For other details see the footnote to Table 3. Data were also collected after 21 d of feeding the two diets and used for analysis of variance. None of the variables in this table were altered by either diet.

Interrelationship of Stearic Acid Content and Triacylglycerol Composition of Lard, Beef Tallow and Cocoa Butter in Rats

Cathy C. Monsma and **Denise M. Ney***
Department of Nutritional Sciences, University of Wisconsin, Madison, Wisconsin 53706

We investigated modes whereby stearic acid (18:0) exerts a neutral or cholesterol-lowering effect using dietary fats which provided graded levels of 18:0 and distinct triacylglycerol (TAG) profiles. Male Sprague-Dawley rats (150–175 g) were fed diets containing 0.2% cholesterol and 16% fat from corn oil, or from 1% corn oil plus 15% lard (13.2% 18:0), beef tallow (19.2% 18:0) or cocoa butter (34.7% 18:0) for 3 wk, and then killed in a fasted or fed state. Chylomicron (CM) fatty acid profiles suggested reduced absorption of 18:0 with greater 18:0 intake. CM TAG profiles indicated a reduction or loss of two TAG species compared to the TAG profiles of the stearate-rich diets: 1-palmitoyl-2-oleoyl-3-stearoyl glycerol (POS) and 1,3-distearoyl-2-oleoyl glycerol (SOS). Hepatic total cholesterol concentrations were 54–77% lower ($P < 0.01$) in the cocoa butter-fed than the lard- and beef tallow-fed groups. The cocoa butter group showed a significantly lower ratio of high-density lipoprotein esterified/free cholesterol than all other groups. Hepatic stearoyl-CoA and oleoyl-CoA concentrations, the substrate and product for hepatic Δ9 desaturase, were not significantly different for corn oil-fed and cocoa butter-fed groups in spite of a large difference in 18:0 intake. These data suggest that the neutral or cholesterol-lowering effect of 18:0 is not due to hepatic conversion of stearic to oleic acid, and that POS and SOS are poorly absorbed from stearate-rich dietary fats.
Lipids 28, 539–547 (1993).

Studies in humans (1–5) and experimental animals (6,7) suggest that ingestion of stearic acid (18:0) has a neutral or hypocholesterolemic effect in contrast to lauric (12:0), myristic (14:0) and palmitic (16:0) acids. Thus, controversy has arisen regarding the classification of stearic acid as a "saturated fat" for dietary recommendations and nutritional labeling purposes (8). This controversy reflects a lack of understanding of the mechanisms responsible for the neutral or hypocholesterolemic effects associated with ingestion of stearic acid. Proposed mechanisms include poor absorption of stearic acid from dietary fat (9–12), rapid conversion of stearic acid to oleic acid by hepatic Δ9 desaturase (13) and effects of the stereospecific triacylglycerol (TAG) structure of stearate-rich dietary fats on their absorption and metabolism (14–16).

Although many studies have examined the effects of feeding stearate-rich fats (commonly defined as having greater than 12% of fatty acids as 18:0), differences in experimental design make it difficult to draw conclusions about the mode(s) of action of stearic acid (17). Using only the fasted state, often a single stearate-rich fat was compared to either a low-stearate saturated fat, an unsaturated fat or both (2,4–7,10–13). Other studies have utilized either synthetic or randomized stearate-rich fats, but these do not reflect the distinct TAG structures of naturally occurring stearate-rich dietary fats (4,9,16). Lastly, some human studies in metabolic ward settings have used liquid formula diets (3,4,17).

The objective of this work was to gain insight into the modes whereby stearic acid exerts its hypocholesterolemic effect. Three naturally occurring dietary fats, lard (13.2% 18:0), beef tallow (19.2% 18:0), and cocoa butter (34.7% 18:0) were fed to provide graded levels of stearic acid, relatively constant amounts of palmitic acid and distinct TAG profiles. Cocoa butter is composed chiefly of three TAG species: 1,3-dipalmitoyl-2-oleoyl glycerol (POP); 1-palmitoyl-2-oleoyl-3-stearoyl glycerol (POS); and 1,3-distearoyl-2-oleoyl glycerol (SOS). It has a relatively simple TAG profile compared to beef tallow and lard which are composed of 7-10 TAG species (15,18,19). We compared both fasting and postprandial plasma and hepatic lipid responses, the fatty acid and TAG profiles of chylomicron (CM) lipids and the levels of hepatic stearoyl-CoA and oleoyl-CoA, the substrate and product for the hepatic Δ9 desaturase system, in rats.

MATERIALS AND METHODS

Animals and diets. Male Sprague-Dawley rats (Harlan Sprague-Dawley, Madison, WI), 150–175 g, were housed in individual stainless-steel cages with free access to water in a room maintained at 25°C using a 12 h reverse light-dark cycle (lights on 2200–1000 h). The animal facilities and protocols were approved by an institutional animal care and use committee. Rats consumed *ad libitum* one of four diets patterned after the AIN 76A diet (20), containing 16% fat from either 16% corn oil, or 15% lard, 15% beef tallow or 15% cocoa butter with 1% corn oil to prevent essential fatty acid deficiency (Table 1). The fatty acid composition of each diet (Table 2) was determined by capillary gas chromatography with flame-ionization detection (GC-FID). All diets contained 0.2% added cholesterol (Sigma, St. Louis, MO) to provide similar amounts of dietary cholesterol (0.465 mg/kcal). Diets were stored at 4°C and fresh diets were presented to animals biweekly. Food intake was calculated weekly based on a 4-d period and body weight was measured biweekly.

Experimental design. A 4 × 2 (DIET × FED/FASTED) factorial design was used (n = 10). After 3 wk of feeding, all rats were fasted overnight and killed during the early portion of the dark cycle. For each of the four diets, one group of animals was killed in a fasted state (FASTED) while the other group was killed in a postprandial state (FED). The FED rats were fed *ad libitum* for 1 h and killed 1.5 h later. During the 1 h *ad libitum* feeding period, animals consumed 6.0 ± 0.3 g diet. All animals were anesthetized with CO_2 and blood (8–10 mL) was collected by cardiac puncture into syringes containing 1 mg ethylenediaminetetraacetic acid and 0.1 mg gentamicin sulfate

per mL blood. Plasma was obtained by centrifugation at 4°C for 20 min at 1200 × *g*. Livers were excised, blotted dry, weighed and divided into two portions. One portion was frozen immediately in liquid nitrogen and stored at −70°C for the analysis of individual acyl-CoA esters, and the other portion was stored at −20°C for hepatic lipid analyses.

Lipid analyses. For all FED and corn oil FASTED rats, CM, very low density lipoprotein (d < 1.006 g/mL, VLDL), low-density lipoprotein (d = 1.006–1.050 g/mL, LDL) and high-density lipoprotein (d = 1.050–1.196 g/mL, HDL) were fractionated by sequential ultracentrifugation from 3-mL plasma samples containing 0.56 mM, 5,5′-dithio-*bis*-nitobenzoic acid and 1 mM phenylmethylsufonylfluoride in isopropanol (21). CM were isolated in the top 2 mL after centrifugation for 1.0 h at d < 1.006 g/mL, extracted with hexane/isopropanol (22), evaporated to dryness under nitrogen at 37°C and redissolved in chloroform/methanol (3:2, vol/vol).

Total and free cholesterol were measured in plasma, CM, VLDL, LDL and HDL, and the concentration of esterified cholesterol was determined by difference (21). Triglycerides in plasma (Sigma Triglyceride Kit, No. 336) and lipoprotein samples were also measured. Total protein (VLDL, LDL, HDL), phospholipid and HDL apolipoprotein A-I concentrations were determined as previously described (21). Lipids were extracted from 1-g liver samples with chloroform/methanol (2:1, vol/vol) and assayed for both total and free cholesterol and triglycerides; esterified cholesterol (EC) was determined by difference (21). Individual fatty acyl-CoA esters were analyzed by reverse-phase high-performance liquid chromatography (23).

Triglyceride and cholesteryl ester from the CM lipid extract were isolated on 3 mL aminopropyl (NH_2) Bond Eluts (catalog no. 1212-4038, Varian, Walnut Creek, CA) using a modification of the method of Kalzuny *et al.* (24). An internal standard containing 500 μg each of triheptadecanoin and cholesteryl pentadecanoate (Sigma) was added to a 500 μL aliquot of CM extract (approximately 1–2 mg total lipid). Triglyceride and cholesteryl ester fractions obtained from the Bond Eluts were evaporated to dryness and stored in chloroform/methanol (2:1, vol/vol; 250 μL) until analyzed by GC-FID for either fatty acid or TAG profiles. This procedure was also used to isolate the triglycerides from the diets for TAG profile analyses.

Fatty acid analyses. Both triglyceride and cholesteryl ester fatty acids obtained from CM lipids were transesterified using methanol/benzene (4:1, vol/vol; 2 mL) and acetyl chloride (200 μL) (25). Fatty acid methyl esters (FAME) were stored in benzene at −20°C until analysis by capillary GC-FID. Fatty acids from the diets were transesterified using 10% BF_3/methanol (w/w) reagent (Supelco, Bellefonte, PA) and stored in pentane at −20°C until analyzed. FAME were analyzed on a Varian 3400 gas chromatograph equipped with a flame-ionization detector, a Varian 1093 SPI temperature programmable injector (Palo Alto, CA), a Supelcowax 10 fused silica column, 30 m × 0.32 mm i.d. 0.25 μm film (Supelco) and an In-Board Data Handling System (IBDH™, Sugarland, TX). The injector temperature was progammed from 50 to 250°C at a rate of 100°C/min and held for 15 min during the analysis. The initial column temperature was held for 2 min at 50°C, programmed to 160°C at a rate of 30°C/min, then programmed to 190°C at a rate of 3°C/min and finally programmed to 227°C at a rate of 4°C/min and held for 15 min for a total analysis time of 40 min. The carrier and make-up gases were helium at 2 mL/min and 30 mL/min, respectively. The detector temperature was 300°C. Fatty acids were identified by comparing the retention times with those of known standards (Nu-Chek-Prep, Elysian, MN) and expressed as the weight percent distribution of FAMEs.

TAG profiles. Intact TAG profiles were determined based on total acyl carbon number (C_n) where n is the total number of carbon atoms from fatty acids esterified to the glycerol backbone. Profiles of triglycerides isolated from the diet and composites of CM lipid extract from each FED diet group (n = 8–9) were obtained on a Varian GC-FID equipped with a TAP CB (75% phenyl, 25% methylpolysiloxane) on a WCOT Ultimetal column, 25 M × 0.25 mm i.d., 0.80 mm o.d., 0.10 μm film (Chrompack, Raritan, NY). The injector was isothermal at 360°C, and injection volume was 0.2 μL of a hexane solution (100 μL)

containing triglycerides obtained from Bond Elut separation of lipid classes. The initial column temperature was 290°C, immediately programmed to 330°C at a rate of 10°C/min, finally programmed to 355°C at a rate of 2°C/min and held for 8 min for a total analysis time of 25 min (18,26,27). The carrier gas was helium at 15 psi column pressure; make-up gas was helium at 22 mL/min. The detector temperature was 370°C. Data were acquired using a Waters Baseline 810 Chromatography Workstation connected *via* a Waters System Interface Module (Waters, Milford, MA). Manual baseline correction and reintegration was required for all samples due to the complexity of the chromatograms. Identification of TAG species from the dietary fats and CM TAG was based upon comparison of retention times to a triglyceride standard (catalog no. 178-11, Sigma) and published chromatograms (18,19). Values are expressed as the area percent of each TAG species.

Statistical analysis. Differences among dietary treatment groups were assessed by either one-way or two-way analysis of variance (ANOVA) using the SAS general linear models (GLM) program (SAS, Cary, NC) (28). Group means were considered to be significantly different at $P < 0.05$ as determined by the protected least significant difference technique. Values are expressed as mean ± SEM; means with different superscripts are significantly different.

RESULTS

Growth, food intake and liver weight. Final body weight and growth did not differ across the treatment groups but diet affected mean daily food intake (Table 3). As the stearic acid content of the diet increased, food intake increased significantly and rats fed the cocoa butter diet ate 10% more than rats fed the corn oil diet. Relative liver weight was significantly affected by both DIET and FED/FASTED states such that FED animals had 11% higher liver weights than FASTED animals.

Plasma and hepatic cholesterol and triglycerides. Plasma cholesterol and triglyceride concentrations did not differ among the groups fed different dietary fats but significant differences occurred between the FED and FASTED groups (Table 4). FED groups had 44% greater plasma triglyceride concentrations and 12.5% lower plasma total cholesterol concentrations than FASTED groups. Lower plasma cholesterol concentrations in FED animals were associated with significantly lower esterified, but not free, cholesterol levels. The esterified/free cholesterol (E/F) ratio was significantly lower for the three FED *vs.* FASTED stearate-rich groups while the corn oil group had similar ratios in both FED and FASTED states.

In contrast, dietary fat affected hepatic cholesterol and triglyceride concentrations more strongly than plasma concentrations and a significant DIET × FED/FASTED interaction was observed for hepatic total, esterified and E/F cholesterol concentrations (Table 5). Compared to fasting, hepatic total and EC decreased after consuming a meal containing corn oil or cocoa butter, showed little change after consuming a meal containing lard and increased after consuming a meal containing beef tallow. Among FED groups, cocoa butter showed 54–142% lower ($P < 0.001$) hepatic total and EC levels than lard and beef tallow. Stearate-rich dietary groups had lower hepatic triglycerides than the corn oil group (corn oil = 15.5; lard, beef tallow and cocoa butter = 6.9–11.0 μmol triolein/g liver, $P = 0.0001$, main effects two-way ANOVA).

Hepatic acyl-CoA concentrations. Individual hepatic acyl-CoA concentrations in FED and FASTED animals are summarized in Table 6. Significant DIET × FED/FASTED interaction was observed for stearoyl-CoA (18:0). In FASTED animals stearoyl-CoA (18:0) concentrations generally reflected 18:0 content of the diet (lard < beef tallow < cocoa butter) but were not significantly different. In contrast, in FED animals there was no association between dietary 18:0 and stearoyl-CoA levels. Most notably, FED stearoyl-CoA concentrations did not differ significantly for corn oil (2.0% 18:0) and

Cocoa butter	2.02 ± 0.12^{a}	1.67 ± 0.12^{a}	0.36 ± 0.01	4.7 ± 0.4^{a,b}	0.91 ± 0.03^{b}
Two-way ANOVA (GLM), *P*-values					
Diet	NS	NS	NS	NS	NS
Fed/fasted	0.0003	0.0001	NS	0.0001	0.0001
Diet × fed/fasted	NS	NS	NS	NS	NS

[a]Values are means ± SEM, n = 9–10. Means with different superscripts in the same column are significantly different [$P < 0.05$, two-way analysis of variance (ANOVA), protected least significant difference]; NS, not significant; E/F ratio, esterified/free; GLM, general linear models.

cocoa butter (34.7% 18:0), but were significantly higher for animals fed lard (13.2% 18:0). Hepatic oleoyl-CoA (18:1) concentrations were affected by DIET but not by FED/FASTED states and, in general, reflected 18:1 dietary intake. The beef tallow dietary group had significantly higher hepatic oleoyl-CoA concentrations than the corn oil group.

Lipoprotein concentration and composition. The concentration and composition of lipoproteins differed significantly among the fed dietary treatment groups. Ingestion of a meal containing cocoa butter resulted in HDL with significantly more (% by wt) protein and free cholesterol and less EC than HDL from animals fed beef tallow or lard (Table 7). The cocoa butter group showed a significantly lower ratio of HDL E/F cholesterol than all other groups. HDL apolipoprotein A-I concentrations did not differ among the groups (data not shown). Taken together, the significantly lower ratio of HDL (Triglyceride + EC)/Protein in the cocoa butter than the beef tallow and lard groups suggests a greater population of lipid-depleted HDL particles with ingestion of cocoa butter than the other stearate-rich fats studied.

The cocoa butter group showed significantly higher concentrations of LDL protein, phospholipid and EC than all other dietary groups which is consistent with a larger number of LDL particles. A different trend was seen in VLDL; beef tallow showed significantly higher VLDL protein, esterified and total cholesterol concentrations and

a significantly lower proportion of VLDL triglycerides than all other groups (data for LDL and VLDL not shown). CM concentrations generally reflected VLDL, and beef tallow showed similar triglycerides but significantly higher concentrations of total cholesterol than lard and cocoa butter.

Fatty acid profiles of CM triglyceride and cholesteryl esters. The fatty acid composition of CM triglyceride is summarized in Table 8. Cocoa butter ingestion resulted in significantly greater CM triglyceride 18:0 (% methyl ester), and beef tallow ingestion resulted in significantly greater 18:1 than all other diets. The corn oil dietary group had significantly less 16:0, 18:0 and 18:1 but significantly more 18:2 and 20:4 than the stearate-rich dietary groups. The fatty acid composition of CM cholesteryl ester followed similar trends but the proportion of 18:0 did not differ among the dietary groups (data not shown). CM cholesteryl ester also contained a large (35.6–47.1%) proportion of arachidonic acid for all dietary groups.

Among the stearate-rich dietary groups, lower 18:0/18:1 ratios were noted in CM TAG compared to the corresponding diets: lard, 0.15 *vs.* 0.30; beef tallow, 0.16 *vs.* 0.40; and cocoa butter, 0.35 *vs.* 1.0, respectively. Regression analysis showed a strong linear relationship ($r^2 = 0.985$, n = 4, $P < 0.01$) between the 18:0 content of CM triglycerides and 18:0 content of the diets but an insignificant correlation ($r^2 = 0.723$, n = 4, $P > 0.1$) between the 18:1 content of CM triglyceride relative to dietary 18:1 (Fig. 1). The proportion of CM 18:1 was significantly greater in the beef tallow than the lard dietary group, although lard and beef tallow diets did not differ in the proportion of dietary 18:1.

TAG profiles of diets and CM based on C_n. Each diet displayed a distinct TAG profile according to separation by C_n (Tables 9–12 and Figs. 2 and 3). Cocoa butter had the simplest profile, with only three major TAG species at C_{50}, C_{52} and C_{54}. Lard and beef tallow TAG contained primarily C_{50}, C_{52} and C_{54}, but the degree of unsaturation was greatly increased compared to cocoa butter as indicated by longer retention times on the polar column. Beef tallow also had more C_{48} species than the other stearate-rich diets.

Only the stearate-rich fats showed changes in the profiles of CM compared to the TAG profiles of the diets (Tables 9-12 and Figs. 2 and 3). Among stearate-rich fats, CM TAG were relatively enriched in unsaturated species within a TAG C_n (Tables 10-12 and Figs. 2 and 3), and the enrichment became more pronounced with increased dietary stearate content. Cocoa butter CM TAG changed most dramatically, with the complete disappearance of two major dietary TAG species, POS and SOS, and formation of several new, more unsaturated species (Fig. 3). Similarly, POS decreased (but was still present) in both lard and beef tallow CM TAG while SOS decreased in beef tallow CM TAG (Fig. 2). Both lard and beef tallow CM TAG were enriched in more unsaturated species at C_{52} and C_{54} but, unlike cocoa butter, these TAG species were also present in the dietary fat.

DISCUSSION

This study provides new information about the effects associated with ingestion of stearic acid during both fasting and postprandial states in the rat. We compared consumption of three naturally occurring, stearate-rich dietary fats providing graded levels of 18:0 and distinct TAG profiles. Our data provide new evidence that both increased 18:0 content and TAG composition influence absorption and intestinal processing of 18:0. For example, a TAG species, identified as POS, was poorly absorbed from all stearate-rich diets while another TAG species, identified as SOS, was poorly absorbed from both the beef tallow and cocoa butter diets. Mattson *et al.* (9) observed that in rats fed a series of TAG isomers, 18:0 esterified at either the *sn*-1 or *sn*-3 position was released as the free acid and poorly absorbed in the presence of calcium and magnesium. Our CM TAG profile data are consistent with

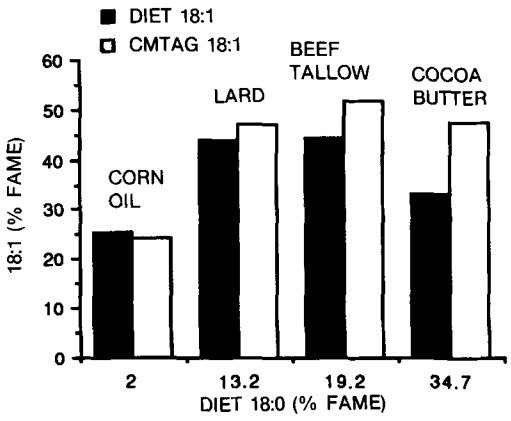

FIG. 1. Relationship between dietary and chylomicron triacylglycerol (CM TAG) oleic acid (18:1) as a function of dietary stearic acid (18:0). Differences between dietary 18:1 and CM TAG 18:1 increased in proportion to the 18:0 content of the diets. Values are weight percent of fatty acid methyl esters (FAME).

this latter observation because 18:0 is esterified primarily at either *sn*-1 or *sn*-3 position in lard, beef tallow and cocoa butter (29), and we observed lower absorption of both SOS and POS species.

Additional evidence for reduced 18:0 absorption is suggested by the observation that rats fed stearate-rich diets showed increased food intake but not increased growth (Table 3). The lower CM than diet TAG 18:0/18:1 ratios, especially in the cocoa butter dietary group, also suggest reduced absorption of 18:0 relative to 18:1 with greater dietary 18:0 intake (10,12,21). These data are supported by the results of another experiment using diets identical to those in the present study where we noted that apparent lipid digestibility decreased with increased dietary 18:0 (30). Apparent lipid digestibility was: cocoa butter, 78% < beef tallow, 82% < lard, 90% < corn oil, 94% ($P < 0.001$).

Other explanations for the lower 18:0/18:1 ratios observed in CM TAG relative to corresponding diets include conversion of dietary 18:0 to 18:1 by intestinal Δ9 desaturase and the contribution of endogenous fatty acids by the intestine prior to reassembly of CM TAG (31,32). Giron *et al.* (31) observed higher Δ9 desaturase activity in duodenal mucosa than in the liver. Perhaps the small intestine plays a regulatory role in fatty acid metabolism by modifying the degree of saturation of dietary fatty acids and TAG structure prior to CM transport out of the enterocyte.

The greater sensitivity of hepatic than plasma cholesterol concentrations to dietary fat was due to differences in fed groups. Differences in the FED response (*i.e.*, increased or decreased hepatic cholesterol concentrations after a meal) to dietary stearate-rich fats emphasize the important role of the intestine in cholesterol metabolism. Among fed rats, hepatic total cholesterol concentrations were 54–77% lower in the cocoa butter than the lard and beef tallow dietary groups. These data support a liver cholesterol-lowering effect of cocoa butter compared to beef tallow and lard.

In general, our research confirms previous observations of differences in hepatic but not plasma total cholesterol concentrations in rats fed stearate-rich *vs.* unsaturated dietary fats and sampled after an overnight fast (6,7,21). A longer feeding period and/or larger amounts of dietary fat, cholesterol and cholic acid may be needed to detect differences in plasma cholesterol given the rats' ability to regulate plasma cholesterol concentrations. For example, Morrissey *et al.* (33) noted that 60 d of feeding 10, 20 or 30% cocoa butter diets to male Sprague-Dawley rats

SOS; and 12,13. unknown. B: Gas-liquid chromatogram of intact TAG species from chylomicrons in rats fed a 15% cocoa butter + 1% corn oil diet. Peak identification (Refs. 18,19): 1. unknown; 2. POP; 3-5,7,9,10,12-15. unknown. See Table 12 for area percent.

was needed to detect a significant decrease in plasma cholesterol concentrations compared to corn oil.

Hepatic concentrations of stearoyl-CoA and oleoyl-CoA provide indirect evidence that little hepatic conversion of 18:0 to 18:1 occurred during feeding of stearate-rich diets (Table 6). Stearoyl-CoA and oleoyl-CoA concentrations were not significantly different for corn oil (2.0% 18:0) and cocoa butter (34.4% 18:0) dietary groups during feeding. If hepatic Δ9 desaturase was rapidly converting dietary 18:0 to 18:1, a higher concentration of hepatic stearoyl-CoA and oleoyl-CoA would be predicted for the cocoa butter than for the corn oil dietary group. Hepatic Δ9 desaturase has been well studied in rats and mice (34-36). Ntambi (36) noted that diets supplemented with essential fatty acids repressed induction of Δ9 desaturase mRNA in mouse liver following fasting and refeeding.

Since our diets contained 1% corn oil, this may explain the apparent lack of hepatic Δ9 desaturase activity suggested by hepatic oleoyl-CoA concentrations.

In conclusion, this study demonstrates that both stearic acid content and TAG composition of stearate-rich dietary fats influence intestinal processing and postprandial hepatic and lipoprotein cholesterol concentrations in the rat. Our data are consistent with reduced absorption of stearate from naturally ocurring stearate-rich dietary fats. Hepatic stearoyl-CoA and oleoyl-CoA concentrations do not suggest rapid conversion of dietary stearate to oleate during feeding. Further research on intestinal Δ9 desaturase and the possible regulatory role of the intestine may provide useful insight into the effects associated with ingestion of stearate-rich dietary fats. Given the distinct TAG profiles of naturally occurring stearate-rich dietary fats, it may not be prudent to make generalized statements about these fats based on stearic acid content alone.

ACKNOWLEDGMENTS

This research was supported by a grant from the National Live Stock and Meat Board and by funds from the College of Agricultural and Life Sciences, University of Wisconsin-Madison, project No. 3096. The authors would like to thank Ambrosia Chocolate, Milwaukee, WI, for their donation of cocoa butter. The technical assistance provided by Mike Grahn and the support of Dr. Rhona Applebaum of the Chocolate Manufacturers Association are greatly appreciated.

Cholesterol Synthesis and Esterification in Isolated Enterocytes: Regulation by Cholesterol and Cholestyramine Feeding

José Iglesias, Dolores Gonzalez-Pacanowska, Carmen Marco and **Eduardo Garcia-Peregrin***
Departamento de Bioquímica y Biología Molecular, Facultad de Ciencias, Universidad de Granada, 18071 Granada, Spain

The purpose of the present study was to investigate the physiological control of the main regulatory enzymes of cholesterol metabolism in isolated enterocytes obtained from chick duodenum, jejunum and ileum. Cholesterol feeding resulted in an inhibition of 3-hydroxy-3-methylglutaryl-CoA reductase and mevalonate 5-pyrophosphate decarboxylase, while cholestyramine feeding increased reductase activity in all the regions studied and decarboxylase activity only in duodenum. Cholesterol feeding markedly increased acyl-CoA:cholesterol acyltransferase, but the effects of cholestyramine were less clear. The effects on transferase activity cannot be due to differences in the availability of acyl-CoA as exogenous substrate as no significant differences were found in acyl-CoA hydrolase activity after any of the dietary treatments. The effects of cholesterol feeding were related to changes in the cholesterol content of epithelial cells, whereas in the case of cholestyramine this relationship was less apparent. *Lipids 28,* 549–553 (1993).

The rate of *de novo* cholesterol synthesis in the intestine is second only to that in the liver, and, in some animal species, it may contribute more cholesterol to the body than does the liver (1). However, the regulatory role of dietary cholesterol on cholesterol biosynthesis in the intestine has been questioned. One of the early studies that did not show a regulatory effect of dietary cholesterol on cholesterol synthesis in the intestine was that of Dietschy and Siperstein (2), and these observations were confirmed in a more recent study (3). Likewise, Shefer *et al.* (4) were unable to suppress the activity of 3-hydroxy-3-methylglutaryl-CoA (HMG-CoA) reductase in intestine of rats fed a diet supplemented with 2% cholesterol. There are species-related differences in the response of intestinal cholesterol biosynthesis to dietary cholesterol. For example, in the hamster (5), guinea pig (6), rabbit (7) and dog (8), diets supplemented with cholesterol were found to readily down-regulate cholesterol biosynthesis in the intestine. We also have reported an inhibitory effect of cholesterol feeding on chick intestine HMG-CoA reductase (9).

Many technical difficulties exist in the use of the intestine as an experimental model to study the regulation of cholesterol metabolism. Data from one report are difficult to compare with data from another. In addition to the known species differences, distinct functional differences along the length of the small bowel also exist (1).

Bile acids regulate intestinal cholesterol metabolism. The binding of bile acids by resins in the lumen of the intestine (10) or surgical diversion of bile from the intestine (10,11) can cause a marked stimulation of cholesterol synthesis and a decrease in cholesterol esterification in the intestine (12). Rat HMG-CoA reductase of both liver and intestine appears to be stimulated after cholestyramine feeding (13,14). Similarly, cholestyramine feeding increased chick liver and intestine reductase activity throughout postnatal development (9).

Although HMG-CoA reductase is considered the rate-limiting enzyme for cholesterogenesis in liver and other tissues (15,16), the existence of a secondary site of regulation at the step catalyzed by mevalonate 5-pyrophosphate (MVAPP) decarboxylase has been suggested (17–20). We have shown that cholesterol or cholestyramine feeding produced similar effects on MVAPP decarboxylase from chick intestine as those observed on HMG-CoA reductase, while other mevalonate-activating enzymes were not affected (21,22). Likewise, there is now substantial evidence that acyl-CoA: cholesterol acyltransferase (ACAT) is the major enzyme involved in cholesterol esterification in intestinal mucosa (23).

The purpose of this study was to investigate the physiological regulation of HMG-CoA reductase, MVAPP decarboxylase and ACAT in chick duodenum, jejunum and ileum in order to define the role of each intestinal segment in cholesterol metabolism. Given the fact that isolated epithelial cells have shown higher levels of enzyme activities compared to those found in mucosal scrapings (24), isolated enterocytes were used in the present experiments.

MATERIALS AND METHODS

Materials. Radioactive reagents [3-^{14}C]HMG-CoA, [2-^{3}H]MVA lactone, [2-^{14}C]MVAPP (ammonium salt), [1-^{14}C]oleoyl-CoA and [6-^{3}H]thymidine, were supplied by Amersham International (Amersham, United Kingdom). [1,2,3,6,7,-^{3}H]Cholesteryl oleate was purchased from New England Nuclear (Boston, MA). Radioactive chemicals were diluted with pure unlabelled compounds to obtain the required specific activities. Nonradioactive reagents were from Sigma Chemical Co. (St. Louis, MO), Boehringer Mannheim (Mannheim, Germany) and E. Merck (Darmstadt, Germany).

Animals and diets. White Leghorn male chicks (*Gallus domesticus*), 35-days-old, were used. Newborn animals were obtained from a commercial hatchery and fed *ad libitum* a commercial diet (Sanders A-00, Granada, Spain) which contained (w/w) 45.2% carbohydrate (mainly starch), 3.5% fat and 20.5% protein. Chicks were maintained in a chamber with a light cycle from 0900 to 2100 h and a controlled temperature (28°C). When required, cholesterol (5%, w/w) was added to the commercial diet and given to the animals for 5 d. Food consumption was similar in the three groups of chicks.

Isolation of epithelial cells. Chicks were killed by decapitation (at 2 pm). Intestines were removed, chilled and then divided into three segments designated as duodenum (between gizzard and bile-duct junction), jejunum (a 12-cm region from 15 cm below the bile-duct junction) and ileum (a 12-cm region proximal to the ileo-caecal junction). Isolated epithelial cells from different locations

Abbreviations: ACAT, acyl-CoA:cholesterol acyltransferase; EDTA, ethylenediaminetetraacetic acid; HMG-CoA, 3-hydroxy-3-methylglutaryl-CoA; MVAPP, mevalonate 5-pyrophosphate; PBS, phosphate-buffered saline.

along the villus-crypt axis were prepared according to Weiser (25) with the modifications suggested by Raul *et al.* (26) consisting of the eversion of the intestinal fragment before incubation in the chelation buffer.

The intestinal segments were immersed in Buffer A (pH 7.3) containing 1.5 mM KCl, 96 mM NaCl, 27 mM sodium citrate, 8 mM KH_2PO_4, 5.6 mM Na_2HPO_4, 11.1 mM glucose and 1 mM dithiothreitol for 15 min and subsequently in Buffer B (pH 7.2) containing 2.7 mM KCl, 137 mM NaCl, 1.5 mM KH_2PO_4, 4.3 mM Na_2HPO_4, 1.5 mM ethylenediaminetetraacetic acid (EDTA), 11.1 mM glucose and 1 mM dithiothreitol for a series of 10-min intervals. After collection of the cell fractions in 15 mL of Buffer B in plastic tubes, they were immediately pelleted at 500 $\times$ *g* for 5 min, resuspended in phosphate-buffered saline solution (PBS) and kept on ice until the final fraction was recovered. Aliquots were stained with 0.05% trypan blue in PBS. Cells excluding the dye were considered viable (90–95%). Other details of enterocyte isolation have been reported previously (24,27). Protein contents were determined by the method of Lowry *et al.* (28) with bovine albumin as standard.

Assay of enzyme activities. HMG-CoA reductase activity was measured essentially as described by Shapiro *et al.* (29) with the modifications described by Alejandre *et al.* (30) for neonatal chicks. MVAPP decarboxylase activity was assayed using [2-^{14}C]MVAPP as substrate as previously described (31,32). ACAT was measured as described by Goodman *et al.* (33) with the modifications described by Iglesias *et al.* (34) for chick enterocytes. Acyl-CoA hydrolase was measured using the same conditions as those employed for ACAT, but after chromatography the band of silica gel G containing free fatty acids was directly scraped into counting vials containing 10 mL of the same scintillation liquid used for transferase determination (34).

Determination of free and esterified cholesterol. Lipids were extracted with chloroform/methanol (2:1, vol/vol) as described by Folch *et al.* (35). Total and free cholesterol contents were determined by enzymic colorimetric methods using "Test-Combination Cholesterol" or "Test-Combination Free Cholesterol," respectively, from Boehringer.

RESULTS

Initial studies were undertaken to determine the effects of both cholesterol and cholestyramine feeding on the major regulatory enzymes of cholesterol biosynthesis in isolated enterocytes obtained from chick duodenum, jejunum and ileum. The different diets were used with the idea of affecting the flux of sterol across the intestinal mucosa. As shown in Table 1, cholesterol feeding decreased HMG-CoA reductase activity considerably in all the intestinal regions studied, but inhibition was maximal in ileum where activity in cholesterol fed animals was approximately 30% of that of controls. Cholestyramine feeding increased reductase activity in all the intestinal segments, but the effect was greater in the enterocytes isolated from duodenum. It is important to note that maximal specific activity in controls was observed in jejunum, a region in which the changes induced by cholesterol or cholestyramine feeding were the smallest.

The effects of the same dietary treatments on MVAPP decarboxylase are shown in Table 2. Cholesterol supplementation to the diet induced a significant decrease in decarboxylase activity. However, differences in values for duodenum, jejunum and ileum were less pronounced than those observed for HMG-CoA reductase. Likewise, the effects found after cholestyramine feeding were similar to those found in reductase activity in duodenum. No significant changes occurred in jejunum and ileum.

We have also studied the effect of different diets on cholesterol esterification in chick enterocytes. Table 3 shows that cholesterol feeding markedly increased ACAT activity, the increase being similar in all the intestinal regions assayed. However, the effects of cholestyramine feeding on ACAT activity were less clear. As can be seen in Table 4, no significant differences were found in acyl-CoA hydrolase activity after any of the dietary treatments.

With regard to the cholesterol content of enterocytes isolated from the different regions, cholesterol feeding resulted in enhanced contents of total cholesterol in duodenum and jejunum, while in ileum this increase was smaller (Table 5). In contrast, decreasing the sterol flux by cholestyramine feeding had practically no effect on the

TABLE 1

Effects of Cholesterol and Cholestyramine Feeding on 3-Hydroxy-3-Methylglutaryl-CoA Reductase Activity in Isolated Enterocytes from Chick Duodenum, Jejunum and Ileum[a]

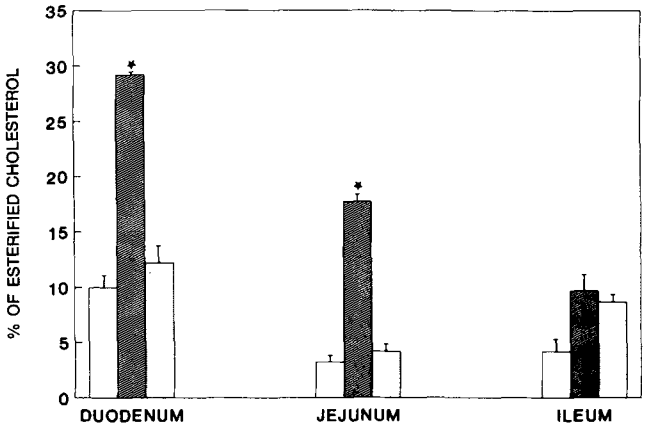

FIG. 1. Effects of cholesterol and cholestyramine feeding on percentage of esterified cholesterol in isolated enterocytes from chick duodenum, jejunum and ileum. Each bar represents the percentage of esterified cholesterol in enterocytes from control (open bars), cholesterol fed (hatched bars) and cholestyramine fed (dotted bars) chicks. Results are expressed as mean values ± SEM of three experiments carried out with pools of three animals. Three determinations were made in each cell pool. Statistical significance is indicated by $*P < 0.001$ for the effect of the different dietary treatments.

cellular total cholesterol content. As can be seen in Figure 1, the changes observed after cholesterol feeding were mainly due to an increase in the percentage of esterified cholesterol in all the intestinal regions assayed.

DISCUSSION

There is still an ongoing debate as to the role of dietary cholesterol in the regulation of cholesterol biosynthesis in intestine. The reasons for the differences between hepatic and intestinal cholesterol metabolism are not entirely clear, although the modes of delivery of cholesterol to the two organs are considerably different (1). Various recent studies suggest that if sufficient cholesterol enters and is accumulated in the intestinal cells, down-regulation of cholesterol synthesis occurs. Our results are in agreement with this fact and with the inhibition of HMG-CoA reductase (9) and MVAPP decarboxylase (21) from chick duodenal mucosa observed after cholesterol feeding. The observed inhibition of decarboxylase due to cholesterol feeding may suggest that a secondary site of regulation does exist at the level of MVAPP decarboxylation.

The location of cholesterol synthesis along the small intestine appears to be dependent on the species that is being studied (1). In the rat, the rate of cholesterol biosynthesis is highest in the duodenum proximal to the ampulla of Vater and in the distal region of the ileum (36,37). Dietschy and Gamel (38) found threefold higher rates of cholesterol synthesis in the human ileum as compared to the rates observed in the duodenum and jejunum. In contrast, the activity of HMG-CoA reductase was shown to be higher in the rabbit jejunum than the activity observed in the ileum (7). Our results are in agreement with those observed on the rabbit, with HMG-CoA reductase activity also being maximal in jejunum.

In contrast to the sterol synthetic enzymes, ACAT activity from chick enterocytes was markedly increased after cholesterol feeding. Our results are in agreement with the fact that this enzyme activity was enhanced after feeding a diet rich in cholesterol to rats (3,39), guinea pigs (40,41) and rabbits (42). The most likely mechanism of stimulation of enzyme activity is an increase in the supply of substrate to an enzyme that is not saturated (23). The finding that the percentage of esterified cholesterol into the chick enterocytes increased after cholesterol feeding (Fig. 1) would support this.

Cholestyramine feeding produced effects of a similar nature on both the HMG-CoA reductase and the MVAPP decarboxylase from chick duodenum. The marked increase in HMG-CoA reductase activity would suggest a decreased cholesterol uptake given the fact that cholesterol levels remain practically unaltered in cells from the cholestyramine fed animals.

On the other hand, the small differences found in acyl-CoA hydrolase activity after cholesterol or cholestyramine feeding suggest that differences in ACAT activity found after the same dietary treatments cannot be due to a different availability of acyl-CoA as exogenous substrate for transferase or to an inhibitory effect on this enzyme due to the presence of free fatty acids (33).

[Received August 5, 1991, and in revised form February 8, 1993; Revision accepted March 11, 1993]

Radioprotection of Mice by Dietary Squalene

Heidi M. Storm[a], Suk Y. Oh[a], Bruce F. Kimler[b,*] and Stata Norton[c]
Departments of [a]Dietetics and Nutrition, [b]Radiation Oncology and [c]Pharmacology, Toxicology and Therapeutics, University of Kansas Medical Center, Kansas City, Kansas 66160-7321

Male C3H mice were fed a diet containing 2% squalene for 14 d prior to and 30 d subsequent to exposure to 6, 7 or 8 Gy of whole body γ-irradiation (Cesium-137). After 14 d on squalene-supplemented diet, plasma and jejunal tissue squalene levels were 2× and 15× that of controls. Seven days after irradiation, total white cell counts and total lymphocyte counts were substantially depressed in a radiation dose-dependent manner. Although counts in the squalene group were consistently (18–119%) higher than those in the corresponding dietary control group, the differences between dietary groups at any single dose were not significant. Nuclear area of villus cells in the jejunum of both dietary groups was significantly reduced (20%) by day 11 post-irradiation but the nuclear area in squalene-fed mice was significantly greater (15%) than in controls, before and after irradiation. There were no differences in body weight as a function of either diet or radiation dose prior to the first observations of animal lethality. Animal survival was decreased from 100 to 0% at 30 d post-irradiation by radiation doses of 6–8 Gy, with the greatest difference between dietary groups being observed at 7 Gy (median survival times of 12 and 16 d for control and squalene groups, respectively). Overall, survival of squalene-fed mice was significantly prolonged compared with control-fed mice ($P = 0.0054$ by censored multiple regression analysis). It is concluded that squalene conferred some cellular and systemic radioprotection to mice receiving these lethal whole-body radiation doses.
Lipids 28, 555–559 (1993).

The consequences of exposure to ionizing radiation, and modifications of these effects, are of considerable interest given the ever-increasing radiation exposure to the population as a result of nuclear power production, energy conservation and radionuclide use. It has been suggested that various chemical structures may protect against the acute cell and tissue toxicities and the delayed carcinogenesis that are induced by radiation *via* generation of free radicals and various ionic species. Among the agents with potential ability to protect cells from radiation damage are those which scavenge or stabilize free radicals. One such compound, β-carotene, is known to offer some protection against radiation-induced toxicity and mortality in mice (1–3). Squalene is a 30-carbon chain with 6 double bonds that is structurally similar to β-carotene. Squalene might also reduce radiation-induced damage, based on the observation that squalene exhibits antioxidant activities (4) and stabilizes oxygen radicals (5). In addition, dietary supplementation with squalene might alter cellular response to radiation *via* a mechanism of enhanced cholesterol metabolism pathways (6).

In humans, about 60% of dietary squalene is absorbed (6) with most serum squalene being in association with the very low density lipoproteins (7). A squalene and sterol carrier protein then appears to carry the nonpolar squalene into the aqueous phase of cells where it is deposited and utilized for cholesterol synthesis (8). Distribution of squalene in human tissues is ubiquitous, with greatest concentrations occurring in the skin and adipose tissue. In rats, dietary squalene supplementation results in an activation of the cholesterol synthesis pathways (9). In other reports, 1% squalene in the diet for periods of 10 to 21 d has been shown to increase tissue levels of squalene, specifically in serum, intestinal mucosa, liver and adipose tissue (10). In intestinal mucosa, squalene increased from an average of 11 μmol/kg to over 1100 μmol/kg after 10 d of dietary supplementation (10).

In the experiment described here, the potential radioprotective effect of dietary squalene was investigated in mice whose diet had been supplemented with 2% squalene starting 14 d prior to exposure to whole body irradiation. The endpoints examined included animal body weight, total white blood cell and lymphocyte counts, nuclear area of jejunal villus cells, plasma and intestinal mucosa levels of squalene and animal survival.

MATERIALS AND METHODS

C3H, male mice aged 5 to 6 wks, weighing 20–25 g, were purchased from Charles River Laboratories (Madison, WI). Appropriate guidelines for humane animal use were followed throughout, after approval by the Institutional Animal Care and Use Committee of the University of Kansas Medical Center (Kansas City, KS). Animals were randomly assigned to receive control or squalene-supplemented diets and within each group to be exposed to 6, 7 or 8 Gy of ionizing radiation. Each of the six groups consisted of 15 mice. Two additional groups of six animals each were randomized to the two diet groups but were not irradiated. These provided non-irradiated controls for the jejunal villus cell measurements and tissue squalene levels. Mice were housed in groups of five or six in plastic mouse cages with microisolation covers in a temperature-controlled facility with a 12-h light/dark cycle. For cage changing, mice were transferred to sterile cages under an air flow hood to minimize the transfer of microorganisms from other mice in the facility. With the exception of cage changing, sterile procedures for animal handling were not followed. After a 3-d acclimation period on arrival, mice were fed, *ad libitum* for 14 d, powdered rodent chow No. 5001 (Ralston Purina, St. Louis, MO) with 2% purified squalene (Sigma Corp., St. Louis, MO) or 2% cornstarch added for two weeks prior to irradiation. Following irradiation, the supplement to the rodent chow was continued for the remaining 30 d of the experiment.

The radiation source was a Cesium-137 blood products irradiator (Model 143-45A, J.L. Shepherd Inc., San Fernando, CA) The mice were irradiated in groups of five in a 10-cm diameter stainless-steel canister which was rotated at 6 rpm to produce a homogeneous dose distribution. The dose rate was 6.2 Gy per minute. The doses delivered to the irradiated mice closely approximated 6, 7 or 8 Gy. All irradiated animals, not otherwise scheduled

*To whom correspondence should be addressed at Department of Radiation Oncology, University of Kansas Medical Center, 3901 Rainbow Boulevard, Kansas City, KS 66160-7321.

for examination, were held for 30 d post-irradiation. The number of surviving mice in each group was recorded daily at 5:00 p.m. All animals were weighed prior to irradiation and then on post-irradiation days 2, 3, 4, 6, 8 and 10. After post-irradiation day 10, survivors were weighed three times per week.

Six mice from each irradiated group were selected for white blood cell count determinations. Blood (1 μL) was taken from the tail (collecting tube applied directly to the cut end of the tail) for the analysis just prior to radiation exposure and then again on post-irradiation day 7. This day was chosen based on other studies of depression of white cell count following irradiation (11). Total white blood cells were counted in a Nebauer hemacytometer using a light microscope at 400× magnification. The differential count for lymphocytes was performed on blood smears from a drop of tail blood stained with Wright's stain.

The six control-fed and six squalene-fed mice in the non-irradiated group were killed after 14 d on the diets for squalene concentration analysis and to serve as controls for jejunal damage in the irradiated mice. Proximal jejunal sections, pooled within diet groups, were frozen by dry ice/acetone immersion. Plasma and jejunal samples were stored at −20°C for later determination of squalene content. Actual concentrations of squalene in the intestinal mucosa and pooled plasma of both groups of non-irradiated mice were determined by gas-liquid chromatography using the method described by Liu *et al.* (7). Pooled jejunal samples, weighing 4 g each in 10 mL of distilled water containing 200 μg of 5α-cholestane as an internal standard, were homogenized using a Polytron Homogenizer (Brinkmann Instruments, Westbury, NY). The analytical procedures for squalene determination were identical for plasma and homogenized jejunum. The non-saponifiable lipids were recovered from the extraction mixture with petroleum ether. Squalene concentrations were determined using a gas chromatograph (model GC 14A, Shimadzu, Kyoto, Japan), equipped with a single flame-ionization detector and a glass column (4 × =1/4″ i.d.) packed with a Dexil 100 supelcoport (Supelco, Bellefonte, PA). A Shimadzu integrating unit (Chromatopac CR-601) was used to compute and record data.

Six survivors from each irradiated group were randomly selected, anesthetized with ether and decapitated on post-irradiation day 11 for study of gastrointestinal damage. This day was chosen as the time when half the animals in the most affected group (8 Gy, control diet) had died. A standard section of proximal jejunum was dissected from each animal and rinsed of residual luminal contents, using phosphate buffered saline. After 4 d in neutral buffered formalin, the jejunal cross sections were processed for histological examination of 2 μm thick plastic sections (L.R. White; Ernest F. Fullam, Inc., Latham, NY). To evaluate intestinal injury, the area of the cross section of nuclei of villus cells was measured using the Zidas digitizing pad at 400× magnification with a Zeiss microscope (Carl Zeiss, Thornwood, NY). The nuclear areas of 10 cells located on a single villus were determined for each intestinal section. A representative villus was chosen, with no areas of significant necrosis or hemorrhages, in which the nuclei of the villus cells were clearly identifiable. Large nuclei at the tips of the villus were measured in cross section to obtain the maximum area through the center of the nucleus.

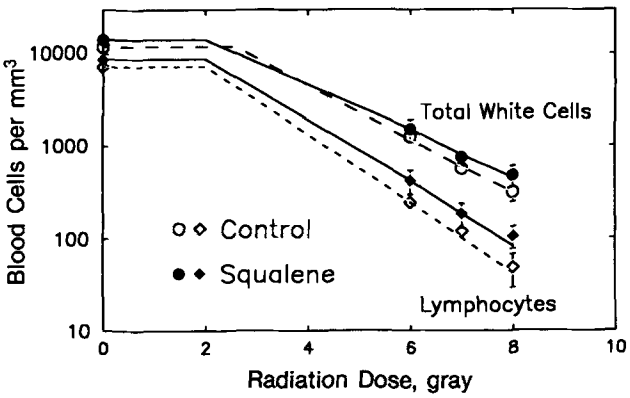

FIG. 1. Total white blood cell counts (circles) and total lymphocyte counts (diamonds) seven days after radiation exposure to control (open symbols) and squalene-treated (closed symbols) animals. The error bars indicate standard errors.

For comparison of post-irradiation survival between groups, a Gehan-Wilcoxon test for single-censored samples was performed. To test for the effect of radiation dose and diet supplementation, a censored multiple regression analysis was conducted using the survival analysis package of the Number Cruncher Statistical Software program (J.L. Hintze, Kaysville, UT). The data for total white blood cell counts, differential lymphocyte counts, body weights and villus nuclear areas all exhibited normal distributions and were analyzed by Analysis of Variance. Blood cell counts were also subjected to linear regression analysis.

RESULTS

Tissue squalene concentrations. Concentrations of squalene in pooled samples of plasma and jejunal tissue of twelve non-irradiated mice, six fed the control diet and six fed the squalene-supplemented diet, were determined. The pooled plasma concentration of squalene in mice maintained on the diet supplemented with squalene was 9.2 mg/dL, over twice the level of the squalene found in the pooled plasma of control animals (4.4 mg/dL). Pooled jejunal squalene concentrations in mice supplemented with squalene exceeded those of control-fed mice by more than 15-fold (squalene diet: 470 μg/g tissue weight, control diet: 30 μg/g).

White blood cell counts. Prior to irradiation, the total white blood cell counts of squalene-supplemented mice were 18% higher than those from control mice, although this was not significantly different (Analysis of Variance, $P = 0.21$). Seven days after irradiation, total white blood cell counts had dropped to 10% or less of control, pre-irradiation levels for all radiation doses ($P < 0.0003$). Squalene-treated mice had white blood cell counts 21–52% greater than did control mice at the same radiation doses, although these differences were again not statistically significant. While the reduction of total white blood cell count occurred in a log-linear fashion with increasing radiation dose (Fig. 1), there was no difference in the slopes of the regression lines between control-fed and squalene-fed groups.

[a]Number of animals contributing to the values.
[b]D, all animals in the group died from radiation.
[c]On day 16, squalene-treated mice receiving 7 Gy had significantly lower body weights than control or squalene-treated mice receiving 6 Gy ($P < 0.05$).

TABLE 2

Nuclear Area of Villus Cells (μm^2 ± SE)[a] in Mice Exposed to Graded Doses of Radiation and Maintained on Squalene-Supplemented or Control Diets

Dose	Diet	
	Control	Squalene
0 Gy	14.85 ± 0.62	17.14 ± 1.00[b]
6 Gy	11.77 ± 0.48[c]	14.53 ± 0.45[b,c]
7 Gy	11.77 ± 0.33[c]	12.63 ± 0.45[c]
8 Gy	11.90 ± 0.52[c]	14.94 ± 0.66[b,c]

[a]The 160 nuclear measurements from six mice per group, with the exception of the control group exposed to 8 Gy, which had only five mice due to one early death.
[b]Significant difference between control and squalene-treated group (Analysis of Variance, $P < 0.05$).
[c]Significantly different from respective non-irradiated groups (0 Gy) (Analysis of Variance, $P = 0.05$).

Similarly, total lymphocyte counts prior to irradiation were 20% higher in squalene-supplemented mice than in control mice although the difference was not significant ($P = 0.14$). Seven days after exposure to ionizing radiation, total lymphocyte counts were profoundly lower in all animals (Fig. 1). Squalene-treated mice had counts 55-119% greater than did control mice at the same radiation doses (not statistically significant). Degree of lymphocytopenia again correlated with radiation dose delivered, with lower counts occurring following higher doses, but the slopes of the regression lines were not significantly different.

Thus, for both total white blood cell count and total lymphocyte count, there was a log-linear decrease as a function of radiation dose received, but no statistically significant differences between blood counts from control diet *vs.* squalene-fed mice. There was also no relationship between animal survival and individual blood counts, or between those animals selected for blood drawing and those not.

Body weights. Weights of control and squalene-supplemented mice exposed to 6 Gy or 7 Gy were compared on post-irradiation days 0, 6, 10, 16 and 20 (Table 1). On post-irradiation days 0, 6, 10, and 20, body weights of mice exposed to 6 or 7 Gy were not significantly different. However, on post-irradiation day 16, weights of squalene-treated mice exposed to 7 Gy were significantly lower than weights of control or squalene-treated mice exposed to 6 Gy ($P < 0.05$). At day 16 post-irradiation, all animals exposed to 8 Gy and most control animals exposed to 7 Gy were dead and thus could not be included in the statistical analysis of weights (Table 1).

Nuclear area of villus cells. The nuclear areas in cross sections of cells located at the tips of villi in the proximal jejunum were determined from histological preparations. In both squalene-treated and control mice, the villus nuclear area was significantly greater in animals not exposed to radiation than in animals exposed to 6, 7 or 8 Gy ($P < 0.05$) (Table 2). However, in both control and squalene-treated mice, no significant dose-related differences in nuclear area were found. Among non-irradiated diet groups, nuclear areas were greater in the squalene-supplemented mice than controls; similarly among irradiated mice, groups supplemented with squalene exhibited greater nuclear areas than did control-fed groups ($P = 0.02$). Post-irradiation nuclear areas of squalene-fed mice approximated those of non-irradiated mice on the control diet.

Survival. The mortality data obtained through post-irradiation day 30 for control and squalene-supplemented mice are presented in Figure 2. Survival times were compared for the animals in each diet/dose group (Table 3). With increasing radiation dose, the survival times of animals decreased in both control and squalene-supplemented mice. The effect of irradiation in both diet groups was marked, with the median survival time following 8 Gy less than half that for 6 Gy. In both diet groups, the survival following 6 Gy was statistically significantly different ($P < 0.002$ by Gehan-Wilcoxon analysis) than after either 7 or 8 Gy. Overall, increasing radiation dose was a significant ($P < 0.0001$ by censored multiple regression analysis) determinant of shorter survival time.

The difference in survival between squalene-supplemented mice and controls was greatest at the radiation dose of 7 Gy (median survival times of 16 *vs.* 12 d).

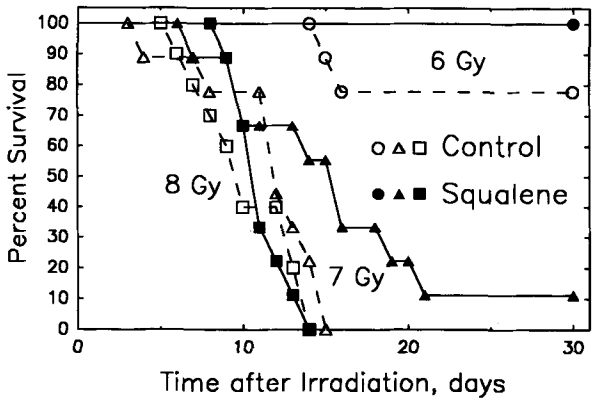

FIG. 2. Survival as a function of post-irradiation time and radiation dose (6 Gy, ○, ●; 7 Gy, △, ▲; 8 Gy, □, ■) for mice on control (open symbols) or squalene-supplemented diets (closed symbols).

TABLE 3

Combined Effects of Diet and Radiation Dose on Survival Post-Irradiation

	Median survival time (range) in days[a]	
Radiation dose	Control diet	Squalene diet
6 Gy	>30 (15-30+)	<30 (30+)
7 Gy	12 (4-15)	16 (7-30+)
8 Gy	11 (6-14)	12 (9-14)

[a]30+ Indicates animals sacrificed at 30 d post-irradiation.

At 6 and 8 Gy, there was no difference in survival between the groups because there was minimal and total lethality, respectively. None of the comparisons between control and squalene diet at individual radiation dose levels were statistically significant by the Gehan-Wilcoxon analysis. However, in a global analysis, supplementation with squalene was identified as a significant ($P = 0.0054$ by censored multiple regression analysis) determinant of greater survival time.

DISCUSSION

The survival time of an animal following exposure to ionizing radiation is related to the primary target tissues affected. The causes of radiation-induced lethality are generally categorized as central nervous system, gastrointestinal or hematopoietic syndromes. Of the animals exposed to radiation doses of 6, 7 or 8 Gy, most deaths occurred after 7 d in both diet groups, implicating death due to the hematopoietic syndrome. A dose-dependent decrease in survival time was observed overall, as well as individually for both diet groups. The greater survival among the squalene-supplemented mice compared with controls demonstrates a protective effect of squalene against lethal radiation-induced injury. Control and squalene-fed animals exposed to 6 Gy had similar survival times, because there was only minimal lethality produced by this dose. Conversely, control and squalene-fed animals exposed to 8 Gy also had similar survival times, reflecting an inability of squalene to prevent or delay death at this lethal radiation dose. The survival rates achieved in the present investigation were similar to those reported for CBA mice given β-carotene (90 mg/kg diet) immediately after exposure to 6 or 7 Gy (3). In that study, β-carotene was shown to prolong survival after radiation.

Leukopenia was observed in all irradiated animals 7 d after radiation exposure. Although not statistically significant, the total white blood cell and lymphocyte counts were consistently higher in the squalene-treated mice. A similar finding of moderation of radiation-induced leukopenia was been reported (1) for C57 mice maintained on diets supplemented with 90 mg β-carotene per kg diet and exposed to 6 Gy of whole body irradiation. The protective effect of dietary squalene on leukopenia in the present study was less pronounced than the protective effect reported for β-carotene. One mechanism suggested for protection from radiation-induced leukopenia was a stimulation of the immune system (12,13). An alternative suggestion is that β-carotene can scavenge free radicals (14) and a similar mechanism (4) may account for the effects of squalene observed here.

After the two-week feeding period, pooled plasma and jejunal squalene concentrations were greater in squalene-fed mice than controls, as reflected by a twofold greater level in blood and an over 15-fold greater level in intestine in the squalene-fed animals. The greater tissue squalene concentrations were expected since squalene supplementation with 1% squalene for 10 d in other studies also resulted in tissue increases (10,15). In view of the greater squalene levels in non-irradiated, squalene-fed mice, it is expected that the irradiated squalene-supplemented mice would have had similar tissue squalene levels, especially at the time of irradiation (14 d after initiation of squalene diet).

Body weight loss and general wasting are important signs of radiation-induced toxicity (3). Based on the times of death in the present investigation, the animals succumbed due to the hematopoietic syndrome and not as a result of gastrointestinal injury. This may explain the absence of weight loss in mice until 16 d post-irradiation. Also, once the smallest (weakest) animals died and were no longer included, the mean weight of the group would increase. Overall, no protection for weight loss was afforded by dietary squalene.

The nuclear area of villus cells in the jejunum of squalene-supplemented mice exceeded the nuclear areas of control-fed mice in both irradiated and non-irradiated groups. The greater villus nuclear area (most likely associated with an increase in nucleolar size) seen in animals supplemented with squalene compared to control-fed animals suggests an enhancement of cellular synthetic rates by squalene. This increased synthetic activity may be specifically related to increased cholesterol synthesis which has been shown to result from increased plasma levels of squalene (16), or may be a general metabolic effect. A low concentration of peroxidized squalene, such as might be present after irradiation, has been shown to increase incorporation of amino acids (17). Other conditions that give rise to increases in nuclear area include normal synthetic activity (18,19) and synthesis prior to cell division (20). The positive relationship observed here for survival and nuclear area between diet groups supports the speculation that squalene might exert an enhancing effect on cellular metabolic processes that would ameliorate the damaging effects of radiation.

The data obtained from this research support the conclusion that dietary squalene provides some protection from the adverse effects of whole-body ionizing radiation. This is expressed at several levels: jejunal villus cell morphology, white blood cell counts and animal survival. However, the latter is demonstrated only at a specific dose, with the survival-prolonging protective effects of squalene greater in mice exposed to a dose of 7 Gy than in mice exposed to 6 or 8 Gy. The mechanisms by which squalene could protect against radiation-induced damage remain speculative, but include scavenging of free radicals or reactive oxygen species, stimulating the immune response, protecting cellular organelles or improving cellular repair responses, or simply stimulating cell proliferation. Whether the high levels of squalene in certain diets already contribute to a protection against radiation-induced carcinogenesis, or whether dietary supplementation of squalene might have potential use in radiation therapy of malignancies, remains even more speculative.

METHOD

2-Alkenyl-4,4-dimethyloxazolines as Derivatives for the Structural Elucidation of Isomeric Unsaturated Fatty Acids

Devanand L. Luthria and **Howard Sprecher***
Department of Medical Biochemistry, The Ohio State University, Columbus, Ohio 43210

Several types of unsaturated fatty acid methyl esters were converted into 4,4-dimethyloxazoline (DMOX) derivatives and analyzed by mass spectrometry to further evaluate the feasibility of using this derivative for locating the positions of double bonds in isomeric fatty acids. Five isomeric 20-carbon tetraenoic acids were analyzed in which the four *cis* double bonds were systematically moved from the 4,7,10,13- to the 8,11,14,17-positions. It was possible to locate the positions of all four double bonds in the 7,10,13,16- and 8,11,14,17-isomers by appropriate ions differing by 12 atomic mass units. In a similar way the three terminal double bonds in the 4,7,10,13-, 5,8,11,14- and 6,9,12,15-isomers could be assigned. Odd-numbered ions at *m/z* 139, 153 and 167 which are accompanied by an even mass ion at 138, 152 and 166, respectively, are diagnostic for DMOX derivatives of acids with their first double bond, respectively, at positions 4, 5 and 6. It was thus possible to assign the location of all four double bonds in these three isomers. A comparison of the spectra of the DMOX derivatives of 17,17,18,18-d_4 *vs.* 9,10,12,13-d_4 linoleic acid suggests that double bonds preferentially migrate toward the polar end of the molecule prior to fragmentation. The merit of using DMOX derivatives to locate double-bond positions in mono- and dicarboxylic acids, produced during β-oxidation of polyunsaturated fatty acids, was evaluated. The spectra of 3-*cis*- and 4-*cis*-decenoic acids differ as do the spectra of 8-carbon dicarboxylic acids with their double bonds at positions 3 and 4.
Lipids 28, 561–564 (1993).

Several techniques have been used to locate the positions of double bonds in polyunsaturated fatty acids. Unsaturated acids may be treated with ozone, and the resulting ozonide may be either reduced or oxidized followed by characterization of the resulting fragments (1). Unsaturated fatty acids may also be cleaved, at the double bond, into short-chain mono- and dicarboxylic acids by treatment with periodate-permanganate (2). Alternatively, double bonds may be converted to osmate esters which, upon reduction, yield diols. Following silyation they are analyzed by mass spectrometry. The fragments produced by cleavage between adjacent trimethylsilyl groups determine the position of the double bonds in the original molecule (3,4).

With the above methods it is often difficult to isolate and characterize all of the fragments produced when degradative techniques are used. The osmium technique determines the sites of unsaturation in the intact molecule, but the resulting silyl derivatives of polyunsaturated acids have long retention times when analyzed by gas chromatography. In addition, many of the smaller mass spectrometers have upper mass limits too low to detect all the fragments produced from polyunsaturated fatty acids containing multiple sites of unsaturation.

A third general method involves derivatizing fatty acids with agents that enhance charge stabilization to minimize double-bond migration. A number of reagents including pyrrolidine (4,5), 3-pyridylcarbinol (4,6) and 2-amino-2-methylpropanol (AMP) (7–11) have been employed as derivatizing agents. The 4,4-dimethyloxazoline (DMOX) derivatives, prepared by reacting either fatty acids (7) or methyl esters (8) with AMP have good chromatographic properties and in general provide definitive information about double bond positions.

In the study reported here, we further evaluated the limitations of the current methodology by comparing the mass spectra of five isomeric 20-carbon acids in which the four *cis*-double bonds were moved from the 4,7,10,13- to the 8,11,14,17-position. The spectra of the DMOX derivatives of 17,17,18,18-d_4 *vs.* 9,10,12,13-d_4 linoleic acid were compared to further determine the mechanism of fragmentation with this derivative. The localization of double bonds in short-chain mono- and dicarboxylic acids produced during the abnormal β-oxidation of unsaturated fatty acids is a difficult problem due to the relatively small amounts of materials produced (12). In the present study we have shown that the spectra of DMOX derivatives of 3-*cis*- *vs.* 4-*cis*-10:1 as well as of 3-*cis*- and 4-*cis*-1,8-octenedioic acids differ sufficiently to readily distinguish these isomeric compounds.

MATERIALS AND METHODS

Materials. 2-Amino-2-methylpropanol was obtained from MTM Research Chemicals (Windham, NH). The methyl esters of 4,7,10,13-, 6,9,12,15-, 7,10,13,16- and 8,11,14,17-eicosatetraenoic acids were made by total synthesis (13). Methyl 5,8,11,14-eicosatetraenoate was from Nu-Chek-Prep (Elysian, MN). Linoleic acid, labeled with deuterium at positions 9,10,12 and 13, was made by reducing 9,12-octadecadiynoic acid with deuterium gas in the presence of Lindlar's catalyst. In order to prepare 17,17,18,18-d_4 linoleic acid, the hydroxyl group of 4-pentyn-1-ol (MTM Research Chemicals) was blocked by reaction with ethyl vinyl ether (Aldrich Chemical Company, Milwaukee, WI). The triple bond was then reduced with deuterium gas in the presence of Wilkinson's catalyst (14). The blocking group was removed by refluxing with methanol in the presence of sulfuric acid (15). The deuterated 1-pentanol was converted to d_4-pentyl bromide which in turn was used to synthesize 9,12-octadecadiynoic acid-17,17,18,18-d_4 (16). Lindlar's reduction with hydrogen yielded the desired ethylenic acid. To determine the isotopic composition of the deuterated linoleic acids, they were derivatized with *N*-methyl-*N*-(*t*-butyl-dimethylsilyl)-trifluoracetamide

Abbreviations: AMP, 2-amino-2-methylpropanol; DMOX, 4,4-dimethyloxazolines; THP, tetrahydropyran.

+ 1% *t*-butyl-dimethylchlorosilane (Regis Chemical Co., Morton Grove, IL) (17). The appropriate ion chromatograms corresponding to the formation of ions at M-57 were then integrated. The isotopic composition in percent of the 9,10,12,13-d_4 and 17,17,18,18-d_4 were d_4, 95.9; d_3, 3.7; d_2, 0.3; d_1, 0.1 and d_4, 94.8; d_3, 3.1; d_2, 2.1; d_1, 0.0, respectively.

4-*cis*-Decenoic acid was prepared by coupling 1-bromopentane with the sodium salt of the tetrahydropyran (THP) derivative of 3-butyn-1-ol in liquid ammonia. The blocking group was removed and the 3-nonyn-1-ol was reduced with Lindlar's catalyst. The 3-*cis*-nonen-1-ol was converted to the mesylate (18) which in turn was reacted with sodium cyanide in dimethyl sulfoxide (19). The resulting nitrile was hydrolyzed to the methyl ester with 25% anhydrous HCl in methanol. To make 3-*cis*-decenoic acid, the sodium salt of the THP derivative of 3-butyn-1-ol was coupled with 1-bromohexane. After cleavage of the blocking group, the alcohol was oxidized to 3-decynoic acid (20) which was then reduced to 3-*cis*-decenoic acid. To make 3-*cis*-1,8-octenedioic acid, the hydroxyl group of 5-hexyn-1-ol was blocked by reaction with dihydropyran. This compound was reacted with sodamide in liquid ammonia followed by addition of ethylene oxide (21). Following cleavage of the blocking group, the 1,8-dihydroxy-3-octyne was oxidized to the acetylenic dicarboxylic acid which in turn was reduced with Lindlar's catalyst to give 3-*cis*-octenedioic acid. To prepare 4-*cis*-octenedioic acid, the sodium salt of the THP derivative of 3-butyn-1-ol was reacted with ethylene oxide in liquid ammonia (21). Following cleavage of the blocking group, the 3-hexyn-1,6-diol was reduced with Lindlar's catalyst. The diol was converted to the dimesylate which in turn was reacted with sodium cyanide in dimethyl sulfoxide. Hydrolysis with 25% anhydrous HCl in methanol yielded dimethyl 4-*cis*-octenedioate.

Analysis of DMOX. The DMOX derivatives were prepared by adding 250 μL of AMP to 500 μg of the fatty acid methyl ester in screw-cap vials. The vials were flushed with N_2, capped and heated at 180°C for 18 h (8). The reaction mixture was cooled and dissolved in 3 mL of dichloromethane which was washed twice with 1 mL of water. After drying the organic phase with anhydrous Na_2SO_4, the dichloromethane was removed under a stream of N_2. The samples were dissolved in *iso*-octane for analysis by gas chromatography/mass spectrometry.

Mass specctrometry was carried out with a Hewlett-Packard model 5970A mass selective detector and a 5790 gas chromatograph (Palo Alto, CA). For the analysis of the five 20-carbon DMOX derivatives, the oven contained a 30 m × 0.25 mm DB-1 capillary column with a film thickness of 0.25 μm (J&W Scientific, Rancho Cordova, CA). All injections were carried out in the splitless mode at 70°C. After 1 min the oven was programmed at 30°C/min to 240°C. All other DMOX derivatives were injected in the split mode at 170°C using a 30 m by 0.25 mm DB-225 capillary column (J&W Scientific) with a film thickness of 0.25 μm. Spectra were recorded at an ionization energy of 70 eV. The Y-axis in all spectra shown represents relative percentage abundance of the ions.

RESULTS AND DISCUSSION

The spectra of the five 20-carbon DMOX derivative all showed major ions at *m/z* 113 and 126 as well as a parent ion at *m/z* 357. The ion at *m/z* 113 is in essence a McLafferty rearrangement ion formed by migration of the γ-hydrogen followed by cleavage between carbon atoms 2 and 3 while the ion at *m/z* 126 is probably a cyclic ion formed by cleavage between carbons 4 and 5 (7). In their analysis of pyrrolidide derivatives of fatty acids, Andersson and Holman (5) observed that the location of double bonds could be determined when an interval of 12 atomic mass units rather than 14 is observed between the most intense peak in a cluster of fragments containing n and n − 1 carbon atoms. The double bond is then located between n and n + 1 carbon atoms in the molecule. The partial mass spectra of the DMOX derivative of 8,11,14,17-20:4 is similar to that published by Yu *et al.* (9) and is shown in Figure 1 along with the spectrum of the 7,10,13,16-20:4 isomer. From these spectra it is clear that all four double bonds in both isomers can be located by the fragmentation pattern. The ions at *m/z* 182 and 194 (Fig. 1A) show that the first double bond is at position 8 in the 8,11,14,17-20:4 isomer (9) while the ions at *m/z* 168 and 180 (Fig. 1B) define that the position of the first double bond of the second isomer is at the 7-position. Double bonds at the other sites were determined in a similar way as shown in Figure 1.

The mass spectrum of the 6,9,12,15-isomer as shown in Figure 2A is similar to that published by Yu *et al.* (9). According to the rule of Andersson and Holman (5), the spectrum should contain an ion at *m/z* 154, which would be formed by cleavage between carbons 5 and 6 while cleavage between carbons 6 and 7 would be expected to produce an ion at *m/z* 166. The spectrum of the DMOX derivative of 6,9,12,15-20:4 had an intense ion at *m/z* 152 as well as ions of about equal intensity at *m/z* 166 and

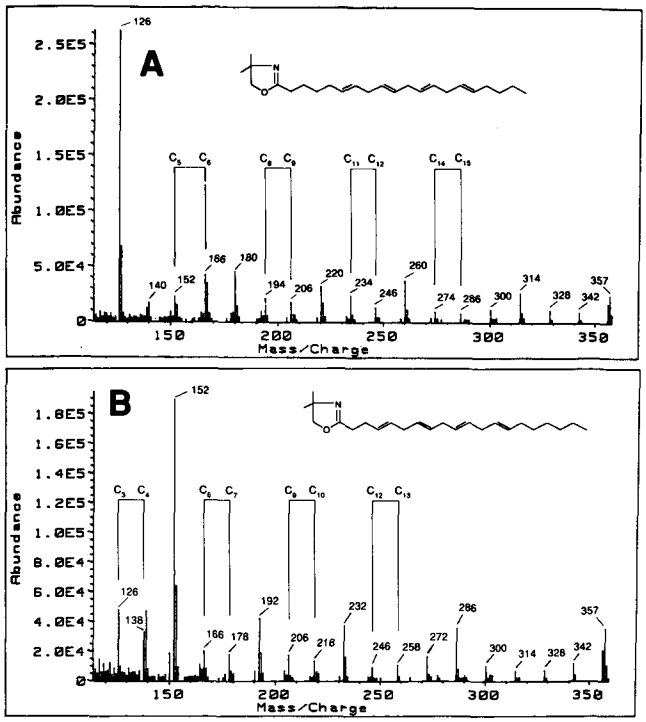

FIG. 2. Mass spectra of the 4,4-dimethyloxazoline derivatives of 6,9,12,15- (A) and 4,7,10,13-eicosatetraenoic acids (B).

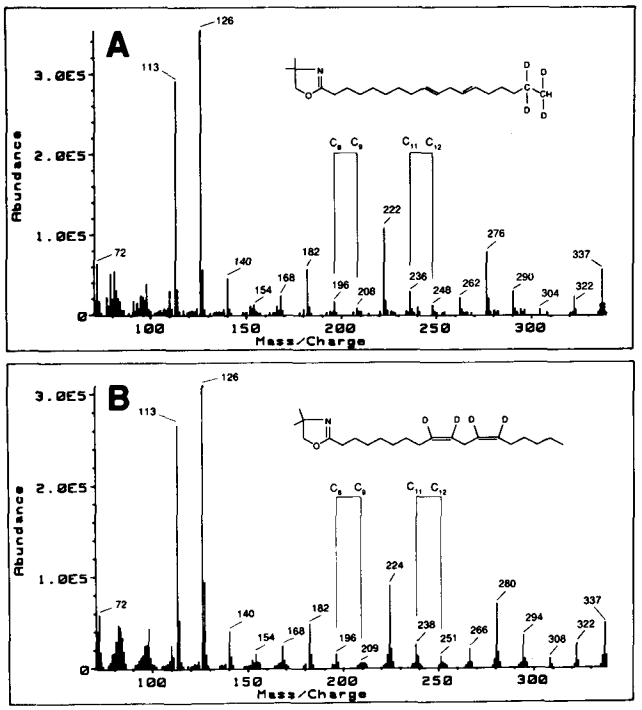

FIG. 3. Mass spectra of the 4,4-dimethyloxazoline derivatives of 17,17,18,18-d_4 (A) and 9,10,12,13-d_4 linoleic acids (B).

167. A similar type of fragmentation pattern has been reported for mono- and polyunsaturated fatty acids with their first double bond at position 6 (7–9). The other three double bonds in the molecule were clearly located by ions which differed by 12 mass units. The spectrum of the DMOX of 5,8,11,14-20:4 was similar to that reported previously in that it had a base peak at *m/z* 113 and an intense odd-numbered ion *m/z* 153 (31% of the base peak) (7). The mechanism for the formation of this ion has not been explained (9). Similar to the DMOX derivative of 4,7,10,13,16,19-22:6 (7), the spectrum of the 4,7,10,13-isomer had an ion at *m/z* 126 and a pair of ions of about equal intensity at *m/z* 138 and 139 (Fig. 2B). Again, the location of the double bonds at positions 7, 10 and 13 could be deduced from the spectra. These results, together with those reported in the literature (7–9), show that the location of all double bonds in a fatty acid can be determined by the interval of 12 mass units between appropriate ion clusters when the first double bond is at position 7 or further down the carbon chain. When the first double bond in the molecule is at carbons 4, 5 or 6, it is possible to locate the position of the three terminal double bonds by the 12 mass unit rule. The location of the first double bond however cannot be defined by an empirical rule. The presence of odd-numbered ions at *m/z* 167, 153 and 139, which are accompanied by *m/z* 166, 152 and 138, respectively, is diagnostic ions in the spectra of DMOX derivatives of acids with their first double bond, respectively, at carbons 6, 5 and 4.

The mass spectra of the DMOX derivative of both 17,17,18,18-d_4 and 9,10,12,13-d_4 linoleic acid had molecular ions at *m/z* 337 (Fig. 3). The introduction of deuterium at carbons 17 and 18 did not alter the ion composition in the low mass region *vs.* that reported for the DMOX derivative of unlabeled linoleate (7). Cleavage between carbons 16 and 17 of both labeled 17,17,18,18-d_4 and unlabeled linoleate (7) gave an ion at *m/z* 304. The presence of an ion at *m/z* 322 in the undeuterated derivative could arise either by cleavage between carbons 17 and 18 or by loss of a methyl group from the oxazoline ring. The presence of an ion at *m/z* 322 in the DMOX derivative of 17,17,18,18-d_4 linoleate (Fig. 3A) shows that this ion is formed by loss of a methyl group from the ring rather than by cleavage between carbons 17 and 18 which would have resulted in the loss of 17 mass units, *i.e.*, loss of $CHD_2^{\bullet}$.

The fragmentation pattern at sites of unsaturation may be visualized as requiring the movement of double bonds one position toward the polar end of the molecule prior to fragmentation (5,9). Cleavage between carbons 9 and 10 of the DMOX derivative of unlabeled or 17,17,18,18-d_4 linoleic acid yields a cluster of small ions, the major one of which is at *m/z* 208 (7). With the 9,10,12,13-d_4 isomer, a small ion peak at *m/z* 209 was detected, but this cluster contained other ions of low intensity (Fig. 3B). Cleavage between carbons 10 and 11 of the 17,17,18,18-d_4 analog yielded an ion at *m/z* 222 *vs.* at 224 for the 9,10,12,13-d_4 isomer thus establishing that carbons 9 and 10 contain deuterium atoms. Cleavage between carbons 12 and 13 of the 17,17,18,18-d_4 linoleate derivative gave an ion at *m/z* 248 which increased to 251 when the acid was labeled with deuterium at the double bonds. Clearly then the major ion formed by cleavage at double bonds can be visualized primarily as requiring the movement of double bonds toward the polar end of the molecule prior to fragmentation as has previously been suggested (5,9).

The DMOX derivatives of both 3- and 4-*cis*-decenoic acids had molecular ions at *m/z* 223 (Fig. 4). The base peak

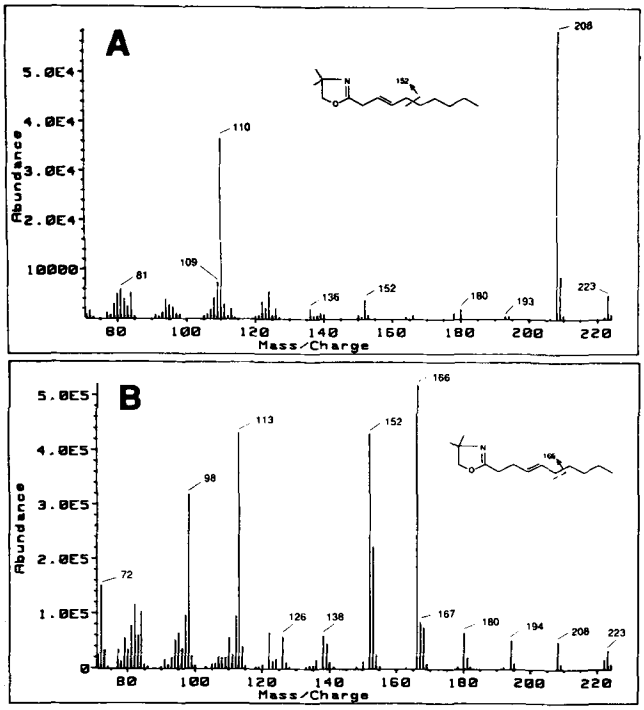

FIG. 4. Mass spectra of the 4,4-dimethyloxazoline derivatives of 3-*cis*- (A) and 4-*cis*-decenoic acids (B).

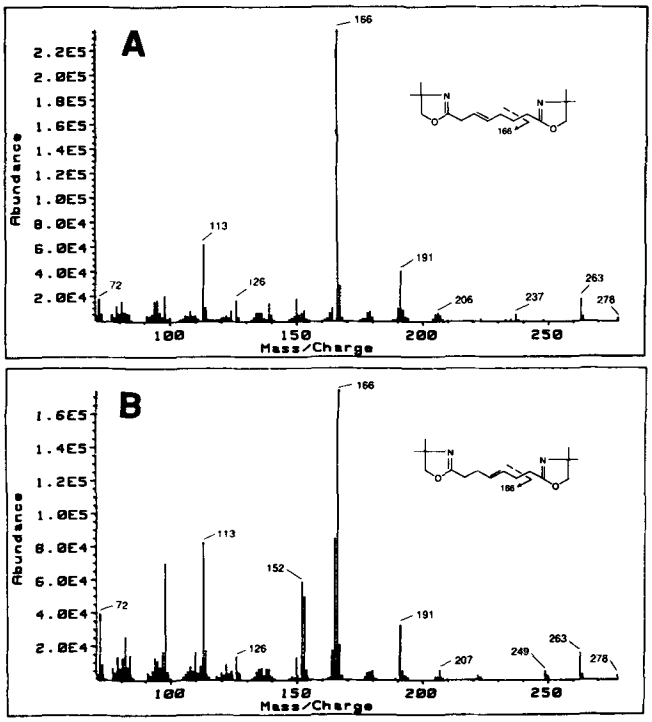

FIG. 5. Mass spectra of the 4,4-dimethyloxazoline derivatives of 3-*cis*- (A) and 4-*cis*-1,8-dicarboxylic acids (B).

for the 3-*cis* isomer was at *m/z* 208 which may be due to the loss of methyl group from the ring. The only other ion of high intensity was one of unknown composition at *m/z* 110. Conversely, the spectrum of 4-*cis* isomer had a base peak at *m/z* 166, and an ion of unknown composition at *m/z* 152 which is characteristic of acids with double bond at position 4 (7-9). The ion at *m/z* 98 corresponds to the fragment formed by the cleavage between carbons 1 and 2 with a positive charge on the heterocyclic ring.

The mass spectra of DMOX derivatives of oct-3-ene-1,8-dicarboxylic acid and oct-4-ene-1,8-dicarboxylic acid are similar in that both had small molecular ion peaks at *m/z* 278 and as well as at 263 (M-15) (Fig. 5). The base peak for both derivatives was at *m/z* 166. The spectrum of the 4-*cis* isomer (Fig. 5B) differs from that of the 3-*cis* isomer in that the ion intensity at *m/z* 113 is almost twice that observed for the 3-*cis* isomer. Most importantly the 4-*cis* isomer had ions at *m/z* 152 and 153 as is observed for other fatty acids with a double bond at position 4 (7-9). The presence of these two ions can readily distinguish the 3-*cis* from the 4-*cis* isomer.

[Received December 3, 1992, and in revised form March 31, 1993; Revision accepted April 4, 1993]

Acidic Hydrolysis of Plasmalogens Followed by High-Performance Liquid Chromatography

Eric J. Murphy[a,*], Ralph Stephens[b], Marianne Jurkowitz-Alexander[a] and Lloyd A. Horrocks[a]
[a]Department of Medical Biochemistry and Neuroscience Program and [b]Department of Pathology, The Ohio State University, Columbus, Ohio 43210

A simple, quantitative method for determining the plasmalogen content of small samples is reported here. The method uses the different susceptibility to acid-catalyzed hydrolysis of the alkyl, alkenyl and acyl linkages to separate the plasmalogen subclass from the other two non-labile subclasses. Hydrolysis of plasmenylethanolamine and plasmenylcholine was complete after 4 and 1 min of acid treatment, respectively. The acid-catalyzed hydrolysis did not alter the phospholipid fatty acid composition, making this method useful for fatty acid compositional analysis of the plasmalogen subclass. High-performance liquid chromatography was used for separations, and phospholipids were quantitated by assay of lipid phosphorus or by direct quantitation of peak area. Using this method, small amounts (10 nmol) of ethanolamine glycerophospholipid and choline glycerophospholipid are subjected to acid-catalyzed hydrolysis and subsequent separation of the resulting lysocompounds obtained from plasmalogens from the more acid-stable alkylacyl and diacyl glycerophospholipid fractions. Our values for plasmalogens from commercial preparations of choline and ethanolamine glycerophospholipids agree with literature values. The usefulness of the method is demonstrated for small glycerophospholipid samples that are equivalent to samples from cultured neural cells.
Lipids 28, 565–568 (1993).

Plasmalogens are important components of cellular membranes and may be involved in signal transduction following agonist-receptor binding (1,2). Recently a plasmalogen specific phospholipid A_2 has been isolated from bovine brain (3). This enzyme may have an important role in releasing arachidonic acid from the *sn*-2 position of the plasmalogens during receptor mediated events. Plasmalogens are also elevated during and following differentiation of N1E-115 cells suggesting plasmalogens have a role in cellular differentiation (4).

Current methods for the quantitation of ethanolamine and choline plasmalogens are not suitable for the limited sample size obtained from cell cultures. Previous methodology has included iodine addition (5,6), alkaline hydrolysis followed by acid hydrolysis (7), mercuric chloride hydrolysis (8) and acidic hydrolysis (9–13). Most of these methods utilize the acid lability of the alkenyl ether linkage at the *sn*-1 position of the plasmalogens. This bond is quantitatively hydrolyzed by HCl fumes (14). The method described here is a modification of the Horrocks and Sun (15) method replacing two-dimensional thin-layer chromatography (TLC) with two high-performance liquid chromatography (HPLC) separations. This method has increased sensitivity, reliability and is less time-consuming than the traditional two-dimensional TLC method.

Abbreviations: ChoGpl, choline glycerophospholipid; EtnGpl, ethanolamine glycerophospholipid; FAME, fatty acid methyl esters; GLC, gas-liquid chromatography; HPLC, high-performance liquid chromatography; HUVE, human umbilical vein endothelial; PBS, phosphate buffered saline; PlsCho, choline plasmalogen; PlsEtn, ethanolamine plasmalogen; TLC, thin-layer chromatography.

MATERIALS AND METHODS

Ethanolamine glycerophospholipid (EtnGpl) from bovine brain and choline glycerophospholipid (ChoGpl) from bovine heart were purchased from Serdary (London, Canada). Primary cultures of human umbilical vein endothelial cells (HUVE) were used to test the procedure. HUVE cells were collected by treating the luminal surface of the umbilical vein with 0.1% type II collagenase (16). The cells were plated upon human fibronectin-coated glass tissue culture flask. Upon reaching confluency, the cells were replated on 100-mm fibronectin-coated glass tissue culture plates. The endothelial origin was confirmed by the presence of factor VIII antigen (17).

Confluent cells were extracted using *n*-hexane/2-propanol (3:2, vol/vol) (18). Prior to extraction, the medium was removed and the cells were washed with two 3-mL portions of cold phosphate buffered saline (PBS). The plates were then placed immediately on solid CO_2 to minimize damage during extraction (19). Two 3-mL aliquots of *n*-hexane/2-propanol (3:2, vol/vol) were used to extract the cells. Cellular debris was removed by filtration through glass wool. Nitrogen was placed over the extracts to minimize autoxidation of lipids. The extracts were stored at −20°C.

Male Wistar rat (300 g, Harlan, Indianapolis, IN) spinal cords were removed after surgically cutting the dorsal roots followed by hydrostatic expulsion of the spinal cord (20). The spinal cords were immediately frozen in liquid nitrogen. The heads of decapitated rats were frozen in liquid nitrogen and the brains removed on ice in a −4°C cold room. The samples were extracted with *n*-hexane/2-propanol (3:2, vol/vol, 18 mL/g tissue) (21). The lipid extracts were filtered using sintered glass funnels to remove cellular debris.

Prior to phospholipid separation, the lipid extracts were filtered using a Rainin 0.2 μm Nylon filter (Woburn, MA). The sample was dried under nitrogen and redissolved in a known volume of *n*-hexane/2-propanol/water (56.7:37.8:5.5, by vol) prior to HPLC.

The lipid extracts were separated into major phospholipid classes by HPLC. Solvents used were HPLC grade *n*-hexane and 2-propanol from E.M. Science (Cherry Hill, NJ). Solvents were filtered through a 0.5 μm Millipore FH-type Nylon filter (Bedford, MA) and degassed. Solvent A was *n*-hexane/2-propanol (3:2, vol/vol) and solvent B was *n*-hexane/2-propanol/water (56.7:37.8:5.5, by vol). Water was purified using a Millipore water purification system (Bedford, MA). The HPLC instrument consisted of two Altex 100Å pumps (Berkeley, CA), an Altex 420/421 controller and an Altex model 210 injection port. The Dupont (Wilmington, DE) Zorbax Silica column (4.6 mm × 250

mm, 5–6 μm) was maintained at a constant temperature of 34°C with a Jones Chromatography heating block (Littleton, CO). An ISCO (Lincoln, NE) V4 UV variable wave length detector was used to detect peaks at 205 nm.

Two HPLC separations were used for this method. The first separation resolved all of the major phospholipids (22). This permitted the resolution of the EtnGpl and ChoGpl peaks, which were then collected for hydrolysis. The solvent was removed under nitrogen and then the test tubes were inverted over five drops of conc. HCl in a test tube cap for 5 min. This caused the complete hydrolysis of the alkenyl ether bond of the plasmalogens while the alkyl ether, acyl ester and diacyl ester bonds remained intact. The sample was reextracted with *n*-hexane/2-propanol (3:2, vol/vol) and rechromatographed using the second separation system.

The second separation was used to separate the 1-lysophospholipids from the acid-stable fractions of EtnGpl and ChoGpl (Fig. 1). Initial conditions were: column temperature 34°C; flowrate 1.8 mL/min; and solvent composition 55% A/45% B. At 0 min the solvent was changed to 24% A/76% B over a 3-min period. At 8 min the solvent was changed to 100% B over a 3-min period. This separation completely resolved the lysophospholipids from the remaining EtnGpl and ChoGpl. The fractions were collected and quantitated by measuring lipid phosphorus (23). We also used peak area as integrated by a Nelson Analytical 760 series interface (Cupertino, CA) to calculate peak areas and subsequent determination of the plasmalogen proportion with respect to its glycerophospholipid class.

To determine the effect of mild acidic hydrolysis of the alkenyl ether linkage on phospholipid fatty acid composition, ethanolamine glycerophospholipids from astrocytes were subjected to mild acidic hydrolysis for 15 min. The fatty acid compositions of acidic hydrolyzed and nonhydrolyzed EtnGpls were compared.

Phospholipid acyl chains were converted to fatty acid methyl esters (FAME) through base-catalyzed transesterification (24). This method, unlike the method with BF_3 for transesterification, avoids oxidative side reactions and the formation of dimethylacetals from the plasmalogens. FAME were extracted with 2 mL of hexane. The upper phase was pipetted off and the remaining methanol phase washed with two 2-mL aliquots of hexane. FAME were stored in a nitrogen atmosphere at −20°C.

FAME were separated and quantitated by gas-liquid chromatography (GLC). A set of standards (Nu-Chek-Prep, Elysian, MN) were used to establish relative retention times and relative correction factors for each FAME. The internal standard was 17:0 methyl ester. The detector response was linear within the concentration range of the samples for all identified fatty acids of varying chain lengths and degrees of unsaturation with correlation coefficients of 0.985 or greater. This standard was used for the standard curves and for each sample run.

The GLC system was comprised of a Shimadzu (Kyoto, Japan) GC-14A, a Supelco (Bellefonte, PA) SP-2330 capillary column (30-m long) and a flame-ionization detector. Column temperature was maintained at 190°C with nitrogen as the carrier gas at a pressure of 0.5 kg/cm^2. Detector and injector temperatures were maintained at 220°C. A split ratio of 50:1 was used. Peak area data were collected with a Nelson Analytical 760 series intelligent interface and computed with Nelson model 2600 software.

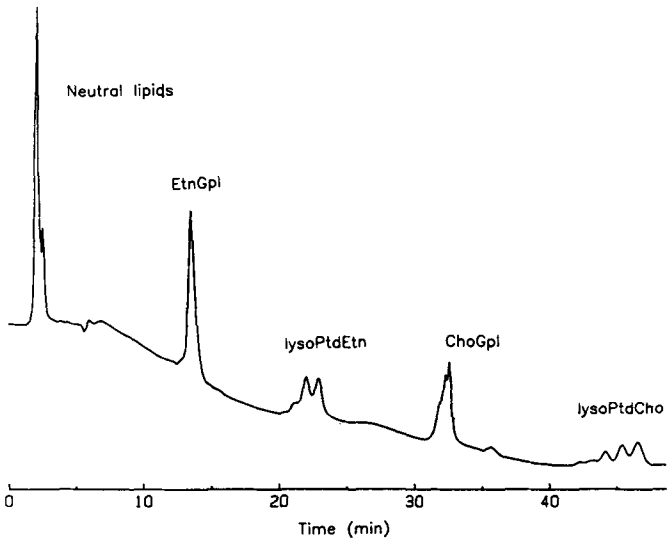

FIG. 1. High-performance liquid chromatographic separation of commercially prepared ethanolamine and choline glycerophospholipid (EtnGpl and ChoGpl) fractions following acidic hydrolysis. The acid-stable ethanolamine and choline glycerophospholipids were separated from the lysophosphatidylethanolamines and cholines (lysoPtdEtn and lysoPtdCho) resulting from the acid labile plasmalogen subclasses. The small peak at ≈35 min represents slight sphingomyelin contamination in the choline glycerophospholipid. The multiple peaks in the fractions are characteristic of the separation and represent partial resolution of molecular species.

RESULTS

Initially we tried to use the method of Renkonen (25) as modified by Yeo and Horrocks (13) with HUVE cell culture samples. In this method the EtnGpl and ChoGpl fractions were collected, solvent removed under a stream of N_2 and dissolved in 1.5 mL $CHCl_3$. Then 1.5 mL of 0.1 M HCl in 95% CH_3OH was added, and the tube was flushed with N_2, capped and vortexed. The sample was incubated at room temperature for 40 min. The ethanolamine plasmalogen (PlsEtn) content ranged from 0 to 100% of EtnGpl for n = 5. The choline plasmalogen (PlsCho) content ranged from 23 to 85% of ChoGpl for n = 3. Such variability suggested this method was unsuitable for samples with EtnGpl or ChoGpl levels at or below 100 nmol.

We used EtnGpl and ChoGpl standards to evaluate the method reported here. The sample sizes were equivalent to cell culture size samples (10–60 nmol) and were subjected to acidic hydrolysis for 1 to 20 min (Fig. 2). PlsCho hydrolysis was complete after 1 min of exposure and PlsEtn hydrolysis was complete after 4 min. No further hydrolysis occurred within the time span of the experiment.

There was little effect of acidic hydrolysis on the fatty acid composition of EtnGpl (Table 1). There was no effect on 20:4n-6 or 22:6n-3 proportions; however, 20:3n-9 proportions were slightly decreased in treated as compared to untreated EtnGpl. Proportions of 18:0 were slightly increased in treated as compared to untreated EtnGpl. These slight alterations, in our experience, would not produce statistically significant alterations.

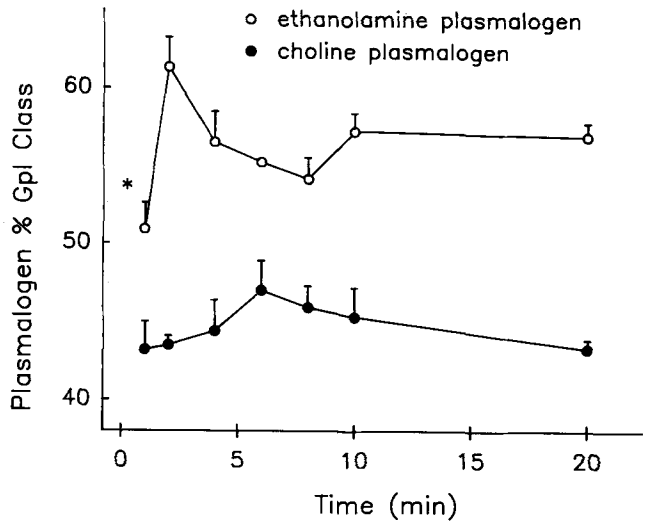

FIG. 2. Concentrated HCl hydrolysis of commercially prepared ethanolamine glycerophospholipid and choline glycerophospholipid. Values are plasmalogen mole % ± SD of the respective glycerophospholipid class and n = 3. For ethanolamine plasmalogen the mole % following 1 min of acidic hydrolysis was less than all other times, $P < 0.05$, Gpl, glycerophospholipid.

TABLE 1

Fatty Acid Composition of Acid-Treated and Untreated Ethanolamine Glycerophospholipid[a]

Fatty acid	Untreated	Treated
16:0	4.1	5.0
16:1	0.6	0.6
18:0	17.5	19.4
18:1	25.0	26.2
18:2	0.3	0.3
20:1	0.4	1.3
20:3n-9	7.1	4.7
20:3n-6	0.4	0.2
20:4n-6	22.0	21.4
20:5n-3	0.8	0.2
22:4n-6	2.4	2.9
22:5n-3	4.7	2.6
22:6n-3	14.7	15.1

[a]Values are fatty acid mole % of ethanolamine glycerophospholipid from non-dibutyryl cyclic adenosine monophosphate treated astrocyte cell cultures in culture for 21 d. Values are n = 1 for each group.

Hydrolysis was quantitated by measuring lipid phosphorus and by peak area integration. Plasmalogen content quantitated by either method produced consistent results (Table 2). The results were not significantly different when comparing between the amount of phospholipid used or by the quantitation method used to determine percent plasmalogen. The plasmalogen contents of HUVE cells, rat spinal cord and rat brain were determined to test the effectiveness of the method on tissue, as well as cell culture size samples (Table 3).

DISCUSSION

A mild acidic hydrolysis procedure for the quantitation of cell culture size samples of plasmalogens is reported here. The procedure is a modification of the Horrocks and

TABLE 2

Comparison of Phosphorus and Peak Area Values for the Quantitation of Plasmalogens[a]

Total nmol	Phosphorus (mole %) ± SD	Phosphorus (mole %) RSD	Peak area (mole %) ± SD	Peak area (mole %) RSD
37.00	82.7 ± 2.5	3.0	76.6 ± 5.9	7.7
18.50	84.7 ± 3.1	3.6	82.9 ± 1.2	1.4
9.25	86.9 ± 4.0	4.6	82.8 ± 3.1	3.7

[a]Values are expressed as mole % ± SD of glycerophospholipid class of semi-purified ethanolamine plasmalogen. Total nmoles represents the total number of nmoles used for the acidic hydrolysis. For each value (n = 3) with analysis done in triplicate. The relative standard deviation (RSD) represents both inter- and intra-sample variability.

TABLE 3

Mole % of Plasmalogen in EtnGpl and ChoGpl[a]

	% EtnGpl	% ChoGpl
Rat spinal cord	73.56 ± 1.43	5.7 ± 0.2
Rat brain	55.94 ± 2.64	12.5 ± 1.9
HUVE cells[b]	40.5 ± 1.90	11.6 ± 0.9

[a]Values are mole % of glycerophospholipid class lipid phosphorus. For rat spinal cord and brain values, n = 3. For HUVE cell values are for n = 4. EtnGpl, ethanolamine glycerophospholipid; ChoGpl, choline glycerophospholipid; HUVE, human umbilical vein edothelial.

[b]Refer to Reference 31.

Sun procedure (15) and utilizes the acid lability of the alkenyl ether linkage in the *sn*-1 position. HPLC was used to separate the phospholipids. Using HPLC to separate phospholipids permits good recovery of all phospholipids, improved phosphorus determination and detection of smaller changes in phospholipid composition with statistical significance due to a lower variance than with TLC (26). The method of Rotstein *et al.* (10) involves the use of a two-phase system to extract the lipids following hydrolysis. Using *n*-hexane/2-propanol (3:2, vol/vol) for all extraction procedures avoids the need for a two-phase system with the losses of lysoglycerophospholipids into the water phase (27). Thus, this procedure optimizes conditions for the separation and quantitation of cell culture size samples of EtnGpl and ChoGpl for plasmalogen content.

Initially, we used the method of Yeo and Horrocks (13) for the hydrolysis of the alkenyl ether. This procedure appeared to completely hydrolyze the fatty acids from the phospholipid, presumably because the samples sizes were very small. The method reported here caused the complete hydrolysis of the plasmalogen linkage while the alkylacyl and diacyl fractions remained intact. After 1 and 4 min, hydrolysis was completed for ChoGpl and EtnGpl, respectively. No more hydrolysis occurred between 4 and 20 min of exposure to acid fumes. Acidic hydrolysis of EtnGpl fraction from astrocytes for 15 min did not significantly alter the phospholipid fatty acid composition.

Literature values were obtained using EtnGpl from bovine brain (28) and ChoGpl from bovine heart (29) over this time period. We used this method to determine the plasmalogen content of EtnGpl and ChoGpl in HUVE cells, rat spinal cord and rat brain. Blank *et al.* (30) found the same plasmalogen content in HUVE cells as we did

with 42.5% PlsEtn in EtnGpl and 6.8% PlsCho in ChoGpl. Using our method, we obtained literature values for plasmalogens from several different sources and species without altering the fatty acid composition. The rapidity of the method, analysis time of approximately 2-3 h depending upon the resolution needed in the first separation, is superior to two-dimensional TLC methods. Furthermore, there are no effects of humidity on the day-to-day separation as seen in TLC. This simple method is suitable for use with cell cultures and for following plasmalogen metabolism.

ACKNOWLEDGMENTS

We thank Lynda Tetterington for invaluable assistance in cell culture work, Diana Carter and Cindy Murphy for typing the manuscript and Robert Hancock and Allen Taylor for assistance in statistical analysis. Steven Sutherland provided the rat brain and spinal cord. Dr. Yutaka Hirashima instructed and assisted on the removal of the rat spinal cord and brain. Supported by NS-10165.

COMMUNICATION

Time Response of Cholesterol Synthesis Inhibition by Compactin-Related Compounds. *In vitro* Quantitation of the "Escape Phenomenon"

Dmitri D. Sviridov[a,*], Akira Endo[b], Michael Y. Pavlov[a] and Vadim S. Repin[a]

[a]Institute of Experimental Cardiology, Cardiology Research Center, Moscow 121552, Russia and [b]Department of Applied Biological Science, Tokyo NoKo University, Tokyo 183, Japan

The time course of the inhibition of cholesterol synthesis by low and high doses of mevinolin and monacolin X were studied in normal human skin fibroblasts, fibroblasts without low density lipoprotein receptor and HepG2 hepatoma cells. Low doses of the inhibitors (0.2 ng/mL) caused a sharp decrease in the rate of cholesterol synthesis during the first 2–3 h, which gradually increased to about 40% during the next 6 h. Further incubation led to a decrease or stabilization of the cholesterol synthesis rate. High doses of the drugs (100 mg/mL) strongly inhibited cholesterol synthesis during the first 2–3 h, followed by a moderate increase during the next 20 h. No drug or tissue selectivity was observed.

***Lipids* 28, 569–571 (1993).**

Compactin-related compounds are competitive inhibitors of 3-hydroxy-3-methylglutaryl coenzyme A (HMG-CoA) reductase, a key enzyme in cholesterol synthesis (1). Associated with the inhibition of cholesterol synthesis by these compounds is an interesting response called "escape phenomenon" (2,3) which is characterized by a many-fold increase in HMG-CoA reductase and HMG-CoA synthase activity in cultured cells. The phenomenon is mainly due to the activation of HMG-CoA reductase and HMG-CoA synthase genes in response to the lowering of the regulatory sterol concentration (4). Although the molecular mechanisms of this phenomenon are being studied intensively, only limited information is available about the time course, the dose dependence and the possible tissue selectivity associated with the drug's action. These parameters may provide important clues as to the events associated with the "escape phenomenon."

MATERIALS AND METHODS

Cells. Human skin fibroblasts from healthy donors and from donors affected by homozygous familial hypercholesterolemia (FH) (the FH fibroblasts were a kind gift from Dr. I.V. Fuki), and human hepatoma cells HepG2 were maintained as previously described (5). Cells were grown to confluency in 24-well multidishes (Costar, Cambridge, MA); average protein concentration was about 100 μg per well.

Cholesterol synthesis. At the beginning of the experiment the medium was changed and replaced with medium (final volume 0.5 mL) containing a low (final concentration 0.2 ng/mL) or high (final concentration 100 ng/mL) dose of mevinolin or monacolin X (6). The rate of cholesterol synthesis was determined by measuring incorporation of sodium [2-^{14}C]acetate (Amersham, Bucks, England; specific activity 40–60 mCi/mmol; final concentration 6 μCi/mL, 0.12 nM) into digitonin precipitable sterols during a 2-h incubation as previously described (5). Incubation time is defined as the total time of incubation in the presence of the drug (*i.e.*, time of incubation with the drug alone plus 2 h incubation with the drug and [^{14}C]acetate). The zero time point refers to the cholesterol synthesis rate in the absence of the drugs. Statistical significance was calculated using Student's *t*-test.

RESULTS

The time course of inhibition of cholesterol synthesis by mevinolin in healthy human skin fibroblasts is shown in Figure 1. The low dose of mevinolin (0.2 ng/mL) after 2 h incubation caused an inhibition of cholesterol synthesis by about 25% ($P < 0.01$). Longer incubation in the presence of mevinolin caused a pronounced increase in cholesterol synthesis rate. After 3 h, the rate had returned to control levels. Comparison of the cholesterol synthesis rate after 2 and 8 h of incubation with a low dose of mevinolin gave a 39% stimulation of cholesterol synthesis during this time period. A high dose of mevinolin (100 ng/mL) caused a 76% inhibition of cholesterol synthesis after 2 h of incubation ($P < 0.001$). Further incubation of the cells with mevinolin at this dose did not cause statistically significant changes in cholesterol synthesis rate.

Exposure to a low dose of mevinolin for 3 h inhibited cholesterol synthesis in human skin fibroblasts lacking low density lipoprotein (LDL) receptors by 36% ($P < 0.01$) (Fig. 2). Longer incubation led to a return of the cholesterol synthesis rate to the control level by the eighth hour; however, by the twentieth hour the rate decreased again (37% inhibition; $P < 0.01$ *vs.* control). Incubation with a high dose of mevinolin for 3 h inhibited cholesterol synthesis by 86% ($P < 0.001$), which was followed by a gradual but statistically significant increase of this rate ($P < 0.001$ 2 h *vs.* 24th h). It should be noted that the absolute rate of cholesterol synthesis in FH fibroblasts was fivefold higher than in healthy cells.

The response to mevinolin by HepG2 cells (Fig. 3A) was quantitatively similar to that in skin fibroblasts without LDL receptors. Low doses of monacolin X, another less potent compactin-related compound, caused 10% inhibition ($P < 0.05$) of cholesterol synthesis during the initial 2–3 h, followed by an increase in the cholesterol synthesis rate up to 123% of the control after 8 h of incubation ($P < 0.01$) (Fig. 3B). A total increase by 37% was observed from the second to the eighth hour of incubation.

Abbreviations: FH, familial hypercholesterolemia; HMG-CoA, 3-hydroxy-3-methylglutaryl coenzyme A; LDL, low-density lipoproteins.

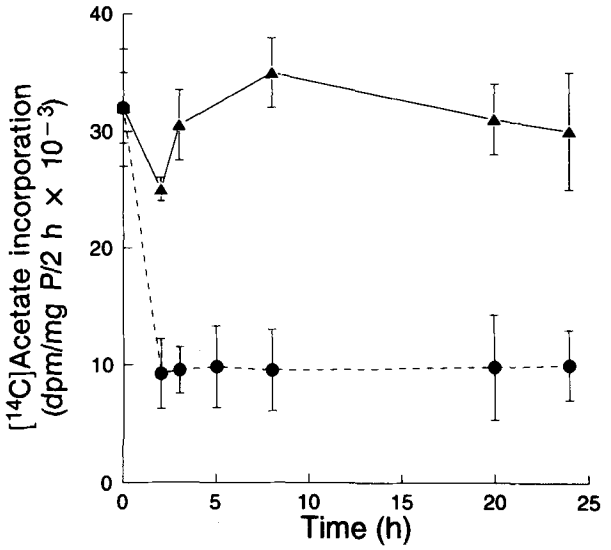

FIG. 1. Time response of cholesterol synthesis inhibition by mevinolin in healthy human skin fibroblasts. Cells were incubated at 37°C for the indicated periods of time in the absence or presence of mevinolin added at a final concentration 0.2 ng/mL (▲) or 100 ng/mL (●). Two hours before the end of the incubation, sodium [^{14}C]acetate was added to the incubation mixture at a final concentration of 6 μCi/mL. After incubation, cells were washed and incorporation of [^{14}C]acetate into digitonin precipitable sterols was determined. Each point represents the mean ± SE of the mean of triplicate or quadruplicate determinations.

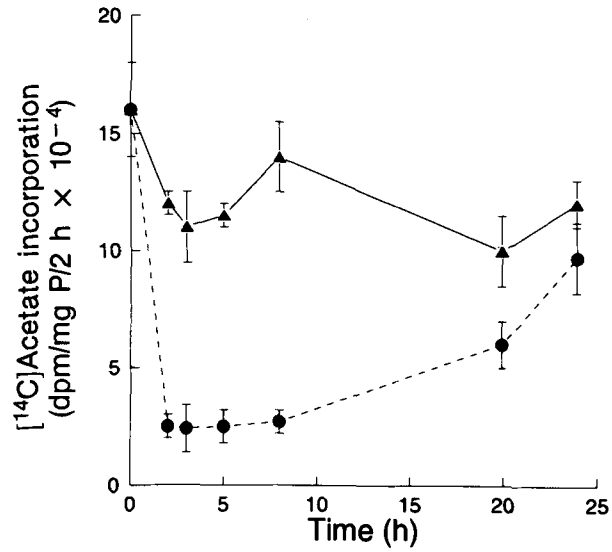

FIG. 2. Time response of cholesterol synthesis inhibition by mevinolin in skin fibroblasts from a patient affected by homozygous familial hypercholesterolemia. Cells were incubated at 37°C for the indicated periods of time in the absence or presence of mevinolin added at a final concentration 0.2 ng/mL (▲) or 100 mg/mL (●). Two hours before the end of the incubation, sodium [^{14}C]acetate was added to the incubation mixture at a final concentration 6 μCi/mL. After incubation, cells were washed and incorporation of [^{14}C]acetate into digitonin precipitable sterols was determined. Each point represents the mean ± SE of the mean of triplicate or quadruplicate determinations.

Further incubation of the cells with monacolin X resulted in a gradual decrease of the cholesterol synthesis rate back to the control level. A high dose of monacolin X inhibited cholesterol synthesis by 53% after a 2-h incubation

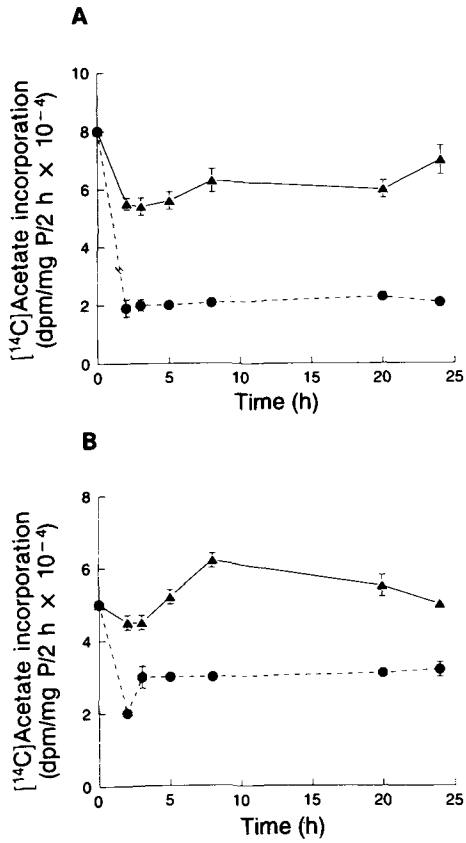

FIG. 3. Time response of cholesterol synthesis inhibition by mevinolin (A) and monacolin X (B) in HepG2 cells. Cells were incubated at 37°C for the indicated periods of time in the absence or presence of mevinolin (A) or monacolin X (B) added at a final concentration 0.2 ng/mL (▲) or 100 ng/mL (●). Two hours before the end of the incubation, sodium [^{14}C]acetate was added to the incubation mixture at a final concentration 6 μCi/mL. After incubation, cells were washed and incorporation of [^{14}C]acetate into digitonin precipitable sterols was determined. Each point represents the mean ± SE of the mean of triplicate or quadruplicate determinations.

($P < 0.01$) followed by a subsequent increase of the cholesterol synthesis rate (38% inhibition after 24 h incubation). A similar response of the other two cell types on the inhibition of cholesterol synthesis by monacolin X was observed (data not shown).

DISCUSSION

In this study, we compared the inhibition of cholesterol synthesis in three human cell types that had been treated for various time periods with two compactin-related compounds at different doses. The low dose (0.2 ng/mL) corresponded to the nonsaturating active dose of compactin-related compounds on the cell types chosen (5). The high dose (100 ng/mL) corresponded to the concentration of Mevacor (trade name of mevinolin) in the plasma of patients treated with this drug (60–100 mg/d) (7,8). Mevinolin is the stronger cholesterol synthesis inhibitor, while monacolin X is a less potent inhibitor. The cells were from healthy humans and FH patients, *viz.* healthy and LDL-receptor defective fibroblasts; HepG2 cells were used as a model derived from the major cholesterol producing organ. Drugs were present in the incubation mixture while

the cholesterol synthesis rate was measured, thus modeling the situation of continuous administration of the drug.

In the experiments with a low dose of the drug, cholesterol synthesis inhibition reached a maximum in all cell types after 2–3 h of incubation. Further incubation, however, resulted in an increase of the cholesterol synthesis rate. This allows the assumption that it takes 2–3 h for the drug to penetrate into the cell, to activate feedback mechanism(s) and to stimulate the rebound of HMG-CoA reductase and HMG-CoA synthase. This is consistent with the rebound activation time found by Stone *et al.* (3) in mononuclear leukocytes of patients treated with lovastatin. The growth of cholesterol synthesis rate continued up to the eighth hour of incubation, similar to what was observed by Hagemenas and Illingworth (8) and Stone *et al.* (3). Very similar increases in cholesterol synthesis rates were noted between the third and eight hour of incubation in all experiments, *i.e.*, 25–39%. The rates did not depend on either the level of inhibition during the first 2–3 h of incubation nor on the basal rate of cholesterol synthesis. While in absolute terms, the effect of mevinolin on cholesterol synthesis in FH fibroblasts was much more pronounced than in healthy cells, the relative effects were very similar. It should be noted, however, that while incubation with the drugs should provide a steady supply of the drugs to the cells, it cannot be excluded that the drugs metabolize, which would change their effective concentration.

Analysis of the time response of inhibition of cholesterol synthesis by the high drug dose showed a rapid inhibition of cholesterol synthesis after 2–3 h of incubation followed by a gradual increase in the cholesterol synthesis rate. This is consistent with a rebound of HMG-CoA reductase in an excess of free inhibitor. The only difference was observed in LDL-receptor defective fibroblasts where the increase in cholesterol synthesis rate was more rapid than in the other cells. The cause of this effect could be associated with the relatively higher absolute rate of cholesterol synthesis in these cells as demonstrated in this study and earlier by Shireman *et al.* (9). The results are also consistent with the notion that continuous administration of a high dose of the drug may be less effective in FH patients than low doses (7,8). No tissue or drug selectivity was observed.

Oxidative Modification of Triglyceride-Rich Lipoproteins in Hypertriglyceridemic Rats Following Magnesium Deficiency

Elyett Gueux, Christine Cubizolles, Laurence Bussière, Andrzej Mazur and **Yves Rayssiguier***
Centre de Recherches en Nutrition Humaine, Laboratoire des Maladies Métaboliques, INRA, Theix, 63122 St-Genès-Champanelle, France

Hypertriglyceridemia observed in magnesium (Mg)-deficient rats was associated with a significant increase in the very low-density lipoprotein (VLDL) plus low-density lipoprotein (LDL) fractions. The results from *in vitro* copper-induced lipid peroxidation, expressed in terms of conjugated dienes and thiobarbituric acid reactive substances content, showed that VLDL + LDL particles from Mg-deficient rats were more susceptible to oxidative damage than lipoproteins from control rats. These results suggest that the mechanism responsible for the atherogenicity and tissue damage characteristic of Mg deficiency may be mediated by an increased susceptibility of triglyceride-rich lipoproteins to peroxidation in hypertriglyceridemic animals.
Lipids 28, 573-575 (1993).

Several studies have provided evidence that magnesium (Mg) deficiency affects lipid metabolism (1,2) and is associated with tissue injury affecting the physical state of bilayer membrane lipids (3). Mg deficiency has been implicated as a risk factor in the development of atherosclerosis. Early studies indicate that Mg deficiency enhances vascular lipid infiltration in rats, rabbits and monkeys fed atherogenic diets (4). Recent studies have confirmed that Mg deficiency can intensify cardiovascular lipid deposition and formation of lesions in animals on atherogenic diets and that dietary Mg supplementation can prevent atherosclerosis (5). Mg deficiency affects lipoprotein metabolism (4,6); however, there has not been agreement that formation of cardiovascular lesions is necessarily correlated with cholesterolemia in Mg-deficient animals (5). The mechanism causing vascular lesions has yet to be identified. An important characteristic of hyperlipemia associated with Mg deficiency in rats is the post prandial accumulation of triglyceride-rich lipoproteins (TGRLP) (7). The relationship between hypertriglyceridemia, TGRLP and atherosclerosis remains obscure, but data suggest that the mechanism responsible for the atherogenicity of the hypertriglyceridemic state may be related to the increased susceptibility of TGRLP to peroxidation (8). The apoprotein B (apoB) molecules contained in TGRLP of hypertriglyceridemic subjects may become partially degraded and such alterations could promote binding to macrophages which act as scavenger cells. The uptake of oxidized lipoproteins by macrophages would lead to accumulation of esterified cholesterol and formation of foam cells (9). Several previous studies have shown that Mg deficiency increased lipid peroxidation (2,10,11). Mg-deficient animals had lower levels of vitamin E in plasma and tissues, and the protection by vitamin E of myocardial necrosis induced by Mg deficiency, as shown recently would suggest that free radicals participate in Mg deprivation-induced injury (12). The present investigation was undertaken to determine the effect of Mg deficiency in rats on the susceptibility of TGRLP to peroxidation.

Abbreviations: AAS, atomic absorption spectrophotometry; apo, apoprotein; BHT, butylated hydroxytoluene; EDTA, ethylenediaminetetraacetic acid; HDL, high-density lipoprotein; LDL, low-density lipoprotein; Mg, magnesium; TBARS, thiobarbituric acid reactive substances; TGRLP, triglyceride-rich lipoproteins; VLDL, very low density lipoprotein.

MATERIALS AND METHODS

Thirty-six weanling male Wistar rats (Iffa-Credo, L'arbresle, France) (≈60 g; 3-wks-old) were divided randomly into Mg-deficient and control groups (18 animals per group). The institution's guide for the care and use of laboratory animals was followed. The animals were pair-fed with the appropriate diets for 8 d using an automatic feeding apparatus. Distilled water was provided *ad libitum.* Diets contained (g/kg) 200 casein, 3 DL-methionine, 702 sucrose, 50 corn oil, 35 mineral mixture and 10 vitamin mixture as described previously (13). Mg levels determined by flame atomic absorption spectrophotometric analysis (model 400, Perkin Elmer, Norwalk, CT) were 30 (deficient) and 990 mg/kg (control). Experiments were performed in nonfasting rats. Plasma from 18 animals per group were obtained from rats anesthetized with sodium pentobarbital (40 mg/kg of body weight). Equal volumes of plasma samples from three animals were pooled for blood analysis and lipoprotein separations.

Ultracentrifugation was performed (14) at 15°C in a Beckman L5-50 model ultracentrifuge (Beckman Instruments Inc., Palo Alto, CA) with a Ti-50 titanium rotor. Ethylenediaminetetraacetic acid (EDTA) (1 mg/mL), and butylated hydroxytoluene (BHT) (4.4 μg/mL) were added immediately before lipoprotein separation. Samples were overlayered with 0.15 M NaCl (d = 1.006 g/mL), and chylomicrons were discarded following two centrifugations for 30 min at 12,000 × *g*. In order to isolate the VLDL + LDL (very low density lipoproteins and low-density lipoprotein) fraction, the infranatant was adjusted to density 1.050 g/mL with solid KBr. The centrifugation was done at 100,000 × *g* for 20 h. The VLDL + LDL fractions were then washed by a further period of ultracentrifugation at the same density. Before oxidation experiments, the purified lipoprotein fractions were dialyzed against 0.01 M phosphate buffer (pH 7.4) containing 0.15 M NaCl, which was made oxygen-free by vacuum degassing followed by purging with nitrogen.

Oxidation experiments were performed as described by Esterbauer *et al.* (15). The EDTA/BHT-free dialyzed lipoproteins were diluted with dialysis buffer to a final concentration of 0.2 mg protein/mL. The same concentrations were used for both experimental groups. Oxidation was initiated by addition of freshly prepared $CuSO_4$ solution at various concentrations (5, 25 and 50 μM). The kinetics of the oxidation of lipoproteins were determined by monitoring the change in the 234 nm absorbance at 37°C on a spectrophotometer Uvikon 820 (Kontron, St-Quentin-en-Yvelines, France) using appropriate dilutions. The in-

itial absorbance at 234 nm was set to zero and the increase in absorbance was recorded. Thiobarbituric acid reactive substances (TBARS) were determined in lipoproteins (16) after lipid peroxidation with 50 μM $CuSO_4$. Plasma Mg was determined with a Perkin-Elmer model 400 AAS after dilution in lanthanum chloride solution containing 1 g/L La. Triglycerides (Biotrol, Paris, France), cholesterol and phospholipids (Biomérieux, Charbonnières-les-Bains, France) were determined in plasma by enzymatic procedures (17–19). Protein concentration of isolated lipoproteins was determined by a modified Lowry method using bovine serum albumin, fraction V (Sigma, L'Isle d'Abeau, France) as a standard (20).

Results are expressed as means ± SEM. Statistical significance of differences between means was assessed by Student's *t*-test.

RESULTS AND DISCUSSION

Mean final body weights of Mg-deficient and pair-fed control rats were 87 ± 3 and 96 ± 2 g (mean ± SEM; n = 18; $P < 0.01$), respectively. Hypomagnesemia was usually observed in Mg-deficient rats (0.13 ± 0.01 *vs.* 0.83 ± 0.03 mM in control rats, $P < 0.001$). Triglyceride plasma levels were significantly higher in Mg-deficient rats than in controls, whereas plasma cholesterol was not altered (Table 1). Hypertriglyceridemia observed in Mg-deficient animals was associated with a significant increase in the VLDL + LDL fraction levels (Table 1). VLDL + LDL fractions from Mg-deficient rats as compared to control rats exhibited increased oxidation *in vitro* as monitored by conjugated diene formation (Fig. 1) and by TBARS activity (Fig. 2).

Previous studies from our laboratory have provided evidence that experimental Mg deficiency in rats produced a dyslipoproteinemia characterized by increased plasma levels of VLDL and LDL and decreased plasma high-density lipoprotein (HDL) (13). The mechanisms behind the hyperlipemia of Mg-deficient rats have been addressed in several studies (6). A recent study indicated that decreased clearance of circulating triglycerides is a major mechanism contributing to hyperlipemia in Mg-deficient rats (7). The hypertriglyceridemic state in humans may act indirectly on the processes leading to atherosclerosis by influencing the metabolism and composition of intermediate density lipoproteins, LDL and HDL (8). There are data that suggest that delayed removal of TGRLP in the hypertriglyceridemic state might contribute to development of cardiovascular disease by uptake of these particles by macrophages (21).

Our results demonstrate that Mg deficiency affects the susceptibility of TGRLP to *in vitro* peroxidation. Because both LDL and VLDL undergo lipid peroxidation and rats have a relatively small amount of LDL, we chose to investigate the effect of Mg deficiency in rats on *in vitro*

TABLE 1

Effect of Dietary Magnesium (Mg) on Concentrations of Plasma Lipids and Lipoproteins[a]

	Control (mg/100 mL)	Mg-deficient (mg/100 mL)
Plasma[a]		
Triglycerides	76 ± 8	290 ± 46[c]
Total cholesterol	44 ± 4	47 ± 8
VLDL + LDL[a]		
Triglycerides	54 ± 6	179 ± 20[c]
Total cholesterol	14 ± 1	30 ± 3[c]
Phospholipids	20 ± 2	56 ± 6[c]
Proteins	15 ± 2	30 ± 4[b]

[a]Means of six determinations per group ± SEM, VLDL, very low density lipoproteins; LDL, low-density lipoproteins.
[b]Significant difference from control rats, $P < 0.01$.
[c]Significant difference from control rats, $P < 0.001$.

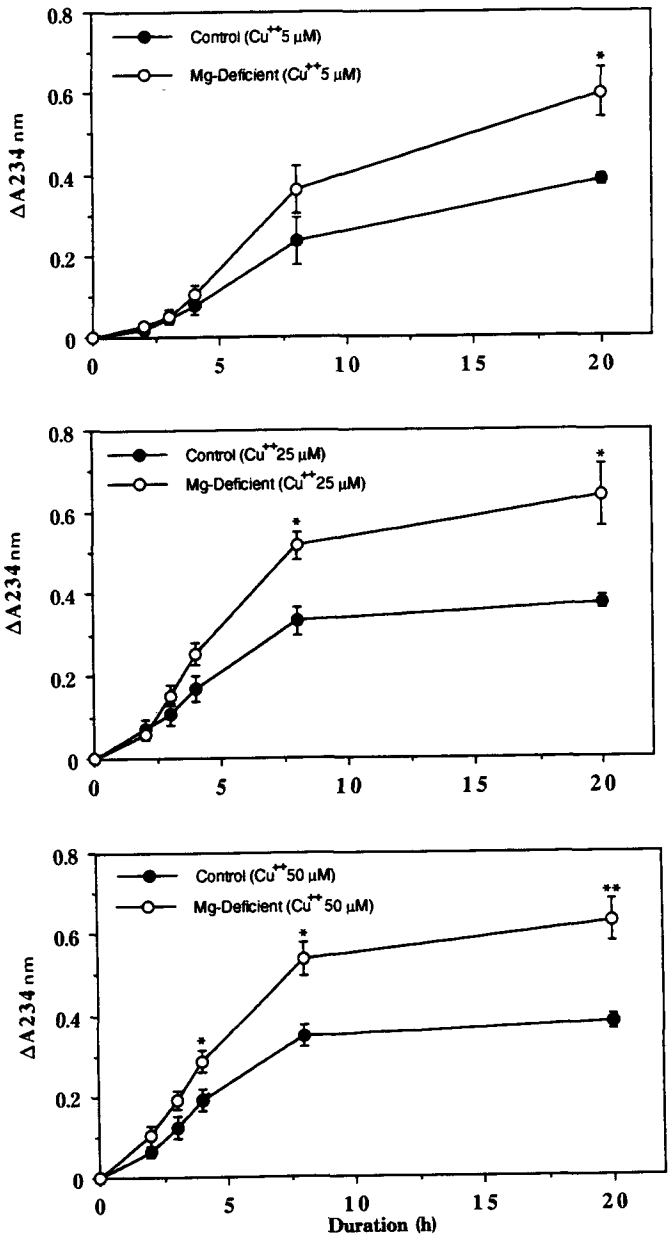

FIG. 1. Rate of formation of conjugated dienes during Cu^{++} stimulated oxidation of very low density lipoprotein + low-density lipoprotein fractions isolated from control and magnesium (Mg)-deficient rats. The results represent the mean (± SEM) of six determinations per group. Those points that were significantly different between control and Mg-deficient rats are designated with an asterisk. *$P < 0.01$; **$P < 0.001$).

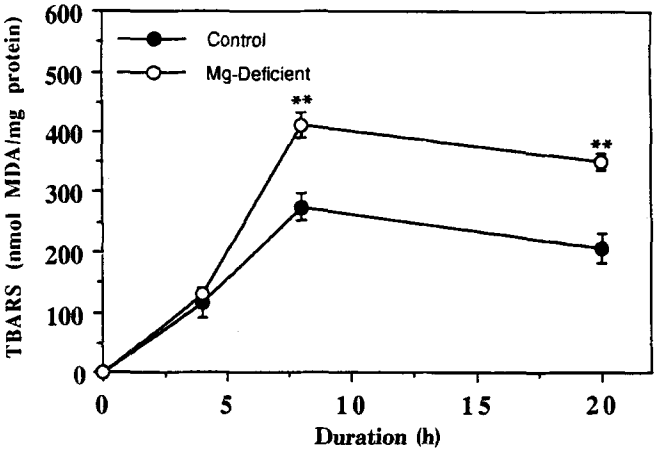

FIG. 2. Production of thiobarbituric acid reactive substances (TBARS) during Cu^{++} (50 μM) stimulated oxidation of very low density lipoproteins + low-density lipoprotein fractions isolated from control and magnesium (Mg)-deficient rats. The results represent the mean (± SEM) of six determinations per group. Those points that were significantly different between control and Mg-deficient rats are designated with an asterisk. $^{**}P < 0.001$. MDA, malondialdehyde.

oxidation of the lipoprotein fraction containing both LDL and VLDL (22). Plasma lipid peroxides have also been reported to be elevated in diabetic rats when plasma triglycerides are increased, with TBARS levels being elevated in lipoprotein fractions containing both VLDL and LDL (23). Enhanced production of lipid peroxides may be attributable either to changes in the lipid composition or to a depleted lipoprotein antioxidant system (24). In lipoproteins from Mg-deficient animals, there is an increase in triglyceride/protein and phospholipid/protein ratios (25) which could theoretically explain the higher rate of oxidation of lipoproteins. Other studies have shown changes in fatty acid metabolism (2) and in fatty acid composition of lipoproteins in Mg-deficient rats as compared to controls, *i.e.*, an increased percent composition of linoleic acid (25). As no information is available concerning the influence of Mg on antioxidant concentration in lipoproteins, further studies will be required to pinpoint the mechanism by which lipoprotein oxidation increases in Mg-deficient animals.

Several studies indicate that TGRLP, when oxidized, become toxic to cells in culture and that oxidatively modified apoB-containing lipoproteins play a role in the recruitment and retention of macrophages. Macrophages themselves are responsible for oxidation and resultant toxicity because of their highly developed oxidation capacity (21,26). Recent studies have demonstrated that such macrophages are more abundant in animals fed diets low in magnesium (5). Thus, increased oxidation of TGRLP combined with the increased abundance of macrophages in Mg-deficient animals may result in excessive uptake of the modified lipoproteins by the scavenger receptor, converting macrophages into foam cells. The results of this study suggest that the mechanism responsible for the atherogenicity and tissue damage characteristic of Mg deficiency may be mediated by increased susceptibility of TGRLP to peroxidation in hypertriglyceridemic animals.

ARTICLE

Inositol 1,4,5-Trisphosphate Accumulation in Brain of Lithium-Treated Rats

Yoshio Ishima[a,1], **Michiyo Fujimagari**[b], **Yasuo Masuzawa**[b] and **Keizo Waku**[b,*]

[a]Department of Neuropsychiatry, Ibaraki Prefectural Hospital, Tomobe, Ibaraki 309-17 and [b]Faculty of Pharmaceutical Sciences, Teikyo University, Sagamiko, Kanagawa 199-01, Japan

The mechanism of action of lithium as a drug for patients with affective disorders was investigated. Three-week-old male rats were orally administered 2.7 mEq Li_2CO_3/kg/d for 1 or 3 wk, and phosphatidylinositol (PI), phosphatidylinositol 4-phosphate (PIP), phosphatidylinositol 4,5-bisphosphate (PIP_2), inositol phosphate (IP), inositol diphosphate (IP_2) and inositol triphosphate (IP_3) levels in brain were measured. The levels of IP were increased 1.7 and 2.4 times after 1 wk and 3 wk of lithium administration, respectively, while PI, PIP, PIP_2, IP_2 and IP_3 levels were not altered. IP_3 was further fractionated by high-performance liquid chromatography into I-1,3,4-P_3 and I-1,4,5-P_3. In the control rat brain, the relative percentages of I-1,3,4-P_3 and I-1,4,5-P_3 were 95.8 and 4.2, respectively. However, after 3 wk of lithium administration, the values were changed to 69.6 and 30.3%, respectively. This increase in the neurotransducer I-1,4,5-P_3 in the brain may be relevant to the mechanism of action in the lithium treatment of patients with manic-depressive disorders. *Lipids 28,* **577-581 (1993).**

Lithium is used for the treatment of manic-depressive illness and other psychiatric disorders (1). Although the mechanisms of the therapeutic action of lithium is not known, this treatment has various endocrine and metabolic effects on the brain (2). The effects of lithium on the metabolism of inositol phosphates (IPs) and inositol phospholipids (3) are among the possible mechanisms involved in the pharmacological action of lithium, since breakdown of inositol phospholipids plays a role in the transducing mechanism of receptor occupation by several neurotransmitters (4). Sherman *et al.* (5) discovered that lithium is a strong inhibitor of inositol phosphate 1-phosphatase. Through this action, lithium administration causes the accumulation of inositol monophosphate and a decrease in the myoinositol level in rat brain (6). These findings suggest that lithium may inhibit the resynthesis of inositol phospholipids resulting in gradual depletion of the inositol phospholipids of the membrane. This might also gradually decrease the levels of IPs, which play an important role in signal transducing mechanisms (7). Clinical observations indicate that at least 2 to 3 wk of lithium treatment is required to achieve an effect in patients with affective disorders (1).

The effects of chronic lithium administration on the levels of several phospholipids and inositol 1-phosphate (I-1-P), as well as an I-1-P phosphatase activity, in rat brain have previously been investigated (5). On the other hand, inositol triphosphate (IP_3) levels have not yet been reported. Inositol-1,4,5-trisphosphate (I-1,4,5-P_3) is known as a key transducer of input signals to output transmitters (8). We therefore estimated the levels of inositol phospholipids, *i.e.*, phosphatidylinositol (PI), phosphatidylinositol 4-phosphate (PIP) and phosphatidylinositol 4,5-bisphosphate (PIP_2) and of IPs, *i.e.* IP, inositol diphosphates (IP_2) and IP_3 in rat brain after chronic lithium administration. In particular, we examined the change in the ratio of I-1,4,5-P_3 to I-1,3,4-P_3 in IP_3. A preliminary report has been published (9).

MATERIALS AND METHODS

Chemicals. Myo-[^{3}H]inositol (2.96 TBq/mmol), D-myo-[2-^{3}H]I-1-P (37 GBq/mmol), D-myo-[2-^{3}H]inositol 1,4-bisphosphate (37 GBq/mmol), and D-[2-^{3}H]inositol 1,3,4,5-tetrakisphosphate (37 GBq/mmol) were purchased from Amersham (Buckinghamshire, United Kingdom). I-1,3,4-P_3 (370 GBq/mmol), [2-^{3}H-*inositol*]PIP (74-370 GBq/mmol), and [2-^{3}H-*inositol*]PIP_2 (74-370 GBq/mmol) were purchased from Dupont/New England Nuclear (Boston, MA). Precoated silica gel thin-layer chromatography (TLC) plates were purchased from Merck (Darmstadt, Germany). All other chemicals were of reagent grade; solvents were distilled before use.

Chronic lithium administration. Three-week-old male Sprague-Dawley rats (eight rats per group) were orally administered with 2.7 mEq Li_2CO_{33}/kg/d for one week or three weeks. At 24 h after the last administration, the rats were decapitated, and the brains were removed as soon as possible (within 15 s) and cooled in an ice-cold isotonic saline solution. After being blotted dry, the brains (1.5 to 2.0 g) were weighed and homogenized in 4 mL of 5% (wt/vol) trichloroacetic acid for measurement of IPs or 4 mL of 0.25 M sucrose for measurement of PI phosphates. A control group of eight rats was fed the same diet without lithium.

Inositol polyphosphate analysis. The homogenized brains in 5% trichloroacetic acid were centrifuged for 5 min at 1000 × *g*. Aliquots (1 mL) of supernatant solution were supplemented with 185 Bq of [^{3}H]IP, [^{3}H]IP_2 and [^{3}H]IP_3. [^{3}H]Inositol tetraphosphates (IP_4) were also added for high-performance liquid chromatography (HPLC). Then the samples were extracted three times with 5 mL each of diethyl ether to remove the trichloroacetic acid.

Separation of inositol polyphosphates by ion exchange resin column chromatography. The samples were diluted with 5 mL of water for application to a Dowex-1-8X ion exchange column (Dow Chemical Co., Midland, MI) as

[1]Present address: Ishima Institute for Neurosciences, 11-7 Higashi-Sanchome, Kunitachi-Shi, Tokyo 186, Japan.

Abbreviations: DPO, 2,5-diphenyloxazole; HPLC, high-performance liquid chromatography; HPTLC, high-performance thin-layer chromatography; I-1,3,4-P_3, inositol 1,3,4-trisphosphate; I-1,4,5-P_3, inositol 1,4,5-trisphosphate; IP, inositol phosphate; I-1-P, inositol 1-phosphate; IP_2, inositol diphosphate(s); IP_3, inositol triphosphate(s); IP_4, inositol tetraphosphate(s); PC, phosphatidylcholine; PE, phosphatidylethanolamine; PI, phosphatidylinositol; PIP, phosphatidylinositol 4-phosphate; PIP_2, phosphatidylinositol 4,5-bisphosphate; POPOP, 1,4-*bis*[2-(5-phenyloxazolyl)]benzene; TLC, thin-layer chromatography.

described by Downes and Michell (10). The column was eluted with 15 mL of water, 15 mL of 0.2 M ammonium formate/0.1 M formic acid (IP), 15 mL of 0.4 M ammonium formate/0.1 M formic acid (IP_2) and 15 mL of 1 M ammonium formate/0.1 M formic acid (IP_3,IP_4). Aliquots were dissolved in scintillation fluid [Triton X-100/toluene (1:2, vol/vol) containing 8.6 g of 2,5-diphenyloxazole (DPO) and 0.26 g of 1,4-*bis*[2-(5-phenyloxazolyl)]benzene (POPOP)/2.4 L of Triton/toluene] and radioactivity was counted. The remainder was lyophilized and fractionated by HPLC.

Separation of inositol polyphosphates by HPLC. The lyophilized samples containing IP were diluted to 1 mL, and one-third was injected into the HPLC. A precolumn of silicic acid (4 × 250 mm; mounted before the injector loop), a Partisil SAX guard column (Whatman, Clifton, NJ; 4.6 × 50 mm) and a Partisil SAX HPLC separating column (4.6 × 250 mm; Cobert Associates, St. Louis, MO) were used as described by Wilson *et al.* (11). The column was eluted with a gradient system of (A) 50 mM ammonium formate, pH 3.8 and (B) 2.7 M ammonium formate, pH 3.8, as follows: 0 min, 0% B; 10 min, 0% B; 30 min, 70% B; 50 min, 100% B; 70 min, 100% B; 70.01 min, 0% B; flow rate 1 mL/min; fractions of 1 mL were collected. Aliquots (0.5 mL) of each fraction were removed and to each aliquot was added 1 mL of water and 10 mL of scintillation fluid for radioactivity counting. Xylitol (20 nmol) was added to the remainder of the samples to check recovery; then the samples were lyophilized.

Digestion of inositol polyphosphates. After lyophilization, the dried residues were digested by alkaline phosphatase (from bovine intestinal mucosa, Type 7-N, Sigma, St. Louis, MO) as described by Rittenhouse and Sasson (12). The incubation conditions were 20 mM ethanolamine, 5 mM $MgCl_2$, 76 unit/mL of enzyme, pH 9.6, total volume μL/tube at 37°C for 5 h. The samples were then desalted with Amberlite MB-2 (mixed ion exchange resin), and inositol was eluted with water.

Derivatization and gas chromatography. The resulting inositol samples were dried under vacuum and 10 nmol of mannitol was added as an internal standard. Then half the sample was removed for radioactivity counting to check the recovery. The remainder was dried under N_2. At this step, the recovery of [^{3}H]inositol was 40–60%. Then 100 μL of a mixture of dry pyridine, trimethylchlorosilane and hexamethyldisilazane (5:2:1, by vol) was added to each sample. The samples were capped and heated for 30 min at 55–60°C. Then 3 mL of water and 3 mL of chloroform were added to each sample to extract the pyridine with water. The water phase was removed, and the chloroform phase was dried under an N_2 flow. The residue was taken up in 2–3 μL of hexane and 1 μL was injected at 260°C onto a 25-m capillary fused silica CBP-5 column (Shimadzu Co., Tokyo, Japan) using He as carrier gas (column temperature, 210°C). Inositol, xylitol and mannitol were quantitated by integration of the flame-ionization detector peak areas. Final results were calculated by considering separately the recoveries of xylitol, mannitol and [^{3}H]inositol.

PI extraction. Total lipids were extracted from the homogenate (0.8 mL), including 185 μBq of [^{3}H]PI, with chloroform/methanol (1:2, vol/vol). The mixture was stirred for 20 min, then 1 mL of chloroform and 1 mL of water were added to each sample. The lower phase was collected, and the upper phase was reextracted twice with 1 mL of chloroform as described by Bligh and Dyer (13).

PI separation. The chloroform layer was evaporated, and the lipids were analyzed by two-dimensional TLC as described by Rouser *et al.* (14). The lipid fractions were detected under ultraviolet light after spraying the plate with 0.001% primuline in acetone/water (4:1, vol/vol). The PI fractions were scraped off the plate and placed into vials for radioactivity counting or into tubes to measure phosphorus content (14).

PIP and PIP_2 extraction. The homogenates including 185 μBq of [^{3}H]PIP and [^{3}H]PIP_2 were washed twice with 7.5 mL of chloroform/methanol (1:1, vol/vol), (containing 60 μmol/g tissue of $CaCl_2$) to remove other major phospholipids [phosphatidylcholine (PC), phosphatidylethanolamine (PE), *etc.*]. Then 5 mL of chloroform/methanol/conc. HCl (200:100:1, by vol) was added, and the samples were stirred for 1 h. One mL of 1 N HCl was added, and the mixture was stirred and centrifuged. The lower phase was collected and the upper phase and interface were reextracted twice with 3.5 mL of fresh lower phase.

PIP and PIP_2 separation. The extract was dried under a stream of nitrogen and applied to high-performance thin-layer chromatography (HPTLC) plates which had been treated with oxalate and heated at 110°C for 30 min as described by Schacht (15). The developing solvent was chloroform/methanol/ammonia/water (90:70:5:15, by vol). The adsorbent bands were scraped off, and the phosphorus contents or radioactivities were estimated as described above.

Lithium analysis. Lithium concentration in blood sera and tissues was determined with a modified atomic absorption spectrophotometric method developed for determining lithium in blood serum (16). The atomic absorption spectrophotometer used was a Model 703 (Perkin-Elmer Corp., Norwalk, CT) with either a single slot burner or a three-slot burner. The lithium hollow-cathode lamp was obtained from Perkin-Elmer Corp. It was used at a wavelength of 668 nm, a slit width of 2, a scale expansion of 1 and a source current of 15 mA. The gas pressure was 8.5 lbs/in for N_2, and the flow rate was 9 mL/s. Standards were analyzed by adding lithium to control tissues and following the same procedure.

Student's t-test. All experiments were repeated several times (n = 3–8) and analyzed by Student's *t*-test.

RESULTS

The lithium content of rat brain after oral administration (2.7 mEq/kg/d) of lithium carbonate is shown in Table 1. The results are in excellent agreement with those of Sherman *et al.* (5). The lithium content in the serum was *ca.* 0.10 mEq/kg throughout the experiment.

The levels of phosphoinositides were estimated relative to normal control levels after the 1st and 3rd wk of lithium administration. The results are shown in Figure 1. There was no significant difference in PI, PIP or PIP_2 when compared with the normal levels in the brains at 1 wk and 3 wk after initiation of lithium treatment. This result is in conflict with that of a previous report (17), but in agreement with the result of another (18). Though the turnover rates of PI, PIP and PIP_2 were not determined, the rates of hydrolysis of inositol phospholipids seemed not to be significantly affected by lithium.

TABLE 1

Lithium Content in Rat Brain After the Indicated Days of Administration[a]

Days after start of Li	Number of rats	Li in brain (mEq/kg)
1	4	0.337 ± 0.11
3	6	0.321 ± 0.03
5	5	0.213 ± 0.03
7	3	0.256 ± 0.05
11	3	0.243 ± 0.03
15	3	0.293 ± 0.01
22	3	0.228 ± 0.02

[a]Three-week-old male Spraque-Dawley rats were administered lithium carbonate at 2.7 mEq Li_2CO_3/kg/d. At 24 h after administration, the rats were decapitated and the brains were removed immediately. Lithium content was estimated by atomic absorption spectrophotometry (Perkin-Elmer, Norwalk, CT, Model 703). Values represent the mean ± SEM.

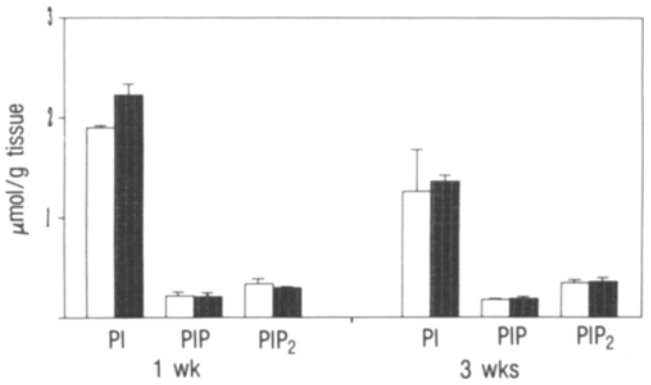

FIG. 1. The effect of lithium on the levels of inositol phospholipids in rat brain. Open bars, control; gray bars, Li-treated. The methods for estimation of phosphatidylinositol (PI), phosphatidylinositol 4-phosphate (PIP) and phosphatidylinositol 4,5-bisphosphate (PIP_2) in rat brain homogenates are described in Materials and Methods. Results are mean ± SEM from 32 rats. Treated groups show no significant difference from the control by Student's two sample *t*-test, $P > 0.1$.

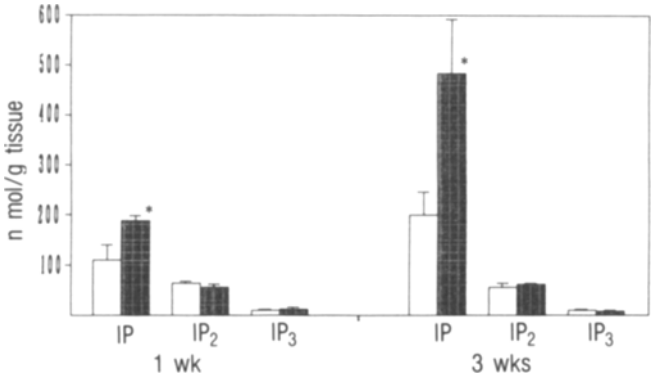

FIG. 2. The effect of lithium on the levels of inositol phosphates (IP) in rat brain. Open bars, control; gray bars, Li-treated. IP, inositol diphosphate (IP_2) and inositol triphosphate (IP_3) were analyzed in rat brain homogenates as described in Materials and Methods. The different control levels of IP at 1 wk and 3 wk seem to reflect the developmental states of 4- and 6-wk-old rats. Results are mean ± SEM from 32 rats. Statistical significance is indicated by *, $P < 0.01$ (Student's two sample *t*-test).

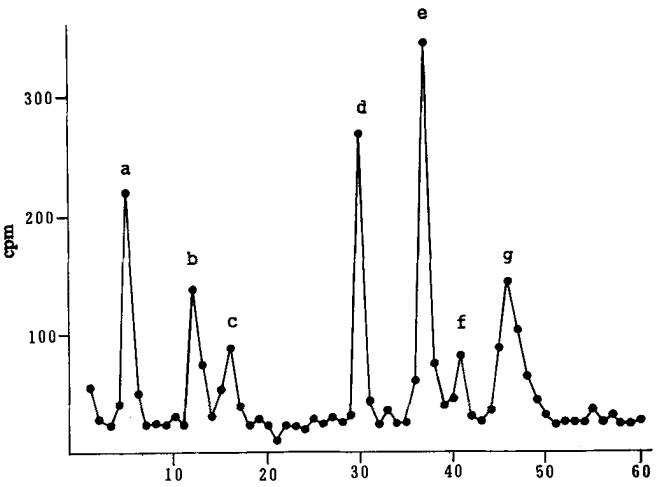

FIG. 3. Fractionation of radioactive inositol phosphates on Partisil SAX high-performance liquid chromatography. a: Inositol; b: inositol 1-phosphate; c: inositol 4-phosphate; d: inositol 1,4-diphosphate; e: inositol 1,3,4-triphosphate; f: inositol 1,4,5-triphosphate; g: inositol 1,3,4,5-tetraphosphate. The details of the experiment are described in Materials and Methods.

Furthermore, we tested the effect of lithium on the IP, IP_2 and IP_3 contents of the rat brains (Fig. 2). The level of I-1-P rose about 1.7-fold from 109 ± 29.2 to 187 ± 9.7 nmol/g tissue in rats after 1 wk of lithium administration and about 2.4-fold from 199 ± 46.3 to 483 ± 108.6 nmol/g tissue after 3 wk of lithium administration. An increase in I-1-P by chronic lithium treatment of the rats for 10 d was also observed by Sherman *et al.* (5). IP_2 showed no significant change (Fig. 2) in response to lithium.

The level of IP_3 at 1 wk was increased from 9.7 ± 1.4 nmol/g tissue to 11.3 ± 3.8 in the lithium group, while at 3 wk, it was decreased from 10.4 ± 0.4 to 7.9 ± 1.0 nmol/g tissue. However, the apparent decrease of IP_3 upon chronic administration of lithium was not statistically significant (Student's *t*-test, $P > 0.1$).

Next, IP_3 was fractionated into I-1,3,4-P_3 and I-1,4,5-P_3 by HPLC (Fig. 3). As shown in Figure 3, the separation of these two IP_3 was satisfactory. I-1,3,4-P_3 accounted for 95.8 ± 2.7% of IP_3 in the control. On the other hand, after 3 wk of lithium administration, the proportion of I-1,3,4-P_3 in IP_3 was decreased to 69.6 ± 11.8%. Our experiments thus showed that the proportion of I-1,4,5-P_3 in IP_3 was increased from 4.2 to 30.4% of total IP_3 in the chronically lithium-administered rat brains, although the total quantity of IP_3 was not significantly altered (Fig. 4).

No significant amounts of IP_4 were detected in the normal or lithium-treated rat brains.

DISCUSSION

Lithium carbonate was given orally to rats, mimicking the route by which patients with affective disorders are treated. The dose of 100 mg/kg/d of lithium carbonate, amounting to 2.7 mEq/kg/d, was a little smaller than that used by other authors, such as Sherman *et al.* (5)

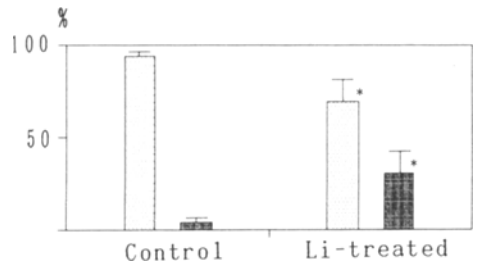

FIG. 4. The effect of lithium on the inositol triphosphate composition. Dotted bars: inositol 1,3,4-triphosphate (1,3,4-P_3); gray bars: inositol 1,4,5-triphosphate (1,4,5-P_3). I-1,3,4-P_3 and I-1,4,5-P_3 were fractionated on a Partisil SAX high-performance liquid chromatography column as described in Materials and Methods. Inositol phosphates were digested with alkaline phosphatase and analyzed by gas–liquid chromatography as described in Materials and Methods. Results are mean ± SEM from 24 rats. Statistical significance is indicated by *, $P < 0.01$ (Student's two sample *t*-test).

(3.6 mEq/kg/d). Nevertheless, the distribution and concentrations of lithium in the rat were in excellent agreement with the results of Sherman *et al.* (5). Further, our routine clinical experience suggested that this dose is sufficient for the effective long-term treatment of patients with affective disorders (19).

Initially, we measured the contents of phosphoinositides in the rat brains after 1 wk and 3 wk of lithium administration as compared with those of normal rats and found no significant differences in the quantities of PI, PIP and PIP_2. Previous studies on inositol phospholipid levels have yielded inconsistent results. Joseph *et al.* (17) estimated a decrease in PI from 3.8 to 2.9% in lithium-administered rat brain, while Honchar *et al.* (18) found no significant change. Although the turnover rates of PI, PIP and PIP_2 were not estimated, our data are in agreement with those of Honchar *et al.* (18). We intend to examine the metabolic rates of all inositol phospholipids as a next step for clarifying the lack of a decrease of PI, PIP and PIP_2.

When we estimated the quantities of IP, IP_2 and IP_3, we found that the quantity of IP rose about 1.7 times after 1 wk and about 2.4 times after 3 wk of lithium administration compared with the levels of normally fed rats. Renshaw *et al.* (20) and Honchar *et al.* (18) reported inconsistent results concerning the effect of lithium ions on IP phosphatase. Renshaw *et al.* (20) observed a doubling of IP phosphatase activity after 24 d of lithium administration to rats, while Honchar *et al.* (18) found no significant increase in this enzyme in rat cerebral cortex. This discrepancy is rather difficult to explain. However, our experiments clearly showed a remarkable accumulation of IP with chronic lithium administration (see Fig. 2).

Then we fractionated IP_3 by HPLC into I-1,3,4-P_3 and I-1,4,5-P_3. Meek (21) had reported that in normal rat brain, I-1,4,5-P_3 accounted for 80.5% of IP_3 after decapitation, but our results showed that 95.8% of IP_3 was I-1,3,4-P_3. In platelets (22,23) and in pancreatic islets (24), most of the IP_3 is present as I-1,3,4-P_3, which is in accordance with our result. Our key finding was that after 21 d of lithium administration, the proportion of I-1,4,5-P_3 in IP_3 had increased from 4.2 to 30.3%. This is a 7.2-fold increase when compared with controls (Fig. 4). This increase in the physiologically active neurotransducer, I-1,4,5-P_3, may play a key role in the therapeutic action of lithium in patients with affective disorders.

Our finding that long-term administration of lithium increased I-1,4,5-P_3 and decreased I-1,3,4-P_3, while the total amount of IP_3 was unchanged, may imply that lithium inhibits the conversion of I-1,4,5-P_3 to I-1,3,4-P_3. Accumulation of I-1,4,5-P_3 inside nerve cells causes the release of calcium ions from the endoplasmic reticulum of the cells into the inside of the axon terminals (4), which in turn causes the release of neurotransmitters contained in the synaptic vesicles of the nerve ending into the synaptic gaps (25,26). On the other hand, I-1,3,4-P_3 has a much weaker ability (*ca.* 1/30) to mobilize the calcium ions from intracellular stores than does I-1,4,5-P_3 (27). Worley *et al.* (28) demonstrated the presence of high-affinity selective binding sites for I-1,4,5-P_3 in rat brain at a level 100–300 times higher than in other tissues. Moreover, they found heterogeneous localizations of the I-1,4,5-P_3 receptor in rat brain, with particularly high concentrations of binding sites in the molecular layer of the cerebellum, prefrontal cortex, hippocampus and the superficial layers of the cerebral cortex. This could explain why lithium is so effective in treating depressive as well as manic disorders. The role of the cortex is commonly believed to be the integration of sensory input information and modulation of output signals along the pathways (29,30). The lower basal ganglia of the brain, which influence emotions when stimulated directly (31), require integrative control from the upper cortex (32). Affective disorders may be attributed to disorders derived from the cerebrum, especially the prefrontal cortex, leading to failure to control the basal ganglia adequately. An increased I-1,4,5-P_3 level might help to amplify the signals in a disordered patient to levels similar to those in normal individuals. Thus, disturbed neurons may recover normal functions.

ACKNOWLEDGMENT

The authors wish to express their sincere gratitude to Professor Michio Tbru of Neuropsychiatry, Tbkyo Medical and Dental University, for his invaluable advice and for reviewing the manuscript.

Characterization of the Diacylglycerol Acyltransferase Activity in the Membrane Fraction from a Fungus

Yasushi Kamisaka*, Toshihiro Yokochi, Toro Nakahara and **Osamu Suzuki**
Biological Chemistry Division, National Chemical Laboratory for Industry, Tsukuba, Ibaraki 305, Japan

In an attempt to clarify the mechanism of lipid accumulation in *Mortierella ramanniana* var. *angulispora*, diacylglycerol acyltransferase (DGAT) in the membrane fraction from this fungus was characterized. The enzyme had an optimum pH of 7.0–7.5, and enzyme activity was blocked by SH-reagents. Metal ions were not essential for maintaining DGAT activity. *n*-Octyl-β-D-glucoside, 3-[(3-cholamidopropyl)dimethylammonio]-1-propanesulfonate and Tween 80 were found to preserve activity, while Triton X-100 and sucrose monolaurate inhibited it. As the inhibition of DGAT activity by Triton X-100 was overcome by the addition of diacylglycerol (DG), the dependency of DGAT activity on exogenous DG was determined in the presence of 0.1% Triton X-100. DGAT activity in the membrane fraction was traced in fungi cultured for different time periods or in media at different carbon to nitrogen (C/N) ratios. Although the increase in total lipid content with culture time was accompanied by an increase in DGAT activity, total lipid changes related to changes in C/N ratio did not correlate with DGAT activity. Factors other than DGAT activity in the membrane fraction would appear to be involved in the regulation of total lipid content in this fungus.
Lipids 28, 583–587 (1993).

The enzyme, diacylglycerol acyltransferase (DGAT) catalyzes the final step in triacylglycerol (TG) biosynthesis. Although the enzyme activity has been studied in animal cells (1), higher plants (2,3) and in microorganisms (4), the physiological role of DGAT still remains unclear. One problem is to determine which enzyme is the rate-limiting step in TG synthesis, as DGAT (5–7) and phosphatidate phosphohydrolase (8–10) have been shown to play a rate-limiting role. Another problem is to show how DGAT contributes to the fatty acid composition of TG. Some reports have shown that DGAT has a broad acyl-donor specificity and that the fatty acid incorporated at *sn*-3 position is dependent on the fatty acid pool available to the enzyme (3,11). Other reports have shown that some fatty acids are preferentially incorporated into TG *via* DGAT in plants (12,13).

Mortierella genus has been found to have a high lipid content and to contain polyunsaturated fatty acids, such as γ-linolenic acid (14–16). γ-Linolenic acid production by the fungus is so efficient that it has become an industrial method (14). Previous studies have characterized the fatty acid incorporation into the lipids of *Mortierella* genus (17,18). It was shown that the fatty acids were effectively incorporated into TG of this fungus. Fatty acid incorporation into TG may be partly mediated *via* phospholipids, such as phosphatidylcholine, phosphatidylethanolamine and phosphatidylserine, as well as phosphatidic acid. DGAT is unique to TG biosynthesis; hence the properties of DGAT and the possible involvement of DGAT in the lipid accumulation in this fungus were examined.

Abbreviations: CHAPS, 3-[(3-cholamidopropyl)dimethylammonio]-1-propanesulfonate; C/N ratio, carbon to nitrogen ratio; DG, diacylglycerol; DGAT, diacylglycerol acyltransferase; EDTA, ethylenediaminetetraacetic acid; TG, triacylglycerol; TLC, thin-layer chromatography.

MATERIALS AND METHODS

Materials. [1-^{14}C]Oleoyl-CoA (58 mCi/mmol) was obtained from New England Nuclear Corporation (Boston, MA). Oleoyl-CoA was purchased from Sigma Chemical Co. (St. Louis, MO). Triton X-100 and Tween 80 were from Nacalai Tesque (Kyoto, Japan). *n*-Octyl-β-D-glucoside and 3-[(3-cholamidopropyl)dimethylammonio)-1-propanesulfonate (CHAPS) were from Dojin Pure Chemical Industries (Kumamoto, Japan). Sucrose monolaurate was obtained from Mitsubishi-Kasei Food Corp. (Tokyo, Japan). Silica gel G thin-layer chromatography (TLC) plates were obtained from Merck (Darmstadt, Germany). All other reagents were of analytical grade.

Microorganisms. Mortierella ramanniana var. *angulispora* (IFO 8187) was obtained from the culture collection of the Institute of Fermentation (Osaka, Japan). The fungi were maintained on a yeast-extract/malt-extract agar medium. The liquid medium was basically as described previously (15), *i.e.*, it contained 30 g glucose, 1.5 g $(NH_4)_2SO_4$, 3 g K_2HPO_4, 0.3 g $MgSO_4 \cdot 7H_2O$, 0.1 g NaCl, 5 g $CH_3COONa \cdot 3H_2O$, 10 mg $FeSO_4 \cdot 7H_2O$, 1.2 mg $CaCl_2 \cdot 2H_2O$, 0.2 mg $CuSO_4 \cdot 5H_2O$, 1.0 mg $ZnSO_4 \cdot 7H_2O$, 1.0 mg $MnCl_2 \cdot 4H_2O$, 2 mg thiamine-HCl and 0.02 mg biotin in 1 L of distilled water (pH 5.7). Cultures were grown in rotary shakers (180 rpm) at 30°C for specified periods. The carbon to nitrogen (C/N) molar ratio was 38. Different C/N ratios were attained by varying the amount of $(NH_4)_2SO_4$ added to the medium.

Preparation of membrane fractions. Fungal cells (100–300 mg dry cell weight) suspended in 20 mL of 10 mM phosphate buffer (pH 7.0) containing 0.25 M sucrose and 1 mM ethylenediaminetetraacetic acid (EDTA) were homogenized with a Braun Homogenizer (Melsungen, Germany) together with 20 mL of glass beads (0.45–0.50 mm diameters). The homogenates were centrifuged at 1500 × *g* for 5 min to remove cell debris and nuclei. The supernatant was centrifuged at 100,000 × *g* for 1 h. The pellet thus obtained was dissolved in 10 mM phosphate buffer (pH 7.0) containing 0.25 M sucrose, and again centrifuged at 100,000 × *g* for 1 h. The pellet was suspended in 10 mM phosphate buffer (pH 7.0) containing 0.25 M sucrose, and all suspensions were stored at −20°C until use. This membrane fraction served as the enzyme source.

DGAT assay. The assay mixture contained 10 mM phosphate buffer (pH 7.0), 150 mM KCl, 3.4 μM (0.2 μCi/mL) [1-^{14}C]oleoyl-CoA, 1 mM 1,2-diolein, 0.1% Triton X-100 and appropriate amounts of the membrane fraction in a final volume of 100 μL. In initial experiments, no 1,2-diolein or Triton X-100 was added to the reaction mixture. When necessary, 10 mM acetate buffer or 10 mM Tris buffer was used to adjust the pH of the assay mixture. The

reaction was carried out at 30°C for 5 min unless otherwise stated, and was stopped by the addition of 3 mL of chloroform/methanol (1:2, vol/vol). Lipids were extracted by the method of Bligh and Dyer (19) and separated by TLC on Silica gel 60 plates with benzene/diethyl ether/ethanol/NH_3 (50:40:2:0.5, by vol) as the first solvent, and hexane/diethyl ether (94:6, vol/vol) as the second solvent for developing the plates from the bottom up both times in the same direction (20). Radioactivity in TG was determined with a Beckman (Fullerton, CA) liquid scintillation system (model LS1701) with automatic quenching correction.

Other methods. Dry cell and total lipid content were measured and expressed in weight units as described previously (15). Protein was measured by the method of Bradford (21). The amount of each lipid class was determined from its fatty acid content measured by gas-liquid chromatography using heptadecanoic acid methyl esters as internal standards (17).

RESULTS AND DISCUSSION

In the present study we characterized DGAT activity in membrane fractions of *Mortierella ramanniana* var. *angulispora*. Although DGAT has been extensively studied in mammalian and plant cells, information on DGAT in fungi is quite limited.

The time course of radioactive TG formation from exogenous [1-^{14}C]oleoyl-CoA was measured in the membrane fraction (Fig. 1). The TG formation was linear for 5 min when using at least 20 μg protein. Figure 1 also shows that TG formation is dependent on the amount of protein at a fixed time of 5 min. The optimum pH for the DGAT activity was 7.0–7.5, this being essentially the same as the optimum pH range previously reported (2,22,23). The effect of oleoyl-CoA concentration on the incorporation of oleate from [1-^{14}C]oleoyl-CoA into TG is shown in Figure 2. Substrate saturation was reached at about 200 μM.

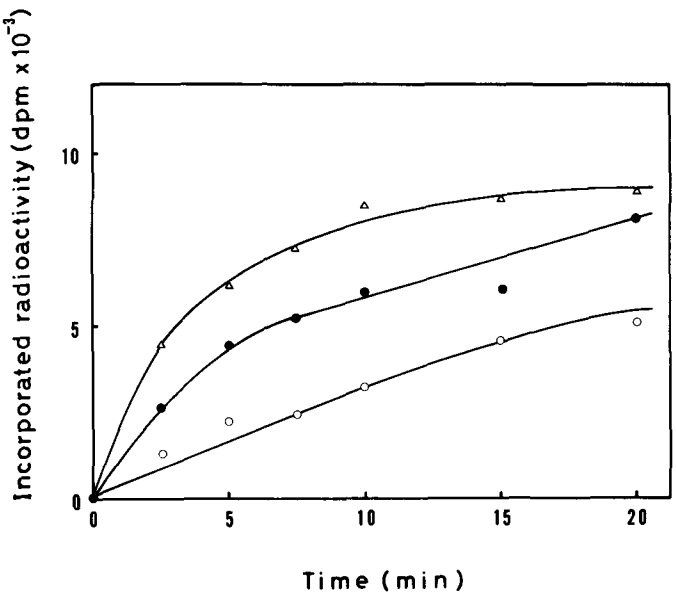

FIG. 1. Time course of the incorporation of oleate from [1-^{14}C]-oleoyl-CoA into triacylglycerol by a membrane fraction obtained from fungal cells cultured for 5 d. Membrane fractions containing 10 μg protein (○), 20 μg protein (●) or 40 μg protein (△) were incubated with [1-^{14}C]oleoyl-CoA for the time periods indicated. The assay mixture did not contain exogenous diacylglycerol or Triton X-100, as described in Materials and Methods. Data are presented as means of duplicates.

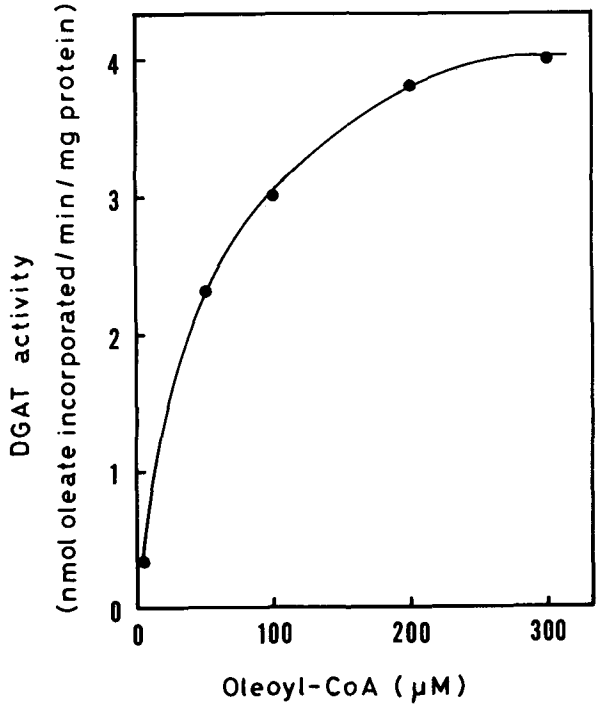

FIG. 2. Effect of oleoyl-CoA concentration on the incorporation of oleate from [1-^{14}C]oleoyl-CoA into triacylglycerol. Diacylglycerol acyltransferase (DGAT) activity was assayed using the membrane fraction (20 μg protein) which was obtained from fungal cells cultured for 5 d. The assay mixture did not contain exogenous diacylglycerol or Triton X-100 as described in Materials and Methods. Data are presented as means of duplicates.

The effects of reagents on DGAT activity are shown in Table 1. There was neither stimulation of DGAT activity by Mg^{2+} nor inhibition by EDTA. DGAT activity decreased by about one-half by the addition of SH-reagents, as previously described (24,25). Trifluoperazine, which caused a decrease in [1-^{14}C]fatty acid incorporation into TG in the intact fungal cells (18), did not change the

TABLE 1

Effect of Additives on Diacylglycerol Acyltransferase (DGAT) Activity in the Membrane Fraction from *Mortierella ramanniana* var. *angulispora*

Additives	DGAT activity[a] (% of control)
Mg^{2+} (5 mM)	104
EDTA (5 mM)	93
N-Ethylmaleimide (1 mM)	66
Dithiothreitol (1 mM)	45
Ethanol (2%)	102
Trifluoperazine (0.5 mM) in 2% ethanol	98

[a]The membrane fraction (20 μg protein) obtained from fungal cells cultured for 5 d was incubated for 5 min with [1-^{14}C]oleoyl-CoA without addition of exogenous diacylglycerol or Triton X-100. EDTA, ethylenediaminetetraacetic acid.

TABLE 2

Effect of Detergents on DGAT Activity in the Membrane Fraction from *Mortierella ramanniana* var. angulispora

Detergents		DGAT activity[a] (% of control)
n-Octylglucoside	(0.1%)	117
	(0.2%)	96
CHAPS	(0.05%)	128
	(0.1%)	72
Tween 80	(0.05%)	87
	(0.1%)	91
Triton X-100	(0.05%)	25
	(0.1%)	28
Sucrose monolaurate	(0.05%)	15
	(0.1%)	10

[a]The membrane fraction (20 μg protein) obtained from fungal cells cultured for 5 d was incubated for 5 min with [1-^{14}C]oleoyl-CoA without addition of exogenous diacylglycerol or Triton X-100. DGAT, diacylglycerol acyltransferase; CHAPS, 3-[(3-cholamidopropyl)dimethylammonion]-1-propanesulfonate.

activity. This is consistent with the interpretation that phospholipid acylation, rather than diacylglycerol (DG) acylation, is affected by trifluoperazine, which eventually leads to inhibition of TG biosynthesis.

While searching for a suitable detergent for solubilizing the enzyme, the effects of various detergents on DGAT activity were tested (Table 2). *n*-Octyl-β-D-glucoside, CHAPS and Tween 80 did not inhibit DGAT activity, whereas Triton X-100 and sucrose monolaurate greatly inhibited this activity. Inhibition of DGAT activity by Triton X-100 has been reported for preparations from higher plants (2,3). DGAT activity from rat liver has been solubilized with Triton X-100 (26) and DGAT from soybean cotyledons with CHAPS (27).

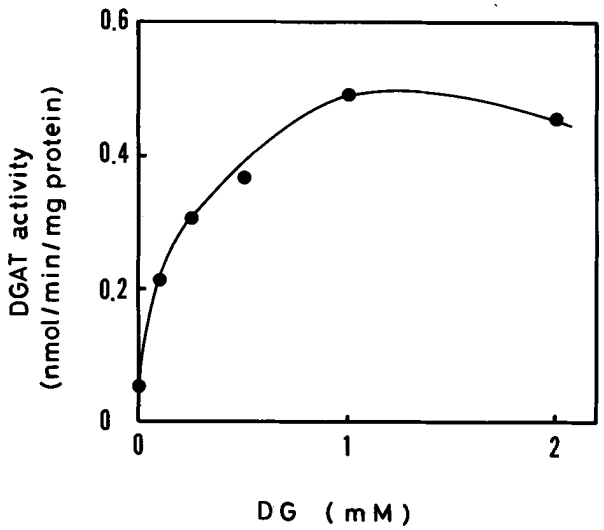

FIG. 3. Diacylglycerol (DG) dependency of DG acyltransferase (DGAT) activity in the presence of 0.1% Triton X-100. DGAT activity was assayed using a membrane fraction (20 μg protein) which was obtained from fungal cells cultured for 5 d. The assay was done in the presence of 0.1% Triton X-100 with increasing concentrations of exogenous 1,2-diolein as described in Materials and Methods. Data are presented as means of duplicates.

In the DGAT assay systems used, DGAT activity could not be shown to be dependent on exogenously added 1,2-diolein, possibly because exogenous DG had no access to the enzyme. This interpretation is consistent with the results of other studies in which it was difficult to show that exogenous DG was a substrate of the enzyme (2,24). Neither could DG dependency of the enzyme activity be demonstrated when DG was administered as ethanol solution. However, DG dependency of DGAT could be demonstrated in the presence of detergents (28).

As is evident from Table 2, Triton X-100 and sucrose monolaurate inhibited DGAT activity. To determine whether exogenous DG could overcome the inhibition of DGAT by Triton X-100, DGAT activity was measured at various concentrations of 1,2-diolein in the presence of 0.1% Triton X-100 (Fig. 3). Figure 3 shows that DGAT

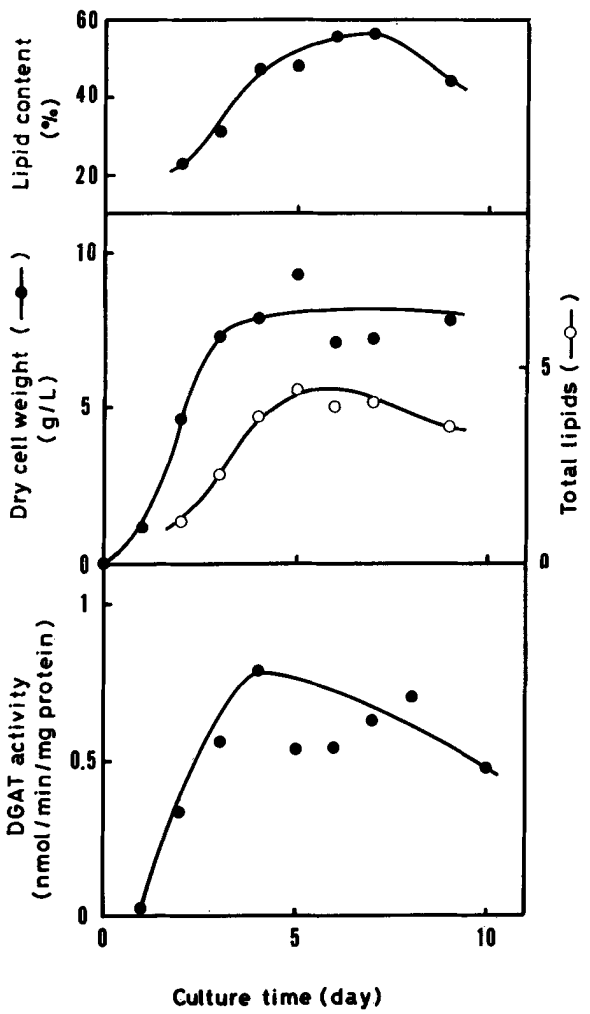

FIG. 4. Diacylglycerol acyltransferase (DGAT) activity in the membrane fraction and lipid accumulation during culture. DGAT activity shown in the lower panel was assayed for 5 min in the presence of 0.1% Triton X-100, 1 mM 1,2-diolein and 3.4 μM (0.2 μCi/mL) [1-^{14}C]oleoyl-CoA using a membrane fraction (20 μg protein) obtained from fungal cells cultured for the time periods indicated (means of duplicates). Triacylglycerol formation was linear for 5 min in all the assays. Dry cell weights (●) and total lipids (○) from fungal cells cultured for the indicated time periods are shown in the center panel (means of duplicates). Lipid content (total lipids/dry cell weight) is shown in the upper panel (means of duplicates).

activity increased with the amount of exogenous DG added and reached a plateau at 1 mM 1,2-diolein. This could be interpreted to mean that Triton X-100 disperses both endogenous and exogenous DG and makes them accessible as substrates. To improve the DGAT assay so that DGAT activity would not be dependent on the amount of endogenous DG in the membrane fraction, 0.1% Triton X-100 and 1 mM 1,2-diolein were therefore included in the assay system.

The effect of culture time on DGAT activity is shown in Figure 4. Fungal cells proliferated throughout the incubation period of 5 d. Lipid synthesis followed with a slight delay. The lipid content measured as total lipids/dry cell weight was highest in the early stationary growth phase, as is typical for lipid accumulation in oleaginous fungi (29). Lipid accumulation, which is associated with increased conversion of carbon substrate into lipids, may be partly due to the depletion of nitrogen in the media (29). Figure 4 shows that DGAT activity increased with culture time, which was accompanied by an increase in total lipid content, which peaked at day 4. The increase in total lipid content was primarily due to TG formation (Table 3), suggesting that DGAT activity could be related to the amount of TG produced. DGAT activity in the soluble fraction (supernatant of 100,000 × *g* centrifugation) on day 5 was 8.4% of the DGAT activity in the membrane fraction on day 5, indicating that membrane-bound DGAT activity was essential to TG formation in this fungus.

To shed light on the possible relationship between DGAT activity and lipid accumulation, DGAT activity under modified culture conditions that could affect lipid accumulation was also followed. When the C/N ratio of the culture medium was increased, which is known to affect lipid accumulation (29–31), it also resulted in lipid accumulation in our system (Fig. 5). The increase in C/N ratio in the medium also changed DGAT activity. However, the pattern of changes in lipid content did not necessarily correlate with DGAT activity, indicating that the relationship is not necessarily direct, but seems more complex.

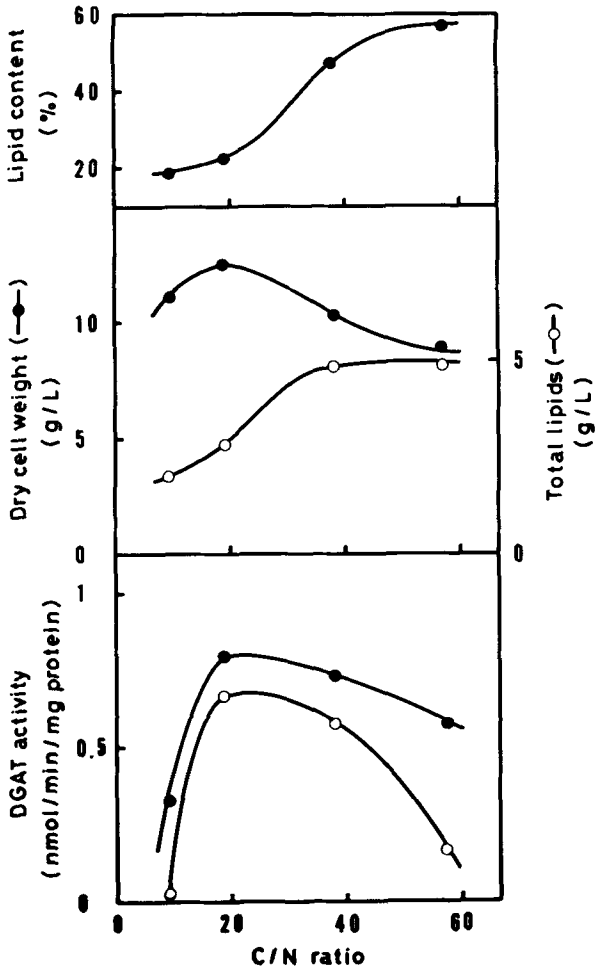

FIG. 5. Effect of carbon to nitrogen (C/N) ratio on diacylglycerol acyltransferase (DGAT) activity in the membrane fraction and on lipid accumulation. DGAT activity shown in the lower panel was assayed for 5 min in the presence of 0.1% Triton X-100, 1 mM 1,2-diolein and 3.4 μM (0.2 μCi/mL) [1-^{14}C]oleoyl-CoA using a membrane fraction (20 μg protein) obtained from fungal cells cultured for 4 d (●) or 5 d (○) at the indicated C/N ratios (means of duplicates). Triacylglycerol formation was linear for 5 min in all the assays. Dry cell weight (●) and total lipids (○) from fungal cells cultured for 5 d at the indicated C/N ratio are shown in the center panel (means of duplicates). Lipid content (total lipids/dry cell weight) is shown in the upper panel (means of duplicates).

TABLE 3

Changes in Lipid Class Distribution as Function of Culture Time in *Mortierella ramanniana* var. *angulispora*

Lipids[b]	Amount of each lipid class[a] (μmol/g dry cell weight)		
	1 Day	5 Days	8 Days
TG	83.7 (55.6%)	330.3 (82.8%)	344.6 (82.2%)
DG	5.7 (3.8%)	30.6 (7.7%)	31.2 (7.4%)
SE	8.1 (5.3%)	7.1 (1.8%)	13.0 (3.1%)

PI	2.2 (1.5%)	2.4 (0.6%)	2.8 (0.7%)
GL[c]	10.1 (6.7%)	6.9 (1.7%)	6.9 (1.6%)
Total	150.8	399.0	419.7

[a]Values for 1 d and 8 d were calculated from data previously reported by us (Ref. 18). Values are expressed as means of triplicates.
[b]TG, triacylglycerol; DG, diacylglycerol; SE, steryl ester; FFA, free fatty acid; PC, phosphatidylcholine; PE, phosphatidylethanolamine; PS, phosphatidylserine; PI, phosphatidylinositol; GL, glycolipids. Free sterol was also detected in the fungal lipids.
[c]The GL fraction was composed of a major unidentified GL and several minor fractions. The amount of GL was calculated on the assumption that GL had one fatty acid moiety.

In the present study, a crude membrane fraction served as the enzyme source. The amount of lipid in the membrane fraction was 1.5 ± 0.5 mg lipids/mg protein (n = 3). TG and DG amounted to about 70 and 7% of total lipids, respectively, as estimated by TLC densitometry (32). Taken together, it appears that DGAT activity in the membrane fraction does not directly correlate with accumulation of TG in the fungus. How DGAT activity is regulated by membranes rich in neutral lipids will still need to be determined.

Lipid Biosynthesis in Cultured Arterial Smooth Muscle Cells Is Related to Their Phenotype

Eric Dusserre, Marie-Claude Bourdillon*, Maryvonne Ciavatti, Chantal Covacho and **Serge Renaud**
National Institute of Health and Medical Research, INSERM U63, Nutrition and Vascular Pathophysiology Unit, F-69675 Bron-Lyon, France

During the atherogenic process *in vivo*, arterial smooth muscle cells (SMC) undergo changes in their phenotype. In the present study, rat SMC from primary cultures and from subcultures before 10 and after 200 passages, showing contractile-like, synthetic and transformed phenotypes, respectively, were compared in regard to their lipid content and biosynthesis. The rationale for comparing these phenotypes rests in the similar changes in phenotype of SMC that occur in the formation and progression of atherosclerotic lesions. Phenotype changes were shown to be associated with changes in the phospholipid content of SMC. Phospholipid levels increased, but not as significantly as did cholesterol levels when passing from contractile to synthetic and transformed cells (1.23 ± 0.18, 2.28 ± 0.26 and 3.25 ± 0.23 $\mu g/10^6$ cells, respectively). Cholesterol normalized in respect to cell protein was increased to the same extent. Lipid synthesis as judged by [^{14}C]acetate incorporation was increased 3- to 12-fold in the synthetic and transformed cells, respectively, compared to contractile cells. After thin-layer chromatography, radioactivity was shown to be markedly increased in most of the lipid fractions, but label in the cholesterol fraction of synthetic and transformed cells was increased by 7- and 21-fold, respectively. Thus, SMC *in vitro* were shown to drastically increase cholesterol biosynthesis associated with phenotype changes. Such changes are known to occur *in vivo* and might represent a critical step in the deposition of excess cholesterol within foam cells.
***Lipids* 28, 589-592 (1993).**

Arterial smooth muscle cells (SMC) play a key role in atherogenesis (1-4). During the initial stages of the process, SMC migrate into the intima, proliferate and produce abundant extracellular matrix components (5,6). Later on, SMC are transformed into foam cells by accumulating lipids. These processes are conditioned by the change in the SMC phenotypic state (7,8). The adult contractile phenotype "dedifferentiates" into a synthetic phenotype expressed in both atherogenic and remodeling processes. Conversely, during the normal organogenesis, the fetal "primary" synthetic SMC differentiate into a contractile state in adult artery (9). Arterial SMC *in vitro* undergo similar changes from the contractile-like to the synthetic state, which is characterized by changes in cytoskeletal and cytoenzymatic features (5,7,10).

Because an important characteristic of the foam cell transformation *in vivo* is the accumulation of cholesterol, it seems of interest to determine whether the *in vitro* transformed SMC would exhibit similar characteristics. The lipid metabolism of cultured SMC has previously been reported to be related to regulating factors, such as atherogenic lipoproteins (11,12), eicosanoids (13) or tumor necrosis factor (14). Only a few studies have correlated SMC in the contractile or synthetic state with changes in lipid metabolism (11,13). Rat aortic SMC have been shown to generate a transformed phenotype which expresses tumorigenic potential as well as some similarities with rapidly proliferating cells (15). This transformed cell model is remarkable in the light of the transforming elements detected in arteriosclerotic plaques (16), and accounts for Benditt's atherogenic monoclonal hypothesis (17).

The aim of the present study was to compare the phospholipid and cholesterol contents and lipid biosynthesis in "contractile-like," "synthetic" and "transformed" SMC phenotypes in culture.

MATERIALS AND METHODS

General. [U-^{14}C]Acetic acid, sodium salt (95mCi/mmol) was purchased from the Commissariat à l'Energie Atomique (Saclay, France). Minimum essential medium (MEM) with Earle's salts, antibiotics and L-glutamine were obtained from BioMèrieux (Marcy l'Etoile, France). Calf serum and trypsin were from GIBCO (Life Technologies Ltd., Paisley, Scotland). Silica gel plates (G60, 20 × 20 cm) were obtained from Merck (Darmstadt, Germany). Radioactivity was scanned with an Intertechnique liquid scintillation scanner, model SL 3000 (Kontron, St. Quentin Yvelines, France). Cells were counted in a Coulter counter (ZBI Coulter, Coultronics, Margency, France). Protein content was measured according to Lowry *et al.* (18).

Cell culture. Aortic SMC were obtained from 6- to 10-week-old rats (19). Thoracic aorta was dissected and SMC dispersed into single cells by collagenase (2 mg/mL, CLSI from Worthington Biochemical Corp., Freehold, NJ) and elastase (0.4 mg/mL, type III from Biosys, Compiègne, France). Cells were seeded in Petri dishes (35 mm) or 6-well plates ($3-5 \times 10^4$ cells/cm^2). Cells were grown in MEM medium supplemented with 10% newborn calf serum, penicillin/streptomycin (100 units/mL and 50 μg/mL, respectively) and glutamine (2 mM). Medium was renewed three times a week. Secondary cultures were initiated after either low or high passages using trypsin (0.08%).

SMC *in vitro* showed numerous morphological and functional changes characteristic of the modulation from the contractile to the synthetic phenotype. Cells in primary culture (Fig. 1A) exhibited "contractile-like" properties. Thus, they were considered as the contractile SMC model of normal adult aorta. Subcultured vascular SMC from the second to the seventh passage (Fig. 1B) displayed the same "synthetic state" as SMC from the diffuse intimal thickening or the embryonic aorta (9,10). They retained several important features of vascular SMC *in situ, i.e.,* a well-developed microfilament system, vimentin-type intermediate filaments, desmin and α-actin cytoskeletal markers. In the present study, synthetic state cells at 5-10 passages were used. The third SMC model described as "transformed phenotype" was obtained from two

Abbreviations: 1,2-DG, 1,2-diacylglycerols; 1,3-DG, 1,3-diacylglycerols; FFA, free fatty acids; HMG-CoA, 3-hydroxy-3-methyl glutaryl coenzyme A; MEM, minimum essential medium; PDGF, platelet-derived growth factor; SMC, smooth muscle cells; TG, triacylglycerols.

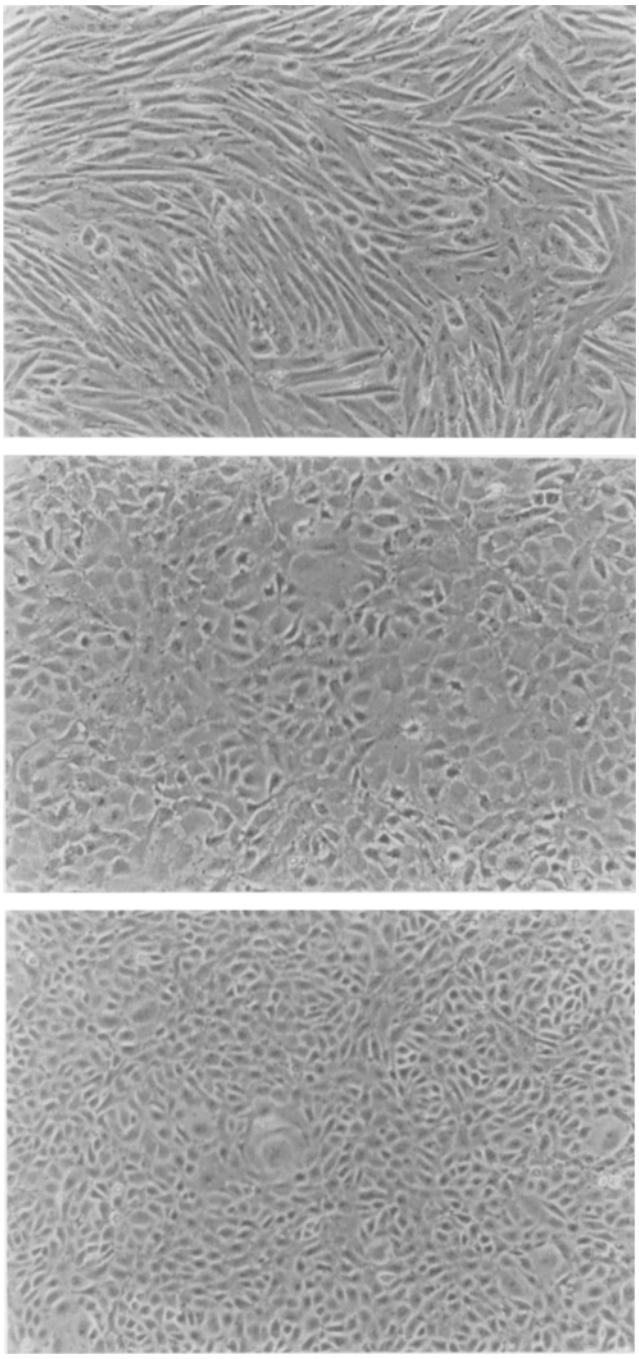

FIG. 1. Phase-contrast micrographs of the three cell phenotypes, exhibiting mono- and multi-layered areas ("hill and valley pattern"), typical of arterial smooth muscle cell growth (Refs. 1,15). At confluency, the elongated "contractile-like" cells in primary cultures (A) are clearly distinct from the spreaded "synthetic" cells of secondary cultures (Passage 6, B) and packed "transformed" cells displaying scattered giant cells (Passage 215, C). Magnification, ×229.6.

established cell lines originating from high-passaged rat aortic SMC (Fig. 1C). In addition to their synthetic features, these two cell lines exhibit immortalized and tumorigenic properties (15). The cells presently used were over 200 passages old.

Cholesterol and phospholipid analysis. Cells were sampled in the confluent state, after trypsinization and cell counting. The cell numbers in contractile, synthetic and transformed cells were 175 ± 11, 170 ± 19 and $257 \pm 16 \times 10^3$ cells/cm^2, respectively. Lipids were extracted according to a modification of the Folch *et al.* (20) method: 1 mL of the cell suspension was added to 25 mL of dichloromethane/methanol (2:1, vol/vol) and 5 mL of NaCl. After decantation, the organic phase was evaporated. Total phospholipids were assayed by the colorimetric method according to Stewart (21). Free cholesterol was assayed using the Omodeo-Sale *et al.* (22) method.

Cholesterol biosynthesis. At confluence, SMC cultures from the three different phenotypes were labeled during 60 min with [U^{14}C]acetic acid (2 μCi/mL) in MEM + 10% newborn calf serum. Lipids were extracted by the modified Folch method and analyzed. The radioactivity of the total lipid fraction was measured on a sample of the lipid extract (20 μL), which was added to 8 mL of scintillating mixture composed of 4 g of diphenyloxazole (J.T. Baker Chemicals, Deventer, Holland), 0.2 g of 1,4 di(2-(5phenyloxazolyl)benzene) (Koch Light Laboratories Ltd., Colnbrook, Bucks, England) and toluene (1000 mL).

The different lipid fractions were separated according to Kunz (23) by one-step one-dimensional thin-layer chromatography using silica gel plates. After development, the plates were air-dried and the lipid fractions were stained with I_2. Radiolabelled fractions were detected by autoradiography (Film Kodak, XRay, Eastman Kodak Co., Rochester, NY). Silica gel bands were scraped off and radioactivity was quantitated by liquid scintillation counting.

Statistical analysis. The significance of differences between the SMC phenotypes were computed using the unpaired Student's *t*-test. Results are presented as means ± SEM.

RESULTS

The different phenotypes (contractile-like, synthetic and transformed cells) exhibited three distinct morphological patterns (Fig. 1). In contractile cells, the protein mass seemed mainly associated with the myofilament compartment (Fig. 1A), whereas there were large amounts of rough endoplasmic reticulum in synthetic and transformed cells (Fig. 1B and 1C). The cholesterol content of contractile-like SMC was extremely low (1.23 ± 0.18 μg/10^6 cells). It increased approximately two- to threefold in synthetic and transformed cells, respectively (Fig. 2). The contractile-like cells were richer in phospholipids (8.0 ± 0.5 μg/10^6 cells, Fig. 2) than in cholesterol. The phospholipid content was moderately increased to 10.1 ± 0.9 and 13.2 ± 1.7 μg/10^6 cells in synthetic and transformed cells, respectively (Fig. 2). This increase was significant only in transformed SMC ($P < 0.05$). The protein content of contractile, synthetic and transformed cells was 53 ± 3.7, 58.7 ± 7.5 and 55 ± 3.8 μg/10^6 cells, respectively ($n = 6$). When cholesterol was normalized in respect to the cell protein content, the cholesterol/protein ratio was increased 1.7-fold in synthetic and 2.6-fold in transformed cells, *vs.* 1.8- and 2.7-fold, when normalized in respect to cell number as shown in Figure 2.

Lipid synthesis followed by [^{14}C]acetic acid incorporation into total lipids was particularly low (2236 ± 362

FIG. 2. Values are means ± SEM. Significance: $P < 0.05$ (*); $P < 0.01$ (**); $P < 0.001$ (***). NS, not significant.

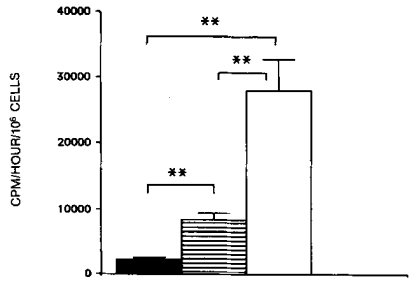

FIG. 3. [^{14}C]Acetic acid incorporation into the total lipids of contractile-like (full bars, n = 5), synthetic (hatched bars, n = 11) and transformed (open bars, n = 12) smooth muscle cell phenotypes in culture. Values are means ± SEM. Significance: $P < 0.01$ (**).

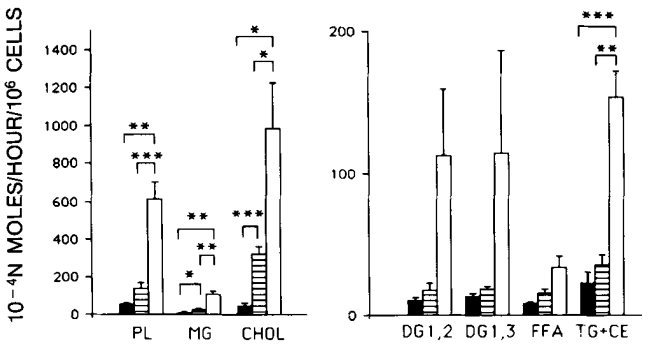

FIG. 4. [^{14}C]Acetic acid incorporation into different lipid fractions of contractile-like (full bars, n = 5), synthetic (hatched bars, n = 11) and transformed (open bars, n = 12) smooth muscle cell phenotypes in culture. PL, phospholipids; MG, monoacylglycerols; CHOL, cholesterol; DG 1,2, 1,2-diacylglycerols; DG 1,3, 1,3-diacylglycerols; FFA, free fatty acids; TG + CE, triacylglycerols + cholesteryl esters. Values are means ± SEM. Significance: $P < 0.05$ (*); $P < 0.01$ (**); $P < 0.001$ (***).

cpm/h/10^6 cells) in slowly proliferating contractile-like SMC (Fig. 3). Total lipid synthesis was increased threefold in the synthetic SMC ($P < 0.01$) and twelvefold in the transformed cells ($P < 0.01$). Lipid synthesis associated with various lipid fractions, namely mono- and diacylglycerols, phospholipids, fatty acids, free and esterified cholesterol (+ triacylglycerols), was low in contractile-like cells, but was much greater in actively proliferating modulated SMC (Fig. 4). In transformed cells, the biosynthesis was increased 12-fold for phospholipids ($P < 0.01$), 21-fold for free cholesterol ($P < 0.05$) and 7-fold for cholesteryl esters and triacylglycerols ($P < 0.001$). In synthetic SMC, [^{14}C]acetate incorporation was enhanced 7-fold in the free cholesterol fraction. In the present experiments, [^{14}C]-acetate incorporation predominantly occurred into the free cholesterol fraction, which reached 25.4% (±6.6) in contractile-like cells, but 51.7% (±3.4) and 42.6% (±3.5) in synthetic and transformed cells, respectively.

DISCUSSION

The present study clearly indicates that cultured SMC of different phenotypes, namely contractile, synthetic and transformed, exhibit marked differences in their lipid content, especially cholesterol, apparently owing to a large increase in lipid biosynthesis. Of interest is that an *in vivo* phenotype modification of SMC in arteries, similar to that observed here in rat aortic cultures after numerous passages, seems to be one of the primary events in atherogenesis (1-3,5,7). A spontaneous change in cell phenotypes was also observed in long-term culture SMC lines originating from bovine carotid artery (24). Of additional interest is that in SMC in atherosclerotic plaques, it is also cholesterol and cholesteryl esters that primarily accumulate (25), rather than phospholipids. Therefore, it would seem that the accumulation of cholesterol shown in SMC, without increased levels of cholesterol in its environment, could result from the proliferation and transformation of these cells, at least as concluded from the present *in vitro* experiments on rat aortic SMC.

To date, very few studies have examined the consequences of *in vitro* SMC dedifferentiation on cellular lipid metabolism (11-13). The present findings in rat confirm the previous work of Tabacik *et al.* (26) in SMC from rabbits that indicated that cholesterol biosynthesis was markedly increased in synthetic cells compared to contractile cells. Nevertheless, near the end of the culture life, *i.e.*, at 16 passages, the authors observed a drastic decrease in cholesterol production that was not noted under our conditions. This could be explained either by the fact that we used cells before 10 or after 200 passages, but not at 16 passages, or that we used cell numbers as the quantitative reference instead of protein mass (26). Cellular and matrix proteins are known to be increased with increasing passages (4,8). For these reasons, as did Campbell *et al.* (11), the results have been expressed on the basis of cell number rather than cell protein, because of the marked changes that occur in the type of cellular organelles with changes in the SMC phenotype. Nevertheless, when cells passed from the contractile to the synthetic and the transformed states, normalization of cholesterol in respect to either cell protein or cell count showed a similar increase (1.7 and 2.6, *vs.* 1.8 and 2.7, respectively).

We noted a low turnover of triacylglycerols (TG) in contractile cells, as was observed in myotubes during myogenic differentiation, contrasting with a large store of TG in myoblasts (27). Thus, in spite of their different structure and function, synthetic SMC and mononucleate myoblasts seem to share enhanced neutral lipid accumulation. The diacylglycerol (DG) turnover was greater than that of TG in the synthetic and transformed phenotypes.

This could be explained by a stimulation of the phosphoinositol cycle under our culture conditions. This would be in accordance with the known activation of inositol triphosphate, DG and protein Kinase C, in response to platelet-derived growth factor (PDGF) (28). PDGF is expressed during the SMC phenotype changes and could be self-amplified in an autocrine way (1,5), particularly in the rapidly replicating SMC (4) and in the transformed cells (15).

A question that can be raised is whether the transformed SMC used in our studies have any relevance to the atherogenic SMC in human arteries. In this context, it has been postulated that only a small group of cells with proliferative properties enters into the formation of an atherosclerotic plaque (17). It seems that these selected cells, known to transform readily into foam cells, could have, in regard to cholesterol biosynthesis, properties similar to those of the transformed cells used in the present study, namely a huge increase in cholesterol biosynthesis. However, under our present experimental conditions, almost solely free cholesterol accumulated in the cultured SMC. By contrast, in atherosclerotic plaques, both free and esterified cholesterol can be found (25). However, it can be postulated that the formation of cholesterol esters depends on the environment, namely the supply of fatty acid and particularly oleate, as shown by previous investigators (12,29,30).

As to the mechanisms involved in the increased cholesterol biosynthesis, these may be related to several different processes. One of them may be increased cell proliferation. Both enhanced [^{3}H]thymidine incorporation and cholesterol levels have been observed in cultured aortic SMC from human atherosclerotic lesions (31), suggesting a close relationship between intracellular lipid accumulation and cell proliferation. In addition, it seems that it is mainly cholesterol biosynthesis that is associated with cell proliferation, since specific inhibitors of cholesterol synthesis reduce cellular proliferative activity (32). HMG-CoA reductase is known to be one of the first dysregulated enzyme in neoplasic proliferating cells. Another possibility is that the increase in the lipid mass of plasma membranes might be related to changes in size and shape of cultured cells (Fig. 1A, B, C). Moreover, cholesterol plays a role in the regulation of ionic pumps and the maintenance of enzymatic functional capacities (33). It has been shown that hydrolase enzymatic activities, such as acid phosphatase and esterase, are more expressed in proliferative SMC (10); cholesterol enrichment might influence this regulation. Finally, cholesterol accumulation in cells *in vitro* could depend on enhanced secretory activities of modulated SMC. Synthetic (5,8) and transformed (15) cells are known to show extensive intracellular membrane-rich endoplasmic reticula.

In conclusion, the results of the present study show that dedifferentiation in cultured arterial SMC, which is characterized by enhanced proliferative capacity, is associated with marked increases in cholesterol biosynthesis and cholesterol accumulation. As it is known that such modulated cells have an increased capacity to metabolize low-density lipoproteins and, particularly, very low density lipoproteins (11), the process could constitute one of the early events in the transformation of SMC into foam cells.

Previous studies have shown that alterations in micronutrient utilization occur in patients with Acquired Immune Deficiency Syndrome. In this study, total plasma fatty acid composition was measured in 36 homosexual men infected with the Human Immunodeficiency Virus 1 (HIV-1) and in 17 HIV-1 seronegative homosexual men in order to evaluate differences associated with early HIV-1 infection. Immunologic assessment included CD4 cell number count and lymphocyte blastogenesis in response to the mitogens phytohemagglutinin (PHA) and pokeweed (PWM). The mean total amount of ω6 polyunsaturated fatty acids (18:2 and 20:4) was significantly lower in the HIV-1 seropositive subjects (38 ± 8.1% SD) as compared to HIV-1 seronegative subjects (43 ± 4.2%; $P = 0.0027$). This was also reflected in a higher level of total saturated fatty acids (16:0 and 18:0) in HIV-1 seropositive subjects (30 ± 2.2% *vs.* 26 ± 2.8%; $P = 0.0001$). The ratio of linoleic to arachidonic acid (18:2 to 20:4) was higher in the HIV-1 seropositive group (6.76 ± 4.88) compared to the HIV-1 seronegative group (4.86 ± 1.37; $P = 0.0213$). The response to PHA in seropositive subjects correlated inversely with total plasma ω6 fatty acids ($r = -0.36$; $P = 0.027$), and directly with the 18:2 to 20:4 ratio ($r = 0.33$; $P = 0.046$). CD4 cell counts and the response to PWM did not correlate with plasma fatty acid levels in HIV-1 seropositive subjects. We conclude that early HIV-1 infection is associated with lower plasma ω6 polyunsaturated fatty acids, notably arachidonic acid, than are controls, and that the changes in the plasma fatty acid profile correlate with some indices of immune function. ***Lipids 28,*** **593–597 (1993).**

The clinical course of infection with the Human Immunodeficiency Virus 1 (HIV-1) varies, but its manifestations include many symptoms or signs that may affect food intake and/or nutritional status (1). In addition, energy requirements may be increased by infectious processes. Oral intake may be adversely affected by mucosal lesions, and absorption may be limited by intestinal infections and other lesions which may lead to diarrhea and malabsorption. Drug treatments may interfere with nutrient absorption and/or metabolism. As a result, many patients with HIV-1 infection suffer from weight loss, various forms of undernutrition and, eventually, severe metabolic wasting. Indeed, many patients appear to die from the consequences of progressive wasting rather than from the viral infection itself.

Regarding studies in subjects with Acquired Immune Deficiency Syndrome (AIDS), there is limited evidence to indicate an association between lipid alteration and disease manifestations of this syndrome. Patients with AIDS exhibit lower total plasma lipid levels and lower levels of individual fatty acids along with higher proportions of the metabolites of arachidonic acid (22:4ω6 and 22:5ω6) (2). While dramatic nutritional consequences are most apparent in the later stages of HIV-1 infection, relatively little is known regarding the nutritional changes that occur during earlier stages of HIV-1 infection. Our research group has recently documented multiple nutritional abnormalities, in association with immune dysfunction, in early HIV-1 infection (3–5). Investigation of the nutritional aspects of HIV-1 infection has been oriented largely toward the clinically advanced stages of HIV-1 infection (that is, AIDS). Clinical nutrition intervention strategies oriented toward earlier stages of the disease might be utilized to delay disease progression. Moreover, they may allow for optimal use of anti-viral chemotherapy, such as zidovudine, dideoxycytidine and soluble CD4.

In this report, a comparison of total plasma fatty acid profiles between HIV-1 seronegative and HIV-1 seropositive asymptomatic homosexual men is documented in order to establish whether changes in plasma fatty acid profiles occur in asymptomatic HIV-1 infection and, if so, whether any of these changes are associated with immune processes.

MATERIALS AND METHODS

Subjects. Subjects recruited for the present investigation were 36 male homosexuals aged a mean of 30.8 years (range 23–45 yr) who were documented to be HIV-1 seropositive (confirmed by Western Blot technique), but who were asymptomatic other than for persistent generalized lymphadenopathy (CDC Stage III) (6,7).

No subject admitted to other risk factors for HIV-1 infection (for example, intravenous drug abuse). All 36 subjects were free of significant past medical history that might influence nutritional status (for example, diabetes mellitus, inflammatory bowel disease) and were not taking any medications known to interfere with nutritional status (for example, isoniazid or cycloserine). Moreover, no subject was or had been involved in any anti-viral chemotherapy protocol (for example, zidovudine, ribavirin, interferon).

The control subjects (n = 17) in the first population were 17 homosexual males aged a mean of 37.7 yr (range 25–64 yr) and were documented to be HIV-1 seronegative. Other than the HIV-1 seronegativity and lack of evidence for persistent generalized lymphadenopathy, this group of controls was matched to the HIV-1 seropositive study subjects. They were of similar age, socio-economic and

Abbreviations: AIDS, Acquired Immune Deficiency Syndrome; ARC, AIDS-related complex; cpm, counts per minute; FAME, fatty acid methyl esters; HIV-1, Human Immunodeficiency Virus 1; NK, natural killer; PBS, phosphate-buffered saline; PHA, phytohemagglutinin; PUFA, polyunsaturated fatty acids; PWM, pokeweed mitogen.

ethnic characteristics, and had a similar aggregate level of education.

Dietary history. All subjects were questioned with respect to their dietary intake by means of Willett's semiquantitative food frequency questionnaire, currently widely employed in epidemiological investigations examining nutritional variables (8).

Clinical examination. All subjects were administered a complete medical history and general physical examination. Subjects were examined for any evidence of nutritional deficiencies or excesses. The comprehensive results of these examinations have been reported elsewhere (5). Self-report measures were recorded for current and historical alcohol use, recreational use of illicit substances (marijuana, cocaine, amphetamines, amyl nitrates, etc.) and smoking (estimated pack use).

Biochemical determinations. Venous blood samples were obtained at 0800 hours for all subjects from the left antecubital vein after a 12-h fast. The schedule was adhered to rigidly, in order to minimize the influence of the last meal and diurnal biochemical variation. Blood was collected in heparinized tubes that were centrifuged immediately at 2000 × *g*. Both the buffy coat and plasma were removed after centrifugation. All plasma samples were stored at −70°C until ready for analysis.

Total plasma lipids were extracted utilizing the Bligh and Dyer method (9). The lipid extracts were dried by flash evaporator and reconstituted in 2 mL methanol and 1 mL benzene containing a 17:0 fatty acid standard and 0.2 mL acetylchloride as catalyst. The tubes were allowed to stand overnight to quantitatively convert all fatty acids to their methyl esters (FAME). After adding 5 mL chilled phosphate buffer (final pH 5.0), the benzene layer containing FAME rose to the top and was transferred to small conical test tubes, and dried in a stream of N_2 at 50°C. The residual FAMEs were reconstituted in 25 μL hexane and injected into 1-μL aliquots. FAME were separated and quantified by gas-liquid chromatography (GLC Model 5880 with a flame-ionization detector Hewlett-Packard, Palo Alto, CA), with a 17:0 fatty acid used as an internal standard. The temperature program used was 160-260°C, increasing at 4°C/min. The carrier gas was nitrogen with a flow rate of 20 mL/min. The peaks were resolved by use of a 2.5-m glass column packed with 10% ethylene glycol succinate on 100 supelcoport (Supelco Inc., Bellefonte, PA). Individual fatty acids were identified and quantified by comparison of retention time against known standards (Sigma Chemical Co., St. Louis, MO).

Immunological determinations. Heparinized blood samples were drawn for lymphocyte surface markers (CD4 and CD8), assays of lymphocyte blastogenesis and of natural killer (NK) cell cytotoxicity. Flow cytometry and monoclonal antibodies were employed to quantitate members of circulating T helper/inducer (CD4) and T suppressor/cytotoxic (CD8) cell number (10). These studies were performed using two-color direct immunofluorescence with monoclonal antibodies conjugated to phycoerythrin to measure the CD4 population or to fluorescein isothiocyanate to measure the CD8 cell population. Both monoclonal antibodies were obtained from Coulter Immunology (Miami, FL).

Lymphocyte blastogenesis in response to the mitogen phytohemagglutinin (PHA), a T cell mitogen, and pokeweed mitogen (PWM), a T cell dependent B cell mitogen, was assessed in triplicate 72-h cultures (11). Assessment of tritiated thymidine incorporation during an additional 6 h of incubation was used to determine the degree of lymphocyte transformation, such transformation serving as an *in vitro* correlate of *in vivo* functional immunocompetence. The appropriate dilution of each mitogen was dispensed in 100-μL aliquots in triplicate to wells of a U-bottom microtiter plate (Costar, Cambridge, MA). Each mitogen was tested at three levels as follows: PHA (Wellcome Diagnostics, Dartford, England) 0.5, 5 and 10 μg/mL; and PWM (GIBCO Laboratories, Chagrin Falls, OH) diluted 1:40, 1:20 and 1:10. Three wells per each sample row received only growth medium of RPMI 1640 containing 100 units penicillin and 50 units streptomycin and 1 mM L-glutamine (GIBCO, Grand Island, NY). Heparinized peripheral blood was diluted 1:5, or 1:10, 1:20, 1:40 and 1:80 in some experiments, with growth medium, and 100 μL of the diluted blood was dispensed to all wells. PHA cultures were incubated for 72 h, and PWM cultures were incubated for 168 h (±2 h) in a humidified atmosphere of 5% CO_2 at 37°C. After the appropriate incubation time, 25 μL of tritiated thymidine was added to each well (1 μCi per well) and cultures were returned to incubation for an additional 6 h (±2 h). At the end of incubation, cultures were placed in the refrigerator at 4°C and harvested after 2 d. Cultures were harvested (Titertek Cell Harvester, Flow Laboratories, McLean, VA) onto glass filter paper disks that were dried, immersed in scintillation cocktail and counted on a beta scintillation counter (LKB Instruments, Rockville, MD) to determine counts per minute (cpm) of incorporated tritiated thymidine. Results were expressed as mean of net cpm of triplicate cultures. The number of lymphocytes present in the cultures was determined from total leukocyte count times percent lymphocytes observed from differential blood smear analyses. Mean of net cpm was transformed to mean cpm/100,000 lymphocytes. Calculations were done by using an MBasic program and an Apple II Plus microcomputer.

NK cell function was evaluated by assays of cytotoxicity. NK cell activity was assessed on a true effector cell basis, thereby minimizing the influence of changes in cell number upon assays of cell function (12). The technique is based upon a ^{51}Cr-release assay, using a K562 tumor target cell line. The assay was performed utilizing whole blood, thereby creating an *in vitro* environment closer to that in which the cell must function *in vivo*, than would be possible employing fractionated mononuclear cells. NK effector cell number was measured using the monoclonal antibody NKH.1 and fluorocytometry.

One-color indirect immunofluorescence surface marker analysis was performed using NKH.1 (Coulter Immunology, Hialeah, FL). Aliquots of 150 μL well-mixed heparinized peripheral blood were incubated with the appropriate monoclonal antibody or isotype control for 15 min at 4°C with shaking. Erythrocytes were lysed with 3 mL lysing buffer (0.155 M NaCl, 0.01 M $KHCO_3$, 0.1 mM ethylenediaminetetraacetic acid) for 10 min. The residual cells were washed two times with phosphate-buffered saline (PBS) and incubated with fluorescein isothiocyanate-conjugated goat antimouse IgG antibody for 15 min at 4°C on ice. The stained cells were washed two times with RPMI 1640 (GIBCO) and resuspended in 1 mL of

PBS and analyzed on the flow cytometer as above. The percent positively stained cells was determined using the Immunohistogram subtract software (Coulter, Hialeah).

A whole blood ^{51}Chromium release assay was used to determine cell-mediated cytotoxicity (CYT) to the NK-sensitive erythroleukemic K562 cell line. Briefly, triplicate aliquots of 150 μL heparinized peripheral blood from each sample were dispensed into wells of 96-well flat-bottom tissue culture trays (Costar, Cambridge, MA). ^{51}Cr-labeled (New England Nuclear, Boston, MA) log-phase K562 target cells at several dilutions, including 2×20^6 cells/mL, 1×10^6 cells/mL, 0.5×10^6 cells/mL were incubated with the blood samples. After 4 h incubation in a humidified atmosphere of 5% CO_2 at 37°C, cell-free supernatants were removed and counted on a gamma counter (LKB Instruments). Natural CYT was expressed as % CYT:

$$\%CYT = \frac{(ER - b) \times \frac{Vt - (Vb \times H)}{Vt} - (SR - b)}{(TR - b) - (SR - b)} \times 100 \quad [1]$$

where ER is the mean cpm of experimental release of the specimen, SR is the mean cpm spontaneous release, TR is the mean cpm total release, Vt is the total volume in well, Vb is the volume of blood in well, H is the specimen hematocrit and b is instrument background. Calculations were done using an MBasic program on an Apple II Plus microcomputer. Percent spontaneous release was less than 20%.

Statistical methods. Comparisons of fatty acid profiles in the HIV-1 seropositive and seronegative groups were made using Wilcoxon rank sums test for independent samples. Most of the immunologic parameters had non-normal distributions. Simple associations between measures of plasma fatty acids and immune parameters (CD4 cell number, CD8 cell number, CD4/CD8 ratio, PHA and PWM response and NK cell cytotoxicity) were determined using Spearman rank order correlations with $P < 0.05$ considered statistically significant for all measurements. Base ten ($\log_{10}$) logarithmic transformations successfully normalized the distributions of these measures, and the $\log_{10}$ transformed values were used in all multivariate analyses. Transformed measures are noted wherever used.

RESULTS

The relative amount of each of the fatty acids measured, expressed as percent of total plasma fatty acids, is described in Table 1. Both palmitic (16:0) and stearic (18:0) acids were significantly higher in the HIV-1 seropositive group ($P = 0.002$). Arachidonic acid (20:4) was significantly lower in the HIV-1 seropositive group ($P = 0.001$).

Comparisons were also made of fatty acids with similar ω unsaturation structure (Table 2). Total saturated fatty acids (16:0 and 18:0) were significantly higher in the HIV-1 seropositive men ($P = 0.0001$). Total ω6 polyunsaturated fatty acids (18:2 and 20:4) were significantly lower in the HIV-1 seropositive group ($P = 0.0027$). There were no statistically significant differences in the amounts of monounsaturated (16:1 and 18:1) and ω3 polyunsaturated (18:3, 20:5 and 22:6) fatty acids between the two groups of subjects.

TABLE 1

Fatty Acid Profiles[a]

	HIV− (n = 17)	HIV+ (n = 36)
16:0	20.3 ± 1.86[b]	22.2 ± 1.96[b]
16:1ω7	2.7 ± 0.698	3.0 ± 0.99
18:0	6.6 ± 0.54[b]	7.4 ± 0.86[b]
18:1ω9	23.6 ± 2.31	24.4 ± 3.23
18:2ω6	35.5 ± 3.53	33.4 ± 4.55
18:3ω3	0.6 ± 0.34	0.6 ± 0.75
20:4ω6	7.7 ± 1.73[c]	5.9 ± 1.89[c]
20:5ω3	0.4 ± 0.24	0.6 ± 0.57
22:6ω3	1.9 ± 1.50	1.6 ± 4.74

[a]Values are expressed as mean % total plasma fatty acids ± SD. Comparisons were made between HIV− subjects and HIV+ subjects using the Wilcoxon Rank Sum test.
[b]$P = 0.001$.
[c]$P = 0.0008$.

The ratios of the elongation and desaturation products of the essential fatty acids were compared (Table 3). The ratio of linoleic to arachidonic acid was significantly higher in the HIV-1 seropositive group ($P = 0.0213$). There were no differences in the ratios of either linolenic to eicosapentaenoic acids, nor in eicosapentaenoic to docosahexaenoic acids.

Both groups consumed a similar amount of calories (3297 kcal ± 1399.6 in the seropositive *vs.* 2549 kcal ± 1144.9 in the seronegative) as well as total fat (65.9 g ± 43.41 *vs.* 38.7 g ± 17.64) and polyunsaturated fats (6.3 en% ± 1.80 *vs.* 6.1 en% ± 2.32). The percentage polyunsaturated fat in the diet correlated with the 18:2 to 20:4 ratio in seronegative subjects ($r = 0.6526$; $P = 0.0114$). It also was inversely related to plasma total saturated fatty acids in seropositive subjects ($r = -0.3326$; $P = 0.0443$). No significant associations between plasma levels of total ω6 polyunsaturated fatty acids and caloric intake, or total fat consumed, were observed in either HIV-1 seronegative or seropositive subjects. Alcohol intake was also compared between seropositive and seronegative subjects. There was no statistically significant difference between the two groups ($P = 0.8337$).

Immune parameters were determined in HIV-1 seronegative and HIV-1 seropositive individuals. CD4 cell count correlated both with total plasma saturated fatty

18:2 to 20:4	4.86 ± 1.374[b] n = 17	6.72 ± 4.745[b] n = 35
18:3 to 20:5	1.66 ± 1.463 n = 15	0.90 ± 0.570 n = 27
20:5 to 22:6	0.28 ± 0.223 n = 17	0.58 ± 0.807 n = 32

[a]Values are expressed as mean ratios of % of total plasma fatty acids ± SD. Comparisons were made between HIV− subjects and HIV+ subjects using the Wilcoxon Rank Sum test.
[b]$P = 0.0213$.

acids ($r = 0.6593$; $P = 0.0055$) and with the ratio of 18:2 and to 20:4 ($r = 0.5235$; $P = 0.0374$) only in seronegative subjects. In HIV-1 seropositive participants the mitogenic response to PHA was found to correlate with both total plasma ω6 polyunsaturated fatty acids ($r = -0.36$; $P = 0.027$) and with the ratio of 18:2 to 20:4 fatty acids ($r = 0.33$; $P = 0.046$).

DISCUSSION

The present findings indicate that the polyunsaturated fatty acid profile is different from controls during the early stages of HIV-1 infection. The mean total amount of ω6 polyunsaturated fatty acids (18:2 and 20:4) was lower in the HIV-1 seropositive subjects compared to HIV-1 seronegative subjects. This was also reflected in higher total saturated fatty acids (16:0 and 18:0) in HIV+ subjects. The mean ratio of linoleic to arachidonic acid (18:2 to 20:4) was higher in the HIV+ group, but there were no statistically significant differences between HIV− and HIV+ subjects when total monounsaturated (16:1 and 18:1) and total ω3 polyunsaturated (18:3, 20:5, and 22:6) fatty acids were compared.

Consistent with the present findings, alterations in plasma fatty acid profiles have been found in the later stages of HIV-1 infection. Begin *et al.* (13) collected blood samples from 11 patients with fully developed AIDS, and lipid fractions were analyzed. Total lipid levels were approximately 75% of normal, and the absolute plasma levels of stearic, oleic and linoleic acids were significantly lower, although proportions of arachidonic acid were not different between the two groups. In another study, Christeff *et al.* (14) found an increase in the relative percentage of polyunsaturated fatty acids in the free fatty acids from plasma of AIDS-related complex (ARC) and AIDS patients. However, with more advanced AIDS disease, the differences in polyunsaturated fatty acids were lost. Differences in results from our study may be attributed to the stage of the disease. Although not clearly specified, it is apparent that the subjects in studies performed by others were CDC Stage IV, in a more advanced state of disease and malnutrition than our subjects, who, except for lymphadenopathy, were asymptomatic.

Changes in lymphocyte membrane phospholipids also occur with progression of HIV-I disease. Klein *et al.* (15) noted an increase in CD4 membrane phospholipid linoleic acid in asymptomatic seropositive homosexuals as the CD4 count dropped below 500×10^6/L. In contrast, symptomatic subjects (ARC or AIDS) showed an increase in oleic acid, and a decline in linoleic and arachidonic acids. These authors suggest that the decrease in concentrations of ω6 fatty acids may represent activation of cyclooxygenase pathways (15).

There is some evidence that serum fatty acid profiles may be altered by other viral infections. Williams *et al.* (16) took monthly measurements of serum total fatty acid profiles of twenty otherwise healthy college students following acute Epstein-Barr virus infection. Clinical symptomatology, such as increased physical malaise, coincided with changes in fatty acid profiles. Specifically, lower levels of arachidonic acid and a reversal of the usual ratio of linoleic and oleic acids were noted. Low levels of linoleic acid content were observed in a subset of subjects who showed continued clinical symptoms. The authors estimated that fatty acid elongation enzyme function was normal, but that desaturation enzyme activities were lower than normal.

The HIV-associated changes in fatty acid profiles may have correlates in other disease states. Alden *et al.* (17) studied the plasma phospholipid polyunsaturated fatty acid profiles in 22 critically ill, hypermetabolic patients. Compared to controls, all patients showed low levels of linoleic and arachidonic acids. However, because levels of docosapentaenoic acid (22:5 ω6), a metabolite of arachidonic acid, were increased, total ω6 metabolites were not different from controls. This study suggests that elongation and desaturation of arachidonic acid in sepsis may be accelerated.

Other inflammatory processes may be associated with altered polyunsaturated fatty acid utilization. Melnick and Plewig (18) have hypothesized that inflammatory skin diseases, such as atopic dermatitis, are linked to alterations in ω6 fatty acid metabolism. They have suggested that reduced formation of Δ6 desaturate products (specifically dihomo-γ-linolenic acid) results in diminished T cell maturation. The levels of linolenic, dihomo-γ-linolenic and arachidonic acids are decreased in patients with atopic dermatitis, whereas the levels of linoleic acid are higher than normal (19,20).

Diseases of the liver also may alter plasma total fatty acid profiles. Almost universally, several groups of investigators have noted a general decrease in polyunsaturated fatty acids in cirrhotic liver disease (21–25). This pattern appears to be exacerbated by alcohol abuse (21) or by malnutrition (22). Biagi *et al.* (26) have measured Δ6 desaturase activity in microsomes from liver specimens of normal and cirrhotic subjects, and have observed a significant decrease in Δ6 desaturase activity.

The changes in fatty acids were also correlated with immune function in our study. The response to PHA in HIV+ subjects correlated inversely with total plasma ω6 fatty acids, and directly with the 18:2 to 20:4 ratio, suggesting that reduced production of arachidonic acid is associated with preservation of the normal lymphocyte response to PHA.

It is known that essential fatty acids have potent effects on immune function. In general, linoleic and arachidonic acids, when added *in vitro*, suppress lectin-induced lymphocyte transformation (27). These effects may be produced by changes in eicosanoic production. In many cases PGE_2 (of which the precursor is linoleic acid) suppresses T cell function, such as response to mitogens

and antigens, rosette formation, generation of cytotoxic cells and production of lymphokines.

We conclude that: (i) early HIV-1 infection is associated with lower plasma ω6 PUFA than controls; (ii) the proportion of arachidonic acid in early HIV-1 infection is lower; (iii) these observations are not due to differences in dietary intake and (iv) the changes in the plasma fatty acid profile correlate with some indices of immune function. Infection with HIV-1 may be associated with alterations of the hepatic enzymes necessary for desaturation and elongation of linoleic acid, which may be reflected in modulation of immune function *via* prostaglandin synthesis.

Nine inbred strains of mice, which are progenitors of recombinant inbred sets, were evaluated for aortic lesion formation and plasma and liver lipid levels. This survey was done to determine if a semi-synthetic high-fat diet could elicit the same extent of diet-induced atherosclerosis as that observed in mice fed a natural ingredient high-fat diet and to discover strain-specific plasma and liver lipid variants for future genetic characterization. Evaluation of aortic lesions after 18 wk of diet consumption showed that strains C57BL/6J, C57L/J, SWR/J and SM/J were susceptible to atherosclerosis and that A/J, AKR/J, C3H/HeJ, DBA/2J and SJL/J were relatively resistant. High-density lipoprotein cholesterol (HDL-C) levels were negatively correlated to lesion formation. Susceptible strains had decreased HDL-C levels when switched from chow to the semi-synthetic high-fat, high cholesterol diet, whereas resistant strains either showed no change or a slight increase in HDL-C levels. The exception to this pattern was found in SM mice, which were susceptible to aortic lesion formation but maintained the same HDL-C level on both chow and high-fat diets. HDL size differed among the strains, and levels of plasma apolipoprotein A-I and A-II correlated with HDL-C levels. Liver damage was not correlated to HDL-C levels or to susceptibility to atherosclerosis. Mice from strain A, which are resistant to atherosclerosis, had evidence of liver damage as observed by elevated levels of plasma alanine aminotransferase activity, by liver histology, by increased liver weight and by exceptionally high hepatic cholesterol content. For all strains, the levels of liver cholesterol and triglycerides were inversely correlated with each other; phospholipids did not vary greatly among strains. No remarkable differences in hepatic fatty acid profile were noted among the strains fed the atherogenic diet, but the fatty acid profile did differ considerably from that found in the diet itself.

Lipids 28, 599-605 (1993).

The mouse model is proving to be an invaluable tool for identifying genetic factors that affect heart disease and lipid metabolism because of the extensive genetic characterization of the inbred mouse strains (1), the special tools available, such as congenic, transgenic and recombinant inbred strains, the reproducible method for measuring aortic lesions (2) and the adaptation of methods to quantitate lipids in small blood volumes available from a single mouse. Previously, inbred strains of mice have been shown to differ in susceptibility to atherosclerosis when fed a natural grain diet high in saturated fat and cholesterol. The diet which was used in these studies was not chemically defined, and measurements of combined plasma very low density lipoprotein (VLDL) and low-density lipoprotein cholesterol (LDL-C) and high-density lipoprotein cholesterol (HDL-C) which have been shown to be associated with heart disease risk in humans were not done (3-5).

In this report, we sought to further develop the mouse model for the study of heart disease and lipoprotein metabolism. The semi-synthetic atherogenic diet which was designed to produce fatty streak lesions but minimize pathological changes in liver and gallstone formation in strain C57BL/6 is utilized in this study (6). However, cocoa butter was replaced by dairy butter as the fat source. The first question we asked was whether susceptibility to atherosclerosis would remain the same in nine inbred strains of mice fed a semi-synthetic high-fat and cholesterol diet rather than the natural ingredient diet used previously. Four susceptible strains (C57BL/6, C57/L, SWR and SM) and five resistant strains (A, DBA/2, AKR, C3H/He and SJL) were chosen for this study. These inbred strains of mice are progenitors of recombinant inbred sets. Secondly, we measured baseline differences in plasma lipid parameters and subsequent changes in these parameters in response to high-fat feeding in order to identify genetic variants in progenitors that could be further characterized and eventually mapped using recombinant inbred strains. In addition, because the liver is intimately involved in lipoprotein metabolism, the composition and levels of liver lipids were determined. The possible associations of the plasma and liver lipids with atherosclerosis susceptibility were also examined.

MATERIALS AND METHODS

Chemicals and diet. Cholesterol oxidase, bovine pancreas cholesteryl ester hydrolase, peroxidase and the plasma alanine aminotransferase assay kit were from Sigma Chemical Co. (St. Louis, MO); the cholesterol reagent kit No. 23691 was from Boehringer Mannheim (Indianapolis, IN); the triglcyeride reagent set No. 46676 was from Seradyn Inc. (Indianapolis, IN); triglyceride blank blend No. 10021 was from Craig Bioproducts (Streamwood, IL); chemicals for gel electrophoresis were from Bio-Rad Laboratories (Richmond, CA); gradient gels (4-30% polyacrylamide) were from Pharmacia (Piscataway, NJ); Oil red O was from Aldrich Chemical Company (Milwaukee, WI); hematoxylin and light green were from Fisher Scientific Co. (Dallas, TX); gentamycin sulfate was from U.S. Biochemical Corp. (Cleveland, OH); and fatty acid methyl ester mixtures were from Supelco (Bellefonte, PA). Other chemicals utilized were of reagent grade or better. Components for the purified diets were purchased from ICN

Abbreviations: ALT, alanine aminotransferase; apo A-I, apolipoprotein A-I; apo-II, apolipoprotein A-II; BW, body weight; EDTA, ethylenediaminetetraacetic acid; HDL-C, high-density lipoprotein cholesterol; LDL-C, low-density lipoprotein cholesterol; TC, total cholesterol; VLDL, very low density lipoprotein.

Biochemicals, Inc. (Cosa Mesa, CA) with the exception of Mazola corn oil (Best Foods, Englewood Cliffs, NJ). Laboratory rat chow (No. 5012) containing 4% fat was obtained from Ralston Purina (St. Louis, MO).

Preparation of diets and formation of the diet mix into pellets has been described previously (6). The high saturated fat diet contained 15% dairy fat, 50% sucrose, 20% casein, 1% corn oil, 5.07% cellulose, 5% AIN-76 mineral mix, 1% AIN-76 vitamin mix, 1% choline chloride, 0.3% DL-methionine, 0.13% DL-α-tocopherol, 0.5% sodium cholate and 1% cholesterol. Of the 1% cholesterol contained in the diet, 0.03% came from the dairy butter. In order to obtain 15% dairy butter, 18.45 g butter was used/100 g diet because of the 18.9% water content of butter.

Animals. Female C57BL/6J (C57BL/6), C57/LJ (C57/L), SWR/J (SWR), SM/J (SM), A/J (A), AKR/J (AKR), C3H/HeJ (C3H), DBA/2J (DBA/2) and SJL/J (SJL) mice, 4–8-wk-old, were obtained from The Jackson Laboratory (Bar Harbor, ME) and maintained in a room illuminated from 7 a.m. through 7 p.m. All animals were allowed to adapt to the environment for at least two weeks prior to dietary treatment and were provided free access to food and water throughout the experiment. Weight gain was monitored every three weeks, and food intake was monitored at weeks 3, 7 and 14. Six female mice were used from each strain for plasma lipid analysis and three were used for liver lipid analysis. After 18 wk of diet consumption, 0 of 6 mice from strains DBA/2, C57BL/6, SWR, C57L and A, 1 of 6 mice from strains SM, SJL and C3H and 3 of 6 mice from strain AKR had died. The reason for death in strains SM, SJL and C3H is unknown. The AKR mice died from exposure due to a water bottle malfunction.

Collection of blood and tissues. Prior to any blood or tissue collection, mice were fasted by removing their food at 5 p.m. on the day prior to the experiment. Blood was obtained from the tail vein of the mice after the two-week adaptation period for baseline measurements, and again after four weeks of consuming the semi-synthetic high-fat and cholesterol diet. At the termination of the experiment, blood was obtained from the brachial artery. Blood was mixed in chilled tubes with ethylenediaminetetraacetic acid (EDTA), sodium azide and gentamycin sulfate at final concentrations of 2 mM, 0.05 mg/mL and 0.05 mg/mL, respectively. Plasma was obtained by centrifugation of whole blood for 5 min at 12,000 $\times$ *g* at 4°C.

Upon termination of the experiments, the heart and the upper section of the aorta were removed and placed in 0.9% saline at room temperature. After one hour, the heart was trimmed of extraneous tissue and placed in 10% saline buffered formalin for 24 h at room temperature. Livers were blotted, quickly frozen in liquid nitrogen and stored at −70°C for lipid analysis. A portion of the liver was placed in a Bouin's fixative, embedded in paraffin wax, sectioned and stained with hematoxylin and eosin. Necropsy observations concerning the stomach and intestines were recorded.

Plasma lipids, lipoproteins and apolipoproteins. Plasma total cholesterol (TC), free glycerol and total glycerol were determined by commercial colorimetric enzymatic assay. HDL-C was measured after selective precipitation of LDL and VLDL with polyethylene glycol (7). The combined VLDL and LDL-C was calculated as the difference between TC and HDL-C. Plasma triglyceride concentrations were estimated by subtraction of free glycerol from total glycerol. Lipid measurements are given as mg/dL ± SEM. Plasma concentrations of apolipoprotein A-I (apo A-I) and apolipoprotein A-II (apo A-II) were estimated by radial immunodiffusion (8). Purified mouse apo A-I and apo A-II served as standards.

Total plasma lipoproteins ($d < 1.21$) were obtained by density ultracentrifugation of pooled plasma from five mice of each strain (9) and subjected to nondenaturing gradient gel electrophoresis (10). Gels were stained with Coomassie blue G-250 to visualize HDL.

Liver lipids and plasma alanine aminotransferase (ALT) activity. Lipids, extracted from livers by the method of Folch *et al.* (11), were assayed for triglyceride (12), cholesterol (13) and phosphorus (14). Phosphorus values were multiplied by a factor of 25 to estimate liver phospholipid content, assuming that phospholipids contain approximately 4% phosphorus by weight based on an average molecular weight for phospholipid of 775. Plasma ALT activity was measured using the Sigma Kit No. DG591K which is based upon a coupled reaction in which nicotinamide adenine dinucleotide is oxidized.

The fatty acyl group composition of lipid extracts from liver was determined by profiling the long-chain fatty acyl groups after transesterification of the fatty acids. Gas-liquid chromatography was performed on a Shimadzu 95A Gas Chromatograph (Columbia, MD) equipped with a 30 m $\times$ 0.25 mm fused silica SP 2330 column (Supelco) and a flame-ionization detector. Standard fatty acid methyl ester mixtures were used to identify the fatty acid methyl esters in the samples.

Evaluation of atherosclerotic lesions. Evaluation of aortic lesions has been described in detail by Paigen *et al.* (2). Briefly, mouse hearts were fixed, stored in 4% phosphate buffered formaldehyde and embedded in 25% gelatin. After removing the lower two-thirds of the heart, the remaining tissue was sectioned on a cryostat at −25°C. Alternate 10 μm sections were saved on slides. Sections were stained with aqueous Oil Red O for neutral lipid and hematoxylin for nuclei and basophilic tissue and counterstained with light green. Five sections at 80 μm intervals were evaluated for the cross sectional area of lesions beginning where the aorta was rounded and valves appeared distinctly through to the endpoint where the valves disappeared, a distance of approximately 350 μm.

Statistical analysis. The Number Cruncher Statistical System, Version 4.21 1/86 (Kaysville, UT) and Statview, Version 1.0 6/85 (Calabasas, CA) was used for statistical analysis. Comparison of data from more than two groups was analyzed by using one-way analysis of variance with Fisher's least significant difference test to determine which means were significantly different at $P < 0.01$. Unpaired *t*-test was used when only two groups were compared. Correlation between aortic lesions and lipid parameters measured were tested by linear regression analysis.

RESULTS

Atherosclerosis susceptibility. The susceptibility to lesion formation is similar in the nine inbred strains of mice fed the semi-synthetic high-dairy-fat diet to that reported earlier (5), when these same strains were fed a natural ingredient diet with cocoa butter as the fat source (Fig. 1).

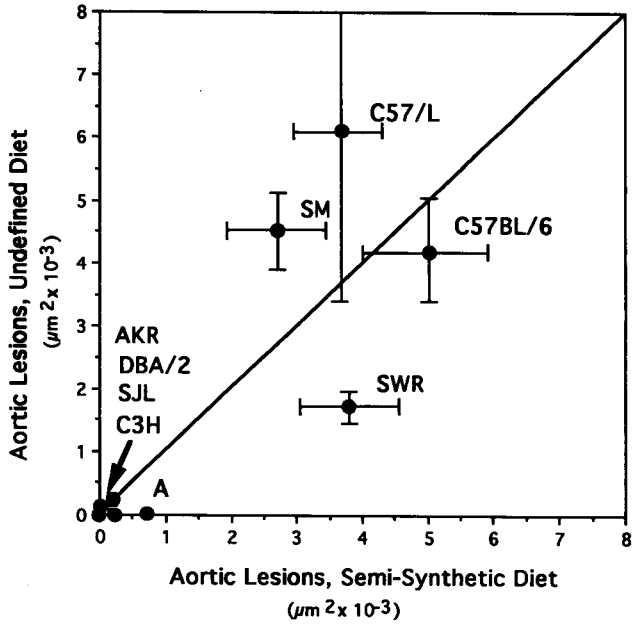

FIG. 1. Comparison of aortic lesions in nine inbred strains fed two different atherogenic diets. The aortic lesion sizes are expressed as the mean size per cross section in $\mu m^2 \times 10^3$. Lesion data for the natural ingredient diet are from Reference 5.

C57BL/6, C57L, SWR and SM are susceptible to lesion formation while the remaining five strains, namely A, AKR, C3H, DBA/2 and SJL, are relatively resistant to atherosclerosis. This difference among strains could not be accounted for by food consumption and weight gain (Table 1) as these parameters were not significantly different from that expected based on the relative sizes of these inbred strains maintained at The Jackson Laboratory. Therefore, the reduction in dietary cholesterol from 1.25% in the undefined diet to 1% in the semi-synthetic diet and the change in the source of fat from cocoa to dairy butter did not affect susceptibility to aortic lesion formation. The intra-strain variability and extent of lesion area was also similar between the two experiments. The one exception was strain SWR, where the lesion area was larger in mice consuming the semi-synthetic rather than the undefined diet (3804 ± 741 *vs.* 1690 ± 280 μm^2, respectively).

TABLE 1

Initial Body Weight, Body Weight Gained and Food Intake of Mice Fed a High-Saturated Fat Diet[a]

Strains	Body weight (g)			Food intake[b] g/d/20 g BW
	Initial	Final	% Normal	
C57BL/6	19.0 ± 0.5	22.4 ± 0.6	100	1.8
C57L	17.4 ± 0.6	24.2 ± 0.9	99	2.7
SWR	18.6 ± 0.6	23.9 ± 0.4	n.a.[c]	2.2
SM	13.8 ± 0.8	20.4 ± 1.0	100	2.7
A	18.0 ± 1.1	21.0 ± 1.0	75[d]	2.3
DBA/2	20.8 ± 0.4	28.7 ± 0.7	104	2.0
AKR	26.9 ± 1.2	44.3 ± 1.6	138	2.2
C3H	21.2 ± 0.8	32.9 ± 1.1	102	2.0
SJL	20.7 ± 0.8	24.9 ± 1.3	92	2.4

[a]Values represent the mean ± SE of at least five animals per group at 4 wk of high-fat diet consumption and at least three animals per group at 18 wk.
[b]Food intake was estimated by weighing food disappearance over a 3- to 5-d period; the values represent the mean of food consumed per 20 g body weight (BW) of mouse per day during weeks 3 through 4 of the experiment.
[c]n.a. = Not available.
[d]This strain lost weight during the last six weeks of the study, presumably because their livers were damaged.

Baseline plasma lipid levels in the nine inbred strains of mice. Significant variation in basal plasma lipids (combined triglyceride and cholesterol) was noted among the strains studied (Fig. 2). Plasma triglyceride levels ranged from 26 ± 3 mg/dL in strain C57/L to 68 ± 5 mg/dL in strain SWR. Plasma cholesterol levels ranged from 45 ± 4 mg/dL in C57/L to 106 ± 4 mg/dL in C3H mice (Fig. 2B). As observed by others (15), the majority of cholesterol in mouse plasma, 71 to 87%, is found in the HDL fraction (Fig. 2C) with 13 to 29% in the VLDL + LDL fraction (Fig. 2D).

Plasma lipid levels in mice fed a diet high in fat and cholesterol for four weeks. Fasting total triglyceride levels did not reflect the high-fat content of the diet (*i.e.* 15% w/w) fed to the mice (Fig. 2A). Triglyceride levels either did not change from basal levels in strains C57BL/6, C57L, SWR, A, AKR, C3H and SJL, or significantly decreased by 38% in SM and 39% in DBA/2.

Unlike plasma triglyceride, total plasma cholesterol levels increased significantly in all strains fed the semi-synthetic atherogenic diet (Fig. 2B). The level of increase ranged from 131 to 295% over baseline values. The majority of the increase in plasma cholesterol could be found in the VLDL + LDL fraction (Fig. 2D). VLDL + LDL-C levels of the nine inbred strains clustered roughly into two groups with C57BL/6, SM, DBA/2, AKR and SJL having levels from 47 ± 4 to 67 ± 19 mg/dL and C57/L, SWR, A and C3H having levels from 94 ± 10 to 132 ± 10 mg/dL (Fig. 2D). HDL-C either decreased significantly from baseline values in strains C57BL/6, C57/L and SWR or showed no significant change in the remaining strains. The decrease in SWR, C57BL/6 and C57/L mice was 19, 32 and 37%, respectively (Fig. 2C).

Liver lipid levels in mice fed the atherogenic diet for 18 wk. Liver weights varied from 1.2 to 3.9 g/animal. When liver weight was normalized (g/100 g body weight) to account for differences in body size, strain A was exceptional in that its liver was more than twice the size observed in other strains. On gross examination, the livers of the animals from all strains fed the semi-synthetic high-fat diet tended to be paler than normal compared to animals fed laboratory chow. C57L, DBA/2 and SJL had livers that were closest to normal in color. This group was followed by strains C57BL/6, C3H, SM, SWR and AKR, which had paler-colored livers. The livers of strain A were chalky white and rigid. In general, the strains with the lowest levels of hepatic cholesterol were most normal in appearance, and as the hepatic cholesterol content of the liver increased, the livers became paler in color. Histological examination of livers (Fig. 3) were consistent with this interpretation. Lipid accumulation observed in the liver as clear areas in the cytosol was least in C57/L (Fig. 3, Panel B), intermediate in C57BL/6 (Fig. 3, Panel C), and most in strain A (Fig. 3, Panel D). As a gross indicator of liver damage, plasma ALT activity was measured. The

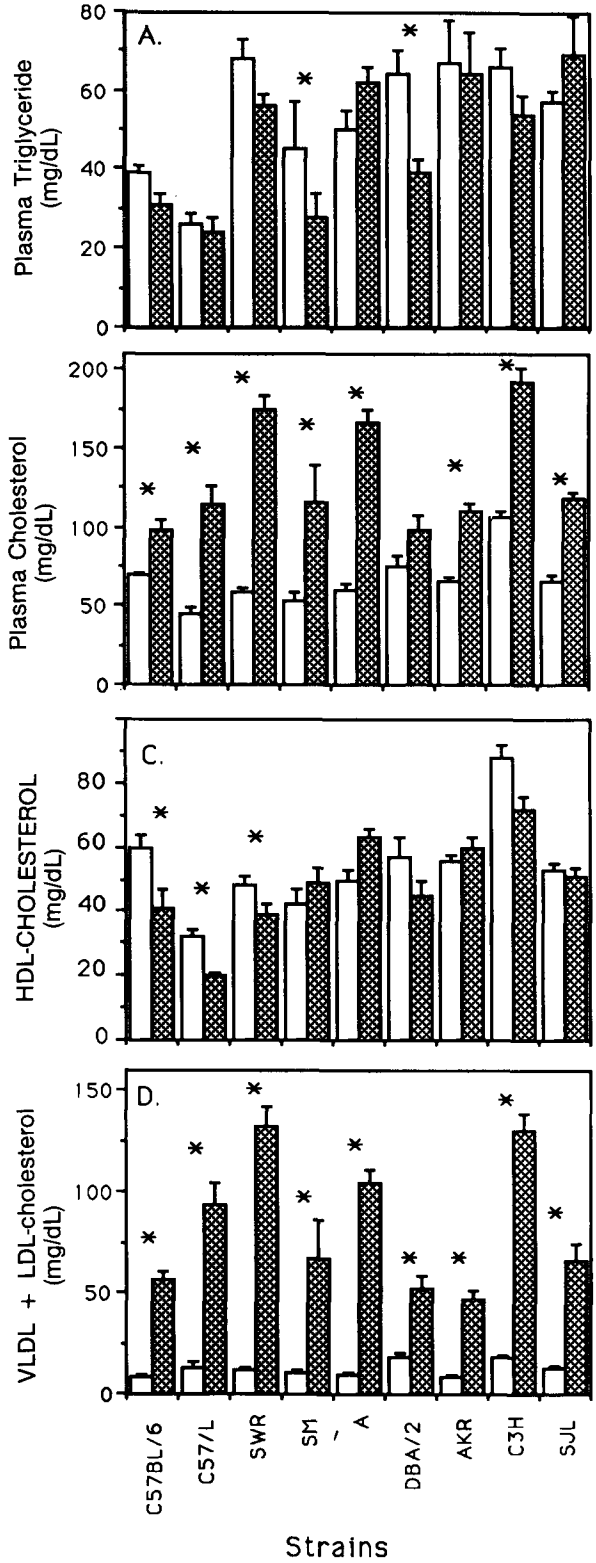

FIG. 2. Comparison of basal and high-fat levels of plasma triglycerides (A), cholesterol (B), high-density lipoprotein (HDL)-cholesterol (C) and combined very low density lipoprotein (VLDL) and low-density lipoprotein (LDL)-cholesterol (D) in nine inbred strains. The solid bars represent mean lipid and lipoprotein levels in mg/dL ± SE in the basal state, and the gray bars represent mean lipid and lipoprotein levels in mg/dL ± SE for animals fed the semi-synthetic atherogenic diet for four weeks. Significance ($P < 0.05$) between basal and high-fat values is indicated by a star above the bars.

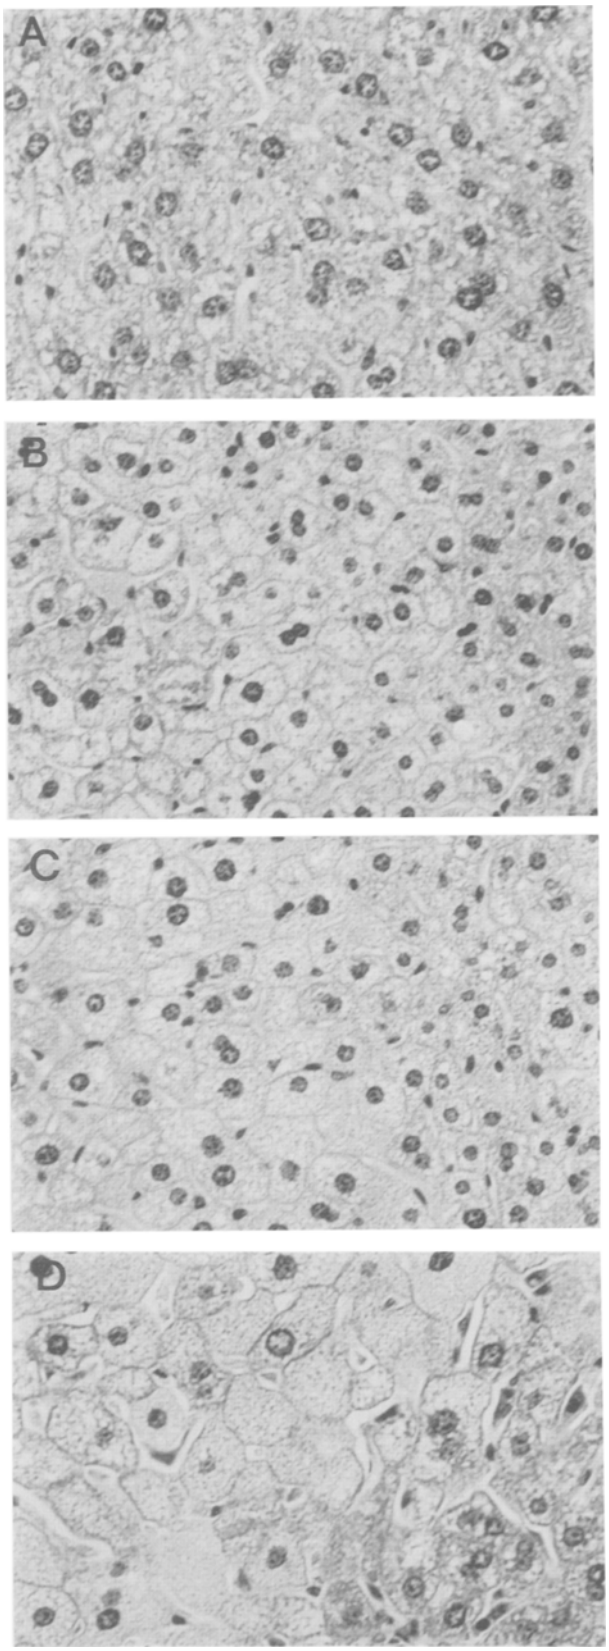

FIG. 3. Liver sections from mice fed chow (A) or the semi-synthetic diet for 7 wk (B–D) stained with hemotoxylin and eosin, 368×. Strain A (A), C57L (B), C57BL/6 (C), and Strain A (D).

TABLE 2

Comparison of Liver Weights and Plasma Alanine Aminotransferase (ALT) Activity in Nine Strains of Mice Fed a High-Saturated Fat Diet (for 18 wk)[a]

Strains	Liver weight		ALT activity[b]
	g/animal	g/100 g BW	μmol/min/mL
C57BL/6	1.5 ± 0.1[c]	6.8 ± 0.4[c,d]	55 ± 12[c,d]
C57L	1.4 ± 0.1[c]	5.9 ± 0.1[c]	29 ± 2[c]
SWR	2.1 ± 0.1[d,e]	8.9 ± 0.3[d]	105 ± 24[d]
SM	1.2 ± 0.1[c]	5.8 ± 0.8[c]	45 ± 16[c,d]
A	3.9 ± 0.1[f]	18.6 ± 0.9[e]	479 ± 28[e]
DBA/2	1.3 ± 0.1[c]	4.4 ± 0.2[c]	67 ± 19[c,d]
AKR	2.6 ± 0.1[e]	5.8 ± 0.2[c]	32 ± 11[c]
C3H	2.1 ± 0.1[d]	6.3 ± 0.2[c,d]	55 ± 8[c,d]
SJL	2.0 ± 0.2[d]	8.2 ± 0.4[d]	68 ± 15[c,d]

[a]Values represent the mean ± SE of at least three animals per group fed a high-saturated fat diet for 18 wk. Values in columns without common superscripts are significantly different, $P < 0.01$. [b]Animals that are fed chow or a low-fat synthetic diet have plasma ALT levels of 16.6 ± 3.1 or 30 ± 4 μmol/min/mL, respectively (Nishina, P.M., unpublished data).

two strains with the highest liver weight/100 g body weight, A and SWR, also had the highest ALT activity (479 and 105 μmol/min/mL, respectively), and both of these strains also had accumulated an extensive number of gallstones. Except for these two strains, plasma ALT levels were not remarkably elevated compared to ALT levels (17 ± 2 μmol/min/mL) measured in chow-fed C57BL/6 mice (Table 2).

Triglyceride, cholesterol and phospholipids were measured in order to determine what lipids were accumulating in the livers (Table 3). Liver cholesterol in C57BL/6 animals fed a low-fat diet is 5 ± 0.2 mg/g liver (6). The liver cholesterol of strains fed the high-fat, high-cholesterol diet ranged from 20 to 63 mg/g liver with strains DBA/2 and C57L accumulating the least, and strains C57BL/6 and A having the most cholesterol. The distribution of cholesterol into free and esterified cholesterol was examined; no significant differences among the strains were observed, and most cholesterol was of the esterified form with only 9 to 13% as free cholesterol (data not shown). Liver triglyceride levels ranged from 3 ± 1 to 24 ± 1 mg/g liver among the different strains. Strain A, which had the highest liver cholesterol concentration, had the lowest concentration of liver triglycerides. The accumulation of liver cholesterol in strain A mice fed a high-fat and high-cholesterol diet has been noted previously (16). Phospholipids, which are necessary for assembly of lipoproteins for secretion from the liver, were less variable than other lipids among strains. Correlation analysis of liver phospholipids, triglyceride or cholesterol showed that concentrations of phospholipids and cholesterol were negatively correlated ($r = -0.90$, $P < 0.01$) among the strains. This suggests that cholesterol may accumulate in livers which have lower concentrations of phospholipid. No correlation was found between plasma lipoproteins and any of the measured hepatic lipid concentrations after 18 wk of receiving the high-fat diet.

TABLE 3

Comparison of Liver Cholesterol, Triglyceride and Phospholipid (mg/g liver) in Nine Strains of Mice Fed a High-Saturated Fat Diet (for 18 wk)[a]

Strains	Cholesterol		Triglyceride	Phospholipid
	Total	Esterified/ free ratio		
C57BL/6	50 ± 4[c]	11 ± 0.5	14 ± 1.4[c,d]	20 ± 0.8[b]
C57L	29 ± 2[b]	7.7 ± 0.5	10 ± 1.9[b,c]	26 ± 1.2[c]
SWR	39 ± 2[c]	8.8 ± 0.6	5.8 ± 0.9[b]	22 ± 0.4[b]
SM	45 ± 6[c]	9.2 ± 0.4	24 ± 1.1[d]	24 ± 2.1[b,c]
A	63 ± 2[d]	7.7 ± 0.5	3.3 ± 0.8[b]	19 ± 0.4[b]
DBA/2	20 ± 1[b]	6.5 ± 0.2	20 ± 1.8[d]	26 ± 0.8[c]
AKR	40 ± 2[c]	8.8 ± 1.0	4 ± 1.7[d]	23 ± 0.3[b,c]
C3H	42 ± 2[c]	9.8 ± 0.3	13 ± 0.6[c]	22 ± 0.4[b,c]
SJL	39 ± 2[c]	8.9 ± 0.4	16 ± 2.6[c,d]	24 ± 0.9[b,c]

[a]Values represent the mean ± SE of at least three animals per group fed a high-saturated fat diet for 18 wk. Values in columns without common superscripts are significantly different, $P < 0.01$, as determined by Fisher's Least Significance Difference test.

In order to determine whether liver fatty acid profiles differed among the nine strains, livers from a minimum of three animals per strain were pooled and analyzed (data not shown[2]). The liver fatty acid profiles did not differ among the strains fed the high-fat diet; approximately 15 to 25% of the fatty acids were saturated, mainly in the form of palmitic acid, 50 to 80% were monounsaturated, mainly in the form of oleic acid, and 5 to 20% were polyunsaturated, mainly in the form of linoleic acid. However, the fatty acid profiles found in livers did differ considerably from those found in the diet where 73% of the fatty acids were saturated, 25% monounsaturated and 2% polyunsaturated.

Relationships between atherosclerosis susceptibility and plasma and liver lipids. Previous studies in mice have shown that the resistance to atherosclerosis cosegregates with elevated levels of HDL-C in crosses or in recombinant inbred strains derived from the susceptible strain C57BL/6 and the resistant strains C3H, BALB/c or A (17-19). In this survey, HDL-C levels in mice receiving the atherogenic diet were inversely related to aortic lesions size ($r^2 = -0.49$, $P < 0.05$). No other significant correlations were observed between aortic lesion formation and plasma or liver lipid levels.

Because of the importance of HDL-C levels in determining resistance to atherosclerosis, the possible biochemical differences in the HDL particles among the inbred strains were examined. The major apolipoproteins associated with these particles, A-I and A-II, were measured. The changes in HDL-C were mirrored by changes in apo A-I and A-II. The correlation among HDL-C, apo A-I and A-II was high; the correlation between HDL-C and apo A-I was 0.79 ($P < 0.0001$, Fig. 4B), between HDL-C and apo A-II was 0.70 ($P < 0.0001$, data not shown) and between apo A-I and apo A-II was 0.64 ($P < 0.0001$, Fig. 4A). Overall, the ratio between these apolipoproteins and HDL-C did not change significantly in inbred mice, whether fed a chow or a high-fat diet. Considerable variation in peak HDL particle sizes occurred among the mouse strains with no obvious correlation to atherosclerosis susceptibility or resistance (data not shown).

[2]A complete liver fatty acid profile of the nine strains of mice fed the semi-synthetic atherogenic diet will be supplied upon request.

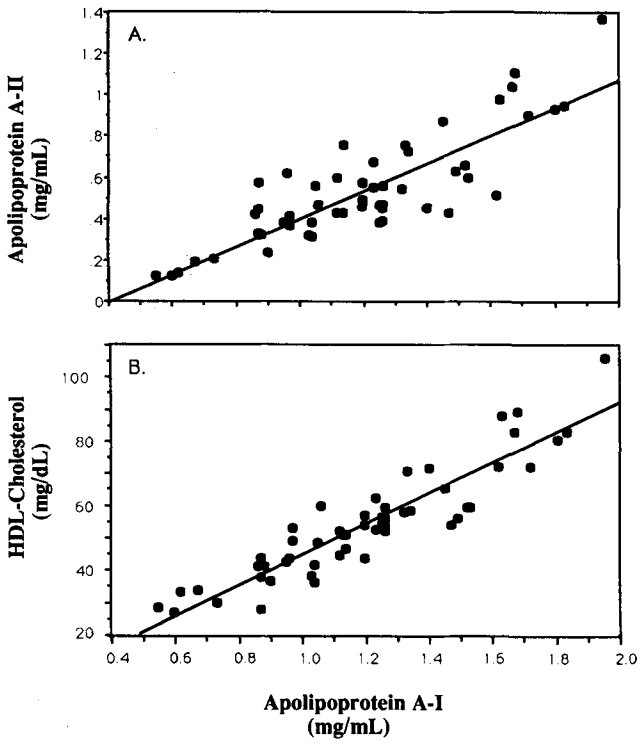

FIG. 4. Correlation analysis of apolipoproteins and high-density lipoprotein (HDL)-cholesterol in mice fed the semi-synthetic diet for four weeks. Panel A. Correlation of apolipoprotein A-II *vs.* apolipoprotein A-I. Panel B. Correlation of HDL-cholesterol *vs.* apolipoprotein A-I.

DISCUSSION

Atherosclerosis susceptibility. The relative susceptibility of nine inbred strains of mice to formation of fatty streak lesions in the aorta did not change when substantial changes were made in the atherogenic diet. The diet which we previously had used contained natural ingredients such as oats and corn, 1.25% cholesterol and cocoa butter as the primary fat source; the diet used in this study was a semi-synthetic diet with 1% cholesterol and dairy butter as the major fat source (5,6). Both diets contain 0.5% sodium cholate (w/w). The fact that the relative susceptibility to lesions did not change with diet indicates that previous conclusions about the genes that affect susceptibility to atherosclerotic lesion formation are applicable to more than one diet. However, it is interesting to note that diet can have an effect on the severity of the disease. Aortic lesion area was twice as large in SWR mice fed the semi-synthetic diet as compared to the undefined atherogenic diet.

The changes in VLDL + LDL-cholesterol and HDL-cholesterol are less than previously reported for C57BL/6 animals fed the natural ingredient atherogenic diet (5). The most likely explanation is the 20% decrease in cholesterol content of the semi-synthetic diet. Consistent with the less dramatic changes in lipoproteins, the length of time which animals needed to be fed the semi-synthetic diet to produce lesions of comparable size as the natural ingredient diet was 18 rather than 14 wk. However, the semi-synthetic diet has considerable advantages over the previous diet because it is defined and dietary components thought to affect development of heart disease can be varied one at a time to determine specific effects. In addition, the semi-synthetic diet produces fewer pathological changes in the liver and a decrease in gallstone formation (6); these pathologies might be further reduced by decreasing the cholesterol and or sodium cholate content of the diet. However, such a reduction would most probably increase the experimental time required to produce aortic lesions.

Liver lipids in response to high-fat diet. Correlation analysis showed no indication of a relationship between liver damage, measured by plasma ALT activity, and a decrease in HDL-C levels or atherosclerosis susceptibility. The disassociation of these two processes is most clearly demonstrated in strain A which shows no drop in HDL-C levels and the greatest liver damage, and strain C57/L, which has the lowest HDL-C and little liver damage when switched from a low- to high-fat diet.

The liver damage observed in these strains is consistent with the histopathology and appears to be associated with the accumulation of cholesterol in the liver. Undoubtedly, the cholesterol accumulated in the liver, in large part, arises from diet consumption. However, *de novo* hepatic cholesterol synthesis may also play a role in Strain A, which exhibits a liver threefold larger than other strains. HMG-CoA reductase activity, the rate-limiting enzyme in cholesterol synthesis, is not diminished when Strain A is switched from a low- to high-fat and cholesterol diet, suggesting that cholesterol synthesis is not down-regulated (Ref. 20; and Paigin, B., Chen, H., and Billheimer, H., unpublished observations). The combination of exogenous and endogenous cholesterol coupled with the lower phospholipid content of the liver may lead to the extreme accumulation of liver cholesterol in Strain A.

Genetic variants in plasma lipids, basal levels and response to high-fat diet. Many aspects of plasma lipids are similar between humans and mice, such as apolipoprotein and lipid composition of the lipoprotein particles and the responses observed with dietary manipulation. Therefore, the mouse model, with its unique advantages for dissecting genetic determinants, may be useful in identifying heritable factors that control lipid metabolism. Differences between humans and mice do occur, such as in the relative proportions of atherogenic lipoprotein particles. In humans, LDL predominates and in mice VLDL predominates (21), presumably because mice lack cholesterol ester transfer activity (22).

The three major observations of this study, which may warrant further investigation, were made when animals were challenged with the high-fat and high-cholesterol diet. The first observation is the lack of change in plasma triglyceride levels in some animals when fed the high-fat diet. A decrease in fasting plasma triglyceride levels would be expected as a result of the dietary fat because long-chain fatty acids inhibit *de novo* lipogenesis (23). This drop occurred in two strains, SM and DBA/2. Srivastava *et al.* (24) also reported similar results; a decrease in plasma triglyceride levels in DBA/2 animals and no change from basal levels in strains C57BL/6, C57/L, SWR and C3H/He. They did, however, see a significant decrease in plasma triglyceride levels in AKR mice when switched from a low fat diet to a semi-synthetic diet containing 21% fat and 2% cholesterol with no cholic acid. The difference in

response among mouse strains to dietary fat and cholesterol intake on plasma triglyceride levels needs to be studied further.

The second interesting difference among the strains was the hyper- or hyporesponsiveness observed in plasma cholesterol levels. This difference in response to a high-fat/high-cholesterol diet has been observed in other species such as primates, rabbits and rats (25) as well as in mice (24,26). As in other species, the changes in plasma cholesterol are due to an increase in cholesterol contained in the VLDL and LDL fraction. In our studies, strains C57L and SWR were hyper-responders and AKR and SJL were hyporesponders. These strains are progenitors of recombinant inbred sets, C57L × AKR and SWR × SJL. The responsiveness of combined VLDL and LDL to dietary lipid in these recombinant inbred sets could be used to identify the genetic determinants involved.

The third observation of interest was the failure of the HDL-C levels to decrease in SM mice fed the semi-synthetic atherogenic diet. A hallmark of susceptibility for aortic lesion development in mice studied thus far is a marked reduction in plasma HDL-C levels (17,18). SM mice, which were susceptible to aortic lesions, had basal HDL-C levels of 42 ± 5 mg/dL and of 59 ± 5 mg/dL after four weeks of consuming the atherogenic diet. Normally, the lack of change or slight increase in HDL-C levels upon high-fat feeding is associated with atherosclerosis-resistant strains of mice such as C3H or A.

ACKNOWLEDGMENTS

The authors thank Cynthia McFarland for the liver histology work and Drs. Edward Leiter and Juergen Naggert for review of the manuscript. Adipose Glycerolipid Formation: Effect of Nutritional and Hormonal States

Subhash C. Jamdar* and **Wang Fang Cao**
Department of Anesthesiology, College of Physicians and Surgeons, Columbia University, New York, New York 10032

The potential of glycerolipid formation from *sn*-glycerol-3-phosphate (GP) and 2-monoacylglycerol (MG) was studied in adipose microsomal fractions under various nutritional and hormonal states. Glycerolipid formation from GP was followed in the presence of [^{14}C]glycerol-3-phosphate and palmitoyl-CoA and was assayed by measuring the formation of butanol-soluble product, consisting mainly of [^{14}C]phosphatidate. Glycerolipid formation from MG was determined in the presence of 2-monooleyl glycerol and [^{14}C]palmitoyl-CoA, and was estimated by the formation of both [^{14}C]di- and triacylglycerol. Glycerolipid formation from GP was decreased significantly during food deprivation, in experimental diabetes, in the presence of lipolytic hormone, and during aging. Glycerolipid formation from MG did not change under these conditions and continued at the same rate as observed in control animals. The rate of glycerolipid formation from GP was 7–20 times greater than from MG in the various fat depots. Measurement of the adipose monoacylglycerol concentration did not show any correlation with the glycerolipid formation from MG. The studies suggest that glycerolipid formation from MG is active in various fat depots, and is substantial when glycerolipid formation *via* GP is impaired.
Lipids 28, 607-612 (1993).

It is now well known that fatty acid esterification in adipose tissue is mediated by the stepwise acylation of either *sn*-glycerol-3-phosphate (1,2), dihydroxyacetone phosphate (3) or 2-monoacylglycerol (4). Comparisons of the relative rates of esterification from various precursors indicate that the *sn*-glycerol-3-phosphate pathway is the major route of glycerolipid synthesis in adipose tissue (5).

In several studies, the changes in glycerolipid synthesis from *sn*-glycerol-3-phosphate were shown to be positively correlated with the rate of triacylglycerol accumulation in adipocytes (6–8). However, such a relationship was not observed in animals over 60 d of age. Adipose glycerolipid synthesis from *sn*-glycerol-3-phosphate in these animals showed a more than 100% decrease compared to young animals, in spite of the increase in triacylglycerol accumulation (8). This suggested that alternative metabolic routes other than the *sn*-glycerol-3-phosphate pathway may be operative in the deposition of triacylglycerol in older adipocytes. Another observation that suggested such a possibility was the stimulation of fatty acid esterification in intact adipocytes by catecholamines (9), when inactivation of several enzymes of the *sn*-glycerol-3-phosphate pathway is known to occur (10,11). Previous studies from our laboratory have shown that glycerolipid synthesis by the monoacylglycerol (MG) pathway is active in aged rats, in spite of the significant decrease in glycerolipid formation by the *sn*-glycerol-3-phosphate pathway (12).

The presence of the MG pathway in adipose tissue has been known for 20 years (4). Comparisons of glycerolipid formation *via* glycerophosphate and monoacylglycerol have indicated that, in hamster adipose tissue, the MG pathway is quite active, *i.e.,* shows about 40% of the activity of the *sn*-glycerol-3-phosphate pathway. Moreover, 2-monooleylglycerol ether, a 2-monoolein analogue which was used to measure the contribution of the MG pathway, inhibited glycerolipid formation *via* the *sn*-glycerol-3-phosphate pathway in both intact adipocytes and in a cell-free system (4,13,14). These observations led Johnston and coworkers (13,14) to propose that the MG pathway may play a significant role in adipose glycerolipid synthesis. In contrast, Dodds *et al.* (5,15) and Christie and Hunter (16) showed an insignificant contribution (<10% of the glycerophosphate pathway) of the MG pathway to glycerolipid synthesis in rat adipose tissue. Thus, the significance of the MG pathway in adipose glycerolipid formation is still not quite clear, although this pathway is considered the major route of glycerolipid synthesis in intestine (17) and in neonatal rat liver (18).

The present study was undertaken to determine the contribution of the MG pathway to glycerolipid formation in adipose tissue under various experimental conditions which are known to impair glycerolipid synthesis from *sn*-glycerol-3-phosphate. This approach was thought to provide information on the physiological importance of the MG pathway in adipose tissue.

MATERIALS AND METHODS

Materials. [U-^{14}C]*sn*-glycerol-3-phosphate (spec. radioactivity, 161 mCi/mmol) and [1-^{14}C]palmitoyl-CoA (spec. radioactivity, 54 mCi/mmol) were purchased from New England Nuclear (Boston, MA). 2-Monoolein and 2-monooleyl glycerol ether were purchased from Serdary Research Laboratories (Port Huron, MI). Other monoacylglycerols were obtained from Nu-Chek-Prep (Elysian, MN). Palmitoyl-CoA, ATP, coenzyme A, dithiothreitol, BSTFA (*bis*[trimethylsilyl]trifluoroacetamide), pyruvate kinase, glycerol kinase, lactate dehydrogenase (LDH), phosphoenolpyruvate, nicotinamide adenine dinucleotide reduced form (NADH), triethanolamine, hexokinase (Type VII from baker's yeast), glucose-6-phosphate dehydrogenase (Type VII from baker's yeast) and streptozotocin were purchased from Sigma Chemical Co. (St. Louis, MO).

Male Sprague-Dawley rats were purchased from Charles River Laboratories (Wilmington, MA). Rats were placed in an air-conditioned animal facility maintained on a 12-h dark (6 a.m.–6 p.m.)/12-h light (6 p.m.–6 a.m.) schedule. Animals were fed laboratory chow (Ralston Purina Laboratory, St. Louis, MO) *ad libitum.* After sedation (by

Abbreviations: BSA, bovine serum albumin; BSTFA, *bis*(trimethylsilyl)trifluoroacetamide; CoA, coenzyme A; LDH, lactate dehydrogenase; MG, monoacylglycerol; MGAT, monoacylglycerol acyltransferase; NAD, nicotinamide adenine dinucleotide; NADH, nicotinamide adenine dinucleotide reduced form; Tris, tris(Hydroxyethyl)-aminomethane.

exposing to CO_2), rats were sacrificed between 8 and 10 a.m. by decapitation.

Preparation of subcellular fractions. The adipose tissue microsomal fractions were prepared from epididymal fat pads from a single animal or pooled from two animals, as described previously (19). In some experiments, in addition to epididymal fat pads, the subcutaneous and perirenal fat pads were used. Adipose tissues from different sources were homogenized with a Teckmar Tissuemizer (Teckmar Company, Cincinnati, OH) with 3 vol of cold Medium A (0.25 M sucrose/1 mM tris(hydroxymethyl)-aminomethane (Tris) (pH 7.5)/1 mM ethylenediaminetetraacetic acid/1 mM dithiothreitol). The homogenate was further processed to isolate microsomal fractions as described previously (19).

Metabolic studies. To investigate the acute effects of hormones on glycerolipid formation from *sn*-glycerol-3-phosphate and 2-monoacylglycerol, epididymal adipose fragments (30–40 mg tissue) were incubated in the presence of either insulin (1,2 milliunit/mL) or 6 μM norepinephrine for 1 h at 37°C in 8 mL Krebs-Ringer-bicarbonate containing 4% bovine serum albumin (BSA), 10 mM glucose and half the recommended amount of Ca^{2+}. All incubations were carried out in a shaking water bath, under an atmosphere of O_2/CO_2 (19:1), in polyethylene vials. Following this incubation, the fragments were washed thoroughly in warm Medium A to remove adherent albumin and hormones. The washed fragments were then homogenized with cold Medium A to isolate microsomal fractions (19), which were used to measure glycerolipid formation from both *sn*-glycerol-3-phosphate and 2-monoacylglycerol. The incubation mixture from metabolic studies was stored frozen at −80°C and used at a later date for the determination of glycerol, which was taken as a measure of lipolytic activity of adipose tissue in the presence of different hormones.

Effect of fasting, refeeding and streptozotocin-induced diabetes on glycerolipid formation. Since the effect of fasting, refeeding and diabetes on glycerolipid formation from 2-monoacylglycerol was not known, we investigated the effect of these experimental conditions on glycerolipid formation from both *sn*-glycerol-3-phosphate and 2-monoacylglycerol. In these studies, rats were deprived of food for 48 h and refed for 48 h following a 48-h fast (48-h fast and 48-h refed group, see Tables 1 and 3). Diabetes was induced in animals by injecting 60 mg/kg of streptozotocin intramuscularly. Control rats received saline. After 72 h, the severity of diabetes in the experimental animals was monitored by measuring plasma glucose concentrations.

Enzyme assays and identification of the reaction products. In the present studies, glycerolipid formation from *sn*-glycerol-3-phosphate and 2-monooleylglycerol was measured in the presence of palmitoyl-CoA, which served as acyl donor for both enzymatic reactions. Initial studies were conducted to determine the optimal concentrations of substrates and cofactors for these reactions. Under the assay conditions, glycerolipid formation from both *sn*-glycerol-3-phosphate and 2-monooleylglycerol was linear with time and the amount of microsomal protein added. Under all our experimental conditions, initial enzyme reaction rates were measured and the appropriate substrates and enzyme blanks were included to estimate the true enzyme activity.

Glycerolipid formation from 2-monooleylglycerol was measured as described previously (20). In a final volume of 1 mL, the reaction mixture contained 24 mM Tris/HCl buffer, pH 7.5, 50 mM KCl, 8.0 mM $MgCl_2$, 0.25 mM monooleylglycerol, 0.75 mM dithiothreitol, 25μ M [^{14}C]-palmitoyl-CoA (0.024 μCi), 20 μL of phospholipid mixture containing 15 μg of phosphatidylcholine and 15 μg of phosphatidylserine, and 1.25 mg of BSA. The reaction was started by the addition of the adipose microsomal protein (80–140 μg). The incubation was carried out at 37°C and was linear with time for 15 min. The formation of both [^{14}C]di- and triacylglycerol was taken as a measure of enzyme activity. In the absence of monooleyl glycerol, very little (less than 5% of total) incorporation of [^{14}C]-palmitoyl-CoA into diacylglycerol and triacylglycerol occurred. The enzyme reaction stopped at zero time was subtracted as blank. The specific activity of the MG pathway was calculated on the basis of radioactivity present in the diacylglycerol fraction plus 1/2 of the radioactivity in the triacylglycerol fraction, as two moles of palmitoyl-CoA were required to form triacylglycerol from 2-monoacylglycerol.

The acylation of *sn*-glycerol-3-phosphate in the presence of palmitoyl-CoA was studied as described previously by Rider and Saggerson (21), with slight modifications. In a final volume of 0.70 mL, the reaction mixture contained 24 mM Tris/HCl buffer, pH 7.5, 50 mM KCl, 0.84 mM *sn*-glycerol-3-phosphate containing [^{14}C]glycerol-3-phosphate (0.1 μCi), 0.8 mM dithiothreitol, 65 μM palmitoyl-CoA and 1.75 mg of BSA. The reaction was started with 15–20 μg microsomal protein and was linear with time for 4 min. Incubation was under air at 30°C in a shaking water bath. Incorporation of [^{14}C]glycerol-3-phosphate into butanol-soluble products, mainly radioactive phosphatidate, was taken as a measure of enzyme activity.

The radioactive lipids formed from 2-monoacylglycerol and [^{14}C]palmitoyl-CoA were extracted as described by van den Bosch and Vagelos (22), and the procedure of Daae and Bremer (23) was followed to isolate the butanol-soluble products formed from [^{14}C]glycerol-3-phosphate and palmitoyl-CoA. The lipids were dried under N_2 and dissolved in 0.5 mL of chloroform/methanol (2:1, vol/vol). Samples were applied in a volume of 0.1 mL and separated on thin-layer plates coated with Silica G (E. Merck, Darmstadt, Germany). The lipid classes were identified by running appropriate standards in an adjacent lane.

Phosphatidate was separated using the solvent system chloroform/methanol/3M-NH_3 (65:38:8, by vol) and chloroform/methanol/acetic acid/water (50:25:8:4, by vol) (24,25). Neutral lipids were separated with hexane/diethyl ether/acetic acid (73:25:2, by vol) (26). The lipids were localized by exposure of the plates to iodine vapors. After sublimation of I_2 at room temperature, appropriate areas from the plates were scraped directly into scintillation vials containing 10 mL of CytoScient (ICN Biochemicals, Irvine, CA). The radioactivity was measured in a Packard (Packard Instrument Company, Meriden, CT) Tricarb 480 scintillation counter.

Analysis of total lipids, monoacylglycerols, glycerol and glucose. Total lipid and monoacylglycerol concentrations were determined in epididymal tissue during fasting and refeeding, in diabetic animals and from adipose fragments incubated in the presence of various hormones. Tissue lipids were extracted by the Folch procedure (27), and the

total lipid concentration was measured spectrophotometrically according to Barnes and Blackstack (28). The monoacylglycerol concentration was measured according to Arner and Ostman (29). For this purpose, monoacylglycerols were separated from other lipids by thin-layer chromatography on silica gel 60 with hexane/diethyl ether/acetic acid (73:25:2, by vol) as solvent system. The silica gel scrapings containing monoacylglycerols were extracted twice with 5 mL of chloroform/methanol (4:1, vol/vol) (29). The combined chloroform/methanol extracts were dried under N_2 and the monoacylglycerols were hydrolyzed at 70°C for 30 min in the presence of ethanolic KOH (29). Following addition of 1.5 mL of 0.05M $MgSO_4$, an aliquot of the supernatant was taken for the enzymatic determination of glycerol (30). In some experiments, we also determined the adipose monoacylglycerol composition. In these experiments, adipose monoacylglycerols, purified as described above, were derivatized with 100 μL BSTFA at 75°C for 45 min in the presence of pyridine (31). The contents were dried under N_2, and the derivatized monoacylglycerols were dissolved in 50 μL of methylene chloride. Two-microliter aliquots (in duplicate) were injected into the gas chromatograph (Hewlett-Packard, Kennet Square, PA; Model 5890, Series II, equipped with a 3396A integrator) and separated on a capillary column (DB1, 30 m × 0.53 mm i.d. 5 μm thickness, J&W PN 1235-1035, obtained from J&W Scientific, Folsom, CA) and analyzed using a flame-ionization detector. Gas chromatographic conditions were as follows. Oven temperature, 280°C, held for 3 min, then increased to 290°C at a rate of 1°C/min. The injector and detector temperatures were maintained at 280 and 320°C, respectively. The carrier gas (helium) flow was at 22 mL/min. The amounts of monoacylglycerols present in samples were determined relative to peak heights of monoacylglycerol standards analyzed at the same time under the same conditions.

Glycerol concentrations were determined spectrophotometrically by using the assay procedure of Thorner and Paulus (30). The reaction velocity was measured in a coupled system through glycerol kinase, pyruvate kinase and LDH. Glycerol was estimated on the basis of the conversion of NADH into nicotinamide adenine dinucleotide $(NAD)^+$ as monitored at 340 nm. Plasma glucose concentrations from diabetic and control animals were measured by the "IL Test"™ (Instrumentation Laboratory Microcentrifugal Analyzer) (32). Glucose concentrations were measured in a coupled system through hexokinase and glucose 6-phosphate dehydrogenase, and quantified based on the conversion of NAD^+ to NADH as monitored at 340 nm.

RESULTS AND DISCUSSION

In adipose tissue, monoacylglycerols are formed during hydrolysis of triacylglycerols by both hormone-sensitive lipase (33) and lipoprotein lipase (34). In spite of the presence of monoglyceride lipase (33), the monoacylglycerols, which can be cytotoxic (35), accumulate in adipose tissue (36). Recycling of monoacylglycerols to diacylglycerols is mediated by the monoacylglycerol acyltransferase (MGAT), an initial reaction of the MG pathway.

Besides being important in glycerolipid formation, the MG pathway may also participate in other aspects of adipose lipid metabolism, including the formation of the second messenger diacylglycerol (37), the proper functioning of lipoprotein lipase by interfering with the product inhibition of this enzyme by monoacylglycerols (34), as well as the protection of adipose tissue against the cytotoxic effects of monoacylglycerols (35). In the present investigation, we have directed our attention mainly on the role of the MG pathway in adipose glycerolipid synthesis and compared its activity with that of the *sn*-glycerol-3-phosphate pathway (Table 1). The rates of glycerolipid formation from *sn*-glycerol-3-phosphate were several times greater than those from 2-monoacylglycerol. This was evident under all the experimental conditions investigated

[a]Epididymal adipose microsomal fractions were used. Expt., experiment.
[b]Glycerolipid formation from *sn*-glycerol-3-phosphate and 2-monoacylglycerol was measured as described in Materials and Methods, and the rates of glycerolipid formation are expressed as nmoles of lipid formed per min per mg microsomal protein. Each value is the mean ± SD from the number of animals referred to in parentheses.
[c]Glycerol concentration in the incubation medium is expressed as μmoles of glycerol released per g of adipose tissue.
[d]Significantly different from control and refed animals, $P < 0.05$.
[e]nd, Not determined.
[f]Significantly different from control and insulin group, $P < 0.001$.

TABLE 2

Adipose Glycerolipid Formation in Various Fat Depots from Young and Old Animals[a]

Age (wk)	Body weight (g)	Source of adipose tissue	Glycerolipid formation[b] from *sn*-glycerol-3-phosphate (A)	Glycerolipid formation[b] from 2-monoacylglycerol (B)	A/B
6-7	223 ± 6.7	Epididymal	76.34 ± 9.96	5.27 ± 0.91	14.48
		Perirenal	70.74 ± 13.31	3.08 ± 0.40	22.96
		Subcutaneous	25.14 ± 4.34[c]	3.17 ± 0.14	7.93
13-14	356 ± 6.83	Epididymal	47.68	4.48 ± 0.14	10.64
		Perirenal	41.90 ± 14.73[d]	3.67 ± 0.14	11.41
		Subcutaneous	14.81 ± 1.01[d]	2.12 ± 1.48	6.98

[a]Adipose microsomal preparations from epididymal, perirenal and subcutaneous fat pads were used.
[b]The rates of glycerolipid formation from *sn*-glycerol-3-phosphate and 2-monoacylglycerol are expressed as nmoles of products formed per min per mg protein. Each value is the mean ± SD from 4-6 experiments, using 6 old and 19 young animals, except for epididymal fat tissue from old animals, where the data from two experiments were pooled.
[c]Significantly different from other fat depots in the same group of animals, $P < 0.001$.
[d]Significantly different from young animals, $P < 0.05$.

so far. The fasting of animals for 48 h did cause a significant reduction in the formation of glycerolipids from *sn*-glycerol-3-phosphate, and refeeding of fasted animals for 48 h partially retrieved this activity (Experiment 1), consistent with our earlier observations (38). However, glycerolipid formation from monoacylglycerol continued at the same rate as control animals during a fasting and refeeding cycle.

Microsomal fractions prepared from adipose tissue fragments pretreated with norepinephrine also showed a significant reduction in the formation of glycerolipids from *sn*-glycerol-3-phosphate (Experiment 2). Such an effect of this lipolytic hormone was also noted by Saggerson and co-workers (10,11) and was attributed to the inactivation of *sn*-glycerol-3-phosphate acyltransferase and Mg^{2+}-dependent phosphatidate phosphohydrolase. The glycerolipid formation from 2-monoacylglycerol continued at a normal rate in the presence of lipolytic hormone, in spite of the significant decrease in the synthesis of glycerolipids from *sn*-glycerol-3-phosphate.

The tissue fragments incubated with insulin did not show any effect on the glycerolipid formation from both 2-monoacylglycerol and *sn*-glycerol-3-phosphate (Experiment 2). However, the microsomal fractions obtained from diabetic animals showed a significant reduction in the rates of glycerolipid formation from *sn*-glycerol-3-phos-

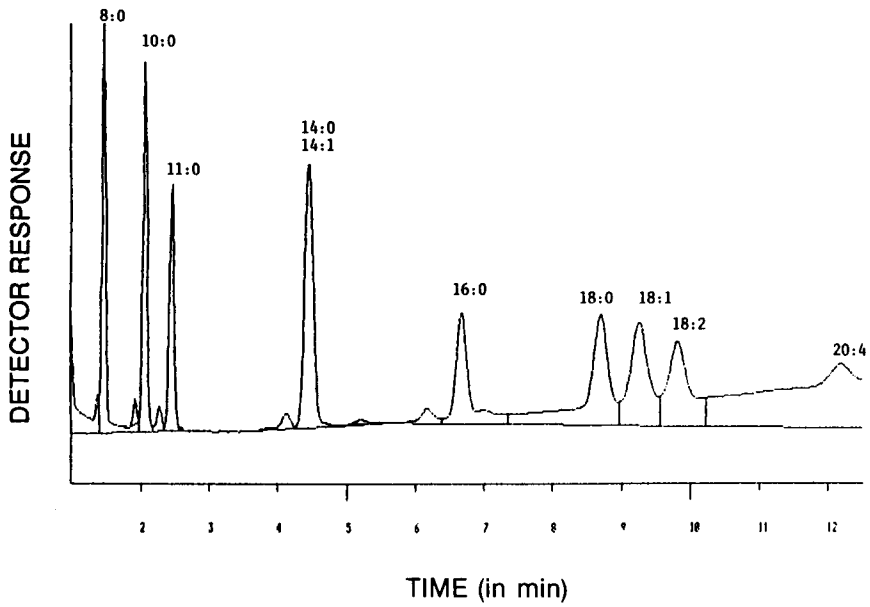

FIG. 1. Gas chromatographic (GC) separation of adipose monoacylglycerols. Adipose tissue monoacylglycerols were isolated and derivatized as described in Materials and Methods. A 2-μL aliquot (containing 250 ng of each monoacylglycerol species) was injected into the gas chromatograph and analyzed by flame-ionization detection. GC conditions: capillary column, 30 m × 0.53 mm i.d., 5 μm thickness, phase DB-1, and temperature program as described in Materials and Methods.

phate as noted previously (39), suggesting that insulin has a role in maintaining the optimal activity of glycerolipid formation from *sn*-glycerol-3-phosphate. Again, glycerolipid formation from 2-monoacylglycerol in diabetic animals continued at the same rate as in control animals. Thus, glycerolipid formation from 2-monoacylglycerol appears more resistant to changes in the hormonal and nutritional status of the animals, whereas glycerolipid formation *via sn*-glycerol-3-phosphate seems more responsive to changes in environmental conditions.

Besides in epididymal tissue, the MG pathway was also found operative in perirenal and subcutaneous adipose tissue of young and old animals (Table 2). However, the contribution of this pathway to glycerolipid formation differed from one adipose depot to the other. Glycerolipid formation from *sn*-glycerol-3-phosphate decreased in all the fat depots as the animals grew older, as noted previously (8), without any significant changes occurring in the rates of glycerolipid formation of 2-monoacylglycerol.

Monoacylglycerols serve as substrates for various enzymatic reactions, including MGAT, monoacylglycerol lipase and monoacylglycerol kinase. Therefore, in some experiments we measured the adipose monoacylglycerol concentration in rats under various hormonal and nutritional states (Table 3). As noted earlier (36), the accumulation of monoacylglycerols in adipose tissue was apparent and was increased further when adipocyte lipolysis was stimulated, *i.e.*, during fasting, refeeding and in diabetic animals, and was decreased when the lipolytic process was inhibited in the presence of insulin (40). Although changes in the monoacylglycerol content did not directly affect MGAT activity measured *in vitro*, the observed increases in the MG content during lipolysis could increase the rate of flux of these lipids *via* MGAT and enhance the recycling of endogenous monoacylglycerols by the MG pathway.

Our data show (Table 3 and Fig. 1) that rat adipose tissue contains both short- and long-chain monoacylglycerols, with some minor changes occurring under different hormonal and nutritional conditions. The most notable change in the composition of monoacylglycerol was apparent in the adipose tissue fragments which were incubated at 37°C for 1 h. The incubated adipose tissue contained very high amounts of 20:4 monoacylglycerols (as high as 80% of total) compared to the adipose tissue fragments, which were subjected to lipid extraction immediately following the excision of adipose tissue (in fed, fasted, refed and diabetic animals). The reason for the increase in 20:4 monoacylglycerol content, during incubation of adipose tissue at 37°C, is presently not clear. However, this increase does not seem to be hormonally related, since it occurred in all samples regardless of the presence of hormones. In addition to 10 monoacylglycerol species identified, the rat adipose tissue also contained three minor peaks of unidentified monoacylglycerols, which were eluted between 8:0 and 14:0 monoacylglycerols (data not reported).

In conclusion, a comparison of adipose glycerolipid formation from *sn*-glycerol-3-phosphate and from 2-monoacylglycerol provided evidence that the *sn*-glycerol-3-phosphate pathway is more active and responds more readily to changes in the hormonal and nutritional status of the animal. The maintenance of the optimal rates of glycerolipid formation from 2-monoacylglycerol, during impairment of glycerolipid formation from

TABLE 3

Effect of Nutritional and Hormonal States on Total Lipid and Monoacylglycerol Concentrations[a]

Nutritional and hormonal state	Total lipid μmoles/g	Monoacylglycerols nmoles/g	% Distribution of Monoacylglycerols of different chain lengths[b]

Multiple Inhibitory Effects of Garlic Extracts on Cholesterol Biosynthesis in Hepatocytes

Rolf Gebhardt*
Physiologisch-Chemisches Institut, University of Tübingen, D-2076 Tübingen, Germany

Exposure of primary rat hepatocytes and human HepG2 cells to water-soluble garlic extracts resulted in the concentration-dependent inhibition of cholesterol biosynthesis at several different enzymatic steps. At low concentrations, sterol biosynthesis from [^{14}C]acetate was decreased in rat hepatocytes by 23% with an IC_{50} (half-maximal inhibition) value of 90 μg/mL and in HepG2 cells by 28% with an IC_{50} value of 35 μg/mL. This inhibition was exerted at the level of hydroxymethylglutaryl-CoA reductase (HMG-CoA reductase) as indicated by direct enzymatic measurements and the absence of inhibition if [^{14}C]mevalonate was used as a precursor. At high concentrations (above 0.5 mg/mL), inhibition of cholesterol biosynthesis was not only seen at an early step where it increased considerably with dose, but also at later steps resulting in the accumulation of the precursors lanosterol and 7-dehydrocholesterol. No desmosterol was formed which, however, was a major precursor accumulating in the presence of triparanol. Thus, the accumulation of sterol precursors seems to be of less therapeutic significance during consumption of garlic, because it requires concentrations one or two orders of magnitude above those affecting HMG-CoA reductase. Alliin, the main sulfur-containing compound of garlic, was without effect itself. If converted to allicin, it resulted in similar changes of the sterol pattern. This suggested that the latter compound might contribute to the inhibition at the late steps. In contrast, nicotinic acid and particularly adenosine caused moderate inhibition of HMG-CoA reductase activity and of cholesterol biosynthesis suggesting that these compounds participate, at least in part, in the early inhibition of sterol synthesis by garlic extracts.
***Lipids 28,* 613–619 (1993).**

Long-term exposure of rats to water-soluble garlic extracts has been reported to result in decreased serum cholesterol and triglyceride levels (1). Similar observations were reported for rabbits with and without feeding cholesterol (2,3) as well as for other species (see Ref. 4). Recently, significant reduction in serum cholesterol after long-term intake of garlic powder tablets has been found for humans in double-blind crossover studies (5,6). Little is known as yet about the mechanism(s) and the active principle(s) responsible for these effects.

Primary cultures of rat hepatocytes provide a suitable model system for studies on the physiological regulation and pharmacological modulation of cholesterol biosynthesis and metabolism (7–13). Likewise, HepG2 cells have been used for characterizing hepatic cholesterol metabolism and its inhibition (14–16). Using rat hepatocyte cultures we have recently described inhibition of cholesterol biosynthesis by water-soluble garlic extracts (17). In the present study, we have carefully analyzed the concentration dependence of these effects and report on the interaction at different points during the biosynthetic pathway of cholesterol depending upon the concentration of the garlic extracts. In addition, the effect of garlic extracts and of some constituents on cholesterol biosynthesis in rat hepatocytes was compared with that in HepG2 cells.

MATERIALS AND METHODS

Materials. The garlic powder used (corresponding to Kwai®/Sapec®, Lichtwer Pharma, Berlin, Germany) is prepared immediately after harvesting of garlic cloves from central China. The garlic of this region is characterized by a very high content of sulfur-containing components. The water is removed from the fresh garlic cloves by careful air drying. The other components (such as alliin and the enzyme alliinase) are maintained in concentrated form in the garlic powder. The powder is standardized to an alliin content of 1.3% (18,19) and a capacity for liberation of allicin of 0.6%. The garlic powder, as well as pure, synthetic alliin (18) were provided by Lichtwer Pharma GmbH. These substances were kept dry at 4°C. Mevastatin, triparanol and ketoconazole were kind gifts from Dr. H.J. Kempen (TNO, Leiden, Netherlands).

[U-^{14}C]Acetate sodium-salt (1.9 GBq/mmol, 51.3 mCi/mmol) and RS-[2-^{14}C]mevalonic acid dibenzylethylenediamine salt (2.1 GBq/mmol, 56.7 mCi/mmol) for cholesterol biosynthesis, as well as [1-^{14}C]oleic acid (1.95 GBq/mmol, 52.6 mCi/mmol) and [4-^{14}C]cholesterol (2.2 GBq/mmol, 59.4 mCi/mmol) for the determination of enzyme activities were obtained from Amersham/Buchler (Braunschweig, Germany).

Collagenase (0.225 U/mg) was from Boehringer (Mannheim, Germany) and was used only from batches which proved suitable for the isolation of hepatocytes in our laboratory. Newborn calf serum was obtained from Sebio (Walchsing, Germany) or Serva (Heidelberg, Germany); Williams Medium E was from Flow Laboratories (Meckenheim, Germany). The Extrelut® 20-columns were from Merck (Darmstadt, Germany). All other chemicals were from Boehringer, Merck or Sigma (Munich, Germany).

Animals. Male Sprague-Dawley rats (220–270 g) were used as hepatocyte donors. They were kept in a controlled 12-h light/dark cycle on a standardized diet of Alma® H 1003 (Botzenhardt, Kempten, Germany) and tap water *ad libitum.*

Isolation and cultivation of rat hepatocytes. Rat hepatocytes were isolated according to the two-step collagenase perfusion technique previously described (20). Viability of the cells averaging to 93.2 ± 3.1% was routinely checked by staining with trypan blue.

Abbreviations: HMG-CoA reductase, hydroxymethylglutaryl-CoA reductase (EC 1.1.1.34); IC_{50}, the concentration for half-maximal inhibition; LDH, lactate dehydrogenase (EC 1.1.1.27); SI-TLC, silver-ion thin-layer chromatography.

Dedication: This article is dedicated to Prof. Dr. D. Mecke on the occasion of his 60th birthday.

The isolated hepatocytes were suspended in Williams Medium E containing 10% newborn calf serum, 2 mM glutamine, penicillin (50 units/mL), streptomycin (50 μg/mL) and 10^{-7} M dexamethasone (17). They were seeded in 2 mL of culture medium at a density of 1.25×10^5 cells/cm^2 into Petri dishes (ϕ 60 mm) precoated with a thin film of collagen (21) and were incubated at 37°C, 90% humidity and 7% CO_2. From 2 h on, serum-free medium was used.

Cultivation of HepG2 cells. The human hepatoma cell line HepG2 was maintained as monolayers as described (22). Confluent cultures were detached with 0.2% trypsin, suspended in medium containing 0.2% trypsin inhibitor and split 1:3 once a week. The cells were used between passages 40–70 (our laboratory). Incubations with garlic extracts were performed in the same serum-free medium used for hepatocytes.

Extraction of garlic powder. Garlic powder stored under dry conditions was extracted with doubly distilled water as described (17), carefully (<30°C) evaporated to dryness and redissolved in Williams Medium E (5 mL/g powder; initial weight). This stock solution was further diluted with Williams Medium E. All concentration data relate to the initial amount of garlic powder per extraction volume, since the amount of the dissolved material (approximately 80%) was not determined. Control media were made using doubly distilled water instead of the garlic extract.

Pure alliin was dissolved directly in Williams Medium E (1 mg/mL) and sterilized by filtration. Dilutions were always made with Williams Medium E. For preincubation with alliinase, alliin (1.66 mg/mL) was directly dissolved in a garlic extract of 5 mg/mL) and was incubated at room temperature for 20 min. These conditions should lead to the complete conversion of all added alliin to allicin (18). The mixture was then diluted 1:100 with Williams Medium E.

Incubation of the primary cultures with the extracts. Eighteen hours after inoculation of the hepatocyte cultures the medium was removed and fresh medium containing [^{14}C]acetate (18.5 KBq/mL; 0.5 μCi/mL), together with the appropriate dilutions of the garlic extracts or compounds to be tested, was added. After incubation at 37°C for 2 h, the medium was removed and the cell layer was washed twice with saline and scraped into 2 mL distilled H_2O. The cells were homogenized by sonication (20 s, grade 3, Ref. 20). In several experiments [^{14}C]-acetate was replaced by [^{14}C]mevalonate (9 KBq/mL, 0.24 μCi/mL).

Determination of acetate incorporation into and separation of nonsaponifiable neutral lipids. The incorporation of [^{14}C]acetate into nonsaponifiable neutral lipids was determined as described using Extrelut®-columns (large-pore kieselgur) for efficient separation (17). The neutral lipophilic nonsaponifiable substances were eluted with *n*-heptane (17). The precursors such as [^{14}C]acetate or [^{14}C]-mevalonate are retained on the column to more than 99%. For measurements of incorporation, the eluate was collected directly in scintillation vials and measured in the scintillation counter after addition of 10 mL of Ultima Gold® (Packard, Merident, CT). The yield of the elution step was 92% (86–95%). Recovery was determined using [^{3}H]cholesterol added to the initial samples. For determination of the newly synthesized sterol pattern, the eluate was evaporated to dryness in a vacuum concentrator (Desaga, Heidelberg, Germany), taken up in 50 μL chloroform and applied to silver-ion thin-layer chromatography (SI-TLC) plates which were developed once using a mixture of *n*-heptane/ethyl acetate (2:1, vol/vol) according to Pill *et al.* (23). With [^{14}C]mevalonate, a similar protocol was used.

Determination of cytotoxicity. Cytotoxicity of garlic extracts and inhibitors was determined by means of the leakage of lactate dehydrogenase (LDH) relative to the total activity of LDH after lysing the hepatocytes with 0.1% Triton X-100 as described (17).

Determination of enzyme activities. For the determination of enzyme activities, a liver homogenate (1:10 wt/vol) in 0.1 M potassium phosphate buffer (pH 7.4) containing 4 mM $MgCl_2$, 1 mM ethylenediaminetetraacetic acid and 2 mM dithiothreitol was prepared with a Dounce homogenizer (Braun Melrungen AG, Melrungen, Germany) from the liver of starved (24 h) rats and diluted 1:8. Either the $10000 \times g$ supernatant or the microsomal fraction was used for the measurements. For testing the garlic extracts, the extracts were added before the dilution step at such a concentration that the proper dilution was reached together with that of the enzyme activities. Enzyme activities were determined as follows: hydroxymethylglutaryl-CoA reductase (HMG-CoA reductase) according to Shapiro *et al.* (24) and fatty acid synthase according to Nepokroeff *et al.* (25). Protein was determined following the procedure of Lowry *et al.* (26).

Statistical evaluation. The IC_{50} values (the concentration for half-maximal inhibition) were determined from the dose response curves by use of curve fitting programs on a PC. The data were evaluated statistically using Student's *t*-test. Data are given as means ± SD.

RESULTS

Incubation of primary rat hepatocyte cultures with water-soluble extracts of garlic inhibited the incorporation of [^{14}C]acetate into the sterol fraction extracted from hepatocyte homogenates. Figure 1 illustrates the effect of concentration. Obviously, there is a strong inhibition above 10 mg/mL, although cytotoxic effects were not found below 125 mg/mL within the incubation period of 2 h (Table 1). Between 0.25 and 5 mg/mL, a plateau was observed which was characterized by a mean inhibition of about 23% (Fig. 1). At lower concentrations the inhibition decreased continuously and an IC_{50} value of approximately 90 μg/mL could be determined. In the presence of the well known inhibitor mevastatin, biosynthesis of nonsaponifiable lipids was inhibited by more than 90% at concentrations above 10^{-6} M.

Similar inhibitory effects by garlic extracts were seen with cultures of HepG2 cells. The range of cytotoxic concentrations was about the same (Table 1), while inhibition of sterol biosynthesis was somewhat more sensitive with an IC_{50} value of approximately 35 μg/mL and a maximal inhibition at the plateau phase of about 28% (Fig. 2). At high concentrations, inhibition with HepG2 cells was less pronounced than with rat hepatocytes.

If the radioactively labeled acetate was replaced by labeled mevalonate, the inhibitory effect of the garlic extracts, as well as that of mevastatin largely disappeared in both types of cells (Table 2) indicating that inhibition

occurs at some enzymatic step prior to the formation of mevalonate.

It is known that mevastatin exerts its inhibitory effect on the level of HMG-CoA reductase activity, and preliminary evidence suggested that the same holds true for garlic extracts (17). Therefore, the direct effect of garlic extracts on some enzymes of cholesterol and fatty acid metabolism was tested in detail using liver homogenates from fasted rats. For HMG-CoA reductase, a concentration-dependent inhibition was found starting at concentrations as low as 25 μg/mL (Fig. 3). Above 500 μg/mL inhibition plateaued at about 15% of total enzymatic activity. In the presence of 10^{-5} M mevastatin, almost complete inhibition of the enzyme activity was noted (not shown). Fatty acid synthase was also inhibited (Fig. 3). However, no significant inhibition was found below 100 μg/mL, while maximal inhibition by slightly more than 15% was reached above 1 mg/mL.

The effect of several compounds present in the garlic powder, namely alliin, nicotinic acid and adenosine, on sterol biosynthesis is shown in Figure 4. There was only slight inhibition at high concentrations of alliin (but not at low concentrations, *c.f.* Table 3). Nicotinic acid was shown to be somewhat more potent. Interestingly, adenosine inhibited sterol synthesis to a much greater extent and showed a biphasic concentration dependence similar to that shown by the extracts. After preincubation of alliin with alliinase (from a garlic extract of low concentration), *i.e.* after conversion to allicin (18), a slight inhibition was observed in HepG2 cells only (Table 3) indicating that allicin but not alliin might, under certain conditions, be an active principle. In accordance with this assumption, alliin did not significantly inhibit HMG-CoA reductase

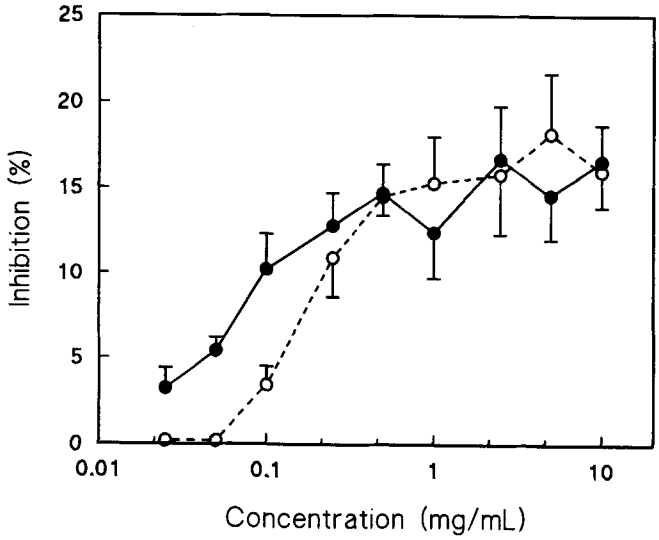

FIG. 3. Dependence of the inhibition of HMG-CoA reductase (● — ●) and fatty acid synthase (O--O) on the concentration of water-soluble garlic extracts. Values represent means ± SD of triplicate determinations.

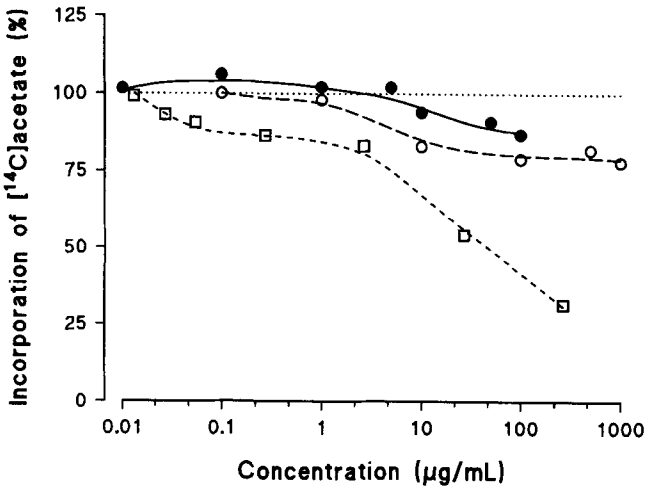

FIG. 4. Dependence of the incorporation of [^{14}C]acetate into nonsaponifiable lipids on the concentration of alliin (● — ●), nicotinic acid (O- - -O) and adenosine (□--□) in cultured rat hepatocytes. The dotted line indicates the control level. Data represent means of duplicate determinations.

in liver homogenates (Fig. 5). Nicotinic acid caused about 10% inhibition above 10 μg/mL. Interestingly, adenosine inhibited HMG-CoA reductase with even greater efficiency (Fig. 5).

When the sterol pattern produced by the rat hepatocytes was analyzed by SI-TLC, cholesterol was shown to be the main sterol formed (Fig. 6, A and B). The precursors lanosterol and 7-dehydrocholesterol amounted to 8 and 4%, respectively. In the presence of garlic extracts at concentrations above 0.5 mg/mL, a shift in the proportions of the sterols could be observed (Fig. 6A). Lanosterol and, to some extent, 7-dehydrocholesterol, increased at the expense of cholesterol indicating an inhibition at several steps during the conversion of lanosterol to cholesterol. The percentage of 7-dehydrocholesterol never exceeded

25% (relative proportion), because at higher concentrations inhibition of lanosterol metabolism predominated. No desmosterol was formed at all concentrations used [an indication to the contrary in a previous abstract (27) was due to inadvertent mislabeling of the respective figure]. With HepG2 cells similar results were obtained (Fig. 6B, Table 4), but pronounced accumulation of lanosterol required even higher concentrations of the extracts than with rat hepatocytes. The proportion of 7-dehydrocholesterol never exceeded 14%. Other (partially unidentified) precursors, presumably dihydrolanosterol (5α-lanost-8-ene-3β-ol), were observed in slightly greater percentages.

Direct addition of several garlic compounds revealed that neither alliin and nicotinic acid nor adenosine (Fig. 7) caused a shift in the composition of the sterol fraction produced by rat hepatocytes. However, when alliin was converted to allicin by preincubation with alliinase, a similar shift in the proportion of cholesterol, lanosterol and

7-dehydrocholesterol was found as with the garlic extracts (Fig. 7). Similar effects were observed with HepG2 cells (Table 4) or after incubation with mevalonate (not shown). In contrast, mevastatin did not change sterol composition in rat hepatocytes, but caused a considerable reduction of acetate incorporation into the sterol fraction only (Fig. 7). Triparanol and ketoconazole caused marked changes in the sterol composition that were considerably different from those observed with the garlic extracts. With the latter inhibitors, large proportions of desmosterol were formed (Fig. 7).

DISCUSSION

In the present study we report on multiple inhibitory effects of garlic extracts at several different steps (early and late) in the cholesterol biosynthetic pathway. The extent of inhibition depended strongly on the concentration of the extracts.

Firstly, inhibition of total sterol biosynthesis was recognized as a biphasic phenomenon caused mainly on the level of HMG-CoA reductase. The fact that rat hepatocytes and human HepG2 cells responded very similarly may indicate that the results are relevant for humans consuming fresh garlic or equally potent garlic preparations. Indeed, the degree of inhibition observed at low concentrations (25-30%) nicely reflects the decrease in cholesterol levels described for rat serum (1) as well as human serum (4,5). The high concentrations studied herein, which cause much stronger inhibition comparable to that by mevastatin, are not likely to be reached even during excessive consumption of garlic preparations.

Studies in which acetate was replaced by mevalonate and direct measurement of enzyme activities suggested that the garlic extracts exert their lowering effect essen-

tially through inhibition of HMG-CoA reductase. A similar inhibition with water-soluble extracts had previously been observed with the chicken liver enzyme (28). Which compounds contained in the extracts are responsible for this inhibition is not known. As shown in this study, nicotinic acid and adenosine may be among the candidates. The relative concentration of nicotinic acid in garlic extracts (approximately 4 μg/mL, estimated from Ref. 29), however, seems too low to account for the total inhibition observed with the garlic extracts. Adenosine, on the other hand, the concentration of which in garlic is higher (approximately 10 μg/mL, estimated from Ref. 29) seems to contribute to the inhibition of cholesterol biosynthesis in an indirect manner, since it is unlikely to enter the hepatocytes. Whether garlic extracts raise the intracellular adenosine level remains to be investigated. The contribution of alliin and its product allicin to the inhibition at the level of HMG-CoA reductase appears of minor importance, although the effect of allicin in HepG2 cells was significant. Thus, it seems most likely that other still unknown components may also be involved in the inhibition. Hepatocyte cultures may aid in further defining these active principles and their mode of action.

Secondly, exposure of rat hepatocytes or HepG2 cells to higher concentrations of garlic extracts resulted in a pronounced shift in the composition of the sterol fraction indicating inhibition at later stages of cholesterol biosynthesis. This inhibition led to the pronounced accumulation of lanosterol and, to a lesser extent, of 7-dehydrocholesterol. The latter compound represents 6-9% of total sterols in subcellular membranes of normal rats (30). The accumulation of lanosterol is comparable to the effect of ketoconazole, a known antimycotic, and of buthiobate which both have been found to inhibit the conversion of lanosterol to demethyllanosterol (14,15,31). Whether the same enzymatic step is inhibited by the garlic extracts remains to be investigated. On the other hand, the accumulation of 7-dehydrocholesterol seems much less than with other inhibitors such as *trans*-1,4-*bis*(2-chlorobenzylaminomethyl)cyclohexane dihydrochloride (32) and 4-(2-[1-(4-chlorocinnamyl)piperazin4-yl]ethyl)benzoic acid (10). This indicates that inhibition of 14α-demethylation by the garlic extracts might be much more pronounced than that of side-chain saturation. Desmosterol, which is known to cause adverse effects as a consequence of massive accumulation, was not formed in the presence of garlic extracts. Thus, side-chain saturation again appears less inhibited. In contrast, triparanol in our hepatocyte cultures gave rise to desmosterol which is in agreement with the known accumulation of desmosterol *in vivo*, particularly in the skin (33,34), as well as *in vitro* (15). Although the interference of garlic compounds with late stages of cholesterol biosynthesis is very interesting from the molecular point of view, it seems to be of minor therapeutic significance, because it requires concentrations one or two orders of magnitude above those affecting the early stage. These concentrations seem too high to be reached during normal and even long-term consumption of garlic preparations.

Neither nicotinic acid nor adenosine seem to be involved in the inhibition at late stages of cholesterol biosynthesis. However, there is some indication that allicin at high concentrations might be involved in this inhibition in both types of cells. Whether this effect is specific for this compound or is observed also with other garlic compounds derived from alliin, which contain sulfur- and allyl-groups, is currently being investigated.

It is concluded that defined compounds present in water-soluble extracts from garlic inhibit the biosynthesis of cholesterol in hepatocytes thus contributing to the reduction of serum cholesterol. The observed gap between the low concentrations inhibiting the early steps and the high concentrations required to inhibit the late steps in the synthetic pathway may aid in lowering cholesterol biosynthesis without accumulating undesirable cholesterol precursors.

ACKNOWLEDGMENT

The excellent experimental assistance of M. Fausel, A. Hanika, C. Mayer and M. Schütte is gratefully acknowledged. This investigation was supported in part by Lichtwer Pharma GmbH, Berlin.

The Esterification of Cholesterol in the Yolk Sac Membrane of the Chick Embryo

J.H. Shand[a], D.W. West[a,*], R.J. McCartney[b], R.C. Noble[b] and B.K. Speake[b]
[a]Hannah Research Institute, Ayr, KA6 5HL and [b]Scottish Agricultural College, Auchincruive, Ayr KA6 5HW, Scotland

The uptake of lipid from the yolk by the yolk sac membrane of the chick embryo is accompanied by the rapid esterification of a large proportion of the yolk cholesterol. This could arise from enhanced acyl-CoA:cholesterol acyltransferase (ACAT) activity and/or inhibition of cholesteryl ester hydrolase (CEH) activity. The activity of ACAT was therefore measured in microsomes obtained from yolk sac membranes at various stages of development. A high level of activity (up to 929 pmol of cholesteryl oleate formed per min per mg protein) was found during the second half of this period. Supplementation with exogenous cholesterol stimulated ACAT activity in microsomes obtained from the tissue at the earlier, but not at the later, stages of development suggesting that the enzyme became saturated with microsomal cholesterol as development proceeded. Correlating with this, the concentration of cholesterol in the microsomes increased 4-fold between 9 and 20 d of development. The activity of CEH was very low in the microsomes and could not be detected in the cytosolic fraction. The activity of a protein, which has been shown to function as an inhibitor of CEH, was found to be present at all stages of development. The high activity of ACAT, together with the low activity of CEH and an active CEH inhibitor protein is a combination well suited to promote an essentially unidirectional conversion of cholesterol to cholesteryl ester. This process may be a major determinant of the rate of lipid transfer from the yolk to the embryo. *Lipids 28,* 621-625 (1993).

The importance of yolk lipids as a source of energy, membrane components and essential fatty acids for the developing chick embryo is well recognized (1). During the early stages of development, the yolk becomes completely surrounded by the yolk sac membrane, a structure which is physically an extension of the embryo's hind-gut (1). This membrane mediates the transfer of nutrients from the yolk to the body of the embryo by absorbing lipids from the yolk and converting them into lipoproteins which are released into the embryonic circulation. In the yolk, cholesterol exists predominantly as the free sterol, but it is extensively (80%) esterified in the yolk sac membrane (1-3). This rapid conversion of yolk cholesterol into cholesteryl esters in the endodermal cells has led to the suggestion that the esterification of cholesterol is important for the formation and stability of the lipoproteins released into the circulation, and may be an important factor in determining the rate of lipid transfer from yolk to embryo (1-3).

Tissues which are very active in cholesterol metabolism, such as the liver and adrenal cortex, often have a high level of acyl-CoA:cholesterol acyltransferase (ACAT) (4,5). Furthermore, such tissues also contain appreciable levels of neutral cholesteryl ester hydrolase (CEH) activity (6-11) which reverse the effects of ACAT action. Thus the net rate of conversion of cholesterol to cholesteryl esters in the yolk sac membrane may be determined by the relative activities of ACAT and CEH at the appropriate subcellular sites in the endodermal cells.

The transfer of lipid to the chick embryo is particularly intensive during the final week of development (1), and this together with the high cholesteryl ester content suggests that the endodermal layer of the yolk sac membrane may contain a high level of ACAT linked to a more moderate CEH activity. To investigate this possibility, we have measured the activities of ACAT and of CEH in the relevant subcellular fractions of yolk sac membranes obtained from embryos at various stages of development. In addition, the activity of a cytosolic protein, which we have recently identified (12,13) and which apparently functions as a physiological inhibitor of CEH, was also measured. Consistent with the role of the yolk sac membrane in converting yolk cholesterol to cholesteryl esters as part of the intensive lipid transfer process, the activities of the relevant enzymic systems in this tissue were found to be very strongly directed toward esterification, with very little propensity for cholesteryl ester hydrolysis.

Some aspects of this work have been previously published in the form of a conference abstract (14).

MATERIALS AND METHODS

Embryos. Fertile eggs from broiler-breeder hens were obtained from commercial poultry suppliers and incubated at 37.8°C and 60% relative humidity in a forced-draught incubator with automatic egg turning. Three separate experiments were performed, and at each developmental stage studied, four replicate groups, each consisting of four yolk sac membranes, were washed free of yolk in ice-cold 0.88% (wt/vol) NaCl and were rapidly frozen in liquid nitrogen. These samples were subsequently used for the determination of the activities of ACAT, CEH and the CEH-inhibitor protein, and for the measurement of microsomal cholesterol and cholesteryl ester levels. Additional samples of yolk sac membrane and yolk were collected, stored at −20°C and subsequently used for the analysis of whole tissue lipid composition.

Lipid analysis. Samples of yolk and of intact yolk sac membrane were homogenized in a suitable excess of chloroform/methanol (2:1, vol/vol), and total lipid extracts were prepared (15). Lipids were separated into their major classes by thin-layer chromatography on silica gel G (Merck, Darmstadt, Germany) using a solvent system of hexane/diethyl ether/formic acid (80:20:1, by vol). Following transmethylation (15), the fatty acid composition of the major lipid classes was determined by gas-liquid chromatography on a packed column of 15% CP Sil 84 on Chromosorb WHP (Chrompak, Middleburg, The Netherlands) in a Packard (Middleburg, The Netherlands) model 428 Gas Chromatograph. The relative proportions of the fatty acids present and the amount of lipid associated with each lipid class were quantified with a

Tissue fractionation. A homogenate was prepared from washed, frozen yolk sac membranes, using the method described for liver by Shand and West (12), and centrifuged at 10,000 × *g* for 15 min. The resulting supernatant was then centrifuged at 100,000 × *g* for 30 min, and the clear cytosol below the floating fat layer was retained. The 100,000 × *g* microsomal pellet was washed in fresh homogenization buffer, centrifuged for a further 30 min at 100,000 × *g* and finally resuspended in 50 mM 2-(*N*-morpholino)ethanesulfonic acid (MES) and 50 mM *tris*-(hydroxymethyl)aminomethane (TRIS)/HCl buffer pH 7.2. Aliquots of the cytosols were converted into acetone/diethyl ether powders as already described (12). Further samples of cytosol were delipidized by treatment with the lipophilic Sephadex derivative, hydroxyalkoxypropyl dextran (Sigma, Poole, United Kingdom) (16) for 10 min at 0°C at a concentration of 2% (wt/vol). The lipophilic dextran was removed by centrifugation and the process repeated once.

Enzyme assays. ACAT was assayed with and without the addition of exogenous cholesterol (250 μg/mL) as a suspension in Triton WR-1339 as previously described (17) except that the incubation time was limited to 5 min to ensure linearity. Neutral CEH was measured in microsomes and cytosol essentially according to Shand and West (12) using 50 μg protein incubated for 45 min with high specific activity substrate (cholesteryl [9,10-^{3}H]oleate, 1.6 × 10^6 dpm, 20 nmol). Cytosols were assayed for CEH in the presence of 0.2% sodium taurocholate before and after delipidation.

Assay of the CEH inhibitor protein. Acetone/diethyl ether powders of the yolk sac membrane cytosols were extracted with 50 mM MES, 50 mM TRIS/HCl buffer pH 7.2 and the extracts assayed for inhibitory activity against the rat mammary microsomal CEH by a modification of the method described by Shand and West (12). Briefly, an ethanolic solution of cholesteryl [9,10-^{3}H]oleate (250,000 dpm, 20 nmol) was added to a suspension of the inhibitory protein (0.2–0.4 μg) in the extraction buffer. After preincubation at 37°C for 5 min, the reaction was started by the addition of a solution of bovine serum albumin (0.2 mg) containing the mammary microsomal suspension (100 μg). After a 20-min incubation period, the reaction was stopped and the extent of ester hydrolysis determined.

Estimation of microsomal cholesterol and cholesteryl esters. Lipids were extracted (18) from the microsomal suspensions and redissolved in ethanol. Free and total cholesterol were assayed in the ethanolic solution by the fluorimetric method of Gamble *et al.* (19) and the esterified cholesterol estimated by difference.

Protein measurement. Protein concentrations in microsomal suspensions and in reconstituted cytosolic acetone powders were assayed by the dye-binding method of Bradford (20).

RESULTS

Comparison of the lipid composition of the yolk and yolk sac membrane. The conversion of yolk cholesterol to cholesteryl ester following uptake of lipid by the yolk sac membrane is illustrated in Table 1. Approximately 80% of total yolk cholesterol is present as the unesterified sterol, with only 20% as the ester. In agreement with previous results (1), these proportions are effectively reversed in the yolk sac membrane, where over 80% of the total cholesterol content is present in the esterified form.

TABLE 1

Lipid Composition of Yolk and Yolk Sac Membrane at Day 14 or Development[a]

Lipid class	Yolk	Yolk sac membrane
Cholesterol	5.4 ± 0.2[b]	1.3 ± 0.1
Cholesteryl ester	1.3 ± 0.1[b]	5.6 ± 0.3
Triacylglycerol	67.4 ± 0.4	67.8 ± 1.2
Phospholipid	25.2 ± 0.3	23.8 ± 1.1
Free fatty acid	0.7 ± 0.1	1.1 ± 0.1
Total lipid content	31.3 ± 0.2	30.8 ± 0.9

[a]Each lipid class is expressed as percentage (wt/wt) of total lipid. Total lipid content is expressed as percentage (wt/wt) of wet tissue. The results are means ± SEM from five separate experiments. Significant differences (Student's *t*-test) between lipid compositions of yolk and yolk sac membrane.
[b]$P < 0.001$.

Activity of ACAT levels of cholesterol and cholesteryl esters in the yolk sac membrane during development. The yolk sac membrane contained high levels of ACAT activity throughout the later developmental period (Table 2). Compared to values reported for various mammalian tissues (17,21–23), the enzyme was already highly active at day 9, but this value was increased nearly 3-fold by day 16. This increase in ACAT correlated with the period of maximal uptake of yolk lipid by the yolk sac membrane (1). The activity of ACAT then decreased (from 929 ± 56 to 592 ± 13 pmol cholesteryl oleate formed per min/mg protein) with the approach of hatching. ACAT activity was increased by the addition of exogenous cholesterol, with the greatest stimulation, approximately 2-fold, occurring at days 9 and 12. Less stimulation was observed at the later stages of development, suggesting that the enzyme in the microsomes may have been approaching saturation

TABLE 2

ACAT Activities in Microsomes Isolated from Yolk Sac Membranes of Embryos During Development[a]

	Cholesteryl oleate formed (pmol/min/mg protein)	
Days of development	Endogenous cholesterol	Exogenous cholesterol
9	326 ± 42[b]	696 ± 72[c]
12	550 ± 71[b]	1100 ± 115
14	720 ± 57[c]	1023 ± 77
16	929 ± 56	1162 ± 49
20	592 ± 13[b]	693 ± 40[c]

[a]Acyl-CoA:cholesterol acyltransferase (ACAT) activities were determined in microsomes obtained from four replicate samples, each consisting of four yolk sac membranes. Exogenous cholesterol was added to the assay mixture as a dispersion in Triton WR1339 to give a final concentration of 250 μg/mL. The data are from one experiment, typical of the three performed, and are the means ± SEM for the four replicate samples. Significant differences from day-16 values were determined by one-way analysis of variance using Fisher's least significant difference test.
[b]$P < 0.001$.
[c]$P < 0.01$.

TABLE 3

Cholesterol and Cholesteryl Ester Content of Yolk Sac Membrane Microsomes[a]

Days of development	Cholesterol (μg/mg microsomal protein)	Cholesteryl ester (μg/mg microsomal protein)
9	26.7 ± 2.5	13.9 ± 1.1
12	33.8 ± 2.0	17.2 ± 1.1
14	37.3 ± 4.1	20.7 ± 1.5
16	60.6 ± 4.8[b]	31.0 ± 2.2[b]
20	102.3 ± 9.8[b]	68.2 ± 7.5[b]

[a]Cholesterol and cholesteryl ester content of microsomes were determined in replicate samples, each derived from four yolk sac membranes. The results are from one experiment, typical of the three performed, and are the means ± SEM of four replicate samples. Significant differences from day-9 values were determined by one-way analysis of variance using Fisher's least significant difference test.
[b]$P < 0.01$.

TABLE 4

The Activities of Microsomal CEH and the CEH-Inhibitor Protein in the Yolk Sac Membrane During Development[a]

Days of development	Microsomal CEH (pmol/min/mg protein)	CEH Inhibitor (% inhibition by 200 ng protein)
9	12.9 ± 1.8	25.8 ± 1.2[b]
12	16.7 ± 1.3	39.3 ± 2.7
14	16.4 ± 0.9	37.1 ± 3.1
16	15.5 ± 1.0	23.6 ± 2.0[b]
20	12.5 ± 0.8	22.4 ± 1.4[b]

[a]The activities of cholesteryl ester hydrolase (CEH) and the CEH-inhibitor protein were determined in the microsomal and cytosolic fractions, respectively, prepared from replicate samples, each consisting of four yolk sac membranes. The results are from one of the three experiments and are the means ± SEM of four replicate samples. Significant differences from day-12 values were determined by one-way analysis of variance employing Fisher's least significant difference procedure.
[b]$P < 0.01$.

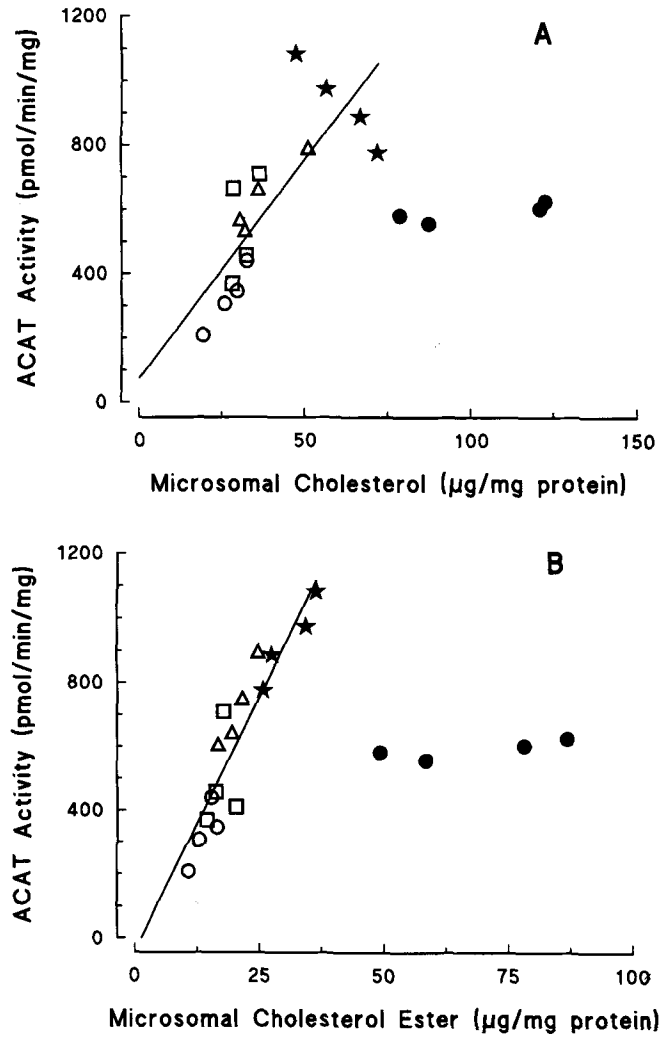

FIG. 1. Scatter diagrams relating acyl-CoA:cholesterol acyltransferase (ACAT) activities, assayed with endogenous cholesterol, to microsomal contents of cholesterol (A) and cholesteryl ester (B). Linear regression analysis was performed on data from day 9 (○), day 12 (□), day 14 (△) and day 16 (★), but data from day 20 (●) were not included. The relationships were linear for both ACAT *vs.* cholesterol (y = 13.63x + 73.33, r = 0.84) and ACAT *vs.* cholesteryl esters (y = 32.89x − 66.45, r = 0.92).

with cholesterol. In support of this concept, the concentration of the endogenous microsomal cholesterol increased almost 4-fold between days 9 and 20 of development (Table 3). A concomitant increase in the microsomal esterified cholesterol was also observed over the same period. ACAT activity was highly correlated with microsomal cholesterol (Fig. 1A) and cholesteryl ester (Fig. 1B) between days 9 and 16 (r = 0.84 and 0.92, respectively), but the correlation coefficient was much lower (r < 0.45) when the day-20 results were included.

Activities of microsomal CEH and the CEH-inhibitor protein in the yolk sac membrane. The microsomal CEH activity was less than 2% of the maximum ACAT activity at each stage studied (Table 4). Moreover, this low enzymic level did not vary significantly over the period of highest yolk lipid mobilization. There was an apparent decrease in activity between days 16 and 20 but this was not significant. Cytosolic CEH activity was undetectable, both before and after delipidation of the cytosols, even when measured in the presence of taurocholate to prevent inhibitor activity (data not shown). In contrast, the cytosolic CEH-inhibitor protein was active throughout the developmental period exhibiting peak activity at day 12 when 200 ng of cytosolic protein caused over 39% inhibition of the mammary microsomal CEH. Inhibitory activity was significantly higher at days 12 and 14 than at the beginning and end of the development period studied (Table 4).

Fatty acid composition of the cholesteryl esters of the yolk sac membrane. Previous studies have established that cholesteryl oleate is the major species of esterified cholesterol synthesized in the yolk sac membrane (1). The data presented in Table 5 show that the proportion of oleic acid increased from approximately 48% at days 9 and 10 to approximately 77% at day 20, indicating that the fatty acid profile of the cholesteryl esters was altered during development.

DISCUSSION

During the final week of chick embryo development, lipid is transferred from the yolk at an average rate of over 500

TABLE 5

Fatty Acid Composition of Cholesteryl Ester in the Yolk Sac Membrane[a]

Fatty acid	Percentage (wt/wt) of total fatty acids		
	Day 9,10[b]	Day 14	Day 20
16:0	11.7 ± 2.2	6.2 ± 0.6	3.3 ± 0.1[c]
16:1	1.6 ± 0.2	1.4 ± 0.4	1.2 ± 0.1
18:0	6.8 ± 1.3	4.7 ± 0.1	3.9 ± 0.1
18:1	47.7 ± 3.6	66.1 ± 1.5[c]	76.9 ± 0.5[d]
18:2	18.6 ± 2.4	17.1 ± 1.8	12.3 ± 0.3
18:3	3.1 ± 2.3	1.5 ± 0.2	1.2 ± 0.1
20:4	2.9 ± 0.1	1.6 ± 0.2[c]	0.6 ± 0.2
22:6	6.1 ± 0.4	n.d.[e]	0.7 ± 0.3[f]

[a]The fatty acid composition of the cholesteryl ester isolated from yolk sac membrane was determined as described in the Materials and Methods section. Only the major fatty acids are shown. The results are means ± SEM of three separate experiments. Significant differences were determined by Student's *t*-test and show differences from day-9,10 values.
[b]In two of the experiments, samples were taken at day 9, whereas in the third experiment the sample was taken at day 10.

[d]$P < 0.01$.
[e]n.d. = not detectable.
[f]$P < 0.001$.

mg per day (1). Over this period the endodermal cells of the yolk sac membrane are highly active in vesicular translocation events involving phagocytosis of yolk contents at the apical surface and the subsequent exocytosis of lipoprotein particles at the basal surface (1,24). The evidence that triacylglycerols and phospholipids are subject to extensive hydrolysis and re-esterification following uptake (1,3) implies that this tissue is also highly active in the biochemical processes involved in the reassembly of lipids and their packaging into lipoprotein particles. In addition, previous work has shown that, within the endodermal cells, yolk lipid is subjected to certain biochemical transformations involving fatty acid desaturation and elongation (1,2). However the most dramatic change in lipid metabolism which occurs during translocation across the endodermal layer is the conversion of the major portion of yolk cholesterol to cholesteryl ester (Refs. 1,2 and Table 1). The present study has demonstrated a corresponding increase in ACAT activity in the yolk sac membrane over the same period.

Measurement of microsomal ACAT activity in the presence of endogenous cholesterol reflects the amount of sterol substrate present in the microsomes, whereas maximal enzyme activity can only be measured in the presence of saturating concentrations of substrate, usually supplied exogenously (25). The results obtained under these two conditions (Table 2), considered in association with the changes in cholesterol content of the microsomes (Table 3), indicate that the increase between day 9 and day 12 and the decrease between day 16 and day 20 are due to alterations in the total activity of the enzyme present (Table 2). In contrast, the change in ACAT activity that occurs from day 12 to day 16 is predominantly due to increases in microsomal cholesterol content (Tables 2 and 3). This corresponds to the period during which the uptake of lipid by the tissue is most rapid. Taken together, the results indicate that the potential for cholesterol esterification in the yolk sac membrane increases between days 9 and 16, due both to an elevation in the activity of ACAT and to the increasing supply of substrate to the enzyme. The decrease in ACAT activity at day 20 occurs despite the presence of abundant endogenous cholesterol. This is reflected in the poor correlation shown between ACAT activity and microsomal cholesterol content at this point (Fig. 1A). Although the reason for this is not clear at present, it is unlikely to be due to inhibition by the large amount (68.2 ± 7.5 μg/mg microsomal protein) of cholesteryl ester present, since addition of cholesteryl oleate (100 μg/mg microsomal protein) gave no evidence of inhibition (data not shown).

The activities of ACAT, reported here for the yolk sac membrane (Table 2) are high in comparison with previously published values for various mammalian tissues. For example, the activities reported for tissues which are not regarded as major sites of cholesterol esterification, such as the mammary gland, heart, brain and pancreas, are generally less than 1% of the activity observed in the yolk sac membrane at day 16 (17,26,27). Even tissues which are actively involved in cholesterol metabolism, such as liver, intestine, ovary and adrenal cortex, typically express levels of ACAT which are less than 20% of those reported here for the yolk sac membrane (21–23,25,28,29). However, in this latter group of tissues, conditions which increase the requirement for cholesterol esterification, such as the feeding of excess cholesterol (27,28,30) or, in the case of the ovary, luteinization (31), elevate ACAT activity to values approaching those of the yolk sac membrane. It is clear that the levels of ACAT expressed in the yolk sac membrane are similar to the highest values so far reported in other systems. In contrast to ACAT, the activity of microsomal CEH was low throughout the developmental period (Table 4). This activity would have been further diminished *in vivo* by the CEH-inhibitory activity present at all of the stages studied (Table 4). Cytosolic CEH activity could not be detected nor was there any evidence for translocation of the putative cytosolic CEH to the "fat cake," as has been reported for hormone sensitive lipase in adipocytes (32), since no activity could be detected either before or after delipidation. Thus, the capacity to hydrolyze cholesteryl esters formed by ACAT was extremely low, suggesting that the relevant enzyme systems in the yolk sac membrane were very strongly directed to the net esterification of incoming cholesterol.

Cholesterol oleate is the major species of cholesteryl ester produced in the yolk sac membrane (1,2), and high levels of this ester also accumulate in the embryo liver (1–3). It is nevertheless clear that the total amount of cholesteryl oleate in the yolk sac membrane increases throughout development. This may reflect either an increase in the specificity of ACAT for oleoyl-CoA, arising from covalent modifications or noncovalent interactions of the enzyme or, more likely, an increased availability of oleic acid due to the action of Δ9 desaturase in this tissue (1,2).

The high proportion of unesterified cholesterol that is found in the yolk is a direct consequence of the mechanism of yolk formation in the laying hen, as discussed by Griffin (33). Yolk lipid is derived from very low density lipoprotein (VLDL) particles secreted by the liver of the laying hen which are not only much smaller than those found

in the immature bird but also have a different apoprotein profile so that they are directed specifically to the ovarian follicle (33). These unusually small VLDL particles have a high surface-to-volume ratio and, since cholesterol is a surface component of such particles while cholesteryl esters are located in the core, this results in a high proportion of cholesterol to cholesteryl esters in the lipoproteins deposited in the ovum. Excess cholesterol is deleterious to membrane function, and cells usually maintain a remarkably constant level of free cholesterol, storing the excess in the esterified form. The influx of the large amount of yolk cholesterol into the endodermal cells of the yolk sac membrane could therefore be potentially damaging if the cellular metabolism could not esterify the excess sterol. It is clear, from the results presented here, that the endodermal cells do adapt by enhancing their effective ACAT activity during the period of most rapid cholesterol transfer. This could arise either from activation of existing enzyme molecules or by an increase in the amount of enzyme protein, although evidence to decide between these two possibilities is not currently available.

Apart from the function of storage, there is also more recent evidence that the production of cholesteryl esters may be an obligatory stage in the assembly of stable lipoproteins (33,34). Cholesteryl esters are synthesized by ACAT at the cytoplasmic face of the endoplasmic reticulum. They are extremely hydrophobic and have been shown to accumulate initially between the leaflets of the endoplasmic reticulum bilayer (35). Nascent apoprotein B is also bound co-translationally to the luminal leaflet of the same subcellular organelle, and it has been proposed that it is only released into the cisternal space following interaction with cholesteryl ester (36). A parallel reduction in the secretion of both cholesteryl esters and apoprotein B was observed when hepatic VLDL production was inhibited by lovastatin (33), and this would also support the idea that their secretion was coupled.

Thus, it appears that the assembly of stable lipoprotein particles may be directly linked to the production of cholesteryl esters, suggesting that in the yolk sac membrane cholesterol esterification may be an important determinant of lipid transfer to the embryo. High pre-hatch mortality in eggs from "young parent" chickens may be related to impaired lipid transfer in the embryo (1,2), and investigations into the efficiency of esterification in such embryos are currently in progress.

ACKNOWLEDGMENT

Nervonic Acid in Red Blood Cell Sphingomyelin in Premature Infants: An Index of Myelin Maturation?

F. Babin[a], P. Sarda[b], B. Limasset[a], B. Descomps[c,*], D. Rieu[b], F. Mendy[d] and A. Crastes de Paulet[a]

[a]Laboratoire de Biochimie A, Institut de Biologie, 34000 Montpellier, [b]Hôpital St-Charles, Service de Pédiatrie II, 34059 Montpellier Cedex, [c]INSERM U.58, 34090 Montpellier and [d]Cetiom-Onidol, Paris, France

The present study addresses the question whether nervonic acid (24:1n-9) accumulation in sphingomyelin (SM) of red blood cells (RBC) could yield information on cerebrum maturation in premature infants. The study included 28 premature eutrophic infants of 31.5 wk gestational age. Eleven were fed with human milk, nine with a regular formula and eight with an α-linolenate-enriched formula. The fatty acid composition of the SM fraction was determined by gas–liquid chromatography on a 50-m fused silica capillary column. At 32 wk gestational age, the main fatty acids in SM were 16:0, 18:0, 20:0, 22:0, 24:0 and 24:1n-9. After five weeks of feeding, at week 37 of postconceptional age, the most striking variation was a rise in 24:1n-9, from 9.9 ± 0.7 to 12.8 ± 0.9 ($P < 0.02$), regardless of regimen in all three feeding groups. The rise in 24:1n-9 after birth in premature eutrophic infants is the beginning of a trend toward the higher levels in 24:1n-9 observed in mature newborns and older infants. The 24:1n-9 level in SM of RBC from premature infants may reflect 24:1n-9 levels in SM of brain and could thus reflect brain maturity.
Lipids 28, 627–630 (1993).

In recent years, the need for n-3 polyunsaturated fatty acids (PUFA) in early brain development has been pointed out by many investigators (1–6). However, few studies have been devoted to the metabolism and the role of nervonic acid (24:1n-9) which, together with lignoceric acid, constitutes the major long chain fatty acid of myelin. Accumulation of these two acids may reflect the increase in myelin during gestation in animals (7) and in humans (8). Nervonic acid, which is synthesized by elongation of oleic acid (9), is also characteristic of the sphingomyelin (SM) of red blood cells (RBC) and is one of the four major fatty acids of this lipid fraction in adults (10,11) and in infants (12).

The only data on nervonic acid distribution in infant RBC had previously been obtained on full-term newborns (12) during the first few hours after birth (13) and during the first month of life (14). The present work was undertaken to investigate whether, in premature infants, nervonic acid might accumulate in SM of RBC as in the cerebrum and thus reflect maturation. It compared three different types of milk-feeding (human, regular formula and α-linolenate-enriched formula) on PUFA metabolism in premature infants. The results suggest that nervonic acid in SM of RBC could indeed be used as an index of maturation in premature newborns.

MATERIALS AND METHODS

The study included 28 premature eutrophic infants (11 males and 17 females) admitted to the Neonatal Department of the Regional Hospital Center of Montpellier for nutritional assessment and treatment. Mean gestational age was 31.5 wk (29 to 33) and mean birthweight 1630 g (1270–1980 g). Eleven infants were fed human milk, nine received regular formula feeding (Pregallia), and eight an α-linolenate-enriched formula (enriched Pregallia). Both formulas were from Nutripharm (Levallois-Perret, France). The α-linolenic acid-enriched formula was obtained by isocaloric partial substitution of fats with colza oil [low-erucic acid rapeseed (LEAR) oil; Codex Alimentarius, Canadian General Standard Board, 1987] from Nutripharm. The fatty acid distribution in percent weight of total diet fatty acids for stearic, oleic, linoleic and α-linolenic acids was 5.05, 25.50, 12.50 and 0.55, respectively, in the regular formula and 5.25, 30.25, 12.50 and 1.95, respectively, in the enriched formula. The percent composition in stearic and oleic acids (the main precursors of nervonic acid) was not very different from that in human milk from the Montpellier lactarium (8.10, 34.90, 12.65, 1.10 for stearic, oleic, linoleic and α-linolenic acids, respectively). Informed consent was obtained from parents and the protocol of the study was approved by the Regional Hospital Center Ethics Committee. Three blood samples were obtained from each of 25 infants at 2 (D_2) and 15 d (D_{15}) of milk-feeding, and the third one (Dterm, the equivalent of full-term) at 37 wk postconceptional age. Two infants discontinued participation in the study before Dterm and one was enrolled after D_2.

Lipid analyses. Blood was collected in Na-heparinized glass tubes. An aliquot was taken for hematocrit measurement in order to determine the precise volume of blood corresponding to 200 μL of RBC pelleted under these conditions. The fatty acid composition of SM could thus be expressed as μg of each fatty acid per mL of RBC.

After centrifugation (2000 rpm for 10 min) the RBC pellet was washed by resuspending and centrifugation in isotonic saline solution containing 1 mM ethylenediaminetetraacetic acid (EDTA). The RBC lipids were extracted according to the method of Folch *et al.* (15) using a chloroform/methanol mixture containing 1 mM butylated hydroxytoluene (BHT) (Sigma Chimie, St-Quentin-Fallavier, France) as an antioxidant. Chloroform, pure analytical grade, was from SDS (Peypin France) and methanol from Prolabo (Paris, France). The extract was left to evaporate until dry under a nitrogen stream and the residue was redissolved in a minimal quantity of chloroform/methanol mixture (1:1, vol/vol) for thin-layer chromatography on Silica gel 60 F_{254} (Merck, Darmstadt, Germany) using chloroform/methanol/H_2O (65:25:4, by vol) as developing solvent (16), to which BHT (1 mM) was added.

The phospholipid fractions were visualized at 250 nm after spraying with 0.2% 2′,7′-dichlorofluorescein in ethanol (Merck). SM was identified by comparison to known standard (Sigma Chimie).

The silica gel bands containing SM were scraped off and 7.5 μg (125 μL of a methanol solution) of free heneicosanoic acid 21:0 (Sigma Chimie) was added as an internal

Abbreviations: BHT, butylated hydroxytoluene; EDTA, ethylenediaminetetraacetic acid; LEAR oil, low-erucic acid rapeseed oil; PUFA, polyunsaturated fatty acids; RBC, red blood cells; SM, sphingomyelin.

standard. The fatty acids were transesterified with sulfuric acid in methanol (1:19, vol/vol) at reflux. The methyl esters were extracted with hexane and analyzed by gas-liquid chromatography (17) with the following modification: a fused silica capillary column (50 m × 0.32 mm) CP Sil 88 from Chrompack (Les Ullis, France) was used on a Fractovap 2900 Chromatograph (Erba Science, Massy, France). The temperatures were: ionization detector, 250°C; inlet, 230°C; oven program, 10°C/min from 100 to 170°C and 2°C/min from 170 to 200°C.

The amount of each fatty acid was calculated by reference to the internal standard of 21:0 using an ENICA-21 integrator (Delsi France, Argenteuil, France). Results are expressed ± SEM, and Student's paired *t*-test was used for statistical analysis.

RESULTS

The fatty acid composition of SM of premature infant RBCs is reported in Table 1. Results are expressed both as a percent distribution of individual fatty acids and as μg per mL of RBC. The main variation over time concerns nervonic acid (24:1n-9)—a significant rise is observed from 9.9 ± 0.7 to 12.8 ± 0.9 percent between D_2 and Dterm ($P < 0.02$), which is compensated for by small declines in percentages of 16:0 and 18:0. Similar observations can be made when the results are expressed as μg of each fatty acid per mL of RBC. Whereas the total amount of SM fatty acid decreased between D_2 and Dterm, the mean concentration of nervonic acid rose from 29.8 ± 3.6 to 34.4 ± 3.4, reflecting an increased contribution of this acid to the total fatty acid content of SM in RBC during this period.

Figure 1 shows the time course of the variations in percent nervonic acid in the SM of the RBC of each infant. There is an overlap zone ranging from 5 to 15% between values at D_2 and Dterm, but about 80% of the infants

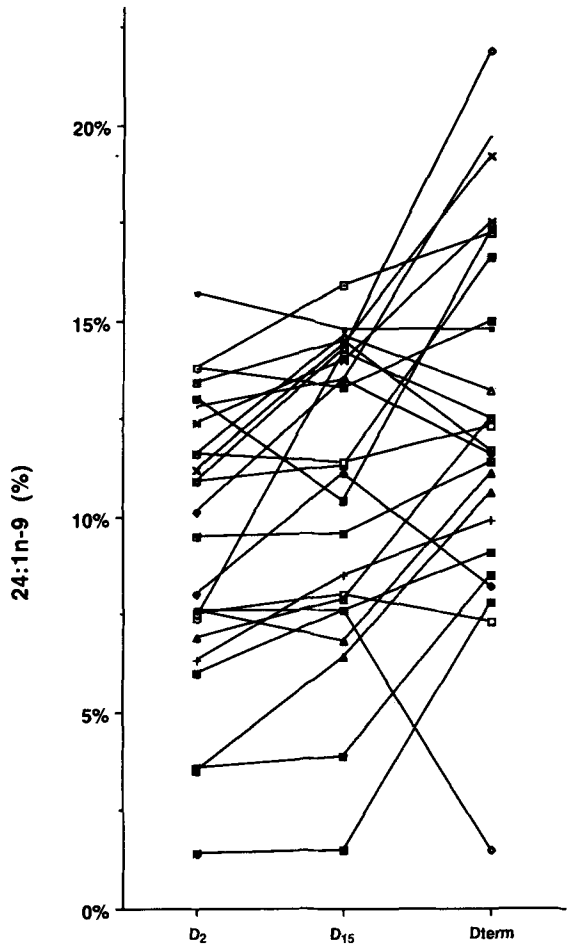

FIG. 1. Time course of the variation in percent nervonic acid in sphingomyelin of red blood cells from 28 premature infants between birth (wk 32 of gestation) and the wk 37 postconceptional age. Abbreviations as in Table 1.

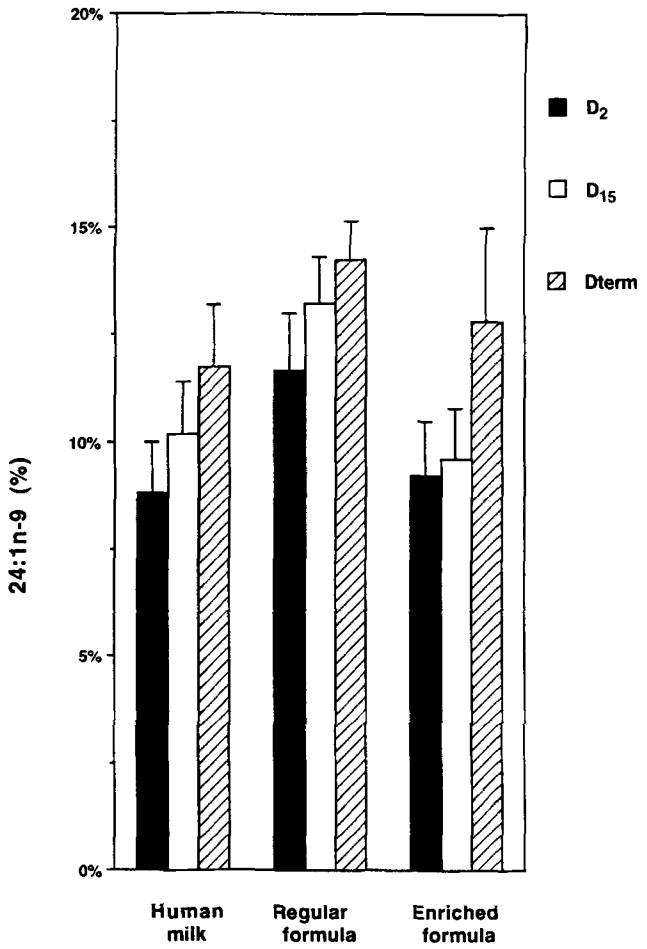

FIG. 2. Time course of the variation in percent nervonic acid in sphingomyelin of red blood cells from three groups of premature infants fed human milk, regular formula and α-linolenate-enriched formula. D_2 and D_{15} correspond to 2 and 15 d of feeding and Dterm to 37 wk postconceptional age.

experienced an increase. In two patients, the pattern was atypical. In the first case, the level, which was 7% on D_2 and D_{15}, drastically declined to 1% at Dterm. In the second case, where the mother had undergone treatment for a pre-eclamptic syndrome, the level rose from 1% (D_2-D_{15}) to 7% (Dterm).

In Figure 2, the infants are considered as a function of their feeding (human milk, regular formula feeding or α-linolenic colza oil-enriched formula feeding). Mean percent nervonic acid increased progressively between D_2 and Dterm in the three groups, suggesting that this increase is independent of the type of feeding (milk or formula feeding).

DISCUSSION

A comparison of the fatty acid composition of the brain of precocial and nonprecocial species has revealed considerable variations in the proportions of nervonic acid around full-term (18). In the guinea pig (precocial species), the main rise (fivefold) in nervonic acid is observed during the 25 d before birth, whereas in the rat (nonprecocial species) it occurs between birth and adulthood (fourfold). In humans, born at term, brain development is accompanied by an approximately 10% increase (15.1-26.4%) in total brain cerebrosides nervonic acid levels and a 15% increase (13.0-28.0%) in sulfatides that occur between birth and two months. Maximum levels are being reached at four years (about 43%) and then remain almost constant until and throughout adulthood (19). This accumulation in brain nervonic acid is related both to an increase in the relative abundance of myelin *vs.* gray matter and to a specific increase in the actual percentage of nervonic acid in myelin SM (10-32% between 1 and 6 yr) (20). The relationships and exchanges between nervonic acid pools in RBC and the central nervous system are not well understood, but published data indicate a rise in nervonic acid in the SM of RBC between birth at term (11.2% at 7 d) (14) and the fifth year of life (25.4%) (21).

The results of the above study indicate that nervonic acid accumulation in SM of RBC starts earlier and that the rise we observe between a postconceptional age of 32-37 wk (from 9.9 to 12.8%) is part of a process extending over a longer period of time and beginning much earlier than full-term. It is to be compared to the accumulation in the cerebrosides observed in the cerebrum of human fetuses obtained after medical termination of pregnancy at this time (1.9-10% of fatty acids between 30-32 wk and full-term) (8). Apparently, nervonic acid levels increase simultaneously in the SM of RBC and in the central nervous system from at least six weeks before full term until the fourth year. This parallelism is surprising as very long chain fatty acids are derived from two different pools—from the circulation and hepatic synthesis for RBC and mainly from *"in situ"* synthesis in the brain. Simultaneous accumulation in two different compartments could imply, amongst other factors, exchanges between the pools or simultaneous maturation of the biosynthetic systems. This needs to be investigated further.

With regard to nervonic acid, the SM of RBC could be an indication of the fatty acid composition of tissue membranes, and especially of myelin cerebrum membranes, and thus nervonic acid could be considered as an index of myelin maturation. Maternal dietary restriction was recently shown to result in a drastic decrease of 24:0 and 24:1n-9 in cerebrosides and sulfatides of suckling rats (7). Whether the levels of 24:1n-9 in SM of RBC could provide information on the consequences of undernourishment in the myelination process of the central nervous system remains to be established. We have recently observed that the levels of stearic and oleic acids are significantly higher in fetal than in maternal plasma lipids between week 18 and week 37 of gestation (22), suggesting that these two acids are of special importance to the fetus, possibly in supplying C_{24} fatty acids. Moreover, in the same study, the oleic acid level decreased by about 25-30% in fetal plasma. Such a decrease at a time of high energy requirements when nervonic acid biosynthesis is particularly active could increase the demand for oleic acid.

In the present study, the premature infants received three different types of feeding (human milk, regular formula and α-linolenic acid-enriched formula). An increase in nervonic acid was observed in all three groups, indicating that endogenous synthesis together with milk or formula feeding provided enough precursors for the

normal evolution of nervonic acid in the SM of RBC and probably in the central nervous system; the percentages of oleic and stearic acids in formula and milk feeding were about 25-35 and 5-8%, respectively. As expected, linolenate supplementation introduced as LEAR oil did not interfere with oleate elongation and conversion to nervonic acid.

A rise in nervonic acid did not occur in a very small number of the infants, probably as a result of individual variations rather than clinical abnormalities as postconceptional ages and birthweights were within the same limited range. One infant, whose mother had pre-eclamptic syndrome and was being treated with glucocorticoids, antimineralocorticoids and a β-blocker, had very low levels of nervonic acid (about 1%) at birth. This might have been due to the medical treatment of the mother, to an alteration in the hemodynamic conditions of the feto-maternal unit or to other factors, such as the specific gestational conditions, because a tendency to recovery occurred several weeks after birth, although this recovery only reached to the lower end of the overall range for the group.

Overall, our results suggest that the incorporation of nervonic acid into membranes in humans, as reflected by its level in RBC, increases between 32 and 37 wk. Results from the literature show that this evolution proceeds during the first years of development, as values of 25.4% have been reported for five-year-old children (21). A steady state is likely to be reached because the percentage of nervonic acid in SM of RBC remains stable thereafter with values ranging from 21 to 25% having been reported for adults (10,11).

Phospholipid Molecular Species from Human Placenta Lipids

Y. Bayon[a], M. Croset[a,*], V. Chirouze[b], J.L. Tayot[b] and M. Lagarde[a]
[a]INSERM U 352, Chimie Biologique INSA-Lyon, 69621 Villeurbanne and [b]IMEDEX, Z.I. Les Troques, 69630 Chaponost, France

The phospholipid molecular species from a large-scale preparation of human placenta lipids were analyzed. The major placental phospholipids were choline glycerophospholipids (CPL) (53.2 wt%), sphingomyelin (21.7 wt%) and ethanolamine glycerophospholipids (EPL) (14.6 wt%). 1,2-Diacyl-glycerophosphocholine was the most abundant subclass of CPL (91.7 mol%), while EPL contained 1,2-diacyl (54.6 mol%) and 1-alk-1′-enyl-2-acyl (43.8 mol%) subclasses. The level of polyunsaturated fatty acids (PUFA) in total phospholipids was remarkably constant (38.4–39.9 mol%) within all placental batches tested. The long-chain PUFA, mainly 20:4n-6 and 22:6n-3 of the n-6 and n-3 series, respectively, were found in high proportion in all phospholipid classes, especially in EPL (46.7 mol%) and in inositol glycerophospholipids (IPL) (39.9 mol%). CPL and serine glycerophospholipids were much richer in 18:1n-9 and 18:2n-6. High levels of molecular species with arachidonic acid in the *sn*-2 position were found particularly in 1-alk-1′-enyl-2-acyl-glycerophosphoethanolamine (with 24.0 mol% 16:0 and 22.0 mol% 18:0 in *sn*-1 position) and in 1,2-diacyl glycerophosphoinositol with 42.6 mol% 18:0 in *sn*-1 position. EPL subclasses were rich in 22:6n-3, which occurs mainly as 16:0/22:6n-3 (11.7 mol%) in the plasmalogen form and as 18:0/22:6n-3, 16:0/22:6n-3 and 18:1/22:6n-3 in the diacyl forms. Based on their availability and composition, placental phospholipids could be of interest, for example, for supplementing artificial milk preparations with n-3 and n-6 long-chain PUFA for newborn infants with insufficiently developed 18:2n-6 and 18:3n-3 desaturation/elongation.
Lipids 28, 631–636 (1993).

Linoleic (18:2n-6) and linolenic (18:3n-3) acids are precursors of the two essential fatty acid families, *i.e.,* the n-6 and n-3 families, respectively. Linoleic acid is the precursor of arachidonic acid (20:4n-6) and other long-chain n-6 fatty acids (1). Its dietary insufficiency leads to various deficiency symptoms such as dermatitis, liver pathologies, impaired growth and reproductive failure (2,3). The effects of dietary 18:3n-3 deficiency remain unclear, but the acid is assumed to be essential in the nervous system through its desaturated/elongated product, docosahexaenoic acid (22:6n-3) (4,5). Docosahexaenoic acid is essential in the development of neural tissues as its depletion in brain and retina, where it occurs at high levels (6,7), is accompanied by functional defects such as reduced visual acuity and peripheral neuropathy in monkeys (8). Moreover, 80% of brain 22:6n-3 accumulate between 26 and 40 wk of gestation and infants born prior to 32 wk of gestation have low concentrations of brain 22:6n-3 (9). Linolenic acid as the sole dietary source of n-3 fatty acids has been shown to be inadequate for optimal retinal development of very low birth weight neonates (10). A supply of long-chain n-3 polyunsaturated fatty acids (PUFA) was shown to be necessary to sustain retinal rod function similar to that found in very low birth weight neonates fed with human milk, which contains 0.1–0.3% of the total fatty acids as 22:5n-3 and 22:6n-3. Therefore, optimal accretion of 20- and 22-carbon n-6 and n-3 PUFA may depend on an adequate dietary supply, rather than on desaturation and elongation of 18:2n-6 and 18:3n-3. Most of the marketed preterm infant artificial milks are deficient in the long-chain PUFA as compared to human milk (11,12) and could thus be supplemented with PUFA of both the n-6 and n-3 series. In this work, we report that phospholipid molecular species prepared from human placenta are rich in n-6 and n-3 PUFA.

Abbreviations: BHT, butylated hydroxytoluene; CPL, choline glycerophospholipids; EPL, ethanolamine glycerophospholipids; GLC, gas-liquid chromatography; GPC, glycerophosphocholines; GPE, glycerophosphoethanolamines; GPI, glycerophosphoinositols; GPS, glycerophosphoserines; HPLC, high-performance liquid chromatography; IPL, inositol glycerophospholipids; PUFA, polyunsaturated fatty acids; SPL, serine glycerophospholipids; TLC, thin-layer chromatography.

MATERIALS AND METHODS

Materials. Phospholipase C *(Bacillus cereus)* was purchased from Boehringer Mannheim (Mannheim, Germany). Standard phospholipids and diacylglycerols, butylated hydroxytoluene (BHT) and 3,5-dinitrobenzoyl chloride were obtained from Sigma Chemical Co. (St. Louis, MO). Silica gel 60G (0.25 and 2 mm) and LK5 plates were provided by Merck (Darmstadt, Germany) and Whatman (Clifton, OH), respectively. Methanol and 2-propanol were from Prolabo (Paris, France). All other solvents were of analytical and high-performance liquid chromatography (HPLC) grade and were purchased from SDS (Peypin, France). The Ultrasphere ODS column (250 × 4.6 mm, 5 μm particle size) was obtained from Beckman (Berkeley, CA).

Preparation of placental lipid batches. Placentae were collected from healthy mothers, carefully examined and selected by the physicians in maternity units and immediately frozen at −20°C until processing. Five different lipid batches (A–E) were prepared. Their countries of origin and their respective wt% were as follows: Batch A: Great Britain, 65; Spain, 16; France, 12; Belgium, 7; Batch B: Thailand, 63; Egypt, 28; Sri Lanka, 9; Batch C: France, 49; Austria, 29; United Sates, 13; Belgium, 6; Thailand, 3; Batch D: Scandinavia, 100; Batch E: Pakistan, 78; Chile, 18; the former Soviet Union, 4. For each preparation, lipids were extracted from 300 kg placenta from full-term human pregnancies. Placentae were chopped and suspended in 300 L of aqueous solution containing 7.5 g/L NaCl and 13% (vol/vol) ethanol. One hundred kg blood-free placental tissue was recovered by pressing in order to thoroughly wash the tissue and to discard all the contaminating blood. Lipids were extracted by addition of 350 L *n*-butanol (13). The preparations were shaken for 4 h at −5°C and were further kept in *n*-butanol for 8 h at 2°C. The butanolic phase was separated by pressing, filtered and stored at −20°C in the presence of 3 g of BHT before concentration.

Purification of lipids. From an aliquot of the preparation, neutral lipids were first removed by preparative

thin-layer chromatography (TLC) using hexane/diethyl ether/acetic acid (60:40:1, by vol) as the developing solvent. Phospholipids were then eluted from the gel with chloroform/methanol/water (5:5:1, by vol), and dried by rotatory evaporation under vacuum at 30°C. Individual phospholipid classes were resolved by TLC on silica gel LK5 plates using chloroform/methanol/40% aqueous methylamine (60:20:5, by vol) as the developing solvent (14). Phospholipid fractions were eluted from the silica gel with chloroform/methanol/water (5:5:1, by vol) and were dried as described above. They were stored at −20°C under nitrogen in the presence of 5×10^{-5} M BHT, prior to fatty acid and molecular species analysis.

Quantitation of phospholipid classes by HPLC. Phospholipid classes were separated and quantified as described by Juanéda *et al.* (15). Briefly, the separation was achieved by normal-phase HPLC, using a 5 μm Lichrosorb Si60 silica column (250 × 7.5 mm) (Merck) and a four-solvent elution gradient (chloroform, hexane, 2-propanol, water). Quantitations were done with a Cunow light-scattering detector.

Separation of phospholipid subclasses. Choline glycerophospholipids (CPL), ethanolamine glycerophospholipids (EPL), serine glycerophospholipids (SPL) and inositol glycerophospholipids (IPL) were isolated on TLC plates as described above and converted to dinitrobenzoate derivatives following phospholipase C hydrolysis (16). Two hundred μg of phospholipids in 0.7 mL 30 mM H_3BO_3, 10 mM Tris-HCl buffer (pH 7.5) containing 0.02% BHT were sonicated for 5 min before addition of 50 U of phospholipase C overnight at 30°C under vigorous shaking. The resulting diradylglycerols were extracted with diethyl ether and converted into their dinitrobenzoyl derivatives by treatment with 3,5-dinitrobenzoyl chloride in anhydrous pyridine for 30 min at 60°C. After cooling, 1 mL H_2O was added to the samples and the products were extracted twice with hexane. The subclasses of dinitrobenzoyldiradylglycerols were further resolved by TLC on silica gel 60 G plates using toluene/hexane/diethyl ether (50:45:4, by vol) as solvent. The 1-alk-1′-enyl-2-acyl, 1-alkyl-2-acyl and 1,2-diacyl subclasses showed R_f values of 0.64, 0.58 and 0.38, respectively, and were separated. An equal amount (approximately 10 μg) of the 17:0/17:0 1,2-diacyl derivative was applied to each fraction as internal standard for the quantitation of molecular species peaks. The band of each subclass was scraped off and extracted twice with a mixture of diethyl ether/hexane (1:1, vol/vol). Because of internal standard coelution with 16:0/18:0 (1,2-diacyl) and 18:0/16:0 (1,2-diacyl), 1,2-diacyl subclasses were also prepared without adding 17:0/17:0 (1,2-diacyl) derivative.

Separation and quantitation of molecular species. Separation and quantitation of molecular species were accomplished by reverse-phase HPLC (16) using a 5 μm Ultrasphere ODS column (250 × 4.6 mm) (Beckman, Berkeley, CA) and an isocratic elution with acetonitrile/2-propanol (90:10, vol/vol) at a flow rate of 1.5 mL/min. The products were quantified by measuring absorbance at 240 nm. Molecular species were identified by comparison of their retention times with those of standards synthesized from known phospholipids and 1,2-diacylglycerols (17); the assignments were verified by the graphical representation method of Patton *et al.* (18).

Quantitation of CPL and EPL subclasses. The subclass compositions of CPL and EPL were calculated from total relative peak areas with respect to the internal standard used in each subclass. The data were confirmed by quantitative separation of the benzoyldiradylglycerol derivatives obtained from CPL and EPL by HPLC using a 5 μm Hypersil-H215 column (250 × 4.6 mm, Société Française Chromato Colonne, Neuilly-Plaisance, France) with cyclohexane/hexane/*t*-butyl methyl ether/acetic acid (375:125:12:0.1, by vol) as the mobile phase (19).

Gas-liquid chromatography (GLC) analysis. Fatty acid methyl esters were prepared by esterification with 14% boron trifluoride in methanol (20). The fatty acid composition of placental phospholipids was determined by GLC, using a Perkin-Elmer (Buckinghamshire, England) chromatograph model 5830, equipped with an SP 2380 capillary column (60 m × 0.25 mm) (Supelco, Bellefonte, PA) (17).

RESULTS

On average, 1.8 kg of total lipids were obtained by extraction of 100 kg of placentae tissue. The total phospholipid fraction accounted for more than 70 wt% of the extracted tissue lipids, whereas free fatty acids, triglycerides and cholesterol represented only 7, 3.5 and 19 wt%, respectively. Trace amounts of steryl esters were found in the butanolic lipid extract.

The composition of the phospholipid fraction of a batch of human placentae from European countries (Batch A) was analyzed in more detail. CPL, EPL and sphingomyelin were the major phospholipid classes, representing 53.19 ± 0.16, 14.60 ± 0.38 and 21.74 ± 0.40 wt%, respectively, of total phospholipids. IPL, SPL and cardiolipin accounted for only 4.39 ± 0.36, 2.88 ± 0.12 and 3.22 ± 0.15 wt% of total phospholipids. Phosphatidic acid, lysophosphatidylcholine and lysophosphatidylethanolamine were below the detection limit, accounting for less than 1 wt% of the total phospholipids. The composition of CPL and EPL was first analyzed by HPLC of each subclass by determining the absolute amount of molecular species relative to diheptadecanoylglycerol used as internal standard. CPL and EPL were also analyzed by straight-phase HPLC and their subclasses were quantitated by measuring UV absorption of each subclass at 240 nm. 1,2-Diacylglycerophosphocholine (GPC) was the major subclass of GPC and accounted for 91.69 ± 1.09 mole% of GPL, while 1-alkyl-2-acyl-GPC and 1-alk-1′-enyl-2-acyl-GPC represented 5.70 ± 0.64 and 2.61 ± 0.42 percent of this phospholipid class, respectively. The composition of EPL was quite different, with 1,2-diacyl and 1-alk-1′-enyl-2-acyl forms occurring at high proportions: 54.60 ± 1.15 mol% and 43.77 ± 1.15 mol% of the total class, respectively, whereas 1-alkyl-2-acyl-glycerophosphoethanolamine (GPE) was a minor component, with 1.63 ± 0.50 mol%.

In order to assess the adequate conservation of the placentae lipids, the fatty acid composition of total phospholipids was analyzed from five placental batches coming from different parts of the world (see Materials and Methods section). Within the five placentae batches, none of the main fatty acids differed by more than 10% from the mean of the five batches (Table 1). As no differences were observed between the fatty acids of the five batches by a X^2 test (contingency table analysis) (Statview, Macintosh), they were considered as having identical fatty acid

composition, and phospholipid molecular species were analyzed on one batch, which was already a pool of 250 placentae. Fatty acid analyses performed on Batch A revealed that all phospholipid classes contain relatively high proportions of n-6 and n-3 long-chain PUFA, mainly 20:4n-6 and 22:6n-3, with 22:6n-3 accounting for most of the n-3 long-chain PUFA (Table 2). The greatest amount of long-chain PUFA was present in EPL (46.7 mol%) and in IPL (39.9 mol%). CPL and SPL were much richer in 18:1n-9 and 18:2n-6. The proportion of 22:6n-3 and 22:5n-3 was 5.9- and 8.7-fold higher in EPL than in CPL, respectively. The data in Tables 3 and 4 represent the first report on the glycerophospholipid molecular species of human placenta. The molecular species composition of the 1,2-diacyl glycerophospholipids were consistent with the fatty acid composition of each class (Table 3). In accordance with the fatty acid composition of SPL, 1,2-diacyl-glycerophosphoserines (GPS) contained a large amount of species with 18:1 at the *sn*-2 position, essentially associated with 18:0 (22.1 mol%) and 16:0 (5.3 mol%) at the *sn*-1 position. In contrast, in 1,2-diacyl-GPC and 1-alkyl-2-acyl-GPC, 18:1 was combined with 16:0 and 18:1 (12.9 and 19.0 mol%, respectively). 1,2-Diacyl-GPC, 1-alkyl-2-acyl-GPC and 1,2-diacyl-GPS were also characterized by high proportions of molecular species containing 18:2n-6. The resolution of 16:0/16:0 and 18:0/18:2n-6 was further achieved by GLC analysis of the HPLC fractions and showed that 16:0/16:0 was present only in trace amounts. High proportions of molecular species with arachidonic acid at the *sn*-2 position were found in all subclasses, especially in 1,2-diacyl-glycerophosphoinositols (GPI) and 1-alk-1′-enyl-2-acyl-GPE, where it was mainly associated with 18:0 (42.6 mol%) and 16:0 (24.0 mol%), respectively. Placenta diacyl-GPC contained high amounts of species with 20:3n-6 at the *sn*-2 position, 16:0/20:3n-6 and 18:0/20:3n-6 representing 17.3 and 12.9 mol% of 1,2-diacyl-GPS and 1,2-diacyl-GPI, respectively. 1-Alk-1′-enyl-2-acyl- and 1,2-diacyl-GPE were the subclasses containing the highest concentration of n-3 fatty acids, namely 22:6n-3 and 22:5n-3, although they were depleted in 18:3n-3 and 20:5n-3. Placentae EPL were rich in 22:6n-3, which occurs mainly as 16:0/22:6n-3 in plasmalogenic form and as 16:0/22:6n-3, 18:1/22:6n-3 and 18:0/22:6n-3 in 1,2-diacyl-GPE. 1-Alk-1′-enyl-2-acyl-GPE was also rich in 22 carbon fatty acids from the n-6 family, mainly 22:4n-6, which was present as 16:0/22:4n-6 (6.0 mol%) and 18:0/22:4n-6 (2.2 mol%).

DISCUSSION

Residual placenta lipids were found to be rich in n-6 and n-3 PUFA. They could be a potential source for the production of phospholipid molecular species enriched in these two fatty acid families. The lipid composition of placenta prepared from bulk tissue was found to be very close to that of individual placentae (21) whose lipids had been extracted by the classical Folch method. Proportions of lipid classes found in our preparations were comparable with those reported in the native tissue (21,22). On average, 1 kg of total phospholipids could be prepared from 100 kg of placentae. CPL, sphingomyelin and EPL occurred as the major phospholipid classes and their

proportions were very close to the values reported for native tissues (21–24). However, the amount of SPL (2.9%) was lower than that reported by Chirouze *et al.* (21) (4.4%) and Nelson (23) (8.7%). This could indicate some selectivity in the large scale butanolic extraction of phospholipid classes. The subclass compositions of CPL and EPL were similar to those of several human tissues, including vascular cells (25), with high proportions of the 1-alk-1′-enyl-2-acyl form in EPL, and the 1,2-diacyl form accounting for more than 90% of CPL. The origin of placenta had no influence on the proportion of PUFAs which was constant within the five placenta phospholipid preparations analyzed and was close to that reported by Chirouze *et al.* (21) and Percy *et al.* (24), suggesting negligible fatty acid degradation during placenta storage and large scale processing of the lipid preparation. The molecular species distribution of human placenta phospholipids resembles that reported for human vascular cells (17,26). 1,2-Diacyl-GPI and 1-alk-1′-enyl-2-acyl-GPE were the subclasses containing the highest proportions of 18:0/20:4n-6. The molecular species with n-6 and n-3 long-chain PUFAs were mostly associated with 1-alk-1′-enyl-2-acyl-GPE. 1,2-Diacyl-GPC contained higher amounts of 18:2n-6 and 18:1. Taking into account that 1,2-diacyl-GPC represents 45 wt% of the total phospholipids, 450 g of molecular species with a fatty acid of nutritional interest at the *sn*-2 position could be purified from 100 kg of placenta. 1,2-Diacyl-GPE and 1-alk-1′-enyl-2-acyl-GPE, which are rich in 20:4n-6 and 22:6n-3, could also be prepared by large-scale processing.

Adequate extraction of placenta CPL, EPL and IPL was achieved by the large scale isolation process. These phospholipids are mostly enriched in PUFAs. The large scale purification of phospholipid classes would allow for production of fractions enriched in n-6 fatty acids, mainly 20:3n-6, 20:4n-6 and 22:4n-6, and fractions enriched in n-3 fatty acids, such as 22:5n-3 and 22:6n-3.

ACKNOWLEDGMENTS

This work was supported by INSERM, and Y. Bayon was a recipient of a grant from IMEDEX. The authors gratefully acknowledge P. Juaneda, INRA, Dijon, for the quantification of the phospholipid classes.

Because triacylglycerol (TAG) structure influences the metabolic fate of its component fatty acids, we have examined human colostrum and mature milk TAG with particular attention to the location of the very long chain polyunsaturated fatty acid on the glycerol backbone. The analysis was based on the formation of various diacylglycerol species from human milk TAG upon chemical (Grignard degradation) or enzymatic degradation. The structure of the TAG was subsequently deduced from data obtained by gas chromatographic analysis of the fatty acid methyl esters in the diacylglycerol subfractions. The highly specific TAG structure observed was identical in mature milk and colostrum. The three major fatty acids (oleic, palmitic and linoleic acids) each showed a specific preference for a particular position within milk TAG: oleic acid for the *sn*-1 position, palmitic acid for the *sn*-2 position and linoleic acid for the *sn*-3 position. Linoleic and α-linolenic acids exhibited the same pattern of distribution and they were both found primarily in the *sn*-3 (50%) and *sn*-1 (30%) positions. Their longer chain analogs, arachidonic and docosahexaenoic acids, were located in the *sn*-2 and *sn*-3 positions. These results show that polyunsaturated fatty acids are distributed within the TAG molecule of human milk in a highly specific fashion, and that in the first month of lactation the maturation of the mammary gland does not affect the milk TAG structure. ***Lipids 28,*** **637–643 (1993).**

Breast milk is considered the optimal form of nutrition for infants (1) and contains both parent essential fatty acids (linoleic acid and α-linolenic acid) and very long chain polyunsaturated fatty acids (VLC-PUFA, *i.e.*, PUFA ⩾ 20 carbons). A balanced amount of these fatty acids is required for normal maturation and function of the nervous system (2–5), as well as for adequate production of eicosanoids (2,3). Several expert committees now recommend the addition of both VLC-PUFA and α-linolenate to infant formulas (6,7).

The structure of the triacylglycerols (TAG) used in commercially prepared formulas influences the pre- and post-enterocyte bioavailability of their constituent fatty acids. For example, the presence of some VLC-PUFAs, such as 20:4n-6, 20:5n-3 and 22:6n-3, at the outer positions of TAG induces resistance to pancreatic lipase hydrolysis *in vitro* (8,9). In addition, the distribution of fatty acid between the outer and the *sn*-2 position in the glycerol molecule governs the lumenal partition between the free and the 2-monoacyl-*sn*-glycerol form (10–12), and subsequently modifies the rate of intestinal fatty acid uptake. The absorption of palmitic acid is improved when it is located in the *sn*-2 position of TAG as compared to the *sn*-1,3 positions (13,14). A similar difference in absorption was observed for stearic acid (15). The molecular form of fatty acid taken up by the enterocyte also modulates its incorporation into either the TAG or the phospholipids fraction of chylomicrons (16), as well as its positional distribution in the TAG of chylomicrons (16–18). As the fatty acids are differently metabolized whether bound primarily to the TAG or phospholipid fraction of chylomicrons (19,20), and because the post-heparin plasma lipoprotein lipase preferentially hydrolyzes the ester bond in the *sn*-1 position (21), the post enterocyte metabolic fate of component fatty acids is expected to depend on the structure of the ingested TAG. For instance, the positional structure of TAG species affects both the fractional plasma clearance rates of chylomicrons and the recoveries of TAG in the liver and spleen (22), modulates the atherogenic features of a given oil (23) and may effect the pharmacological actions of dietary n-3 VLC-PUFA used for therapeutic purposes (24,25). Because breast milk is the natural source of fat for the newborn, the structure of its TAG may be used as a biological reference point. However, the proportion of VLC-PUFA in each position of the glycerol backbone has not been carefully determined in human milk TAG. Furthermore, whether the TAG structure changes with maturation of the mammary gland along with changes observed in the fatty acid composition (26–28) is unknown. To address these questions, we have examined the distribution of fatty acids in human colostrum and mature milk TAG.

MATERIALS AND METHODS

Subjects and milk collection. Fifteen Caucasian, healthy mothers living in the Loire Valley area of France volunteered for this study. Women taking drugs, including alcohol, or with self-selected diets (vegetarian, vegan, food fad) or with complications of pregnancy, including cesarian section, were not included in the study. All mothers were on their usual diets and no dietary modifications were proposed. Milk samples (4–5 mL) were taken prior to the mother's lunch. Colostrum was obtained on day 5 and mature milk on day 30 after delivery. All samples were immediately frozen and then stored at −70°C within one hour. The protocol was approved by the Ethics Committee of our institution. Lipid analyses were performed within a week following milk collection.

Chemicals and reagents. All solvents (chloroform, hexane, heptane, diethyl ether and di-isopropyl ether) were of high-performance liquid chromatography grade. Solvents and glacial acetic acid were purchased from Carlo Erba (Milan, Italy). Diethyl ether was purchased in small amounts and used within weeks to minimize peroxidation. Methanol and ammonia (25%) were from Prolabo (Vitry sur Seine, France). Pyridine and toluene were from Merck (Darmstadt, Germany). Fatty acid methyl ester standards were from Nu-Chek-Prep (Elysian, MN) or Supelco

Abbreviations: BHT, butylated hydroxytoluene; DHA, docosahexaenoic acid; GPC, glycerophosphocholine; PUFA, polyunsaturated fatty acids; TAG, triacylglycerol; TLC, thin-layer chromatography; VLC-PUFA, very long chain polyunsaturated fatty acids.

(Bellefonte, PA). Tri-tridecanoin, 1,2-dipentadecanoyl-*sn*-glycero-3-phosphocholine (GPC), 2,3-di-hexadecanoyl-*sn*-glycero-1-phosphocholine, choline chloride, butylated hydroxytoluene (BHT) and boron trifluoride in methanol were purchased from Sigma (St. Louis, MO). Boric acid and phosphorus oxychloride were purchased from Merck and ethyl magnesium bromide from Aldrich (Milwaukee, WI). Thin-layer chromatography (TLC) plates (type LK6 plates, 250 μm layer, 5 × 20 cm) were from Whatman (Maidstone, England). Porcine pancreatic lipase (EC 33.1.1.3, type VI-S) and phospholipase C from *C. welchii* (EC 3.1.4.3, type I) were from Sigma. All chemical and enzymatic reactions were carried out under nitrogen, with BHT added as an antioxidant (0.005%, wt/vol). BHT was also added to all TLC developing solvents (0.05%, wt/vol), except as noted.

TAG quantification. In order to carry out each stereospecific analysis with an equal amount of TAG and to compensate for variations in milk fat content between the individuals, the TAG concentration in each milk sample was measured. Tri-tridecanoin (150 μg) was added to 3 mL of milk as an internal standard. Lipids were then extracted as previously described (29) and a measured aliquot was used to purify TAG by TLC on silica gel plates. Hexane/diethyl ether/acetic acid (75:25:1, by vol) without BHT was used as the developing solvent. TLC plates were sprayed with 2′,7′-dichlorofluorescein (2% in ethanol), and lipid fractions were visualized under ultraviolet light and identified by comparison of their R_f values with those of authentic standards. Quantification of TAG was achieved by gas chromatography after conversion of TAG to fatty acid methyl esters. The internal tridecanoic acid methyl ester was used as the standard for both fatty acid and TAG quantification, and the mass of fatty acid methyl esters was considered as a close approximation of that of TAG. The milk volume per sample was then adjusted to arrive at the desired amount of TAG in each sample.

Fatty acid analysis. Fatty acids were converted to the methyl esters with 14% (wt/vol) boron trifluoride in methanol (30). All reactions were carried out under nitrogen. Fatty acid methyl esters were analyzed by gas chromatography (Carlo Erba type GC 6000, Vega series 2) using a 50 m × 0.32 mm i.d. fused silica capillary column with a 0.25 μm film of carbowax 20 M (Star, Cergy-Pontoise, France), an on-column injector and a flame-ionization detector connected to a digital integrator (Spectraphysics SP4270, San Jose, CA). Operating conditions have been detailed previously (29). The areas of nonidentified peaks were less than 2%. Results were expressed in mol% of the identified fatty acid methyl esters after conversion of the respective peak areas. Inter- and intra-assay coefficients of variation have been evaluated previously (29).

Stereospecific analysis of milk TAG. This method is based upon the random generation of 1,3-diacyl-*sn*-glycerol along with an equimolar mixture of 1,2- and 2,3-diacyl-*sn*-glycerols (*rac*-1,2-diacylglycerols) by Grignard degradation of TAG. *rac*-1,2-Diacylglycerols were converted to *rac*-phosphatidylcholines by chemical means, and the 1,2-diacyl-*sn*-glycero-3-phosphocholine was selectively hydrolyzed by phospholipase C. This allowed the separation of enantiomeric 1,2-diacyl-*sn*-glycerol from the remaining 2,3-diacyl-*sn*-glycero-1-phosphocholine as described by Myher and Kuksis (31).

In brief, 30 mg of TAG were purified from the milk total lipid extracts by preparative TLC on boric acid-impregnated plates (by submerging the TLC plates in a 5% methanolic solution for 5 min) in order to minimize isomerization. The TAG fraction was eluted from the gel with chloroform/methanol/water (4:4:3.8, by vol). The TAGs were dried by evaporation after ethanol addition, dissolved in 1.2 mL of anhydrous diethyl ether, transferred to a glass flask and stirred under nitrogen at room temperature. Ethyl magnesium bromide (3 M in diethyl ether, 0.1 mL) was added to the TAG solution, and the reaction was stopped after 25 s by addition of acetic acid/diethyl ether (1:9, vol/vol). The mixture was thoroughly washed as described (31), and dried. The *rac*-1,2-diacylglycerols were separated from the 1,3-diacyl-*sn*-glycerols on borate-impregnated silica gel plates using chloroform/acetone (97:3, vol/vol) as developing solvent (31). The fatty acids from the 1,3-diacyl-*sn*-glycerol and from an aliquot of the *rac*-1,2-diacylglycerols were converted to fatty acid methyl esters (30) for gas chromatographic analysis.

For the synthesis of *rac*-phosphatidylcholines, the remaining *rac*-1,2-diacylglycerols were evaporated to dryness from ethanol and dissolved in 0.65 mL of a mixture of chloroform/pyridine/phosphorus oxychloride at 0°C (47.5:47.5:5, by vol). The mixture was allowed to stand at 0°C for 1 h and then at 25°C for 1 h (31). Choline chloride (200 mg, acetone-dried powder) was added, and the mixture was stirred at 30°C for 15 h. After addition of 20 μL of water and 30 min of subsequent stirring, the volume was reduced under nitrogen, and the reaction products were extracted and thoroughly dried (31). The *rac*-phosphatidylcholines were separated from the unreacted *rac*-1,2-diacylglycerols by TLC on borate-impregnated silica gel plates (31). The fatty acid composition of the *rac*-1,2-diacylglycerols and of the *rac*-phosphatidylcholines were identical, ensuring that the synthetic process did not alter the fatty acid composition nor did selective reaction occur with respect to particular diacylglycerol species.

1,2-Diacyl-*sn*-glycero-3-phosphocholines were stereospecifically hydrolyzed from the *rac*-phosphatidylcholine fraction with phospholipase C, as previously described (31). The resulting 1,2-diacyl-*sn*-glycerols and 2,3-diacyl-*sn*-glycero-1-phosphocholines were resolved by TLC on borate-impregnated K6 plates using chloroform/methanol/acetic acid (20:90:10, by vol) as the developing solvent. Specificity of phospholipase C used for the *sn*-3 position of the phosphocholine group was ascertained using 1,2-pentadecanoyl-*sn*-glycero-3-phosphocholine and 2,3-hexadecanoyl-*sn*-glycero-1-phosphocholine as substrates.

Hydrolysis of milk TAG with pancreatic lipase. 2-Monoacyl-*sn*-glycerols were obtained from milk TAG upon hydrolysis of the acyl group in the 1- and 3- positions of glycerol using porcine pancreatic lipase (31). Purified milk TAGs (2.5 mg) were resuspended by vigorous shaking in 0.5 mL of TRIS/HCl buffer (1 M, pH 8.0) containing gum Arabic (10%) and 14 μL of a $CaCl_2$ solution (45% in water). The solution was submitted to pancreatic lipase hydrolysis (5000 units dissolved in 0.5 mL buffer, 10 min at 37°C with vigorous stirring). The reaction products were extracted with diethyl ether and the 2-monoacyl-*sn*-glycerols purified on K6 borate-impregnated plates with heptane/iso-propyl ether/acetic acid (60:40:4, by vol) as developing solvent. Fatty acid composition was

determined by gas chromatography of the fatty acid methyl esters (29).

Determination of the TAG structure. The structure of the original TAG was calculated from the fatty acid composition of each lipid fraction (1,2-diacyl-*sn*-glycerol, 2,3-diacyl-*sn*-glycero-1-phosphocholine and 1,3-diacyl-*sn*-glycerol). The proportion of individual fatty acids found in the three positions of the TAG was calculated according to the following equations (32):

$$2\text{-}sn\ (\text{mol}\%) = 2 \times rac\text{-}1,2\text{-diacylglycerol}\ (\text{mol}\%) - 1,3\text{-diacyl-}sn\text{-glycerol}\ (\text{mol}\%) \quad [1]$$

$$1\text{-}sn\ (\text{mol}\%) = 2 \times 1,2\text{-diacyl-}sn\text{-glycerol}\ (\text{mol}\%) - 2\text{-}sn\ (\text{mol}\%) \quad [2]$$

$$3\text{-}sn\ (\text{mol}\%) = 2 \times 2,3\text{-diacyl-}sn\ \text{GPC}\ (\text{mol}\%) - 2\text{-}sn\ (\text{mol}\%) \quad [3]$$

The 2-position fatty acid composition was also directly obtained by analysis of the 2-monoacyl-*sn*-glycerol fraction produced after pancreatic lipase hydrolysis of TAG.

Statistical analysis. Data were computed using Statview 512+® (Brain Power Inc., Calabassas, CA). Results are presented as the means ± SD (mol%). The content of each fatty acid found in the *sn*-2 position by the pancreatic lipase method or deduced from the diacylglycerol species produced by Grignard degradation was compared by the Mann and Whitney signed rank test. The P value was set at 0.05.

RESULTS

Under our experimental conditions, the theoretical and observed ratios of selected fatty acids in *rac*-1,2- and in 1,3-diacyl-*sn*-glycerols obtained after Grignard degradation of TAG standards were very similar (Table 1).

For all milk fatty acids except 18:0, the relative proportion found in the *sn*-2 position was not statistically different whether determined by pancreatic lipase hydrolysis or calculated from the diacylglycerol species produced by Grignard degradation. However the difference was close to significant for 22:6n-3 (1.07% and 0.83%, with the pancreatic lipase method and the Grignard degradation method, respectively; n = 13; $P = 0.06$). The gas chromatographic quantification of lipid fractions obtained after phospholipase C action on standards showed that 98.9% of the 1,2-diacyl-*sn*-glycero-3-phosphocholines were hydrolyzed to produce 1,2-diacyl-*sn*-glycerol, whereas only 1.13% of the 2,3-diacyl-*sn*-glycero-1-phosphocholines were hydrolyzed to 2,3-diacyl-*sn*-glycerol and phosphocholine.

The positional distribution of fatty acids in TAG from human colostrum is presented in Table 2. The *sn*-1 position was esterified predominantly with 18:1 (48%), 18:2n-6 (14%), 16:0 (13%) and 18:0 (11%) fatty acids. The *sn*-2 position was esterified primarily with 16:0 (54%), 18:1 (13%), 14:0 (11%) and 18:2n-6 (8%) fatty acids. The *sn*-3 position was principally composed of 18:1 (37%), 18:2n-6 (17%), 16:0 (11%) and 14:0 (10%) fatty acids.

The relative distribution of each saturated fatty acid (from 10:0 to 18:0) at the three sites of esterification is shown in Figure 1. The proportion of 10:0 to 16:0 fatty acids found in the *sn*-2 position increased with the length of the carbon chain with a commensurate decrease in the *sn*-3 position. Conversely, 64% of stearic acid was found in the *sn*-1 position, 26% in the *sn*-3 position and only 9% in the *sn*-2 position. The profile of the positional distribution of major monounsaturated fatty acids is depicted in Figure 2. The profile observed for 18:1 fatty acids was similar to the one seen for its saturated homologue (see Figs. 1 and 2). The 18-carbon essential fatty acids (18:2n-6

and 18:3n-3) had identical distribution profiles at the glycerol molecule (Fig. 3). Their longer chain analogues, 20:4n-6 and 22:6n-3 (Fig. 4A) and 22:4n-6 and 22:5n-3 (Fig. 4B), were similar.

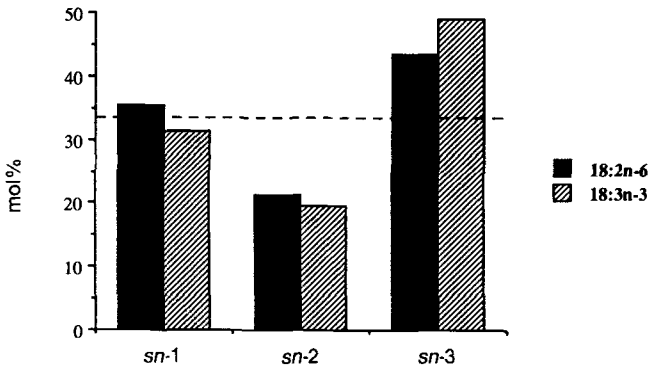

FIG. 3. Positional distribution of 18-carbon essential fatty acids in colostrum triacylglycerols. The horizontal dashed line indicates the proportion of each fatty acid expected on the basis of a random positional distribution (33.3%).

Although the VLC-PUFA content decreased from colostrum to mature milk, a similar positional distribution of each individual fatty acid in TAG was observed (see Tables 2 and 3).

DISCUSSION

This study demonstrates that in human milk TAG, the VLC-PUFAs, especially 20:4n-6 and 22:6n-3, are found primarily esterified in the *sn*-2 and *sn*-3 positions and that, more generally, the highly specific positional distribution of fatty acids is maintained throughout the first month of lactation.

Several authors (31,33,34) found that Grignard degradation caused significant acyl migration in the diacylglycerol moiety, especially for the 1,3-diacyl-*sn*-glycerols. Under our experimental conditions, the good agreement between theoretical and experimental 18:1/16:0 or 16:0/18:1 ratios found in the 1,2(2,3)-diacyl-*sn*-glycerols and in the 1,3-diacyl-*sn*-glycerols generated from TAG standards (Table 1) showed that Grignard degradation did not lead to pronounced acyl migration. For all the milk fatty acids but stearate, the content found in the *sn*-2 position was similar whether calculated from diacylglycerols produced

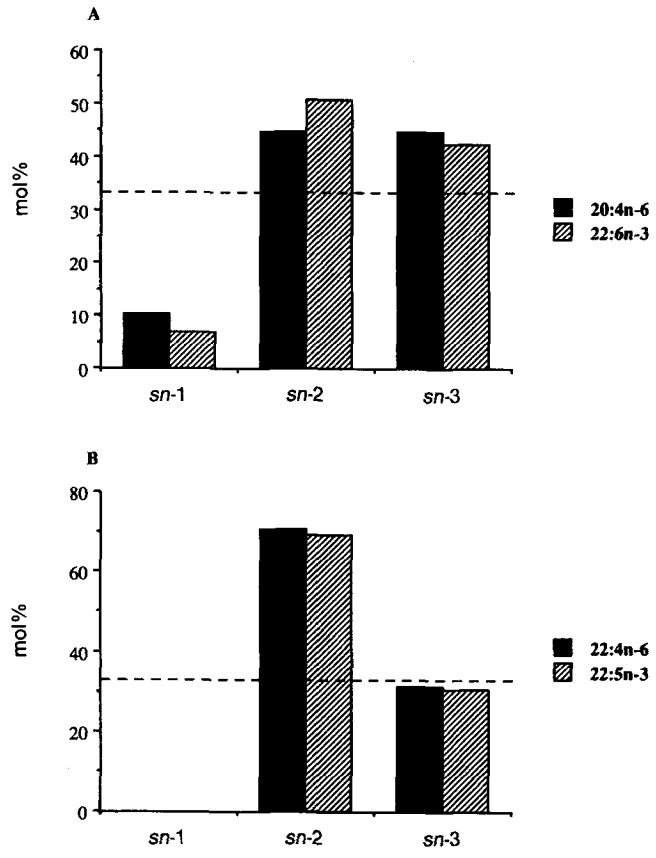

FIG. 4. Positional distribution of selected 20 and 22-carbon polyunsaturated fatty acids in colostrum triacylglycerols. The horizontal dashed line indicates the proportion of each fatty acid expected on the basis of a random positional distribution (33.3%).

by Grignard degradation (*i.e.*, 1,2(2,3)-diacyl-*sn*-glycerols and 1,3-diacyl-*sn*-glycerols) or determined after pancreatic lipase action on TAG. The difference found for stearic acid between the two methods has been previously described by Lawson and Hughes (35). It is known that some VLC-PUFA (20:4n-6, 20:5n-3 and 22:6n-3) are resistant to pancreatic lipase hydrolysis when linked to the outer positions of glycerol. Consequently, an overestimation of their relative proportion in the 2-monoacyl-*sn*-glycerol moiety after pancreatic lipase action was expected (8,9,36). Indeed, the 22:6n-3 content of the *sn*-2 position obtained with the pancreatic lipase method was higher than the content obtained by calculation after Grignard degradation. Because the difference was close to significance ($P = 0.06$), and as one of our aims was to focus on VLC-PUFA distribution, we chose the Grignard degradation method in order to most accurately assess the positional distribution of the fatty acids.

The stereospecificity of phospholipase C and the completeness of the reaction induced by this enzyme were significant to selectively measure the distribution of fatty acids in the resulting 1,2-diacyl-*sn*-glycerols and in the 2,3-diacyl-*sn*-glycero-1-phosphocholines, which were then used to calculate the fatty acid content in the *sn*-1 and *sn*-3 positions.

The positional distribution of saturated, monounsaturated and 18-carbon essential fatty acids observed in the present study agrees with previous data (see Table 4). There are, however, minor discrepancies that may be accounted for in part by differences in the number of samples examined. Medium-chain saturated fatty acids showed a highly selective distribution in human colostrum and mature milk TAG. The proportion of saturated fatty acids increased in the *sn*-2 position and decreased in the *sn*-3 position as the carbon chain lengthened from 10 to 16 carbons. Such data indicate that the length of the carbon chain is a discriminating factor in the acylation process of medium-chain saturated fatty acids, especially to the *sn*-2 and *sn*-3 positions. However, this was not true for fatty acids with more than 16 carbons and/or with one or more double bonds as similar profiles were observed for 18:2n-6 and 18:3n-3, for 18:0 and 18:1, for 20:4n-6 and 22:6n-3 and for 22:4n-6 and 22:5n-3. Whether common biochemical pathways are responsible for the incorporation of these specific pairs of fatty acids into milk TAG or whether specific acyl transferases and/or a fatty acid binding protein (37) are involved in the stereospecific distribution of fatty acids in the glycerol molecule is unknown.

In humans, the stereospecific distribution of the TAG fatty acids differs between milk and adipose tissue (Table 4). This underlines the relative specificity of the mammary gland for the placement of the fatty acids in the three positions of milk TAG.

The similarities of the fatty acid positional distribution in colostrum and mature milk TAG indicate that the maturation of the mammary gland does not affect the acylation of fatty acids to the glycerol backbone.

About half of the 20:4n-6 and 22:6n-3 content of human milk TAG is found in the *sn*-2 position, the other half is esterified to the *sn*-3 position. From this positional distribution, one may surmise that a similar proportion of 20:4n-6 and 22:6n-3 is absorbed as 2-monoacyl-*sn*-glycerol and as free fatty acid by the newborn enterocytes after intestinal hydrolysis of ingested human milk TAG. This is likely to be the case in the breast-fed infant inasmuch as the resistance of the arachidonate and docosahexaenoate located at the outer positions to pancreatic lipase hydrolysis (8,9,36) is circumvented by gastric lipase and bile salt stimulated lipase (38–44). Indeed, it has been shown that in the small intestine of five-week-old dogs, freshly expressed milk TAGs are almost completely hydrolyzed by these three lipases mainly to yield free fatty acids and monoacylglycerols (45).

In contrast to human milk, infant formulas are devoid of any bile salt stimulated lipase activity, and a consequent reduction in hydrolysis of the *sn*-1 and *sn*-3 ester bonds of TAG may be expected. This limitation could be overcome if the source of TAG was adequately chosen to fortify formulas with VLC-PUFA in the *sn*-2 position of TAG.

Based on our results, the docosahexaenoic acid (DHA) status of infant fed formulas which are fortified only with a physiological amount of DHA equally distributed between the free and the 2-monoacyl-*sn*-glycerol form, would be worthy of further investigation.

In conclusion, the highly specific positional distribution of VLC-PUFA in human milk TAG is likely to be of biological significance. These findings could prove valuable in designing efficient lipid sources for infant formulas.

ACKNOWLEDGMENTS

The authors are indebted to the participants of this study for their interest and cooperation and to Norman Salem, Jr., for his advice in the presentation of this manuscript. We thank the staff of the Clinique Gynécologique et Obstétricale and of the lactarium for their collaboration in milk collection. We are most grateful to T. Niyongabo and J. Laugier for their help in recruiting the volunteers. The excellent technical assistance of Y. Frangin is acknowledged.

[Received March 22, 1993; Revision accepted May 5, 1993]

Dietary Saturated, Monounsaturated, n-6 and n-3 Fatty Acids, and Cholesterol Influence Platelet Fatty Acids in the Exclusively Formula-Fed Piglet

Sheila M. Innis[a,*], Roger Dyer[a], Louis Wadsworth[b], Paul Quinlan[c] and Deborah Diersen-Schade[d]
[a]Departments of Paediatrics and [b]Pathology, University of British Columbia, Vancouver, British Columbia, V5Z 4H4, Canada, [c]Unilever Research, Colworth Laboratory, Sharnbrook, Bedford, MK441LQ, United Kingdom and [d]Mead Johnson Research Center, Evansville, Indiana 47721-0001

Platelet lipid composition is important to normal platelet morphology and function, and is influenced by dietary fatty acids and cholesterol. The fatty acid composition and cholesterol content of infant formulas differs from those of human milk, but the possible effects on platelet lipids in young infants is not known. This was studied in piglets fed from birth to 18 d of age with one of eight formulas differing in saturated fatty acid chain length, or content of 18:1, 20:5n-3 plus 22:6n-3, or cholesterol. A reference group of piglets fed sow milk was also studied. Sow milk has a fatty acid composition and cholesterol content similar to that of human milk. Piglets fed formulas high in 18:1 (34.9–40.8% wt fatty acids) and low in 16.0 (≤6.5% wt fatty acids) had lower platelet counts and greater platelet size than piglets fed sow milk (40.4% 18:1, 30.7% 16:0). Piglets fed formulas high in 16:0 (27–29.6%) and 18:1 (40–40.6%), or low in both 16:0 (5.9–6.1%) and 18:1 (10.8–11.2%), had similar platelet counts and size to piglets fed sow milk. Platelet phospholipid % 20:4n-6 was lower in all the groups of piglets fed formula than in the group fed sow milk. Addition of fish oil with 20:5n-3 plus 22:6n-3 to the formula further decreased platelet phospholipid 20:4n-6. Addition of cholesterol to the formula increased the platelet phospholipid % 20:4n-6 and platelet volume. *Lipids 28,* **645–650 (1993).**

Numerous studies in adult humans and other species have shown that dietary fat composition influences the fatty acid composition of platelet phospholipids and that changes in platelet phospholipid fatty acids may be accompanied by alterations in platelet function and platelet number (1–15). Diets containing marine animal fat or fish oil are known to increase platelet membrane levels of eicosapentaenoic acid (20:5n-3) and docosahexaenoic acid (22:6n-3) and decrease arachidonic acid (20:4n-6), alter platelet half-life, size and number, decrease aggregatory activity and increase bleeding time (2–7). Studies that show that dietary saturated fat, saturated to monounsaturated fatty acid balance and oleic acid (18:1) and linoleic acid (18:2n-6) content alter platelet phospholipid fatty acids, platelet number and/or platelet function have been published (1–5,8–12). High dietary intakes of cholesterol, on the other hand, have been found to increase platelet phospholipid 20:4n-6 levels (8,13) and sensitivity to some aggregatory agonists (13–15).

Fat represents about 45–50% of the energy in human milk and infant formulas, and milk or formulas often provide the sole source of nutrition for infants for at least three months after birth. The fatty acid composition and cholesterol content of infant formulas usually differs from that of human milk (16). Human milk fatty acids usually contain 20–25% palmitic acid (16:0), 32–38% oleic acid (18:1), 7–16% linoleic acid (18:2n-6), small amounts of linolenic acid (18:3n-3), 20:4n-6 and 22:6n-3 and about 20 mg cholesterol/dL milk (16,17). Infant formulas often contain much lower amounts of 16:0 and 18:1, higher 18:2n-6 and little or no 20:4n-6, 22:6n-3 or cholesterol. Formulas for preterm and other infants who may have low bile salt pools and/or lipase activity often contain medium-chain fatty acids (8:0 plus 10:0), whereas formulas for term infants often contain 12:0 and 14:0, rather than 16:0, as the major source of saturated fatty acids. Some formulas contain 16:0, but the positional distribution of fatty acids in the triglycerides differs from that in milk fats (16,17). Fish oils have recently been added to some preterm infant formulas to provide a dietary source of 22:6n-3 (18,19). The information published on the effects of dietary fat on platelet lipid composition, size and number in adult humans and other species suggests that the differences in fat composition among formulas and milk may result in differences in platelet lipid composition, possibly in platelet size and number and in infants. The effects of formula feeding on platelet lipids or morphology in human infants has not been reported and is difficult to study because of practical limits in blood sample size.

Pig milk has a lipid composition similar to that of human milk, and pathways of lipid digestion, absorption and metabolism are also similar in piglets and in human infants (20,21). The objective of the present studies was to determine the effect of the saturated fatty acid chain length (8:0 plus 10:0, 12:0 plus 14:0, or 16:0), 18:1 content, addition of 20:5n-3 and 22:6n-3 from fish oil, and cholesterol content of formula on platelet phospholipid fatty acid composition, platelet size and number in piglets fed with formulas from birth. For practical reasons related to the number of samples studied, and difficulty of extrapolating results from *in vitro* tests of platelet function to physiological events *in vivo*, tests of platelet aggregatory activity were not included.

MATERIALS AND METHODS

Animals and diets. Male Yorkshire piglets of term gestation were taken within 12 h of birth and randomly assigned to one of eight formula groups. Piglets fed sow milk were identified at birth, but left with their natural mothers. Animals within a dietary group were not littermates. Piglets were fed the formulas by bottle every 3–4 h from 0700 to 2400 h until the eighteenth day after birth. Passive immunity was provided by addition of pig serum-derived immunoglobulin to the formula for the first 72 h (20).

Eight formulas, identical in all respects except for fat composition, were designed as two groups, four formulas each, as shown in Table 1 and 2. The formulas in Group 1 had similar amounts of 18:2n-6 and 18:3n-3, and all

[a]MCT, medium-chain triglycerides.
[b]High oleic safflower or sunflower oil.

contained a low amount of 16:0 (Table 2). In three of the formulas, 40% of the fat blend was medium-chain triglyceride oil (MCT, 42.5 wt% formula fatty acids as 8:0 plus 10:0) with 10.8–11.2% 18:1; one formula had no additions (A), one had 3% fat blend as fish oil [0.5 and 0.3 wt% formula fatty acids as 20:5n-3 and 22:6n-3, respectively (B)] and one had 42 mg cholesterol (10 mg free cholesterol, 32 mg cholesteryl palmitate)/dL (C) (Table 1). The other formula in Group 1 had 20% of the formula fat blend as MCT (21.2 wt% formula fatty acids as 8:0 plus 10:0) with 18:1 increased to 34.9% 18:1 (D) (Table 2). The formulas in Group 2 contained similar amounts of 18:1, 18:2n-6 and 18:3n-3 but differed in the chainlength of the predominant saturated fatty acids; 8:0 plus 10:0 (E), 10:0 plus 12:0 (F) or 16:0 (G and H). Formula G had 27.0% 16:0, largely from palm oil (Table 2), with 6.5% 16:0 esterified to the 2-position of the triglyceride glycerol (22). Formula H contained Betapol, a synthetic triglyceride which had 29.6% 16:0, of which about 70% was esterified to the 2-position of the triglyceride glycerol (22), as it is in human (17) and in pig (22) milk. Formula H was included because previous studies found that the position of 16:0 in formula triglycerides influenced the fatty acid composition of plasma lipids in formula-fed piglets (22). All procedures used in these studies were approved by the University of British Columbia Animal Care Committee and conformed to guidelines set by the Canadian Council on Animal Care.

Analytical procedures. Blood was collected (20) from anesthetized piglets (Ketamine, MTC Pharmaceuticals, Cambridge, Ontario, Canada; plus Rompun, Bayvet Division, Chemagro Ltd. Etobicoke, Ontario, Canada; 37.5 mg/kg plus 3.75 mg/kg, respectively) after an overnight fast. The first 10 mL blood collected was not used for platelet assays. Platelet-rich plasma was prepared from blood by centrifugation for 15 min at 120 × *g* at 4°C. The platelets were recovered by further centrifugation, 15 min at 1100 × *g* at 4°C, using plastic tubes. The platelets were washed twice with 3 mM ethylenediaminetetraacetic acid in saline. Plasma was separated by centrifugation of whole blood at 2500 × *g* for 15 min at 4°C. Samples for lipid analyses were stored at −70°C. Measurements of platelet count, volume and platelet distribution width (PDW, a measure of the variation in platelet volume) and of prothrombin time (PT) and activated partial thromboplastin time (APTT) were done by routine procedures used in the Hematopathology Laboratory of the B.C. Children's Hospital, employing an automated multiparameter blood counter TOA Sysinex NE-8000, NE-5500 (CanLab, Vancouver, British Columbia, Canada).

Plasma and platelet lipids were extracted, and phospholipids, triglycerides and cholesteryl esters were separated by thin-layer chromatography and recovered (20). Platelet and plasma phospholipid fatty acids were converted to their respective methyl esters with methanolic HCl (1:5, vol/vol) at 100°C for 5 min. Methyl esters of fatty acids in plasma triglycerides and cholesteryl esters were prepared by reaction with BF_3/benzene/methanol (25:20:55, by vol) at 100°C for 30 min and BF_3/benzene/methanol (35:30:35, by vol) at 100°C for 45 min, respectively. Methyl esters were recovered, separated and quantitated by capillary column gas-liquid chromatography (GLC) with 17:0 as the internal standards (20). The fatty acid composition of plasma lipids from these piglets has been published (22).

TABLE 2

Major Fatty Acid Components[a]

Fatty acids (% total fatty acids by wt)	Formula								Pig milk
	Group 1				Group 2				
	A	B	C	D	E	F	G	H	
8:0	30.5	30.5	30.5	15.2	22.2	3.2	0.5	0.6	0.1
10:0	12.0	12.0	12.0	6.0	8.2	1.9	0.4	0.4	0.2
12:0	9.4	9.4	9.4	4.7	0.6	19.1	3.3	3.3	0.2

16:0	5.9	6.1	5.9	6.0	4.3	6.5	27.0	29.6	30.7
18:0	2.4	2.3	2.4	3.7	3.0	3.4	5.6	3.1	4.4
18:1	11.2	10.8	11.2	34.9	40.8	39.0	40.0	40.6	40.4
18:2n-6	21.7	20.2	21.7	23.7	16.2	15.6	16.4	16.4	8.2
18:3n-3	3.1	2.9	3.1	3.2	3.4	3.2	3.1	3.2	0.8
20:1					0.5	0.4	0.4	0.4	0.1
20:5n-3		0.5							0.2
22:6n-3		0.3							0.1

[a]The formulas contained no C_{20} or C_{22} ± n-6 fatty acids, the sow milk had 0.7% 20:4n-6. Levels of 22:1 did not exceed 0.1% fatty acids in any formula.

The cholesterol content in extracted platelet lipid was determined with enzymatic kit reagents (BioPacific Diagnostic Inc., North Vancouver, British Columbia, Canada). Phospholipid content was calculated from the quantitative analyses of phospholipid fatty acids by GLC. Phospholipid fatty acid unsaturation indices (UIs) were calculated as described previously (23).

Statistical analysis. Differences between a group of formula-fed and the sow milk-fed piglets, differences between piglets fed Formula B, C or D and piglets fed Formula A, and differences among the groups fed Formulas E, F, G and H were determined using two-way analysis of variance. The number of animals in each group was six, except for the Formula G with saturated fatty acids from palm oil, in which there were five piglets. The statistical analyses were performed with the Number Cruncher Statistical System, version 5.01 (Kaysville, UT).

RESULTS

Platelet number and size. Considerable variability in platelet numbers, PDW and volume was found among the piglets (Table 3). Similar variability in platelet size and numbers also occurs within and among healthy humans (24). Piglets fed Formula D with 20% MCT plus 34.9% 18:1 had significantly lower platelet numbers and higher platelet PDW and volumes than piglets fed sow milk, and lower platelet numbers than piglets fed Formula A with 40% MCT plus 11.2% 18:1 (Table 2). Piglets fed Formulas E and F with high 18:1 and saturated fatty acids as 8:0 plus 10:0, or 12:0 plus 14:0, also had significantly lower platelet numbers and higher platelet PDW and volumes than piglets fed sow milk or piglets fed Formulas G and H with high 18:1 and saturated fatty acids as 16:0. The three formulas (D, E and F) associated with reduced platelet number and increased platelet size differed from sow milk and Formulas A, B, C, G and H in that they contained high 18:1 (34.9 to 40.8% fatty acids) but low 16:0 (4.3 to 6.5% fatty acids) (Table 2).

Piglets fed Formula C with 40% MCT and cholesterol had a significantly higher mean platelet volume than piglets fed sow milk; the value, however, was not significantly different from that of piglets fed the same formula without cholesterol (Formula A). Addition of n-3 fatty acids from fish oil to the formula had no significant effect on platelet number or size. No significant differences in PT or APTT were found among the groups of formula- and sow milk-fed piglets.

Platelet phospholipid and cholesterol. The platelet lipid cholesterol/phospholipid (mol/mol) ratio was significantly higher in piglets fed Formula A, B, E, F, G or H than in piglets fed sow milk (Table 4). Piglets fed Formula C with cholesterol, or Formula D with low 16:0 and high 18:1 had lower cholesterol/phospholipid ratios in platelet lipid than piglets fed Formula A with low 16:0 and low 18:1, and no added cholesterol. No significant statistical relationships were found between the plasma cholesterol concentration (data not shown) and the platelet lipid cholesterol/phospholipid ratio.

Platelet phospholipid fatty acids. Formulas A, B, C and D contained lower levels of 16:0 (5.9–6.1% fatty acids) and higher 18:2n-6 (20–24%) and 18:3n-3 (2.9–3.2%) than the sow milk (Table 2). The platelet phospholipids of piglets fed these formulas had a significantly lower percentage of 16:0 and 20:4n-6 and significantly higher 18:0 and 18:2n-6 than piglets fed sow milk (Table 4). The platelet phospholipid 18:1 percentage was significantly lower in piglets fed Formulas A, B and C containing 10.8–11.2%, than in piglets fed Formula D with 34.9% 18:1, or piglets fed sow milk. The 18:1 percentage in platelet phos-

[a]Values given are means ± SEM; fatty acids (% wt total); cholesterol/phospholipid (mol/mol). The composition of the formulas is described in Tables 1 and 2. Trace indicates value <0.1% fatty acids; Σ, sum; UI, fatty acid unsaturation index. Fatty acids C<14:0 and 18:3n-3 represented less than 0.1% fatty acids in all groups.
[b,c]Values for piglets fed formula which are significantly different from values for piglets fed sow milk are indicated as [b]$P < 0.05$, [c]$P < 0.0125$. [d,e]Values for piglets fed formula B, C or D were compared to values for piglets fed formula A; a superscript[d] or [e] indicates value significantly different from the value for piglets fed Formula A, $P < 0.05$ or $P < 0.0125$, respectively. [f,g,h,i]Values for piglets fed Formulas E, F, G and H were compared to each other; values with a different superscript are significantly different, $P < 0.05$.

pholipids from piglets fed Formula D, however, was higher than in piglets fed the sow milk containing 40.4% 18:1. Although Formulas A and D had similar amounts of 18:0, 18:2n-6 and 18:3n-3, the platelet phospholipid % 18:0, 18:2n-6 and 22:5n-3, and the phospholipid fatty acid UI was significantly lower in piglets fed Formula D than in piglets fed Formula A.

Piglets fed Formula B with fish oil had significantly higher platelet phospholipid 20:5n-3, 22:5n-3 and 22:6n-3 and significantly lower % 20:4n-6, 22:4n-6 and 22:5n-6 than piglets fed Formula A without fish oil (Table 4). The C_{20} plus C_{22} n-6 to n-3 fatty acid ratio was 4.7 ± 0.3 in piglets fed Formula B, compared to 11.7 ± 0.4 in piglets fed sow milk and mean values of 13.6–15.5 in piglets fed Formulas A, C and D (Table 4). The UI, however, was similar in piglets fed Formula A and B, and significantly lower than in piglets fed sow milk.

Although the fatty acid composition of Formulas A and C were similar, piglets fed Formula C with cholesterol had a significantly lower % 16:0 and higher % 20:4n-6 in platelet phospholipids than piglets fed Formula A without cholesterol. The UI value of piglets fed Formula C was also significantly increased when compared to piglets fed Formula A, but it was not different from that of piglets fed sow milk. Piglets fed Formulas E, F, G and H with 39–40.8% 18:1 and 15.6–16.4% 18:2n-6 had a significantly higher % 18:1 and 18:2n-6 and a significantly lower % 20:4n-6, 22:4n-6 and 22:5n-6 in their platelet phospholipids than piglets fed sow milk (Table 4). The % 16:0 and 18:0 in the phospholipid was significantly, and inversely, altered by the saturated fatty acid composition of the formula fed. Piglets fed Formulas E or F containing 8:0 plus 10:0 or 12:0 plus 14:0 had significantly higher 18:0 and lower 16:0 in platelet phospholipids than in piglets fed sow milk or Formulas G or H with 16:0. The % 18:1, 20:4n-6, 22:5n-3 and 22:6n-3 in platelet phospholipids was also influenced by the saturated fatty acid composition of the formula. Piglets fed Formulas G or H with 27–29.6% 16:0 had a significantly lower % 18:1 and higher % 20:4n-6, 22:5n-3 and 22:6n-3 in platelet phospholipids than piglets fed Formulas E or F with 8:0 plus 10:0 or 12:0 plus 14:0 (Table 4). The % 18:1 and 18:2n-6 was significantly higher, and % 20:4n-6, 22:4n-6 and 22:5n-6 was significantly lower in platelet phospholipids of piglets fed Formulas E, F, G and H than in piglets fed sow milk. The platelet phospholipid % 20:5n-3 in piglets fed Formula F, G or H and the % 22:6n-3 in piglets fed Formula G was significantly higher, but the % 22:5n-3 in piglets fed Formula E was lower than in piglets fed sow milk. The platelet phospholipid UI was similar among piglets fed sow milk and Formulas G or H, but piglets fed Formulas E or F had a significantly lower UI than in piglets fed sow milk. The difference in the position of 16:0 in the triglycerides of Formulas G and H had no apparent effect on the fatty acid composition of the platelet phospholipids.

DISCUSSION

The results of these studies show that the fat composition of the formula fed to young piglets influences the lipid composition, number and size of platelets. Diet-related changes in platelet phospholipid fatty acids could occur during *de novo* phospholipid synthesis, or later during exchange of intact phospholipids with plasma lipoprotein

phospholipids, or by phospholipid deacylation and reacylation (25–27). The fatty acid composition of human platelet phospholipid is known to show a high degree of correspondence with plasma phospholipid, triglyceride and cholesteryl ester fatty acids (28). The piglet platelet phospholipid % 16:0, 18:1 and 18:2n-6 was significantly ($P < 0.001$, n = 53 piglets) correlated with the % 16:0, 18:1 and 18:2n-6 in plasma phospholipids, r = 0.53, 0.95, 0.85; triglycerides, r = 0.70, 0.95, 0.91; and cholesteryl esters, r = 0.78, 0.91, 0.89, respectively. The platelet phospholipid % 20:4n-6 showed a significant correlation to the % 20:4n-6 in plasma phospholipid (r = 0.46, $P < 0.01$), but not in triglyceride or cholesteryl ester fatty acids. These relationships suggest that changes in platelet phospholipid fatty acid composition should be considered in infants known to have altered plasma lipid fatty acid compositions due to formula rather than breast-feeding.

Significant inverse correlations between the platelet phospholipid % 16:0 and 18:0, r = −0.71 $P < 0.001$; 18:1 and 18:2n-6, r = −0.70, $P < 0.001$; and 18:2n-6 and 20:4n-6, r = −0.40 $P < 0.05$; and a positive correlation between the % 16:0 and 20:4n-6, r = 0.51, $P < 0.001$, were also found. Palmitic acid (16:0) and 18:0 are usually esterified to the 1-position, whereas most of the 18:1, and almost all of the 18:2n-6 and 20:4n-6, is usually esterified to the 2-position of platelet phospholipids (26,29,30). An inverse relationship between 16:0 and 18:0 is apparent in other studies on the effects of dietary fat on human and animal platelet phospholipid fatty acids (5,10). As particular saturated fatty acids are preferentially combined with certain unsaturated fatty acids (30), it seems possible that the changes in 16:0 and 18:0 may have been secondary to diet-induced changes in 18:1, 18:2n-6 or 20:4n-6 at the 2-position of the platelet phospholipids. The higher % 18:2n-6 in the platelet phospholipids of piglets fed the formulas than in piglets fed sow milk was consistently accompanied by a lower % 20:4n-6. Competition between 18:2n-6 and 20:4n-6 for acylation into phospholipids has been suggested (31), and could be the result of the higher amounts of 18:2n-6 in the formulas than in the sow milk (Table 2). Lower platelet phospholipid 20:4n-6 has been reported for animals fed diets high in 18:2n-6 rather than saturated fat (8), and vegetable oils high in 18:1 or 18:2n-6 have been found to decrease platelet phospholipid 20:4n-6 in humans (1,10,11). The small amount of 20:4n-6 in sow milk, but absence of 20:4n-6 in the formula, could also explain the lower platelet 20:4n-6 in piglets fed formula rather than milk.

The increased % 20:4n-6 in the platelet phospholipid of piglets fed the formula with cholesterol (Table 4) is consistent with published data on the effects of dietary cholesterol on platelet cholesterol and 20:4n-6 in other species (8,13). The increase in platelet phospholipid 20:4n-6 was not accompanied by increased plasma phospholipid 20:4n-6 (6.6 ± 0.4% and 6.9 ± 0.4%, piglets fed Formula A with cholesterol and Formula C without cholesterol, respectively). Whether cholesterol as a component of natural milk is related to high platelet phospholipid % 20:4n-6 has not been considered.

Platelet phospholipid levels of 20:5n-3 are increased and 20:4n-6 is decreased in humans and in other animals fed diets containing marine lipid (2–7). Formula B with fish oil contained only 0.5% formula fatty acids as 20:5n-3, but still resulted in a significant decrease in the % 20:4n-6 in the platelet phospholipids of piglets fed the product (Table 4). Premature infants fed with formula have low plasma phospholipid levels of 20:4n-6, and 20:4n-6 is further reduced when these infants are fed formula with fish oil (18). The % 20:5n-3 in the platelet phospholipids of piglets fed Formula B was much higher than the % 22:6n-3 (2.2 ± 0.1, 0.8 ± 0.1% 20:5n-3 and 22:6n-3, respectively). Liver and brain of piglets fed similar formulas with fish oil, in contrast, contained only small amounts of 20:5n-3, and 22:6n-3 was present in much higher amounts (32). Evidence that 20:5n-3 may be incorporated into platelet phospholipids in higher amounts than 22:6n-3 has been published for humans consuming marine oils (3,7) and rats fed fish oil (5). The activity of rat platelet 1-acylglycerophosphocholine acyltransferase has been reported to be higher with 20:5n-3 than with 22:6n-3 as the substrate (33). Such enzyme substrate selectively could explain the apparent greater propensity of platelets than other cells to accumulate dietary 20:5n-3.

Liberation of 20:4n-6 from platelet phospholipid and subsequent oxygenation to proaggregatory eicosanoids is part of the mechanism involved in platelet reactivity (26,34,35). Although the availability of 20:4n-6 is a major determinant of platelet reactivity, this can be modified by other fatty acids, such as 20:5n-3, or fatty acid metabolites which compete or antagonize 20:4n-6 or its products. Changes in membrane cholesterol or phospholipid can also influence the response to stimuli by altering the physical properties of the membrane structure. Decreased platelet sensitivity to aggregating agonists has been found after feeding diets high in marine lipids (6,7), 18:2n-6 (9,10,12) or 18:1 (1,11), which also decreased platelet 20:4n-6. Oral administration of 20:4n-6 and diets high in saturated fat or cholesterol, on the other hand, have been found to increase platelet aggregability and 20:4n-6 (7,10,15,25,36).

Platelet volume is known to vary inversely, although not linearly, with platelet number in adult humans (24). The inverse changes in platelet number and size found in piglets in response to the different formula diets is, therefore, not unusual. The relationship of changes in platelet numbers and size to thrombopoiesis, and/or destruction, however, is not well understood. Decreased platelet numbers accompanied by increased platelet size was found in these studies in piglets fed formulas high in 18:1 (34.9–40.8%) and low in 16:0 (4.3–6.3%), but not in piglets fed formulas high in both 18:1 and 16:0 (27.0–29.6%), or low in both 16:0 (5.9–6.1%) and 18:1 (10.8–11.2%). Reduced platelet number and increased platelet size has been associated with reduced responsiveness to some aggregating agonists and lower platelet lipid 20:4n-6 (6,10,37). The decrease in platelet number has been suggested to possibly reflect decreased reactivity of platelets low in 20:4n-6, leading to reduced thrombopoiesis by reason of decreased thrombopoietin (37). Whether or not the lower platelet phospholipid 20:4n-6 in piglets fed formula rather than milk was accompanied by any change in platelet activity, survival rates, or thrombopoiesis is not known.

Our studies with piglets fed formulas with fat blends similar to those in infant formulas emphasize the need to consider the possible effects of formula feeding on platelet lipid composition and, more importantly, platelet size, number and function in human infants. The statistical

relationships between plasma and platelet lipid fatty acid composition may be of value in predicting possible groups at risk for diet-related changes in platelet composition. The possible sensitivity of platelet phospholipids to accumulate 20:5n-3 should be considered in the choice of oils used to provide a source of 22:6n-3 for infant formulas.

Three groups of sixteen male rats each were fed semipurified diets containing 15% by weight of lipid for a period of 4 wk. The diets contained the same amount of polyunsaturated fatty acids (PUFA) (20% of total fatty acids) and saturated fatty acids (19% of total fatty acids). Dietary PUFA were represented exclusively by linoleic acid (18:2 diet), or 10% linoleic acid and 10% linolenic acid (18:3 diet), or 10% linoleic acid and 10% long-chain n-3 fatty acids (LCn-3 diet). The overall amount of vitamin E was similar in the three diets, *i.e.*, 140, 133 and 129 mg/kg diet, respectively. Following appropriate extraction, tocopherol levels in heart, liver, brain, adipose tissue (AT) and plasma were measured by high-performance liquid chromatography. The level of vitamin E in the heart decreased with n-3 PUFA diets, most markedly with LCn-3 PUFA. Liver and AT vitamin E contents also decreased with n-3 PUFA diets when expressed as μg/mg total lipids and μg/mg phospholipids, respectively. Total plasma vitamin E was lower in rats fed the LCn-3 diet, but there was no significant difference when expressed as μg/mg total lipids. Brain vitamin E was not affected by the various diets. *In vitro* cardiac lipid peroxidation was quantified by the thiobarbituric acid reactive substances (TBARS) test. Heart homogenates were incubated at 37°C for 15 and 30 min in both the absence (uninduced) or presence (induced) of a free radical generating system (1 mM xanthine, 0.1 IU per mL xanthine oxidase, 0.2 mM/0.4 mM Fe/ethylenediaminetetraacetic acid). TBARS release was time-independent but significantly higher when LCn-3 fatty acids were fed to rats in either the uninduced or induced system. The study demonstrated that n-3 PUFA diets can influence vitamin E status of rats even in short-term experiments and can change the susceptibility of the heart to *in vitro* lipid peroxidation.
***Lipids* 28, 651–655 (1993).**

Polyunsaturated fatty acids (PUFA) of vegetable or marine origin have been recommended to lower the incidence of coronary heart disease. Epidemiological studies in particular have shown an apparent beneficial effect of marine n-3 PUFA intake in reducing mortality from heart disease (1,2). Fish oils contain the longest chain n-3 PUFA, namely eicosapentaenoic acid (20:5n-3, EPA) and docosahexaenoic acid (22:6n-3, DHA). These PUFA have five and six double bonds, respectively, and when they are present in the diet, they are readily incorporated into membrane phospholipids (PL), mainly at the expense of arachidonic acid (20:4n-6) (3). The result is an increase in the unsaturation of the membranes, making them more susceptible to peroxidation *in vitro* and *in vivo* (4–6). The major lipid-soluble chain-breaking antioxidant in plasma, red cells and tissues is vitamin E (7). The most potent antioxidant and biological form of the vitamin is α-tocopherol which scavenges peroxyl radicals by donating its phenolic hydrogen to them. Although several studies of feeding fish oils on the vitamin E status of animals have been carried out, few have compared diets providing the same amount of PUFA (5,6,8).

In the present study, rats were fed diets containing not only the same amount of PUFA from the n-6 and/or n-3 families [20% of the total fatty acids (FA)] but also the same amount of saturated FA. Dietary PUFA were represented exclusively by linoleic acid (18:2 diet), by 10% linoleic acid and 10% linolenic acid (18:3 diet), or by 10% linoleic acid and 10% long chain n-3 fatty acids (LCn-3 diet). The vitamin E status of the rats was measured, and the susceptibility to induced or uninduced heart lipid peroxidation conferred by n-6 or n-3 PUFA was determined.

MATERIALS AND METHODS

Animals and diets. Male specific pathogen-free rats of the Sprague-Dawley (Iffa Credo, L'Arbresle, France) strain were used. The animals weighed 80–100 g at the start of the experiment and were housed in individual stainless steel cages in a room of controlled temperature (21 ± 1°C), humidity (55–60%) and lighting (12 h dark-light cycle). The animals were allowed free access to food and sterile water. The rats were maintained on a commercial nonpurified diet (Usine d'Alimentation Rationnelle, Villemoisson-sur-Orge, France) for 5 d before transfer on the experimental diets (9). Three groups of sixteen animals each were fed semipurified diets for 4 wk. The diets contained 15% by weight of fat varying in the n-6 and n-3 PUFA content and type, but the total amount of PUFA was kept constant (20% of total FA). The 18:2 diet contained small amounts of n-3 PUFA (0.4% of total FA), the 18:3 diet contained linolenic acid as the only source of n-3 PUFA (10% of total FA), the LCn-3 diet contained the same amount of LCn-3 C_{20} and C_{22} PUFA (10% of the total FA). Saturated FA content was similar in all diets (19% of total FA). Various mixtures of refined vegetable oils (olive, palm, sunflower, linseed) and menhaden oil were used to obtain the appropriate fatty acid composition of the dietary fats (Table 1). The overall amount of vitamin E was high and similar in the three diets, *i.e.*, 140, 133 and 129 mg/kg diet for 18:2, 18:3 and LCn-3 diets, respectively. Thus, these levels were well above the 50 mg/kg vitamin E normally recommended for rat diets (10,11). Animals were given free access to diets which were freshly prepared and changed every two days.

Blood and tissue sampling. At the end of the feeding period, six rats of each diet group were anaesthetized with an air/diethyl ether mixture, and blood was collected over ethylenediaminetetraacetic acid (EDTA) *via* the abdominal aorta. The samples were immediately centrifuged at

[a]Expressed as percentage (w/w) of total dietary fats. PUFA, polyunsaturated fatty acids. LCn-3, long chain n-3 fatty acids.
[b]Expressed as percentage (w/w) of total fatty acids present.
[c]Represented by the sum of the values for 15:0, 16:1n-9, 17:0, 22:0, each being lower than 0.2%.
[d]Represented by the sum of the values for 15:0, 16:1n-9, 16:2n-4, 16:3n-4, 16:4n-1, 17:0, 18:2n-4, 18:3n-6, 18:3n-4, 18:4n-1, 20:1n-7, 20:2n-6, 20:3n-6, 20:4n-6, 20:3n-3, 22:0, 22:1n-11, 22:1n-9, 22:5n-6, 24:0, 24:1n-9, each being lower than 0.2%.

+4°C to collect plasma. After the animals were killed, the hearts were rapidly excised and rinsed in ice-cold saline solution. Liver, brain and adipose tissue were also taken. Plasma and all organs were divided into two portions; one part was frozen in liquid nitrogen and stored at −80°C awaiting vitamin E analysis, and the other part was stored in chloroform/methanol (2:1, vol/vol) prior to lipid analysis. Ten rats from each diet group were sacrificed as described above, but only the hearts were removed and frozen in liquid nitrogen for use in lipid peroxidation studies.

Vitamin E extraction and quantification. Prior to extraction, tissues were homogenized in 3 vol of distilled water. Vitamin E was extracted from the plasma, the heart and the brain, using a method based on that mentioned by Burton *et al.* (12). To 0.5 mL of plasma, or 0.5 mL of tissue homogenate, were added 1 mL of 0.1 M sodium dodecylsulfate (SDS) and 2 mL of ethanol. The mixture was vortex-stirred for 30 s. Then, 1 mL of *n*-heptane was added, the sample was vigorously mixed by vortexing for 30 s and the aqueous and the organic layers were separated by centrifugation for 2 min at 1700 × *g*. The organic layer was carefully drawn off and measured with a 1-mL syringe and transferred to a screw-cap vial. The residue was reextracted two times with 1 mL of *n*-heptane as described above. The extracts were combined and stored at −20°C for analysis.

The method for measuring vitamin E in liver and adipose tissue was adapted from that by Butriss and Diplock (13). To 0.5 mL of tissue homogenate was added 2 mL of 1% pyrogallol in absolute ethanol. After 2 min equilibration at 70°C, 0.3 mL of saturated potassium hydroxide was added, and the resulting mixture was incubated for another 30 min at 70°C. After cooling in ice, 1 mL of distilled water was added, followed by 1 mL of *n*-heptane. The organic layer was removed, and the residue was reextracted two times with 1 mL of *n*-heptane as described above.

Separation and quantification of the four isomers of tocopherol was accomplished by high-performance liquid chromatography (HPLC) coupled with fluorescence spectrophotometric detection (Kontron, Milan, Italy). The analytical column used a 5-μ amino bonded phase (4.6 mm i.d. × 15 cm length). The mobile phase was *n*-heptane/2-propanol (98:2, vol/vol), and the flow rate was 1.6 mL/min. Fluorimetric measurements of tocopherols were done at 285 nm excitation and 325 nm emission. Quantification was done relative to solutions containing known amounts of α, β, γ and δ tocopherol.

Lipid analysis. It has been suggested that expressing vitamin E content as milligrams of tocopherol per gram of fat is a better index than using milligrams per gram of fresh tissue (14). Tissue and plasma total lipids (TL) were therefore extracted according to Folch *et al.* (15), and in the case of tissues total PL were separated from nonphosphorus lipids (NPL) using silicic acid cartridges (16).

In vitro *lipid peroxidation in heart homogenates. In vitro* heart lipid peroxidation was measured on heart homogenates in phosphate buffer (10%, wt/vol). One mL of heart homogenate was incubated in vials in a shaking waterbath at 37°C for 15 or 30 min in the absence (uninduced) or presence (induced) of xanthine/xanthine oxidase/Fe-EDTA (X/XO/Fe-EDTA. 1 mM/0.1 IU per mL/0.2 mM/0.4 mM) as free radical generating system. Heart lipid peroxidation was measured by the thiobarbituric acid reactive substances (TBARS, nmol/g wet weight) assay in the medium after incubation (17).

Statistical analysis. One-way analysis of variance was applied to the data. Group means were compared by the Newman Keuls' test.

RESULTS

Food consumption, animal weight gains and organ weights were similar in the three dietary groups. Only the α-tocopherol isomer could be detected in extracts, and the levels found in plasma and organs were similar or even higher than those found in earlier studies (6,8,18,19). Vitamin E and lipid levels in various organs are shown in Figures 1-4 and Table 2.

Tissues and plasma vitamin E. Heart α-tocopherol content (μg/g wet tissue) was significantly lower when n-3 PUFA were fed to rats (Fig. 1). It decreased by about 20% when the diet was rich in LCn-3. TL, NPL and PL were not significantly affected by the diets (Table 2). The α-tocopherol concentrations expressed as μg/mg of TL (Fig. 2) and NPL (Fig. 3) were not different between the three groups. Only the α-tocopherol concentration expressed

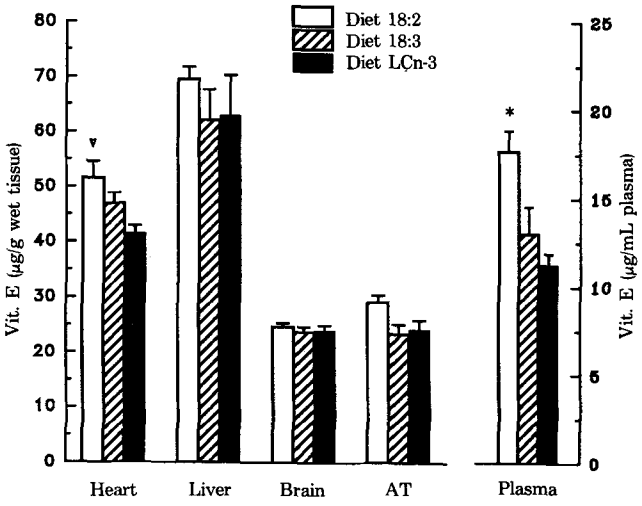

FIG. 1. Total vitamin E (Vit. E) content expressed per g wet tissue or per mL of plasma from rats fed experimental diets. The data are means ± SEM (n = 6). For the plasma, the value bearing an asterisk is significantly different from the other dietary treatments ($P < 0.01$). For the heart, the value bearing a triangle is significantly different from the long-chain n-3 fatty acids (LCn-3 diet) ($P < 0.01$). AT, adipose tissue.

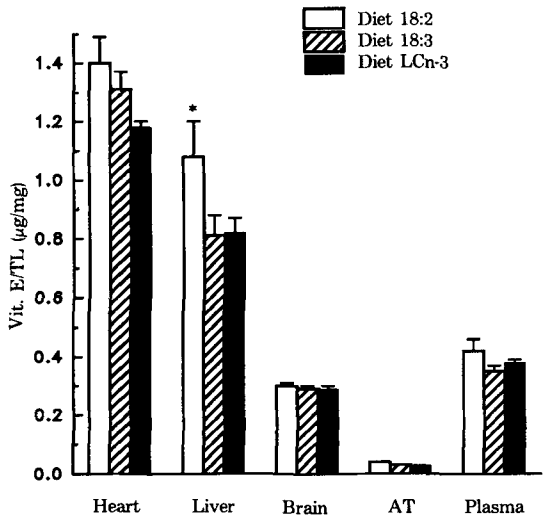

FIG. 2. Total vitamin E content expressed per mg of total lipids (TL) in tissues and plasma of rats fed experimental diets. The data are means ± SEM (n = 6). For the liver, the value bearing an asterisk is significantly different from the other dietary treatments ($P < 0.05$). For abbreviations, see Figure 1.

as μg/mg of PL differed significantly between the 18:2 diet and the LCn-3 diet (Fig. 4).

Liver α-tocopherol concentrations (μg/g wet tissue) were not significantly different in the three diets (Fig. 1). As for the heart, the diets did not significantly modify lipid parameters (Table 2). However, when the liver α-tocopherol concentration was expressed as μg/mg TL, the two n-3 PUFA diets caused significantly lower values (Fig. 2). This decrease could be related to an increase in TL in liver with n-3 FA feeding.

The diets had no effect on α-tocopherol and lipid contents in the brain (Figs. 1-4, Table 2). The α-tocopherol concentration in AT was not affected when n-3 FA were present in the diet (Fig. 1). However, vitamin E content, expressed as μg/mg PL, was significantly decreased by n-3 PUFA diets (Fig. 4). This could be explained by the higher PL content of adipose tissue when n-3 PUFA were added to the diet (Table 2).

Vitamin E concentrations in plasma were significantly decreased by n-3 PUFA (Fig. 1). Lipid levels were also reduced by 30% when the LCn-3 diet was administered (Table 2). Therefore, plasma vitamin E contents when expressed as μg/mg plasma TL were not significantly different from one diet to the other (Fig. 2).

In vitro *heart lipid peroxidation.* As expected, the free radical generating system X/XO/Fe-EDTA enhanced heart lipid peroxidation, but in a time-independent manner. TBARS were significantly higher in the LCn-3 fed animals than in rats fed the 18:2 or 18:3 diets after 15 min at 37°C in either an uninduced or induced system (Fig. 5). The

	NPL (mg/g tissue)	826.8 ± 37.6	878.3 ± 8.5	867.3 ± 10.3
	PL (mg/g tissue)	8.2 ± 1.7[b]	13.4 ± 1.3[c]	11.4 ± 0.7[b,c]
Plasma	TL (mg/mL plasma)	4.3 ± 0.4[b]	3.7 ± 0.4[b,c]	2.9 ± 0.1[c]

[a]Values are expressed as means ± SEM (n = 6). Within a line, values bearing different superscript letters differ at $P < 0.05$. Abbreviations: LCn-3, long-chain n-3 fatty acids; TL, total lipids; NPL, nonphosphorous lipids; PL, phospholipids.

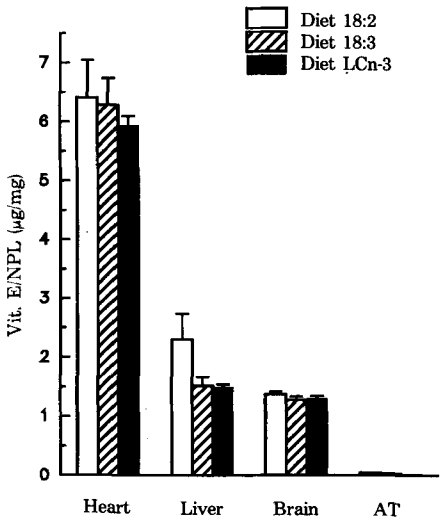

FIG. 3. Total vitamin E content expressed per mg of nonphosphorus lipids (NPL) in tissues of rats fed experimental diets. The data are means ± SEM (n = 6). For other abbreviations, see Figure 1.

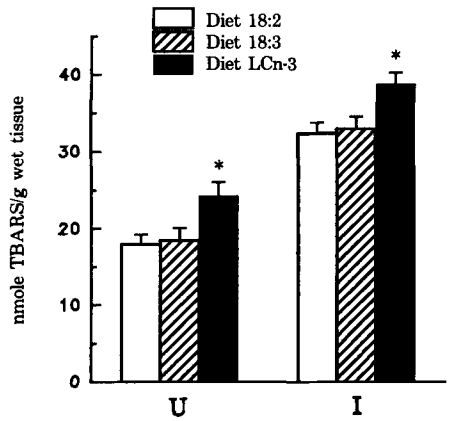

FIG. 5. Lipid peroxidation of heart homogenates from rats fed experimental diets. The data are means ± SEM (n = 10). Heart homogenates were incubated at 37°C for 15 min in the absence (U) or presence (I) of a free radical generating system (1 mM xanthine, 0.1 IU per mL xanthine oxidase, 0.2 mM/0.4 mM Fe/ethylenediaminetetraacetic acid). The values bearing an asterisk are significantly different from the other dietary treatments in the same incubation system ($P < 0.05$). TBARS, thiobarbituric acid reactive substances. LCn-3, long chain n-3 fatty acid.

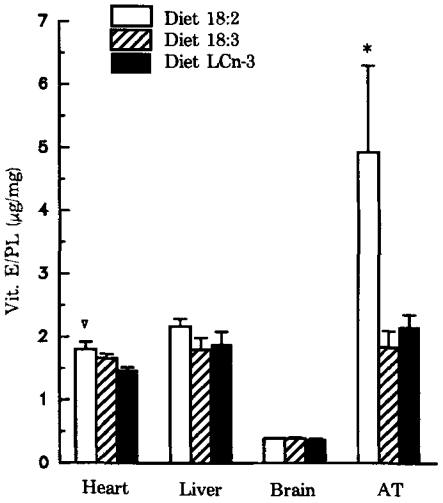

FIG. 4. Total vitamin E content expressed per mg of phospholipids (PL) in tissues of rats fed experimental diets. The data are means ± SEM (n = 6). For the adipose tissue, the value bearing an asterisk is significantly different from the other dietary treatments ($P < 0.01$). For the heart, the value bearing a triangle is significantly different from the LCn-3 diet ($P < 0.05$). For other abbreviations, see Figure 1.

same profiles were observed after 30-min incubation at 37°C, but differences between groups were no longer significant.

DISCUSSION

In the present study we compared the effect of three diets varying in the type and composition of PUFA on vitamin E status and on heart lipid peroxidizability in rats. Membrane PUFA composition and consequently susceptibility to peroxidation is largely dependent on the dietary supply of PUFA. When studying the effect of the type of PUFA administered (*i.e.*, n-6 *vs.* n-3) on both vitamin E status and tissue peroxidizability, care must be taken to feed the rats the same amount of total PUFA. Previous studies (5,6,8,20) have compared diets which supplied total PUFA or saturated FA unequally thus making data interpretation difficult. In the present study, all rats were fed with 20% of the total FA as PUFA as well as saturated FA. Consequently, the PUFA/saturated ratio was the same in the three diets and only the nature of the PUFA varied; 18:2n-6 was partially replaced by 18:3n-3 or LCn-3 PUFA (essentially 20:5 and 22:6n-3). Moreover, our protocol permitted a comparison of n-6 PUFA *vs.* n-3 PUFA on the one hand, and of the precursor (α-linolenic acid) *vs.* its metabolites (essentially EPA and DHA) on the other. In a previous study (3), significant increases in unsaturation in heart PL were seen in rats fed n-3 PUFA in comparison to n-6 PUFA. It was also clearly demonstrated that dietary LCn-3 PUFA had a stronger effect on the fatty acid composition of rat heart PL than their precursor α-linolenic acid which was also present at the same level in the diet. Dietary consumption of LCn-3 PUFA resulted in a much greater incorporation of 20:5n-3 and 22:6n-3 and a much lesser proportion of 20:4n-6 into heart phosphatidylcholine and phosphatidylethanolamine than an equivalent intake of 18:3n-3.

In the present study, it was shown that the type of dietary PUFA also significantly affected the heart vitamin E content which decreased with the n-3 diets, most markedly with the LCn-3 diet. Our data are not in complete agreement with those of Chautan *et al.* (8) who showed that heart α-tocopherol levels in rats fed LCn-3 PUFA were higher than those in rats fed 18:2n-6. In fact, these authors found vitamin E concentrations similar to ours in rats fed LCn-3 diets, but obtained much lower values for animals fed 18:2n-6. This discrepancy between the two sets of data remains to be explained inasmuch as the levels of dietary 18:2n-6 and vitamin E administered to the rats in Chautan's study (8) were higher than

those used in our study. The decrease in heart vitamin E content observed with the n-3 diets in the present study could suggest that more tissue E is required to protect a membrane enriched in n-3 PUFA against peroxidation. Our *in vitro* experiments on heart peroxidation, indeed, confirmed that membranes enriched in n-3 are more susceptible to peroxidation. The data are also in agreement with other studies (5,6) showing that peroxidation in liver and kidney homogenates as well as in liver and heart slices was enhanced by fish oil diets. Disappearance of vitamin E in hearts of rats fed LCn-3 PUFA is therefore likely to be due to mechanisms that take place within the organ, such as peroxyl radical scavenging by vitamin E (21).

Although total plasma vitamin E content was shown to be lower in rats fed LCn-3 PUFA, it was not different from that of the other dietary groups when expressed as μg/mg TL. Our results agree with those by Chantan *et al.* (8) who found the same α-tocopherol/(cholesterol + triglycerides) ratio for all diets they used.

Liver and AT are the major storage sites for α-tocopherol. Both stores tend to be lowered when n-3 PUFA are fed to rats, but the decrease in vitamin E content is significant only if expressed as μg/mg PL in AT or as μg/mg TL in liver. Our results agree with those of other studies which have shown that fish oils lower the α-tocopherol content in the liver of both rats (8) and mice using α-tocopherol supplemented diets (20). However, Leibovitz *et al.* (6) did not find any difference in rat liver α-tocopherol levels following corn oil–lard or menhaden oil diets. In spite of the high levels of vitamin E in the diets (180 mg/kg), the values they found were very low in comparison with ours (about 17 μg vitamin E/g tissue *vs.* more than 60 μg/g), and it cannot be excluded that vitamin E was incompletely extracted. According to Drevan (22), an increased dietary intake of EPA may enhance the demand and utilization of α-tocopherol as an antioxidant by various tissues and, consequently, the amount of vitamin E available for hepatic secretion may be reduced in hepatocytes exposed to dietary EPA.

Brain vitamin E was not affected by dietary PUFA. This could be expected since PUFA composition of brain lipids was not modified by feeding rats the same diets for four weeks (Javouhey-Donzel, A., unpublished data). Many studies have shown that brain fatty acid composition is more resistant to changes in dietary lipids than are other tissues (*e.g.*, Ref. 23).

We conclude that n-3 PUFA diets can influence the vitamin E status of rats even in short-term experiments and that n-3 PUFA can change the susceptibility of the heart to peroxidation. Beneficial cardiovascular effects of fish oils could thus be counterbalanced by an increase in lipid peroxidation. This would suggest that caution would be warranted in using fish oil concentrates as n-3 PUFA supplements of the human diet.

The purpose of this study was to determine the effects of dietary fat quantity and fatty acid composition on hepatic H_2O_2-metabolizing systems, activities of NADPH-generating enzymes and lipid peroxidation. One-month-old male C57BL/6J mice were fed one of six diets: (i) 5% fat, rich in 18:2n-6 fatty acid (5% N-6); (ii) 20% fat, rich in 18:3n-3 (N-3); (iii) 20% fat, rich in 18:2n-6 (N-6); (iv) 20% fat, rich in 18:1n-9 (N-9); (v) 20% fat, rich in saturated fatty acids (SAT); and (vi) 20% fat, deficient in essential fatty acids (EFAD); for 11 wk. Comparisons between animal groups receiving different fat quantities showed that activities of glucose-6-phosphate dehydrogenase (G6PDH, EC 1.1.1.49) and malic enzyme (ME, EC 1.1.1.40) and the levels of conjugated dienes were significantly lower in the N-6 than in 5% N-6 group. Conversely, activities of catalase (CAT, EC 1.11.1.6) and selenium-glutathione peroxidase (SeGSHPx, EC 1.11.1.9) were higher in the N-6 than in 5% N-6 group. Among the five dietary groups receiving 20% fat but differing in fatty acid composition, CAT activity was lower in the N-9 group, SeGSHPx activity was lower in the EFAD group, and glutathione reductase (GSSGR, EC 1.6.4.2) activity was higher in the N-6 than in the N-3, N-9, SAT and EFAD groups. The EFAD group had much higher levels of total lipids and conjugated dienes, as well as activities of NADPH-generating enzymes, including G6PDH, ME and isocitrate dehydrogenase (EC 1.1.1.42), than the other four high-fat groups. The hepatic levels of malondialdehyde were not different among the five groups fed 20% fat. In the EFAD group, higher hepatic lipid content can be attributed to higher activities of NADPH-generating enzymes, and the elevation of conjugated diene levels may be related to increased oxygenation of 20:3n-6 (Mead acid) *via* the lipoxygenase/cyclooxygenase pathway. In short, both dietary fat quantity and fatty acid composition selectively affected hepatic H_2O_2-metabolizing systems, activities of NADPH-generating enzymes and lipid peroxidation status.

Lipids 28, 657–662 (1993).

The β-oxidation of fatty acids in peroxisomes is distinct from that of mitochondria in that the location, enzymes involved, end products and regulation of the processes are different between these two systems (1). Of particular interest is that peroxisomal, but not mitochondrial, fatty acyl-CoA oxidase produces H_2O_2 as the by-product (1). Although H_2O_2 is a weak oxidant and is not very active in the aqueous environments of cells, it may cross biological membranes and participate in the iron-catalyzed Fenton reaction, generating highly reactive hydroxyl radicals under physiological conditions (2). Thus, H_2O_2 may cause or promote oxidative damage to macromolecules at sites distal to its production (2).

The primary H_2O_2-detoxifying systems are catalase (CAT) and selenium-glutathione peroxidase (SeGSHPx). CAT is a peroxisomal enzyme and induction of peroxisomal β-oxidation by peroxisome proliferators and high-fat diets is associated with up to a twofold increase in CAT activity (3). SeGSHPx is mainly a cytosolic enzyme capable of reducing H_2O_2 and organic hydroperoxides with the cofactor reduced glutathione (GSH). For the action of SeGSHPx, the intracellular GSH needs to be maintained at a proper concentration, which can be achieved by regenerating from oxidized glutathione (GSSG) *via* NADPH-dependent glutathione reductase (GSSGR) and by synthesis *via* γ-glutamylcysteine synthase (4). The NADPH needed for GSH regeneration may be provided by various NADPH-generating enzymes, such as glucose-6-phosphate dehydrogenase (G6PDH), malic enzyme (ME) and isocitrate dehydrogenase (ICDH) (4). The finding that NADPH is tightly bound to mammalian CAT (5,6) suggests that CAT may also be a NADPH-dependent enzyme. Thus, the provision of NADPH for regeneration of GSH from GSSG, as well as to protect CAT from inactivation by H_2O_2, is of great physiological significance.

Certain high-fat diets, such as diets high in n-3, n-6 or saturated fatty acid (SAT), cause a significant increase in hepatic peroxisomal β-oxidation (7–10) and the activities of CAT and/or SeGSHPx (7,8). High-fat diets have also been shown to affect antioxidant defense mechanisms and lipid peroxidation status (11,12). However, most of these studies used fats varying in several fatty acids (7–12). Thus, a quantitative comparison using one single variable has not been achieved. In the present study we use blends containing comparable fatty acid compositions to study the effects of fat quantity and fatty acid composition on hepatic H_2O_2-metabolizing systems, activities of NADPH-generating enzymes and lipid peroxidation status in C57BL/6J mice.

MATERIALS AND METHODS

Chemicals. Methanol, isobutanol, chloroform, hexane, sulfuric acid and H_2O_2 were purchased from Fisher Scientific (Fair Lawn, NJ). NADPH, NADP, GSSGR, GSH, GSSG, glucose-6-phosphate (G6P), malic acid, isocitrate, 5,5′-dithio*bis*(2-nitrobenzoic acid), bovine serum albumin

Abbreviations: BSA, bovine serum albumin; CAT, catalase (EC 1.11.1.6); EFA, essential fatty acid; EFAD, essential fatty acid deficiency; G6P, glucose-6-phosphate; G6PDH, glucose-6-phosphate dehydrogenase (EC 1.1.1.49); GSH, reduced glutathione; GSSG, oxidized glutathione; GSSGR, glutathione reductase (EC 1.6.4.2); ICDH, isocitrate dehydrogenase (EC 1.1.1.42); MDA, malondialdehyde; ME, malic enzyme (EC 1.1.1.40); SAT, saturated fatty acid(s); SeGSHPx, selenium-glutathione peroxidase (EC 1.11.1.9); TBA, 2-thiobarbituric acid.

(BSA), 1,1,3,3-tetramethoxypropane, trichloroacetic acid and 2-thiobarbituric acid (TBA) were obtained from Sigma Chemical Co. (St. Louis, MO). Ethanol was from Midwest Grain Products of Illinois (Perkin, IL) and potassium dichromate from Allied Chemical Co. (Morristown, NJ). Dietary components were purchased from Teklad Test Diets (Madison, WI). Linseed, safflower, olive, corn and hydrogenated coconut oils were purchased from Bio-Serv (Frenchtown, NJ).

Diet preparation. Modified AIN-76 diets were composed as described in Table 1. High- (20%) and low-fat (5%) diets contained equal amounts of protein, vitamins, minerals and fiber per calorie consumed. The fats used were blends of several plant oils resulting in fats of defined fatty acid compositions. Fat blends contained approximately equal basal amounts of SAT, linoleic acid (18:2n-6), linolenic acid (18:3n-3) and oleic acid (18:1n-9). An essential fatty acid deficient (EFAD) diet was made with hydrogenated coconut oil devoid of unsaturated fatty acids. The basal fatty acids accounted for 11% of the diets, and additional fatty acids (SAT, 18:1n-9, 18:2n-6 or 18:3n-3) accounted for 9% of the total diet. These six diets (detailed in Table 2) were: (i) 5% fat, rich in 18:2n-6 fatty acid (5% N-6); (ii) 20% fat, rich in 18:3n-3 (N-3); (iii) 20% fat, rich in 18:2n-6 (N-6); (iv) 20% fat, rich in 18:1n-9 (N-9); (v) 20% fat, rich in SAT; and (vi) 20% fat, EFAD.

Animal care. Male weaning C57BL/6J mice (Jackson Laboratories, Bar Harbor, ME), five or six per group, were fed one of the six diets (described in Tables 1 and 2) for 11 wk. Feed and water were provided *ad libitum.* In order to minimize autoxidation of dietary lipids, diets were prepared in small batches and stored at -20°C until use. Packets containing one week's worth of food were stored at 4°C, and feed was changed daily. Mice were housed in plastic cages with pine shavings as bedding with a 12-h light/dark cycle.

Tissue preparations and methods. Mice were sacrificed by cervical dislocation following light diethyl ether anesthesia, and the liver was removed immediately. Body and liver weights were recorded. The liver was washed, blotted dry and homogenized in 3 vol of 1.15% KCl in 0.05 M phosphate buffer, pH 7.4. An aliquot of liver homogenate was centrifuged at 9,000 × *g* for 30 min and the supernatant (S9 fraction) stored at −70°C until analyzed. Hepatic GSH (13) and CAT (14) activities were measured in homogenates. Activities of SeGSHPx (15), GSSGR (16), G6PDH (17), ME (18) and ICDH (19) were determined in the S9 fraction. Lipid peroxidation indices were measured by the assays of malondialdehyde (MDA) (20) and conjugated dienes (21) in homogenates. The TBA–MDA complex was detected by high-performance liquid chromatography with fluorescence detection and quantified relative to authentic MDA as standard. Protein was measured by the method of Miller (22) using BSA as standard, and hepatic total lipids by the method of Chiang *et al.* (23) with corn oil as standard.

Statistics. Data are expressed as means ± SD with n = 5–6 per group; differences in mean were analyzed by one-way analysis of variance followed by Newman-Keuls multiple comparison test at $P = 0.05$ (24). Statistical

Temperature was increased from 160 to 210°C at 2°C/min.
[b]5% N-6 group, consisting of four parts safflower oil and one part olive oil. 20% N-3 group, consisting of 16.75 parts linseed oil, 0.25 parts safflower oil and three parts hydrogenated coconut oil. 20% N-6 group, consisting of 12 parts corn oil, 6.5 parts safflower oil and 1.5 parts olive oil. 20% N-9 group, consisting of 14.75 parts olive oil, 0.3 parts safflower oil, 3 parts corn oil and 1.95 parts hydrogenated coconut oil. 20% saturated fatty acids (SAT) group, consisting of 11 parts of hydrogenated coconut oil, 4.5 parts olive oil and 4.5 parts corn oil. 20% essential fatty acid deficient (EFAD) group, consisting of 20 parts hydrogenated coconut oil.

comparisons were performed between the groups 5% N-6 and N-6 and among the five high-fat diet groups N-3, N-6, N-9, SAT and EFAD.

RESULTS

Effects of fat quantity. The effects of dietary fat quantity on various parameters are summarized in Table 3. Mice consuming the N-6 diet had significantly higher body weight than those fed the 5% N-6 diet. However, this change was not reflected in wet liver weight, liver to body weight ratio or hepatic lipid content. The N-6 group had significantly higher activities of CAT (Fig. 1a) and SeGSHPx (Fig. 1b), but significantly lower activities of G6PDH (Fig. 2a) and ME (Fig. 2b), and conjugated diene levels (Table 4) than the 5% N-6 group. No difference was found in GSSGR (Fig. 1c) and ICDH (Fig. 2c) activities, or in GSH (Fig. 1d) and MDA (Table 4) levels.

Effects of fatty acid composition. The effects of enrichment of N-3, N-6, N-9, fatty acids or SAT and deficiency in EFA in the 20% fat diets on body weight, liver weight and hepatic total lipids are summarized in Table 3. The N-3 group had significantly higher body weight than the N-6 and EFAD groups and the N-9 and SAT groups were higher than the EFAD group. The order of body weights is as follows: N-3 N-9 SAT > N-6 > EFAD. However, this effect was not reflected in liver weight or liver to body weight ratios. As for hepatic lipid content, the EFAD group was significantly higher than the N-3, N-6, N-9 and SAT groups, and no difference was found among the latter four groups.

The N-9 group had significantly lower CAT activity than the N-3 and N-6 groups, but not the SAT and EFAD groups; there was no difference in CAT activity among the N-3, N-6, SAT and EFAD groups (Fig. 1a). The EFAD group had a significantly lower activity of SeGSHPx than the other high-fat diet groups (Fig. 1b). The N-6 group had a higher activity of GSSGR than the N-3, N-9 and EFAD groups, but not the SAT group; there was no difference in GSSGR activity among the N-3, N-9, SAT and EFAD groups (Fig. 1c). As for hepatic GSH levels, there was no statistically significant difference among the five groups (Fig. 1d).

Activities of G6PDH and ME were markedly increased in the EFAD group as compared to the N-3, N-6, N-9 and SAT groups (Figs. 2a and b). ICDH activity was also significantly higher in the EFAD group than in N-6, N-9 or SAT, but not in N-3 (Fig. 2c). There were no differences among the latter four groups. The indices of lipid peroxidation are summarized in Table 4. Conjugated diene levels were significantly higher in the EFAD group than in the N-3, N-6, N-9 and SAT groups, and there was no difference in the levels of MDA among all five groups.

DISCUSSION

To better understand the effects of dietary fat quantity and fatty acid composition on hepatic H_2O_2 metabolism, we have devised several diets containing fat blends differing in only one type of fatty acid. Our results show that even though high-fat diets increase mouse body weight, not all high-fat diets of the same quantity affect body weight to the same extent. For instance, the high-fat diet rich in linolenic acid was most effective in increasing body weight, while the high-fat diet rich in linoleic acid or EFAD was less effective.

Similarly, both fat content and fatty acid composition can affect the activities of H_2O_2-metabolizing enzymes in a selective manner. For example, where other studies showed that the activities of CAT and SeGSHPx were increased in animals fed corn oil or other fats high in polyunsaturated fatty acids (7–10), our results indicate that not all high-fat diets increase these two enzyme activities. In our study, a high-fat diet rich in linoleic or linolenic acid increased activities of SeGSHPx and CAT. The latter activity is frequently used as an indicator of peroxisome induction (3). Our results, however, also suggest that a high-fat diet rich in oleic acid does not induce CAT activity and perhaps peroxisomal β-oxidation to the same extent as other diets rich in either linoleic acid or linolenic acid. Thus, oleic acid is probably not a good substrate for peroxisomal β-oxidation *in vivo*. Indeed, this is supported by *in vitro* evidence showing that linoleic and linolenic acids were β-oxidized more quickly than oleic acid by peroxisomal β-oxidation enzymes (25,26). Additionally, the EFAD group had lower SeGSHPx activity than the other

TABLE 3

Effects of Dietary Fat Quantity and Fatty Acid Composition on C57BL/6J Mouse Body Weight (g), Liver Weight (g and %) and Hepatic Lipid Content (mg/g)

Dietary group	Body weight[a] (g)	Liver weight (g)	Liver weight (%)[b]	Hepatic lipids (mg/g)
5% N-6	26.9 ± 2.3	1.49 ± 0.21	5.47 ± 0.95	104 ± 11
20% N-3	35.9 ± 2.0[d]	1.59 ± 0.18[d]	4.53 ± 0.36[d]	75 ± 6[d]
20% N-6	31.2 ± 2.4*[e,f]	1.57 ± 0.23[d]	5.04 ± 0.62[d]	80 ± 11[d]
20% N-9	34.5 ± 2.5[d,e]	1.70 ± 0.23[d]	4.92 ± 0.31[d]	90 ± 15[d]
20% SAT[c]	34.0 ± 4.8[d,e]	1.74 ± 0.35[d]	5.15 ± 0.91[d]	96 ± 19[d]
20% EFAD[c]	29.0 ± 2.2[f]	1.65 ± 0.16[d]	5.69 ± 0.36[d]	146 ± 23[e]

[a]Data represent the means and SD of five or six mice maintained on the respective diets for 11 wk. Statistical analysis was performed by analysis of variance coupled with Newman-Keuls multiple comparisons test at $P = 0.05$ (Ref. 24). Significant differences between the 5% N-6 and 20% N-6 groups are indicated by an asterisk; differences among all 20% fat diet groups are indicated by different superscript letters (d–f).
[b]Expressed as percent of body weight.
[c]Abbreviations as in Table 2.

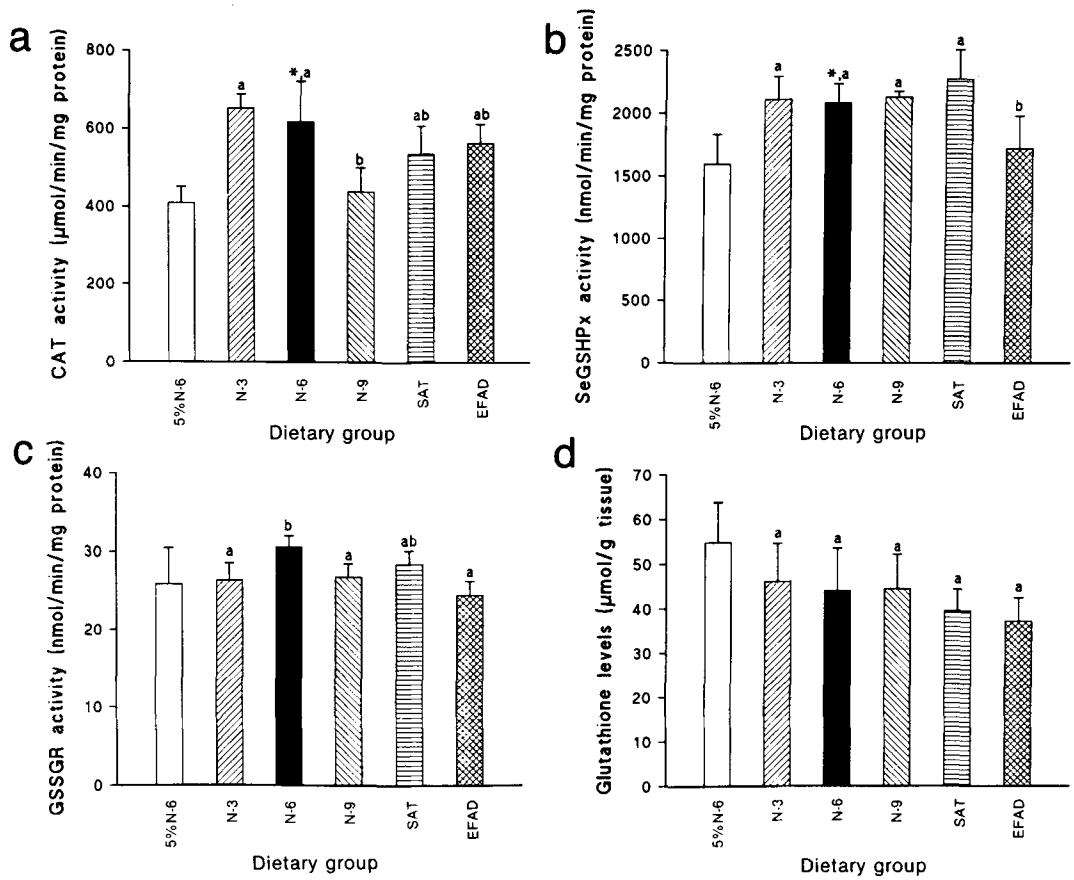

FIG. 1. Effects of dietary fat quantity and fatty acid composition on hepatic (a) catalase (CAT), (b) selenium-glutathione peroxidase (SeGSHPx), (c) glutathione reductase (GSSGR) activities and (d) on reduced glutathione levels. For 11 wk, male weaning C57BL/6J mice were fed one of the six diets described in Tables 1 and 2. Other treatments are detailed in the Materials and Methods section. Each column and bar represent the mean and SD of five or six animals. Differences in means were analyzed by one-way analysis of variance coupled with Newman-Keuls multiple comparisons test at $P = 0.05$ (Ref. 24). An asterisk indicates significant difference between the means of the 5% N-6 and the N-6 groups. The differences among the five 20% fat diet groups are denoted by different letters. Throughout all the figures: 5% N-6 signifies a 5% fat diet rich in N-6 fatty acid; N-3 signifies 20% fat rich in N-3 fatty acid; N-6 signifies 20% fat rich in N-6 fatty acid; N-9 signifies 20% fat rich in N-9 fatty acid; SAT signifies 20% fat rich in saturated fatty acid; and EFAD signifies 20% fat deficient in essential fatty acids.

TABLE 4

Hepatic Lipid Peroxidation Indices in C57BL/6J Mice Fed Diets Containing Different Fat Quantities and Fatty Acid Compositions

Dietary group	Malondialdehyde[a] (nmol/g tissue)	Conjugated dienes[b] (unit/mg lipid)
5% N-6	16.8 ± 5.0	0.425 ± 0.008
20% N-3	17.6 ± 3.6[d]	0.311 ± 0.003[d]
20% N-6	15.7 ± 2.2[d]	0.298 ± 0.001[d]
20% N-9	15.9 ± 2.2[d]	0.344 ± 0.010[d]
20% SAT[c]	17.6 ± 3.3[d]	0.334 ± 0.002[d]
20% EFAD[c]	15.2 ± 2.7[d]	0.543 ± 0.014[e]

[a]Data represent the means and SD of five or six mice maintained on the respective diets for 11 wk. Data were analyzed by analysis of variance coupled with Newman-Keuls multiple comparisons test (Ref. 24). Significant differences ($P < 0.05$) between the means of the 5% N-6 and 20% N-6 groups are indicated by an asterisk and the comparison among all 20% fat diet groups by different superscript letters (d–e).

[b]Expressed as the ultraviolet absorbance at 234 nm per mg lipid.

[c]Abbreviations as in Table 2.

four high-fat diet groups, indicating that EFA are necessary for the increase in SeGSHPx activity in mice fed high-fat diets. Fat content of the diet did not affect GSSGR activity except that enrichment with linoleic acid (n-6 fatty acid) increased it. The reason why enrichment with linoleic acid increased GSSGR activity is not clear at present.

The pentose phosphate pathway is involved in several functions, including regenerating GSH for the degradation of H_2O_2 by SeGHSPx (4). However, the provision of NADPH for the metabolism of hydroperoxides may not be solely dependent on the pentose phosphate shunt, as in the case of red blood cells (4). Other enzymes, such as ME and ICDH, may provide some NADPH for GSH regeneration (4,27). Induction of peroxisomes by peroxisome proliferators often accompanies the induction of ME and G6PDH (28–31). Dietary fat content is known to affect hepatic lipogenesis. In particular, high-fat diets suppress activities of lipogenic enzymes, *i.e.*, G6PDH and ME (32). Although high-fat diets and peroxisome proliferators

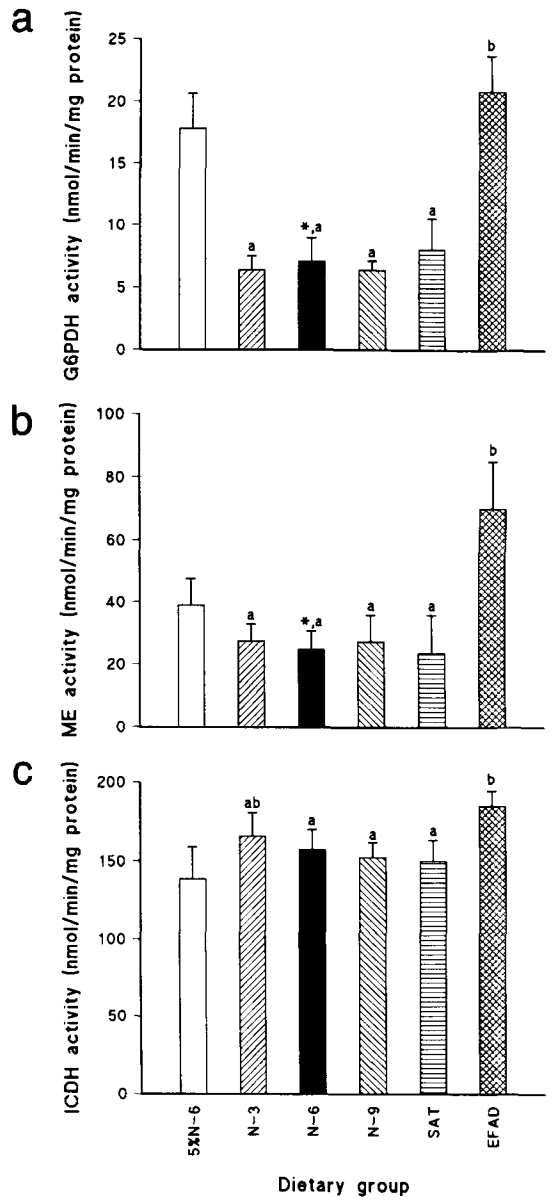

FIG. 2. Effects of dietary fat quantity and fatty acid composition on hepatic (a) glucose-6-phosphate dehydrogenase (G6PDH), (b) malic enzyme (ME) and (c) isocitrate dehydrogenase (ICDH) activities. For details of diet preparation and animal treatment see the Materials and Methods section. Data are the means and SD of five or six mice. Significant differences in means are indicated by an asterisk or different letters as analyzed by one-way analysis of variance and Newman-Keuls multiple comparisons test at $P = 0.05$ (Ref. 24). All symbols and designations are the same as described for Figure 1.

similarly induce peroxisomal β-oxidation, they differ in their effects on ME and G6PDH activities. Nevertheless, EFA deficiency overcomes this suppression and increases the activities of all three NADPH-generating enzymes. This may be due to the increased lipogenesis and synthesis of 20:3n-6 (Mead acid) (33). It has been shown that ICDH and enzymes of the pentose phosphate pathway are present in peroxisomes (34). Moreover, treatment with the peroxisome proliferator clofibrate increases peroxisomal, but not cytosolic, G6PDH activity (34). It is possible that increased H_2O_2 production in peroxisomes may subsequently increase the oxidation of NADPH and activate antioxidant defense mechanisms, such as the pentose phosphate shunt, GSH regenerating pathways and SeGSHPx.

It is interesting that mice fed the 5% N-6 diet or the EFAD diet had significantly higher levels of hepatic conjugated dienes. A similar effect was also seen with hepatic lipid content in these two groups. Although NADPH-producing capacity was elevated in the EFAD and 5% N-5 groups, it did not help prevent conjugated diene formation. However, the greatly increased levels of conjugated dienes in the EFAD groups may not be due to lipid peroxidation and/or impairment of antioxidant defense mechanisms. First, the hepatic vitamin E levels in the EFAD groups were approximately twice as much as the other four high-fat diet groups (data not shown), without impairment of other antioxidant defense mechanisms. Secondly, the source of dienes are unlikely of dietary fat origin, as in the case of rats fed choline devoid diet (35). We hypothesize that the accumulation of conjugated dienes is due to increased oxygenation of 20:3n-9 fatty acid *via* the cyclooxygenase and/or lipoxygenases. This particular fatty acid is not normally seen in animal tissues except when devoid of EFA (33). There is evidence showing that 20:3n-9 can be metabolized to a variety of hydroxy eicosanoids by cyclooxygenase (36) and leukotriene A_3 by 5-lipoxygenase (37). However, it is known that the measurement of conjugated dienes is subject to interference of various origin (38). Further chemical analyses are needed to confirm this effect. Whether this mechanism of enzymatic oxygenation (to linoleic acid and its elongated and desaturated derivatives) can be attributed to the increase in conjugated diene levels in the 5% N-6 group also warrants exploration.

Both fat quantity and fatty acid composition were expected to affect the generation of lipid peroxidation products. However, dietary fat was not found to cause any difference in MDA levels. Generally, it is assumed that the formation of conjugated dienes will eventually lead to β-scission of lipid hydroperoxides leaving at least two double bonds, forming MDA (39). Similar to the cases of EFAD and the 5% N-6 groups in this study, treatments with peroxisome proliferators have been shown to elevate hepatic levels of conjugated dienes without increasing MDA levels (40–42). Elevated conjugated diene levels were not reflected in increased MDA levels in our study or in previous investigations. Perhaps the liver possesses active enzymatic systems for aldehydic products (43), which is inducible by treatment with peroxisome proliferators (44). Also, the procedure we used for the measurement of MDA was more specific (20), which may partly explain our findings.

In summary, the levels of dietary fat and fatty acid compositions were found to selectively affect hepatic H_2O_2-metabolizing systems, activities of NADPH-generating enzymes and lipid peroxidation status. The 5% N-6 and EFAD groups had higher activities of NADPH-generating enzymes than their respective counterparts; consequentially, both groups also had higher hepatic lipid content. EFAD resulted in elevated levels of conjugated dienes, possibly due to increased oxygenation of 20:3n-9 *via* the lipoxygenase/cyclooxygenase pathway.

ACKNOWLEDGMENTS

The authors would like to thank Dr. Clare Hasler for critical review of the manuscript and V. Tatum, M. Baker and S.-Y. Lee for technical assistance. The study was supported in part by The College of Allied Health Professions and the Agricultural Experiment Station of the University of Kentucky.

Diabetes Increases Excretion of Urinary Malonaldehyde Conjugates in Rats[1]

Daniel D. Gallaher*, A. Saari Csallany, Don W. Shoeman and **Judith M. Olson**
Department of Food Science and Nutrition, University of Minnesota, St. Paul, Minnesota 55108

The effect of streptozotocin-induced diabetes on the urinary excretion of thiobarbituric acid test-positive materials was examined. In diabetic rats, urinary excretion of thiobarbituric acid reactive substances was increased 5-fold over that in nondiabetic animals. High-performance liquid chromatography of urine samples revealed that five of the six fractions previously found to be increased in vitamin E deficiency [Lee, H.-S., Shoeman, D.W., and Csallany, A.S. (1992) *Lipids 27,* 124-128] were also significantly increased in streptozotocin-induced diabetes. The data suggest that a high level of oxidative stress is induced by uncontrolled diabetes in rats.
***Lipids 28,* 663-666 (1993).**

Lipid peroxidation, the nonenzymatic autooxidation of polyunsaturated fatty acids, has numerous deleterious effects on biological systems (1) and has been implicated in the process of aging as well as the pathogenesis of several diseases (2). One of the most studied products of lipid peroxidation is malonaldehyde (MDA), a dialdehyde known to react with proteins (3-5) and amino acids (6,7). Several studies have shown a positive relationship between *in vivo* lipid peroxidation and urinary excretion of MDA (8,9).

Diabetes mellitus is a disease characterized by a state of prolonged hyperglycemia. Jain (10) has demonstrated that red blood cells exposed to high concentrations of glucose (45 mM) *in vitro* showed increased levels of membrane peroxidation. Further, the level of thiobarbituric acid reactive substances (TBARS), which include MDA, was found to be higher in the red blood cells of streptozotocin-induced diabetic rats compared to nondiabetic animals (11). Serum TBARS have also been reported to be increased in diabetes, both in rats (12) and humans (13). These results suggest that diabetes increases oxidative stress.

Recently, Lee *et al.* (14) have fractionated the TBARS from urine of normal and vitamin E-deficient rats using high-performance liquid chromatography (HPLC). They demonstrated that, in the state of increased oxidative stress caused by vitamin E deficiency, the amount of several of these materials was significantly increased. The purpose of the present study was to determine if a similar increase occurs under another condition of oxidative stress, *i.e.*, in streptozotocin-induced diabetes.

METHODS AND MATERIALS

Animals. Male Wistar rats (initial weight, 150-175 g) were purchased from Harlan Sprague-Dawley (Indianapolis, IN) and housed individually in suspended wire-mesh stainless steel cages in a temperature-controlled room (22°C) with a 12-h light/dark cycle. Animals were given *ad libitum* access to food and water.

Experimental design. All animals were fed the semi-purified diet prior to the beginning of the experiments to allow adaptation to the diet and environment. The diet consisted of (g/kg): cornstarch, 650; casein, 200; cellulose, 50; corn oil, 50; AIN-76 mineral mix (U.S. Biochemical Corp., Cleveland, OH), 35; AIN-76 vitamin mix (U.S. Biochemical Corp.), 10; DL-methionine, 3; and choline bitartrate, 2. This diet provides 50 mg rac-α-tocopherol acetate per kg, equivalent to 35 mg *D*-α-tocopherol per kg, from the vitamin mix and approximately 9 mg per kg diet of α-tocopherol activity from the corn oil, for a total α-tocopherol equivalent of 44 mg/kg diet. Butylated hydroxytoluene (10 mg/kg) and menadione sodium bisulfite (1.33 mg/kg) were also added.

In the first experiment, the animals were adapted to the semi-purified diet for 9 d before administration of intraperitoneal injections of either streptozotocin (60 mg/kg body wt in 0.1 M citrate, pH 4.5) to induce diabetes, or a sham injection of citrate buffer alone. All animals continued on the semi-purified diet. After 12 wk, the animals were anesthetized, blood was collected by cardiac puncture for determination of glycated hemoglobin (GHb) and both kidneys were removed and weighed.

Body weights were determined at the beginning of the experiment, at week 2 and weekly thereafter. Twenty-four hour food intake was determined once a week at week 2 and weekly thereafter. At the beginning of the experiment and weekly thereafter, the animals were transferred to stainless steel metabolic cages once a week. Twenty-four-hour urine samples were collected and the volumes accurately measured. The collection from week 11 was centrigued to remove debris and an aliquot was frozen at −20°C for determination of the urinary excretion of TBARS and for fractionation by HPLC.

A second experiment was conducted to determine whether diuresis *per se* was responsible for the increase in urinary TBARS found in the diabetic animals. Male Wistar rats were adapted to the semi-purified diet for 10 d. The animals were housed in metabolic cages and given intraperitoneal injections of hydrochlorothiazide (120 mg/kg dissolved in PEG 200) (Sigma Chemical Co., St. Louis, MO) four times over 24 h. Control animals were injected with vehicle only. Body weight at the time of injection ranged from 220-270 g. Twenty-four hour urine samples were collected, the volume noted and aliquots stored at −20°C until analyzed for urinary TBARS.

Analyses. GHb was determined on whole blood by affinity chromatography using a commercial kit (GlycAffin, Isolabs, Akron, OH).

Abbreviations: GHb, glycated hemoglobin; HPLC, high-performance liquid chromatography; MDA, malonaldehyde; TBA, thiobarbituric acid; TBARS, thiobarbituric acid reactive substances.

The levels of TBARS in urine samples were measured by the modified filtration procedure of Tarladgis *et al.* (15), as described by Lee *et al.* (14). Chromatographic fractionation and free MDA analysis of urine samples were carried out by HPLC using a TSK G1000 PW column (7.5 mm i.d. × 30 cm) (Beckman Instruments, Berkeley, CA) with a mobile phase of 0.1 M Na_3PO_4 buffer, pH 8.0, at a flow rate of 0.6 mL/min, and monitoring the eluant at 267 nm (16).

Statistics. Group means were compared by Student's *t*-test. Differences were considered significant at $P < 0.05$.

RESULTS AND DISCUSSION

As shown in Figure 1, the diabetic animals exhibited typical signs of diabetes. Panel A shows that the control group gained weight steadily over the course of the experiment, whereas the diabetic group gained relatively little weight. Food intake (Panel B) was greatly increased in the diabetic group compared to the control group during the entire 12-wk experiment. Twenty-four hour urine volume increased immediately in the diabetic compared to the control group and remained elevated throughout the 12-wk experiment (Panel C). The urine volume in the diabetic group compared to that in the control group was significantly greater at each week except week 8.

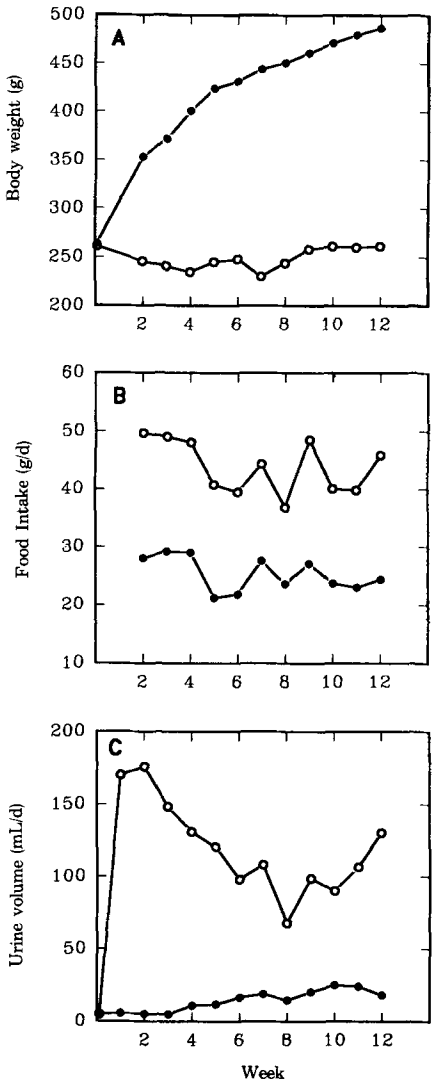

FIG. 1. Body weight change (Panel A), food intake (Panel B) and 24-h urine volume (Panel C) in normal (●) or diabetic (○) rats. Values are means of eight to nine animals per group. Body weight and food intake differences between the control group and the diabetic group were statistically significant ($P < 0.05$) at all time points, as judged by Student's *t*-test. Urine volume differences between the groups were statistically significant ($P < 0.05$) at all time points except week 8.

The GHb values and kidney weights (per 100 g body weight) are shown in Table 1. GHb is a measure of long-term blood glucose level used routinely in monitoring human diabetics and reflects the time-averaged blood glucose concentration over the preceding 60 to 90 d (17). The degree of glycation correlates well with other measures of diabetic control, such as fasting blood glucose concentration, response to a glucose tolerance test and urinary glucose excretion (18,19). The mean hemoglobin glycation of ≈14% in the diabetic group indicates that these animals had experienced high plasma glucose concentrations. The diabetic group also showed an increase in relative kidney weights compared to the control group. Renal enlargement in rats is known to begin within days of the induction of diabetes and continues for at least 6 wk (20). The degree of enlargement has been correlated to the degree of glycemic control, as measured by fasting plasma glucose concentration (21). The significantly enlarged kidneys in the diabetic animals relative to the nondiabetic controls further confirm the diabetic state of these animals.

Diabetic rats excreted approximately five times more urinary TBARS per 24 h compared to nondiabetic controls, a statistically significant increase (Fig. 2). Draper *et al.* (4) had demonstrated that most (75%) of the MDA-containing components of rat urine was present as *N*-α-acetyl-ε-(2-propenal)lysine. They further demonstrated that this MDA adduct increased with the feeding of a highly polyunsaturated fat. None of the nondiabetic animals and only two of six diabetic animals had detectable amounts of free MDA in urine when analyzed by HPLC. The absence of free MDA could result from the fact that most MDA is rapidly metabolized by the liver (22) and thus only a very minor fraction of the body burden of MDA is excreted in the urine. Another possibility is that the reactivity of free MDA might lead to its rapid combination with other compounds and excretion in the urine in a derivatized form (23). This MDA would be released from its derivatized forms by acid hydrolysis during the determination of TBARS. A third possibility

TABLE 1

Glycated Hemoglobin and Kidney Weight in Normal and Diabetic Rats After 12 Weeks[a]

	Normal	Diabetic
Glycated hemoglobin (%)	3.9 ± 0.1	14.4 ± 0.5[b]
Kidney weight, g/100 g body weight	0.67 ± 0.06	1.33 ± 0.03[b]

[a]Values are means ± SEM of eight to nine animals per group.
[b]Significantly ($P < 0.001$) different from the normal group by Student's *t*-test.

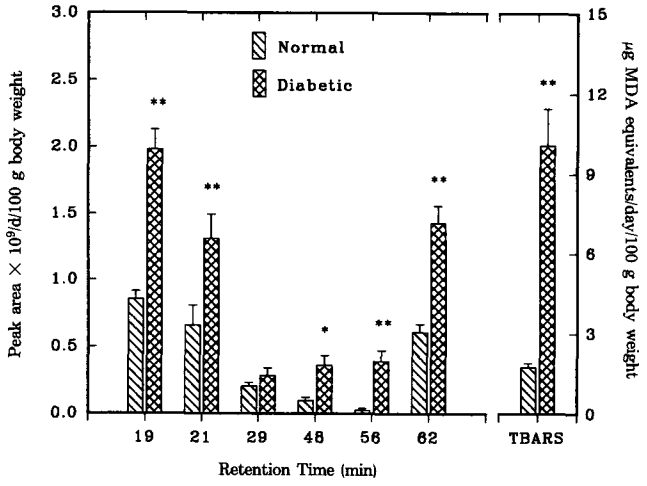

FIG. 2. Comparisons of high-performance liquid chromatography (HPLC) separated urinary carbonyl-containing compounds, as measured by absorbance at 267 nm, and of urinary excretion of thiobarbituric acid reactive substances (TBARS), both per 24 h per 100 g body weight in normal and diabetic rats. Values represent means ± SEM of five to six animals per group for HPLC fractions and eight to nine animals per group for TBARS. *$P < 0.002$; **$P < 0.001$, by Student's *t*-test. MDA, malonaldehyde.

is the presence in urine of certain carbonyl compounds besides derivatized MDA (14). The carbonyl groups present in urine could be derived from short- or medium-chain secondary lipid peroxidation products which also react with the TBA reagent.

To examine the possibility that the increased urinary TBARS in the diabetic animals were due only to diuresis, diuresis was induced in normal animals with hydrochlorothiazide. Table 2 shows that in these nondiabetic animals, the increase in urine volume of >250% was not accompanied by a statistically significant ($P = 0.22$) increase in urinary TBARS. Thus, diuresis *per se* does not appear to influence urinary TBARS.

In a previous study, urine was fractionated on a Spherogel-TSK 1000 PW column and the effluent monitored at 267 nm. In this system, free MDA (when present) is well separated [retention time (R_t), 44 min] from a number of other fractions found in urine (14). The areas of six of these fractions (R_t, 19, 21, 29, 48, 56, 62 min) were larger in the vitamin E-deficient group than in the control group. It was suggested that these six urine fractions are vitamin E-deficiency dependent, and therefore may be related to *in vivo* lipid peroxidation.

TABLE 2

Urine Volume and 24-Hour Urinary TBARS in Normal and Hydrochlorothiazide-Treated Rats[a]

	Control	Hydrochlorothiazide treated
Urine volume (mL/24 h)	17.7 ± 2.0	46.6 ± 4.9[b]
Urinary TBARS (Mg equiv. MDA/24 h/100 g body weight)	3.5 ± 0.6	4.5 ± 0.5

[a]Values are means ± SEM of five animals per group.

[b]Significantly ($P < 0.001$) different from the control group by Student's *t*-test.

In the present study, the areas of five of six peaks previously identified as lipid peroxidation-related were significantly increase ($P < 0.002$) (Fig. 2) in diabetic rats over nondiabetic controls. The magnitude of the difference between the groups in this study was equal to or greater than the difference between the normal and vitamin E-deficient animals found in the previous study. This suggests that diabetes induced by streptozotocin increase *in vivo* lipid perioxidation to a level comparable to that which occurs during severe vitamin E deficiency.

The increase in *in vivo* peroxidation in diabetes could be due to elevated blood glucose concentrations. Jain *et al.* (11) found increased red blood cell thiobarbituric acid (TBA) reactivity *in vitro* with increasing concentrations of glucose. TBA reactivity of red blood cells was also increased in streptozotocin-induced diabetic rats compared to non-diabetic animals (12). However, in animals whose blood glucose concentration was normalized by insulin treatment, no significant increase in TBA reactivity occurred (12).

How elevated blood glucose concentrations might increase the oxidative stress of an animal remains to be established. However, Hunt *et al.* (24) have presented evidence from *in vitro* studies that glucose undergoes metal-catalyzed autooxidation reactions leading to the production of hydroxyl radicals. These highly reactive radicals are known to attack polyunsaturated fatty acids in biomembranes, inducing increased lipid peroxidation. In this way, high blood glucose concentrations could produce a metabolic state similar to vitamin E deficiency. Whether increased levels of chelating agents or quenchers of free radicals such as vitamin E could interrupt this sequence of events, and thereby reduce the oxidative stress of diabetes, is a question deserving further study.

METHOD

A Multivariate Optimization of Triacylglycerol Analysis by High-Performance Liquid Chromatography

Magnus H.J. Bergqvist[a] and **Peter Kaufmann**[b,*]
[a]Department of Analytical Chemistry, Stockholm University and [b]Karlshamns LipidTeknik AB, Stockholm, Sweden

In the present study we have used statistical experimental design and multivariate optimization to formally optimize a reversed-phase high-performance liquid chromatography method for the analysis of triacylglycerol molecular species of natural oils. The optimal conditions found were, on an octadecylsilan-column, from acetonitrile/isooctane (90:10, vol/vol) to acetonitrile/ethanol/isooctane (40:35:25, by vol), at a column temperature of 50°C and a flowrate of 1.5 mL/min using a negative exponential gradient profile. Several examples of separations of natural seed and animal oils, *i.e.*, soybean oil, rapeseed oil, palm oil, linseed oil, tallow and fish oil, are given. A version of the equivalent carbon number concept, utilizing the Snyder polarity index, was used to identify the molecular species. *Lipids 28,* **667–675 (1993).**

Triacylglycerols (TAG) are the most abundant lipid class found in nature. TAG are also the most complex with n^3 potential molecular species possible, n being the number of fatty acids. The TAG molecular species profile represents a key to the understanding of the physical characteristics of an oil and also is a unique means of identification which has been utilized in various instances (1,2). The degree of certainty in the identification is dependent upon the complexity of the oil and on the degree of separation attainable in a given chromatographic system. In order to minimize ambiguity, optimal separation between molecular species is desirable. This has been accomplished in some cases by high resolution gas chromatography (HRGC) at temperatures above 300°C (3). However, due to the tendency of species containing polyunsaturated fatty acids to decompose at high temperatures, there has been a major trend toward the use of reversed-phase high-performance liquid chromatography (RP-HPLC) (2,4–9).

Choosing the solvent system in HPLC is often a time-consuming and tedious chore which requires the localization of the region of optimal separation in the multidimensional solvent mixture space. Statistical experimental design and multivariate modeling (10–15) have been shown to drastically reduce the experimental task to arrive at optimal conditions.

The choice of the solvent system is also dependent on the mode of detection used. A lack of strong chromophores in TAG molecules makes ultraviolet (UV)-detection difficult. In addition, in UV-dectection the response depends on the degree of unsaturation in a given molecular species, which can be highly variable. Refractive index detection limits the choice of solvent to isocratic systems resulting in a concomitant loss in resolution. The light-scattering detector has gained in popularity due to its ability to permit gradient elution and thus comes close to the ideal detector for lipid analysis. It is not without drawbacks, however, as its response function is sigmoidal in shape, necessitating careful calibration for quantitative work.

In RP-HPLC of TAG molecular species, retention is a function of both the total chainlength of the fatty acyl moieties and the total number of double bonds. Increasing chainlength increases the elution time while increasing the degree of unsaturation reduces the elution time. This relationship has been utilized in the partition number (PN) concept (16), a general rule of thumb being that $PN = CN - 2 \times U$, where CN is the total number of carbons and U is the total number of double bonds in the fatty acyl chains. This simple relationship can be extended into the equivalent carbon number (ECN) concept, where differences between species of equal PN are taken into consideration. This last relation is empirically derived by building a mathematical model between the retention times of a set of saturated standards and their respective ECN values (1,2,5,9,17,18), thereby enabling one to predict ECN values for unknown species from their retention times.

The goal of the present study was to optimize an existing RP-HPLC system developed in our laboratory for the analysis of natural TAG oils utilizing statistical experimental design and response surface modeling. The utility of the method is illustrated for the analysis of several natural TAG oils, *i.e.*, soybean oil, rapeseed oil, palm oil, linseed oil, tallow and fish oil. The separated peaks were identified by their ECN values.

MATERIALS AND METHODS

Materials. Chromatographically purified natural oils were obtained from Karlshamns LipidTeknik AB (Stockholm, Sweden). TAG standard mixtures were obtained from Larodan (Malmö, Sweden) and from Sigma (St. Louis, MO). Acetonitrile and isooctane were of analytical grade and purchased from E. Merck (Darmstadt, Germany). Ethanol was of spectroscopic grade (99.5 vol%) from Kemetyl (Stockholm, Sweden). A mixture of standards containing the saturated molecular species tridecanoin (DDD), trilaurin (LaLaLa), trimyristin (MMM), tripentadecanoin (PdPdPd), tripalmitin (PPP), triheptadecanoin (HdHdHd) and tristearin (StStSt) was used to develop the ECN models.

HPLC. The HPLC system consisted of two Shimadzu LC-6A pumps (Kyoto, Japan) integrated with a Shimadzu SCL-6B system controller and an ODS-column (Superspher RP-100, 250 × 4.6 mm, 100 Å) from Merck. The column was thermostatted with a water bath. Detection was

done with a light-scattering detector from Cunow, model DDL 11 (Cergy, St. Christophe, France). The detector nebulizer was set at 35 psi and held at a temperature of 90°C. Collection and integration of data was done on the PC integration Pack (Kontron, Milan, Italy).

Sample preparation. Twenty-five mg of the oil was dissolved in 5 mL of ethanol/isooctane (3:1, vol/vol). One hundred mg of each standard mixture was dissolved in 25 mL ethanol/ isooctane (3:1, vol/vol), and 10 μL of each sample was injected.

Multivariate methods. These methods have been described in detail in the literature (19–21), and their use in lipid analysis has recently been reviewed (22). In brief, the underlying strategy of partial least squares correlations in latent variables (PLS), which is a widely used method for multivariate calibration, is to consider each experimental variable (vol% of a solvent, etc.) and response variable (peak resolution, etc.) as coordinate axes in two separate multidimensional spaces. The goal is thereafter to build the defining relationship between the two different blocks of variables, *i.e.,* the independent and the dependent blocks. Each object (object = sample) is described by a vector containing the values of the experimental variables or the response variables and can thus be seen as a point in each respective space. A set of objects with the same measured variables form a swarm of points in this space and objects similar to each other will be near to each other, so that distance therefore constitutes a measure of similarity/dissimilarity. New variables representing a maximum amount of the systematic variance present in the data are calculated as linear combinations of the experimental and response variables. These are often called the latent factors, which describe the intrinsic, underlying variance structure of the system under study. The defining relationship between the two blocks is built by using information from the dependent block to adjust or rotate the latent factors from the independent block until maximal linear correlation is obtained between the blocks. PLS thus models both the dependent and independent blocks simultaneously. The PLS method can also be used to extract certain specified portions of the systematic variance from the experimental data (19–22).

Optimization procedure. Optimization of an existing method was done in two sequential steps utilizing statistical experimental design, response-surface modelling (10,11,22) and PLS regression (19,20). Optimization was done using chromatographically purified soybean oil throughout the study. Calculations were done in Excel (Microsoft, Seattle, WA); response surface modelling was done in Statgraphics (STSC, Rockville, MD); PLS regression was done in SIMCA 3B (Sepanova, Enskede, Sweden) and calculation of ECN values were done in MATLAB (Mathworks, Natick, MA).

In the first step, the composition of eluent B was optimized. This was done in two different blocks, the first was a screening block where the important factors were determined *via* a highly reduced factorial design (Plackett-Burman). The design and experimental domain are shown in Table 1. The eight chromatograms, conditions given by each row in Table 1, were evaluated quantitively and ranked using a multivariate ranking function, where optimal chromatographic conditions are attained at the minimum of the function. The chromatographic resolution statistic (CRS) function takes peak resolution, peak distribution and total analysis time into account, thus enabling an objective and quantitative ranking (23).

In the second block of the first step, the best chromatogram from the first block was used as the basis for a new experimental design (Table 1, row 6). The experimental factors identified as influential in the first block were varied according to a fractional factorial design (2^{4-1}) shown in Table 2. These chromatograms were also evaluated and ranked according to the above described procedure.

Response surfaces of the experimental domain were developed in two different ways, either by fitting a linear

polynomial function in the experimental factors to the corresponding CRS values and plotting two factors at a time, or by developing a PLS regression model relating the experimental factors to the resolution and peak asymmetry factors and the total analysis time. These response surfaces enabled location of optimal experimental conditions for the B eluent.

The optimal A eluent composition was obtained in the second step by varying the content of isooctane, *i.e.*, altering the elution strength of the solvent system.

Identification. The TAG molecular species were identified on the basis of their ECN values. These were determined using the Snyder's polarity index values (P') (24), calculated for the solvent system composition at the time of elution of the set of TAG standards. The ECN values were determined by fitting a fifth degree polynomial in the calculated P' to the known ECN values of a set of saturated TAG standards, where

$$ECN_i = \beta_0 + \beta_1 P'_i + \beta_2 P'^2_i + \beta_3 P'^3_i + \beta_4 P'^4_i + \beta_5 P'^5_i \quad [1]$$

and the vector of regression coefficients was found by matrix least squares

$$\beta = (X'X)^{-1}X'Y \quad [2]$$

where Y is the vector of ECN values of the saturated set of nine TAG standards and the X-matrix is the right-hand side of the ECN equation. Thereafter the ECN values were predicted for unknown TAG molecular species. The relative prediction (PRED) error (E_R) for each standard (STD) species was calculated as

$$E_R = (ECN_{STD} - ECN_{PRED})/ECN_{STD} \quad [3]$$

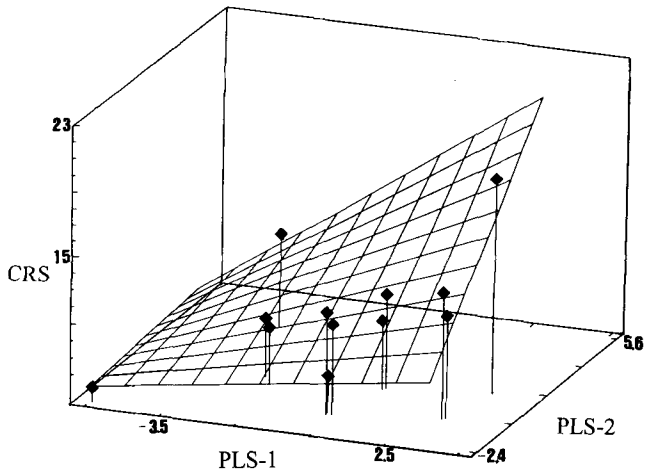

FIG. 1. Partial least squares correlations in latent variables (PLS) response surface plot, chromatographic resolution statistic (CRS) value as a function of the first and second linear combinations of the original experimental variables.

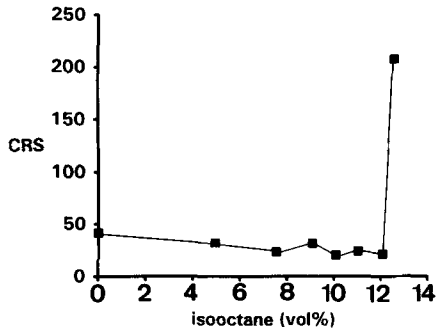

FIG. 2. Chromatographic resolution statistic (CRS) value as a function of isooctane level in the A eluent.

RESULTS AND DISCUSSION

The results of the optimization can be seen in Figures 1 and 2. The experimental domain was mapped by response-surface modelling and PLS response surface modelling which thus enabled the graphical localization of optimal chromatographic conditions. The PLS-1 and PLS-2 axes are the linear combinations of the original experimental variables, the so-called latent factors, which have maximal linear correlation to the response variable, the CRS values (Fig. 1). In this plot the location of each experiment on the response surface can be seen (Fig. 1). As stated above, optimal chromatography is attained where the CRS function shows a minimum, in this figure at the bottom left corner (Fig. 1). The correlations between the original experimental variables and the latent factors can be utilized to elucidate the relation between the chromatographic conditions and the quality of the chromatography, expressed as the CRS value. The response surfaces can be compared with one another, in order to graphically locate experimental conditions at the minimum of the function, thus enabling optimization of chromatographic conditions. Optimal values of the chromatographic conditions can also be directly predicted using PLS regression. These were from acetonitrile/isooctane (90:10, vol/vol) to acetonitrile/ethanol/isooctane (40:35:25, by vol), at a column temperature of 50°C, a flowrate of 1.5 mL/min and a gradient of 100% A to 100% B in 80 min with a negative exponential profile.

The results from the optimization are strongly dependent on the optimization criteria; different chromatographic systems can be obtained by altering the goal of the optimization. In order to develop a system showing maximal separation within the explored domain, with no regard to the total analysis time, the resolution factors can be emphasized in the PLS regression. The system predicted to give maximal resolution (within the explored domain) had the composition of acetonitrile to acetonitrile/ethanol (59:41, vol/vol), at a column temperature of 50°C and a flowrate of 1.5 mL/min.

Some general remarks can be made based on Table 1. A lower elution temperature causes a decrease in the CRS values. Temperature was subsequently held at 50°C in the second set of experiments. The flowrate was also held constant at 1.5 mL/min in order to reduce the number of variables. Increasing the amount of isooctane in eluent A up to 12% (Fig. 2) was shown to yield lower CRS values. The final analysis time was shown to be strongly

dependent on the amount of isooctane in both eluent A and B.

Retention indices such as the ECN concept have found widespread use in lipid analysis, especially for the identification of molecular species of TAG (2,16,17). In the ECN concept, a mathematical model is built between the retention times of the TAG molecular species and a weighted sum of the total number of carbon atoms and the number of double bonds in the fatty acyl chains present in the TAG molecule. The most common mathematical model used is a logarithmic relation (4,9). The results have been used to provide a means of identifying TAG molecular species and also to predict the chainlength and number of double bonds (4,9,17,18).

Different nomenclatures are used by workers in this field. In the present study we will restrict ourselves to the nomenclature used by Podlaha and Töregård (9). Our choice of using a polynomial expansion to model the data was motivated by the fact that we use gradient elution. Any nonlinearity in the data due to the solvent gradient would therefore be properly handled by choosing the appropriate degree of the polynomial. A fifth degree polynomial model was found to give the lowest relative prediction error (approximately 1%). We also used P′ (Snyders polarity index; Ref. 24) instead of the retention times in the ECN model in order to compensate for different gradient profiles. The P′-value is a measure of the chromatographic environment experienced by each individual molecular species at the time of elution and can thus be considered as a more pertinent description of the chemical characteristics of the molecule. The P′-value for the solvent mixture at the time of elution can be estimated by calculating the amounts of the different solvents present in the mobile phase and by using the volume fractions as coefficients in a simple linear function of each pure solvent P′ (24). Further, our use of the ECN values is restricted to simply obtaining an identification or an ordering number for each of the separated peaks. The results can thus be compared to virtually any RP-HPLC system just by employing a set of saturated TAG standards to build the ECN model.

Prediction of the ECN values for molecular species was done for a range of different natural oils (Table 3). Molecular species that are not determined in this chromatographic system are placed in the expected elution order (25,26). The separation potential of the system can be described by comparing the number of carbons and the degree of unsaturation in the fatty acid moieties, *i.e.*, the partition number, PN, to the observed P′ differences of different TAG, a selection of which are listed in Table 4.

[a]Abbreviations: Ad, arachidonic acid; D, decanoic acid; PN, partition number; ECN, equivalent carbon number; Hd, heptadecanoic acid; Ln, linolenic acid; La, lauric acid; L, linoleic acid; Nd, nonadeanoic acid; O, oleic acid; P, palmitic acid; Pd, pentadecanoic acid; St, stearic acid.

[b]Fatty acids given in arbitrary order in regard to the glycerol backbone.

[c]Calculations not corrected for system void volume.

[d]n.d., Not determined, species given in the expected elution order according to References 25 and 26.

TABLE 4

P′ Relation to Partition Number (PN)

PN difference in TAG	Example of fatty acid substitution[a]	P′ difference
0	P replaced with O	0.02–0.01
2	P replaced with L	0.11–0.06
2	O relaced with L	0.09–0.05
2	L replaced with Ln	0.09–0.06
2	St replaced with O	0.10–0.02
2	St replaced with P	0.08–0.01
4	P replaced with Ln	0.20–0.12
4	O replaced with Ln	0.18–0.11
4	St replaced with L	0.19–0.06
6	St replaced with Ln	0.28–0.12

[a]Abbreviations: TAG, triacylglycerols; see Table 3 for other abbreviations.

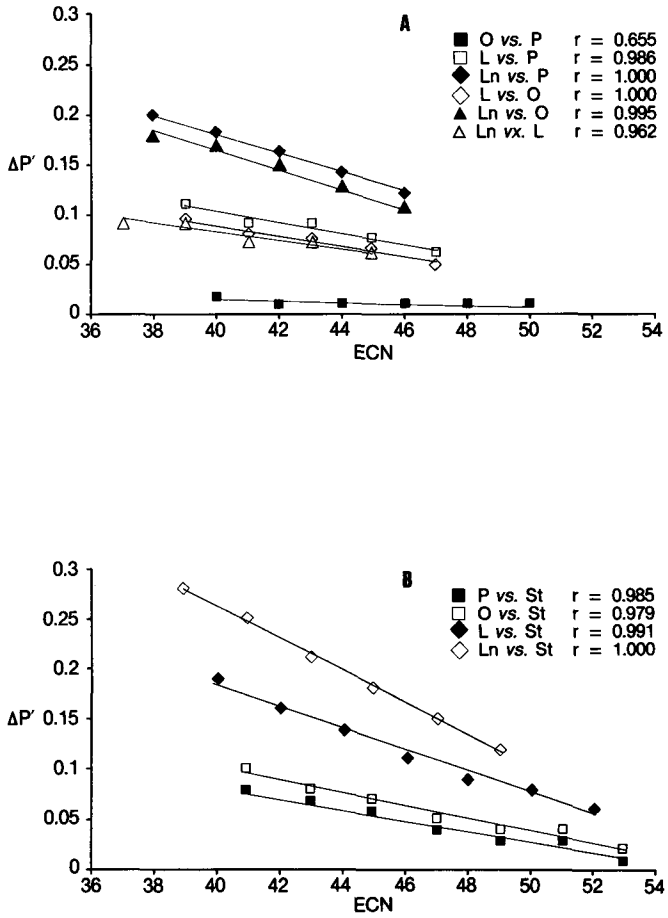

FIG. 3. P′ difference as a function of average equivalent carbon number (ECN) of (A) triacylglycerol (TAG) molecular species and (B) TAG molecular species containing stearic acid. Abbreviations: O, oleic; P, palmitic; L, linoleic; Ln, linolenic.

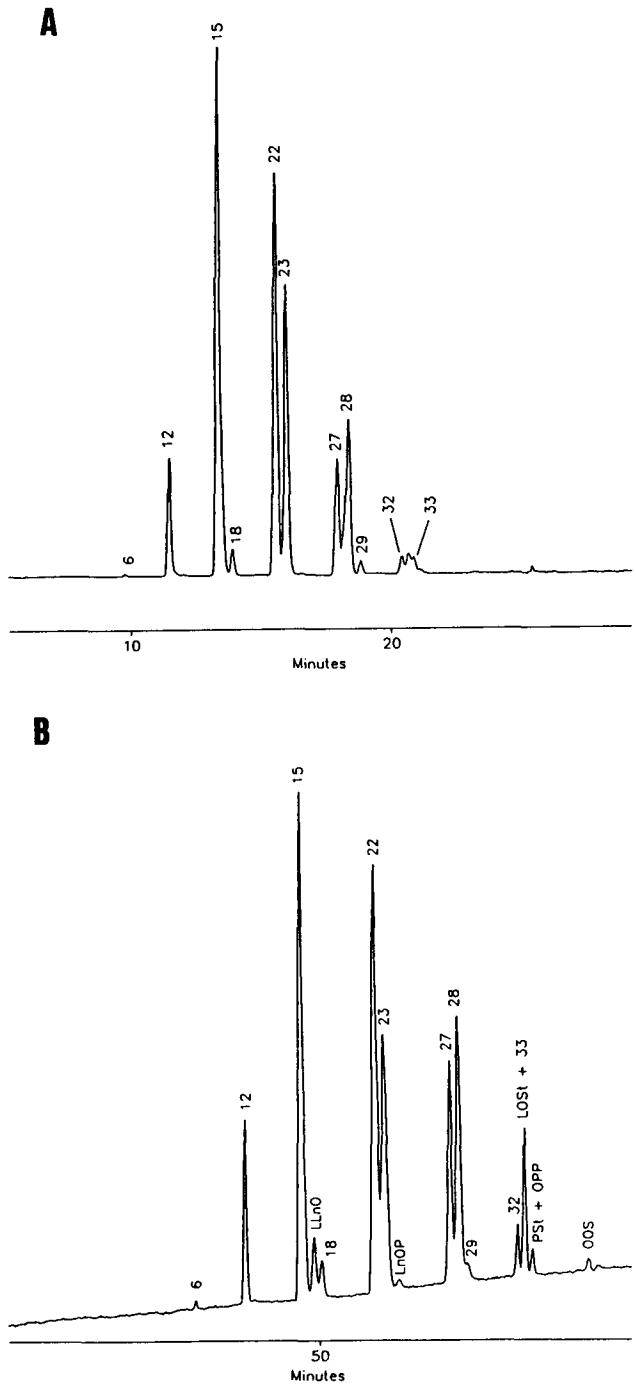

FIG. 4. Reversed-phase high-performance liquid chromatograms for soybean oil. Solvent system for (A): acetonitrile/isooctane (90:10, vol/vol) to acetonitrile/ethanol/isooctane (40:35:25, by vol), and for (B): acetonitrile to acetonitrile/ethanol (59:41, vol/vol). Conditions: see text. Peak numbering refers to Table 4. See Figure 3 for abbreviations.

Plots of these (Fig. 3) show decreasing trends when moving from low ECN values (early-eluting) to high values (late-eluting). Species that will coelute in this system, provided they coexist in the same oil, can be seen in this plot where the lines intersect (Fig. 3B).

The number of RP-HPLC distinguishable molecular species (not considering positional or optical isomers) is given by $(n^3 + 3n^2 + 2n)/6$, where n is the number of fatty acids (27). This number is the upper limiting value, the random distribution. The number of species found in most biosystems is much lower. Also, many of the species included in this number are probably present at levels below the detection limit (100 ng). Soybean oil (Fig. 4A) with 6 major fatty acids can contain at the most 56 molecular species (random distribution); 12 peaks are separated and 11 are identified, these are listed in Table 5. By changing the optimization criteria as mentioned above to emphasize separation at the expense of total analysis time, the average resolution can be enhanced from 3.9 to 4.4 (Fig. 4A), thus separating 16 peaks (Fig. 4B). Rapeseed oil (Fig. 5A) has 5 major fatty acids and can exhibit 35 molecular species at the most according to the random distribution, 12 are separated and identified in this chromatogram (Fig. 5A, Table 5). Palm oil (Fig. 5B) also has 5 major fatty acids as does linseed oil (Fig. 6A), 11 and 13 peaks are separated and identified, respectively (Figs. 5B, 6A, Table 5). Tallow has a more complex fatty acid composition with 9 major fatty acids (Fig. 6B), 165 random combinations are possible while 16 peaks are separated and 12 are identified (Fig. 6B, Table 6). The decidedly more complex fish oil, a commercial commodity (Fig. 7), has a fatty acid com-

[c]The species OOSt (7.2%) and OPSt do not coelute, as can be seen in Figure 6B, but have the same P' value in this sample of tallow.

position of 15 major fatty acids with 680 possible random combinations. This oil contains molecular species of quite a different nature than those present in seed oils, due to the high content of polyunsaturated fatty acids. However, in less than 25 min some 46 species are separated, of which 24 are major (>0.8 area %) (Fig. 7, Table 6).

In conclusion, we have formally optimized an RP-HPLC method for the separation of TAG molecular species using statistical experimental design and multivariate optimization. This strategy enables great flexibility in the development process to tailor the system after desired specifications, limited only by the chosen experimental domain. The system thus developed afforded excellent resolution within a short total analysis time, which was exemplified on several examples of natural seed oils, tallow and fish oil. Identification of the TAG species was done utilizing the ECN concept with Snyders P' at the time of elution instead of retention times. This concept was shown, through Δ P'-ECN plots, to furnish a means of detecting potentially critical pairs of molecular species present in different oils.

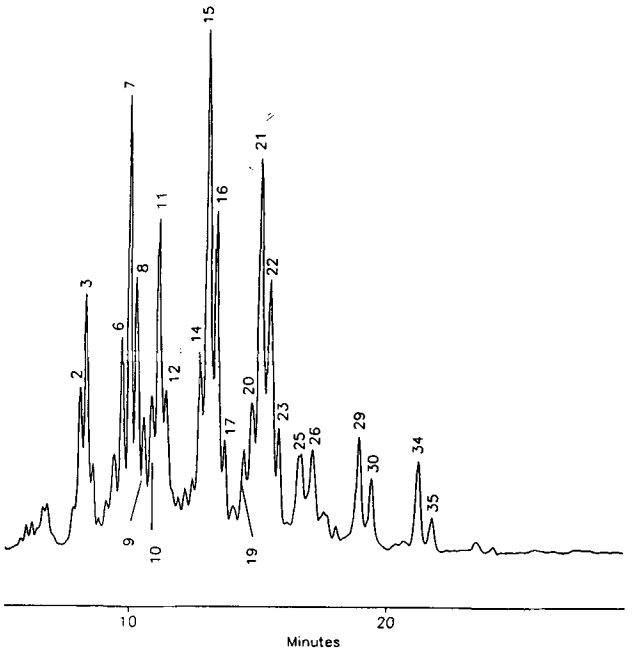

FIG. 7. Reversed-phase high-performance liquid chromatogram for fish oil. Solvent system: acetonitrile/isooctane (90:10, vol/vol) to acetonitrile/ethanol/isooctane (40:35:25, by vol). Conditions: see text. Peak numbering refers to Table 5.

ARTICLE

Maternally-Supplied Fish Oil Alters Piglet Immune Cell Fatty Acid Profile and Eicosanoid Production[1]

Kevin L. Fritsche*, David W. Alexander, Nancy A. Cassity and Shu-Cai Huang[2]
Department of Animal Sciences, University of Missouri, Columbia, Missouri 65211

This study was designed to examine the incorporation of omega-3 (n-3) fatty acids into the immune tissues of pigs nursing fish oil-fed sows and to determine the effect of maternal dietary n-3 consumption on *in vitro* immune cell eicosanoid production. On day 107 of gestation, 12 sows were randomly allotted to a diet containing either 7% menhaden fish oil (MFO) or lard (LRD). The fatty acid profile of serum, liver, thymus, splenocytes and alveolar macrophages (AM) of 18–21-day-old pigs was significantly affected by the fat source provided to the sow. Arachidonic acid (20:4n-6) content was typically reduced by more than 50% in MFO as compared with LRD pigs. In MFO pigs, eicosapentaenoic acid (20:5n-3) was the major n-3 polyunsaturated fatty acid, and its levels matched or exceeded those of arachidonic acid. Basal release of prostaglandin E, thromboxane B and leukotriene B by AM was 60–70% lower in MFO *vs.* LRD pigs. However, when these immune cells were stimulated with calcium ionophore A23187, release of leukotriene B was similar in MFO and LRD pigs. In conclusion, substituting MFO for LRD in a sow's late-gestation and lactation diet greatly elevated the content of n-3 fatty acids in the nursing pig immune cells and generally reduced *in vitro* eicosanoid release by pig immune cells.
***Lipids* 28, 677–682 (1993).**

Apart from their role as storage and transport forms of metabolic fuel, the fatty acid portion of dietary fats serves several other important functions in the body. These include providing for the essential fatty acid requirements, acting as structural components of cell membranes and serving as precursors for eicosanoid production. Eicosanoids, such as prostaglandins and leukotrienes, are recognized as important modulators of humoral and cell-mediated immune responses (1,2). Considerable evidence has accumulated which demonstrates that dietary fats influence the immune response, partly through their ability to modulate eicosanoid production (3). The fatty acid moieties of phospholipids determine many membrane functions. The possible influence of lipids on receptor binding, signal transduction and lymphocyte proliferation makes knowing the fatty acid composition of immune cells of particular interest (4,5).

With the increased interest in providing premature infants and neonates lipid emulsions or infant formulas enriched with n-3 polyunsaturated fatty acids (PUFA), it is important that we understand the potential impact of these lipids on immune tissues in this age group. Little is known about the influence that maternal dietary fat source has on the fatty acid composition and eicosanoid production of neonatal immune cells. The use of swine in biomedical research has been growing steadily. Miller and Ullrey (6) have described some of the advantages of using the pig as a model for human nutrition research. Previous studies in this laboratory demonstrated that the inclusion of fish oils in sow diets during late-gestation and lactation significantly elevated n-3 PUFA levels in the blood of nursing pigs (7).

The objectives of this study were: (i) to determine the incorporation of n-3 PUFA into the immune cells of pigs nursing fish oil-fed sows and (ii) to quantitate the impact of n-3 PUFA incorporation on eicosanoid production by pig immune cells.

MATERIALS AND METHODS

Animals and diets. On day 107 of gestation, 12 crossbred sows (Landrace × Duroc, Columbia, MO) were randomly allotted to one of two diets, in which menhaden fish oil (MFO) was substituted for lard (LRD) at 7% by weight of the diet. Diets were isocaloric and formulated to meet National Research Council requirements (8). See Table 1

TABLE 1

Composition of Experimental Diets Fed to Sows

Ingredient	Dietary treatment groups	
	LRD (g/100 g)	MFO (g/100 g)
Ground corn	58.9	58.9
Oats	10.1	10.1
Soybean meal (44% crude protein)	20.0	20.0
Lard (LRD)[a]	7.0	—
Menhaden fish oil (MFO)[b]	—	7.0
Dicalcium phosphate	2.7	2.7
Vitamin mix[c]	0.5	0.5
Trace mineral salt mix[d]	0.5	0.5
Ground limestone	0.4	0.4

Abbreviations: AA, arachidonic acid; AM, alveolar macrophage; EDTA, ethylenediaminetetraacetate; EPA, eicosapentaenoic acid; HEPES, *N*-2-hydroxyethylpiperazine *N'*-2-ethanesulfonic acid; LRD, lard; LTB, leukotriene B; MEM, Minimal Essential Medium; MFO, menhaden fish oil; PGE, prostaglandin E; PUFA, polyunsaturated fatty acids; TXB, thromboxane B.

for complete composition. Sows were individually fed 1.8–2.1 kg of experimental diets daily from day 107 of gestation until farrowing. An additional 0.45 kg was fed to each sow per day for each suckling pig during the 28-d lactation period. Additional details regarding housing and handling of animals is described elsewhere (7). Housing, handling and sample collection procedures conformed to policies and recommendations of the University of Missouri's Laboratory Animal Care Advisory Committee.

Sample collection. At 3–4 wk of age, one pig from each litter (n = 6) was killed for tissue collection. The pigs were anesthetized with ketamine (20 mg/kg) and acepromazine (1 mg/kg). Blood (20 mL) was collected by venipuncture and left to clot for subsequent serum isolation. A portion of the spleen was removed and placed on ice in a 50-mL tube filled with sterile-filtered ice-cold Hank's balanced salt solution without Ca^{2+} and Mg^{2+} (UMC Immunobiology Core Facility, Columbia, MO) for subsequent splenocyte isolation. Single cell suspensions of splenocytes were made by forcing the spleen sample through a tissue sieve (Sigma, St. Louis, MO) equipped with an 80-mesh stainless steel screen. Using a 10-mL syringe without a needle, cell clumps were dispersed by several gentle washings through the sieve. Red blood cells and dead cells were removed by centrifugation of the spleen cell suspension over lymphocyte separation medium, density 1.077–1.080 g/mL at 20°C, as described by the manufacturer (Organon Teknika Corp., Durham, NC). Mononuclear cells at the interface (predominantly lymphocytes and monocytes) were collected, washed twice and stored in 1 mL 10 mM ethylenediaminetetraacetate (EDTA). Samples of the liver and thymus were snap frozen in 20-mL glass vials using a dry ice-acetone bath. All samples were stored at −80°C until lipid analysis.

Alveolar macrophage (AM) and peritoneal cell isolation and eicosanoid production. Resident peritoneal cells were collected by filling the peritoneal cavity with ≈400 mL of sterile ice-cold Hank's. The abdomen was gently massaged, then fluid was removed with a 60-mL syringe. Total recovery averaged ≈200 mL. For the collection of AM, the trachea was clamped shut and the lungs were excised. The lungs were filled with 60 mL of ice-cold Hank's and gently shaken. The contents of the lungs were filtered through sterile gauze into 50-mL tubes on ice. This process was repeated twice (total recovery was ≈100 mL).

The tubes containing the AM or resident peritoneal cells were spun down (500 × *g* for 15 min) and washed twice with Minimal Essential Medium (MEM) with 2 mM L-glutamine, 10 mM *N*-2-hydroxyethylpiperazine *N'*-2-ethanesulfonic acid (HEPES), penicillin (100,000 U/L) and streptomycin (0.17 mmol/L), pH 7.4 (MEM). The cells were then spun at 500 × *g* for 10 min and resuspended in 10 mL of MEM. Cells were counted electronically (Coulter Electronics, Inc., Hialeah, FL) and resuspended at a final concentration of 5×10^6 cell/mL of MEM. The AM were more than 95% macrophages based on morphology, Wright-Giemsa staining (9) and adherence properties. The resident peritoneal cell preparations were 60–70% macrophages based on the same criteria.

To each well of a 24-well cell culture plate, 0.5 mL (2.5×10^6) of the AM or peritoneal cell suspension was added in addition to 0.5 mL of MEM with 10% autologous serum. Plates were placed in an incubator at 37°C with 5% CO_2 for 4 h to allow cells to adhere. After washing the adhered cells three times with MEM, 0.5 mL of MEM with 10% autologous serum was added to each well. Then 0.5 mL/well of MEM alone (controls) or containing lipopolysaccharide from *E. coli* O111:B4 (5 μg/mL) or calcium ionophore A23187 (2 μg/mL) was added to wells in order to stimulate eicosanoid production. At the times indicated, supernatants were collected in 1.5-mL polypropylene microcentrifuge tubes, spun (10,000 rpm, 3 min), then transferred into a new tube and stored at −80°C.

Lipid extraction and analysis. Lipids were extracted from the serum, liver, thymus, splenocytes and AM following the Folch method as described elsewhere (10). Methyl esters of fatty acids were prepared by transmethylation using 4% H_2SO_4 in methanol. Fatty acid methyl esters were identified using a Hewlett-Packard gas chromatograph (Sunnyvale, CA) Model 5890A with a 30 m capillary column (Supelcowax 10, Supelco, Bellefonte, PA). Results, expressed as percent of total fatty acids, were determined using a Hewlett-Packard 3396A integrator.

Eicosanoid analysis. The concentration of prostaglandin E_2 (PGE_2), thromboxane B_2 (TXB_2) and leukotriene B_4 (LTB_4) in the cell supernatants was determined using commercially available enzyme immunoassay kits for each eicosanoid as described by the manufacturer (Advanced Magnetics Inc., Boston, MA). Information on the cross-reactivity of these antisera with eicosapentaenoic acid (EPA)-derived metabolites (*e.g.*, PGE_3, TXB_3 and LTB_5) was not available from the manufacturer. Therefore results are expressed as micrograms of PGE or LTB per liter of supernatant. All cell supernatants were assayed in duplicate. When necessary, supernatants were diluted with MEM prior to analysis. The linear portion of a typical standard curve ranged from 20.0 to 0.027 ng/mL for PGE and 10.0 to 0.014 ng/mL for TXB and LTB, respectively.

Statistical analysis. Fatty acid data were subjected to one-way analysis of variance (ANOVA) to test for an effect of fat source. Eicosanoid (*i.e.*, PGE, LTB) data were log transformed to achieve homogeneity of variance then analyzed by ANOVA. All analyses were conducted on a Macintosh II computer using version 1.03 of StatView II (Abacus Concepts, Inc., Berkeley, CA).

RESULTS

Fatty acid composition. The replacement of LRD with MFO in the late gestation and lactation diet of sows significantly modified the fatty acid profile of the serum, liver and immune tissues of nursing pigs (Tables 2 and 3). The two fat sources differed significantly in the amount of saturated fatty acids and PUFA they contained. However, there was little difference in the total saturated fatty acid content in the serum or tissues examined. Total PUFA content in the serum and liver, but not immune tissues, was altered by dietary fat source. Oleic acid (18:1n-9) was the major monounsaturated fatty acid in both diets and in the samples analyzed. The level of 18:1n-9, as well as the total monounsaturated fatty acids, were higher ($P < .05$; Tables 2 and 3) in the serum, liver, thymus and alveolar macrophages from the LRD pigs as compared with the MFO pigs. These differences were a reflection of dietary oleic acid and total monounsaturated fatty acid content of the diets.

The relative levels of individual and total n-6 and n-3 PUFA in the pigs were significantly altered by the source

of fat fed to the sow. Feeding fish oil to the sows lead to an elevation of n-3 PUFA with a concomitant decrease in n-6 PUFA. For example, arachidonic acid (AA; 20:4n-6) levels in the serum, liver and immune tissues were decreased by more than 50% ($P < 0.005$; Tables 2 and 3) in MFO pigs as compared to LRD pigs. The levels of the other major n-6 PUFA, linoleic acid (18:2n-6), were only affected modestly ($P < 0.05$; Tables 2 and 3). In fact, 18:2n-6 levels in the immune tissues were not significantly different between LRD and MFO pigs.

In LRD pigs, EPA (20:5n-3) was found only in trace amounts (<0.5%). Feeding MFO to the sows greatly increased the amount of this n-3 PUFA in the serum, liver, and immune tissues of pigs ($P < 0.0005$). In the serum, liver, splenocytes and alveolar macrophages of the MFO pigs, the level of EPA exceeded that of AA. The levels of other n-3 PUFA, 22:5n-3 and 22:6n-3, were also elevated in those pigs suckling MFO-fed sows. Total n-3 PUFA content of the serum and tissues sampled accounted for between 7–17% of the total PUFA in LRD pigs, while in MFO pigs they accounted for between 46–65% of the total PUFA. However, total PUFA levels in the thymus, splenocytes and AM did not significantly differ between LRD and MFO pigs.

Eicosanoid production. The impact of maternal dietary fat source on piglet immune cells PGE production is shown in Table 4. There was a 12-fold reduction in PGE release over a 24-h period by unstimulated (basal) AM isolated from the MFO-piglets as compared to the LRD piglets. Co-culturing piglet AM with either calcium ionophore or endotoxin elevated the release of PGE into the supernatants. Menhaden fish oil–AM stimulated with endotoxin released 70% less PGE than those from LRD piglets ($P < 0.05$). When we examined another source of immune cells (*i.e.*, resident peritoneal macrophages), similar trends were noted. However, these data were considerably more variable than the AM data. The only diet-related difference that approached statistical significance

TABLE 4

Prostaglandin E (PGE) Production by Alveolar Macrophages (AM) and Resident Peritoneal Cells from Piglets Suckling Sows Fed Diets Containing 7% (by wt) of Either Lard (LRD) or Menhaden Fish Oil (MFO)

	Immune cell types[a]			
	AM		Peritoneal cells	
	Maternal fat source			
Culture conditions[b]	LRD	MFO	LRD	MFO
	(pg/0.1 mL)[c]			
Basal	94[d]	8[e]	1511	777
A23187-stimulated	156	20	2902	1245
Endotoxin-stimulated	1490[d]	425[e]	2802	2764

[a]Resident peritoneal cells were collected from three to four week old piglets by filling the peritoneal cavity with ≈400 mL of sterile ice-cold Hank's, and AM were collected from excised lungs with two 60-mL flushes of ice-cold Hank's.
[b]The isolated immune cells (2.5×10^6/well) were incubated (37°C and 5% CO_2) 24-well cell culture plates. After 4 h, nonadherent cells were washed away and remaining cells were co-cultured with media alone for 24 h (basal), 2 μg/mL of calcium ionophore for 4 h (A23187-stimulated) or 5 μg/mL of lipopolysaccharide from *E. coli* O111:B4 for 24 h (endotoxin-stimulated).
[c]The concentration of PGE in the cell supernatants was determined by enzyme immunoassay (Advanced Magnetics, Inc.). Data were log transformed to achieve homogeneity of variance then analyzed by ANOVA. Values shown represent the mean (n = 4-6).
[d,e]Values within rows that do not share a common superscript are statistically different ($P < 0.05$).

($P < 0.08$) was with the A23187-stimulated peritoneal cells preparations.

The production of other eicosanoids by isolated pig AM was also influenced by supplementing the sow's diet with fish oil. In a follow-up experiment the impact of n-3 enrichment on LTB and TXB production by piglet AM was investigated. Cells were isolated from three to four week old piglets born to sows fed either fish oil- or lard-containing diets as described above. However, for this study AM were collected from piglets after weaning. In order to prevent the reversal of the maternal fat source effects, weaned piglets were fed diets which contained the same fat source assigned to the sow.

As in the first study, spontaneous and calcium ionophore-stimulated PGE production was significantly lower in the MFO piglets as compared with the LRD piglets (Fig. 1, top panel). Spontaneous thromboxane A production (measured as the stable metabolite, TXB) was significantly lower in the MFO piglets as compared with the LRD piglets (Fig. 1, middle panel). Ionophore stimulation greatly increased TXA release in both MFO and LRD piglets (6.5-fold *vs.* 3-fold, respectively). However, the net release by stimulated AM from the MFO piglets was still significantly lower than that from the LRD piglets ($P < 0.05$). The basal release of LTB was significantly reduced in the MFO pigs compared with LRD pigs (Fig. 1, bottom panel). As observed with other eicosanoids measured, LTB release was greatly enhanced by co-culturing the cells with the calcium ionophore, A23187. However, when AM were stimulated with calcium ionophore, release of LTB was similar for both MFO and LRD pigs.

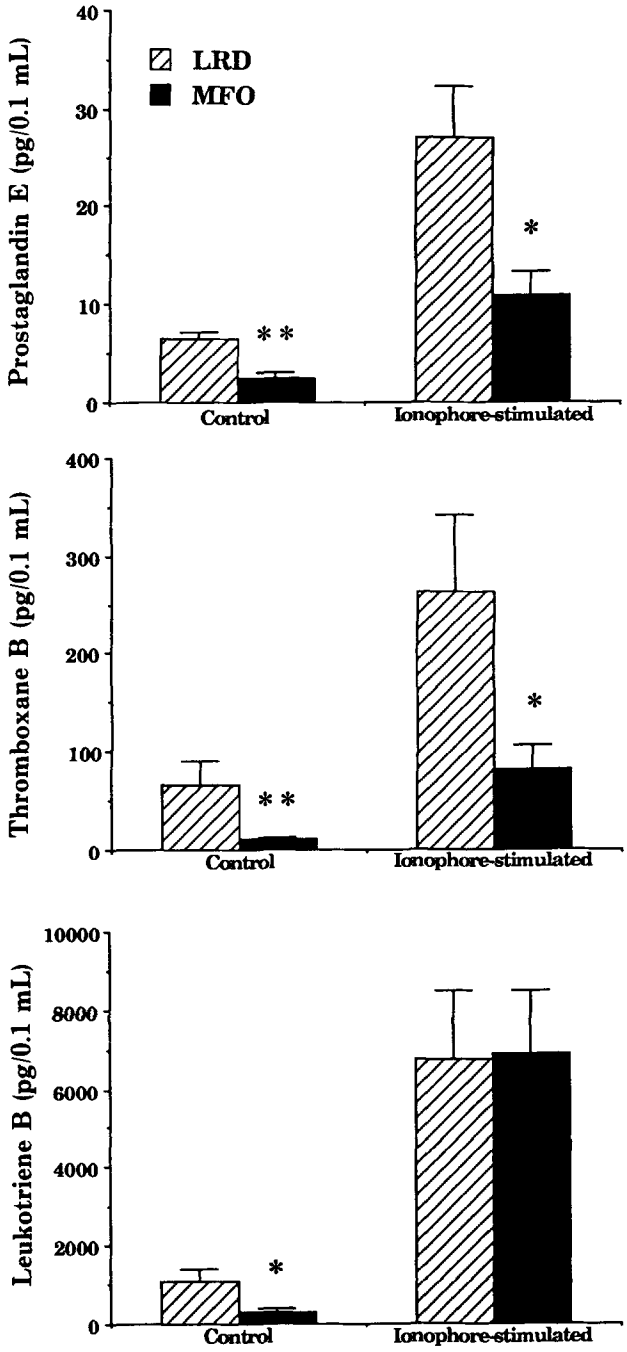

FIG. 1. Production and release of prostaglandin E (PGE), thromboxane B (TXB) and leukotriene B (LTB) from alveolar macrophages (AM) isolated from three- to four-week-old pigs suckling menhaden fish oil-fed (MFO) or lard-fed (LRD) sows. After adherence, 2.5 × 10^6 AM were rinsed and then incubated for 1 h in the presence of 2 μg/mL of calcium ionophore (A23187) or medium with vehicle only (controls). Supernatants were analyzed for PGE, TXB and LTB by enzyme immunoassay. Data represent the means (n = 6) with error bars representing the SEM. Values for the MFO group are significantly lower from the LRD group (*$P < 0.05$; **$P < 0.005$) as determined by ANOVA.

DISCUSSION

Our data demonstrate that sufficient n-3 PUFA were in the milk of fish oil-fed sows such that the immune tissues and cells from pigs suckling these sows were enriched with n-3 PUFA. The most substantial changes in immune cell fatty acid profiles occurred in the relative levels of the eicosanoid precursors, AA (20:4n-6) and EPA (20:5n-3). Immune cell AA levels dropped by one-half in the MFO pigs as compared to the LRD pigs. In the MFO pigs the level of EPA in the immune cells exceeded the AA that remained. This may seem somewhat surprising in view of the relatively small amount of EPA in the milk of fish oil-fed sows (≈3% of the total fatty acids in the milk; see Ref. 7). However, such a selective enrichment of EPA is probably a consequence of the greater rate of oxidation of the fatty acids <20 carbons in length and the preferential incorporation of 20–22 carbon fatty acids into membrane phospholipids. In 1991, Arbuckle *et al.* (10) reported that the fatty acid composition of a number of pig tissues (*e.g.*, brain, liver and red blood cells) could be enriched with n-3 PUFA by providing pigs a formula supplemented with menhaden fish oil. Enrichment of immune cells with n-3 fatty acids has been demonstrated in rats (11,12), mice (13), chickens (14) and humans (15). However, in each of these cases, the n-3 PUFA were provided directly in the diet of the experimental subject.

As predicted, the changes in immune cell fatty acid composition led to a significant alteration in eicosanoid production by these same cells. The reduction in prostaglandin production by immune cells enriched with n-3 PUFA has been documented in several other species, including rats (11,12), mice (16–18), chickens (19) and humans (15,20). This is the first report of porcine immune cell eicosanoid production being altered by enriching cellular n-3 PUFA content. n-3 PUFAs alter eicosanoid produc-

tion through metabolic competition between the two major families of PUFA, the n-6 and the n-3. Upon fish oil feeding, EPA and other n-3 PUFA displace some of the AA from immune cell membrane phospholipids. Because EPA is a poor substrate for the cyclooxygenase enzyme, its conversion into prostaglandins is limited. Therefore, when cellular fatty acid profiles are altered as described above, these changes lead to a reduced capacity for prostaglandin and thromboxane synthesis. Additionally, it has been reported that docosahexaenoic acid (22:6n-3) reduces *in vivo* macrophage eicosanoid production (21). Thus the decrease in AA and the increase in n-3 PUFA in the immune cells from the MFO-pigs probably account for most of the changes in eicosanoid production observed in our study.

The impact of n-3 PUFA enrichment on production of LTB is more complex than that described above for PGE and TXB. Unlike for the cyclooxygenase, 20:5n-3 is a good substrate for the 5-lipoxygenase enzyme. Thus one would expect the production of substantial amounts of LTB from this n-3 fatty acid when its levels are elevated. The findings of Leitch *et al.* (22) and Lee *et al.* (20) support such a conclusion. However, the form of eicosanoid analysis used in this study (*i.e.,* enzyme immunoassay) does not allow us to distinguish between LTB_4 (derived from AA) and LTB_5 (derived from EPA). It seems highly probable that a sizable proportion of the immunoreactive LTB measured in this study was LTB_5. It is unclear why we observed a difference between the LRD- and MFO-pigs in the basal release of LTB, but not upon ionophore-stimulation. It is possible that basal release of EPA from membrane phospholipids is less than AA or that reincorporation is faster. Alternatively, differential alteration of AA and EPA levels across distinct phospholipid pools may be important.

AA metabolites play an important role in the pathophysiologic responses of the lung, and AM are a major source for these products (23). The reduction in PGE and TXB production and the replacement of LTB_4 with LTB_5 could be of biological significance. LTB_5 has been reported to be 1/30 to 1/60 as potent as LTB_4 in eliciting neutrophil chemotaxis (22). Thus immune tissues enriched with 20:5n-3 would be expected to cause less pro-inflammatory activity than those not enriched. Furthermore, a decline in infectious disease resistance has also been reported for n-3 PUFA-enriched animals. D'Ambola *et al.* (24) reported that *in vivo* pulmonary bacterial clearance in neonatal rabbits was diminished by fish oil-supplementation. Feeding mice fish oil significantly reduced survival from a live bacterial challenge (25). Whether such changes in immune status are a consequence of altered eicosanoid production remains to be determined.

In conclusion, we believe these data support our hypothesis and that the transfer of n-3 PUFA from fish oil-fed sows to the nursing pig is of sufficient magnitude to elevate n-3 PUFA levels in immune cells, which leads to a significant alteration in eicosanoid production by these same cells. This may be of practical importance as a variety of immune and inflammatory processes have been shown to have been influenced by eicosanoids and n-3 PUFA. Therefore, we believe that further studies are warranted to examine the impact of maternal n-3 PUFA intake on the immunological and inflammatory responses in the newborn.

ACKNOWLEDGMENTS

This paper is a contribution from the Missouri Agriculture Experiment Station; Journal Series Number 11840. Financial support for this research was provided by the Food for the 21st Century Program and the University of Missouri Agriculture Experiment Station. We are grateful to Zapata Haynie Inc., Reedville, VA, for supplying the menhaden fish oil.

The Hypotriglyceridemic Effect of Eicosapentaenoic Acid in Rats Is Reflected in Increased Mitochondrial Fatty Acid Oxidation Followed by Diminished Lipogenesis

Nina Willumsen[a,*,1], Jon Skorve[a,2], Sofie Hexeberg[b,2], Arild C. Rustan[c] and Rolf K. Berge[a]

[a]University of Bergen, Laboratory of Clinical Biochemistry, Haukeland Sykehus, 5021 Bergen, [b]Department of Anatomy, University of Bergen, 5009 Bergen and [c]Institute for Nutrition Research, University of Oslo, Oslo, Norway

The effect of eicosapentaenoic acid (EPA) on fatty acid oxidation and on key enzymes of triglyceride metabolism and lipogenesis was investigated in the liver of rats. Repeated administration of EPA to normolipidemic rats resulted in a time-dependent decrease in plasma triglycerides, phospholipids and cholesterol. The triglyceride-lowering effect was observed after one day of feeding whereas lowering of plasma cholesterol and phospholipids was observed after five days of treatment. The triglyceride content of liver was reduced after two-day treatment. At that time, increased mitochondrial fatty acid oxidation occurred whereas mitochondrial and microsomal glycerophosphate acyltransferase was inhibited. The phosphatidate phosphohydrolase activity was unchanged. Adenosine triphosphatecitrate lyase, acetyl-CoA carboxylase, fatty acid synthetase and glucose-6-phosphate dehydrogenase were inhibited during the 15 d of EPA treatment whereas peroxisomal β-oxidation was increased. At one day of feeding, however, when the hypotriglyceridemic effect was established, the lipogenic enzyme activities were reduced to the same extent in palmitic acid-treated animals as in EPA-treated rats. In cultured rat hepatocytes, the oxidation of [^{14}C]palmitic acid to carbon dioxide and acid-soluble products was stimulated in the presence of EPA. These results suggest that the instant hypolipidemia in rats given EPA could be explained at least in part by a sudden increase in mitochondrial fatty acid oxidation, thereby reducing the availability of fatty acids for lipid synthesis in the liver for export, *e.g.*, in the form of very low density lipoproteins, even before EPA induced peroxisomal fatty acid oxidation, reduced triglyceride biosynthesis and diminished lipogenesis.
Lipids 28, 683–690 (1993).

Marine oils are rich in polyunsaturated fatty acids of the n-3 family, especially eicosapentaenoic acid (EPA, 20:5) and docosahexaenoic acid (DHA, 22:6). Dietary intake of these fatty acids reduces plasma triglycerides and inhibits production of very low density lipoproteins (VLDL) in human hyper- and normolipidemic subjects and in experimental animals (1–12). The mechanism of this effect has also been studied in cultured cells (4,5) and the results obtained indicate that inhibited lipogenesis (13) and decreased triglyceride synthesis are important factors that contribute to the reduced secretion of VLDL triglycerides.

Glycerol 3-phosphate acyltransferase which catalyzes the initial esterification step in triglyceride synthesis, could not be shown to be involved in the observed triglyceride-lowering effect of fish oil (5,14). On the other hand, contradictory results were obtained in regard to the potential role of phosphatidate phosphohydrolase. Wong and Marsh (15), Marsh *et al.* (16) and Al-Shurbaji *et al.* (14) reported a decrease in phosphatidate phosphohydrolase activity in response to fish oil while in other studies such an inhibition could not be demonstrated (17,18). Differing results on the effect of ω3 fatty acids on diacylglycerol acyltransferase activity were also reported (14, 16–19).

We have recently demonstrated that EPA (95% pure) shows both hypotriglyceridemic and hypocholesterolemic properties (18,20). Our data suggested that the hypotriglyceridemic effect may have been due in part to a reduced supply of fatty acids for hepatic triglyceride synthesis because of increased fatty acid oxidation. The present investigation was undertaken to further explore how EPA feeding affects hepatic lipid metabolism, especially in mitochondria, and how it affects several of the enzymes involved in triglyceride biosynthesis and lipogenesis.

MATERIALS AND METHODS

Chemicals. Ethyl EPA, purity 95%, was obtained from Norsk Hydro AS, Research Center (Porsgrunn, Norway). Palmitic acid (PMA) was from Sigma Chemical Co. (St. Louis, MO). All other chemicals were obtained from common commercial sources and were of reagent grade.

Animals and treatments. Male Wistar rats from Møllegaard Breeding Laboratory (Ejby, Denmark), weighing 182–210 g, were housed in groups of three in grid-bottom metal wire cages in a room maintained at a 12-h light/dark cycle and at a temperature of 20 ± 3°C. The animals were acclimated for at least 1 wk before the start of the experiment. All animals had free access to food and water and were given a standard rat diet (18). EPA and PMA were suspended in 0.5% sodium carboxymethylcellulose (CMS) and 0.5% tocopherol.

In the time study a daily dose of 1500 mg/kg body weight of EPA or PMA was administered by gastric intubation in volumes of 0.75–1.9 mL. The EPA-treated animals were killed on day 1, 3, 5, 10 or 15 after 12 h of fasting while animals treated with PMA were killed on day 2 or 10 and served as control groups. The animal experiments were approved by the local Ethics Committee for Animal Experiments.

Body weights were recorded daily. At the end of the experiments, the rats were fasted and weighed. Cardiac puncture was performed under neuroleptic anesthesia to

Abbreviations: ADGAT, acyl-CoA:diacylglycerol acyltransferase; ATP, adenosine triphosphate; CMS, carboxymethylcellulose; CPCT, CTP:phosphocholine cytidylyltransferase; DHA, docosahexaenoic acid; EDTA, ethylenediaminetetraacetic acid; EPA, eicosapentaenoic acid; Hepes, *N*-(2-hydroxyethyl)piperazine-*N*′-(2-ethanesulfonic acid); L-fraction, peroxisome-enriched fraction; M-fraction, mitochondrial fraction; NADH, nicotinamide adenine dinucleotide; P-fraction, microsomal fraction; PMA, palmitic acid; S-fraction, cytosolic fraction; VLDL, very low density lipoprotein.

obtain blood samples, and the liver was removed immediately, weighed and then chilled on ice. Plasma was prepared by centrifugation of the clotted whole blood at 1000 × *g* for 10 min at 5°C.

Preparation of cultured hepatocytes. Hepatocytes were prepared according to Seglen (21). In short, the rats were anesthetized with barbiturates, and hepatocytes were isolated by collagenase perfusion, washed and plated in Dulbecco's modified Eagle's medium containing *N*-(2-hydroxyethyl)pyperazine-*N*-(2 ethanesulfonic acid (Hepes) (20 mM), Ultroser G (2%) and gentamicin (50 μL) at a density of 3×10^6 cells/dish or culture flask (1×10^6 cells/mL). The culture medium was replaced after 6–7 h (2 mL/dish, medium as before). The cells were incubated at 37°C in an atmosphere of air containing 5% CO_2.

Fatty acid oxidation. Fatty acid oxidation to acid soluble products and CO_2 (to determine the rate of β-oxidation) was measured as described by Christiansen *et al.* (22). To the cultured hepatocytes was added 2 mL Dulbecco's modified Eagle's medium containing Hepes (20 mM), gentamicin, [1-^{14}C]PMA (0.5 μCi/mL, 200 μM) and 500 μM L-carnitine hydrochloride, and the hepatocytes were incubated for 9 h in the presence of EPA.

The culture flasks contained a center well (Kontes, Vineland, NJ) and a folded filter paper and were closed with stopper tops (Kontes). After incubation, 300 μL of phenylethylamine/methanol (1:1, vol/vol) was added to the center well and 300 μL of $HClO_4$ (1 M) to the cells through the stopper top by means of syringe, and the flasks were further incubated for 1 h at room temperature to trap all $^{14}CO_2$. After incubation, the well was cut off and radioactivity was measured by liquid scintillation counting.

Analytical methods. Individual livers were homogenized in ice-cold sucrose medium [0.25 M sucrose in 10 mL Hepes buffer, pH 7.4 and 1 mM ethylenediaminetetraacetic acid (EDTA)] using a Potter-Elvehjem homogenizer at 720 rpm and two strokes of a loose-fitting Teflon pestle. After centrifugation, the resulting nuclear plus postnuclear fractions were used as the total homogenate.

A mitochondrial-enriched fraction (M-fraction) was prepared from the postnuclear fraction at 12000 × *g* for 10 min (SS 34 rotor). A peroxisome-enriched fraction (L-fraction) was prepared by centrifugation at 14000 × *g* for 30 min. A microsomal-enriched fraction (P-fraction) was isolated from the postperoxisomal fraction at 100000 × *g* for 1 h (Ti 60 rotor). The remaining supernatant was collected as the cytosolic fraction (S-fraction).

Protein was assayed using the Bio-Rad protein assay kit (BioRad, Richmond, CA).

Lipid analyses were carried out using the monotest cholesterol enzymatic kit (Boehringer Mannheim, Germany) and the Biopak triglyceride enzymatic kit (Biotrol, Paris, France).

Plasma free fatty acids were determined by an enzymatic colorimetric method (WACO Nefa C) (23).

Enzyme assays. Enzymatic activities of palmitoyl-CoA dependent dehydrogenase measuring peroxisomal β-oxidation with palmitoyl-CoA as substrate (20,24), fatty acyl-CoA oxidase (20), carnitine palmitoyl-transferase with no malonyl-CoA present (20,24), palmitoyl-CoA synthetase (21), palmitoyl-CoA hydrolase (24), phosphatidate phosphohydrolase (25), CPCT (CTP:phosphocholine cytidylyltransferase) (25), fatty acid synthetase (25), mitochondrial β-oxidation (25), glucose-6-phosphate dehydrogenase (25) and diacylglycerol acyltransferase (26) were determined as described earlier.

Adenosine triphosphate (ATP)-citrate lyase activity was assayed according to Rose-Kahn and Bar-Tana (27). The reaction mixture contained 100 mM Tris-HCl buffer, pH 8.6, 10 mM $MgCl_2$, 10 mM dithiothreitol, 0.33 mM CoA, 0.14 mM nicotinamide adenine dinucleotide (NADH), two units of malate dehydrogenase, K-citrate as stated and 5–10 μL of freshly thawed supernatant as enzyme source in a final volume of 1 mL. After 5 min of preincubation of the enzyme with the reaction mixture, the reaction was started by the addition of 50 μL of 0.1 M ATP and the oxidation of NADH recorded at 340 nm at room temperature. Activity was expressed in nanomoles of citrate converted to acetyl-CoA per min.

Acetyl-CoA carboxylase was determined in the cytosolic fraction as incorporation of $NaH^{14}CO_3$ into malonyl-CoA (28).

Statistical analysis. Unless otherwise stated, the *in vivo* results are means ± SD of duplicate measurements on three animals of each experimental group and of six control animals. The effects of PMA and EPA treatment were tested by a two-way analysis of variance. $P < 0.05$ was used as the significance levels to express PMA or EPA effects. For isolation of some cellular fractions from livers, the postnuclear fractions from three animals were pooled. In this case the results are given only as means. Results from cultured rat hepatocytes are presented as mean ± SD of at least three culture dishes/flasks of hepatocytes from two or more animals. Statistical analysis was by Student's *t*-test and $P < 0.05$ was taken to be statistically significant.

RESULTS

Body and liver weights. The rats fed a normolipidemic diet supplemented with EPA and PMA gained weight per day at the same rate as did the controls. Food consumption was similar in each experimental group irrespective of the dietary regimen indicating that appetite was not affected and that the acids were well tolerated (data not shown). All animals treated with the fatty acids as a function of time appeared healthy and looked and behaved normal. No hepatomegaly resulted after PMA or EPA feeding even at a dose of 1500 mg/day/kg body weight (Table 1). The hepatic concentration of protein remained unchanged in all experimental groups (Table 1).

Plasma and liver lipids. Repeated administration of EPA to rats caused a significant ($P < 0.05$) time-related reduction of plasma triglycerides (50–60% decrease, Fig. 1A), cholesterol (30–50% decrease, Fig. 1A) and phospholipids (30–50% decrease, Fig. 1A). The triglyceride-lowering effect was significant ($P < 0.05$) after one day of treatment, whereas significant ($P < 0.05$) lowering of plasma cholesterol and phospholipids was observed after 5 d of EPA treatment. Consistent with previous observations (20), plasma triglycerides, cholesterol and phospholipids were not significantly lowered after administration of PMA (Fig. 1B).

Figure 1A shows that treatment of rats with EPA tended to decrease the plasma free fatty acids (Fig. 1A). The reduction was not significant. However, PMA feeding increased plasma free fatty acids (Fig. 1B).

TABLE 1

Time-Dependent Changes of Liver Weight and Liver Lipids in Rats Treated with EPA or PMA at a Dose of 1500 mg/d/kg Body Weight[a]

Parameters	Compound	Exposure time (days) 0	1	2	3	5	10	15
Liver g/g	PMA	3.32 ± 0.21		3.18 ± 0.35			3.19 ± 0.18

μmol/g liver	EPA	3.1 ± 0.5	2.9 ± 0.6	2.2 ± 0.2	4.1 ± 0.5	4.5 ± 1.5	4.1 ± 1.4	3.6 ± 0.5

[a]The hepatic values represent means ± SD of six control animals and groups of three rats in each experimental group. Abbreviations: EPA, eicosapentaenoic acid; PMA, palmitic acid.
[b]$P < 0.05$ for difference between control and treated rats.

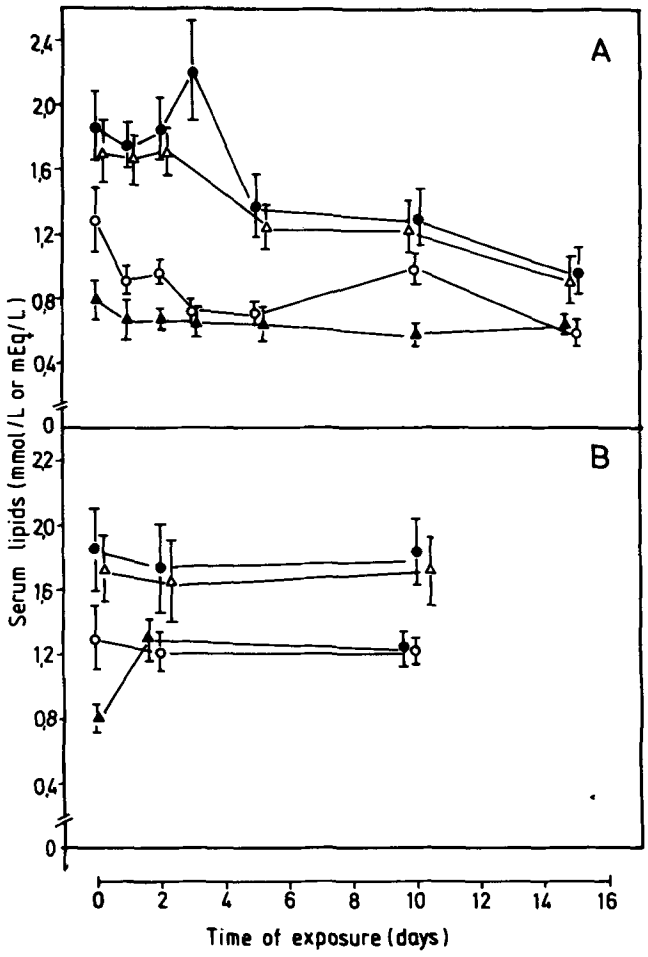

FIG. 1. Time course of plasma triglycerides (○), cholesterol (△), phospholipids (●) and free fatty acids (▲) in rats given eicosapentaenoic acid (A) or palmitic acid (B). The values represent means ± SD of nine control animals and three rats in each experimental group. Plasma triglycerides, cholesterol and phospholipids are given in mmol/L, whereas plasma free fatty acids are in Eq/L.

EPA caused a significant ($P < 0.05$) reduction of the hepatic concentration of triglycerides (Table 1) during the first two days of treatment when compared to 0 d. Repeated administration of EPA or PMA had no effect on the concentration of hepatic cholesterol and phospholipids (Table 1).

Mitochondrial and peroxisomal β-oxidation. Figure 2A shows that in animals fed EPA the mitochondrial oxidation of fatty acids increases. This was seen with palmitoyl-CoA and especially with palmitoyl-L-carnitine as substrate where oxidation of palmitoyl-L-carnitine was rapidly increased to its maximum after one day of feeding EPA. At that time, mitochondrial β-oxidation was increased 1.8-fold. The oxidation of palmitoyl-CoA was maximally increased after 2 d of feeding. Subsequently, in EPA-treated rats, the oxidation of palmitoyl-CoA and palmitoyl-L-carnitine fell to almost normal values (15 d).

Repeated administration of EPA tended to increase carnitine palmitoyltransferase activity in a time-dependent manner (Table 2). At 15 d of feeding, significant enzyme activity was observed.

EPA treatment also caused an increase in both fatty acyl-CoA oxidase (Fig. 2B) and peroxisomal β-oxidation (Table 2) after 5–15 d of feeding. The two enzyme activities were increased about 3- and 2.5-fold, respectively, after 15 d of feeding. Peroxisomal β-oxidation was not affected up to 3 d of EPA feeding (Table 2), whereas fatty acyl-CoA oxidase showed a significant increase in that feeding period (Fig. 2B).

Effect of EPA on the oxidation of [^{14}C]PMA in cultured hepatocytes. The oxidation of [^{14}C]PMA to carbon dioxide and acid-soluble products was stimulated in cultured hepatocytes in the presence of EPA (Fig. 3). This effect was already seen at the lowest concentration of EPA used (50 μM).

Palmitoyl-CoA synthetase and palmitoyl-CoA hydrolase. The level of long-chain acyl-CoA is likely to reflect the balance between the rate of activation of fatty acids to acyl-CoA and the rate of utilization for oxidation, esterification and hydrolysis. As adaptive changes in the

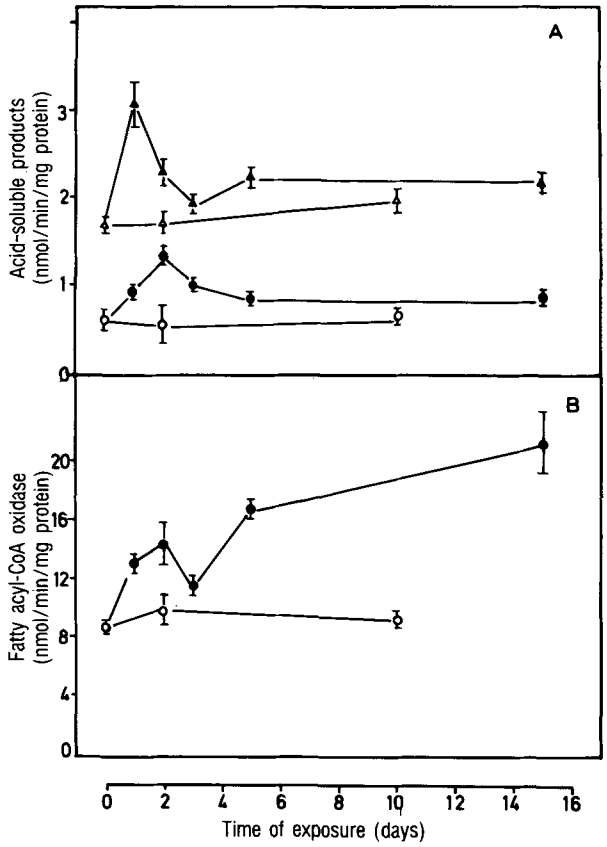

FIG. 2. Time course of β-oxidation of [1-^{14}C]palmitoyl-L-carnitine (△,▲) and [1-^{14}C]palmitoyl-CoA (○,●) (A) and fatty acyl-CoA oxidase activity (○,●) (B) in liver homogenates of rats treated with eicosapentaenoic acid (▲,●) or palmitic acid (△,○). The values represent means ± SD of six control rats and three animals in each experimental group.

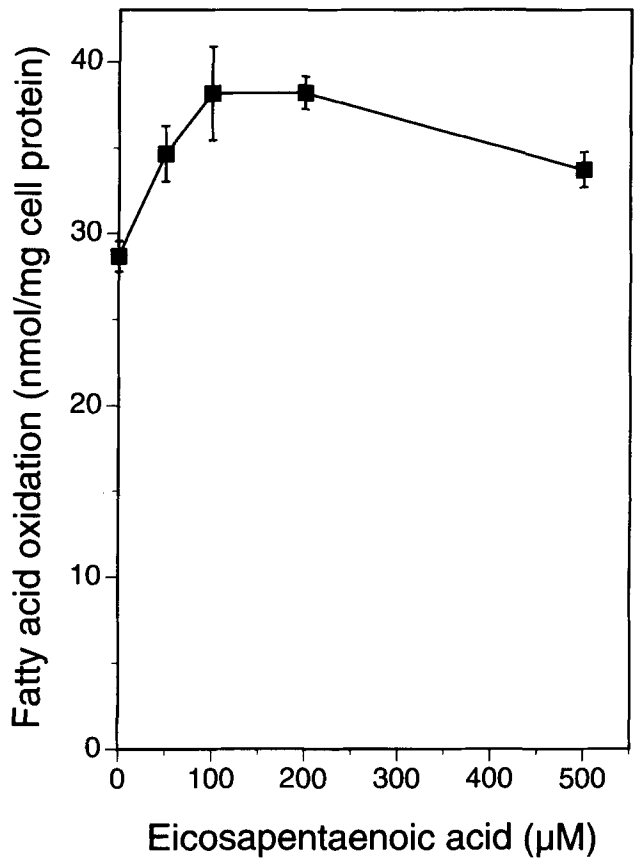

FIG. 3. Effect of eicosapentaenoic acid on fatty acid oxidation of [^{14}C]palmitic acid by cultured rat hepatocytes. Hepatocytes were incubated for 4 h in Dulbecco's modified Eagle's medium containing Hepes (20 mM), L-carnitine hydrochloride (0.5 mM) and [1-^{14}C]palmitic acid (0.25 μCi/mL, 200 μM) and various concentrations of eicosapentaenoic acid. After incubation, labelled carbon dioxide and acid soluble radioactivity were collected as described in Materials and Methods. Oxidation of palmitic acid in the presence of oleic acid (200 μM) was 33.3 ± 1.2 nmol/mg cell protein. Data are presented as means ± SD of triplicate cultures and show total fatty acid oxidized (carbon dioxide plus acid soluble radioactivity).

activities of the enzymes involved in these pathways may reflect alterations in the metabolic flux through the pathways, we examined whether palmitoyl-CoA synthetase activity and palmitoyl-CoA hydrolase activity were changed upon EPA feeding.

Figure 4A shows that administration of EPA significantly ($P < 0.05$) increased palmitoyl-CoA synthetase activity in total liver homogenates at 10 d of feeding. This increase may be attributed to stimulation of peroxisomal palmitoyl-CoA synthetase activity (Fig. 4A).

Repeated administration of EPA to rats had no effect on palmitoyl-CoA hydrolase activity in total liver homogenates, although there may have been a small effect in microsomes (Fig. 4B). In contrast to feeding sulfur-substituted fatty acids, which increase the cytosolic palmitoyl-CoA hydrolase activity (20), EPA-treatment tended to decrease this activity (Fig. 4B).

Glycerophosphate acyltransferase and phosphatidate phosphohydrolase. Upon EPA feeding, both the mitochondrial and microsomal glycerophosphate acyltransferase activities were decreased within 2 d (Table 3). Subsequently, the activities rose almost to normal values (3 d), and showed stimulation at 15 d. At this time, the microsomal glycerophosphate acyltransferase activity was increased 1.5-fold whereas the mitochondrial enzyme activity showed a nearly 1.3-fold increase (Table 3).

Repeated administration of EPA had no effect on the phosphatidate phosphohydrolase activity associated with the microsomal and cytosolic fractions (Table 3).

TABLE 2

Time Course of Carnitine Palmitoyltransferase of Rats Treated with Eicosapentaenoic Acid[a]

Time of exposure (days)	Carnitine palmitoyltransferase (nmol/min/mg protein)		Peroxisomal β-oxidation (nmol/min/mg protein)
	Total liver homogenates	Mitochondrial fraction

[b]$P < 0.05$ for differences between control and treated rats.

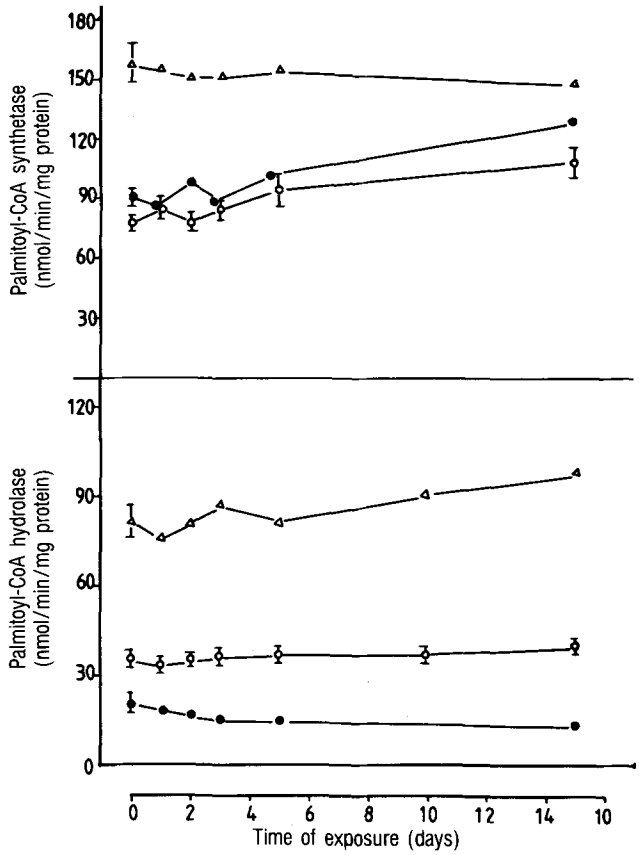

FIG. 4. Effect of eicosapentaenoic acid exposure on palmitoyl-CoA synthetase activity (top) and palmitoyl-CoA hydrolase activity (bottom). Palmitoyl-CoA synthetase activity in total liver homogenates (○), peroxisome-enriched fraction (●) and microsomal fraction (△). Palmitoyl-CoA hydrolase activity in total liver homogenates (○), microsomal fraction (△) and cytosolic fraction (●). Values for liver homogenates are reported as means ± SD for three to six rats. For the other cellular fractions values are reported as means of three rats in each experimental group.

Acyl-CoA:diacylglycerol acyltransferase (ADGAT) and CPCT. Hepatic ADGAT activity was increased with increasing feeding time of EPA. At 15 d, a 1.5-fold increase was observed (Table 4). The ADGAT activity was unchanged upon PMA administration (Table 4).

CPCT activity in the microsomal fraction (Table 4) and in the cytosolic fraction (data not shown) was unaffected by EPA and PMA administration.

Liver lipogenic enzymes. As inhibition of *de novo* fatty acid synthesis could account for a reduction of VLDL triglyceride secretion by the liver, we also investigated how EPA alters the activities of some lipogenic enzymes. Figure 5 and Figure 6 show that PMA and EPA inhibited the activities of ATP-citrate lyase, acetyl-CoA carboxylase and fatty acid synthetase. However, the inhibition was most pronounced in the EPA-treated rats. At 2 d of feeding EPA, the activities of ATP-citrate lyase (Fig. 5) and acetyl-CoA carboxylase (Fig. 6A) were reduced by 45–50%. At this time, PMA decreased these enzyme activities by only about 15%. It is also noteworthy that EPA treatment reduced fatty acid synthetase activity after one day (Fig. 6B). Feeding EPA for 2 d reduced glucose-6-phosphate dehydrogenase activity to a greater extent than in PMA-treated rats (Table 5).

DISCUSSION

The studies show that a high intake of EPA lowers plasma triglyceride levels in rats (Fig. 1). This decrease is already established within 1 to 2 d of treatment (Fig. 1). Repeated administration of EPA also decreases the hepatic triglyceride content (Table 1). It seems likely, therefore, that the observed triglyceride lowering effect is due to a reduction in triglyceride biosynthesis.

Dietary fat and marine oils in particular increase fatty acid oxidation (29,30). The present study shows that pure EPA stimulates fatty acyl-CoA oxidase (Fig. 2) activity and peroxisomal β-oxidation (Table 2). It is therefore likely that induction of peroxisomal β-oxidation by high fat diets and fish oils is due to its content of EPA and DHA, *i.e.*, fatty acids which are poorly oxidized by mitochondria. The present study also shows that administration of pure EPA stimulates fatty acid oxidation in mitochondria. It is noteworthy that stimulation of mitochondrial β-oxidation is a rapid event, *i.e.*, it occurs after 1 and 2 d of feeding (Fig. 2) even before EPA induces peroxisomal β-oxidation. This mechanism has now been further evaluated using cells in culture. The present study has shown for the first time that mitochondrial β-oxidation is stimulated in

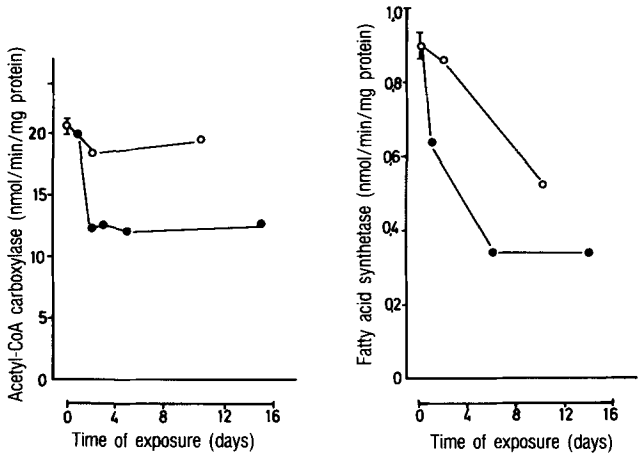

FIG. 6. Time course of acetyl-CoA carboxylase activity (left) and fatty acid synthetase activity (right) in cytosolic fractions of rats treated with eicosapentaenoic acid (●) or palmitic acid (○). The results are expressed as stated in the legend to Figure 1.

cultured hepatocytes in the presence of EPA (Fig. 3). The effects are in line with our results from fish oil feeding experiments where mitochondrial β-oxidation preceded peroxisomal β-oxidation (29). However, the data are in contrast to the findings of Neat *et al.* (31) that partially hydrogenated fish oil stimulated mitochondrial and peroxisomal oxidative activity simultaneously. In accordance with our results, Wong *et al.* (6) found that rats fed fish oil had increased ketone production.

As EPA rapidly increased mitochondrial fatty acid oxidation (Figs. 2 and 3) and decreased glycerol-3-phosphate acyltransferase activity within 1 d (Table 3), it is possible that the initial triglyceride-lowering effect (Fig. 1) of EPA is associated with reduced fatty acid availability for triglyceride biosynthesis through increased mitochondrial fatty acid oxidation, even before EPA induces peroxisomal β-oxidation (Table 2). Thus, the induction of peroxisomal β-oxidation is not a prerequisite for hypotriglyceridemia due to EPA. It is of interest that non-β-oxidizable thia fatty acids as well as EPA stimulated mitohondrial fatty acid oxidation before peroxisomal β-oxidation when fed to rats, thereby decreasing the flux of fatty acids into triglyceride formation and secretion (32). Thus, after feeding relatively poor substrates for mitochondrial β-oxida-

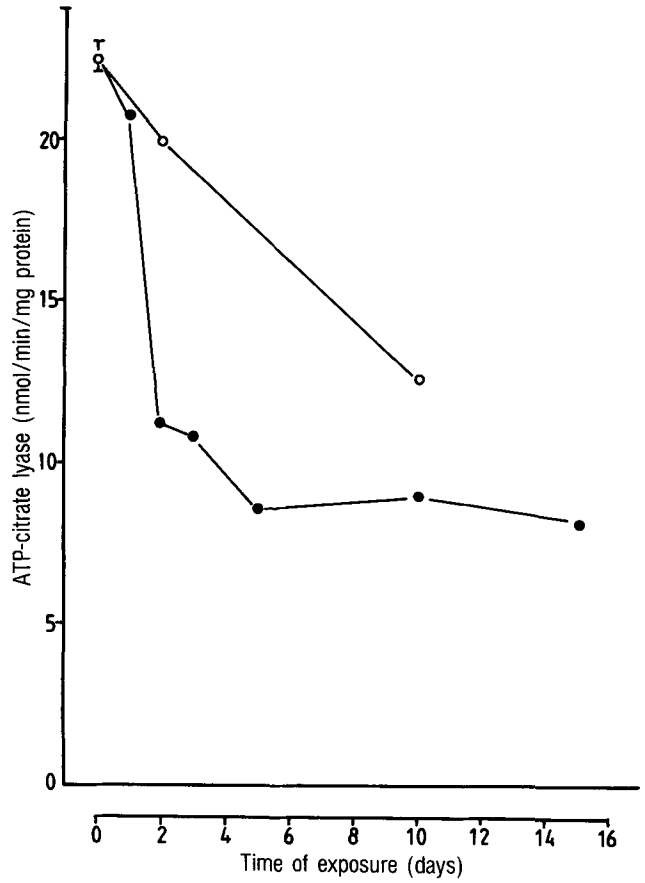

FIG. 5. Time course of adenosine triphosphate (ATP)-citrate lyase activity in cytosolic fractions of rats treated with eicosapentaenoic acid (●) or palmitic acid (○). Values are reported as means ± SD for nine rats and means of three rats in each experimental group.

TABLE 5

Effect of Eicosapentaenoic Acid (EPA) and Palmitic Acid (PMA) on the Activity of Glucose-6-Phosphate Dehydrogenase in the Liver Cytosolic Fraction of Rats[a]

Days of treatment	Compound	Glucose-6-phosphate dehydrogenase (% of control)
0		100
1	EPA	130 ± 20
2	EPA	70 ± 15
3	EPA	78 ± 10
5	EPA	44 ± 16
10	EPA	60 ± 10
15	EPA	38 ± 12
2	PMA	90 ± 10
10	PMA	61 ± 8

[a]The enzyme activity is calculated relative to that of pellet-fed controls (= 100%). The values represent means ± SD of three to six rats in each experimental group.

tion, the hypotriglyceridemic effect may be dissociated from induction of peroxisomal β-oxidation (33).

Glycerol-3-phosphate acyltransferase which catalyzes the first esterification step in triglyceride biosynthesis could be a potential site of regulation as both the mitochondrial and the microsomal glycerol-3-phosphate acyltransferase activities were reduced in EPA-treated rats after 1 d of feeding (Table 3). This is, however, in contrast to the findings of Wong *et al.* (5) and Al-Shurbaji *et al.* (14) where this enzyme was not found to be affected by ω3 fatty acids. The glycerol-3-phosphate acyltransferase activity, however, does not seem to correlate with the rate of triglyceride biosynthesis in EPA-treated rats. For longer feeding times, hepatic triglyceride concentrations were decreased (Table 1) whereas glycerol-3-phosphate acyltransferase activity was increased (Table 3).

Both phosphatidate phosphohydrolase and CPCT are found in the microsomal and in soluble fractions of liver homogenates, and the relative partitioning between cytosol and microsomes has been implicated in the regulation of glycerolipid synthesis (34–39). Phosphatidate phosphohydrolase is a key enzyme in the regulation of triglyceride biosynthesis, and we have recently reported that this enzyme was inhibited in tetradecylthioacetic acid-treated rates (25); however, no translocation of phosphohydrolase was observed. CPCT, the rate-limiting enzyme in the CDP-choline pathway, was stimulated by 3-thia fatty acids (25); however, no translocation of cytidylyltransferase was observed. The present results show that feeding pure EPA did not affect the phosphohydrolase and cytidylyltransferase activities in cytosolic as well as in microsomal fractions (Table 3). This observation is in accordance with Rustan *et al.* (17), but in contrast to the findings by Marsh *et al.* (16), Halminski *et al.* (34) and Al-Shurbaji *et al.* (14); these authors suggested that part of the triglyceride-lowering effect of ω3 fatty acids might be mediated by an inhibition of the phosphatidate phosphohydrolase.

The final step in the triglyceride synthetic pathway involves the conversion of 1,2-diglyceride to triglyceride which is catalyzed by ADGAT. ADGAT activity was increased in EPA-treated rats (Table 4) in accordance with data reported by Al-Shurbaji *et al.* (14), Halminski *et al.* (34), and Marsh *et al.* (16). As the activity of ADGAT does not seem to change in parallel with the rate of triglyceride biosynthesis, this step does not appear to be the site where EPA affects triglycerde levels, although this is not in agreement with the findings by Rustan *et al.* (17,19).

Although triglyceride formation seems to be reduced by EPA due to increased mitochondrial fatty acid oxidation, diminished lipogenesis may be a contributing factor to the overall lipid-lowering effect of EPA. Repeated administration of EPA inhibited several lipogenic enzyme activities, *i.e.,* ATP-citrate lyase (Fig. 5), acetyl-CoA carboxylase and fatty acid synthetase (Fig. 6), when compared with PMA-treated rats.

Acetyl-CoA carboxylase appears to be the rate-limiting enzyme in *de novo* fatty acid synthesis, and it is regulated by long-chain acyl-CoA (40). Long-chain acyl-CoA levels are rapidly increased after repeated administration of ω3 fatty acid and high fat diets (41). Figure 4 shows that the enzyme activity involved in the formation of long-chain acyl-CoA, *i.e.,* palmitoyl-CoA synthetase, was increased. Thus, the inhibitory effect of acetyl-CoA carboxylase activity in EPA-treated rats may be due to accumulation of long-chain acyl-CoA. Inhibition of acetyl-CoA carboxylase activity and glucose-6-phosphate dehydrogenase activity may reduce the production of malonyl-CoA and thereby reduce fatty acid synthetase activity. It is worth noting that at day 1 of feeding, when the hypotriglyceridemic effect of EPA was already established (Fig. 1), the lipogenic enzyme activities were reduced to the same extent in PMA-treated animals as in EPA-treated rats except for the fatty acid synthetase activity (Fig. 6B) which was more inhibited after EPA feeding. Thus, the inhibition of the *de novo* fatty acid synthesis could be secondary to increased fatty acid oxidation and thereby a reduced triglyceride formation.

Acyl-CoA esters accumulate in the liver of rats fed partially hydrogenated fish oil diets (41). Whether an increase in fatty acid oxidation represents an effort to minimize this pool should be considered. EPA is incorporated into triglycerides to a lesser degree than oleic acids (4,19). Thus, the presence of CoA-ester of EPA may result in an increased flux of fatty acids through both mitochondrial and peroxisomal fatty acid oxidation pathways.

A protein-free microemulsion (LDE) with a lipid composition resembling that of low-density lipoprotein (LDL) was used in metabolic studies in rats to compare LDE with the native lipoprotein. LDE labeled with radioactive lipids was injected into the bloodstream of male Wistar rats, and plasma kinetics of the labeled lipids were followed on plasma samples collected at regular intervals for 12 h after injection. The 24-h LDE uptake by different tissues was also measured in tissue samples excised after the animals had been sacrificed. We found that LDE plasma kinetics were similar to those described for native LDL [fractional clearance rate (FCR) of cholesteryl ester, 0.42 ± 0.11 h^{-1}]. The major site for LDE uptake was the liver, and the tissue distribution of the LDE injected radioactivity was as one would expect for LDL. To test whether LDE was taken up by the specific LDL receptors, the LDE emulsion was injected into rats treated with 17α-ethinylestradiol, which is known to increase the activity of these receptors; as expected, removal of LDE from the bloodstream increased (FCR = 0.90 ± 0.35 h^{-1}). On the other hand, saturation of the receptors that remove remnants by prior infusion of massive amounts of lymph chylomicrons did not change LDE plasma kinetics. These results indicate that LDE is cleared from plasma by B,E receptors and not by the E receptors that remove remnants. Incorporation of free cholesterol into LDE increased LDE plasma clearance. Incubation studies also showed that LDE incorporates a variety of apolipoproteins, including apo E, a ligand for recognition of lipoproteins by specific receptors. Our data suggest that LDE can be a useful tool to test LDL metabolism and B,E receptor function.

Lipids 28, 691–696 (1993).

Low-density lipoprotein (LDL), which carries most of the plasma cholesterol in humans, can be considered a biological microemulsion consisting of a core of cholesteryl esters (45–50% of the particle weight) and residual triglycerides (3–4%) surrounded by a monolayer of phospholipids (16–25%) and unesterified cholesterol (5–8%). The protein moiety of LDL is apolipoprotein (apo) B-100.

LDL is the final product in the lipolysis of very low density lipoprotein (VLDL), a triglyceride-rich lipoprotein synthesized by the liver. VLDL triglycerides are progressively lost from the particles through the action of lipoprotein lipase on the endothelium of capillary vessels of peripheral tissues, such as muscle and adipose tissue. The enzyme is stimulated by a co-factor, apolipoprotein CII, present on the surface of VLDL particles. LDL is removed from plasma by the B,E receptors that recognize the receptor-binding domain of apo B-100. The lipoprotein is then internalized and LDL cholesterol is utilized in various cellular processes (1).

It is possible to model the metabolism of chylomicrons or VLDL with protein-free triglyceride-rich emulsions of defined lipid composition (2–5). In the bloodstream the emulsions acquire apolipoproteins from the circulating lipoproteins undergoing lipolysis. Subsequently, apo E serves as ligand for the binding of the triglyceride-depleted particles to hepatic receptors that take up remnants (E receptors).

In the present study, we tested the hypothesis whether a microemulsion resembling the lipid phase of LDL (6,7), without apo B, could mimic the metabolism of native LDL. The microemulsion (LDE) labeled with radioactive lipids was injected into the bloodstream of control rats to determine the plasma kinetics and the percent uptake of the emulsion by different organs. To confirm the role of the specified LDL receptors in removing LDE from plasma, the LDE plasma kinetics and tissue uptake were also followed in a group of rats treated with 17α-ethynilestradiol, which enhances the activity of these receptors. To test whether the remnant receptors could take up the emulsion, LDE was also injected into rats following infusion of lymph chylomicrons resulting in saturation of these receptors. The effects of hypothyroidism and of LDE supplementation with free cholesterol were also evaluated. Our data show that LDE can be useful to test *in vivo* LDL metabolism and B,E receptor function.

MATERIALS AND METHODS

Preparation of LDE. Egg phosphatidylcholine was purchased from Lipid Products (Surrey, United Kingdom), and triolein, cholesteryl oleate and cholesterol were from Nu-Chek-Prep (Elysian, MN). [4-^{14}C]Cholesteryl oleate, [1α,2α(n)-^{3}H]oleate were from Amersham (Amersham, United Kingdom). Lipids were judged >99% pure by thin-layer chromatography (TLC). The microemulsion utilized in this study was prepared from lipid mixtures composed of 40 mg of egg phosphatidylcholine, 20 mg of cholesteryl oleate and 0.6 mg of triolein, with addition of radioactive lipids. In some experiments, 5% (w/w) cholesterol was also added to the mixture.

The lipid mixtures were sonicated and purified to obtain the microemulsion according to the procedures described by Ginsburg *et al.* (5). Lipid mixtures were dried under an N_2 stream followed by overnight vacuum desiccation at 4°C to remove residual solvent. Dried lipids were resuspended in 10 mL of 0.1 M KCl, 0.01 M Tris HCl at pH 8.0. The suspension was sonicated using a Branson Cell Disruptor model B-30 (São Paulo, Brazil), with 125 Watts output in the "continuous" operating mode, for 180 min under an N_2 atmosphere. The temperature was kept between 53–55°C, as monitored by a thermocouple inserted into the vial. The emulsified lipid suspension was then transferred to clean tubes for ultracentrifugation at 195,000 × *g* (30 min) in an SW 40 rotor of a Beckman

L8-M ultracentrifuge (Palo Alto, CA). The top 10% of the solution, containing particles that float at a background density of approximately 1.006 g/mL, was removed by aspiration with a needle. The remaining solution was adjusted to a background density of approximately 1.22 g/mL by adding solid KBr and was then centrifuged at 195,000 × *g* (120 min) at 4°C. The top 20–30% of the sample was collected by aspiration at room temperature, and dialyzed overnight in buffer to remove KBr from the solution. The microemulsion fraction was analyzed for lipid composition (phospholipids, cholesteryl esters, triacylglycerols) by standard laboratory methods (8–10) and utilized in the experiments described below. Before analysis, the microemulsion containing cholesterol was also submitted to preparative TLC in the solvent system described below to allow separate determination of cholesterol and cholesteryl ester.

Animals. Male Wistar rats, weighing 250–300 g and fed a standard commercial chow (Anderson Clayton, São Paulo, Brazil) *ad libitum*, were utilized in this study. One group of rats was treated with 17α-ethinylestradiol for five days. The drug was dissolved in ethanol (100 μg/μL) and propyleneglycol to a final concentration of 1 mg/mL, and injected subcutaneously at a daily dose of 5 mg/kg of body weight (11). Another group of rats was rendered hypothyroid by addition of propylthiouracil to their drinking water (100 mg/dL) for 30 d (12).

LDE plasma kinetics and tissue uptake. Microemulsions labeled with radioactive core lipids were injected into the bloodstream of control rats and of rats treated with 17α-ethinylestradiol or propylthiouracil to measure the rates of lipid disappearance from plasma.

The animals were anesthetized with diethyl ether, and a polyethylene cannula (Intramedic PE 50) was inserted into the left carotid artery. Clotting inside the cannula was prevented by pretreatment with silicon (Clay Adams, Parsippany, NJ). The animals were kept in individual cages for at least 90 min for recovery from anesthesia. The microemulsion was then injected as a bolus of approximately 3 mg of total lipid, in a volume of approximately 0.5 mL. At intervals of 0.5 g, 1, 2, 4, 7, 9 and 12 h, when the animals were sacrificed by air embolization, blood samples of 0.3 mL were collected into tubes containing 20 μL heparin.

To measure the uptake of LDE by the tissues, the microemulsion was labeled with [1α,2α(n)-^{3}H]cholesteryl oleyl ether. Selected organs were excised 24 h after the injection of the emulsion into three control rats. Plasma samples for determination of emulsion clearance were not taken from these rats.

Determination of radioactivity in plasma and tissues. Lipids were extracted (13) with chloroform/methanol (2:1, vol/vol) from 100 μL aliquots of the separated blood plasma and from approximately 1 g samples of the excised organs. The extracted lipids were concentrated and resolved into classes by TLC using hexane/diethyl ether/acetic acid (70:30:1, by vol) as developing solvent. The cholesteryl ester and triacylglycerol bands were then placed separately into vials with 7 mL scintillation solution [5 g PPO/0.5 g dimethyl POPOP (Sigma, St. Louis, MO)/333 mL Triton X-100/667 mL toluene] (14); and radioactivity was measured by liquid scintillation spectrometry with a LKB model 1211 Spectrometer (Upsala, Sweden).

Competition between LDE and lymph chylomicrons for removal from plasma. Intestinal lymph was collected from male Wistar rats, weighing 300–400 g, over ice with ethylenediaminetetraacetic acid (EDTA) added (final concentration, 1 mM) over 24 h through a cannula implanted into the mesenteric lymph duct. After surgery the rats were maintained in restriction cages, and cottonseed oil was infused (0.035 mL/h) through a gastrostomy tube. Water was accessible *ad libitum.* Saline (5 mL, pH 7.0), d = 1.006 g/mL, containing EDTA (1 mM) was layered on lymph (5 mL) in Beckman SW 40 rotor tubes and centrifuged at 24,500 rpm for 20 min at 20°C (15). Chylomicrons were recovered from 1.5 mL of the creamy top layer aspirated from each tube, and the triglyceride concentration was determined (10). Samples were kept at 4°C and used within 24 h in the experiments.

Lymph chylomicrons were injected into the rats through a carotid cannula, in a bolus corresponding to 7.2 mg of triglyceride every 10 min for 5 h. The labeled microemulsion was injected through the same cannula 5 min after the first injection of lymph chylomicrons. LDE was also injected into three rats in which saline solution (0.8 mg/dL) was substituted for an equivalent volume of lymph chylomicrons (16).

Incubation of LDE with rat plasma high-density lipoprotein (HDL) and with rat plasma HDL apolipoproteins. Microemulsions containing approximately 280 μg of total lipid were incubated with rat HDL (230 μg of HDL protein) obtained by ultracentrifugation of plasma in discontinuous saline gradients (17). Buffer solution (0.01 M Tris-HCl, pH 8.2) was added to attain a 4.0 final volume in each tube. Incubation was for 15 min in a shaking water bath at 37°C. Solid KBr was then added to raise the density to 1.21 g/mL. The mixture was then placed in a Beckman SW41 rotor tube and centrifuged in discontinuous density gradients for 24 h at 20°C (17). The microemulsion particles were recovered in the 1.5 mL top volume of the tube and assayed for protein content (18). Apos associated with the microemulsions were separated by 15% sodium dodecyl sulfate (SDS)-glycerol polyacrylamide gel electrophoresis (19).

Microemulsions (200 μg) were also incubated with rat plasma HDL apo (200 μg), obtained by ultracentrifugation of plasma on discontinuous gradients (17) followed by delipidation of the HDL fraction (20). The incubation, recovery and analysis of the protein associated with LDE were according to the procedures described.

Calculation of LDE removal from plasma. A compartmental model was utilized for the analysis of plasma decaying curves of the emulsion's radioactive lipids (21). The model implies two intravascular (pools 1 and 2) and one extravascular (pool 3) compartment, assuming that the system was in dynamic equilibrium. The emulsion is instantaneously introduced in pool 1. During the elapsed time, a fraction of pool 1 (k_{13}) migrates to pool 3, while another fraction (k_{12}) is transferred to pool 2. A fraction of pool 2 (k_{23}) also migrates to pool 3. Rates of transfer k_{12}, k_{13} and k_{23} were estimated using nonlinear least squares procedures (22,23). Fractional clearance rate (FCR) of the labeled lipids from the intravascular compartment was estimated according to Matthews (24):

$$FCR = \frac{(k_{12} + k_{13}) \cdot k_{23}}{k_{12} + k_{23}} \quad [1]$$

The Student's *t*-test was used to analyze differences between means.

RESULTS

LDE prepared without cholesterol had approximately 63% phospholipids, 36% cholesteryl ester and 1% triacylglycerol, whereas LDE prepared with cholesterol consisted of approximately 61% phospholipids, 35% cholesteryl ester, 2% cholesterol and 3% triacylglycerol. The cholesteryl ester/phospholipid molar ratio was approximately 0.7 in both microemulsions.

When LDE was simultaneously labeled with [4-^{14}C]-cholesteryl oleate and [1α,2α(n)-^{3}H]cholesteryl oleyl ether and injected into four control rats, the removal rate for both labels was nearly identical (FCR = 0.40 ± 0.02 and 0.40 ± 0.04 min^{-1}, respectively). This indicates that practically no recirculation of the LDE cholesteryl ester occurred over 12 h (25). In the rat the cholesteryl ester or ether can indeed be considered the marker of removal of the emulsion from plasma because it is not selectively removed from the emulsion particles (26).

FCR of the LDE cholesteryl ester and triacylglycerols injected in the bloodstream of control, estrogen-treated and hypothyroid rats is shown in Table 1. In control rats, the emulsion triacylglycerols were removed from plasma three times faster than was cholesteryl ester. In the animals treated with estrogen, cholesteryl ester was removed two times faster than in controls, but the removal of triacylglycerols was not affected (Fig. 1). In contrast, treatment with propylthiouracil did not significantly change the removal of cholesteryl ester, but the FCR of triacylglycerols was twice as rapid. The uptake by organs of [^{3}H]cholesteryl ether of emulsions injected in three control rats is shown in Table 2. Most of the emulsion radioactivity was taken up by the liver.

In the rats that were infused lymph chylomicrons, the plasma triacylglycerols raised from 12 to 27 mg/dL 1 h after the beginning of the infusion to 106 mg/dL after 3 h, and 72 mg/dL after 5 h. Figure 2 shows that the clearance of the emulsion cholesteryl ester in these rats (n = 6) was not different from that measured in rats (n = 3) in which the chylomicron infusion was replaced by infusion of an equal volume of isotonic saline solution (0.44 ± 0.19 and 0.51 ± 0.17 h^{-1}, respectively). This suggests that LDE was not removed from the plasma by the mechanisms that remove chylomicron remnants.

When free cholesterol was added to LDE (Fig. 3), FCR of either cholesteryl ester (0.54 ± 0.15 h^{-1}) or triacylglycerols (3.23 ± 0.68 h^{-1}) of the emulsion injected in control rats was significantly increased as compared to LDE

TABLE 1

Effects of Estrogen Treatment and Hypothyroidism on the Removal of Microemulsion Lipids from Plasma[a]

Treatment	Removal from plasma (FCR, h^{-1})	
	Cholesteryl esters	Triacylglycerols
Controls (n = 15)	0.42 ± 0.09	1.40 ± 0.63
Estrogen-treated (n = 10)	0.90 ± 0.35[b]	1.62 ± 0.59
Hypothyroid (n = 7)	0.39 ± 0.09	2.76 ± 0.94[b]

[a]Micromulsions without free cholesterol, and labeled with [4-^{14}C]cholesteryl oleate and glycerol tri[10(n)-^{3}H]oleate were injected into the carotid artery of control rats and rats treated with 17α-ethinylestradiol (5 mg/kg body wt/d during 5 d) or propylthiouracyl (100 mg/dL in drinking water for 30 d). Blood was sampled at regular intervals during 12 h, and the fractional clearance rate (FCR) was calculated from the curves of radioactivity remaining in plasma according to a three-compartmental model. Results are means ± SD.

[b]$P < 0.05$ compared to control values.

Adrenal	0.62 ± 0.09	15.52 ± 3.81

[a]The microemulsion did not contain free cholesterol. Tissues were excised for lipid extraction and radioactivity determination 24 h after injection of the emulsion. The results are means ± SD of three experiments.

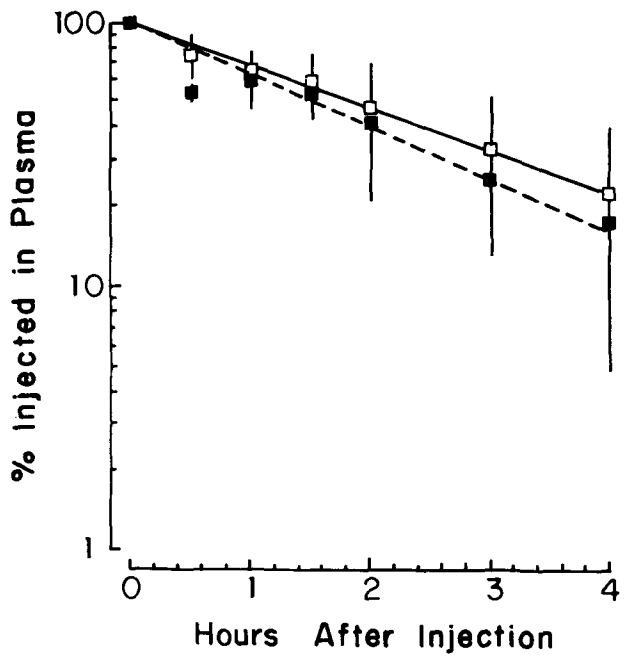

FIG. 2. Removal from plasma of [4-^{14}C]cholesteryl oleate of the microemulsion in rats infused with isotonic saline solution (□) or with lymph chylomicrons (■).

without free cholesterol ($P < 0.05$). FCR of the labeled free cholesterol of the emulsion was 0.92 ± 0.41 h^{-1}.

After incubation with HDL or HDL apo, LDE incorporated apos AI, AIV, E, CII and CIII. As observed in the SDS polyacrylamide gels, no difference was seen in the proportion of incorporated apos in LDE with and without cholesterol.

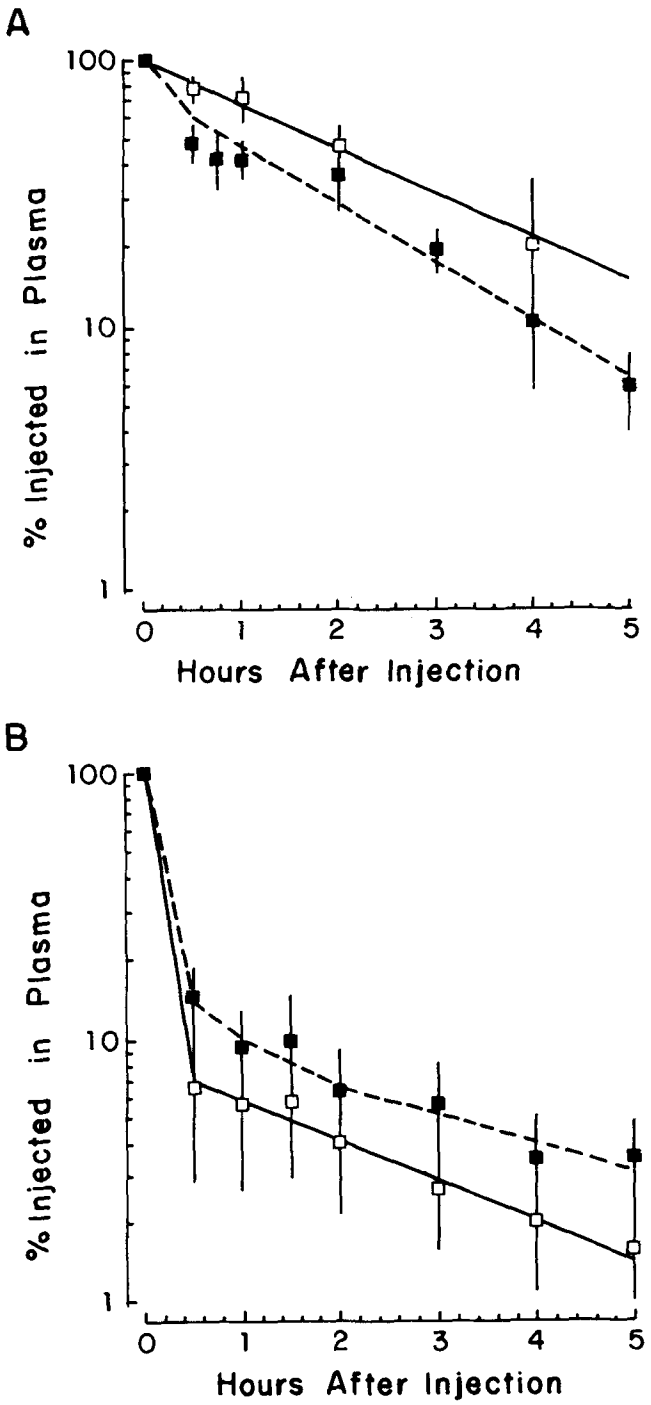

FIG. 3. Removal from plasma of (A) [4-^{14}C]cholesteryl oleate of the microemulsion with (■) or without cholesterol (□) and of (B) [^{14}C]cholesterol (□) and glycerol tri[10(n)-^{3}H]oleate (■) of the microemulsion with cholesterol.

DISCUSSION

The structure of protein-free microemulsions containing egg phosphatidylcholine and cholesteryl oleate, similar to those utilized in the current investigation, has been well-defined previously (5–7). These systems were shown to mimic the lipid portion of native LDL, and incorporation of unesterified cholesterol up to 15% molar did not affect their LDL-like size characteristics (7).

LDL interacts with B,E receptors through apo B-100, but the receptors can also recognize apo E, which is not usually present in the LDL particles. We hypothesized whether LDE, when injected into the bloodstream, could pick up apo E molecules from native lipoproteins, enabling recognition and uptake of the microemulsion by the B,E receptors. In fact, the incubation of LDE with HDL

or HDL apos confirmed that apo E binds the emulsion, together with other exchangeable apos like apos AI and CII and CIII.

The present results show that LDE has a markedly different metabolic behavior in rats as compared to the triglyceride-rich emulsions resembling chylomicrons described in our previous studies (2-4). Whereas the chylomicron-like emulsion was rapidly removed from plasma, LDE was retained for several hours, as native LDL would be. This emphasizes the importance of the lipid portion of these particles for their metabolic behavior, as both emulsions were capable of incorporating the various exchangeable apos present in the plasma. As occurs with native LDL, the liver was the main site of removal of LDE from the circulation. Evidence was gathered here that LDE was taken up by B,E receptors that remove native LDL, instead of by the E receptors that bind chylomicron remnants. Firstly, treatment of the rats with high doses of 17α-ethinylestradiol, which enhances the activity of the B,E receptors severalfold (27,28), resulted in nearly twofold increase in the rate of LDE removal from the plasma. This behavior is identical to that of native LDL injected in estrogen-treated rats (29-31), and different from chylomicron-like emulsions, which were slowly cleared in rats under estrogen treatment (2). Secondly, when LDE was injected in rats infused with amounts of lymph chylomicrons capable of saturating the removal sites of remnants (E receptors) (16), the plasma kinetics of the radioactive cholesteryl ester remained unchanged, suggesting that LDE is not removed by this mechanism.

LDE was also tested in hypothyroidism, a metabolic disorder in which lipoprotein plasma kinetics are well-documented in rats. The results again resembled those of native LDL and were markedly different from the kinetics of chylomicrons and triglyceride-rich emulsions. The plasma clearance of native LDL in hypothyroid rats has been found to be only slightly decreased (32), whereas in our experiments the LDE clearance was unchanged. In contrast, the removal of remnants of chylomicrons and triglyceride-rich emulsions was pronouncedly slowed down (33).

Despite the minimum content of triacylglycerols in LDE, the emulsion underwent lipolysis, as shown by a triacylglycerol FCR greater than that of cholesteryl ester (2,3). Lipolysis was greater in the rats made hypothyroid, probably due to increased lipoprotein lipase activity under this condition (12).

In the current study, we found that addition of free cholesterol to LDE led to acceleration of its removal from plasma. In protein-free lipid model systems for LDL, unesterified cholesterol is located primarily at the particle surface (7). This allows the conjecture that the introduction of cholesterol into LDE could favor the incorporation of apo E into the surface of the microemulsion particles, thus facilitating clearance. Moreover, apo C is known to decrease the binding of apos to receptors, and the addition of free cholesterol could also increase the ratio apo E/C, as previously documented with triacylglycerol-rich emulsions (3,34). However, after incubation with HDL or HDL apos, we found no difference between LDE with and without free cholesterol in regard to the proportion of associated apos.

Plasma kinetics of LDE radioactive, free cholesterol (Fig. 3) were similar to native LDL, as described by Eisenberg *et al.* (35). It is also noteworthy that triglyceride clearance was accelerated by addition of free cholesterol to LDE, which is probably due to enhanced removal of emulsion particles rather than to increased lipolysis.

Extensive studies of LDL plasma kinetics in human subjects could be very useful to understand the pathophysiology of lipid metabolism and atherosclerosis. However, these studies have been restricted by the laborious procedures of isolation and labeling of native LDL and the obligatory use of autologous lipoprotein due to the risk of transmission of HIV or hepatitis virus into recipient subjects. Need of a standard LDL preparation for injection into multiple individuals was already emphasized by Goldstein and Brown in a 1984 review (36) as a requirement for uniform kinetic studies. Our study raises the possibility for the use of LDE as a tool to evaluate LDL metabolism and B,E receptor function. Consistent with this assumption, the rate of removal of LDE from plasma has been shown to be slower in patients with familial hypercholesterolemia, as expected for native LDL (37). In contrast, LDE was rapidly removed from the plasma in patients with acute myeloid leukemia (AML) (38), which is expected because AML cells overexpress B,E receptors and avidly take up the native LDL (39,40). Finally, we would like to suggest that our results provide a rationale for the utilization of LDE to deliver antitumor drugs to neoplastic cells with enhanced expression of LDL receptors.

Plasma Clearance and Hepatic Utilization of Stearic, Myristic and Linoleic Acids Introduced *via* Chylomicrons in Rats

Shu Wang and **Sung I. Koo***
Department of Foods and Nutrition, Kansas State University, Manhattan, Kansas 66506

The primary objective of the present study was to compare the rates of plasma clearance and hepatic utilization of stearic (18:0), myristic (14:0) and linoleic (18:2) acids, as introduced *via* chylomicrons. Lymph chylomicrons were specifically labeled *in vivo* with [^{14}C]stearic and (SA), [^{14}C]myristic acid (MA), or [^{14}C]linoleic acid (LA) by infusing donor rats intraduodenally with the labeled fatty acids in a lipid emulsion. Following intravenous injection of recipient rats with the labeled chylomicrons, the rates of plasma clearance and incorporation of the label in triglycerides (TG), phospholipids (PL) and other lipids in the liver were compared at 5, 15 and 30 min. [^{14}C]SA was cleared at a slightly faster rate ($t_{1/2}$ = 7.0 min) than [^{14}C]MA ($t_{1/2}$ = 8.1 min) and [^{14}C]LA ($t_{1/2}$ = 8.0 min) ($P < 0.05$). [^{14}C]SA was accumulated in the liver at a significantly faster rate than [^{14}C]MA and [^{14}C]LA. At the peak (15 min) of hepatic uptake, 30.3% of [^{14}C]SA, 26.2% of [^{14}C]LA and 21.9% of [^{14}C]MA were recovered in the liver. At 30 min, 33.5% of [^{14}C]SA was taken up by the liver, whereas 27.8% of [^{14}C]LA and only 15.2% of [^{14}C]MA were removed. In the liver, the percentage of [^{14}C]SA incorporated into PL steadily increased with time, whereas the percent-age incorporated into TG decreased. [^{14}C]SA was preferentially incorporated into PL at all time intervals, as compared with [^{14}C]MA and [^{14}C]LA. At 30 min, 38.6% of [^{14}C]SA was found in PL, and only 5.2% of [^{14}C]MA and 12.0% of [^{14}C]LA were present in PL. A large proportion of hepatic [^{14}C]MA remained unesterified (free fatty acid) throughout the 30-min period, with a small proportion incorporated into PL and TG. Of the total liver ^{14}C radioactivity recovered at 30 min, 63.8% of [^{14}C]MA, 48.8% of [^{14}C]LA and 25.5% of [^{14}C]SA were found unesterified. During 30 min, a significantly greater amount of [^{14}C]MA (76.9%) was oxidized in both the liver and the peripheral tissue combined, compared with [^{14}C]LA (64.7%) and [^{14}C]SA (61.2%). A higher proportion of [^{14}C]LA was incorporated into TG than into PL at all time intervals. No differences were noted in the relative distribution of ^{14}C in cholesterol and other lipids among the three fatty acids. Using labeled fatty acids incorporated *in vivo* into chylomicrons, the present study demonstrated that SA, MA and LA are distinctly different in their metabolic behavior. During the initial 30 min after their entry into the blood, 92–95% of the fatty acids were cleared. During this early phase of metabolism, [^{14}C]SA was preferentially utilized for liver PL synthesis, whereas [^{14}C]LA was better incorporated into TG. [^{14}C]MA was poorly incorporated into hepatic lipids, but was preferentially oxidized in the liver or utilized by the peripheral tissue.
***Lipids* 28, 697–703 (1993)**

Compared with polyunsaturated fatty acids, such as linoleic acid (LA), dietary long-chain saturated fatty acids generally have been regarded as hypercholesterolemic. However, unlike other saturated fatty acids, such as myristic acid (MA) and palmitic acid (PA), stearic acid (SA) lowers plasma cholesterol and is less atherogenic, as has been demonstrated in various animal models (1). The proposed mechanisms for its hypocholeterolemic effect include (i) incomplete digestion of fats high in SA and its inefficient intestinal absorption (2,3); (ii) reduced intestinal absorption of cholesterol with diets high in SA (2); and (iii) its metabolic conversion to oleic acid (OA) by desaturation (4–6).

At present, little information exists concerning how SA may differ from other fatty acids, especially when introduced into the circulation *via* chylomicrons, which are the principal carriers of dietary fats. In a recent study (7), we compared the rates of plasma clearance and hepatic metabolism of SA, PA and OA in rats after intravenous injection of chylomicrons labeled *in vivo* with the fatty acids. The findings from this study (7) suggest that the hypocholesterolemic effect of SA is not associated with its conversion to oleic acid, but with its preferential utilization for phospholipid (PL) synthesis. PA, on the other hand, is most rapidly removed from the plasma and incorporated into triglyceride (TG) in the liver. This observation suggests that PA is more stimulatory to hepatic lipogenesis and, hence, the synthesis of very low density lipoprotein (VLDL) contributing to hyperlipemia. The results also indicate that OA is more readily taken up by the peripheral tissue and/or oxidized in the liver.

The present study was undertaken to compare the metabolic fates of SA, MA and LA immediately after their transport into the circulation *via* chylomicrons. We prepared chylomicrons enriched and radiolabeled *in vivo* with these fatty acids, instead of using free fatty acids (FFA) (8). The rates of plasma clearance and hepatic utilization of these fatty acids were compared after intravenous injection of the labeled chylomicrons.

MATERIALS AND METHODS

Animals and diets. Fifty-one male albino rats (Harlan Sprague Dawley, Inc., Indianapolis, IN), weighing 266 ± 16 g, were housed individually in stainless-steel cages and subjected to a cycle with a 1500–0300 light period and a 0300–1500 dark period. Temperature and humidity were controlled at 23–25°C and 55–75%, respectively. The animals were cared for in an animal care facility accredited by the American Association for the Accreditation of Laboratory Animal Care. The rats were fed a nutritionally adequate diet, formulated according to the recommendations (9,10) of the American Institute of Nutrition (AIN), except for its fat content. The diet, as shown in Table 1, contained 5% beef tallow in addition to the 5% corn oil recommended by the AIN. This modification was made to better simulate the amount and type of dietary fat present in a typical American diet. All animals were fed the diet *ad libitum* and allowed free access to deionized water throughout the experiment.

[a]According to the recommendations of the American Institute of Nutrition (Refs. 9 and 10).

Cannulation of mesenteric lymph duct. In order to obtain chylomicrons labeled with specific fatty acids, the mesenteric lymph duct was cannulated by a modification of the procedure described in our previous studies (11,12). At the end of 8 wk, the rats were fasted for 24 h before surgery. Under halothane anesthesia, an abdominal incision was made along the midline with a cauterizer. The major intestinal lymph duct was cannulated with vinyl tubing (SV. 31 tubing; 0.50 mm i.d., 0.80 mm o.d. Dural Plastics, Auburn, Australia). Following the cannulation, an indwelling infusion catheter (Silastic medical grade tubing; 1.0 mm i.d., 2.1 mm o.d., Dow Corning, Midland, MI) was inserted *via* the gastric fundus into the upper duodenum and secured by a purse-string suture (4-0 Silk; Ethicon Inc., Somerville, NJ). After the abdominal incision was closed, the rats were placed in restraining cages (13) in a heated chamber (30°C) for 24 h to prevent hypothermia after surgery. During this postoperative recovery period, the rats were infused (Model 5B, Auto-syringe Inc., Londonderry Turnpike, Hookset, NH) *via* the duodenal catheter with a maintenance solution consisting of 5% glucose, 0.87% NaCl and 0.03% KCl at the rate of 2.5 mL/h. The volume of lymph ranged from 1.8 to 2.2 mL/h.

Preparation and labeling of chylomicrons. Chylomicrons were labeled *in vivo* with a [1-^{14}C]fatty acid as follows. Six lymph-fistula rats weighing 432 ± 32 g were divided into three groups. Each of the donor rats was infused *via* the duodenal catheter with a lipid emulsion (infusate) containing SA, MA and LA. The infusate was obtained by mixing 18–20 mL of Intralipid (10% soybean oil, 1.2% egg yolk phospholipid and 2.25% glycerin, USP, KabiVitrum, Alameda, CA) containing 10 mg α-tocopherol and an emulsion of SA, MA and LA prepared by sonication in 0.75 g Na-taurocholate in 40–42 mL phosphate buffered saline (6.75 mM Na_2HPO_4, 16.5 mM NaH_2PO_4, 115 mM NaCl, 5 mM KCl and 2.5 g glucose, pH 6.4). The total concentrations of SA, MA and LA in the mixture were 0.74, 0.58 and 0.58 g per 60 mL, respectively. More SA was added to the infusate because of its relatively inefficient intestinal absorption. After addition of 15–25 μCi of the specific [1-^{14}C]-labeled SA, MA or LA, the infusate was sonicated for 10 min to obtain uniform mixing of the label (W-375; Heat Systems-Ultrasonics, Long Island, NY). The radiochemical purities of all ^{14}C-labeled fatty acids (NEN, Du Pont, Wilmington, DE; specific activities, 56–58 mCi/mmol) were 98.9–99.0% by thin-layer chromatography (TLC).

TABLE 2

Distribution (%) of Radioactivity Among Different Lipid Classes in Chylomicrons Produced by Infusing Lipid Emulsions[a]

	PL	MG	DG + CH	FFA	TG	CE
MA	0.8	0.0	1.5	0.8	96.7	0.3
LA	3.8	0.4	4.8	0.0	92.1	0.8
SA	3.4	0.0	0.5	0.4	92.3	3.4

[a]PL, phospholipid; MG, monoglyceride; DG + CH, diglyceride and cholesterol; FFA, free fatty acid; TG, triglyceride; and CE, cholesteryl ester. Chylomicrons labeled with MA, [^{14}C]myristic acid; LA, [^{14}C]linoleic acid; and SA, [^{14}C]stearic acid.

After a steady flow of lymph was established during the postoperative recovery period, the donor rats were infused *via* the duodenal catheter with the respective lipid emulsion at 2.5 mL/h. Lymph was collected for about 20 h at 30°C in a sterilized 50-mL plastic tube. The lymph was defibrinated by passing through glass wool. The filtrate was overlayered with 150 mM NaCl (pH 7.4) in polyallomer tubes and centrifuged at $1.3 \times 10^6 \times g$/min at 28°C using a Beckman 50.3 Ti rotor in a Beckman L5-75B ultracentrifuge (Spinco Division, Palo Alto, CA). The packed top fraction of chylomicrons was separated and suspended in 150 mM NaCl, pH 7.4, by passage through a 23-gauge hypodermic needle. The dispersed chylomicrons were preheated at 55–60°C for 2 min under N_2 and cooled to 37°C prior to injection. Previously (14), it was found that reheating to 58°C was necessary to restore the spherical shape of the lymph lipoproteins rich in saturated fat exposed to temperatures of 23–26°C. Approximately 92–97% of the ^{14}C radioactivity of the chylomicrons was associated with TG, as determined by TLC (Table 2). The fatty acid composition of the chylomicrons closely reflected that of the duodenal infusates (Table 3), as analyzed by gas chromatography (Hewlett-Packard Model 5880A Gas Chromatograph, Hewlett-Packard, Palo Alto, CA).

Determination of the rate of plasma clearance. Forty-five recipient rats were divided into three groups with 15 rats each. After fasting for 10 h, each of the three groups was injected *via* the jugular vein with a dose of chylomicrons labeled with [^{14}C]SA, [^{14}C]MA or [^{14}C]LA. The

[a]Infusates labeled with MA, [^{14}C]myristic acid; LA, [^{14}C]linoleic acid; and SA, [^{14}C]stearic acid. Chylomicrons labeled with MA, LA and SA.

average body weights for the SA, MA and LA groups were 403 ± 18, 406 ± 16 and 400 ± 16 g, respectively. A dose of chylomicrons labeled with [^{14}C]SA, [^{14}C]MA or [^{14}C]LA contained 13.5, 10.2 and 10.2 mg of TG, respectively. Five rats from each group were killed under diethyl ether anesthesia at 5, 15 and 30 min after dosing. These specified time intervals (5, 15 and 30 min) were chosen because of the rapid rate of clearance of chylomicron fatty acids from the plasma. Blood samples (2 mL) were collected *via* the orbital sinus (15), and plasma was separated by centrifugation at 1000 × *g* for 60 min. Aliquots (200 μL) of plasma were mixed with scintillation liquid (ScintiVerse, Fisher Scientific, Fairlawn, NJ) and counted to determine the plasma ^{14}C radioactivity (Beckman LS 8000; Beckman Instruments, Fullerton, CA). Total volume of plasma was estimated at 3.35% of the body weight as determined by a radioisotopic dilution method (16). Percent clearance of the injected dose at each interval was computed following the equation (^{14}C dpm at t_i/^{14}C dpm at t_0) × 100; where t_i is a given time interval and t_0 is time of dosing. The rate of clearance for each fatty acid was expressed by half life ($t_{1/2}$), which is the time taken for the ^{14}C radioactivity to decrease to one-half of the total amount injected. The $t_{1/2}$ was determined by the equation for the rate of an exponential change, $t_{1/2} = -0.693/k$; where k is the slope of the time-course clearance curve of ^{14}C radioactivity.

Hepatic uptake and utilization of ^{14}C fatty acids in different lipid classes. After exsanguination of rats under halothane anesthesia, livers were removed, blotted with absorbent paper, weighed and frozen at −70°C until analysis. The whole liver was finely minced with a razor blade. A 2-g sample was taken and used for extraction of lipids by the method of Folch *et al.* (17). The total ^{14}C radioactivity taken up by the liver was determined by counting an aliquot (250 μL) of liver lipid extract and expressed as percent of the dose injected. Distribution of ^{14}C radioactivity in different lipid classes was determined by separating the liver lipids by TLC on silica gel G (20 × 20 cm, 250 μ; Analtech, Newark, DE) with *n*-hexane/diethyl ether/glacial acetic acid (70:30:2, by vol). The solvent system gave an excellent separation of cholesteryl ester, TG, FFA, monoglyceride and PL, except for cholesterol and diglyceride, which comigrated and were collected as one fraction. Separated lipids were visualized with iodine vapor. The lipid spots on TLC plates were scraped into counting vials and eluted with 1.0 mL of 100% ethanol for 10 min prior to mixing with scintillation liquid (ScintiVerse, Fisher Scientific). The distribution (%) of ^{14}C radioactivity among liver lipids was calculated. The fatty acid composition of liver lipids also was determined by gas chromatography.

Distribution of ^{14}C radioactivities of chylomicrons and liver lipid extracts between saturated and unsaturated fatty acids. The chylomicron and liver lipids were further saponified and methylated using methanolic BF_3 as described by Slaver and Lanza (18). Methyl esters of saturated and unsaturated fatty acids were separated by silver-nitrate impregnated TLC (silica gel G impregnated with 10% $AgNO_3$, 20 × 20 cm, 250 μ; Analtech). The plates were developed in 100% chloroform, and lipid fractions were visualized by spraying with water. The separated lipids were scraped into counting vials, eluted with 100% ethanol and counted to determine ^{14}C radioactivity.

Statistics. Analysis of variance with the least significant difference test of the SAS statistical package was used to determine differences ($P < 0.05$) between group means. All data were expressed as mean ± SD.

RESULTS

Comparison of the rates of plasma clearance. Figure 1 shows the time-course ^{14}C-clearance curves for the labeled fatty acids. The rates of ^{14}C-clearance ($t_{1/2}$) during the 30-min period for SA, MA and LA were 7.0 ± 0.3, 8.1 ± 1.2 and 8.0 ± 0.3 min, respectively. [^{14}C]SA was removed at a slightly faster rate ($P < 0.05$) than [^{14}C]MA and LA. Initially (at 5 min), there was no significant difference in clearance rates among the three fatty acids. At 15 min, 75% of [^{14}C]SA, 64% of [^{14}C]LA and 53% of [^{14}C]MA were cleared. At 30 min, 92–95% of the fatty acids was removed from the plasma. The plasma ^{14}C radioactivities of both SA and LA decreased almost linearly with time. The ^{14}C radioactivity of MA, however, was cleared in a curvilinear fashion. The clearance curve for [^{14}C]MA was characterized by an initial slow phase followed by a rapid phase of clearance.

Comparison of hepatic and extrahepatic uptake. Figure 2 compares the time course changes in the ^{14}C radioactivities recovered in the liver. The hepatic ^{14}C radioactivities, as expressed in percent dose, generally reflected the amounts of the ^{14}C cleared from the plasma. The hepatic ^{14}C radioactivities increased rapidly with time up to 15 min and plateaued at 30 min, except for [^{14}C]MA, which decreased significantly from 15 min, despite its rapid removal from the plasma. Between 15 and 30 min, the liver radioactivity of [^{14}C]MA decreased by 6%, suggesting a faster rate of oxidation in the liver. At 15 min,

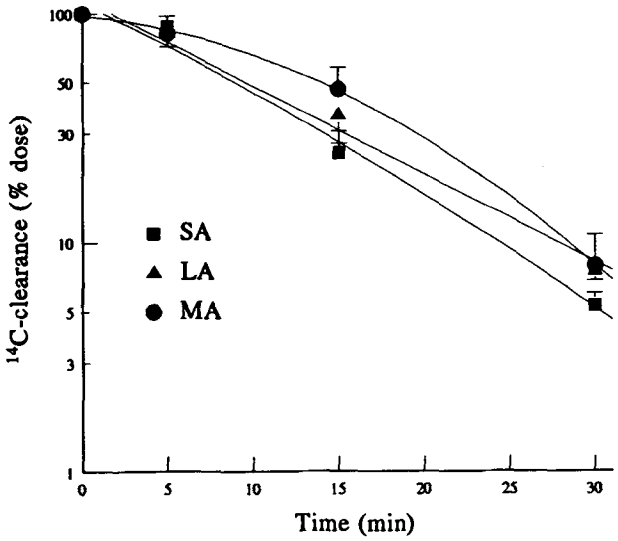

FIG. 1. Clearance of ^{14}C-labeled stearic, myristic and linoleic acids from plasma. Clearance rate (half time, $t_{1/2}$) was determined by the equation $t_{1/2} = -\ln 2/k = -0.692/k$; where k is the slope of the clearance curve. The rates of ^{14}C clearance for stearic, myristic and linoleic acids were 7.0 ± 0.3, 8.1 ± 1.2 and 8.0 ± 0.3 min, respectively. [^{14}C]Stearic acid (SA) was cleared at a slightly faster rate ($P < 0.05$), as compared with [^{14}C]linoleic acid (LA) and [^{14}C]myristic acid (MA) (n = 5 each data point).

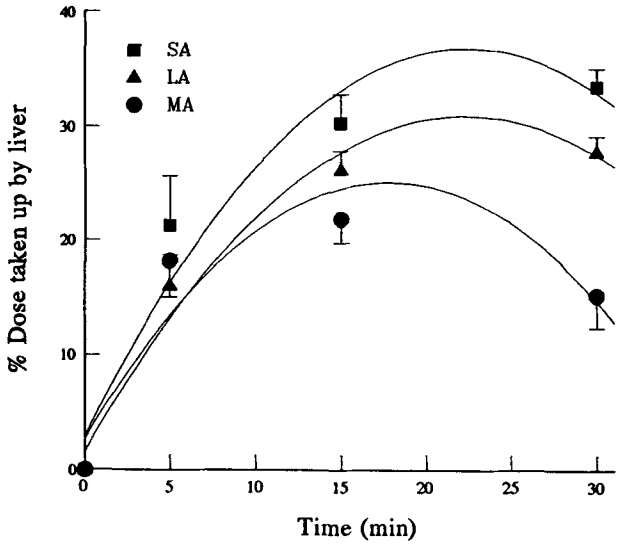

FIG. 2. Time-dependent changes (% dose) in ^{14}C radioactivity in the liver after intravenous injection of chylomicrons labeled with ^{14}C-labeled stearic, linoleic and myristic acids (n = 5 each data point). At 15 and 30 min, significantly greater percentages of the [^{14}C]SA dose were taken up by the liver, compared with [^{14}C]LA and [^{14}C]MA. At the same intervals, a greater percentage of the [^{14}C]LA dose appeared in the liver, as compared with [^{14}C]MA. The radioactivities of [^{14}C]LA and [^{14}C]SA increased linearly with time and plateaued at 30 min, whereas the radioactivity of [^{14}C]MA increased up to 15 min, but precipitously declined at 30 min. Abbreviations as in Figure 1.

30.3% of [^{14}C]SA, 26.2% of [^{14}C]LA and 21.9% of [^{14}C]MA were removed by the liver. At 30 min, 33.5% of [^{14}C]SA, 27.8% of [^{14}C]LA and 15.2% of [^{14}C]MA were recovered.

The loss of ^{14}C radioactivity was calculated as the initial ^{14}C dose minus the ^{14}C radioactivities recovered from the liver and remaining in the plasma at each time interval (Table 4). Thus, the difference was attributable to the ^{14}C taken up by the peripheral tissue and the fraction of the liver ^{14}C radioactivity lost through oxidation. As determined at 30 min, a significantly higher amount of [^{14}C]MA (76.9%) than [^{14}C]LA (64.7%) and [^{14}C]SA (61.2%) was attributable to peripheral uptake and oxidation.

The percentages of the ^{14}C dose appearing in different liver lipids are shown in Table 5. For all fatty acids, less than 3.7% of the ^{14}C dose was present in the combined fractions of monoglyceride, diglyceride and free and esterified cholesterol. Much of each injected ^{14}C dose was associated with FFA (unesterified), TG and PL. The time course appearance of ^{14}C-fatty acids in these lipids in the liver, as expressed in percent dose, is presented graphically in Figure 3. The upper panel compares the [^{14}C]SA, [^{14}C]MA and [^{14}C]LA appearing as FFA. Among the three fatty acids, [^{14}C]MA accumulated most rapidly as FFA in the liver. At 5 min, almost 15% of the dose of [^{14}C]MA was recovered in the FFA fraction. The unesterified [^{14}C]MA increased to 17% at 15 min and decreased to 10% of the dose at 30 min. Between 5 and 15 min, the free [^{14}C]MA represented 78-82% of the total hepatic [^{14}C]MA radioactivity. In contrast, the radioactivities of

TABLE 4

[a]Mean ± SD, n = 5. Values not sharing common superscripts within the same lipid class are significantly different ($P < 0.05$). MG, monoglyceride; DG + CH, diglyceride plus cholesterol; and CE, cholesteryl ester. Chylomicrons labeled with MA, [^{14}C]myristic acid; LA, [^{14}C]linoleic acid; and SA, [^{14}C]stearic acid.

free [^{14}C]SA and [^{14}C]LA remained significantly lower at all time intervals. The radioactivity of free [^{14}C]SA increased slowly with time from 6.1 to 8.6% of the dose, despite its faster clearance from the plasma and uptake by the liver. The radioactivity of free [^{14}C]LA tended to rise more rapidly and plateaued at 15 min, but decreased to 7.3% at 30 min.

At all time points, [^{14}C]MA was minimally utilized for the synthesis of TG, whereas [^{14}C]SA and [^{14}C]LA were incorporated into TG in significantly greater proportions (middle panel, Fig. 3). Initially, both [^{14}C]SA and [^{14}C]LA were rapidly utilized for TG synthesis at a similar rate. The incorporation of the fatty acids into TG reached a maximum at 15 min and tended to plateau thereafter. At 30 min, 13.6% of [^{14}C]LA and 10.5% of [^{14}C]SA were incorporated in TG, whereas only 3.8% of [^{14}C]MA was found in this lipid. Among the three fatty acids, the incorporation (percent dose) of [^{14}C]SA into PL was most

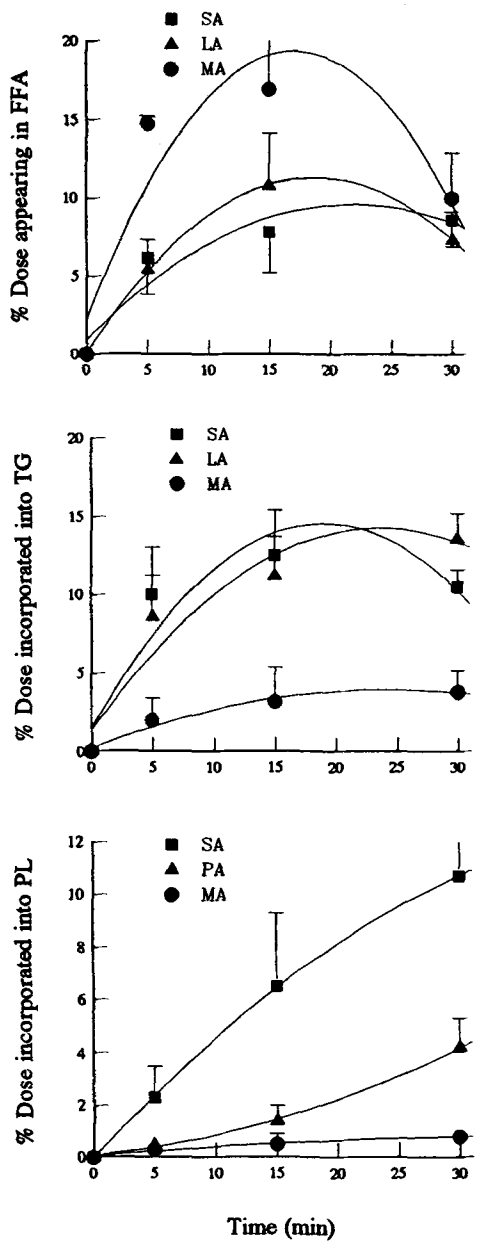

FIG. 3. Time course changes (% dose) in the ^{14}C radioactivity appearing in different lipid classes of the liver after intravenous injection of chylomicrons labeled with ^{14}C-labeled stearic, myristic and linoleic acids (n = 5 each data point). Upper panel: ^{14}C radioactivity (% dose) appearing in free (unesterified) fatty acid (FFA). At 5 min, a significantly greater percentage of [^{14}C]MA appeared as FFA, compared with [^{14}C]LA and [^{14}C]SA. The unesterified [^{14}C]MA remained elevated up to 15 min, but declined precipitously to the levels of [^{14}C]LA and [^{14}C]SA at 30 min. Middle panel: ^{14}C radioactivity (% dose) appearing in triglyceride (TG). No difference was observed between [^{14}C]LA and [^{14}C]SA incorporated into TG up to 15 min, with a slight increase in [^{14}C]LA in TG at 30 min. [^{14}C]MA was most slowly incorporated into TG. At any given interval, less than 4% of [^{14}C]MA dose appeared in TG. Lower panel: ^{14}C radioactivity (% dose) appearing in phospholipid (PL). At all time points, a significantly greater incorporation of [^{14}C]SA into PL was noted, compared with [^{14}C]LA and [^{14}C]MA. No difference between [^{14}C]LA and [^{14}C]MA was observed up to 15 min. At 30 min, a significantly greater percentage of [^{14}C]LA was found in PL compared with [^{14}C]MA. The incorporation of [^{14}C]MA did not change appreciably with time. Less than 1.0% of [^{14}C]MA dose appeared in PL at any time interval. Abbreviations as in Figure 1.

rapid and increased sharply with time (lower panel, Fig. 3). The incorporation of [^{14}C]LA into PL increased linearly with time, but at a much slower rate than that of [^{14}C]SA. [^{14}C]MA was poorly utilized for PL synthesis in the liver. At 30 min, 10.7% of [^{14}C]SA and 4.2% of [^{14}C]LA were found in PL, whereas only 0.8% of [^{14}C]MA was incorporated into this lipid.

Interconversion between ^{14}C fatty acids. The distribution of ^{14}C radioactivity of chylomicrons and hepatic lipids between saturated and unsaturated fatty acids is shown in Table 6. More than 93% of [^{14}C]SA and 95% of [^{14}C]MA were distributed in the saturated fatty acid fraction in both chylomicrons and liver lipids, indicating that 5-7% of these fatty acids were desaturated in the liver. All [^{14}C]LA was found in the unsaturated fatty acid fraction.

DISCUSSION

Several previous studies have compared the metabolic fates and utilization of various fatty acids in intact animals (8), as well as in isolated livers (19,20) and hepatocytes *in vitro* (21). Using chylomicrons labeled *in vivo* with [^{14}C]MA, [^{14}C]SA and [^{14}C]LA, we compared the rates of their plasma clearance and hepatic utilization. The present study was designed specifically to examine the metabolic patterns of these fatty acids immediately after their entry into the circulation *via* chylomicrons, the principal carriers of dietary fatty acids.

The results of this study showed that: (i) SA is removed from the plasma at a slightly but significantly faster rate than MA and LA; (ii) once taken up by the liver, SA is preferentially incorporated into PL; (iii) LA is better utilized for the synthesis of TG than PL; (iv) MA remains largely unesterified in the liver during the early stage of its metabolism and is poorly utilized for lipid synthesis; and (v) with time, MA is more readily oxidized by the peripheral tissue and the liver.

Much of the fatty acids incorporated into chylomicron TG are released during lipolysis by lipoprotein lipase (LPL) on the endothelial surface of the peripheral tissue (22). Chylomicron remnants with residual TG are enriched in apo-E and rapidly removed by the liver *via* the apo-E (chylomicron remnant) receptor (23). Because the bulk of the total fatty acids is present in TG, the rate of plasma clearance of a chylomicron fatty acid is largely determined by the rates of both peripheral lipolysis and hepatic removal. The present data showed that, during the early stage of chylomicron metabolism (up to 15 min), [^{14}C]SA and [^{14}C]LA were removed at a similar rate, but more rapidly than [^{14}C]MA, suggesting a slower rate of peripheral release of [^{14}C]MA from chylomicron TG. With time, however, the clearance of [^{14}C]MA was accelerated, and its plasma radioactivity declined to the level of [^{14}C]LA. These observations suggest that SA and LA are first liberated by LPL from chylomicron TG. As these fatty acids are removed, glycerides containing MA are cleared at progressively accelerated rates.

The hepatic uptake of the fatty acids increased sharply immediately after the labeled chylomicrons were injected and plateaued at 15 min, reflecting their initial rates of plasma clearance. After being taken up by the liver, the fatty acids were distinctly different in their metabolic patterns. [^{14}C]SA was most preferentially incorporated into

TABLE 6

Distribution (%) of ^{14}C Radioactivities of Injected Chylomicron and Liver Lipids Between Saturated and Unsaturated Fatty Acids[a]

	Chylomicrons		Liver removed at 5 min		Liver removed at 15 min		Liver removed at 30 min	
	SAT	UNSAT	SAT	UNSAT	SAT	UNSAT	SAT	UNSAT
MA	99.4	0.6	95.9 ± 2.1	4.1 ± 2.1	98.8 ± 0.8	1.2 ± 0.8	95.4 ± 4.9	4.6 ± 4.9
LA	0	100	0	100	0	100	0	100
SA	99.0	1.0	97.8 ± 2.1	2.2 ± 2.1	98.3 ± 0.8	1.7 ± 0.8	93.8 ± 3.8	6.2 ± 3.8

[a]SAT, saturated; UNSAT, unsaturated. Chylomicrons labeled with MA, [^{14}C]myristic acid; LA, [^{14}C]linoleic acid; and SA, [^{14}C]stearic acid.

PL (Fig. 3), as was also observed in our previous study (7). The present data showed that the [^{14}C]SA radioactivity in PL steadily increased, with a reciprocal linear decline in [^{14}C]SA present in TG. This indicates that SA released from chylomicron remnant TG is continually channeled into PL synthesis. Previously, Leyton *et al.* (8) compared the metabolic utilization of various fatty acids after oral administration of ^{14}C-labeled fatty acids to fed weanling rats. At 24 h after dosing, a significantly greater percentage of [^{14}C]SA was found in liver PL, as compared with [^{14}C]MA and [^{14}C]LA. Elovson (24) also observed a rapid incorporation of [^{14}C]SA into PL in the rat liver. In this study (24), nearly 15% of the fatty acid was recovered in PL at 30 s after intraportal injection of the labeled fatty acid bound to albumin. In addition, SA was found to be oxidized most slowly among the saturated fatty acids with chain lengths ranging from C_{12} through C_{18} (8). The rates of oxidation decreased with increasing chain length. At 1 h, 0.3% of the oral dose of [^{14}C]SA was expired as $^{14}CO_2$, compared with 3.1% from [^{14}C]MA (8). In the present study using fasted rats, we also found that a significantly lower percentage of SA (61%) than MA (77%) was oxidized during a 30-min period.

The above observations, taken together, indicate that SA is more slowly oxidized, but more efficiently utilized for PL synthesis than is MA. Much (63–80%) of the liver [^{14}C]MA remained unesterified. Among the three fatty acids, unesterified [^{14}C]MA accumulated most rapidly in the liver, even during the first 15 min. This initial rapid accumulation occurred despite the significantly lower hepatic uptake of [^{14}C]MA from the plasma, suggesting that the MA present in chylomicron remnant TG is more rapidly liberated in the liver. Compared with [^{14}C]SA and [^{14}C]LA, a significantly greater percentage of the unesterified [^{14}C]MA was lost by oxidation in the liver. This was evidenced by a rapid rise followed by a precipitous decline in free [^{14}C]MA at 30 min, with minimal incorporation into TG or PL (Fig. 3). Thus, free MA is largely oxidized and minimally utilized for lipid synthesis. The preferential incorporation of SA into PL strongly suggests that much of the hepatic SA is destined for incorporation into cellular membranes and lipoprotein surface coats. Such metabolic preference may partly explain the hypolipidemic effect of SA compared with that of other saturated fatty acids (1). However, the rapid oxidation and minimal incorporation of MA into hepatic lipids is not consistent with its well-known hypercholesterolemic effect (1,25,26). Previous research has suggested that MA lowers the turnover of sterols and stimulates the intestinal absorption of cholesterol (27). Also, it has been suggested that MA may suppress expression of the low-density lipoprotein (LDL) receptor (21).

Compared with SA, LA appeared more slowly into the liver. This was partly due to its slower uptake and perhaps to a faster rate of oxidation within the liver after its uptake. Proportionally, more of the hepatic LA was incorporated into TG (31.6–33.0%) than into PL (7.0–12.0%). Compared with [^{14}C]SA, the [^{14}C]LA radioactivity in TG continued to increase with time and significantly exceeded the amount of [^{14}C]SA incorporated into TG at 30 min. On the other hand, the radioactivity of [^{14}C]LA appearing in PL reached only 39% of that of [^{14}C]SA in PL. The difference in the relative incorporation of the label in TG or PL was not related to a difference in intrahepatic dilution of the labeled fatty acids. The percent distributions of total SA and LA, as determined at 30 min, were 20.0 ± 1.9 and 17.4 ± 1.1%, respectively. Our observation is in agreement with the previous finding of an increased appearance of orally-fed [^{14}C]LA in hepatic TG (8). This suggests that dietary LA, as transported *via* chylomicrons, is largely repackaged into TG in the liver, and may accelerate VLDL synthesis. Consistent with these findings, Ohtani *et al.* (28) showed that the secretion of VLDL was markedly increased in cultured hepatocytes from rats fed 5% dietary LA. In addition, using perfused rat livers, Wilcox *et al.* (29) had found that the total output of TG was significantly greater when the livers were perfused with LA, as compared with saturated fatty acids such as SA and MA. The VLDL particles secreted in response to LA or other unsaturated fatty acids contained relatively more TG and less cholesterol (29). Therefore, the observations suggest that the hypocholesterolemic effect of LA may not be associated with a suppression of VLDL synthesis (30), but primarily with a faster catabolism of VLDL enriched with LA. Available evidence, indeed, indicates that VLDL produced by feeding LA-rich fats are more efficiently removed (19,31), and LDL is more rapidly taken up from the plasma, perhaps because of its increased fluidity (20,32). The increased catabolic rate of plasma LDL also may be associated with an increase in LDL-receptor activity by high intake of dietary LA (33–35).

In summary, the present findings clearly illustrate the existence of distinct metabolic patterns for chylomicron fatty acids with different chain lengths and degrees of saturation. SA, MA and LA differ metabolically with respect to their rates of plasma clearance and the extents of their utilization as the substrates for specific lipid

synthesis. The present results confirm our previous finding (7) that SA, as transported in the form of chylomicron lipids, is more rapidly and preferentially incorporated into PL. In addition, based on the rapid increase followed by a decline in unesterified [^{14}C]MA with its minimal incorporation into TG and PL (Fig. 3), MA is more readily oxidized, but poorly utilized for lipid synthesis in the liver. LA is better incorporated into TG than into PL (Fig. 3), which may be stimulatory to hepatic VLDL synthesis. Therefore, its hypocholesterolemic effect may be related not to an inhibition of VLDL production (29,30), but to an increase in the rate of VLDL catabolism (19,20,31,32).

Isoprene is a normal constituent of human breath and may be derived from the cholesterol synthetic pathway. Acute and chronic lovastatin and a cholesterol-supplemented diet were used to determine whether a mechanistic link exists between isoprene and cholesterol biosynthesis *in vivo* in humans. The acute effects of lovastatin, a competitive inhibitor of the rate-limiting step of cholesterol biosynthesis, on breath isoprene excretion was determined by administering a single 20, 40 or 80 mg dose of this drug to five healthy male subjects at 8 p.m. and measuring their breath isoprene levels every 4 h for one 24 h cycle before and after treatment. When compared to the baseline cycle, all three doses of lovastatin significantly reduced breath isoprene levels at 6 and 10 h post-drug treatment. Chronic lovastatin therapy (40 mg b.i.d. for 6 wk) reduced 6 a.m. breath isoprene levels (time of maximum baseline value) by 27 ± 9% (SEM) and cholesterol synthesis measured in freshly isolated mononuclear leukocytes (ML) by 12 ± 6%. A cholesterol-supplemented diet (1070 mg, total) ingested for 6 wk reduced breath isoprene excretion and ML sterol synthesis by 16 ± 5 and 19 ± 4%, respectively. The parallel decreases in isoprene excretion and cholesterol synthesis caused by these pharmacologic and dietary means suggest that breath isoprene is derived from the cholesterol synthesis pathway.

Lipids 28, 705–708 (1993).

Hypercholesterolemia continues to be a major health problem. The majority of serum cholesterol is derived from *de novo* synthesis (1). The rate-limiting step of cholesterol synthesis is catalyzed by 3-hydroxy-3-methyl-glutaryl coenzyme A (HMG-CoA) reductase, which reduces HMG-CoA to mevalonate and CoA. With the advent of a new class of compounds aimed at decreasing serum cholesterol by inhibiting HMG-CoA reductase activity, renewed interest in monitoring cholesterol synthesis *in vivo* in response to dietary and pharmacologic treatment has emerged.

The classical clinical procedure for assessing sterol synthesis is the sterol-balance method, where dietary intake of cholesterol is subtracted from fecal excretion of acidic and neutral sterols (2). Although this method continues to be used, it is cumbersome, cannot measure short-term changes in sterol synthesis, and is only valid when the patient is in a steady state. These disadvantages have limited the use of the sterol-balance method and, in response, other more indirect methods of assessing changes in cholesterol synthesis have been developed. These include measurements of serum mevalonate levels (3), quantitation of other cholesterol precursors in serum (4) and measurement of cholesterol synthesis or HMG-CoA reductase activity in freshly isolated mononuclear leukocytes (ML; Refs. 5–10).

Abbreviations: DMPP, dimethylallyl pyrophosphate; HMG-CoA, 3-hydroxy-3-methyl-glutaryl coenzyme A; ML, mononuclear leukocytes.

Isoprene (2-methyl-1,3-butadiene) is a major component of human breath (11). The production of isoprene from mevalonate has been demonstrated in rat liver cytosol, and isoprene is thought to be a normal by-product of cholesterol synthesis formed by the nonenzymatic degradation of dimethylallyl pyrophosphate (DMPP; Refs. 12,13). Although measurable isoprene levels have not been found in the expired air of rats and several other animal species, isoprene has been identified in blood from these species by mass spectrometry (14).

The exact origin of isoprene found in human breath is not known. Cholesterol synthesis in humans appears to undergo a circadian rhythm with the peak at 6 a.m. (15). One of our laboratories has described a circadian rhythm for isoprene excretion with the peak between 2–6 a.m. (11). These results suggest that isoprene might also be produced from mevalonate as a by-product of cholesterol biosynthesis in humans. Therefore, a change in the rate of sterol synthesis might cause a comparable change in the amount of isoprene excreted. To investigate this possibility, we manipulated the rate of cholesterol biosynthesis of healthy volunteers using lovastatin or a cholesterol-enriched diet and compared breath isoprene excretion with their rate of cholesterol synthesis in isolated ML.

MATERIALS AND METHODS

Materials. Isoprene was purchased from Aldrich (Milwaukee, WI) and [^{14}C]acetate from ICN Radiochemicals (Irvine, CA). Other chemicals and reagents were purchased from common commercial sources.

Subjects. The acute studies with lovastatin were conducted in five healthy male laboratory personnel ranging in age from 18 to 50 years. For the chronic studies, eight healthy male subjects without significant heart or liver disease were recruited from the patient population of the Minneapolis VA Medical Center. The subjects ranged in age from 30–72 years, and their baseline serum cholesterol ranged from 189–318 mg/dL. All unnecessary medications were discontinued prior to the study, and necessary medications were continued throughout the study period.

In the chronic studies, all subjects ate meals prepared by the metabolic kitchen at the Minneapolis VA Medical Center consisting of 35% fat, 45% carbohydrates and 20% protein, with a cholesterol intake of 250 mg/d. For the cholesterol-supplemented diet, five eggs were isocalorically substituted so that the cholesterol-enriched diet contained 1070 mg total cholesterol per day. Weight was monitored at weekly intervals and calories readjusted to maintain a constant weight. These studies were approved by the Human Studies Committee of the Minneapolis VA Medical Center, and informed consent was obtained from all subjects.

ML harvest and sterol synthesis. ML were harvested from heparinized blood by gradient centrifugation and sterol synthesis quantitated in freshly isolated ML as previously described (5). Briefly, this consisted of measuring

the incorporation of [^{14}C]acetate (4.46 mmol, 2.24 mCi/mmol) into ML sterols by incubating 10^7 cells for 2 h in 5 mL of autologous serum.

Breath isoprene excretion. End expiratory alveolar breath samples were collected by having subjects exhale through a polyethylene tube into a glass collecting vial which allows all except the last 20 mL of breath to be vented. The vials were immediately capped and placed on dry ice until analyzed. Samples were collected in triplicate over a 3-min period and analyzed using a Perkin-Elmer (Norwalk, CT) sigma 2000 gas chromatograph equipped with an HS-100 headspace autosampler and a flame-ionization detector. Isoprene standards were prepared by volatilizing a 10-μL aliquot of pure isoprene in a 1.2-L gas septum bottle containing dry nitrogen gas. Serial dilutions of the latter were prepared using gas-tight syringes for the construction of a standard curve. Room air blanks and triplicate 31.6 nM isoprene gas standards were included in routine isoprene breath analyses. Prior to analysis, the samples were equilibrated for 10 min at 55°C in the heating compartment of the autosampler. Other gas chromatographic parameters were: column, 1/8 in. × 6 ft stainless steel; packing, Porapak Q (Alltech, Deerfield, IL); oven temperature, 150°C; carrier gas, nitrogen; carrier gas flow rate, 40 mL/min. The retention times for acetone and isoprene, the two most prominent peaks in breath, were 3.6 and 5.1 min, respectively. Breath isoprene values were calculated from the integrated peak areas of the breath samples and isoprene standards and expressed in units of nmol/L.

The inter- and intra-assay variability for the 31.6 nM isoprene standard based on peak area integration units from ten consecutive experiments and expressed as coefficient of variation were 3.1 and 2.3% respectively. The 10:00 a.m. breath isoprene for one subject determined over a period of 1 yr was 11.1 ± 1.4 nM (SD; n = 10), and the mean coefficient of variation for triplicate determinations of these same samples was 10.7%.

Statistical analysis. Statistical significance was determined by comparing each subject's value in response to a treatment to his baseline value using a paired *t*-test. All results are presented as the mean ± SEM.

RESULTS

Effect of lovastatin on breath isoprene excretion. We have previously demonstrated that as early as three h after an acute 80-mg dose of lovastatin, cholesterol synthesis (measured in freshly harvested ML) is inhibited by 57% (5). Therefore, we administered a graded dose of lovastatin to determine what effect the inhibition of cholesterol synthesis has on breath isoprene excretion. Breath isoprene showed a circadian rhythm with the peak between 2 and 6 a.m. in all five subjects tested (Fig. 1). The three doses of lovastatin administered at 8 p.m. (about 9 h prior to peak isoprene) caused a significant reduction in breath isoprene excretion at 2 and 6 a.m. of ⩾ 36% as compared to baseline values.

Chronic administration of lovastatin (40 mg b.i.d.) for 6 wk resulted in a modest 12% decrease in ML sterol synthesis (Table 1), a value similar to that previously reported (5), whereas breath isoprene was reduced by 26% in these subjects (Table 1). Their low-density lipoprotein and total cholesterol were reduced 41 and 32%, respectively (Table 1).

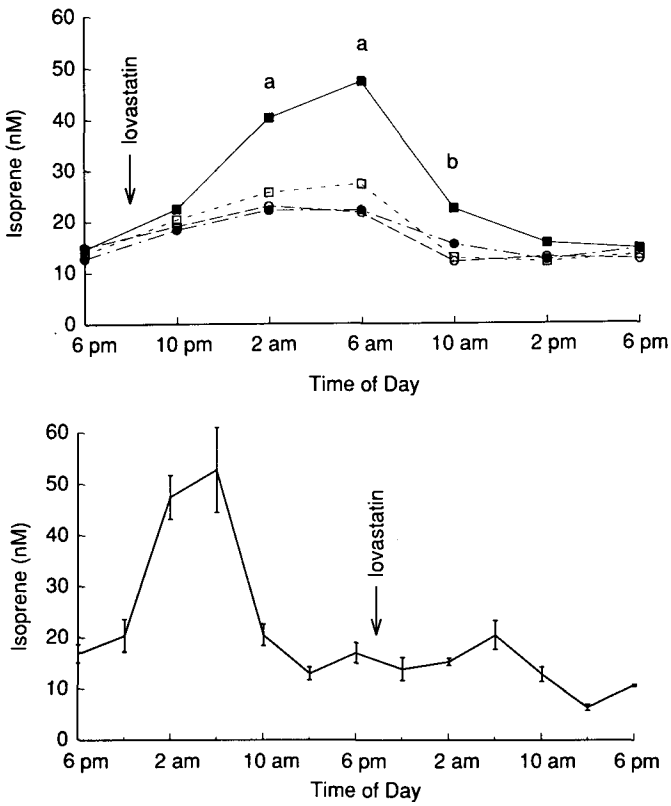

FIG. 1. Effect of acute lovastatin administration on breath isoprene excretion of five male subjects (upper panel); and a 24-h isoprene excretion cycle before and after lovastatin (80 mg) administration in a single subject (lower panel). Breath isoprene excretion was measured every four hours in five male subjects at baseline (■) and after the administration of a 20 mg (□), 40 mg (○) or 80 mg (●) dose of lovastatin. The doses were administered at 8 p.m., as shown. a, Different from baseline at all doses, $P < 0.05$; b, different from baseline for the 20 and 80 mg dose only, $P < 0.05$.

Effect of cholesterol feeding on breath isoprene excretion. Cholesterol feeding results in a decreased total body cholesterol synthesis due to feedback inhibition of HMG-CoA reductase (16,17). If isoprene is formed as a by-product of the cholesterol synthetic pathway, a decrease in sterol synthesis should reduce breath isoprene excretion. A high cholesterol diet (average 1070 mg/d) ingested for 6 wk reduced ML sterol synthesis 19% as compared to the rate of ML sterol synthesis measured on a low cholesterol diet (baseline; Table 1). A similar 16% reduction in breath isoprene excretion was observed at the end of the six-week period of high cholesterol intake (Table 1). However, the effect of increasing cholesterol intake on breath isoprene excretion could be appreciated as early as the first day, as evidenced by a 35 and 53% decrease in 6 a.m. breath isoprene levels of two subjects one day after cholesterol supplementation.

DISCUSSION

Isoprene is a normal occurrence, as well as the major hydrocarbon found in human breath, although its precise metabolic origin has not been established. Earlier reports

TABLE 1

Effect of Chronic Lovastatin and Cholesterol Feeding on Breath Isoprene Excretion and Mononuclear Leukocytes (ML) Sterol Synthesis[a]

Treatment	Breath isoprene (nM/L)	ML sterol synthesis (pmol/10^6/min)	LDL cholesterol (mg/dL)	Total serum cholesterol (mg/dL)
None (baseline)	21.7 ± 6.4	11.3 ± 0.8	122 ± 14	203 ± 6
Lovastatin	16.0 ± 4.5[b]	9.9 ± 0.7[b]	71 ± 10[c]	142 ± 11[d]
	(74 ± 9)	(88 ± 6)	(59 ± 5)	(68 ± 3)
Cholesterol	18.3 ± 5.5[b]	9.2 ± 0.8[b]	134 ± 10	212 ± 12
	(84 ± 5)	(81 ± 4)	(117 ± 13)	(103 ± 3)

[a]Breath isoprene and ML sterol synthesis were measured before (baseline) and after six weeks of lovastatin (40 mg b.i.d.) or a cholesterol-supplemented diet. The breath and blood samples were collected from male subjects between 6:00 and 7:00 a.m. Breath isoprene was measured in only six of the eight subjects studied. Data in parentheses are expressed as percent of baseline values. LDL, low-density lipoprotein.
[b]$P < 0.05$ relative to baseline.
[c]$P < 0.01$ relative to baseline.
[d]$P < 0.001$ relative to baseline.

have suggested that the amount of isoprene eliminated *via* the breath is not influenced by diet, age, sex or fasting (18), but rather is influenced by sleep patterns (19). We took advantage of the hypocholesterolemic agent, lovastatin, to test if isoprene originated from the cholesterol biosynthetic pathway *in vivo*. Our results demonstrated that acutely administered lovastatin blunted the early morning rise in breath isoprene excretion (Fig. 1), using doses of this drug that are known to inhibit sterol biosynthesis (5). Chronic lovastatin administration resulted in a small, but significant, decrease in isoprene excretion which agreed well with the decrease in sterol synthesis measured in ML (Table 1). The smaller effect of lovastatin on breath isoprene in the chronic situation is likely due to induction of HMG-CoA reductase by the competitive inhibitor, lovastatin (5). This enzyme induction tends to return cholesterol synthesis toward the pre-lovastatin baseline value.

In contrast to a pevious report suggesting that the dietary intake does not influence breath isoprene excretion (18), we found that a cholesterol-supplemented diet given for six weeks modestly reduced isoprene excretion (Table 1). The mechanism of this effect likely relates to the concurrent decrease in cholesterol synthesis (measured in ML) that occurs by feedback inhibition (16,17). Therefore, whereas most dietary changes likely will not influence breath isoprene excretion, those dietary manipulations that change total body cholesterol synthesis may also alter breath isoprene excretion.

The rate limiting step of sterol synthesis is catalyzed by HMG-CoA reductase and the products of this reaction are mevalonate, CoA and $NADP^+$. Mevalonate is then converted in the cytosol to isopentenyl pyrophosphate, which undergoes isomerization to DMPP (20). Upon acidification, rat liver cytosolic DMPP is rapidly converted to isoprene *via* an acid-catalyzed elimination reaction, which proceeds through a carbonium ion intermediate (12,13). However, it is not clear whether this nonenzymatic reaction accounts for isoprene formation under physiologic conditions. Certain plants also produce isoprene from DMPP. In these plants, this reaction is catalyzed by an Mg^{2+}-dependent enzyme (21). A similar, but still unidentified, enzyme may also be responsible for the conversion of DMPP to isoprene in mammalian tissue. A possible enzyme candidate for catalyzing isoprene formation is the Mg^{2+}-dependent isopentenyl pyrophosphate isomerase, which catalyzes the interconversion of isopentenyl pyrophosphate and DMPP. This isomerization reaction proceeds through the same carbonium ion intermediate (22) as occurs in the acid-catalyzed nonenzymatic conversion of DMPP to isoprene (13). A loss of a single proton from this carbonium ion would result in the formation of isoprene.

In conclusion, the parallel decrease in isoprene secretion and sterol synthesis in ML caused by feeding a cholesterol-supplemented diet or by acute or chronic lovastatin administration suggests that breath isoprene is derived from the cholesterol synthesis pathway in humans *in vivo*.

Bile Acid and Very Low Density Lipoprotein Production by Cultured Hepatocytes from Hypo- or Hyperresponsive Rabbits Fed Cholesterol

Evgeniy A. Podrez[a,*], Vladimir A. Kosykh[a], Yuri V. Lakeev[a], Evgeniy I. Kosenkov[a], Elvira T. Mambetisaeva[a], Vadim S. Repin[a], Vladimir N. Smirnov[a] and Tatu A. Miettinen[b]

[a]Cardiology Research Center, Academy of Medical Sciences, Moscow 121552, Russia and [b]Second Department of Medicine, University of Helsinki, Helsinki, Finland

Two groups of rabbits, either hyperresponsive or hyporesponsive to dietary cholesterol, were selected after ten weeks of cholesterol feeding (0.2 g cholesterol/kg body weight per day). Bile acids and very low density lipoprotein (VLDL) production were determined in primary hepatocyte cultures from control, hyper- and hyporesponsive rabbits. Free cholesterol and cholesteryl ester contents in hepatocytes of the hyperresponsive rabbits was significantly increased. In contrast, lipid composition in hepatocytes of the hyporesponders was similar to that of control cells. Cholic acid was the predominant bile acid in the culture medium of hepatocytes together with small amounts of chenodeoxycholic and deoxycholic acids. The rate of cholic acid production by hepatocytes in the hyporesponsive group was two times higher than that in the hyperresponsive group. Bile acid production by control hepatocytes was slightly higher than in the hyperresponsive group. In contrast, secretion of VLDL cholesteryl ester was significantly increased by hepatocytes of the hyperresponsive rabbits. Similar differences in bile acid production were found between hypo- and hyperresponsive rabbits selected after five days of cholesterol feeding and subsequent maintenance on a low cholesterol diet for a period of one month. The results suggest that the increased rate of bile acid production could contribute to the apparent resistance of hyporesponders to the atherogenic diet.

***Lipids* 28, 709–713 (1993).**

The inconsistent response of plasma cholesterol levels to increased dietary cholesterol intake has been described in rabbits, in various other animal species and in humans (1–7). Upon cholesterol feeding, plasma cholesterol concentrations usually vary from severe hypercholesterolemia in most animals (hyperresponders) to virtually unaltered cholesterol level in a small fraction of animals (hyporesponders). Hyperresponsiveness is characterized by accumulation of lipoprotein particles enriched in cholesteryl esters (8–10). The actual mechanism(s) of hyper- or hyporesponsiveness in various species, including humans, is not clear. Hyporesponsiveness to cholesterol ingestion could be due to: (i) low intestinal absorption of cholesterol; (ii) effective suppression of endogenous cholesterol biosynthesis; (iii) increased secretion of bile cholesterol; and (iv) a high rate of cholesterol oxidation to bile acids. The results of several recent studies allow one to suggest that an enhanced rate of cholesterol conversion to bile acids in the liver is a factor contributing to the hyporesponsiveness to a dietary cholesterol challenge (4–7). However, direct measurements on bile acid production in hepatocytes from hyper- and hyporesponders have not been reported. There are no data on altered lipoprotein production by the liver in hyper- and hyporesponsiveness.

Recent studies have shown that primary cultures of hepatocytes retain the ability to synthesize, metabolize and secrete bile acids (11–14). In addition, the hepatocyte culture model possesses the capacity to express *in vitro* the changes in bile acid secretion that have been induced *in vivo* (13,14). We used primary cultures of hepatocytes from rabbits that were hyper- or hyporesponsive to dietary cholesterol to determine whether this responsiveness is related to the rates of bile acid and very low density lipoprotein (VLDL) production.

MATERIALS AND METHODS

Materials. All chemicals used were reagent grade. Minimal essential medium (MEM) with Earle's salts, fetal bovine serum (FBS), MEM nonessential amino acids, kanamycin, L-glutamine, and 150-mm and 100-mm culture dishes were purchased from Flow Laboratories, Inc. (Zwanenburg, The Netherlands). Collagenase 1200 units/mg and trypsin inhibitor were products of Sigma Chemical Co. (St. Louis, MO).

Animals. Male rabbits of the Chincilla breed, weighing 2.5–3 kg, were used. All rabbits were kept individually in stainless steel cages with wire-mesh bases. In the first series of experiments, control animals were maintained on a standard laboratory rabbit chow and, in addition, received vegetables. The experimental group (44 animals) received crystalline cholesterol mixed with vegetables (0.2 g/kg body weight per day). Vegetables were shredded and thoroughly mixed with crystalline cholesterol (6 g cholesterol/kg vegetable). Each animal received and ate 80–100 g of the mixture, according to body weight. Groups of rabbits hyperresponsive or hyporesponsive to dietary cholesterol were selected from the upper and lower sextiles of the plasma cholesterol concentrations after ten weeks of cholesterol feeding. Six animals from each group were used for the preparation of hepatocyte cultures. Blood samples were taken from the ear vein before killing, and samples of bile were collected from the gallbladder immediately after killing the animals. All samples were taken at the same time of the diurnal cycle (between 11 a.m. and 12 a.m.). In a second series of experiments, the group of rabbits (30 animals) with plasma cholesterol levels ranging from 19.3 to 235.7 mg/dL (average level, 66.1 ± 7.9 mg/dL) received standard laboratory chow and crystalline cholesterol mixed together with vegetables (0.2 g/kg body weight per day). After five days of feeding, blood samples were taken from the ear vein and the five

Abbreviations: B/E, apoprotein B and apoprotein E; FBS, fetal bovine serum; GLC, gas–liquid chromatography; HPTLC, high-performance thin-layer chromatography; MEM, Eagle's minimum essential medium; VLDL, very low density lipoprotein.

rabbits with the lowest plasma cholesterol concentration were designated as hyporesponders, and the five rabbits with the highest plasma cholesterol concentration were designated as hyperresponders. Then cholesterol was omitted from the diet, and both groups of rabbits received standard laboratory chow for one month. After this period, the plasma cholesterol levels in both groups were within control limits. Three animals from each group were killed and used for the preparation of primary hepatocyte cultures.

Preparation and culture of hepatocytes. Rabbit liver cells were isolated by perfusion with 0.05% collagenase and 0.005% trypsin inhibitor as described in detail elsewhere (15). The cells were plated in 100-mm dishes (3 or 6 dishes per animal) at a density of 2×10^5 cells/cm^2 and cultured in MEM supplemented with 10% FBS, 2 mM L-glutamine, kanamycin (100 μg/mL) and nonessential amino acids (1%) at 38°C in a 95% air/5% CO_2 atmosphere. The characteristics of primary cultures of rabbit hepatocytes have been described earlier (16). Cells were incubated for 24 h in MEM supplemented with 10% FBS, then for 24 h in MEM supplemented with 10% of control rabbit serum and then for 24 h in MEM without serum. Samples of the serum-free medium were analyzed.

Analytical methods. Bile acids in the culture medium and bile were quantitated with gas–liquid chromatography (GLC) using a 50-m SE-30 capillary column (Alltech Associates, Inc., Deerfield, IL) (17–19). Bile acids used as a standard for GLC were purchased from Calbiochem (La Jolla, CA). Allodeoxycholic acid was synthesized as described previously (20), and purified by preparative thin-layer chromatography. All bile acids were at least 98% pure as judged by GLC. Conjugated bile acids were extracted after isolation of a total lipid fraction (21) using a reverse-phase cartridge (Sepak C-18, Waters Associates, Milford, MA) according to Kempen *et al.* (22) and were separated by high-performance thin-layer chromatography (HPTLC) using chloroform/methanol/glacial acetic acid/water (15:5:1:1, by vol) as developing system. Densitometry (564) nm) on HPTLC plates was carried out after treatment with 10% phosphomolybdenic acid and subsequent bleaching of the background in ammonia vapor. Taurocholate, taurodeoxycholate and glycocholate were used as references. VLDL fractions secreted by the cells were isolated by preparative ultracentrifugation of the medium using an SW-55 rotor (Beckman Instruments, Palo Alto, CA) at 45,000 rpm for 18 h at 10°C. VLDL were collected from the centrifugation tubes at d < 1.006 g/mL (1 mL from the top). Neutral lipids of VLDL, plasma and cells were extracted according to Goldstein *et al.* (23), and individual lipid fractions were separated by HPTLC (silica gel plates; Merck, Darmstadt, Germany) with hexane/diethyl ether/acetic acid (70:30:2, by vol) as developing system. Triacylglycerols, free cholesterol and cholesteryl esters were quantitated by densitometry on the HPTLC plates (24,25) using an automated Camag HPTLC/TLC scanner (Muttens, Switzerland) connected to a recording integrator SP 4100 (Spectra Physics, Darmstadt, Germany). Each determination was compared with standard run using known amounts of cholesterol, triolein and cholesteryl oleate.

Plasma total cholesterol for selection of experimental groups was assayed enzymatically using the Total Cholesterol Kit (Medix, Helsinki, Finland) and the Chemistry Analyzer FP-901 (Labsystems, Oy, Finland). Ten μL of plasma or standard solution was combined with 1 mL of cholesterol enzymatic reagent and incubated at 37°C for 20 min. Absorbance at 500 nm was measured for each sample against a reagent blank.

Statistical analysis. Results were analyzed by Student's *t*-test and expressed as means ± SE of the mean. Values of $P < 0.05$ were considered significant.

RESULTS

Analysis of plasma samples by GLC showed that after 10 wk of cholesterol feeding mean cholesterol concentrations in the hyperresponsive group were 17 times higher than in the control group, whereas the hyporesponsive rabbits showed only insignificant increase in cholesterol levels (Table 1). Esterification of plasma cholesterol was significantly increased in the hyperresponsive rabbits, which is typical for alimentary hypercholesterolemia in rabbit (26).

The bile acid composition of rabbit gallbladder bile is shown in Table 2. Secondary bile acids, *i.e.,* deoxycholic acid, allodeoxycholic acid and a small amount of lithocholic acid, were the predominant biliary bile acids. Primary bile acids, *i.e.,* cholic acid and traces of chenodeoxycholic acid, were also present. The mean biliary bile acid concentrations were similar in all groups. Yet, there was a tendency toward an increase in cholic acid concentration in the hyporesponsive group.

There was no significant difference in plating efficiency of hepatocytes obtained from animals of the three experimental groups. The viability of hepatocyte monolayers after 24 h in culture was determined as described earlier (27), and was greater than 90%. The free cholesterol and, particularly, the cholesteryl ester contents of hepatocytes

of the hyperresponsive animals were significantly higher (by 26 and 102%, respectively) than those of control cells (Table 3). In contrast, only cholesteryl ester content was slightly increased in cells of hyporesponders. It is noteworthy that the triacylglycerol content was decreased in the hyperresponsive group.

In agreement with previous studies (11), cholic acid was the major primary bile acid in the hepatocytes culture medium, while the amount of chenodeoxycholic acid was small. In addition, the presence of traces of secondary bile acids, deoxycholic, lithocholic and ursodeoxycholic acids could be detected. Figure 1 shows the time-course of primary bile acid accumulation in medium and cells in rabbit primary monolayer hepatocyte cultures over a period of 30 h. The cholic acid and chenodeoxycholic acid concentrations in the medium increased at a constant rate for 30 h, and only 1-5% of the amount was associated with the hepatocytes during this period. The data demonstrate that under our experimental conditions secretion of *de novo* synthesized primary bile acids does occur, that secretion of bile acids previously absorbed from the serum is very small and that bile acid content in culture medium mainly reflects bile acid biosynthesis by the hepatocytes.

Cholic acid production comprised more than 90% of total bile acid production in each group. After ten weeks of cholesterol feeding, the production of cholic acid by hepatocytes from the hyporesponsive rabbits was twofold higher than that from the hyperresponsive animals (Table 4), while the values for the latter group were within the control limits. In contrast to cholic acid, secretion of VLDL cholesteryl esters by hepatocytes was increased in the hyperresponsive group. In the hyporesponsive group, secretion of VLDL cholesteryl ester was only moderately enhanced and was accompanied by a proportional increase in VLDL triacylglycerol secretion. Secretion of free cholesterol tended to increase in both cholesterol-fed groups.

To test the hypothesis that observed differences in bile acid production between hypo- and hyperresponsive animals were induced by prolonged cholesterol intake, groups of hypo- and hyperresponsive rabbits were selected after five days of cholesterol feeding (see Materials and Methods). After these five days the plasma cholesterol level of the hyporesponsive rabbits was essentially unchanged, whereas in hyperresponsive rabbits it was increased 2.1-fold (Table 5). Hepatocytes were isolated from the liver of hypo- and hyperresponders after one month of feeding the low cholesterol diet. Bile acid production

by primary hepatocytes was measured by HPTLC to determine whether there was any difference between these two groups in the production of glyco- and taurocholic conjugates. Table 6 shows that the production of both taurocholic and glycocholic acids was significantly increased in the hyporesponsive group as compared to the hyperresponsive group (1.5- and 2-fold, respectively). The difference in taurocholic/glycocholic acid ratio was not statistically significant. The results suggest that differences in the rate of bile acid production are not due to prolonged cholesterol intake.

DISCUSSION

The mechanisms responsible for the large differences in the response of plasma cholesterol levels to dietary cholesterol intake have been investigated in many animal and human studies (1-7, 28-30). It has been shown that there is a small but significant increase in cholesterol absorption efficiency in hyperresponsive rabbits as compared to hyporesponsive ones (5,6). In addition, in some human populations cholesterol absorption efficiency was shown to correlate with plasma cholesterol levels (31). At the same time it was found that in low-responders, cholesterol feeding significantly increased fecal excretion of bile acids. In hyperresponders this increase was either not observed or was insignificant (4-6). These results suggest that effective oxidation of absorbed cholesterol to bile acids, as well as decreased cholesterol absorption, could explain resistance to increased dietary cholesterol intake.

The present study showed for the first time that primary hepatocytes of hyporesponsive rabbits produce significantly higher amounts of bile acids as compared to control and hyperresponsive animals. The observed tendency toward an increase in cholic acid concentration in the hyporesponsive group apparently reflects a higher rate of synthesis. However, we found that the concentrations of secondary bile acids were the same in the bile of hypo- and hyperresponsive rabbits. It seems possible that increased production of bile acids in hyporesponders is balanced by increased fecal loss. Recently it has been shown that fecal loss of bile acids is increased in hyporesponsive rabbits (5). The results of the second series of experiments demonstrate that the difference in bile acid production between hypo- and hyperresponsive animals is not induced by prolonged cholesterol feeding and suggest that the differences that are seen between the experimental groups of animals existed before the cholesterol challenge.

It is known that the rate of bile acid production is dependent upon the activity of 7α-hydroxylase and that enhanced production, as a rule, is the result of increased enzyme activity. It seems probable that the low level of bile acid production in hyperresponders may be related to the low activity of 7α-hydroxylase. This would agree with the finding that the activity of 7α-hydroxylase is considerably lower in hyperresponsive pigeons than hyporesponsive ones (32). The cause for the different activity of 7α-hydroxylase in hyper- and hyporesponsive animals remains unclear. It is generally assumed that the rate of bile acid synthesis is regulated by bile acids returning to the liver *via* the portal vein. Recently, in rats and rabbits it was found that different bile acids suppress bile acid synthesis and 7α-hydroxylase activity to different extents (33-35). Therefore, the activity of this enzyme and rate of bile acid production can be linked to the composition of the existing bile acid pool. However, the similar bile acid compositions of gallbladder bile in hypo- and hyperresponsive animals (Table 2) suggest that this explanation is not valid in the present case.

Liver cells from hypercholesterolemia-resistant rabbits appear to show an altered cholesterol metabolism, as compared to normal animals (36). Liver membranes prepared from resistant animals have increased activity of apoprotein B and apoprotein E (B/E) receptors and 3-hydroxy-3-methylglutaryl coenzyme A (HMG-CoA) reductase and decreased acyl-coenzyme A:cholesterol acyltransferase activity both during cholesterol feeding and on a low-cholesterol diet. The resistant animals maintain a low intracellular cholesterol concentration, and it was suggested that the liver cells in these animals are able to degrade cholesterol by an undefined mechanism (36). Our data suggest that this mechanism is the oxidation of excess cholesterol to bile acids and that decreased bile acid production contributes to the accumulation of free and esterified cholesterol in hepatocytes of hyperresponsive rabbits. According to previous studies (8-10), an increase in the cellular cholesteryl ester pool was accompanied by stimulated secretion of cholesteryl ester in VLDL. While hepatocytes of hyporesponsive rabbits secreted moderately increased amounts of VLDL neutral lipids, hepatocytes of hyperresponsive rabbits secreted significantly increased amounts of total cholesterol and cholesteryl ester. Because cholesterol accumulation in cells inhibits the activity of B/E receptors, our data could explain the low B/E receptor activity found in the liver of hyperresponders (30,36). Decreased activity of B/E receptors and an increased rate of lipoprotein cholesterol secretion could account for the rapid accumulation of cholesterol in the blood of hyperresponsive rabbits.

The present studies demonstrate that the rate of bile acid production in hyperresponsive rabbits is significantly lower than in the hyporesponsive rabbits. Prolonged cholesterol feeding induces significant increase in secretion of VLDL free and esterified cholesterol in hyperresponders; in contrast, only a slight increase in secretion of VLDL cholesteryl esters is observed in hyporesponders. These data suggest that, in rabbits, a defect in the elimination of cholesterol from the body in the form of bile acids could contribute to the development of hypercholesterolemia.

ACKNOWLEDGMENT

We wish to thank Pia Hoffstrom for excellent technical assistance with the GLC procedures.

Mouse Alveolar Surfactant: Characterization of Subtypes Prepared by Differential Centrifugation

M. Oulton[a,*], J. MacDonald[a], D.T. Janigan[b] and G.T. Faulkner[c]

Departments of [a]Obstetrics/Gynecology and Physiology/Biophysics, [b]Pathology and [c]Microbiology, Dalhousie University, Halifax, Nova Scotia, B3H 4H7 Canada

To characterize the properties of alveolar surfactant subfractions obtained from mouse lung by differential centrifugation, lavage fluid, following a preliminary centrifugation at 140 × *g* for 5 min to yield a cellular pellet (Pc), was sequentially centrifuged at 10,000 × *g* for 30 min, 60,000 × *g* for 60 min and 100,000 × *g* for 15 h; and the resultant pellets, respectively referred to as P10, P60 and P100, were harvested for electron microscopy, phospholipid analysis and surface tension measurements. Ultrastructural differences were observed, in that P10 contained large multilamellated structures which were typical of newly secreted surfactant, P100 contained small unilamellar vesicular structures, typical of catabolic end products of alveolar surfactant and P60 appeared to contain a mixture of structures present in P10 and P100 in addition to numerous, large unilamellar vesicles which were not present in either P10 or P100. Slight but significant differences were found in the phospholipid compositions of the three subfractions but not in the fatty acid composition of their phosphatidylcholine (PC) component. There were no significant differences in their disaturated PC/total PC ratios, but significant differences in their phospholipid/protein ratios. P60 had the highest proportion of phospholipid to protein. P10 and P60 demonstrated surface activity but P100 did not. Total alveolar surfactant phospholipid was evenly distributed among the three fractions. This pattern of distribution was significantly different from that observed in rabbit subfractions prepared by the same procedure. These data indicate that mouse alveolar surfactant consists of three distinct subfractions or subtypes which can be separately and quantitatively isolated by differential centrifugation. They also suggest that there may be species differences in the relative proportions of the individual subtypes present in normal adult lung.

***Lipids* 28, 715–720 (1993).**

Pulmonary surfactant is a phospholipid-rich material which lines the mammalian lung and functions to promote alveolar stability by reducing the surface tension at the air-alveolar interface (1,2). Surfactant is synthesized in the large alveolar Type II cell and stored in multilamellar intracellular vesicles (lamellar bodies) which are ultimately released to the alveolar space (3).

Recent evidence indicates that alveolar surfactant exists in at least three macromolecular forms, or subtypes, that can be separated on the basis of their sedimentation properties (4–9). Characterized according to their ultrastructure, surface properties and composition (see Refs. 10 and 11 for reviews), labelling studies have suggested that these subtypes may be in metabolic sequence such that the larger, heavier subtypes, which consist of multilamellated structures and tubular myelin figures, constitute a newly secreted form of alveolar surfactant, whereas the smaller, ligher subtypes, which consist of small unilamellar vesicular structures, appear to be catabolic end products of the secreted material and thus represent a used or "spent" form of alveolar surfactant. Current evidence suggests that this catabolic end product may ultimately be taken up and reutilized by the Type II cell for new lamellar body production (12–14).

In considering the entire "life cycle" of the pulmonary surfactant, the processes controlling synthesis, secretion and re-uptake have been the most thoroughly studied (11). Recent interest has focused on the intra-alveolar processing or metabolism of the secreted surfactant particularly, as it is becoming increasingly apparent that these processes may be drastically altered in certain pathological conditions involving lung injury (15–18). However, as the number of studies reported to date has been somewhat sparse (4,9,15–20), our current knowledge of this topic is still rather limited.

One part of the problem is the lack of uniformity among investigators in the preparation of the subfractions for analysis. In earlier studies, done primarily on rabbits (4,6) and rats (7), stepwise differential centrifugation schemes were used. Though there was some variation in the precise scheme used, there appeared to be species differences in the pattern of distribution of phospholipids over the subfractions. In the rabbit, for example, the bulk of the phospholipid was recovered in the pelleted fractions, whereas in the rat, large amounts of phospholipid were recovered in the final supernatant fraction. This suggests the possibility of species variation in the relative rates of subtype conversion and/or uptake, an important point to consider in attempting to understand the entire surfactant "life cycle" not only in the normal lung but in the diseased lung as well.

The mouse provides a useful model for studying alveolar injury, having been used not only by ourselves (21) but by several other investigators as well (8,9,13,15). Though this model has been extensively studied by Gross and co-workers (8,9,14,15,16), this group did not use a differential centrifugation scheme to isolate the alveolar subfractions, but rather a somewhat more elaborate density gradient technique which requires the dropwise collection of fractions for characterization and analysis. This is not only time-consuming and cumbersome, but it also makes interspecies comparisons difficult. It would therefore be of value to develop a more convenient and equally consistent and reliable technique for isolating the individual subfractions in this model. The objective of this study was therefore to employ a differential centrifugation scheme to prepare alveolar surfactant subfractions from normal mouse lung, characterize the properties of the individual fractions and, where pertinent, make comparisons with fractions similarly prepared from healthy, adult rabbit lung.

MATERIALS AND METHODS

Random-bred, pathogen-free, Carworth Farms White, male mice, 8–9-weeks-old, were used in the study. Following an intraperitoneal injection of sodium pentobarbital, the lungs were lavaged with 0.85% NaCl in 4 × 1.0 mL aliquots, as described previously (22).

The lavage washings from 2–5 mice were pooled and, following a 5 min centrifugation at 140 × *g* to remove a cellular pellet (Pc), surfactant subfractions were obtained by sequential centrifugation at 10,000 × *g* for 30 min, 60,000 × *g* for 60 min and 100,000 × *g* for 15 h. The pellet subfractions are referred to as P10 (10,000 × *g* pellet), P60 (60,000 × *g* pellet) and P100 (100,000 × *g* pellet), respectively. The final (100,000 × *g*) supernatant is referred to as S100.

Following the lavage procedure, the lungs were removed and pooled (as indicated above for the lavage) for isolation of the tissue-stored surfactant (lamellar bodies) using a procedure involving differential and density gradient centrifugation as previously described (23).

Aliquots of each lavage fraction and lamellar body preparation were extracted with chloroform/methanol (2:1, vol/vol) for phospholipid analysis as described previously (23). Individual phospholipids were separated by two-dimensional thin-layer chromatography (TLC) as described elsewhere (24). Further aliquots were removed for analysis of disaturated phosphatidylcholine (PC) according to the method of Mason *et al.* (25) as previously described (26). For fatty acid analysis of PC and phosphatidylglycerol (PG), these two phospholipid classes were scraped individually from the TLC plate following two-dimensional TLC as described (24), and methyl esters of their fatty acyl chains were obtained by transesterification with 10% BF_3 in methanol (wt/vol) and extraction with petroleum ether (27).

The methyl esters were analyzed by gas–liquid chromatography as described by Cook (28).

Aliquots of each surfactant fraction were removed for protein analysis according to the procedure of Lowry *et al.* (29). To prevent interference from the lipid constituents, each sample was extracted with an equal volume of chloroform before reading the absorbance as previously described (30). Surface activity was assessed using the pulsating bubble surfactometer as described by Enhorning (31). For these measurements the concentration of each preparation was adjusted so that it contained 5 mg phospholipid/mL. In some experiments samples were fixed in 0.1 M cacodylate buffered 2.5% glutaraldehyde (pH 7.3) and processed for electron microscopy as described previously (18).

For comparative purposes, several adult male New Zealand white rabbits (weighing 2.0–2.5 kg) were used to prepare alveolar surfactant subfractions and lamellar bodies. With the exception that 50-mL aliquots were used for the lavage procedure, all other procedures were as described above. Only phospholipid analyses were performed on these fractions.

Statistical comparison of the results was performed using Student's *t*-test (32) or Duncan's new multiple range test (33). For the Duncan's test, an analysis of variance was performed before the test. The F value was significant to 5%.

RESULTS

Electron microscopy of the individual lavage fractions obtained from mouse lung revealed ultrastructural differences in the material sedimenting under the different centrifugal conditions used in this study (Fig. 1). As

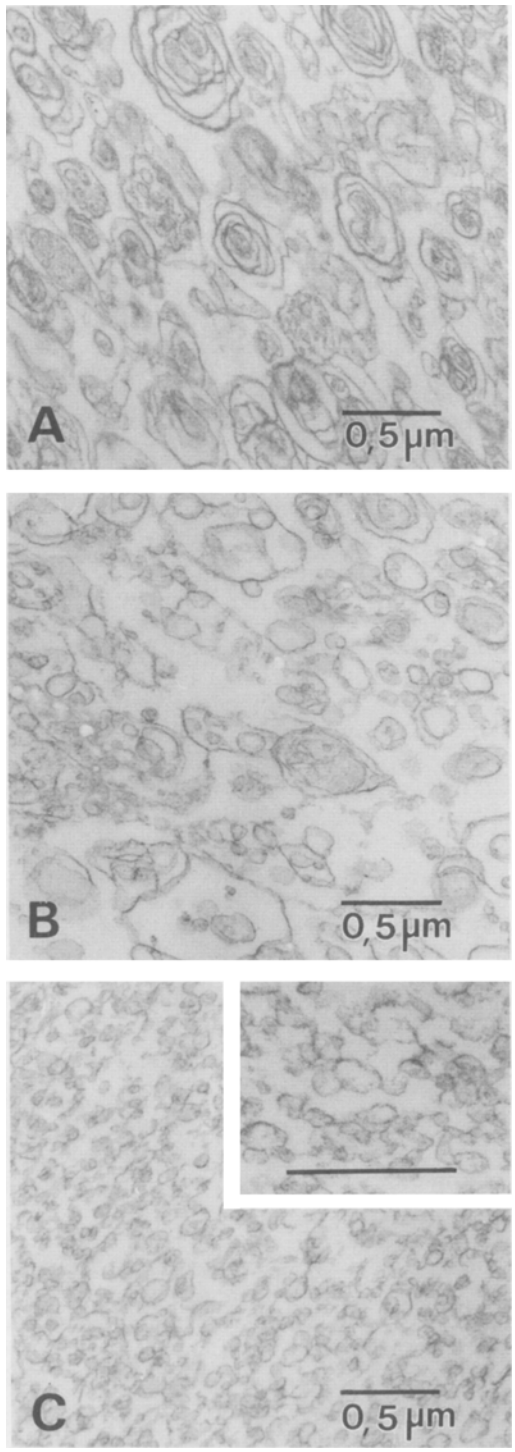

FIG. 1. Electron micrographs of mouse alveolar surfactant subfractions prepared as pellets by sequential centrifugation of lavage returns at (A): 10,000 × *g* for 30 min (P10); (B): 60,000 × *g* for 60 min (P60); and (C): 100,000 × *g* for 15 h (P100) following a preliminary centrifugation for 5 min at 140 × *g* to remove a cellular pellet. Magnification: A × 26,250; B × 26,250; C × 26,250 (inset × 48,750).

TABLE 1

Surface Activity of Mouse Surfactant Subfractions[a]

Fraction	n	γ Max.	γ Min.	Time to reach γ min. (s)
P10	4	37.4 ± 6.7	1.8 ± 3.4	0
P60	2	45.2[b]	7.4[c]	420
P100	3	54.3 ± 12.1	16.6 ± 3.4	317 ± 75
Lamellar bodies	5	37.7 ± 2.5	2.7 ± 1.7	10 ± 5

[a]Alveolar subfractions were prepared by sequential centrifugation of mouse lung lavage as described in the legend to Figure 1, and lamellar bodies by a procedure of differential and density gradient centrifugation as previously described (Ref. 23). Each sample contained 5.0 mg phospholipid/mL. γ, Surface tension (mN/m) as measured by pulsating bubble technique; γ max., surface tension at maximum bubble radius (0.55 mm); γ min., surface tension at minimum bubble radius (0.25 mm); each value represents the mean ± 1 SD for the number of determinations shown.
[b]Individual values: 45.8, 44.5.
[c]Individual values: 4.9, 9.8.

TABLE 2

Phospholipid/Protein Ratio of Mouse Alveolar Surfactant Subfractions[a]

Fraction	μmol Phospholipid/mg protein[b]
Lavage fluid	1.108 ± 0.299
Pc	0.536 ± 0.222
P10	3.205 ± 0.697[c]
P60	7.463 ± 1.509[c]
P100	4.403 ± 0.614[c]
S100	0.080 ± 0.062

[a]Fractions P10, P60 and P100 were prepared as described in the Legend to Figure 1. Pc represents the cellular pellet and S_{100} the final supernatant fraction obtained following the 15-h centrifugation at 100,000 × *g*.
[b]Each value represents the mean ± 1 SD for five determinations.
[c]Significantly different from unfractionated lavage fluid and each of the individual subfractions ($P < 0.01$ by Duncan's Multiple Range Test).

indicated, P10 (Fig. 1A), which represents the most easily sedimentable subfraction, consisted mainly of multilamellated structures typical of newly-released surfactant while P100 (Fig. 1C), which represents the least easily sedimentable subfraction, consisted of much smaller unilamellar vesicular structures typical of catabolic forms of P10. P60 was less easily defined. Although it appeared to contain structures which were present in both P10 and P100, it also contained many large unilamellar vesicles which were not found in either P10 or P100. Also of interest is that the membranes of the structures present in P100 were much more diffuse than those in either P10 or P60. Not enough material was present in Pc for electron microscopy.

Differences were also observed in the surface properties of the surfactant subfractions (Table 1). Of the alveolar subfractions only P10 and P60 could be regarded as being surface active, in that they both reduced the surface tension to less than 10 mN/m, with P10 being more surface active than P60 in that it reduced the surface tension to lower values and in less time. In this regard the surface activity profile of P10 was similar to that of the isolated lamellar body fractions.

The phospholipid/protein ratios of the individual pellet subfractions obtained from the mice were significantly different from each other (Table 2). Each was also significantly different from that of the unfractionated lavage fluid, the cellular pellet and the final resultant supernatant fraction (S100). Of all the pellet subfractions, P60 had the highest ratio of phospholipid to protein. There were small but significant differences in the phospholipid composition of the mouse alveolar surfactant subfractions (Table 3) in that P100 contained relatively more PC than P10 and P60 and slightly less PG and phosphatidylethanolamine (PE) than P10. In a previous report (18) we found that the cellular pellet contained somewhat less (approximately 70% of the total lipid phosphorus) PC than is reported here for the surfactant subfractions, as well as up to 5% lysophosphatidylcholine, a phospholipid not present in the surfactant subfractions.

No significant differences were found in the disaturated PC/total PC ratio of the individual surfactant subfractions obtained from mouse lung. These values were 0.569 ± 0.033, 0.589 ± 0.022, 0.566 ± 0.025 and 0.597 ± 0.027 (n = 6) for P10, P60, P100 and S100, respectively. Not enough material was available for analysis of Pc.

No significant differences were found in the PC fatty acyl composition of the alveolar surfactant subfractions (Table 4). Palmitic acid (16:0) was the most abundant fatty acid for all three subfractions. Although this fatty acid also constituted the most abundant species in the isolated lamellar bodies, it was slightly but significantly reduced in comparison to the alveolar subfractions. Oleic acid (18:1) was slightly higher in lamellar bodies than in the alveolar surfactant subfractions.

Only a few samples were available for PG fatty acyl analysis. As with PC, the most abundant fatty acid

TABLE 3

Phospholipid Composition of Mouse Alveolar Surfactant Subfractions[a]

Fraction	Number of determinations	Percent of total lipid phosphorus[b]						
		PC	PG	PI	PS	SM	PE	X
P10	5	81.2 ± 0.8	13.0 ± 0.4	1.8 ± 0.2	0.5 ± 0.1	0.2 ± 0.5	2.4 ± 0.5	0.9 ± 0.6
P60	3	81.8 ± 0.7	11.7 ± 1.2	1.8 ± 0.1	1.5 ± 1.2	0.4 ± 0.4	2.1 ± 0.4	0.6 ± 0.5
P100	5	83.8 ± 0.7[c]	11.4 ± 0.8[d]	1.7 ± 0.6	0.7 ± 0.5	0.2 ± 0.3	1.4 ± 0.4[d]	0.8 ± 0.7

[a]Fractions were prepared as pellets by sequential centrifugation of alveolar lavage returns as described in the legend to Figure 1.
[b]Each value represents the mean ± 1 SD for the number of determinations shown. Phospholipids include: PC, phosphatidylcholine; PG, phosphatidylglycerol; PI, phosphatidylinositol; PS, phosphatidylserine; SM, sphingomyelin; PE, phosphatidylethanolamine; X, unidentified phospholipid.
[c]Significantly different from P10 and P60 ($P < 0.05$ by Duncan's Multiple Range Test).
[d]Significantly different from P10 ($P < 0.05$ by Duncan's Multiple Range Test).

TABLE 4

Phosphatidylcholine Fatty Acyl Composition of Mouse Surfactant Subfractions[a]

Fatty acid	P10 (3)	P60 (3)	P100 (3)	Lamellar bodies (5)
14:0	3.3 ± 0.6	3.2 ± 0.3	3.4 ± 0.3	3.1 ± 0.7
16:0	76.7 ± 5.3	74.8 ± 4.4	73.8 ± 4.8	67.0 ± 4.9[b]
16:1	12.8 ± 5.9	14.6 ± 2.6	13.7 ± 0.4	19.3 ± 4.2
18:0	1.2 ± 0.3	1.3 ± 0.5	1.0 ± 0.0	1.8 ± 0.7
18:1	3.8 ± 0.3	3.5 ± 0.8	3.6 ± 0.5	4.9 ± 0.6[b]
18:2	2.1 ± 0.5	2.3 ± 0.9	2.1 ± 0.8	2.9 ± 0.6
Other[c]	0.2 ± 0.3	0.1 ± 0.2	2.3 ± 0.6	0.9 ± 0.5

[a]Alveolar subfractions (P10, P60, P100) were prepared as described in Table 2. Lamellar bodies were prepared from the post-lavage lung tissue. The results are expressed as percentage by weight (± 1 SD) of the total fatty acid methyl esters. Fatty acid methyl esters were identified by reference to known methyl ester standards.
[b]Significantly different from alveolar subfractions ($P < 0.05$ by Duncan's Multiple Range Test).
[c]Contains 20:4 and other unidentified long chain constituents.

TABLE 5

Phosphatidylglycerol Fatty Acyl Composition of Mouse Surfactant Subfractions[a]

Fatty acid	P10 (2)	P60 (2)	P100 (3)	Lamellar bodies (5)
14:0	0.5 ± 0.6	4.2 ± 2.0	1.2 ± 1.0	2.3 ± 1.5
16:0	57.3 ± 6.2	56.9 ± 9.6	58.1 ± 4.7	53.8 ± 3.4
16:1	8.5 ± 1.6	6.0 ± 2.8	5.1 ± 3.4	6.8 ± 2.6
18:0	5.1 ± 1.2	7.5 ± 3.5	4.8 ± 1.4	4.6 ± 1.5
18:1	19.8 ± 2.4[b,c]	12.7 ± 2.1	17.6 ± 1.3[c]	15.8 ± 1.4
18:2	8.2 ± 2.5	6.3 ± 3.0	7.9 ± 0.6	8.8 ± 1.3
Other[d]	0.8 ± 1.1	6.5 ± 1.8	5.4 ± 0.5	8.0 ± 4.1

[a]Alveolar subfractions and lamellar bodies were prepared as indicated in Table 3. Expression of results and statistical analysis are also as described for Table 3.
[b]Significantly different from lamellar bodies.
[c]Significantly different from P60.
[d]Includes 20:4 and other unidentified long chain constituents.

TABLE 6

Phospholipid Distribution over Alveolar Surfactant Subfractions: Mouse *vs.* Rabbit[a]

Fraction	% Total alveolar lavage phospholipid[b]	
	Mouse	Rabbit
Pc	10.9 ± 3.5	9.7 ± 4.5
P10	26.6 ± 3.2	48.4 ± 9.9[c]
P60	24.0 ± 4.6	12.9 ± 6.1[c]
P100	27.1 ± 2.4	20.9 ± 10.1
S100	11.3 ± 2.0	8.1 ± 4.2

[a]Alveolar surfactant subfractions, pellets, P10, P60, P100, and the resultant supernatant, S100, were prepared as described in the legend to Figure 1; following a preliminary centrifugation for 5 min at 140 × *g* to harvest a cellular pellet (Pc).
[b]Each value represents the mean ± 1 SD for six determinations in mice and seven in rabbits.
[c]Significantly different from mouse ($P < 0.01$ by Student's *t*-test).

esterified to PG in both the alveolar subfractions and the isolated lamellar bodies was 16:0 (Table 5), although its relative proportion of the total fatty acids was considerably less for PG than for PC. Although 18:1 constituted a minor PC fatty acid, it appeared to represent the second most abundant PG fatty acid. Of the samples analyzed, P60 appeared to contain the least amount of this fatty acid.

The total phospholipid content of unprocessed mouse alveolar lavage fluid was 1083.4 ± 69.9 μg/g lung, of which 88.2 ± 4.0% could be accounted for following fractionation. For rabbits, these values were 1263.6 ± 260.6 μg phospholipid/g lung and 87.3 ± 4.5% recovery. The quantity of phospholipid recovered in the individual subfractions was consistent in both species. However, significant differences were found between the two species in the pattern of distribution of phospholipid over the individual subfractions (Table 6). The cellular pellet comprised approximately 10% of the total recoverable phospholipid in both species and the lavage 100,000 × *g* supernatant (S100) another 10%, but in the mouse the sedimentable surfactant phospholipid was more or less evenly distributed over the remaining individual subfractions, whereas in the rabbit almost 50% of the total recoverable phospholipid was present in the most easily sedimentable subfraction, P10, with less than 15% in the intermediate fraction, P60.

DISCUSSION

Previous studies in rats (7) and rabbits (4,6) have shown that pulmonary surfactant obtained from alveolar lavage can be separated by differential centrifugation into subtypes or subfractions that have distinctive morphologies as well as different compositions, surface properties and labelling patterns. Though a variety of centrifugation schemes have been employed to isolate these subfractions, it can nevertheless be generalized that the most easily sedimented fractions, obtained as pellets by using g forces up to 10,00 × *g*, consist of large multilamellated structures which are typical of newly or recently secreted lamellar bodies, whereas the most difficult to sediment fractions, requiring g forces up to 100,000 × *g* for as long as 15 h, consist of much smaller unilamellar vesicles which are believed to represent catabolic end products of the secreted surfactant; and that pelleted material obtained under centrifugal conditions intermediate between these extremes contains intermediate metabolic forms of the alveolar surfactant (for a review, see Ref. 10).

In our laboratory we have recently adopted a three-step differential centrifugation scheme for the study of alveolar surfactant subfractions in fetal, newborn and adult rabbits. After an initial 5-min centrifugation to remove a cellular pellet, this scheme involves: (i) a 30-min centrifugation at 10,000 × *g*, which we had previously found to pellet virtually all of the large multilamellated structures typical of newly secreted surfactant present in fetal and newborn lung (23); (ii) a 60-min centrifugation at 60,000 × *g*, which has been shown by other investigators to harvest intermediate alveolar surfactant forms (4,6,7); and (iii) a 15-h centrifugation at 100,000 × *g* to harvest the small unilamellar vesicles which are present in newborn and adult (4,6), but not fetal (5,6,23), lung. By applying this fractionation scheme to lavage fluid obtained from

adult mice, we were able to identify at least two morphologically distinct subfractions, namely, the large multilamellar vesicles present in the 10,000 × *g* pellet (P10) and the small unilamellar vesicles present in the 100,000 × *g* pellet (P100). Both of these fractions were characteristically similar to those described by ourselves (23) and others for rabbits (4,6) and rats (7) using appropriately comparable conditions of centrifugation. The fraction which we designate as P60 is less well defined than P10 and P100. It appears to contain a mixture not only of the structures found in P10 and P100, but also of structures which are not present in either of these two subfractions. Another distinguishing feature of P60 is its phospholipid/protein ratio, which is significantly greater than that of any of the other subfractions. These observations suggest that P60 may indeed be distinct from the other two pellet fractions and it may, in fact, represent a metabolic form that is intermediate between them. This would be in agreement with previously reported findings in other species (4,6,7).

An interesting observation along this line is a recent finding (to be reported in a separate communication) in our laboratory that smoke exposure, which had previously been shown to increase the total alveolar surfactant phospholipid pool nearly twofold (21), had no effect on the phospholipid content of this P60 pellet but significantly increased the other lavage subfractions. This suggests the possibility of an important regulatory role for this intermediate fraction in the alveolar processing of secreted surfactant. This concept is supported by the recent studies of Gross (15,16), which suggest that the generation of this subfraction may be catalyzed by an enzyme, which this referred to as convertase.

The latter studies have also isolated and identified three alveolar surfactant subtypes in mouse lavage fluid. It was shown that these subtypes were in metabolic sequence and that metabolic conversions from one form to another could be induced *in vitro* (9). The subtype referred to as "light" would correspond to our P100 subfraction, whereas the fractions designated as "ultra heavy" and "heavy" would correspond to our P10 and P60 subfractions. One difference between our studies and those of Gross and Narine (8,9) is that they found tubular myelin figures in their "ultra heavy" and "heavy" subfractions, whereas we did not find these figures in any of our subfractions. The absence of tubular myelin could be due to structural rearrangement during the isolation procedure (34) or the absence of calcium ions, which might be required to preserve these structures (35), from the lavage and isolation procedures. Another possibility is that these structures were present in the low-speed pellet (Pc) which we did not examine by electron microscopy. The major difference between our study and that of Gross and Narine (8,9) is that they employed a technique involving centrifugation to equilibrium on continuous sucrose gradients, a somewhat more tedious and time-consuming (requiring 60 h to reach equilibrium) procedure than the differential centrifugation scheme used for the present study. It also makes interspecies comparisons difficult, given that most reported studies have employed a stepwise differential centrifugation scheme to prepare individual subtypes or subfractions (4,6,7).

In the present study in which we applied the same isolation technique to lavage samples obtained from both adult mice and rabbits, we found highly reproducible and consistent phospholipid recoveries in the individual surfactant subfractions obtained from both species. The difference in distribution of phospholipid over the subfractions in the two species suggests that there may be species differences in the rates of subtype conversion and/or uptake. The low levels of P10 present in mice, which is in agreement with previous findings of Gross and Narine (8) in mice and Spain *et al.* (7) in rats, in comparison to the much higher levels present in the rabbit, as reported in this and other (4,6,18) studies suggests that the first step in the metabolic processing of the newly secreted surfactant may occur more readily in murine than in rabbit lung. Whether or not this could be due to inherent properties of the surfactants is not known. There are only slight interspecies differences in the overall phospholipid composition and fatty acyl composition of some of the individual phospholipids, as shown in this and other (4,8) reports. However, the interspecies differences observed in SP-A (36,37), the major surfactant-specific protein, which has been suggested to play a role in the unwinding of newly-released surfactant, could possibly contribute to this effect. Another surfactant-associated protein which may contribute to this effect is the newly-identified SP-D (38), which has recently been shown to counteract the effects of SP-A (39) and appears to be differentially distributed among the lavage subfractions in at least two species (rat and bovine) studied to date (40). Studies are in progress in our laboratory to investigate these possibilities.

The differences that we and others (4,8) observed in the surface activity among the three alveolar surfactant subtypes might also be attributable to differences in composition. While there are only slight differences in the phospholipid composition of these fractions in both mice and rabbits (4,8) there appear to be differences in protein composition. For example, it has been shown (4–6) that the least surface-active fraction obtained from rabbits, which is comparable to our P100 subfraction, is virtually devoid of SP-A, which, in addition to its function discussed above, has been purported to play at least an ancillary role in the expression of surface activity (for a review, see Ref. 37). Preliminary studies in our laboratory suggest the absence of SP-A not only from the P100 subfraction but also from P60. The surface activity of the latter fraction might thus be attributable to its high proportion of phospholipid to protein as observed in the present study. Further studies are required to clarify these issues.

In summary, we have identified three subfractions or subtypes of mouse alveolar surfactant that can be quantitatively and reproducibly harvested by a three-step differential centrifugation scheme. These preliminary studies provide us with an excellent model for extensively studying surfactant metabolism in this species. We have also demonstrated differences in the distribution of phospholipids over these subfractions obtained from the mouse and rabbit, suggesting the possibility of interspecies differences in the rates of conversion and/or uptake of secreted surfactant.

ACKNOWLEDGMENTS

This work was supported by grants from the medical Research Council of Canada (MT 5908) and the Nova Scotia Lung Association. The technical expertise of Marlene Fraser and Margery Dolphin is grate-

fully acknowledged. We are also grateful to Drs. Harold Cook and Susan Powell for their assistance with the fatty acid analysis and the use of their GLC equipment.

The Role of Arginines in Stabilizing the Active Open-Lid Conformation of *Rhizomucor miehei* Lipase

Mats Holmquist, Martin Norin and **Karl Hult***
Department of Biochemistry and Biotechnology, Royal Institute of Technology, S-100 44 Stockholm, Sweden

Molecular dynamics simulations for the lid covering the active site of *Rhizomucor miehei* lipase [EC 3.1.1.3] postulated that, among other interactions, Arg86 in the lid stabilized the open-lid conformation of the protein by multiple hydrogen bonding to the protein surface. Chemical modification of arginine residues in *R. miehei* lipase with 1,2-cyclohexanedione or phenylglyoxal resulted in residual activities in the hydrolysis of tributyrin of 66 and 46%, respectively. Tryptic maps of native and phenylglyoxal-reacted *R. miehei* lipase showed that Arg86 was the residue modified most, when the lipase was inhibited to the greatest extent. Guanidine, a structural analog to an arginine side chain, inhibited both the native enzyme and the arginine-modified enzymes, resulting in residual activities of 26% as compared to the native enzyme. The inhibition was not an effect of enzyme denaturation. The native enzyme was also inhibited by 1-ethylguanidine, benzamidine and urea, but to a lesser degree than by guanidine. Lipases from *Humicola lanuginosa* and porcine pancreas in 100 mM guanidine showed residual activities of 88 and 70%, respectively. The lipases from *Candida antarctica, C. rugosa, Pseudomonas cepacia* and *P. fluorescens* were not inhibited by guanidine. The inhibition of *R. miehei* lipase by structural analogs of the arginine side chain and after chemical modification of arginine residues suggest a role of an arginine residue in stabilizing the active open-lid conformation of the enzyme.
***Lipids 28,* 721–726 (1993).**

Lipases [EC 3.1.1.3] need the hydrophobic interface formed by their water insoluble ester substrates to express full catalytic activity in hydrolytic systems (1–3). The interfacial activation has been proposed to be due to a conformational change in the enzyme (2,4). The three-dimensional structures of the lipases from *Rhizomucor miehei* (5), human pancreas (6) and *Geotrichum candidum* (7) have been published. These enzymes all have an active site hidden under a lid which must be displaced to expose the active site of the enzyme to the substrate. The three-dimensional structures of two *R. miehei* lipase-inhibitor complexes have been solved, showing the displacement of the lid (8,9). In these complexes the lid exposes its hydrophobic side to the substrate, and its hydrophilic side is buried in a polar cavity of the enzyme (8,9). Asn87 in the lid has been shown to form new interactions with the polar cavity when the lid is open (9). Other polar residues in the lid might also stabilize the active open-lid conformer of the enzyme.

In this paper we report the effects of chemical, arginine-specific modifications of *R. miehei* lipase and the results of inhibition studies with structural analogs to the side chain of arginine.

MATERIALS AND METHODS

Chemicals. Tributyrin, dithiothreitol, bovine serum albumin, 2-{[2-hydroxy-1,1-*bis*(hydroxymethyl)ethyl]amino}-ethanesulfonic acid (TES) and gum arabic were purchased from Sigma (St. Louis, MO). 1,2-Cyclohexanedione, phenylglyoxal, guanidine hydrochloride, 1-ethylguanidine hydrochloride, benzamidine hydrochloride hydrate, iodoacetamide, trichloroacetic acid and trifluoroacetic acid (spectrophotometric grade) were from Aldrich-Chemie (Steinheim, Germany). [7-^{14}C]Phenylglyoxal with a specific activity of 855 KBq/mol was obtained from Amersham (Buckinghamshire, England). Urea, ammonium bicarbonate and calcium chloride were obtained from Merck (Darmstadt, Germany). All chemicals used were of analytical grade.

Enzymes. Highly purified lipase [EC 3.1.1.3] from *R. miehei* (7800 units/mg), *Humicola lanuginosa* (5400 units/mg), *Pseudomonas cepacia* (3400 units/mg), *Candida antarctica* A (180 units/mg) and *C. antarctica* B (340 units/mg) were generous gifts from Novo Nordisk A/S (Bagsvaerd, Copenhagen, Denmark). No contaminants could be detected in the *R. miehei* lipase after sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS–PAGE) analysis. One unit of lipase produces 1 μmol butyric acid per minute from tributyrin at pH 7.0 at 25°C.

Commercial lipase from *C. cylindracea* (recently reclassified as *C. rugosa*) [1010 units/mg solid (7770 units/mg protein)] and porcine pancreas [53 units/mg solid (143 units/mg protein)] were obtained from Sigma. These enzymes were purified from insoluble material by collecting the supernatant after centrifugation of crude enzyme dissolved in 10 mM TES, pH 7.5. One unit of lipase splits off 1 μmol of fatty acid from olive oil in one hour at 37°C and pH 7.2 *(C. rugosa)* or pH 7.7 (porcine pancreas).

Lipase from *P. fluorescens* (31.5 units/mg) was purchased from Fluka (Buchs, Switzerland). One unit of lipase liberates 1 μmol oleic acid per minute from triolein at pH 8.0 and 40°C.

Trypsin [EC 3.4.21.4] (sequencing grade) was obtained from Boehringer Mannheim GmbH (Mannheim, Germany).

Enzyme activity assay. The substrate solution containing tributyrin (0.10 M), calcium chloride (0.10 M) and gum arabic (5%, wt/vol) in water, was emulsified by sonication for one minute. The pH was adjusted to 7.0 with sodium hydroxide (100 mM). The solution (2.0 mL) was equilibrated for 2 min in a stirred, thermostatted pH-stat cuvette at 25°C. The enzyme (*R. miehei* 11–17 μg/mL, *H. lanuginosa* 54 μg/mL, porcine pancreas 50 mg/mL,

Abbreviations: CD, circular dichroism; DHB, 2,5-dihydroxy-benzoic acid; HPLC, high-performance liquid chromatography; LDMS, laser desorption mass spectrometry; PDMS, plasma desorption mass spectrometry; SDS–PAGE, sodium dodecyl sulfate polyacrylamide gel electrophoresis; TES, 2-{[2-hydroxy-1,1-*bis*(hydroxymethyl)ethyl]-amino}ethanesulfonic acid; UV, ultraviolet.

C. antarctica A 0.40 mg/mL, *C. antarctica* B 0.22 mg/mL, *C. rugosa* 6.4 mg/mL, *P. cepacia* 35 μg/mL and *P. fluorescens* 2.3 mg/mL) was dissolved in 10 mM TES buffer, pH 7.5. The reaction was started by the addition of 50 μL enzyme solution to the stirred, thermostatted cuvette. The activity was determined under nitrogen using a Radiometer (Copenhagen, Denmark) pH-stat, equipped with an ABU91 autoburette (1 mL) connected to a VIT90 videotitrator. The pH was automatically maintained at 7.0 with sodium hydroxide (100 mM). The reactions were run for five minutes. In experiments with inhibitors, the inhibitor was added to both the substrate emulsion and the enzyme solution before the assay was performed. The coefficients of variation for the activity determinations were 3–8% (3–7 determinations on 8 samples) with the same substrate preparation and 1–18% (4–5 determinations on 3 samples) with different substrate preparations.

Modification of arginine residues. The *R. miehei* lipase [100 μM, $\varepsilon = 47000\ M^{-1}\ cm^{-1}$ at 280 nm (Novo-Nordisk A/S)] was incubated with 1,2-cyclohexanedione (30 mM) in 0.2 M sodium borate, pH 9.0, at 37°C (10) or the enzyme (4 μM) was treated with phenylglyoxal (3 mM) in 0.2 M sodium bicarbonate, pH 8.2, at 25°C (11). All reactions were performed in the dark. Under the conditions described, both 1,2-cyclohexanedione (10) and phenylglyoxal (11,12) are highly specific for arginine residues. Phenylglyoxal also reacts with free α-amino groups to give a residue of the corresponding α-keto acid as a side reaction (11). Reference lipase samples were treated and incubated as described above, omitting the modifying reagent. The reaction mixtures (1.0–1.7 mL) were incubated in an end-over-end incubator. Samples (50 μL) were removed for assay of enzymatic activity. The modified enzyme was purified from excess reagent by gel filtration through a PD-10 column (Sephadex® G-25 M, bed vol 9.1 mL, Pharmacia Biotechnology, Uppsala, Sweden) equilibrated with 10 mM TES, pH 7.5.

Stoichiometry of [7-^{14}C]phenylglyoxal to lipase. *R. miehei* lipase (4 μM) was incubated with [7-^{14}C]-phenylglyoxal (3 mM; specific activity 11 KBq/mol) under the same reaction conditions as described above, in a reaction volume of 100 μL. After the specified reaction time, bovine serum albumin (100 μL, 1 mg/mL, previously treated with a 500-fold molar excess of unlabeled phenylglyoxal) was added as a nonspecific protein carrier. The incorporation of [7-^{14}C]phenylglyoxal into *R. miehei* lipase was determined by precipitation of the protein by the addition of trichloroacetic acid (60 μL, 50% wt/vol). The precipitates were collected by centrifuging the mixture at 8000 × *g* for 30 min and washed (3 × 0.5 mL) with trichloroacetic acid (5% wt/vol). The pellets were resuspended in 8 M urea and transferred to scintillation vials, and the radioactivity was measured in 10 mL of Ready safe™ (Beckman Instruments Inc., Fullerton, CA). The instrument used was a Packard Tri-Carb® 1500 liquid scintillation analyzer (Downers Grove, IL).

Proteolytic digestion. Native (150 μg) or arginine-modified *R. miehei* lipase (150 μg) was dissolved in 50 μL 8 M urea and 0.4 M ammonium bicarbonate. Dithiothreitol (5 μL, 45 mM) was added, and the mixture was kept at 50°C for 15 min. After cooling to room temperature, iodoacetamide (5 μL, 100 mM) was added, and the solution was incubated at room temperature for 15 min. After dilution with water (140 μL), trypsin (10 μg in 10 μL 0.01% trifluoroacetic acid) was added. The reaction mixture was incubated at 37°C for 24 h. The peptides produced were separated on a reversed-phase high-performance liquid chromatography (HPLC) column.

Chromatography. The proteolytic digests were analyzed by reversed-phase HPLC on a C18-column (Vydac 218 TP, 4.6 × 250 mm, 5 μm, Hesperia, CA). The chromatograms were developed at 25°C with a gradient of an increasing concentration of acetonitrile. Mobile phase A consisted of trifluoroacetic acid/water (0.1:100, vol/vol) and mobile phase B was acetonitrile/mobile phase A (60:40, vol/vol). The gradient was designed as follows: 0–5 min, 0% B (100% A); 5–45 min, 0–45% B; 45–100 min, 45–55% B; 100–145 min, 55–100% B; 145–150 min, 100% B; 150–155 min, 0% B. The flow rate was 0.5 mL/min. Fractions were collected and peptides were identified by plasma desorption mass spectrometry (PDMS). The HPLC system consisted of two pumps (LKB, model 2150), a gradient programmer (LKB, model 2152), a Rheodyne injection valve with a 100 μL sample loop. Peptides were detected with an ultraviolet (UV) detector (214 nm; LKB, model 2140) or an FS 970 L.C fluorimeter (excitation wavelength 280 nm, emission filter 270 nm; Schoeffel Instrument GmbH, Trappenkamp, Germany). Data were collected with a Macintosh SE personal computer equipped with the software Dynamax® (Rainin Instrument Company Inc., Woburn, MA).

Mass spectrometry. PDMS analyses were performed on lyophilized HPLC fractions containing the relevant peptides, using a Bio-Ion 20 instrument (Bio-Ion AB, Uppsala, Sweden) and the nitrocellulose foil-spin drying technique as published by Jardine (13).

Laser desorption mass spectrometry (LDMS) was carried out directly on the lyophilized mixture of tryptic peptides. The instrument used was a LDI-1700 Mass Monitor (Linear Scientific Inc., Reno, NV). In order to achieve good mass dynamic ranges, experiments were performed using 2,5-dihydroxy-benzoic (DHB) acid and sinapinic acid as matrices. DHB was best suited for low molecular weight constituents (<2 kDa) while sinapinic acid worked well for high-molecular weight peptides. DHB solutions were 100 mM in 10% (vol/vol) aqueous ethanol. Sinapinic acid solutions were 100 mM in 40% (vol/vol) acetonitrile in 10% (vol/vol) aqueous ethanol. The lyophilized peptide mixtures were reconstituted using 250 μL of 0.1% (vol/vol) trifluoroacetic acid in 50% (vol/vol) aqueous acetonitrile. Samples were mixed with matrix at 1:3 or 1:4 dilutions. For the most part, molecular weights were determined using an external standard based upon a calibration mixture of vasopressin, calcitonin, synacthen and hirudin. In some experiments, the samples were spiked with this solution to function as an internal standard.

Determination of enantioselectivity. Hydrolysis of racemic heptyl 2-methyldecanoate was done in a pH-stat. After 30% conversion, the enantiomeric excess (14) of the 2-methyldecanoic acid produced was determined. The enantiomeric ratio (E) was calculated according to Chen *et al.* (15). The synthesis of the substrate (16) work-up procedures (16) and the determination of the enantiomeric excess (17) have been described elsewhere.

Circular dichroism. CD spectra (205–250 nm) of *R. miehei* lipase (0.10 mg/mL in 10 mM TES, pH 7.0) were recorded at 25°C in the presence of guanidine (0–4.0 M),

using a JASCO J-720 (Tokyo, Japan) spectropolarimeter. The fraction of folded protein was determined at 222 nm.

RESULTS

Chemical modification of arginines. Arginine-specific chemical modification of *R. miehei* lipase with 1,2-cyclohexanedione or phenylglyoxal, resulted in residual activities of 66 and 46%, respectively, as compared to untreated enzyme, with tributyrin as substrate (Fig. 1). The reduction of activity during arginine modification plateaued in three hours with both reagents.

The amount of ^{14}C-labeled phenylglyoxal bound to *R. miehei* lipase was determined by trichloroacetic acid precipitation. These labeling studies showed that approximately 8 mol of phenylglyoxal was bound to 1 mol of the enzyme, when the lipase had been inhibited to the full extent achieved here.

Identification of modified arginines. Tryptic digestion of native *R. miehei* lipase and subsequent LDMS analyses of the peptide mixture showed that all the peptides predicted were produced. The masses recorded were all within 0.6% of the expected values (data not shown).

Phenylglyoxal-reacted arginine residues in proteins are known to be resistant to tryptic cleavage (11). Tryptic peptides of native lipase were separated on an HPLC system and identified by PDMS analyses (Table 1 and Fig. 2). The comparison of peak heights of specific tryptic peptides, produced from native and phenylglyoxal treated lipase, showed that a number of arginines in the lipase had reacted with phenylglyoxal (Fig. 2). Arg86 (based on the absence of T9) was the residue modified to the highest degree (>85%). Arg30 (T3), Arg68 (T5) and Arg160 (T13) were all found to be modified to a significantly lower extent (<70%) than Arg86 in the inhibited lipase. The degrees of modification based on fluorescense detection were 58% for Arg30 (T3), 56% for Arg68 (T5) and 85% for Arg86 (T9) (data not shown). The quantification in the fluorescense chromatogram was more reliable for these peaks because of lower noise and fewer peaks than in the UV chromatogram. For several other arginines, it could be shown that they were only partially modified when the lipase was inhibited to the full extent achieved. It was shown by the combined disappearance of T17 (70%) and T18 (30%) that both Arg197 and Arg202 had reacted to some extent (40 and 30%, respectively). According to the constant peak height of peptide T1, Arg7 was not modified. Arg178 was not modified since peptides T13 and T14 were similarly decreased, due to modification of Arg160 (T13). The degree of modification of Arg80 (T7) and Arg196 (T15) could not be unambiguously determined as T2, T7 and T15 were coeluted. But based on the total amount of incorporated phenylglyoxal, it can be concluded that none of the residues Arg80 or Arg196, alone or together, were modified to more than 60 mol%.

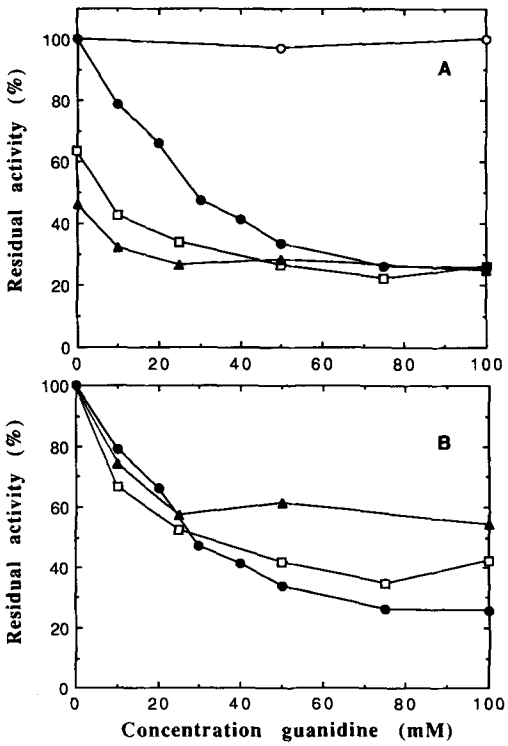

FIG. 1. Residual activity of native (●,○), 1,2-cyclohexanedione-reacted (□) and phenylglyoxal-reacted (▲) *Rhizomucor miehei* lipase as a function of guanidine concentration. Guanidine was present in both the enzyme solution and the substrate emulsion (●, □, ▲) or only in the substrate emulsion (○), before mixing enzyme and substrate. Activity was determined with tributyrin as substrate at pH 7.0 and 25°C. The experimental points are mean values of repeated experiments. In A, 100% residual activity corresponds to the activity of native enzyme in the absence of guanidine. In B, 100% residual activity corresponds to the activity in the absence of guanidine of native lipase or the activity of lipase obtained after chemical modification.

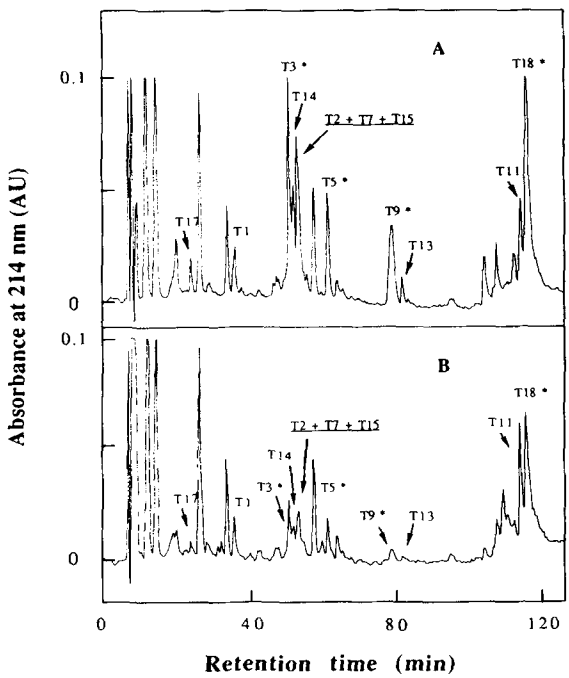

FIG. 2. Reversed-phase high-performance liquid chromatography chromatograms of tryptic peptides from control (A) and phenylglyoxal-reacted (B) *Rhizomucor miehei* lipase. Eight mol phenylgloxal (B) were incorporated into 1 mol lipase. Peptides were identified by plasma desorption mass spectrometry analyses. The chromatograms were recorded with a ultraviolet detector (λ 214 nm). The peptides detected with a fluorescence detector are indicated with an asterisk (*). Decreased peaks (B compared to A) not outlined contained peptides not recognized as tryptic peptides from *R. miehei* lipase.

[a]Theoretical tryptic peptide sequences (T1-T18) and masses were based on the published lipase sequence (18; see also footnote f). The experimentally determined peptide masses were used to assign the peaks in the high-performance liquid chromatography (HPLC) chromatogram (Fig. 2).
[b]Peptide mass was calculated using the computer software MacProMass 1.0; Vemuri, S., and Lee, T.D., Division of Immunology, Beckman Research Institute of the City of Hope, 1450 East Duarte Road, Duarte, CA 91010.
[c]Peptide mass was experimentally determined by plasma desorption mass spectrometry analyses of HPLC-separated peptides.
[d]Mass was corrected for the alkylation of cystein-residues.
[e]This peptide was also detected as the methionine oxidized species (MH^+ 1756.9 Da).
[f]Residue 156 has incorrectly been assigned as G (Gly) in the published lipase sequence (Ref. 18) and should be D (Asp) according to the Protein Data Bank at Brookhaven (Ref. 19), entry number 1TGL.
[g]This peptide was also detected as an alkylated species (MH^+ 2081.5 Da).

Inhibition by arginine side chain analogs. Native enzyme and 1,2-cyclohexanedione- or phenylglyoxal-treated enzymes were all inhibited by guanidine. The enzyme and the substrate solutions had to be mixed separately with guanidine before the reaction was started by the addition of enzyme to the substrate (Fig. 1). The same residual activity, 26%, was obtained either by guanidine inhibition of native enzyme or chemical arginine-modification plus guanidine inhibition of native enzyme (Fig. 1A). The concentrations of guanidine which resulted in half of maximum inhibition, the apparent inhibition constants were 20 mM and 10 mM for the native and arginine-modified enzymes, respectively (Fig. 1B). The inhibition produced by guanidine was not an effect of enzyme denaturation, as ascertained by circular dichroism spectroscopy at 222 nm, pH 7.0, at 25°C. The enzyme was found to have an intact secondary structure in 0.5 M guanidine. The enzyme was partially and fully unfolded in 1.0 M and 4.0 M guanidine, respectively.

The native enzyme was also inhibited by 1-ethylguanidine, benzamidine or urea, but their inhibiting effects were lower than that of guanidine (Table 2).

Guanidine reduced the enantioselectivity of the enzyme. With racemic heptyl 2-methyldecanoate as substrate, the enantiomeric ratio [$E = (V_{max}/K_m)_S/(V_{max}/K_m)_R$, where S and R denote the enantiomers (15)] changed from 8.5 (no inhibitor) to 1.9 in the presence of 100 mM guanidine.

Lipases from porcine pancreas and *H. lanuginosa* were also inhibited by guanidine under the conditions described above, showing residual activities of 70 and 88%, respectively, in 100 mM guanidine (Table 3). In contrast, lipases from *C. antarctica* (A and B), *C. rugosa*, *P. cepacia* and *P. fluorescens* were not inhibited by guanidine (Table 3).

DISCUSSION

It has recently been shown that Asn87 in the lid of *R. miehei* lipase interacts with a polar cavity of the enzyme

TABLE 2

Residual Activity of *Rhizomucor miehei* Lipase in the Presence of Inhibitors

Inhibitor	Residual activity[a] (%)
Guanidine	26 ± 5
1-Ethylguanidine	58 ± 8
Benzamidine	56 ± 11
Urea	78 ± 7

[a]Reference samples were assayed in the absence of inhibitor. Activity was determined with an inhibitor concentration of 100 mM and tributyrin as substrate at pH 7.0 at 25°C. SD is based on three separate experiments.

TABLE 3

Residual Activity of Different Lipases in the Presence of 100 mM Guanidine

Lipase	Residual activity[a] (%)
Rhizomucor miehei	26 ± 5[b]
Porcine pancreas	70 ± 9[b]
Humicola lanuginosa	88 ± 2[b]
Candida antarctica A	97
C. antarctica B	102
C. rugosa	101 ± 3[c]
Pseudomonas cepacia	95
P. fluorescens	95

[a]Reference samples were assayed in the absence of guanidine. Activity was determined with tributyrin as substrate at pH 7.0 at 25°C.
[b,c]SD is based on three and two separate experiments, respectively.

when the lid is open (9). Other polar residues in the lid might also stabilize the active open-lid conformer of the enzyme. Three arginine residues in the structure, Arg30, Arg80 and Arg86, have been reported to have multiple conformations in the open lipase-inhibitor complex (9). Arg86 is located in the lid whereas the side chains of Arg30 and Arg80 are situated in the region referred to as the polar cavity.

Molecular dynamics simulations on *R. miehei* lipase, starting from the closed-lid conformer (Fig. 3A) (5), indicated that Arg86 in the lid could be an important residue in the stabilization of the open-lid conformation (20). Running the simulation on the enzyme where Arg86 had been mutated to an alanine residue showed a significantly decreased stabilization of the open-lid conformation (20).

Tryptic maps of native and phenylglyoxal-reacted *R. miehei* lipase showed that Arg86 was the amino acid that had been modified to the highest degree while Arg30, Arg68 and Arg160 were modified to a lesser degree in the inhibited lipase. Arg7, Arg80, Arg178, Arg196, Arg197 and Arg202 were not, or only to a small extent, modified. This is consistent with the result of the ^{14}C-phenylglyoxal labeling experiments which indicated that either four arginines were modified quantitatively or that more than four arginines were modified partially, since two phenylglyoxal molecules react with one arginine (21). The finding that Arg86 was modified most when the lipase was inhibited to the fullest extent and that further incubation with phenylglyoxal did not inhibit the lipase further, suggests that the modification of Arg86 plays an important role in the inhibition of the lipase. Arg30 and Arg80 are located in a region of the lipase structure where the polar side of the lid interacts with the protein surface in the open form (Fig. 3). It seems reasonable to assume that the modification of these arginines also could affect the stabilization of the open-lid conformation. Arg68 and Arg160 are located far away from the lid and the active site of the lipase, suggesting that the modification of these residues should not affect enzyme activity. To unambiguously determine which arginines are important for enzyme activity, specific mutants of the enzyme are needed. Unfortunately no such mutants have been obtained to date.

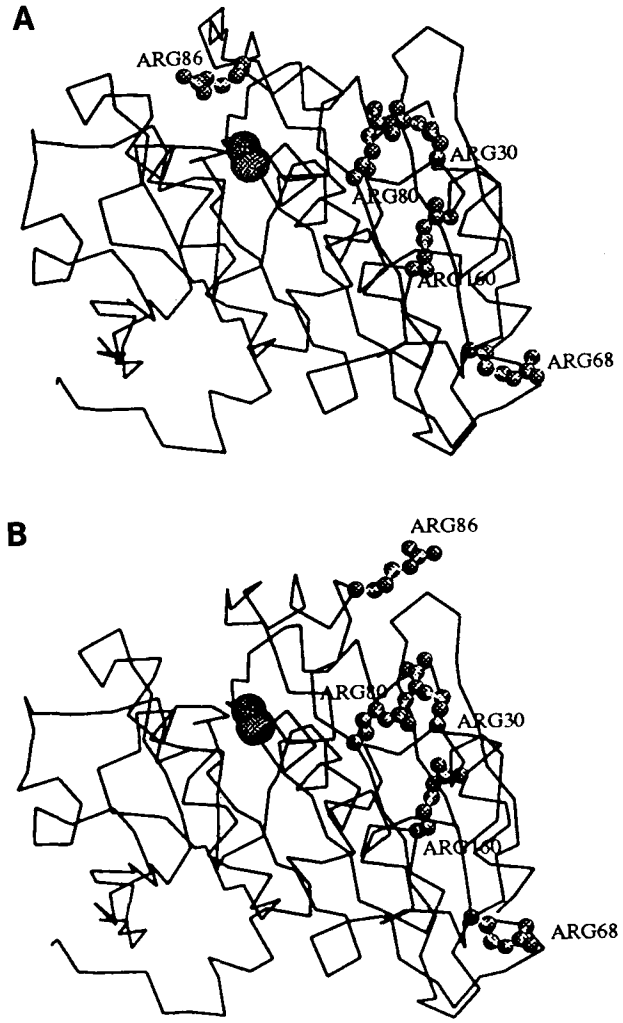

FIG. 3. Structures showing the positions of Arg30, Arg68, Arg80, Arg86 and Arg160 in the closed form (A) (5) and the open form (B) (9) of the *Rhizomucor miehei* lipase. The van der Waals surface of the active site residue Ser144 is shown dotted.

Modification of Arg86 with 1,2-cyclohexanedione or phenylglyoxal should not prevent Arg86 from forming hydrogen bonds or ionic bonds, but the arginine residue would become more bulky, which could affect lid opening and enzyme activity. The lower residual activity obtained after phenylglyoxal treatment, may be an effect of such a bulkier product (11) formed with this reagent, compared to that obtained by 1,2-cyclohexanedione treatment (10).

Guanidine, structurally resembling the side chain of an arginine residue, might specifically compete with Arg86 for its binding site and thus destabilize the active open-lid conformation of the enzyme. The order in which substrate, enzyme and guanidine were mixed was essential. When guanidine was present only in the substrate solution, which affects the final concentration very little, no inhibition was seen. But when guanidine was added to both the enzyme solution and the substrate, the lipase was inhibited to the full extent achieved here (Fig. 1A). Probably the enzyme obtained its active conformation at the substrate interface faster than guanidine was bound to

TABLE 4

[a]The possible lid region of *H. lanuginosa* lipase was identified after alignment of the primary sequence to the *R. miehei* lipase sequence. These enzymes show about 32% sequence identity.

the enzyme. Once the enzyme attained its open-lid conformation at the substrate interface, guanidine could not remove Arg86 from its binding site. However, when the enzyme solution but not the substrate emulsion contained guanidine, the extent of inhibition varied from a full effect to a moderate one, in spite of a substantial dilution of the inhibitor. The degree of inhibition would be correlated to the fraction of enzyme molecules having guanidine bound, at the moment of adsorption, to the substrate interface.

The same residual activity was obtained by guanidine inhibition of native enzyme or chemical arginine-modification plus guanidine inhibition, showing that inhibition produced by guanidine and the chemical modification of arginine residues were complementary. The lower apparent inhibition constants of guanidine for the arginine-modified enzymes compared to the native enzyme is consistent with the hypothesis that both arginine-modification and the presence of guanidine hinder the interaction of Arg86 with its binding site.

The hydrophobic interaction between substrate and the hydrophobic side of the lid, exposed in the open-lid conformation, stabilizes the enzyme in an open form, as described by Brzozowski *et al.* (8) and Derewenda *et al.* (9). Arg86 may take part in anchoring the lid in its optimal position for catalysis. When Arg86 was prevented from binding its hydrogen bonding site, due to the presence of guanidine or after chemical modification, the lid was not in its optimal position, resulting in lower activity and altered enantioselectivity. The altered enantioselectivity of the lipase in the presence of guanidine showed that the inhibition was not just a result of reducing the number of active lipase molecules.

Examination of the amino acid sequences of the lid regions of the lipases from *R. miehei*, porcine pancrease, *H. lanuginosa* and *C. rugosa* showed the presence of an arginine residue only in those lipases that were found to be inhibited by guanidine (Tables 3 and 4). The lack of inhibition by guanidine of some lipases showed that the inhibition was specific and not a general feature of lipases or an artifact of the analyses. The future evaluation of three-dimensional structures of lipases, protein engineering, molecular dynamic simulations and inhibition studies will contribute to the understanding of lipase catalysis.

ACKNOWLEDGMENTS

We thank the National Swedish Board for Technical Development (STU/NUTEK) and Nordisk Industrifond (NIF) for financial support. We also thank Novo-Nordisk A/S (Bagsvaerd, Copenhagen, Denmark) for kindly providing purified enzymes and detailed coordinates of the closed and open form of *R. miehei* lipase. Björn Nilsson and Per Persson, Kabi Pharmacia Bioscience Center, Stockholm, Sweden, are kindly acknowledged for helping us with the circular dichroism and PDMS studies, respectively. Larry Lidman (Metric-Analys AB, Mölndal, Sweden) is acknowledged for the LDMS analyses.

Effect of Phosphatidylcholine Structure on the Adenylate Cyclase Activity of a Murine Fibroblast Cell Line

Lido Calorini, Gabriele Mugnai, Antonella Mannini and **Salvatore Ruggieri***
Institute of General Pathology, University of Florence, 50134 Florence, Italy

To determine which structural characteristics of membrane phospholipids influence adenylate cyclase activity, we measured basal and sodium fluoride- or forskolin-stimulated activity in a murine fibroblast cell line, *i.e.*, Balb/c3T3 cells grown in media supplemented with fetal calf serum (FCS), lipid-depleted FCS (LD-FCS) or LD-FCS complexed with different phosphatidylcholine (PC) molecular species. Cells grown in the presence of LD-FCS showed a substantial decrease in their basal and NaF-stimulated adenylate cyclase activities; however, their forskolin-stimulated activity was not altered, suggesting that the enzyme's catalytic site is not affected by changes in membrane lipids. Media supplemented with different LD-FCS/PC complexes were shown to prevent the LD-FCS-mediated reduction of basal and NaF-stimulated adenylate cyclase activity to different extents. Addition of *cis*-9-16:1/*cis*-9-16:1, *cis*-9-18:1/*cis*-9-18:1 or *cis*-9-18:1/*cis*-9,12-18:2 *sn*-glycerophosphocholine (GPC) completely restored adenylate cyclase activity, while *cis*-11-18:1/*cis*-11-18:1 GPC was not effective and only a partial recovery was observed with 16:0/16:0, 16:0/*cis*-9-18:1 and *trans*-9-18:1 GPC. Considering the structural features of these seven PC molecular species, the findings suggest that an optimal lipid environment is conferred to the enzyme by the presence of two *cis* double bonds, each located in Δ9 position of the PC acyl chains. The limited effect of *cis*-9-16:1/*cis*-9-18:1 GPC and *cis*-9-18:1/*cis*-9-16:1 GPC suggests that an equal length of the terminal hydrocarbon chains extending beyond the Δ9 double bonds is also important. Moreover, complete restoration of adenylate cyclase activity in cells exposed to 16:0/*cis*-9,12-18:2 GPC suggests that two *cis*-9,12 double bonds located on the same chain are as effective as two *cis*-9 double bonds each located on two different chains of PC. As the four double bonds of 16:0/*cis*-5,8,11,14-20:4 GPC had no effect, a mere increase in the number of double bonds seems insufficient to build an optimal lipid microenvironment for the enzyme. *Lipids 28,* 727–730 (1993).

Adenylate cyclase [ATP pyrophosphate lyase (cyclizing), EC 4.6.1.1] is a membrane-associated enzyme which, by producing the second messenger cAMP, affects various cellular physiological activities (1). The dependence of adenylate cyclase on lipids has been shown by a number of studies, including dietary manipulation (2–11), treatment with phospholipases (12–17), and incorporation into cell membranes of exogenous fatty acids (18–23), intact phospholipid molecules (24–32) or variations in phospholipid polar head groups (19,20,33). We feel that, under physiological conditions, the activity of adenylate cyclase may well be affected by the phospholipid molecular species present in the membranes (34). This relationship, has only been explored in a few instances (28–32), and only for a limited number of molecular species.

In the present study we determined to what extent phosphatidylcholines (PC) with a defined acyl chain composition affect the reduction of the adenylate cyclase activity which occurs in cell cultures grown in media supplemented with lipid-free serum (22). Adenylate cyclase activity was measured in a murine fibroblast cell line, *i.e.*, Balb/c3T3 cells grown in media supplemented with fetal calf serum (FCS), lipid-depleted FCS (LD-FCS), or in LD-FCS complexed with a series of PC which differed in the length of their acyl chains and in the number, location and configuration of their double bonds. We measured the basal activity of adenylate cyclase as well as the activity stimulated by sodium fluoride or forskolin to explore the G_s protein and the catalytic unit of the enzyme, respectively (35). Using this protocol, we determined which structural features of the phospholipids are important to restore the activities of the regulatory and/or catalytic unit of the adenylate cyclase complex.

MATERIALS AND METHODS

Synthesis of PC. Symmetric PC, dipalmitoyl (16:0/16:0), dipalmitoleoyl (*cis*-9-16:1/*cis*-9-16:1), dioleoyl (*cis*-9-18:1/*cis*-9-18:1), divaccenoyl (*cis*-11-18:1/*cis*-11-18:1) and dielaidoyl (*trans*-9-18:1/*trans*-9-18:1) *sn*-glycero-3-phosphocholines (GPC) were synthesized by reaction of fatty acid anhydrides with the cadmium chloride/GPC complex in the presence of 4-pyrrolidinopyridine as catalyst (36). Asymmetric PC molecules, namely 1-palmitoyl-2-oleoyl (16:0/*cis*-9-18:1), 1-palmitoleoyl-2-oleoyl (*cis*-9-16:1/*cis*-9-18:1), 1-oleoyl-2-palmitoleoyl (*cis*-9-18:1/*cis*-9-16:1), 1-palmitoyl-2-linoleoyl (16:0/*cis*-9,12-18:2) and 1-oleoyl-2-linoleoyl (*cis*-9-18:1/*cis*-9,12-18:2) GPC, were synthesized by submitting the respective symmetric PC (16:0/16:0, *cis*-9-16:1/*cis*-9-16:1, *cis*-9-18:1/*cis*-9-18:1 GPC) to phospholipase A_2 hydrolysis, followed by acylation of the 1-acyl-GPC in position 2 with the appropriate fatty acid anhydrides, using 4-pyrrolidinopyridine as catalyst (36). 1-Palmitoyl-2-arachidonoyl (16:0/*cis*-5,8,11,14-20:4) GPC was supplied by Avanti Polar Lipids (Alabaster, AL). All PC used in this study were free of hydroperoxides and hydrolysis products, as was shown by high-performance liquid chromatographic (HPLC) analysis (37,38).

Preparation of LD-FCS, reconstituted FCS and LD-FCS/PC complexes. LD-FCS was prepared by successive extractions of FCS with an ethanol/diethyl ether (3:1, vol/vol) mixture at −25°C (39). Lipids extracted from FCS were solubilized in a small volume of chloroform and mixed with dry LD-FCS in order to obtain the reconstituted FCS (R-FCS). Individual PC (200 μg per mL of serum) together with cholesterol (100 μg per mL of serum) were also solubilized in a small volume of chloroform and mixed with dry LD-FCS in order to obtain the various LD-FCS/PC complexes. The dry LD-FCS, R-FCS and LD-FCS/PC complexes were solubilized with distilled water under sonication and brought to the original volume of FCS that had been submitted to lipid extraction. The concentrations of each PC molecular species and cholesterol

Abbreviations: DMEM, Dulbecco's modified Minimal Essential Medium; FCS, fetal calf serum; GPC, *sn*-glycero-3-phosphocholine; HPLC, high-performance liquid chromatography; LD-FCS, lipid-depleted fetal calf serum; PC, phosphatidylcholine; PMV, plasma membrane vesicles; R-FCS, reconstituted fetal calf serum.

complexed with LD-FCS corresponded to the concentrations of the total PC fraction (200 μg per mL) and free cholesterol (100 μg per mL) found in the original FCS (40).

Cells and growth conditions. Balb/c3T3 cells (clone A31) were seeded at 1×10^6 cells per dish (100-mm Falcon tissue culture dishes) and grown at 37°C in a humidified atmosphere of 5% CO_2 in air using Dulbecco's modified Minimal Essential Medium (DMEM) (Grand Island Biological Company, Grand Island, NY) supplemented with 10% FCS (Boehringer Mannheim, Mannheim, Germany). After three days, cell cultures were shifted to DMEM supplemented with 10% LD-FCS, R-FCS or LD-FCS/PC complexes and maintained in this media for 24 h. As shown in a previous study (41), this time period was sufficient to cause changes in the phospholipid fatty acid profiles, which were consistent with the structure of the incorporated PC. Cell layers were then washed with cold 40 mM Tris-HCl buffer, pH 8.3, and scraped from the dish using a rubber policeman. Balb/c3T3 cells cultured for the entire 4-d period in the presence of FCS served as control.

Balb/c 3T3 cells were also exposed for 24 h to media supplemented with LD-FCS complexed with di[1-^{14}C]palmitoyl (16:0/16:0), 1-palmitoyl-2-[1-^{14}C]oleoyl (16:0/*cis*-9-18:1), di[1-^{14}C]oleoyl (*cis*-9-18:1/*cis*-9-18:1) or 1-palmitoyl-2-[1-^{14}C]-linoleoyl (*cis*-9-18:1/*cis*-9,12-18:2) GPC (NEN DuPont, Boston, MA); the specific activities of these radiolabeled PC in the complexes were 2521, 2575, 2698 and 2569 dpm/nmol, respectively. These cultures were used for the preparation of plasma membrane vesicles (PMV) and for the determination of the amounts of the radiolabeled PC which became incorporated into plasma membranes of Balb/c3T3 cells. These amounts served as an indicator of the enrichment of Balb/c3T3 plasma membranes with the various PC used in our experimental protocol.

Incorporation of radiolabeled PC into PMV. Balb/c3T3 cells grown for 24 h in the presence of radiolabeled PC were treated with 25 mM formaldehyde/2 mM dithiothreitol in phosphate-buffered saline to prepare PMV according to Scott *et al.* (42). Measurement of cholesterol (43) and phospholipid (44) content in our preparations of PMV from Balb/c3T3 cells gave a 0.793 cholesterol/phospholipid molar ratio, which is close to the value reported by Scott *et al.*(42). Radiolabeled lipids were extracted from PMV according to Folch *et al.* (45) and fractionated by HPLC following the procedure reported by Schlager and Jordi (38). Chromatography was performed on a 250 × 4.6 mm Silica B5 column mounted in a Perkin-Elmer HPLC apparatus Series 3B (Norwalk, CT), and radioactivities of the various lipid fractions were monitored by using a Flo-One radiochromatographic detector (Radiomatic, Meriden, CT).

Adenylate cyclase assay. Adenylate cyclase activity was determined by measuring the conversion of [α-^{32}P]ATP into cyclic [^{32}P]AMP. The incubation assay was started by adding the cell suspension (22.5–135.0 μg of protein) to the reaction mixture (100 μL final volume) containing 40 mM Tris-HCl (pH 8.3), 2 mM ATP, 2 mM $MgCl_2$, 8 mM theophylline, creatine kinase (6 mg/mL), 5 mM phosphocreatine and [α-^{32}P]ATP (30 Ci/mmol; Amersham, England) ($4–6 \times 10^6$ cpm). Stimulated activity was measured in the presence of 10 mM NaF or 0.01 mM forskolin (Calbiochem, San Diego, CA). The reaction was carried out at 37°C for 15 min, during which time the production of cyclic AMP was linear and proportional to protein concentration. The reaction was terminated by the addition of 100 μL of a solution containing 45 mM ATP, 1.3 mM cyclic AMP and 2% sodium laurylsulfate, and the reaction tubes were placed in a boiling water bath for 3 min until cell proteins were completely solubilized. The reaction mixtures were brought to 1.2 mL with distilled water, and the cyclic [^{32}P]AMP was isolated from the other reaction products by using the chromatographic system described by Salomon (46). The recovery of cyclic [^{32}P]AMP through this chromatographic system ranged from 73 to 86%, as assessed by using a cyclic [^{3}H]AMP internal standard. Proteins were determined by the method of Lowry *et al.* (47) using bovine serum albumin as standard.

RESULTS AND DISCUSSION

As shown in Table 1, the basal adenylate cyclase activity of Balb/c3T3 cells grown in control medium was increased 3.5 and 19 times upon stimulation with NaF or forskolin, respectively. Balb/c3T3 cells grown in a medium supplemented with LD-FCS showed a 40% reduction in adenylate cyclase activity. This effect was also found in a neuroblastoma × glioma hybrid line grown in the presence of lipid-free serum (22), and recalls the reduced adenylate cyclase activity shown in plasma membranes of animals fed an essential fatty acid-deficient diet (2,5). The reduction of the adenylate cyclase activity of cells grown in LD-FCS medium was due only to lipid depletion of the medium, in view of the fact that cells grown in a R-FCS medium showed the same enzymic activity as that found in cells grown in an FCS medium.

The basal adenylate cyclase activity of Balb/c3T3 cells grown in media containing LD-FCS complexed with 16:0/16:0 GPC was higher than that of cells grown in LD-FCS alone, although it did not reach the level found in the cells grown in an FCS medium. A partial restoration of the enzymic activity was also found in Balb/c 3T3 cells grown in the presence of LD-FCS complexed with 16:0/*cis*-9-18:1 GPC.

The adenylate cyclase activity was completely restored in Balb/c3T3 cells grown in the presence of *cis*-9-16:1/*cis*-9-16:1 or *cis*-9-18:1/*cis*-9-18:1 GPC, molecular species characterized by two double bonds, each located at the Δ9 position of the hydrocarbon chain. Divaccenoyl-GPC, with its double bonds at Δ11 positions, was completely ineffective in re-establishing adenylate cyclase activity of Balb/c3T3 cells, which suggests that a specific location of double bonds at Δ9 position is needed in order to bring the adenylate cyclase activity back to normal. Moreover, a *cis* configuration of the Δ9 double bonds is required to achieve normal enzymic activity in view of the lesser effect shown by *trans*-9-18:1/*trans*-9-18:1 GPC. A further requirement appears to be that the terminal hydrocarbon chains extending beyond the Δ9 double bonds be of equal length as growth in the presence of *cis*-9-16:1/*cis*-9-18:1 or *cis*-9-18:1/*cis*-9-16:1 GPC was only partially effective in restoring adenylate cyclase activity.

A complete restoration of adenylate cyclase activity of Balb/c3T3 cells was also obtained by growing the cells in the presence of *cis*-9-18:1/*cis*-9,12-18:2 GPC, which could be explained by the symmetric location of double bonds in Δ9 position of both oleic and linoleic acids. It may also be that linoleic acid, with its double bonds located in Δ9 and Δ12 positions, is sufficient *per se* to restore the enzymic activity. Indeed, 16:0/*cis*-9,12-18:2 GPC produced

[a]Growth media consisted of Dulbecco's Modified Minimal Essential Medium supplemented with 10% fetal calf serum (FCS) 10% lipid-depleted FCS (LD-FCS), 10% reconstituted FCS (R-FCS) or 10% LD-FCS complexed with various phosphatidylcholines. Values are means ± SEM of the number of experiments listed in parentheses. Adenylate cyclase activities of cells grown in manipulated media are also reported as percentages (numbers in italics) of the enzymic activity found in the cells grown in the presence of FCS. GPC, glycero-3-phosphocholine.
[b]Statistically different ($P \leq 0.05$, Student's *t*-test) from the adenylate cyclase activity of cells grown in the presence of FCS.
[c]Statistically different ($P \leq 0.05$, Student's *t*-test) from the adenylate cyclase activity of cells grown in the presence of LD-FCS.

the same adenylate cyclase activity as cells grown in FCS-medium. Adenylate cyclase activity had also been restored to normal in a neuroblastoma × glioma hybrid cell line grown in the presence of lipid-free serum by supplementing growth medium with linoleic acid (22). On the other hand, 16:0/*cis*-5,8,11,14-20:4 GPC was not effective in restoring adenylate cyclase activity. Previous studies (17,21) also had shown that incorporation of arachidonic acid into plasma membranes decreased adenylate cyclase activity. This suggests that a mere increase in the number of double bonds is not sufficient to build an optimal lipid microenvironment for adenylate cyclase.

Adenylate cyclase activity stimulated by NaF was also reduced by growing Balb/c3T3 cells in LD-FCS medium, but this reduction was not observed by growing the cells in R-FCS medium. Moreover, the various PC exhibited almost the same relative stimulatory effects on NaF-stimulated adenylate cyclase activity as they did on the enzyme's basal activity. On the other hand, adenylate cyclase activity stimulated by forskolin was not significantly modified by growth in the presence of LD-FCS or of most LD-FCS/PC complexes, indicating a lack of sensitivity of the catalytic site to changes in the lipid microenvironment. Balb/c3T3 cells grown in the presence of *cis*-11-18:1 *cis*-11-18:1 GPC showed a lower forskolin-stimulated adenylate cyclase activity, possibly due to a specific inhibitory effect of this molecular species on the enzyme.

As shown in Table 2, 16:0/*cis*-9,12-18:2 GPC showed the highest degree of incorporation into PMV, compared to the other radiolabeled PC tested while differences in the incorporation among 16:0/16:0, 16:0/*cis*-9-18:1 and *cis*-9-18:1 GPC failed to reach significance. However, the

[c]Percent (means ± SEM) of total lipid radioactivity associated with the PC fraction obtained by high-performance liquid chromatography of total lipids (Ref. 38).
[d]The amount of each radiolabled PC incorporated into PMV was calculated from the radioactivity associated with the PC fraction (taking into consideration the specific activity of the radiolabeled molecular species). Values are means ± SEM.
[e]Statistically different ($P < 0.05$, Student's *t*-test) from the amounts of incorporated 1-palmitoyl-2-oleoyl- and 1,2-dioleoyl-GPC.

degrees of incorporation of the various radiolabeled PC into PMV did not correlate at all with the different effects exerted by these molecular species on adenylate cyclase activity (see Table 1). Thus, the observed effects on adenylate cyclase activity are likely to be related to the structural features of the molecular species studied, and not to the degree of their incorporation into plasma membranes.

Our results support the hypothesis that the activity of the regulatory unit of adenylate cyclase may be controlled by specific molecular species whose number, location and configuration of double bonds in their acyl chains serve to establish an optimal lipid microenvironment.

ACKNOWLEDGMENTS

This study was supported by CNR (Progetto Finalizzato A.C.R.O.), AIRC and MURST (40 and 60%). The authors thank Professor A. Fonnesu, chairman of the Institute of General Pathology, University of Florence (Italy) for his interest in this work, and Dr. Raymond Manning of the Department of Biological Sciences, University of Durham (United Kingdom), for fruitful discussion during the preparation of the manuscript.

[Received January 30, 1993; Revision accepted May 30, 1993]

Investigations on the Cellular Uptake of Hexadecylphosphocholine

Eduard A.M. Fleer[a,b,*], Dinko Berkovic[a], Hansjoerg Eibl[b] and Clemens Unger[a]

[a]Department of Hematology and Oncology, University Clinic of Goettingen and [b]Max-Planck-Institute for Biophysical Chemistry, 37077 Goettingen, Germany

The uptake of [(9,10)-^{3}H]hexadecylphosphocholine (HePC) in six tumor cell lines was studied. All cell lines incorporated HePC in similar amounts, with the exception of the epidermoid cancer cell line KB, which took up higher amounts of HePC. The uptake of HePC at 37°C was shown to be time and concentration dependent. At 20°C, uptake was drastically reduced and at 4°C it was blocked completely. Binding of HePC, at 4°C, was not saturable at concentrations between 5 μg/mL (11.8 μM) and 100 μg/mL (235.3 μM), indicating that cell surface binding is not receptor-mediated. Furthermore, the effects of inhibitors of endocytosis were investigated. We observed a pronounced inhibitory effect by monensin and cytochalasin B. Colchicine was somewhat less effective whereas chloroquine was almost without effect. From these data we conclude that uptake of HePC is most probably mediated *via* a receptor-independent endocytotic mechanism.

***Lipids* 28, 731–736 (1993).**

The ether lipid analogue hexadecylphosphocholine (HePC) is a representative of the group of alkylphosphocholines (1). It is cytotoxic for a variety of tumor cell lines in culture (2,3). Oral treatment of tumor-bearing animals with HePC resulted in significant antitumor activity (4,5); however, the effects were highly specific for certain tumor types. Autochthonous, carcinogen-induced rat tumors as well as some human tumor cell lines transplanted onto nude mice were extremely sensitive whereas classical murine screening models such as P388 and L1210 were completely insensitive (4).

Early clinical trials with a topical application of HePC in cutaneous metastases of patients with mammary carcinomas have already indicated that this compound is also active in human cancer (6,7).

The molecular mechanism of action of HePC is still unknown. Studies on the metabolism of HePC in the human leukemia Raji cell line revealed that HePC is only slowly degraded with more than 90% of the radiolabel still being associated with the parent compound after three days of incubation (2). Generation of toxic metabolites does not seem to be the key event of HePC cytotoxicity since a nondegradable analogue of HePC showed similar antiproliferative activities (8). There are, however, several lines of evidence that suggest that HePC may interfere with signal transduction mechanisms in proliferating cells. In this respect, an inhibition of protein kinase C in bombesin-induced NIH 3T3 fibroblasts and also in phorbol-stimulated HL60 cells has been reported (9,10). In interleukin-2 dependent polymorphonuclear cell cultures, a HePC-induced enhancement of interferon-gamma and an increased expression of interleukin-2 receptors could be demonstrated (11). In U937 cells, HePC stimulates an increase of histone H_1^0 gene expression, which clearly precedes growth retardation (12). In addition it has been demonstrated that low doses of HePC amplify the hematopoietic growth factor dependent proliferation of progenitor cells *in vitro* (13).

A prerequisite for any kind of biological effect of HePC and other ether lysophospholipid analogues, however, is the fact that cells are able to incorporate these substances into their membranes. The aim of this study was to investigate the mechanism of uptake of HePC into human tumor cell lines.

MATERIALS AND METHODS

Materials. HePC was synthesized as described before (14). [9,10-^{3}H]HePC (11.4 Ci/mmol) was a gift of Asta-Pharma AG (Frankfurt, Germany) and was diluted to 60 mCi/mmol prior to purification on preparative thin-layer chromatography (TLC) plates. The cholesterol determination kit, colchicine, monensin, chloroquine, cytochalasin B and desoxyglucose were from Sigma (Munich, Germany). Sodium thiocyanate was from Merck (Darmstadt, Germany). Ficoll-Hypaque was from Biochrom (Berlin, Germany). Neutrophile isolation medium (NIM) was from Packard (Los Alamos Diagnostics, Los Alamos, NM). Sephadex G-15 was from Pharmacia (Freiburg, Germany) and the phosphorus determination kit, according to Eibl and Lands (15), was from Serva (Munich, Germany). All other chemicals were of commercial grade and used without further purification.

Cell lines. All cells were from the American Type Culture Collection (ATCC, Rockville, MD). KB is a human epidermoid cancer cell line; MDA MB 231 is a human mammary carinoma derived cell line. Swiss 3T3 is a murine fibroblast cell line. HL 60, U937 and K 562 are human leukemic cell lines of myeloid origin. The Raji cell line was isolated from a human Burkitt lymphoma (16).

Cell culture. The cells were all maintained in Click's/RPMI 1640 medium supplemented with 20 mM *N*-(2-hydroxyethyl)piperazine-*N'*-(3-ethanesulfonic acid), pH 7.3, 100 U/mL penicillin, 100 μg/mL streptomycin, 10 mM L-glutamin and 10% fetal calf serum (FCS). Cell cultures were checked for mycoplasma contamination at regular time intervals. For subcultering or experiments. adherent cells were detached from the culture flasks by 0.025% trypsin in 20 mM EDTA and washed twice in fresh medium. Suspension culture cell lines were centrifuged and resuspended in fresh medium. Cell number and viability was determined in a Neubauer cell counting chamber by trypan blue dye exclusion (17).

Proliferation assay. Cells ($0.5–2 \times 10^6$/well) were incubated in six-well plates (5 mL medium/well) with HePC for 48 h at 37°C and pulsed with [^{3}H]thymidine (2 μCi/mL) for the last 6 h of culture. Aliquots were taken from each well and transferred to a 96-well microtiter plate, which was then processed in a semi-automatic cell harvester (Cambridge Technology, Cambridge, MA). Cells were collected on glass-fiber filters, and the amount of

Abbreviations: ATP, adenosine triphosphate; FCS, fetal calf serum; HePC, hexadecylphosphocholine; NaSCN, sodium thiocyanate; NIM, neutrophile isolation medium.

[^{3}H]thymidine incorporated was determined by liquid scintillation counting using a Packard model Tricarb counter (Packard Instruments, Frankfurt, Germany). The rest of the cultures was transferred into 15-mL tubes, centrifuged at 400 × *g* for 10 min and resuspended in 1 mL culture medium. Cell number and viability were determined in a Neubauer cell counting chamber by Trypan blue dye exclusion.

[^{3}H]HePC uptake. Cells (0.5 to 4 × 10^6/mL) were incubated at 37°C for 2 h before [^{3}H]HePC (0.1 μCi/mL) was added. Simultaneously, unlabeled HePC was added at the desired concentration. During this preincubation time, cells were either left untreated, treated with endocytotic inhibitors or treated with inhibitors of adenosine triphosphate (ATP) generation. At indicated time intervals, aliquots were taken and washed three times in ten volumes of ice-cold phosphate buffered saline containing 5% FCS. Cell pellets were finally lysed in liquid scintillation fluid, and cell associated radioactivity was measured by liquid scintillation counting.

Phospholipid and cholesterol contents. Cellular lipids were extracted from a known number of cells with hexane/isopropanol (3:2, vol/vol) and dried under nitrogen. The extracts were then redissolved in chloroform/methanol/water (5:10:2, by vol), desalted over a Sephadex G-15 column, and dried again. Lipid phosphorus was then determined by the method of Eibl and Lands (15). Total cholesterol was assayed by an enzymic color reaction according to Sale *et al.* (18).

Preparation of blood leukocytes. Citrated whole blood was layered on top of a Ficoll-Hypaque/NIM (1:4, vol/vol) mixture. After centrifugation at 400 × *g* for 45 min, granulocytes and lymphocytes were collected with a Pasteur pipette from the upper interface and the lower interface, respectively. The granulocyte and the lymphocyte fractions were tested for contaminating cells in an automated cell counter and were found to be more than 90% pure. Both cell fractions were washed three times in fresh medium and incubated at 37°C for 1 h before [^{3}H]HePC and HePC was added. Uptake of HePC was monitored as described for the cultured cells.

RESULTS

Lipid content of the cell lines. The cell lines used in this study showed a large variation in membrane phospholipid and cholesterol content reflecting their different cell size (Table 1). Besides having varying lipid contents, these cell lines also reacted quite differently to HePC. The sensitivity toward HePC in our proliferation assays (Table 2) ranged from 0.5 μg/mL (1.18 μM) HePC for the most sensitive cell line (KB) to above 35 μg/mL (82.4 μM) for K562 cells.

The difference in sensitivity for HePC between the cell lines, however, neither correlated with the phospholipid content nor with the cholesterol content of the cells. Also, no correlation between sensitivity toward HePC and the phospholipid-to-cholesterol ratio was found between different cells.

Time dependence of uptake. The uptake of HePC (10 μg/mL, 23.5 μM) was investigated at 37°C on the cell lines listed in Table 1 and on freshly prepared human granulocytes, lymphocytes and erythrocytes (Fig. 1). To account for cell size differences, uptake of HePC was expressed as nmol per 100 nmol cellular phospholipids. All cells incorporated HePC in a time-dependent manner. With the exception of the KB cell line, uptake was linear with time for the first 2–3 h of incubation. Independent of the

TABLE 1

Cellular Lipid Content[a]

Cell line	Lipid phosphorus (nmol/10^6 cells)	Cholesterol (nmol/10^6 cells)	Ratio[b]
KB	108.8 ± 13.1	16.0 ± 4.8	6.8
MDA MB 231	110.8 ± 11.5	24.4 ± 7.5	4.5
HL 60	40.7 ± 7.1	7.4 ± 3.0	5.5

Swiss 3T3	143.9 ± 14.4	29.5 ± 18.3	4.9

[a]Lipid phosphorus and cholesterol content were determined on lipid extracts of a known number of cells. Data represent the mean ± SD of at least five independent determinations.
[b]The ratio of lipid phosphorus *vs.* cholesterol, calculated from the mean values.

TABLE 2

Sensitivity of the Cell Lines to Hexadecylphosphocholine[a]

Cell line	ID_{50} (a) (μM)	ID_{50} (b) (μM)	LD_{50} (c) (μM)
KB	1.6 ± 0.6	5.4 ± 3.0	3.1 ± 2.3
MDA MB 231	19.1 ± 3.1	50.4 ± 12.9	41.2 ± 6.5
HL 60	6.6 ± 4.5	5.4 ± 3.2	5.2 ± 2.6
K 562	56.7 ± 4.3	66.6 ± 4.5	>85
U 937	5.9 ± 3.0	8.0 ± 0.7	17.6 ± 2.3
Raji	7.1 ± 4.2	16.9 ± 7.2	58.8 ± 6.0
Swiss 3T3	>85	n.d.	>85

[a]ID_{50} values were calculated based on cell count (a) or [^{3}H]-thymidine incorporation data (b). LD_{50} values were calculated from trypan blue dye exclusion asays (c). Data are the mean values ± SD of three to six independent experiments; n.d., not determined.

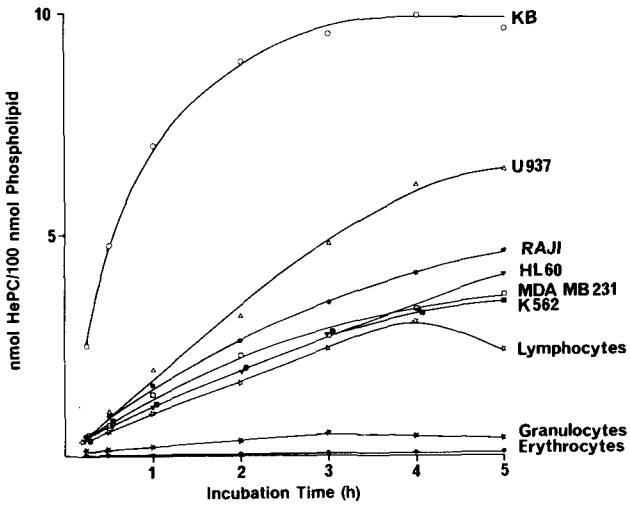

FIG. 1. Time-dependent uptake of hexadecylphosphocholine (HePC) in different cells. The amount of HePC taken up is calculated per 100 nmol cell phospholipid. Incubation conditions are given in Materials and Methods. Data show the mean values of three independent experiments.

number of cells in incubation (0.5 to 4 × 10^6/mL), the rate of uptake of HePC per 100 nmol cellular phospholipids was constant for each cell line tested. However, saturation was not reached even after 5 h of incubation. For KB cells, uptake was very fast and apparently saturation was reached already after 3 h of incubation. A correlation between the uptake rate of HePC and sensitivity for this compound was not observed, since Swiss 3T3 and HL 60, the most resistant and one of the most sensitive cell lines, respectively, took up HePC at similar rates, leading to an almost identical HePC-to-phospholipid ratio.

Concentration dependence of uptake. For subsequent investigations we selected four tumor cell lines: KB, MDA MB 231, HL 60 and K 562. A concentration-dependent uptake of HePC (5–20 μg/mL, 11.8–47.1 μM) at 37°C for the selected cell lines is shown in Figure 2, indicating that the uptake of HePC was linearly dependent on the HePC concentration.

Temperature dependence of uptake. Next we studied the effect of lower temperatures on the uptake of HePC (Fig. 3). In all four cell lines the uptake was strongly inhibited at 20°C. At 4°C no uptake was observed at all.

Furthermore, the release of [^{3}H]HePC from cells preloaded for 1 h at 37°C was also found to be temperature-dependent (data not shown). After 2 h of incubation in HePC-free medium, cells had lost about 30% HePC at 37°C and about 10–15% at 4°C. At the lower temperature, however, an increasing amount of the cells became trypan blue positive after prolonged incubation so that the real amount of HePC release was probably much lower.

Binding at 4°C. To test the possibility of receptor-mediated binding of HePC, the cells were incubated with 1 μCi [^{3}H]HePC and increasing amounts of unlabelled HePCat 4°C. Binding was linear with HePC concentration up to 100 μg/mL (235.3 μM), indicating that HePC binding is probably not receptor-mediated (Fig. 4). The maximum concentration was high enough to lyse the cells after about 3 h of incubation, even in the presence of 10% FCS. KB cells, for instance, were damaged severely as

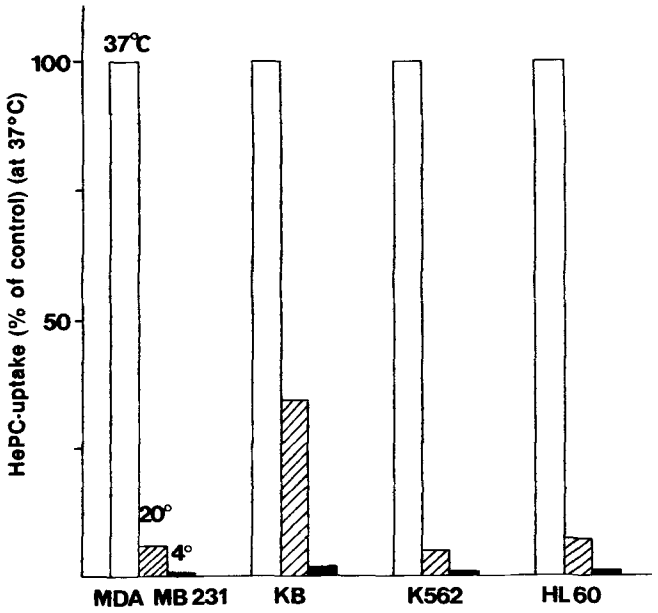

FIG. 3. Influence of low temperature on hexadecylphosphocholine (HePC) incorporation. Cells were incubated at the indicated temperature for one hour before HePC was added. Then incubation was continued for another two hours. After this period the cells were processed by the standard procedures as described in Materials and Methods. Data shown are the mean values of two independent experiments in duplicate.

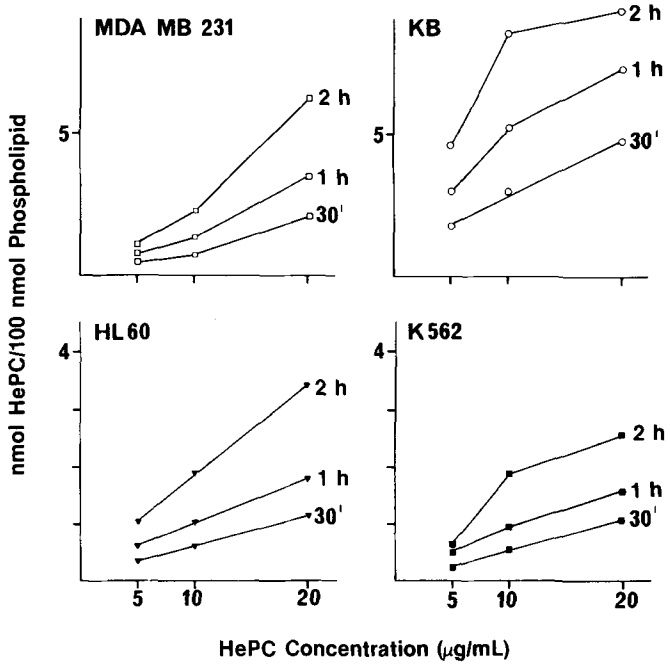

FIG. 2. Concentration-dependent uptake of hexadecylphosphocholine (HePC) in four selected cell lines. The incubation time was 45 min at 37°C. Data shown are the mean values of two independent experiments in duplicate.

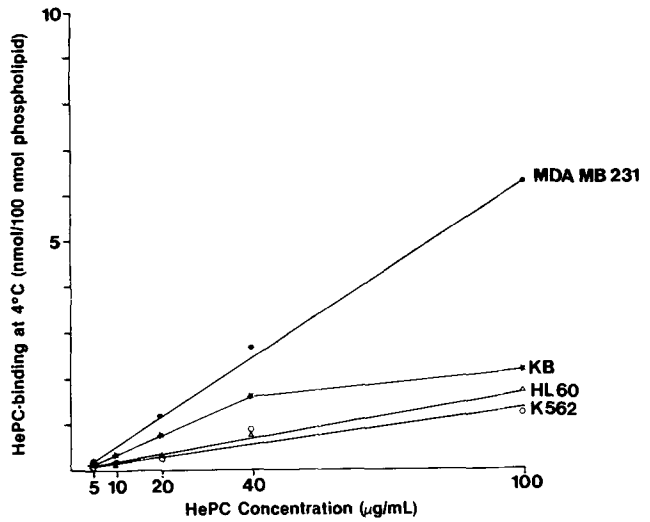

FIG. 4. Binding of hexadecylphosphocholine (HePC) to the extracellular surface of the plasma membrane. Binding studies were performed at 4°C to prevent internalization of HePC. The amount of HePC bound to the extracellular surface was determined after two hours of incubation at the concentration of HePC indicated. Data shown are the mean values of two independent experiments in duplicate.

shown by trypan blue dye exclusion, which leads to a loss of cells in the washing procedure and, consequently, to a decrease in the observed binding of HePC.

Influence of FCS. The effect of FCS in the medium on the incorporation of HePC (5 μg/mL, 11.8 μM) into the tumor cell lines is shown in Figure 5. In the absence of FCS, the cells incorporated substantially higher amounts of HePC showing faster uptake kinetics than in the presence of FCS. We were not able to study uptake kinetics at higher concentrations of HePC or for longer time periods in the absence of FCS because under such conditions the cells were increasingly damaged. In the presence of FCS, however, at 10 μg/mL (23.5 μM) the cells showed no adverse effects for incubation times as long as five hours.

Energy depletion. To investigate whether the uptake of HePC is energy-dependent, the cells were preincubated with sodium thiocyanate (NaSCN, 13.4 μM) and desoxyglucose (62.9 μM), which block oxidative phosphorylation and the glycolytic pathway, respectively (19,20). The compounds alone had little effect on the uptake of HePC (Fig. 6), but a combination of both compounds decreased uptake to between 60 to 80% of controls.

Inhibition of intracellular vesicle transport. The effects of monensin, colchicine, cytochalasin B and chloroquine, well known inhibitors of intracellular transport, are shown in Figure 7. In general, cytochalasin B (41.8 μM) and monensin (29.8 μM) showed rather strong effects, with uptake inhibition up to 50% for monensin and 70% for cytochalasin B. Chloroquine (62.5 μM) and colchicine (3.75 μM) were weaker uptake inhibitors. However, individual cell lines reacted differently to these compounds.

Coprecipitation of HePC with membrane particles. When HL 60, MDA MB 231 or KB cells were loaded for

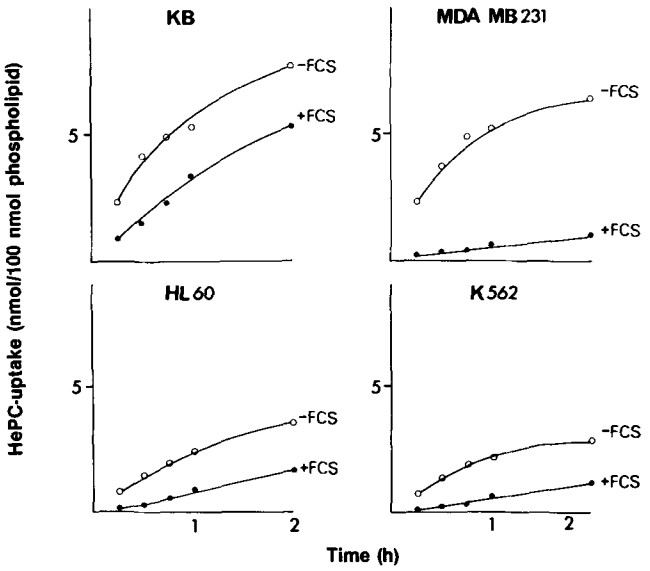

FIG. 5. Influence of fetal calf serum (FCS) on hexadecylphosphocholine (HePC) incorporation. Four selected cell lines were incubated in the presence or absence of 10% FCS, with 5 μg/mL HePC. At indicated time points, aliquots of the cell suspension were taken and incorporation of HePC determined as described in Materials and Methods. Data shown are the mean values of two independent experiments in duplicate.

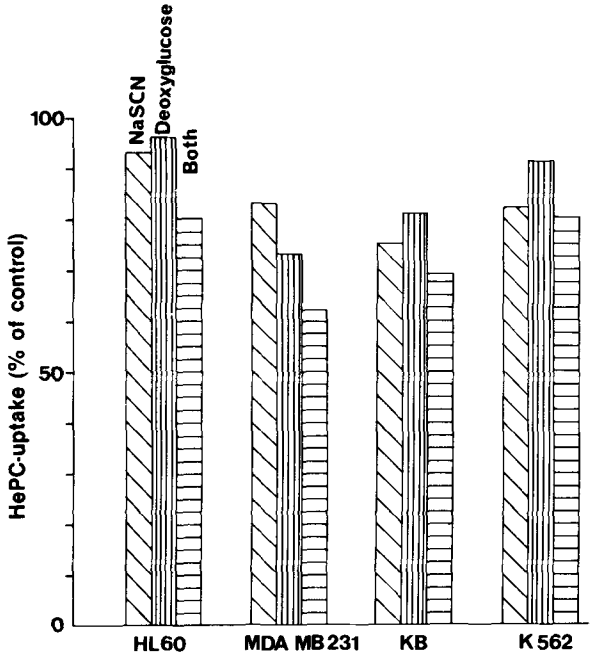

FIG. 6. Effect of energy depletion on hexadecylphosphocholine (HePC) uptake. Cells were preincubated for one hour at 37°C with medium alone (control), sodium thiocyanate (NaSCN) (123.4 μM), deoxyglucose (62.9 μM), or both. Then HePC (10 μg/mL, 13.5 μM) was added, and after two hours of incubation the amount of HePC incorporated in the cells was determined. Data shown are the mean values of three independent experiments.

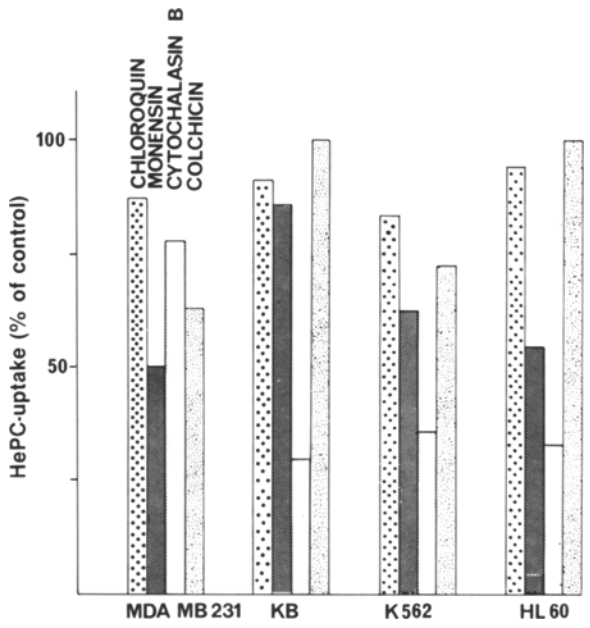

FIG. 7. Effects of inhibitors of intracellular vesicle transport on hexadecylphosphocholine (HePC) incorporation. Cells were preincubated at 37°C for one hour with medium alone (control), monensin (29.8 μM), cytochalasin B (41.8 μM), colchicine 3.75 μM) or chloroquine (62.5 μM). After further incubation with 10 μg/mL (13.5 MM) HePC for one hour, incorporation of HePC in the cells was determined as described above. Data shown are the mean values of two independent experiments in duplicate.

[a]Hexadecylphosphocholine (HePC) incorporation in fetal calf serum (FCS)-washed whole cells.
[b]HePC incorporation in cell pellets after freezing with distilled water and washing with isotonic NaCl.
[c]HePC incorporation in cell pellets after freezing with distilled water and washing with isotonic NaCl plus 10% FCS.
[d]HePC contents were calculated per 100 nmol phospholipid. Data are mean values ± SD of two independent experiments.

2 h with 10 μg/mL (23.5 μM) of HePC and subsequently washed three times with medium containing 10% FCS, no further removal of HePC from the cells was observed (data not shown). After lysis of these cells by freezing with distilled water, followed by washing with isotonic NaCl, the HePC-to-phospholipid ratio in the cell pellets was very similar to that of the total cells (Table 3). However, when the pellets were washed with NaCl containing 10% FCS, a substantial amount of incorporated HePC could be removed, leading to lower HePC-to-phospholipid ratios for all three cell lines studied.

DISCUSSION

When following the incorporation of lysolipid analogues, such as HePC, which favor various membrane sites of the cells, differences in cell size and membrane lipid content have to be considered. Since HePC is incorporated into cellular membranes, cells with higher amounts of membrane lipids are likely to accommodate more HePC than cells containing less membrane lipid. To account for this possibility, we determined the lipid phosphorus contents of the cells under study and normalized HePC uptake to nmol HePC per 100 nmol cellular phospholipid.

Based on such calculations, we found that under physiological conditions at 37°C, both sensitive and insensitive cell lines took up HePC in similar amounts. Thus, a direct correlation between uptake of HePC and sensitivity toward HePC was not apparent. The epidermoid cancer cell line KB, that is very sensitive to HePC and incorporated about twice the amount as other cells, seemed to have a higher capacity of HePC uptake.

Another parameter that could account for differences in sensitivity is the presence of cholesterol in the cellular membranes, since cholesterol is known to protect against the action of ether lysophospholipids (21) in such a way that even stable liposomes can be prepared from 1-to-1 molar mixture of lysophosphatidylcholine and cholesterol (22). Here again, when comparing different cells, no correlation between the cellular level of cholesterol and HePC sensitivity was found. For instance, HL 60 and Raji cells have a very similar cholesterol content, but showed at least a tenfold difference in LD50. Therefore a simple mechanism for HePC cytotoxicity based on HePC accumulation followed by cell lysis seems unlikely.

For further investigations on the mechanism of HePC uptake, we selected two HePC sensitive cell lines, KB and HL 60, and two resistant lines, MDA MB 231 and K562. In these experiments, we could not detect any significant difference in uptake when comparing monolayers or suspension cultures prepared from the adherent cell lines.

When the cells were incubated with varying concentrations of HePC, uptake was linear with increasing concentrations up to 40 μg/mL (94.1 μM). At 40 μg/mL, the HePC concentration is well above the critical micellar concentration determined for HePC in absence of FCS (*ca.* 8 μM). At 37°C, in the presence of 10% FCS, 42 μg/mL HePC (100 μM) began to induce erythrocyte lysis (not shown), whereas in 40 μg/mL (94.1 μM) the erythrocytes were stable for at least 2 h. Apparently, HePC uptake is not saturable.

For another ether phospholipid, platelet activating factor (PAF), the existence of specific cell membrane receptors has been established (23,24). Therefore, incubations with increasing concentrations of HePC were performed at low temperatures. Under these conditions, uptake of HePC was inhibited (Fig. 3). No saturation of HePC binding sites was attained up to a concentration of 100 μg/mL (235.3 μM), indicating that HePC association with cell membranes is probably not receptor-mediated. The uptake of HePC in the cells is only moderately sensitive to energy depletion. A one-hour preincubation with sodium thiocyanate and deoxyglucose led to a reduction of uptake of about 30%. Since pump proteins normally need ATP as their source of energy (25), or act through a sodium gradient that is maintained by a sodium dependent ATPase (26), we conclude that no HePC specific pump protein is present.

Cytochalasin B, a drug known to desintegrate actin filaments (27), has been reported to be a strong inhibitor for endocytosis (28,29). Also, it drastically decreased the uptake of HePC. Another potent inhibitor of HePC-uptake was monensin. This substance elevates lysosomal and endosomal pH levels thereby leading to a loss of endocytotic activity. It impairs a variety of cellular functions (30,31) and also interferes with the action of certain parasites (32). However, chloroquine, which is also known to elevate the pH in acidic intracellular compartments (33), showed a much weaker effect on HePC uptake. Colchicine, which stabilizes microtubuli and thereby interferes with endocytotic processes (34), was not very active in reducing HePC uptake.

The drastic effects observed with cytochalasin B and monensin strongly point in the direction of a nonspecific endocytosis-dependent mechanism for the uptake of HePC.

Probably, HePC-uptake is based on a membrane renewal process driven by pinocytosis. It has been shown for a variety of cells that high amounts of extracellular fluid or medium and solutes present in the medium are ingested by pinocytosis (35,36), resulting at the same time in substantial exchange of lipids between the plasma membrane and intracellular membranes. Uptake rates of HePC in the presence of serum proteins are about two- to threefold lower than in the absence of serum proteins.

Serum albumin, a protein known to bind lysophosphatidylcholines (37-43), has been reported to also bind ether lysophospholipids such as ET-18-OCH_3 (44) and HePC (45). Serum albumin is also known to extract lysophosphocholines from membranes (39-43). It is therefore also likely to lower the net endocytotic ingestion of HePC by re-extracting this compound from the plasma membrane back into the medium (see Table 3). Thus, serum albumin lowers the effective amount of HePC that is immediately available to the cell *via* membrane recycling.

Our data show, that, with the exception of KB cells, HePC is taken up by the cells to a similar HePC-to-phospholipid ratio in resistant as well as in sensitive cell lines. Uptake is temperature-dependent and can be blocked by inhibitors of endocytosis. In the presence of FCS, HePC-uptake in the cells is lowered, due to binding of HePC to serum albumin (45). Serum albumin is likely to re-extract HePC back from the plasma membrane into solution (Table 3). Since HePC-uptake between 5 μg/mL (11.8 μM) and 40 μg/mL (94.1 μM) is linearly dependent on HePC-concentration, it seems that HePC uptake is not protein-dependent. We therefore suggest that HePC-uptake takes place, after intercalation with the plasma membrane, by a membrane-recycling-dependent endocytotic mechanism. This conclusion is in agreement with data by Bazill and Dexter (46), who found that ET-18-OCH_3 is taken up by an endocytotic mechanism, that can be blocked by the same endocytotic inhibitors as we have used. However, Bazill and Dexter (46) concluded that resistance of cells to ether lysophospholipids is due to a reduced uptake, since resistant cells used in their study were found to incorporate less ET-18-OCH_3. Obviously, HePC must be incorporated into the cells before it can affect cell growth and cell viability, so that inhibition of uptake is one way of protecting cells from the cytotoxic effects of ether lysophospholipids. However, based on our finding, uptake alone can not account for variations in sensitivity for the different cells tested, since the most resistant cell line (3T3) and one of the most sensitive cell lines (HL60) incorporated HePC to reach almost identical HePC-to-phospholipid ratios.

The composition of the glycosphingolipids of the human gastrointestinal tract was studied. The major neutral glycosphingolipids were ceramide monohexosides (*e.g.*, GalCer, GlcCer), LacCer, Gb_3Cer, Gb_4Cer and more polar ones with more than four sugars, whereas neither Gg_3Cer nor Gg_4Cer were present. The acidic glycosphingolipids consisted of sulfatides and gangliosides such as G_{M3}, G_{M1}, G_{D3} and G_{D1a}. Also a large amount of sulfatides was found in the gastric mucosa and duodenum. The concentrations of sulfatides in the fundic mucosa, antral mucosa and duodenum amounted to 416.0, 933.8 and 682.9 nmol/g of dry weight, respectively, exceeding those in the gastric mucosa and kidney of other mammals. The major molecular species of the sulfatides were identified as I^3SO_3-GalCer with hydroxylated longer-chain fatty acids based on the analyses by gas–liquid chromatography and negative ion fast-atom bombardment mass spectrometry. In contrast, gangliosides in these regions showed a tendency to be lower than sulfatides, and the molar ratios of sulfatides to gangliosides were about 2.0, whereas those in other parts were less than 0.5. A high content of sulfatides in the gastric and duodenal mucosa, where mucosa is easily insulted by acid, pepsin and bile salts, may be closely related to their roles in mucosal protection.

Lipids 28, 737-742 (1993).

Gastrointestinal mucosa is a metabolically and mitotically active tissue, with various cells being engaged in digestion and absorption. In particular, gastric mucosa consisting of predominantly parietal cells, chief cells and mucous cells has unique functions, such as hydrochloric acid and pepsin secretion, while protecting the mucosa from such a severe environment. It is therefore of interest to clarify in detail the composition, distribution and metabolism of glycosphingolipids in the gastrointestinal tract. Previous studies on gastrointestinal mucosa have focussed on the characterization of fucolipids with blood group activities (3,4), on the characteristic expression of glyosphingolipids in the intestinal epithelium according to cellular differentiation and development (5-7) and on the structural characterization of sulfoglycosphingolipids in the gastric mucosa (8-11). However, systematic and detailed studies on the glycosphingolipid compositions of the whole gastrointestinal tract from esophagus to colon have not been undertaken.

In a previous paper, we have reported that sulfatides (I^3SO_3-GalCer with hydroxylated longer-chain fatty acids) were enriched in the rabbit gastrointestinal mucosal regions which are continuously exposed to acid and which were more resistant to acid hydrolysis than G_{M3}, the major ganglioside in the mucosal regions (12). Therefore, we have assumed that sulfatides might play a role in mucosal protection from acid environment. To extend our previous findings, we have attempted in the present study to systematically determine the glycosphingolipid composition of the human gastrointestinal tract.

MATERIALS AND METHODS

Tissues. The tissues (esophagus, stomach, duodenum, jejunum, colon and rectum) used in this study were obtained at autopsy from patients who had died of lung cancer, uterine cancer or Parkinson's disease. The whole intact mucosa was separated from the outer fibrosal and muscular layer, rinsed thoroughly with saline at 4°C and kept at −70°C until lipid extraction. Nine mucosal tissue samples were studied (Samples 1-9). Fundus Samples 2 and 3 as well as antrum Samples 4 and 5 were obtained from specific individuals, respectively.

Extraction and separation of glycosphingolipids. Tissues were homogenized in water and lyophilized. Total lipids were extracted from the lyophilized powder successively with chloroform/methanol/water (20:10:1, 10:20:1, 20:10:1, 10:20:1, by vol) and chloroform/methanol (1:1, vol/vol) at 40°C. Aliquots of the combined extracts were used for quantitation of cholesterol and lipid-bound phosphorus, and the remainder of the extracts was applied to a column of DEAE-Sephadex (A-25, acetate form) to separate into neutral and acidic lipid fractions as described previously (13). Neutral glycosphingolipids were prepared from the neutral lipid fraction by acetylation, Florisil column chromatography and deacetylation (14), while acidic glycosphingolipids were prepared from the acidic lipid fraction by mild alkaline hydrolysis. Salts in the neutral and acidic glycosphingolipids were removed by dialysis.

Thin-layer chromatography (TLC). Individual glycosphingolipids were chromatographed on silica gel 60 high-performance thin-layer chromatography (HPTLC) plates (E. Merck Co., Darmstadt, Germany) using the solvent

The nomenclature used for gangliosides and other glycosphingolipids follows the system of Svennerholm (Ref. 1) and the recommendation of the IUPAC-IUB Commission (Ref. 2), respectively.

systems A, chloroform/methanol/water (65:35:8, by vol) and B, chloroform/methanol/aqueous 0.5% $CaCl_2$ (55:45:10, by vol) and were detected with orcinol/H_2SO_4 reagent for neutral glycosphingolipids and sulfoglycosphingolipids and with resorcinol/HCl reagent for gangliosides. The mobilities in TLC were compared with those of standard neutral glycosphingolipids (GalCer, LacCer, Gg_3Cer, Gb_4Cer, Gg_4Cer), gangliosides (G_{M3}, G_{M2}, G_{M1}, G_{D3}, G_{D1a}, G_{D1b}, G_{T1b}) and sulfatides (I^3SO_3-GalCer).

Quantitative analysis. Cholesterol and lipid-bound phosphorus in the total lipid extracts were determined by gas–liquid chromatography (GLC) using 5α-cholestane as an internal standard (13) and by the method of Bartlett (15) after wet digestion with $HClO_4$ and H_2O_2, respectively. Lipid-bound sialic acid in the acidic glycosphingolipid fraction was measured by the resorcinol/HCl method (16). The individual neutral glycosphingolipids, sulfatides and gangliosides were quantitated densitometrically with a dual wavelength TLC densitometer (CS-9000; Shimadzu Co., Kyoto, Japan) after locating the spots with either orcinol/H_2SO_4 or resorcinol/HCl reagent. Orcinol-positive glycosphingolipids and resorcinol-positive gangliosides were monitored at 420 and 580 nm, respectively, while the control wavelength was set at 710 nm.

TLC-immunostaining. Immunostaining of glycosphingolipids on TLC plates was done as described previously (17). Briefly, after development of the glycosphingolipids on plastic TLC plates (Polygram; Macherey-Nagel, Düren, Germany), the plates were soaked in the blocking buffer [1% polyvinylpyrrolidone (PVP), 1% ovalbumin, 0.02% NaN_3 in phosphate-buffered saline (PBS)] at 37°C for 1 h. Then the developed plates with neutral glycosphingolipids were incubated with rabbit anti-Gg_3Cer (asialo G_{M2}) and anti-Gg_4Cer (asialo G_{M1}) antisera. On the other hand, the developed plates with acidic glycosphingolipids were incubated with cholera toxin (Sigma, St. Louis, MO), which has a strong affinity to G_{M1}, followed by incubation with rabbit anti-cholera toxin antiserum, and with mouse anti-G_{M2} monoclonal antibody, YHD-06, which detects GalNAcβ1-4Gal(3-2αNeuAc or NeuGc)β-structure (18). After the plates were washed five times with the washing buffer (0.1% Tween 20 in PBS) and reacted with blocking buffer at 37°C for 15 min, the antibodies bound to the plates were detected with horseradish peroxidase-conjugated goat anti-rabbit or anti-mouse Ig (G + M + A) (Miles Scientific Lab., Naperville, IL) and the enzyme substrate (H_2O_2 and 4-chloro-1-naphthol).

Preparative TLC. Ceramide monohexoside (CMH) and sulfatides were isolated by preparative TLC using solvent systems A and B, respectively. Bands with mobilities similar to CMH and sulfatides, as judged by staining a strip of the TLC plates with orcinol/H_2SO_4 reagent, were scraped from the plates, extracted by sonication in chloroform/methanol/water (10:10:1, by vol), and glycolipids were eluted from the gel by column chromatography.

Carbohydrate and fatty acid analyses. CMH and sulfatides isolated by preparative TLC were subjected to methanolysis with 1 M methanolic HCl at 80°C for 20 h. Fatty acid methyl esters were extracted with *n*-hexane, and the methanolic phase was used for carbohydrate analysis. The fatty acid methyl esters were analyzed by GLC on 3% OV-101 coated on Chrolite using temperature programming from 150 to 250°C at 2°C/min. The peak areas were corrected by comparison with the areas of peaks of an authentic mixture of fatty acid methyl esters, KF and KD (Applied Science Laboratories, State College, PA). The methanolic phase was evaporated to dryness under a flow of nitrogen, and reacetylated with methanol/acetic anhydride (4:1, vol/vol) at room temperature overnight. After evaporation, the carbohydrates in the residues were analyzed by GLC as the *N*-acetyl-*O*-trimethylsilyl derivatives using the same column and temperature programming from 150 to 200°C at 2°C/min.

Structure of sulfatides. Sulfatides were isolated from the acidic glycosphingolipid fraction by Iatrobeads (6RS8060; Iatron Lab., Tokyo, Japan) column chromatography with a linear gradient system of chloroform/methanol/water (70:30:0.5 and 70:30:5, by vol). The homogeneity of the isolated sulfatides was examined by comparing their mobilities on a TLC plate with those of standard sulfoglycosphingolipids, I^3SO_3-GalCer and II^3SO_3-LacCer. The structure of the isolated sulfatides was then analyzed by negative ion fast-atom bombardment mass spectrometry (FABMS) as follows. About 5 μg of the isolated sulfatides was mixed with about 5 μL of triethanolamine, and the resultant mixture was put on a stainless-steel sample holder to be inserted into the FABMS ion source. Analysis was performed by bombardment with a neutral xenon beam with a kinetic energy of 4–6 keV and detection of negative ions with a mass spectrometer (JMS HX-110; JEOL, Tokyo, Japan) equipped with a JMA-3500 computer system (JEOL). Assignment of mass numbers was achieved by comparing the spectrum with that of perfluoroalkyl phosphazine (Ultramark; PCR Inc., Jacksonville, FL).

RESULTS

Neutral glycosphingolipids of the human gastrointestinal tract. A thin-layer chromatogram of the neutral glycosphingolipids from different regions of the human gastrointestinal tract is shown in Figure 1. Neutral glycosphingolipids with mobilities similar to those of GalCer,

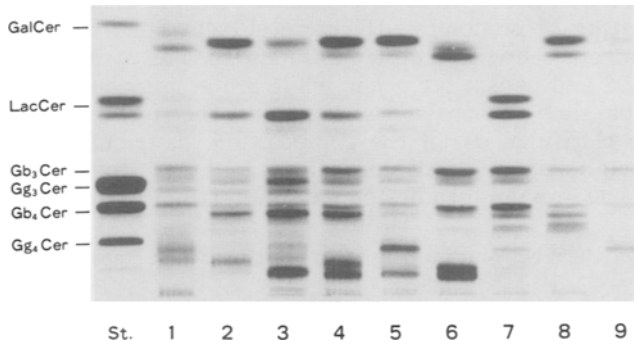

FIG. 1. Thin-layer chromatography of neutral glycosphingolipids from different regions of the human gastrointestinal tract. Lane 1, esophagus (Sample No. 1); lane 2, fundic mucosa (Sample No. 2); lane 3, fundic mucosa (Sample No. 3); lane 4, antral mucosa (Sample No. 4); lane 5, antral mucosa (Sample No. 5); lane 6, duodenum (Sample No. 6); lane 7, jejunum (Sample No. 7); lane 8, colon (Sample No. 8); lane 9, rectum (Sample No. 9); St., standard neutral glycosphingolipids. The amount of lipid applied to each lane corresponded to 2.7 mg dry weight of the respective tissue. Neutral glycosphingolipids were chromatographed on a high-performance thin-layer chromatography plate with solvent system A, and fractions were visualized with orcinol/H_2SO_4 reagent.

LacCer, Gb_3Cer and Gb_4Cer were clearly separated and resolved further into two or three bands presumably due to differences in molecular heterogeneity in their ceramide portion. As described in the result of TLC-immunostaining, neither Gg_3Cer nor Gg_4Cer were present in the normal gastrointestinal mucosa, but several bands corresponding to glycosphingolipids having more than four sugars were seen below Gb_4Cer.

Acidic glycosphingolipids of the human gastrointestinal tract. As clearly shown in Figure 2, sulfatides (I^3SO_3-GalCer) were present in much higher concentration in the gastric mucosa and duodenum than in the other parts of gastrointestinal tract. The mobilities of sulfatides in the antral mucosa and duodenum on a TLC plate were lower than those of standard sulfatides from human brain, indicating that the greater part of these sulfatides contained more hydroxylated, longer-chain fatty acids. The principal gangliosides in the human gastrointestinal tract were G_{M3}, G_{M1}, G_{D3} and G_{D1a}. They amounted for more than 80% of all gangliosides.

Detection of glycosphingolipids by TLC-immunostaining. In order to confirm the structure of glycosphingolipids, TLC-immunostaining with carbohydrate-specific ligands was used. With rabbit anti-Gg_3Cer and anti-Gg_4Cer antisera, neither Gg_3Cer nor Gg_4Cer was detected in the neutral glycosphingolipids from human gastrointestinal mucosa. Binding of cholera toxin to G_{M1} was observed in the acidic glycosphingolipids from all tissues examined. Although the concentration of G_{M1} in the human gastrointestinal mucosa was 30 nmol/g of dry weight as the highest level, which could hardly be detected by conventional TLC using resorcinol/HCl reagent, G_{M1} was easily detected by TLC-immunostaining with cholera toxin (Fig. 3). Gangliosides having the nonreducing carbohydrates of G_{M2} were not detected in the human gastrointestinal mucosa by TLC-immunostaining with mouse anti-G_{M2} monoclonal antibody YHD-06 (18).

Carbohydrate and fatty acid compositions of CMH and sulfatides. The carbohydrate and fatty acid compositions of CMH and of sulfatides are listed in Table 1 and Table 2,

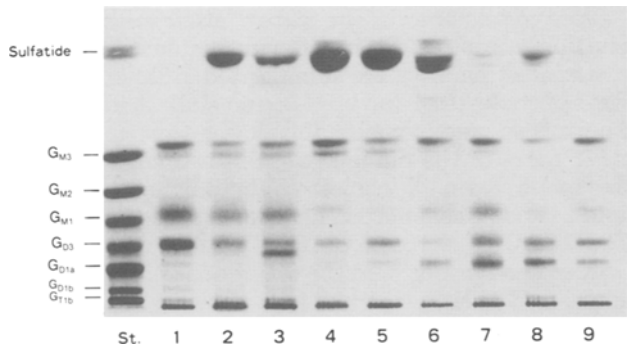

FIG. 2. Thin-layer chromatography of acidic glycosphingolipids from different regions of the human gastrointestinal tract. The lane numbers, 1 to 9, correspond to those in Figure 1. St., standard sulfatides (I^3SO_3-GalCer from human brain) and gangliosides. The amount of lipid in each lane corresponded to about 10 mg dry weight of the respective tissue. Sulfatides and gangliosides were chromatographed on a high-performance thin-layer chromatography plate with solvent system B, and fractions were located with orcinol/H_2SO_4 reagent.

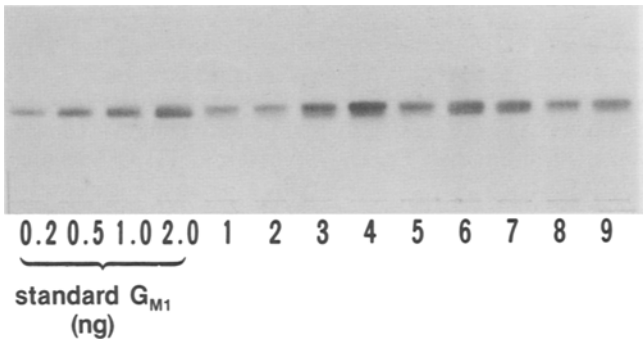

FIG. 3. Thin-layer chromatography (TLC)-immunostaining of ganglioisides from different regions of the human gastrointestinal tract using cholera toxin. Total acidic glycosphingolipids from 0.06–0.07 mg dry weight of the respective tissues and standard G_{M1} (0.2–2.0 ng of sialic acid) were chromatographed on a plastic TLC plate using solvent system B. The plate was tested for cholera toxin binding by TLC-immunostaining. The plate numbers, 1 to 9, correspond to those in Figure 1. A compound without carbohydrate, probably derived from a dialysis bag, was contaminating the region close to G_{M1} and gave a brown spot, not a purple one as for gangliosides, upon resorcinol/HCl staining (see Fig. 2). To assess the correct concentration of G_{M1}, cholera toxin, a specific ligand for G_{M1}, was used. The contaminant explains differences in apparent intensity in the G_{M1} regions in Figure 2 and Figure 3.

respectively. As shown in Table 1, the concentration of GalCer was higher than that of GlcCer in the gastric mucosa, colon and rectum. In the antral mucosa, the molar ratio of galactose to glucose in CMH was 2-2.5, and the higher proportion of GalCer corresponded to the relatively higher concentration of sulfatides in the antral mucosa that may serve as possible substrate for the synthesis of sulfatides. On the other hand, GlcCer was the predominant CMH in the esophagus, duodenum and jejunum. The fatty acids of CMH and sulfatides in the human gastrointestinal mucosa consisted mostly of nonhydroxylated fatty acids with chain lengths of C_{16} to C_{20} and hydroxylated fatty acids with chain lengths of C_{22} to C_{26}. In particular, more than 60% of the fatty acids of sulfatides in the antral mucosa and duodenum were the hydroxylated longer-chain fatty acids, about 10% of which were 28h:0 (h, hydroxy). Also, there were close similarities between the fatty acid compositions of CMH and of sulfatides in the antral mucosa.

Structure determination of sulfatides. Sulfatides were isolated from the acidic glycosphingolipid fraction of the fundic mucosa (Sample No. 3) by Iatrobeads column chromatography. The isolated sulfatides showed the same mobility on TLC as did I^3SO_3-GalCer from human brain and were directly analyzed by negative ion FABMS. As shown in Figure 4, intense molecular ions, $[M-H]^-$, were observed at *m/z* 778, 794, 878, 890, 906 and 934, corresponding to the sulfatides (I^3SO_3-GalCer) with 4-sphingenine and the fatty acids 16:0, 16h:0, 22h:0, 24:0, 24h:0 and 26h:0, respectively. The relative intensities of the ions were in good agreement with the fatty acid compositions of the sulfatides isolated from the fundic mucosa (Sample No. 3) as determined by GLC (Table 2). In addition, the fragment ions of the terminal sulfate group at *m/z* 97, $[HSO_4]^-$, were clearly identified.

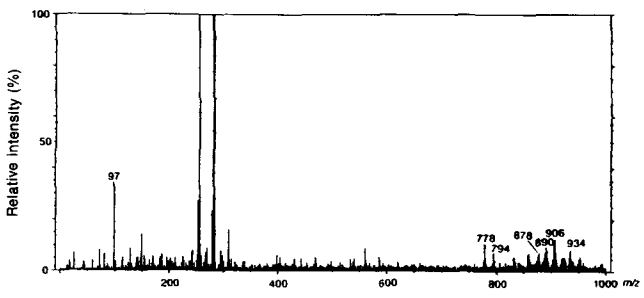

FIG. 4. Negative ion fast-atom bombardment mass spectrometry (FABMS) spectrum of the sulfatides isolated from the human gastric fundic mucosa. About 5 μg of the isolated sulfatides was analyzed by negative ion FABMS with 5 μL of triethanolamine as the matrix solvent.

Lipid composition of the human gastrointestinal tract. The lipid compositions in different regions of the human gastrointestinal tract are summarized in Table 3. The contents of cholesterol and lipid-bound sialic acid in the fundic mucosa were considerably lower than those in the other parts of the human gastrointestinal mucosa, and the molar ratio of cholesterol/lipid-bound sialic acid/lipid-bound phosphorus in the fundic mucosa was 12.0-15.0:0.4-0.7:100.0. CMH (GlcCer, GalCer), LacCer, Gb_3Cer and Gb_4Cer were the major neutral glycosphingolipids, and their concentrations varied in the different regions. Although sulfatides were present throughout the human gastrointestinal tract, the highest content of sulfatides was observed in the gastric mucosa and duodenum. The concentrations of sulfatides in the fundic mucosa, antral mucosa and duodenum amounted to 416.0, 933.8 and 682.9 nmol/g of dry weight, respectively. In contrast, the total amounts of lipid-bound sialic acid in the gastric mucosa and duodenum were lower than those in the other parts, and molar ratios of sulfatides to lipid-bound sialic acid were 1.37-1.97, 2.10-2.33, and 1.95 for the fundic mucosa, antral mucosa and duodenum, respectively, whereas those in the other parts were about 0.5 or below (Table 3).

DISCUSSION

We have previously shown that sulfatides are preferentially enriched in the rabbit gastroduodenal mucosa (12). In the present study, it was clearly demonstrated that human gastric mucosa and duodenum also contains large amounts of sulfatides, exceeding those present in the gastric mucosa of other mammals (8-12,19). More than 60% of the sulfatides in the antral mucosa and duodenum were identified as I^3SO_3-GalCer having hydroxylated longer-chain (C_{22} to C_{28}) fatty acids. α-Hydroxylation of fatty acids in I^3SO_3-GalCer is frequently observed in kidney (20-22) or epithelial cells of mammals (7). For example, contents of I^3SO_3-GalCer with α-hydroxylated

TABLE 3

Lipid Composition in Different Regions of the Human Gastrointestinal Tract[a]

longer-chain (C_{22} to C_{26}) fatty acids in the total sulfatides have been reported to be 72% in rat kidney (20), 84% in house musk shrew kidney (21), 37% in human kidney (22), 35% in hog gastric mucosa (8) and 70% in rabbit fundic mucosa (12). It has been proposed that as the fatty acids in the ceramide part of sphingolipids become more hydroxylated and longer-chained, the more stable and impermeable the membranes become (23,24). To protect the cells in the strong acid environment, a more sturdy and acidically charged cell membrane that can resist high concentrations of hydrochloric acid may be required. I^3SO_3-GalCer with hydroxylated longer-chain fatty acids is likely to be a most suitable molecule for that purpose.

In the present study, it was shown that the major neutral glycosphingolipid components in the human gastrointestinal tract are CMH (GalCer, GlcCer), LacCer, Gb_3Cer, Gb_4Cer and probably lacto-series glycosphingolipids including fucolipids. Human gastric mucosa (25) and small intestine (3) are known to be a rich source of fucolipids, which possess antigen activities of the human ABH and Lewis blood group types. On the other hand, the ganglio-series neutral glycosphingolipids (Gg_3Cer and Gg_4Cer) were not present, whereas gangliosides belonging to the ganglio-series were detected in the normal gastrointestinal mucosa. In addition, CMH in the antral mucosa was shown to have a higher proportion of GalCer and a close similarity in fatty acid composition to that of sulfatides, indicating that CMH may serve as the precursor of sulfatides in the antral mucosa. G_{M3}, G_{M1}, G_{D3} and G_{D1a} were the principal gangliosides comprising more than 80% of all gangliosides. We could not find G_{M2} in the normal gastrointestinal mucosa by TLC-immunostaining with anti-G_{M2} monoclonal antibody YHD-06. G_{M2} is considered to be one of the cancer-associated glycosphingolipids in melanoma (26,27), lung carcinoma (28), colonic carcinoma (29) and gastric carcinoma (30). As clearly shown in the result of the binding of cholera toxin to G_{M1} by TLC-immunostaining, G_{M1} is present in the surface of virtually all regions of human gastrointestinal mucosa. *Vibrio cholerae* produces the secretory cholera toxin, which specifically binds to G_{M1} in cell membranes and activates membrane-bound adenylate cyclase through ADP-ribosylation of GTP-binding protein, leading to severe diarrhea (31-33). However, there is no convincing evidence that the cholera toxin has any direct effect on any regions other than the small intestine through G_{M1} receptors. Moreover, little is known about the mechanisms of specific targetting of *V. cholerae* in the small intestine.

It is known that sulfatides exist in the mammalian nervous system, kidney, testis and avian salt gland. A high content of sulfatides in these tissues has been thought to be involved in myelin sheath formation (34), ion transport (35-38) and spermatogenesis (39). Although the presence of sulfatides in the mucosal tissue is well established, their biological function in the gastrointestinal tract has not yet been clarified. However, the preferential enrichment of sulfatides in the gastric mucosa and duodenum, which are continuously exposed to aggressive factors, such as acid, pepsin and bile salts, strongly indicates that sulfatides play an important role in mucosal protection. In addition, in our preliminary study of the effect of sulfatides against experimental ulcers in rats, sulfatides showed antiulcer activity (detailed data to be published elsewhere). Conversely, it has been recently reported that sulfated glycolipids may serve as the mucosal receptor for colonization of *Helicobacter pylori* (40,41), which colonizes only in the gastric epithelium and is now considered to be associated with gastritis and peptic ulcer (42-44). In our experiments, viable *H. pylori* showed a strong binding to sulfatides by TLC-immunostaining with rabbit anti-*H. pylori* antiserum (45). Sulfatides in the gastric mucosa may serve as receptor for the attachment and colonization of *H. pylori*. However, it is still unclear why *H. pylori* has not yet been detected in the duodenum, which also contains a large amount of sulfatides. Further studies on the cellular localization and on the conformation of sulfatides are needed to elucidate the mechanisms of specific attachment and colonization of *H. pylori* in the gastric epithelium.

Fish Erythrocytes as a Tool to Study Temperature-Induced Responses in Plasma Membranes

I. Dey[a], T. Szegletes[b], Cs. Buda[a], J. Nemcsók[b] and T. Farkas[a,*]

[a]Institute of Biochemistry, Biological Research Centre, Hungarian Academy of Sciences, H-6701 Szeged and [b]Institute of Biochemistry, József Attilla University, Szeged, Hungary

The dorsal aorta of carp (*Cyprinus carpio* L.) was cannulated, and the fish were kept in thermostated aquaria at 5°C for 24 h. The water temperature was then gradually increased to 25°C at a rate of 0.5°C/h, and then decreased to 5°C at the same rate. Blood was withdrawn at five-degree intervals to determine the fluidity of erythrocyte plasma membranes upon *ex vivo* incorporation of the fluorescent dye, 3-[*p*-(6-phenyl-1,3,5-hexatrienyl)phenyl]propionic acid. Steady-state anisotropy (R_{ss}) of the plasma membranes increased and decreased with the increase and decrease in water temperature, respectively. The sterol-to-phospholipid ratio remained unchanged throughout the thermal shifts. The fatty acid compositions of the total phospholipids, of phosphatidylcholine and of phosphatidylethanolamine remained virtually unchanged, except for the level of arachidonic acid, which increased in erythrocytes from fish at the higher temperature (25°C). The molecular species compositions of phosphatidylcholines and phosphatidylethanolamines also remained unaffected throughout the thermal shifts. The erythrocyte plasma membranes were more responsive to temperature shifts *in vivo* than *in vitro* when percent efficacy was compared. Thus, factors other than lipid changes are conceivably involved in the adaptation of erythrocyte plasma membranes to short-term thermal changes.

Lipids 28, 743-746 (1993).

An inherent property of cells is their ability to maintain the structural and functional integrity of their membranes under changing environmental conditions. Temperature is one of the major external factors influencing membranes in poikilothermic animals. Changes in the composition and physical state of the membranes in response to changes in the prevailing ambient temperature have been observed in most cases studied so far (1,2). Restructuring of existing phospholipids, activation of different desaturases and adjustment of deacylation/reacylation reactions are examples of changes that occur in membranes in response to thermal shifts (3-8). Conventionally, such responses have been studied by disturbing the *status quo* of an experimental specimen and by looking for corrective responses in membranes or membrane lipids in the acclimated state. However, the mode of control of the physical state of membranes under conditions such as those often faced by poikilotherms, *i.e.,* the problem of maintaining function despite fluctuations in ambient temperature, is not well understood.

Abbreviations:DPH-PA, 3-[*p*-(6-phenyl-1,3,5-hexatrienyl)phenyl]propionic acid; GLC, gas-liquid chromatography; HPLC, high-performance liquid chromatography; PC, phosphatidylcholine; PE, phosphatidylethanolamine; TLC, thin-layer chromatography.

Most approaches involving the use of higher poikilotherms as experimental models do not allow us to follow the response to external variations within a single specimen. Moreover the specimens usually need to be sacrificed to gather response information. Thus, several specimens are usually required for such studies, and the response observed needs to be measured against variations between specimens.

Fish erythrocytes can be used to study adaptive responses to thermal changes at the membrane level within short time spans as these cells are nucleated and express many functions as do somatic cells. The advantage of studying erythrocytes over isolated membranes from other tissues or cells is the ease of their preparation. Furthermore, a recently introduced fluorescence label 3-[*p*-(6-phenyl-1,3,5-hexatrienyl)phenyl]propionic acid (DPH-PA), permits the study of the physical properties of plasma membranes *in situ* shortly after collecting the cells (9). The present study thus provides evidence that carp erythrocytes, obtained from a single specimen in which the dorsal aorta was cannulated, adjust the state and order of their plasma membranes, but not their lipid composition, in response to changes in environmental temperature.

MATERIALS AND METHODS

Experimental design. Male winter-acclimated carp (0.50-0.75 kg), used in these experiments, were obtained from the Tisza Fish Farm (Szeged, Hungary; November 1991-January 1992) at water temperatures of 3-7°C. The fish were kept in thermostated aquaria in the laboratory at 5°C for 3 d for equilibration before the experiments were carried out. Preliminary experiments had indicated that 24 h would be adequate for temperature equilibration for carp of this weight. The fish were anesthetized with MS 222 (10 mg/L) before cannulation of the dorsal aorta by the method of Hughes *et al.* (10). Following cannulation, the fish were kept separately in appropriate compartments for 24 h before starting the experiments. The compartments (two in each experiment, each 3.5 L capacity) were connected to a thermostated water reservoir, from which water was circulated. The water temperature was raised by 0.5°C/h from 5 to 25°C in five-degree steps and then decreased to 5°C again at the same rate. After each step (up-shift or down-shift), the temperature was held for 24 h before sampling. Sufficient blood (50-100 μL) was withdrawn through the cannula (the outlet was otherwise closed) into an Na-heparinized syringe at each temperature (5, 10, 15, 20 and 25°C). For lipid analyses on erthrocytes, 1 mL of blood was withdrawn from separate fish on each occasion.

Labeling of the erythrocytes. To ensure consistency of fluorescence measurements, the optical density of the cell suspension was adjusted to 0.05 absorbance units at 366 nm (the excitation wavelength of DPH-PA) to standardize light scattering of the cells. For cell labeling, 5 μL

of 1×10^{-3} M DPH-PA (Molecular Probes Inc., Eugene, OR) in tetrahydrofuran was added to the cell suspensions in an isotonic buffer solution at pH 7.4 in a 4-mL quartz cell (the lipid-to-probe ratio was 200:1). Labeling was complete within 5 min, as measured by following changes in fluorescence intensity. Washing of the erythrocytes took 10 min, and labeling was complete within 5 min (11).

Fluorescence anisotropy measurements. Fluorescence anisotropy measurements were carried out with a computer-controlled thermostated Hitachi MPF-2A (Hitachi Ltd., Tokyo, Japan) spectrophotofluorimeter. The sample was excited with vertically polarized light at 366 nm at a slit width of 6 nm, and vertically (I_{vv}) and horizontally (I_{vh}) polarized emitted light was read at 430 nm at a slit width of 12 nm. Anisotropy values given are the average of 10 measurements. The standard error of individual determinations was always less than 0.005.

Steady-state fluorescence anisotropy was calculated according to the formula $R_{ss} = I_{(vv)} - Z \cdot I_{(vh)} + 2\,Z \cdot I_{(vh)}$, where $Z = 0.92$, calculated based on the formula $Z = I_{(vh)}/I_{(hh)}$. To correct the fluorescence intensity and R_{ss} for light scattering, measurements were also made on unlabeled samples under identical conditions. The measurements were done according to Kuhry *et al.* (12), who had shown that both the fluorescence intensity and (R_{ss}) are affected by scatter:

$$I_{(measured)} = I_{(fluorescence)} + I_{(scatter)} \quad [1]$$

$$R_{s\,(measured)} = f\,R_{s\,(fluo)} + (1 - f) \cdot R_{s\,(scatter)} \quad [2]$$

where f (a balanced fluorescence intensity factor) = $I_{fluo}/I_{fluo} + I_{scatter}$.

Extraction and analysis of lipids. Lipids were extracted with isopropanol/chloroform (11:1, vol/vol) as recommended by Freyburger *et al.* (13). The extracted lipids were dissolved in benzene containing 0.02% butylated hydroxytoluene as an antioxidant, and stored at −20°C until assayed. Phospholipids were separated by silicic acid column chromatography, using chloroform to elute neutral lipids and methanol to elute phospholipids. Phospholipids were subfractionated by thin-layer chromatography (TLC) according to Fine and Sprecher (14) using pre-coated G-60 silica gel plates (E. Merck, Darmstadt, Germany). Phospholipids were transmethylated under nitrogen with methanol containing 5% hydrochloric acid at 80°C for 2.5 h. Fatty acids were separated on 10% FFAP on 80–100 mesh Supelcoport (Supelco, Bellefonte, PA) using a 2-m column (2 mm i.d.). A Hitachi 263-80 (Hitachi Ltd.) gas–liquid chromatograph (GLC) connected to a Hitachi 263-80 data processor was used for analysis. For measuring the sterol-to-phospholipid ratio, total lipids were separated on TLC plates using petroleum ether/diethyl ether/acetic acid (75:15:1, by vol) as solvent. Phospholipids which did not move from the point of sample application were isolated for quantitative determination of phosphorus according to Rouser *et al.* (15). Free sterols were extracted with diethyl ether and quantitated by gas chromatography using a 3% SP 2250 on 100–200 mesh Supelcoport (Supelco) column as stationary phase and 5 α-cholestane as internal standard. Aliquots of the total lipid extracts were saponified with 0.1 N KOH in ethanol, and nonsaponifiable residues were separated by GLC as described earlier. Phospholipid phosphorus was also determined on the same aliquot.

Molecular species of phosphatidylcholine (PC) and phosphatidylethanolamine (PE) were analyzed according to Takamura *et al.* (16), by high-performance liquid chromatography (HPLC) (Waters Associates, Milford, MA; Model 440) and detected at 254 nm; the instrument was connected to an integrator (Hitachi 263-80). The dinitrobenzoyl derivatives of the diacylglycerols obtained by phospholipase C (Sigma Chemicals, St. Louis, MO) hydrolysis were separated on a Nucleosyl C-18 (5 μm, 4 mm, i.d. × 250 mm) column with acetonitrile/2-propanol (80:20, vol/vol) of HPLC grade (Carlo Erba, Milan, Italy) used isocratically as mobile phase (flow rate of 1.0 mL/min). Peaks were identified by comparison with those of derivatives of authentic 1,2-diacylglycerol standards and also on the basis of their relative elution times (17); 16:0/22:6 and 18:0/22:6 were obtained from Avanti Polar Lipids (Alabaster, AL), and 16:0/20:4, 18:0/20:4 and 16:0/18:1 were from Sigma; 16:0/22:6 was used as internal standard.

RESULTS

Due to its anionic nature (9), DPH-PA partitions into the outer leaflet of the erythrocyte plasma membrane, which is rich in positively charged phospholipids (18). DPH-PA thus can show changes in the physical state of the plasma membrane due to external stimuli. Dilution of labeled erythrocytes with buffer without DPH-PA leads to the almost complete and rapid efflux of DPH-PA, consistent with the fact that DPH-PA labels only the outer leaflet of plasma membranes (19). In the present study, fish acclimated to a low environmental temperature (5°C) were subjected to controlled up-shifts and down-shifts of ambient water temperature, and changes in fluorescence anisotropy of the probe incorporated into the erythrocyte plasma membranes were followed. The heating and cooling rates were set to mimic, to some extent, the diurnal variations which these fish experience under natural conditions.

Figure 1 reveals that the fluorescence anisotropy of the DPH-PA probe in the erythrocyte plasma membranes *in vivo* varied in a continuous fashion with the change in

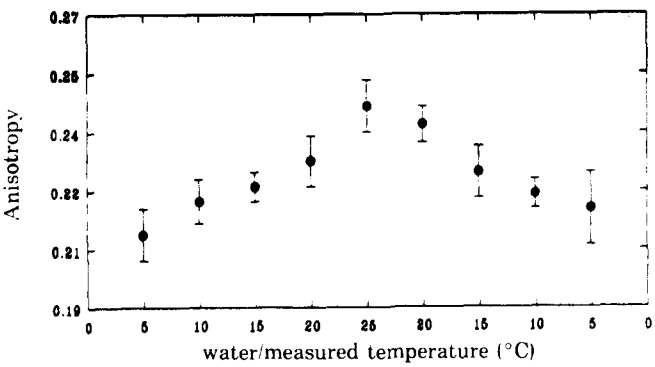

FIG. 1. Changes in 3-[*p*-(6-phenyl-1,3,5-hexatrienyl)phenyl]propionic acid fluorescence anisotropy of fish (*Cyprinus carpio* L.) erythrocytes in response to temperature shifts under *in vivo* conditions. Readings were made at the actual (incubation) body temperature (means ± SD of eight experiments).

temperature. The cells responded to an increase in temperature with increased rigidity of their membranes (increase in R_{ss}) and *vice versa*. This raises the possibility that the cells of higher poikilotherms, such as fish, continuously adjust to changes of environmental/body temperature in terms of the physical state of their membranes. Wodtke and Cossins (20) recently reported that carp liver microsomes also adjust their microviscosity according to the actual water/body temperature.

Figure 2 shows a comparison of *in vitro* and *in vivo* experiments, which illustrates that the red blood cells responded *in vitro* in the same way as they did *in vivo*. Figure 2 also shows that, despite these similarities in the response of erythrocytes to temperature up-shifts and down-shifts, the response was always greater *in vivo* than *in vitro*.

Phospholipid analyses showed that there were no significant differences in phospholipid class composition (data not shown). Table 1 gives the fatty acid composition, the total saturated fatty acids and the saturated-to-unsaturated fatty acid ratios of total phospholipids and of PC and PE, and the sterol-to-phospholipid ratios of the erythrocytes at 5 and 25 °C (temperature up-shifted fish). The data show that there was no marked change in the fatty acid composition except for the elevated level of arachidonic acid (20:4) in the temperature up-shifted fish. There also was no change in the saturated-to-unsaturated ratio. The decrease in unsaturated fatty acids and the higher saturated-to-unsaturated fatty acid ratio in the total phospholipids in the erythrocytes before the temperature up-shift may be due in part to the elevated level of myristic acid (14:0). If 14:0 is omitted from the calculations, the ratio decreases from 0.57 to 0.31, which is the same as that for temperature up-shifted cells calculated in the same way. The sterol-to-phospholipid ratio, which is known to affect the physical state of membranes (21–23), also remained unchanged (Table 1).

Table 2 lists the major molecular species of PCs and PEs. Although retailoring of these phospholipids during thermal acclimatization has been demonstrated in unicellular organisms (3,4) and in fish (5), carp erythrocytes did not show such a response during the temperature up-shifts (Table 2) or down-shifts (data not shown). There were only minor changes in the levels of 16:0/20:4, 18:0/22:6 and

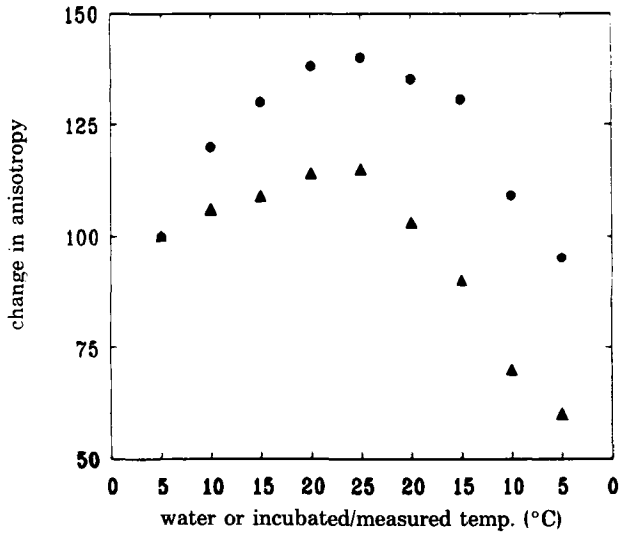

FIG. 2. Comparison of changes in 3-[*p*-(6-phenyl-1,3,5-hexatrienyl)-phenyl]propionic acid anisotropy of fish (*Cyprinus carpio* L.) erythrocytes in relation to temperature shifts under *in vivo* (●—●) and *in vitro* (▲—▲) conditions. In the *in vitro* experiments, erythrocytes were incubated as described in Reference 11. Readings were made at the incubation temperature of the blood/fish in both the cases (actual temperature). Anisotropy values at 25°C were 0.207 ± 0.006 SD in *in vitro* and 0.245 ± 0.007 SD in *in vivo* experiments (means ± SD of eight experiments).

16:0/18:1. Our observations thus suggest that the physical properties of fish erythrocyte plasma membranes can vary in response to changes in environmental temperature without changes in lipid composition or sterol-to-phospholipid ratio.

DISCUSSION

The physical state of biomembranes has been shown to depend on their lipid constituents, and temperature-induced changes in membrane fluidity would be expected to be reflected in changes in membrane lipid composition. In the present study, the total phospholipids of the entire erythrocyte were considered representative of those of the average cell membrane, although individual membranes may differ in respect to their lipid components and fluidity, as has been demonstrated for fish liver and muscle (24,25). An inverse relationship between fatty acid unsaturation and temperature has repeatedly been observed (6,26-28). However, our data presented in Table 1 show that under our experimental conditions, carp erythrocytes did not change their saturated-to-unsaturated fatty acid ratio. The sterol-to-phospholipid ratio, which is also known to contribute to the physical state of biomembranes (22,23), has been shown to decrease in fish erythrocytes (21) and mitochondria (21) upon long-term adaptation to lower temperatures. However, in the present study, this ratio remained unchanged irrespective of whether this ratio was expressed in terms of the ratio of free sterols (Table 1) or of total sterols-to-phospholipids (data not shown). It appears, therefore, that these ratios would not play a major role in the short-term acclimatization of fish to temperature. As no differences in fatty acid, phospholipid polar headgroup or molecular species composition were observed, it appears that phospholipid anisotropy does not respond in the same way as it does in intact cells, as we have earlier demonstrated previously (11).

To gain further insight into the nature of the observed control, erythrocytes collected from cold-acclimated fish were also incubated under *in vitro* conditions. In the latter experiments, the whole blood was incubated instead of isolated erythrocytes. As in the *in vivo* experiments, the incubation temperature *in vitro* was also raised from 5 to 25°C and again decreased to 5°C at a rate of 0.5°C/h. The temperature-induced changes in fluorescence anisotropy *in vitro* and *in vivo* (Fig. 2) indicated that the cells were more responsive to temperature changes *in vivo*, although the response was also evident under *in vitro* conditions. It can be speculated that some component of the blood plasma that may exchange with the outer erythrocyte membrane in response to variations in temperature, or some other factors not present in the *in vitro* system, may be involved in the control process. Because blood glucose remained at normal levels throughout the experiment (data not shown), activation of the adrenal gland can be ruled out. Besides catecholamines and other hormones, such as glucocorticoids, adrenocorticotrophic hormone, glucagon and insulin have also been shown to inhibit Δ5 desaturase (29) activity. Thus, their putative effect in temperature up-shifted fish would not need to be taken into consideration either. Further investigations are needed to determine how such a sensitive control of the physical state of the erythrocyte membrane can occur in response to short-term temperature changes in carp.

ACKNOWLEDGMENTS

We are grateful to the Tisza Fish Farm (Hungary) for supplying fish. This study was supported by an OTKA grant of the Hungarian National Science Foundation, contract # T5163.

Kinetic Study of the Prooxidant Effect of Tocopherol. Hydrogen Abstraction from Lipid Hydroperoxides by Tocopheroxyls in Solution

Kazuo Mukai[a,*], Kouhei Sawada[a], Yasuhiro Kohno[a] and Junji Terao[b]

[a]Department of Chemistry, Faculty of Science, Ehime University, Matsuyama 790 and [b]National Food Research Institute, Ministry of Agriculture, Forestry and Fisheries, Tsukuba, Ibaraki 305, Japan

A kinetic study of the prooxidant effect of vitamin E (tocopherol, TocH) has been carried out. The rates of hydrogen abstraction (k_{-1}) from methyl linoleate hydroperoxide (ML-OOH) by α-tocopheroxyl (α-Toc•) (1) and eight types of alkyl substituted Toc• radicals (2-9) in benzene solution have been determined spectrophotometrically. The results show that the rate constants decrease as the total electron-donating capacity of the alkyl substituents on the aromatic ring of Toc• increases. The k_{-1} value ($5.0 \times 10^{-1}M^{-1}s^{-1}$) obtained for α-Toc• (1) was found to be about seven orders of magnitude lower than the k_1 value ($3.2 \times 10^{6}M^{-1}s^{-1}$) for the reaction of α-TocH with peroxyl radical, which is well known as the usual radical-scavenging reaction of α-TocH. The above reaction rates (k_{-1}) obtained were compared with those (k_3) of methyl linoleate with Toc• (1-9) in benzene solution. The rates (k_{-1}) were found to be about six times larger than those (k_3) of the corresponding Toc•. The results suggest that both reactions may relate to the prooxidant effect of α-TocH at high concentrations in foods and oils. The effect of the phytyl side chain on the reaction rate of Toc• in micellar dispersions has also been studied. We have measured the rate constant, k_{-1}, for the reaction of phosphatidylcholine hydroperoxide with a Toc• radical in benzene, *tert*-butanol and in Triton X-100 micellar dispersions, and compared the observed k_{-1} values with the corresponding values for ML-OOH.

***Lipids* 28, 747-752 (1993).**

The role of vitamin E (α-, β-, γ- and δ-tocopherols) as an important biological antioxidant has been well recognized in recent years. The antioxidant properties of tocopherols (TocH) have been ascribed to hydrogen abstraction from the OH group in TocH by a peroxyl radical (LOO•). The hydrogen abstraction produces a tocopheroxyl radical (Toc•), which combines with another LOO• (Reactions [1] and [2]) (Refs. 1,2).

$$LOO^{\bullet} + TocH \xrightarrow{k_1} LOOH + Toc^{\bullet} \quad [1]$$

$$LOO^{\bullet} + Toc^{\bullet} \xrightarrow{k_2} LOO\text{-}Toc \text{ (nonradical product)} \quad [2]$$

In recent years, several investigators demonstrated that α-TocH at high concentrations acts as a prooxidant during the autoxidation of polyunsaturated fatty acids (LH) in aqueous medium and in bulk phase (3-9). This prooxidant effect of α-TocH leads to an increase of the level of hydroperoxides (LOOH) with conjugated diene structure. Loury *et al.* (3) and Terao and Matsushita (9) have proposed that Toc• radicals participate in this prooxidant effect through Reactions [3] and [4]:

$$Toc^{\bullet} + LH \xrightarrow{k_3} TocH + L^{\bullet} \quad [3]$$

$$Toc^{\bullet} + LOOH \xrightarrow{k_{-1}} TocH + LOO^{\bullet} \quad [4]$$

where Reaction [3] is the chain transfer reaction and Reaction [4] is the reverse of Reaction [1]. A more complex reaction scheme, including a great number of elementary reaction steps, has been proposed by Rousseau-Richard *et al.* (10,11). However, so far the kinetics of Reactions [3] and [4] related to the prooxidant effect of vitamin E have not been studied. The reactions are considered important to the understanding of the prooxidant properties of vitamin E.

We have recently reported the second-order rate constant, k_3, for the reaction of LH esters (ethyl linoleate, ethyl linolenate, ethyl arachidonate and *all cis*-4,7,10,13,16,19-docosahexaenoic acid ethyl ester) with Toc• (5,7-diisopropyltocopheroxyl 5) (12,13). The rate constant, k_3, obtained was 1.82 to $9.05 \times 10^{-2}M^{-1}s^{-1}$ in benzene at 25°C. The rate of k_3 is about 7 to 8 orders of magnitude lower than k_1 for Reaction [1] of α-TocH with LOO• (1). Furthermore, we recently succeeded in measuring the rate constant (k_{-1}) for the reaction of 5,7-diisopropyltocopheroxyl radical 5 with *n*-, *sec*- and *tert*-butyl hydroperoxides used as lipid hydroperoxide model systems (14). The observed rate, k_{-1}, was 1.34 to $3.65 \times 10^{-1}M^{-1}s^{-1}$ in benzene solution at 25°C. The values of k_{-1} are only about one order of magnitude higher than those of k_3.

In the present work, we have determined the second-order rate constant, k_{-1}, for the reactions of methyl linoleate hydroperoxide (ML-OOH) with nine types of alkyl substituted Toc• radicals 1-9 in benzene (see Fig. 1). The rate, k_{-1}, was compared with k_1 for Reaction [1] and with k_3 for Reaction [3]. The effect of alkyl substituents on the aromatic ring of Toc• has also been studied. It is of interest to know how the rate of the reaction of ML-OOH with Toc• is different from that of the phospholipid hydroperoxide. We have thus measured the rate constant, k_{-1}, for the reaction of phosphatidylcholine hydroperoxide (PC-OOH) with a Toc• radical in benzene, *tert*- butanol and in micellar dispersions, and compared the observed k_{-1} values with the corresponding values for ML-OOH. The effect of the phytyl side chain on the reaction rate of Toc• in micellar dispersion also has been studied. In Figure 1 we give the structures of the molecules studied in this work. The study was intended to provide a basis for the interpretation of similar reactions in more complex biological systems.

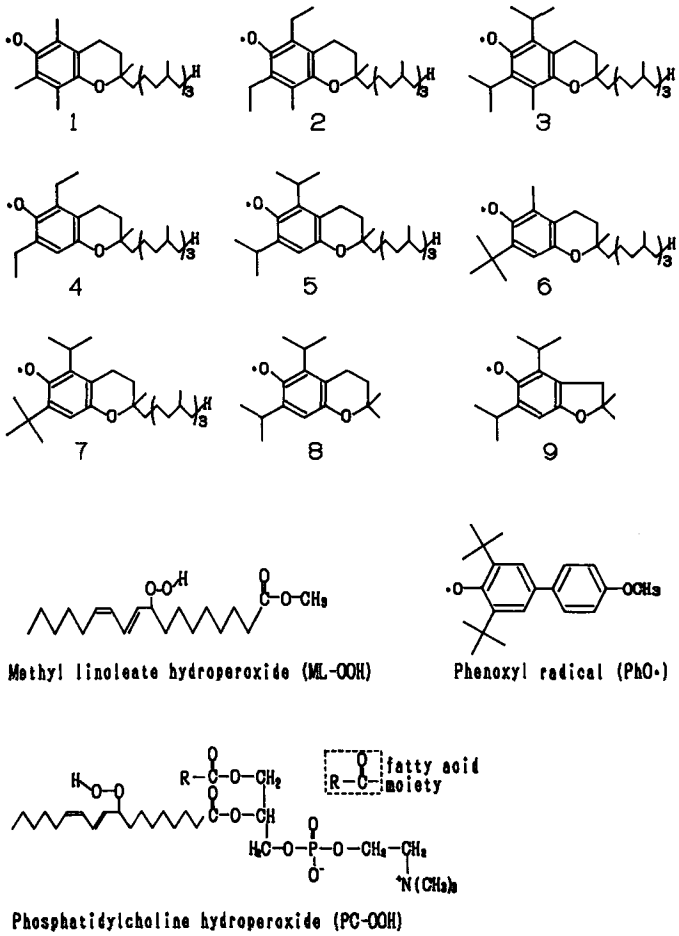

FIG. 1. Molecular structures of tocopheroxyl radicals 1–9, PhO•, ML-OOH (methyl linoleate hydroperoxide) and PC-OOH (phosphatidylcholine hydroperoxide).

MATERIALS AND METHODS

Sample preparation. Methyl linoleate (linoleic acid methyl ester, LH) (>99%) was obtained from Sigma Chemical Co. (St. Louis, MO) and used without further purification. Hydroperoxide levels in methyl linoleate were estimated by measuring absorption at 234 nm (15) and were found to be less than 0.3%. Egg phosphatidylcholine (PC) (>95%) was kindly supplied by Nippon Oil Fats Co. (Amagasaki, Japan). The average molecular weight of the PC was assumed to be 774 (13). The amount of hydroperoxides in the sample was found to be negligible as judged by thin-layer chromatography (TLC). α-TocH was supplied by Eisai Co. (Tokyo, Japan). Triton X-100 was purchased from Nacalai Tesque Inc. (Kyoto, Japan) and was used as received. The 2,6-di-*tert*-butyl-4-(4′-methoxyphenyl)phenoxyl (PhO•) **10** was prepared by the method of Rieker and Scheffler (16).

ML-OOH was prepared by photosensitized oxidation of methyl linoleate using methyleneblue as a sensitizer (17). The oxidation product was purified by SiO_2 column chromatography. PC-OOH was prepared by the oxidation of PC with $^1O_2$, following the method of Terao *et al.* (18). The hydroperoxide was separated from the oxidation products by reverse-phase liquid chromatography. The average molecular weight of the PC-OOH was assumed to be 806, based on that of PC (774).

The preparation of TocH **2p–9p** was reported previously (19–21). The Toc• radicals **3, 5, 6, 7, 8** and **9** are fairly stable, and were prepared by PbO_2 oxidation of the corresponding TocH in benzene solution under a nitrogen atmosphere. However, in the cases of TocH **1p, 2p** and **4p**, the Toc• radicals **1, 2** and **4** produced were not very stable, and absorption spectra decreased rapidly with time. Therefore, Toc• **1, 2** and **4** were prepared by reaction between the stable PhO• radical **10** and the corresponding TocH in benzene at 25°C under a nitrogen atmosphere and were reacted immediately with ML-OOH solution.

Micellar dispersions of Triton X-100 (5.0 wt%) containing Toc• **5** were prepared as follows (22). 5,7-Diisopropyltocopherol **5p** (15–20 mg, 32–42 μmol) was dissolved in 5-mL of diethyl ether, and the solution was poured into a small flask. The diethyl ether was removed on a rotary evaporator to obtain a thin film on the flask wall. Twenty mL of aqueous Triton X-100 (5.0 wt%, in 0.1 M phosphate buffer, pH 7) was added, and the flask was shaken vigorously in a Vortex mixer for 1 min. PhO•-containing solutions of Triton X-100 (5.0 wt%) were prepared similarly and reacted with the above TocH-containing micellar dispersions. The PhO• radical is very stable in the absence of 5,7-diisopropyltocopherol and shows absorption peaks at $\lambda_{max} = 377$ and 577 nm in aqueous Triton X-100 dispersions (5.0 wt%). Upon mixing the micellar dispersion of TocH (0.66 mM) with the micellar dispersion of the PhO• radical (0.60 mM) (1:1, vol/vol) at 25.0°C, the absorption spectrum characteristic of the PhO• radical immediately changed to that of Toc• **5**. The new absorption maxima in the visible region ($\lambda_{max} = 397$ and 417 nm) are due to Toc• **5** (23). Because Toc• **5** is stable at 25.0°C, the absorption intensity decreases only gradually with time.

Measurements. The kinetic data were obtained on a Shimadzu UV-2100S (Kyoto, Japan) spectrophotometer by mixing equal volumes of solutions of Toc• and ML-OOH (or PC-OOH). The oxidation reactions were studied under pseudo-first-order conditions, and the observed rate constants (k_{obsd}) were calculated in the usual way, using standard least-squares analysis. All measurements were performed at 25.0°C, because Toc• **1, 2** and **4** used are not stable at 37°C.

RESULTS AND DISCUSSION

Reaction between ML-OOH and Toc• 1–9 in benzene. 5,7-Diisopropyltocopheroxyl **5** is comparatively stable in the absence of ML-OOH and shows absorption peaks at $\lambda_{max} = 417$ nm and 397 nm in benzene (Fig. 2). When adding a benzene solution of excess ML-OOH to a benzene solution of Toc•, the absorption spectrum of the Toc• gradually disappeared. Figure 2 shows an example of the results of the interaction between 5,7-diisopropyltocopheroxyl **5** (*ca.* 0.15 mM) and ML-OOH (21.5 mM) in benzene. The rate was measured by following the decrease in absorbance at 417 nm of Toc• **5**. Under these conditions, the rate of disappearance of Toc• in the presence of a constant concentration of ML-OOH is first-order in regard to Toc•. The pseudo-first-order rate constants, k_{obsd}, were obtained by varying the concentration of ML-OOH:

$$-d[Toc^•]/dt = k_{obsd}[Toc^•] \quad [5]$$

Toc• **5** shows a slow natural decay in benzene. Therefore,

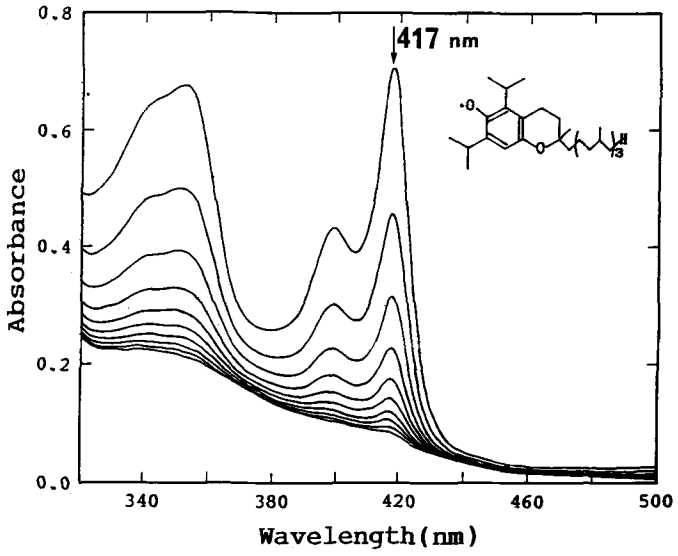

FIG. 2. Changes in the absorption spectrum of 5,7-diisopropyltocopheroxyl radical 5 in the course of the reaction of Toc• 5 with ML-OOH in benzene at 25.0°C. $[Toc^{\bullet}]_{t=0}$ = *ca.* 0.15 mM and $[ML\text{-}OOH]_{t=0}$ = 21.5 mM. The spectra were recorded at 100-s intervals. Arrow indicates decrease (↓) of absorbance with time. Abbreviation as in Figure 1. TOC•, tocopheroxyl radical.

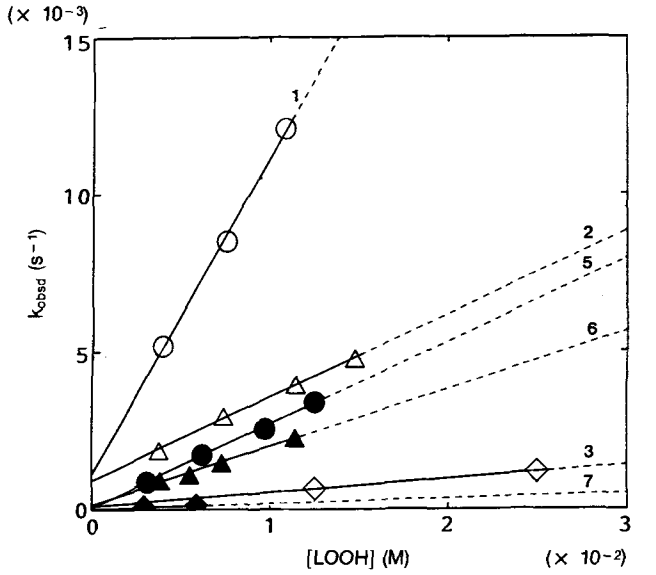

FIG. 3. Dependence of the pseudo-first-order rate constants, k_{obsd}, of Toc• radicals 1, 2, 3, 5, 6 and 7 on the concentration of ML-OOH in benzene at 25.0°C. Abbreviations as in Figures 1 and 2.

the pseudo-first-order rate constant, k_{obsd}, for Toc• bleaching is given by Equation 6:

$$k_{obsd} = k_o + k_s\,[LOOH] \qquad [6]$$

where k_o is the rate constant for the natural decay of Toc• in benzene solution, and k_s is the apparent second-order rate constant for the reaction of Toc• with added ML-OOH. These rate parameters are obtained by plotting k_{obsd} against [ML-OOH]. Similar measurements were made for the reactions of Toc• 1-9 with ML-OOH. As shown in Figure 3, the first-order decay constant, k_{obsd}, is proportional to the concentration of ML-OOH.

As reported by Mahoney and DaRooge (24,25), the results are consistent with Reactions [7] and [2]:

$$Toc^{\bullet} + LOOH \underset{k_1}{\overset{k_{-1}}{\rightleftharpoons}} TocH + LOO^{\bullet} \qquad [7]$$

$$LOO^{\bullet} + Toc^{\bullet} \xrightarrow{k_2} LOO\text{-}Toc \qquad [2]$$

where $k_2[Toc^{\bullet}] >> k_1[TocH]$; k_2 is the second-order rate constant for the reaction of Toc• with LOO•. A combination product of Toc• and LOO•, that is, LOO-Toc, was isolated by Yamauchi *et al.* (26). Under these conditions, the rate of disappearance of Toc• is given by the expression (24,25):

$$-d[Toc^{\bullet}]/dt = \{k_o + 2k_{-1}[LOOH]\}\,[Toc^{\bullet}] \qquad [8]$$

The values of k_{-1} calculated from k_{obsd} are listed in Table 1. The experimental errors in the k_{-1} value for Toc• radicals 3, 5, 6, 7, 8 and 9 were less than ±7%. The natural decays of Toc• 1, 2 and 4 are much faster, and therefore we could only estimate the approximate rate constants.

Several investigators have measured the rate constant, k_1, for the reaction between LOO• and vitamin E derivatives (Reaction [1]) (27,28, and references therein). The most reliable k_1 value was reported by Burton *et al.* (27), using the inhibited autoxidation of styrene method. For example, the k_1 value obtained for the reaction of α-TocH with poly(peroxystyryl)peroxyl radical was $3.20 \times 10^6 M^{-1}s^{-1}$ in chlorobenzene at 30°C. Therefore, the k_{-1} value ($5.0 \times 10^{-1} M^{-1}s^{-1}$) obtained for α-Toc• 1 in the present study is about seven orders of magnitude lower than the above-mentioned k_1 value.

Effect of alkyl substituents in Toc• radicals. In the present work, we have determined the second-order rate constants, k_{-1}, for the reaction of ML-OOH with Toc• 1-9 in benzene. As listed in Table 1 for the Toc• radicals 4, 5, 6 and 7, having two alkyl substituents at the *ortho* positions to the OH group, the k_{-1} values obtained in benzene are $2.5 \times 10^{-1} M^{-1}s^{-1}$ for radical 4, $1.33 \times$

TABLE 1

Second-Order (k_{-1} and k_3) Rate Constants for the Reaction of Toc• 1-9 with Methyl Linoleate Hydroperoxide and Methyl Linoleate, Respectively, in Benzene at 25.0°C and Relative Rate Constants (k_{-1}/k_3)

Toc•	k_{-1}[a] ($M^{-1}s^{-1}$)	k_3[a] ($M^{-1}s^{-1}$)	k_{-1}/k_3
1	5.0×10^{-1}	—	—
2	1.3×10^{-1}	2.3×10^{-2}	5.7
3	2.11×10^{-2}	3.27×10^{-3}	6.45
4	2.5×10^{-1}	5.0×10^{-2}[b]	5.0
5	1.33×10^{-1}	1.86×10^{-2}[b]	7.15
6	9.14×10^{-2}	1.61×10^{-2}[b]	5.68
7	7.77×10^{-3}	1.10×10^{-3}[b]	7.06
8	1.31×10^{-1}	1.83×10^{-2}	7.16
9	8.41×10^{-2}	2.01×10^{-2}	4.18

[a]Experimental errors in k_{-1} and k_3 values were less than 7% for Toc• 3 and 5-9 and 20% for Toc• 1, 2 and 4. Toc•, tocopheroxyl radical.

[b]These values were previously reported (Ref. 13).

$10^{-1}M^{-1}s^{-1}$ for **5**, $9.14 \times 10^{-2}M^{-1}s^{-1}$ for **6** and $7.77 \times 10^{-3}M^{-1}s^{-1}$ for **7**. The values of k_{-1} decrease in the order of **4** > **5** > **6** > **7**, as the size of the two *ortho*-alkyl groups in the Toc• radical increases. The Toc• **4** is 32-times as reactive as the Toc• **7**. The results clearly indicate that the decrease in k_{-1} is due to steric factors. Inductive effects on the reaction rate of these Toc• radicals with ML-OOH would not be significant, because methyl, ethyl, isopropyl and *tert*-butyl groups have electron-donating properties that are not too different.

Further, the rate constants of Toc• radicals **1**, **2** and **3**, which have two alkyl substituents at the *ortho* positions and a methyl substituent at C-8 decrease in the order **1** > **2** > **3**. This result also suggests that the effect of steric hindrance on the reaction rate is considerable.

Both 5,7-diisopropyl-8-methyltocopheroxyl **3** and 5,7-diisopropyltocopheroxyl **5** have two isopropyl substituents at the ortho positions and, in addition, **3** has a methyl substituent at the *meta* position. When comparing the rate constant, k_{-1}, observed for Toc• **5** with that for Toc• **3**, compound **5** is 6.3 times more reactive than **3**. Similarly, 5,7-diethyltocopheroxyl **4** is 1.9 times as reactive as the 5,7-diethyl-8-methyltocopheroxyl **2**. The results indicate that substitution on the aromatic ring by an electron-donating methyl group (at C-8) results in a decrease in the second-order rate constant, k_{-1}. In other words, in the reaction between the Toc• and ML-OOH, the Toc• acts as an electron acceptor, and thus the rate constants will decrease as the total electron-donating capacity of the alkyl substituents on the aromatic ring of the Toc• increases (29).

Effect of alkyl side chain of Toc• radical on its reaction rate in benzene and in micellar dispersion. In order to clarify the effect of the phytyl side chain of the Toc• radical on the reaction rate, we have measured the rate constants, k_{-1}, for the reaction of ML-OOH with 5,7-diisopropyltocopheroxyl **5** and 5,7-diisopropyltocopheroxyl model **8** in benzene and in micellar dispersion.

As shown in Table 2, the Toc• **5** and Toc• **8** without phytyl side chain in 2-position reacted with the ML-OOH at a similar rate in benzene. On the other hand, in 5 wt% Triton X-100 micellar dispersion, the k_{-1} value ($6.93 \times 10^{-2}M^{-1}s^{-1}$) of Toc• **5** is 0.61 times that ($1.14 \times 10^{-1}M^{-1}s^{-1}$) of Toc• **8**. The result shows that the phytyl side chain of vitamin E has little effect on reactivity in homogeneous solution, whereas it has considerable effect on reactivity in micellar dispersion (1,2,30–33). The significance of the above changes in the rate constants, k_{-1}, is not clear at present, but it may relate to the biological activity of TocH. For instance, although both α-TocH models and α-TocH have high *in vitro* antioxidant activity in solution, the former has no *in vivo* vitamin E activity (34,35).

Reaction between PC-OOH and Toc• 5. It is of interest to examine whether or not the rate constant of hydrogen abstraction of PC-OOH is the same as that of ML-OOH, which is one of the hydroperoxide derivatives (LOOH) of the fatty acid moieties contained in the PC.

The rate constants for hydrogen abstraction from PC-OOH and ML-OOH by Toc• **5** (k_{obsd}) have been measured in benzene, *tert*-butanol and 5 wt% Triton X-100. The second-order rate constants, k_{-1}, are obtained by plotting k_{obsd} *vs.* [LOOH]. The k_{-1} values obtained are given in Table 3.

The observed k_{-1} value of PC-OOH was only 8% of that of ML-OOH in the nonpolar benzene solvent, whereas the k_{-1} value of PC-OOH was 1.9 times larger than that of ML-OOH in the more polar *tert*-butanol solvent. Furthermore, in micellar dispersion, PC-OOH reacted at a rate that was only about 30% of that observed for ML-OOH. There is, as yet, no unambiguous explanation for this apparent contradiction, but some possible explanations are offered in the following.

Firstly, the formation of reverse micelles in benzene solution must be considered, as PC molecules are known to aggregate into reverse micelles in nonpolar solvents (36,37). The solubility of Toc• **5**, which has a nonpolar phytyl side-chain, is high in benzene, but low in PC liposome. Thus, formation of reverse micelles might prevent Toc• **5** from reacting with the hydroperoxide group of PC-OOH, causing a smaller rate constant, k_{-1}, for PC-OOH than for ML-OOH. This would be in agreement with the results obtained for the hydrogen abstraction reaction from PC and from unsaturated fatty acids (LH) by Toc• **5** in benzene (13). Therefore, we measured the rate constant, k_{-1}, in polar *tert*-butanol solvent in which PC-OOH does not form reverse micelles. As the two fatty acid moieties are quite close in PC-OOH, Toc• **5** may not

TABLE 2

Pseudo-First-Order (k_{obsd}) and Second-Order (k_{-1}) Rate Constants for the Reaction of Toc• 5 and 8 with ML-OOH in Benzene or 5 wt% Triton X-100 (pH = 7.0, 0.1 M phosphate buffer) at 25.0°C

	Toc• 5			Toc• 8		
Solution	[ML-OOH] (mM)	k_{obsd} (s^{-1})	k_{-1}[a] ($M^{-1}s^{-1}$)	[ML-OOH] (mM)	k_{obsd} (s^{-1})	k_{-1}[a] ($M^{-1}s^{-1}$)
Benzene	3.12	8.81×10^{-4}	1.33×10^{-1}	4.68	1.42×10^{-3}	1.31×10^{-1}
	6.24	17.3		9.37	2.79

Micellar dispersion	3.96	5.29×10^{-4}	6.93×10^{-2}	3.05	2.60×10^{-4}	2.02×10^{-2}
	7.46	9.82		5.99	3.65	
	11.22	15.3		7.98	4.61	

[a]Experimental error in k_{-1} values was less than 7%. Abbreviations as in Figure 1.

be able to easily approach the active site, that is, the -OOH group of PC-OOH. In such a case, the k_{-1} value of PC-OOH will be smaller than that of ML-OOH. However, the observed k_{-1} value ($4.68 \times 10^{-3}M^{-1}s^{-1}$) of PC-OOH was 1.9 times larger than that ($2.49 \times 10^{-3}M^{-1}s^{-1}$) of ML-OOH in *tert*-butanol. The reason for this is not clear at present.

In Triton X-100, PC-OOH reacted with Toc• 5 at a rate that was only about 30% of that observed with ML-OOH. As the accessibility of the ML-OOH appears to be greater than that of PC-OOH in micellar dispersion, the reactivity of ML-OOH was higher than that of PC-OOH.

The cause of the prooxidant effect of TocH. We recently reported the second-order rate constants, k_3, for the reactions of the Toc• radicals 4–7 with methyl linoleate (LH) in benzene using a spectrophotometric monitoring system (Reaction [3]) (12,13). We have also measured the rate constants, k_3, for the reactions of Toc• 1, 2, 3, 8 and 9 with LH in benzene at 25.0°C. As described in a previous section, α-Toc• 1 is unstable, and we could not determine the rate constant, k_3. The rate constants, k_3, obtained are summarized in Table 1, together with those reported for Toc• 4, 5, 6 and 7. The results indicate that the effect of substitution on the reaction rates, k_3, observed for Toc• 2–9 is very similar to that on k_{-1}. The values of k_{-1} were plotted against k_3. As shown in Figure 4, the k_{-1} values were found to correlate linearly with the k_3 values (correlation coefficient = 0.96). The ratio of k_{-1} to k_3 was estimated to be about 6 ± 1 from the values given in Table 1 (Eq. 9).

$$k_{-1} = (6 \pm 1) \times k_3 \quad [9]$$

It is well known that tocopherols (vitamin E) are present in biomembranes and in oils, where they function as antioxidants. The antioxidant properties of TocH have been ascribed to the initial oxidation by the LOO• radical of the phenolic hydroxyl group, producing a Toc• radical (Reaction [1]) (1,2). On the other hand, several investigators have demonstrated that α-TocH at high concentrations acts as a prooxidant during the autoxidation of LH in aqueous medium and in bulk phase (3–11). This prooxidant effect of α-TocH leads to an increase of the level of LOOH with a conjugated diene structure. Loury *et al.* (3) and Terao and Matsushita (9) have proposed that Toc• radicals participate in this prooxidant effect through Reactions [3] and [4].

In the present work, we have measured the rate constants, k_{-1}, for the reaction of ML-OOH with Toc• 1–9. The k_{-1} values were found to be about six times larger than those (k_3) of the corresponding Toc• radicals for Reaction [3]. The results suggest that both Reactions [3] and [4] may relate to the prooxidant effect of α-TocH at high concentrations. Therefore, if LH coexists with LOOH in edible oils or in membranes, the rate of disappearance of Toc• will be represented by Equation 10:

$$-d[Toc•]/dt = k_3[LH][Toc•] + k_{-1}[LOOH][Toc•] \quad [10]$$

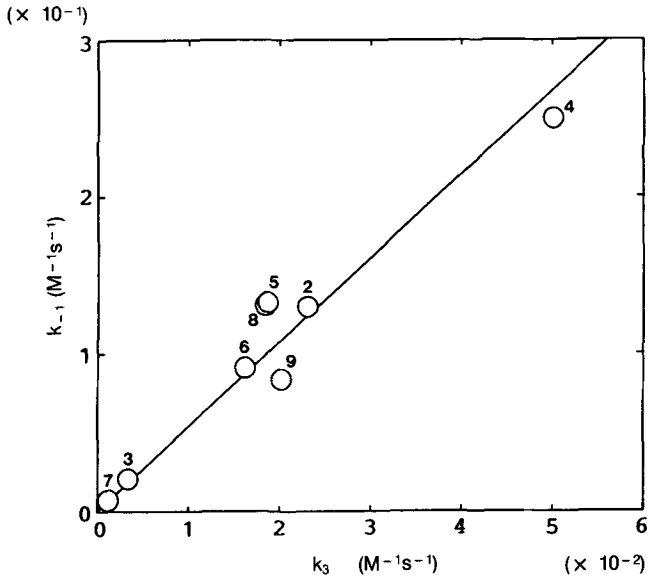

FIG. 4. Plot of k_{-1} *vs.* k_3 for tocopheroxyl radicals 2–9.

In the initial stage of lipid degradation, the concentration of LOOH will be much lower than that of LH, and thus the second term in Equation 10 is negligible. Consequently, the prooxidant effect of α-TocH in edible oils and fats will be induced by the hydrogen abstraction Reaction [3] between Toc• and LH. On the other hand, if the autoxidation proceeds, the level of LOOH increases. When the concentration of LOOH approaches approximately 17% of that of LH, the radical decay Reactions [3] and [4] will approach similar rates. These facts suggest that not only the chain transfer Reaction [3] is due to Toc•, but also that Reaction [4] between Toc• and LOOH participates in the prooxidant effect of α-TocH.

ACKNOWLEDGMENTS

We are very grateful to Dr. Shiro Urano for his advice on synthesizing TocH **2p** and **3p**. We are also grateful to Prof. Shin-ichi Nagaoka for valuable discussions. We wish to thank Hironobu Hosose, Seiji Kikuchi, Hitoshi Morimoto and Aya Kuranaka for the preparation of TocH **2p–9p**. We also wish to thank Yuji Okauchi for the measurement of reaction rates, k_3, of Toc• **3**, **8** and **9**. We express our gratitude to the Eisai Co. Ltd. and Nippon Oil Fats Co. Ltd. for the generous gifts of α-TocH and egg PC, respectively.

Kinetic Study of Reactions Between Tocopheroxyl Radicals and Fatty Acids

Kazuo Mukai*, Hitoshi Morimoto, Yuji Okauchi and **Shin-ichi Nagaoka**
Department of Chemistry, Faculty of Science, Ehime University, Matsuyama 790, Japan

A kinetic study on the prooxidant effect of vitamin E derivatives has been carried out. Rates of hydrogen abstraction from various fatty acids and egg yolk lecithin by tocopheroxyl radicals were determined spectrophotometrically. The rate constants measured in micellar dispersion were compared with those obtained in homogeneous solutions. The effects of structural variations of the vitamin E derivatives on their prooxidant activities were examined. The formation of lecithin reverse micelles in benzene appears to prevent the tocopheroxyl radicals from reacting with the phospholipid fatty acid moieties.
***Lipids* 28, 753–756 (1993).**

It is well known that vitamin E (α-, β-, γ- and δ-tocopherols) inhibits the autoxidation of organic molecules in liquid phase. The mechanism involved has been studied extensively by several investigators (1–4). Vitamin E is present in cellular membranes and in edible oils and acts as an antioxidant by protecting polyunsaturated fatty acids and other lipids from peroxidation.

The antioxidant properties of tocopherols (TocH) have been ascribed to hydrogen transfer from the OH group in the TocH to a peroxyl radical (LOO•). The hydrogen transfer produces a tocopheroxyl radical (Toc•) which combines with another LOO• (reactions [1] and [2]) (5,6).

$$\text{LOO}\bullet + \text{TocH} \xrightarrow{k_1} \text{LOOH} + \text{Toc}\bullet \quad [1]$$

$$\text{LOO}\bullet + \text{Toc}\bullet \rightarrow \text{Nonradical products} \quad [2]$$

On the other hand, several investigators have shown that α-TocH in high concentration acts as a prooxidant during the autoxidation of polyunsaturated fatty acids (LH) (7,8). This prooxidant effect of α-TocH leads to an increase of hydroperoxides with a conjugated diene structure. Loury *et al.* (7) and Terao and Matsushita (8) proposed that Toc• radicals participate in this prooxidant effect through the following reactions [3] and [4]:

$$\text{Toc}\bullet + \text{LH} \xrightarrow{k_3} \text{TocH} + \text{L}\bullet \quad [3]$$

$$\text{Toc}\bullet + \text{LOOH} \xrightarrow{k_{-1}} \text{TocH} + \text{LOO}\bullet \quad [4]$$

where reaction [3] is a hydrogen abstraction from LH and a chain transfer reaction. Reaction [4] is a reversal of reaction [1]. These reactions are important in the understanding of the antioxidant and prooxidant properties of vitamin E. However, so far the kinetics of these reactions have not been studied extensively.

We have recently determined the rate constant k_{-1} for reactions of alkyl hydroperoxides with Toc• (9,10). We also determined the second-order rate constant k_3 for reactions of various fatty acid esters with Toc• (11,12). The rate k_3 was compared with k_{-1}. In order to interpret observed features of k_3 quantitatively, we carried out *ab initio* calculations of models for the fatty acid esters. Calculated results were consistent with the experimental results. It was shown that the observed features of k_3 can be explained in terms of the pseudo-π-conjugation between the C=C double bond and the active hydrogen-carbon bond. The effect of substituent groups at the 5- and 7-positions of Toc• was also studied. Furthermore, we measured k_3 of egg yolk lecithin.

There remain, however, a few questions that still need to be answered. Firstly, it would be worthwhile to know how k_3 values change when going from homogeneous solutions to inhomogeneous systems, such as micellar dispersions. Although a direct *in vivo* approach to the study of the prooxidant reaction is very difficult, it should prove useful to study such inhomogeneous lipid systems, because the information that can be obtained may be relevant to membranes. It would be of interest, for example, to measure k_3 of egg yolk lecithin in micelles. Secondly, the effect of structural variation of TocH on prooxidant activity has not been studied previously. Information about the effects of the phytyl side chain, the heterocyclic ring and the methyl at the 8-position will be needed.

We have carried out a kinetic study of the prooxidant effect of TocH. Rates of hydrogen abstraction from various fatty acids and egg yolk lecithin by Toc• were determined spectrophotometrically.

MATERIALS AND METHODS

Stearic acid (18:0), oleic acid (18:1), linoleic acid (18:2), linolenic acid (18:3), arachidonic acid (20:4n-6), *cis*-4,7,10,13,16,19-docosahexaenoic acid (22:6n-3), their methyl esters (Med18:0, etc.), and their ethyl esters (Et18:0, etc.) (>99% pure) were obtained from Sigma Chemical Co. (St. Louis, MO). In order to estimate the ratios of hydroperoxides in the unsaturated fatty acids and their esters, we measured the absorption at 234 nm due to the hydroperoxides (12). Hydroperoxide levels in the samples were found to be lower than 0.3%. In the present work, we assumed that the k_3 values of the fatty acids are close to those of the corresponding esters. In fact, since the carboxyl group is located far from the active site (allylic hydrogen) in the fatty acids, esterification may not have a large influence on k_3.

As reported previously (9), vitamin E radicals are not stable, and thus stable radicals were used for the present work. The preparation of 5,7-diisopropyl-tocopherol (di-iPr-TocH), 6-hydroxy-2,2-dimethyl-5,7-diisopropyl-chromane

(di-iPr-TbcHM) and 2,3-dihydro-5-hydroxy-2,2-dimethyl-4,6-diisopropyl-benzofuran (di-iPr-TbcH5) has been described previously (13–15). 5,7-Diisopropyl-8-methyl-tocopherol (di-iPr-8-Me-TbcH) was prepared according to published methods (16). 6-Hydroxy-2,2-dimethyl-5,7-diisopropyl-8-methyl-chromane (di-iPr-8-Me-TbcHM) was synthesized by reaction of paraformaldehyde with di-iPr-TbcHM in 1,4-dioxane (16,17). 5,7-Diethyl-8-methyl-tocopherol (di-Et-8-Me-TbcH) and *d*-α-TbcH were kindly supplied by Dr. Shiro Urano of Tokyo Metropolitan Institute of Gerontology and Eisai Co, Ltd., respectively, both from Tokyo, Japan. In the experiments done in homogeneous solution, the radicals (di-iPr-Tbc• etc) were prepared by PbO_2 oxidation of the corresponding TbcH in a nitrogen atmosphere. Tbc• radical containing micellar dispersions of Triton X-100 were prepared as reported (18).

Egg yolk lecithin was isolated according to the method reported by Singleton *et al.* (19). Lecithin fatty acid moieties were analyzed by gas chromatography of the methyl esters obtained by transmethylation of lecithin. The values obtained are as follows: palmitic acid (16:0), 41.3%; palmitoleic acid (16:1), 2.5%; 18:0, 8.7%; 18:1, 29.5%; 18:2, 16.5%; and 20:4n-6, 1.7%. The average molecular weight of the lecithin was estimated to be 763.7. The amount of hydroperoxides in the sample was found to be negligible as judged by thin-layer chromatography.

Commercial Triton X-100 was used without further purification. The aqueous solution (1.0 wt%) was buffered at pH 7.0 by use of KH_2PO_4 and $NaHPO_4$. Benzene and *t*-butanol were distilled before use.

The experimental procedures used for measurement of the rate constants were described previously in detail (9–12). Briefly, the kinetic data were obtained with a Shimadzu UV-2100S spectrophotometer by mixing equal volumes of solutions of 18:0, etc., or egg yolk lecithin and Tbc• under a nitrogen atmosphere. The molar concentration of Tbc• and LH before the beginning of reaction was 5×10^{-5} and $1\text{–}3 \times 10^{-3}$ M, respectively. All measurements were performed at 25.0 ± 0.5°C; Tbc• is unstable at 37°C.

The pseudo-first-order rate constant for reaction [3] (k_{obsd}) was determined by following a decrease in absorbance of Tbc• around 420 nm; k_{obsd} is given by equation [5]:

$$k_{obsd} = k_0 + k_3 [LH] \qquad [5]$$

where k_0 denotes the rate constant for natural decay of Tbc•, k_3 stands for the second-order rate constant for reactions of 18:0, Me18:0, Et18:0, etc., or egg yolk lecithin (LH) with Tbc• and [LH] refers to the molar concentration of LH. The rate parameters were obtained by plotting k_{obsd} against [LH]. Experimental errors were less than ±5%.

RESULTS AND DISCUSSION

The k_3 values of the reactions of 18:0, Me18:0, etc., with di-iPr-Tbc• in micellar dispersion and *t*-butanol are given in Table 1. As reported previously (11,12), k_3 increases as the number of C=C double bonds in the fatty acids and fatty acid esters increases (18:0<18:1<18:2<18:3<20:4n-6< 22:6n-3 and Me18:0<Me18:1<18:2<18:3<20:4n-6< Me22:6n-3). Allylic hydrogen abstraction plays a major role in the high reactivity of the unsaturated fatty acid and the ester in reaction [3]. The allylic hydrogen is activated by the π-electron system (C=C double bond).

The rate k_3 of 18:1 (Me18:1) is much smaller than that of 18:2 (Me18:2). While 18:1 (Me18:1) has four hydrogen atoms activated by a single π-electron system, 18:2 (Me18:2) has two hydrogen atoms activated by two π-electron systems. Thus, the two hydrogen atoms activated by two π-electron systems will contribute to the high reactivity of 18:2 (Me18:2). As reported previously (12), the k_3 observed can be explained in terms of the pseudo-π-conjugation between the C=C double bond and the active hydrogen-carbon bond.

The free acids 18:2, 18:3, 20:4n-6 and 22:6n-3 (or Me18:2, Me18:3, Me20:4n-6 and Me22:6n-3) have two, four, six and ten hydrogen atoms activated by two π-electron systems, respectively. The rate constants per active hydrogen (k_{abstr}/H's) are given in Table 1. In *t*-butanol, k_{abstr}/H values for Me18:2, Me18:3, Me20:4n-6 and Me22:6n-3 are similar. However, in micellar dispersion, k_{abstr}/H decreases as the number of C=C double bond in 18:2, 18:3, 20:4n-6 and 22:6n-3 increases. This could be explained as follows: The micelles contain Tbc• and LH which have a polar "head" (-O• and -COOR, respectively) and a long hydrocarbon "tail". The polar "head" is located on the outer surface of the micelle facing the water phase. Since the polar "head" of Tbc• (-O•) cannot easily approach the hydrophobic end of the long hydrocarbon "tail" of LH in the micelles, the probability of a reaction occuring with an

active hydrogen located near the tip of the "tail" is small. Accordingly, k_{abstr}/H is not the same for 18:2, 18:3, 20:4n-6 and 22:6n-3 in micellar dispersions.

The idea that the Toc• radicals and lipid chains within micelles are locally restricted may, of course, be somewhat simplistic, as micelles are dynamic structures. Also diffusion control between micelles might affect k_3 values here, especially for Tocs• with phytyl side chains.

When LH and Toc• are contained in micelles, the actual local concentration of LH and Toc• are much larger than the nominal concentration of the solution. As a result, the apparent second-order rate constant k_3 ($M^{-1}s^{-1}$) in micellar dispersions is larger than that in homogeneous solutions. Since the specific gravity of Triton X-100 is close to that of water, and the concentration is 1.0% by weight, k_3 in micellar dispersion must become larger than that in *t*-butanol by about two orders of magnitude. However, as shown in Table 1, k_3 in micellar dispersion is larger than that in *t*-butanol by only one order of magnitude. This supports our view that the active site of Toc• (-O•) cannot easily access that of LH (allylic hydrogen) which is concealed behind Triton X-100, which prevents Toc• from reacting with LH.

The k_3 values of the reactions of Toc• with Me18:2 are given in Table 2 together with the rate constants for the antioxidant reaction of TocH with a phenoxyl, k_s, (14,15, 20–22). Di-iPr-Toc• and di-iPr-8-Me-Toc• have prooxidant reactivity similar to that of di-iPr-TocM• and di-iPr-8-Me-TocM•, respectively, in benzene. As in the case of the antioxidant reaction (20), the effect of the phytyl side chain on the prooxidant activity is not very pronounced in homogeneous solution.

In the antioxidant reaction, k_s increases when going from TocH with a 6-membered heterocyclic ring to the corresponding TocH with a 5-membered ring (di-iPr-TocM•< di-iPr-Toc5•). This can be explained in terms of an increase in orbital overlap between the 2p type lone pair on the ring oxygen and the aromatic π electrons (21). However, in the prooxidant reaction, di-iPr-TocM• having a 6-membered heterocyclic ring has a reactivity similar to that of di-iPr-Toc5• having a 5-membered ring. The effect of the heterocyclic ring on the prooxidant activity is not significant.

Table 2 shows that the bulkier the substituent groups at the 5- and 7-positions of Toc•, the smaller k_3 [5-isopropyl-7-*t*-butyl-tocopheroxyl radical (iPr-tBu-Toc•) <di-iPr-Toc•<5,7-diethyl-tocopheroxyl radical (di-Et-Toc•) and di-iPr-8-Me-Toc•<di-Et-8-Me-Toc•<*d*-*α*-Toc•]. As reported previously (12), the pronounced substituent effect in the prooxidant reaction in homogeneous solution is due to the steric hindrance by the substituent groups at the 5- and 7-positions. In contrast, the steric hindrance does not have a large influence on the antioxidant activity of TocH (14,15,20–22).

Methylation at 8-position of Toc• decreases k_3 (di-iPr-Toc•>di-iPr-8-Me-Toc•, di-iPr-TocM•>di-iPr-8-Me-TocM•, and di-Et-Toc•>di-Et-8-Me-Toc•), while methylation at 8-position of TocH increases k_s (di-iPr-TocH<di-iPr-8-Me-TocH, di-iPr-TocHM<di-iPr-8-Me-TocHM and di-Et-TocH<di-Et-8-Me-TocH). Its methylation increases and decreases the antioxidant and prooxidant activities of TocH, respectively. In this context, it is suggestive that all natural TocH have a methyl group at 8-position. The increase in k_s can be explained in terms of an increase in electron donating capacity of TocH and a charge transfer ability of the antioxidant reaction (21). At present, we cannot explain the decrease in k_3 upon methylation, but the following possibilities exist. Firstly, methylation at the 8-position may stabilize Toc• and reduce prooxidant activity. Then since k_3 of di-iPr-8-Me-Toc• (di-iPr-8-Me-TocM•) is much smaller than that of di-iPr-Toc• (di-iPr-TocM•), methylation may increase steric hindrance by the substituent groups at the 7-position. Figures 1a and b show a schematic sketch of molecular structures of di-iPr-Toc• and di-iPr-8-Me-Toc•, respectively. By methylation at the 8-position, the active site of Toc• (-O•) is concealed behind two methyl groups of the isopropyl group at the 7-position, which could prevent Toc• from reacting with LH.

The effect of the phytyl side chain of Toc• on the prooxidant activity was examined also in micellar dispersion. In benzene, the k_3 values of di-iPr-Toc• and di-iPr-TocM• are similar. However, in micellar dispersion, k_3 of di-iPr-Toc• is much smaller than k_3 of di-iPr-TocM•. We believe that this can be explained in terms of the structure of the micelles. Since the polar "head" of di-iPr-Toc• (-O•) can probably not gain easy access to the tip of the long hydrocarbon "tail" of LH in the micelle, the

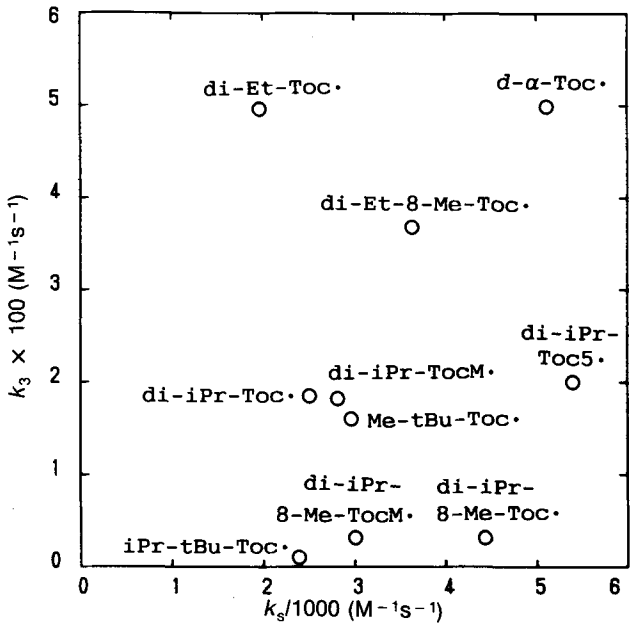

FIG. 2. Plot of k_3 obtained in benzene *vs.* k_s.

probability of the reaction of the active hydrogen located near the tip of the "tail" is small. However, this is not the case for di-iPr-TocM• which does not have a phytyl side chain and thus is more mobile in the micelles. Accordingly, k_3 of di-iPr-TocM• is larger than that of di-iPr-Toc•. The effects of the phytyl side chain on the mobility in heterogeneous system, such as micelle and membranes, have already been the subject of some experimental studies (1,23,24).

It is interesting to examine whether or not the second-order rate constant of the hydrogen abstraction of egg yolk lecithin (k_{leci}) is the same as that expected for the fatty acid moieties of lecithin (k_{expd}). The k_{leci} values obtained in the reaction with di-iPr-Toc• in benzene, *t*-butanol and in micelles are given in Table 3 together with the k_{expd} data. The k_{expd} was calculated as described previously (12). The k_{expd} values in benzene, *t*-butanol and micellar dispersion were estimated by the use of k_3 of Et18:0, etc. (12), Me18:0, etc. and 18:0, etc. (Table 1), respectively. In *t*-butanol and micelles, k_{leci} is similar to the corresponding k_{expd}. Steric hindrance between the two fatty acid moieties of lecithin is unlikely to affect the kinetics. However, in benzene, k_{leci} is about 30% of the corresponding k_{expd}. Lecithins are prone to aggregate as reverse micelles in nonprotic solvents such as benzene (25,26), but not in *t*-butanol (25). Formation of reverse micelles prevents di-iPr-Toc• from reacting with the fatty acid moiety in benzene.

It is desirable to compare k_s and k_3 of various TocH in order to find useful antioxidants. Figure 2 shows a plot of k_3 obtained in benzene *vs.* k_s. A useful antioxidant should satisfy the requirement that k_s is large and k_3 is small. From Figure 2, it is suggested that di-iPr-Toc5• meets these criteria. TocH with bulky substituents at 5- and 7-positions and TocH with a methyl group at 8-position should also be useful.

ACKNOWLEDGMENTS

We thank Dr. Shiro Urano of Tokyo Metropolitan Institute of Gerontology and Eisai Co., Ltd. for the generous gifts of di-Et-8-Me-TocH and *d*-α-TocH, respectively. We also thank Professor William A. Pryor of Louisiana State University and Prefessor René Martin of Universite de Nancy for valuable discussions.

The Urinary Excretion of Thiobarbituric Acid Reactive Substances and Malondialdehyde by Normal Adult Males After Consuming a Diet Containing Salmon

Gary J. Nelson[a,*], Virginia C. Morris[b], Perla C. Schmidt[a] and Orville Levander[b]
[a]Western Human Nutrition Research Center, Agricultural Research Service, U.S. Department of Agriculture, Presidio of San Francisco, California 94129 and [b]Beltsville Human Nutrition Research Center, ARS, USDA, Beltsville, Maryland 20705

In this study we investigated the output of thiobarbituric acid reactive substances (TBARS) and malondialdehyde (MDA), as thiobarbituric acid (TBA)–MDA adduct, in the urine from subjects eating a diet in which the only source of n-3 long-chain, polyunsaturated fatty acids was fresh salmon. Nine healthy men, ages 30–65, were confined in the United States Department of Agriculture Western Human Nutrition Research Center, San Francisco, CA, for 100 d; food intake and exercise levels were controlled. All subjects were placed on a stabilization diet (StD) for 20 d, then six were fed the salmon diet for 40 d. The others remained on the StD. The groups switched diets for the last 40 d. Both diets were isocaloric (16% protein, 54% CHO and 30% fat by energy %). The salmon diet contained 7.5% of calories from n-6 fatty acids (FAs) and 2% from n-3 FAs, primarily eicosapentaenoic acid and docosahexaenoic acid in a 50:60 ratio, while the StD contained 7.5% from n-6 FAs and < 0.3% n-3 FAs (with presumably no significant amounts of C_{20} or C_{22} n-3 FAs). Twenty-four hour urinary output was collected, and 2% 3-d pool samples prepared for analysis of urinary TBARS and the TBA–MDA adduct. The total urinary output of each individual varied considerably, and on a daily basis the concentration of autoxidation products in an individual's urine varied also. However, the mean daily output (in μmoles TBA–MDA equivalents/day) at the end of the salmon diet feeding period was significantly greater (7.05 ± 1.33 TBARS, $P < 0.05$; and 7.07 ± 1.73 TBA–MDA adduct, $P < 0.01$) compared to when the subjects were eating the StD (5.65 ± 1.09 TBARS and 4.65 ± 0.76 TBA–MDA adduct). When the TBARS and TBA–MDA adduct values were normalized relative to creatinine output (in nmoles TBA–MDA equivalents/μmole creatinine), the data achieved even greater statistical significance. The mean output of the group eating the salmon diet was 0.478 ± 0.076 for TBARS ($P < 0.01$) and 0.476 ± 0.082 for the TBA–MDA adduct ($P < 0.001$) *vs.* 0.345 ± 0.059 for TBARS and 0.283 ± 0.041 for the TBA–MDA adduct when the subjects were consuming the StD. Thus, the consumption of cooked fish may increase one's exposure to MDA and other autoxidation products, compounds that may be carcinogenic or mutagenic.
Lipids 28, 757–761 (1993).

Fish oil supplements and diets containing fish have been purported to promote cardiovascular health and alleviate several other human afflictions, such as cancer, arthritis and psoriasis (1–5). Some investigators have questioned the adequacy of the antioxidant level in the typical Western diet if individuals start consuming increased amounts of n-3 long-chain polyunsaturated fatty acids (FAs) (6–9). An experimental approach to answer this question was attempted by Draper and colleagues (10) who measured the malondialdehyde (MDA) levels in urine from normal volunteers who had consumed fish oil supplements. They found that MDA excretion in the urine was increased after consumption of a fish oil supplement but concluded that this increase was the result of autoxidation products in the supplement rather than an increased production of these substances *in vivo*. They suggested that fish oil supplements that were not previously autoxidized do not necessarily increase the amount of MDA produced *in vivo*, although they did state that protracted consumption of n-3 FAs must be presumed to increase the vitamin E requirement. There is no comparable information about the excretion of lipid autoxidation products in the urine after consumption of fresh fish.

In a recent study (11,12) directed primarily toward the effect of a diet with increased n-3 polyunsaturated FAs on FA metabolism, blood lipids and platelet function, 24-h urine samples were collected and stored at −70°C (no urine was lost). The source of the n-3 long-chain polyunsaturated FAs in this study was fresh salmon rather than a fish oil supplement. The stored urine samples provided an opportunity to examine the excretion of thiobarbituric acid reactive substances (TBARS) and MDA in urine samples from human volunteers eating a diet containing fresh fish. The results of these analyses are reported here.

MATERIALS AND METHODS

Materials. All foods were purchased at local food markets. The salmon (Pacific, chinook, *Oncorhynchus tshawytscha*) was purchased fresh from a seafood wholesale supply company as a large batch from a single boat. It was frozen until used for meal preparations during the study.

Subjects. Twelve volunteers, consisting of men between the ages of 30 and 65, were recruited from the West Coast. All volunteers were given complete physical examinations. Body weights had to be within −10 to +20% of ideal body weights using the Metropolitan Life Insurance Company tables (medium frame values from the 1983 edition). Evidence of existing illness or chronic disease was an exclusion criterion. Smoking, excessive alcohol consumption or evidence of narcotic abuse were also exclusionary. The physical characteristics of the final nine volunteers who completed the study were previously published (11).

Experimental design. All the volunteers were confined to the Nutrition Research Unit of the Western Human Nutrition Research Center, San Francisco, CA during the study. A crossover design was used. The subjects were

Abbreviations: En%, energy percent; FA, fatty acid; HPLC high-performance liquid chromatography; MDA, malondialdehyde; RDA, Recommended Dietary Allowance; StD, stabilization diet; TBA, thiobarbituric acid; TBARS, thiobarbituric acid reactive substances; TMP, 1,1,3,3-tetramethoxy-propane.

fed a stabilization diet (StD), containing less than 1% n-3 long-chain, polyunsaturated FAs for twenty days. On day 21 of the study, the subjects were divided into two groups. One, designated Group A, was then placed on the salmon diet for 40 d. The other group, designated Group B, remained on the StD for forty more days. On day 61, the groups switched diets for the remaining 40 d of the study. Statistical comparisons of the measured parameters were made using day 20 as the baseline value for each subject in group A and day 60 for each subject in group B. Subjects served as their own controls.

Diets. The diets consisted of foodstuffs accessible in grocery stores in San Francisco, CA. No dietary supplements were given except α-tocopherol to bring the diet to 200% of the Recommended Dietary Allowance (RDA) for this vitamin because diets containing large amounts of polyunsaturated FA may deplete the reserves of antioxidant nutrients. (A complete description of the diets, listing all the major and minor nutrients, is available upon request.) There was a five-day menu cycle used throughout the study. No alcohol was included in the diets. The diets were designed around a prudent diet concept of 30:55:15 fat, carbohydrate and protein in energy percent (En%). The nutrient composition of the diet was calculated from a computerized nutrient data bank and adjusted to provide at least the RDA for known essential nutrients. Dietary quantities of saturated and n-6 FAs were held constant in these diets. The StD had less than 1% n-3 FAs (mostly as α-linolenic acid) and approximately 50% monounsaturated FAs (mostly oleic acid). The salmon diet had approximately 7.5% long-chain polyunsaturated n-3 FAs with a concomitant reduction in the level of monounsaturated FAs. All participants were weighed every day, and the caloric value of their meals adjusted daily, if necessary, to maintain their weight within the design limits of the study (±2%). If all the intakes for each volunteer were averaged during the entire study, the mean energy intake was approximately 2800 Kcal/d. As no two subjects ate the same amount of salmon each day, the amount of n-3 FAs is best expressed in terms of percent of calories per day rather than grams of n-3 FAs consumed per day. In this study each volunteer fed the salmon diet received 2.1% of his calories from long-chain, n-3 polyunsaturated FAs. If, for example, an individual in this study was receiving 3000 Kcal/d, he would have consumed about 2.1 g of 20:5n-3, 0.8 g of 22:5n-3 and 3.0 g of 22:6n-3, or about 6 g/d of n-3 polyunsaturated FAs.

Analysis of urinary TBARS, thiobarbituric acid (TBA)—MDA adduct and creatinine. Urine samples were stored frozen at −70°C until thawed for analysis. Fresh aliquots were taken from the 3-d pools for each analysis. TBARS were determined by the method of Buege and Aust (13). Aliquots of urine were added to the TBA reagent (0.375% TBA, 15% trichloroacetic acid, 0.25N HCl and 0.2% butylated hydroxytoluene). Samples and standards were heated in a water bath at 80°C for 30 min, cooled in ice water and centrifuged for 10 min at 1000 × *g*. Absorbance of the supernatant was read at 535 nm, and the concentration of TBA-MDA equivalents was calculated from a standard curve derived from the acid hydrolysis of 1,1,3,3-tetramethoxypropane (TMP).

Since the TBARS assay for human tissues and body fluids is subject to interference by substances other than MDA (14), a TBA test based on high-performance liquid chromatography (HPLC) was also used for comparison. The TBA-MDA adduct (assumed to Form in a 2:1 ratio, see Ref. 14) was determined by a modification of the method of Tatum *et al.* (15). Aliquots of urine were added to TBA reagent (0.27% TBA 0.13N HCl and 0.2% butylated hydroxytoluene). Samples and standards were heated at 80°C for 30 min, cooled, and centrifuged for 10 min at 1000 × *g*. The TBA-MDA complex was extracted in butanol, mixed with 1/2 vol of methanol and injected into the HPLC. HPLC conditions were as follows: mobile phase, 1:1 (vol/vol) mixture of methanol and 0.05% tetrabutyl ammonium dihydrogen phosphate as the ion-pairing reagent; column 5 μ C_{18} reversed phase (Beckman Instruments, Fullerton, CA); flow rate, 1 mL/min and detection, fluorimeter set at an excitation wavelength of 550 nm. The TBA-MDA adduct was calculated from a standard of TMP carried through the same procedure.

Creatinine in the urine was measured by an alkaline picrate colorimetric procedure in a Centrifichem System 600 (Baker Instruments, Allentown, PA) using reagents purchased from Trace America, Inc. (Miami, FL).

Statistical analysis. The data were analyzed with a two-tailed, paired *t*-test. All statistical analyes were done with the PC SAS data system, Version 6.03 (SAS Institute, Chapel Hill, NC 1988).

RESULTS

Tables 1 and 2 give the results of the TBARS test and the TBA-MDA adduct analyses (in μmoles TBA-MDA equivalents/day), respectively, for the nine subjects who completed this study. The total urinary output of each individual varied considerably, consequently the daily concentration of autoxidation products in the urine also varied. Despite this variation, the mean daily output of oxidation products at the end of the salmon diet feeding period was significantly greater (approximately 20% for the TBARS and 50% for TBA-MDA adduct) than the output of these substances when the subjects were eating the StD. The TBARS test combined means were significantly different at the $P < 0.05$ level while the TBA-MDA adduct means were significantly different at the $P < 0.01$ level.

When the TBARS test and the TBA-MDA adduct values were normalized relative to the creatinine content of the urine (nmoles TBA-MDA equivalents/μmole creatinine), the data achieved greater statistical significance. This is shown in Tables 3 and 4 for the TBARS test and the TBA-MDA adduct, respectively. Combined mean urinary output for all subjects on the salmon diet was 50% greater for the TBARS test ($P < 0.01$) and 75% percent greater for the TBA-MDA adduct analysis ($P < 0.001$) than the combined means before the subjects consumed the salmon diet for forty days.

The above results were obtained using the combined data from Groups A (n = 6) and B (n = 3) to give a total n of nine for the study. As this was a crossover study, Group A returned to the stabilization diet for the last 40 d of the study. It is apparent from the tables that both the TBARS and TBA-MDA adduct values for Group A in the urine at day 100 of the study had returned to their pre-salmon feeding values (day 20). For Group A the day 100 values for the TBARS test (Table 1) were lower than

Combined means ± SD		5.65 ± 1.09	7.05 ± 1.33	—

[a]Differences between the combined means, using baseline day 20 and end day 60 for Group A and baseline day 60 and end day 100 for Group B, were significant at the $P < 0.05$ level. Abbreviations: TBARS, thiobarbituric acid reactive substances; TBA, thiobarbituric acid; MDA, malondialdehyde.

the 20 day values, but this difference vanished when the TBARS values were normalized relative to daily creatinine output (Table 3).

DISCUSSION

It has been established that increased MDA ingestion from oxidized fish oil increases the excretion of MDA in the urine (10,16,17). The work presented here shows that the ingestion of cooked fish containing n-3 long-chain polyunsaturated FAs increases the excretion of both TBARS and MDA in the urine. Both methods used to measure MDA in the urine (the colorimetric TBARS test and the fluorimetric HPLC determination of the TBA-MDA adduct) gave essentially the same results when the subjects were consuming the salmon diet, but the TBARS test yielded somewhat higher values than the TBA-MDA adduct determination while the subjects were fed the StD diet. This suggests the presence of interfering substances in the urine when the subjects were fed the StD diet. Under these conditions, therefore, measurement of urinary MDA by HPLC of the TBA-MDA adduct is more accurate than the TBARS test. Kosugi *et al.* (18) reported that HPLC separation was necessary for accurate quantitation of the red pigment formed in the TBA assay of human urine.

The quantity of MDA excreted daily in the urine by our North American male subjects (eight Caucasians and one Asian) agrees closely with the amounts found recently in the urine of Japanese subjects when expressed on a body

weight basis. Our subjects (mean of 84 ± 13 kg, see Ref. 11) excreted 55 and 84 nmoles of TBA-MDA equivalents/kg/day when fed the stabilization and salmon diets, respectively (HPLC analysis of TBA-MDA adduct). Twelve healthy Japanese subjects (six males and six females with an overall mean body weight of 53 kg) excreted from 26 to 95 nmoles of red pigment/kg/day (TBA-reactive material in urine separated by HPLC, see Ref. 18).

MDA is a mutagen in the Ames test (19) and is thought to be a carcinogen (20). However, because ingested MDA usually becomes conjugated to lysine during the absorption process (16), it may not be as hazardous as MDA produced *in vivo* from n-3 long-chain polyunsaturated FAs. Thus, the question arises whether the MDA found in the urine of these subjects was produced *in vivo* or in the cooking process before the fish was eaten. Siu and Draper (21) have suggested that less than 10% of the ingested MDA is excreted in the urine. Unfortunately, no measurements of the MDA content of the cooked fish were made in this study so that the endogenous or exogenous origin of the TBARS and MDA excreted in the urine cannot be established with any certainty. However, we believe that it is unlikely that the MDA was present in the fresh fish as it was kept frozen at −20°C until it was ready for cooking. (Commercial salmon fishing boats usually keep the fish alive in salt water or packed in ice until they dock. The fish in this study were filleted and frozen at a dockside processing plant within hours of docking.) Also, the fish fillets were not flame exposed during cooking to minimize oxidation. Fish, because of its high water content and low fat content, cooks internally at 100°C or less,

[a]Differences between the combined means, using baseline day 20 and end day 60 for Group A and baseline day 60 and end day 100 for Group B, were significant at the $P < 0.001$ level. See Table 1 for abbreviations.

largely independent of the set cooking temperature. It should be noted also that the diet contained twice the RDA of tocopherol. Work by Draper and colleagues (8,10) and others (22,23) suggests that added tocopherol will suppress the oxidation of long-chain polyunsaturated FAs *in vivo*. Also, as it is known that the amount of free MDA in the diet, plasma and urine is negligible, the mutagenicity and carcinogenicity of dietary MDA may not be a major problem. The lysine adduct of MDA, the form in which it is absorbed, is nonmutagenic. This does not mean, however, that dietary n-3 FAs cannot be potential risk factors because they could lead to increased lipid peroxidation *in vivo*. The peroxides could then produce MDA in tissues where it could react with cellular DNA.

Kaasgaard *et al.* (24) reported that livers from Cynomolgus monkeys after feeding menhaden oil showed variable but increased lipofuscin levels despite a diet that had been supplemented with a fourfold excess of tocopherol. This suggests that excess tocopherol at that level may not halt lipid peroxidation *in vivo*.

The subjects in this study may have either ingested or produced much more MDA than was detected in the urine if the speculation of Siu and Draper (21) concerning the small percent of MDA excreted in urine is correct. Whether the increased excretion of TBARS and MDA found here indicates any adverse health consequence related to consumption of food containing n-3 polyunsaturated FAs remains to be determined. However, none of the subjects in this short term study showed any adverse effects ascribable to lipid oxidation. Their *in vitro* platelet aggregation as measured by sensitivity to adenosine diphosphate and arachidonic acid was reduced, and their *in vivo* bleeding times were unchanged. The total serum cholesterol was unchanged but their very low density lipoprotein and triglycerides levels were reduced and their high-density lipoprotein cholesterol level went up significantly. Their risk factor profile was in fact healthier at the end of the study by the usual criteria, such as lipid profiles, platelet function, etc. The complete report on the health parameters studied in the volunteers is found in References 11 and 12. If subsequent work does show that the increased urinary excretion of lipid peroxidation byproducts is the result of *in vivo* processes, increased intake of antioxidant nutrients, preferably through dietary food sources containing these compounds, may be warranted.

ACKNOWLEDGMENTS

The authors wish to express their appreciation to the staff of the Jones Operation and Maintenance Company for preparations of the diets and the care of the volunteers while domiciled at the Nutrition Suite at the Western Human Nutrition Center.

COMMUNICATION

Novel Brominated Phospholipid Fatty Acids from the Caribbean Sponge *Agelas* sp.

Néstor M. Carballeira* and **Anastacio Emiliano**
Department of Chemistry, University of Puerto Rico, Rio Piedras, Puerto Rico 00931

The very long-chain fatty acids, (5*E*,9*Z*)-6-bromo-5,9-tetracosadienoic, (5*E*,9*Z*)-6-bromo-23-methyl-5,9-tetracosadienoic, (5*E*,9*Z*)-6-bromo-5,9-pentacosadienoic and (5*E*,9*Z*)-6-bromo-24-methyl-5,9-pentacosadienoic acids, were identified in the phospholipids (mainly phosphatidylethanolamine) of the sponge *Agelas* sp. Structure elucidation was accomplished by means of mass spectrometry and chemical transformations, including deuteration with Wilkinson's catalyst. All of the sterols from the sponge had the Δ5,7 nucleus, with 24-methylcholesta-5,7,22-trien-3β-ol (ergosterol) and 24-ethylcholesta-5,7,22-trien-3β-ol being the most abundant.
***Lipids* 28, 763–766 (1993).**

Phospholipids with brominated fatty acids are particularly rare in nature. Only two reports of naturally-occurring phospholipid brominated fatty acids have appeared and both were concerned with sponges. Two heptacosadienoic acids with the rare 5,9-diene pattern, *iso*/*anteiso* methyl branching, and the bromovinyl function were isolated from the marine sponges *Petrosia ficiformis* and *Petrosia hebes* (1). Likewise, the long-chain fatty acid (5*E*,9*Z*)-6-bromo-5,9-hexacosadienoic acid (**3a**) was also isolated from the phospholipids of a *Hymeniacidonid* sponge (2). It is significant to note that all of these fatty acids were found principally in phosphatidylethanolamine (PE) and that the bromine atom was always found at the vinylic carbon 6-position of the 5,9-diene functionality of the demospongic acid, regardless of carbon chain length or methyl branching.

SCHEME 1

These brominated phospholipid fatty acids in marine sponges are of particular interest, as the number of halogenated fatty acids found in marine organisms is extremely small in comparison with the number of halogenated secondary metabolites reported to date (2). A few other free halogenated long-chain fatty acids have been reported in the marine environment. Six fatty acid chlorohydrins of palmitic and stearic acids (mainly with the combinations 9-chloro-10-hydroxy and 10-chloro-9-hydroxy) were found in the total lipids of the jellyfish *A. aurita* (3). This finding was followed by the elegant work of Schmitz and Gopichand (4), who isolated (7*E*,13ζ,15*Z*)-14,16-dibromo-7,13,15-hexadecatrien-5-ynoic acid from the marine sponge *Xestospongia muta*, the first dibrominated straight-chain acetylenic acid from a sponge. Other examples include a monobrominated straight-chain C_{18} bisacetylenic acid from *X. testudinaria* (5) and six mono- and dibrominated straight-chain unsaturated C_9, C_{16} and C_{18} acids from the same genus (6). Although all of the latter reports are on free fatty acids, the only halogenated fatty acids in phospholipids have been found in sponges.

In our present work we wish to report the isolation and structural elucidation of four new brominated phospholipid fatty acids, namely (5*E*,9*Z*)-6-bromo-5,9-tetracosadienoic acid (**1a**), (5*E*,9*Z*)-6-bromo-5,9-pentacosadienoic acid (**2a**), (5*E*,9*Z*)-6-bromo-23-methyl-5,9-tetracosadienoic acid (**2b**) and (5*E*,9*Z*)-6-bromo-24-methyl-5,9-pentacosadienoic acid (**3b**), from the phospholipids of an *Agelas* sp., which was collected during a recent expedition to Mona Island, Puerto Rico. We also wish to report the unusual sterol composition of this sponge.

EXPERIMENTAL PROCEDURES

Agelas sp. was collected August 1, 1992, near Mona Island, Puerto Rico, at a depth of 25 m. The sponge was freeze-dried in a Labconco Freeze Dryer 4.5 (Model 77510; Kansas City, MO). The sponge (36 g) was carefully cleaned of all nonsponge debris and cut into small pieces. Extraction with 250 mL of chloroform/methanol (1:1, vol/vol) yielded the total lipids. The neutral lipids, glycolipids and phospholipids (20 mg) were separated by column chromatography on silica gel (60–200 mesh) using the procedure of Privett *et al.* (7). The phospholipid classes were fractionated by thin-layer chromatography (TLC) using silica gel 60 and chloroform/methanol/NH_4OH (65:35:5, by vol) as solvent. The fatty acyl components of the phospholipids were obtained as their methyl esters by reaction of the phospholipids with methanolic hydrogen chloride (8) followed by column chromatographic purification and elution with hexane/diethyl ether (9:1, vol/vol). The resulting methyl esters were analyzed by gas chromatography/mass spectrometry (GC/MS) using a Hewlett-Packard 59970 MS ChemStation (Hewlett-Packard, Palo Alto, CA) equipped with a 30 m × 0.32 mm nonpolar fused silica column (Supelco, Bellefonte, PA) with SPB™-1 as the bonded phase. GC/Fourier transform infrared (FTIR) spectra were

recorded on a Nicolet (Madison, WI) 740 FTIR spectrometer. For the location of double bonds, pyrrolidides were prepared by direct treatment of the methyl esters with pyrrolidine/acetic acid (10:1, vol/vol) in a capped vial (2 h at 100°C) followed by ethereal extraction from the acidified solution and purification by preparative TLC (9). The double bond position of the monoenoic acids was elucidated by preparing the corresponding dimethyl disulfide derivatives by dissolving the esters (2 mg) in dimethyldisulfide (0.2 mL) and adding a solution (0.05 mL) of iodine in diethyl ether (60 mg/mL) and heating the solution at 50°C for 24 h, followed by the standard work-up (10). Hydrogenations were carried out in 10 mL of absolute methanol in the presence of catalytic amounts of platinum oxide (PtO_2). Deuterations were also carried out in 10 mL of methanol in the presence of catalytic amounts of Wilkinson's catalyst [$RhCl(PPh_3)_3$]. Deuterium was obtained from the reaction of sodium and D_2O. Spectral data for the key fatty acids for this discussion follows.

N-(5*E*,9*Z*)-6-bromo-24-methylpentacosa-5,9-dienoylpyrrolidine. MS (70 eV) *m/z* (relative intensity), 525($C_{30}H_{54}$-$NOBr^+$, 0.1), 523(0.1), 444(M^+-Br,17), 260(13), 258(C_{11}-$H_{17}NOBr^+$, 16), 180($C_{11}H_{18}NO^+$, 5.4), 126(6.7), 113(100), 98(20), 85(11.7).

RESULTS AND DISCUSSION

The principal phospholipid from *Agelas* sp. was identified by TLC as PE, but small amounts of phosphatidylserine, phoshatidylinositol and phosphatidylcholine were also detected. The major fatty acids from the phospholipids of the sponge were identified in the standard way from the GC equivalent chain length values (ECL) and electron impact mass spectra of the methyl esters and the *N*-acylpyrrolidides. The complete list of fatty acids identified is shown in Table 1. Branched-chain fatty acids (particularly

TABLE 1

Principal Phospholipid Fatty Acids from *Agelas* sp.[a]

ECL[b]	Fatty acid	Abundance wt%)
13.00	Tridecanoic (13:0)	6.2

27.90	6-Bromo-5,9-hexacosadienoic (26:2)	0.3

[a]The aldehyde heneicosanal (21:0) was also identified in the mixture (1.2%).

[b]Equivalent chain length (ECL) values are those of the methyl esters of the acids.

[c]These acids have not been described before in nature.

iso/*anteiso*) were predominant in the mixture, accounting for up to 56% of the total fatty acid composition. Of interest are the large amounts in this particular sponge of tridecanoic acid (13:0), which is not a common fatty acid in most sponges. Phytanic acid, namely 3,7,11,15-tetramethylhexadecanoic acid (20:0), was also observed in the mixture as the most abundant fatty acid (10%); no other isoprenoid fatty acid was detected in the sponge. The main demospongic fatty acids in the sponge, *i.e.*, those with the Δ5,9 diene function, were characterized as 5,9-tetracosadienoic acid, 5,9-pentacosadienoic acid and 5,9-hexacosadienoic acid. It is interesting to note that the recently discovered 23-methyl-5,9-tetracosadienoic acid was also identified in the mixture (2% relative abundance). The complete characterization of all of these fatty acids has been previously described (11).

The most interesting fatty acids in the sponge were a series of five brominated Δ5,9 demospongic acids. One of the fatty acids was identified as the 6-bromo-5,9-hexacosadienoic acid (**3a**), as confirmed by comparing its spectral data with that published in the literature (2). The other four brominated fatty acids in the phospholipids of *Agelas* sp. were further characterized as the corresponding 6-bromo derivatives of the principal demospongic acids present in the sponge. All of the brominated fatty acids showed similar spectral characteristics. The main feature of the ^1H nuclear magnetic resonance (NMR) spectrum was the presence of multiplets between 5.32 and 5.41 ppm for the C-9 and C-10 hydrogens, while the C-5 hydrogen was observed further downfield as a triplet at 5.84 ppm, due to the electronegative vicinal bromine at C-6. The GC/MS of the brominated fatty acid methyl esters showed strong mass spectral peaks at *m/z* 74 (due to the McLafferty rearrangement typical of fatty acid methyl esters) and M^+-79 peaks as molecular ions, indicating facile loss of bromine under electron impact.

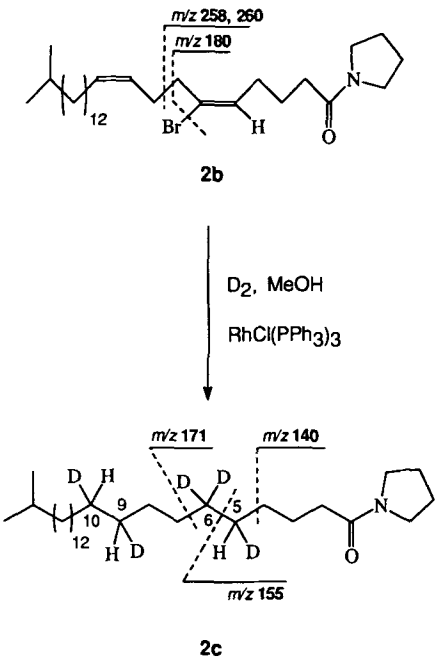

FIG. 1. Key mass spectral fragmentations for the N-(5*E*,9*Z*)-6-bromo-23-methyltetracosa-5,9-dienoylpyrrolidine (2b) and the N-[5,6,6,9,10-$^2H_5$]23-methyltetracosanoylpyrrolidine (2c).

The GC/MS of the corresponding brominated fatty acid pyrrolidides was critical for identifying the position of the bromine substituent. For example, N-(5*E*,9*Z*)-6-bromo-23-methyltetracosa-5,9-dienoylpyrrolidine (**2b**) afforded molecular ion peaks as doublets of equal intensity at *m/z* 511 and *m/z* 509, indicating the presence of bromine, and a strong peak at *m/z* 430 due to the loss of bromine. Similar peaks were observed for the pyrrolidides of the other fatty acids, differing by 14 amu depending on the chain-length. However, common to all of these pyrrolidides was a base peak at *m/z* 113 due to McLafferty rearrangment, a peak not so prominent at *m/z* 180, which corresponded to a double allylic fragmentation between C-6 and C-9 with the loss of bromine, and a strong doublet of equal intensity at *m/z* 258 and *m/z* 260 due to the same fragmentation with the bromine substituent intact (Figs. 1 and 2). This information limited the point of attachment of the bromine between C-1 and C-7.

Catalytic hydrogenation (PtO_2) of the brominated methyl esters yielded the corresponding saturated fatty acids. For example, 6-bromo-5,9-tetracosadienoic acid afforded tetracosanoic acid, 6-bromo-23-methyl-5,9-tetracosadienoic acid afforded 23-methyltetracosanoic acid, etc. It was then possible to calculate the corresponding ECL values for these methyl esters, and to locate the branching in the original molecules. For example, 23-methyltetracosanoic acid afforded an ECL value of 24.66 and 24-methylpentacosanoic acid, resulting from the hydrogenation of 6-bromo-24-methyl-5,9-pentacosadienoic acid, afforded an ECL value of 25.60. Therefore, the methyl branching in the original fatty acids is located at the penultimate carbon, corresponding to the *iso*-isomer. This methyl substitution was confirmed by GC co-injection with authentic samples.

The exact location of the bromine substituent was confirmed by deuteration of the pyrrolidides utilizing Wilkinson's catalyst [$RhCl(PPh_3)_3$] in methanol in order to avoid deuterium scrambling (Fig. 1). Five deuteriums were incorporated into the brominated fatty acid pyrrolidides. In all of the deuterated fatty acid pyrrolidides, a difference of 15 amu was observed between C-4 and C-5, between C-8 and C-9, and between C-9 and C-10, indicating the addition of deuterium atoms to the double bonds. Moreover,

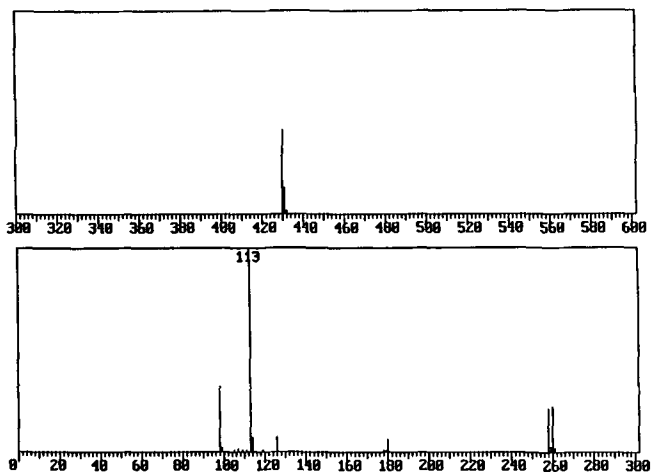

FIG. 2. Partial mass spectrum of the N-(5*E*,9*Z*)-6-bromopentacosa-5,9-dienoylpyrrolidine.

a difference of 16 amu was detected between C-5 (*m/z* 155) and C-6 (*m/z* 171), clearly demonstrating an additional replacement of bromine with deuterium at C-6 (1).

The GC/FTIR spectra of the original brominated fatty acid methyl esters displayed absorption peaks at 3018, 2993, 2956, 2878, 1739, 1592, 1453, 1264 and 1123 cm^{-1}. No peak at 980–968 cm^{-1} was observed, indicating *cis* rather than *trans* unsaturation for the Δ9 double bond, as is usual for demospongic acids (11). The stereochemistry at the Δ5 double bond was previously established as *E* by a microscale metal-halogen exchange reaction followed by protonolysis (2).

The sterols from *Agelas* sp. were also isolated, using reverse-phase high-performance liquid chromatography for the final separation. The particular sterols were characterized by 300 MHz ^1H NMR, MS and by comparison with authentic samples. The following sterols were characterized: cholesta-5,7,22-trien-3β-ol (9%), cholesta-5,7-dien-3β-ol (8%), 24-methylcholesta-5,7,22-trien-3β-ol (39%), 24-methylcholesta-5,7-dien-3β-ol (6%) and 24-ethylcholesta-5,7,22-trien-3β-ol (38%). For most of these sterols, the ^1H NMR spectrum showed the C-18 and C-19 angular methyl signals at δ 0.63 and 0.94 ppm, respectively, and two ring-olefinic signals deshielded to δ 5.38 and 5.58 ppm, corresponding to the Δ5,7 protons. It was particularly striking that neither cholesterol nor 24-ethylcholesterol was present in this sponge, as they are common sterols in sponges. This sponge seems to prefer Δ5,7 sterols. Whether these findings bear any connection with the unprecedented brominated phospholipids isolated in this work is just a matter of speculation at this point.

In this paper we have expanded present knowledge on the occurrence of brominated phospholipid fatty acids in marine sponges. Four new acids have been identified. As to their origin, we can only speculate but it is possible that they originated by the action of a bromoperoxidase on their nonbrominated counterparts, which were also found in their sponge (12). In fact, the biosynthesis of the 6-bromo-5,9-hexacosadienoic acid (**3a**) was previously investigated by Lam *et al.* (2) utilizing radiolabeled precursors, and they concluded that the bromination was the terminal step in the biosynthesis of these unusual acids. Based on the data available in the literature, we believe that the biosynthesis of the brominated acids follows the biosynthetic route shown below, as an example, for the 6-bromo-23-methyl-5,9-tetracosadienoic acid (**2b**).

i-15:0 → i-25:0 → i-Δ^5-and Δ^9-25:1 → i-$\Delta^{5,9}$-25:2 → i-6-Br-$\Delta^{5,9}$-25:2

Work is in progress trying to elucidate the origin of these unusual fatty acids in sponges.

ACKNOWLEDGMENTS

We thank Dr. Abimael Rodriguez, as well as Jaime Rodriguez and Edgardo Rodriguez, for their help with the expedition to Mona Island, Puerto Rico. Dr. Vance Vicente from the United States Department of the Interior Fish and Wildlife Service classified the sponge. We thank Javier Santiago for technical assistance in the initial extraction of the sponge. This work was supported by the National Science Foundation under Grant No. CHE-8715649 and the National Institutes of Health (NIH-MBRS Program) under Grant No. S06 GM08102-20. N. Carballeira thanks NSF for a two-year creativity extension award.

The Steryl Ester and Phospholipid Fatty Acids of the Sponge *Agelas conifera* from the Colombian Caribbean

Carmenza Duque*, Nestor Cepeda and **Alejandro Martínez**
Departamento de Química, Universidad Nacional de Colombia, Bogotá, Colombia

The steryl ester and phospholipid fractions of the marine sponge *Agelas conifera* were isolated and analyzed. The fatty acyl components of the steryl ester and phospholipid fractions as determined by gas chromatography and gas chromatography/mass spectrometry were very similar and consisted of 56.8 and 62.7% of C_{14}–C_{20} acids (normal; branched, especially *iso* and *anteiso*; and monounsaturated, particularly Δ^9 and Δ^{11} acids) and of 43.1 and 35.5% of C_{24}–C_{26} acids ($\Delta^{5,9}$ diunsaturated acids), respectively. The major constituent fatty acids detected were 13-methyltetradecanoic, *n*-hexadecanoic, 10-methylhexadecanoic, 11-octadecenoic, 12-methyloctadecanoic, 5,9-pentacosadienoic and 5,9-hexacosadienoic acids. The phospholipids isolated were identified as phosphatidylcholine (37%), phosphatidylserine (34%), phosphatidylethanolamine (16%) and phosphatidylinositol (11%). The distribution of fatty acids within the phospholipid classes was also determined.
***Lipids* 28, 767–769 (1993).**

Agelas (family Agelasidae) is a genus that had been classified in the past as belonging to the order Poeilosclerida, but based on similarities in free amino acid patterns between *Agelas* and some Axinellidae, *Agelas* was more recently reassigned to the order Axinellida (1). However, further information on other *Agelas* constituents would still be desirable to substantiate the correctness of the new classification. As part of our studies on the chemical composition of marine sponges occurring in Colombian coastal waters (2–4), we therefore turned our attention to *Agelas conifera*, a very abundant sponge in the Caribbean Sea.

In 1989, we reported the sterol composition of *A. conifera* (4) (Δ^0 + Δ^7 sterols) which showed great similarities with that of *A. oroides* (5), *A. mauritiana* (6) and *A. dispar* (7). Recently, the presence of bromopyrrole metabolites in *A. conifera* (8) was also reported, a characteristic which is also shared with some members of Axinellidae. In continuation of this work and of earlier work by others (9–11), we here report our findings on the steryl ester and phospholipid fatty acids of *A. conifera*.

MATERIALS AND METHODS

A. conifera was collected from a depth of 10–20 m at Santa Marta Bay on the Caribbean coast of Colombia on three different occasions during one year. Sponge specimens were immediately cleaned and frozen. Total lipids were extracted by treating the thawed sponges (570 g) at 0°C for 5 min with chloroform/methanol (1:1, vol/vol) (12) followed by filtering and washing the organic layer twice with water containing sodium chloride.

Isolation of steryl esters. A portion of the crude total lipid extract (10 g) was purified by silica gel column chromatography using benzene/ethyl acetate (10:2, vol/vol) as the mobile phase to yield 620 mg of a mixture of steryl esters.

Isolation and analysis of phospholipids. Another portion of the crude lipid extract (0.8 g) was subjected to column chromatography using silicic acid (100 mesh) treated with ammonium hydroxide according to the procedure of Privett *et al.* (13) to separate the phospholipids from the neutral lipids and glycolipids.

The phospholipids thus obtained were kept under nitrogen at −10°C in chloroform/methanol (1:1, vol/vol) containing 0.002% of butylated hydroxytoluene. Subsequently, the phospholipids were further separated into classes by thin-layer chromatography (TLC) using double development and chloroform/methanol/28% ammonium hydroxide (65:35:8, by vol) as solvent. Fractions were made visible with molybdenum blue spray reagent. Phospholipid classes were identified by cochromatography with standards, and by use of Dragendorff, ninhydrine and periodate-Schiff spray reagents (14). Individual phospholipid classes were isolated by preparative TLC using above solvent and rhodamine 6G as spray agent. Phospholipids classes were quantified by a spectrophotometric phosphorus assay using molybdenum blue reagent (14).

Analysis of fatty acids. Saponification of the steryl ester fraction and methanolic hydrogen chloride treatment of the total phospholipid extract and of individual phospholipid classes were used to prepare both methyl esters and *N*-acyl pyrrolidides (15) for gas chromatography (GC) and gas chromatography/mass spectrometry (GC/MS).

The methyl esters were analyzed by GC using a Hewlett-Packard (Avondale, PA) 5700A gas chromatograph equipped with a crosslinked OV-101 fused silica capillary column (25 m × 0.31 mm, i.d.) and a flame-ionization detector (FID). The temperature program was started at 170°C and raised at 2°C/min to 270°C. Flow rates of carrier and make-up gases were 1 mL/min and 30 mL/min, respectively. Detector and injector temperatures were kept at 250 and 300°C, respectively.

GC/MS analyses were performed on a Shimadzu (Kyoto, Japan) 9020 DF gas chromatograph/mass spectrometer using the GC conditions mentioned above. Mass spectra were obtained in the electron impact mode under the following conditions: temperature of the ion source, 250°C; electron energy, 70 eV; ionizing current, 60 mA; injection volumes, 0.1 μL. Helium was used as the carrier gas.

The *N*-acyl pyrrolidides were analyzed by GC/MS under the conditions used for the methyl esters, except that the column temperature program was started at 230°C and raised at 4°C/min to 290°C.

Fatty acids were identified by GC based on equivalent chain length (ECL) values and by GC/MS based on the mass spectra of the methyl esters and pyrrolidides. Quantitations were based on integrated GC/FID peak areas.

Abbreviations: ECL, equivalent chain length; FID, flame-ionization detector; GC, gas chromatography; GC/MS, gas chromatography/mass spectrometry; PC, phosphatidylcholine; PE, phosphatidylethanolamine; PI, phosphatidylinositol; PS, phosphatidylserine; TLC, thin-layer chromatography.

RESULTS AND DISCUSSION

The phospholipids identified in the *A. conifera* marine sponge were phosphatidylcholine (PC) at 37%, phosphatidylserine (PS) at 34%, phosphatidylethanolamine (PE) at 16%, phosphatidylinositol (PI) at 11%, and one unidentified phospholipid at 2%.

High percentages of PE and PS, and at times PC, seem to be characteristic of marine sponges (15–18). By contrast, PI, which is one of the major phospholipids in bacteria, occurs only in very small amounts in eukaryotes. However, PI was found in significant quantities in preparations of *A. conifera*, which suggests that the PI originates from bacteria which live in symbiosis with the sponge. Vacelet and Donadey (19), in studies done on the associations between sponges and bacteria, have in fact demonstrated the presence of intercellular bacteria in several species of the genus *Agelas*, although no specific information on *A. conifera* was provided. Thus, the phospholipids reported here are likely to reflect the composition of *A. conifera* containing symbiotic bacteria.

The fatty acyl compositions of the total phosholipids, of the steryl esters and of individual phospholipid classes, as determined by GC and GC/MS analysis of the methyl esters and pyrrolidides are shown in Table 1. The table lists 25 fatty acids, which were identified together with the ECL values of the methyl esters. Identifications were made based on ECL values and comparison with the ECL values of standards. In addition the mass spectra of the methyl esters provided molecular weight information and helped in assessing branching in the saturated esters. The mass spectra of the *N*-acyl pyrrolidides confirmed these identifications and also provided information which helped in localizing the positions of double bonds in most of the unsaturated acids. The spectral data were also compared with those of authentic reference compounds and with other published spectra (Environmental Protection Agency National Institutes of Health mass spectral library).

The fatty acid distributions in the steryl ester and in the phospholipid classes were found to be very similar. In both fractions there were normal chain saturated acids (C_{14}, C_{15}, C_{16}, C_{17}, C_{18} and C_{20}), branched chain and particularly *iso* and *anteiso* saturated acids (C_{15}, C_{16}, C_{17}, C_{18}, C_{19} and C_{20}), monounsaturated acids, *i.e.* mainly Δ^9 and Δ^{11} (C_{16}, C_{17}, C_{18}, C_{19} and C_{23}) and $\Delta^{5,9}$ normal chain diunsaturated acids (C_{24}, C_{25} and C_{26}). The diunsaturated compounds comprised about 43% of the total fatty acids in the steryl ester fraction and 35% in the phospholipid fraction; the monounsaturated fatty acids represent 15 and 17% in the steryl ester and in the phospholipid fractions, respectively, amounting to a total of 58 and 52% of unsaturated fatty acids in these two fractions. Of the remaining fatty acids, 20% correspond to saturated normal chain and 22% to saturated branched chain acids within the steryl esters, and 14% to saturated normal chain and 31% to saturated branched chain acids in the phospholipids.

It is important to point out the high percentage of fatty acids found in this sponge having an odd number of

TABLE 1

Steryl Ester and Phospholipid Fatty Acids of *Agelas conifera*[a]

Number	ECL	Fatty acid	Abundance (%)						
			Steryl ester fraction	Phospholipid fraction	PE	PC	PS	PI	Unknown phospholipid

[a]Equivalent chain length (ECL) values are those of the methyl esters of these acids. Averages from the analyses of the three samples collected over one year (seasonal variations were not observed). A dash indicates an abundance of less than 0.4%. Abbreviations: PE, phosphatidylethanolamine; PC, phosphatidylcholine; PS, phosphatidylserine; PI, phosphatidylinositol.

carbon atoms (41% in the steryl ester fraction and 43% in the phospholipid fraction), which cannot be attributed only to associated bacteria.

From the distribution of fatty acids within the phospholipid classes it is apparent (Table 1) that short-chain fatty acids occur mainly in PC, PI and in the unidentified phospholipid, with tetradecanoic, hexadecanoic, 12-methyloctadecanoic and octadecanoic acids being the major components. The long-chain $\Delta^{5,9}$ fatty acids are mainly found in PE and PS. These results are in general agreement with the analyses done on other sponges (16–18) which have consistently shown that demospongic acids are primarily found in phospholipids containing a free amino group. Our results also indicate that bacterial type fatty acids predominate in PI, PC and in the unknown phospholipid.

According to Bergquist *et al.* (10), only the broad descriptive parameters of the fatty acid mixtures (straight and branched, even and odd, unsaturated and long-chain fatty acids) are relevant to taxonomic considerations. Thus, the fatty acid profile of *A. conifera* is characterized by a high percentage (35%) of long-chain fatty acids with a predominance in even-carbon numbered acids, medium levels (36%) of branched fatty acids with a prodominance in odd-carbon numbered acids, and high levels (63%) of straight chain acids with a predominance of even-carbon numbered compounds. Except for the high odd and branched acid content, these results seem to agree well with the fatty acid profile reported for some species from the other two Axinellida families (10). In contrast, it is important to mention the low content (11%) of long-chain fatty acids reported by Carballeira *et al.* (20) for the sponge *A. dispar.*

Although the results seem to indicate homogeneity in the fatty acid patterns in the Axinellida families, it is also clear that a number of additional *Agelas* species need to be analyzed as to their fatty acid composition in order to obtain a more complete picture of the fatty acid patterns in the Agelasidae family.

ACKNOWLEDGMENTS

Dr. Sven Zea from the Biology Department of the National University of Colombia collected and classified the sponge. Financial support was provided by Colciencias (Fondo Colombiano de Investigaciones Científicas) and by the European Communities [Grant No. CI1*.0448.C(JR)]. The valuable help of Prof. Dr. Robert D. Walkup is also greatly acknowledged.

Identification of Two Novel Dihydroxysterols from *Pavlova*

Glenn W. Patterson[a,*], Patricia K. Gladu[b], Gary H. Wikfors[c], Edward J. Parish[d], Peter D. Livant[d] and William R. Lusby[e]

[a]Department of Botany, University of Maryland, College Park, Maryland 20742, [b]Department of Biology, Lindsey-Wilson College, Columbia, Kentucky 42728, [c]NOAA, National Marine Fisheries Service, Northeast Fisheries Center, Milford Laboratory, Milford, Connecticut 06460, [d]Department of Chemistry, Auburn University, Auburn University, Alabama 36849 and [e]Insect Neurobiology and Hormone Laboratory, USDA, Beltsville, Maryland 20705

***Pavlova gyrans* and *P. lutheri* were cultured, and the dihydroxysterols were isolated from the free sterol and the polar sterol fractions. Four dihydroxysterols were detected in amounts greater than 1% of total sterol by gas chromatography and were analyzed by gas chromatography/mass spectrometry. The two principal sterols were isolated by chromatography on alumina followed by hydrophobic Sephadex column chromatography. The two sterols appeared to differ by having either a methyl or an ethyl group at C-24; they were termed "methylpavlovol" and "ethylpavlovol." Analysis by 400 MHz nuclear magnetic resonance showed that methylpavlovol is 4α,24β-dimethylcholestan-3β,4β-diol and ethylpavlovol is 4α-methyl,24β-ethylcholestan-3β,4β-diol. The 4α-methyl,4β-hydroxy configuration has not been observed previously in a natural sterol. Dihydroxysterols make up approximately one-third of the total sterols in these *Pavlova* species. Neither the biosynthetic origin of these dihydroxysterols nor their role in the biochemistry of *Pavlova* is known.**

***Lipids* 28, 771-773 (1993).**

Bivalves feed on phytoplankton and other particulate matter. Attempts to culture bivalves, such as oysters and clams, have utilized various phytoplankton as food. Supplementation with other factors, including carbohydrates, proteins, lipids and polyunsaturated fatty acids, as well as sterols, has also been shown to be important in the oyster's diet (1,2). Species of *Pavlova* have been included frequently in oyster diets (3). *Pavlova gyrans* and *P. lutheri* were found to have an unusual sterol composition and to contain C_{28} and C_{29} Δ^5-sterols, 4α-methyl sterols with a saturated nucleus and a group of unknown sterols apparently bearing two hydroxyl groups (4). The sterol content of these phytoplankton is unusually high (7-9 mg/g dry wt) compared to that of most other phytoplankton we have examined (Patterson, G.W., and Wikfors, G.H., unpublished). Sterols are found as free sterols, steryl esters or steryl glycosides in plants (5), but in algae most sterols occur in the free form (Patterson, G.W., and Wikfors, G.H., unpublished). *P. gyrans* is unusual in that about one-third of its sterols is found in the polar fraction where the principal components were poriferasteryl glucoside and ethylpavlovol monoglucoside (6). The objective of this study was to isolate, characterize and identify the major dihydroxysterols of *P. gyrans* and *P. lutheri*.

MATERIALS AND METHODS

P. gyrans Butcher, strain designation "93" and *P. lutheri* "MONO" were obtained from the Milford laboratory culture collection (Milford, CT) and were cultured axenically in enriched seawater medium "E" formulation and harvested in stationary phase as described previously (4). The lipid fraction was obtained from lyophilized algae by $CHCl_3/CH_3OH$ extraction in a Soxhlet apparatus. Sterols obtained from the free sterol and the polar sterol fractions after fractionation of the total lipid on Biosil A (4) contained dihydroxysterols at 25-50% of the total sterols, with the largest percentages occurring in the polar sterol fraction. The free sterol fraction and free sterols generated from the polar sterol fraction by acid hydrolysis were pooled and chromatographed by alumina column chromatography to separate dihydroxy and monohydroxy sterols. Dihydroxy sterols were further fractionated by lipophilic Sephadex chromatography (7) which produced samples of a C_{29} dihydroxysterol (methylpavlovol) and a C_{30} dihydroxysterol (ethylpavlovol) in amounts permitting analysis by 400 MHz nuclear magnetic resonance (NMR). ^{13}C and ^1H NMR spectra were obtained with a Bruker AM-400 (Karlsruhe, Germany) spectrometer operating at frequencies of 400.179 MHz for ^1H and 100.619 MHz for ^{13}C using tetramethylsilane as an internal standard (8). Specific pulse sequences used included DEPT-135 (9), NOESY (10), COSY (11) and C-H correlation (12) experiments, which were conducted as referenced. Electron impact mass spectra were measured at 70eV and an ionization temperature of 150°C. Data were recorded with an Incos Data System (Incos Finnigan Corp., San Jose, CA).

RESULTS AND DISCUSSION

In *P. gyrans*, four dihydroxysterols were detected by capillary gas chromatography in the late-eluting fractions from alumina chromatography. These compounds had retention times relative to cholesterol of 2.06, 2.13, 2.22 and 2.52 in capillary gas chromatography on SPB-1. *P. lutheri* contained each of these compounds except 2.13. Compounds 2.06 and 2.52 eluted slightly earlier and were separated from compounds 2.13 and 2.22 on alumina chromatography, but could not be separated from each other by this method. Gas chromatography/mass spectrometry (GC/MS) was performed on the mixture of compounds 2.06 and 2.52. The major peaks observed are listed in Table 1. The mass spectra indicate the presence of C_{29} and C_{30} homologs which are saturated sterols having two hydroxyl groups. Apparently these are sterols with C_9 and C_{10} side chains possessing an "extra" carbon on the nucleus. This extra carbon is probably at C-4, as the strong M-15 peak characteristic of 14-methyl sterols is not present. Acetylation of these sterols yielded only monoacetates, suggesting the presence of a tertiary hydroxyl.

Volkman *et al.* (13) had noted that a dihydroxysterol from *P. salina* dehydrated in the presence of BF_3/methanol to produce a C_{29} methylstanone, suggesting that the compound in question was a 3,4-dihydroxy

4-methyl sterol. The homologous dihydroxysterols from *P. gyrans*, which we have termed "methylpavlovol" and "ethylpavlovol," were separated by column chromatography on lipophilic Sephadex and analyzed by ^{13}C and ^1H NMR spectrometry. The assignments for ethylpavlovol were readily made based on the results obtained by various NMR techniques and by comparison with literature values (14,15). Two hydroxy-bearing signals were detected from ethylpavlovol (2.52), at 75.65 ppm and 74.17 ppm, but only the signal at 75.65 ppm was detected in a DEPT-135 experiment. The C-3 hydroxy, arising from a methine carbon, gives the signal at 75.65 ppm and the 74.17 ppm signal arises from a quaternary carbon (C-4). The chemical shift of C-3 at 75.65 ppm is consistent with the presence of a methyl at C-4 (C-3 of 4α-methylcholestan-3β-ol resonates at 76.6 ppm and the C-3 of 4β-methylcholestan-3β-ol at 74.1 ppm) (16). There are also three singlet methyl signals in the ^1H NMR spectrum. 1D NOE difference experiments, with irradiation at H-30 or H-19, revealed no detectable interaction between these two methyls. A NOESY experiment (650 ms mixing time) did not detect a crosspeak between H-30 and H-19, but did detect an H-3 *vs.* H-30 crosspeak. Thus, the 4α-methyl-4β-hydroxy structure is preferred over the 4β-methyl-4α-hydroxy structure. Coincidentally, molecular mechanics calculations showed that the 4α-methyl-3β,4β diol is more stable by 1.48 kcal/mole than the 4β-methyl-3β,4α-diol structure. ^1H NMR analysis of the methyl signals showed the orientation of the C-24 ethyl to be β as it is in most algae (17). The structure of ethylpavlovol, therefore, is 4α-methyl-24β-ethylcholestan-3β,4β-diol (Fig. 1).

^{13}C and ^1H NMR analyses of methylpavlovol gave results similar to those of ethylpavlovol (Table 2) with the exception of the side chain signals. These signals correspond to those of a C-24β(24S) methyl by the closer fit of the C-20, C-23, C-24, C-25, C-26 and C-27 peaks (36.21, 30.65, 39.13, 31.52, 17.64 and 20.51 ppm, respectively) to those reported for the 24β/S side chain (36.3, 30.7, 39.2, 31.5, 17.7, 20.6 ppm) (16), than to those reported for the

TABLE 2

NMR Results for Methylpavlovol and Ethylpavlovol[a]

[a]Results given in ppm. NMR, nuclear magnetic resonance.
[b]Protons 3, 18, 19, 21, 26, 27, 28 (methylpavlovol), 29 (ethylpavlovol) and 30 were measured directly from the 1D NMR spectra. The remainder were obtained from C–H correlation spectra and are reported to fewer significant figures.

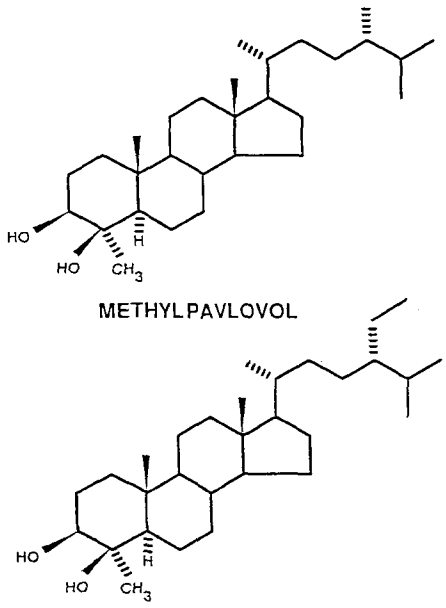

FIG. 1. The structures of methylpavlovol (4α,24β-dimethylcholestan-3β,4β-diol) and ethylpavlovol (4α-methyl-24β-ethylcholestan-3β,4β-diol) from *Pavlova gyrans* and *P. lutheri*.

24α/R side chain (36.0, 30.4, 38.9, 32.5, 20.3, 18.3 ppm) (16). Methylpavlovol and ethylpavlovol differ from the stanols 4α-methylergostanol and 4α-methylporiferastanol, already identified in *Pavlova* (4), *Prototheca* and *Dictyostelium* (15) only by the presence of the 4β-hydroxyl group. The 4α-methyl-4β-hydroxy grouping has not been observed previously to occur on a natural sterol. The biosynthetic relationship between the dihydroxysterols and the other sterols of *Pavlova* has not been investigated. Work is continuing to identify two other C_{29} dihydroxysterols in *P. gyrans*.

The levels of phosphatidylcholine hydroperoxide in serially cultured human fetal diploid fibroblasts at various population doubling levels were determined by high-performance liquid chromatography combined with chemiluminescence detection. This methodology utilizes a mixture of cytochrome *c* and luminol as post-column hydroperoxide group specific luminescent reagents. The cellular hydroperoxide content increased with age from 0.34 to 27.72 pmol/10^6 cells. At the end of the cells' *in vitro* lifespan (51st population doubling level), the hydroperoxide content per 10^6 cells reached about 80 times the level found in cells of the 20th population doubling level. Supplementation of exogenous α-tocopherol to the culture medium prevented hydroperoxide accumulation, but did not extend the lifespan *in vitro*. The results indicate that substantial intracellular phospholipid hydroperoxide accumulation occurred in the course of aging of human fetal diploid fibroblasts.

Lipids 28, 775–778 (1993).

Peroxidation of membrane lipids has been suggested as one of the basic deteriorative reactions in cellular senescence (1–4). Since Harman (1) proposed the "free radical theory of aging" in 1956, numerous studies have been undertaken to determine the relationship between the aging process and lipid peroxidation. Yet, direct evidence for such a relationship is still lacking. In previous studies, the link between aging and tissue lipid peroxidation could not be sufficiently assessed because the thiobarbituric acid (TBA) test commonly employed in such experiments is not specific for lipid hydroperoxides (5–7). Measurement of expired hydrocarbon gas from rats (8) and lipofuscin pigment measurements in rat tissues (9) and cultured diploid cells (10) also have been used as a lipid hydroperoxidation index relative to aging, but these methods rely on the measurement of secondary oxidation products. To assess the degree of lipid hydroperoxidation in biological membranes, the direct detection of primary peroxidation products, such as phospholipid hydroperoxides, seems to be advantageous. Changes in intracellular Na^+ and K^+ content, membrane fluidity and membrane lipid transition temperature following aging have been reported (11,12). Because phospholipids are a major constituent of membranes and contribute to membrane function, direct measurement of phospholipid hydroperoxide seems to be an important approach to assess membrane lipid peroxidation.

We have previously developed a sensitive and selective assay for phospholipid hydroperoxides using high-performance liquid chromatography (HPLC) combined with chemiluminescence (CL) detection (13–15). This CL–HPLC method has been successfully applied to the estimation of phospholipid hydroperoxide levels in human blood plasma (14,16), serum lipoproteins (17), liver of carbon tetrachloride intoxicated rats (18) and hepatocarcinogenesis in rats on choline-deficient and ethionine-enriched diets (19). The CL–HPLC method has also been employed in other laboratories to determine hydroperoxides (20–22).

In the present study, we investigated the age-dependent changes of phosphatidylcholine hydroperoxide (PCOOH) levels in cultured human fetal diploid cells as determined by the CL–HPLC method. The effect of α-tocopherol, a potent biological antioxidant, on PCOOH content and cellular lifespan was examined.

MATERIALS AND METHODS

Cell culture. Normal human diploid fibroblasts (HE-1) were established by Dr. Sato, Institute of Osaka Oriental Medicine (Osaka, Japan); their final population doubling level (PDL) is the 51st. The cells were serially cultured in 20 mL of Eagle's minimum essential medium that contained 10% fetal calf serum. A single lot of fetal calf serum (Whittaker M.A. Bioproducts, Rockville, MD) was used throughout the experiments. Cultures were maintained in 250-mL Falcon flasks at 37°C in an atmosphere of 95% air and 5% carbon dioxide. The cells were subcultured weekly at a 1:2 split ratio using 0.25% trypsin containing 0.01% butylated hydroxytoluene as an antioxidant.

α-Tocopherol treatment. d,l-α-Tocopherol was solubilized by mixing it into growth medium using polyethylene glycol No. 400 (Tokyo Kasei Kogyo Co., Tokyo, Japan). *d,l-α*-Tocopherol (Eisai Co., Tokyo, Japan) was added to the medium at 0.1, 1 and 10 μg per mL after the 42nd PDL to examine its antioxidant effect. The final concentration of polyethylene glycol in the medium was 0.1% throughout all experiments using a three-graded amount of exogenous α-tocopherol. α-Tocopherol content was determined by the fluorescence–HPLC method (23) on the total lipids extracted as described below. Cells were counted with a Coulter Counter ZBI (Coulter Electronics, Hialeah, FL).

Lipid extraction. Cells were harvested by treatment with 0.25% trypsin containing 0.01% butylated hydroxytoluene and centrifuged at 1,000 rpm for 5 min. Two mL of 0.15 M sodium chloride containing 0.002% butylated hydroxytoluene was added to 5×10^6 cells, and the mixture was homogenized in a Teflon-glass homogenizer under ice cooling. The homogenate obtained was added to 5 mL of chloroform/methanol (2:1, vol/vol) (24,25) and mixed vigorously for 1 min. The mixture was centrifuged at 3,000 rpm for 10 min. The lower chloroform layer containing total lipid was dried over anhydrous sodium sulfate, the solvent was removed in a rotary evaporator and the residue was dried under a nitrogen stream. The total lipid obtained was dissolved in 100 μL of a mixture of

chloroform/methanol (2:1, vol/vol), and a 20 μL portion was subjected to the hydroperoxide assay by CL-HPLC (18,19).

CL-HPLC analysis. The CL-HPLC system and experimental conditions for measuring PCOOH in the total lipids prepared from human diploid cells were essentially as described previously by Miyazawa *et al.* (14,16-18) and Yoshida *et al.* (19). Analytical conditions were as follows: the HPLC column was a JASCO Finepak SIL (5 μm, 250 × 4.6 mm; Japan Spectroscopic Co., Tokyo, Japan), the mobile phase was a mixture of chloroform/methanol/water (1:9:0.1, by vol), and the flow rate was 1.1 mL/min using a JASCO 880-PU pump. After passing through a JASCO 875-UV detector set at 234 nm to monitor conjugated diene, the column eluant was mixed with a luminescent reagent at a post-column mixing joint (Y type; Kyowa Seimitsu, Tokyo, Japan). The luminescent reagent was prepared by dissolving 10 μg/mL of cytochrome *c* (from horse heart, type VI; Sigma Chemical Co., St. Louis, MO) and 1 μg/mL of luminol (3-aminophthaloyl hydrazine; Wako Pure Chemical Co., Osaka, Japan) in 50 mM borate buffer (pH 9.3) and was pumped at 1.0 mL/min with a JASCO 880-PU pump. The CL generated by reacting the hydroperoxide with the luminescent reagent was measured with a CLD-100 CL detector (Tohoku Electronic Industries Co., Sendai, Japan) or a JASCO 825-CL detector. Calibration of PCOOH was done with authentic PCOOH, which was prepared from egg yolk phosphatidylcholine (98.6%, Nippon Oil & Fats Co., Tokyo, Japan) by photooxidation as described previously (13-15).

RESULTS AND DISCUSSION

Figure 1 shows the CL chromatogram of PCOOH when the total lipids extracted from cultured human diploid cells (48th PDL) were subjected to the CL-HPLC assay. PCOOH (R_t = 13 min) was eluted and measured as a single sharp peak by CL detection. This PCOOH peak has the same retention time as does authentic PCOOH. The retention time was also confirmed by cochromatography with the authentic PCOOH. By treatment of total lipid with sodium borohydride, the chemiluminescence peak ascribed to PCOOH disappeared as PCOOH was reduced to the corresponding nonluminescent hydroxyl phosphatidylcholine. Other CL peaks detected near 2 and 4 min were tentatively assigned to mixtures of phosphatidylethanolamine hydroperoxide, phosphatidylserine hydroperoxide and neutral lipid hydroperoxides. These CL peaks also disappeared after sodium borohydride treatment.

Figure 2 shows the content of PCOOH per 10^6 cells as a function of PDL. The cellular content of PCOOH was increased with advancing serial subcultures. The cells at the 20th PDL corresponded to the middle of the active multiplication period (phase II) as defined by Hayflick and Moorhead (26). The cellular PCOOH content at all PDLs was compared with that of the 20th PDL (figures in parentheses of Fig. 2). From the 20th PDL to the 47th PDL, the PCOOH content increased less than threefold, but then PCOOH levels markedly increased after the 48th PDL. The PCOOH level of the 48th PDL was about thirteen times that of the 20th PDL, the 50th PDL fifty times that and the 51st PDL eighty times that of the 20th PDL.

Table 1 shows the effect of α-tocopherol addition to the culture medium on cell numbers, and α-tocopherol and PCOOH contents in cultured cells. The cell numbers of control (not treated with α-tocopherol) showed a decrease

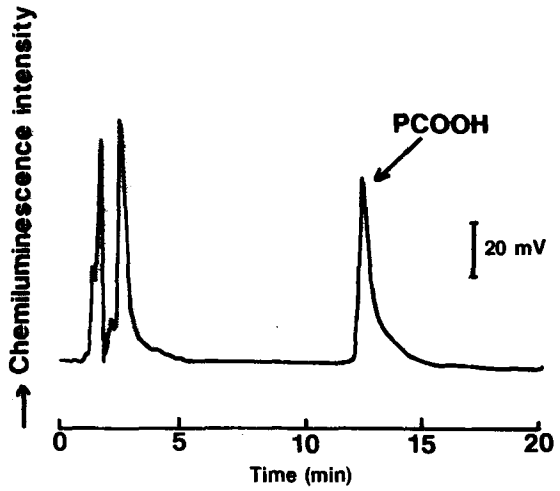

FIG. 1. Chemiluminescence chromatogram of phosphatidylcholine hydroperoxide (PCOOH) when total lipid extracted from cultured human diploid cells (48th population doubling level) was subjected to chemiluminescence-high-performance liquid chromatography assay. The PCOOH concentration detected on the chemiluminescent chromatogram corresponded to 4.5 pmol of PCOOH/10^6 cells.

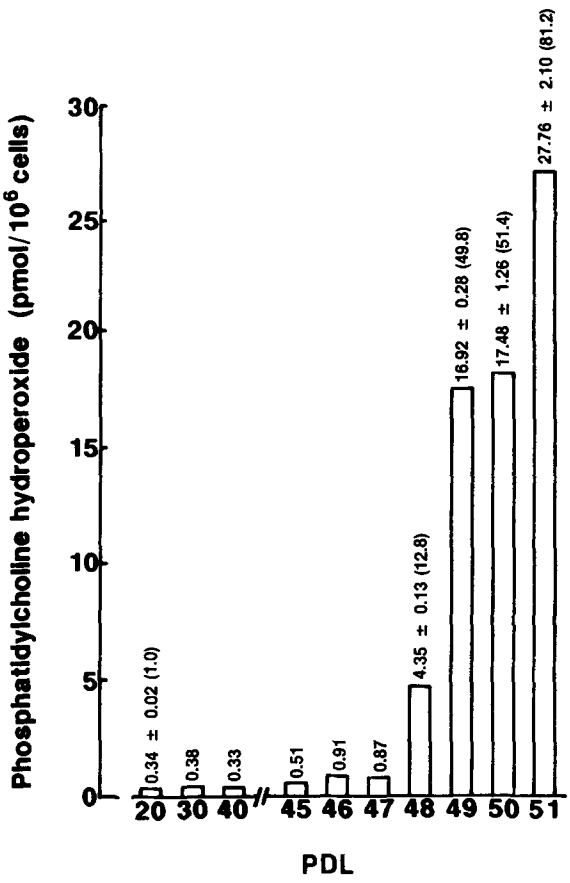

FIG. 2. Changes in the phosphatidylcholine hydroperoxide content per 10^6 cells as a function of population doubling level (PDL). Values are the mean of three experiments and SD. Figure in parentheses is the value relative to young cells (20th PDL).

after the 49th PDL. Supplementation with 1 or 10 μg of α-tocopherol/mL medium decreased cell numbers more rapidly when compared to controls. α-Tocopherol levels in cultured cells increased in relation to the amount of exogenous α-tocopherol added to the medium. About 1.0–8.6% of α-tocopherol exogenously added to the growth medium was incorporated into the cells (3.2% at 0.1 μg/mL, 3.2% at 1 μg/mL and 8.6% at 10 μg/mL at the 45th PDL; 3.5% at 0.2 μg/mL, 1.8% at 1 μg/mL and 2.2% at 10 μg/mL at the 49th PDL; 1.0% at 0.1 μg/mL and 1.0% at 1 μg/mL at the 51st PDL). Sakagami and Yamada (27) had reported that 2.0–4.0% of α-tocopherol added to the medium was incorporated into the cells.

Accumulation of cellular PCOOH with serial subculturing was also related to a decrease in the cellular proliferation rate. According to the original concept of Hayflick and Moorhead (26) and Hayflick (28), the limited *in vitro* lifespan of cells was characteristic of phase III, which is the period of an apparent decrease in the rate of cell proliferation accompanied by morphological, biochemical and cytological changes. The present results suggest that cellular phospholipid hydroperoxidation occurred in phase III. The lifespan of cultured diploid cells is known to be reduced under hyperbaric oxygen (29) and is extended under lower oxygen concentrations (30). These results also suggested that oxidative deterioration of membrane lipids associated with membrane phospholipid hydroperoxidation contributes to cellular aging.

Supplementation of 0.1 or 1 μg/mL of α-tocopherol to the growth medium effectively prevented PCOOH accumulation for all PDL as compared to controls. A higher PCOOH accumulation was observed when 10 μg/mL of α-tocopherol was added to the medium as compared to the addition of 0.1 or 1 μg/mL of α-tocopherol. α-Tocopherol is commonly considered a potent antioxidant, but in this case of lipid autoxidation, α-tocopherol in high concentrations showed a prooxidant effect (31,32). In cultured cells, an optimum α-tocopherol concentration that can effectively prevent membrane lipid hydroperoxidation should be maintained. Although supplementation of small amounts of α-tocopherol (0.1 and 1 μg/mL medium) prevents the accumulation of PCOOH, it is possible as previously reported (27,33), that a lifespan extension could not be observed in the present study.

We recently found that PCOOH accumulated significantly in the liver and brain of rats with age (34). The PCOOH content of *Drosophila melanogaster* flies was reciprocally proportional to their lifespan (35,36).

In conclusion, in the present study accumulation of cellular PCOOH was clearly shown to be associated with an increase in cellular PDLs. Supplementation with 0.1 or 1 μg/mL medium of α-tocopherol prevented cellular phospholipid hydroperoxide accumulation, but did not extend *in vitro* lifespan.

The aim of this investigation was to determine whether the regioselectivity found for lipoxygenases in the formation of fatty acid hydroperoxides from linoleic acid is reflected in the formation of dimeric products in secondary reactions involving linoleic acid, product hydroperoxide and lipoxygenase. A method was therefore developed for the separation and identification of dimers formed by fusion of two linoleic acid radicals or a linoleic acid radical and linoleate. The method includes solid-phase extraction, preparative separation of products by thin-layer chromatography, derivatization to the corresponding fully hydrogenated methyl esters and capillary gas chromatography (GC) coupled with electron impact mass spectrometry. We present evidence that the formation of octadecadienoate dimers, during the secondary reaction of soybean lipoxygenase-1 or lipoxygenase-3, is a nonenzymic process that can be envisaged by nonspecific association of intermediate fatty acid radicals (L•) that have dissociated from the enzyme. We could show that the relative amounts of different octadecadienoate dimers formed remain unaltered, regardless of pH and type of soybean isoenzyme used. Quantitative analysis by GC showed that under the reaction conditions used, the formation of dimers branching at the 13-position is preferred.

Lipids 28, 779–782 (1993).

Lipoxygenases (LOX; linoleate:oxygen oxidoreductases, EC 1.13.11.12) comprise a class of enzymes that catalyze the regio- and stereoselective dioxygenation of polyunsaturated fatty acids containing one or more (1*Z*,4*Z*)-pentadiene systems. The products are chiral *Z,E*-conjugated fatty acid hydroperoxides. In mammalian tissues, LOX are involved in the initial steps of the biosynthesis from arachidonic acid of physiologically active compounds, including leukotrienes and lipoxins (1). In plants, these enzymes have been suggested to play a role in germination and possibly in the formation of anti-pathogens (2,3). Furthermore, LOX has been shown to be involved in the biosynthesis of 12-oxo-phytodienoic acid (4), a precursor of jasmonic acid (5). Considerable attention has been paid to the plant LOX, and in particular the soybean isoenzymes have been thoroughly investigated.

Three distinct types of LOX isoenzymes can be purified from soybeans, usually designated as LOX-1, LOX-2 and LOX-3. These isoenzymes differ with respect to isoelectric point, reactivity toward substrates, and optimal reaction conditions. The product of the aerobic reaction of LOX-1 with linoleic acid is almost exclusively 13*S*-hydroperoxy-9*Z*, 11*E*-octadecadienoic acid, while with LOX-2 and LOX-3, regio- and stereospecificity are less pronounced. Privett *et al.* (6) have reported that in addition to this primary reaction, lipoxygenases are also capable of performing a secondary reaction during which, among others, polymeric compounds are formed. Garssen *et al.* (7) were the first to identify the mechanism of this secondary reaction in which dimeric compounds, oxodienoic acids and *n*-pentane are formed *via* a coupled enzymic reaction of linoleic acid and product hydroperoxide. LOX-1 shows this secondary reaction only under anaerobic conditions (7). With LOX-3 it can occur both under aerobic and anaerobic conditions whereas LOX-2 shows very little formation of such products under any condition (8). In previous studies only limited information on the structures of the linoleic acid radical-derived dimeric products that are formed during the secondary reaction of lipoxygenases with linoleic acid could be obtained (9,10). This was mainly due to the lack of suitable methods for the separation and analysis of the various positional isomers. The aim of this investigation was to determine whether the regiospecificity found for soybean LOX in the formation of fatty acid hydroperoxides is reflected in the formation of dimeric products. To this end, the positional isomers of the octadecadienoate dimers were completely separated and analyzed.

MATERIALS AND METHODS

LOX-1 and LOX-3 were isolated from soybeans (11,12). Specific activities, as measured polarographically using a thermostated Clark-type oxygen electrode (Hansatec, King's Lynn, United Kingdom) were 230 μmol min^{-1} for LOX-1 (pH 9.0) and 25 μmol min^{-1} mg^{-1} for LOX-3 (pH 6.6). Regiospecificity of the different isoenzymes was determined by performing small-scale (10 mL) incubations with linoleic acid (100 μM) dissolved in oxygen-saturated 0.1 M sodium borate (pH 9.0) or 0.1 M sodium phosphate buffer (pH 6.6) at 25°C. After acidification of the reaction mixtures to pH 3.0 followed by extraction with octadecyl reversed-phase extraction columns (J.T. Baker, Deventer, The Netherlands), the crude hydroperoxides were analyzed by reversed-phase high-performance liquid chromatography on a CP-Spher-C18 column (5 μm, 4.6 × 250 mm) (Chrompack, Middelburg, The Netherlands) with tetrahydrofuran/methanol/water/acetic acid (25:30:45:0.1, by vol) at a flow rate of 1.0 mL min^{-1} as eluent. Detection was by a ultraviolet (UV) detector (Kratos Spectroflow 783, Separations, H.-I. Ambacht, The Netherlands) set at 234 nm. All preparative reactions were carried out at 25°C, by incubation of linoleic acid (500 μM) with either LOX-1 (36 nM) or LOX-3 (200 nM) in 250 mL air-saturated 0.1 M sodium borate (pH 9.0) or 0.1 M sodium phosphate buffer (pH 6.6), using reaction flasks with an airtight seal cap ($[O_2]$ = 240 μM). The appearance of secondary reaction products was monitored by the change in absorbance at 285 nm, corresponding to the absorption maximum of oxodienoic acids, in a Hewlett-Packard model 8450A UV-visible spectrophotometer (Hewlett-Packard, Amstelveen, The Netherlands).

Abbreviations: GC, gas chromatography; GC/MS, gas chromatography/mass spectrometry; LOX, lipoxygenase(s); TLC, thin-layer chromatography; UV, ultraviolet.

The reaction mixtures were acidified and extracted as described above. The free fatty acids were esterified by reaction with diazomethane and separated by preparative thin-layer chromatography (TLC) on precoated plates (Silicagel 60 F_{254}, 0.5 mm, E. Merck, Darmstadt, Germany) using the solvent system *n*-hexane/diethyl ether (40:60, vol/vol). The fractions, containing dimers were collected and, after extraction with methanol, hydrogenated over a platinum catalyst (PtO_2, MeOH). The hydrogenated fractions were analyzed on a Hewlett-Packard model 5890 series-II gas chromatograph equipped with a split injector. Gas chromatography (GC) was done under isothermal conditions for 2 min at 280°C followed by temperature programming to 320°C at 2°C min^{-1} using an HT-5 fused silica capillary column (25 m × 0.33 mm i.d., 1-μm phase thickness, Siloxane-Carborane, 5% phenyl equivalent; SGE, Ringwood Victoria, Australia) at a column pressure of 5 kPa with He as carrier gas (flow rate, 2 mL min^{-1}). The injector temperature was kept at 300°C. The column outlet was connected directly to the ionization source of a JEOL AX 505-W mass spectrometer (JEOL Ltd., Tokyo, Japan), operated at an ionization energy of 70 eV and kept at a temperature of 230°C. Gas chromatography/mass spectrometry (GC/MS) scanning was from *m/z* 35–700, and the following ions were selected in the mass chromatogram: *m/z* 297, 381, 409, 437, 463, 467, 491 and 594 (scan rate, 1 s^{-1}). The relative amounts of different positional isomers were determined by integration of the mass chromatograms.

RESULTS AND DISCUSSION

By use of a high-temperature capillary column (HT5) for the purification of the octadecadienoate dimers formed during the secondary reaction of soybean LOX, we were able to completely separate and analyze all positional isomers, as can be judged from the mass chromatograms obtained for the reaction of LOX-1 at pH 9.0 (Fig. 1). The mass spectra were collected at the center of each peak. Each fragmentation pattern is indicative of one type of linkage between the C_{18}-chains of the dimeric compounds only (Fig. 2 and Table 1). In addition to the major peaks, a small shoulder eluting at 10.7 min can be observed (Fig. 1, Trace 1). The mass chromatograms (Fig. 1) suggest that this shoulder could stem from a very minor amount of C(11)-C(11′)-linked positional isomer since the mass fragments characteristic for compounds branching at C(11) were more abundant, as compared to the spectra B [C(9)-C(11′)isomer] and D [C(11)-C(13′)-isomer] (Fig. 2). At least five positional isomers are formed during the secondary reaction of LOX-1 at pH 9.0 [C(9)-C(9′); C(9)-C(11′); C(9)-C(13′); C(11)-C(13′); C(13)-C(13′) and possibly a very minor amount of C(11)-C(11′)]. This finding extends the results reported by Garssen *et al.* (9), who detected only four of the positional isomers under identical reaction conditions and did not report any C(9)-C(9′)-linked compounds. The authors suggested that the formation of octadecadienoate dimers involves nonenzymic processes that can be conceived as a coupling of either two enzymically formed linoleic acid radicals or an enzymically formed linoleic acid radical and linoleate in the proximity of the enzyme (9). Studies on the reticulocyte enzyme corroborate the proposal of nonspecific association of linoleic acid radicals or a linoleic acid radical and linoleate (13).

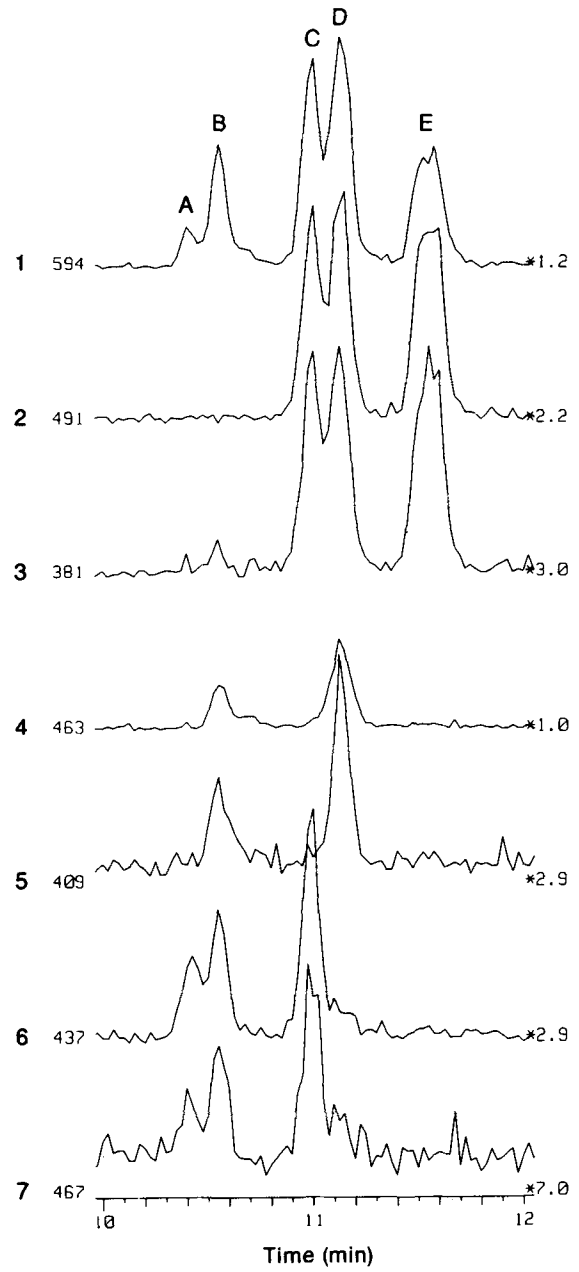

FIG. 1. Single-ion chromatograms from the gas chromatography/mass spectrometry analysis of octadecadienoate dimers from the reaction of lipoxygenase-1 with linoleic acid at pH 9.0. Trace 1: *m/z* 594, indicative of octadecadienoate dimers in general; Trace 2: *m/z* 491, indicative of C(13); Trace 3: *m/z* 381, indicative of C(13); Trace 4: *m/z* 463, indicative of C(11); Trace 5: *m/z* 409, indicative of C(11); Trace 6: *m/z* 437, indicative of C(9); Trace 7: *m/z* 467, indicative of C(9). A: C(9)-C(9′)-isomer; B: C(9)-C(11′)-isomer; C: C(9)-C(13′)-isomer; D: C(11)-C(13′)-isomer; E: C(13)-C(13′)-isomer.

Our results show that the relative amounts of isomeric octadecadienoate dimers formed during the secondary reactions of LOX-1 and LOX-3 (Fig. 3) remain unaltered, regardless of the regiospecificities found under aerobic conditions. This observation, and the fact that all positional isomers that could be expected from the reaction of free linoleic acid radicals in solution are formed, further corroborates the notion of nonenzyme controlled dimer formation. As only a very small amount of the

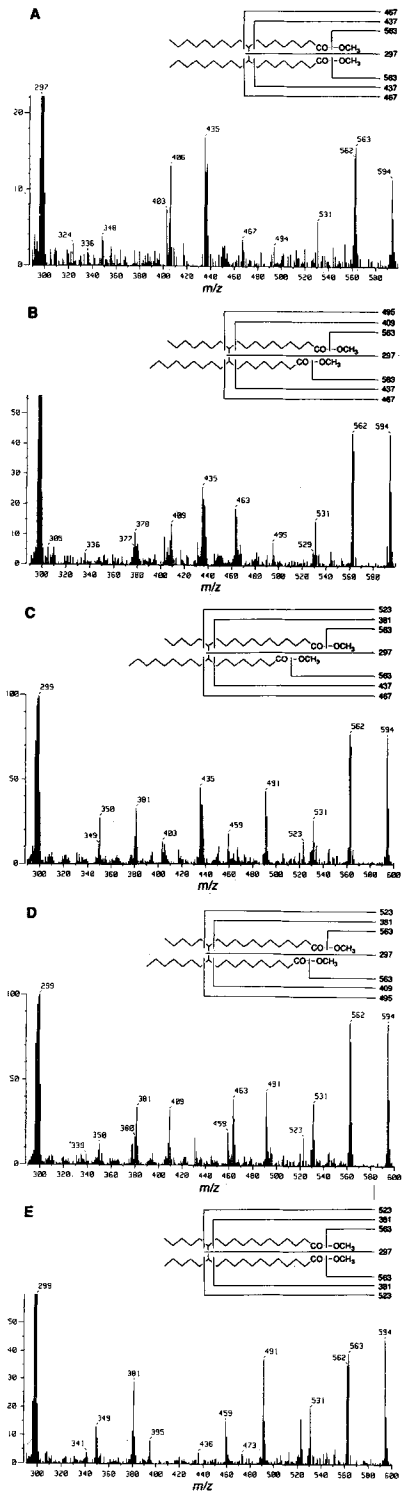

FIG. 2. Mass spectra of the regioisomeric octadecadienoate dimers from the secondary reaction of soybean lipoxygenase-1 with linoleic acid at pH 9.0. Lettering corresponds to that of the peaks in Figure 1 (Trace 1).

C(11)-C(11′)-linked isomer is produced, whereas the C(9)-C(11′) and the C(13)-C(11′)-linked isomers are among the major products, it can be concluded that the latter positional isomers are formed by the reaction of a free linoleic

acid radical with linoleate in solution. This is in agreement with the observation that only coupling to the C(13) and the C(9) positions of the linoleic acid radicals occurs in experiments in which the water-soluble radical scavenger 2-methyl-2-nitrosopropanol was used (14). Quantitative analyses of the octadecadienoate dimers show that in all cases dimeric compounds linked *via* C(13) are more abundant than those linked *via* C(9)-branched isomers (Table 2). Chan and Newby (15) have reported similar results for hemoprotein or metal-ion catalyzed peroxidations of linoleic acid in aqueous solution. These authors found that under a variety of reaction conditions13-hydroperoxylinoleic

acid constitutes 65–72%, and 9-hydroperoxylinoleic acid constitutes 28–35% of the total amount of hydroperoxy compounds formed in nonenzymic oxidations of linoleic acid. This result, and the observation that regioselectivity is greatly diminished when methyl linoleate was used as a substrate instead of the free acid, or when linoleic acid was oxidized in organic solvents, led them to suggest that the relative reactivity of C(9) and C(13) of linoleic acid in aqueous media is determined by the carboxylate group. The results reported here reflect a similarly remarkable deviation from the occurrence of C(13)- and C(9)-derived products in a 1:1 ratio.

Divinyl Ethers and Hydroxy Fatty Acids from Three Species of *Laminaria* (Brown Algae)[1]

Philip J. Proteau and **William H. Gerwick***
College of Pharmacy, Oregon State University, Corvallis, Oregon 97331

Three species of brown algae, *Laminaria sinclairii, L. saccharina* and *L. setchellii*, have been investigated for the presence of oxylipins. From one, *L. sinclairii*, three new divinyl ether fatty acids have been characterized as methyl ester derivatives (methyl 12-[1′(*Z*),3′(*Z*)-hexadienyloxy]-6(*Z*), 9(*Z*),11(*E*)-dodecatrienoate, methyl 12-[1′(*Z*),3′(*Z*)-hexadienyloxy]-9(*Z*),11(*E*)-dodecadienoate, and methyl 14-[1′(*Z*),3′(*Z*)-hexadienyloxy]-5(*Z*),8(*Z*),11(*Z*),13(*E*)-tetradecatetraenoate) by a variety of spectroscopic methods. In addition, one new [13(*S*)-hydroxy-6(*Z*),9(*Z*),11(*E*),15(*Z*)-octadecatetraenoic acid] and four known monohydroxy polyunsaturated fatty acids have been isolated from all three species as their methyl ester derivatives. The occurrence of these compounds in brown algae strongly suggests that these organisms possess an active lipoxygenase(s) with ω6 specificity.
Lipids 28, 783–787 (1993).

Investigations of marine red algae have yielded a wide variety of oxylipins (1,2). Oxylipin has been introduced as an encompassing term for oxygenated compounds which are formed from fatty acids by reactions involving at least one step of mono- or dioxygenase-dependent oxidation (3,4). Representatives of these compounds in the brown algae have been scarce. The ecklonialactones (5,6), the epoxy and tetrahydrofuran lipids from *Notheia anomala* (7,8) and the cymathere ethers (9) are the only reported examples. As an extension of our work in this area of natural products chemistry, we examined several species of *Laminaria* and have discovered that these brown algae show evidence for active lipoxygenase metabolism (10).

MATERIALS AND METHODS

General. Nuclear magnetic resonance (NMR) spectra were recorded on a Bruker (Karlsruhe, Germany) AC300 instrument operating at 300.13 MHz for ^{1}H NMR and at 75.46 MHz for ^{13}C NMR. Proton spectra were referenced to internal tetramethylsilane at 0.00 ppm. Carbon spectra were referenced to $CDCl_3$ at 77.00 ppm. Infrared (IR) spectra were obtained using a Nicolet (Madison, WI) 510 Fourier transform IR (FTIR) spectrometer. Ultraviolet (UV) spectra were run on a Hewlett-Packard (Palo Alto, CA) 8452a spectrophotometer. High-resolution electron-impact mass spectra (HR EIMS) were recorded on a Kratos (Manchester, England) MS 50 TC. High-performance liquid chromatography (HPLC) utilized a Waters (Milford, MA) M6000 pump, Rheodyne (Cotati, CA) 7125 injector and a Waters Lambda-Max 480 LC spectrophotometer. Optical rotations were obtained on a Perkin-Elmer (Norwalk, CT) 141 polarimeter. Merck (Darmstadt, Germany) aluminum-backed thin-layer chromatography (TLC) sheets (silica gel 60 F_{254}) were used for TLC. Compounds were detected by UV illumination or by heating plates sprayed with a 50% H_2SO_4 solution. Gas chromatography/mass spectrometry (GC/MS) was done utilizing a Hewlett-Packard 5890 Series II GC connected to a Hewlett-Packard 5971 mass spectrometer. Trimethylsilyl (TMS) ethers were prepared using TriSil® reagent (Pierce Chemicals, Rockford, IL). Hydrogenation reactions were carried out with 0.1–0.2 mg samples in ethanol using hydrogen gas and 5% palladium on activated carbon catalyst (Aldrich, Milwaukee, WI).

Collection, extraction and isolation. Laminaria sinclairii (Harvey *ex* Hooker f. *et* Harvey) Farlow, Anderson *et* Eaton was collected from the low intertidal at Strawberry Hill on the Oregon coast in May 1990. The algal material was immediately frozen with dry ice and stored at −20°C until extraction. Extraction of the defrosted alga (640 g dry wt) with warm $CHCl_3$/MeOH (2:1, vol/vol) provided 7 g of a viscous, dark brown oil which was fractionated by vacuum chromatography (7.5 cm × 5 cm, Merck Silica Gel G for TLC) using increasingly polar mixtures of hexanes and ethyl acetate. Fractions eluting with 40–50% EtOAc showed UV-active, brown charring reactions on TLC. These were combined (497 mg) and methylated with diazomethane. The methylated material was fractionated by flash chromatography (Merck Kieselgel 60, 230–400 mesh) using a stepped gradient from 5 to 20% EtOAc in hexanes. Fractions eluting with 5–10% EtOAc in hexanes were enriched with divinyl ether compounds, while those eluting with 20% EtOAc contained monohydroxy fatty acid methyl esters (236.6 mg). The divinyl ethers were further purified by HPLC (Maxsil Silica 10 μ, 500 mm × 10 mm; Phenomenex, Torrance, CA; 2.5% EtOAc/hexanes) to give ≈40 mg of methyl 12-[1′(*Z*),3′(*Z*)-hexadienyloxy]-6(*Z*), 9(*Z*),11(*E*)-dodecatrienoate (2) plus methyl 14-[1′(*Z*),3′(*Z*)-hexadienyloxy]-5(*Z*),8(*Z*),11(*Z*),13(*E*)-tetradecatetraenoate (4) and 3.4 mg of methyl 12-[1′(*Z*),3′(*Z*)-hexadienyloxy]-9(*Z*),11(*E*)-dodecadienoate (6). Compounds 2 and 4 were unstable, and attempts to separate these compounds led to their degradation. The monohydroxy compounds (50.7 mg portion) were fractionated initially by normal-phase HPLC (Maxsil Silica 10 μ, 500 mm × 10 mm, 15% EtOAc/hexanes) and then by reverse-phase HPLC (Merck Lichrosorb RP-18 7 μ, 250 mm × 10 mm, 85% MeOH/H_2O) to yield: (i) a mixture of methyl 13(*S*)-hydroxy-6(*Z*),9(*Z*),11(*E*),15(*Z*)-octadecatetraenoate (8) and minor related species (ii) methyl 15(*S*)-hydroxy-5(*Z*),8(*Z*), 11(*Z*),13(*E*),17(*Z*)-eicosapentaenoate (10), methyl 13(*S*)-hydroxy-9(*Z*),11(*E*),15(*Z*)-octadecatrienoate (12), and methyl 12-hydroxy-9,13,15-octadecatrienoate (17) and (iii) methyl 15(*S*)-hydroxy-5(*Z*),8(*Z*),11(*Z*),13(*E*)-eicosatetraenoate (14) plus methyl 13(*S*)-hydroxy-9(*Z*),11(*E*)-octadecadienoate

[1]A preliminary summary of this work was presented at the XIVth International Seaweed Symposium, Brest, France, August 1992 (10).

(16). Final purification of compounds 8 (5.9 mg), 14 (4.7 mg), and 16 (2.4 mg) was accomplished by HPLC (Versapack Silica 10 μ, 2 × 4.1 mm × 30 cm; Alltech, Deerfield, IL; 10% EtOAc/hexanes). Separation of compound 10 (6.4 mg) and a 4:1 mixture of 12 and 17 (4.8 mg; ratio determined by integration of GC peaks) was also achieved by HPLC (Versapack Silica 10 μ, 2 × 4.1 mm × 30 cm, 0.75% isopropanol/hexanes). All pure compounds were colorless oils.

Laminaria setchellii Silva was collected at Boiler Bay on the Oregon coast in April, 1991, and *L. saccharina* (L.) Lamouroux was obtained from Puget Sound, Washington in July 1990. Both of these algae were processed in a manner similar to the above procedure to obtain compounds 8, 10, 12, 14 and 16. Neither of these algae showed any evidence for the divinyl ether fatty acids.

LR EIMS *m/z* (rel. intensity) of hydrogenated 2: 283 (M^+-OCH_3, 3), 229 (47), 214 (36), 197 (100), 181 (20), 171 (27), 163 (24), 143 (60), 129 (22), 97 (46), 87 (87), 74 (85), 69 (51), 55 (63).

Methyl 14-[1′(Z),3′(Z)-hexadienyloxyl]-5(Z),8(Z),11(Z),13(E)-tetradecatetraenoate (4). LR EIMS *m/z* (rel. intensity) of 4 or a geometrical isomer: 330 (M^+, 1), 250 (10), 233(8), 201 (20), 183 (33), 159 (16), 150 (23), 131 (27), 121 (100), 117 (46), 105 (40), 91 (85), 79 (77), 67 (51). LR EIMS *m/z* (rel. intensity) of hydrogenated 4: 342 (M^+, 0.5), 311 (M^+-OCH_3, 2), 257 (29), 242 (31), 225 (42), 199 (23), 143 (44), 111 (25), 97 (44), 87 (83), 74 (100), 69 (59), 55 (62).

Methyl 12-[1′(Z),3′(Z)-hexadienyloxy]-9(Z),11(E)-dodecadienoate (6). A colorless oil. UV (EtOH) λ_{max} = 268 nm (ε = 30000); FTIR (neat) 2929, 2855, 1740, 1647, 1595, 1434, 1250, 1228, 1164 cm^{-1}. LR EIMS *m/z* (rel. intensity) 306 (M^+, 49), 275 (5), 245 (6), 149 (35), 131 (40), 107 (34), 96 (48), 81 (100), 67 (86), 55 (96). For ^{1}H NMR data, see Table 1. HR EIMS: Found, 306.220; calcd. for $C_{19}H_{30}O_3$ (M^+), 306.219.

Methyl 13(S)-hydroxy-6(Z),9(Z),11(E),15(Z)-octadecatetraenoate (8). A colorless oil. $[\alpha]_D^{27}$ = +12° (c = 0.66, acetone), UV (MeOH) λ_{max} = 238 nm (ε = 27000); FTIR (neat) 3438 (broad), 3011, 2960, 2934, 1740, 1437, 1212, 1202, 1175, 985 cm^{-1}. LR EIMS *m/z* (rel. intensity) 306 (M^+, 0.5), 288 (M^+-H_2O, 7), 275 (2), 237 (35), 219 (22), 205 (41), 187 (40), 159 (50), 107 (78), 81 (100), 69 (57). For ^{1}H and ^{13}C NMR data, see Table 1. HR EIMS: Found, 306.219; calcd. for $C_{19}H_{30}O_3$ (M^+), 306.219. LR EIMS *m/z* (rel. intensity) of TMS derivative: 363 (M^+-CH_3, 0.7), 347 (M^+-OCH_3, 0.7), 309 (100), 243 (10), 219 (6), 187 (10), 145 (19), 129 (16), 103 (21), 91 (24), 73 (89).

Methyl 15(S)-hydroxy-5(Z),8(Z),11(Z),13(E),17(Z)-eicosapentaenoate (10). A colorless oil. $[\alpha]_D^{29.5}$ = +9.9° (c = 0.71, acetone). Based on the known positive optical rotation for ethyl 15-*S*-HETE (11), this positive rotation also indicates *S* stereochemistry at position-15. The predominantly *S* stereochemistry was confirmed by oxidative ozonolysis of the (−)-menthoxycarbonyl derivative (12) and subsequent comparison by GC/MS of the malate derivative with standards prepared from D- and L-malate (13). The experimentally obtained malate fragment significantly enriched the peak corresponding to the L-malate derivative when co-injected into the GC/MS with a mixture of D- and L-standards (due to incomplete resolution of the D- and L-malate-derived standards under our GC/MS conditions, quantitative determination of the *R* and *S* enantiomers was not possible). ^{1}H

[a]^{1}H chemical shifts are reported relative to internal tetramethylsilane at 0.00 pm. ^{13}C shifts are referenced to $CDCl_3$ at 77.00 ppm. All spectra were recorded in $CDCl_3$. NMR, nuclear magnetic resonance; 13-HODTA, 13-hydroxyoctadecatetraenoic acid.
[b]Assignments based on a ^{1}H-^{13}H-^{13}C heteronuclear chemical shift correlation spectroscopy experiment and by comparison to model compounds (15).

NMR ($CDCl_3$; δ) 6.56 (1H, *dddd*, J = 15.2, 11.1, 1.1, 1.1 Hz, H-13), 6.00 (1H, *dd*, J = 11.1, 10.8 Hz, H-12), 5.73 (1H, *dd*, J = 15.2, 6.3 Hz, H-14), 5.58 (1H, *bdt*, J = 10.8, 7.2 Hz, H-18), 5.39 (6H, *m*, H-5, H-6, H-8, H-9, H-11, H-17), 4.23 (1H, *m*, H-15), 3.67 (3H, *s*, OCH_3), 2.96 (2H, *bdd*, J = 6.3, 6.0 Hz, H-10), 2.81 (2H, *bdd*, J = 5.4, 5.3 Hz, H-7), 2.34 (2H, *m*, H-16), 2.33 (2H, *t*, J = 7.4 Hz, H-2), 2.10 (2H, *m*, H-4), 2.09 (2H, *m*, H-19), 1.84 (1H, *d*, J = 4.0 Hz, OH), 1.71 (2H, *tt*, J = 7.4, 7.4 Hz, H-3), 0.97 (3H, *t*, J = 7.5 Hz, H-20). ^{13}C NMR [$CDCl_3$; assignments based on model compounds (compound 8 and Ref. 11); δ]: 174.14 (C-1), 135.77 (C-14), 135.27 (C-18), 130.21 (C-11), 128.74 (C-5), 128.98 (C-6), 128.59 (C-8), 127.97 (C-9), 127.56 (C-12), 125.34 (C-13), 123.70 (C-17), 71.98 (C-15), 51.53 (OCH_3), 35.26 (C-16), 33.40 (C-2), 26.52 (C-4), 26.10 (C-10), 25.62 (C-7), 24.72 (C-3), 20.73 (C-19), 14.20 (C-20).

Methyl 13(S)-hydroxy-9(Z),11(E),15(Z)-octadecatrienoate (**12**). A colorless oil. $[\alpha]_D^{29} = +5.1°$ (c = 0.44, acetone) for a 4:1 mixture (by GC integration) of **12** and **17**.

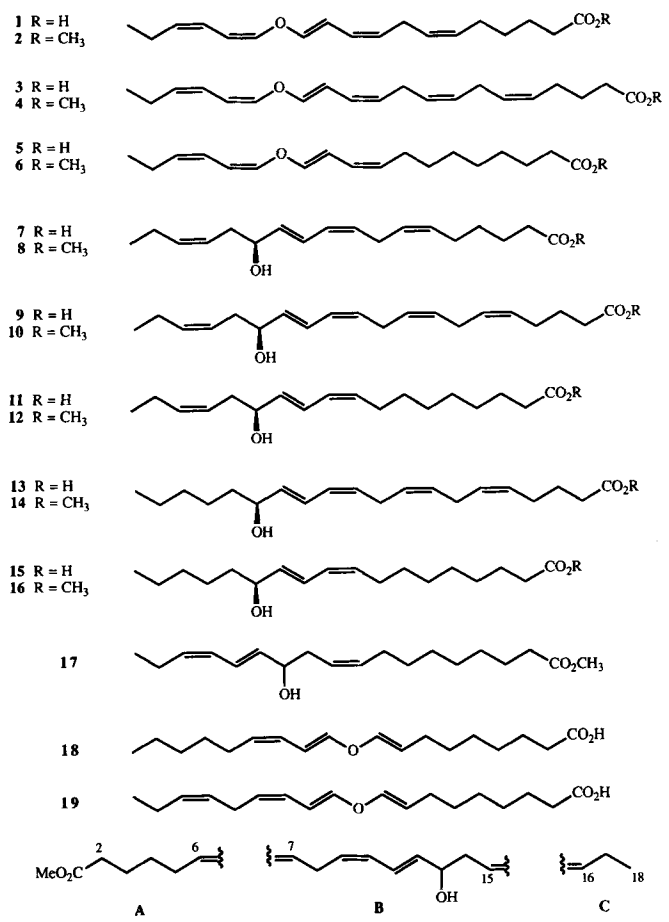
Methyl 15(S)-hydroxy-5(Z),8(Z),11(Z),13(E)-eicosatetraenoate (**14**). A colorless oil. $[\alpha]_D^{32} = +9.0°$ (c = 0.52, acetone), $[\alpha]_D^{32} = +4.4°$ (c = 0.52, hexanes), $[\alpha]_D^{32} = +8.8°$ (c = 0.52, EtOH). ^1H and ^{13}C NMR data correlated well with previously reported values (11).

Methyl 13(S)-hydroxy-9(Z),11(E)-octadecadienoate (**16**). A colorless oil. $[\alpha]_D^{27} = +8.9°$ (c = 0.27, acetone).

Methyl 12-hydroxy-9,13,15-octadecatrienoate (**17**). [This compound was previously characterized from a green alga (14).] LR EIMS *m/z* (rel. intensity) 308 (M^+, 0.15), 290 (M^+-H_2O, 3), 227 (2), 195 (3), 133 (3), 111 (100), 93 (12), 81 (11), 67 (12), 55 (14). A C_{18} hydroxy acid methyl ester with three double bonds was indicated by the ion at *m/z* 308 (M^+). The base peak at *m/z* 111 suggested placement of the hydroxy at C-12 with a diene unit oriented toward the methyl terminus. Assuming an α-linolenic acid precursor to this compound, the third olefin was positioned at C-9. The LR EIMS spectrum of the TMS-derivative of the hydrogenated species matched well with an authentic spectrum of methyl 12-(TMS)oxyoctadecanoate (91% match with spectrum #45118 of the National Bureau of Standards mass spectral library #NBS54k included with the Hewlett-Packard 5971 MS operating software), confirming the placement of the hydroxyl at position-12. The stereochemistries of the olefins for compound **17** are proposed based on biogenetic arguments.

RESULTS AND DISCUSSION

Laminaria sinclairii was collected on the Oregon coast and immediately frozen with dry ice. Extraction of the defrosted alga with warm $CHCl_3$/MeOH provided a viscous, dark brown oil which was fractionated by vacuum silica gel chromatography. Several nonpolar fractions showed UV active, brown-charring spots on TLC. These were combined, methylated with CH_2N_2, and further fractionated to provide material rich in divinyl ethers and monohydroxy fatty acid methyl esters. The divinyl ethers were finally purified by normal-phase HPLC to yield a 4:1 mixture of compounds **2** and **4** (determined by GC integration of hydrogenated **2** and **4**) and pure compound **6**. Attempts to isolate **2** and **4** in pure form were unsuccessful as the compounds degraded with each step of purification.



Since compounds **2** and **4** were not separable without extensive decomposition, data were collected for the mixture. The ^1H NMR spectrum showed minor shoulders on several of the olefinic peaks and distortions in upfield patterns indicating that **2** and **4** were closely related. The ^{13}C NMR data (Table 1) and HR EIMS provided a molecular formula of $C_{19}H_{28}O_3$ for the major component. An analysis of the NMR data revealed five olefins and one ester carbonyl. Despite the presence of compound **4**, two isolated spin systems [H(2)-H(12) and H(13)-H(18)] were obtained from the ^1H-^1H chemical shift correlation spectroscopy (COSY) spectrum. Since two of the oxygens in the formula are contained in the ester function, the remaining oxygen logically would connect the two spin systems. The resulting divinyl ether structure explains the polarization of the olefinic carbons at the termini of these spin systems (C-12, δ147.91, C-11, δ106.48; C-13, δ141.79, C-14, δ105.70). The magnitudes of the coupling constants for the olefins adjacent to the ether oxygen are also consistent with a divinyl ether structure. Enol ethers show distinctive coupling constants with J_{trans} = 12.0-12.6 Hz and J_{cis} = 6.2-6.7 Hz (15). Thus, the C(11)- C(12) double bond was *trans* (11.9 Hz) while the C(13)-C(14) olefin was *cis* (6.2 Hz). The C(9)-C(10) (10.5 Hz) and C(15)-C(16) (11.3 Hz) protons showed coupling constants of more typical *cis* olefins. The C(5)-C(6) olefin was also *cis* based on the ^{13}C shifts of the adjacent methylene carbons (16) (H-6 and H-7 were a degenerate multiplet). Hence, structure **2** was defined as methy 12-[1′(Z),3′(Z)-hexadienyloxy]-6(Z),9(Z),11(E)-dodecatrienoate.

The ^1H-^1H COSY spectrum of the mixture of 2 and 4 suggested that compound 4 was a C_{20} analog based on an extra correlation from δ2.10 (H-4) to δ1.71 (H-3). The H-3 protons of Δ5 C_{20} polyunsaturated fatty acids and derivatives typically occur at δ1.71. Also, the bisallylic methylene at δ2.86 in 2 appeared to have small, broad, doublets of doublets obscured to both the downfield and upfield sides of the main pattern, indicating the presence of two bisallylic methylenes in compound 4. Analysis by GC/MS supports this conclusion. Although divinyl ethers 2 and 4 thermally isomerize to olefin isomers under GC/MS conditions, a peak that eluted after the major enol ether 2 showed a peak at *m/z* 330 which corresponds to the M^+ for a C_{20} species with six olefins. A fragment peak at *m/z* 233 indicated an ether oxygen between C-14 and C-15. The mixture of divinyl ethers 2 and 4 was hydrogenated, and the derivatized minor component had a M^+ 342 peak which implied six olefins in 4 and a major fragment peak at *m/z* 257, consistent with the loss of a C_6H_{13} unit to the distal side of the oxygen. Since the ^1H NMR patterns of 2 and 4 essentially overlap and the above GC/MS evidence supports a C_{20} analog with six double bonds, we propose structure 4, methyl 14-[1′(*Z*), 3′(*Z*)-hexadienyloxy]-5(*Z*),8(*Z*),11(*Z*),13(*E*)-tetradecatetraenoate, for the minor component. The olefin geometries shown are consistent with the functionality of 2 and the likely C_{20} fatty acid precursor, 5(*Z*),8(*Z*),11(*Z*),14(*Z*),17(*Z*)-eicosapentaenoic acid.

Compound 6, the least polar divinyl ether from *L. sinclairii*, contained the same chromophore as in 2 (λ_{max} 268 nm). The ^1H NMR spectrum of 6 was highly comparable to that of 2, except for two less olefinic protons and four more protons in the high field region of the spectrum (see Table 1). This suggested that 6 was the C(6)-C(7) dihydro analog of 2 which was further supported by ^1H-^1H COSY analysis. Confirmation of this structure was obtained from mass spectral analysis. A significant M^+ 306 peak was present (49%), and the base peak at *m/z* 81 is consistent with cleavage to the distal side of the ether oxygen. Hydrogenation of compounds 2 and 6 and subsequent GC/MS analysis showed that these two hydrogenated products were identical.

The only known examples of divinyl ether fatty acids in nature are colneleic (18) and colnelenic (19) acids from potato tubers (17) and polyneuric acid from the marine red alga *Polyneura latissima* (18). Compounds 1 and 5 differ from colneleic and colnelenic acids in the position of oxygenation and in the double-bond stereochemistry about the oxygen linkage. Colneleic and colnelenic acids have a *trans* olefin on either side of the ether oxygen, while compounds 1 and 5 have a *cis* double bond to one side of the oxygen and a *trans* olefin on the other side. The potato tuber fatty acids arise from a pathway initiated by a 9-lipoxygenase acting on linoleic or α-linolenic acid (19). Assuming an analogous pathway to the new compounds, a 13-lipoxygenase is indicated in the formation of 1 and 5 from C_{18} precursors and a 15-lipoxygenase in the formation of 3 from a C_{20} precursor (ω6 in each case). Divinyl ether 1 would derive from stearidonic acid, and compound 5 would arise from α-linolenic acid.

The complex mixture of monohydroxy polyunsaturated fatty acid methyl esters from *L. sinclairii* was purified by a combination of normal- and reverse-phase HPLC to yield five major components: 8, 10, 12, 14 and 16. Four of these were known compounds: methyl 15(*S*)-hydroxy-5(*Z*),8(*Z*),11(*Z*),13(*E*),17(*Z*)-eicosapentaenoate [methyl 15(*S*)-HEPE, 10], methyl 13(*S*)-hydroxy-9(*Z*),11(*E*),15(*Z*)-octadecatrienoate [methyl 13(*S*)-HOTE, 12], methyl 15(*S*)-hydroxy-5(*Z*),8(*Z*),11(*Z*),13(*E*)-eicosatetraenoate [methyl 15(*S*)-HETE, 14] and methyl 13(*S*)-hydroxy-9(*Z*),11(*E*)-octadecadienoate [methyl 13(*S*)-HODE, 16]. Methyl 15(*S*)-HETE, methyl 15(*S*)-HEPE and methyl 13(*S*)-HOTE were identified by ^1H NMR, ^{13}C NMR, ^1H-^1H COSY, optical rotations and GC/MS analysis of TMS derivatives and comparison to literature data (11,20–24). Methyl 13(*S*)-HODE was characterized by ^1H NMR, optical rotation (25) and GC/MS analysis of the TMS derivative (26). The fifth compound, 8, was closely related to the above hydroxy acid methyl esters by NMR and analyzed for $C_{18}H_{30}O_3$ by HR EIMS. The H(2)–H(6) (**A**), H(7)–H(15) (**B**) and H(16)–H(18) (**C**) spin systems could be assembled based on ^1H-^1H COSY data, but due to overlap in the olefinic and allylic methylene regions, connection of these fragments was not possible. The two possibilities for combining these fragments gave rise to either a 9-hydroxy or a 13-hydroxy compound. Biogenetic arguments would favor the 13-hydroxy compound based on the co-occurrence of methyl 13-HOTE and methyl 13-HODE. LR EIMS supported this by showing a significant fragment at *m/z* 237, corresponding to cleavage distal to C-13. Further proof for oxidation at C-13 in 8 was obtained by separately hydrogenating small amounts of methyl 13-HODE, methyl 13-HOTE and compound 8 and analyzing the products as TMS ethers by GC/MS. All three samples were analyzed for the TMS ether of methyl 13-hydroxystearate (27). Carbon NMR shifts in 8 (Table 1) were assigned based on a ^1H-^{13}C XHCORR experiment and model compounds (11). The positive optical rotation obtained for this sample indicated *S* stereochemistry at position-13, based on the known positive rotations of methyl 13(*S*)-HOTE (24) and methyl 13(*S*)-HODE (25). This stereochemical assignment was verified by analyzing the ozonolysis product of the (−)-menthoxycarbonyl derivative (12) by GC/MS and comparison to known standards (13). The malate-derived product significantly enriched the peak corresponding to the L-malate derivative when co-injected into the GC/MS with a mixtue of D- and L-standards. These data allowed the assignment of the new structure as methyl 13(*S*)-hydroxy-6(*Z*),9(*Z*),11(*E*),15(*Z*)-octadecatetraenoate (methyl 13(*S*)-HODTA, 8). All five of these hydroxy acid derivatives were also obtained in 0.15–0.4% yield from extracts of *L. setchellii* and *L. saccharina* (10).

The occurrence of these hydroxy acids 7, 9, 11, 13, and 15 in several species of *Laminaria* suggests that algae of this genus possess a lipoxygenase with positional specificity for C-13 in C_{18} substrates and C-15 in C_{20} substrates (ω6 in both structure classes). The presence of oxylipins in *Ecklonia stolonifera* (5,6), *Cymathere triplicata* (9) and now in several species of *Laminaria* suggests that other brown algae of the Laminariaceae offer a potential source of these novel fatty acid derivatives. The physiological relevance of these compounds in the algae is unknown, but related compounds appear to act as endogenous elicitors of phytoalexin production in rice plants which have been challenged with a fungal infection (28). The role that the divinyl ethers play is also unknown, although colneleic acid has shown *in vitro* activity as a 5-lipoxygenase inhibitor (29).

ACKNOWLEDGMENTS

We thank Brian Arbogast and Don Griffin of the OSU College of Agricultural Chemistry for some mass spectrometric measurements. This work was supported by the Oregon Sea Grant Program (R/SH-5) and NIH (CA52955). P.J.P. would like to thank the NSF for a predoctoral fellowship. We also gratefully acknowledge the assistance of OSU in obtaining a Hewlett-Packard GC/MS.

Age-Dependent Accumulation of Phosphatidylcholine Hydroperoxide in the Brain and Liver of the Rat

Teruo Miyazawa*, Toshihide Suzuki and Kenshiro Fujimoto
Department of Applied Biological Chemistry, Tohoku University, Tsutsumidori, Sendai 981, Japan

Age-related changes in phosphatidylcholine hydroperoxide (PCOOH) content as an index for oxidative membrane lipid damage were determined by high-performance liquid chromatography using chemiluminescence detection. Brain and liver PCOOH content increased significantly in male and female rats with age. The brain PCOOH content of male 18-month-old rats was 4.4 times that of 1-month-old rats, and that of female 18-month-old rats was 3.5 times that of 1-month-old females. The liver PCOOH content of the male 18-month-old rats was 9.3 times that of the 1-month-old; and of the female 18-month-old rats was 4.7 times that of the 1-month-old. PCOOH levels in heart and lung did not show age dependency. In both brain and liver (but not in heart and lung), the phosphatidylcholine content significantly decreased upon aging. The results indicate that oxidative deterioration, such as phospholipid hydroperoxidation, is prevalent in the membrane lipids of brain and liver of the rat due to aging.
***Lipids* 28, 789–793 (1993).**

Peroxidation of membrane lipids has been implicated as one of the basic mechanisms of age-related pathological changes (1–3). The thiobarbituric acid (TBA) assay has previously been employed to estimate lipid peroxides in human plasma (4) and in tissues of rodents as a function of age (5–11). Several investigators have reported an increase in TBA reactants in rat brain (5,8,9,11) and liver (8,9,11) with aging whereas others could not show such changes (6,7,10). These inconsistencies may well be attributable to methodological problems, because the TBA assay also responds to aldehydes, amino acids and carbohydrates unrelated to lipid peroxides (12,13).

Alternatively, expiration of hydrocarbon gas by aged rats (14), conjugated diene absorption of tissue lipids upon aging (15) and age-related fluorescence pigment formation (16) have been measured to follow membrane lipid hydroperoxide formation. However, to accurately assess the degree of lipid hydroperoxidation in biological membranes, the direct measurement of primary peroxidation products, such as phospholipid hydroperoxides, is most desirable.

A new, sensitive and selective assay of phospholipid hydroperoxides by high-performance liquid chromatography (HPLC) combined with chemiluminescence (CL) detection was first described by Miyazawa and colleagues (17–20). This CL–HPLC method was successfully applied to measure phospholipid hydroperoxides present in human plasma (19, 21), serum lipoproteins (22) and in liver and brain of rodents (20,23,24). More recently, this method was used to establish that the phosphatidylcholine hydroperoxide (PCOOH) content of *Drosophila melanogaster* flies is reciprocally proportional to the flies' life span (25,26). PCOOH accumulation in cultured human diploid cells, upon reaching cellular population doubling levels, was also measured by this method (27). A similar HPLC method with CL detection was independently described by Frei *et al.* (28), although these authors could not detect phospholipid hydroperoxides in human blood plasma due to methodological limitations.

In the present paper, we primarily determined the age-related changes that occur in PCOOH levels in the internal organs of the rat using the CL–HPLC method to follow the oxidative damage of membrane lipids in this *in vivo* rodent system.

MATERIALS AND METHODS

Animals. Male and female Sprague-Dawley rats (n = 42) were fed a standard laboratory diet (F-2 pellet rations; Funabashi Farm Co., Chiba, Japan; containing 5 mg of vitamin E per 100 g of diet) *ad libitum* for 1, 7, 12 and 18 mon for male rats (body weight, 140, 557, 678 and 722 g, respectively; n = 6 for each group); and for 1, 7 and 12 mon for female rats (body weight, 112, 334 and 443 g, respectively; n = 6 for each group). Groups of three rats each were housed in stainless steel cages and maintained at 25°C on a 12 h (8 a.m. to 8 p.m.) light–dark cycle. The rats were fasted for 20 h prior to dissection and were sacrificed by exsanguination under light diethyl ether anesthesia. The livers were perfused *in situ* with ice-cold 0.15 M saline, and then the brain, liver, heart and lung were removed.

Total lipid (TL) extraction. TL were extracted with a mixture of chloroform and methanol (2:1, vol/vol) (29) from brain, liver, heart and lung as described previously (23,24).

CL–HPLC. The CL–HPLC system and conditions for measuring PCOOH in total lipids from rat tissues were essentially the same as those previously described by Miyazawa *et al.* (23,24).

Determination of phosphatidylcholine (PC) and α-tocopherol. The PC content in tissue TL was measured by an Iatroscan thin-layer chromatography (TLC)/flame-ionization detection method using an Iatroscan TH-10 apparatus (Iatron Laboratories Inc., Tokyo, Japan) as described by Hazel (30). α-Tocopherol content was measured by the fluorescence-HPLC method (31).

Fatty acid analysis. PC was separated from tissue TL lipids by TLC (silica gel 60; Merck, Darmstadt, Germany) using chloroform/methanol/acetic acid/water (25:15:4:2, by vol) as developing solvent (32). Fatty acid methyl esters derived from TL and from PC were prepared by acid-catalyzed transmethylation (33). Methyl esters were extracted with hexane and were analyzed using a Shimadzu GC-8A gas chromatograph equipped with a glass column (300 × 0.2 cm) containing 10% Silar 10C on Chromosorb W (60/80 mesh; Supelco, Bellefonte, PA). Column temperature was programmed from 170 to 220°C at 1°C/min. Fatty acid methyl esters were identified by comparison of their retention times with those of standards.

*To whom correspondence should be addressed.

Abbreviations: CL, chemiluminescence; DHA, docosahexaenoic acid; HPLC, high-performance liquid chromatography; PC, phosphatidylcholine; PCOOH, phosphatidylcholine hydroperoxide; PEOOH, phosphatidylethanolamine hydroperoxide; TBA, thiobarbituric acid; TL, total lipids; TLC, thin-layer chromatography.

Statistical analysis. The data are expressed as mean values with standard deviations. All data were analyzed using the Student's *t*-test.

RESULTS

Figure 1 shows the CL chromatograms of PCOOH from brain TL of young male rats (1-month-old, Fig. 1A) and of aged male rats (18-month-old, Fig. 1B). PCOOH (retention time at 11.0 min) was clearly separated and detected as a single sharp peak by CL detection. This peak had the same retention time as did authentic PCOOH; its identity was further confirmed by cochromatography with authentic PCOOH. The chemiluminescent peak due to the hydroperoxide group in PCOOH completely disappeared upon reduction of the tissue TL with sodium borohydride to give the corresponding hydroxyl derivative, as has been previously reported (18–20). As shown in Figure 1, the PCOOH peak intensity observed for the brain sample from 18-month-old rats (767 pmol PCOOH/g brain) was more intense than that for 1-month-old rats (140 pmol PCOOH/g brain). By measuring conjugated diene absorption (lower chart of Fig. 1), a slight, but insignificant, increase was observed for 18-month-old rats compared to 1-month-old rats. The lack of significance was probably due to the comparatively low sensitivity of the conjugated diene method.

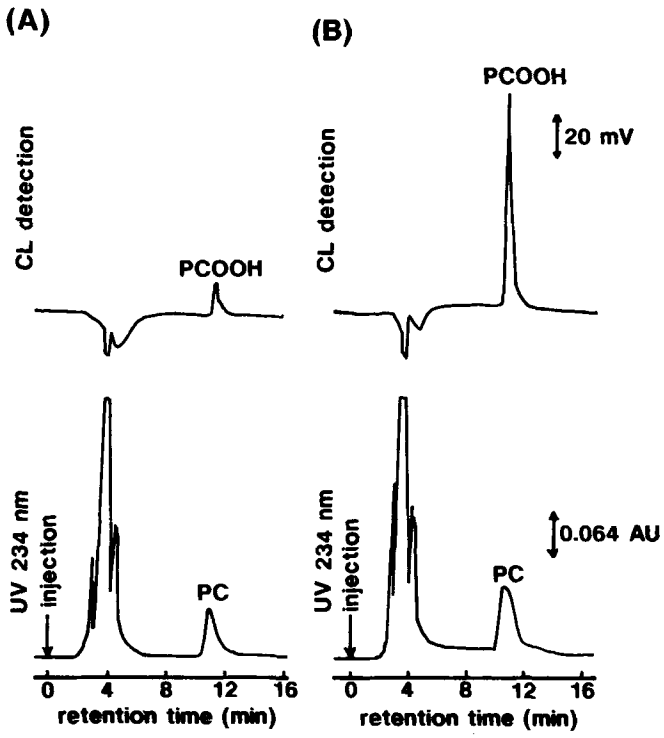

FIG. 1. Chemiluminescence (CL)-high-performance liquid chromatography chromatograms of phosphatidylcholine hydroperoxides (PCOOH) from brain total lipids prepared from male rats. Panel A, 1-month-old rats. Panel B, 18-month-old rats. The PCOOH concentration detected on the chemiluminescent chromatogram corresponded to 140 pmol/g brain (A) and 767 pmol/g brain (B). The upper chart shows CL detection, the lower chart shows conjugated diene (234 nm) detection. UV, ultraviolet.

Brain. For both sexes, brain weights, TL and α-tocopherol content at 7, 12 and 18 mon were significantly higher than those at one month (Table 1). The brain PC content expressed per brain weight was constant during the 18-mon feeding period, but the PC content in the TL showed an age-dependent decrease for both sexes. The brain PCOOH was increased with aging in both male and female rats. The brain PCOOH content of the 18-month-old male rats was 4.4 times that of the 1-month-old, and of the 18-month-old female rats was 3.5 times higher than that of the 1-month-old.

Liver. Liver weights increased with aging (Table 2). However, TL contents were not age-dependent, except for the 18-month-old female rats that had the highest content. The PC content of TL in males was lower at 12 and 18 mon than at 1 and 7 mon, and in females PC content was lower at 18 mon than at 1 and 7 mon. α-Tocopherol contents both in male and female rats were not age-dependent. Female liver α-tocopherol contents were significantly higher than those of male livers for all age groups examined. Liver PCOOH increased proportionally with age in both sexes. The PCOOH content of the 18-month-old male rats was 9.3 times higher than that of the 1-month-old, and that of the 18-month-old female rats was 4.7 times that of the 1-month-old. Female rats had a higher liver PCOOH content at the early ages (1- and 7-month-old) compared with male rats, and the 18-month-old females had a lower liver PCOOH content than the 18-month-old males.

Heart and lung. The heart weights of the 7-, 12- and 18-month old rats were higher than those of the 1-month-old rats (Table 3). Lung weights increased with aging. TL

18	2.3 ± 0.1[d]	20.5 ± 2.6	5.9 ± 0.5	268 ± 14	17.9 ± 1.3[c]	92 ± 37

[a]Values are means ± SD of six rats per each age group. Means not followed by the same letter, [b,c] or [d], are significantly different ($P < 0.001$) within each organ. See Table 1 for abbreviations.

contents of the heart and lung were not age-dependent. PC contents in the heart and lung were constant during the entire feeding period, except that a higher PC content in heart TL was observed for the 18-month-old rats. α-Tocopherol content in the heart and lung did not change with age. PCOOH levels in the heart increased slightly in the 18-month-old rats, but PCOOH levels in the lung did not increase.

Molar ratio of PC and PCOOH. Table 4 shows the changes in molar ratio of PC and PCOOH in rat tissues with aging. For both the brain and liver, age-dependent proportional increases in PCOOH/PC ratios were clearly evident in male and in female rats. The brain PCOOH/PC ratio for the 1-month-old male rats was 0.6×10^{-5} and that for the 18-month-old male rats was 3.5×10^{-5}. The rate of increase in brain PCOOH/PC ratio was essentially the same males and females. The liver PCOOH/PC ratio of 1-month-old male rats was 1.9×10^{-5} and that of 18-month-old male rats was 19.7×10^{-5}. A similar increase was observed for female liver, although the increase in PCOOH/PC ratio with time for the females was lower than that of the males. The change in PCOOH/PC ratio in the heart did not correlate with aging, and the lung PCOOH/PC ratio showed no change with aging.

Fatty acids composition. Table 5 shows the changes in fatty acid composition of brain TL and PC following aging in male rats. In the TL, oleic acid (18:1n-9), eicosenoic acid (20:1n-9) and docosatetraenoic acid (22:4n-6) levels in the 7–18-month-old rats were significantly higher than those in the 1-month-old rats. Docosahexaenoic

[a]Values are means ± SD of six rats per each age group. Means not followed by the same letter, [c,d] or [e], are significantly different ($P < 0.001$).
[b]Individual fatty acids are designated by the number of carbon atoms and the number of double bonds, n represents the position of the first double bond from the methyl end.

acid (DHA, 22:6n-3) content was lower in 12- and 18-month-old rats than in 1- and 7-month-old rats. Saturated fatty acid (16:0, 18:0) content remained constant during the 18-mon experimental period. In brain, PC decreased in saturated fatty acids (16:0, 18:0) and increased in unsaturated fatty acids (18:1, 20:1, 20:4, 22:6) with aging.

DISCUSSION

In the present study, we have demonstrated the accumulation of PCOOH in the brain and in the liver of rats with aging by use of a CL-HPLC method for hydroperoxide determination. Such an age-dependent increase in PCOOH was not observed in lung and heart. We also showed that PCOOH was present in all the internal organs we examined at levels of 100 to 2500 pmol per gram of tissue (Tables 1–4). These values are much lower than previous data reported for lipid peroxide levels (hundreds of nanomoles per gram tissue) based on TBA measurements (5–11).

In previous studies, age-related accumulation of lipid peroxides as measured by TBA assay was reported to be 2 or 3 times higher in rat brain (5,8,9,11,15) and liver (8,9,11,15), and 1.2 times higher in rat liver lipids based on conjugated diene measurements (15). In the present study, it was shown that the age-related formation of PCOOH in brain (3.5–4.4 times) and liver (4.7–9.3 times) was more pronounced than previously observed (5,8,9,15). From the evidence provided here based on data obtained on aging rodents, membrane phospholipids in brain and liver appear more susceptible to hydroperoxidation than the lipids in heart and lung.

We recently reported the presence of phosphatidylethanolamine hydroperoxide (PEOOH) in addition to PCOOH in rat brain and liver (20). In rat brain, PEOOH content was generally higher than PCOOH levels. Phosphatidylethanolamine in brain and liver is also richer in unsaturated fatty acids than is PC; hence, the present findings are not surprising. Liver phospholipid hydroperoxide content is affected by dietary supplementation, *e.g.*, with fish oil, which increases liver PCOOH and PEOOH levels (20).

An age-dependent decrease in phospholipid levels has been reported for rat liver (34), human brain (35), rat brain and liver microsomes (36,37) and for erythrocyte membranes (38). In the present study, a slight decrease in brain PC content (Table 1), as well as a decrease in brain PC content relative to brain TL, was evident (Table 1). The liver PC content was decreased whether expressed relative to liver weight or to liver TL (Table 2). This PC decrease relative to TL and the changes in phospholipid composition may have a significant effect on membrane fluidity (38,39) in these organs and thus might change membrane function as well (40). As shown in this study, the organs showing a decrease in PC content were the brain and the liver, and only in these two organs was an age-dependent accumulation of PCOOH observed. The PC decrease may have resulted from peroxidative breakdown of PC as well as from changes in phospholipid metabolism that may occur during aging. The changes in phospholipid composition also seem to directly correlate with the susceptibility to hydroperoxidation of the membrane phospholipids themselves (40,41).

The content of α-tocopherol as one of the antioxidants in biomembranes did not decrease in the brain and liver upon aging (Tables 1 and 2), although PCOOH had significantly accumulated in these two organs. It thus appears that α-tocopherol cannot effectively function as an antioxidant and inhibit PC hydroperoxidation due to aging in brain or liver. It could alternatively suggest that higher α-tocopherol levels may be required to prevent phospholipid hydroperoxidation in the membranes of brain and liver during aging, as was suggested by Meydani *et al.* (42). Upon aging, an increase in superoxide radical formation (8) and a decrease in superoxide dismutase activity, catalase activity (11) and glutathione content (9) have been reported to occur in rat brain and in rat liver. The increase in PCOOH in rat brain and liver with age, as shown here, should also affect membrane association and activation of protein kinase C. It has been reported that oxidative modification of membrane lipids can result in persistent activation of protein kinase C (43,44).

The livers of 18-month-old male rats showed 10.4-fold higher PCOOH/PC ratios than 1-month-old rats (Table 4).

This enhanced PCOOH/PC molar ratio in liver lipids of the aged rats was however, significantly lower than that reported for the liver of mice (32.3×10^{-5}) fed a hepatocarcinogenic choline-deficient diet containing ethionine (24).

DHA content decreased in TL of the brain with aging. On the other hand, arachidonic acid and DHA content significantly increased in PC in aged brain. Brain PC containing arachidonic acid or DHA would be expected to be sensitive to hydroperoxidation in the course of aging.

In the present study, we have demonstrated that PCOOH accumulates as a primary peroxidation product of membrane phospholipids in brain and liver of the rat upon aging. These findings provide important evidence that oxidative damage occurs to membrane phospholipids in the course of senescence and aging as shown in this *in vivo* system.

[Received September 25, 1992, and in revised form February 8, 1993; Revision accepted June 16, 1993]

Modulation of Phosphatidylcholine Biosynthesis by Peroxisome Proliferating Fatty Acid Analogues

Jon Skorve[a,*], Asbjørn M. Svardal[b], Mohammed A. Mansoor[b] and Rolf K. Berge[a]

[a]Laboratory of Clinical Biochemistry and [b]Department of Pharmacology and Toxicology, University of Bergen, Haukeland Sykehus, 5021 Bergen, Norway

The modulation of phosphatidylcholine (PC) and phosphatidylethanolamine (PE) biosynthesis by sulfur-substituted fatty acid analogues has been investigated in rats. We have compared the effects of two non-β-oxidizable fatty acid analogues, 3-thiadicarboxylic acid and tetradecylthioacetic acid, which induce proliferation of peroxisomes, with those of the analogue tetradecylthiopropionic acid, which is a weak peroxisome proliferator. Repeated administration of 3-thiadicarboxylic acid for seven days resulted in increased hepatic concentrations of both PC and PE, but the PC/PE ratio was decreased. PC synthesis was increased, as evidenced by increased incorporation of [^{3}H]choline into PC and an increased activity of cytidinetriphosphate (CTP): phosphocholine cytidylyltransferase. This was accompanied by a reduction in the pool sizes of choline and phosphocholine. The *S*-adenosylmethione/*S*-adenosylhomocysteine ratio (AdoMet/AdoHcy) was marginally affected, indicating no increase in the rate of methylation of PE to PC. Administration of tetradecylthioacetic acid also resulted in increased hepatic phospholipid levels, increased AdoMet/AdoHcy ratios and in slightly elevated activity of CTP:phosphocholine cytidylyltransferase. The most striking effect observed after tetradecylthiopropionic acid treatment was the development of fatty liver. The activity of CTP:phosphocholine cytidylyltransferase and the incorporation of [^{3}H]choline into PC was reduced compared to 3-thiadicarboxylic acid treatment. Although the rate of methylation of PE seemed to be increased at an elevated AdoMet/AdoHcy ratio, this resulted in only minor changes in the hepatic PC and PE levels, and the PC/PE ratio remained unchanged. Furthermore, the hepatic levels of choline and phosphocholine were reduced in these rats. The activities of the two enzymes competing for choline in the liver, choline kinase and choline dehydrogenase were changed in opposite directions, with the activity of choline kinase increasing approximately 1.5-fold. In addition, it was found that the level of homocysteine was elevated in the liver of tetradecylthiopropionic acid-treated rats. The possibility is discussed that this reflects a reduced flux of choline through the oxidative pathway in the liver. In tetradecylthiopropionic acid-treated rats, there seemed to be a coordinated regulation of the two pathways for PC biosynthesis, with an increase in the methylation of PE to PC and a reduced synthesis *via* the CDPcholine pathway. The increase in PC observed in rats treated with 3-thiadicarboxylic acid and tetradecylthioacetic acid suggests that increased PC synthesis is linked to peroxisome proliferation.

Lipids 28, 795–801 (1993).

3-Thiadicarboxylic acid [HOOC-CH_2-S-$(CH_2)_{10}$-S-CH_2-COOH] and tetradecylthioacetic acid [CH_3-$(CH_2)_{13}$-S-CH_2-COOH] have been shown to be lipid-lowering agents and to decrease triacylglycerol, cholesterol and phospholipid levels in plasma (1–3). In addition, these agents are strong peroxisome proliferators, the dicarboxylic acid being the most potent (1). Both peroxisomal and mitochondrial β-oxidation are stimulated by these analogues (3–5). Tetradecylthiopropionic acid [CH_3-$(CH_2)_{13}$-S-CH_2-CH_2-COOH] is a weak peroxisome proliferator which inhibits mitochondrial β-oxidation, leading to the development of fatty liver. The agent is hypolipidemic when fed to rats in relatively high doses (2–4).

Phosphatidylcholine (PC) is the major phospholipid present in plasma lipoproteins and in liver (6). PC is synthesized mainly through the cytidinediphosphate(CDP)choline pathway (*de novo* pathway), but in the liver PC may also be synthesized by methylation of phosphatidylethanolamine (PE) (7). It is widely accepted that in the former pathway the rate-limiting step is the formation of CDPcholine from cytidinetriphosphate (CTP) and phosphocholine catalyzed by CTP:phosphocholine cytidylyltransferase (CPCT). It has been postulated that the activity of this enzyme is regulated by translocation of the inactive cytosolic form to the active microsomal form (8). The biosynthesis of PC may, however, be increased by an increase in the total activity of CPCT without any changes in the relative distribution of the enzyme (9,10). We have previously reported that sulfur-substituted fatty acid analogues modulate the activities of microsomal and cytosolic CPCT to the same extent (5). The enzyme was not translocated from the cytosolic to the microsomal fraction *in vivo*, although translocation of CPCT has been observed *in vitro* (11).

The methylation of PE to PC is catalyzed by PE *N*-methyltransferase, an enzyme associated with the microsomal fraction from rat liver. This enzyme is mainly regulated by the availability of the substrates PE and *S*-adenosylmethionine (AdoMet) (7) and, more importantly, the methylation of PE is modulated by the ratio between AdoMet and *S*-adenosylhomocysteine (AdoHcy) (12). Several studies have pointed to a coordinated control of the methylation pathway and the CDPcholine pathway, *i.e.*, one pathway is upregulated if the other is downregulated (7), although this is not always the case (13).

We wanted to extend our earlier studies on the effect of sulfur-substituted fatty acid analogues on the metabolism of phospholipids in rat liver and, in particular, further explore the differences between analogues which are strong and weak peroxisome proliferators. During the process of peroxisome proliferation, there must be an increase in membrane biosynthesis and, therefore, an increased demand for phospholipids. The more potent peroxisome proliferators increase the oxidation of fatty acids in contrast to the fatty

liver-promoting analogue, which inhibits the oxidation of fatty acids. The supply of fatty acids for glycerolipid synthesis may thus be quite different with these two groups of agents, which might in turn influence the biosynthesis of PC. In addition, it was of interest to examine the relative contribution of the two pathways in the synthesis of PC and to determine to what extent these pathways are coordinatedly regulated.

MATERIALS AND METHODS

Chemicals and drugs. 3-Thiadicarboxylic acid, tetradecylthioacetic acid and tetradecylthiopropionic acid were prepared as described earlier (3,14). *S*-Adenosyl-L-[*methyl*-^{3}H]methionine (62 Ci/mmol), [*methyl*-^{3}H]choline chloride (76 Ci/mmol), [*methyl*-^{14}C]choline chloride (55 mCi/mmol), CDP[*methyl*-^{14}C]choline (50 mCi/mmol) and phosphoryl-[*methyl*-^{14}C]choline (50 mCi/mmol) were purchased from the Radiochemical Centre (Amersham, England), and CDP[*ethanolamine*-1,2-^{14}C] (52 mCi/mmol) from ICN (Costa Mesa, CA). Choline chloride, CDPcholine, CDPethanolamine, phosphorylcholine, 1,2-dioleoyl-*sn*-glycerol and choline kinase were obtained from Sigma Chemical Co. (St. Louis, MO). Alkaline phosphatase was from Boehringer (Mannheim, Germany). All other chemicals were obtained from common commercial sources and were of reagent grade.

Animals and treatments. Male Wistar rats from Møllegaard Breeding Laboratory (Ejby, Denmark) weighing 150–200 g were housed individually in metal wire cages in a room maintained at a 12-h light-dark cycle and at a constant temperature of 20 ± 3°C. The animals were acclimatized for at least 5 d under these conditions before the start of the experiments. The fatty acid analogues were suspended in 0.5% sodium carboxymethyl cellulose and administered by gastric intubation in a volume of 0.7–1.0 mL once a day. The control animals received only sodium carboxymethyl cellulose. All animals had free access to water and food. At the end of the experiments, the fasted rats (12 h) were lightly anesthetized and cardiac puncture was performed. The livers were removed and immediately chilled on ice and weighed.

In experiments with [*methyl*-^{3}H]choline chloride, rats were lightly anesthetized and the radioactive isotope (40 μCi in 0.4 mL saline) was injected through the tail vein. Rats were killed 15 min later and 1 g of fresh liver was immediately extracted with 20 mL of chloroform/methanol (2:1, vol/vol) (15). The incorporation of labeled choline into PC was determined by subjecting an aliquot of the washed chloroform phase to silicic acid thin-layer chromatography (TLC) in chloroform/metanol/acetic acid/water (50:30:7:3, by vol.) The bands were visualized with I_2 vapor, and the bands corresponding to PC were scraped into liquid scintillation vials and counted.

Preparation of total homogenate and cellular fractions. The livers from individual rats were homogenized in ice-cold sucrose medium [0.25 M sucrose in 10 mM *N*-(2-hydroxyethyl)piperacine-*N'*-(2-ethanesulfonic acid) (HEPES) buffer, pH 7.4] and 2 mM ethylenediaminetetraacetic acid (EDTA). The postnuclear fraction was used for further analysis by differential centrifugation. Samples from three animals were pooled and mitochondria-enriched, peroxisome-enriched, and microsomal and cytosolic fractions were isolated (1).

Other analytical methods. The activity of cholinephosphotransferase was measured in the microsomal fraction as described by Weinhold *et al.* (16), with some modifications. The assay mixture contained 50 mM Tris/HCl (pH 8.0), 20 mM $MgCl_2$, 1 mM dithiothreitol (DTT), 1 mM ethyleneglycol-*bis*(β-aminoethyl ether(*N,N'*-tetraacetic acid (EGTA), 1 mM 1,2-dioleoyl-*sn*-glycerol and 0.2 mg/mL Tween 20. The mixture was sonicated, microsomes (0.2 mg/mL) and CDP[*methyl*-^{14}C]choline (1 mM) were added, and the reaction mixture was incubated for 15 min at 37°C. Ethanolaminephosphotransferase activity was assayed by an identical assay except for the use of CDP-[*ethanolamine*-1,2-^{14}C]ethanolamine as substrate instead of CDP[*methyl*-^{14}C]choline. Choline dehydrogenase was assayed oxygraphically in the mitochondrial fraction as described previously (17). Choline kinase was assayed in the cytosolic fraction with [*methyl*-^{14}C]choline chloride as substrate (18). CPCT was assayed in the cytosolic and in the microsomal fraction with phosphoryl[*methyl*-^{14}C]choline as substrate (19). PE *N*-methyltransferase activity was measured in the microsomal fraction as incorporation of [*methyl*-^{3}H] from *S*-adenosyl-L-[*methyl*-^{3}H]methionine into PE (20), and the products were isolated and quantitated by TLC as described by Schanche *et al.* (21).

The amounts of choline and phosphocholine were determined in the water-soluble fraction after lipid extraction of the liver. Aliquots were analyzed as described by Post *et al.* (22), except that the column (Dowex AG1-X8) was eluted as described in the assay for choline kinase. The level of homocysteine (Hcy) in the liver was determined with a radio-enzymic assay (23), whereas AdoHcy and AdoMet were determined in an acid extract by high-performance liquid chromatography (HPLC) (24).

Total phospholipid content was determined using the Monotest phospholipids enzymatic kit (Boehringer). Hepatic levels of PE and PC were quantitated using an Iatroscan TH-10 TLC + FID (latron) instrument. One-μL samples were spotted on Chromarods consisting of sintered layers precoated with silica gel. The rods were developed first in ethyl acetate/isooctane/glacial acetic acid/water (9:5:2:10, by vol; upper phase) and then in chloroform/methanol/40% methylamine (120:35:5, by vol), and the resulting chromatograms were analyzed using software from Boreal (Flotec, France). Standard curves for PE and PC were used in calculating the amounts of phospholipids present in the samples.

Statistical analysis. The results are presented as means ± SD from three animals unless otherwise stated. Enzymatic activities were determined in pooled fractions from three treated animals, and in this case the results are given only as means. Control activities were determined in nine to twelve animals and are given as means ± SD. Differences were tested by a two-way analysis of variance at 95% confidence interval using a statistical software package (StatView SE; Abacus Concepts Inc., Brain Power Inc., Calabasas, CA).

RESULTS

Plasma and liver phospholipid levels. Administration of the hypolipidemic fatty acid analogues, 3-thiadicarboxylic acid and tetradecylthioacetic acid significantly lowered plasma phospholipid levels consistent with what has been observed previously (1) (Table 1). These two analogues at

TABLE 1

Hepatic and Plasma Phospholipid Levels in Rats Fed Sulfur-Substituted Fatty Acid Analogues for Seven Days[a]

Treatment	Dose (mg/d/kg body weight)	Hepatic phospholipids (μmol/g liver)	Plasma phospholipids (μmol/mL)
Control	0	19.0 ± 1.4	1.50 ± 0.18
3-Thiadicarboxylic acid	75	21.1 ± 0.2[b]	1.10 ± 0.15[b]
	250	22.6 ± 0.4[b]	0.82 ± 0.30[b]
Tetradecylthioacetic acid	75	21.6 ± 1.8	1.05 ± 0.25
	250	23.2 ± 2.2[b]	0.90 ± 0.15[b]
Tetradecylthiopropionic acid	75	19.5 ± 1.1	1.60 ± 0.15
	250	20.1 ± 0.9	1.90 ± 0.10[b]

[a]The tabulated values are the means ± SD of twelve control animals and three rats in each experimental group.
[b]$P < 0.05$ for difference between control and treated rats.

the highest dose used also increased hepatic phospholipid levels by approximately 15–20%. The agents have also been shown to cause moderate hepatomegaly increasing relative liver weights by 30–40% after 7 d of feeding (1,4). Taking this into account, the increase in liver phospholipids is actually greater than seen from Table 1. Tetradecylthiopropionic acid, on the other hand, only marginally affected hepatic phospholipid levels, but increased plasma phospholipid levels.

To further elucidate the effect of the fatty acid analogues on phospholipid metabolism, an experiment was carried out in which rats were fed 3-thiadicarboxylic acid and tetradecylthiopropionic acid for seven days. The rats were then injected intravenously with [^{3}H]choline and killed 15 min later. Hepatic PC levels and PE levels were measured, and as can be seen from Table 2 the levels of both changed in the same direction. 3-Thiadicarboxylic acid increased both the PC and PE content, and in these rats the rate of synthesis of PC increased as shown by a higher incorporation of [^{3}H]choline into PC as compared to controls and to tetradecylthiopropionic acid-treated rats. In contrast, no significant changes were observed in the hepatic concentrations of PC and PE and in the incorporation of [^{3}H]choline into PC after tetradecylthiopropionic acid administration (Table 2). It is worth noting, however, that the changes observed in the PC and PE levels were not of the same order, resulting in a decreased ratio of PC to PE in the 3-thiadicarboxylic acid-fed animals. Tetradecylthiopropionic acid treatment, on the other hand, tended to increase the ratio between PC and PE compared to 3-thiadicarboxylic acid-treated rats (Table 2).

Regulation of the CDPcholine pathway. The enzyme choline kinase catalyzes the phosphorylation of choline, the first step in the CDPcholine pathway of PC biosynthesis. This enzyme competes for choline with choline dehydrogenase, which catalyzes the oxidation of choline to betaine (25). Betaine acts as a methyl donor in the conversion of Hcy to methionine in the liver (Fig. 1).

The activities of these two enzymes have been measured in liver of rats treated with the different fatty acid analogues. Tetradecylthiopropionic acid increased the activity of choline kinase (Table 3), whereas all three analogues decreased the activity of choline dehydrogenase. More informative, however, is to compare the ratio of choline dehydrogenase and choline kinase activities (Fig. 2). This ratio was decreased after administration of tetradecylthiopropionic acid. After seven days of feeding this analogue, the ratio was decreased nearly threefold, indicating a change in the choline flux away from the oxidative pathway. In contrast, 3-thiadicarboxylic acid and tetradecylthioacetic acid marginally elevated the ratio between choline dehydrogenase and choline kinase activities.

TABLE 2

Changes in Hepatic Levels of Phospholipids, Phosphocholine and Choline and in the Incorporation of [^{3}H]Choline into Phosphatidylcholine in Liver of Rats Treated with Fatty Acid Analogues for Seven Days at a Dose of 150 mg/d/kg Body Weight[a]

	Control	3-Thiadicarboxylic acid	Tetradecylthiopropionic acid
PC (mg/g liver)	11.33 ± 0.81	13.42 ± 1.01[b]	10.51 ± 1.07[c]
PE (mg/g liver)	5.90 ± 0.48	7.72 ± 1.10[b]	5.23 ± 0.72[c]
Ratio (PC/PE)	1.94	1.76	2.02
Choline (μmol/g liver)	0.114 ± 0.025	0.053 ± 0.016[b]	0.072 ± 0.025[b]
Phosphocholine (μmol/g liver)	1.54 ± 0.21	1.12 ± 0.16[b]	1.19 ± 0.28[b]
Incorporation of [^{3}H]choline into PC (cpm/15 min/g liver)	4783 ± 670	8415 ± 1570[b]	4560 ± 990[c]

[a]The tabulated values are the means ± SD of four to five rats in each experimental group. Phosphatidylcholine, PC; phosphatidylethanolamine, PE.
[b]$P < 0.05$ for difference between control and treated rats.
[c]$P < 0.05$ for difference between the two treatment groups.

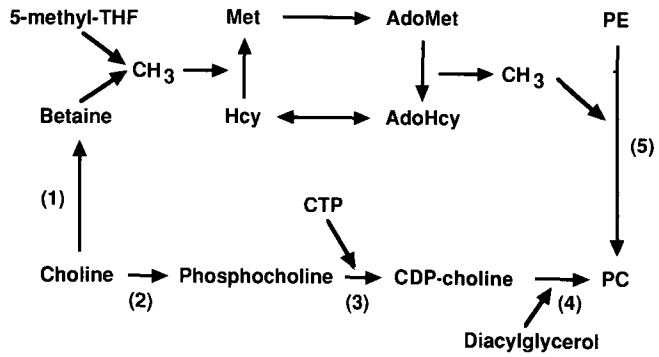

FIG. 1. Interrelationship between choline, methionine and phosphatidylcholine metabolism; THF, tetrahydrofolate; Met, methionine; AdoMet, *S*-adenosylmethionine; AdoHcy, *S*-adenosylhomocysteine; Hcy, homocysteine; CTP, cytidinetriphosphate; PE, phosphatidylethanolamine; PC, phosphatidylcholine; (1), choline dehydrogenase; (2), choline kinase; (3), CTP:phosphocholine cytidylyltransferase; (4), cholinephosphotransferase; (5), PE *N*-methyltransferase.

We have previously reported that CPCT activity is elevated in rats treated with 3-thiadicarboxylic acid and tetradecylthioacetic acid, in which hepatic phospholipid levels are also increased. The activity changed in parallel fashion in the microsomal and the cytosolic fractions (5). This also can be seen from Tables 2 and 3, where the hepatic PC levels and the changes in the total enzyme activities are tabulated. In contrast, the total CPCT activity was reduced by approximately 25% in tetradecylthiopropionic acid-trated rats (Table 2).

The activity of the last enzyme in the CDPcholine pathway, cholinephosphotransferase, was only marginally affected by tetradecylthiopropionic acid for up to 7 d of feeding, but was stimulated by 25% after 14 d. 3-Thiadicarboxylic acid increased cholinephosphotransferase activity after administration for a few days, whereas tetradecylthioacetic acid decreased it by more than 25% after only one day of feeding (Fig. 3).

Hepatic choline and phosphocholine levels were also changed in rats fed the fatty acid analogues. 3-Thiadicarboxylic acid reduced the levels of both significantly, and tetradecylthiopropionic acid feeding tended to decrease the pool sizes of both metabolites, although to a lesser extent than did the dicarboxylic acid (Table 2).

PE synthesis and the methylation pathway to PC. PE is synthesized *via* the CDPethanolamine pathway, which parallels the CDPcholine pathway. The final enzyme in this pathway, ethanolaminephosphotransferase, catalyzes the transfer of CDPethanolamine to 1,2-diacyl-*sn*-glycerol. The enzyme PE *N*-methyltransferase can then *N*-methylate phosphatidylethanolamine by successive transfer of methyl groups from AdoMet, giving the final product PC (Fig. 1). Repeated administration of 3-thiadicarboxylic

TABLE 3

Changes in Relative Specific Activities of Enzymes Involved in Choline Metabolism in Rats Treated with Fatty Acid Analogues for Seven Days at a Dose of 150 mg/d/kg Body Weight[a]

Enzyme	3-Thiadicarboxylic acid	Tetradecylthioacetic acid	Tetradecylthiopropionic acid
Choline dehydrogenase	83.1	86.2	69.1
Choline kinase	78.3	67.7	152.0
CPCT (total)	122.0	109.3	75.2
Cholinephosphotransferase	116.7	75.6	105.0

[a]The enzyme activities represent the means of pooled fractions from three treated animals and are presented relative to those of nine control animals (see Materials and Methods). Control values (100%): Choline kinase, 42.7 ± 5.8; cytidinetriphosphate:phosphocholine cytidylyltransferase (CPCT), 53.8 ± 5.3; cholinephosphotransferase, 249.45 ± 21.6; choline dehydrogenase, 396.2 ± 35.0 nmol/min/g liver.

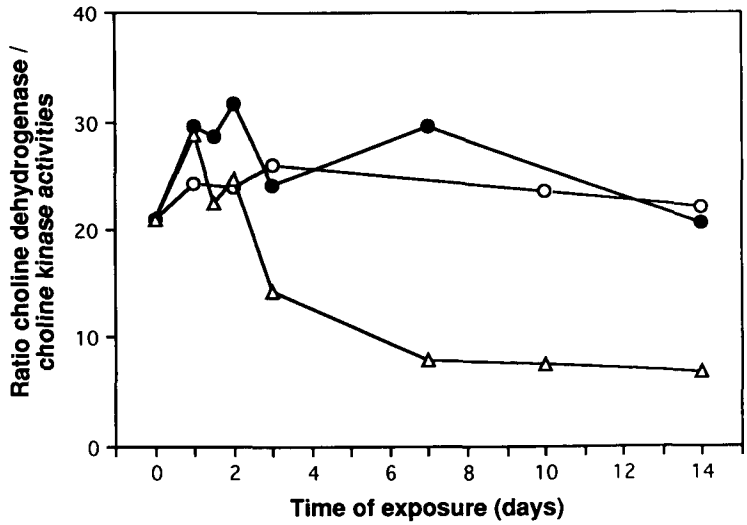

FIG. 2. Effect of 3-thiadicarboxylic acid (○), tetradecylthioacetic acid (●), and tetradecylthiopropionic acid (△) on the ratio of choline dehydrogenase and choline kinase activities. Rats were fed fatty acid analogues at a dose of 150 mg/day/kg body weight. Enzyme activities were determined in pooled fractions from three animals as described in Materials and Methods.

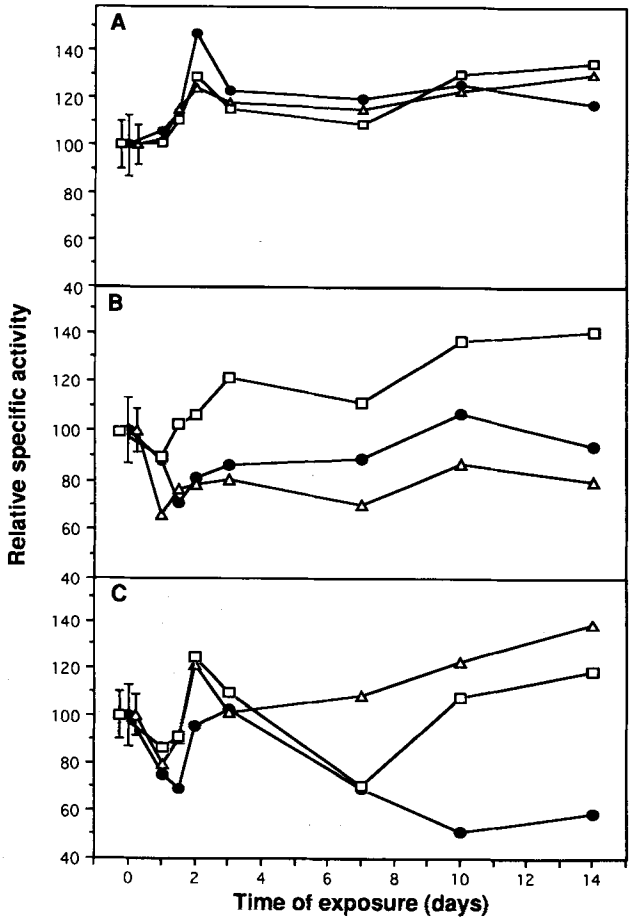

FIG. 3. Effect of 3-thiadicarboxylic acid (A), tetradecylthioacetic acid (B), and tetradecylthiopropionic acid (C) on the activities of phosphatidylethanolamine (PE) *N*-methyltransferase (●), cholinephosphotransferase (△), and ethanolaminephosphotransferase (□). Rats were fed fatty acid analogues at a dose of 150 mg/d/kg body weight. The enzyme activities represent the means of pooled fractions from three treated animals and are presented relative to those of nine control animals (see Materials and Methods). Control values (100%); PE *N*-methyltransferase, 4.23 ± 0.53; cholinephosphotransferase, 249.45 ± 21.6; ethanolaminephosphotransferase, 71.95 ± 7.2 nmol/min/g liver.

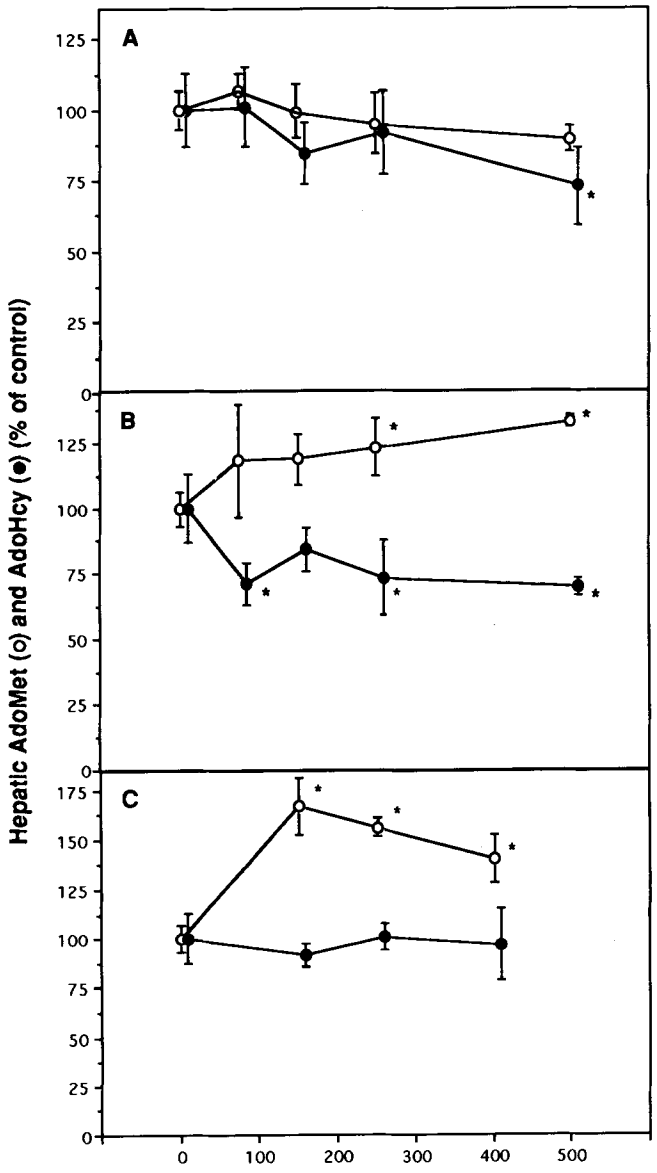

FIG. 4. Effect of 3-thiadicarboxylic acid (A), tetradecylthioacetic acid (B), and tetradecylthiopropionic acid (C) on hepatic AdoMet (○) and AdoHcy (●) levels. Rats were fed fatty acid analogues for seven days. The tabulated values are the means ± SD of twelve control animals and three rats in each experimental group. *$P < 0.05$ for difference between control and treated rats. Control values (100%); AdoMet, 151.1 ± 10.1; AdoHcy, 20.7 ± 2.6 nmol/g liver. Abbreviations as in Figure 1.

acid significantly enhanced the level of PE (Table 2). The activities of ethanolaminephosphotransferase and PE *N*-methyltransferase were both increased, an effect that was apparent after two days of feeding (Fig. 3). Tetradecylthioacetic acid had the same effect on the former enzyme, whereas the activity of PE *N*-methyltransferase was essentially unchanged. In contrast, the fatty liver producing analogue, tetradecylthiopropionic acid, decreased the activity of the latter enzyme; PE *N*-methyltransferase activity was decreased by more than 50% after prolonged feeding.

AdoMet functions as a methyl donor in cells, which provides methyl groups for a variety of acceptors, including PE. AdoHcy, the by-product in these reactions, is hydrolyzed to Hcy. Hcy can then be remethylated to methionine, obtaining methyl groups either from 5-methyltetrahydrofolate or from betaine (Fig. 1).

Repeated administration of 3-thiadicarboxylic acid slightly decreased the hepatic level of both AdoMet and AdoHcy (Fig. 4). Calculation of the AdoMet/AdoHcy ratio showed that this parameter was unchanged (Table 4). Tetradecylthioacetic acid increased the hepatic level of AdoMet, amounting to a 40% increase at the highest doses used, while the AdoHcy level was decreased. Overall, this resulted in an increased AdoMet/AdoHcy ratio (Table 4). Tetradecylthiopropionic acid also increased the AdoMet/AdoHcy ratio, in this case mainly due to an increase in AdoMet. The ratio increased by nearly 70% at a dose of 150 mg/d/kg body weight (Fig. 4).

The level of Hcy was increased in liver (Table 4) and plasma (data not shown) after feeding tetradecylthiopro-

TABLE 4

Effect of Sulfur-Substituted Fatty Acid Analogues on the Amount of Sulfur-Containing Metabolites in Liver and Plasma of Rats Fed Fatty Acid Analogues for Seven Days[a]

Treatment	Dose (mg/d/kg body weight)	Ratio AdoMet/AdoHCy	Homocysteine (nmol/g liver)
Control	0	7.4 ± 1.0	6.3 ± 1.1
3-Thiadicarboxylic acid	150	8.7 ± 1.3[b]	n.d.
	250	7.8 ± 1.8[c]	8.6 ± 1.3[b]
Tetradecylthioacetic acid	150	10.4 ± 0.7[d]	9.9 ± 2.5
	250	10.8 ± 1.7[d]	7.5 ± 2.2
Tetradecylthiopropionic acid	150	13.4 ± 1.1[d]	n.d.
	250	11.4 ± 0.7[d]	13.3 ± 2.4[d]

[a]The tabulated values are the means ± SD of nine control animals and three rats in each experimental group. n.d., not determined. AdoMet, *S*-adenosylonethionine; AdoHCy, *S*-adenosylhomocysteine.
[b]$P < 0.05$ for different means from tetradecylthiopropionic acid-treated rats.
[c]$P < 0.05$ for different means from tetradecylthioacetic acid- and tetradecylthiopropionic acid-treated rats.
[d]$P < 0.05$ for different means from the control rats.

pionic acid, while 3-thiadicarboxylic acid and tetradecylthioacetic acid tended to increase the hepatic homocysteine levels, although not significantly.

DISCUSSION

In this study we have investigated the modulation of phospholipid metabolism in the liver of rats fed different fatty acid analogues. The fatty acid analogues can conveniently be divided into two groups. 3-Thiadicarboxylic acid and tetradecylthioacetic acid act as strong peroxisome proliferators and have hypolipidemic effects. Tetradecylthiopropionic acid is a weak peroxisome proliferator (1,4). The most striking effect observed in rats treated with this analogue is the formation of fatty liver. The peroxisome proliferating analogues increase hepatic phospholipid levels (Table 1), which may be rationalized by an increased demand for membrane biosynthesis. Tetradecylthiopropionic acid, as a very weak peroxisome proliferator, does not elevate hepatic phospholipid levels.

The strongest peroxisome proliferator, 3-thiadicarboxylic acid, increases hepatic levels of both PC and PE (Table 2). The PC/PE ratio decreased, however, as the increase in PE was greater than the increase in PC. The same phenomenon has been observed in rats treated with other peroxisome proliferators, such as di(2-ethylhexyl)phthalate (26). The higher PC level may be due either to increased synthesis *via* the CDPcholine pathway or to increased methylation of PE. 3-Thiadicarboxylic acid increased the choline flux through the CDPcholine pathway, as evidenced by a higher incorporation of [^{3}H]choline into PC (Table 2). It can also be seen that the pool sizes of choline and phosphocholine were decreased, suggesting an increased utilization of these metabolites. The amount of [^{3}H]choline incorporated into PC is probably an overestimation of the rate of PC synthesis, as the decreased pool size of choline will increase the specific activity of [^{3}H]choline in the 3-thiadicarboxylic-treated rats. However, the incorporation of choline was clearly higher than in rats administered tetradecylthiopropionic acid as the choline pool was also decreased in these rats. The activity of the rate-limiting enzyme in the CDPcholine pathway, CPCT (microsomal plus cytosolic) was increased (Table 3), again suggesting an increased PC synthesis *via* this pathway. The activity was increased both in the microsomal and in the cytosolic fraction (5). Studies with partially hepatectomized rats (10) provided results very similar to those obtained in the 3-thiadicarboxylic-treated rats. In hepatectomized rats the increase in total CPCT activity was found to be due to increased enzyme mass as shown by immunotitration.

The increase in hepatic PC in 3-thiadicarboxylic acid treated rats may also result from increased methylation of PE. The PE *N*-methyltransferase activity measured *in vitro* was increased (Fig. 3), which may be related to the relative increase in PE in the membranes (Table 2). It has been reported that the level of PE in the membrane may influence the activity of this enzyme *in vitro*, while the *in vivo* activity was shown to be dependent on the availability of substrates (27). The amount of AdoMet was slightly decreased, and the ratio AdoMet/AdoHcy did not change significantly (Table 4). Altogether, this points to only small changes in the rate of methylation of PE in the 3-thiadicarboxylic-treated rats.

The weak peroxisome proliferator, tetradecylthiopropionic acid, had only minor effects on the levels of PC and PE, which were slightly, although not significantly, reduced. The incorporation of [^{3}H]choline into PC was well below what was found in 3-thiadicarboxylic acid-treated rats (Table 2), while the choline pool tended to be decreased. The decrease in the activity of CPCT (Table 3) points to a reduced synthesis of PC *via* the CDPcholine pathway. It can also be seen that the ratio of the activities of the choline metabolizing enzymes choline dehydrogenase and choline kinase was greatly reduced (Fig. 2), mainly due to a 1.5-fold increase in choline kinase activity. Choline kinase has an apparent K_m value for choline that is much smaller than the corresponding value for choline dehydrogenase (17,28). The observed changes may thus reflect a change in the choline flux away from the oxidative pathway and into the CDPcholine pathway in tetradecylthiopropionic acid-treated rats. However, this seems not to be sufficient to prevent a reduced synthesis of PC by this pathway. The hepatic level of AdoMet and the AdoMet/Ado-Hcy ratio are, however, elevated in these rats (Fig. 4). This could result in increased methylation of PE

to PC (7) to compensate for the decrease in PC synthesis *via* the CDPcholine pathway. In a recent report (29) in which the diurnal variation of PE methylation was described, a high AdoMet/AdoHcy ratio was found to correlate with a high PC/PE ratio, suggesting a high flux of methyl groups from AdoMet to PE under these conditions.

It has been reported that ethionine, a structural analogue of methionine, changes the choline flux in much the same way as does tetradecylthiopropionic acid (30). Both ethionine and tetradecylthiopropionic acid treatment result in a substantial increase in the hepatic level of Hcy and cause fat accumulation in the liver (31). The increase in the hepatic Hcy level observed in tetradecylthiopropionic acid-treated rats (Table 4) could thus be due to the reduced flux of choline through the oxidative pathway, thereby reducing the availability of methyl groups for methylation of homocysteine to methionine (Fig. 1). The higher AdoMet level observed in the same rats might contribute to this effect, as AdoMet may act as an allosteric inhibitor of 5,10-methylenetetrahydrofolate reductase (32), thereby reducing the level of 5-methyltetrahydrofolate, which is the other possible methyl donor for methylation of Hcy.

The AdoMet/AdoHcy ratio is also elevated in tetradecylthioacetic acid-treated rats (Table 4), and the total activity of CPCT is increased slightly (Table 3). The increase in hepatic PC content observed in these rats might thus be due both to an enhanced rate of methylation of PE and to a slight stimulation of the CDPcholine pathway.

The results presented in this study are in accordance with CPCT being the rate-limiting enzyme in the synthesis of PC *via* the CDP-choline pathway. Tetradecylthiopropionic acid is the only analogue which does not increase the hepatic phospholipid level, and is also the only analogue that does not increase the CPCT activity. The other two analogues increase the activity of both the microsomal and cytosolic cytidylyltransferase; translocation of the enzyme from the cytosolic to the microsomal fraction could not be observed (10).

In tetradecylthiopropionic acid-treated rats there seems to be a coordinated regulation of the two pathways for PC synthesis, the increase in the methylation of PE compensating for a reduced flux through the CDPcholine pathway. The possibility should be considered that limited availability of choline could increase the flux through the methylation pathway, thereby stimulating *de novo* synthesis of choline. In 3-thiadicarboxylic acid- and tetradecylthioacetic acid-treated rats, where hepatic phospholipid levels are elevated, the methylation of PE to PC seems to be increased if the CDPcholine pathway cannot supply the required amount of PC.

ACKNOWLEDGMENTS

The authors are grateful to Svein Krüger and Terje Bjørndal for excellent technical assistance. We wish to thank Dr. Holm Holmsen for valuable assistance in determining the levels of hepatic phospholipids. The work was supported by the Norwegian Council on Cardiovascular Diseases, The Norwegian Cancer Society, Odd Fellow Vitenskapelige Forskningsfond and Nordisk Insulinfond.

Distribution of Ubiquinone and Ubiquinol Homologues in Rat Tissues and Subcellular Fractions

Takayuki Takahashi, Tadashi Okamoto, Koichi Mori, Hiroteru Sayo and **Takeo Kishi***
Faculty of Pharmaceutical Sciences, Kobe-Gakuin University, Nishi-ku, Kobe 651-21, Japan

The oxidized (UQ_{ox}) and reduced (UQ_{red}) forms of ubiquinone (UQ) homologues in rat tissues and subcellular fractions were analyzed to elucidate their distribution and physiological role. UQ-9 and UQ-10 were detected in all tissues studied, and UQ-9 was the predominant homologue. The total amount of UQ_{ox}-10 and UQ_{red}-10 was 20–50% that of UQ_{ox}-9 and UQ_{red}-9. The levels of these homologues were highest in heart with lesser amounts occurring in kidney, liver and other organs. In liver and blood plasma, the UQ_{red} homologue amounted to 70–80% of the total UQ (UQ_{ox} + UQ_{red} = t-UQ). UQ_{red} was less than 30% of t-UQ in other tissues and blood cells. t-UQ was much higher in leukocytes and platelets in blood than in erythrocytes. In erythrocytes, t-UQ was exclusively located in the cell membranes. UQ_{ox} and UQ_{red} were also found in all subcellular fractions isolated from liver and kidney in about the same ratio as UQ_{red}/t-UQ was present in the whole organ. The levels of UQ_{ox} and UQ_{red} per mg protein in subcellular fractions from liver were highest in mitochondria, with lesser amounts present in plasma membranes, lysosomes, Golgi complex, nuclei, microsomes and cytosol. In the mitochondria, the outer membranes were richer in t-UQ than the inner membranes. In the Golgi complex, the light and intermediate fractions were rich in t-UQ when compared to the heavy fraction. The possible physiological role of UQ_{ox} and UQ_{red} in tissues and subcellular fractions is discussed.
Lipids 28, 803–809 (1993).

It is well-known that ubiquinone (UQ) functions as one of the indispensable electron carriers in the mitochondrial respiratory chain (1). This is the only established role of UQ in mammalian tissues. UQ can be synthesized *de novo* at the mitochondrial inner membrane (2) where the respiratory chain is located.

However, UQ has been detected not only in mitochondria, but also in other subcellular fractions (3,4). In addition, some of the UQ in tissues was reported not to be the oxidized form (UQ_{ox}), but the reduced form, ubiquinol (UQ_{red}) (5,6). UQ was also found in human and in animal blood plasma (7,8). A certain level of serum UQ is detected even in patients on long-term UQ-free total parenteral nutrition (9). Therefore, UQ appears to be a native component of plasma lipids.

Recently, Dallner and colleagues (4,10) showed that subcellular organelles of rat liver other than the mitochondria, such as the endoplasmic reticulum and Golgi apparatus, are able to synthesize UQ *de novo* and that UQ synthesized at these sites was then secreted into the bloodstream by the endoplasmic reticulum/Golgi system.

In a previous paper (11) we reported that 85% of the total amount of UQ_{ox} and UQ_{red} (t-UQ) in serum exists as UQ_{red}, and that such a high ratio of UQ_{red}/t-UQ was maintained even when the level of t-UQ in serum was enhanced by oral supplementation with UQ_{ox}. This means that UQ_{ox} taken orally is also reduced to UQ_{red} at the expense of reducing equivalents such as NAD(P)H. It is not known why serum needs to maintain such a high level of UQ_{red} and where and how UQ_{ox}, either taken orally or synthesized *de novo*, is hydrogenated and converted to UQ_{red}.

However, these observations strongly suggested that UQ_{ox} and UQ_{red} in plasma and in subcellular fractions other than the mitochondria may play some physiologically important roles. Therefore, a systematic analysis of the distribution of UQ_{ox} and UQ_{red} in animal tissues and subcellular organelles was considered necessary.

In this study we have analyzed the amounts of t-UQ and UQ_{red} homologues in subcellular fractions of liver and kidney, as well as other rat tissues.

MATERIALS AND METHODS

Materials. The UQ_{ox}-9 and UQ_{ox}-10 were donated by Eisai Co. (Bunkyo-ku, Tokyo, Japan). UQ_{red} homologues were prepared by reducing the corresponding UQ_{ox} homologues with 0.25% sodium borohydride in ethanol solution. All other chemicals used were of the highest grade commercially available. Specific pathogen-free, male Wistar rats (8-weeks-old and 180–200 g body weight) were purchased from SLC Co. (Shizuoka, Japan) and fed MF, a commercial diet (Oriental Yeast Co., Tokyo, Japan), prior to the experiments.

Cell fractionation. The rats were anesthetized with diethyl ether, injected with 0.2 mL of a heparin (1,000 U/mL) through the femoral vein, and then dissected. First, blood was drawn from the abdominal aorta into a heparinized vacutainer. Next, the liver was perfused with 20 mL of a chilled isotonic saline through the hepatic portal vein to the inferior *vena cava*, and then the organs intended for UQ analysis were removed. Blood was fractionated into plasma and cells, such as erythrocytes, leukocytes and platelets, using the Shibata and Kobayashi method (12). The erythrocyte fraction was purified by removing leukocytes and platelets by the Beutler and West method (13). Ghost cells and endosomes of erythrocytes were prepared by the method of Dodge *et al.* (14). Upon removal, the organs were homogenized immediately with 4 vol of chilled 50 mM Tris-HCl buffer (pH 7.4) containing 0.25 M sucrose and 1 mM ethylenediaminetetraacetic acid using a Potter-Elvehjem glass-Teflon homogenizer. Nuclei, mitochondria, crude lysosomes, crude microsomes (containing Golgi complex) and the cytosolic fraction were prepared from tissue homogenates by differential centrifugation at 600 × *g* for 10 min,

Abbreviations: LDH, lactate dehydrogenase; LDL, low-density lipoprotein; Mg^{2+}-ATPase, Na^+,K^+-insensitive Mg^{2+}-adenosinetriphosphatase; Na^+-K^+-ATPase, Na^+,K^+-sensitive Mg^{2+}-adenosinetriphosphatase; NADPH-cyt.c, NADPH-cytochrome c; RNA, ribonucleic acid; suc-cyt.c, succinate-cytochrome c; UQ, ubiquinone; UQ_{ox}, oxidized form of ubiquinone; UQ_{red}, reduced form of ubiquinone (ubiquinol); t-UQ, oxidized and reduced forms of ubiquinone.

6,500 × *g* for 20 min, 10,000 × *g* for 15 min, 105,000 × *g* for 60 min and 105,000 × *g* for 60 min, respectively, essentially as described by Hogeboom (15). The nuclear fraction was purified further by the Blobel and Potter method (16) from the residues precipitated at the centrifugation step at 600 × *g* for 10 min. The purities of the subcellular fractions were ascertained by measuring marker enzyme activities. The distribution of marker enzymes in the subcellular fractions prepared from liver and kidney is summarized in Table 1.

Nucleoli, nucleolar wash and extranucleolar fractions were isolated from the nuclear fraction by the Muramatsu and Busch method (17).

Subfractions of the mitochondrial inner and outer membranes and the matrix were prepared from the mitochondrial pellets (see above) by the method of Sottocasa *et al.* (18). The specific activities (means ± SEM of three preparations, nmol/mg protein/min) of succinate-cytochrome c (suc-cyt.c) reductase, a marker enzyme of the inner membranes, were 229 ± 61 for the inner membrane fractions, 42.7 ± 18.2 (19% that of the inner membranes) for the outer membrane fractions, and 5.2 ± 4.4 (2%) for the matrix fractions. On the other hand, the specific activities (means ± SEM of three preparations, nmol/mg protein/min) of monoamine oxidase (EC 1.4.3.4), a marker enzyme of the outer membranes, were 105 ± 12 for the outer membrane fractions, 10.4 ± 5.3 (10% of that of the outer membranes) for the inner membrane fractions, and 10.6 ± 2.5 (10%) for the matrix fractions.

The crude lysosomes were further fractionated to the following subfractions: Ly-1 ($d \leqslant 1.109$), Ly-2 ($1.109 < d < 1.135$), Ly-3 ($1.135 < d < 1.145$) and Ly-4 ($1.145 \leqslant d$), using discontinuous metrizamide gradient centrifugation as described by Wattiaux *et al.* (19). From the marker enzyme activities, 70% of lysosomes in the crude lysosomes was located in Ly-2, which also contained 16% of mitochondria, 41% of microsomes and 3% of peroxisomes found in the crude lysosomes. At the same time, 76% of mitochondria and 83% of peroxisomes in the crude lysosomes were found in Ly-4.

Subfractions of the Golgi complex, *i.e.,* the light fraction, the intermediate fraction and the heavy fraction, were prepared directly from the liver homogenates of rats which had been orally given 0.6 g ethanol/100 g body weight (as 50% ethanol solution) 90 min before the enucleation using the sucrose density-gradient centrifugation method of Ehrenreich *et al.* (20). Contamination of the Golgi fractions with other subcellular fractions were estimated to be less than 3% based on measurement of marker enzyme activities, *i.e.,* suc-cyt.c reductase, acid phosphatase (EC 3.1.3.2),, NADPH-cytochrome c (NADPH-cyt.c) reductase (EC 1.6.2.4) and lactate dehydrogenase (LDH, EC 1.1.1.27), and ribonucleic acid (RNA) content.

Smooth and rough endoplasmic reticular fractions were also separated by the Ikehara and Pitot method (21) from the residues obtained by centrifugation at 75,000 × *g* for 3 h in preparing the Golgi fractions mentioned previously. RNA levels (means ± SEM of three preparations, nmol/mg protein), a marker of the rough endoplasmic reticulum, were 201 ± 4 for the rough endoplasmic reticular fractions and 22 ± 6 (11% of the former) for the smooth endoplasmic reticular fractions. Contamination of the microsomal fractions with other subcellular fractions were estimated to be less than 5%, based on measurements of marker enzyme activities.

Plasma membrane fractions, independent of previously described sequential fractionation of subcellular fractions, were also prepared from normal rat liver by the method of Koizumi *et al.* (22). The specific activities of the marker enzymes in the plasma membranes are also shown in Table 1.

Enzyme assays. Microsomal NADPH-cyt.c reductase activity was determined based on the rate of reduction of ferricytochrome c by the subcellular fractions in the presence of NADPH (23). The activity of suc-cyt.c

TABLE 1

Distribution of Marker Enzyme Activities in Subcellular Fractions of Rat Liver and Kidney[a]

Subcellular fractions	Suc-cyt.c reductase	Acid phosphatase	NADPH-cyt.c reductase	LDH	Mg^{2+}-ATPase	Na^{+}-K^{+}-ATPase
Liver

[a]The values are means ± SEM of relative enzyme activities (%) measured on four rats used for liver preparations and three rats used for kidney preparations. The specific activities of marker enzymes in liver and kidney were as follows (respectively): 157 ± 22 and 22.8 ± 3.6 nmol/mg protein/min for succinate-cytochrome c (suc-cyt.c) reductase in the mitochondria; 745 ± 26 and 12.8 ± 3.3 nmol/mg protein/min for acid phosphatase in crude lysosomes; 51 ± 5 and 13.3 ± 0.6 nmol/mg protein/min for NADPH-cyt.c reductase in the crude microsomes; and 14.1 ± 0.1 and 6.72 ± 3.23 units/mg protein/min for lactate dehydrogenase (LDH) in cytosol. The specific activities of Na^{+},K^{+}-insensitive Mg^{2+}-adenosinetriphosphatase (Mg^{2+}-ATPase) and Na^{+},K^{+}-sensitive Mg^{2+}-adenosinetriphosphatase (Na^{+}-K^{+}-ATPase) in plasma membranes from rat liver were 28.7 ± 1.7 and 4.10 ± 0.65 μmol phosphate released/mg protein/h, respectively. These values were defined as 100% of relative enzyme activity for each marker enzyme.

reductase was determined by the Tisdale method (24). The activity of acid phosphatase, a marker enzyme for lysosomes, was measured by the Walter and Schütt method (25), and LDH activity, a marker enzyme for the cytosol, was measured by the Bergmeyer and Bernt method (26). The activities of Na^+-K^+-insensitive and Na^+-K^+-sensitive Mg^{2+}-adenosinetriphosphatases (Mg^{2+}-ATPase and Na^+-K^+-ATPase, EC 3.6.1.3), which are marker enzymes for plasma membranes, were measured by the Komatsu and Fujii method (27). Monoamine oxidase activity was assayed by the Nagatsu method (28). The activities of catalase (EC 1.11.1.6), a marker enzyme for peroxisomes, was measured by the method of Baudhuin *et al.* (29). RNA content was assayed by the Le Pecq and Paoletti method (30), and the protein content of subcellular fractions by the method of Lowry *et al.* (31).

Determination of UQ_{red} and t-UQ. The UQ_{ox} and UQ_{red} homologues in the tissues and subcellular fractions were extracted with ethanol and *n*-hexane in a nitrogen atmosphere and determined by high-performance liquid chromatography with electrochemical detection, as previously described (32).

RESULTS

Distribution of UQ_{ox} and UQ_{red} homologues in rat tissues. The content of t-UQ and UQ_{red} homologues in plasma and some major organs of Wistar rats is summarized in Table 2. Two kinds of UQ homologues of UQ-9 and UQ-10 were detected in the tissues analyzed. UQ-9 was the predominant homologue and UQ-10 was a minor one in all of the tissues sampled. The amounts of UQ_{red}-9 and UQ_{red}-10 were 70–80% of the corresponding t-UQ homologues in liver and plasma, but were less than 30% in heart, kidney and spleen. Low amounts of the UQ_{red} forms were also observed in lung, brain and skeletal muscle (data not shown). The difference between the amounts of UQ_{red} in the liver and in other organs could not be due to the oxidation of UQ_{red} to UQ_{ox} during extraction because all organs were treated equally. The samples were always prepared from freshly removed organs, and the UQ_{red} forms were measured immediately to avert oxidation to the corresponding UQ_{ox} forms.

Distribution of UQ_{ox} and UQ_{red} homologues in rat blood cells. The content of t-UQ and UQ_{red} homologues in rat blood cells is summarized in Table 3. UQ-9 and UQ-10 were detected in all blood cells isolated. Leukocytes and platelets, which have mitochondria, contained higher amounts of t-UQ-9 and t-UQ-10 than did erythrocytes, which do not have mitochondria. The UQ_{red} forms were below 10% of the t-UQ in erythrocytes and leukocytes, although they were not detected in platelets. In erythrocytes, interestingly, UQ was detected only in the cell membranes (ghost cells). This may be due to the lack of a biosynthetic system for UQ in erythrocytes.

Subcellular distribution of UQ_{ox} and UQ_{red} homologues in rat liver and kidney. The levels of t-UQ and UQ_{red} homologues in subcellular fractions prepared from fresh rat liver and kidney are listed in Tables 4 and 5, respectively. All fractions tested contained significant amounts of UQ-9 and UQ-10. The levels of the UQ_{red} forms reached 60–70% of those of the t-UQ homologues in most subcellular fractions of liver and amounted to about 25% of those in kidney. The content of the t-UQ homologues in plasma membranes was comparable to that in mitochondria, but the amounts of the UQ_{red} forms present were half of those in the latter fractions. These extremely low levels of the UQ_{red} forms in plasma membranes may be partly due to their oxidation to the corresponding UQ_{ox} forms during the rather complicated isolation process. On the basis of protein content, the crude microsomes, a mixture of both the endoplasmic reticulum and Golgi complex, which may be involved in the *de novo* synthesis of UQ and in supplying UQ for blood plasma (4), showed the lowest level of t-UQ homologues among the subcellular organelles. The t-UQ content in the crude lysosomes from liver and kidney, which are known to efficiently take up extracellular UQ (33) was, respectively, about one-fourth and one-half of that in mitochondria. However, these low levels of t-UQ in crude lysosomes from liver appeared to be contaminated with microsomes and peroxisomes, because the levels in lysosomes, which were purified by metrizamide-gradient centrifugation, were almost equal to those in mitochondria. The cytosolic fractions obtained at the final stage of the cell fractionation process tended to show higher levels of UQ_{red} forms

[c]$\{[UQ_{red}]/[t\text{-}UQ]\} \times 100$.

than did other subfractions. This may be attributed to a UQ reductase activity in the cytosol, which can reduce UQ_{ox} to UQ_{red} in the presence of NADPH (23).

Liver nuclei were fractionated further into three fractions, namely nucleoli, a nucleolar wash and an extranucleolar fraction. Liver mitochondria were also separated into three fractions, inner membranes, outer membranes and matrix. The distribution of t-UQ-9 and t-UQ-10 in these fractions is shown in Table 6. The amounts of UQ_{red} in the mitochondrial and nuclear fractions were excluded from the table, as they had decreased to about 50–70% of the original levels of UQ_{red}. This was probably due to autoxidation during fractionation (data not shown). In mitochondria, surprisingly, the amounts of t-UQ-9 and t-UQ-10 in the outer membranes were about twice as high as those in the inner membranes where UQ participates in the respiratory chain. Furthermore, the matrix fraction also contained a high amount of t-UQ, which is comparable to that in the inner membranes.

The crude lysosomes were further fractionated to subfractions Ly-1 to Ly-4 by discontinuous metrizamide gradient centrifugation as shown in Table 7. Most proteins of the crude lysosomes were located in Ly-2 and Ly-4. Based on marker enzyme activities, Ly-2 was a lysosome-rich fraction, whereas Ly-4 was rich in mitochondria and peroxisomes.

Rough and smooth endoplasmic reticula and Golgi complex were also isolated from the crude microsomal fractions. The distribution of t-UQ-9 and t-UQ-10 in these fractions is shown in Table 8. The amounts of UQ_{red} homologues were omitted from the table because they had dropped to 35–75% of the levels of the original crude microsomes during the preparation. The amounts of t-UQ in Golgi subfractions were 5–6 times higher than those in submicrosomal fractions. Furthermore, the content of t-UQ homologues, in light and in intermediate fractions, was more than three times higher than that in the heavy fraction. This is in line with the hypothesis that UQ, either synthesized *de novo* or taken up by the endoplasmic reticulum, is concentrated at the Golgi complex before exocytosis (4).

TABLE 6

Distribution of Total Ubiquinones in Rat Liver Nuclei and Mitochondria[a]

Fractions	t-UQ-9	t-UQ-10
Nuclei	302 ± 132	34.1 ± 14.6
Nucleoli	518 ± 216	50.1 ± 26.6
Nucleolar wash	609 ± 204	54.0 ± 26.6
Extranucleolar fraction	245 ± 63	32.2 ± 9.1
Mitochondria	1,670 ± 360	225 ± 76
Inner membranes	559 ± 226	125 ± 68
Outer membranes	1,290 ± 380	284 ± 75
Matrix	339 ± 138	86 ± 41

[a]The values are means ± SEM (ng/mg protein) of seven rats. t-UQ is the sum of UQ_{ox} and UQ_{red} of each homologue. Abbreviations as in Table 2.

TABLE 7

Distribution of Total Ubiquinones in Rat Liver Lysosomes[a]

[a]The values are means ± SEM (ng/mg protein) of seven rats. t-UQ is the sum of UQ_{ox} and UQ_{red} of each homologue. Abbreviations as in Table 2.

DISCUSSION

The present results show that all tissues and subcellular fractions isolated from both liver and kidney contain significant amounts of UQ, as was reported by Kalén *et al.* (4,34). The data also reveal that 70–80% of the total amounts of each UQ_{ox} and UQ_{red} homologue in the liver and plasma, as well as 20–30% of those in other tissues, exist as the reduced hydroquinone form. Recently, Matsura *et al.* (35) suggested, based on studies in rabbits, that each UQ homologue may have a specific function with UQ-10 acting as an electron carrier and UQ_{red}-9 as an antioxidant. In rats, however, the distribution patterns of UQ-9 and UQ-10 were not that different between mitochondria and other subcellular fractions.

Recently, Dallner and colleagues (10) reported that nonaprenyl-4-hydroxybenzoate transferase, an enzyme responsible for UQ biosynthesis, was detected in all subcellular fractions except for peroxisomes and cytosol from rat liver. Kang *et al.* (36) also found 1-methoxy-5-polyprenylphenol, a known intermediate of UQ synthesis, in a microsomal fraction from human hepatoma cells, though they could not detect the activity of *p*-hydroxybenzoate polyprenyl transferase in this fraction. These findings suggest that most subcellular organelles, including mitochondria, have their own pathways of UQ biosynthesis. These findings, as well as our results, further indicate that UQ may be one of the intrinsic structural components of subcellular membranes, just like cholesterol or α-tocopherol, and that UQ_{red} may play an important role in membrane physiology.

It is still obscure whether the UQ_{ox} and/or the UQ_{red} present in subcellular fractions other than mitochondria serve some indispensable function. It has been suggested that UQ_{red} may act as a lipid-soluble antioxidant (37). According to Kagan *et al.* (38,39), however, UQ_{red} is a much weaker antioxidant against lipid peroxidation than is α-tocopherol, and the antioxidative effect of long chain homologues, such as UQ_{red}-9 and UQ_{red}-10, is much weaker than that of short chain homologues, shorter than UQ_{red}-5. Therefore, it is still controversial whether or not the long chain homologues existing widely in animal tissues serve as physiological antioxidant systems. However, some disagreements on the antioxidant effects of UQ_{red} appear to result from a disregard of the location of UQ homologues in bilayer lipid membranes. It has been assumed that the long chain UQ homologues, such as UQ-10, are mainly located in the hydrophobic core of the bilayer, while the short chain homologues are assumed to be located near the membrane surface (40,41) in parallel with aliphatic chains of the phospholipids with their polar heads exposed beyond the membrane surface, similar to α-tocopherol. Therefore, the antioxidative effects of native UQ homologues, such as UQ_{red}-9 and UQ_{red}-10, should be examined under experimental conditions in which the molecules are appropriately located, *i.e.*, within the hydrophobic core of the membranes. Leibovitz *et al.* (42) showed that lipid peroxidation induced by *t*-butyl hydroperoxide in tissue slices from rats was depressed by feeding the rats diets fortified with UQ_{ox}-10 before the experiment. Marubayashi *et al.* (43) reported that in hepatic ischemia and subsequent reperfusion, the decrease in the levels of the reduced form of glutathione was not observed in rats pretreated by UQ_{ox}-10 injections. Frei *et al.* (44) reported that UQ_{red}-10, but not UQ_{ox}-10, acted as an effective antioxidant against lipid peroxidation induced by 2,2′-azo*bis*(2,4-dimethyl-valeronitrile) in lecithin liposomes and that UQ_{red}-10 could work in concert with α-tocopherol through a coupled redox cycling system. According to these findings, the UQ_{red} forms appear to be more important antioxidants than are the UQ_{ox} forms. The fact that about one-fourth of t-UQ exists in the hydroquinone form, which seems to be formed by consuming reducing equivalents equimolar to NAD(P)H (23), supports the concept under consideration.

UQ in plasma is mostly associated with lipoprotein fractions (8); plasma itself does not seem to have UQ-reducing activity (data not shown). Extremely high levels of UQ_{red} in both liver and plasma, in comparison with other tissues, lead us to the conclusion as was proposed by Kalén *et al.* (4), that UQ is synthesized and concentrated in the endoplasmic reticulum-Golgi complex system of the liver and then secreted into plasma as lipoprotein vesicles. The high ratio of UQ_{red}/t-UQ in plasma compared to the ratio of UQ_{red}/t-UQ in other tissues is also very interesting. It can be argued that the peroxidation of plasma lipoprotein lipids is one of the causative events in arteriosclerosis (45,46). Recently, Stocker *et al.* (47) reported that UQ_{red}-10 protects human low-density lipoprotein (LDL) more efficiently from lipid peroxidation than does α-tocopherol. The protection of plasma LDL from the peroxidation may thus be a major role of UQ_{red}-10 in plasma. Of course, plasma UQ may also serve as UQ pool for other tissues with insufficient UQ biosynthetic capacity. We recently also found that serum UQ_{ox} is necessary for the regular and rhythmic beating of cultured mouse fetal myocardial cells (48).

Other possible roles of UQ, as Sun *et al.* (49) reported, may include that UQ could serve as a transmembrane electron carrier in plasma membrane redox systems and may be essential for cell growth. In addition, it has also been assumed that UQ may contribute to the fluidity of phospholipid bilayer membranes (50) and may control fatty acid release from membrane phospholipids by phospholipases (51).

High levels of UQ_{red} must be maintained by consuming biological reducing equivalents, such as NAD(P)H, in the presence of the proper enzyme systems. Takada *et al.* (52) reported that in guinea pig liver, microsomes and cytosol, as well as mitochondria, had a reducing activity for UQ_{ox}-10 and that DT-diaphorase (= quinone reductase, EC 1.6.99.2) was one of the enzymes responsible for the reduction of UQ_{ox}-10 in cytosol. DT-diaphorase is widely distributed in animal tissues, but its favorite substrates are not the long chain UQ_{ox} homologues, but rather vitamin K and the short chain UQ_{ox} homologues (53). We recently found that in the liver cytosol there exists a novel NADPH-UQ reductase activity, a favorite substrate of which is UQ_{ox} rather than naphthoquinone derivatives (23). Therefore the question still remains to be answered: Whether or not the high levels of UQ_{red} in tissues, especially in the liver, can be maintained by DT-diaphorase or NADPH-UQ reductase, or both, possibly in cooperation with some other enzymes. Further studies are necessary to elucidate the mechanisms of the reduction of UQ_{ox}, as well as its physiological role at sites other than mitochondria.

Effect of Dietary α-Linolenic Acid and Its Ratio to Linoleic Acid on Platelet and Plasma Fatty Acids and Thrombogenesis

Joanna K. Chan[a,1], Bruce E. McDonald[a,*], Jon M. Gerrard[b], Vivian M. Bruce[a], Bonnie J. Weaver[c] and Bruce J. Holub[c]

[a]Department of Foods and Nutrition, University of Manitoba, Winnipeg, R3T 2N2 Canada, [b]Department of Pediatrics and Child Health, University of Manitoba, Winnipeg, R3A 1S1 Canada and [c]Department of Nutritional Sciences, University of Guelph, Guelph, N1G 2W1 Canada

The effect of dietary α-linolenic acid (18:3n-3) and its ratio to linoleic acid (18:2n-6) on platelet and plasma phospholipid (PL) fatty acid patterns and prostanoid production were studied in normolipidemic men. The study consisted of two 42-d phases. Each was divided into a 6-d pre-experimental period, during which a mixed fat diet was fed, and two 18-d experimental periods, during which a mixture of sunflower and olive oil [low 18:3n-3 content, high 18:2/18:3 ratio (LO-HI diet)], soybean oil (intermediate 18:3n-3 content, intermediate 18:2/18:3 ratio), canola oil (intermediate 18:3n-3 content, low 18:2/18:3 ratio) and a mixture of sunflower, olive and flax oil [high 18:3n-3 content, low 18:2/18:3 ratio (HI-LO diet)] provided 77% of the fat (26% of the energy) in the diet. The 18:3n-3 content and the 18:2/18:3 ratio of the experimental diets were: 0.8%, 27.4; 6.5%, 6.9; 6.6%, 3.0; and 13.4%, 2.7, respectively. There were appreciable differences in the fatty acid composition of platelet and plasma PLs. Nevertheless, 18:1n-9, 18:2n-6 and 18:3n-3 levels in PL reflected the fatty acid composition of the diets, although very little 18:3n-3 was incorporated into PL. Both the level of 18:3n-3 in the diet and the 18:2/18:3 ratio were important in influencing the levels of longer chain n-3 fatty acid, especially 20:5n-3, in platelet and plasma PL. Production of 6-keto-$PGF_{1\alpha}$ was significantly ($P < 0.05$) higher following the HI-LO diet than the LO-HI diet although dietary fat source had no effect on bleeding time or thromboxane B_2 production. The present study showed that both the level of 18:3n-3 in the diet and its ratio to 18:2n-6 were important in influencing long-chain n-3 fatty acid levels in platelet and plasma PL and that prostanoid production coincided with the diet-induced differences in PL fatty acid patterns.

Lipids 28, 811-817 (1993).

Coronary heart disease is a degenerative process involving atherosclerosis and thrombogenesis (1,2). Dietary fat affects both of these phenomena (3). Polyunsaturated fatty acids (PUFA) of the n-3 and n-6 families may influence thrombus formation through their effects on the production of prostanoids in the endothelial wall and in the circulating platelets (4-6).

Dietary linoleic acid (18:2n-6) can be desaturated and elongated to arachidonic acid (20:4n-6), which is the precursor of thromboxane A_2 (TXA_2) and prostacyclin (PGI_2) (6,7). Similarly, dietary α-linolenic acid (18:3n-3) can be desaturated and elongated to eicosapentaenoic acid (20:5n-3), the precursor of TXA_3 and PGI_3 (6,7), but the efficiency of conversion has been reported to be relatively low in humans (8,9). TXA_2 is a potent prothrombogenic agent whereas TXA_3 is a weak platelet aggregating agent. By contrast, both PGI_2 and PGI_3 are antithrombogenic (2).

Most of the research on the antithrombogenic effect of dietary fatty acids has focused on dietary 20:5n-3, mainly because it is the direct precursor of antithrombogenic prostanoids and a powerful inhibitor of n-6 PUFA metabolism (9). However, 20:5n-3 and docosahexaenoic acid (22:6n-3) are not effective in lowering blood cholesterol levels (10). Thus, interest has turned to the possible antiatherogenic and antithrombogenic role of dietary 18:3n-3. Both 18:2n-6 and 18:3n-3 share the same enzyme system for desaturation and elongation (2,6,7); hence, there is the possibility for competition between them. Thus, the relative and absolute amounts of these fatty acids in the diet could have an effect on the metabolism of n-6 and n-3 fatty acids which, in turn, could alter prostanoid metabolism and thrombogenesis. The importance of the 18:2/18:3 ratio in the diet has been studied by several investigators (8,11,12). However, a comparison of the effect of the absolute amounts of 18:2n-6 and 18:3n-3 and their ratio in the diet on plasma fatty acid patterns and thrombogenic tendency in the human has not been reported.

The present study was designed to investigate the effect of dietary 18:2n-6 and 18:3n-3 and their ratio on n-3 and n-6 PUFA patterns in platelet and plasma phospholipids (PL) and on bleeding time and on bleeding-time prostanoid formation. Fatty acid patterns of phosphatidylcholine (PC), phosphatidylethanolamine (PE) and alkenylacyl glycerophosphoethanolamines (PPE) are reported. PPE has been shown to be the major storage site for 20:5n-3, although an appreciable amount also is found in the diacyl PC and PE fractions of platelet PL (13,14).

MATERIALS AND METHODS

Experimental design. The study consisted of two 42-d phases with a 2-mon break between phases. Each phase was divided into three periods: a 6-d pre-experimental period and two 18-d experimental periods. Eight male subjects participated in the study. All subjects were fed a mixed fat diet during the pre-experimental period of each phase. In the first experimental period of phase I, two subjects were randomly assigned to one of four experimental diets: sunflower and olive oil [low 18:3n-3 content, high 18:2/18:3 ratio (LO-HI)]; soybean oil [intermediate 18:3n-3 content, intermediate 18:2/18:3 ratio (IN-IN)]; canola oil [intermediate 18:3n-3 content, low 18:2/18:3 ratio (IN-LO)]; and sunflower, olive and flax oil [high 18:3n-3 content, low 18:2/18:3 ratio (HI-LO)]. In the

Abbreviations: EDTA, ethylenediaminetetraacetic acid; GLC, gas-liquid chromatography; HI-LO, high 18:3n-3 content, low 18:2/18:3 ratio; IN-IN, intermediate 18:3n-3 content, intermediate 18:2/18:3 ratio; IN-LO, intermediate 18:3n-3 content, low 18:2/18:3 ratio; LO-HI, low 18:3n-3 content, high 18:2/18:3 ratio; PC, phosphatidylcholine; PE, phosphatidylethanolamine; PGI, prostacyclin; PL, phospholipid(s); PPE, alkenylacyl glycerophosphoethanolamines; PPP, platelet-poor plasma; PUFA, polyunsaturated fatty acids; TXA, thromboxane.

subsequent experimental periods of phases I and II, each pair of subjects was switched to a different diet according to the following order: LO-HI to IN-IN; IN-IN to IN-LO; IN-LO to HI-LO; and HI-LO to LO-HI.

Subjects. The subjects, who ranged in age from 20 to 34 yr, were students at the University of Manitoba. They were normolipidemic with plasma total cholesterol levels between 3.80 and 5.86 mmol/L at the beginning of the study. The subjects engaged in their normal activities and resided in their own residences throughout the study. They were instructed not to use aspirin during the study and to consult the directors before taking any medication. One subject left after the completion of phase I, and a replacement was recruited for phase II. All meals were served in the metabolic unit located in the Faculty of Human Ecology. The study protocol was approved by the Faculty of Human Ecology Ethics Committee, and written consent was obtained from each subject.

Diets. A two-day cyclic menu of conventional foods was used during the study. Diets used in the study were identical in all respects except sources of added fat which accounted for approximately 26% of total energy (77% of the 120 g/d of total dietary fat). The fatty acid composition of the diets is presented in Table 1. The LO-HI and the IN-LO diets had similar amounts of oleic acid (18:1n-9) and 18:2n-6, but the latter contained about eight times more 18:3n-3. The IN-IN diet was similar in 18:3n-3 content to the IN-LO diet but contained twice the level of 18:2n-6. The levels of 18:2n-6 and 18:3n-3 in the HI-LO diet were approximately twice those in the IN-LO diet, but the 18:2/18:3 ratio was similar to that of the IN-LO diet (3.0 *vs.* 2.7). A one-day composite of each diet was collected during each phase of the study. The composites were homogenized and aliquots lyophilized for chemical analysis. Fat content of the diets was determined by the method of Bligh and Dyer (15). Fatty acid methyl esters were prepared using sodium methoxide in methanol (16), and the fatty acid composition was determined by gas-liquid chromatography (GLC).

TABLE 1

Fatty Acid Composition of the Diets[a]

	Diets[b]				
Fatty acid	Mixed fat	LO-HI	IN-IN	IN-LO	HI-LO
	Percent of total fatty acids				
14:0	4.5	1.5	1.5	1.5	1.6
16:0	23.8	13.0	14.5	9.8	11.7
16:1n-7	1.8	0.8	0.6	0.7	0.6
18:0	12.4	4.7	5.2	3.8	5.6
18:1n-9	38.5	56.0	24.8	54.2	29.6
18:2n-6	12.0	21.9	44.9	19.5	36.0
18:3n-3	1.0	0.8	6.5	6.6	13.4

[b]Source of added fat: Mixed fat, 11% corn oil, 22% lard, 22% tallow, and 22% shortening; low 18:3n-3 content, high 18:2/18:3 ratio (LO-HI), 20% sunflower oil and 80% olive oil; intermediate 18:3n-3 content, intermediate 18:2/18:3 ratio (IN-IN), 100% soybean oil; intermediate 18:3n-3 content, low 18:2/18:3 ratio (IN-LO), 100% canola oil; and high 18:3n-3 content, low 18:2/18:3 ratio (HI-LO), 47% sunflower oil, 20% olive oil and 33% flax oil.
[c]Less than 0.05%.

Fatty acid analysis of platelet and plasma PL. Blood samples were collected from the subjects into ethylenediaminetetraacetic acid (EDTA)-containing tubes following a 12-h overnight fast at the end of each experimental period. The samples were centrifuged at 250 × *g*, 18°C for 15 min to remove the red blood cells. Platelets were separated from the resulting plasma by centrifuging at 1400 × *g*, 4°C for 15 min. Platelet-poor plasma (PPP) was removed from the samples and stored under nitrogen at −10°C. Washed suspensions of the platelets were prepared by the method of McKean *et al.* (17). The final suspension was in 1 mL of cold buffer (2 mmol Na_2EDTA/L, 0.15 mol NaCl/L, 0.02 mol Tris hydroxyaminomethane/L; pH 7.4). The tubes containing the final suspensions were flushed with nitrogen, stored at −22°C and then shipped on dry ice to the University of Guelph. The platelet suspensions were thawed on ice and the lipids extracted by the method of Bligh and Dyer (15). The PPP samples were thawed in the refrigerator and the lipids extracted immediately by the method of Folch *et al.* (18). The PL in the platelets and plasma were separated using two-directional thin-layer chromatography on pre-coated plates (Merck silica gel 60 HR, Terochem Laboratories Ltd., Toronto, Canada). The spotted plates were first developed in chloroform/methanol/ammonium hydroxide (65:35:5.5, by vol) and then in a second direction in chloroform/methanol/formic acid (55:25:5, by vol). Following the first run, the plates were dried under nitrogen and placed in a chamber containing HCl fumes for 10 min to hydrolyze the alkenyl group from the PPE fraction (19). Following development, the plates were sprayed with dichlorofluorescein dye, exposed to ammonia fumes and the lipid factors were localized under ultraviolet light. The PC, PE and PPE fractions were scraped into test tubes and transmethylated with 6% sulfuric acid in methanol in the presence of known amounts of monopentadecanoin as internal standard (Nu-Chek-Prep, Elysian, MN) in the case of platelet PL and with sodium methoxide in methanol (16) in the presence of internal standard in the case of the plasma PL. Similar areas of gel were scraped from blank plates and processed as for the samples. The fatty acid methyl esters were separated by GLC as described previously for platelets (20) and plasma (21) PL fractions. The amounts of fatty acids in each sample were adjusted by subtracting the amounts present in the spots scraped from the blank plates, relative to the amount of monopentadecanoin in each.

Bleeding time and prostanoid production. Bleeding time and the bleeding-time production of TXB_2, the stable metabolite of TXA_2, and of 6-keto-$PGF_{1\alpha}$, the stable metabolite of PGI_2, were measured at the end of each experimental period. Duplicate bleeding times were measured by making incisions 5 mm long and 1 mm deep on the volar surface of the arm using a sterile, disposable, standardized device (Simplate, General Diagnostics, Warner Lambert, Morris-Plains, NJ). A constant pressure was maintained with a sphygmomanometer cuff on the upper arm inflated to 44 mm Hg. Bleeding time was measured with a stopwatch. Blood from the edge of the incision was collected into heparinized microhematocrit tubes containing 10 μL of 1 g indomethacin/L for the determination

of TXB_2 and 6-keto-$PGF_{1\alpha}$. Immediately following collection of the blood, 3000 dpm of [^{3}H]PGE_2 (sp. act., 185 Ci/mmol) was added to each sample in order to correct for recovery of TXB_2 and 6-keto-$PGF_{1\alpha}$. The tubes were centrifuged, the plasma volume measured and the plasma removed for prostanoid measurement. Plasma samples were loaded onto a C_{18} Sepak cartridge (Waters Scientific, Mississauga, Canada). Water (20 mL), 10% (by vol) ethanol (20 mL) and petroleum ether (10 mL) were passed through the cartridges, and the prostanoids were then extracted with 7.5 mL methyl formate. This fraction was evaporated under a stream of nitrogen and the sample reconstituted in 0.5 mL bovine serum albumin in phosphate-buffered saline. The amounts of 6-keto-$PGF_{1\alpha}$, and TXB_2 were assayed by using highly specific anti-6-keto-$PGF_{1\alpha}$ and anti-TXB_2 in an enzyme-linked immunosorbent assay (22,23). Bleeding-time values for prostanoid production refer to blood collected in the first 4 min after incision. TXB_2 is expressed as a concentration (μg/L) whereas 6-keto-$PGF_{1\alpha}$ is expressed in terms of rate of production (pg/min) (23,24).

Statistical analysis. The experimental design of the study was a modified Latin square (25). F tests were performed on the estimated diet effects obtained from regression analysis of the data for plasma PL fatty acids, bleeding times and bleeding-time prostanoid production (25). Analyses were performed using the SAS computer program (1984, 1986 SAS Institute Inc., Cary, NC). Diet effects on the platelet fatty acid composition were determined for adjusted treatment means compared by protected least significant differences (26). All means were adjusted for the withdrawal of a subject after the completion of phase I.

RESULTS

Fatty acid patterns of platelet and plasma PL. Fatty acid patterns of platelet (Tables 2–4) and plasma (Tables 5–7) PL reflected the fatty acid composition of the diets even though there were some major differences in fatty acid composition between the platelet and plasma fractions, *e.g.*, appreciably higher 20:4n-6 and lower 18:2n-6 and 22:6n-3 levels in platelet than plasma PL. The 18:1n-9 levels were significantly higher in all PL fractions following the LO–HI and IN–LO diets, which were appreciably

higher in 18:1n-9 content (Table 1), than following the IN-IN and HI-LO diets. Similarly, the 18:2n-6 levels were significantly higher following the IN-IN and HI-LO diets than following the LO-HI and IN-LO diets. Although only small amounts of 18:3n-3 were incorporated into PL, the LO-HI diet led to significantly lower levels of 18:3n-3 than the other diets while the levels following the HI-LO diet were significantly higher for the plasma PL (Tables 5-7). Levels of long-chain PUFA in platelet and plasma PL also were affected by the fatty acid composition of the diets although dietary fatty acid composition had no effect on the 20:4n-6 content, the principal PUFA in the PL fraction, except for the lower level in plasma PC following the HI-LO diet (Table 5) and in platelet PE following the IN-LO diet (Table 3). However, differences in PUFA content among the diet groups were less pronounced than for 18:1n-9, 18:2n-6 and 18:3n-3. In general, the PL tended to be higher in long-chain n-3 PUFA following the HI-LO diet and lower following the LO-HI diet although dietary fat source had little effect on 22:6n-3, the major n-3 fatty acid in the PL fractions. The ratio of 18:2/18:3 in the diet also had an effect on PUFA levels in the PL fractions. The levels of 20:5n-3 were significantly higher following the IN-LO and HI-LO diets than following the LO-HI and IN-IN diets in all fractions for both tissues (Tables 2-7). By contrast, the level of 22:4n-6 in the platelet PPE fraction (Table 4) was significantly lower following the IN-LO and HI-LO diets than the LO-HI and IN-IN diets.

Thrombogenic effect of the experimental diets. No differences in bleeding time and in bleeding-time TXB_2 production were observed among the experimental diets, although levels of TXB_2 tended to be lower following the IN-LO and HI-LO diets than following the LO-HI and IN-IN diets (Table 8). Production of 6-keto-$PGF_{1\alpha}$ in blood collected from the bleeding time wounds was significantly higher following the HI-LO diet than the LO-HI diet. 6-Keto-$PGF_{1\alpha}$ production following the IN-LO and IN-IN diets fell midway between the values on the HI-LO and LO-HI regimen. As a result, the 6-keto-$PGF_{1\alpha}$ to TXB_2 ratio tended to be higher following the HI-LO and IN-LO diets than following the LO-HI and

6-Keto-$PGF_{1\alpha}$/TBX_2 ratio	0.81 ± 0.17[a,b]	0.74 ± 0.12[a]	1.08 ± 0.16[a,b]	1.52 ± 0.31[b]

[a]Values in the same row with the same superscript letter (a-b) do not differ significantly ($P > 0.05$). All values are mean ± SEM; n = 8; see Table 1 for abbreviations.

IN-IN diets; the ratio following the HI-LO diet was significantly ($P < 0.05$) higher than the ratio following the IN-IN diet.

DISCUSSION

Levels of 18:1n-9, 18:2n-6 and 18:3n-3 in platelet and plasma PL following the consumption of the experimental diets reflected the difference in the levels of these fatty acids in the diets. Similar effects of dietary fat sources on the fatty acid composition of platelet and plasma PL have been reported (8,21,27-29). The magnitude of the differences in the fatty acid composition of the platelet and plasma PL, however, was small compared to the differences in dietary fatty acid composition, especially for 18:3n-3. The small amount of 18:3n-3 incorporated into

the PL could be due to its preferential oxidation for energy purposes. Leyton *et al.* (30) found that 18:1n-9 and 18:3n-3 were oxidized more rapidly than other long-chain fatty acids. Restricted incorporation of 18:3n-3 into PL or competition for the elongase and desaturase enzymes present in the liver and other tissues also could be responsible for the limited changes observed in platelet and plasma fatty acid composition (12, 31).

The IN-LO and HI-LO diets, which had relatively low 18:2/18:3 ratios, were associated with significantly higher levels of platelet and plasma long-chain n-3 PUFA, in particular the level of 20:5n-3, which was double that following the LO-HI and IN-IN diets. These results confirm previous studies (9,12,21,27-29) which indicated that humans can desaturate and elongate 18:3n-3 to higher homologs and that desaturation-elongation varies with the level of 18:3n-3 in the diet (12,21,27-29,31,32) and its ratio to 18:2n-6 (12,33,34). However, the *in vivo* conversion of dietary 18:3n-3 to 20:5n-3 is not as effective in raising n-3 levels in platelet and plasma PL as is direct supplementation with 20:5n-3 (8,9). The fact that the IN-LO diet, which had a lower dietary 18:2/18:3 ratio than the IN-IN diet, resulted in significantly higher levels of platelet and plasma 20:5n-3 suggests that the higher 20:5n-3 levels associated with the lower 18:2/18:3 ratio could be due to the effective competition of 18:3n-3 for the Δ6 desaturase enzyme (35). Results of the present study also suggest that the 18:2/18:3 ratio has to be less than 6.9 to have a significant effect on the level of long-chain n-3 PUFA.

Neither the lower level of 18:3n-3 in the diet nor its ratio to 18:2n-6 had any consistent effect on the longer chain n-6 homologs in platelet or plasma PL. Lasserre *et al.* (34) also found that dietary 18:3n-3 at a level of 1.5% of total energy (slightly less than the levels in the IN-IN and IN-LO diets in the present study) had no effect on serum levels of n-6 PUFA. By contrast, supplementing subjects with 30 mL linseed oil per day (approximately 16 g/d of 18:3n-3, which was similar to the amount present in the HI-LO diet) (31) or 60 mL/d (32) led to significant decreases in plasma 20:4n-6 levels.

The dietary fat source also had no effect on plasma 22:6n-3 levels in the present study. Sanders and Younger (8), Renaud *et al.* (27) and Lasserre *et al.* (34) also found that dietary 18:3n-3 had no effect on plasma 22:6n-3 levels. Mest *et al.* (31), on the other hand, reported an increase in 22:6n-3 level following linseed oil supplementation.

Individual PL species were analyzed in the present study so as to avoid the possibility that a large amount of one fraction might conceal changes in the fatty acid composition of other fractions. The apparent rates of incorporation of individual fatty acids differed among the three PL species reported here. For instance, appreciably higher levels of 20:4n-6, 22:4n-6, 22:5n-3 and 22:6n-3 were incorporated into the PPE than into the PC or PE fractions. However, the pattern of change was similar for the three PL species. Likewise, changes in the fatty acid composition of platelet and plasma PL responded in a similar way to differences in dietary fatty acid composition in spite of major differences in the fatty acid composition of the platelet and plasma PL, *e.g.*, higher levels of 20:4n-6 and lower levels of 18:2n-6 and 22:6n-3 in platelets.

Renaud *et al.* (27) and Budowski *et al.* (32) reported significant decreases in platelet aggregability and platelet coagulant activity following an increase in 18:3n-3 intake. Borchgrevink *et al.* (36), on the other hand, failed to find any effect of a linseed oil supplement on bleeding time. A study similar to the present (37), however, reported longer bleeding times and higher bleeding-time prostacyclin production following a canola oil diet, which provided 2.7% of total energy as 18:3n-3, than following a mixed fat diet (0.4% of energy as 18:3n-3). However, sunflower oil (0.3% of energy as 18:3n-3) produced a similar response to that of canola oil. In the present study, the experimental diets did not affect bleeding times even though bleeding-time production of 6-keto-$PGF_{1\alpha}$ was significantly higher following the HI-LO diet, in which 18:3n-3 provided 4.6% of total energy, than following the LO-HI diet, in which 18:3n-3 provided only 0.3% of total energy. There is no obvious explanation for the higher production of 6-keto-$PGF_{1\alpha}$ on the HI-LO diet. In fact, the n-6 fatty acid level in plasma PC was significantly lower following the HI-LO diet; however, plasma PL fatty acid levels may not reflect vascular tissue PL composition, the assumed source of PGI in the bleeding-time blood analyzed in the present study. Although there were no differences in bleeding-time TXB_2 production due to diet, TXB_2 production tended to be lower following the HI-LO and IN-LO diets, both of which resulted in higher 20:5n-3 levels in platelet and plasma PL. Morita *et al.* (38) reported a strong inhibition of *in vitro* TXA_2 synthesis by human platelets as a result of adding 20:5n-3 to the medium. It has been suggested (6,39) that higher tissue levels of 20:5n-3 may inhibit prostanoid formation from 20:4n-6 through an effect on cyclooxygenase activity or the availability of 20:4n-6. However, Mest *et al.* (31) found no relation between 20:5n-3 levels in serum PL and *in vitro* TXA_2 production by platelets. The ratio of 6-keto-$PGF_{1\alpha}$/TXB_2 was highest following the HI-LO diet and lowest following the IN-IN diet; the ratio following the IN-LO diet was intermediate between the HI-LO and the IN-IN regimens. Since TXA_2 promotes and PGI_2 inhibits platelet aggregation, the balance between *in vivo* production of TXA and PGI is important (39). It is interesting to note that the levels of 20:5n-3 in the PL fractions were significantly higher following the HI-LO and IN-LO diets than following the LO-HI and IN-IN diets but that the level of 20:4n-6 was significantly lower only for the platelet PE and the plasma PC fractions following the IN-LO and HI-LO diets, respectively.

A significant effect of diet on prostacyclin production and on the ratio of prostacyclin to thromboxane production under conditions where there was no significant change in the bleeding time requires comment. It is possible that the HI-LO diet may have an antithrombotic effect (on the basis of altered prostanoid production) without producing an increased tendency to bleed, a situation that would be very desirable from the point-of-view of coronary heart disease. On the other hand, it is possible that the apparent beneficial effect of the HI-LO diet, in terms of prostanoid production, could be balanced by changes in other factors, not measured in this study, so that the overall antithrombotic effect may not be as significant as the changes in prostanoid production would suggest. Which of these alternative interpretations of our results is more pertinent will still require further investigation.

The results of the present study indicate that dietary 18:3n-3 intake has an appreciable effect on the fatty acid

composition of platelet and plasma PL. The ratio of 18:2/18:3 in the diet appears especially important in influencing n-3 PUFA patterns. The changes in the production of TXB_2 and 6-keto-$PGF_{1\alpha}$ were found to coincide with the differences in the n-3 PUFA patterns of platelet and plasma PL.

ACKNOWLEDGMENTS

This research was supported by grants from the Canola Council of Canada and the Flax Council of Canada. We gratefully acknowledge the competent technical assistance of Stacey Johnson, Sandra Singhroy and Elena Duta, the participation and cooperation of the subjects, and the helpful advice of Dr. Bruce Johnston with the statistical analysis. Canola oil and sunflower oil were kindly supplied by CSP Foods Ltd. (Winnipeg, Canada) and soybean oil by Canada Packers Ltd. (Toronto, Canada).

Effect of Diets Rich in Linoleic or α-Linolenic Acid on Phospholipid Fatty Acid Composition and Eicosanoid Production in Atlantic Salmon (*Salmo salar*)

J. Gordon Bell*, James R. Dick and **John R. Sargent**

N.E.R.C. Unit of Aquatic Biochemistry, School of Natural Sciences, University of Stirling, Stirling FK9 4LA, Scotland, United Kingdom

Atlantic salmon post-smolts were fed diets rich in linoleic acid (sunflower oil, SO), α-linolenic acid (linseed oil, LO) or long-chain polyunsaturated fatty acids (fish oil, FO) for a period of 12 wk. In the liver phospholipids of fish fed SO, the levels of 18:2n-6, 20:2n-6, 20:3n-6 and 20:4n-6 were significantly elevated compared to both other treatments. In choline phospholipids (CPL), ethanolamine phospholipids (EPL) and phosphatidylserine (PS) the levels of 22:4n-6 and 22:5n-6 were significantly elevated in fish fed SO. In liver phospholipids from fish fed LO, 18:2n-6, 20:2n-6 and 20:3n-6 were significantly elevated but 20:4n-6, 22:4n-6 and 22:5n-6 were similar or significantly decreased compared to fish fed FO. Liver phospholipids from fish fed LO had increased 18:3n-3 and 20:4n-3 compared to both other treatments while EPL and phosphatidylinositol (PI) also had increased 20:5n-3. In fish fed LO, 22:6n-3 was significantly reduced in CPL, PS and PI compared to fish fed FO. Broadly similar changes occurred in gill phospholipids. Production of 12-lipoxygenase metabolites in isolated gill cells stimulated with the Ca^{2+}-ionophore A23187 were significantly reduced in fish fed either SO or LO compared to those fed FO. However, the ratio 12-hydroxy-5, 8, 10, 14-eicosatetraenoic acid (12-HETE)/12-hydroxy-5, 8, 10, 14, 17-eicosapentaenoic acid (12-HEPE) was significantly elevated in stimulated gill cells from SO-fed fish. Although mean values of thromboxane B_2 (TXB_2) and prostaglandin E_2 (PGE_2) were increased in fish fed SO, they were not significantly different from those of the other two treatments. *Lipids 28,* 819–826 (1993).

The so-called essential fatty acids, linoleic acid (18:2n-6) and linolenic acid (18:3n-3), are the precursors of the long-chain n-6 and n-3 species which are important components of the phospholipid bilayer of cell membranes. It is generally accepted that both the n-6 and n-3 fatty acids are metabolized by the same sequence of desaturating and elongating enzymes (1). In these pathways the desaturation steps are generally rate-limiting while elongation is rapid (2), and thus competition between substrate fatty acids at desaturase binding sites will determine the nature of the resulting polyunsaturated fatty acids (PUFA) and ultimately the composition of cellular membranes. In competitive terms, the n-3 PUFA are much more potent inhibitors of n-6 PUFA metabolism than *vice versa* although the relative concentrations of the two substrates will also determine the products that result (3,4). Many species of freshwater fish, including Atlantic salmon (*Salmo salar*), possess the enzymes necessary to elongate and desaturate 18:3n-3 to docosahexaenoic acid (DHA, 22:6n-3) (5) and are capable of metabolizing 18:2n-6 similarly, resulting in increased arachidonic acid (AA; 20:4n-6) in membrane phospholipids (6).

In mammals, AA is the major precursor for biologically active eicosanoids and in humans consuming a typical "Western-type" diet, overproduction of AA-derived eicosanoids may explain the prevalence of the many inflammatory conditions occurring in the developed world (7). Fish provide a useful model system for the study of eicosanoid metabolism since, although AA may be the preferred eicosanoid substrate (8,9), fish contain considerable amounts of eicosapentaenoic acid (EPA, 20:5n-3) and DHA, which can attenuate the production and efficacy of AA-derived eicosanoids (10). EPA can be metabolized by both cyclooxygenase and lipoxygenase enzymes resulting in products of lower bioactivity when compared to their AA homologues (11,12). EPA can also competitively inhibit the prostaglandin synthetase enzyme complex, thereby reducing production of AA-derived prostanoids (13). A number of recent studies have suggested that feeding oils rich in 18:3n-3 can reduce production of AA-derived eicosanoids by increasing levels of EPA in membrane phospholipids (14,15). In addition 18:3n-3 can directly inhibit cyclooxygenase activity (16). In previous studies with salmon we have shown that a high level of dietary 18:2n-6 can result in development of a severe cardiomyopathy involving active necrosis of both atrium and ventricle (17) and altered eicosanoid metabolism in blood leucocytes and gill cells (18).

The objective of the present study was to investigate the metabolism of 18:2n-6 and 18:3n-3 in salmon fed diets containing either sunflower oil (SO), linseed oil (LO) or fish oil (FO) by measuring phospholipid fatty acid compositions in liver and gill. The 12-lipoxygenase products and the cyclooxygenase products prostaglandin E_2 (PGE_2) and thromboxane B_2 (TXB_2) were measured in isolated gill cells stimulated with the calcium ionophore A23187.

MATERIALS AND METHODS

Animals and diets. Three hundred and thirty Atlantic salmon S1 smolts (salmon undergoing transition to seawater in one year) were obtained from the S.O.A.F.D. Fish Cultivation Unit (Aultbea, Wester Ross, Scotland) and distributed randomly into three tanks of 2000 L capacity each, which were supplied with seawater at a rate of 26 L/min. The fish (mean weight *ca.* 86 g) were subject to natural photoperiod, and the water temperature during the experimental period (August–November) varied from 15–10°C. Diets were supplied by automatic feeders which were adjusted to provide 20 g/kg biomass per day. Fish were weighed every 28 d and the ration adjusted accordingly.

Abbreviations: AA, arachidonic acid; BHT, butylated hydroxytoluene; CPL, choline phospholipids; DHA, docosahexaenoic acid; EPA, eicosapentaenoic acid; EPL, ethanolamine phospholipids; FO, fish oil; HDHE, hydroxy-4, 7, 10, 13, 16, 19-docosahexaenoic acid; HEPE, hydroxy-5, 8, 10, 14, 17-eicosapentaenoic acid; HETE, hydroxy-5, 8, 10, 14-eicosatetraenoic acid; HPLC, high-performance liquid chromatography; LO, linseed oil; PGE_2, prostaglandin E_2; PI, phosphatidylinositol; PS, phosphatidylserine; PUFA, polyunsaturated fatty acid; SO, sunflower oil; TLC, thin-layer chromatography; TXB_2, thromboxane B_2; UV, ultraviolet.

The diets were formulated to meet the nutritional requirements of salmonid fish (19) and contained 47% protein and 16% lipid. The composition of the basal diet has been described in detail previously (20) and contained fishmeal (650 g/kg) (LT94, Ewos Ltd., Westfield, Lothian, Scotland), pre-cooked starch (150 g/kg), vitamin mix (10 g/kg), mineral mix (24 g/kg), α-cellulose (65.5 g/kg) and choline chloride (4 g/kg). The dietary lipid (100 g/kg) was supplied either as fish oil (Fosol, Seven Seas Ltd., Hull, United Kingdom), sunflower oil (Tesco, Cheshunt, United Kingdom) or linseed oil (ICN Biomedical Ltd., High Wycombe, United Kingdom). An antioxidant mix (0.4 g/kg) was mixed with the oil before adding to the other diet components (20). The fatty acid compositions of the diets are shown in Table 1.

Lipid extraction and fatty acid analysis. Samples were collected after 12 wk of the dietary trial and stored at −80°C until analyzed. Lipids were extracted from liver and gill tissue by the method of Folch *et al.* (21). Total lipid extracts were separated into choline phospholipids (CPL), ethanolamine phospholipids (EPL), phosphatidylserine (PS) and phosphatidylinositol (PI) fractions by thin-layer chromatography (TLC) as described by Vitiello and Zanetta (22). The plates were sprayed with 0.1% 2′,7′-dichlorofluorescein in 97% methanol containing 0.05% butylated hydroxytoluene (BHT), and the lipid bands were visualized under ultraviolet (UV) light. Acid-catalyzed transmethylation was carried out overnight at 50°C as described by Christie (23). The fatty acid methyl esters were separated and quantified by gas–liquid chromatography (Carlo Erba Vega 6000, Fisons Ltd., Crawley, United Kingdom) on a 50 m × 0.32 mm capillary column (CP-Wax 51, Chrompak Ltd., London, United Kingdom). Hydrogen was used as carrier gas, and temperature programming was from 50°C at 35°C/min to 150°C and then to 225°C at 2.5°C/min. Individual methyl esters were identified by comparison with known standards and by reference to published data (24).

Preparation of isolated gill cells. The procedure used for isolating gill cells has been described in detail previously (18). Minced gill filaments were incubated in a Hanks' medium specially formulated for use with salmonid fish (25) containing 0.1% collagenase (type IV, Sigma Chemical Co., Poole, United Kingdom) for 45 min at room temperature with constant stirring. After filtering through nylon gauze, the cells were collected by centrifugation at 400 × *g* for 2 min, washed twice in Hanks' medium and finally resuspended in 1 mL of the same medium containing 1 mM $CaCl_2$.

Ionophore challenge and eicosanoid extraction. Isolated gill cells prepared as described above were placed in glass tubes pre-coated with Sigmacote and incubated in a shaking water bath at 18°C for 10 min. Calcium ionophore was added in 2 μL of dimethyl sulfoxide at a final concentration of 10 μM and the incubation continued for a further 20 min. The cells were sedimented by centrifugation

(12000 × *g*, 2 min) and the eicosanoids extracted from the supernatant using C_{18} Sep-Pak minicolumns (Millipore Ltd., Watford, United Kingdom) according to Powell (26)

High-performance liquid chromatography (HPLC). The hydroxy acids 12-hydroxy-5, 8, 10, 14-eicosatetraenoic acid (12-HETE), 12-hydroxy-5, 8, 10, 14, 17-eicosapentaenoic acid (12-HEPE) and 14-hydroxy-4, 7, 10, 13, 16, 19-docosahexaenoic acid (14-HDHE) were separated and quantified by reverse-phase HPLC using a Spherisorb 5 μm octadecyl silane (ODS 2) column (25 cm × 4.6 mm, Anachem, Luton, United Kingdom). The chromatographic system was equipped with Waters Model M-45 pumps (Waters Chromatography, Warford, United Kingdom) and the effluent was monitored at 235 nm using a Pye-Unicam LC-UV detector (Pye-Unicam, Cambridge, United Kingdom). An isocratic solvent system containing acetonitrile/methanol/water/acetic acid (40:29:30:0.5, by vol) was used at a flow rate of 1 mL/min. Quantification was based on use of external standards of 12-HETE and 12-HEPE. Identification of 14-HDHE was done as described previously (18).

Measurement of PGE_2 and TXB_2. PGE_2 and TXB_2, the stable metabolite of thromboxane A_2, were measured by enzyme immunoassay using kits supplied by Cascade Biochemicals Ltd. (Reading, United Kingdom).

Materials. All solvents were of HPLC grade and were obtained from Rathburn Chemicals Ltd. (Walkerburn, Scotland, United Kingdom). TLC plates (20 cm × 20 cm × 0.25 mm), pre-coated with silica gel 60 were obtained from Merck (Darmstadt, Germany). 12(*R,S*)-HETE and 12(*S*)-HEPE were obtained from Cascade Biochemicals Ltd. (Reading, United Kingdom). Sigmacote and A23187 were obtained from Sigma Chemical Co. Ltd. (Poole, Dorset, United Kingdom).

Statistical analysis. Significance of difference ($P < 0.05$) between dietary treatments was determined by analysis of variance using a Statgraphics (system 3.0) computer package. Data which were identified as nonhomogeneous were subjected to either arcsine square root or log transformation before analysis. Differences between means were determined by Tukey's test.

RESULTS

The fatty acid compositions of liver CPL are shown in Table 2. Total monoenoic fatty acids were significantly reduced in SO-fed fish compared to FO-fed fish. In SO-fed fish 18:2n-6, 18:3n-6, 20:2n-6, 20:3n-6, 20:4n-6, 22:4n-6 and 22:5n-6 were all significantly increased compared to both other dietary treatments. Fish fed LO had significantly increased 18:2n-6, 18:3n-6, 20:2n-6, 20:3n-6 and total n-6 PUFA but significantly reduced 22:5n-6 compared to fish fed FO. LO fish had significantly increased 18:3n-3, 18:4n-3, 20:3n-3 and 20:4n-3 compared to both other dietary treatments but had significantly reduced DHA compared to FO-fed fish. In fish fed SO 18:3n-3, 20:4n-3, EPA, 22:5n-3 and total n-3 PUFA were significantly reduced compared with both other dietary treatments while DHA was significantly reduced compared to FO-fed fish. The n-3/n-6 PUFA ratio was significantly different in the three dietary treatments with the highest value in FO-fed fish and the lowest in SO-fed fish.

The fatty acid compositions of liver EPL are shown in Table 3. Total monoenoic fatty acids were significantly different for each dietary treatment with the highest levels in FO-fed fish and the lowest levels in SO-fed fish. Also, 18:2n-6, 20:2n-6, 20:3n-6 and total n-6 PUFA were

significantly affected by dietary treatment with the highest levels in SO-fed fish and the lowest levels in FO-fed fish. Levels of 22:5n-6 were also significantly different in each dietary group with highest values in SO-fed fish and lowest in LO-fed fish. AA and 22:4n-6 were significantly increased in fish fed SO compared to both other dietary treatments. Also, 18:3n-3, 20:4n-3 and EPA were significantly different in each dietary treatment with highest levels in LO-fed fish and lowest in SO-fed fish. 22:5n-3 was significantly increased in LO-fed fish compared to SO-fed fish whereas DHA was significantly greater in FO-fed fish compared to both other treatments. Total n-3 PUFA were significantly lower in SO-fed fish while total PUFA were significantly different in each dietary treatment with the highest levels in SO-fed fish and the lowest in FO-fed fish. The ratio of n-3/n-6 PUFA was significantly different in each dietary treatment with the highest value in FO-fed fish and the lowest in SO-fed fish. The AA/EPA ratio of eicosanoid precursors was significantly increased in SO-fed fish compared to both other treatments.

The fatty acid compositions of liver PS are shown in Table 4. Total saturated fatty acids were significantly increased whereas total monoenoic fatty acids were significantly decreased in fish fed SO and LO compared to those fed FO. The level of 20:3n-6 was significantly different in each dietary treatment with the highest levels in SO-fed fish and the lowest in FO-fed fish. AA and 22:5n-6 were also significantly different in each treatment with the highest levels in SO-fed fish and the lowest in LO-fed fish. 18:2n-6, 20:2n-6, 22:4n-6 and total n-6 PUFA were all significantly increased in fish fed SO compared to the other dietary treatments. Levels of 18:3n-3 and 20:4n-3 were significantly greater in fish fed LO than in the two other treatments while EPA was significantly reduced in SO-fed fish compared to LO-fed fish. Total n-3 PUFA were significantly reduced in SO-fed fish compared to both other treatments while DHA was reduced in fish fed SO compared to those fed FO. Total PUFA were significantly greater in SO-fed fish compared to LO-fed fish. The n-3/n-6 PUFA ratio was significantly lower and the AA/EPA ratio significantly greater in SO-fed fish compared to both other treatments.

The fatty acid compositions of liver PI are shown in Table 5. Total saturated fatty acids were significantly elevated in fish fed SO and LO compared with those fed FO. Total monoenoic fatty acids were significantly different in all treatments with the highest levels in fish fed FO and the lowest in those fed SO. Levels of 18:2n-6 and total n-6 PUFA were significantly increased in SO-fed fish compared to the other two treatments whereas 20:3n-6 was significantly greater in LO-fed fish compared to the other treatments. AA was significantly different in all dietary treatments with the highest level in SO-fed fish and the lowest level in LO-fed fish. Also, 18:3n-3, 20:4n-3 and total n-3 PUFA were significantly reduced in fish fed SO compared to the other two treatments. EPA was significantly different in all treatments with the highest level in LO-fed fish and the lowest in SO-fed fish. Levels of 22:5n-3 and DHA were significantly different in all treatments with the highest levels in FO-fed fish and the lowest in SO-fed fish. Total PUFA were significantly greater in SO-fed fish compared to LO-fed fish. The n-3/n-6 PUFA ratio was significantly lower and the AA/EPA ratio significantly greater in fish fed SO compared to both other treatments.

The major PUFA in gill CPL and EPL are shown in Figure 1. in CPL 18:2n-6 and 20:3n-6 were significantly

[a]Results are % by weight ± SD from four fish per treatment; t = trace value <0.05%. SD <0.05 are recorded as 0.0. PUFA, polyunsaturated fatty acids. Values in the same row with different superscript letters b, c, d are significantly different ($P < 0.05$).

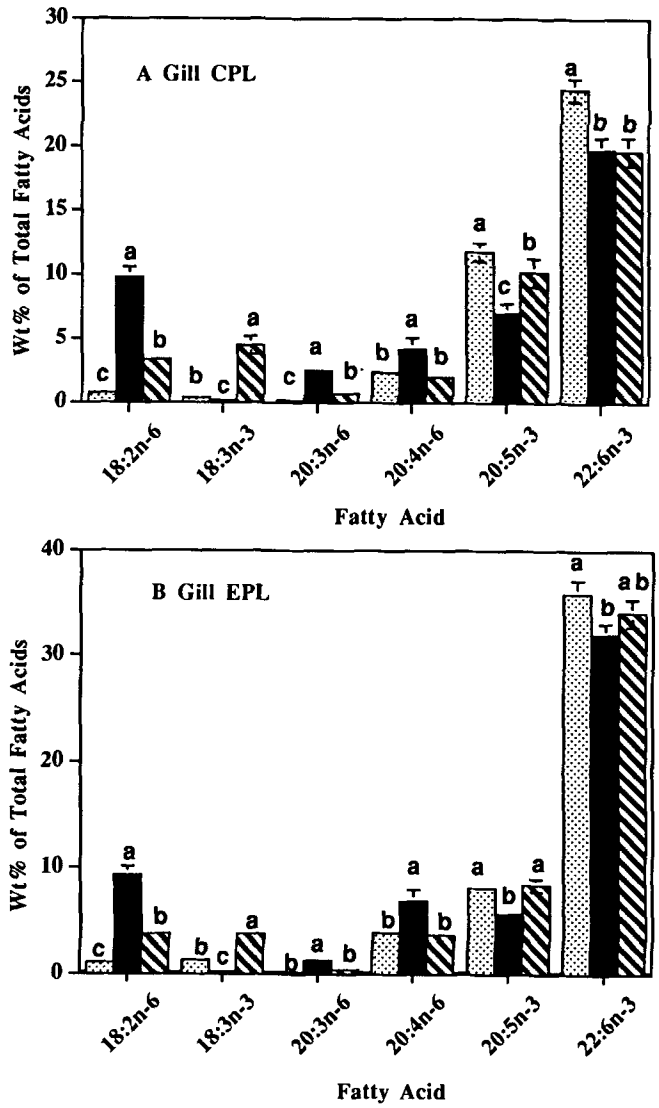

FIG. 1. The levels of the major polyunsaturated fatty acids of gill choline phospholipids (CPL) (A) and ethanolamine phospholipids (EPL) (B) from salmon fed diets containing either fish oil (dotted bars), sunflower oil (filled bars) or linseed oil (hatched bars). Values are means ± SD for four fish per treatment. Values for each fatty acid having a different column letter are significantly different ($P < 0.05$).

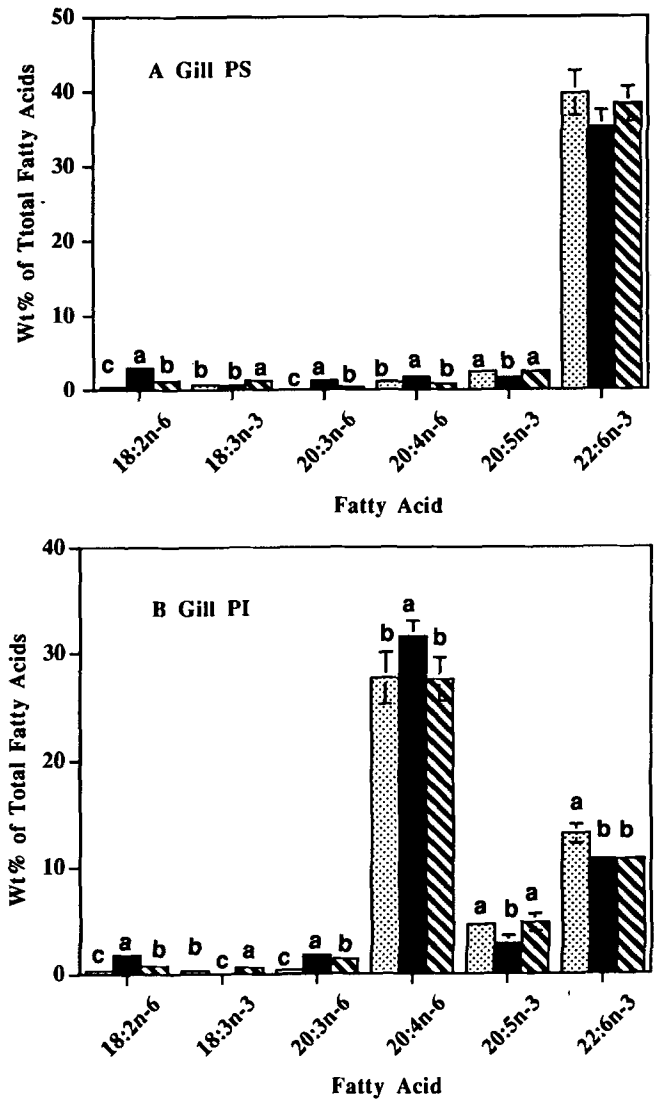

FIG. 2. Levels of the major polyunsaturated fatty acids of gill phosphatidylserine (PS) (A) and phosphatidylinositol (PI) (B) from salmon fed diets containing either fish oil (dotted bars), sunflower oil (filled bars) or linseed oil (hatched bars). Values are means ± SD for four fish per treatment. Values for each fatty acid having a different column letter are significantly different ($P < 0.05$).

different in all dietary treatments with the highest levels in SO-fed fish and the lowest levels in FO-fed fish. AA was significantly increased and EPA significantly reduced in SO-fed fish, resulting in an increased AA/EPA ratio when compared to fish fed either FO or LO. In gill PI the results were largely similar to PS except that DHA was significantly greater in fish fed FO than in both other dietary treatments.

The production of eicosanoids by isolated gill cells stimulated by A23187 is shown in Table 6. The production of 12-HETE, 12-HEPE and 14-HDHE were all significantly reduced in fish fed both LO and SO compared to those fed FO. However, the ratio of 12-HETE/12-HEPE was significantly increased in fish fed SO compared to both other treatments. While mean values of both TXB_2 and PGE_2 were greatest in fish fed SO, they were not significantly different from either of the other dietary treatments.

DISCUSSION

Feeding SO results in increased levels of 18:2n-6, 20:2n-6, 20:3n-6 and AA in all liver phospholipids while 22:4n-6 and 22:5n-6 were increased in CPL, EPL and PS compared to both other treatments. 20:3n-6, the product of Δ6 desaturation and elongation of 18:2n-6, was also increased in fish fed LO, whereas AA, the product of Δ5 desaturation, was generally decreased in those fish compared to fish fed FO. Similarly 22:5n-6, the product of Δ4 desaturation and elongation of AA was decreased in fish fed LO compared to those fed FO. Therefore it appears that feeding LO, which contains 18:2n-6 and 18:3n-3 in a ratio

TABLE 6

Eicosanoids from Isolated Salmon Gill Cells Stimulated with the Ca^{2+}-Ionophore A23187

Eicosanoid[a]	Fish oil diet	Sunflower oil diet	Linseed oil diet
12-HETE	17.7 ± 9.6[b]	5.7 ± 2.9[c]	5.8 ± 0.5[c]
12-HEPE	45.2 ± 12.4[b]	7.8 ± 3.2[c]	21.2 ± 8.2[c]
12-HETE/12-HEPE	0.354 ± 0.094[c]	0.791 ± 0.189[b]	0.327 ± 0.138[c]
14-HDHE	34.1 ± 11.8[b]	6.8 ± 3.8[c]	10.4 ± 1.9[c]
TXB_2	142.8 ± 80.4	229.0 ± 120.9	172.0 ± 59.6
PGE_2	192.3 ± 54.0	807.3 ± 562.3	510.3 ± 177.9

[a]Values are mean ± SD from four fish per treatment. Values for 12-HETE, 12-HEPE and 14-HDHE are ng/mg protein, whereas those for TXB_2 and PGE_2 are pg/mg protein. [b,c]Values in the same row with different superscript letters are significantly different ($P < 0.05$). HETE, hydroxy-5, 8, 10, 14-eicosatetraenoic acid; l HEPE, hydroxy-5, 8, 10, 14, 17-eicosapentaenoic acid; HDHE, hydroxy-4, 7, 10, 13, 16, 19-docosahexaenoic acid; TXB_2, thromboxane B_2; PGE_2, prostaglandin E_2.

of 1:3, has an inhibitory effect on Δ5 (and possibly Δ4) desaturase which is responsible for AA production. The ability of 18:3n-3 to reduce the conversion of 18:2n-6 to AA, by inhibition of Δ6 desaturase, has been recorded previously in mammals (27,28). The differences in 20:3n-6 and AA production by fish fed either SO or LO can be explained by considering the competitive influences of the different dietary fatty acid compositions. In SO-fed fish the high 18:2n-6 level makes AA production inevitable whereas the presence of 18:3n-3 in LO-fed fish results in competition which reduces 20:3n-6 production from 18:2n-6. At the same time Δ6 desaturation and elongation of 18:3n-3 results in increased 20:4n-3 in LO-fed fish, and this, coupled with reduced 20:3n-6, results in reduced AA production and an apparent inhibition of Δ5 desaturase. Similar competitive effects presumably operate to increase or reduce 22:5n-6 levels in SO- and LO-fed fish, respectively.

In a previous study using the related salmonid, the rainbow trout, no increase in elongated and desaturated products of 18:3n-3 were observed in the polar lipid fraction of fish fed 18:3n-3 enriched diets (29). However, in the present study with Atlantic salmon, although dietary EPA levels were similar in both SO and LO diets, the fatty acid compositions of phospholipid classes of both liver and gill showed decreased EPA in SO-fed fish, but LO-fed fish had EPA values greater than or equal to those of FO-fed fish. These results suggest that salmon are capable of EPA production from 18:3n-3 utilizing the pathways of Δ6 and Δ5 desaturation and elongation. Although some phospholipid classes from liver of LO-fed fish had elevated 22:5n-3, there was no apparent increase in DHA compared to fish fed FO. Previous studies with Atlantic salmon parr have demonstrated that they are capable of converting 18:3n-3 to DHA (5) but in the larger post-smolts used in the present study Δ4 desaturation is either very low or, more likely, the requirement for DHA is met by dietary input.

Both AA and EPA can be metabolized by cyclooxygenase to yield prostaglandins of the 2 and 3 series and by lipoxygenase to yield leukotrienes of the 4 and 5 series and a number of HETE and HEPE isomers (14,30). It is generally regarded that EPA is a poorer substrate for cyclooxygenase than AA and thus acts as a competitive inhibitor (16). The biological activity of the EPA-derived prostanoids and leukotrienes is considerably less than that of their AA-derived equivalents (12,31) which explains the ability of so-called 'MaxEPA' preparations to attenuate many of the pathophysiological conditions which occur in humans (7). In the present study feeding LO decreases AA and increases EPA in tissue phospholipids of Atlantic salmon and might therefore be expected to alter the spectrum of eicosanoids produced by these fish.

Gill cells were chosen since they are known to possess a highly active 12-lipoxygenase (18,32) and also to contain cyclooxygenase activity (5). While overall production of 12-lipoxygenase products was greatest in fish fed FO, the ratio of 12-HETE/12-HEPE was increased in SO-fed fish and was similar in both FO- and LO-fed fish. Although no specific physiological role has been identified for products of 12-lipoxygenase, a number of recent studies have implicated 12-HETE as a modulator of ion channels (33,34). Clearly this activity would be particularly important in gills which, along with posterior kidney, are vital in controlling osmoregulation in fish. Diet-induced changes in gill lipoxygenase products might therefore affect the ability of salmon to adapt to varying salinity.

In a previous study Atlantic salmon given increasing dietary linoleic acid produced decreasing amounts of gill 12-lipoxygenase products (18). In the present study salmon fed LO also produced significantly less 12-lipoxygenase products compared to fish fed FO. A similar decrease was also observed in platelet 12-lipoxygenase products from rats fed 18:3n-3 compared to those fed FO (14). One possible explanation is that changes in membrane phospholipid fatty acid composition might affect the activity of phospholipase A_2 which provides the precursors for eicosanoid production. Recent studies have established that phospholipase A_2 activity can be either increased or decreased in different tissues as a result of decreasing the membrane n-3/n-6 PUFA ratio (35,36).

The tendency for the PI fraction to accumulate 20-carbon fatty acids in fish has resulted in the hypothesis that this phospholipid might be the source of precursor fatty acids for eicosanoid production (5,37). However, the ratio of 12-HETE/12-HEPE produced by stimulated gill cells in the current experiment was most similar to the AA/EPA ratio present in gill CPL (0.20, 0.61 and 0.20 for FO, SO and LO diets, respectively). Comparison of the precursor fatty acid ratios of both CPL and PI would make the former class the more likely source of lipoxygenase substrate fatty acids. A similar result has been recorded in mammalian platelets (38) and cultured umbilical cells (39).

The present study demonstrated that while diets rich in 18:2n-6 result in increased AA in membrane lipids of

salmon, the fatty acid compositions can be 'normalized' to the position in fish fed FO, by feeding 18:3n-3. In this context linseed oil could be useful, when used in conjunction with marine oils, as an inhibitor of inflammatory activity in fish.

ACKNOWLEDGMENT

We would like to thank all S.O.A.F.D. personnel involved in running the Fish Cultivation Unit, Aultbea, for their expertise and assistance with fish husbandry.

[Received December 15, 1992, and in revised form June 28, 1993; Revision accepted June 29, 1993]

Dietary Fish Oil Inhibits Human Breast Carcinoma Growth: A Function of Increased Lipid Peroxidation

Michael J. Gonzalez[a], Rachel A. Schemmel[a], LeRoy Dugan, Jr.[a], J. Ian Gray[a] and Clifford W. Welsch[b,*]
[a]Department of Food Science and Human Nutrition and [b]Department of Pharmacology and Toxicology, Michigan State University, East Lansing, Michigan 48824

Female athymic nude mice were implanted subcutaneously with human breast carcinoma MDA-MB231. Seven to ten days later, the mice were divided into groups and fed a purified diet containing the following types of fat (% of diet): (i) 20% corn oil (CO); (ii) 15% CO:5% fish (menhaden) oil (FO); (iii) 10% CO:10% FO; (iv) 5% CO:15% FO; (v) 1% CO:19% FO; and (vi) 1% CO:19% FO plus antioxidants (α-tocopherol acetate, 2000 IU/kg diet and tertiary butylhydroquinone, 2% of total fat). The linoleic acid levels (% of diet) of the groups were 12.0, 9.1, 6.2, 3.3, 0.9 and 0.9%, respectively. After 6–8 wk, the carcinomas were assessed for tumor volume (cm^3) and assayed for thiobarbituric acid reactive substances (TBARS). Human breast carcinoma growth was suppressed in mice consuming FO diets without antioxidants as compared to mice fed CO; the greater the amount of dietary FO fed, the greater the carcinoma growth suppression ($P < 0.05$). The addition of antioxidants to the FO diet significantly ($P < 0.05$) reversed the FO-induced carcinoma growth suppression. Concentrations of TBARS in the human breast carcinomas were increased in all the FO (without antioxidants) fed mice, compared to mice fed CO; the level of increase in TBARS was directly related to the increase in the level of FO fed ($P < 0.05$). The addition of antioxidants to the FO diet significantly ($P < 0.05$) reduced the concentration of TBARS in the breast carcinomas. Thus, these results provide evidence that dietary FO can significantly suppress growth of human breast carcinoma MDA-MB231, even in the presence of substantial amounts of linoleic acid (3.3–9.1%). The inhibitory effect of FO on growth of these carcinomas was associated with an increased concentration of TBARS in the tumor tissue. In conclusion, dietary FO induced suppression of human breast carcinoma growth is a function, at least in part, of an accumulation of lipid peroxidation products in the tumor tissues.
Lipids 28, 827–832 (1993).

Fish oil (FO), which contains elevated levels of long-chain ω3 polyunsaturated fatty acids, particularly eicosapentaenoic acid (EPA, 20:5) and docosahexaenoic acid (DHA, 22:6), has been shown to suppress mammary gland tumorigenesis in rodent models (1–4). In addition, FO has been shown to inhibit the growth of human breast carcinomas maintained in immune-deficient animals (5–9). To explain how FO inhibits mammary tumorigenic processes, many investigators (2–4) have focused on EPA- and/or DHA-induced alterations in eicosanoid metabolism. Other investigators (10,11) suggested that dietary FO inhibits mammary tumorigenesis because it may not provide a sufficient amount of essential fatty acids, such as linoleic acid (18:2). Indeed, a direct relationship between the amount of dietary linoleic acid and mammary tumor growth has been clearly shown (12). In contrast, we have explored yet another potential mechanism, *i.e.*, that high levels of dietary FO inhibit mammary tumorigenesis by causing an increased accumulation of cytostatic and/or cytotoxic lipid peroxidation products in the tumor tissue (9).

In this communication, we further examine the relationship between dietary FO and growth of human breast carcinomas in athymic nude mice by pursuing the following objectives: (i) to determine whether or not high levels of dietary FO, in the presence of substantial amounts of linoleic acid, can inhibit growth of these tumors and (ii) whether or not there is a correlation between tumor growth and the quantity of lipid peroxidation products in the tumor tissues of mice fed FO.

MATERIALS AND METHODS

Animals and diet. One hundred and sixty-four female athymic nude mice (Harlan Sprague Dawley Inc., Madison, WI), 4–5-wk-old, were used in these studies. The mice were housed under aseptic conditions (enclosed overhead laminar flow hood, sterilized cages, bedding and water) in a temperature (24°C) and light-controlled (14 h/d) room. All experimental procedures pertaining to the athymic mice were performed under aseptic conditions. Autoclaved laboratory mouse chow (Purina Mills Inc., St. Louis, MO) was fed *ad libitum* before and up to 7–10 d after human breast carcinoma transplantation. Thereafter, mice were fed purified diets (Table 1) *ad libitum.* The percentages of the predominant fatty acids (1% or greater, manufacturer's specifications) of the dietary oils are shown in Table 2. The diets were prepared weekly in our laboratory, individually packed in small, plastic zipper-sealed bags of sufficient size for one day's feed, flushed with nitrogen, sealed and stored at −20°C. Mice were fed daily and nonconsumed food was discarded daily. Because the purified diets were not sterilized, antibiotics (bacityracin combined with streptomycin or neomycin, 1 g/L) were added to the distilled drinking water.

Human breast carcinoma transplantation. Palpable MDA-MB231 human breast carcinomas (American Type Culture Collection, Rockville, MD) were surgically excised from female athymic mice, cut into slices (2 × 4 mm, 0.1–0.3 mm thick) and implanted into recipient mice. Mice were anesthetized with sodium pentobarbital (60 μg/g, *i.p.*) prior to transplantation. An incision was made in the integument, the tumor slices were placed subcutaneously in the dorsum at distances from each other of at least 2 cm, 3–4 slices/mouse. Between one and three palpable human breast carcinomas were pooled to provide the tissue slices. Mice were placed on the experimental diets 7–10 d after carcinoma transplantation. This period allows the carcinoma grafts to become established in the host animals before the onset of experimental dietary treatments. Athymic mice bearing human breast carcinoma grafts

Docosahexaenoic (22:6)	—	12.1

[a]Fatty acid concentrations <1% are not included.

were fed the experimental diets for a period of 6–8 wk. At the termination of the studies, all tumors were excised and their volume determined ($V = 4/3\ \pi\ r^3$) with a vernier caliper. Four separate studies were carried out; each study was a complete individual experiment.

Study 1. The experimental design of this study is provided in Table 3. The purpose of this study was to determine if varying levels of FO mixed with varying levels of linoleic acid-rich corn oil (CO) are capable of modifying the human breast carcinoma growth suppressive effect of a FO diet. In addition, we sought to determine if a relationship exists between human breast carcinoma growth and the level of lipid peroxidation products in the tumor tissue. The level of lipid peroxidation products of excised 10 g tumor composites in each group were determined by measuring 2-thiobarbituric acid reactive substances (TBARS) using a modified macro-thiobarbituric acid (TBA) assay (9).

Macro-TBA assay. Subcutaneously growing human breast carcinomas were surgically excised, placed individually in a 0.9% NaCl solution, immediately frozen (−20°C) and stored for one day. Immediately before the TBA assay, the tumors were thawed and tumor samples pooled to obtain 10-g composites. Once sufficient tumor homogenate was obtained from pooling (10-g composite), this constituted one sample. To obtain other samples, other tumors within the same group were also pooled to form 10-g samples. Three to five samples (10-g composites) were done in triplicate for each group. An antioxidant [tertiary butylhydroquinone (TBHQ); Eastman Chemical Products, Kingsport, TN], at 0.02% of total fat, as determined by a dry column extraction method (13) was added to the samples; the samples were homogenized (4°C) in a Polytron homogenizer (Ultra Turrax SDT 1810; Tekmar Co., Cincinnati, OH). The homogenates were transferred into distillation flasks containing 2.5 mL 4N HCl plus 0.5 mL silicone antifoam (Thomas Scientific Co., Swedesboro, NJ) with sufficient distilled water to yield a total volume of 100 mL/flask and distilled to collect 50 mL. Five mL of this distillate plus 5 mL of freshly prepared TBA (0.2N aqueous solution; Sigma Chemical Co., St. Louis, MO) were used for the assay. Samples were prepared in triplicate, heated in a boiling water bath for 35 min to develop the pigment, cooled and the absorbance read on a spectrophotometer (Spectronic 2000; Bausch & Lomb, Rochester, NY) at 532 nm. The absorbance values obtained were multiplied by an adjustment factor of 6.2 (14). Results were reported as μg of TBARS per g of sample.

Study 2. The experimental design of this study is provided in Table 4. The purpose and experimental design of this study was similar to Study 1, but two additional dietary groups (1% CO/19% FO and 1% CO/19% FO plus antioxidants) were added. A modified micro-TBA assay (15) was used in this study in order to individually assay each excised tumor for TBARS.

Micro-TBA assay. Subcutaneously growing human breast carcinomas were surgically excised, frozen (−20°C) for one day, thawed and individually homogenized (4°C) in the presence of an antioxidant (TBHQ, 0.02% of total fat) in a Polytron homogenizer. One mL of homogenate was combined with 2.0 mL of TBA (0.375% wt/vol), trichloroacetic acid (15.0% wt/vol) and HCl (0.25N) and mixed thoroughly. The solution was heated for 15 min in a boiling water bath. After cooling, the precipitate was removed by centrifugation (1,000 × *g* for 10 min) and the supernatant kept for analysis. The absorbance of the sample was determined at 535 nm against a blank that contains all reagents minus the homogenate. This TBA assay is a slightly modified version of the Buege and Aust assay (15). TBARS concentration of the sample was calculated using an extinction coefficient of $1.56 \times 10^5\ M^{-1}\ cm^{-1}$ (16) and reported as nmoles TBARS per mg of protein. The protein concentration of tumors was determined according to the method of Lowry *et al.* (17).

Study 3. The experimental design of this study is shown in the legend of Figure 1. The purpose of this study was to determine if the concentration of TBARS in individual human breast carcinomas correlated with tumor size from a single FO dietary group (1% CO:19% FO). Excised

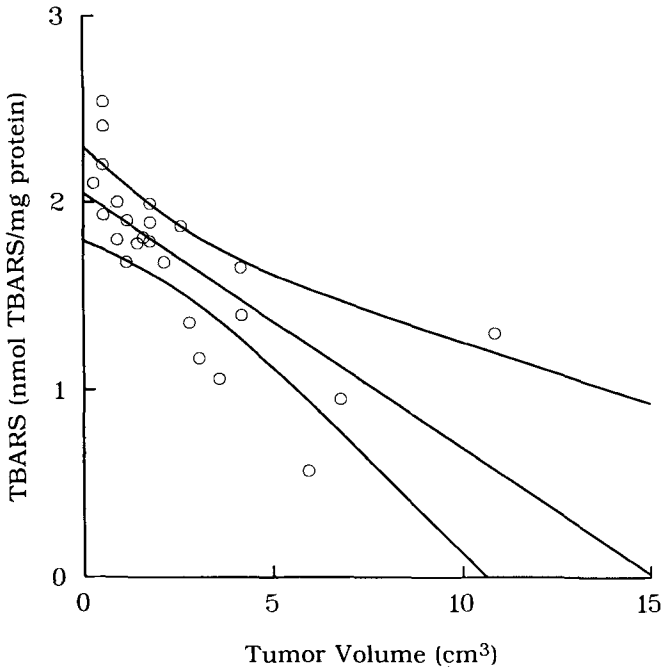

FIG. 1. Relationship between mean carcinoma volume (cm^3) and mean carcinoma thiobarbituric acid reactive substances (TBARS) concentrations per individual MDA-MB231 human breast carcinoma in athymic nude mice fed a 1% corn oil:19% fish oil diet (n = 24). There were eight animals in this dietary group. Curved lines represent a 95% confidence interval. The Pearson correlation coefficient = 0.725 ($P < 0.05$).

tumors were individually assayed for TBARS by the modified micro TBA assay.

Study 4. The experimental design of this study is provided in Table 5. The purpose of this study was to determine if the length of time the FO diet is allowed to remain in the food jar, under feeding conditions, *i.e.*, 24, 48 and 72 h after feeding, influences human breast carcinoma growth and carcinoma concentration of TBARS. The jars with diet were changed every 24, 48 or 72 h. Excised tumors were individually assayed for TBARS by the modified micro-TBA assay.

Statistical analyses. Data in Studies 1, 2 and 4 were analyzed by one-way analysis of variance and the Newman-Keuls multiple comparison test (18). Significance was set at $P < 0.05$. Data for Study 3 were examined by Pearson's correlation coefficient (18).

RESULTS

Human breast carcinoma growth. In Study 1, mean human breast carcinoma volumes (cm^3) obtained from the four dietary groups at experiment termination ranked (from largest to smallest) as follows: 20% CO > 15% CO:5% FO > 10% CO:10% FO > 5% CO:15% FO (Table 3). Mean carcinoma volumes in mice fed each of the three FO diets were significantly ($P < 0.05$) smaller than the mean carcinoma volume of mice fed CO as their sole source of fat (20% CO). Body weight gains were not significantly different among the mice in the different dietary groups.

In Study 2, mean human breast carcinoma volumes (cm^3) obtained from the six dietary groups at termination of the experiment ranked (largest to smallest) as follows: 20% CO > 15% CO:5% FO > 1% CO:19% FO plus antioxidants > 10% CO:10% FO > 5% CO:15% FO >1% CO:19% FO (Table 4). Mean carcinoma volume in mice fed 20% CO was numerically higher than those of the 15% CO:5% FO- and 1% CO:19% FO plus antioxidants-fed mice, but this difference did not reach a level of significance. However, each of these three groups had mean carcinoma volumes which were significantly ($P < 0.05$) larger than those produced by the 10% CO:10% FO, 5% CO:15% FO and 1% CO:19% FO dietary groups. Body weight gains were not significantly different among the mice in the different dietary groups.

In Study 4, mean human breast carcinoma volume (cm^3) obtained from the three dietary groups at termination of the experiment ranked (largest to smallest) as follows: 24 h, 1% CO:19% FO > 48 h, 1% CO:19% FO > 72 h, 1% CO:19% FO (Table 5). Mean carcinoma volumes in mice in which the diet (1% CO:19% FO) was changed

TABLE 5

Effect of the Length of Time the Fish Oil Diet Remained in the Food Jar Under Usual Feeding Conditions on the Growth and Lipid Peroxidation Product Concentrations of MDA-MB231 Human Breast Carcinomas in Athymic Nude Mice

Length of time diet remained in the food jar[a]	Mean mouse body weight (g) ± SE[b]	Number of tumors	Mean tumor volume (cm^3) ± SE[b]	Mean tumor lipid peroxidation product levels (nmol/TBARS/mg protein) ± SE[b]
24 h (1% corn oil: 19% fish oil)	30.6 ± 0.9[c]	24	0.70 ± 0.17[c]	2.04 ± 0.09[c]
48 h (1% corn oil: 19% fish oil)	28.5 ± 0.9	28	0.48 ± 0.11[d]	2.40 ± 0.10[d]
72 h (1% corn oil: 19% fish oil)	27.4 ± 0.5[d]	26	0.25 ± 0.27[e]	3.69 ± 0.14[e]

[a]Eight to nine animals/group.
[b]Values with different superscript letters in the same column are significantly different at $P < 0.05$. TBARS, thiobarbituric acid reactive substances.

every 24 h was significantly larger ($P < 0.05$) than in the 48-h or 72-h diet groups. The mean carcinoma volume of the 48-h diet group was significantly larger ($P < 0.05$) than that of the 72-h diet group. Body weight gains were significantly lower ($P < 0.05$) for the 72-h diet group as compared to the 24-h diet group.

Human breast carcinoma lipid peroxidation product levels (TBARS). The ranking of mean human breast carcinoma TBARS concentrations in the four dietary groups of Study 1 at termination was: 5% CO:15% FO > 10% CO:10% FO > 15% CO:5% FO > 20% CO (Table 3). Mean human breast carcinoma TBARS concentrations in mice fed each of the three FO diets were significantly ($P < 0.05$) greater than the mean carcinoma TBARS value in mice fed CO as their sole source of fat (20% CO). In Study 2, the ranking of the mean human breast carcinoma TBARS concentrations in the six dietary groups at termination was: 1% CO:19% FO > 5% CO:15% FO > 10% CO:10% FO > 15% CO:5% FO > 20% CO > 1% CO:19% FO plus antioxidants (Table 4). Mean tumor TBARS concentrations were virtually identical in the 1% CO:19% FO plus antioxidants- and 20% CO-fed animals. Mean tumor TBARS concentration in mice fed each of the four nonantioxidant-supplemented FO diets were significantly ($P < 0.05$) greater than the mean tumor TBARS concentrations in mice fed the antioxidant-supplemented FO and in the group fed only CO as their sources of fat. In Study 3, an inverse relationship is shown between volumes of individual human breast carcinomas and carcinoma TBARS concentrations in mice fed the 1% CO:19% FO diet ($P < 0.05$) (Fig. 1), *i.e.*, the smaller the tumor volumes, the greater the concentration of TBARS. In Study 4, mean carcinoma TBARS concentration in mice in which the diet (1% CO:19% FO) was changed every 24 h was significantly lower ($P < 0.05$) than in the 48- or 72-h diet groups (Table 5). The mean carcinoma TBARS of the 48-h diet group was significantly less ($P < 0.05$) than that of the 72-h diet group.

DISCUSSION

This study provides evidence that supplementation of a high-fat (CO) diet with even a modest amount of FO (*e.g.*, 15% CO/5% FO) can result in a suppression of growth of a human breast carcinoma (MDA-MB231) maintained in athymic nude mice. Other laboratories have provided evidence that FO-containing diets inhibit mammary gland tumorigenesis in rodents (1–4) and suppress growth of human breast carcinomas in athymic nude mice (5–9). Such studies often utilize diets containing FO as their only source of fat. FO is extremely low in the essential fatty acid linoleic acid (18:2). It is conceivable, therefore, that the suppression of mammary tumorigenesis exerted by diets high in FO may be *via* essential fatty acid (linoleic acid) insufficiency. Indeed, supplementation of FO diets with modest amounts of linoleic acid, in certain mammary tumor animal models, has been reported to block (4) or partially block (19) the tumorigenic inhibitory activities of a diet high in FO. In this study, we were still able to attain growth inhibition of MDA-MB231 human breast carcinomas in athymic nude mice by feeding FO diets containing substantial amounts of linoleic acid (3.3–9.1%). The estimated nutrient requirement for adequate growth and reproduction of mice for linoleic acid is 0.3% w/w of diet (20), but the level required for optimal tumorigenic processes may be substantially higher. For example, Ip *et al.* (12) have reported that approximately 4.4% of linoleic acid in the diet is required for optimal (maximal) mammary tumor development in a rodent model. In our study, diets containing FO and substantial amounts of linoleic acid (up to 9.1% of diet) still suppressed growth of this human breast carcinoma. Thus, it is likely that dietary FO-induced suppression of growth of human breast carcinoma MDA-MB231 is not due to insufficient dietary linoleic acid.

Inhibition of growth of human breast carcinoma MDA-MB231 by dietary FO may be *via* the accumulation within the tumor of cytostatic and/or cytolytic lipid peroxidation products. Evidence presented in our study which supports this conclusion is as follows. (i) As the FO content of the diet is increased, a concurrent significant increase in carcinoma TBARS concentrations is observed. (ii) Increasing the FO content of the diet decreases carcinoma growth. (ii) Those carcinomas that have the highest concentrations of TBARS have the least tumor growth. (iv) Allowing the FO diet to remain in the food jar for as long as 72 h, a feeding protocol that substantially increases the level of TBARS and the peroxide values in the diet (21), results in an increased accumulation of TBARS in the carcinomas and a concordant suppression of carcinoma growth. (v) The addition of efficacious antioxidants to the FO diet substantially decreases carcinoma TBARS concentrations and concurrently increases carcinoma growth. Collectively, these results clearly support the concept that lipid peroxidation products are relevant to the process of dietary FO-induced inhibition of breast carcinoma growth. Recent evidence from our laboratory (21) indicates that dietary FO-derived lipid peroxidation products are formed extensively in the food jar under normal feeding conditions. After feeding FO, such products are not only found in tumor tissue but are found in normal tissues as well.

The mechanism by which lipid peroxidation products retard or inhibit tumor growth processes is not certain (22). Secondary products of lipid peroxidation (measured by the TBA assay) are capable of decreasing cell proliferation through damaging cell membranes, by changing cellular composition and/or cytoskeleton assembly. These modifications in the molecular architecture of the membrane can lead to the inactivation of membrane transport systems and/or membrane bound enzymes (23–25). This phenomenon may adversely affect the entering of cells into the cell cycle or it may accelerate their exit (*i.e.*, cell death). Furthermore, secondary products of lipid peroxidation can decrease tumor cell survival by inactivating polymerase reactions (26), forming inter- and/or intramolecular linkages between amino acid sulfhydryl groups and biomolecules (DNA, RNA and proteins) (27) and inhibiting polyamine synthesis (28). Such processes may not only result in inhibition of cell proliferation but may also lead to an increase in cell death. Indeed, Garbor and Abraham (4) reported that dietary FO inhibits mammary tumor growth processes by increasing mammary tumor cell death rather than suppressing mammary tumor cell proliferation.

Although under certain conditions secondary products of lipid peroxidation may decrease tumor growth *via* a cytostatic/cytolytic mechanism, under other

circumstances such products could stimulate tumor growth. For example, a peroxidation product of linoleic acid, *i.e.*, 13-hydroxy (hydroperoxy) octadecadienoate, is more mitogenic to rat colonic mucosa cells (29) or to hamster embryo fibroblasts (30) than is the parent compound. In addition, a peroxidation product of arachidonic acid, *i.e.*, hydroxy (hydroperoxy) eicosatetraenoic acid, stimulates rat colonic mucosa cell proliferation while the parent compound itself lacks stimulatory activities (29). Thus, peroxidation products derived from fatty acids in dietary FO (particularly EPA, DHA and possibly linoleic acid) could be stimulatory to tumor growth processes. In the tumor model used in this study (MDA-MB231 human breast carcinoma maintained in athymic nude mice), however, we find no evidence of dietary FO-induced stimulation of tumor growth.

The results of our study clearly show that the addition to the FO diet of large amounts of antioxidants (vitamin E and TBHQ) significantly counteracted the inhibitory effects of dietary FO on human breast carcinoma growth. In essence, high levels of antioxidants, in the presence of dietary FO, stimulated tumor growth. Other laboratories have provided evidence that supplementation of the diet with antioxidants inhibits tumorigenesis. Clearly dietary antioxidants can suppress carcinogen activation in experimental tumor models (31). Occasionally it is reported that antioxidant supplementation can suppress tumor growth (32,33), although there is considerable evidence to the contrary (34–36). Thus, it is likely that various antioxidants can suppress genotoxic induced initiation and/or progression events in tumorigenesis; evidence that antioxidants can effectively suppress tumor growth processes, however, has not been consistent or compelling.

In conclusion, the results of this study provide evidence that dietary FO can significantly suppress the growth of MDA-MB231 human breast carcinomas maintained in athymic nude mice, even in the presence of substantial amounts of dietary linoleic acid. The suppressive effect appears to be directly related to the accumulation of TBARS in the tumor tissues.

An analytical method for the determination of cholesterol sulfate (CS) in plasma using gas–liquid chromatography was developed. We measured plasma CS concentrations in patients with liver cirrhosis and hypercholesterolemia as examples of disorders that involve aberrations in cholesterol metabolism. Patients with liver cirrhosis had plasma CS concentrations that were significantly higher than those of control subjects (444.6 ± 51.7 *vs.* 253.0 ± 24.6 μg/dL, mean ± SE). The levels of other lipids were lower in cirrhotics, although the differences were not significant. There was no correlation between the levels of CS and sulfated bile acids in cirrhotic patients. CS levels in plasma were also higher in subjects with hypercholesterolemia (413.7 ± 44.5 μg/dL); however, the ratio of CS to total cholesterol (TC) clearly differed between cirrhotics and hypercholesterolemic subjects ($1.44 \pm 0.11 \times 10^{-3}$ *vs.* $3.31 \pm 0.63 \times 10^{-3}$; $P < 0.05$). Both in subjects with hypercholesterolemia and in healthy controls, the CS/TC ratio was similar and CS accounted for roughly 0.14% of the TC concentration.

***Lipids* 28, 833–836 (1993).**

Cholesterol sulfate (CS) is a minor constituent of various mammalian tissues and fluids, including erythrocytes (1,2), spermatozoa (3), hair (4), epidermal lipid (5,6) and feces (7,8). However, little is known about the nature and quantity of CS in these sources. Only under certain conditions can CS be transformed to sulfated steroid hormones without desulfation (9). However, in healthy individuals, this transformation does not occur to any significant extent (10). The measurement of plasma CS levels is important in some clinical conditions, such as in placental or microsomal steroid sulfatase deficiency (11), and in recessive X-linked ichthyosis (12–15).

Huang *et al.* (16) have reported that substantially higher plasma CS levels are found in hypercholesterolemia. However, as far as we know, CS levels in patients with liver cirrhosis have not been reported. In cirrhotic patients, the synthesis of cholesterol is reduced and sulfation of bile acids (BA), which are the main products of cholesterol, is increased (17). We report here a reliable method for measuring the minute amounts of CS that occur in human plasma using gas–liquid chromatography (GLC) with dihydrocholesterol-3-sulfate (DHCS) as internal standard. We applied this method to determine plasma CS levels in healthy subjects as well as in patients with hypercholesterolemia and liver cirrhosis.

*To whom correspondence should be addressed at Third Department of Internal Medicine, Hirosaki University School of Medicine,5 Zaifu, Hirosaki, Aomori 036, Japan.

Abbreviations: BA, bile acids; CS, cholesterol sulfate; DHCS, dihydrocholesterol-3-sulfate; EC, esterified cholesterol; FC, free cholesterol; GLC, gas–liquid chromatography; HBs, hepatitis B surface; HCV, hepatitis C Virus; HDL-C, high-density lipoprotein-cholesterol; LDL-C, low-density lipoprotein-cholesterol; TC, total cholesterol; TG, triglyceride; TMS, trimethylsilyl.

MATERIALS AND METHODS

Subjects. The subjects studied included 11 healthy control subjects (64.8 ± 2.6 years old; 6 male and 5 female), 13 patients with liver cirrhosis (63.4 ± 1.6 years old) and 7 age-matched subjects with primary hypercholesterolemia (64.6 ± 5.1 years old).

The cirrhotics (10 male and 3 female) included 7 cases with positive hepatitis C virus (HCV) antibody, 1 with positive hepatitis B surface (HBs) antigen, 2 with chronic alcoholism and 3 with unknown etiology. Cirrhosis was diagnosed by clinical signs (*i.e.*, spider teleangiectasia, splenomegaly and ascites) and abnormal liver tests. Diagnosis was confirmed by percutaneous liver biopsy and/or autopsy in five cases. Five of the 13 cirrhotics were in uncompensated stage. Three patients also had hepatocellular carcinoma.

In seven patients with hypercholesterolemia (two male and five female), four patients were suspected to have heterozygous familial hypercholesterolemia due to xanthelasma and Achilles tendon thickness. Other diseases or effects of medications that might have caused secondary hyperlipemia were ruled out.

Chemicals. All chemicals used were of analytical grade. Free cholesterol (FC) and DHCS were purchased from Sigma Chemical Co. (St. Louis, MO). [4-^{14}C]Cholesterol (specific activity, 51.0 mCi/mmol) was purchased from New England Nuclear Corporation (Boston, MA) and purified before use on a silica column.

Measurement of plasma CS. Fasting venous blood was obtained and stored at −20°C until assayed. Two mL of plasma was used for the analysis and 20 μg of DHCS (Sigma) was added as internal standard. The plasma was added into a mixture of 20 mL of acetone/ethanol (1:1, vol/vol) in an extraction flask, and the mixture was sonicated in an ultrasonic bath (18). The dispersion was then filtered through filter paper, and the paper was washed with 10 mL of acetone/ethanol (1:1, vol/vol). The filtrate was dried under N_2. The residue was dissolved in 4 mL of chloroform and was applied to a column of silica gel (400 mg; Gaskuro Kogyo Co., Ltd., Tokyo, Japan). The column was eluted with 8 mL of chloroform and 6 mL of ethyl acetate to completely remove FC and cholesteryl esters (19). Then CS was eluted with 6 mL of chloroform/methanol (1:1, vol/vol). The dried residue was subjected to solvolysis. After adding 3 mL of tetrahydrofuran/methanol/trifluoroacetate (900:300:1, by vol), the mixture was allowed to stand at 45°C for 2 h and was then evaporated to dryness (20). Then desulfated free cholesterol and dihydrocholesterol were dissolved in chloroform and purified by passing again through the silica column. The eluate was evaporated, and the residue was heated with trimethylsilylating (TMS) reagent (SIGMA-SIL-A, Sigma) at 60°C for 30 min. After drying under a flow of N_2, the sample was analyzed by GLC (Shimadzu GC-8A, Shimadzu, Kyoto, Japan) using flame-ionization detector and a capillary column Hi-Cap (Shimadzu) coated with cross-linked methylsilicone

(25 m × 0.32 i.d.). Oven temperature was maintained at 260°C.

The quantity of CS was calculated as followings: CS (μg) = DHCS (internal standard, 20 μg) × Ac/Ad × response factor (1.009), where Ac is the peak area of cholesterol and Ad the peak area of dihydrocholesterol; the response factor, 1.009, was derived from the detector response of a standard mixture of cholesterol and dihydrocholesterol after solvolysis and TMS derivatization.

Separation of FC from CS on the silica column was tested using the mixture of 4 mg of cold and 8 μg of ^{14}C-labeled free cholesterol in two experiments.

Plasma lipids and BA. Plasma total cholesterol (TC) and FC, as well as triglyceride (TG) levels were determined by enzymatic methods using reagent kits (Cholesterol C-test, Free Cholesterol C-test and Triglyceride G-test, respectively; Wako, Osaka, Japan). The levels of esterified cholesterol (EC) were calculated by subtracting FC from TC. High-density lipoprotein cholesterol (HDL-C) was measured enzymatically after precipitating very low density lipoprotein (VLDL) and low-density lipoprotein (LDL) with heparin and $MnCl_2$ (HDL-C test, Wako). LDL-cholesterol was calculated using Friedewald *et al.* (21) formula. Total BA levels were assayed enzymatically using 3α-hydroxysteroid dehydrogenase (Enzabile 2, Daiichikagaku, Tokyo, Japan). In patients with liver cirrhosis, sulfated BA was extracted using a Sep-Pak C_{18} cartridge (Waters Associates, Inc., Milford, MA) (22). BA levels of the extracts from the Sep-Pak were measured before and after solvolysis using the enzymatic kit. The level of sulfated BA was calculated as the difference between the values obtained before and after solvolysis (20).

Statistics. The data are expressed as a mean ± SE. To compare mean values among the three groups, analysis of variance and the least significant difference were used. A P value of < 0.05 was considered statistically significant. Correlation was examined by Spearman rank correlation coefficient analysis.

RESULTS

Plasma lipid levels. Fasting plasma lipid levels of control subjects and patients with liver cirrhosis and hypercholesterolemia are summarized in Table 1. Plasma lipid levels were higher in hypercholesterolemia and lower in cirrhotics as compared to controls. Lipid levels in the cirrhotic group were lower than those of the control group; however, no statistically significant differences were observed except for the EC/TC ratio. The total BA level was significantly elevated in cirrhotics ($P < 0.01$). The plasma TC levels were over 230 mg/dL (average 289.4 ± 29.4 mg/dL) and LDL-C levels were also elevated (198.0 ± 26.5 mg/dL) in hyperecholesterolemia.

Evaluation of the CS assay. Radioactive tracer experiment showed that FC was well separated from the CS fraction in silica column chromatography. When 2,349,380 dpm of ^{14}C-labeled FC was separated using a silica column, 72.54% (1,704,244 dpm) was eluted with 4 mL of chloroform, 29.37% (690,008 dpm) with the following 8 mL of chloroform, 0.48% (11,394 dpm) with 6 mL of ethyl acetate and 0.002% (60 dpm) with 6 mL of chloroform/methanol (1:1, vol/vol). Total recovery was 102.40%. Therefore, the contamination of the CS fraction with FC was estimated to be 2.55×10^{-3}% (values are the average of two experiments).

TABLE 1

Fasting Plasma Lipids in Control (C) Subjects and Patients with Liver Cirrhosis (LC) and Hypercholesterolemia (HC)[a]

	C (n = 11)	LC (n = 13)	HC (n = 7)
Age	64.8 ± 2.6	63.4 ± 1.6	64.5 ± 5.1
TC (mg/dL)	168.0 ± 6.7	151.5 ± 12.1	289.4 ± 29.4[b]
FC (mg/dL)	37.9 ± 1.3	48.7 ± 4.6	75.6 ± 12.5[b]
EC (mg/dL)	136.1 ± 6.7	102.8 ± 9.2	213.9 ± 18.2[b]
EC/TC (%)	77.1 ± 1.1	67.7 ± 1.9[c]	74.5 ± 1.6
HDL-C (mg/dL)	38.6 ± 3.1	36.1 ± 3.0	58.3 ± 6.8[b]
LDL-C (mg/dL)	110.8 ± 5.8	96.4 ± 10.8	198.0 ± 26.5[b]
TG (mg/dL)	105.6 ± 9.4	95.3 ± 13.9	165.4 ± 22.2[b]
Total BA (μM)	8.5 ± 3.0	30.5 ± 5.3[d]	2.9 ± 0.8

[a]Each value is the mean ± SE. Abbreviations: TC, total cholesterol; FC, free cholesterol; EC, esterified cholesterol; HDL-C, high-density lipoprotein-cholesterol; LDL-C, low-density lipoprotein-cholesterol; TG, triglyceride; BA, bile acid(s).
[b]Differs from LC and C groups, $P < 0.05$.
[c]Differs from HC and C groups, $P < 0.05$.
[d]Differs from HC and C groups, $P < 0.01$. However, values were not compared as the analytical methods used were different (see text).

The retention times in GLC of TMS ethers of cholesterol and of dihydrocholesterol relative to 5β-cholestane were 2.09 and 2.14, respectively (Fig. 1). Figure 2 shows the peak areas against the amounts of standard CS analyzed by GLC.

The average value of recovery of 10 μg or 20 μg of CS, which was added to a pooled sample of normal plasma, were 90.4 ± 7.7% and 100.8 ± 12.1%, respectively (n = 8). To check the reproducibility of the CS assay, eight samples from control subjects and seven samples from cirrhotics were measured in triplicate. The coefficient of variation was 10.1 ± 3.9% in controls and 14.9 ± 5.3% in cirrhotics.

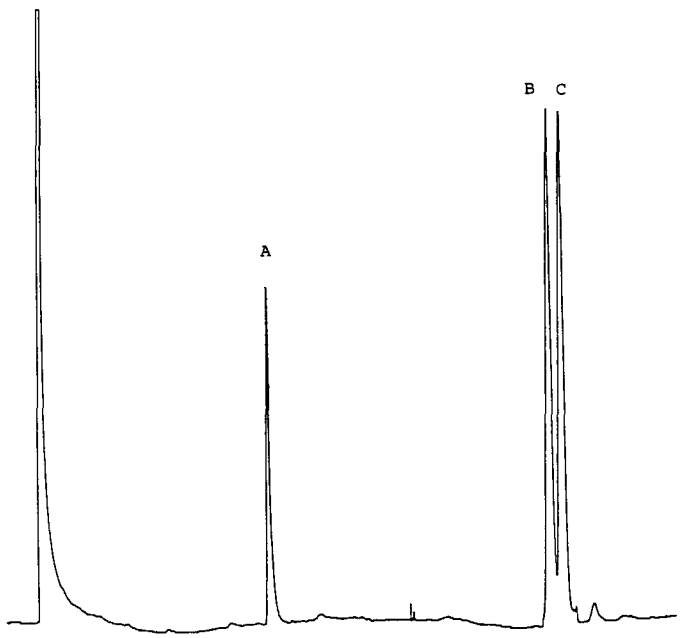

FIG. 1. Chromatographic profiles obtained from an authentic mixture of free cholesterol and dihydrocholesterol. The retention time of the trimethylsilyl ether of cholesterol (B) and dihydrocholesterol (C) relative to 5β-cholestane (A) was 2.09 and 2.14, respectively.

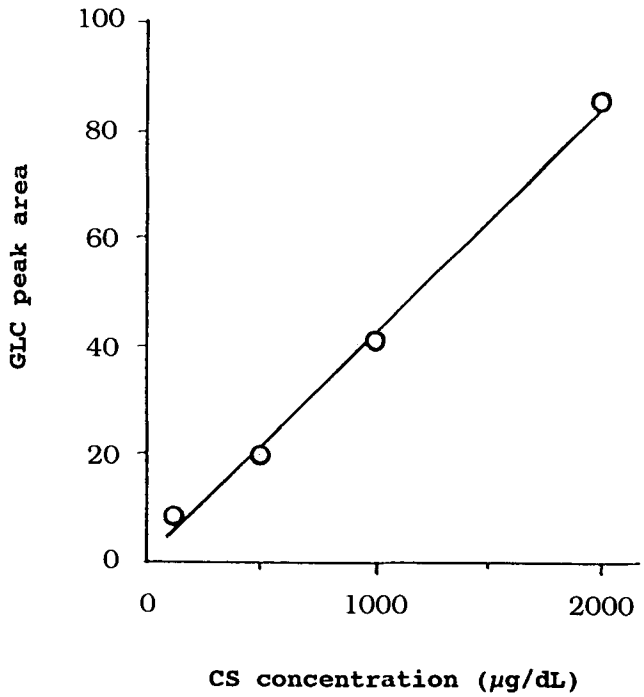

FIG. 2. Relationship between the gas–liquid chromatography (GLC) peak area and various amounts (125–2000 μg/dL) of cholesterol sulfate (CS). CS were measured as a trimethylsilyl ether of free cholesterol. A linear relationship was observed.

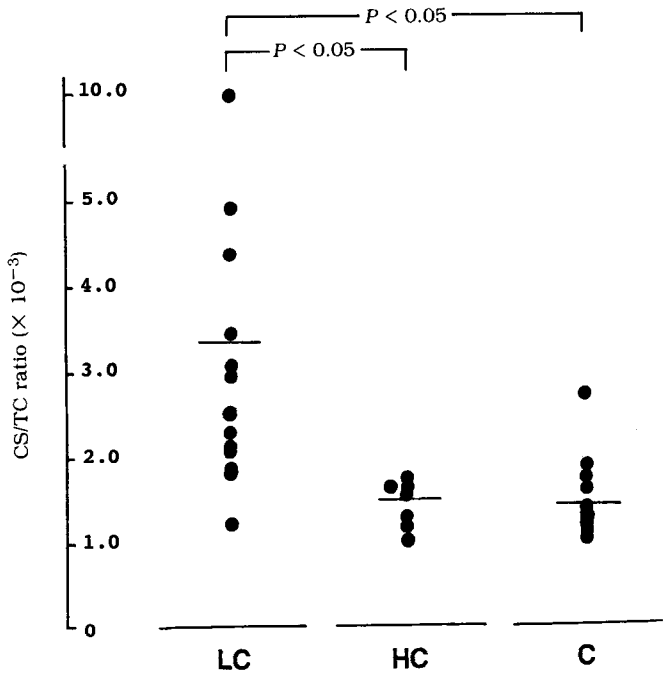

FIG. 3. The mean values of the CS/TC (cholesterol sulfate/total cholesterol) ratio in patients with liver cirrhosis (LC) and hypercholesterolemia (HC) and in control (C) subjects. The average values of the CS/TC ratio ($\times 10^{-3}$) were 3.31 ± 0.63 in the LC group, 1.44 ± 0.11 in the HC group and 1.51 ± 0.14 in the C group. The ratio in LC patients was larger than in HC or C ($P < 0.05$).

Plasma CS levels in liver cirrhosis and hypercholesterolemia. The mean values in cirrhotics and hypercholesterolemic subjects were 444.6 ± 51.7 and 413.7 ± 44.5 μg/dL, respectively. These values were significantly ($P < 0.05$) higher than the control values (253.4 ± 24.6 μg/dL).

Figure 3 shows the difference in CS/TC ratio among the three groups. The mean value of the CS/TC ratio was 3.31 ± 0.63 × 10^{-3} in cirrhotic patients, 1.44 ± 0.11 × 10^{-3} in hypercholesterolemic subjects and 1.51 ± 0.14 × 10^{-3} in control subjects. The CS/TC ratio clearly distinguished cirrhotics from hypercholesterolemics, due to the decreased plasma TC concentration in cirrhotics. In patients with uncompensated cirrhosis, CS levels (476.3 ± 117.3) were higher than those of compensated patients (424.81 ± 56.6); however, difference was not statistically significant.

Plasma BA levels were elevated in patients with liver cirrhosis (30.5 ± 5.3 μM), and sulfated BA corresponded to 22.1 ± 0.5% of total BA. There was no significant correlation between CS and total or sulfated BA. Sulfated BA levels were not assayed in control subjects and patients with hypercholesterolemia.

Plasma CS in relation to lipid levels in subjects with normal liver function. The CS/TC ratios were nearly identical in hypercholesterolemic and control subjects. When the two groups were combined as subjects with normal liver function, CS corresponded to 0.14 ± 0.09% of TC levels (n = 18). There were significant correlations ($P < 0.01$) between CS and TC (r = 0.63), EC (r = 0.67) or LDL-C (r = 0.64). However, no correlation was observed between CS and FC, HDL-C, TG or total BA.

DISCUSSION

Because our analytical procedure measures the FC liberated upon CS solvolysis, complete removal of free and acylated cholesterol from the CS fraction is an absolute requirement (23). Radioactive tracer experiments revealed that all the FC was removed from CS by elution in the silica column with chloroform and ethyl acetate.

Both CS and DHCS behaved identically throughout the various analytical steps including extraction, column chromatography and solvolysis. Thus DHCS can be used as an appropriate internal standard for the measurement of CS. Previous reports on normal human plasma CS concentrations cover a range from 105 to 350 μg/dL (14–16, 24,25) or about 0.1% of TC levels. In our analysis, the CS levels in healthy subjects were 253.4 ± 24.6 μg/dL, which is well within the range reported previously.

CS is widely distributed in the human body, including the central nervous system (23), erythrocytes (1,2), plasma (14–16,22,24,26), bile (7,8), feces (7,8), skin (5,6), nails and hair (4). Hochberg *et al.* (27) reported that liver, skin, lung and kidney could sulfurylate cholesterol. CS in plasma has been reported to bind to LDL particles (13) and chylomicrons (28). Our present results show that CS levels correlate well with LDL-C, TC and EC. This may suggest that LDL and chyromicron metabolism may be affected by an increased CS content, as an increased content of CS is known to affect the electronegativity of LDL particles (13).

The steroid sulfatase enzyme (sterol sulfate sulfohydrolase, EC 3.1.6.2) is a microsomal enzyme that removes the sulfate group from the 3-position of sterols and steroids

such as CS, dehydroepiandrosterone sulfate, pregnenolone sulfate and estrone sulfate (29). Tissues may utilize CS in sterol production by transforming CS to pregnenolone sulfate and to other 3β-hydroxy-Δ5-steroid sulfates (9,30).

Measurement of plasma CS is an important diagnostic procedure in patients with X-linked ichthyosis, because extremely elevated plasma CS levels (1500–4000 μg/dL) are observed due to steroid sulfatase deficiency (12–15). Although the increase in cirrhotics was not as pronounced as in patients with X-linked ichthyosis, we cannot rule out that decreased cholesterol sulfatase activity also occurs in cirrhotic patients. We must also consider the possibility of increased sulfation because sulfated BA increased in these patients, as they do in many other liver diseases. It has been suggested that hepatic sulfation and glucuronidation, which form more polar metabolites, enhance fecal and urinary excretion and may represent a protective mechanism in cirrhosis (17). To investigate the altered metabolism of CS in liver disease, it would also be necessary to analyze CS levels in urine and bile.

In conclusion, we have developed a method for measuring plasma CS using DHCS as internal standard. In patients with liver cirrhosis, plasma CS levels were significantly higher than those of normal subjects. The average CS/TC ratio was also significantly higher in cirrhosis due to lower TC levels. In subjects with hypercholesterolemia, plasma CS was higher but CS/TC ratios were almost the same as those in controls. In control and hypercholesterolemia subjects, plasma CS reached about 0.14% of TC and correlated with LDL-C, TC and EC, but not with FC, HDL-C and TG. The mechanism of elevated CS levels in liver cirrhosis is currently being studied in our laboratory.

[Received November 7, 1992, and in final revised form June 10, 1993; Revision accepted June 10, 1993]

Phospholipids from the Free-Living Nematode *Caenorhabditis elegans*

Kiyoshi Satouchi[a,*], Kaoru Hirano[a], Masamitsu Sakaguchi[a], Hisaaki Takehara[b] and Fumito Matsuura[b]
[a]Department of Food Science and Technology and [b]Department of Biotechnology, Fukuyama University, Fukuyama 729-02, Japan

The phospholipid and the fatty chain compositions of diacyl, alkylacyl and alkenylacyl glycerophospholipids of the free-living nematode, *Caenorhabditis elegans*, were investigated. The phospholipids were comprised of 54.5% ethanolamine glycerophospholipid (EGP), 32.3% choline glycerophospholipid (CGP), 8.1% sphingomyelin and 5.1% others. The most abundant fatty acid in CGP was eicosapentaenoic acid (20:5n-3). The fatty acids in CGP were more unsaturated than those in EGP. Alkenylacyl and alkylacyl subclasses accounted for 1.0 and 2.6%, respectively, of CGP and 14.0 and 19.6%, respectively, of EGP. At least 80% of the alkenyl and alkyl groups were 18:0 chains and the remaining were odd numbered chains. The potential presence of platelet-activating factor (PAF) was examined by bioassay, but PAF-like activity was not detected in the extracts of this nematode.
***Lipids* 28, 837–840 (1993).**

Nematodes can be divided into three major groups according to their feeding habits—plant-parasitic nematodes, animal-parasitic nematodes and free-living or microbivorous nematodes. Among the latter, *Caenorhabditis elegans* has been widely used as a model organism for the study of behavioral genetics and experimental gerontology, because these nematodes can be grown readily on a layer of bacteria and have a small, nearly constant cell number (1). Recently, the complete sequencing of the *C. elegans* genome has been initiated as a model for the human genome sequencing project (2). Using the long-lived *age-1* mutant, an attempt to biochemically explain senescence with respect to the free-radical theory was reported (3). Although *C. elegans* has been intensively studied by molecular geneticists and developmental biologists, biochemical studies on the lipids of this nematode have been limited, except for the extensive studies on its metabolism of plant sterols (4) and its fatty acid composition (5). It is known that several lower invertebrates contain remarkably high amounts of ether phospholipids, suggesting their importance in the invertebrate life cycle (6). Recently, it has also been demonstrated that the biologically active phospholipid, platelet-activating factor (PAF 1-*O*-alkyl-2-acetyl-*sn*-glycero-3-phosphocholine) which is metabolically derived from alkylacyl choline glycerophospholipids (CGP), is widely distributed in lower multicellular invertebrates (7). However, the available data on nematode ether phospholipids are fragmentary, with the exception of the studies of ether phospholipids from a free-living nematode, *Turbatrix aceti* (8) and a plant-parasitic nematode, *Meloidogyne javanica* (9).

Abbreviations: CGP, choline glycerophospholipids; EGP, ethanolamine glycerophospholipids; GC/MS, gas chromatography/mass spectrometry; GPC, glycerophosphocholine; GPE, glycerophosphoethanolamine; PAF, platelet-activating factor; *t*BDMS, *tert*-butyldimethylsilyl; TLC, thin-layer chromatography; 17:Δ, *cis*-9,10-methylenehexadecanoic acid; 19:Δ, *cis*-11,12-methyleneoctadecanoic acid.

In the present study, we analyzed the phospholipids from the free-living nematode *C. elegans*, cultured on *Escherichia coli*, and also examined these lipids for the presence of the PAF molecule.

EXPERIMENTAL PROCEDURES

Chemicals. Iso-myristic acid, *anteiso*-myristic acid and *iso*-palmitic acid were from Larodane Fine Chemicals (Westbury, NY), 20:3n-9 was from Biomol (Plymouth Meeting, PA), 20:3n-6 homo-γ-linolenic acid and 20:3n-3 were from Nu-Chek-Prep (Elysian, MN), and 20:4n-6 arachidonic acid, 20:5n-3 eicosapentaenoic acid and 22:6n-3 docosahexaenoic acid were from Sigma Chemical Co. (St. Louis, MO). Glyceryl ethers (16:0 and 18:0) were purchased from Sigma, and 18:1 glyceryl ether was from Serdary Research Laboratories (London, Ontario). Phosphatidylinositol (soybean), phosphatidylserine (bovine brain), cardiolipin (*E. coli*) and phospholipase C (EC 3.1.4.3, *Bacillus cereus*) were from Sigma. Pre-coated thin-layer plates (Silica gel 60) were obtained from Merck (Darmstadt, Germany). Silic AR (100–200 mesh) was the product of Mallinckrodt (Paris, KY). Bovine serum albumin, 1-*O*-hexadecyl-2-acetyl-*sn*-glycero-3-phosphocholine (PAF) and calcium ionophore A23187 were from Sigma. *tert*-Butyldimethylchlorosilane/imidazole reagent and 10% methanolic HCl reagent were from GL Sciences and Tokyo Kasei (Tokyo, Japan), respectively. Trypton and yeast extract were the products of Difco Laboratories (Detroit, MI).

Growth of E. coli. *E. coli* (OP50 strain) was grown in a phosphate buffer (pH 7.4) with trypton and yeast extract. *E. coli* from late-logarithmic cultures were isolated by centrifugation and resuspended in S medium (10). *E. coli* phospholipids were comprised of 80% phosphatidylethanolamine, 19% phosphatidylglycerol and 1% cardiolipin. No ether-linked subclasses (1-alkyl-2-acyl or 1-alk-1′-enyl-2-acyl) were detected in the ethanolamine glycerophospholipid (EGP) fraction. The fatty acid composition was 14:0, 4.8%; 15:0, 1.6%; 16:0, 41.2%; 16:1n-7, 4.0%; *cis*-9, 10-methylenehexadecanoic acid 17:Δ, 31.2%; 18:1n-7, 10.0%; and *cis*-11,12-methyleneoctadecanoic acid 19:Δ, 7.3%.

Growth of C. elegans. The standard wild-type strain N2 was propagated on NGM agar seeded with *E. coli*. Upon observation under the microscope, the plates rich with adult worms were washed with M-9 buffer (10) and samples were collected by centrifugation. Nematodes in a small volume of M-9 buffer were layered over 35% sucrose and centrifuged at 1800 × *g* for 5 min. *E. coli* and the dead worms were sedimented, and *C. elegans* was recovered on the sucrose layer and repeatedly rinsed with distilled water.

Lipid extraction and fractionation. Upon adding liquid nitrogen, frozen nematodes (from 2 to 15 g of each harvest) were thoroughly ground in a mortar with a pestle. Chloroform and methanol were added to obtain a one-phase system (11), which was sonicated for 30 min. Equal volumes of chloroform and water were added to this crude

extract, and the two phases were separated by centrifugation at 1800 × g for 5 min. The lower phase extract was then subjected to silic AR column chromatography. For 1 mg lipid-phosphorus of the extract, 1 g of silicic acid was employed. Neutral lipids were eluted with 30 mL of chloroform, and phospholipids were recovered with 30 mL of methanol. Phospholipid classes were separated by two-directional thin-layer chromatography (TLC) using the solvent systems chloroform/methanol/28% NH_4OH (65:35:5, by vol) for the first development and chloroform/acetone/methanol/acetic acid/H_2O (5:2:1:1.3:0.5, by vol) for the second development (12). For the large-scale preparation of CGP and EGP, the methanol fraction was subjected to preparative TLC using the solvent system chloroform/methanol/H_2O (65:35:6, by vol). Lipid spots were detected under ultraviolet light after spraying the plate with 0.02% 6-*p*-toluidino-2-naphthalenesulfonic acid solution. The relative amounts of CGP and EGP subclasses were determined by the successive degradation of phospholipids with mild alkali and acid, respectively (13). The phosphorus contents of the total lipids and of individual phospholipid classes were determined by the method of Bartlett (14).

Fatty chain analyses of phospholipid subclasses. Samples (1 μmol) of CGP or EGP were hydrolyzed with phospholipase C (15). Alkenylacyl, alkylacyl and diacyl subclasses of CGP and EGP were separated by TLC as 1,2-diradyl-3-acetyl-glycerols first with petroleum ether/diethyl ether/acetic acid (90:10:1, by vol) and then with toluene as developing solvents (12). The procedures for the derivatization of the fatty chains of each subclass were described previously (16). Fatty acid methyl esters were analyzed by gas chromatography (GC) (Shimadzu 14A, Kyoto, Japan) using a capillary column coated with a 0.25-μm film of polar CBP20 (0.22 mm × 30 m; Shimadzu). The temperature of the injector and flame-ionization detector was 250°C. For routine analyses, the initial column temperature was set at 170°C and then raised to 255°C at 5°C/min. For determining relative retention times, the column was maintained at a constant 200°C. Fatty acid analyses were also carried out on a Shimadzu QP-2000 quadrupole mass spectrometer equipped with an interface for capillary GC (column coated with a 0.25-μm film of nonpolar CBJ1, 0.25 mm × 30 m). The analyses were done with the injector, ion source and interface temperatures at 250°C. Samples in *n*-hexane were injected (1–2 μL) in the split mode. The oven temperature was raised from 200 to 250°C at a rate of 5°C/min for methyl esters and kept at 250°C for *tert*-butyldimethylsilyl (*t*BDMS) derivatives. Glyceryl ethers were analyzed as *t*BDMS derivatives with the oven programmed from 250 to 290°C at rate of 5°C/min. The ionization energy was 70eV.

Bioassay. Nematodes (2.24 g) isolated from 60 NGM agar plates were suspended in 20 mL of S medium, and the sample was divided into two tubes. One tube was stimulated with 1×10^{-6} M ionophore A23187, and 10 μL of vehicle, dimethylsulfoxide, was added to the other. The samples were incubated at 20°C for 15 min and then centrifuged. Lipids were extracted from the supernatant and the pellet (11), and the lipids (18 μmol phospholipid in the pellet fraction) were subjected to preparative TLC using chloroform/methanol/H_2O (65:35:6, by vol) for development. Six fractions including the PAF fraction, were suspended in an appropriate volume of 2.5 mg bovine serum albumin/mL saline solution. PAF was assessed on the basis of its ability to cause aggregation of washed rabbit platelets (17). A calibration curve was prepared for 1-*O*-hexadecyl-2-acetyl-*sn*-glycero-3-phosphocholine ranging from 5×10^{-11} to 5×10^{-10} M.

RESULTS

Phospholipid content and composition. C. elegans was shown to contain phospholipids at a level of 187 ± 46.7 μg lipid phosphorus equivalents/gram fresh body weight based on five different samples of nematodes measured and expressed as mean ± SD. The major phospholipid constituents were EGP and CGP, accounting for 54.4 ± 4.7 and 32.3 ± 3.0% of the total phospholipids, respectively. Sphingomyelin accounted for 8.1 ± 0.7%. Other constituents were cardiolipin, inositol glycerophospholipids and lysoCGP, each of which accounted for about 1%.

Subclasses of CGP and EGP. Alkenylacyl, alkylacyl and diacyl subclass compositions of CGP and EGP are shown in Table 1. A large portion of CGP was accounted for by the diacyl subclass, whereas the alkylacyl subclass, a precursor of PAF (18), accounted for only 2.6 ± 0.6%. In contrast, EGP contained substantial amounts of alkylacyl and alkenylacyl subclasses, as well as the diacyl form.

Fatty alkyl chain composition. Alkyl and alkenyl chain compositions of 1-alkyl-2-acyl glycerophosphocholines (GPC), 1-alkyl-2-acyl glycerophosphoethanolamines (GPE) and 1-alkenyl-2-acyl GPE were determined on the di-*t*BDMS derivatives. In GC/mass spectrometry (MS), the derivatives yielded ions at *m/z* 57, 73 and 171, common to all samples, and $[alkenyl + 56]^+$ and $[alkyl + 130]^+$, indicative of each of the glyceryl ether structures.

The di-*t*BDMS derivatives obtained from 1-alkyl-2-acyl GPC were monitored on the common ion *m/z* 171 and on the individual ions $[alkyl + 130]^+$. Major species were 18:0, followed by the 19:1, 19:0, 17:0 and 18:1 alkyl moieties, whereas 16:0 alkyl was quite low (Fig. 1). Similarly, 18:0 comprised the largest percentages (89.7 and 93.8) of the alkyl and alkenyl moieties in 1-alkyl-2-acyl GPE and 1-alkenyl-2-acyl GPE, respectively. The alkyl and alkenyl compositions of CGP and EGP are shown in Table 2.

Fatty acid composition. Upon injection of the fatty acid methyl esters prepared directly from CGP and EGP, 17 peaks occurred (excluding the dimethylacetal peak due to 18:0 plasmalogen in EGP) (Table 3). These peaks were

TABLE 1

Subclass Compositions of Choline and Ethanolamine Glycerophospholipid in the Free-Living Nematode, *Caenorhabditis elegans*[a]

Subclass	CGP (%)	EGP (%)
Diacyl	96.4 ± 1.2	66.4 ± 3.7
Alkylacyl	2.6 ± 0.6	19.6 ± 2.1
Alkenylacyl	1.0 ± 0.7	14.0 ± 1.6

[a]Values are mean ± SD from four harvests of nematodes. CGP, choline glycerophospholipids; EGP, ethanolamine glycerophospholipids.

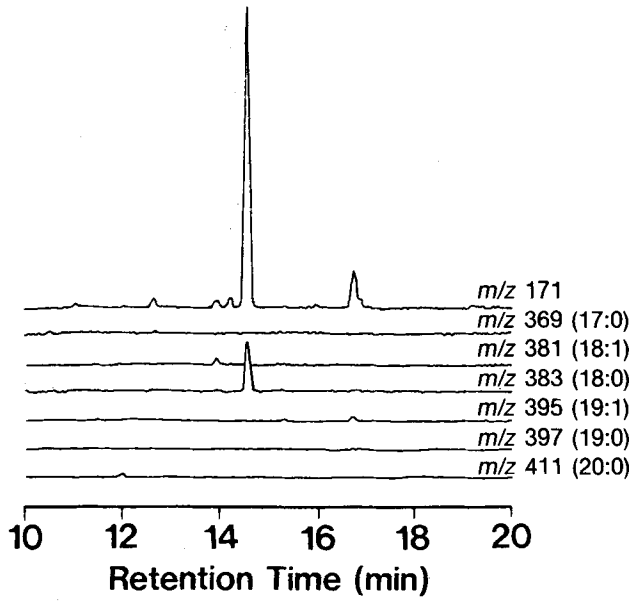

FIG. 1. Selected ion monitoring of the di-*tert*-butyldimethylsilyl derivatives of 1-alkyl glycerol from nematode choline glycerophospholipid. The alkyl chains were identified by the ions at *m/z* 396 (17:0), *m/z* 381 (18:1), *m/z* 383 (18:0), *m/z* 395 (19:1), and *m/z* 397 (19:0). The retention time of di-*tert*-butyldimethylsilyl derivative of 1-hexadecyl glycerol was 11 min 04 s. Peaks at 13 min 93 s in the tracings of ions *m/z* 171 and *m/z* 381 were due to 18:0 alkenyl.

identified as follows: (i) By comparison of their retention times with those of fatty acids from egg yolk phosphatidylcholine, peaks 3, 4, 9, 10, 12 and 15 were identified as 16:0, 16:1n-7, 18:0, 18:1n-9, 18:2n-6 and 20:4n-6. (ii) Peaks 8, 11 and 13 were identified as 17:Δ, 18:1n-7 and 19:Δ by comparison of their retention times with those of fatty acids from *E. coli* phosphatidylethanolamine. (iii) Mass spectral data demonstrated that the molecular ion of peak 1 corresponded to 15:0; peaks 2 and 3 had the same molecular weight and corresponded to 16:0; and peaks 5, 6 and 7 corresponded to 17:0. Based on relative retention time plots obtained under isothermal conditions on normal saturated fatty acids, including 12:0, 14:0, 16:0 and 18:0, branched fatty acids, *iso* 14:0, *iso* 16:0 and *anteiso* 14:0, peak 1 was identified as *iso* 15:0, peak 2 as *iso* 16:0, peak 5 as *iso* 17:0, peak 6 as *anteiso*17:0, and peak 7 as normal 17:0. (iv) Peaks 14–17 were shown to belong to a series of 20-carbon polyunsaturated fatty acids because they eluted as a single fraction upon catalytic hydrogenation over platinum oxide, the mass spectrum confirmed the C_{20} chainlength. Subsequently, the fatty acid methyl esters were saponified and then converted to their *t*BDMS derivatives, because the methyl esters of polyunsaturated

TABLE 2

Alkyl and Alkenyl Compositions of CGP and EGP from the Free-Living Nematode, *C. elegans*[a]

Chain	CGP	EGP	
	Alkyl (%)	Alkyl (%)	Alkenyl (%)
17:0	2.3 ± 0.4	2.5 ± 0.7	1.6 ± 0.2
18:1	1.8 ± 0.1	1.0 ± 0.6	—
18:0	80.4 ± 1.1	89.7 ± 0.7	93.8 ± 0.8
19:1	12.0 ± 0.1	3.7 ± 0.5	—
19:0	3.4 ± 1.6	3.1 ± 0.9	3.6 ± 0.7

[a]Ion $[alkyl + 130]^+$ or $[alkenyl + 130]^+$ was selectively monitored, and the intensities of seven ions ranging from 16:0 to 20:0, including 18:1 and 19:1, species were integrated. Values are presented as mean ± SD from three harvests; ions of less than 1% were omitted. Similar distributions were obtained by monitoring at *m/z* 171. Abbreviations as in Table 1.

TABLE 3

Fatty Acid Compositions (%) of Subclasses of CGP and EGP from Free-Living Nematode, *C. elegans*[a]

Peak no.	Fatty acid	CGP		EGP		
		Diacyl	Alkylacyl[a]	Diacyl	Alkylacyl	Alkenylacyl
1.	15:0 *iso*	1.9 ± 0.4	—	7.2 ± 3.0	1.3 ± 0.3	1.2 ± 0.2
2.	16:0 *iso*	1.4 ± 0.2	1.8 ± 0.3	—	1.2 ± 0.1	1.2 ± 0.2
3.	16:0	4.0 ± 1.5	24.7 ± 2.4	11.1 ± 0.6	4.4 ± 0.6	5.7 ± 1.2
4.	16:1 n-7	2.5 ± 0.5	10.5 ± 3.7	12.6 ± 4.0	2.8 ± 0.3	2.7 ± 1.2
5.	17:0 *iso*	2.4 ± 0.5	—	3.9 ± 1.5	1.7 ± 0.1	1.3 ± 0.1
6.	17:0 *ante*	—	—	1.5 ± 0.3	—	—
7.	17:0	1.0 ± 0.1	1.9 ± 0.1	1.6 ± 0.3	1.5 ± 0.9	—

9.	18:0	4.4 ± 0.9	8.0 ± 1.0	8.8 ± 1.7	2.4 ± 0.6	2.5 ± 0.5
10.	18:1n-9	5.0 ± 0.5	10.0 ± 2.2	2.3 ± 0.6	4.0 ± 0.7	4.6 ± 0.7
11.	18:1n-7	18.8 ± 2.4	5.0 ± 1.4	19.4 ± 2.0	33.4 ± 2.4	34.8 ± 4.4
12.	18:2n-6	5.8 ± 0.5	3.6 ± 1.0	3.8 ± 1.0	18.2 ± 1.3	8.9 ± 1.4
13.	19:Δ	4.8 ± 1.4	—	3.1 ± 0.9	1.2 ± 0.1	1.3 ± 0.1
14.	20:3n-6	6.2 ± 0.3	1.3 ± 0.9	2.8 ± 0.6	2.9 ± 0.5	4.3 ± 0.8
15.	20:4n-6	5.6 ± 0.7	1.0 ± 0.7	1.2 ± 0.2	2.1 ± 0.5	2.9 ± 0.9
16.	20:4n-3	5.5 ± 0.5	—	1.9 ± 0.5	1.8 ± 0.3	1.9 ± 0.4
17.	20:5n-3	22.0 ± 4.2	3.9 ± 1.2	5.3 ± 0.7	3.9 ± 1.1	4.2 ± 1.2

[a]Values are based on percent areas and are presented as mean ± SD from three harvests; ions of less than 1% were omitted. Other fatty acids detected in alkylacyl GPC were 14:0, 5.5%; 15:0, 3.5%; 16:0 *ante*, 1.2%; and 20:3n-9, 3.0%. Fatty acids in alkylacyl GPE were 14:0, 1.0%; and 20:3n-9, 2.1%; and in alkenylacyl GPE were 14:0, 1.3%; 16:0 *ante*, 1.2%; and 20:3n-9, 1.8%. Abbreviations as in Table 1.

[b]Because of the very low amount of alkenylacyl subclass, alkylacyl and alkenylacyl GPC were combined as ether-linked subclass.

fatty acids did not yield information on molecular weights in reliable (GC/MS). The *t*BDMS derivatives gave prominent $[M-57]^+$ ions, which were useful for molecular weight determinations (19). Selected ion monitoring focused on the ion $[M-57]^+$ at *m/z* 363 for 20:3, *m/z* 361 for 20:4, and *m/z* 359 for 20:5. Comparison of retention times with those of standards (20:3n-3, 20:3n-6, 20:3n-9, 20:4n-6, 20:5n-3) revealed that peak 14 was 20:3n-6, peak 15 was 20:4n-6, peak 15 was 20:4n-3 and peak 17 was 20:5n-3.

The fatty acid compositions of CGP and EGP are shown in Table 3. Branched, cyclopropane-ringed and polyunsaturated fatty acids were detected in the phospholipids from *C. elegans*. The major fatty acids in CGP were eicosapentaenoic acid and *cis*-vaccenic acid. Interestingly, the amount of eicosapentaenoic acid was lower in EGP, as well as in the ether-linked subclass of CGP.

Detection of PAF. PAF-like activity was not detected in the supernatant or pellet of *C. elegans*, although 18 μmol of phospholipid was purified by TLC to isolate the PAF fraction for the bioassay, which can detect a few pmol of 1-*O*-hexadecyl-2-acetyl-*sn*-glycero-3-phosphocholine and uses washed rabbit platelet. PAF activity was also not found in *C. elegans* stimulated with calcium ionophore A23187, suggesting that PAF was not present or synthesized in this nematode.

DISCUSSION

Ether-linked phospholipids are widely distributed in the animal kingdom and occur in several microorganisms, but are scarce in the plant kingdom (20). CGP and EGP are the two glycerophospholipid classes that have been analyzed extensively for the acyl composition of their ether-linked subclasses (21). General conclusions that can be drawn from these extensive analyses include the following: (i) the ether-linked subclasses of CGP and EGP usually contain a greater percentage of polyunsaturated fatty acid than do the diacyl subclasses, (ii) the subclasses of EGP often contain greater percentages of polyunsaturated fatty acids than do the corresponding subclasses from CGP and (iii) the ratio of 16:0 to 18:0 alkyl and/or alkenyl is higher in the CGP subclasses than in the EGP subclasses from the same tissue (22).

The results we obtained on the phospholipids from *C. elegans* contrast from the above general rules. *C. elegans* contains several types of fatty acids, including saturated, unsaturated (n-3, n-6, n-7 and n-9), branched and cyclopropane-ringed ones. The latter are likely to have originated from the nematodes' food, *i.e., E. coli*. This appears not to be the case for *cis*-vaccenic acid because this acid was also the major acid of *C. elegans* maintained on an aqueous medium containing heated beef liver extract (5). Moreover, CGP and at least the ether-linked EGP were synthesized by *C. elegans*, because these phospholipids do not exist in *E. coli*. CGP from *C. elegans* contained a greater percentage of polyunsaturated fatty acids than did EGP, and the alkyl and alkenyl moieties were exclusively composed of 18:0 compound. A similar situation exists in another free-living nematode, *T. aceti* (8) and in the plant-parasitic nematode, *M. javanica* (9).

PAF-like lipids are widely distributed among various lower animals, *e.g.*, 370 nmol PAF/mol total phospholipid was detected in the slug, *Incilaria bilineata*, and the alkyl chain composition of PAF agreed well with that of alkyl-acyl GPC (23). In the present study, however, PAF-like activity was not detected in *C. elegans*. Recently, Hogaboam *et al.* (24) also reported that the animal-parasitic nematode, *Nippostrongylus brasiliensis*, failed to show any secreted or worm-associated PAF-like activity.

Although PAF-like lipids occur in lower invertebrates, *e.g.*, in Annelida, Mollusca and Platylhelminthes, which contain a large amount of alkylacyl glycerophospholipids (7), nematodes appear to be quite different with respect to the molecular phospholipid species that are present, and by the absence of the phospholipid mediator PAF.

ACKNOWLEDGMENTS

We thank Dr. Y. Yamaguchi, Department of Biotechnology, for supplying the original culture of *C. elegans* (N2 strain). This study was financially supported in part by the Agricultural Chemical Research Foundation (1991).

γ-Linolenic Acid in *Anemone* spp. Seed Lipids

Nansadyn Tsevegsüren[1] and **Kurt Aitzetmüller***
Institute for Chemistry and Physics of Lipids, Federal Center for Cereals, Potato and Lipid Research (BAGKF), D-48147 Münster, Germany

γ-Linolenic acid containing oils have been found in seed lipids of a number of plants, but are restricted to certain genera and families, *e.g.*, the Boraginaceae. Some of these oils have found considerable interest for pharmaceutical and dietary use, *e.g.*, borage oil and evening primrose oil in treatment of essential fatty acid and Δ6 desaturase deficiency. Our investigation of the seed lipids of certain Mongolian and other Ranunculaceae has now shown the presence of unusual fatty acids, including considerable amounts (up to 20%) of γ-linolenic acid in certain species of *Anemone*, whereas this acid was found to be absent in other species of *Anemone*. A number of other unusual fatty acids are present in *A. rivularis* but have not yet been identified. The significance of the presence of γ-linolenic acid, a Δ6 acid, is discussed in relation to Δ5 fatty acids that had been reported to occur in the same plant family. *Lipids* 28, 841–846 (1993).

γ-Linolenic acid-containing oils are of considerable interest in the pharmaceutical industry and for use in dietary food specialties (1). In general, the distribution of γ-linolenic acid (γLn) in the plant kingdom is not well understood. γLn occurs throughout the family Boraginaceae, where it is of chemotaxonomic significance. However, it also occurs in clusters of closely related species in several other plant families (2).

The family Ranunculaceae provides us with many plant genera and species which produce seed lipids containing unusual or technically interesting fatty acids. Kaufmann and Barve (3) investigated *Aquilegia*, which still is the most prominent source (up to 70%) of columbinic acid (*E,Z,Z*-5,9,12-octadecatrienoic acid), an acid which is also found in significant amounts in many *Thalictrum* species (4,5). Other unusual fatty acids have been found in larger amounts in *Delphinium* (6), *Consolida* (7) and *Caltha* (8,9), as well as in other species of Ranunculaceae. Apart from *Caltha*, Ranunculaceae which exhibit regular flowers of radial symmetry, such as *Anemone, Adonis, Clematis* and *Ranunculus*, have been thought to contain mostly the normal set of fatty acids in their seed lipids, *i.e.*, essentially palmitic, oleic, linoleic and α-linolenic acids. Earlier research has largely confirmed this (3–10), but there is one report on the occurrence of γ-linolenic acid in *Anemone cylindrica* (11). Earle *et al.* (10) mention the occurrence of 2.6% conjugated diene in *A. coronaria* seed oil but do not give data on individual fatty acid composition. Only two reports on seed fatty acid composition of *Anemone* were found in the older literature (4,11). It was therefore of interest to determine whether *Anemone* spp. are generally capable of synthesizing γ-linolenic acid and could be used as a source of this acid.

Fatty acids in Ranunculaceae seed lipids have been reported to contain unusual Δ5 *trans* and Δ5 *cis* double bonds and chainlengths of 20 and 22 carbon atoms (3–11). It should therefore be investigated whether the early report on the occurrence of γ-linolenic acid in *A. cylindrica* (11) could be confirmed using modern analytical techniques, or if perhaps another C_{18} fatty acid with another double bond position or double bond configuration (*e.g.*, Δ5 *trans* or Δ5 *cis*) and a similar gas–liquid chromatography (GLC) retention time would be present. In addition, it was hoped that the present investigation could contribute to a better understanding of the chemotaxonomic significance of the large number of different, unusual fatty acids that have been reported to be present in various genera of the plant family Ranunculaceae.

MATERIALS AND METHODS

Seeds and seed oils. During an investigation of the local flora of Mongolia, a number of seeds from wild plant species, including *A. crinita*, were collected by a Mongolian botanical expedition. Seeds of *A. crinita* were collected in Tuv aimak, Erdene sum region, Mongolia, in August 1991. Seeds of *A. rivularis, A. nemorosa, A. ranunculoides, A. narcissiflora, A. cylindrica* and *A. altaica* were from a commercial source (Jelitto, Hamburg, Germany). Evening primrose oil was purchased in a local health shop. Cleaned seeds were ground for 10 min using a ball mill. Ground seed (0.2–5.0 g, mixed with Na_2SO_4 and sea sand) were extracted with 80 mL of hexane in a flow-through extractor. After removal of the solvent (50°C, slight vacuum), the extracts were dried under nitrogen and weighed.

Saponification and methyl ester preparation. Oil samples (200–250 mg) were saponified in 10 mL 1 N ethanolic KOH (30 min, water bath, reflux), and the unsaponifiables were removed by extraction with diethyl ether. The combined soap solutions were acidified with conc. HCl and extracted three times with 20 mL of diethyl ether each. After washing and drying, the solvent was removed under vacuum and the isolated fatty acids were weighed. The DGF BF_3 method (12) was used for the preparation of methyl esters from the fatty acids. Fatty acids (100–200 mg) were boiled under reflux on a water bath in *ca.* 5 mL 0.5 N methanolic KOH. Five mL of BF_3/MeOH was added to the mixture and boiling was continued for another 5 min. After cooling the flask, 5 mL of *n*-hexane and 20 mL of saturated aqueous NaCl solution were added and the methyl esters were extracted with *n*-hexane (3 × 20 mL). The combined hexane extracts were washed, dried and filtered, and evaporated under vacuum using a rotary evaporator and weighed.

Capillary GLC. Two gas chromatographs (Hewlett-Packard HP 5890, Palo Alto, CA) equipped with fused silica WCOT capillary columns, 50 m × 0.25 mm (Chrompack, Middleburg, The Netherlands), one with CP-SIL-88, and one with Silar 5 CP, were used for the separation and quantitation of fatty acid methyl esters. For peak area

Abbreviations: γLn, γ-linolenic acid (18:3n-6); GLC, gas–liquid chromatography; HPLC, high-performance liquid chromatography; L, linolenic acid (18:2n-6); Ln, α-linolenic acid (18:3n-3); O, oleic acid (18:1); P, palmitic acid (16:0); S, stearic acid (18:0); TG, triacylglycerol(s).

integration, a Chromato-Integrator D 2000 (Merck-Hitachi, Darmstadt, Germany) was used. Peak identification was by comparison of relative retention times with those obtained on test mixtures of known composition on two different columns.

GLC conditions. Silar 5 CP: The temperature was held at 165°C for one minute, then programmed from 165 to 205°C at 1°C/min, then held at 205°C for *ca.* 60 min before cooling down the column to 165°C. CP-SIL-88: The temperature was held at 140°C for 15 min, then programmed from 140 to 200°C at 0.7°/min. Then the column was allowed to cool to 140°C. With both columns, the detector temperature was 260°C and the injector temperature was 230°C. Flow rates were 1.13 mL N_2/min for the Silar 5 CP column and 0.86 mL N_2/min for the CP-SIL-88 column.

High-performance liquid chromatography (HPLC) of triacylglycerols. HPLC was carried out as described (13) using acetonitrile/2-propanol/hexane (70:20:10, by vol) as solvent and ultraviolet detection at 210 nm. Column was Supersphere 100 RP-18, 4 μm, 250 × 4 mm (Merck, Darmstadt, Germany).

RESULTS

Table 1 lists the species investigated here, the fat content of the seeds and the fatty acid composition of the total seed lipids after saponification and methylation. We found that some *Anemone* species contained only the usual set of fatty acids, whereas three species (*A. cylindrica, A. altaica* and *A. crinita*) contained considerable amounts (17–20%) of an acid with a gas chromatography (GC) retention time identical to that of γ-linolenic acid. A fourth species (*A. narcissiflora*) contained 6.3% of this acid. The identity of this acid as γ-linolenic acid was ascertained by co-chromatography with authentic γ-linolenic acid methyl ester on two capillary columns of different selectivity. The assignment was also confirmed by GLC/mass spectrometry and by double bond positional analysis of γ-linolenic acid from *A. crinita* and by a more detailed study of the GLC behavior of various Δ5 and Δ6 18:3 acids (14). Several short-chain saturated fatty acids (9:0, 10:0, 11:0) that were previously claimed to be present in *A. protracta* (4), were not found, and 15:0 was shown to be present in trace amounts only.

Figure 1 shows capillary gas chromatograms for three of the *Anemone* species that we have investigated for the first time, and two of which (*A. narcissiflora* and *A. altaica*) contain γ-linolenic acid.

In Figure 2, the gas chromatogram of the fatty acid methyl esters and the HPLC tracings of the triacylglycerols (TG) of Mongolian *A. crinita* seed oil are shown. Figure 3 shows comparable chromatograms for commercial evening primrose oil (*Oenothera biennis*). At first sight, the GLC tracings of *A. crinita* and *O. biennis* fatty acid methyl esters seem almost identical. The higher γLn content in *A. crinita* (19.5 *vs.* 9.7% in *Oenothera*) is, however, clearly seen in TG HPLC by the increased peaks representing TG containing two γLn residues (LγLnγLn, OγLnγLn and PγLnγLn); the different P/O (P = palmitic acid; O = oleic acid) ratio is reflected in the different TG peak area ratios of OLL/PLL and OγLnL/PγLnL (*cf.* Figs. 2 and 3, bottom).

For all the *Anemone* seed oils, the HPLC profiles of the TG are highly specific and could be used as "fingerprints." Figure 4 shows a few additional examples. The peaks were

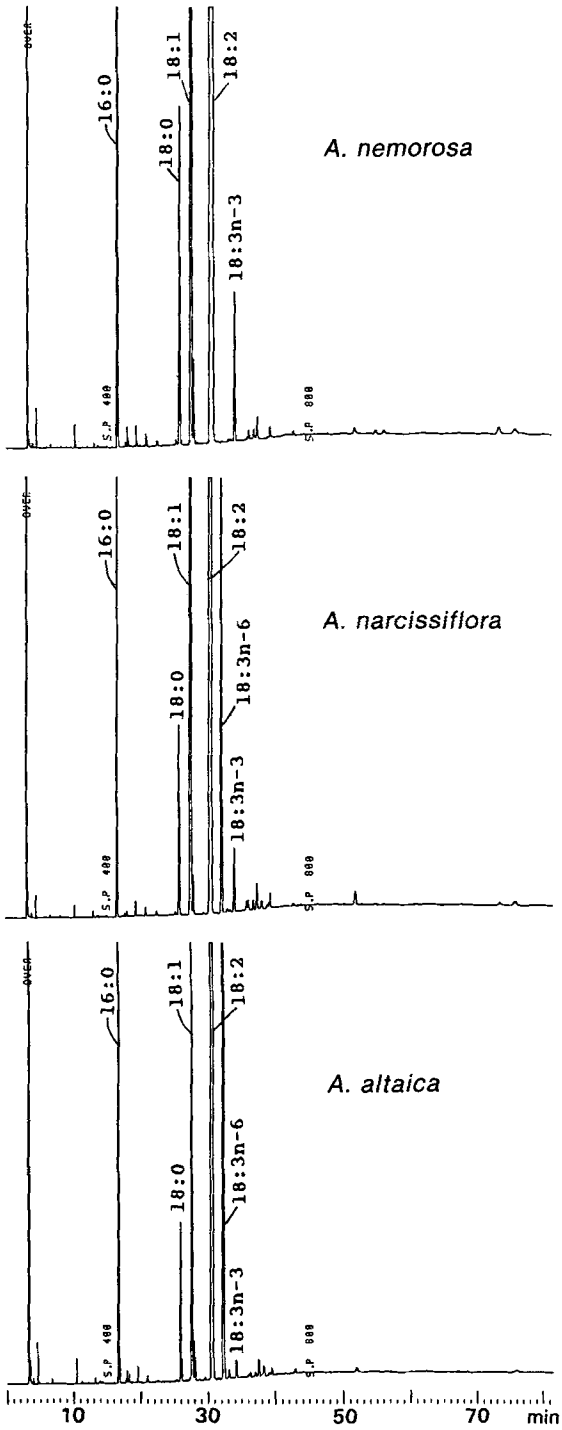

FIG. 1. Gas-liquid chromatography (GLC) of fatty acid methyl esters of *Anemone* seed lipids with and without γ-linolenic acid. The Silar 5 CP column was used; for GLC conditions, see text. Chromatograms obtained for three different species (*Anemone nemorosa, A. narcissiflora* and *A. altaica*) are shown; the fatty acid methyl ester peaks are labeled as usual.

identified in the usual way by comparison with other seed oils of known composition (13). γ-Linolenic acid-containing TG were tentatively identified by comparison with *Ribes nigrum* and *Borago officinalis* oils, and by calculating the known relative retention contribution of 18:3n-6 residues as compared with those of 18:2n-6 and 18:3n-3 residues (13). All *Anemone* oils with a high γLn content (17–20%) exhibited a large LγLnγLn peak in TG HPLC, and in this respect were similar to borage oil (13).

A totally different fatty acid pattern was found in another species, *A. rivularis*. The seed oil of this species contains two unusual fatty acids in amounts of between 7 and 10% each, but no γ-linolenic acid (Fig. 5). One of the components is 20:2n-6 (7.5%), which was also identified by co-chromatography with an authentic sample. This acid was recently found in larger quantities (up to 23%) in seeds of two *Leucojum* species (Aitzetmüller, K., unpublished data). The other major unusual fatty acid in *A. rivularis* (x_3) has not yet been identified. However, it is definitely not dihomo-γ-linolenic acid (20:3n-6). The structures of the minor fatty acids labeled x_1, x_2 and x_4 are not known.

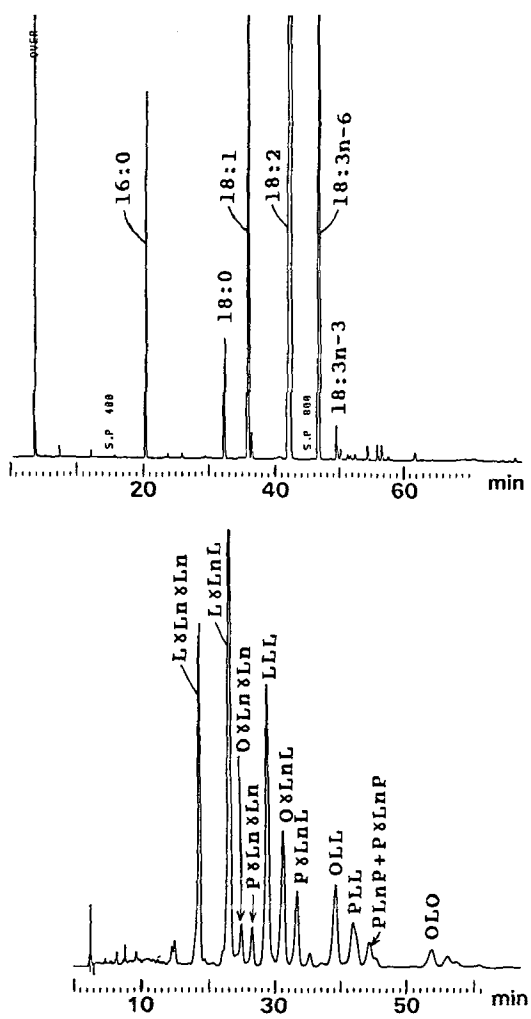
DISCUSSION

The accumulation of γ-linolenic acid in certain *Anemone* species, but not in others, could indicate a closer botanical relationship between the former species. It is possible that γ-linolenic acid is present only in the seeds of the members of one or two botanical sections within the genus *Anemone*, as it was postulated for sections of *Astelia* (15). Similarly, stearidonic acid (18:4n-3, another Δ6 acid) was recently found in one section of *Primula* (16). In the Boraginaceae, a similar case has been reported where γ-linolenic acid is completely absent in one species of the genus *Lithospermum* (in *L. officinale*), but is present in significant amounts in all other species of *Lithospermum* (17–19). Similar cases have been reported for the Liliaceae (15) and for the genus *Oenothera* (Onagraceae) (20).

The results shown here indicate a wider distribution of γLn in the plant kingdom. Apart from the Boraginaceae (17–19, 21–23), Onagraceae (20,24), Saxifragaceae (25), Aceraceae (26), Moraceae (27), Liliaceae (15), Scrophulariaceae (19) and Primulaceae (16), γLn has now been observed in at least four species belonging to the family Ranunculaceae.

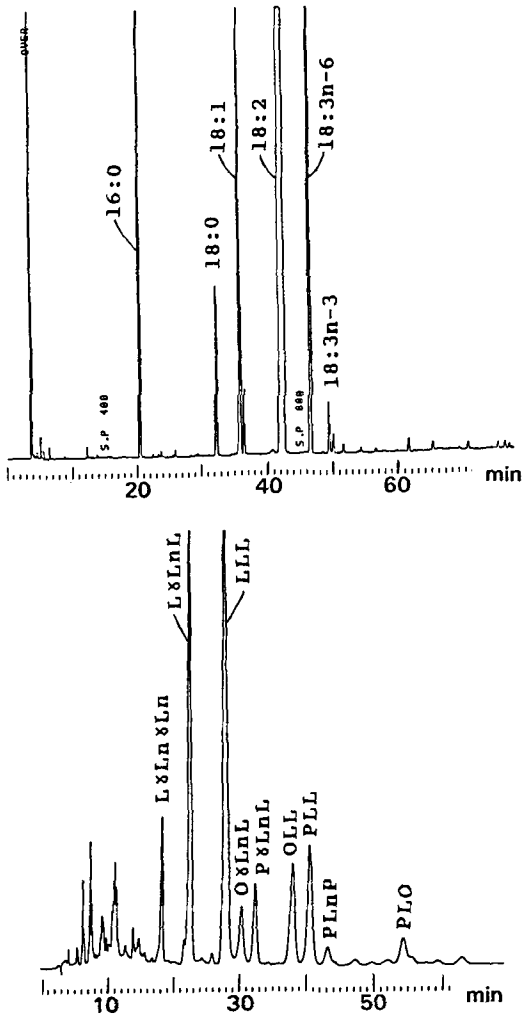
From the GC retention times, the unknown fatty acid x_3 in *A. rivularis* could perhaps be a positional or *trans* isomer of a 20:2 acid or a 20:3 fatty acid with Δ5 unsaturation [possibly the same as in *Caltha* (8)]. The same fatty acid pattern, including the unidentified fatty acids designated x_1–x_4 in Figure 5, but in lower abundance, has recently been observed for the seed lipids of another species in the Ranunculaceae, *Cimicifuga ramosa* (Aitzetmüller, K., unpublished data). The unknown peaks labeled x_1 and x_2 in Figure 5 and in Table 1 could be 16:1 Δ5 and 18:1 Δ5. Δ5-Acids of these types had been postulated to occur in the seed fats of three other genera of the family Ranunculaceae, *viz.* in *Aquilegia* (3,28), *Thalictrum* (4, 28–30) and *Caltha* (8).

Chain elongation to C_{20} acids is often observed in other genera of the Ranunculaceae [*cf.* up to 40% 20:1 in *Delphinium* and *Consolida* (6,7) and 23% 20:3 in *Caltha* (8)], but was not observed before in *Anemone*. To a lesser extent, chain elongation occurs in Boraginaceae (17–19, 21–23) where 20:1 and 22:1 (erucic) acids often accompany γLn. On the other hand, we have recently seen that chain elongation does not occur in the genus *Primula* (16), where



Anemone crinita

FIG. 2. Fatty acid [gas–liquid chromatography (GLC), top] and triacylglycerol (TG) [high-performance liquid chromatography (HPLC), bottom] chromatograms of Mongolian *Anemone crinita* seed oil. The CP-SIL-88 column was used for the GLC shown here. For GLC and HPLC conditions, see text. Fatty acid and TG peaks are labeled as usual (Ref. 13). The designation (*e.g.*, OγLnL) does not imply positional assignments.



Oenothera biennis

FIG. 3. Fatty acid (GLC, top) and triacylglycerol (HPLC, bottom) chromatograms of commercial evening primrose oil (*Oenothera biennis*). The experimental conditions were the same as for Figure 2 (GLC, CP-SIL-88 column). Abbreviations as in Figure 2.

C_{18} fatty acids (linoleic and linolenic) are further desaturated both in the Δ6 and n-3 positions to produce γLn and stearidonic acid (18:4n-3). In any case, it is interesting to note that one species (*A. rivularis*) should deviate so strongly in its seed fatty acid pattern from all other *Anemones* investigated.

From the results shown in Table 1, it seems that in two species (*A. nemorosa* and *A. ranunculoides*) fatty acid biosynthesis stops at 18:2n-6 and that this acid accumulates (up to 74% of the total), whereas in *A. altaica*, *A. crinita* and *A. cylindrica*, 18:2n-6 is further desaturated (at Δ6) to 18:3n-6. On the other hand, Δ6 desaturation does not occur in *A. rivularis*, where chain elongation successfully competes (to possibly produce 20:2n-6 from 18:2n-6). Surprisingly, 18:3n-3 is low in all species. In the 18:3 fatty acids, no evidence was found for double bonds in the Δ5 position (*cf.* Δ5,9,12-18:3 in other Ranunculaceae). Interestingly, the sum of all 18:2 plus 18:3 acids in all *Anemone* species investigated except *A. rivularis* is fairly constant (72–78%) so that an increase in 18:3n-6 seems to correlate with a corresponding decrease in 18:2n-6. This observation is consistent with the data of an earlier investigation of the seed fatty acids of *A. cylindrica* and *A. decapetala* (11). In view of the present findings, however, data on *A. protracta* published in the older literature (4) seem rather unlikely, and this species deserves to be reinvestigated. The earlier authors (4) also did not sufficiently define the term "isolinoleic" acid.

Thus, current evidence seems to suggest that with regard to seed fatty acid composition at least five different patterns or groups exist within the genus *Anemone*: Group 1: *A. nemorosa*, *A. ranunculoides*, *A. decapetala*; Group 2: *A. narcissiflora;* Group 3: *A. altaica*, *A. crinita*,

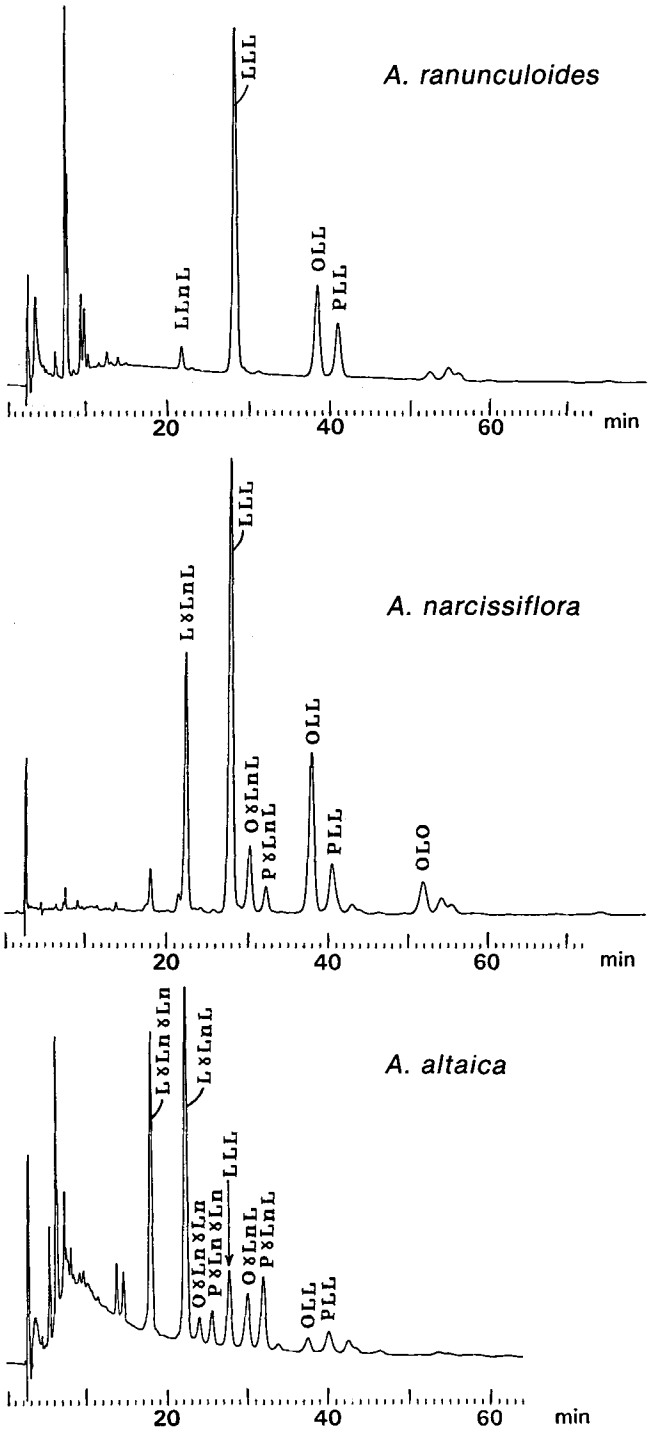


FIG. 4. HPLC chromatograms for *Anemone ranunculoides*, *A. narcissiflora* and *A. altaica* seed oil triacylglycerols. For HPLC conditions, see text. Triacylglycerol peaks, including those containing γ-linolenic acid residues, are labeled as usual (Ref. 13). The designation includes all positional isomers. Abbreviations as in Figure 2.

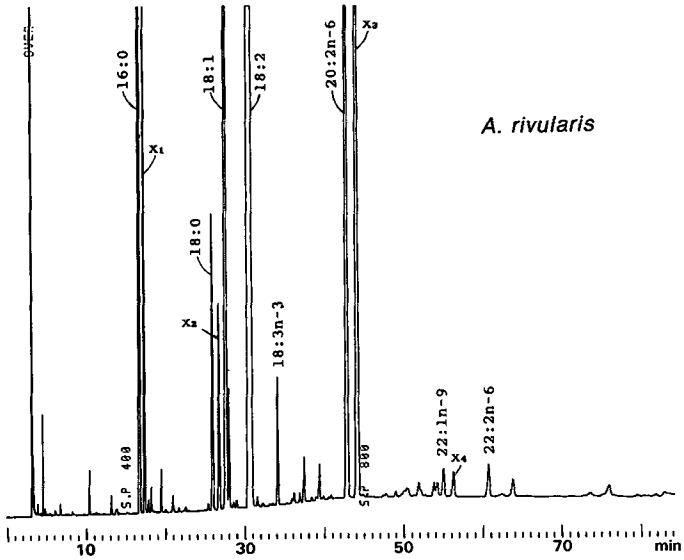

FIG. 5. Gas–liquid chromatography (GLC) of fatty acid methyl esters in *Anemone rivularis* seed oil. For GLC conditions, see text. The Silar 5CP column was used in this case (conditions as for Fig. 1). Unidentified peaks are labeled x_1–x_4, other peaks are labeled as usual.

A. cylindrica; Group 4: *A. rivularis*; and possibly Group 5: *A. protracta*. However, this is to some extent in contradiction to morphological botanical taxonomy (31), where *A. nemorosa* (2n = 30), *A. ranunculoides* (2n = 32) and *A. altaica* (2n = 16) belong to Sectio Anemonanthea; A. rivularis (2n = 16) is in Sectio Rivularidium, *A. cylindrica* and *A. decapetala* (both 2n = 16) are in Sectio Eriocephalus, whereas *A. narcissiflora* and *A. crinita* (both 2n = 14) are listed in Sectio Homalocarpus (31).

The situation in the Ranunculaceae might warrant a closer examination of the biogenetic pathways and of the enzyme systems involved in closely related species of one and the same plant family. There is Δ5 desaturation in some species [*trans* in *Aquilegia*, *cis* in *Caltha* and perhaps *trans* and *cis* in *Thalictrum* (28)], whereas we now find indication for Δ6 desaturation in several species of *Anemone*. There is chain elongation in *A. rivularis*, in *Caltha* and in *Delphinium/Consolida*. On the other hand, all three pathways are absent in *A. nemorosa* and *A. ranunculoides*. One Δ5 acid (18:3Δ5*t*,9*c*,12*c*) occurs in large quantities (30–70% of total seed fatty acids) in all the previously investigated species of *Aquilegia* and *Thalictrum*, but only in these two genera. One could pose the question whether the Δ5 18:3-producing enzyme systems in *Aquilegia* and *Thalictrum* represent a "γ-linolenic acid production gone wrong" due to a mutation of the original Δ6 desaturase? The Δ5 and Δ6 double bonds have never been observed to occur together in one species, so that the presence of isomerases seems unlikely. These relationships could become quite interesting, not only chemotaxonomically, but also for a better understanding of the biosynthesis of γLn and for biotechnological applications aiming at increased production of γLn, *e.g.*, by gene manipulation or gene transfer.

Despite the basic importance of our findings, it appears unlikely that *Anemone* will become a commercial source for γLn, because other sources, notably seeds of *Ribes*, of *Oenothera* and of *Boraginaceae*, are more readily accessible.

ACKNOWLEDGMENTS

The authors acknowledge the assistance of Tsch. Otgonbajar (Chemistry Institute, Mongolia) and Dr. Dariimaa (Botanical In-

stitute, Mongolia) for seed collection and their botanical identification; and of Dr. K. Vosmann of this institute for mass spectrometric identification of γ-linolenic acid. The authors also are indebted to Prof. Dr. U. Jensen, University of Bayreuth, for helpful advice. N.T. acknowledges financial assistance by a DAAD grant during his three-month stay in Germany. The authors wish to thank G. Werner and M. Grönheim for their skillful assistance with the GLC and HPLC work. They also thank G. Jelitto, Jelitto Staudensamen, D-2000 Hamburg 56, for the gift of the *Anemone* seeds.

Effect of Some Potassium Selective Crown Ethers on the Permeability and Structure of a Phospholipid Membrane

M. Szögyi[a], T. Cserháti[b,*] and F. Tölgyesi[a]

[a]Institute of Biophysics, Semmelweis Medical University, Budapest and [b]Central Research Institute for Chemistry, Hungarian Academy of Sciences, H-1525 Budapest, Hungary

The effect of some new crown ethers on the cation efflux and phase transition parameters of dipalmitoyl phosphatidylcholine liposomes was studied. The effects were correlated with the lipophilicity of the crown ethers. The results indicate that the presence of two crown ring structures in one crown ether molecule is a prerequisite for the increase of ion permeability of liposomes. The effective crown ethers decrease the temperature, enthalpy and cooperativity of the gel-to-liquid crystalline phase transition. The crown ethers increase membrane permeability for potassium and, to a lesser extent, for rubidium and sodium. The ratio of permeability increase for potassium/rubidium significantly correlates with the lipophilicity of the crown ethers.
***Lipids 28,* 847-851 (1993).**

An important function of biological membranes is the regulation of transport of sodium and potassium ions. Certain antibiotics (valinomycin, enniatin, nigericin, monensin, X 537 A, salinomycin, narasin, etc.) show similar capabilities to differentially influence sodium and potassium transport through biological and model membranes (1-9). The effect of ionophores (nigericin and valinomycin) on the cation efflux of lipid vesicles has been studied at different temperatures. The ionophores increased the cation efflux at temperatures above the pretransition temperature, and the effect prevailed above the main transition temperature (10). Because crown ethers also exhibit marked ion selectivity (11-16), it was expected that they would selectively influence the efflux of ions through biological and model membranes. However, to increase membrane permeability, the crown ethers have to be incorporated into the membrane, and this requires special structural characteristics and optimal lipophilicity of the molecule. The objectives of our study were to determine the effect of new crown ethers on the permeability and melting properties of dipalmitoyl phosphatidylcholine (DPPC) liposomes and to assess the effect of the lipophilicity of crown ethers on their membrane-modifying properties. The correlation between structural and functional changes is similar in the bilayers of biological and model membranes (17). Therefore, hydrated DPPC appears to be a suitable model to study the effects of membrane modifying agents (18-23).

Abbreviations: DPPC, dipalmitoyl phosphatidylcholine; ΔH_m, enthalpy of the main transition; r, coefficient of correlation; $r_{95-99\%}$, tabulated value of r corresponding to 95 and 99% significance level; R_M, lipophilicity; s_{b1-2}, standard deviations of slopes 1 and 2; S, ion selectivity; $\Delta T_{1/2}$, half-width of the main transition; T_m, main transition temperature; T_p, pretransition temperature; $t_{95\%}$, tabulated t value corresponding to 95% significance level.

MATERIALS AND METHODS

DPPC, purchased from Sigma Chemical Co. (St. Louis, MO), was used without further purification. The crown ethers were prepared at the Department of Organic Chemical Technology of the Technical University of Budapest by Agai and co-workers (24,25). The chemical structures of the crown ethers used in this study are shown in Schemes 1 and 2. For the preparation of the phospholipid

vesicles, 100 mg of DPPC was dispersed in 5 mL of 0.16 M KCl, NaCl or RbCl solution (containing 2 MBq of ^{42}KCl, $^{24}NaCl$ or $^{86}RbCl$) by mechanical shaking for 10 min. The lipid dispersion was then sonicated for 20 min by placing the tube in a small bath treatment vessel of the sonicator (Measuring Scientific Equipment Ltd., Manor Royal, Crawley, Sussex, England; Model 150 watt Ultrasonic Disintegrator, operating frequency, 20 kHz) working under a nitrogen stream. The bath temperature was maintained at 42°C by circulating water. After sonication, the dispersion was almost clear and the ultraviolet spectrum did not indicate oxidation. Deacylation products of DPPC were not detected by thin-layer chromatography, which was performed as described (26).

Determination of liposome permeability. After overnight equilibration at room temperature, the lipid dispersion was passed through a column of Sephadex G-50 Superfine (Pharmacia Fine Chemicals, Uppsala, Sweden) (1.5 × 30 cm) to remove excess tracers not trapped within the liposomes. The use of overnight equilibration was motivated by the fact that 8–10 h minimum are needed to reach the equilibrium of isotopes between the outer and the inner phase of liposomes (27). The liposomes were eluted from the column with 0.16 M KCl, NaCl or RbCl solutions, respectively (flow rate 0.5 mL/min). The liposome peak, which was eluted with the void volume, was collected. The initial ^{42}K, ^{24}Na or ^{86}Rb content of the liposomes (N) was determined in a gamma scintillation counter. The crown ethers were dissolved in chloroform, making a stock solution (the concentration of the stock solutions varied between 0.5–1.5 mg crown ether/mL chloroform depending on the molecular weight of the crown ether). An aliquot (0.05 mL) of stock solution was pipetted into a tube and the chloroform was evaporated at room temperature under a flow of air. Three-mL portions of eluted liposomes were added and the tube was shaken thoroughly. The crown ether/DPPC molar ratio was held constant at 1:100. Liposomes without crown ethers served as controls. The 3-mL portions (V_1) were dialyzed against 10 mL of 0.1 M KCl, NaCl or RbCl solution (V_2), respectively, at 38°C.

We are well aware of the fact that at temperatures below the gel-to-liquid crystalline phase transition temperature, there is an increased likelihood for ion leakage through a bilayer in the gel phase. However, since it has been previously established that ionophores can also increase the cation efflux between the pretransition and main transition temperatures (10) and because the experimental temperature (38°C) used in this study was above the pretransition temperature of DPPC, we made the reasonable assumption that the permeability changes observed reflected the changes caused by the crown ethers and were not due to nonspecific leakage through the DPPC bilayer.

The dialysis solutions were changed every 15 min for 2 h. The amount of radioactive tracer (n_2) in each dialysate was also determined in a scintillation counter. (The amount of lipid was determined in separate experiments by the quantitative determination of the inorganic phosphate content of the samples after $HClO_4$ treatment.) In order to compare the effects of crown ether derivatives to those of valinomycin on the ion permeability of liposomes, valinomycin was used at a molar ratio of 1:200, because at the molar ratio of 1:100, valinomycin disorganized the DPPC liposomes. Each experiment was run in quadruplicate. The permeability time constants were calculated according to the method of Johnson and Bangham (28):

$$P = \ln[V_2/(V_1 + V_2) - n_2/N] \cdot 1/t \quad [1]$$

where P is the permeability time constant, V_1 the volume of the liposome solution, V_2 the volume of dialysing solution, n_2 the amount of radioactive tracer in the dialysate, N the initial content of radioactive tracer of the liposomes and t the dialysis time in minutes. The degree of permeability increase caused by the crown ethers was calculated according to Equation 2 (ΔP):

$$\Delta P = (P - P_0) \cdot 10^{-4} \cdot s^{-1} \quad [2]$$

where P is the permeability time constant of DPPC liposomes determined in the presence of crown ethers and P_0 is the permeability time constant of DPPC liposomes determined in the absence of crown ethers.

To assess the selectivity differences among the crown ether derivatives, linear correlations were calculated between the ΔP_K, ΔP_{Rb} and ΔP_{Na} values for each compound:

$$y = a + b \cdot x \quad [3]$$

where y and x are various ΔP values determined for K^+ (ΔP_K), Rb^+ (ΔP_{Rb}) and Na^+ (ΔP_{Na}). When the equation shows a high correlation (high value for the coefficient of correlation), the ion selectivities are similar. The intercepts of linear correlations are related to the average difference of ΔP values of the compounds.

Ion selectivity (S) was defined as the ratio of the permeability increase of various monovalent cations caused by crown ethers:

$$S_{K^+/Rb^+} = \Delta P_K/\Delta P_{Rb} \quad [4]$$

$$S_{K^+/Na^+} = \Delta P_K/\Delta P_{Na} \quad [5]$$

where S_{K^+/Rb^+} is the K − Rb selectivity of crown ethers under the experimental conditions, S_{K^+/Na^+} is the K − Na selectivity of crown ethers under the experimental conditions and ΔP_K, ΔP_{Na} and ΔP_{Rb} are the permeability increases caused by crown ether incorporation.

Determination of lipophilicity of crown ethers. The lipophilicity of crown ethers was determined by reversed-phase thin-layer chromatography (29,30). Silufol UV_{254} plates (Kavalier, Brno, Czechoslovakia) were impregnated by overnight prerunning in a solution of 5% paraffin oil in *n*-hexane. The crown ethers were dissolved in dimethylformamide at a concentration of 1 mg/mL, and 5 μL of each solution was spotted onto the plates. As the crown ethers exert their effect in an ionic environment and the ions considerably modify the lipophilicity of bioactive compounds (31), the lipophilicity of crown ethers was determined in ion-free (water/acetone, 3:7, vol/vol) and in ion-containing eluents (water/acetone, 3:7, vol/vol; NaCl added to a 0.23 M final concentration). After developing, the plates were dried at 105°C and the fractions were detected by their absorption spectra in visible and ultraviolet light. Five independent developments were carried out for each lipophilicity determination.

The lipohilicity values (R_M) were calculated from the measured R_f values according to Equation 6 (29,30):

$$R_M = \log (1/R_f - 1) \quad [6]$$

The lipophilicity values determined under ionic and ion-free conditions were correlated with the membrane damaging effect (ΔP) and selectivity (S):

$$\Delta P_{K^+} = a + b_1 \cdot R_M + b_2 \cdot R_M^2 \quad [7]$$

$$S_{K^+/Rb^+} = a + b_1 \cdot R_M + b_2 \cdot R_M^2 \quad [8]$$

Determination of the melting properties of DPPC. DPPC and the crown ethers were dissolved in chloroform in the molar ratio of 100:1, and then the solvent was evaporated under a stream of nitrogen at room temperature. Twice-distilled water was added to the sample in a weight ratio of water/DPPC (4:1). The samples were vigorously mixed for 30 min above the phase transition temperature of DPPC in a Vortex mixer. The measurements were carried out on a DuPont Thermoanalyzer 990 (Barley Mill, Wilmington, DE) at a heating rate of 5°C/min and at a sensitivity range of 0.1-0.2 milliwatt/cm.

The equipment was calibrated using indium. High heating rates were required because the pretransition temperatures were not detectable at lower heating rates due to the limited sensitivity of the calorimeter. In order to prove that the differences between the half widths of the main transition of the various samples are not an artifact of the 5°C/min heating rate, the differential scanning calorimetry behavior of pure DPPC and DPPC with compound 11 mixtures were determined at 0.5, 1, 2 and 5°C/min heating rates, and the half widths were plotted against the heating rate. Three parallel determinations were carried out for each DPPC/crown ether mixture. The pretransition temperature (T_p) and main transition temperature (T_m), the half width of the main transition ($\Delta T_{1/2}$) related to the cooperativity, and the enthalpy of the main transition (ΔH_m) were calculated.

RESULTS AND DISCUSSION

The lipophilicity (R_M), the increase of permeability of liposomes caused by crown ethers, and their ion selectivity are compiled in Tables 1 and 2. The permeability time constants of the control were 0.3×10^{-4} s^{-1} for K^+ and Rb^+ and 0.5×10^{-4} s^{-1} for Na^+. Compounds containing two crown rings in the molecule showed a considerable permeability increase which was highest for potassium, followed by rubidium and sodium. This indicates that the effect of these compounds is commensurate with that of valinomycin (Fig. 1). Significant linear correlations were found between the potassium/rubidium and potassium/sodium permeabilities (Table 3). The calculated coefficient of correlation values were higher than the corresponding tabulated ones: $r_{99\%} = 0.6851$ for K^+/Rb^+ and $r_{95\%} = 0.8114$ for K^+/Na^+. These findings support the idea that the permeability increase exerted by crown ethers consists of at least two components: (i) their ability to disarrange the membrane structure and (ii) their ability to selectively increase potassium efflux.

As the permeabilities for different monovalent cations correlate well with each other, factor (i) has to be independent of selectivity. Factor (ii) is assumed to account for the selectivity: P_K values are generally higher than P_{Rb} values.

The ability of crown ethers to increase the potassium permeability of DPPC liposomes was independent of their lipophilicity. The F values of Equation 6 were 2.15 and 2.05 for R_M values determined in ion-free and ion-containing eluents, respectively.

[a]Calculated from the permeability increase of liposomes caused by crown ethers.
[b]Determined by reversed-phase thin-layer chromatography. Abbreviations: a, intercept, b_1, b_2, slope; b_1,%, b_2, %, normalized slope; r^2, ratio of the dependent variable determined by the change of independent variable; s, SD; s_{b1}, s_{b2}, SD of slopes 1 and 2; F, calculated value of the F test.

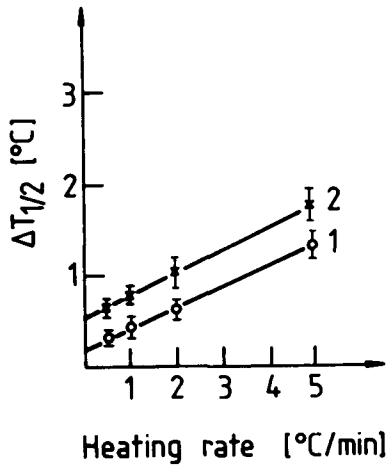

FIG. 2. Effect of heating rate on peak half-widths of DPPC (line 1) and DPPC/compound 11 (line 2) mixtures. Abbreviation as in Figure 1. $\Delta T_{1/2}$, half-width of the main transition.

The potassium/rubidium selectivity (S_{K^+}/S_{Rb^+}) correlated well with the lipophilicity values (Table 4), and the correlation was better for the R_M values determined in an ionic environment. The data suggest that not only the steric parameters, such as dimensions of the crown ring and those of the substituents, but also the lipophilicity, considerably affects the selectivity. The results indicate that the perturbation induced in the membrane bilayers by the crown ethers was related to the lipid solubility of the crown ethers. However, the change in lipophilicity accounts for only about half of the change in selectivity (r^2 values are 0.51 and 0.63 for the ion-free and ionic environment, respectively), which means that other parameters seem to influence the selectivity as well.

The peak half-width of main transition temperature of DPPC and DPPC/compound 11 mixtures decreased linearly with decreasing heating rate (Fig. 2). However, the peak half-widths of DPPC and DPPC/compound 11 mixtures significantly differed even at the lowest heating rate showing that the differences observed between the peak half-widths are not artefacts of the high heating rate. The effect of crown ethers on the melting properties of DPPC are compiled in Table 5. The pretransition and the main transition temperatures of DPPC agree well with the corresponding data in the literature (32–34); however, the ΔH_m is higher than the accepted value (33,34). This discrepancy may be due to the low sensitivity of the calorimeter; however, we believe that the differences observed between the enthalpies of the main transition temperatures reflect the real differences between the melting properties of the samples.

The crown ethers with one ring structure in the molecule have a negligible effect on the main transition temperature of DPPC/water dispersions. The *bis*-crown ethers with two ring structures per molecule decrease the ΔH_m, the T_p and main transition (T_m) temperatures, and broaden the temperature interval of the main transition ($\Delta T_{1/2}$). These data suggest interactions between the *bis*-crown ethers and DPPC. As a consequence, the crown ethers decrease

TABLE 5

[a]Dipalmitoyl phosphatidylcholine (DPPC)/crown ether molar ratio 100:1. Compounds 1-5 had no effect on the thermal parameters.

the lateral order of the bilayer and the phase transition temperature.

In summary, we conclude that the type of crown ethers studied modify the structure of the lipid bilayers and increase membrane permeability. The effects depend on the lipophilicity and on the structural characteristics (mono- or *bis*-crown) of the crown ether derivatives.

ACKNOWLEDGMENTS

The authors express their gratitude to Dr. Prof. Györgyi Rontó for helpful discussions and to Dr. Béla Agai for the gift of the crown ethers. This work was supported in part by the grant OTKA 2670 of the Hungarian Academy of Sciences.

Synthesis of Ethyl Arachidonate-19,19,20,20-d_4 and Ethyl Dihomo-γ-linolenate-19,19,20,20-d_4

Devanand L. Luthria and **Howard Sprecher***
Department of Medical Biochemistry, The Ohio State University, Columbus, Ohio 43210

Ethyl 5,8,11,14-eicosatetraenoate-19,19,20,20-d_4 and ethyl 8,11,14-eicosatrienoate-19,19,20,20-d_4 were synthesized by Grignard coupling of the methanesulfonyl ester of 2,5-undecadiyn-1-ol-10,10,11,11-d_4 with 5,8-nonadiynoic acid and 8-nonynoic acid, respectively. The coupled products upon Lindlar reduction, followed by the preparation of their ethyl esters, yielded deuteriated ethyl arachidonate and ethyl dihomo-γ-linolenate, which were completely characterized by ^{13}C and ^1H nuclear magnetic resonance and mass spectral analysis.
Lipids 28, 853–856 (1993).

Deuterium-labeled arachidonic acid is frequently used as an internal standard to quantify the amount of arachidonic acid released from membrane lipids in response to agonists (1). Deuteriated arachidonic acid also serves as the precursor for the biosynthesis of eicosanoids (2). Reduction of 5,8,11, 14-eicosatetraynoic acid by deuterium gas in the presence of Lindlar's catalyst yields arachidonic acid labeled with deuterium at the double bonds. These preparations generally are a mixture of about 85% octadeuteriated and 15% hepta- and hexadeuterio-arachidonic acid with no unlabeled compound (2–4). The synthesis of arachidonic acid labeled with deuterium atoms at the double bonds suffers in that a high isotopic purity is not always obtained (2–4). When these preparations of arachidonic acid are used to synthesize eicosanoids the isotopic composition of the resulting compounds may be altered further (3).

The β-oxidation of fatty acids results in the repeated loss of acetate units from the carboxyl end of the molecule. Numerous inborn errors of fatty acid oxidation have been described which result in the accumulation of chain-shortened intermediates (5). Recent studies have shown that the removal of the double bond at position 5, during unsaturated fatty acid oxidation, proceeds *via* a novel sequence of enzymatic reactions (6,7). Acids labeled with deuterium at or near the methyl terminus of the fatty acid would be of considerable value as the deuterium would not be isomerized when the acid is used as a substrate for eicosanoid biosynthesis. Secondly, these acids would be valuable probes for determining what metabolites accumulate during fatty acid oxidation in that the label would be retained during the entire β-oxidation spiral. Emken, Rakoff and their colleagues (8–13) have made extensive use of Wittig chemistry to introduce deuterium on internal carbons in fatty acids. In this study we describe, for the first time, the synthesis of deuteriated ethyl arachidonate and ethyl dihomo-γ-linolenate containing deuterium at carbon atoms 19 and 20.

RESULTS AND DISCUSSION

A primary objective of this study was to synthesize a common deuteriated precursor, in good yield, which could then be used to prepare both title compounds. The pathway for synthesis of 1-bromo-2-octyne-7,7,8,8-d_4 (1) (Scheme 1) utilizes a series of reactions described in the literature (14–17). The overall yield of 1 from 1-bromopentane-4,4, 5,5-d_4 was 80%. Deuteriated 2,5-undecadiyn-1-ol (2), the central intermediate, was obtained in 85% yield by reacting the diGrignard complex of propargyl alcohol with 1 in tetrahydrofuran (THF) with cuprous cyanide as catalyst (Scheme 2). The methanesulfonyl ester of compound 2 was synthesized in 97% yield by the procedure described by

Abbreviations: GLC, gas-liquid chromatography; NMR, nuclear magnetic resonance; THF, tetrahydrofuran.

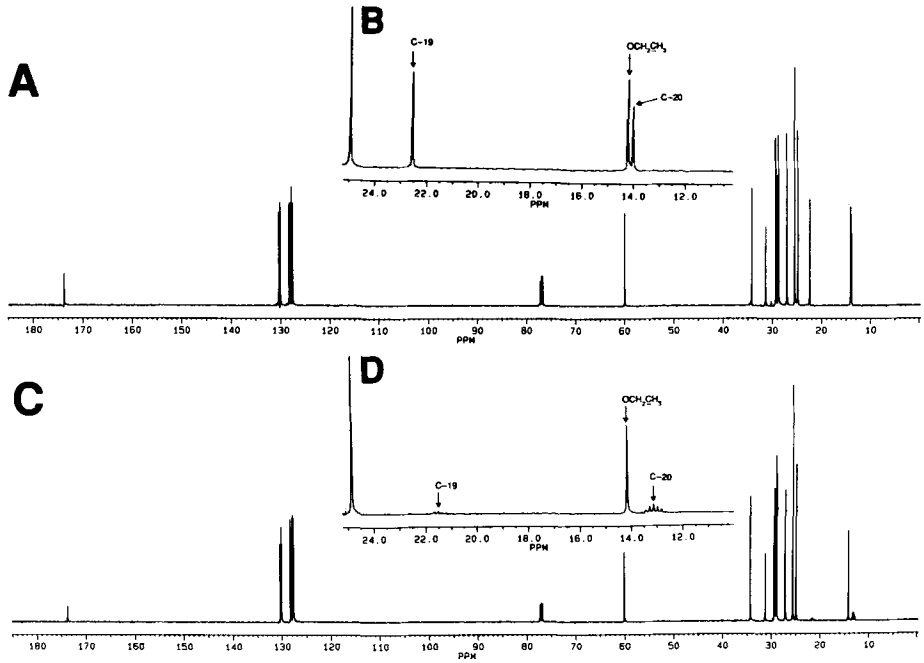

FIG. 1. ^{13}C Nuclear magnetic resonance spectra of ethyl 8,11,14-eicosatrienoate: (A) nondeuterated sample, (B) expansion between 10–25 ppm, (C) deuterated sample, (D) expansion between 10–25 ppm.

Crossland and Servis (18) and coupled directly with the diGrignard adduct of 8-nonynoic acid to give 8,11,14-eicosatriynoic acid-19,19,20,20-d_4 (5). In a similar way, the mesylate of the central intermediate 2 was coupled with 5,8-nonadiynoic acid to give 5,8,11,14-eicosatetraynoic acid-19,19,20,20-d_4 (4). 5,8-Nonadynoic acid was prepared as described by Osbond *et al.* (19), except that the mesylate of propargyl alcohol was used as the coupling agent. In the procedure described by Osbond *et al.* (19), substituted 1-bromo-2-alkynes are coupled with terminal acetylenic acids. Kunau (20) reported that yields could be improved if 1-iodo-2-alkynes were used as coupling agents. In his procedure, substituted 2-alkyn-1-ols were converted to tosylates and then to iodides (20). In our study, we show that mesylates can be directly coupled with alkynoic acids, as 4 and 5 were obtained in yields of 40 and 45%, respectively. Upon reduction with Lindlar's catalyst, these acetylenic acids gave the acids 6 and 7. The purity of these compounds was estimated by gas–liquid chromatography (GLC) after conversion to the ethyl esters 8 and 9 as 89 and 93%, respectively. Final purification was achieved by silver nitrate thin-layer chromatography. Deuteriated ethyl arachidonate and ethyl dihomo-γ-linolenate were characterized by ^1H and ^{13}C nuclear magnetic resonance (NMR) and mass spectral analysis (21–24). The signals for carbons (C-19 and C-20) bearing two deuteriums were diminished significantly, such that they were hardly detected (Figs. 1 and 2). Thus, no peaks for terminal carbons (C-19 and C-20) were observed in the ^{13}C NMR of deuteriated compounds 8 and 9.

EXPERIMENTAL PROCEDURES

Reagents. The following compounds and reagents were used as received: 4-pentynol was purchased from Farchan Laboratories (Gainesville, FL), *tris*(triphenylphosphine)-chlororhodium from Strem Chemicals (Newburyport, MA), methanesulfonyl chloride from Mallinckrodt Inc. (Paris, KY), magnesium from J.T. Baker Inc. (Phillipsburg, NJ), Lindlar catalyst from Fluka Chemical Co. (Ronkonkoma, NY) and lithium aluminum hydride from Aldrich Chemical Company (Milwaukee, WI). THF was freshly distilled over $LiAlH_4$.

Gas chromatography. A 30 m × 0.25 mm DB-WAX capillary column (i.d., 0.25 mm) from J&W Scientific (Folsom, CA) was used to analyze the purity of compounds.

^{13}C and ^1H NMR. NMR spectra were recorded with a Bruker AM 500 pulsed Fourier transform spectrometer (Karlsruhe, Germany) operating at 125.69 MHz for ^{13}C and 500 MHz for ^1H at ambient temperature. For ^{13}C, *ca.* 7500 transients were collected on solutions in $CDCl_3$, which served as both the internal lock and the secondary reference, using 5 mm tubes. Sweep widths of 250 ppm and 32K data points limited acquisition time to 0.49 s and were used to obtain chemical shifts within ± 1.2 Hz, *i.e.*, ± 0.008 ppm. A pulse width of 4 μs (50°) was employed with a delay of 0.3 s between pulses. Decoupling power was held to *ca.* 1W with Waltz 16 composite pulse decoupling, which was used to minimize sample heating. The signals from the carbons bearing two deuterium atoms were diminished (Figs. 1 and 2) to such an extent that they were not observed. Thus no peaks were detected for terminal carbons 19 and 20 for compounds 8 and 9.

Gas chromatography/mass spectrometry. Mass spectrometry was carried out using a Hewlett-Packard (Palo Alto, CA) 5970A mass selective detector equipped with a 30 m × 0.25 mm DB-225 capillary column.

2,5-Undecadiyn-1-ol-10,10,11,11-d_4 (2). Bromoethane (98.1 g, 0.9 mol) in dry THF (75 mL) was added to a stirred

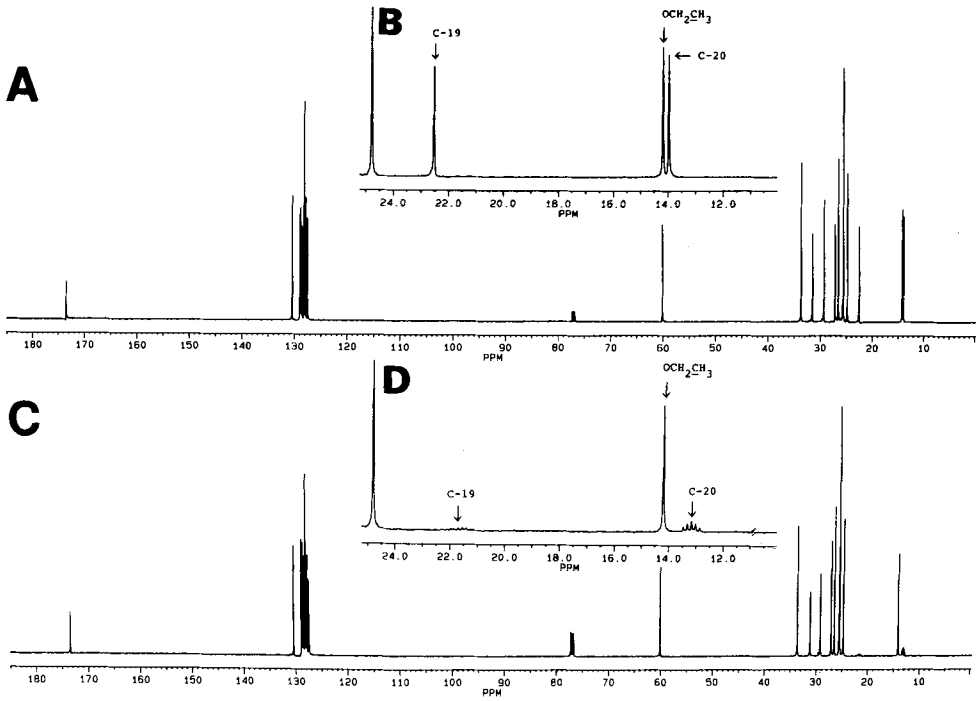

FIG. 2. ^{13}C Nuclear magnetic resonance spectra of ethyl 5,8,11,14-eicosatetraenoate: (A) nondeuterated sample, (B) expansion between 10–25 ppm, (C) deuterated sample, (D) expansion between 10–25 ppm.

suspension of Mg (18.9 g, 0.78 mol) under THF (300 mL) at 0°C. Propargyl alcohol (22.4 g, 0.4 mol) in THF was added to the Grignard reagent with stirring at 3–5°C during 30–45 min, and then at 20°C for 2 h. The solution was cooled to 5°C, cuprous cyanide (200 mg) was added and, after 15 min, 1-bromo-2-octyne-7,7,8,8-d_4 (48 g, 0.25 mol) in THF (75 mL) was added dropwise during 20–30 min. The solution was then allowed to stir at room temperature for *ca.* 3 h and was then heated under gentle reflux overnight (*ca.* 14 h). The reaction mixture was added to 2N H_2SO_4 (*ca.* 600 mL) and ice, extracted with diethyl ether (3 × 200 mL), brine (*ca.* 75 mL), and dried over Na_2SO_4. The alcohol was distilled at 87–89°C at 10^{-3} mm Hg (19) to yield 36 g of 2 (85.7%).

2,5-Undecadiynol-10,10,11,11-d_4 *(3).* Methanesulfonyl chloride (16.1 g, 0.14 mol) was added dropwise to a stirred solution of alcohol 2 (17 g, 0.1 mol) in dichloromethane (350 mL) and triethylamine (18.1 g, 0.18 mol) at 0 to −10°C over a period of 15 min. Stirring for an additional 1.5 h completed the reaction (18). The reaction mixture was transferred to a separatory funnel with the aid of methylene chloride. The mixture was first extracted with water, followed by 10% HCl, saturated bicarbonate solution and brine. Drying of the methylene chloride solution over anhydrous Na_2SO_4, followed by solvent removal under reduced pressure, gave product 3 (24.2 g, 97.2%). This product was used for coupling without further purification.

Ethyl 5,8,11,14-eicosatetraenoate-19,19,20,20-d_4 *(6).* The synthesis of compound 6 was carried out in three steps as described below:

Step 1: 5,8,11,14-Eicosatetraynoic-19,19,20,20-d_4 *acid (4).* Bromoethane (38.1 g, 0.35 mol) in THF (*ca.* 75 mL) was added to a stirred suspension of Mg (6 g, 0.25 mol) in THF (*ca.* 200 mL) at 0°C. 5,8-Nonadiynoic acid in THF (*ca.* 75 mL) was added to the Grignard reagent over a period of 30 min. The mixture was then stirred at 20°C for about 2 h, cooled to 0°C and 200 mg of cuprous cyanide was added. After stirring for 20 min, a solution of 3 in THF (*ca.* 75 mL) was added over 30 min. The mixture was stirred at room temperature for about 3 h and then gently refluxed overnight (*ca.* 14 h). The reaction mixture was cooled and poured into 2N H_2SO_4 (*ca.* 300 mL) and ice, extracted with diethyl ether (3 × 200 mL), washed with 2N HCl (100 mL), water (3 × 100 mL), brine (100 mL) and dried over Na_2SO_4. The product 4 was crystallized with hexane/diethyl ether (90:10, vol/vol), 12 g, 40%.

Step 2: 5,8,11,14-Eicosatetraenoic-19,19,20,20-d_4 *acid (6).* Compound 4 (4 g) in 100 mL ethyl acetate was reduced with hydrogen in the presence of Lindlar's catalyst (1.5 g) and quinoline (1.5 mL) in a hydrogenation apparatus. When hydrogen uptake stopped (100 ± 5% of theroy), the catalyst was removed by vacuum filtration, and the ethyl acetate was distilled under reduced pressure in a rotary evaporator. The product was dissolved in diethyl ether (250 mL), washed with 2N HCl (50 mL), water (2 × 100 mL), brine (50 mL) and dried over Na_2So_4. Removal of solvent yielded product 6 in 97% yield.

Step 3: Ethyl 5,8,11,14-eicosatetraenoate-19,19,20,20-d_4 *(8).* One mL of acetyl chloride was added dropwise at 0–5°C to the stirred solution of compound 6 (1 g) in absolute ethanol (10 mL). The mixture was stirred at ambient temperature overnight (*ca.* 16 h). The mixture was diluted with water (20 mL) and extracted with diethyl ether (2 × 30 mL), washed with brine (15 mL) and dried over anhydrous Na_2SO_4. Removal of solvent under reduced pressure yielded product 8 (1 g, 95%, GLC purity 89%). Compound 8 was purified by silver nitrate thin-layer

chromatography in 65% yield. Deuterium distribution: 0.0% d_0, 0.0% d_1, 1.2% d_2, 4.04% d_3, 94.76% d_4. ^{1}H NMR ($CDCl_3$): δ 5.30-5.41 (*m*, 8H, CH=CH), 4.11 (*q*, 2H, $COOCH_2$), 2.79-2.92 (*m*, 6H, $C{=}CCH_2C{=}C$), 2.29 (*t*, 2H, CH_2COO), 2.08-2.12 (*m*, 2H, $C{=}CCH_2$), 2.06-2.02 (*m*, 2H, $CH_2C{=}C$), 1.66-1.72 (*m*, 2H, CH_2CH_2COO), 1.27-1.38 (*m*, 4H, $\{CH_2\}_2$), 1.24 (*t*, 3H, OCH_2CH_3), 0.82 (*s*, 1H, CD_2H). ^{13}C NMR (ppm): C-1, 173.5; C-2, 33.7; C-3, 24.78; C-4, 26.5; C-5, 128.9; C-6, 128.8; C-7, C-10, C-13, 25.6; C-8, 128.1; C-9, 128.1; C-11, 127.8; C-12, 128.5, C-14, 127.5; C-15, 130.4; C-16, 27.2; C-17, 29.2, C-18, 31.2; OCH_2, 60.0; OCH_2CH_3, 14.2.

Ethyl 8,11,14-eicosatrienoate-19,19,20,20-d_4 *(9).* Compound **9** was prepared by coupling 8-nonynoic acid with compound **3** to give compound **5** in 45% yield. This, upon Lindlar's reduction, furnished compound **7**, which was converted to the ethyl ester **9** by ethanolic HCl. GLC analysis of the ethyl ester indicated its purity as 93%. Purification of 1 g of this product by silver nitrate thin-layer chromatography yielded 700 mg of the product. Deuterium distribution: 0.04% d_0, 0.17% d_1, 4.17% d_2, 3.69% d_3, 91.92% d_4. ^{1}H NMR ($CDCl_3$): δ 5.34-5.37 (*m*, 6H, CH=CH), 4.10 (*q*, 2H, $COOCH_2$), 2.74-2.78 (*m*, 4H, $C{=}CCH_2C{=}C$), 2.26 (*t*, 2H, CH_2COO), 2.03-2.06 (*m*, 4H, $CH_2C{=}C$), 1.59-1.62 (*m*, 2H, CH_2CH_2COO), 1.21-1.34 (*m*, 13H, $\{CH_2\}_5$ and OCH_2CH_3), 0.82 (*s*, 1H, CD_2H). ^{13}C NMR (ppm): C-1, 173.6; C-2, 34.2; C-3, 24.9; C-4, 28.8; C-5, 29.0; C-6, 29.2; C-7, 27.1; C-8, 130.0; C-9, 127.8; C-10, C-13, 25.6; C-11, 128.1; C-12 128.2; C-14, 127.6; C-15, 130.3; C-16, 27.1, C-17, 29.4; C-18, 31.2; OCH_2, 60.0; OCH_2CH_3, 14.2.

METHOD

Continuous Monitoring of Lipid Peroxidation by Measuring Conjugated Diene Formation in an Aqueous Liposome Suspension

Renée C.R.M. Vossen[a,*], Maria C.E. van Dam-Mieras[c], Gerard Hornstra[b] and Robert F.A. Zwaal[a]
Departments of [a]Biochemistry and [b]Human Biology, Cardiovascular Research Institute Maastricht (CARIM), University of Limburg, Maastricht and [c]Department of Natural Sciences, Open University of The Netherlands, Heerlen, The Netherlands

A method is described for the direct and continuous monitoring of lipid peroxidation in an aqueous suspension of sonicated liposomes. By means of ultraviolet difference spectroscopy using tandem cuvettes, the formation of conjugated dienes during liposome peroxidation can be followed. Using this technique, the effect of the fatty acid composition of liposomes on lipid peroxidation can be studied. The results show that both the extent and the time scale of lipid peroxidation are influenced by the fatty acid composition of the phosholipid liposomes. This was confirmed also by other methods, such as measurement of the formation of lipid hydroperoxides and measurement of the decrease in polyunsaturated fatty acids. The advantage of the method described is the direct and continuous monitoring of phospholipid peroxidation in an aqueous environment, without subsampling and extraction of peroxidation products into organic solvents. Using this experimental approach based on difference spectra the contributions from changes in liposome, $CuSO_4$ and H_2O_2 concentrations are canceled, thus improving sensitivity. The method can be employed for measuring the susceptibility to peroxidation of membrane phospholipids from fatty acid modified endothelial cells.
Lipids 28, 857–861 (1993).

Lipid peroxidation has been defined as the oxidative deterioration of polyunsaturated lipids by free radical reactions (1). The polyunsaturated fatty acids in biological membranes are very susceptible to lipid peroxidation, and their oxidation is thought to be involved in various physiological and pathological phenomena, such as the formation of local messengers (prostaglandins) during tissue activation, cellular aging, radiation damage, mutagenesis, carcinogenesis and atherogenesis (1–4). Radical chain reactions involving polyunsaturated fatty acids cause an initial rearrangement of the double bonds leading to conjugated dienes. Upon reaction with oxygen, lipid hydroperoxides are formed, which readily decompose into various other products including malondialdehyde.

Several methods for measuring lipid peroxidation have been developed (1,3). Lipid peroxidation is usually assessed by measuring the major initial peroxidation products (conjugated dienes, lipid hydroperoxides) and/or minor breakdown products (malondialdehyde, hexanal, volatile hydrocarbons) (3). As proteins and DNA can interfere with the accurate determination of lipid peroxidation, lipids are usually extracted from tissues or cells prior to measurement of peroxidation.

Abbreviations: BHT, butylated hydroxytoluene; TBARS, thiobarbituric acid reactive substances; PC, phosphatidylcholine; PL, phospholipid; Tris, tris(hydroxymethyl)aminomethane; UV, ultraviolet.

The methods commonly used for determining conjugated dienes are based on measuring their absorption at 233–236 nm (3,5,6). Sensitivity is limited by the fact that the diene absorption appears as a rather imprecise shoulder on the strong absorption peak of the unperoxidized fatty acid itself. This is especially problematic when small amounts of conjugated dienes have to be determined. By using second derivative spectra, sensitivity can be increased (7). These methods, however, usually involve discontinuous end point analyses in organic solvents, and the lipids need to be extracted first. We therefore developed a method for the continuous monitoring of liposome peroxidation in an aqueous environment, based on the method for measuring low-density lipoprotein peroxidation according to Esterbauer *et al.* (8) and the use of tandem cuvettes to measure the formation of conjugated dienes by ultraviolet (UV) difference spectroscopy. Lipid liposomes were used as a model membrane system to assess lipid peroxidation in aqueous environment (2). Using this technique, we determined the effect of liposome fatty acid composition on lipid peroxidation profiles. The results were compared with those obtained by other methods for monitoring lipid peroxidation, such as the formation of lipid hydroperoxides and the decrease in polyunsaturated fatty acids.

MATERIALS AND METHODS

1-Palmitoyl-2-palmitoleoyl-*sn*-glycero-3-phosphocholine (16:0/16:1 PC), 1-stearoyl-2-oleoyl-*sn*-glycero-3-phosphocholine (18:0/18:1 PC), 1-palmitoyl-2-linoleoyl-*sn*-glycero-3-phosphocholine (16:0/18:2 PC), 1-stearyl-2-arachidonoyl-*sn*-glycero-3-phosphocholine (18:0/20:4 PC), and butylated hydroxytoluene (BHT) were purchased from Sigma (St. Louis, MO). 1,2-Dilinoleoyl-*sn*-glycero-3-phosphocholine (18:2/18:2 PC), 1,2-dilinolenoyl-*sn*-glycero-3-phosphocholine (18:3/18:3 PC) and 1,2-diarachidonoyl-*sn*-glycero-3-phosphocholine (20:4/20:4 PC) were from Applied Science Laboratories (Deerfield, IL). Hydrogen peroxide (30% solution) was from Baker B.V. (Deventer, The Netherlands). $GuSO_4$ was from Merck (Darmstadt, Germany). All other reagents were of the highest grade of purity available.

The susceptibility for peroxidation of different lipid samples was determined by measuring conjugated diene formation in aqueous environment according to an adaptation of the method described by Esterbauer *et al.* (8) for low-density lipoproteins. In our setup, we introduced sonicated phospholipid (PL) liposomes and tandem cuvettes for UV difference spectroscopy. The reasoning behind the choice for tandem cuvettes is that we were interested in measuring the optical signal obtained upon interaction between lipids and $CuSO_4/H_2O_2$, which are both UV absorbing. Tandem cuvettes allowed for comparison of the

same amounts of lipid and $CuSO_4/H_2O_2$ mixed in the sample beam and separated in the reference beam.

Lipid liposomes were peroxidized by 200 μM $CuSO_4$ and 2 mM H_2O_2, as described by Kuypers *et al.*(9), and the UV spectrum was monitored continuously by difference spectroscopy using tandem cuvettes (2 cm, 232QS; Hellma B.V., The Hague, The Netherlands). Absorption spectra were recorded on a Uvikon 860 spectrophotometer equipped for data handling (Kontron Instruments, Zürich, Switzerland). UV difference spectra (205–300 nm) were recorded every 5 min for the time periods indicated. By using the curve overlay option, curves were plotted in one figure.

For the preparation of the sonicated liposomes, PLs (300–500 nmol) in methanol were dried in a glass tube by a stream of nitrogen. In case of 18:2/18:2 PC, 18:3/18:3 PC and 20:4/20:4 PC, each of these lipids was mixed 1:1 (mol/mol) with 16:0/16:1 PC in order to obtain 500 nmol phosphatidylcholine (PC) giving 500 nmol oxidizable polyunsaturated fatty acid. One mL of 50 μM Tris buffer [50 mM tris(hydroxymethyl)amino methane in water set to pH 7.5 with hydrochloric acid] presaturated with nitrogen was added to the dried lipid and a dispersion was made by vortexing under nitrogen. PL liposomes were prepared by sonication for 10 min under nitrogen while cooling with ice.

Prior to the peroxidation experiments, lipid liposomes were diluted 1:5 (vol/vol) in 50 μM Tris buffer, and 2 mL was added to the first compartment of the tandem cuvettes in both the reference and the sample beam as shown in Figure 1. The second compartments of both tandem cuvettes were filled with 2 mL of 50 μM Tris buffer alone. The temperature of the cuvettes was kept at 37°C. The UV difference spectra (205–300 nm) recorded at this point showed a straight line. Lipid peroxidation was initiated by addition of 20 μL 200 mM H_2O_2 and 20 μL 20 mM $CuSO_4$ to the lipid liposomes in the first compartment of the sample cuvette (final concentrations 2 mM and 200 μM, respectively). To correct for the effects of lipid dilution and of adding H_2O_2 and $CuSO_4$, the same amounts of H_2O_2 and $CuSO_4$ were added to the buffer containing compartment of the reference cuvette, while 40 μL of distilled water was added to both the lipid-containing compartment of the reference cuvette and the buffer-containing compartment of the sample cuvette. UV difference spectra from 205–300 nm were recorded continuously. The final conditions were 60–100 μM PL liposomes, 2 mM H_2O_2 and 200 μM $CuSO_4$. In this setup the formation of conjugated dienes (233–235 nm) from PLs in the sample cuvette was measured against unperoxidized PLs in the reference cuvette. By this experimental design the contributions from changes in the liposome, $CuSO_4$ and H_2O_2 concentrations to the difference spectra was canceled. The method allows for the sensitive and continuous monitoring of conjugated dienes in an aqueous environment without the necessity of subsampling and extraction of the peroxidation products formed.

Lipid hydroperoxides were determined by the iodometric assay described by Hicks and Gebicki (10). The decrease in polyunsaturated fatty acids due to lipid peroxidation was determined by gas–liquid chromatography as described earlier (11). Lipids were extracted from endothelial cell membranes by the method of Bligh and Dyer (12) using BHT as antioxidant, and PLs were separated from neutral lipids by thin-layer chromatography as described before (11), but BHT in the organic solvents was omitted. Phosphorus content of PLs was quantified according to Böttcher *et al.* (13).

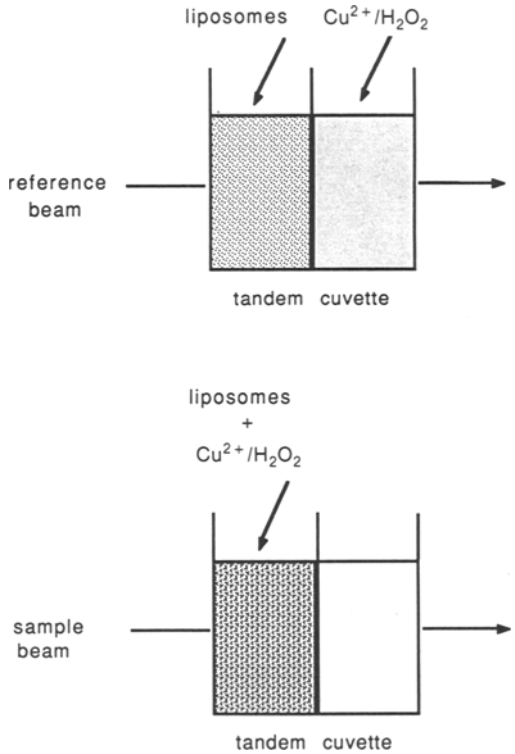

FIG. 1. Ultraviolet difference spectroscopy using tandem cuvettes for monitoring peroxidation of phospholipid liposomes. Peroxidation was started in the sample cuvette by addition of $CuSO_4$ and H_2O_2 to the liposomes. In the reference cuvette, no liposome peroxidation was initiated as $CuSO_4$ and H_2O_2 were added to a separate compartment. The difference spectra were recorded continuously.

RESULTS AND DISCUSSION

Peroxidation profiles of PC liposomes with different fatty acid compositions. We studied the influence of fatty acid composition on the peroxidation profiles of PC liposomes by UV difference spectroscopy using tandem cuvettes. The peroxidation profiles of 16:0/18:2 PC, 16:0/18:3 PC and 18:0/20:4 PC are shown in Figure 2. Peroxidation of 16:0/18:2 PC resulted in an absorption maximum at 234 nm, which first increased with time and then gradually decreased, representing the formation and decomposition of conjugated dienes. The absorption maximum at 234 nm of 16:0/18:3 PC shifted with time toward 225 mm with the concomitant appearance of a dip at 210 nm. This shift may be explained by formation of alkenals and hydroxyalkenals, typical products of lipid peroxidation with absorption maxima at 220–225 nm (6). Two other absorption maxima at 270 and 280 nm were observed, which probably represent the formation of conjugated trienes (6). Conjugated triene formation started later and was lower than conjugated diene formation. The species 18:0/20:4 PC showed a comparable peroxidation profile, but on a slower time scale and without distinct maxima at 270 and 280 nm, probably because a mixture of conjugated trienes is formed. Conjugated triene formation from 18:0/20:4 PC was much lower than from 16:0/18:3 PC. Surprisingly,

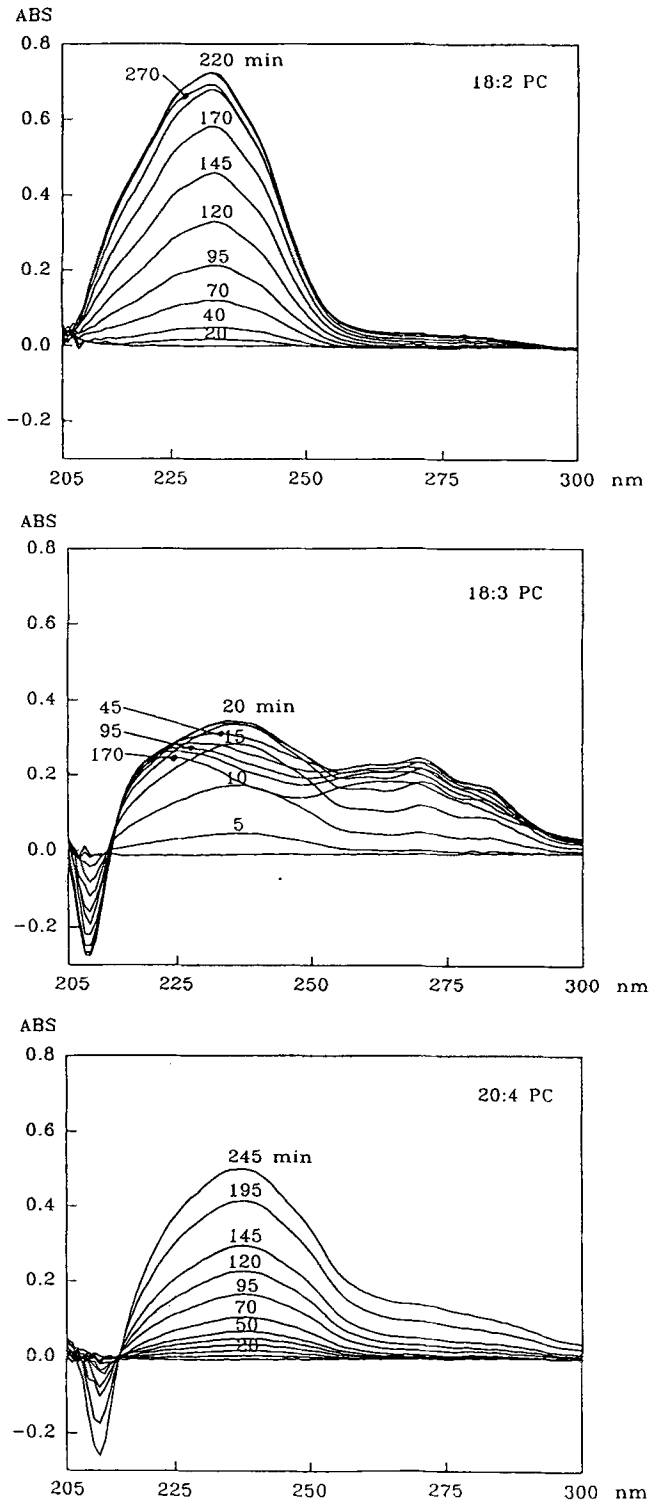

FIG. 2. Change of the ultraviolet (UV) difference spectrum of phosphatidylcholine (PC) liposomes with different fatty acid compositions during peroxidation. Liposomes (100 μM) prepared from 16:0/18:2 PC (top box), 16:0/18:3 PC (middle box) and 18:0/20:4 PC (bottom box) were peroxidized by $CuSO_4$ (200 μM) and H_2O_2 (2 mM). Conjugated diene formation was monitored continuously by UV difference spectroscopy (205–300 nm) using tandem cuvettes. Peroxidation profiles are shown as UV absorption units (ABS) against wavelength (nm) for the time points indicated.

after 250 min of peroxidation, still no decrease in conjugated diene formation was seen with 18:0/4 PC.

The fatty acid composition of the liposomes thus considerably influenced the peroxidation profile (Fig. 2) as well as the time scale of the peroxidation process and the maximal extent of conjugated diene formation (Fig. 3). The 16:0/18:3 PC showed a rapid but relatively low conjugated diene formation, while conjugated diene formation form 16:0/18:2 PC was slower but relatively high in amount. The 18:0/20:4 PC showed a slow but progressive formation of conjugated dienes. Both the peroxidation profiles and the maximal extent of conjugated diene formation were reproducible, standard deviations being below 6%. When conjugated diene formation was measured after relatively short peroxidation times, more variable results were observed, possibly because of the presence of small amounts of preexisting lipid peroxides in the samples used.

We also studied the influence of liposome concentration on the lipid peroxidation process (Fig. 4). It can be seen in Figure 4A that there is a linear relationship between the maximal amount of conjugated dienes formed and the amount of 16:0/18:2 PC liposomes present during peroxidation. The extent of lipid peroxidation was dependent on the amounts of $CuSO_4/H_2O_2$ added; addition of $CuSO_4$ or H_2O_2 alone resulted in a much lower peroxidation rate (data not shown). Addition of the antioxidant BHT to the liposomes during preparation resulted in a lag phase at low BHT concentrations, while total inhibition of lipid peroxidation occurred with higher amounts of BHT (Fig. 4B). Similar effects of liposome, $CuSO_4/H_2O_2$ and BHT concentrations were found with 16:0/18:3 PC and 18:0/20:4 PC. We also measured the UV absorption spectra of known amounts of a standard fatty acid-derived conjugated diene (13-hydroxy-9,11-octadecaenoic acid), and

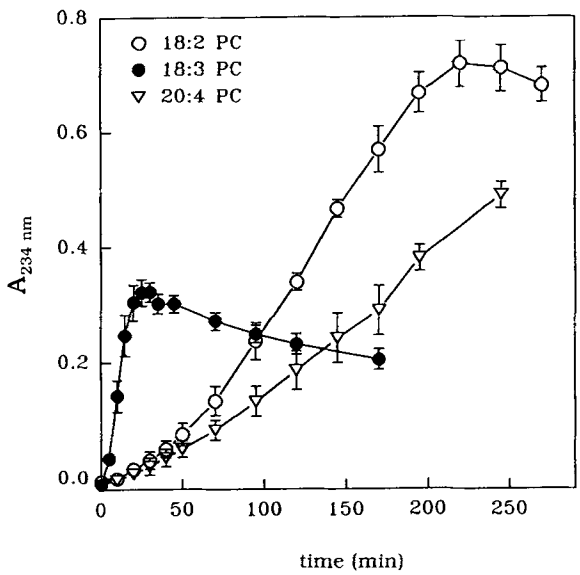

FIG. 3. Time scale of conjugated diene formation of phosphatidylcholine (PC) liposomes with different fatty acid compositions during peroxidation. For procedure details, see Figure 2. Ultraviolet absorption at 234 nm (conjugated diene formation) is plotted against peroxidation time. The mean values ± SD of five separate liposome preparations measured on three different days are shown. Wavelength, nm.

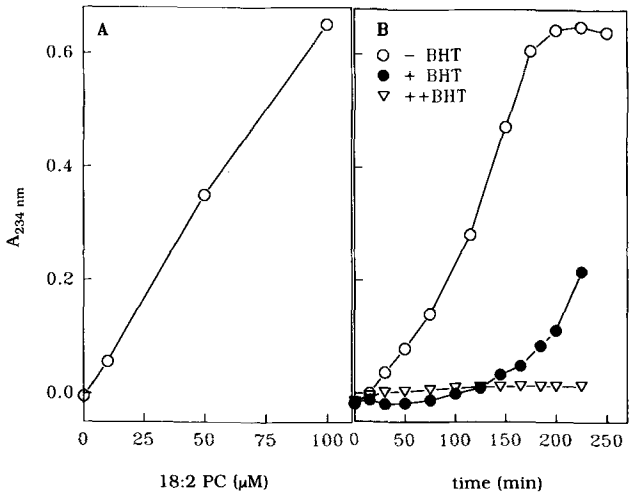

FIG. 4. Influence of liposome concentration and butylated hydroxytoluene (BHT) on conjugated diene formation (for procedural details, see Fig. 2). Figure 4A shows the maximal conjugated diene formation during peroxidation of 16:0/18:2 PC liposomes with a final concentration of 10 μM, 50 μM or 100 μM. In Figure 4B, the influence of BHT [0.05 nmol BHT/nmol 16:0/18:2 phosphatidylcholine (PC) for closed circles and 0.5 nmol BHT/nmol 16:0/18:2 PC for open triangles] on the peroxidation of 100 μM 16:0/18:2 PC is shown. Wavelength, nm.

found a linear increase in absorption at 234 nm with increasing amounts (data not shown).

As expected, no formation of conjugated dienes was observed with liposomes consisting of 16:0/16:1 PC or 18:0/18:1 PC. When we recorded peroxidation profiles of 18:2/18:2 PC 1:1 mixed with 16:0/18:1 PC, no differences were found with that of 16:0/18:2 PC. In both liposome preparations, the amount of oxidizable linoleic acid is equal. These observations suggest that only the polyunsaturated fatty acids are peroxidized within the time scale used, and that the amount, but not the position, of the polyunsaturated fatty acid within the PL molecule influences lipid peroxidation in these liposomes.

Comparison of the continuous conjugated diene measurement with other discontinuous methods for estimating lipid peroxidation in vitro. We compared our conjugated diene measurement with other lipid peroxidation assays, such as measurement of the decrease in polyunsaturated fatty acids by gas-liquid chromatography and measurement of the formation of lipid hydroperoxides by an iodometric assay.

The formation of conjugated dienes (as a measure for initial lipid peroxidation) and the decrease in polyunsaturated fatty acids (as a measure of total lipid peroxidation) for liposomes containing 16:0/18:2 PC, 16:0/18:3 PC or 18:0/20:4 PC was measured after 80 min of peroxidation. The relation between both methods is shown in Table 1. We also measured the sensitivity to peroxidation of PLs obtained from fatty acid modified endothelial cells. As a lipid source, we used PLs which were extracted from endothelial cell membranes having different fatty acid compositions. Fatty acid modified endothelial cells were cultured as described before (11). Liposomes (60 μM phospholipid) were prepared from endothelial phospholipids with (A) a normal fatty acid composition, (B) an increased oleic acid content, (C) an increased linoleic acid and arachidonic acid content or (D) an increased eicosapentaenoic acid and docosahexaenoic acid content. (The fatty acid compositions are shown in Table 2). The liposomes were peroxidized for 80 min with 2 mM H_2O_2 and 200 μM $CuSO_4$ (final concentrations), and conjugated diene formation was measured continuously. As an example Figure 5A shows the peroxidation profile of liposomes prepared from endothelial cells with a normal fatty acid composition, and Figure 5B shows that of liposomes obtained from cells with increased oleic acid content. both difference spectra obtained during peroxidation showed characteristics of the 18:0/20:4 PC and 16:0/18:2 PC spectra (Fig. 2). This was to be expected for cellular PLs containing a mixture of various fatty acids, because PC comprises 53.4% of total PLs (11), and linoleic acid and arachidonic acid are the most abundant polyunsaturated fatty acids in these endothelial cells (Table 2). Figure 5 shows that the extent of conjugated diene formation in liposomes with increased oleic acid content was decreased compared to liposomes with normal fatty acid composition. As was shown earlier (11), the polyunsaturated fatty acid content of the membrane PLs was decreased when the oleic acid content increased. Table 2 shows that endothelial cell PLs with normal fatty acid composition (A) contained 0.29 nmol linoleic acid and 0.21 nmol arachidonic acid, while cells modified with oleic acid (B) contained 0.15 nmol linoleic acid and 0.13 nmol arachidonic acid in their membrane PLs. Probably the decreased availability of the polyunsaturated fatty acids linoleic acid and arachidonic acid

TABLE 1

Conjugated Diene Formation and Decrease of Polyunsaturated Fatty Acids During Peroxidation of Phosphatidylcholine (PC) Liposomes with Different Fatty Acid Compositions[a]

Liposomes	Decreased fatty acids nmol/nmol PL	Conjugated dienes A_{234}
15:0/18:2 PC	0.49	0.21
16:0/18:3 PC	0.74	0.26
18:0/20:4 PC	0.23	0.11

[a]Liposomes [100 μM phospholipids (PL)] were prepared and peroxidized for 80 min by addition of $CuSO_4$ (200 μM) and H_2O_2 (2 mM). Conjugated diene formation (absorption at 234 nm) was monitored continuously by ultraviolet difference spectroscopy using tandem cuvettes. Decrease in polyunsaturated fatty acids (nmol/nmol PL) was measured by gas-liquid chromatography.

TABLE 2

Fatty Acid Composition of Phospholipids (PL) Extracted from Fatty Acid-Modified Endothelial Cells[a]

Fatty acids	nmol/nmol PL			
	A	B	C	D
18:1n-9	0.33	0.67	0.20	0.29
18:2n-6	0.29	0.15	0.35	0.24
20:4n-6	0.21	0.13	0.30	0.11
20:5n-3	0.01	—	—	0.12
22:6n-3	0.06	0.04	0.01	0.11

[a]Fatty acid composition (nmol/nmol PL) of endothelial phospholipids with (A) a normal fatty acid composition, (B) an increased oleic acid content, (C) an increased linoleic acid and arachidonic acid content or (D) an increased eicosapentaenoic acid and docosahexaenoic acid content. Cells were cultured as described before (11).

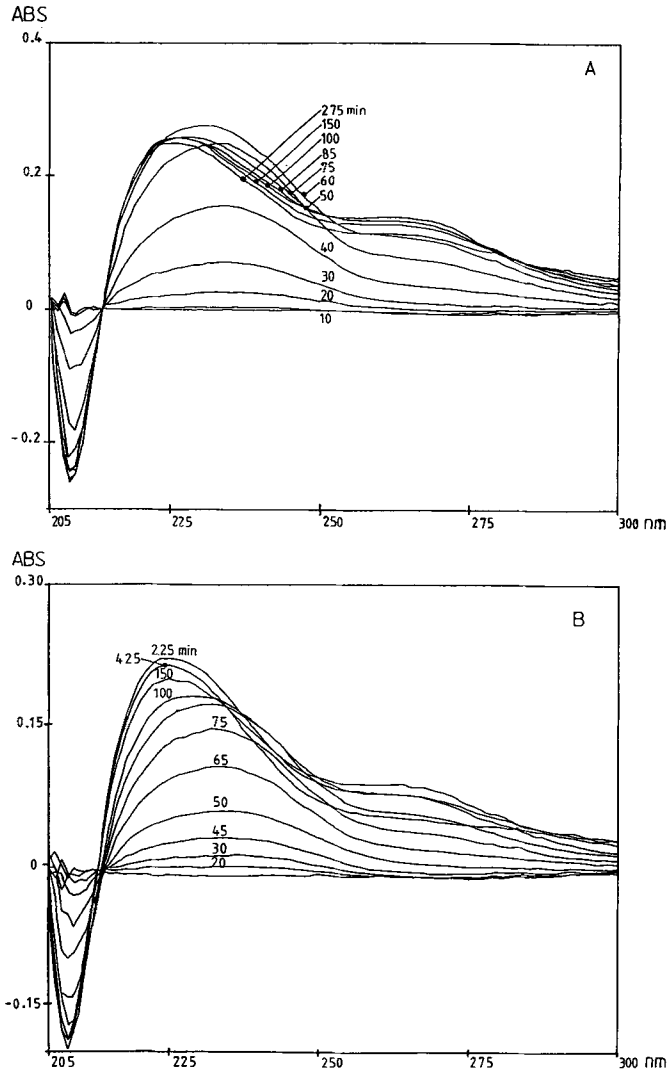

FIG. 5. Change of the ultraviolet (UV) difference spectrum during peroxidation of liposomes prepared from endothelial cell phospholipids. Phospholipids were extracted from endothelial cells with normal fatty acid composition or with increased oleic acid content and liposomes were prepared. Peroxidation with $CuSO_4$ and H_2O_2 was monitored by UV difference spectroscopy as in Figure 2. Wavelength, nm; absorption units, ABS.

was reflected in a decreased formation of conjugated dienes in these liposomes, as oleic acid itself cannot form conjugated dienes.

In the same batch of endothelial cell-derived liposomes, the amount of lipid hydroperoxides formed after 80 min of peroxidation was measured. Also the fatty acid compositions of both peroxidized (80 min) and nonperoxidized liposomes were determined, and the decrease in polyunsaturated fatty acids during peroxidation was calculated. The relation between the measurement of conjugated diene formation, the decrease in polyunsaturated fatty acids and the formation of lipid hydroperoxides during 80 min of peroxidation are shown in Table 3. It is also shown in Table 3 that the fatty acid composition of the endothelial cell PLs influenced the extent of lipid peroxidation as measured by three different methods.

In conclusion, we describe here a method for the continuous monitoring of lipid peroxidation by measuring conjugated diene formation by UV difference spectroscopy using tandem cuvettes and sonicated liposomes. Our method allows the direct and continuous monitoring of PL peroxidation in an aqueous environment, without the disadvantages of subsampling and extraction of peroxidation products into organic solvents. We have shown that the time course and extent of lipid peroxidation are considerably affected by the fatty acid composition of the PL liposomes. This was confirmed by other methods for measuring lipid peroxidation, such as by measuring the decrease in polyunsaturated fatty acids and the formation of lipid hydroperoxides.

TABLE 3

Conjugated Diene Formation, Lipid Hydroperoxide Formation and Decrease in Polyunsaturated Fatty Acids During Peroxidation of Endothelial Cell Phospholipids (PL)[a]

Liposomes	Decreased fatty acids nmol/nmol PL	Lipid hydroperoxides nmol/nmol PL	Conjugated dienes A_{234}
A	0.265	0.0054	0.287
B	0.161	0.0036	0.173
C	0.323	0.0108	0.315
D	0.282	0.0064	0.285

[a]PLs were extracted from endothelial cells with different fatty acid compositions: (A) cells with normal fatty acid composition, (B) cells with increased oleic acid (n-9) content, (C) cells with increased linoleic and arachidonic acid (n-6) content and (D) cells with increased eicosapentaenoic and docosahexaenoic acid (n-3) content. Liposomes (60 μM PL) were prepared and peroxidized for 80 min. Conjugated dienes, lipid hydroperoxides and decrease in polyunsaturated fatty acids were measured.

ACKNOWLEDGMENTS

The authors wish to acknowledge Carina Pernot for technical assistance with the lipid hydroperoxide measurements and Mariet Molenaar for typing the manuscript.
