REVIEW

Gangliosides and Atherosclerosis

N.V. Prokazova and **L.D. Bergelson***
Institute of Experimental Cardiology, Russian Cardiology Research Center, Academy of Medical Sciences, Moscow, Russia

The ganglioside levels in atherosclerotic lesions of human aorta are considerably higher than those in unaffected areas of aorta, and atherosclerotic patients frequently have increased concentrations of serum gangliosides. The present review summarizes recent findings that suggest the possible involvement of aortic gangliosides in platelet activation and adhesion of platelets to the vessel wall. The effect of gangliosides on the structure of low density lipoproteins (LDL), on the interaction of LDL with macrophages and hepatic cells and on the LDL-regulated biosynthesis of cholesterol is also discussed. *In vitro* experiments have demonstrated that a major ganglioside of the intima of atherosclerotic aorta induces rapid adhesion, aggregation and spreading of platelets. Moreover, gangliosides present in elevated amounts in the intercellular space of atherosclerotic aortic tissue modify the surface structure and stimulate aggregation of LDL. Ganglioside-modified LDL are readily recognized and taken up by macrophages, while preincubation of LDL with low concentrations of gangliosides inhibits LDL binding to hepatic cells. Thus, ganglioside enrichment of LDL is likely to interfere with LDL clearance *via* the hepatic cells. Thus, ganglioside enrichment of LDL is likely to interfere with LDL clearance *via* the hepatic LDL receptor, and to stimulate binding of LDL to the scavenger receptor of macrophages. It is postulated that high ganglioside levels in the aorta and serum may be an additional risk factor in atherosclerosis.
***Lipids* 29, 1–5 (1994).**

In the development of atherosclerosis, the aortic wall is damaged, and platelets, monocytes and low density lipoproteins (LDL) arrive at the site of injury and contribute to the formation of atherosclerotic plaques that eventually lead to thrombosis. In 1975, Breckenridge *et al.* (1) reported that the ganglioside content of the aorta increased dramatically during atherosclerosis. Although gangliosides were subsequently implicated in cell adhesion (2) and LDL-cell interactions (3,4), Breckenridge *et al.*'s finding attracted little attention, and today only sparse data on the involvement of gangliosides in the events leading to atherosclerosis are available. We summarize the results of some recent studies aimed at clarifying the effect of gangliosides on the structure and function of LDL, and on platelet adhesion, plaque formation and atherogenesis.

Abbreviations: ApoB, apolipoprotein B; GSL, glycosphingolipids; LDL, low density lipoproteins; MAH, mouse ascites hepatoma; WHHL rabbits, Watanabe hereditable hyperlipidemic rabbits.

The abbreviations used for gangliosides are standard abbreviations as recommended by Svennerholm [Svennerholm, L. (1964) *J. Lipid Res. 5*, 145–155].

Ganglioside changes in aortic tissue related to atherosclerosis. According to Breckenridge *et al.* (2), the level of total gangliosides (lipid-bound sialic acid) in healthy aorta is low, but increases progressively in aortas containing fatty streaks, plaques and ulcerated lesions. These studies were performed on whole aorta tissue. In order to obtain additional information, we studied the glycosphingolipids (GSL) of intima and of underlying areas of aortas taken from subjects who had died after myocardial infarction (5–7).

Our data showed important differences between the GSL profiles of the intima and the underlying areas, as well as between cells taken from affected and unaffected areas of the aorta. In unaffected areas a major difference between the intima and the underlying media was the absence in intima of glucosyl and lactosylceramide, whereas in the underlying media these substances accounted for at least one-third of the neutral GSL (6). The main ganglioside in both intima and media was GM3; however, in contrast to the media, the intima proved to contain relatively high amounts of GD3 (5). A similar characteristic ganglioside pattern was detected in the aorta of Watanabe hereditable hyperlipidemic (WHHL) rabbits, an animal model for human familial hypercholestrolemia (8). In the aorta of these rabbits, the level of total gangliosides increases 12-fold in comparison to that in normal rabbit aorta. One of the most predominant gangliosides in the aorta of WHHL rabbits (next to GM3) is GD3, which, in normal aortas, is almost undetectable. While GM3 is the major ganglioside in all normal extraneural tissues, GD3 is considered a characteristic antigen of many fast-growing, undifferentiated or malignant cells (see Ref. 9 for a review). It has been suspected for a long time that there might be similarities between tumor growth and the fast proliferation of smooth muscle cells during the development of atherosclerosis (10). During recent years a considerable body of evidence has accumulated suggesting a special role of gangliosides in tumorigenesis (11). Some facts supporting this theory include the effect of gangliosides on the loss of contact inhibition in tumor cells (11), the enhancement of tumor formation by gangliosides produced by highly tumorigenic cells in weakly tumorigenic cells (12), the suppression of natural immunity by gangliosides shed by tumor cells (13,14) and the high expression in tumor cells of certain gangliosides, such as GD3 and GD2, which are little or not at all expressed in normal extraneural tissues (reviewed in Ref. 9). Thus, the comparatively high level of GD3 in the intima of atherosclerotic aorta supports the idea that some analogy exists between certain steps in atherogenesis and in tumorigenesis.

It is noteworthy that in whole tissues of the atherosclerotic aorta, the ganglioside concentration is considerably higher than in isolated cells, suggesting that even higher amounts of gangliosides may accumulate in the intercellular space (7). This again is reminiscent of the situation with many tumor cells that intensively shed

their gangliosides, thus creating high ganglioside concentrations within their microenvironments (reviewed in Ref. 9).

In this context, it is interesting to note that antibodies raised to intimal cells have been found to be directed against gangliosides (15). This prompted us to study the role of gangliosides in the adhesion of platelets to the vessel wall. To this end we investigated the interaction of human platelets with individual aortic gangliosides adsorbed to plastic (16). In these experiments only GD3, but no other ganglioside, dramatically stimulated platelet adhesion, spreading and aggregation (Fig. 1). Taken together, this suggests that intimal GD3 exposed to the lumen after endothelial injury may be a factor responsible for platelet attachment to the damaged vessel wall.

The binding of gangliosides to LDL. A high LDL concentration in serum is a major risk factor for atherosclerosis, and it is now firmly established that the cholesterol that accumulates in atherosclerotic lesions originates primarily from LDL. Incidentally, LDLs are also the main carriers of plasma gangliosides (17), but until recently little was known about the effect of gangliosides on LDL structure and function. In order to fill this gap, we undertook an investigation of the binding of gangliosides to LDL and of the changes in LDL structure brought about by their interaction with gangliosides present in human plasma (18,19).

The ganglioside content of serum has been studied intensively. For normal serum most authors reported average values in the order of 10 nmol/mL of serum (17,20–24), and LDL isolated from normal plasma contain only a few ganglioside molecules per lipoprotein particle (17,24). In hypercholesterolemia, however, the serum ganglioside level was found to be considerably higher (25).

We found that even larger amounts of gangliosides can associate with lipoproteins upon incubation of isolated LDL with exogenous gangliosides (19). Such ganglioside-rich LDL may be postulated to form *in vivo* in situations where lipoproteins exist in a relatively high-ganglioside environment, for example, in the local microenvironment of stimulated macrophages, which are known to actively release gangliosides, particularly GD3 (26). In the concentration range of 20–120 μM, the ganglioside uptake by LDL proved to be proportional to the ganglioside concentration without any trend toward saturation. Washing with salt solutions removed only a minor portion of the gangliosides bound, indicating that nonelectrostatic forces seem to play an important role in the formation of LDL-ganglioside adducts.

Nevertheless, a small yet saturable binding component, due to specific interaction of ganglioside with certain sites on LDL apolipoprotein B (apoB), also appears to exist. This was demonstrated in a study on the binding of gangliosides to LDL that was immobilized on Sepharose (18). The binding of mono- and disialogangliosides to Sepharose-immobilized LDL was saturable and depended on the specific ganglioside structure (18). Ganglioside binding to the LDL-affinity gel could be reversed by washing the gel with dilute salt solutions. Mild trypsinization of the ganglioside-loaded LDL-affinity gel also removed most of the gangliosides.

In radioligand assays of LDL, the extent of specific binding can be evaluated by adding excess heparin to the incubation medium. The amount of LDL that binds to cells under such conditions corresponds to nonspecific interaction. When excess heparin was added to the LDL-affinity gel simultaneously with gangliosides, binding of the latter was substantially reduced (18).

Thus, while the uptake of gangliosides by native LDL particles (*i.e.*, LDL isolated from plasma by standard

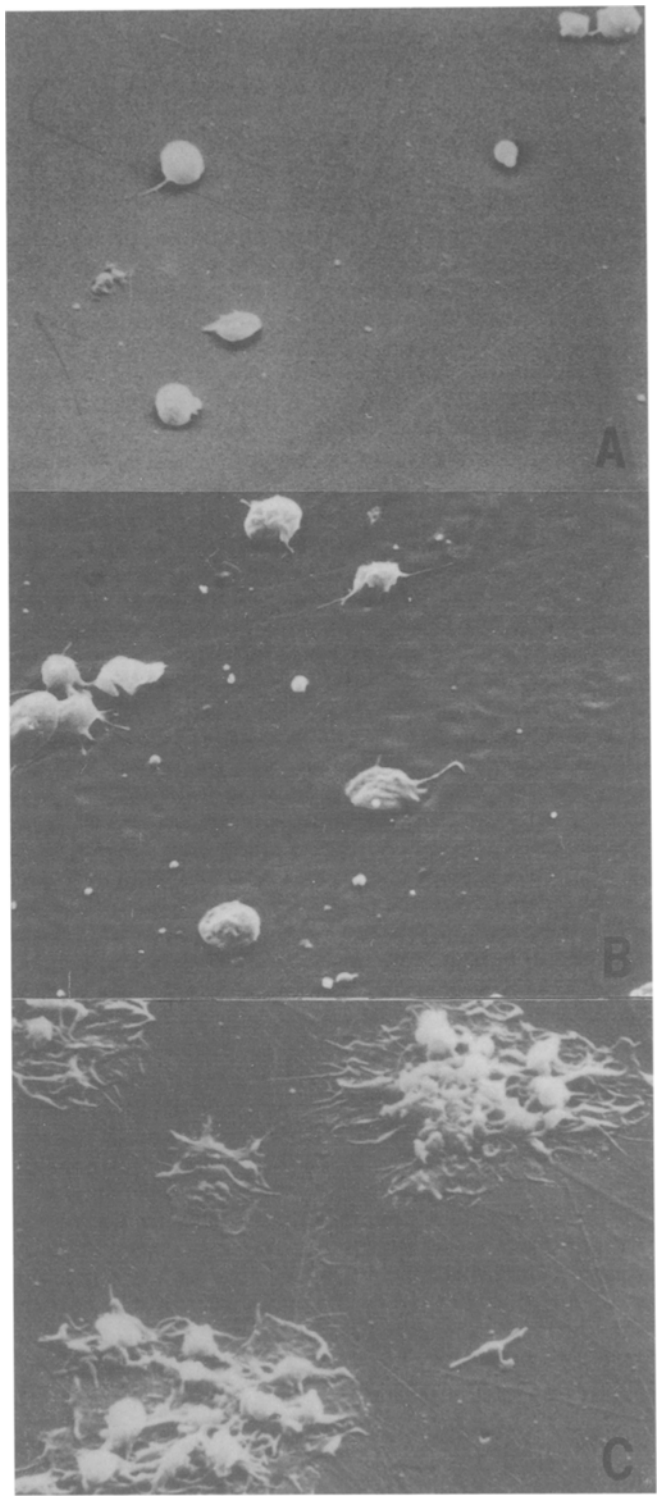

FIG. 1. Interaction of platelets with gangliosides coated on plastic. A, no ganglioside; B, GM1, C, GD3 (Ref. 16).

methods) is predominantly nonspecific and hydrophobic, the binding of gangliosides to immobilized LDL appears to be largely hydrophilic and more specific.

Gangliosides modify LDL structure. Even small amounts of gangliosides are able to induce a molecular reorganization of the LDL surface. This can be deduced from the fact that ganglioside binding to LDL is accompanied by changes in the intrinsic fluorescence of apoB which contains more than 30 tryptophan residues (19). Upon incubation with gangliosides, the apoB fluorescence maximum is shifted to longer wavelengths indicating that some of the tryptophyls are translocated to more polar environments (19). On the other hand, the apoB tryptophyls become, on the average, less accessible to quenching by aqueous iodide. Thus gangliosides appear to cause certain conformational changes of apoB molecules on the LDL surface. These changes, in turn, alter the molecular packing of the LDL surface phospholipids that surround apoB. This conclusion is based on the observation that small amounts of gangliosides had a pronounced effect on the fluorescence anisotropy of LDL labeled with fluorescent phospholipids in the outer monolayer (Fig. 2) (18). Interestingly, the mobility of the probes and, hence, the fluidity of their microenvironment, changed in different directions depending on the carbohydrate structure of the ganglioside. The effect was saturated at concentrations corresponding to less than 10 ganglioside molecules per LDL particle. As a result of the ganglioside-induced changes of the LDL surface, the LDL particles slowly aggregate, forming small adducts containing an average of three native LDL particles (19).

Involvement of gangliosides in LDL-cell interactions. The removal of LDL from the plasma is achieved by two alternate pathways. The main pathway is mediated by specific LDL receptors that are present on the surface of most mammalian cells (27). However, some cell types lacking the "normal" LDL receptors are able to take up modified forms of LDL, recognizing them by so-called "scavenger" receptors. Typical representatives of cells expressing the normal LDL receptor are fibroblasts and hepatocytes, whereas monocytes (macrophages), Kupffer cells and endothelial cells are characterized by the presence of scavenger receptors (for a recent review, see Ref. 28). Binding of LDL to the normal receptor is followed by internalization of the lipoprotein particle, and this initiates a chain of events, including the inhibition of cholesterol synthesis, the stimulation of cholesterol esterification and the inhibition of LDL-receptor synthesis (29).

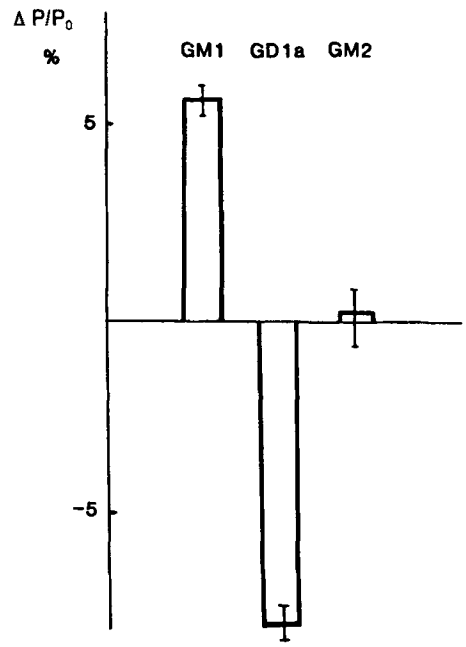

FIG. 2. Ganglioside-induced changes in the fluorescence polarization of low density lipoprotein (LDL) labeled in the outer monolayer by a fluorescent analogue of sphingomyelin (Ref. 18). Ganglioside concentration, 10^{-9} M; LDL concentration, 1 mg protein/mL. $\Delta P = P - P_0$ where P_0 and P are the fluorescence polarization values before and after addition of ganglioside, respectively.

Studies on the effect of gangliosides and other sialoglycoconjugates on LDL-cell interactions have led to apparently conflicting results. According to some investigators, the receptor-mediated uptake of LDL increases after enzymatic desialylation of the lipoproteins (3,30; see also Ref. 31). On the other hand, it has been noted by some authors that increasing the number of sialic acid residues on the surface of recipient cells stimulates receptor-mediated LDL uptake (32), whereas others found that the uptake increased after partial desialylation of the cells (33). These differences may be related to the use of different recipient cells with different ganglioside profiles and different LDL receptor types. In our studies we therefore employed two cell types of well-known ganglioside composition expressing different types of LDL receptors as LDL recipients, namely mouse ascites hepatoma (MAH) cells having the high affinity receptor for native human LDL (18) and mouse resident peritoneal macrophages characterized by the presence of scavenger receptors. In the liver cholesterol, synthesis is under feedback control. In many hepatomas this control mechanism is impaired or lost (34); however, we found that in MAH cells, human native LDL inhibited cholesterol synthesis in a manner similar to liver cells (18).

To elucidate the role of cell-surface gangliosides in the interaction of these cells with LDL, we compared the binding of LDL to native MAH cells, neuraminidase-treated cells and neuraminidase-treated cells subsequently loaded with gangliosides. The results revealed that LDL binding correlated positively with the number of sialic acid residues on the cell surface, whereas preincubation of LDL with gangliosides inhibited LDL binding to MAH cells (18). Such behavior may be explained by assuming the existence on the LDL surface of binding sites recognizing accessible sialic acid residues. Upon incubation with exogenously added gangliosides, these sites are blocked. Conversely, during preincubation of neuraminidase-treated cells with gangliosides, part of the latter insert their lipophilic ceramide moieties into the outer leaf of the plasma membrane thus increasing the number of LDL binding sites on the cell surface. As shown in Figure 3, neuraminidase treatment of the cells abolished the inhibitory effect of LDL on cholesterol biosynthesis, and this effect could be restored by ganglioside loading of the neuraminidase-treated cells (18). Taking into account that MAH cells still retain many features of normal hepatocytes, it seems probable that exogenous gangliosides could affect binding of LDL to the liver in a similar way, thus modulating the main pathway of LDL removal from the bloodstream.

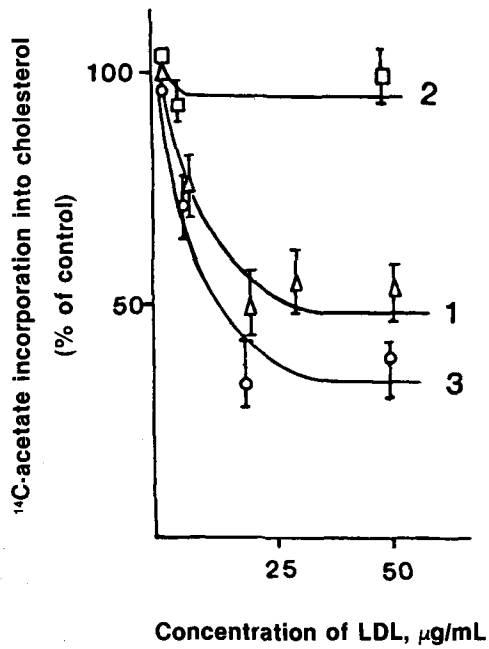

FIG. 3. Effect of low density lipoprotein (LDL) and gangliosides on cholesterol biosynthesis in mouse ascites hepatoma cells (Ref. 18). 1, Native cells; 2, neuraminidase-treated cells; and 3, neuraminidase-treated cells subsequently loaded with GDIa.

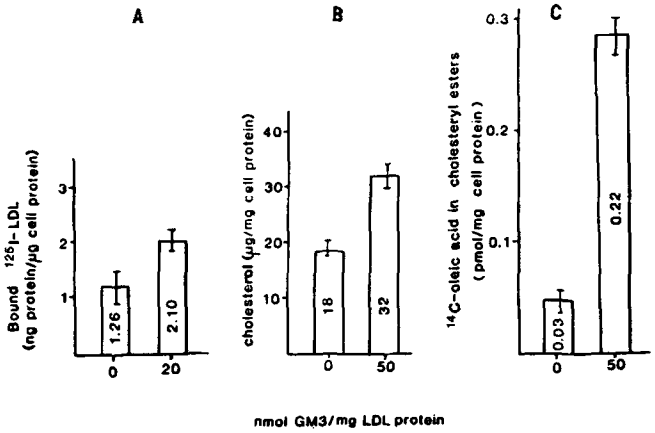

FIG. 4. Effect of gangliosides on the interaction of low density lipoproteins (LDL) with mouse peritoneal macrophages (Ref. 35). A, [^{125}I]LDL uptake (ng LDL protein/μg cell protein); B, cholesterol accumulation (ng cholesterol/μg cell protein); C, cholesteryl ester biosynthesis (pmol of [^{14}C]oleate/mg cell protein); 10^6 cells were incubated with 100 μg LDL protein or LDL preincubated wth 5 nmol of ganglioside GM3.

As mentioned above, monocytes/macrophages are another cell type playing a key role in the pathogenesis of atherosclerosis. One of the earliest events in atherogenesis is the migration of monocytes from blood into the arterial wall where they differentiate into macrophages and accumulate high amounts of cholesteryl esters and other lipids. These lipid-loaded cells are called foam cells. The lipid that accumulates in foam cells is believed to be derived from LDL, in spite of the fact that native LDL are poorly recognized by macrophages *in vitro* and that even high amounts of native LDL, when incubated with macrophages, do not induce accumulation of much cholesteryl ester within the cells (29). It has been shown, however, that several *in vitro* modifications of LDL can transform them into particles which are rapidly taken up by macrophages *via* the scavenger receptor and can cause them to accumulate cholesterol and to transform into foam cells (reviewed in Ref. 28). It is therefore believed that some type of LDL modification that transforms LDL into a form recognized by the scavenger receptor on macrophages occurs *in vivo* in the arterial intima. One possibility is LDL peroxidation induced by monocytes and endothelial cells; however, the exact nature of the *in vivo* LDL modification is as yet unknown. As a possible candidate we suggest the changes in LDL structure brought about by interaction of the lipoprotein with gangliosides. As shown in Figure 4, addition of small amounts of ganglioside markedly increased the uptake of LDL by mouse peritoneal macrophages (35). For still unknown reasons, with native LDL, the uptake by macrophages was relatively intense; nevertheless pretreatment of the LDL with GM3 resulted in a twofold increase in LDL uptake and accumulation of cholesterol (Figs. 4a and b). Moreover, the stimulating effect of GM3-treated LDL on the synthesis of cholesteryl esters in macrophages was at least seven times higher than in the presence of native LDL (Fig. 4c, Ref. 35). A similar enhancement was seen in regard to the accumulation of triglycerides (not shown). These data indicate that in ganglioside-rich, damaged regions of the aorta, LDL ganglioside complexes may be formed, which aggregate and are taken up by phagocytes residing within the lesions, eventually giving rise to foam cells.

The exact nature of the ganglioside-induced modifications of LDL that allows scavenger receptor binding remains unknown. One possibility is neutralization of the lysine ε-aminogroups of apoB by the negatively charged gangliosides. Similar charge neutralizations have been suggested to be the result of various chemical modifications converting native LDL into species recognized by the scavenger receptor (29,36-38). Charge neutralization may also be the reason for the enhancement of LDL aggregation induced by gangliosides (19). However, it was recently demonstrated that LDL uptake by macrophages requires neither charge neutralization nor aggregation (39). Thus, the understanding of the ganglioside-induced changes ultimately responsible for LDL uptake by macrophages will require additional studies, particularly of the competition between ganglioside-modified LDL and other modified forms of the lipoprotein.

Taken together, the evidence for involvement of gangliosides in atherogenesis still remains fragmentary. However, the coincidence of many facts, such as the relatively high ganglioside level in sera of atherosclerotic patients and in atherosclerotic aortas, the ability of intimal gangliosides to induce platelet adhesion, spreading and aggregation, the effects of gangliosides on receptor-mediated LDL-cell interactions, the modification of LDL by gangliosides and the ability of macrophages to recognize ganglioside-modified LDL, undoubtedly deserves further investigation.

Regulation of Rat Liver Microsomal Cholesterol Ester Hydrolase by Reversible Phosphorylation

María J. Martínez, María L. Hernández, Mercedes Lacort and **Begoña Ochoa***
Department of Physiology, University of the Basque Country Medical School, 48080 Bilbao, Spain

The regulation of neutral cholesterol ester hydrolase activity by changes in its phosphorylation state was studied in rat liver microsomes. Treatment with cAMP-dependent protein kinase resulted in increased enzyme activity, which was further enhanced by the addition of cAMP and MgATP. Consistent activations were also achieved with $MgCl_2$ and MgATP, the magnesium effect being abolished by ethylenediaminetetraacetic acid and adenosine triphosphate. Cholesterol ester hydrolase was activated twofold by free calcium and Ca^{2+}/calmodulin; this latter effect was blocked by the chelator ethyleneglycol-*bis*(β-aminoethyl ether)*N,N,N',N'*-tetraacetic acid and the calmodulin antagonist trifluoperazine. The phosphatase inhibitors pyrophosphate and glycerophosphate led to marked and dose-dependent increases in esterase activity, whereas okadaic acid elicited no effect. Furthermore, pyrophosphate and okadaic acid did not change the increases in enzyme activity promoted by Ca^{2+}, Ca^{2+}/calmodulin, Mg^{2+} and MgATP. Cholesterol ester hydrolase was inactivated in a concentration-dependent manner by nonspecific alkaline phosphatases. In cAMP-dependent protein kinase/cAMP- or Ca^{2+}/calmodulin-activated microsomes, a time-dependent loss of activation in cholesteryl oleate hydrolysis was caused by alkaline phosphatase. These findings suggest that microsomal cholesterol ester hydrolase is activated through cAMP and Ca^{2+}/calmodulin phosphorylation, whereas enzyme deactivation is dependent on phosphatase action.
***Lipids* 29, 7–13 (1994).**

Free and esterified cholesterol in liver are subject to constant turnover. Acyl-CoA:cholesterol acyltransferase (ACAT) esterifies excess intracellular cholesterol with long chain fatty acids (1), and the resulting cholesteryl esters are utilized for bile and lipoprotein synthesis or stored in cytosolic lipid droplets and in the membranes of the endoplasmic reticulum (2). Mobilization of these esters, when required, is brought about by the catalytic action of the neutral cholesterol ester hydrolases (CEH) located in the cytosol and in microsomes (3,4). Soluble cholesterol esterase has been purified and rather well characterized (5,6); however, few studies have been reported on the regulation and function of the microsomal enzyme. Rat liver neutral microsomal CEH has been partially solubilized (7), and 75% of its activity was found on the luminal side of the rough endoplasmic reticulum (8). The enzyme displays a circadian rhythm unrelated to the feeding status (9). Contradictory reports have appeared with respect to the existence of compensatory changes in microsomal CEH activity in rat (10) and hamster (11) in response to altered cholesterol flux to the liver. The activity of neutral microsomal CEH was found to be different from that of hormone-sensitive lipase (12), neutral retinyl ester hydrolase and acid CEH, also located in microsomes (13). It is thought that microsomal CEH may be involved in controlling the partitioning of cholesteryl esters toward the bile canaliculi or the blood stream and in maintaining the balance between free and esterified cholesterol in endoplasmic reticulum. Moreover, CEH may hydrolyze esterified cholesterol stored in the cytosol (14), although the cytosolic CEH is believed to be mainly responsible for this process (15,16).

Reversible phosphorylation is one of the most remarkable mechanisms involved in the complex regulation of cholesterol metabolism. The regulatory role of reversible phosphorylation is fairly well documented for 3-hydroxy-3-methylglutaryl CoA (HMG-CoA) reductase (17–19), whereas controversial results have been reported for cholesterol 7α-hydroxylase (20–23) and ACAT (24–27). Many studies have demonstrated that cytosolic CEH can be activated by cAMP-dependent phosphorylation in steroidogenic and other nonhepatic tissues (28–33). Whether liver-soluble CEH is regulated by covalent modification remains unresolved. Evidence for activation of cytosolic CEH by cAMP- and Ca^{2+}-mediated phosphorylation has been presented in rat liver (34), while evidence suggesting inactivation by phosphorylation was presented in hepatocyte suspensions (35,36).

To our knowledge, it is not known what effect, if any, cellular protein kinases and phosphoprotein phosphatases have on the liver microsomal CEH reaction. The present study is the first attempt to address this question. A cell-free system and several agents that are widely used to promote either protein phosphorylation or dephosphorylation have been utilized. The results presented here offer considerable evidence (although indirect) that neutral microsomal CEH may be activated through cAMP- and Ca^{2+}/calmodulin (CaM)-mediated mechanisms, whereas enzyme inhibition is dependent on phosphatase action.

MATERIALS AND METHODS

Chemicals. Cholesteryl [1-^{14}C]oleate (52 mCi/mmol) and [1-^{14}C]oleic acid (57.4 mCi/mmol) were purchased from the Radiochemical Centre (Amersham, United Kingdom). Bovine serum albumin (essentially fatty acid free), cholesteryl oleate, sodium taurocholate, adenosine triphosphate (ATP), cAMP, okadaic acid, trifluoperazine, calmodulin, ethylenediaminetetraacetic acid (EDTA), ethyleneglycol-*bis*(β-aminoethyl ether)*N,N,N'N'*-tetraacetic acid (EGTA), pyrophosphate, glycerophosphate, cAMP-dependent protein kinase (Type I), and bovine kidney (Type XXXI), chicken intestine (Type V) and *Escherichia coli* (Type III) alkaline phosphatases were from Sigma Chemical Co. (St. Louis, MO). One unit of calmodulin will stimulate 0.016 activated units of phosphodiesterase,

Abbreviations: ACAT, acyl-CoA:cholesterol acyltransferase; ATP, adenosine triphosphate; CaM, calmodulin; CEH, cholesterol ester hydrolase; EDTA, ethylenediaminetetraacetic acid; EGTA, ethyleneglycol-*bis*(β-aminoethyl ether)*N,N,N',N'*-tetraacetic acid; HMG-CoA, 3-hydroxy-3-methylglutaryl CoA.

3′:5′-cyclic nucleotide, to 50% of the maximum activity of the enzyme when saturated with activator, in the presence of 0.01 mM Ca^{2+}, pH 7.5, at 30°C. One unit of alkaline phosphatase is defined as the amount that hydrolyzes 1 μmol of *p*-nitrophenyl phosphate per minute in a 0.1 M glycine buffer, pH 10.4, containing 1 mM $ZnCl_2$ and 1 mM $MgCl_2$, at 37°C. Egg yolk lecithin was from Lipid Products (Nutfield, United Kingdom). All other chemicals were reagent grade.

Preparation of rat liver microsomes. Female Sprague-Dawley rats (180–200 g) were kept at alternating 12-h light/dark periods (lights on from 0700 to 1900) and used at 0900. Rats were given free access to drinking water and a pelleted rat chow low in fat (A04 Panlab; Panlab, Barcelona, Spain). Animals were anesthetized by exposure to diethyl ether vapors and killed by exsanguination. The livers were immediately removed, rinsed in ice-cold saline solution, blotted dry, weighed and homogenized in 4 vol of 20 mM Tris-HCl buffer, pH 7.4, containing 200 mM sucrose, 10 mM EDTA and 50 mM NaF. Microsomal membranes were prepared by differential centrifugation (1,000 × *g*, 15 min; 22,000 × *g*, 20 min; 105,000 × *g*, 60 min), washed once with the homogenization buffer and resuspended in 1 vol of 20 mM Tris-HCl buffer, pH 7.4, containing 250 mM sucrose. The entire fractionation was done at 4°C. Microsomes were stored at −20°C under nitrogen. CEH activity remained essentially unchanged at this temperature for at least seven days.

Assay of CEH activity. Substrate was prepared as mixed micelles of cholesteryl oleate, lecithin and sodium taurocholate in a 1:4:2 molar proportion basically as described by Hajjar *et al.* (37). In pilot experiments, assay conditions for CEH activity were optimized for time, protein amount and substrate concentration. The enzyme activity was linear up to 75 min of incubation and from 0.1 to 1 mg protein, and showed typical Michaelis-Menten kinetics with an apparent Km of around 90 μM. The assay mixture typically contained, in a total volume of 0.4 mL, 40 nmol cholesteryl oleate (6.25 mCi/mmol), 0.4 mg microsomal protein and 100 mM imidazole-HCl buffer, pH 6.8. The mixture was preincubated at 37°C for the time and with the agents as indicated in the legends to the figures (shown later) prior to the addition of micellar substrate to initiate the reaction. The incubation was run for 45 min and was stopped by the addition of 5 mL chloroform/methanol/*n*-heptane (1.25:1.4:1, by vol) containing unlabeled cholesteryl oleate as carrier and 1 mL of 50 mM sodium carbonate/50 mM sodium borate buffer, pH 11. The labeled free fatty acids released were measured by liquid scintillation counting in aliquots of the upper phase. The partitioning of free fatty acids was monitored by the addition of known amounts of [1-^{14}C]oleic acid to blank assays with routine recovery of 85%. CEH activity was expressed as Units/mg protein, one Unit corresponding to the hydrolysis of one pmol cholesteryl oleate per minute at 37°C.

Chemical and statistical analysis. Protein was determined as described by Bradford (38), using bovine serum albumin as standard. The unpaired Student's *t*-test was used to determine significance.

RESULTS

Activation of neutral microsomal CEH by phosphorylating agents. To induce CEH phosphorylation, microsomes were treated with commercial cAMP-dependent protein kinase or with compounds which selectively activate the various protein kinases associated with the microsomal preparation. As seen in Table 1, cAMP-dependent protein kinase produced a marked increase in CEH activity, which was further enhanced by cAMP and MgATP. This stimulation was slightly reduced in the presence of uncomplexed ATP (Table 1), whereas ATP alone (0.5–5 mM) had no effect on CEH activity (data not shown). Treatment of microsomes with $MgCl_2$ or MgATP also resulted in concentration-dependent activation (Fig. 1).

TABLE 1

Effect of cAMP-Dependent Protein Kinase (PK), cAMP, Adenosine Triphosphate (ATP) and MgATP on Neutral Microsomal Cholesterol Ester Hydrolase (CEH) Activity[a]

Additions	CEH (relative activity, %)
None	100 ± 3
PK, 50 μg	124 ± 3[b]
PK, 100 μg	137 ± 5[b]
PK, 100 μg + cAMP, 100 μM	158 ± 3[b]
PK, 100 μg + cAMP, 1 mM	196 ± 18[b]
PK, 100 μg + cAMP, 100 μM + MgATP, 2 mM	179 ± 6[b]
PK, 100 μg + cAMP, 100 μM + ATP, 2 mM	126 ± 5[b]

[a]Microsomes were preincubated for 10 min in the presence of the specified compounds before assaying CEH activity, as described in the Materials and Methods section. The absolute value of 100% activity was 39.2 ± 1.2 Units/mg protein. The values are the mean ± SE of three experiments done in duplicate.
[b]$P \leq 0.005$ *vs.* incubations without additions.

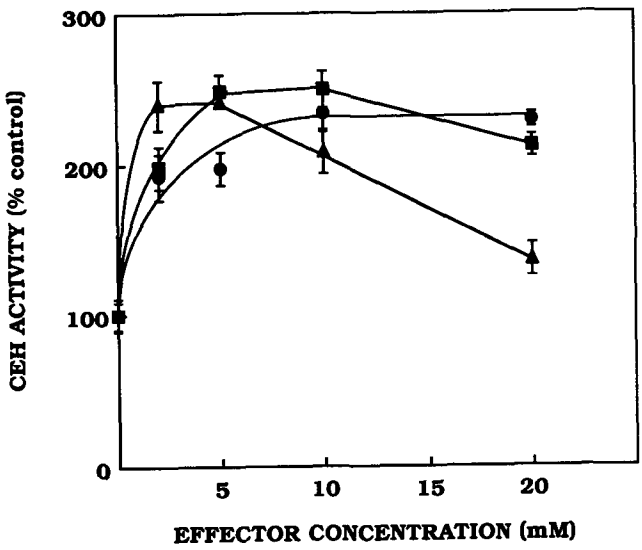

FIG. 1. Activation of neutral microsomal cholesterol ester hydrolase (CEH) by $MgCl_2$ and MgATP. Microsomes were preincubated for 20 min in the presence of $MgCl_2$ (●) or MgATP (■) (1:1, molar ratio) before starting the reaction as described in the Materials and Methods section. In (▲), 5 mg microsomal protein was preincubated for 60 min with $MgCl_2$, then microsomes were re-isolated (105,000 × *g* for 60 min) and assayed for CEH activity. The absolute value of 100% activity was 49.7 ± 3.9 Units/mg protein in microsomes without re-isolation, and 31.7 ± 1.6 in re-isolated microsomes. Each value represents the mean ± SE of three experiments done in duplicate. Vertical bars not shown lie within symbols.

The Mg^{2+} activation was not dependent on the presence of the cation in the enzyme assay mixture, inasmuch as activation of CEH in microsomes re-isolated after preincubation with $MgCl_2$ for 60 min was similar to that observed when the cation was not removed (Fig. 1). An altered sedimentation of the membranes induced by the above physiological salt concentration (39) could account for the decrease in activity found with 20 mM $MgCl_2$. In microsomes re-isolated after activation with $MgCl_2$ (control, 31.7 ± 1.6; 5 mM $MgCl_2$-treated, 72.9 ± 3.8 Units/mg protein), CEH was also enhanced by the addition of 100 μg cAMP-dependent protein kinase and 100 μM cAMP (up to 89.5 ± 6.2 Units/mg protein). These data strongly suggest that $MgCl_2$ promotes a persistent modification of the enzyme, which is reflected in a positive change in activity and which is independent of the cAMP signal transduction system.

The effects of $CaCl_2$ and the Ca^{2+}-binding protein CaM on microsomal CEH activity were studied next. As seen in Table 2, $CaCl_2$ increased CEH activity in a concentration-dependent manner. An even greater enhancement of activity was achieved by addition of CaM, whereas CaM in the absence of exogenous calcium had no effect. The Ca^{2+}/CaM-induced activation was completely blocked by EGTA and by the CaM antagonist trifluoperazine (Fig. 2). The latter compound by itself produced a notable decrease of activity in untreated microsomes. It is evident that both Ca^{2+} and CaM are necessary for maximal enzyme activation and that calcium may also activate CEH activity directly. Stimulation of CEH by the metal ions Mg^{2+} and Ca^{2+} was reversed by ATP and selectively inhibited by the chelators EDTA and EGTA (Table 3). The Ca^{2+} activation of CEH was specifically blocked by EGTA, whereas the Mg^{2+}- and the MgATP-enhanced CEH activity was markedly decreased by EDTA. Mg^{2+} and Ca^{2+}/CaM together produced a greater stimulatory effect than either agent did individually (Table 3). The Mg^{2+} effect seems to dominate, as EGTA did not suppress activation but EDTA did.

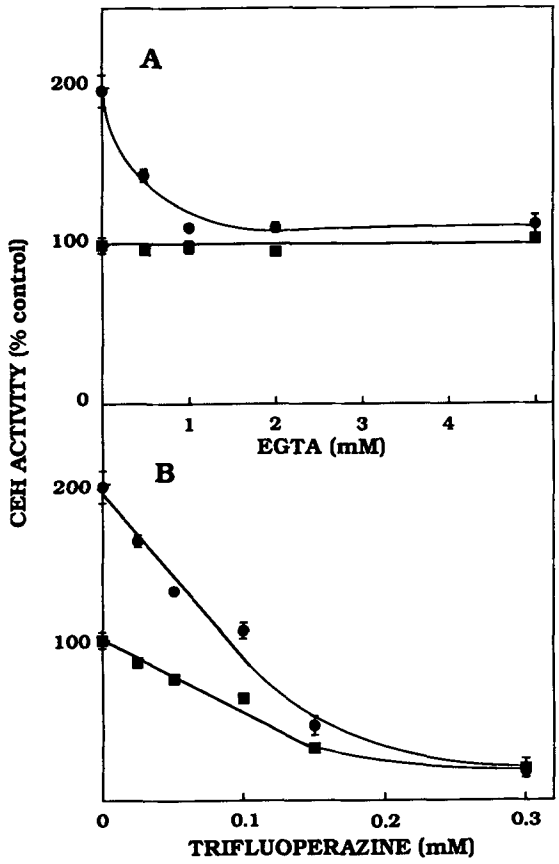

FIG. 2. Effects of ethyleneglycol-*bis*(β-aminoethyl ether)*N,N,N',N'*-tetraacetic acid (EGTA) and trifluoperazine on the Ca^{2+}/calmodulin-induced stimulation of neutral microsomal cholesterol ester hydrolase (CEH) activity. Microsomes were preincubated for 5 min without (■) or with 1 mM $CaCl_2$/10 Units CaM(●), and increasing concentrations of EGTA (A) or trifluoperazine (B) were added before starting the enzyme reaction. The absolute value of 100% activity was 47.3 ± 2.6 Units/mg protein. Each value represents the mean ± SE of triplicate determinations from a representative experiment of a total of three performed. Vertical bars not shown lie within symbols.

TABLE 2

Effect of Ca^{2+} and Ca^{2+}/Calmodulin on Neutral Microsomal CEH Activity[a]

Additions	CEH (relative activity, %)
None	100 ± 3
$CaCl_2$, 1 mM	137 ± 2[b]
$CaCl_2$, 2 mM	153 ± 8[b]
$CaCl_2$, 5 mM	165 ± 6[b]
Calmodulin, 10 Units	114 ± 9
Calmodulin, 100 Units	102 ± 6

$CaCl_2$, 2 mM + Calmodulin, 100 Units	234 ± 9[b]
$CaCl_2$, 2 mM + Calmodulin, 200 Units	258 ± 8[b]

[a]Microsomes were preincubated for 10 min in the presence of the specified compounds before assaying cholesterol ester hydrolase (CEH) activity, as described in the Materials and Methods section. The absolute value of 100% activity was 48.5 ± 1.8 Units/mg protein. The values are the mean ± SE of three experiments done in duplicate.

[b]$P \leq 0.005$ *vs.* incubations without additions.

To determine whether the activating effect of Mg^{2+}, MgATP, Ca^{2+} and Ca^{2+}/CaM might depend on an endogenous phosphatase-related dephosphorylation, CEH activity was measured in the presence of the nonspecific phosphatase inhibitor pyrophosphate or of the types 1 and 2A phosphatase inhibitor okadaic acid (40,41), in microsomes treated with Mg^{2+}, MgATP, Ca^{2+} or Ca^{2+}/CaM (Table 4). Two significant results were obtained. First, pyrophosphate increased neutral CEH activity in control microsomes about 40%. Second, Mg^{2+}, MgATP, Ca^{2+} and Ca^{2+}/CaM activated CEH in the presence of the phosphatase inhibitors.

Inactivation of neutral microsomal CEH by dephosphorylating agents. Treatment of microsomes with nonspecific alkaline phosphoprotein phosphatases from bovine kidney, chicken intestine and *E. coli* resulted in marked concentration-dependent decreases in activity, though the extent of inhibition varied (Fig. 3). Addition of five Units of phosphatase inhibited CEH activity by 50–100%, whereas maximum inhibition was produced by relatively low amounts of *E. coli* phosphatase. A correlation between enzyme activity and the inhibition of

TABLE 3

Effect of ATP, EDTA, EGTA on Neutral CEH Activity in Mg^{2+}-, MgATP-, Ca^{2+}- and Mg^{2+}/ca^{2+}/CaM-Treated Microsomes[a]

Additions	CEH activity (Units/mg protein)			
	Mg^{2+}-treated	MgATP-treated	Ca^{2+}-treated	Mg^{2+}/Ca^{2+}/CaM-treated
None	74.5 ± 3.0	87.3 ± 3.1	78.9 ± 2.9	109.7 ± 6.2
ATP, 2 mM	74.2 ± 3.8	—	66.6 ± 2.1[b]	—
ATP, 5 mM	65.6 ± 2.7[b]	—	52.9 ± 2.4[b]	—
ATP, 10 mM	53.9 ± 2.2[b]	—	46.7 ± 1.8[b]	—
EDTA, 5 mM	51.8 ± 4.5[b]	55.3 ± 1.1[b]	75.2 ± 3.7	63.8 ± 2.7[b]
EGTA, 2 mM	70.3 ± 1.8	91.6 ± 2.9	49.7 ± 2.3[b]	99.7 ± 4.8

[a]Microsomes were preincubated for 10 min with 2 mM $MgCl_2$ or 2 mM MgATP or 2 mM $CaCl_2$ or with 2 mM $MgCl_2$ plus 1 mM $CaCl_2$ and 10 Units of CaM. Then ATP, EDTA or EGTA was added before measuring CEH activity, as described in the Materials and Methods section. Enzyme activity in untreated microsomes was 48.1 ± 2.0 Units/mg protein. The values are the mean ± SE of three experiments done in duplicate. Abbreviations as in Table 1; EDTA, ethylenediaminetetraacetic acid; EGTA, ethyleneglycol-*bis*(β-aminoethyl ether)*N,N,N',N'*-tetraacetic acid; CaM, calmodulin.
[b]At least $P < 0.05$ *vs.* activity without additions.

endogenous phosphatases was demonstrated in microsomes treated with the phosphatase inhibitors pyrophosphate and glycerophosphate (Table 5). Concentration-dependent increases in CEH activity were observed with both compounds, although glycerophosphate was less effective than pyrophosphate. The stimulation by pyrophosphate persisted during the incubation, although the effect diminished with time (92, 86, 77 and 69% of increase at 15, 30, 45 and 60 min of incubation, respectively; data not shown). The pyrophosphate-induced activation was slightly enhanced by 5 mM ATP (10%) and 2 mM $MgCl_2$ (17%), and attenuated (34%) by 1 Unit of chicken intestine phosphatase (data not shown). NaF, the phosphatase inhibitor most widely employed, progressively inhibited cholesteryl oleate hydrolysis, even in the presence of the activators, cAMP-dependent protein kinase, Mg^{2+} or Ca^{2+}/CaM (data not shown). The inhibition was found to be reversible, inasmuch as dilution or removal of fluoride from the medium resulted in full recovery of CEH activity (data not shown). Thus, 50 mM NaF was added to the homogenization buffer to avoid spontaneous changes in CEH activity during microsome isolation, but it was excluded from the buffers used for resuspension and the enzyme assay.

These findings suggest a role for endogenous serine/threonine phosphatases in the inactivation of this CEH. Further support for this view is provided by the observation that treatment of microsomes with 1–100 μM orthovanadate, a tyrosine phosphatase inhibitor, did not modify CEH activity (data not shown).

Reversibility of the changes induced by phosphorylation of neutral microsomal CEH. The existence of an activation/deactivation cycle for CEH was investigated using cAMP-dependent protein kinase/cAMP or Ca^{2+}/CaM as activators, and the nonspecific alkaline phosphatase from chicken intestine as an inhibitor. As depicted in

TABLE 4

Effect of Pyrophosphate and Okadaic Acid on Neutral CEH Activity in Mg^{2+}-, MgATP-, Ca^{2+}- and Ca^{2+}/CaM-Treated Microsomes[a]

Microsomal treatment	CEH activity (Units/mg protein)		
	None	Pyrophosphate	Okadaic acid
None	50.0 ± 1.9	70.7 ± 1.1	52.6 ± 2.4
$MgCl_2$	88.5 ± 1.6	90.2 ± 3.4	81.4 ± 1.5
MgATP	81.1 ± 3.7	—	82.7 ± 3.8
$CaCl_2$	73.7 ± 2.4	92.3 ± 7.7	75.6 ± 1.7
$CaCl_2$/CaM	83.4 ± 5.8	87.5 ± 2.6	85.8 ± 1.1

[a]Microsomes were preincubated for 20 min with 2 mM $MgCl_2$, 2 mM MgATP, 1 mM $CaCl_2$ or 1 mM $CaCl_2$ and 10 Units CaM before adding 50 mM pyrophosphate or 1 μM okadaic acid and assaying CEH activity, as described in the Materials and Methods section. Okadaic acid was dissolved in 10% dimethyl sulfoxide (final volume 0.5% of total), and an equivalent amount of the solvent was added to control incubations. The values are the mean ± SE of three experiments done in duplicate. Abbreviations as in Table 3.

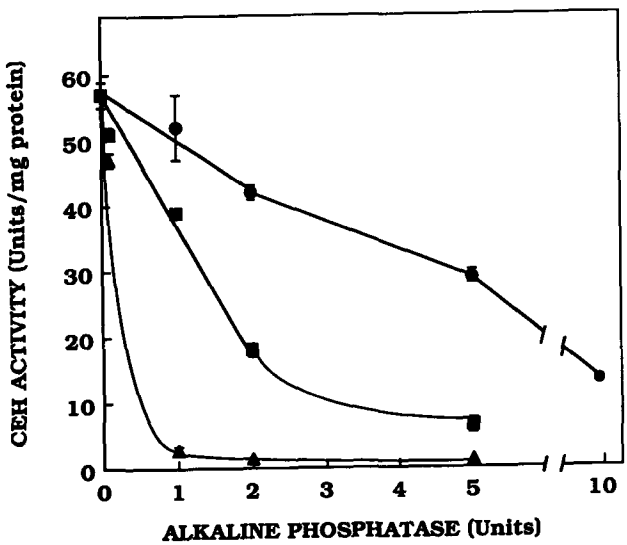

FIG. 3. Concentration-dependent inactivation of neutral microsomal cholesterol ester hydrolase (CEH) by alkaline phosphoprotein phosphatases. Microsomes were preincubated for 20 min with increasing amounts of *Escherichia coli* (▲), chicken intestine (■) and bovine kidney (●) alkaline phosphatases before assaying CEH activity as described in the Materials and Methods section. Each value represents the mean ± SE from three experiments done in duplicate. Vertical bars not shown lie within symbols.

TABLE 5

Effect of Pyrophosphate and Glycerophosphate on Neutral Microsomal CEH Activity[a]

Phosphatase inhibitor (mM)	CEH (relative activity, %)
Pyrophosphate	
5	122 ± 2[b]
10	144 ± 4[b]
20	163 ± 6[b]
50	202 ± 8[b]
Glycerophosphate	
5	106 ± 2
10	110 ± 3
20	133 ± 5[b]
50	172 ± 6[b]

[a]Microsomes were preincubated for 20 min with the specified amount of pyrophosphate or glycerophosphate before assaying cholesterol ester hydrolase (CEH) activity, as described in the Materials and Methods section. The absolute value of 100% activity was 44.8 ± 1.9 Units/mg protein. The values are the mean ± SE of triplicate determinations from a representative experiment of a total of three performed.
[b]At least $P \leq 0.05$ *vs.* activity without additions.

Figure 4, phosphatase counteracted the cAMP-dependent protein kinase/cAMP- and Ca^{2+}/CaM-promoted activations in a similar order of potency, reducing CEH activity almost to the control value after 60 min incubation. A similar experimental design was followed to ascertain whether treatment of deactivated esterase with Ca^{2+}/CaM or cAMP-dependent protein kinase/cAMP would reactivate the enzyme. The phosphatase-induced decrease in CEH activity was not modified by any of the treatments (Fig. 4), even when (at 15 min incubation) phosphatase was blocked by 10 mM pyrophosphate or when 2 mM MgATP was also added (data not shown). However, the addition of 100 μg cAMP-dependent protein kinase and 100 μM cAMP, together with 1 Unit phosphatase, to the microsomal suspension not only counteracted the decrease in CEH but raised its activity *ca.* 80% above the control value (control, 13.4 ± 0.2; phosphatase, 11.3 ± 0.8; phosphatase/cAMP-dependent protein kinase/cAMP, 24.0 ± 1.7 Units/mg protein).

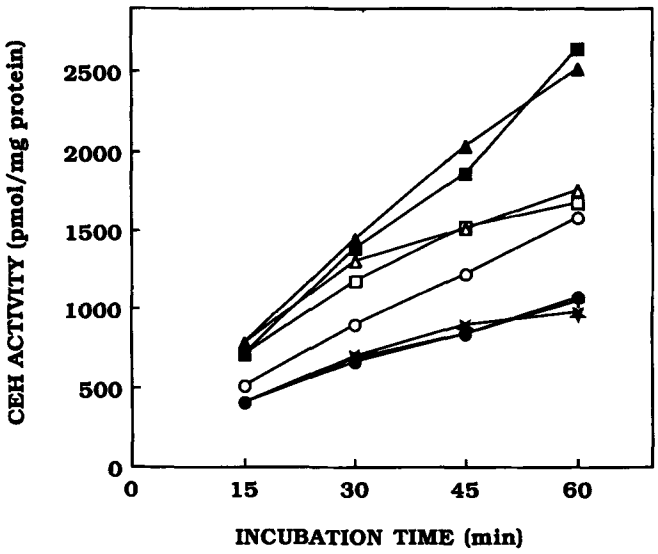

FIG. 4. Time-dependent activation/deactivation of neutral microsomal cholesterol ester hydrolase (CEH) activity. Microsomes were assayed for CEH activity as a function of time after the following treatments: a) none (○); b) 100 μg cAMP-dependent protein kinase/100 μg cAMP (▲); c) 1 mM $CaCl_2$/10 Units CaM (■); and d) 1 Unit chicken intestine phosphatase (●). After 15 min incubation, 1 Unit alkaline phosphatase was added to b (△) and c (□), and 100 μg cAMP-dependent protein kinase/100 μM cAMP (★) or 1 mM $CaCl_2$/10 Units CaM (⊕) were added to d. Points represent the mean values from three experiments.

DISCUSSION

Our results are the first reported evidence that rat liver microsomal CEH might belong to the group of enzymes controlled by reversible phosphorylation. In particular, we provide evidence that *in vitro* conditions favoring phosphorylation in microsomal preparations enhance the rate of cholesteryl oleate hydrolysis, whereas marked decreases in CEH are correlated with the presence of phosphatase activity.

Liver microsomes are known to contain several protein kinases, among them one dependent on cAMP and one dependent on Ca^{2+}/CaM, in addition to phosphoprotein phosphatases and substrates for both classes of enzymes (42). Our findings are consistent with the view that when a microsomal or exogenous cAMP-dependent protein kinase cascade is triggered, CEH activity is enhanced. The potential involvement of a Ca^{2+}/CaM-dependent protein phosphorylation in the activation of CEH is also suggested.

A significant aspect of this work is that the metal ions Mg^{2+} and Ca^{2+} induce consistent increases in CEH activity, which seem to be independent of protein kinases and differ in their response to chelators. Modification of the surface charge of the microsomal membranes by the cations might account for these effects. However, the effect of Ca^{2+} could also be mediated by endogenous CaM bound to the microsomal membranes. This view is supported by the finding that CEH activity in untreated microsomes was inhibited by the CaM antagonist trifluoperazine. These results are in apparent disagreement with those of Coleman and Haynes (43), who reported that rat liver microsomal CEH is not affected by Ca^{2+} and Mg^{2+}. Discrepancies could be due to the way in which the substrate was presented, namely as lipid dispersions in acetone and on the addition of phosphatidylcholine/phosphatidylserine (1:1, w/w) to the incubation medium. The latter addition could alter the interaction between enzyme and cholesteryl oleate which, in turn, may mask further effects of the cations.

Inhibition of CEH by commercial nonspecific phosphatases suggests that microsomal cholesterol esterase is deactivated under conditions at which other proteins are dephosphorylated. An unexpected finding was that the low CEH activity displayed by phosphatase-treated microsomes could not be restored by either cAMP-dependent protein kinase or Ca^{2+}/CaM, whereas the inactivation was prevented when the activators and phosphatase were added to microsomes simultaneously. This suggests that some minimal phosphorylation of the enzyme might be required for activation or, alternatively, that dephosphorylation destabilizes or irreversibly inactivates the enzyme.

If CEH were, indeed, regulated by a reversible phosphorylation mechanism *in vivo*, as suggested by these studies, then endogenous phosphatases should inhibit CEH activity. In fact, CEH was activated and its deactivation prevented by the nonspecific serine/threonine phosphatase inhibitors, pyrophosphate and glycerophosphate. This is the first evidence for involvement of endogenous phosphatases in microsomal CEH inactivation. Serine/threonine phosphatases are classified by their Mg^{2+}, Ca^{2+} and Mn^{2+} dependence and their sensitivity to various inhibitors (40,41). Type 1, 2A, 2B and 2C phosphatases, which account for virtually all detectable phosphatase activities in liver extracts, are directed toward many phosphoproteins, including those controlling cholesterol and fatty acid synthesis (40,41,44-46). Type 1 is the major phosphatase associated with liver endoplasmic reticulum (70%) and glycogen (30%) (40,47). Okadaic acid is particularly useful for distinguishing phosphatases, as it has an especially high affinity for the catalytic subunits of type 1 and 2A phosphatases (41,48). Because the endogenous inhibitor acting on CEH is insensitive to okadaic acid, it is not likely to be a type 1 or 2A phosphatase. Nevertheless, proof of this hypothesis will require systematic studies with purified phosphatases.

Our experiments confirm and extend the idea that a single short-term regulatory mechanism, protein phosphorylation, operates on intracellular cholesterol homeostasis through different mediators. Stimuli shifting phosphorylation through the cAMP or the Ca^{2+}/CaM protein kinase cascade would enhance cholesteryl ester mobilization to supply cholesterol and fatty acids, the former being used for bile acid synthesis (20-23). In contrast, the availability of substrates for cholesteryl ester synthesis is reduced by the AMP-activated protein kinase, which inactivates HMG-CoA reductase and acetyl-CoA carboxylase and antagonizes the activation of the hormone-sensitive lipase by cAMP-dependent protein kinase (49,50). Whether liver ACAT is regulated by protein phosphorylation remains to be determined (24-27). Inasmuch as the present scheme for a coordinated regulation of cholesterol metabolism envisions the liver as a major site of cholesteryl ester hydrolysis in the rat, the *in vivo* role of microsomal CEH calls for further study. Regulation of neutral microsomal CEH by protein phosphorylation cannot be confirmed without examination at the cellular and molecular level. Purification of the enzyme and studies of phosphorylation in isolated rat liver cells are the subject of ongoing investigations.

Biphasic Modulation of Choline Uptake and Phosphatidylcholine Biosynthesis by Vasopressin in Rat Cardiac Myocytes

Adrian S. Man, Edmund Lee and **Patrick C. Choy***
Department of Biochemistry and Molecular Biology, Faculty of Medicine, University of Manitoba, Winnipeg, Manitoba, R3E 0W3 Canada

The effect of vasopressin on choline uptake and phosphatidylcholine biosynthesis in isolated rat heart myocytes was investigated. Myocytes were incubated with labelled choline in the presence of 0.05–1.0 μM vasopressin. Uptake of choline was enhanced (25%) by a low concentration (0.2 μM) of vasopressin, but was attenuated (19%) by a higher vasopressin concentration (1.0 μM). The biosynthesis of phosphatidylcholine was also affected by vasopressin in a biphasic manner. At low concentrations of vasopressin, a general increase in cytosine triphosphate:phosphocholine cytidylyltranferase activity was observed that caused an enhanced conversion of phosphocholine to phosphatidylcholine *via* the cytidine diphosphocholine pathway. At high vasopressin concentrations, a decrease in the activity of cytidylyltransferase was detected, which was caused by the translocation of the enzyme from the microsomal fraction to the cytosolic fraction. The decrease in enzyme activity coincides with a reduction in the conversion of labelled phosphocholine to phosphatidylcholine. In view of the fact that phospholipid biosynthesis in rat hepatocytes is inhibited by vasopressin at all concentrations, the biphasic modulation of phosphatidylcholine biosynthesis in rat heart myocytes illustrates the diverse effects of this hormone in different mammalian tissues.
Lipids 29, 15–19 (1994).

Phosphatidylcholine is the principal phospholipid in mammalian tissues (1). In mammalian hearts, the vast majority of phosphatidylcholine is synthesized *via* the cytidine diphosphocholine (CDPcholine) pathway (2,3). In this pathway, choline taken up by the heart is rapidly phosphorylated into phosphocholine by the action of choline kinase. Phosphocholine is then converted into CDPcholine by the action of cytosine triphosphate (CTP):phosphocholine cytidylyltransferase. The CDPcholine is condensed with diacylglycerol by the action of CDPcholine:diacylglycerol cholinephosphotransferase to form phosphatidylcholine. Although the first committed step in this pathway is catalyzed by choline kinase, the rate-limiting step is catalyzed by the cytidylyltransferase (4). The latter enzyme is located in both microsomal and cytosolic fractions, and translocation of the enzyme from one compartment to another is regarded as an important mechanism for the *in vivo* regulation of enzyme activity (5).

The effects of hormones on phosphatidylcholine biosynthesis have been investigated in mammalian tissues. Steroids, including diethylstilbestrol and glucocorticoids, have been found to stimulate phosphatidylcholine biosynthesis in the rooster and fetal lung (6–8). Alternatively, norepinephrine and vasopressin have been shown to inhibit phosphatidylcholine biosynthesis (9–11). The inhibitory effect of vasopressin in hepatocytes is mediated *via* the modulation of the CTP:phosphocholine cytidylyltransferase activity without affecting the uptake or phosphorylation of choline (9). In another study, high levels of vasopressin appear to inhibit the CDPcholine:1,2-diacylglycerol cholinephosphotransferase activity through increased levels of intracellular calcium (10). Vasopressin has also been shown to exhibit biphasic effects in the perfused heart with respect to changes in peak ventricular pressure (12). However, the effect of vasopressin on phosphatidylcholine biosynthesis in cardiac cells has not been reported.

In this study, the effects of vasopressin on choline uptake and phosphatidylcholine biosynthesis in cardiac myocytes were investigated. Our results show that both choline uptake and phosphatidylcholine biosynthesis in myocytes were enhanced at low vasopressin concentrations, but that the biosynthesis of phosphatidylcholine is attenuated at high vasopressin concentrations.

MATERIALS AND METHODS

Materials. Phospho[*methyl*-^{14}C]choline, CDP[*methyl*-^{14}C]-choline, [*tyrosyl*-^{3}H]arginine and vasopressin were obtained from Amersham Canada Ltd. (Oakville, Ontario, Canada). The [*methyl*-^{3}H]choline was purchased from New England Nuclear Division of Dupont (Mississauga, Ontario, Canada). Oxytocin and [arginine]vasopressin were products of Boehringer Mannheim Canada Ltd. (Laval, Quebec, Canada). Minimal essential medium (Joklik-modified), Medium 199, Dulbecco's phosphate buffered saline, phosphocholine, choline, cytidine 5′-diphosphocholine, *tris*-base, CTP, adenosine triphosphate, hyaluronidase and ethylenediaminetetraacetic acid (EDTA) were obtained from Sigma Chemical Co. (St. Louis, MO). Phosphatidylcholine (pig liver) and 1,2-diacylglycerol (pig liver) were purchased from Serdary Research Laboratory (London, Ontario, Canada). Magnesium acetate and magnesium chloride were products of Fisher Scientific Co. (Fair Lawn, NJ). Sephadex G-15 (fine) gel filtration media was purchased from Pharmacia Fine Chemicals (Uppsala, Sweden). Collagenase (Class 2) was obtained from Worthington Biochemical Corporation (Freehold, NJ). All other chemicals were of analytical grade and obtained locally from the Canlab Division of Baxter Co. (Edmonton, Alberta, Canada) Sprague Dawley rats of either sex, 250 ± 50 g, were obtained from Charles River Canada, Inc. (St. Constante, Quebec, Canada).

Isolation of rat cardiac myocytes. Myocardial cells were obtained from hearts of Sprague Dawley rats. Rats were maintained on Agway rodent chow and tap water *ad libitum*. Myocytes were isolated by the procedure of Langer *et al.* (13). Briefly, the heart was perfused in

Langendorff mode with buffer A for 5–10 min followed by perfusion with buffer B for another 15–20 min. Following perfusion, the digested tissue was placed in buffer A and the cells were dislodged from the tissue by gentle agitation. Myocytes were suspended with buffer A in a culture tube and separated by sedimentation and removal of supernatant containing other cardiac cells. The myocyte preparation, which was relatively free of other cardiac cells, was resuspended in a small volume of buffer A, and two volumes of the growth medium (containing 1.8 mM calcium) were slowly added to the myocyte suspension over a period of 45 min. Finally, myocytes were placed in the growth buffer, incubated in a petri dish for 60 min in order to allow attachment and used immediately after incubation. All incubations were carried out at 37°C and all the buffers used were saturated with 95% oxygen/5% carbon dioxide. Buffer A contained 11 g/L minimum essential medium-Jokliks/(MEM-Jokliks) buffer preparation, 60.0 mM taurine, 2.0 mM DL-carnitine, 1.0 mM adenosine, 3.4 mM magnesium chloride, 50.0 mM sodium bicarbonate, 15.0 mM glucose, 0.1 mM octanoic acid, 8.0 mM L-glutamate, 0.1 g/L penicillin and 0.1 g/L streptomycin. Buffer B contained 4 mg/mL collagenase (class 2), 2 mg/mL hyaluronidase and 0.1 mM calcium chloride dissolved in buffer A. The growth medium contained 9.8 g/L of Medium 199, 2.0 mM L-glutamine, 2.2 g/L sodium bicarbonate, 0.1 g/L penicillin and 0.1 g/L streptomycin. The viability of the myocytes was tested by trypan blue exclusion and contractile activity. Over 90% of the cells isolated were viable and in rod shape throughout the experiment.

The determination of choline uptake and analysis of choline-containing metabolites. Myocytes were used immediately after attachment to the petri dish. Each dish (containing 200–300 μg protein) was incubated with 2 mL of growth medium containing 10 μM labelled choline (0.15 mCi/μmol) for the prescribed time period. The medium containing labelled choline was removed, and the cells were washed twice with 2 mL of Dulbecco's phosphate buffered saline followed by the addition of 1 mL methanol. The cell suspension was transferred to a glass test tube, and an equal volume of chloroform was added. An aliquot of the mixture was taken for the determination of total choline uptake. Lipid extraction of the myocytes was performed by the method of Folch *et al.* (14). Subsequent to phase separation, the phosphatidylcholine fraction in the lower phase was isolated by thin-layer chromatography on silica G-25 plates with a solvent containing chloroform/methanol/water/acetic acid (70:30:4:2, by vol). Choline-containing metabolites in the upper phase were separated by thin-layer chromatography with a solvent system containing methanol/0.6% sodium chloride/57% ammonium hydroxide (50:50:5, by vol). The locations of the radioactive fractions on the thin-layer chromatographic plate were detected by a Bioscan System 200 Imaging Scanner.

The determination of enzyme activities. Choline kinase activity was assayed by determining the conversion of [*methyl*-^{3}H]choline to phosphocholine (15). CTP:phosphocholine cytidylyltransferase activity was assayed by the conversion of phospho[*methyl*-^{14}C]choline to CDPcholine (16). The reaction mixture contained 100 mM Tris-succinate (pH 7.5), 12 mM magnesium acetate, 2.5 mM CTP, 1.0 mM phospho[*methyl*-^{14}C]choline and enzyme preparation to a final volume of 100 μL. A total cardiac phospholipid extract (containing 0.1 μM lipid phosphorus) was added to the assay mixture when the cytosolic fraction was used. The reaction was carried out at 37° for 20 min and stopped by boiling. The labelled CDPcholine was separated from labelled substrate by thin-layer chromatography with a solvent system containing methanol/0.6% aqueous sodium chloride/57% ammonium hydroxide (50:50:5, by vol). CDPcholine:1,2-diacylglycerol cholinephosphotransferase activity was determined by the conversion of CDP[*methyl*-^{14}C]choline to phosphatidylcholine (17). The reaction mixture contained 100 mM Tris-HCl (pH 8.5), 10 mM magnesium chloride, 1 mM EDTA, 0.4 mM CDP[*methyl*-^{14}C]choline, 1.0 mM diacylglycerol (prepared in 0.015% Tween 20 by sonication) and enzyme preparation to a final volume of 1.0 mL. The reaction was carried out at 37° for 20 min and terminated by the addition of 3 mL of chloroform/methanol (2:1, vol/vol) to the mixture. Water (0.5 mL) was added to cause phase separation. The lower phase (containing the labelled phosphatidylcholine) was washed twice with 40% methanol, and an aliquot was taken for radioactivity determination.

Subcellular fractionation. Microsomal and cytosolic fractions were obtained from cardiac myocytes by differential ultracentrifugation. Myocytes were suspended in 10 mM Tris-HCl (pH 7.4)/0.25 M sucrose/1 mM EDTA and homogenized in a glass Dounce homogenizer. Myocyte disruption after homogenization was verified under a phase contrast light microscope. The cellular suspension was centrifuged at 20,0000 × *g* for 10 min, and the supernatant obtained was centrifuged at 100,000 × *g* for 60 min. The supernatant (cytosol) was collected, and the precipitate (microsomal pellet) was resuspended in the homogenizing buffer.

Other analytical procedures. Protein was determined by the method of Lowry *et al.* (18) with bovine serum albumin as standard. Radioactivity was determined by liquid scintillation counting. Student's *t*-test was used for statistical analysis of data. The significance level was set at $P < 0.05$.

RESULTS

The effect of vasopressin on choline uptake and phosphatidylcholine biosynthesis. Cardiac myocytes were incubated in the growth medium containing 10 μM [*methyl*-^{3}H]choline in the presence of 0.2 and 1.0 μM [arginine]vasopressin for 20–120 min. Myocytes incubated in the same medium without vasopressin were used as controls. Subsequent to incubation, total uptake of choline by myocytes was determined. As depicted in Figure 1, choline uptake by myocytes was linear up to 60 min in the presence or absence of vasopressin. The presence of 0.2 μM vasopressin caused an enhancement of choline uptake (25%) at all time points, whereas the presence of 1 μM vasopressin caused a significant reduction (19%) in choline uptake.

The effect of other vasopressin concentrations (0.01–5 μM) on choline uptake and phosphatidylcholine biosynthesis was investigated. Myocytes were incubated with growth medium containing 10 μM labelled choline for 60 min at various vasopressin concentrations. Subsequently, the uptake of choline and the amount of radioactivity in the phosphatidylcholine fraction in the myocytes were determined. No change in the uptake of choline was detected at 0.01 μM vasopressin. An enhancement of choline

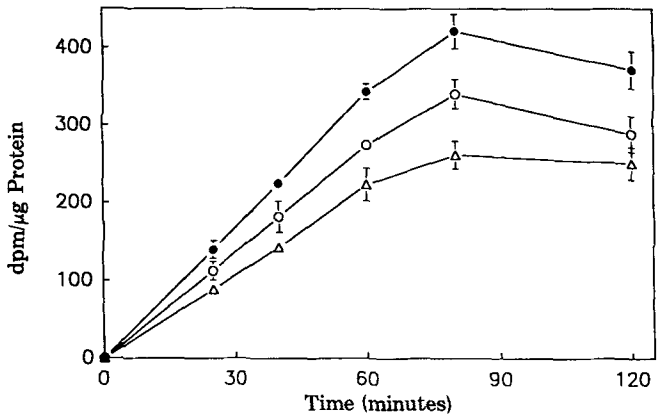

FIG. 1. Time course of choline uptake in rat cardiac myocytes. Rat cardiac myocytes were incubated with 10 μM [*methyl*-^{3}H]choline (150 μCi/μmol) in the absence (○) or presence of 0.2 μM (●) or 1.0 μM (△) vasopressin. The total amount of radioactivity incorporated into the myocytes at each time point was determined. Each point represents the mean value of four determinations from two separate experiments, and the vertical bar represents the SD.

uptake was observed with a corresponding increase in the labelling of phosphatidylcholine at 0.05–0.3 μM vasopressin (Table 1). At higher vasopressin concentrations (0.4–1.0 μM), choline uptake was attenuated, together with a reduction in the labelling of phosphatidylcholine. It appears that choline uptake in myocytes was modulated by vasopressin in a biphasic manner, with a transition occurring between 0.3–0.4 μM. However, the change in the labelling of phosphatidylcholine was not proportional to the change in choline uptake, which indicates that vasopressin might also affect phosphatidylcholine biosynthesis in myocytes.

The nature of vasopressin response was investigated by using a specific V_1 receptor antagonist [d(CH_2)$_5$, D-tyr(OEt)^2, val^4, cit^8]-vasopressin. Myocytes were incubated with 10 μM [*methyl*-^{3}H]choline with 0.2 μM vasopressin for 60 min in the presence or absence of 0.1 μM vasopressin antagonist. As shown in Table 1, both the choline uptake and the labelling of phosphatidylcholine were not affected by the vasopressin antagonist. However, the stimulatory effect of 0.2 μM vasopressin on choline uptake and labelling of phosphatidylcholine was attenuated by the presence of the vasopressin antagonist.

Analysis of choline-containing metabolites. The effect of vasopressin on the radioactivities associated with the choline-containing metabolites in myocytes was determined. The choline-containing metabolites in the upper phase of the cellular extract were separated by thin-layer chromatography with a solvent system containing methanol/0.6% sodium chloride/57% ammonium hydroxide (50:50:5, by vol). In the presence of 0.2 μM vasopressin, the increase in the labelling of choline (24%) commensurated with the increase in choline uptake (Table 2). However, the increase in the labelling of phosphocholine (15%) was less than that shown in choline uptake. In the presence of 1 μM vasopressin, the decrease in choline uptake was also reflected in the labelling of choline (23%), but not in the labelling of phosphocholine. The labelling of CDPcholine was not significantly changed in both cases.

TABLE 1

Effect of Vasopressin on Choline Uptake and Incorporation of Labelled Choline into Phosphatidylcholine[a]

Hormone	Total choline uptake (dpm/μg protein)	Phosphatidylcholine (dpm/μg protein)
Control	274 ± 8 (5)	68 ± 3 (8)
0.05 μM vasopressin	301 ± 10 (5)[b]	79 ± 3 (8)[b]
0.1 μM vasopressin	304 ± 14 (3)[b]	82 ± 3 (3)[b]
0.2 μM vasopressin	343 ± 10 (5)[b]	97 ± 11 (6)[b]
0.3 μM vasopressin	324 ± 15 (3)[b]	73 ± 9 (3)
0.4 μM vasopressin	229 ± 7 (3)[b]	58 ± 8 (3)[b]
0.5 μM vasopressin	323 ± 19 (3)[b]	60 ± 2 (3)[b]
1.0 μM vasopressin	223 ± 21 (4)[b]	41 ± 4 (9)[b]
0.1 μM V_1 antagonist	267 ± 8 (8)	68 ± 4 (3)

[a]Cardiac myocytes were incubated with growth medium containing 10 μM [*methyl*-^{3}H]choline (150 μCi/μmol) for 60 min in the presence of vasopressin and 0.1 μM [d(CH_2)$_5$, D-tyr(OEt)^2, val^4, cit^8] vasopressin (V_1 antagonist). Subsequently, the total choline uptake and the incorporation of label into phosphatidylcholine were determined. Each set of values represents the mean ± SD (number of experiments).
[b]$P < 0.05$.

TABLE 2

Effect of Vasopressin on the Incorporation of Radioactivity into Choline-Containing Metabolites[a]

Vasopressin	Choline (dpm/μg protein)	Phosphocholine (dpm/μg protein)	CDPcholine (dpm/μg protein)
Control	53 ± 3 (6)	163 ± 9 (4)	8.8 ± 2.9 (6)
0.2 μM	66 ± 4 (6)[b]	187 ± 14 (5)[b]	9.4 ± 1.8 (3)
1.0 μM	41 ± 11 (13)[b]	152 ± 7 (3)	6.8 ± 2.6 (9)

[a]Cardiac myocytes were incubated with growth medium containing 10 μM [*methyl*-^{3}H]choline for 60 min in the presence of 0.2 or 1.0 μM vasopressin. Subsequently, the radioactivity associated with the choline-containing metabolites of the cytidine diphosphocholine (CDPcholine) pathway in the myocytes were determined. Each set of values represents the mean ± SD (number of experiments).
[b]$P < 0.05$.

Activities of enzymes in the CDPcholine pathway. The disproportionate changes between choline uptake and labelling of phosphatidylcholine suggest that the conversion of metabolites in the CDPcholine pathway was affected by vasopressin. This postulation was substantiated by the analysis of the choline-containing metabolites. In order to elucidate the mechanism leading to these changes, the activities of the enzymes in the CDPcholine pathway were determined. Myocytes were homogenized to yield a cellular homogenate for enzyme activity determinations. The presence of 0.2 or 1.0 μM vasopressin to the assay mixture had no effect on any of the enzyme activities. In another set of experiments, myocytes were incubated with 0.2 or 1.0 μM vasopressin for 60 min prior to homogenization. Myocytes incubated in the absence of vasopressin were used as controls. The activities of choline kinase, CTP:phosphocholine cytidylyltransferase and CDPcholine:diacylglycerol cholinephosphotransferase were determined and results obtained are shown in Table 3. Incubation with 0.2 μM vasopressin caused a twofold enhancement of the cytidylyltransferase activity, but the

The Effect of Vasopressin on the Activities of the Phosphatidylcholine Biosynthetic Enzymes[a]

Vasopressin	Choline kinase (nmol/min/mg protein)	CTP:phosphocholine cytidylyltransferase (nmol/min/mg protein)	Cholinephosphotransferase (nmol/min/mg protein)
Control	0.018 ± 0.003 (4)	0.254 ± 0.035 (8)	0.116 ± 0.012 (8)
0.2 μM	0.018 ± 0.005 (3)	0.495 ± 0.065 (5)[b]	0.119 ± 0.008 (5)
1.0 μM	0.015 ± 0.002 (3)	0.118 ± 0.017 (4)[b]	0.124 ± 0.007 (5)

[a]Cardiac myocytes were incubated with growth medium in the presence or absence of vasopressin. Subsequently, the myocytes were homogenized, and enzyme activities in the homogenate were determined. Each set of values represents the mean ± SD (number of experiments). CTP, cytosine triphosphate.
[b]$P < 0.05$.

activities of other enzymes in the pathway were not affected. Incubation with 1.0 μM vasopressin caused a severe (54%) reduction in the cytidylyltransferase activity. The activities of choline kinase and cholinephosphotransferase were not significantly changed by this treatment.

The mechanism for the change of cytidylyltransferase activity at different vasopressin concentrations was examined. Myocytes incubated with 0.2 or 1.0 μM vasopressin were homogenized, and subcellular factions were obtained by differential centrifugation. Enzyme activities in the microsomal and cytosolic fractions were determined, and the results are depicted in Table 4. In the presence of 0.2 μM vasopressin, enhancement of enzyme activities in both the microsomal and cytosolic fractions was observed. In the presence of 1.0 μM vasopressin, there was a severe reduction in enzyme activity in the microsomal fraction, with a corresponding increase in enzyme activity in the cytosolic fraction.

The uptake of vasopressin in cardiac myocytes. The ability of the cardiac myocytes for vasopressin uptake was investigated. Myocytes were incubated with 0.2 or 1.0 μM [^{3}H-tyr]vasopressin (1.5 μCi/nmol) for 60 min in growth medium followed by two washings with growth buffer containing 10 μM nonlabelled vasopressin. After incubation, the cells were homogenized in 0.25 M sucrose/10 mM Tris-HCl buffer (pH 7.5), and an aliquot of the homogenate was taken for radioactivity determination (Table 5). The uptake of vasopressin by the myocytes was found to be dose-dependent, but not in a linear fashion. The fate of the vasopressin taken up by the cells was also examined.

TABLE 5

The Uptake of Vasopressin by Rat Cardiac Myocytes[a]

Vasopressin in medium	Vasopressin uptake (fmol/μg protein)
0.2 μM	5.5 ± 1.1 (6)
1.0 μM	22.2 ± 8.0 (6)

[a]Cardiac myocytes were incubated in the presence of [^{3}H-tyr]vasopressin (1.5 μCi/nmol) for 60 min. After incubation, medium was removed and cells were washed with unlabelled vasopressin (10 μM). The myocytes were homogenized and the amount of radioactivity in the homogenate was determined. Each set of values represents the mean ± SD (number of experiments).

The myocyte homogenate was centrifuged at 100,000 × *g* for 60 min to obtain the cytosolic fraction, and an aliquot was applied to a Sephadex G-15 (fine) column equilibrated with 10 mM Tris-HCl (pH 7.5)/0.1 M KCl. In a control experiment, vasopressin was applied and eluted from the same column. None of the radioactivity was found in the fractions that contained vasopressin, but most of the radioactivity was eluted in subsequent fractions that normally contained tyrosine (data not shown). It appears that the vasopressin taken up by the cell was metabolized into the corresponding labelled amino acid and its metabolites.

DISCUSSION

It is clear from this study that vasopressin affects phosphatidylcholine biosynthesis in isolated myocytes. Two modes of regulation have been identified: (i) the modulation of choline uptake and (ii) the regulation of the CTP:phosphocholine cytidylyltransferase activity.

The uptake of choline by the cell has been regarded as a plausible mechanism for the control of phosphatidylcholine biosynthesis. In nonneural cells, choline is taken up *via* the low-affinity Na^+-independent transport system (19). In the mammalian heart, the uptake of choline follows Michaelis-Menten kinetics and appears to consist of a single uptake system (2,20). The uptake of choline is inhibited by ethanolamine and other choline analogs (21,22). Interestingly, choline uptake is enhanced by amino acids in some mammalian tissues (20,23). This is the first report that choline uptake could also be regulated by hormonal control. The modulation of choline uptake by vasopressin appears to be quite specific as the action of vasopressin could not be duplicated by similar

amounts of oxytocin (data not shown). Experiments conducted with [d(CH_2)$_5$, D-tyr(OEt)^2, val^4, cit^8]-vasopressin, a specific V_1 receptor antagonist (24), indicate that the action of vasopressin might be associated with the V_1 receptors.

The disproportionate changes between choline uptake and radioactivity incorporated into the phosphatidylcholine fraction suggest that the biosynthesis of the phospholipid is also modulated by vasopressin. It is interesting to note that vasopressin at lower concentrations (0.05–0.3 μM) regulates choline uptake and the synthesis of phosphatidylcholine in a synergistic manner. Analyses of the choline-containing metabolites revealed that the conversion of phosphocholine to CDPcholine and, subsequently, phosphatidylcholine, was enhanced, and the cytidylyltransferase activities were elevated in both the microsomal and cytosolic fractions. In order to determine whether the enzyme might be modulated directly by the hormone, the ability of the myocytes to take up vasopressin was examined. Only a very small proportion (fmol/μg cellular protein) of vasopressin was internalized by the myocytes, and practically all of the internalized vasopressin was catabolized into amino acids and their metabolites. Furthermore, the addition of vasopressin to the assay mixture *in vitro* did not cause any changes in the cytidylyltransferase activity. Hence, the modulation of the cytidylyltransferase was not a direct interaction between the enzyme and vasopressin.

One intriguing aspect of this study is the biphasic action of vasopressin on both choline uptake and phosphatidylcholine biosynthesis. In view of the fact that the concentrations of vasopressin used in this study are much higher than the physiological values, the role of the hormone in the regulation of phosphatidylcholine biosynthesis *in vivo* remains undefined. The V_1 receptor is the predominant type of vasopressin receptors in nonrenal organs and the ability of vasopressin to activate protein kinase C at high concentrations *via* the V_1 receptor is well documented (24). However, it is not clear if the protein kinase C produced by the action of vasopressin may cause the phosphorylation of the cytidylyltransferase, which results in its translocation from the microsomal to the cytosolic form (5,25). Alternatively, vasopressin at lower concentrations may produce a yet unidentified cellular response that activates the cytidylyltransferase in both subcellular fractions. The ability of a hormone to produce dual second messengers *via* a single receptor has recently been identified (26,27). Interestingly, vasopressin displays no effect on the choline uptake in isolated rat hepatocytes, but inhibits the incorporation of labelled choline into phosphatidylcholine (9). Similar to the present study, the mechanism of inhibition appears to be at the cytidylyltransferase level. Hence, the biphasic effect of vasopressin on choline uptake and phosphatidylcholine biosynthesis observed in this study illustrates the diverse effects of this hormone on different tissues.

Isolation, Characterization and Biological Activity of Inositol Sphingophospholipids from *Phytophthora capsici*[1]

Véronique Pivot[a], Maud Bruneteau[a,*], Pierre Mas[b], Gilbert Bompeix[c] and Georges Michel[a]

[a]Laboratoire de Biochimie Microbienne, Université Claude Bernard Lyon I, F-69622 Villeurbanne Cedex, [b]Station de Pathologie Végétale, Institut de la Recherche Agronomique, Domaine St Maurice, F-84140 Montfavet and [c]Laboratoire de Pathologie Végétale, Université Pierre et Marie Curie, F-75252 Paris Cedex 05, France

Several inositol sphingophospholipids (ISPL) were isolated from mycelia of *Phytophthora capsici*, a phytopathogenic fungus of pepper (*Capsicum annuum* c.v. Yolo Wonder). The sphingophospholipids induce a protective response by cotyledons of young peppers against necrotic lesions caused by the pathogen *P. capsici*. The ISPL structures were determined by chemical methods, fast atom bombardment mass spectrometry and by fast atom bombardment collision-induced tandem mass spectrometry. All ISPL consisted of ceramides linked to inositol phosphate. The amide-linked fatty acids were found to have 16, 20 and 22 carbon chains. The long chain bases were identified as trimethylsilyl derivatives and shown to be C_{16}-sphingosine and C_{16}-dihydrosphingosine. The protective effect of the ISPL on cotyledons of young peppers against necrotic lesions caused by the pathogen *P. capsici* was shown not to be dependent on the unsaturation of the C_{16}-sphingosine base and the nature of the acyl chain. We also investigated the effect of growth conditions on the ISPL produced in three different, chemically defined media that are commonly used for fungi cultures. We showed that *P. capsici* synthesized one major class of compounds with molecular weights of M_r = 833 and 835 containing the 16:1 base and the 22:1 or the 22:0 *N*-acyl group, independent of the growth medium used. The presence of phosphite or fosetyl-Al did not affect the result.

***Lipids* 29, 21–25 (1994).**

Various lipids from parasitic fungi have been shown to be elicitors of plant defense reactions (1–3). We have previously reported that lipid components of *Phytophthora capsici* mycelia induced protection in pepper (*Capsicum annuum* c.v. Yolo Wonder) against the pathogen (4). The most active lipid fraction was identified as inositol sphingophospholipids (ISPL) (5). ISPL have not previously been shown to occur in *P. genus*.

Earlier studies had shown that ISPL are cell membrane components which appear to play an important role in host-parasite interactions (6). ISPL have been found in plants (7–11), yeasts (12–14), fungi (15), and protozoa (6,16,17), and all were shown to be derived from myoinositol phosphorylceramide (6,13). The ceramides typically contain C_{16} or C_{18} sphingosine or C_{18} phytosphingosine (5,6,13) as long chain base (LCB), which is acylated with palmitic, stearic (6,16), 2- or 3-hydroxyhexacosanoic or 4-hydroxy-2-docosenoic acid (5,13) to form the backbone of the glycosphingophospholipids (18).

Abbreviations: CID, collision-induced dissociation; FAB, fast atom bombardment; FAME, fatty acid methyl esters; GC, gas chromatography; HPTLC, high-performance thin-layer chromatography; ISPL, inositol sphingophospholipid; LCB, long chain base; MS, mass spectrometry; MS/MS, tandem mass spectrometry.

Lhomme *et al.* (5) have shown that *P. capsici* strains 15-12A and 197 synthesize nonglycosylated ISPL. Because these ISPL are biologically active by rendering plants resistant to pathogenic fungi, it was of interest to determine whether inositol sphingophospholipids were present in other strains of *P. capsici* and whether their composition was dependent on growth conditions.

It had previously been shown that phosphite, the active breakdown product of fosetyl-Al in plant tissues (19), stimulates plant defense mechanisms (20,21). Thus, it was important to determine whether sphingophospholipid structure is affected when the fungus is grown in either phosphite or fosetyl-Al containing media.

MATERIALS AND METHODS

Microorganisms and growth. Three strains, 107, 197 and 375, of *P. capsici* were grown on various media; strain 107 on M1, M2 and M3 media; strain 197 on M1 and M2 media; and strain 375 on M1, M4 and M5 media.

M1 was a chemically defined medium (22) which contained (g/L): sucrose, 50; malt extract (crystallized), 5; $Ca(NO_3)_2$, 2; KNO_3, 0.5; $MgSO_4 \cdot 7H_2O$, 0.5; KH_2PO_4, 0.5; $FeSO_4$, $MnSO_4 \cdot H_2O$, Cu $SO_4 \cdot 5H_2O$ and Zn $SO_4 \cdot 7H_2O$, 0.001; citric acid, 0.025; malic acid, 0.025; malic acid, 0.025; boric acid, 0.015; with pH adjusted to 4.5. M2 medium had the same composition as M1 but was supplemented with 10 mg/L fosetyl-Al. M3 was the Plich and Rudnicki medium (23) which contained (g/L): glucose, 25; yeast extract, 5; L-asparagine, 1; thiamine, 0.001; KH_2PO_4, 0.5; $MgSO_4 \cdot 7H_2O$, 1; with pH adjusted to 6. M4 was the Ribeiro synthetic medium modified according to Fenn and Coffey (24), which contained (g/L): glucose, 10; L-asparagine, 0.1; KNO_3, 0.15; KH_2PO_4, 1; $CaCl_2$, 0.1; $MgSO_4 \cdot 7H_2O$, 0.5; $Na_2MoO_4 \cdot 2H_2O$, 0.004; $ZnSO_4 \cdot 7H_2O$, 0.009; $CuSO_4 \cdot 5H_2O$, 0.008; $MnSO_4 \cdot H_2O$, 0.001; $Na_2B_4O_7$, 0.0005; $FeCl_3 \cdot 6H_2O$, 0.005; ethylenediaminetetraacetic acid, 0.026; KOH, 0.015; thiamine, 0.001; with pH adjusted to 6.5. M5 medium was M4 medium supplemented with 5 mM disodium phosphite and 0.8 mM KH_2PO_4.

Fungi were grown at 24°C under 16 h of light on M1, M2, M4 and M5 media. Strain 107 was grown in the dark on M3 medium. Mycelia were collected after three weeks of growth.

Extraction and fractionation of lipids. Mycelial walls were isolated from fungi as described by Fabre *et al.* (25), and were treated with chloroform/methanol (2:1, vol/vol). The extracted lipids were separated by column chromatography on Bio-Sil HA silicic acid (BioRad, Ivry sur Seine, France) with chloroform and chloroform containing increasing concentrations of methanol as eluents. ISPL were eluted with chloroform/methanol (50:50, vol/vol) and purified further by column chromatography on DEAE-cellulose according to Rouser *et al.* (26). ISPL were eluted with a mixture containing 50 parts of a 0.04 M ammonium acetate solution in chloroform/methanol (4:1, vol/vol) and 1 part of 29% ammonia solution.

Thin-layer chromatography of lipid fractions eluted from the silicic acid column. Lipid fractions were analyzed by high-performance thin-layer chromatography (HPTLC) on silica gel 60 plates (Merck, Darmstadt, Germany) that were developed with chloroform/methyl acetate/*n*-propanol/methanol/0.25% aqueous KCl (25:25:28:10:7, by vol) (27). Fractions were made visible by spraying with 0.2% vanillin (wt/vol) in 10% sulfuric acid (vol/vol).

Phospholipids were analyzed by two-dimensional HPTLC with the solvent system described by Rouser *et al.* (28). Fractions were detected by spraying with a Dittmer and Lester reagent as modified by Vaskovsky and Kostetsky (29) and identified by comparison with authentic standards.

Analytical methods. Phospholipids were hydrolyzed with 4 N or 6 N HCl for 48 h at 100°C. Fatty acids were recovered from the hydrolysate by chloroform extraction and esterified with diazomethane. Inositol was acetylated with acetic anhydride/pyridine (1:1, vol/vol) at 100°C for 15 min before analysis by gas chromatography.

Sphingosines were released by methanolysis according to Laine *et al.* (30), and their *N*-acetyl derivatives were prepared by addition of a mixture of methanol/acetic anhydride (4:1, vol/vol) and reaction overnight at room temperature. Silylation of hydroxyl groups was performed with the *N,O-bis*(trimethylsilyl)trifluoracetamide silylating reagent for 30 min at 60°C. Phosphorus was measured by the colorimetric method of Lowry *et al.* (31).

Gas chromatography. Fatty acid methyl esters (FAME) were separated by gas chromatography (GC) using an Intersmat instrument (Model 120FL; Intersmat, Lyon, France) fitted with an SP2100 glass capillary column (60 m × 0.32 mm). The column temperature was programmed from 140 to 260°C at 4°C/min. An SP2380 glass capillary column (30 m × 0.32 mm) was used for analysis of hexaacetylinositol.

Combined GC/mass spectrometry (GC/MS) of trimethylsilyl-*N*-acetyl-sphingosines was performed on a Ribermag R10 (Nermag SA, Rueil-Malmaison, France) apparatus which was connected to a gas chromatograph (Hewlett-Packard 437; Hewlett-Packard, Les Ulis, France) equipped with an OV-1 capillary column (25 m × 0.32 mm). The column temperature was programmed from 210 to 250°C at 2°C/min.

GC/MS of FAME was performed on a UG-Micromass 305 apparatus equipped with a DB-1 capillary column (30 m × 0.3 mm). Oven temperature was held at 60°C for 1 min, then increased at 30°C/min to 120°C, and then at 2°C/min to 180°C where it was maintained for 2 min.

MS. Fast atom bombardment (FAB) mass spectra of phospholipids were recorded in the negative ion mode on a VG ZAB2 SEQ mass spectrometer (Manchester, United Kingdom). The instrument was equipped with a VG FAB standard source with a cesium ion gun delivering about 2 μA of cesium ion current at about 35 kV.

Spectra were obtained at a magnet scan rate of 20 s/decade over a mass range of *m/z* 200–2000 at 8 kV. The mass range was calibrated using cesium iodine clusters. The spectra were collected and processed using the VG II-250 J data system. Samples were dissolved in chloroform/methanol (1:1, vol/vol) and mixed with an equal volume of triethanolamine. The sample (2 μL) was deposited on the FAB probe tip mixed with matrix, *i.e.*, glycerol.

Low-resolution FAB and FAB collision-induced decomposition (CID) tandem mass spectra (MS/MS) were obtained with a JEOL HX110/HX110 tandem mass spectrometer (Tokyo, Japan), operated at ±10 kV accelerating voltage; with ±18.5 kV post-acceleration at the detector. The JEOL DA-5000 data system was used for instrument control and data acquisition and processing.

Elicitor activity assay. Cotyledons from young peppers (*C. annuum* c.v., Yolo Wonder, susceptible to *P. capsici*) were removed and placed in water. Onto the lower side of the cotyledon, 25 μL of the elicitor fraction were added. On the same site, after 24 h, the cotyledons were infected using a 10-μL zoospore suspension (62550 zoospores/mL) that was produced as previously described (32). After four days of incubation at 22°C at a 16-h light cycle, the symptoms of infection were noted by the necrosis of whole cotyledons. Each trial involved 15–20 cotyledons. The cumulated results were expressed as susceptibility percentage corresponding to percentage necrotic cotyledons.

RESULTS

Lipids of P. capsici. The percentages of total lipids extracted from the mycelial cell walls are given in Table 1. The differences observed indicate that for strains 107 and 197, the lipid content is somewhat affected by the nature of the growth medium. *P. capsici*, strain 375, is characterized by a large total lipid content.

Total lipids were fractionated on a column of Bio-Sil HA silicic acid to measure the relative amounts of neutral and polar lipids (Table 1). The polar lipids consisted of phospholipids as revealed by HPTLC and by spraying with phosphorus reagent. Two-dimensional HPTLC showed the presence of a major compound that comigrated with ISPL, as previously described (5). The polar lipid fraction was then further purified by DEAE cellulose chromatography.

ISPL content. ISPL was identified by acid hydrolysis and methanolysis according to Laine *et al.* (30), followed by the identification of inositol, FAME and a compound that comigrated with standard sphingosine (R_f 1.14) in HPTLC using the solvent system described by Heape *et al.* (27). The inositol moiety was identified by GC as hexaacetyl derivative, and confirmed by FAB MS analysis of intact ISPL. The sphingosine moiety was characterized by GC/MS of the *N*-acetyl-*O*-trimethylsilyl derivative. The mass spectrum was identical to that of a C_{16} sphingosine and C_{16} dihydrosphingosine mixture described in 1966 (33) with molecular ions at *m/z* 283 and *m/z* 285, a peak at *m/z* 174 from the cleavage between carbon atoms 2 and 3, and a small peak at *m/z* 103 due to the terminal CH_2-O-Si$(CH_3)_3$ ion.

The FAMEs of the polar lipid fraction when analyzed by GC/MS (Table 2) were identified as hexadecanoic (16:0), octadecenoic (18:1), octadecanoic (18:0), eicosanoic (20:0), docosenoic (22:1), docosanoic (22:0) and hydroxydocosenoic (22h:1) acids. Fatty acid analyses of the polar lipid fraction from the various strains showed that their acyl moieties consisted of 16 to 22 carbon fatty acids, as previously reported (5,34). Although the same fatty acids are present in the three strains, there are significant differences in their relative abundance depending on the strain and the growth medium. This is especially true in regard to the C_{18}, C_{20} and C_{22} fatty acids. Thus, the

TABLE 1

Lipid Accumulation in Fungi[a]

P. capsici strain	Culture medium	Total lipid content[b] (%, w/w)	Percentage of each lipid fraction[c] (%, w/w)	
			Neutral lipids	Polar lipids
107	M1	9.5	76.5	23.5
	M2	9.2	68.0	32.0
	M3	11.3	69.9	30.1
197	M1	6.3	70.4	29.6
	M2	8.5	72.5	27.5
375	M1	29.6	68.4	31.6
	M4	10.1	67.6	32.4
	M5	10.7	75.8	24.2

[a]Three strains of *Phytophthora capsici* were examined. Strain 107 was grown on M1, M2 and M3 media. M1 was a chemically defined medium (Ref. 22); M2 has the same composition as M1 and was supplemented with 10 mg/L of foselyl-Al; M3 was the Plich and Rudnicki medium (Ref. 23). Strain 197 was grown on M1 and M2 media. Strain 375 was grown on M1, M4 and M5 media. M4 was the Ribeiro medium modified according to Fenn and Coffey (Ref. 24). M5 was the same medium supplemented with 5 mM disodium phosphite and with 0.8 mM KH_2PO_4. The compositions of M1, M3 and M4 media and the conditions of the cultures are described in the Materials and Methods section.
[b]These cultures were used to prepare the lipid extracts from fungal cell walls. The wt% of total lipid content is expressed as a percentage of the dry weight of fungal cell walls.
[c]The weight percentage of neutral and polar fractions from Bio-Sil HA silicic acid chromatography is expressed as a percentage of total lipids extracted.

TABLE 2

Fatty Acids from the Polar Lipid Fraction from *Phytophthora capsici*[a]

Fatty acid[b]	Abundance %[c]							
	Strain 107			Strain 197		Strain 375		
	M1	M2	M3	M1	M2	M1	M4	M5
Saturated								
Hexadecanoic (16:0)	46	44	33	46	37	51	41	55
Octadecanoic (18:0)	11	4	3	10	10	10	15	8
Eicosanoic (20:0)	6	8	7	10	14	5	10	11
Docosanoic (22:0)	4	13	21	15	10	5	25	13
Monounsaturated								
Octadecenoic (18:1)	20	4	2	4	5	6	0	1
Docosenoic (22:1)	12	19	32	13	20	21	10	7
Hydroxy and monounsaturated acid								
Hydroxydocosenoic (22h:1)	0	8	2	3	4	2	0	6

[a]Three strains of *P. capsici* were examined. See Table 1 for the composition of the growth media. The cultures were used to prepare the polar lipid fraction, which was hydrolyzed and used for the isolation of fatty acids.
[b]Fatty acids were analyzed by gas chromatography/mass spectrometry. For details see the Materials and Methods section.
[c]Data are given as percentage of total fatty acids present.

amounts of octadecanoic (18:0) and octadecenoic (18:1) acids in the strain 107 were higher in M1 medium than in M2 and M3 media, while the amounts of docosanoic (22:0) and docosenoic (22:1) acids were higher in a Plich medium (M3).

An increase in 22:0 fatty acid was also observed when strain 375 was grown on Ribiero medium (M4). Phosphite or fosetyl-Al (medium M5) only affected the percentage of saturated and unsaturated C_{22} fatty acids. In addition, hydroxydocosenoic acid (22h:1) appeared only in *P. capsici* grown in M5 medium.

Molecular species of ISPL. The negative ion FAB mass spectrum of the ISPL fraction from each strain showed two major molecular species with $[M - H]^-$ ions at *m/z* 832 and 834. As an example, Figure 1 shows the mass spectrum of the ISPL fraction from *P. capsici*, strain 197 (medium M1). The presence of other molecular species was indicated by ions at *m/z* 750, 752, 806, 808, 848 and 850.

In each spectrum, the ion $[Y_0PO_3H]^-$ corresponding to the cleavage of the inositol-phosphate bond, $[M - H - 162]^-$, and ions at *m/z* 241 and 259 were observed. Formation of these ions is shown in Figure 2 as previously reported (16,35,36). The fragments, assigned to inositol phosphate (37), provide evidence that the inositol and the ceramide are linked through a phosphate group.

In the CID MS/MS spectrum, additional fragments from the $[M - H]^-$ precursor ion were evident and

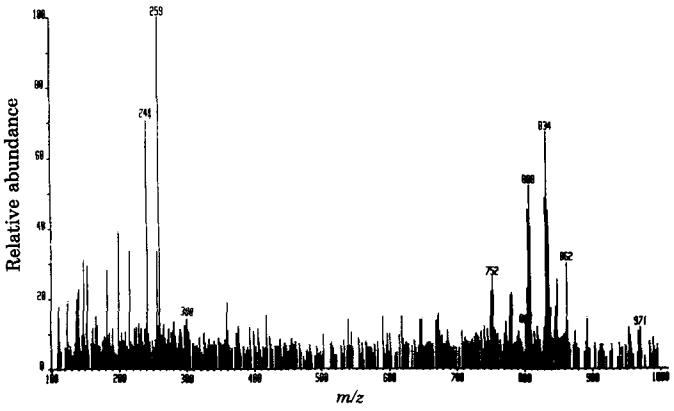

FIG. 1. The negative fast atom bombardment mass spectrum of inositol sphingophospholipids from *Phytophthora capsici* strain 197, grown on synthetic medium M1. The ions at *m/z* 752, 808 and 834 correspond to the individual molecular species present. Acyl groups and long chain bases were assigned to a particular molecular species in a mixed sample as confirmed by tandem mass spectrometry analysis of individual $[M - H]^-$ ions (see Table 3). Other fragments in the spectrum at *m/z* 241, 259 and 300 are characteristic of an inositol sphingophospholipid (see Fig. 2).

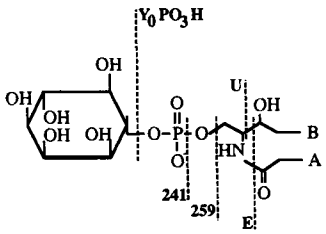

FIG. 2. Structures of major molecular species of inositol sphingophospholipids of molecular weights 833 (B = -CH=CH-$(CH_2)_{10}$-CH_3; A = -$(CH_2)_n$-CH=CH-$(CH_2)_m$-CH_3, n + m = 18; E = 300; U = 620; Y_0PO_3H = 670) and 835 (B = -CH=CH-$(CH_2)_{10}$-CH_3; A = -$(CH_2)_{20}$-CH_3; E = 300; U = 622; Y_0PO_3H = 672) present in *Phytophthora capsici*. Fragmentations are characteristic of an inositol sphingophospholipid as reported by Dommon and Costello (Ref. 35).

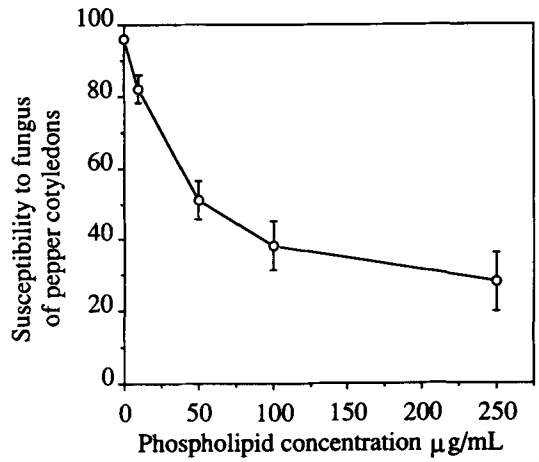

FIG. 3. Biological activity of inositol sphingophospholipids from *Phytophthera capsici* strain 197 grown on synthetic medium M1.

characterized by CID spectra of the ceramides, namely the ions E and the ions U (Fig. 2), as reported previously by Dommon and Costello (35). These ions were consistent with C_{16} sphingosine and C_{16} dihydrosphingosine containing ceramides. Analysis of the spectra made it possible to determine the LCB and the fatty acyl composition of the ceramide. The molecular species of ISPL in *P. capsici*, which differ in the unsaturation of the LCB and in the nature of the *N*-acyl chain, are summarized in Table 3. The result is in agreement with the structure (M_r = 833, M_r = 835) shown in Figure 2 for the most abundant ISPL of *P. capsici* strains 107, 197 and 375.

Biological activity. ISPL induce a protective mechanism by *C. annuum* (Yolo Wonder) against *P. capsici* (Fig. 3). When ISPL was applied onto *C. annuum* cotyledons at increasing concentrations, *i.e.*, 50–100 μg/mL of ISPL, the sensitivity of *Capsicum* cotyledons to the pathogen decreased by 70%. The same protective effect was observed when ISPL from each of the strains were examined. As an example (Fig. 3), an antinecrotic factor was detected in the ISPL fraction isolated from strain 197 grown on medium M2.

DISCUSSION

The present study confirms earlier observations that the major mycelial phospholipids in *P. capsici* are sphingophospholipids containing inositol (5). The structure

[a]The assignments of major ions of collisionally activated daughter spectra of the deprotonated molecular ions $[M - H]^-$ of inositol sphingophospholipids from *P. capsici* are based on interpretation of the collision-induced dissociation (CID) mass spectra of such compounds as reported by Domon and Costello (Ref. 35). An example of the fragmentations is given in Figure 2 for both major molecular species with $[M - H]^-$ ions at *m/z* 832 and 834 corresponding to the molecular weights 833 and 835.
[b]LCB, long chain base analogous to sphingosine and dihydrosphingosine identified based on ion $[M - H]^-$ and U ion (see Fig. 2).
[c]Identifications are based on both U and E ions (see Fig. 2).

of these inositol sphingophospholipids from *P. capsici* strains 107, 197 and 375 cultivated on different growth media were established by MS. FAB-CID-MS/MS was found to be a valuable technique for characterizing mixed molecular species composition of ISPL. The major ISPL contains a C_{16} dihydrosphingosine LCB linked *via* a docosanoyl (22:0) or docosenoyl (22:1) amide bond. The inositol and ceramide in turn, are linked through a phosphate group. Some differences among the strains of *P. capsici* were observed in the degree of unsaturation of the LCB and in the nature of the acyl group. The results confirm that ISPL produced by *P. capsici* are not glycosylated. They are similar to ISPL isolated from *Saccharomyces cerevisiae* (13) and *Leishmania dovani* (6).

With *P. capsici*, we observed only slight variations in the structure of ISPL with changes in the culture conditions. The only significant variation was in regard to the level of fatty acids with 22 carbon atoms.

Previously Lhomme *et al.* (5) have shown that in strains 15-12 and 197 of *P. capsici* grown on dextrose medium, the major ISPL corresponded to the compound of molecular mass 849, *i.e.*, an ISPL with 22h:1 fatty acid (Table 3), which was only a minor compound in the present systems. This difference suggests that the dextrose medium is not completely defined because strains 15-12 and 197 grown on a synthetic medium (M1) produced an ISPL with $M_r = 835$ as the major compound.

The biological activity of the sphingophospholipids had already been previously demonstrated (5). Our results indicate that the protective effect against the necrosis of young pepper cotyledons induced by the pathogen *P. capsici* is not dependent on the unsaturation of C_{16} sphingosine and on the nature of *N*-acyl side chain.

ACKNOWLEDGMENTS

We thank Dr. C.E. Costello (Massachussetts Institute of Technology, Mass Spectrometry Facility, Cambridge, MA) and Dr. M. Becchi (Service Central d'Analyses du Centre National de la Recherche Scientifique, Solaize, France) for mass spectral analyses and for useful discussions. The study was supported by the Centre National de la Recherche Scientifique (ER. X0018).

Interaction of Dietary Fatty Acids and Cyclosporine A in the Borderline Hypertensive Rat: Tissue Fatty Acids

David E. Mills[a,*], **Roberto de Antueno**[b] and **James Scholey**[c]

[a]Department of Health Studies, University of Waterloo, Waterloo, Ontario N2L 3G1, [b]Efamol Research Institute, Kentville, Nova Scotia B4N 4H8 and [c]Department of Medicine, University of Toronto, Toronto, Ontario M5G 1L7 Canada

In this study we examined (i) the effects of cyclosporine A (CS) on tissue lipid composition and (ii) the effect of changes in dietary n-6 fatty acids on tissue responses to CS. Fatty acid composition of liver, kidney, heart and brain were determined after 4 wk of treatment with CS (10 mg/kg•d p.o.) in male borderline hypertensive rats (BHR, n = 4/group), whose diet was supplemented with either safflower oil or evening primrose oil (EPO). Phosphatidylcholine, phosphatidylethanolamine, phosphatidylserine/phosphatidylinositol, triglyceride and cholesteryl ester fatty acids were measured in kidney, heart, brain and liver. The same parameters were also measured in safflower-fed BHR (n = 4) receiving placebo. The effects of CS on liver microsomal Δ9, Δ6 and Δ5 desaturases *in vitro* were also followed. CS affected the fatty acid composition of all tissues examined, with the greatest changes seen in the renal phosphatidylcholine and phosphatidylserine/phosphatidylinositol fractions. All CS-induced changes that occurred in the liver, brain and renal fatty acids were reversed by EPO. CS elevated Δ9 desaturase but had no effect on Δ6 and Δ5 desaturase. In light of (i) the observation that EPO normalizes renal function and blood pressure in CS-treated BHR, and (ii) the importance of the kidney in blood pressure regulation, the data suggest that the beneficial effects of EPO on CS toxicity may involve changes in renal phospholipid fatty acid profiles.

Lipids 29, 27–32 (1994).

The use of the immunosuppressive drug cyclosporine A (CS) following organ transplantation in humans is often accompanied by both elevations in systemic blood pressure (1–6) and renal arteriolar resistance, and reductions in renal plasma flow and glomerular filtration rate (7–11). While it has been difficult to reproduce this combination of hypertension and nephrotoxicity by administering CS in animal models, it has recently been demonstrated in the borderline hypertensive (BHR) rat using moderate doses of CS (12).

The mechanisms by which CS administration causes hypertension and nephrotoxicity are not fully understood, and it is not known whether CS-induced hypertension is secondary to, or independent of, CS nephrotoxicity. The alteration of renovascular eicosanoid production by CS is one of the postulated mechanisms through which CS may exert its cardiovascular and renal actions. CS has been shown to enhance production of thromboxane A_2 and prostaglandin E_2, as well as to alter prostacyclin synthesis (13–16). Acute CS nephrotoxicity has been reversed by the administration of both thromboxane synthetase inhibitors (17,18) and a prostaglandin E_1 analogue (19).

The ability of dietary fish oils (high in eicosapentaenoic acid, 20:5n-3) and evening primrose oil (EPO; high in γ-linolenic acid, 18:3n-6) to reduce CS-related nephrotoxicity and hypertension may also involve alterations in renal eicosanoid metabolism (12,20,21). High levels of dietary eicosapentaenoic acid lead to a replacement of arachidonic acid (20:4n-6), the precursor of the 2-series prostaglandins, with eicosapentaenoic acid in tissue phospholipids (PL), reducing the amount of substrate available for arachidonic acid-derived eicosanoid synthesis (22,23). The endogenous synthesis of n-3 and n-6 polyunsaturated fatty acids has several rate-limiting steps, namely the Δ6 and Δ5 desaturases which convert 18:2n-6 to 18:3n-6 and 20:3n-6 to 20:4n-6, respectively. As the activities of these enzymes may be affected by certain physiological and/or pathological conditions (24), bypassing these rate-limiting steps through dietary supplementation with γ-linolenic acid, which increases tissue PL levels of its metabolite, dihomo-γ-linolenic acid (the direct precursor for prostaglandin E_1) (25–27), may potentially alter the balance of 1-series and 2-series eicosanoids. It is also possible that CS may alter tissue fatty acid composition and/or metabolism, thereby altering the amount of substrate available for eicosanoid production, and that dietary γ-linolenic acid attenuates CS toxicity by normalizing tissue fatty acid composition.

The purpose of the present study was to examine the effects of (i) CS and EPO on tissue fatty acid composition and (ii) CS administration on the activities of liver microsomal Δ6, Δ5 and Δ9 desaturase enzymes in the genetically BHR.

MATERIALS AND METHODS

Animals. Male BHR, the F_1 offspring of the cross between male Wistar Kyoto and female spontaneously hypertensive rats, were used in these studies. Animals were bred at the University of Waterloo animal facility (21 ± 1°C, 12L/12D) and weaned at 24 d of age onto chow (No. 5001; Ralston Purina, St. Louis, MO) and tap water *ad libitum.*

Protocol. At 36 d of age, rats were randomly assigned into groups (n = 4/group) receiving chow supplemented with 10% (total calories) of either safflower oil (SAF, 2 groups), high in linoleic acid (62% 18:2n-6) or EPO (Efamol Ltd., Guildford, United Kingdom), high in linoleic and γ-linolenic acids (72% 18:2n-6 and 9% 18:3n-6) for 5 wk. One week after being placed on the test diets, one SAF-fed group and the EPO-fed group were administered CS (Sandoz Canada, Dorval, Quebec) at a dose of 10 mg/kg•d p.o. in 0.1 mL olive oil vehicle for 4 wk. The second SAF-fed group received a CS placebo (PLAC; Sandoz Canada, Dorval, Quebec) in 0.1 mL olive oil. All animals were treated

Abbreviations: BHR, borderline hypertensive rat; CE, cholesteryl ester; CS, cyclosporine A; EPO, evening primrose oil; PC, phosphatidylcholine; PE, phosphatidylethanolamine; PI, phosphatidylinositol; PL, phospholipids; PLAC, CS placebo; PS, phosphatidylserine; SAF, safflower oil; TG, triglyceride.

once daily between 0930–1030 h. As CS in high doses has been reported to reduce body weight gain in experimental animals, the groups receiving CS/EPO (CS treatment and EPO-supplemented diet) and PLAC/SAF (PLAC treatment and SAF-supplemented diet) were pair-fed to the CS/SAF group (CS treatment and SAF-supplemented diet), which was fed *ad libitum*. At the end of the treatment period, liver, kidneys, heart and brain were removed from halothane-anesthetized animals, frozen in liquid nitrogen and stored at −85°C for tissue fatty acid analaysis.

In a second study, eleven male BHR of 36 d of age were placed on SAF-supplemented chow diets and administered either PLAC (n = 5) or CY (n = 6) for 4 wk, as described above. At the end of the treatment period, systolic blood pressure measurements were made on conscious animals, using the tail-cuff method (28). Livers were then removed as described above, quickly rinsed in cold saline (0.9% NaCl) and frozen in liquid nitrogen for later isolation of microsomes and measurement of *in vitro* microsomal Δ9, Δ6 and Δ5 desaturase activities.

Fatty acid analysis. Lipids were extracted from approximately 1.5 g tissue with chloroform/methanol (2:1, vol/vol), as previously described (28). Total PL, phosphatidylcholine (PC), phosphatidylethanolamine (PE), phosphatidylserine/phosphatidylinositol (PS/PI), triglyceride (TG) and cholesteryl ester (CE, liver only) fractions were then separated by thin-layer chromatography and subsequently transmethylated with BF_3-methanol (29). The fatty acid methyl esters were analyzed on a Perkin Elmer gas chromatograph (model 8420; Norwalk, CT) equipped with a flame-ionization detector and a 30-m capillary column (Supelcowax 10; Supelco, Bellefonte, PA). The temperature was programmed to be held for 2 min at 180°C, followed by a 2°C/min increase to 220°C, and a 2 min hold at 220°C. Fatty acids were identified by comparison of their retention time with those of known standards.

Measurement of desaturase activity. Microsomes were prepared from 5 g liver tissue within 24 h of freezing, as previously described (30), and stored at −80°C until analysis. The activities of Δ9, Δ6 and Δ5 desaturases were determined by measuring the conversion of [1-^{14}C]-palmitic acid (16:0) to [1-^{14}C]palmitoleic acid (16:1n-7), of [1-^{14}C]linoleic acid to [1-^{14}C]γ-linolenic acid and of [1-^{14}C]dihomo-γ-linolenic acid to [1-^{14}C]arachidonic acid, respectively. Reactions were started by adding microsomal protein (5 mg) to pre-incubated tubes containing 25 μCi of the substrate fatty acid at a final concentration of 53.3 μM in 1.5 mL of the incubation solution, containing ATP (1.30 mM), NADH (0.87 mM) and coenzyme A (0.06 mM) as previously described (31). The tubes were vortexed vigorously and, after 15 min incubation in a shaking water bath (37°C), the reactions were stopped by the addition of 2 mL 10% (wt/vol) KOH in ethanol. Lipids in the incubation mixture were saponified at 80°C for 45 min under N_2. After acidification, fatty acids were extracted with hexane. Radiolabelled fatty acids were analyzed according to the method of Narce *et al.* (32). Analyses were carried out in a high-performance liquid chromatograph (model 510 pump and 712 WISP autosampler; Waters, Milford, MA) equipped with a variable wavelength UV-vis monitor (model 450, set at 205 nm) and a radioisotope detector (model 171; Beckman, Fullerton, CA). Fatty acids were separated isocratically with acetonitrile/water (95:5, vol/vol) at a flow rate of 1 mL/min and were identified by comparison with authentic standards.

Statistics. Fatty acid composition data across the three treatment groups were analyzed in each tissue using a one-way analysis of variance. Where a significance of $P < 0.05$ was achieved, specific group differences were evaluated using the Student Newman-Keuls test. Blood pressure and desaturase activity data from the two treatment groups were analyzed using the Student's *t*-test.

RESULTS

Body weight gain did not significantly differ among the treatment groups in this study (data not shown).

Effects of CS and diet on tissue fatty acid composition. CS supplementation of SAF-fed animals did not affect fatty acid composition (% total fatty acids) of the hepatic total PL, TG, PS/PI, PC or the CE fraction (data not shown). However, EPO feeding of CS-treated animals affected the levels of several fatty acids independent of CS. Specifically, EPO feeding increased 18:1n-7 ($P < 0.001$) and decreased 18:3n-3 ($P < 0.05$) in the total PL fraction, decreased 18:0 ($P < 0.01$) in the PC fraction, and decreased 18:0 ($P < 0.01$), 18:2n-6 ($P < 0.001$), and 22:5n-3 ($P < 0.05$) in the CE fraction *vs.* the CS/SAF group (data not shown). In contrast, in the PE fraction (Table 1), administration of CS to SAF-fed rats significantly increased 16:0 ($P < 0.05$), 18:1n-9 ($P < 0.01$), and 18:2n-6 ($P < 0.05$) *vs.* PLAC. These changes were reversed by the presence of dietary EPO with CS. EPO-feeding also independently decreased 18:0 and 20:4n-6 ($P < 0.05$) *vs.* CS/SAF in this fraction.

In the kidney, CS administration to SAF-fed animals significantly altered fatty acid levels in several lipid fractions *vs.* the PLAC/SAF group (Table 2). Specifically, CS increased 18:2 ($P < 0.05$) in the TG fraction, increased 16:0 ($P < 0.001$) and decreased 20:4n-6 ($P < 0.01$) in the PS/PI fraction, and decreased 18:0 ($P < 0.05$) and 18:1n-9 ($P < 0.01$) in the PC fraction. All of these changes were reversed by feeding EPO to CS-treated animals, restoring their

[a]$P < 0.05$ *vs.* PLAC/SAF, [b]$P < 0.01$ *vs.* PLAC/SAF, [c]$P < 0.001$ *vs.* PLAC/SAF, [d]$P < 0.05$ *vs.* CS/SAF. [e]$P < 0.001$ *vs.* CF/SAF. See Table 1 for abbreviations.

levels to those of the PLAC/SAF group (Table 2). EPO feeding also independently increased 20:3n-6 ($P < 0.05$) in total PL (data not shown) and 20:3n-6 and 22:6n-3 ($P < 0.05$) in kidney TG (Table 2), and increased 18:0 and 22:4n-6 ($P < 0.05$) in the PS/PI fraction *vs.* CS/SAF (data not shown).

In cardiac tissue, CS administration to SAF-fed rats increased 20:4n-6 ($P < 0.05$) *vs.* PLAC/SAF in the total PL, decreased 18:1n-9 ($P < 0.05$) and increased 20:4n-6 and 22:6n-3 ($P < 0.05$) in the PE fraction. It also increased 16:0 ($P < 0.001$), 18:1n-9 and 18:1n-7 ($P < 0.05$) and decreased 20:4n-6 ($P < 0.05$) in the PC fraction (Table 3). CS administration also decreased 18:0 ($P < 0.001$) and 18:1n-9 ($P < 0.01$) and increased 18:1n-7 ($P < 0.01$), 20:4n-6 ($P < 0.05$) and 22:6n-3 ($P < 0.001$) *vs.* PLAC in the PS/PI fraction. Due to a loss of samples from the CS/EPO group of this fraction, only the SAF-fed groups are reported. EPO-feeding of CS-treated animals did not reverse the effects of CS administration (with the exception of 18:1n-9 in the PC fraction). EPO independently decreased 18:1n-9 ($P < 0.01$) and increased 20:3n-6 ($P < 0.05$) in the total PL and TG, respectively (data not shown).

In the brain, CS administration significantly increased 20:5n-3 ($P < 0.05$) in brain TG, and increased 18:0, 18:1n-9 ($P < 0.01$), and 18:1n-7 ($P < 0.05$) in the PE fraction *vs.* PLAC/SAF (Table 4). EPO feeding to CS-treated animals reversed the CS effects on 20:5n-3 in the TG fraction, and 18:0 and 18:1n-9 in the PE fraction. EPO feeding also increased 16:0 ($P < 0.01$) in the TG fraction. EPO feeding had independent effects on brain fatty acid composition in other fractions, decreasing 18:0 ($P < 0.05$) *vs.* CS/SAF in total PL, and decreasing 20:3n-6, 20:4n-6, 22:4n-6 ($P < 0.05$), and 22:6n-3 ($P < 0.001$) in the PC fraction (data not shown).

Blood pressure in PLAC and CS-treated BHR. After 4 wk of treatment, conscious resting blood pressure in SAF-fed rats was higher in the group receiving CS than in those receiving PLAC (152 ± 2 mm Hg *vs.* 134 ± 1 mm Hg, $P < 0.001$).

Liver desaturase activities. The effects of CS on liver microsomal Δ9, Δ6 and Δ5 desaturase activities are shown in Figure 1. CS significantly elevated the activity of Δ9

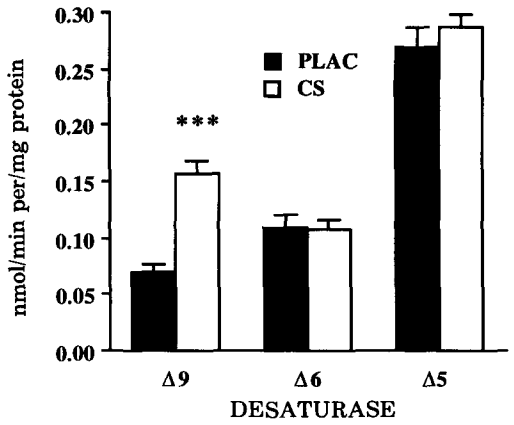

FIG. 1. ***In vitro*** **activities (nmol/min•mg protein) of liver microsomal Δ9, Δ6 and Δ5 desaturase enzymes following 4 wk of treatment with either cyclosporine A (CS) (10 mg/kg•d p.o.) or placebo (PLAC) (n = 5/group) in borderline hypertensive rats fed safflower oil. Values are $\bar{X}$ ± SE.**

desaturase *vs.* PLAC by 124%, but had no effect on the activities of either Δ6 or Δ5 desaturase.

DISCUSSION

The use of CS as an immunosuppressant in humans has frequently been reported to be accompanied by toxic renal, cardiovascular and psychological side effects, which can limit its usefulness in the clinical setting (33). These undesirable side effects have been reported to be prevented by dietary supplementation with either eicosapentaenoic acid (20:5n-3, in the form of fish oil) or γ-linolenic acid (18:3n-6, in the form of EPO) (20,21). As these fatty acids may alter endogenous eicosanoid metabolism, their attenuation of the side effects of CS may involve alterations of tissue eicosanoid metabolism (Scholey and Mills, unpublished observation).

The present study demonstrated that, in the BHR, chronic administration of CS was accompanied by significant changes in the fatty acid composition of PL in a variety of tissues, most often affecting the 16 and 18 carbon fatty acids.

A second finding of the study was that the substitution of EPO for SAF in the diet of animals treated with CS led to a normalization of PL fatty acid composition in almost every case in the liver and kidney, so that the fatty acid levels were similar to those of the PLAC/SAF treatment group. In addition to reversing the changes in PL fatty acid composition brought about through CS administration, dietary EPO itself appeared to affect fatty acid composition in liver, heart and kidney. Of particular interest in this regard are (i) the increase in 20:3n-6, a precursor for prostaglandin E_1 and other eicosanoids, seen in the TG fractions of kidney and heart and in the PL of kidney and liver, and (ii) the decrease in 20:4n-6 seen in liver PE. TG stores of the renal medulla have been shown to be a source of fatty acids for prostaglandin synthesis (34). Increased 20:3n-6 levels in this fraction may, through their role as eicosanoid substrates, shift the balance of prostanoid production in the renal medulla. While not conclusive, the present results are supportive of the theory of fatty acid and eicosanoid involvement in CS-induced nephrotoxicity as well as a renal component in CS-induced hypertension. The normalization of renal PL fatty acid composition by dietary EPO may also contribute to its ability to alleviate CS-induced nephrotoxicity and hypertension.

The level of Δ6 desaturase activity observed in the prsent study is similar to that previously reported in Wistar rats of a similar age at a similar time of the year (35). The absence of an effect of CS on the *in vitro* activity of liver microsomal Δ6 and Δ5 desaturases in the present study suggests that CS-induced changes in tissue fatty acid composition do not involve alterations of the rate-limiting steps in essential fatty acid metabolism. This is consistent with an absence of changes in Δ6 and Δ5 desaturated n-6 and n-3 fatty acids in the liver of CS-treated rats. The activity of Δ9 desaturase that we observed in the control, PLAC, group was lower than that previously reported for Wistar rats of a similar age at a similar time of the year (35). Whether this discrepancy between the two studies is due to differences in the strains of rat used is unknown. However, the activity observed in the present study is within the range previously observed across the seasons of the year (35). Nonetheless, despite a significant increase in the *in vitro* activity of liver microsomal Δ9 desaturase caused by CS, this was not reflected in the fatty acid composition of total lipid extracts from livers from CS-treated rats. This suggests that CS-induced changes in tissue lipids may involve other aspects of fatty acid metabolism, *e.g.*, incorporation into and/or removal from tissue PL.

It has been suggested that CS nephrotoxicity may reflect a renal transmembrane signalling disorder and that this defect in signal transduction may result in an enhanced vasoconstriction in the whole kidney (36). CS administration has been observed to increase both basal and stimulated cytosolic calcium levels in both mesangial and vascular smooth muscle cells in culture (37-39), a process that involves the activation of phospholipase C and a subsequent inositol triphosphate-mediated release of calcium from intracellular stores, followed by a calcium influx from the external environment (40,41). Furthermore, CS has been shown to inhibit the release of 20:4n-6 from the PL fraction in isolated glomeruli and endothelial cell preparations (35,42,43), an effect which may reduce the avaiability of vasodilatory prostaglandins. It is possible that the alteration of renal PS/PI fatty acid composition following CS administration may contribute to this process, and that the normalization of the serine/inositol PL fatty acid composition, as well as the increase in TG 20:3n-6, by EPO may partially explain its attenuation of CS nephrotoxicity and hypertension.

ACKNOWLEDGMENTS

This work was supported by an operating grant from the Natural Sciences and Engineering Research Council of Canada to D. Mills, and operating grants from the Medical Research Council of Canada and the Kidney Foundation of Canada to J. Scholey. Dr. Scholey was a Scholar of the Kidney Foundation of Canada and the Pharmaceutical Manufacturers Association of Canada. The authors would like to thank Sandoz Canada and Efamol Ltd., for the generous donations of CS and EPO, respectively, which were used in this study.

Effects of Dietary Protein and Cholesterol on Phosphatidylcholine and Phosphatidylethanolamine Molecular Species in Mouse Liver

Kazunori Koba, Linda A. Rozee, David F. Horrobin and **Yung-Sheng Huang***
Efamol Research Institute, Kentville, Nova Scotia, B4N 4H8 Canada

The present study examined the effects of two atherogenic factors, animal protein and cholesterol, on the distribution of fatty acids and the molecular species of major liver phospholipids in mice. Weanling mice were fed a semisynthetic diet supplemented with either casein or soy protein (20%, w/w) in the presence or absence of 0.5% cholesterol for 4 wk. Results from mouse liver showed that animal protein and, more so, dietary cholesterol modified the fatty acid profiles of the phospholipids. Animal protein had no significant effect on the concentration of lipids, but it altered the relative distribution and fatty acid profiles of the phospholipids, phosphatidylcholine and phosphatidylethanolamine. Dietary cholesterol, on the other hand, significantly increased the concentration of liver lipids, but it did not alter the relative distribution of phosphatidylcholine and phosphatidylethanolamine. In cholesterol-fed mice, the proportions of molecular species containing 18:2n-6 were increased, whereas those containing 20:4n-6 were decreased, indicating that dietary cholesterol suppressed linoleic acid metabolism. Since cholesterol feeding selectively decreased the ratio of 18:0/20:4n-6 in phosphatidylcholine, whereas it increased the 18:0/18:2n-6 ratio in phosphatidylethanolamine, this finding suggests that dietary cholesterol may affect the incorporation of fatty acids but not the rate of synthesis of phosphatidylcholine and phosphatidylethanolamine.
***Lipids* 29, 33-39 (1994).**

In several experimental animals, dietary animal protein and cholesterol (CHOL) are both known to be atherogenic, but they influence fatty acid metabolism differently (1). In rats, dietary supplementation with animal protein, in comparison with vegetable protein, increases the activity of Δ6 desaturase in liver microsomes (2-6), and the ratio of 20:4n-6/18:2n-6 in liver phospholipids (PL) (2-8). CHOL feeding, on the other hand, suppresses the metabolism of n-6 fatty acids (9-12). Since the effective conversion of 18:2n-6 to long-chain n-6 fatty acids is essential to the CHOL-lowering effect of dietary polyunsaturated fatty acids (PUFA, mainly 18:2n-6) (13-15), it is paradoxical that these two atherogenic factors (animal protein and CHOL) affect the metabolism of linoleic acid in such a divergent fashion.

The interaction of CHOL, protein and PUFA has previously been examined in rats. Since rats, in comparison with other animal species, have active linoleic acid metabolism, it is of interest to examine whether the above-mentioned interactions also take place in other species with less active linoleic acid metabolism.

It is known that enzymes that are responsible for linoleic acid metabolism are associated with microsomal membranes and that PL constitute the major components of membranes. We examined in the present study whether dietary CHOL and protein would affect the molecular species of two major PL fractions in liver microsomes in C57BL/6 mice. This animal species, like the human, has a relatively low rate of linoleic acid metabolism (16) and is susceptible to CHOL feeding (17).

MATERIALS AND METHODS

Chemicals. Cold-pressed safflower oil (containing 6.8%, 16:0; 2.6%, 18:0; 12.3%, 18:1n-9; and 77.1%, 18:2n-6) and linseed oil (containing 5%, 16:0; 3.6%, 18:0; 23.3%, 18:1n-9; 14.2%, 18:2n-6; and 53.5%, 18:3n-3) were purchased from a local health food store. CHOL and phospholipase C (*Bacillus cereus*, Type III) were supplied by Sigma Chemical Co. (St. Louis, MO). Highly purified casein (CAS, 89% protein and 0.06% lipids), soy protein isolate (SOY, containing 89% protein and 0.4% lipids), vitamin mix (AIN-76), mineral mix (AIN-76), cellulose and corn starch were obtained from Teklad Test Diets (Madison, WI). All solvents were of high-performance liquid chromatography (HPLC) grade and were supplied by Fisher Scientific (Nepean, Ontario, Canada).

Animals and diets. Twenty weanling male C57BL/6 mice (3-week-old), purchased from Charles River Breeding Laboratories (Montreal, Quebec, Canada), were given free access to a CHOL-free diet consisting (by weight percent) of CAS, 21.8; fat mixture, 2.0; cellulose, 5.4; DL-methionine, 0.3; mineral mix, 3.8; vitamin mix, 1.1; calcium carbonate, 0.08; and sucrose, 65.5. After 7 d of acclimatization, the mice were divided into four groups (five animals each), which received different dietary proteins: CAS or SOY, with or without an additional 0.5% (w/w) CHOL. The animals were maintained *ad libitum* on the assigned diets for 2 wk. The details of the diets, prepared according to the formula recommended by the American Institute of Nutrition (18), are shown in Table 1. The dietary fat was a 72:28 (w/w) mixture of safflower oil and linseed oil to give an n-6/n-3 ratio of 3.9 (Table 1). At the end of the study, mice were lightly anesthetized with diethyl ether and sacrificed by exsanguination through cardiac puncture. The liver was excised immediately and frozen at −80°C prior to extraction.

Lipid analysis. Total liver lipids were extracted by the method of Folch *et al.* (19). The concentrations of liver CHOL were measured by gas-liquid chromatography (GLC) (9), and liver PL were quantified by phosphorus content following the method of Rouser *et al.* (20). Phosphatidylcholine (PC), phosphatidylserine (PS), phosphatidylinositol (PI), phosphatidylethanolamine (PE), sphingomyelin and lysophospholipids were separated by thin-layer chromatography using chloroform/ethanol/water/triethylamine (4:5:1:5, by vol) as the developing solvent. The

[b]A mixture of safflower oil and linseed oil (72:28, w/w), containing 6.3%, 16:0; 2.8%, 18:0; 15.3%, 18:1n-9; 59.7%, 18:2n-6; and 15.4%, 18:3n-3. The n-6/n-3 ratio was 3.9.
[c]—, not added in the diet.

distribution of PL classes was determined by their phosphorus content (19). The fatty acid composition of liver PC and PE was determined by GLC after transmethylation with BF_3 methanol (21).

For separation of molecular species, approximately 1 mg of either PC or PE in diethyl ether (2 mL) was incubated for 3 h at room temperature with 1 mg of phospholipase C (*Bacillus cereus,* Type III) in 2 mL of 0.5 M tris buffer (pH 7.5) and 2 mM calcium chloride (22). The resultant mixture of diacylglycerols was acetylated with acetic anhydride/pyridine (1:2, vol/vol) at 37°C for 1 h (23). The solution was taken to dryness, and the residue was redissolved in acetonitrile. The molecular species were separated by reverse-phase HPLC on a Zorbax ODS column (250 mm × 4.6 mm, i.d.) (DuPont Co., Wilmington, DE), using an isocratic solvent system of acetonitrile/2-propanol/methyl *t*-butyl ether/water (72:18:8:2, by vol) at a flow rate of 0.5 mL/min)24). For identification of molecular species in each fraction, the fractions detected at 205 nm with a variable wavelength detector (Diode Array Detector Module 168; Beckman, Palo Alto, CA) were collected, and the fatty acid composition was determined by GLC (21). The distribution of peaks was assessed using a mass (light-scattering) detector (ACS Model 740/14; Applied Chromatography Systems, Macclesfield, United Kingdom). The detailed distribution and identification of PL molecular species (in the form of acetylated diacylglycerol) co-eluted in the same fraction were determined based on a computer program similar to that described previously (25). Briefly, it is based on random probability using the fatty acid composition of the purified PL fraction and on the retention times, which reflect the equivalent chain lengths. Figure 1 shows typical HPLC chromatograms.

Statistical analysis. Data were expressed as mean ± SD of five animals. Statistical analyses were performed using analysis of variance through a computer statistical system, SYSTAT (26). The 2 × 2 factorial analysis determining the protein and CHOL effects and interactions

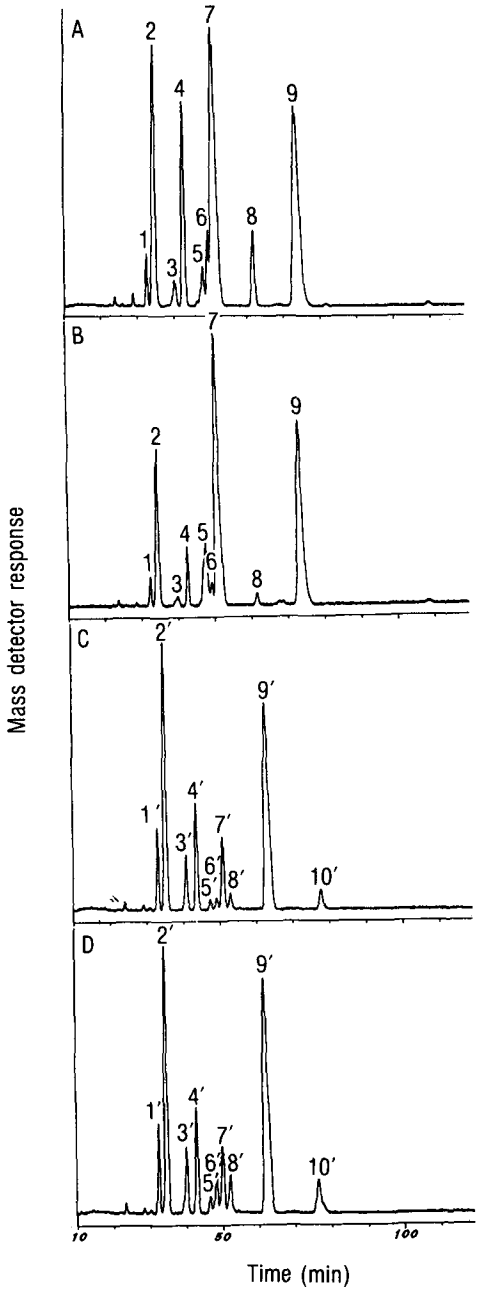

FIG. 1. Typical high-performance liquid chromatography chromatograms of liver phosphatidylcholine (panels A and B) and phosphatidylethanolamine (panels C and D) molecular species in mice fed a casein diet without (panels A and C) or with (panels B and D) 0.5% cholesterol. In panels A and B, fraction 1 contains 16:0/20:5n-3 and 18:1/22:6n-3; fraction 2 contains 16:0/22:6n-3, 16:1/18:2n-6, 18:2n-6/18:2n-6 and 16:1/20:3n-6; fraction 3 contains 18:1/20:4n-6, 16:0/22:5n-3 and 16:0/18:3n-6; fraction 4 contains 16:0/20:4n-6; fraction 5 contains 18:1/18:2n-6, 18:1/20:3n-6, 16:0/16:1 and 16:1/18:1; fraction 6 contains 18:0/22:6n-3; fraction 7 contains 16:0/18:2n-6 and 16:0/20:3n-6; fraction 8 contains 18:0/20:4n-6; and fraction 9 contains 18:0/18:2n-6, 16:0/18:1 and 18:0/20:3n-6. In panels C and D, fraction 1′ contains 18:1/22:6n-3 and 16:0/20:5n-3; fraction 2′ contains 16:0/22:6n-3; fraction 3′ contains 18:1/20:4n-6 and 16:0/22:5n-3; fraction 4′ contains 16:0/20:4n-6; fraction 5′ contains 18:0/20:5n-3 and 16:0/22:5n-6; fraction 6′ contains 18:1/18:2n-6, 16:0/16:1 and 18:1/20:3n-6; fraction 7′ contains 18:0/22:6n-3; fraction 8′ contains 16:0/18:2n-6, 18:0/18:3n-3, 16:1/18:1 and 16:0/20:3n-6; fraction 9′ contains 18:0/20:4n-6; and fraction 10′ contains 18:0/18:2n-6, 18:0/20:3n-6, and 16:0/18:1.

between dietary protein and CHOL was followed by the least-square mean multiple comparison to identify the dietary group differences.

RESULTS

Body and liver weight. Table 2 shows that there were no significant differences between dietary groups in either the initial or the final body weights, or the relative liver weights at the time of killing. The concentrations of PL and CHOL and the CHOL/PL ratio in liver were not affected by different dietary protein sources but were increased significantly by CHOL supplementation. However, the PL distribution was modulated by both dietary protein and CHOL. CAS, as compared to SOY, increased the proportion of liver PC, whereas it decreased that of PI, independent of CHOL feeding. Dietary CHOL decreased the proportion of PE whereas PS was increased in both protein groups. The PC/PE ratio was higher ($P = 0.016$) in mice fed the CAS diets than in those fed the SOY diets.

Fatty acid profiles of liver PL. In liver, PC and PE represent the two major PL classes. Hence, we have chosen to report only the changes in these two PL fractions. Table 3 shows the fatty acid composition of liver PC. CHOL feeding significantly increased the proportion of 18:2n-6, whereas it decreased those of 20:4n-6 and 22:6n-3. As a result, CHOL feeding depressed significantly the ratios of (18:3n-6 + 20:3n-6 + 20:4n-6)/18:2n-6 and of 20:4n-6/20:3n-6. Dietary protein, on the other hand, had little

[b]—, Not statistically significant.

effect on the distributin of fatty acids except for slight changes in the proportions of 18:3n-6 and 22:5n-3.

Table 4 shows the fatty acid composition of liver PE. CHOL feeding significantly affected the distribution of all fatty acids. The proportions of 18:1, 18:2n-6 and 20:3n-6 were increased, and those of 20:4n-6 and 22:6n-3 were reduced. Thus, CHOL feeding significantly depressed the ratio of (20:3n-6 + 20:4n-6)/18:2n-6 and 20:4n-6/20:3n-6. Dietary protein decreased the proportions of 16:1, whereas it increased those of 22:5n-3 and 22:6n-3. However, no dietary protein-dependent changes of the ratios of (20:3n-6 + 20:4n-6)/18:2n-6 and 20:4n-6/20:3n-6 were observed in liver PE.

Molecular species of liver PL. The distribution of molecular species in liver PC is shown in Table 5. Among the 18:2n-6 containing molecular species, the proportion of 16:0/18:2n-6, the major molecular species in liver PC, was significantly elevated in mice fed the CAS + CHOL as compared to that in those fed the CAS diet. The same trend was also observed between the SOY and the

[b]—, Not statistically significant.

SOY + CHOL groups. CHOL feeding also increased the proportions of 18:1/18:2n-6 and 18:2n-6/18:2n-6, but it did not affect the proportion of 18:0/18:2n-6. The latter was significantly higher in the CAS than in the SOY groups, independent of CHOL feeding.

The proportions of 20:3n-6 containing molecular species were generally higher in the CHOL-fed groups than in the CHOL-free groups. The difference was more pronounced in mice fed the SOY diet than the CAS diet. On the other hand, CHOL feeding decreased significantly the proportion of molecular species containing 20:4n-6 (16:0/20:4n-6 and 18:0/20:4n-6) and 22:6n-3 (16:0/22:6n-3 and 18:0/22:6n-3) irrespective of the source of dietary proteins.

In the liver PE fraction, the major PUFA were 20:4n-6 and 22:6n-3 (Table 4), and, as expected, the major molecular species contained 20:4n-6 or 22:6n-3 (Table 6). The relative proportions of the molecular species, 18:0/20:4n-6 and 18:1/20:4n-6 were not affected by either dietary protein or CHOL, whereas the proportions of molecular species, 16:0/20:4n-6, 16:0/22:6n-3 and 18:0/22:6n-3, were depressed significantly by CHOL feeding.

Among the 18:2n-6 containing molecular species, CHOL feeding increased the proportion of 18:0/18:2n-6 and 18:1/18:2n-6, but not 16:0/18:2n-6. The effect on the proportion of 18:0/18:2n-6 was more evident in mice fed the CAS diets than the SOY diet.

DISCUSSION

It has been reported previously that CAS in comparison with SOY enhanced Δ6 desaturase activity in rats (2–6). However, the results of the present study (Tables 3 and 4) as well as our previous report (27) have shown that dietary protein had no significant effect on fatty acid profiles in mice: the ratios of 20:4n-6/18:2n-6 in liver total PL were comparable between mice fed CAS and those fed SOY. These findings suggest that the response of Δ6 desaturase activity to dietary protein was less significant in mice than in rats. This may be due in part to a significantly lower level of Δ6 desaturase activity in mice than in rats (16).

It is also known that *in vivo* CHOL feeding suppressed the microsomal Δ6 desaturase activity in rat liver (28,29). Leikin and Brenner (30,31) have shown that desaturase activity in liver microsomes is affected by the ratios of CHOL/PL and PC/PE. Since *in vivo* CHOL feeding increased the CHOL/PL ratio in both rat (29) and mouse liver (Table 2), the inhibitory effect of CHOL feeding on linoleic acid metabolism in both rats and mice could be related to an increase in the CHOL/PL ratio (32). On the other hand, the inhibitory effect could not be related to a specific modulation of PC synthesis, since CHOL feeding increased the proportion of PC and the PC/PE ratio in rat liver (29) but not in mouse liver (Table 2). An alternative explanation for the inhibitory effect of dietary CHOL on Δ6 desaturase activity is that it might modify PC and PE fatty acid profiles in microsomal membranes, since the degree of unsaturation of PC and PE might modulate the enzyme activity in liver microsomes.

In rat liver PL, saturated fatty acids (16:0 and 18:0) are mainly located at the *sn*-1 position, and mono- and polyunsaturated fatty acids at the *sn*-2 position (33). In mice, the major saturated fatty acids in liver microsomal PC

and PE were also 16:0 and 18:0 (Tables 3 and 4). The major PUFA in PC were C_{18} and C_{20}, and in PE were C_{20} and C_{22} (Tables 5 and 6). To compare the level of incorporation of PUFA into 16:0 and 18:0 containing molecular species in PC and PE, we have calculated the relative distribution of PUFA in 16:0 and 18:0 containing molecular species. Table 7 shows that the ratio of 16:0-containing to 18:0-containing molecular species in liver PC ranged from 2 to 5. This finding indicated that molecular species in liver microsomes containing either type of PUFA were approximately two to five times more likely to also contain 16:0 than 18:0. In the PE fraction, the ratio of 16:0-containing to 18:0-containing molecular species ranged from 0.3 to 1.0 when 18:2n-6, 20:3n-6, 20:4n-6 or 20:5n-3 was also present in the same molecule (Table 7). This result suggests that C_{18} and C_{20} PUFA were incorporated preferentially into PE molecular species containing 18:0 rather than 16:0. However, not all PUFA behave the same way. The ratios of 16:0-containing to 18:0-containing molecular species in PC and PE ranged from 2 to 5 when 22:6n-3 was also present in the same molecule, suggesting that C_{22} PUFA was incorporated preferentially into PC and PE molecular species containing 16:0 rather than those containing 18:0. These observations are also in consistence with the report that the total carbon number of fatty acids in different PE molecular species is around 38, and that in PC molecular species is 36 to 38 (34).

CHOL feeding increased the ratio of 16:0-containing to 18:0-containing molecular species in liver PC, particularly in those containing 20:4n-6. Since CHOL feeding lowered the proportions of 20:4n-6 in both 16:0- and 18:0-containing molecular species, the increased ratio of 16:0-containing to 18:0-containing molecular species was attributed to a greater decrease of 18:0-containing molecular species. Similarly, CHOL feeding suppressed the proportion of 22:6n-3-containing molecular species in both PC and PE (Tables 5 and 6). CHOL feeding also reduced the proportion of 18:0/22:6n-3 molecular species to a greater extent than that of 16:0/22:6n-3 (Table 7).

In order to examine whether there exists any specific pattern in the distribution of common molecular species between PC and PE, and whether this pattern was modulated by dietary protein or CHOL feeding, we have also calculated the relative distribution of common molecular species in both PC and PE fractions. Table 8 shows that PC, as compared to PE, contained a greater proportion of molecular species containing 18:1, 18:2n-6 and 20:3n-6. The molecular species, such as 16:0/20:4n-6 and 16:0/20:5n-3, were evenly distributed between PC and PE, whereas 18:0/20:4n-6 and molecular species containing 22:6n-3 constituted a greater proportion in PE than in PC. Dietary protein did not affect the relative distribution of common molecular species in PC and PE. However, CHOL feeding decreased the relative distributions of molecular species containing 20:4n-6, 20:5n-3 and 22:6n-3, and those of 18:0/18:2n-6 in PC and PE. The reduction was due to either an increase in the proportions of the PE fraction, such as 18:0/18:2n-6 and 16:0/20:5n-3, or a decrease in the PC fraction, such as 16:0/20:4n-6. Thus, CHOL feeding affects differently the incorporation of long-chain PUFA into PL classes (PC and PE).

In summary, the results of the present study on mouse liver show that CHOL feeding inhibited linoleic acid metabolism without affecting the concentration of PC, whereas animal protein raised the relative concentration of PC in total PL, but exerted little or no effect on linoleic acid metabolism. CHOL feeding, and to a lesser extent animal protein, affected the constituent molecular species of the PC and PE fractions that were characteristically different. The CHOL-induced effect is probably expressed through modulation of the incorporation of long-chain PUFA into PC and PE which, in turn, changes the physical properties of the microsomal membrane.

Effect of Dietary Fish Oil on Blood Levels of Free Fatty Acids, Ketone Bodies and Triacylglycerol in Humans

Pieter C. Dagnelie[a,*,1], Trinette Rietveld[a], G. Roelof Swart[a], Theo Stijnen[b] and J. Willem O. van den Berg[a]

[a]Institute of Internal Medicine II and [b]Department of Epidemiology and Biostatistics, Erasmus University of Rotterdam, 3000 DR Rotterdam, The Netherlands

Although the reduction of serum triacylglycerol concentrations by dietary fish oil is a well-known effect, the exact mechanism of this effect has not been previously studied in human subjects. Therefore, the aim of this study was (i) to examine the effect of short-term fish oil supplementation on blood concentrations of ketone bodies, free fatty acids and triacylglycerol in healthy humans and (ii) to verify whether the observed relationships between these variables would be consistent with reduced lipolysis and/or enhanced hepatic fatty acid oxidation after fish oil supplementation. Twenty subjects (21–23 years, normal liver function tests) were randomly divided into two groups to supplement their usual diet with either 30 g/d of fish oil (n = 11) or olive oil (n = 9). Venous blood samples were drawn after an overnight fast, before and after 1, 3 and 7 d of fish oil/olive oil supplementation. Blood concentrations of triacylglycerol and free fatty acids decreased consistently after fish oil supplementation; the reduction was already significant after one day of fish oil ($P < 0.001$ for triacylglycerol and $P = 0.01$ for free fatty acids). In contrast, neither of these blood values changed after olive oil supplementation ($P > 0.10$). No significant changes in glucose, insulin or ketone body levels were observed in either group after supplementation. After fish oil, but not after olive oil supplementation, the ratio of blood ketone body levels to free fatty acid levels increased significantly ($P < 0.05$). Furthermore, after fish oil supplementation only, free fatty acid levels were significantly correlated with levels of ketone bodies (day 7 of supplementation: $r = 0.90$, $P < 0.001$) and triacylglycerol (maximum value on day 3: $r = 0.77$, $P < 0.01$). These findings suggest that reduced lipolysis and increased hepatic β-oxidation/ketogenesis may contribute to reduced triacylglycerol levels after ω3 fatty acid supplementation in humans. Turnover studies are needed in order to further quantitate these processes.

Lipids 29, 41–45 (1994).

The ω3 fatty acids eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA) in fish oil have aroused increasing interest over the past two decades because of their potential role in the prevention and treatment of cardiovascular disease (1,2). One of the well-described effects of ω3 fatty acids from fish oil on humans is the reduction of serum triacylglycerol concentrations (3–7). The exact mechanism of this effect on humans is unknown. Animal studies have mainly focused upon the inhibitive effects of ω3 fatty acids on very low density lipoprotein (VLDL) formation and secretion (8,9), especially triacylglycerol synthesis (10–15). Recently, it was suggested that a slower formation of plasma VLDL triacylglycerols in rats fed fish oil may be due to a faster rate of hepatic fatty acid oxidation (16). There are also recent animal data suggesting that ω3 fatty acids may reduce lipolysis from adipose tissue, thus limiting the availability of free fatty acids as a substrate for hepatic triacylglycerol formation (17,18).

Although the ultimate goal of animal studies is to gain insight into potential mechanisms of the action of ω3 fatty acids in humans, no human studies on the effect of ω3 fatty acids on lipolysis and ketone body production have been reported so far. Therefore, the aim of the present study was to investigate the effects of dietary fish oil on blood levels of free fatty acids, ketone bodies and triacylglycerol in healthy human subjects, and to verify whether the observed relationships between these variables would be consistent with reduced lipolysis and/or enhanced hepatic fatty acid oxidation after fish oil supplementation.

MATERIALS AND METHODS

Subjects and study design. The study protocol was approved by the Research Ethics Committee of the University Hospital of Rotterdam, and written informed consent was obtained from all subjects prior to the study. Eligible for the study were healthy medical students aged 21–23 yr who were on normal, nonslimming diets with, at most, one meal of fish per week. All subjects had normal liver function tests and took no fish from one week prior to the study and throughout. Twenty-two subjects were randomly distributed over an experimental and a placebo group in a double-blinded fashion. Two subjects from the placebo group did not show up on the first day of the study, leaving eleven subjects in the experimental group and nine in the placebo group. Subjects in the experimental group took 30 g of MaxEPA fish oil per day, containing a total of 9 g ω3 fatty acids per day (EPA, 5.4 g/d; DHA, 3.6 g/d) for 7 d. Subjects in the placebo group took 30 g of olive oil per day during the same period. Capsules of fish oil and olive oil (indistinguishable by addition of peppermint oil and ferrous oxide coloring) were kindly provided by Seven Seas Ltd. (Hull, United Kingdom), and taken as 3 × 10 capsules per day with the main meals.

Measurements. Following an overnight fast of approximately 12 h, subjects came to the laboratory between 8 and 9 a.m., before (day 0) and after supplementation (days 1, 3 and 7). On these days, subjects were weighed, and venous blood samples were drawn from the forearm. Height was measured once preceding the study.

Laboratory analyses. Glucose concentrations in whole blood were determined by an enzymatic assay using an Epos 5060 analyzer (Merck-Eppendorf, Darmstadt, Germany) with reagents from Boehringer (Mannheim, Germany). Triacylglycerol in serum was determined enzymatically on a Chem-1 analyzer (Bayer-Technicon,

*To whom correspondence should be addressed at Institute of Internal Medicine II, Erasmus University of Rotterdam, P.O. Box 1738, 3000 DR Rotterdam, The Netherlands.

[1]P.C.D. is a Fellow of the Royal Netherlands Academy of Arts and Sciences.

Abbreviations: CPT, carnitine palmitoyl transferase; DHA, docosahexaenoic acid; EPA, eicosapentaenoic acid; VLDL, very low density lipoprotein(s).

Tarrytown, New York). Free fatty acids were determined in ethylenediaminetetraacetic acid-treated plasma using an enzymatic colorimetric method (NEFA C test kit; Wako Chemicals, Neuss, Germany). A conversion factor of 0.282 was used (derived from the molecular weight of oleic acid) for conversion of these values (from μmol/L into mg/L). For determination of ketone bodies in whole blood, 4 mL of blood was poured immediately into a glass bottle containing 4 mL ice-cold perchloric acid, and, after neutralization with KOH (19), stored at −20°C until the study was completed. Acetoacetate and β-hydroxybutyrate concentrations were determined according to Mellanby and Williamson (19) and Williamson and Mellanby (20), respectively. Insulin in serum was determined using a commercial radioimmunoassay test kit (Medgenix, Brussels, Belgium).

Compliance. For each subject, the number of capsules taken per day was calculated by pre- and post-weighing supplied capsules, and used as an indicator of compliance.

Statistical analysis. Blood values are expressed as means ± SEM, except for free fatty acids, ketone bodies and the ketone body/free fatty acid ratio. As the latter showed a skewed distribution which best fitted normal distribution after log-transformation, log-transformed data were used for statistical calculations of these parameters, and data for these parameters are presented as geometrical means and range. Changes in blood values within one group were tested for statistical significance using Student's paired *t*-test. Comparison of the effects of fish oil *vs.* olive oil supplementation on blood values was tested after adjustment for baseline values by analysis of covariance. Mean values and 1, 3 and 7 d of supplementation were used for the previously mentioned statistical calculations. For comparing residual variances between groups, the standard F-test was used (21). Changes in residual standard deviation after supplementation within one group were tested by 11 "repeated measurements analysis of variance" using module 5V of BMDP (22). *P* values less than 0.05 were considered statistically significant.

RESULTS

Anthropometric measurements. Baseline values of body weight and height were similar in the fish oil group and the olive oil group. The quetelet index was 21.7 ± 0.6 kg/cm² (mean ± SEM) in the fish oil group and 22.5 ± 1.3 kg/cm² in the olive oil group. No relation between quetelet index and baseline values of any of the measured blood parameters was detected. No significant changes in weight were observed in either group during the study (fish oil group, 0.2 ± 0.1 kg; olive oil group, −0.5 ± 0.3 kg).

Compliance. Participants had been instructed to take 30 g of the provided supplement per day. The estimated "actual" intake ranged from 29–31 g/d in the fish oil group and from 29–32 g in the olive oil group, indicating good compliance.

Blood values. Blood glucose and insulin concentrations did not change systematically after fish or olive oil supplementation (Table 1). Triacylglycerol concentrations decreased by 24% ($P < 0.001$) within 1 d of fish oil supplementation. After 7 d of fish oil supplementation, triacylglycerol had decreased by 46% ($P < 0.001$), as compared to baseline (Table 1). Olive oil supplementation had no significant effect on triacylglycerol levels ($P > 0.10$; Table 1). The effects of fish oil and olive oil supplementation on triacylglycerol levels were significantly different ($P = 0.001$).

Free fatty acid concentrations decreased by 39% ($P = 0.01$) within 1 d of fish oil supplementation and remained significantly depressed at 3 and 7 d of supplementation for each ($P < 0.05$ as compared to baseline; Table 2). In contrast, no significant change in free fatty acid levels was observed after olive oil supplementation ($P > 0.10$). The effects of fish oil and olive oil supplementation on free fatty acid levels were significantly different ($P = 0.03$). No significant changes in ketone body levels were observed after either fish oil or olive oil supplementation ($P > 0.10$; Table 2).

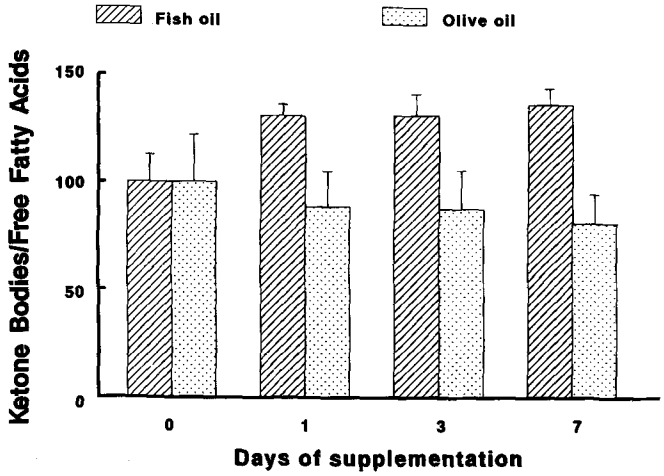

FIG. 1. Ratios of blood ketone body concentrations to plasma free fatty acids before and after 1, 3 and 7 d of fish oil or olive oil supplementation. Healthy human subjects took a daily supplement of either 30 g fish oil (9 g ω3 fatty acids; n = 11) or 30 g olive oil (n = 9). Boxes and bars represent means and SEM, respectively, of logarithmic values (expressed as a percentage of values before supplementation). Significance of change after fish oil supplementation (paired *t*-test of mean value of 1, 3 and 7 d of supplementation *vs.* baseline value), $P < 0.05$; olive oil supplementation, $P > 0.10$. Comparison of the effects of fish oil *vs.* olive oil supplementation (mean values of 1, 3 and 7 d of supplementation, adjusting for baseline values by analysis of covariance), $P = 0.02$.

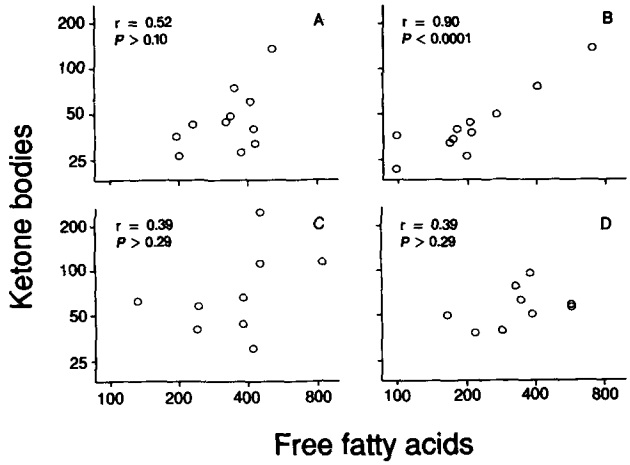

FIG. 2. Blood ketone body concentrations (μmol/L) as a function of plasma free fatty acid concentrations (μmol/L) before and after supplementation with fish or olive oil; (A) before fish oil supplementation, (B) after 7 d of fish oil supplementation, (C) before olive oil supplementation, (D) after 7 d of olive oil supplementation. The methods used are those given in the caption for Figure 1.

Ratios of ketone body levels relative to free fatty acid levels (Fig. 1) increased significantly after fish oil supplementation ($P < 0.05$), but did not change after olive oil supplementation ($P > 0.10$). Again, the effects of fish oil and olive oil supplementation were significantly different ($P = 0.02$).

In Figure 2, ketone bodies are plotted as a function of free fatty acids before and after seven days of supplementation with fish oil or olive oil. No significant correlation between free fatty acid levels and ketone body concentrations was observed in either group before supplementation, or after olive oil supplementation ($P > 0.10$). In contrast, these two parameters were highly correlated after seven days of fish oil supplementation ($r = 0.90$, $P < 0.001$). The residual standard deviation of blood ketone body levels against free fatty acid levels was consistently reduced after seven days of fish oil supplementation ($P \leq 0.01$), and residual standard deviation was significantly lower after fish oil supplementation than after olive oil supplementation (day 7: $P < 0.001$). As the total variation in ketone body levels did not increase after fish oil supplementation (Table 2 and Fig. 2), the increase in correlation between free fatty acid and ketone body levels after fish oil supplementation (and the difference in correlation when compared with olive oil supplementation) was exclusively attributed to a reduction in residual standard deviation after fish oil supplementation.

Free fatty acid levels were not significantly correlated with triacylglycerol concentrations in either group before supplementation or after olive oil supplementation ($P > 0.10$). An increased correlation was observed after seven days of fish oil supplementation which, however, did not reach statistical significance ($r = 0.52$; $P = 0.10$). After three days of fish oil supplementation, the correlation between free fatty acid and triacylglycerol levels was highly significant ($r = 0.77$, $P < 0.01$).

DISCUSSION

Although it is well known that marine ω3 fatty acids reduce serum triacylglycerol concentrations in humans (3-7), the mechanism underlying this effect is not completely understood. Most of the effects described so far, observed in animal models *in vivo* and *in vitro*, were related to reduced production and secretion of triacylglycerol-rich lipoproteins (VLDL) by the liver. Effects of ω3 fatty acids on nearly every major pathway of hepatic fatty acid metabolism have been demonstrated. Reduction of triacylglycerol synthesis by ω3 fatty acids has been attributed to reduced activities of phosphatidate phosphohydrolase (10,11) and acyl-coenzyme A:1,2-diacylglycerol acyltransferase (12,23), and to a diversion toward phospholipid synthesis (13-15,24). At high dosage of ω3 acids, an inhibition of VLDL assembly and/or secretion has been reported (9).

A number of animal studies have also demonstrated increased hepatic β-oxidation capacity and ketone body production after fish oil feeding (11,24-30). Surette *et al.* (31) observed an increased activity of hepatic carnitine palmitoyltransferase (CPT) in fish oil-fed Syrian hamsters, which was highly correlated ($r = -0.97$) with the diet-induced change in serum triacylglycerol levels. Wong *et al.* (25) observed a decreased sensitivity of mitochondrial CPT to inhibition by malonyl-CoA.

Recently, attention has been drawn to the possibility that fish oil decreases peripheral lipolysis from adipose tissue, thereby reducing the availability of substrate for triacylglycerol synthesis in the liver (17,18,27). The activities of lipoprotein lipase and hepatic lipase, enzymes which are involved in VLDL catabolism, are unaffected by fish oil supplementation (6).

Because there is little information about these processes in humans, a randomized, placebo-controlled study on the effects of fish oil supplementation on blood values of free fatty acids, ketone bodies and triacylglycerol, and the relationship between these blood values was carried out. Results demonstrate that fish oil supplementation induced a rapid parallel reduction in blood concentrations of triacylglycerol and free fatty acids, whereas ketone body levels remained constant. Changing blood values were not due to increased fat consumption *per se*, because supplementation with placebo (olive oil) did not affect either free fatty acid or triacylglycerol levels.

Although the reduction in free fatty acid levels after fish oil supplementation has not been systematically studied in healthy human subjects, Singer *et al.* (17) recently reported that dietary supplementation with ω3 fatty acids resulted in a marked decrease in free fatty acid levels during a standard glucose tolerance test in hyperlipidemic patients. Otto *et al.* (18) observed a dose-dependent reduction in plasma free fatty acids by ω3 fatty acids in rats fed *ad libitum*, but not in rats fasted overnight. Since insulin concentration were constant and glucose concentrations increased, the authors (18) concluded that lower plasma free fatty acid levels could not be explained by either increased insulin concentrations or improved insulin sensitivity of adipose tissue. Preliminary data from another recent study (32) in rats fed marine ω3 fatty acids confirmed a marked reduction in free fatty acid levels. In addition, a significant reduction of fatty acid mobilization from epididymal adipocytes of these rats was demonstrated (32). Our finding of reduced blood values of free fatty acids in spite of constant glucose and insulin levels after fish oil supplementation is consistent with these recent reports.

In their studies with rats, Otto *et al.* (18) observed a positive correlation ($r = 0.71$) between blood values of free fatty acids and triacylglycerol. A similar correlation ($r = 0.77$) was observed in the present study after three days of fish oil supplementation. This would suggest that the lowering of plasma free fatty acids by dietary fish oil may have contributed to the decrease in serum triacylglycerol levels.

In spite of the decrease in plasma free fatty acid levels after fish oil supplementation, we did not detect any significant changes in blood ketone body levels. As a consequence, the ratio of ketone bodies to free fatty acids increased significantly after fish oil supplementation. It is unlikely that this was caused by decreasing ketone body removal from the blood, as ketone body uptake by peripheral tissues is thought to be controlled by the ketone body concentrations presented to them (33,34). Arterial ketone body levels closely reflect hepatic ketone body production (35). Therefore, the increased ratio of ketone bodies to free fatty acids, combined with the markedly high correlation ($r = 0.90$) between these blood values after fish oil supplementation, suggests an increased capacity for fatty acid oxidation and/or ketogenesis in the liver. This suggestion is consistent with animal studies that demonstrated increased β-oxidation and ketogenesis by dietary ω3 fatty acids (11,24-31).

If increased hepatic β-oxidation and ketogenesis would not be counteracted by reduced lipolysis from adipose tissue, ketosis would occur (36). It is speculated that the combination of decreased lipolysis and increased capacity or hepatic β-oxidation/ketogenesis may be a concerted mechanism whereby fish oil reduces triacylglycerol formation in the liver without, however, simultaneously inducing ketosis.

In conclusion, our study shows that dietary fish oil, in addition to its well-known effect of reducing serum triacylglycerol concentrations, induces a rapid reduction in blood free fatty acids, and a parallel rise in the ratio of ketone bodies relative to free fatty acids. These effects appear not to be due to changes in insulin concentration or sensitivity, and because they occur within one day of supplementation, they are unlikely to be related to altered membrane composition by ω3 fatty acids. Our findings are consistent with the notion that reduced lipolysis and increased hepatic β-oxidation/ketogenesis may contribute to reduced triacylglycerol levels after ω3 fatty acid supplementation in humans. Turnover studies are needed in order to provide further quantitation of these processes.

[Received February 27, 1993; Revision accepted October 13, 1993]

Lipid Peroxidation and Antioxidant Status Is Affected by Different Vitamin E Levels When Feeding Fish Oil

Sung-Hee Cho[a,*] and **Young-sun Choi**[b]

[a]Department of Food Science and Nutrition, Hyosung Women's University and [b]Department of Food and Nutrition, Taegu University, Kyung-buk, Korea

The protective role of vitamin E and changes in the status of several physiological antioxidants after feeding rats a fish oil diet were investigated. Six-week-old male Sprague-Dawley rats were divided into four groups and fed experimental diets for 8 wk. Three fish oil (FO) groups were fed a menhaden fish oil and soybean oil (SO) (9:1) mixture as 10% (w/w) of the diet. These groups were provided with ≤3, 45 or 209 IU of vitamin E/kg diet. One SO group was used as control and was fed ≤45 IU of vitamin E/kg diet. Plasma vitamin E levels, when expressed as vitamin E per mL plasma, were extremely low in the group fed FO and ≤3 IU of vitamin E, and were lower in the groups fed FO than in the group fed SO. However, plasma vitamin E levels when expressed per mg plasma lipid were higher in the FO groups provided with ≤45 and 209 IU of vitamin E than in the SO group. Compared with the SO group, plasma levels of thiobarbituric acid reactive substances (TBARS), when expressed per mg lipid, were higher in the three FO groups, plasma retinol levels were lower in the FO groups provided with ≤3 and 45 IU of vitamin E, and ascorbic acid levels were lower only in the FO group provided with ≤3 IU of vitamin E. Blood glutathione (GSH) levels were lower in all three FO groups than in the SO group. Liver vitamin E levels increased as the dietary level of vitamin E increased, but all FO groups had higher liver levels of TBARS than the SO group. The dietary vitamin E levels were correlated positively with plasma vitamin E ($r = 0.71$) and negatively with TBARS in both the plasma and liver of rats fed FO. Among the antioxidants measured, correlations were found between plasma retinol and vitamin C ($r = 0.64$), and plasma vitamin C, uric acid ($r = 0.72$) and blood GSH ($r = 0.60$). Weaker correlations were found between plasma retinol, uric acid and blood GSH. It is concluded that vitamin E requirements are higher when feeding fish oil. Vitamin E seems necessary to prevent enhanced lipid peroxidation and to maintain appropriate levels of other physiological antioxidants.

Lipids 29, 47-52 (1994).

During the past two decades, epidemiologic studies on animals and humans have shown the beneficial effects of marine oils in preventing or retarding coronary heart disease and other chronic illnesses (1). Observed positive effects include the lowering of blood lipid levels, especially of triglyceride, the lowering of blood pressure, and reduced platelet aggregation and inflammation (1). However, increased levels of long-chain n-3 fatty acids may render membranes more susceptible to oxidation and may increase the requirement for antioxidants. Lipid peroxidation , *in vivo* (2-6) and *in vitro* (7,8), has been shown to increase in animals fed fish oil (FO) as well as in isolated cells enriched with eicosapentaenoic acid and docosahexaenoic acid (9); tissue vitamin E levels concomitantly decreased (2-4). It also has been shown in human studies that plasma vitamin E levels were decreased upon long-term FO supplementation (10), and that this effect was alleviated by higher dietary vitamin E intake (11). These studies, however, did not lead to recommendations on appropriate vitamin E supplementations in order to maintain normal antioxidant status during fish oil feeding.

Although vitamin E is the most important cellular antioxidant (12), ascorbic acid (13,14), retinol (15), carotenoid (16), glutathione (14,16) and uric acid (14) are also important antioxidants that work cooperatively with vitamin E. Following consumption of vitamin E, changes in the status of these antioxidants do occur, which may have detrimental effects of peroxidation and may impair normal functions.

In the present study we investigated the effects of FO and of vitamin E supplementation on lipid peroxidation as well as the relationship between various physiological antioxidants in plasma and liver of rats fed FO.

MATERIALS AND METHODS

Diets and animals. Starch and glucose were purchased from Je-il Feed Co. (Seoul, Korea). Vitamin-free casein, mineral mix, cellulose, choline, inositol and DL-methionine were purchased from Teklad Test Diets (Madison, WI); DL-α-tocopheryl acetate was obtained from Sigma Chemical Co. (St. Louis, MO). Menhaden oil (MO) was kindly donated by Zapata Haynie Inc. (Reedville, VA), and soybean oil (SO) was purchased from a local market. Tertiary butylhydroxyquinone (TBHQ, 0.02%; Eastman Kodak, Rochester, NY) was added to keep MO and SO from deteriorating. Other precautions for maintaining the freshness of the diets were followed (17). To prevent linoleic acid deficiency in feeding MO, one part SO was mixed with nine parts MO for the FO diet at the level of 10% (w/w) fat in the diet. The composition of the diets is shown in Table 1. Table 2 shows the fatty acid compositions and peroxide values of the two dietary oils. Fatty acid composition was analyzed by gas chromatography as described below, and peroxide values were determined according to AOAC methods 28.025 and 28.026 (18). In the FO diet, the level of linoleic acid was 1.07% (w/w) and comprised about 2.2 cal%. Since SO and MO contained ≤26 IU vitamin E and ≤0.8 IU vitamin E per 100 g oil, respectively, the amounts of DL-α-tocopherol were adjusted to the three different levels (≤3, 45, 209 IU per kg diet) of vitamin E in the FO diets and ≤45 IU vitamin E per kg of the SO diet. Six-week-old male Sprague-Dawley rats

Abbreviations: BHT, butylated hydroxytoluene; FO, fish oil; G6PDH, glucose-6-phosphate dehydrogenase; GR, glutathione reductase; GSH, reduced glutathione; GSSG, oxidized glutathione; HPLC, high-performance liquid chromatography; MO, menhaden oil; PUFA, polyunsaturated fatty acid; SO, soybean oil; TBARS, thiobarbituric acid reactive substances; TBHQ, tertiary butylhydroxyquinone; UV, ultraviolet.

TABLE 1

Compositions of Experimental Diets[a]

	Vitamin E (IU/kg)			
	≤45	3	45	209
Components	SO diet	FO (MO/SO = 9:1) diets		
	per kg			
Starch	370 g			
Glucose	190 g			
Casein	240 g			
Mineral mix (AIN-76A)	40 g			
Vitamin E-free vitamin mix[b]	10 g			
Cellulose	40 g			
Choline	0.5 g			
Inositol	0.5 g			
DL-Methionine	2.2 g			
Soybean oil	100	10	10	10 g
Menhaden oil		90	90	90 g
DL-α-Tocopheryl acetate	19	0	42	206 mg

[a]Four experimental diets were formulated using menhaden oil (MO) and soybean oil (SO) as fat sources and three different levels of vitamin E. SO was used as the sole fat source for the SO diet while an MO and SO (9:1) mixture was used in three FO diets at the level of 10% (w/w) to provide 2.2 cal% as linoleic acid. Since SO and MO contained ≤26 and ≤0.8 IU vitamin E per 100 g oil, respectively, the amounts of DL-α-tocopherol were adjusted to the three different levels (≤3, 45, 209 IU per kg diet) of vitamin E in the FO diets, and to ≤45 IU vitamin E per kg in the SO diet.

[b]Vitamin E-free vitamin mix (per kg) contained thiamin•HCl, 0.6 g; riboflavin, 0.6 g; pyridoxin•HCl, 0.7 g; nicotinic acid, 3.0 g; Ca pantothenate, 1.6 g; folic acid, 0.2 g; biotin, 0.02 g; vitamin B_{12}, 0.001 g; retinyl acetate, 4.0×10^5 units; ergocalciferol, 1.6×10^5 units; menadione, 0.075 g; glucose, 992.5 g.

22:6n-3	ND	8.8
Total PUFA	63.0	41.7
n-3/n-6	0.13	2.9
PI[b]	70.3	131.7
Peroxide value[c]	0.75	2.9

[a]Not detected. Abbreviation: PUFA, polyunsaturated fatty acids; see Table 1 for other abbreviations.

[b]Peroxidizability index = (% dienoic × 1) + (% trienoic × 2) + (% tetraenoic × 3) + (% pentaenoic × 4) + (% hexaenoic × 5).

[c]Peroxide values were determined according to the AOAC method (18).

Experimental Animal Management Division, National Institute of Health, Seoul, Korea) were divided into four groups of eight animals each and fed the four respective diets for eight weeks.

Sample preparation. At the end of the feeding period, the rats were fasted for 16 h before sacrifice. Under ether anesthesia, blood was drawn by heart puncture and plasma was prepared with heparin. Liver was immediately removed, washed in saline and rapidly frozen in liquid nitrogen. Plasma and liver was stored at −60°C until analysis.

Chemical assays. Thiobarbituric acid reactive substances (TBARS) in plasma and liver were measured by the methods of Yagi (19) and Hu *et al.* (7), respectively, using 1,1,3,3-tetraethoxypropane (Sigma Chemical Co.) as standard. Plasma uric acid (20), and blood and liver blood glutathione (GSH) (21) were enzymatically assayed. Liver vitamin E was determined according to method of Kayden *et al.* (22). Ten percent liver homogenate in saline was saponified with KOH in the presence of 2% pyrogallol and extracted with hexane. Total tocopherol in the hexane phase was reacted with ferric chloride and dipyridyl. The optical density was measured at 520 nm (22). Vitamin C was extracted from the liver with 5% metaphosphoric acid and measured at 540 nm by the hydrazine method.

High-performance liquid chromatographic analysis. Plasma vitamin A and E were extracted with hexane and determined simultaneously by high-performance liquid chromatography (HPLC) (23) using retinyl acetate (ICN Biochemicals, Cleveland, OH) and (±)-D-tocopheryl acetate (Sigma) as internal standards. A C-18 micro-Bondapak (Waters, Milford, MA) 300 × 8 mm stainless-steel column was used and the analysis (Waters HPLC 510) was carried out isocratically with methanol/H_2O (95:5, vol/vol) as mobile phase and using ultraviolet (UV) detection at 280 nm. To analyze liver vitamin A, tissues were lyophilized, extracted with $CHCl_3$ in the presence of butylated hydroxytoluene (BHT) (50 μg/mL), the extracts saponified with 10% ethanolic NaOH, and reextracted with hexane. HPLC conditions for liver samples were identical to those used for plasma, except that UV detection was at 312 nm. Plasma vitamin C was extracted with 5% metaphosphoric acid and analyzed by HPLC using a Lichrosorb-NH_2 column (250 × 4 mm i.d.), phosphate buffer (pH 3.3) as the mobile phase, and dithioerythrol as standard (24).

Lipid analysis. Plasma total lipids were measured by the method of Frings and Dun (25). Total lipids from 0.5 to 1 g of liver were extracted according to Folch *et al.* (26) and analyzed as for plasma. The lipid extract was subjected to thin-layer chromatography on Silica Gel G 60 plates (Merck, Darmstadt, Germany) using the solvent system petroleum ether (b.p. 30–60°C)/diethyl ether/acetic acid (85:15:1, by vol; Ref. 24) to separate phospholipids from triglyceride and cholesterol. Total liver phospholipids were methylated with BF_3/methanol (14%, w/w) reagent (27). The fatty acid composition of the methyl esters was determined by gas chromatography (Hewlett-Packard, North Hollywood, CA; Model 5890) using a stainless-steel column (2 m × 3 mm i.d.) packed with 20% DEGS on chromosorb W (60–70 mesh) (Gasukuro Kogyo Inc., Tokyo, Japan) and helium as carrier gas at a flow rate of 30 mL/min. The analysis by gas chromatography was performed isothermally at 200°C.

Statistical analysis. Data were analyzed by analysis of variance, and treatment differences were evaluated by

Tukey's test. Correlations between dietary vitamin E levels and biochemical measurements were examined (28).

RESULTS

TBARS levels in tissues. Plasma TBARS levels (per mL) in the FO group reached up to 140% of those in the SO group when rats were fed very low levels (≤3 IU) of vitamin E (Table 3). TBARS levels decreased upon vitamin E supplementation. The FO group had higher levels of plasma TBARS than the SO group fed an equal amount of vitamin E (≤45 IU). This difference became significant when expressed per mg total plasma lipid, which reflected the reduction in total lipids in the FO group (0.83 mg/mL compared with 1.56 mg/mL in the SO group). Supplementation with vitamin E up to ≤209 IU in the FO group decreased the levels of plasma TBARS to those in the SO group. In the liver, TBARS levels (per g tissue) were significantly increased, namely 3.9-fold, 2.6-fold and 2.5-fold in the FO groups with ≤3, ≤45 and ≤209 IU, respectively, when compared to the SO group. When expressed per mg tissue lipid, a similar trend was observed, except that the differences were greater between the FO group with ≤3 IU and the other three groups.

Tissue levels of antioxidants. Plasma vitamin E levels were extremely low in the FO group fed ≤3 IU vitamin E. They were lower in the FO group fed ≤209 IU than in the SO group when expressed as per mL plasma. But they were higher in the FO group than in the SO group at the same level of dietary vitamin E when expressed per mg total plasma lipid, due to the 50% reduction in plasma total lipid in the FO group. Plasma retinol levels were lower in the FO groups at low (≤3 IU/kg) and medium (≤45 IU/kg) levels of dietary vitamin E than in the other two groups. Plasma ascorbic acid levels were significantly lower only in the FO group with ≤3 IU vitamin E, as compared to the SO group. Uric acid levels could not be shown to be different among the groups due to the high variations in measurements. Blood GSH levels in the FO groups were lower than those in the SO group, but the levels were increased in the FO group at ≤209 IU vitamin E when compared with the FO group at ≤3 IU.

In the liver, vitamin E levels (per g tissue) in the FO groups progressively increased with the increase in dietary vitamin E. Vitamin E levels in the SO group were higher than in the FO group at ≤3 IU, but lower than in the other two FO groups. When expressed in per mg liver lipid, the vitamin E level increased only in the FO group at ≤209 IU dietary vitamin E. The hepatic levels of retinol, vitamin C and GSH were not significantly different among the groups.

Correlations of dietary vitamin E with other measured parameters. On the basis of the data obtained on the FO groups (Table 3), correlations of the dietary vitamin E level with various other measurements are presented in Table 4. Dietary vitamin E levels correlated negatively with plasma TBARS ($r = -0.78$, $P < 0.01$) and positively with plasma vitamin E ($r = 0.71$, $P < 0.01$), retinol ($r = 0.53$, $P < 0.05$), vitamin C ($r = 0.64$, $P < 0.05$) and blood GSH (0.56, $P < 0.05$). Consequently, plasma TBARS levels were negatively correlated with plasma vitamin E and blood GSH. Among the plasma and blood antioxidants, fairly strong correlations were found between retinol and vitamin C ($r = 0.64$, $P < 0.05$), and between vitamin C and

Uric acid						0.07

[a]Values represent correlation coefficients analyzed from seventeen pairs of observations except those including plasma vitamin C which were from eleven pairs. The values with nonitalic superscript letters c and d have P values of less than 0.05 and 0.01, respectively. See Tables 1 and 3 for abbreviations.
[b]Calculated as per mL plasma.

TABLE 5

Correlations Between the Levels of Dietary Vitamin E and Liver Vitamin E, TBARS and Retinol in Rats Fed FO (MO/SO = 9:1)[a]

	Liver		
	Vitamin E	TBARS	Retinol
Log dietary vitamin E	0.24	−0.57[b]	0.01
Liver vitamin E		0.05	0.39

[a]Values represent correlation coefficients analyzed from seventeen pairs of observations; superscript letter b indicates a P value of less than 0.05. See Tables 1 and 3 for abbreviations.

uric acid ($r = 0.72$, $P < 0.05$) and GSH ($r = 0.60$, $P < 0.05$). Weak correlations were found between retinol and uric acid and GSH. In the liver (Table 5), a significant correlation was seen between dietary vitamin E and liver TBARS ($r = -0.57$, $P < 0.05$). Multiple regression analysis revealed that dietary vitamin E was the sole factor exerting influence on TBARS value in plasma ($R^2 = 0.554$) and liver ($R^2 = 0.358$) and that the effects of antioxidants on TBARS levels in tissues were mediated by dietary vitamin E.

Fatty acid composition of liver phospholipids. The fatty acid compositions of liver phospholipids from the SO group and the FO group with ≤45 IU of dietary vitamin E are presented in Table 6. The fatty acid composition was not different among the FO groups as three different dietary levels of vitamin E and reflected the fatty acid composition of the dietary oil fed.

Comparing the fatty acid composition of liver phospholipids in the FO group with that in the SO group, there was an increase in 16:0 fatty acid content and a reduction in 18:0 fatty acid. Arachidonic (20:4n-6) but not linoleic acid (18:2n-6) in the SO group may have been replaced in part by the n-3 polyunsaturated fatty acid (PUFA) 20:5 and 22:6 and partly by the monounsaturated fatty acids, 16:1 and 18:1n-9. In the FO group, there was a small decrease in total PUFA and virtually no change either in the peroxidizability index or in the unsaturation index, but a 4.6-fold increase in n-3/n-6 ratio was observed when compared with the SO group.

TABLE 6

Fatty Acid Composition (%) of Liver Phospholipids from Rats Fed Diets Containing SO and MO + SO (9:1) with ≤45 IU Vitamin E per kg Diet[a]

Fatty acid	SO diet	FO (MO/SO = 9:1) diets

22:0	0.4 ± 0.1	0.7 ± 0.3
22:5n-3	0.2 ± 0.1	0.7 ± 0.5
22:6n-3	3.9 ± 1.1	7.8 ± 3.5[b]
Total PUFA	43.6	36.8
Total n-3 PUFA	4.3	12.6
n-3/n-6	0.12	0.56
PI[c]	117	112
UI[d]	165	160

[a]All values are means ± SD from five to six rats. Values with nonitalic superscript letter b are significantly different from the SO group at $P < 0.05$. Abbreviations in Tables 1 and 2.
[c]Peroxidizibility index is the same as described in Table 2.
[d]Unsaturation index represents the sum of percentages of individual unsaturated fatty acids × number of double bonds.

DISCUSSION

Our study showed that dietary FO increases lipid peroxide levels. The accumulation of lipid peroxide is more pronounced in liver than in plasma. One of the reasons for this difference may be the decreased plasma lipid levels resulting from increased dietary n-3 fatty acid intake (2,29). Lipid content of the liver decreased (30) little or not at all (2,29), or even increased (31). Another reason for increased TBARS levels in liver, even at higher levels of dietary vitamin E, may be that fatty acid peroxides from dietary FO contain a considerable amount of lipid peroxides (2.90 mEq/kg *vs.* 0.75 mEq/kg in SO). The lipid peroxides accumulate and are not secreted into plasma lipoproteins. The increase in lipid peroxide content in the liver of rats fed FO seems to be related to the tissue fatty acid composition as tissue TBARS levels increased parallel with increasing n-3 PUFA content when compared with n-6 PUFA content in tissue phospholipids. Our results showing liver TBARS accumulation in rats fed a FO-supplemented diet and an excess amount (≤209 IU) of

vitamin E is consistent with results described by others (5,6).

TBARS levels in the plasma and in the liver of rats fed FO showed an inverse relation to log dietary vitamin E levels, although the negative correlation of plasma TBARS levels with dietary vitamin E levels was stronger ($r = 0.78$) than that of liver TBARS ($r \approx -0.57$) (Tables 4 and 5). There was a moderate correlation between plasma TBARS with plasma vitamin E ($r = -0.53$, $P < 0.05$) (Table 4), while there was no correlation between liver TBARS and liver vitamin E (Table 5). Leibovitz *et al.* (8) reported a strong correlation between liver TBARS and liver vitamin E, which is not in agreement with our data. This discrepancy may be due in part to differences in experimental conditions, such as the age of rats and differences in the FO used. Rats used in this study were 6-weeks-old and weighed over 150 g, *i.e.*, the animals were older than those used by Leibovitz *et al.* (8). Our rats also maintained substantial liver vitamin E levels even after 8 wk of very low vitamin E (≤3 IU) intake. Another reason could be possible differences in intake of lipid peroxides present in the FO. This points to the practical problems of feeding FO since FO used in most animal experiments have been reported to contain lipid peroxides at levels of 6–22 mEq/kg (17). Some oil products also contain oxidative polymeric materials, although various antioxidants were included (32).

In the present study, we observed not only effects of dietary vitamin E on the status of various antioxidants but also an interrelationship with plasma antioxidant status. Dietary vitamin E showed positive correlations with the status of plasma retinol and vitamin C and blood GSH as well as plasma vitamin E (Table 4). Positive correlations were also found between plasma and blood antioxidants (Table 4). Similar observations have been reported by other investigators (33–38), but these earlier studies were limited to the interactions of a few selected antioxidants. Vitamin E deficiency has been shown to reduce plasma and liver vitamin A levels in rats (33) but not in chickens (34). It is of significance that in the present study vitamin A status was affected by a broad range of vitamin E intake levels. Retinol is known to act as an antioxidant, but its *in vivo* role has not been emphasized as much as that of β-carotene. Tom *et al.* (35) have provided evidence that vitamin A deficiency significantly increased lipid peroxidation in rat lung microsomes, whereas an excess of dietary vitamin A decreased lipid peroxidation. Therefore, retinol may have worked against oxidation in rats fed the FO diet.

Although significant positive correlations were found between plasma retinol, vitamin C, uric acid and blood GSH, the levels of vitamin C, uric acid and GSH were not correlated with plasma vitamin E levels. The roles of GSH and vitamin E in antioxidation have been recognized in earlier studies on liver nuclear membranes (39), microsomes (40) and platelets (41). Regardless of the mechanisms of GSH action, it appears critical to maintain a sufficient amount of total glutathione and to efficiently recycle the oxidized form (GSSG) to the reduced form (GSH). In rat heart and liver (36,37), vitamin A deficiency has been shown to increase the total glutathione pool, whereas in rat lung microsomes (35), both a deficiency and an excess of vitamin A reduced the glutathione content. Reduction of GSSG to GSH occurs by the action of glutathione reductase (GR), which is not influenced by dietary factors (42). NADPH, the reductant in the GR reaction, is supplied mainly by the glucose-6-phosphate dehydrogenase (G6PDH) reaction and appears to determine recycling (38). The increase in erythrocyte NADP was associated with a reduced GSH/GSSG ratio (38). FO decreases G6PDH activity (29,43), which in turn slows down the formation of NADPH. This may explain the low level of GSH in the FO group fed ≤209 IU vitamin E, in spite of the sparing action of vitamin E in this group.

Plasma vitamin C levels were significantly decreased in the FO group fed ≤3 IU vitamin E despite the fact that rats can synthesize vitamin C *in vivo*. Studies by Ingold's group (44) have shown the antioxidant activity of vitamin C in cooperation with vitamin E in an aqueous solution containing phospholipid liposomes, but could not demonstrate its sparing effect *in vivo* using guinea pigs (45). More recently, however, Igarashi *et al.* (46) have observed the synergistic action of vitamin E and C in mutant rats, called osteogenic disorder Shionogi (ODS) rats (47), which are genetically incapable of synthesizing vitamin C. In humans, who need relatively large amounts of vitamin C, the body status of vitamin C is more likely to be disturbed under conditions of oxidative stress brought about by the intake of FO and/or an insufficient amount of vitamin E.

The present study demonstrates an increase in vitamin E requirements with FO feeding not only to prevent enhanced lipid peroxidation but also to maintain an appropriate status of other antioxidants. More studies are needed to determine what an adequate ratio of dietary vitamin E to FO should be.

[Received July 9, 1993, and in revised form October 27, 1993; Revision accepted October 31, 1993]

Effect of Maternal Dietary Arachidonic or Linoleic Acid on Rat Pup Fatty Acid Profiles

Eric L. Lien*, Fran G. Boyle, Rebecca J. Yuhas and Charles F. Kuhlman
Wyeth-Ayerst Laboratories, Nutritional Research Department, Philadelphia, Pennsylvania 19101

Rapidly growing neonatal mammals accrete relatively large quantities of long chain ($\geq C_{20}$) polyunsaturated fatty acids (LCP) in membrane phospholipids. We have examined accumulation of ω6 LCP in suckling neonatal rat pups during the first 14 d of life when their dams received essential fatty acids in the form of triglycerides containing linoleic acid or arachidonic acid. Dietary levels of these fatty acids were either 1 or 5% of total dietary fatty acids. The fatty acid profile of pup stomach contents (composed solely of the dams' milk) and plasma lipids, as well as liver and brain phospholipids, were determined. Stomach linoleic and arachidonic acid levels reflected the diet of the dams. Pup plasma and liver arachidonic acid levels increased progressively from the group receiving 1% linoleic acid to 5% linoleic acid and from 1% arachidonic acid to 5% arachidonic acid. Interestingly, brain phosphatidylethanolamine and phosphatidylcholine arachidonic acid levels were more stable than plasma or liver levels. These results suggest that the brain may be capable of either selective transport of ω6 LCP or chain elongation/desaturation of linoleic acid. These data indicate that care must be exercised when adding LCP to infant formula since widely divergent accretion rates of arachidonic acid may occur in various tissues. ***Lipids 29*****, 53–59 (1994).**

Polyunsaturated fatty acids of the ω6 family are essential nutrients, as clearly delineated by Burr and Burr (1,2). Deficiencies of these fatty acids result in impaired growth and reproductive performance, skin lesions and inappropriate activity of the immune system (3). In newborn, rapidly growing mammals the requirements for essential fatty acids are particularly high. For example, during the last three months of pregnancy and first 18 mon of life, humans rapidly accumulate fatty acids in the central nervous system in a process termed the brain growth spurt (4–6). Both ω3 and ω6 long chain polyunsaturated fatty acids (LCP, $\geq C_{20}$) are accumulated, although ω6 accretion rates are higher than ω3 rates (5,6). Microsomal desaturation and chain elongation pathways may be submaximal during this time period, thus, optimal rates of LCP accretion may be dependent on appropriate supplies of preformed LCP or on appropriate dietary levels of precursor ω3 and ω6 fatty acids.

Human milk contains 10–15% linoleic acid and 0.5–1.0% arachidonic acid, the chain elongation/desaturation product of linoleic acid (7). Similarly, both α-linolenic acid and ω3 LCP are present in human milk. Clandinin *et al.* (8) calculated that the levels of ω6 and ω3 LCP in breast milk are sufficient to meet the needs of rapidly growing infants. Currently, infant formulas employ vegetable oils or a mixture of vegetable and animal oils to meet the essential fatty acid requirements of the infant, as defined by numerous pediatric advisory organizations and regulatory agencies (9). In general, minimal linoleic acid levels are set between 300 and 500 mg per 100 kcal of formula. The oils employed in formulas do not contain LCP of either the ω3 or ω6 class. Although breast-fed infants have relatively constant circulating levels of ω3 and ω6 LCP, some reports document that formula-fed preterm (10–12) and term (13) infants undergo a time-related decrease in circulating ω3 and ω6 LCP levels. Concern that low ω3 LCP levels may result in reduced visual acuity in preterm infants has led several groups to examine the addition of fish oils to preterm formulas (10,14,15). During a long-term feeding study, Carlson *et al.* (10) noted that although the ω3 LCP status of preterm infants fed marine oil-supplemented formula was improved, circulating arachidonic acid levels fell significantly. Thus, addition of both ω3 and ω6 LCP to formula (mimicking breast milk) may be prudent.

Sources of ω3 LCP are readily available from a variety of marine oil sources (16). However, economically viable sources of ω6 LCP are much more difficult to develop. In the present study we have employed a suckling rat model previously described by Yeh *et al.* (17) to examine tissue ω6 LCP accretion, comparing an oil source rich in linoleic acid (peanut oil) to a novel triglyceride source of arachidonic acid. Diets containing 1 or 5% linoleic or arachidonic acid were fed to dams and the resulting fatty acids quantitated in their milk. The incorporation of ω6 LCP in the pups was determined in liver and brain phospholipids as well as plasma lipids.

MATERIALS AND METHODS

Animals and diets. Sprague-Dawley rats (Harlan, Indianapolis, IN) were housed in a room controlled for temperature (21 ± 1°C), humidity (40–50%) and light (lights on 0600–1800 h). The rats were housed in suspended wire mesh cages before and during the mating period. They received a standard rodent chow (Purina Rat Chow; Ralston Purina, St. Louis, MO). The female rats were mated (monogamous mating one male/one female) for a two-week period. After the mating period, the female rats were divided into four groups (five dams/group). The pregnant rats were housed individually in plastic cages with ALPHA-dri™ bedding and given free access to food and water.

Newborn pups were delivered naturally and were weighed within 24 h of birth. Semi-purified diets containing either 1 or 5% linoleic acid, or 1 or 5% arachidonic acid were introduced to the dams on postpartum day 2. The diets containing arachidonic acid were prepared and stored at −70°C under argon. The diets containing linoleic acid were prepared and stored at 5°C. All four diets contained 22% casein, 1% cellulose, 4% Bernhart-Tomarelli Salt Mixture, 1% AIN-76 vitamin mix (both salt mix and vitamin mix from United States Biochemical Corp., Cleveland, OH), 0.1% choline chloride, 56.9% dextrose and 15% fat. Oil sources for the diets were hydrogenated

[a]Diet A: 3.4% peanut oil, 96.6% hydrogenated coconut oil.
[b]Diet B: 17.0% peanut oil, 83.0% hydrogenated coconut oil.
[c]Diet C: 5.0% arachidonic acid-containing oil, 95.0% hydrogenated coconut oil.
[d]Diet D: 25.0% arachidonic acid-containing oil, 75.0% hydrogenated coconut oil.

coconut oil and either peanut oil (both from ICN Biomedicals, Inc., Aurora, OH) or an arachidonic acid-rich triglyceride. Table 1 provides the fatty acid profiles of the diets.

On postpartum day 0, the litter size (number live/number dead) was determined. On day 7, the pups were weighed, sexed and culled to four males and four females per litter. On day 15, the pups were weighed, anesthetized with an intraperitoneal injection of Nembutal™ (5 mg/100 g body weight) and blood obtained by cardiac puncture with a 1-mL syringe containing ethylenediaminetetraacetate sodium. Approximately 1.0 mL of blood was routinely obtained per pup; plasma was collected and pooled from each litter. The brain, liver and stomach contents were obtained from one male rat per litter. The brain and liver were immediately rinsed in ice-cold saline. All samples were stored at −70°C until lipid analysis.

Lipid extraction and analyses. Lipids were extracted from tissues and plasma according to the procedure of Folch *et al.* (18). For analyses of plasma fatty acids, a 1-mL aliquot was added to 20 mL of a chloroform/methanol (2:1, vol/vol) mixture for lipid extraction. The tissues were weighed, distilled water was added (10 mL for every gram of tissue) and homogenized. For analyses of phospholipid fatty acids, an aliquot of the homogenate (1 mL) was added to 20 mL of a chloroform/methanol (2:1, vol/vol) mixture for lipid extraction.

Phospholipid classes were separated by thin-layer chromatography using LK6 silica plates and a solvent system consisting of chloroform/methanol/petroleum ether (b.p. 30–60°C)/acetic acid/boric acid (40:20:30:10:1.8, vol/vol/vol/vol/wt) (19). Santoquin™ was added to the methanol as antioxidant.

Lipids were methylated and extracted using the method of Morrison and Smith (20). Fatty acid methyl esters were analyzed by gas chromatography (Hewlett-Packard Model 5890 GC interfaced with an HP 3365 Chemstation; Palo Alto, CA) using a capillary column (Omegawax, 30 m, 0.32 mm i.d.; Supelco, Bellefonte, PA) and flame-ionization detection. The following operating parameters were used: column temperature, 200°C, isothermal; injector, 230°C; detector, 250°C; split ratio, 65:1; carrier gas, helium. Appropriate standards were analyzed to determine retention times and response factors (Nu Chek-Prep, Inc., Elysian, MN). Fatty acid composition was expressed as the weight percent of the total fatty acids.

Statistics. Data were analyzed using the Student-Newman-Keuls test ($P = 0.05$) with a one-way completely randomized design.

RESULTS

Growth. The weight gain of the pups from postpartum day 1 to day 15 was not statistically different between groups (mean ± SEM;1% linoleic acid, 23.5 ± 0.8 g; 5% linoleic, 26.2 ± 0.5 g; 1% arachidonic, 22.2 ± 2.3 g; 5% arachidonic, 21.3 ± 2.9 g). Weights of livers and brains were also similar for all groups (data not shown). Diet had no statistically significant effect on the weights of the dams at postpartum day 15.

Stomach contents. Stomach content of the pups is a reflection of maternal milk composition. As expected, the fatty acid profile of the pup stomach contents varied in several fatty acids (Table 2). The linoleic acid content from pups whose dams received 5% dietary linoleic acid was significantly elevated compared to the other groups. Similarly, the high-dose arachidonic acid group had elevated stomach arachidonate levels compared to the

TABLE 2

Effect of Maternal Dietary Fat Composition on Suckling Pup Stomach Content Fatty Acid Composition[a]

Fatty acid	Group A: low linoleic acid	Group B: high linoleic acid	Group C: low arachidonic acid	Group D: high arachidonic acid
		(percentage by weight)

14:0	19.2 ± 0.41	16.7 ± 0.56	18.0 ± 1.28	17.1 ± 0.68
16:0	24.5 ± 1.46	20.1 ± 0.68	23.9 ± 2.13	21.1 ± 0.91
16:1ω7	0.5 ± 0.14[b]	0.5 ± 0.12[b]	0.7 ± 0.19[b]	2.0 ± 0.12[c]
18:0	8.8 ± 0.18	9.1 ± 0.63	9.8 ± 1.19	8.5 ± 0.38
18:1ω9	6.5 ± 0.44[b]	10.1 ± 0.32[c]	6.3 ± 0.41[b]	5.5 ± 0.85[b]
18:2ω6	0.8 ± 0.15[b]	2.9 ± 0.12[c]	0.5 ± 0.08[b]	0.7 ± 0.14[b]
20:4ω6	0.3 ± 0.07[b]	0.3 ± 0.02[b]	0.5 ± 0.09[b]	2.2 ± 0.10[c]

[a]Values reported are weight percent and are means ± SEM (n = 4-5).
[b,c]Values not bearing the same superscript letters are different at $P < 0.05$.

other groups. The low-dose arachidonic acid group contained a numerically higher (not statistically significant) arachidonic acid level compared to the linoleic acid groups.

Liver phospholipid levels. Liver phosphatidylcholine (PC) linoleic acid levels increased in a dose-related manner in the groups whose dams received either 1 or 5% linoleic acid (Table 3), although differences were small compared to stomach content levels. Interestingly, the groups receiving dietary arachidonic acid showed a statistically significant dose-related decrease in liver PC linoleic acid levels, even though this was not reflected in the pups' stomach contents. Liver PC arachidonic acid levels increased progressively from the 1 to 5% linoleic acid group and the 1 to 5% arachidonic acid group. Levels of 22:4ω6 were significantly elevated in the high-dose arachidonic acid group compared to the other groups. No significant differences occurred in liver docosahexaenoic acid (DHA) in any of the groups.

Trends similar to the liver PC profiles described above were also noted for liver phosphatidylethanolamine (PE) (Table 3), with the exception that the arachidonic acid response was not as striking in PE as in PC. Additionally, DHA levels fell significantly and in a dose-related manner as ω6 LCP levels increased (DHA level in 1% linoleic acid group, 17.9%; DHA level in 5% arachidonic group, 10.7%; $P < 0.05$).

[a]Values reported are weight percent and are means ± SEM (n = 4-5).
[b-e]Values not bearing the same superscript letters are different at $P < 0.05$.

Plasma lipids. Pup total plasma linoleic acid levels increased in a dose-related manner in the 1 and 5% linoleic acid groups, and progressively decreased in the 1% and 5% arachidonic acid groups (Table 4), similar to the liver PC data. Pup plasma arachidonic acid levels increased more than threefold from the 1% linoleic group to the 5% arachidonic group. Similarly, 22:4ω6 increased in a dose-related manner. No significant alterations occurred in ω3 LCP.

Brain fatty acid levels. In distinct contrast to the liver and plasma data, no significant differences occurred between groups for brain PC or PE levels of arachidonic acid (Table 5). Interestingly, brain PC linoleic acid levels were significantly higher in groups whose dams received dietary linoleic acid compared to the arachidonic acid groups (Table 5). No significant differences were noted in brain PC or PE DHA levels between any of the groups, although a trend to lower DHA levels was found in the high arachidonic acid group.

DISCUSSION

The present study employed maternal dietary alteration as a method of delivering diets of various fatty acid compositions to rapidly growing rat pups. The direct effect of maternal dietary unsaturated fatty acid composition on resultant milk fatty acid profiles has been clearly demonstrated in humans (7) and in rodents (17,21,22). In the present study, we observed a correlation of maternal dietary ω6 fatty acid profile and stomach ω6 fatty acid profile of pups. Interestingly, the levels of expression of ω6 fatty acids in the dams' milk were lower than the dietary levels of supplemented fatty acids, suggesting a concentration gradient from maternal diet and plasma to milk. The efficiency of LCP transfer from the circulation to milk is relatively poor; maternal circulating levels of LCP are much higher than milk LCP levels in both humans (23-25) and rodents (26). Essential fatty acids may be diluted in milk, since nonessential fatty acids may be synthesized *de novo* by the mammary gland, while essential fatty acids must be provided from the circulation.

Liver and plasma arachidonic acid levels in the pups followed an extremely strong dose-related pattern, increasing progressively from the group receiving 1% linoleic acid to the group receiving 5% arachidonic acid. Arachidonic acid content in milk was equivalent in the groups receiving 1 and 5% linoleic acid (milk arachidonic acid levels were 0.3 ± 0.07 wt% and 0.3 ± 0.02 wt%, respectively), while there was a fourfold difference in the milk linoleic acid levels of these groups (Table 2). These data suggest that hepatic chain elongation and desaturation must be active in these young rats. Substrate supply for ω6 LCP synthesis was substantially different, resulting in significant differences in hepatic arachidonic acid levels. Previous studies demonstrated that fatty acid chain elongation and desaturation at the level of the liver is active in young mammals. Hepatic Δ6 desaturase increases rapidly in newborn mice, reaching a maximum at day 7 postpartum followed by a slow decline (27). Hepatic synthesis of arachidonic acid from linoleic acid increases tenfold when fetal piglets are compared to newborn piglets (28,29).

Even though arachidonic acid can be synthesized from linoleic acid, administration of dietary arachidonic acid is clearly a superior means of promoting hepatic LCP accretion. Not only are hepatic phospholipid levels of arachidonic acid elevated in groups directly receiving arachidonic acid (Table 3), but analysis of total liver lipid also indicates a dramatic increase in total arachidonic acid (data not shown). Previous studies in both rats (30) and mice (31) have also demonstrated that dietary arachidonic acid is much more potent in supporting hepatic arachidonate accretion than is linoleic acid. This may be due to relatively limited conversion of linoleic acid to arachidonic acid (32) or relatively rapid oxidation of linoleic acid compared to arachidonic acid (33).

In the present study, dietary arachidonic acid resulted in a significant reduction of hepatic and plasma linoleic acid levels. The effect was dose-related and independent of the level of linoleic acid the pups received (the stomach

TABLE 5

Effect of Maternal Dietary Fat Composition on Suckling Pup Brain Phospholipid Fatty Acid Composition[a]

linoleic acid contents of pups in the 1% linoleic group, 1% arachidonic group and 5% arachidonic group were equivalent). Thus, arachidonic acid may replace linoleic acid for incorporation into phospholipid membranes. A similar observation was made by Mohrhauer and Holman (30) in young rats fed increasing doses of arachidonic acid. As the dietary level of arachidonic acid was increased, liver linoleic acid levels decreased. Seyberth *et al.* (34) also reported decreased plasma levels of linoleic acid following ethyl arachidonate administration to adult humans.

Brain PE and PC arachidonic acid levels were similar in all groups. This is surprising in light of a threefold difference in plasma arachidonic acid concentration between groups. This highly protected brain arachidonic acid profile may be achieved in one of two ways: (i) by active transport of arachidonic acid from the circulation or (ii) through chain elongation/desaturation of linoleic acid in brain. Sinclair (35) demonstrated rapid uptake of [^{14}C]arachidonic acid by suckling rat pup brain and incorporation into phospholipids. When radiolabeled linoleic acid was administered, accumulation of phospholipid arachidonic acid was approximately three times lower than when radiolabeled arachidonic acid was administered. The preferential transport of LCP *vs.* C_{18} precursors was supported by similar data comparing α-linolenic acid transport to DHA transport in suckling rats (36). The second possibility, existence of chain elongation/desaturation pathways in the brain of developing animals, must also be considered. The level of brain Δ6 desaturase is relatively high at birth and falls rapidly during the first three weeks of life in the suckling mouse (27). In contrast, synthesis rates of chain elongation/desaturation products in the piglet brain are similar at birth and in older animals (28,29); however, these rates are less than 10% of the hepatic synthesis rates. With only the relative transport and synthesis data outlined above, no firm conclusions can be drawn concerning the mechanism of arachidonic acid accretion that we have observed.

The data of Mohrhauer and Holman (37) demonstrated that brain arachidonic acid levels could be altered in a dose-related manner by orally administered ethyl esters of ω-6 fatty acids; ethyl arachidonate was more potent and yielded higher maximal arachidonic acid levels than ethyl linoleate. This study employed ethyl esters as the sole source of lipid in weanling rats studied for 100 d. The present study, employing the rodent dam to provide nutrition to rapidly growing pups, allows for less controlled fatty acid delivery. All pups received a basal level of

arachidonic acid from their mothers' milk. The level of arachidonic acid received in the linoleic acid groups (0.3% of fatty acids, or about 0.2% of calories) would be sufficient to promote modest brain arachidonic acid accretion if placed in the context of the Mohrhauer and Holman (37) dose levels. The previous experiment determined total brain fatty acid profiles, while the present results report brain PC and PE levels. We have also measured brain total fatty acid profiles (data not shown) and found no significant differences in arachidonic acid levels between groups. Therefore, the discrepancies between the previous results and current data cannot be due to a brain lipid fraction response occurring independently of PC and PE.

The possibility that the C_{18} precursors of LCP found in infant formula may be sufficient for needs during infancy is an area of current investigation (38). Our results demonstrate that modest levels of dietary linoleic acid can support normal brain arachidonic acid accretion, even though plasma and hepatic arachidonic acid levels may appear to be low. However, the current study was conducted with a small number of animals (limiting its statistical power) and for a relatively short duration. It is conceivable that a longer study with more animals may have demonstrated statistically different brain fatty acid levels.

Arbuckle and Innis (39) have made an observation similar to ours in the retina of formula-fed piglets when studying ω3 status. Animals receiving formulas relatively low in α-linolenic acid had retinal DHA levels equivalent to animals receiving a fish oil supplemented diet, while higher levels of dietary α-linolenic acid produced both brain and retinal levels of DHA similar to sow-fed controls. Although these results may suggest that C_{18} precursors of LCP may be useful for supplying the infant with LCP, the optimal means of supplying ω3 and ω6 essential fatty acids appears to be the direct addition of LCP to formula. Numerous studies in term and preterm infants have demonstrated reduced levels of ω3 and ω6 LCP in the circulation of formula-fed infants compared to infants receiving human milk (10–13). The addition of ω3 LCP to preterm formula has resulted in improved visual acuity and has evoked visual potential (40,41). Unfortunately, feeding of a formula containing ω3 LCP alone suppresses circulating arachidonic acid levels and may lead to slower growth and altered indices of mental development (42,43). Addition of both ω3 and ω6 LCP thus appears to be appropriate.

The results of the current experiment suggest that linoleic acid is capable of supporting normal arachidonic acid brain accretion. However, the diets employed in this study were virtually free of ω3 fatty acids. Inclusion of ω3 LCP in the diets of rodent dams appears to inhibit chain elongation/desaturation of linoleic in the pups (44). Thus, animals receiving ω3 LCP plus linoleic acid have lower brain ω6 LCP accretion than animals receiving dietary ω3 and ω6 LCP (44). The arachidonic acid source employed in the present study may be appropriate for addition to infant formula, but should be added in the presence of a source of ω3 LCP.

***Retinitis pigmentosa* (RP) is a hereditary retinal degeneration of unknown etiology, resulting in progressive night blindness, loss of peripheral vision, abnormal retinal pigmentation and reduced electroretinographic response. Docosahexaenoic acid (22:6ω3) is found in high concentration in the rod outer segment membranes of the retina. Previous reports of low 22:6ω3 in blood lipids or phospholipids in RP patients prompted us to evaluate the complete fatty acid (FA) profiles of plasma phospholipids (PL), cholesteryl esters, triglycerides (TG) and nonesterified fatty acids (NEFA) in ten patients with RP. In the PL fraction, we found significantly depressed levels of 22:6ω3, 22:5ω3, total ω3, 22:5ω6, 22:4ω6 and total ω6 polyunsaturated FA (PUFA), and elevated total saturated acids. Plasma TG showed normal levels of PUFA, normal total saturated FA and total monounsaturated FA. The NEFA fraction showed significant elevation in total saturated FA with depressed total ω6 PUFA. Evidence is accumulating that RP is associated with abnormal PUFA and lipid metabolism.**

***Lipids* 29, 61-65 (1994).**

Retinitis pigmentosa (RP) is a hereditary retinal degeneration with symptoms of reduced night vision and loss of peripheral visual field, beginning in young adults. By an unknown mechanism, the photoreceptors and retinal pigment epithelium (RPE) are injured with resulting reduced light sensitivity, loss of pigmentation of the RPE and pigment deposition in the sensory retina (1). Familial inheritance of retinal epithlium may be autosomal dominant, autosomal recessive or X-linked, but a "simplex" presentation with no known affected family members, or "multiplex" with two or more affected siblings without other affected relatives is also common (2). Prevalence in the general population is approximately 1 in 4000 (3).

The polyunsaturated fatty acid (PUFA) 22:6ω3, docosahexaenoic acid (DHA), accounts for about 50% of the fatty acid (FA) content of the rod outer segments (ROS) of the vertebrate retina (4-6) and is highly conserved even after severe dietary deprivation of ω3 FA (4,6). Physiologic needs, which may explain this high content of PUFA in the ROS, remain speculative, but enhanced membrane fluidity has been correlated with high 22:6ω3 content in human retinoblastoma cells in tissue culture (7). Using radioactive molecular labelling in an animal model, the recycling of 22:6ω3 has been demonstrated from ROS to the RPE and back to the ROS across the interphotoreceptor matrix (8).

Converse and colleagues (9) in 1983 discovered low plasma DHA in patients from three unrelated Scottish families with RP. Since their report, several groups have described abnormal DHA levels in blood phospholipids (PL) or total lipids of patients with RP, most finding diminished levels (10-12), but in one report, elevated DHA was found in patients from a single autosomal dominant pedigree (13). Lipid measurements for patients in these studies were compared to unaffected family members.

We have made a comprehensive analysis of FA composition in plasma lipids from ten patients with RP. Four major lipid fractions were isolated, and the content of 25 FA was measured in PL, triglycerides (TG), nonesterified fatty acids (NEFA) and cholesteryl esters (CE). The compositions for RP patients were compared to normal values for 100 healthy controls, which have recently been published (14).

MATERIALS AND METHODS

The nature of the study was explained to, and informed consent obtained from, ten patients with RP from Western New York State. These patients represented seven unrelated families, four with autosomal dominant RP, two simplex presentations (no known family history) and one multiplex familiity with two of two affected siblings without prior family history. A diagnosis of RP was based on clinical presentation, family history and at least one family member with electroretinographic documentation of RP.

After an overnight fast of at least 12 h, plasma was obtained in citrated vacutainer vials by venipuncture for analysis of FA composition. Samples were centrifuged and the plasma transferred to freezing vials for storage at −20°C until analysis was performed at The Hormel Institute (Austin, MN).

Total lipids were extracted from plasma with chloroform/methanol (2:1, vol/vol), the water layer removed, the extract filtered to remove protein and the chloroform layer blown to dryness. The residual lipids were dissolved in a minimum amount of chloroform and applied to a silicic acid thin-layer chromatography plate and developed in a mixture of petroleum ether (b.p. 30-60°C), diethyl ether and acetic acid (80:20:1, by vol) to separate the PL, NEFA, TG and CE. Each lipid fraction was scraped separately from the plate, extracted from silicic acid, esterified with 12% BF_3 in methanol to form the fatty acid methyl esters (FAME), and then extracted with petroleum ether (b.p. 30-60°C) for capillary gas chromatographic analysis.

A model 428 chromatograph (Hewlett-Packard, Palo Alto, CA) equipped with a 50 m × 0.25 mm bonded 007 FFAP-based silica capillary column (Quandrex, New Haven, CT) was used to separate the FAME. The instrument temperature was programmed from 170 to 220°C at 2°C/min with a final hold of 25 min, separating 12:0 to 22:6ω3. The detector temperature was 250°C. Helium

Abbreviations: CE, cholesteryl ester; DBI, double bond index; DHA, docosahexaenoic acid; EFA, essential fatty acid; EPA, eicosapentaenoic acid; FA, fatty acids; FAME, fatty acid methyl esters; LCAT, lecithin-cholesterol acyl transferase; MMP, mean melting point; NEFA, nonesterified fatty acids; PL, phospholipids; PUFA, polyunsaturated fatty acids; ROS, rod outer segments; RP, *Retinitis pigmentosa;* RPE, retinal pigment epithelium; TG, triglycerides.

carrier gas was used at a flow rate of 1.4 mL/min and a split ratio of 1:65. The FAME were identified by comparison with authentic FAME standards, and peak areas were integrated as wt% with a microprocessor. Individual peaks were distinguished representing as little as 0.05% of the FAME in the fraction.

Statistical analysis of the data was performed with the PC-SAS package (15) on a microcomputer. Significance testing for differences between the RP and control groups was performed using Student's *t*-test. For our primary hypothesis (abnormal DHA levels in RP patients), the resulting *P* value should be taken at face value. For all other results (25 measured variables), single differences at the $P < 0.05$ level should be interpreted cautiously as preliminary findings because interdependent variables are expected to show such a correlation by chance alone. Differences with $P < 0.01$ level are more persuasive, and those variables showing $P < 0.001$ remain highly significant even taking into account the numerous comparisons. Significant patterns of change in metabolically related fatty acids cannot be explained by chance.

The normalcy ratio is calculated by dividing the average of the RP group by the average of the controls, and *P* values are calculated on the differences between the two groups. Normalcy ratios are the equivalent of Z-scores.

Mean melting point (MMP) is a measure of lipid fluidity based upon the measurement of the full range of FA in a lipid class. It is based upon the near linearity of the plot of mixed melting points *vs.* composition of mixtures. It is the sum of the products of mole fraction × melting point for each FA in the sample:

$$MMP = \Sigma(MF_1)\,(MP_1) + (MF_2)\,(MP_2) \cdots (MP_n)\,(MP_n)$$

where MF is the mole fraction and MP is the melting point. MMP has the advantage that it measures an inherent property of each of the FA present, and does not involve the use of external probes unnatural to lipids.

Double bond index (DBI) is the number of double bonds per acyl group within a lipid, and heretofore has been a useful indicator of fluidity, based upon the content of unsaturated FA in the lipid. For example, DBI of PL of normal rats is above 1.5, whereas severely essential fatty acid (EFA)-deficient rats exhibit values as low as 0.8 (16). MMP improves upon DBI by including contributions to fluidity by saturated and branched FA of the full range of chain lengths.

RESULTS

Plasma PL. Compositions, reflecting PL composition of tissue membranes, are given in Table 1.

Analysis of the PL from RP patients showed that the nutritionally EFA, α-linolenic (18:3ω3) and linoleic (18:2ω6), are present in normal proportions. However, the polyunsaturated long-chain FA 20:4ω6, 22:4ω6 and 22:5ω6 of the ω6 series, as well as 22:5ω3 and 22:6ω3 of the ω3 family, are significantly lower than in the healthy controls. Total saturated FA are found in higher proportion in the RP patients, and the individual components accounting for this rise are shown in Table 1 and in the graphic profile for PL in RP shown in Figure 1. Total monounsaturated FA are not abnormal in the PL. The total PUFA and DBI are greatly diminished as shown by the high level of statistical significance when compared to the 100 healthy controls. The products of Δ5 and Δ4 desaturation, and the products of elongation of C_{20} to C_{22} FA, shown in Figure 1, are diminished in PL in the RP group.

abnormal value, namely 22:5ω6, which was significantly elevated. Several saturated FA were elevated, as were ω9 FA. Summary indices showed small diminutions of total PUFA and products of Δ6 desaturation. Other product/substrate ratios were normal.

Plasma TG. TG compositions for the RP patients and controls are given in Table 3, and the full graphic profile for plasma TG, including the ω6 and ω3 elongation and desaturation products, is shown in Figure 3. The total saturated FA were different from the control group. Although the total of monounsaturated FA were normal, 20:1ω9 was significantly elevated. Total PUFA and the DBI were normal as were the products of desaturation and elongation.

Plasma NEFA. NEFA plasma levels are given in Table 4, and a full graphic profile of NEFA is shown in Figure 4. The sole ω3 FA to show an abnormality was 22:5ω3, which was significantly elevated in RP patients. Total ω6 FA were depressed in the NEFA fraction, as were 18:2ω6 (linoleic acid) and 20:4ω6 (arachidonic acid), the dominant individual ω6 FA. However, the products of the elongation and desaturation of 20:4ω6, 22:4ω6 and 22:5ω6 were significantly elevated. Nearly all saturated FA were elevated, as were Δ9 desaturation and elongation products.

DISCUSSION

PL. The normal levels of the dietary precursor 18-carbon EFA in the PL fraction of RP patients suggest normal dietary intake and intestinal absorption of these nutrients. This observation is also supported by normal EFA levels in the TG fraction, a reflection of recent dietary intake.

The products of α-linolenic acid, 18:3ω3, in PL after undergoing Δ6 desaturation, elongation to C_{20}, and Δ5 desaturation remain at normal levels in RP. However, the C_{22} chain elongation product, 22:5ω3 (DHA) is significantly low in the RP group as is 22:6ω3 (DHA), the Δ4 product. For the ω6 series, the Δ6 desaturation and C_{20} chain elongation products appear to be normal in the RP group, but Δ5 desaturation, C_{22} elongation and final products all are lower than normal. These blocked steps are illustrated in Figure 1 by arrows. In the ω3 series, the blockage is at elongation to C_{22}, whereas in the ω6 series it is at Δ5 desaturation.

Δ6 and Δ5 desaturation and chain elongation steps to C_{20} and C_{22} acids occur in many tissues, but the liver may be the most important site physiologically (17). The final Δ4 product, derived *via* retroconversion (18), has been demonstrated in only a limited number of tissues, including human retinoblastoma cells (19,20), rat retina (21), rat adrenocortical cells (22), human fetal fibroblasts (20) and liver (17).

The highly significant depression of long-chain PUFA of plasma in the RP patients that we have studied suggests altered enzyme activity in tissues producing 22:5ω3, 22:6ω3, 20:4ω6 and 22:5ω6, notably liver. In this study the elongation of C_{20} PUFA appears to be the more affected step, leading to lesser levels of 22:5ω3 and 22:6ω3. If the ROS membranes of patients with RP have similarly reduced total PUFA and DBI, the consequent substantially reduced membrane fluidity, indicated by elevated calculated MMP, could contribute to biochemical alterations in visual pigment cycling, causing toxic injury to the outer retina and RPE.

Alternatively, the abnormal PL FA composition could represent a consequence of retinal injury rather than a cause. If we postulate a cause of the pathologic and pigmentary changes in RP unrelated to PUFA metabolism, breakdown of the blood retinal barrier would be a likely consequence. However, loss of PUFA from retinal tissue may tend to elevate the blood PL PUFA levels, at least temporarily. Thus, if systemic lipid changes are secondary in RP, a more complex mechanism than diffusion across a damaged blood retinal barrier must be at work.

CE analyses showed depression only of 20:5ω3 (EPA) in the ω3 series, which was modestly significant, and elevation of 22:5ω6 of the ω6 FA, which was highly significant. Lower content of the product of retroconversion of 22:6ω3 and higher content of substrate for ω6 retroconversion could explain these observations. The synthesis of plasma CE occurs largely in high density lipoprotein by action of lecithin-cholesterol acyl transferase (LCAT), as well as in liver. The changes observed in plasma PL are not reflected in plasma CE, although LCAT transfers the unsaturated acids from position 2 of phosphatidylcholine to cholesterol.

TG results, given in Table 2, showed completely normal proportions of all PUFA, suggesting normal dietary intake and adsorption as mentioned above. Saturated and monounsaturated totals were also normal, but several individual saturated FA were elevated or depressed, and Meade's FA (20:3ω9) was very high despite normal levels of EFA. The 20:3ω9 is the product of Δ5 desaturation in the ω9 series of which oleic acid is the precursor. Although 20:3ω9 was not elevated in plasma PL, its increase in TG is an indication that Δ5 desaturation may have been elevated in RP, and that the nonfunctional product, 20:3ω9, may have been shunted into TG.

NEFA demonstrated normal total ω3 FA, and normal individual FA with the exception of elevated 22:5ω3. Depressed 18:2ω6 in NEFA with normal PL and TG levels

suggests that linoleic acid may have been shunted away from adipose tissue. NEFA are the preferred energy source for some metabolically active tissues, such as heart, in transit from the adipose tissue and other storage sites. Recently, retroconversion of C_{22} and C_{20} PUFA in fibroblasts and vascular endothelial cells has been documented (17). Diminished retroconversion of C_{22} to C_{20} PUFA could explain the apparent increase of C_{22} elongase activity in our NEFA results.

FA profiles of plasma lipids provide rapid visual comparison of individual FA or groups of FA in two populations, and the changes of profile shown here may be compared readily with similar previous comprehensive studies of other diseases, nutritional states and physiological states (23-25). By expressing the compositions of FA as ratios to normal values on a logarithmic scale, bars for equifold increases or decreases appear as equal changes in concentrations of substrate FA, affecting metabolic kinetics equally. The profiles measured upon plasma or serum PL are a measure of those in structural membranes in body tissues, because the same deficiencies of PUFA measured analytically occur in PL of tissues as occur in plasma PL of nutritionally EFA-deficient animals and man. FA profiles assess the individual or group status with respect to both ω6 and ω3 EFA, and also indicate metabolic aberrations in the metabolism of PUFA if they occur. In instances of EFA deficiencies, the FA profile also indicates which nutritionally nonessential FA increase in replacement of the deficient EFA. For example, in Figure 1 the very significant decreases of 20:4ω6, 22:4ω6, 22:5ω6, 22:5ω3 and 22:6ω3 are compensated by increases of saturated and monounsaturated FA with less than 20 carbon atoms, whereas saturated and monounsaturated FA with more than 18 carbon atoms are suppressed, all in a stepwise fashion. Similar observations led to the calculation of estimated MMP as a measure of fluidity (22-24).

In the present study, DBI of plasma PL was consistently lower in the ten RP patients than the DBI of controls, averaging 83.9% of that value. MMP of the plasma PL of RP patients was consistently higher than the MMP of the control group, averaging 140% of control mean. Thus, the relative difference from control value was more than twice as great for MMP as for DBI, making MMP the more discriminating index of fluidity.

Relationship to protein defects in RP. Recently, amino acid substitutions in the visual pigment rhodopsin have been found in 25-30% of RP families, this protein defect being found only in the affected individuals in the pedigree (26,27). The mechanism of retinal injury in these patients remains unknown, and it is also not known whether rhodopsin defects are associated with abnormal long-chain PUFA. Further investigation will be necessary to determine whether abnormal PUFA and rhodopsin may define biochemically distinct RP groups.

The data presented here indicate that patients with RP have significantly low levels of both ω6 and ω3 PUFA. Deficiency of ω3 FA has been demonstrated to be associated with neuropathy (28). The retina is an extension of the nervous system, and abnormalities of vision observed in RP are demonstrated here to be associated with long-chain ω3 PUFA depletion of FA of circulating PL. Although dietary supplies of 18:3ω3 seemed to be normal in the RP patients, their long chain ω3 PUFA and ω6 PUFA were deficient. These long-chain FA occur in fish and meat products and might be enhanced in plasma PL by supplementation with fish oil (25) or by diets containing fish and meat (29). Measurement of plasma response in RP patients to dietary supplementation may be an appropriate first step to determine suitable intake levels of ω3 and ω6 long-chain PUFA prior to comparative clinical studies.

In the present study, the effect of normal (5% by wt) and high (23.5% by wt) corn oil diets on prostanoid production and on the lipid composition of preneoplastic colonic epithelium was investigated. CF_1 mice (female, 3–4-weeks-old) were fed a normal corn oil diet *ad libitum* and were treated with the colon carcinogen 1,2-dimethylhydrazine (DMH, 20 mg/kg/wk) or saline (control) for 24 wk. At this stage, all animals received the AIN-76 diet (normal corn oil) *ad libitum*. Following the last injection, half of the animals from each treatment group were randomly allocated to a high corn oil diet for 5 to 10 wk, whereas the remaining animals continued on the normal corn oil diet. After 5 wk of feeding, the colonic mucosa of carcinogen-treated animals had a higher level of bicyclic prostaglandin E_2 (PGE_2) than had the animals in the control groups; prostanoid synthesis in the colonic mucosa of control animals was unaffected by the high corn oil diet. Preneoplastic colonic mucosa of animals fed the high corn oil diet had a significantly higher level of PGE_2 than corresponding control colonic mucosa. The 6-keto-prostaglandin $F_{1\alpha}$/thromboxane B_2 ratio was significantly lower in the DMH-treated groups than in the control groups, and was unaffected by dietary treatments. After 10 wk of feeding a particular diet, the differences in the fatty acid composition between the control and DMH-treated groups were minor. Our findings demonstrate that the preneoplastic colonic epithelium differs from that of normal epithelium with respect to prostanoid synthesis.
Lipids 29, 67–71 (1994).

As dietary factors are recognized as being important in modulating the carcinogenic process, dietary fats have received particular attention. Epidemiological studies suggest that there is an association between the consumption of a high-fat diet and the incidence of colon cancer (1,2), which is supported by studies on animal models (3). The effect of dietary fats on colon tumorigenesis depends not only on the amount of fat consumed, but also on the type of fat and its fatty acid composition (3).

Prostanoids derived from arachidonic appear to be important in the tumorigenic process (4–9), and neoplastic cells have been shown to produce more prostaglandins than do normal surrounding tissue. It has also been shown that inhibitors of prostaglandin synthesis inhibit colon tumorigenesis and aid regression of adenomatous polyps in patients with familial polyposis (10–12). One mechanism by which dietary fats may affect colon tumorigenesis is by modulating eicosanoid synthesis in the colonic mucosa (13).

In a previous study (14), we demonstrated that normal colonic epithelia (without preneoplastic changes) of animals fed high corn oil or beef tallow diets had higher levels of phosphatidylcholine compared to those of animals on corresponding low-fat diets. The fatty acid composition of the total phospholipids and triacylglycerols reflected the composition of the dietary fat. It was noteworthy that the levels of three eicosanoids, prostaglandin E_2 (PGE_2), prostacyclin (PGI_2) and thromboxane A_2 (TXA_2), which are well known to be involved in the carcinogenic process (4–6), were unaffected by the dietary fat regimens.

Since preneoplastic or neoplastic cells may respond differently to environmental factors than do normal cells, we reasoned that the preneoplastic colonic tissue may respond differently to dietary lipids than would its normal counterpart.

The main objective of the present study was to assess the effect of a high corn oil diet on the lipid composition and the production of PGE_2, PGI_2 and TXA_2 in preneoplastic colonic tissue.

METHODS AND MATERIALS

Animals, diets and carcinogen treatment. Three- to four-week-old female CF_1 mice were obtained from Charles River Canada (Montreal, Quebec, Canada). The mice were housed five to a plastic cage in a room under controlled environmental conditions (21°C) with a 12-h light–dark cycle. After one week of acclimatization, the mice were randomly divided into two groups. One group was given weekly intraperitoneal injections of 1,2-dimethylhydrazine (DMH) (Aldrich, Milwaukee, WI) at a dose of 20 mg/kg body weight for 24 wk. The DMH was dissolved in 1 mM ethylenediaminetetraacetic acid (EDTA), pH 6.5. The other group was injected with vehicle and served as control. The mice were fed an AIN-76 diet (15), which contained 5% corn oil by weight, for up to 24 wk. At various time intervals, including 16 and 24 wk after initiation of DMH treatment, three animals from the carcinogen-treated and the control groups were killed and their colons examined histologically to monitor neoplastic changes. At week 24, the animals were randomly allocated to either a normal or a high corn oil diet (20 DMH-treated and 20 control animals/diet). The high corn oil diet contained 23.5% corn oil by weight, and was made by substituting corn oil for an isocaloric amount of sucrose (Table 1). Animals were killed at 5 wk to determine prostanoid production, and at 10 wk to determine mucosal fatty acid composition.

Determination of prostanoids. Five DMH-treated mice and five control mice fed either the high or the normal corn oil diet were killed by cervical dislocation. The colons were removed and rinsed thoroughly in Krebs Ringer, the mucosae were separated by scraping with a glass slide and the scrapings were placed in tubes containing 20 mL of Krebs Ringer. Tissue weights were determined, and the tissues were incubated for 30 min at 37°C in Krebs Ringer to allow for synthesis of prostanoids from endogenous sources as described previously (14). The amount of prostanoids produced by the mucosal tissue was determined by radioimmunoassay (Amersham Corp., Arlington

Heights, IL). In the case of PGE_2, the assay system is based on the conversion of the major PGE_2 metabolite 13,14-dihydro-15-keto-prostaglandin E_2 to the stable, bicyclic compound 11-deoxy-13,14-dihydro-15-keto-11,16-cyclo-prostaglandin E_2 (bicyclic PGE_2). This assay utilizes antiserum specific for bicyclic PGE_2. The cross-reactivity of this radioimmunoassay with prostaglandin E_1 is less than 0.01%, and with TXB_2 or $PGF_{1\alpha}$ is less than 0.0001%. The cross-reactivity of the 6-keto-$PGF_{1\alpha}$ assay was 5.1% for PGE_2 and 0.014% for TXB_2. Cross-reactivity of PGE_2 and $PGF_{1\alpha}$ with the TXB_2 antiserum was 0.003% or less. TXA_2 and PGI_2 are both very unstable compounds and readily undergo hydrolysis to form the stable inactive metabolites thromboxane B_2 (TXB_2) and 6-keto-prostaglandin in $F_{1\alpha}$ ($PGF_{1\alpha}$).

Determination of colonic fatty acids. Mice from the control and DMH-treated groups were fed the normal or high corn oil diets for 10 wk, after which time their colons were removed, washed thoroughly in Krebs Ringer, and the mucosal and muscle layers were separated. Ten animals from each treatment were used, and two mucosae were pooled for each analysis.

The tissues were placed immediately in chloroform/methanol (2:1, vol/vol), and lipids were extracted as described by Folch *et al.* (16). The major lipid classes were separated by thin-layer chromatography, and fatty acid methyl esters were prepared by the method of Morrison and Smith (17). The fatty acid methyl esters were analyzed by gas chromatography using a Hewlett Packard 5890A instrument equipped with a flame-ionization detector (Palo Alto, CA) and with a fused silica capillary column, 30 m × 0.25 mm. The gas chromatograph was programmed from 190 to 220°C at 10°C/min using helium as carrier gas at a flow rate of 45 cm/s.

Statistical analysis. Statistical significance of the data was determined by analysis of variance in combination with Duncan's Multiple Range Test at $P \leq 0.05$.

RESULTS

In the present study the test animals were given weekly injections of 1,2-DMH for 24 wk. None of the animals developed polyps within 24 wk, but showed microscopic lesions when examined histologically (Fig. 1). Histological sections of the colons treated with carcinogen revealed the presence of preneoplastic changes in the crypts characterized by mild to severe dysplasia (18). At week 34, two out of ten animals in the normal and six out of ten animals in the high corn oil group had macroscopic lesions.

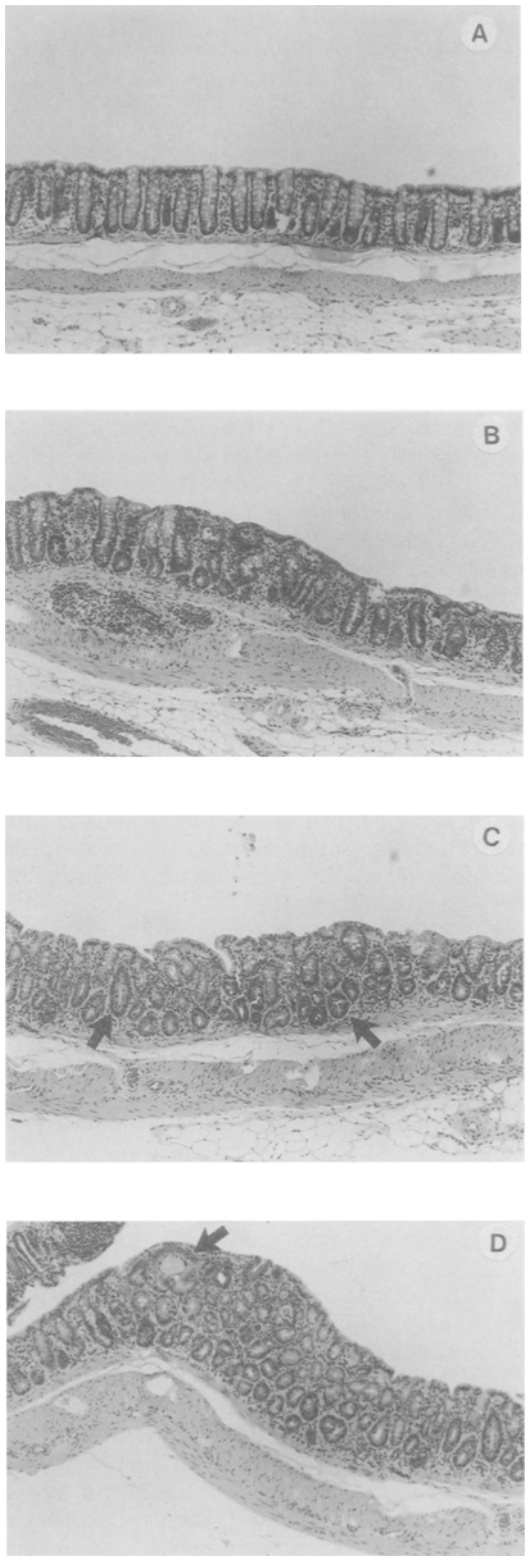

FIG. 1. Histological sections of mouse colons (H & E × 400). Mice were treated with vehicle solution (A) or DMH for 24 wk (B, C, D). A. Normal colon depicting longitudinal section of crypts. B–D. Preneoplastic epithelium exhibiting histological and proliferative atypia. B. Absence of complete longitudinal sections of crypts because of increased tortuosity. C. Note the presence of dysplasia, the absence of goblet cells (arrow), and the increased mitosis (arrow). D. In addition to changes described in B and C, note the presence of a prominent focal preneoplastic lesion (arrow).

[a]Mice were injected with DMH for 24 wk then allowed to eat a normal or a high corn oil diet for 5 wk. Values given are the mean (n = 5) of five samples of colonic tissue ± SEM expressed as ng/g/30 min. Means in a row without a common superscript [b,c,d] are significantly different ($P < 0.05$). Numbers in parentheses represent values as percent of control. Abbreviations: DMH, 1,2-dimethylhydrazine; PGE_2, prostaglandin E_2; $PGF_{1\alpha}$, 6-ketoprostaglandin $F_{1\alpha}$; TxB_2, thromboxane B_2.

In control animals, synthesis of PGE_2, TXA_2 and PGI_2 in the colonic mucosae measured as their stable metabolites, *i.e.*, bicyclic PGE_2, TXB_2, and $PGF_{1\alpha}$, respectively, was unaffected by the dietary treatments at 5 wk (Table 2), consistent with our earlier observations (14). The colons treated with DMH had higher bicyclic PGE_2 levels than the control colons, but this effect was significant only for the high corn oil, DMH-treated group. The values for preneoplastic colons from the high or the normal corn oil groups were not significantly different from each other. The levels of $PGF_{1\alpha}$ were similar in all groups. The TXB_2 levels were significantly higher for the DMH-treated groups than the control groups. In this case, the normal corn oil DMH-treated group exhibited the highest value (202% of the control). The ratio between $PGF_{1\alpha}$ and TXB_2 was significantly lower for the DMH-treated groups compared to the controls, but the effect of the dietary treatment was not evident.

Changes in the fatty acid composition between control and DMH-treated mucosa for a particular dietary treatment were generally minor (Table 3). The phospholipid fractions of the high corn oil group had decreased levels of 18:1 with a concomitant increase in 18:2 and 20:3 compared to the normal corn oil group. The level of 20:4 in the mucosal phospholipids did not vary across the treatment groups. The only significant DMH-treatment effect seen was a small rise in 18:2. In addition, a significant ($P < 0.05$) decrease in the ratio of 18:0/18:1 in the phospholipid fractions of normal corn oil DMH-treated mucosa was noted when compared with the control mucosa, but this was not seen in the high corn oil group. The fatty acid composition of the mucosal triglycerides is shown in Table 4. Among the mucosal triglycerides, the normal corn oil DMH-treated group contained less 18:1 and more 18:2 than the control group. Similar changes in the lipid composition of colonic mucosa were seen as early as within 5 wk of dietary treatments (results not shown).

DISCUSSION

Our objective was to investigate the effect of a high corn oil diet on prostanoid production and lipid composition of the preneoplastic colonic epithelium. Differences were observed between the colonic epithelium with preneoplastic changes and normal colon. The levels of PGE_2 in the DMH-treated, normal or high corn oil groups were 124 and 178% higher, respectively, than in the corresponding control groups. The ratio between the levels of $PGF_{1\alpha}$ and TXB_2, the stable metabolites of PGI_2 and TXA_2, was significantly lower in the DMH-treated groups than in the control groups. However, the fatty acid composition of the total phospholipid and triacylglycerol fractions was similar in the preneoplastic and normal colonic mucosa, regardless of the level of fat in the diet. The colonic mucosa of the high corn oil DMH-treated group synthesized substantially higher levels of PGE_2 than did normal epithelium. However, this effect was masked when the DMH-treated colonic epithelia from the normal corn oil group were included in the analyses. There was no difference in PGE_2 production between the two DMH-treated groups. Recently, Rao and Reddy (13) have reported that preneoplastic epithelium of animals fed a high corn oil diet synthesized significantly higher levels of PGE_2 than did normal epithelium; however, animals fed normal corn oil diets were not included in their analyses. The subtle increase in the synthesis of PGE_2 by preneoplastic colonic epithelium in the high corn oil group compared to the normal corn oil group may be significant when one considers the physiological potency of prostanoids.

It is somewhat perplexing that we found the PGE_2 levels in the preneoplastic murine colonic epithelium of animals on the normal corn oil diet in the DMH-treated group only moderately elevated when compared with controls. Yamaguchi *et al.* (19) reported significantly higher levels of PGE_2 in the colon of rats several weeks after they were exposed to a carcinogen. This may suggest that mice are more resistant to carcinogens or diet-induced changes in their colons than rats. Furthermore, the large intragroup variability observed in our study indicates that the number of animals per group should be larger. The ratio between the levels of $PGF_{1\alpha}$ and TXB_2 was significantly lower in the carcinogen-treated colonic mucosa, which supports the conjecture that an imbalance in the ratio of these two eicosanoids may be important in neoplastic cell growth (20). Since all eicosanoids measured in our study are derived from arachidonic acid, it can be suggested that the altered prostanoid production in preneoplastic colons is well-regulated and may reflect a metabolic and/or an adaptive response of the neoplastic cells.

It has been proposed that a low saturation index, reflected in a consistently lower ratio of stearic to oleic acid in total lipid extracts of tumor *vs.* nontumor areas, may be a marker for malignancy (21–23). Our findings partially support this suggestion. A significant decrease was observed in the ratio of 18:0/18:1 in the phospholipids of the mucosa in the normal corn oil DMH-treated group, but not in the high corn oil DMH-treated group. Although some of the changes were statistically significant, it is not clear to what extent the changes are biologically significant.

The changes in the production of prostanoids by preneoplastic colonic mucosa were not accompanied by changes in the fatty acid composition of total phospholipids or triglycerides. However, this does not exclude the possibility that changes could occur within different phospholipid classes. There is limited information on the factors that regulate the synthesis and utilization of prostanoids in tissues (24). Therefore, further work is required on the various phospholipid classes and activities of enzymes involved in prostanoid synthesis in the preneoplastic colonic mucosa and in preneoplastic lesions.

Our findings demonstrate that prostanoid production is modified in the preneoplastic colon and that colonic mucosa that is preneoplasticly altered exhibits marked changes in the ratio of $PGF_{1\alpha}$ and TXB_2. The significance of these changes and their relationships to dietary lipids and tumorigenesis require further evaluation.

METHOD

An Improved Method for the Measurement of Malondialdehyde in Biological Samples

Xiu-Yan Li and **Ching K. Chow***
Department of Nutrition and Food Science, University of Kentucky, Lexington, Kentucky 40506-0054

An improved method was developed for measuring malondialdehyde (MDA) as its thiobarbituric acid (TBA) complex. Samples were initially incubated with 1% potassium iodide and 0.1% butylated hydroxytoluene at 50°C for 20 min, and then with 0.4% TBA at 60°C for 60 min. The MDA–TBA complex formed was extracted with isobutyl alcohol and measured by high-performance liquid chromatography with fluorescence detection. The improved method allows for a more specific determination of MDA present in biological samples.
Lipids 29, 73–75 (1994).

Due to its relative simplicity and high sensitivity, measurement of malondialdehyde (MDA) as thiobarbituric acid (TBA) adduct has been extensively used to assess the extent of lipid peroxidation in a variety of pathological conditions (1). In recent years, many improved procedures for measuring the MDA-TBA chromophore have been reported (1–3). Factors, such as reaction time, temperature and pH, as well as the presence of transition metals, antioxidants and reducing agents can markedly affect the formation of both the TBA–MDA chromophore and of artifacts during sample processing. We previously reported a selective and sensitive method for measuring MDA in biological samples using high-performance liquid chromatography (HPLC) with fluorescence detection (4). In the procedure described here, the possibility of artifact formation was further decreased by reacting the sample with KI prior to the formation of the MDA-TBA adduct. Thus, a more specific quantitation of MDA present in the assay system can be achieved. In addition, the quantitative relationship between conjugated dienes, hydroperoxides and MDA was examined in peroxidized fatty acids.

MATERIALS AND METHODS

Chemicals and reagents. Butylated hydroxytoluene (BHT), TBA, linoleic acid, linolenic acid, 1,1,3,3-tetramethoxypropane (TMP), KI, hydrogen peroxide (30%) and soybean lipoxygenase (type I) were purchased from Sigma Chemical Company (St. Louis, MO). Boric acid and isobutyl alcohol were from Mallinckrodt (St. Louis, MO); methanol (HPLC grade), glacial acetic acid and hydrochloric acid were from Fisher Scientific (Fair Lawn, NJ); tetrabutylammonium dihydrogen phosphate was from Aldrich Chemical Company (Milwaukee, WI); and ethanol (95%) was from Midwest Grain Products of Illinois (Pekin, IL).

Abbreviations: BHT, butylated hydroxytoluene; HPLC, high-performance liquid chromatography; LOH, hydroxy fatty acid; LOOH, fatty acid hydroperoxide; MDA, malondialdehyde; TBA, thiobarbituric acid; TMP, 1,1,3,3-tetramethoxypropane.

Preparation of standards. The stock solution of MDA was prepared by dissolving 0.1 M TMP in 0.02 N HCl. Hydrogen peroxide, 0.1 μM, was prepared in distilled water. Working standards for MDA and hydrogen peroxide, ranging from 0.1–10.0 μM, were prepared fresh before use.

Enzymatic oxidation of fatty acids. Stock solutions of linoleic acid and linolenic acid (0.05 M) were prepared with 20% ethanol in 0.1 M potassium borate buffer, pH 8.0. The stock solution (0.5 μL) was mixed with 2.5 mL of 0.1 M borate buffer. Samples were oxidized by adding 3,000 units of lipoxygenase (5) at room temperature. The contents were then aliquoted before and 10 min after the addition of lipoxygenase for measuring the levels of lipid peroxidation products, MDA, lipid hydroperoxides and conjugated dienes.

Measurement of lipid peroxidation products. For MDA measurements, aliquots of the enzymatically peroxidized fatty acids (50–200 μL) and MDA standards (0.1–1.0 nmol) were added to test tubes that contained 0.1 mL of 0.1% BHT in 95% ethanol and 0.5 mL of 1% KI in methanol/acetic acid (2:1, vol/vol). The test tubes were then incubated at 50°C for 20 min. After adding 1 mL 0.4% TBA in 0.02N HCl, the contents were incubated at 60°C for 60 min, cooled to room temperature and extracted with isobutyl alcohol. The concentration of MDA was measured by HPLC with fluorescence detection using a C-18 reverse-phase column as described previously (4). Tetrabutylammonium dihydrogen phosphate, 0.5%, was added to the mobile phase (methanol/water, 1:1, vol/vol) as ion-pairing reagent.

The levels of diene conjugation in fatty acids were measured at 233 nm (6). Lipid hydroperoxides were quantified by the triiodide procedure described by Gebicki and Guille (7) using hydrogen peroxide as a standard.

Measurement of MDA in biological samples. To evaluate the applicability of the procedure to biological samples, freshly obtained human plasma was assayed for MDA levels. One-tenth to one-half mL of plasma was pipetted into a test tube that contained 0.5 mL of 1% KI in methanol/acetic acid (2:1, vol/vol) and 0.1 mL of 0.1% BHT in 95% ethanol. After incubation at 50°C for 20 min, the contents were mixed with 0.5 mL 0.4% TBA in 0.02N HCl and incubated at 60°C for 60 min. The samples were then extracted with 2 mL of isobutyl alcohol and measured for relative fluorescence by HPLC as described above. The differences between the sample means were analyzed using analysis of variance followed by Honest's multiple comparison test (Turkey Honest Significant Difference Test). A 95% ($P < 0.05$) of confidence level was used to determine statistical significance.

RESULTS

KI and BHT, individually or combined, had no effect on the formation of MDA–TBA chromophore over the

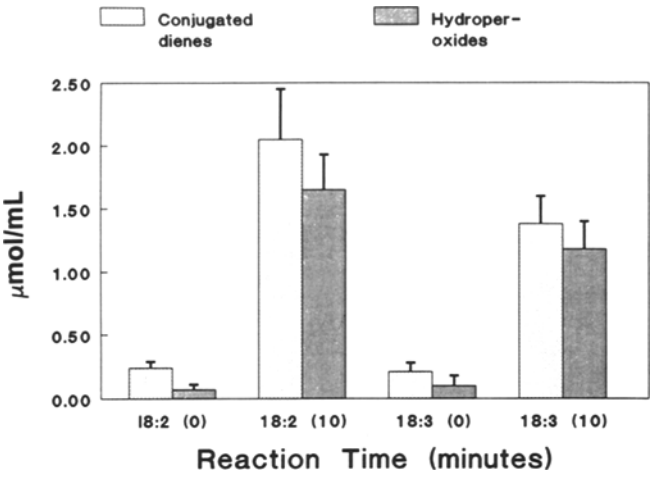

FIG. 1. Effect of KI and butylated hydroxytoluene on the formation of conjugated dienes and hydroperoxides. Linoleic acid (18:2) and linolenic acid (18:3) were incubated with lipoxygenase for 0 or 10 min. The reaction mixture consisted of 25 μmol fatty acid and 3,000 units of lipoxygenase in 3.0 mL of 0.1 M borate buffer (8.33 μmol fatty acid/mL). Results are expressed as μmol of conjugated dienes or hydroperoxides/mL of reaction mixture. The values represent means ± standard deviation of five experiments.

concentration range of 0.10–10 μM. The same was observed when the concentrations of KI and BHT were doubled or halved (results not shown).

The formation of conjugated dienes and hydroperoxides from linoleic acid and linolenic acid following reaction with lipoxygenase is shown in Figure 1. At 0 time, an average of 0.24 and 0.21 μmol/mL of conjugated dienes and 0.07 and 0.10 μmol/mL of hydroperoxides were detected for linoleic acid and linolenic acid, respectively. Ten minutes after the addition of lipoxygenase, an average of 2.05 and 1.38 μmol/mL of conjugated diene and 1.65 and 1.18 μmol/mL of hydroperoxides were found for linoleic acid and linolenic acid, respectively. This compares to less than 0.004 μmol/mL of MDA-TBA detected in the peroxidized

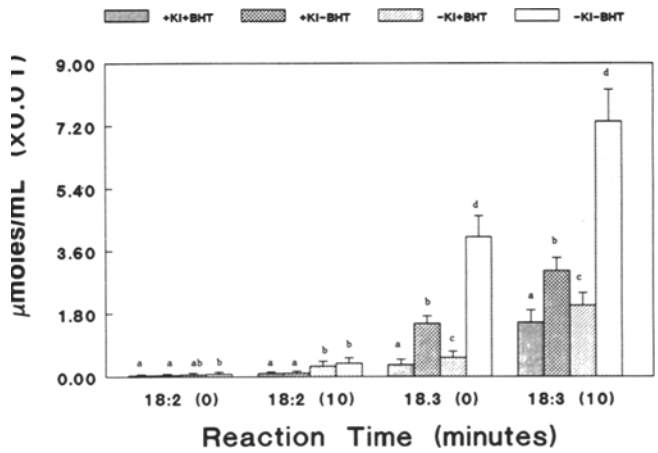

FIG. 2. Effect of KI and butylated hydroxytoluene (BHT) on the formation of malondialdehyde-thiobarbituric acid chromophore. Linoleic acid (18:2) and linolenic acid (18:3) were incubated with lipoxygenase for 0 or 10 min. The values represent the mean ± standard deviation of five experiments. See Figure 1 legends for additional experimental details. The means that have different lower case letters are significantly different ($P < 0.05$).

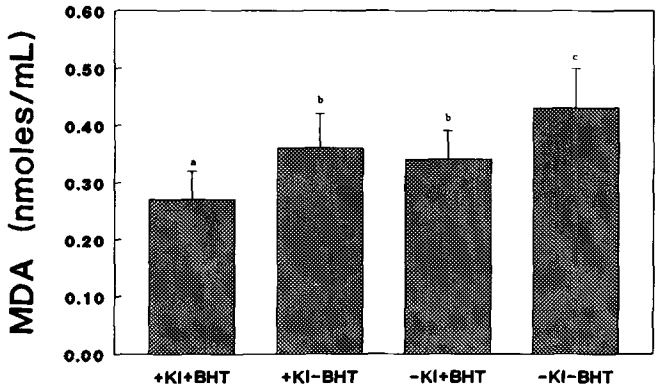

FIG. 3. Effect of KI and BHT on the measurement of MDA in human plasma. The values represent the mean ± standard deviation of fourteen samples. The means that have different lower case letters are significantly different ($P < 0.05$). See text for experimental details. Abbreviations: See Figure 2, and MDA, malondialdehyde.

linoleic acid and less than 0.08 μmol/mL in the peroxidized linolenic acid (Fig. 2) whether KI and/or BHT were included in the reaction mixture or not. As is also shown in Figure 2, the amounts of MDA-TBA found were highly variable depending upon the experimental conditions. The levels of MDA-TBA were decreased by the presence of BHT or KI in the reaction mixture; the addition of both KI and BHT had the greatest effect.

The applicability of the method to measuring MDA in biological samples was tested on human plasma samples. As is shown in Figure 3, the MDA values were significantly lower for plasma samples prepared with KI and/or BHT than for those without. The averaged values of 14 plasma samples were 0.27, 0.36, 0.34 and 0.43 nmol/mL for samples treated with +KI + BHT, +KI − BHT, −KI + BHLT and −KI − BHT, respectively.

DISCUSSION

Due to its sensitivity and simplicity, the measurement of the MDA-TBA chromophore has been widely employed to assess the extent of lipid peroxidation. However, autoxidation of unoxidized lipids and generation of MDA-like compounds during sample processing are among the most critical and confounding factors limiting the accurate measurement of MDA (1–4). In biological samples, the assay is further complicated by the nature of the peroxidized intermediates generated, their reactivity with other components, and by the presence of MDA-like compounds and their precursors. In the present study, an improved method for assaying MDA was developed based on procedures previously reported by us (4) and others (8–10). The key feature of the assay is the prevention or reduction of artifact formation by both KI and BHT during sample processing. A classic procedure for measuring lipid hydroperoxides in fats and oils is based on the ability of KI to reduce lipid hydroperoxides (LOOH), except endoperoxides, to their corresponding alcohols (LOH) (Reaction I) (8,9). Iodometric procedures have been preposed for measuring lipid hydroperoxides in biological samples (7,9).

$$LOOH + 2H^+ + 2\ I^- \rightarrow LOH + H_2O + I_2 \text{ (Reaction I)}$$

The ability of KI to reduce lipid hydroperoxides also reduces free radical generation *via* homolytic cleavage. In addition, KI and/or released I_2 may saturate double bonds of unsaturated fatty acids (10) and thus further decrease the autoxidation potential of the fatty acids present. KI seems to complement the antioxidant property of BHT. In the presence of both KI and BHT, the generation of MDA or MDA-like substances from unoxidized fatty acids, hydroperoxides or other biomolecules can thus be prevented or minimized. However, it remains possible that not all types of artifacts formation are prevented under these experimental conditions.

As is shown in Figures 1 and 2, only small and highly variable amounts of lipid hydroperoxides were converted to MDA. Therefore, estimation of MDA *per se* is not a reliable measure of lipid hydroperoxides. Similarly, as is also shown in Figure 1, the levels of conjugated dienes vary widely depending on the state of oxidation; thus, estimation of conjugated diene is not a suitable measure of lipid hydroperoxides, either.

It has long been recognized that MDA and other aldehydes can be metabolized *in vivo* and *in vitro* by aldehyde dehydrogenases and related enzymes (6,11-13). In addition, MDA may react with various cellular components and thereby decrease cellular levels. Thus, the MDA levels present in fresh biological samples can be expected to be very low. The MDA levels measured as TBA values and reported for normal human plasma varied widely and ranged from 0.32 to 47.2 nmol/mL (3). Whether the average MDA levels in human plasma measured in the present study, 0.27 nmol/mL, represents the steady-state concentration remains to be seen. Nevertheless, by further decreasing the possibility of artifact formation during sample processing, the present method is an improvement over the quite selective and sensitive method we reported previously (4), and affords a more specific measurement of MDA present in biological samples.

The composition of the molecular species of various phospholipid subclasses was examined in myelin isolated from brain of 15-, 21- and 90-day-old rats. The molecular species of diacylglycerophosphocholine (PtdCho), diacylglycerophosphoethanolamine (PtdEtn) and plasmenylethanolamine (PlsEtn) were quantified by high-performance liquid chromatography (HPLC) after phospholipase C treatment and dinitrobenzoyl derivatization. In rat brain myelin, each phospholipid subclass showed a specific pattern of molecular species that changed during development. PtdCho contained large amounts of saturated/monounsaturated and disaturated species and low amounts of saturated/polyunsaturated species. During brain development, the levels of saturated/monounsaturated molecular species increased whereas those of the disaturated and saturated/polyunsaturated species decreased. PtdEtn were characterized by their low levels of disaturated species and a high content of saturated/monounsaturated and saturated/polyunsaturated species, of which those containing fatty acids of the n-3 series decreased, whereas those containing fatty acids of the n-6 series did not change during brain development. The levels of saturated/monounsaturated species increased in PtdEtn. No disaturated molecular species could be detected in PlsEtn. This alkenylacyl subclass contained large amounts of saturated/polyunsaturated, saturated/monounsaturated and dimonounsaturated molecular species. During development, the levels of saturated/polyunsaturated molecular species decreased while those of the two others increased. The data indicated that myelin sheaths undergo phospholipid changes during brain development and maturation.
Lipids 29, 77-81 (1994).

In the central nervous system, myelin is formed by oligodendroglial cells and constitutes the major portion of these cells (1,2). A number of observations support the idea that myelin sheaths are assembled by successive addition of myelin components to the plasma membrane of oligodendroglial cells, leading to changes in the composition of this membrane during maturation (3-6). During the early stage of myelin development, myelin lipids vary among species more than do the lipids of other subcellular fractions (7,8). Changes have also been observed for the various phospholipid classes. As myelination proceeds, the content of phosphatidylcholine (PtdCho) on a percent basis decreases, whereas plasmenylethanolamine (PlsEtn) and polyphosphoinositide levels increase several fold (3,8-10). Moreover, each class of phospholipids is characterized by a specific fatty acid composition suggesting that each class is a mixture of a large number of well-defined molecular species (4,11,12). The fact that the phospholipid fatty acid distribution changes during myelin maturation (5,13) suggests that specific molecular species are required to support the characteristic functions of this membrane. However, the analysis of total fatty acids alone cannot describe the changes in the distribution of myelin phospholipid molecular species during development. Therefore, a study was undertaken to determine the PtdCho, phosphatidylethanolamine (PtdEtn) and PlsEtn molecular species in rat brain myelin in the course of maturation.

MATERIALS AND METHODS

Isolation of rat brain myelin. Rats were bred in our own animal facility. Before being used in this study, rats had been fed for several generations on a pelleted diet containing linoleic and linolenic acids (54.5 and 4.2% by weight of the lipid fraction, respectively) as the only polyunsaturated fatty acids. Whole brains of 15- or 21-day-old or adult rats were excised and homogenized in 0.32 M sucrose, and the myelin was isolated according to the method by Norton and Poduslo (8) adapted for different ages. To isolate myelin from 15- and 20-day-old rats involved keeping the amount of brain per tube constant (approximately 5%, wt/vol) in the first step to minimize contamination. With this modification, preparations of similar purity (at least 95% pure) were obtained at all ages examined (8). The myelin fractions were stored after lyophilization at −80°C until use.

Extraction and characterization of phospholipid molecular species. Lipids from lyophilized myelin were extracted and partitioned according to the procedure of Folch *et al.* (14). Choline and ethanolamine phospholipids were separated by one-dimensional thin-layer chromatography (TLC) after purification by silicic acid column chromatography (15).

The molecular species composition of each phospholipid subclass was determined by high-performance liquid chromatography (HPLC) of the dinitrobenzoyl derivatives. Briefly, diradylglycerols were prepared by hydrolysis of each phospholipid class with phospholipase C from *Bacillus cereus* (Sigma Chemical Co., St. Louis, MO) and then converted to their dinitrobenzoyl derivatives as reported by Kito *et al.* (16) and Francescangeli *et al.* (17). The diacyl-, alkylacyl- and alkenylacylglycerol derivatives were separated by TLC (Silica Gel G60 plates; Merck, Darmstadt, Germany) using benzene as solvent (R_f values of 0.23, 0.39 and 0.56 respectively; Ref. 18). The molecular species of each subclass were eluted with

hexane/diethyl ether (1:1, vol/vol) from the silica gel and characterized and quantified by HPLC (column 4.6 mm × 15 cm Resolve C_{18}, 5 μm; Waters Cidra, Puerto Rico), using acetonitrile as solvent at a flow rate of 2 mL/min at 13°C and ultraviolet detection at 230 nm. Data were processed with a Spectra physics SP 4290 integrator (San Jose, CA). Individual molecular species were identified as reported by Leray *et al.* (18) by gas–liquid chromatography (15), using various diacylglycerol species from commercial sources (Larodan Fine Chemicals, Malmö, Sweden) as standards and by developing a RRT/carbon number plot as previously described (19,20).

The phospholipid composition of myelin was assessed by phosphorus analysis (21) after separating phospholipids by two-dimensional TLC (22).

RESULTS

Phospholipid composition of rat myelin during development. The phospholipid composition of the myelin isolated from rat brain at different ages is presented in Table 1. The data show that between the 15th and 90th day the percentages of PtdCho and PtdEtn decreased by about 18 and 62%, respectively. This decrease was compensated for by a large increase (about 90%) in PlsEtn levels whereas the percentages of the other phospholipid did not change significantly.

Molecular species of choline and ethanolamine phospholipids. Molecular species analysis of PtdCho, PtdEtn and PlsEtn revealed that each of these classes contained about 17 well-defined molecular species (Fig. 1). In myelin of 15-day-old rats, each class had a specific pattern of molecular species that changed in the course of development.

PtdCho. In myelin of young rats, the saturated/monounsaturated species and specifically 16:0/18:1n-9 and 18:0/18:1n-9 (Table 2) amounted to about 55%. The content of saturated/monounsaturated species increased in adult myelin to about 70% resulting from the increase in 18:0/18:1n-9 (from 18 to 33%) while the 16:0/18:1n-9 levels remained unchanged. PtdCho also contained a large amount (about 24%) of the disaturated species 14:0/16:0, 16:0/16:0 and 16:0/18:0, which decreased between 2- and

[a]Results are expressed in mol% and represent the mean values ± SD of duplicate determinations from three different experiments.
[b]—, Not detected.

7-fold in adult myelin. The polyunsaturated molecular species amounted to only about 17% in myelin of 15-day-old rats, the major molecular species being 16:0/22:6n-3, 18:0/22:6n-3, 16:0/20:4n-6 and 18:0/20:4n-6. The percentage of the saturated/polyunsaturated species decreased about 1.5- to 2.0-fold in adult myelin.

PtdEtn. In contrast to PtdCho, the PtdEtn of 15-day-old rat brain myelin contained much less saturated/monounsaturated molecular species (about 27%) and only very low amounts of saturated/saturated species (about 5%) (Table 3). About 58% of the molecular species were saturated/polyunsaturated, including 18:0/22:6n-3 and 18:0/20:4n-6. This subclass also contained noticeable amounts of 18:0/22:4n-6, which was essentially absent in PtdCho. During development, a 2- and 5-fold decrease, respectively, in the percentages of 22:6n-3 containing molecular species and in disaturated species was observed whereas species containing 20:4n-6 remained unchanged while the percentage of 18:0/22:4n-6 nearly doubled. Among the saturated/monounsaturated species, only 18:0/18:1n-9 increased (about 1.8-fold) whereas 16:0/18:1n-9 decreased by approximately 30%. No significant changes were observed in dimonounsaturated molecular species.

PlsEtn. This subclass was characterized by the absence of saturated/saturated species (Table 4). About 60% of the molecular species contained polyunsaturated fatty acids in position-2 of the glycerol, mainly 22:6n-3 and 20:4n-6, but also noticeable amounts of 22:5n-3 and 22:4n-6. The saturated/monounsaturated species accounted for about 25% (mainly 16:0/18:1n-9, 18:0/18:1n-9) with appreciable amounts of dimonounsaturated species (about 15%), mainly 18:1/18:1n-9 and 18:1/20:1n-9. The maturation of myelin was associated with a 2- to 4-fold decrease in molecular species containing 22:6n-3 and 20:4n-6 except for 18:1/20:4n-6, which remained constant. This decrease was compensated for by a 2- to 4-fold increase in saturated/monounsaturated molecular species except for 16:0/18:1n-9 which did not change significantly. In contrast to PtdCho and PtdEtn, the dimonounsaturated species (18:1/18:1n-9 and 18:1/20:1n-9) in PlsEtn increased significantly (about 2- to 3-fold).

DISCUSSION

Myelinogenesis begins in rat brain at about the 10th day after birth. The maximum rate of myelination occurs between the 15th and 30th day after birth, but myelination continues at a lower rate throughout life. Earlier studies showed that although the proportion of total protein to total lipids appears to be relatively constant at all ages, the myelin in brains of young animals has a different composition than that of adults. Major changes are the increase in total galactolipids and the decrease in total phospholipids (5). Our data show a decrease in PtdCho and PtdEtn with age, which is compensated for by an increase in PlsEtn. The percentage of the other phospholipids does not change significantly. These observations are in agreement with those reported by Horrocks (7) and Eng and Noble (9), and it was suggested that the molecular species of the various phospholipids may also undergo developmental changes. The findings of a decrease in polyunsaturated fatty acids and an increase in monoenoic acids in the various myelin phospholipid subclasses are consistent with this hypothesis. However, until now no conclusions could be drawn as to the type of molecular species

involved in these developmental changes, since phospholipid fatty acid composition alone does not indicated the combinations of fatty acids that are present in a particular phospholipid.

In rat brain myelin, each phospholipid subclass showed a specific molecular species composition (Tables 2–4) as had been shown for whole brain (23) and cerebellum (18).

Although specific changes were observed in each phospholipid subclass, the major changes were the marked increase in only the 18:0/18:1n-9 species in PtdCho and PtdEtn and in the 18:0/18:1n-9 and 18:1/18:1n-9 species in PlsEtn, confirming our hypothesis that these two molecular species are preferentially located in the myelin sheaths (18). The increases were mainly compensated for by a decrease in disaturated and/or polyunsaturated fatty acid containing species. Ousley and Morell (24) reported that in rat myelin the different molecular species of choline and ethanolamine phospholipids turned over at different rates, and that for both phospholipids the 18:0/18:1 species had the slowest turnover. It thus becomes clear that, during maturation, myelin becomes enriched in phospholipid molecular species with slow turnovers, indicating that myelin may require specific phospholipids to maintain function.

One of the major issues raised by the present observations concerns the mechanism by which the specific phospholipid composition of the myelin and changes during maturation may be controlled. The assembly of the phospholipids in myelin involves the synthesis of the various molecular species, their transport to the membrane, their sorting and insertion into the membrane, as well as subsequent fatty acid remodelling. The addition of newly synthesized lipids to myelin does not depend on the addition of newly synthesized protein (25). Thus, the assembly of specific phospholipids in myelin is not only controlled by the mechanisms that regulate their insertion into this membrane, but also by the mechanisms that regulate their synthesis, their transport and the remodelling of their fatty acid composition.

The *de novo* synthesis of phospholipids occurs in the endoplasmic reticulum of the oligodendroglial cells which is followed by transport to the plasma membrane. In this respect, the observations that the synthesis of polyunsaturated fatty acids decreases greatly, whereas that of saturated and monounsaturated fatty acids is maximal during intense myelination (26), suggest that the increase in 18:0/18:1n-9 phospholipids in myelin may be controlled at the site of their synthesis and not by lipid transfer proteins involved in their transport. However, this would not explain the different phospholipid molecular species composition in the various intracellular membranes. Therefore it seems likely that the specific assembly of phospholipid molecules in myelin may also be controlled by mechanisms involved in the sorting and integration of the various molecular species. It appears likely that various enzymes of phospholipid metabolism participate in this control. The presence of such enzymes in myelin sheaths, including phospholipases (27,28), acyl-CoA:lysophospholipid acyltransferases (29), acyl-CoA:synthetase (30) and choline and ethanolamine phosphotransferases (31), is consistent with this hypothesis. These enzymes would be expected to participate in the remodelling of certain phospholipid molecules in the myelin in the course of maturation.

ACKNOWLEDGMENTS

We wish to thank G. Gutbier and D. Dalençon for excellent technical assistance, and Dr. K. Langley for critical reading of the manuscript.

ARTICLE

Synthesis of a Phosphatidyl Derivative of Vitamin E and Its Antioxidant Activity in Phospholipid Bilayers

Takuro Koga[a,*], Akihiko Nagao[b], Junji Terao[b], Kohei Sawada[c] and Kazuo Mukai[c]

[a]Noda Institute for Scientific Research, Noda-shi, Chiba 278, [b]National Food Research Institute, Ministry of Agriculture, Forestry and Fisheries, Tsukuba-shi, Ibaraki 305 and [c]Department of Chemistry, Faculty of Science, Ehime University, Matsuyama-shi, Ehime 790, Japan

A novel phospholipid containing a chromanol structure at its polar head group was synthesized from egg yolk phosphatidylcholine and 2,5,7,8-tetramethyl-6-hydroxy-2-(hydroxyethyl)chroman by transphosphatidylation catalyzed by phospholipase D from *Streptomyces lydicus*. The structure of the product synthesized was shown by spectral analysis to be 1,2-diacyl-*sn*-glycero-3-phospho-2'-hydroxyethyl-2',5',7',8'-tetramethyl-6'-hydroxychroman. The phosphatidylchromanol (PCh) showed antioxidant activity against radical chain oxidation of methyl linoleate in solution in a manner similar to that of *d*-α-tocopherol (α-Toc) and 2,2,5,7,8-pentamethyl-6-chromanol. However, PCh was less effective as a chain-breaking antioxidant than was α-Toc when unilamellar egg yolk phosphatidylcholine liposomes were exposed to either a water-soluble or a lipid-soluble radical initiator. It is likely that the phospholipid nature of PCh affects the location and the mobility of the chromanol moiety in the membrane bilayer resulting in a decrease in antioxidant activity. On the other hand, the antioxidant activity of PCh was little different from that of α-Toc in unilamellar liposomes when exposed to a lipid-soluble radical initiator in the presence of ascorbic acid. It appears that PCh in phospholipid bilayers can be regenerated by ascorbic acid in aqueous phase as can be α-Toc. The new phospholipid, phosphatidylchromanol, should prove useful as a chain-breaking antioxidant in phospholipid membranes. *Lipids* 29, 83–89 (1994).

Lipid peroxidation in biomembranes contributes significantly to oxidative damage in biological systems (1). It is also known that biomembranes possess an antioxidant defense against lipid peroxidation (2), in which *d*-α-tocopherol (α-Toc) is thought to act as a potent chain-breaking reagent (3). The mechanism of radical scavenging by α-Toc in homogenous solution is well understood (4,5). It is also known that α-Toc prevents phospholipid peroxidation in biomembranes (6–8). Although a number of studies have been undertaken using liposomes as a membrane model (6–10), the mechanism of antioxidant action of α-Toc in biomembranes is still not entirely clear. In particular, the location in the phospholipid bilayer of the chromanol ring, which is the active moiety of α-Toc for radical-scavenging that interferes with the reaction with chain-propagating lipid peroxyl radicals, is still a subject of discussion (10–13).

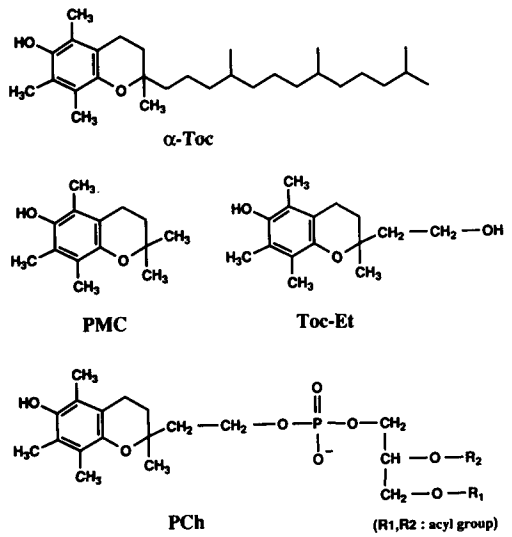

FIG. 1. Molecular structures of *d*-α-tocopherol, (α-Toc), 2,2,5,7,8-pentamethyl-6-chromanol (PMC), 2,5,7,8-tetramethyl-6-hydroxy-2-(hydroxyethyl)chroman (Toc-Et) and phosphatidylchromanol (PCh).

The transphosphatidylation activity of phospholipase D (PLD) is commonly used to modify the polar head group of phospholipids (14,15). We previously described the synthesis of 6-phosphatidyl-L-ascorbic acid catalyzed by PLD (16). This phosphatidyl derivative of ascorbic acid was shown to prevent liposomal lipid oxidation more effectively than ascorbic acid (17). This, in turn, prompted us to synthesize a phospholipid containing a chromanol ring, as such an α-Toc analogue would seem helpful in investigating the antioxidant action of α-Toc in membranes.

In the present work, we report on the synthesis of a new phospholipid containing a chromanol ring (Fig. 1), as well as on the antioxidant activity of the phosphatidylchromanol (PCh) synthesized in unilamellar liposomes and in hexane/isopropanol solution.

MATERIALS AND METHODS

Chemicals. Phosphatidylcholine (PC) from egg yolk and dimyristoyl PC were purchased from Sigma Chemical Co. (St. Louis, MO). *d*-α-Toc and 2,2,5,7,8-pentamethyl-

6-chromanol (PMC) (Fig. 1) were obtained from Eisai Co. (Tokyo, Japan). 2,5,7,8-Tetramethyl-6-hydroxy-2-(hydroxyethyl)chroman (Toc-Et) was kindly supplied by Kuraray Co. Ltd. (Kurashiki, Japan) (Fig. 1). PLD from *Streptomyces lydicus* was kindly supplied by Honen Co. (Yokohama, Japan). 2,2'-Azo*bis*(2-amidinopropane) dihydrochloride (AAPH) and 2,2'-azo*bis*(2,4-dimethylvaleronitrile) (AMVN) were obtained from Wako Pure Chemical Co. (Osaka, Japan). All other chemicals used were of reagent grade.

Preparation of PCh. PCh was synthesized by reacting 2.5 mL of 25 mM egg yolk PC and 25 mM Toc-Et in diethyl ether and 25 mL of 10 U of PLD and 10 mM $CaCl_2$ in 10 mM acetate buffer (pH 5.1) at 37°C with continuous shaking. After 2 h of incubation, 3 mL of 6 N HCl was added, and the product was extracted three times with 30 mL of chloroform/methanol (2:1, vol/vol). The combined chloroform layers were washed with 20 mL of water, and evaporated in a rotary evaporator. The residue was dissolved in chloroform/methanol (95:5, vol/vol) at 10 mg/mL and placed onto a silica gel column (Lichroprep Si 60 40–63 μm; Merck, Darmstadt, Germany) that had previously been equilibrated with the same solvent. The product was eluted at a flow rate of 1.8 mL/min, 1.0-mL fractions were collected, and fractions were monitored by thin-layer chromatography (TLC) (Silica gel 60; Merck) using chloroform/methanol (8:2, vol/vol) as developing solvent. Phospholipids were visualized by spraying with Dittmer's reagent (18). Reducing activity in TLC fractions was detected by exposure to ferric ion reagent (19). Fractions containing PCh were redissolved in methanol, and then stored at –20°C until use.

Assay of PCh and phosphatidic acid (PA) in the reaction mixture. PCh and PA were assayed by high-performance liquid chromatography (HPLC) on an aminopropane-bonded silica column (Shim-Pack FLC-NH_2, 4.6 × 50 mm, 3 μm; Shimadzu Co., Kyoto, Japan) using *n*-hexane/isopropanol/10% phosphoric acid (70:30:0.5, by vol) at a flow rate of 2.0 mL/min. PCh and PA eluted at 1.5 and 2.2 min, and were monitored at 295 and 206 nm, respectively.

Spectral analyses. Infrared spectra were measured on KBr pellets using a JASCO FT/IR-7300 infrared spectrophotometer (Japan Spectroscopic Co., Ltd., Tokyo, Japan). Mass spectra were measured in the sputtered ion mass spectrometry (SIMS) mode using a Hitachi M-80B instrument (Hitachi Co., Tokyo, Japan). ^1H and ^{13}C nuclear magnetic resonance (NMR) spectra were measured with a JEOL GSX-270 FT NMR spectrometer (Japan Electronic Optics Laboratory Co., Tokyo, Japan) at 270 and 67.9 MHz, respectively. Samples were dissolved in $CDCl_3/CD_3OD$ (2:1, vol/vol), and tetramethylsilane was used as internal standard.

Peroxyl radical-scavenging activity in solution. Peroxyl radical-scavenging activities of α-Toc, PMC and PCh in homogeneous solution were determined by measuring the inhibition of free radical oxidation of methyl linoleate that was initiated by a lipid-soluble azo compound (17,20). The reaction mixture contained 110 μmol of methyl linoleate and 0.1 μmol of antioxidant in 1.0 mL of *n*-hexane/isopropanol (7:3, vol/vol). Oxidation was initiated by adding 110 mM AMVN (100 μL) in the same solvent. The mixture was incubated at 37°C with continuous shaking in the dark and aliquots were withdrawn at regular intervals to measure methyl linoleate hydroperoxides (MeL-OOH) (21).

Preparation of unilamellar liposomes. Liposomes [large unilamellar vesicles (LUV)] were prepared by an extrusion method (22). First, PC was purified to remove contaminant peroxides by reverse-phase column chromatography as described previously (23). A stock solution of purified PC in chloroform, with or without antioxidants, was placed into a test tube and was evaporated under a stream of nitrogen, then *in vacuo.* The thin lipid film on the glass wall was dispersed with a vortex mixer for 1 min in 0.7 mL Tris-HCl buffer (0.01 M, pH 7.4) containing 0.5 mM diethylenetriaminepentaacetic acid (DTPA) followed by ultrasonic irradiation with a Heat Systems Sonifier (Model W-380; Farmingdale, NY) for 30 s. LUV were obtained by extruding the suspension through polycarbonate filters mounted in an extrusion apparatus (LiposoFast, Avestin, Inc., Ottawa, Canada), and the LUV were diluted with the same volume of Tris-buffer.

Lipid peroxidation of LUV initiated by radical initiators. In the experiments with a water-soluble radical initiator, oxidation was started by the addition of AAPH to the LUV suspension. Oxidation was carried out in the dark at 37°C under air with continuous shaking. In the experiments with lipid-soluble radical initiator, AMVN was mixed with PC before the preparation of the liposomes, and the reaction mixture was kept at 50°C during the oxidation. Aliquots (10 μL) were withdrawn at specific time intervals and phosphatidylcholine hydroperoxides (PC-OOH) were quantified by HPLC as described previously (24). The octane-bonded silica column (TSK-gel OCTYL-80TS column, 6 × 150 mm, 5 μm; TOSOH, Tokyo, Japan) was eluted with methanol/water (93.5:6.5, vol/vol). Standard PC-OOH was prepared as described (24).

Determination of antioxidants during liposomal peroxidation. α-Toc, PMC and PCh were measured by HPLC on an octodecane-bonded silica column (YMC-pack ODS, 6 × 150 mm, 5 μm; Yamamura Chemical Laboratories, Kyoto, Japan) that was eluted with acetonitrile/ethanol (60:40, vol/vol) at a flow rate of 2.5 mL/min. The eluent was monitored fluorometrically at an excitation wavelength of 298 nm and an emission wavelength of 325 nm using a JASCO Spectrofluorometer 821-FP (Tokyo, Japan). α-Toc, PMC and PCh were eluted at 4.5, 1.5 and 1.7 min, respectively. Ascorbic acid (AsA) was assayed by HPLC using a cation exchange column (TSK gel SCX, 7.8 × 300 mm, 5 μm, TOSOH) with 2 mM phosphoric acid as eluent at a flow rate of 1.2 mL/min. The eluent was monitored at 254 nm; AsA was eluted at 6.6 min.

RESULTS

Synthesis of PCh. The time course of the enzymatic reaction for the synthesis of PCh catalyzed by PLD is

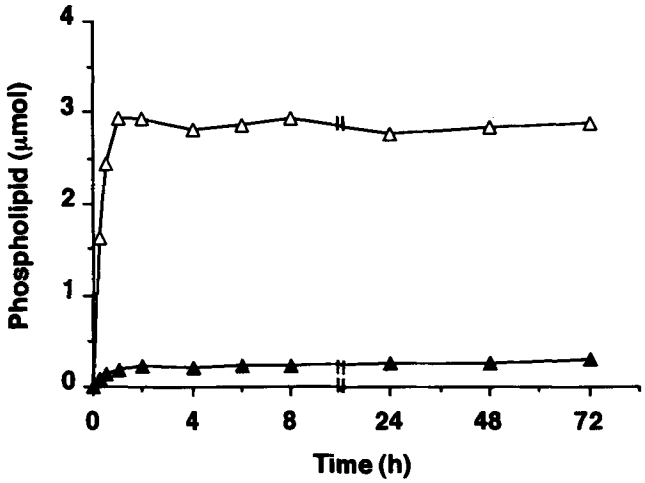

FIG. 2. Time course for the synthesis of phosphatidylchromanol catalyzed by phospholipase D. The amounts of PCh and phosphatidic acid (PA) were calculated from high-performance liquid chromatography peak areas using calibration curves; (△), PCh; (▲), PA.

shown in Figure 2. The reaction reached a plateau after 1.5 h of incubation, and PC was converted to the new product in high yield (approximately 94%). Little PA accumulated throughout the reaction period, indicating that little hydrolysis occurred. The new product gave a blue spot on TLC with Dittmer reagent and a red spot with ferric ion reagent, indicating that the new compound was a phospholipid with reducing activity.

Spectral analyses were carried out to identify the structure of the phospholipid synthesized from 1,2-dimyristoyl-*sn*-glycero-3-phosphocholine. The SIMS spectrum showed an [M + H^+] ion at *m/z* 825. The infrared spectrum indicated the presence of a phosphate group and of hydroxyl at the chromanol ring (KBr, cm^{-1} : 1745, C=O; 1457,–OH; 1246, P=O; 1027, P-O-C). To elucidate the structure in detail, ^{13}C NMR chemical shifts were assigned to the carbons of the dimyristoylglycerophosphate and the chroman ring moieties (Table 1). The ^{13}C chemical shifts of the dimyristoylglycerol moiety of the product were essentially the same as those of 1,2-dimyristoyl-*sn*-glycero-3-phosphocholine (16). The ^{13}C chemical shifts of the chroman ring moiety were essentially the same as those of Toc-Et except for the C-1' and C-2' shifts. The C-2' signal was shifted downfield (3.24 ppm) relative to that of Toc-Et, while the C-1' signal was shifted slightly upfield (1.43 ppm). Such ^{13}C chemical shifts for carbons proximal to phosphate were also observed in the spectra of 6-phosphatidyl-L-ascorbic acid (16) and other phosphoesters (14). Based on these data and on ^1H NMR spectra (data not shown), the compound was identified as 1,2-dimyristoyl-*sn*-glycero-3-phospho-2'-hydroxyethyl-2',5',7',8'-tetramethyl-6'-hydroxy-chroman.

Peroxyl radical-scavenging activity of PCh, α-Toc and PMC in solution. Peroxyl radical-scavenging activities of PCh and of related compounds were evaluated by measuring the inhibition of methyl linoleate peroxidation initiated by AMVN in hexane/isopropanol solution. A

TABLE 1

^{13}C NMR Spectra of PCh, Dimyristoyl PC and Toc-Et[a]

	Chemical shifts (δ)		
Carbons	PCh	Dimyristoyl PC[b]	Toc-Et
Dimyristoyl glycerol moiety			
CH_2O (*sn*-1)	62.85	63.01

[a]Chemical shifts are given downfield from tetramethylsilane.
[b]Data for dimyristoyl PC are those reported by Nagao *et al.* (16).
Abbreviations: NMR, nuclear magnetic resonance; PCh, phosphatidylchromanol; Dimyristoyl PC, 1, 2-dimyristoyl-*sn*-glycero-3-phosphocholine; Toc-Et, 2, 5, 7, 8-tetramethyl-6-hydroxy-2-(hydroxyethyl) chroman.

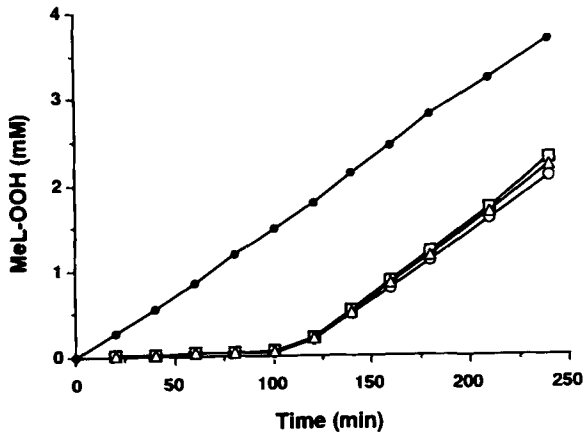

FIG. 3. Inhibition of the 2,2'-azo*bis*(2,4-dimethylvaleronitrile) (AMVN)-initiated oxidation of methyl linoleate in solution by α-Toc, PMC and PCh. The reaction system consisted of methyl linoleate (100 mM), antioxidant (90.9 μM) and AMVN (10 mM) in *n*-hexane/isopropanol (7:3, vol/vol); (●), no addition; (○), α-Toc; (□), PMC; (△), PCh. See Figure 1 for other abbreviations; MeL-OOH, methyl linoleate hydroperoxides.

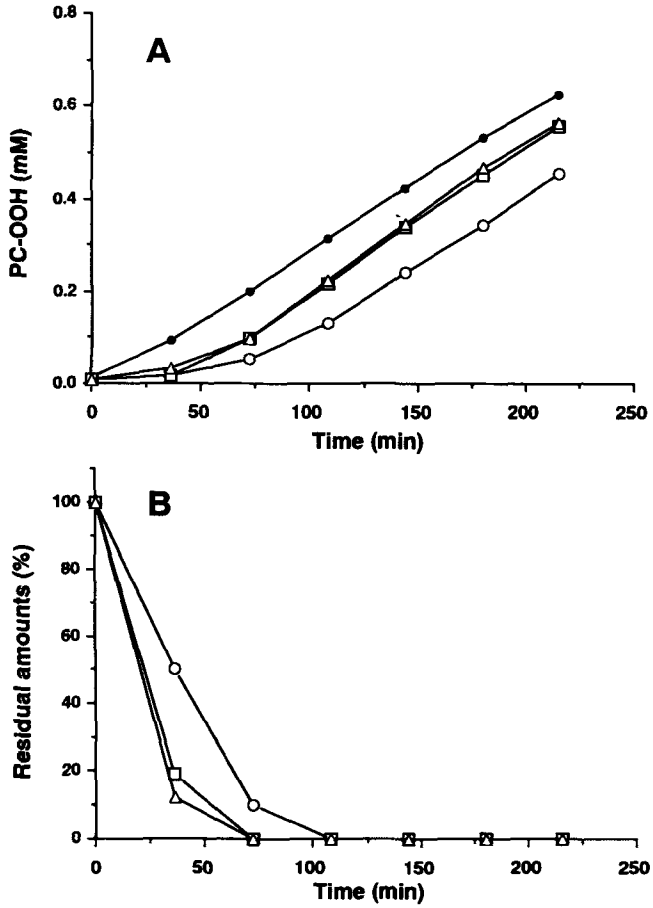

FIG. 4. Accumulation of phosphatidylcholine hydroperoxides (PC-OOH) (A) and loss of α-Toc, PMC and PCh (B) during phospholipid peroxidation in large unilamellar vesicles exposed to 2,2'-azo*bis*(2-amidinopropane)hydrochloride (AAPH). The reaction system consisted of PC (5 mM), α-Toc, PMC or PCh (10 μM), diethylenetriaminepentaacetic acid (0.5 mM) and AAPH (10 mM) in 1.1 mL of Tris-HCl buffer; (●), no addition; (○), α-Toc; (□), PMC; (△), PCh. See Figure 1 for other abbreviations.

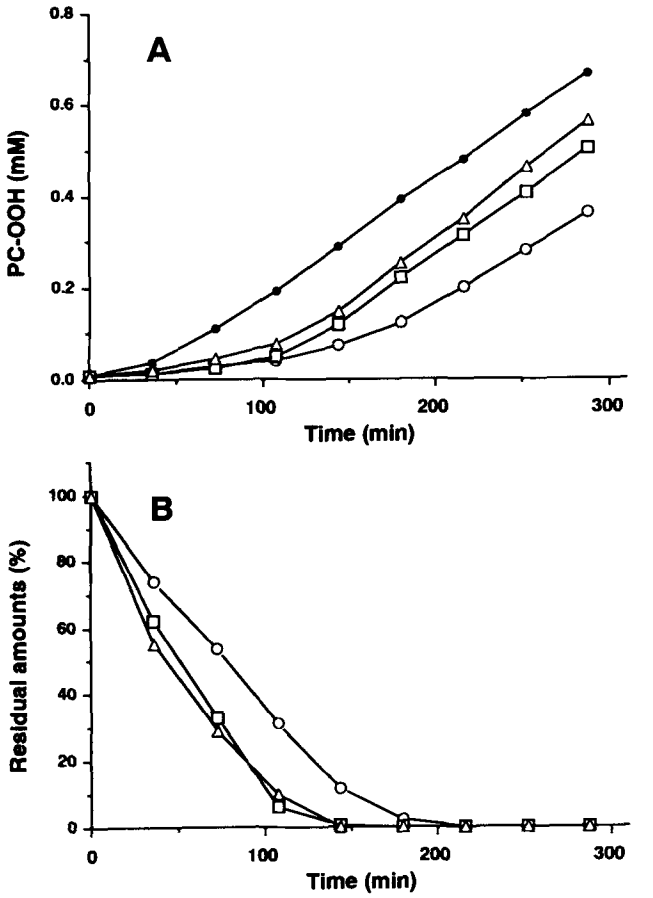

FIG. 5. Accumulation of PC-OOH (A) and loss of α-Toc, PMC and PCh (B) during phospholipid peroxidation in large unilamellar vesicles exposed to AMVN. The reaction system consisted of PC (5 mM), α-Toc, PMC or PCh (5 μM), DTPA (0.5 mM), and AMVN (1 mM) in 1.1 mL of Tris-HCl buffer; (●), no addition; (○), α-Toc; (□), PMC; (△), PCh. See Figures 1, 3 and 4 for abbreviations.

typical example of the inhibition seen is shown in Figure 3. From the data we obtained from three independent experiments, we calculated kinetic parameters by the method of Ingold and colleagues (4,25). PCh, α-Toc and PMC showed almost the same induction periods (t_{inh}; 7190 ± 610 s, 7090 ± 420 s and 7290 ± 490 s for α-Toc, PMC and PCh, respectively). The rates of oxidation (R_{inh}) during the induction period were (9.97 ± 3.16)× 10^{-9} M/s, (4.79 ± 1.56)× 10^{-9} M/s, (5.69 ± 1.02)× 10^{-9} M/s for PCh, α-Toc and PMC, respectively. This indicates that the number of radicals trapped by PCh (n) was the same as that trapped by α-Toc and PMC as n is a function of t_{inh}. The k_{inh}/k_p values, the ratio of the rate constant for the inhibition reaction *vs.* that of the propagation reaction, were calculated from t_{inh} and R_{inh} as described previously (26). For PCh, k_{inh}/k_p was 1480 ± 400, which was slightly lower than for α-Toc (3040 ± 770) and PMC (2520 ± 280).

Free radical-scavenging activity of PCh, α-Toc and PMC in unilamellar liposomes. We used LUV and estimated the antioxidant activities of α-Toc and its analogues against phospholipid peroxidation initiated by free radical generators. Figure 4 shows a typical example of the inhibition of the peroxidation initiated by AAPH by α-Toc and its analogues. The water-soluble radical initiator produces peroxyl radicals in the aqueous phase and thereby attacks phospholipids from the aqueous phase at the membrane surface (27). PC-OOH, the primary products of peroxidation, accumulated in the initial stage of the reaction without antioxidants. α-Toc suppressed the accumulation of PC-OOH with a pronounced induction period (65 min). Although PCh and PMC also retarded lipid peroxidation, their induction periods were shorter than that of α-Toc (36 min for PCh, and 39 min for PMC). In addition, both PCh and PMC were consumed faster than α-Toc.

When we used a lipid-soluble azo compound to initiate peroxyl radical-driven lipid peroxidation within the liposomal membranes, α-Toc showed a longer induction period (126 min) than PCh (94 min) and PMC (97 min), and α-Toc was consumed less rapidly than were the latter two compounds (Fig. 5). Thus, PCh was less effective

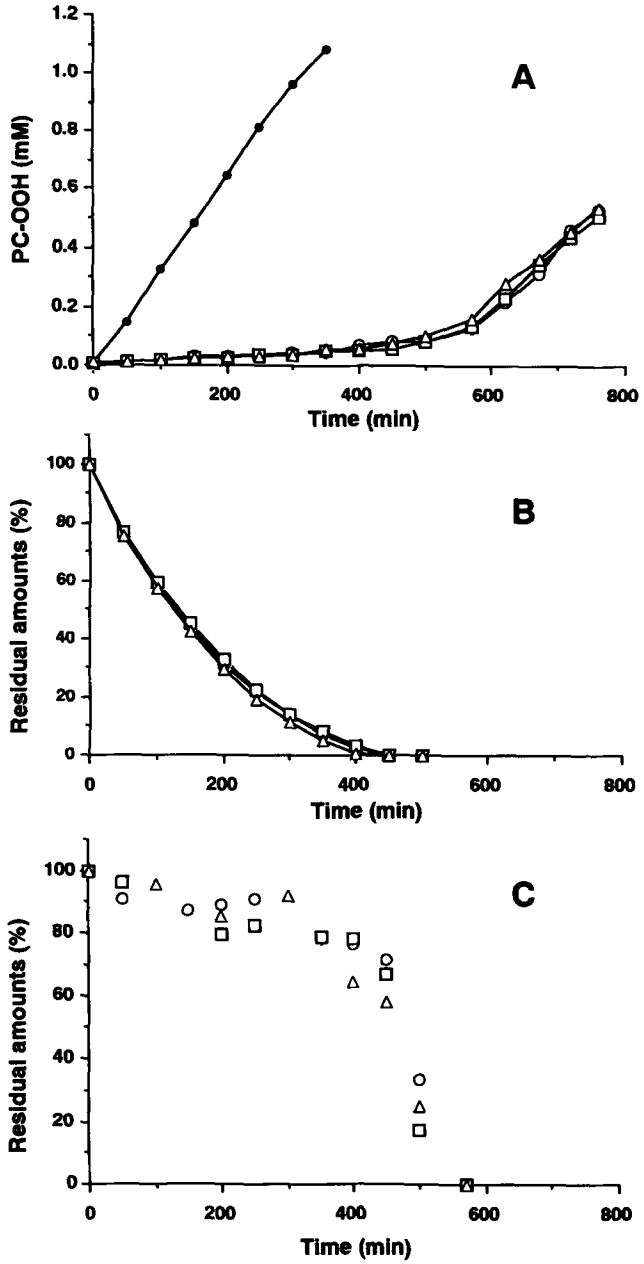

FIG. 6. Accumulation of PC-OOH (A), loss of ascorbic acid (AsA) (B), and loss of α-Toc, PMC or PCh (C) during phospholipid peroxidation in large unilamellar vesicles exposed to AMVN. The reaction system consisted of PC (5 mM), AsA (100 μM), α-Toc, PMC or PCh (5 μM), diethylenetriaminepentaacetic acid (0.5 mM), and AMVN (1 mM) in 1.1 mL of Tris-HCl buffer; (●), no addition; (□), α-Toc; (△), PMC; (○), PCh. See Figures 1, 3 and 4 for abbreviations.

than α-Toc as a chain-breaking antioxidant when either a water-soluble or a lipid-soluble initiator was used to induce the radical chain reaction.

Effect of ascorbic acid on the inhibition by PCh, α-Toc and PMC in liposomal phospholipid peroxidation. Figure 6 shows the inhibition of PC-OOH accumulation by α-Toc or its analogues in the presence of ascorbic acid. It is apparent that the presence of ascorbic acid increased the induction period significantly as indicated by comparison of the data in Figure 6 and Figure 5. Ascorbic acid was consumed in the initial stage, and the levels of α-Toc or its analogues always decreased after ascorbic acid was consumed. Interestingly, there were only small differences in the induction periods and in the consumption of ascorbic acid between the three compounds. Thus, in the presence of AsA PCh exerted the same antioxidant activity as did α-Toc.

DISCUSSION

We previously synthesized phosphatidyl AsA (16) and showed that this phospholipid derivative could be incorporated into phospholipid bilayers, and that it exerted antioxidant activity against oxidative attack from the aqueous phase more efficiently than did ascorbic acid (17). Because vitamin E is a major lipophilic chain-breaking antioxidant in cellular membranes, we now synthesized phosphatidyl vitamin E by the transphosphatidylation catalyzed by PLD. The reaction proceeded with a high yield, and there was little hydrolysis (Fig. 2) as was reported for the hydrolysis of phosphatidylinositol catalyzed by this enzyme (28). Resistance against PLD-catalyzed hydrolysis appears to be due to steric hindrance at the polar head group moiety.

α-Toc consists of two structural domains. One is the chromanol structure responsible for radical scavenging activity and the other is the phytyl side chain which is required for anchoring α-Toc within phospholipid bilayers (29). The product we synthesized by the PLD reaction contains a phospholipid moiety and chromanol moiety, and thus can be considered an α-Toc analogue in which the phytyl side chain is replaced by a phosphatidyl group. The product thus is lipophilic, much like α-Toc. However, introduction of the phosphatidyl group could affect the radical scavenging activity of the chromanol moiety by changing its location in the phospholipid bilayer.

It has already been shown that the phytyl side chain does not affect the free radical scavenging activity of α-Toc in solution (30). Our data show that PMC and α-Toc gave similar kinetic parameters, *i.e.*, k_{inh}/k_p and n values, for free radical oxidation in solution, and this is consistent with the view that the phytyl side chain is not responsible for the inherent antioxidant activity of chromanol. The fact that PCh gave the same n value furthermore suggests that PCh scavenges free radicals by the same mechanism as does α-Toc. The slightly smaller k_{inh}/k_p value for PCh may be due to the lower mobility of PCh in solution or to steric hindrance of scavenging peroxyl radicals as the phospholipids exist in the aggregated form in apolar solvents (31).

Niki and his co-workers (7,10) have shown that the antioxidant effect of α-Toc in phospholipid membranes is lower than in homogeneous solution, and that PMC is more effective than α-Toc in scavenging free radicals in membranes. The higher activity of PMC in membranes could be explained by differences between PMC and α-Toc in location and mobility. Previous studies suggest that the chromanol moiety of α-Toc is located in the hydrophobic region near the membrane surface and that the mobility of chromanol is restricted by the hydropho-

bic side chain, while PMC can move more freely within the membrane (10–13). Our results show that PCh is less active as a chain-breaking antioxidant in phospholipid membranes, regardless of the site of the chain initiation reaction. When a radical generator is used for initiating lipid peroxidation in membranes, α-Toc can scavenge chain-initiating peroxyl radicals as well as chain-propagating lipid peroxyl radicals. We presume that the chromanol moiety of PCh is located on the membrane surface and that the phospholipid moiety is inserted into the phospholipid bilayer, thereby restricting the mobility of PCh within the hydrophobic bilayer region. This location of PCh in membranes would lower the reactivity with chain-propagating lipid peroxyl radicals. The lateral diffusion rate of phospholipids in bilayers was reported to be about 270 times lower than that of α-Toc (32,33). Therefore, the lateral diffusion of the chromanol group of PCh would also be likely to be restricted within phospholipid bilayers resulting in the apparent lower activity with scavenging lipid peroxyl radicals.

We found that PMC is also less effective than α-Toc in preventing free radical initiated lipid peroxidation in the membrane model (Figs. 4 and 5) in spite of its ability to move freely within the bilayer. In addition, PMC and PCh were consumed more rapidly than α-Toc. α-Toc donates a hydrogen atom to a peroxyl radical to form an α-tocopheroxyl radical (8). Subsequent reaction of the d-α-tocopheroxyl radical with a second peroxyl radical gives both a stable product and an unstable product that may produce an alkoxyl radical (34-36). The lower effectiveness of PMC and PCh could be explained by the assumption that the reaction that produces the unstable products occurs quite easily in the case of PMC and PCh. Among the three compounds, α-Toc acts most efficiently as chain-breaking antioxidant in phospholipid bilayers. This supports the idea that the phytyl side chain of α-Toc arranges the chromanol moiety at a site suitable for scavenging chain-carrying lipid peroxyl radicals in biological membranes (7,10).

On the other hand, when the liposomal peroxidation was initiated in the presence of ascorbic acid, the antioxidant activity of PCh and PMC was the same as that of α-Toc (Fig. 6). Although ascorbic acid cannot inhibit lipid peroxidation within liposomes directly, it is known that it acts in the aqueous phase as a synergist by regenerating α-Toc (37,38). Bowry *et al.* (39) pointed out that the regeneration of α-Toc by ascorbic acid is required to prevent the prooxidant effect of α-Toc. We also found that ascorbic acid prolonged the induction period of α-Toc and its analogues in liposomal suspensions. It should also be emphasized that there is no difference in the antioxidant activity between α-Toc and PCh, although PCh is less effective in the absence of ascorbic acid. It appears that the regeneration by ascorbic acid is quite important in determining antioxidant activity in phospholipid bilayers when ascorbic acid is present in the aqueous phase.

In conclusion, we synthesized a new vitamin E phospholipid with antioxidant activity, which works as a chain-breaking antioxidant in phospholipid bilayers. Its activity is comparable to that of vitamin E in the presence of ascorbic acid, but its activity is lower in the absence of ascorbic acid. The new vitamin E phospholipid should be active in biological systems, provided the chromanol moiety is regenerated by ascorbic acid.

ACKNOWLEDGMENTS

The authors thank Sinbo M. and Shiono M. for kindly supplying PLD and Toc-Et, respectively. We are very grateful to Ishida N., Yamashita C., Matsudo T. and Uchida R. for their help in spectral analyses and for valuable discussions.

Butylated Hydroxyanisole Inhibits Tumor Necrosis Factor-Induced Cytotoxicity and Arachidonic Acid Release

Ole-Lars Brekke[a,*], Terje Espevik[b] and Kristian S. Bjerve[a]

[a]Department of Clinical Chemistry and [b]Institute of Cancer Research, University Hospital, University of Trondheim, N-7006 Trondheim, Norway

The mechanisms by which the antioxidant butylated hydroxyanisole (BHA) inhibits recombinant tumor necrosis factor alpha (rTNF-α)-induced cytotoxicity have been studied in WEHI 164 clone 13 (WEHI) and L929 fibrosarcoma cells. When BHA was added simultaneously with rTNF-α, it completely inhibited rTNF-α cytotoxicity in the WEHI and L929 cells. BHA also inhibited the toxicity when added 2 h after rTNF-α in WEHI cells, suggesting that BHA inhibits some late intracellular event(s) in rTNF-α cytotoxicity. Pretreating WEHI cells with BHA for 4 h did not decrease the binding of rTNF-α to its receptors as measured using flow cytometry. BHA inhibited rTNF-α toxicity in the presence of actinomycin D and cycloheximide, indicating that neither mRNA nor protein synthesis is necessary for the BHA effect. The antioxidant butylated hydroxytoluene (BHT) and indomethacin did not inhibit the rTNF-α–induced cytotoxicity nor the rTNF-α-induced release of [^{3}H]arachidonic acid. By comparison, BHA completely inhibited the rTNF-α-induced release of arachidonic acid, suggesting that BHA somehow inhibits rTNF-α-induced activation of phospholipase(s). In WEHI cells, rTNF-α increased the level of protein-associated thiobarbituric acid reactive substances (TBARS) dose-dependently. BHA, but not BHT, blocked rTNF-α-induced cytotoxicity and rTNF-α-induced accumulation of protein-associated TBARS, suggesting that rTNF-α cytotoxicity is correlated with protein-associated TBARS. In conclusion, the results suggest that BHA blocks some post receptor event in rTNF-α-induced cytotoxicity, and that activation of phospholipase(s) coupled with the enzymatic formation of specific oxidized lipids could be a pivotal event in rTNF-α-induced cytotoxicity.
***Lipids* 29, 91–102 (1994).**

Tumor necrosis factor (TNF) is a potent mononuclear macrophage derived cytokine with a variety of effects including the ability to enhance the growth of fibroblasts (1), to stimulate superoxide anion production by neutrophils (2) and to kill certain sensitive cancer cells (3,4).

Although the effects of TNF have been intensively studied both *in vivo* and *in vitro*, the biochemical events involved in TNF-induced cell killing are still not known in detail. TNF binds to cell membrane receptors (5,6), and two different receptors with different molecular weight have been identified (7). Heller *et al.* (8) recently reported that one of these receptors probably mediates TNF-induced cytotoxicity in murine TA1 cells. Following binding of TNF to its receptors, TNF activates several signal transduction pathways, including phosphatidylcholine specific phospholipase C (9), protein kinase C (9) and phosphorylation of intracellular proteins (10). Protein kinase C activity is probably not required for the TNF-induced activation of the transcription factor NF_KB, at least not in Jurkat cells (11). TNF also activates the sphingomyelin signal transduction pathway in a cell free system (12). In addition, a recent report suggested that TNF stimulates protein phosphatases (13). Clark *et al.* (14) showed that TNF stimulates phospholipase A_2 activity through induction of a phospholipase-activating protein in endothelial cells. In osteoblast-like cells, TNF stimulates phospholipase A_2 through receptor-mediated activation of G-proteins (15). Both TNF-induced cytotoxicity (16,17) and TNF-induced growth enhancement in FS-4 fibroblasts (17) are associated with enhanced release of arachidonic acid. However, which of these events are essential for TNF-induced cytotoxicity has not been clarified in detail. The intracellular calcium level does not change, at least not immediately after the addition of TNF to U937 cells (9). Several reports indicate that cyclooxygenase and lipoxygenase inhibitors (16,18), some antioxidants (18), dexamethasone (19) and the phospholipase A_2 inhibitor quinacrine (20), decrease TNF-induced cytotoxicity *in vitro*. TNF-induced cytotoxicity is associated with oxidative damage measured as increased levels of oxidized glutathione in some cell lines (21). Yamauchi *et al.* (22) showed that hydroxyl radicals are formed during TNF-induced cytotoxicity. Matthews *et al.* (18) reported that TNF induces accumulation of peroxides measured as thiobarbituric acid reactive substances (TBARS) in L929 cells sensitive to TNF-induced cytotoxicity, but not in TNF-resistant sublines.

We have recently shown that the antioxidant butylated hydroxyanisole (BHA) completely blocks the rTNF-α and rTNF-ß (lymphotoxin) toxicity in WEHI 164 clone 13 and L929 fibrosarcoma cells, while the structurally similar antioxidant butylated hydroxytoluene (BHT) had only little effect (23,24). BHA also inhibited rTNF-α-induced growth enhancement, but not interleukin-1ß-induced growth enhancement in FS-4 fibroblasts (24). Since TNF-induced cytotoxicity probably induces oxidative damage (18,21,22), the antioxidants BHA and BHT may be useful tools to study mechanism(s) involved in TNF-induced cytotoxicity. The present study therefore examined the mechanisms by which BHA inhibits rTNF-α-induced cytotoxicity in

WEHI 164 and L929 fibrosarcoma cells. The effects of BHA and BHT on rTNF-α-induced cytotoxicity, accumulation of TBARS and release of arachidonic acid are reported.

MATERIALS AND METHODS

Materials. Fetal calf serum (FCS), L-glutamine, Dulbecco's phosphate-buffered saline (PBS) without calcium and magnesium, trypsin solution and RPMI-1640 were obtained from Gibco Laboratories (Paisley, Scotland). RPMI-1640 without leucine and phenolic red was prepared from the RPMI-1640 select-amine kit (Gibco) and was sterilized by filtration through a 0.22 μm Sterivex-GS filter obtained from Millipore Corp. (Bedford, MA). Actinomycin D, arachidonic acid, bovine serum albumin (BSA), cycloheximide, *dl*-α-tocopherol, ethylenediaminetetraacetic acid (EDTA), indomethacin, 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT), quinacrine, sodium dodecylsulfate, 1,1,3,3-tetraethoxypropan, 2-thiobarbituric acid, trypan blue and BHT were obtained from Sigma Chemical Co. (St. Louis, MO). Gentamicin sulfate was obtained from Schering Corp. (Kenilworth, NJ), and ethanol was obtained from Vinmonopolet A/S (Oslo, Norway). BHA (mixture of 2-BHA and 3-BHA) and 4-hydroxymethyl-2,6-di-*t*-butylphenol was part of the food additive kit-92 from Supelco (Bellefonte, PA). Hydroxyeicosatetraenoic acids (HETE), prostaglandins and epoxy fatty acid standards for high-performance liquid chromatography (HPLC) were purchased from Cayman Chemical Co. (Ann Arbor, MI). Citric acid monohydrate, trichloroacetic acid (TCA), hydrochloric acid, ethyl acetate of Uvasol quality, 1-butanol of pro analysis quality and methanol of Lichrosolv quality were obtained from E. Merck (Darmstadt, Germany). *n*-Hexane of HPLC quality was obtained from Fisons (FSA Laboratory Supplies, Loughborough, England). Propan-2-ol and acetonitrile (HPLC grade) were purchased from Rathburn Chemicals Ltd. (Walkerburn, Scotland), and acetic acid of HPLC grade was obtained from Pierce Chemical Co. (Rockford, IL). The octadecyl (C_{18}) columns (500 mg) were purchased from Bond Elut (Varian SPP., Harbor City, CA). Murine rTNF-α with a specific activity of 8×10^7 U/mg protein, and human rTNF-α with a specific activity of 7.6×10^7 U/mg protein, as determined in a bioassay, were kindly provided by Genentech Inc. (South San Francisco, CA). Murine rTNF-α was used if not otherwise indicated. Streptavidin-phycoerythin was purchased from Becton-Dickinson & Co. (Mountain View, CA). L-[4,5-^{3}H]leucine (135 Ci/mmol), [5,6,8,9,11,12,14,15-^{3}H]arachidonic acid (219 Ci/mmol) and [5,6,8,11,12,14,15(n)-^{3}H]prostaglandin E_2 (140 Ci/mmol) were obtained from Amersham International (Buckinghamshire, United Kingdom). Optifluor® scintillation fluid was purchased from Packard Instrument Company, Inc. (Downer's Grove, IL).

Cell culture. The WEHI 164 clone 13 cell line (termed WEHI clone 13 cells) which is highly sensitive to rTNF-α-induced cytotoxicity, was previously isolated from the WEHI 164 parental cell line (25). The L929 cell line was a generous gift from Dr. D. Løvhaug (Nycomed Bioreg, Oslo, Norway). WEHI and L929 cells were cultured in 75-cm^2 flasks (Costar 3275, Cambridge, MA) in RPMI-1640 containing 2 mM L-glutamine and 10% (vol/vol) heat-inactivated (56°C, 30 min) fetal calf serum (FCS-M). Cells were passed twice a week using trypsin and cultured at 37°C in a humidified atmosphere of 95% air and 5% CO_2. Antioxidants were added to the FCS-M dissolved in ethanol. Ethanol at a final concentration of 0.05% (vol/vol) had no effect on rTNF-α-induced cytotoxicity.

Chromium release assay. rTNF-α-induced cytotoxicity was measured using the chromium release assay and was performed as previously described (23). The percent specific cell lysis was calculated as $100 \times (E\text{-}S)/(T\text{-}S)$, where E represents experimental [^{51}Cr]-release, S represents spontaneous release and T total release after lysing the cells with sodium dodecylsulfate at a final concentration of 0.5% (wt/vol).

Cell survival assay. Cell survival after exposure to rTNF-α was measured using the MTT assay as described (24). The stock solution contained MTT (5 g/L) dissolved in Dulbecco's PBS (without calcium and magnesium). WEHI clone 13 or L929 cells were trypsinized and seeded at 2×10^3 cells per well in microtiter plates (Costar 3598) using 200 μL FCS-M/well. The medium was removed after 48 h culture if not otherwise indicated. After 22 h incubation at 37°C with murine rTNF-α and the indicated inhibitors, the medium was again removed and 110 μL/well of FCS-M containing MTT at a final concentration of 0.45 g/L were added. The cultures were incubated for 4 h at 37°C, 50 μL of the supernatant was removed and 100 μL propan-2-ol containing 0.04 N HCl was added to dissolve the formazan. After the formazan had been dissolved, the optical density (OD) was measured on a Titertek Multiskan MCC/340 MK II microplate reader (Flow Lab, Irvine, Scotland) as described (24). Percent cell survival was calculated as: 100 × (OD in wells with TNF)/OD in wells without TNF).

rTNF-α receptor binding. WEHI clone 13 cells were seeded in 1400-mm microbiological petri dishes (Nunc A/S, Roskilde, Denmark) at 2×10^6 cells/dish, and cultured as nonadherent cultures in 15 mL FCS-M. After 22–24 h incubation, 5 mL FCS-M containing BHA or BHT (100 μM) was added, and the incubation continued for 4 h. Cells were pelleted at +4°C, FCS-M added (+4°C), and kept at 0–4°C. Thereafter, 10^6 cells were treated with biotinylated human rTNF-α in PBS containing BSA (PBS/BSA) for 45 min, washed twice in PBS/BSA and stained with streptavidin–phycoerythrin for 45 min at 0–4°C. Cells were subsequently washed in PBS, fixed in 2% (vol/vol) formalin and stored at 0–4°C. Thereafter, 5×10^3 cells were analyzed on a FACScan flow cytometer (Becton Dickinson & Co.) as previously described (6).

Protein synthesis assay. Protein synthesis was measured essentially as described by Sandvig *et al.* (26). WEHI clone 13 cells were seeded at a density of 2×10^3 cells/well in microplates using 200 μL FCS-M/well, and the incubation continued for 44 h. Protein synthesis was measured by adding [^{3}H]leucine (1 μCi/well) in 10 μL

RPMI-1640 without leucine and phenolic red, and continuing the incubation for 30 min. The medium was carefully removed and cell proteins precipitated and washed once with 5% (wt/vol) TCA (26). Proteins were dissolved in 40 µL KOH (0.1 M), samples mixed with 10 mL Optifluor^R scintillation fluid and radioactivity determined using an LKB Wallac 1211 Rackbeta counter (Turku, Finland).

TBARS assay. WEHI clone 13 or L929 cells were trypsinized and seeded in 1400-mm microbiological petri dishes at 2×10^6 cells/dish in 10 mL FCS-M. After 4 h of incubation, control medium or medium (10 mL) containing unlabeled arachidonic acid was added as indicated. After approximately 47 h of total incubation, the cells preincubated with arachidonic acid were resuspended, centrifuged and seeded in microbiological petri dishes at 1×10^6 cells/mL in FCS-M. Cells received rTNF-α in the absence or presence of antioxidant after approximately 48 h of total incubation. The cells were resuspended 22 h later and aliquots taken for cell counting and determination of viability by trypan blue exclusion. The cells were counted using a Coulter Counter ZF (Coulter Electronics, Dunstable Beds, England) or a Bürker counting chamber. Cells were pelleted at +4°C ($800 \times g$, 15 min), washed twice in 0.9% (wt/vol) NaCl at +4°C, and finally resuspended in 0.8 mL NaCl (+4°C). Aliquots were taken for protein analysis using the Coomassie brilliant blue technique (27) with BSA as standard. Thereafter, cells were lysed and proteins precipitated by adding 10% (wt/vol) TCA. TBARS were measured according to Chow *et al.* (28), using reduced reagent volumes to increase sensitivity. When TBARS in non-TCA precipitable material were measured, samples were centrifuged after precipitation of cell proteins and the supernatant moved to a new tube before addition of thiobarbituric acid. Thereafter, TBARS were extracted with 1-butanol and analyzed in cells from two wells to further increase sensitivity of the assay. 1,1,3,3-Tetraethoxypropane from 1 to 10 µM was used as standard. Absorbance at 532 nm was measured on a Perkin Elmer Lambda 5 spectrophotometer (Norwalk, CT), or on the Titertek Multiskan microplate reader in the dual wavelength mode with test and reference wavelengths set at 540 and 620 nm, respectively. The characteristic peak at 532 nm in the ultraviolet (UV)-spectrum was measured in test samples and standards using the Perkin Elmer Lambda 5 spectrophotometer.

Release of [3H]arachidonic acid. The effect of BHA and BHT on rTNF-α-induced release of arachidonic acid from L929 cells was investigated in cells prelabeled with [^{3}H]arachidonic acid. L929 cells were seeded at 0.5×106 cells in 60-mm petri dishes (Costar 3060). Approximately 24 h after seeding, cells received RPMI-1640 containing 1% (vol/vol) FCS, 2 mM L-glutamine and [^{3}H]arachidonic acid (1 mCi/L) in a total volume of 2 mL. After 24 h of further incubation, the culture medium was removed and cells were washed three times with FCS-M (37°C) to remove extracellular [^{3}H]arachidonic acid. Thereafter, rTNF-α and antioxidants were added as indicated in 2 mL FCS-M. FCS-M containing RPMI-1640 without phenolic red was used to avoid quenching during liquid scintillation counting. The culture medium was removed at the indicated time points after the addition of rTNF-α and centrifuged ($500 \times g$, 10 min) to remove loose cells. Thereafter, aliquots (100 µL) of the supernatants were mixed with 10 mL Optifluor^R scintillation fluid and radioactivity measured by liquid scintillation counting on the LKB Wallac 1211 Rackbeta counter. In some experiments, the culture medium was removed after 4 h of incubation with rTNF-α and the adherent cells detached by adding 1 mL trypsin containing 0.2 g/L of EDTA (37°C). After detachment of the cells, the trypsin-EDTA solution was immediately neutralized by addition of 1 mL FCS-M (+4°C). The culture medium was centrifuged at +4°C ($500 \times g$, 10 min), and the pellet containing nonadherent cells was combined with the trypsinized cells before determination of viability using trypan blue exclusion.

Viability. Cell viability was determined by dye exclusion using trypan blue at a final concentration of 0.2% (wt/vol). The samples were kept at +4°C, and 100 cells were counted two or three times in each sample using a hemocytometer. The release of lactate dehydrogenase to the medium was measured using a standard UV method.

Extraction and HPLC of arachidonic acid metabolites. Arachidonic acid metabolites were extracted according to Powell (29) and analyzed by HPLC as previously described (24). Recovery of [^{3}H]arachidonic acid and [^{3}H]prostaglandin E_2 added to FCS-M was 97 ± 4% and 88 ± 4% (mean ± SD, n = 3), respectively. The samples were analyzed by HPLC using a 5 µm Supelcosil LC-18 (150 mm × 4.6 mm i.d.) reversed-phase column. The HPLC method used in this report measured prostaglandins, HETE and free fatty acids, but did not measure peptido-leukotrienes (29). Metabolites were identified by coelution with standards in two different HPLC gradients.

Statistics. The data were compared by one-way analysis of variance (ANOVA) using the SPSS-PC+ version 4.01 statistical program obtained from SPSS Inc. (Chicago, IL).

RESULTS

Effect of the antioxidant BHA on rTNF-α-induced cytotoxicity. Addition of BHA simultaneously with rTNF-α completely inhibited cytotoxicity both in WEHI clone 13 (Fig. 1A) and L929 cells (Fig. 1B). To examine whether BHA inhibited early or late events in rTNF-α-induced cytotoxicity, we also added BHA at different time points after rTNF-α addition (Fig. 1). Adding BHA 2 or 4 h after rTNF-α gave approximately the same protection as when BHA was added simultaneously with rTNF-α (Fig. 1). When BHA was added 8 h after rTNF-α in the L929 cells, cell death decreased from 37% in the control to 21% when BHA was added (Fig. 1B). However, since 20% of the cells were already dead at the time when BHA was added, the protection of the remaining viable cells was still approximately 94%. Similar results were found in the WEHI cells (Fig. 1A). This indicates that BHA inhibits rTNF-α-induced cytotoxicity as late as

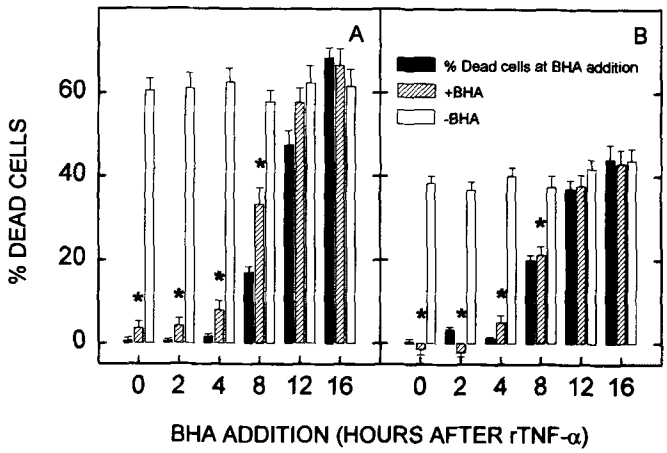

FIG. 1. The effect of delayed addition of butylated hydroxyanisole (BHA) on recombinant tumor necrosis factor α (rTNF-α)-induced cytotoxicity in (A) WEHI clone 13 cells and (B) L929 cells. All incubations were started by adding 40 ng/L (WEHI clone 13) or 160 ng/L of rTNF-α (L929 cells). Explanation of symbols: filled bar: no additions, percent dead cells at the indicated times; hatched bar: medium containing 100 μM BHA added at the indicated times, and percent dead cells measured 16 h after the addition of rTNF-α. Open bar: control medium without BHA added at the indicated times, and percent dead cells measured 16 h after the addition of rTNF-α. Cell death was measured using the [^{51}Cr]-release assay. Spontaneous release of [^{51}Cr] after 16 h incubation was 20 and 24% of total in WEHI and L929 cells, respectively. The results are from one of two similar experiments (WEHI) and one experiment (L929), and are given as means ± SD of six parallels. *BHA significantly different ($P < 0.05$) from control medium when analyzed by one-way analysis of variance using Duncan multiple comparison test.

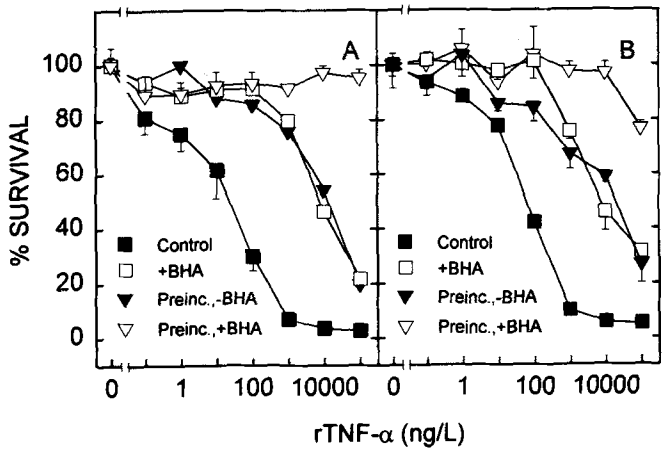

FIG. 2. The effect of BHA after 2-h pretreatment with rTNF-α in (A) WEHI clone 13 cells and (B) L929 cells. Cells were seeded in microtiter plates, and further incubated for 48 h. Thereafter, the medium was removed, and the cells were incubated 22 h with the indicated concentrations of rTNF-α without BHA (■), or in the presence of 100 μM BHA (□). In some wells, rTNF-α was removed after 2 h of incubation, and the cells washed three times with complete medium before continuing the incubations in control medium (▼), or medium containing 100 μM of BHA (▽). Cell survival was quantitated by the 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide assay after a total of 22 h of incubation. The results are from one of two similar experiments, and are presented as mean ± SD of triplicates. See Figure 1 for abbreviations.

6–8 h after the binding of rTNF-α to its receptors, suggesting that BHA probably inhibits some late event(s) in rTNF-α-induced cytotoxicity.

We next examined whether BHA mediates its effect by binding or inactivating rTNF-α in the culture medium. Cells were preincubated for 2 h with rTNF-α and any remaining extracellular rTNF-α was removed by washing the cells extensively before adding BHA (Fig. 2). BHA inhibited the toxicity also when extracellular rTNF-α had been removed by washing, indicating that BHA does not act by binding or inactivating rTNF-α in the culture medium.

We thereafter tested whether BHA down-regulated rTNF-α receptor binding. Preincubation with BHA or BHT did not decrease the binding of human rTNF-α to its receptors in WEHI clone 13 cells as measured using flow cytometry. This suggests that BHA probably affects some post receptor event in rTNF-α-induced cytotoxicity. Since we used human rTNF-α in the receptor binding studies, we verified that BHA and BHT (100 μM) affected human rTNF-α toxicity similarly as murine rTNF-α toxicity (data not shown).

Effect of preincubation with BHA. Since others have reported that BHA induces the activity of several enzymes, including the glutathione *S*-transferase (30), we examined whether preincubation with BHA protected against rTNF-α cytotoxicity. Preincubation with BHA for 24 or 48 h followed by removal of BHA neither had any effect on rTNF-α cytotoxicity, nor on BHA protection against rTNF-α cytotoxicity (Table 1). This indicates that BHA probably does not mediate its effect by inducing enzyme synthesis, or by activating some unknown defense mechanism to give a lasting protection against rTNF-α-induced cytotoxicity.

BHA protection in the presence of actinomycin D or cycloheximide. We next examined whether the inhibitory effect of BHA on rTNF-α cytotoxicity depends on mRNA or protein synthesis. BHA protected completely against rTNF-α cytotoxicity in the presence of the mRNA synthetase inhibitor actinomycin D at rTNF-α concentrations up to 1 ng/L, corresponding to 25% death in the control cells using [^{51}Cr]-release (Fig. 3A). BHA protected only partially at higher rTNF-α concentrations, possibly because actinomycin D potentiated rTNF-α toxicity. Similarly, BHA completely inhibited rTNF-α toxicity in the presence of the protein synthesis inhibitor cycloheximide up to 10 ng/L of rTNF-α (Fig. 3B). This suggests that BHA does not depend on protein synthesis to protect against rTNF-α cytotoxicity. However, since actinomycin D and cycloheximide were added simultaneously with rTNF-α, we could not exclude that BHA stimulated protein synthesis before it was inhibited by actinomycin D or cycloheximide.

In the next experiment, cells were preincubated for 4 h with actinomycin D or cycloheximide to ensure that protein synthesis was inhibited when rTNF-α and BHA were added (Fig. 4). BHA again inhibited rTNF-α cytotoxicity

TABLE 1

Effect of Preincubation with BHA on rTNF-α-Induced Cytotoxicity in WEHI Clone 13 Cells

	Optical density[a]			
	24-h Preincubation		48-h Preincubation	
	-BHA	+BHA	-BHA	+BHA
Incubation[b]				
Control	0.78 ± 0.10	0.75 ± 0.12	0.83 ± 0.11	0.75 ± 0.11
rTNF-α	0.25 ± 0.07[c]	0.26 ± 0.07[c]	0.21 ± 0.08[c]	0.24 ± 0.07[c]
BHA	0.77 ± 0.17	0.74 ± 0.16	0.81 ± 0.18	0.76 ± 0.18
rTNF-α + BHA	0.75 ± 0.08	0.68 ± 0.10	0.74 ± 0.06[c]	0.70 ± 0.09

[a]WEHI clone 13 cells were seeded at 2×10^3 cells/well in microplates in 200 µL 10% (vol/vol) heat-inactivated fetal calf serum in RPMI-1640 medium containing 2 mmol/L L-glutamine and 40 mg/L gentamicin sulfate (FCS-M). All cells were preincubated for 48 h, and butylated hydroxyanisole (BHA) (100 µM) was present during the last 24 or 48 h of preincubation as indicated.

[b]Additions during incubation. After preincubation, the medium was removed, and the cells received either control medium, recombinant tumor necrosis factor alpha (rTNF-α) (1 µg/L), BHA (100 µM) or rTNF-α plus BHA. Cell density was measured using the 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide assay as described in Materials and Methods, and the results are expressed as optical density. The results are from five experiments, each performed in quadruplicate, and are given as means ± SD of 20 determinations.

[c]Statistically different ($P < 0.05$) from the control when each preincubation was analyzed separately by one-way analysis of variance using Duncan multiple comparison test.

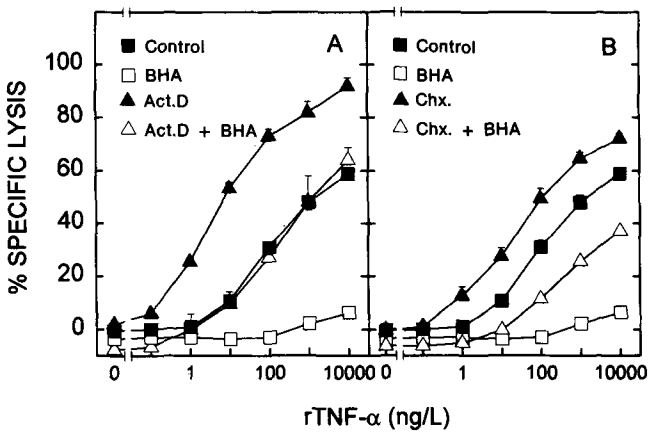

FIG. 3. The effect of BHA on rTNF-α cytotoxicity in L929 cells in the presence of (A) actinomycin D (Act.D) or (B) cycloheximide (Chx.) Cells received Act.D (2 mg/L) or Chx. (2 mg/L) simultaneously with rTNF-α in the presence or absence of BHA (100 µM), and cytotoxicity was measured 16 h later using the [^{51}Cr]-release assay as described in Materials and Methods. Results are expressed as percentage specific lysis and given as means ± SD of triplicates. The spontaneous release after 16 h of incubation was 23% of total release. Additions: A: (■) none; (□) 100 µM BHA; (▲) 2 mg/L of Act.D; (△) 2 mg/L of Act.D and 100 µM BHA; B: (■) none; (□) 100 µM BHA; (▲) 2 mg/L of Chx.; (△) 2 mg/L of Chx. and 100 µM BHA. See Figure 1 for other abbreviations.

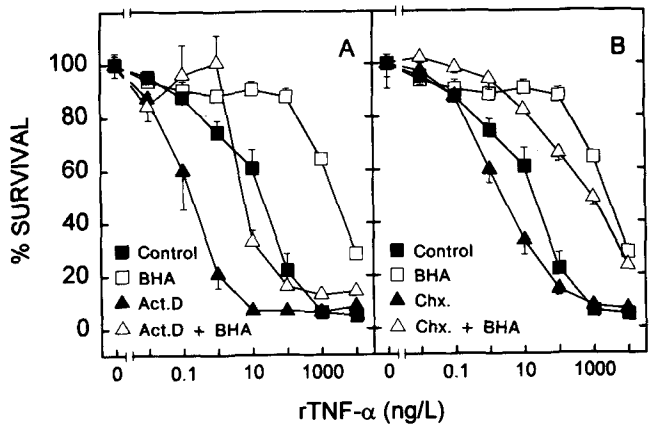

FIG. 4. The effect of BHA on rTNF-α-induced cytotoxicity in WEHI clone 13 cells preincubated 4 h in the absence or presence of (A) 1 mg/L of Act.D and (B) 1 mg/L of Chx. After 44 h of incubation, the medium was removed and control medium, Act.D (1 mg/L) or Chx. (1 mg/L) added in 100 µL 10% (vol/vol) heat-inactivated fetal calf serum in RPMI-1640 medium containing 2 mmol/L L-glutamine and 40 mg/L gentamicin sulfate (FCS-M) and after 4 h further incubation, rTNF-α was added in tenfold dilutions in the presence or absence of BHA in a total volume of 200 µL FCS-M/well. The percentage cell survival was measured after 22 h further incubation using the 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide assay. The results are from one of four similar experiments, and are given as means ± SD of quadruplicates. Additions: A: (■) none; (□) 250 µM BHA; (▲) 1 mg/L Act.D; (△) 1 mg/L of Act.D and 250 µM of BHA; B: (■) none; (□) 250 µM BHA; (▲) 1 mg/L Chx.; (△) 1 mg/L of Chx. and 250 µM of BHA, and the mean optical density in the absence of rTNF-α was: 0.90, 0.86, 0.38, 0.34, 0.90, 0.86, 0.43 and 0.38, respectively. See Figures 1 and 3 for other abbreviations.

almost completely at rTNF-α concentrations up to 1 ng/L in the presence of actinomycin D (Fig. 4A), while BHA protection became negligible at rTNF-α concentrations above 100 ng/L in WEHI cells. BHA increased the effective dose

TABLE 2

Effect of Actinomycin D and Cycloheximide on Protein Synthesis in WEHI Cells[a]

	Incorporation of [^{3}H]leucine (percent of control)					
	4 h[b]			4 + 4 h[b]		
Addition[c]	Control	+ Chx.	+ Act.D	Control	+ Chx.	+ Act.D
None	100 ± 13.7	13 ± 3.1[d]	70 ± 10.7[d]	100 ± 7.9	10 ± 2.4[d]	48 ± 10.6[d]
rTNF-α	94 ± 30.2	12 ± 2.4[d]	66 ± 8.4[d]	88 ± 15.4[d]	9 ± 2.0[d]	22 ± 5.8[d,e]
BHA	82 ± 19.4[d]	9 ± 0.9[d]	69 ± 6.0[d]	84 ± 23.5[d]	11 ± 1.9[d]	50 ± 5.7[d]
rTNF-α + BHA	70 ± 10.7[d]	8 ± 2.5[d]	54 ± 14.8[d,e]	72 ± 23.5[d]	7 ± 1.9[d]	29 ± 12.9[d,e]

[a]WEHI clone 13 cells were seeded at 2×10^3 cells/well in microplates using 200 µL FCS-M/well and the medium was changed after 44 h of incubation. See Table 1 for other abbreviations.

[b]Protein synthesis was measured after 4 h of preincubation with control medium, cycloheximide (Chx., 1 mg/L) or actinomycin D (Act.D, 1 mg/L) as indicated, or after 4 h of preincubation followed by 4 h of incubation with the indicated additions.

[c]Additions during incubation and during assay of protein synthesis. After 4 h of preincubation, cells were incubated further for 4 h with control medium, rTNF-α (1 µg/L), BHA (250 µM) or rTNF-α plus BHA in the presence or absence of Chx. or Act.D as indicated. Protein synthesis was measured by adding [^{3}H]leucine (1 µCi/well) as described in Materials and Methods. The results are calculated as percent of mean cpm in controls (14783 cpm and 21522 cpm after 4 h of preincubation and 4 + 4 h of incubation, respectively). The results are from three experiments, each performed in triplicate and are given as means ± SD of data from nine cultures.

[d]Significantly different ($P < 0.05$) from the control with no addition when analyzed by one-way analysis of variance (ANOVA) using Duncan multiple comparison test. Each time point was analyzed separately.

[e]Significantly different ($P < 0.05$) from Chx. with no addition or Act.D with no addition, when analyzed by one-way ANOVA using Duncan multiple comparison test. Each time point was analyzed separately.

reducing cell density to 50% of control (ED_{50}) of rTNF-α approximately 180-fold in the absence, and approximately 75-fold in the presence of actinomycin D. BHA also inhibited rTNF-α-induced cytotoxicity after 4 h preincubation with the protein synthesis inhibitor cycloheximide (Fig. 4B). At an rTNF-α concentration giving 30% survival, BHA increased cell survival to approximately 80% in the presence and 90% in the absence of cycloheximide. Preincubation with cycloheximide or actinomycin D for 4 h reduced protein synthesis measured as incorporation of [^{3}H]leucine to 13 and 70% of control, respectively (Table 2). BHA alone (250 µM) inhibited protein synthesis only slightly. The results also confirmed that actinomycin D and cycloheximide inhibited protein synthesis also during incubation with rTNF-α and/or BHA (Table 2).

Effect of BHA on rTNF-α-induced TBARS. We next examined whether BHA inhibited the rTNF-α-induced peroxidation measured as TBARS. rTNF-α dose-dependently increased both the percentage of dead cells and of protein-associated TBARS (Fig. 5A). However, there was no linear relationship between TBARS accumulation and cell death. BHA (100 µM) reduced rTNF-α toxicity from 85 to 13% dead cells, respectively, and at the same time decreased TBARS from 517 to 126% of controls (Fig. 5B). rTNF-α increased TBARS also when TBARS were calculated as pmol/culture well or as pmol/10^6 cells. We did not detect TBARS in the culture medium (results not shown). In a control experiment, WEHI cells treated with water contained 100% dead cells and 134 pmol TBARS/mg protein compared to control cells which contained only 5% dead cells and 138 pmol TBARS/mg protein (mean, n = 3). This suggests that TBARS were not only a measure of cell death.

To examine whether the effect of BHA on TBARS accumulation and rTNF-α cytoxicity was due to its antioxidant effect, we compared BHA with the similar antioxidant

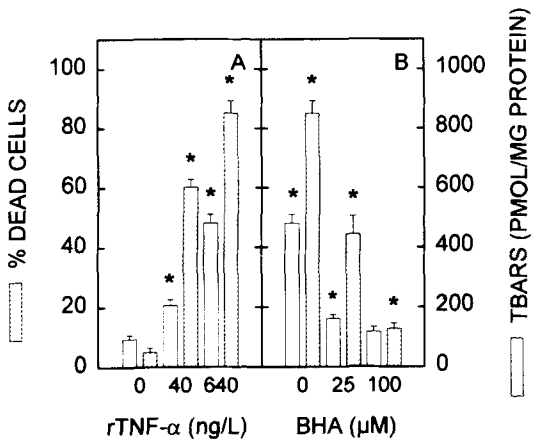

FIG. 5. The effect of BHA on rTNF-α-induced accumulation of protein-associated thiobarbituric acid reactive substances (TBARS) in WEHI clone 13 cells. The WEHI cells were incubated for 22 h with (A): 0, 40 or 640 ng/L of rTNF-α or (B): 640 ng/L of rTNF-α in the presence of 0 µM, 25 µM and 100 µM of BHA. Percentage of dead cells was measured by trypan blue exclusion, and TBARS were analyzed as described in Materials and Methods. Hatched bars: percentage of dead cells given as mean ± SD of six determinations; open bars: pmol TBARS per mg protein given as mean ± SD of triplicate cultures. One of two similar experiments is shown. *$P < 0.05$ as compared to the control when analyzed by one-way analysis of variance using Duncan multiple comparison test. See Figure 1 for other abbreviations.

BHT (Table 3). In WEHI clone 13 cells, rTNF-α gave 29% dead cells and increased protein-associated TBARS to 262% of the control without antioxidant. BHT neither inhibited rTNF-α cytotoxicity nor TBARS accumulation. In comparison, BHA blocked rTNF-a toxicity completely and at the same time reduced protein-associated TBARS to the control level. Similar results were also obtained using

TABLE 3

Effect of BHA and Butylated Hydroxytoluene (BHT) on rTNF-α-Induced TBARS Accumulation[a]

	−rTNF-α		+rTNF-α

[a]WEHI clone 13 and L929 cells were cultured in 1400-mm petri dishes for 48 h as described in Materials and Methods. Thereafter, cells received 40 ng/L of rTNF-α (WEHI clone 13) or 160 ng/L (L929 cells) as indicated, and the incubation continued for 22 h. Thereafter, cell proteins were precipitated using trichloroacetic acid and protein-associated thiobarbituric acid reactive substances (TBARS) measured as described in Materials and Methods. The results are from two independent experiments in WEHI cells and are given as means ± SD of quadruplicate cultures. The results in L929 cells are from one experiment and are given as means ± SD of duplicates. Percent dead cells was measured using trypan blue exclusion, and the results are given as means ± SD of quadruplicate cultures (WEHI) or duplicate cultures (L929). See Table 1 for other abbreviations.

[b]Significantly different ($P < 0.05$) when compared to the WEHI cell control when analyzed by one-way analysis of variance using Duncan multiple comparison test.

L929 cells (Table 3). In a control experiment, BHT was added during the heating of the samples as described by Asakawa and Matsushita (31). Again BHA, but not BHT, inhibited rTNF-α-induced protein-associated TBARS, suggesting that TBARS were not due to peroxidation during the TBARS assay (data not shown). The results suggest that the protective effect of BHA on accumulation of protein-associated TBARS and rTNF-α cytotoxicity is probably not related to its antioxidant effect.

To test whether rTNF-α increases water-soluble TBARS, TBARS were measured in the supernatant after precipitation of the cell proteins with TCA. TBARS in non-TCA precipitable material were below the detection level in WEHI clone 13 cells not preincubated with arachidonic acid (data not shown). However, when WEHI cells were preincubated for 44 h with 50 μM arachidonic acid, rTNF-α induced the accumulation of TBARS in non-TCA precipitable material (Fig. 6). Both BHA and BHT similarly inhibited the rTNF-α-induced accumulation of TBARS in non-TCA precipitable material (Fig. 6). Since only BHA protected against rTNF-α cytotoxicity (Fig. 6), these TBARS are not associated with rTNF-α cytotoxicity. However, BHA, but not BHT, inhibited the rTNF-α-induced accumulation of protein-associated TBARS in WEHI cells enriched with arachidonic acid (data not shown), indicating again that protein-associated TBARS are associated with rTNF-α toxicity.

Differential effect of BHA and BHT on rTNF-α-induced release of [3H]arachidonic acid and prostaglandin E_2 synthesis. Since others have reported that TNF enhances the release of arachidonic acid in cells sensitive to TNF toxicity (32), we tested whether BHA and BHT affected the rTNF-α-induced release of [^{3}H]arachidonic acid. To avoid nonspecific release of [^{3}H]arachidonic acid secondary to cell lysis, we compared the effect of antioxidants after 4 h of incubation with rTNF-α. At this time, cell death had been induced (Fig. 2), but was not yet detectable (Table 4).

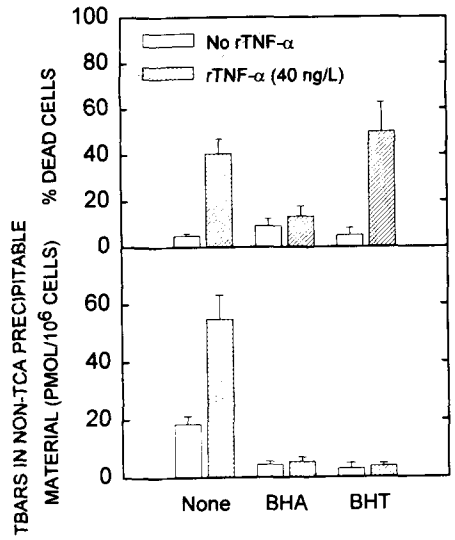

FIG. 6. The effect of BHA and butylated hydroxytoluene (BHT) on rTNF-α-induced formation of TBARS in non-trichloroacetic acid (TCA) precipitable material in WEHI clone 13 cells. The WEHI cells were seeded at 2×10^6 cells per dish, added 50 μM unlabeled arachidonic acid after 4-h culture, and the incubation continued for 44 h. Thereafter the medium was changed, and cells received control medium (open bar) or 40 ng/L of rTNF-α (hatched bar) in the presence of either 100 μM of BHA or BHT as indicated and the incubation continued for 22 h. TBARS in non-TCA precipitable material were measured in the supernatant after precipitation of cellular proteins with TCA as described in Materials and Methods. Upper panel: percentage of dead cells measured using trypan blue exclusion and given as mean ± SD of triplicates. Lower panel: TBARS in non-TCA precipitable material per 10^6 cells. Data are from three independent experiments and are given as mean ± SD of triplicates. See Figures 1 and 5 for other abbreviations.

rTNF-α enhanced the release of [^{3}H]arachidonic acid to 231% of control, and BHA inhibited this release dose dependently (Fig. 7A). BHT alone slightly increased the spontaneous release of [^{3}H]arachidonic acid, while it had

TABLE 4

The Influence of Antioxidants and Indomethacin on rTNF-α-Induced Release of [^{3}H]Arachidonic Acid in L929 Cells

Additions[a]	AA release (cpm/well)[b]	Dead cells (%)	LDH release (%)
Control	11503 ± 155[d]	3.1 ± 1.8	7.2 ± 0.2
BHA	11393 ± 372	2.1 ± 0.2	7.9 ± 0.3
HBP	10006 ± 186[d]	2.6 ± 1.3	7.2 ± 0.4

rTNF-α + indomethacin	29991 ± 1636[c]	2.1 ± 0.5	—[e]

[a]L929 cells were seeded at 0.5 × 10^6 cells/petri dish in 3 mL FCS-M. After approximately 24 h of incubation, the medium was changed to 1% (vol/vol) FCS-M containing 1 mCi/L of [^{3}H]arachidonic acid. After further 24 h incubation, the cells were washed three times with FCS-M and rTNF-α (1 μg/L) added simultaneously with 100 μM of BHA, 4-hydroxymethyl-2,6-di-*t*-butylphenol (HBP), *dl*-α-tocopherol or indomethacin, as indicated in 2 mL FCS-M containing RPMI without phenolic red. The supernatants were harvested after 4 h of incubation. Aliquots were counted in a liquid scintillation counter, and the results expressed as cpm/well and given as mean ± SD of duplicate cultures from one of three similar experiments. Percent dead cells was determined by trypan blue exclusion after trypsinization of the cells, and the results are pooled from two experiments and given as means ± SD of three or four incubations. Release of lactate dehydrogenase (LDH) is expressed as percent of total release in control cells lysed with Triton-X-100 and is given as means ± SD of duplicate incubations. See Table 1 for other abbreviations.

[b]Release of [3H]arachidonic acid (AA) into the cell culture medium.

[c]$P < 0.05$ compared to the control when analyzed by one-way analysis of variance (ANOVA) using Duncan multiple comparison test.

[d]$P < 0.05$ compared to rTNF-α when analyzed by one-way ANOVA using Duncan multiple comparison test.

[e]—, Not determined.

no effect on the rTNF-α-induced release (Fig. 7A). Separate time course experiments showed that the rTNF-α-enhanced release of [^{3}H]arachidonic acid started approximately 1–2 h after the addition of rTNF-α (Fig. 7B). This is approximately 2–3 h before the onset of cell death.

We next compared the effect of BHA on rTNF-α-induced release of [^{3}H]arachidonic acid with other antioxidants and indomethacin (Table 4). The antioxidant 4-hydroxymethyl-2,6-di-*t*-butylphenol, which completely blocks rTNF-α-induced toxicity (24), inhibited the rTNF-α-induced release of [^{3}H]arachidonic acid in L929 cells. By comparison, α-tocopherol or indomethacin neither inhibited rTNF-α-induced release of [^{3}H]arachidonic acid nor rTNF-α-induced cytotoxicity as previously shown (23,24). Indomethacin itself increased the release of [^{3}H]arachidonic acid into the culture medium. After 4 h, rTNF-α enhanced the release of [^{3}H]-arachidonic acid without any increase in dead cells, suggesting that this release was not secondary to cell death. In a separate experiment, the phospholipase inhibitor quinacrine (10 μM) inhibited the rTNF-α-induced release of [^{3}H]arachidonic acid by 70 ± 5.5% (mean ± SD, n = 2) after 4 h of incubation with rTNF-α, suggesting that rTNF-α induces phospholipase activity in L929 cells. Quinacrine also inhibited rTNF-α cytotoxicity by 59 ± 13% (mean ± SD, n = 3) as determined by trypan blue exclusion after 22 h of incubation with rTNF-α (1 μg/L). Addition of rTNF-α did not inhibit the incorporation of [^{3}H]arachidonic acid into L929 phospholipids (data not shown), indicating that the enhanced release of [^{3}H]arachidonic acid was not due to a reduced incorporation of the fatty acid.

Since the rTNF-α-induced release of [^{3}H]arachidonic acid was inhibited by BHA but not by BHT, we thereafter examined whether rTNF-α stimulated the release of arachidonic acid metabolites in L929 cells using HPLC analysis. Approximately 90% of the radiolabel released into the medium after 4 h of incubation with rTNF-α was arachidonic acid as measured using HPLC (data not shown). Addition of rTNF-α induced the synthesis of prostaglandin E2, which started approximately 4 h after the addition of rTNF-α (Table 5). Both BHA and indomethacin inhibited prostaglandin synthesis completely after 12 h of incubation with rTNF-α, while BHT had minimal effects. Since only BHA, but not BHT and indomethacin, inhibited rTNF-α-induced cytotoxicity both in WEHI clone 13 (23) and L929 cells (data not shown), the effect of BHA on rTNF-α toxicity cannot be explained through inhibition of prostaglandin E_2 synthesis only.

DISCUSSION

The present report shows that the antioxidant BHA inhibited rTNF-α-induced cytotoxicity in L929 and WEHI clone 13 fibrosarcoma cells, while BHT had no effect. The results suggest that BHA, but not BHT, inhibits rTNF-α-induced phospholipase activity, and that the effect is independent of protein or mRNA synthesis. BHA may inhibit rTNF-α-induced toxicity by at least three different mechanisms that will be discussed below.

TABLE 5

The Influence of BHA and BHT on rTNF-α-Induced-Prostaglandin E_2 Synthesis in L929 Cells

Additions[a]	Incubation time with rTNF-α	
	4 h	12 h
Control	ND[b]	ND[b]
BHA	ND	ND
BHT	ND	ND
Indomethacin	ND	ND
rTNF-α	12 (0–64)	294 (281–307)
rTNF-α + BHA	ND	ND
rTNF-α + BHT	ND	214 (198–230)
rTNF-α + indomethacin	ND	ND

[a]L929 cells were seeded in 60-mm petri dishes and cultured as described in Materials and Methods. The medium was removed and rTNF-α (1 μg/L) added simultaneously with 100 μM of BHA, BHT or indomethacin as indicated. The supernatants were harvested after 4 h or 12 h of incubation, and eicosanoids extracted and analyzed by high-performance liquid chromatography. The amount of prostaglandin E_2 is given as the relative areas on the radioactivity detector. The detection limit was approximately 150 cpm of [^{3}H]prostaglandin E_2, corresponding to a relative area of 29. The results are the means and ranges from 2–4 separate experiments. See Tables 1 and 3 for abbreviations.

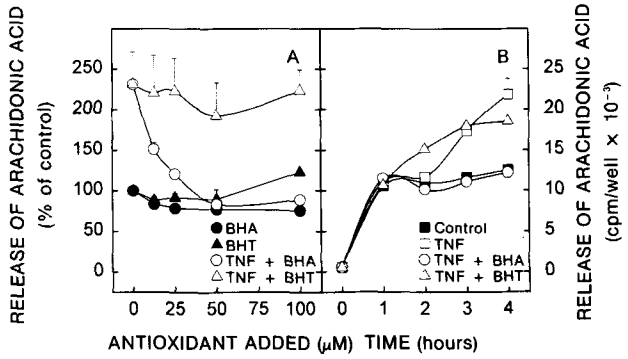

FIG. 7. The effect of BHA and BHT on rTNF-α-induced release of [^{3}H]arachidonic acid in L929 cells. A: Dose-dependent effect of BHA and BHT on the release of [^{3}H]arachidonic acid 4 h after the addition of rTNF-α. Cells were seeded in petri dishes and after 24 h culture, the medium was changed to 1% (vol/vol) fetal calf serum in RPMI-1640 containing [^{3}H]arachidonic acid (1 mCi/L). After approximately 24 h further incubation, the cells were washed to remove extracellular [^{3}H]arachidonic acid. In panel (A), cells received either BHA (●, ○) or BHT (▲, △) at the indicated concentrations in the absence (●, ▲) or presence of 1 μg/L rTNF-α (○, △) in a total volume of 2 mL FCS-M. The medium was removed after 4 h, centrifuged and aliquots taken for determination of radioactivity. The results are expressed as percent of the mean cpm/well in control wells (13264 cpm). The data are pooled from two separate experiments and given as mean ± SD of quadruplicates. B: Time course of rTNF-α-induced release of [^{3}H]arachidonic acid. The cells were washed and received either control medium (■), 1 μg/L of rTNF-α (□); rTNF-α plus 50 μM of BHA (○) or rTNF-α plus 50 μM of BHT (△). The medium was removed at each time point, centrifuged and aliquots taken for determination of radioactivity. The results are expressed as cpm/well, and are given as mean ± SD of duplicates from one of two similar experiments. See Figures 1 and 6 for abbreviations.

One possible mechanism is that BHA induces or activates existing defense mechanisms that protect the cell against rTNF-α cytotoxicity. TNF induces expression of mRNA for manganous superoxide dismutase (33), probably as a defense against TNF-induced radical formation. Both actinomycin D and cycloheximide increased TNF cytotoxicity (Figs. 3 and 4) in agreement with previous results (34), probably due to inhibition of protein synthesis-dependent resistance against TNF cytotoxicity. Others have shown that BHA induces the glutathione *S*-transferase enzyme (30), known to be involved in the cellular defense against free radicals. This report shows that BHA protects nearly completely against rTNF-α cytotoxicity up to 1 ng/L of rTNF-α, also in the presence of cycloheximide or actinomycin D, suggesting that BHA protection is independent of mRNA or protein synthesis. The reduced protection seen at higher rTNF-α concentrations is probably explained by the increased toxicity of rTNF-α in the presence of cycloheximide (34) or actinomycin D (Figs. 3 and 4). BHA did not reduce the effect of cycloheximide or actinomycin D on protein synthesis, suggesting that it did not inhibit rTNF-α cytotoxicity in the presence of cycloheximide through overall stimulation of protein synthesis. On the contrary, BHA alone slightly inhibited protein synthesis (Table 2). Several other observations also suggest that BHA protection is independent of protein synthesis. Firstly, preincubating WEHI cells with BHA, followed by the removal of the BHA, had no effect on rTNF-α cytotoxicity (Table 1). Secondly, adding BHA as late as 8 h after rTNF-α rescued all remaining viable cells (Fig. 1).

A recent report confirms that BHA inhibits TNF cytotoxicity in L929 cells in the presence of actinomycin D (35). However, the same study also showed that BHT partially inhibited TNF cytotoxicity at a concentration (200 μM) that we have reported killed 83% of L929 cells (24). In our hands, BHT did not inhibit rTNF-α cytotoxicity (23,24), even when we used the same experimental design as Schulze-Osthoff *et al.* (35) (data not shown). We therefore speculate that different strains of L929 cells have been used.

A second possible mechanism is that BHA inhibits rTNF-α-induced cytotoxicity through its antioxidant effect, causing trapping of free radicals. Several other reports indicate that TNF stimulates oxygen radical formation (18,21,22,35). However, BHA does probably not inhibit rTNF-α-induced cytotoxicity through a nonspecific antioxidant effect, since the antioxidants BHT (24) and α-tocopherol (18,20,24) do not inhibit rTNF-α-induced cytotoxicity, and since both BHA and BHT inhibited formation of rTNF-α-induced TBARS in non-TCA precipitable material (Fig. 6). We therefore speculate that both BHA and BHT inhibit the propagation of cell peroxidation, leading to water-soluble, non-TCA precipitable end products, while only BHA can inhibit initiation and/or the accumulation of those primary peroxides leading to cell death. This is also consistent with our observation that TNF cytotoxicity is correlated with the accumulation of protein-associated TBARS, but not with the non-TCA precipitable TBARS. This shows that only some of the rTNF-α-induced TBARS are associated with rTNF-α-induced cell death,

which would also explain the nonlinear relationship observed between protein-associated TBARS and TNF toxicity (Fig. 5). Others have already shown that different antioxidants have a different ability to inhibit TNF-induced cytotoxicity (18,20,24) supporting the idea that a generally increased formation of nonenzymatically formed radicals is probably not the key event in TNF-induced toxicity.

The differential effect of BHA and BHT on rTNF-α toxicity and protein-associated TBARS is probably not due to differences in solubility or in their antioxidant efficacy, since both inhibit the accumulation of TBARS in non-TCA precipitable material (Fig. 6), and since BHT has been shown to inhibit TBARS accumulation in other cell culture systems (36). Their similar solubility also makes it unlikely that these antioxidants accumulate at different sites inside the cell. One possible explanation of these results is that BHA, in addition to its well-known peroxide scavenging effects, specifically inhibits one or more enzyme(s) involved in both protein-associated TBARS formation and rTNF-α-induced cell death, or by some other mechanism inhibits the accumulation of specific lipid peroxides leading to cell death. Arachidonic acid increased both rTNF-α-induced protein-associated TBARS and TBARS in non-TCA precipitable material, possibly due to increased substrate for oxidation. However, preincubation with arachidonic acid increases rTNF-α cytotoxicity (23). To what extent this reflects unspecifically increased oxidative damage, or the biosynthesis of oxidized metabolites of arachidonic acid that signals rTNF-α-induced cell death, is difficult to judge because of the low specificity of the TBARS assay (37).

A third possible mechanism is that BHA interferes with one of the TNF-activated signal transduction pathways. It has been reported that following the binding of rTNF-α to its receptors, the internalization of TNF occurs within approximately 2 h in L929 cells (5). Our data suggest that BHA inhibits rTNF-α-effects by interfering with some post receptor event since BHA almost completely inhibited the toxicity of a 2-h preincubation with rTNF-α (Fig. 2). This is further supported by the observations that preincubation with BHA or BHT did not down-regulate the rTNF-α receptors (data not shown), and that BHA had no effect on TNF-induced adhesion in human endothelial cells (24). However, we cannot totally exclude the possibility that BHA affects the rTNF-α-induced turnover of its receptors as observed with the free radical scavenger desferrioxamine (38). However, this seems unlikely since BHA inhibits rTNF-α cytotoxicity completely when added 2 h after rTNF-α in WEHI and L929 cells, and protects nearly all remaining viable cells when added as late as 8 h after rTNF-α (Fig. 1B). We therefore speculate that BHA inhibits some of the late rTNF-α-induced intracellular events possibly not related to the initial TNF-induced signals.

Prostaglandins are also a part of the TNF-induced signal transduction mechanism(s). Prostaglandin E_2 is a messenger molecule in the TNF-induced regulation of CSF-1 mRNA levels in HL-60 cells (39), but the involvement of prostaglandin E_2 in TNF cytotoxicity has not been established convincingly. This report, as well as others (40), have shown that rTNF-α stimulates prostaglandin E_2 synthesis and that antioxidants have different potency in inhibiting the cyclooxygenase, BHA generally being much more potent than BHT (41,42). Since indomethacin had no effect on rTNF-α-induced cytotoxicity (23), and prostaglandin E_2 itself does not cause cell death in L929 cells (43), it seems unlikely that prostaglandin E2 directly mediates rTNF-α cytotoxicity. However, prostaglandin E_2 and other compounds may increase TNF cytotoxicity through elevation of cellular cAMP levels (43). Hayakawa *et al.* (44) showed that TNF stimulates both release of arachidonic acid and prostaglandin E_2 production in sensitive, but not in resistant, L929 cells. One critical event in TNF cytotoxicity may therefore be the TNF-induced release of arachidonic acid, a conclusion in agreement with other reports (16,17,18,32,45).

Since BHA, but generally not BHT, is an inhibitor of the lipoxygenase (46), another possible explanation is that BHA inhibits rTNF-α-induced synthesis of lipoxygenase products that could be involved in signal transduction and/or peroxide formation. Haliday *et al.* (47) reported that arachidonic acid itself and its lipoxygenase metabolite 5-hydroperoxyeicosatetraenoic acid regulate *c-fos* mRNA levels in preadipocytes, and TNF-induced lipoxygenase metabolites mediate oxidative stress in TA1 cells (48). However, we could not detect TNF-induced HETE in the supernatants from L929 cells (data not shown). Since these metabolites can accumulate intracellularly and deteriorate easily during storage, we cannot totally exclude that rTNF-α-induced lipoxygenase metabolites are produced. However, we have previously shown that nordihydroguaretic acid does not inhibit rTNF-α cytotoxicity in WEHI clone 13 cells (23), which argues against lipoxygenases being involved in rTNF-α-induced cytotoxicity in these cells.

BHA, but not BHT or indomethacin, inhibited rTNF-α-enhanced release of [^{3}H]arachidonic acid from prelabeled L929 cells (Table 4 and Fig. 7). However, none of the tested antioxidants inhibited the unstimulated release seen in the absence of rTNF-α. This indicates that BHA specifically inhibits rTNF-α-enhanced release of arachidonic acid, possibly due to the inhibition of cellular phospholipase(s). This would also reduce accumulation of lysophospholipids. BHA thereby inhibits one of the rTNF-α-induced intracellular signal mechanisms. It has been shown that phospholipase inhibitors decrease TNF-induced cytotoxicity (18,20,32). However, to our knowledge, BHA has not previously been shown to directly inhibit phospholipases. It has recently been shown that transfection of a cytosolic phospholipase A_2 into resistant L929 cells makes them susceptible to rTNF-α toxicity (49), supporting that TNF-induced activation of phospholipase A_2 is a key event in TNF toxicity. This may also explain why BHA can inhibit rTNF-α-induced cytotoxicity when protein synthesis is blocked, since many cell types constituently express phospholipase activity. The serum-induced release of arachidonic acid is not cytotoxic to L929 cells (45), and TNF stimulates both arachidonic acid release as well as growth in FS-4 fibroblasts (17), indicating that enhanced arachidonic acid release alone is not sufficient to induce cyto-

toxicity. Rather, our results suggest that the TNF-induced release of arachidonic acid must be coupled to a second mechanism when cell death is induced. We speculate that this involves the enzymatic formation of oxidized lipids since protein-associated TBARS are correlated with TNF cytotoxicity (Fig. 5).

BHA rescues remaining viable WEHI and L929 cells as late as 8 h after rTNF-α addition, while the rTNF-α-enhanced release of arachidonic acid starts 1–2 h after its addition, which is prior to cell death (Fig. 7). The most likely explanation for this apparent discrepancy is that arachidonic acid release alone is insufficient to induce cell death as discussed above. If the formed oxidized lipid metabolites exert a positive feedback on the phospholipase activity, this could explain why BHA both inhibits formation of the protein-associated TBARS, and at the same time inhibits arachidonic acid release. Another possible explanation is that rTNF-α cytotoxicity requires the ongoing release of arachidonic acid, which is then effectively inhibited by BHA.

It is also possible that BHA blocks the rTNF-α-induced increase in intracellular Ca^{2+} concentration, which starts 2–3 h after rTNF-α addition (50). Dornand *et al.* (51) have reported that BHA inhibits receptor-mediated increase in intracellular Ca^{2+}. If BHA blocks the rTNF-α-induced late increase in intracellular Ca^{2+}, this could indirectly inhibit the activity of calcium-dependent enzymes, including phospholipases.

In summary, the present report indicates that BHA, but not BHT, inhibits rTNF-α-induced cytotoxicity, rTNF-α-induced release of arachidonic acid as well as rTNF-α-induced accumulation of protein-associated TBARS. The results may suggest that activation of a phospholipase followed by the specific formation of one or more oxidized lipid metabolites mediates rTNF-α toxicity. Further studies are needed to elucidate whether fatty acid peroxides formed enzymatically from arachidonic acid are the more direct mediators of TNF-induced cytotoxicity.

Mass Determination of the Fatty Acids Released from Tannin-Stimulated Rabbit Alveolar Macrophages

Nicholas V.C. Ralston* and **Michael S. Rohrbach**[1]

Department of Biochemistry and Thoracic Diseases Research Unit, Mayo Clinic and Foundation, Rochester, Minnesota 55905

Previous studies with macrophages that had been prelabeled with [^{14}C]arachidonic acid (20:4) have shown that condensed tannin is a potent agonist for the release of arachidonic acid. However, it has not been demonstrated that the percentage release of [^{14}C]20:4 accurately reflects the metabolic activity of the endogenous 20:4 pool. In order to measure the 20:4 mass release relative to the total cellular 20:4 pool, the free fatty acids of freshly isolated alveolar macrophages were derivatized with a fluorescent reagent, and then separated and quantified by high-performance liquid chromatography. The amounts of esterified fatty acids were measured by gas chromatography of the methyl esters. Free fatty acid levels were compared to those of the total esterified plus unesterified fatty acids to determine the actual percentage released of each fatty acid. Tannin-stimulated release of 20:4 mass reflected that previously reported for the release of [^{14}C]20:4 label but at a slower rate and at a much lower percentage indicating that [^{14}C]20:4 had been incorporated into part of a more reactive pool. The specificity of the fatty acid release induced by tannin and β-1,3-glucan, a known agonist for 20:4 release, was also examined. Both agonists promoted an increase in the levels of free 20:4 and of other fatty acids. A comparison of the absolute increases of each of the fatty acids indicated that tannin caused a preferential increase in the mass of free 20:4, whereas β-1,3-glucan evoked a selective increase in the mass of 16:0.

***Lipids* 29, 103–109 (1994).**

Resident alveolar macrophages are the principal cells responsible for the clearance and/or detoxification of inhaled airborne occupational or environmental pollutants. Interaction of alveolar macrophages with the inhaled foreign material activates the cells and initiates a sequence of events that often results in pulmonary inflammation. Condensed tannin, a polymer of monoflavanoid subunits, is one of the major water-soluble components present in the airborne dust generated from the processing of a wide variety of woody plants (1). Inhalation of tannin or tannin-containing organic dust has been shown to evoke an acute pulmonary inflammatory response. Several of the inflammatory mediators released following tannin inhalation suggested the involvement of alveolar macrophages (2). Subsequent *in vitro* studies have shown that condensed tannin can profoundly change the functional capacity of alveolar macrophages (3–8).

Among the macrophage functions found to be modulated by condensed tannin are the release and metabolism of arachidonic acid (20:4). A recent study using alveolar macrophages prelabeled with [^{14}C]20:4 demonstrated that tannin was a potent agonist for 20:4 release. Tannin stimulated the release of up to 20% of the incorporated [^{14}C]20:4 in a time- and dose-dependent manner (7). However, rabbit alveolar macrophages are not suited to long-term culture, and hence must be loaded under nonequilibrium conditions, *i.e.*, using 2 h of labeling. With such a short loading period, it was questionable whether the labeled substrate distributed sufficiently to accurately reflect the metabolic activity of the endogenous 20:4 pool it was intended to represent.

The present study addresses this question by using a sensitive, fluorescence-based method (9) to measure the release of endogenous 20:4 mass from tannin-stimulated alveolar macrophages. As the total amount of 20:4 esterified in alveolar macrophage glycerolipids can also be measured, the percentage released from the total 20:4 pool was also determined and compared to similar data previously obtained on [^{14}C]20:4-prelabeled cells (7). In addition, because the fluorescence method permits measurement of all free fatty acids simultaneously, the specificity of the fatty acid release from tannin-stimulated alveolar macrophages was examined and compared to that evoked by β-1,3-glucan, a well-characterized agonist for 20:4 release from alveolar macrophages.

MATERIALS AND METHODS

Materials. The fatty acid standards, palmitic acid (16:0), stearic acid (18:0), oleic acid (18:1), linoleic acid (18:2), arachidonic acid (20:4) and heptadecanoic acid (17:0) were purchased from Nu-Chek-Prep (Elysian, MN). The fluorescent probe, 9-anthryldiazomethane (ADAM) was obtained from Molecular Probes (Eugene, OR). Medium 199 RPMI 1640, fatty acid-free bovine serum albumin (BSA) and particulate β-1,3-glucan isolated from *Saccharomyces cerevisiae* were purchased from Sigma Chemical Co. (St. Louis, MO). High-performance liquid chromatography (HPLC)-grade solvents were obtained from EM Science (Gibbstown, NJ). A 4.5 × 250 mm, 5 μm particle size ODS reverse-phase HPLC column was purchased from Beckman Instruments (Fullerton, CA). Tissue culture plates were obtained from Costar (Cambridge, MA).

Isolation of cotton bract tannin. Condensed tannin was isolated as previously described (10) from the presenescent bracts of Acala SJ-5 cotton grown in California in 1982. The bracts were a generous gift of Dr. Robert Jacobs of Cotton, Incorporated (Raleigh, NC). The purified tannin was stored as a desiccated, lyophilized powder at –20°C. Fresh solutions were made immediately before use by dissolving the tannin in calcium- and magnesium-free Hank's balanced salt solution (HBSS), and the concentration of tannin was deter-

[1]Deceased.

Abbreviations: ADAM, 9-anthryldiazomethane; BSA, bovine serum albumin; HBSS, Hank's balanced salt solution; HPLC, high-performance liquid chromatography.

mined by the spectrophotometric method of Bell and Stipanovic (11).

Preparation of particulate β-1,3-glucan. Particulate β-1,3-glucan was prepared by suspension in HBSS at 5 mg/mL and was subjected to tip sonication just prior to use to separate any adherent particles. Following sonication, the number of particles/mL was measured on a hemacytometer.

Isolation of rabbit resident alveolar macrophages. Resident alveolar macrophages were obtained by bronchoalveolar lavage of healthy, adult New Zealand white rabbits as previously described (12). Cell differentials performed on Wright's-stained cytospin preparations revealed that the percentage of macrophages exceeded 95% in all cases. The cells were resuspended at a concentration of 1.5×10^6 cells/mL in culture medium (a 1:1 mixture of Medium 199 and RPMI 164 supplemented with 2 mM glutamine, 100 U/mL penicillin and 100 µg/mL streptomycin). One-mL aliquots of the macrophage suspension were added to each well of 6-well tissue culture plates, and the plates were incubated for 1 h at 37°C in a fully-humidified atmosphere of 95% air/5% CO_2 to permit the macrophages to adhere. The wells were then washed three times to remove any nonadherent cells, then 1 mL of mixed media +0.1% BSA was restored to each well.

Quantification of total phospholipids and esterified fatty acids in macrophages. Lipids were extracted from 1×10^7 freshly isolated rabbit alveolar macrophages by the method of Bligh and Dyer (13). After removal of the solvent under nitrogen, the lipids were redissolved in 1 mL of chloroform/methanol (2:1, by vol). Aliquots of this extract were assayed for lipid phosphorus by the method of Bartlett (14) and for total esterified fatty acids by transesterification with 0.2 N methanolic NaOH and gas chromatography analysis of the methyl esters in the presence of an internal standard.

Determination of the time and dose dependence for tannin-mediated 20:4 release. To define the time dependence of tannin-mediated 20:4 release, adherent macrophages were incubated at 37°C in a fully-humidified atmosphere of 95% air/5% CO_2 in 1 mL of culture medium containing 100 µg/mL tannin. After 30, 60, 90 and 120 min of incubation, the cells were freed from the plates by scraping with a silicone policeman. The suspended cells from 2–4 wells were combined, transferred to acid-washed 50-mL glass tubes and 2.000 µg of 17:0 was added to each tube to serve as an internal standard. The fatty acids were then extracted by the method of Bligh and Dyer (13). Cells extracted immediately after addition of the tannin-containing medium defined the basal level of 20:4 at the onset of the study. Following extraction, the organic solvent was removed under nitrogen and the fatty acids redissolved in 200 µL of methanol and stored at -70°C until derivatization and analysis.

To define the dose dependence of tannin-mediated 20:4 release, adherent macrophages were incubated at 37°C in a fully-humidified atmosphere of 95% air/5% CO_2 in 1 mL of culture medium containing 25, 50, 100 or 200 µg/mL tannin. After 90 min, the fatty acids were extracted and stored until analysis, as described above. Two sets of controls were run in parallel accompanying each experiment. Macrophages incubated with culture medium alone served as controls to define the basal release of 20:4. Wells containing culture medium, but no cells, served to define the level of fatty acids present in the medium.

Comparison of fatty acid release by tannin and β-1,3-glucan. To compare the release of all fatty acids from macrophages stimulated by tannin with that stimulated by β-1,3-glucan, adherent macrophages were stimulated with either culture medium containing 100 µg/mL tannin or 2×10^7 particles/mL of β-1,3-glucan for 90 min at 37°C in a fully-humidified atmosphere of 95% air/5% CO_2. The fatty acids were then extracted and stored until analysis as described above.

Separation and quantification of the free fatty acids. To prepare fluorescent derivatives of the extracted free fatty acids, a 200-µL aliquot of 10 mg/mL ADAM in methanol was added to the extracted fatty acids in methanol prepared as described above. The reaction tubes were purged with nitrogen, sealed and incubated for four hours in the dark at room temperature. Samples were then stored at -20°C until analysis. All samples were analyzed within 24 h after completion of the derivatization. Preliminary studies demonstrated that the fluorescent fatty acid derivatives were stable for at least this period of time.

Separation and quantification of the fluorescently-derivatized fatty acids was performed by HPLC using the method described by Nakagawa and Waku (9). Aliquots of 100 µL of the fluorescently-derivatized fatty acids were subjected to chromatography on a Waters Maxima HPLC system (Milford, MA) equipped with an in-line model 470 fluorescence detector. Separation of the derivatized fatty acids was achieved by chromatography on an ODS reverse-phase column with isocratic elution using a mobile phase of acetonitrile/isopropanol/water (90:9:1, by vol) at a flow rate of 1.6 mL/min. The derivatized fatty acids were detected by monitoring fluorescence emission at 412 nm resulting from excitation at 365 nm. The elution profiles of a standard mixture of ADAM-derivatized fatty acids were used to identify the individual fatty acid derivatives present in the cell extracts. Mass values for each of the fatty acids were determined by comparison of the integrated peak area of each fatty acid derivative and that of the derivatized internal standard, 17:0.

Statistical analysis. Comparisons of statistical significance were made using the paired Student's *t*-test. A $P < 0.05$ was taken as the limit to indicate statistical significance.

RESULTS

Total phospholipid and esterified fatty acids in alveolar macrophages. Total lipid phosphorus was determined to be 64.0 ± 2.3 nmol/10^6 cells (n = 4), a value very similar to that reported by Sugiura *et al.* (15). Fatty acid methyl esters obtained by methanolysis of the total lipid extract, amounted to 106.6 ± 3.2 nmol/10^6 cells (n = 4). About 98% of these consisted of the five predominant

fatty acids 16:0, 18:0, 18:1, 18:2 and 20:4. While the most abundant esterified fatty acid was 18:1, which comprised 33.0% of the total, the rest were present in nearly equal amounts of 15 to 17% each (Table 1).

Free fatty acid in alveolar macrophages. The free fatty acids in freshly isolated or tannin-stimulated rabbit alveolar macrophages were extracted, derivatized with a fluorescent probe, separated by HPLC (as illustrated in Fig. 1). In unstimulated cells, the mass of free fatty acids present ranged from a low of 12 ± 4 ng/10^6 cells for 20:4 to a high of 1200 ± 80 ng/10^6 cells for 16:0 (Table 1). When expressed as a percentage of the total amount of free fatty acids present in the macrophages, 16:0 accounted for approximately 56% of the total free fatty acids; 18:2, 18:1 and 18:0 represented 11, 17 and 16% of the total, respectively; and 20:4 accounted for only 0.5%. These values agree well with those previously reported for freshly isolated rabbit alveolar macrophages by Nakagawa and Waku (9).

When the amount of unesterified fatty acid was expressed as nmol/10^6 cells and compared to the total nmol/10^6 cells present in the alveolar macrophages (Table 1), it was found that approximately 7% of the total fatty acids present in the macrophages were unesterified. Individually, the relative amount of each free fatty acid present in the free fatty acid pool varied from 20:4, of which only 0.2% was unesterified, to 16:0, of which nearly 23% was present as free fatty acid. The relative amounts of the other free fatty acids (18:2, 18:1 and 18:0) ranged from 4–7% of their total amounts.

TABLE 1

Free Fatty Acid Composition of Freshly Isolated Alveolar Macrophages

Fatty acids	FFA[a] ng/10^6 cells	FFA[a] nmol/10^6 cells	Esterified FA[b] nmol/10^6 cells
16:0 (% free)[c]	1200 ± 80	4.69 ± 0.30 (22.7 ± 1.4%)	16.0 ± 0.8
18:0 (% free)	409 ± 63	1.44 ± 0.22 (7.5 ± 1.1%)	17.8 ± 0.4
18:1 (% free)	440 ± 41	1.56 ± 0.14 (4.2 ± 0.4%)	35.2 ± 0.7
18:2 (% free)	274 ± 57	0.98 ± 0.20 (5.2 ± 1.1%)	17.8 ± 0.6
20:4 (% free)	12 ± 4	0.04 ± 0.01 (0.2 ± 0.0%)	17.9 ± 1.1
Total[d] (% free)	2340 ± 160	8.69 ± 0.59 (6.6 ± 0.4%)	106.6 ± 3.2

[a]The values shown are the means ± SEM mass for each of the individual fatty acids (FA) determined on six independent preparations of alveolar macrophages. FFA, free fatty acids.

[b]The values shown are the means ± SEM nmol for each of the individual fatty acids determined on four independent preparations of alveolar macrophages.

[c]The percentage of each fatty acid present in the unesterified form calculated as (nmol FFA/10^6 cells) ÷ (total FFA + esterified FA).

[d]The other fatty acids, *e.g.*, 16:1, 20:5, etc., were present in low abundance (>2% of the total combined) and are not reported. Their contribution to the total fatty acids of the macrophage are, however, reflected in the total.

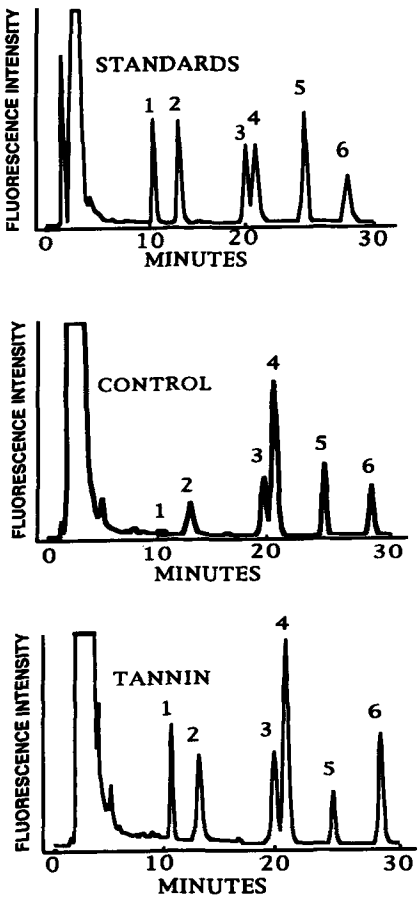

FIG. 1. Separation of fatty acid 9-anthryldiazomethane esters by reverse-phase high-performance liquid chromatography. Shown in the top panel is a chromatogram of a mixture of standard fatty acids following derivatization and chromatography on a reverse-phase ODS column. The mixture has resolved into individual fractions corresponding to 20:4 (1); 18:2 (2); 18:1 (3); 16:0 (4); 17:0 (5); and 18:0 (6). Shown in the center and bottom panels are the profiles of the fatty acids extracted from 4.5 × 10^6 control or tannin-stimulated (100 μg/mL) alveolar macrophages, respectively. In each case, 17:0 was added to each sample prior to extraction to serve as an internal standard to calculate recovery and quantitate the mass of each fatty acid.

Effect of alveolar macrophage adherence on free fatty acid levels. Since all subsequent experiments utilized macrophages that had been allowed to adhere to tissue culture plates, it was necessary to determine whether any changes occurred as a result of adherence. Freshly isolated macrophages contained 8.69 ± 0.59 nmol free fatty acids/10^6 cells compared to 8.43 ± 0.62 nmol free fatty acids/10^6 cells found in macrophages after one hour of adherence, a difference that was not statistically significant ($P = 0.74$). Adherence did, however, alter the mass distribution among the five free fatty acids detected in rabbit alveolar macrophages, as shown in Figure 2. Comparison of the mass of individual free fatty acids in freshly isolated cells with that in cells after one hour of adherence revealed that the mass of all three un-

saturated fatty acids increased. The mass of free 20:4 increased from 0.04 ± 0.1 to 0.13 ±0.03 nmol/10^6 cells, while free 18:2 increased from 0.98 ± 0.20 to 1.67 ± 0.17 nmol/10^6 cells, and free 18:1 increased from 1.56 ± 0.14 to 1.79 ± 0.26 nmol/10^6 cells. However, the increase in these free fatty acid levels reached statistical significance only for 18:2 ($P = 0.023$). In contrast, the masses of both saturated fatty acids, 18:0 and 16:0, decreased from 1.44 ± 0.22 to 1.11 ± 0.15 nmol/10^6 cells and 4.69 ± 0.30 to 3.75 ± 0.26 nmol/10^6 cells, respectively, but only the decrease in 16:0 was statistically significant ($P = 0.05$).

Time dependence of tannin-mediated release of arachidonic acid. Exposure of alveolar macrophages to tannin resulted in the time-dependent release of 20:4. Macrophages challenged with 100 µg/mL tannin for 2 h released 1.26 ± 0.23 nmol 20:4/10^6 cells as compared to the basal release of 0.08 ± 0.04 nmol 20:4/10^6 cells observed over a 2-h period from adherent, unstimulated control macrophages. As illustrated in Figure 3, 20:4 release was initially modest, with only 15% of the maximal release observed 30 min after exposure to tannin. This was followed by a rapid release over the next 30 min so that by 1-h post-exposure, 95% of the maximal release of 20:4 had occurred. This lag in the time course for endogenous 20:4 release differed from the previously reported determination of the time dependence of 20:4 release based on the measurement of the liberation of [^{14}C]20:4 from prelabeled alveolar macrophages (7). The time dependence for the release of [^{14}C]20:4 is included in Figure 3 to allow comparison with the time dependence of endogenous 20:4 release. As illustrated, the release of [^{14}C]20:4 was significantly greater and faster than that observed for the release of 20:4 mass determined in the present study. While only 15% of the maximal release of endogenous 20:4 mass occurred within 30 min after exposure, 65% of the maximal [^{14}C]20:4 release occurred within that time. However, measurements made by either method demonstrated that arachidonate release reached a plateau after 60 min of tannin stimulation.

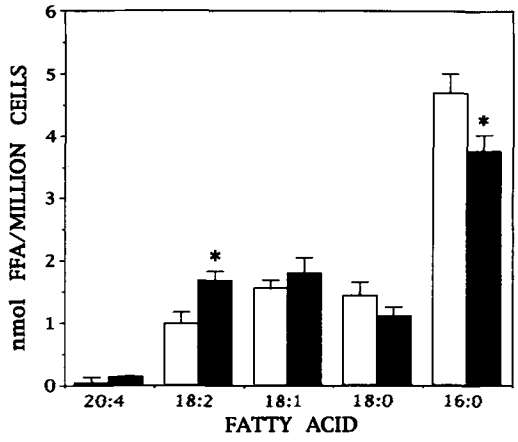

FIG. 2. Comparison of the mass of free fatty acid (FFA) in freshly-isolated, nonadherent alveolar macrophages and macrophages one hour after adherence. The levels of free fatty acids, expressed as nmol of free fatty acid/10^6 cells are shown for both freshly-isolated, nonadherent alveolar macrophages (open bars) and macrophages 1 h after adherence (closed bars). The values shown are the means ± SEM for five independent preparations. Levels of free fatty acid in adherent macrophages that differed statistically ($P < 0.05$) from those in freshly-isolated nonadherent macrophages are indicated by an asterisk.

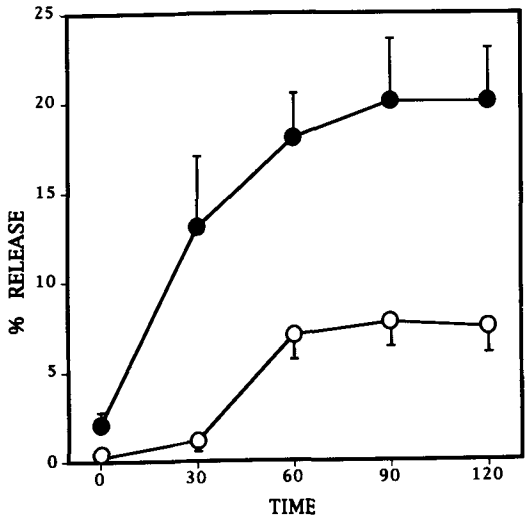

FIG. 3. Time course for tannin-mediated release of 20:4. Shown is the time-dependent increase in the mass of free 20:4 in alveolar macrophages stimulated with 100 µg/mL tannin (open circles). Each value is the mean ± SEM from four independent preparations. For comparison, the previously published (7) time-dependent release of [^{14}C]20:4 from alveolar macrophages prelabeled for 2 h with [^{14}C]20:4 is also shown (closed circles). Although the actual percentage release was significantly greater ($P < 0.05$) at all points for the radioactive 20:4 release, a comparison of 20:4 release expressed as a percentage of the maximal release, *i.e.*, the release determined at 90 min post-exposure to tannin measured by these two methods, was different only at 30 min ($P < 0.001$).

Dose dependence of tannin-mediated release or arachidonic acid. Previous studies had indicated an unusual dose dependence for the tannin-mediated release of [^{14}C]20:4 from prelabeled rabbit alveolar macrophages (7). No release of [^{14}C]20:4 above basal levels was observed at tannin concentrations below 25 µg/mL. Although the release of [^{14}C]20:4 was consistently higher, the pattern was similar to the dose-dependent release of endogenous 20:4 measured 90 min after exposure to tannin. No increase in the mass of free 20:4 occurred with tannin concentrations at or below 25 µg/mL, but near-maximal release occurred at 100 µg/mL (Fig. 4). The similarity between these two different methods of assessing the dose dependence of tannin-stimulated arachidonate release is also apparent by comparison of the EC_{50} for each method. The EC_{50} for tannin-mediated 20:4 release based on mass was 65 µg/mL as compared to the previously reported EC_{50} of 75 µg/mL based on the release of incorporated [^{14}C]20:4.

Comparison of the specificity of fatty acid release evoked by tannin and β-1,3-glucan. Because the fluorescence technique permitted the quantification of all free fatty acids released, it was possible to assess the specificity of the release of fatty acids in response to tannin

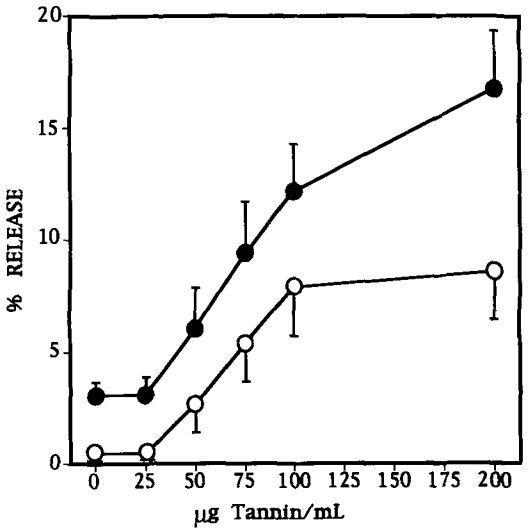

FIG. 4. Dose dependence of the tannin-mediated release of 20:4. Shown is the dose-dependent increase in the mass of free 20:4 in alveolar macrophages 90 min after the onset of exposure to the indicated concentrations of tannin (open circles). Each value is the mean ± SEM from five independent alveolar macrophage preparations. For comparison, the previously published (7) dose-dependent release of [^{14}C]20:4 from alveolar macrophages prelabeled for 2 h with [^{14}C]20:4 is also shown (closed circles). The percentage release of [^{14}C]20:4 was significantly greater ($P < 0.05$) than the release of endogenous 20:4 for all tannin concentrations.

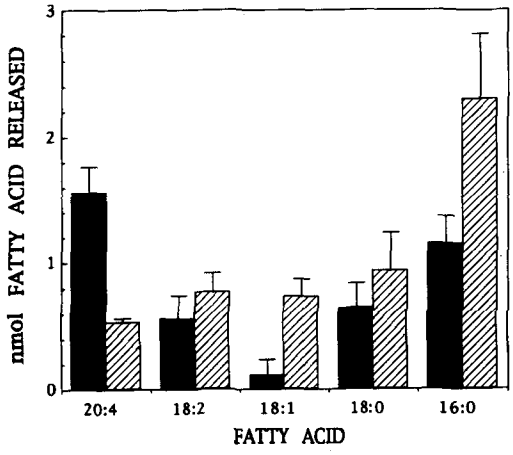

FIG. 5. Comparison of the absolute increases in the mass of free fatty acids in alveolar macrophages stimulated with tannin or β-1,3-glucan. The absolute increase in the mass of each free fatty acid, expressed as nmol of free fatty acid/10^6 cells, is shown for alveolar macrophages stimulated for 90 min with 100 μg/mL tannin (black bars) or 2 × 107 particles/mL of β-1,3-glucan (hatched bars). The levels were calculated by subtraction of the mass of each free fatty acid in control macrophages from the mass of the corresponding fatty acid in the stimulated cells. The values shown are the means ± SEM for eight independent preparations. The increase in free 20:4 was greater ($P < 0.05$) than that of 18:2, 18:1 and 18:0 in tannin-stimulated cells. The release of 16:0 was greater ($P < 0.05$) than that of all the other fatty acids released by β-1,3-glucan.

TABLE 2

Mass of Free Fatty Acids in Control, Adherent Rabbit Alveolar Macrophages and Adherent Macrophages Challenged with Tannin or β-1,3-Glucan[a]

Fatty acid	Control	Tannin	β-1,3-Glucan
16:0	3.44 ± 0.35	4.58 ± 0.40[b] (1.14 ± 0.23)[c]	5.72 ± 0.57[b] (2.29 ± 0.52)
18:0	0.92 ± 0.11	1.57 ± 0.21[b] (0.64 ± 0.19)	1.85 ± 0.31[b] (0.93 ± 0.31)
18:1	1.82 ± 0.18	1.93 ± 0.26 (0.11 ± 0.12)	2.55 ± 0.28[b] (0.73 ± 0.14)
18:2	1.70 ± 0.26	2.25 ± 0.28[b] (0.55 ± 0.19)	2.47 ± 0.28[b] (0.77 ± 0.15)

Total	8.06 ± 0.90	12.06 ± 1.09[b] (4.00 ± 0.65)	13.29 ± 1.24[b] (5.23 ± 0.99)

[a]The values shown are the means ± SEM mass (nmol/10^6 cells) for each of the individual fatty acids in control macrophages after two hours of incubation in culture medium (Control), culture medium plus 100 μg/mL tannin (Tannin) or culture medium plus 20 × 10^7 particles of β-1,3 glucan. The values represent the average of eight independent preparations of alveolar macrophages.

[b]Values were statistically significantly greater ($P < 0.05$) than the corresponding value in the control cells.

[c]The mean ± SEM nmol/10^6 cells increase for each fatty acid over the level detected in control macrophages.

or any other agonist. Challenge of alveolar macrophages with 100 μg/mL tannin resulted in a 50% increase in the level of total free fatty acids. As seen in Table 2, tannin-stimulated macrophages released more 20:4 than any other fatty acid, 1.55 nmol/10^6 cells, which was significantly greater ($P > 0.05$) than the release of other free fatty acids except 16:0. For comparison, the fatty acid release induced by β-1,3-glucan was also determined. β-1,3-Glucan is a well-characterized component of zymosan, a yeast cell fragment responsible for liberation and secretion of arachidonate from alveolar macrophages (16). As also shown in Table 2, macrophages stimulated with 2 × 10^7 β-1,3-glucan particles/mL responded with a 65% increase in free fatty acids, similar in total mass to that resulting from tannin stimulation. However, the profile of free fatty acids was quite different (Fig. 5). Whereas tannin caused a release of similar amounts of saturated and unsaturated fatty acids, β-1,3-glucan stimulated a release of saturated fatty acids, which was much greater than the release of unsaturated fatty acids. The most predominant fatty acid released by β-1,3-glucan was 16:0, which at 2.29 nmol/10^6 cells, was significantly ($P < 0.05$) more than any other fatty acid.

Comparisons based on the percentage increase in the level of any free fatty acid are dependent upon the basal level of each fatty acid. Although tannin caused a 10-fold, and β-1,3-glucan caused a 4-fold, increase in free 20:4, referring to their release in this way can be specious because the basal levels of free 20:4 are so low relative to the other fatty acids. To achieve a more meaningful indication of the selectivity of fatty acid release in

response to agonist stimulation, we have chosen in Figure 5 to compare the increase in actual mass of each fatty acid over the basal levels in the agonist-stimulated cells. Depicted in this way, it is apparent that the increase in mass of 20:4 was less than that for all the other fatty acids in β-1,3-glucan-stimulated macrophages. Thus, despite the fact that β-1,3-glucan induced a fourfold increase in the level of free 20:4, it did not induce a selective release of 20:4. In fact, the level of free 16:0, which increased 70% relative to controls, represented the greatest mass release of any fatty acid. A quite different picture emerged from the analysis of the mass changes of the fatty acids in tannin-treated macrophages. In these cells, the largest increase in mass was observed for 20:4, which was significantly greater than that observed for 18:2, 18:1 or 18:0. These data indicate that, unlike β-1,3-glucan, tannin evoked a fatty acid release which was preferential for 20:4.

DISCUSSION

The mechanisms and factors involved in the agonist-dependent release of 20:4 levels have been studied in many cell types by examining the levels of radioactive 20:4 released from prelabeled cells. In such studies, it is important to know when the added radioactive arachidonate achieved isotopic equilibrium within the phospholipid pools of the cells, and if not, what effect this isotropic heterogeneity would have on stimulated release. Several factors can contribute to heterogeneous 20:4 distribution within cellular lipid pools. First, it is well established that the rates at which different phospholipid classes are labeled with exogenous radioactive 20:4 are quite different. Phosphatidylcholine and phosphatidylinositol are labeled much more rapidly than phosphatidylethanolamine (17). Second, within the phosphatidylcholine and phosphatidylethanolamine pools, the diacyl phospholipids are labeled more rapidly than either the alkylacyl or alkenylacyl phospholipids (18). Finally, the rates at which the same phospholipid present in the membranes of different subcellular organelles are labeled may also differ (19). Thus, it was not unexpected to find that the level of [^{14}C]20:4 released from the radiolabeled pools was different than the endogenous 20:4 release.

Several conclusions can be drawn from the measurements of endogenous fatty acid mass released from alveolar macrophages, especially in relation to the amounts of each in free and esterified pools. Upon consideration of the fatty acid levels in basal nonadherent cells, the low level of free 20:4 and high level of free 16:0 are most striking. Although 20:4 and 16:0 comprise similar amounts of the total esterified fatty acids found in the macrophage, 16.8 and 15%, respectively, their levels as free fatty acids are quite differently controlled in the cell (20). Although the low level of free 20:4 in alveolar macrophages was anticipated from earlier work, the finding that 23% of the cells' 16:0 was in the unesterified form was unforeseen. One important factor to be considered in this regard is that the pulmonary surfactant fluid in which the alveolar macrophages reside is markedly enriched in dipalmitoyl phosphatidylcholine. The high levels of free 16:0 in the alveolar macrophages might be the result of dipalmitoyl phosphatidylcholine ingestion and degradation (21,22). Furthermore, free 16:0 represents more than 50% of the free fatty acids in this lipid-rich milieu (data not shown). Thus, until their removal from the lavage fluid, the alveolar macrophages are exposed to substantial amounts of 16:0.

The decrease in the levels of free saturated fatty acids and increase in free unsaturated fatty acids observed during the process of cell adherence is consistent with the conclusion that cell adherence leads to a increased turnover of the phospholipid fatty acids with a release of unsaturated fatty acids such as 20:4. This supports the previous observation by Kousan and colleagues (23) that adherence of alveolar macrophages to a plastic surface results in the release of 20:4. A more recent study of monocyte adherence by Lefkowith and colleagues (24) suggested that adherence and spreading not only results in the activation of cellular phospholipases but also the release of 20:4 is a necessary and integral part of the adhesion process. Inhibition of the phospholipases resulted in decreased adherence and spreading.

The difference in rate for the release of [^{14}C]20:4 and endogenous 20:4 mass suggest that at least two pools of 20:4 exist within the alveolar macrophage that differ in the rate at which 20:4 is released following cell stimulation. The [^{14}C]20:4 incorporated into the alveolar macrophages during a two-hour labeling period appears to enter a more "reactive" pool since the rate at which the [^{14}C]20:4 is released is faster and greater than the percent of endogenous 20:4 mass released from the cells' lipid pools. Several previously published reports (25–27) have suggested the existence of different intracellular pools of 20:4 which are distinguishable on the basis of the rates at which they either incorporate or release 20:4. Fonteh and Chilton (28) have recently reported that the increase in extracellular 20:4 released from antigen-activated mast cells was more rapid than the increase in free intracellular 20:4 or 20:4 metabolites. The extracellular 20:4 also differed in specific radioactivity from free intracellular 20:4 or 20:4 metabolites. They concluded that the extracellular 20:4 and intracellular free 20:4 arose from mobilization of different pools of 20:4. If a similar situation also occurs in rabbit alveolar macrophages, it could explain the discrepancy between the initial rates of 20:4 release from the tannin-stimulated macrophages measured by release of pre-incorporated [^{14}C]20:4 and the release of total 20:4 mass measured. The previously reported measurement of [^{14}C]20:4 release from prelabeled macrophages quantified only the extracellular [^{14}C]20:4 while the mass determinations used in the present study measured the combined total mass of free intracellular and extracellular 20:4. However, it is interesting to note that tannin-mediated arachidonate release from [^{14}C]20:4 prelabeled cells was similar to that from endogenous 20:4 in terms of dose response and time dependence.

β-1,3-Glucan is presumed to stimulate the deacylation of phospholipids by activation of phospholipase A_2 (29) and is known to have little or no effect on the activity of

the enzymes involved in reacylation (7). However, as is apparent from the release of saturated fatty acids at a greater rate than the unsaturated fatty acids, it appears that the glucan-stimulated deacylation activity is not selective for fatty acids located in the *sn*-2 position. On the contrary, comparison of the amounts of individual fatty acids released in response to β-1,3-glucan reveals that 16:0 was selectively released. This selectivity of β-1,3-glucan-stimulated fatty acid release was not observed in cells prelabeled with [^{14}C]20:4 and [^{14}C]16:0 (16) and requires further study.

While β-1,3-glucan stimulated a significant release of all fatty acids, tannin-mediated release was significant for all fatty acids, except 18:1, which remained at a virtually constant level in macrophages challenged with tannin. As 18:1 is twice as abundant as any other macrophage fatty acid at ~37% of the total, it is remarkable that it is the least affected by tannin (Table 2).

Finally, comparison of tannin- and β-1,3-glucan-stimulated macrophage free fatty acid levels is consistent with the hypothesis that the mechanism responsible for fatty acid release is different for these two agonists. Whereas β-1,3-glucan appears to stimulate phospholipase A activity, tannin may increase fatty acid levels by inhibiting reacylation (7). The fact that tannin induces the greatest increase in the mass of free 20:4 is consistent with our previous observation that the inhibition of reacylation of fatty acids in tannin-treated macrophages was most pronounced for 20:4 (30). Together, these results suggest that rabbit alveolar macrophages may contain a 20:4-specific acyl-CoA synthetase as has been reported for human platelets (31) and that inhibition of this enzyme by tannin is responsible for the selective increase in free levels of 20:4. Further studies are currently underway to investigate this possibility.

ACKNOWLEDGMENTS

This paper is dedicated to the memory of Michael S. Rohrbach, who knew what was important in matters of science and cared about what was important in life.

This work was supported by Grant HL 28669 from the National Heart, Lung and Blood Institute, and by funds from the Mayo Foundation. We wish to thank Pat Schmid, who provided assistance in GC quantitation of total lipid esters, and Harald Schmid, whose advice and comments were invaluable in preparation of this manuscript.

Essential Fatty Acids Alter the Activity of Manganese-Superoxide Dismutase in Rat Heart

Andreas C. Phylactos*, Laurence S. Harbige[1] and Michael A. Crawford

Nuffield Laboratories of Comparative Medicine, Institute of Zoology, Regent's Park, London NW1 4RY, United Kingdom

The effects of oil-derived dietary essential fatty acids on the activities of mitchondrial Mn-SOD (manganese-superoxide dismutase) and cytosolic cupric zinc-superoxide dismutase (Cu/Zn-SOD) were investigated in rat heart. A control group of rats was fed a stock diet for 29 d, and a second group was fed on a fat-free diet. Three other groups were fed fat-free diets that were supplemented with (i) borage oil, which is rich in linoleic (18:2n-6) and γ-linolenic (18:3n-6) acids, (ii) fungal oil, which is rich in γ-linolenic, but low in linoleic acid, or (iii) evening primrose oil, which is rich in linoleic acid and low in γ-linolenic acid. An increase in the percentage composition of arachidonic acid (20:4n-6) in both the choline and ethanolamine phospholipids, together with a decrease in linoleic acid in ethanolamine phospholipids, were found in heart membranes after feeding the rats with diets containing borage oil or fungal oil as compared to those fed the stock diet. The respective activities of Mn-SOD in rats fed the borage or fungal oil diets were also significantly higher than in rats fed the stock diet alone. No change in cytosolic Cn/Zn-SOD activity was observed. Dietary supply of linoleic acid-rich evening primrose oil resulted in an increased proportion of choline phospholipid linoleic acid without any changes in arachidonic acid content or in the activity of Mn-SOD. By contrast, a reduction in the activity of Mn-SOD was detected in rats fed a fat-free diet. These results show that the activity of heart mitochondrial Mn-SOD is influenced by dietary essential fatty acids, whereas the activity of cytosolic Cu/Zn-SOD remained unaffected.
***Lipids* 29, 111–115 (1994).**

Superoxide radicals are physiologically generated in mammalian cells during the transport of electrons along the mitochondrial respiratory chain (1,2) through metabolic processes catalyzed by oxidative metallo-enzymes and through nonenzymatic oxidoreductive reactions (3,4). The radicals are dismutated to hydrogen peroxide and molecular oxygen by mitochondrial matrix-soluble manganese-superoxide dismutase (Mn-SOD) and cytosolic soluble cupric zinc-superoxide dismutase (Cu/Zn-SOD) (5). The enzymatic dismutation of these radicals at their sites of formation offers protection to cellular structures from peroxidative damage (4).

During myocardial ischemia, the activity of mitochondrial Mn-SOD is reduced by approximately 50%, and reperfusion does not restore the activity of the enzyme (6). A quantitatively similar reduction in Mn-SOD activity has also been reported in the iris ciliary body during endotoxin-induced acute ocular inflammation, where activity is restored within seven days as the inflammatory reaction declines (7). It is not known how and why the activity of Mn-SOD is reduced, although it is known that under both myocardial ischemia and ocular inflammation, mitochondria show structural alterations, impairment of respiratory function, inhibition of SH-dependent enzymes and changes in calcium transport kinetics (7–9). In addition, membrane-bound arachidonate is released and peroxidized to eicosanoids (10–12). Release of catecholamines from membrane vesicles (13,14), activation of xanthine dehydrogenase to oxidase (3,15) and generation of superoxide radicals (16–18) have also been detected in the heart during ischemia. Membrane lipid peroxidation, inhibition of ATPase, release of catecholamines and impairment of respiratory mitochondrial function have been observed during cardiotoxicity induced by adriamycin (19,20), a drug known to generate superoxide radicals in the mitochondria, following complexation with iron (21,22). Furthermore, iron-induced lipid peroxidation of isolated myocardial mitochondria is inhibited by addition of superoxide dismutase (SOD) and catalase (23).

Most of the above data point toward peroxidative damage and suggest that under oxidative stress the antioxidant defenses of the heart are unable to dispose of oxygen radicals and thus cannot protect against oxygen-induced toxicity. The activities of the protective antioxidant enzymes are comparatively low in the heart (6,24,25). Since cardiac phospholipid composition can be altered by dietary fatty acids with associated changes in the activities of some enzymes (26–28), the present study was undertaken to investigate the effects of diets containing borage oil (BOO), fungal oil (FGO) and evening primrose oil (EPO) as sources of essential fatty acids on the activities of mitochondrial Mn-SOD and cytosolic Cu/Zn-SOD in rat heart tissue.

MATERIALS AND METHODS

Reagents. Xanthine, buttermilk xanthine oxidase, *p*-iodonitrotetrazolium violet (INT), SOD and bovine serum albumin were purchased from Sigma Chemical Co. (Poole, Dorset, United Kingdom). Inorganic salts were of the AnalaR Grade and were obtained from British Drug House (Poole, Dorset, United Kingdom).

Animals and diets. Fifteen six-week-old female Wistar rats were obtained from Bantin & Kingman Ltd. (Hull,

Abbreviations: BOO, borage oil; CPL, choline phospholipids; Cu/Zn-SOD, cupric zinc-superoxide dismutase; EPO, evening primrose oil; EPL, ethanolamine phospholipids; FFD, fat-free diet; FGO, fungal oil; HPLC, high-performance liquid chromatography; INT, *p-iodonitrotetrazolium violet*; Mn-SOD, manganese-superoxide dismutase.

TABLE 1

Composition of Diets[a]

Nutrient	Fat-free diet (wt%)	Stock diet[b]
Protein	15.3	14.7
Fat	0.0	2.6
Fiber	4.6	5.3
Carbohydrate	70.5	61.5
Ash	4.5	5.9
Moisture	5.0	10.0

[a]Vitamin and mineral composition: vitamin A, 2.9 mg/kg; vitamin E, 97 mg/kg; vitamin C, 47.6 mg/kg; iron 65.1, mg/kg; copper, 11.6 mg/kg; zinc, 27.2 mg/kg; selenium, 69.9 mg/kg; manganese 50 mg/kg.
[b]Percentage of main fatty acids in stock diet: palmitic acid, 0.32%; oleic acid, 0.76%; linoleic acid, 0.71%; α-linolenic acid, 0.06%; arachidonic acid, 0.13%.

United Kingdom) and fed one of five diets for 29 d. Diet 1 was a stock rodent diet RM1 (see Table 1) supplied by Special Diet Services Ltd. (Witham, Essex, United Kingdom). Diet 2 was a fat-free rodent diet (FFD), also supplied by Special Diet Services Ltd. (see Table 1). Diets 3, 4 and 5 consisted, respectively, of FFD 2 and EPO *(Oenothera biennis)* to provide a linoleic acid-enriched Diet 3, BOO *(Borago officinalis)* to provide a linoleic acid and γ-linolenic acid-enriched Diet 4, and FGO *(Mucor javanicus)* to provide a low linoleic acid and high γ-linolenic acid-enriched Diet 5. Each oil was added at 5% of the total dietary energy. The fatty acid compositions of the oils before diet mixing are shown in Table 2. The synthetic antioxidant 2,6-di-*tert*-butyl-4-methylphenol (butylated hydroxytoluene) was added, at 50 mg/100 g, to the oils. Animals were housed three per experimental group in grid bottomed cages at a mean room temperature of 21 ± 1.5°C and a light/dark cycle of 14 h light and 10 h dark.

Sacrifice of animals and collection of tissues. Animals were euthanized with diethyl ether after 29 d on the diets. The heart was immediately removed and placed on ice. About 100 mg of tissue was excised from the apex of the heart and homogenized in 4 mL of 0.25 M sucrose in 0.1 M potassium phosphate buffer (pH 7.2) at 4°C. Homogenization was done using a borosilicate tube and a Teflon plunger with a clearance of 0.20 mm at 2,000 rpm. The remaining heart was frozen at −20°C for subsequent fatty acid analysis.

Subcellular fractionation. Exactly 1.0 mL of the homogenate was removed and kept at −20°C for enzyme assays. The remaining 3 mL were centrifuged at 37,000 × g at 4°C for 20 min using a Beckman model J2-21 centrifuge (Beckman, Palo Alto, CA). At the end of the run, the mitochondria-rich pellet was separated from the cytosolic supernatant, washed twice and suspended in 2 mL of sucrose phosphate buffered medium (pH 7.2). Succinate dehydrogenase was used as a mitochondrial marker enzyme to test the effectiveness of the subcellular fractionation of the homogenate into a mitochondria-rich fraction and a cytosolic supernatant.

Protein determination. The concentration of protein in 100-μL aliquots of heart homogenates, and of mitochondrial and cytosolic fractions, were estimated by the biuret method (29).

Tests for SOD. In preliminary experiments, pretreatment of heart mitochondrial suspension (200 μL) with 150 μL of chloroform/ethanol (2:1, vol/vol) abolished the activity of superoxide dismutase. In separate tests, addition of 3 mM potassium cyanide to the assay mixture did not exert a significant inhibitory effect on the activity of mitochondrial SOD. In contrast, the activity of the cytosolic SOD was inhibited by 3 mM potassium cyanide, but remained unaffected by the chloroform/ethanol mixture. This indicated that the mitochondrial fraction contained mainly the chloroform/ethanol inactivated, cyanide insensitive Mn-SOD form, whereas the cytosolic supernatant contained the cyanide-sensitive Cu/Zn-SOD form.

Assay for SOD (EC 1.15.1.1) activity. Heart homogenates, mitochondrial pellets and cytosolic supernatants were separately assayed for SOD (7,30). The assay was carried out at a temperature of 25°C in a 3-mL mixture contained in a spectrophotometric cuvette and consisting of 2.5 mL of 0.04 M phosphate buffer (pH 7.45), 0.25 mM xanthine as substrate, 0.3 mM INT as the chromogenic reagent and 0.1 mM ethylenediaminetetraacetic acid as chelator for transition metal ions. The reaction was initiated by addition of 10 milliunits of buttermilk xanthine oxidase (one milliunit of xanthine oxidase, E.C. 1.1. 3.22, converts one nanomole of xanthine to uric acid at pH 7.5 at 25°C). The change in absorbance (0.25–0.45 Units) against a xanthine oxidase blank sample was recorded for 10 min at 550 nm using a Perkin-Elmer 402 spectrophotometer (Perkin-Elmer Ltd., Beaconsfield, Bucks, United Kingdom). An aliquot of 200 μL containing 155–455 μg of protein of the heart sample under test was added to both the blank and the experimental cuvettes, and the change in absorbance was recorded for another 10 min. The percent inhibition of heart SOD on the xanthine/oxidase/INT reaction was measured and the activity of the enzyme calculated from calibrated SOD graph, in which one SOD unit exerted 50% inhibition on the xanthine/xanthine oxidase/INT reaction under the conditions of the assay.

[a]Abbreviations: EPO, evening primrose oil; BOO, borage oil; FGO, fungal oil. Oils were supplied by John E. Sturge Ltd. (Yorkshire, United Kingdom) and ViPONTE Ltd. (Hull, United Kingdom).

Assay for succinate dehydrogenase activity (EC 1.3.99.1). Succinate dehydrogenase activity was assayed at 25°C (31) in 3.0 mL of a mixture containing 0.1 M potassium phosphate buffer, pH 7.8, 0.63 mM potassium ferricyanide, 50 mM sodium succinate, and 160–325 µg of protein of the mitochondrial suspension or 190–325 µg of protein of the cytosolic supernatant. The reaction was followed at 420 nm for 20 min, and the activity of the enzyme was calculated from the change in absorbance and the µM absorption coefficient of potassium ferricyanide, and expressed in µmoles of succinate per min (Units) per mg of protein.

Lipid extraction and fatty acid analysis. Hearts (0.5–0.7 g) were homogenized in 100 vol (wt/vol) of chloroform/methanol (2:1, vol/vol) until a fine suspension was formed, and then extracted overnight at 5°C. The lipid extracts were filtered and then processed according to Folch *et al.* (32). Total lipids were concentrated under a stream of nitrogen and redissolved in 1.0 mL of chloroform and separated by high-performance liquid chromatography (HPLC) on a Varian model 5000 (Varian, Palo Alto, CA). The chromatographic column was a 25 cm × 8 mm prepacked Lichrosorb 5 silica 60 column (Thames Chromatography, Berkshire, United Kingdom), which contained silica of a particle size of 5 µm. The mobile phase solvent system was used isocratically (33). Briefly, Solvent A, 95% acetonitrile, and Solvent B, 5% methanol/85% orthophosphoric acid [methanol/H_3PO_4 (85%) 5:1.5 vol/vol], were delivered to the column at a flow rate of 1 mL/min at a pressure of 26 bar (382 PSI) at 27°C, and detected at 203 nm. Fractions were identified by comparison of their retention times with those of phospholipid standards obtained from Sigma Chemical Co. Choline phospholipids (CPL) and ethanolamine phospholipids (EPL) separated by HPLC were evaporated to dryness under a stream of nitrogen and transmethylated with 5 mL of methanol containing 5% sulfuric acid for 3 h at 70°C, in a nitrogen atmosphere. Methyl esters were recovered by addition of an equal volume of 5% saline and extracted into 3 × 2 mL of petroleum hydrocarbon (b.p. 30–40°C). The extract was dried over anhydrous sodium sulfate, evaporated to dryness and redissolved in 3 mL of Analar grade heptane. Methyl esters were analyzed by gas–liquid chromatography (34).

Statistics. Student's unpaired *t*-test was used to compare and evaluate significant differences between stock diet and experimental results.

RESULTS

Enzymatic activities. The overall (combined) specific activities of SODs (Mn-SOD and Cu/Zn-SOD) in homogenates of hearts from rats fed BOO or FGO diets were significantly higher than the activities in heart homogenates from rats fed the stock diet. Similarly, the respective specific activities of Mn-SOD in heart mitochondrial fractions from borage or fungal oil fed rats were also significantly higher as compared to the activity of heart mitochondrial Mn-SOD from rats fed the stock diet. There was no significant difference between the specific activities of Mn-SOD in heart mitochondria from rats fed BOO or FGO. The activities of Cu/Zn-SOD in cytosolic supernatants from the hearts of rats fed borage, fungal or stock diets were not statistically different. There were no significant changes in the activities of SOD(s) in the homogenate, mitochondrial or cytosolic fractions from hearts of EPO fed rats relative to the respective activities detected in rats fed the stock diet. The overall (combined) specific activity of Mn-SOD and Cu/Zn-SOD detected in heart homogenates from rats fed the FFD was decreased in comparison to the activity in rats fed the stock diet. Similarly, heart mitochondrial fractions from FFD rats exhibited decreased Mn-SOD activity relative to heart mitochondria from stock diet fed rats. No statistical difference was found between the activity of Cu/Zn-SOD in the cytosol of FFD fed rats and that of stock diet fed rats (Table 3).

The activities of the mitochondrial marker succinate dehydrogenase in mitochondria-rich fractions from the hearts of EPO fed rats were 15.15 ± 3.03 µmoles of succinate per min (Units) per mg of protein, from BOO fed rats 13.05 ± 2.40 Units/mg of protein and from FGO fed rats 16.88 ± 2.10 Units/mg of protein. No succinate dehydrogenase activity was found in the cytosolic supernatants. This indicated that mitochondria-rich pellets containing Mn-SOD were effectively separated by centrifugation at 37,000 × *g* from the cytosolic supernatant that contained Cu/Zn-SOD.

Heart CPL fatty acids. A significant increase was detected in the proportion of CPL-linoleic acid (18:2n-6) in the hearts of rats fed EPO relative to the level of 18:2n-6 in the hearts of stock diet fed rats. This resulted in a reduced arachidonic acid to linoleic acid ratio. In contrast, rats fed BOO or FGO showed an increase in heart CPL-arachidonic acid compared to stock diet fed rats. As a consequence, the arachidonic to linoleic acid ratio was increased (Table 4).

Heart EPL fatty acids. In heart tissues of rats fed BOO- and FGO-rich diets, the proportions of EPL-linoleic acid were significantly reduced relative to that in the heart of stock diet fed animals. By contrast, the proportions of heart EPL-arachidonic acid were increased in BOO- and FGO-fed rats. These fatty acid changes in the heart, induced by BOO and FGO diets, resulted in a respective fourfold and eightfold rise in the ratio of EPL-arachidonic to EPL-linoleic acid relative to the ratio in stock diet fed rats (Table 4).

DISCUSSION

The results of the present study suggest that an increase in the ratio of arachidonic to linoleic acid is related to the increase in the activity of mitochondrial Mn-SOD. This is apparent from the effects of the BOO-supplemented diet that resulted in a twofold increase in the activity of the enzyme and a fourfold increase in the EPL-arachidonic to EPL-linoleic acid ratio. Similarly, the FGO-containing diet also resulted in a twofold increase in the activity of Mn-SOD, and an eightfold rise in the EPL-arachidonic to EPL-linoleic acid ratio. In contrast, in EPO fed rats where there was no change in the ratio of EPL-arachidonate to EPL-linoleate, there was no effect on Mn-SOD activity. The increases in the proportion of heart arachidonate

FFD	3.27 ± 0.15	15.36 ± 2.08	4.69 ± 0.43

[a]Data are reported as means ± SD (n = 3). One superoxide dismutase (SOD) unit exerted 50% inhibition on the assay reaction (0.25 mM xanthine, 10 mUnits xanthine oxidase, 0.3 mM *p*-iodonitrotetrazolium violet, 0.1 mM ethylene diaminetetraacetic acid in 3.0 mL of 0.04 M phosphate buffer, pH 7.45). Abbreviations as in Table 2.
[b–f]*P* values relative to control stock diet: [b]< 0.001; [c]< 0.005; [d]< 0.01; [e]< 0.025; [f]< 0.05.

effected with the BOO and FGO diets probably arose from the high content of γ-linolenic acid. The latter bypasses the rate-limiting Δ6 desaturase step and is readily converted to arachidonic acid (35,36). The finding that Mn-SOD activity is reduced in the heart of rats fed the FFD diet is consistent with the decrease in the activity of adenylate cyclase in the heart of essential fatty acid-deficient rats (37). Interestingly, it has also been reported (38) that dietary n-3 fatty acids decrease the activities of SODs in rat heart. This, when compared to our findings, suggests that n-6 and n-3 fatty acids have differential effects on mitochondrial SOD activity. Changes in the EPL ratio of arachidonic to linoleic acid, brought about by dietary manipulations, have also been observed in the erythrocytes of monkeys with respective changes in the susceptibility of membranes to peroxidative damage (34). One hypothesis that can be advanced to explain the increases in the activities of Mn-SOD observed in the present investigation is that the increased heart membrane arachidonate in rats fed the BOO and FGO diets increases the "peroxidizable index," which may stimulate Mn-SOD activity as a consequence of superoxide radical formation. Mammalian Mn-SOD is a tetrameric metallo-protein consisting of two dimeric subunits (5,39). The enzyme may exhibit allosteric kinetic properties in the presence of reduced or increased quantities of the substrate (superoxide ions). This may explain the 50% decrease in the activity of the enzyme in the mitochondrial fractions from FFD fed rats. It

TABLE 4

Effects of Dietary Oils on Choline Phospholipid and Ethanolamine Phospholipid Fatty Acids of Rat Heart[a]

Diet	LA	AA	AA/LA ratio	Relative % change
Choline phospholipid				
STK	8.8 ± 1.4	18.9 ± 2.0	2.1	100.0
BOO	8.8 ± 1.3	26.2 ± 4.0[f]	2.9	138.1%
FGO	10.2 ± 1.7	28.5 ± 4.3[f]	2.8	133.3%
EPO	16.0 ± 2.2[d]	21.4 ± 2.6	1.3	61.9%
Ethanolamine phospholipids				
STK	2.81 ± 0.60	25.8 ± 3.5	9.2	100.0
BOO	0.80 ± 0.24[d]	32.3 ± 3.5	40.3	438.0%
FGO	0.46 ± 0.17[c]	35.2 ± 3.6[f]	76.5	831.5%
EPO	3.40 ± 0.54	27.6 ± 3.8	8.1	88.0%

[a]Data are means ± SD (n = 3). Abbreviations as in Table 2. LA, linoleic acid (18:2n-6); AA, arachidonic acid (20:4-6).
[c,d,f]*P* values: [c]< 0.005; [d]< 0.01; [f]< 0.05.

would also explain the twofold rise in enzymatic activity with the fourfold or eightfold increases in EPL-arachidinate to EPL-linoleate ratio in the heart of BOO- or FGO-fed rats. A second hypothesis is that the level of membrane arachidonate may modulate the induction/transcription of the Mn-SOD gene (40), possibly *via* the activation of oxidative stress-responsive transcription factors (41).

The dependence of Mn-SOD activity on membrane fatty acid composition may explain the absence or low activity of this enzyme in some leukemia cells (42) of reduced polyunsaturated fatty acid status (43). Similarly, the inactivity of Mn-SOD in Morris hepatoma of high superoxide ion production (44,45) may arise from decreased levels of polyunsaturated fatty acids as a result of peroxidation.

In summary, our studies suggest that mitochondrial Mn-SOD activity is influenced by the fatty acid composition of membrane phospholipids and, in particular, by the proportions of the unsaturated fatty acids linoleic and arachidonic acid.

Gradient for D-Glucose and Linoleic Acid Uptake Along the Crypt-Villus Axis of Rabbit Jejunal Brush Border Membrane Vesicles

R.J. Fingerote, K.A. Doring and A.B.R. Thomson*

Nutrition and Metabolism Research Group, Division of Gastroenterology, Department of Medicine, University of Alberta, Edmonton, Alberta, T6G 2C2 Canada

Glucose uptake into jejunal brush border membrane (BBM) varies along the crypt-villus axis (CVA). In the present study, the question was addressed whether uptake of the essential long-chain fatty acid linoleic acid also varies along the CVA. Using agitation techniques, five jejunal enterocyte fractions were sequentially isolated from female New Zealand white rabbits. A sixth and final fraction of lower-villus/crypt cells was obtained by the scraping of the remaining jejunal mucosa. Cell fraction along the CVA was proven histologically, by noting decreasing alkaline phosphatase activities in sequentially isolated fractions, and by demonstrating [^{3}H-*methyl*]thymidine uptake mainly in the final fraction of the lower villus/crypt cells. BBM vesicles were prepared from the upper-, mid- and lower-villus/crypt enterocyte fractions, using differential centrifugation and divalent ion precipitation. D-Glucose uptake into each fraction showed an Na^+-gradient dependent time-course "overshoot" with linear uptake to 15 s and a subsequent decline to a steady-state plateau. Varying D-glucose concentrations from 50–1000 μM demonstrated saturation kinetics of uptake, with maximal transport rates (V_{max}) and Michaelis affinity constants (K_m) varying between fractions; the K_m and V_{max} were both lowest in the upper-villus fraction. A linear relationship existed between linoleic acid concentration (25–200 μM) and uptake in each fraction. Linoleic acid uptake was equivalent in all fractions when expressed per mg protein, but when expressed in terms of the estimated minimal BBM, vesicle surface area uptake was greater in the upper- than in the lower-villus/crypt fractions. Thus, BBM vesicle uptake of both linoleic acid and glucose vary along the crypt-villus axis of the rabbit jejunum.

***Lipids* 29, 117–127 (1994).**

Enterocytes originate in the crypt of the intestinal villus and mature as they advance along the crypt-villus axis (CVA). During this advance, the enterocytes change from cuboidal to columnar cells, and the microvilli change from being broad and relatively sparse in the crypt cells to the narrower and more numerous microvilli of the upper-villus enterocytes (1). The length of the microvilli increases as rat enterocytes advance along the CVA, with lengths of 1.8 mm in microvilli from enterocytes from the upper-villus, as compared to values of 1 and 0.8 mm in mid- and lower-villus enterocytes, respectively (2). As enterocytes advance along the CVA, the intracellular activity of thymidine kinase decreases while the brush border membrane (BBM) activities of alkaline phosphatase (ALP) and invertase (INV) increase (3–13).

Following a meal rich in dietary fats, lipid droplets are seen predominantly in upper-villus enterocytes (14). Autoradiographic studies have demonstrated that the uptake of palmitic acid occurs mainly in the upper-villus fraction of the CVA (15). Similar studies have demonstrated that amino acids and hexose uptake also occur predominantly in the enterocytes of the upper third of the villus (16–19). *In vitro* studies using BBM vesicles prepared from enterocyte fractions harvested from along the CVA have established that there is greater uptake of amino acids and hexoses in the upper than in the lower portions of the CVA (3,5,9,20). Indeed, it has been suggested that a second hexose carrier may appear as the enterocytes migrate along the CVA (3,5,21–23), and that the kinetic properties of carrier-mediated transport vary along the CVA (3,5,9). Taken together, these findings give support to the concept that nutrients are absorbed principally in the upper portion of the villus.

BBM vesicles have been shown to be a useful tool to assess the uptake of linoleic acid (LA) by the small intestine (24,25). However, no published studies are available comparing the uptake of this essential long-chain fatty acid by BBM vesicles obtained from enterocytes originating at different levels of the CVA. Accordingly, the present study was undertaken to test the null hypothesis that there is no gradient in the uptake of LA or D-glucose along the CVA of rabbit jejunum. The results suggest that the null hypothesis is rejected, and that they passive permeability properties for LA, and the maximal transport capacity (V_{max}) and Michaelis affinity constant (K_m) for glucose uptake, are greater for the BBM of enterocytes from the upper as compared to the lower portions of the CVA.

MATERIALS AND METHODS

Preparation of tissue. The guiding principles in the care and use of laboratory animals, approved by the Canadian Federation of Biological Societies (Ottawa, Ontario) and by the Council of the American Physiological Society (Washington, D.C.), were observed in the conduct of this study. Mature female New Zealand white rabbits weighting 1.6–2.2 kg were given *ad libitum* access to standard Purina® (Ralston-Purina, St. Louis, MO) rabbit chow and water until the morning of study. Animals were sacrificed by a lethal injection of sodium thiopental (240 mg/kg) into a marginal ear vein. The abdominal cavity was rapidly opened, and 80 cm of jejunal

*To whom correspondence should be addressed at Division of Gastroenterology, 519 Robert Newton Research Building, University of Alberta, Edmonton, Alberta, T6G 2C2 Canada.

Abbreviations: ALP, alkaline phosphatase; BBM, brush border membrane; CVA, crypt-villus axis; F, fraction of enterocytes along the crypt-villus axis; $FABP_m$, fatty acid binding protein in brush border membrane; Hepes, *N*-(2-hydroxyethyl) piperazine-*N*-(2-ethanesulfonic acid); INV, invertase; K_m, Michaelis affinity constant of glucose uptake; LA, linoleic acid (18:2n-6); $SGLT_1$, sodium dependent glucose transporter; TK, thymidine kinase; UWL, unstirred water layer; V_{max}, maximal transport capacity of D-glucose uptake.

distal to the ligament of Trietz was removed. This jejunal segment was gently flushed with 100 mL iced saline and was divided into 20-cm segments. The intestinal mesentery was removed, and the jejunal loops were everted over glass rods. The tissue was kept at 4°C.

The subsequent steps of enterocyte harvesting were begun within 20 min of sacrificing the rabbits. The two ends of each jejunal segment were tied after filling the segment with isolation buffer I (154 mM NaCl, 10 mM NaH_2PO_4, 1.5 mM ethylenediaminetetraacetic acid, 0.5 mM glutathione, 0.1 mM phenylmethylsulfonyl fluoride, pH 7.3). Segments of jejunum were individually suspended in beakers containing 20 mL of citrated buffer solution (96 mM NaCl, 1.5 mM KCl, 8.0 mM KH_2PO_4, 5.6 mM Na_2HPO_4, 27 mM sodium citrate, 0.1 mM phenylmethylsulfonyl fluoride, pH 7.3), and were gently shaken for 15 min in a water bath heated to 37°C. This initial exposure to citrated buffer solution promoted enterocyte dissociation from the underlying lamina buffer. The initial solutions, labeled Fraction 1 (F1), were pooled in 250-mL polypropylene bottles and stored on ice. After 40 min of agitation, the resultant solutions were labeled Fraction 2 (F2) and pooled in a 250-mL polypropylene bottles for further processing. Next, the jejunal segments were transferred to beakers containing 20 mL of isolation buffer, and were agitated for 10 min. Solutions from this step were pooled as Fraction 3 (F3), and the segments were transferred to a fourth series of beakers containing isolation buffer. After 25 min of agitation, incubation solutions were recovered, labeled Fraction 4 (F4) and pooled in cooled 250-mL polypropylene bottles. Intestinal segments were then transferred to a final series of beakers for 10 min of agitation. The resultant solutions were labeled Fraction 5 (F5) and were pooled in a similar fashion as the previous collected fractions. The intestinal segments were then opened longitudinally, and the remaining mucosa was removed by gently scraping with a microscopic slide. Mucosal scrapings were pooled in cooled 250-mL polypropylene bottles containing 160 mL of isolation bugger, labeled as Fraction 6 (F6) and saved for further processing.

In order to produce more distinct populations of enterocytes from along the CVA, enterocytes from F1, F3 and F5 were not utilized in the study of nutrient uptake along the CVA, and therefore BBM vesicles were not prepared from these fractions. However, all six fractions were utilized in histological and enzyme assay studies to validate the technique of enterocyte fractionation along the CVA.

All subsequent steps were carried out at a temperature of 4°C. Each fraction (F2, F4, F6) was treated separately in a similar fashion. Fractions were centrifuged in a Beckman JA-1 rotor (Beckman Instruments, Inc., Palo Alto, CA) at 2,400 × *g* for 5 min. Aliquots were taken from each fraction for protein determination by a modification of the Lowry method using bovine serum albumin (26,27), and for DNA determination by a modification of the Dische reaction of DNA with diphenylamine (28,29). The resultant supernatant was discarded, and the pellets were resuspended in 115 mL of mannitol-Tris buffer (300 mM D-mannitol/10 mM tris-HCl, pH 7.0) in 250-mL polypropylene bottles. Fractions were then homogenized using a Brinkmann Polytron® (Brinkmann Instruments, Westbury, NY) at a setting of "6" for 10 s, and were centrifuged at 600 × *g* in a Beckman JA-14 rotor for 15 min. $CaCl_2$ was added to the supernatants to yield final concentrations of 10 mM $CaCl_2$. The resultant solutions were stirred on ice for 10 min to precipitate subcellular components, and were then centrifuged at 7,800 × *g* for 20 min. The pellets were discarded, and the supernatants were centrifuged at 30,000 × *g* for 20 min. Following this, supernatants were discarded, and the pellets were resuspended in 20 mL of isolation buffer II [300 mM D-mannitol/10 mM *N*-(2-hydroxyethyl)piperazine-*N*-(2-ethanesulfonic acid)(Hepes)-Tris, pH 7.4]. The resultant solutions were homogenized using a Brinkmann Polytron® at a setting of "6" for 15 s, and were then centrifuged at 30,000 × *g* for a final 20 min. The supernatant was discarded, and the pellet was resuspended in 1.0–1.5 mL of Isolation Buffer II. Aliquots of the resultant BBM vesicle-enriched suspension were taken from each fraction for protein determination by a modification of the Lowry method using bovine serum albumin (26,27).

Sections 1 cm in length were taken from jejunal segments at the end of each step in the fractionation process. These specimens were fixed in formaldehyde solution, embedded in paraffin wax, sectioned parallel to the CVA for light microscopy, and stained with hematoxylin and eosin. Photomicrographs were obtained of each specimen to determine villus height in each fraction, as well as the depth of mucosal scraping in F6.

Photomicrographs of histological sections of segments of jejunum demonstrated a progressive decline in the height of villi with each successive fractionation step, with F2 demonstrating removal only of the upper-villus enterocytes and F4 demonstrating removal of the upper-villus and mid-villus enterocytes. Histology of F6 showed virtual absence of villi (data not shown).

Enzyme determinations. Enzyme activity was assayed in both enterocyte homogenates and in the BBM vesicle suspensions. ALP activity was measured by incubating the samples with 2-amino-2-methyl-1-propanol buffer in the presence of $MgCl_2$ at pH 10.25. With the addition of *p*-nitrophenyl phosphate, *p*-nitrophenol was formed as a result of ALP-induced hydrolysis, and the solution changed color. Photometric determination of the resultant color change allowed a quantification of ALP activity in each specimen. INV activity was measured by incubation of the sample with sucrose, with assay by a glucose-specific hexokinase reaction of the glucose formed. Enrichment of enzyme activity in BBM vesicle suspensions as compared to cell homogenates was demonstrated by ratios of 4.1 for INV activity in F2, 6.1 for F4 and 5.1 for F6, and by ratios of ALP activity for 2.6 for F2, 4.0 for F4 and 5.3 for F6.

To indirectly assess thymidine kinase activity, rabbits were injected intravenously with 400 mCi of [^{3}H-*methyl*]thymidine (86 Ci/mmol; Amersham International, Amersham, United Kingdom) in 0.9% NaCl solution, and were sacrificed two hours later. Enterocytes

were isolated from along the CVA, and cell homogenates were prepared from each fraction and transferred to scintillation counting vials (20 mL; Fisher Scientific, Montreal, Quebec, Canada). Scintillation cocktail (Ready-Safe Liquid Scintillation cocktail; Beckman Instruments Inc., Fullerton, CA) was added, and specific activity of [^{3}H-*methyl*]thymidine was determined for each fraction.

Glucose uptake. To determine glucose uptake as a function of incubation time, a solution of 100 mM D-glucose was made up in D-glucose transport buffer (100 mM NaSCN/1 mM $MgCl_2$/2mM $CaCl_2 \cdot 2H_2O$/100 mM D-mannitol/10 mM Hepes-Tris, pH 7.4). D-Glucose in this solution consisted of 1% D-[^{3}H]glucose (4.4 Ci/mmol; Amersham International), which had been dried down under nitrogen in the presence of 99% reagent grade D-glucose. The selected times of incubation were 5, 10, 15, 30 and 45 s and 1, 1.5, 2, 3, 5, 10 and 15 min.

BBM vesicle uptake of glucose was studied at room temperature (20°C). The vesicles had been initially suspended in Na^+-free solution so that a 100 mM inwardly-directed Na^+ gradient was present at the start of the incubation. Incubations of under 1.0 min were carried out by mixing 20 mL of BBM vesicle suspension with 20 mL of D-glucose solution in 17 × 100 mm polystyrene test tubes (Fisher Scientific). For time trials of 1.0 min and longer, incubations of 50 mL of both vesicle suspension and D-glucose solutions were used in similar polystyrene tubes. Reactions were initiated by the mixing of the solutions with a vortex mixer. Uptake was terminated by the use of a stopping buffer (100 mM NaSCN/0.6 mM phlorizin/0.15 M KCl/2 mM Hepes-Tris, pH 7.4). Aliquots of the solution were rapidly filtered through a 0.45-m nitrocellulose filter (Micron Separations, Inc., Westboro, MA) under the vacuum on an Amicon Filtration Manifold VFMI. Filters were prewashed with stopping buffer. The filters were rinsed with 4 mL stopping buffer and were placed in scintillation counting vials. The filters were air-dried for 10 min at 55°C, and 7.0 mL of scintillation cocktail was added to each scintillation vial. Radioactivity associated with the filter was measured using a Beckman LS 9800 liquid scintillation counter (Beckman Instruments, Inc., Irvine, CA).

The value of radioactivity used to calculated uptake for each BBM vesicle sample was the net radioactivity after subtraction of the nonspecific binding of radioactivity to the filter, as determined by measuring the uptake of radioactive substrate by the filter in the absence of vesicle suspension. D-glucose uptake trials were carried out in identical fashion for BBM vesicle suspensions derived from enterocytes isolated from F2 (upper-villus), F4 (mid-villus) and F6 (lower-villus/crypt). Each data point represents the average of four duplicate determinations each tested on a minimum of four rabbits.

The time-course study of D-glucose uptake for each fraction showed an "overshoot" phenomenon, with initial linear rates of uptake to 15 s. Accordingly, a 5-s duration of incubation was considered representative of substrate uptake at "initial rate" and was selected for the subsequent studies of D-glucose uptake by the BBM vesicles at varying D-glucose concentrations. BBM vesicle uptake as a function of D-glucose concentration was studied with D-glucose concentrations varied from 50 to 1000 mM at increments of 50 mM. Studies were carried out in an equivalent fashion for BBM vesicle suspensions derived from each fraction. Each data point of glucose uptake represents an average of six duplicate studies from a minimum of four rabbits.

LA uptake. The uptake of LA, 18:2n-6 by jejunal BBM vesicle was studied in a similar fashion as D-glucose uptake: 100 mM LA solutions were suspended in lipid transport buffer (1 mM $MgCl_2$/2 mM $CaCl_2 \cdot 2H_2O$/100 mM D-mannitol/10 mM Hepes-Tris/2 mM taurocholic acid, pH 7.4). LA in this solution consisted of 20% [^{14}C]LA (55.6 mCi/mmol; Amersham International) and 80% reagent grade LA (Sigma Chemical, St. Louis, MO). In the preparation of the LA incubation solution, a 600 mM unlabelled LA stock solution was prepared by dissolving the required amount of LA in 25 mL chloroform. Aliquots were pipetted into tubes, dried under nitrogen and stored at -80°C. On the day of the experimentation, the appropriate amount of unlabelled LA was reconstituted in chloroform with the addition of the required amount of radiolabelled LA. The labeled and unlabelled LA were then dried down under nitrogen and reconstituted in lipid transport buffer.

Studies on BBM vesicle uptake of LA were carried out for 5, 10, 15, 30 and 45 s, and for 1, 1.5, 2, 3, 5, 10 and 15 min. Uptake was arrested using stopping buffer (0.2 mM phloretin/0.15 M KCl/2 mM Hepes-Tris, pH 7.4). To prevent the filters from binding LA, the filters were prewashed with 2.0 mL of cold wash solution (2 mM TC/500 mM LA/0.15 M KCl/2 mM Hepes-Tris). Otherwise, similar filters were used, as described above, for the studies of D-glucose uptake. To determine LA uptake as a function of concentration, as incubation time of 5 s was chosen. LA concentrations of 25–200 mM were used. Each data point of LA uptake represents the average of six duplicate studies from a minimum of four rabbits.

Expression of results and statistical analysis. Since the effective resistance of the intestinal unstirred water layer (UWL) is negligible for isolated cells or BBM vesicle (30), the value of the apparent Michaelis affinity constant was taken as the value of the true constant, K_m. Glucose uptake kinetics were determined by nonlinear regression analysis (Michaelis-Menten) using the Enzfitter® software package (Biosoft; Elsevier-Biosoft, Cambridge, United Kingdom), and using the Systat (SYSTAT Inc., Evanston, IL) program for best-fit curves. The analysis was performed by fitting the observed data points to the Michaelis-Menten equations. As the variance increased with the size of the variable Y (rate of uptake of glucose), data points were weighted in proportion to the reciprocal of the within-concentration estimates of variance. Nonlinear regression analysis was estimated for each treatment. The iterative analysis employed sought to minimize the residual sum of squares between the observed and predicted values. Convergence occurred with 20 iterations using the nonlinear regression modules of Systat. The values of V_{max} and K_m were also assessed by linear regression analysis of the Lineweaver-Burke plot (inverse of glucose uptake *vs.* in-

verse of glucose concentration), and the Eadie-Hofstee plot (glucose uptake *vs.* uptake/glucose concentration).

All values given in the table and figures represent the mean ± standard error. Analysis of variance analysis and Student Newman-Keul's test were used to search for differences between means, with 0.05 taken as the upper limit of significance.

BBM vesicle uptake data are usually normalized to unit protein. When using protein as the denominator, it is assumed that the proportion of glucose carrier to total membrane protein remains constant along the CVA. Morphological data suggests that the number of glucose carriers per unit membrane surface area remains constant from crypt to villus tip (2), but it is unknown whether this is the case for the membrane fatty acid binding protein that is thought to play a role in the uptake of fatty acids, particularly at low concentrations (31). In addition, the BBM surface are becomes amplified as the enterocytes migrate up the CVA (2), so that the appearance of greater uptake of nutrients from the upper rather than the lower portion of the CVA may not necessarily be from a greater true V_{max} of individual glucose carriers per unit BBM surface area from upper-villus cells, but instead may be due to a greater total surface area. For this reason, it may be necessary to use other denominators of uptake. In the time-course studies of D-glucose uptake, the equilibrium values of glucose uptake were lower in F2 than in F6 (Fig. 1); longer periods of incubation confirmed the differences in equilibrium uptake rates of glucose (data not shown). We

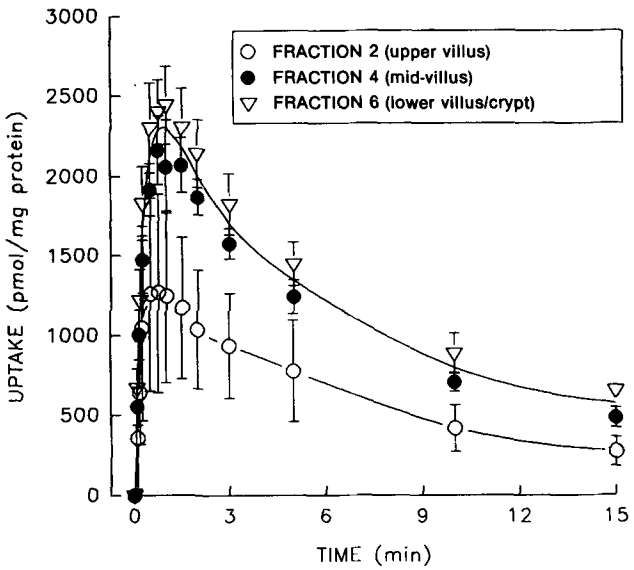

FIG. 1. Uptake of 100 μM D-glucose by brush border membrane (BBM) vesicles, isolated from along the crypt-villus axis, during varying incubation times. BBM vesicles were suspended in 300 mM D-mannitol/10 mM Hepes-Tris, pH 7.4, and uptake of 100 μM D-glucose suspended in 100 mM NaSCN/1 mM $MgCl_2$/2 mM CaCl2 · $2H_2$/100 mM D-mannitol/10 mM Hepes-Tris, pH 7.4, was assayed at 25°C. BBM vesicle uptake of substrate was stopped by the addition of 100 mM NaSCN/0.6 mM phlorizin/0.15 M KCl/2 mM Hepes-Tris, pH 7.4; mean ± SEM.

wished to use a second method of expressing the uptake data on the basis of rate of uptake per glucose carrier or per unit microvillus membrane, but we did not have available to us the molecular biological methods to measure the sodium-dependent glucose transporter ($SGLT_1$), the membrane fatty acid binding protein ($FABP_m$), or the microvillus surface area. We chose to use the equilibrium values for glucose uptake to determine intravesicular volume, and then to calculate the minimum surface area of the BBM vesicles obtained from F2, F4 and F5. We recognize that this approach assumes that the average size of BBM vesicles is similar from F2, F4 and F6. Accepting the limitations of this approach, in some studies glucose and LA uptake were expressed as pmol · unit BBM vesicle surface $area^{-1} \cdot 5\ s^{-1}$, and nmol · unit BBM vesicle surface area · $5\ s^{-1}$, respectively. At equilibrium, the concentrations of D-glucose in the intravesicular space is equal to the D-glucose concentration in the external solution. Since the intravesicular space is substantially smaller than the extravesicular space, the concentration of D-glucose on both sides of the vesicle wall following equilibrium will not be significantly less than the concentration of D-glucose in the external solution at the beginning of the time trial. Thus, at equilibrium, the concentration of D-glucose in the intravesicular space will be very close to this value. The uptake of D-glucose by the vesicular solution at equilibrium was: F2, 275 pmol/mg protein; F4, 487 pmol/mg protein; and F6, 655 pmol/mg protein. Analysis of uptake at equilibrium demonstrated statistically significant differences ($P < 0.05$) between F4 and F6 and between F2 and F6. The calculated intravesicular volumes of the vesicles in F2 is 2.75 mL/mg protein, while that of F4 is 4.87 mL/mg protein and that of F6 is 6.55 mL/mg protein.

The value of the equilibrium uptake has been previously used as a denominator for expression of vesicle uptake. Vinay *et al.* (32) studied lactate transport in basolateral membrane vesicles isolated from both outer medulla and from thick ascending limb segments isolated from the dog kidney. They expressed uptake as a percentage of equilibrium uptake value. We chose to use the values for equilibrium uptake to calculated the surface area of the BBM vesicle, and to express glucose and LA uptake on this basis.

As BBM vesicle form spheres in solution, the total volume of the BBM vesicles can be expressed by the formula $4.3 \cdot \pi R^3$, where R equals the radius of the sphere. The calculated values of R are therefore: F2 0.869 μm, F4 1.052 μm and F6 1.161 μm. The minimum surface area of the BBM vesicle sphere is expressed by the formula $4 \cdot \pi R^2$. The calculated surface area of the BBM vesicle is: F2 9.49 μm^2/mg protein, F4 13.89 μm^2/mg protein and F6 16.93 μm^2/mg protein. The ratios of the surface areas of the BBM vesicles, with the surface area of F2 vesicles assuming the value of 1.0, would be: F2 1.0, F4 1.46 and F6 1.78. Thus, for every unit of surface area in F2 that contains one until of protein, F4 contains 0.68 units and F6 contains 0.56 units. Therefore, the uptake of glucose at initial rate was expressed as pmol · mg $protein^{-1} \cdot s^{-1}$ and pmol · unit BBM surface $area^{-1} \cdot s^{-1}$, and the uptake of LA at initial rate was expressed as

$nmol^{-1} \cdot mg\ protein^{-1} \cdot 5\ s^{-1}$, and nmol · unit BBM vesicle surface area · $5\ s^{-1}$.

RESULTS

Validation of techniques. Numerous methods have been reported in the literature to express the activities of ALP, INV or thymidine kinase (TK). So that our results could be compared to those of others, we chose to express the activities of ALP, INV and TK in several ways. In order to determine the validity of expressing enzyme activity results in terms of the protein or DNA contents of the enterocyte suspensions, the relationship between protein and DNA content of the enterocyte suspensions along the CVA was assessed. The amount of DNA present per cell remains constant as the cell matures along the CVA, but cellular morphology changes along the CVA. Thus, it might be anticipated that the protein content of the enterocyte would also vary along the CVA, with resultant changes in the ratio protein/DNA in each cellular fraction. The lowest ratio of protein/DNA was in F1, highest in F3 and declining in F4–6 (Fig. 2). For this reason, the enzyme activities in the different fractions were expressed on the basis of mg protein as well as mg DNA.

The cumulative amount of protein and DNA obtained from along the CVA in the six fractions was determined, and the percentage of protein or DNA in each fraction relative to the total amount obtained was calculated. The relative position of each fraction on a continuum of protein and DNA content along the CVA could then be determined. The cumulative activity of each enzyme in all six fractions was calculated, and the percentage of total enzyme activity in each fraction was determined. Enzyme activity could thus be analyzed in several ways and expressed in each fraction relative to the protein or DNA content of that fraction, or as percentages of the total amount of enzyme, protein and DNA harvested. Initially collected fractions represented early percentages, with subsequent fractions being added to previous fractions. F2 represented the point at which 6 to 18% of the total protein and DNA had been collected, while F4 was located at the point at which 30 to 45% of protein and DNA had been collected. F6 represented the point at which 100% of protein and DNA had been collected.

ALP activity was lower in enterocyte fractions enriched in mid-villus and lower-villus/crypt cells, as compared to fractions enriched in upper-villus cells (Fig. 3); this was observed regardless of whether ALP activity was expressed relative to the protein or DNA content of the sample, or was expressed as a percentage of the total protein or DNA of the six fractions (F1–F6). INV activity was highest in F1 when expressed as INV/mg protein in the six fractions, or as a percentage of the total pro-

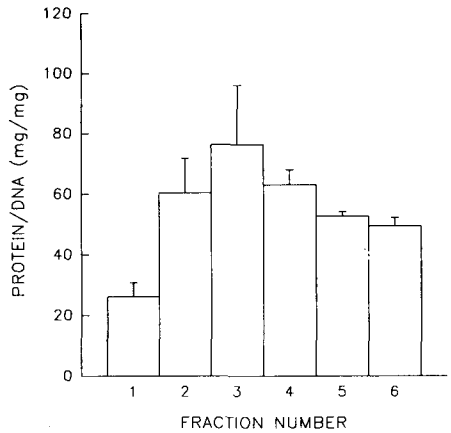

FIG. 2. Ratio of protein content *vs.* DNA content in each fraction along the crypt-villus axis.

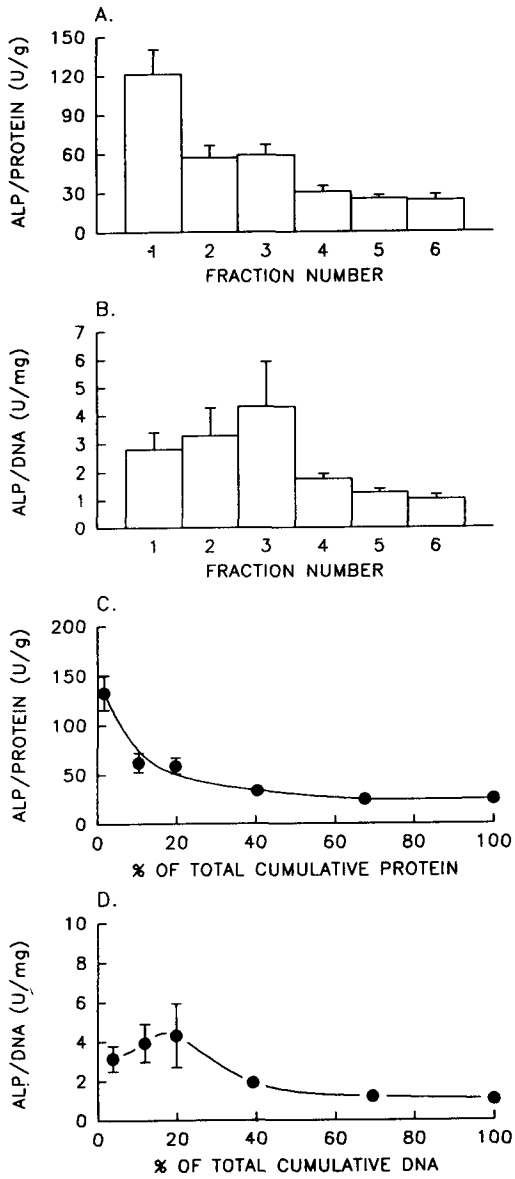

FIG. 3. Specific activity of alkaline phosphatase (ALP) in each enterocyte fraction along the crypt-villus axis. ALP activity in each enterocyte fraction (F1–F6) is expressed per gram protein (A) or milligram DNA (B), or per gram protein *vs.* a percentage of total cumulative protein (C), or per milligram DNA *vs.* a percentage of total cumulative DNA (D); mean ± SEM.

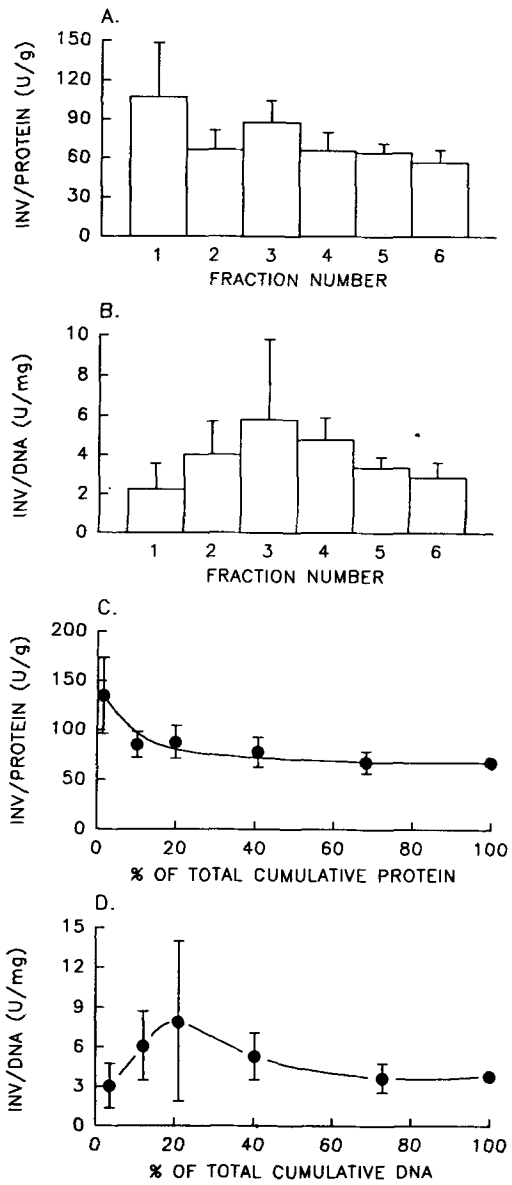

FIG. 4. Specific activity of invertase (INV) in each enterocyte fraction along the crypt-villus axis. INV activity in each enterocyte fraction (F1–F6) is expressed per gram protein (A) or milligram DNA (B), or per gram protein *vs.* a percentage of total cumulative protein (C), or per milligram DNA *vs.* a percentage of total cumulative DNA (D); mean ± SEM.

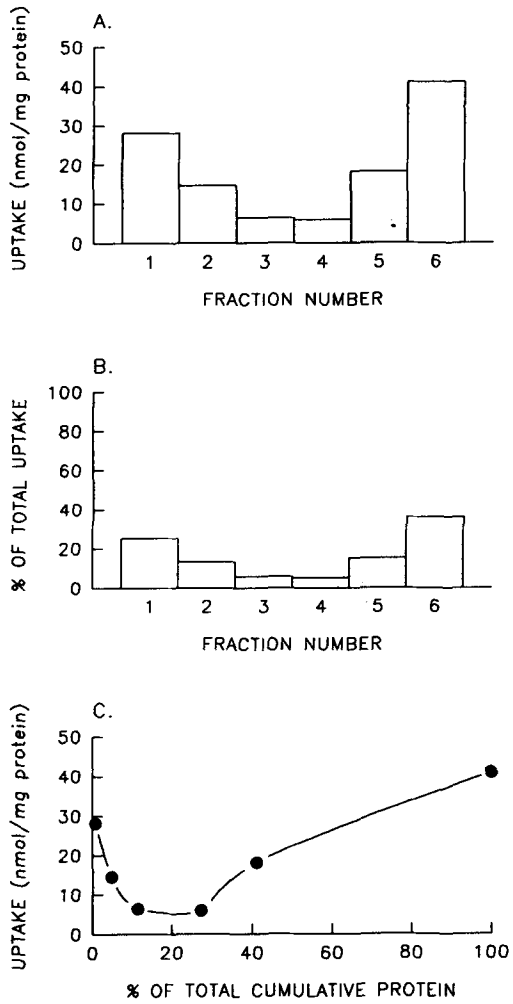

FIG. 5. [^{3}H-*methyl*]thymidine uptake in each enterocyte fraction along the crypt-villus axis. The *in vivo* [^{3}H-*methyl*]thymidine uptake in each enterocyte fraction (F1–F6) is expressed as nmol/mg protein (A), percentage of total uptake (B) or as nmol/mg protein *vs.* percentage of total cumulative protein (C); mean ± SEM.

tein or DNA, and was highest in F3 when expressed as INV/mg DNA (Fig. 4). The uptake of [^{3}H–*methyl*]thymidine was highest in F6 when uptake was expressed as dpm/mg protein or percentage of total uptake in the six fractions. or as dpm/mg protein *vs.* percentage of total protein (Fig. 5).

D-Glucose. The Na^+ dependent uptake of 100 mM D-glucose into BBM vesicles isolated from F2, F4 and F6 showed a time-course "overshoot" with initial rates of uptake being linear up to 15 (Fig. 1). Peak glucose uptake was almost twice as high in fractions enriched in mid-villus and crypt enterocytes (F4 and F6) as compared with the fraction enriched in upper-villus enterocytes (F2). And equilibrium state was achieved within 15 min of onset of incubation of BBM vesicle in D-glucose.

Varying D-glucose concentrations from 50 to 1000 mM and using an incubation of 5 s demonstrated a curvilinear relationship between D-glucose concentration and uptake. The uptake of glucose was similar in all fractions, up to a glucose concentration of 400 mM. At higher concentrations, uptake of glucose was lower in F2 than in F4 or F6. The absolute values of the K_m and V_{max} varied depending upon the method used to estimate the kinetic constants (Table 1, Panel A).

The value of the V_{max} was F2 < F6 < F4 using Systat, Enzfitter with proportional and proportional plus robust weighting, Sigmaplot and Eadie Hofstee plot; the relative ratios were F6 < F2 < F4 for Lineweaver-Burke plot and Enzfitter with simple weighting. When the value of V_{max} was expressed on the basis of the estimated BBM

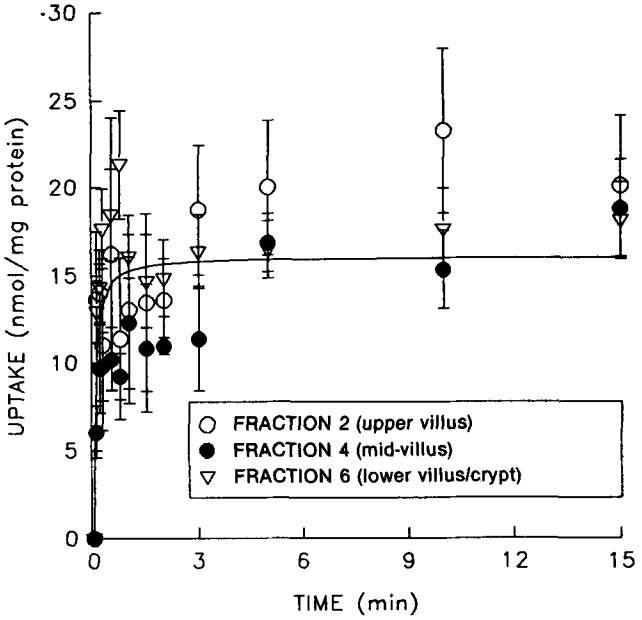

FIG. 6. Time-course of uptake of 100 μM linoleic acid (LA) by brush border membrane (BBM) vesicles isolated from along the crypt-villus axis, with incubation times between 5 s and 15 min. BBM vesicles were suspended in 300 mM D-mannitol/10 mM Hepes-Tris, pH 7.4, an uptake of 100 μM LA suspended in 100 μM LA, 1 mM $MgCl_2$/2mM $CaCl_2 \cdot 2H_2O$/100 mM D-mannitol/10 mM Hepes-Tris/2mM taurocholic acid, pH 7.4, was assayed at 25°C. BBM vesicle uptake of substrate was stopped by the addition of 0.2 mM phloretin/0.15 M KCl/2 mM Hepes-Tris, pH 7.4; mean ± SEM.

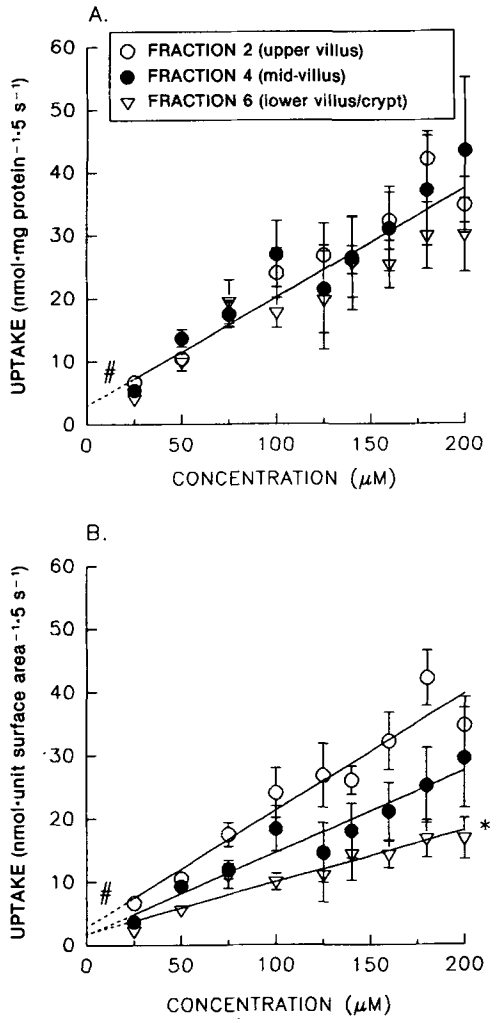

FIG. 7. Effect of varying concentration of linoleic acid (LA) on its uptake by brush border membrane (BBM) vesicles isolated from along the crypt-villus axis as initial rate (5 s). BBM vesicles were suspended in 300 mM D-mannitol 10 mM Hepes-Tris, pH 7.4, and incubated with 25 to 200 μM LA suspended in 1 mM $MgCl_2$/2mM $CaCl_2 \cdot H_2O$/100 mM D-mannitol/10 mM Hepes-Tris/2 mM taurocholic acid, pH 7.4. LA uptake by BBM vesicle suspensions was stopped after 5 s of incubation by the addition of 0.2 mM phloretin/0.15 M KCl/2 mM Hepes-Tris, pH 7.4. Uptake is expressed as nmol · mg protein^{-1} · 5 s^{-1} (A), or as nmol · unit surface area^{-1} · s^{-1} (B), mean ± SEM.

vesicle minimum surface area, the highest values were for the mid-villus (Table 1, Panel B). In all methods of analysis, the value of the K_m was lowest in F2, but the relative values of K_m in F4 and F6 varied between the method of estimation of the kinetic constants.

LA. No overshoot was noted for the rate of uptake of 100 mM LA in F2, F4 and F6, with a plateau of the rate of uptake occurring beyond 5 min of incubation (Fig. 6). With a 5-s incubation and solubilization of LA in 2 mM taurocholic acid, a linear relationship was noted between LA concentration and uptake (nmol/mg protein/5 s) in F2, F4 and F6 (Fig. 1A). The slope of the linear relationship between LA concentration (25–200 mM) and uptake represents the passive permeability coefficient of the BBM. This value was similar for the three fractions and was 0.172 nmol · 5 s^{-1} · mg $protein^{-1}$ · mM^{-1}. The vertical intercept was greater than zero ($P < 0.05$). When LA uptake was expressed on the basis of the calculated BBM vesicle surface area, the passive permeability coefficient was higher for F2 than for F4, and for F4 than for F6 (Fig. 7B), with values of 0.185, 0.130 and 0.079 nmol · 5 s^{-1} · unit surface $area^{-1}$ · mM^{-1} for F2, F4 and F6, respectively. Although the relationship between BBM vesicle LA uptake and concentration was linear, the vertical intercept for each fraction was significantly ($P < 0.05$) greater than zero.

DISCUSSION

Isolation method. Enterocytes can be isolated sequentially from along the CVA, and their origin can be established by determining their profile of enzyme activities (3–10,12,13,33). Cells in the intestinal crypt are rich in enzymes involved in protein synthesis, whereas in the mid- and upper-villus, the major cell functions include the digestion, absorption and metabolism of luminal nutrients. Thus, enterocytes in these fractions of the CVA are rich in enzymes such as ALP and INV, and have decreasing amounts of TK and therefore incorporate less [^{3}H-*methyl*]thymidine (Fig. 5). These findings are simi-

lar to those described by others. For example, using a technique that involved assaying enzyme activity in segments of intestinal wall sectioned horizontally from along the CVA in adult Wistar rats, Nördstrom *et al.* (11) demonstrated highest values for ALP from the upper quarter of the villus, with values declining toward the base. INV was also low closer to the villus base, but persisted over a greater length of the villus. Sundaram *et al.* (12) reported ALP as a percentage of the values in the villus tip component. This was the highest value, and the activity of INV declined moving from the villus tip to the base. Freeman *et al.* (5) also found the highest ALP to be in the villus tip fraction, with values declining progressively toward the mid-portion of the villus, with little further change between that point and the base of the villus. ALP and INV activities were expressed as mmol · min^{-1} · mg $protein^{-1}$, and were plotted against the percent of isolated cells. There was a progressive and similar decline in activity moving from the initial 20% to the final 100% of isolated cells. Morrill *et al.* (10) plotted sucrase/isomaltase activity relative to protein or DNA content, as well as plotting enzyme activity *vs.* the percentage of total protein or the percentage of total DNA. They found that the highest values appeared in the mid-portion of the CVA when expressed as units/mg protein *vs.* percentage of total protein, whereas sucrase/isomaltase activity was highest in the villus tip when expressed as units/mg DNA or *vs.* percentage of total DNA. This was presumably because the ratio of protein/DNA declined from the villus tip to the crypt. We confirm this finding (Fig. 4). Hartman *et al.* (6) expressed sucrase activity as units/gram protein and determined that the highest activity was in the mid-villus fraction, with lower values at the villus tip and lower-villus/crypt. Dudeja *et al.* (3) demonstrated highest values of sucrase when expressed on the basis of protein, in villus tip cells as compared with low values in lower-villus and intermediate values in the mid-villus. Thus, the pattern of distribution of ALP and INV activity varies from method to method, and with the manner

used to express the results, but activities are generally higher in the upper than in the lower portion of the villus (Figs. 3 and 4).

Regardless of the method of expression of TK used in previous studies (3,5,9), greater than 60% of activity appears in the lower-villus fraction. In our study, the highest uptake of [^{3}H-*methyl*]thymidine was found in the basal portion of the villus (Fig. 5). Thus, F2 represents the upper portion of the villus while F6 represents the basal portion of the villus and the crypt cells, and F4 represents the mid-portion of the villus. It is critical to note, however, that the pattern of change reported in our study and those reported by others depend upon the method used to express the result. It is likely that our upper-, mid- and lower-villus fractions may have been different from those reported by other authors.

Glucose uptake. Glucose entry into enterocytes occurs as the result of Na^+ dependent coupling to a cotransporter in the BBM (3,5,9,21,22). In this study, glucose transport in the presence of an inwardly-directed Na^+ gradient ($NaSCN_{out}$ = 100 mM; $NaSCN_{in}$ = 0) at a D-glucose concentration of 100 mM demonstrated the expected time-course "overshoot" phenomenon in BBM vesicle derived from all three fractions (Fig. 1). Incubation of BBM vesicle with glucose in concentrations between 50 and 1000 mM demonstrated saturation kinetics (Table 1). Although the intestinal $SGLT_1$ has been isolated and cloned (34–38), the kinetic characterization of intestinal glucose transport remains focused on the estimation of the values of the V_{max}, the K_m and the passive permeability coefficient. Theoretical and experimental considerations have demonstrated the importance of correction for the intestinal UWL resistance (39). Using isolated BBM vesicles minimizes the contribution of passive permeation and the effective resistance of the UWL (30), but there remains considerable variability in the magnitude of the estimates of V_{max} and K_m, dependent on the methods used to estimate them (30).

Linear transformations on the Michaelis-Menten equation may not always produce valid estimates of V_{max} and K_m, particularly in the presence of an UWL and when the magnitude of the passive component is not taken into account (40–43). The nonlinear methods of estimating V_{max} or K_m does not change, or may obscure the demonstration of differences where such differences do, in fact, exist. In addition, differences may result from the use of parametric *vs.* nonparametric methods to estimate the magnitude of V_{max} and K_m (45,46). Furthermore, the lack of consensus for the optimal method of estimating these kinetic constants results in difficulty comparing experimental results obtained in one laboratory using one method with those obtained in another laboratory using a second method. Accordingly, we chose to analyze the kinetic data for glucose uptake, V_{max} and K_m, with several methods of analysis.

Utilizing BBM vesicles harvested from along the CVA using fractionation techniques, other investigators have established that a gradient of glucose uptake exists along the CVA of the proximal small intestine. Meddings *et al.* (9) demonstrated in fasted young male New Zealand white rabbits that the highest rates of transport of glucose occurred in BBM vesicles isolated from upper- and mid-villus cells. These fractions are approximately comparable to our F2 and F4. They recorded a K_m for glucose uptake by BBM vesicle obtained from enterocytes isolated from the lower-villus/crypt, F6 (Table 1). Also, Meddings *et al.* (9) used the Systat program to obtain estimates of V_{max} that were highest in cells from the upper-villus, intermediate in cells from the mid-villus and lowest from the lower-villus (47.8, 40.0 and 7.7 nmol · mg protein^{-1} · min^{-1}, respectively). These findings have been supported by autoradiography in *in vivo* glucose studies by Kinter and Wilson (18) and Fedorak *et al.* (47), which demonstrated that most glucose uptake occurred in the enterocytes of the upper-villus.

Dudeja *et al.* (3) used the Lineweaver-Burke method to estimate the value of V_{max} and K_m. They demonstrated, in fasted adult male Lewis rats, a K_m for D-glucose transport of 121 mM for BBM vesicles derived from the villus tip cells, a value of 164 mM for BBM vesicles derived from the mid-villus level and 44 mM for BBM vesicles derived from crypt cells. Values for V_{max} of 904, 1296 and 498 pmol · mg protein^{-1} · min^{-1} from higher *vs.* lower portions of the villus, and K_m values of 482 and 14 mM from the same positions along the CVA. Thus, in these three studies using male rabbit and rat BBM vesicle, V_{max} and K_m were highest in upper- and mid-villus enterocytes, when uptake was expressed on the basis of mg protein and when different methods were used to estimate the values of V_{max} and K_m. This was opposite to the gradient described in this study when our data were expressed as pmol · mg protein^{-1} · 5 s^{-1} (Table 1).

In the present study with each of the methods used to estimate the value of V_{max}, the lowest value was obtained in F2. Similarly, the value for K_m was lowest in F2 for each method of analysis. The relative ratio of the V_{max} or K_m between F2, F4 and F6 varied depending upon the method of analysis. For example, for V_{max} the relative values were F2 < F6 < F4 using Systat, Enzfitter with proportional and proportional plus robust weighting, Sigmaplot and Eadie-Hofstee plot. By contrast, the relative ratios were F6 < F2 < F4 for Lineweaver-Burke plot and Enzfitter with simple weighting. Differences were also noted in the relative values of the K_m depending upon the method used for these estimations. The K_m values were F2 < F6 < F4 with Systat, Enzfitter simple and proportional weighting groups as well as the Eadie-Hofstee and Lineweaver-Burke plots. In contrast, the ratio was F2 < F4 < F6 for Systat, Sigmaplot and Enzfitter proportional and robust analyses. Thus, since it is not possible to determine which of these is the "correct" value for estimation of V_{max} and K_m, it is suggested that Systat and at least one other program be utilized. Regardless of which methods of kinetic analysis were used, the values of the V_{max} and K_m were either lowest in F2 as compared with F4 and F6, or the value of V_{max} was unchanged and the value of the K_m more than doubled between F2 and F6. Thus, different methods of kinetic analysis are unlikely to have been the explanation for our inability to confirm

the qualitative nature of the previously-reported gradient of kinetic constants for glucose uptake along the CVA of the jejunum.

These differences in the relative values of V_{max} and K_m between the villus fractions may have been due to a different population of enterocytes harvested from along the CVA. For example, intestinal scraping to obtain crypt cells was not employed in the studies of Dudeja *et al.* (3) or Freeman *et al.* (5). Our upper-villus fraction used to determine glucose uptake (F2) may have had different transport properties than the very most distal cells sometimes used by others. Other differences between these and out studies included the age or gender of the animals used, and variations in their recent intake of food. In this study, mature female rabbits were used with weights in the range of 1.6 to 2.2 kg, as compared to younger male rabbits with a weight range of 0.5 to 0.75 kg used in the studies of Meddings *et al.* (9). In a male Wistar rat model, Na^+-dependent D-glucose transport varied with age, with young animals having a greater capacity for Na^+-dependent D-glucose transport (48). The male rats studied by Dudeja *et al.* (3) were fasted for 18 h prior to sacrifice. Rabbits studied by Meddings *et al.* (9) underwent overnight fasts before being sacrificed. Rabbits used in this study were allowed *ad libitum* access to food and water up until time of sacrifice. Prior experiments have demonstrated that changes occur in the BBM as a result of malnutrition that may influence transport characteristics (49,50). It is unknown whether simple fasting overnight without previous protein–energy malnutrition or dietary carbohydrate changes alters the relative values of V_{max} and K_m for glucose uptake along the CVA. It is also unknown what effect gender differences might have on the expression of sugar or lipid transport along the CVA.

The mechanism of these changes in glucose uptake kinetics along the CVA is unclear. Meddings *et al.* (9) postulated that glucose transport is influenced by BBM fluidity: these workers noted that V_{max} is higher across the rigid BBM of the mid- and upper-villus enterocytes, as compared to the more fluid BBM of the crypt cells. Dudeja *et al.* (3) did not demonstrate an association between membrane fluidity and glucose uptake: despite being less fluid than their control counterparts, upper-villus BBM vesicles from diabetic rats had similar glucose uptake rates.

Several studies have postulated that more than one D-glucose carrier is present in the BBM. Harig *et al.* (21) using BBM vesicles prepared from human jejunum and ileum, detected a single high-affinity, low-capacity transporter along the entire small intestine, plus a second low-affinity, high-capacity carrier limited to the proximal jejunum. Kaunitz and Wright (22), using bovine and rabbit small intestine preparations, similarly demonstrated two Na^+-dependent saturable transporter systems: a high-capacity, low-affinity system and a second system with a lower capacity and higher affinity. Malo (23) was able to identify a low-affinity high-capacity system as well as a high-affinity low-capacity system in studies of human fetal small intestine, but not when using vesicles obtained from human adult tissue donors (45,46). Both Freeman *et al.* (5) and Dudeja *et al.* (3) have postulated that at least two distinct Na^+-dependent D-glucose transporters are present in the BBM along the CVA. This possibility has been raised previously, based on theoretical considerations (51), and the variations in glucose uptake along the CVA may reflect different proportions of the two postulated carriers. each of which has different kinetic properties. However, molecular biological methods have not suggested the presence of multiple intestinal carriers (34), and Enzfitter analysis of nonparametrically-assessed uptake rates in adult animals is compatible with a single glucose carrier (45,46) (Table 1). Thus, variations in the ratio of two postulated hexose carriers would not likely explain the qualitative differences in the values of the V_{max} and K_m reported for different CVA fractions in our study, as compared with findings by other authors.

LA uptake. The intestinal uptake of lipids has been considered to be by a process of passive diffusion (52). The UWL and the BBM represent the major barriers to the movement of lipids into the enterocyte. The UWL has been considered the rate-limiting factor in the mucosal uptake of fatty acids (53). An $FABP_m$ of rat jejunum has been identified, and it has been suggested that the uptake of fatty acids by the BBM may be mediated in part by $FABP_m$ (31). In a study of LA transport by rabbit BBM vesicles, Ling *et al.* (25) demonstrated an overshoot phenomenon of uptake as a function of time. We were unable to confirm the presence of an overshoot either in this study (Fig. 6) or in a previous study using a homogenate of enterocytes obtained from along the entire CVA of mature rabbit Jejunum (24). This in contrast to the pressure of such an overshoot for the uptake of D-glucose (Fig. 1), which suggests the presence of a sodium-dependent uptake step (24). A linear relationship was found between LA concentrations of 25–200 mM and uptake at the initial rate of 5 s. This is consistent with a process of passive uptake, but does not exclude the possibility of the presence or importance of $FABP_m$. This point is particularly relevant because the Y-axis intercept of the relationship between LA concentration and uptake was different from zero (Fig. 7).

Autoradiographic studies with [^{3}H]palmitic acid have demonstrated higher uptake in villus tip enterocytes than in enterocytes found in the crypt (15). It is possible that the *in vivo* uptake of fatty acids varies along the CVA as a result of changes in the effective resistance of the UWL (54). The fluidity of the BBM falls from crypt to villus tip (9), so that these differences in lipid uptake along the CVA cannot be explained by variations in BBM fluidity. There is no gradient of LA uptake in F2, F4 or F6 when expressed as nmol · mg protein^{-1} · 5 s^{-1} (Fig. 7A) but when LA uptake is expressed as nmol · unit surface area^{-1} · 5 s^{-1}, the permeability coefficient was greater for F2 than for F4 or F6 (Fig. 7B). Thus, lipid uptake *in vivo* may be greater in the upper portion of the villus because of variations in the dimension of the UWL, greater membrane surface area of the enterocytes from the upper than from the lower portion of the CVA, greater passive permeability coefficients of BBM isolated from enterocytes near the upper portion of the vil-

lus or differences along the CVA in the contribution of the $FABP_m$.

The intestine is capable of adaptation, with variations in nutrient uptake occurring, with aging (48), dietary lipid changes (55), diabetes mellitus (3,16,47,56), bowel resection (57) or ethanol ingestion (58,59). In rats rendered hyperglycemic by the injection of streptozotocin, glucose uptake in the ileum is increased by "recruitment" of enterocytes from more distal locations along the CVA (47). It remains controversial whether this is the mechanism of increased glucose uptake in the jejunum in diabetes (3,16). It also remains to be established whether altered uptake of lipids in these models of intestinal adaptation results from changes in the passive permeability coefficients of enterocytes on the upper portion of the villus, or from changes in all of the BBM from enterocytes from along the CVA.

ACKNOWLEDGMENTS

The authors wish to express appreciation for financial support from Glaxo Pharmaceuticals (Canada) for a research fellowship for Dr. R.J. Fingerote. The support of the Medical Research Council (Canada) is gratefully acknowledged. We also thank Marilyn Bradshaw for secretarial assistance and S. Burdick, T. Cheng, D. Luethe and M. Tavernini and B. Wirzba for technical assistance. A special acknowledgment is given for the expert technical and statistical assistance of M. Keelan.

The Effect of Dietary Fat Level and Quality on Plasma Lipoprotein Lipids and Plasma Fatty Acids in Normocholesterolemic Subjects

Kerrie Sanders[a], **Leeann Johnson**[a], **Kerin O'Dea**[a] and **Andrew J. Sinclair**[b,*]

[a]School of Nutrition and Public Health, Deakin University, Geelong, 3217, Victoria and [b]Department of Applied Biology and Biotechnology, Royal Melbourne Institute of Technology, Melbourne, 3000, Victoria, Australia

This study examined the effect on the plasma lipids and plasma phospholipid and cholesteryl ester fatty acids of changing from a typical western diet to a very low fat (VLF) vegetarian diet containing one egg/day. The effect of the addition of saturated, monounsaturated or polyunsaturated fat (PUFA) to the VLF diet was also examined. Three groups of 10 subjects (6 women, 4 men) were fed the VLF diet (10% energy as fat) for two weeks, and then in the next two weeks the dietary fat in each group was increased by 10% energy/week using butter, olive oil or safflower oil. The fat replaced dietary carbohydrate. The VLF diet reduced both the low density lipoprotein (LDL)- and high density lipoprotein (HDL)-cholesterol levels; addition of the monounsaturated fats and PUFA increased the HDL-cholesterol levels, whereas butter increased the cholesterol levels in both the LDL- and HDL-fractions. The VLF diet led to significant reductions in the proportion of linoleic acid (18:2ω6) and eicosapentaenoic acid (20:5ω3) and to increases in palmitoleic (16:1), eicosatrienoic (20:3ω6) and arachidonic acids (20:4ω6) in both phospholipids and cholesteryl esters. Addition of butter reversed the changes seen on the VLF diet, with the exception of 16:1, which remained elevated. Addition of olive oil resulted in a significant rise in the proportion of 18:1 and significant decreases in all ω3 PUFA except 22:6 compared with the usual diet. The addition of safflower oil resulted in significant increases in 18:2 and 20:4ω6 and significant decreases in 18:1, 20:5ω3 and 22:5ω3. These results indicate that the reduction of saturated fat content of the diet (<6% dietary energy), either by reducing the total fat content of the diet or by exchanging saturated fat with unsaturated fat, reduced the total plasma cholesterol levels by approximately 12% in normocholesterolemic subjects. Although the VLF vegetarian diet reduced both LDL- and HDL-cholesterol levels, the long-term effects of VLF diets are unlikely to be deleterious since populations which habitually consume these diets have low rates of coronary heart disease. The addition of safflower oil or olive oil to a VLF diet produced favorable changes in the lipoprotein lipid profile compared with the addition of butter. The VLF diets and diets rich in butter, olive oil or safflower oil had different effects on the 20 carbon eicosanoid precursor fatty acids in the plasma. This suggests that advice on plasma lipid lowering should also take into account the effect of the diet on the fatty acid profile of the plasma lipids.
***Lipids 29,* 129–138 (1994).**

It is generally accepted that high plasma cholesterol levels are associated with an increased risk of occlusive vascular disease (1). Since it is possible to manipulate the plasma cholesterol level in most people by dietary means, numerous studies have been conducted examining the effect of different foods and dietary treatments on plasma cholesterol levels. In particular, there has been a focus of research on the relationship between dietary fats and cholesterol on plasma cholesterol levels. The results have led to recommendations to the populations in many western countries to reduce the total fat content of their diets, and particularly the amount of saturated fat. Both monounsaturated fat and polyunsaturated (PUFA) are considered beneficial, although in Australia recent advice on dietary modification has suggested that, where possible, saturated fats should be replaced by monounsaturated fats (2). There is also an increasing awareness of the importance of the two different families of PUFA (ω6 and ω3), and national committees in a number of countries have recommended that the level of the ω3 PUFA in the diet should be increased (2).

Much of the research on reducing plasma lipid levels has focused on the quality (fatty acid type) of the fats and less on the total fat content of the diet. Generally, the recommendations have suggested that the total fat intake should be reduced to about 30% of energy. There is concern about reducing the fat level below this for a number of reasons, including difficulty in achieving compliance to low-fat diets and the adverse effect of low-fat diets on high density lipoprotein (HDL)-cholesterol levels (3).

The purpose of the present investigation was to examine the effect of both the quantity and the quality of the fat on plasma lipid levels and plasma fatty acids. The study was designed so that all subjects started from the same point by eating a very low-fat (VLF) vegetarian diet (<10% energy) containing one egg daily for 2 wk and then increasing the fat content of their diet over a 2-wk period to 30% energy from fat using one of the following three fat sources: butter (saturated fat), olive oil (monounsaturated fat) or safflower oil (polyunsaturated fat).

METHODS

Subjects. Thirty free-living subjects (18 women, 15 premenopausal and 3 postmenopausal, and 12 men) participated in the study. Mean body mass index for the women was 22.4 ± 2.6 kg/m^2 (mean ± SD) and for the men was 24.0 ± 1.6 kg/m^2. The subjects were randomly assigned to three groups of 10 subjects (6 women, 4 men), who were designated to the butter group, the olive oil group or the safflower oil group. In the butter group, the mean age was 35.2 ± 14.6 yr, the mean weight was 67.3 ± 12.1 kg and the mean body mass index 23.1 ± 2.3 kg/m^2. In the olive oil group, the mean age was 35.3 ± 13.7 yr, the mean weight was 68.0 ± 10.8 kg and the mean body mass index 23.2 ± 1.9 kg/m^2. In the safflower oil group, the mean age was 39.3 ± 13.3 yr, the mean weight was 66.0 ± 12.0 kg and the mean body mass index was 22.9 ± 3.0 kg/m^2. There was no

significant difference in age, weight or body mass index among the three groups (analysis of variance).

Design of the study. The protocol was approved by the Ethics Committee of Deakin University (Geelong, Victoria, Australia). All subjects gave their written voluntary consent before participating and were free to withdraw from the study at any stage. The subjects were each provided with digital kitchen scales and asked to weigh and record all food and liquid intake for the full five weeks of the study. The subjects reported to the University on a weekly basis for dietary counseling and supervision. During this appointment, fasting blood samples were taken, the previous week's food diary was collected and checked, and subjects were instructed of any changes to be made to their diet for the coming week. The subjects prepared most of their meals at home and were closely monitored each week through seven-day weighed food records. They were asked to maintain their usual pattern of physical activity. Any sign of illness, medications used and any deviations to the diet were reported weekly to the dietitian. Several subjects who started the diets could not complete the full study and their results were not included; the reasons for failure to complete included personal problems, lack of motivation and inability to maintain weight.

Each study lasted for five weeks with each subject acting as his or her own control using a protocol we have previously devised (4,5). In our experience and that of others, serum lipid levels stabilize within 7–14 d following a dietary change (4–6). Volunteers followed their habitual diet, which was not vegetarian, during the one-week baseline period. In the second and third weeks they consumed a VLF vegetarian diet with the addition of one egg per day. The addition of the egg to the vegetarian diet was to provide a constant cholesterol intake in the low to normal range typically found in the Australian diet. Because of the low energy density and high bulk of the diet, a carbohydrate supplement (a glucose polymer) was provided to maintain energy intake and to prevent weight loss (Polycose®; Ross Laboratories, Columbus, OH). This supplement was adjusted on an individual basis to be equivalent to 20% energy and was provided as two drinks daily. We have previously used this supplement to maintain energy intakes in similar studies on VLF diets (5). In the fourth and fifth weeks, the subjects continued to eat one egg/day; however, the fat content of the diet was increased in a stepwise fashion to 20% energy in week 4 and 30% energy in week 5 by substituting butter, olive oil or safflower oil, for either one-half of the carbohydrate supplement (week 4) or all of it (week 5). This ensured that there were no major changes in the composition of the diet over the weeks 2 to 5, except for substitution of fat for carbohydrate supplement. The average quantities of added fats (butter, olive oil, safflower oil) were 22 and 44 g/d in weeks 4 and 5, respectively.

A research dietitian instructed each subject individually to eat a wide variety of suitable foods to ensure a nutritionally adequate diet and to maximize the palatability of the diet. Allowable foods included skim milk and other nonfat dairy products, grains and cereal products, such as bread and pasta, fruit and vegetables, except soybeans, olives and avocados. Jam, soft drinks and nonfat confectioneries were also allowed. Fats, oils, nuts, meat, fish, chicken and commercial foods with added fat were excluded from the diet. An extensive list of nonfat vegetarian recipes and some preprepared low-fat vegetarian meals were supplied to provide variety and convenience (Spotless Catering; North Geelong, Victoria, Australia).

Dietary composition was calculated using *Microdiet* (Salford University, Surrey, United Kingdom) and SODA (Computer Models, Cottesloe, W.A., Australia) software packages, based on United Kingdom and Australian data, respectively, but with our own data incorporated for cholesterol content of Australian eggs (389 mg/100 g edible egg) (7). Body weights were measured to the nearest 0.1 kg on a weekly basis.

These studies were conducted over a 2-yr period (July 1988–June 1990), and subjects were enrolled into the diet groups in random order to reduce any possible effects of time on the results. In most cases, there were 4–6 subjects on diets at any one time.

Lipoprotein lipid analysis. Cholesterol and triglyceride levels in fasting plasma were measured enzymatically after enzymatic hydrolysis on a centrifugal analyzer (Centrifichem System 500; Interscience Group, Moorabin, Victoria, Australia) using commercially available kits (Cholesterol Monotest; Triglyceride GPO-PAP; Boehringer, Mannheim, Germany). In our laboratory, the normal range for cholesterol concentrations in fasting plasma is 3.5–5.5 mmol/L and for triglycerides 0.5–2.0 mmol/L; quality control samples were routinely analyzed with each batch of samples examined. Very low density lipoproteins (VLDL) were separated by ultracentrifugation of plasma at 436,000 × *g* for 3 h (Beckman TK 100 ultracentrifuge; Beckman Australia, Mt. Waverley, Victoria, Australia). HDL were separated within two hours of blood collection by precipitation with 15% polyethyleneglycol 6000 (BDH Chemicals, Kilsyth, Victoria, Australia). Lipids in low density lipoproteins (LDL) were calculated by difference between whole plasma and the sum of VLDL- plus HDL-cholesterol concentrations (4). Triglyceride concentrations were measured in whole plasma and VLDL fractions only.

Plasma cholesteryl ester (CE) and phospholipid (PL) fatty acid analyses. Lipids were extracted from plasma by standard techniques, and the CE and PL fractions were separated from the other plasma lipids by thin-layer chromatography (8). The methyl esters were formed by saponification followed by transesterification in BF_3 in methanol, and these were separated by capillary gas–liquid chromatography using a 50 m by 0.32 mm i.d. fused silica column CP Sil 88 column (Chrompak, Middelburg, The Netherlands) as described previously (8).

Statistical analyses. The paired *t*-test was used to compare results within groups and a two-sample analysis of variance to compare results between men and women. All results are expressed as mean ± SD; significance was taken as $P < 0.05$. Spearman's rank correlation (r_s) was used to evaluate the relative change in plasma cholesterol among the subjects for the different dietary procedures.

RESULTS

The changes in body weight and dietary composition of the three groups of subjects are shown in Table 1. The carbo-

hydrate supplement ensured that the energy intake remained relatively constant throughout the study period despite major changes to the dietary fat composition imposed by the dietary protocol. The mean body weight did not change significantly in the olive oil group, but in both the other groups there was one time point in the 5 wk when there was a significant decrease in body weight for the group (week 3, butter group and week 4, safflower group).

As planned, the proportion of energy derived from fat in weeks two and three fell to just below 10% during the VLF diet, which was compensated for by an increase in carbohydrate using the carbohydrate supplement. The trend toward increased fiber was significant in each of the three groups at most of the time intervals ($P < 0.05$). In the group fed butter, the dietary cholesterol increased in weeks four ($P < 0.05$) and five ($P < 0.001$), and the percentage of fat energy contributed from saturated fatty acids also increased as expected during this time. In the groups fed olive oil or safflower oil, the dietary cholesterol remained constant throughout weeks two to five, inclusive.

The percentage of energy from fat contributed by PUFA, monounsaturated fatty acids and saturated fatty acids changed as expected in weeks four and five on the addition of the different fats. In the butter group, the proportion of saturated fats was higher in week five than during week one (1.2×), while the percentage of energy derived from PUFA was less than 1/3 of the baseline value. Subjects who supplemented their diet with olive oil during weeks four and five of the study had an increased percentage energy from monounsaturated fatty acids in week five compared with the baseline value (1.4×), while there was a 2/3 drop in the proportion of saturated fatty acids in the same period. In the subjects who supplemented their diet with safflower oil, the percentage energy from PUFA in week five was approximately double that of the subjects' usual diet, the proportion of saturated fatty acids dropped by about 2/3 in week five compared with the usual diet and that from monounsaturated fatty acids fell by about one-half in the same period. The mean dietary P/S ratio at baseline was 0.5 for all 30 subjects compared with 0.7 on the VLF diet, and 0.2, 0.9 and 2.6 after 2 wk on butter, olive oil or safflower oil, respectively.

The changes in cholesterol and triglyceride concentrations in lipoprotein lipids over the 5-wk study period are presented in Table 2. Total cholesterol concentrations fell significantly ($P < 0.01$) within one week of commencing the VLF diet by a mean of 0.53 mM for all 30 subjects. After two weeks on the VLF diet, the mean reduction of total plasma cholesterol was 0.60 mM (12%) for all 30 subjects. The decline in total cholesterol was observed in 28/30 subjects, and the range of responses varied from an increase of 0.9 mM to a decline of 1.9 mM (Fig. 1). After two weeks on the VLF diet, LDL-cholesterol in all 30 subjects fell by a mean of 0.38 mM (11%) ($P < 0.01$), while the HDL-cholesterol concentrations also decreased significantly ($P < 0.001$) by a mean of 0.36 mM (26%). These changes were evident after one week on the VLF diet. Plasma triglyceride and VLDL triglyceride both rose significantly ($P < 0.001$) during the 2 wk on the VLF diet in all three study groups. VLDL-cholesterol concentrations

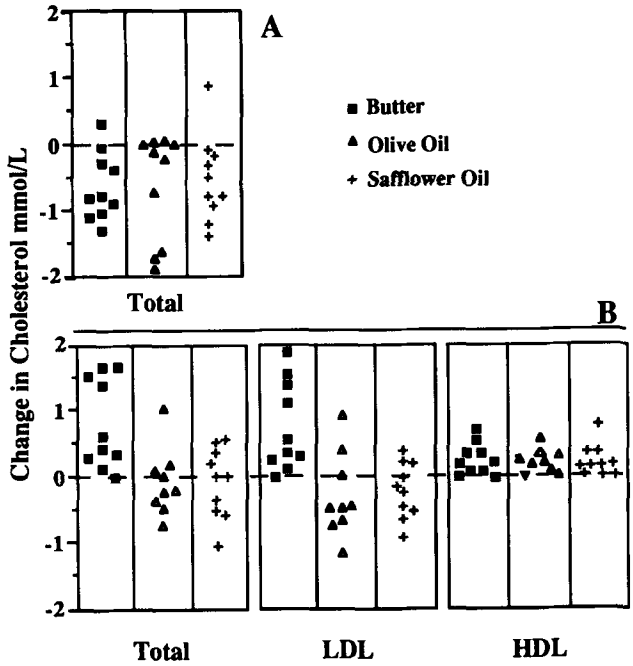

FIG. 1. Changes in plasma total, low density lipoprotein (LDL)- and high density lipoprotein (HDL)-cholesterol levels. A. The difference in total plasma cholesterol between subjects on the usual diet (week 1) and on the very low fat (VLF) diet (week 3) is plotted for each subject. The three columns represent the values for individuals in each of the three diet groups (butter, olive oil and safflower oil). B. The difference in total, LDL- and HDL-cholesterol levels between the VLF diet (week 3) and diets containing butter, olive oil, or safflower oil (week 5) is plotted for each subject. The three columns represent the values for individuals in each of the three diet groups (butter, olive oil and safflower oil).

increased significantly in 2/3 groups on the VLF diet. There was no significant difference between the response of the men and the women to the VLF diet in terms of changes in total plasma cholesterol, LDL-cholesterol or HDL-cholesterol.

In the group supplemented with butter during weeks four and five of the study, the total, LDL- and HDL-cholesterol levels increased significantly each week ($P < 0.01$) compared with the VLF diet (week 3). Total cholesterol had increased by 20% upon the addition of butter for two weeks while LDL- and HDL-cholesterol concentrations increased by 29 and 16%, respectively, during this time. The rise in total and LDL-cholesterol occurred in 9/10 subjects and 7/10 subjects for the HDL-cholesterol (Fig. 1). There was no significant rank correlation for the degree of change in the total plasma cholesterol from the usual diet to the VLF diet compared with the change from the VLF diet to the butter-enriched diet ($r_s = 0.36, P > 0.05$). Values for both total cholesterol and LDL-cholesterol concentrations at the end of week 5 were significantly above the baseline level of this group ($P < 0.05$), which is consistent with the increase in dietary saturated fat and cholesterol in this period. Triglyceride concentrations decreased during weeks 4 and 5 with the addition of butter to the VLF

[a]Mean ± SD; n = 10. Abbreviations: LDL, low density lipoprotein; HDL, high density lipoprotein; VLDL, very low density lipoprotein.

[b–d]Significantly different from week 1; [b]$P < 0.001$; [c]$P < 0.01$; [d]$P < 0.05$.

[f,g]Significantly different from week 3; [f]$P < 0.01$; [g]$P < 0.05$.

diet, but they still remained significantly higher than the baseline value ($P < 0.01$).

In contrast to the group supplemented with butter, total cholesterol concentrations remained significantly lower ($P < 0.05$) than the values on the subjects' usual diet when either olive oil or safflower oil were added to the VLF diet (Table 2), although there were different individual responses to the addition of unsaturated oils ranging from a decrease in total cholesterol of 1.1 mM to an increase of 1.1 mM (Fig. 1). For each of the diets containing the added unsaturated oils, 6/10 subjects showed a decrease in the total cholesterol concentration compared with the value on the VLF diet. There was no significant rank correlation for the degree of change in the total plasma cholesterol from the usual diet to the VLF diet compared with the change from the VLF diet to the olive oil-enriched diet ($r_s = -0.04, P > 0.05$). However, there was significant negative correlation in the safflower oil-fed group ($r_s = -0.66$, $P < 0.05$) (*i.e.*, the subjects showing the greatest decrease in plasma cholesterol on the VLF diet showed the greatest rise on the safflower oil diet). The LDL-cholesterol concentrations in week 5 after the addition of either of the unsaturated oils were significantly lower than the values determined in these subjects on their usual diet ($P < 0.01$), although they were not significantly different from the levels on the VLF diet at week 3 of the study. HDL-cholesterol concentrations were significantly higher in week 5 on addition of either olive oil ($P < 0.01$) or safflower oil ($P < 0.05$) compared with the VLF diet at week 3 of the study, by 23 and 17%, respectively.

The LDL/HDL ratios rose following the change from the usual diet to the VLF diet for the 30 subjects (from 2.9 to 3.4, $P < 0.05$). The ratio remained elevated on the butter diet (ratio = 3.5); however, the ratio fell significantly ($P < 0.05$) on the safflower oil diet to a value of 2.7. The ratio fell in 7/9 subjects on the olive oil diet, but the mean value was not significantly different from the value on the VLF diet. Triglyceride concentrations fell during weeks 4 and 5 with the addition of olive oil or safflower oil. For both these groups this decrease was significant when compared with week 3. The mean triglyceride concentration at week 5 in the olive oil group was less than the week 1 baseline values. VLDL triglyceride concentrations followed a similar trend to total plasma triglycerides.

There were significant changes in the fatty acid composition of the plasma PL in the subjects during the VLF period compared with the usual baseline diet (Table 3). The major changes in all three groups of subjects were significant reductions in the percentage of 18:2ω6 ($P < 0.01$) and 20:5ω3 ($P < 0.05$) and significant rises in 16:1 ($P < 0.05$), 20:3ω6 ($P < 0.01$) and 20:4ω6 ($P < 0.05$). There was a decline in the percent of stearic acid which was significant in 2/3 groups ($P < 0.01$). There were rises in palmitic acid (16:0) and docosahexaenoic acid (22:6ω3), which were significant in 2/3 groups ($P < 0.05$). The inclusion of butter in the diet was associated with a normalization of the plasma PL fatty acid profile with the exception of 16:1 and 20:3ω6, which remained significantly elevated ($P < 0.05$). The addition of olive oil led to a significant increase in oleic acid (18:1ω9) ($P < 0.05$) whereas 18:3ω3, 20:5ω3 and docosapentaenoic acids (22:5ω3) remained significantly lower than on the usual diet ($P < 0.05$). The safflower oil-fed group had increased levels of 20:4ω6 ($P < 0.01$) and 22:6ω3 ($P < 0.05$) compared with the usual diet and significantly decreased levels of 16:0, 18:1, 20:5ω3 and 22:5ω3.

There were significant changes in the fatty acid composition of the plasma CE in the subjects during the VLF period compared with the usual baseline diet (Table 4). The major changes in all subjects were reductions in the percentage of 18:2ω6 ($P < 0.01$) and a rise in the percentages of 16:0 ($P < 0.01$), 16:1 ($P < 0.01$), 18:1ω9 ($P < 0.01$), 20:3ω6 ($P < 0.05$) and 20:4ω6 ($P < 0.05$). The proportion of 20:5ω3 decreased significantly in 2/3 groups ($P < 0.05$). The addition of butter had little effect on the fatty acid composition of the CE fraction compared with the composition on the VLF diet, except for a decrease in the proportion of 20:4ω6. The addition of either olive oil or safflower oil led to a normalization of the 16:0 and 16:1 values and a significant reduction in the proportion of 18:3ω3 ($P < 0.05$) and 20:5ω3 ($P < 0.01$) compared with the usual diet. In the case of olive oil, the level of 18:1ω9 ($P < 0.001$) and 20:3ω6 ($P < 0.05$) remained significantly elevated compared with week 1 (baseline), and the proportion of 18:2ω6 rose but was still significantly below the baseline value ($P < 0.001$). In the safflower oil-fed group, the 18:1ω9 and 20:5ω3 proportions fell below the baseline value ($P < 0.001$) and that of 18:2ω6 rose above the baseline ($P < 0.01$). In the latter two groups, the proportion of 20:4ω6 remained significantly elevated above the baseline value ($P < 0.01$).

DISCUSSION

This study was designed to compare the effect of the total fat content (<10% and up to 30% of energy from fat) and the quality of the fat in subjects consuming one egg per day on plasma cholesterol levels. The results indicate that a reduction in the saturated fat content of the diet (<6% dietary energy) either by reducing the total fat content of the diet (VLF diet) or by exchanging saturated fat with unsaturated fat reduced the total plasma cholesterol levels by approximately 12% in normocholesterolemic subjects. The VLF diet reduced the levels of both plasma LDL- and HDL-cholesterol while the 30% fat diets containing monounsaturated fats or PUFA maintained the low LDL-cholesterol levels and increased HDL-cholesterol levels. The 30% fat diet rich in saturated fat (butter) led to an increase in all cholesterol-containing fractions in the plasma.

The design of this study was chosen in order to compare the effect of major changes in both fat content and fat quality over a short time period. Since the usual diet of the subjects contained 34% energy from fat (range 21–47%), it was felt the design would allow, firstly, a comparison between this medium to high-fat diet and the VLF diet, and secondly, that adding different types of fat back to the VLF diet gave an opportunity to examine the effect of *marked* changes in dietary fat quality. For example, the change in saturated fat in the group fed butter was from 14% on the usual diet, to 4% on the VLF diet, then to 16% of energy during the addition of butter to the diet. This design, therefore, allowed a comparison of a substantial decrease

and then an increase in saturated fat. Other designs, which start from modest to high fat levels, do not allow comparisons of changes in saturated fat of this magnitude. If the butter diet had merely followed the subjects' usual diet, without the intervention of the VLF diet period, the change in saturated fat would only have been from 14% (usual diet) to 16% (butter diet). Because of the variations in the fat intake of the subjects on their usual diet, such a change would have meant a reduction in saturated fat for some subjects and an increase in saturated fat for others, thus leading to potentially different effects on plasma cholesterol levels. Although the dietary periods in the study were only of 1–2 wk duration, others have reported that serum cholesterol levels can reach a steady state within 7–14 d of commencing a new dietary regime (4–6) and maintain these levels over several months (6,9). In confirmation of these observations, the changes in plasma cholesterol in the present study took place rapidly with the greatest changes occurring in the first 7 d on the VLF diet. In contrast, addition of butter at 10% energy for 7 d and then at 20% energy for an additional 7 d was associated with a continuous increase in the plasma cholesterol concentration. We acknowledge that the dietary periods were of a relatively short duration, and we cannot exclude the possibility that the cholesterol levels measured were not in a steady state. The study design chosen involved substantial changes to the level and quality of fat, and in such circumstances we were concerned about poor compliance to these diets if the diet periods had been extended in time.

When subjects were on the VLF diet, there were reductions in both the LDL- and HDL-cholesterol levels as reported by our group and others in previous studies with diets very low in fat (5,8,10,11). It would be expected that both the decrease in saturated fat from 15 to 3% and the increase in fiber from 23 to 35 g/d (12,13) would have contributed to this plasma cholesterol reduction. VLF diets (high-carbohydrate diets) are frequently associated with increased VLDL production and increased plasma triglyceride concentrations (14), as was observed in the groups on the VLF diet. The carbohydrate increased from 48 to 76% of energy in this period. The reduced HDL-cholesterol concentration we observed may have been due, in part, to an exchange of triglyceride and CE between VLDL and HDL, resulting in a relative depletion of cholesterol from the HDL particle (15). Recent work investigating the turnover of apolipoprotein A (transport and catabolic rates), in a group of subjects who consumed both low- and high-fat diets, has suggested that mechanisms which result in the decrease in HDL-cholesterol levels observed in the subjects on the VLF diet differ from those mechanisms which lead to low HDL-cholesterol levels in some individuals on high-fat diets (10). There has been some discussion recently about the HDL-cholesterol lowering effect of low-fat diets with Sacks and Willett (3) arguing that, on balance, there is insufficient evidence to conclude that lowering of HDL-cholesterol by reduction in the total fat intake is innocuous. However, populations which habitually consume low-fat diets have low levels of both LDL- and HDL-cholesterol and also have low rates of coronary heart disease (16).

The effect of increasing the fat content of the diet from below 10 to 30% over the final 2 wk of the study depended on the quality of the fat introduced. The inclusion of butter, which increased the saturated fat and the cholesterol content of the diet, was associated with significant rises in total, LDL- and HDL-cholesterol levels; both the total and LDL values significantly exceeded the prediet values. In contrast, the unsaturated oils did not significantly change the total cholesterol concentration, but there were significant increases in the HDL-cholesterol fraction on both diets ($P < 0.05$), which were partially compensated for by nonsignificant decreases in the LDL-cholesterol values. The main difference between the olive oil and safflower oil diets was that the HDL-cholesterol was not significantly different from pretrial values in the olive oil group, whereas the HDL-cholesterol was still 16% lower than the starting values ($P < 0.01$) in the safflower group. Although it is recognized that dietary linoleic acid at 30–50% energy lowers both LDL- and HDL-cholesterol (17,18), there is evidence that at more realistic intakes (*e.g.*, 10% energy) there are effects only on the LDL-cholesterol concentrations (19,20). However, a more recent long-term study of a comparison between olive oil and sunflower oil, in which the PUFA intake was 12–13% energy, showed that there were significantly higher concentrations of HDL-cholesterol in the subjects on the olive oil diet (21). The present result, at 20% energy safflower oil, indicates a difference between the olive oil and safflower oil groups, but whether this is the result of the high level of linoleic acid, the relatively short term nature of this experiment or the effect of individual responses is not clear.

These results highlight the observations of others who have reported a wide variability in the response of plasma cholesterol concentration to changes in diet between individuals (22–24). Apolipoprotein polymorphism, particularly apoE and apoB phenotypes, may contribute to the variation in responses of individuals to changes in the amounts of dietary fat and cholesterol (25,26). Apoprotein phenotypes were not measured in the present study, and therefore, it is not possible to make generalizations about the subjects' individual variations.

Subjects experienced difficulty in maintaining their weight on the VLF diet, and this result is similar to that of other investigators who have reported low-fat diets to be an effective means of achieving weight reduction even when no limitations are placed on the quantity consumed (27). However, a diet which replaces saturated fat with monounsaturated fats or PUFA rather than carbohydrate is easier to comply with and, therefore, presents a more realistic and achievable goal for public health messages. A moderate-fat diet allows greater scope for variety than a VLF diet, thereby helping to ensure an adequate supply of nutrients. Such a diet may also minimize both the increase in triglycerides and the decrease in HDL-cholesterol accompanying substantial increases in carbohydrate intake.

There were changes in the fatty acid composition of the plasma CE and PL in subjects on the VLF diet which were similar to those reported in our previous studies on VLF diets (4,5,8). These included increases in 16:0 and 16:1 and decreases in the proportion of 18:2ω6. The former in-

creases are presumably the result of increased synthesis of fat from the high carbohydrate diet and the latter decrease maybe due to the very low level of the essential 18:2ω6 in the diet. Additionally, the VLF diet was associated with increases in 20:3ω6, 20:4ω6 and decreases in 20:5ω3 in both lipid fractions and increases in 22:6ω3 in the PL. These latter changes may be due to the fact that all subjects were consuming one egg/day which provided 20:3ω6, 20:4ω6 and 22:6ω3 at levels of 8, 77 and 31 mg per 50 g egg, respectively (7). We have previously reported that VLF vegetarian diets (egg-free) consumed for a similar 2-wk period were associated with decreases in 18:2ω6 and 20:5ω3 only, whereas VLF diets containing low levels of long-chain PUFA, such as 20:4ω6, 20:5ω3 and 22:6ω3 (20–80 mg long-chain PUFA/100 g edible food) derived from either lean meat or fish, were associated with increases in the plasma PL and CE levels of 20:3ω6, 20:4ω6 and 22:6ω3 (8).

The addition of the three dietary fats/oils to the VLF diet resulted in interesting changes in the plasma lipid fatty acid profiles, particularly for the 20 carbon PUFA. The butter diet resulted in a raised 20:3ω6 and 20:5ω3 and decreased 20:4ω6 compared with the VLF diet. In contrast, both the olive and safflower oil diets decreased 20:3ω6 and 20:5ω3 levels and maintained the elevated 20:4ω6 level seen on the VLF diet. The latter two diets also decreased the level of 18:3ω3. Lasserre *et al.* (28) have previously reported similar effects of diet on the 20 carbon PUFA of plasma PL in subjects fed diets rich in milk fat or sunflower oil, respectively, for 5 mon. A possible explanation for these results is based on the known competition between oleic, linoleic and linolenic acids for metabolism *via* the Δ6 desaturase (29). Diets rich in milk fat contain a low level of linoleic acid and a low 18:2ω6:18:3ω3 ratio (about 3:1) which would enhance the formation of 20:5ω3 relative to 20:4ω6 (30). In contrast, the diets rich in olive oil and safflower oil were essentially devoid of 18:3ω3, and thus the high level of 18:1ω9 or the 18:2ω6 would effectively block metabolism of any small quantity of linolenic acid to 20:5ω3 (31).

There is general agreement that the ratio of the ω6 to ω3 PUFA is too high in the current Western diet. It has been postulated that this dietary imbalance leads to a tissue PUFA imbalance and a consequent exaggerated metabolism of 20:4ω6 to eicosanoids (32). On this basis there is concern that diets which raise tissue 20:4ω6 relative to 20:5ω3 might be pro-thrombotic since increased platelet 20:4ω6 could lead to an increased production of thromboxane A_2 with resultant platelet aggregation (33). On the other hand, 20:5ω3 has been shown to effectively reduce production of thromboxane by platelets and to reduce platelet aggregation (34). The present results demonstrate that the VLF diet and the diets containing olive oil or safflower oil increased the 20:4ω6/20:5ω3 ratio in the plasma PL. In addition to these two 20 carbon PUFA, it may also be necessary to consider the plasma levels of 20:3ω6 since this fatty acid is a precursor of prostaglandin E1, which prevents platelet aggregation and thus might be potentially antithrombotic (35). The VLF and the butter diets increased the 20:3ω6 level in the plasma lipids, whereas both oils reduced the level of this PUFA. Although the changes described in the proportion of plasma PL PUFA in this study were quite small, we have preliminary evidence that diets which induce similarly minor changes in C20 PUFA are associated with significant changes in the *in vivo* production of prostacyclin (as measured by gas chromatography/mass spectrometry of the main urinary metabolite; Mann, N.J., and Sinclair, A.J., unpublished data). These data suggest that advice on plasma lipid lowering should also take into account the effect of the diet on the fatty acid profile of the plasma lipids. To establish the biological significance of the present dietary changes in plasma PUFA, it will be necessary to determine the effects on eicosanoid production and platelet aggregation.

ACKNOWLEDGMENTS

This study was supported by a grant from the Egg Industry Research and Development Council of Australia. We would like to thank Kerryn Chisholm, Peta Hanley and Helen Leyden for assistance in the design of the diets, conduct of the dietary trials and collation of results, and Pinder Singh for statistical advice. Unilever Australia Ltd. (EOI Foods Pty. Ltd.) are thanked for the generous provision of the olive oil-based margarine.

Interactions Between Medium-Chain and Long-Chain Triacylglycerols in Lipid and Energy Metabolism in Growing Chicks

Remedios T. Mabayo, Mitsuhiro Furuse*, Atsushi Murai and Jun-ichi Okumura

Laboratory of Animal Nutrition, School of Agriculture, Nagoya University, Nagoya 464-01, Japan

The combined effects of dietary medium-chain triacylglycerols (MCT) and long-chain triacylglycerols (LCT) on lipid and energy utilization in chicks were investigated. Corn oil was used as the LCT source, and trioctanoin (8:0) was used as the MCT source. The efficiency of dietary energy utilization (such as metabolizable energy values and fat and energy retention) decreased linearly as the level of MCT increased, but the efficiency of dietary protein utilization (protein retained per protein consumed) was not affected in a consistent manner. Fecal saturated and monounsaturated fatty acid composition was dependent on the dietary fatty acid composition, whereas fecal linoleic acid content was not. It is concluded that dietary MCT and LCT influence each other to some degree, with respect to protein and lipid metabolism in chicks. Moreover, in most cases, the nutritional characteristics of each triacylglycerol, including food efficiency and fat and energy retention, are independent of each other in growing chicks.

***Lipids* 29, 139–144 (1994).**

In chicks, a high level of long-chain triacylglycerols (LCT) in the diet was shown to increase the efficiency of energy utilization, but the LCT diet has a tendency to cause fat deposition in the body compared to medium-chain triacylglycerols (MCT) diet. However, the efficiency of protein utilization is improved by dietary MCT (1). Metabolizable energy (ME) (1) and net energy (NE) (2) values for MCT are lower than those for LCT. The metabolism of MCT is carnitine-independent and does not require chylomicron formation. MCT are easily oxidized and utilized as fuel, and have little tendency to deposit as fat (3). On the other hand, dietary LCT alleviate essential fatty acid deficiency (4). High-fat diets increase peroxisomal ß-oxidation activity in rats (5), but the contribution of peroxisomal ß-oxidation to total hepatocellular long-chain fatty acid (LCFA) oxidation depends on both the concentration and the chain length of the fatty acids involved (for a review, see Ref. 6). Thus, dietary MCT have both advantages and disadvantages as a dietary fat source. In order to take full advantage of the nutritional characteristics of both MCT and LCT, further insights must be gained.

It has been demonstrated that dietary MCT and LCT mutually affect each other. For instance, when MCT were administered together with LCT, oxidation was slowed down (7), and release of medium-chain fatty acids (MCFA) into the bloodstream was delayed (8). When LCT and MCT were ingested simultaneously, the energy absorbed was greater than that when either one of the fats was ingested alone (9).

*To whom correspondence should be addressed.

Abbreviations: CCK: cholecystokinin; LCFA, long-chain fatty acid(s); LCT, long-chain triacylglycerol(s); MCFA, medium-chain fatty acid(s); MCT, medium-chain triacylglycerol(s); ME, metabolizable energy; NE, net energy.

In the present study we investigated the effects of a diet containing MCT and LCT on the lipid and energy metabolism in chicks.

MATERIALS AND METHODS

One-day-old Single Comb White Leghorn male chicks were given a commercial starter diet for seven days. The diet consisted of 21.5% crude protein and 12.1 kJ/g ME (Marubeni Shiryo Ltd., Tokyo, Japan). On day 8, the chicks were individually weighed after fasting overnight and were divided into six groups of five chicks each, so that mean body weights per group were as uniform as possible. The chicks in the sixth groups were killed by cervical dislocation and were used to determine base values. The remaining five groups of chicks were individually housed in stainless-steel metabolic cages and were fed *ad libitum* the experimental diets from day 8 to day 18.

Table 1 shows the composition of the experimental diets. Corn oil was used as the LCT source and Coconado RK® (glyceryl tricaprylate, 8:0; donated by Kao Corporation, Wakayama, Japan) was used as the MCT source. The dietary oil (200 g/kg diet) contained MCT/LCT combinations in five different proportions, namely 0:200, 50:150, 100:100, 150:50 or 200:0 g MCT/LCT/kg diet. The 200 g MCT/kg diet thus was devoid of linoleic acid.

The chicks were killed by decapitation on day 18. The carcass was minced in a meat grinder, the mince frozen in liquid nitrogen, minced for the second time and then dried at 55°C for 48 h. Nitrogen (N) in the diets and carcasses was determined by the Kjeldahl procedure, and protein was calculated as N × 6.25. The fat of the carcasses was extracted overnight (about 16 h) with diethyl ether using a Soxhlet apparatus and measured gravimetrically. Gains in protein, fat and energy over the experimental period were determined by subtracting the values for the initial body composition from the final experimental values. The energy content of the chicks was calculated using the values 39.12 and 23.68 kJ/g for fat and protein, respectively (10). Droppings were collected during the last three days to determine the N-corrected ME values of the diets (11). The trays in which the droppings were collected were filled with 0.05% HCl solution to prevent N loss and fecal fat saponification. An automatic bomb calorimeter (Shimadzu CA-4; Shimadzu Co., Kyoto, Japan) was used to determine the gross energy content of the diets and droppings. Total fecal bile acids were extracted by the method of Malchow-Moller *et al.* (12) and measured enzymatically by a Total Bile Acid Test® (Wako Pure Chemicals, Osaka, Japan). Fecal fat was extracted as was fat from carcasses. The total lipid extract was filtered, dried under a gentle stream of nitrogen and the residual lipids were redis-

[a]MCT, medium-chain triacylglycerols; LCT, long-chain triacylglycerols.

[b]Contained 20.7 g $CaHPO_4 \cdot 2H_2O$, 14.8 g $CaCO_3$, 10 g K_2HPO_4, 3 g KCl, 6 g NaCl, 3 g $MgSO_4$, 0.5 g $FeSO_4 \cdot 7H_2O$, 0.35 g $MnSO_4 \cdot 5H_2O$, 2.6 mg KI, 40 mg $CuSO_4 \cdot 5H_2O$, 62 mg ZnO, 1.7 mg $Na_2MoO_4 \cdot 2H_2O$, 0.4 mg Na_2SeO_3, 0.93 mg $CoCl_2$.

[c]Contained 15 mg calcium pantothenate, 6 mg riboflavin, 4 mg pyridoxine hydrochloride, 40 mg nicotinic acid, 1.5 mg folic acid, 0.2 mg biotin, 0.02 mg cyanocobalamin, 3 mg thiamin hydrochloride, 200 ICU vitamin D_3, 0.5 mg vitamin K_3, and 1.93 g glucose. The DL-α-tocopheryl acetate (10 IU) and retinyl acetate (1700 IU) were dissolved in glyceryl tricaprylate or corn oil.

[d]Coconado RK®, glyceryl tricaprylate (Kao Corp., Wakayama, Japan).

solved in 2.8% sodium methoxide to obtain fatty acid methyl esters. The solution was incubated at 45°C for 2 h and extracted three times with 2 mL of hexane. An aliquot of the hexane solution was used for determining the fatty acid composition. Fatty acid methyl esters were analyzed on a gas chromatograph (GC-14A; Shimadzu Co.) fitted with a 25 m × 0.25 mm i.d. PEG-20M capillary column (Gasukuro Kogyo Inc., Tokyo, Japan). The chromatograph was equipped with a data system (CR-4A; Shimadzu Co.) to calculate fatty acid composition. The fatty acid composition of the diet was analyzed in the same manner as described for feces.

The data were subjected to analysis of variance, and the significance of differences between means was determined by Duncan's multiple range test using a commercially available statistical analysis package (SAS, 1985; Ref. 13). Regression equations were also fitted to the data.

RESULTS

The effect of dietary MCT and LCT at different ratios on body weight gain, food intake, food efficiency, protein retention and protein utilization is shown in Table 2. All parameters, except for the efficiency of protein utilization, decreased linearly as the proportion of MCT in the diet increased. The efficiency of protein utilization was somewhat improved at the 50:150 and 150:50 ratios, compared with LCT and MCT alone.

Table 3 gives the energy utilization values of diets containing LCT and MCT in various proportions. ME values and ME intake, fat and energy retention, and efficiency of energy utilization decreased linearly as the proportion of dietary MCT increased.

Table 4 shows total fecal fat content and bile acid secretion for chicks given diets with different MCT/LCT ratios. No significant differences were observed between the different ratios in both parameters.

The effects on fecal fatty acid composition are shown in Table 5. The levels of fatty acids with 8:0, 10:0, 12:0 carbon chains increased linearly as MCT levels increased. The levels of 16:0, 18:1n-9, 20:3n-9 and 20:4n-6 decreased linearly as the MCT levels increased. The excretion of linoleic acid (18:2n-6) was not changed as the ratio of MCT/LCT was altered.

TABLE 4

Total Fecal Fat and Fecal Bile Acids of Chicks Fed Diets Containing Medium- (MCT) and Long-Chain Triacylglycerol (LCT) at Different Ratios[a]

Parameter	MCT/LCT ratio (g/kg diet)					Pooled SEM
	0:200	50:150	100:100	150:50	200:0	
Fecal fat (%)	6.48	5.90	6.82	5.94	6.30	0.482
(mg fat)	27.58	24.31	27.95	24.15	23.40	0.091
(mg/g fat intake)	9.80	8.40	11.2	9.2	9.6	0.008
Bile acid (%)	0.138	0.084	0.079	0.106	0.094	0.03
(mg/d)	5.98	3.29	3.22	4.19	3.37	1.08
(mg/g fat intake)	2.05	1.22	1.26	1.53	1.41	0.412

[a]Values are mean of five birds. Details of triacylglycerol sources are described in Table 1.

The levels of total saturated fatty acids (8:0 + 12:0 + 14:0 + 16:0 + 18:0) increased linearly while the levels of total monounsaturated fatty acids (16:1n-7 + 18:1n-9) decreased linearly as the MCT levels increased. However, the levels of the polyunsaturated fatty acids (n-6; 18:2n-6 + 18:3n-6 + 20:4n-6) were not altered by a change in MCT/LCT ratio.

DISCUSSION

In the diet containing MCT alone as fat source, the requirement for linoleic acid (10 g/kg diet; National Research Council; Ref. 14) was not met. However, symptoms of linoleic acid deficiency, such as growth depression, did not become apparent within the short experimental period. Therefore, the effects seen in the present study were attributed to the nutritional characteristics of MCT *per se*. Feeding the MCT diet reduced the food intake of chicks when compared to those in the LCT diet (1). In the present study an increase in the levels of MCT linearly decreased the food intake by the chicks (Table 2); thus, most of the parameters measured were affected by food intake. The depressive effect of dietary MCT on food intake by chicks has been attributed to the enhanced release of cholecystokinin (CCK); a known satiety hormone (15). Furuse *et al.* (16) have shown, however, that injection of Devazepide, a type A receptor antagonist of CCK, did not block the decrease in food intake caused by MCT in chicks. Denbow *et al.* (17) have shown that intrahepatic administration of MCT suppressed food intake of birds within 1 h, whereas intragastric infusion of MCT resulted in delayed reduction in food intake. The rate of absorption of MCT from the gut could be one of the satiety factors (17). Another reason for the reduced food intake by chicks could be the unpalatability of the MCT diet; chicks preferred the LCT diet when allowed to choose between the MCT and LCT diets (16). This, however, was not true for rats. Given a choice, rats did not show a preference for the LCT diet over the MCT diet (18).

The ME values of the diets also decreased as the dietary MCT concentration increased. According to Clark and Holt (9), the energy absorbed was greater when a combination of MCT and LCT was used than when either fat was ingested alone. Furuse *et al.* (1) calculated the ME of MCT to be 30.7 kJ/g (0.82 of that of LCT, 37.5 kJ/g; Ref. 19). In the present study, no improvement of energy utilization was seen with any combination of MCT and LCT, because as the levels of MCT increased, the ME of the diet decreased. Thus, energy utilization in chicks might be dependent on the energy value of each fat source. As a result, the ME intake was synergistically decreased by both the reduction in food intake and in ME values. All parameters except for the efficiency of protein utilization were associated with the ME intake (equations not shown). It was also reported, however, that when chicks were given the same amount of food (similar ME intake between MCT and LCT groups), fat retention remained low with the MCT diet (20). MCT are hydrolyzed by intestinal enzymes and pancreatic lipase more rapidly than LCT (21), and MCFA are oxidized in larger amounts and more rapidly than are LCFA; thus energy expenditure from MCT is greater (22). In fact, not only the ME value, but also the ME value of MCT is lower than that of LCT in growing chicks (2).

Previous studies have shown that MCT improved the efficiency of protein utilization in chicks (1,20). In these two previous experiments, the MCT diet also contained LCT (180 g MCT and 20 g LCT/kg diet). In the present study, no significant difference was seen in the efficiency of protein utilization between the diets containing LCT alone and MCT alone. However, some combinations of LCT and MCT improved the efficiency of protein utilization, the reason for which is presently not understood. In humans, it was shown that the nitrogen balance was better when total parenteral nutrition patients received lipids containing MCT rather than when LCT alone was given (23).

In the present study, the levels of fat and bile acids in the droppings were measured to evaluate the combined effect of MCT and LCT on the excretion of fatty acids and bile acids that may have resulted from metabolic changes in the chicks. However, there were no differences in the bile acid excretion at different combinations of diet on MCT and LCT. Rubin *et al.* (24) demonstrated that infusion of LCT or MCT, or of a mixture of MCT and LCT, as emulsions did not affect bile flow and bile acid secretion in rats. In chickens, bile flow in the cystic duct was not affected by the dietary fat sources (Mabayo, Furuse and Okumura, unpublished data), although MCT were potent stimulators of CCK secretion (15). LCT require bile acids for micelle formation to facilitate its absorption, whereas MCT do not (25). It was concluded, however, that the reabsorption of bile acids might be independent of the dietary fat source. There were no differences in the amount of fat excreted between the different treatments, which may imply that in chicks, total absorption of dietary fat was probably the same. Possible differences between the MCT and LCT could be explained by different rates of absorption from the gut, by different hepatic fatty acid synthesis and fatty acid oxidation, and by differences in the fate of the fatty acids released from triacylglycerols in the peripheral tissues.

[a]Values are means of five birds.

[b–f]Values having different superscript letters are significantly different at $P < 0.05$. Details of triacylglycerol sources are described in Table 1.

[g]Saturated fatty acid (SFA) = 8:0 + 12:0 +14:0 + 16:0 + 18:0.

[h]Monounsaturated fatty acid (MUFA) = 16:1n-7 + 18:1n-9.

[i]Polyunsaturated fatty acid (PUFA) (n-6) = 18:2n-6 + 18:3n-6 + 20:4n-6.

These factors have been pinpointed in chicks fed dietary MCT when food intake and fat retention in the body were decreased, but, conversely, liver fat was increased (1) when compared to LCT. Fat in the feces is present because of incomplete absorption of dietary fat, and partly because of intestinal lipid secretions and the presence of desquamated cells derived from endogenous sources. No specific effect was seen at any combination of the two dietary triacylglycerols on the content of fecal fat; however, there was an effect on specific fatty acids. Octanoic acid (8:0) is absorbed efficiently and rapidly, and it probably does not accumulate in the intestinal mucosa (26); hence, the fecal 8:0 seen in the present study may have been due to the high level of fat present in the diet. The increasing levels of 10:0 and 12:0 seen as dietary MCT levels were increased may have been due to elongation of 8:0 prior to completion of ß-oxidation and may have been the result of intestinal secretion. In the dietary fat, 16:0, 20:3n-9 and 20:4n-6 were present at decreasing levels as the MCT level increased. A similar trend was seen in the fecal fatty acid composition. Linoleic acid (more than 50% of the fatty acid content of corn oil used as LCT source) was not excreted at variable levels into the feces, whereas 18:1n-9 was excreted in a dose-dependent manner. This could mean that 18:2n-6 is absorbed better than 18:1n-9. The predominant mechanism of linoleic acid absorption at high concentrations is thought to be simple diffusion (27), resulting in a linear relationship between linoleic acid concentrations and transport rates (28). Oleic acid was well utilized by chicks with an absorbability of 88% (29). However, the uptake of oleic acid by jejunal mucosal cells is mediated by a membrane-bound fatty acid binding protein, and addition of linoleic acid decreased oleic acid absorption rates (30) accounting for the differences in excretion between oleic acid and linoleic acid. In the present study, the excretion of 8:0 in high concentrations relative to fecal fat raises questions in regard to the absorption mechanism of this fatty acid. Although the absorption of 8:0 was the same after total bile diversion as it was before (31), it is possible that micelle formation is required when 8:0 is given in large amounts. Bloom *et al.* (32) reported that MCT were more completely hydrolyzed than LCT and that their fatty acids were rapidly absorbed *via* the portal vein. Intraduodenal infusion of trioctanoin reduced the steady state absorption of oleic acid, but the absorption of 8:0 was not inhibited by oleic acid. This may imply a competition for some membrane site which may be involved in the mucosal uptake of these fatty acids (9). There might be other mechanisms involved in the absorption of 8:0 when given in high concentration, although Stremmel (30) suggested that 8:0 does not interfere with micelle formation and is taken up by a transport mechanism other than fatty acid binding membrane protein.

We conclude that dietary MCT and LCT affect each other with respect to protein and lipid metabolism in chicks. However, in most cases, the nutritional characteristics of each triacylglycerol, including food efficiency and fat and energy retention are independent of each other.

Forty healthy volunteers were allocated in a double blind, randomized study to receive either 20 g of n-3 polyunsaturated fatty acids (PUFA) or 20 g of n-6 PUFA at their evening meal. The effect on plasma lipids and lipoproteins of this single dose of fish oil *vs.* corn oil was studied the next morning, 14 h after ingestion. Plasma triglycerides and very low density lipoprotein-cholesterol significantly decreased (33%) after n-3 PUFA ($P < 0.001$), and significantly ($P < 0.01$) more than after intake of n-6 PUFA. The decrease in plasma triglycerides after n-3 PUFA ingestion was more pronounced in subjects with higher baseline levels of triglycerides ($P < 0.001$). Total cholesterol decreased after both supplements, but did not differ between the supplements. Low density lipoprotein-cholesterol did not change, and high density lipoprotein-cholesterol significantly decreased in subjects given n-3 PUFA compared to baseline, but not when compared to subjects receiving n-6 PUFA. In conclusion, we have shown that a single very high dose of n-3 PUFA has a pronounced hypotriglyceridemic effect, which is directly related to the initial plasma level.

***Lipids* 29, 145–147 (1994).**

Fish oils rich in n-3 polyunsaturated fatty acids (PUFA) have been shown to lower plasma triglycerides in normo- and hypertriglyceridemic subjects (1–4) in a dose-dependent fashion (5). It has also been shown that the presence of n-3 PUFA in the diet reduces the postprandial lipemia 1–8 h after an oral fat load (6–9). The reduction in plasma triglycerides is most likely caused by an inhibition of very low density lipoprotein (VLDL) production in the liver (1). Even a moderate intake (5 g/d for 6 wk) of n-3 PUFA was recently shown to attenuate the lipemic response to a standard fat meal (10). In contrast, studies examining the effect of an acute load of n-3 PUFA on plasma lipids and lipoproteins in subjects on their habitual diets have given inconsistent results (6–8,11).

The present study was undertaken to investigate the effects of a single very high dose of n-3 PUFA on plasma lipids and lipoproteins 14 h after ingestion in a group of healthy subjects.

[1]This study has been presented in part as a poster at the Omega-3 Symposium, Oslo, Norway, 1992.

TABLE 1

Composition of Fish and Vegetable Oils Used in the Study

Composition	Fish oil (%)[a]	Vegetable oil (%)[a]
Main fatty acids		
16:0	2.6	10.4
18:1	8.3	26.4
18:2	2.4	59.2
20:5	34.0	0
22:5	3.5	0
22:6	19.0	0
Total n-6	<5	61
Total n-3	68	0
Monounsaturated	17	27
Saturated	<5	12
Free fatty acids	<1	<1
Unspecified	<5	<1
Cholesterol (mg/g)	<1	1.3
Vitamin E (IU/g)	2	2

[a] % w/w of total fat.

MATERIALS AND METHODS

Patients and oil supplements. Forty apparently healthy, nonobese volunteers, who did not consume alcohol on a regular basis, were included in a randomized, double blind placebo-controlled study. Twenty females (aged 21–51 yr; median age 37.5 yr) and twenty males (aged 20–45 yr; median age 31.5 yr), all free of medication for at least 2 wk prior to the study, were included. Block randomization was used to secure an equal distribution with respect to gender. The subjects were randomly allocated to receive at the time of their evening meal at 6 p.m., either 30 capsules of a fish oil triglyceride concentrate (Epax 5500 TG; produced by Pronova Biocare a.s., Lysaker, Norway, delivered as Pikasol(R) by Lube a.s., Hadsund, Denmark) containing a total of 20 g of n-3 PUFA, or 30 capsules of corn oil (delivered by Pronova Biocare a.s.) containing 20 g of n-6 PUFA. The composition of the oil is given in Table 1.

The subjects were advised to eat their usual evening meal on the two days before blood testing, but meals containing any fish or high amounts of fat were not allowed.

Blood sampling and analyses. The subjects had blood sampled after an overnight fast resting in the supine position for 15 min at 8:00 a.m. on Day 1. Blood was drawn from an antecubital vein using minimal stasis, and the first few milliliters of blood were discarded. At 6 p.m. on the same day, the subjects took either 30 capsules of fish oil or vegetable oil with their evening meal. The next morning at 8 a.m. (14 h after ingestion of the capsules)

the subjects again had blood drawn (Day 2) using the same procedures as on Day 1. Triglyceride and total cholesterol in plasma were measured using a Cobas Mira (Roche, Switzerland). Triglycerides were measured using Triglycerides PAP(R) (Roche, Basel, Switzerland), and total cholesterol was determined using Monotest(R) (Boehringer Mannheim, Mannheim, Germany). Plasma high density lipoprotein (HDL)-cholesterol was determined after precipitation of apo B containing lipoproteins with phosphotungstic acid and magnesium. VLDL-cholesterol was determined as plasma triglycerides divided by 2.2, and low density lipoprotein (LDL)-cholesterol was calculated using the Friedewald formula (12). The study was approved by the Ethics Committee of Northern Jutland.

Statistics. Pratts test was used for comparison of results within each of the two groups. The n-3 PUFA group was compared to the n-6 PUFA (control) group using Mann-Whitney's test for unpaired data. Correlation analyses were performed by Spearman's test. A *P*-value less than 0.05 (two-tailed) was considered statistically significant.

RESULTS

Despite the large number of capsules ingested, the supplements were well tolerated. The only adverse effects noted were nausea, belching with a fishy taste and loose stools in a few of the subjects receiving fish oil.

The results on plasma lipids and lipoproteins are shown in Table 2. Total cholesterol decreased significantly after both n-3 PUFA and n-6 PUFA by 7.7 and 1.5%, respectively. The difference in the reduction between the two groups approached, but did not reach, statistical significance ($0.1 > P > 0.05$). Plasma LDL-cholesterol did not change significantly in any of the two groups, or between groups. Plasma HDL-cholesterol decreased significantly by 9.1% in the group given n-3 PUFA, whereas there was an insignificant decline in the n-6 group. However, there was no significant difference between the two supplements. VLDL-cholesterol and plasma triglycerides decreased significantly after supplementation with both n-3 PUFA and n-6 PUFA by 33 and 12%, respectively (Fig. 1). Plasma triglycerides decreased in all subjects given n-3 PUFA, and the decrease

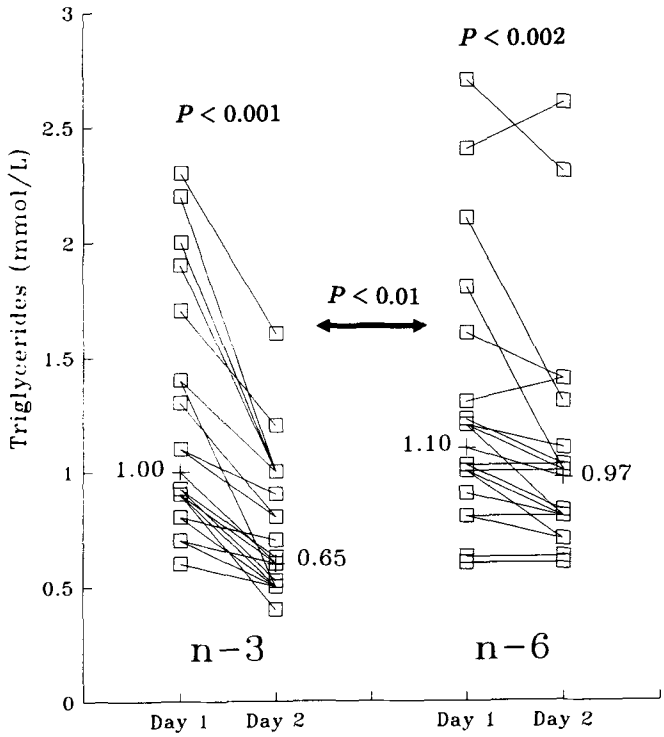

FIG. 1. The effect on plasma triglycerides of a single dose of n-3 or n-6 polyunsaturated fatty acids. Medians (+) are shown and *P*-values within and between groups are indicated.

in triglycerides was significantly greater ($P < 0.01$) in the n-3 group than in the group receiving n-6 PUFA. The hypotriglyceridemic effect in subjects receiving n-3 PUFA was significantly ($P < 0.001$) correlated to the baseline levels of plasma triglycerides, whereas such a correlation could not be demonstrated in the n-6 group.

DISCUSSION

The main finding in the present study was a decrease in plasma triglycerides in all subjects (n = 20) given n-3 PUFA with a median decrease in plasma triglycerides of 33%. This decrease was more pronounced in subjects with higher baseline levels of plasma triglycerides, as there was a significant correlation between baseline

TABLE 2

Plasma Lipids and Lipoproteins (mmol/L) Before and After Supplementation with n-3 PUFA or n-6 PUFA[a]

	n-3 PUFA		n-6 PUFA	
	Day 1	Day 2	Day 1	Day 2
Triglycerides	1.00(0.82–1.63)	0.65(0.52–0.98)[b,e]	1.10(0.92–1.52)	0.97(0.77–1.25)[c]
Total cholesterol	5.30(4.30–6.55)	4.80(3.93–6.45)[b]	6.00(5.43–6.40)	5.60(4.93–6.47)[d]
VLDL-cholesterol	0.46(0.38–0.75)	0.30(0.23–0.46)[b,e]	0.50(0.43–0.70)	0.46(0.37–0.57)[b]
LDL-cholesterol	3.05(2.35–4.30)	2.95(2.22–4.40)	3.85(3.13–4.28)	3.70(3.30–4.35)
HDL-cholesterol	1.65(1.30–1.88)	1.50(1.20–1.72)[d]	1.63(1.22–1.88)	1.53(1.23–1.88)

[a]Results are shown as medians with interquartiles (25–75%) in parentheses. PUFA, polyunsaturated fatty acids; VLDL, very low density lipoprotein; LDL, low density lipoprotein; HDL, high density lipoprotein.
[b]$P < 0.001$.
[c]$P < 0.002$.
[d]$P < 0.05$.
[e]$P < 0.01$, comparing n-3 PUFA with n-6 PUFA.

triglyceride levels and the reduction in plasma triglycerides. Plasma levels of total cholesterol decreased after n-3 PUFA due to a reduction in HDL-cholesterol and, mainly, in VLDL cholesterol levels, while plasma LDL-cholesterol was unaltered.

While low and moderate doses of n-3 PUFA do not affect, or slightly increase, plasma HDL cholesterol, the lowering of HDL-cholesterol in the present study is in accordance with findings from studies in which n-3 PUFA were given in very high daily doses for a few weeks (1,13). The present study extends previous findings and shows that the reduction of HDL cholesterol levels by very high doses of n-3 PUFA occurs rapidly, although the mechanism by which it occurs is unknown. Thus, there is no convincing evidence that dietary n-3 PUFA decrease apolipoprotein A synthesis or enhance removal of HDL-cholesterol from the circulation. Also, studies that examined the effects of n-3 PUFA on key enzymes involved in HDL kinetics, such as cholesterol ester transfer protein and lecithin cholesterol acyltransferase, have yielded inconsistent results (14–18). It should be noted that in our study, plasma HDL-cholesterol did not significantly differ between intakes of PUFA from the n-3 *vs.* the n-6 family. Our results do not indicate, however, whether plasma triglycerides were decreased due to increased clearance of triglyceride-rich lipoproteins from the circulation or due to reduced hepatic VLDL secretion, although based on literature data, the latter may be the more likely mechanism (1,19).

The results from our study are in agreement with the findings from a recent trial in which a single dose of n-3 PUFA (50 mg/kg) was given to nine healthy subjects who had plasma triglycerides measured at baseline, and at 24, 48 and 72 h after the supplements (20). In that study, triglyceride levels significantly decreased by 15% at 24 h and 16% at 48 h, but began to normalize 72 h after n-3 PUFA intake.

The impact of treatment of hypertriglyceridemia on coronary heart disease remains controversial (21,22). However, patients with plasma levels of triglycerides above 10 mmol/L are at risk for abdominal symptoms and pancreatitis (23), and could potentially benefit from treatment with n-3 PUFA (4,13).

Fat elimination from the diet is considered the cornerstone in the treatment of patients with acute pancreatitis. However, highly concentrated preparations of n-3 PUFA could, due to their rapid lowering of plasma triglycerides and chylomicrons, be considered for study in patients with acute pancreatitis, especially as n-3 PUFA are now becoming available for intravenous infusion (24,25). Before such investigations are undertaken, the acute effects of n-3 PUFA in patients with hypertriglyceridemia should, however, be established.

In conclusion, we have shown that a single very high dose of n-3 PUFA has a pronounced hypotriglyceridemic effect in healthy subjects. The magnitude of this effect is directly related to the initial plasma triglyceride level.

ACKNOWLEDGMENT

The authors wish to thank Inge Aardestrup for excellent technical assistance.

Singlet Oxygen Quenching Ability of Naturally Occurring Carotenoids

Osamu Hirayama*, Kyoko Nakamura, Syoko Hamada and **Yoko Kobayasi**

Department of Food Nutrition, Faculty of Agriculture, Kinki University, Nara 631, Japan

The singlet oxygen quenching ability of various naturally occurring carotenoids was examined by measuring toluidine blue-sensitized photooxidation of linoleic acid. To assess quenching, the oxidation of linoleic acid was followed by measuring oxygen consumption and ultraviolet absorbance at 235 nm. We found that oxygen quenching increased as the number of conjugated double bonds in the carotenoids increased, but quenching varied with chain structure and functional groups. Acyclic carotenoids enhanced quenching more than did cyclic carotenoids. Conjugated keto groups and the presence of a cyclopentane ring stimulated quenching, while hydroxy, epoxy and methoxy groups showed lesser effects. The photosynthetic bacterial carotenoids, spirilloxanthin and rhodopin, were found to be most effective as quenchers, followed by the cayenne carotenoid, capsorbin.
***Lipids 29,* 149–150 (1994).**

There is currently much interest in the role of active oxygen and free radicals in disease processes. It is being realized that active oxygen species, such as superoxide anion, hydrogen peroxide and singlet oxygen, can induce destructive events, including enzyme inactivation, DNA-strand cleavage and membrane lipid peroxidation (1–3).

A number of studies have indicated that ß-carotene is able to quench singlet oxygen (4) and oxygen free radicals (5). Earlier research on carotenoid function was mostly focussed on ß-carotene. Recently, several other carotenoids and xanthophylls were examined, and lycopene and astaxanthin were reported to be more effective antioxidants than ß-carotene (6,7).

In the present study we investigated the relative singlet oxygen quenching abilities of several additional naturally occurring carotenoids. Quenching was measured by monitoring toluidine blue-sensitized photooxidation of linoleic acid. The relationship between structure and quenching ability of the carotenoids will be discussed.

MATERIALS AND METHODS

Nineteen carotenoids were prepared from higher plants, animals, marine algae and photosynthetic bacteria (PSB) according to the published methods (8,9). A simple and rapid method for the measurement of linoleic acid photooxidation was employed, using toluidine blue as the photosensitizing dye. In a micro glass vial (2 mL), toluidine blue (final concentration, 0.05 mM) and linoleic acid (final concentration, 60 mM) with or without carotenoids (final concentration, 15 µM) were added, and the final volume was adjusted to 1 mL with *n*-hexane/ethanol (1:1, vol/vol). The vial was tightly closed with a screw cap that had a septum. The mixture was illuminated at 11,000 lux at 30°C for 2 h in a photochamber (LX-3000, Taitec Co., Saitama, Japan). After completion of the reaction, 100 µL of headspace gas was removed with a microsyringe and gas chromatographed on a molecular sieve 13X column to estimate oxygen consumption. In addition, 100 µL of the reaction mixture was removed and diluted to 3 mL with ethanol, and the absorbance at 235 nm was measured to estimate the formation of conjugated dienes.

RESULTS AND DISCUSSION

Table 1 shows the inhibitory effects of various naturally occurring carotenoids on photooxidation of linoleic acid, which were measured by monitoring oxygen consumption and ultraviolet absorbance at 235 nm (conjugated diene formation). Based on the oxygen consumption rate in the reaction, it was found that the quenching ability varied greatly, depending on the structures of carotenoids. As reported previously (10,11), the number of conjugated double bonds is the most effective parameter to assess singlet oxygen quenching ability. Comparison of the structure and quenching ability of ß-carotene with those of lycopene, and those of cryptoxanthin and rhodopin, indicates that an open chain has a higher quenching ability than a ß-ionone ring. Smaller differences between the abilities of ß-carotene and cryptoxanin, and of spheroidene and OH-spheroidene, suggest that the hydroxy group has a positive effect but is less effective as quencher. Similarly, epoxy and methoxy groups have lesser effects. The effects of capsanthin and capsorbin were more pronounced than those of ß-carotene and cryptoxanthin, although they have the same number of conjugated double bonds. This higher potency could be due to the presence of conjugated keto groups and of the cyclopentane rings. Isolated C=C double bonds seem to have an additional effect on quenching. The relatively higher potency of lycopene than of other carotenoids with the same number of conjugated double bonds can probably be attributed to the presence of the two isolated double bonds and an acyclic chain effect.

The oxidation of linoleic acid by singlet oxygen is expected to result in roughly half the products consisting of conjugated diene hydroperoxides, and half being nonconjugated. The pattern of conjugated diene formation measured by absorbance at 235 nm was similar to that of O_2 consumption rates, suggesting that absorbance at 235 nm could be used as index for singlet oxygen-quenching by carotenoids.

It is of interest that photosynthetic bacterial cells have a large amount of highly effective acyclic carotenoids, such as spirilloxanthin, rhodopin, anhydrorhodovibrin and lycopene. The observed therapeutic effects of PSB cells on growing young fish (12) may be related, in part, to oxygen quenching by carotenoids. The

Inhibition of Human Neutrophil Leukotriene B_4 Synthesis in Essential Fatty Acid Deficiency: Role of Leukotriene A Hydrolase

Leslie G. Cleland[a,*], Michael J. James[a], Susanna M. Proudman[a], Mark A. Neumann[b] and Robert A. Gibson[b]

[a]Rheumatology Unit, Royal Adelaide Hospital, Adelaide, South Australia and [b]Department of Paediatrics, Flinders Medical Centre, Bedford Park, South Australia, Australia

A female subject dependent on long-term total parenteral nutrition developed an aversion and noncompliance to a prescribed weekly lipid infusion designed to meet essential fatty acid (EFA) requirements. Fatty acids (FA) in the subject's plasma and isolated peripheral blood neutrophils were analyzed in search of biochemical evidence of EFA deficiency. Neutrophil 5-lipoxygenase metabolism was examined to assess the possible effects of EFA deficiency on neutrophil eicosanoid metabolism. EFA deficiency was confirmed by marked depletion of linoleic acid (18:2n-6) and accumulation of eicosatrienoic acid (ETrA; 20:3n-9) in plasma and neutrophil phospholipids. In the neutrophils, ETrA comprised 5.2% of phospholipid FA (normal reference values <0.1%), and arachidonic acid (AA; 20:4n-6) comprised 8.6% of phospholipid FA (normal reference range 10–16%). When stimulated by A23187 *in vitro* on three separate occasions, the subject's neutrophils displayed impaired synthesis of leukotriene B_4 (LTB_4), but produced normal amounts of 5-hydroxyeicosatetraenoic acid and *all-trans* isomers of LTB_4 formed nonenzymatically from leukotriene A_4 (LTA_4). This pattern of synthesis suggested inhibition of LTA hydrolase and was also seen in neutrophils from healthy subjects by addition of exogenous ETrA *in vitro*. Comparative studies of the effects of ETrA and eico-sapentaenoic acid (20:5n-3) on neutrophils *in vitro* suggested that ETrA is the more potent inhibitor. Accumulation of ETrA, rather than depletion of AA, appears principally responsible for the observed impairment of neutrophil LTB_4 synthesis seen in this EFA-deficient subject.
***Lipids* 29, 151–155 (1994).**

Eicosanoid mediators of inflammation, such as prostaglandins, thromboxane and leukotrienes are typically derived from arachidonic acid (AA, 20:4n-6) as n-6 fatty acids (FA) are the prevalent essential fatty acids (EFA) in the Western diet, which contains relatively little n-3 FA. In the presence of severe dietary EFA deficiency, oleic acid (18:1n-9), which can be synthesized endogenously, becomes the predominant substrate for the hepatic desaturase/elongase enzymes that normally convert dietary linoleic acid (LA; 18:2n-6) to AA. As a result, plasma and cellular levels of eicosatrienoic acid (ETrA; 20:3n-9) increase, and the overall cellular content of 20 carbon highly unsaturated fatty acids is maintained, in spite of AA depletion (1,2).

EFA deficiency has been associated with reduced inflammatory responses in animals (3,4), including amelioration in models of inflammatory disease (5–8). Early studies demonstrated that EFA-deficient animals with experimentally-induced inflammation had reduced production of prostaglandins derived from AA *via* the cyclooxygenase pathway (3). Prostaglandins can have ambivalent effects on inflammation, including mediation of enhanced nociception (8) and tissue oedema (9,10), but decreased T lymphocyte responses (11).

More recently, the potential importance of the alternate 5-lipoxygenase pathway of AA metabolism has been recognized. This pathway is active in both mononuclear phagocytes and neutrophils and, in the latter, is the principal pathway of AA metabolism (12). An important product of this pathway is leukotriene B_4 (LTB_4), which is a very potent neutrophil chemotaxin and also stimulates neutrophil degranulation and oxidative burst activity (12). LTB_4 can have pro-inflammatory effects on mononuclear cells, including enhancement of production of the key inflammatory cytokines interleukin-1 (13,14), interleukin-2 (15) and interferon-gamma (15,16). LTB_4 inhibits mitogen-induced proliferation of $CD4^+$ T cells and enhances proliferation of $CD8^+$ T cells (17,18) and, accordingly, may also modulate immunological responses. EFA deficiency in rats is associated with marked inhibition of LTB_4 production by neutrophils stimulated *in vivo* (19,20). The effect of EFA deficiency on LTB_4 production in humans has not been reported.

A woman receiving total parenteral nutrition with intolerance to intravenous lipid therapy and severe EFA deficiency has provided the opportunity to assess this issue in a human subject. *In vitro* studies, in which neutrophils from healthy volunteers were treated with ETrA, were also undertaken to assess the possible relationship between the observed ETrA accumulation and impaired LTB_4 synthesis in the neutrophils of the EFA-deficient subject.

MATERIALS AND METHODS

Experimental subject. A 33-year-old female had been maintained on total parenteral nutrition *via* an indwelling subclavian catheter for 12 years, following subtotal resection of the small and large bowel for idiopathic intestinal pseudo-obstruction. She also had three successful pregnancies during this period. Complications included superior vena cava obstruction, recurrent septicaemia, proximal myopathy and an osteoporotic rib

*To whom correspondence should be addressed at Rheumatology Unit, Royal Adelaide Hospital, North Terrace, Adelaide, South Australia, Australia 5000.

Abbreviations: AA, arachidonic acid (20:4n-6); EFA, essential fatty acids; EPA, eicosapentaenoic acid; ETrA, n-9 eicosatrienoic acid (20:3n-9); FA, fatty acid(s); HPLC, high-performance liquid chromatography; LA, linoleic acid (18:2n-6); LTA, leukotriene A; LTB_4, leukotriene B_4; 5-HETE, 5-hydroxyeicosatetraenoic acid.

fracture. Typically, the intravenous regimen involved daily 1800-mL infusions containing glucose, amino acids and electrolytes (Vamin or Synthamin; Baxter Health Care, Sydney, NSW, Australia). MVI-12 (Rhone-Poulenc, Melbourne, Victoria, Australia) was given daily to provide water-soluble vitamins (one 5-mL vial) and fat-soluble vitamins (one 5-mL vial). Intralipid 20% (Baxter Health Care), 500 mL weekly, was prescribed as the source of dietary fat, including EFA. Due to intolerance of the fat infusion, the interval of self-administration was typically two weeks, and the infusion was not completed. Concentrations of fat soluble vitamins in plasma were as follows: vitamin A, 0.9 mmol/L (R 2.1–6.7); vitamin E, 10.5 mmol/L (R 12–46) and vitamin D, 39 nmol/L (R 40–160). Vitamin K was not measured because the subject was receiving warfarin treatment. Forearm bone content was between the first and tenth percentiles with bone mineral content 0.86 g/cm (fat corrected to 0.91) and bone mineral density 344 mg/mL (expected 426). The selenium concentration was 1 mmol/L (normal range >1) and zinc 14.2 mmol/L (R 9–18). Total carnitine was 13 mmol/L (R 35–65) with free carnitine 12 mmol/L (R 30–60), acylated carnitine 1 mmol/L and the ratio of acylated to free 0.08 (R 0.10–0.75). *In vitro* tests of neutrophil function revealed normal degranulation, oxidative burst and bactericidal activity.

Healthy subjects. Peripheral venous blood samples from healthy subjects were used to establish reference ranges for analysis of (i) fatty acids in plasma (n = 40) and neutrophil phospholipid (n = 29) and (ii) neutrophil 5-lipoxygenase pathway responses (n = 44). No difference was seen between males and females for any of these analyses. Healthy laboratory personnel (one male, two female) provided blood samples for studies on the effects of exogenous fatty acids added to neutrophils *in vitro* prior to cell stimulation.

FA analysis. Neutrophil phospholipid fractions were isolated by chloroform/methanol extraction and thin-layer chromatography. The phospholipids were then subjected to acid methanolysis by using 1% H_2SO_4 in methanol at 70°C for 3 h. Fatty acid methyl esters were resolved and quantified by capillary gas–liquid chromatography on 50 M WCOT columns coated with SP2330 (Chromalytic Technology, Boronia, Victoria, Australia), as described previously (21). All organic solvents contained 0.005% butylated hydroxyanisole. The analysis allowed quantification of saturated and unsaturated fatty acids, including n-7 fatty acids, which are increased in EFA deficiency.

Leukotriene and 5-hydroxy acid production. Peripheral blood neutrophils were isolated using a double noncontinuous Percoll gradient, as previously described (22). Neutrophils (10^6/mL) were stimulated with A23187 (0.5 µmol/L final concentration, Sigma Chemical Co., St. Louis, MO). After 5 min at 37°C, the mixture was acidified with 0.25 mL of 100 mM citric acid; 15-hydroxyeicosatetraenoic acid (15-HETE) (Cayman Chemical, Ann Arbor, MI) was added as an internal standard. Leukotrienes and hydroxy acids, including 5-HETE and the *all-trans* isomers of LTB_4, were assayed by high-performance liquid chromatography as previously described (23). 20-Hydroxy LTB_4, formed by ω-oxidation of LTB_4, was also measured. Under the stimulation conditions used, 20-carboxy LTB_4 constituted 13% (±2%) of the total ω-oxidation products, and as the low values were frequently near the limits of detection, the values for 20-carboxy LTB_4 were not compiled.

To assess the effects of exogenous FA added *in vitro*, ETrA (Cayman Chemical) or eicosapentaenoic acid (EPA) (Sigma Chemical Co.) were added to neutrophils from healthy volunteers (10^6/mL; final concentration of fatty acids, 1–5 µmol/L; methanol, 0.05%) followed by pre-incubation at 25°C (5 min) prior to stimulation with A23187, as described in the previous paragraph.

RESULTS

Plasma and leukocyte FA. Analysis of FAs in the experimental subject's plasma revealed a triene/tetraene (ETrA/AA) ratio of 4.3. A ratio of greater than 0.2 indicates EFA deficiency (1). Accumulation of n-7 and n-9 FAs, including ETrA, was seen in total plasma FA and neutrophil phospholipids. In the leukocyte phospholipids, ETrA constituted 5.2% of total FA, and AA was reduced compared with levels found in leukocytes from healthy subjects (Table 1). These data indicate severe EFA deficiency.

Effect of EFA deficiency on neutrophil LTB_4 synthetic pathway. Neutrophil LTB_4 production, as assessed by assaying LTB_4 and 20-hydroxy LTB_4, was reduced to more than two standard deviations below the mean for healthy subjects (Fig. 1). 5-HETE and the *all-trans* isomers of LTB_4 (LTB_4 isomers) were not reduced (Fig. 1). The ratio of (LTB_4 + 20-hydroxy LTB_4)/(LTB_4 + 20-hydroxy LTB_4 + LTB_4 isomers), which is an index of the fraction of available leukotriene A_4 (LTA_4) converted by LTA hydrolase to LTB_4, was reduced compared to the normal range for healthy subjects (Fig. 2). The observed

[a]Reference (Ref.) ranges were established using samples from healthy subjects (plasma, n = 40; neutrophil phospholipids, n = 29). The range shown is from two standard deviations above and below the mean for healthy subjects.

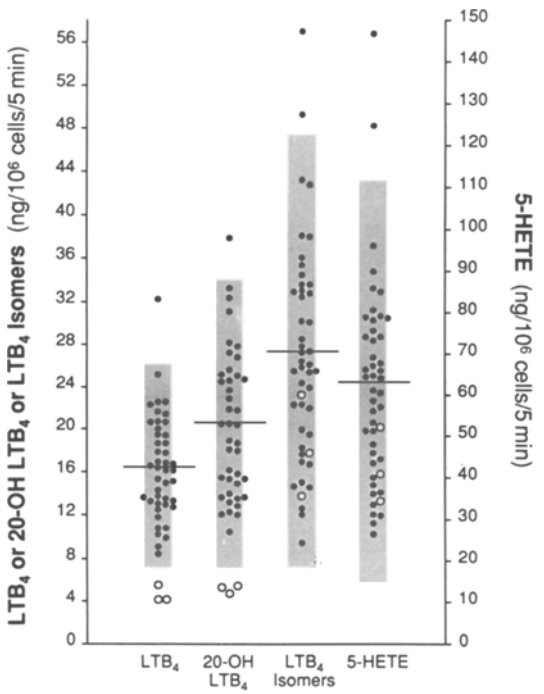

FIG. 1. Production of leukotriene B_4 (LTB_4) 20-hydroxy LTB_4, LTB_4 isomers and 5-hydroxyeicosatetraenoic acid (5-HETE) by neutrophils stimulated by A23187, as described in the Materials and Methods section. Results from the essential fatty acid-deficient subject's neutrophils studied on three separate occasions (open circles) and neutrophils from healthy volunteers (closed circles) are shown. The shaded areas indicate two standard deviations above and below the mean (horizontal lines) for healthy subjects.

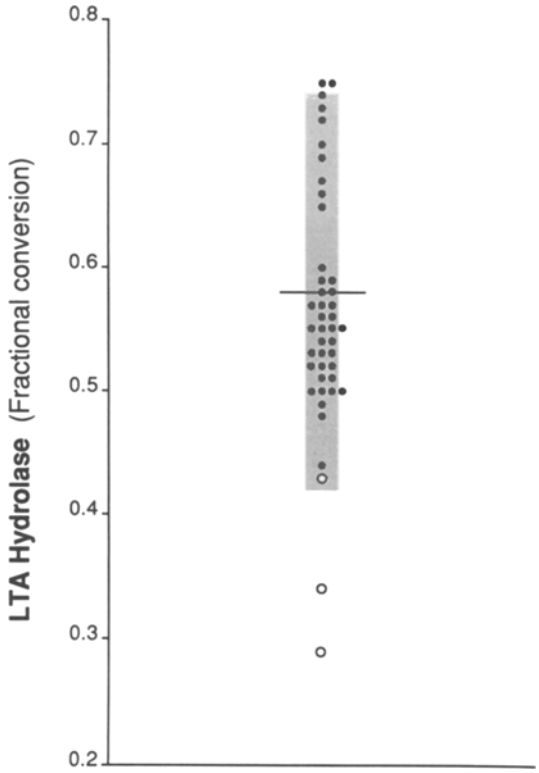

FIG. 2. Leukotriene A (LTA) hydrolase fractional conversion is computed as (LTB_4 + 20-hydroxy LTB_4)/(LTB_4 + 20-hydroxy LTB_4 + LTB_4 isomers). The denominator reflects the substrate potentially available to LTA hydrolase for enzymatic conversion to LTB_4. Open circles indicate values obtained with neutrophils isolated from the essential fatty acid-deficient subject on three separate occasions. Closed circles indicate values obtained with neutrophils from healthy subjects. The data used for these computations are those shown in Figure 1. The shaded areas indicate two standard deviations above and below the mean (horizontal line) for healthy subjects. LTB, leukotriene B.

normal production of 5-HETE and LTB_4 isomers suggests normal availability of AA for metabolism by 5-lipoxygenase, whereas reduced fractional conversion of LTA_4 to LTB_4 suggests inhibition of LTA hydrolase.

LTB_4 had a retention time of 11.6 min. Dual high-performance liquid chromatography (HPLC) peaks at slightly longer retention times were observed with ratios of retention times relative to LTB_4 of 1.48 and 1.29. These peaks were not observed in control subjects.

Correction of EFA deficiency. Once it was established that the subject was EFA deficient, the following adjustments were made to the regimen for lipid infusion. Intralipid (500 mL) was diluted with dextrose solution (50%, 500 mL) and an electrolyte solution (Synthamin 17, 750 mL) prior to infusion, and the infusion was carried out over a longer period of time. With these adjustments, the subject was able to complete the weekly lipid infusion without significant unwanted effects. After approximately two years on this revised regimen, neutrophil fatty acid values were: LA, 6.2%; ETrA, 0.5%; and AA, 12.4%. Rates of synthesis of 5-lipoxygenase products were as follows (ng/10^6 cells/5 min): LTB_4, 18.5; 20-hydroxy LTB_4, 17.8; 5-HETE, 53.3; *all-trans* isomers of LTB_4, 19.6 (the normal reference ranges are shown in Fig. 1).

Effect of exogenous ETrA on neutrophil LTB synthetic pathway. Addition of ETrA *in vitro* to neutrophils from

[a]Human neutrophils from a healthy subject were pre-incubated with fatty acids and stimulated with A23187 as described in the Materials and Methods section. Incubations were performed in triplicate.

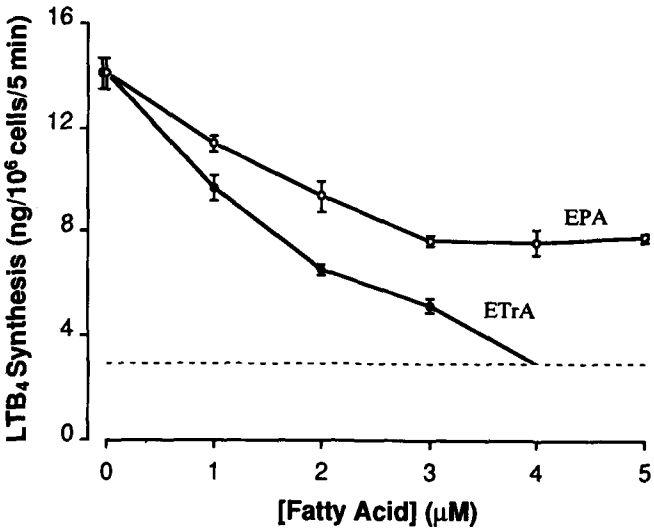

FIG. 3. Effect of exogenous eicosapentaenoic acid (EPA) (open circles) and eicosatrienoic acid (ETrA) (closed circles) on LTB_4 production by human neutrophils in response to A23187 under conditions described in the Materials and Methods section. Results are expressed as mean ± SEM of triplicate incubations. The horizontal dashed line represents the minimum detectable amount. Data shown are with neutrophils isolated from a single healthy subject. Similar findings were obtained with neutrophils from two additional subjects (data not shown). See Figure 2 for other abbreviations.

three healthy subjects reproduced the pattern of hydroxy acid synthesis observed in the EFA-deficient subject, *viz.*, reduced production of LTB_4 (Fig. 3) and 20-hydroxy LTB_4, but not LTB_4 isomers (data not shown). Thus the pattern of neutrophil LTA hydrolase inhibition found in the EFA-deficient subject was induced in normal neutrophils by addition of ETrA *in vitro*. Dual peaks with ratios of retention times relative to that of the LTB_4 peak of 1.50 and 1.30 were observed in chromatograms from ETrA-treated, but not control, cell preparations.

Comparison of effects of ETrA and EPA. Exogenous ETrA was a more potent inhibitor of LTB_4 production than exogenous EPA (Fig. 3 and Table 2). Additive inhibitory effects of EPA and ETrA added *in vitro* on neutrophil LTB_4 production were seen (Table 2).

DISCUSSION

The altered pattern of synthesis of 5-lipoxygenase products seen in this EFA-deficient subject is consistent with inhibition of LTA hydrolase (24–26). The appearance of dual HPLC peaks with retention times slightly greater than that of LTB_4 when neutrophils were treated with ETrA, is consistent with the formation of the *all-trans* isomers of LTB_3, which are nonenzymatic breakdowns of LTA_3 and which are resolved in this manner relative to LTB_4 (24). Whatever the identity of these peaks, their presence in the chromatogram from the EFA-deficient subject suggests that ETrA formed *in vivo* was metabolized by the EFA-deficient neutrophils. Dietary supplementation with EPA-rich fish oils and addition of exogenous EPA to neutrophils *in vitro* yielded a similar alteration in n-6 products (27,28), which was attributed to inhibition of LTA hydrolase by LTA_5 derived from EPA (29). Both ETrA and EPA can be converted to products, i.e., LTA_3 and LTA_5, respectively, which are less efficiently metabolized by LTA hydrolase than LTA_4 derived from AA, but which can act as competitive inhibitors of LTB_4 production. Insignificant amounts of LTA_3 are converted to LTB_3 (26). Although LTB_5 is formed in measurable amounts, this compound has much less chemotactic activity than does LTB_4 (30–32).

Dietary fish oil supplements containing EPA lessen symptoms in rheumatoid arthritis and reduce neutrophil LTB_4 synthesis *ex vivo* (27,28,33,34). However, it has been reported that suppression of LTB_4 production is greater in EFA-deficient rats than in fish oil-supplemented rats (20). EFA deficiency has been consistently associated with reduced inflammation and reduced organ damage in animal models of inflammation (3–6). Although no direct experimental comparisons have been reported, in small laboratory rodents, EFA deficiency seems to be associated with suppression of inflammation to a degree at least as great as that achieved with fish oil diets. Indeed, fish oil treatment can have ambiguous effects in animal models of inflammation (35–37) and has yielded only modest symptomatic improvement in patients with rheumatoid arthritis (27,28,33,34) and psoriasis (38,39). This lack of potency may, in part, relate to the ambivalent effects of EPA on production of inflammatory mediators. For example, inhibition of LTB_4 production potentially reduces leukocyte recruitment and degranulation (12), whereas alteration in prostacyclin/thromboxane balance in favor of the vasodilatory effects of prostacyclin could increase tissue oedema (8,9). Unlike AA and EPA, ETrA cannot be metabolized to prostacyclin or other ring structure prostaglandins that might potentiate tissue oedema, but it does inhibit LTB_4 production and thus might be expected to exert a more consistent anti-inflammatory effect than EPA.

When normal dietary requirements for LA are met, there is very little conversion of the 18 carbon fatty acids of the n-3 and the n-9 series to their respective 20 carbon fatty acids, EPA (n-3) and ETrA (n-9) (40,41). The present case indicates that EFA deficiency can be relatively well tolerated, as the subject accepted the dryness and scaliness of her skin as preferable to the unpleasant effects of bolus therapy with Intralipid. However, avoidance of dietary LA sufficient to allow accumulation of ETrA is not a realistic approach to the treatment of inflammatory diseases in free-living human subjects. Direct fortification of the diet with ETrA could provide a more practical strategy.

The n-3 analogue of ETrA, EPA can be incorporated into cell membranes in competition with n-6 fats when introduced directly within an EFA-sufficient diet, as evinced by numerous animal and human intervention studies (42–44). Similarly, ETrA was incorporated into the cell membranes of rabbits when fed together with an EFA-sufficient diet, with a broadly similar efficiency to that reported for EPA (Gibson, R.A., and Neumann,

M.A., unpublished results). Thus, dietary supplementation with ETrA could conceivably result in accumulation of ETrA in cell membranes sufficient to influence synthesis of inflammatory eicosanoids.

Cold water fish are rich in n-3 fats and fish oils, and extracts of cultures of certain marine bacteria and yeasts (45,46) provide commercially available sources of concentrated EPA for dietary supplementation. The lack of a similar high yield biological source of ETrA or a cheap synthetic process is an obstacle to the evaluation of the possible anti-inflammatory effects of ETrA. Because ETrA lacks the unpleasant odor of EPA-rich marine oil preparations and is chemically more stable than EPA, because it is less unsaturated, it could be integrated into foods. Such an approach should be far more acceptable to consumers than the strategy of giving fish oils in gelatin capsules. This advantage, plus the effect of ETrA on LTA hydrolase, which can be the rate-limiting enzyme in the LTB_4 synthetic pathway (47), justifies further investigations into the anti-inflammatory effects of ETrA and biosynthetic sources for its production.

[Received September 9, 1993, and in revised form January 5, 1994; Revision accepted January 5, 1994]

The Effect of Linoleic, Arachidonic and Eicosapentaenoic Acid Supplementation on Prostacyclin Production in Rats

Neil J. Mann[a,*], Glenda E. Warrick[a], Kerin O'Dea[a], Howard R. Knapp[b] and Andrew J. Sinclair[c]

[a]School of Nutrition and Public Health, Deakin University, Geelong, Victoria, 3217, Australia, [b]Department of Internal Medicine, University of Iowa Hospitals and Clinics, Iowa City, Iowa 52240 and [c]Department of Applied Biology, Royal Melbourne Institute of Technology, Melbourne, Victoria, 3000, Australia

We examined the effect of dietary supplementation of linoleic acid (LA), arachidonic acid (AA) or eicosapentaenoic acid (EPA) to rats fed a diet low in linoleic acid on *in vitro* and *in vivo* production of prostacyclin. Male Sprague Dawley rats were fed a high-fat diet (50% energy as fat, 1.5% linoleic acid) for two weeks. Three of the groups were then supplemented orally with either 90 mg/d of LA, AA or EPA, all as the ethyl esters, for a further two weeks while remaining on the high-fat diet. Forty-eight hour urine samples were collected at the end of the second and fourth weeks. *In vivo* prostacyclin production was determined by a stable isotope dilution, gas chromatography/mass spectrometry assay for the major urinary metabolite of prostacyclins (2,3-dinor-6-keto-$PGF_{1\alpha}$ or PGI_2-M and Δ^{17}-2,3-dinor-6-keto-$PGF_{1\alpha}$ or PGI_3-M). *In vitro* prostacyclin production was determined by radioimmunoassay of the stable metabolite (6-keto-$PGF_{1\alpha}$) following incubation of arterial tissue. Oral supplementation with AA resulted in a rise in plasma and aorta 20:4n-6, and increased *in vitro* prostacyclin and urinary PGI_2-M production. EPA supplementation resulted in a rise in plasma and aorta 20:5n-3 and 22:5n-3, and a decline in plasma 20:4n-6, but not in the aorta. In the EPA-supplemented group, the *in vitro* prostacyclin and the urinary PGI_3-M increased, but urinary PGI_2-M decreased. The increase in *in vitro* prostacyclin production in the EPA-supplemented rats was unexpected and without obvious explanation. Supplementation with LA had minimal effect on fatty acid composition of plasma or aorta and caused no change in prostacyclin production with either method. The *in vivo* measure of prostacyclin production was positively correlated with aorta AA levels, and negatively correlated with aorta levels of EPA. There was a significant positive correlation between the *in vitro* production of prostacyclin and the *in vivo* production (as measured by the urinary prostacyclin metabolite level), despite the differences observed in the EPA-fed group. There was a high inter-animal variability in prostacyclin production using either method. These results indicate that dietary AA stimulates and dietary EPA reduces *in vivo* PGI_2 production in the rat. An equivalent amount of dietary LA was without effect.
***Lipids* 29, 157–162 (1994).**

We have previously shown that when rats were fed high-fat diets low in linoleic acid [1.2–1.5% linoleic acid (LA)] with a relatively low n-6/n-3 polyunsaturated fatty acids (PUFA) ratio (as either beef tallow or butter) there was a decrease in arachidonic acid (AA) and an increase in eicosapentaenoic acid (EPA) in phospholipids (PL) of plasma, platelets and aorta of the rats compared with rats fed low-fat diets (1-4). These fatty acid changes were associated with a decrease in the *in vitro* arterial prostacyclin production and collagen-induced thromboxane production [as measured by radioimmunoassay (RIA) of their stable metabolites] (1–4). In subsequent studies, we showed that when rats fed high-fat diets (containing butter) were supplemented with 80 mg/d of AA for 2 wk there was complete restoration of tissue AA levels and also of the *in vitro* levels of prostacyclin and thromboxane production (5).

Therefore, the *in vitro* prostacyclin and thromboxane production appeared to be regulated either directly by tissue levels of their precursor AA or indirectly by levels of EPA and docosahexaenoic acid (DHA, 22:6n-3), which may competitively inhibit AA metabolism *via* the cyclooxygenase pathway (6), or a combination of both. In these studies, the relative importance of decreased AA levels or increased EPA levels on eicosanoid synthesis in the rat has not been established.

In vitro methods for determining eicosanoids are subject to some major limitations and the aim of this study was to compare the *in vitro* method for prostacyclin used in our previous studies with an *in vivo* assessment of prostacyclin. With the *in vitro* method used, there is a propensity to produce artifactual results due to *ex vivo* activation of arterial endothelium during sampling. Prostacyclin I_2 (PGI_2) is rapidly converted to its nonenzymatic hydrolysis product 6-keto-$PGF_{1\alpha}$ under physiological conditions (7), and it is this primary metabolite which is assayed by the *in vitro* method. Secondly, it is unlikely that the *in vitro* RIA assay for prostacyclin distinguishes between the metabolite derived from PGI_2 (6-keto-$PGF_{1\alpha}$) and that derived from prostacyclin I_3 (PGI_3, Δ^{17}-6-keto-$PGF_{1\alpha}$). Since both sets of metabolites are potentially produced in rats with a low AA/EPA ratio in endothelial cells (such as in our previous studies), the interpretation of RIA results could be ambiguous.

These problems can be overcome by the measurement of the systemic production of prostacyclin *in vivo* by quantification of the characteristic metabolites of prostacyclin in urine (8). In humans (9,10) and rats (11) the ß-oxidized metabolite of PGI_2, 2,3-dinor-6-keto-$PGF_{1\alpha}$ is the major metabolite excreted in urine, whereas 6-keto-$PGF_{1\alpha}$ mainly reflects renal synthesis (12). With the application of combined gas chromatography/mass spectrometry (GC/MS) to the identification and quantification of urinary metabolites of prostaglandins, an accurate assessment of systemic PGI_2 production has been made possible. Thus potential artifacts related to sampling and handling of arterial tissue are

*To whom correspondence should be addressed.

Abbreviations: AA, arachidonic acid (20:4n-6); BSTFA, *N,N-bis*(trimethylsilyl) trifluoroacetamide; DHA, docosahexaenoic acid (22:6n-3); EPA, eicosapentaenoic acid (20:5n-3); GC/MS, gas chromatography/mass spectrometry; KRB, Krebs Ringer bicarbonate buffer; LA, linoleic acid (18:2n-6); NICI, negative ion chemical ionization; PGI, prostaglandin I (prostacyclin); PGI_2-M, 2,3-dinor-6-keto-$PGF_{1\alpha}$; PGI_3-M, Δ^{17}-2,3-dinor-6-keto-$PGF_{1\alpha}$; PL, phospholipid; PUFA, polyunsaturated fatty acid; RIA, radioimmunoassay; SIM, selected ion monitoring; TLC, thin-layer chromatography.

avoided and the exact identity of the metabolite being measured is known.

The aims of the present study were (i) to determine the effect of feeding LA, AA or EPA on *in vivo* prostacyclin production in the rat and (ii) to compare the standard *in vitro* RIA method for the determination of prostacyclin production with the *in vivo* GC/MS urinary assay for prostacyclin metabolites.

MATERIALS AND METHODS

Materials. Sodium thiopentone was purchased from Abbott Australasia (Sydney, Australia). Scintillation proximity assay RIA kits for 6-keto-$PGF_{1\alpha}$ were purchased from Amersham Australia Pty Ltd. (Sydney, Australia). Standard 2,3-dinor-6-keto-$PGF_{1\alpha}$ was purchased from Biomol Research Laboratories (Plymouth Meeting, PA). Tetradeuterated [19,19,20,20-$^2H_4$]2,3-dinor-6-keto $PGF_{1\alpha}$ was a generous gift from Upjohn (Kalamazoo, MI). *N,N-bis*(trimethylsilyl) trifluoroacetamide (BSTFA), pentafluorobenzyl bromide, methoxylamine hydrochloride and triethylamine were purchased from Pierce (Rockford, IL). "Clinelute" disposable columns (CE 1005) used for urinary extraction were purchased from Analytichem International (Harbor City, CA). All solvents were high purity grade (Suprapur) supplied by BDH-Merck (Poole, England), unless otherwise indicated. Diisopropylamine was supplied by the Aldrich Chemical Company (Milwaukee, WI). Ethyl arachidonate and ethyl linoleate were supplied by Nu-Chek-Prep (Elysian, MN). Ethyl eicosapentaenoate was purchased from Marubeni Corporation (Tokyo, Japan). Thin-layer chromatography (TLC) was performed on four-channel Silica Gel 60 A (LK6DF) plates from Whatman International (Maidstone, England). Metabolic cages were supplied by IFFA Credo (Domaine des Oncins, France). Disposable polypropylene tubes were supplied by Sarstedt (Rommelsdorf, Germany). BP-1 capillary columns were purchased from SGE (Melbourne, Australia), and CP-SIL 88 capillary columns from Chrompak (Middelburg, The Netherlands). Diheptadecanoyl phosphatidylcholine was supplied by Sigma Chemical Co. (St. Louis, MO).

Animals. Forty male Sprague Dawley rats (140–220 g) were housed in a temperature-controlled room with a 12-h light-dark cycle. Ten rats were randomly allocated to each of four dietary groups. Food and water were provided *ad libitum* and food consumption and body weight recorded three times per week. Rats were placed in metabolic cages on days 1, 14 and 28 and urine collected for 48 h into containers packed in dry ice. The urine was then stored at -80°C for later extraction of the prostacyclin metabolite and its subsequent quantification by GC/MS.

Diets. The nutrient composition of the high-fat diet per 100 g diet was 29.5 g corn starch, 18.9 g casein, 18.9 g unprocessed bran, 26.8 g butter (salt reduced), 0.2 g choline chloride, 4.2 g mineral mix, 1.2 g vitamin mix and 0.3 g methionine, giving 50% energy from fat, 30% energy from carbohydrate and 20% energy from protein. The quantities of vitamins and minerals added were calculated to reach the levels recommended by the American Institute of Nutrition (13). Detailed fatty acid analysis of the diet was as previously described (1), the major fatty acids being (% composition): 8:0, 1.8%; 10:0, 3.6%; 12:0, 3.6%; 14:0, 11.4%; 16:0, 28.7%; 16:1, 1.7%; 18:0, 12.3%; 18:1, 25.8%; 18:2n-6, 3.0%; 18:3n-3, 1.0%; total saturated fatty acids (FA) 61.4%; monoenoic FA, 27.5%; polyenoic FA, 4.0%. All four groups of ten rats were fed the high-fat diet for four weeks. During the final two weeks, three of the groups were supplemented orally with 90 mg/d of either LA, AA or EPA as ethyl esters. One group of rats received no PUFA supplementation and was designated as a high-fat control group.

In vitro *prostacyclin production.* At the conclusion of the four-week feeding period, the rats were anaesthetized with sodium thiopentone (75 mg/kg intraperitoneally). Blood was taken by cardiac puncture for plasma PL FA analysis. Immediately after blood collection, rats were perfused with Krebs Ringer bicarbonate buffer (KRB), pH 7.4, containing 5.5 mM glucose, to flush out the remaining blood, leaving the circulatory system free of adhering blood clots. The abdominal aorta was carefully dissected free of connective tissue and the distal 2-cm segment above the bifurcation removed. This was then split longitudinally and allowed to stabilize in KRB at 37°C for 15 min in a shaking water bath to minimize artifactual contribution of prostacyclin production due to mechanical stimulation of the arterial tissue. The artery strip was then carefully transferred to another vial and incubated in KRB for a further 15 min, after which a 200-µL aliquot was taken and stored at -20°C for RIA of 6-keto-$PGF_{1\alpha}$. At the end of the incubation, aortic segments were removed, blotted on filter paper and weighed to obtain the 'wet weight,' then freeze-dried and reweighed to obtain the 'dry weight.'

FA composition of plasma and aorta PLs. Lipid extracts were prepared from plasma and thoracic aorta by chloroform/methanol extraction (14). Following separation of the PL from the neutral lipids by TLC in the solvent system hexane/diethyl ether/acetic acid (85:15:2, by vol), the PL FA were converted to their methyl esters (15). The concentration of component FA was then determined by gas–liquid chromatography on a 50 m x 0.32 mm fused silica capillary column coated with CP-SIL 88, using diheptadecanoyl phosphatidylcholine as an internal standard, as previously described (15).

Assessment of in vivo *prostacyclin production.* Endogenous prostacyclin production (PGI_2 and PGI_3) was determined by measuring the urinary levels of the major systemic metabolite of PGI_2, 2,3-dinor-6-keto-$PGF_{1\alpha}$ and its Δ^{17} analog from PGI_3. Both were measured by stable isotope dilution assay using negative ion chemical ionization GC/MS in the selected ion monitoring mode (SIM) as has been described previously (8,16–18).

In brief, urine samples were thawed and centrifuged (2000 g for 5 min), after which a 3-mL aliquot was spiked with 10 ng tetradeuterated [19,19,20,20-$^2H_4$]2,3-dinor-6-keto-$PGF_{1\alpha}$. The endogenous compound and the internal standard were then extracted and purified by sequential steps of column chromatography and TLC. The purified compounds were then derivatized to their

methyloxime pentafluorobenzyl ester form and purified by TLC. The derivatized sample was extracted from the silica gel and further derivatized to the trimethylsilyl ether with BSTFA/pyridine. It was then dried down under nitrogen and made up in 20 µL dodecane ready for GC/MS analysis (16).

The derivatized dinor metabolite of the dienoic prostacyclin (PGI_2) and the corresponding trienoic metabolite derived from PGI_3, were quantified simultaneously by GC/MS using SIM and monitoring m/z 586 for PGI_2-M and 584 for PGI_3-M and 590 for the tetradeuterated internal standard (19). Gas chromatography was performed on a Hewlett Packard 5890, operated in splitless mode with a 12 m x 0.22 mm BP-1 fused silica capillary column. Injector temperature was 250°C, interface temperature 260°C. The oven was kept at 190°C for 1 min, then heated to 300°C at a rate of 20°C/min, then held for a further 5 min. The carrier gas was helium at a column head pressure of 87 KPa. The gas chromatograph was interfaced to a Hewlett Packard 5988A single quadrapole mass spectrometer operated in negative ion chemical ionization mode with methane as the ionization gas. Source temperature was 100°C, electron energy 70 eV, emission current 300 mA and electron multiplier voltage 1889 V.

Statistical analyses. Differences between groups were established using analysis of variance in conjunction with multiple comparison tests. Dunnet's test was used for FA analyses and *in vitro* prostacyclin. Tukey's test was used for weight gain and food consumption. *In vivo* PGI_2 and PGI_3 production were assessed using paired *t*-test. The relationship between *in vitro* and *in vivo* prostacyclin production was established using Pearson's correlation coefficient. All statistical analyses were performed on Minitab Version 8 (Minitab Inc., State College, PA). Results were expressed as mean ± SEM, $P < 0.05$ for all significant changes, unless otherwise indicated.

RESULTS

There was no significant difference in energy consumption between any of the diet groups. Similarly there was no significant difference in weight gain between the groups in the first 14 d (7.0 ± 0.3 g/d), or during the second two-week period while receiving FA supplements (3.6 ± 0.2 g/d).

Supplementation of the high-fat diet with LA resulted in a significant decline in plasma PL 22:5n-3 and 22:6n-3, with no significant change in aortic PL FA, relative to the high-fat control group (Tables 1 and 2). AA supplementation resulted in significant decreases in plasma 18:2n-6, 20:3n-9, 20:3n-6 and 22:6n-3, while 20:4n-6 showed a significant increase. In aortic PL, 18:2n-6, 20:3n-9, 20:5n-3 and 22:6n-3 all fell, while 20:4n-6 increased significantly. EPA supplementation resulted in a significant decrease in 20:4n-6, while 20:5n-3 and 22:5n-3 increased in the plasma PL. The aortic PL of this group showed a significant rise in 20:5n-3 and 22:5n-3.

Supplementation of animals on the high-fat diet with LA showed a nonsignificant trend toward increased prostacyclin production by the abdominal aorta *in vitro* (Fig. 1). The groups supplemented with AA and EPA both showed significant increases in *in vitro* prostacyclin production, with the greatest increase in the AA-

[a]Rats were fed the high-fat diet for two weeks then supplemented with ethyl linoleate (LA), ethyl arachidonate (AA) or ethyl eicosapentaenoate (EPA) for a further two weeks.

[b]Significantly different from the high-fat control group ($P < 0.05$).

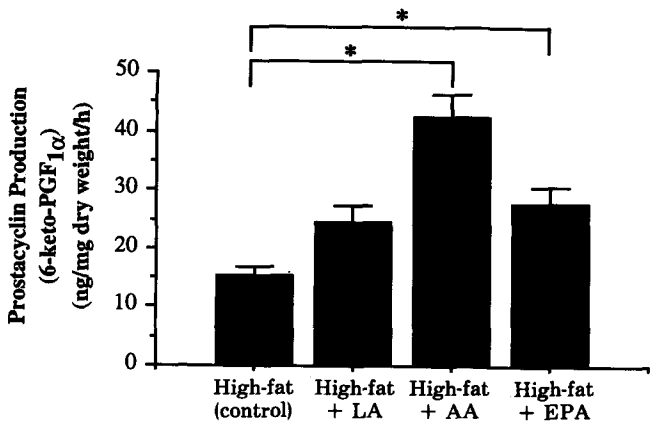

FIG. 1. *In vitro* aortic prostacyclin production in rats fed a high-fat diet and supplemented with fatty acids where indicated; measured as 6-keto-$PGF_{1\alpha}$; mean ± SEM. *Significant difference from the high-fat control diet ($P < 0.05$). Abbreviations: LA, linoleic acid (18:2n-6); AA, arachidonic acid (20:4n-6); EPA, eicosapentaenoic acid (20:5n-3).

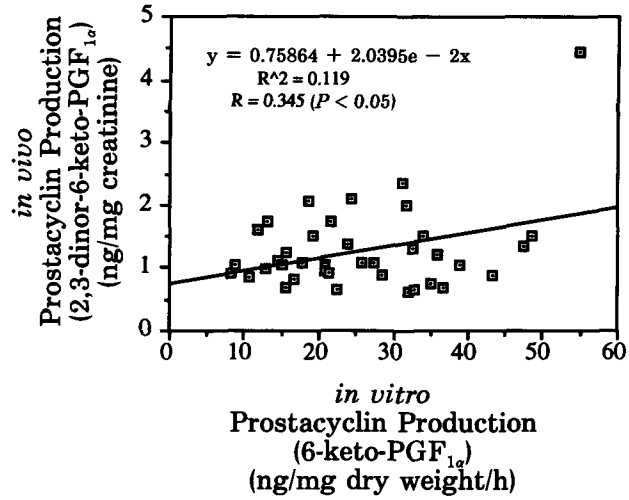

FIG. 2. Correlation of an radioimmunoassay measure of prostacyclin production *in vitro* by incubated aortic strips, with *in vivo* prostacyclin production, as measured by urinary metabolite level with gas chromatography/mass spectrometry; r = 0.345 ($P < 0.05$).

supplemented group representing a 2.8-fold increase over the high-fat control group.

Quantitative analysis was carried out for the two endogenous metabolites of prostacyclin (PGI_2-M or 2,3-dinor-6-keto-$PGF_{1\alpha}$ and PGI_3-M or Δ^{17}-2,3-dinor-6-keto-$PGF_{1\alpha}$) in each of the three dietary groups receiving FA supplements, with each group being their own control as they went from high-fat control diet to high-fat diet plus FA supplement (Table 3). AA supplementation significantly increased (66.7%, $P < 0.01$) the excretion of PGI_2-M, conversely PGI_2-M excretion was decreased significantly (60.0%, $P < 0.01$) by EPA supplementation. The PGI_3-M was significantly increased (100%, $P < 0.01$) by EPA supplementation. LA supplementation did not lead to an increase in the PGI_2-M production.

TABLE 3

The Effect of PUFA Supplementation on Production of Urinary PGI_2 and PGI_3 Metabolites as Determined by Gas Chromatography/Mass Spectrometry

Diet group[a]	PGI_2-M		PGI_3-M	
	Before	After	Before	After
High-fat (n = 10)	1.27 ± 0.13[b]		0.08 ± 0.02	
High-fat + LA (n = 10)	1.20 ± 0.12	1.13 ± 0.12	0.04 ± 0.01	0.04 ± 0.01
High-fat + AA (n = 8)	1.23 ± 0.12	2.05 ± 0.36[c]	0.05 ± 0.01	0.02 ± 0.01
High-fat + EPA (n = 9)	1.26 ± 0.15	0.80 ± 0.06[c]	0.05 ± 0.01	0.10 ± 0.01[c]

[a]Rats were fed the high-fat diet for two weeks then supplemented with ethyl linoleate (LA), ethyl arachidonate (AA) or ethyl eicosapentaenoate (EPA) for a further two weeks. Urine was collected before and after the two-week supplementation period. PUFA, polyunsaturated fatty acids; PGI, prostaglandin I.

[b]Values are means ± SEM (ng/mg creatinine).

[c]Significantly different from their own baseline ($P < 0.05$).

There was a significant positive correlation between the *in vitro* and *in vivo* methods for the determination of prostacyclin production (r = 0.345, $P < 0.05$) (Fig. 2). In addition, there was a significant positive correlation between the *in vivo* production of PGI_2-M and the AA level in aorta PL (r = 0.473, $P < 0.01$) and a significant negative correlation with the EPA level in the aorta PL (r = 0.411, $P < 0.05$).

DISCUSSION

In this study we found that dietary AA led to increases in plasma and aorta PL AA levels in the rat and that these changes were associated with an increase in both the *in vitro* and *in vivo* prostacyclin production. We have previously noted that dietary AA increases aorta PL AA levels and *in vitro* prostacyclin production; however, to our knowledge this is the first time that dietary AA has been shown to increase the production of PGI_2-M (which is considered to reflect the systemic production of prostacyclin) in any species. Falardeau and Martineau (20) found AA induced a fourfold increase in urinary PGI_2-M in rats when injected subcutaneously. These results are also in agreement with data from other groups who have shown that increased AA levels in aortic PL, achieved by manipulation of dietary LA and n-3 PUFA rather than by AA supplementation, were accompanied by increased *in vitro* prostacyclin production (21, 22).

The addition of AA to bovine arterial endothelial cells in culture leads to increases in eicosanoid production (23) presumably by increasing the substrate availability and reducing the level of competitor FA, such as EPA and DHA. This explanation may also be true in the *in vivo* situation in the rat since there was a significant positive correlation between the aorta PL AA level and the urinary PGI_2-M level and a significant negative correlation between the aorta PL EPA level and the urinary PGI_2-M level.

There was an 18% rise in the AA in the aorta PL; however, the increase in the production of prostacyclin was more than doubled in the *in vitro* assay and was increased by 67% in the *in vivo* assay. In order to account for this greater increase in prostacyclin production than the increase in the tissue AA levels, it is necessary to consider the likely pools of AA used for eicosanoid synthesis. Phosphatidylinositol and phosphatidylethanolamine are considered to be the reservoir of substrate (4) for eicosanoid synthesis, and it is possible that the AA supplementation results in a differential enrichment of AA in these particular PL. Alternatively, it has been suggested that the speed with which eicosanoids are produced from dietary AA and DHA indicates that the dietary PUFA may not have to be incorporated into tissue PL before being available as an eicosanoid precursor (24,25). Lands and others (24,26) have suggested that the likely pool is a nonesterified FA fraction.

Supplementation of the rats with the same amount of dietary LA as AA did not increase the plasma or aorta PL AA levels, nor did it alter the production of prostacyclin. It has been well established that dietary AA is a more effective precursor of tissue AA than is dietary LA in the rat (27). The reasons advanced for this difference are that AA is conserved better than LA, due to a lower rate of ß-oxidation and that LA is found in most lipid classes in tissues with only a fraction of that ingested available for conversion to AA (28). Knapp and Fitzgerald (18) have previously shown that LA supplementation (in the form of safflower oil) in humans did not increase the urinary output of 2,3 dinor-6-keto-$PGF_{1\alpha}$. This is presumably due to a failure of this dietary regime to significantly increase the tissue AA levels.

The dietary supplementation of the rats with 90 mg/d of EPA led to significant increases in the EPA level in plasma and aorta PL and to a significant reduction in AA levels in the plasma PL but not in the aorta PL. The level of urinary PGI_2-M decreased significantly following supplementation with EPA. Knapp and Salem (29) also obtained a decrease in PGI_2-M production following the dosing of rats with fish oil for 14 d, but the decrease was not significant, presumably due to the small number of animals used (n = 4). While there was no decrease in the AA level in the aorta PL in the present experiment, the decreased PGI_2-M may have been the result of a reduced availability of AA in a particular PL in the aorta, or as discussed above from the nonesterified FA pool used for eicosanoid synthesis. This result supports previous *in vitro* studies (3,30,31) and the suggestion by Needleman *et al.* (6) that EPA competitively inhibits AA metabolism by cyclooxygenase. However, it is not consistent with the results of Fischer and Weber (32), Knapp *et al.* (19) and Fischer *et al.* (25), who found no decrease in urinary PGI_2-M levels in humans fed diets rich in fish oil or purified n-3 PUFA. There is no immediate explanation for these contradictory findings; however, they may be the result of differences in eicosanoid metabolism between species, or the form in which the EPA was administered, or the dose rate. It should be noted that in the latter study of Fischer *et al.* (25) there was a substantial variation in response between individuals (2 increased, 4 decreased). The EPA supplementation led to a small but significant increase in urinary PGI_3-M, which is consistent with the data of Knapp and Salem (29) who fed fish oil (9% wt/wt) to rats for 14 d.

The *in vitro* prostacyclin production by arterial strips in the group supplemented with EPA exhibited a significantly increased prostacyclin production, although this was less marked than with AA supplementation. Other groups feeding fish oil or EPA in the free acid form have obtained significant decreases in *in vitro* prostacyclin production by rat aorta (30,33); however, Hamazaki *et al.* (34) also fed EPA to rats as the ethyl ester and found an increase in the production of prostacyclin by aortic rings using a bioassay method. The mechanism of increase in *in vitro* prostacyclin by ethyl ester of EPA has not been determined, but may be accounted for by the fact that the aortic PL 20:4n-6 level was unchanged and the 20:5n-3 was significantly increased. Thus together this could lead to an increase in total prostacyclin production, due to unaltered PGI_2 production coupled with increased PGI_3 production. It is highly unlikely that the antibody used in this RIA technique is capable of differentiating between the PGI_2-stable metabolite, 6-keto-$PGF_{1\alpha}$ and its PGI_3 analog Δ^{17}-6-keto-$PGF_{1\alpha}$. It is also possible that this is an artificial result observed after feeding the ethyl ester of EPA, but not present when fish oils or free acid form of EPA is used. We conclude that increased levels of tissue 20:5n-3 have different effects on the *in vivo* systemic production of prostacyclin and the *in vitro* production by arterial tissue in this rat model. In humans, DeCaterina *et al.* (35) found increased 6-keto-$PGF_{1\alpha}$ production *ex vivo* in arterial tissue from patients taking fish oil, following coronary bypass surgery.

The data presented here show that there is a significant positive correlation between the two methods for determination of prostacyclin, namely the *in vitro* production of 6-keto-$PGF_{1\alpha}$ by arterial preparations and the *in vivo* prostacyclin production as measured by the urinary level of one of the main prostacyclin metabolites in the rat (2,3-dinor-6-keto-$PGF_{1\alpha}$). In both methods, there is considerable variation between animals within the one dietary group. The *in vitro* method may have an inherent variability due to the procedures involved in obtaining the arterial strips from each animal and the possibility of having different proportions of endothelial cells and smooth muscle cells between preparations. In the case of the *in vivo* assay, this variation can be overcome to some extent since it is possible to measure the PGI_2-M levels before and after treatment.

Finally our results suggest that the systemic prostacyclin levels closely parallel aorta PL 20:4n-6 levels and that EPA reduces AA conversion to PGI_2 by cyclooxygenase *in vivo*, but not in aortic tissue *in vitro* in the rat. Future studies will be aimed at examining the effect of these dietary treatments on the systemic levels of thromboxane using similar GC/MS methodology. The potential physiological consequences of these dietary changes can be assessed when we have data on both these eicosanoids.

ACKNOWLEDGMENTS

The authors are grateful to Andrew Sanigorski and Leeann Johnson for their skilled technical assistance, advice and support throughout the study. This work was supported by grants from the

Meat Research Corporation, Australia and by NIH grants HL-48827 and HL-49264. Dr. Knapp is an Established Investigator of the American Heart Association.

Characterization of Calcium-Independent Cytosolic Phospholipase A_2 Activity in the Submucosal Regions of Rat Stomach and Small Intestine

Takeshi Fukushima and **Ginette Serrero***

W. Alton Jones Cell Science Center, Lake Placid, New York 12946

This study was undertaken to compare the calcium-independent phospholipase A_2 (PLA_2) activities in the cytosols of twelve rat tissues and to determine whether their activities were distinct. 1-*O*-Alk-1'-enyl-2-[^{14}C]-oleoyl-*sn*-glycero-3-phosphocho-line (PlsC) and 1-*O*-Alk-1'-enyl-2-[^{14}C]oleoyl-*sn*-glycero-3-phosphethanolamine (PlsE) were synthesized and used as substrates, instead of phosphatidyl compounds, to exclude hydrolysis by cytosolic PLA_1 activity that could be present in some of the cytosolic preparations. For each tissue, we examined substrate specificity, pH optimum, and effect of adenosine triphosphate (ATP) and ATP analogues. PLA_2 activity was detected in eleven out of the twelve issues examined. Based on substrate specificity and pH optimum, cytosolic calcium-independent PLA_2 were classified in three groups. The first group, which included PLA_2 from small intestine, stomach and spleen, had the highest specific activity with PlsC as substrate (1253, 309 and 75 nmol/mg protein/hour, respectively) and an optimal pH at 6.5. Activity with PlsE as substrate was much lower (20–37%) than with PlsC. The second group of PLA_2 activities included the cytosolic activities from thymus, lung, liver and pancreas that showed lower specific activities for both substrates (14–23 nmol/mg protein/hour with PlsC) and had a broader optimal pH range of 6.1 to 7.5. The cytosols from brain, kidney, heart and muscle comprised the third PLA_2 group that was found to have a higher specific activity with PlsE (5–20 nmol/mg protein/hour) than PlsC and an optimal pH range from 7.4 to 7.9. Since the highest specific activity was found in the cytosol from small intestine, this PLA_2 was examined further. PLA_2 activity was found to be equally distributed in the cytosol of the submucosal portion of duodenum, jejunum and ileum with an optimal pH of 6.1 and a 5-fold higher activity with PlsC than PlsE as substrate. Moreover, this PLA_2 activity was inhibited by treatment with detergents. These results indicate the presence in the submucosal portion of the intestine of a calcium-independent cytosolic PLA_2 with a high specific activity toward PlsC and properties distinct from those described for the PLA_2 found in the intestinal brush-border.

***Lipids* 29, 163–169 (1994).**

Phospholipase A_2 (PLA_2) catalyzes the hydrolysis of the acyl group at the *sn*-2 position of glycerophospholipids. PLA_2 plays an important role in phospholipid catabolism and in the remodeling of the acyl groups of phospholipids in general. In addition, intracellular phospholipase A_2 plays an important role in the release of arachidonic acid, which is the precursor for metabolites of the cyclooxygenase and lipoxygenase pathways (1). Although several types of PLA_2 have been purified from various tissues or biological fluids and cloned, most of them are Ca^{2+} dependent. Type I and type II secreted 14 kDa phospholipases A_2 have been extensively studied in many laboratories. Recently, cDNA encoding a calcium-dependent 85 kDa PLA_2 was cloned (2,3). In addition to these calcium-dependent PLA_2, reports in the literature are pointing to the existence of calcium-independent PLA_2 in a wide variety of animal tissues (4–20), including guinea pig intestine, hamster, dog and human hearts, bovine brain and rat parotid gland. However, a systematic evaluation of the activities between tissues has not been carried out except for the study by Pierik *et al.* (19). This has made the comparison of PLA_2 activity from various tissues difficult since the nature and presentation of the substrates, pH and composition of the buffers can influence enzymatic activity measurements.

In the present study, systematic experiments were carried out to evaluate the calcium-independent PLA_2 activity in the cytosols of twelve different rat tissues using plasmalogens as substrates. The purpose of these experiments was to identify tissues containing high calcium-independent PLA_2 specific activity and to characterize these activities in the various tissues with respect to substrate specificity, pH optimum and response to inhibitors. The data presented here also show the presence in small intestine cytosol of a calcium-independent PLA_2 with high specific activity. Since calcium-independent PLA_2 activity has been previously observed in ileal brush border (10,11), the activity detected here in the small intestine cytosol was further examined. Evidence for differences between the PLA_2 in the intestinal cytosol and that in the intestinal brush-border membrane is also provided.

MATERIALS AND METHODS

Substrates. 1-*O*-Alk-1'-enyl-2-[^{14}C]oleoyl-*sn*-glycero-3-phosphocholine (plasmenylcholine, PlsC) and 1-*O*-alk-1'-enyl-2-[^{14}C]oleoyl-*sn*-glycero-3-phosphoethanolamine (plasmenylethanolamine, PlsE) were prepared in our laboratory according to the procedure of Paltauf and Hermetter (21). The specific radioactivity of these plasmalogens was 0.5 mCi/mmol. Plasmalogens containing 2-[^{14}C]arachidonoyl instead of 2-[^{14}C]oleoyl were also synthesized. Similarly, nonradioactive PlsC and PlsE and plasmalogens containing the 2-arachidonoyl moiety in the *sn*-2 position instead of 2-oleoyl were synthesized.

Abbreviations: AMP-PCP, adenosine-5'(β,γ,methylene)triphosphate; AOG, 1-*O*-alk-1'enyl-2-[^{14}C]oleoyl-*sn*-glycerol; AOGP, 1-*O*-alk-1'-enyl-2-[^{14}C]oleoyl-*sn*-glycero-3-phosphate; ATP, adenosine triphosphate; ATPγS, adenosine 5'-*O*-(3-thio)triphosphate; CHAPS, 3-[(3-cholamidopropyl)-dimethylannonio]-1]propanesulfonate; DTNB, 5,5'-dithio*bis*(2-nitrobenzoic aicd); HPLC, high-performance liquid chromatography; PLA_2, phopholipase A_2; PlsC, plasmenylcholine, 1-*O*-alk-1'-enyl-2-oleoyl-*sn*-glycero-3-phosphcholine; PlsE, plasmenylethanolamine, 1-*O*-alk-1'-enyl-2-oleoyl-sn-glycero-3-phosphoethanolamine; TLC, thin-layer chromatography.

1-*O*-Alk-1'-enyl-2-[^{14}C]oleoylglycerol (AOG) and 1-*O*-alk-1'-enyl-2-[^{14}C]oleoylglycerophosphate (AOGP) were prepared from [^{14}C] PlsC by incubation with phospholipase C and phospholipase D, respectively, and subsequent purification by thin-layer chromatography (TLC).

Preparation of tissue cytosols. Male Sprague-Dawley rats (3-month-old) were subjected to ether anesthesia and killed by exsanguination. Tissues were excised and rinsed with a chilled saline solution. Each tissue was weighed, minced and homogenized on ice with a glass homogenizer or a Polytron (Brinkmann Instruments, Westbury, NY) in 2 or 3 vol of extraction buffer (0.25 M sucrose, 10 mM imidazole and 10 mM KCl at pH 7.5) containing a cocktail of protease inhibitors (0.1 mM phenylmethylsulfonyl fluoride, 1 μg/mL leupeptin and 1 μg/mL pepstatin). Homogenates were centrifuged at 14,000 × *g* for 20 min, and the supernatants were then ultracentrifuged at 105,000 × *g* for 60 min. The final supernatant cytosolic fractions were prepared and used either immediately or after being stored at -70°C.

Preparation of mucosal and submucosal fractions from small intestine. Rat small intestine was rinsed by perfusion with cold saline containing the protease inhibitor cocktail described above. The intestine was then divided into duodenum, jejunum and ileum. Each portion was slit open on a chilled plate. Mucosa was collected by gentle scraping with a spatula and then was homogenized in 2 mL of the extraction buffer. The homogenate was ultracentrifuged at 105,000 × *g*, and the supernatant representing the mucosal cytosolic fraction was collected. The particulate fraction corresponding to the brush border fraction was treated with 1.5 mL of 1% Triton X-100 (10) for 30 min at 0°C. The mixture was centrifuged at 14,000 × *g* for 20 min, and the supernatant (solubilized brush-border membranes) was collected. After removal of mucosa, the remaining intestinal portion corresponding to the submucosa was homogenized as described above. Homogenate was centrifuged at 105,000 × *g* and the supernatant, corresponding to the submucosal cytosol, was used in the experiments.

Assay of PLA_2 activity using radiolabeled plasmalogens as substrates. PLA_2 activity was measured by the method of Dole and Meinertz (22), with slight modification, using radiolabeled PlsC and PlsE as substrates. Substrates were dispersed by sonication for 10–20 s in 0.5% Triton X-1000. The assay mixture (100 μL) consisted of a 2-fold dilution of a 100 mM wide range pH buffer (23) with 5 mM ethylenediaminetetraacetic acid, 5 mM ethyleneglycol-*bis*(β-aminoethylester)*N,N,N',N'*-tetraacetic acid, 0.125% Triton X-100, 40–45 nmol of the substrate (0.5 mCi/mmol) and the enzyme solution. Prior to performing the assay, the pH of the reaction mixture was measured in the absence of substrate. After incubation at 37°C for 7.5–60 min, liberated [^{14}C]oleic acid was isolated and measured by liquid scintillation counting. The incubation time for each cytosol was chosen so that more than 85% of the substrate remained at the end of the incubation period.

Analysis of reaction products by TLC. In some experiments, in addition to PlsC and PlsE, radiolabeled AOG and AOGP were used as substrates. At the end of the incubation period, to the reaction mixture (100 μL) was added 2 mL of chloroform/methanol (2:1, vol/vol) and 0.4 mL of water. The lower chloroform phase was collected, and the upper phase was re-extracted twice with 1 mL portions of the chloroform/methanol mixture. The combined extracts were washed twice with 1 mL of aqueous methanol (1:1, vol/vol) and dried. The residue was resolved by TLC using chloroform/methanol/ammonia (60:35:3, by vol) as solvent, and analyzed by autoradiography. Fractions were scraped from the plates and counted in a liquid scintillation counter.

Assay of PLA_2 activity by high-performance liquid chromatography (HPLC). The composition of the assay mixture was the same as that used in the standard assay except that nonradiolabeled substrate was used. At the end of the incubation at 37°C, the reaction mixture was extracted by the Dole and Meinertz procedure (22), and 1 mL of the heptane phase was dried. the residue was phenacylated (24) and analyzed by HPLC on a reverse-phase C18 column (5 m, 4.6 × 250 mm, 218TP; Vydac, The Nest Group, Southboro, MA). The reaction products were eluted isocratically with 90% acetonitrile in water containing 0.1% trifluoroacetic acid at a flow rate of 1 mL/min. The retention times for the derivatives of arachidonic acid and oleic acid were 10 and 20 min respectively.

Protein determination. Protein concentration was measured by the Bradford method (Bio-Rad, Richmond, CA) using bovine serum albumin as standard.

RESULTS AND DISCUSSION

Presence of Ca^{2+}-independent PLA_2 in rat tissue cytosols. The Ca^{2+}-independent PLA_2 activity was examined in the cytosols of twelve tissue extracts. Activity was determined at various pH values (from pH 5 to 9) using PlsC and PlsE as substrates. PLA_2 activity was detected in each of the cytosols except in that from the submaxillary gland. The PLA_2 specific activities in the eleven tissue cytosols and their optimal pH values or optimal pH ranges are shown in Table 1. The highest PLA_2 specific activity was observed in the cytosol from small intestine, followed by stomach and spleen. Based on the pH-activity curves of PLA_2 and the specific activities measured with both PlsC and PlsE, the PLA_2 activities of the eleven cytosols can be divided into three groups. The first group included the cytosolic PLA_2 from intestine, stomach and spleen that exhibited sharp activity peak at about pH 6.5 with PlsC as substrate (Fig. 1A). Their activities towards PlsE were 64–81% lower than the ones obtained with PlsC (Fig. 1A). The second group included the cytosolic PLA_2 from lung, thymus, liver and pancreas. It also showed higher activities toward PlsC than PlsE, but the difference in activities between the two substrates was only about 2-fold. In addition, the optimal pH value for this group of cytosolic PLA_2 was about 6.5. However, the pH-activity representation for the second group showed broad peaks between 6.0 and 7.0, especially with PlsE as substrate. The third group included the cytosolic PLA_2 from brain, kidney, heart and skeletal muscle. This group was characterized by

TABLE 1

Phospholipase A_2 (PLA_2) Activity and pH Optimum in Eleven Rat Tissue Cytosols[a]

	Plasmenylcholine (PlsC)		Plasmenylethanolamine	
Tissue	pH Optimum	PLA_2 activity (nmol/mg protein/hour)	pH Optimum	PLA_2 activity (nmol/mg protein/hour)
Intestine	6.5 (6.5)	1253 ± 70	6.5 (6.5)	241 ± 8.3
Stomach	6.5 (6.5)	309 ± 40	6.5 (6.5)	79.3 ± 2.0
Spleen	6.1 (6.1)	75.4 ± 9.5	6.1 (6.1)	27.7 ± 3.9
Lung	6.2–7.5 (7.2)	23.2 ± 1.6	6.2–7.5 (7.2)	17.2 ± 0.8
Thymus	5.9–7.5 (6.3)	16.3 ± 2.6	5.9–7.5 (6.3)	6.8 ± 0.4
Liver	6.1–6.9 (6.5)	16.3 ± 0.8	6.1–7.9 (6.5)	8.3 ± 0.3
Pancreas	6.1–6.8 (6.4)	14.2 ± 1.8	6.1–7.8 (6.4)	8.5 ± 0.4
Brain	6.3–8.5 (7.9)	11.9 ± 0.8	6.3–8.5 (7.9)	19.7 ± 0.5
Kidney	6.0–8.3 (7.4)	9.6 ± 0.7	6.8–8.3 (7.4)	14.9 ± 0.4
Heart	5.5–7.8 (7.8)	5.5 ± 0.2	6.2–8.3 (7.8)	9.3 ± 0.9
Muscle	5.7–8.0 (7.5)	2.9 ± 0.1	6.6–8.5 (7.5)	4.7 ± 0.1

[a]Activity was measured by the Dole and Meinertz assay (Materials and Methods) in the presence of 1 mM adenosine triphosphate and 1 mM dithiothreitol using radiolabeled PlsC and PlsC as substrates. Measurements were done at various pH values as described in Materials and Methods and in Figure 1. Broad pH optima are shown as ranges. Values of activity are expressed in nmol/mg protein/hour and correspond to the mean ± SD from four determinations at the optimal pH indicated in parentheses.

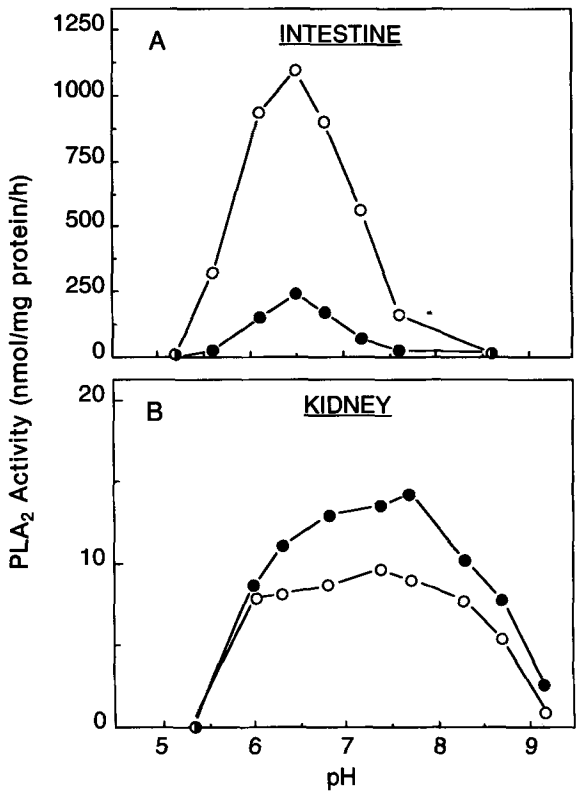

FIG. 1. The pH optimum of phospholipase A_2 activity of cytosols from intestine and kidney. Activity was measured by the Dole assay (Materials and Methods) using plasmenylcholine (PlsC) (○) and plasmenylethanolamine (PlsE) (●) as substrates. Each reaction mixture contained 1 mM adenosine triphosphate and 1 mM dithiothreitol. A. Cytosol of small intestine, 80 μg of protein was incubated for 7.5 min with PlsC and 15 min with PlsE. B. Cytosol of kidney, 525 μg of protein ws incubated for 60 min with either one of the substrates. Each point is the mean of duplicate analysis.

higher activities toward PlsE than PlsC (about 2-fold) at essentially all pH tested. As illustrated for the kidney cytosol (Fig. 1B), the pH-activity curves for this group showed broad peaks between pH 6 and 8.5. The Ca^{2+}-independent PLA_2 activities in the cytosols from rat kidney, heart, pancreas, spleen liver, lung and brain have been detected previously (19). However, the specific enzymatic activities we found in our assays were from 4-fold higher for brain to 96-fold higher for spleen than those reported previously (19). These differences could be attributed to the differences in assay conditions, such as pH, buffer composition, preparation and the nature of substrates. In addition, the data in Table 1 show the presence of PLA_2 activities in the cytosols from small intestine, stomach, thymus and skeletal muscle that had not been described previously.

The PLA_2 activities given above were obtained by measuring the release of radiolabeled oleic acid from the *sn*-2 position of the substrates. Since the assay was done with cytosolic extracts, additional experiments were carried out to determine whether the release of radiolabeled oleic acid resulted from the direct action of PLA_2 only or whether other enzymes present in the cytosols indirectly contributed to this activity. We therefore used two other substrates, namely AOG and AOGP, in addition to PlsC and PlsE. At the end of the incubation time, the reaction mixtures were extracted and analyzed by TLC. The results obtained with the cytosols from intestine and kidney are shown in Figure 2. The TLC analysis of reaction mixture obtained by incubating intestinal cytosol (80 μg protein) with PlsC (45 nmol) is shown in lane 1 of Figure 2A. In this case, about 25% of the radioactivity of the substrate was recovered as oleic acid (11 nmol), and little radioactivity was recovered from fractions corresponding to AOG or AOGP. When AOG (12 nmol) or AOGP (8 nmol) were incubated with the same amount of intestinal cytosol, little release of

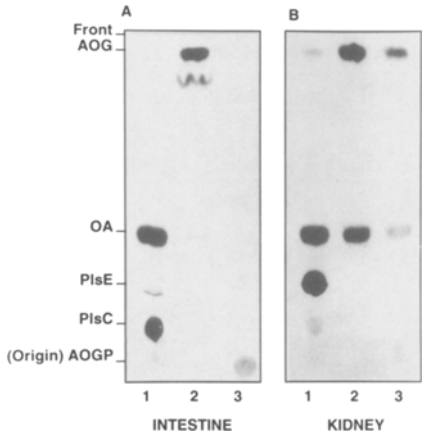

FIG. 2. Thin-layer chromatography (TLC) analysis of the reaction products obtained by incubating tissue cytosols with different radiolabeled substrates. A. 80 μg of intestinal cytosol extract was incubated for 7.5 min at 37°C with either 45 nmol of [^{14}C]PlsC (lane 1), 12 nmol of [^{14}C]1-*O*-alk-1'-enyl-2-[^{14}C]oleyl-*sn*-glycerol (AOG) (lane 2) or 8 nmol of [^{14}C]1-*O*-alk-1'-enyl-2-[^{14}C]oleyl-*sn*-glycero-3-phosphate (AOGP) (lane 3). B. 525 μg of kidney cytosolic extract was incubated for 60 min at 37°C with either 45 nmol of [14C]PlsE (lane 1), 12 nmol of [14C]AOG (lane 2) or 8 nmol of [14C]AOGP (lane 3). At the end of the incubation period, reaction products were extracted and separated by TLC on a silica gel plate as described in Materials and Methods. Products were analyzed by autoradiography on the plate. Fractions were also scraped from the plates and counted in a scintillation counter. The minor band in lane 1 at the position of PlsE (panel A) corresponds to a contamination. The identity of the fraction below AOG in lane 2 (panel A) is unknown; OA, oleic acid. See Figure 1 for other abbreviations.

radiolabeled oleic acid was observed (lanes 2 and 3 of Fig. 2A). In the case of kidney cytosol (525 μg protein), 8 nmol of oleic acid was produced from PlsE (45 nmol), 4 nmol from AOG (12 nmol) and 1 nmol from AOGP (8 nmol), respectively (lanes 1–3, Fig. 2B). In contrast to intestinal cytosol, kidney cytosol released relatively large amounts of oleic acid from AOG and converted most of AOGP to AOG. However, in both cases, little accumulation of AOG and AOGP was observed when PlsC or PlsE was used as substrate. Radioactivity was only recovered in the AOG or AOGP fraction when AOG and AOGP themselves were used as substrates, indicating that no hydrolysis took place under these conditions. The results suggest that the release of oleic acid in the presence of the cytosolic extract from intestine or kidney did not take place *via* formation and subsequent hydrolysis of AOG and AOGP but rather directly from the plasmalogens. Similar results were obtained from these analyses that were carried out with the cytosolic extracts from brain, stomach, spleen and liver (data not shown). Thus, the radiochemical method used in this work appears appropriate for measuring PLA_2 activity in rat tissue cytosols.

*Effects of ATP and 5,5'Dithio*bis*(2-nitrobenzoic acid) (DTNB).* In a preliminary investigation we found that ATP and dithiothreitol increased PLA_2 activity of kidney cytosol. Therefore, we examined the effects of ATP, adenosine 5'-*O*-(3-thio)triphosphate (ATPγS) and DTNB on PLA_2 activity of eleven cytosols. All cytosolic fractions examined lost 10 to 40% of their PLA_2 activities in the absence of ATP when PlsE served as substrate

TABLE 2

Effects of ATP and ATPγS on Phospholipase A_2 Activity of Tissue Cytosols[a]

[a]Activity was measured by the Dole and Meinertz assay (Ref. 22); the complete reaction system contained 1 mM adenosine triphosphate (ATP) and 1 mM dithiothreitol in the standard mixture (Materials and Methods). Assays for each cytosol were carried out at the optimal pH used for activity measurement as in Table 1. Each data point is the mean ± SD of duplicate analyses and expressed as percent of the activity of each complete system. Specific activity of the complete system of each cytosol was essentially the same as that given in Table 1.

[b]Adenosine 5'-*O*-(3-thio)triphosphate (ATPγS) was added at 1 mM.

[c]Not measured.

[a]Phospholipase A_2 (PLA_2) activity was measured with unlabeled substrates. At the end of the incubation period, reaction products were extracted and analyzed by high-performance liquid chromatography as described in Materials and Methods. Each data point is the mean ± SD of duplicate analyses and expressed as nmol/mg protein/hour.

(Table 2). Activity was mostly restored to the level observed with ATP by addition of ATPγS. In the case of intestinal cytosol, ATPγS gave a much higher PLA_2 activity than ATP. When PlsC was used as substrate, omission of ATP resulted in a smaller decrease than when PlsE was used. It is not clear whether or not these results point toward the presence of two types of PLA_2. Similar or slightly lower activities were observed in the presence of adenosine-5'(β,γ-methylene)triphosphate (AMP-PCP) instead of ATP or ATPγS. The fact that AMP-PCP is as efficient as ATP and ATPγS in activating or stabilizing PLA_2 in the presence of high concentrations of chelators would indicate that the phosphorylation or hydrolysis of ATP is not involved in the increase of PLA_2 activity with ATP.

According to Hazen *et al.* (14,15), Ca^{2+}-independent PLA_2 of myocardial cytosol is stimulated and stabilized by ATP, AMP-PNP and ATPγS. As similar stimulation or stabilization effect of ATP on PLA_2 activity was observed in rat parotid gland (18) and in an adipogenic cell line (Fukushima and Serrero, submitted for publication). Our present results suggest that modulation of Ca^{2+}-independent PLA_2 by ATP is not specific for cardiac PLA_2 and also occurs in other tissues (Table 2).

The effect of DTNB on PLA_2 activity was also examined. DTNB (0.1 mM) inhibited by 78 to 98% cytosolic PLA_2 activity in ten of eleven tissues studied. Liver cytosolic PLA_2 activity was not inhibited by 0.1 mM DTNB, but complete inhibition was observed with 1 mM DTNB. In our studies, rat lung cytosolic PLA_2 was completely inhibited by DTNB. However, a DTNB-insensitive PLA_2 has also been purified from rat lung cytosol (6). These data suggest that similar to Ca^{2+}-independent PLA_2 of the myocardial cytosol (15), PLA_2 in most rat tissue cytosols assayed requires the presence of intact thiol(s) for activity.

Substrate specificity of PLA_2 activity. PLA_2 activities from six tissues that represented each of the three PLA_2 groups previously defined were measured by HPLC using 2-oleoyl and 2-arachidonoyl PlsC and PlsE as substrates (Table 3). None of the cytosolic extracts examined showed higher activities with 2-arachidonoyl species of either of the plasmalogens compared to the 2-oleoyl species. By contrast, it has been previously reported that calcium-independent PLA_2 from myocardium, which is stabilized by ATP, showed a 2-fold higher activity for plasmalogens containing arachidonoyl instead of oleoyl in the 2-position (15).

Further examination of PLA_2 activity in rat small intestine and stomach. A Ca^{2+}-independent PLA_2 activity had previously been detected and partially characterized in the brush border of rat and guinea pig ileum (10,11). This PLA_2 activity had an alkaline pH optimum, was localized in the brush border, was solubilized with endogenous proteinases (10) and was activated by bile salts and by 1% 3-[(3-cholamidopropyl)dimethylammonio]-1-propanesulfonate (CHAPS) (10,11). Based on these characteristics, this PLA_2 activity was assumed to play a role in lipid digestion. Therefore, the PLA_2 activity that we detected in the small intestine was further characterized, and its properties were compared to those of ileal brush border PLA_2. Rat small intestine was divided into the duodenum, jejunum and ileum, and PLA_2 activity was measured in the cytosols of the submucosa and the mucosa and also in the solubilized brush-border membranes of each portion. In all samples, activity was measured with PlsC and PlsE as substrates, at pH 6.5 or pH 8.5, and in the absence or in the presence of CHAPS. As illustrated in Table 4, the submucosal cytosols from the three small intestine regions showed high PLA_2 activities when assayed with PlsC at pH 6.5, indicating this PLA_2 activity is not localized in one particular region of the small intestine. In the three cases, only 15–25% of the activity was observed with PlsE as substrate when compared with PlsC. Very little activity was detected at pH 8.5 with either of the substrates. The activity of the cytosols was fully inhibited with 1% CHAPS. Deoxycholate (0.2%) also inhibited the activity of the cytosols (data not shown). The mucosa cytosols from the duodenum and jejunum showed activity patterns similar to those of the submucosal cytosols although the specific activities were 60% lower. However, the cytosol of ileal mucosa was found to be different. In the absence of CHAPS, PLA_2 activity measured with PlsC as substrate was high at pH 6.5 and very low at pH 8.5; with PlsE, low activity was observed at both pH. In

TABLE 4

PLA_2 Activity in Rat Small Intestine[a]

	PLA_2 activity (nmol/mg protein/hour)

Ileum	111	682	87	837	50	753	52	854

[a]Rat small intestine was divided into duodenum, jejunum and ileum. Mucosa was separated from submucosa, and brush-border membranes were prepared according to the procedure described in Materials and Methods. Phospholipase A_2 (PLA_2) activity was measured with 1 mM adenosine and 1 mM dithiothreitol using PlsC and PlsE at pH 6.5 and 8.5 without (–) or with (+) 1% 3-[3-cholamidopropyl)dimethylammonio]-1-propanesulfonate (CHAPS). Values are expressed as nmol/mg protein/hour.

the presence of CHAPS, activity toward PlsC was decreased by more than 50% at pH 6.5 but was increased more than 7-fold at pH 8.5. With PlsE as substrate, activity increased in the presence of CHAPS and was similar to that obtained with PlsC at both pH. The solubilized brush-border membrane fraction of the ileum showed high activity with both substrates only in the presence of CHAPS, and the activity was slightly higher at pH 8.5 than 6.5. In this case, little difference in activities was seen with PlsE and PlsC as substrates. The results shown in Table 4 indicate that the calcium-independent cytosolic PLA_2 described here is preferentially distributed in the submucosa of all three portions of the intestine. In contrast, CHAPS-activated PLA_2 is localized mainly in the ileal brush-border membranes and appears to be similar to the PLA_2 already reported by Pind and Kuksis (10).

In summary, submucosal cytosolic PLA_2 has a very narrow pH optimum at pH 6.5, is inhibited by CHAPS and deoxycholate and its specific activity toward PlsC is much higher than that toward PlsE. By contrast, brush border PLA_2 has a broad pH optimum, requires CHAPS for full activity and shows little substrate selectivity between PlsC and PlsE. This indicates that the PLA_2 activity found in cytosol of submucosa of the small intestine has properties that are distinct from those of the brush-border PLA_2 described previously.

Since high PLA_2 activity was also detected in the stomach (Table 1), its distribution was examined. Cytosol prepared from the submucosa of the stomach showed a slightly higher activity than cytosol from the mucosa (330 *vs.* 230 nmol/mg protein/hour). As observed with PLA_2 from small intestine, PLA_2 activity from stomach was fully inhibited with 0.2% deoxycholate (data not shown).

The data presented here demonstrate the presence of calcium-independent PLA_2 activities in eleven of the twelve rat tissues cytosols examined suggesting that cytosolic calcium-independent PLA_2 is quite ubiquitous. Based on specific activity, substrate specificity and pH optimum, we divided these PLA_2 into three classes, each with different properties. At this point our data do not allow us to conclude that this classification reflects the existence of various isoforms of calcium-independent PLA_2 in different tissues, as this diversity could equally reflect the heterogeneous nature of the membrane lipid constituents in the different tissues serving as natural PLA_2 substrates. A more detailed characterization of the PLA_2 activities in the different tissues will be necessary to determine whether these activities correspond to different molecular species or PLA_2 isoforms or are due to the variation in sample composition. Recently, the existence of two isoforms of calcium-independent PLA_2 has been reported in human myocardium (25). One form with a pH optimum of 7.0 is the major form and has a preference for arachidonoyl plasmalogens, whereas the other form, which is a minor form, has an optimum pH of 8.5 and hydrolyzes other phospholipids as well as plasmalogens. In addition, two distinct types of calcium-independent PLA_2 have been characterized from bovine brain cytosol (26).

The data reported here are also of interest because they demonstrated the presence of a calcium-independent PLA_2 with a high specific activity in mucosal and submucosal fractions of small intestine, which has different properties from the brush border PLA_2 character-

ized previously (10,11). The role of this cytosolic PLA_2 is not clear. Various prostaglandins are synthesized in the stomach and intestine, and it is known that these organs are highly sensitive to prostaglandins (27,28). To date, the release of arachidonic acid for prostaglandin synthesis has mainly been attributed to calcium-dependent cytosolic PLA_2 activity (2). However, a recent report showed that calcium-independent PLA_2 mediated the hormonally-induced release of arachidonic acid in aortic smooth muscle cells (29). PLA_2 activities so far characterized in the gastrointestinal tract include group I PLA_2 in the gastric mucosa, group II PLA_2 and calcium-independent PLA_2 present in secretory glands and in brush-border membranes (30–32). Based on their location, all these PLA_2 activities appear to function extracellularly. Yet, the cytosolic intestinal PLA_2 described here appears to be different. Although this PLA_2 is not arachidonic acid-specific, its role could be to supply fatty acid, including arachidonic acid within tissues. Since the PLA_2 activity in the intestine was very high, this PLA_2 may play an important role in intracellular lipid metabolism in this tissue. Moreover, our data indicate that submucosal portions of the intestine appear to be adequate sources for the further characterization of this PLA_2.

ACKNOWLEDGMENTS

The Reaction of Low Levels of Nitrogen Dioxide with Methyl Linoleate in the Presence and Absence of Oxygen

Aris A. Gallon and **William A. Pryor***

Chemistry Department and the Biodynamics Institute, Louisiana State University, Baton Rouge, Louisiana 70803

The reaction of methyl linoleate with low levels of nitrogen dioxide in a carrier gas, such as helium or air, at nitrogen dioxide concentrations ranging from 2 to 228 ppm was studied and the products formed were monitored. In both aerobic and anaerobic conditions, low concentrations of nitrogen dioxide reacted with methyl linoleate predominately to form allylic products. When a 1:1 mixture of methyl palmitate/methyl linoleate was layered over an aqueous buffer and a nitrogen dioxide stream was passed from underneath, so that the stream passed through the aqueous layer before contacting the organic layer, allylic products again predominated. In the absence of air, the allylic products consisted of allylic nitro and nitrite derivatives of linoleate, whereas in the presence of air, allylic hydroperoxides were the principal products. The findings suggest that fatty acids with doubly allylic hydrogen atoms react preferentially by a hydrogen atom abstraction reaction rather than by the addition of nitrogen dioxide to a double bond.
***Lipids* 29, 171–176 (1994).**

Nitrogen dioxide has been shown to initiate the autoxidation of unsaturated fatty acids both *in vivo* and *in vitro* (1–6). The oxidation of lung lipids is thought to be involved in the pathology caused by the inhalation of nitrogen dioxide-containing polluted air (1–6), which includes diseases such as pulmonary edema, bronchitis, pulmonary fibrosis and perhaps cancer (7–9). We have previously shown that low concentrations of nitrogen dioxide react with cyclohexene predominantly by a hydrogen atom abstraction mechanism rather than by the addition mechanism that had been assumed to apply (10,11). We also have identified the allylic nitrate and nitro compounds formed when methyl linoleate and methyl linolenate react with NO_2 in the absence of oxygen (12). Recently, Postlethwait and Bidani (13) have reported that ^{15}N-labeled NO_2 was not taken up by the lipids of isolated, perfused rat lungs that were exposed to NO_2; they interpreted these results to mean that nitrogen dioxide reacts *in vivo* by a H atom abstraction mechanism.

According to our H atom abstraction mechanism (10,11), nitrogen dioxide abstracts a hydrogen atom from an allylic or doubly allylic position, forming a resonance-stabilized radical and nitrous acid (see Scheme 1). In the absence of oxygen, the allylic radical **(A)** can combine with a molecule of nitrogen dioxide to form an allylic nitro **(B)** or nitrite compound **(C)**. In the presence of oxygen, the radical reacts to form a peroxyl radical **(D)**.

Nitrogen dioxide can also react with alkenes by an additional mechanism. According to this mechanism (10,11), nitrogen dioxide adds to the double bond in a reversible step (14), forming a carbon-centered radical (compound **E** in Scheme 2). In the absence of oxygen, the carbon-centered radical can react with a second molecule of nitrogen dioxide, forming a dinitro **(F)** or nitro–nitrite compound **(G)**. These dinitro or nitro–nitrite compounds can eliminate nitrous acid to form a vinyl nitro or vinyl nitrite compound **(H)**. In the presence of oxygen, the carbon-centered radical can react with a molecule of oxygen to form a nitro-peroxyl radical **(I)** (15).

In the present paper, we report studies of the reaction of nitrogen dioxide (2–230 ppm in helium or air) with neat methyl linoleate and a solution of methyl

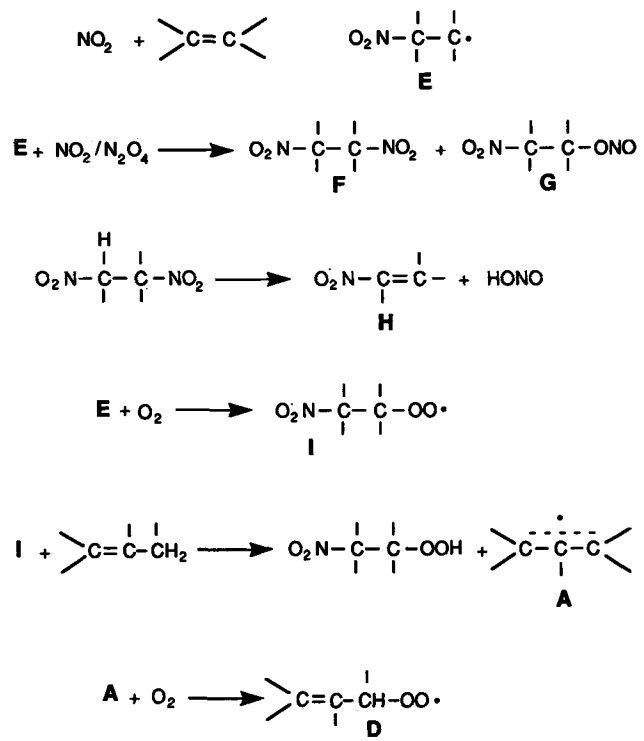

SCHEME 2

linoleate/methyl palmitate (1:1 molar) layered over a sodium phosphate buffer.

EXPERIMENTAL PROCEDURES

Materials. Methyl linoleate [99% pure by gas chromatography (GC) Sigma, St. Louis, MO] was purified from hydroperoxide contaminants by passing the ester in oxygen-free hexane [high-performance liquid chromatography (HPLC) grade, Mallinckrodt, St. Louis, MO] sequentially through four Pasteur pipette columns containing 1.0 g of alumina (neutral; Aldrich, Milwaukee, WI). The last column contained 0.02 g of diethylenetriaminepentaacetic acid (DTPA) in the tip to remove any trace metals. The columns were rinsed with oxygen-free hexane before adding the unsaturated fatty acid ester solution. The entire purification process was performed in a glove bag under an atmosphere of nitrogen. The hexane was evaporated using a stream of nitrogen.

Methyl palmitate, methyl elaidate, methyl linolelaidate (*trans*-9, *trans*-12-octa-decadienoate; 99% by GC; Sigma) and *d*-carvone (96% pure; Aldrich) were used as internal standards for GC and HPLC analysis. Dinitrogen tetroxide (99.5% pure; Matheson, Secaucus, NJ) was added to a glass bulb containing phosphorus pentoxide (97% pure; Aldrich) and purged of oxygen with argon by freezing and thawing three times. Hexane, isopropanol (HPLC grade; Mallinckrodt), and helium (99.9999% chromatographic grade; Air Products, Allentown, PA) were also used. A thymol trap was made by dissolving 0.4 g of thymol (Sigma) and 4 g of sodium hydroxide (97% pure; EM Science, Gibbstown, NJ) in 1 L of deionized water.

Instrumentation. Ultraviolet (UV) spectra were taken on a Hewlett-Packard (Avondale, PA) 8451 A diode array spectrophotometer; infrared (IR) spectra were obtained on an IBM (Armonk, NY) IR/45 spectrometer. HPLC on a Varian (Palo Alto, CA) 5000 series instrument with a UV detector set at a 215 nm wavelength with a 16 nm slit width was used to analyze the reaction mixtures. A 25 × 0.46 cm silica column (Rainin, Woburn, MA) was used with hexane/isopropanol (99:1, vol/vol, oxygen free) as solvent system at a flow rate of 1 mL/min. Proton magnetic resonance [^{1}H nuclear magnetic resonance (NMR)] analyses were performed on a Bruker (Billerica, MA) 200 MHz instrument using deuterated chloroform as solvent. A Hewlett-Packard 5890 GC/mass spectrometer equipped with a 100 m × 0.25 mm SP-2560 fused silica column was used to separate the *cis/trans* isomers of methyl linoleate. The column was maintained isothermally at 230°C for 15 min, and the mass range 10–500 amu was scanned. A gas chromatograph (Varian 3740 series) equipped with a flame-ionization detector and a 100 m × 0.25 mm SP-2560 fused silica column maintained isothermally at 210 and 200°C was used to determine the amount of addition/elimination products formed in the reactions. The GC injection port was maintained at 250°C. Negative chemical ionization (NCI) (0.5 Torr methane) was performed on a Finnigan MAT (San Jose, CA) TSQ 4500 mass spectrometer using a direct exposure probe ramped to 1 A at a rate of 10 mA/s and scanning a mass range of 44–800 amu. The source temperature was 150°C and the manifold temperature was 100°C.

The reaction of methyl linoleate with nitrogen dioxide in a carrier gas. The bubbler apparatus shown in Figure 1 was assembled in a glove bag under an atmosphere of nitrogen. The nitrogen dioxide bulb was opened slightly and the nitrogen dioxide gas flow equilibrated for one hour. The concentration of nitrogen dioxide in a helium

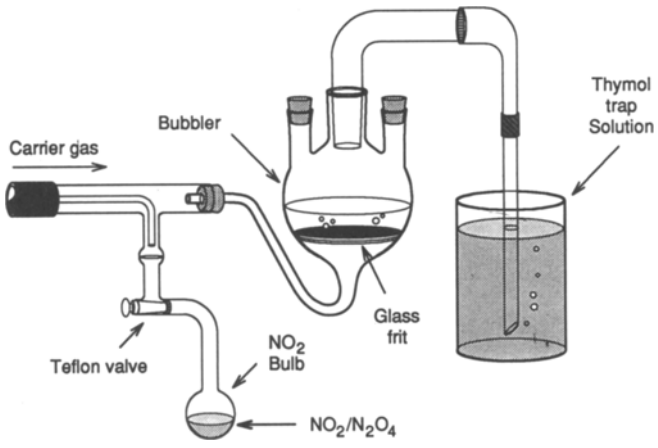

FIG. 1. The apparatus used for the reactions. A low level of NO_2/N_2O_4 is placed in the bulb to allow a low rate of delivery of NO_2 to the system. The NO_2 bulb is opened slightly and equilibrated for one hour. A one-hour blank is run to determine NO_2 concentration in the carrier gas. The methyl linoleate is placed on the glass frit, and NO_2 in the carrier gas is bubbled through the fatty acid ester for one hour.

or air carrier gas at flow rates of 60 and 30 mL/min were determined by bubbling the nitrogen dioxide into a 1 L or 100 mL thymol trap for 1 h at 37°C. In the anaerobic reactions, ultrapure helium was the carrier gas and in the aerobic reactions compressed air was used. The efficiency of the thymol trap shown in Figure 1 was 70 ± 4.0 and 83 ± 2.1% for the 100 mL and 1 L trap solutions, respectively. All runs were one hour long.

The difference in the amount of nitrogen dioxide in the thymol trap solution used with the blank vs. that used with the reaction solution was taken as the amount of nitrogen dioxide incorporated into the unsaturated fatty acid esters. The amount of nitrogen dioxide in the thymol traps was determined using the Saltzman analysis (16). For some of the lower concentrations of nitrogen dioxide, the Saltzman analysis was not sensitive enough to measure the small amounts of unreacted nitrogen dioxide; for these runs, the total amount of nitrogen dioxide delivered was used.

For studies using fatty acids layered over an aqueous layer, nitrogen dioxide in a carrier gas was bubbled through the buffer to determine the amount of nitrogen dioxide/nitrogen tetroxide that was consumed by a dismutation reaction to form nitrate and nitrite ions.

The reaction of nitrite/nitrate anions with methyl linoleate at 37°C in the absence of oxygen. A solution that was 1.1×10^{-3} M in both sodium nitrite and sodium nitrate in a sodium phosphate buffer (pH 7.4; 0.5 M) containing DTPA was prepared. This concentration of nitrite and nitrate anions is equivalent to the concentration of these ions that would be formed from the disproportionation of 228 ppm of NO_2 in air at a flow rate of 60 mL/min bubbling through 10 mL of buffer for one hour (17). The nitrite/nitrate solution was purged of oxygen and allowed to react with methyl linoleate for one hour.

The study of fatty acids over an aqueous layer. Nitrogen dioxide introduced into the bottom of the apparatus was bubbled through a buffer (approximately 4 cm in height) consisting of 10 mL of 0.5 M sodium phosphate (pH 7.4) before coming in contact with a methyl palmitate/methyl linoleate (1:1 molar) solution (approximately 0.4 cm in height) layered on the surface of the buffer. The organic layer of the aqueous reaction mixture was extracted with dichloromethane, dried with $MgSO_4$, filtered and concentrated by blowing a stream of nitrogen over the solution.

Identification of products. A mixture of methyl *cis*-9,*trans*-12-octadecadienoate and methyl *trans*-9,*cis*-12-octadecadienoate isomers (*c,t*-18:2) was analyzed by GC/MS (18). The isomers, which have identical electron ionization (EI) mass spectra to those of methyl linoleate and methyl linolelaidate (18), were identified by their order of elution. The same elution order of the geometrical isomers of methyl linoleate under similar GC conditions was reported by Kobayashi (19).

Methyl 9-nitro-9,12-octadecadienoate, and methyl 13-nitro-9,12-octadecadienoate (vinyl nitro isomers) coeluted in HPLC and GC analysis. The mixture of isomers was isolated by HPLC from a methyl linoleate and nitrogen dioxide reaction mixture and was identified by NMR, IR and NCI. Proton NMR showed signals at 5.4 ppm (*br, m,* 3H vinyl), 3.66 ppm (*s,* 3H CH_3O), 2.7 ppm (*dd,* 2H), and 2.3 ppm (*t,* 2H). The vinylic proton absorption appearing at 5.4 ppm instead of about 7 ppm is caused by the substitution of a nitro and an alkyl group on the same vinylic carbon. This type of upfield shift has previously been seen with other electron-withdrawing functional groups, e.g., crotonic acid vs. methacrylic acid and 1-bromo-1-propene vs. 2-bromopropene (20). IR: nitro 1552 cm^{-1}, 1362 cm^{-1}, *cis* double bond 723 cm^{-1}, and a vinylic double bond 989 cm^{-1} (21). Methane NCI was used to determine the molecular weight *m/z* 339 and to confirm the presence of a nitro functional group by the appearance of a *m/z* 46 ion (22). NCI $[M^-] = m/z$ 339 (9%), $[M - H]^- = m/z$ 338 (30%), $[C_8H_{13}O_2N]^- = m/z$ 155 (<1%), $[C_7H_{13}]^- = m/z$ 97 (<1%), $NO_2^- = m/z$ 46 (100%).

Methyl 9-nitrato-9,12-octadecadienoate, methyl 10-nitrato-9,12-octadecadienoate, methyl 12-nitrato-9,12-octadecadienoate, methyl 13-nitrato-9,12-octadecadienoate (vinyl nitrate) also coeluted in HPLC and GC. The mixture of isomers was isolated by HPLC and identified by NMR, IR and NCI analysis. NMR: 5.40 ppm (*br, m,* 3H vinyl), 3.66 ppm (*s,* 3H CH_3O), 2.7 ppm (*dd,* 2H) and 2.3 ppm (*t,* 2H). The IR spectrum of the mixture of isomers has absorbances at 1634 cm^{-1} (NO_2 asymmetrical stretch), 1257 cm^{-1} (symmetrical vibration), 856 cm^{-1} (N-O stretch) and 682 cm^{-1} (NO_2 vibration); these absorbances demonstrate the presence of a nitrate functional group (20). The NCI analysis was used to determine the molecular weight and to confirm the presence of a nitrate functional group by the appearance of an *m/z* 62 ion (21). NCI: $[M^-] = m/z$ 355 (15%), $[M - H]^- = m/z$ 354 (9%), $[M - O]^- = m/z$ 339 (12%), $[M - OH]^- = m/z$ 338 (8%), $[M - H_2O]^- = m/z$ 337 (28%), $NO_3^- = m/z$ 62 (37%), and $NO_2^- = m/z$ 46 (100%). The hydroperoxide and allylic nitro (nitrite) isomers of methyl linoleate were identified by NMR and NCI (12).

Methyl 9-nitrato-*trans*-10,*trans*-12-octadecadienoate, which elutes after the hydroperoxides of methyl linoleate, was isolated and identified by NCI analysis. The position of the functional group was obtained from the detection of an *m/z* 151 ion in the NCI spectrum, which is indicative of the fragmentation of the compound in the source to form 2,4-decadienal. NCI: $[M^-] = m/z$ 355 (17%), $[M - NO_2]^- = m/z$ 309 (25%), $[M - H_2NO_2]^- = m/z$ 307 (39%), $[M - CH_3NO_3]^{-1} = m/z$ 277 (52%), $[M - C_9H_{18}NO_4]^{-1} = m/z$ 151 (28%), $NO_3^{-1} = m/z$ 62 (100%), $NO_2^{-1} = m/z$ 46 (65%).

RESULTS

Reaction of nitrogen dioxide with methyl linoleate. We have measured the yields of products from the reaction of nitrogen dioxide with neat methyl linoleate as well as with an equimolar solution of methyl palmitate/methyl linoleate layered over an aqueous buffer. The product compositions formed using either helium or air as the carrier gas are presented later in Tables 1–4. The data shown are averages from five HPLC analyses and four GC analyses of the reaction mixture using *d*-carvone

TABLE 1

Moles of Products Formed from the Reactions of NO_2 and Methyl Linoleate Under Helium at 37°C[a]

KCL[b]	3.5 ± 0.2	0.95 ± 0.06	0.74 ± 0.04

[a]For clarity, standard errors (determined from at least five analyses) are shown only in this table; however, the data presented in all of the tables have similar errors (see Ref. 16).

[b]KCL (kinetic chain length) is defined as the moles of products formed divided by the moles of nitrogen dioxide reacted. *c,t, cis, trans; c,t*-18:2, mixture of methyl *cis*-9, *trans*-12-octadecadienoate and methyl *trans*-9, *cis*-12-octadecadienoate; 9c, 11*t*-13AN, mixture of methyl 13-nitrito-*cis*-9, *trans*-11-octadecadienoate and methyl 13-nitro-*cis*-9, *trans*-11-octadecadienoate; 9*t*,11*t*-13AN, mixture of methyl 13-nitrito-*trans*-9,*trans*-11-octadecadienoate and methyl 13-nitro-*trans*-9,*trans*-11-octadecadienoate; 10*t*,12*c*-9AN, mixture of methyl 9-nitrito-*trans*-10,*cis*-12 octadecadienoate and methyl 9-nitro-*trans*-10,*cis*-12-octadecadienoate; 10*t*,12*t*-9AN, mixture of methyl 9-nitrito-*trans*-10,*trans*-12-octadecadienoate and methyl 9-nitro-*trans*-10,*trans*-12-octadecadienoate.

and methyl linolelaidate as internal standards (17). The response factor for the hydroperoxides was used to quantify the allylic nitrite(nitro) compounds as the nitrite(nitro) compounds decompose when the solvent is removed. The concentration of nitrogen dioxide in the carrier gas, the identity of the carrier gas (He or air) and the percent conversion is given in each table. As before (10), we have used the nature of the products, allylic or nonallylic, to assess the fraction of nitrogen dioxide that reacted by a hydrogen atom abstraction or addition mechanism. Products that are assigned to arise from an addition mechanism (*c,t*-18:2, vinyl nitro and vinyl nitrate) and an H atom abstraction mechanism (9*c*,11*t*-13AN, 9*c*,11*t*-13HP, 9*t*,11*t*-13AN, 9*t*,11*t*-13HP, 10*t*,12*c*-9AN, 10*t*,12*c*-9HP, 10*t*,12*t*-9AN, and 10*t*,12*t*-9HP) are tabulated separately in each table. The total moles of products detected and nitrogen dioxide that reacted are listed at the bottom of the tables. The values for the kinetic chainlength (KCL), defined as the moles of products formed divided by the moles of nitrogen dioxide reacted, also are given. The products identified account for 96 ± 12 mole % of the methyl linoleate that was consumed in the reactions.

Anaerobic reactions of methyl linoleate. Table 1 displays the identity and quantity of products formed when neat methyl linoleate is allowed to react with various concentrations of nitrogen dioxide in ultrapure helium. In agreement with our previous results (10,11), these low concentrations of nitrogen dioxide react predominantly with methyl linoleate by an H atom abstraction mechanism.

Aqueous reactions of methyl linoleate. To determine whether low concentrations of nitrogen dioxide can pass through an aqueous environment and abstract a hydrogen atom from methyl linoleate, nitrogen dioxide was bubbled through a buffer with a methyl palmitate/methyl linoleate (1:1, molar) solution layered on top of the surface. Table 2 displays the moles of products formed in this system.

In this system, the *c,t*-18:2 addition/elimination product is not detected at the low concentrations of nitrogen dioxide used. Allylic nitrite isomers are presumed to be formed but to be hydrolyzed to allylic alcohols (23). Therefore, the H abstraction products are taken to be the sum of the allylic nitro and allylic alcohol isomers, compounds that co-elute under our HPLC conditions. An equimolar mixture of nitrate and nitrite anions did not react with methyl linoleate under our experimental conditions (17).

[a]Allylic nitrates of methyl linoleate.

[b]KCL is defined as the moles of products formed divided by the moles of nitrogen dioxide reacted. Abbreviations as in Table 1; 9*c*,11*t*-13HP, methyl 13-hydroperoxy-*cis*-9, *trans*-11-octadecadienoate; 9*t*,11*t*-13HP, methyl 13-hydroperoxy-*trans*-9, *trans*-11-octadecadienoate; 10*t*,12*c*-9HP, methyl 9-hydroperoxy-*trans*-10,*cis*-12-octadecadienoate; 10*t*,12*t*-9HP, methyl 9-hydroperoxy-*trans*-10,*trans*-12-octadecadienoate.

Aerobic reactions of nitrogen dioxide with methyl linoleate. Reactions of nitrogen dioxide with methyl linoleate also were performed in air (Tables 3 and 4). When air was used as the carrier gas, only hydrogen atom abstraction products were detected. The *c,t*-18:2 addition/elimination product and the nitro-hydroperoxide isomers of methyl linoleate were not detected; the only nitrogen-containing compound detected was the allylic isomer, methyl-9-nitrato-*trans*-10,*trans*-12-octadecadienoate.

[a]Allylic nitrates of methyl linoleate.

[b]KCL is defined as the moles of products formed divided by the moles of nitrogen dioxide reacted. Abbreviations as in Tables 1 and 3.

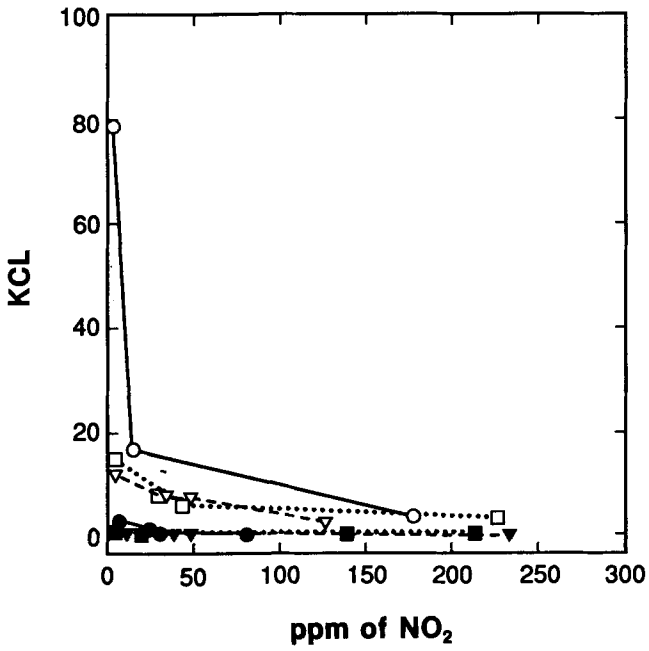

FIG. 2. The kinetic chain length (KCL) (moles of products/moles of NO_2 reacted) for the reactions of nitrogen dioxide and methyl linoleate in the absence (closed symbols) and the presence (open symbols) of oxygen. Open circle, neat methyl linoleate in air; closed circle, neat methyl linoleate in the absence of air; open triangle, a 50:50 mixture of methyl linoleate and methyl palmitate in air (Ref. 16); closed triangle, the same mixture in the absence of air (Ref. 16); open square, a 50:50 mixture of methyl linoleate and methyl palmitate in the aqueous system under air; closed square, the same mixture in the aqueous system without air.

KCL. KCL values, calculated from the moles of products formed per mole of nitrogen dioxide reacted, are shown in Figure 2 for the anaerobic and aerobic reactions of nitrogen dioxide with methyl linoleate. The KCL is larger in the aerobic reactions than in the anaerobic reactions. Diluting methyl linoleate with methyl palmitate decreases the KCL of the reactions (Fig. 2).

DISCUSSION

Methyl linoleate H abstraction and addition products. Our studies demonstrate that under anaerobic conditions, low concentrations of nitrogen dioxide predominantly abstract a hydrogen atom from methyl linoleate (Tables 1 and 2; Scheme 1). Small yields of products formed *via* the addition mechanism (Scheme 2), which predominates at high concentrations of nitrogen dioxide, were detected at low concentrations of nitrogen dioxide under anaerobic conditions (Tables 1 and 2). In agreement with our earlier results (10,11), in the absence of oxygen and as the concentration of nitrogen dioxide decreased, an increasing fraction of the reaction occurred by the H atom abstraction mechanism.

KCL. The KCL is approximately unity for most of the reactions run in the absence of air (Tables 1 and 2). However, for some of the anaerobic reactions, the chain

length is somewhat larger than one (Tables 1 and 2). A KCL greater than one in anaerobic reactions can be explained by the decomposition of the allylic nitrite compounds to an alkoxyl radical and nitric oxide (24). [Isolated allylic nitrite(nitro) isomers of the unsaturated fatty acid esters decompose when concentrated.] The alkoxyl radical formed in this decomposition could abstract a hydrogen atom from methyl linoleate, giving a carbon-centered radical. Reaction of the carbon-centered radical with nitric oxide will result in the formation of a nitroso compound that can rearrange to an oxime (21); the presence of an oxime was supported by the appearance of an IR absorption at 1587 cm^{-1} (25). This observation is in agreement with our earlier study of the reaction of nitrogen dioxide with cyclohexene in the absence of oxygen, in which the amount of oxime formed increased as the concentration of nitrogen dioxide decreased (10).

Aqueous reactions. Nitrogen dioxide was shown to be able to diffuse through an aqueous environment and then to react with unsaturated fatty acids. Bubbling nitrogen dioxide through a buffer solution over which a solution of methyl palmitate/methyl linoleate (1:1, molar) had been layered gave products that were primarily allylic, indicating that methyl linoleate reacted primarily by a hydrogen atom abstraction mechanism in this experimental design (Table 2).

Explanation for addition products not being detected in aerobic reactions. Table 4 shows a similar reaction system in which air was used as the carrier gas. Again allylic products were formed, but in this case they were primarily the allylic hydroperoxides, resulting from the chain autoxidation of methyl linoleate. In the presence of oxygen, the carbon-centered radical formed by the addition of nitrogen dioxide to the double bond of an unsaturated fatty acid can be trapped by oxygen (Scheme 2) (10,11). Accordingly, the addition/elimination product of methyl linoleate (*c,t*-18:2) was not detected in the presence of oxygen (Tables 3 and 4). The nitro-hydroperoxides that could be formed in addition reactions also were not detected, possibly because of the limit of detection of the HPLC UV detection method (Tables 3 and 4). The only nitrogen-containing products detected in aerobic reactions at low concentrations of NO_2 were allylic nitrates; these may have originated from the decomposition of peroxynitrates (which may have been formed from nitrogen dioxide reacting with peroxyl radicals) (26–28). Peroxyl radicals, of course, would result from the autoxidation of methyl linoleate, a chain reaction that would result in larger yields of peroxyl radicals than of individual addition or H atom abstraction products.

Rationale for the change in the mechanism from addition to H atom abstraction. The H atom abstraction mechanism (Scheme 1) predominates over the addition mechanism (Scheme 2) at low concentrations of nitrogen dioxide because the addition mechanism is reversible (10,11). Thus, the irreversible H atom abstraction step predominates at low NO_2 concentrations.

In conclusion, our results demonstrate that low concentrations of nitrogen dioxide in the absence of oxygen react predominantly with methyl linoleate by an H atom abstraction mechanism in either the presence or the absence of water. We propose that the same mechanism occurs in the presence of oxygen. These results corroborate the findings of Postlethwait and Bidani (13), as well as our earlier results (10,11) that *in vivo*, environmental concentrations of nitrogen dioxide will react with polyunsaturated fatty acids in pulmonary lipids exclusively by an H atom abstraction mechanism, a process that can initiate autoxidation.

ACKNOWLEDGMENTS

We thank Dr. S. Barker, D.R. Laine, T. Meyer and M. Nauman for their assistance in analyzing the products. This work was supported in part by a MERIT Award, HL-16029, from the NIH.

[Received January 30, 1993, and in revised form December 11, 1993; Revision accepted December 13, 1993]

Vitamin E Isomers in Grain Amaranths (*Amaranthus* spp.)

James W. Lehmann[a,*], Daniel H. Putnam[b] and Asaf A. Qureshi[c]

[a]Institute for the Development of Amaranth Products, Bricelyn, Minnesota 56014, [b]Department of Agronomy, University of Minnesota, St. Paul, Minnesota 55108 and [c]Advanced Medical Research, Inc., Madison, Wisconsin 53705

Vitamin E isomers are important antioxidants, but their variation is poorly documented in pseudocereal grains such as amaranths. Using normal-phase, high-performance liquid chromatography with fluorescence detection, seeds of thirteen amaranth (*Amaranthus cruentus* L., *A. hypochondriacus* L.) accessions were surveyed for the composition of tocols. The most common tocols found were α-tocopherol (2.97 to 15.65 mg/kg seed) and β-tocotrienol (5.92 to 11.47 mg/kg seed) and γ-tocotrienol (0.95 to 8.69 mg/kg seed), while some *A. cruentus* accessions contained δ-tocotrienol (0.01 to 0.42 mg/kg seed). This is the first report of tocotrienols in amaranths. *Amaranthus cruentus* grain-types of Mesoamerican origin had significantly ($P \leq 0.01$) greater levels of four tocols than did *A. cruentus* African vegetable-types. Unlike many cereal grains, amaranths have significant amounts of both β- and γ-tocotrienols; however, β-tocopherol was not detected in any of the amaranths. Using multiple linear regressions, α-tocopherol variation of both species and types was consistently explained by variation in tocols other than α-tocopherol. On the whole, fresh amaranth samples of both species tended to have higher levels of tocotrienols than samples stored for two years. Storage effects on amaranth tocol composition are suspected.

***Lipids* 29, 177–181 (1994).**

Tocotrienols (T3) are unsaturated analogs of vitamin E, which have been recently shown to regulate cholesterol metabolism (1,2), to have antitumor activity (3) and to possess high *in vitro* antioxidative activity (4). Both tocopherols (T) and T3 have important antioxidant properties and are widespread in cereals (5). However, limited data on tocol (T and T3) variation exist for grain germplasm, for breeding materials and for different varieties.

Among the pseudocereals, grain amaranths, including *Amaranthus caudatus* L., *A. cruentus* L. (CRU) and *A. hypochondriacus* L. (HYP), have gained attention due to the high quality protein content of the seed (6). In some parts of the world, such as Africa, grain amaranths like CRU are used predominantly as vegetables rather than as grains and are termed vegetable-type amaranths. Similarly, grain-type amaranths are cultivars with a high harvest index (ratio of grain to total phytomass).

Grain amaranth germplasm contains 5–9% lipids, with most lipids concentrated in the seed coat-germ fraction (7). Becker (8) has reviewed the nutritional implications of amaranth seed oil. As far as we are aware, published data on amaranth tocols include brief reference to total seed tocopherols for three grain *Amaranthus* species (69.4 to 82.8 mg % g [sic] of total T), including *A. caudatus*, CRU and *A. mantegazzianus* Passerini (9), to CRU T (10), and to leaf T in *A. retroflexus* L. (11). Therefore, a more complete characterization of *Amaranthus* tocols is needed. The objective of this study was to evaluate the tocol composition of amaranth accessions, including domestic grain-type cultivars and germplasm representing diverse origins and types, grown over several environments.

MATERIALS AND METHODS

Seed origin and experimental design. Thirteen amaranth accessions of HYP or CRU were surveyed using seed from three field experiments (Table 1). Experiment 1 included accessions 9–12 grown in three replicate, randomized blocks at Rosemont (MN) Experiment Station, University of Minnesota in 1989. Experiment 2 included HYP grain cultivars, var. K343 and K432, grown in three replicate, randomized blocks at Grand Rapids, Albert Lea and Morris (MN) in 1989. Experiment 3 included accessions 1 through 8 grown in two replicate, randomized blocks at the North Central Regional Plant Introduction Station (Ames, IA) in 1987. Experiment 3 seed was stored for two years at 4°C and 40% relative humidity, while seed from Experiments 1 and 2 was tested immediately after the growing season.

Abbreviations: CRU, *Amaranthus cruentus* L.; HPLC, high-performance liquid chromatography; HYP, *A. hypochondriacus* L.; LSD, least significant difference; T, tocopherol(s) (α-T, β-T, γ-T, δ-T); T3, tocotrienol(s) (α-T3, β-T3, γ-T3, δ-T3).

Tocol analyses. Amaranth seeds were ground with a Cyclone Sample Mill (UDY Corporation, Fort Collins, CO) into a fine powder (1 g) and extracted with 7.0 mL methanol in a disposable screw-capped tube in a variable speed shaker for 20 min, and centrifuged at 2000 rpm for 10 min. The supernatant was then transferred into a second disposable conical tube, and solvent was removed under vacuum at 40°C using an BI Vortex evaporator (Haake Buchler Instruments, Inc., Saddle Brook, NJ). Tocols (T and T3) were extracted with hexane (2 mL) by shaking on a horizontal shaker for 2 min, and the liquid was transferred into a 0.3 mL injection vial. The vial was capped and centrifuged in an Eppendorff 5413 centrifuge (WACO, Chicago, IL) for 4 min. The material was injected into the high-performance liquid chromatography (HPLC) unit for separation and quantitation of various tocols and standards according to the method of Hakkarainen *et al.* (12).

The HPLC system that was used consisted of a Model 6000A HPLC pump (Waters, Milford, MA), a Model RF-535 fluorescence monitor (Schimadzu, Wood Dale, IL) set at an excitation wavelength of 295 nm and an emission wavelength of 330 nm, a Model 231/401 auto-sampler injector (Gilson, Middleton, WI) equipped with a 20-microliter loop and a Waters 10-micrometer silica column, 30 cm × 4.0 mm i.d. Chromatograms were recorded and peak areas determined by using a Schimadzu Model C-R3A integrator. The mobile phase was 0.2% (vol/vol) 2-isopropanol/hexane at a flow rate of 1.0 mL/min. The injection volume was 30 microliters. All solvents used were chromatographic grade. Pure standards of the eight common vitamers of E were extracted from palm or barley oil and were purified by silicic acid column chromatography (1,2). Peaks from amaranth samples were identified by comparing their scan spectra (Fig. 1) with spectra of pure standards.

Statistical analyses. Data from all experiments were analyzed by one-way or two-way analysis of variance and by multiple linear regression (13). For Experiment 2, a combined analysis of variance was performed on each tocol. Homogeneity of error variances was tested before combining sites (14). For Experiment 3, orthogonal contrasts were computed using four African vegetable-types and four grain-types of Mesoamerican origin. When the F test indicated a significant effect, the differences between the means were analyzed using a protected least significant difference (LSD) test. Pooled phenotypic correlations, similar to those used when evaluating indirect selection criteria in amaranth germplasm (15), were assessed within species and types.

RESULTS AND DISCUSSION

Evaluation of tocol composition. Seven of the eight reported tocols, excluding β-T, were present in the amaranths surveyed (Tables 2–4). The γ-T, α-T3 and δ-T3 were sometimes absent from, or not detected in, the accessions. For Experiment 1, HYP var. K343, contained significantly ($P \leq 0.05$) higher levels of both α-T and γ-T3 than did the three CRU grain-type accessions (Table 2). Using two commercial HYP cultivars in Experiment 2, data on tocol stability over environments was mostly inconclusive due to heterogeneous error variances among sites (Table 3). The only significant ($P \leq 0.05$) difference between locations was that of α-T at the Grand Rapids and Morris sites. In Experiment 3, orthogonal contrasts indicated that grain-types of Mesoamerican origin contained significantly ($P \leq 0.01$) greater concentrations of γ-T, α-T3, γ-T3 and δ-T3 in the seed than did African vegetable-types (Table 4). Similar orthogonal contrasts of

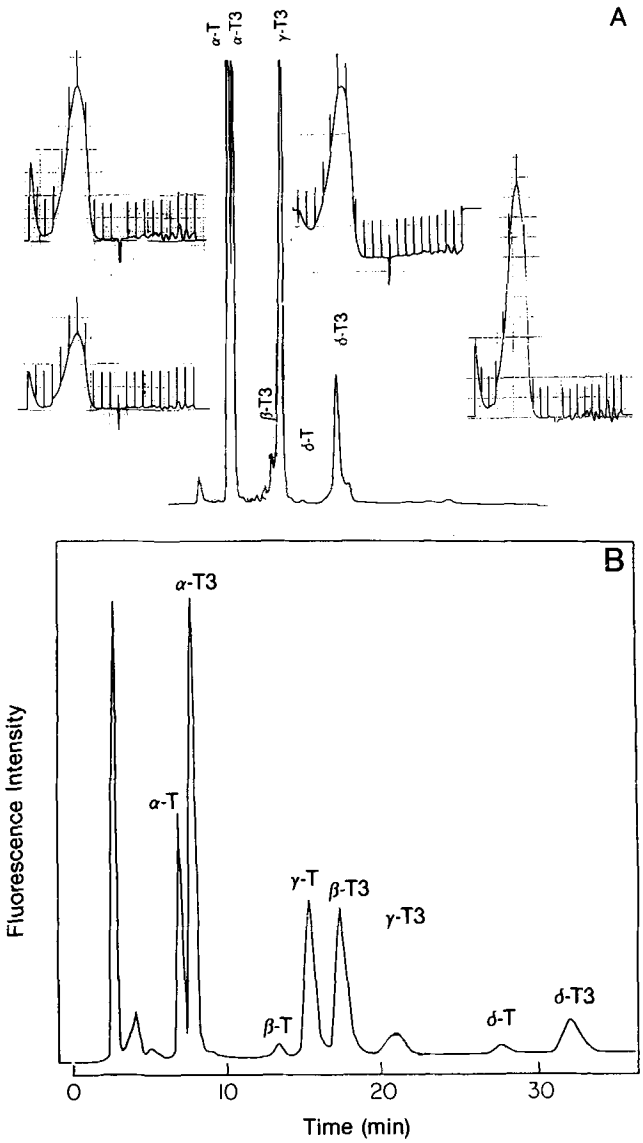

FIG. 1. Separation of tocols by high-performance liquid chromatography with fluorescence detection. The scan from the amaranth sample (A) is compared with and quantitated against a sample containing purified standards of the four tocopherols and four tocotrienols (B). The amaranth sample (A) was scanned from 240 to 440 nm for each peak, with the λ maximum for each tocol component occurring from 290 to 300 nm. The eluting solvent was 0.5% isopropanol in hexane and the chart speed was 2 mm/min. The eight pure tocol standards (B) were run with 0.2% isopropanol in hexane as solvent and at a chart speed of 5 mm/min (12). T3, tocotrienol; T, tocopherol.

Grand Rapids	5.14	2.93	0	0	0	0	0	0	0	0.01	7.24	6.97	8.31	7.96	0	0
Albert Lea	9.45	7.34	0	0	0.26	0.01	0.01	0.02	0.01	0	9.60	11.44	7.10	6.06	0	0.03
Morris	8.37	7.93	0	0	0.07	0.05	0	0.01	0	0	9.06	11.47	8.22	7.58	0	0

[a]Except for α-tocopherol, all locations were not significantly different for tocols or the error variances at sites were found heterogeneous by Barlett's test; thus, it was inappropriate to combine some sites for analysis of variance.

[b]Highly significant effects ($P \leq 0.01$) between Morris and Grand Rapids were found.

total tocols and of T3 as a percent of tocols were not significant, while the latter measure had a $P \leq 0.07$.

The data obtained represent the first report of T3 in grain amaranths, with β-T3 and γ-T3 being most prevalent and ranging from 5.92 to 11.47 mg/kg seed and from 0.95 to 8.69 mg/kg seed, respectively. The magnitude and range of these values are typical of cereal grains (16). The δ-T3 isomers were rarely detected in HYP grains, but they ranged from none to 0.42 mg/kg seed in CRU grains. Comparatively, CRU has δ-T3 concentrations akin to those in rice (*Oryza sativa* L., 0.2 mg/kg seed), but less than the δ-T3 levels in two-row barley (*Hordeum distichon* L., 0.6 mg/kg seed) and bulrush millet (*Pennisetum americanum* L., K. Leeke, 2.0 mg/kg seed) (16). Among the tocopherols, α-T was most abundant in the tested amaranths, ranging from 2.97 to

[a]Means from pooled grain- and vegetable-types were used (15).

[b]T, tocopherol; T3, tocotrienol.

[c]Significance at $P \leq 0.01$.

[d]Significant at $P \leq 0.05$.

[e]Correlation unavailable due to lack of a tocol.

15.65 mg/kg seed with the other tocopherols contributing a maximum of 0.50 mg/kg seed to total tocopherols. Bertoni and Cattaneo (9) previously had found total T from 7.56 to 7.89 mg/kg seed in two CRU accessions. Most common cereal grains, except barley, contain significant quantities of either β- or γ-tocotrienols (5); thus, excluding the lack of β-T, amaranths more closely resembled tocols composition of barley than that of wheat, oats or rye. The tocols levels determined here may have been influenced by storage. Storage effects on tocols are known from maize, where stored maize lost up to 10% of its tocols (17), and from barley, where stored barley exhibited interconversion of tocols due to methylation and saturation (18–21).

Because amaranths were variously utilized as grains, vegetables or forages during the last seven centuries, artificial selection and storage may have influenced their tocol chemistry, too. For example, δ-T3, putative precursor of the other seven tocols (19–21), was found in most Mesoamerican CRU grain-types of Experiment 3, but was often absent in CRU African vegetable-types. Further research would be needed to determine whether differences in δ-T3 and other tocol levels were due to genetic drift, mutation, selection, storage or other phenomena.

The pathways for biosynthesis of tocols are currently not well understood. In plants, synthesis of δ-tocotrienol as the initial precursor has been postulated in one biosynthetic pathway (19–22). This compound is synthesized *in vivo* by the condensation of homogentisic acid and geranylgeranyl pyrophosphate (19). The γ-, β- and α-tocotrienols are formed from the δ isomer by successive methylation on the 5 and 7 positions of the chroman ring. Corresponding tocopherols are formed by the reduction of double bonds in the phytyl tails (19–22). α-Tocopherol is the end product of tocol biosynthesis. This pathway has been worked out in *Hevea brasilinensis* (19,20).

In order to better understand the relationships among the various tocol forms, we examined pooled phenotypic correlations between tocols in amaranth CRU vegetable-types and in grain-types of both species (Table 5). Curiously, HYP and CRU grain-types exhibited opposite signs in significant phenotypic correlations for α-T and β-T3. Using multiple linear regressions of proposed tocol precursors, variation in α-T was consistently explained by variation in tocols other than α-T (Lehmann, J., unpublished data, 1992). In all three experiments, backwards and stepwise regressions showed that β- and γ-T3 contributed to high coefficient of multiple determination values in equations predicting α-T variation. Statistical evaluations do not reveal intra-pathway substrates for transmethylation or hydrogenation; rather, the pathway(s) and their substrates might be elucidated by radioisotope studies (23).

Implications. Whereas nutritionally valuable protein complementation occurs between grains such as maize and amaranth (24), beneficial tocol complementation or supplementation may also happen. Notably, γ-T3, a plentiful vitamin E analogue in the HYP grains tested and in some corn inbreds (17), has been shown to inhibit cholesterol synthesis in humans (25). Compared to reported values for other grains, amaranth has a relatively high ratio of T3 types to tocols (T plus T3). This ratio is a rough measure of a grain's cholesterol suppression when 3-hydroxy-3-methyl-glutaryl coenzyme A reductase (EC 1.1.1.34) is involved (1); here amaranths ranged from 39 to 74% T3 as a percentage of total tocols, and thus they resemble the more cholesterol-suppressive grains like barley (>70%) and oats (>80%) (1). The variation could be due to natural variation in germplasm and to interconversion of tocol isomers during storage. Amaranths of varied T3 compositions were recently tested in chickens, and these accessions lowered low density lipoprotein-cholesterol and regulated an hepatic enzyme (Qureshi, A.A., and Lehmann, J.W.,

unpublished data, 1991). Similarly, Danz and Lupton (26) found that CRU lowered serum cholesterol in rats when it was fed as a fiber supplement.

Like oat flours with a high oil content for grains, flours milled from amaranth seed or popped amaranth are often oxidatively unstable. The concentration of tocols, particularly the T3 isomers, was found to be higher in popped amaranth than in seed. This might indicate that tocols are most probably protein bound or phosphorylated on the phenolic group of the molecule (Qureshi, A.A., unpublished data, 1992). An amaranth accession such as CRU var. PI 477913, with its higher levels of γ- and δ-tocols, could be used to stabilize amaranth products; however, the relative contribution of enzymic oxidation would need to be assessed.

Taken together, the data suggest that the amaranths tested contain genetic variability for some tocols (excluding β-T) and that certain accessions contain γ- and δ-T3. Because relatively higher T3 levels were present in fresh vs. stored grains, storage effects on tocol composition are suspected. High T3 levels in stored grains with high fat content are consistent with Green's hypothesis (27), wherein non-α-tocopherols act as more effective *"in vitro"* antioxidants than α-tocopherol and thus protect the stored fat. Amaranths with differing tocol levels merit further study for nutritional or medicinal applications.

ACKNOWLEDGMENTS

We thank Dr. David Peterson and the staff of the USDA Cereal Crops Laboratory (Madison, WI) for their technical assistance and Dr. Bradley Pearce of Bristol-Myers and Squibb (Princeton, NJ) for providing pure tocol standards. Also, this work was supported, in part, by a grant No. 241976 from the Minnesota State Department of Agriculture.

^{31}P nuclear magnetic resonance (NMR) spectroscopy was used to measure the rate of acyl transfer from phosphatidylcholine (lecithin, PC) in whole plasma and in high density lipoprotein (HDL). Spectral deconvolution was used to resolve overlapping resonances in the ^{31}P NMR spectra of the phospholipids. Mean values of the acyl group transfer rates from PC in plasma and HDL were 36 μmol $L^{-1}h^{-1}$ and 19 μmol $L^{-1}h^{-1}$, respectively. The reciprocal nature of the decrease in the spectral peak intensities of PC, compared to the increase in the intensities of the lysolecithin (lysoPC) peaks, suggested a substrate/product relationship consistent with the action of lecithin:cholesterol acyltransferase (LCAT), the enzyme responsible for the esterification of free cholesterol in plasma. LCAT involvement was confirmed by measuring the cholesterol esterification rate based on the ^{13}C NMR spectra obtained on lipid extracts from plasma that had been incubated at 37°C. Within experimental error, the rate of lysoPC formation in plasma was shown to be equal to that of cholesteryl ester formation.

Lipids 29, 183–188 (1994).

The transfer of a fatty acid residue from the *sn*-2 position of phosphatidylcholine (lecithin, PC) onto carbon-3 of cholesterol in human plasma is catalyzed by lecithin:cholesterol acyltransferase (LCAT; EC 2.3.1.43) (1–3). The reaction products are cholesteryl ester and lysophosphatidylcholine (lysolecithin, lysoPC). The reaction typically utilizes high density lipoprotein (HDL) (4,5), which contains apolipoprotein A-I, an activator of LCAT (6–8), although there is also evidence that the enzyme can act directly on low density lipoprotein (LDL) (9). The cholesteryl ester newly synthesized in HDL is then transferred to, and exchanged between, very low density lipoprotein and LDL, replacing triglyceride (9,10). This maintains a concentration gradient for the flux of additional unesterified cholesterol from cellular membranes and from other lipoproteins to HDL. The exchange process is mediated by a glycoprotein, namely cholesteryl ester transfer protein (CETP) (10–13).

The most widely used clinical biochemical methods for measuring cholesterol esterification rates, or cholesteryl ester transfer activity, use radioactive tracers. In these assays, a radiolabelled cholesterol/albumin emulsion is added to the plasma or lipoprotein fraction and is pre-incubated at 4°C to allow equilibration of the labelled cholesterol with endogenous free cholesterol (14) before incubation to achieve acyltransfer at 37°C. After extraction and separation of the cholesterol and the cholesteryl ester fractions, the radioactivity associated with cholesteryl esters is measured by liquid scintillation counting (14).

We have developed a ^{31}P nuclear magnetic resonance (NMR) method to measure the rate of conversion of PC to lysoPC in human plasma and HDL. The method obviates the need to add exogenous substrates and to extract and separate the products. The reciprocal relationship we observed between the rate of decrease in PC and the rate of increase in lysoPC during plasma incubation suggested a substrate/product relationship consistent with the action of LCAT, the enzyme responsible for esterification of free cholesterol in plasma. The rate of lysoPC formation was also shown to be directly correlated with the formation of cholesteryl ester in plasma based on natural abundance ^{13}C NMR analyses on plasma extracts. The ^{31}P NMR method provides a simple, one-step means to measure the rate of acyl group transfer from PC to cholesterol in plasma. The LCAT reaction rates we measured were very similar to those that have been obtained by traditional methods.

MATERIALS AND METHODS

Materials. PC and lysoPC, both from egg yolk, as well as cholesterol, sphingomyelin, cholesteryl palmitate and dihydrocholesterol, were obtained from Sigma Chemical Co. (St. Louis, MO). D_2O (99.75%) was from the Australian Institute of Nuclear Science and Engineering (Lucas Heights, NSW, Australia). $CDCl_3$ was from Merck, Sharpe & Dohme Isotopes (Montreal, Quebec, Canada). All other reagents were analytical grade. Tris-HCl (0.1 M) containing 140 mM NaCl, pH 7.4, and 20% D_2O (vol/vol) served as pH buffer.

Plasma samples. Pooled plasma was obtained from outpatients at the Royal Prince Alfred Hospital (NSW, Australia), who were there for conditions other than cardiovascular disease. Subjects were excluded if they had suffered any acute illness during the previous 3 mon, or if they had any condition or treatment which was likely to affect lipid metabolism. Venisection was performed following a 12-h, overnight fast. Blood samples were anticoagulated with ethylenediaminetetraacetic acid (0.1% wt/vol final concentration), and plasma was separated immediately by centrifugation at 3000 × *g* for 10 min at 4°C.

*To whom correspondence should be addressed.

Abbreviations: CETP, cholesteryl ester transfer protein; DTNB, 5,5-dithio*bis*(-2-nitrobenzoic acid); GPC, glycerophosphorylcholine; HDL, high density lipoprotein; LCAT, lecithin:cholesterol acyltransferase; LDL, low density lipoprotein; lysoPC, lysophosphatidylcholine; PC, phosphatidylcholine; SPH, sphingomyelin.

Preparation of HDL. HDL was isolated following precipitation of lipoproteins containing apolipoprotein B according to the method of Warnick *et al.* (15).

Sample preparation. Plasma and HDL were concentrated over 3–9 h at 4°C by use of a Minicon concentration (W.R. Grace, Danvers, MA). After concentration (about threefold), 2.5 mL of plasma or HDL was transferred to a 10-mm NMR tube, and the volume was brought up to 3 mL with D_2O Tris buffer, pH 7.4 (see Materials and Methods section). The samples were then ready for incubation and NMR measurements. Standard samples were prepared by adding a known concentration of lysoPC in Tris buffer to plasma.

Extraction of lipids. Total lipids of plasma (10 mL) were extracted according to the method of Bligh and Dyer (16), and dried under a stream of nitrogen. Dried lipids were then dissolved in 3 mL of $CDCl_3$ for NMR measurements.

NMR spectroscopy. All ^{31}P NMR spectra were acquired under identical conditions on a Bruker AMX-400 NMR spectrometer (Karlsruhe, Germany) operating at 161.98 MHz in the Fourier transform mode; probe temperature was kept at 37 ± 1°C. Broadband proton decoupling was applied to eliminate ^{1}H-^{31}P peak multiplicities. All measurements were done on 3-mL samples in 10-mm NMR tubes with D_2O as internal field/frequency lock. Samples were spun at 12 Hz, and a 15 µs (90°) pulse, a 1 s pulse delay, a 0.67 s acquisition time, 16k data points and 256 transients were used. Free induction decays (FID) were processed with 6 Hz line broadening to improve apparent signal-to-noise ratio. ^{31}P and ^{13}C NMR measurements on plasma extracts were done on $CDCl_3$ solutions with $CDCl_3$ also serving as the internal field/frequency lock; the probe temperature was 25 ± 1°C. ^{13}C NMR spectra were acquired at 100.61 MHz, using the method by Homer and Roberts (17). Spectra were derived by Fourier transformation of 2124 summed transients, and FID were processed with 1 Hz line broadening.

Quantification of lipids. Automatic Lorentzian deconvolution was used to resolve overlapping phosphorus resonances of PC and lysoPC. To measure reaction rates, areas of deconvoluted ^{31}P NMR spectra that were obtained on plasma extracts at different time points were quantified, and the areas were compared with those obtained for known concentration of authentic compounds. However, for measurements on plasma and HDL, peak heights rather than peak areas were used, for quantification, because small changes in the widths of the phospholipid phosphorus resonances were observed in the course of the LCAT reaction and good results were obtained based on peak height measurements.

Free cholesterol and cholesteryl esters were quantified based on peak areas of the ^{13}C NMR resonances for carbon-3 of these lipids relative to carbon-3 of dihydrocholesterol used as the internal standard. The differences between the peak areas of dihydrocholesterol used as internal standard and those of cholesterol and cholesteryl ester, due to different relaxation rates of the respective nuclei, were corrected by a coefficient that was determined by addition of known amounts of standard samples and by measuring the areas of the resulting ^{13}C NMR signals. Peak areas were determined using automatic Lorentzian deconvolution rather than direct integration, because small overlapping resonances were seen in the spectra.

RESULTS

^{31}P NMR on plasma. A ^{31}P NMR spectrum obtained on fresh human plasma is shown in Figure 1A. The resonances seen include those due to PC at −0.31 ppm, lysoPC at 0.15 ppm, and inorganic phosphate at 2.9 ppm. These assignments were confirmed by adding authentic PC, as liposomes, as well as lysoPC to the plasma as internal standards. Chemical shift assignments are referenced relative to methylenediphosphonic acid, kept in a coaxial capillary with a signal at 16.89 ppm relative to 85% orthophosphoric acid at 0.000 ppm (18).

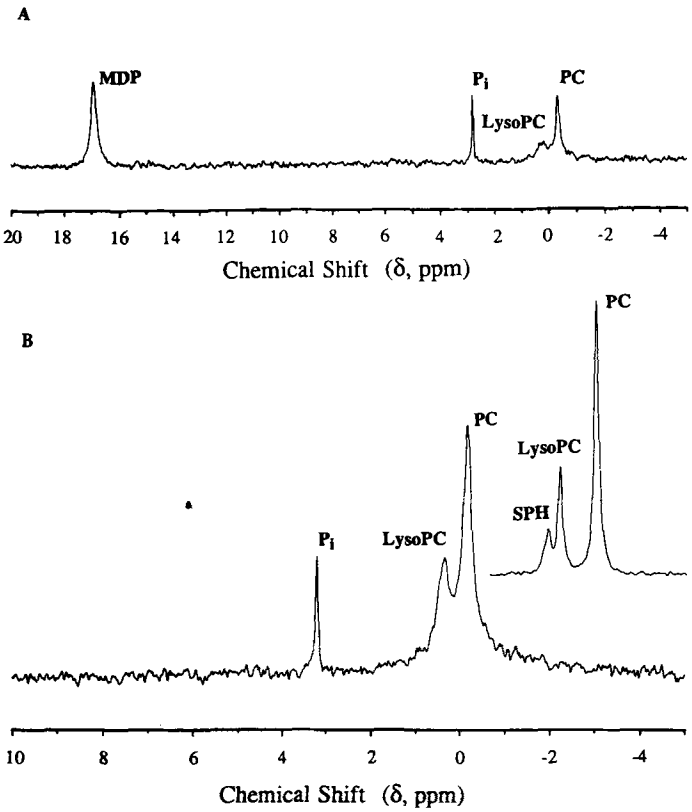

FIG. 1. A, ^{31}P nuclear magnetic resonance (NMR) spectrum of human plasma (2 mL nonconcentrated plasma with 1 mL 0.1 M Tris buffer, pH 7.4 at 25°C). Resonance assignments were confirmed by adding lecithin [phosphatidylcholine (PC)] liposomes and lysolecithin [lysophosphatidylcholine (lysoPC)] to the plasma sample. The chemical shifts were referenced relative to methylenediphosphonic acid (MDP) at 16.89 ppm. P_i denotes inorganic phosphate. B, ^{31}P NMR spectrum of threefold concentrated plasma and a total lipid extract of plasma (plasma was incubated for 5 h prior to extraction) in $CDCl_3$ (A, chemical shift scale offset, ≈3 ppm). Resonance assignments for the phospholipids in the plasma extract were confirmed by adding authentic PC, lysoPC and sphingomyelin (SPH) to the solution of the plasma extract.

The phosphorus resonances obtained on plasma (e.g., Fig. 1A) can be of low intensity and can be difficult to fully resolve. This difficulty can be overcome by either using a greater number of transients at the expense of accumulation time, or by increasing the sample concentration. A ^{31}P NMR spectrum of threefold concentrated plasma is shown in Figure 1B. As can be seen, the amplitudes of the signals obtained under otherwise identical spectral conditions are significantly increased when compared with those obtained on native plasma. In Figure 1B, the top insert shows a ^{31}P NMR spectrum of a total lipid extract from plasma in $CDCl_3$ in which the sphingomyelin (SPH) resonance is distinguishable from the lysoPC peak, and the PC resonance is fully resolved.

Plasma and HDL time course. Figure 2A shows the ^{31}P NMR signals obtained on 1.85-fold concentrated plasma samples over a time course of about 16 h. The incubation temperature was 37°C, and the reaction was monitored by recording sequential spectra at the time points indicated. A plot of the amplitudes of the PC and lysoPC peaks obtained on the deconvoluted spectra, as shown in Figure 2A, vs. time, is given in Figure 2B. For this and similar time courses, regression analyses indicated that the slopes of the curves for PC decline and lysoPC increase indicated very similar reaction rates. Figure 3 shows a plot of lysoPC concentrations in 2.77-fold concentrated HDL, incubated at 37°C, and of those in concentrated plasma. As can be seen, the increase of lysoPC concentration in plasma (37 ± 3.8 μmol $L^{-1}h^{-1}$) was faster than that in HDL (15 ± 3.2 μmol $L^{-1}h^{-1}$).

Acyl transfer activity, which is reflected in the rate of lysoPC formation, was calculated from the initial slope of the lysoPC concentration increase in concentrated plasma and in HDL. In Table 1 the results of six separate experiments used for the determination of acyl transfer activity from PC in plasma are presented. Also, in three of these experiments, the acyl transfer rate in HDL isolated from the same plasma was measured.

The effect of plasma concentration. To assess the effect of plasma concentration on the measured reaction rate, parallel time-course experiments were carried out with concentrated and native plasma samples. In order to improve the signal-to-noise ratio of the spectra, the number of transients was increased from the 256 used for concentrated plasma samples to 1280 (5-fold) for nonconcentrated plasma samples. The rates of acyl transfer measured were not significantly different after correcting (scaling) for the different concentrations used (Table 1). Thus, the use of concentrated plasma permits more precise estimates of reaction rates within a much shorter period of time.

^{13}C NMR study. Experiments were carried out to directly compare the formation of lysoPC and of cholesteryl ester, i.e., acyl transfer due to LCAT activity. The plasma samples were incubated at 37°C, extracted, and

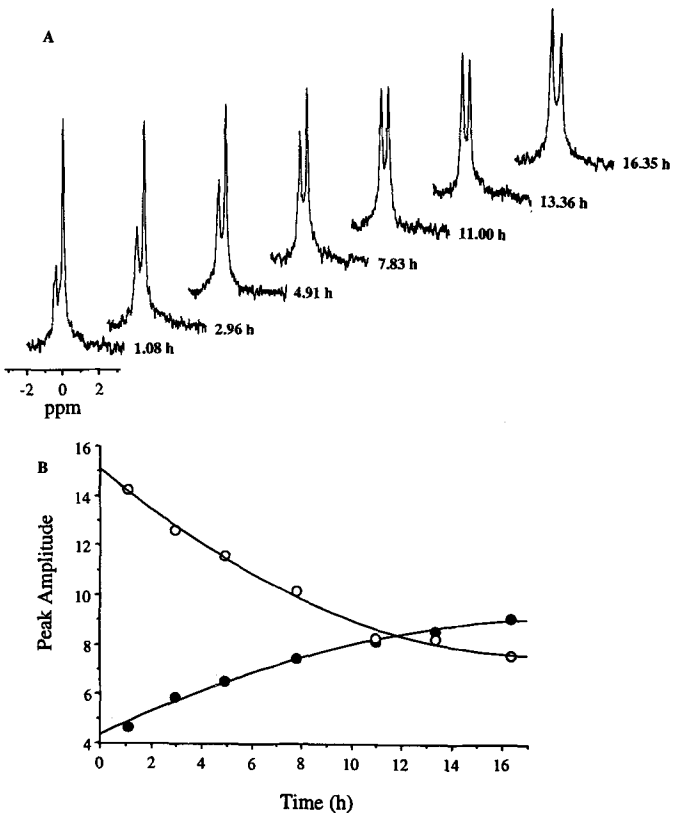

FIG. 2. A, sequential ^{31}P NMR spectra of 1.85-fold concentrated plasma incubated at 37°C for the times indicated. B, plot of PC (open circles) and lysoPC (closed circles) peak amplitudes (arbitrary units) derived from deconvolutions of the spectra shown in A. The decline in PC peak intensities mirrors the increase in lysoPC peak intensities. The curves were drawn using an empirical quadratic polynomial $y = a + bt + ct^2$, where t is the time and the fitted parameters for lysoPC and PC had the values a = 4.326, b = 0.497, c = -1.282×10^{-2}, and a = 15.107, b = −0.846, c = 2.382×10^{-2}, respectively. Abbreviations as in Figure 1.

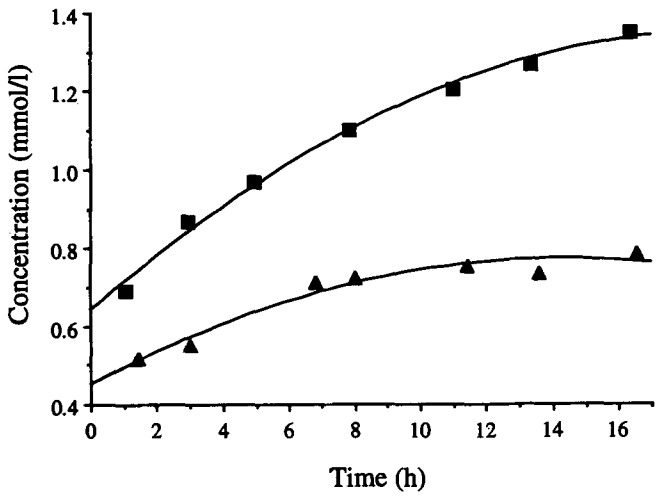

FIG. 3. Comparison of lysoPC concentrations derived from deconvoluted ^{31}P NMR spectra of 2.77-fold concentrated high density lipoprotein (HDL) that was incubated at 37°C (triangles), and of plasma as derived from Figure 2A (squares). The curves were drawn using an empirical quadratic polynomial $y = a + bt + ct^2$. Fitted parameters for HDL and plasma lysoPC concentration increase had the values a = 0.450, b = 4.485×10^{-2}, c = -1.563×10^{-3}, and a = 0.640, b = 7.350×10^{-2}, c = -1.895×10^{-3}, respectively. Abbreviations as in Figure 1.

TABLE 1

Rates of Acyl Transfer (μmol L^{-1} h^{-1}) from Phosphatidylcholine in Plasma and HDL[a]

Experiment	Concentrated plasma	Nonconcentrated plasma	HDL[b]
1	39 ± 4.2	37 ± 7.4	
2	42 ± 4.3	40 ± 6.0	
3	36 ± 7.7		
4	37 ± 3.8		15 ± 3.2
5	48 ± 19		25 ± 4.5
6	32 ± 2.8		20 ± 1.8
Weighted means[c]	36	39	19

[a]The rates of acyl transfer were calculated from the slopes of the plot of lysophosphatidylcholine (lysoPC) concentration vs. incubation time in concentrated and nonconcentrated plasma, and in high density lipoprotein (HDL), in six separate experiments. LysoPC concentrations were derived from sequential ^{31}P nuclear magnetic resonance spectra over time, as shown in Figures2A. The concentration of lysoPC in concentrated plasma and HDL was calculated as μmol (L plasma)$^{-1}$ of lysoPC in the initial sample (before concentration). Values are means ± SD.

[b]HDL was isolated by precipitation of apo B-containing lipoproteins, and was then concentrated (see Materials and Methods section).

[c]We used the "statistical weight," 1/variance.

TABLE 2

Cholesterol Esterification Rate (μmol L^{-1} h^{-1}) in Human Plasma

Experiment	Cholesterol esterification rate[a]
1	55 ± 9
2	53 ± 4
3	32 ± 12
Weighted mean[b]	51

[a]The cholesterol esterification rate was calculated from the initial slope of the plot of cholesteryl ester concentration in plasma vs. incubation time. Cholesteryl ester concentration was derived from sequential ^{13}C nuclear magnetic resonance spectra of total lipid extracts of plasma over time (see Materials and Methods section). Values of rate constants are means ± SD and are expressed in μmol (L plasma)$^{-1}$ h^{-1}.

[b]We used the "statistical weight," 1/variance.

the products measured by ^{31}P and ^{13}C NMR. The cholesterol esterification rate was calculated from the initial slope of either the cholesteryl ester concentration increase or the free cholesterol concentration decline. Separate time courses were obtained by ^{31}P and ^{13}C NMR, and the rates of acyl transfer from PC to yield lysoPC and cholesterol ester were measured. In a typical example, for plasma from a single donor, the rates based on lysoPC and cholesteryl ester formation were 41 ± 9 μmol $L^{-1}h^{-1}$ and 32 ± 12 μmol $L^{-1}h^{-1}$, respectively. The two rates were statistically not different. This was done when the weighted mean rates in plasma of lysoPC formation (Table 1, 39 μmol $L^{-1}h^{-1}$) and of cholesteryl ester formation (Table 2; 51 μmol $L^{-1}h^{-1}$) were compared; the rates again were quite similar. As the samples were from different donors, some of the variance may actually be due to biological variations between the donors. Although the rate estimates have a relatively large standard deviation, the results obtained by ^{13}C and ^{31}P NMR corroborate each other and are consistent with acyl transfer from PC to free cholesterol catalyzed by LCAT.

DISCUSSION

Incubation of concentrated plasma at 37°C resulted in the simultaneous increase in lysoPC levels and the decrease in PC levels with similar velocities (Fig. 2), which is consistent with lysoPC formation directly from PC in the course of cholesterol esterification (4) catalyzed by LCAT activity. The rates of acyl transfer we observed in plasma *in vitro* (Table 1) were quite similar to those for cholesterol esterification by LCAT, that had been reported by others (19,20). LysoPC formation from HDL–PC (Fig. 3) accounted for an increasingly smaller proportion relative to lysoPC formation in whole plasma as the incubation progressed. This decrease in HDL was most likely due to the depletion of substrate (PC) and the accumulation of reaction products that inhibit LCAT. In whole plasma, additional substrates (PC and cholesterol) can be exchanged from other lipoproteins while the product, cholesteryl ester, is removed from HDL by CETP and possibly other carrier proteins. In addition, a smaller proportion of the increase in lysoPC concentration in plasma could be due to LCAT acting on LDL (9), which also may account, in part, for the higher apparent LCAT activity in whole plasma seen later in the incubation when compared with HDL (Fig. 3). Furthermore, LDL-activated lysoPC acylation by LCAT has been reported to occur. This transfer of an acyl group from PC in LDL to lysoPC (21,22) however, would not cause a net change in the total mass of PC or lysoPC and would therefore have no effect on the net LCAT activity measured by the present method. In addition to this transesterification reaction, the acyl group of PC can be transferred to water, which amounts to a phospholipase-like activity of LCAT (23,24). However, this reaction occurs only when cholesterol levels are very low, such as in cholesterol-deficient liposomes, and this activity is distinct from that of phospholipase A_2 (25). Brasure *et al.* (26) have previously used ^{31}P NMR to monitor the hydrolysis of phospholipids in human HDL_3 upon addition of exogenous phospholipase A_2. They observed the changes in the spectra of HDL_3 produced by digestion with snake venom phospholipase A_2 *(Crotalus adamanteus)* when incubated at 28°C and noted that PC was completely converted to lysoPC in the course of the reaction. Although Brasure *et al.* used ^{31}P NMR to monitor lipid-enzymatic changes by an approach similar to ours, these authors utilized an exogenous enzyme from a source other than human plasma. LDL and apolipoprotein B, on the other hand, have been reported to exhibit phospholipase A_2-type activity toward phospholipids containing an oxidized or a short fatty acyl chain at position-2 (27,28). This phospholipase activity, however, has been shown to produce only glycerophospho-

rylcholine (GPC) and not lysoPC, up to the complete hydrolysis of the substrate (28). In our studies, we were unable to detect any GPC resonance by ^{31}P NMR on plasma extracts, even after extended (several hours) incubation times; also GPC is usually not considered to be a major constituent of human plasma (29,30). This would not exclude, however, that such activity by LDL may be exhibited toward an exogenous substrate in an isolated or in an *in vitro* system.

For quantification of lysoPC and PC in plasma by ^{31}P NMR, peak amplitudes, rather than areas, were used because the apparent peak widths of PC and lysoPC changed with plasma incubation time. NMR line width is known to be affected by a number of parameters, including translational and rotational motions (T_2) of the nuclei involved and by inhomogeneities in the magnetic microenvironments (31). For example, for phospholipid vesicles, changes in vesicle size directly affect rotational motions and line widths (32,33), and similar differences in ^{31}P NMR linewidths have been reported for phospholipids in HDL and LDL (34). Phospholipids in plasma are continuously being exchanged between different lipoproteins of different size and lipid/protein compositions. On the other hand, the chemical shift of each class of phospholipids depends upon the composition of the particles (34,35). Thus, small changes in chemical shifts of close ^{31}P NMR resonances would also result in a change in apparent linewidths. If subsequent deconvolution involves fitting a line shape with less than the full complement of peaks, then the fit to the broadened lines will attempt to accommodate this increase and lead to larger "wings" on the fitted function, which would manifest itself as an increase in the apparent peak area. Any of these effects would make it difficult to obtain quantitative estimates from peak areas. A practical solution was to use peak heights as measure for the quantification of phospholipid concentrations in plasma. Using this approach, we demonstrated in plasma that the velocities of the increases in lysoPC levels and decreases in PC levels were the same within experimental error.

The phosphorus resonances in the ^{31}P spectra of concentrated plasma (Fig. 1B, lower) can be primarily attributed to PC, lysoPC and SPH, of which the resonances of lysoPC and SPH are more difficult to resolve. Earlier ^{31}P NMR studies on phospholipids and estimates of phospholipid concentrations in plasma have been published (29,30,36,37), although our study is the first whose aim was to develop, evaluate and apply an NMR-based LCAT assay.

Standard procedures for measuring the rate of cholesterol esterification and transfer from HDL typically involve radiolabelling. For this purpose, plasma or lipoprotein fractions are first preincubated with a radioactive cholesterol/albumin mixture to allow equilibration between labelled exogenous cholesterol and endogenous native cholesterol. In most of these assays, LCAT is first inhibited with 5,5-dithio*bis*-2-nitrobenzoic acid (DTNB), and the inhibition is then reversed by incubation with mercaptoethanol (14). The cholesterol esterification and transfer rates are then estimated by measuring, after chromatographic separation, the radioactivity that is associated with cholesteryl ester in plasma or in the lipoprotein fraction. Although these assay methods are used extensively, they suffer from several disadvantages: (i) cholesterol esterification is not completely inhibited by DTNB during the preincubation period, and mercaptoethanol may alter the esterification rate (14); (ii) complete equilibration of radioactive cholesterol with endogenous cholesterol during preincubation is uncertain, and it is difficult to determine whether the labelled cholesterol has been distributed uniformly among the lipoproteins; and (iii) other assays of LCAT activity or cholesteryl ester transfer activity with artificial substrates, such as PC/cholesterol liposomes, may not necessarily be representative of the activities *in vivo*.

In conclusion, the novel ^{31}P NMR procedure we developed for measuring the rate of acyl transfer from PC to free cholesterol in plasma, or HDL, mediated by LCAT, has a number of advantages for assaying LCAT activity. The introduction of NMR spectroscopy into clinical biochemistry should entail the development of ancillary procedures to replace older methods, or the development of new procedures for assaying enzyme activities and metabolites that have proven intractable by other means.

ACKNOWLEDGMENTS

The work was supported by funds from the Australian NH & MRC, the Australian Research Council, and the Royal Prince Alfred Hospital Fund. The authors thank Prof. W.J. Hensley for helpful discussions and the provision of facilities to undertake this research. Assoc. Prof. N.S. Agar is also thanked for valuable discussions. Brian Bullman and Drs. Bill Bubb and Bob Chapman are thanked for help with computing and NMR spectroscopy, respectively.

Garlic Reduces Plasma Lipids by Inhibiting Hepatic Cholesterol and Triacylglycerol Synthesis

Yu-Yan Yeh* and **Shaw-Mei Yeh**

Nutrition Department, The Pennsylvania State University, University Park, Pennsylvania 16802

Prompted by the reported hypolipidemic activity of garlic, the present study was undertaken to elucidate the mechanism(s) underlying the cholesterol-lowering effects of garlic. Rat hepatocytes in primary culture were used to determine the short-term effects of garlic preparations on [1-^{14}C]acetate and [2-^{3}H]glycerol incorporation into cholesterol, fatty acids and glycerol lipids. When compared with the control group, cells treated with a high concentration of garlic extracts [i.e., petroleum ether- (PEF), methanol- (MEF) and water-extractable (WEF) fractions from fresh garlic] showed decreased rates of [1-^{14}C]acetate incorporation into cholesterol (by 37–64%) and into fatty acids (by 28–64%). Kyolic containing *S*-allyl cysteine and organosulfur compounds inhibited cholesterogenesis in a concentration dependent manner with a maximum inhibition of 87% at 0.4 mM. At this concentration, Kyolic decreased [1-^{14}C]acetate incorporation into fatty acids by 67%. *S*-allyl cysteine at 2.0 and 4.0 mM inhibited cholesterogenesis by 20–25%. PEF, MEF and WEF depressed the rates of [2-^{3}H]glycerol incorporation into triacylglycerol, diacylglycerol and phospholipids in the presence of acetate, but not in the presence of oleate. The results suggest that the hypocholesterolemic effect of garlic stems, in part, from decreased hepatic cholesterogenesis, whereas the triacylglycerol-lowering effect appears to be due to inhibition of fatty acid synthesis. Primary hepatocyte cultures as used in the present study have been proven useful as tools for screening the anticholesterogenic properties of garlic principles.

***Lipids* 29, 189–193 (1994).**

Aside from its general use as a condiment, garlic (*Allium sativum*) is known for its pharmacological and nutritional properties (1). Among the potential therapeutic applications of garlic, its antilipidemic effects have been demonstrated in studies on humans (2–6), as well as on animals, including rats (7–13), rabbits (14,15), chicken (16–17) and swine (18). Garlic is known to contain a variety of sulfur compounds, in addition to amino acids, vitamins and minerals (19). Although some of these sulfur compounds, such as *S*-methylcysteine sulfoxide and *S*-allyl cysteine sulfoxide, are known to reduce cholesterol levels in the liver and plasma (10), the principle(s) foremost responsible for the hypolipidemic action of garlic is presently not known. Likewise, the mechanism(s) underlying the hypocholesterolemic effects of garlic constituents(s) have not been fully elucidated (20).

Abbreviations: DME, Dulbecco's modified Eagle medium; HEPES, *N*-(2-hydroxyethyl)piperazine-*N*'-(2-ethanesulfonic acid); FBS, fetal bovine serum; MEF, methanol-extractable fraction of garlic; PEF, petroleum ether-extractable fraction of garlic; PL, phospholipid; TG, triacylglycerol; WEF, water-extractable fraction of garlic.

The liver is a major site of cholesterol and lipoprotein synthesis and of cholesterol clearance *via* low density lipoprotein-receptor mediated processes (21,22). Previous studies by other investigators have shown that garlic supplemented diets can depress the activities of various lipogenic enzymes including glucose-6-phosphate dehydrogenase and malic enzyme (9,10,17), as well as of the cholesterogenic enzyme, 3-hydroxy-3-methyl-glutaryl-CoA reductase (16–18). It therefore seems reasonable to postulate that the hypolipidemic effect of garlic results from impaired lipogenesis and cholesterogenesis in the liver.

The goal of the present study was to determine whether garlic suppresses cholesterol and glycerol lipid biosynthesis in hepatocytes in primary culture. The results we obtained demonstrated that extracts prepared from fresh and aged garlic exert a marked inhibition on cholesterol and fatty acid synthesis.

MATERIALS AND METHODS

Chemicals. Radioactive substrates were purchased from Amersham Corp. (Arlington Heights, IL). Collagenase D was obtained from Boehringer Mannheim Corp. (Indianapolis, IN). Culture media, fetal bovine serum (FBS) and antibiotics were the products of GIBCO (Gaithersburg, MD). Aged garlic powder, Kyolic (liquid form of aged garlic), and *S*-allyl-cysteine were provided by Wakunaga of America Co., Ltd. (Mission Viejo, CA). Substrates and other chemicals were purchased from Sigma Chemical Co. (St. Louis, MO). Diet ingredients were supplied by ICN Biochemicals (Costa Mesa, CA).

Animals and diets. Male Sprague-Dawley rats were obtained from Harlan Sprague-Dawley Co. (Indianapolis, IN) and fed a nonpurified diet (Purina Rat Chow; Ralston Purina, St. Louis, MO). The animals were housed individually in stainless steel cages at approximately 24°C and 50% relative humidity on a 12-h light/dark cycle (0600–1800). In experiments on the effects of garlic on plasma lipids, two groups of five animals each (140–150 g body weight) were fed high-fat diets (20 g corn oil/100 g diet), and one group was fed the diet supplemented with 2% aged garlic powder. Thus, the compositions of the two diets were the same, except for the presence of garlic in the experimental group (Table 1). The diets were isocaloric and provided 98.3 kJ/100 g diet. The diets were stored under nitrogen at –20°C and provided fresh to the animals daily. Unconsumed portions of the diets were discarded each day.

Hepatocyte culture. Liver cells were isolated from rats (200–250 g body weight) according to the method of Berry and Friend (23), as modified by Seglen (24). Rats were anesthetized with nembutal (5 mg/100 g body weight), and the hepatic portal vein was cannulated for perfusion with buffer [NaCl, 142 mM; KCl, 6.7 mM;

TABLE 1

Composition of Control and Experimental Diets[a]

Ingredient	Control (g/kg diet)	Experiment (g/kg diet)
Casein	172	172
Sucrose	203	203
Corn starch	295	295
Corn oil	200	200
AIN-76 mineral mix	35	35
AIN-76A vitamin mix	10	10
Fiber, cellulose	50	48
Choline, dihydrogen citrate	2	2
L-Methionine	3	3
Agar	30	30
Aged garlic powder[b]	0	2

[a]All diet ingredients were purchased from ICN Biochemicals (Costa Mesa, CA). Both diets contained the same energy density, i.e., 98.3 KJ/100 g.

[b]Aged garlic powder was provided by Wakunaga of America Co., Ltd. (Mission Viejo, CA).

N-(2-hydroxyethyl)piperazine-*N'*-(2-ethanesulfonic acid) (HEPES), 10 mM; NaOH, 5.5 mM; pH 7.4] for 15 min. Immediately after perfusion *in situ*, the liver was carefully excised and perfusion with collagenase buffer (NaCl, 67 mM; KCl, 6.7 mM; HEPES, 100 mM; $CaCl_2 \cdot H_2O$, 5.4 mM; NaOH, 66 mM; pH 7.6; 50 mg collagenase D/100 mL) was continued for 15 min. The enzyme-treated liver was then subjected sequentially to mincing, incubation, filtration and centrifugation for cell isolation and purification. From each liver, 100–250 $\times 10^6$ cells were obtained with a viability of 95–98% as judged by trypan blue exclusion. The cells were resuspended in Dulbecco's modified Eagle medium (DME) supplemented with 5.6 mM glucose, 10% FBS and antibiotics (100 units penicillin/mL, and 100 μg streptomycin/mL) to obtain 0.8–1.0 $\times 10^6$ cells/mL of suspension. Two-mL aliquots of the suspension were plated per well in a six-well culture plate (Becton Dickinson Labware, Lincoln, NJ) and incubated at 37°C under an atmosphere of 95% air and 5% CO_2. After 6 h of incubation, nonadhering cells were removed and discarded. Hepatocytes that adhered to the culture plate were refed with DME and incubated for24 h.

Metabolic studies. At the end of the 24-h incubation, cells were washed three times with 2 mL of FBS-free DME, followed by incubation with 2 mL of the same medium containing [1-^{14}C]acetate (specific activity, 37 MBq/mmol) and 0.5 mM nonlabeled sodium acetate, or [2-^{3}H]glycerol (specific activity, 18.5 MBq/mmol) and 0.1 mM nonlabeled glycerol in the presence or absence of the agents to be tested, i.e., garlic extracts, Kyolic and *S*-allyl cysteine. After 4 h of incubation, the medium was collected and cells were harvested with 1.3 mL of ice-cold water by scraping with a rubber policeman. [1-^{14}C]Acetate and [2-^{3}H]glycerol were used to estimate cholesterogenic and lipogenic rates (25).

Lipid analysis. The harvested cells were mixed with 20 mL of chloroform/methanol (2:1, vol/vol) to extract the lipids according to the method of Folch *et al.* (26). For measurement of [1-^{14}C]acetate incorporation into cholesterol and fatty acids, the lipid extract was saponified in 6 mL of 3.75% methanolic KOH at 90°C for 4 h (27). Nonsaponifiable lipids were extracted with petroleum ether (b.p. 35–60°C), and cholesterol was precipitated with digitonin (27). After removal of the nonsaponifiable fraction, the extracts were acidified with concentrated HCl, and the fatty acids were extracted with petroleum ether. For quantification of [2-^{3}H]glycerol incorporation into glycerol lipids, lipids were separated into triacylglycerols (TG), diacylglycerols and phospholipids (PL) by thin-layer chromatography on Silica Gel G coated plates using hexane/diethyl ether/acetic acid (80:20:1, by vol) as developing solvent (28). The radioactives of ^{14}C- and ^{3}H-labeled products were measured by liquid scintillation counting (Beckman Model LS 6800; Beckman Instruments, Houston, TX).

Preparation of garlic extracts. Fresh garlic purchased from a local market was used in the study. Husk-free garlic bulbs (100 g) were homogenized with petroleum ether to obtain a petroleum ether-extractable fraction (PEF) according to the method of Qureshi *et al.* (17). Semiliquid residues that remained after petroleum ether extraction were freeze-dried for 72 h and yielded 36.6 g of dry powder. Two portions of 10 g each were used for preparation of methanol- (MEF) and water-extractable (WEF) fractions, as described elsewhere (17). The final preparations of PEF, MEF and WEF were resuspended in ethanol, methanol and water, respectively. All extracts were sterilized by microfiltration through 0.22 μm cellulose acetate filters. The concentrations of PEF, MEF and WEF used for the metabolic studies were adjusted so that 1 × and 5 × extracts were equivalent to 0.25 mg and 1.25 mg of dried powder, respectively. Five microliters of the extract were added to 2 mL of the incubation medium.

Statistics. Data are presented as means ± SE, and the difference in values between control and experimental groups in the *in vivo* study was analyzed by Student's *t*-test. The comparisons of the test compounds *in vitro* were made by one-way analysis of variance. When statistical significance was indicated by the analysis of variance, Duncan's Multiple Range test was used to identify the significant difference between the groups at $P < 0.05$.

RESULTS

Prior to our *in vitro* studies, a feeding experiment was carried out to confirm the hypolipidemic effects of garlic that have been observed by other investigators in different animal species (7–18). One group of rats was fed a high-fat diet containing 2% aged garlic powder, and the other group received a similar diet without garlic for four weeks. As shown in Table 2, at the conclusion of the feeding experiment there was no difference in body weights between the two groups of rats on the two diets. The fasting plasma TG and total cholesterol concentrations in the garlic group were lowered by 30 and 15%, respectively, relative to those in the group fed the garlic-free diet. High density lipoprotein cholesterol levels

[b]Indicates a significant difference from the corresponding value of the control group at $P < 0.05$.

[c]High density lipoprotein.

were the same in the two groups. These findings led us to the subsequent *in vitro* experiments that were aimed at investigating the mechanism(s) that would underlie the cholesterol-lowering effect of garlic.

The rates of hepatic *de novo* fatty acid and cholesterol synthesis were determined using [1-^{14}C]acetate as substrate. The rate of [1-^{14}C]acetate incorporation into cholesterol was lowered 36% by PEF and 44% by MEF at the 5 × concentration (Table 3). No significant inhibition by these extracts was seen at the 1 × concentration. On the other hand, WEF at 1 × lowered acetate incorporation by 52%, but an increase of the concentration to 5 × did not further reduce the rate of incorporation. WEF and MEF were equally effective in inhibiting [^{14}C]acetate incorporation into fatty acids. Inhibition at 1 × and 5 × concentrations ranged from 59 to 64%. The rate of fatty acid synthesis was inhibited by PEF at 5 ×, but not at 1 × concentration.

To further characterize the inhibitory effect of garlic constituents on lipid biosynthesis, Kyolic and *S*-allyl cysteine were tested for their effectiveness. *S*-Allyl cysteine is a major sulfur-containing amino acid derivative in garlic. Kyolic preparation used in the study contained 700 mg *S*-allyl cysteine/L (equivalent to 4.3 mM) and other, not specified, water-soluble compounds. The rate of [1-^{14}C]acetate incorporation into cholesterol was not influenced by *S*-allyl cysteine at concentrations below 1.0 mM (Table 4). At high concentrations (i.e., 2.0 and 4.0 mM), the rates were 20–25% lower than those in the controls. Fatty acid synthesis from [1-^{14}C]acetate was not altered by *S*-allyl cysteine at all concentrations tested. Kyolic at a concentration equivalent to 0.05 mM *S*-allyl cysteine was effective in reducing the rate of [1-^{14}C]acetate incorporation into cholesterol, and the inhibition was shown to be concentration dependent (Table 4). At a higher concentration equivalent to

TABLE 3

Inhibition of [1-^{14}C]Acetate Incorporation into Lipids of Hepatocytes by Garlic Extracts[a]

Treatment[b]	[1-^{14}C]Acetate incorporation into	
	Cholesterol	Fatty acid
	(pmol acetate incorporated/mg protein/4 h)	
Control	120 ± 11[c]	704 ± 55[c]
PEF		
1 ×	108 ± 11[c]	642 ± 23[c]

5 ×	67 ± 10[d]	291 ± 35[e]
WEF		
1 ×	57 ± 8[d]	253 ± 25[e]
5 ×	43 ± 4[d]	270 ± 16[e]

[a]Hepatocytes were incubated in 2 mL serum-free Dulbecco's modified Eagle medium containing 0.5 mM [1-^{14}C]acetate (specific activity, 1.0 mCi/mmol or 37 MBq/mmol).

[b]PEF (petroleum ether), MEF (methanol) and WEF (water)-extractable fractions of fresh garlic were resuspended in ethanol, methanol and water, respectively; 1 × extract was equivalent to 0.25 mg and 5 × to 1.25 mg of dry garlic powder. Five μL of the extracts was added to the incubation medium.

[c–e]Values are means ± SE of three experiments. The average of three wells measured in each experiment was considered a data point. When compared with the control group, addition of 5 μL ethanol decreased the incorporation of [1-^{14}C]acetate into cholesterol by 26 pmol/mg protein/4 h and increased the incorporation into fatty acid by 162 pmol/mg protein/4 h. On the other hand, addition of 5 μL methanol reduced the incorporation into cholesterol and fatty acid by 17 pmol and 63 pmol/mg protein/4 h, respectively. Accordingly, the values of PEF- and MEF-treated cells were corrected for these effects. Values in each column with a different superscript letter are significantly different at $P < 0.05$.

[a]Hepatocytes were incubated in serum-free Dulbecco's modified Eagle medium containing 0.5 mM [1-^{14}C]acetate (specific activity, 1.0 mCi/mmol or 37 MBq/mmol).

[b]The mean specific activities of [1-^{14}C]acetate incorporation into cholesterol and fatty acid ranged from 121–158 and 610–825 pmol acetate/mg protein/4 h, respectively. The values for treatment groups are expressed as % of the control based on the mean specific activity determined from each of four experiments.

[c]Kyolic concentrations are expressed as *S*-allyl cysteine equivalents contained in the liquid garlic extract.

[d–f]Values are means ± SE for three experiments. The average of three wells measured in each experiment was considered a data point. Values in each column with a different superscript letter are significantly different at $P < 0.05$.

[g]Indicates a significant difference from the corresponding value of the control group.

TABLE 5

Effects of Garlic Extracts on the Rate of [2-^{3}H]Glycerol Incorporation into Glycerolipids of Hepatocytes[a]

Treatment[b]	[2-^{3}H]Glycerol + oleic acid		[2-^{3}H]Glycerol + acetic acid		
	Triacylglycerol	Phospholipids	Triacylglycerol	Diacylglycerol	Phospholipids
	(pmol glycerol incorporated/mg protein/4 h)				
Control	1076 ± 39[d]	352 ± 7[d]	1035 ± 27[c]	86 ± 1[c]	482 ± 9[c]
PEF	1157 ± 32[c,d]	349 ± 8[d]	895 ± 12[d]	68 ± 1[e]	357 ± 6[d]
MEF	1235 ± 26[c]	383 ± 8[c]	945 ± 32[d]	78 ± 1[d]	379 ± 13[d]
WEF	1174 ± 44[c,d]	452 ± 26[c]	906 ± 32[d]	69 ± 2[e]	382 ± 10[d]

[a]Hepatocytes were incubated in serum-free Dulbecco's modified Eagle medium containing 0.1 mM [2-^{3}H]glycerol (specific activity, 0.5 mCi/mmol or 18.5 MBq/mmol) and either 0.5 mM oleic acid complexed with bovine serum albumin or 1.0 mM sodium acetate. Garlic extracts equivalent to 1.25 mg of dry garlic powder in 5 μL was included in the incubation. When compared with the control group, addition of 5 μL ethanol or methanol decreased slightly (<2%), but not significantly, the rates of [2-^{3}H]glycerol incorporation into glycerolipids.

[b]PEF (petroleum ether), MEF (methanol) and WEF (water)-extractable fractions of fresh garlic were resuspended in ethanol, methanol and water, respectively.

[c–e]Values are means ± SE for three experiments. The average of three wells measured in each experiment was considered a data point. Values in each column with a different superscript letter are significantly different at $P < 0.05$.

0.4 mM *S*-allyl cysteine, Kyolic depressed the rate of synthesis by 87%. The rate of [1-^{14}C]acetate incorporation into fatty acids was inhibited by Kyolic at the high concentration (i.e., 0.4 mM equivalent), but was stimulated at 0.1 mM concentration.

Plasma TG levels depend in part on TG synthesis and secretion by the liver. TG synthesis, on the other hand, also competes with PL synthesis for substrates. Unlike the effects of the garlic extracts on cholesterol and fatty acid synthesis, none of the extracts inhibited the rate of [2-^{3}H]glycerol incorporation into TG when oleic acid was present in the culture medium (Table 5). The rate of incorporation into TG was increased 15% by MEF as compared to controls. Similarly, the rate of [2-^{3}H]glycerol incorporation into PL was not affected by PEF or MEF, but stimulated by 28% in the presence of WEF.

In a subsequent experiment, the rate of [2-^{3}H]glycerol incorporation into lipids was measured in the presence of 1.0 mM sodium acetate. As shown above, acetate is readily used by hepatocytes for fatty acid synthesis. Under our experimental conditions, the rates of [2-^{3}H]glycerol incorporation into TG were decreased 9–14% by PEF, MEF or WEF as compared to controls (Table 5). The rate of glycerol incorporation into diacylglycerol was lowered by all three garlic extracts. The garlic extracts were also effective in reducing the rate of glycerol incorporation into PL by 21–26%.

DISCUSSION

Garlic powder (7,10,12), garlic extracts (4,6,9,13,16–18), essential oils of garlic (12–14) and purified sulfur compounds from garlic (10,14) are known to reduce plasma of total cholesterol, low density lipoprotein-cholesterol and TG levels in animals and in humans. The present study on rats not only confirms these hypocholesterolemic and hypotriglyceridemic effects, but provides some additional insights into the mechanism(s) by which garlic lowers lipid levels in the circulation. Our data strongly suggest that the cholesterol-lowering action of garlic stems in part from its inhibition of hepatic cholesterol synthesis, which is consistent with conclusions drawn based on *in vitro* experiments with Hep G2 cells, a human hepatoma cell line and cultured rat hepatocytes (20). Maximal inhibition of cholesterogenesis, however, appears to require multiple components of garlic, as became evident through the following observations. First, PEF, MEF and WEF were all effective in depressing cholesterol synthesis, indicating that the active components of garlic are hydrophobic, or hydrophilic, or both. The inhibition of cholesterol synthesis coincided with a marked reduction in plasma total cholesterol levels by organic solvent and water-extractable garlic constituents fed to the animals (9,16–18). Second, the rate of [1-^{14}C]acetate incorporation into cholesterol was not altered by *S*-allyl cysteine at 0.05–1.0 mM and was decreased by only 20–30% in the presence of higher concentrations (i.e., 2.0 and 4.0 mM). Third, Kyolic, at a concentration equivalent to 0.04 mM *S*-allyl cysteine, inhibited hepatic cholesterogenesis to the same extent as did 2.0–4.0 mM purified *S*-allyl cysteine. A maximal inhibitory effect (i.e., 87%) was attained by Kyolic at a concentration equivalent to 0.4 mM *S*-allyl cysteine. A recent study by Sendl *et al.* (29) had shown that cholesterol synthesis *in vitro* could be markedly depressed by a variety of sulfur containing compounds from garlic (e.g., allicin, ajoene, diallyl disulfide) at 0.5–1.0 mM concentrations. In addition to *S*-allyl cysteine, Kyolic also contains other organosulfur compounds such as methyl sulfide, allyl disulfide and allylmethyl trisulfide (30). Thus, the potent inhibitory effects of Kyolic are likely to be due to the combined effects of these sulfur containing compounds.

The depressed rates of cholesterogenesis observed in the cultured hepatocytes may be related to the decreased activities of 3-hydroxy-3-methyl-glutaryl-CoA

reductase measured in the liver of animals fed diets supplemented with different garlic preparations (16–18). This notion is supported by the results of a recent study, that showed that water-soluble garlic extracts, when incubated with cultured hepatocytes, lowered the activity of the reductase (20), the rate-limiting enzyme early in cholesterol synthesis. Furthermore, when purified diallyl disulfide was preincubated with liver microsomes, the reductase was irreversibly inactivated (31). However, it should be pointed out that the garlic extracts could also inhibit steps later in the cholesterol metabolic pathway (20). For example, garlic extracts fed to chicken have been shown to decrease hepatic cholesterol 7α-hydroxylase activity (16,17). Furthermore, allicin has been shown to inhibit the activity of bovine acetyl CoA synthetase (32). Acetyl-CoA synthetase, in turn, was shown to exist both in the cytoplasm and in the mitochondria of rat liver (33). As [1-^{14}C]acetate was used as the substrate for cholesterol synthesis in the present study, it may be speculated that the decreased rate of [1-^{14}C]acetate incorporation into cholesterol induced by garlic extracts and Kyolic could involve inhibition of acetyl-CoA synthetase.

Likewise, the mechanism(s) underlying the hypotriglyceridemic effect of garlic is not completely understood. As hepatic TG production is an important factor in the regulation of plasma levels, the use of [2-^{3}H]glycerol for measuring the hepatic capacity for TG synthesis permitted us to ascertain a causal relationship between hepatic TG production and TG appearance in the circulation. The incorporation of [2-^{3}H]glycerol into TG is dependent upon the formation of *sn*-glycerol-3-phosphate and its esterification with fatty acids. Thus, any limitation in the availability of the glycerol backbone or of fatty acid could lead to a reduction in TG synthesis. In a series of experiments, we found that the rate of [2-^{3}H]glycerol incorporation into TG was significantly inhibited by PEF, MEF and WEF under conditions where acetate was provided as fatty acid precursor to the hepatocytes in the incubation medium. Such an inhibition was not observed when a fatty acid (i.e., oleic acid) was supplemented. Clearly, the TG-lowering effect of active garlic components must in part be attributed to a decreased rate of TG synthesis in the liver, which, in turn, is the result of depressed *de novo* fatty acid synthesis. Various garlic extracts fed to animals have been shown to decrease the activities of NADPH producing enzymes and of fatty acid synthetase (9,10,16–18). Therefore, it is likely that the impairment of fatty acid synthesis observed in the cultured cells stems partly from the inhibition of the lipogenic enzymes. The inhibition of TG production, however, does not seem to be due to competition with diacylglycerol or PL synthesis, which were similarly inhibited by the garlic extracts.

In summary, the cholesterol- and lipid-lowering effects of long-term treatment with garlic reported in various human intervention (2–6) and animal feeding studies (7–18) were assessed and confirmed here in short-term experiments using primary hepatocyte cultures. This cell culture model should prove useful for further screening of various garlic principles for their anticholesterogenic properties.

[a]Institute of Internal Medicine II, Erasmus University of Rotterdam, 3000 DR Rotterdam, The Netherlands, [b]NMR Unit, Royal Postgraduate Medical School, Hammersmith Hospital, London W12 0HS, [c]NMR Facility, Department of Chemistry, Queen Mary and Westfield College, London E1 4NS, [d]Department of Neurochemistry, Institute of Neurology, London WC1N 3BG and [e]Department of Urology, [f]Department of Histopathology, Hammersmith Hospital, London, W12 0HS United Kingdom

The aim of this study was to investigate whether tumor-induced cachexia and aberrations in host liver metabolism, induced by the MAT-LyLu variant of the Dunning prostate tumor, could be prevented by ω3 fatty acids from fish oil. On day 0, adult Copenhagen-Fisher rats fed normal chow *ad libitum* were inoculated with 10^6 MAT-LyLu cells (n = 14) or saline (n = 9). On day 7, when tumors were palpable, four tumor-bearing (TB) and four nontumor-bearing (NTB) rats were put on isocaloric diets with 50% of total energy as fish oil. The introduction of fish oil-enriched diets caused a reduction in energy intake to less than half of the energy intake by animals fed normal diets during days 7–14 (difference by dietary group: NTB, $P < 0.001$; TB, $P < 0.001$). During days 14–21, energy intake in fish oil-fed animals returned to approximately 75% of energy intake by animals fed normal diets (difference by dietary group: NTB, $P < 0.003$; TB, $P = 0.001$). Carcass weight of animals on day 21, when the study was terminated, was significantly related to initial weight ($P = 0.05$) and mean food intake during the study ($P = 0.01$). When data were adjusted for these variables using analysis of covariance, with NTB animals on normal diets being the reference group, significant loss of carcass weight was observed in TB animals on normal diets only (mean ± SEM 58 ± 10 g loss, $P < 0.001$), but not in TB animals on fish oil diets (8 ± 18 g loss, $P = 0.67$). This positive effect of fish oil diets on carcass weight in TB animals was statistically significant (50 ± 19 g, $P < 0.02$), implicating that the fish oil enriched diet inhibited tumor-induced weight loss by more than 85%. No effect of fish oil diets on tumor growth was detected. In all TB animals, regardless of diet, hepatic [P_i]/[adenosine triphosphate] ratios measured by ^{31}P magnetic resonance spectroscopy (MRS) *in vivo* and *in vitro* were elevated, and absolute concentrations of phosphocholine, glycerophosphocho-line, glycerophosphoethanolamine and glucose-6-phosphate as determined by ^{31}P MRS *in vitro* were reduced. Ultrastructural studies of liver tissue revealed increased numbers of mitochondria and increased amounts of endoplasmic reticulum in the host liver of TB animals, without differences between dietary group. In conclusion, fish oil supplementation partially inhibited MAT-LyLu tumor-induced cachexia, but did not prevent the majority of ^{31}P MRS-detectable alterations in host liver metabolism.

***Lipids* 29, 195–203 (1994).**

There is increasing evidence suggesting that ω3 fatty acids from fish oil, eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA), may inhibit carcinogenesis and tumor growth (1–8). In cultures of human cancer cell lines, EPA, but not DHA, was cytotoxic to tumor cells to a greater extent than to nontumorigenic cells (3). In a number of chemically-induced and transplanted tumors, fish oil reduced tumor incidence, delayed tumor appearance, and decreased the growth rate and size of tumors (4–7). In a cachexia-inducing rodent tumor, fish oil given after tumors were palpable, inhibited tumor growth and carcass weight loss in a dose-dependent fashion (8). Different possible mechanisms underlying these effects, such as modulation of oncogene expression, cell-mediated immune response, prostaglandin synthesis and lipid metabolism, have been discussed (1–8).

We have recently reported (9) that the MAT-LyLu variant of the Dunning prostrate tumor, when transplanted into Copenhagen-Fisher rats, induces weight loss and marked alterations in host liver metabolism despite lack of metastatic involvement in the liver, and without a concomitant reduction in food intake. These alterations in the host liver included a rise in [P_i]/adenosine triphosphate (ATP)] ratios and a marked reduction in glycerophosphocholine (GPC) and glycerophosphoethanolamine (GPE) concentrations (9). In contrast, fish oil supplementation in healthy animals significantly increased hepatic GPC levels (10). Based on these findings and previous reports on anticachectic effects of fish oil (8), the present study was aimed at investigating the effects of fish oil supplementation on weight loss and host liver metabolism in rats bearing MAT-LyLu tumor allografts.

MATERIALS AND METHODS

Animals. Fourteen 12-week-old male Copenhagen-Fisher F1 hybrid rats (Harlan-Olac Ltd., Bicester, Oxford, United Kingdom) were used for this study. Mean (± SEM) weight of the animals was 321 ± 2 g. All animals were treated identically throughout the study, unless stated otherwise.

Tumor inoculation. MAT-LyLu rat prostate carcinoma cells were obtained from Dr. J. Isaacs (Johns Hopkins Cancer Center, Baltimore, MD) and cultured as previously described (11). At confluence, cells were harvested using 0.025% trypsin in 10 mM sodium phosphate buffer (pH 7.4) without Ca^{2+} or Mg^{2+}. Animals were inoculated into subcutaneous tissues of the left flank with 1×10^6 tumor cells suspended in 500 μL of sterile saline. Nine animals were injected with saline as controls.

Abbreviations: ADP, adenosine diphosphate; ATP, adenosine triphosphate; DHA, docosahexaenoic acid; EPA, eicosapentaenoic acid; F6P, fructose-6-phosphate; GPC, glycerophosphocholine; GPE, glycerophosphoethanolamine; G3P, glyceraldehyde-3-phosphate; G6P, glucose-6-phosphate; MRS, magnetic resonance spectroscopy; NTB, nontumor-bearing; *sn*-GP, *sn*-glycerol-3-phosphate; TB, tumor-bearing; TR, repetition time.

Diet and body weight. After tumor inoculation, animals were maintained in adjacent individual cages with water and standard food available *ad libitum*. The standard food was rat and mouse breeding diet (Pilsbury's Ltd., Birmingham, United Kingdom), which contained 50% carbohydrate, 20% protein, and 4.1% crude oil and supplied 11.5% of the energy as fat. Essential fatty acids comprised 1.45% of the diet (8). Seven days after tumor inoculation, when tumors were just palpable in all tumor-bearing (TB) animals, four TB and four nontumor-bearing (NTB) rats were changed onto a diet containing 50% of total energy as fish oil. The fish-oil enriched diet was prepared as an isocaloric isonitrogenous diet by decreasing the carbohydrate content and supplying the remaining energy from MaxEPA fish oil (kindly supplied by Seven Seas Ltd., Hull, United Kingdom) (8). The peroxide value (12) of fish oil was 4.6 mg/kg, which is within the quality specification for vacuum deodorized fish oil from the National Oceanic and Atmospheric Administration of the United States (13). Food was prepared fresh daily throughout the study. Body weight, as well as food and water intake, was monitored daily. Carcass weight was calculated by subtracting the weight of primary and metastatic tumors from total body weight.

Anesthesia. At 21 d after tumor inoculation, animals were fasted overnight and anesthetized using 0.5 mL/kg Hypnorm^{R} (Janssen Pharmaceutical Ltd., Grove, Oxford, United Kingdom), containing 0.315 mg fentanyl citrate and 10 mg fluanisone per mL, and 1 mg/kg Hypnovel (midezolam; Roche Laboratories, Division of Hoffmann-La Roche Inc., Nutley, NJ). A midline laparotomy was performed, and a two-turn, 14-mm diameter coil was placed immediately over the liver with an aseptic layer of film placed between the coil and the exposed tissue. Animals were maintained at 37°C throughout the experiment *via* a heated pad.

Magnetic resonance spectroscopy (MRS) in vivo. MRS data were acquired *in vivo* using an SIS MR imaging spectrometer (Spectroscopy Imaging Systems Corporation, Sunnyvale, CA) interfaced to an Oxford 4.7 Tesla, 30-cm bore superconducting magnet (Oxford Instruments Ltd. Eynsham, Oxford, United Kingdom). In order to optimize magnetic field homogeneity in the region of the coil, the coil was transmission line tuned to 200.06 MHz for detection of ^{1}H MRS signals. Typical linewidths of 50 Hz were observed for the water resonance. ^{31}P MRS data were then acquired with the coil tuned to 80.98 MHz, using a pulse of approximately 45° at the center of the coil, and a repetition time (TR) of 8 s (collecting 64 signal averages). Spectral quantification was carried out identically for all ^{31}P MRS data, in a blinded fashion. First, baseline correction was performed as follows: for each data set, Fourier transformation was carried out twice, applying line broadening of 20 Hz and 500 Hz, respectively. The two resulting spectra were then subtracted to obtain a spectrum corrected for the broad phospholipid signal (14). Resonances of interest were identified by chemical shift and quantitated by manual integration. For peaks which were not completely resolved, (i.e. phosphomonoesters, P_i and phosphodiesters), peak areas were defined as previously described (15). It was found empirically that use of TR 8 s and a pulse angle of 45° allowed for adequate relaxation of all resonances of interest obtained on the liver, i.e., use of a longer TR did not make a significant difference to the relative ratios of the measured resonance intensities. Hence, no correction for saturation was necessary.

MRS in vitro. On completion of MRS *in vivo*, part of the liver was freeze-clamped *in situ* at liquid nitrogen temperature (16). Tissue samples were extracted with perchloric acid (17), and adjusted to pH 7.5 using potassium hydroxide. The resulting supernatant was lyophilized and redissolved in D_2O. After adding ethylenediaminetetraacetic acid to a final concentration of *ca.* 100 mM, pH was readjusted to 7.5. High resolution ^{31}P MRS spectra were acquired on a 8.4 Tesla Bruker system (Bruker Spectrospin Ltd., Coventry, United Kingdom), using a 35° excitation pulse with TR 10 s. Proton scalar coupling interactions were removed by using low power proton decoupling. Metabolites *in vitro* were identified in a related study (17) by a combination of chemical shift, pH titration and standard addition of known compounds. A peak was considered identified if all these criteria were fulfilled. Concentrations *in vitro* were corrected for saturation and nuclear Overhauser effects by obtaining spectra at long TR (20 s) and by limiting the use of low power proton decoupling to the period of spectral acquisition only. Absolute concentrations of metabolites were obtained by calculating the peak area of each metabolite relative to the peak area of a standard metabolite of known chemical shift and concentration (phosphocreatine), which was added to the medium.

Microscopy. For light microscopy, specimens were fixed in fresh, neutral-buffered formaldehyde (10% vol/vol). After routine embedding in paraffin wax, tissue sections were cut at 3 μM thickness with a microtome and stained with hematoxylin and eosin. For electron microscopy, 1-mm cubes of tissue were fixed in 2% glutaraldehyde buffered with 0.2 M sodium phosphate-buffer (pH 7.2). Tissue blocks were post fixed in 1% osmium tetroxide in Millonig's buffer (18) for 1 h at room temperature. Thereafter, following two washes for 30 min each in distilled water, blocks were dehydrated in graded alcohols followed by three changes of TAAB^{R} resin (TAAB Laboratories, Aldermaston, United Kingdom) for one hour each. Tissue blocks were embedded in polyethylene capsules (BEEM capsules; TAAB Laboratories) in fresh identical resin. Polymerization was performed at 60°C overnight. Blocks were cut at 1 mm on a Reichert ultranicrotome using a glass knife. Serial ultrathin sections were then cut at 80 nm thickness using a diamond knife. Sections were placed onto uncoated nickel grids and stained in saturated methanolic uranyl acetate for 3 min followed by Reynold's lead citrate (19) for 8 min, both at room temperature. After drying, sections were examined and photographed using a Philips CM10 electron microscope (Philips Export BV, Eindhoven, The Netherlands) at 80 kV.

Statistical analysis. Results as expressed as means ± SEM in μmol per g wet weight and analyzed for significance by Student's *t*-test for independent groups; for

concentrations on P_i and P_i/ATP ratios (which were not distributed normally), Wilcoxon's rank sum test was used. Multivariate models were fitted in order to investigate whether the effect of fish oil diets on body weight gain during days 7–14 and days 14–21 was different in NTB and TB animals, including as covariates dummy variables for: (i) TB state; (ii) dietary group; and (iii) interaction of TB state and diet. In order to determine the effect of TB state and diet on changes in carcass weight after adjustment for food intake, analysis of covariance was used, including, as covariates: initial weight, mean daily food intake during the study, and dummy variables for: (i) TB state and (ii) interaction between TB state and diet. P values less than 0.05 were considered statistically significant.

RESULTS

Tumor weight. No effect of fish oil diets on primary or metastatic tumor weights was detected. Primary tumor weight on day 21 after tumor inoculation, when the study was terminated, was 67 ± 6 g (mean ± SEM) in TB animals on normal diets and 67 ± 8 g in animals on fish oil diets ($P > 0.10$). Metastatic tumor weight on day 21 was 9 ± 2 g in TB animals on normal diets and 7 ± 4 g in TB animals on fish oil diets ($P > 0.10$).

Food intake, total body and carcass weight. Food intake in NTB animals on normal diets (control group) was constant during the first two weeks of the study, but decreased during the third week (Fig. 1; $P < 0.002$, as compared to week 2). This decrease in food consumption was paralleled by attenuation of growth during the third week of the study (Fig. 2; days 18–21 as compared to days 14–18, $P < 0.002$), reflecting the animals reaching adult age (i.e., 14–15 wk of age).

Food intake during the first week of the study, when normal diets were given to all animals, was not significantly different between any of the NTB and TB groups ($P > 0.10$). However, the introduction of fish oil-enriched diets in part of NTB and TB animals on day 7 caused a reduction in food and energy intake to less than half of the energy intake by animals on normal diets during the second week of the study (difference by dietary group: NTB, $P < 0.001$; TB, $P < 0.001$). In the third week of the study, food intake in fish oil-fed animals returned to levels of approximately 75% of those in animals on normal

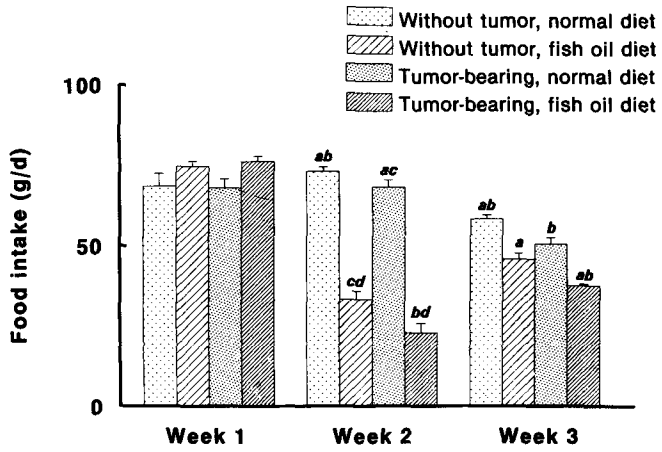

FIG. 1. Food intake by healthy rats and rats with tumors, on different diets. Boxes show means and bars SEM; values within one period with the same letter are significantly different (Students' *t*-test, $P < 0.05$). From days 0–7 (week 1), all animals received standard rat chow *ad libitum*. From day 7 onward (weeks 2 and 3), part of the animals were given a diet with 50% of energy from fish oil. As seen in the figure, the introduction of fish oil diets induced a sharp temporary reduction in food intake in fish oil-fed animals during the second week of the study. In the third week, food intake of these animals returned to levels close to those in animals fed normal diets.

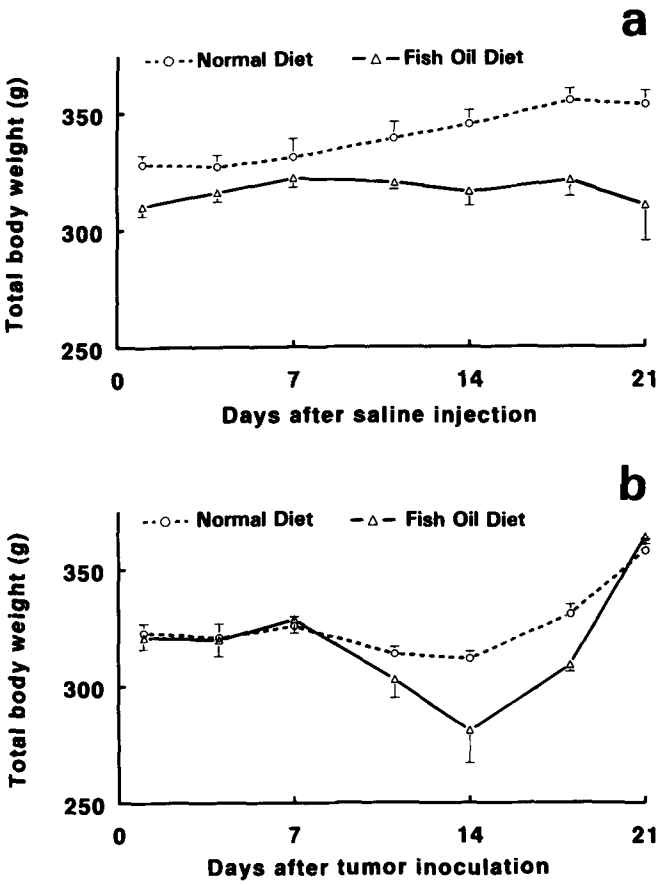

FIG. 2. Total body weight of (a) nontumor-bearing (NTB) rats and (b) tumor-bearing (TB) rats, on different diets. Fish oil-enriched diets were given from day 7 onward. Between-group differences in weight gain: days 1–7, no significant differences; days 7–14, a relative weight reduction is observed in NTB and TB animals on fish oil diets when compared to NTB and TB animals on normal diets, respectively (NTB, $P = 0.03$; TB, $P < 0.005$), with no significant interaction between the effects of diet and TB state (detected by multivariate analysis as described in the Materials and Methods section, $P > 0.10$). From days 14–21, weight gain in NTB animals fed fish oil diets was still depressed ($P > 0.10$ as compared to NTB animals on normal diets), whereas TB animals fed fish oil diets showed accelerated weight gain as compared to TB animals fed normal diets ($P < 0.02$). This positive effect of fish oil diets on weight gain in TB animals was significantly different from the effect of diet on weight gain in NTB animals (multivariate analysis, $P = 0.03$).

diets (Fig. 1), but differences by dietary group were still statistically significant (NTB, $P < 0.003$; TB, $P = 0.001$).

Changes in total body weight of animals during the study are shown in Figure 2a (NTB animals) and Figure 2b (TB animals). In the first week of the study, when all animals received normal diets, no significant differences in body weight or in weight gain were observed between any of the NTB or TB groups. During the second week (days 7–14), TB animals on normal diets lost weight relative to NTB (control) animals on normal diets (Fig. 2; $P < 0.001$). Over the same period, NTB and TB animals on fish oil diets showed significant weight loss when compared with NTB and TB animals on normal diets, respectively (Fig. 2, difference by dietary group: NTB, $P = 0.03$; TB, $P < 0.005$). This effect of dietary group was not significantly different between NTB and TB animals ($P > 0.10$). During the third week of the study (days 14–21), weight gain in NTB animals on fish oil diets remained depressive relative to NTB animals on normal diets, even though the difference no longer reached statistical significance (Fig. 2a; $P > 0.10$). In contrast, TB animals on fish oil diets showed a marked catch-up in body weight during the same period (Fig. 2b; $P < 0.02$, as compared to TB animals on normal diets). This positive effect of fish oil diets on body weight in TB animals was significantly different from that in NTB animals ($P = 0.03$). Because, as already described, final tumor weight was similar in TB animals irrespective of diet, the effect of fish oil diets on body weight of TB animals was attributed to changes in carcass weight.

Effect of food intake on carcass weight. The effect of fish oil enriched diets on final carcass weight on day 21, when the study was terminated, was further analyzed using analysis of covariance. In this model, initial weight and food intake over the three-week study period were included as covariates because they were significantly related with carcass weight on day 21 (for initial weight, $P = 0.05$; for food intake, $P = 0.01$). Taking NTB animals on normal diets as the reference group, significant loss of carcass weight was demonstrated in TB animals on normal diets only (58 ± 10 g loss, $P < 0.001$), but not in TB animals on fish oil diets (8 ± 18 g loss, $P = 0.67$). This positive effect of fish oil diets on carcass weight in TB animals was statistically significant (50 ± 19 g, $P < 0.02$), implicating that fish oil diets inhibited tumor-induced weight loss by more than 85%.

Liver metabolism. We previously reported (9) a rise in $[P_i]$/[ATP] ratios in TB animals on normal diets when compared to NTB animals on normal diets. Similarly elevated $[P_i]$/ATP] ratios were observed in TB animals on fish oil diets (Fig. 3 and Table 1). No significant differences in [phosphomonoester]/[ATP] ratios were observed between any of the groups. [Phosphodiester]/[ATP] ratios were reduced in TB animals on fish oil diets when

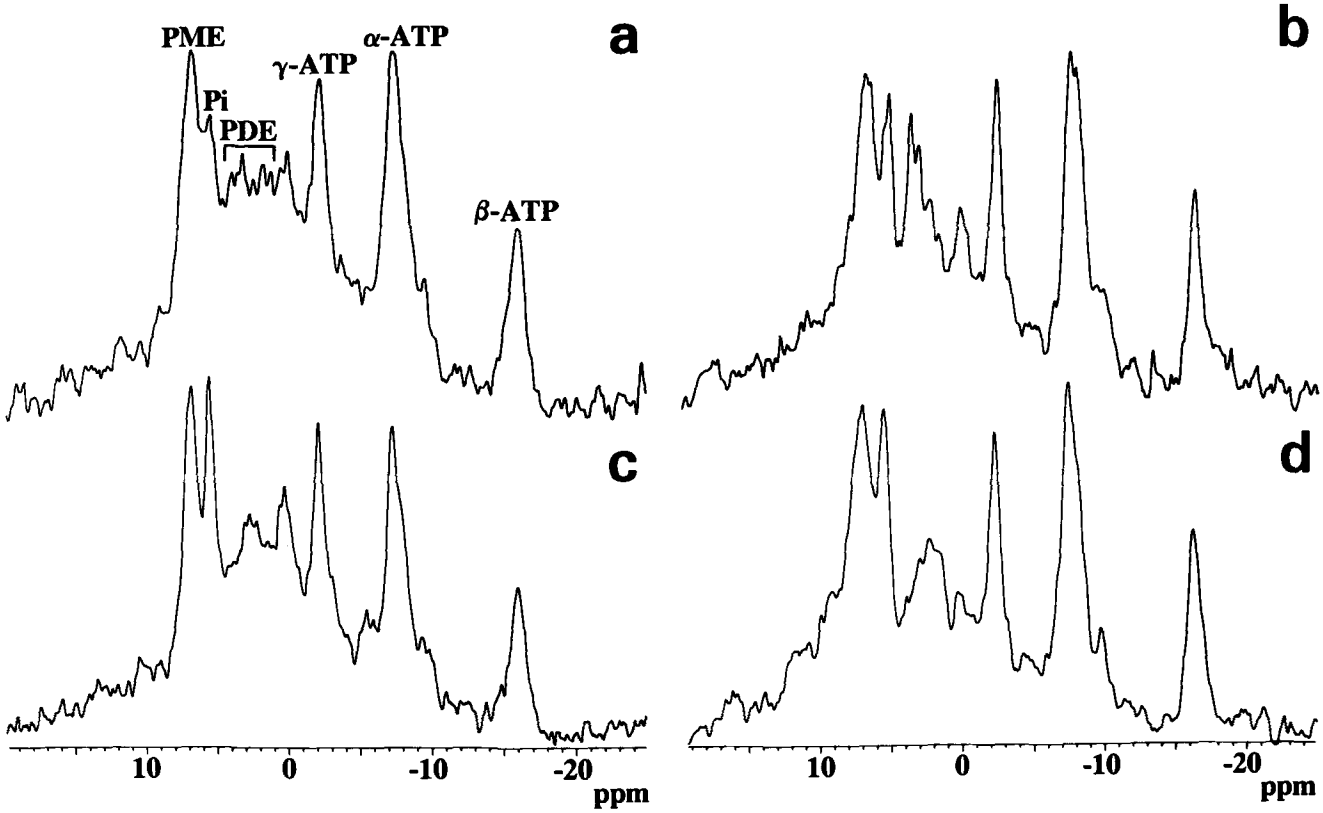

FIG. 3. ^{31}P magnetic resonance spectroscopy spectra *in vivo* of the liver from healthy rats and rats with tumors, on different diets: (a) animals without tumors and taking normal diets; (b) animals without tumors taking fish oil-enriched diets; (c) tumor-bearing animals on normal diets; and (d) tumor-bearing animals on fish oil-enriched diets. MRS spectra were obtained at 4.7 Tesla (45° acquisition pulse, repetition time 8 s) as described in the Materials and Methods section. Peak assignments: α-ATP, β-ATP, γ-ATP: α-, β- and γ-phosphate groups of adenosine triphosphate. PDE, phosphodiesters; PME, phosphomonoesters.

compared with TB animals on normal diets ($P < 0.005$), and with NTB animals on either diet ($P < 0.05$). No significant difference in intracellular pH was observed between any of the groups.

^{31}P MRS of liver extracts (Fig. 4 and Table 2) confirmed the elevated $[P_i]/[ATP]$ ratios observed *in vivo* in TB animals of either dietary group. Furthermore, absolute adenosine monophosphate concentrations in the liver of TB animals on fish oil diets were more than twice the levels in the other three groups. No difference in adenosine diphosphate concentrations was observed between any of the groups. Glucose-6-phosphate (G6P) concentrations were reduced in all TB animals regardless of diet, even though the difference from NTB animals reached statistical significance for TB animals on normal diets only ($P < 0.04$). In contrast, fructose-6-phosphate (F6P) concentrations were significantly higher in TB animals on fish oil diets ($P = 0.001$) than in TB animals on normal diets, reaching values close to NTB animals on normal diets. Concentrations of *sn*-glycerol-3-phosphate (*sn*-GP) were significantly higher in TB animals on fish oil diets when compared with the other groups ($P \leq 0.02$, Table 2). Glyceraldehyde-3-phosphate (G3P) levels were also increased, but this difference was only significant when compared with NTB animals on fish oil diets. No differences in 3-phosphoglycerate concentrations were observed. Phosphocholine, GPC and GPE concentrations were significantly decreased in the liver of all TB animals regardless of diet (Fig. 5).

Histological and ultrastructural studies of liver tissue. Microscopic examination revealed no region of congestion of ischemia within the liver of any of the animals. Histological examination confirmed the absence of metastatic tumor cells from the host liver of all TB animals. Microscopic appearance of the liver was normal,

[a]Animal preparation as in Table 1. Liver was freeze-clamped *in situ,* and ^{31}P MRS spectra of tissue extracts were acquired at 8.4 Tesla, as described in the Materials and Methods section.
[b]Abbreviations: ADP, adenosine diphosphate; AMP, adenosine monophosphate; ATP, adenosine triphosphate; F6P, fructose-6-phosphate; G3P, glyceraldehyde-3-phosphate; G6P, glucose-6-phosphate; 3PGA, 3-phosphoglycerate; *sn*-GP, *sn*-glycerol-3-phosphate; MRS, magnetic resonance spectroscopy.
[c–e]Values shown are means ± SEM in μmol/g wet tissue. Values in a row with the same superscript letter are significantly different ($P < 0.05$, using Student's *t*-test, except for P_i and $[P_i]/[ATP]$, where Wilcoxon's rank sum test was used). Control values from tumor-bearing and nontumor-bearing animals on normal diets were taken from Reference 9, with permission.

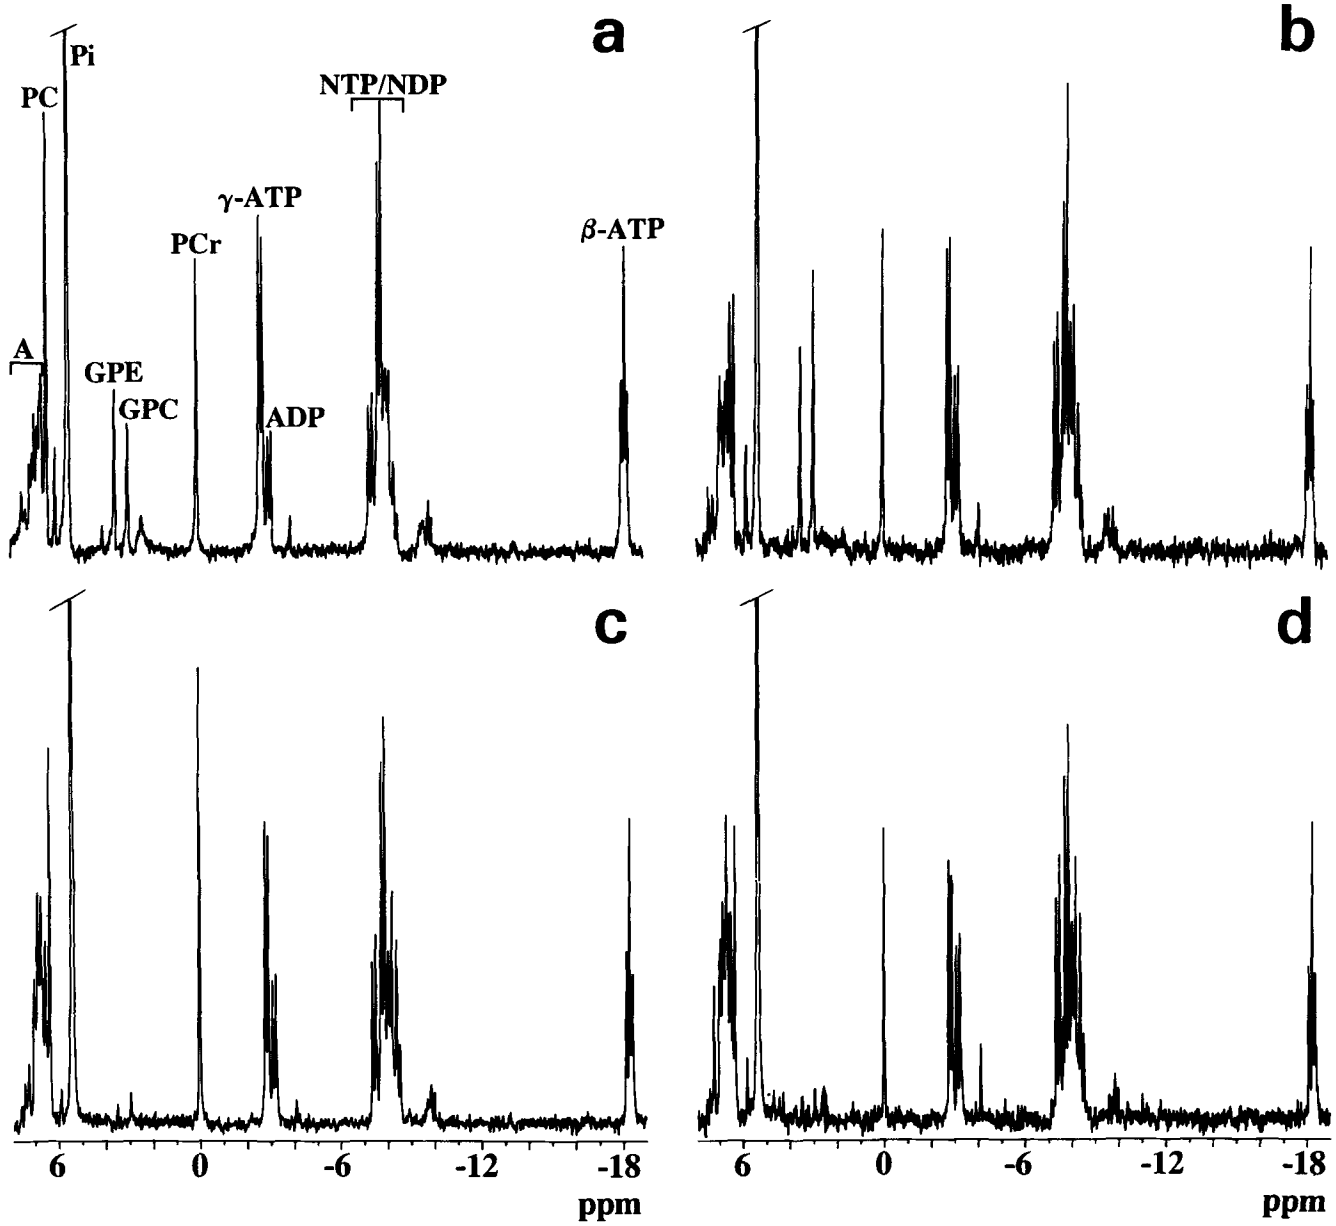

FIG. 4. ^{31}P MRS spectra of tissue extract in *in vitro* from liver of healthy rats and rats with tumors, on different diets: (a) animals without tumors and taking normal diets; (b) animals without tumors taking fish oil-enriched diets; (c) tumor-bearing animals on normal diets; and (d) tumor-bearing animals on fish oil-enriched diets. MRS spectra were obtained at 8.4 Tesla as described in the Materials and Methods section. The scale of the four spectra shown has been standardized to equal peak heights of β-ATP. Peak assignments: A, phosphomonoesters, including adenosine monophosphate, sugar phosphates and phosphocholine; β-ATP, γ-ATP: β- and γ-phosphate groups of adenosine triphosphate, G6P, glucose-6-phosphate; GPC, glycerophosphocholine; GPE, glycerophosphoethanolamine; NTP/NDP, nucleotide triphosphates and diphosphates; PC, phosphocholine; PCr, phosphocreatine (added as an internal chemical shift reference and quantitative standard).

without any inflammatory cell infiltration. Ultrastructural studies of liver tissue revealed the presence of small amounts of retained intracytoplasmic lipid within the cytoplasm of hepatocytes from NTB animals fed fish oil diets (Fig. 6). In all other respects, no differences were observed in the ultrastructural appearances of the NTB groups. However, there were distinct differences between NTB and TB animals. In both TB groups, mitochondria were increased in number. Typically, they were enlarged, swollen and irregular in appearance. In both groups of TB animals, the endoplasmic reticulum was increased in amount and in distribution throughout the hepatocyte cytoplasm. Individual cisternae of the rough endoplasmic reticulum were longer and more convoluted than those of the NTB groups. Generally, a much closer apposition of the cisternae to mitochondria was observed in hepatocytes from TB animals when compared to NTB animals. In contrast to the NTB animals fed on

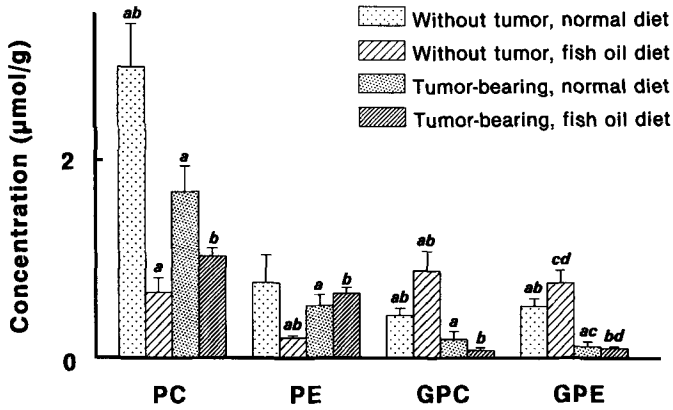

FIG. 5. Absolute concentrations of intermediates of phospholipid metabolism in the liver of healthy rats and rats with tumors, on normal or fish oil-enriched diets. Concentrations were measured using ^{31}P MRS *in vitro*. Abbreviations as in Figure 3, and PE, phosphoethanolamine. Boxes show means and bars SEM in µmol/g wet tissue. Values of one metabolite with the same letter are significantly different (Student's *t*-test, $P < 0.05$).

fish oil diets, hepatocytes of TB rats on fish oil diets did not contain cytoplasmic lipid droplets.

DISCUSSION

The aim of this study was to determine whether a diet rich in ω3 fatty acids from fish oil could reverse tumor-induced cachexia and changes in hepatic metabolism reported previously (9) in the host liver of rats with malignant prostate tumors. For this purpose, the MAT-LyLu variant of the Dunning prostate tumor was chosen as a cachexia model for two reasons. First, MAT-LyLu cells do not metastatize to the liver, as was confirmed by the absence of metastatic tumor cells at histological and electron microscopic examination of liver tissue. Second, as previously reported (9), loss of carcass weight in animals with MAT-LyLu tumors fed normal diets occurs without a significant reduction in food intake, suggesting that the cachexia induced by this tumor model is due to metabolic abnormalities in the host.

The introduction of a diet containing 50% of energy as fish oil, seven days after tumor/saline inoculation, caused a marked temporary reduction in food intake during the second week of the study, regardless of whether or not rats had tumors. Although food intake recovered to almost normal levels in the third week of the study, the temporary reduction was unexpected in the view of earlier reports, where an identically prepared fish oil diet did not lead to any decrease in food intake by NMRI mice with MAC16 colon carcinomas (8, 20). The cause of this reduced food intake in our study remains uncertain. Peroxidation of fish oil diets is unlikely to have played a significant role, as the fish oil used contained low peroxide levels and diets were freshly prepared every day throughout the study. The observation that in the third week of the study, food intake in fish oil fed animals returned to a level close to that in animals on normal diets (Fig. 1), would suggest that the animals initially did not find the fish oil diet palatable, and had to get used to this diet.

Nevertheless, when data were adjusted for differences in food intake, a significant inhibition of tumor-induced loss of carcass weight by more than 85% over the three-week study period was demonstrated in TB animals on fish oil diets when compared with TB animals on normal diets. It is noteworthy that TB animals fed fish oil diets showed a marked catch-up in body weight during the third week of the study (Fig. 2b), when their food intake was almost normal (i.e., at the same level as in TB animals fed normal diets), whereas no positive effects of fish oil diets on body weight were detected during the second week of the study, when the animals' intake of fish oil diets was low. This observation further supports a specific inhibition of weight loss in TB animals by fish oil diets. Our findings confirm earlier reports by Tisdale and co-workers (8), who found that a diet containing 50% of energy as fish oil, or the equivalent dose of pure EPA (21), completely prevented weight loss in mice with MAC16 tumors.

In contrast with the observations in MAC16 TB mice (8), fish oil diets did not inhibit the growth of MAT-LyLu tumors in this study. The possibility that this was due to the temporary reduction of food intake in animals on fish oil diets appears unlikely, as caloric restriction was previously reported to potentiate the inhibition of tumor growth by fish oil in experimental carcinomas (2). Therefore, the lack of inhibition of growth of the MAT-LyLu tumor is more likely to be related to kinetic properties of this tumor when compared with the MAC16 tumor. The latter is a slowly growing tumor producing cachexia at an early stage, when tumor mass is less than 1% of body weight (20,22), whereas the MAT-LyLu tumor is a rapidly growing tumor. This highly aggressive tumor may not allow for any inhibition of tumor growth by relatively mild therapeutic modalities, such as fish oil.

Fish oil diets did not prevent the majority of tumor-induced alterations in host liver metabolism as measured by ^{31}P MRS. A dramatic reduction in hepatic phosphorylation status and in concentrations of phosphocholine, GPC, GPE and G6P was observed in all TB animals, regardless of diet. The reduction in GPC levels in TB animals on fish oil diets was in marked contrast with the previously reported increase in GPC levels in NTB animals on fish oil diets (10). Our data suggest that a fish oil-enriched diet is not able to prevent these major ^{31}P MRS-detectable disturbances in host liver metabolism of animals with MAT-LyLu tumors, even though the rise in F6P concentrations in fish oil-fed animals would be compatible with an effect of ω3 fatty acids on the glycolytic/gluconeogenic pathway within the liver.

Ultrastructural examination of hepatocytes from all four groups of animals within this study demonstrated the presence of free cytoplasmic lipid droplets in hepatocytes from NTB animals on fish oil diets only. Triacylglycerol accumulation in the liver was previously reported in healthy rats on diets containing 30% of energy as fish oil and attributed to inhibition of triacylglycerol secretion by fish oil (23). In contrast, we did not detect

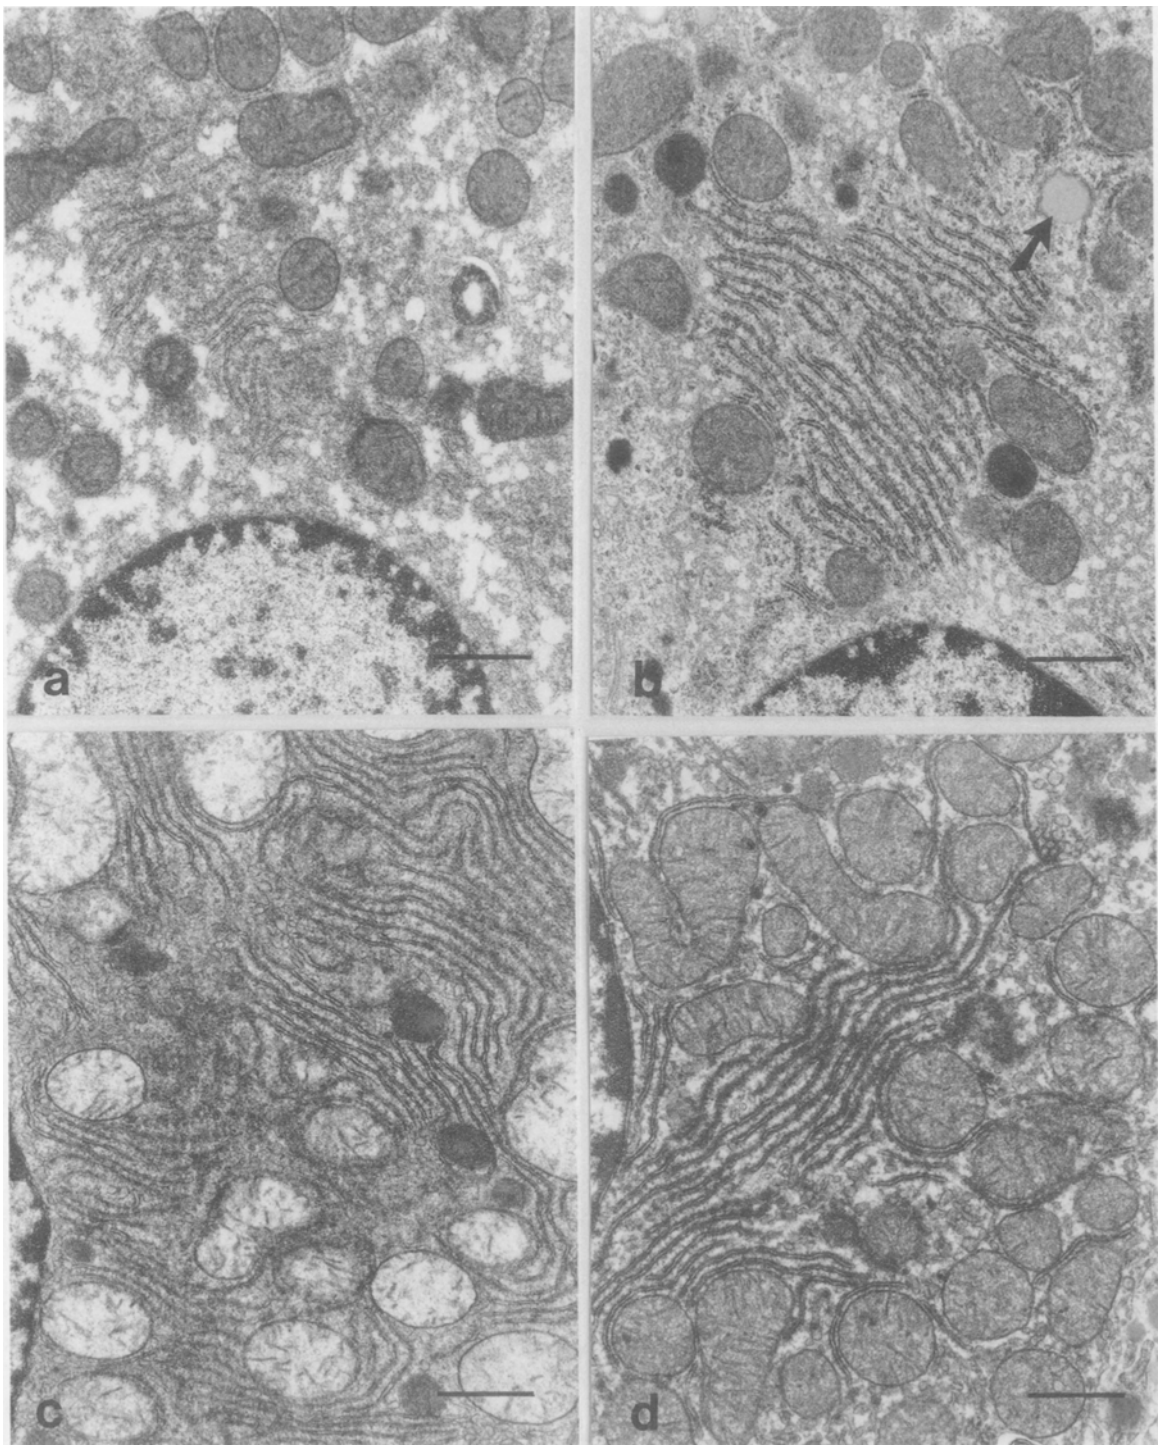

FIG. 6. Ultrastructural appearances of hepatocytes from healthy rats and rats with tumors, on different diets: (a) animals without tumors and taking normal diets; (b) animals without tumors taking fish oil-enriched diets; (c) tumor-bearing animals on normal diets; and (d) tumor-bearing animals on fish oil-enriched diets. Liver tissue was removed at 21 d after tumor inoculation (controls: saline injection) and fixed as described in the Materials and Methods section. In all control livers, mitochondria appeared small, uniform and compact. The endoplasmic reticulum was concentrated into well-localized regions adjacent to the nuclei. Hepatocytes from control rats fed high-fat diets appeared similar, but also contained lipid droplets (arrow). Hepatocytes from both groups of tumor-bearing animals contained increased numbers of "open," enlarged and irregularly-shaped mitochondria. The endoplasmic reticulum was increased in amount and in distribution throughout the cytoplasm. Cytoplasmic lipid droplets were not a characteristic feature of tumor-bearing animals fed high fat diets. In each electron micrograph, the bar indicates 1 μm.

any formation of lipid droplets in hepatocytes in TB animals on fish oil diets. This could be due to either decreased fatty acid precursor supply to the liver, to kinetic alterations within the liver or to increased peripheral utilization of triacylglycerols. The presence of a circulatory lipid mobilizing factor has been demonstrated in blood from mice with MAC16 tumors (21) and in cancer patients (22). EPA inhibited tumor-induced lipolysis from adipose tissue, leading to a reduction in plasma free fatty acid levels (21) and, thus, to decreased fatty acid supply to the liver. We recently reported (24) a rapid and marked reduction in free fatty acid concentrations in the blood of healthy humans after fish oil supplementation, suggesting that inhibition of lipolysis by fish oil may be a general phenomenon that is not specific to the TB state. Therefore, it is unlikely that reduced lipolysis would be the sole explanation of the absence of lipid droplets from the liver of TB animals. An alternative explanation is that fish oil may induce specific kinetic alterations within the liver of TB animals. The observation that, only in TB animals, fish oil diets induced a rise in *sn*-GP levels (Table 2) draws attention to the possible inhibition of an early step in glycerolipid synthesis by ω3 fatty acids (25). The simultaneous elevation of G3P (Table 2) would appear to exclude an alternative explanation for rising *sn*-GP, i.e., altered redox status of hepatocytes.

Generally speaking, however, the major differences in ultrastructure of hepatocytes in this study were observed between animals in the TB vs. NTB state, irrespective of diet. TB animals showed appearances similar to those previously reported (9), suggesting that the main influence on morphology was not the effect of diet, but of the tumors.

In conclusion, this study has shown that a diet containing 50% of total energy as fish oil significantly inhibited tumor-induced weight loss in rats with MAT-LyLu tumors. However, the fish oil-enriched diet did not reverse the majority of ^{31}P MRS-visible metabolic aberrations or ultrastructural abnormalities in the host liver of these rats. Furthermore, no effect of fish oil on the growth rate of MAT-LyLu tumors was detected.

ACKNOWLEDGMENTS

We are very grateful to Prof. M.J. Tisdale for valuable advice regarding the design of this study and the composition of the diets. We would also like to thank Sue Keefe and Ashley Reynolds for assistance in the design and implementation of the experiments. The helpful assistance by Dr. F.W. Vas Dias (Seven Seas Ltd., Hull, United Kingdom) is gratefully acknowledged. This work was supported in part by the Dutch Cancer Society. P.C. Dagnelie is a fellow of the Royal Netherlands Academy of Arts and Sciences.

Alteration in Membrane Lipid Order and Composition in Metabolically Hyperactive Fatty Rat Adipocytes

Michèle Guerre-Millo[a,*], Phillipe Guesnet[b], Colette Guichard[a], Georges Durand[b] and Marcelle Lavau[a]

[a]INSERM U177, Institut biomédical des Cordeliers, 75006 Paris and [b]INRA, Laboratoire de Nutrition et Sécurité Alimentaire, 78350 Jouy en Josas, France

We have previously shown that adipose cells from young genetically obese Zucker rats are characterized by very high metabolic activity together with an increase in a wide range of membrane-mediated functions. The aim of the present study was to examine whether the physical properties of the membranes and the composition of the membrane lipids were altered in these cells. Plasma membranes and two intracellular membrane fractions were prepared by differential ultracentrifugation from inguinal adipose cells of 30-day-old obese (fa/fa) and lean (Fa/fa) littermates. The lipid order as measured by steady-state fluorescence polarization of diphenylhexatriene used as probe was markedly decreased in the plasma membranes of obese rat adipose cells. Consistent with this, the cholesterol-to-phospholipid ratio was significantly decreased, and the degree of unsaturation of the phospholipid fatty acids was significantly increased. In intracellular membranes, none of these parameters were altered by the different genotype. In fat cells from obese rats, both plasma and intracellular membranes exhibited a 2-fold decrease in the ratios of n-6/n-3 fatty acids mainly due to an enrichment in docosahexaenoic acid (22:6n-3). The data show that the fatty genotype is a determinant of membrane lipid order and composition in adipose cells. The alterations reported here for young obese Zucker rat adipocytes might be related to the metabolic hyperactivity of these cells.

***Lipids* 29, 205–209 (1994).**

The obesity of the (fa/fa) rat, first described by Zucker and Zucker (1), is due to a single recessive autosomal gene mutation, the nature of which remains unknown. This rat develops a syndrome which shares many features with human obesity, which recently has been shown to also have a genetic etiology (2) and for which the Zucker rat serves as an excellent model. The first phenotypic trait that develops in the mutant rat is a hypertrophy of fat cells (3). In post-weaning 30-day-old rats, these cells reach a size four times that in lean (Fa/fa) rats. Furthermore, the cells show a very high metabolic activity together with an increase in a wide range of membrane-mediated functions. Thus, obese rat fat cells show marked hyperresponsiveness to insulin in regard to the tyrosine kinase activity of the receptor (4), glucose transport (5,6) and glucose metabolism (7). In addition, these cells display a marked increase in the specific binding of several ligands, including growth hormone (8), α2 adrenoceptor agonists (9) and adenosine (10). These apparently unrelated abnormalities could be accounted for, at least in part, by a change in lipid order and/or composition of the plasma membranes as a common determinant. Indeed, increasing evidence suggests that membrane-mediated events, including transport functions, enzymes activities and ligand/receptor interactions, are influenced by the order and the composition of their lipid environment (11–13). The aim of the present study was to examine whether the physical properties and the composition of plasma membrane lipids were altered in metabolically hyperactive fatty rat adipocytes.

Abbreviations: DBI, double bond index; DPH, 1,6-diphenyl-1,3,5-hexatriene; HDM, high density microsomes; LDM, low density microsomes; PC, phosphatidylcholine; PE, phophatidylethanolamine; PI, phosphatidylinositol; PS, phosphatidylserine; SPH, sphingomyelin; Tris, tris(hydroxymethyl)aminoethane.

MATERIALS AND METHODS

Animals. The Zucker rats used in this study were bred from pairs originally provided by the Harriet B. Bird Laboratory (Stow, MA). Known lean heterozygous (Fa/fa) females and homozygous (fa/fa) males were mated. From this mating, 50% of the pups are expected to be obese (fa/fa) and 50% lean (Fa/fa). The rats were housed at 22–23°C and exposed to light from 7:00 a.m. to 7:00 p.m. The pups were studied at 30 d of age and were kept on the dam diet (AO4; Unité d'Alimentation Rationnelle, Epinay/Orge, France) until two days before the experiments. The fatty acid composition of this diet has been reported previously (14). Rats were killed by decapitation, between 9:00 and 10:00 a.m.

Subcellular fractionation of isolated adipocytes. Isolated adipocytes were prepared from the inguinal fat pads of approximately 35 lean and 35 obese rats by collagenase digestion. Cells were homogenized in a buffer containing 10 mM tris(hydroxymethyl)aminomethane (Tris), 1 mM ethylenediaminetetraacetic acid and 255 mM sucrose, pH 7.4, at 4°C, and the homogenates were centrifuged at 16,000 × *g* max for 15 min. Plasma membrane fractions were prepared from the 16,000 × *g* pellet by centrifugation on a Percoll/sucrose gradient (15). High density microsomes (HDM) and low density microsomes (LDM) were prepared by differential ultracentrifugation of the 16,000 × *g* supernatant, as described previously (5). Proteins were determined using the Bio-Rad assay and bovine serum albumin as standard. Approximately 4-fold greater amounts of protein were recovered in membrane fractions from obese rat adipocytes as compared to those from lean littermates. Typically, the protein recovery was 1.3, 2.1 and 2.8 mg/ten obese rats compared to 0.33, 0.46 and 0.73 mg/ten lean rats for the plasma membrane, HDM and LDM, respectively. To assess the reproducibility of the cell fractionation procedure, marker enzyme activities, including 5'-nucleotidase and galactosyltransferase activities, were routinely measured, as previously described (5).

Adipocyte membrane fluidity. Adipocyte membrane lipid order was monitored by steady-state fluorescence

polarization measurements using the fluorescent probe 1,6-diphenyl-1,3,5-hexatriene (DPH) (16). Membranes were incubated for 45 min at 37°C in 1 mL of the homogenization buffer, in the presence of DPH at a final concentration of 10^{-7} M. Membrane proteins were adjusted to ensure a DPH/phospholipid molar ratio in the order of 1/200. Due to large variations in the phospholipid-to-protein ratios among the different membrane species (see Table 2), 20 to 100 μg of protein were used. The turbidity of the samples was always below 0.150 absorbance units at 360 nm (excitation wavelength of DPH). Steady-state fluorescence polarization measurements were made at 37°C on a SLM 8000 spectrofluorimeter (Urbana, IL). The excitation wavelength was 360 nm, and a 418 nm cutoff filter (rejecting more than 99.99% of the excitation light) was used for emission. Five measurements were averaged for each sample. The background without the probe was measured under identical conditions. The fluorescence polarization value was calculated according to $(I_{pa}-I_{pe})/(I_{pa}+I_{pe})$, where I_{pa} and I_{pe} are the fluorescence intensities emerging parallel and perpendicular to those of the original light source. This parameter gives an estimate of the resistance of DPH to rotational motion within the membrane lipid phase and is taken as a measure of the average orientational order of the lipid matrix (16–19).

Lipid composition of adipocyte membrane. Total lipids were extracted according to Folch *et al.* (20), from individual or pooled membrane preparations containing at least 1 mg of protein. Cholesterol was determined by the method of Liese *et al.* (21), and total phospholipid by the method of Bartlett (22). The membrane content in the five major phospholipid classes was determined by two-dimensional thin-layer chromatography followed by phosphorous assay of the fractions. The fatty acid composition of total phospholipid was determined by gas–liquid chromatography of the fatty acid methyl esters using a Carlo Erba (Milan, Italy) 4180 gas–liquid chromatograph, equipped with a flame-ionization detector. Authentic fatty acid methyl esters were used to assign fractions based on their retention times (14).

Statistical analysis. Results are expressed as mean ± standard error of the mean (SEM); *P* values were obtained using the unpaired Student *t*-test.

RESULTS

Fluorescence polarization of the DPH probe was determined in the plasma membrane and in two intracellular membrane fractions (HDM and LDM) from lean and obese Zucker rat adipose cells (Table 1). This parameter was markedly decreased in the plasma membranes from obese as compared to lean rat fat cells, indicating a lower lipid order. In contrast, there was no effect of genotype on DPH fluorescence polarization values in the intracellular membranes. Independent of the genotype, the intracellular membranes gave DPH fluorescence polarization values that were significantly lower than those for the plasma membranes.

The phospholipid and cholesterol contents of the subcellular membrane fractions from Zucker rat adipose cells are shown in Table 2. The phospholipid-to-protein ratio was similar in the plasma membranes from lean and obese rat adipocytes. By contrast, the cholesterol concentration was two times lower in obese than in lean rat adipocyte plasma membrane, resulting in a lower cholesterol/phospholipid ratio. In intracellular membranes, the amounts of lipid (phospholipid and cholesterol) per mg of membrane protein were markedly lower than in the plasma membranes of the same cells, but similar between the two groups.

TABLE 1

Steady-State DPH Fluorescence Polarization in Three Subcellular Membrane Fractions from 30-day-old Zucker Rat Adipocytes[a]

	Fluorescence polarization	
	Lean (Fa/fa)	Obese (fa/fa)
Plasma membranes (11)	0.215 ± 0.009	0.185 ± 0.007[b]
HDM (12)	0.127 ± 0.007[c]	0.130 ± 0.007[c]
LDM (12)	0.146 ± 0.008[c]	0.147 ± 0.008[c]

[a]Values are means ± SEM for the number of separate membrane preparations shown in parentheses. Abbreviations: DPH, 1,6-diphenyl1,3,5-hexatriene; HDM, high density microsomes; LDM, low density microsomes.

[b]Differs significantly ($P < 0.05$) from lean rat adipocyte plasma membranes.

[c]Differs significantly ($P < 0.01$) from the plasma membranes of the same cells.

The data in Table 1 and Table 2 suggest that a relationship exists between the value of DPH fluorescence polarization and the cholesterol/phospholipid ratio. By plotting individual data, we found a positive correlation ($r = 0.46$, $n = 22$, $P < 0.05$) between the two parameters, in agreement with previous reports (23,24).

The proportions of the five major phospholipid classes in adipocyte membrane fractions are shown in Table 3. The phospholipid composition of plasma and intracellular membranes was quite similar in the two groups, except for a significant decrease in the pool phosphatidylserine (PS) + phosphatidylinositol (PI) in the plasma membranes from obese rat adipocytes.

The fatty acid composition of plasma membrane phospholipids is shown in Table 4. The relative amounts of saturated and monounsaturated fatty acids were not significantly altered by the fatty genotype. By contrast, significant changes became apparent between the two groups in the polyunsaturated fatty acid levels. In obese as compared to lean rat fat cells, the proportion of n-6 fatty acids tended to be lower, whereas the amounts of n-3 fatty acids were significantly increased, with a particularly high contribution from docosahexaenoic acid (22:6n-3). Thus, the ratio of n-6/n-3 fatty acids was markedly decreased (2-fold) in the plasma membranes of obese rat adipocytes. This feature was also seen in the intracellular membranes, where the ratios of n-6/n-3 fatty acids were 4.5 and 5.0 in obese rat adipocyte compared to 10.8 and 8.2 in lean rat adipocyte HDM and LDM, respectively (means of two experiments). In addition, the degree of unsaturation of fatty acids, as measured by the double bond index (DBI), was significantly

[b]Differs significantly ($P < 0.05$) from lean rat adipocyte plasma membranes.

higher in the plasma membranes from obese as compared to lean rat adipocytes, but was unaffected by the genotype in intracellular membranes.

DISCUSSION

This study shows, for the first time, the effect of the fatty genotype on the physical properties and lipid composition of adipocyte subcellular membranes. The data illustrate that there is a substantial decrease in the plasma membrane lipid order in obese rats, together with a decrease in the cholesterol-to-phospholipid ratio and an increase in fatty acyl unsaturation. In contrast to plasma membranes, no change could be detected in intracellular membranes. This suggests that the regulation of adipocyte membrane lipids by the fatty genotype affects mainly, if not exclusively, the plasma membrane.

The genetic dependence of adipocyte plasma membrane lipid order and/or lipid composition has been previously shown in two strains of obese mice, ob/ob and db/db (25–27). In ob/ob mice, plasma membrane lipid order was also found to be decreased as compared to lean mice. However, in these mice there was no change in the phospholipid/cholesterol ratio or fatty acyl unsaturation (25,26). In db/db mice, the fatty acids of adipocyte plasma membranes were shown to be less unsaturated than in lean mice (27). Thus, from the studies in obese mice and based on our present data, it is clear that the lipid composition of the adipocyte plasma membrane is regulated in a genotype-specific manner.

The large changes in lipid order and composition we found in the plasma membranes of obese rat adipocytes could be implicated in the altered membrane-associated functions displayed by these metabolically hyperactive cells (4–10). The relationship between lipid order and/or composition and functional properties of membranes has been suggested by several models. Relevant observations have been made in 3T3-F442A adipocytes where a decrease in plasma membrane lipid order and in cholesterol/phospholipid ratio and an increase in phospholipid fatty acid unsaturation was observed during adipose conversion when cells undergo changes in several

[b]$P < 0.05$ vs. adipocyte plasma membranes from lean rat.

integral membrane functions (28). In reconstituted plasma membrane vesicles, both the binding and the kinase activity of the insulin receptor (29) as well as the glucose transport activity have been shown to correlate with the degree of fatty acid unsaturation of the surrounding phospholipids (30). The Zucker rat provides a physiological model supporting the conclusion from these *in vitro* studies that decreased lipid order or increased fatty acid unsaturation is associated with increased membrane functional activity. One could speculate that changes in the physiochemical properties of the fat cell plasma membrane could affect vesicle fusion and budding involved in exocytosis, endocytosis and recycling, which, in turn, affects the quantity and exposure of receptors and transport proteins at the cell surface. It is also possible that the increase in docosahexaenoic acid, that we found in obese rat adipocytes, plays a role in the metabolic hyperactivity of these cells. Indeed, in ongoing experiments we have observed that dietary fish oil rich in n-3 fatty acids induces a marked increase in both the insulin responsiveness and the lipid storage capacity of the adipose cells when compared to the effect of dietary saturated or n-6 fatty acid (Hainault, I., Guichard, C., and Lavau, M., unpublished data).

The mechanism through which the fatty genotype influences the fatty acyl composition of the adipocyte plasma membrane is far from being clear. The fatty acid composition of phospholipids from various tissues in Zucker rats has been recently reported (14,31). A decrease in the ratios of n-6/n-3 fatty acids was observed in liver and kidney but an increase was observed in heart, and no change was seen in brain or retina. Taken together, the data thus point toward a tissue specificity of the fatty genotype effect.

In conclusion, our work demonstrates that the genetic background influences the lipid order and composition of the adipocyte plasma membrane, thereby having the potential to modify membrane-mediated control of cellular activity. The alterations revealed by the present study in adipocytes from young obese Zucker rats could be involved in the metabolic hyperactivity of these cells.

ACKNOWLEDGMENTS

We wish to express our thanks to Dr. F. Baugé and Dr. J. Gallay for their help in fluorescence measurements.

[Received October 1, 1992, and in revised form November 26, 1993; Revision accepted November 26, 1993]

Synthesis and Structural Analysis of Stereospecific 3,4,5-Trisubstituted γ-Butyrolactone Phospholipids

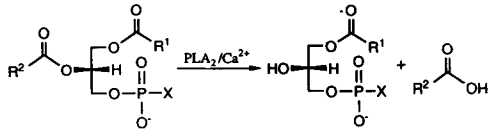
Xun Li* and **David P. Rotella**

Department of Pharmacognosy, School of Pharmacy, University of Mississippi, University, Mississippi 38677

The first synthesis of stereospecific 3,4,5-trisubstituted γ-butyrolactone phospholipids has been achieved by a ten-step sequence starting from *N,N*-dimethylacetamide (9). Alkylation of 9 with 1-bromohexane gave *N,N*-dimethyloctanamide (11), which was subjected to aldol condensation with acrolein and afforded the *erythro*-*N,N*-dimethyl-3-hydroxy-2-hexyl-4-pentenamide (6) and its *threo* isomer 7, both of which were subsequently converted to the corresponding 3-oxy(hexanoyl) esters 15 and 16. Stereospecific cyclization of diastereomeric allylic amides (6,7,15 and 16) *via* iodolactonization gave 3,4,5-trisubstituted γ-butyrolactones (19–25) in satisfactory yields (68–89%) and with high stereoselectivity (at least 6:1), except for the *threo* amide 16 (2:1). Conversion of the 6-iodo-group of the major iodolactones 23 and 24 to the corresponding 6-hydroxy lactones 31 and 32 through a wet Prévost reaction also resulted in 4-hydroxy lactones 30 and 33, and a mechanism for this reaction is proposed. Further phosphorylation of 4- or 6-hydroxy lactones 30, 31 and 32 with diphenyl chlorophosphate gave the corresponding diphenyl phosphoric acid lactone esters 34, 35 and 36, whereas 33 underwent an elimination reaction under formation of a C(3)–C(4) double bond. Hydrogenolysis of the diphenyl groups of esters 34, 35 and 36 over Adams' catalyst [platinum(IV) oxide] yielded the corresponding phosphoric acid lactone esters 38, 39 and 40, which were finally treated with choline tetraphenylborate to afford the desired lactone phospholipids 41, 42 and 43 in overall yields of 9, 30 and 18%, respectively. The structures of all new compounds were unambiguously assigned by analysis of their ^{1}H and ^{13}C one-dimensional and two-dimensional nuclear magnetic resonance (NMR) spectra obtained on a 300 MHz NMR spectrometer, and the structures were confirmed by low or high resolution mass spectrometry as well as elemental analysis. The stereoisomeric purity of the final products (98.2, 99.0 and 98.5% for 41, 42 and 43, respectively) was determined by high-performance liquid chromatography.

***Lipids* 29, 211–224 (1994).**

The mechanism and the inhibition of phospholipase A_2 (PLA_2) (EC 3.1.1.4) action are topics of much current biological and medical interest. PLA_2 specifically cleaves the *sn*-2 acyl bond of phospholipids and produces equimolar amounts of lysophospholipid and free fatty acid (Scheme 1) (1–4). Thus, PLA_2 also plays an important role in the release of arachidonic acid, the sole precursor for the biosynthesis of eicosanoids, that include prostaglandins, leukotrienes and thromboxanes (5–7). Eicosanoids have been implicated in the pathophysiology of many diseases, and especially those involving inflammation and allergy (6–8). Therefore, inhibition of PLA_2 is a logical approach to the treatment of these conditions.



$R^1, R^2 = C_mH_{2m+n}$, m = 13, 15, 17, 19; n = 1, -1, -3, -5, -7, etc...
X = -OH, $-OCH_2CH_2N^+(CH_3)_3$, $-OCH_2CH_2NH_2$, etc...

SCHEME 1

In the design and synthesis of potential PLA_2 inhibitors, phospholipid analogues have attracted considerable attention. It is known that for a compound to serve as a PLA_2 substrate, a fatty acid ester must be bonded vicinally to a phosphate ester (9). Noticeable progress has been made in the preparation of acyclic phospholipids as PLA_2 inhibitors by systematically modifying the structure of phosphatidylcholine (9), using computer assisted molecular modeling (10–12) and total synthesis of various phospholipid analogues (13–20). However, few studies have been undertaken with specifically designed and conformationally restricted phospholipids. By this approach, one restricts the flexibility of a substrate phospholipid and permits PLA_2 to select the preferred orientation of the side chain(s), so that the orientation preferred by PLA_2 can be determined.

One decade ago, Hancock *et al.* (21) pioneered the synthesis of cyclopentanoid analogues of phosphatidylcholine and investigated the physical properties of these compounds. Following this work, Barlow *et al.* (22) prepared a short acyl-chain phosphatidylcholine analogue, the glycerol backbone of which was replaced by the all *trans* cyclopentane-1,2,3-triol; this compound was tested as a substrate for PLA_2 from *Naja naja naja* venom. Moreover, Magolda and Galbraith (23) reported a series of new 1′-(3′,5′-disubstituted)pyrrolidinyl-alkyl/arylcarboxamide phospholipids (so called proximal isomer and distal isomer), which were tested as inhibitors of porcine pancreatic PLA_2. Campbell and co-workers (12), starting from 4-hydroxymethyl-γ-butyrolactone, synthesized two conformationally restricted 3,4-disubstituted γ-butyrolactone phospholipid analogues, namely the 3-arachidonyl substituted lactone, which exhibited an IC_{50} (inhibitory concentration to produce 50% inhibition) value of 64 μM against PLA_2 in a cell-free preparation and 44 μM in a macrophage test, and the 3-butanoyl substituted lactone that showed no inhibitory activity toward the enzyme. However, 3,4,5-trisubstituted

γ-butyrolactone phospholipids, in which the glycerol backbone is part of the γ-butyrolactone ring and which represent novel types of conformationally restricted substrate analogues, have not been studied so far. Cyclization of C(1) or C(3) of the acyclic glycerophospholipid **1** to the α-carbon of the C(2) acyl side chain, as indicated by arrows **a** and **b** (Scheme 2), allows for two regioisomeric possibilities. Based on regioisomers **2** and **3**, a series of stereoisomers can be designed, and this new class of 3,4,5-trisubstituted γ-butyrolactone phospholipids (**41, 42** and **43**) has been synthesized. The inhibitory activity of the compounds is presently under investigation, and the results will be published in a separate paper. In the present paper, we wish to report on the synthesis, the structural assignment, and on the stereochemistry of these novel stereospecific phospholipid analogues.

RESULTS AND DISCUSSION

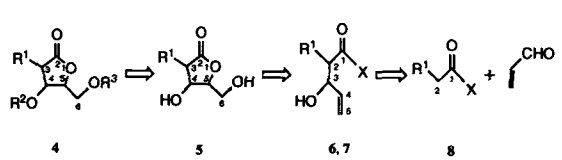
Retrosynthesis. The preparation of the target phospholipid lactones **4** (R_1 = alkyl, R_2/R_3 = ester/choline phosphate or choline phosphate/ester, respectively) is based on the regioselective manipulation of dihydroxylactone **5** (Scheme 3). Access to intermediate **5** is expected to arise *via* cyclization (such as iodolactonization) of *erythro* diastereomer **6** or *threo* isomer **7** [X = $N(CH_3)_2$ or OCH_3; R_1 = alkyl]. The intermediates (**6** and **7**) could be derived from **8** *via* aldol condensation of the appropriate carboxylate derivative with acrolein (24,25), a process that has been studied widely over the past two decades.

Synthesis. In practice, the diastereomeric allylic amides **6** and **7** were prepared in four steps (67% overall yield), starting from *N,N*-dimethylacetamide (**9**). Thus **9** was converted to its enolate with lithium diisopropylamide (LDA), which after treatment with 1-bromohexane afforded *N,N*-dimethyloctanamide (**11**). The enolate of **11** was condensed with acrolein to form diastereomers **6** and **7** (*erythro/threo*, 2:1) in 66% yield after chromatographic purification (24,26).

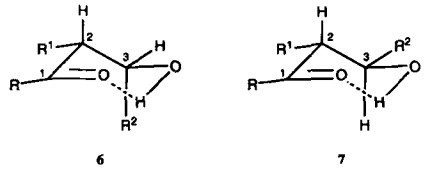
There is some divergence in the literature with regard to the *erythro* and *threo* designation for vicinally asymmetric centers in acyclic molecules. In the present paper, we use the convention of Heathcock *et al.* (24,25). When the backbone of an aldol is written in an extended (zigzag) fashion, and when the α-alkyl substituent and β-hydroxy substituent both extend toward the viewer or away from the viewer, this is the *erythro* diastereomer. When the α-alkyl group extends toward the viewer, but the β-hydroxy group is directed away or *vice versa*, as illustrated in Scheme 4, this is the *threo* diastereomer. In order to make stereochemical assignments of the allylic hydroxy amides **6** and **7**, the ^1H nuclear magnetic resonance (NMR) spectra of two isomers were examined. The NMR coupling constant (J), $J_{H2,H3}$ is smaller for isomer **6** (J = 4.2 Hz) than for isomer **7** (J = 7.5 Hz). This could be explained (Scheme 5) by postulating that isomer **7** has pseudo *trans* diaxial protons H-2 and H-3 on the hydrogen-bonded, six-membered ring in chair conformation with the maximum number of substituents in equatorial positions (26). The R_f value in thin-layer chromatography (TLC) of isomer **6** (0.26) was higher than that of isomer **7** (0.11; hexane/ethyl acetate, 3:1, vol/vol), suggesting that isomer **6** may be hydrogen bonded to a greater extent and may be less capable of interacting with the stationary phase than the more polar isomer **7** (27). This can be confirmed by evaluating the NMR coupling constants (26). Based on these considerations, the β-hydroxy amide isomer **6** was assigned the *erythro* configuration, and **7** was determined to be the *threo* isomer.

Esterification of the allylic hydroxy groups of **6** and **7** by treatment with hexanoic anhydride and catalytic 4-dimethylaminopyridine (DMAP) at room temperature gave the corresponding 3-oxy(hexanoyl) esters **15** and **16** in over 95% yield. In order to study the stereochemistry of 5-iodomethyl-γ-butyrolactones in the next step, the synthesis of amide derivatives **12, 13, 14, 17** and **18** was undertaken in a similar manner beginning with *N,N*-dimethylpropionamide **10** (Scheme 6).

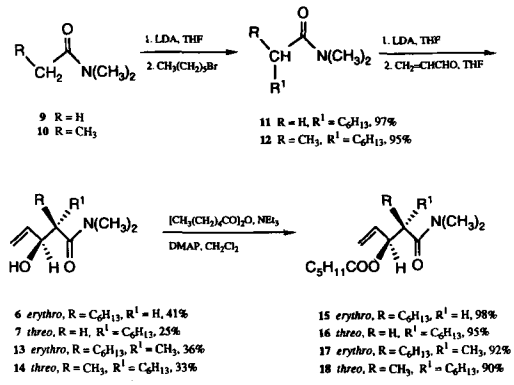
Stereospecific cyclization of diastereomers **6** and **7** to the γ-butyrolactones was accomplished through iodolactonization, which has been extensively utilized (28–30) for the efficient and highly stereocontrolled preparation of substituted γ-butyrolactones (31–36). For the trisub-



SCHEME 3



SCHEME 5



SCHEME 6

stituted lactones, the α and β terminology of IUPAC was used to express the stereochemical relationship of the substituents on the lactone ring. Tamaru *et al.* (29) reported that in structurally simpler systems, α-alkyl-β-oxy-substituted pentenamides cyclized with a high degree of stereocontrol and/or greater yield when compared to the analogous carboxylates (30). As part of our efforts in this area, we investigated the iodolactonization of diastereomeric allylic 3-hydroxy amides **6, 7, 13, 14** and their hexanoyl esters **15, 16, 17** and **18**. In order to more fully elucidate the stereostructure-activity relationship in this reaction, novel 3,4,5-trisubstituted γ-butyrolactones **19, 20, 21, 22, 23, 24, 25** and **26, 27, 28, 29, 44, 45** were prepared by treatment of the respective amides with iodine in aqueous tetrahydrofuran (THF) at ambient temperature. Theoretically, the generation of a new chiral center (such as at C-5 in a 5-iodomethyl-γ-butryolactone) could lead to two possible diastereomers. In practice, *erythro* **6** underwent highly stereoselective cyclization, giving **19** and **20** as a 7:1 mixture of C-5 epimers (68% yield). By a similar process, iodolactones **21/22** (6:1) were produced from the *threo* isomer **7** in 74% yield. Iodolactonization of **15** and **16** was accomplished under the same conditions. *Erythro* isomer **15** gave almost exclusively **23** [(3α,4β,5β)/(3α,4β,5α), >95:5] in 86% isolated yield. *Threo* compound **16** gave a mixture [**24/25**, (3α,4α,5β)/(3α,4α,5α), 2:1] with low stereoselectivity but very high yield (89%). Two other pairs of diastereomers (**13/14** and **17/18**) were prepared following the method described for the synthesis of **6** and **7**. By iodolactonization of amides **13, 14, 17** and **18**, iodolactones **26, 27, 28** and **29** were obtained with high stereoselectivity in good to excellent yields (70–98%). The results of these iodolactonization experiments are summarized in Table 1.

TABLE 1

Iodolactonization[a] of Erythro/Threo Allylic Amides

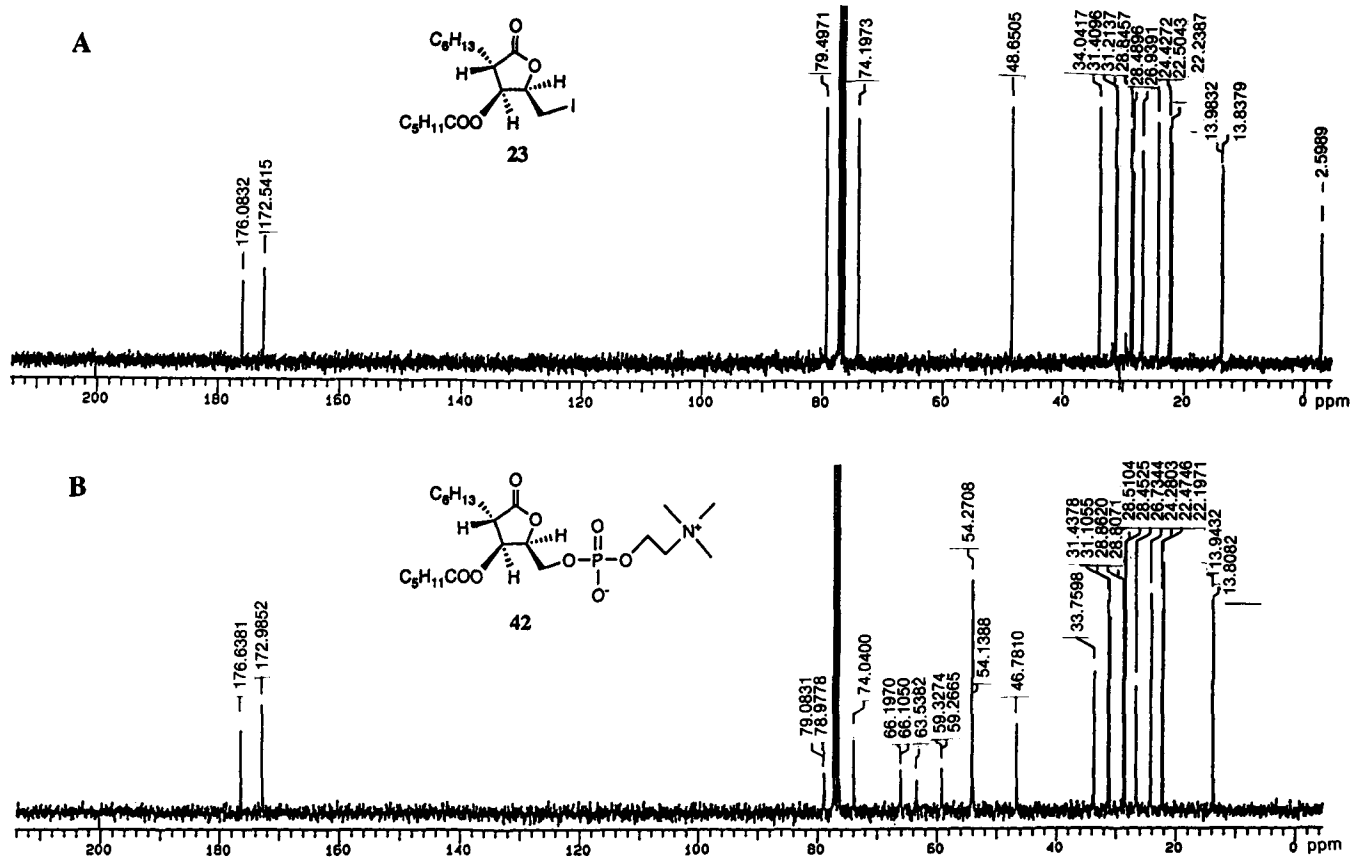

FIG. 1. ^{13}C Nuclear magnetic resonance spectra (75.47 MHz, chloroform-*d* for A, chloroform-*d*/methanol-d_4 (3:1, vol/vol) for B of A iodolactone 23 and B lactone phospholipid 42.

In order to arrive at unambiguous structural assignments for all iodolactonization products, the spectral characteristics of each of the iodolactones were analyzed in detail. The characterization of iodolactone **23**, one of the key intermediates, is chosen here to illustrate this. Two intense absorptions were seen in the infrared (IR) spectra of **23** at 1785 and 1748 cm^{-1}, suggesting the presences of carbonyls, of a saturated γ-lactone and an aliphatic ester, respectively. The electron impact mass spectrum of **23** showed an [M^+ – 127] ion peak at *m/e* 297, which indicated a molecular weight of 424, corresponding to **23** losing iodide. McLafferty rearrangements of either the 4-oxy(hexanoyl) ester or the 3-hexyl side chain resulted in the fragmentation ions at *m/e* 241 [M^+ – I-$C_2H_5CH{=}CH_2$] or *m/e* 213 [M^+ – I-$C_4H_9CH{=}CH_2$], respectively, while α-cleavage of the hexanoyl from the 4-oxygen gave rise to the fragmentation ion peak *m/e* 198 [M^+ – I-$C_5H_{11}CO^+$]. The ^{13}C NMR spectrum (Fig. 1A) of **23** shows the characteristic signals of 3-hexyl-4-oxy(hexanoyl)-5-iodomethyl-γ-butyrolactone at δ 176.1 (C-2), 172.5 (C-1′), 79.5 (C-5), 74.2 (C-4), 48.7 (C-3) and –2.6 (C-6), plus two terminal methyl carbons (C-12 and C-6′) at δ 13.8 and 14.0 ppm, respectively, and 9 methylene carbons in the region of 22.2–34.0 ppm. The representative protonated carbons (C-5, C-4, C-3 and C-6) in the two-dimensional heteronuclear correlation (HETCOR) spectrum (Fig. 2A) were correlated with the proton signals in the ^1H NMR spectrum of **23** at δ 2.63, 3.32/3.38, 4.76 and 5.28 ppm for H-3, H-6A/H-6B, H-5 and H-4, respectively. Furthermore, the structure of **23** was in good agreement with the results of high-resolution mass spectrometry (HRMS). The structural assignment of the other iodolactones was accomplished similarly.

The stereochemistry of the iodolactones was determined by 300-MHz nuclear Overhauser effect spectroscopy (NOESY) and based on vicinal coupling constants of the γ-butyrolactone ring protons. It was observed that when both vicinal hydrogens were in either α or β stereorelationship, the *J* value was at least 3 Hz or larger. If one of the adjacent protons was α and the other was β, or *vice versa*, the *J* value was smaller, ranging from *ca.* 1–2 Hz (28). Strong NOESY interactions were evident between hydrogen atoms that were both in an α or β relationship, and in case of geminally substituted lactones derived from **13, 14** and **18**, where both β-H-4 and β-H-5 clearly showed interaction with the 3β-methyl group, as in iodolactones **26, 27, 29** (Fig. 3A) (28). However, when the 3-methyl group was substituted in α phase while H-4 and H-5 were still in β phase, such as in the lactone **28**, H-4 interacted with two protons (H-7A and H-7B) on the 7-methylene carbon (which was adjacent to C-3), whereas H-5 interacted with only one, as shown in Figure 3B. Furthermore, the H-4 and H-5 protons of iodolactone **23** showed the same interaction pattern (Fig. 3C) as observed for **28**; thus, lactone **23**

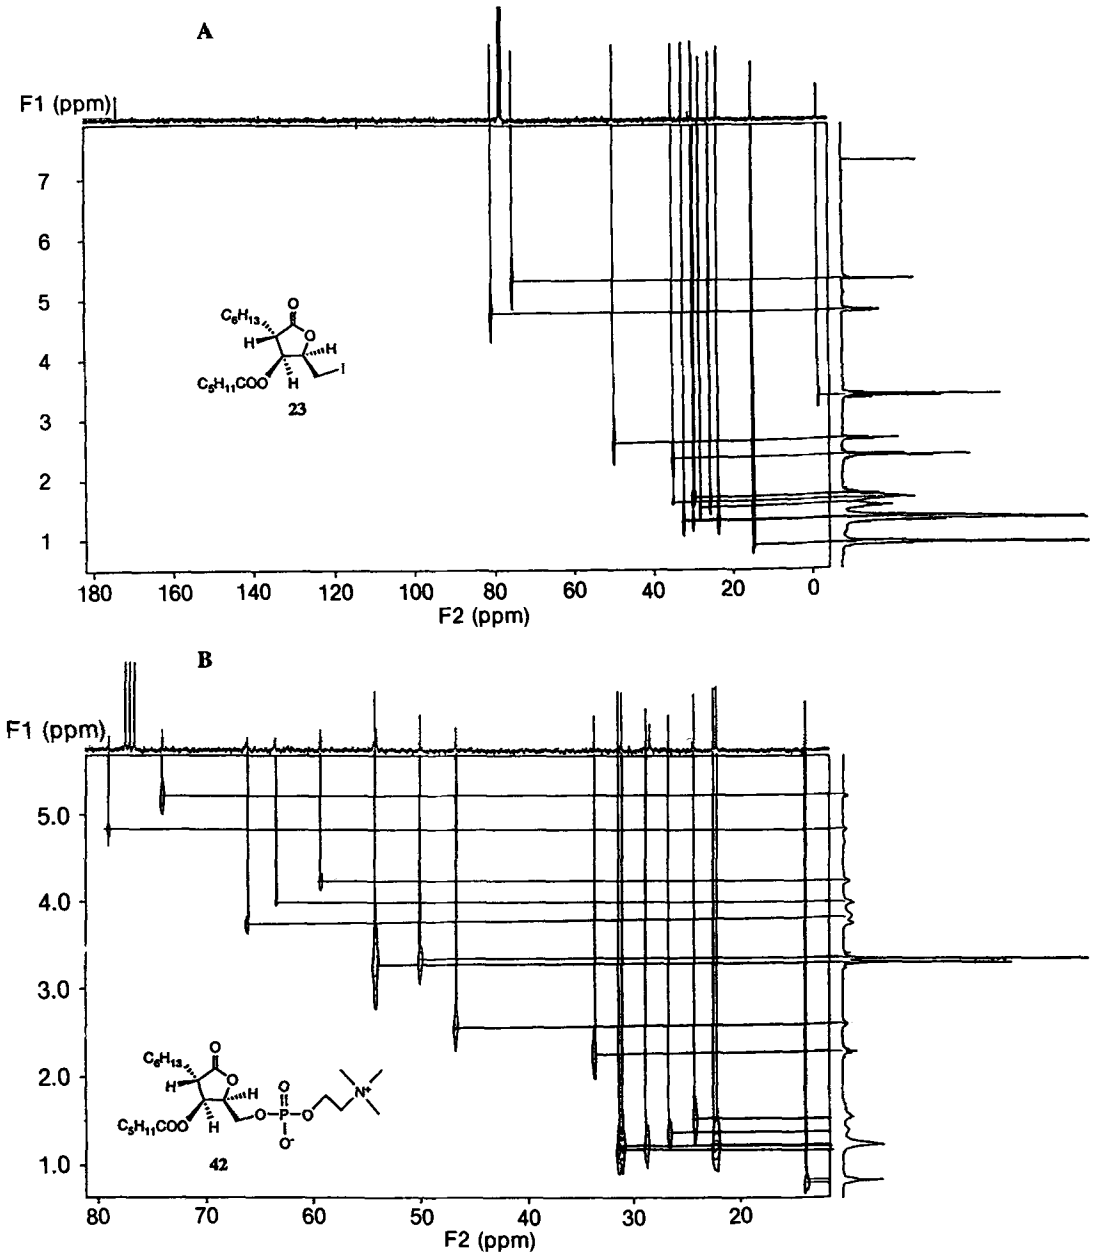

FIG. 2. Nuclear Overhauser effect spectra (300.13 MHz, chloroform-*d*) of the iodolactones A, 29, B, 28 and C, 23.

was assigned to have the (3α,4β,5β)-trisubstituent stereorelationship, which was consistent with the coupling constants $J_{H\text{-}3,H\text{-}4}$(1.3 Hz) and $J_{H\text{-}4,H\text{-}5}$(4.5 Hz) in the ^1H NMR spectrum of **23**. The stereochemical relationship of 3,4,5-trisubstituents of other iodolactones was elucidated in a similar manner. As a further confirmation of the lactone stereochemistry, molecules having a free hydroxy group were converted to their corresponding hexanoyl esters (37) and compared to previously characterized authentic samples prepared independently by iodolactonization. In general, the total yields of the iodolactonization products were good to excellent, and with only one exception (**16**) each isomer stereospecifically cyclized to a preparatively useful extent (at least 4:1). It is significant that, in most cases, both isomers of a given diastereomeric amide cyclized with a higher level of stereocontrol than had been observed in other studies with related compounds (29,30). The general tendency (29) for the newly created stereocenter at C-5 to be *cis* to the oxygen substituent at C-4 was apparent in each instance except for **16**, and the basis for this reversal is unknown at the present time. The reason for the increased stereoselectivity observed during cyclization of the *threo* derivatives of the hexanoylated amides is likewise obscure. It does not appear to be a function of either the amount of water present or of the solvent employed. Analogous results were obtained when diethyl ether was replaced by THF, or when the amount of water in THF was increased to 40 equivalents or decreased to 5 equivalents. It is possible that there were

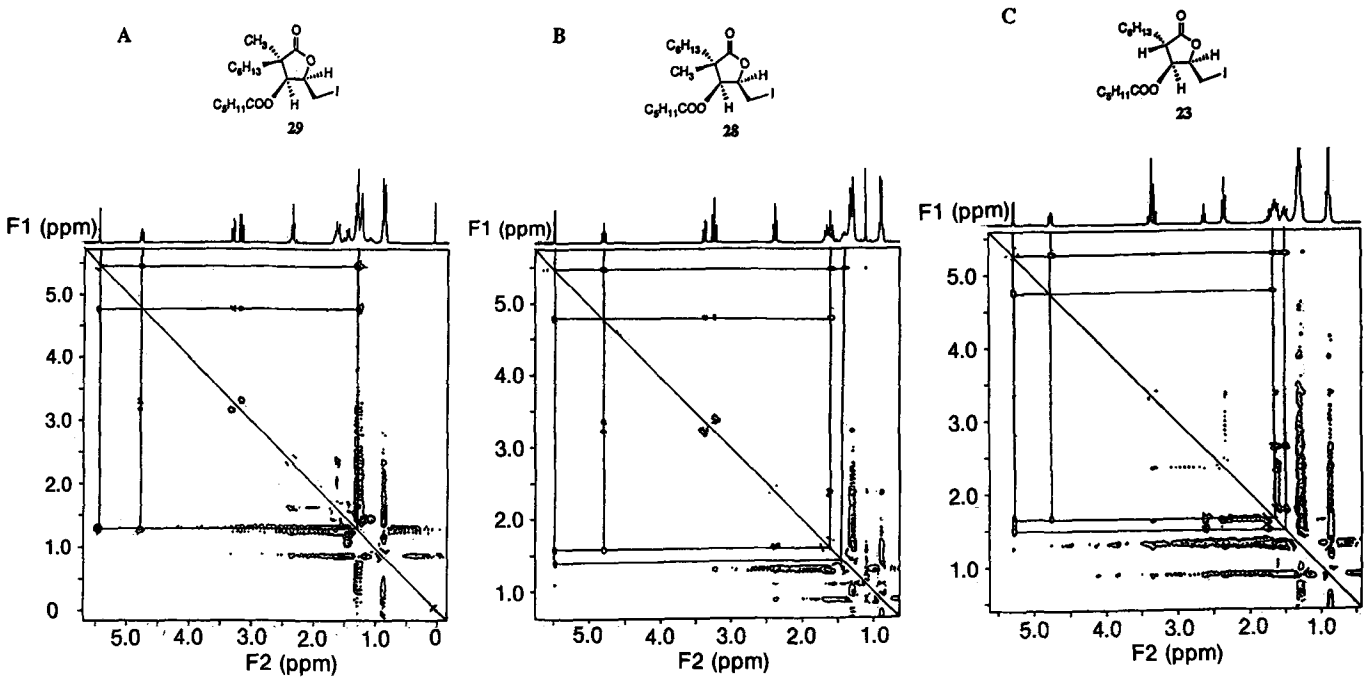

FIG. 3. Heteronuclear correlation spectra (300.13 MHz for ^1H and 75.47 MHz for ^{13}C, chloroform-*d* for A, chloroform-*d*/methanol-d_4 (3:1, vol/vol) for B of A iodolactone 23 and B lactone phospholipid 42.

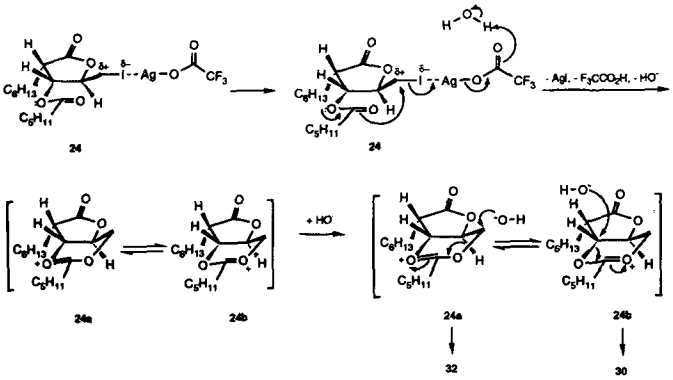
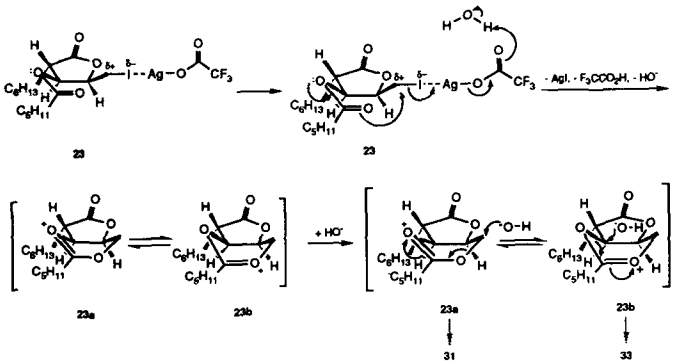
subtle changes induced by the lipophilic substituents in C(2) and/or C(3) positions of the allylic amide that sufficiently influenced the conformational bias (and hence lowered E_{act}) in favor of one of the rotamers, leading to the observed results.

The final step in the synthesis was the introduction of the choline phosphate side chain at the 4- or 6-hydroxy group of the lactones. Thus, the 6-iodo substituent of the major products **23** and **24** that were obtained by iodolactonization was converted to the corresponding 6-hydroxy function *via* a wet Prévost reaction (38,39) by stirring with silver(I)trifluoroacetate and water in nitromethane (33). Mixtures of two alcohol products **30/32** and **31/33** were obtained, respectively. Mass spectral analysis suggested that the products were regioisomeric in both cases. IR, ^1H NMR and ^{13}C NMR spectra of compounds **30, 31, 32** and **33** indicated that all four products contained both 4- and 6-oxygenated species. However, the ^1H NMR spectra were of little assistance in the assignment, because the key resonance signals were not resolved at 300 MHz in $CDCl_3$ solution. In order to shed more light on the reaction, the chromatographic behavior of the compounds on TLC was investigated further. When compounds **30, 31, 32** and **33** were run in the same solvent system (hexane/ethyl acetate, 3:1, vol/vol), compounds **30** (R_f = 0.30) and **33** (R_f = 0.32) showed higher R_f values than did their isomers **31** (R_f = 0.22) and **32** (R_f = 0.18). Due to differences in steric hindrance, the R_f values of the 6-hydroxy lactones would be expected to be lower than those of the 4-hydroxy compounds, because the primary alcohols would interact more strongly with the adsorbent than a secondary alcohol would. Thus, the less polar hydroxy lactones **30** and **33** were assigned the 4-hydroxy-6-oxy(hexanoyl) ester lactone structure, while the more polar regioisomers **31** and **32** were designated as 6-hydroxy-4-oxy(hexanoyl) derivatives. All products obtained in this reaction from **23** and **24** were useful intermediates for the conversion to the desired target lactone phospho-



SCHEME 7



SCHEME 8

lipids. The mechanism we propose for the wet Prévost reaction is shown in Schemes 7 and 8. When the silver atom of silver trifluoroacetate approaches the 6-iodide, it polarizes the bond between C-6 and iodine, resulting in the formation of a silver iodine complex. The migration of the electron pair at the 4-oxygen then initiates a nucleophilic attack, in which the carbonyl oxygen of both α- and β-4-oxy(hexanoyl) attacks the polarized electron-deficient carbon (C-6) from either the α phase (in the case of **24**) or the β phase (in the case of **23**) in the lactone planes, followed by a series of electron transfers that lead to the chair-like (**24a** and **24b**) or boat-like (**23a** and **23b**) six-membered ring (4,5) conjugated γ-butyrolactone intermediates, together with other products, including insoluble silver iodide, which moves the reaction completely toward the product side. The hydroxy ion (HO^-), which is generated nucleophilicly, attacks C-4 from the β phase (in the case of **24b**) or the α phase (in the case of **23b**) of both the lactones and six-membered rings and then opens the chair-like or boat-like six-membered rings by an S_{N2} reaction mechanism leading to 4-hydroxy-6-oxy(hexanoyl) ester lactones **30** and **33** with inversion (Walden inversion) of the configuration at C-4. On the other hand, 6-hydroxy-4-oxy(hexanoyl) ester lactones **31** and **32** (from the boat-like intermediate **23a** and the chair-like intermediate **24a**, respectively) are produced when the hydroxy ion nucleophilicly attacks the C-6 positions, while in both cases the stereochemistry at C-4 remains the same as in the 5-iodomethyl-γ-butyrolactones used as starting materials. The conversion was effected in high yields (98% from **23**, and 86% from **24**) but, not unexpectedly, each iodolactone gave two hydroxy lactone products, namely **31/33** (7:3) and **32/30** (5:3) with the stereochemistry at C-4 either identical to that of the starting material (**31** and **32**) or with inverted configuration (**30** and **33**) (Scheme 9).

In order to phosphorylate the 4- or 6-hydroxyl group of these lactones, the usefulness of the three-step method described by Magolda and Johnson (40) was investigated. It involves the treatment of the hydroxy compound with phosphorus oxychloride in triethylamine and anhydrous diethyl ether at 0°C to give a dichlorophosphate ester followed by exposure of the dichlorophosphate to ethylene glycol in the presence of triethylamine to effect the conversion to the corresponding cyclic phosphate. Final heating in acetonitrile with trimethylamine in a sealed tube for 30 h at 75°C affords the phosphocholine. However, our starting lactones decomposed under these conditions. An alternate phosphorylation approach that utilizes a two-step protocol, as outlined by Yuan *et al.* (18), proved more successful. The hydroxy lactones (**30, 31** and **32**) were treated with diphenyl chlorophosphate in anhydrous pyridine and afforded the corresponding diphenyl phosphoric lactone esters in good to excellent yields (70, 82 and 95% for compounds **35, 36** and **34**, respectively), whereas compound **33** gave exclusively a C(3)-C(4) elimination product (**37**, 96% yield) (Scheme 9). Several unsuccessful attempts were made to obtain the 4-oxy(phosphate) of **33**, that involved the use of different solvents, such as anhydrous *N,N*-dimethylformamide, methylene chloride and THF, as well as lower reaction temperatures and the use of different phosphorylating reagents. One possible reason for this undesired reaction taking place may be the *trans*-relationship between the 3-proton and 4-hydroxy group, which may facilitate elimination of the sterically hindered oxygen substituent.

Removal of the diphenyl moieties of diphenyl phosphoric acid lactone esters was accomplished in high yield (>90%) by hydrogenation of **34, 35** and **36** in the presence of Adams' catalyst [platinum(IV)oxide, PtO_2] with methanol as solvent at room temperature for 12–36 h (Scheme 10). The last step was the introduction of the choline side chain. Compounds **38, 39** and **40** were treated with choline tetraphenylborate and 2,4,6-triisopropylbenzenesulfonyl chloride in anhydrous pyridine at 35°C for 4 h (18). This afforded the target 3,4,5-trisubstituted lactone phospholipids **41, 42** and **43** in 36, 68 and 43% yields, respectively, after chromatographic purification (Scheme 10).

The ^{13}C NMR spectrum (Fig. 1B) of the lactone phospholipid **42** derived from iodolactone **23** showed signals at δ 176.6 (C-2), 172.9 (C-1′), 79.0 (C-5), 74.0 (C-4), 63.5 (C-6), and at 46.8 (C-3), at 66.2, 59.3 and 54.3 for the phosphocholine group, and the two terminal methyl carbons at 13.8 and 13.9 ppm along with 9 methylene carbons in the region of 22.2–33.8 ppm. The two- and three-bond ^{31}P-^{13}C couplings and the ^{15}N-^{13}C one-bond couplings were consistent with the assignments. Similar heteronuclear coupling patterns were observed in the ^{13}C NMR spectra of two other lactone phospholipids **41** and **43**. The automatic distortionless enhancement by polarization transfer (ADEPT) spectrum of **42** (Fig. 4) was consistent with the presence of 3 methine, 12 methylene and 5 methyl carbons. The carbonyl carbons were not seen in the ADEPT spectrum. The proton assignment of the ^1H spectrum of **42** was confirmed by HETCOR (Fig. 2B). The lactone phospholipids **41** and **43**

were assigned in a similar fashion. The stereoisomeric purity of **41, 42** and **43** was determined to be 98.2, 99.0 and 98.5% respectively, by high-performance liquid chromatography (HPLC).

EXPERIMENTAL PROCEDURES

General. Unless otherwise noted, materials obtained from commercial suppliers were used without further purification. Diethyl ether (Et_2O) and THF were distilled from sodium/benzophenone immediately prior to use. Solvents for reactions, *i.e.*, acetonitrile (CH_3CN), dichloromethane (CH_2Cl_2) and pyridine (C_5H_5N) were distilled from calcium hydride and stored over molecular sieves (4 Å) under nitrogen. All reactions except those involving water were carried out under a nitrogen atmosphere. Melting points were measured on a Thomas Hoover (Buffalo, NY) capillary melting point apparatus and are uncorrected. IR spectra were determined with a Perkin-Elmer 281B infrared spectrometer (Norwalk, CT). ^1H NMR spectra were measured at 300.13 MHz, while ^{13}C NMR were measured at 75.47 MHz on a Varian VXR-300 spectrometer (Palo Alto, CA). Solvents used were $CDCl_3$ or $CDCl_3/CD_3OD$ (3:1, vol/vol). Chemical shifts are expressed in parts per million (ppm, δ) downfield from internal tetramethylsilane. Characteristic ^1H NMR data are tabulated in the following format: multiplicity (*s*, singlet; *d*, doublet; *t*, triplet; *q*, quartet; *m*, multiplet; *br*, broad; *exch*, exchangeable), coupling constant(s) (*J*, in Hertz), number of protons. Low resolution mass spectra (LRMS) were obtained on a Finnigan 320 gas chromatograph/mass spectrometer (Winsford, England). HRMS were measured at the Department of Chemistry, University of Kansas (Lawrence, KS). Elemental analyses were done by Scandinavian Microanalytical Laboratory (Herlev, Denmark). Flash chromatography was carried out as described (41) on Kieselgel 60 (0.040–0.063 mm) (E. Merck, Darmstadt, Germany). TLC was done using 0.25-mm silica gel plates and Solvent A (hexane/ethyl acetate, 3:1, vol/vol) or Solvent B (methylene chloride/methanol/water, 10:10:1, by vol), or other solvent systems as specified.

Fractions were visualized by dipping the plates in a solution of ammonium molybdate (IV)tetrahydrate/water/concentrated sulfuric acid (1:9:1, wt/vol/vol) followed by heating at 115°C for 10 min, or by exposure to iodine vapors. All organic extracts were dried over anhydrous magnesium sulfate ($MgSO_4$) prior to concentration. The purity of all final and new products was checked by HPLC on a Waters Model 600E (Millipore, Milford, MA) equipped with a Waters 600E System Controller, a Waters 991 Photodiode Array Detector, a Waters automated Switching valve, a Computer NEC Power Mate SX/16 and a NEC Pinwriter P6200 (Tokyo, Japan), using a C_{18}-Nova-Pak 4.0 μm column (Waters) (Taunton, MA), or a Nova-Pak CN HP 4.0 μm column with either acetonitrile/methanol (80:20, vol/vol or acetonitrile/water (50:50, vol/vol) as mobile phase. The flow rate was 1 mL/min.

Materials. *N,N*-Dimethylacetamide, 1-bromohexane, acrolein, lithium diisopropylamide mono-tetrahydrofuran (1.5 M solution in cyclohexane, LDA), iodine (resublimed, 99.8%), triethylamine (Et_3N), DMAP, hexanoic anhydride, diphenyl chlorophosphate, platinum-(IV)oxide, 2,4,6-triisopylbenzenesulfonyl chloride, tetraphenylboron sodium and choline chloride were purchased from Aldrich (Milwaukee, WI). Silver trifluoroacetate was purchased from Spectrum Chemical MFG. Corp. (Gardena, CA).

Purification of acrolein. Acrolein was first distilled from calcium hydride into a flask that contained catechol (42) (1.0 g) in an ice bath. Anhydrous copper(II)sulfate (1.0 g) was added to this solution, which was then stirred and redistilled into a flask containing molecular sieves (4 Å) in an ice bath. Redistilled acrolein was stored in a freezer.

Preparation of choline tetraphenylborate. Sodium tetraphenylborate (6.85 g, 20.0 mmol) in water (30 mL) was added to choline chloride (4.20 g, 30.0 mmol) in the same volume of water (43). The gelatinous precipitate was filtered, washed with water (4 × 100 mL), pressed dry on the filter and then dried azeotropically with anhydrous ethanol (EtOH) and benzene (C_6H_6). Recrystallization from CH_3CN gave large hexagonal prisms (5.97 g, 65% yield), m.p. 249–251°C. IR (KBr, cm^{-1}) 3502 (*sh*), 3022, 2980, 1590, 1470, 1420, 1265, 1076, 720. ^1H NMR (pyridine-d_5) δ 2.99 (*s*, 9 H, 3 CH_3), 3.37 (*ddd, J* = 2.0, 4.1, 4.9 Hz, 2 H, CH_2), 4.1 (*br m*, 2 H, CH_2), 5.1 (*br s*, 1 H, OH), 7.12 (*dd, J* = 7.1, 7.1 Hz, 8 ArH), 7.27 (*dd, J* = 7.4, 7.5 Hz, 12 ArH). ^{13}C NMR (C_5D_5N) δ 165.9, 165.2, 164.6, 163.9, 137.0 (8 C), 126.3, 126.2, 126.2, 126.2, 122.4 (8 C), 68.8, 56.1, 54.0, 53.9, 53.9.

Preparation of N,N-*dimethyloctanamide* (**11**). To a solution of LDA (6.4 g, 59.8 mmol) in dry THF (50 mL) at -78°C was added dropwise over 3 min anhydrous *N,N*-dimethylacetamide (5.0 g, 57.4 mmol) in THF (5 mL), and the mixture was stirred at -78°C for 1 h. 1-Bromohexane (11.3 g, 68.4 mmol) in THF (5 mL) was added rapidly at -78°C and stirred for 15 min. The reaction mixture was warmed to room temperature and stirred for 1 h. The reaction was quenched with saturated aqueous NH_4Cl solution (4 mL), diluted with H_2O (50 mL), and extracted with Et_2O (3 × 100 mL). The combined organic phases were washed with brine, dried and concentrated *in vacuo*. This gave a colorless oil (9.5 g, 97% yield) after chromatography (Solvent A). Distillation at 145°C/55 mmHg afforded compound **11** (7.20 g, yield 74%); R_f = 0.25 (Solvent A). IR (neat, cm^{-1}) 2937, 1655, 1495, 1379. ^1H NMR (90 MHz) ($CDCl_3$) δ 0.92 (*dd, J* = 7.2, 7.2 Hz, 3 H, CH_3), 1.2–1.8 (*m*, 10 H, 5 CH_2), 2.32 (*dd, J* = 4.6, 6.8 Hz, 2 H), 2.94 (*s*, 3 H, NCH_3), 3.1 (*s*, 3 H, NCH_3).

N,N-*Dimethyl-2-methyl-octanamide* (**12**). This was prepared from *N,N*-dimethylpropionamide (10.4 g, 102.4 mmol): Colorless oil (18.0 g, yield 95%), R_f = 0.31 (Solvent A). IR (neat, cm^{-1}) 2940, 1660, 1485, 1380. ^1H NMR (90 MHz) ($CDCl_3$) δ 0.84–0.94 (*m*, 3 H, CH_3), 1.2–1.8 (*m*, 10 H, 5CH_2), 1.24 (*d, J* = 4.7 Hz, 3 H, CH_3), 2.46 (*m*, 1 H), 2.97 (*s*, 3 H, NCH_3), 3.0 (*s*, 3 H, NCH_3).

General procedure for the Aldol condensation. The reaction was carried out as described by Heathcock *et al.* (25). To a solution of LDA (4.22 g, 39.40 mmol) in THF (52 mL) at –20°C (ice-salt bath), was added a solution of *N,N*-dimethyloctanamide (6.15 g, 36.0 mmol) in THF (3.0 mL). The reaction mixture was stirred at –20°C for 1 h and then cooled to –78°C. Acrolein (2.41 g, 43.0 mmol) was added as rapidly as possible by means of a syringe, and the reaction mixture was stirred vigorously at –78°C for 1 h. The reaction was followed by TLC (Solvent A), which revealed two products with R_f values of 0.26 and 0.11, respectively. The reaction was quenched with saturated aqueous NH_4Cl solution (6 mL) and then warmed to room temperature. The mixture solution was diluted with water (20 mL) and extracted with Et_2O (3 × 50 mL). The combined ether extracts were washed with brine (40 mL) and dried (Na_2SO_4). Removal of the solvent *in vacuo* resulted in an oily crude residue that was purified by flash chromatography (Solvent A); it afforded *erythro-N,N*-dimethyl-3-hydroxy-2-hexyl-4-pentenamide (**6**): Colorless oil, 3.38 g, 41% yield; IR (neat, cm^{-1}) 3400 (*br*), 2920, 2850, 1640, 1620, 1490, 1395, 1260. ^1H NMR ($CDCl_3$) δ 0.82-0.90 (*m*, 3 H, CH_3), 1.17–1.27 (*m*, 8 H, 4 CH_2), 1.57–1.71 (*m*, 2 H, CH_2), 2.74 (*ddd, J* = 4.2, 4.2, 9.6 Hz, 1 H, H-2), 2.95 (*s*, 3 H, NCH_3), 3.0 (*s*, 3 H, NCH_3), 4.1 (*br s*, 1 H, OH), 4.2 (*dd, J* = 5.3, 4.2 Hz, 1 H, H-3), 5.1 (*ddd, J* = 1.5, 1.7, 10.5 Hz, 1 H, H-5A), 5.3 (*ddd, J* = 1.8, 1.8, 17.2 Hz, 1 H, H-5B), 5.8 (*ddd, J* = 5.2, 10.5, 17.3 Hz, 1 H, H-4). ^{13}C NMR ($CDCl_3$) δ 176.1, 138.3, 115.4, 72.9, 45.5, 37.8, 35.5, 31.7, 29.5, 27.8, 26.8, 22.6, 13.9. LRMS *m/e* 170, 156, 143, 126, 100, 87, 72, 57. HRMS calcd. for $C_{13}H_{25}O_2N$, 227.1884; found 227.1872.

Threo-N,N-*Dimethyl-3-hydroxy-2-hexyl-4-pentenamide* (**7**). Colorless oil (2.03 g, 25% yield). IR (neat, cm^{-1}) 3630 (*sh*), 3390 (*br*), 2950, 2850, 1640, 1620, 1455, 1390, 1260. ^1H NMR ($CDCl_3$) δ 0.83–0.90 (*m*, 3 H, CH_3), 1.1–1.4 (*m*, 8 H, 4 CH_2), 1.65–1.72 (*m*, 2 H, CH_2), 2.9 (*s*, 3 H, NCH_3), 3.0 (*s*, 3 H, NCH_3), 2.75 (*ddd, J* = 7.2, 4.3, 7.3 Hz, 1 H, H-2), 4.16 (*br d, J* = 3.3 Hz, 1 H, OH), 4.38 (*br d, J* = 7.5 Hz, 1 H, H-3), 5.08 (*ddd, J* = 1.3, 1.5, 10.4 Hz, 1 H, H-5A), 5.25 (*ddd, J* = 1.5, 1.5, 17.1 Hz, 1 H H-5B), 5.80 (*ddd, J* = 5.7, 10.5, 17.1 Hz, 1 H, H-4). ^{13}C NMR ($CDCl_3$) δ 175.8, 139.8, 115.2, 73.6, 45.4, 37.7, 35.2, 31.6, 30.1, 29.4, 27.3, 22.5, 14.0. LRMS *m/e* 226 (M^+ – 1), 184, 170, 157, 140, 114, 101, 72, 57. HRMS calcd. for $C_{13}H_{25}O_2N$, 227.1884; found 227.1879.

Erythro-N,N-*Dimethyl-3-hydroxy-2-methyl-2-hexyl-4-pentenamide* (**13**). Colorless oil (3.92 g, 36% yield). IR (neat, cm^{-1}) 3405 (*br*), 2920, 2860, 1645, 1620, 1495, 1395, 1260. ^1H NMR ($CDCl_3$) δ 0.83–0.89 (*dd, J* = 7.1,7.2 Hz, 3 H, CH_3), 1.20–1.36 (*m*, 9 H, 3 CH_2, CH_3), 1.52–1.80 (*m*, 2 H, CH_2), 2.22–2.40 (*m*, 4 H), 3.10 (*s*, 6 H, 2 NCH_3), 4.21 (*br s*, 1 H, OH), 5.10–5.30 (*m*, 2 H), 5.70–5.90 (*m*, 2 H). ^{13}C NMR ($CDCl_3$) δ 176.7, 139.3, 116.5, 72.9, 49.5, 37.8, 35.5, 31.7, 29.5, 27.8, 26.8, 22.6, 21.4, 13.9. LRMS *m/e* 241 (M^+), 226. HRMS calcd. for $C_{14}H_{27}O_2N$, 241.1908; found 241.1912.

Threo-N,N-*Dimethyl-3-hydroxy-2-methyl-2-hexyl-4-pentenamide* (**14**). Colorless oil (3.53 g, 33% yield). IR (neat, cm^{-1}) 3610 (*sh*), 3390 (*br*), 2960, 2840, 1645, 1625, 1455, 1396, 1270. ^1H NMR ($CDCl_3$) δ 0.84–0.90 (*m*, 3 H, CH_3), 1.21 (*s*, 3 H, CH_3), 1.24–1.32 (*m*, 6 H, 3 CH_2),

1.41–1.72 (*m*, 2 H, CH_2), 2.37 (*dd, J* = 6.9, 7.1 Hz, 2 H), 2.98 (*s*, 3 H, NCH_3), 3.02 (*s*, 3 H, NCH_3), 5.23 (*dd, J* = 1.8, 7.6 Hz, 1 H), 5.37 (*ddd, J* = 1.7, 1.9, 10.3 Hz, 1 H), 5.76–5.81 (*m*, 1 H), 5.84 (*dd, J* = 7.3, 10.4 Hz, 1 H). ^{13}C NMR ($CDCl_3$) δ 176.8, 138.9, 115.0, 72.9, 48.4, 37.7, 35.2, 31.6, 30.1, 29.4, 27.3, 22.5, 20.3, 14.0. LRMS *m/e* 240 (M^+ – 1), 198, 180. HRMS calcd. for $C_{14}H_{27}O_2N$, 241.1908; found 241.1903.

General procedure for the hexanoylation of N,N-*dimethyl-3-hydroxy-2-hexyl-4-pentenamide.* To a solution of *erythro-N,N*-dimethyl-3-hydroxy-2-hexyl-4-pentenamide (**16**) (2.96 g, 13.0 mmol) in anhydrous CH_2Cl_2 (60 mL) and stirring at 0°C, hexanoic anhydride (3.35 g, 15.65 mmol), Et_3N (1.58 g, 15.65 mmol) and DMAP (0.32 g, 2.61 mmol) were added and the mixture was stirred at 0°C for 40 min (37). The reaction was monitored by TLC (Solvent A). The reaction mixture was diluted with Et_2O (100 mL) and extracted with 1.0 M H_3PO_4 (2 × 100 mL). The organic phase was washed with brine and dried over Na_2SO_4. Removal of the solvent resulted in the crude product, which was purified by flash chromatography (hexane/ethyl acetate, 4:1, vol/vol). *Erythro-N,N*-dimethyl-2-hexyl-3-[oxy(hexanoyl)]-4-pentenamide (**15**) was obtained as colorless oil (4.25 g, 98% yield). R_f = 0.46 (Solvent A). IR (neat, cm^{-1}) 2960, 2848, 1730, 1640, 1615, 1460, 1375, 1240. ^1H NMR ($CDCl_3$) δ 0.81–0.94 (*m*, 6 H, 2 CH_3), 1.04–1.40 (*m*, 12 H, 6 CH_2), 1.50–1.70 (*m*, 4 H, 2 CH_2), 2.22 (*dd, J* = 7.4, 7.5 Hz, 2 H, CH_2), 2.95–3.05 (*m*, 4 H, NCH_3 + CH), 3.11 (*s*, 3 H, NCH_3), 5.22–5.36 (*m*, 3 H), 5.75 (*ddd, J* = 7.0, 10.4, 17.4 Hz, 1 H, H-4). ^{13}C NMR ($CDCl_3$) δ 172.9, 172.2, 134.1, 118.8, 76.1, 45.2, 37.6, 35.8, 34.4, 31.6, 31.2, 29.1, 28.3, 27.2, 24.5, 22.5, 22.2, 14.0, 13.8. LRMS *m/s* 325 (M^+), 297, 181, 126, 99, 87, 73, 57. HRMS calcd. for $C_{19}H_{35}O_3N$, 325.2615; found 325.2620.

Threo-N,N-*Dimethyl-2-hexyl-3-[oxy(hexanoyl)]-4-pentenamide* (**16**). Colorless oil (4.60 g, 95% yield). R_f = 0.37 (Solvent A). IR (neat, cm^{-1}) 2920, 2840, 1735, 1640, 1620, 1460, 1395, 1240. ^1H NMR ($CDCl_3$) δ 0.81–0.89 (*m*, 6 H, 2 CH_3), 1.05–1.40 (*m*, 12 H, 6 CH_2), 1.50–1.65 (*m*, 4 H, 2 CH_2), 2.30 (*dd, J* = 7.4, 7.5 Hz, 2 H, CH_2), 2.95–3.04 (*m*, 4 H, NCH_3 + CH), 3.11 (*s*, 3 H, NCH_3), 5.20–5.36 (*m*, 3 H), 5.76 (*ddd, J* = 7.0, 10.0, 17.1 Hz, 1 H, H-4). ^{13}C NMR ($CDCl_3$) δ 172.8, 172.2, 134.1, 118.9, 76.1, 45.1, 37.5, 35.8, 34.4, 27.2, 31.6, 31.1, 29.3, 28.3, 24.5, 22.5, 22.2, 14.0, 13.8. LRMS *m/s* 325 (M^+), 297, 181, 126, 99, 87, 73, 57. HRMS calcd. for $C_{19}H_{35}O_3N$, 325.2165; found 325.2167.

Erythro-N,N-*Dimethyl-2-methyl-2-hexyl-3-[oxy(hexanoyl)]-4-pentenamide* (**17**). Colorless oil (0.56 g, 92% yield). R_f = 0.46 (Solvent A). IR (neat, cm^{-1}) 2945, 2835, 1730, 1645, 1615, 1475, 1370, 1230. ^1H NMR ($CDCl_3$) δ 0.84–0.96 (*m*, 6 H, 2 CH_3), 1.24 (*s*, 3 H, CH_3), 1.26–1.42 (*m*, 8 H, 4 CH_2), 1.56–1.70 (*m*, 4 H, 2 CH_2), 2.34 (*dd, J* = 7.4, 7.5 Hz, 2 H, CH_2), 3.06 (*br s*, 6 H, 2 NCH_3), 5.10–5.18 (*m*, 1 H), 5.18 (*d, J* = 1.2 Hz, 1 H), 5.71–5.81 (*m*, 1 H), 5.85 (*dd, J* = 4.9, 5.2 Hz, 1 H). ^{13}C NMR ($CDCl_3$) δ 180.1, 173.3, 133.7, 117.2, 75.8, 50.9, 38.2, 36.2, 34.4, 34.0, 31.6, 31.2, 29.8, 24.7, 24.3, 22.6, 22.3, 19.3, 13.9, 13.8. LRMS *m/s* 339 (M^+), 311, 181, 126, 99. HRMS calcd. for $C_{20}H_{37}O_3N$, 339.2771; found 339.2779.

Threo-N,N-*Dimethyl-2-methyl-2-hexyl-3-[oxy(hexanoyl)]-4-pentenamide* (**18**). Colorless oil (0.54 g, 90% yield). R_f = 0.37 (Solvent A). IR (neat, cm^{-1}) 2930, 2845, 1740, 1635, 1610, 1475, 1395, 1230. ^1H NMR ($CDCl_3$) δ 0.83–0.91 (*m*, 6 H, 2 CH_3), 1.20–1.40 (*m*, 13 H, 5 CH_2 + CH_3), 1.52–1.74 (*m*, 4 H, 2 CH_2), 2.26 (*dd, J* = 7.2, 7.4 Hz, 2 H, CH_2), 2.32 (*dd, J* = 7.3, 7.5 Hz, 2 H, CH_2), 3.02 (*br s*, 6 H, 2 NCH_3), 5.22 (*dd, J* = 1.5, 6.6 Hz, 1 H), 5.27 (*ddd, J* = 1.7, 1.9, 9.7 Hz, 1 H), 5.72–5.78 (*m*, 1 H), 5.81 (*dd, J* = 6.4, 10.2 Hz, 1 H). ^{13}C NMR ($CDCl_3$) δ 180.1, 173.3, 133.7, 117.2, 75.8, 50.9, 38.2, 36.2, 34.4, 34.0, 31.6, 31.2, 29.8, 24.7, 24.3, 22.6, 22.3, 19.3, 13.9, 13.8. LRMS *m/e* 339 (M^+). HRMS calcd. for $C_{20}H_{37}O_3N$, 339.2771; found 339.2764.

General procedure for iodolactonization. To a solution of *erythro-N,N*-dimethyl-2-hexyl-3-[oxy(hexanoyl)]-4-pentenamide (**15**) (4.37 g, 12.40 mmol) in THF (100 mL), iodine (4.72 g, 18.60 mmol) and water (4.84 mL, 268.67 mmol) were added. The flask was wrapped with aluminum foil and stirred at room temperature (30). The reaction was followed by TLC (hexane/ethyl acetate, 3:2, vol/vol). After the starting material had disappeared (12–24 h), the reaction mixture was diluted with Et_2O (200 mL), washed with 5% sodium sulfite solution (3 × 150 mL) until the ether layer was colorless. Then the ether layer was washed with brine, dried over Na_2SO_4, filtered and concentrated *in vacuo*. The crude product was purified by flash chromatography (hexane/ethyl acetate, 3:2, vol/vol) which afforded (3α, 4β, 5β)dihydro-4-[oxy(hexanoyl)]-5-(iodomethyl)-3-hexyl-2(3H)-furanone (**23**) as pale oil (4.90 g, 86% yield). R_f = 0.75 (hexane/ethyl acetate, 3:2, vol/vol). IR (neat, cm^{-1}) 2960, 2860, 1785, 1740, 1460, 1240. ^1H NMR ($CDCl_3$) δ 0.86–0.92 (*m*, 6 H, 2 CH_3), 1.21–1.34 (*m*, 10 H, 5 CH_2), 1.46–1.55 (*m*, 2 H CH_2), 1.58–1.80 (*m*, 4 H, 2 CH_2), 2.36 (*ddd, J* = 1.5, 7.2, 7.3 Hz, 2 H, CH_2), 2.63 (*ddd, J* = 1.3, 7.5, 7.5 Hz, 1 H, H-3), 3.32 (*ABq, J* = 8.6, 9.8 Hz, 1 H, H-6A), 3.38 (*ABq, J* = 5.6, 9.4 Hz, 1 H, H-6B), 4.76 (*ddd, J* = 5.9, 4.5, 8.8 Hz, 1 H, H-5), 5.28 (*dd, J* = 1.5, 4.5 Hz, 1 H, H-4). ^{13}C NMR ($CDCl_3$) δ 176.1, 172.5, 79.5, 74.2, 48.7, 34.4, 26.9, 31.4, 31.2, 28.8, 28.5, 24.4, 22.5, 22.3, 14.0, 13.8, -2.6. LRMS *m/e* 297 (M^+ – I), 241, 213, 198, 100, 84, 71, 57. HRMS calcd. for $C_{17}H_{29}O_4$ (M^+ – I), 297.2065; found 297.2059.

(3α,4β,5β)Dihydro-4-hydroxy-5-(iodomethyl)-3-hexyl-2(3H)-furanone (**19**). Pale oil (0.07 g, 60% yield). R_f = 0.62 (Solvent A). General procedure for the conversion of iodolactones to hydroxy lactones. Preparation of (3α, 4β, 5β)dihydro-4-[oxy(hexanoyl)]-5-(hydroxymethyl)-3-hexyl-2(3H)-furanone (**31**). Silver trifluoroacetate (3.26 g, 14.75 mmol) was added in one portion to a stirred solution of iodolactone **23** (4.17 g, 9.84 mmol) and 1 equivalent of water (0.18 g) in nitromethane (100 mL) at 60°C. During 1–3 h, the formation of insoluble silver iodide was observed (33). After all the starting material had disappeared (20 h), as judged by TLC (Solvent A), the reaction mixture was filtered through Celite and concentrated. Flash chromatography on silica gel (Solvent A) afforded compounds **31** (2.17 g, 70% yield) and **33** (0.93 g, 28% yield). Compound **31**: white waxy solid, R_f = 0.22 (Solvent A), m.p. 42–43°C. IR (KBr, cm^{-1}) 3620–3300 (*br*), 2960, 2840, 1760, 1740, 1445, 1250, 1170. ^1H NMR ($CDCl_3$) δ 0.84–0.91 (*m*, 6 H, 2 CH_3), 1.20–1.32 (*m*, 10 H, 5 CH_2), 1.40–1.78 (*m*, 6 H, 3 CH_2), 2.34 (*dd, J* = 7.4, 7.4 Hz, 2 H, CH_2), 2.60 (*ddd, J* = 3.6, 7.6, 8.0 Hz, 1 H, H-3), 4.28–4.34 (*m*, 1 H, H-4), 4.44 (*ddd, J* = 12.4, 9.9, 5.2 Hz, 2 H, H-6), 4.51-4.60 (*m*, 1 H, H-5). ^{13}C NMR ($CDCl_3$) δ 177.3, 174.2, 79.0, 72.7, 61.6, 48.9, 34.0, 31.5, 31.2, 28.9, 28.6, 26.9, 24.4, 22.5, 22.2, 13.9, 13.8. General procedure for the preparation of diphenyl phosphoric acid esters of hydroxy lactones. Phosphoric acid, (3α,4α,5β)dihydro-4-[oxy(hexanoyl)]-3-hexyl-2(3H)-furanone-5-[methyleneoxy-(diphenyl)] ester (**36**). The hydroxy lactone **32** (1.0 g, 3.19 mmol) was dissolved in dry pyridine (20 mL) in a 100-mL, tightly stoppered flask with a stir bar. Diphenyl chlorophosphate (2.44 g, 9.08 mmol) in C_5H_5N (6 mL) was added, and the mixture was stirred at room temperature for 3 h (18). The reaction was followed by TLC (Solvent A). Water (4 mL) was added, and then the mixture was concentrated to a small volume *in vacuo*. The residue was added to a mixture of water and Et_2O. The organic phase was separated, and the aqueous phase was extracted with Et_2O (2 × 40 mL). The ether extracts were combined, and concentrated *in vacuo*, and the residue was purified on silica gel (Solvent A) to yield **36** (1.42 g, 82% yield): Pale yellowish oil, R_f = 0.51 (Solvent A). IR (neat, cm^{-1}) 2960, 2860, 1780, 1736, 1588, 1482, 1350, 1288, 1180. ^1H NMR ($CDCl_3$) δ 0.81–0.90 (*m*, 6 H, 2 CH_3) 1.18–1.38 (*m*, 13 H, CH_2), 1.70–1.88 (*m*, 3 H, CH_2), 2.33 (*ddd, J* = 3.5, 7.4, 7.5 Hz, 2 H, CH_2), 2.57 (*ddd, J* = 6.9, 5.2, 9.7 Hz, 1 H, H-3), 5.30 (*d, J* = 6.9 Hz, 1 H, H-4), 4.49–4.53 (*ddd, J* = 2.6, 2.8, 5.5 Hz, 2 H, H-6), 4.43–4.46 (*m*, 1 H, H-5), 7.30–7.40 (*m*, 4 ArH), 7.16–7.24 (*m*, 6 ArH). ^{13}C NMR ($CDCl_3$) δ 176.1, 173.1, 150.2, 150.1, 129.9 (4 C), 124.9 (2 C), 119.9 (2 C), 119.8 (2 C), 81.4, 71.7, 67.4, 42.6, 33.9, 31.5, 31.1, 29.1, 27.5, 24.4, 24.1, 22.5, 22.2, 13.9, 13.8. General procedure for the hydrogenolysis of diphenyl phosphoric acid esters. Phosphoric acid, (3α,4α,5β)dihydro-4-[oxy(hexanoyl)]-3-hexyl-2(3H)-furanone-5-(methyleneoxy) ester (**40**). The phosphoric acid diphenyl ester (**36**) (1.37 g, 2.51 mmol) in CH_3OH (50 mL) was mixed with PtO_2 (0.29 g, 1.25 mmol) in an 100-mL flask attached to a balloon filled with hydrogen (18). The reaction was stirred at room temperature, and the reaction progress was monitored by TLC (hexane/ethyl acetate, 1:1, vol/vol) to detect the loss of the starting material and, with methanol as solvent, to detect the much slower loss of the monophenyl ester. The reaction time varied, but averaged about 12–24 h. The reaction mixture was filtered through a pad of Celite, and the filtrate was concentrated *in vacuo*. The product **40** (1.03 g, 99% yield) was directly used without further purification: Colorless oil, R_f = 0.70 (Solvent B). IR (neat, cm^{-1}) 3640–3000 (*br*), 2962, 2860, 1780, 1720, 1460, 1355, 1150, 980. ^1H NMR ($CDCl_3$) δ 0.84–0.93 (*m*, 6 H, 2 CH_3), 1.20–1.76 (*m*, 16 H, 8 CH_2), 2.32 (*dd, J* = 7.5, 7.6 Hz, 2 H, CH_2), 2.90-3.0 (*m*, 1 H, H-3), 4.20–4.38 (*m*, 2 H, H-6), 4.49 (*br s*, 1 H, H-5), 5.43 (*d, J* = 6.8 Hz, 1 H, H-4), 7.3-7.8 (*br s*, 2 H, OH). ^{13}C NMR ($CDCl_3$) δ 177.9, 173.3, 82.5, 72.2, 65.7, 42.9, 34.1, 31.4, 31.2, 29.2, 27.3, 24.6, 24.3, 22.5, 22.2, 13.9, 13.7. ARTICLE

Effect of Nonionic Detergents on Lipoxygenase Catalysis

Maria J. Schilstra, Gerrit A. Veldink* and Johannes F.G. Vliegenthart

Bijvoet Center for Biomolecular Research, Department of Bio-Organic Chemistry, Utrecht University, The Netherlands

In many studies on lipoxygenase catalysis, nonionic detergents are used to obtain an optically transparent solution of the fatty acid substrate. In order to resolve some controversies that exist with regard to the interpretation of kinetic data obtained with solutions containing nonionic detergents, a systematic investigation was undertaken into the effects of Lubrol, Tween-20 and Triton X-100 (0–0.8 g/L) on the kinetics of linoleate (2.5–110 μM) dioxygenation, catalyzed by lipoxygenase-1 or lipoxygenase-2 from soybean, at pH 9 or 10, at 25°C. Under most conditions, it was found that the detergents slowed down the reaction. However, at high linoleate concentrations, where substrate inhibition of lipoxygenase is significant, small amounts of detergent increased the dioxygenation rate. In a quantitative analysis of the results, a kinetic model in which the incorporation of linoleate in the detergent micelles is formulated as a simple reversible equilibrium, and in which both lipoxygenase-1 and -2 interact with free linoleate, but not with linoleate incorporated in the micelles, appeared to be sufficient to predict experimental results over a wide range of experimental conditions. According to this model, the changes in the dioxygenation kinetics caused by the presence of nonionic detergents are similar (but not equal) to those caused by competitive inhibitors. The conclusions that monomeric, nonmicellar linoleate is the preferred substrate for lipoxygenase and that the observed inhibition and stimulation are solely due to changes in the effective linoleate concentration strongly corroborate the earlier observations by Galpin and Allen [*Biochim. Biophys. Acta* 488 (1977), 392–401].

***Lipids* 29, 225–231 (1994).**

Lipoxygenases (EC 1.13.11.12) catalyze the dioxygenation of polyunsaturated fatty acids that contain one or more (1*Z*,4*Z*)-pentadiene systems. The reaction products are hydroperoxides with a conjugated (*E*,*Z*)-diene moiety (for reviews see Refs. 1–3). Soybean lipoxygenase-1, the most thoroughly characterized of all plant lipoxygenases, shows optimum activity at pH 9–11. At these pH values, the critical micelle concentration (CMC) of linoleic acid is high (50 μM at pH 9, 200 μM at pH 10; Ref. 4). However, many other lipoxygenases have a pH optimum around 7. At pH 7, the CMC of linoleic acid is much lower (<20 μM, Ref. 4), and the solutions are often turbid. In studies on lipoxygenases at neutral pH, nonionic detergents, such as Tween-20 or Triton X-100 (source information in Experimental Procedures section), are frequently added to the reaction mixture to obtain an optically transparent solution.

Detergents are known to affect the dioxygenation rate. Many investigators have observed inhibition and/or stimulation of the dioxygenation reaction by surfactants (e.g., Refs. 5–8), but controversy exists about the interpretation of the data. In two recent studies on the effect of surfactants on the lipoxygenase reaction (7,8), the observed inhibition and activation were attributed to direct interactions between the detergents and lipoxygenase. In their analysis of the data, the authors did not take into account the fact that linoleate is itself an amphiphile and can, therefore, interact with the detergent micelles. On the other hand, in 1977 Galpin and Allen (9) published a study on the influence of micelle formation on lipoxygenase kinetics in which they used *n*-alcohols and *n*-carboxylic acids to modify the CMC of linoleate. Their results provided convincing evidence that lipoxygenase interacts mainly with monomeric linoleate, and that virtually all of the inhibition or activation effects of the alcohols and carboxylic acids could be attributed to changes in the concentration of nonmicellar linoleate. Furthermore, in a recent analysis of lipoxygenase catalysis in reversed micelles, Perez-Gilabert *et al.* (10) found that their data were best predicted by a model in which linoleate dissolved in the water phase was the sole substrate for lipoxygenase-1, and interactions between lipoxygenase and interfacial linoleate were neglected.

In order to resolve the controversies concerning the interpretation of dioxygenation data collected in the presence of a detergent, we have studied the dioxygenation kinetics over a wide range of linoleic acid and detergent concentrations. In most experiments we have used the nonionic detergent Lubrol (source information in Experimental Procedures section), which does not absorb at the wavelength used to monitor the dioxygenation (243 nm), but we have also studied the effect of two other commonly used detergents, Tween-20 and Triton X-100. Furthermore, we recorded the pH profile for lipoxygenase-1 activity in buffers containing detergent and compared it with the profile obtained in the absence of detergent.

We present a quantitative analysis of the data obtained at pH 9 and 10. Because the Michaelis–Menten formulation, which is often used to describe dioxygenation data, is only valid under certain conditions (11), we have analyzed the data in terms of the more comprehensive two-step model for lipoxygenase catalysis (11–13).

EXPERIMENTAL PROCEDURES

Materials. Lipoxygenase-1 was prepared from soybeans (White Hilum; Central Soya, Utrecht, The Netherlands) as described previously (Ref. 11 and references therein). The preparation had a specific activity of 200 μmol · min^{-1} · mg^{-1} at pH 9, and of 40 μmol · min^{-1} · mg^{-1} at pH 7 (measured at 100 mM linoleate). It showed one major band after sodium dodecylsulfate (SDS) gel electrophoresis upon Coomassie Brilliant Blue staining. Lipoxygenase-1 was stored in 0.1 M sodium acetate, pH 5.5, containing 134 g/L ammonium sulfate. Partially purified lipoxygenase-2 was obtained in the second ion exchange chromatographic step (DEAE-Sepharose; Pharmacia, Uppsala, Sweden) in the same purification procedure. Lipoxygenase-2 activity was found in a small peak preceding the lipoxygenase-1 peak. The protein in the lipoxygenase-2 peak was precipitated with 320 g/L ammonium sulfate, then resuspended in 0.1 M sodium, acetate pH 5.5, and used without further purification. The specific activity of the lipoxygenase-2 preparation was 1 mmol · min^{-1} · mg^{-1} at pH 6 (measured at the linoleic acid concentration at which the rate is maximal, 25 mM, see Fig. 3a later in article) and was 0.3 mmol · min^{-1} · mg^{-1} at pH 9.

Linoleic acid [(9*Z*,12*Z*)-octadecadienoic acid] was obtained from Janssen Chimica (Beerse, Belgium) and was stored under argon as a 300 mM solution in methanol p.a. (Merck, Darmstadt, Germany) at 4°C. Lubrol (unspecified polyoxyethyleneglycols from fatty alcohols) was purchased from ICN (Cleveland, Ohio), Tween-20 from Fluka (Buchs, Switzerland), and Triton X-100 from Serva (Heidelberg, Germany).

Kinetic measurements. A Hi-Tech (Salisbury, United Kingdom) SF-51 stopped-flow spectrophotometer was used for the kinetic experiments. The formation of hydroperoxylinoleate (HPOD) was followed by recording the absorbance at 243 nm (UG-5 filter, 45% transmission at 243 nm) in a 10-mm light-path observation chamber. The molar absorbance for HPOD at 243 nm was 17.8×10^3 M^{-1} · cm^{-1}. The absorbances at 243 nm of 1 g/L Tween-20 and 1 g/L Triton X-100 were 0.15 and 0.48 cm^{-1}, respectively. Measurements were performed at 25°C in 0.09 M Na-borate (pH 7.9–10.7) or 0.09 M sodium phosphate (pH 6.7–9.0) buffers. A small amount of methanol from the linoleic acid stock solution was carried through into the final reaction mixture (maximally 0.03% vol/vol). As methanol is known to have a slight effect on the kinetics of the lipoxygenase reaction (11), the methanol concentration was kept constant (0.03% vol/vol) in all reaction mixtures by adding an appropriate amount of extra methanol. The reactions were initiated by mixing lipoxygenase (in syringe 1) with linoleate and detergent (in syringe 2). The final lipoxygenase concentration was 50 nM, unless otherwise indicated.

Interpretation of the data. An analytical steady-state rate equation for lipoxygenase catalyzed oxygenation of linoleate was derived in previous studies (11,13). The steady-state rate, *r*, at given linoleate (*S*) and HPOD (*P*) concentrations is given by:

$$r = \frac{V_{max}[S]}{\{K_S^*(1 + [P]/K_P^*) + [S]\} + \alpha \cdot \{K_P(1 + [S]/K_S) + [P]\} \cdot [S]/[P]} \quad [1]$$

In this expression, V_{max} is the maximum rate, K_S^*, K_P^*, K_S and K_P are the dissociation constants of the iron(III)-lipoxygenase- (K^*) and iron(II)-lipoxygenase (K) -*S* and -*P* complexes. The parameter α is a constant, provided $[O_2]$ does not change by more than 20%.

All observed curves showed an initial increase in rate (the induction period), followed by a short period of maximum rate, r_{max} (note that r_{max} is not equal to V_{max}). Numerical simulations of the lipoxygenase reaction indicate that the steady-state approximation may be applied in analyzing r_{max} as a function of [linoleate] and [HPOD] (13). The observed values of r_{max} (indicated as *r* in the rest of the text) were fitted to the steady-state rate equation using a nonlinear least-squares program (Levenberg-Marquardt algorithm, Ref. 14) for evaluating functions of multiple independent variables. The values for [*S*] and [*P*] used in the fitting procedure were estimated from the absorbance at 243 nm at the start of the maximum rate period. Since the concentration of O_2 in water, at 25°C under air, is 240 μM, and *r* is measured at 3 μM < [*P*] < 5 μM, $[O_2]$ varies less than 5% in the experiments, and therefore the value of α is constant within the experimental error.

RESULTS

Effect of Lubrol on the dioxygenation rate at alkaline pH. The dioxygenation of 2.5–110 μM linoleate, catalyzed by 50 nM soybean lipoxygenase-1 at pH 10, was recorded in the absence of detergent. After completion of the reaction, all linoleate (within the experimental error of 5%) appeared to be converted into HPOD. The steady-state rates are shown in Figure 1a. The values of V_{max} and K_S^* were estimated from a nonlinear least-squares fit of these data to Equation 1 (Experimental Procedures section). Because the other parameters are highly correlated under the conditions of the experiments ($[O_2]$ = 240 μM and [HPOD] < 5 μM), they were entered as constants: K_P^* = 25 μM (11,13), K_P = 15 μM (15), K_S = 20 μM and α = 0.01 (11,13). The best fit values for V_{max} and K_S^* were 15.0 ± 0.2 μM/s and 20 ± 1 μM, respectively (Chi square = 1.5).

In Figure 1b we illustrate the effect of increasing concentrations of Lubrol (0.025–0.8 g/L) on the steady-state rate (r) at four different linoleate concentrations (9, 30, 55 and 110 μM). At all linoleate concentrations, the presence of detergent decreases the dioxygenation rate. However, all of the linoleate is eventually converted into HPOD. The effect of Lubrol at a concentration of 1.7 nM lipoxygenase is the same as the effect at 50 nM. The r_{max} values measured at 50 nM lipoxygenase were 30 times larger than the values measured at 1.7 nM lipoxygenase at all Lubrol concentrations.

The data presented in Figure 1 are not compatible with two simple inhibition modes in which the detergent acts directly on the enzyme (uncompetitive and simple noncompetitive inhibition). Competitive inhibition or a more

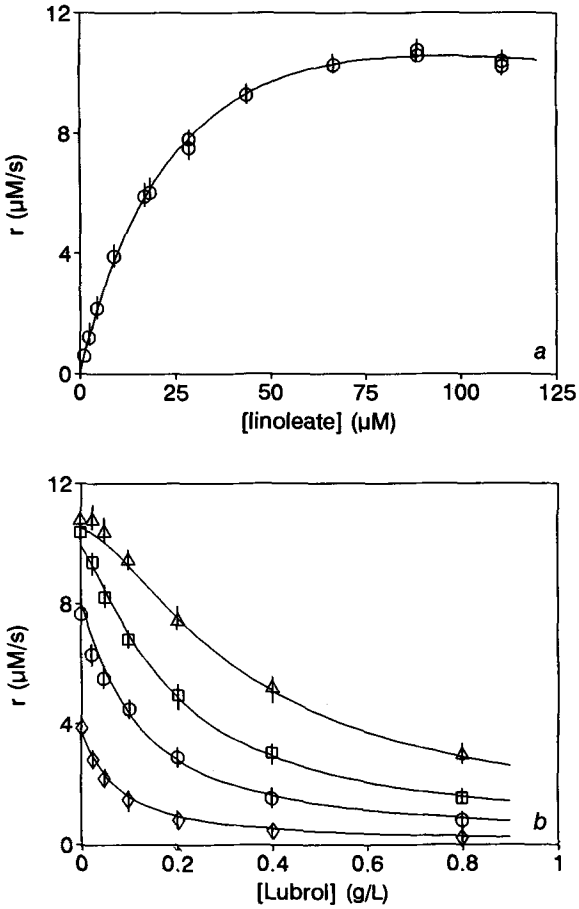

FIG. 1. Effect of Lubrol on the dioxygenation of linoleate catalyzed by 50 nM lipoxygenase-1. Reactions were carried out in 0.1 M sodium borate at pH 10. *a*: Steady-state rates in the absence of Lubrol at varying linoleate concentrations; circles, observed rates; solid lines show rates calculated with V_{max} = 15 μM/s, K_S^* = 20, K_P^* = 25, K_S = 20, K_P = 15 μM and α = 0.01. *b*: Steady-state rates measured at different Lubrol concentrations, starting with 9 (diamonds), 30 (circles), 55 (squares) and 110 (triangles) μM linoleate. Solid lines: rates calculated with the parameters mentioned under (*a*) and K_D = 32 μM, *f* = 770 μmol/g and CMC_d = 0. CMC_d, concentration of nonmicellar detergent.

complicated mode of enzyme inactivation is not excluded by the data. However, the presence of detergent would also slow down the reaction if micelle-bound linoleate were a poor substrate for lipoxygenase. Such a model would be in good agreement with the results of Galpin and Allen (9) and those of Perez-Gilabert *et al.* (10). In order to investigate this possibility, we used a kinetic model with the following features: (i) The fatty acid molecules interact with "fatty acid binding sites" on the detergent micelles in a simple reversible equilibrium, described by the dissociation constant K_D, (ii) only micelles can bind the fatty acid molecules, monomeric detergent molecules have no effect; (iii) the micelle-bound form of the fatty acid cannot interact with the enzyme; (iv) reactions between the fatty acid molecules and the detergent micelles are much faster than the enzyme-catalyzed reaction, and are not, therefore, rate limiting. For the sake of simplicity, we assume that the concentration of nonmicellar detergent (CMC_d) is constant at all linoleate concentrations. If 1 g of detergent can adsorb *f* μmoles of fatty acid, then B_0, the total concentration of "binding sites," is equal to $f \cdot (D - CMC_d)$, where *D* is the concentration of detergent in g/L. At a total fatty acid concentration A_0 μM, the concentration of free fatty acid [*A*] is given by:

$$[A] = \{[(K_D + B_0 - A_0)^2 + 4 \cdot K_D \cdot A_0]^{1/2} - (K_D + B_0 - A_0)\}/2 \quad [2]$$

In the nonlinear least-squares fit of the data with this model, the concentrations of free linoleate and HPOD ([*S*] and [*P*]) for use in Equation 1 were calculated from Equation 2 by substituting the appropriate total concentrations S_0 and P_0 for A_0. All data presented in Figure 1 were evaluated simultaneously (see Experimental Procedures section). The accuracy of the data does not allow separate estimations of K_D for Lubrol-linoleate and Lubrol-HPOD, because under the conditions of the measurements (3 < [HPOD] 5 μM), the rate is mainly determined by the concentration of linoleate. The best fit values are: V_{max} = 15.0 ± 0.2 μM/s, K_S^* = 20 ± 1 μM, *f* = 770 ± 80 μmoles/g and K_D = 32 ± 5 μM (Chi square = 2, but see below). The concentration of noninteracting detergent (CMC_d) must be very small, and cannot be determined accurately from these data. Its upper limit is estimated to be 10 mg/L. The experimental data satisfy the simple model very well. This can be seen in Figure 1b, in which the calculated data have also been indicated.

The values of K_D and *f* appeared to be correlated—other values of *f* and K_D also fit the data well, as long as f/K_D is approximately 25 L/g and K_D > 15 μM. Therefore, the absolute values of K_D and *f* (and their errors) have little physical significance. The correlation indicates that the total number of binding sites B_0 is much larger than the number of occupied sites, [*AD*], even at the highest concentration of linoleate used in these experiments. When $B_0 - [AD] \approx B_0$, the expression for the concentration of free linoleate becomes:

$$[A] = A_0/(1 + (D - CMC_d) \cdot f/K_D) \quad [3]$$

When Equation 3 was used instead of Equation 2 for the calculation of free linoleate, the fit of the data was equally good (Chi square = 2). The best fit value for f/K_D was 21 ± 5 L/g.

When the rate is measured as a function of the linoleate concentration and the concentration of detergent is constant, the observed rates coincide with the predicted values within the experimental error. However, at low substrate concentrations (<15 μM), the observed rates are systematically somewhat lower, and at high substrate concentrations (50–100 μM), the values are slightly higher than the predicted rates (not shown). This effect may be due to exclusion phenomena such as those described, for example, by McGhee and Von Hippel (16). Binding of one molecule of linoleate to a detergent micelle presumably excludes binding of other linoleate molecules to potential "binding sites" in its vicinity. In that case, f/K_D is a function of the linoleate

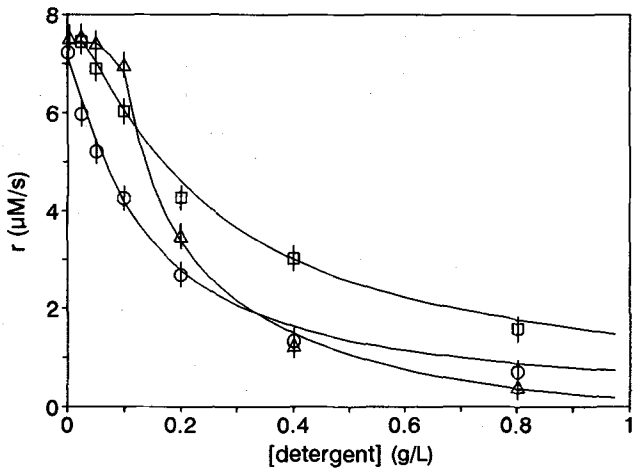

FIG. 2. Comparison of the effects of Lubrol (circles), Tween-20 (squares) and Triton X-100 (triangles) on the steady-state oxygenation rates. Reactions were performed with 50 nM lipoxygenase-1 and 30 μM linoleate in 0.1 M sodium borate, pH 10. Solid lines show rates calculated with parameters obtained from best fits of data obtained at 10, 30, 50 and 100 μM linoleate: f/K_D = 24 L/g, CMC_d = 0 (for Lubrol data); f/K_D = 10 L/g, CMC_d = 0.031 g/L (for Tween-20 data) and f/K_D = 30 L/g and CMC_d = 0.091 g/L (for Triton X-100 data). All other parameters and abbreviation are as in Figure 1.

concentration rather than a constant, and the estimated value for f/K_D is merely an average.

Effect of other nonionic detergents. Because Triton X-100 and Tween-20 are also commonly used to solubilize linoleic acid, we investigated whether the model described for the action of Lubrol holds for these compounds. We measured the dioxygenation rates at 10, 30, 50 and 100 μM linoleate, in the presence of 0–0.8 g/L detergent. In Figure 2 the effects of increasing concentrations of Tween-20 or Triton X-100 are compared with the results obtained for Lubrol (see Fig. 1b, linoleate concentration, 30 μM). Addition of less than approximately 0.05 g/L Tween-20 or 0.1 g/L Triton X-100 has little effect (all linoleate concentrations), but higher concentrations of either detergent cause the dioxygenation rate to decrease. After completion of the reactions, all of the linoleate (within the experimental error of approximately 5%) had again been converted into HPOD. The data for Tween-20 and for Triton X-100 (all linoleate concentrations) were successfully fitted to Equations 1 and 2. The best fit values for K_D and f were correlated, and the use of Equation 3 instead of Equation 2 gave equally good results. The best fit values of f/K_D are 10 L/g for the Tween-20 data, and 30 L/g for the Triton X-100 data. The best fit values for CMC_d were 0.031 ± 0.008 and 0.091 ± 0.003 g/L, respectively. These values are lower than the CMCs that have been reported for these detergents in pure form (0.06 g/L for Tween-20 and 0.19 g/L for Triton X-100, Refs. 17 and 18). However, the concentration of monomeric detergent in equilibrium with mixed micelles is always lower than the CMC of the pure detergent (19). Furthermore, we used commercial detergent preparations, whose CMCs may have been smaller than the published values, owing to inhomogeneity or impurities.

Effect of Lubrol on the lipoxygenase-2 reaction. If the inhibition of the dioxygenation reaction by Lubrol is solely due to adsorption of the fatty acid substrate, then the effect of Lubrol on the reaction catalyzed by other lipoxygenases must be predictable from the data obtained with lipoxygenase-1. Therefore, we investigated

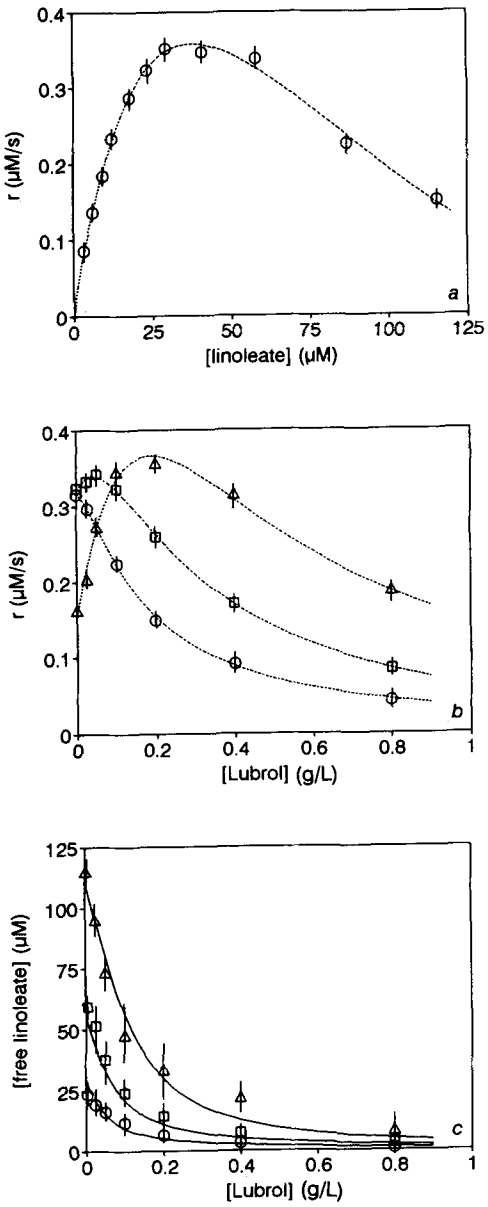

FIG. 3. Effect of Lubrol on the dioxygenation of linoleate, catalyzed by lipoxygenase-2. Data obtained with a partially purified enzyme preparation in 0.1 M sodium borate at pH 9. *a*: Rates in the absence of Lubrol at varying linoleate concentrations. *b*: Rates measured in the presence of varying Lubrol concentrations, starting with 30 (circles), 55 (squares) and 110 (triangles) μM linoleate. *c*: Comparison of concentrations of free (nonmicellar) linoleate, estimated from the data obtained with lipoxygenase-2 with calculated values. Solid lines: calculated concentrations (K_D = 32 μM and f = 770 μmol/g). Other symbols: concentration of free linoleate estimated by comparing the rates from *b*, those obtained in the absence of Lubrol (*a*). Total linoleate concentrations: 30 (circles), 55 (squares) and 110 (triangles) μM.

the effect of Lubrol on the reaction catalyzed by lipoxygenase-2 from soybean.

Lipoxygenase-1 and -2 have different substrate specificities (20) and form different products (21). In the lipoxygenase-2 reaction, 10–35% of all linoleate is converted into compounds other than HPOD (see Ref. 22), as judged by the increase of absorbance at 285 nm during the reaction (in the lipoxygenase-1 reaction, over 95% of the linoleate is converted into HPOD). The steady-state kinetics are also different. A plot of the steady-state dioxygenation rate for lipoxygenase-2 as a function of linoleate concentration, obtained at pH 9 and at a protein concentration of 0.25 μg/mL, is shown in Figure 3a. The curve shows a marked decrease in rate at linoleate concentrations greater than 25 μM. A similar decrease in rate appears in the lipoxygenase-1 reaction, but only at linoleate concentrations above 100 μM (not shown). The rate decrease is due to substrate inhibition (11). This effect is much more pronounced for lipoxygenase-2 reaction than for lipoxygenase-1.

Addition of Lubrol to the lipoxygenase-2 reaction mixture merely slows down the reaction when the linoleate concentration is 30 μM (Fig. 3b). However, at a linoleate concentration of 55 μM, a slight stimulation of the reaction is observed at Lubrol concentrations up to 0.05 g/L. Concentrations greater than 0.1 g/L are again inhibitory. A much larger stimulation is observed in the reaction with 110 μM linoleate. At a Lubrol concentration of 0.2 g/L, the rate is twice as high as in the absence of detergent. At higher Lubrol concentrations, the reaction proceeds more slowly than at 0.2 g/L Lubrol. In spite of the apparently different effects of Lubrol on lipoxygenase-1 and -2, the results can still be explained with the same model. The micelles adsorb a certain fraction of the linoleate, which cannot then be bound by lipoxygenase. When the total linoleate concentration is smaller than 25 μM, addition of Lubrol only results in a reduced reaction rate. At higher linoleate concentrations, substrate inhibition of lipoxygenase-2 is substantial. Decreasing the concentration of free linoleate will result in a decreased substrate inhibition and, thus, in a rate increase. Addition of more detergent eventually results in a rate decrease, because the concentration of free linoleate drops below 25 μM.

Because of the lack of sufficient *a priori* knowledge of the values of K_P^*, K_S, K_P and α for the lipoxygenase-2 reaction, it is not possible to perform a quantitative analysis similar to the one applied to the lipoxygenase-1 data. Assuming that the model for the action of detergents is correct, it is possible to estimate the concentrations of free linoleate simply by comparing the rates observed in the presence of Lubrol with the values obtained in the absence of detergent (Fig. 3a). The dioxygenation rate in the absence of detergent at 35–60 μM linoleate is approximately constant (0.35 ± 0.2 μM/s). Therefore, the estimate of the concentration of free linoleate corresponding to a rate of 0.35 ± 0.2 μM/s is rather inaccurate (48 ± 13 μM). The error on the other estimates is smaller (approximately 5 μM for estimates smaller than 25 μM, 10 μM for estimates above 70 μM). In Figure 3c we compare these estimates with values calculated from Equation 2, with K_D = 32 μM and f = 770 μmol/g, the parameter values calculated for the lipoxygenase-1 reaction. The concentrations of free linoleate estimated from the dioxygenation rates agree very well with the ones calculated with Equation 2. This indicates that the fraction of linoleate incorporated in micelles is independent of the type of lipoxygenase used in the assay.

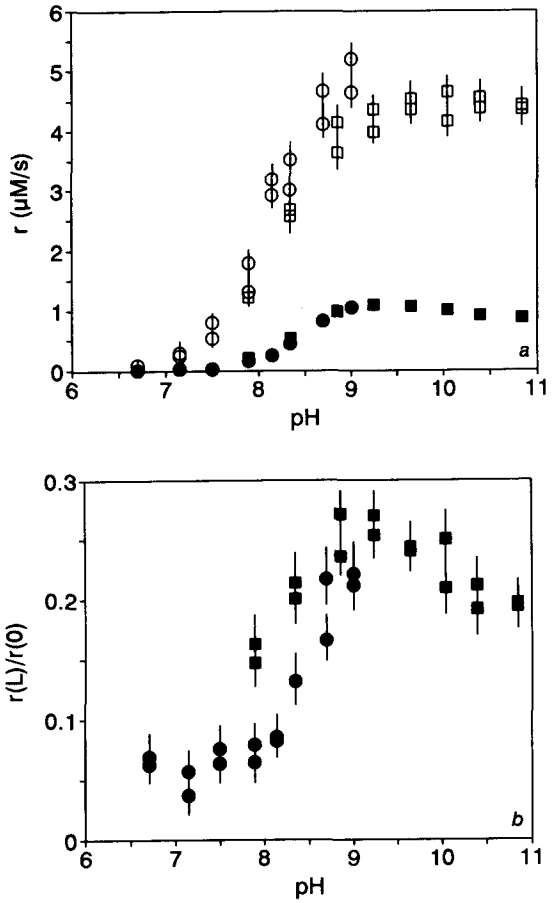

FIG. 4. Effect of pH. *a*: Steady-state dioxygenation rates in the absence or presence of 0.2 g/L Lubrol. The concentration of lipoxygenase-1 was 50 nM, the total linoleate concentration was 10 μM. Open symbols, no Lubrol; closed symbols, 0.2 g/L Lubrol; circles, 0.1 M Na-phosphate buffers; squares, 0.1 M Na-borate buffers. *b*: Ratio r(L)/r(0) of rates in buffers with [r(L)] and without [r(0)] 0.2 g/L Lubrol.

The effect of pH. The effect of detergent on the pH profiles of lipoxygenase-1 is shown in Figure 4. The profile was obtained at 10 μM linoleic acid. We used this low-linoleate concentration to minimize effects due to substrate inhibition or aggregation. The plots show a steep increase in rate between pH 7 and 9. The rates measured in the presence of Lubrol are significantly lower (Fig. 4a). If the composition of the detergent-fatty acid micelles were independent of pH, the concentration of free fatty acid would be the same at each pH. In that case, the ratio of the rates in buffers with or without Lubrol would be constant. However, this ratio varies quite strongly (Fig. 4b). At pH <7.5, dioxygenation in the absence of Lubrol is approximately 20 times faster than in the presence of Lubrol. At pH >9, the rate in the absence

of Lubrol is only 4 to 5 times higher. This means that the concentration of free lipid substrate is significantly smaller at pH <7.5 than at pH >9.

It has been proposed (6) that the activity of soybean lipoxygenase-1 depends on the charge of the fatty acid substrate. Lipoxygenase-1 reacts best with charged substrates (such as the linoleate anion), but seems to have a much lower affinity for uncharged compounds (such as unionized linoleic acid). The apparent pK_a value for linoleic acid is 7.9 (6). The pH profile of lipoxygenase-1 obtained in the absence of detergent is consistent with this. One would also expect that the amount of linoleic acid incorporated in the mixed micelles would decrease upon increasing the pH, owing to the repulsive interactions between the negatively charged head groups. The curve of the ratios (Fig. 4b) has the same sigmoidal shape as the activity profile (Fig. 4a), because the presence of detergent merely exaggerates the effect of pH on the lipoxygenase-1 activity. However, the presence of Lubrol can cause a shift in the pH optimum of lipoxygenases that have highest affinity for less polar substrates (unpublished observations). The results presented here do not exclude the possibility that Lubrol has some pH-dependent effect on lipoxygenase itself, nor that the pK_a of linoleic acid is affected by the presence of Lubrol. Nonetheless, the experiments indicate that pH profiles obtained in buffers containing detergent are different from those obtained in buffers without detergent.

DISCUSSION

The results presented above strongly favor a model in which lipoxygenase has a substantially higher affinity for monomeric substrate than for fatty acid incorporated in micelles. A quantitative model, in which the detergent simply decreases the effective substrate concentration, accurately predicts the results for more than one type of lipoxygenase, without requiring any further assumptions. It is not possible to reconcile the present results with an equally simple model in which a detergent acts directly on the enzyme. Such a model would require many assumptions, for which no experimental evidence exists, to explain the observed inhibition and stimulation.

The influence of micelle formation on lipoxygenase kinetics was studied by Galpin and Allen (9). Our findings confirm their conclusion that the effects of amphiphiles on the dioxygenation reaction could be ascribed to physicochemical interaction of these compounds with the substrate rather than to a direct interaction with the enzyme itself.

In many studies on lipoxygenase, a nonionic detergent is routinely added to solubilize the substrate. If quantitative conclusions are to be drawn from the experiments, it is essential to characterize the system in detail. When such a characterization is omitted, it is quite possible that phenomena caused by changes in the effective substrate concentration are incorrectly attributed to direct interactions between the enzyme and the detergent. For instance, the rate increase that is observed after addition of small amounts of detergent at high fatty acid concentrations (see Fig. 3) is easily mistaken for direct stimulation of the lipoxygenase activity (cf. Ref. 8). Furthermore, changes in K_m and V_{max} may be erroneously interpreted as indicative for competitive inhibition, for the following reason: The steady-state rate equation (Equation 1) for lipoxygenase-1 catalysis simplifies to the Michaelis-Menten equation for linoleate concentrations below 75 μM and HPOD concentrations from 3 to 5 μM, because the second term in the denominator and the value of $[P]/K_P^*$ are both small (11). Substitution of the substrate concentration in the Michaelis-Menten equation with the expression for $[A]$ from Equation 3 yields an equation that is identical to the expression for the rate in the presence of a competitive inhibitor. Therefore, the model predicts that, under certain conditions, the presence of detergents causes changes in K_m and V_{max} that are very similar to those caused by competitive inhibitors. As the Michaelis-Menten equation is only an approximation, straight lines generated in a Lineweaver-Burk plot will intersect slightly off the ordinate (which is generally interpreted as "mixed inhibition"; cf. Ref. 8). However, the results obtained with lipoxygenase-2 exclude competitive inhibition. A competitive inhibitor would enhance the effect of product and substrate inhibition, and merely decrease the dioxygenation rate.

In the interpretation of results of experiments in which detergents are used, it should also be taken into account that: (i) pH profiles obtained in buffers containing detergent are different from those obtained in buffers without detergent; (ii) lipoxygenase inhibitors and activators may associate with micelles and therefore seem to be less effective than in the absence of detergent; and (iii) it is possible that the addition of negatively charged amphiphiles to the nonionic detergent/linoleate solution will limit the amount of fatty acid that can be incorporated into the micelles, and thus stimulate the reaction (23). Positively charged amphiphiles may have the opposite effect (8).

It has been reported that some mammalian lipoxygenases are able to oxygenate biological membranes without prior action of a phospholipase (24). From the present study, it seems highly likely that lipoxygenase-1 and -2 from soybean interact preferentially with free linoleate, and not with linoleate included in a matrix of (nonionic) amphiphiles. Therefore, investigations are underway into the ability of plant lipoxygenases to oxygenate artificial and biological lipid bilayers.

This study was aimed at determining the effect of fish oil supplementation on copper-catalyzed oxidation of low density lipoproteins (LDL) from nine hypertriglyceridemic human subjects. A rapid headspace gas chromatographic method was used to measure the volatile oxidation products from LDL. Propanal and hexanal were the major volatile products formed in the oxidation of n-3 and n-6 polyunsaturated fatty acids (PUFA), respectively. Fish oil supplementation resulted in a significant increase in propanal formation from 3.7 to 13.4 nmol/mL LDL ($P < 0.01$); it also resulted in small decreases in pentanal formation from 14.7 to 11.4 nmol/mL LDL and in hexanal formation from 138 to 108 nmol/mL LDL ($P < 0.05$). The changes in peroxidation products paralleled the changes in LDL composition, which showed a significant increase in n-3 PUFA from 3.2 to 14.6% ($P < 0.01$) and a decrease in n-6 PUFA from 43.7 to 35.0% ($P < 0.05$). Propanal formation was highly and significantly correlated with n-3 PUFA content ($r = 0.950$, $P < 0.001$). Since total volatiles remained unchanged, this indicated that the two groups of LDL samples did not differ in overall oxidative susceptibility. Although fish oil intake did not alter the oxidative susceptibility of LDL, the chemically modified LDL particles generated a distinct pattern of volatile oxidation products that reflected changes in their fatty acid composition.

***Lipids* 29, 233–236 (1994).**

Modification of low density lipoproteins (LDL) by oxidation of their polyunsaturated lipid components has been implicated in the etiology of atherosclerosis (1–3). Oxidation proceeds by interaction of polyunsaturated fatty acids (PUFA) with active oxygen species or with lipid oxidation products. Moreover, there are indications that lipid oxidation promotes premature coronary atherosclerosis since susceptibility to LDL oxidation has been associated with the severity of coronary heart disease (4). Protection against oxidation can come from antioxidants, antioxidant enzymes and cofactors (5). The use of antioxidants to inhibit LDL oxidation has been reviewed extensively (2,6). Under *in vivo* conditions, there exists a competition between oxidative and protective processes that depend on PUFA composition and on antioxidant levels.

Oxidation of human LDL leads to the formation of various aldehydes and to fluorescent apoprotein B (apo B) (7). This fluorescence is assumed to come from the Schiff bases formed by reaction of aldehydes with the lysine residues of apo B. Several studies have demonstrated that the fatty acid composition of LDL is influenced by diets rich in oleic acid (8–10) and by supplementation with fish oil n-3 PUFA (11–13). Oleate-rich LDL particles from diets rich in oleic acid were reported to be highly resistant to oxidation based on formation of thiobarbituric acid-reactive substances (TBARS) (8–10) and conjugated dienes. The oleate-rich LDL particles were also resistant to oxidaton induced by endothelial cells (8,9). Oxidation of LDL from smokers fed fish oil resulted in significantly higher TBARS than from nonsmokers fed fish oil (11). In another study (12), the susceptibility to Cu^{2+}-catalyzed peroxidation as measured by TBARS was similar in LDL from subjects on fish oil or on corn oil diets.

Although the validity of TBARS as an index of lipid peroxidation in biological samples has been a matter of considerable debate (14), the TBARS assay has been used most commonly to measure the degree of oxidation and the susceptibility to oxidation of LDL. However, the lack of specifity of the thiobarbituric acid (TBA) test makes results difficult to interpret (5,15).

We previously described a rapid method using headspace gas chromatography (GC) for the determination of hexanal, an important decomposition product in n-6 PUFA peroxidation. We used this method to examine rat liver samples (16), human red blood cell membranes (17) and human LDL (18). In this latter study, LDL from ten individuals showed a wide variation in susceptibility to oxidation, and hexanal values correlated significantly with total PUFA, 18:2 and n-6 PUFA contents of LDL, but poorly with 20:4 and vitamin E levels (18). Thus, we concluded that dietary PUFA is an important factor in determining the oxidative susceptibility of human LDL. However, vitamin E is not the sole determinant of oxidative susceptibility, and other endogenous antioxidants or inhibitors may contribute to the resistance of LDL to oxidation (18). Consistent with this we have shown, for example, that phenolic compounds in red wine contribute antioxidant activity and inhibit *in vitro* oxidation of human LDL (19).

With the new methodology on hand, we can now address the question whether LDL composition does affect the oxidative stability of lipoprotein particles. The present paper reports the application of headspace GC in a nutritional study to test the effect of fish oil supplementation on the susceptibility of LDL fractions to oxidation. Appearance of specific volatile peroxidation products was found to be correlated with the fatty acid profile but not with the tocopherol content of LDL.

MATERIALS AND METHODS

Blood was obtained from hypertriglyceridemic subjects who were enrolled in a 12-week, double blind, randomized

clinical trial (University of California at Davis Human Subjects Committee No. 92-086). Blood samples were taken during a period after the subjects had consumed 5.1 g of fish oil each day for 6 wk (supplemented). Unsupplemented samples were taken when fish oil was absent from the diet. The fish oil supplement contained 58.9% PUFA, including 8.6% n-6 PUFA and 44.3% n-3 PUFA (comprising 28.2% 20:5n-3 and 11.6% 22:6n-3), and 25 IU vitamin E. Plasma was separated from blood, and LDL fractions were prepared by density ultracentrifugation as described previously (18).

Prior to oxidation, LDL was exhaustively dialyzed with deoxygenated phosphate-buffered (10 mM, pH 7.4) saline (100 mM) for 24 h. The final concentration of each LDL sample was diluted with phosphate-buffered saline (10 mM) to the same protein concentration (1 mg/mL LDL). The freshly prepared LDL fractions from the unsupplemented and fish oil-supplemented periods were compared by the headspace GC method (18) to determine the volatile products formed by oxidation in the presence of copper. Samples of LDL in phosphate-buffered saline in the presence of 80 μM $CuSO_4$ were sealed in headspace bottles and incubated in a water bath shaker at 37°C. After incubation, the headspace bottles were pressurized with helium as carrier gas for 30 s, and an aliquot of the gas phase was injected into the gas chromatograph.

The fatty acid composition of LDL fractions was determined as described previously (18); vitamin E contents were measured by high-performance liquid chromatography (20). The least significant difference between mean values was determined by analysis of variance (21) of duplicate analyses.

RESULTS

To investigate the effect of LDL composition on the oxidative susceptibility of lipoprotein particles, a method is required that can discriminate between the various peroxidation products derived from different lipid components. The headspace GC technique was used to measure the volatile peroxidation products formed from n-6 PUFA and n-3 PUFA upon copper-catalyzed oxidation of human LDL. The products of n-6 PUFA have been shown to include pentane, pentanal and hexanal. The main product of n-3 PUFA oxidation is propanal (22). To compare the susceptibility to oxidation of human LDL samples, total volatiles were also determined by summation of the peak areas of all the volatiles detected.

A representative gas chromatographic analysis of the products of copper-oxidized LDL from a human subject on a fish oil-supplemented diet shows that the peak due to propanal increased dramatically (Fig. 1b) when compared to the LDL sample from the same subject on the unsupplemented diet (Fig. 1a). In both the supplemented and unsupplemented LDL samples, hexanal was the main volatile. This result is consistent with the fatty acid analyses showing an abundance of n-6 PUFA in the LDL samples (Table 1). Similarly, in the oxidized LDL from the subjects consuming the unsupplemented diet, the peaks due to pentane and pentanal were both larger than the peak due to propanal. Since pentane and pentanal reflect the

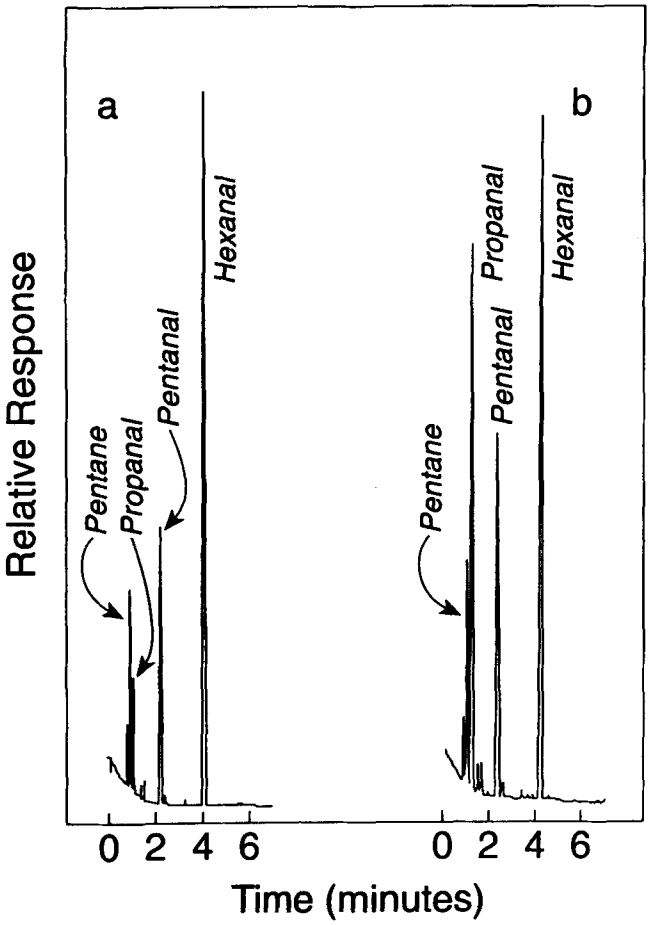

FIG. 1. Headspace gas chromatograms of human low density lipoprotein after incubation for 2 h at 37°C in the presence of 80 μM $CuSO_4$; a, unsupplemented subject; b, fish oil supplemented subject.

oxidation of n-6 PUFA while propanal reflects n-3 PUFA oxidation, headspace GC allowed us to determine the origin of various volatile products of lipid oxidation.

Figure 2 shows time plots of propanal and hexanal formation obtained from six samples of LDL oxidized with copper. After 2 and 4 h of oxidation at 37°C, propanal formation was more pronounced in LDL from subjects that had consumed a fish oil-supplemented diet than those that had consumed the unsupplemented diet (Fig. 2a). On the other hand, hexanal formation did not vary as much as propanal formation but after 2 and 4 h of oxidation it tended to be higher in the LDL samples from unsupplemented diets than in the LDL samples from fish oil-supplemented diets (Fig. 2b). The most consistent differences between the two types of LDL samples were observed after 2 h of oxidation.

Variation in oxidative susceptibility and the nature of the volatile peroxidation products were studied in nine LDL samples from subjects that had consumed an unsupplemented diet, and in nine samples from subjects that had consumed a fish oil-supplemented diet. The headspace GC analyses of the volatile products formed were compared with the fatty acid composition and the vitamin E contents of the lipid extracts (Table 1). A significant,

TABLE 1

Effect of Fish Oil Supplementation on LDL Oxidation

Analyses	Unsupplemented (n = 9)	Supplemented (n = 9)	$P <$
Volatiles (nmol/mL LDL)[a]			
Pentane	9.6 ± 4.2	7.5 ± 2.1	N.S.
Propanal	3.7 ± 1.1	13.4 ± 3.7	0.01
Pentanal	14.7 ± 6.8	11.4 ± 2.7	0.05
Hexanal	138 ± 41	108 ± 22	0.05
Total[b]	189 ± 51	189 ± 41	N.S.
Fatty acids (%)			
n-6 PUFA	43.7 ± 3.2	35.0 ± 3.5	0.05
n-3 PUFA	3.2 ± 0.6	14.6 ± 2.3	0.01

[b]Expressed as hexanal.

3.6-fold higher propanal production was observed in the LDL fractions from subjects after consumption of the fish oil supplement than from subjects on the unsupplemented diets ($P < 0.01$). This increase in propanal production coincided with a statistically significant 4.6-fold increase in n-3 PUFA content of LDL ($P < 0.01$). Small but significantly higher pentanal and hexanal levels ($P < 0.05$) were also observed in the oxidized LDL from the unsupplemented than the supplemented periods, consistent with the significantly higher content of n-6 PUFA in the LDL from subjects without fish oil supplementation. No significant changes were observed in pentane formation or total PUFA or tocopherol content between LDL samples from subjects on supplemented and unsupplemented diets.

The total volatiles were not different between the two groups of LDL samples. Thus, based on total volatiles generated, fish oil supplementation had no effect on the oxidative susceptibility of LDL from nine subjects with hypertriglyceridemia. Yet fish oil supplementation had a dramatic effect on the types of volatile oxidation products formed from LDL.

The correlation between propanal and n-3 PUFA was significant ($r = 0.950$, $P < 0.001$) (Fig. 3). Propanal values of nine oxidized LDL samples from subjects on unsupplemented diets varied only from 2.3 to 4.6%, while those from subjects on fish oil-supplemented diets varied from 11 to 17%. These large differences between LDL from subjects on unsupplemented diets and LDL from subjects on fish oil-supplemented diets are consistent with the significant increase in n-3 PUFA content of LDL (Table 1).

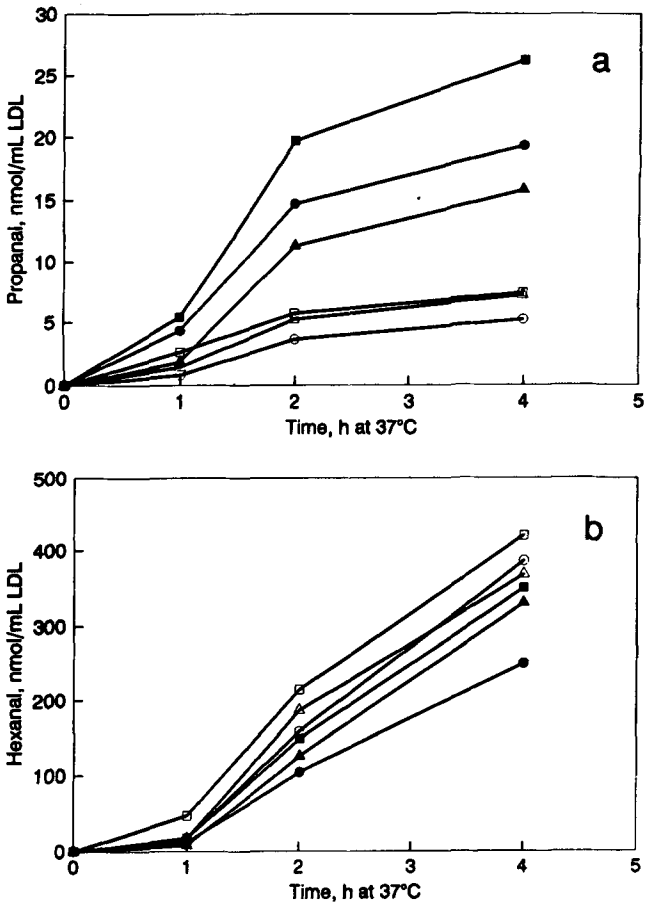

FIG. 2. Kinetics of volatile formation in six samples of human low density lipoprotein (LDL) oxidized in the presence of 80 μM $CuSO_4$; a, propanal; b, hexanal. Lines with closed symbols represent individual subjects consuming fish oil supplements, and lines with open symbols represent individual subjects on unsupplemented diets.

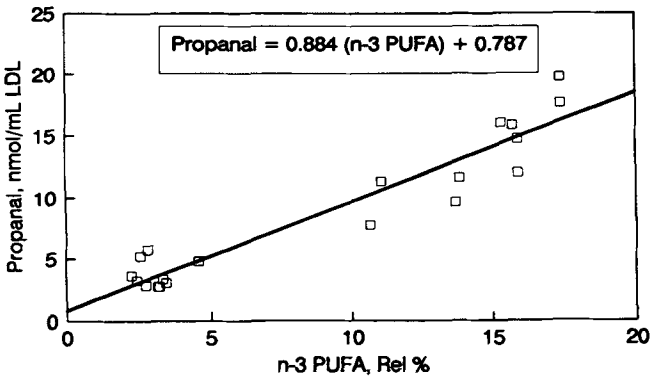

FIG. 3. Correlation of propanal vs. n-3 polyunsaturated fatty acids (PUFA) ($r = 0.950$, $P < 0.001$). LDL, low density lipoproteins.

DISCUSSION

In the present study, fish oil supplementation produced marked changes in the profiles of volatile peroxidation products of LDL from hypertriglyceridemic subjects. These changes in the distribution of oxidation products paralleled the altered fatty acid composition of LDL lipids. Thus, significant increases in propanal formation were observed during oxidation with copper in LDL from subjects supplemented with fish oil (Table 1). This increase in propanal can be directly attributed to increases in n-3 PUFA in the LDL lipids.

In spite of the marked changes in the types of aldehydes formed in the peroxidation of different LDL samples, no changes were observed in the formation of total volatiles. Therefore, there was no apparent difference in the overall oxidative susceptibility of LDL between subjects consuming fish oil and those on the unsupplemented diets. This result is consistent with the similar total PUFA levels observed in the two groups of LDL samples.

The headspace GC procedure used in the present work can be compared to the ultraviolet (UV) conjugated diene method that is used to measure the lag phase to assess the oxidative susceptibility of LDL and the effects of dietary antioxidants (3). In contrast to the UV method, the headspace GC procedure is based on the amounts of volatile oxidation products formed after the lag phase (Fig. 2), when the antioxidants are usually depleted. Thus, the headspace GC method may be expected to provide data that are more closely related to the variation in fatty acid composition of LDL than to the antioxidant protection.

Although the effect of n-3 PUFA from fish oils in reducing the plasma triglyceride level is well established (23–25), only a few reports have appeared on their effects on the oxidative susceptibility of human LDL. One study reported that LDL from human subjects consuming fish oil and corn oil showed similar susceptibility to copper-catalyzed oxidation based on lipid peroxide determinations (12). However, other studies reported significant increases in the formation of TBARS resulting from fish oil diets (11,13). Because TBARS are formed by oxidative degradation of PUFA containing more than two double bonds (26), the oxidation of any lipids containing n-3 PUFA would be expected to produce high levels of TBARS. Therefore, TBARS cannot be used as the sole determinant of oxidative susceptibility to compare the effects of dietary n-6 vs. n-3 PUFA on LDL oxidation. For the same reason the TBA assay cannot be used to estimate the oxidation of dietary oleic acid in LDL oxidation (8–10).

At the level of fish oil supplementation used in the prsent study, although n-3 PUFA from fish oils were incorporated into the LDL, no significant changes were observed in either LDL total PUFA or overall oxidative susceptibility based on total volatile production as determined by headspace GC. Thus, with adequate antioxidant protection, replacement of significant quantities of n-6 with n-3 PUFA may not represent a dramatic enhancement in oxidative susceptibility. However, whether or not the n-3 unsaturated aldehydes expected from oxidation of n-3 PUFA may be more reactive with proteins such as apo B than those produced from n-6 PUFA is not known. Treatment of fresh LDL with 2,4-heptadienal, a product of 18:3n-3 PUFA oxidation (22), led to a fluorogenic apo B, while hexanal did not (7).

The use of headspace GC permits the identification of some of the unique volatile aldehydes produced from n-6 and from n-3 PUFA, and allows a more complete comparison of the oxidizability of LDL particles of varying fatty acid composition. This approach thus affords the discriminatory methodology necessary to investigate the effect of LDL composition on the oxidation of lipoprotein particles. An important area that requires further investigation is to determine how the individual aldehydes produced by oxidation of different dietary PUFA react with apo B and how this relates to the atherogenic effects of oxidized LDL particles.

Superoxide Production by Macrophages Stimulated *in vivo* with Synthetic Ether Lipids

Barbara M. Schreiber*, Matthew D. Layne and **Edward J. Modest**

Boston University School of Medicine, Department of Biochemistry, Boston, Massachusetts 02118

The anticancer activity of synthetic ether lipids may depend in part upon their ability to activate cells of the monocyte/macrophage lineage. In the present study, we have sought to determine whether 1-*O*-octadecyl-2-*O*-methyl-*rac*-glycero-3-phosphocholine (ET-18-OMe) and related ether lipids enhance superoxide production by mouse peritoneal macrophages. Ether lipids were administered intraperitoneally to C57BL/6 mice 4 d after injection with thioglycollate broth. Elicited peritoneal macrophages were harvested and purified one day later, and superoxide production was detected by measuring the superoxide dismutase inhibitable reduction of cytochrome c. Low levels of superoxide were secreted by macrophages in the absence of phorbol 12-myristate 13-acetate (PMA). When PMA was added *in vitro* to macrophages from ET-18-OMe-treated mice, these cells secreted 194.2 nmol superoxide/mg protein in comparison to 53.5 nmol superoxide/mg protein for PMA-treated control cells. The *in vitro* treatment of the macrophages with ET-18-OMe was not effective in stimulating superoxide secretion. Macrophages harvested from mice treated with a series of ether lipids (with and without phosphorus) were examined, and superoxide secretion was found to vary with structure. AM-18-OEt and CP-7 were the most effective compounds, secreting 8.6 and 11.9 times more superoxide, respectively, than PMA-stimulated control cells. Moreover, direct cytotoxicity of the compounds for HL60 human promyelocytic leukemic cells did not necessarily correlate with the ability of each drug to increase macrophage superoxide production.

***Lipids* 29, 237–242 (1994).**

Membrane-targeted synthetic ether phospholipids, alkyllysophospholipids (ALP), have been shown to exert antitumor properties by direct cytotoxicity and cytostasis (1–4), by induction of differentiation of malignant cells to the normal phenotype (5,6), and by activation of macrophages to the tumoricidal state (2,7–9). These compounds are currently showing promise as a new class of clinical cancer chemotherapeutic drugs (10–12) and are also in clinical trial as bone marrow purging agents (13).

It has been shown that lysophosphatidylcholine (LPC) accumulates in response to a variety of biological response modifiers and that membrane phospholipids can act as immunomodulators (14,15). Immunomodulation of macrophages may involve activation of phospholipase A_2, resulting in degradation of the membrane phospholipid phosphatidylcholine (PC) to the lyso derivative LPC (2,14). Accordingly, synthetic glycero-3-phosphocholine analogs of LPC were originally designed as stable immunomodulators with longer half-lives than LPC (1,2). These compounds are structural but not functional analogs of LPC and platelet-activating factor, with long-chain ether linkages at position 1 and short-chain ether groups at position 2 of the glycerol backbone.

These agents have been shown to enhance macrophage cytotoxicity (7,16,17) and to activate macrophages (9,18–20). The naturally occurring ether phospholipid, platelet-activating factor, has been shown to stimulate the oxidative burst of guinea pig peritoneal macrophages (21) and to increase glucose consumption in these cells (19). One hallmark of an activated tumoricidal macrophage is the increased production of reactive oxygen metabolites, such as H_2O_2 and superoxide. In this study, the ability of synthetic long-lived ether lipids to stimulate the production of superoxide by mouse peritoneal macrophages was explored as a means of further defining the potential mechanism of anticancer action of this novel class of cancer chemotherapeutic agents.

MATERIALS AND METHODS

Chemicals. The ether lipid ET-18-OMe was kindly provided by Dr. R. Nordström, Medmark Pharma GmbH (Munich, Germany). All other ether lipids were synthesized by Dr. Claude Piantadosi and colleagues, School of Pharmacy, University of North Carolina (Chapel Hill, NC). The structures of the compounds studied are given in Scheme 1. Ether lipid stock solutions were made in ethanol and stored at –20°C, or in phosphate buffered saline (PBS) and sterile filtered immediately prior to use. All other chemicals were from Sigma Chemical Co. (St. Louis, MO) unless otherwise indicated. Stock solutions included cytochrome c (horse heart type III) dissolved in Hank's balanced salt solution (HBSS) without phenol red to 1.2 mM, phorbol 12-myristate 13-acetate (PMA) solubilized in DMSO to 1 mg/mL and superoxide dismutase (SOD) from bovine erythrocytes dissolved in water at 5 mg/mL.

Animals. Male C57BL/6 mice 4–5 weeks of age were obtained from Jackson Laboratories (Bar Harbor, ME).

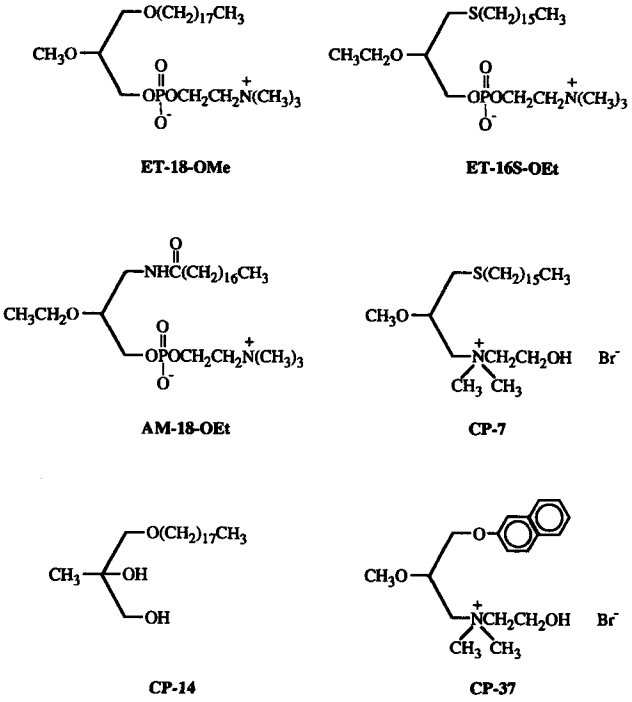

SCHEME 1

For *in vivo* activation experiments, mice were injected intraperitoneally with 2 mL of thioglycollate broth. Four days later, intraperitoneal injections (1 mL) of either PBS (control mice) or ether lipid (see Scheme 1) were administered. Twenty-four hours later mice were killed and peritoneal macrophages harvested as described below. For *in vitro* activation experiments, mice were injected intraperitoneally with 2 mL of thioglycollate broth. Four days later mice were killed and peritoneal macrophages harvested as described below.

Macrophage isolation and culture. Peritoneal macrophages were harvested and plated essentially as described by Schreiber *et al.* (22). Mice were killed by cervical dislocation, and macrophages were harvested by peritoneal lavage with 4–5 mL of cold Eagle's minimal essential medium (MEM) supplemented with 2.2 g/L sodium bicarbonate, 1.5× MEM vitamins, 2 mM L-glutamine, 1% nonessential amino acids, 1 mM sodium pyruvate, 100 U/mL penicillin, 100 μg/mL streptomycin (all purchased from Gibco, Grand Island, NY) and 2 U/mL heparin (Elkins-Sinn Inc., Cherry Hill, NJ). Exudates were pooled for each treatment group (3–5 mice). Cells were centrifuged at 400 × *g* for 10 min, resuspended in MEM, counted and assessed for viability (which was always >95% by trypan blue dye exclusion), and then plated in 24-well tissue culture plates (Corning Glass Works, Corning, NY). Cells were purified by allowing them to adhere to the plastic surface. They were incubated for 2 h at 37°C in an atmosphere of 5% CO_2 in air and then washed three times with HBSS to remove nonadherent cells. By modified Wright's staining (Sigma Diagnostics, St. Louis, MO; according to manufacturer's instructions) and "nonspecific esterase" staining (23), it was determined that the adherent cells consisted primarily of monocytic cells (99%). Cells were incubated in MEM at 37°C in a humidified atmosphere containing 5% CO_2. For *in vivo* activation experiments, superoxide production was then measured; for *in vitro* activation experiments, the cells were then treated with ET-18-OMe prior to determining superoxide production.

Superoxide assay. Superoxide production by purified macrophages was detected by the SOD inhibitable reduction of cytochrome c (24). Cytochrome c stock solutions were diluted in HBSS to 3.5×10^{-4} M and added directly to washed cultures (0.75 mL/well) in the presence or absence of PMA (0.5 μg/mL). Additional cultures also received SOD (40 μg/mL). Cells were incubated for 60 min at 37°C in a humidified atmosphere containing 5% CO_2 and then placed on ice. The reaction mixtures were transferred to microcentrifuge tubes and were centrifuged at 10,000 × *g* for 5 min at 4°C to remove any cell debris. Spectrophotometric analysis was performed at 550 nm with a Perkin-Elmer spectrophotometer (Palo Alto, CA). Superoxide production was calculated using the extinction coefficient of E_{550} 21.0×10^3 M^{-1} cm^{-1} (25) and expressed as a function of total cellular protein, which was determined as described below.

Protein determinations. After the removal of incubation mixtures from the macrophage cultures, the cells were washed twice with 1.0 mL HBSS, and digested in 0.2 N NaOH overnight at 4°C. Total cellular protein was determined according to Lowry *et al.* (26) with bovine serum albumin as a standard.

Cytotoxicity assay. HL60 human promyelocytic leukemic cells (ATCC, Bethesda, MD) were routinely maintained as suspension cultures in RPMI 1640 medium (Gibco Laboratories) supplemented with 2 mM L-glutamine, 100 U/mL penicillin, 100 μg/mL streptomycin and 10% heat-inactivated fetal bovine serum (Sigma). Cells were subcultured at 2–3-day intervals and incubated at 37°C in a humidified 5% CO_2 atmosphere. Cells in log phase growth were dispensed into 96-well tissue culture plates (Falcon; Becton Dickinson & Co., Lincoln Park, NJ) at 5×10^4 cells/well, and ether lipids were added. Twenty-four hours later, 1.0 μCi/well of [*methyl*-^{3}H]thymidine (6.7 Ci/mmol; Dupont NEN Research Products, Boston, MA) was added, and cells were incubated for an additional 24 h. Cells were harvested directly onto glass fiber filters using a MASH II harvester (MA Bioproducts, Walkersville, MD) and counted by liquid scintillation spectroscopy. The ID_{50}, i.e. the amount of compound required to reduce [^{3}H]thymidine incorporation into DNA to 50% of the control value, was determined for each analog tested.

RESULTS AND DISCUSSION

In order to determine the effect of ET-18-OMe on superoxide production by peritoneal macrophages, the SOD inhibitable reduction of cytochrome c was compared in thioglycollate broth elicited cells harvested from control and ET-18-OMe treated mice. Figure 1 shows that macrophages from control animals secreted some superoxide (expressed as a function of cell protein), and the addition of PMA to the cultured cells increased this activity. When macrophages from mice treated intraperi-

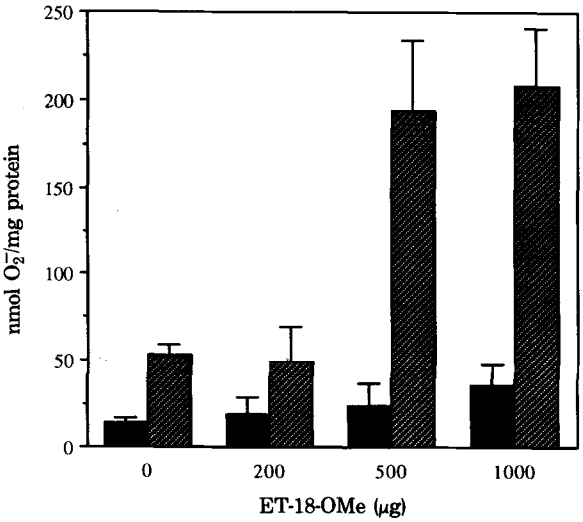

FIG. 1. Superoxide production by PMA-stimulated macrophages from ET-18-OMe-treated mice. Four days after injection of thioglycollate broth, mice were treated with various doses of ET-18-OMe. One day later, peritoneal macrophages were harvested, plated at a density of 5×10^5/well and purified as described in the Materials and Methods section. Superoxide production was determined in the absence (blackened bars) or presence of PMA (hatched bars) as described in Materials and Methods. The values determined from multiple experiments were averaged and the data are expressed as mean ± SEM (n = 7, 3, 5 and 4 for 0, 200, 500 and 1000 μg, respectively).

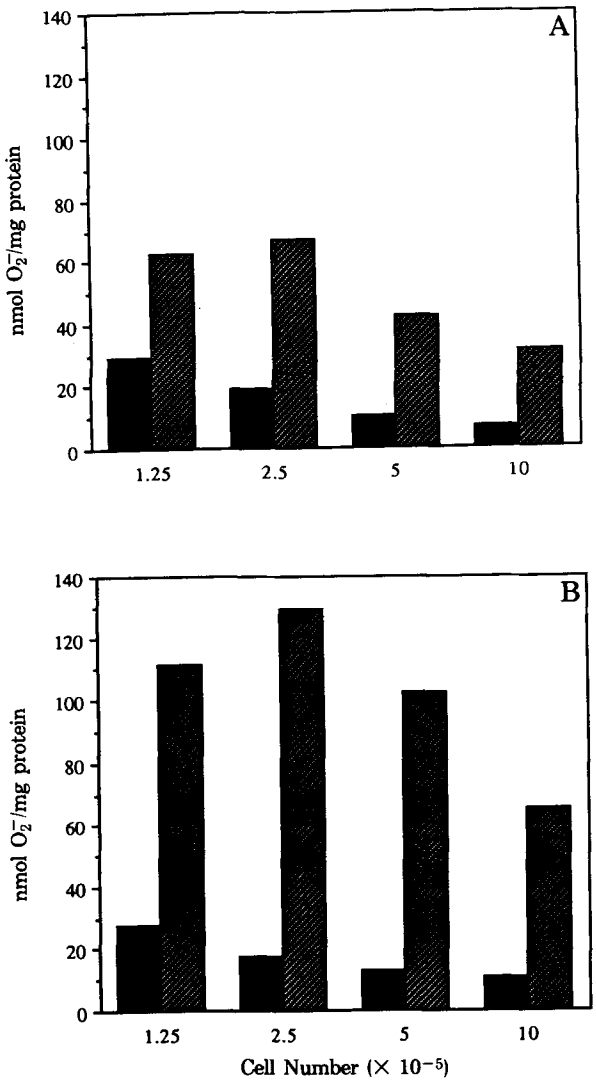

FIG. 2. Superoxide production as a function of macrophage plating density. Four days after injection of thioglycollate broth, mice were treated with either 0 (control; panel a) or 500 μg of ET-18-OMe (panel b). One day later, peritoneal macrophages were harvested, plated at various densities as shown on the X axis, and purified as described in Materials and Methods. Superoxide production was determined in the absence (blackened bars) or presence of PMA (hatched bars) as described in Materials and Methods. The data from a representative experiment are expressed as mean of duplicate determinations.

toneally with various doses of ET-18-OMe were assessed, there were small increases in activity in comparison to control cells. However, when PMA was added *in vitro* to the macrophages from mice treated with 500 or 1000 μg ET-18-OMe, there was a substantial increase in superoxide. The PMA-induced increase was apparent at the time the cells were isolated from the animal as shown, as well as 2 h later, although the stimulation decreased by 24 h later (data not shown). For all subsequent studies, the dose of 500 μg was used.

It has previously been shown (27) that the amount of superoxide produced per cell decreases as cell numbers increase. Therefore, the effect of plating density on superoxide production by macrophages from ET-18-OMe treated mice was examined. Figure 2A shows that as the number of cells plated from control mice increased, superoxide production on a per mg protein basis decreased; however, PMA stimulation was apparent at all cell concentrations. Likewise, Figure 2B shows that at the highest plating density of cells from ET-18-OMe treated mice, the levels of superoxide were lowest, but once again the PMA-induced increase was apparent.

In order to determine whether ET-18-OMe can increase superoxide production by macrophages treated with the drug *in vitro,* cells were harvested 4 d after injection with thioglycollate broth. The cells were purified as for the previous experiments and then treated with ET-18-OMe for various periods of time. In this manner, the cell population that was treated *in vitro* with the drug was similar to that treated *in vivo,* i.e., the cells elicited 4 d after treatment of the mice with thioglycollate broth. Figures 3A and 3B show the effect of treatment with ET-18-OMe for 2 h and 24 h, respectively, on superoxide production. As shown before, the PMA-induced increase was apparent; however, no significant differences were noted between control untreated cells and drug treated cells. Higher concentrations of ET-18-OMe (10 μM) were toxic to the cell cultures; in comparison to control cultures, levels of cell protein were 70 and 30% in the presence of the drug after 2 and 24 h, respectively. It therefore appears that at least under the conditions tested, *in vitro* stimulation to the activated state was not possible and that activation required additional stimuli encountered *in vivo* such as soluble

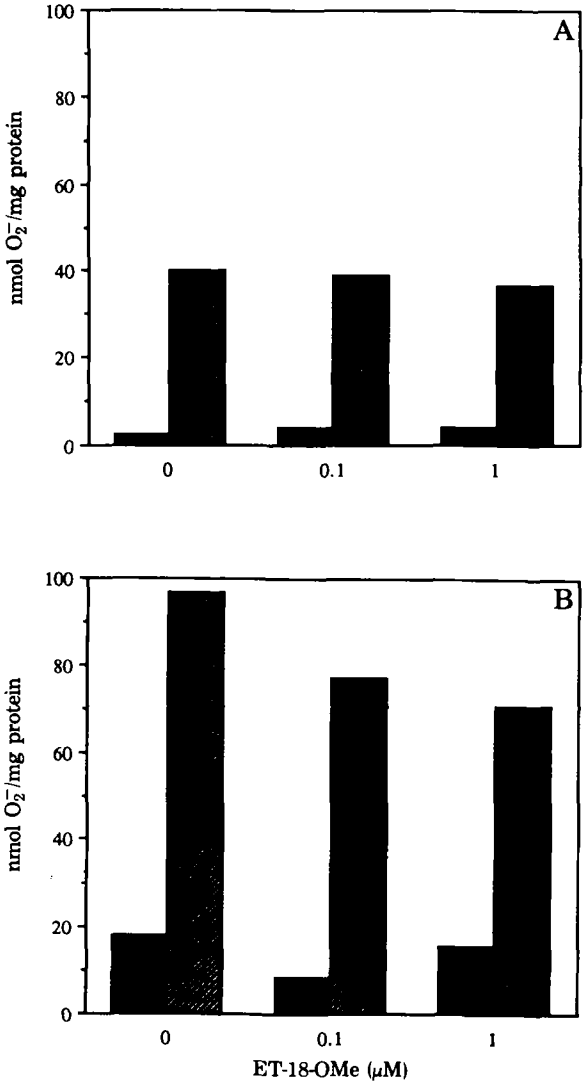

FIG. 3. Superoxide production by macrophages treated *in vitro* with ET-18-OMe. Four days after injection of thioglycollate broth, peritoneal macrophages were harvested, and purified as described in Materials and Methods. After 2 h (panel a) or 24 h (panel b) treatments *in vitro* with ET-18-OMe at the indicated concentration, superoxide production was determined in the absence (blackened bars) or presence of PMA (hatched bars) as described in Materials and Methods. The data from a representative experiment are expressed as mean of duplicate determinations.

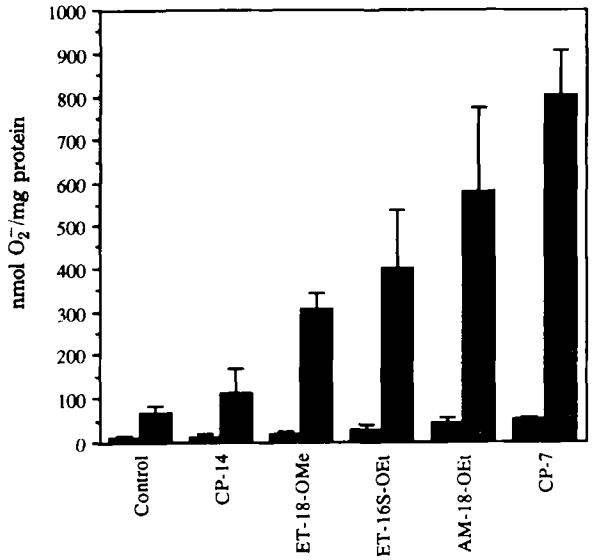

FIG. 4. Superoxide production by PMA-stimulated macrophages from mice treated with various ether lipids. Four days after injection of thioglycollate broth, mice were either sham-treated (control) or treated with 500 μg of CP-14, ET-18-OMe, ET-16S-OEt, AM-18-OEt or CP-7. One day later, peritoneal macrophages were harvested, plated at a density of 2.5×10^5/well and purified as described in Materials and Methods. Superoxide production was determined in the absence (blackened bars) or presence of PMA (hatched bars) as described in Materials and Methods. The values determined from multiple experiments were averaged, and the data are expressed as mean ± SEM (n = 3 for CP-14, ET-16S-OEt, AM-18-OEt and CP-7; n = 4 for control and ET-18-OMe).

mediators or lymphocytes. Similarly, Talmadge *et al.* (9) found that macrophage-mediated cytotoxicity for mouse melanoma B16-BL6 target cells was apparent only when the ether lipid was administered *in vivo*.

The studies on ET-18-OMe were extended to examine the effect of a variety of synthetic ether lipids (structures given in Scheme 1) on superoxide production. In this series of experiments, mice that had received thioglycollate broth 4 d earlier were treated with 500 μg of the appropriate compound. Twenty-four hours later mice were killed, peritoneal macrophages harvested and superoxide production evaluated in the presence and absence of PMA. The data in Figure 4 show that some of the compounds stimulated superoxide production, which was further enhanced by PMA treatment. Macrophages displayed a wide range of activity depending upon the initial drug treatment. Superoxide production by cells from mice treated with CP-37 (data not shown) and CP-14 was approximately equivalent to controls, in that there was no stimulation. ET-18-OMe and ET-16S-OEt displayed a "mid" range of activity and yet others, AM-18-OEt and CP-7, were 8.6 and 11.9 times, respectively, more active than the PMA-stimulated control cells.

Table 1 shows the direct cytotoxicity to HL60 tumor cells of the drugs tested above. In an assay in which HL60 cells were exposed to the drugs for 48 h, the dose at which [^{3}H]thymidine incorporation into DNA was 50% of the control value was determined. The data show that the compounds that were most highly cytotoxic to tumor cells were not necessarily the most potent macrophage activators.

Undoubtedly, regulation of the generation of reactive oxygen metabolites is critical to maintaining the balance between the positive role these products play in antimicrobial and antitumor activities and the potential negative effects they may have in promoting tissue damage. It has been shown that a number of agents including LPS (28) and cytokines such as interferon-γ (29–33) can "prime" macrophages for an enhanced respiratory burst. We refer to the effect noted here as "priming," which implies persistence of the cells' response to the initial agent (ET-18-OMe) even after its removal; however, we

TABLE 1

The Direct Cytotoxicity of Synthetic Ether Lipids to HL60 Cells[a]

Compound	ID_{50} (μM)
ET-16S-OEt	2.19 ± 0.44 (3)[b]
ET-18-OMe	2.38 ± 0.40 (21)[b]
AM-18-OEt	3.30 ± 0.37 (5)[b]
CP-7	4.34 ± 0.55 (5)[b]
CP-14	19.06 ± 1.82 (6)
CP-37	>100

[a]HL60 cells were exposed to the compounds for 48 h (the last 24 h of which was in the presence of [^{3}H]thymidine). ID_{50} represents the dose (μM) at which [^{3}H]thymidine incorporation into DNA was 50% of the control value. Each experiment was performed in quadruplicate. The average for each experiment (number of experiments listed in parentheses) was used to determine mean ± SD.

[b]These values were previously reported by Morris-Natschke *et al.* (36).

cannot rule out a synergistic effect mediated by a potential interaction of PMA with residual ET-18-OMe. If this were the case, however, *in vitro* treatment of the macrophages with the ether lipid would be expected to have resulted in stimulation of superoxide production. Although there was no statistically significant difference between cell yields from sham-treated vs. drug-treated mice (data not shown), the possibility that drug treatment has selected for a population of cells *in vivo* that is more responsive to a PMA-induced respiratory burst still exists.

Although it is generally accepted that PMA action involves activation of protein kinase C activity, ET-18-OMe inhibits the activity of this enzyme (6,34). Others have suggested that ether lipids exert a biphasic effect on protein kinase C, stimulating the enzyme at low concentrations and causing inhibition at higher concentrations (2,35). Clearly, more work is needed to determine the mechanism(s) by which ether lipid "primed" macrophages respond to PMA with an enhanced respiratory burst, or how "primed" macrophages may be cytotoxic to tumor cells *in vivo*.

Our studies demonstrate that various synthetic ether lipids have the potential to stimulate macrophage superoxide secretion. Both phosphorus and nonphosphorus containing compounds show macrophage activating properties. The tumoricidal activity of any of these ether lipids may result from a combination of its direct cytotoxicity and its tumoricidal macrophage activating potential. Although the direct cytotoxicity by these compounds is undoubtedly the major contribution to their tumoricidal capacity, these studies reinforce that they can potentially activate tumoricidal macrophages as well. Since the ability of a particular analog to activate tumorigenic macrophages does not necessarily correlate with direct tumor cytotoxicity, designs for effective therapeutic modalities may necessitate inclusion of a combination of ether lipids.

ACKNOWLEDGMENTS

The authors would like to extend thanks to Dr. Claude Piantadosi and his colleagues, School of Pharmacy, University of North Carolina, Chapel Hill, NC, for providing samples of the ether lipids used in this study, and Drs. Lee Swendsen and Linda McPhail (Department of Biochemistry, Bowman Gray School of Medicine, Winston Salem, NC) for valuable suggestions in designing this research project. This investigation was supported in part by research grant CA 41314 from the National Cancer Institute, Department of Health and Human Services.

[Received July 9, 1993, and in revised form February 7, 1994; Revision accepted February 7, 1994]

Modification of Lysine Amino Groups by the Lipid Peroxidation Product 4,5(*E*)-Epoxy-2(*E*)-heptenal

Rosario Zamora* and **Francisco J. Hidalgo**

Instituto de la Grasa y sus Derivados, Sevilla, Spain

The reaction between 4,5(*E*)-epoxy-2(*E*)-heptenal (EH) and L-lysine was studied to characterize some of the compounds that may be produced when proteins react with peroxidizing lipids. A mixture of EH and lysine was incubated overnight at room temperature and then fractionated by high-performance liquid chromatography (HPLC). Fractions were freeze-dried and characterized by ^{1}H and ^{13}C nuclear magnetic resonance (NMR) and mass spectrometry. Four major pyrrole derivatives were obtained, namely 1-(5'-amino-1'-carboxypentyl)-pyrrole (3), 1-(5'-amino-1'-carboxypentyl)-2-(1"-hydroxypropyl)pyrrole (diastereomers 5 and 8), 1-(5'-amino-5'-carboxypentyl)pyrrole (7), and 1-(5'-amino-5'-carboxypentyl)-2-(1"-hydroxypropyl)pyrrole (9). In addition, several lysine complexes were detected. A polymer (1b) that was responsible for the color and the fluorescence produced in the reaction was isolated by gel filtration chromatography from a fraction obtained by HPLC. Formation of pairs of analogs (5 and 3, 9 and 7) with and without a substituent in position 2 of the pyrrole ring suggested that the compounds were produced by the same mechanism, with the formation of the 2-unsubstituted pyrroles corresponding to the loss of the 2-substituent as propanal; propanal was detected by headspace capillary gas chromatography. A reaction mechanism is proposed based on the NMR data obtained when the reaction was monitored in real time in an NMR tube. The results suggest that pyrrolic amino acids 7 and 9 may be present in proteins that have been damaged by peroxidizing lipids.

***Lipids* 29, 243–249 (1994).**

The reactions of free radicals, such as peroxyl and hydroxyl radicals, with biomolecules are important in physiology and pathology (1). Lipid peroxidation is the result of free radical mediated reactions that occur *in vivo* in aerobic organisms (2) and is known to be accompanied by the formation of a complex mixture of products, including aldehydes (3). Among these aldehydes, the formation of 4,5-epoxy-2-alkenals, mainly 4,5(*E*)-epoxy-2(*E*)-heptenal (EH) and 4,5(*E*)-epoxy-2(*E*)-decenal, has been reported (4,5). The products are assumed to be formed by cleavage of the carbon chain of intermediary epoxyhydroperoxy fatty acids (6). Thus, for example, 12,13(*E*)-epoxy-9-hydroperoxy-10(*E*)-octadecenoic acid, which was identified in the reaction of 13-hydroperoxylinoleic acid with either soybean extracts or ferric chloride/cysteine solution (7), produced the C_{10} epoxyaldehyde 4,5(*E*)-epoxy-2(*E*)-decenal.

EH is a product of the oxidation of ω3 pentaenoic fatty acids (8). EH has also been detected in homogenates from fish (Zamora and Hidalgo, unpublished results) that have a high content of ω3 eicosapentaenoic acid. The reaction of EH with amines and amino acids very rapidly develops color and fluorescence similar to that of lipofuscin-like fluorescent substances (9). The mechanism of color and fluorescence formation has been investigated for the reaction of EH with butylamine and glycine methyl ester which produced 1-alkyl-2-(1'-hydroxyalkyl)pyrroles. The color and fluorescence produced in this polymerization reaction was characterized (10).

The objective of the present study was to identify and characterize the reaction products formed from EH and lysine to extend the results obtained with simple amines to lysine, the amino acid that is usually lost in the course of protein deterioration caused by peroxidizing lipids (11). The complete characterization of these products should provide the basis for the development of an analytical method that can measure the formation of these products in damaged proteins.

MATERIALS AND METHODS

EH was prepared from 2(*E*)-4(*E*)-heptadienal as described by Swoboda and Peers (4). 2(*E*)-4(*E*)-heptadienal, L-lysine monohydrochloride and 3-chloroperoxybenzoic acid were purchased from Aldrich Chemical Co. (Milwaukee, WI). All other chemicals used were analytical grade and were purchased from reliable commercial sources. ^{1}H and ^{13}C nuclear magnetic resonance (NMR) spectra at 300 and 75.4 MHz, respectively, were determined on a Bruker AC-300P instrument (Karlsruhe, Germany) using sodium-3-(trimethylsilyl)-1-propanesulfonate as internal standard. Two-dimensional NMR was used to assign ^{13}C NMR spectra. Mass spectra were obtained on an AEI-MS-30SB-VG mass spectrometer (VG Analytical, Manchester, United Kingdom). Gel filtration chromatography (GFC) was performed on a Sephadex G-25 (Pharmacia LKB, Uppsala, Sweden) column (55 × 1 cm) equilibrated with 50 mM sodium phosphate, pH 7. Fractions (900 μL) were collected at a flow rate of 9 mL/h, and tested for absorption at 430 nm, and for fluorescence with excitation at 390 nm and emission at 450 nm. The column was calibrated with dextran sulfate [molecular weight (MW) 5000], bacitracin (MW 1423) and glucotropaeoline potassium salt (MW 447.5). Assays were also done on a Biogel P-2 (Bio-Rad Laboratories, Hercules, CA) column of similar dimensions.

Reaction of EH with lysine. An emulsion of EH (0.5 mmol) in 4 mL of 0.3 M sodium borate, pH 9.0, was treated with lysine (1 mmol) and stirred overnight at

Abbreviations: EH, 4,5(*E*)-epoxy-2(*E*)-heptenal; GC/MS, gas chromatography/mass spectrometry; GFC, gel filtration chromatography; HPLC, high-performance liquid chromatography; MS, mass spectrometry; MW, molecular weight; NMR, nuclear magnetic resonance.

room temperature. The reaction mixture was fractionated by semipreparative high-performance liquid chromatography (HPLC) on a C18 column (25 × 1 cm) using 5% acetonitrile in deionized water as eluent at 40°C. The flow rate was 5 mL/min with detection of absorbance at 250 nm. Products were collected from successive injections, and combined. Solutions were dried in a stream of nitrogen to remove acetonitrile, and were freeze-dried. The compounds isolated were characterized by ^{1}H and ^{13}C NMR and by mass spectrometry (MS).

Headspace capillary gas chromatography (GC) detection of propanal. Propanal was detected by GC/MS. Samples of EH (8 mg, 64 μmol) and lysine monohydrochloride (23.8 mg, 130 μmol) in 0.3 M sodium borate buffer pH 9.0 (500 μL) were introduced into special 10-mL headspace bottles, which were sealed with silicone rubber and Teflon caps and incubated overnight at room temperature. Thereafter, samples were pressurized for 30 s before injection. GC/MS analyses were done on a Hewlett-Packard (Palo Alto, CA) 5890 Series II gas chromatograph interfaced, *via* an open coupling system, to an AEI-MS-30SB-VG mass spectrometer. A DB-5 bonded-phase fused-silica capillary column (JW Scientific, Folsom, CA) kept at 30°C was used, and helium served as carrier gas. Standard propanal (Aldrich) was used for identification purposes.

NMR study of the EH / lysine reaction. EH (0.16 mmol) was suspended in 1 mL of deuterated water and sonicated with a Braun Labsonic U sonicator (B. Braun Diessel Biotech GmbH, Melsungen, Germany) until completely emulsified. Lysine (0.32 mmol) was then added, and the resulting solution was introduced into a 5-mm NMR tube. The pH of the solution was taken to slightly basic by adding a few drops of deuterated sodium hydroxide, and ^{1}H and ^{13}C NMR spectra were taken at different time points. Zero time was considered the time before adding alkali.

RESULTS

Reaction of EH with lysine. The reaction between EH and lysine rapidly produced color and fluorescence (9). A characteristic chromatogram of the reaction mixture after overnight incubation is shown in Figure 1. Fourteen fractions were isolated, and the structures of the components were determined by ^{1}H and ^{13}C NMR, and by MS. When a fraction consisted of only one compound, the fraction number was also used as compound number. When the fraction consisted of two compounds, each compound was identified by the number of the fraction, followed by a letter. Figure 2 shows the structures of the compounds identified in this study.

Fraction **1** (474.3 mg, 87.4%) was composed of a mixture that was subsequently fractionated by GFC. It consisted of unreacted lysine (compound **1a**, more than 95% of the fraction) and a polymer (**1b**) that was responsible for the color and fluorescence produced in the reaction. Figure 3 shows the fluorescence spectra of the reaction mixture and of fraction **1** and of the polymer **1b** isolated by GFC. The spectra did not change in the course of the purification. The spectra also were similar to those produced by the lipofuscin-like fluorescent substances that we described earlier (10). Polymer **1b** eluted in the void volume of the Biogel P-2 column, which has a fractionation range of MW 100–1800. The chromatographic elution pattern of polymer **1b** from Sephadex G-25 is shown in Figure 4. The polymer showed an apparent MW of 1900 daltons.

Fraction **2** (1.6 mg, 0.3%) was unstable, but could be characterized by ^{1}H NMR. Its spectrum showed signals at δ 8.25 *d* (*J* = 17 Hz) and 8.17 *d* (*J* = 12 Hz) and was tentatively identified as an olefin derived from EH and lysine. The spectral integrals suggested an EH/lysine adduct ratio of 1:1. Additional studies will be necessary for the complete characterization of fraction **2**.

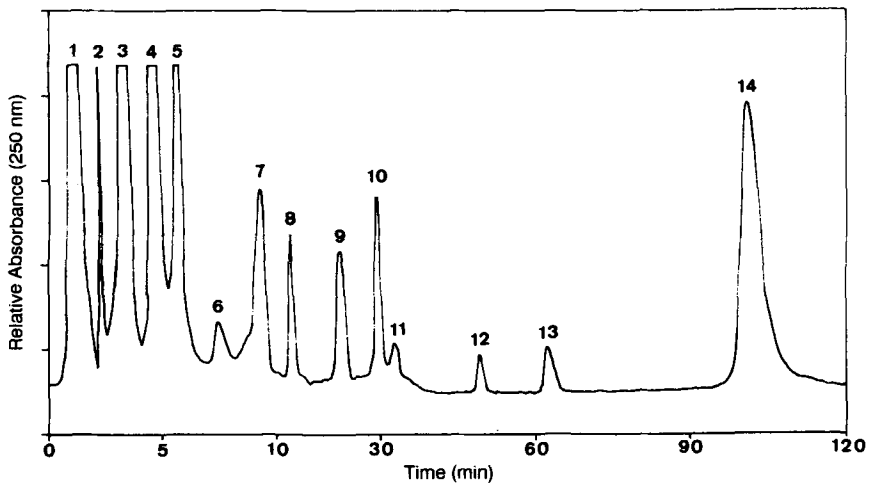

FIG. 1. High-performance liquid chromatogram of the (*E*)-4,5-epoxy-(*E*)-2-heptenal/lysine reaction after stirring overnight at room temperature.

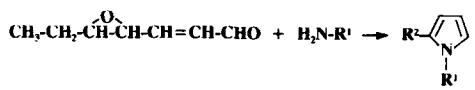

Compound	R^1	R^2
1a	$(CH_2)_4$-CH(NH_2)COOH	
3	CH(COOH)-$(CH_2)_4NH_2$	H
5	CH(COOH)-$(CH_2)_4NH_2$	CH(OH)CH_2CH_3
7	$(CH_2)_4$-CH(NH_2)COOH	H
8	CH(COOH)-$(CH_2)_4NH_2$	CH(OH)CH_2CH_3
9	$(CH_2)_4$-CH(NH_2)COOH	CH(OH)CH_2CH_3

FIG. 2. Structures of the compounds isolated from the 4,5(*E*)-epoxy-2(*E*)-heptenal/lysine reaction by high-performance liquid chromatography and characterized by ^1H and ^{13}C nuclear magnetic resonance and mass spectrometry.

Fraction **3** (7.1 mg, 1.3%) was identified as 1-(5'-amino-1'-carboxypentyl)pyrrole (**3**). ^1H NMR (D_2O) showed the pyrrole signals listed in Table 1. Other signals appeared at δ 1.30 *m* (2H, H-3'), 1.67 *m* (2H, H-4'), 2.06 *m* (2H, H-2'), 2.94 *t* (2H, $J_{5',4'}$ = 7.6 Hz, H-5'), and 4.52 *dd* (1H, *J* = 5.8 Hz and *J* = 9.8 Hz, H-1'). ^{13}C NMR (D_2O) showed the pyrrole signals listed in Table 1. Other signals appeared at δ 25.4 *t* (C-3'), 29.0 *t* (C-4'), 34.6 *t* (C-2'), 42.0 *t* (C-5'), 67.1 *d* (C-1'), and 181.7 *s* (COOH). The mass spectrum (70 eV) *m/e* (%, ion structure) was as follows: 196 (2, M^+), 178 (83, $M^+ - H_2O$), 152 (48, $M^+ - CO_2$), 135 (37, 152 – NH_3), 120 (59), 106 (42), 94 (71, ethylpyrrole – H), 80 (76, methylpyrrole – H), 67 (100, pyrrole). MS (70 eV) of the methyl ester obtained by reaction of **3** with diazomethane, *m/e* (%, ion structure): 210 (59, M^+), 193 (16, $M^+ - NH_3$), 178 (11, $M^+ - CH_3OH$), 151 (68, $M^+ - CO_2CH_3$), 134 (100, 151 – NH_3).

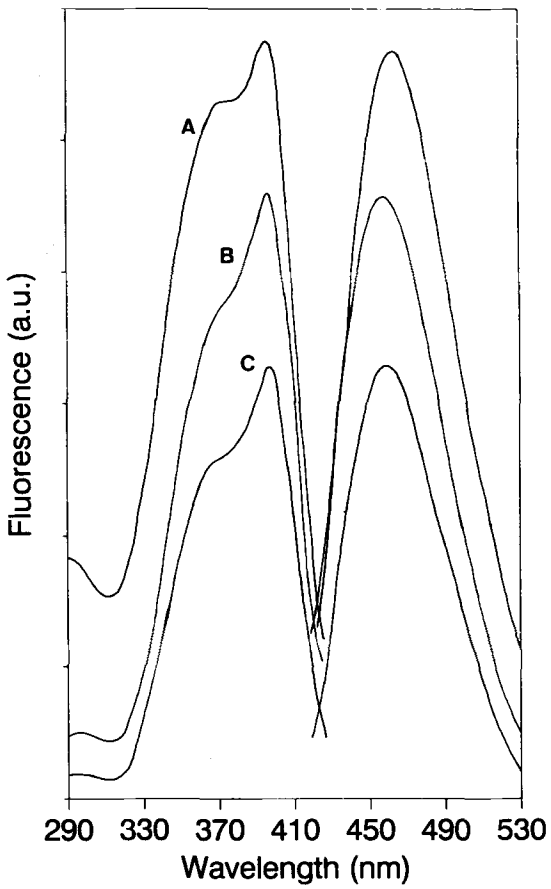

FIG. 3. Fluorescence spectra of the 4,5(*E*)-epoxy-2(*E*)-heptenal/lysine reaction mixture (A), fraction 1 (B) and polymer 1b (C).

Fraction **4** (3.8 mg, 0.7%) was unstable and its structure could not be determined. The ^1H spectrum showed signals at δ 7.41 *t* (1H, *J* = 7.8 Hz), 7.52 *dq* (1H, *J* = 7.8 Hz, *J* = 1.1 Hz, *J* = 1.1 Hz, *J* = 1.1 Hz), 7.54 *dt* (1H, *J* = 7.8 Hz, *J* = 1.1 Hz, *J* = 1.1 Hz) and 7.82 *t* (1H, *J* = 1.1 Hz); the ^{13}C NMR spectrum showed signals at d 129.0, 130.6, 132.9 and at 131.7 ppm, suggesting a heterocyclic structure, most probably due to a pyridinium salt. Proton and carbon signals corresponding to lysine were also present. Additional studies are necessary for the complete characterization of a fraction **4**.

Fraction **5** (2.3 mg, 0.4%) was identified as 1-(5'-amino-1'-carboxypentyl)-2-(1"-hydroxypropyl)pyrrole (**5**). ^1H NMR (D_2O) showed the pyrrole signals listed in Table 1. Other signals appeared at δ 0.91 *t* (3H, $J_{2",3"}$ = 7.4 Hz, H-3"), 1.36 *m* (2H, H-3'), 1.69 *m* (2H, H-4'), 1.86 *m* (2H, H-2"), 2.13 *m* (2H, H-2'), 2.94 *t* (2H, $J_{4',5'}$ = 7.3 Hz, H-5'), 4.56 *t* (1H, $J_{1",2"}$ = 7.0 Hz, H-1") and 4.72 *dd* (1H, *J* = 5.7 Hz, *J* = 9.6 Hz, H-1'). ^{13}C NMR (D_2O) showed the pyrrole signals listed in Table 1. Other signals appeared at δ 12.7 *q* (C-3"), 25.6 *t* (C-3'), 29.1 *t* (C-4'), 31.5 *t* (C-2"), 34.2 *t* (C-2'), 42.0 *t* (C-5'), 63.5 *d* (C-1'), 69.4 *d* (C-1") and 181.8 *s* (COOH). MS (70 eV) *m/e* (%, ion structure): 236 (7, $M^+ - H_2O$), 192 (7, $M^+ - H_2O - CO_2$), 134 (38, 192 – $C_3H_6NH_2$), 84 (100, tetrahydropyridine + H^+). MS (70 eV) of the methyl ester obtained by reaction with diazomethane, *m/e* (%, ion structure): 236 (7, M^+ – MeOH), 218 (21, $M^+ - H_2O$ – MeOH), 179 [27, 1-methoxycarbonylmethyl-2-(1-propenyl)pyrrole], 134 [42, 1-ethenyl-2-(1-propenyl)pyrrole + H^+], 108 [34, 2-(1-propenyl)pyrrole + H^+], 84 (100, tetrahydropyridine + H^+).

Fraction **6** (1.5 mg, 0.3%) was a minor compound and only could be studied by ^1H NMR. The spectrum showed heterocyclic proton signals at δ 6.17, 6.79 and 6.82 ppm, suggesting the presence of a 1,2-disubstituted pyrrole ring. The spectrum also showed the signals corresponding to the lysine protons, and the signal corresponding to proton H-1" (the alcohol produced upon epoxide ring opening) appeared at δ 4.55 *t* (1H, *J* = 6.8 Hz). Additional analyses will be needed for the complete characterization of **6**.

Fraction **7** (8.0 mg, 1.5%) was identified as 1-(5'-amino-5'-carboxypentyl)pyrrole (**7**). ^1H NMR (D_2O) showed the pyrrole signals listed in Table 1. Other signals appeared at δ 1.34 *qu* (2H, *J* = 6.8 Hz, H-3'), 1.83 *m* (4H, H-2' and H-4'), 3.68 *t* (1H, $J_{4',5'}$ = 6.1 Hz, H-5'), and 3.97 *t* (2H, $J_{1',2'}$ = 6.9 Hz, H-1'). ^{13}C NMR (D_2O) showed

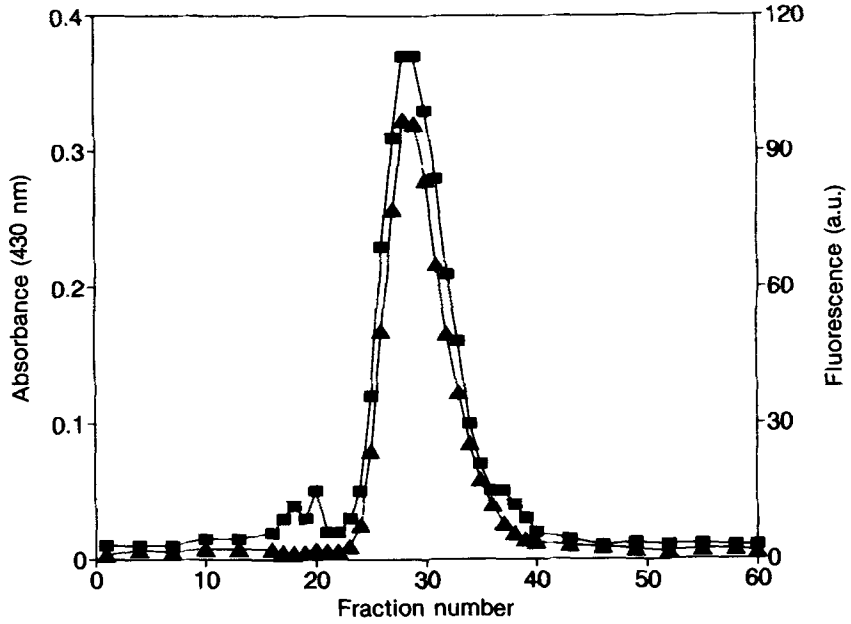

FIG. 4. Gel filtration chromatography of fraction 1 on a Sephadex G-25 column. Absorbance at 430 nm (■) and fluorescence at 390/450 nm (▲) were measured for each fraction. Void and total volumes corresponded to fractions 20 and 48, respectively.

the pyrrole signals listed in Table 1. Other signals appeared at δ 24.4 *t* (C-3'), 33.0 *t* and 33.2 *t* (C-2' and C-4'), 51.4 *t* (C-1'), 57.6 *d* (C-5') and 181.4 *s* (COOH). MS (70 eV) *m/e* (%, ion structure): 196 (61, M^+), 178 (20, $M^+ - H_2O$), 152 (16, $M^+ - CO_2$), 134 (58, 152 – NH_4), 122 (47, $M^+ - C_2H_4NO_2$), 109 (27, propylpyrrole), 94 (37, ethylpyrrole – H), 81 (100, methylpyrrole). MS (70 eV) of the methyl ester obtained by reaction with diazomethane, *m/e* (%, ion structure): 210 (45, M^+), 178 (22, $M^+ - CH_3OH$), 134 (100, $M^+ - CO_2CH_3 - NH_3$), 122 (26, butylpyrrole – H), 108 (15, propylpyrrole – H), 80 (68, methylpyrrole – H).

Fraction **8** (4.9 mg, 0.9%), in analogy to fraction **5**, was found to be 1-(5'-amino-1'-carboxypentyl)-2-(1"-hydroxypropyl)pyrrole (**8**). ^1H NMR (D_2O) showed the pyrrole signals listed in Table 1. Other signals appeared at δ 0.91 *t* (3H, $J_{2",3"}$ = 7.4 Hz, H-3"), 1.38 *m* (2H, H-3'), 1.67 *m* (2H, H-4'), 1.86 *m* (2H, H-2"), 2.13 *m* (2H, H-2'), 2.92 *t* (2H, $J_{4',5'}$ = 7.5 Hz, H-5'), 4.62 *t* (1H, $J_{1",2"}$ = 7.1 Hz, H-1"), and 4.71 *dd* (1H, *J* = 5.6 Hz and *J* = 9.9 Hz, H-1'). ^{13}C NMR (D_2O) showed the pyrrole signals listed in Table 1. Other signals appeared at δ 12.8 *q* (C-3"), 25.6 *t* (C-3'), 29.2 *t* (C-4'), 31.4 *t* (C-2"), 34.6 *t* (C-2'), 42.0 *t* (C-5'), 63.8 *d* (C-1'), 70.0 *d* (C-1") and 181.5 *s* (COOH).

[a]Assignments may be interchanged. [b]$J_{3,5}$ = 1.8 Hz, $J_{3,4}$ = 3.4 Hz. [c]Synthesis of compound **15** was described previously (10). Spectra were taken in $(CD_3)_2CO$, and Me_4Si was used as internal standard. [d]$J_{3,5}$ = 1.5 Hz, $J_{3,4}$ = 3.5 Hz, $J_{4,5}$ = 2.9 Hz.

MS (70 eV) *m/e* (%, ion structure): 236 (6, $M^+ - H_2O$), 192 (15, $M^+ - H_2O - CO_2$), 134 (40, 192-$C_3H_6NH_2$), 84 (100, tetrahydropyridine + H^+). MS (70 eV) of the methyl ester obtained by reaction with diazomethane, *m/e* (%, ion structure): 268 (3, M^+), 236 (11, M^+ – MeOH), 218 (8, $M^+ - H_2O$ – MeOH), 179 [30, 1-methoxycarbonylmethyl-2-(1-propenyl)pyrrole], 134 [38, 1-ethenyl-2-(1-propenyl)pyrrole + H^+], 108 [18, 2-(1-propenyl)pyrrole + H^+], 84 (100, tetrahydropyridine + H^+). Compounds **5** and **8** had analogous ^1H and ^{13}C NMR spectra, as well as mass spectra. The only significant difference observed between the spectra was the proton H-1" chemical shift that was characteristic for each compound. Compounds **5** and **8** are considered to be the diastereomers [1'(*S*),1"(*R*) and 1'(*S*),1"(*S*)]. Compound **9** (see next paragraph) should be a similar mixture of diastereomers; however, these isomers could not be separated under our conditions.

Fraction **9** (7.5 mg, 1.4%) was identified as 1-(5'-amino-5'-carboxypentyl)-2-(1"-hydroxypropyl)pyrrole (**9**). ^1H NMR (D_2O) showed the pyrrole signals listed in Table 1. Other signals appeared at δ 0.93 *t* (3H, $J_{2",3"}$ = 6.7 Hz, H-3"), 1.36 *m* (2H, H-3'), 1.79 *m* (4H, H-2' and H-4'), 1.88 *m* (2H, H-2"), 3.62 *t* (1H, $J_{4',5'}$ = 6.0 Hz, H-5'), 3.97 *m* (2H, H-1'), and 4.65 *t* (1H, $J_{1",2"}$ = 6.9 Hz, H-1"). ^{13}C NMR (D_2O) showed the pyrrole signals listed in Table 1. Other signals appeared at δ 12.8 *q* (C-3"), 24.5 *t* (C-3'), 31.7 *t* (C-2"), 33.4 *t* (C-2' or C-4'), 33.4 *t* (C-4' or C-2'), 48.6 *t* (C-1'), 57.5 *d* (C-5'), 69.3 *d* (C-1"), and 181.1 *s* (COOH). MS (70 eV) *m/e* (%, ion structure): 236 (9, $M^+ - H_2O$), 218 (13, 236 – H_2O), 192 (11, $M^+ - H_2O - CO_2$), 134 (40, 192 – $C_3H_6NH_2$), 84 (100, tetrahydropyridine + H^+). MS (70 eV) of the methyl ester obtained by reaction with diazomethane, *m/e* (%, ion structure): 268 (8, M^+), 250 (43, $M^+ - H_2O$), 191 (22, $M^+ - H_2O - CO_2CH_3$), 174 (53, 191 – NH_3), 162 (47, 250 – $CH(NH_2)CO_2CH_3$), 134 [100, 1-ethenyl-2-(1-pro-penyl)-pyrrole + H^+], 120 [45, 1-methyl-2-(1-propenyl)pyrrole – H), 84 (53, tetrahydropyridine + H^+).

Fractions **10** (4.9 mg, 0.9%), **11** (6.5 mg, 1.2%), **12** (7.7 mg, 1.4%), and **13** (7.1 mg, 1.3%) gave ^1H and ^{13}C NMR spectra very similar to those of lysine, and are therefore undefined complexes between lysine molecules and some lipid ligands. Fraction **14** (5.4 mg, 1.0%) was unstable and decomposed after concentration. No spectral data could be obtained on this fraction.

Detection of propanal. The formation of pairs of analogous compounds (**5** and **3**, **9** and **7**) with and without a substituent in position 2 of the pyrrole ring suggested that the compounds were produced by the same mechanism. According to the mechanism proposed for this reaction (see below), loss of the substituent at position 2 would imply the formation of propanal. Indeed, propanal was detected by GC/MS after incubation of the reaction mixture in a special headspace bottle. Identification of the aldehyde was confirmed by comparison with standard propanal.

NMR study of the EH/lysine reaction. An initial ^1H NMR spectrum (Fig. 5A) was acquired before the reaction mixture was treated with deuterated sodium hydroxide, and it showed the additive spectra of EH and lysine. Signals were assigned as follows. Signals for EH: A (H-1), B (H-3), C (H-2), F (H-4), G (H-5), K (H-6) and M (H-7). Signals for lysine: E (H-2), H (H-6), I (H-3), J (H-5) and L (H-4). Signal D was due to water. Addition of a few drops of NaOD to the mixture initiated the reaction causing rapid spectral changes (Fig. 5B). The aldehyde (A) and epoxy (F and G) proton signals rapidly

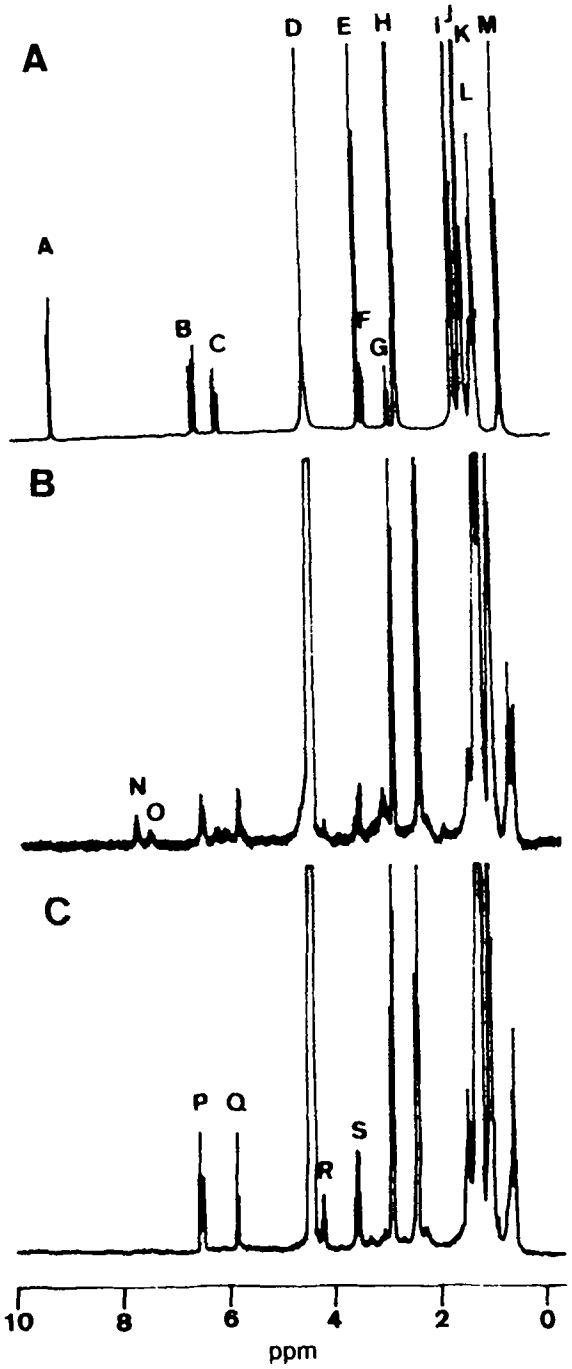

FIG. 5. Changes produced in the ^1H nuclear magnetic resonance spectrum of the 4,5(*E*)-epoxy-2(*E*)-heptenal/lysine reaction with incubation time: A, initial spectrum of the mixture without NaOD; B, spectrum taken at 2–4 min after adding a few drops of NaOD; C, spectrum taken after 2 h.

disappeared, the olefinic proton signals were transformed (B and C), and new signals appeared. Some of the signals corresponded to intermediates (see, for example, signals N and O), which again disappeared later. The final spectrum (Fig. 5C), which remained unchanged after 2 h into the reaction, showed at least four new signals (P, Q, R and S) that were not present in the original spectrum, and suggested that the epoxy and olefin protons were altered. The number of scans for consecutive spectra was increased with incubation time to maintain similar signal-to-noise ratios. Formation of polymers was consistent with observed signal loss and was also suggested by the increase in brown color with incubation time. Similar results were also obtained by ^{13}C NMR (spectra not shown), with the final spectrum showing the appearance of carbon signals at δ 105–130 ppm, consistent with the presence of heterocyclic carbons.

DISCUSSION

The reaction of EH with lysine is very rapid, produces a brown color, as well as fluorescence within a short period of time. When the reaction was followed by NMR in a sample tube, EH aldehydic, olefinic and epoxy protons disappeared after a few minutes (Fig. 5). The final spectrum (Fig. 5C) was quite simple and suggested the presence of only a few products. However, when the mixture was fractionated by HPLC, 14 fractions were isolated to be further studied by NMR and MS. Five of these fractions (fractions **3, 5, 7, 8** and **9**) corresponded to pyrrole monomers that were produced from one molecule of EH linked to one amino group of lysine. These five fractions were the major products, with the exception of fraction **1**, that included excess lysine remaining in the reaction. The sum of the spectra of these fractions was very similar to final spectrum of the reaction (Fig. 5C). A possible mechanism for the pyrrole formation is suggested in Figure 6. It implies the formation of an imine at a first stage that would produce the pyrrole ring by intramolecular attack of the nitrogen at one of the epoxy carbons. The departure of a proton, which may be accompanied by formation of propanal, would produce the pyrroles isolated. This mechanism is also in agreement with the detection of propanal by headspace GC, and with the results obtained when EH/lysine reaction was monitored by ^{1}H and ^{13}C NMR. Thus, signals N and O in Figure 5B may be assigned to the imine proton of the first intermediate, and the final spectrum (Fig. 5C) showed the presence of the pyrrolic monomers corresponding to signals P, Q, R and S.

Other fractions (fractions **2, 4** and **6**) from the EH/lysine reaction mixture also corresponded to single structure with olefinic bonds (compound **2**) or heterocyclic rings (compounds **4** and **6**). The olefinic and heterocyclic proton signals of compounds **2** and **4** (δ ≈ 8.2 and ≈ 7.5 ppm, respectively) were not detected in the reaction spectrum (Fig. 5C), suggesting that they were minor compounds in the reaction.

That polymerization occurred in this reaction was consistent with the ^{1}H and ^{13}C NMR spectra taken on the reaction mixture where the number of scans had to

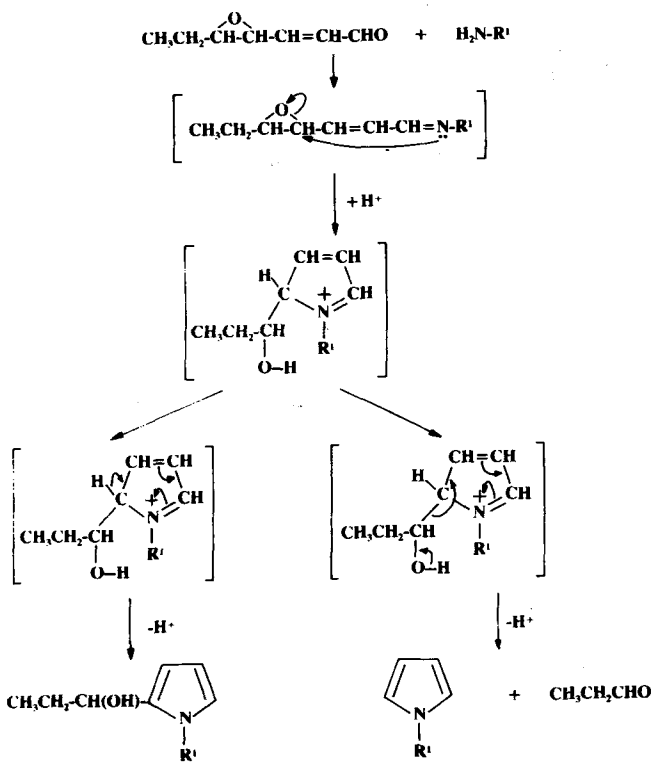

FIG. 6. Proposed mechanism of pyrrole formation in the reaction of 4,5(*E*)-epoxy-2(*E*)-heptenal with lysine.

be increased with incubation time to obtain analogous signal-to-noise ratios. The polymer appeared in fraction **1** together with the unreacted lysine. The polymer was responsible for the color and the fluorescence produced in the reaction and had an apparent MW of 1900 daltons. This result is very similar to that expected for a polypyrrolic structure, as described previously (10), and is consistent with a structure of this type for polymer **1b.** The results obtained in this study confirm that the reaction between EH and lysine at pH 9.0, or under physiological conditions (12), follows an analogous mechanism and consequently produces compounds analogous to those formed in previously described model reactions between EH and butylamine or glycine methyl ester (10). The pyrrole monomers **3, 5, 7, 8** and **9,** may therefore be produced *in vivo,* and additional studies are needed to confirm their formation. Pyrrole monomers **7** and **9** are the only ones of the pyrroles described that can be formed with the ε-amino group of lysine and, accordingly, may be present in protein hydrolysates. However, the other pyrroles might also be produced by reaction with the existing pool of free amino acids. Further studies of the formation of pyrrole amino acids with proteins should reveal the role of epoxyaldehydes in the overall modification of proteins by lipid peroxidation products.

Incorporation of *trans* Long-Chain n-3 Polyunsaturated Fatty Acids in Rat Brain Structures and Retina[1]

During heat treatment, polyunsaturated fatty acids and specifically 18:3n-3 can undergo geometrical isomerization. In rat tissues, 18:3 Δ9*c*,12*c*,15*t*, one of the *trans* isomers of linolenic acid, can be desaturated and elongated to give *trans* isomers of eicosapentaenoic and docosahexaenoic acids. The present study was undertaken to determine whether such compounds are incorporated into brain structures that are rich in n-3 long-chain polyunsaturated fatty acids. Two fractions enriched in *trans* isomers of α-linolenic acid were prepared and fed to female adult rats during gestation and lactation. The pups were killed at weaning. Synaptosomes, brain microvessels and retina were shown to contain the highest levels (about 0.5% of total fatty acids) of the *trans* isomer of docosahexaenoic acid (22:6 Δ4*c*,7*c*,10*c*,13*c*,16*c*,19*t*). This compound was also observed in myelin and sciatic nerve, but to a lesser extent (0.1% of total fatty acids). However, the ratios of 22:6 *trans* to 22:6 *cis* were similar in all the tissues studied. When the diet was deficient in α-linolenic acid, the incorporation of *trans* isomers was apparently doubled. However, comparison of the ratios of *trans* 18:3n-3 to *cis* 18:3n-3 in the diet revealed that the *cis* n-3 fatty acids were more easily desaturated and elongated to 22:6n-3 than the corresponding *trans* n-3 fatty acids. An increase in 22:5n-6 was thus observed, as has previously been described in n-3 fatty acid deficiency. These results encourage further studies to determine whether or not incorporations of such *trans* isomers into tissues may have physiological implications.

***Lipids* 29, 251–258 (1994).**

During heat treatment of oils and fats, geometrical isomerization of linolenic (1,2) and linoleic (3) acids occurs. Three major isomers of linolenic acid (18:3 Δ9*c*,12*c*,15*t*; 18:3 Δ9*t*,12*c*,15*c* and 18:3 Δ9*t*,12*c*,15*t*) are formed, as well as some minor isomers. The *trans* compounds were identified as well in commercial frying oils (4), in deodorized oils (1) and in low-calorie spreads (5). Little is known about the metabolism and physiological effects of these *trans* isomers of linolenic acid (6,7). However, a recent study (8) has indicated that the intestinal absorption of these compounds is similar to that of linolenic acid.

Furthermore, 18:3 Δ9*c*,12*c*,15*t*, an isomer of linolenic acid, could undergo further desaturation and elongation to yield *trans* isomers of eicosapentaenoic (EPA) and docosahexaenoic (DHA) acids, i.e., 20:5 Δ5*c*,8*c*,11*c*,14*c*,17*t* (20:5 Δ17*t*) and 22:6 Δ4*c*,7*c*,10*c*,13*c*,16*c*,19*t* (22:6 Δ19*t*). These isomers were identified in the liver of rats fed heated linseed oils (9) and were found to be incorporated into almost all lipid classes, including phospholipids (10).

It is possible that these compounds can also be incorporated into tissues rich in n-3 polyunsaturated fatty acids (PUFA), such as retina or certain brain structures (synaptosomes, capillaries and microvessels). The nervous system is, indeed, rich in structural lipids, and the essential character of the n-3 fatty acids for the development and function of the brain and retina is now well-documented (11). Moreover, some other nervous structures, such as myelin and sciatic nerve, are known to have an apparently lower turnover of their fatty acids (12) and seem better protected than other organs against n-3 deficiency (13). It was the purpose of the present work to determine whether *trans* PUFA would be incorporated into brain structures using diets adequate or deficient in α-linolenic acid.

MATERIALS AND METHODS

Preparation of concentrates of trans *fatty acids.* The geometrical isomers of α-linolenic acid were prepared by two methods that were previously described (14). In the first method, a purified fraction (99%) of methyl α-linolenate was obtained from linseed oil after urea inclusion and preparative high-performance liquid chromatography (HPLC). This fraction was then isomerized with nitrous acid, and the 18:3 isomers were purified by column chromatography. The second method uses linseed oil that was heated for 12 h at 275°C under nitrogen. The fatty acid methyl esters (FAME) obtained from the heated oil were then purified by column chromatography. The cyclic monomers were removed by urea inclusion, and the geometrical isomers of α-linolenic acid were concentrated by preparative HPLC. The composition of the two fractions is detailed in Table 1. The two fractions, which were the methyl esters, were then transformed into ethyl esters by saponification (batch of 300 g) and subsequent esterification with ethanol by refluxing in the presence of 0.5% sulfuric acid for 5 h under nitrogen.

Animals and diets. All studies were done within the guidelines set for the care and use of laboratory animals, in agreement with official French regulations (authorizations 3273 and A 21100). Wistar rats from Iffa-Credo (L'Arbresle, France) were fed for two generations with a

[a]Values are means of at least three determinations. Each fatty acid is expressed as percent of the total fraction.

[b]The purified fractions containing the *trans* isomers of linolenic acid were prepared as follows: Fraction A was obtained by isomerization of pure methyl α-linolenate, using nitrous acid and the 18:3 isomers were then purified by column chromatography. For fraction B, fatty acid methyl esters obtained from a heated linseed oil (275°C, 12 h, under nitrogen) were purified by column chromatography, urea inclusion and preparative high-performance liquid chromatography.

[c]*cis,trans* and *trans,cis* conjugated linoleic acid.

[d]*trans,trans* conjugated linoleic acid.

TABLE 2

Composition of the Diets of the Female Rats During Mating, Gestation and Lactation

	Groups A	B, C, D
	g/kg diet	g/kg diet
Casein	205	205
DL-Methionine	5	5
Starch	427	425
Saccharose	277	276
Lipids[a]	16	19
Agar-agar	20	20
Mineral mixture[b]	50	50
Vitamin mixture[c]	+	+

[a]Group A received 5 g/kg diet of fraction A obtained by chemical isomerization of α-linolenate and 11 g/kg diet of sunflower oil ethyl esters. Group B received 10 g/kg diet of fraction B extracted from heated linseed oil and 9 g/kg diet of sunflower oil ethyl esters. Groups C and D received 19 g/kg diet of the same blend of soybean, peanut and linseed oils (35:44:21), but group C received it as ethyl esters and group D as triglycerides.

[b]Composition of the mineral mixture (g/kg of diet): $CaHPO_4$, 10; $CaCO_3$, 10; KH_2PO_4, 12.5; NaCl, 5; $MgSO_4 \cdot 7H_2O$, 5; 4 $MgCO_3$/Mg $(OH)_2 \cdot 5\ H_2O$, 2; oligoelements (mg/kg of diet): $FeSO_4 \cdot 7\ H_2O$, 500; $MnSO_4 \cdot H_2O$, 250; $ZnSO_4 \cdot 7H_2O$, 300; $CuSO_4 \cdot 5\ H_2O$, 60; $KAl(SO_4)_2 \cdot 12\ H_2O$, 10; NaF, 5; $NiSO_4 \cdot 7\ H_2O$, 5; $CoSO_4 \cdot 7\ H_2O$, 5; K_2CrO_4, 5; KIO_3, 2; $(NH_4)_6Mo_7O_{24} \cdot 4\ H_2O$, 1; NH_4VO_3, 0.5; Na_2SeO_3, 0.3.

[c]Vitamin mixture was prepared in water-soluble form (except for inositol and *para*-aminobenzoic acid) and was added each day to water, lipids and dry diet to provide the semi-liquid diet. The composition was as follows (per kg dry diet): DL-α-tocopheryl acetate, 100 mg; choline chloride, 1 g; biotin, 0.2 mg; folic acid, 2 mg; thiamin · HCl, 10 mg; riboflavin, 10 mg; pyridoxine · HCl, 10 mg; pantothenic acid, 30 mg; niacin, 60 mg; vitamin B_{12}, 0.05 mg; ergocalciferol (in alcohol), 1000 IU; *trans* retinol palmitate (water dispersable), 6000 IU; phytomenadione, 1 mg; inositol, 200 mg; *para*-aminobenzoic acid, 100 mg.

pellet diet (T87) containing only 320 mg n-3 fatty acids per k/g of diet (15). This diet, which contained (in g/100 g) wheat 22, casein 17.5, methionine 0.5, skim milk powder 10, brewer's yeast 5, corn starch 27, cellulose 4, sunflower oil 10, and mineral and vitamin blend 4, was pelleted by Fabrique de Mélanges Expérimentaux (Inra, La Minière, France).

Ninety-six female adult rats of the pellet-fed animals were mated and fed the experimental diets (Table 2) during mating, gestation and lactation. The purified semi-liquid diet was prepared fresh daily by blending dry diet, water, vitamin solution and experimental lipids. The animals were fed *ad libitum*. Four groups of 24 rats each (A, B, C and D) were used. The groups differed only by the type of lipids in their diet. Groups A and B were the experimental groups and received the two fractions containing linolenic acid *trans* isomers. Group A received 5 g/kg diet of the first fraction obtained by chemical isomerization of α-linolenic acid (Table 1, A) and group B 10 g/kg diet of the second fraction extracted from heated linseed oil (Table 1, B). Sunflower oil ethyl esters were added to these two diets to provide a sufficient quantity of linoleic acid (11 and 9 g/kg diet, respectively). Groups C and D were the control groups. They were fed the same diet containing 19 g/kg of a blend of soybean, peanut and linseed oils (35:44:21, by wt) as lipids. However, group D received this blend as triglycerides, while group C received it as ethyl esters. The esters were obtained from the blend by saponification and subsequent esterification, as previously described. These two control groups were necessary because the isomer fractions were obtained as fatty acids. Dietary lipids are usually present mostly as triglycerides, and some studies suggest that the intestinal absorption and metabolism of PUFA are not necessarily the same for the triglycerides, ethyl esters and fatty acids (16).

The quantitites of the different sources of lipids were chosen to arrive at (i) equivalent quantities of linoleic acid in the four groups, (ii) equivalent levels of all *cis* α-linolenic acid in groups A, C and D, and (iii) comparable levels of the desaturable *trans* isomer of α-linolenic acid (18:3 Δ9*c*,12*c*,15*t*) in groups A and B (Table 3). The quantities of total n-3 fatty acids (*cis* + *trans*) were similar in groups B, C and D, and the total 18:3 *trans* isomers in groups A and B differed only by about 20%. However, it was not possible to have the same level of total lipids in group A compared to the other groups (16 vs. 19 g/kg); compensation was achieved by adding 1 g/kg of saccharose and 2 g/kg of starch (Table 2).

Large litters of animals were reduced to eight pups at birth. The survival of pups, the food intake of dams, and

[a]Values are means of at least three determinations.

the weight of the litters and of the dams were recorded. The pups were killed at weaning by decapitation. After exsanguination, the brain, sciatic nerve, retina and liver were dissected and removed. Myelin and nerve endings (synaptosomes) were obtained, and their purity was checked as described previously (17).

Brain capillaries were separated according to Goldstein (18), and their purity was checked as described previously (19). All fractions were lyophilized. After dissection, the livers of the weanling rats were immediately placed in a mixture of chloroform/methanol (2:1, vol/vol).

Fatty acid analyses. The liver lipids were extracted according to Folch *et al.* (20), and the lipids of the lyophilized preparations were obtained using the method of Pollet *et al.* (21). The lipids were transmethylated with BF_3/methanol according to Metcalfe and Schmitz (22). The FAME were freed from dimethylacetals by thin-layer chromatography (TLC) on silica plates (ref. 5720; Merck, Darmstadt, Germany) using toluene as solvent, as described by Morrison and Smith (23). The structures of the dimethylacetals were verified by gas–liquid chromatography (GLC) coupled with mass spectrometry.

The FAME were analyzed by GLC. GLC analyses were carried out on a Becker-Packard 417 or 420 (Middleburg, The Netherlands), fitted with a solid injector, or on a Carlo Erba Mega 5300 (Milano, Italy), equipped with an on-column injector. All chromatographs utilized flame-ionization detection. Fused silica capillary columns were used, principally a CP Sil 88 column (Chrompack, Middleburg, The Netherlands) 50 m long, internal diameter 0.32 mm, film thickness 0.25 μm. Other columns used were a DB 23 and a DB Wax (J&W Scientific, Rancho Cordo, CA), 30 m long, internal diameter 0.25 mm, film thickness 0.25 μm. The analyses were done isothermally at 175 or 185°C, or programmed from 50 to 200°C at 15°C/min. The temperature of both the injector and detector was 240°C. Helium was the carrier gas. Quantitative data were obtained using Vista CDS 401 (Varian, Les Ulis, France) or Chromjet (Spectraphysics, Les Ulis, France) integrators.

Fatty acids were identified by comparison with commercial standards (Nu-Chek-Prep, Elysian, MN) whenever possible. In addition, 20:5 Δ5*c*,8*c*,11*c*,14*c*,17*t* and 22:6 Δ4*c*,7*c*,10*c*,13*c*,16*c*,19*t*, which we previously prepared and identified (9), were used as GLC standards. FAME of identical preparations were also pooled and then separated by $AgNO_3$–TLC for further identification. Silica gel plates (Merck; 0.25 mm layers, 20 cm × 20 cm) were impregnated by immersing them for 30 min into a solution of $AgNO_3$ in acetonitrile (0.59 mol/L). The developing solvent was toluene/diethyl ether (90:10, vol/vol). The bands were visualized after spraying with a 0.2% solution of 2'7'-dichlorofluorescein in ethanol under ultraviolet light at 54 nm and then were scraped into glass centrifuge tubes. Release of the unsaturated fatty acids from the $AgNO_3$ adsorbent was facilitated by washing with NaCl in methanol/water following a modification (2) of the method of Hill *et al.* (24). FAME were also analyzed by GLC on different columns. Finally, some structures (saturated, mono- and di-ethylenic FAME, dimethylacetals) were also checked by GLC coupled with mass spectrometry. A Hewlett-Packard 5970 Mass Selective Detector (Palo Alto, CA) coupled to a Hewlett-Packard 5890 gas chromatograph was used. A DB Wax fused silica column (30 m long, internal diameter 0.25 mm, film thickness 0.5 μm; J&W Scientific) was employed in the splitless injection mode. The temperature was programmed from 50 to 200°C at 20°C/min, held at 200°C for 45 min, then programmed from 200 to 220°C at 20°C/min, and finally held at 220°C until completion of the analysis. Helium was the carrier gas.

Statistical anallysis. Food intake of the dams during pregnancy, the number of live pups by litter and the weight of the pups at day 19 were analyzed by analysis of variance. The differences in weight of live pups at birth were calculated using the analysis of covariance, the covariable being the total number of pups born (alive and stillborn). Fetuses born dead and postnatal mortality were compared using analysis of variance on angular transforms of proportions, according to Gabriel (25). In all cases, the effect of *trans* isomers (A,B vs. C,D), linolenic acid deficiency (B vs. A,C,D) and ethyl esters (D vs. A,B,C) were calculated.

Concerning the fatty acid composition of brain structures, only three pools were available in each group (but only one pool for retina), and it was not possible to efficiently calculate the significance of differences for these conditions.

RESULTS AND DISCUSSION

The reproduction characteristics of the different groups were quite similar (Table 4), and no effects of the *trans* fatty acids or of the form of administration (triglyceride vs. fatty acid ethyl esters) were detected under our experimental conditions. The dietary deficiency in *cis* α-linolenic acid was also not sufficient to induce an increase in perinatal mortality, as already observed (26). The apparent higher level of postnatal mortality in group C was produced principally in one litter, and the effect was not significant. Only one significant effect could be seen in the growth of the young, namely that the weights of the rats fed the diet containing triglycerides as lipid source (group D) was significantly higher than those of the rats

TABLE 4

Reproduction Characteristics and Growth of Rats Fed *trans* Isomers of Linolenic Acid

	Groups				Effect of analysis of variance[a]		
	A	B	C	D	*Trans* isomers	18:3n-3 deficiency	Ethyl esters
Number of experimental female rats	24	24	24	24			
Number of litters born	12	16	17	16			
Food intake of dams during pregnancy (g dry matter)[b]	578.4 ± 31.8	553.5 ± 41.0	565.8 ± 41.7	578 ± 35.3	NS	NS	NS

Fetuses born dead (as % of total pups born)[d]	1.65	2.08	3.12	1.24	NS	NS	NS
Postnatal mortality (from birth to day 3)[d]	4.76	3.23	9.3	3.33	NS	NS	NS
Number of litters weaned	12	16	16	15	—	—	—
Weight of young of the litter of eight pups at day 19 (g)[b]	43.17 ± 1.88	42.08 ± 3.86	41.94 ± 5.51	46.95 ± 2.53	NS	NS	**

[a]Analyses of variance and covariance were done as described in the Materials and Methods section. The following factors were tested: *trans* isomers = (A,B vs. C,D); linolenic acid deficiency = (B vs. A,C,D); ethyl ester = (D vs. A,B,C). NS, not significant ($P > 0.05$); **significant for $P < 0.001$.

[b]Values are means ± SE.

[d]Significance of differences calculated using analysis of variance on angular transformations.

receiving the ethyl esters. However, this effect did not impair the comparison of the composition of lipid fatty acids between groups.

The fatty acid composition of brain structures was determined by at least three chromatographic analyses on CP Sil 88 phase and ascertained by GLC on two other phases, as well as by isolating samples by $AgNO_3$–TLC. These analyses made it possible to detect differences in the retention times of *trans* long-chain fatty acids compared to normal *cis* fatty acids on the three GLC phases (Fig. 1). The equivalent chain lengths of some of the important PUFA on carbowax 20 M column had been previously measured (9). The CP Sil 88 column, which affords the same type of separation as the carbowax 20 M column, was more efficient. The separation of the same compounds on the DB 23 phase is different as the two *trans* isomers of 22:5n-3 and 22:6n-3 have a shorter retention volume than their *all cis* homologs. These particularities proved very useful for the identification of these compounds in the various lipid fractions. With the very small quantities available it was not possible to check for the presence of the *trans* ethylenic bond by GLC coupled with Fourier transform infrared spectroscopy.

The fatty acid composition of the nerve endings (synaptosomes) is presented in Table 5. The control groups C and D had fatty acid compositions similar to those described previously (17). The synaptosomes from group A contained a lower level of 22:5 Δ7*c*,10*c*,13*c*,16*c*,19*t*, the *trans* isomer of 22:5n-3, and a higher level of 22:6 Δ4*c*,7*c*,10*c*,13*c*,16*c*,19*t*, the *trans* isomer of 22:6n-3. It is important to note that the incorporation of such *trans* compounds apparently did not affect the levels of the *cis* n-3 or n-6 long-chain PUFA, which were similar to those of the control groups. If we compare the level of 18:3 Δ9*c*,12*c*,15*t* in the diet (19.7% of the desaturable 18:3; see Table 3) with the level of *trans* 22:6 in synaptosomes [0.49/(15.65 + 0.49) = 3% of total 22:6], it is obvious that there is less deposition of *trans* 22:6 than of *cis* DHA in synaptosomes. *Trans* isomers of α-linolenic or EPA were also not detected. This observation confirms some preliminary earlier results (10) and suggests that these *trans* PUFA are present in the lipid classes or tissues in which their corresponding *cis* analogs are usually found.

It could be hypothesized that the incorporation of *trans* PUFA would be higher in lipids of animals of group B that were slightly deficient in α-linolenic acid, and this was, in effect, the case. The level of 22:6 Δ4*c*,7*c*,10*c*,13*c*,16*c*,19*t* in group B was more than twice that in group A. However, this increase was not sufficient to compensate for the decrease in 22:6n-3. As has been observed in other cases of linolenic acid deficiency (17,27,28), the level of 22:5n-6 was higher than that in group A and in the controls. Not even traces of 22:5 Δ7*c*,10*c*,13*c*,16*c*,19*t* were detectable in group B. Moreover, the level of 22:5n-3 decreased. It seems that all the n-3 fatty acids available were further elongated toward the final compounds of the series.

In brain capillaries and microvessels (Table 6) and in retina (Table 7), the results were similar, except that no

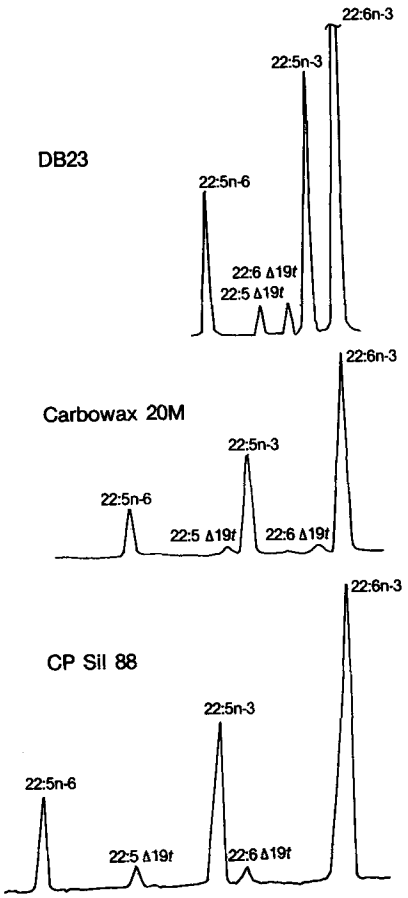

FIG. 1. Gas–liquid chromatograms of some *cis* and *trans* docosapentaenoic and docosahexaenoic acids (standards were prepared and characterized by Grandgirard *et al.*, Ref. 9). The three GLC phases used were DB23 (J&W Scientific, Rancho Cordo, CA), Carbowax 20M (J&W, Palo Alto, CA) and CP Sil 88 (Chrompack, Middleburg, The Netherlands). The chromatographic conditions used are described in Materials and Methods section.

22:5 Δ7*c*,10*c*,13*c*,16*c*,19*t* was detected in brain microvessels of group A and that a small quantity of this compound was found in the retina of group B. Moreover, in retina of group B not only 22:5n-6 but also 22:4n-6 and 20:4n-6 increased. However, due to the very low weight of retina, only one pool was available in each group.

Myelin and sciatic nerve have fatty acid compositions different from those of synaptosomes, brain microcapillaries and retina. Myelin and sciatic nerve are rich in saturated and monoenic fatty acids and relatively low in PUFA (12,17,29). It is generally thought that the fatty acids of myelin and sciatic nerve have relatively long turnover times. However, under our experimental conditions, small, but relevant, quantities of *trans* n-3 PUFA were incorporated into the tissues of group A (Tables 8 and 9). The level of 22:6 Δ4*c*,7*c*,10*c*,13*c*,16*c*,19*t* was approximately doubled in myelin and tripled in sciatic nerve of group B compared to group A. As has already been reported for other tissues, this increase was not sufficient to compensate for the large decrease in 22:6n-3. The levels of 22:5n-6 were increased as in other brain structures and in retina. However, in sciatic nerve, also some other changes in fatty acid composition were observed in group B. The 22:4n-6 and 20:4n-6 levels apparently increased, while linoleic acid levels decreased. In this case, it is possible that the formation of long-chain n-6 PUFA was depressed by the n-3 fatty acids in group A and that the significant decrease in n-3 levels in group B allowed linoleic acid to be desaturated and elongated to a much greater extent.

All brain tissues studied contained the *trans* 22:6n-3 isomer when *trans* isomers of linolenic acid had been part of the diet. When *all cis* dietary α-linolenic acid was sufficient (group A), the levels of this *trans* 22:6n-3 isomer ranged from 0.08 to 0.64% of total FAME. However, if the incorporation of *trans* long-chain PUFA is calculated as the percentage of DHA that was of *trans* geometry, it becomes evident that the incorporation of *trans* DHA is similar (from 2.6 to 3.7%) in all the brain structures (Table 10).

Others	1.39	1.99	1.22	2.23

[a]Values are % of total fatty acids and were determined using one pool. Retina was obtained from pups at weaning and lyophilized. After extraction of the lipids and methylation, fatty acid methyl esters were analyzed by gas–liquid chromatography on three columns: CP Sil 88, DB 23 and DB Wax. The chromatographic conditions and the procedures for peak identification are given in the Materials and Methods section. See Table 5 for abbreviation.

Our objective was furthermore to compare the incorporation of the *trans* DHA into brain and into other tissues. The *trans* isomers of 22:6n-3, 22:5n-3 and 20:5n-3 had been detected in various tissues, such as liver, kidney, heart, adrenals and testes (9,10,30), and the liver was chosen for the comparison with brain structures in this experiment. For the liver of the same weanling animals, 22:6 Δ4*c*,7*c*,10*c*,13*c*,16*c*,19*t* (Table 10) represented only 4.5% of total 22:6n-3, which is similar to the results obtained for the brain structures. In the α-linolenic acid-deficient group, the percentage of *trans* 22:6 ranged from 14.6 to 24.6% in the brain structures. These values are in the same range as those for the liver (25%). It appears that the brain structures are only slightly more protected than other tissues against the incorporation of *trans* isomers. It would be interesting to determine whether this is valid only during brain development or also later in life such as during growth and in maturity.

In this, as well as in previous studies (10,30), the *trans* n-3 PUFA were present only in tissues or lipid classes in which their corresponding *cis* compounds were found. For example, in our experiment, no 20:5 Δ5*c*,8*c*,11*c*,14*c*,17*t* was

Others	2.41 ± 0.39	2.68 ± 0.32	2.04 ± 0.22	2.04 ± 0.19

[a]Values are % of total fatty acids and are means ± SE of three pools. Sciatic nerve was obtained from pups at weaning and was lyophilized. After extraction of the lipids and methylation, fatty acid methyl esters were analyzed by gas–liquid chromatography on three columns: CP Sil 88, DB 23 and DB Wax. The chromatographic conditions and the procedures for peak identification are given in the Materials and Methods section. See Table 5 for abbreviation.

observed in synaptosomes, brain microvessels, retina and myelin; in these cases also no *all cis* EPA was observed. Sciatic nerve contains only some *trans* EPA and only small quantities of EPA. The metabolism of *trans* n-3 PUFA thus appears to parallel the metabolism of *all cis* n-3 PUFA. When *all cis* α-linolenic acid is deficient, *trans* PUFA are incorporated to a greater extent into the brain structures. However, their levels never reach the levels of the corresponding *cis* compounds in rats that are not deficient in α-linolenic acid. It is possible that the level of 18:3

[a]Values are % of total 22:6.

Δ9*c*,12*c*,15*t* (about 600 mg/kg diet) was not sufficient compared to the initial level of linolenic acid (about 2500 mg/kg diet). However, as in previous experiments, it appears that the *cis* n-3 PUFA were probably more easily desaturated and elongated than the corresponding *trans* compounds. This is consistent with the levels of *trans* long-chain n-3 PUFA incorporated into these tissues compared with the percentage of their precursor in the diet (Table 3).

We know that geometrical isomers of α-linolenic acid can be present in the human diet. The low-calorie spreads marketed in France can contain up to 28% of their 18:3 as *trans* compounds (5). Moreover, in some frying oils about 40% of linolenic acid was of *trans* configuration (4). It can therefore be argued that the ratios of *trans* isomers of α-linolenic acid used in the present experiments (47.5 of total 18:3 in group A) were quite realistic. The compounds can be desaturated and elongated *in vivo* and thus provide *trans* isomers of EPA or DHA, even in brain structures. Although our studies were done in rats, evidence for the occurrence of isomers of EPA and DHA in human tissues was brought forward recently by Chardigny *et al.* (31) who identified the *trans* isomer of EPA in most of the fourteen samples of human platelets studied. The *trans* isomer of DHA was also detected but to a lesser extent and only in four samples. It will be necessary to determine whether or not these amounts could have physiological implications. In another study done on human platelets (32), 20:5 Δ5*c*,8*c*,11*c*,14*c*,17*t* was shown to be a less powerful antiaggregant than EPA, and 22:6 Δ4*c*,7*c*,10*c*,13*c*,16*c*,19*t* was shown to be more efficient than DHA in inhibiting aggregation induced by arachidonic acid.

Hepatic Phospholipid Molecular Species in the Guinea Pig. Adaptations to Pregnancy

Graham C. Burdge* and **Anthony D. Postle**

Child Health, University of Southampton, Southampton SO9 4XY, United Kingdom

Incorporation of polyunsaturated fatty acids (PUFA), particularly 22:6n-3, into fetal brain at specific gestational ages is critical for development of normal brain function. We have studied adaptations to maternal liver phospholipid molecular species compositions that may be related to the supply of PUFA to fetal brain. The increment of 22:6n-3 in brain phosphatidylethanolamine (PE) was maximal at day 25 to day 35 of gestation, consistent with early prenatal development of guinea pig brain. At the same gestational ages, there was a transient increase in maternal liver concentration of 16:0/22:6 phosphatidylcholine (PC), which preceded the progressive increase in total PC concentration toward term (day 68). This effect was specific for the *sn*-1 16:0 species, as there was no significant increase in 18:0/22:6 PC concentration. These results are consistent with a specific role for 16:0/22:6 PC in the directed supply of 22:6n-3 from maternal liver to the fetus. Concentrations of all PE species in maternal liver decreased at day 25 and day 35 of gestation. The gradual accumulation of 22:6n-3 in fetal liver throughout gestation did not correlate with the pattern of acquisition of 22:6n-3 into fetal brain PE. Maternal plasma PC and cholesterol concentrations decreased dramatically by day 25 of gestation, and remained low until term. This hypolipidemia of pregnancy in the guinea pig may be due to increased lipase-mediated turnover of plasma lipoproteins and contrasts strongly with the well-characterized hyperlipidemia in human and rat gestation.

***Lipids* 29, 259–264 (1994).**

Optimal fetal growth requires an adequate supply of essential polyunsaturated fatty acids (PUFA) at defined periods in gestation. Failure to acquire sufficient and appropriate PUFA at such critical periods in fetal development may have irreversible and harmful consequences for post-natal growth and function. The major PUFA arachidonate (20:4n-6) and docosahexaenoate (22:6n-3) must be derived from the essential fatty acids linoleate (18:2n-6) and α-linolenate (18:3n-3) in the maternal diet. Studies in preterm human infants fed formula either lacking or supplemented with marine oils (1,2) have shown that the capacity of the fetus and neonate to desaturate and chain elongate 18:2n-6 and 18:3n-3 is inadequate to meet the demands of rapid growth in development. The conclusion from these and many other studies is that the bulk of the long-chain PUFA must be synthesized by the mother and supplied to the fetus and neonate either by placental transport or through the milk. Further evidence to support this view was provided by analysis of phospholipid fatty acid composition in cerebral cortex obtained from victims of Sudden Infant Death Syndrome, who had been born at term (3). Brain phosphatidylethanolamine (PE) 22:6n-3 was deficient in infants who had been fed formula not supplemented with preformed 22:6n-3 as compared with breast-fed infants. The mechanisms regulating the maternal synthesis of 20:4n-6 and 22:6n-3 destined for supply to the fetus are still not understood. Indeed, despite knowledge of the maternal hyperlipidemia of human pregnancy for almost 150 years (4), it is still not clear which lipid or lipoprotein subfraction in the circulation is the principal carrier of PUFA to the placenta.

A significant proportion of the 22:6n-3 delivered to the fetus is destined for incorporation into neuronal membranes of the developing brain, preferentially as PE (5). The period of 22:6n-3 accumulation in brain PE is associated with the process of neurite extension and axonal formation and precedes the brain growth spurt characterized by the incorporation of saturated fatty acids into brain myelin (6). The timing of maximal 22:6n-3 incorporation into brain PE and brain development differs considerably between animal species (7). Consequently, for any given species, any adaptations of maternal lipid metabolism proposed to be involved in the directed supply of 22:6n-3 must correlate temporally with its accumulation in fetal brain.

In human development, 22:6n-3 incorporation into fetal brain is initiated early in gestation, at about 16 wk (8,9), and continues into early post-natal life. This process in the rat is restricted to the post-natal period (10). Analyses of the ontogeny of the accumulation of 22:6n-3 in fetal guinea pig brain phospholipids have not previously been reported. However, neuronal differentiation is essentially prenatal in the guinea pig (11), and the timing of neuritogenesis at about day 40 of gestation term (term = 68 d) (12) suggests that brain 22:6n-3 accumulation should also be substantially prenatal.

In maternal rat liver (13) and in maternal human plasma (14), the period of 22:6n-3 accumulation by perinatal brain is preceded by an increased concentration of the phosphatidylcholine (PC) molecular species, 16:0/22:6 PC. This suggested that 16:0/22:6 might be a preferential carrier for transport of 22:6n-3 from the maternal liver either to fat stores destined for use during lactation or to the placenta for supply to the developing fetus.

In the present study we have characterized the molecular species compositions of PC and PE in fetal and maternal liver and in maternal plasma throughout guinea pig gestation, and have compared the adaptations with the ontogeny of PUFA accumulation in fetal brain.

Abbreviations: DPH, 1,6-diphenyl-1,3,5-hexatriene; FA, fatty acid(s); GC, gas chromatography; PC, phosphatidylcholine; PE, phosphatidylethanolamine; PUFA, polyunsaturated fatty acid(s); TFE, trifluoroethanol; UV, ultraviolet.

MATERIALS AND METHODS

Materials. HPLC grade methanol and trifluoroethanol (TFE) were obtained from Rathburn Ltd. (Walkerburn, Scotland). Chloroform, choline chloride and 1,6-diphenyl-1,3,5-hexatriene (DPH) were purchased from Merck Ltd. (Poole, Dorset, United Kingdom). All other reagents and lipid standards were from Sigma (Poole, Dorset, United Kingdom).

Animal procedures. Outbred adult female Dunkin–Hartley guinea pigs were fed maintenance diet (FD1; Special Diet Services, Witham, Essex, United Kingdom) *ad libitum* before mating and throughout pregnancy. The diet contained 3.4% fat by weight, and its fatty acid (FA) content, expressed relative to total esterified fatty acids, was 22.2% saturated FA, 30.9% monounsaturated FA, 22.7% linoleic acid (18:2n-6), 16.3% α-linolenic acid (18:3n-3) and 7.9% PUFA, mainly 20:4n-6. At gestational ages 25, 35, 55 and 68 (term) days, fetal guinea pigs were delivered by Caesarian section (15). Maternal livers, fetal livers and fetal brains were collected, immediately frozen in liquid nitrogen and stored at –20°C. Obtaining fetal tissues at earlier gestational ages was not technically feasible.

HPLC analysis of phospholipid molecular species. Liver or brain tissue, approximately 100 mg, was homogenized in 0.8 mL of 0.9% (wt/vol) NaCl with an Ultra-Turrax homogenizer (Janke & Kunkel, Staufen, Germany). One hundred nmoles each of 14:0/14:0 PC in TFE and 14:0/14:0 PE in chloroform were added to liver homogenates as internal standards. Lipids were extracted with chloroform/methanol (16); PC and PE were purified using aminopropyl BondElut cartridges (Jones Chromatography, Hengoed, Mid Glamorgan, United Kingdom) (15,17). Intact liver PC and PE molecular species were resolved by reverse-phase HPLC on a 25 cm × 4.6 mm APEX II ODS column (Jones Chromatography) (15,18) maintained at 50°C using a mobile phase of methanol/water (925:75, vol/vol) containing 40 mM choline chloride. These isocratic conditions were chosen as a compromise between optimal resolution of phospholipid species containing PUFA, and the ability to resolve 16:0/16:0 and 16:0/18:1 species effectively. Although adding acetonitrile up to 20% (by vol) improved the resolution of PUFA-containing species, this modification resulted in co-elution of 16:0/18:1 and 18:0/22:6 species, and consequently was not used. The elevated temperature of 50°C was essential to control the elution order of phospholipid species (18). The mass of eluted PC and PE molecular species was determined by fluorescence detection following post-column derivatization with DPH (18). Ultraviolet (UV) absorbance at 205 nm, recorded simultaneously with the fluorescence signal, was routinely used to confirm the identity of molecular species. For all chromatographic peaks of PC and PE, the principal component species, determined by gas chromatography (GC), is quoted. Calculation of the ratio of UV absorbance to fluorescence responses for each eluted peak at each gestational age confirmed that the gestational changes observed in phospholipid composition were substantially due to the major species indicated.

Analysis of brain phospholipid fatty acids by GC. Brain PC and PE fractions eluted from BondElut cartridges were dried under nitrogen and dissolved in 20 μL of chloroform/methanol (2:1, vol/vol). Twenty nmoles of 17:0/17:0 PC was added as internal standard. Fatty acid methyl esters, prepared by transmethylation of phospholipids with sodium methoxide, were resolved by GC using a fused silica capillary column (30 m × 0.25 mm, DB225; Jones Chromatography).

Statistical analysis. Statistical analysis was carried out using the Mann–Whitney U-test.

RESULTS

Fatty acid composition of fetal guinea pig brain PC and PE. The fatty acid composition of the major phospholipid classes PC and PE in fetal guinea pig brain were analyzed at intervals throughout gestation to define the timescale for the acquisition of the PUFAs 22:6n-3 and 20:4n-6. The concentration (mole %) of the principal FAs in fetal brain PC, 16:0 and 18:1n-9, remained essentially constant between day 25 and day 68 (term) (Fig. 1). The corresponding values for 20:4n-6 and 22:6n-3 both increased significantly in early gestation, reaching maxima at day 55. These FAs, however, remained minor components of fetal brain PC throughout gestation, and neither contributed more than 6% to total PC. In contrast, the gestational changes in fetal brain PE were considerably more marked. Both 20:4n-6 and 22:6n-3 were major components of brain PE at term (Fig. 2); the concentration (mole %) of 22:6n-3 in brain PE increased dramatically between gestational ages of day 25 and day 35, and then continued to increase steadily toward term. The accumulation of 20:4n-6 in brain PE occurred slightly earlier in gestation. At day 25, the earliest time

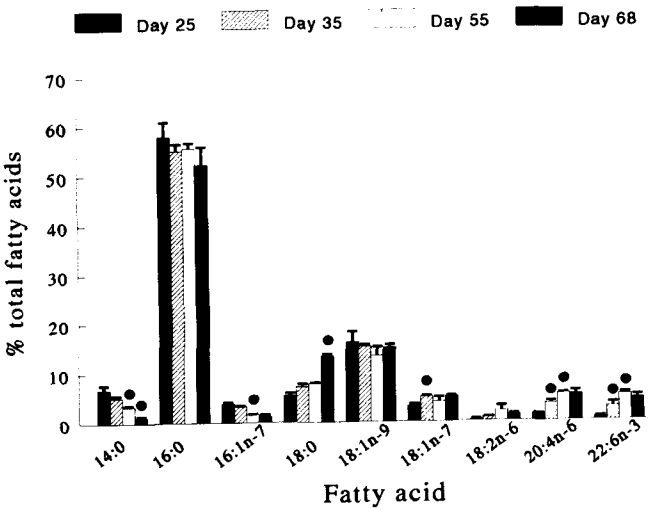

FIG. 1. Phosphatidylcholine (PC) fatty acid composition (mole %) of developing fetal guinea pig brain during gestation. Concentrations of PC fatty acids were measured by gas chromatography. The fatty acids reported account for > 97% of the total fatty acids present. Values are the mean ± SD of n = 6 samples at each gestational age. Circles indicate values that were significantly different ($P > 0.05$) from the preceding gestational age.

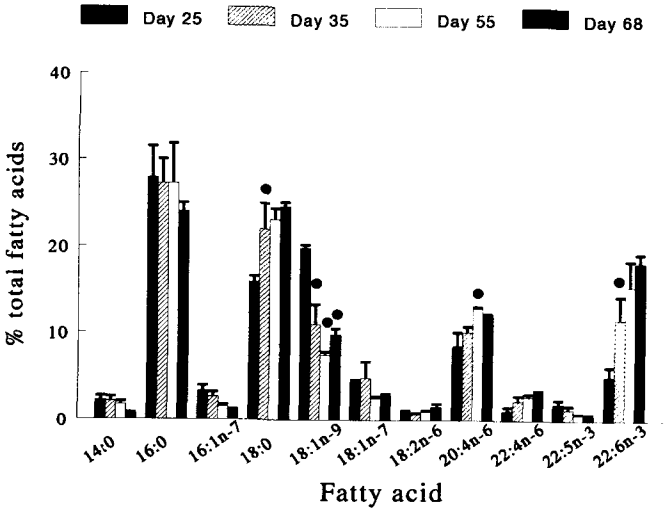

FIG. 2. Phosphatidylethanolamine (PE) fatty acid composition (mole %) of developing fetal brain during gestation. The concentrations of PE fatty acids were measured by gas chromatography. Fatty acids reported accounted for >97% of the total fatty acids detected. Values are the mean ± SD of n = 6 samples at each gestational age. Circles indicate values that were significantly different ($P > 0.05$) from the preceding gestational age.

point feasible for analysis, brain PE was already enriched in 20:4n-6 to a value of 80% of that measured at term (Fig. 2). Over the same time period in early gestation, the increases in PUFA components in brain PE were accompanied by a parallel increase in 18:0 and a decrease in 18:1n-9 (Fig. 2).

Molecular species composition of maternal guinea pig liver PC. Ten PC molecular species were consistently identified in both maternal and fetal guinea pig liver, and these species accounted for more than 97% of total PC (15). Total PC concentration in maternal liver increased significantly over the second half of gestation, from a nonpregnant value of 8.59 ± 1.91 to 14.10 ± 0.41 μmol/g wet weight at term (Table 1). Within this overall increase, there were strikingly different temporal patterns for changes to the concentrations of individual molecular species. For species containing long-chain PUFA, significantly increased concentrations were evident only in those with 16:0 at the *sn*-1 position, and these were seen early in gestation. For example, the concentration of 16:0/22:6 PC increased to a maximum at day 35 of gestation, and then decreased toward term (Table 1). In contrast, no significant gestational change was observed for the concentration of 18:0/22:6 PC. Similarly, the concentration of 16:0/20:4 PC increased threefold to a maximum at the earliest time measured (day 25) and then decreased until term, whereas no significant alteration was observed for 18:0/20:4 PC (Table 1). The patterns of changes to concentrations of PC species containing 18:2n-6 during gestation were completely different from those observed in PUFA-containing PC species. Neither 16:0/18:2 PC nor 18:0/18:2 PC concentration changed significantly until day 35 of gestation, after which the concentrations of both species continued to increase until term. In addition to these alterations to hepatic concentrations of polyunsaturated PC species in the pregnant guinea pig, significant changes were apparent in the concentrations of both disaturated and monounsaturated PC species. The concentration of 16:0/16:0 PC increased gradually throughout gestation, whereas that of 18:0/18:1 PC reached a maximum at day 35 of gestation and then decreased to nonpregnant values by term.

Molecular species composition of maternal guinea pig liver PE. In contrast to the gestational increase in maternal liver PC concentration, the total PE concentration decreased in early gestation from a nonpregnant value of 9.63 ± 0.21 to 6.19 ± 0.79 μmol/g wet weight at

[a]Results of high-performance liquid chromatography analyses of phosphatidylethanolamine molecular species compositions in maternal guinea pig liver expressed as mean ± SD; n = 3 samples/gestational age.

[b–e]Results significantly ($P < 0.05$) different from nonpregnant, day 25-pregnant, day 35-pregnant and day 55-pregnant, respectively.

day 25 of gestation (Table 2), and then subsequently returned to the original concentration by term. Moreover, there was no significant temporal discrimination in concentration changes between the individual molecular species of PE. The concentrations of all the major PE species in maternal liver tended to decrease early in gestation and then increase again toward term. Again, in contrast to PC, the major changes to maternal liver PE were apparent in species containing *sn*-1 18:0 rather than *sn*-1 16:0 (Table 2).

Lipid composition of maternal guinea pig plasma. Concentrations of total cholesterol and PC decreased significantly in maternal plasma by day 25 of gestation compared with the nonpregnant values (Table 3), and both then remained low throughout the remainder of gestation. Plasma triglyceride concentration did not change significantly at any time in gestation. Molecular species analysis of plasma PC showed that all species containing 22:6n-3, 20:4n-6 and 18:2n-6 decreased to similar extents in gestation (Table 3).

Molecular species composition of fetal guinea pig liver PC and PE. The apparent increase in fetal liver total PC between day 35 and day 68 of gestation was not significant. In contrast, fetal liver PE concentration doubled over the same period (Table 4). The mass of fetal liver at day 25 was too low (10 ± 2 mg) for molecular species analysis. Molecular species of PC and PE containing 22:6n-3 and 20:4n-6 were already substantially enriched in fetal liver at day 35 of gestation. The concentrations of all PC and PE species containing 22:6n-3 then increased

[a]Results of high-performance liquid chromatography analysis of developing fetal guinea pig liver PC and PE expressed as mean ± SD nmol/g wet tissue; n = 6 samples/gestational age.

[b]Values that differed significantly ($P < 0.05$) from the preceding gestational age. The wet weights of fetal livers were 0.29 ± 0.08 g (day 35), 2.79 ± 0.18 g (day 55) and 5.94 ± 0.83 g (day 68, term).

gradually until term. By contrast, concentrations of PC and PE species containing 20:4n-6 did not significantly change between day 35 and day 68 of gestation.

DISCUSSION

The results from this study showed, for the first time, the patterns of changes of maternal and fetal guinea pig liver PC and PE molecular species and their temporal relationship to the accumulation of 22:6n-3 in fetal guinea pig brain PE. Differentiation and functional maturation of the guinea pig brain are essentially prenatal events (4,11,12). Our results confirm that, as might be expected, the accumulation of 22:6-3 in fetal brain PE was also substantially prenatal. The period of most rapid accumulation was between day 25 and day 35 of gestation (Fig. 2), which preceded both the reported onset of electrical activity (days 46–48) (19) and the expression of the neurite growth cone-associated protein GAP-43 (day 40) (20). This result is consistent with the incorporation of 22:6n-3 into the membranes of maturing neurones prior to, and in support of, neurite extension and axon formation. One consequence of this demonstration of the early timescale for the accumulation of 22:6n-3 in fetal guinea pig brain is that any adaptations to maternal lipid metabolism that might regulate the supply of 22:6n-3 to the developing fetus must also be functional early in gestation. Analysis of hepatic PC composition of the pregnant guinea pig, compared with control values in nonpregnant animals, demonstrated specific increased concentrations of 16:0/22:6 PC and 16:0/20:4 PC at day 25 and day 35 of gestation that were not apparent in 18:0/22:6 PC, 18:0/20:4 PC or in PC species containing *sn*-2 18:2. These observations are consistent with comparable measurements in human and rat pregnancy. The concentration of *sn*-1 16:0 PC species, including 16:0/22:6 PC, increased in the plasma of pregnant women in late gestation, with no change in the concentrations of *sn*-1 18:0 PC species (14). Similarly, there was a dramatic increase in 16:0/22:6 PC concentration in maternal rat liver and plasma at term (13) in anticipation of the lactational supply of 22:6n-3 to the rat neonate (10).

Comparison between these three animal species suggests a possible role for 16:0/22:6 PC in the directed transport of 22:6n-3 from the maternal liver to the fetus or neonate. Previous reports of the analysis of the specificity of PC synthesis in adult rat hepatocytes (21) and fetal guinea pig liver (15) further suggest a number of potential regulatory mechanisms. For both the rat and guinea pig, there is preferential synthesis *de novo via* CDPcholine of *sn*-1 16:0 PC species; *sn*-1 18:0 PC species are formed largely by acyl remodeling and exhibit longer turnover times. Consequently, assuming no alteration to the mechanisms of PC acyl remodeling, an increased rate of total hepatic PC synthesis might be expected to result in a shift from *sn*-1 18:0 to *sn*-1 16:0 PC species. Any contribution of altered fatty acid supply to these mechanisms is unclear, as the composition of the diacylglycerol substrate pool for hepatic PC synthesis is not known. Finally, a significant portion of the 22:6n-3, and essentially all the 20:4n-6 in guinea pig liver is derived by *N*-methylation of the entire liver PE pool (15). As liver PE is substantially enriched in species containing 22:6n-3 and 20:4n-6 as compared with PC, increased flux through *N*-methylation would lead to an increased concentration of these FAs in the product PC. It is possible that the decreased maternal liver PE concentration at days 25 and 35 of gestation (Table 2), coincident with the increased PC concentration at the same gestational ages, is a reflection of such an increased rate of conversion by the *N*-methylation pathway.

The analysis of plasma lipid concentrations in the pregnant guinea pig (Table 3) demonstrates clearly that the regulatory mechanisms responsible for supply of 22:6n-3 to the developing fetus cannot be completely identical for all animal species. In contrast to the hyperlipidemia of late gestation in pregnant women (4,22) and the pregnant rat (23), the pregnant guinea pig exhibited a pronounced hypolipidemia from early gestation until term. Previous reports have shown that the guinea pig has a unique lipoprotein composition, with very low concentrations of high density lipoprotein in adult plasma, and that concentrations of cholesterol and triglyceride are greater in fetal than in maternal guinea pig plasma at term (24). In addition, circulating triglyceride has a half-life of minutes in the guinea pig (25), placental hydrolysis of esterified lipid is rapid (26,27), and circulating maternal plasma lipids contribute significantly to the massive hepatic and plasma hyperlipidemia of the fetal guinea pig in late gestation (24). This evidence suggests that the rapid rate of lipoprotein clearance in the guinea pig, enhanced in pregnancy by the high activity of placental lipoprotein lipase (26), is a major determinant of circulating lipid concentration. Consequently, under such conditions, the rate of maternal hepatic lipoprotein synthesis and secretion may not correlate with the plasma lipid concentration. In effect, the increased contents of 20:4n-6 and 22:6n-3 in maternal liver, derived either directly from the diet or by endogenous synthesis from dietary essential fatty acids, may act as transient store before rapid mobilization, hepatic lipoprotein secretion and placental transfer to the fetus.

The pattern of change of PC and PE molecular species containing 22:6n-3 in fetal guinea pig liver between day 35 and day 68 of gestation (Table 4) did not correlate with the timing of acquisition of 22:6n-3 in fetal brain PE. The rapid growth of the fetal liver after day 35 (Table 4) suggests only a limited possible role for this organ in the regulation of the 22:6n-3 supply to fetal brain early in gestation. Additionally, the fetal guinea pig liver in early gestation is immature and contains relatively few hepatocytes (27), further restricting any potential for involvement in essential fatty acid supply to other tissues.

While the coordination between increased maternal liver 16:0/22:6 PC and the accumulation of 22:6n-3 in fetal brain PE suggests a specific adaptation of maternal liver phospholipid metabolism to supply the requirements of the developing fetus, confirmation of this hypothesis requires extensive metabolic analysis defining rates of synthesis, turnover and catabolism of individual molecular species in the various phospholipid pools. Such information will be essential to determine, for instance, whether plasma lipid concentrations decrease in the pregnant guinea pig as a consequence of increased lipoprotein clearance, and whether these decreased concentrations are consistent with increased flux of lipid through the plasma lipoprotein pools. Similarly, while the absence of any alteration to the composition of PUFA-containing phospholipids in fetal liver coincident with the accumulation of 22:6n-3 in fetal brain PE at day 25 and day 35 of gestation suggests little involvement of fetal liver metabolism in directing PUFA supply to the fetal brain, this supposition needs to be validated by metabolic analysis. Such studies are currently being undertaken in our laboratory.

Dietary Protein Deficiency Affects n-3 and n-6 Polyunsaturated Fatty Acids Hepatic Storage and Very Low Density Lipoprotein Transport in Rats on Different Diets

Mahmoud Bouziane, Josiane Prost and **Jacques Belleville***

Unité de Recherches de Nutrition Cellulaire et Métabolique, Université de Bourgogne, Faculté des Sciences Mirande, 21004 Dijon Cedex, France

Fatty livers and the similarity between the skin lesions in kwashiorkor and those described in experimental essential fatty acid (EFA) deficiency have led to the hypothesis that protein and EFA deficiencies may both occur in chronic malnutrition. The relationship between serum very low density lipoprotein (VLDL) and hepatic lipid composition was studied after 28 d of protein depletion to determine the interactions between dietary protein levels and EFA availability. Rats were fed purified diets containing 20 or 2% casein and 5% fat as either soybean oil rich in EFA, or salmon oil rich in eicosapentaenoic (EPA) and docosahexaenoic (DHA) acids, or hydrogenated coconut oil poor in EFA. Animals were divided into six groups, SOC (20% casein + 5% soybean oil), SOd (2% casein + 5% soybean oil), COC (20% casein + 5% hydrogenated coconut oil), COd (2% casein + 5% hydrogenated coconut oil), SAC (20% casein + 5% salmon oil) and SAd (2% casein + 5% salmon oil). After 28 d, liver steatosis and reduced VLDL-phospholipid contents ($P < 0.001$) were observed in protein-deficient rats. In protein deficiency, triacylglycerol and phospholipid fatty acid compositions in both liver and VLDL showed a decreased polyunsaturated-to-saturated fatty acid ratio. This ratio was higher with the salmon oil diets and lower with the hydrogenated coconut oil diets. Furthermore, independent of the oil in the diet, protein deficiency decreased linoleic and arachidonic acids in VLDL phospholipids. Conversely, despite decreased proportions of EPA at low protein levels, DHA levels remained higher in rats fed salmon oil diets. While in rats fed the hydrogenated coconut oil-fed diets the amount of 22:5n-6 was lower in liver, it was higher in VLDL lipids at low protein levels. Both EPA and arachidonic acid are precursors of eicosanoids and their diminution may be related to certain clinical symptoms seen in infants suffering from kwashiorkor.

***Lipids* 29, 265–272 (1994).**

In protein malnutrition, lipoprotein formation and function appear to be altered, leading to liver steatosis (1). The occurrence of fatty liver and the similarity between the skin lesions (the loss of hair, dry scaly dermatitis with a tendency for superinfection and increased water permeability) in kwashiorkor and those seen in experimental essential fatty acids (EFA) deficiency have led to the hypothesis that protein and EFA deficiencies may both occur in chronic malnutrition (2,3). Hill and Holman (4) reported the effects of various dietary protein levels (5 to 40%) on EFA availability in rats fed hydrogenated coconut oil (CO) and noted that EFA deficiency symptoms are amplified at low protein intake.

Food intakes of infants before hospital admission are difficult to determine, and data on polyunsaturated fatty acids (PUFA) composition reported in several studies are inconsistent (5). It was found in some studies on malnourished children that PUFA were lowered in plasma lipids. Yet in other studies, both linoleic and arachidonic acids (3), or arachidonic alone (6), or linoleic acid in kwashiorkor and arachidonic acid in marasmus (7), were found to be decreased in plasma lipids. Thus, the data indicated a relationship between protein levels and the development of EFA deficiency. It is difficult to study these relationships with accuracy because numerous dietary deficiencies are usually associated with kwashiorkor.

Research on protein malnutrition has focused primarily on protein metabolism. Limited attention has been given to the effects of, and the interactions between, protein and different dietary fatty acids. Human EFA metabolism is quite distinct from that of the rat, and the results of the present study should therefore be extrapolated to humans only with great care. Yet, the rat is a good model to study both protein malnutrition (8) and EFA deficiency (9).

In our previous paper (10) we provided evidence for the effects of protein depletion on the pool size and composition of serum very low density lipoprotein (VLDL), and that VLDL composition was modified dependent on the origin and the quantity of the protein in the low protein diets. In the present experiments, fatty acid and protein intakes were monitored with great accuracy throughout the short-term feeding trials (28 d). Our goal was to assess the qualitative and quantitative differences in liver and VLDL fatty acid composition in growing rats fed combinations of adequate or low levels of casein with soybean oil (SO) (adequate in EFA), CO (deficient in EFA) or salmon oil (SA) (rich in long-chain n-3 PUFA). The present study was also undertaken to determine whether a short period of protein deficiency would also diminish n-3 and n-6 PUFA availability independent, or not, of the fat source and whether changes found in VLDL serum levels would be accompanied by similar alterations in apolipoprotein and lipid composition.

Abbreviations: Apo, apolipoprotein; CO, hydrogenated coconut oil; COC, 20% casein + 5% hydrogenated coconut oil; COd, 2% casein + 5% hydrogenated coconut oil, DHA, docosahexaenoic acid; EDTA, ethylenediaminetetraacetate (disodium); EFA, essential fatty acids; EPA, eicosapentaenoic acid; MUFA, monounsaturated fatty acids; PL, phospholipids; PUFA, polyunsaturated fatty acids; SA, salmon oil; SAC, 20% casein + 5% salmon oil; SAd, 2% casein + 5% salmon oil; SFA, saturated fatty acids; SO, soybean oil; SOC, 20% casein + 5% soybean oil; SOd, 2% casein + 5% soybean oil; TG, triacylglycerols; TLC, thin-layer chromatography; VLDL, very low density lipoprotein.

MATERIALS AND METHODS

Animals and diets. Sixty male Wistar rats (Iffa Credo, l'Arbresle, Lyon, France) initially weighing 83 ± 5 g were allowed free access to an adequate diet (20% casein and 5% olive oil) for 10 d. After this adaptation period, when body weights reach 115 ± 7 g, the animals were fed purified diets containing 20 or 2% casein and 5% fat as either SO rich in EFA or SA rich in eicosapentaenoic (EPA) and docosahexaenoic (DHA) acids, or CO poor in EFA. Rats were randomly divided into six groups, SOC (20% casein + 5% soybean oil), SOd (2% casein + 5% soybean oil), COC (20% casein + 5% hydrogenated coconut oil), COd (2% casein + 5% hydrogenated coconut oil), SAC (20% casein + 5% salmon oil) and SAd (2% casein + 5% salmon oil). The diets are described in Table 1, and the fatty acid compositions of the various oils are described in Table 2.

The six diets were isocaloric (16.28 MJ/kg) and contained identical amounts of lipids, vitamins, minerals and fiber. Animals were kept in wire-bottom cages at constant temperature (24°C) and humidity (60%) at a 12-h light cycle (0700–1900). The rats ate and drank *ad libitum*. The general guidelines for the care and use of laboratory animals (Council of European Communities, 1986) (11) were followed.

[a]Traces, <0.1%; n.d., "not detected." PUFA, polyunsaturated fatty acids. See Table 1 for other abbreviations.

Blood samples. On day 28 of the experiment, after overnight fasting, rats were bled from the abdominal aorta under anesthesia (sodium pentobarbital, 60 mg/kg body weight). Serum was obtained by low-speed centrifugation and preserved with 0.26 mmol disodium ethylenediaminetetraacetic (EDTA) and 3 mmol sodium azide.

Isolation of VLDL fraction from total lipoproteins. The VLDL fraction was isolated by a single spin discontinuous gradient following the method of Redgrave *et al.* (12) as modified by Meghelli-Bouchenak *et al.* (13). The purified VLDL fraction (d < 1.006) was dialyzed against 0.15 M NaCl, 1 mM EDTA, pH 7.4, at 4° for 24 h, using Spectra/Por 2 dialysis tubing (Spectrum Medical Industries, Los Angeles, CA).

Apolipoprotein (apo) electrophoresis. After partial delipidation, VLDL-apos were estimated using sodium dodecyl sulfate polyacrylamide gel electrophoresis according to Meghelli-Bouchenak *et al.* (13). Linear gradient acrylamide gels (2.5–20% acrylamide) were poured, using two chamber gravity flow gradient markers (14). Electrophoresis was performed in an LKB 2001-001 vertical electrophoresis unit (LKB, Bromma, Sweden) at 4°C for 18 h with 20 mA/slab gel. After staining with Coomassie brilliant blue G 250, destained gels were scanned at 600 nm with a densitometer (Model Profil 26; Sebia, Issy les Moulineaux, France). The proportions of the various apo were determined semiquantitatively

based on the densitometry tracings. The concentration of each apo was calculated based on the percentage of the area for each apo relative to the total area for each serum sample. Data are expressed as arbitrary units (AU)/L serum. The apo samples for the six groups were electrophoresed in parallel, but staining affinity of each peptide was not determined. However, when 50–200 μg of total protein were applied, the chromo-genicity of each major band was shown to change linearly relative to the amount of total protein applied to the gel. In order to affirm the validity of our calculations, immunoelectrophoresis according to Laurell (15) was also used for apo A-I, apo A-IV and total apo B quantitation.

Livers. The animals were killed, and the livers were removed, washed with cold saline, quickly blotted and weighed. About 1 g of the largest lobe was homogenized in an ultraturax homogenizer (Bioblock Scientific, Illkirch, France) for lipid extraction. About 100 mg of the same lobe was homogenized at 4°C in a Potter Elvejhem homogenizer and used for protein determination.

Chemical analyses. Total lipids of VLDL and liver were extracted according to the method of Folch *et al.* (16). Lipid classes were isolated by thin-layer chromatography (TLC) according to the method of Stahl *et al.* (17). The solvents used for lipid extraction and TLC contained 2,6-di-*tert*-butyl-*p*-cresol (50 mg/L) as antioxidant, and the lipid extracts were stored under nitrogen in the dark at -20°C to prevent oxidation.

Internal standards [17:0 fatty acid, di-17:0 phosphatidylcholine, tri-17:0 triacylglycerol (TG) and 17:0 cholesteryl ester] were added to the samples prior to extraction. Phospholipids (PL) were quantified by measuring their phosphorus contents by the Bartlett method (18). PL and TG fractions were transmethylated and fatty acids were analyzed by gas–liquid chromatography (19). The Becker Gas Chromatograph Packard 417 (Downers Grove, IL) used was equipped with a glass capillary column, 39 m × 0.3 mm i.d., coated with carbowax 20M as stationary phase. The flow rate (H_2) was 6 mL/min, the inlet temperature was 202°C, and the detector temperature was 240°C, using pentadecanoic acid methyl ester as internal standard. Identification of fatty acids was by comparison of relative retention times with those of commercial standards. Peak areas were calculated with an ENICA 21 integrator (Delsi Instrument, Suresnes, France). The average molecular weight of the fatty acids was determined (after correction for recovery relative to 17:0 internal standards) based on which the amounts of TG were calculated. Proteins were determined according to Lowry *et al.* (20) using bovine serum albumin as standard.

Statistical analysis. Results are reported as means for each group with standard errors of the means. In fatty acid analysis, when percentage data were not normally distributed, statistical analyses were carried out using the variance-equalizing transformation (arcsin transformation) according to Zar (21). Student's *t*-test was used to determine the significance of differences between pairs of particular means (2% vs. 20% casein). The effects of dietary fat, protein level and any interaction between the two (interaction "protein* oil"), when the CO and SA diets were compared to the SO diets (controls), were assessed by means of a two-way analysis of variance. The level of significance was 0.05.

RESULTS AND DISCUSSION

Animals. The daily average food intake per rat was 20.5 ± 4.8, 9.9 ± 1.5, 20.5 ± 4.8, 9.9 ± 1.2, 22.0 ± 4.4 and 10.1 ± 1.5 g/24 h for SOC, SOd, COC, COd, SAC and SAd, respectively. After 28 d, body weight was significantly affected by the level of protein in the diet. The protein-deficient groups, SOd, COd and SAd, weighed only 49, 43 and 44% ($P < 0.001$) of their respective controls. With the 20% casein diets, no difference was observed in body weights (293 ± 8, 286 ± 11 and 291 ± 46 g) for COC, SAC and SOC, respectively, independent of the oil in diet, which may have been due to the short experiment time.

Liver and VLDL TG and PL contents. The liver weights (Table 3) were lower in rats fed the low protein diets compared to their respective controls, i.e., SOd (–38%), COd (-40%) and SAd (–52%) (2% vs. 20% casein, $P < 0.001$), but there was no effect of the dietary fat source on liver weight. In protein-deficient rats, total hepatic lipids were markedly elevated as had been observed in previous experiments by Meghelli-Bouchenak *et al.* (10). A gain in liver total lipids, which was mostly due to TG increases, was observed in all protein-deficient groups ($P < 0.001$) (Table 3). This lipid accumulation in liver was attributed by Flores *et al.* (22) and Meghelli-Bouchenak *et al.* (13) to impaired hepatic TG secretion *via* VLDL. Yet, as liver TG levels (per gram of liver) were increased by protein malnutrition, PL levels in both liver and VLDL were decreased, especially in the CO-fed group, but not significantly for liver–PL in the SA-fed group. The highest liver–TG contents were observed with the CO diets ($P < 0.001$). As protein deficiency induced a reduction in VLDL-apo synthesis, TG levels carried by VLDL were decreased (Table 3).

Liver and VLDL fatty acid changes. PUFA occur in tissues as essential components of structural lipids of cellular and subcellular membranes. The properties of these membranes are affected by the PUFA composition of their constituent PL. Thus, PUFA status is best measured by the percentage of PUFA in the total fatty acids bound in PL, rather than by the overall PUFA concentration in tissues or fluids (23). In the present study, when comparing dietary variables, we have only considered the relative percentages, per weight, and not the actual amounts of fatty acids present. The fatty acid compositions of liver and VLDL lipids (expressed as percentage of total fatty acids) from rats on the different treatments are listed in Tables 4–7. In general, the fatty acid profiles of the lipid fractions studied reflected the fatty acid contents of the oils ingested by the various groups, particularly with 20% rather than with 2% casein in the diets. Thus, linoleic and arachidonic acid levels were highest in lipids from the SO-fed groups, and lowest in the SA- and CO-fed groups, reflecting the differences in the linoleic acid contents of the oils. Similarly, the long-chain n-3 PUFA were not detectable in

TABLE 3

[a]Values are means for six rats ± SEM; abbreviations are as in Table 1 and VLDL, very low density lipoprotein. [b]*P*-values for hydrogenated coconut oil (CO) or salmon oil (SA) vs. soybean oil (SO). [c]*P*-values for 2% casein vs. 20% casein. [d]*P*-values for the interaction between oil type effect and protein levels; NS, nonsignificant.

these lipid fractions when rats were fed the CO diets and when the 22:5n-6 was replaced by DHA in rats fed the SA diets.

The amounts of total n-6 PUFA, i.e., linoleic and arachidonic acids, were lower with the CO and SA diets when compared to control values obtained with the SO diets ($P < 0.001$). The 20:3n-9/20:4n-6 ratio, a biochemical index of EFA deficiency (limit of normality is <0.2 in PL of serum) (23) was enhanced with the CO and SA diets (low in EFA), but more markedly with the coconut oil diet ($P < 0.001$). Yet, this ratio was not always increased in each of the lipid fractions by protein deficiency. Holman *et al.* (6) and Naismith (24) observed a significant increase in this ratio of plasma lipids of malnourished children, which was attributed to a moderate EFA deficiency. Koletzko *et al.* (3) found that the plasma lipids of malnourished children showed an EFA deficiency with only a slight rise in the triene/tetraene ratio in TG, but not in PL. These authors concluded that the ratio is not necessarily a reliable indicator of EFA status in protein malnutrition. Some studies on erythrocyte membrane lipids in malnourished children also showed lower proportions of eicosatrienoic acid (20:3n-9). Furthermore, one of these studies (7) showed low levels of linoleic and arachidonic acids in kwashiorkor and or arachidonic alone in marasmus; another study (25) reported lower proportions of arachidonic in the marasmic group than in the kwashiorkor group, and a higher unsaturated/saturated fatty acids (SFA) ratio in the kwashiorkor group than in the control group. These results are inconsistent, which may be due to the different degrees and duration of protein malnutrition and perhaps due to different dietary fat sources. The polyunsaturated/saturated (P/S) ratio was always depressed by protein deficiency in TG and PL of both liver and VLDL

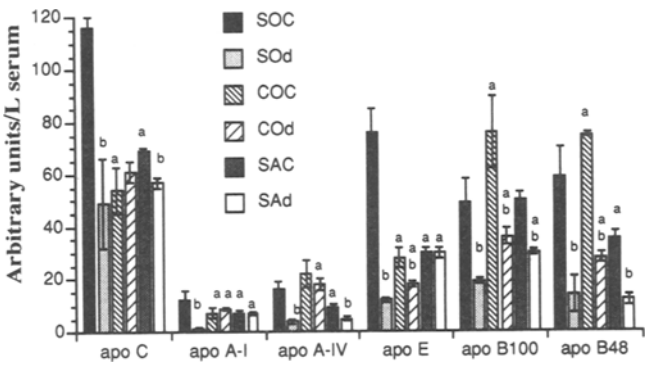

FIG. 1. Very low density lipoprotein-apolipoprotein (apo) distribution in young rats fed protein-deficient diets with coconut (CO) or salmon (SA) oils vs. soybean oil (SO), for 28 d. Values are expressed as arbitrary units (AU)/L. Serum values are means ± SEM for six rats per group. SOC, 20% casein + 5% SO; SOd, 2% casein + 5% SO; COC, 20% casein + 5% CO; COd, 2% casein + 5% CO; SAC, 20% casein + 5% SA; SAd, 2% casein + 5% SA. The level of significance, *P*, was determined by a *t*-test against the corresponding control; a or b indicates values with significant differences from controls with a *P*-value of at least $P < 0.05$; a, CO or SA vs. SO (COC or SAC vs. SOC and COd or SAd vs. SOd); b, 2% vs. 20% casein (COd vs. COC, or SAd vs. SAC, or SOd vs. SOC).

[a]Values are means for six rats ± SEM; abbreviations are as in Tables 1 and 4. [b]*P*-values for CO or SA vs. SO. [c]*P*-values for 2% casein vs. 20% casein. [d]*P*-values for the interaction between oil type effect and protein levels. [e]Polyunsaturated/saturated fatty acid ratio; n.d., not detected; traces, <0.1; NS, nonsignificant.

($P < 0.001$), and the highest ratio was always obtained with the SA diets ($P < 0.001$).

Thus, protein malnutrition does not have the same effects on the fatty acid composition with using the SA diets or the CO diets. In VLDL–PL (Table 7), protein deficiency diminished total monounsaturated fatty acids (MUFA) with the CO diets but raised them with the SA diets. The total amounts of n-6 fatty acids, i.e., 18:2n-6 (not significantly for SAd) and 20:4n-6, were diminished in both liver- and VLDL–PL of rats fed the protein-deficient diets independent of the oil (Tables 5 and 7).

Hill and Holman (4) reported that when CO is fed at various protein levels in the diet, PUFA profiles of liver–PL showed significantly lower amounts of n-6 fatty acids at low levels of protein, except for the amount of 22:4n-6, which was significantly higher. In our study, "protein* oil" interaction was seen in regard to the elongation products of the n-6 (with the CO diets) and n-3 (with the SA diets) series. Low protein levels together with coconut oil lowered the amounts of 22:5n-6 in liver lipids (TG + PL) ($P < 0.001$), but the amounts of 22:5n-6 were elevated in VLDL lipids. In previous studies using young rats, we have shown that in α-linolenic acid deficiency and with adequate linoleate intake, protein deficiency increased the amount of 22:5n-6 in VLDL–PL (26, 27). This fatty acid seemed to be secreted to a greater extent when both protein and n-3 fatty acid deficiencies were present. The increased amount of 22:5n-6 in VLDL could also be attributable to a lower utilization of this acid by tissues other than liver. Similarly, the SAd group showed reduced amounts of total n-3 fatty acids in liver–PL and VLDL–TG, but despite the lower amounts of 20:5n-3, 22:6n-3 was increased in all lipid fractions (interaction protein* salmon oil). We have previously observed the same phenomenon in the PL of liver microsomes from rats fed similar diets (28). The data may indicate that the conversion of EPA to DHA is accelerated by protein malnutrition with the SA diets.

VLDL apo. The CO diets enhanced apo B100, apo B48 and apo A-IV more effectively than either the SO or the SA diets (Fig. 1). Total VLDL-apo were reduced by protein deficiency (Table 3), probably because of reduced synthesis as was also observed by Yagasaki and Kametaka (29) and Meghelli-Bouchenak *et al.* (10). Previous data indicate that the reduced synthesis by liver of VLDL-apo is a cause of impaired hepatic TG export, and thus fatty liver. Apo B and apo C, which are the main apo synthesized by the liver of rats, are particularly depressed by protein deficiency and sunflower oil diets (13–30). In the present work, total VLDL-apo were decreased in rats fed low protein diets independent of the dietary oil. The decline was mainly due to apo B100 and apo B48. Apo A-I was not decreased when feeding CO or SA oils, while all apo were decreased with SO and in protein deficiency. We have shown previously that protein deficiency reduces the half-lives of VLDL-apo and increases their clearance, probably because of increased peripheral uptake by different organs, but not due to a higher uptake by liver (31).

In conclusion, in spite of the short feeding period (28 d) used in the present study, protein malnutrition was shown to accentuate the impairment in PUFA supply, i.e., the P/S ratio was lowered in rats fed the low-protein diets. Yet, dependent on the type of oil used, the magnitude of the observed changes differed. In rats fed 20% casein, the fatty acid profiles of the various lipid fractions better reflected the fatty acid composition of the dietary oils, than in rats fed 2% casein. Protein deficiency severely diminished the amounts of linoleic, arachidonic and EPA acids, but did so to a lesser extent with SA than with CO. Conversely, despite decreased proportions of EPA at low protein levels, DHA remained higher in rats fed the SA diets, whereas in the CO-fed rats, the amount of 22:5n-6 was lower in liver but higher in VLDL lipids at low protein levels. Arachidonic acid and EPA are precursors of prostaglandins, thromboxanes and leukotrienes, and the possible consequences of their diminution due to protein malnutrition may be an underlying cause of some of the common clinical symptoms in kwashiorkor, such as hair loss, dry scaly dermatitis and increased water permeability.

Blood Polyunsaturated Fatty Acids in Patients with Peroxisomal Disorders. A Multicenter Study

Manuela Martinez*, Isabel Mougan, Manuel Roig and **Angel Ballabriga**

Biomedical Research Unit, University Maternity-Children's Hospital, Valle de Hebron, 08035 Barcelona, Spain

The purpose of the study was to compare the polyunsaturated fatty acid (PUFA) status in patients with X-linked adrenoleukodystrophy or adrenomyeloneuropathy (X-ALD/AMN) with that in disorders of peroxisome biogenesis (PB). Total fatty acids and plasmalogens were quantified in plasma and red cells from 28 patients with X-ALD/AMN, 26 patients with generalized peroxisomal disorders, and 37 controls. Total fatty acid methyl esters and plasmalogen dimethyl acetals were obtained by direct transmethylation and separated by capillary column gas chromatography. The results confirm previous findings in that docosahexaenoic acid (DHA, 22:6n-3) was greatly decreased in both plasma and erythrocytes from patients with PB disorders. When nutritional conditions were adequate, patients with X-ALD/AMN had normal levels of DHA. A highly significant positive correlation was found between the levels of DHA and those of plasmalogens in peroxisomal patients. As in other tissues, the parent n-6 fatty acid, linoleic acid (LA, 18:2n-6) was significantly increased in red cells from PB patients, whereas arachidonic acid (20:4n-6) was virtually within normal limits. In clear contrast to red cells and other tissues, arachidonate was significantly lower in plasma from PB patients. The decrease in plasma arachidonate and the high tissue levels of LA suggest a defect of Δ6 desaturase and/or Δ5 desaturase in PB patients. The n-6 fatty acids were normal in X-ALD/AMN patients. The present data show that X-ALD/AMN patients do not have the profound PUFA alterations that PB patients have, at least in blood.

***Lipids* 29, 273–280 (1994).**

Generalized peroxisomal disorders are a group of genetic diseases that are characterized by the absence or by a significant decrease in the number of peroxisomes, particularly in liver and kidney (1). The biogenesis of peroxisomes seems to be defective in these diseases, so that the name "disorders of peroxisome biogenesis" has recently been proposed (2). Various peroxisomal enzyme functions are impaired in this group of disorders. One of the impairments more consistently found is the defective β-oxidation of very long chain fatty acids (VLCFA), i.e., fatty acids with more than 22 carbon atoms, which leads to accumulation in tissues of 24:0, 26:0 and 26:1n-9 (3). Detection of VLCFA in plasma and skin fibroblasts in culture is widely used to diagnose peroxisomal disorders (4,5).

There are also various other functions associated with peroxisomes that are affected in peroxisomal disorders. Plasmalogen synthesis is altered (6) by a defect in dihydroxyacetonephosphate acyltransferase (7). Also, very often accumulation of phytanic acid (8) and bile acid intermediates (9) occurs, and abnormal excretion of dicarboxylic acids is observed (10). Classification of the disease is based on clinical symptoms and on the different enzyme functions that are affected, as well as on complementation analysis (11). The disease prototype, Zellweger's syndrome (ZS), is the most severe form of these disorders (12). In ZS, all peroxisomal functions are defective, and patients are profoundly affected from birth by characteristic craniofacial dysmorphias, hypotony, convulsions, hepatomegaly, mental retardation, and visual and auditory defects. Deterioration is very rapid, and the patients usually die totally demented during their first months of life. Microscopically, liver biopsies show the absence of peroxisomes. Post-mortem examination reveals dysmyelination and neuronal heterotopias.

Milder variants of ZS are neonatal adrenoleukodystrophy (NALD; 13) and infantile Refsum's disease (IRD; 14). However, classification is often arbitrary, and overlap occurs between the different clinical forms. Children with IRD and NALD are less severely affected than those with ZS, and they often live until their second decade. A related disease is X-linked adrenoleukodystrophy (X-ALD; 15). In this disorder, peroxisomes are present and microscopically normal, but β-oxidation of VLCFA is defective (16). The affected reaction seems to be the conversion of VLCFA to the corresponding acyl-CoA esters (17). The onset of the disease is at 5–8 years of age, followed by progressive deterioration of cerebral and motor functions leading to death within a few years. In a variant of X-ALD, adrenomyeloneuropathy (AMN), the spinal cord and the peripheral nervous system are affected (18). The disease does not manifest itself until adulthood, and the clinical symptoms are milder than in X-ALD. AMN patients live for several decades.

Although many studies have been undertaken, and a genetic defect in some X-ALD patients has now been pinpointed (19), the immediate cause of the neurological deterioration in these patients remains unknown. Phytanic acid toxicity has been associated with the adult form of Refsum's disease, but the levels of phytanate in IRD are usually much lower. Thus, much of the damage has been attributed to VLCFA, although these fatty acids are normal components of myelin at lower levels. Also, in patients with another peroxisomal disorder, rhizomelic chondrodysplasia punctata (20), β-oxidation of VLCFA is normal. The lower levels of plasmalogens could be an important factor, since plasmalogens are

Abbreviations: AA, arachidonic acid; AMN, adrenomyeloneuropathy; DHA, docosahexaenoic acid; DMA, dimethyl acetals; EPA, eicosapentaenoic acid; FAME, fatty acid methyl esters; IRD, infantile Refsum's disease; LA, linoleic acid; NALD, neonatal adrenoleukodystrophy; PB, peroxisome biogenesis; PUFA, polyunsaturated fatty acids; RCDP, rhizomelic chondrodysplasia punctata; VLCFA, very long chain fatty acids; X-ALD, X-linked adrenoleukodystrophy; ZS, Zellweger's syndrome.

abundant in the brain, especially in myelin. However, in pseudo-Zellweger's syndrome (21), a variant of ZS due to defective 3-oxoacyl-CoA thiolase (22), plasmalogen levels are normal, although the disease is very similar, and almost as severe as classic ZS.

Recently, a marked deficiency of docosahexaenoic acid (DHA, 22:6n-3) has been observed in brain, retina, liver and kidney from patients with defective peroxisome biogenesis (PB) (23–25). This DHA decrease can also be seen in plasma and erythrocytes (26). DHA is an important component of brain and retinal membrane phospholipids, and its deficiency has been associated with neurological and visual impairment in the rhesus monkey (27), as well as in the human infant (28). A decrease in brain DHA of the magnitude found in patients with defective peroxisomal biogenesis could be responsible for many of the symptoms in these patients. DHA synthesis in rat liver has been shown to occur by β-oxidation of the VLCFA 24:6n-3 (29). If this metabolic route is also prevalent in humans, patients with other β-oxidation defects, such as X-ALD/AMN patients, might also suffer from DHA deficiency (30). It was, therefore, of interest to assess whether DHA deficiency in patients with late onset peroxisomal disorders, such as X-ALD and AMN, was the same as that in patients with early onset disorders of PB. Our study shows that differences exist in polyunsaturated fatty acid (PUFA) composition in red cells and in the plasma of patients with disorders of PB and with X-ALD/AMN. For comparison, the PUFA compositions of omnivore and vegetarian controls are also presented.

MATERIALS AND METHODS

The study included 53 patients of different ages with different forms of peroxisomal disorders. The patients could be subdivided into two major groups. One group consisted of 28 patients with ages ranging from 5 to 44 yr, with X-ALD or AMN. The other group consisted of 25 patients with disorders of PB that ranged from extremely severe to relatively mild; these patients' ages were between 2 mon and 19 yr. All patients in this group had been diagnosed as having ZS, NALD or IRD. About 5 mL of blood was collected under fasting conditions, using ethylenediaminetetraacetic acid as anticoagulant. The sample was shipped on ice by express courier and usually arrived in the laboratory within 48 h of collection. Erythrocytes were separated from plasma and leukocytes on the day of arrival and washed twice with isotonic saline solution. When possible, erythrocytes and plasma were analyzed immediately. Otherwise, the two fractions were stored at 4°C for as short a period of time as possible. Freezing of erythrocytes was avoided since it damages the cell membranes and causes PUFA losses (31), as was confirmed in our laboratory.

Total acyl groups were quantified as methyl esters using 13:0 as internal standard. Plasmalogens were quantified, after conversion of the alkenyl group to the DMA (32) of the corresponding long chain aldehydes (mostly 16:0, 18:0 and 18:1 DMA). Total fatty acid methyl esters (FAME) and long-chain DMA were obtained by direct transmethylation (33) of red cell and plasma lipids with HCl/methanol as described (24). Briefly, 2 mL of methanol/benzene (4:1, vol/vol) containing 100 μg of tridecanoic acid (13:0) was added to 100 μL of plasma or washed red cells in a methanolysis tube (Corning, NY). The tube was vigorously vortexed, while 0.2 mL of acetyl chloride was slowly added. The tube was tightly stoppered and then placed into a heating block (Thermolyne 7600 Dri-Bath, Dubuque, IA) at 100°C for 1 h. After centrifugation at 4,000 rpm for 5 min, an aliquot of the upper phase (2–7 μL) containing FAME and DMA was analyzed by capillary column gas chromatography on a Hewlett-Packard 5890 gas chromatograph (Palo Alto, CA) with a 30 m × 0.25 mm i.d. SP-2330 column (Supelco, Bellefonte, PA). The carrier gas was helium at a column head pressure of 15 psi. Samples were injected at a split ratio of about 50:1, and the column was programmed from 140 to 200°C at 3°C/min. Using this program and separation conditions, all components including VLCFA and PUFA methyl esters as well as plasmalogen DMA were well separated. Injector and detector temperatures were 250°C. Detector response linearity was periodically checked with quantitative standard mixtures; recovery was found to be very good within the whole range of compounds studied.

Peak areas were measured with a Hitachi D-2000 computer-integrator (Hitachi Ltd., Tokyo, Japan), and components were identified by comparison of their retention times with those of pure standards and of mixtures with know composition. Peak assignments were confirmed by mass spectrometry of the DMA, methyl esters and/or picolinyl esters (34) using a Hewlett-Packard 5970B mass selective detector. Spectra were obtained at an ionization potential of 70 eV.

RESULTS

In confirmation of previous studies (23–26), patients with disorders of PB showed a marked decrease in the total concentration of DHA, 22:6n-3 both in plasma (Table 1 and Fig. 1) and in erythrocytes (Table 2 and Fig. 2). An exception was a child, who was only mildly affected neurologically and had virtually normal red cell DHA levels (MR in Fig. 1 and 2). Another child (NE in both figures) had an atypical variant of the disease, without dicarboxylic aciduria and had DHA levels in erythrocytes within normal range. In contrast to patients with PB disorders, all but two X-ALD/AMN patients had normal values of DHA in plasma as well as in red cells. The exceptions were two X-ALD patients (MSG and MC), who were fed by intubation on "elemental diets" (special, easily digestible mixtures used in patients that cannot be nourished normally, and composed of known quantities of purified defined elements, providing the basic nutritional requirements of carbohydrate, protein, fat vitamins and minerals), low in n-3 fatty acids.

The 22:6n-3/22:5n-3 ratio was typically low in PB patients, and normal in X-ALD/AMN patients, in plasma as well as in erythrocytes (Tables 1 and 2). Interestingly, normal and strictly vegetarian Indian children had

[a]These two patients with X-linked adrenoleukodystrophy (X-ALD) were fed on elemental diets by intubation. The others had a more complete diet. The most characteristic fatty acid ratios that are usually altered in peroxisomal patients are displayed in the table. Fatty acids are given in nanomoles per mL of plasma. Grouped data are means ± 1 SD. The range, rather than the mean, is given for oleic and erucic acids, and for the longer derivatives 24:1 and 26:1 and their corresponding ratios to 22:0, because these values are very variable in X-ALD patients treated or not with monounsaturated oil mixtures (glyceryl trioleate/glyceryl trierucate). The same applies to phytanic acid that is very variable with age and diet in peroxisome biogenesis (PB) patients. AMN, adrenomyeloneuropathy.

levels of DHA almost as low as those in PB patients, and the 22:6n-3/22:5n-3 ratio was also reduced, as it was in X-ALD patients fed low PUFA diets. Like DHA, eicosapentaenoic acid (20:5n-3) was low in normal vegetarians, PB and malnourished X-ALD patients, and normal in well-nourished X-ALD/AMN patients.

As for the n-6 series in plasma from PB patients, linoleic acid (LA, 18:2n-6) was just below the normal limit, and arachidonic acid (AA, 20:4n-6) was markedly decreased (Table 1). In contrast to plasma, however, the LA levels in the red cells were significantly increased (Table 2), and AA levels were within normal limits. As found in other tissues (23–25), some n-6 intermediates, such as 20:3n-6 (dihomo-γ-linolenic acid), were slightly increased in red cells of PB patients and were normal in X-ALD/AMN patients, with the exception of the two malnourished children. In plasma from PB patients, AA and 20:3n-6 were both decreased, so that the ratio between the two was not much affected. Like in red cells, the 20:4n-6/18:2n-6 ratio was slightly decreased in the plasma from these patients.

In general, X-ALD/AMN patients had normal levels of both LA and AA in plasma as well as in red cells. The two X-ALD patients kept on elemental diets had low levels of LA, but AA was normal and the ratio between the two remained within normal limits. This was in contrast to PB patients, who had high LA and normal-to-low AA levels, with a 20:4n-6/18:2n-6 ratio close to 1.00 (Table 2). Vegetarian controls also had a high erythrocyte LA concentration, but, unlike PB patients, AA was also high so that a normal 20:4n-6/18:2n-6 ratio was maintained.

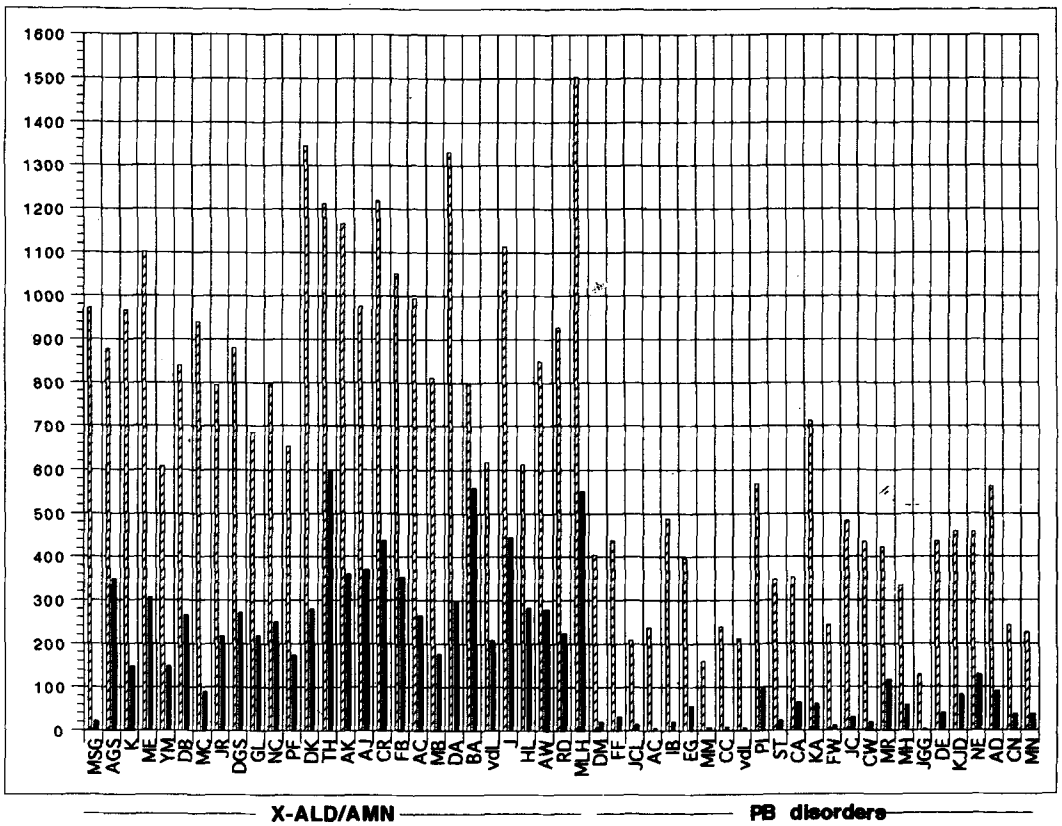

FIG. 1. Bars represent nmol/mL of docosahexaenoic (black bars) (DHA) and arachidonic (striped bars) (AA) acids in plasma of peroxisomal patients. Even with the wide individual variation found in plasma, a clear difference in DHA levels between X-linked adrenoleukodystrophy/ adrenomyeloneuropathy (X-ALD/AMN) patients and generalized peroxisomal patients is seen. The latter have very low DHA values, some are almost undetectable; the X-ALD/AMN patients have in general normal values, although their diets are very low in fat. The exceptions were two patients (first and seventh bar groups, MSG and MC) who were fed very low PUFA diets (see text). Plasma AA levels were also within normal limits in X-ALD/AMN patients and were low in peroxisome biogenesis (PB) patients.

Plasmalogen levels were normal in X-ALD/AMN patients on complete diets but decreased in the two patients on low PUFA diets (Tables 3 and 4). As found in peroxisomal patients under DHA therapy (26), a clear positive correlation was seen between the levels of DHA and those of total plasmalogens (Fig. 3), irrespective of the diagnostic group. Such a clear correlation was not found within the normal population (data not shown). In contrast to malnourished X-ALD/AMN and PB patients, vegetarian controls had normal red cell plasmalogen levels, despite their low blood DHA values (Tables 1 to 4).

DISCUSSION

Our data suggest that important differences exist in PUFA metabolism between patients with so-called defects of PB and those with late onset peroxisomal disorders, such as X-ALD and AMN. The major difference is in the DHA content, which is consistently low in red cells and plasma from patients with generalized peroxisomal disorders, and normal in well-nourished X-ALD/AMN patients. Interestingly, the only two X-ALD/AMN patients who showed DHA deficiency in red cells were the ones who received the "elemental diets" low in PUFA. The importance of nutrition and its effect on red cells PUFA patterns was reemphasized by the fact that normal children nourished on strictly vegetarian diets had levels of DHA almost as low as PB patients. In contrast to normal controls, however, the DHA deficiency was present in patients with defective PB, even when the diet was complete, and it was very pronounced in tissues, including brain and retina (25).

An interesting finding was the significant positive correlation between red cell DHA levels and plasmalogen levels, irrespective of disorders. This is consistent with observations made on monkeys fed fish oil (35) and on peroxisomal patients treated with DHA ethyl ester (26). The basis for such a relationship between DHA and plasmalogens is presently not clear. It has been known for some time, however, that ethanolamine plasmalogens are rich in PUFA (36), and selective reacylation of alkenyl lysophospholipids by DHA has been demonstrated in some cells (37). Therefore, it might be speculated that DHA is preferentially used in plasmalogen synthesis. This could also explain why plasmalogen levels in red cells were lower in some peroxisomal patients

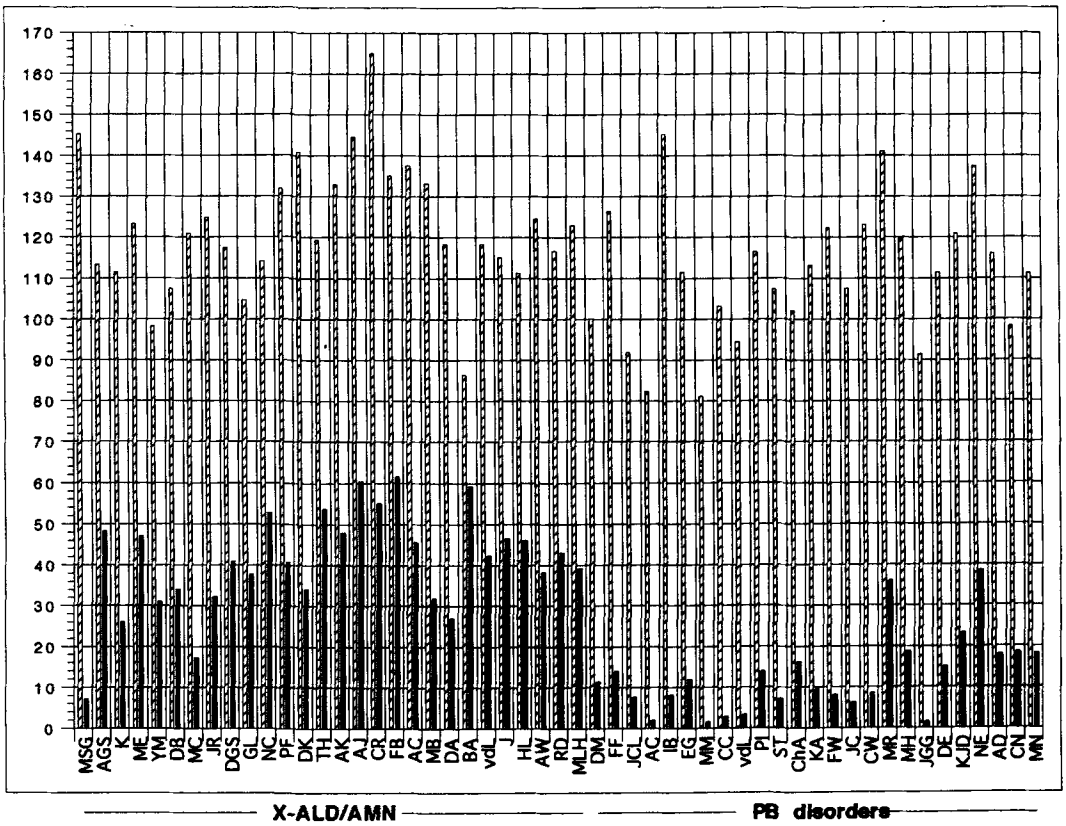

FIG. 2. Bars represent pmol/10^6 cells of docosahexaenoic (black bar) (DHA) and arachidonic (striped bar) (AA) acids in erythrocytes of peroxisomal patients. The red cell levels of DHA are notably low in PB patients, except for two cases (MR and NE) with atypical clinical pictures. In all but two X-ALD/AMN patients, DHA was normal. The two exceptions (MSG and MC) were patients with very low polyunsaturated fatty acid intakes. AA levels are within normal limits in all cases, in X-ALD/AMN as well as in PB patients. See Figure 1 for abbreviations.

while the activity of dihydroxyacetonephosphate acyltransferase in cultured skin fibroblasts was normal (26). The *in vitro* bovine medium, which is relatively rich in n-3 fatty acids, might provide enough substrate for plasmalogen synthesis in the fibroblasts *in vitro*, whereas *in vivo* the low DHA plasma levels seem insufficient to synthesize plasmalogens at a normal rate.

As for n-6 fatty acids, the differences were more subtle. In red cells from PB patients, as in other tissues (23–25), LA was slightly increased and AA was within normal limits; in well-nourished X-ALD/AMN patients, both LA and AA had normal values. An unexpected finding was a significant decrease in AA in plasma of PB patients, which was not detected in any other tissue. This is intriguing, and, together with the increase in LA present in most tissues (23–25), could indicate the possible coexistence of some other enzyme defects, such as low Δ6 or Δ5 desaturase activities. However, since plasma LA was decreased rather than increased, the low levels of AA could be simply due to nutritional deficiency. Peroxisomal patients are usually subjected to very strict diets, virtually devoid of fat and very low in long PUFA. Under these conditions, it does not seem surprising that all AA generated would be utilized for membrane phospholipid synthesis, especially in the brain and retina, with low AA levels remaining in plasma. In any case, it is clear that the AA deficiency, if at all present in tissues, is much less severe than the DHA deficiency, as indicated by the very low DHA/AA ratio in all tissues, including the retina (25). In the brain, in particular, AA was not decreased, and AA even was somewhat increased in ZS, quite in contrast to DHA.

It can be thus concluded that under adequate nutritional conditions X-ALD/AMN does not seem to significantly affect PUFA metabolism, whereas in disorders of PB DHA is consistently decreased; this decrease is clearly seen in erythrocytes. Our present results on red cells from X-ALD/AMN patients do not support the hypothesis that the cause of DHA deficiency in peroxisomal patients is defective β-oxidation of VLCFA (29,30). However, the study of the PUFA patterns in one X-ALD patient showed low brain DHA levels (25). The possibility that there is some defect in brain DHA metabolism that is not reflected in blood cannot be ruled out at the present time, and more X-ALD brains should be studied before drawing any definitive conclusion.

In PB patients, LA is generally high in red cells and in other tissues, but usually low in plasma. AA is within

[a]Patients with X-ALD that were fed on elemental diets by intubation. Fatty acids are given in picomoles per million of cells. Grouped data are means ± 1 SD. The most characteristic fatty acid ratios that are usually altered in peroxisomal patients are shown in the table. The range, rather than the mean, is given for 22:1, 24:1 and 26:1, and for the ratios of the latter two fatty acids to 22:0 because of the wide variation due to diet (see footnote to Table 1). Abbreviations as in Table 1.

the normal range in red cells and low in plasma. In well-nourished X-ALD/AMN patients, these fatty acids are normal, and in vegetarian healthy children both are high. In confirmation of previous studies (38,39), the present results indicate that, in the developing human, nutrition plays an important role even under normal conditions, and that in normal children, as well as in X-ALD and AMN patients, DHA deficiency may be artificially produced by a low n-3 intake. In normal children, however, brain DHA levels are preserved whereas in PB patients they are drastically decreased (23–25). Similarly, insufficient n-6 PUFA intake may also cause insidious arachidonate deficiency in peroxisomal patients, that unlike n-3 deficiency, does not decrease AA tissue levels. Even so, the possibility of a Δ6 and/or Δ5 desaturase defect as a cause of AA deficiency should be further investigated. Although only seen in plasma, it is well possible that suboptimal levels of arachidonate may play some role in the pathogenesis of the disease. Peroxisomal patients do not grow normally, and a correlation has lately been found between the levels of blood AA and growth in preterm human infants (40).

In view of our findings, we believe that it is important to monitor blood PUFA patterns in patients with disorders of PB to detect DHA deficiency early. When DHA deficiency is seen in red blood cells, it would be advisable to provide DHA orally to possibly normalize brain DHA levels in peroxisomal patients. Although DHA ethyl ester is not yet approved as a drug, early clinical trials (made possible thanks to a grant from the National Institutes of Health, Bethesda, MD) have produced promising results (26); other clinical trials with DHA ethyl ester are underway in Europe. As an n-3/n-6 imbalance may exist in peroxisomal patients, it is necessary to closely monitor AA levels, especially when providing DHA, and to increase the dietary AA intake when necessary. Normalization of all PUFA aberrations in peroxisomal patients, at least in blood, would seem to be

TABLE 3

[a]Plasmalogen figures are given in picomoles per million of red cells; (see Table 3 for additional explanations and abbreviation). See Table 1 for other abbreviation.

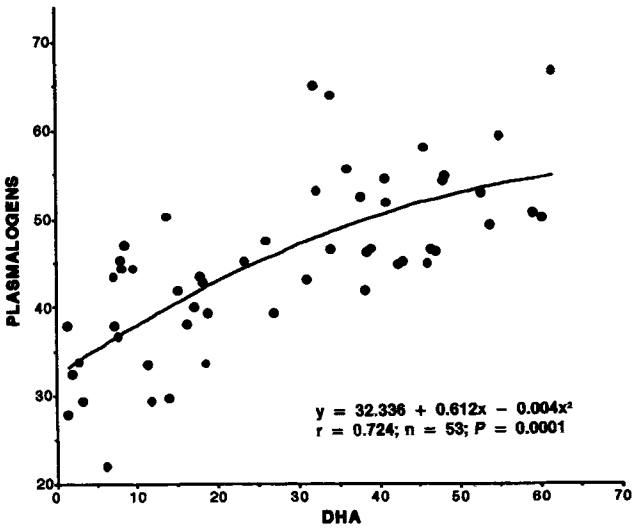

FIG. 3. Total plasmalogens, as measured by gas chromatography of the dimethyl acetals derived from the major aldehydogenic chains (16:0, 18:0 and 18:1), plotted against DHA concentration in red blood cells of patients with peroxisomal disorders. All cases (but not normal controls) are included in this graph, i.e., X-ALD/AMN as well as PB patients (n = 53). Values are pmol/10^6 cells. The parabolic regression line obtained is statistically very significant. See Figure 1 for abbreviations.

an important first step in clarifying the pathogenesis of peroxisomal disorders.

Differential and Interactive Effects of Calcium Channel Blockers and Cholesterol Content of the Diet on Jejunal Uptake of Lipids in Rabbits

D.A. Hyson[a–d], A.B.R. Thomson[a,*] and C.T. Kappagoda[b]

[a]Divisions of Gastroenterology and [b]Cardiology, the [c]Nutrition and Metabolism Research Group and the [d]Surgical-Medical Research Institute, Department of Medicine, University of Alberta, Edmonton, T6G 2C2 Canada

The present study was undertaken to determine the effects of two classes of calcium channel blockers (CCB), nisoldipine (N) and verapamil (V), on the jejunal uptake of lipids in rabbits. The uptake of cholesterol and long-chain fatty acids into rabbit jejunum was examined after 6 and 36 min of exposure to N or V *in vitro* ("acute" studies), and after 3-wk feeding of N or V ("chronic" studies). Animals were fed either a low (0.08%) cholesterol diet (LCD) or a high (2.8%) cholesterol diet (HCD), with or without N or V added. Acute *in vitro* exposure of the jejunum to N or V did not affect the uptake of cholesterol or palmitic acid in rabbits fed LCD or HCD. The effect of N or V feeding depended upon the cholesterol content of the diet; adding N or V to LCD increased cholesterol uptake while adding N or V to HCD enhanced or lowered cholesterol uptake, respectively. Both N and V increased the uptake of stearic acid in LCD. N in HCD had no effect on fatty acid uptake, whereas V lowered the uptake of stearic and linoleic acids and increased the uptake of oleic acid. These changes in lipid uptake were not due to variation in the animals' food intake, body weight gain, or intestinal mucosal surface area. The chronic administration of N or V results in an intestinal adaptive process that alters the jejunal uptake of lipids, the direction of which is influenced by the class of CCB, and by the cholesterol content of the diet. The serum lipid-lowering effect of administering N to rabbits fed HCD demonstrated previously is unlikely to be the result of a decrease in intestinal lipid uptake.
***Lipids* 29, 281–287 (1994).**

Pharmacologic agents that block calcium entry into cells can be chronically administered for the treatment of several disorders, including angina pectoris, hypertension, supraventricular tachycardia and posthemorrhagic cerebral vasospasm (1). In addition, numerous accounts of the potential antiatherogenic effects of these compounds, collectively referred to as calcium channel blockers (CCB), have been published (2–9). Administering CCB to animals fed a high cholesterol diet (HCD) reduces the formation of atherosclerotic lesions by a mechanism that is still unclear. Some, but not all (10–13), studies in humans also suggest a favorable influence of CCB on atherosclerosis. The mechanisms of this action are unknown (14–17).

Abbreviations: ACAT, acyl coenzyme A:cholesterol acyltransferase; CCB, calcium channel blockers; HCD, high cholesterol diet; Isc, short circuit current; LCD, low cholesterol diet; N, nisoldipine; TDC, taurodeoxycholic acid; UWL, unstirred water layer; V, verapamil.

In our previous study using a rabbit model of atherosclerosis, serum total cholesterol levels were reduced by 23–44% in animals administered the CCB nisoldipine (N; oral dose 1 mg/kg), and aortic cholesterol content was also significantly diminished by feeding N (9). Reductions in serum cholesterol levels have been reported by others (5,8,18,19).

Recently, radioligand binding and short circuit current (Isc) studies have suggested the presence of voltage-dependent calcium channels in rabbit ileum (20); the magnitude of the effects may vary with different classes of CCB. The effect of chronic intestinal CCB exposure on lipid uptake processes in the small intestine has not been reported previously. The present study was undertaken to determine whether *in vitro* jejunal lipid uptake is affected by the administration of two different classes of CCB, a 1,4-dihydropyridine, N, and a phenylalkylamine, verapamil (V). The results suggest that a modified intestinal uptake of lipids due to CCB does not represent the mechanism by which N reduces serum and tissue lipid levels in the rabbit.

MATERIALS AND METHODS

Animals. Sixty male New Zealand white rabbits (8–10 wk old, 1.5–2.0 kg) were used in the study. All animals were maintained on Baby Rabbit Pellets (United Feeds, Edmonton, Alberta, Canada) for 1 wk before being assigned randomly to control or to experimental groups. The rabbits were housed individually under identical conditions with controlled lighting and ventilation. Food intake and body weight were monitored, and water was provided *ad libitum*. Blood samples were collected from the marginal ear vein for determination of serum cholesterol, triglyceride and glucose concentrations at the initiation and completion of the treatment period.

Study design. The study was designed to determine whether jejunal uptake *in vitro* was affected by 6 and 36 min *in vitro* ("acute" exposure) and 3-wk feeding ("chronic" exposure) to the dihydropyridine derivative, N, and to the phenylalkylamine, V. Acute effects of N exposure on the jejunal uptake of cholesterol and palmitic acid (16:0) were determined. Chronic effects of N or V on the uptake of cholesterol, stearic acid, oleic acid and linoleic acid were also followed.

Acute experiments. In the acute experiments, one group of twelve animals was maintained on Purina Chow (hereafter referred to as low cholesterol diet or LCD) and a second group of twelve rabbits was fed the same pellets modified to contain 2.8% cholesterol (w/w) (referred to as HCD). The HCD was prepared by adding cholesterol (Sigma Chemical Co., St. Louis, MO) to the

low cholesterol pelleted chow diet. Briefly, 4 kg allotments of chow were thoroughly mixed with 100 g of cholesterol dissolved in 500 mL of diethyl ether (reagent grade; Fisher Scientific Ltd., Fair Lawn, NJ). The prepared food mixture was then spread out on trays and placed in a fume hood to dry for 48 h. The cholesterol content of eight random duplicate samples of the prepared diet was estimated, using a modified Folch's lipid extraction procedure (21,22) and a commercial enzymatic colorimetric test for cholesterol determination (Boehringer Mannheim, Mannheim, Germany), in which the organic layer was reconstituted in isopropanol. The cholesterol content of HCD was 2.8 ± 0.2 (mean ± SEM), and the cholesterol content of LCD was 0.8% (8 mg/kg).

Chronic experiments. For the chronic drug feeding experiments, animals were divided into six groups: LCD; HCD; LCD + N; LCD + V; HCD + N and HCD + V. There were six animals in each of these six groups.

Drug doses and administration. Animals were treated for a period of 3 wk. Solubilized N and V (as described below) were provided orally by syringe feeding at daily doses of 1 mg/kg body weight and 4 mg/kg, respectively. The dose of N was selected to duplicate the model of Senaratne *et al.* (9) and to avoid hemodynamic effects of the drug. A dose of 1 mg/kg N effectively reduces atherosclerosis and is also well below the dose of 20 mg/d, which was previously shown to decrease mean arterial pressure in cholesterol-fed New Zealand white rabbits (6). The V dose of 4 mg/kg was selected to approximate clinical doses used in humans (240–360 mg/d on average for a 70 kg body weight adult) (23), rather than the higher doses used in most animal studies reported (3,4). This dose is also not associated with hemodynamic effects (4).

In preliminary studies, the introduction of aqueous solution by a syringe into the mouth was shown not to influence the effect of cholesterol feeding (Kappagoda, C.T., unpublished observations). Thus, a control vehicle was not used in the present study.

Chemicals. Unlabelled cholesterol and fatty acids were all >99% pure as supplied by Sigma Chemical Co. Taurodeoxycholic acid (TDC) was obtained from Calbiochem Corp. (La Jolla, CA). To measure the intestinal adherent mucosal fluid volume, [^{3}H]inulin (molecular weight approximately 5000) was cited, which was obtained from Amersham Canada Ltd. (Oakville, Canada). The [1-^{14}C]-labelled cholesterol was also obtained from Amersham Canada Ltd., and [1-^{14}C]-labelled palmitic acid, stearic acid, oleic acid and linoleic acid were obtained from New England Nuclear (Boston, MA). All other compounds used (Fisher Scientific Ltd.) were of reagent grade.

N in powdered form (Miles Pharmaceutical Ltd., New Haven, CT) was solubilized in 3.5 mL of 95% ethanol (<1.5% of the final administration volume) and distilled deionized water for oral administration. V (Sigma Chemical Co.) was solubilized in distilled deionized water. The drugs were used at a concentration so that the average quantity of fluid provided daily to achieve the required dose was 0.35 mL. The mean quantity of ethanol received each day by the N administered rabbits was 5.4 µL, which is well below the chronic ethanol levels (approximately 26 mL/d for 6–7 wk) associated with altered uptake of lipids and glucose in rabbit jejunum (24).

Preparation of incubation solutions. Test solutions containing cholesterol or fatty acids were prepared as described previously (25). All fatty acid concentrations in the micellar solutions were 0.1 mM in 20 mM TDC. Cholesterol concentrations of 0.1 mM in both 10 and 20 mM TDC were used. For the acute studies, test solutions were prepared with the addition of N in concentrations ranging from 10^{-8}M to 10^{-4}M. All preparation and experimentation with N was conducted in a darkened room to avoid possible photodegradation of the drug.

Tissue preparation. The rabbits were anesthetized with pentobarbitone sodium (25 mg/kg), and the jejunal segment was quickly removed and rinsed with 150 mL of ice cold saline. A previously-validated method for determining *in vitro* nutrient uptake was used (26). For acute exposure experiments, half of the tissues were preincubated in Krebs-bicarbonate containing N ranging from 10^{-8}M to 10^{-4}M for 30 min while the other half was preincubated in the drug-free Krebs solution for the same time period. The rate of lipid uptake was expressed as nmol of probe taken up into the mucosa per 100 mg dry weight of mucosa (nmol/100 mg mucosa · min^{-1}). The weight of the mucosa as well as the ratio of mucosa/submucosa was determined by scraping the mucosal layer from the underlying layer with a glass slide. Uptake rates were also calculated as nmol of probe taken up per minute per unit serosal surface area.

The morphology of the jejunal tissue was assessed as previously described (27–29).

The values obtained for the different groups of animals are reported as the mean ± SEM of the results from 6–12 animals in each group.

Serum cholesterol and triglyceride determinations. The cholesterol, triglyceride and glucose measurements in the serum were made by use of an automated system (Multistat III; Instrumentation Laboratories, Lexington, KY), which incorporated the methods of Allain *et al.* (30) and Pinter *et al.* (31).

RESULTS

Animal characteristics. The oral administrations of N and V were well tolerated, and there were no deaths or significant adverse events during the 3-wk course of the study. All rabbits consumed the same amount of food, with the exception of the higher food intake in animals fed LCD + N as compared with LCD, yet body weight gain was equal among all groups (Tables 1–3).

As expected, serum cholesterol and triglyceride concentrations were higher in rabbits fed HCD as compared with those fed LCD (Table 1). Adding V to LCD (LCD + V) or HCD (HCD + V) did not significantly affect the lipid levels (Table 2). However, rabbits fed HCD + N (Table 2) had lower serum cholesterol levels (880.6 ± 93.6 mg/dL in animals fed HCD vs. 587.5 ± 22.6 mg/dL in the HCD + N group). Although serum triglyceride levels were lower in animals fed HCD + V vs. those fed

[b]$P < 0.05$ LCD vs. HCD.

HCD (Table 3), this difference was not statistically significant. Serum glucose levels were similar in animals fed LCD or HCD with or without N or V (Tables 2 and 3).

Intestinal morphology. Adding N or V to HCD lowered the dry weight of the jejunum (HCD + N or HCD + V vs. HCD), but adding a CCB to LCD did not affect the weight of the jejunum (Table 4). Because of these differences in jejunal weight, and the lower percentage of the intestinal wall comprised of mucosa in animals fed HCD + V, rates of uptake were expressed on the basis of the dry weight of the mucosa rather than the dry weight of the entire wall of the jejunum.

The jejunal villus height was significantly increased in HCD + N and HCD + V groups as compared to HCD animals not given CCB, but because of adjustments in the dimensions of the width and thickness of the villi, the mucosal surface area was not altered among any of the groups.

Lipid uptake: acute studies. The jejunal uptake of 0.1 mM cholesterol and 0.1 mM palmitic acid (16:0) in 20 mM TDC was unaffected by 6 and 36 min *in vitro* exposure to increasing concentrations (10^{-8}–10^{-4}M) of N (data not shown). No change was observed in rabbits fed either LCD or HCD. The effect of V on the *in vitro* uptake of lipids in animals fed LCD or HCD was not studied.

Lipid uptake: chronic studies. The effect of feeding of N for 3 wk on the jejunal uptake of cholesterol depended upon the ratio of TDC/cholesterol in the test solution (Table 5). When 10 mM TDC was used to solubilize 0.1 mM cholesterol, uptake was increased in both LCD + N and HCD + N groups, as compared to the LCD or HCD groups. In contrast, when 20 mM TDC was used to solubilize cholesterol, cholesterol uptake was reduced in the LCD + N group as compared to that in the LCD group. By comparison, when V was added to LCD, cholesterol uptake increased compared to that in the LCD group, while feeding HCD + V decreased cholesterol uptake compared to HCD alone (Table 6). Thus, adding N or V to LCD increased cholesterol uptake, while V + HCD lowered cholesterol uptake and N + HCD enhanced uptake. Both N and V increased the jejunal uptake of stearic acid (18:0) in LCD. N in HCD had no effect on fatty acid uptake compared to HCD alone, whereas V lowered the uptake of stearic and linoleic acids yet increased the uptake of oleic acid (Tables 5 and 6).

DISCUSSION

Lipid uptake into the jejunum is differentially affected by the two classes of CCB. In addition, the direction of these effects is influenced by the level of cholesterol in the diet. The effects of N or V are likely due to an adaptive process in the intestine occurring over the 3 wk of feeding, because N did not affect cholesterol or palmitic acid uptake when added directly to the incubation medium.

Interestingly, the ratio of cholesterol/TDC used to solubilize cholesterol affected the direction of uptake response in animals administered N but not V. Increasing the ratio of TDC/cholesterol has previously been shown to lower *in vitro* cholesterol uptake, possibly due to reduced partitioning from the micelle to the monomeric phase adjacent to the brush border membrane (25,32). The reduction in cholesterol uptake by N + LCD when

[a]LCD + V, low cholesterol diet plus verapamil; HCD + V, high cholesterol diet plus verapamil. See footnote a in Table 1 for other abbreviations and details. [b]$P < 0.05$ HCD, HCD + V vs. LCD, LCD + V.

solubilized in 20 mM TDC and the enhancement of cholesterol uptake by N + LCD with 10 mM of TDC (Table 5) may have been due to the effect of N on the partitioning of cholesterol from the TDC micelle. This possibility is strengthened by the observation of a variable effect of N in HCD on cholesterol uptake. The directionally similar effects on cholesterol uptake of V in LCD and HCD with 10 and 20 mM TDC may be due to greater intestinal binding of V (20), or to variable degrees of tissue specificity among the CCB (33). In this study, we did not assess the effect of N or V on intestinal uptake of calcium, so we are not able to say whether the influence of CCB on the intestine morphology and function is actually the result of a change in Ca^{2+} flux.

A similar pattern was identified for the uptake of stearic acid; an enhanced uptake of 18:0 was observed in animals fed N or V while on the LCD, but a reduced uptake was found in animals given V while on the HCD. However, not all of the fatty acids behaved in the same manner (Tables 5 and 6). Possible heterogeneity of the uptake of lipids has been suggested based on theoretical considerations (34), and the variable effect of N or V on the mono- or polyunsaturated as compared with the saturated fatty acids would support this view. In addition, however, there were qualitative differences in the effect of N or V on the uptake of fatty acids. Thus, although the mechanisms of the effect of CCB lipid uptake have not been established in this study, the mechanisms appear to vary between these two different classes of drugs.

The differential effects of N and V on the intestine were particularly apparent in the animals fed HCD, and this differential effect has been noted in other tissues. In cholesterol-enriched but not in control-perfused rabbit aorta, V and diltiazem have been shown to antagonize the effect of norepinephrine-stimulated calcium influx (35), and it was suggested that cholesterol enrichment of the plasma membrane may have exposed sites that were otherwise unavailable for binding to the CCB. In our

TABLE 5

Effect of Chronic Oral N Intake (1 mg/kg • d^{-1}) on Jejunal Uptake of Cholesterol and Fatty Acid[a]

Substrate	LCD	LCD + N	HCD	HCD + N
Cholesterol[1]	0.16 ± 0.03	0.08 ± 0.02[b]	0.13 ± 0.02	0.10 ± 0.01
Cholesterol[2]	0.30 ± 0.06	1.01 ± 0.10[b]	0.13 ± 0.02	1.31 ± 0.13[c]
Stearic acid (18:0)	0.30 ± 0.04	0.56 ± 0.11[b]	0.30 ± 0.04	0.46 ± 0.04
Oleic acid (18:1)	0.30 ± 0.04	0.21 ± 0.05	0.24 ± 0.05	0.29 ± 0.05
Linoleic acid (18:2)	0.21 ± 0.03	0.32 ± 0.06	0.42 ± 0.10	0.59 ± 0.08

[a]See Table 2, footnote a, for details and abbreviations. The concentration of cholesterol was either (0.1 mM) in 20 mM taurodeoxycholic acid (cholesterol[1]) or 0.1 mM in 10 mM taurodeoxycholic acid (cholesterol[2]). The concentration of the fatty acids was 0.1 mM in 20 mM taurodeoxycholic acid. The rate of uptake was expressed as nmol/100 mg mucosa • min^{-1}. [b]$P < 0.05$ LCD vs. LCD + N. [c]$P < 0.05$ HCD vs. HCD + N.

cholesterol-fed model, alterations in enterocyte membrane lipid composition achieved by feeding cholesterol (HCD vs. LCD) (36) may affect the binding site for V differently than that of N because different CCB appear to bind to different sites on calcium channel proteins (37).

Several possible mechanisms of intestinal adaptation to various stimuli have been suggested (38,39), including changes in the effective resistance of the unstirred water layer (UWL) or the lipid composition of the brush border membrane (28,29,38,40,41). The effective resistance of the UWL has been reported to decrease in animals fed high-cholesterol diets, and this would be expected to be associated with a higher uptake of lipids (42). In this study, we did not assess the effective resistance of the UWL. However, we did observe a reduced uptake of most lipids in the HCD + V group and no reductions in the HCD + N group (Tables 5 and 6). Thus, it is unlikely that the effect of N or V on cholesterol or fatty acid uptake was due to an effect on UWL resistance. The movements of lipids through the intestinal brush border membrane is believed to be mainly a passive process, although a carrier-mediated component has been suggested for fatty acids and possibly cholesterol (43). The *in vitro* CCB have been associated with the *de novo* synthesis of LDL receptors, suggesting their potential for synthetic activity of membrane-bound proteins (16). We have not assessed the effect of N or V on brush border membrane lipid composition or membrane fatty acid binding protein, so it remains unknown whether the altered membrane permeability might have been due to an effect of N or V on enterocyte lipid metabolism and brush border membrane lipid composition.

In spite of a significant increase in villus height in both the HCD + N and the HCD + V animals, no variations in the mucosal surface area were observed between drug-administered vs. control groups (Table 4). Two-dimensional measurements (villus height and width) of mucosal surface area do not necessarily provide reliable assessments of surface area. For example, in this study the villus density (number of villi/mm^2 serosa) decreased in animals fed HCD + N and HCD + V, countering the increase in villus height, so that the mucosal surface area was unchanged. Thus, the effect of feeding N and V with LCD or HCD cannot be explained on the basis of variations in the intestinal mucosal surface area, nor can the results be explained on the basis of any difference in the animals' body weight gain or food intake (Tables 1–4).

Effects of CCB on intracellular lipid metabolizing enzymes (such as fatty acid desaturase, acylation and deacylation enzymes, or the cholesterol and phospholipid metabolizing enzymes) could alter brush border membrane lipid composition, thereby resulting in altered permeability properties of the membrane (44). A calcium, calmodulin-dependent kinase has been suggested to play a role in the short-term regulation (*via* phosphorylation and concomitant inactivation) of HMG–CoA reductase, the rate-limiting enzyme for cholesterol synthesis (45). Reduced calcium flux might upregulate the expressed activity HMG–CoA reductase by promoting the dephosphorylation of the enzyme. However, if a calcium-dependent step was affected by the presence of

TABLE 6

Effect of Chronic Oral V Intake (4 mg/kg • day^{-1}) on Jejunal Uptake of Cholesterol and Fatty Acid[a]

Substrate	LCD	LCD + V	HCD	HCD + V
Cholesterol[1]	0.35 ± 0.03	0.94 ± 0.11	0.97 ± 0.12	0.36 ± 0.04[c]
Cholesterol[2]	0.53 ± 0.05	1.08 ± 0.15[b]	0.95 ± 0.07	0.41 ± 0.04[c]
Stearic acid (19:0)	0.89 ± 0.07	1.29 ± 0.11[b]	1.60 ± 0.11	0.99 ± 0.05[c]

Linoleic acid (18:2)	1.21 ± 0.12	1.12 ± 0.10	1.95 ± 0.21	1.45 ± 0.12[c]

[a]See Table 3, footnote a, and Table 5, footnote a, for details and abbreviations. [b]$P < 0.05$ LCD vs. LCD + V. [c]$P < 0.05$ HCD vs. HCD + V.

CCB in the enterocyte, both classes of drug would be expected to affect the intracellular synthesis of cholesterol and thereby would have directionally similar effects on the brush border membrane composition of cholesterol. In rat brush border membrane vesicles intraluminal calcium decreased the fluidity by alterations in membrane sphingomyelin content by unknown, presumably indirect, mechanisms (46). In cultured macrophages, CCB inhibit cholesterol esterification (47). The mechanism for this has not yet been defined, but it is apparently independent of the calcium-blockade effect, and could involve a direct effect on the acyl coenzyme A:cholesterol acyltransferase (ACAT) reaction in this tissue. Furthermore, not all classes of CCB showed this inhibitory effect. It is unknown whether a similar effect might apply to the intestine, but clearly alterations in the activity of ACAT also influence the intestinal uptake of cholesterol (48). The upregulated state of ACAT following cholesterol feeding as well as possible differential effects of CCB on this enzyme could account for some of the variable effects noted between CCB and diet effects.

CCB affect Isc measured across the ileal tissue, with V having a quantitatively greater effect than other classes of CCB (20). This change in Isc represents the net effect of calcium channel blockade on the flux of anions and cations from the mucosa to the serosa, and from the serosa to the mucosa. In the presence of CCB, equally enhanced mucosal-to-serosal movement of sodium and chloride exceed serosal-to-mucosal movement of these ions. Residual fluxes (likely bicarbonate ions) and Isc are decreased (49). Removal of sodium from the bulk phase reduces the uptake of fatty acids (43,50), but it is unknown what effect an enhanced mucosal-to-serosal flux of sodium might have on lipid uptake. In cardiac myocytes and peritoneal mast cells, reductions in extracellular calcium increase sodium influx and permeability; these effects are associated with an enhancement of sodium pump (Na^+/K^+-ATPase) activity (51). It is unknown whether calcium plays a role in the physiological control of the intestinal basolateral membrane sodium pump, or whether CCB exert an important effect. There appear to be at least two isoforms of this ATPase in the intestine (52), which could also be differentially affected by cholesterol feeding or by different classes of CCB. CCB in the serosal medium bathing jejunal tissue reduce the magnitude of glucose stimulated Isc in LDC but not in HCD animals (Hyson, D.A., Thomson, A.B.R., Fedorak, A.N., and Kappagoda, C.T., in preparation). However, the variable effect of V on the uptake of the three fatty acids examined in this study suggest that the mechanism cannot likely be explained solely on the basis of altered effects of sodium gradients across the enterocyte.

Studies in rabbit ileal brush border (53) and chicken enterocytes (54) have suggested a role for calcium in regulating the activity of the intestinal Na/H^+ antiporter. Protein kinase C and cAMP mediated inhibition of the activity of the Na/H^+ antiporter was associated with increased cell surface pH in rat jejunal villus cells (55). Although calcium ionophores did not cause a similar inhibition, it is unknown whether altered intracellular calcium levels were achieved; thus, a role for calcium was not ruled out. It is unknown if CCB would enhance Na/H^+ exchange. However, it would be expected that increasing the activity of the antiporter would increase the pH of the acidic microclimate adjacent to the mucosal membrane (56). Since fatty acids would be protonated at a low pH, their solubility in micelles would be reduced, and partitioning into the lipid membrane would be enhanced (57). In this study, both N and V enhanced stearic acid uptake in animals fed LCD, and V increased the uptake of oleic acid in animals given HCD.

Our initial interest of the possible effect of CCB on intestinal lipid uptake was stimulated by the observation of the cholesterol-lowering effects (both in serum and aorta) in animals fed N simultaneously with an HCD (9). This cholesterol-lowering effect of N was clearly not due to a decline in the intestinal uptake of lipids (Table 5). While V reduced the uptake of lipids in animals fed HCD (Table 6), it did not reduce levels of cholesterol in serum (Table 3). Thus, it is likely that the effect of N on cholesterol concentration lies beyond the intestine.

Δ^{22}-β-Muricholic Acid in Monoassociated Rats and Conventional Rats

Takayuki Kayahara[a], Toshihide Tamura[a], Yoshiki Amuro[b], Kazuya Higashino[b], Hirotsune Igimi[c] and Kiyohisa Uchida[c,*]

[a]Department of Bacteriology and [b]3rd Department of Internal Medicine, Hyogo College of Medicine, Nishinomiya 663 and [c]Division of Diagnostics, Shionogi & Co., Ltd., Settsu, Osaka 566, Japan

Bile acids were analyzed in the bile, small and large intestines, and feces of germ-free rats after a single inoculation with one of six intestinal bacteria that had been originally isolated from human feces. *Bacteroides vulgatus* and *Bifidobacterium longum* preferentially deconjugated tauro-β-muricholic acid and taurocholic acid, respectively. *Clostridium ramosum, Peptostreptococcus productus* and *Lactobacillus gasseri* deconjugated both bile acids, but *Escherichia coli* did not deconjugate either one. Rats inoculated with bacteria that deconjugated tauro-β-muricholic acid produced Δ^{22}-β-muricholic acid in the feces. In contrast, Δ^{22}-cholic acid could not be detected in rats inoculated with bacteria that deconjugated taurocholic acid.
***Lipids* 29, 289–296 (1994).**

Intestinal bacteria are known to influence bile acid metabolism (1–3). Deconjugation and desulfation of bile acids have been demonstrated in rats inoculated with a single strain of bacteria (4–6); 7-dehydroxylation, oxidation–reduction and epimerization of bile acids in rats have also been reported (7,8). Recently, Eyssen *et al.* (9) suggested that the side chain of β-muricholic acid might be desaturated in the feces of gnotobiotic rats after a single inoculation with *Eubacterium lentum* that had been isolated from the ceca of conventional rats. Subsequently, this group of investigators also reported the formation of Δ^{22}-β-muricholic acid in the feces of rats after inoculation with *Clostridium* sp. Cl_8 obtained from conventional rats (10).

In the present study we show that desaturation of the side chain of β-muricholic acid (Δ^{22}-β-muricholic acid) occurs upon a single inoculation with predominant bacteria obtained from human feces.

MATERIALS AND METHODS

Determination of tauro-Δ^{22}-β-muricholic acid. Bile acids in bile obtained from conventional rats and germ-free rats were analyzed by high-performance liquid chromatography (HPLC). For this purpose, a Cosmosil $5C_{18}$ column (15 cm × 4.6 mm i.d.; Nakarai Kagaku Co., Kyoto, Japan) was used, and 0.3% ammonium phosphate (pH 7.0)/acetonitrile (20:7, vol/vol) served as mobile phase; the eluent was monitored at 210 nm.

The peak with a relative retention time of 0.36 (peak A) relative to taurocholic acid was detected in bile of conventional rats, while it could not be detected in bile of germ-free rats.

Fraction A was isolated directly from bile of conventional rats by preparative HPLC using a TSK-gel ODS-120T column (25 cm × 2 cm i.d.; Tosoh, Tokyo, Japan) and 0.3% ammonium phosphate (pH 7.0)/acetonitrile (20:8, vol/vol) as mobile phase (monitored at 220 nm) (11). The structure of the compound representing peak A was determined by ^1H and ^{13}C nuclear magnetic resonance (NMR) spectrometry.

^1H NMR spectra were recorded on a Varian XL-400 instrument (Varian, Palo Alto, CA) at 399.950 MHz and ^{13}C NMR spectra on a Varian XL-200 instrument at 50.309 MHz using [$^2H_5$]pyridine as solvent and tetramethylsilane as internal standard (δ_HO and δ_CO). The accuracies of δ_H, J and δ_C were ±0.002 ppm, ±0.3 Hz and ±0.03 ppm, respectively. 2D INADEQUATE (incredible natural abundance double-quantum transfer experiment) ^{13}C NMR spectra were taken with the Varian XL-400 at 100.571 MHz using the CCC2DQ pulse sequence (12,13) of the standard Varian software. The concentration of β-muricholic acid was 498 mg in 1.8 mL of [$^2H_5$]pyridine using a 10-mm sample tube. Fourier transform (FT) conditions were as follows: spectral width, 7936.5 Hz; acquisition time, 0.258 s; pulse delay, 1.5 s; number of transients, 1280; number of free induction decays, 96; conversion time (τ), 6.94 milliseconds (J = 36 Hz). Total experiment time was 60 h. An FT experiment was performed on the 4096 × 2048 matrix with zero-filling in the first domain, and with line-broadening weighting of 40 and 5 Hz, in the first and in the second domain, respectively.

Animals and treatments. Germ-free Wistar male rats (*ca.* 4 months old) bred at Shionogi Aburahi Laboratories (Shiga, Japan) had been housed under germ-free conditions and were monoassociated orally with six strains of bacteria, i.e., *Escherichia coli, Bifidobacterium longum, Bacteroides vulgatus, Clostridium ramosum, Peptostreptococcus productus* and *Lactobacillus gasseri.* These bacteria had originally been isolated from normal human feces, and represented the predominant strain of each group. Each bacterium was cultured for 72 h at 37°C in GAM semifluid medium (Nissui Co., Tokyo, Japan) and then homogenized with a stirrer without access of air. A 1-mL portion of the culture medium containing 10^8–10^9 bacteria/mL was administered to the rats. Conventional rats of the same strain and the same age were also examined.

The rats were fed a commercial diet (Oriental CMF Diet; Oriental Kobo Co., Tokyo, Japan) which had been sterilized by radiation with ^{60}Co (50 KGy). Feces from each rat were collected before inoculation and also each day after inoculation for 6 d. A portion of the feces collected on the last day was utilized to confirm that the

TABLE 1

Fecal Bacterial Count in Monoassociated Rats Six Days After Inoculation

	Inoculated bacterial count log N/mL	Bacterial count log N/g wet weight feces
Escherichia coli	9.1	9.8
Bifidobacterium longum	8.4	9.7
Bacteroides vulgatus	8.4	10.6
Clostridium ramosum	8.6	9.4
Peptostreptococcus productus	8.5	9.7
Lactobacillus gasseri	8.5	9.4

bacterial counts were more than 10^9/g wet weight of feces (Table 1) using the method of Benno *et al.* (14), and the remainder was used for bile acid analysis.

Soon after the final collection of feces, the rats were anesthetized with sodium pentobarbital (50 mg/kg, i.p.), and the bile duct was cannulated with a PE-10 polyethylene tube to collect bile for 30 min, with the rectal temperature being kept at 37°C by means of an electrical heating plate (15). After removing blood from the abdominal aorta to sacrifice the animals, the small intestine and the large intestine, including the cecum, were removed along with their contents.

Bile acid determination. Bile acids were extracted from bile with 20 vol of ethanol at 85–90°C for 10 min. After filtration, a portion of the extract was dried under a stream of nitrogen and subjected to PHP-LH-20 column chromatography (16) to obtain the fractions of free, glycine-conjugated, taurine-conjugated and sulfated bile acids.

The small and large intestinal contents were homogenized with 20 mL of distilled water, and a portion of the homogenates was lyophilized. Bile acids were extracted from the dry preparation with absolute ethanol at 85–90°C for 1 h, and the mixture was filtered. This extraction procedure was repeated three times (17), and the extracts were combined and dried. A solution in 90% ethanol was subjected to PHP-LH-20 column chromatography (16).

The feces were lyophilized and ground in a small mill. Bile acids were extracted from a portion of the feces (usually 0.5 g) by treatment with 15 mL of absolute ethanol at 85–90°C for 1 h, and a filtered solution was obtained (17). The extraction procedures were the same as those used for the intestinal contents.

The fractions obtained after PHP-LH-20 column chromatography were purified on a Sep-Pak C_{18} cartridge (Water Associates, Milford, MA) and then concentrated under reduced pressure (18). The sulfate fraction was subjected to solvolysis (19). The glycine- and taurine-conjugated bile acids were hydrolyzed using cholylglycine hydrolase (EC 3.5.1.24; Sigma, St. Louis, MO) (20), and the deconjugated bile acids were extracted with diethyl ether after acidification with 2 N hydrochloric acid.

The bile acids were methylated with freshly prepared diazomethane and then trifluoroacetylated with trifluoroacetic anhydride (17,21). The bile acid derivatives were quantified by gas–liquid chromatography utilizing a Hewlett Packard (Palo Alto, CA) gas-chromatograph, Model HP5890A, equipped with a hydrogen flame-ionization detector and an HP-7673A autoinjector. A capillary column (15 m × 0.25 mm i.d.) coated with DB-17 (J&W Scientific, Folsom, CA) was used. The column was programmed from 200–280°C at a rate of 5°C/min; the injection port was kept at 280°C, and the detector at 300°C.

RESULTS

Enzymatic hydrolysis of the compound eluted as peak A (compound A) with cholylglycine hydrolase and methylation with diazomethane produced a methyl ester. The ^{1}H NMR spectrum of the methyl ester derived from compound A was quite similar to that of the methyl ester of β-muricholic acid except for two additional signals at δ_H 5.978 (*dd*, J = 15.5 and 0.6 Hz, 23-H) and δ_H 7.080 (*dd*, J = 15.5 and 9.0 Hz, 22-H), as is compared in Table 2. The chemical shifts and couplings (J = 15.5 Hz) of these signals indicate the presence of an *E*-double bond with one hydrogen at the vicinal position. The down-field shifts of the 20-methyl signal (δ_H 1.076, *d*, J = 6.6 Hz, 21-H) and the ester methyl signal (δ_H 3.731, *s*, $COOCH_3$) suggest that the methyl ester of compound A is the methyl ester of β-muricholic acid having an *E*-double bond at C-22 and C-23. The presence of an α, β-unsaturated carboxy ester system is consistent with the observed UV absorption at 214 nm (22). The ^{1}H NMR spectrum of compound A is essentially the same as that of the methyl ester of compound A except for the presence of three signals at δ_H 3.531 (*t*, J = 6.7 Hz, CH_2SO_3H), δ_H 4.332 (*brq*, J = 6.0 Hz, CH_2N), and δ_H 8.705 (*t*, J = 5.8 Hz, NH) and the absence of the ester methyl signal. These three additional signals of compound A can be assigned to the hydrogens of the taurine moiety. Thus, compound A is proposed to be tauro-Δ^{22}-β-muricholic acid.

The ^{13}C NMR spectrum of β-muricholic acid obtained in [$^2H_5$]pyridine has been reported by Kuroki *et al.* (23). We have mostly confirmed the assignments of these signals by 2D INADEQUATE ^{13}C NMR spectroscopy (12,13,24) as shown in Figure 1. In the 2D INADEQUATE spectrum of β-muricholic acid, all connectivities of the carbons were established except for C-1, C-2, C-3 and C-4, whose signal intensity was too low. However, our assignments were not in agreement with those of Kuroki *et al.* (23) with respect to C-14 and C-17.

The ^{13}C NMR signals of the methyl ester of β-muricholic acid were assigned by chemical shift comparisons with β-muricholic acid. The chemical shift changes for C-1 through C-21 of the methyl ester vs. the acid are within 0.24 ppm. The changes for C-22 through C-24 are –0.70, –0.38 and –2.22 ppm, respectively, which are greater due to the methyl esterification (see Ref. 25, and references therein). The methyl ester methoxy signal appears at δ_C 51.25.

The ^{13}C NMR spectrum of the methyl ester of compound A resembles that of the methyl ester of β-muricholic acid except for the signals originating from the side-chain carbons. The ^{13}C NMR signals were assigned based on data reported for a number of bile acids (23;

and Ref. 26 and references therein) and sterols (11, and for example, Ref. 27) and by taking into consideration chemical shift rules (25,28, and references therein) and known solvent effects in [^{2}H]chloroform and [$^{2}H_5$]pyridine (e.g., 28). The chemical shift changes for C-1 through C-16, and for C-18 and C-19, as well as for the methoxy carbon, between the methyl ester of compound A and the methyl ester of β-muricholic acid are within

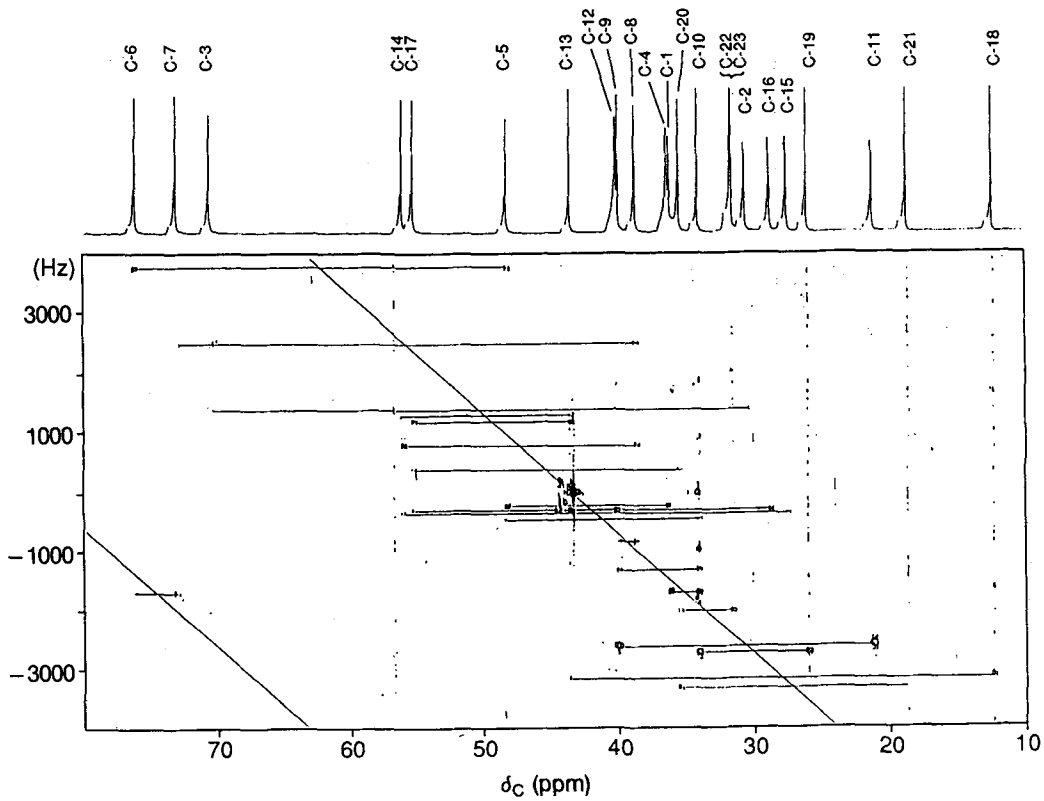

FIG. 1. 2D incredible natural abundance double-quantum transfer experiment spectrum of β-muricholic acid in [$^2H_5$]pyridine (for details, see text).

0.26 ppm. The differences for C-17 and for C-20 through C-24 are −0.82, +4.29, +0.90, +124.19, +87.61 and −7.11 ppm, consistent with the presence of a double bond (11,25,27). The *E* double bond in the methyl ester of compound A is also indicated by the ^1H-^1H spin-spin coupling of 15.5 Hz between 22-H and 23-H in the ^1H spectrum. Based on the data presented here, the methyl ester of compound A is confirmed to be methyl (22-*E*)-3α,6β,7β-trihydroxy-5β-chol-22-en-24-oate.

A comparison of the ^{13}C NMR signals of compound A with those of its methyl ester derivative shows that instead of the ester methyl signal (δ_C 51.24), compound A has two signals at δ_C 36.74 and δ_C 51.65, which are assigned to the two carbons of the taurine moiety. The chemical shift changes for C-22, C-23 and C-24 between the methyl ester of compound A and compound A are −6.90, +3.62 and −0.72 ppm, respectively, which are consistent with a change from an α,β-unsaturated ester to an α,β-unsaturated amide. This confirms that compound A is tauro-(22-*E*)-3α,6β,7β-trihydroxy-5β-chol-22-en-24-oate.

The data in Table 3 give the bile acid components in the feces of germ-free, monoassociated and conventional rats. The fecal bile acids in the germ-free rats were taurine-conjugated, while those in the conventional rats were almost completely deconjugated and only a trace amount of taurine conjugates was detected. *E. coli* did not detectably deconjugate bile acids; however, the other five bacteria caused deconjugation although their activity varied from 8 to 47% deconjugation. The total amounts of fecal bile acids in the germ-free and monoassociated rats were about half those in the conventional rats.

In conventional rats, several secondary bile acids were found in the feces, including deoxycholic, 7-oxo-deoxycholic, 12-oxo-lithocholic, lithocholic, hyodeoxycholic and ω-muricholic acids, in addition to the primary bile acids. In germ-free rats, the fecal bile acids consisted of only the primary bile acids; i.e., mainly cholic and β-muricholic acids and small amounts of chenodeoxycholic and α-muricholic acids. In the monoassociated rats, the pattern of fecal bile acids was almost the same as that in the germ-free rats, except that Δ^{22}-β-muricholic acid was detected in the feces of the rats inoculated with *B. vulgatus, C. ramosum, P. productus* or *L. gasseri* (Table 4).

The bile acid compositions in the large intestine, as shown in Table 5, were very similar to those in the feces. The bile acid compositions of the bile and the small intestine, as shown in Tables 6 and 7, were also very similar to each other. The ratio of cholic acid was high and that of β-muricholic acid was low in the bile and in the small intestine.

The percentages of the deconjugated form of cholic acid, β-muricholic acid and Δ^{22}-β-muricholic acid, in the small intestine, in the large intestine, and in the feces were calculated and are shown in Table 8. No deconjugated bile acid was detected in the bile of all the groups. Deconjugation of bile acid did not occur in the germ-free rats and in the rats inoculated with *E. coli* as reported

earlier (4). Hardly any deconjugated bile acid was found in the small intestine of the monoassociated rats. Most of the deconjugated bile acids were detected in the large intestine and in the feces in the monoassociated rats, except for the rats inoculated with *E. coli*. In the conventional rats, the bile acids were deconjugated (about 30%) even in the small intestine. *Bacteroides vulgatus*, preferentially deconjugated tauro-β-muricholic acid, and *B. longum* deconjugated taurocholic acid. *C. ramosum, P. productus* and *L. gasseri* deconjugated both bile acids.

Δ^{22}-β-Muricholic acid was not formed at all in the germ-free rats and in the monoassociated rats inoculated with *E. coli* and *B. longum*. The rats inoculated with *B. vulgatus, C. ramosum, P. productus* or *L. gasseri* formed Δ^{22}-β-muricholic acid, which was mainly found in the large intestine and in the feces. A small amount of tauro-Δ^{22}-β-muricholic acid was detected in the bile and in the small intestine of rats given a single inoculation of *B. vulgatus, C. ramosum* or *P. productus*. In conventional rats, Δ^{22}-β-muricholic acid was not detected in the large intestine or the feces, but accounted for about 1% of total bile acids in the bile and in the small intestine. Some of the bacterial strains examined in the present study, especially *B. longum, C. ramosum* and *P. productus*, deconjugated taurocholic acid but Δ^{22}-cholic acid could not be detected after treatment with these strains.

DISCUSSION

The present study has shown that Δ^{22}-β-muricholic acid was formed in monoassociated rats inoculated with *B. vulgatus, C. ramosum, P. productus* or *L. gasseri*. It was interesting that these strains of human intestinal bacteria could desaturate β-muricholic acid even though this bile acid is not present in human bile and feces. Its formation seems to be correlated with the deconjugation activity of tauro-β-muricholic acid in feces. *Bacteroides vulgatus* showed the highest activity in the deconjugation of tauro-β-muricholic acid and also showed the highest ratio of Δ^{22}-β-muricholic acid to total bile acid. The germ-free rats and rats monoassociated with *E. coli* did not deconjugate tauro-β-muricholic acid and formed no Δ^{22}-β-muricholic acid. The rats monoassociated with *B. longum* could deconjugate tauro-β-muricholic acid, but the activity was low, and Δ^{22}-β-muricholic acid could not be detected.

Since deconjugation does not occur in the small intestine, Δ^{22}-β-muricholic acid should be formed after deconjugation in the large intestine in the monoassociated rats. Δ^{22}-β-Muricholic acid in the bile and in the small intestine of the monoassociated rats was taurine-conjugated, suggesting that it was absorbed from the large intestine and excreted into the bile after conjugation with taurine in the liver.

In the conventional rats, a small amount of Δ^{22}-β-muricholic acid was found in the bile and in the small intestine. About 30% of tauro-β-muricholic acid had been deconjugated in the small intestine probably because of bacterial upward colonization. This may explain why Δ^{22}-β-muricholic acid was detected in the bile and in the small intestine. Δ^{22}-β-Muricholic acid was not detected in the large intestine or in the feces of conventional rats, even though β-muricholic acid had been completely deconjugated. It is difficult to explain this discrepancy; however, we can presume that the anaerobic conditions in the large intestine would be different between monoassociated and conventional rats. It is also possible that there are other bacteria in the large intestine of conventional rats that can reduce Δ^{22}-β-muricholic acid.

The presence of a monounsaturated β-muricholic acid in rat bile has been reported in several studies (9,10,29,30). Kuriyama *et al.* (31) detected β-muricholic acid with a double bond in the side chain in rat bile by gas chromatography/mass spectrometry (GC/MS). Although *B. vulgatus, C. ramosum, P. productus* and *L. gasseri* did deconjugate tauro-β-muricholic acid and formed Δ^{22}-β-muricholic acid, *B. longum, C. ramosum, P. productus* and *L. gasseri* did deconjugate taurocholic acid but formed no Δ^{22}-cholic acid in our experiments.

Murata *et al.* (32) noted that they could not detect cholic acid with a double bond in the side chain in rat bile by GC/MS analysis. Robben *et al.* (10) also mentioned that they could not find Δ^{22}-cholic acid in rats inoculated with *Clostridium* sp. Cl_8. The results suggest that the mechanism of taurocholic acid deconjugation is different from that of tauro-β-muricholic acid deconjugation. The mechanism by which the double bond is introduced is not known, although desaturation between C-22 and C-23 may be achieved in a manner similar to that which occurs in the β-oxidation of fatty acid via acyl-CoA dehydrogenase.

Deconjugation, 7-dehydroxylation, oxidation–reduction and epimerization activities have all been reported for intestinal bacteria (1–3), but deconjugation activity is most widely found in many bacteria, including *Bacteroides, Bifidobacterium, Clostridium, Eubacterium, Peptostreptococcus, Lactobacillus* and *Streptococcus*. In the present study the deconjugation activity for rat endogenous bile acids was detected in *B. longum, B. vulgatus, C. ramosum, P. productus* and *L. gasseri* but not in *E. coli*. *Bacteroides vulgatus* preferentially deconjugated tauro-β-muricholic acid, and *B. longum* preferentially deconjugated taurocholic acid, while *C. ramosum, P. productus* and *L. gasseri* deconjugated both.

ACKNOWLEDGMENTS

We thank Haruto Takase, Yasuharu Nomura and Yukari Nakamura of the Research & Development Division of Diagnostics, Drs. Yohko Yoshimura, Atsuko Uomori and Shujiro Seo of Research Laboratories, and Hiroyuki Nakao of Aburahi Laboratories, Shionogi & Co., Ltd., for their help and valuable discussions. We also thank Dr. Yoshimi Benno of the Institute of Physical and Chemical Research for furnishing the organisms used. We also thank Keiko Suzumura and Enatsu Komori for help in preparing the manuscript.

The fatty acid composition of phospholipids from the New Caledonian sponge *Cinachyrella* aff. *schulzei* Keller was studied. More than 60 fatty acids were identified as methyl esters and *N*-acyl pyrrolidides by gas chromatography and gas chromatography/mass spectrometry. Two isoprenoid fatty acids also were shown to be present, namely 4,8,12-trimethyltridecanoic and 5,9,13-trimethyltetradecanoic acids. The unusual 6-tetradecenoic, 6-pentadecenoic, 12-nonadecenoic and 26-methylheptacosanoic (*iso*-28:0) acids were found for the first time in sponge phospholipids. A series of six n-7 monoenoic long-chain fatty acids (C_{23} to C_{28}) were identified, including the rare 16-tricosenoic, 18-pentacosenoic and 21-octacosenoic acids. Fifteen fatty acids possessing the typical 5,9 dienoic moiety accounted for 30% of the total fatty acid mixture. Two new fatty acids were identified, namely 5(Z)-octacosenoic and 27-methyl-5(Z),9(Z)-octacosadienoic (*iso*-5,9-29:2). Based on gas chromatography/Fourier transform infrared experiments, the double bonds were assigned the (Z) configuration.
***Lipids* 29, 297–303 (1994).**

Marine sponges are rich sources of long-chain phospholipid fatty acids possessing unique branched or substituted carbon chains probably arising from unique biosynthetic pathways (1–4). Many aspects of sponge phospholipid chemistry and biochemistry have been reviewed by Djerassi and Lam (5). We recently described the phospholipid fatty acid composition of *Cinachyrella alloclada* from the Senegalese coast (6), and have continued our investigations on sponge species belonging to the *Cinachyrella* genus collected in different geographical locations to provide comparative data that also may serve as chemotaxonomic criteria. Some isoprenoid fatty acids have been reported to occur in sponges, especially 4,8,12-trimethyltridecanoic acid (4,8,12-TMTD), which rarely occurs in abundance; however, it amounted to about 20% of total fatty acids in *C. alloclada* and *Spheciospongia vesparium* (6,7). It was in the phospholipids of *C. alloclada* that two different isoprenoid fatty acids were first found, namely the 4,8,12-TMTD (6) and the unusual 5,9,13-trimethyltetradecanoic acid (5,9,13-TMTD). *Iso*- and *anteiso*-saturated long-chain fatty acids are not common in nature, but some have been reported to be associated with sponge phospholipids (8). Straight-chain monoenoic fatty acids with Δ5, Δ6 or Δ8 unsaturation are also not very common in the phospholipids of sponges. Thus, only a few examples of Δ5 monoenoic long-chain fatty acids (LCFA) have been reported (9,10) even though they are known to be intermediates in the biosynthesis of 5,9-dienoic demospongic acids (11,12).

Our search of novel fatty acids in sponge phospholipids is also intended to find potential biosynthetic intermediates of sponge fatty acid metabolism. The biosynthetic route operative in marine sponges involves an elongation process in the n-7 monoenoic series from short-chain homologues, which extends only to C_{26} unsaturated fatty acids (12,13). The Senegalese sponge *Higginsia tethyoides* contains a complete series of such n-7 monoenoic LCFA, but all are α-methoxy-substituted analogues (2). 16-Tricosenoic acid was found first in *C. alloclada* (6). This acid and several other monoenoic LCFA have been found by Carballeira *et al.* (14) in *Amphimedon compressa* and *Mycale laevis*. In this respect, our findings of naturally occurring 23-triacontenoic and 9,23-triacontadienoic acids in *Trikentrion loeve* would seem to be of considerable interest (1), as these acids have been postulated to be intermediates in the biosynthesis of the relatively abundant 5,9,23-triacontatrienoic acid (15). One feature common to many sponge fatty acids is the occurrence of the 5,9-dienoic system in fatty acids, with even and odd long carbon chains. However, very few sponges studied to date have been shown to contain many of these acids (16,17). Brominated demospongic fatty acids are rare and, to our knowledge, only three have been described to date (18,19).

We report here the phospholipid fatty acid composition of the sponge *Cinachyrella* aff. *schulzei* obtained from the lagoon of Noumea, New Caledonia.

EXPERIMENTAL PROCEDURES

Specimens of *Cinachyrella* aff. *schulzei* Keller (1891) (Demospongia, Tetractinomorpha, Spirophorida, Tetillidae) were collected by hand in Canal Woodin, Noumea, New Caledonia, at a depth of 25–30 m in late 1990. The sponge, referenced as MNHN R 1467 New Caledonia, is

Abbreviations: ECL, equivalent chain length; FAME, fatty acid methyl ester(s); GC/MS, gas chromatography/mass spectrometry; GC/FT–IR, gas chromatography/Fourier transform infrared; LCFA, long-chain fatty acid(s); MS, mass spectrum; TLC, thin-layer chromatography; 4,8,12-TMTD, 4,8,12-trimethyltridecanoic acid; 5,9,13-TMTD, 5,9,13-trimethyltetradecanoic acid.

80 × 70 × 60 mm with porocalices 6 × 3 to 13 × 11 mm; its skeleton has an hispidation, 5 mm; sigmaspires, 22 μm; oxeas, 4.3 mm; small oxeas, 200–260 μm; anatriaenes, 5 mm, with studded or knobby clades, 25 μm, or with normal clades, 35–50 μm; protriaenes like anatriaenes; several prodiaenes. A similar species is *C. hirsuta* Dendy (1889).

The sponges were washed in sea water, carefully cleaned, cut into small pieces and lyophilized. Sponge pieces were ground in a Waring blender, using chloroform/methanol (1:1, vol/vol), and steeped twice in this solvent for 24 h (room temperature). The combined extracts yielded the crude total lipids. Phospholipids were separated from other lipids by column chromatography on silica gel (70–230 mesh) using hexane, chloroform, acetone and methanol (phospholipids) as successive eluents. About 55 mg of phospholipids was recovered from 90 g of sponge (dry weight). Phospholipid composition was analyzed by thin-layer chromatography (TLC) using chloroform/methanol/water (65:25:4, by vol) as eluent, and fractions were identified by comparison with phospholipid standards. Phospholipid fatty acids were converted to methyl esters by reaction (30 min under reflux) with methanolic hydrogen chloride (20), and the residue was dissolved in hexane and purified by column chromatography (silica gel; hexane/diethyl ether, 10:1, vol/vol). The resulting methyl esters were analyzed by gas–liquid chromatography using a Carlo Erba 4130 chromatograph (Milano, Italy) and a nonpolar OV-1 silica capillary column (A.M.L.-Chromato, Limoges, France) (25 m × 0.32 mm i.d., 0.40 μm film thickness); hydrogen was used as carrier gas (0.5 bar; split ratio, 5:100). Standard fatty acid methyl esters (from C_{20} to C_{31}) and standard phospholipid samples were purchased from Sigma Chemical Co. (St. Louis, MO). *N*-Acyl pyrrolidide derivatives were prepared by treatment of methyl esters with pyrrolidine/acetic acid (10:1, vol/vol) under reflux (2 h) and were purified by TLC on 0.5-mm layers of silica gel with hexane/diethyl ether (1:2, vol/vol) as developing solvent. Fatty acid methyl esters were hydrogenated by stirring (4 h) at ambient pressure and temperature dissolved in methanol in the presence of catalytic amounts of platinum (IV) oxide (Adam's catalyst). Combined gas chromatography/mass spectrometry (GC/MS) was performed on a Hewlett-Packard HP-5890 instrument linked to an HP 9000/345 integrator (Palo Alto, CA). The GC column was a 0.32 mm × 30 m fused silica capillary column coated with DB-1 (0.25 μm film thickness). The carrier gas was helium. Column temperature was programmed from 180 to 310°C, at 3°C/min, for methyl esters and pyrrolidides.

Gas chromatography/Fourier transform infrared (GC/FT-IR) spectra were measured in Marseille, France, on a 20SxB Nicolet spectrometer (Madison, WI), interfaced with a 5300 Mega Carlo Erba chromatograph (flame-ionization detector additional detection) fitted with an on-column injector. The GC/IR light pipe is a gold-coated borosilicate cylinder (1 mm × 16 cm) with KBr windows. A medium range Hg-Cd-Te liquid-nitrogen cooled detector was used. The GC capillary column was a 60 m × 0.32 mm i.d. fused silica (J & W Scientific, Folsom, CA) coated with DB-1 phase (0.25 μm film thickness). The flow rate of the helium carrier gas (140 kPa) was about 2 mL/min. The column was then directed to the GC/IR light pipe through an inlet stainless steel glass lined transfer line maintained at 300°C. The oven was initially set at 70°C with a 2 min isotherm and then programmed to reach 130°C at 15°C/min, followed by a rate of 15°C/min to reach 290°C, and then maintained at this temperature for 40 min. For the experiment, the light pipe was heated to 293°C. Vapor phase IR spectra were recorded with a resolution of 8 cm^{-1} over the range of 4,000–650 cm^{-1}; 16 data scans were collected, and co-added per data file (2.03 for each spectrum). The IR reconstructed chromatogram was done using the Gram-Schmidt algorithm.

RESULTS

The major phospholipid classes were shown to be phosphatidylethanolamine and phosphatidylserine as judged by TLC analysis. Many of the fatty acids were identified by comparing their equivalent chain length (ECL) values as fatty acid methyl esters (FAME) with those of known compounds and with fatty acids from mixtures of known composition, as well as by co-injection with commercial standards (normal LCFA up to 31:0). Capillary GC analysis of a hydrogenated aliquot also provided information useful for identification (*iso* and *anteiso* compounds) of unsaturated fatty acids. The complete list of phospholipid fatty acids from *C.* aff. *schulzei* is given in Table 1.

LCFA with more than 22 carbons accounted for more than 50% of all acids. The major LCFA were 25-methyl-5,9-hexacosadienoic (*iso*-27:2; 7.2%), 19-hexacosenoic (26:1; 6.8%), 5,9,21-octacosatrienoic (28:3; 5.8%) and 26-methyl-5,9-heptacosadienoic (*iso*-28:2; 3.6%) acids. Unsaturated LCFA comprised about 90% of the total LCFA. Fifteen LCFA containing the 5,9 diene system accounted for 30% of total; this is the greatest number of Δ5,9 dienoic acids found to date in a marine sponge. However, for many acids, GC/MS data on pyrrolidide derivatives were obtained to confirm the structures and to determine the double bond and branching positions (21). The mass spectral data of some of the most interesting fatty acids are as follows:

8-Heptadecenoic acid pyrrolidide. MS *m/z* (rel. intensity), 321 (M^+, 2.0), 292 (1.3), 278 (1.8), 266 (1.5), 264 (2.0), 251 (2.2), 250 (4.4), 249 (3.1), 237 (1.3), 236 (2.9), 223 (1.8), 222 (1.6), 208 (1.5), 196 (0.7), 195 (1.8), 194 (2.2), 182 (4.1), 168 (4.3), 167 (2.0), 155 (2.6), 154 (2.8), 140 (5.7), 126 (39.6), 113 (85.4), 98 (46.5), 70 (45.8), 55 (100).

12-Nonadecenoic acid pyrrolidide. MS *m/z* (rel. intensity), 349 (M^+, 2.0), 334 (0.3), 320 (0.9), 306 (1.6), 292 (1.6), 278 (2.2), 264 (1.8), 252 (0.8), 250 (1.2), 239 (0.9), 238 (1.1), 224 (1.2), 222 (0.9), 210 (1.3), 196 (2.5), 182 (3.1), 168 (3.5), 154 (1.5), 141 (1.4), 140 (4.1), 126 (37.1), 113 (100), 98 (17.6), 70 (37.2), 55 (74.5).

18-Pentacosenoic acid pyrrolidide. MS *m/z* (rel. intensity), 433 (M^+, 3.1), 418 (0.3), 404 (0.8), 390 (1.7), 376 (1.6), 363 (3.5), 362 (3.1), 348 (2.2), 334 (1.2), 322 (1.3),

TABLE 1

Major Phospholipid Fatty Acids from *Cinachyrella* aff. *schulzei*[a]

Fatty acid	Symbol	ECL (FAME)	Abundance (%)
Dodecanoic	12:0	12.00	0.7
Tridecanoic	13:0	13.00	0.5
6-Tetradecenoic[b]	14:1	13.70	0.3
Tetradecanoic	14:0	14.00	2.6
4,8,12-Trimethyltridecanoic	16:0	14.49	8.8
14-Methyltetradecanoic	15:0	14.63	0.5
6-Pentadecenoic[b]	15:1	14.72	0.2
Pentadecanoic	15:0	15.00	0.8
5,9,13-Trimethyltetradecanoic	17:0	15.39	0.5
6-Hexadecenoic	16:1	15.74	0.7
9-Hexadecenoic	16:1	15.79	2.4
Hexadecanoic	16:0	16.00	10.3
10-Methylhexadecanoic	17:0	16.42	0.5
8-Heptadecenoic	17:1	16.82	0.6
Heptadecanoic	17:0	17.00	0.6
9,12-Octadecadienoic	18:2	17.52	0.6
16-Methylheptadecanoic	*i*-18:0	17.66	1.0
9-Octadecenoic	18:1	17.75	2.1
11-Octadecenoic	18:1	17.78	1.6
Octadecanoic	18:0	18.00	6.9
12-Nonadecenoic[b]	19:1	18.84	1.2
Heneicosanoic	21:0	21.00	0.5
Docosanoic	22:0	22.00	0.6
16-Tricosenoic	23.1	22.79	0.3
Tricosanoic	23:0	23.00	0.5
21-Methyltricosanoic	*a*-24:0	23.72	1.1
17-Tetracosenoic	24:1	23.79	2.2
Tetracosanoic	24:0	24.00	0.8
23-Methyl-5,9-tetracosadienoic	*i*-25:2	24.12	0.4
18-Pentacosenoic	25:1	24.81	1.0
24-Methyl-5,9-pentacosadienoic	*i*-26:2	25.08	0.8
5,9-Hexacosadienoic	26:2	25.43	2.6
17-Hexacosenoic	26:1	25.68	2.2
19-Hexacosenoic	26:1	25.79	6.8
Hexacosanoic	26:0	26.00	0.8
25-Methyl-5,9-hexacosadienoic	*i*-27:2	26.06	7.2
24-Methyl-5,9-hexacosadienoic	*a*-27:2	26.17	1.5
5,9-Heptacosadienoic	27:2	26.40	2.3
20-Heptacosenoic	27:1	26.80	0.5
Heptacosanoic	27:0	27.00	0.5
26-Methyl-5,9-heptacosadienoic	*i*-28:2	27.05	3.6
5,9,21-Octacosatrienoic	28:3	27.15	5.8
5,9,23-Octacosatrienoic	28:3	27.25	0.7
5,9-Octacosadienoic	28:2	27.40	2.6

5-Octacosenoic acid pyrrolidide. MS *m/z* (rel. intensity), 476 (MH^+, 1.6), 446 (0.4), 432 (0.3), 431 (0.4), 418 (1.8), 404 (0.4), 390 (0.3), 376 (3.2), 362 (0.4), 348 (0.8), 334 (0.5), 322 (0.5), 320 (0.3), 308 (0.6), 292 (0.7), 278 (1.8), 266 (1.7), 264 (1.4), 252 (1.3), 250 (1.2), 236 (1.7), 222 (1.6), 210 (1.8), 209 (2.9), 208 (2.1), 195 (3.8), 194 (4.5), 180 (2.0), 168 (1.1), 166 (1.4), 152 (7.3), 140 (4.7), 126 (20.9), 113 (67.3), 98 (30.4), 70 (78.4), 55 (100).

21-Octacosenoic acid pyrrolidide. MS *m/z* (rel. intensity), 475 (M^+ 3,4), 446 (0.3), 432 (0.4), 430 (0.5), 418 (1.2), 404 (1.2), 390 (0.6), 376 (0.8), 364 (0.3), 350 (0.5), 340 (0.3), 336 (0.5), 322 (0.6), 308 (1.4), 295 (0.7), 294 (1.0), 280 (2.7), 266 (1.3), 252 (0.7), 238 (0.6), 224 (0.7), 210 (1.3), 198 (1.4), 196 (1.6), 182 (2.2), 180 (2.0), 168 (1.8), 154 (1.6), 140 (3.5), 126 (19.8), 113 (100), 98 (17.5), 70 (30.2), 55 (59.3).

27-Methyl-5,9-octacosadienoic acid pyrrolidide. MS *m/z* (rel. intensity), 487 (M^+, 2.3), 472 (0.8), 444 (1.7), 435 (0.8), 417 (0.8), 375 (1.7), 360 (2.2), 346 (1.8), 318 (1.6), 300 (0.7), 276 (2.5), 262 (2.4), 248 (1.2), 235 (2.2), 234 (1.2), 221 (2.0), 207 (4.6), 192 (2.0), 180 (20.5), 168 (2.5), 166 (2.4), 154 (2.0), 152 (2.4), 140 (5.2), 126 (17.9), 113 (100), 98 (21.8), 85 (12.3), 71 (14.5).

Bromo-5,9-heptacosadienoic acid pyrrolidide. MS *m/z* (rel. intensity), 458 ($[M - Br]^+$, 5.5), 260 (4.2), 258 (4.0), 210 (1.2), 180 (6.3), 126 (8.3), 113 (100), 98 (18.4), 85 (11.6), 72 (23.0), 70 (23.0).

Four homologous series of fatty acids were recognized (Fig. 1) when the retention times of the LCFA (as methyl esters) were plotted vs. the carbon numbers. These were the straight-chain acids, n-7 monoenoic acids, normal Δ5,9 dienoic acids and *iso*-5,9-dienoic acids.

Saturated fatty acids. We readily identified two saturated isoprenoid acids, 4,8,12-TMTD (8.8%) and 5,9,13-TMTD acids (0.5%). GC mobilities and GC/MS data for the methyl esters and pyrrolidides of these compounds were described in a recent paper (6). 26-Methylheptacosanoic acid (*iso*-28:0) was also present (1.2%) and readily identified as its methyl ester. It had an ECL of 27.63, and the molecular ion peak was at *m/z* 438, with additional fragments at *m/z* 74 (base peak), 87 and 395

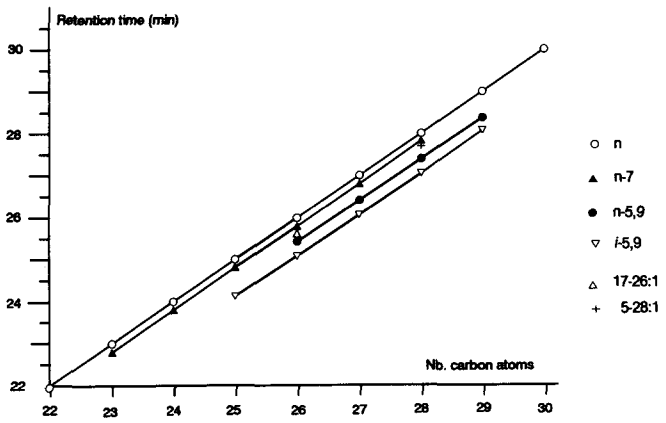

FIG. 1. Plot of retention time (min) vs. number of carbon atoms for four series of fatty acid methyl esters from *Cinachyrella* aff. *schulzei*. The monoenoic acids 5-28:1 and 17-26:1 are located outside the n-7 monoenoic straight line.

(M – 43). The GC peak did not change upon catalytic hydrogenation.

Monoenoic fatty acids. Three interesting monoenoic fatty acids were identified in *C.* aff. *schulzei* (14:1, 15:1, 16:1). Although they were present in small amounts, these acids could readily be identified based on GC mobility and GC/MS data. On the other hand, they were converted to 14:0, 15:0 and 16:0 derivatives, respectively, upon catalytic hydrogenation. Mass spectra of the pyrrolidide derivatives showed the key fragments at m/z 154 and 166 (with a difference of 12 amu occurring between the C-5 and C-6 fragments), clearly indicating Δ6 unsaturation, and molecular ions at m/z 279 (14:1), 293 (15:1) and 307 (16:1), respectively. No diminished homologous fragment was observed, thus excluding branching. Another rare fatty acid identified, namely 8-heptadecenoic acid (0.6%), had an ECL value as methyl ester (FAME) of 16.82 and a molecular ion peak at m/z 282. The mass spectrum of the corresponding pyrrolidide derivative showed a 12 amu difference between peaks m/z 182 and 194 (Δ8 unsaturation). The unusual 12-nonadecenoic acid (1.2%) was readily identified as its methyl ester had an ECL value of 18.84 and a molecular ion peak at m/z 310. Upon catalytic hydrogenation, this compound was converted to the nonadecanoic acid methyl ester. The mass spectrum of the pyrrolidide derivative exhibited a molecular ion peak at m/z 349 and key fragments at m/z 238 and 250 (Δ12 unsaturation). An interesting monoenoic LCFA was found in *C.* aff. *schulzei.* Its methyl ester had an ECL value of 27.75 and a molecular peak at m/z 436, indicating that it was an octacosenoic acid methyl ester. The MS of the pyrrolidide exhibited a molecular ion peak at m/z 476 (MH^+) and key fragments at m/z 140 and 152, indicating desaturation at Δ5 (Fig. 2). This 5-octacosenoic acid (5-28:1, 0.6%) had not been found previously in any natural source.

In addition to the usual 17-tetracosenoic and 19-hexacosenoic acids of the n-7 monoenoic series, we identified the 16-tricosenoic acid that we recently found in *C. alloclada* (6), as well as three other very rare fatty acids lately found for the first time in Caribbean sponges (14) and characterized by GC/MS of the dimethyl disulfide adducts, namely 18-pentacosenoic, 20-heptacosenoic and 21-octacosenoic.

The first acid (18-25:1, 1.0%) showed and ECL value as FAME of 24.81 and a molecular ion peak at m/z 394. It was converted to pentacosanoic acid methyl ester upon catalytic hydrogenation. The mass spectrum of its pyrrolidide showed a molecular peak at m/z 433 and key fragments at m/z 322 and 334, indicating Δ18 unsaturation. We were thus able to identify the 18-pentacosenoic acid previously described to occur in *M. laevis* (14). The second acid, 21–28:1, (0.8%) was identified in the same way; its methyl ester had an ECL value of 27.83 and a molecular peak at m/z 436 and, converted to octacosanoic acid methyl ester upon catalytic hydrogenation, was characterized by comparison with an authentic sample. The MS of its pyrrolidide derivative showed a molecular ion peak at m/z 475 and key fragments at m/z 364 and 376, indicating Δ21 unsaturation. This fatty acid was the 21-octacosenoic acid already identified in *A. compressa* (14). The third fatty acid was identified as a heptacosenoic acid (27:1, 0.5%); its methyl ester had an ECL value of 26.80 and a molecular ion peak at m/z 422. The corresponding peak disappeared upon catalytic hydrogenation. Unfortunately, a suitable MS of the pyrrolidide derivative was not obtained owing to the small amount available and the fact that the spectrum was obscured by fragments derived from the stationary silicone phase. When retention time vs. carbon number was plotted, this compound fell exactly in line with the other n-7 monoenoic FAME (Fig. 1), especially the homologous 19–26:1 and 21–28:1. In Figure 1 the second line includes the heptacosenoic acid in question, but not closely related monoenoic acids, such as 17-hexacosenoic and 5-octacosenoic (as FAME). Thus, the 20-heptacosenoic structure was only tentatively assigned to this fatty acid, which was previously identified in *A. compressa* (14). The FT-IR spectra of the n-7 monoenoic methyl ester (Fig. 3) showed absorptions at 3013 cm^{-1} (stretching frequency of the ethylenic bond) and 703 cm^{-1} (out-of-plane bending vibration) character-

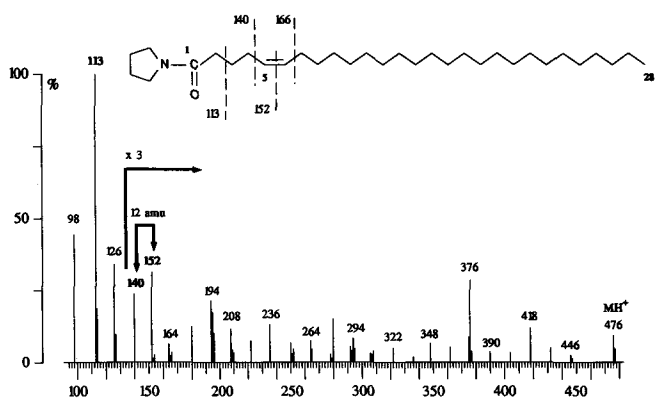

FIG. 2. Mass spectrum of 5-octacosenoic acid pyrrolidide.

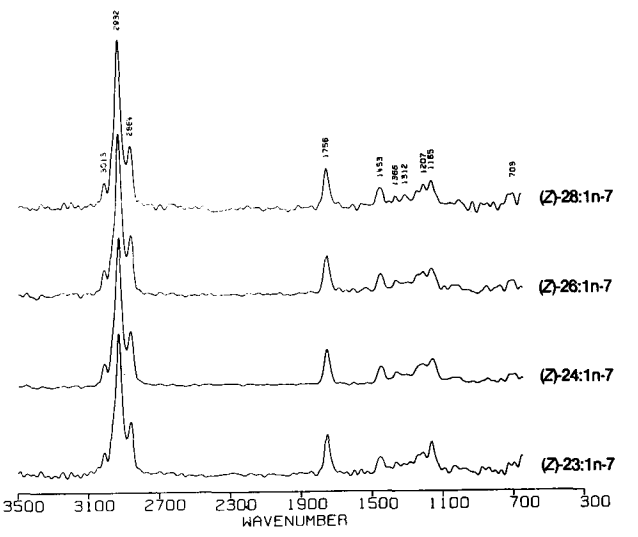

FIG. 3. Gas chromatography/Fourier transform infrared spectra of several n-7 monoenoic fatty acid methyl esters.

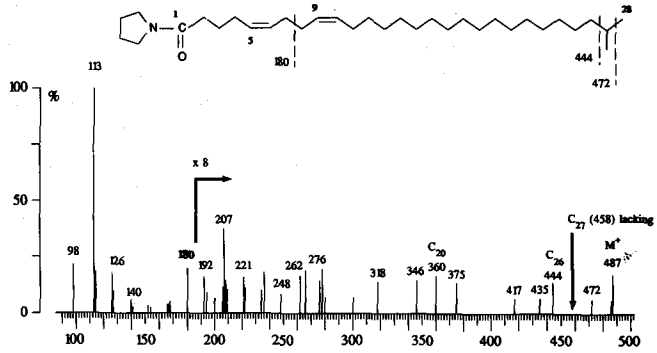

FIG. 4. Mass spectrum of 27-methyl-5,9-octacosadienoic acid pyrrolidide showing the typical fragmentation peak at *m/z* 180 and lack of a peak at *m/z* 458 (C_{27} fragment).

istic of a *cis* configuration (no absorption near 960 cm^{-1}) (22,23).

Long-chain Δ5,9 dienoic fatty acids. One main feature of *C.* aff. *schulzei* is the presence of fifteen long-chain fatty acids possessing typical sponge Δ5,9 unsaturation. This pattern was readily identified (MS), as all these fatty acids afforded the characteristic peaks at *m/z* 81 and 180 as methyl esters and pyrrolidides, respectively. Catalytic hydrogenation yielded the corresponding saturated FAMEs that had a normal *iso* or *anteiso* hydrocarbon chain for the two latter fractional chain lengths of 0.62–0.65 and 0.72–0.75, respectively. Most of them have been already found in sponges. In addition to the rare 23-methyl-5,9-tetracosadienoic acid (24,25), we also identified another compound belonging to the series of *iso*-5,9-dienoic fatty acids for which the MS of the FAME (ECL 28.08) exhibited a molecular ion peak at *m/z* 448, indicating a 29:2 structure. The base peak was the typical peak at *m/z* 81, indicating a 5,9-dienoic structure. This FAME gave the 27-methyloctacosanoic acid methyl ester (*iso*-29:0, ECL 28.64) upon catalytic hydrogenation. The MS of the corresponding pyrrolidide derivative (Fig. 4) showed a molecular ion peak at *m/z* 487 (29:2) and the typical major ion at *m/z* 180 (5,9-29:2). Methyl branching at the C-27 position was indicated by significant peaks at *m/z* 444 (C_{26}) and *m/z* 472 (C_{28}) and by absence of the C_{27} fragment at *m/z* 458. Thus a novel fatty acid was identified, namely 27-methyl-5,9-octacosadienoic (*iso*-5,9-29:2).

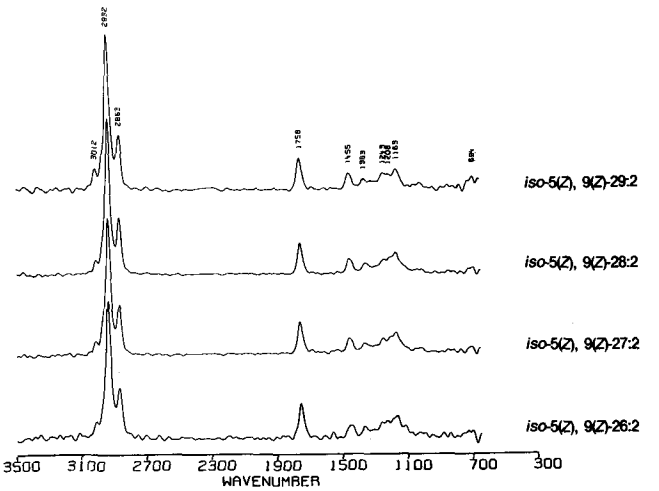

FIG. 5. Gas chromatography/Fourier transform infrared spectra of several *iso*-5,9 long-chain fatty acid methyl esters.

A complete series of *iso*-5,9 long-chain fatty acids (C_{25}–C_{29}) occurs in *C.* aff. *schulzei.* In Figure 5, the double bonds are in *cis* configuration as all infrared spectra exhibited absorptions at 3012 cm^{-1} and 694 cm^{-1} (out-of-plane bending vibration) (22,23). No absorption band was present near 960 cm^{-1}. Finally, it is noteworthy that this novel FAME fell in line with the *iso*-5,9-dienoic methyl esters in Figure 1. Moreover, an interesting 5,9-dienoic fatty acid with an ECL value of 28.18 was also detected. The MS of the methyl ester showed a peak at *m/z* 74 (McLafferty rearrangement) and a major peak at *m/z* 81 characteristic of the 5,9-dienoic moiety. In addition, the MS showed a series of peaks at *m/z* 331, 345, 355, 373 and 404, which closely corresponded to those obtained with the 5,9-heptacosadienoic acid methyl ester (*m/z* 332, 346, 356, 374 and 406). These data suggest the presence of a labile substituent that can be easily lost under electron impact, according to the observations of Lam *et al.* (19). The MS of the pyrrolidide derivative was very simple, with the usual base peak at *m/z* 113 and the typical peak at *m/z* 180, confirming the presence of a 5,9-dienoic pattern. However, the usual series of homologous fragments was absent. There was a significant peak at *m/z* 458 and a doublet of equal intensity at *m/z* 258 and 260, suggesting that the labile substituent was, in fact, a bromine atom. Thus, the double allylic fragmentation between C-7 and C-8 (typical of 5,9-dienoic acid pyrrolidides) gave the usual ion at *m/z* 180 after bromine loss and peaks at *m/z* 258 and 260 with the bromine substituent intact, so that the peak at *m/z* 458 corresponded to the molecular ion peak after bromine loss. These data imply that the point of bromine attachment was between C-2 and C-7. The bromine substituent is at a vinylic position in all known brominated fatty acids (18,19,26), especially in brominated 5,9-dienoic long-chain fatty acids (18,19). Unfortunately, we were unable to identify the precise position of bromine attachment by nuclear magnetic resonance experiments, due to the small amount of sample available. The acid could be identical to the LCFA (5*E*,9*Z*)-6-bromo-5,9-heptacosadienoic recently described in *Petrosia* sp. (27).

Δ5,9 Trienoic LCFA. We identified three Δ5,9-trienoic acids (MS of FAME and *N*-acyl pyrrolidides) already known to occur in sponges, particularly the major one (5.8%), 5,9,21-octacosatrienoic acid, in addition to the common 5,9,23-tricontatrienoic acid. Traces of another tricontatrienoic acid were also detected. This compound was readily identified as methyl ester possessing the typical Δ5,9 unsaturation pattern (ECL 29.20, M^+ at *m/z* 460 and prominent peak at *m/z* 81), but the exact position of the third double bond could not be assigned due to the very small amount of pyrrolidide available.

DISCUSSION

The co-occurrence of two saturated isoprenoid fatty acids in a marine sponge was an interesting finding. It had been previously suggested (7) that it would be unlikely that the two isoprenoid fatty acids would occur in the same sponge. We initially found two such acids, namely 4,8,12-TMTD and 5,9,13-TMTD acids, in the Senegalese sponge *C. alloclada* (6), and two other isoprenoid fatty acids, 4,8,12-trimethyl-13:0 and phytanic acid, have recently been identified in *Dysidea fragilis* (25). It is surprising that *C.* aff. *schulzei*, from a quite different location, also contains these two isoprenoid fatty acids. The former acid is frequently found, though not in all sponges, whereas the latter is a very rare compound identified here only for the second time in a sponge. In addition, all specimens studied of the Senegalese sponge *C. kükenthali*, either from deep or shallow waters, contained both these isoprenoid acids (28). The co-occurrence of these two isoprenoid fatty acids would thus seem to characterize a sponge belonging to the genus *Cinachyrella*. Work is in progress in our laboratory to verify this feature for other *Cinachyrella* species collected from different geographical locations and to elucidate the biosynthetic pathways. The very rare 26-methylheptacosanoic acid (*iso*-28:0) was identified here for the first time in a sponge. It had already been mentioned as a hydrogenation product of *iso*-5,9-28:2 acid found in some sponges (16,17). Only a few natural sources of *iso*-28:0 were previously known, and none was associated with natural phospholipids, although it was recently reported to occur as a minor component of the total lipid fatty acids from sulfate-reducing bacteria (29).

Two unusual monoenoic fatty acid patterns were found in *C.* aff. *schulzei*. The identification of the rare 8-heptadecenoic acid is the second report of this acid in a sponge after its recent identification by Carballeira and Restituyo in *A. complanata* (30). We reported the rare 8-hexadecanoic acid in *C. alloclada* (6). These acids could have a dietary or a symbiotic origin. We also identified small amounts of 6-tetradecenoic, 6-pentadecenoic and 6-hexadecenoic acids. The latter acid had earlier been found in the sponge *A. complanata* (30), but we have not been aware of a report of 6-tetradecenoic and 6-pentadecenoic acids in any marine sponge. The 6-monoenoic acids were recently found to be biomarkers of planktonic input (31). 6-Heptadecenoic and 6-nonadecenoic acids were identified in the marine sponges *Strongylophora durissima* (10) and *Calyx niceaensis* (32), respectively, and 14-methyl-6-pentadecenoic acid was detected in *Tethya aurantia* (33). Several marine organisms, such as turtles (34), sunfish (35), whales (36), sea anemones (37), jellyfish and gorgonians (38), have been shown to contain *trans*- or *cis*-6-hexadecanoic acid. These 6-monoenoic fatty acids may also be of bacterial origin. As previously suggested by Carballeira and Maldonado for *Eurypongia rosea* (39), we think that a Δ6 desaturase may be operative in *C.* aff. *schulzei*.

One of the main findings of the present study is the occurrence in *C.* aff. *schulzei* of a series of n-7 LCFA possessing even- and odd-numbered carbon chains. The odd monoenoic series contains the 12-nonadecenoic, 13-tricosenoic, 18-pentacosenoic and the tentatively assigned 20-heptacosenoic acids. The rare 12-nonadecenoic acid, previously identified from *Thiobacillus* strains (40), is reported here for the first time as being present in sponge phospholipids. In fact, few nonadecenoic acids are known to occur in nature, the most common examples being 9-19:1 and 11-19:1. The 6-nonadecenoic acid was found in sponges (27), and we reported the 13-nonadecenoic acid, probably of bacterial origin, in *C. alloclada* (6). 16-Tricosenoic acid was previously identified in the Senegalese sponge *C. alloclada* (6), together with 10-heptadecenoic acid and an uncharacterized pentacosenoic acid. The 18-pentacosenoic acid described here was already found in *M. laevis* (14). Thus, from *Cinachyrella* sponges, we isolated a complete series of odd n-7 monenoic fatty acids (17–27 carbon atoms) with the exception of 14-21:1, which would also be expected to be present in sponge phospholipids. A complete series of n-7 monoenoic LCFA is known to occur in human brain lipids (41). The phospholipids of the Senegalese sponge *Higginsia tethyoides* (2) contain acids 2-methoxy-18-pentacosenoic, 2-methoxy-20-heptadecenoic and 2-methoxy-21-octacosenoic. This seems to suggest that in *H. tethyoides* methoxyl is introduced in a last step. In addition to the known 17-24:1 and 19-26:1 acids, *C.* aff. *schulzei* was shown to contain the 21-28:1 acid, which was encountered before only in *A. compressa*. The acid was recently synthesized (42). An interesting octacosenoic isomer was also characterized, namely 5-octacosenoic acid, not previously found in a sponge. The co-occurrence of 21-octacosenoic, 5-octacosenoic and 5,9,21-octacosatrienoic acids suggests a role for the first of these acids as a biosynthetic intermediate toward the 5,9,21-octacosatrienoic acid *via* elongation from palmitoleic or vaccenic acid. The 21-28:1 acid was postulated as such an intermediate (43), but in *C.* aff. *schulzei* Δ9 desaturation appears to be the last biosynthetic step. In addition to the well known 5,9,23-30:3, we detected another distinct 30:3 possessing typical Δ5,9 desaturation. As we found both 5,9,21-28:3 and 5,9,23-28:3 acids in *C.* aff. *schulzei*, it is likely, and in accordance with our GC data, that this tricontatrienoic fatty acid is the 5,9,25-30:3 that we recently identified in *T. loeve* (1). Work is in progress in our laboratory on other *Cinachyrella* sponge specimens to identify this new tricontatrienoic acid. Only one of the tricontatrienoic acids has been reported to date in marine sponges, the relatively abundant 5,9,23-30:3 acid. The finding of a brominated demospongic acid also seems of interest. Lam *et al.* (19) recently demonstrated that biological bromination occurs at the final step in the biosynthesis of such fatty acids.

ACKNOWLEDGMENT

We wish to thank Gilbert NOurrisson (CNRS, Laboratoire de Synthèse Organique, Faculté des Sciences, Nates) for GC/MS measurements.

METHOD

A Simple and Precise Method for the Routine Determination of Platelet-Activating Factor in Blood and Urine

Constantinos A. Demopoulos[a,*], Nikolaos K. Andrikopoulos[b] and Smaragdi Antonopoulou[a]

[a]University of Athens, Department of Chemistry, Panepistimioupolis, GR-157 71 Athens and [b]Harokopio University of Home Economics, Department of Dietetics, GR-176 71 Athens, Greece

A simple and precise method is described for the measurement of platelet-activating factor (PAF) in blood and urine. The method involves the isolation of PAF from blood samples by two successive steps. In the first step, blood proteins are precipitated with ethanol and the "free" PAF, i.e., the PAF which is extractable with ethanol, is recovered. In the second step, "bound" PAF, i.e., PAF not extractable with ethanol, is extracted from the protein precipitate with chloroform/methanol/water. The extraction of PAF from urine samples requires only the ethanol extraction step. "Free" and "bound" PAF are then each fractionated by silicic acid column chromatography, and the methanol/water eluent containing PAF is then further fractionated by high-performance liquid chromatography using an isocratic solvent system of acetonitrile/methanol/water. PAF is then quantitated by measuring its ability to induce platelet aggregation in an aggregometer. Application of the method to blood and urine samples from twenty-three healthy volunteers revealed PAF levels in blood of 140–480 pg/mL (630–254.4 pg "free" PAF/mL and 64–225.6 pg "bound" PAF/mL), and of 1.2–4.0 pg PAF/mL in urine. The method overcomes various technical problems and was shown to be very precise. It should prove useful for monitoring PAF levels in various disease conditions.
***Lipids* 29, 305–309 (1994).**

Platelet-activating factor (PAF), i.e., 1-*O*-alkyl-2-acetyl-*sn*-glycero-3-phosphocholine (1–3), is one of the most potent mediators of acute allergic and inflammatory reactions (4). PAF is synthesized and released from a variety of eucaryotic (4,5) and procaryotic (6,7) cells and has been detected in human body fluids (8–11).

To investigate the possible role of PAF in the pathogenesis of various immune complex diseases and systemic allergic reactions, much attention has been paid to the estimation of PAF levels in biological fluids. Differences between PAF levels in normal biological fluids and in samples gathered in several disease states are consistent with the hypothesis that PAF is involved in the pathogenesis of a number of diseases. PAF levels in biological fluids have been investigated in cases of allergic rhinitis (8), allergic reactions induced by drugs (9), post-transfusion reactions (10), gastrointestinal cancer (11), lupus erythematosus (12), allergic inflammation in experimental animals (13), anephric individuals (14), peritoneal inflammation (15) and cirrhosis of the liver (16).

In this type of study, the purification of PAF from other contaminants in the samples examined remains a major difficulty. Incomplete purification of PAF affects PAF analyses and can unpredictably alter the PAF values obtained by up to one or two orders of magnitude. Current methods for the purification of native PAF are based on the extraction with organic solvents and isolation by thin-layer chromatography systems (8,13,14). These procedures are time-consuming, and their success largely depends on the type of tissue studied. Ethanol extraction was found to be advantageous for the isolation of PAF and its precursors from human polymorphonuclear neutrophils, monocytes and lymphocytes (17) as well as from plasma and whole blood (18). In blood, a significant portion of native PAF is known to be bound to lipoproteins. Deproteinization with HCl and a solid-phase purification step have previously been used in the assay of PAF in human polymorphonuclear leukocytes stimulated with ionophor A23187 (19). High-performance liquid chromatography (HPLC) is then commonly used as the final step in the purification of PAF(8–11,17–19).

In an effort to develop a routine method for the assay of PAF, that would be generally applicable, we found that ethanol extraction followed by chloroform/methanol/water extraction when combined with a suitable system of silicic acid column chromatography and semi-preparative HPLC gave precise and highly reproducible results. The present method is simple enough to permit the analysis of large numbers of samples and the separate estimation of native "bound" PAF and "free" PAF. The method may facilitate clarifying the role of PAF in various disorders.

MATERIALS AND METHODS

Samples. Blood and urine samples (5 mL) were collected from twenty-three healthy volunteers. The samples were immediately poured into absolute ethanol and refrigerated.

Materials and reagents. All reagents were of analytical grade and purchased from Merck (Darmstadt, Germany). HPLC solvents were purchased from Rathburn (Walkerburn, Peebleshire, United Kingdom). Lipid standards of HPLC grade were obtained from Supelco (Bellefonte, PA). Semisynthetic PAF and lysoPAF (80% C_{16} PAF and 20% C_{18} PAF) were synthesized in our laboratory as previously described (1). [^{3}H]PAF (NET 910) was

*To whom correspondence should be addressed.

Abbreviations: BSA, bovine serum albumin; HPLC, high-performance liquid chromatography; LPC, lysophosphatidylcholine; LPE, lysophosphatidylethanolamine; PAF, platelet-activating factor, 1-*O*-alkyl-2-acetyl-*sn*-glycero-3-phosphocholine; PC, phosphatidylcholine; PE, phosphatidylethanolamine; SM, sphingomyelin; TLC, thin-layer chromatography.

purchased from NEN (Dupont, Boston, MA). Silicic acid, 35–70 mesh, ASTM 7733 (Merck) was used for column chromatography.

Silicic acid column preparation. The silicic acid was washed with water and methanol and activated overnight at 120°C. The glass column (10 mm i.d.), was slurry-packed (20 cm height) using methanol/water (1:1.5, vol/vol). Lipid samples were applied in 1–2 mL of the same solvents.

Instrumentation. HPLC was done on a Perkin-Elmer Series 3B liquid chromatograph (Norwalk, CT) equipped with a Rheodyne (Berkley, CA) 7105 loop valve injector (175 µL). A Model 551 UV-VIS spectrophotometer (Perkin-Elmer) with a special 8-µL flow microcell was used as detector. The spectrophotometer was connected to a Model 2 integrator (Perkin-Elmer) and a Model 550 recorder (Perkin-Elmer). The cation exchange column used was a SS 10 µm Partisil, 25 cm ¥ 4.6 mm i.d., PXS 10/25 SCX from Whatman (Clifton, NJ). PAF-induced platelet aggregation was measured in a Chrono-Log (Havertown, PA) aggregometer linked to an Omniscribe recorder (Houston, TX). Radioactivity was measured in a 1209 RackBeta-Flexivial β-counter (LKB-Pharmacia, Turku, Finland).

Biological assays. The PAF assay was done by measuring the aggregatory activity toward washed rabbit platelets (1) and by comparing the PAF-induced aggregation and/or [^{3}H]serotonin secretion with that induced by known concentrations of semisynthetic PAF (1).

[^{3}H]PAF estimation. In separate experiments, [^{3}H]PAF was added to several blood samples (5 mL), to test and calibrate the method. Radioactivity was then measured in the eluents from (i) the ethanol extraction, (ii) the silicic acid column and (iii) the HPLC column. In addition, [^{3}H]PAF was also added to some blood samples (5 mL) before the entire procedure was carried out, and remaining radioactivity was measured at the end of the procedure. Samples were dried under a nitrogen stream before radioactivity was measured in the β-counter.

RESULTS

Extraction. Blood samples were poured immediately after collection into 20 mL of absolute ethanol in 50-mL centrifuge glass tubes. After thorough mixing, the tubes were centrifuged at 1,000 ¥ *g* for 20 min. The supernatant containing "free" PAF was collected by decantation. The remaining pellet was mixed with 25 mL of chloroform/methanol/water (1:2:0.8, by vol) and, after thorough swirling, the tubes were centrifuged as above. The supernatant that was collected by decantation contained the "bound" PAF. Appropriate volumes of chloroform and water were then added to both supernatants to arrive at a final chloroform/methanol/water ratio of 1:1:0.9 (by vol) (20). Both chloroform phases were collected separately and evaporated to dryness at 35°C in a flash evaporator. The dry residues were transferred into test tubes using small volumes of chloroform/methanol (1:1, by vol), and the samples were dried under a stream of nitrogen. Urine samples were poured immediately after collection into 20 mL of absolute ethanol in 50-mL glass centrifuge tubes. After thorough mixing, the tubes were centrifuged at 1,000 × *g* for 20 min. The precipitate was discarded, and the supernatant was portioned with chloroform (20). The chloroform phase was dried as described for blood samples.

Silicic acid column chromatography. Each of the extracts was redissolved in 1–2 mL of methanol and applied to a silicic acid column with a 300 mL solvent dispenser. The column was eluted with 45 mL of methanol/water (1:1.5, vol/vol) followed by 50 mL of methanol/water (2:1, vol/vol). The initial 45-mL eluate containing the bulk of protein and other nonlipid components was discarded. The following 50-mL eluates, which contain PAF, were collected and portioned by adding chloroform and methanol to arrive at a final ratio of chloroform/methanol/water of 1:1:0.9 (by vol). The chloroform phase containing PAF and lipid impurities was evaporated to dryness at 35°C in a flash evaporator. The residue was transferred into a test tube using a small volume of chloroform/methanol (1:1, vol/vol) and dried under a stream of nitrogen.

Semi-preparative HPLC. The dry residue obtained in the previous step was redissolved in 50 µL of chloroform/methanol (1:1, vol/vol) and subjected to HPLC *via* the loop injector. The tube was washed with 50 µL of solvent, and the entire sample was injected into the column. PAF and other lipids were isocratically eluted with acetonitrile/methanol/water (300:150:35, by vol) at a flow rate of 1.5 mL per min; detection was at 206 nm. PAF was eluted at 12 min (21). The retention time of PAF is initially determined by starting each series of analyses with the injection of a standard sample containing sphingomyelin (SM) and lysophosphatidylcholine. Using [^{3}H]PAF, it was shown that in our system elution of PAF started at about 60 s after elution (Fig. 1A) and that essentially all radioactivity (98–100%) was recovered within 1.5 mL of eluate. The eluates collected before and after the PAF sample (1.5 mL each) did not cause inhibition of platelet aggregation induced by PAF under standard conditions. Hence, collection of the PAF fraction can begin about 30 s after elution of SM and can be completed after collecting 2–3 mL of eluate to avoid any losses.

Biological assay. The PAF fraction obtained by HPLC was dried down and then redissolved in 100 µL of a solution containing 2.5 mg bovine serum albumin (BSA) per mL saline. For the biological assay, appropriate volumes of the BSA solution were added to the aggregometer cuvettes as described in the Materials and Methods section.

Application of the method to blood and urine samples. Blood samples from ten healthy volunteers and urine samples from five healthy volunteers were used to determine PAF according to the present method. As shown in Table 1, native PAF levels measured ranged from 140–480 pg/mL of blood (63–254.4 pg "free" PAF/mL and 64–225.6 pg "bound" PAF/mL). PAF levels in urine samples ranged from 1.2–4.0 pg/mL of urine as summarized in Table 2.

[^{3}H]PAF recovery. [^{3}H]PAF was added to some blood samples and used internal standard. Recovery of

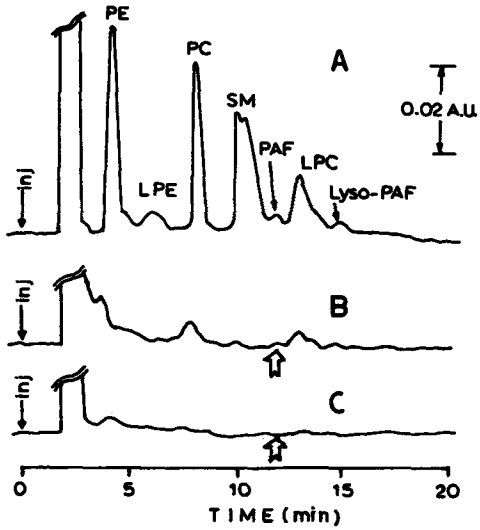

FIG. 1. High-performance liquid chromatography separation of platelet-activating factor (PAF) in biological samples and standards. A, standard lipids, PAF and lyso-PAF. B, a representative chromatogram from a blood sample as obtained either after ethanol extraction of whole blood or chloroform/methanol/water extraction of the ethanolic precipitate and purification by silicic acid column chromatography. C, a representative chromatogram of a urine sample as obtained after ethanol extraction and silicic acid column chromatography. Chromatographic conditions are as described in the text. The open arrows indicate the retention time of PAF as determined by biological assay. Abbreviations: Inj, injection; PE, phosphatidylethanolamine; LPE, lysophosphatidylethanolamine; PC, phosphatidylcholine; SM, sphingomyelin; LPC, lysophosphatidylcholine; a.u., absorbance unit.

radioactivity was 95% in ethanol extracts, 98% after silicic acid column chromatography and 98% after HPLC. The recovery at the end of the entire purification procedure was 96%.

DISCUSSION

Initial ethanol treatment of blood samples was shown to be superior to other extraction procedures as it effectively removes the bulk of protein and dark-colored pigments. As shown by use of [^{3}H]PAF, essentially all the radioactivity is recovered in the ethanol extracts. In addition, ethanol is known to inhibit PAF acetylhydrolase activity of erythrocytes (22). Also, plasma acetylhydrolase is completely inactivated under the present experimental conditions (personal observations). Although 95% of [^{3}H]PAF was recovered in the ethanol extracts, subsequent treatment of the precipitate with chloroform/methanol/water exhaustively extracted the blood samples. This second step alone yielded about 60% of the total PAF from blood samples of healthy individuals (see Table 1), thus indicating the presence of two distinct PAF pools in blood. The ethanol-extractable PAF, which we defined as "free" PAF, is probably loosely bound to serum proteins and lipoproteins (18). It was previously reported (18) that PAF bound to lipoproteins comigrated in HPLC with phosphatidylcholine, while in the present procedure "free" PAF eluted with a retention time equal to that of standard PAF. This would be expected as the silicic acid column chromatographic step and successive evaporation and redilution with polar solvents (chloroform/methanol) prior to HPLC purification would destroy proteolipid-type complexes. The PAF not extractable with ethanol, which we defined as "bound" PAF, may be the PAF strongly bound to lipoproteins and cellular structures and thus may not be quantitatively releasable with ethanol. "Bound" PAF was extracted only with a chloroform/methanol mixture from the ethanol precipitate. PAF co-migrated in HPLC with standard PAF. Initial use of chloroform/methanol/water for extraction of PAF is not recommended as it causes the formation of emulations and other technical problems. The second-step extraction with chloroform/methanol/water was omitted with urine samples since PAF was not detected in the ethanol precipitate. The effectiveness and simplicity of the extraction with ethanol has been well recognized by other investigators (17,18) even though

the presence of PAF in the ethanol precipitate had not been further investigated.

To find appropriate procedures for the purification of PAF, several approaches were tested. Addition of trichloroacetic acid at different concentrations to the ethanol extract failed to precipitate the residual proteins. Tests done with commercially available C_{18} and silica cartridges resulted in the incomplete removal of other lipids from the PAF fraction. Cartridge eluates containing PAF contained large amounts of other lipids, and especially SM, which caused insufficient resolution in the subsequent HPLC step as has also been reported by others (23). When the Sephadex G-25 purification was tested with [^{3}H]PAF as tracer (24), proteins were retained on the column, but [^{3}H]PAF was co-eluted with the total lipids. This led to a serious overload of the HPLC-column, causing insufficient resolution. Although the problem could be overcome by re-chromatography of the Sephadex-eluted lipid fraction on a silicic acid column (10 cm × 1 cm i.d.), which was eluted with methanol/water (2:1, vol/vol), the successive use of two columns made the method less suitable for routine analysis. To avoid the two column purification steps, the effectiveness of a single silicic acid column and the use of three different solvent mixtures containing methanol and water in different proportions was tested. Elution with methanol/water (2:1, vol/vol) caused complete overlap of PAF with nonlipid impurities; with methanol/water (1:1, vol/vol) PAF was eluted just following the nonlipid impurities; and elution with methanol/water (1:1.5, vol/vol) permitted the complete removal of impurities without any PAF losses, but required a significant volume of eluting solvents (220 mL).

Finally, the present method utilizes a silicic acid column and two successive eluting systems. The nonlipid impurities are removed with 45 mL of methanol/water (1:1.5, vol/vol) while PAF is eluted with the next 50 mL of methanol/water (2:1, vol/vol). The bulk of lipids is retained on the column, but can be removed with 40 mL of chloroform/methanol/water (1:2:0.8, by vol). Lipid–phosphorus analyses indicated that the PAF fraction consisted of only 1–2% of total phospholipids.

Several methods for the isolation and purification of PAF have previously been reported. According to Salari (19), proteins were precipitated by adjusting the pH to 5 with 1 M HCl, and PAF was then purified by XAD-2 solid-phase column chromatography. The protein precipitation step was found time-consuming and difficult for routine use. In addition, the protein precipitated with either ethanol/water or by ultracentrifugation would carry along significant amounts of PAF (18). Even more time-consuming and complex are the deproteinization and solid-phase column chromatographic purification steps that are used in PAF-RIA kits by Dupont (Platelet Activating Factor [^{125}I]radioimmunoassay kit NEK-062; NEN). Finally, the receptor-binding method (25) is not suitable for blood samples as has previously been reported (25).

HPLC is used in the present method for the final purification of PAF. The HPLC step has the advantage that PAF can be completely separated from other low-level phospholipids, including lysoPAF (21) (Fig. 1A) and various endogenous PAF inhibitors (26). As shown in Figures 1B and 1C, no significant HPLC peaks could be detected after silicic acid column chromatography. The necessity of the HPLC purification step for the complete purification of the blood samples was shown by comparative analyses, with and without HPLC purification, on ten and seven blood samples, respectively. The results shown in Table 1 indicate that omission of the HPLC purification step for blood extracts leads to PAF values that are almost two orders of magnitude lower than those obtained after HPLC purification. As shown in Table 1, "total" PAF ("free" plus "bound") ranged from 140–480 pg/mL of blood in the samples examined by the present method while 2.2–13.8 pg "total" PAF /mL were measured in blood samples examined without prior HPLC purification. HPLC purification is not required for the analysis of urine samples. The five urine samples examined by the present method were found to contain 1.2–4.0 pg PAF/mL urine, and four other samples gave similar values (4.0–13.8 pg PAF/mL) when examined without prior HPLC purification (Table 2).

The reproducibility of the method was tested by performing four analyses on each of three blood samples. The results shown in Table 3 indicate that the precision of the method is remarkable; standard deviations of the reproducability (SD overall) were less than 1% of the measured values of "free," "bound" and "total" PAF.

TABLE 3

Reproducibility of Native Platelet-Activating Factor (PAF) Assay on Selected Blood Samples[a]

m[b]	Subject number	"Free" PAF (pg/mL)	"Bound" PAF (pg/mL)	"Total" PAF (pg/mL)
1	12	140.3 ± 0.68	205.84 ± 2.5	346.15 ± 2.58
2	13	157.5 ± 1.28	220.5 ± 1.30	378.00 ± 0
3	14	138.2 ± 0.58	192.4 ± 0.94	330.65 ± 1.42
SD overall		0.90	1.72	1.70

[a]The blood samples selected were Nos. 12, 13 and 14 (Table 1); mean values ± SD; n = 4; SD overall = $\sqrt{\frac{\sum SD_i^2}{m}}$, where i = 1, 2, 3 . . . m, and m = 3.

[b]The number of samples.

ARTICLE

Lipid Composition of the Pineal Organ from Rainbow Trout *(Oncorhynchus mykiss)*

R.J. Henderson[a,*], M.V. Bell[a], M.T. Park[a], J.R. Sargent[a] and J. Falcon[b]

[a]N.E.R.C. Unit of Aquatic Biochemistry, Department of Biological and Molecular Science, University of Stirling, Stirling FK9 4LA, Scotland, United Kingdom and [b]Laboratoire de Neurobiologie et de Neuroendocrinologie Cellulaires, URA CNRS 290, Faculte des Sciences, 86022 Poitiers Cedex, France

The lipid composition of the pineal organ from the rainbow trout (*Oncorhynchus mykiss*) was determined to establish whether the involvement of this organ in the control of circadian rhythms is reflected by specific adaptations of lipid composition. Lipid comprised 4.9% of the tissue wet weight and triacylglycerols were the major lipid class present (47% of total lipid). Phosphatidylcholine (PC) was the principal polar lipid, and smaller proportions of other phospholipids and cholesterol were also present. Plasmalogens contributed 11% of the ethanolamine glycerophospholipids (EGP). No cerebrosides were detected. The fatty acid composition of triacylglycerols was generally similar to that of total lipids in which saturated, monounsaturated and polyunsaturated fatty acids (PUFA) were present in almost equal proportions. Each of the polar lipid classes had a specific fatty acid composition. With the exception of phosphatidylinositol (PI), in which 20:4n-6 comprised 27.4% of the total fatty acids, 22:6n-3 was the principal PUFA in all lipid classes. The proportion of 20:5n-3 never exceeded 6.0% of the fatty acids in any lipid class. The predominant molecular species of PC were 16:0/22:6n-3 and 16:0/18:1, which accounted for 33.2 and 28.5%, respectively, of the total molecular species of this phospholipid. Phosphatidylethanolamine (PE) contained the highest level of di-22:6n-3 (13.0%) of any phospholipid. There was also 4.9% of this molecular species in phosphatidylserine (PS) and 4.1% in PC. In PE, the species 16:0/22:6, 18:1/22:6 and 18:0/22:6 totalled 45.1%, while in PS 18:0/22:6 accounted for 43.9% of the total molecular species. The most abundant molecular species of PI was 18:0/20:4n-6 (37.8%). The lipid composition of the pineal organ of trout, and particularly the molecular species composition of PI, is more similar to the composition of the retina than that of the brain.

***Lipids* 29, 311–317 (1994).**

In fish, as in all vertebrates, the retina of the eye and the pineal organ of the brain are essential components of the circadian system that measures the period and phase of the daily light–dark cycle and ultimately controls rhythmic processes (1,2). In keeping with this role, the pineal organ of fish contains photoreceptor cells that display close cyto-functional analogies with the photoreceptors of the retina (3,4). The photoreceptor cells from both tissues translate the light–dark information into a neural output of excitatory neurotransmitter (5) and a neurohormonal output in the form of melatonin (3). In addition to being multimessenger cells, the photoreceptor cells of the pineal organ are also multieffectors and can transduce information supplied by other eternal (such as temperature) or internal (catechol-amines, adenosine, steroids) factors. Whereas retinal melatonin acts preferentially in an autocrine/paracrine manner, the melatonin secreted by the pineal contributes largely to the circulating levels and may be involved in the control of seasonal events, particularly reproduction, in vertebrates (3,6–8).

The structural phospholipids of the retina and brain of vertebrates, including fish, are known to contain high levels of the polyunsaturated fatty acid (PUFA) 22:6n-3 (9,10). Within the retina, the 22:6n-3 is apparently concentrated in the membranous outer segments of the photoreceptor rod cells (11), and these cells isolated from frog retina exhibit a selective uptake of 22:6n-3 *in vitro* (12). A requirement for 22:6n-3 in the visual process has been demonstrated in studies with newborn primates and preterm human infants, which have shown that the visual acuity is affected by deprivation of 22:6n-3 during postnatal development of the infant (13). Peroxidation of 22:6n-3 is one of the primary events observed in inherited or traumatically induced photoreceptor degeneration (9,14).

Di-22:6n-3 phospholipids are known to be major components of rod outer segment membranes in frog and rat (15,16). Recent analyses of the phospholipids of the brain and retina of trout and cod have shown that di-22:6n-3 molecular species are major constituents of phosphatidylcholine (PC), phosphatidylethanolamine (PE) and phosphatidylserine (PS) in these tissues and that this is particularly true of the retina, where the amounts are considerably higher than those found in terrestrial mammals (17,18). The importance of 22:6n-3 in the visual process of fish is also indicated by the observation that the proportion of di-22:6n-3 in the phospholipid of the developing eyes of herring larvae increases with age as the rods are recruited into the photoreceptor population (19). The results of these nutritional studies and the presence of large amounts of di-22:6 phospholipid in the photoreceptors of the retina suggest that 22:6n-3 has an essential and unique role in the primary events associated with the absorption and transduction of photons. This might be of crucial importance for the photoperiodic control of the production of messages, such as melatonin.

Abbreviations: EGP, ethanolamine glycerophospholipids; HPLC, high-performance liquid chromatography; HPTLC, high-performance thin-layer chromatography; PC, phosphatidylcholine; PE, phosphatidylethanolamine; PG, phosphatidylglycerol; PI, phosphatidylinositol; PS, phosphatidylserine; PUFA, polyunsaturated fatty acids; SM, sphingomyelin; TAG, triacylglycerols. Molecular species are abbreviated as follows: e.g., 16:0/22:6 PC is 1-palmitoyl-2-docosahexaenoyl-*sn*-glycero-3-phosphocholine.

By analogy with the retina, it is probable that 22:6n-3 is a major PUFA of the lipids in the photoreceptor cells of the fish pineal organ. To examine this hypothesis, we determined in the present study the detailed lipid composition of the trout pineal with particular attention to the PUFA content and molecular species of phospholipids. As far as we are aware, the detailed lipid composition of the pineal organ from fish has not been reported previously and only a limited amount of information is available on the lipids of the organ from mammals (20,21). Information gained from the analysis of the trout pineal organ is of basic importance as mammalian pinealocytes are accepted as being phylogenetically derived from the fish pineal photoreceptor cells (2).

MATERIALS AND METHODS

Fish and pineal organs. Rainbow trout (*Oncorhynchus mykiss*) of average weight 800 g were obtained from a commercial fish farm (Pisciculture Bellet, Angouleme, France) where they had been maintained under natural conditions of water temperature and photoperiod. One hundred fish were killed by decapitation. Pineal organs were removed immediately from the fish, frozen in liquid nitrogen and stored at –80°C until taken for analysis.

Chemicals and solvents. Phospholipase C from *Bacillus cereus* was purchased from Boehringer Corporation (London) Ltd. (Lewes, East Sussex, England). Oxalyl chloride and anthracene 9-carboxylic acid were supplied by Aldrich Chemical Co. (Gillingham, Dorset, England). All other chemicals and biochemicals were purchased from Sigma (Poole, Dorset, England), and solvents of high-performance liquid chromatography (HPLC) grade were obtained from Rathburn Chemicals (Walkerburn, Peeblesshire, Scotland).

Lipid extraction and analysis. After thawing, the pineal organs were weighed and transferred to a Teflon-in-glass homogenizer. The organs were homogenized in 37 mL of chloroform/methanol (2:1, vol/vol) essentially as described by Christie (22) to extract lipids. Solvent was removed under a stream of nitrogen and the resulting lipid extract desiccated overnight under vacuum in a preweighed tube. The tube and contents were then reweighed to obtain the weight of the lipid extract which was redissolved in chloroform/methanol (2:1, vol/vol) and stored under an atmosphere of nitrogen at –70°C between analyses.

To establish the lipid class composition, aliquots of lipid extract were subjected to high-performance thin-layer chromatography (HPTLC) alongside authentic standards using hexane/diethyl ether/glacial acetic acid (80:20:2, by vol) as the developing solvent for the separation of neutral lipid classes and methyl acetate/propan-2-ol/chloroform/methanol/0.25% (wt/vol) aq. KCl (25:25:25:10:9, by vol) for the separation of polar lipids. To confirm which polar lipid classes were present, aliquots of total lipid were also subjected to two-dimensional HPTLC. The polar lipid developing solvent system described previously was used for development in the first dimension and chloroform/acetone/methanol/acetic acid/water (10:4:2:2:1, by vol) was employed for development in the second dimension. Developed chromatograms were visualized with copper acetate in phosphoric acid (23). Lipid class composition was quantitated by double-development HPTLC coupled with scanning densitometry, as described elsewhere (24). Estimates of the relative amounts of the plasmalogen and the diacyl forms of ethanolamine glycerophospholipids (EGP) were obtained by acid hydrolysis of the isolated EGP *in situ* on an HPTLC plate followed by chromatography and quantitative phosphate staining as described by Bell and Dick (25).

For the analysis of fatty acid composition, individual lipid classes were separated by two-dimensional TLC on 20 × 20 cm glass plates coated with silica gel G 60 (0.25 mm thick) using the solvent systems described here. The separated classes were visualized by spraying the chromatogram with 0.1% 2′,7′-dichlorofluorescein in methanol containing 0.01% butylated hydroxytoluene and by viewing under ultraviolet light. Triacylglycerols (TAGs) were purified by redeveloping the chromatogram in the reverse direction of the second development using hexane/diethyl ether/glacial acetic acid (80:20:2, by vol) after removal of the individual polar lipid classes. The fatty acids of the separated lipid classes were converted to their methyl esters on the adsorbent by acid-catalyzed transesterification (22). An aliquot of total lipid was also subjected to the same procedure. The resulting fatty acid methyl esters were purified by HPTLC and recovered from the adsorbent with hexane/diethyl ether (1:1, vol/vol).

Fatty acid methyl esters were analyzed on a Packard 439 gas chromatograph equipped with a fused silica capillary column (50 m × 0.22 mm i.d.) coated with FFAP phase (S.G.E., Milton Keynes, United Kingdom). Sample application was by on-column injection, and hydrogen was used as the carrier gas. During the course of an analysis, the oven temperature was programmed to increase from 50 to 225°C. Samples were also analyzed using an Omegawax 250 fused silica column (30 m × 0.25 mm i.d., Supelchem U.K. Ltd., Essex, United Kingdom) with the oven temperature programmed from 50 to 260°C. Fatty acid components were identified by reference to a well-characterized fish oil fatty acid mixture, and the unsaturated nature of components was confirmed by re-analysis of samples after catalytic hydrogenation over PtO_2. The separated components were quantitated using a recording integrator linked to the chromatograph.

Analysis of molecular species. A 500-μg portion of total lipid was separated into the component phospholipids by HPTLC alongside 20 μg of a cod retina total lipid standard using methyl acetate/propan-2-ol/chloroform/methanol/0.25% (wt/vol) aq. KCl (25:25:25:10:9, by vol) as the developing solvent. The standard spots and the edge of the bands of pineal organ lipids were visualized by exposure to iodine vapor, and the bands of adsorbent, containing PC, PS, phosphatidylinositol (PI) and EGP, were scraped from the plate. The phospholipids were hydrolyzed on the silica with phospholipase C using a two-phase system of 1 mL diethyl ether and 1 mL of 0.1 M sodium borate buffer, pH 7.5 at room tem-

perature under nitrogen for 2 h (26). At the end of the incubation period, 1,2-diradylglycerols were extracted, dried down under nitrogen and finally desiccated under vacuum for 1 h. 9-Anthroyl chloride was prepared from 9-anthracene carboxylic acid and oxalyl chloride as described by Goto *et al.* (27). The diradylglycerols were derivatized and purified by a modification of the method of Takamura and Kito (28) as described elsewhere (19). The 1-*O*-alk-1′-enyl-2-acyl derivatives were removed during the final HPTLC purification step. The 1,2-diacyl-3-anthrocyl-*sn*-glycerols were separated by HPLC at 19–20°C on an ODS column (25 × 0.46 cm, 5 μm particle size; Beckman Instruments U.K. Ltd., High Wycombe, Buckinghamshire, United Kingdom) using a Pye Unicam PU4010 pump (Pye Unicam Ltd., Cambridge, England) and two isocratic solvent systems, methanol/propan-2-ol (4:1, vol/vol) at a flow rate of 1.0 mL/min, and acetonitrile/propan-2-ol (7:3, vol/vol) at a flow rate of 1.0 mL/min as described by Takamura and Kito (28). Peaks were detected using a Waters 470 scanning fluorescence detector (Millipore UK Ltd., Edinburgh, Scotland) with excitation and emission wavelengths of 360 and 460 nm, respectively, and quantified using a Shimadzu CR3A recording integrator (Anachem, Luton, United Kingdom). Peaks were identified by their relative retention time using 16:0/22:6n-3 as a reference peak. Di-docosahexaenoylglycerol (di-22:6n-3; Nu-Chek-Prep, Elysian, MN) was also available for direct comparison of retention times, as were a range of samples of known composition from previous studies (17,18,29). Each sample was chromatographed three times in each solvent system and the standard deviations calculated. Where final peak areas were calculated by subtraction, the standard deviations of the contributing peaks were added to give the final error.

RESULTS

The lipid content and lipid class composition of trout pineal organ are presented in Table 1. Around 4.9% of the wet weight of the pineal organs was lipid, of which almost half (47%) was in the form of TAG. PC was the major polar lipid present (16.5% of total lipid), followed by EPG (9.9%). No choline plasmalogens were detected, whereas ethanolamine plasmalogens accounted for 11% of the total EPG fraction. PI and PS each accounted for less than 5% of the total lipid, and both phosphatidylglycerol (PG) and spingomyelin (SM) were present at less than 2%. No cardiolipin or cerebrosides were detected.

Palmitic acid (16:0) comprised 23.7% of the fatty acids in the total lipids and was the most abundant fatty acid in the pineal organ (Table 2). The monounsaturated 18:1n-9 and polyunsaturated 22:6n-3 accounted for 17.6 and 12.4%, respectively, of the total fatty acids. Overall, saturated, monounsaturated and polyunsaturated fatty acids accounted for similar proportions of the total lipid fatty acids. The fatty acid composition of TAGs (Table 2) was generally similar to that of the total lipid although the proportion of 18:2n-6 (12.8%) was notably higher, and that of 16:0 lower, than in total lipids.

TABLE 1

Lipids of Trout Pineal Organ: Lipid Class Composition[a]

Lipid class	% Total lipid
Cholesteryl esters	3.3 ± 0.2
Triacylglycerols	47.0 ± 2.1
Free fatty acids	3.4 ± 0.6
Cholesterol	8.7 ± 0.4
Diacylglycerols	1.5 ± 0.1
Ethanolamine glycerophospholipids	9.9 ± 0.6
Phosphatidylglycerol	1.4 ± 0.1
Phosphatidylinositol	3.2 ± 0.3
Phosphatidylserine	3.4 ± 0.3
Phosphatidylcholine	16.5 ± 0.8
Sphingomyelin	1.7 ± 0.1

[a]Values are means ± SD of three determinations.

[a]PG, phosphatidylglycerol; PI, phosphatidylinositol; PS, phosphatidylserine; SM, sphingomyelin; PUFA, polyunsaturated fatty acids.

Each of the polar lipid classes had a specific fatty acid composition. In PC, 16:0 and 22:6n-3 were the principal components and together accounted for nearly 60% of the total fatty acids present in this phospholipid (Table 2). In contrast, 16:0 comprised only 10.7% of the fatty acids in EGP, whereas the level of 22:6n-3 (36%) was the highest observed in any lipid class. As a consequence, the total content of PUFA in EGP (56.2%) was the highest of all lipid classes. Only the EGP fraction produced dimethyl acetals by transmethylation of 1-*O*-alk-1′-enyl linked ether chains.

PI was unique among the lipid classes in that 20:4n-6 was a major component and accounted for 27.4% of the fatty acids, whereas 22:6n-3 comprised only 7.0% (Table 3). As a consequence, the overall ratio of n-3 to n-6 PUFA in PI was the lowest of any lipid class. The saturated fatty acid 18:0 was also a major fatty acid in PI. PS was characterized by a high content of 18:0 and 22:6n-3, coupled with a low content of 16:0. PG was rich in monounsaturated fatty acids and PUFA which comprised 44.1 and 37.1%, respectively, of the total fatty acids in this phospholipid (Table 3). The levels of 16:1n-7 and 18:1n-7 (17.0 and 10.2%) in PG were higher than in any other lipid class, and, of all the phospholipids PG had the highest content of 18:2n-6. In SM more than half (58.2%) of the fatty acids were monounsaturated, mainly due to the presence of a very high proportion of 24:1 (45.9%). PUFA comprised only 8.9% of the SM fatty acids (Table 3).

In all lipid classes, 20:5n-3 was present in small amounts and never exceeded 6.0% of the component fatty acids. The long chain monoenoic fatty acid 22:1n-11 observed in total lipid was concentrated in TAG, where it accounted for around 2% of the fatty acids. Of all the lipid classes, TAG also contained the highest level of 14:0.

The principal molecular species of PC, PE, PS and PI are presented in Table 4. Two molecular species predominated in PC, namely 16:0/22:6n-3 and 16:0/18:1, which accounted for 33.2 and 28.5%, respectively, of the total molecular species of this phospholipid. Di-PUFA, disaturated and di-monounsaturated species each comprised less than 6% of the total PC and the content of monounsaturated-PUFA species totalled 4.9%, within which 18:1/22:6n-3 was the major component. Molecular species containing 22:6n-3 were particularly abundant in PE. Di-22:6n-3 comprised 13.0% of the total, and 16:0/22:6 and 18:1/22:6 were both present at levels of more than 15%. In PS, 18:0/22:6n-3 accounted for almost half (43.9%) of the total molecular species, and 16:0/22:6n-3 was the only other species present at a level of greater than 10%. The most abundant molecular species of PI was 18:0/20:4n-6 which accounted for 37.8%. Another species containing 20:4n-6, 16:0/20:4n-6, comprised 14.0% of the molecular species of PI and 18:0/20:5n-3 accounted for 10.8%, the highest level for a species containing 20:5n-3 observed in any of the phospholipids examined.

DISCUSSION

Although the pineal organ is an adjunct of the brain, it is known to have evolved from a well-differentiated photoreceptive organ that is frequently considered to be a functional third eye in lower vertebrates (3). In fact, to date, the properties established for the pineal photoreceptors have been extended to the retinal photoreceptors and *vice versa* (3). The major difference between the pineal and retina relates to the neuronal organization, which is simple in the pineal but complex in the retina. Thus, pineal photoreceptors make contact with second order neurons that send their axons to brain centers. Retinal photoreceptors, on the other hand, are in contact with bipolar cells that, in turn, communicate with ganglion cells and numerous interneurons that are present (horizontal, amacrine, interpexiform cells). Consequently, the ratio of photoreceptors to other neurons is much higher in the pineal than in the retina, and the lipid composition of the pineal organ can be expected to reflect that of the photoreceptor cells.

[a]Values are mol% and are means of triplicate determinations ± 1 SD. It was assumed that the most saturated fatty acids were located on the *sn*-1 position. Molecular species containing minor fatty acids or fatty acid isomers were not resolved from the major components. Molecular species containing 18:2n-6 co-elute with those containing 22:5n-3 and 22:5n-6. PC, phosphatidylcholine; PE, phosphatidylethanolamine; PI, phosphatidylinositol; PS, phosphatidylserine; PUFA, polyunsaturated fatty acids.

The lipid content of the trout pineal (4.9% of wet weight) is almost exactly halfway between that found for the brain and retina (6.8 and 3.1%, respectively) of the same species (10). However, the level of TAG in the lipid of the pineal (47%) is considerably higher than the 8.4 and 30% found in the lipid of the brain and retina, but is nevertheless closer to the latter. The levels of TAG in brains and retina of trout are known to be higher than in the same tissues from cod (10). An influencing factor may be the fact that the trout examined were farmed fish. It is well known that farmed fish, including trout, have higher lipid contents in their flesh than their wild counterparts (30). Whether the lipid class content of neural tissues differs between wild and farmed fish or whether high TAG levels are a specific feature of the lipids of trout neural tissues remains to be established.

A notable feature of the brain of fish and animals in general is the high proportion of EGP in the total lipid (10,31). In both cod and trout, the EGP/PC ratio in brain lipid is approximately 1:1 (10). The level of EGP in the pineal lipid is notably lower than that of PC, the EGP/PC ratio being 0.6:1. This value is closer to the 0.7:1 observed for the ratio of these two phospholipids in the retina of both trout and cod (10). The ethanolamine plasmalogen content of the pineal is much lower than that of fish brain (36–38% of EGP) (25) and closer to that of retina (<5% of EGP; Bell, M.V., unpublished data). The absence of cerebrosides in the lipids of the pineal is also more typical of retina than brain, as is the low amount of ethanolamine plasmalogens (31). The absence of cardiolipin in significant amounts in pineal lipids is unusual as this lipid class is a common component of mitochondrial membranes and has been found in lipid extracted from both fish retina and brain (10).

The total lipid and component lipid classes of the pineal organs, with the exception of SM, were characterized by high contents of PUFA. Nevertheless, the content of PUFA in the total lipid of trout organ (31.2%) is lower than the corresponding values of 41.4 and 40.6% reported for the brain and retina, respectively, of the same species (10), and is considerably less than the PUFA content (43.6%) of total lipid from rat pineal (20). The distribution of fatty acids among the various lipid classes conforms to well established patterns. For example, the long-chain monoenoic fatty acid 22:1n-11 occurred only in TAG. The absence of this fatty acid, which

originates in calanoid zooplankton, is a common feature of fish phospholipids (32). The PUFA 18:2n-6 was also confined to TAG. It is notable that the total lipid of pineal gland contains higher levels of this fatty acid than brain in the rat (20), although it remains to be established whether the 18:2n-6 is specifically associated with TAG. The presence of high levels of 16:0 in PC is a characteristic feature of this phospholipid, including that extracted from trout brain and retina (10) and bovine pineal organ (21). The EGP of neural tissues are known to be specifically enriched in 22:6n-3 (31), and this was also a notable feature observed in the present study of the EGP from the trout pineal. The value for 22:6n-3 in EGP (36%) is slightly higher than the content in EGP from trout brain (34%), but less than that of the retina EGP (46.3%) of the same species (10). Interestingly, the 22:6n-3 contents of PC, PI and PS found here in the pineal are all intermediate between those found in the brain and in the retina.

The PI of the pineal organ conformed to the well established pattern in fish tissues, whereby PI has a higher content of 20:4n-6 than other phospholipids and is consequently characterized by a low ratio of n-3 to n-6 PUFA (32). The actual content of 20:4n-6 in the pineal PI (27.4% of total fatty acids) is markedly higher than that reported for trout brain (10.2%) and retina (14.8%) and for the same tissues of cod (4.4 and 12.5%, respectively) (10). The results suggest that in terms of the 20:4n-6 content of PI the pineal exceeds retina which, in turn, exceeds brain. In the rat, the level of 20:4n-6 in the total lipids from the pineal organ is also higher than that found in brain lipids (20). This is consistent with the idea according to which phototransduction might activate phospholipase A_2 with the subsequent formation of eicosanoids (33). An involvement of eicosanoids derived from 20:4n-6 in the light-dependent control of melatonin production is therefore indicated.

Consistent with the overall fatty acid composition of EGP, PE contained the highest level (13.0%) of di-22:6 molecular species of the phospholipids examined. However, the value was less than that observed previously in trout brain (14.9%), and considerably less than that in trout retina (41.3%) (17). Likewise, di-22:6 molecular species of PC and PS were less abundant in the pineal than the retina, and only pineal PC had a higher di-22:6 content than the corresponding phospholipids from brain. The other molecular species were all as expected, with 16:0/22:6 and 16:0/18:1 dominating PC, 16:0/22:6, 18:1/22:6 and 18:0/22:6 each comprising 9.6–20.1% of PE, and 18:0/22:6 being the predominant PS species. In contrast, PI from fish is known to be relatively impoverished with respect to 22:6n-3 containing molecular species, while C_{20} PUFA species are abundant (17,18). In trout, retinal PI was predominantly 18:0/20:4n-6 (40.1%) and brain PI 18:0/20:5n-3 (42.3%) (17). This tissue specificity in the molecular species composition of PI was confirmed in cod, in which 18:0/20:4n-6 was the predominant species in liver and roe (36.7 and 49.1%, respectively) and 18:1/20:4n-6 was the next most abundant (18,29). In brain, 18:0/20:5n-3 and 18:1/20:5n-3 comprised over half the PI (18) with arachidonyl species totalling only 15.3%, whereas in retina 16:0/22:6, 18:0/20:4, 18:0/22:6 and 18:0/20:5 were the most abundant species, in that order, totalling 84.5% of PI (18).

The PI from trout pineal organ thus closely resembles that of trout retina with 18:0/20:4n-6 predominant. The 18:0/20:5n-3 species so characteristic of PI from trout and cod brain comprised only 10.8% of trout pineal PI. Thus, although it is situated adjacent to the brain and is very closely associated with the brain, the pineal is almost identical to retina in terms of PI composition. Furthermore, no 18:1/24:1 was found in the PC of the pineal organ, whereas this molecular species comprises between 9 and 13% of fish brain PC (17,18).

Although the total lipid of the trout pineal organ has a lower content of 22:6n-3 than that found in brain or retina, the level is nevertheless still higher than that usually observed in other non-neural tissues, such as liver or muscle (32). Furthermore, the 22:6n-3 content of individual phospholipids is similar to that found in the retina and brain. Consequently, the lipid composition of the pineal organ displays features typical of nervous tissues.

Di-22:6n-3 molecular species may be unique to photoreceptor membranes as these are abundant in rod outer segments of many animal species and have recently also been found, albeit in smaller amounts, in the all-cone retina of larval herring (19). The outer segments of the pineal photoreceptors, which correspond to cone-like cells, are not as well developed compared to those of the retinal photoreceptor (3), and the overall amount of outer segment membrane per photoreceptor cell is probably considerably less in the pineal than in the retina. This might explain why the high levels of di-22:6n-3 molecular species which characterize the PC, and especially PS and PE, of trout and cod retina (17,18) were not observed in the trout pineal.

In conclusion, the present study demonstrates for the first time that, in terms of lipid composition, the pineal resembles the retina more closely than the brain or other tissues. Photoreceptor membranes can now be isolated from a population of purified pineal cells (34) and analysis of their component lipids may disclose specific adaptations in lipid composition. This opens interesting perspectives for the study of the light-dependent signal production by these cells.

Comparison of Body Weight and Adipose Tissue in Male C57Bl/6J Mice Fed Diets with and without *trans* Fatty Acids

Subodh Atal[a,1], Mary Jane Zamowski[b], Samuel W. Cushman[b] and Joseph Sampugna[a,*]

[a]Department of Chemistry and Biochemistry, University of Maryland, College Park, Maryland 20742 and [b]National Institute of Diabetes and Digestive and Kidney Diseases, National Institutes of Health, Bethesda, Maryland 20872

The effect of a diet containing *trans*-fatty acids (*t*FA) on the fatty acid composition and fat accumulation in adipose tissue was investigated in mice. Male C57Bl/6J mice were fed Control or Trans Diets that were similar, except that 50% of the 18:1, which was all *cis* in the Control Diet, was replaced by *t*FA in the Trans Diet. At selected ages, body weight, epididymal fat pad weight, perirenal fat yield, adipose tissue cellularity and fatty acid composition were examined. Over the time period studied (2–24 mon), the proportion of 18:0 and 16:0 tended to decrease while *cis*-18:1 levels increased. Compared to the Control Diet, the Trans Diet resulted in adipose tissue lipids with higher percentages of 14:0 and 18:2n-6 and lower percentages of *cis*-18:1 and 20:4n-6. In polar lipids, *t*FA replaced saturated fatty acids, whereas *t*FA replaced *cis*-18:1 in the nonpolar lipids. Body weights at 16 and 24 mon of age and epididymal fat pad weights at 8–24 mon of age were lower in mice fed the Trans Diet as compared to those fed the Control Diet. At the ages studied, the Trans Diet also resulted in lower values for perirenal fat weights, triacylglycerol to polar lipid ratios, and adipose cell size. The data suggest that chronic consumption of *t*FA affects lipid metabolism and results in decreased fat accumulation in murine adipose tissue.

***Lipids* 29, 319–325 (1994).**

Trans fatty acids (*t*FA) are not products of *de novo* fatty acid synthesis in animal cells. Nevertheless, *t*FA are incorporated into most animal and human tissues (1–7). The ultimate metabolic fate and the physiological effects of *t*FA have not been fully characterized. However, in light of recent findings (8–10), it has become increasingly clear that the physiological properties of *t*FA may be substantially different from those of their *cis*-monounsaturated counterparts.

Earlier studies that examined the biological effects of *t*FA have not always included adequate control diets. When comparisons are made between diets that differ not only in *t*FA, but also in the proportions of other fatty acids, caution must be used not to attribute differences solely to the presence of *t*FA. In our laboratory (11) we attempted to blend dietary fats by mixing various edible oils so that the diets differed only in the ratio of 18:1*t* to 18:1*c* fatty acids; by doing so, differences observed are more likely related to differences in *t*FA in the diets.

Previous work in our laboratory with properly matched diets had demonstrated that diets containing *t*FA can depress the percentage of fat in mouse milk (11). As the major lipids synthesized in mammary tissue are triacylglycerols, and the major products of lipid metabolism in adipose tissue are also triacylglycerols, we initiated studies using epididymal fat pads of male C57Bl/6J mice to determine whether lipid metabolism in adipose tissue is also affected by dietary *t*FA. As we pursued these studies, it became clear that diets containing *t*FA affected the fat depot weights and the ratios of triacylglycerol to phospholipid in epididymal fat pads. These findings led us to explore in further detail age-related changes in adipose depots of mice fed diets containing *t*FA compared to mice fed a control fat. the results of these studies are described here.

MATERIALS AND METHODS

Materials. Unless otherwise indicated, all solvents used were reagent grade or better. Chloroform, methanol, methylene chloride, hexane, diethyl ether and petroleum ether were obtained from J.T. Baker (Phillipsburg, NJ); isooctane used as solvent for glass capillary gas–liquid chromatography (GCGLC) was obtained from Burdick and Jackson (Muskegan, MI). Quadrex (New Haven, CT) and Supelco (Bellefonte, PA) were the sources of the fused silica GCGLC columns coated with SP2340 and SP2560, respectively. Standard fatty acid methyl ester (FAME) mixtures that were used for calibration were from Nu-Check-Prep (Elysian, MN). Silica Gel G used for thin-layer chromatography (TLC) of FAME and for the separation of nonpolar from polar lipids was a product of E. Merck (Elmsford, NY). Silica Gel LK 5D TLC plates (20 × 20 cm, 250 μm) used in TLC spectrodensitometry were purchased from Whatman (Clifton, NJ).

Some of the dietary components [casein, alphacel, American Institute of Nutrition (AIN) (Bethesda, MD) mineral mix-76, AIN vitamin mix-76A, dl-methionine and choline bitartrate] were obtained from ICN Nutritional Biochemicals (Cleveland, OH). Sucrose was from Mazzeo and Sons (Hyattsville, MD). Commercial frying shortening was from Auth Brothers (Washington, DC), cocoa butter was from Wilbur Chocolate Co. (Lititz, PA) and Pope olive oil from Continental Smelkinson (Jessup, MD). Mazola corn oil and soybean oil were purchased from local Giant Food supermarkets.

Diets. The diet ingredients used are given in Table 1. Except for the fat source, the two diets were identical. The Trans Diet contained a mixture of shortening, corn oil and soybean oil, while the source of fat in the Control Diet was a mixture of olive oil, corn oil and cocoa butter. The fats were blended to yield fatty acid compositions (Table 2) that were essentially the same except that ≈50% of the 18:1, which was all *cis* in the Control Diet, was replaced by *t*FA in the Trans Diet. Both diets contained ≈6 cal% linoleic acid and were in compliance with AIN rodent nutritive guidelines (12).

Animals. Mice used in these studies were housed in our animal facility under controlled conditions of

temperature (≈23°C), humidity (≈60%) and lighting (12 h day/night cycle) and were provided food and water *ad libitum*. Handling and care of mice were done strictly according to guidelines of the Animal Care and Use Committee of the University of Maryland (College Park, MD).

Weanling C57Bl/6J mice, obtained from Jackson Laboratories (Bar Harbor, ME), were randomly assigned as mating pairs and fed one of the two diets described above. Male offspring were weaned at three weeks of age, assigned to the same diet as their respective parents and used at selected ages in the various studies. Selection of animals used in all experiments was done randomly such that for each experiment the animals selected from a particular diet comprised individuals pooled from different litters.

For each of the following studies, the number of animals from each diet used at each age is given in parentheses. Mice were examined at 2, 4, 6, 8, 12, 15, 16 and 24 mon of age to measure epididymal fat pad weight (n = 4–6), body weight (n = 4–5) and epididymal fat pad fatty acid composition (n = 3). Studies on the amount of perirenal fat (n = 20) were done using eight-month-old mice, investigations on triacylglycerol/polar lipid ratios (n = 3–5) were done on ten-month-old mice, and studies on adipose cell size and number (n = 3) were done on 24-month-old mice. Mice at eight months of age were used for studies on the fatty acid composition of the nonpolar and of the polar lipids of epididymal fat pads (n = 3, pooled samples of four mice each).

Adipose tissue weights and body weights. Body weights were recorded prior to killing the animals with CO_2. Epididymal fat pads and, in some cases, perirenal fat tissue, were excised and weighed.

Lipid extraction and preparation of FAME. Lipids were extracted essentially as described by Folch *et al.* (13). Tissues were minced and homogenized in 19 vol of chloroform/methanol (2:1, vol/vol) containing 0.01% butylated hydroxytoluene as an antioxidant. The crude lipid extract was separated into an organic and an aqueous phase by the addition of an appropriate amount of 0.58% NaCl. The lipid in the lower organic phase was concentrated, and aliquots (≈25 mg) were transesterified with methanolic HCl for 16 h at 80°C. The resulting FAME were purified on Silica Gel G TLC plates. The extraction, esterification and purification procedures have been described previously (14).

Separation and analysis of polar and nonpolar lipid. Pooled lipids from epididymal fat pads of four mice were applied (≈2 g/plate) to 20 × 20 cm TLC plates coated with a 0.5-mm layer of Silica Gel G. The plates were developed three times to the top with diethyl ether. After spraying with dichlorofluorescein, the polar and nonpolar lipid bands were visible under ultraviolet light. Then the polar lipid area and a longitudinal portion of the much larger, nonpolar lipid area were scraped into test tubes. Sufficient anhydrous methanolic HCl (2 mL) and methylene chloride (3 mL) were added to cover the silica; the tubes were vigorously vortexed and incubated at 80°C for 16 h to prepare FAME. The transesterified lipids were extracted with hexane, and the purified FAME were isolated using silica gel TLC as described (14).

GCGLC. Purified FAME were concentrated under a stream of nitrogen and dissolved in isooctane for analysis by GCGLC. Analyses were conducted on 5830, 5840 or 5880 Hewlett-Packard gas chromatographs (Avondale, PA) equipped with flame-ionization detectors and capillary split injection ports. A glass column (15 m × 0.25 mm) coated with SP2340 was used in some of the work, but most of the analyses were conducted on fused silica columns (25 m × 0.25 mm coated with SP-2340 or 100 m × 0.25 mm coated with SP-2560). Column conditions and other parameters were essentially as described previously (14).

Authentic mixtures of FAME were used to identify components and to obtain appropriate response factors. When the shorter columns were used, correction factors were required as *trans*-octadecenoates (18:1*t*) were underestimated and *cis*-octadecenoates (18:1*c*) were overestimated. To establish the correction factors, argentation TLC was used to isolate the 18:1*t* and 18:1*c* fractions from the Trans Diet fat as described previously (14). After adding internal standards to the separated 18:1 fractions, a series of mixtures were prepared, the mixtures were analyzed on the 15- and 25-m columns, appropriate correction factors were determined, and an equation relating the correction factors and the observed percentage of the 18:1*t* in the total 18:1 was developed

TABLE 2

Fatty Acid Composition of Control and Trans Diets[a]

for each column essentially as described previously (14). The equation was then used to obtain the correction factor for the 18:1*t* fraction in each sample analyzed on that specific column. Because the sum of the 18:1*c* and 18:1*t* before and after correction should be identical, corresponding correction factors for the 18:1*c* fraction in each sample were obtained algebraically.

Triacylglycerol/polar lipid ratio. Relative levels of triacylglycerols to polar lipids were determined using TLC densitometry. Duplicates of total lipid extracts for each sample were spotted on Whatman silica gel LK 5D 20 × 20 cm, 250-μm plates. Graded amounts of triacylglycerol (previously isolated from mouse epididymal fat pads) and phospholipid (egg phosphatidylcholine, ≈99% purity; Sigma Chemical Co., St. Louis, MO) were spotted on separate lanes to obtain a standard curve for the nonpolar and polar lipid fractions. The plates were developed in hexane/diethyl ether/formic acid (80:20:2, by vol), allowed to air-dry, dipped momentarily in 2% sulfuric acid, and charred at 170°C, essentially as described by Bitman *et al.* (15). The plates were then scanned using a Shoeffel Instruments Model SD3000 spectrodensitometer (Westwood, NJ) equipped with a Hewlett-Packard 3390A Reporting Integrator.

Adipose tissue cellularity. Epididymal fat pads were excised and immediately transferred to normal saline at 37°C. Pools of proximal, distal and medial fragments totalling less than 100 mg per fat pad were used for osmium fixation as described by Hirsch and Gallian (16).

Statistics. The results of most experiments were analyzed using the *t*-test or analysis of variance. Regression analysis was used to test the inverse relationship between body weights and adipose tissue 18:1*t* content.

RESULTS

Body weights and epididymal fat pad weights for mice on the two diets are given in Figure 1. The general patterns obtained over the time period examined were similar. Both body weight and epididymal fat pad weight increased up to 15 or 16 mon of age and then appeared to decline sharply. Compared to mice fed the Control Diet, mice on the Trans Diet had lower body weights ($P < 0.05$) at the two oldest ages examined (16 and 24 mon) and lower epididymal fat pad weights ($P < 0.05$) at all ages examined between 8 and 24 mon. When the body weights of the mice on the Trans Diet were plotted against their epididymal fat 18:1*t* content (Fig. 2), a significant inverse correlation ($r = 0.68$, $P < 0.002$) was observed.

Diet related differences were also evident when the amount of perirenal fat at eight months of age (Fig. 3) was examined and when epididymal fat pad triacylglycerol to polar lipid ratios were studied at ten months of age (Fig. 4). The yield of perirenal fat from mice fed the Trans Diet was only about half of that isolated from mice fed the Control Diet ($P < 0.0004$), and the triacylglycerol to polar lipid ratio in epididymal fat pad lipids of mice fed the Trans Diet was about one-fourth ($P < 0.025$) of that observed in mice fed the Control Diet. These differences were apparently related primarily to changes in cell size rather than cell number, as studies of adipose cellularity at 24 mon of age (data not shown) revealed that the average size of epididymal fat pad cells isolated from mice fed the Trans Diet was about 25% less ($P < 0.0001$) than that of cells isolated from mice fed the Control Diet. Differences in cell numbers were not statistically significant.

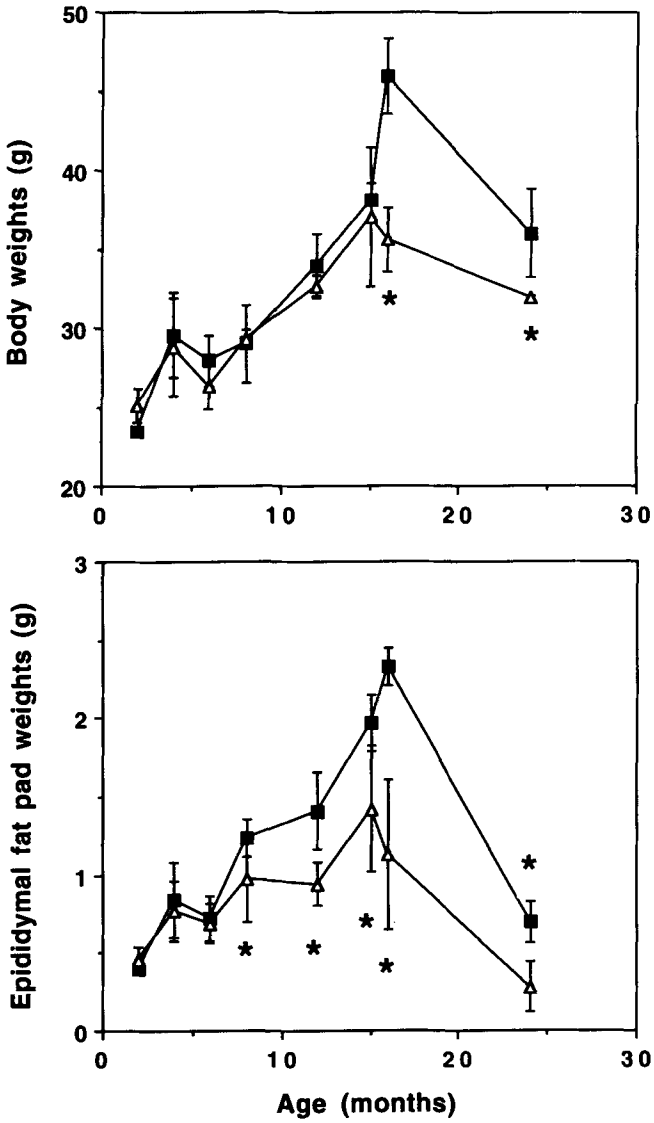

FIG. 1. Top panel depicts body weights of mice on Control Diet or Trans Diet at various ages. Bottom panel depicts epididymal fat pad weights of mice on the two diets at various ages. Squares are data for mice on the Control Diet; the triangles are data for mice on the Trans Diet. Values are means ± SEM of three mice per diet at each age group; * indicates that values from mice fed the Trans Diet were significantly smaller ($P < 0.05$) than those fed the Control Diet.

The effects of diet and age on fatty acid composition of epididymal fat pads in mice are depicted in Table 3. Age-related trends include a decrease in the proportion of 16:0 and possibly 18:0 as well as an increase in the proportion of 18:1*c* with age. Compared to the Control Diet, the Trans Diet tended to result in higher proportions of 14:0 and 18:2n-6 and lower proportions of 18:0, 18:1*c*

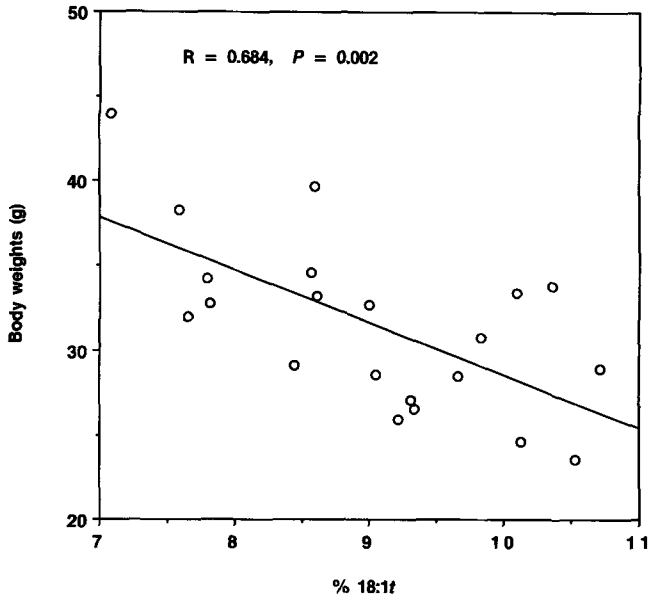

FIG. 2. Relationship between % *trans* 18:1 in epididymal adipose tissue and mouse body weights. Values are for 21 mice on the Trans Diet.

and 20:4n-6. Relative to the percentages present in the diets, proportionately more 18:1*c* was present in epididymal fat pads isolated from mice fed the Trans Diet.

The fatty acid compositions of polar and nonpolar lipids of epididymal fat pads isolated from eight-month-old mice fed the Control or Trans Diet are summarized in Tables 4 and 5. In the polar lipids (Table 4), the incorporation of 18:1*t* was accompanied by a reduction in the proportion of 16:0 and 18:0, but not of 18:1*c*. By contrast, in the nonpolar lipids (Table 5), the Trans Diet caused significantly lower proportions of 18:1*c*, but not of 16:0 and 18:0. In the polar lipids, but not in the nonpolar lipids, the value for the sum of 18:1*t* plus saturated fatty acids in tissue isolated from mice fed the Trans Diet was close to the value for total saturated fatty acids in tissues isolated from mice fed the Control Diet.

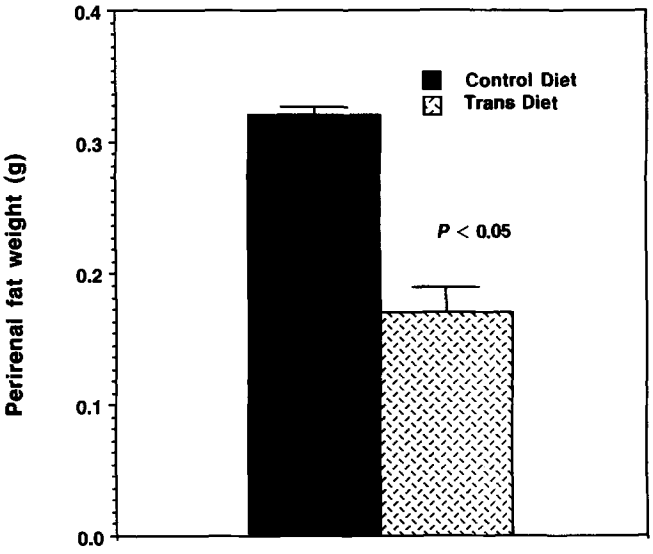

FIG. 3. Perirenal fat weights of eight-month-old mice. Values are means ± SEM from three mice on each diet.

DISCUSSION

The major observations made in the present study were the effects of diet on fat accumulation in male mice. Compared to mice on the Control Diet, mice fed the Trans Diet for at least eight months had lower epididymal fat pad weights, a lower triacylglycerol/polar lipid ratio in lipids isolated from epididymal fat pads, a lower perirenal fat weight and a smaller epididymal fat cell size. Also, at the two oldest ages examined, the mice on the Trans Diet had lower body weights than the mice fed the Control Diet. These findings suggest that compared to the Control Diet, chronic consumption of the Trans Diet resulted in decreased fat accumulation in different adipose depots. Recent studies (17) with 3T3-L1 cells, a subclone of Swiss mouse embryo 3T3 fibroblasts, suggest that this phenomenon may be common for adipose tissue in mice.

These data are in conflict with those of Ostlund-Linqvist *et al.* (18), who reported that adipocytes from rats fed *t*FA had significantly larger adipose cells as compared to those fed a control diet. Species-specific differences with regard to the effects of dietary fats or the extent of feeding may account for the conflicting data. In the earlier study (18), four-week-old rats were fed for only two months. However, differences in the methodology used to examine adipose cell size may also be responsible. Adipocytes are very fragile under *ex vivo* conditions, and the possibility of cell breakage cannot be ruled out. In addition, differences in fatty acid composi-

tion may alter cell membrane properties and differentially affect the type and extent of cell damage. In the earlier study (18), the epididymal fat pads were frozen prior to estimating cell size by visual counting techniques, and potentially extensive cell damage with differential effects on membranes of different composition may have occurred.

It was of interest in our study that the diet- and age-related results obtained in the body weight and epididymal fat pad weight (Fig. 1) experiments closely paralleled each other, especially at the older ages. Similar effects of age and diet on body weights of mice have been noted previously (19). Regardless of diet, male mice continued to exhibit body growth till ≈1.5 years of age, after which time the body weights tended to decline sharply. As the average life span for male mice has been described as being 1–2 years (20), the growth curve phenomenon may simply reflect the normal aging process.

Of greater relevance to the present studies were the earlier results obtained with diets containing *t*FA. Compared to other diets, those containing 19 and 61% *t*FA resulted in lower body weights of mice at 13 and 19 mon

of age, but not at the younger ages examined (19). This was similar to our present observations. In the earlier studies (19), differences in body growth due to diet were ascribed to essential fatty acid deficiency, as the 18:2n-6 levels in the diets were different. In our studies, a simple essential fatty acid deficiency was unlikely as the levels of both 18:2n-6 and 18:3n-3 were equivalent in both diets. It is more likely that the presence or absence of *t*FA was responsible for the effect of diet on the growth curve of mice, because the most obvious characteristic common to the earlier (19) and present studies was that mice with lower body weights were chronically fed partially hydrogenated fats.

When the body weights of mice on the Trans Diet were plotted against the percent 18:1*t* in their epididymal fat pads, a statistically significant inverse correlation was obtained (Fig. 2). No such relationship was detected between body weight and other major tissue fatty acids for mice on either diet. Because *t*FA are not synthesized by animal tissues and deposition of 18:1*t* in adipose tissue is highly correlated to the level of dietary 18:1*t* (21), one would expect 18:1*t* in adipose tissue to be a positive marker of food intake. If higher tissue 18:1*t* is a reflection of higher food intake, a positive correlation with body weight would be predicted, rather than the inverse, as was observed herein. In the present studies, mice were fed *ad libitum* and food intake was not measured. However, a role of food intake to explain the above phenomena seems unlikely, as we have data from other studies (22–24) that indicate that food intake between mice fed Trans and Control Diets is quite similar.

Detailed analysis of the fatty acids in epididymal fat tissue (Tables 3–5) revealed several significant patterns. The major adipose tissue saturated fatty acids, 16:0 and 18:0, appeared to decrease with age, while the major *cis*-unsaturated fatty acid, 18:1*c* appeared to increase with age. These findings agree with and further confirm earlier reports (25,26) that show changes in fatty acid composition of adipocytes with age. Comparisons of 18:1*c* in epididymal adipose tissue of mice fed the two diets revealed that the percentages of 18:1*c* in the tissues were not in proportion to the percentages in the diet, suggesting that preferential synthesis or incorporation of 18:1*c* may have occurred in epididymal fat pads of mice fed the Trans Diet.

When the composition of the nonpolar and polar lipids was examined (Tables 4 and 5), the pattern of incorporation of *t*FA resembled that of saturated fatty acids in the polar lipids and that of the *cis*-monounsaturated fatty acids in the nonpolar lipids. Wood (4) observed a similar phenomenon in rats. Although the functional significance of these observations cannot be ascertained from the present studies, it is tempting to suggest that the ability of acylating enzymes to recognize *t*FA differs greatly for different lipid classes.

In the present studies, diet related effects on 14:0, 18:2n-6 and 20:4n-6 were also noted. Levels of both 14:0 and 18:2n-6 tended to be higher in epididymal fat pads of mice fed the Trans Diet, whereas 20:4n-6 tended to be lower. In view of the potential role of 14:0 as an essential component of many acylated proteins (27), the higher levels of myristic acid, which were seen in total and nonpolar lipids, but not in polar lipids, may be important. The effect of *t*FA on 18:2n-6 and 20:4n-6 has been noted previously and has been attributed to inhibition of desaturation in the conversion of 18:2n-6 to 20:4n-6 (28).

Whether the results of these studies can be extrapolated to other species, including humans, is unknown and would require thorough investigation. One of the major problems in extrapolating dietary studies of *t*FA in animals to humans is the lack of information on the *t*FA content of common foods and disagreement regarding the dietary intake of *t*FA in humans (21,29). Recent estimates of the average intake of *t*FA in the United States have been reported to be 8.1 g (29) or 13.3 g (21) per capita. Based on these values and NHANES III (Third National Health and Nutrition Examination Survey) estimates of ≈2,100 calories (30) for the average per capita total food energy intake in the United States, the per capita *t*FA intake would be ≈3.5% or ≈5.7% of total calories in humans. In our mouse study, the 18:1*t* represented 5.6% of the total calories, and the minimum required to observe effects on adipose tissue was not determined.

Although the threshold required for the effect is unknown, it is clear that chronic consumption of diets containing partially hydrogenated fat influences lipid metabolism and the amount of lipid deposited in adipose tissue of mice. The results are consistent with an effect of dietary *t*FA on the synthesis or breakdown of triacylglycerols; however, the underlying mechanisms involved are unclear. Various metabolic factors, including lipogenic enzymes, influence fat storage. Additional studies are underway to examine the effects of dietary *t*FA on selected lipogenic enzyme activities in adipose cells.

Liver Δ5 and Δ6 Desaturase Activity Differs Among Laboratory Rat Strains

Roberto J. de Antueno*, Michele Elliot and **David F. Horrobin**
Efamol Research Institute, Kentville, Nova Scotia, B4N 4H8 Canada

This study was designed to examine the variations among rat strains in hepatic fatty acid desaturase activities and to determine the correlations between the activities of these enzymes and the levels of each microsomal fatty acid. Wistar rats from two different sources as well as Long-Evans and Sprague-Dawley rats were selected to assess, under standard and identical experimental conditions, the liver Δ5 and Δ6 desaturase activities. Both desaturase activities were significantly reduced by 56% in Sprague-Dawley rats when compared to BB-Wistar control rats, whereas intermediate reduced values were detected in Wistar (CR) and Long-Evans strains. The activities of Δ5 and Δ6 desaturases were significantly and positively correlated with each other. However, no significant correlations were detected between either Δ5 or Δ6 desaturase activities and levels of any of their fatty acid substrates or any other of the major microsomal fatty acids. Fatty acid composition of microsomal total lipids showed strain dependency. A positive correlation was detected between the microsomal levels of the two major final products of both desaturases, namely 20:4n-6 and 22:6n-3. In general, the sum of n-3 or n-6 fatty acids but not the ratio of one to the other, varied among rat strains. The study demonstrated that Δ6 and Δ5 desaturase activities are strain-related. The data also suggested that (i) the desaturation activity should be measured and not predicted from the fatty acid composition and (ii) different rat strains should be used for lipid metabolic studies before conclusions are drawn for rats in general.
***Lipids* 29, 327–331 (1994).**

There are several fatty acid desaturases that are membrane-bound and immunologically distinct enzymes (1,2). Delta-5 and Δ6 desaturases are required to convert dietary linoleic acid (18:2n-6) and α-linolenic acid (18:3n-3) to their metabolites, such as dihomo-γ-linolenic acid (20:3n-6), arachidonic acid (20:4n-6), eicosapentaenoic acid (20:5n-3) and docosahexaenoic acid (22:6n-3), for membrane phospholipid and eicosanoid synthesis (3). Polyunsaturated fatty acids of the n-9 type are also produced by these enzymes. Age, season (4), circadian rhythm (5), disease, hormonal (6) and dietary status (7) are factors that alter Δ5 and Δ6 desaturase activities through different mechanisms (8). The activities of these enzymes also vary between animal species as well as between different organs of the same species (9,10). For example, there is a lack or near lack of Δ6 desaturase in felines (11) while rat hepatocytes desaturate linoleic acid rapidly relative to the rates found in rat heart or kidneys (10).

Abbreviations: EDTA, ethylenediaminetetraacetic acid; FAME, fatty acid methyl ester; HPLC, high-performance liquid chromatography.

Rat liver microsomes are the most thoroughly studied system and are generally considered as the standard model for desaturation experiments (12). However, the rat strains used in the studies differ from one laboratory to another, and in some cases, in the same laboratory between experiments.

Rats of different genetic origin are known to differ in various biological and biochemical responses, including their susceptibility to adjuvant disease (13), their chylomicron metabolism and cholesterolemic response (14), and in their resistance to the myocardial lesions caused by dietary erucic acid (15). Dietary fatty acids also affect plasma lipids and 5-lipoxygenase products of different rat strains in different ways (16,17). However, the variations in the activity of fatty acid desaturases among rat strains had not been examined previously.

We therefore determined the liver Δ5 and Δ6 desaturase activities of four commonly used strains of laboratory rats under identical experimental conditions. The correlations between the two enzyme activities and between the microsomal fatty acid concentrations are also presented.

MATERIALS AND METHODS

Chemicals and radiochemicals. All organic solvents and chemicals were of reagent grade and were obtained from British Drug House Inc. (Toronto, Ontario, Canada). Lipid standards were from Nu-Chek-Prep (Elysian, MN). Niacinamide, *N*-acetylcysteine, ATP, co-enzyme A and NADH were obtained from Sigma Chemical Co. (St. Louis, MO). [1-^{14}C]Linoleic and [1-^{14}C]dihomo-γ-linolenic acids (99% radiochemical purity; 53.0 and 54.9 mCi/mmol, respectively) were purchased from DuPont Canada Inc. (Markham, Ontario, Canada).

Animals and diets. Female Wistar (CR), Long-Evans and Sprague-Dawley rats were obtained from Charles River Canada Inc. (St. Constant, Quebec, Canada). Female BB-Wistar control rats were kindly provided by the Health Protection Branch of Health and Welfare (Ottawa, Ontario, Canada). Animals were housed three per cage in a temperature-controlled environment (22 ± 2°C) with a 12 h light/dark cycle and were fed Rodent Laboratory Chow No. 5001 (Ralston Purina Co., St. Louis, MO) and water, *ad libitum*, for 7 d immediately after arrival. All rats were two months old weighing 190 ± 5 g at the time of sacrifice.

Isolation of hepatic microsomes. Nonfasted rats were sacrificed by cervical dislocation at 9:30 a.m. to avoid variations in enzyme activity caused by circadian rhythm (5) and to obtain a substantial and even, though not maximal, activity of liver desaturase (5,7). Livers were quickly rinsed with cold 0.9% NaCl solution, weighed and minced with scissors. All procedures were performed at 4°C unless specified otherwise. Micro-

somes were isolated by differential ultracentrifugation as previously described (18). Briefly, livers were homogenized in a solution (1:3, wt/vol) containing 0.25 M sucrose, 62 mM potassium phosphate buffer (pH 7.0), 0.15 M KCl, 1.5 mM *N*-acetylcysteine, 5 mM $MgCl_2$ and 0.1 mM ethylenediaminetetraacetic acid (EDTA) using four strokes of a Potter-Elvehjem tissue homogenizer. The homogenate was centrifuged at 10,400 × *g* for 20 min to eliminate mitochondria and cellular debris. The supernatant was filtered through a three-layer cheesecloth and was centrifuged at 105,000 × *g* for 60 min. The microsomal pellet was gently resuspended in the same homogenization solution with a small glass/Teflon homogenizer and kept frozen at −70°C until used, as reported elsewhere (19). The absence of mitochondrial contamination was enzymatically assessed as previously described (20). The protein concentration was measured by the method of Lowry *et al.* (21) with bovine serum albumin as the standard.

Desaturase assays. The activities of Δ5 and Δ6 desaturases were determined by measuring the conversion of [1-^{14}C]20:3n-6 (dihomo-γ-linolenic acid) to [1-^{14}C]20:4n-6 (arachidonic acid) and of [1-^{14}C]18:2n-6 (linoleic acid) to [1-^{14}C]18:3n-6 (γ-linolenic acid), respectively. The conditions for the desaturation assays were those described by Leikin and Brenner (22), under which the enzymes are saturated with substrates and the reactions are linear with incubation time. Reactions were started by adding 2 and 3 mg of microsomal protein for Δ5 and Δ6 desaturase, respectively, to preincubated tubes containing 0.20 μCi of the substrate fatty acid at a final concentration of 33.3 μM in 1.5 mL of the homogenization solution, containing NaF (42 mM), niacinamide (0.33 mM), ATP (1.57 mM), NADH (1.01 mM) and coenzyme A (0.09 mM) as described (22). The tubes were vortexed vigorously, and after 15 min incubation in a shaking water bath (37°C) the reactions were stopped by the addition of 2 mL of 10% (wt/vol) KOH in ethanol. Lipids in the incubation mixture were saponified at 80°C for 45 min under N_2. The samples were then left in ice for 5 min before acidification. The fatty acids were extracted with hexane and esterified with BF_3/methanol at 90°C for 30 min (23).

Radiolabeled fatty acid methyl esters (FAME) were analyzed as previously described (24). Analyses were done by high-performance liquid chromatography (HPLC) using a Waters instrument (Waters Associates, Milford, MA) equipped with a variable wavelength ultraviolet-vis monitor (set at 205 nm), a radioisotope detector (model 171; Beckman, Palo Alto, CA) with a solid scintillator cartridge (97% efficiency for ^{14}C-detection) and an ultrasphere ODS column 25 cm × 4.6 mm i.d. (5 μm particle size; Beckman). FAME were separated isocratically with acetonitrile/water (95:5, vol/vol) at a flow rate of 1 mL/min, and were identified by comparison with authentic standards.

Lipid analysis. Lipids were extracted from liver microsomes with chloroform/methanol (2:1, vol/vol) according to the method of Folch *et al.* (25) and were transesterified to form methyl esters as previously described (23). The fatty acid composition of microsomal total lipids was determined by gas–liquid chromatography using a Hewlett-Packard instrument (model 5880; Avondale, PA) equipped with flame-ionization detector and a glass column (2 mm i.d. × 180 mm) packed with GP 10% SP-2330 (Supelco Canada Ltd., Oakville, Ontario, Canada) as previously described (26).

Statistical analysis. The results are expressed as means ± standard deviation. The significance of differences was determined using a two-tailed Student's *t*-test. A difference was considered significant at $P < 0.01$ unless specified otherwise in the text. Regression analysis was by the least-squares method.

RESULTS

Strain variations in hepatic Δ5 and Δ6 desaturase activity are shown in Figure 1. Both desaturase activities were significantly reduced by 56% in Sprague-Dawley rats when compared to BB-Wistar control rats, whereas intermediate reduced values were detected in Wistar (CR) and Long-Evans strains. A linear regression analysis of these data showed a significant positive correlation (correlation coefficient, r = 0.81; $P < 0.01$) between Δ5 and Δ6 desaturase activities (Fig. 2). This figure shows two areas defined by the desaturase activities of Sprague-Dawley and BB-Wistar control rats that enclose a third area determined by the Long-Evans and Wistar-CR desaturase activities.

The fatty acid composition of the microsomal total lipids showed strain dependency (Table 1). The percentages of the major polyunsaturated fatty acids, 20:4n-6 and docosahexaenoic acid (22:6n-3), and the sum of n-6 fatty acids minus 18:2n-6 were significantly lower in Sprague-Dawley rats as compared to the other three strains. This decrease was balanced by an increase in palmitic (16:0), linoleic (18:2n-6) and eicosapentaenoic

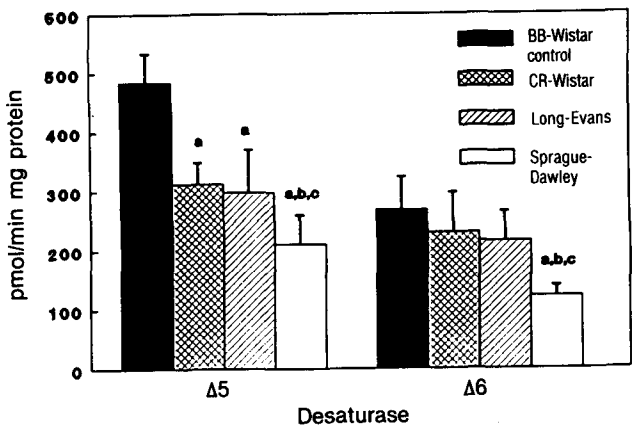

FIG. 1. Liver microsomal Δ5 and Δ6 desaturase activity in four rat strains. Animals were treated and incubations were performed under identical experimental conditions. The activities of Δ5 and Δ6 desaturases were determined by measuring the conversion of [1-^{14}C]20:3n-6 to [1-^{14}C]20:4n-6 and of [1-^{14}C]18:2n-6 to [1-^{14}C]18:3n-6, respectively, as detailed under the Materials and Methods section. Values are the means ± SD of at least four animals. The superscripts denote statistically significant differences ($P < 0.01$) to [a]BB-Wistar control, [b]Wistar-CR and [c]Long-Evans.

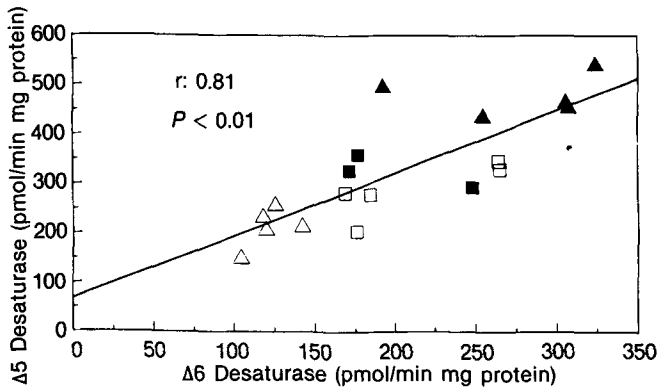

FIG. 2. Relationship between Δ5 and Δ6 desaturase activities of (▲) BB-Wistar control, (■) Wistar-CR, (□) Long-Evans and (△) Sprague-Dawley rats. The activities of Δ5 and Δ6 desaturases were determined by measuring the conversion of [1-^{14}C]20:3n-6 to [1-^{14}C]20:4n-6 and of [1-^{14}C]18:2n-6 to [1-^{14}C]18:3n-6, respectively, as detailed under the Materials and Methods section. Regression analysis was by the least-squares method. Each point represents the mean of duplicate determinations.

(20:5n-3) acid concentrations. In general, the sum of n-3 and n-6 fatty acids, but not the ratio of the two, varied significantly among the strains. Table 1 also shows that the ratios of Δ5 and Δ6 desaturase activities were not significantly different among the rat strains studied.

Linear regression analyses were performed relating the concentration of 17 major microsomal fatty acids to the Δ5 or Δ6 desaturase activity. The 18:2n-6 levels were modestly and negatively correlated with Δ5 desaturase activity (r:0.51, $P < 0.05$); no significant correlations were found with any fatty acid concentration and Δ6 desaturase activity.

The relationships between the microsomal levels of various pairs of fatty acids were also assessed. In general, no significant correlations were seen except for the following: Stearic acid (18:0) and 16:0 contents were negatively correlated with 20:4n-6 and 22:6n-3 levels, respectively (Figs. 3 and 4). A positive correlation was seen between 20:4n-6 and 22:6n-3 contents (Fig. 4C). Eicosapentaenoic acid (20:5n-3) levels were positively correlated with the content of its precursor, α-linolenic acid (18:3n-3) (Fig. 5B) and with the levels of its elongation product, docosapentaenoic acid (22:5n-3) ($r = 0.58$, $P < 0.02$, data not shown). Linoleic acid (18:2n-6) content also correlated positively with 20:5n-3 levels (Fig. 5A).

DISCUSSION

Wistar rats from two different sources and two other commonly used laboratory rat strains were selected to assess liver Δ5 and Δ6 desaturase activities and to determine the relationship between the activities of these enzymes and the levels of individual microsomal fatty acids. All strains were examined under precisely identical conditions to facilitate comparisons.

The data show that the desaturase activities are clearly strain related (Fig. 1). Since both Δ5 and Δ6 desaturase activities were significantly and positively correlated (Fig. 2) and since there was an approximately constant ratio between these activities (Table 1), a proportional flow of n-3 and n-6 polyunsaturated fatty acids

TABLE 1

Fatty Acid Composition (%) of Liver Microsomes from Different Rat Strains[a]

Fatty acid	BB-Wistar control	CR-Wistar	Long-Evans	Sprague-Dawley
16:0	12.4 ± 0.8	11.7 ± 0.7	11.8 ± 0.5[d]	13.4 ± 0.6[c,d]

Δ5/Δ6[b]	1.9 ± 0.6	1.7 ± 0.4	1.4 ± 0.2	1.8 ± 0.2

[a]Abbreviations: LA, linoleic acid, 18:2n-6; MUFA, monounsaturated fatty acids; SFA, saturated fatty acids; Δ5/Δ6, ratio of Δ5 to Δ6 desaturase activities. Minor fatty acids make up the balance. Values are the mean of three rats ± SD.

[b]Data from Figure 1.

[c,d,e]Significantly different ($P < 0.01$, two-tailed Student's t-test) to BB-Wistar-control, CR-Wistar and Long-Evans, respectively.

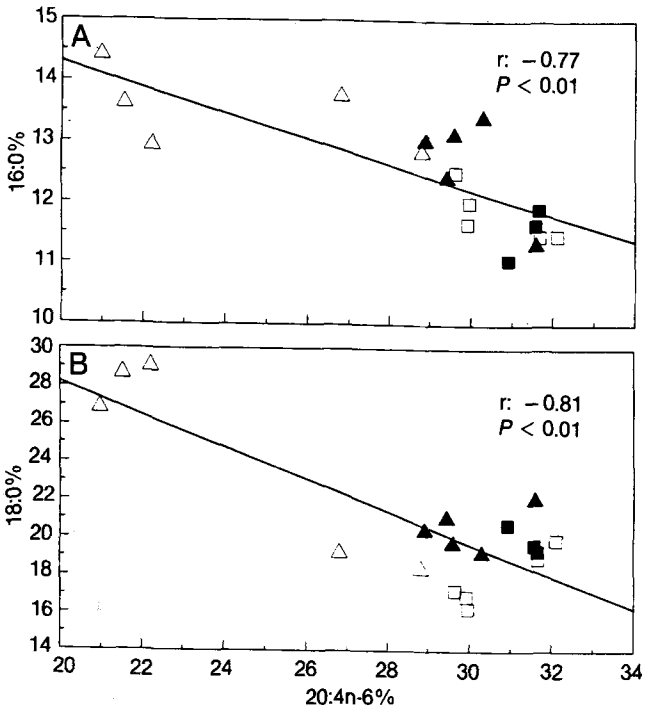

FIG. 3. Relationships between the 20:4n-6 and 16:0 or 18:0 percentages of total lipid microsomal fatty acid composition of (▲) BB-Wistar control, (■) Wistar-CR, (□) Long-Evans, and (△) Sprague-Dawley rats. Lipids were extracted from liver microsomes with chloroform/methanol. The fatty acid composition of microsomal total lipids was determined by gas–liquid chromatography. Regression analysis was by the least-squares method. Each point represents the mean of duplicate determinations.

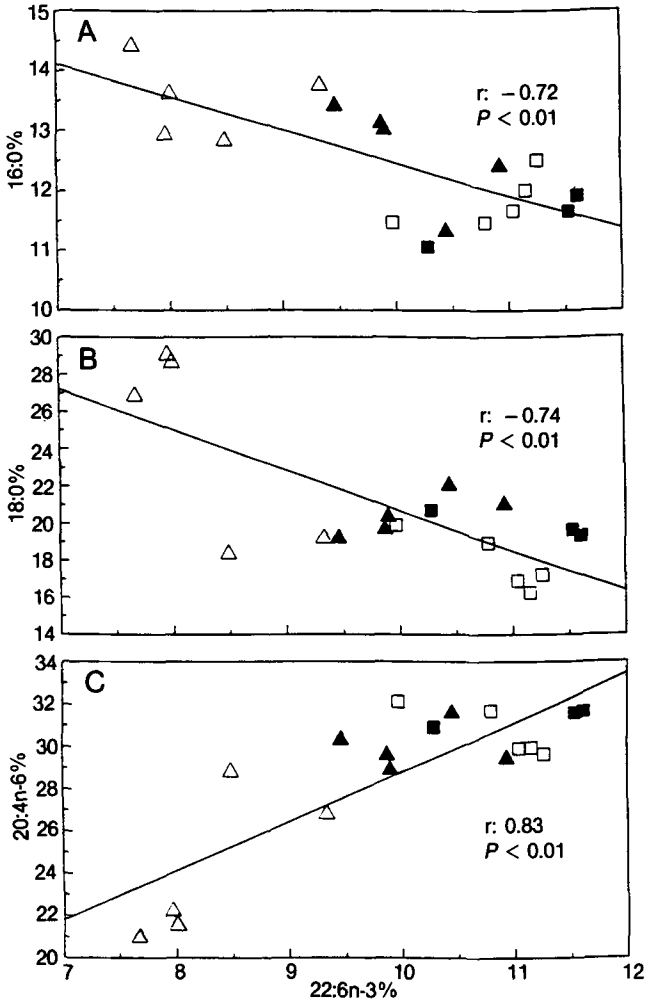

FIG. 4. Relationships between the 22:6n-3 and 16:0, 18:0 or 20:4n-6 percentages of total lipid microsomal fatty acid composition of (▲) BB-Wistar control, (■) Wistar-CR, (□) Long-Evans and (△) Sprague-Dawley. Lipids were extracted from liver microsomes with chloroform/methanol. The fatty acid composition of microsomal total lipids was determined by gas–liquid chromatography. Regression analysis was by the least-squares method. Each point represents the mean of duplicate determinations.

without any accumulation or excessive synthesis of post-Δ6 and/or post-Δ5 desaturation products seems to be assured in all strains. This also explains the positive correlation found between the microsomal levels of the two major final products formed by the two desaturases, namely 20:4n-6 and 22:6n-3 (Fig. 4C), and in the relatively constant ratio of the sum of n-6 to the sum of n-3 fatty acids (Table 1). On the other hand, the high desaturase activities found in certain strains are not mirrored in high levels of 20:5n-3 (post-Δ6 and post-Δ5 desaturation products) or in a low content of the precursor, α-linolenic acid (18:3n-3) (Figs. 2 and 5). It is noteworthy that no significant correlations were found between either Δ6 or Δ5 desaturase activities and any of their fatty acid substrates or products or any other of the major microsomal fatty acids. Our data expand on those previously reported on Wistar rats and support the concept that desaturase activities are not a major controlling factor in establishing liver microsomal fatty acid composition (27). Thus desaturation activity should be measured and should not be predicted from the fatty acid composition. We have previously reported that the total fatty acid composition of liver did not significantly differ from that of its microsomes (28). Thus, it is probably that the correlations, or the lack of them, with regard to microsomal fatty acid levels are also representative of the whole liver. Increased levels of 20:4n-6 and 22:6n-3 were counterbalanced by a decrease in the content of saturated fatty acids (16:0 and 18:0), which in turn serve as substrates of the Δ9 desaturase. Brenner (10) could not detect relationships between Δ6 and Δ9 desaturase activities when both enzymes were measured simultaneously in the same microsomes of rats with different hormonal or dietary treatments. The analyses of all data taken together lead us to suggest that polyunsaturated fatty acid synthesis is coordinated and that monoenoic fatty acids are not involved in modifying the proportional Δ6 desaturation of fatty acids of the n-6 and n-3 families.

Since the desaturase activities and the microsomal fatty acid composition are different in each rat strain, the lipid metabolic response to different stimuli (disease, hormones, dietary treatment, etc.) may also be

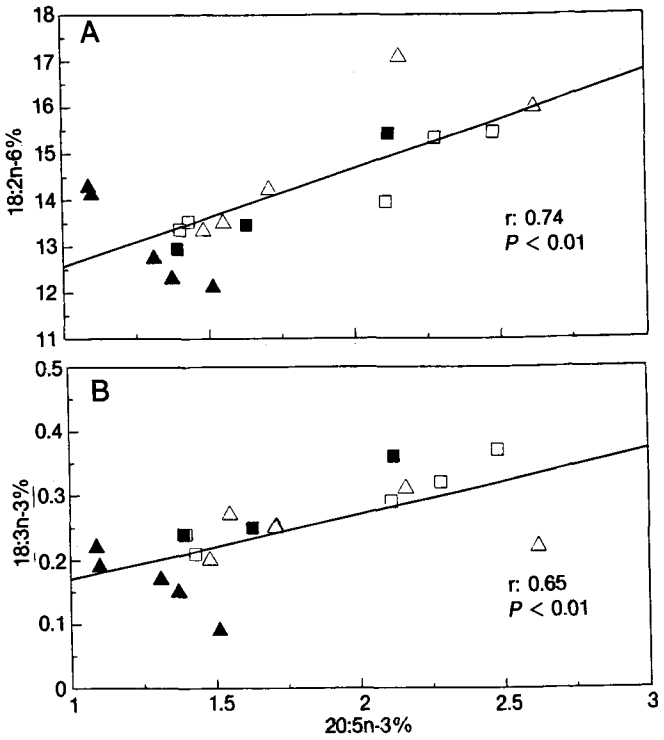

FIG. 5. Relationships between the 20:5n-3 and 18:2n-6 or 18:3n-3 percentages of total lipid microsomal fatty acid composition of (▲) BB-Wistar control, (■) Wistar-CR, (□) Long-Evans and (△) Sprague-Dawley. Lipids were extracted from liver microsomes with chloroform/methanol. The fatty acid composition of microsomal total lipids was determined by gas–liquid chromatography. Regression analysis was by the least-squares method. Each point represents the mean of duplicate determinations.

strain-dependent. We propose that several rat strains should be used for lipid metabolism studies before conclusions are drawn for the rat species as a whole. Extrapolations from one species to another are likely to be unreliable.

ACKNOWLEDGMENTS

The authors wish to thank S. Churchill and M. Coldwell for skillful assistance in the care of the animals.

Lipoprotein Lipase and Hepatic Lipase in Wistar and Sprague-Dawley Rat Tissues. Differences in the Effects of Gender and Fasting

Xavier Galan, Miquel Llobera and **Ignasi Ramírez***

Departament de Bioquímica i Fisiologia, Facultat de Biologia, Universitat de Barcelona, Barcelona, Spain

To evaluate the effects of strain, gender and fasting in the regulation of lipoprotein lipase (LPL) and hepatic lipase (HL) activities were measured in tissues of male and female Wistar and Sprague-Dawley rats after feeding or a 24-h starvation period. It is noteworthy that an effect of gender on LPL activity was observed in Wistar, but not in Sprague-Dawley rats, not only in the basal (fed) activity in several tissues, such as white and brown adipose tissues, heart, and brain, but also in response to fasting which affected LPL activity in brown adipose tissue, heat and lung of female but not of male Wistar rats. By contrast, HL activity in liver, plasma and adrenals of Sprague-Dawley rats was higher in females than in males. No effect of gender on HL activity was observed in Wistar rats. Our results indicate that differences exist between Wistar and Sprague-Dawley rats in the regulation of both LPL and HL. Some of the contradictory results found in the literature may be explained by the differences between rat strains and gender, as well as differences in the nutritional status of the animals.

***Lipids* 29, 333–336 (1994).**

Lipoprotein lipase (E.C. 3.1.1.34; LPL) and hepatic lipase (HL) are lipolytic enzymes that are involved in the metabolism of circulating lipoproteins. LPL catalyzes the hydrolysis of circulating triacylglycerols in chylomicra and in very low density lipoproteins (1). Many tissues express the LPL gene, but LPL activity is particularly high in adipose tissue, heart and skeletal muscles, and in lactating mammary gland (2). The liver also expresses high levels of LPL activity during the perinatal period (3). The enzyme is functional at the luminal side of the endothelial cells, but is synthesized inside the parenchymal cells (4–6). HL participates in the clearance of cylomicron remnants by the liver (7) and in the conversion of high density lipoproteins (HDL_2 into HDL_3) thus contributing to the reverse cholesterol transport to the liver (see Ref. 8 for review). It is important that HL is also located at the vasculature (9), although the enzyme is synthesized within the hepatocytes (10). The presence of a lipolytic activity with characteristics similar to those of hepatic lipase was also demonstrated in some steroidogenic tissues, such as adrenals and ovaries in several animal species (11,12), although the enzyme does not appear to be synthesized in these tissues (13,14). It was therefore proposed that the hepatic lipase found in these tissues may originate in the liver (13). Low but significant levels of HL activity were also reported in the plasma of rats (15), as well as of humans (16).

Both LPL and HL are under nutritional control. LPL is increased in white adipose tissue (WAT) but is decreased in heart of fasted rats (see Refs. 17 and 18 for review), although some of the data reported in the literature are in conflict (4,19–22). We have recently observed that the effect of fasting on LPL activity in the liver of neonatal rats depends on the rat strain used as model (23). We have therefore studied the differences between strains in the effect of fasting on both LPL and HL activities in various tissues.

MATERIALS AND METHODS

Animals. Wistar and Sprague-Dawley rats were obtained from Charles River (Barcelona, Spain). Animals were sacrificed by decapitation at the age of 60 d, and tissues [liver, heart, lungs, epididymal or periuterine WAT, interscapular brown adipose tissue (BAT), adrenal glands and brain] were immediately excised, cleaned and frozen in liquid N_2. The blood was collected in heparinized vials, and plasma was obtained by centrifugation (30 min at 1,000 × *g* at 4°C). Plasma was kept at –40°C until used to determine lipolytic activities. Tissue homogenates were prepared in 10 mM Hepes [*N*-(2-hydroxyethyl)piperazine-*N'*-(2-ethanesulfonic acid)], pH 7.5, containing 1 mM ethylenediaminetetraacetate and 1 mM dithiothreitol using a Polytron (Kinematica GmbH, Luzern, Switzerland) homogenizer. Homogenates were cleared up by centrifugation (10 min at 10,000 × *g* at 4°C). When necessary, the upper fatty layer was removed, and the supernatant centrifuged again until no lipid layer remained.

LPL assay. LPL activity was determined as described (24). The assay mixture contained 0.6 mM glycerol tri[9,10(n)-^{3}H]oleate (12 Ci/mol), 50 mM $MgCl_2$, 0.05% albumin (fatty acid-free), 3% serum (preheated for 60 min at 50°C), 25 mM Pipes [piperazine-*N,N'-bis*(2-ethanesulfonic acid)], pH 7.5, and 0.02 mL of sample in a final volume of 0.2 mL. The incubation was carried out for 30 min at 25°C. The reaction was terminated, and the released [^{3}H]oleate was quantified, as previously described (25). One unit of enzyme activity was defined as the amount of enzyme that catalyzes the release of 1 μmol of oleate per min.

HL assay. HL activity was determined as previously described (26). The assay mixture contained 2.5 mM glycerol tri[9,10(n)-^{3}H]oleate (0.3 Ci/mol), 0.75 M NaCl, 3% albumin (fatty acid-free), 50 mM Tris [tris(hydroxymethyl)-aminomethane], pH 8.5, and 0.05 mL of sample in a final volume of 0.2 mL. The incubation was carried out for 30 min at 25°C. The reaction was terminated, and the released [^{3}H]oleate was quantified as described above for LPL.

Abbreviations: BAT, brown adipose tissue; HDL, high density lipoproteins; Hepes, *N*-(2-hydroxyethyl)piperazine-*N'*-(2-ethanesulfonic acid); HL, hepatic lipase; LPL, lipoprotein lipase; Pipes, piperazine-*N,N'-bis*(2-ethanesulfonic acid); Tris, tris(hydroxymethyl)aminomethane; WAT, white adipose tissue.

RESULTS

Effect of gender. At the age of 60 d, the body weight was lower in Wistar than in Sprague-Dawley rats (Table 1). Body weights of females were about 40% lower than those of males in both strains. Similar differences were also observed in several tissues, notably in liver, weights, but also in heart and lung weights.

In both Wistar and Sprague-Dawley rats, the distribution of LPL activity between tissues was similar (Table 2). However, gender affected LPL activity in tissues of Wistar but not in tissues of Sprague-Dawley rats. Thus, in Wistar rats LPL activity in WAT and brain was lower in females than in males, but the activity in heart and BAT was higher in females than in males. LPL activity was not detectable in liver and plasma of adult animals (data not shown). The lack of an effect of gender on LPL activity in Sprague-Dawley rats has already been reported (27).

We studied HL activity in liver, plasma and adrenals (Table 3). As previously described (11,12), we found that HL activity was higher in liver than in adrenals and that a substantial amount could be detected in plasma. No effect of gender was seen in Wistar rats (this agrees with previous results from our laboratory; see Ref. 28), but in Sprague-Dawley rats HL activity was 35–55% higher in females than in males, not only in the liver but also in plasma and adrenals.

As shown in Table 3, fasting caused a decrease in the HL activity not only in liver but also in plasma of Wistar and Sprague-Dawley rats. No significant differences were found between female and male animals in their response to fasting. In adrenals, fasting also produced a decrease in HL activity, but the differences were only significant in male Wistar and in female Sprague-Dawley rats.

DISCUSSION

Several studies have demonstrated differences in both adipose tissue (29–31) and postheparin plasma (32) LPL activity between men and women. For rodents, scarce and conflicting results have been reported (27,33,34). Our data indicate that the effect of gender on both tissue LPL and HL very much depends on the rat strain used.

The effect of gender on LPL activity is likely to be related to the role of estrogens. It is well established that, in female rats, ovariectomy increases LPL activity in WAT (33), and estrogen treatment restores the lower LPL activity in this tissue (33,5). In the heart, LPL activity is increased by estrogen treatment (27). Androgens may not be directly involved in the effect of gender on LPL, as castration of male rats did not produce any alteration in adipose tissue LPL activity (27). In humans, where LPL activity in WAT is higher in women than in men, estrogen treatment increases LPL activity (see Ref. 17 for review). The role of estrogen in the effect of gender on HL is not clear for the rat. Malendowicz and Paluszak (36) found that ovariectomy had no effect on HL-like activity in adrenals, and Staels *et al.* (37) described that the increase in both hepatic lipase activity and *m*RNA relative content in the liver of ovariectomized rats was not observed in pair-fed animals. They also found no differences between female and male Wistar rats in HL *m*RNA relative content in the liver (37). Androgens are more likely involved in the effect of gender on hepatic lipase, as it was reported that orchiectomy resulted in an increase in the HL-like activity in adrenals, and that testosterone-replacement therapy restored normal values (36). In humans, the relationship between estrogens and hepatic lipase is well established (38). Estrogen administration to postmenopausal women decreased postheparin plasma HL activity (39), even in diet-controlled trials (40). Furthermore, changes in postheparin plasma HL activity were countercurrent to those of 15-β-estradiol in the course of the estral cycle (41). In addition, HL activity in postheparin plasma was shown to be higher in men than in women (42). Therefore, profound differences between rats and humans appear to exist in the effect of sex hormones on both LPL and HL. Our results further suggest that differences between rat strains may exist in the effects of these hormones.

[a]Tissues were obtained from 60-day-old rats either fed or fasted and processed to determine lipoprotein lipase activity. Results are expressed in mU/g tissue and are means ± SE of 5–6 animals per group. Statistical comparisons were made by Student's *t*-test. NS, nonsignificant differences.

There is a general agreement in the literature concerning the effect of fasting on PL activity in WAT (see Ref. 17 for review), and we have found that LPL activity in this tissue was decreased by fasting in all animals studied. For the heart, there exists some consensus that fasting increases LPL activity, but some studies failed to show such an effect (see Ref. 18 for review). Our results indicate that this apparent contradiction may be due, at least in part, to the gender or the strain of rats used in these studies, as we found that fasting produced a stronger effect in the heart of Sprague-Dawley rats (about a 2-fold increase) than in the heart of Wistar rats (1.2-fold increase in females and no effect in males).

LPL activity in rat brain is known to be decreased by extended (three days) fasting (43,44). Our results, indicating no effect of 24-h fasting, are in agreement with those reported by Gavin *et al.* (44). Little is known about the effect of the nutritional status on LPL activity in BAT and lung. Very early studies by Hamosh and Hamosh (45) on the effect of fasting in Sprague-Dawley rats showed no effect on

TABLE 3

Hepatic Lipase Activity in Tissues of Wistar and Sprague-Dawley Rats[a]

	Wistar			Sprague-Dawley		
	Fed	Fasted	*P* vs. fed	Fed	Fasted	*P* vs. fed
Liver (mU/g)						
Male	633 ± 33	433 ± 21	<0.001	546 ± 18	372 ± 22	<0.001
Female	627 ± 31	494 ± 36	<0.05	739 ± 29	473 ± 32	<0.001
P vs. male	NS			<0.05		
Plasma (mU/mL)						
Male	6.6 ± 0.4	3.9 ± 0.2	<0.001	5.9 ± 0.4	3.9 ± 0.2	<0.01
Female	6.2 ± 0.2	4.9 ± 0.5	<0.05	8.1 ± 0.5	4.7 ± 0.4	<0.001
P vs. male	NS			<0.05

P vs. male	NS			<0.05		

[a]Hepatic lipase activity was determined in the liver, plasma and adrenals of Wistar and Sprague-Dawley rats, fed or fasted (24 h). Results are means ± SE of five animals per group. Statistical differences were determined by Student's *t*-test. NS, nonsignificant differences.

LPL activity in lungs. In BAT of male Wistar rats, it was shown that after three days of fasting, LPL activity in this tissue was decreased (46). Our results showing that fasting affected LPL activity in both BAT and lung only in female Wistar rats are consistent with these reports.

The results indicate that in Wistar rats differences exist between females and males not only in the LPL activity in several tissues, but also in their response to fasting. This suggests that sex hormones may affect the action of hormones directly responsible for the effect of fasting. Differences between female and male rats in their response to hormones have been described. For example, the sensitivity of hepatocytes to the stimulation of glycogen phosphorylase by adrenaline is an order of magnitude higher in male than in female rats (47). This is known to be due to the different mechanism of action of catecholamines in the liver, i.e., the α_1-receptor-mediated calcium mobilization in males and the β-receptor-mediated cAMP increase in females (48). Also, the sensitivity of adipocytes to stimulation of glucose metabolism by insulin is greater in female than in male rats (49). Furthermore, while in hepatocytes from male rats prostaglandins of the E series inhibit hormone-stimulated glycogenolysis, in hepatocytes from female rats they do not (50). The mechanisms by which sex hormones produce these differences are largely unknown. The relationship between sex and other hormones in the regulation of LPL in rat tissues has not yet been explored. To address this question and to elucidate the reasons for the differences in the response of LPL to fasting between rat strains will give new insights into how this important enzyme of lipoprotein metabolism is regulated.

Diets Rich in Lean Beef Increase Arachidonic Acid and Long-Chain ω3 Polyunsaturated Fatty Acid Levels in Plasma Phospholipids

Andrew J. Sinclair[a,*], Leeann Johnson[b], Kerin O'Dea[b] and Ralph T. Holman[c]

[a]Department of Medical Laboratory Science, Royal Melbourne Institute of Technology, Melbourne, Victoria 3001, [b]Deakin Institute of Human Nutrition, Deakin University, Geelong, Victoria 3217, Australia and [c]The Hormel Institute, University of Minnesota, Austin, Minnesota 55912

Diets rich in meat are claimed to contribute to the high tissue arachidonic acid (20:4ω6) content in people in Westernized societies, but there are very few direct data to substantiate this assertion. Because meat contains a variety of long-chain polyunsaturated fatty acids (PUFA) that are susceptible to oxidation, we initially examined the effect of cooking on the long-chain PUFA content of beef, and then determined the effect of ingestion of lean beef on the concentration of long-chain PUFA in plasma phospholipids (PL). First, we examined the effect of grilling (5–15 min) and frying (10 min) different cuts of fat-trimmed lean beef on the long-chain PUFA content. Second, we investigated the effect of including 500 g lean beef daily (raw weight) for 4 wk on the fatty acid content and composition of plasma PL in 33 healthy volunteers. This study was part of a larger trial investigating the effect of lean beef on plasma cholesterol levels. In the first two weeks, the subjects ate a very low-fat diet (10% energy) followed by an increase in the dietary fat by 10% each week for the next 2 wk. The added fat consisted of beef fat, or olive oil (as the oil or a margarine) or safflower oil (as the oil or a margarine). This quantity of beef provided 60, 230, 125, 140 and 20 mg/d, respectively, of eicosatrienoic acid (20:3ω6), 20:4ω6, eicosapentaenoic acid (20:5ω3), docosapentaenoic acid (22:5ω3) and docosahexaenoic acid (22:6ω3). Grilling for 10–15 min, but not frying, of the fat-trimmed lean beef resulted in 20–30% losses of the 20 and 22 carbon PUFA. The consumption of the lean beef during the first two-week period, when there was a very low level of dietary fat, was associated with significant increases in the proportion and concentration of 20:3ω6, 20:4ω6, 20:5ω3 and 22:5ω3 in the plasma PL and a significant decrease in the proportion and content of 18:2ω6. The addition of beef fat or olive oil to the diets containing lean beef did not alter the plasma PL fatty acid profile compared with the very low-fat diet, whereas the addition of safflower oil maintained the significant increases in 20:4ω6 and 22:5ω3 but led to decreases in 18:3ω3 and 20:5ω3 compared with the very low-fat diet. The results showed that diets rich in lean beef increased the 20:3ω6, 20:4ω6 and the long-chain ω3 PUFA levels in the plasma PL. A high level of linoleic acid in diets rich in lean beef prevented the rise in the plasma level of 20:3ω6 and 20:5ω3, two fatty acids known to antagonize the effects of 20:4ω6 on platelet aggregation.
***Lipids* 29, 337–343 (1994).**

Following the intensive research in the 1980s on the role of ω6 and ω3 polyunsaturated fatty acids (PUFA) in human nutrition, there is now general agreement that the ratio of the ω6 to ω3 PUFA is too high in the current Western diet (1). This dietary imbalance is known to cause an imbalance in the ratio of ω6 to ω3 PUFA in tissues and a consequent exaggerated metabolism of arachidonic acid (20:4ω6) to eicosanoids (2).

The main PUFA in the Western diet is linoleic acid (18:2ω6), with lesser proportions of other PUFA such as α-linolenic acid (18:3ω3), arachidonic acid (20:4ω6), eicosapentaenoic acid (20:5ω3) and docosahexaenoic acid (22:6ω3). The intake of 18:2ω6 is of the order of 10–20 g/d, and this constitutes more than 85% of total PUFA intake (3,4). The high level of ω6 PUFA in tissues is a result of the dominance of the current food supply by 18:2ω6, which is the precursor of 20:4ω6, which, in turn, is the substrate for the eicosanoids. The fatty acid 18:3ω3 can compete with 18:2ω6 for metabolism *via* the desaturation and chain elongation enzymes (5), but because the dietary intake of this PUFA is low there is little restraint on the production of 20:4ω6.

Another source of tissue 20:4ω6 is that which originates directly from the diet, from foods such as meat, organ meats, eggs and fish (6). It is known that dietary 20:4ω6 is efficiently incorporated into tissue lipids in animals and humans (7–10), although there are very low levels of 20:4ω6 in the diet relative to linoleic acid.

There is little information on the average daily intake of 20:4ω6 in typical Western diets, and data for the content of this fatty acid in specific foods are incomplete. Phinney *et al.* (11) have suggested that, for U.S. adults eating eggs and meat, the intake is probably in the range 200–1000 mg/d. This agrees with the figure of about 500 mg/d determined on a mixed food omnivorous diet by Garg *et al.* (12). The 1985 Victorian Nutrition Survey reported 20:4ω6 intakes of 0.4–0.5 g/d based on a semi-quantitative food frequency questionnaire that used the British food tables as the nutrient data base, with additional data for some Australian foods (4). Based on a 24-hour dietary recall method and using Food Tables from the University of Minnesota, Dolecek (3) estimated the 20:4ω6 level in the MRFIT study at about 200 mg/d.

Diets rich in meat are claimed to contribute to the high tissue 20:4ω6 content in people in Westernized societies (13,14), but there are very few direct data to substantiate this assertion. Phinney *et al.* (11) have reported that omnivores with a relatively high intake of meat had a higher plasma 20:4ω6 level than did vegetarians. Sinclair *et al.* (10) reported that diets rich in kangaroo meat (100 mg 20:4ω6/100 g meat) induced higher plasma 20:4ω6 levels than did vegetarian diets.

Abbreviations: PGE_1, prostaglandin E_1; PL, phospholipids; P/S, polyunsaturated fatty acid/saturated fatty acid ratio; PUFA, polyunsaturated fatty acids; TXA_2, thromboxane A_2.

The present study was designed to test whether diets rich in lean beef were associated with increases in plasma 20:4ω6 levels. This study is part of a larger trial investigating the effect of lean beef on plasma cholesterol levels, the results of which have been reported previously (15,16). Because meat contains a variety of long-chain PUFA that are susceptible to oxidation, we initially examined the effect of cooking on the long-chain PUFA content of beef, and then determined the effect of ingestion of lean beef (500 g/d) on the concentration of long-chain PUFA in plasma phospholipids (PL) using capillary gas chromatography.

MATERIALS AND METHODS

The meat for the dietary study and the fatty acid analyses was obtained from commercial butcher shops at the Queen Victoria Market, Melbourne, Australia and from retail outlets in Geelong, Australia. The subjects for the study were recruited through the Department of Medicine, Royal Melbourne Hospital and the Department of Human Nutrition, Deakin University, Geelong, as described previously (15,16). The protocols for the beef plus beef fat study and the beef plus olive oil or safflower oil studies were approved by the Ethics Committees of the Royal Melbourne Hospital and Deakin University, respectively.

Subjects. Volunteers for these studies were thirty-three free living, weight stable subjects (16 men, 17 women) with plasma cholesterol levels below 6 mM. In Study 1 (lean beef plus beef fat), the mean age and body weight of the 11 subjects (5 males and 6 females) were 25 ± 2 yr and 70 ± 3 kg (mean ± SD), respectively. In Study 2 (lean beef plus olive oil), the mean age and weight of the 11 subjects were 47 ± 14 yr and 71 ± 9 kg, respectively (for 5 males and 6 females), and in Study 3 (lean beef plus safflower oil), the mean age and weight of the 11 subjects were 38 ± 11 yr and 73 ± 15 kg, respectively (for 6 males and 5 females).

Diets. The details of the diets have been published previously together with the results on the effect of the diets on the plasma lipoprotein cholesterol and triglyceride composition (15,16). There were three studies, each lasting 5 wk with subjects acting as their own controls. The subjects weighed and recorded all food and liquid intake for the duration of the study. The first week was a baseline period in which subjects consumed their habitual diets containing their usual intake of 30–100 g beef per day. In the second and third weeks, the subjects consumed a very low-fat diet (10% energy) derived from vegetables, fruit, cereals, and nonfat dairy products, together with 500 g per day (raw weight) of fat-trimmed lean beef. If the subject's usual daily energy intake was less than 1800 kcal, the daily beef allowance was reduced to 400 g. The lean beef was supplied to the subjects in fat-trimmed preweighed packages daily, and it consisted of topside, rump, minced topside and diced steak. Samples were taken regularly for total fat analysis with the mean (±SD) fat content being 4.9 ± 0.9 g/100 g wet weight (n = 24). In the fourth and fifth weeks, the subjects continued to consume the lean beef, but the fat content of the diet was increased 10% energy per week so that in week 4 the total fat content was 20% of energy, and in week 5 it was 30% of energy. In Study 1, the fat was provided in the form of beef fat, in Study 2 the fat was olive oil or an olive oil-based margarine and in Study 3 the fat was safflower oil or a safflower oil-based margarine. The energy intake was maintained constant throughout each study. Because of the low-energy density and high bulk of the diet in weeks 2 and 3, the subjects were provided with a carbohydrate supplement (a glucose polymer; Polycose, Ross Laboratories, Columbus, OH) that was equivalent to 20% of energy in weeks 2 and 3. In weeks 4 and 5, the intake of the carbohydrate supplement was reduced as the fat was increased, thus ensuring a constant energy intake. As reported previously (15,16), the fat intake of all 33 subjects on their usual diets was 36.6% of total energy with a ratio of polyunsaturated to saturated fatty acids (P/S) of 0.38. On the very low-fat diet containing lean beef, the dietary fat contributed 9.3% dietary energy with a P/S ratio of 0.49. After two weeks on the lean beef plus beef fat diet (week 5 of Study 1), the dietary fat level was 29.1% dietary energy with a P/S of 0.21. On the lean beef plus olive oil diet, the total fat intake was 29.6% energy with a P/S of 0.63, and on the lean beef plus safflower oil diet the fat intake was 27.9% energy with a P/S of 2.89. The long-chain PUFA content of the beef was based on the analysis of samples of lean beef collected from the same outlets used to supply the beef consumed during the studies. The analytical procedures used are described below. The 500 g lean beef contained the following amounts of 20:3ω6, 20:4ω6, 20:5ω3, 22:5ω3 and 22:6ω3 (in mg): 60, 230, 125, 140, 20, respectively. There were no other dietary sources of these fatty acids during the 4-week period of beef consumption.

Analytical methods. To determine the effect of cooking on the fatty acid content of lean beef, five pieces of rump steak (approx. 800 g) were purchased from five separate commercial outlets. The visible fat was trimmed from the steak, and it was then divided into six portions each of about 100 g. One portion of steak from each of the five pieces was grilled in a gas stove for 15 min (well-done), one for 10 min (medium), one for 5 min (rare) and one left uncooked. An additional piece was fried without added fat or oil in a Teflon-coated frying pan for 10 min, and the remaining piece was minced and then fried as above for 5 min. After cooking, the steaks were allowed to cool on a piece of absorbent paper towel, the meat was minced and a 10 g sample was extracted in chloroform/methanol (2:1, vol/vol) containing antioxidant as previously described (17). The moisture content was determined on a 2 g sample by heating in an oven at 105°C for 24 h. The total lipid content was determined gravimetrically, and on a separate aliquot the methyl esters of the total fatty acids were formed by saponification in KOH in methanol followed by esterification with BF_3 in methanol (17). The fatty acid methyl esters were separated by capillary gas–liquid chromatography using a 50-m × 0.32-mm i.d. fused silica column coated with CP Sil 88 (Chrompak, Middleburg, The Netherlands), and the amounts were quantified using heptadecanoic acid as an internal standard (17). The cholesterol content was determined by capillary gas–liquid

chromatography using a 25-m × 0.22-mm i.d. fused silica bonded-phase column (BP-1) (S.G.E., Melbourne, Australia). Dihydrocholesterol (5α-cholestanol) was used as an internal standard. Aliquots of the total lipid plus 5α-cholestanol were saponified, extracted and then derivatized with *bis*(trimethylsilyl)trifluoroacetamide in pyridine (Pierce Chemical Company, Rockford, IL) for 30 min at room temperature.

Fasting blood samples (10 mL into heparinized tubes) were obtained from the subjects at weekly intervals throughout the study. The plasma was stored at —20°C until analyzed. Lipids were extracted from the plasma using chloroform/methanol (2:1, vol/vol), and the phospholipids were separated from the neutral lipids by thin-layer chromatography (10). A known amount of diheptadecanoyl phosphatidylcholine (internal standard) was added to the plasma prior to extraction. The methyl esters of the PL fatty acids were formed by a saponification step followed by transesterification in BF_3 in methanol (17), and the fatty acid methyl esters were separated by capillary gas–liquid chromatography as described above.

Statistics. The paired *t*-test was used to compare results within groups. Results are expressed as mean ± SEM; significance was taken as $P < 0.05$.

RESULTS

The lean, fat-trimmed raw beef contained about 4.3 g of total lipid, including 49 mg cholesterol, and 74.3 g of water per 100 g fresh weight. Cooking decreased the moisture content of all samples. When this loss of moisture was considered, there was no significant decrease in either total lipid or cholesterol (Table 1). The main PUFA in the samples were (in decreasing order of concentration): 18:2ω6, 20:4ω6, 20:5ω3, 22:5ω3, 18:3ω3, 20:3ω6 and 22:6ω3. The 20:4ω6 and 20:5ω3 concentrations of the fat-trimmed lean beef were 37 and 23 mg/100 g wet weight, respectively. There were significant ($P < 0.05$) decreases in the contents of all the 20 and 22 carbon PUFA in the grilled beef compared with the raw samples, although there was no consistent loss of a specific PUFA as the length of cooking increased. Frying minced or whole steaks did not lead to significant losses of the PUFA, apart from a significant decrease in 22:5ω3 in the minced steak (Table 2). There were no significant changes in the concentration of the major saturated or monounsaturated fatty acids following cooking.

TABLE 1

The Effect of Cooking on the Total Lipid and Cholesterol Content of Lean Beef[a]

Beef sample	Cooking technique	Total lipid (g)	Cholesterol (mg)
Raw		4.3 ± 0.7	49 ± 2
Rare	Grilled	3.3 ± 0.3	50 ± 2
Medium		3.6 ± 0.4	52 ± 2
Well-done		3.6 ± 0.2	51 ± 1
Minced		3.5 ± 0.3	50 ± 1
Fried	Pan-fried	3.4 ± 0.2	50 ± 1

[a]Results are expressed per 100 g equivalent fresh weight, mean ± SEM. There were five samples analyzed for each cooking method. The results for the cooked samples are expressed per 100 g equivalent raw sample, i.e., adjusted for the moisture loss on cooking (see Materials and Methods). There were no significant differences between the cooked samples and the raw sample.

Significant changes in the plasma PL fatty acid composition of the thirty-three subjects occurred after they had consumed a very low-fat diet containing 500 g/d of fat-trimmed lean beef for 2 wk. The effect of this dietary change on the fatty acid composition of the plasma PL is shown in Table 3 and Figure 1. The proportion of 18:2ω6 decreased ($P < 0.001$), while that of the other ω6 PUFA increased significantly, namely 20:3ω6 ($P < 0.001$), 20:4ω6 ($P < 0.001$), 22:4ω6 ($P < 0.001$) and 22:5ω6 ($P < 0.001$). The proportions of 20:5ω3 ($P < 0.001$) and 22:5ω3 ($P < 0.001$) also increased. The proportion of 18:0 decreased $P < 0.05$) while that of 16:0, 16:1 and 18:1 increased ($P <$ 0.001). There were also significant elevations, in plasma PL, in all 20 and 22 carbon PUFA levels except 22:6ω3. The increases in the long-chain PUFA were 11 mg/L for 20:3ω3 ($P < 0.001$), 28 mg/L for 20:4ω6 ($P < 0.001$), 5 mg/L for 20:5ω3 ($P < 0.001$) and 7 mg/L for 22:5ω3 ($P < 0.001$). There were also statistically significant changes in the proportions of the plasma PL PUFA one week after commencing the very low-fat diet (data not shown).

TABLE 2

The Effect of Cooking on the Mean Content of Polyunsaturated Fatty Acids in Fat-Trimmed Lean Beef[a]

Sample	Treatment	18:2ω6	18:3ω3	20:3ω6	20:4ω6	20:5ω3	22:5ω3	22:6ω3
Raw	—	61 ± 9	17 ± 2	10 ± 1	37 ± 5	23 ± 2	23 ± 0.4	3 ± 0.4
Rare	Grilled	60 ± 6	18 ± 2	8 ± 1[b]	32 ± 3	20 ± 2	21 ± 0.4[c]	3 ± 0.3
Medium	Grilled	54 ± 5	16 ± 1	8 ± 1[b]	30 ± 3[c]	18 ± 2[d]	18 ± 2[c]	2 ± 0.3[c]
Well-done	Grilled	57 ± 6	17 ± 1	8 ± 1[b]	29 ± 3[c]	18 ± 1[c]	19 ± 1[c]	2 ± 0.2[b]
Minced	Fried	63 ± 7	19 ± 2	8 ± 1[b]	32 ± 4	21 ± 2	21 ± 1[b]	3 ± 0.4
Medium	Fried	54 ± 7	16 ± 2	9 ± 1	32 ± 3	22 ± 2	22 ± 2	3 ± 0.4

[a]The results for the five samples are expressed as mg per 100 g raw sample, mean ± SEM. For the cooked samples, the results are given per 100 g equivalent raw sample (i.e., adjusted for the moisture loss on cooking).

[b–d]Significantly different from raw sample (paired *t*-test), [b]$P < 0.05$, [c]$P < 0.01$, [d]$P < 0.001$.

TABLE 3

Fatty Acid Composition of Plasma Phospholipids over the Five-Week Intervention in Subjects Fed a Very Low-Fat Diet Rich in Lean Beef in Weeks 2–3 and Then Supplemented with Beef Fat, Olive Oil or Safflower Oil in Weeks 4–5[a]

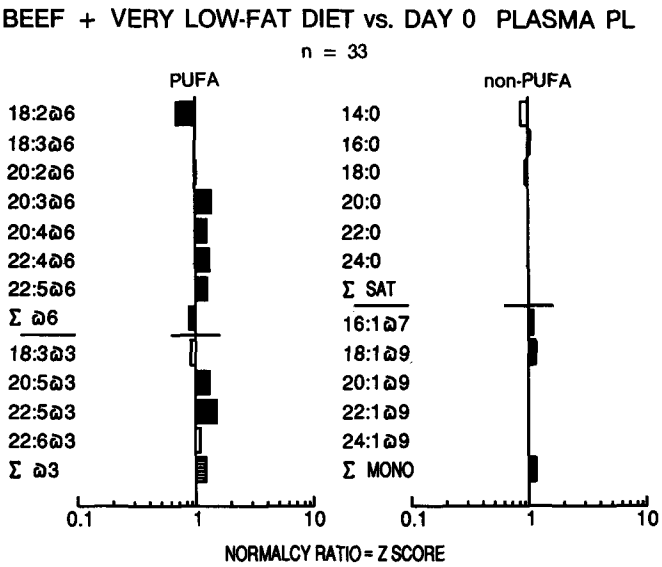

FIG. 1. Plasma phospholipid (PL) fatty acid profile expressed as a normalcy ratio for subjects on very low-fat diet rich in lean beef compared with the fatty acid profile on the subject's usual high-fat diet. The normalcy ratio is the value for a fatty acid on the very low-fat diet divided by the value on the usual diet (see Ref. 31). The black bars indicate $P < 0.001$; closely striated bars, $P < 0.01$; widely striated bars, $P < 0.05$; and open bars nonsignificant change. PUFA, polyunsaturated fatty acids; SAT, saturated; MONO, monounsaturated.

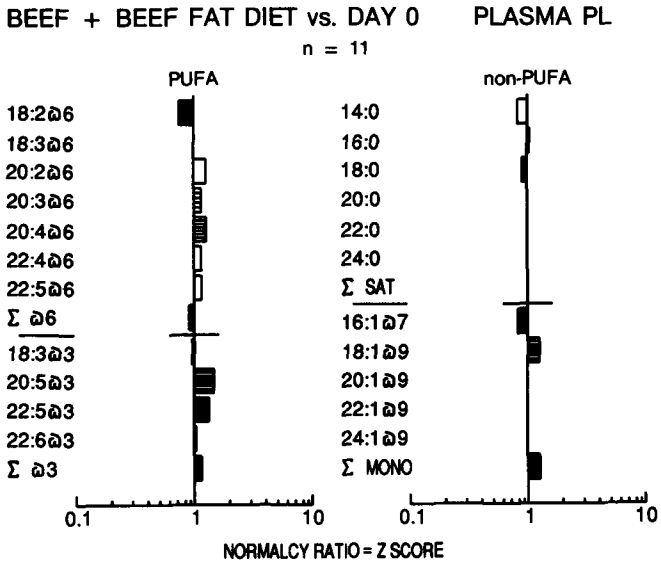

FIG. 2. Plasma PL fatty acid profile expressed as normalcy ratio for subjects on a high-fat diet rich in beef fat plus lean beef compared with the fatty acid profile on the subject's usual high-fat diet. Significant differences and abbreviations as in Figure 1.

The addition of fat to the very low-fat diet containing lean beef was associated with significant changes in the plasma PL fatty acids that were dependent upon the nature of the fat included in the diet (Table 3 and Figs. 2–4). Beef fat plus lean beef, and olive oil plus lean beef, were associated with significant increases in the percentage of 18:1, 20:3ω6, 20:4ω6, 20:5ω3 and 22:5ω3 and a significant decrease in 18:2ω6 compared with the values obtained when the subjects were on their usual diets. In contrast, safflower oil plus lean beef led to a significant decrease in oleic acid, 18:3ω3 and 20:5ω3 and an increase in 18:2ω6, 20:2ω6, 20:4ω6, 22:4ω6 and 22:5ω3.

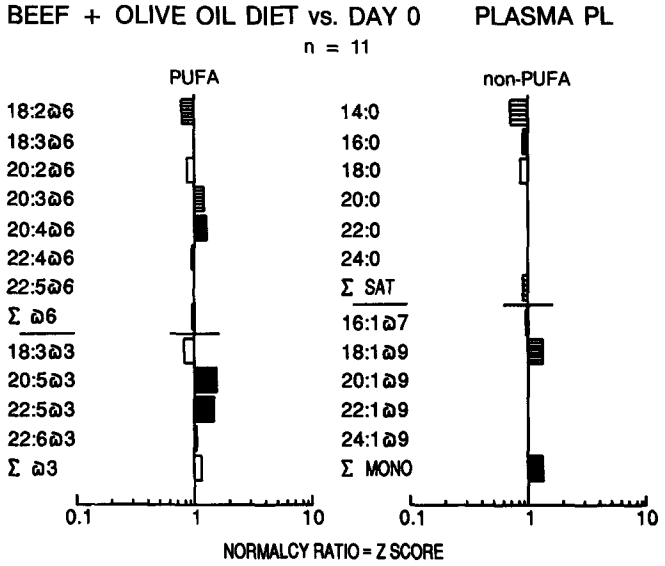

FIG. 3. Plasma PL fatty acid profile expressed as normalcy ratio for subjects on a high-fat diet rich in olive oil plus lean beef compared with the fatty acid profile on the subject's usual high-fat diet. Significant differences and abbreviations as in Figure 1.

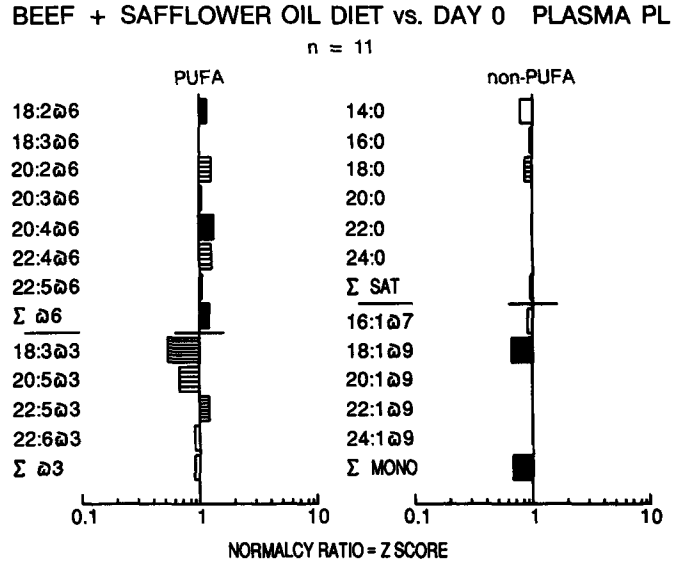

FIG. 4. Plasma PL fatty acid profile expressed as normalcy ratio for subjects on a high-fat diet rich in safflower oil plus lean beef compared with the fatty acid profile on the subject's usual high-fat diet. Significant differences and abbreviations as in Figure 1.

This dietary study was also designed to determine the effect of inclusion of lean beef on plasma lipoprotein lipid concentrations. The results have been reported previously (15,16), and they indicated that the inclusion of 500 g lean beef daily in the very low-fat diet was associated with a significant decline in total plasma cholesterol concentration ($P < 0.001$) compared with the subject's usual diet. This effect was maintained when either olive or safflower oils were added back to this diet ($P < 0.001$); however, the addition of beef fat was associated with a significant elevation in the total plasma cholesterol level ($P < 0.01$).

DISCUSSION

The first purpose of this study was to determine the effect of cooking on the long-chain PUFA content of beef. Although the USDA Handbook on the composition of meat lists 20:4ω6 as the only long-chain PUFA in a variety of beef cuts (18), there have been recent reports from the United States and Australia, based on analyses conducted using capillary gas-chromatographic columns, of significant levels of 20:3ω6, 20:4ω6, 20:5ω3 and 22:5ω3 in pasture and grain-fed beef (17,19). There were significant losses of some PUFA with increasing time of grilling, particularly the 20 and 22 carbon PUFA, in which case the losses amounted to 20–33%. Previous studies on the effect of cooking on the fatty acid composition of the intramuscular PL or total lipids found no difference between the proportion of 18-carbon PUFA in raw and cooked samples of beef, although the most highly unsaturated fatty acids (20 and 22 carbon ω3 PUFA) were not determined in those studies (20–22). The losses of the more highly unsaturated fatty acids are not surprising since they are more susceptible to oxidation than the 18-carbon PUFA (23).

The second purpose of this study was to learn whether long-chain PUFA in beef can make a significant contribution to plasma PL fatty acids of subjects consuming 500 g/d of lean beef. The inclusion of lean beef in the diet of the subjects was associated with significant rises in the proportion and concentration of 20:3ω6, 20:4ω6, 20:5ω3 and 22:5ω3 and a significant decline in 18:2ω6 in the plasma PL. We ascribe these changes to the meat in the diet rather than the change to the very low-fat diet because these fatty acids were present in the lean beef, and we have previously shown that similar very low-fat vegetarian diets did not lead to increases in these PUFA in plasma PL (10). These fatty acids were all present in the lean beef, even though the levels were as low as 50 mg/d (from 500 g raw beef) in the case of the 20:3ω6. There was no increase in either 18:3ω3 or 22:6ω3 in the plasma PL although these two fatty acids were also present in the beef. The 22:6ω3 was found in the lowest concentration (20 mg/500 g beef), whereas the 18:3ω3 was present at a higher level (85 mg/500 g beef). The 18:3ω3 may have partitioned into the plasma triglyceride fraction, or it may have been preferentially metabolized *via* oxidation or conversion to 20:5ω3. The former two possibilities may be more likely explanations (24).

The addition of dietary fat to the very low-fat beef diet was associated with fat-specific changes in the plasma PL fatty acid profile. Both beef fat and olive oil added at a level of 20% energy led to increases in 20:3ω6, 20:4ω6, 20:5ω3 and 22:5ω3. The same changes were observed in the plasma PL on the very low-fat diet. In contrast, the addition of 20% energy from safflower oil was associated with rises in all the ω6 PUFA (except 20:3ω6) and in 22:5ω3 and significant decreases in 18:3ω3 and 20:5ω3 in the plasma PL. These results show that the three diets with the lowest 18:2ω6 levels (very low-fat diet, beef plus

beef fat diet and beef plus olive oil diet; all less than 5% energy as 18:2ω6) had similar effects on the fatty acid profile of the plasma PL. This suggests that at very high 18:2ω6 levels (beef plus safflower oil >14% of energy), the 18:2ω6 reduces the metabolism of 18:3ω3 to 20:5ω3 and/or competes more effectively with 18:3ω3 and 20:5ω3 in the acylation into PL. High dietary 18:2ω6 levels have previously been reported to result in low 20:5ω3 levels in the serum PL fraction in a five-month dietary study (25).

The results from this study show that a variety of long-chain ω6 and ω3 PUFA found in lean beef, not just 20:4ω6, contribute to the pool of these PUFA found in plasma PL. However, the effects of beef on the plasma PL of humans are modulated by the level of 18:2ω6 in the diet. If the diet contains lean beef and a modest to low 18:2ω6 level, the effect on the plasma PUFA profile is an increase in 20:3ω6, 20:4ω6 and 20:5ω3. In contrast, if the diet containing lean beef is also rich in 18:2ω6, only increases in 18:2ω6 and 20:4ω6 in plasma PL are observed. We recognize that the amount of lean beef consumed in this study was high relative to the usual intakes of lean meat in this country (4). However, we have preliminary evidence that lower intakes of lean beef (300 g/d) also result in significant increases in the proportion of long-chain PUFA in plasma PL in human subjects (Sinclair, A.J., and Morgan, S.A., unpublished data).

There is a concern that diets that raise 20:4ω6 might be prothrombotic (13,14,26), and meat has been viewed as a major source of dietary 20:4ω6. The present results show that this view may be too simplistic. We acknowledge that the changes described in the proportion of plasma PL PUFA in this study were quite small. However, we have preliminary evidence that diets rich in lean red meat, which induced similar changes in 20 carbon PUFA in the plasma PL of seven subjects, were associated with significant reductions in the *in vivo* production of prostacyclin (as measured by gas chromatography/mass spectrometry of the main urinary metabolite; Mann, N.J., and Sinclair, A.J., unpublished data). We have not yet determined the effect of this diet on thromboxane production.

We propose that diets that increase the proportion of 20:3ω6, 20:4ω6 and 20:5ω3 in plasma (and presumably tissue) PL might not have the same effect on thrombosis as diets that raise 20:4ω6 alone, for the following reasons. Increased levels of plasma 20:4ω6 may lead to increases in platelet 20:4ω6 that upon appropriate stimulation could lead to the production of thromboxane A_2 (TXA_2) with resultant platelet aggregation (9). Increased levels of 20:3ω6 and 20:5ω3 might be potentially antithrombotic since the former is a precursor of prostaglandin E_1 (PGE_1) that prevents platelet aggregation (27), and the latter (20:5ω3) has been shown to effectively reduce production of TXA_2 by platelets and platelet aggregation (28). Thus, raised levels of all three eicosanoid precursors (20:3ω6, 20:4ω6 and 20:5ω3) may result in a different outcome in terms of eicosanoid production and platelet aggregation. It may be possible to substantiate this hypothesis by determining the effect of diets rich in lean beef on platelet fatty acid composition, platelet aggregation and the analysis of the main urinary metabolites of thromboxane and prostacyclin (29) in humans.

The importance of a balance of dietary ω3 to ω6 fatty acids is becoming recognized gradually, although the competition between these two families of PUFA has been known for decades (5). The cholesterol-lowering properties of linoleic acid-containing oils have been known even longer, and the modern food industry has developed and now produces several stable linoleate-rich oils. Linolenic acid oils have been avoided as food fats, largely because of the unsavory oxidation products of linolenic acid. The result of these developments has been to induce a very low ratio of ω3/ω6 fatty acids in the Western diet on a wide scale. The extreme situation of ω3 deficiency has been observed in a child with accompanying neurological disturbances (30). Recent studies of the PUFA profile in plasma have revealed that many diseases of the modern Western world are accompanied by suppression of total ω3 PUFA and total ω6 PUFA when compared with healthy controls, as well as a lessened fluidity of the plasma PL (31).

It is tempting to correct the low ω3 profiles by supplements of fish oils rich in long-chain ω3 PUFA, but this strategy, imposed in the context of a typical Western diet rich in 18:2ω6, can lead to profiles rich in 18:2ω6 and the long-chain ω3 PUFA and a suppression of the long-chain ω6 PUFA such as 20:3ω6, 20:4ω6 and 22:4ω6. The beneficial effects of lean beef in enhancing the plasma PL status of these PUFA should be emphasized and could be utilized without concern of hypercholesterolemia, since the diets low in saturated fat and rich in lean beef used in this study actually lowered circulating cholesterol levels (15,16).

The Influence of Vitamin E and Selenium on Lipid Peroxidation and Aldehyde Dehydrogenase Activity in Rat Liver and Tissue

Hye-Sung Lee[1] and **A. Saari Csallany***

Department of Food Science and Nutrition, University of Minnesota, St. Paul, Minnesota 55108

Malondialdehyde (MDA) production and cytosolic aldehyde dehydrogenase (ALDH) response were examined in rat liver tissues after feeding different levels of dietary vitamin E and/or selenium and polyunsaturated fat for 12–38 wk. MDA production was significantly increased by vitamin E deficiency or by high levels of polyunsaturated fat intake, but not by selenium deficiency. The activity of cytosolic ALDH increased upon increased production of MDA after 12–16 wk of feeding the lipid peroxidation-inducing diets. However, ALDH activity was suppressed after 38 wk of feeding the vitamin E-deficient diet. The results indicate that the hepatic cytosolic ALDH may be involved in the metabolism of MDA during a relatively short-term increase in *in vivo* lipid peroxidation, but that ALDH activity becomes suppressed after more severe *in vivo* lipid peroxidation has been produced. Hepatic and plasma α-tocopherol levels and lipid peroxidation products were measured for the various dietary groups. *Lipids* 29, 345–350 (1994).

Malondialdehyde (MDA) is a highly reactive and cytotoxic aldehyde and is one of the major products formed in the course of peroxidative degradation of membrane lipids. It has been assumed that the MDA released from mitochondrial and microsomal membranes during polyunsaturated fatty acid (PUFA) peroxidation is metabolized by hepatocytes. Mammalian liver contains a variety of pyridine nucleotide-linked aldehyde dehydrogenases (ALDH; EC 1.2.1.3) that possess wide substrate specificities and are widely distributed among the mitochondrial, microsomal and cytosolic fractions (1–3).

Early investigators (4–6) had concluded that MDA is predominantly oxidized by the mitochondrial fraction of rat liver. By contrast, Hjelle and Petersen (7) more recently suggested that the capacity to metabolize MDA is greatest in rat liver cytosol rather than in mitochondria. Further work by Hjelle and Petersen (8) provided evidence, based on *in vitro* kinetic properties, that the cytosolic ALDH isozyme may in fact predominate in MDA metabolism. This concept is also consistent with the findings of Pirozhkov and Panchenko (9), Marselos and Vasiliou (10) and Vasiliou and Marselos (11). However, because these studies were done on isolated tissues and tissue subfractions, direct information concerning the involvement of cytosolic ALDH in the *in vivo* metabolism of MDA could not be obtained.

In the present study, *in vivo* lipid peroxidation was experimentally induced by administering diets deficient in vitamin E or selenium (Se), or both, and by diets high in PUFA. The objective of the study was to determine the extent of hepatic MDA accumulation induced by the treatments. In addition, hepatic and plasma α-tocopherol levels and lipid peroxidation products were determined. Because hepatic ALDH may play a role in MDA metabolism, changes in the activity of the low affinity cytosolic form of this enzyme induced by the various diets were also measured.

MATERIALS AND METHODS

Induction of in vivo *lipid peroxidation.* Three different animal feeding protocols were used to induce *in vivo* lipid peroxidation.

Experiment 1. In vivo lipid peroxidation was induced by long-term vitamin E deficiency. For 38 wk, one group of 10 female weanling Sprague-Dawley rats was fed a modified basal vitamin E-deficient diet containing 0.05 ppm Se, as described by Draper *et al.* (12), which was adequate in all respects except for vitamin E (–E), while a second group was fed a basal diet supplemented with 30 ppm vitamin E (as *RRR*-α-tocopheryl acetate; 1.36 IU/mg, Type 3; Sigma Chemical Company, St. Louis, MO) (NE). Diet and water were provided *ad libitum.*

Experiment 2. In vivo lipid peroxidation was modulated by administering three levels of dietary PUFA. Groups of 10 female weanling Sprague-Dawley rats were fed either a low- (LP), medium- (MP) or high- (HP) PUFA diet containing 30 ppm vitamin E for 16 wk. The composition of the diets is shown in Table 1. The content of dietary fat was 15%, and the degree of unsaturation of dietary fat was adjusted by using combinations of lard, corn oil and cod liver oil.

Experiment 3. In vivo lipid peroxidation was induced by deficiencies in Se, vitamin E, or both. Four groups of 10 female weanling Sprague-Dawley rats were fed one of the following diets for 12 wk: (i) a Torula yeast-based Se- and vitamin E-deficient basal diet, as described by Schwartz and Fredga (13) (see Table 2), for the double deficient group (–Se–E); (ii) a basal diet supplemented with 30 ppm vitamin E as *RRR*-α-tocopheryl acetate for the Se-deficient group (–Se+E); (iii) a basal diet supplemented with 0.2 ppm Se as sodium selenite for the vitamin E-deficient group (+Se–E); or (iv) a basal diet supplemented with 30 ppm vitamin E and 0.2 ppm Se for the control group (+Se+E).

Measurement of hepatic MDA production. The extent of hepatic lipid peroxidation was measured by the thiobarbituric acid (TBA) test and by a high-performance liquid

Composition of Diets with Different Levels of Polyunsaturated Fatty Acids

Ingredients	Low PUFA (%)	Medium PUFA (%)	High PUFA (%)
Anhydrous d(+)-dextrose[a]	60.4	60.4	60.4
Vitamin-free casein[a]	20.0	20.0	20.0
Lard (stripped)[b]	15.0	10.0	
Corn oil (stripped)[b]		5.0	10.0
Cod liver oil[a]			5.0
Salt mix[c]	4.0	4.0	4.0
Vitamin mix[d]	0.5	0.5	0.5
Choline chloride[e]	0.1	0.1	0.1
Vitamin A[f]	10,000 IU/kg diet	10,000 IU	10,000 IU
Vitamin D_2[g]	1,000 IU/kg diet	1,000 IU	1,000 IU
Vitamin E[h]	30 mg/kg diet	30 mg	26.47 mg[i]

[a]United States Biochemical Corp., Cleveland, OH.
[b]Eastman Kodak Co., Rochester, NY.
[c]Salt mix 4164 (ICN Nutritional Biochemicals, Cleveland, OH).
[d]Vitamin Mix composition (g/kg mix); riboflavin 1.0, thiamine hydrochloride 2.0, nicotinic acid 5.0, pyridoxine hydrochloride 1.0, pantothenic acid (hemi-calcium salt) 2.0, menadione 0.2, folic acid 0.2, biotin 0.02 (all from Sigma Chemical Co., St. Louis, MO). Vitamin B_{12} (0.1% trituration with mannitol) 20.0 (ICN Nutritional Biochemicals), and d(+)-dextrose 968.58.
[e]Sigma Chemical Co.
[f]Vitamin A palmitate water dispersible (250,000 IU/g) (General Drug and Chemical Co., N. Kansas City, MO).
[g]Vitamin D_2 water dispersible (500,000 IU/g) from ICN Nutritional Biochemicals.
[h]*RRR*-α-tocopheryl acetate (Sigma Chemical Co.).
[i]From high-performance liquid chromatography analysis, 50 g cod liver oil/kg diet contained 2.52 mg of α-tocopherol which corresponds to 3.53 mg of α-tocopheryl acetate based on the biological activity. For this reason, the amount of α-tocopheryl acetate supplemented for the high polyunsaturated fatty acid (PUFA) diet was adjusted accordingly.

chromatography (HPLC) method. TBA reactive substances (TBARS) in liver tissues were measured by a modification of the method by Uchiyama and Mihara (14). TBARS in the samples were expressed as MDA equivalents. The amounts of free MDA produced in hepatic tissues were measured by the HPLC method developed by Csallany *et al.* (15). Details of the procedures have been described in a previous paper (16). MDA was prepared by hydrolysis of MDA tetramethyl acetal (Eastman Kodak, Rochester, NY) in 0.01N HCl for 1 h at 50°C. The hydrolyzed solution was titrated to pH 7.4 with 1N NaOH and then diluted with ice-cold 50 mM phosphate buffer (pH 7.4) to produce a 50 mM concentration of MDA. The concentration of MDA was then calculated from absorbance measurements at 267 nm based on the molar extinction coefficient of MDA (3.18×10^4 M^{-1} cm^{-1}).

Composition of Selenium and Vitamin E-Deficient Basal Diets

Ingredients	%
Torula yeast[a]	30
Sucrose[b]	59
Stripped corn oil[c]	5
Salt mix[b,d]	5
Vitamin mix[b,e]	1

[a]United States Biochemical Corp., Cleveland, OH.
[b]ICN Nutritional Biochemicals, Cleveland, OH.
[c]Eastman Kodak Co., Rochester, NY.
[d]Hubbel, Mendel and Wakeman Salt mix.
[e]Vitamin mix composition (g/kg mix); Vitamin A acetate (500,000 IU/g) Vitamin D concentrate (850,000 IU/g) 0.125, ascorbic acid 45.0, inositol 5.0, niacin 4.25, riboflavin 1.0, pyridoxine hydrochloride 1.0, thiamine hydrochloride 1.0, calcium pantothenate 3.0, biotin 0.02, folic acid 0.090, vitamin B_{12} 0.00135, dextrose 855.46365.

Hepatic ALDH assay. Rats were deprived of food but had access to water *ad libitum* for 12 h before sacrifice. The rats were killed by decapitation, and the livers were removed immediately and rinsed thoroughly with ice-cold physiological saline. The fresh tissues were then homogenized in five volumes of ice-cold 1.15% KCl 10 mM phosphate buffer with 5 mM ethylenediamine tetraacetic acid tetrasodium salt (EDTA) (pH 7.4) using a Brinkman Polytron (Brinkman Instruments, Westbury, NY). The homogenates were centrifuged at 600 × *g* for 10 min and then at 9000 × *g* for 15 min in a Sorvall RC-5B refrigerated centrifuge (DuPont Instruments, Des Plaines, IL). The supernatants were subjected to further centrifugation on a Beckman L2-65B Ultracentrifuge (Beckman Instruments, Fullerton, CA) for 60 min at 105,000 × *g*. The resultant supernatant (cytosolic fraction) was used for the enzyme assay.

The enzyme activity was determined spectrophotometrically by monitoring absorbance increases at 340 nm caused by the reduction of NAD^+ to NADH. The molar extinction coefficient of NADH (6.3×10^3 M^{-1} cm^{-1}) was used to calculate the concentration of NADH (17). Reaction mixtures contained NAD (1 mM), pyrazole (2 mM), substrate (MDA, 5 mM), and enzyme in 50 mM phosphate buffer (pH 7.4). The absorbance changes were monitored

at 34°C for the initial 10 min using a Beckman DU-8 spectrophotometer (Beckman Instrument Co., Berkeley, CA) equipped with a Kinetics Compuset and were corrected for the absorbance changes of the blank (minus substrate). Because methanol is produced during the hydrolysis of MDA tetramethyl acetal, pyrazole was added to the reaction mixture to inhibit possible alcohol dehydrogenase-mediated NADH production.

The amount of protein in the cytosolic fraction was measured by the Lowry method (18) using bovine serum albumin as the standard.

Hepatic α-tocopherol determination. The concentrations of α-tocopherol in liver tissues were measured by the HPLC method developed by Zaspel and Csallany (19).

Measurement of plasma TBARS. Blood samples from the carotid artery of the rats were collected into 15-mL centrifuge tubes containing heparin. Plasma was separated by centrifuging blood samples at 478 × *g* for 15 min. Plasma TBARS were analyzed by a modified filtration procedure of Tarladgis *et al.* (20). Duplicate samples of 0.5 mL plasma were mixed thoroughly with 3 mL of 5% trichloroacetic acid and 1 mL of 0.06 M TBA solution in a screw-capped culture tube. The mixture was heated in an 80°C water bath for 90 min, cooled to room temperature, and then centrifuged at 478 × *g* for 15 min to remove the fine precipitate. The absorbance of the supernatant was read at 535 nm. Known amounts of standard MDA were treated in the same way. The amounts of plasma TBARS were expressed as MDA equivalents.

Statistical data analysis. The results were analyzed for their significance by Student's *t*-test in the comparison of two means, or by one-way analysis of variance followed by Tukey's multiple comparison test (21) in the comparisons of more than two means. Differences were considered significant when the *P* value was less than 0.05.

RESULTS AND DISCUSSION

Effect of dietary vitamin E on in vivo *lipid peroxidation.* The production of TBARS and free MDA and the specific activity of cytosolic ALDH in the long-term (38 wk) vitamin E-deficient and control rat liver tissues are shown in Figure 1. The extent of hepatic lipid peroxidation measured by TBARS and free MDA concentration was significantly higher in the vitamin E-deficient animals than in the controls. A greater difference between the two groups was observed in the free MDA levels. ALDH activity did not respond to the increased lipid peroxidation resulting from long-term vitamin E deficiency. The activity of the enzyme seemed slightly suppressed in vitamin E-deficient tissues as compared to vitamin E-supplemented tissues, although the difference was not statistically significant. The results suggest that hepatic cytosolic ALDH is not induced by increased substrate MDA and may not be actively involved in the metabolism of MDA in liver tissues in the chronic state of vitamin E deficiency. Accordingly, high levels of TBARS and free MDA in the vitamin E-deficient liver tissues seem to be the consequence of increased membrane lipid peroxidation and decreased rate of MDA metabolism.

A severe depletion of α-tocopherol in hepatic tissue was seen in the vitamin E-deficient group, whereas the control

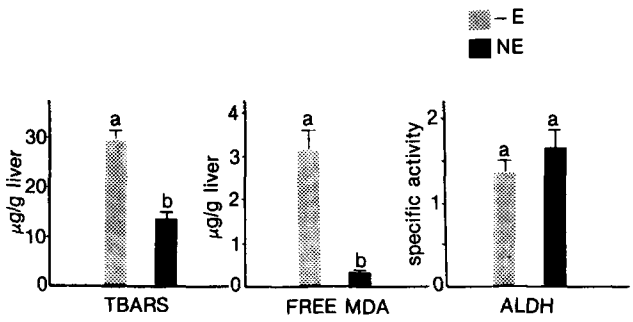

FIG. 1. The levels of thiobarbituric acid reactive substance (TBARS), free malondialdehyde (MDA) and cytosolic aldehyde dehydrogenase (ALDH) activities of liver tissues from rats fed vitamin E-deficient (–E) or vitamin E-supplemented (NE) diets for 38 wk. The levels of TBARS are represented as MDA equivalents. Enzyme activities are expressed as nmol of NADH produced per min per mg protein. Values represent means ± SEM of ten samples per treatment. Different letters on the top of the bars indicate significant differences between two groups ($P < 0.05$).

group showed hepatic α-tocopherol concentration of 35 μg/g tissue (Table 3). Plasma TBARS levels were measured to quantitate lipid peroxidation products present in the circulatory system. The level of plasma TBARS (Table 3) was significantly higher in the vitamin E-deficient condition as compared to the normal condition. The magnitude of this difference was as great as that observed in the liver tissues. Such increased plasma TBARS may be due to peroxidation of erythrocyte membrane lipids and other blood lipids or the mobilization of peroxidation products from other tissues as well. There are two possible ways whereby TBARS in the circulatory system could be eliminated. One is diffusion into the hepatic tissue to be metabolized, because liver is the major site of aldehyde oxidation and detoxification (22). The other way is excretion through urine.

Effect of dietary PUFA on in vivo *lipid peroxidation.* The TBARS, free MDA production and ALDH activity in the liver of rats fed different levels of dietary PUFA for 16 wk are shown in Figure 2. The levels of hepatic TBARS and free MDA were significantly higher in the HP group than in the LP and MP groups. This result is in agreement with the work done byHafeman and Hoekstra (23), who demonstrated that the substitution of dietary cod liver oil for dietary lard caused a large increase in ethane evolution.

TABLE 3

Effect of Dietary Vitamin E on the Levels of Plasma TBARS and Liver α-Tocopherol of Rats

Group	α-Tocopherol (μg/g liver)	Plasma TBARS[a] (ng/mL plasma)
–E	1.43 ± 0.21[b]	125.96 ± 15.63[b]
NE	34.74 ± 3.06[c]	34.84 ± 4.30[c]

[a]TBARS, thiobarbituric acid reactive substances; –E, vitamin E-deficient diet; NE, diet supplemented with 30 ppm vitamin E.
[b,c]Values within each column not sharing a common superscript letter are significantly different ($P < 0.05$) by Student's *t*-test. Means ± SEM for ten rats per treatment.

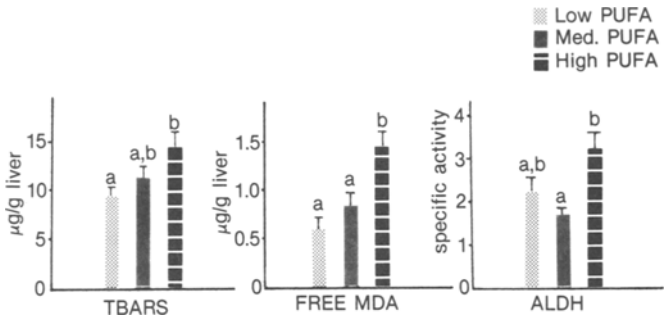

FIG. 2. The levels of TBARS, free MDA and cytosolic ALDH activities of liver tissues from rats fed diets with different levels of polyunsaturated fatty acid (PUFA) for 16 wk. The levels of TBARS are represented as MDA equivalents. Enzyme activities are expressed as nmol of NADH produced per min per mg protein. Values represent means ± SEM of ten samples per group. Different letters on the top of the bars indicate significant differences between groups by a multiple comparison test ($P < 0.05$). Abbreviations as in Figure 1.

Cod liver oil, which comprised 5% of the HP diet in this study, is a rich source of n-3 unsaturated fatty acids. Consumption of cod liver oil by animals is known to increase the levels of these fatty acids in both adipose fat and membrane phospholipids (24). Draper *et al.* (25) confirmed the enrichment of liver tissue and epididymal fat pads with eicosapentaenoic (20:5n-3) and docosahexaenoic acid (22:6n-3) in rats fed an HP diet containing cod liver oil. Therefore, lipid peroxidation in tissues of rats fed an HP diet containing cod liver oil is expected to increase because these highly unsaturated n-3 fatty acids are good substrates for lipid peroxidation.

The activity of hepatic ALDH was significantly increased in the HP group as compared to the LP group. However, no significant difference was observed between the LP and MP groups. In the present experiment, hepatic ALDH appears to respond to the increased tissue lipid peroxidation and may be involved in the metabolism of MDA in the animals fed an HP diet with normal levels of vitamin E supplementation. However, this finding is in contrast to previous result showing suppressed ALDH activity in spite of increased tissue lipid peroxidation in long-term vitamin E deficiency.

Tocopherol concentrations in liver tissues of rats fed different levels of dietary PUFA are shown in Table 4. Overall, tissue tocopherol levels were 30% lower than the value (35 μg/g tissue) found in a group fed the same amount of dietary vitamin E and 8% corn oil (Experiment 1) (Table 3). This difference must be due to the increased consumption of dietary fat (15%) by the animals. However, the HP group had 20% less hepatic vitamin E storage than the other two groups, but the difference was not statistically significant in the LP, MP and HP groups.

Plasma TBARS levels also showed a positive correlation with the amounts of dietary PUFA (Table 4). The differences in plasma TBARS levels among the dietary groups showed the same pattern as those in hepatic TBARS levels.

Effects of dietary Se and vitamin E on in vivo *lipid peroxidation.* The effects of Se and vitamin E on liver TBARS,

Effect of Different Levels of Dietary PUFA on the Levels of Plasma TBARS and Liver α-Tocopherol of Rats[a]

Group	α-Tocopherol (μg/g liver)	Plasma TBARS (ng/mL plasma)
LP	24.95 ± 2.14[b]	75.52 ± 2.21[b]
MP	24.24 ± 2.30[b]	81.60 ± 3.72[b]
HP	19.55 ± 1.94[b]	107.00 ± 4.68[c]

[a]Abbreviations as in Tables 1 and 3; LP, low-PUFA diet; MP, medium-PUFA diet; HP, high-PUFA diet.
[b,c]Values within each column not sharing a common superscript letter are significantly different ($P < 0.05$) by Tukey's multiple comparison test. Means ± SEM for ten rats per treatment.

free MDA levels and ALDH activity are shown in Figure 3. The doubly-deficient group produced the highest amounts of TBARS and free MDA in liver tissues, followed by the vitamin E-deficient group. Notably, the production of free MDA in liver tissues of these two groups was significantly higher than that of the control group. The increase in tissue lipid peroxidation caused by Se deficiency alone was not statistically significant, nor was an apparent additive effect of vitamin E and Se on the induction of *in vivo* lipid peroxidation seen in this experiment. It has been generally assumed that if Se deficiency were to exist, *in vivo* peroxidation would be increased because of an inability of the cells to scavenge H_2O_2 and a decreased ability to handle lipid hydroperoxides. However, the influence of Se deficiency on the extent of lipid peroxidation in isolated organs or in the intact animal is not yet conclusive. Although a vital role of Se was established for the seleno-enzyme, glutathione peroxidase, in the reduction of hydroperoxides *in vitro* (26), significant lipid

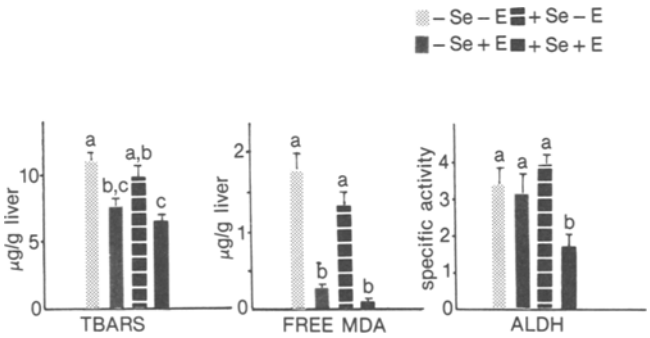

FIG. 3. The levels of TBARS, free MDA and cytosolic ALDH activities of liver tissues from rats fed diets deficient in or supplemented with selenium or vitamin E for 12 wk. The levels of TBARS are represented as MDA equivalents. Enzyme activities are expressed as nmol of NADH produced per min per mg protein. Values represent mean ± SEM of tensamples per treatment. Different letters on the top of the bars indicate significant differences between groups by multiple comparison test ($P < 0.05$). −Se−E, selenium- and vitamin E-deficient diet; −Se+E, diet supplemented with 30 ppm vitamin E as *RRR*-α-tocopheryl acetate; +Se−E, diet supplemented with 0.2 ppm selenium as sodium selenite for the vitamin E-deficient group; +Se+E, diet supplemented with 30 ppm vitamin E as *RRR*-α-tocopheryl acetate and 0.2 ppm selenium. Other abbreviations in Figure 1.

peroxidation could not be detected in Se-deficient, vitamin E-supplemented rats as measured by the alkane production in exhaled air (23). In contrast, Doni *et al.* (27) reported that after a three-month feeding, heart and kidney MDA, as measured by the TBA tests, were significantly higher both in vitamin E-deficient and Se-deficient rats than in control rats. It was found in the present study that *in vivo* lipid peroxidation is more dependent on vitamin E deficiency than on the Se deficiency. This is in agreement with the results of Hafeman and Hoekstra (28), who reported that vitamin E had a greater effect than Se in reducing ethane evolution after CCl_4 administration to rats, suggesting that vitamin E is a more potent biological antioxidant than Se. The failure of MDA to accumulate in Se deficiency may be explained by the fact that the primary substrate for Se-dependent glutathione peroxidase is H_2O_2 rather than fatty acyl peroxides (29). A further explanation may be that Se-independent glutathione peroxidase is present in tissues (30).

Hepatic ALDH activity increased significantly in the Se- or vitamin E-deficient groups, as well as in the double-deficient group compared to the control group. In the vitamin E and doubly-deficient groups, the enzyme activity appears to increase in response to the increased hepatic lipid peroxidation; however, ALDH is activated in Se deficiency in spite of low lipid peroxidation in liver tissue. Such an increase in the activity of ALDH may be explained as a compensatory action of the enzyme for the decreased glutathione peroxidase activity usually observed in Se deficiency (31). Other antioxidant enzymes, such as catalase and superoxide dismutase, were also reported to increase their activities in liver and brain of chicks during Se deficiency (32).

The α-tocopherol content of liver tissue showed a correlation with dietary tocopherol levels (Table 5). The control and Se-deficient groups had significantly higher storage levels of liver α-tocopherol than the vitamin E-deficient and the doubly-deficient groups. The decrease in tissue α-tocopherol level produced by Se deficiency was not statistically significant. Observations by several investigators have indicated that Se deficiency can affect α-tocopherol metabolism. Fisher and Whanger (33) showed a greater rate of tritium excretion in the urine of Se-deficient rats than that of controls after administration of tritiated α-tocopherol. They concluded that vitamin E is metabolized more rapidly in Se-deficient rats than in controls. This finding is consistent with the report that Se deficiency in rats depressed hepatic microsomal α-tocopherol content (34). Thus, Se deficiency appears to favor an increased rate of loss of a α-tocopherol from the body. The cause of this loss most likely relates to increased α-tocopherol oxidation under conditions where Se-dependent antioxidant mechanisms are impaired.

Plasma TBARS levels showed the same trend as liver tissue TBARS levels (Table 5), demonstrating that plasma TBARS levels can be as useful an index of *in vivo* lipid peroxidation as are liver tissue TBARS levels.

The extent of hepatic lipid peroxidation was determined by measuring the accumulation of free MDA and TBARS in the presence or absence of dietary vitamin E and/or Se and at various levels of PUFA administration. The response of hepatic cytosolic ALDH to the tissue lipid peroxidation state was examined. Hepatic lipid peroxidation was significantly increased by vitamin E deficiency and by high levels of PUFA intake. The increase of hepatic lipid peroxidation by Se deficiency was not statistically significant. The hepatic cytosolic ALDH responded to the increased tissue lipid peroxidation after 12 or 16 wk of feeding diets deficient in vitamin E, diets deficient in both vitamin E and Se, or diets with high levels of PUFA. However, hepatic ALDH activity was found to be suppressed after 38 wk of feeding diets deficient in vitamin E. These results indicate that liver cytosolic ALDH may be involved in the metabolism of MDA during *in vivo* lipid peroxidation induced by relatively short-term feeding, but the enzyme activation does not persist during severe *in vivo* lipid peroxidation caused by long-term vitamin E deficiency.

Liver α-tocopherol levels showed an inverse relationship with the extent of tissue lipid peroxidation. However, the decreases in tissue α-tocopherol levels at high levels of PUFA administration and Se deficiency were not significant. Levels of plasma TBARS showed exactly the same patterns as those of the hepatic tissues, indicating that the measurement of plasma TBARS can be used as an index for *in vivo* lipid peroxidation.

Effects of Dietary Oils and Methyl Ethyl Ketone Peroxide on *in vivo* Lipid Peroxidation and Antioxidants in Rat Heart and Liver

Gudrún V. Skúladóttir[a,*], Du Shi-Hua[b], Ann E. Brodie[c], Donald J. Reed[c] and Rosemary C. Wander[b]

[a]Science Institute, University of Iceland, 107 Reykjavík, Iceland, and Departments of [b]Nutrition and Food Management and [c]Biochemistry and Biophysics, Oregon State University, Corvallis, Oregon 97331

Weanling male Sprague-Dawley rats were fed diets for four weeks which differed in their content of n-6 (corn oil; CO) and n-3 fatty acids (fish oil; FO), but were similar in their content of saturated and monounsaturated fatty acids and vitamin E. At the end of the four-week feeding period, each dietary group was subdivided into two groups. One group received a single placebo injection of α-tocopherol-stripped corn oil (TSCO); the other group received a single injection of the free radical generator, methyl ethyl ketone peroxide (MEKP), in TSCO. Twenty-four hours after injection, the effect of dietary oil and MEKP treatment on endogenous lipid peroxide (LPO) production (measured as methylene blue formed by the "Determiner LPO" assay), glutathione (GSH) and vitamin E content, and fatty acid composition of phosphatidylcholine and phosphatidylethanolamine in heart and liver from unfasted animals were measured. FO-fed rats had significantly heavier hearts and livers, increased levels of n-3 fatty acids in membrane phospholipids, and higher liver LPO levels than CO-fed rats. MEKP treatment resulted in significantly lower body weights and liver GSH levels. The data indicate that dietary n-3 fatty acids increase lipid peroxidation in liver somewhat more than in heart. The study also demonstrates that the effect of induced oxidative stress due to a single dose of MEKP on lipid peroxide formation and antioxidant status in tissues from unfasted animals was independent of the dietary oils.

***Lipids* 29, 351–357 (1994).**

Dietary supplementation with highly polyunsaturated fats, such as those containing the n-3 fatty acids found in fish oil, is associated with an increased tendency for lipid peroxide formation in certain tissues (1–3). Lipid peroxidation mediated by free radicals is considered to be a prevalent mechanism of cell membrane destruction and cell damage and has been suggested to be associated with the initiation and development of atherosclerosis (4). Little is known about how the organism responds to an increase in oxidative stress (i.e., activation of free-radical reactions), such as lipid peroxidation. In view of the suspected role of oxidative degradation of lipids in the etiology of atherogenesis, such information is useful.

Dietary fatty acids influence the composition of membrane phospholipids in heart and liver (5,6). Indeed, membrane phospholipids with a high level of polyunsaturated fatty acids (PUFA) are more sensitive to hydroxy radicals (7,8). Susceptibility to peroxidation is also influenced by free radical scavengers and antioxidants such as vitamin E and glutathione (GSH) (9). Induced oxidative stress is accompanied by a decrease in the content of the antioxidants vitamin E and/or GSH (10). Further, increased lipid peroxidation is associated with a decrease in liver GSH (11–13).

In the above experiments, animals were fasted overnight prior to sampling. The standard practice to fast animals overnight before drug administration in experimental research is to ensure uniform absorption of the test compound. However, deprivation of food and/or water is a powerful stressor. Experiments in rats have shown that food deprivation induces alterations in free radical-scavenging systems that differ from tissue to tissue (14). Elevated turnover rates of liver GSH have been reported during fasting in rats (15). Furthermore, fasting in rats lowers the GSH level of the liver without changing its level in the heart (15–17).

Data that indicate that feeding fish oil (FO) induces higher lipid peroxidation in tissues has been based on the thiobarbituric acid reactive substances (TBARS) test. This method measures the end product, malondialdehyde, which results from the breakdown of lipid peroxides (LPOs) and nonlipid compounds. Several investigators have criticized the use of the TBARS test since the test is not a reliable index of lipid peroxidation in organ systems (18–20). A preferable procedure is to measure LPO levels, using the Determiner LPO assay, a colorimetric method that specifically detects hydroperoxides, endoperoxides and peroxy radicals (20,21).

The present study was undertaken to investigate the effects of dietary n-6 and n-3 PUFA and free radicals generated by methyl ethyl ketone peroxide (MEKP) on the extent of lipid peroxidation and on antioxidant status, i.e., vitamin E and GSH content, in heart and liver tissues of rats. MEKP is a toxic, lipid-soluble peroxide that has been shown to rapidly initiate lipid peroxidation *in vivo* and *in vitro* (22,23). To avoid the possible potentiating effect of fasting on detoxification systems, the effect of MEKP on *in vivo* oxidation processes was studied in unfasted normal animals. The lipid peroxidation was measured by a new method, the Determiner LPO assay (20,21).

MATERIALS AND METHODS

Animals and diets. Forty-one male weanling Sprague-Dawley rats were obtained from Simonson Laboratories (Los Angeles, CA). The rats were housed individually in wire cages under standard conditions of 22°C, 45% relative humidity, using a 12-h light–dark cycle. The animal care procedures used in this study were approved by the Animal Care and Use Committee at Oregon State

Abbreviations: CO, corn oil; FO, fish oil; GSH, glutathione; GSSH, oxidized GSH; HPLC, high-performance liquid chromatography; i.p., intraperitoneal; LPO, lipid peroxide; LSD, least significant difference; MEKP, methyl ethyl ketone peroxide; PC, phosphatidylcholine; PE, phosphatidylethanolamine; PI, peroxidizability index; PUFA, polyunsaturated fatty acids; TBARS, thiobarbituric acid reactive substances; TBHQ, tertiary butylhydroquinone; TSCO, α-tocopherol stripped corn oil.

University (Corvallis, OR). Following a one-week acclimation period, the rats were randomized into two dietary groups and maintained for four weeks on diets that differed in their polyunsaturated n-6 (corn oil diet; CO diet) and n-3 (FO diet) fatty acid contents. The compositions of the diets were based on the AIN-76 diet for rats (24) with part of the carbohydrate replaced with fat so that both diets were 20% fat by weight. The base diet was a fat-free, vitamin E-deficient diet (Teklad, Madison, WI). The CO diet contained 15% vitamin E-stripped corn oil (TSCO; Teklad), 4.5% cocoa butter and 0.5% coconut oil. The FO diet contained 16.75% FO, 2.0% TSCO and 1.25% olive oil. Small amounts of hydrogenated coconut oil (Teklad), olive oil (Teklad), and/or cocoa butter (Teklad) were added to the diets to equalize the contents of monounsaturated and saturated fatty acids. In addition, the diets contained the following (g/kg): casein 200, methionine 3, sucrose 350, cornstarch 150, cellulose 50, mineral mix 35, vitamin mix 10 and choline bitartrate 2. The cholesterol content of the diets was matched at 0.34 g/kg by adjusting the CO diet. dl-α-Tocopheryl acetate (a generous gift from Eastman Kodak, Kingsport, TN) was added to the diets at a level of 50 IU per kg diet. FO was obtained from the National Institutes of Health Fish Oil Test Material Program with tertiary butylhydroquinone (TBHQ) (0.2 g/kg oil) added as an antioxidant. TBHQ was added to the CO diet in an amount equal to that of the FO diet. Twenty-four hour food intake was measured each week, and there were no significant differences observed between the two dietary groups.

The fatty acid composition (g/100 g) of the diets is shown in Table 1. To minimize oxidation, diets were prepared biweekly, aliquoted into daily portions and stored frozen under nitrogen. The diets given to the rats were changed daily, and unused portions were discarded. The rats received their respective diets and water *ad libitum* throughout the study.

At the end of the four-week feeding period, each diet group was subdivided into two groups. One group received a single intraperitoneally (i.p.) placebo injection of α-tocopherol-stripped corn oil (TSCO); the other group received (i.p.) a single dose (40 mg/kg body wt) of MEKP in TSCO. The same volume (0.7 μL/g animal) of placebo and MEKP was injected. The body weight was recorded once each week, immediately before and 24 h after TSCO or MEKP administration. The unfasted rats were anesthetized with a mixture of ketamine (60 mg/kg) and xylazine (10 mg/kg) 24 h after TSCO or MEKP administration. Beginning at 08:00 h every day, for five days, one animal was anesthetized each 1/2 h until 12:00 h. This was done to circumvent diurnal variation of liver GSH levels. The abdomen was opened to provide access to the vena cava. Heart and liver were thoroughly perfused with isotonic saline solution, rapidly excised, weighed, quickly frozen in liquid nitrogen and pulverized at liquid nitrogen temperature, then stored at –70°C until analyzed.

Analysis of fatty acids. Heart and liver lipids were extracted by the method of Bligh and Dyer (25). A portion of this extract was used for measuring LPOs. The antioxidant butylated hydroxytoluene was added to the extraction medium at 5 mg/100 mL. Phospholipids were separated on thin-layer plates (Adsorbosil H; Alltech, Deerfield, IL) developed in a solvent system consisting of chloroform/methanol/acetic acid/water (75:40:12:5, by vol). The phospholipid fatty acids were transmethylated for 90 min at 95°C using 14% boron trichloride/methanol (Sigma Chemical Co., St. Louis, MO). The methyl esters were analyzed using a gas chromatograph (Hewlett-Packard 5890; Hewlett-Packard, Palo Alto, CA) equipped with a capillary column, 30 m × 0.25 mm i.d., coated with a 0.25-μm film of SP2330 (Supelco, Bellefonte, PA). The oven temperature was programmed to maintain 170°C for 4 min, then was increased at 2°C/min to 200°C, and then at 3°C/min to 218°C. The carrier gas was helium at a flow rate of 0.6 mL/min. The fatty acid methyl ester peaks were calibrated against those of commercial standards (Sigma; Nu-Chek-Prep, Elysian, MN). The peroxidizability index (PI) was calculated as follows: PI = (% dienoic × 1) + (% trienoic × 2) + (% tetraenoic × 3) + (% pentaenoic × 4) + (% hexaenoic × 5).

Quantitative analysis of LPO. LPOs were quantitatively determined by measuring colorimetrically the methylene blue formed using a Determiner LPO assay kit (Kamiya Biomedical Company, Thousand Oaks, CA), modified as discussed by Turini *et al.* (20). One-half milliliter of the first reagent (275 U/mL ascorbic oxidase, 35 U/mL lipoprotein lipase, stabilizer, 50 mM Good's buffer and surfactants) was added to 100 μL of heart or liver lipid extract in methanol, which contained approximately 10 mg protein. Tubes were mixed and incubated in a shaking water

Total monoenoic	5.64	5.55
Total (n-6)	9.55	2.25
Total (n-3)	0.18	5.01

[a]Values represent the average of three determinations. Dietary fat was 20% by weight of the diet.

[b]Minor components (percent at less than 1% when expressed as weight percent of the total fatty acids).

bath at 30°C for 5 min. One milliliter of the second reagent (2.2 μmol MCDP, i.e., 10-*N*-methyl-carbamoyl-3,7-dimethylamino-10H-phenothiazine, plus 50 mM Good's buffer, 33.8 μg/mL hemoglobin and surfactants) was added to the tubes. The contents were then mixed and incubated at 30°C for 10 min. The absorbance was measured at 675 nm in a Gilford Model 252 spectrophotometer (Gilford Instrument Laboratories Inc., Oberlin, OH). Sample concentrations were calculated using a standard solution of 50 nmol/mL cumene hydroperoxide. LPO values are expressed as nmole equivalents of cumene hydroperoxides per mg tissue protein. Protein was measured by the method of Lowry *et al.* (26) on the heart and liver homogenates.

Quantitative analysis of GSH and vitamin E. The procedures for the measurement of reduced GSH and for the extraction and analysis of vitamin E from heart and liver were those by Warren and Reed (10). Care was taken to avoid substantial exposure of samples to light and air. Briefly, an internal standard of δ-tocopherol and water were added to a portion (approximately 300 mg) of frozen, pulverized heart or liver tissue that was then thoroughly mixed by sonication on ice. Portions of the heart and liver homogenates were removed for measurement of protein, GSH and vitamin E. GSH levels were measured by high-performance liquid chromatography (HPLC) (27). Vitamin E was extracted with heptane and quantitated by reverse-phase HPLC using fluorimetric detection (10,28). Values for GSH and vitamin E are expressed as nmol/mg tissue protein.

Statistical analysis. The effect of dietary oil and treatment was examined by two-way analysis of variance using SAS (29) general linear model procedures. Where significant interactions were found, comparisons of different treatments in rats receiving either FO- or CO-enriched diet were performed with the Fisher's least significant difference (LSD) test (30). Differences were considered significant at $P < 0.05$.

RESULTS

The weights of the animals at the end of the feeding trial before the injection of TSCO or MEKP were not significantly different (Table 2). By 24 h, injection of MEKP decreased the weight of rats in both dietary groups ($P < 0.01$). Figure 1 shows the change in body weight 24 h after TSCO or MEKP treatment, compared to the average weight gain per 24 h over the four-week feeding period in both dietary groups. There was no significant difference in body weight gains per 24 h between the four groups over the four-week feeding period. However, a single injection of TSCO led to a slightly smaller increase in weight in the 24 h interval following the injection compared to the gain previously experienced in both dietary groups (4.6 ± 1.2 g in CO-fed group, 3.5 ± 1.8 g in FO-fed group vs. 6.4 ± 0.2 g and 6.5 ± 0.03 g, respectively). A single injection of MEKP caused a body weight loss within 24 h in both dietary groups that was more pronounced in the CO-fed rats (–6.0 ± 1.7 g in CO-fed group and –2.2 ± 1.4 g in FO-fed group).

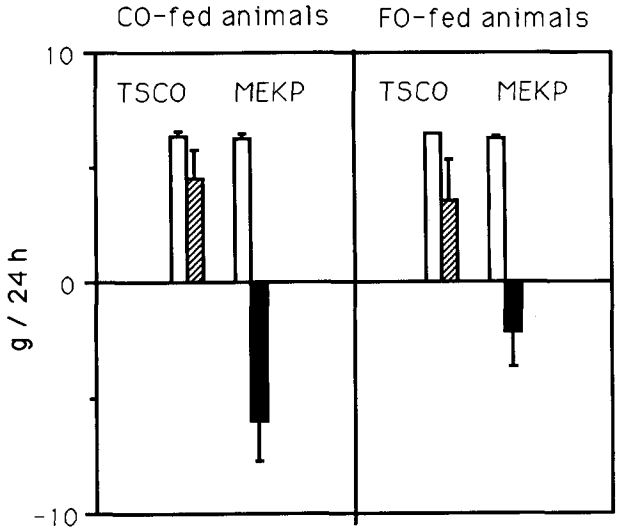

FIG. 1. Average weight gain (g) per 24 h over the four-week feeding period (open bars); weight gain (g) within 24 h following TSCO (tocopherol-stripped corn oil) treatment (hatched bars); and weight loss (g) within 24 h following MEKP (methyl ethyl ketone peroxide) treatment (full bars). CO, corn oil; FO, fish oil.

Body, heart and liver weights of rats fed CO- or FO-rich diets and treated either with TSCO or MEKP are shown in Table 2. The two diets led to significant differences ($P < 0.05$) in the mean and relative mean weights of hearts and livers. Rats fed the FO-rich diet had significantly

[a]Values are mean ± SEM for 10–11 rats. TSCO, α-tocopherol-stripped corn oil; MEKP, methyl ethyl ketone peroxide.

[b]NS, not significant at $P < 0.05$; O, effect of dietary oil; T, effect of MEKP treatment.

[c]Expressed as percent, g tissue per g body weight × 100.

heavier hearts and livers than those fed the CO-rich diet. These differences prevailed when the data were expressed on a relative weight basis. The livers of the MEKP-treated rats were lighter than those that did not receive the injection, when the data were expressed on a absolute basis but not on a relative basis.

The highly polyunsaturated n-6 and n-3 fatty acids in the diets were efficiently incorporated into the major classes of membrane phospholipids, phosphatidylcholine (PC) and phosphatidylethanolamine (PE; data not shown), of heart and liver. The fatty acid levels of phospholipids in heart and liver were significantly different between the two dietary groups with respect to most of the fatty acids analyzed. Pronounced increases in n-3 fatty acids in heart and liver membrane phospholipids have been shown repeatedly, and since the effect of the treatment and the interaction between the effects of dietary oil and treatment caused minimal changes in the fatty acid levels of heart and liver PE, the data from PE are not given here. The interaction between dietary oil and treatment was significant in six fatty acids and in the PI of heart PC (Table 3) and in two fatty acids of liver PC (Table 4). Within the CO group, MEKP treatment significantly decreased the level of 18:2n-6. Within the FO group, the level of 16:0 was significantly increased, and the levels of 20:4n-6, 22:5n-3, 22:6n-3 and the PI were significantly decreased after a single MEKP injection. MEKP treatment changed the fatty acid levels of liver PC only within the CO group, where the levels of 18:1n-9 and 18:2n-6 were decreased. In heart PE, there was one interaction where the PI values decreased in MEKP-injected FO-fed rats from 239.2 ± 3.3% to 221.3 ± 4.3% but remained virtually unchanged in CO-fed rats (148.8 ± 2.0% to 146.6 ± 4.5%).

The effects of the dietary oils and MEKP treatment on GSH, vitamin E and LPO levels are shown in Table 5. Liver GSH was significantly reduced ($P < 0.003$) by MEKP treatment while dietary oils had no effect. Heart GSH was unaffected by dietary oil or MEKP treatment. Liver GSH was roughly three times that of the heart. Vitamin E in heart and liver was unaffected by dietary oil or MEKP treatment. However, heart vitamin E was roughly twice that in the liver (2 nmol/mg protein vs. 1, respectively). Liver LPO was significantly higher ($P < 0.05$) in the FO-fed group compared to the CO-fed group, while heart LPO was unaffected. MEKP treatment did not affect the LPO levels in heart or liver in either of the dietary groups.

Figure 2 shows the relationship between PI in heart PC, vitamin E and LPO levels from rats on the FO-diet and being MEKP-treated. The PI was positively correlated with vitamin E levels and negatively correlated with LPO levels.

DISCUSSION

The present study has shown that rats fed n-3 enriched diets do not respond differently to induced oxidative stress from a single dose of MEKP as evidenced by LPO formation and antioxidant status, compared to rats fed n-6 enriched diets. As anticipated, the injection of MEKP stressed the animals, as evidenced by their weight loss within 24 h after injection (Fig. 1). The changes in body weight effected by MEKP might be due to loss of appetite and lower food intake in addition to metabolic changes. The injection of TSCO or the handling associated with the injection was also a stressor, as evidenced by the smaller weight gain experienced by the rats after this injection.

This occurred despite the fact that the rats were handled frequently and that great care was taken to assure that the injection was made causing a minimum of discomfort. The data suggest that stress can confound results from studies in which animals are subjected to procedures such as an injection.

The highly polyunsaturated n-6 fatty acids in CO and n-3 fatty acids in FO were efficiently incorporated into the major classes of phospholipids, i.e., PC and PE, of heart and liver, which is in agreement with previous studies (5,6). The contribution of individual fatty acids to lipid peroxidation has been shown to reflect the degree of unsaturation of n-3 fatty acids more than that of the n-6 type (31). In our study, a single MEKP injection caused significant reduction in the levels of PUFA, 20:4n-6, 22:5n-3 and 22:6n-3 of heart PC from FO-fed rats. The interaction between dietary FO and MEKP treatment on fatty acid levels was evident to a lesser extent in heart PE (data not shown) and liver PC. The fatty acid levels of liver PE (data not shown) were unaffected by MEKP in each of the dietary groups. In sarcolemma of myocardial cells, PC is preferentially present in the outer monolayer, and PE in the inner (32). The observed reduction in the levels of highly PUFA in heart PC could indicate that PC is less

TABLE 5

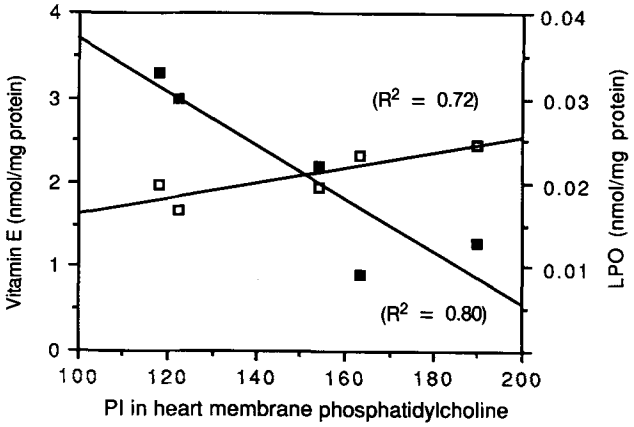

FIG. 2. Relationship between peroxidizability index (PI) in phosphatidylcholine, vitamin E (open symbols) and lipid peroxide (LPO, closed symbols) levels in heart from rats on fish oil-rich diet being methyl ethyl ketone peroxide treated.

protected from oxidation induced by MEKP. The observed changes in fatty acid composition of heart phospholipids did not resemble changes induced by stress, i.e., exogenous epinephrine (5). Repeated administration of epinephrine caused increased levels of 20:4n-6 and 22:6n-3 in PC, decreased or unaltered 20:4n-6 and increased 22:6n-3 in PE and decreased level of 18:2n-6 in PC and PE. These changes were qualitatively similar although different dietary fats were used, i.e., butter, corn oil or cod liver oil (5).

The phospholipids of heart and liver from the FO-fed rats contain high levels of the highly peroxidizable polyunsaturated n-3 fatty acids (Tables 3 and 4) causing the higher PI values. Even though the PI of the phospholipids was higher in heart than in liver of FO-fed rats, lipid peroxidation was higher in the liver, i.e., the LPO levels were higher in liver than in heart of FO-fed rats (Table 5). Vitamin E is thought to act as one of the most important antioxidants *in vivo* because of its role in blocking the propagation of LPO in the membrane. Vitamin E levels in the heart were twice those in the liver, and LPO levels were lower in heart than in liver. The insensitivity of heart from FO-fed rats to lipid peroxidation could be explained by the high vitamin E level, which seems to be sufficient to suppress the *in vivo* peroxidation of n-3 fatty acids in heart phospholipids of normal rats.

Mouri *et al.* (3) and Chautan *et al.* (33) showed that the heart vitamin E content dramatically increased as the membranes became enriched in n-3 PUFA, whereas liver became depleted of vitamin E. However, in our study, no differences in the level of vitamin E in heart or liver were found between FO-fed and CO-fed rats (Table 5). The role of vitamin E in preventing the oxidative destruction of PUFA in cell membranes has been elusive (34). It has been suggested that vitamin E stabilizes the cell membrane through interaction of its phytyl side chains with the polyunsaturated fatty acyl groups of phospholipids (35). Vitamin E levels and PUFA contents were shown to influence membrane susceptibility to lipid peroxidation, and below a certain vitamin E threshold, differences in membrane susceptibility to peroxidation could be reasonably predicted based on the content of individual peroxidizable fatty acids only (31). Furthermore, a strong positive correlation was found between heart vitamin E and n-3 fatty acids of total lipids in heart membranes of rats, which suggests that n-3 PUFA in cell membranes are efficiently protected against lipid peroxidation (33). Individual data from this study showed that only after an induced peroxidative stress, i.e., a single MEKP injection, was there a positive correlation between vitamin E levels and PI values and a negative correlation between LPO levels and PI values in hearts from FO-fed rats (Fig. 2). No such correlation was found in hearts from TSCO-treated rats in either of the dietary groups.

The products of lipid peroxidation are mainly the hydroperoxides of fatty acyl moieties. In the present study, the lower levels of highly PUFA of heart PC induced by MEKP are not reflected in higher levels of LPO in heart. It is suggested that membrane-bound phospholipase A_2 produces an "antioxidant" effect by excising LPOs from the membrane, thereby preventing them from participating in free radical propagation reactions (36). The membrane-bound phospholipase A_2 is hence considered as one of the scavenger and antioxidant enzymes that act to preserve cellular structure and function.

GSH in liver is thought to be used as a cysteine reservoir for GSH synthesis in peripheral organs during periods of enhanced consumption or limited supply (37,38) and as a defense mechanism against oxidative stress (39). It has been shown that the reduction of GSH levels in liver as a consequence of oxidative stress was more pronounced in livers from fasted than from fed rats (40). A significant reduction in liver GSH levels was only observed in unfasted rats 24 h after an MEKP injection (Table 5). The reduced level of liver GSH was not reflected in an increased oxidized level of GSH (GSSG). The liver and heart GSSG levels were less than 1 nmol/mg protein in both dietary groups (data not shown).

In summary, the effect of MEKP treatment on GSH levels on the levels of PUFA of membrane phospholipids and on tissue weights differed between heart and liver. One should therefore be cautious in extrapolating results from one tissue to another. The present results also support the idea that in studies on lipid peroxidation and radical-scavenging defense mechanisms, attention must be paid to the biochemical changes that are associated with fasting (14,41). In the present study, no deleterious effect of increased susceptibility to lipid peroxidation due to the n-3 fatty acid-enriched dietary intake was seen in heart and liver of unfasted animals. The reduced levels of highly PUFA in heart PC induced by MEKP were not reflected in higher levels of LPO in heart from FO-fed rats. The fate of the peroxidized PUFA will require further study.

Fourteen cases of intracranial meningioma were characterized after chloroform/methanol extraction by ^{31}P nuclear magnetic resonance (NMR) spectroscopy at 202.4 MHz. Each phospholipid class detected in the extracts was identified and quantitated in terms of its molar percentage relative to the total phospholipids measured. The following phospholipids were assayed by ^{31}P NMR: phosphatidylglycerol, phosphatidic acid, diphosphatidylglycerol, ethanolamine plasmalogen, phosphatidylethanolamine (PE), lysophosphatidylinositol, phosphatidylserine, sphingomyelin, lysophosphatidylcholine (LPC), phosphatidylinositol (PI), sphingosylphosphorylcholine and phosphatidylcholine. In addition, two unidentified phospholipids were detected with resonances at 0.13 and –0.78 ppm, respectively. Three distinct types of spectra were obtained on the extracts and grouped accordingly for comparison purposes. Type 1 tumors showed unusual ^{31}P NMR profiles with low levels of PE and PI and elevated levels of LPC; type 2 tumors were characterized by low levels of the ethanolamine phospholipids and near equivalent levels of PI and LPC. The spectra of type 1 and type 2 tumors were characteristic of degenerative cells that lacked membrane permeability associated with loss of ethanolamine plasmalogen in the presence of significant phospholipid turnover. Meningiomas belonging to the third spectral type showed characteristics similar to those of normal tissues with normal levels of PE and ethanolamine plasmalogen, as well as very low levels of LPC relative to PI. Type 3 tumors lacked the characteristic signs of degeneration noted in type 1 and type 2 tumors. The data corroborate and augment *in vivo* spectroscopic findings reported earlier and demonstrate the value of ^{31}P NMR spectroscopic phospholipid analysis on lipid extracts for the characterization of meningiomas.

***Lipids* 29, 359–364 (1994).**

Meningiomas and other types of intracranial tumors have been characterized and differentiated *in vivo* using magnetic resonance spectroscopy and magnetic resonance imaging (1–11). When ^{31}P nuclear magnetic resonance (NMR) is performed *in vivo,* spectral differences are often attributed to perturbations in phospholipid metabolism (3,7–9,11–17) as the integrated phosphomonoester and phosphodiester resonance signals, which arise from low-molecular weight, water-soluble phosphorylated phospholipid precursors, differ when comparing different tissue types.

The phosphomonoester resonance band, detected by *in vivo* methods, represents the membrane phospholipid precursors phosphocholine (PC) and phosphoethanolamine (PE), while the phosphodiester resonance band accounts for the phospholipid metabolic intermediates glycerol 3-phosphocholine and glycerol 3-phosphoethanolamine. Although it is generally true that these metabolites contribute substantially to the signal intensity of the respective resonance bands, to describe spectral changes in precursor metabolic profiles only in terms of phospholipid metabolism is often simplistic because these phospholipid precursors and products are known to play roles other than metabolic ones (18–21).

Tissue phospholipids can be extracted from surgical tissue specimens with chloroform/methanol and can be identified and quantitated by ^{31}P NMR (22). The spectroscopic phospholipid profiles thus obtained are characteristic of the disease state and can be used for classification purposes. In the present study, meningioma surgical tissue specimens were acquired from fourteen patients undergoing craniotomy and were analyzed to obtain quantitative spectral profiles. Statistical analysis of the spectral profiles permitted subclassification of the tumors into three groups thus allowing for a more refined biochemical differentiation of the disease states. Because ^{31}P NMR detects and resolves most phospholipids in the extract, novel and uncharacterized phospholipids can also be detected and quantified.

MATERIALS AND METHODS

Surgery. Human meningioma surgical tissue specimens were obtained from patients undergoing scheduled craniotomy. The unfixed tissue specimens were partitioned within five minutes into separate portions for histopathologic examination and NMR spectroscopic analysis. The portion taken for analysis was promptly submerged in liquid nitrogen for storage. Specimens ranged from 0.5 to 1.5 g. The remaining surgical tissue specimens were sectioned and examined microscopically for histologic diagnosis after staining with hematoxylin and eosin or other stains as required. Brains were also obtained from two C3H/He mice, which were euthanized by lethal injection of euthanasia-5 solution containing pentobarbital; the brains were dissected, removed and rinsed with physiologic saline to remove extraneous blood, and then were immediately

Abbreviations: ATP, adenosine triphosphate; CPLAS, choline plasmalogen; CPLIP, choline phospholipid; DPG, diphosphatidylglycerol, cardiolipin; EDTA, (ethylenedinitrilo)tetraacetic acid; EPLAS, ethanolamine plasmalogen; LPC, lysophosphatidylcholine; LPI, lysophosphatidylinositol; NMR, nuclear magnetic resonance; PA, phosphatidic acid; PC, phosphatidylcholine; PE, phosphatidylethanolamine; PG, phosphatidylglycerol; PI, phosphatidylinositol; PS, phosphatidylserine; SM, sphingomyelin; SPC, sphingosylphosphorylcholine; U, unidentified phospholipid.

frozen in liquid nitrogen. The material was used to obtain reference spectra to confirm spectral assignments.

Phospholipid extraction. A simple, modified Folch extraction (23) for meningioma phospholipids was used in which the backwashing step utilized potassium salt of (ethylenedinitrilo)tetraacetic acid (EDTA), 0.2 M, in EDTA, pH 6.0 (24). Meningioma tissue specimens, frozen in liquid nitrogen, were pulverized to a fine powder using a stainless-steel mortar and pestle that had been chilled with liquid nitrogen. The tissue powder (0.5–1.5 g/tissue sample) was then added to 20 mL of chloroform/methanol (2:1, vol/vol). The homogenate, consisting of a single liquid phase, was filtered into a separatory funnel. The extract was washed with 4 mL of 0.2 M potassium EDTA and allowed to separate thoroughly for 24 h in a separatory funnel. The chloroform phase was recovered and evaporated using a rotary evaporator at 37°C.

Phospholipid solvent for ^{31}P NMR. The solvent for phospholipid analysis by ^{31}P NMR was hydrated chloroform/methanol (25,26) designed to permit the quantitative determination of phospholipids (22,24,25,27). The solvent consists of two parts: (A) Reagent-grade chloroform, containing 5% benzene-d_6 and an appropriate concentration of trimethylphosphate; and (B) Reagent-grade methanol containing 0.2 M aqueous Cs EDTA, pH 6 (4:1, vol/vol). The final methanol reagent is prepared by dissolving 1 mL of the aqueous Cs EDTA solution in 4 mL methanol. Benzene-d_6 is used to serve as internal field-frequency lock. The concentration of the trimethylphosphate chemical-shift and quantitation reference (7) can be varied depending on the phospholipid concentration. The Cs EDTA used is generated by titrating an aqueous suspension of EDTA with CsOH to pH 6, at which point a solution is obtained. For ^{31}P NMR analysis, a lipid sample (0.01–100 mg) is dissolved in 2 mL of Reagent A and transferred into an NMR sample tube; 1 mL Reagent B is added, and the sample is mixed thoroughly. A small amount of aqueous phase which separates is allowed to rise to the top of the sample (1 min). Ordinarily, there is no need to remove this small amount of aqueous phase, which contains no detectable amounts of phospholipids; its presence above the sample ensures that proper equilibria are maintained and that organic solvent loss during analysis is minimized.

^{31}P Magnetic resonance spectroscopy. The NMR spectrometer used was a GE 500NB system (General Electric, Fremont, CA) operating at 202.4 MHz for ^{31}P. The spectrometer was equipped with an Oxford Instruments (Oxford, United Kingdom) 500/52 magnet having an operating magnetic field of 11.75 Tesla and deuterium field-frequency locking capability. Tissue extracts were placed in standard 10-mm NMR sample tubes, and spun at 8 Hz during data acquisition. Proton broadband decoupling was used throughout. Chemical shift data are reported relative to 85% inorganic orthophosphoric acid (28); however, the primary internal reference standard was PC (chemical shift, –0.84 ppm) or trimethylphosphate. Spectrometer conditions were as follows: pulse sequence, one pulse; pulse width, 18 μs (45° flip angle); acquisition delay, 500 μs; cycling delay 500 ms; number of acquisitions, 12,000; number of points per free induction decay, 4096; acquisition time 1.02 s; sweep width ± 1000 Hz. The total average acquisition time per sample was 6 h. The free induction decay was Fourier transformed and filtered using a line broadening factor of 0.6 Hz.

Assignment of phospholipid resonances. Phospholipid signals in the ^{31}P NMR spectra were sequentially identified by adding known quantities of individual phospholipid standards (29,30). Phospholipid standards were obtained from the Sigma Chemical Company (St. Louis, MO) and Life Sciences, Inc. (Milwaukee, WI). In those instances where resonance signals were not fully resolved, spectral deconvolution was used. In the more concentrated samples, overlap between the phosphatidylserine (PS) and sphingomyelin (SM) resonances was significant enough to introduce substantial errors in the analysis. In such instances, the samples were further diluted with additional solvent mixture (25). Dilution caused a downfield chemical shift of PS while having little effect on the chemical shift of SM. This permitted resolution of the PS and SM signals and their quantitation by integration.

A spectrum of mouse brain (C3H/He) obtained using the same procedures is presented in Figure 1 to illustrate the resolving power of the method under optimal conditions. In the figure, the prominent PC resonance is off-scale so that the minor phospholipid resonances can be observed. The bottom spectrum illustrates the identification of the lysophosphatidylcholine (LPC) signal through addition of 1-stearoyl-*sn*-glycero-3-phosphocholine (0.4 mg; Sigma), which was introduced by microsyringe as chloroform solution. Alternative methods for obtaining rat brain NMR phospholipid spectra have been described (31).

Data analyses. Phospholipid concentrations in relative mole percentages were computed for all phospholipid resonances in the tumors analyzed. For each phospholipid, mean phospholipid concentrations were calculated and compared for the three spectral types using an analysis of variance. For those resonances for which significance was shown to exist (F probability, $P < 0.05$), a post-hoc Scheffé comparison procedure was applied with significance determined at the $P < 0.05$ level. Under most conditions, analysis of variance requires the assumption that the underlying variances between tested means be equal; therefore, for those resonances for which significance was established, homogeneity of variance was confirmed using Cochran's C and the Bartlett-Box F tests.

RESULTS

The fourteen meningioma spectra obtained in this study were qualitatively divided into three groups—type 1, type 2 and type 3. Representative meningioma spectra are shown in Figure 2. Starting downfield, the following phospholipids were identified: phosphatidylglycerol (PG), phosphatidic acid (PA), diphosphatidylglycerol (cardiolipin; DPG), ethanolamine plasmalogen (EPLAS), PE, lysophosphatidylinositol (LPI), PS, SM, LPC, phosphatidylinositol (PI), sphingosylphosphorylcholine (SPC) and PC. Two unidentified phospholipids, U and choline phospholipid (CPLIP), were also detected with signals at 0.13 and –0.78 ppm.

Type 1 spectra (Table 1) are characterized by low levels of the ethanolamine phospholipids and PI, and elevated

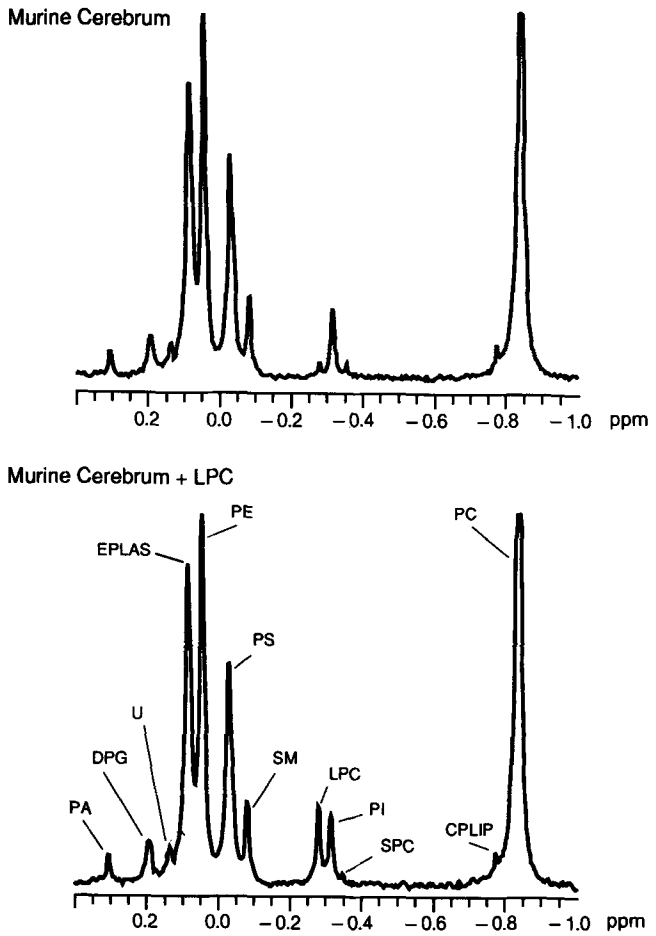

FIG. 1. ^{31}P nuclear magnetic resonance phospholipid spectrum of normal mouse cerebrum: PA, phosphatidic acid; DPG, diphosphatidylglycerol; U, an unidentified phospholipid; EPLAS, ethanolamine plasmalogen; PE, phosphatidylethanolamine; PS, phosphatidylserine; SM, sphingomyelin; LPC, lysophosphatidylcholine; PI, phosphatidylinositol; SPC, sphingosylphosphorylcholine; CPLIP, choline phospholipid; and PC, phosphatidylcholine. The bottom spectrum shows the effect of adding the equivalent of 0.4 mg of LPC standard in chloroform to the sample, giving the top spectrum.

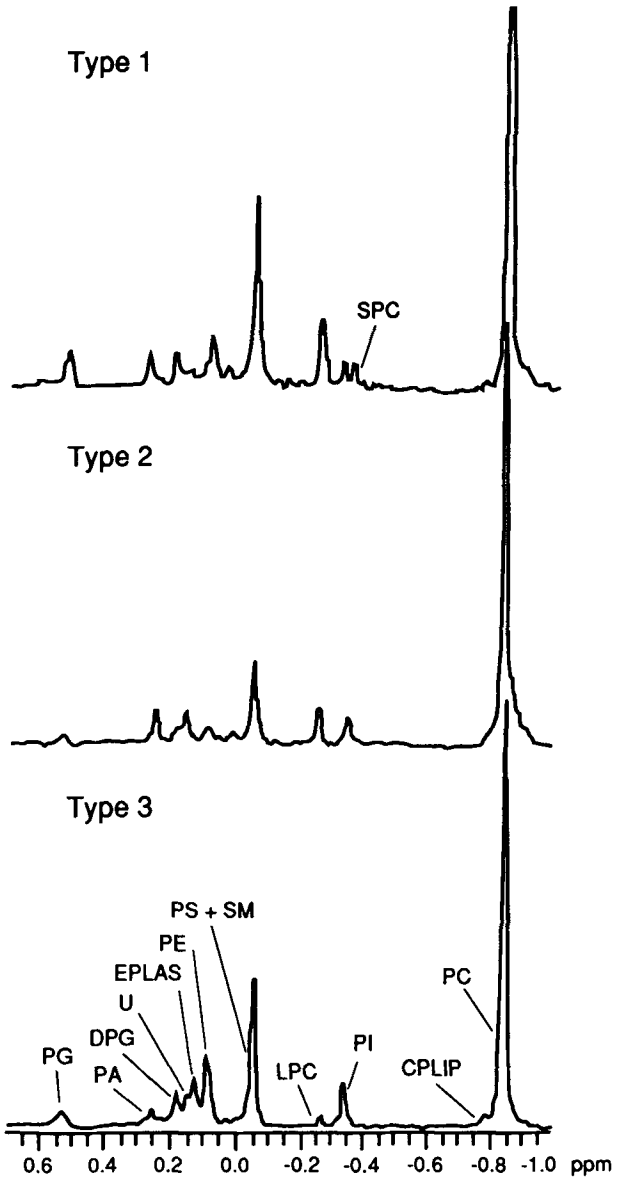

FIG. 2. Characteristic ^{31}P nuclear magnetic resonance phospholipid spectral profiles of human intracranial meningiomas. The resonance signals starting from downfield (0.6 to −1.0 ppm) are as follows: PG, phosphatidylglycerol; PA; DPG; U; EPLAS; PE; PS; SM; LPC; PI; SPC; CPLIP, choline phospholipid; and PC. Abbreviations as in Figure 1.

levels of LPC. All of these tumors were located in the vicinity of the frontal lobes, including one olfactory nerve meningioma. Three of the five tumors included in this category were considered transitional meningiomas as judged by histological analysis, while the remaining two specimens were defined as syncytial.

Type 2 spectra are unique because they contain near equivalent levels of LPC and PI and little or no ethanolamine phospholipids. Two of the three tumors were histologically syncytial, one transitional, and two out of the three were obtained from patients with recurrent disease.

Type 3 spectra include six samples that have the appearance of typical neural and nonneural tissue spectra. These tumors have very low levels of LPC relative to PI, while the presence of the ethanolamine phospholipids is noted to be within the normal range of concentrations that exists in most human tumors. This group of tumors was comprised evenly of transitional and syncytial histological types and lacked a prevalent site of origin. Temporal, frontal and parietal lobe tumors are included in this spectral type.

The relative concentration of the individual phospholipids was determined for each of the samples analyzed in this study. Subsequently, the mean relative mole percentage of the phospholipids was determined for each tissue type (Table 1). This analysis provided a basis for comparison of the three tumor types based on their phospholipid class composition. The tissue spectra all share some common features, such as the presence of PG, PA, DPG, U (0.13 ppm), PS, LPC, PI, CPLIP (–0.78 ppm) and PC. In

TABLE 1

Phospholipid Profiles of Intracranial Meningioma as Measured by ^{31}P Nuclear Magnetic Resonance[a]

Phospholipid	Relative mol% of phosphorus ± SE					
	Type 1		Type 2		Type 3	
Phosphatidylglycerol	3.63	0.42	3.84	1.39	3.40	0.46
Phosphatidic acid	4.47	0.76	4.31	0.46	2.04	0.33
Diphosphatidylglycerol	2.68	0.67	2.47	0.27	2.97	0.37
Sphingomyelin	3.42	0.55	3.04	0.50	2.58	0.32
Ethanolamine plasmalogen			2.50		9.29	1.01
Phosphatidylethanolamine	4.79	0.58	6.06	1.16	9.62	0.45
Lysophosphatidylinositol	3.18	0.32	2.30	0.005		
Phosphatidylserine	24.79	1.54	18.71	4.96	24.62	1.70

Sphingosylphosphorylcholine	0.05	0.001	0.05

[a]n.s., Not significant.

all spectra, the resonances of PC and PS dominate, whereas variations in the relative concentrations of the other phospholipids make it possible to differentiate the three meningioma groups.

The spectra of the three groups were studied using an intergroup comparison procedure (Table 1, concentration; Table 2, statistical probability value). Type 1 spectra showed significantly diminished levels of PI and increased levels of LPC and SPC when compared with type 2 spectra. In addition, the spectra showed significantly depressed levels of PI and PE, and increased levels of PA, LPC and SPC relative to type 3 spectra. Type 2 spectra showed significantly lower levels of PE and increased levels of PI, LPC and SPC when compared to type 3 spectra. LPI was absent in type 3 spectra, and EPLAS was absent in type 1 spectra and present in only 1 of 3 type 2 spectra.

DISCUSSION

In this comparison of meningioma phospholipids, a number of observations can be made: (i) based on qualitative assessment of spectral profiles, three tumor subgroup types can be identified; (ii) all three tissue types show the presence of PA and of the lysophospholipids LPI and LPC, compounds often associated with phospholipid catabolism; (iii) significant spectral differences that make it possible to distinguish between tissue types were noted for the minor phospholipids PA, LPC, PI and SPC; exceptions to this included the absence of EPLAS in type 1 and type 2 tumors and the significant differences in the levels of PE between type 1 and type 3 tumors; and (iv) significant differences between the tissue types in the level of phospholipids typically associated with the inner leaflet of the plasma membrane, such as the ethanolamine phospholipids.

The very low level of EPLAS, found in two of the three meningioma types (type 1 and type 2), is an outstanding feature of these tumors, as EPLAS can be a major component of human tissue phospholipids. For example, in the human brain myelin (27), EPLAS has been shown to account for 38% of total phospholipids, and thus exceeds even PC (24%). Most meningiomas arise from arachnoid cells and, therefore, differ from other intracranial neoplasms in their gross appearance and histology. Meningiomas are usually grossly nodular, encapsulated, and often show calcification. Histologically, the calcifications give rise to psammomatous whorls that are composed of concentrically laminated structures formed by the deposition of calcium in degenerated tumor cells. In type 3 meningiomas, the concentration of the ethanolamine phospholipids is within the expected range of other mammalian tissue types. This may reflect the profiles of those cells that are, biologically, in the early stages of the neoplastic process. Lammelar structures may be formed by degenerating cells, or by cells that have a low concentration of EPLAS. These cells are characterized by a marked decrease in membrane permeability and reflect an altered membrane messenger transport as well as poor perfusion capability. Such changes lead to a disruption of normal intracellular communication and represent end-stage processes. In meningiomas, the formation of psammoma bodies results from the precipitation of accumulated intracellular calcium or from cellular processes that allow calcium to exceed normal equilibrium concentrations. Healthy cells have a balance of ethanolamine and choline phospholipids. The absence of ethanolamine phospholipids in type 1 and type 2 tissues indicates the presence of degenerative cells that are no longer viable. Changes in phospholipid profiles may presage the degenerative processes that are often identified histologically in meningiomas. Precursors or products of these processes may serve as a means of differentiating meningiomas from other neural or non-neural tissue types. If such an interpretation were accurate, the appearance of LPI in the spectra of type 1 and type 2 meningiomas would appear to be as significant as the absence of the ethanolamine phospholipids from the same tissue types and indicative of the aforementioned degenerative processes.

According to the ^{31}P NMR measurements of Cadoux-Hudson *et al.* (3), meningiomas are more alkaline (pH = 7.19 ± 0.02) than normal brain tissue (pH = 7.03 ± 0.02). The elevated pH observed in tumor cells was ascribed to a potential alteration in Na^+/H^+ antiport activity within these cells. Similarly, Heindel *et al.* (7) reported from their studies that meningiomas were generally not acidotic. They also reported that the phosphocreatine/adenosine triphosphate ratio was significantly lower compared to healthy brain tissue. Cadoux-Hudson *et al.'s* (3) study also showed elevated levels of phosphomonoester and phosphomonoester/adenosine triphosphate that were accompanied by reduced levels of phosphocreatine when compared to tissue spectra from seven controls (3). The reduction in phosphocreatine was interpreted as resulting from extensive necrosis (>20%) that was observed histologically. In this series, particularly low levels of phosphocreatine were measured within the tumor center, and low to normal levels in the tumor periphery. In agreement with this finding, Hubesch *et al.* (9) reported a significantly decreased phosphocreatine/inorganic orthophosphate ratio. These findings agree with our results that show the presence of phospholipids commonly associated with catabolic processes, and support the idea that low-energy processes may predominate in meningiomas.

In separate studies, both Hubesch *et al.* (9) and Brenton *et al.* (32) reported that PE was a major component of the phosphomonoester resonance band, and, as had been previously suggested, ribose-5-phosphate or adenosine monophosphate were not. This information, coupled with the results of a ^1H NMR spectroscopic study by Bruhn *et al.* (5), which showed a prominent choline signal in the spectra of these tumors as well as diminished levels of phosphodiester, would suggest that the relative concentrations of phosphoethanolamine and phosphocholine should be elevated in tissue extracts. These *in vivo* findings corroborate the need for a more detailed and specific *in vitro* study of the phospholipid composition of meningiomas.

Heindel *et al.* (7) compared ^{31}P NMR spectra of 13 meningiomas with spectra from "healthy tissue." The former showed obvious changes, including decreased levels of phosphocreatine below those of both the γ- and α-phosphates of adenosine triphosphate (ATP) but above that of β-ATP. The phosphodiester resonance was reduced in these tumors relative to normal tissue while the phosphomonoester resonance was occasionally elevated. Changes in the phosphomonoester resonance were thought to indicate the presence of phosphoethanolamine, a precursor and an indicator of active membrane biosynthesis within the tumor. Studies by Cerdan *et al.* (33) and Burt *et al.* (34) suggested that the phosphodiester resonance has substantial contributions from a small fraction of mobile phospholipids. It should be mentioned in this context that the phospholipids in eggs are detectable as fairly narrow resonances in high-resolution ^{31}P NMR, and that it is believed that these signals arise because the lipids are contained in mobile lipoprotein particles (35) that are similar to circulating plasma lipoproteins (36). Even if the phospholipids were sufficiently mobile to allow for signals to contribute to the phosphodiester resonance band *in vivo*, the ethanolamine phospholipids would not be substantial contributors to the phosphodiester band in meningiomas.

In human brain tumors examined by Horrocks and Sharma (37) for phospholipid and acyl group composition, the proportion of EPLAS as a percentage of total phospholipids was low and varied from 0.8 to 11.8%. The proportion of alkylacyl glycerophosphocholine was elevated in three out of five tumor types. The resonance at –0.78 ppm, which has been interpreted by Edzes *et al.* (27) to be due to alkylacyl glycerophosphocholine was only 0.1% in control specimens, but was elevated to 0.8–3.4% in tumors. By comparison, in our study alkylacyl glycerophosphocholine (–0.78 ppm) measured less than 1% of all phospholipid components. Cultured cells, and both primary and metastatic tumors, generally contain 2–3% of this component and 1–13% of EPLAS (35).

The phospholipids in malignant neural tumors have been studied using NMR and other analytical techniques. Many neoplastic tissues have been found to have markedly elevated levels of 1-alkyl-2,3-diacyl-*sn*-glycerols (38). This was proposed as pointing to a potential tumor marker; however, lower levels of this phospholipid found in hepatocellular carcinoma, and high levels induced by staph infections made this less tenable (38). In human brain tumors examined by Albert and Anderson (38) for phospholipid and acyl group composition, the proportions of EPLAS were found to be rather low, but varied from 0.8 to 11.8%. The proportion of alkylacyl glycerophosphocholine was elevated in three out of five tumor types. Choline plasmalogen (CPLAS) was only 0.1% in the control, but was elevated to 0.8–3.4% in the tumors. By comparison, in our study the CPLAS measured less than 1% in all tissues, while it has been noted that cultured cells, both primary and malignant, generally have 2–3% CPLAS and 1–13% EPLAS.

Ronen and Degani (39), using ^{13}C NMR spectroscopy on isolated cells, reported an increase in phosphomonoester metabolites in tumor cells when compared to the profiles of normal cells. Both phosphocholine and phosphoethanolamine were elevated in cancerous tissues, and, subsequent to therapy, the concentration of both of these species diminished. Other investigators have reported similar findings (11,40).

Daly and Cohen (11) found a consistent elevation of the choline and ethanolamine phosphomonoesters in a variety of neoplasms, including prolactinomas and metastatic lymphomas within the central nervous system, lung, breast, skin, liver and bone. Hubesch *et al.* (9) reported that the phosphomonoester resonance signal was elevated in cancerous tissues relative to other metabolites detected in the profile; however, the absolute concentration of both the phosphomonoester and phosphodiesters was lower in the tumors. Such a finding is consistent with the pronounced edema and presence of extracellular debris ordinarily found in tumors with degenerative processes where the presence of these extracellular components decreases the relative volume of viable cells. None of the six meningiomas studied by Daly and Cohen (11) showed a statistically significant rise in the concentration of the phosphomonoester. This finding is consistent with

the data obtained in our study regarding type 3 tissue spectra, including the "normal" or "near-normal" concentrations of ethanolamine phospholipids. Thomsen *et al.* (6) found no significant differences in phospholipid precursors in central nervous system tumors when compared with normal brain.

The identity of the unidentified phospholipids labeled CPLIP and U in Figure 2 is in question. CPLIP has been identified both as the choline plasmalogen (25), having an enol ether function at glycerol carbon-1, and as the corresponding alkylacyl glycerophosphocholine (27). However, these assignments are not certain because of the inability, thus far, of producing chemically pure standard samples. It is suspected (27) that the phospholipid labeled U is the corresponding alkylacyl glycerophosphoethanolamine, but this assignment is even less certain than that for the corresponding choline phospholipids. It should be noted, however, that the assignment of resonance U to alkylacyl glycerophosphoethanolamine is consistent with data reported for the chemical and spectroscopic properties of an unknown phospholipid at 0.13 ppm in eye tissues (41–45), as well as in other human tissues (46–48). The discovery of potentially new phospholipids is a significant advantage of the ^{31}P NMR approach.

In summary, *in vitro* ^{31}P NMR on phospholipid extracts from human intracranial meningiomas can provide phospholipid concentration profiles and can identify statistically significant differences among tumors and thus can differentiate between meningioma subgroups. The data corroborate and supplement *in vivo* spectroscopic findings on phospholipid metabolites and demonstrate the value of ^{31}P NMR phospholipid analyses on tissue extracts in the characterization of meningiomas of the central nervous system.

METHOD

A Rapid Method for the Preparation of Ganglioside $G_{lac}2$ (GD3)

Richard Jennemann and **Herbert Wiegandt***

Physiologisch-Chemisches Institut, Philipps-Universität, 3550 Marburg, Germany

A method is described for the preparation of ganglioside $G_{lac}2$ [(II^3(NeuAc)$_2$-LacCer, GD3] from cream of bovine milk using liquid-phase extraction with methanol or ethanol followed by anion exchange chromatography. The method is rapid and inexpensive; 1 kg cream, centrifuged from 14–15 L of bovine milk, yields approximately 70 mg of pure ganglioside $G_{lac}2$. The sialic acid constituent of ganglioside $G_{lac}2$ isolated from bovine milk cream consists solely of the *N*-acetylneuraminic acid derivative. The major components of its ceramide consist of octadecasphing-4-enine and the 22:0 (behenic acid) and 23:0 fatty acids.

***Lipids* 29, 365–368 (1994).**

Early reports on the occurrence of ganglioside $G_{lac}2$ [II^3(NeuAc)$_2$-LacCer, GD_3) in the late sixties had suggested a wide distribution of this disialoglycosphingolipid in various tissues of many different animal species (2–5). $G_{lac}2$ is not only found cell-bound but is also contained in body fluids such as serum and milk, where it is probably conjugated to lipophilic carrier proteins (6,7) (see also Table 1).

In spite of its disialogrouping, $G_{lac}2$ has a simple structure as compared, for example, to the higher brain gangliosides. It may, therefore, be considered a developmental precursor of the latter, more complex sialoglycolipids. Ganglioside $G_{lac}2$, and cells binding the $G_{lac}2$-specific monoclonal antibody R24 have been found in cell types at later embryonic stages and in adult tissues and tumors that may indicate some neuroectodermal association of this sialoglycolipid. A possible functional role of $G_{lac}2$ was pointed out for epithelial-mesenchymal cell interactions (8).

In a variety of cancers, ganglioside $G_{lac}2$ and its 9-*O*-acetyneuraminyl derivatives accumulate, possibly as a consequence of the cells' inability to synthesize the respective higher analogs (see Table 1). In addition, cancer cells are believed to shed tumor-associated glycolipids, that in turn may contribute to increased serum levels of ganglioside $G_{lac}2$ as suggested for human melanoma (9), glioma (10) and, possibly, alteration of the immune status of melanoma patients (11–13).

An involvement of ganglioside $G_{lac}2$ in cell surface interactions and cell adhesion has recently been postulated (8,14,15). Ganglioside $G_{lac}2$ together with its 9-*O*-acetylneuraminyl or lactone derivatives is also suspected of playing a functional role in the development of the nervous system.

In view of the putative roles of ganglioside $G_{lac}2$ in various tumor-associated phenomena as well as other biological interactions, it appears likely that a demand for this glycolipid will arise in the future. We have therefore developed a simple and inexpensive method for the convenient isolation of $G_{lac}2$. The procedure we describe for the preparation of pure ganglioside $G_{lac}2$ uses cream from bovine milk as a safe and readily available source and methanol or ethanol as a solvent for the liquid-phase extraction of the sialoglycolipid.

MATERIALS AND METHODS

Extraction of ganglioside. To 1 kg of cream from fresh, nonhomogenized bovine milk is added two liters of methanol, and the mixture is stirred mechanically for 15 min at room temperature. After centrifugation for 30 min at 3,000 × *g* at 4°C, the clear supernatant is decanted and the pellet residue reextracted twice, each time with 2 L of methanol. The three extracts obtained contain 32, 60 and 8% of the total extracted ganglioside $G_{lac}2$, respectively. Further continuation of extraction did not significantly increase the yield of ganglioside. Instead of methanol, ethanol may be used for extraction with similar efficiency.

The three extracts are then sequentially passed over a DEAE-Sephadex A25 column (Pharmacia, Uppsala, Sweden; r = 1.75 cm, l = 25 cm, vol, 250 mL) that had been prewashed with methanol. All gangliosides are thereby retained and can be eluted under standard conditions. The column is then eluted sequentially with 2 L of methanol (eluting neutral compounds) and 2 L of 0.02 M methanolic ammonium acetate [eluting the predominant portion of the monosialogangliosides with $G_{lac}1$ (GM3) as the major compound]. The ganglioside $G_{lac}2$ is eluted from the column with 2 L of 0.2 M methanolic ammonium acetate. After reducing the solvent to approximately 100 mL by rotary evaporation, the fraction is then dialyzed for 48 h against 5 L of distilled water with five changes of the dialysis medium. Finally, the fraction is evaporated to dryness by rotary evaporation.

Final purification of ganglioside $G_{lac}2$. The disialoganglioside fraction containing trace amounts of monosialoganglioside $G_{lac}1$ (see Fig. 2, fractions I/H/W 55:37:8-2 and 55:36:9-1) besides 9-*O*-acetylated $G_{lac}2$ (see Fig. 2, fractions 55:36:9-2, 55:36:9-3 and 55:35:10-1) is dissolved in *iso*propanol/*n*-hexane/water (I/H/W; 55:40:5, by vol) and applied to a silica gel column (Silica Gel 60; Merck, Darmstadt, Germany; r = 1.5 cm, l = 28 cm; vol, 200 mL). For ganglioside separation a stepwise gradient of I/H/W containing 5 to 10% water is used. The gradient consisted of 800 mL each of I/H/W

*To whom correspondence should be addressed at Physiologisch-Chemisches Institut, Philipps-Universität, D-35043 Marburg-18, Lahnberge, Germany.

Abbreviations: DEAE, diethylaminoethyl; I/H/W, *iso*propanol/*n*-hexane/water; TLC, thin-layer chromatography.

Short hand notations for gangliosides are according to Wiegandt (Ref. 1). $G_{lac}2$, (II^3(NeuAc)$_2$-LacCer) is NeuAcα,8NeuAcα,-3Galß,4Glcß,1Cer; $G_{tet}1$, (II^3NeuAc-Gg_4Cer) is Galß,3GalNAcß,-4(NeuAcα,3)Galß,4Glcß,1Cer.

(55:40:5 and 55:29:6, by vol); 400 mL each of I/H/W (55:38:7, 55:37:8 and 55:36:9, by vol), and 1200 mL of I/H/W (55:35:10, by vol). The fractions I/H/W (55:40:5–55:38:7, by vol) containing the major portion of the phospholipids are discarded. The eluate obtained with I/H/W (55:37:8, by vol) is collected in two, the I/H/W (55:36:9, by vol) eluate in three and the I/H/W (55:35:10, by vol) eluate in six consecutive fractions. The latter six fractions were free of detectable phospholipids and contained pure ganglioside $G_{lac}2$ (Figs. 1 and 2).

Identification of ganglioside $G_{lac}2$ sialic acid. $G_{lac}2$ (50 µg) in 200 µL 0.05 M aqueous HCl is heated to 70°C for 60 min. After removal of HCl by repeated evaporation with water, the hydrolysate is applied to a small column of 200 µL silica gel RP-18. Sialic acid is eluted with 1 mL water. The eluate is then brought to dryness, and the sialic acid identified by chromatography on cellulose high performance thin-layer chromatography (TLC) plates (Merck). The plates are pre-run with 0.1 M HCl and dried overnight in a desiccator over potassium hydroxide/phosphorus pentoxide. The probes are then applied to the plates and chromatographed using *n*-butanol/*n*-propanol/0.1 M aq. HCl (1:2:1, by vol). Sialic acid is visualized with Ehrlichs reagent, i.e., spraying with 0.6% dimethylaminobenzaldehyde in ethanol/37% aq. HCl (8:2, vol/vol), and heating to 110°C for approximately 10 min beneath a preheated glass plate.

RESULTS AND DISCUSSION

Ganglioside $G_{lac}2$ is widely distributed in cells and body fluids of vertebrates. Among these, bovine milk has been reported to be particularly rich in this sialoglycosphingolipid (Table 1). Ganglioside $G_{lac}2$ has, therefore, been prepared previously by several workers from milk (7) or buttermilk (16–18). Bovine milk was shown to contain 5.64 µmol/L of ganglioside $G_{lac}2$, of which 92.3 and 7.5% was present in the cream and the buttermilk, respectively (7). We therefore chose the cream fraction as starting material for the ganglioside $G_{lac}2$ preparation.

The first step in the previously described ganglioside $G_{lac}2$ isolation procedures (16–18) involved the evaporation of water from the starting material and the subsequent extraction of the dry powder with organic solvents, tetrahydrofuran (16,19), or in all other cases chloroform/methanol.

The innovation introduced in our present procedure avoids these steps, i.e., the drying-down of the starting material, the use of costly and potentially hazardous solvents, and a heterogeneous phase extraction. Instead, bovine milk cream is treated in homogeneous phase with dilute methanol, and the extraction residue formed thereby is separated by low-speed centrifugation or filtration. The gangliosides are isolated by simply passing the methanol extract over an anion-exchange column. The retained gangliosides are subsequently obtained by stepwise elution according to standard procedures. The final purification of the ganglioside $G_{lac}2$ involves silica gel column chromatography under standard conditions.

Using this procedure, from 1 kg cream (prepared by centrifugation of 14–15 L fresh bovine milk, 30 min, 3,000 × *g*, 4°C) 70 mg of pure ganglioside $G_{lac}2$ (53.8 µmol ≈ a yield of 3.8 µmol/L milk; Fig. 1) was isolated. Ganglioside yield determinations were by TLC and subsequent quantification by resorcinol/HCl staining and scanning at 580 nm with a Shimadzu TLC scanner CS-9000 (Tokyo, Japan). The compositional analysis of the $G_{lac}2$ lipid moiety showed octadecasphing-4-enine (d18:1) and 23:0 fatty acid as well as behenic acid (22:0) to be the major ceramide constituents (Table 2). This

TABLE 1

Distribution of Ganglioside $G_{lac}2$

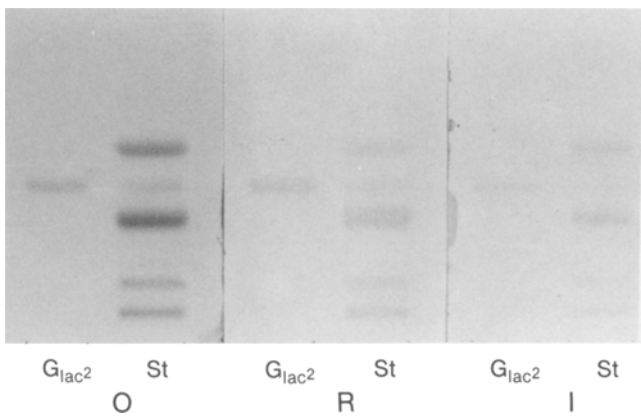

FIG. 1. Thin-layer chromatogram of ganglioside $G_{lac}2$ from bovine milk-cream. Running solvent, chloroform/methanol/0.2% $CaCl_2$, 45:45:10 (by vol); $G_{lac}2$, 2 µg were applied to the plate; St, standard brain gangliosides; O, orcinol/H_2SO_4 staining; R, resorcinol/HCl staining; I, iodine vapor staining.

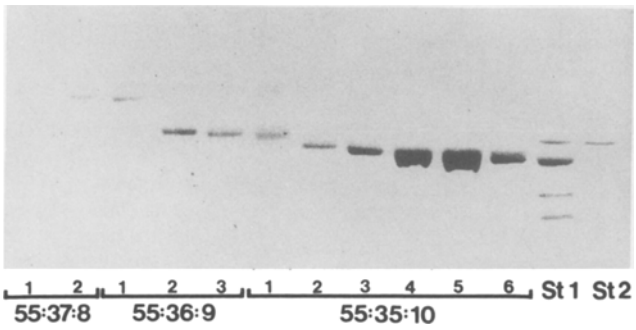

FIG. 2. Thin-layer chromatographic analysis of the fractions obtained by silica gel chromatography of bovine milk cream disialogangliosides. Abscissa: elution by *iso*propanol/*n*-hexane/water (I/H/W) in the proportions given (numbers 1 to 6, indicate consecutively collected fractions); St 1, standard brain gangliosides; ST 2, standard ganglioside $G_{tet}1$. Fractions I/H/W 55:37:8/-2 and 55:36:9/-1, $G_{lac}1$; 55:36:9/-2,3 and 55:35:10/-1, 9-*O*-acetyl-$G_{lac}2$; 55:35:10/-2,3,4,5,6, $G_{lac}2$. Detection was with resorcinol/HCl spray reagent.

finding is in general agreement with a previous report (17). The isolation requires approximately nine one-person working days.

Ganglioside $G_{lac}2$ prepared from bovine milk cream contained exclusively *N*-acetylneuraminic acid as its sialic acid constituent. *N*-glycolylneuraminic acid, if present, was below detection limits. Even though, in addition to *N*-acetylneuraminic acid, the presence of the *N*-glycolyl derivative has been described for gangliosides of bovine mammary gland and milk (7), our findings would be consistent with the notion that only the *N*-acetyl variant is present in gangliosides of bovine milk (16,17).

TABLE 2

Sphingoid and Fatty Acid Composition of Ganglioside $G_{lac}2$ from Bovine Milk Cream[a]

Fatty acid		Sphingoid	
16:0	3.4	d16:1	10.9
18:1	3.7	d16:0	5.3
18:0	8.8	t16:0	7.7
20:0	3.2	d18.1	52.6
21:0	3.0	d18.0	6.5
22:0	26.4	d19:1	5.0
23:0	28.8	d21:1	5.9
24:1	3.2	t22.0	6.1
24:0	16.7		
25:0	2.9		

[a]Data are given in percentage of the total. Sphingoid was analyzed by gas chromatography/mass spectrometry after hydrolysis of $G_{lac}2$ (Ref. 48), isolation of the long-chain base (Ref. 49), and oxidation with lead tetraacetate of the aldehydes produced (Ref. 50). Fatty acids were determined as their methyl esters by gas chromatography.

When highly unsaturated fatty acids are added to cell cultures, it can become important to include antioxidants in the culture medium to prevent cytotoxic peroxidation. To find an optimal antioxidant for this purpose, the effect of 50 μM α-tocopherol, γ-tocopherol, α-tocopheryl acetate, α-tocopheryl acid succinate, or α-tocopheryl phosphate, or of 1 μM *N,N'*-diphenyl-1,4-phenylenediamine, was investigated with respect to the agent's ability to prevent lactate dehydrogenase leakage in long-term rat hepatocyte cultures supplemented with 0.5 mM highly unsaturated fatty acids. Formation of thiobarbituric acid reactive substances in the cultures was also measured. α-Tocopheryl acid succinate was found to be the most effective cytoprotective compound, followed by *N,N'*-diphenyl-1,4-phenylenediamine, α-tocopherol, γ-tocopherol and α-tocopheryl acetate, and α-tocopheryl phosphate was without effect.

***Lipids* 29, 369–372 (1994).**

When studying the effect of various highly unsaturated fatty acids (HUFA) in cell cultures, it can become desirable to prevent cytotoxic effects due to lipid peroxidation. α-Tocopherol (α-T) is the major lipid-soluble, chain-breaking antioxidant in biological systems (1) and has been shown to protect membranes from polyunsaturated fatty acids and lysophospholipids (2). Esters of α–T are commonly added to cell culture media, as these esters probably are more readily taken up by the cells than is α-T, and are then hydrolyzed by esterases, thereby releasing the active α-T. The synthetic antioxidant *N,N'*-diphenyl-1,4-phenyl-enediamine (DPPD) has also been shown to have vitamin E-like activity (1).

We have previously reported that supplementing rat hepatocytes in long-term culture with 0.5 mM HUFA resulted in leakage of intracellular lactate dehydrogenase (LDH) (3). This cytotoxic effect could be attenuated by supplementing the medium with 50 μM α-tocopheryl acid succinate (TS) or α-tocopheryl phosphate (TP), the former being more effective than the latter (3). In the present study we have investigated a number of tocopherol derivatives as well as DPPD for their effect on LDH-leakage and formation of thiobarbituric acid reactive substances (TBARS) in long-term rat hepatocyte cultures supplemented with 0.5 mM arachidonic acid.

Abbreviations: DMSO, dimethylsulfoxide; DPPD, *N,N'*-diphenyl-1,4-phenylenediamine; HUFA, highly unsaturated fatty acids; LDH, lactate dehydrogenase; MDA, malondialdehyde; α-T, α-tocopherol; γ-T, γ-tocopherol; TA, α-tocopheryl acetate; TBARS, thiobarbituric acid reactive substances; TP, α-tocopheryl phosphate; TS, α-tocopheryl acid succinate.

MATERIALS AND METHODS

Reagents. Enzymes, coenzymes, collagen, horse serum, hormones and fatty acids were prepared or obtained as described previously (3). DPPD and ferric chloride hexahydrate were obtained from Aldrich Chemie (Steinheim, Germany). All other chemicals were from Sigma Chemical Co. (St. Louis, MO).

Cell culture. Hepatocytes were isolated from 48-h starved female Wistar rats, weighing 210–250 g before starvation, and the cells were cultured in a modified Waymouth medium (4) as described earlier (3). A starvation period of 48 h was chosen as this increased the susceptibility of the cultured cells to the effects of HUFA as compared to cells from 16-h starved rats (3). The hepatocytes (approximately 45 μg DNA per dish) were maintained in culture for 72 h, with the medium being changed every 24 h. During the last 48 h, the medium was supplemented with 1% (wt/vol) fatty acid-free albumin, 0.1 μM insulin, 0.1 μM dexamethasone, 0.5 mM fatty acid and antioxidants. The following antioxidants were used (final concentration, solute): DPPD [1 μM, dimethylsulfoxide (DMSO)]; (±)α-T (50 μM, acetone); (+)-γ-tocopherol (γ-T) (50 μM, acetone); (±)-α-tocopheryl acetate (TA) (50 μM, acetone); (±)-TP (50 μM, water) and (+)-TS (50 μM, DMSO). The concentrations of DMSO and acetone added to the media, 0.46% (vol/vol) and 0.1% (vol/vol), respectively, had no effect on any of the parameters measured. Specific solvents were chosen to facilitate solubilization of the agents in the aqueous phase. The solubilization of the tocopherols was confirmed by measuring the absorbance between 284 and 292 nm in the culture media after tenfold dilution.

Peroxidation of arachidonic acid during the preparation and storage of fatty acid-containing media, even at 37°C, was negligible as TBARS measurements in media with and without arachidonic acid gave similar values, i.e., about 1.7–2.0 μM TBARS (n = 1).

Determination of LDH leakage and DNA content. LDH-leakage and DNA content were measured as described earlier (3). In short, cells and medium were separated, the cells were homogenized by ultrasonication, and aliquots of cell homogenate and medium were analyzed for LDH activity by measuring NADH formation at 340 nm. The DNA content in the cell homogenate was measured fluorimetrically. Cell viability was measured as percentage of LDH released into the medium.

Determination of TBARS. Lipid peroxidation was expressed as TBARS accumulated in the medium (5). TBARS were determined as described previously (3), in the presence of ferric chloride and butylated hydroxytoluene while heating (6), and by measuring absorbance at 532 nm (7). After subtraction of the background, due to

the phenol red in the culture medium, absorbance was converted to TBARS and expressed in malondialdehyde (MDA) equivalents; a standard curve for MDA was generated based on hydrolyzed 1,1,3,3-tetraethoxypropane. Lipid peroxidation was expressed as nmol TBARS (MDA equivalents)/mg DNA.

Statistical evaluation. Statistical significance of differences was assessed by analysis of variance; the Scheffe test was used for comparison of means. $P < 0.05$ was considered statistically significant.

RESULTS

In this study, cytotoxicity was defined as the increase in LDH-leakage seen upon exposure of the cells to fatty acid. The LDH in the culture medium originates from hepatocytes that have lost their membrane barrier properties; the LDH that leaks into the medium is typically not degraded within 24 h (8).

Figure 1 illustrates that fatty acids with more than three double bonds cause greater LDH-leakage and TBARS formation than less unsaturated fatty acids. The addition of TS caused a significantly lower LDH leakage compared to TP, when the cells were incubated with linoleic acid, columbinic acid, arachidonic acid, eicosapentaenoic acid or docosahexaenoic acid (Fig. 1A). A similar pattern was seen for the production of TBARS with columbinic acid, arachidonic acid and eicosapentaenoic acid (Fig. 1B). Measurements of LDH-leakage 2 h after fatty acid addition to the cultures indicated that none of the fatty acids were cytotoxic by themselves in our experimental system (1–3% LDH-leakage, n = 7).

The cytoprotective effect of 50 μM α-T, γ-T, TA, TP, TS and 1 μM DPPD in cultures supplemented with 0.5 mM arachidonic acid is shown in Figure 2. TS, α-T, γ-T and DPPD had similar effects on LDH leakage, whereas a significantly smaller protective effect was seen with TA and TP. The production of TBARS showed a similar pattern, as did LDH-leakage (Fig. 3).

The dose-response relationship between antioxidant concentration and LDH-leakage was tested in the presence of 0.5 mM arachidonic acid in the range from 25 to 200 μM tocopherols and 1 to 50 μM DPPD. Only TP showed a dose-response relationship, i.e., increasing concentrations of TP gave an increase in LDH-leakage, suggesting a cytotoxic effect of TP at higher doses (data not shown, n = 3). Cultures incubated with antioxidants (tocopherols, 50 and 200 μM, DPPD, 1 and 50 μM) and without fatty acid showed that none of the tocopherols were cytotoxic at 50 μM, whereas addition of 200 μM TP or TS resulted in an LDH-leakage of 66 and 35%, respectively (mean, n = 3). DPPD showed no cytotoxic effects in the concentration range studied.

DISCUSSION

HUFA at 0.5 mM was found to be cytotoxic in our *in vitro* cell system, an effect that was thought to be due to lipid peroxidation (3). A similar cytotoxic effect of exogenous HUFA has previously been seen in other cell culture systems (9,10).

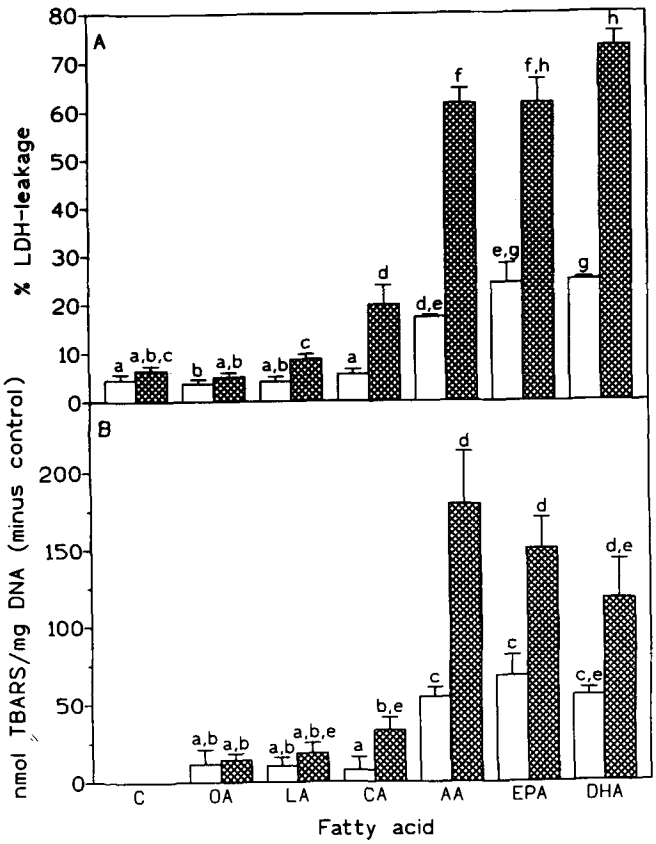

FIG. 1. The cytoprotective effect of α-tocopheryl acid succinate (TS) and α-tocopheryl phosphate (TP) in cultures supplemented with various polyunsaturated fatty acids. (A) % Lactate dehydrogenase (LDH)-leakage; (B) formation of thiobarbituric acid reactive substances (TBARS). Hepatocyte monolayers were prepared from 48-h starved rats and maintained in culture for 48 h in the presence of 50 μM TS (open bars) or 50 μM TP (cross-hatched bars) and 0.5 mM oleic acid (OA), linoleic acid (LA), columbinic acid (CA), arachidonic acid (AA), eicosapentaenoic acid (EPA) or docosahexaenoic acid (DHA). (A) C is the control without fatty acid and antioxidant. Each bar represents the mean ± SE of four separate cultures. (B) The control value (134–177 nmol TBARS/mg DNA) was subtracted. Each bar represents the mean ± SE of three separate cultures. Values with different letters are significantly different.

In the present study, the cell cultures were heavily loaded with tocopherols (50 μM tocopherol derivative, or 150 nmol per culture dish containing *ca.* 10^6 cells). Nevertheless, none of the antioxidants tested could fully prevent HUFA-induced LDH-leakage. This, and the lack of a correlation between LDH-leakage and TBARS production (Figs. 1–3), would suggest that HUFA cytotoxicity is partly caused by mechanisms that are not related to tocopherol-suppressible lipid peroxidation. It has been seen in many cases that inhibition of lipid peroxidation does not prevent oxidative stress-induced cell injury (11). Fariss (5) and Carini *et al.* (12) reported TS to be a better antioxidant than α-T in hepatocyte suspensions, where oxidative stress was induced by an atmosphere of 95% O_2, 5% CO_2 and the presence of adenosine diphosphate/iron, cumene hydroperoxide or carbon tetrachloride.

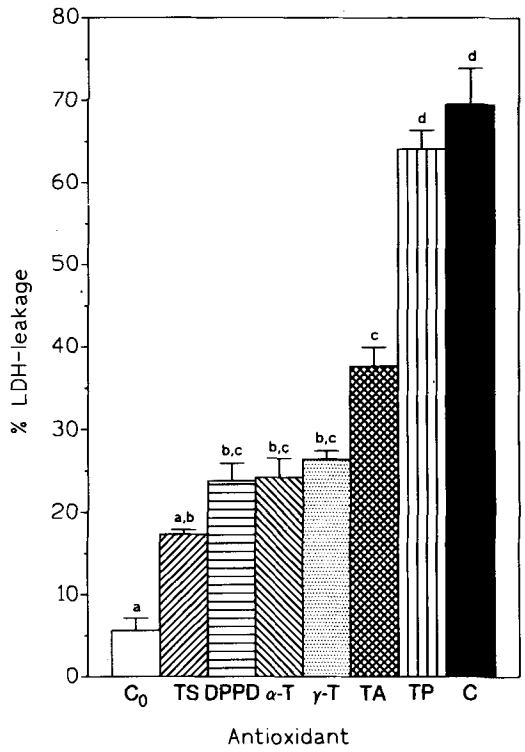

FIG. 2. The cytoprotective effect of various antioxidants in cultures supplemented with arachidonic acid. Hepatocyte monolayers were prepared from 48-h starved rats and maintained in culture for 48 h with 0.5 mM arachidonic acid and 50 μM of tocopherol or 1 μM DPPD added. C_0 is the control without arachidonic acid and without antioxidant; C is the control with arachidonic acid and without antioxidant. Each bar represents the mean ± SE of three separate cultures. Values with different letters are significantly different. DPPD, *N,N'*-diphenyl-1,4-phenylenediamine; α-T, α-tocopherol; γ-T, γ-tocopherol; TA, α-tocopheryl acetate. Other abbreviations in Figure 1.

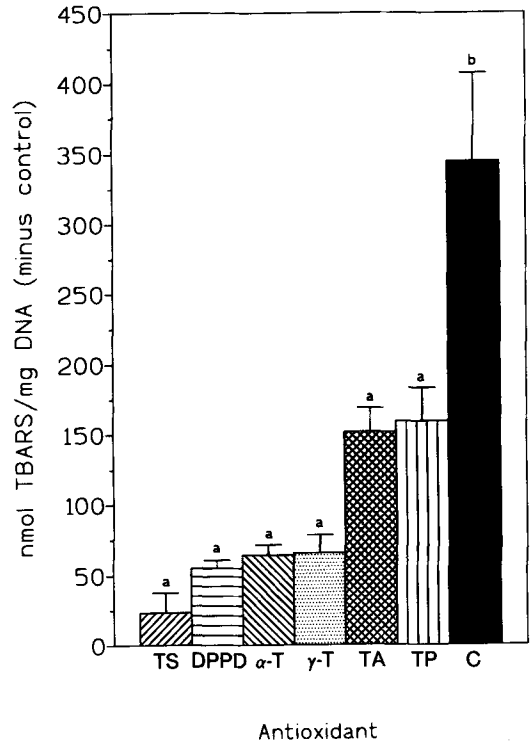

FIG. 3. The effects of various antioxidants on the formation of TBARS. Hepatocyte monolayers were prepared from 48-h starved rats and maintained in culture for 48 h with 0.5 mM arachidonic acid and 50 μM of tocopherol or 1 μM DPPD added. C is the control with arachidonic acid and without antioxidant. The control values without arachidonic acid and antioxidant (168–196 nmol TBARS/mg DNA) were subtracted. Each bar represents the mean ± SE of three separate cultures. Values with different letters are significantly different. Abbreviations as in Figures 1 and 2.

It is reasonable to suggest that the different tocopheryl esters need to be hydrolyzed by esterases and that the actual cytoprotective effect is exerted by α-T. TS has been suggested to act as a carrier of α-T enabling the release and accumulation of α-T at specific and critical cellular sites (12). The different effects of the tocopherols and their esters may thus reflect differences in transmembrane mobility and in the rates of ester hydrolysis by intracellular esterases. α-T may also have a lower rate of transmembrane mobility than TS, as α-T may exist in micellar form in the medium (13). In addition, the tocopheryl esters are hydrolyzed at different rates by membrane-bound esterases (14). The succinate moiety of TS may have an additional effect, consistent with the proposal by Maguire *et al.* (15), who showed that submitochondrial particles containing the succinate–ubiquinone reductase complex protected α-T from consumption which may suggest the reduction of the α-tocopheryl radical to α-T.

In summary, we have shown that it is important to supplement culture media with antioxidant and to monitor cell viability when culturing cells with exogenous HUFA. The tocopherols we investigated differ significantly in their cytoprotective effect, with TS being the most effective.

Thermal Adaptation Affects the Fatty Acid Composition of Plasma Phospholipids in Trout

Charlotte Wallaert and **Patrick J. Babin***

Laboratoire de Physiologie Cellulaire et Métabolique des Poissons, U.R.A. 1134 du Centre National de la Recherche Scientifique, Université Paris-Sud, 91405 Orsay, France

The adaptive changes in the fatty acid (FA) composition of plasma phospholipids (PL) in response to alterations in environmental water temperature were investigated in juvenile rainbow trout *(Oncorhynchus mykiss)*. The changes observed during thermal adaptation from 22°C in summer to 8°C in winter were reproduced by laboratory cold acclimation (CA) at 6°C of 22°C-summer-acclimated animals. In cold-acclimated and winter-acclimated trout, the increase in the unsaturation of PL fatty acids was mainly due to an enrichment of approximately 7% in the total weight percentage of 22:6n-3, while a concomitant significant decrease in the levels of 18:0 and of the monoenoic n-9 FA was observed. A time course study revealed that the changes in PL fatty acids became significant after 10 d of CA and were complete after one month. These changes in the composition of the fatty acyl chains of plasma total PL indicate that the FA composition of plasma lipoprotein PL does not remain constant during thermal adaptation. This would suggest that plasma lipoproteins provide a rapid systemic supply of lipids containing more or less unsaturated FA during thermal adaptation of poikilothermic animals.

***Lipids* 29, 373–376 (1994).**

The metabolic changes that occur during thermal adaptation of poikilothermic animals cause alterations in membrane lipid composition that assure the maintenance of normal membrane functions under thermal stress. This homeoviscous adaptation (1) to environmental temperature is responsible for maintaining membrane fluidity and function at low temperatures. It involves restructuring of the polar headgroup composition of phospholipid (PL) classes, together with modification of the unsaturation of their fatty acyl chains (2–6).

Salmonids are eurythermic fish that undergo temperature variations in their natural environment (7). In these fish, PL have a complex fatty acid (FA) pattern characterized by a large proportion of polyunsaturated fatty acids (PUFA) (8). The renewal and restructuring of membrane lipids following thermal adaptation could involve plasma lipids and lipoproteins, since the capacities for lipogenesis and FA desaturation vary from one tissue to another. Numerous studies in different fish species (for a review, see Ref. 3, and also Refs. 9–11) have demonstrated structural and composition changes of membrane PL following thermal adaptation but there are no data on the effect of temperature changes on the FA composition of plasma lipids in poikilotherms. A circannual variation in the FA composition of plasma and high density lipoprotein PL have been recently demonstrated in rainbow trout (12), a teleost fish that remains active at low temperatures.

The objectives of the present study were to investigate in trout the effects of thermal adaptation in the laboratory on the composition of plasma PL fatty acids and to compare the changes induced to those observed in response to seasonal temperature variations.

MATERIALS AND METHODS

Animals. Juvenile rainbow trout (*Oncorhynchus mykiss*) of both sexes were used. The animals were offsprings of a single male and female and were exposed to the natural photoperiod throughout the experiment. Before the experiments, the trout were nourished *ad libitum* three times a week with a standard commercial granule diet (Aqualim, Nersac, France) containing 11% lipids. The diet composition was held constant regardless of the water temperature at which the animals were kept. Trout were anesthetized with ethylenglycol monophenyl ether (0.3 mL/L). Blood was removed over ethylenediaminetetraacetic acid disodium salt and NaN_3 (3 and 0.15 mg/mL blood) dissolved in 0.15 M NaCl, final pH 7.4, by cardiac puncture with a fine catheter (diameter 0.58 mm) and kept at 4°C throughout the procedure. Plasma was obtained by centrifugation (3000 × *g*, 10 min).

Experimental design. Juvenile trout, 1½-years-old, acclimated to 22°C in August, were randomly divided into two groups. Ten days after the first blood sampling, the first group was subjected to cold acclimation (CA) at 6°C by progressively decreasing water temperature from 22 to 6°C within 20 h. The second group was subjected to summer variation of water temperature from 22 to 21°C. Blood was drawn at an interval of 4 or 7 d between successive samples over a period of 41 d. Trout were given free access to food at least 4 h after each sampling and were left unfed until the next sampling. Furthermore, in order to determine the effects of seasonal thermal adaptation on plasma PL fatty acids, marked juvenile trout were sampled in summer at 22°C and in winter at 8°C.

FA analysis. FA composition of plasma PL was determined as previously described (13). Lipid standards or 10 µL of plasma were applied directly to the preadsorbent zones of thin-layer silica gel plates (G-1520, 20 × 20 cm; Schleicher & Schuell, Dassel, Germany). The thin-layer chromatography plates were partially developed with methanol followed by chloroform/methanol (1:1, vol/vol) to approximately 1.5 cm above the preadsorbent border. The plates were then fully developed to 15 cm above the adsorbent band in hexane/diethyl

Abbreviations: ANOVA, analysis of variance; CA, cold acclimation; FA, fatty acids; HDL, high density lipoproteins; PL, phospholipids; PUFA, polyunsaturated fatty acids; UI, unsaturation index; U/S, ratio of unsaturated to saturated fatty acids.

ether/acetic acid (80:20:1, by vol) to separate the major lipid classes. The resulting bands were located by spraying the plate with rhodamine 6 G (0.07% in 95% ethanol) and viewing under ultraviolet light. Fractions corresponding to PL were scraped into screw-capped tubes, and treated with boron trifluoride/methanol as previously described (13). Heptadecanoic acid (17:0) and tricosanoic acid methyl ester (23:0 Me) were used as internal standards. FA methyl esters were analyzed with a Carlo Erba 4100 gas chromatograph (Milan, Italy), equipped with a Ross needle type injector and a flame-ionization detector, coupled to an ENICA 10 integrator (Delsi, Suresnes, France). The silica capillary column (25 m × 0.32 mm i.d.) was coated with OV-1 (Chrompack, Middelburg, The Netherlands). The column temperature was programmed from 150 to 180°C at 5°C per min after an initial 25 min at 150°C, and was held at 180°C for 60 min. Hydrogen was used as carrier gas at a pressure of 0.7 bar. FA methyl esters were identified by comparison of their relative retention times to those of known standards. A small amount of arachidonic acid (20:4n-6) methyl ester was present but was not resolved from the eicosapentaenoic acid (20:5n-3) methyl ester on the OV-1 capillary column. The unsaturated to saturated FA ratio (U/S) was calculated from the total weight percentages of monoenoic FA + PUFA/total weight percentages of saturated FA. The unsaturation index (UI) of plasma PL FA, defined as the average number of double bonds per FA, was calculated as the sum of the weight percentage multiplied by the number of double bonds for each FA in the mixture/100.

Statistics. Data are presented as means ± SEM and were tested for statistical significance by analysis of variance (ANOVA) followed by an evaluation employing Tukey-Kramer's multiple range test. For comparisons between FA weight percentages, data subjected to ANOVA were transformed (arcsin) prior to statistical analysis. Comparisons between summer- and winter-acclimated trout or summer-acclimated and cold-acclimated trout were done by two-tailed Student's *t*-test. Results were evaluated with the Statistical Analysis System (SAS) computer programs (14). The *P* value chosen for statistical significance was 0.05.

RESULTS

Plasma PL of 8°C-winter-acclimated or 6°C-acclimated trout contained larger quantities of docosahexaenoic acid (22:6n-3) and smaller quantities of oleic acid (18:1n-9) and gondoic acid (20:1n-9) than 22°C-summer-acclimated animals (Table 1). A significant reduction in the level of stearic acid (18:0), the saturated FA precursor of the n-9 family, also occurred during cold adaptation (Table 1). The time courses of the changes in the weight percentages of the two major unsaturated FA of trout plasma PL, 18:1n-9 and 22:6n-3, during CA are shown in Figure 1. After 6 d of CA, there was a significant decrease in the percentage of 18:1n-9 in plasma PL (10.63 ± 0.24 vs. 13.75 ± 0.64%, $P < 0.05$), which became highly significant after 10 d of CA (9.24 ± 0.13%, $P < 0.001$). The proportion of 22:6n-3 evolved inversely to that of 18:1n-9. The increase in 22:6n-3 became very significant after 17 d of CA (37.06 ± 1.34 vs. 31.41 ± 0.63%, $P < 0.005$) and was similar to that of 8°C-winter-acclimated trout (36.51 ± 1.25%). The increase in the proportion of 22:6n-3 during seasonal thermal adaptation from 22 to 8°C or during CA to 6°C corresponds to an enrichment of this PUFA in plasma PL of approximately 7% (Table 1).

TABLE 1

Fatty Acid Composition of Plasma Phospholipids from Summer-Acclimated, Winter-Acclimated and Cold-Acclimated Juvenile Trout[a]

Fatty acid	Summer (22°C)	Winter (8°C)	Cold-acclimated (6°C)
14:0	1.66 ± 0.15	1.84 ± 0.07	2.15 ± 0.23
16:0	25.38 ± 0.64	24.79 ± 0.83	26.53 ± 0.61
18:0	10.31 ± 0.50	6.46 ± 0.71[d]	5.89 ± 0.18[e]
16:1n-7	3.38 ± 0.18	3.12 ± 0.10	2.68 ± 0.43
18:1n-9	11.88 ± 0.42	10.02 ± 0.71[b]	8.96 ± 0.37[d]
20:1n-9	2.01 ± 0.04	1.48 ± 0.14[c]	1.38 ± 0.07[e]
18:2n-6	2.47 ± 0.10	2.31 ± 0.16	2.50 ± 0.07
20:3n-6	1.47 ± 0.18	1.37 ± 0.13	1.38 ± 0.14
20:5n-3	8.94 ± 0.35	10.01 ± 0.90	8.27 ± 0.39
22:5n-3	2.05 ± 0.15	2.10 ± 0.10	2.14 ± 0.09
22:6n-3	30.53 ± 0.77	36.51 ± 1.25[d]	38.16 ± 1.83[d]
U/S	1.65 ± 0.01	1.99 ± 0.04[e]	1.89 ± 0.05[d]
UI	2.61 ± 0.04	2.99 ± 0.05[d]	2.99 ± 0.02[e]

[a]Values are means ± SEM, n = 5 in each group. Data are presented as weight percentages. Only the major fatty acids are listed (percentage values >1%). Marked juvenile trout were blood sampled in summer at 22°C and in winter at 8°C. In order to determine the effects of low-temperature adaptation on plasma phospholipids fatty acids, trout acclimated to 22°C in summer were subjected to cold acclimation by decreasing water temperature from 22 to 6°C. Trout were cold-acclimated to 6°C during 31 d before blood sampling. The significance for the differences between 2°C-summer- and 8°C-winter-acclimated trout was tested with the paired two-tailed Student's *t*-test. Comparisons between 22°C-summer-acclimated and 6°C-cold-acclimated trout were by unpaired two-tailed Student's *t*-test. U/S, ratio of unsaturated to saturated fatty acids; UI, unsaturation index.

[b]$P < 0.05$; [c]$P < 0.01$; [d]$P < 0.005$; [e]$P < 0.0001$.

The net result of these compositional changes was a significant increase in the U/S ratio at low temperatures (Table 1). The elevated proportion of 22:6n-3 during CA or during seasonal adaptation from summer to winter resulted in an increase in the UI of FA at low temperatures (Table 1 and Fig. 2). This index increased very significantly after 10 d of CA (2.90 ± 0.03 vs. 2.62 ± 0.09, $P < 0.005$) and became identical to that of winter-acclimated trout after 31 d of CA (Table 1 and Fig. 2). At that time, the UI of the acyl chains was very different from that calculated for the PL of summer-acclimated trout (Table 1).

DISCUSSION

The maintenance of biomembrane functions in poikilotherms, regardless of the environmental temperature, involves changes in the lipid composition. At low temperatures, the modifications involve changes that result in an increase in the degree of FA unsaturation in dif-

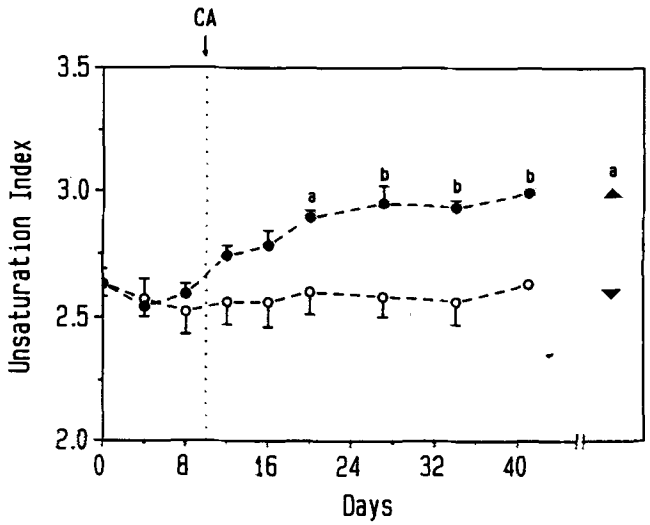

FIG. 1. Temporal changes in the weight percentage of 22:6n-3 (circle) and 18:1n-9 (square) in plasma phospholipid molecular species, in cold-acclimated (●,■) and in summer-acclimated juvenile trout (○,□). For details in experimental design, see Materials and Methods. Values are means ± SEM, n = 5 (SEM within data points are not shown). For each group of animals, the significance of the differences between the value observed on day 8 and the other values observed was tested by analysis of variance (ANOVA) and Tukey-Kramer's multiple range test. The weight percentage of 22:6n-3 and 18:1n-9 determined in trout acclimated in winter at 8°C (▲,❖) or in summer at 22°C (▼,◆) appears on the right-hand side of the figure for comparison. The difference between the two means was tested by the paired two-tailed Student's *t*-test. CA, cold acclimation. $^{a}P < 0.05$; $^{b}P < 0.01$; $^{c}P < 0.005$; $^{d}P < 0.001$.

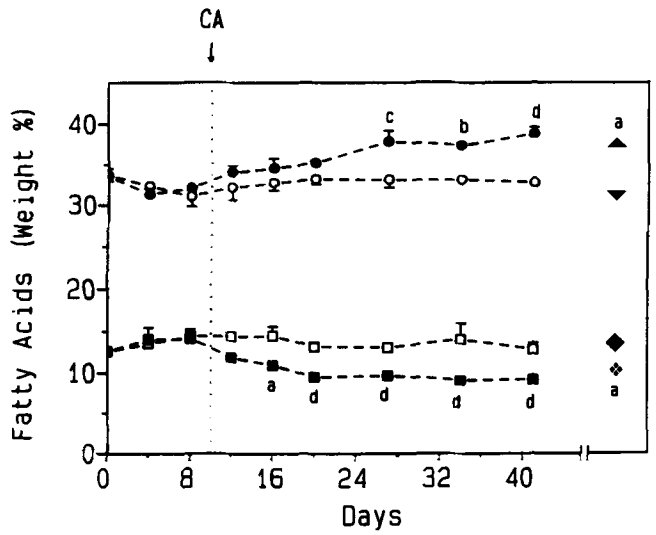

FIG. 2. Changes in the unsaturation index (UI) of fatty acids of plasma phospholipids during CA in juvenile trout. For details in the experimental design, see Materials and Methods. Values are means ± SEM, n = 5 (SEM within data points are not shown). For each group of animals, cold-acclimated (●) or summer-acclimated trout (○), the significance of the differences between the value observed on day 8 and the other values observed was tested by ANOVA and Tukey-Kramer's multiple range test. The UI determined in trout acclimated in winter at 8°C (▲) or in summer at 22°C (▼) appears on the right-hand side of the figure for comparison. The difference between these two means was tested by the paired two-tailed Student's *t*-test. $^{a}P < 0.005$; $^{b}P < 0.001$. See Figure 1 for abbreviations.

ferent PL molecular species and in their proportion of unsaturated FA (3–5). The changes in the FA composition of plasma PL that can be induced by thermal adaptation have not been investigated previously in poikilotherms. Our data show that adaptive compositional changes occur in response to natural changes in environmental water temperature. The present study also demonstrates that the changes in the FA composition of plasma PL observed during seasonal thermal adaptation can also be produced in juvenile trout by imposing controlled and rapid temperature changes in the laboratory. The changes that occur due to low temperature are consistent with the prior descriptions of CA effects in trout liver PL (11,15). The increase in the UI of plasma PL FA during CA, or during seasonal adaptation to low temperature in winter is primarily due to a very significant increase in the relative proportion of PUFA, e.g., 22:6n-3. CA results in a decrease in the quantity of 18:1n-9 in plasma PL as in hepatic PL (11,15). However, there is a decrease of 18:0 in plasma PL instead of palmitic acid (16:0) as it is observed in hepatic PL (11,15). A time course study revealed that the changes in plasma PL FA became significant after 10 d of CA. A comparison between the UI of fatty acids of 6°C-cold-acclimated and 8°C-winter-acclimated trout indicates that the process is complete after one month. This period has been previously shown to be adequate for thermal adaptation of various physiological functions in fish (16).

In fish, almost all plasma lipids are associated with lipoproteins (17), which, in turn, transport and distribute endogenous and exogenous lipids within the organism. In trout, high density lipoproteins (HDL) predominate in plasma lipoproteins (17–19). HDL lipids are rich in unsaturated FA of the linolenic acid (n-3) family (20). Changes in the composition of the fatty acyl chains of plasma total PL observed in trout during CA or low-temperature seasonal adaptation indicate that the FA composition of plasma lipoprotein PL does not remain constant during thermal adaptation. These modifications may be due to changes in the molecular species composition of PL classes and/or in the proportion of each PL in plasma lipoproteins. We have recently demonstrated in trout that the weight percentage of 22:6n-3, the U/S ratio and the UI of FA of HDL PL are inversely correlated with water temperature (12). The rapid restructuring of PL in the liver at low temperature and the later increase in the proportion of unsaturated FA due to the stimulation of hepatic desaturation activities (for a review, see Ref. 4) would result in the release of lipoproteins whose FA composition has been adapted to environmental changes. Thus, the plasma lipoproteins can rapidly supply lipids with the degree of unsaturation required for thermal adaptation.

ACKNOWLEDGMENT

The authors thank Jean-Claude Sulpice for valuable help and advice with gas–liquid chromatographic analysis.

ARTICLE

Alteration of Chain Length Selectivity of a *Rhizopus delemar* Lipase Through Site-Directed Mutagenesis[1]

Rolf D. Joerger[2] and **Michael J. Haas***
ERRC, ARS, USDA, Philadelphia, Pennsylvania 19118

The coding sequences of the *Rhizopus delemar* lipase and prolipase were altered by oligonucleotide-directed mutagenesis to introduce amino acid substitutions. The resulting mutant enzymes, synthesized by the bacterial host *Escherichia coli* BL21 (DE3), were tested for their ability to hydrolyze the triglycerides triolein (TO), tricaprylin (TC) and tributyrin (TB). Mutagenesis and lipase gene expression were carried out using plasmid vectors derived from previously described recombinant plasmids [Joerger and Haas (1993) *Lipids 28*, 81–88] by introduction of the origin of replication of bacteriophage f1. Substitution of threonine 83 (thr83), a residue thought to be involved in oxyanion binding, by alanine essentially eliminated lipolytic activity toward all substrates examined (TB, TO and TC). Replacement of thr83 with serine caused from two- to sevenfold reductions in the activity toward these substrates. Introduction of tryptophan (trp) at position 89, where such a residue is found in closely related fungal lipases, reduced the specific activity toward the three triglyceride substrates. For the mutagenesis of residues in the predicted acyl chain binding groove, mutagenic primers were designed to cause the replacement of a specific codon within the prolipase gene with codons for all other amino acids. Phenylalanine 95 (phe95), phe112, valine 206 (val206) and val209, were targeted. A phenotypic screen was successfully employed to identify cells producing prolipase with altered preference for olive oil, TC or TB. In assays involving equimolar mixtures of the three triglycerides, a prolipase with a phe95 → aspartate mutation showed an almost twofold increase in the relative activity toward TC. Substitution of trp for phe112 caused an almost threefold decrease in the relative preference for TC, but elevated relative TB hydrolysis. Replacement of val209 with trp resulted in an enzyme with a two- and fourfold enhanced preference for TC and TB, respectively.
***Lipids* 29, 377–384 (1994).**

The fungus *Rhizopus delemar* [presently designated *R. oryzae* (1)] produces extracellular lipases that have been used in research for many years. One of these lipases has been purified and characterized (2), and a complementary DNA (cDNA) encoding this lipase has been cloned and its nucleotide sequence has been determined (3). This lipase, like its closely related counterpart produced by the fungus *Rhizomucor miehei* (4), exhibits a strong preference for the hydrolysis of ester bonds at the *sn*-1 and *sn*-3 positions of a triacylglycerol. As opposed to this pronounced positional selectivity, there is little selectivity for hydrolysis of substrates with different fatty acid moieties. In assays with triglyceride mixtures, tributyrin (TB) was the least preferred substrate. Triacylglycerols with longer chain fatty acids, both saturated and unsaturated, were hydrolyzed at only marginally different rates (5). In contrast, some lipases from *Candida cylindracea* exhibit little positional specificity (6), a lipase from *Geotrichum candidum* has a strong preference for the hydrolysis of *cis*-9 unsaturated fatty acids (6,7) and a lipase from *Penicillium camembertii* (Pc) hydrolyzes only mono- and diglycerides (8). The molecular bases for these selectivities are either still completely unknown or are just beginning to be revealed. Three-dimensional structures determined by X-ray crystallography are now available for several lipases (9–12), and continued refinement and analyses will provide new insights into the phenomenon of selectivity.

Rational mutagenesis provides another route for investigating the structure–function relationship of enzymes (13). Using this technique, it should be possible to gather useful information regarding the role of sequence and structure in determining the activity, selectivity and stability of these enzymes. In order to facilitate studies on the *R. delemar* (Rd) lipase, the cloned cDNA encoding this lipase was used to construct expression plasmids for the high-level production of the proenzyme and mature form of the lipase in the bacterium *Escherichia coli* (14).

We have now modified the expression plasmids to create plasmids that permit site-directed mutagenesis and expression to be carried out with the same vector. This system was used to create mutations in the lipase and prolipase genes and to express these altered genes. The gene products were then tested for their ability to hydrolyze TB, tricaprylin (TC) and triolein (TO).

MATERIALS AND METHODS

DNA manipulations. Plasmid DNA was isolated by an alkaline lysis procedure (15) followed by phenol/chloroform extraction. Single-stranded DNA was isolated from cul-

ture fluids by precipitation with 1/4 vol of 20% polyethylene glycol in 3.75 M ammonium acetate (NH_4OAc). The precipitate was resuspended in Tris/ethylenediaminetetraacetic acid (TE) buffer (10 mM Tris-HCl, 1 mM ethylenediaminetetraacetic acid, pH 8) and extracted repeatedly with phenol/chloroform. DNA was stored in TE buffer. Restriction enzyme digestions and ligations were performed as recommended by the suppliers. Plasmid DNA was introduced into *E. coli* cells either by transformation of $CaCl_2$-treated cells (16) or by electroporation using a Gene Pulser™ (Bio-Rad Laboratories, Richmond, CA) according to the manufacturer's directions. Sequencing of DNA was carried out by the method of Sanger *et al.* (17) using the Sequenase™ Version 2.0 DNA Sequencing Kit (United States Biochemical, Cleveland, OH).

Vector construction. The origin of replication of bacteriophage f1 was introduced into the lipase expression plasmid pET11-d-431 (14) in a procedure similar to that described by Richardson and Richardson (18). The f1 origin of replication was isolated from plasmid pTZ18R (purchased from Pharmacia LKB Biotechnology Inc., Piscataway, NJ) as a 1060-bp *Sca*I-*Hind*III fragment. Plasmid pET11-d-431 was cleaved with restriction enzyme *Sca*I and the linearized plasmid incubated with *Hind*III under conditions favoring partial digestion. The resulting fragments were separated by agarose gel electrophoresis, and the band corresponding to a *Sca*I-*Hind*III fragment approximately 6 kbp in size was excised from the gel, extracted and purified. This fragment was ligated to the f1 ori-containing *Sca*I-*Hind*III fragment from pTZ18R to yield a plasmid, pET11-d-f1-431, that retained the features required for lipase gene expression and also allowed production of single-stranded circular DNA for use in site-directed mutagenesis.

Under inducing conditions, cells harboring pET11-d-f1-431 produce inactive lipase that has to be refolded into active enzyme. Direct production of active mature Rd lipase in *E. coli* is not possible due to the toxic nature of this enzyme. However, a plasmid allowing expression of active prolipase in *E. coli* BL21 (DE3) (19) was constructed. To achieve this, the *Eco*RI-*Xba*I fragment from pET11-d-f1-431, which contains the gene for mature lipase, was replaced with an *Eco*RI-*Xba*I fragment encoding prolipase. This fragment was isolated from plasmid pTM-N-1231, which consists of vector pTM-N (20) and the Rd prolipase gene fused to DNA encoding the OmpA signal peptide. The new plasmid, pET11-d-f1-1231s, was used for isolation of single-stranded DNA and for production of active prolipase.

Plasmids for the production of mature lipases carrying the amino acid substitutions found in previously characterized prolipases were constructed by replacement of the 600-bp *Kpn*I-*Eco*RI fragment in pET11-d-f1-431 with the corresponding fragments from the pET11-d-f1-1231s mutant plasmids. These pET11-d-f1-431 derivatives were used for the production of mature mutant lipases in inactive forms as inclusion bodies. Active enzyme was obtained after refolding as described previously (14).

Production of single-stranded DNA from pET11-d-f1-431 and pET11-d-f1-1231s. Single-stranded DNA was obtained by infecting plasmid-containing *E. coli* JM101 cells with helper phage M13KO7 as described by Viera and Messing (21). Packaged single-stranded DNA was precipitated with PEG/NH_4OAc and purified by repeated phenol/chloroform extractions. For the production of single-stranded DNA for use in mutagenesis experiments according to the methods of Kunkel (22), plasmids were first introduced into *E. coli* strain CJ236. Uracil-containing single-stranded DNA was prepared from the culture supernatant of M13KO7-infected cells as indicated above.

Oligonucleotide-directed mutagenesis. Site-directed mutagenesis was carried out by the method of Kunkel (22) using the Muta-Gene M13 *in vitro* Mutagenesis Kit (Bio-Rad Laboratories). Mutagenic primers were obtained from the Department of Chemistry, University of Pennsylvania (Philadelphia, PA). The nucleotide sequences of the primers used are listed in Table 1. Primer-mediated nucleotide sequence changes affecting restriction enzyme recognition sites were so chosen as not to alter the amino acid sequence of the lipases.

TABLE 1

[a]During primer synthesis, an equimolar amount of A, C, G and T was used at the positions indicated by the letter N. Only equimolar amounts of C and G were used at the positions indicated by letter X.

[b]Amino acids are numbered as in Reference 3; aa indicates that any one of the twenty possible amino acids could be present after mutagenesis. Abbreviations: thr, threonine; ala, alanine; ser, serine; trp, tryptophan; phe, phenylalanine.

[c]The pos. numbers are as in Reference 3 and denote the position of the first nucleotide of the restriction enzyme recognition site.

Mutant screening. Mutated versions of pET11-d-f1-431 were identified initially by acquisition or loss of a restriction enzyme site (see Table 1). DNA sequencing was then used to confirm the presence of the desired base changes. A phenotypic screening for cells carrying mutated versions of pET11-d-f1-1231s consisted of replica-plating cells onto solid LB-agar medium (rhodamine B medium) containing dispersed triglyceride (25 mL/L), ampicillin (100 μg/mL), isopropyl-β-D-thiogalactopyranoside (IPTG) (0.2 mM) and rhodamine B (0.0005%) (3). Fatty acids produced by lipase activity cause the rhodamine B to acquire a bright pink color and to fluoresce under ultraviolet light. Cells acquire a similar coloration and become surrounded by halos. Lipase negative cells remained cream-colored. Plasmid DNA was isolated from cells producing mutant lipases of interest for this study, and the nucleotide sequence of the region expected to carry a mutation was determined.

Induction of lipase gene expression. Escherichia coli BL21 (DE3) harboring recombinant plasmids were grown on solid LB medium (23) containing ampicillin (100 μg/mL). Cells containing pET11-d-f1-431 or its mutagenized derivatives were cultured in liquid medium and induced for lipase expression by the addition of IPTG to a final concentration of 1 mM as previously described (14). Cells containing pET11-d-f1-1231s or its mutant forms were induced in liquid culture (2 to 10 mL of LB medium containing ampicillin) by the addition of IPTG to a final concentration of 0.2 mM when the optical density (at 600 nm) of the culture reached 0.7 to 1.0. Cells were harvested 3 to 4 h after the addition of inducer.

Preparation of mature and prolipase samples. Wild-type and mutant versions of mature lipase were refolded and purified, and their purity and specific activities were determined as previously described (14). Briefly, the lipase inclusion bodies were solubilized in 8 M urea, and refolding was initiated by dilution. The refolded lipase preparation was purified to homogeneity by affinity and ion-exchange chromatography. Purity was assessed visually by examination of acrylamide electrophoresis gels stained with Coomassie Blue.

Cells induced for prolipase production were resuspended in 20 mM sodium phosphate buffer, pH 6.5, and sonicated. The lysate was used directly in lipase activity assays.

Determination of lipase activity. Activity determinations were carried out titrametrically as described previously (14) using a VIT 90 Video titrator (Radiometer, Copenhagen, Denmark) and 0.1 N NaOH as titrant. The assays were conducted at 25°C at pH of 7.5. The reaction mixture consisted of 200 mM olive oil, TC or TB (Sigma, St. Louis, MO) in 4.2% aqueous gum arabic solution and 14 mM $CaCl_2$. Lipase activity was calculated from the maximum rate of titrant addition using a lipase titrametric assay program (Cichowicz, D.J., *et al.,* unpublished). A unit (U) of activity released one μmole of fatty acid per minute.

Substrate selectivity was determined in an assay containing 500 μL of 50 mM sodium phosphate, pH 7.5, and 200 μmoles each of TO, TC and TB. The reactions were started by the addition of purified mature enzyme or prolipase-containing lysates. Samples to which only buffer or heat-inactivated cell sonicate had been added served as controls. The tubes were incubated at 30°C on an orbital shaker that was rotated at 300 rpm. After two hours, 20 μmoles of palmitic acid in 50 μL pyridine was added to the tubes to serve as internal standard, the content of the tubes was thoroughly emulsified, and 10 μL was quickly withdrawn to another tube. Then, 100 μL of dry pyridine was added, followed by 400 μL of *bis*(trimethylsilyl)trifluoroacetamide (Sigma). The tubes were incubated for 15 min in a boiling waterbath (24), cooled to room temperature, and hexane was added to obtain a solution appropriately diluted for gas chromatography. The samples were injected on-column into a Hewlett-Packard (Palo Alto, CA) 5890 gas chromatograph containing a 15-m nonpolar high-temperature column (DB1-HT) with an inner diameter of 0.32 mm and a film thickness of 0.1 μm (J&W Scientific, Folsom, CA). The helium flow rate was 5.5 mL per min. Detection was by flame ionization. The oven temperature was maintained at 40°C for 0.5 min, then increased to 100°C at a rate of 20°C per min, and then increased to 120°C at a rate of 2°C per min. The temperature was finally raised to 350°C at a rate of 20°C per min. This triphasic temperature profile was necessary to separate TB from monocaprylin. Data collection and processing was done on a Hewlett-Packard 3396 SeriesII Integrator.

RESULTS AND DISCUSSION

Mutagenesis experiments. The system for the expression of the Rd prolipase and mature lipase genes in *E. coli* described previously (14) allowed the synthesis and subsequent purification of relatively large amounts of these lipases. The modification of the expression vectors to include the bacteriophage f1 origin of replication was undertaken to produce vectors that can be used to bring about mutagenesis and expression without cloning in two different vectors. This approach had been proven successful previously in studies of the gene for the transcription termination factor, rho (18).

In initial experiments, threonine (thr) 83 was replaced with either alanine (ala) or serine (ser). Thr83 occupies the same position in the Rd lipase as ser82 in the *Rhizomucor miehei* (Rm) lipase (4). This residue has been implicated in oxyanion binding during hydrolysis of triglycerides by the Rm lipase (9,10). Cells harboring mutagenized plasmids were induced to produce inactive lipase in the form of inclusion bodies. The mutant lipases were then refolded, purified and characterized (14). Replacement of thr83 with ala caused a decrease in the specific activity by almost three orders of magnitude (Table 2). A similar loss of activity was observed when a corresponding ser residue was replaced by glycine (gly) in the mono- and diglyceride lipase from Pc (25). These reductions in activity are not unexpected because the loss of anion stabilization would be expected to profoundly reduce the activity of the enzyme. Neither gly nor ala can supply a hydroxyl group to attain this stabilization. On the other hand, replacement of thr83 with ser resulted in a lipase whose specific activity on various substrates was between one-fifth and one-half that of the wild type (Table 2). Presumably, the ser hydroxyl can partially substitute for the thr hydroxyl, but

[c]Micromoles fatty acid released per min per mg of protein. The values are averages of two experimental determinations.

the difference in the positioning of the side chains of the two amino acids is significant enough to reduce the specific activity of the ser variant.

Residues 86 to 92 in the Rd lipase are predicted to form a "lid" that would cover the active site of the lipase, as was shown by crystallographic studies of the related Rm lipase (9,10). It has been postulated, and demonstrated using inhibitors (9,10), that this lid is displaced when substrate analogues bind to the active site. This displacement exposes the active site and increases the potential lipase-substrate interface by enlarging the hydrophobic surface area of the enzyme. These features are thought to underlie the requirement, demonstrated by all lipases, that an interface be present before activity is manifested. Ala89 occupies a position in the Rd lipase where tryptophan (trp) is found in the lipases from *R. miehei, Humicola lanuginosa* (Hl) and Pc (25; Derewenda, Z.S., personal communication). It was postulated that this trp might play a role in the interfacial activation process (9). Recently, Clausen *et al.* (26) reported that in the Rm lipase, replacement of the trp did not abolish interfacial activation, but that substrate penetration was changed. By replacing ala89 in the Rd lipase with trp, we attempted to obtain more insight into the role of hydrophobic residues in the lids of these fungal lipases, especially as it relates to enzyme–substrate interaction. We found that replacement of ala89 with trp caused a 22 to 42% reduction in the specific activity relative to the corresponding activity of the purified wild-type lipase (Table 2). However, compared to the wild-type enzyme there was no profound change in the relative activity of this modified enzyme toward the various substrates tested (Tables 2, 3; Figs. 2, 3). Further studies, such as determination of the interfacial activation curve of the wild-type and mutant enzymes, and elucidation of the three-dimensional structures of these proteins will be required in order to precisely identify the roles of specific amino acids in the lid of the enzyme.

The plasmid system described above for the mutagenesis and expression of the thr and ala mutants has the advantage of supplying relatively large quantities of pure lipase, but the disadvantage of requiring isolation of the inactive lipase as inclusion bodies with subsequent refolding to produce active enzyme. Despite many attempts to find an expression system that would allow the production of active, mature lipase, no system could be developed that was able to overcome the toxic effect of this enzyme on the bacterial host (14). Thus, a plasmid that allows the production of active prolipase, which appears to be less toxic, was constructed for the experiments with mutagenic primers containing a randomized codon (Table 1). Our goal was to determine whether or not it was possible to alter the substrate specificity of the Rd lipase by replacement of specific amino acid residues. The residues chosen [phenylalanine (phe) 95, phe112, valine (val) 206, val 209], are well conserved in the Rd, Rm, Hl and Pc enzymes and are predicted to reside in a groove that might accommodate the acyl chain of a substrate glyceride bound in the active site (9,10) (Fig. 1).

TABLE 3

Hydrolysis of an Equimolar Mixture of Triolein, Tricaprylin and Tributyrin by Refolded, Purified Recombinant Mature Lipases

Source	μg of lipase in assay	% Hydrolyzed[a]		
		Triolein	Tricaprylin	Tributyrin
pET11-d-f1-431	2.5	80.1	83.9	42.4
pET11-d-f1-431-T83A	435.0	21.8	24.2	5.7
pET11-d-f1-431-T83S	2.7	58.0	56.4	10.2

[a]Percent hydrolyzed = $(TG_C - TG_H)/(TG_C) \times 100$ where TG_C equals the amount of triglyceride present in enzyme-free reaction and TG_H is the amount of triglyceride remaining after incubation with the lipase.

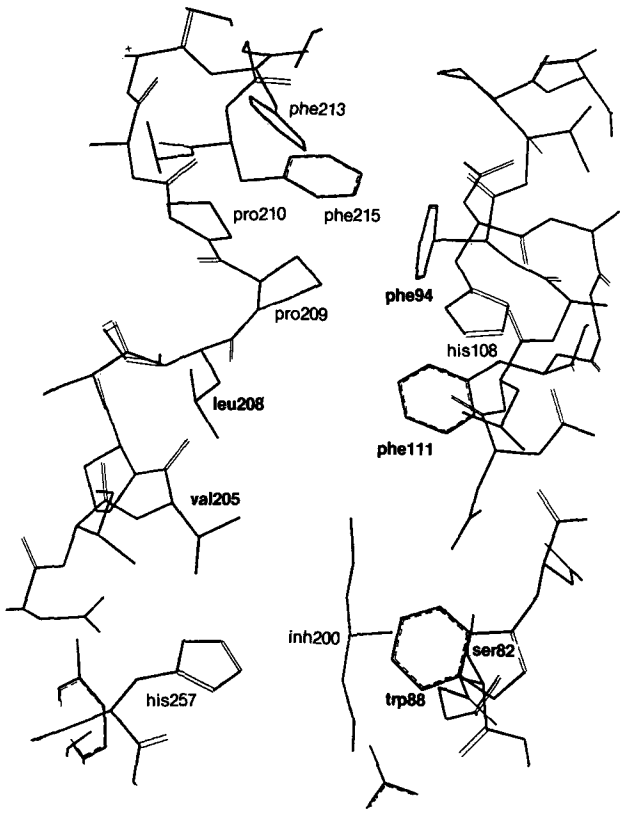

FIG. 1. Structure of a part of the *Rhizomucor miehei* (Rm) lipase with the active site inhibitor (INH200) *n*-hexylphosphonate ethylester (9). The oxyanion-binding ser82 as well as residues lining the fatty acid-binding groove are shown. The corresponding residues in the *Rhizopus delemar* lipase are thr83 in place of Rm (ser82), phe95 (phe94), his109 (his108), phe112 (phe111), val206 (val205), val209 (leu208), pro210 (pro209), pro211 (pro210), phe214 (phe213), phe216 (phe215), his257 (his257). Crystallographic coordinates kindly provided by Z. Derewenda. Abbreviations: ser, serine; thr, threonine; phe, phenylalanine; val, valine; pro, proline; his, histidine.

To scan large numbers of mutants, the phenotypic lipase assay of Kouker and Jaeger (27) was employed. In this procedure, colonies arising after mutagenesis were replicated onto rhodamine medium (see Materials and Methods section). Thus colonies could be identified that differed from the wild type in their capacity to hydrolize the components of olive oil or TC. This phenotype was ascertained to be stable by retesting on the rhodamine B media. The majority of colonies arising after mutagenesis had an appearance on rhodamine B media that was indistinguishable from that of wild-type colonies. This is due in part to mutagenesis efficiencies of less than 100%. However, the wild-type phenotype predominated even among colonies that contained mutated plasmids as indicated by the occurrence of a mutagenic primer-induced restriction enzyme susceptibility. This suggests that, despite the conserved character of the residues subjected to mutagenesis, a number of replacements are tolerated without a major change in the lipolytic phenotype. The nature of these neutral substitutions is not known because no sequence determinations were made. A second group of mutants exhibited a lipase-negative phenotype. Presumably, some of the substituting amino acids have side chains that prevent either proper folding of the enzyme or the conformational changes required for interfacial activation, substrate binding or catalysis.

Hydrolysis of olive oil, TO, TC and TB. The activities of mutant lipases were tested titrametrically against the individual substrates. For the pure wild-type and mutant mature enzymes, specific activities could be assigned for each substrate (Table 2) and a profile of the relative activities, with the activity against olive oil set at 100%, was established (Fig. 2). The reduction in the specific activity as a result of the replacement of thr83 by ser or ala has been noted previously. In addition to this reduction in activity, these mutant enzymes display an alteration in their substrate preferences, with the activity toward TB, relative to that toward TO, being reduced roughly threefold compared with the wild-type enzyme (Fig. 2). The titrametric assay using individual substrates allowed the relatively rapid screening of potential mutant lipases and provided information concerning the activities of the enzymes. However, to overcome differences in the emulsion properties of TB, TC and olive oil, experiments were also conducted that presented the enzymes with mixtures of three substrates. Activity was determined by measuring the disappearance of each substrate during incubation with the enzymes. TO was used in place of olive oil in these assays to simplify the gas-chromatographic analyses. As with the wild-type enzyme, purified mutant lipases had similar activities toward TC and TO (Table 3). However, compared to the wild-type enzyme, the thr83 and ala89 mutant lipases showed a reduction in their relative activities toward TB (Table 3, Fig. 3).

The lipolytic activities, toward individual triglyceride substrates, of lysates containing wild-type or mutant prolipases are listed in Table 4. Since these data were collected using impure enzyme preparations, the activities are listed in units per mL of cell lysate, and absolute activity values cannot be compared with one another. Nevertheless, the relative activities can be compared (Fig. 4A). As seen with the mature wild-type lipase (Table 2, Fig. 2),

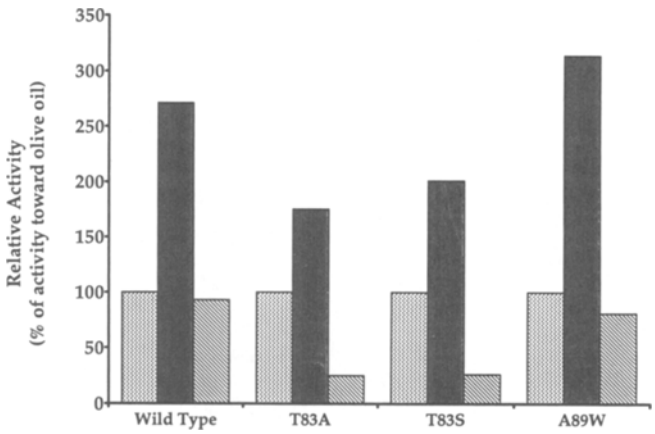

FIG. 2. Relative activities calculated from the results of the titrametric assays on olive oil (dotted bars), tricaprylin (dark bars), and tributyrin (hatched bars), listed in Table 2. The activity on olive oil was set at 100%.

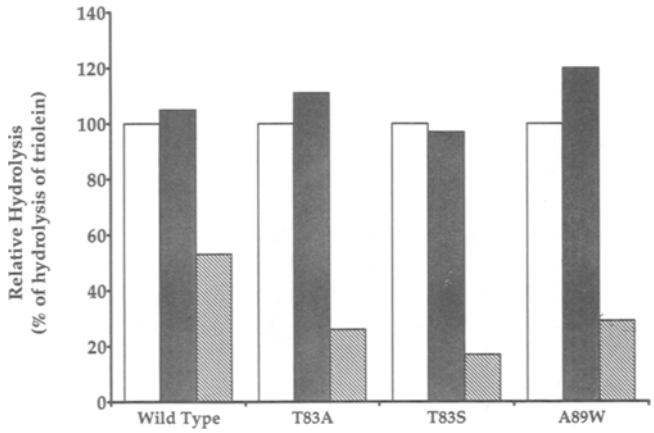

FIG. 3. Relative activities calculated from the results, listed in Table 3, of hydrolysis experiments with substrate mixtures composed of triolein (light bars), tricaprylin (dark bars) and tributyrin (hatched bars). The percent hydrolysis of triolein was set at 100%.

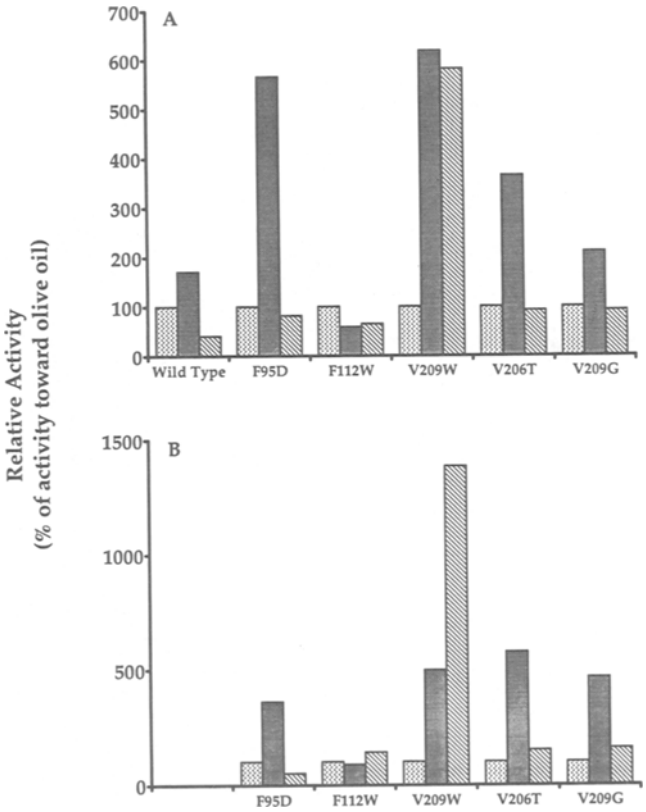

FIG. 4. The relative lipolytic activities of prolipase (A) and mature lipase (B) mutants against the single substrates olive oil (dotted bars), tricaprylin (dark bars) and tributyrin (hatched bars). Activity on olive oil was set at 100%. Data from Tables 4 and 6, respectively.

the wild-type prolipase is most active with TC as substrate and least active against TB. This was confirmed by incubation of the enzymes in the simultaneous presence of the three substrates (Table 5, Fig. 5A). However, there was only a small difference between the hydrolysis of TO and TC in this case as opposed to the experiments using single substrates (Table 4).

The prolipase expressed from pET11-d-f1-1231s-F95D exhibits more than a threefold higher activity toward TC than does the wild enzyme in the single substrate titration assay (Table 4, Fig. 4A), and an almost twofold higher activity in the mixed substrate assay (Table 5, Fig. 5A). Whether this is caused by a higher hydrolytic activity toward TC or a reduced activity toward TO cannot be determined with these impure preparations.

Replacement of phe112 by trp greatly effected the substrate preference of the prolipase. In contrast to the wild type, the lysate from a strain harboring pET11-d-f1-1231s-F112W exhibited its lowest activity toward TC (Tables 4, 5). Relative to the wild-type enzyme, this mutant enzyme hydrolyzed TB about 50% better, with the ratio of TO activity to TB activity being 1.6, compared to 2.4 for the wild type (Table 4, Fig. 4A). Against mixed substrates, TC was again least preferred, while TB was hydrolyzed to a large extent (Table 5, Fig. 5A). Thus the mutagenic replacement of a large side chain by an even bulkier one reduced the relative activity toward triglycerides with medium-chain fatty acids and increased activity toward those with short chains.

Mutant plasmid pET11-d-f1-1231s-V209W encodes a prolipase with a substitution of val209 by a trp residue. *Escherichia coli* cells bearing this plasmid produced a prolipase with highest activity on TB in the mixed substrate

[a]Calculated by the method defined in Table 3. Abbreviations as in Tables 1 and 4.

assay (Table 5, Fig. 5A) and toward TC and TB in the single substrate assay (Table 4, Fig. 4A). Apparently, this enzyme has a relatively low activity on TO, but as before, it will only be possible to verify this through purification of the prolipase. As with the mutant prolipase (F112W) described above, the change in substrate preference of the V209W mutant prolipase toward the substrate with the shortest acyl chains, TB, was caused by the replacement of a hydrophobic amino acid, val, with a bulky residue, trp.

The replacement of val206 with thr, and the replacement of val209 with gly, caused an increase in the relative activity of the prolipases toward TC in the single substrate assay (Fig. 4A). However, in the mixed substrate assay, the V206T mutant prolipase hydrolyzed the three substrates in a manner similar to that of the wild-type enzyme and the V209G mutant prolipase hydrolyzed each of the three substrates almost equally (Fig. 5A).

The production of mutant lipases as active proenzymes is an efficient way to rapidly screen for enzymes with altered properties. The presence of the propeptide and the need to use crude preparations, however, raises the question as to whether the properties observed are also those that would be observed with the corresponding mature enzymes. In order to address this question, the mutations carried by the prolipase genes were introduced into the gene for mature lipase by replacement of a *Kpn*I-*Eco*RI fragment from this gene with the corresponding fragments from the mutated prolipase genes. The resulting mutant lipase genes were expressed, and active mutant lipase enzymes were obtained after refolding of the inactive enzymes from inclusion bodies. Specific activities were obtained for the partially purified lipase preparations for the single substrates olive oil, TC and TB (Table 6). The relative activities (activity toward olive oil equals 100%) are shown in Figure 4B. Comparison of the data in Figure 4A and 4B indicates that the crude prolipase preparations and the partially purified refolded mature lipase samples behave similarly. Differences in the relative activities toward TC, mainly by the V209W mutant, however, could be

[a]Values are average from two assays; 5 μg of protein was added to each reaction tube.

noted. The reasons for these differences remain to be elucidated.

The refolded mutant lipase samples were also tested in mixed substrate assays (Table 7). As seen in the single substrate assay, the relative hydrolysis data for the mutant prolipases and the mature mutant lipases closely resembled each other (Fig. 5).

Overall, the phenotypes observed so far indicate that it is possible to manipulate the substrate specificity of the Rd lipase through site-directed mutagenesis. Additional mutagenesis experiments, involving such targets as phe214 and phe216 (see Fig. 1), or deletions or insertions near residues that might interact with the acyl chain of triglycerides, should increase the spectrum of mutants. The combining of different mutations into one mutant lipase might yield enzymes with even higher substrate preferences. The determination of the three-dimensional structure of the Rd lipase (28), should allow the identification of additional mutagenesis targets and possibly provide explanations for the phenotypes caused by the mutations studied here.

ACKNOWLEDGMENTS

We thank G. McNeill for help with the hydrolysis assays and Z. Derewenda for collaborative discussions and for the X-ray coordinates of the Rm lipase.

Phosphorylation of Lipids in Rat Primary Glial Cells and Immortalized Astrocytes (DITNC)

Wei Tong and **Grace Y. Sun***

Biochemistry Department, University of Missouri, Columbia, Missouri 65212

Phosphatidylinositol 4,5-bisphosphate, a substrate in the signal transduction pathway involving phospholipase C, is synthesized in cell membranes by phosphorylation of phosphatidylinositol (PI) and phosphatidylinositol 4-phosphate (PI-4-P). Incubation with [γ-^{32}P]adenosine triphosphate of membranes isolated from primary glial cells in culture and from an immortalized astrocyte cell line (DITNC) and subsequent separation of the lipids by high-performance thin-layer chromatography revealed a number of labeled lipid bands. Further analysis of the deacylated products by high-performance liquid chromatography indicated the presence of two PI-4-P bands and a band corresponding to lysoPIP (PIP, PI phosphate). The two PI-4-P bands were more prominent in the samples from astrocyte cell membranes than from synaptic plasma membranes and plasma membranes. Analysis of the fatty acid composition of PI by gas–liquid chromatography revealed that both 20:3n-9 and 20:4n-6 were present in PI of cultured cell membranes, whereas the brain membranes contained exclusively 20:4n-6. The two PI-4-P bands in these membranes can be attributed to the presence of different molecular species of PI. Assignment of the fraction corresponding to lysoPIP was consistent with the observation that an increase in label in this lipid band occurred upon incubation of DITNC cell supernatant with lysoPI (1-stearoyl PI). This suggests that endogenous lysoPI present in the cell membranes can be phosphorylated to form lysoPIP.

***Lipids* 29, 385–390 (1994).**

Although phosphoinositides (phosphatidylinositol, PI; phosphatidylinositol-4-phosphate, PI-4-P; and phosphatidylinositol 4,5-bisphosphate, PI-4,5-P_2) comprise only a small portion of cell membrane lipids, they play an important role in the cell signaling cascade (1,2). In particular, PI-4,5-P_2 serves as substrate for phospholipase C, which is stimulated by receptor agonists to yield two second messengers, namely diacylglycerol (DG) and inositol trisphosphate (IP_3) (2). The PI-4,5-P_2 pool, which is depleted upon cell stimulation, can in turn be replenished by sequential phosphorylation of PI catalyzed by PI- and PIP-kinases (PIP, PI phosphate) (3,4). In most instances, the second messengers generated in cells due to stimulated hydrolysis of PI-4,5-P_2 are rapidly removed, e.g., IP_3 *via* IP_3-kinase and phosphatase and DG *via* DG-kinase (1,2). Although different isoforms of DG-kinases are present in brain cytosol (5,6), some of these isoforms may associate with membranes through a calcium-mediated translocation process (6). Despite the important role of the lipid kinases in cell signaling mechanisms, factors modulating their activities have remained relatively unexplored.

In previous studies, incubation of brain subcellular membrane fractions with [γ-^{32}P]adenosine triphosphate (ATP) has been shown to result in the labeling of three major lipid classes, namely phosphatidic acid (PA), PI-4-P and PI-4,5-P_2 (7,8). However, the results from our recent experiments with membranes from cultured cells have indicated the presence of more than three labeled lipid bands after separation by high-performance thin-layer chromatography (HPTLC). There is evidence that some transformed cells can phosphorylate PI to yield phosphatidylinositol-3-phosphate (PI-3-P) and phosphatidylinositol-3,4-bisphosphate (PI-3,4-P_2) (9–11). Therefore, a more detailed analysis of the lipids formed upon incubation of cell membranes with [^{32}P]ATP seemed warranted. The major objective for the present study was to examine lipid phosphorylation in primary glial cells as well as in an immortalized astrocyte cell line (DITNC) (12).

MATERIALS AND METHODS

Materials. [γ-^{32}P]ATP (3000 Ci/mmol) was obtained from New England Nuclear Research Products, Inc. (Boston, MA). [^{3}H]Inositol-1 monophosphate, inositol-1,4-bisphosphate and inositol-1,4,5-trisphosphate (1.0 Ci/mmol) were purchased from American RadioChemicals, Inc. (St. Louis, MO). ATP, polyPI, PA, lysoPA, PI-4-P and lysoPI were from Sigma Chemical Co. (St. Louis, MO). Whatman HP-K high-performance silica gel plates (10 × 10 cm, 200 μ thick) were obtained from Fisher Scientific Co. (St. Louis, MO). Sprague-Dawley rats were purchased from Taconic Farm (Germantown, NY). Partisil 10 SAX high-performance liquid chromatography (HPLC) analytical column (10 μm, 25 cm) with a Solvecon pre-column (25 cm) was from Whatman International Ltd. (Maidstone, England). BioSafe-NA scintillation fluid was from Research Product International Corp. (Mount Prospect, IL). UniverSol scintillation fluid was from ICN Radiochemicals (Covina, CA). Cell culture reagents were from Cell and Immunobiology Core Facilities (University of Missouri, Columbia, MO). Kodak X-OMAT-AR imaging films were from Eastman Kodak Company (Rochester, NY). An immortalized astrocyte cell line (DITNC) was kindly provided by Dr. C.F. Deschepper (Clinical Research Institute of Montreal, Montreal, Canada) (12). This cell

Abbreviations: ATP, adenosine triphosphate; DG, diacylglycerol; DITNC, immortalized astrocytes from rat diencephalon; DMEM, Dulbecco's modified Eagle's medium; EGTA, ethyleneglycol bis(β-aminoethyl ether) *N,N,N',N'*-tetraacetic acid; FAME, fatty acid methyl ester; GLC, gas–liquid chromatography; G-3-P, glycerol-3-phosphate; HPLC, high-performance liquid chromatography; HPTLC, high-performance thin-layer chromatography; IP, inositol monophosphate; IP_3, inositol trisphosphate; PI, phosphatidylinositol; PI-3-P, phosphatidylinositol-3-phosphate; PI-4,5-P_2, phosphatidylinositol 4,5-bisphosphate; PI-4-P, phosphatidylinositol-4-phosphate; PI-3,4-P_2, phosphatidylinositol 3,4-bisphosphate; PIP, phosphatidylinositol phosphate; PM, plasma membranes; SPM, synaptic plasma membranes.

line was originally derived from rat diencephalon, and exhibits many of the characteristics of the type 1 astrocytes (12).

Cell culture and isolation of cell membranes. DITNC cells were maintained in Dulbecco's modified Eagle's medium (DMEM) containing 10% fetal bovine serum, 1% penicillin, 1% streptomycin and 1% fungizone. The primary glial cell culture was prepared from cerebral hemispheres of new-born Sprague-Dawley rats following the procedure described by Murphy (13) with minor modifications. Briefly, brains were minced and dissociated in a medium containing DMEM with 0.25% trypsin, and the mixture was incubated at 37°C for 20 min. After dissociation, cells were collected by centrifugation at 200 × *g* for 10 min and resuspended in the same medium as for DITNC cells. Cells were plated on poly-L-lysine-coated dishes and incubated at 37°C in a Steri-Cult 200 incubator (Forma Scientific, Marietta, OH) under a humidified atmosphere of 95% air and 5% CO_2. Culture medium was changed twice weekly, and cells were used for experiments after 2–4 passages. Microscopic examination of the primary glial cultures indicated the presence of astrocytes as well as a small proportion of microglial cells.

Cells were harvested by brief exposure to trypsin followed by neutralization, centrifugation and resuspension in buffer A containing 10 mM Tris-HCl (pH 7.4) with 10 mM $MgCl_2$ and 1 mM ethyleneglycol *bis*(β-aminoethyl ether (EGTA) (14). Cells were disrupted by sonication (5 times for 5 s each and with a 15-s interval between each burst). The broken cell suspension was centrifuged at 105,000 × *g* for 5 min to obtain membrane and supernatant fractions.

Synaptic plasma membranes (SPM) and somal plasma membranes (PM) were isolated from rat cerebrum by differential speed and sucrose gradient centrifugation according to the procedure described by Sun *et al.* (15). Membranes were suspended in buffer A (14).

Incubation of membrane fractions with [γ-^{32}P]ATP. The procedure used for incubation of membrane fractions with [γ-^{32}P]ATP was similar to that described by Stubbs *et al.* (7). In a typical incubation, 20 μg of membrane protein in 25 μL of buffer A was preincubated at 30°C for 5 min and then incubated with [γ-^{32}P]ATP (3 μCi in 7.5 μM, NEN) at 30°C for 60 s. The reaction was terminated by adding 3 mL of chloroform/methanol/12N HCl (2:1:0.025, by vol). The lipid extract was made acidic by adding 0.6 mL of 0.6N HCl to form a two-phase system. After phase separation, the lower organic phase was collected and washed twice with 1.5 mL of chloroform/methanol/0.6N HCl (3:48:47, by vol). The organic phase was dried under nitrogen and applied to an HPTLC plate that had previously been impregnated with a solution containing 1% potassium oxalate and 2 mM EGTA (diluted with methanol 3:2, vol/vol). In some instances, appropriate standards were added to the samples to aid in visualizing the fractions. The HPTLC plates were developed in a solvent system containing chloroform/methanol/acetone/ammonium hydroxide (35:20:5:5, by vol). After the first development, plates were dried and then developed again in the same direction using chloroform/methanol/ammonium hydroxide/water (36:28:2:6, by vol). After development, HPTLC plates were exposed to Kodak X-OMAT film for various periods of time to identify and quantify the fractions. Lipid fractions on HPTLC plates were visualized either by exposure to iodine vapors or by charring upon spraying with a copper acetate/phosphoric acid reagent (3 g copper acetate in 100 mL of 8% phosphoric acid). Bands were scraped into scintillation vials for measurement of radioactivity. In some instances, total lipid extracts or individual lipid classes recovered after one-dimensional HPTLC were further separated by two-dimensional HPTLC, as described by Sun (16).

In experiments that were designed to further analyze the lipid bands by HPLC, various amounts of membrane proteins and [γ-^{32}P]ATP were used so that enough labeled materials were obtained for HPLC analysis. In some experiments, exogenous lipids such as PA, PI, lysoPI and PIP were added to the incubation system to test their effects on the lipid kinases.

Deacylation of lipids and separation by HPLC. To further analyze the lipid bands by HPLC, it was necessary to deacylate the glycerolipids. The procedure used was similar to that described by Ascoli *et al.* (17) and Pignataro and Ascoli (18) with minor modifications. Briefly, individual adsorbent bands scraped from the HPTLC plates were transferred into test tubes, and the lipids were extracted with chloroform/methanol/0.2N HCl (5:10:4, by vol). A two-phase system was obtained by adding chloroform and water. The lower phase was neutralized with 60 μL of 1N ammonium hydroxide before drying under nitrogen. The dried samples were dissolved in 50 μL of chloroform and 75 μL of methanol and then saponified in 125 μL of 0.2N NaOH in methanol. After reaction at 25°C for 20 min, 200 μL of chloroform, 50 μL of methanol and 225 μL of water were added to each sample, and the mixture was separated into two phases aided by centrifugation. The upper phase was removed, and the lower phase was further extracted with 500 μL of methanol/water (10:9, vol/vol). The two portions of upper phase were combined, and 37.5 μL of 1M HEPES was added to neutralize the mixture. The resulting deacylated products were vacuum-dried and reconstituted in water to appropriate volumes for analysis by HPLC using a Dionex BioLC system (Dionex, Westmont, IL). Samples (50 μL) were fractionated on a Partisil 10 SAX analytical column and a Solvecon pre-column using a discontinuous linear gradient solvent system containing 1.7M ammonium formate buffered to pH 3.7 with orthophosphoric acid. The percentage of ammonium formate was increased from 0 to 44% within 40 min, to 60% at 50 min and to 100% at 70 min. The flow rate was set at 1 mL per min. The eluates were collected in test tubes as one-minute fractions, mixed with 5 mL of scintillation fluid (Universol) each, and radioactivity was counted with a Beckman LS5801 scintillation spectrometer (Beckman Instrument, Fullerton, CA).

Analysis of PI fatty acids by gas–liquid chromatography (GLC). In one experiment, the lipid extracts from primary glial cells and DITNC cells were separated by two-dimensional HPTLC (16). Individual lipid fractions were recovered from the plate, and the acyl groups were converted to their fatty acid methyl esters (FAME) by base-catalyzed methanolysis with 0.2N NaOH in methanol. A known

amount of 17:0 methyl ester (Sigma) was added to each sample as internal standard. The FAME were resolved using a Hewlett-Packard gas–liquid chromatograph (HP 5890; Hewlett-Packard, Avondale, PA) with an SP-2330 (30 m × 0.32 mm i.d.) fused silica capillary column (Supelco, Bellefonte, PA). Conditions used for GLC were similar to those described previously (16).

RESULTS

The membrane fractions that were isolated from primary glial cells and immortalized astrocytes (DITNC) were incubated with [^{32}P]ATP. Subsequent analysis of the labeled lipids by HPTLC revealed as many as eight labeled lipid bands (lanes C and D in Fig. 1). For comparison, incubation of SPM and PM from rat brain with [^{32}P]ATP also resulted in a number of labeled lipid bands (lanes E and F) but showed different labeling patterns. In lanes A and B of Figure 1, the migration patterns of lipids from A (primary glial cells) and B [a commercial polyPI standard containing PI, PIP and PIP_2 (Sigma)] are seen after exposing the HPTLC plate to iodine vapors. Most of the nonradioactive lipids migrated to the top half of the plate, whereas the labeled lipids were retained in the lower half (Fig. 1).

The separation of PA, PI and lysoPI by HPTLC was verified with commercial standards. Lane A in Figure 2 shows the migratory pattern of a polyPI standard (Sigma). In lanes B and C, it is shown that the PA standard migrates to a position slightly lower than does PI. In fact, this standard contained an impurity that was later identified as lysoPA. LysoPI (lane E) migrated to a level similar to that of PA. However, when labeled lipid bands 1 and 2 (Fig. 1) were separated using the two-dimensional HPTLC system, radioactivity correlated well with the PA and lysoPA fractions and not with PI or lysoPI (data not shown).

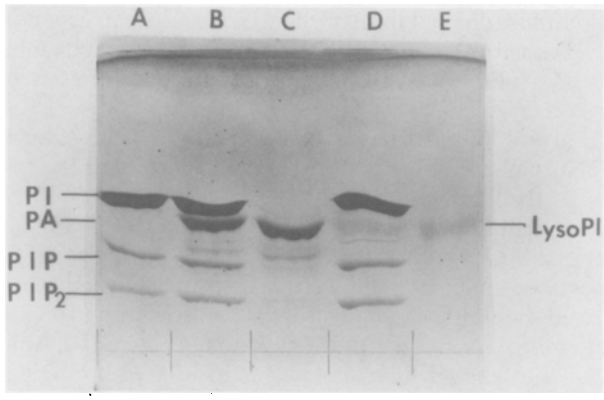

FIG. 2. Separation of polyPI (PI, phosphatidylinositol) standards, phosphatidic acid (PA) and lysoPI by high-performance liquid chromatography. Lipid bands were visualized by charring the plate upon spraying with copper acetate reagent. Bands: (1) PI; (2) PA or lysoPI; (3) PI phosphate (PIP); and (4) PIP_2. Lanes: (A) polyPI standard; (B) polyPI plus PA; (C) PA; (D) polyPI plus lysoPI; and (E) lysoPI.

For further identification of the lipid fractions, especially those that do not correspond to PA, PIP and PIP_2, individual lipid bands were recovered from the HPTLC plate and deacylated. The water-soluble products were analyzed by HPLC. In Figure 3, the radioactive peak at 17–24 min was found to correspond well to the elution profile of glycerol-3-phosphate (G-3-P), the deacylation product of PA. The peak at 25–30 min corresponded to gPIP, the deacylation product of PIP, and the peak at 46–50 min corresponded to $gPIP_2$, the deacylation product of PIP_2. In addition to the elution profile for the [^{32}P]labeled deacy-

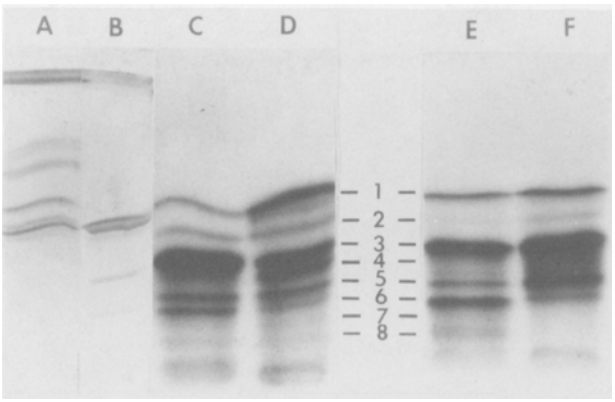

FIG. 1. High-performance thin-layer chromatographic separation of ^{32}P-labeled phospholipids produced by incubation of [γ-^{32}P]adenosine triphosphate (ATP) with membranes isolated from primary glial cells and immortalized astrocytes (DITNC). The data are compared with those for synaptic plasma membranes (SPM) and plasma membranes (PM) from rat brain. Lipids in lanes A and B were visualized by exposure to iodine vapors; lanes C–F were autoradiographs. A, phospholipids in primary astrocyte membranes; B, polyPI standards (Sigma Chemical Co., St. Louis, MO); C, primary glial cells; D, DITNC cells; E, SPM from rat brain; F, PM from rat brain.

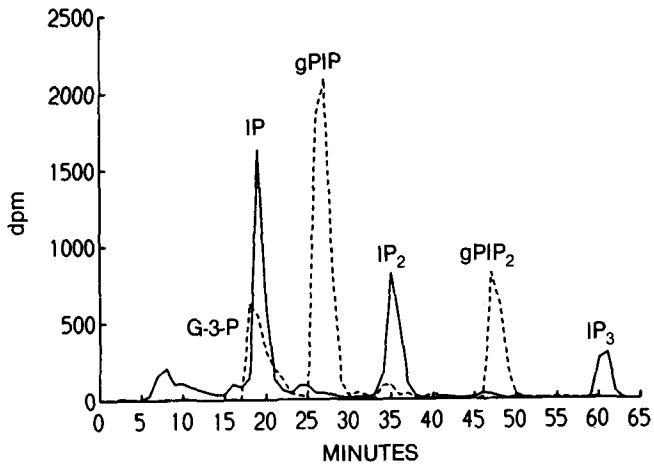

FIG. 3. High-performance liquid chromatography separation of the phospholipids from ^{32}P-labeled SPM upon deacylation (dotted line) and comparison with ^{3}H-labelled inositol monophosphate (IP), inositol biphosphate (IP_2) and inositol trisphosphate (IP_3) standards (solid line). The glycerol-3-phosphate (g-3-P), gPIP and $gPIP_2$ peaks correspond to deacylated PA, PIP and PIP_2 on the high-performance thin-layer chromatography plate, respectively. Abbreviations as in Figures 1 and 2.

lated lipids (dashed line), radioactive peaks corresponding to [^{3}H]inositol-1-phosphate (IP), inositol 1,4-bisphosphate and IP_3 (solid line) are shown in the same figure for comparison (Fig. 3).

Analysis of the deacylated lipids after incubating DITNC cell membranes with [^{32}P]ATP revealed the presence of three major radioactive peaks with elution times corresponding to PA, PIP and PIP_2, respectively (Fig. 4A). When the labeled lipid in band 1 (lane D of Fig. 1) was deacylated and applied to HPLC, the elution profile showed a single radioactive peak corresponding to G-3-P, confirming the identity of this lipid as PA (Fig. 4B). Analysis of the labeled lipid in band 2 also gave a single radioactive peak with an elution time identical to that of G-3-P (Fig. 4B). To further verify that the lipid in band 2 is lysoPA, the lipid was recovered and further resolved by two-dimensional HPTLC. The result obtained indicated that the lipid fraction comigrated with lysoPA (data not shown). The deacylated lipids of bands 3, 4 and 5 each eluted as a single radioactive peak with the elution time of the deacylated PIP peak (Fig. 4C). Based on its migratory pattern in comparison with authentic PI-4-P standard, lipid band 3 was firmly identified as PI-4-P. Lipid band 4 could be due to (i) PI-4-P molecular species different from those in band 3; (ii) PI-3-P; or (iii) lysoPIP. The possibility of lipid band 4 being PI-3-P was eliminated because HPLC eluted a deacylated [^{32}P]PI-3-P sample (provided by Dr. P. Wilden, Pharmacology Department, University of Missouri, Columbia, MO) 2 min earlier than PI-4-P (data not shown). Since lipid band 5 was later confirmed as lysoPIP by incubation of membrane fractions with exogenous lysoPI (see below), lipid band 4 was assigned to PI-4-P by elimination. Lipid band 6 was identified as PIP_2 because its migration rate in HPTLC corresponded well to that of the commercial PIP_2 standard. Analysis by HPLC resulted in the elution of a single radioactive peak with an elution time similar to that of $gPIP_2$ (Fig. 4D). Elution of lipid band 7 also gave a radioactive peak with an elution time identical to that of $gPIP_2$ (Fig. 4D). Consequently, this band is assigned to PIP_2 molecular species.

In order to further clarify the identity of lipid bands 5 and 6, which migrated close to each other in HPTLC, exogenous lysoPI, or PIP, was added to the incubation mixture containing [γ-^{32}P]ATP and a supernatant fraction from DITNC cells. This supernatant fraction probably contained both microsomal membranes as well as cell cytosol. Incubation in the absence of exogenous lipids gave a labeling profile in which PIP was the major lipid band and lysoPIP and PIP_2 were minor lipid bands (lane A, Fig. 5). However, addition of lysoPI to the incubation mixture resulted in an increase in the label in band 5 (lane B), whereas an increase in label in band 6 could be observed after addition of PIP (lane D). When both lysoPI and PIP were added, an increase in label in both lipid bands 5 and 6 could be observed (lane C). In this experiment, it was demonstrated that in addition to labeling of PIP and PIP_2, exogenous lysoPI, or PIP, could decrease labeling of the PA band (Fig. 5). The data in Figure 6 further indicate an increase in labeled PIP_2 with increasing amounts of exogenous PIP added to the incubation system.

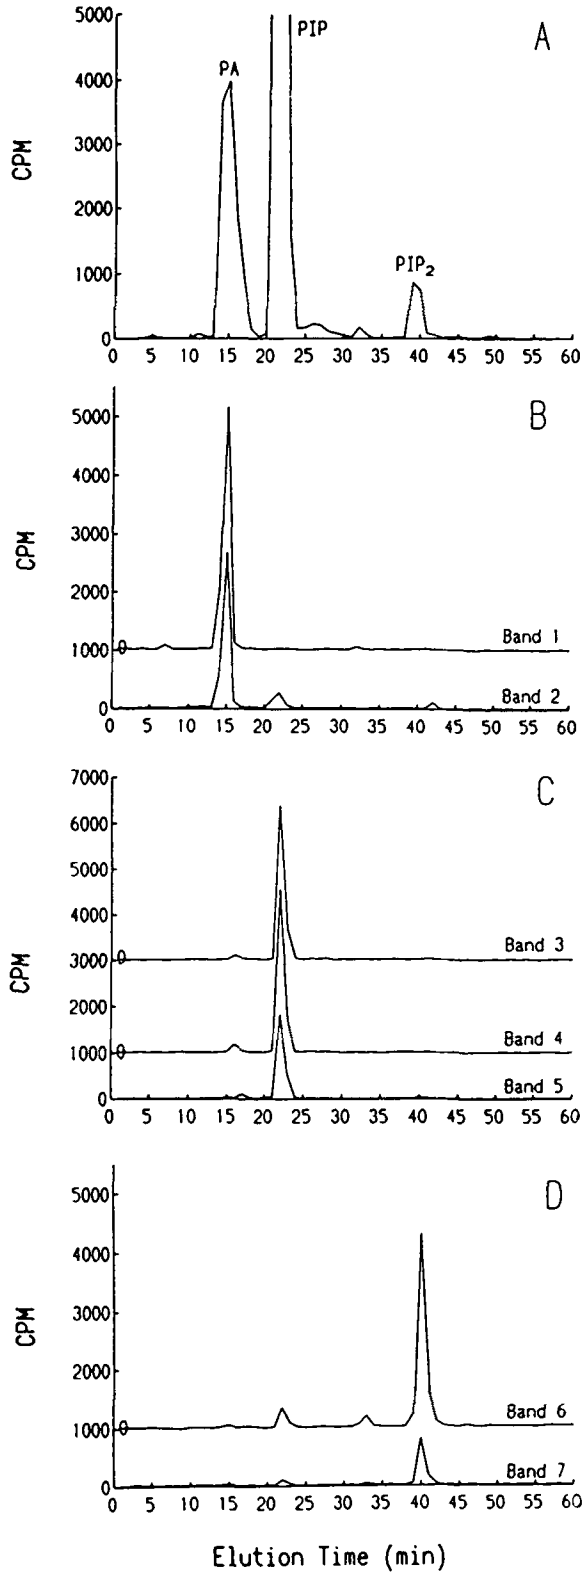

FIG. 4. Identification of ^{32}P-labeled lipid bands after incubation of DITNC cell membranes with [^{32}P]ATP. Panel A: The high-performance liquid chromatography profile of the total phospholipids from DITNC cells; Panel B, lipid bands 1 and 2; Panel C, lipid bands 3, 4 and 5; and Panel D, lipid bands 6 and 7. Lipid band numbers correspond to the numbering used in Figure 1. Abbreviations as in Figures 1 and 2.

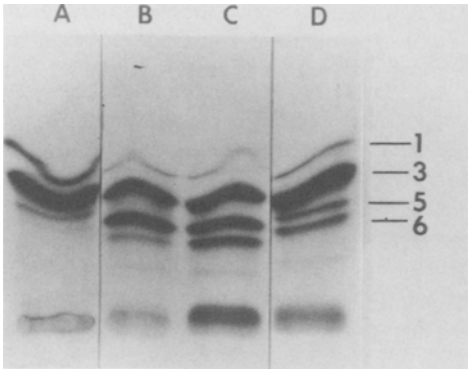

FIG. 5. Incubation of DITNC cell supernatant fraction with [^{32}P]ATP in the presence and absence of exogenous lysoPI and PIP. Band identification: (1) PA; (3) PIP; (5) LysoPIP; and (6) PIP_2. Incubation conditions: Lane A, control, no addition; Lane B, addition of lysoPI (note the increase in labeling of lysoPIP); Lane C, addition of lysoPI and PIP (note the increase in labeling of both lysoPIP and PIP_2); Lane D, addition of PIP (note the increase in labeled PIP_2). Abbreviations as in Figures 1 and 2.

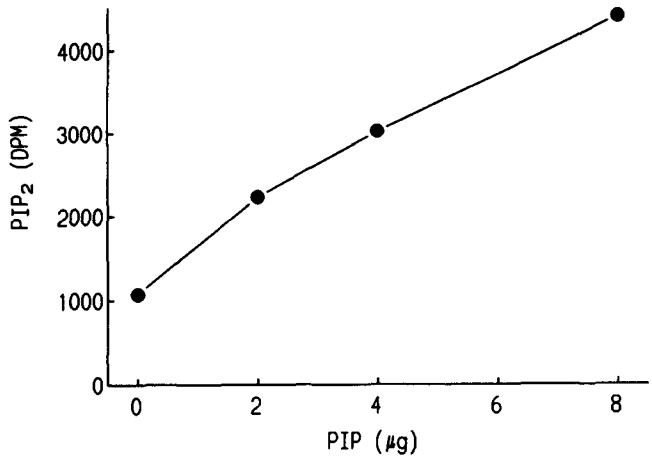

FIG. 6. Increase in labeling of PIP_2 following addition of exogenous PIP to the DITNC cell supernatant fraction. Abbreviations as in Figures 1 and 2.

Although the amounts of PIP and PIP_2 present in the cultured cells were too small to accurately determine their fatty acid composition, it is reasonable to assume that the polyPI have a similar fatty acid composition as does PI, which is present at substantially higher levels. The fatty acid profiles of PI of primary glial cells and DITNC cells are shown in Table 1, together with those of rat brain SPM and PM (12) and rat brain oligodendroglial cells (19). It can be seen that the polyunsaturated fatty acids of PI from the cell cultures are comprised of a considerable amount of 20:3n-9 in addition to 20:4n-6, whereas those from brain membranes contain almost exclusively 20:4n-6 (Table 1).

DISCUSSION

Covalent modification of biological molecules by ATP-dependent phosphorylation is one of the more important mechanisms of cellular regulation. Despite intensive studies on proteins and carbohydrates, the understanding of the enzymes responsible for phosphorylation of lipid mol-

[a]Primary glial cells and DITNC (immortalized astrocytes from rat diencephalon) cells were cultured in 100-mm dishes under the conditions described in the Materials and Methods section. Lipids from cells in each dish were extracted and were separated by two-dimensional high-performance thin-layer chromatography as described (Ref. 16). The phosphatidylinositol fraction was removed, and the fatty acids were converted to their methyl esters for gas–liquid chromatographic analysis. Data are means ± SD of four determinations.

[b]Data for rat oligodendroglial (ROC-1) cells (Ref. 19).

[c]Data for rat brain plasma membranes (PM) and synaptic plasma membranes (SPM) (Ref. 14).

ecules is still limited. Recent studies have demonstrated the importance of sequential phosphorylation of PI to PI-4-P and PI-4,5-P_2 which serves as substrate in the polyPI signal transduction pathway (1–4). On the other hand, a novel class of PI-kinases that phosphorylate PI to form PI-3-P and PI-3,4-P_2 has gained attention, especially as they function in transformed cells (9–11). The latter polyPI isomers seem to play important roles in cellular metabolism and function other than serving as substrates for phospholipase C.

In the present study, incubation of membrane fractions from primary glial cells and immortalized astrocytes (DITNC) with [γ-^{32}P]ATP resulted in the phosphorylation of a number of lipids. Two approaches were used to identify these lipids after separation by HPTLC. First, the chromatographic properties of these labeled lipids were compared with those of authentic standards in one- or two-dimensional HPTLC. Secondly, individual lipid fractions were recovered from the HPTLC plates, deacylated, and the products were analyzed by HPLC. Based on results obtained by the two approaches, it was concluded that lipid bands 1, 2, 3 and 5 (Fig. 1) correspond to PA, lysoPA, PIP and PIP_2, respectively.

In the system we used, incubation of membrane fractions with [^{32}P]ATP also resulted in phosphorylation of DG to PA. This indicates that DG-kinases are present in the membrane preparations, as has been reported for brain (5,6). In most instances, a small amount of lysoPA can be found, probably due to hydrolysis of PA catalyzed by phospholipase A_2. Indeed, incubation of purified PA (labeled with [^{14}C]arachidonic acid) with brain cytosol indicated the susceptibility of this phospholipid to hydrolysis by phospholipase A_2 (unpublished observation).

The possibility that some of the lipid bands of cultured cells appearing in the PIP area could belong to PI-3-P was ruled out after deacylating the lipids and HPLC analysis. The results rather favor the presence of different molecular species of PI-4-P. Indeed, the PI fatty acids from cultured cells contain substantial amounts of 20:3n-9 in addition to 20:4n-6, which is normally present in brain membranes (19,20). The study by Stubbs *et al.* (20) further suggested that fatty acids of phosphoinositides of cultured cells can be readily modified by altering the fatty acids in the culture medium (20). As polyPI are derived by phosphorylation of PI, it is reasonable to assume that the molecular species for all three phosphoinositides are similar under the culture condition (21).

Our results have clearly demonstrated the presence of lysoPIP as one of the phosphorylation products. Careful examination of lipid band 5 indicates that this lipid is present in both the cell and the brain membranes, albeit at different levels (Fig. 1). Because incubation with exogenous lysoPI resulted in an increase in labeled lysoPIP, it is reasonable to conclude that lysoPIP is formed by phosphorylation of lysoPI and not by hydrolysis of labeled PIP. As the lysoPIP band migrated closely to the PIP_2 band in the one-dimensional HPTLC system, it is important that studies with lipid kinases utilize rigorous analytical techniques.

ACKNOWLEDGMENTS

This research was supported in part by Grant No. AA 06661 from NIAAA and Grant No. NS 30178 from NIH. Thanks are also due to Nicole Takahashi for her help in the analysis of phospholipid fatty acids in cultured cells.

The Effect of Lidocaine on *de novo* Phospholipid Biosynthesis in the Isolated Hamster Heart

Jason T. Wong, Ricky Y.K. Man and Patrick C. Choy*

Departments of Biochemistry and Molecular Biology, and Pharmacology, Faculty of Medicine, University of Manitoba, Winnipeg, Manitoba, R3E 0W3 Canada

Lidocaine is used clinically as an antiarrhythmic agent, but its effect on cardiac phospholipid metabolism has not been defined. In this study, hamster hearts were perfused with [1,3-^{3}H]glycerol in the presence of 0.5 mg/mL lidocaine. The incorporation of radioactivities into lysophosphatidic acid, phosphatidic acid, phosphatidylethanolamine, cytidine diphosphate diacylglycerol, phosphatidylinositol, phosphatidylserine, diacylglycerol and triacylglycerol were enhanced by lidocaine treatment, whereas the labelling of phosphatidylcholine was reduced. Analyses of enzyme activities in the heart after perfusion with lidocaine revealed that the activities of phosphatidate phosphatase and acyl-coenzyme A (CoA):1,2-diacylglycerol acyltransferase were enhanced. The presence of lidocaine in the assay did not directly stimulate these enzymes. However, the activity of acyl-CoA:glycerol-3-phosphate acyltransferase was stimulated by lidocaine whereas the activity of cytidine diphosphocholine:1,2-diacylglycerol cholinephosphotransferase was inhibited by lidocaine. We conclude that lidocaine affects the regulation of phospholipid biosynthesis in the heart by both direct and indirect modulation of phospholipid biosynthetic enzymes.
***Lipids* 29, 391–396 (1994).**

Phospholipids are the major lipid component of biological membranes (1). In the mammalian heart, the appropriate phospholipid content and composition are important for the maintenance of cellular integrity and proper membrane function, including the conduction of electrical signals across the cardiac membrane (2). Consequently, the biosynthesis and catabolism of phospholipids in the heart must be under rigid control. The participation of certain phospholipids such as phosphatidylinositol as precursors for second messengers in the transduction of biological signals across the cell membrane has been documented (3). More recently, phosphatidylcholine has also been shown to be a precursor of diacylglycerol and phosphatidic acid during agonist stimulation (4). In the last decade, the pathways for the syntheses of the major phospholipids in the heart have been elucidated. However, the mechanisms for the control of these metabolic pathways have not been defined.

A number of amphiphilic compounds have been shown to exhibit regulatory effects on the biosynthesis of phospholipids in mammalian tissues (5–10). Lidocaine is an amphiphilic drug with local anaesthetic properties and is commonly used for the treatment of cardiac arrhythmias. Surprisingly, the effect of lidocaine on the biosynthesis of phospholipids in the heart has not been elucidated. In the present study, the ability of lidocaine to modulate phospholipid biosynthesis in the isolated hamster heart was investigated. Hearts were perfused with labelled glycerol to monitor the *de novo* synthesis of the cardiac phospholipids. Our results show that lidocaine has the ability to modulate the biosyntheses of the major phospholipids in the hamster heart.

MATERIALS AND METHODS

Materials. Palmitoyl-coenzyme A (CoA), DL-α-glycerophosphate, cytidine diphospho(CDP)choline, CDPethanolamine, Tris/HCl, Tris/maleate, ethylenediaminetetraacetic acid (EDTA) and ethyleneglycol-*bis*(β-aminoethyl ether)*N,N'*-tetraacetic acid (EGTA) were obtained from Sigma Chemical Co. (St. Louis, MO). Lidocaine was obtained from Astra Pharmaceutical Products (Mississauga, Ontario, Canada). [1,3-^{3}H]Glycerol, [1-^{14}C]-oleoyl-CoA, [1-^{14}C]palmitoyl-CoA, [5-^{3}H]cytosine triphosphate (CTP), *myo*-[2-^{3}H]inositol and [^{3}H]acetic anhydride were obtained from Amersham Canada (Oakville, Ontario, Canada). CDP[*methyl*-^{14}C]choline and CDP[1,2-^{14}C]ethanolamine were obtained from NEN division, Dupont Co. (Dorval, Quebec, Canada). 1-Palmitoyl-glycero-3-phosphate, phosphatidic acid (from egg lecithin), phosphatidylcholine (pig liver), phosphatidylethanolamine (pig liver), phosphatidylserine (bovine brain), phosphatidylinositol (pig liver), dipalmitoyl CDP-diacylglycerol, 1,2-diacylglycerol (pig liver) and triacylglycerol (pig liver) were products of Serdary Laboratories (London, Ontario, Canada). All other chemicals and solvents were of reagent grade and were obtained locally from the Canlab Division of Baxter Co. (Winnipeg, Manitoba, Canada).

Perfusion of the isolated hamster heart. Syrian golden hamsters weighing 120 ± 20 g were used throughout the study. Animals were decapitated and the hearts were removed. The isolated hamster hearts were perfused for 30 to 90 min in the Langendorff mode with Krebs-Henseleit buffer containing 0.3 to 2.0 mM [1,3-^{3}H]glycerol (45 μCi total radioactivity), in the presence or absence of 0.5 mg/mL lidocaine. For some enzyme studies, hearts were perfused for 60 min with Krebs-Henseleit buffer containing 1.0 mM glycerol, with or without 0.5 mg/mL lidocaine.

Determination of uptake and incorporation of [^{3}H]glycerol. Subsequent to perfusion, 10 mL of fresh Krebs-Henseleit buffer was forced through the cannula to remove the remaining perfusate. The heart was cut into pieces, blotted dry, weighed and homogenized in chloroform/methanol (1:1, vol/vol). The homogenate was cen-

Abbreviations: CDPcholine, cytidine diphosphocholine; CDP-diacylglycerol, cytidine diphosphate diacylglycerol; CDPethanolamine, cytidine diphosphoethanolamine; CoA, coenzyme A; CTP, cytosine triphosphate; EDTA, ethylenediaminetetraacetic acid; EGTA, ethyleneglycol-*bis*(β-aminoethylether)*N,N'*-tetraacetic acid; TLC, thin-layer chromatography.

trifuged at 1000 × *g* for 10 min, and the pellet was re-extracted twice with the same solvent. The supernatants were pooled, and a sample of the tissue extract was taken for scintillation counting to determine total glycerol uptake. A 0.25 M KCl solution and chloroform were added to cause phase separation, and samples of the aqueous and organic phases were taken for scintillation counting. The extraction efficiency of labelled phospholipids by this method was 88–90%, and was not affected by lidocaine. The phospholipid and neutral lipid classes in the organic phase were separated by thin-layer chromatography (TLC). Phosphatidylcholine, phosphatidylethanolamine, phosphatidylinositol and phosphatidylserine fractions were separated using chloroform/methanol/15 M aqueous NH_3/water (35:15:2:1, by vol) as developing solvent. The solvent for the separation of phosphatidic acid and lysophosphatidic acid contained chloroform/methanol/HCl (87:13:0.2, by vol) (11). The CDP-diacylglycerol fraction was resolved using a solvent containing chloroform/meth-anol/acetic acid/water (52:20:7:3, by vol) (12). The solvent used for the separation of neutral lipids contained light petroleum (b.p. 35–60°C)/diethyl ether/acetic acid (60:40:1, by vol). After visualization by iodine staining, the fractions with migration rates similar to those of authentic standards were scraped into scintillation vials, and their radioactivities were determined by scintillation counting.

Lipid quantification. Phospholipids were quantified by the procedure of Bartlett (13). Diacylglycerol was quantified by acetylation with labelled acetic anhydride by the method of Ishidate and Weinhold (14).

Preparation of subcellular fractions. For the determination of enzyme activities, hearts were removed from the animals and homogenized in a buffer containing 0.25 M sucrose and 10 mM Tris/HCl, pH 7.5. Microsomes were prepared from the tissue homogenate by differential centrifugation as previously described (4). Protein concentrations were determined by the method of Lowry *et al.* (15).

Preparation of [^{14}C]phosphatidic acid and determination of phosphatidate phosphatase activity. Phosphatidic acid was obtained from 1-palmitoyl-2-[^{14}C]oleoyl-*sn*-glycerophosphocholine by phospholipase D treatment (16). The substrate (50 μmol, 2000 dpm/nmol) was suspended in 2 mL of diethyl ether, and phospholipase D (1.33 mg) in 2 mL of 100 mM sodium acetate (pH 5.6)/100 mM $CaCl_2$ was added to the substrate suspension in a sealed tube. After 30 min of incubation at 42°C, the reaction mixture was cooled, and 1.33 mg of fresh enzyme was added to the mixture. The reaction mixture was reincubated at 42°C for another 30 min. The reaction was terminated by removing the diethyl ether under N_2. A chloroform/methanol (2:1, vol/vol) mixture (6 mL) was added to cause phase separation. The lower phase was analyzed by TLC with a solvent system of chloroform/methanol/water/acetic acid (50:37:2:3, by vol). The silica gel containing phosphatidic acid was removed, and the phospholipid was extracted from the gel by the method of Arvidson (17).

Phosphatidate phosphatase activity was assayed by determining the production of 1-palmitoyl-2-[^{14}C]oleoyl-*sn*-glycerol from 1-palmitoyl-2-[^{14}C]oleoyl-*sn*-glycero-3-phosphate (18). Phosphatidate phosphatase was found to be more active with a phosphatidic acid containing the 1-palmitoyl-2-oleoyl species than the 1,2-dipalmitoyl species. The assay mixture (100 μL) contained 100 mM Tris/HCl (pH 7.4), 1 mM dithiothreitol, 0.2 mg of bovine serum albumin, 0.6 mM 1-palmitoyl-2-[^{14}C]oleoyl-*sn*-glycero-3-phosphate (2000 dpm/nmol), 0.4 mM phosphatidylcholine, 1 mM $MgCl_2$, 1 mM EGTA, 1 mM EDTA, 0.75 mM oleic acid and approximately 0.1 mg protein. Postmitochondrial and cytosolic fractions were preincubated with oleic acid for 20 min at 37°C prior to being added to the reaction mixture. The reaction was initiated by addition of $MgCl_2$, and the mixture was incubated at 37°C for 60 min. The reaction was terminated by addition of 2 mL of chloroform/methanol (2:1, vol/vol). Water was added to cause phase separation, and the labelled diacylglycerol in the organic phase was separated by TLC with a solvent containing light petroleum (b.p. 35–60°C)/diethyl ether/acetic acid (60:40:1, by vol). The radioactivity in the diacylglycerol fraction was determined.

Acyl-CoA:glycerol-3-phosphate acyltransferase and acyl-CoA:lysophosphatidic acid acyltransferase assays. Enzyme activities were determined by the procedure of Batenburg *et al.* (19) with the hamster heart homogenate. For the acylation of glycerol-3-phosphate, the assay mixture consisted of 100 mM Tris/HCl (pH 7.5), 1.5 mM *rac*-glycerol-3-phosphate, 90 mM sucrose, 0.5 mg of bovine serum albumin, 1 mM dithiothreitol, 40 μM [1-^{14}C]oleoyl-CoA (4000 dpm/nmol) and 0.1–0.2 mg of protein in a volume of 500 μL. The reaction was initiated by addition of the enzyme, and the mixture was incubated at 30°C for 30 min. The reaction was terminated by addition of 3 mL of chloroform/methanol (2:1, vol/vol). Water was added to cause phase separation. The labelled lysophosphatidic acid in the lower phase was resolved by TLC with a solvent containing chloroform/methanol/15 M NH_3/water (35:15:2:1, by vol), and the radioactivity in the lysophosphatidic acid fraction was determined.

For the acylation of lysophosphatidic acid, the reaction was carried out under the same conditions, except that glycero-3-phosphate was replaced with 0.2 mM 1-palmitoylglycero-3-phosphate (19). The labeled phosphatidic acid formed was separated by TLC, and the radioactivity in the phosphatidic acid fraction was determined.

Acyl-CoA:1,2-diacylglycerol acyltransferase assay. Enzyme activity was assayed by determining the transfer of [1-^{14}C]palmitoyl-CoA to 1,2-diacylglycerol (20) in the hamster heart homogenate. The reaction mixture (0.5 mL) contained 25 mM Tris/HCl (pH 7.4), 50 μM [1-^{14}C]palmitoyl-CoA (2000 dpm/nmol), 2 mM 1,2-diacylglycerol (dispersed by sonication with a Fisher sonic dismembrator fitted with a microprobe; Fisher Scientific, Winnipeg, Manitoba, Canada), 18 mM $MgCl_2$, 0.5 mg of bovine serum albumin and 1 mM dithiothreitol. The reaction was initiated by addition of 0.2–0.3 mg of protein, and the mixture was incubated at 37°C for 10 min. The reaction was terminated by addition of 3 mL of chloroform/methanol (2:1, vol/vol). Water was added to cause phase separation. The product in the organic phase was separated by TLC with a solvent containing light petroleum (b.p. 35–60°C)/diethyl ether/acetic acid (60:40:1, by vol), and the radioactivity in the triacylglycerol fraction was determined.

CTP:phosphatidic acid cytidylyltransferase assay. Enzyme activity was determined in hamster heart homogenate and in the microsomal fraction. The reaction mixture contained 50 mM Tris/maleate (pH 6.5), 20 mM $MgCl_2$, 15 mM Triton X-100, 1.0 mM [5-^{3}H]CTP (10000 dpm/nmol) and 0.5 mM phosphatidic acid (21). The reaction was initiated by addition of the enzyme protein (0.3 mg), and the mixture was incubated at 37°C for 15 min. The reaction was terminated by addition of 2.5 mL of 0.1 M HCl in methanol. After cooling, 5 mL of chloroform was added to the mixture. The chloroform/methanol mixture was washed three times with 10 mL of 2 M $MgCl_2$ (22), and the total radioactivity in the organic phase was determined by scintillation counting. TLC analysis showed that over 98% of the radioactivity in the organic phase migrated to the CDP-diacylglycerol fraction.

Phosphatidylinositol synthase and serine base exchange enzyme assays. Phosphatidylinositol synthase activity was assayed with the hamster heart postmitochondrial fraction by the procedure of Imai and Gershengorn (23). The reaction mixture contained 100 mM Tris/HCl (pH 7.5), 1 mM EGTA, 3 mM $MgCl_2$, 3 mM $MnCl_2$, 0.2% Triton X-100, 0.1 mM CDP-dipalmitoylglycerol and 0.1 mM *myo*-[^{3}H]inositol (5×10^5 dpm/nmol). The reaction mixture was incubated at 37°C for 30 min, and the reaction was terminated by addition of 1 mL of chloroform/methanol/HCl (100:100:1, by vol) and 0.4 mL of 0.9% KCl. After phase separation, the labelled phosphatidylinositol in the organic phase was separated by TLC with a solvent containing chloroform/methanol/15 M NH_3/water (35:15:2:1, by vol), and the radioactivity in the phosphatidylinositol fraction was determined.

Serine base exchange enzyme activity in the microsomal fraction was assayed using labelled serine (24). The reaction mixture contained 10 μM *N*-2-hydroxyethylpiperazine-*N'*-2-ethanesulfonic acid (pH 7.3), 0.8 μmol phosphatidylethanolamine, 20 nmol [^{3}H]serine (78000 dpm/nmol), 6 μmol $CaCl_2$, 50 μg bovine serum albumin and microsomes in a total volume of 250 μL. The reaction was carried out at 37°C for 15 min, and was stopped with 2 mL of chloroform/methanol (2:1, vol/vol). After phase separation, the radioactivity of phosphatidylserine in the lower phase was determined.

CDPcholine:1,2-diacylglycerol cholinephosphotransferase and CDP ethanolamine:1,2-diacylglycerol ethanolamine phosphotransferase assays. Cholinephosphotransferase activity was assayed in the microsomal fraction by determining the transfer of CDP-[^{14}C]choline to diacylglycerol (25). The reaction mixture contained 10 mM Tris-HCl (pH 8.5), 10 mM $MgCl_2$, 1 mM EDTA, 0.4 mM CDP-[^{14}C]choline (1.0 μCi/μmol), 0.2 mM diacylglycerol (prepared in 0.015% Tween 20) and approximately 0.1 mg protein in a final volume of 200 μL. The reaction was initiated by the addition of labelled CDPcholine, and the mixture was incubated at 37°C for 15 min. The reaction was terminated by the addition of 3 mL of chloroform/methanol (2:1, vol/vol), and water was added to cause phase separation. The organic phase was washed twice with 2 mL of 40% methanol and the radioactivity was determined. Analysis by TLC revealed that over 98% of the radioactivity in the lower phase was in the phosphatidylcholine fraction (25). Ethanolaminephosphotransferase activity was assayed in the microsomal fraction by measuring the transfer of CDP-[^{14}C]ethanolamine to diacylglycerol (26). The reaction mixture contained 10 mM Tris-HCl (pH 8.5), 10 mM $MnCl_2$, 1 mM EDTA, 0.2 mM CDP-[^{14}C]ethanolamine (1.0 μCi/μmol), 0.2 mM diacylglycerol (prepared in 0.015% Tween 20), and approximately 0.1 mg protein in a final volume of 200 μL. The reaction was initiated by the addition of labelled CDPethanolamine, and the mixture was incubated at 37°C for 15 lmin. The reaction was terminated by the addition of 3 mL of chloroform/methanol (2:1, vol/vol), and water was added to cause phase separation. The organic phase was washed twice with 2 mL of 40% methanol, and the radioactivity was determined.

Statistical analysis. Statistical analysis was performed using a two-tailed independent Student's *t*-test. The level of significance was set at $P < 0.05$.

RESULTS

The effect of lidocaine on glycerol uptake and phospholipid biosynthesis. Isolated hamster hearts were perfused with 1.0 mM [^{3}H]glycerol (3 μCi/μmol) for 30 to 90 min in the absence or presence of 0.5 mg/mL lidocaine. Subsequent to perfusion, the total uptake of radioactivity in the heart was determined. The total uptake of radiolabelled glycerol was found to be linear up to 60 min. An enhancement of uptake (88–128%) at all time points (Table 1) was observed when lidocaine was added to the perfusate. In a separate experiment, hearts were perfused with 0.1–2.0 mM glycerol (4.5 μCi/μmol) for 60 min. The uptake of glycerol was found to increase in a concentration-dependent manner between 0.1–1.0 mM (data not shown). The vast majority of the increase in radioactivity uptake was located in the lower (organic) phase of the tissue extract.

TABLE 1

The Effect of Lidocaine on the Uptake of Labelled Glycerol in the Perfused Hamster Heart[a]

	Uptake (10^{-3} × dpm/g wet weight of heart)		
Fraction	30 min (n = 4)	60 min (n = 11)	90 min (n = 3)
Total uptake			
Control	1808 ± 52	3463 ± 575	3826 ± 258
Lidocaine	3977 ± 31[b]	6504 ± 668[b]	8724 ± 1789[b]
Aqueous phase			
Control	948 ± 192	658 ± 113	707 ± 245
Lidocaine	875 ± 23	872 ± 145[b]	973 ± 350
Organic phase			
Control	1057 ± 66	3027 ± 600	3030 ± 799
Lidocaine	3131 ± 124[b]	5926 ± 702[b]	7777 ± 1499[b]

[a]Hamster hearts were perfused for the indicated times with Krebs-Henseleit buffer containing 1 mM [^{3}H]glycerol (3 μCi/μmol) in the absence or presence of 0.5 mg/mL lidocaine. After perfusion, the hearts were homogenized in chloroform/methanol (1:1, vol/vol). The tissue extracts were separated into aqueous and organic phases, and aliquots of the two phases were used for radioactivity determination. The results are expressed as mean ± standard deviation for n sets of experiments.

TABLE 2

The Effect of Lidocaine on the Labelling of Phospholipids and Neutral Lipids in the Hamster Heart[a]

Fraction	Uptake (10^{-3} × dpm/g wet weight of heart)	
	Control	Lidocaine
Lysophosphatidic acid	3.2 ± 0.7 (13)	9.0 ± 2.3[b] (12)
Phosphatidic acid	17.9 ± 3.7 (13)	42.1 ± 8.1[b] (12)
Phosphatidylcholine	172.0 ± 40.5 (9)	103.5 ± 11.9[b] (10)
Phosphatidylethanolamine	174.4 ± 29.4 (14)	448.4 ± 61.7[b] (9)
CDP-diacylglycerol	6.44 ± 1.2 (5)	16.22 ± 4.7[b] (4)
Phosphatidylinositol	35.0 ± 9.9 (13)	61.2 ± 10.2[b] (12)
Phosphatidylserine	22.0 ± 3.1 (13)	41.9 ± 5.5[b] (11)
Diacylglycerol	125.8 ± 29.0 (11)	450.4 ± 110.4[b] (8)
Triacylglycerol	1820.3 ± 508.4 (13)	3995.0 ± 671.1[b] (12)

[a]Hamster hearts were perfused for 60 min with Krebs-Henseleit buffer containing 1 mM [^{3}H]glycerol (3 μCi/μmol) in the absence or presence of 0.5 mg/mL lidocaine. After perfusion, the lipid fractions were separated by thin-layer chromatography, and the radioactivity in each fraction was determined. The results are expressed as mean ± standard deviation (number of experiments in parentheses).

[b]$P < 0.05$.

The labelling of phospholipids and neutral lipids in the heart after perfusion was determined. Phospholipid fractions in the lower phase of the tissue extract were separated by TLC, and the radioactivity in each fraction was determined. In a similar manner, neutral lipid fractions in the lower phase were separated by TLC, and the radioactivities associated with diacylglycerol and triacylglycerol were determined. As depicted in Table 2, perfusion of the heart with lidocaine for 60 min caused increases in the incorporation of radioactivities into lysophosphatidic acid (181%), phosphatidic acid (135%), phosphatidylethanolamine (157%), CDP-diacylglycerol (152%), phosphatidylinositol (75%) and phosphatidylserine (90%). The levels of labelling in diacylglycerol and triacylglycerol were also increased by lidocaine perfusion. In contrast, the labelling of the phosphatidylcholine fraction was decreased by 40%.

The determination of lipid contents in the heart after perfusion. Changes in the labelling of lipid fractions after perfusion with lidocaine might be caused by changes in pool sizes of these factions. Analysis of pool sizes of the various lipid fractions showed that lidocaine treatment did not cause any significant changes in the total amounts of phosphatidic acid, phosphatidylcholine, phosphatidylethanolamine, phosphatidylserine or phosphatidylinositol in the hamster heart (Table 3). In addition, the pool of CDP-diacylglycerol (12.1 ± 0.1 nmol/g wet weight) was unaffected by lidocaine treatment. However, perfusion with lidocaine caused increases in lysophosphatidic acid (50%) and diacylglycerol (67%) levels.

The effect of lidocaine on the activities of enzymes for the biosynthesis of cardiac lipids. The observed changes in the labelling of cardiac lipids might be caused by perturbations in the activities of the phospholipid biosynthetic enzymes.

TABLE 3

The Effect of Lidocaine on the Phospholipid and Neutral Lipid Contents in the Hamster Heart[a]

Fraction	Content (μmol lipid P/g wet weight of heart)	
	Control	Lidocaine
Lysophosphatidic acid	0.06 ± 0.01 (3)	0.09 ± 0.01[b] (3)
Phosphatidic acid	0.34 ± 0.08 (6)	0.28 ± 0.07 (6)
Phosphatidylcholine	11.14 ± 1.39 (6)	11.85 ± 1.12 (6)
Phosphatidylethanolamine	10.41 ± 1.18 (6)	9.61 ± 0.55 (6)
Phosphatidylserine	1.80 ± 0.32 (6)	1.55 ± 0.25 (6)
Phosphatidylinositol	1.23 ± 0.66 (6)	1.07 ± 0.43 (6)
Diacylglycerol[c]	3.29 ± 0.36 (6)	5.49 ± 0.95[b] (5)

[a]Hamster hearts were perfused for 60 min with Krebs-Henseleit buffer containing 1 mM glycerol. After perfusion, the lipid fractions were separated by thin-layer chromatography, and the amount of lipid in each fraction was determined. The results are expressed as mean ± standard deviation (number of experiments in parentheses).

[b]$P < 0.05$.

[c]Diacylglycerol content is expressed as μmol glycerol/g wet weight of heart.

TABLE 4

The Direct Effect of Lidocaine on the Activities of Lipid Biosynthetic Enzymes[a]

Enzyme	Activity (nmol/h per mg protein)	
	Control	Lidocaine (0.5 mg/mL)
Acyl-CoA:glycerol-3-phosphate acyltransferase (n = 3)	2.97 ± 1.13	6.64 ± 1.23[b]
Acyl-CoA:lysophosphatidic acid acyltransferase (n = 5)	1.05 ± 0.31	1.09 ± 0.31
Phosphatidate phosphatase (n = 3)	66.16 ± 19.16	75.16 ± 15.33
Acyl-CoA:1,2-diacylglycerol acyltransferase (n = 4)	36.90 ± 8.10	31.50 ± 10.50
CDPcholine:1,2-diacylglycerol cholinephosphotransferase (n = 3)	69.57 ± 22.19	40.33 ± 14.72[b]
CDPethanolamine:1,2-diacylglycerol ethanolaminephosphotransferase (n = 3)	19.72 ± 3.30	15.71 ± 1.35
CTP:phosphatidic acid cytidylyltransferase (n = 3)	0.33 ± 0.07	0.40 ± 0.10
Phosphatidylinositol synthase (n = 3)	0.52 ± 0.10	0.40 ± 0.03
Serine base exchange enzyme (n = 3)	0.13 ± 0.04	0.05 ± 0.03

[a]Enzyme activities were assayed in the presence of 0–0.5 mg/mL lidocaine. The results are expressed as mean ± standard deviation for n sets of experiments, each of which was performed in duplicate. Results were analyzed using a paired *t*-test. CoA, coenzyme A; CDPcholine, cytidine diphosphocholine; CDPethanolamine, cytidine diphosphoethanolamine; CTP, cytosine triphosphate.

[b]$P < 0.05$.

Hence, the direct effects of lidocaine on the activities of these enzymes were determined in subcellular fractions of the hamster heart. As depicted in Table 4, the activity of acyl-CoA:glycerol-3-phosphate acyltransferase was stimulated by lidocaine, which might account for the increased labelling of lysophosphatidic acid. The inhibition of CDPcholine:1,2-diacylglycerol cholinephosphotransferase activity might explain the decrease in the labelling of phosphatidylcholine. The activities of the other phospholipid biosynthetic enzymes were not significantly changed by lidocaine treatment.

The effect of lidocaine perfusion on the activities of the phospholipid biosynthetic enzymes in cardiac subcellular fractions was also examined. Hamster hearts were perfused for 60 min with 1 mM glycerol, in the absence or presence of 0.5 mg/mL lidocaine. Subsequent to perfusion, subcellular fractions of the hamster heart were prepared, and enzyme activities were determined in these fractions. As depicted in Table 5, perfusion with lidocaine did not cause any significant change in the activities of acyl-CoA:glycerol-3-phosphate acyltransferase or CDPcholine:1,2-diacylglycerol cholinephosphotransferase. A small enhancement (24%) of acyl-CoA:1,2-diacylglycerol acyltransferase was detected. There was no change in the total activity of phosphatidate phosphatase in the postmitochondrial fraction; however, the activity of this enzyme in the microsomal fraction was enhanced by lidocaine perfusion.

DISCUSSION

The *de novo* synthesis of phospholipids in mammalian tissues occurs *via* the progressive acylation of glycerol-3-phosphate. Because glycerol-3-phosphate does not readily permeate the plasma membrane, radiolabelled glycerol is usually used as a general precursor for studying phospholipid biosynthesis (6,10,20,27,28). In the hamster heart, the labelled glycerol is taken up rapidly and phosphorylated to glycerol-3-phosphate by glycerol kinase (10). The labelled glycerol-3-phosphate is then acylated to form lysophosphatidic acid and phosphatidic acid followed by the labelling of other phospholipids.

In the present study, perfusion of the isolated hamster heart with 0.5 mg/mL lidocaine elicited an enhancement of

TABLE 5

The Effect of Lidocaine Perfusion on the Activities of Lipid Biosynthetic Enzymes[a]

Enzyme	Activity (nmol/h per mg protein)	
	Control	Lidocaine
Acyl-CoA:glycerol-3-phosphate acyltransferase (n = 3)	2.84 ± 0.95	2.61 ± 0.73
Acyl-CoA:lysophosphatidic acid acyltransferase (n = 3)	1.68 ± 0.38	2.10 ± 0.39
Phosphatidate phosphatase		
Cytosolic (n = 6)	36.67 ± 8.28	35.51 ± 4.10
Microsomal (n = 3)	60.56 ± 4.22	76.20 ± 1.75[b]
CDPcholine:1,2-diacylglycerol cholinephosphotransferase (n = 3)	35.94 ± 12.61	53.84 ±
CDPethanolamine:1,2-diacylglycerol ethanolaminephosphotransferase (n = 3)	23.44 ± 2.21	29.08 ± 4.66
Acyl-CoA:1,2-diacylglycerol acyltransferase (n = 3)	41.40 ± 5.34	51.32 ± 3.02[b]
CTP:phosphatidic acid cytidylyltransferase (n = 3)	1.27 ± 0.32	1.16 ± 0.42
Serine base exchange enzyme (n = 3)	1.11 ± 0.36	1.54 ± 0.15

[a]Hearts were perfused with Krebs-Henseleit buffer containing 1.0 mM glycerol in the absence or presence of 0.5 mg/mL lidocaine. Enzyme activities were assayed in the subcellular fractions after perfusion. Results are expressed as mean ± standard deviation for n sets of experiments. Abbreviations as in Table 4.

[b]$P < 0.05$.

glycerol uptake. The drug concentration used in this study was significantly higher than the therapeutic dosage used in the treatment of cardiac arrhythmias (an initial dose of 200 mg administered over 15 min). Increases in the labelling of acidic phospholipids, phosphatidylethanolamine and neutral glycerolipids were detected. The increases in the labelling and the pool size of lysophosphatidic acid indicate that the biosynthetic process of acylation was also elevated. The direct stimulation of the acyl-CoA:glycerol-3-phosphate acyltransferase by lidocaine might provide an explanation for the increase in the labelling and the pool size of lysophosphatidic acid. Although the other phospholipid biosynthetic enzymes were not stimulated by lidocaine, the 2.8-fold increase in the labelling of lysophosphatidic acid would cause an increase in the labelling of phosphatidic acid and, subsequently, the other phospholipids.

The inability of lidocaine to elicit a direct stimulation of the activity of phosphatidate phosphatase did not provide an adequate explanation for the observed increase in the labelling of diacylglycerol. Hence, the modulation of enzyme activity by lidocaine perfusion was also explored. When the heart was perfused with lidocaine, acyl-CoA:glycerol-3-phosphate acyltransferase activity was not affected, but phosphatidate phosphatase and acyl-CoA:1,2-diacylglycerol acyltransferase activities were stimulated. At present, the exact mechanism for the modulation of these enzyme activities by lidocaine in the perfused heart remains undefined. It appears that the increase in the microsomal phosphatidate phosphatase activity did not result from a translocation of enzyme from the cytosol since the activity in the cytosolic fraction was unchanged. Two distinct types of phosphatidate phosphatase are associated with the microsomal fraction (29,30). In this study, we made no attempt in our assays to distinguish between the two enzyme types since both types hydrolyze phosphatidic acid to yield diacylglycerol. The stimulation of the microsomal phosphatase activity (31) may explain the increase in the labelling and pool size of diacylglycerol. The enhancement of acyl-CoA:1,2-diacylglycerol acyltransferase activity might also contribute to the observed increase in the labelling of triacylglycerol.

The decrease in the labelling of phosphatidylcholine was probably caused by a direct inhibition of cholinephosphotransferase activity by lidocaine. It is rather intriguing that similar inhibition of cholinephosphotransferase was not detected in the microsomes of the hamster heart after perfusion with lidocaine. The structural similarity between lidocaine and CDPcholine suggests that inhibition might take place at the substrate level. However, kinetic studies (data not shown) revealed that the inhibition was of the "mixed type," which suggests that lidocaine did not inhibit the reaction in a competitive manner. The fact that the labelling of phosphatidylcholine was reduced during lidocaine perfusion indicates that the direct inhibition of enzyme activity by lidocaine might also be an important mechanism for the regulation of phospholipid biosynthesis in the hamster heart. The differential effect of lidocaine on cholinephosphotransferase and ethanolaminephosphotransferase also suggests that there are separate and independent controls for the biosynthesis of phosphatidylcholine and phosphatidylethanolamine in the hamster heart.

Effects of Soybean Lipoxygenase-1 on Phosphatidylcholines Containing Furan Fatty Acids

Andreas Batna and **Gerhard Spiteller***

Lehrstuhl für Organische Chemie I, Universität Bayreuth, D-95440 Bayreuth, Germany

Naturally occurring tetraalkylsubstituted furan fatty acids (F-acids) were tested as potential substrates for soybean lipoxygenase-1. For this purpose, F-acid methyl ester and phosphatidylcholines containing F-acids at the *sn*-2 position of the glycerol residue were incubated with the enzyme. Oxidation of F-acids only occurs in the presence of linoleic acid as co-substrate. Linoleic acid is converted by lipoxygenase to the corresponding hydroperoxide that oxidizes the F-acid, probably in a radical reaction, to form an unstable dioxoene compound. This intermediate then forms, dependent on pH, unsaturated furanoid acids or isomers with cyclopentenolone structure that can be detected by gas chromatography/mass spectrometry (GC/MS). F-acids located at the *sn*-2 position of a synthetic phosphatidylcholine (PC), containing linoleic acid in the *sn*-1 position, are co-oxidized to a greater extent by incubation with soybean lipoxygenase-1 than are F-acids bound to PC with myristic acid in the *sn*-1 position when subjected to the enzyme in the presence of a great excess of linoleic acid. The results suggest that F-acids may play a strategic role in antioxidative processes in plant cells.

***Lipids* 29, 397–403 (1994).**

Furan fatty acids (F-acids) (**1**) (Scheme 1), first shown by Glass *et al.* (1,2), to occur in freshwater fish are apparently ubiquitous components of animal (3–6) and plant (7–9) tissues. Biogenesis (10–13) and metabolism (14–17) of F-acids have been studied intensively, but the biological role of F-acids is still obscure. First speculations that F-acids may be involved in animal reproduction rhythm (2) and embryo development (18) could not be confirmed yet. Nevertheless the wide distribution of F-acids and their similarities with physiologically active eicosanoids (19–21) and octadecanoids (22–24) seem to indicate that F-acids are not merely metabolic waste-products.

The furan ring in F-acids is highly reactive (2,25,26), and there is evidence that the oxidative opening of the furan ring yielding 1,4-dioxoenoic acids (**2**) may be of physiological importance. This reaction can be induced by singlet oxygen, organic peroxides and free radicals (27–30) (Scheme 1). Significant differences in the reactivity between naturally occurring tetraalkysubstituted F-acids (**1b**) and α-dialkylsubstituted model compounds (**1a**) were observed: Synthetic F-acids (**1a**), lacking methyl groups in the ß-positions of the furan ring, are oxidized *via* the *cis*-isomer **2a** to the corresponding stable *trans*-dioxoene compound **3** (29). In contrast, it is not possible to isolate analogous products by oxidation of tetraalkylsubstituted F-acids (**1b**): Alkaline extraction of their oxidation products **2b** yields isomers with cyclopentenolone structures **4** and **5** due to intramolecular

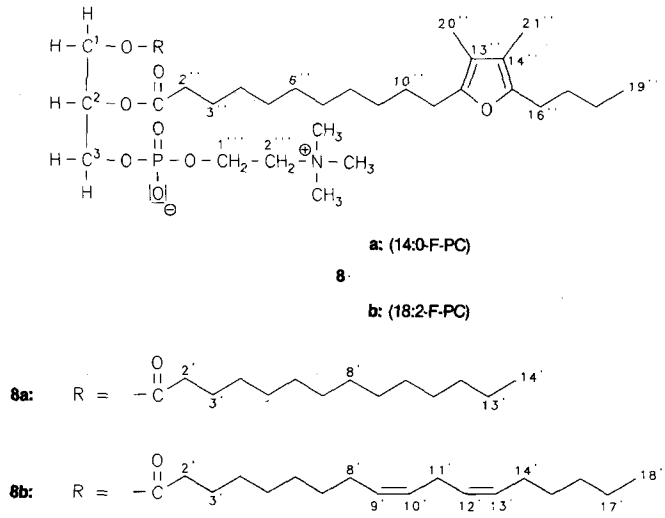

SCHEME 2

aldol condensation (31) (Scheme 1), while under acidic conditions **2b** reacts to isomeric unsaturated furanoid acids **6** and **7** by recyclization with introduction of a conjugated double bond (32) (Scheme 1).

Originally, the oxidation of F-acids (**1**) to the corresponding dioxoene compounds **2** was assumed to be directly effected by lipoxygenase (29,33). Recently it was demonstrated that dialkylsubstituted F-acids (**1a**) are not substrates of the enzyme (34,35).

In the present study the effects of soybean lipoxygenase-1 (LOX) on naturally occurring tetraalkylsubstituted F-acids (**1b**) were investigated. F-acid methyl ester, as well as phosphatidylcholines (PC) containing tetraalkylsubstituted F-acid in the *sn*-2 position of the glycerol residue, and either myristic acid (14:0-F-PC) (**8a**) or linoleic acid (18:2-F-PC) (**8b**) in the *sn*-1 position (Scheme 2, shown with chemical shift assignments) served as substrate for the experiments.

MATERIALS AND METHODS

Materials. All chemicals were of highest grade available and used without further purification. The solvents, if no other data are given, were of technical standard and freshly distilled before use.

Synthesis of 11-(3,4-dimethyl-5-butyl-furan-2-yl)undecanoic acid methyl ester. The methyl ester of tetra-alkyl-substituted F-acid (**1b**) was prepared following the methods of Rahn *et al.* (36) and Schödel and Spiteller (31) from 3,4-dimethyl-2-butylfuran by Friedel-Crafts acylation with undecanedioic acid monomethylester monochloride (37) followed by Huang-Minlon reduction (38). Purity according to gas chromatography (GC) was 94.2%; R_i = 2360.

*Preparation of 1-tetradecanoyl-2-[11-(3,4-dimethyl-5-butyl-furan-2-yl)undecanoyl]-*sn*-glycero-3-phosphocholine* (**8a**). Tetraalkylsubstituted F-acid methyl ester (15.2 mg, 43 µmol) was saponified with 2 mL 1 M NaOH (methanol/water, 9:1, vol/vol) at 60°C under argon for 90 min (39). After cooling, acidification with HCl (pH 1) and addition of water (50 mL), the acid **1b** was extracted with *n*-hexane/diethyl ether (50 mL; 4:1, vol/vol). The organic layer was washed twice with water (2 × 20 mL) and the organic solvent removed under reduced pressure. The residual yellow oil was evaporated to dryness under reduced pressure with addition of cyclohexane to azeotropically remove water from the sample. Condensation to **8a** was accomplished following a modification of the method by Mena and Djerassi (40): 4-dimethylaminopyridine (DMAP; 8 mg, 65.5 µmol, >98% by GC; Fluka, Neu-Ulm, Germany), 15 mg (32 µmol) 1-tetradecanoyl-*sn*-glycero-3-phosphocholine [99% by thin-layer chromatography (TLC); Sigma, Deisenhofen, Germany] and 9.6 mg (50 µmol) *N*-ethyl-*N'*-(3-dimethylaminopropyl)carbodiimide hydrochloride (EDC; >99%; Fluka) were suspended together with the F-acid (**1b**) in 5 mL dry dichloromethane (p.a.; Fluka). The mixture was stirred for 8 h under argon (Linde, Unterschleissheim, Germany). Excess dichloromethane was removed in a stream of nitrogen (Linde), and the 14:0-F-PC (**8a**) produced was extracted according to Bligh and Dyer (41). The crude product was purified by preparative TLC on Silica Gel 60 PF_{254} (Merck, Darmstadt, Germany) using chloroform/methanol/25% aqueous ammonia (65:35:7, by vol) as solvent system. A single band corresponding to 14:0-F-PC (**8a**) was identified by spraying the dry plates with Zinzadze reagent (42) (R_f = 0.29). Zinzadze reagent detects phosphoric acid by development of blue stain. The silica band was scraped off and eluted with 50 mL chloroform/methanol (1:1, vol/vol). Yield of 14:0-F-PC (**8a**): 16.2 mg (48%). The product was dissolved in benzene to obtain a stock solution that was frozen under argon at –20°C. The concentration of this stock solution was determined to be 7.65 µg 14:0-F-PC/µL. Quantification was done by peak area integration of GC measurements after saponification of a known amount of phospholipid. For that, 9-(3,4-dimethyl-5-butyl-furan-2-yl)nonanoic acid methyl ester was used as internal standard. Liquid secondary ion mass spectrometry (LSI–MS): $[M + H]^+$, *m/z* 786. ^1H nuclear magnetic resonance (NMR) (500 MHz) in C_6D_6/CD_3OD (2:1, vol/vol). δ 0.77 (3H, *t*, *J* = 7 Hz, H-19″), 0.81 (3H, *t*, *J* = 7 Hz, H-14′), 1.08–1.28 (34 H, *m*, H-4′ –H-13′, H-4″ – H-9″, H-18″), 1.44–1.58 (8H, *m*, H-3′, H-3″, H-10″, H-17″), 1.70 (3H, *s*, H-20″/H-21″), 1.72 (3H, *s*, H-20″/H-21″), 2.13 (2H, *t*, *J* = 7.5 Hz, H-2′/H-2″), 2.19 (2H, *t*, *J* = 7.6 Hz, H-2′/H-2″), 2.41 (2H, *t*, *J* = 7.1 Hz, H-11″/H-16″), 2.42 (2H, *t*, *J* = 7.0 Hz, H-11″/H-16″), 2.77 (9H, *s*, N-CH_3), 3.20–3.23 (2H, *m*, H-2‴), 4.06–4.13 (4H, *m*, H-1 and H-1‴), 4.19 (1H, *dd*, J_1 = 12.1 Hz, J_2 = 7.0 Hz, H-3a), 4.47 (1H, *dd*, J_1 = 12.1 Hz, J_2 = 3.1 Hz, H-3b), 5.33–5.38 (1H, *m*, H-2).

*Preparation of 1-(*cis*-9,*cis*-12-octadecadienoyl)-2-[11-(3,4-dimethyl-5-butyl-furan-2-yl)undecanoyl]-*sn*-glycero-3-phosphocholine* (**8b**). 1,2-Dilinoleoyl-*sn*-glycero-3-phosphocholine (25 mg, 32 µmol, 99% by TLC; Sigma) was dissolved in 5 mL diethyl ether and 250 µL H_3BO_3 solution (100 mM, pH 7.2) was added. After addition of 0.7 mg phospholipase A_2 (from *Naja mocambique mocambique*, isoenzyme pI = 8.8, lyophilized powder, 1540 units/mg protein; Sigma), which was suspended in 250 µL of buffer solution (100 mM Tris-HCl/4 mM $CaCl_2$,

pH 7.5) (Sigma), the mixture was homogenized with a vortex mixer (Bender & Hobein, Zürich, Switzerland). Then the suspension was shaken for 3.5 h under argon at 26.7°C in a water bath with repeated vortexing. After evaporation of the diethyl ether in a stream of nitrogen, the lysophosphatidylcholine produced was extracted according to Bligh and Dyer (41) (15 mL methanol, 15 mL chloroform, 13 mL 0.88% KCl solution). The organic solvent was removed under reduced pressure and the residue purified by TLC on Silica Gel 60 PF_{254} (Merck) plates using chloroform/methanol/25% aqueous ammonia (65:80:13, by vol) as solvent system. 1-(*cis*-9,*cis*-12-octadecadienoyl)-*sn*-glycero-3-phosphocholine was detected with Zinzadze-reagent (42) and eluted with 30 mL chloroform/methanol (1:1, vol/vol) and 20 mL methanol. Condensation of linoleoyl lysophosphatidylcholine was carried out as described for 14:0-F-PC (**8a**) by dissolving the PC in 5 mL dichloromethane and addition of an excess of *ca.* 19.5 mg F-acid (**1b**) (in 4 mL dichloromethane), 100 mg EDC and 20 mg DMAP. After purification by TLC (R_f = 0.57), the yield of 18:2-F-PC (**8b**) was 5 mg (19%). The 18:2-F-PC (**8b**) was dissolved in benzene, and the concentration of this stock solution was determined to be 13.6 µg 18:2-F-PC/µL as described for 14:0-F-PC. LSI–MS: $[M + H]^+$, *m/z* 838. ^1H NMR (500 MHz) in C_6D_6/CD_3OD (2:1, vol/vol). δ 0.80 (3H, *t*, *J* = 7.4 Hz, H-19″), 0.82 (3H, *t*, *J* = 6.7 Hz, H-18′), 1.10–1.62 (36H, *m*, H-3′ – H-7′, H-15′ – H-17′, H-3″ – H-10″, H-17″ and H-18″), 1.73 (3H, *s*, H-20″/H-21″), 1.75 (3H, *s*, H-20″/H-21″), 1.97–2.02 (4H, *m*, H-8′ and H-14′), 2.15 (2H, *t*, *J* = 7.4 Hz, H-2′/H-2″), 2.22 (2H, *t*, *J* = 7.5 Hz, H-2′/H-2″), 2.44 (2H, *t*, *J* = 7.3 Hz, H-11″/H-16″), 2.46 (2H, *t*, *J* = 7.3 Hz, H-11″/H-16″), 2.73 (9H, *s*, N-CH_3), 2.76–2.80 (2H, *m*, H-11′), 3.17–3.21 (2H, *m*, H-2‴), 4.11–4.17 (4H, *m*, H-1 and H-1‴), 4.24 (1H, *dd*, J_1 = 12.1 Hz, J_2 = 7.0 Hz, H-3a), 4.52 (1H, *dd*, J_1 = 12.0 Hz, J_2 = 3.0 Hz, H-3b), 5.33–5.45 (5H, *m*, H-9′ and H-10′, H-12′, and H-13′, H-2).

Incubation of 11-(3,4-dimethyl-5-butyl-furan-2-yl)undecanoic acid methyl ester. F-acid methyl ester (0.42 mg, 1.2 µmol), dissolved in 0.15 mL of acetone, was added to 5 mL of borate buffer (0.2 M, pH 9). The solution was stirred at 20°C for 1 h in the presence of pure oxygen (Linde) and in the darkness as well as under irradiation with two white fluorescent lamps (Gro-Lux Sylvania 20W; Fa. Feustel, Bayreuth, Germany; and Tungsram F-25 U-White 20W; Tungsram, Vienna, Austria). The experiment was also done under the following conditions: (i) with addition of linoleic acid (0.75 mg, 99% by GC; Fluka); and (ii) with addition of LOX (7 mg, lyophilized powder, 150000 U/mg protein, M_r *ca.* 108000; Fluka); and (iii) with addition of linoleic acid (0.75 mg, 2.7 µmol) and soybean lipoxygenase (7 mg, 64 nmol) to the solution of F-acid methyl ester in borate buffer. After acidification with concentrated HCl (pH 1–2), each sample was extracted with chloroform (2 × 10 mL) and, after dissolving in methanol, esterified with diazomethane in diethyl ether at room temperature. Excess reagent was removed in a stream of nitrogen, and the residual solution was evaporated to dryness under reduced pressure. The extracts were dissolved in benzene (0.5 mL) and analyzed by GC and GC/mass spectrometry (GC/MS). Quantification was done by peak area integration.

Oxidation experiments with 14:0-F-PC (**8a**) *and 18:2-F-PC* (**8b**). The 5.5 µL 14:0-F-PC stock solution (*ca.* 40 µg or 54 nmol 14:0-F-PC **8a**) were evaporated to dryness under a stream of nitrogen. The substrate was suspended in 500 µL borate buffer (0.2 M, pH 9) containing 2 mmol sodium deoxycholate, and this mixture was stirred for 1 h at room temperature under pure oxygen (Linde). The experiment was repeated under addition of 1 mg LOX (Fluka) to the buffer solution. Another incubation was done with 14:0-F-PC (**8a**) by further addition of *ca.* 15 mg (53 µmol) linoleic acid (99%, Fluka) and 1 mg LOX. Incubations with 18:2-F-PC **8b** were carried out with 3 µL 18:2-F-PC stock solution (*ca.* 40 µg/48 nmol 18:2-F-PC **8b**). Reactions were done with and without addition of LOX as described for 14:0-F-PC. After incubation for 1 h, the samples were extracted using a modified Bligh and Dyer procedure (41,43,44) (19 mL methanol, 19 mL chloroform, 17 mL 0.88% KCl solution). The dry extracts were transesterified (45) and, after addition of 9-(3,4-dimethyl-5-butyl-furan-2-yl)-nonanoic acid methyl ester as internal standard, were methylated with diazomethane in methanol/diethyl ether. Excess reagent was removed in a stream of nitrogen and the residue dissolved in benzene (20 µL). Each sample was trimethylsilylated for 12 h in the darkness at room temperature by addition of *N*-methyl-*N*-trimethylsilyltrifluoroacetamide (MSTFA; 20 µL, Macherey & Nagel, Düren, Germany) and analyzed by GC and GC/MS.

GC and GC/MS. GC was done on a Packard model 438S, United Technologies (Delft, The Netherlands), on a 30 × 0.3 mm fused-silica column DB 1 temperature programmed from 100 to 280°C at 2°C/min. Injector and flame-ionization detector (FID) temperatures were kept at 270 and 290°C, respectively. Carrier gas was hydrogen, and the split ratio was 1:30. Quantification was by peak area integration using a Shimadzu (Duisburg, Germany) C-R3A integrator. Retention indices were determined according to Kováts (46) with *n*-alkanes (C_{12} to C_{30}) as reference compounds.

GC/MS measurements were performed on a Finnigan MAT 95 (Bremen, Germany) double-focusing spectrometer with a MAT-ICIS data system. Electron impact mass spectra were recorded at an ionization energy of 70 eV. For GC, an HP (Hewlett-Packard, Böblingen, Germany) 5890 series II instrument was used with a 30 m × 0.3 mm fused-silica column DB 1. The carrier gas was hydrogen, and the temperature was programmed as used for analytical GC.

LSI–MS. LSI–MS mass spectra were obtained on a Finnigan MAT 8500 mass spectrometer using an SS 300 data system. The target surface was bombarded with an energized Cs^+ ion beam (3 KeV) using a Cs^+ gun (AMD Intectra, Beckeln, Germany). The sample was dissolved in 0.3 µL of acetonitrile (Zinsser Analytik, Frankfurt/M., Germany)/0.1% aqueous trifluoroacetic acid (Fluka) (1:9, vol/vol) and the solution added to 0.5 µL glycerol matrix (Sigma). The exchangeable stainless-steel target has a sample area of 2 mm^2.

NMR spectroscopy. ^1H NMR spectra were recorded on a Bruker (Rheinstetten, Germany) AM 500 spectrometer in C_6D_6/CD_3OD (2:1, vol/vol) (Aldrich, Steinheim, Germany). Chemical shifts are reported relative to tetramethylsilane.

RESULTS

Incubation experiments with F-acid methyl ester. The methyl ester of F-acid **1b** was dissolved in borate buffer (pH 9) and the solution stirred under pure oxygen for 1 h either in the darkness or by irradiation with two white fluorescent lamps. The F-acid was recovered unchanged, as it was when linoleic acid was added to the solution. Also no oxidation was observed after incubation of F-acid methyl ester together with LOX, but in absence of linoleic acid. Only if the co-oxidant linoleic acid was added to the mixture, was the F-acid oxidized. The extent of oxidation did not depend on whether the incubation was carried out in the darkness or with illumination. Due to quantification of GC measurements, approximately 30% of the F-acid methyl ester was recovered unchanged, while the rest was converted to the isomeric unsaturated furanoid esters (**6**) and (**7**) during the acidic extraction procedure. Products **6** and **7** were identified by GC/MS, and Table 1 shows the major, analytically important MS peaks. During the incubation, the co-substrate linoleic acid was almost totally oxidized by the enzyme. Apart from several oxidation products (47), *ca.* 1.0% of linoleic acid was recovered after 1 h. These experiments prove that naturally occurring tetraalkylsubstituted F-acids are not substrates of the enzyme lipoxygenase.

Oxidation experiments with 14:0-F-PC (**8a**) *and 18:2-F-PC* (**8b**). The ability of LOX to oxidize doubly unsaturated fatty acids is not limited to free acids and methyl esters (48), but PC are equally susceptible to oxygenation by the enzyme (49,50). This reaction depends on the solubility of the phospholipid, which is mediated by addition of bile salts (49). The rate of oxidation shows a complex dependency on the concentration of bile salts in the aqueous solutions (49). We investigated in a model system the reactivity of PC-bound tetraalkylsubstituted F-acids in the course of phospholipid oxygenation catalyzed by LOX in the presence of sodium deoxycholate.

TABLE 2

Oxidation Rate of Furan Fatty Acid (F-acid) Bound to Phosphatidylcholine (PC) During Lipoxygenase-Catalyzed Phospholipid Oxygenation[a]

Incubation	Recovered F-acid (%) Control	Recovered F-acid (%) With LOX[b]	Oxidized F-acid (% conversion) (Control = 100%)
14:0-F-PC	88.6 ± 4.6	88.5 ± 1.7	—
14:0-F-PC + 18:2	86.5 ± 5.0	48.6 ± 3.9	43.8
18:2-F-PC	92.7 ± 0.9	42.7 ± 6.6	53.9

[a]Data were obtained by peak area integration of gas chromatography measurements using an internal standard for quantification. Values are shown as mean ± SD (n = 3).

[b]LOX (soybean lipoxygenase), lyophilized powder, M_r ~ 108.000, 150.000 U/mg protein.

In control experiments (Table 2) designed to test the oxidative stability of the substrate, solutions of 14:0-F-PC (**8a**), 18:2-F-PC (**8b**) or 14:0-F-PC and added linoleic acid were stirred for 1 h under an oxygen atmosphere in the absence of lipoxygenase. After alkaline transesterification, F-acids were recovered in high yields ranging from 86.5 to 92.7% as judged by integration of GC peak areas (Table 2). Due to oxidation during the extraction procedure, the residual amount of F-acids was oxidized to the two corresponding cyclopentenolone isomers **4** and **5** as confirmed by GC/MS (Table 1).

When 14:0-F-PC (**8a**) was subjected to LOX-induced oxygenation, no reaction occurred, and the same amount of F-acid (*ca.* 88.5%) was recovered as in the control experiment without added enzyme (Table 2).

By contrast, after addition of LOX to the solution of 18:2-F-PC, more than 50% of the F-acid was oxidized (Table 1). Correspondingly higher amounts of the cyclopentenolone isomers **4** and **5** were detected after the alkaline extraction procedure together with several oxidation products of linoleic acid (47). About 3.8% of linoleic acid originally bound to PC was recovered in this experiment.

After incubation of a mixture of 14:0-F-PC (**8a**) and a thousandfold excess of linoleic acid with LOX, a lower yield of F-acid oxidation products (*ca.* 44%) was seen than was observed by incubation of 18:2-F-PC (**8b**) alone with LOX (Table 2). But the oxidation rate of linoleic acid was much higher than that measured when 18:2-F-PC was incubated with LOX. Only *ca.* 2% of the added linoleic acid were recovered.

DISCUSSION

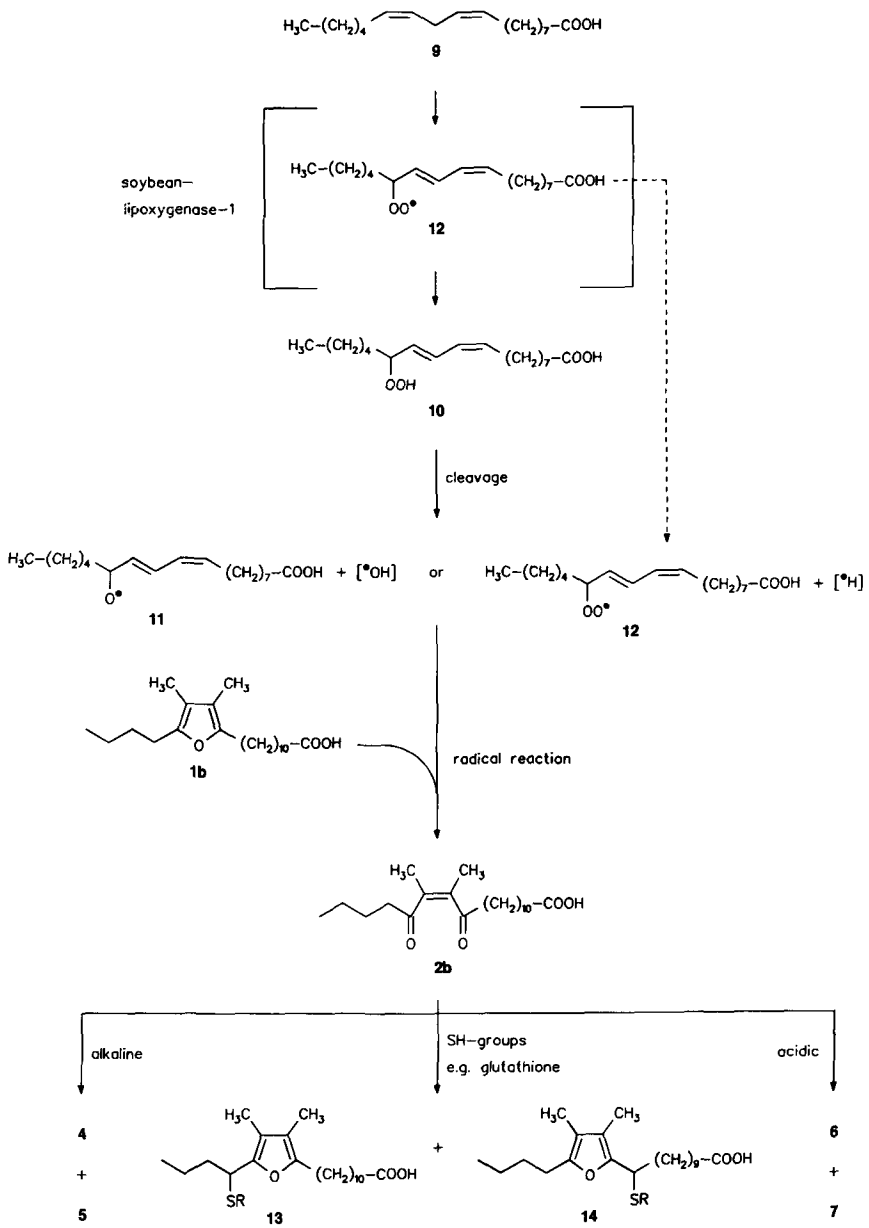
Recently, Zabolotsky *et al.* (34) have shown that dialkyl-substituted F-acids (**1a**) are not attacked by lipoxygenase. Studies in our laboratory have revealed that F-acids lacking methyl groups in ß-position of the furan ring (**1a**) are oxidized in the course of the reaction of LOX with linoleic acid (**9**) (35). Oxidation also occurs by addition of preformed linoleic acid hydroperoxide to the F-acid (35). The reaction can be suppressed by inclusion

of EDTA into the reaction system. This substance is well known for complexing of transition metal ions, especially Fe^{2+}, which induce the decomposition of the hydroperoxide. This behavior is a strong indication for a radical induced transformation of F-acids (35). Only small amounts of oxidation products (**3**) (<1%) could be detected due to the relatively low reactivity of the furan ring in dialkylsubstituted F-acids (35).

In the present paper we demonstrate that tetraalkylsubstituted F-acids (**1b**), either as their methyl ester or when incorporated in PC (**8**), are oxidized by LOX only in the presence of substrates of the enzyme, e.g., linoleic acid. Under these reaction conditions, tetraalkylsubstituted F-acids (**1b**) were converted to the corresponding intermediate dioxoene compounds (**2b**) in yields of *ca.* 50% when bound to PC and *ca.* 70% when present as methyl ester. Thus tetraalkylsubstituted F-acids do not serve as enzyme substrates, but they are co-oxidized much more readily in the course of the lipoxygenase reaction than are the dialkylsubstituted F-acids.

These results are in agreement with the previous observation that F-acids with four substituents on the furan ring are capable of scavenging free radicals as they are generated during oxidation reactions, while dialkylsubstituted F-acids showed only little reactivity in this respect (51). This susceptibility of the furan ring to oxidation led to the assumption that F-acids may serve as antioxidants in biological systems (51,52).

Based on this, we propose the reaction sequence for the co-oxidation of F-acids as illustrated in Scheme 3 to describe the biological relevance of F-acids. The biosynthetic sources of F-acids are plants (9,53), where they



SCHEME 3

are predominantly bound to phospholipids (54). For instance, in the course of cell injury, plant cells liberate *via* phospholipases polyunsaturated fatty acids, e.g., linoleic acid (**9**) from phospholipids (55). These can be converted by activated lipoxygenases (55) to the corresponding hydroperoxides (**10**) (56). The primary oxidation products (**10**) may be cleaved either to the alkoxyl- (**11**) or peroxyl-radicals (**12**) (47,57). While the alkoxyl radial cyclizes rapidly to an epoxyallylic radical (58) the lifetime of the peroxyl radical is quite long (59), and therefore it is able to oxidize furans (60). We speculate that one of these species oxidizes tetraalkylsubstituted F-acids (**1b**) to the dioxoene compounds (**2b**). The latter are unstable and are further converted to other products, dependent on the pH of the medium (33) (Scheme 3).

Alternatively, during enzymatic hydroperoxide formation, highly reactive peroxyl radicals (**12**) are formed (61). In a type-1 lipoxygenase reaction, the substrates seem to have relatively good mobility when bound to LOX (62). Based upon electron spin resonance measurements, the motion of intermediate peroxyl radicals was found not to be restricted during enzymatic fatty acid oxidation (61). It appears that the lifetime of the intermediate peroxyl radical is possibly long enough to react with F-acids (**1b**) producing the corresponding dioxoenoic acids (**2b**), which are further converted as described above (Scheme 3).

To simulate the reactivity of F-acids bound to cell membranes, we investigated the co-oxidation of F-acids bound to phospholipids during enzymatic oxidation with lipoxygenase. The synthetic model compounds 14:0-F-PC and 18:2-F-PC were incubated with the enzyme. Due to the increased oxidation rate of 18:2-F-PC as compared to the oxidation of 14:0-F-PC and a great excess of linoleic acid with LOX (Table 1), our experiments strengthen the hypothesis of a possibly favored intramolecular mechanism. The radical intermediates **11** or **12** may attack the adjacent F-acid in PC more easily than F-acid of another PC molecule, producing a dioxoene-compound (**2b**), which could further react to products **4–7**.

The reactions of the chemically highly reactive intermediate dioxoene compounds (**2b**) (63,64) with thiols, e.g. cysteine or glutathione may be of physiological importance. In the course of these reactions, isomeric thio ethers (**13**) and (**14**) are formed (33,65) (Scheme 3). Therefore, the oxidative opening of the furan ring may introduce changes in structure of cell proteins by reaction with amino acids containing a sulfhydryl group. Thus, the reaction sequence discussed could play a crucial part in the plant defense system against cell injury.

ACKNOWLEDGMENTS

We thank the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie for financial support. We are obliged to Dr. J. Reiner for measurement of NMR spectra and to M. Glaessner for recording the mass spectra. We are also grateful to D. Laatsch for maintenance of the gas chromatograph and to W. Kern for distillation of solvents. Special thanks are due to K. Hannemann for experimental assistance.

Cholesterol Secretion from Hepatocytes Induced by Triacylglycerol and Apolipoprotein E

Steven H. Quarfordt*, Barry A. Landis, Marwan O. Farouk and Brian S. Oswald

Departments of Medicine and Surgery, Durham Veterans Administration and Duke University Medical Center, Durham, North Carolina 27705

The mechanism for the increase in plasma cholesterol levels in cholesterol-fed rats following chylomicron transport was investigated in intact animals, in isolated perfused liver, and in hepatocytes in monolayer cultures. Intravenous administration of egg phosphatidylcholine in amounts greater than those required to cause a plasma cholesterol response when given as chylomicrons was without effect. This makes it unlikely that increased plasma cholesterol levels resulted from the recruitment of tissue cholesterol by the plasma chylomicron phospholipids that persisted in the plasma after triacylglycerol clearance. The hepatic origin of the increased plasma cholesterol levels was directly confirmed by two hepatic perfusion experiments. When cholesterol-fed rats received intravenous chylomicrons prior to isolated hepatic perfusion, more cholesterol was secreted by the liver than when the rats were injected intravenously with buffer. Perfusion of apolipoprotein E (apo E)-rich triacylglycerol emulsions through the livers also enhanced cholesterol secretion. The increase in hepatocyte cholesterol secretion seen with cholesterol-fed rats was also noted in monolayer cultures following incubation with apo E rich-triacylglycerol emulsions. The apolipoprotein or the emulsion alone, or apo E-rich phosphatidylcholine liposomes, had no effect. The data confirm previous indirect observations that the liver is the source of cholesterol that appears in plasma following transport of chylomicrons or following a lipid-rich meal in cholesterol-fed rats. The data also re-emphasize the importance of providing apo E with triacylglycerol emulsions to initiate secretion of lower density lipoproteins by the liver.

***Lipids* 29, 405–410 (1994).**

Chow-fed rats transport plasma cholesterol primarily in high density or alpha lipoproteins. Cholesterol feeding provokes a modest increase in plasma cholesterol concentration as well as a lipoprotein shift to lower density (d < 1.063) lipoproteins with broad beta mobility (1). This lipoprotein response to cholesterol feeding is only partially understood (2,3). Livers from cholesterol-fed rats have considerably more cholesterol, primarily as cholesteryl esters, than do livers from chow-fed animals, and they secrete more lower density/broad beta lipoprotein cholesterol during isolated hepatic perfusion. The increased cholesterol intake would also reduce the number of low density lipoprotein (LDL) receptors and thus limit LDL catabolism (3).

Human plasma cholesterol concentrations and lipoprotein patterns appear to be influenced more by the amounts and types of triglycerides in the diet than by dietary cholesterol (4). This critical effect of plasma chylomicron flux on plasma LDL cholesterol concentration in humans is not yet well understood (5). Aside from providing a vehicle for the delivery of intestinal cholesterol to the liver for storage, it is likely that the influx of chylomicron remnants signals to the liver to alter plasma lipoprotein flux.

We have observed (6,7) a potent effect of chylomicrons or of particulate triacylglycerol emulsions on plasma cholesterol concentrations in cholesterol-fed rats. Six hours after the plasma clearance of the particulate triacylglycerols, a large (often 2–3-fold) increase in lower density (d < 1.063) lipoprotein cholesterol levels was observed. This was only noted in rats that respond to dietary cholesterol with appreciable increases (greater than threefold) in hepatic cholesterol levels. The effect was unrelated to the inevitable hepatic influx of free fatty acids following triacylglycerol clearance, and did not occur in the anhepatic cholesterol-fed rat (6). These indirect data indicate that the liver may be responsible for the cholesterol increase following plasma particulate triacylglycerol clearance. To test this, a more direct investigation into the role of liver in these processes was undertaken using the isolated perfused liver and hepatocyte in monolayer cultures. The results described here are consistent with our previous suggestion that hepatic secretion is responsible for plasma cholesterol increases and suggest that this secretion is triggered by the final step in plasma triacylglycerol clearance, the uptake of remnants by the cholesterol-loaded liver.

EXPERIMENTAL PROCEDURES

Animals and surgical procedures. Male Sprague-Dawley rats (250–400 g) were purchased from Charles River (Raleigh, NC). The rats were maintained either on conventional chow or on chow supplemented with 2% cholesterol (ICN Chemicals, Costa Mesa, CA) under a 6 a.m.–6 p.m. light cycle. Chylomicrons, triolein (Sigma, St. Louis, MO) emulsions, or egg phosphatidylcholine (Avanti, Alabaster, AL) dispersions were injected through the penile vein with the rats under light pentobarbital anesthesia. The rats were bled from the tail vein. Chylomicrons were obtained from the mesenteric lymphatics after duodenal infusion of 50 mg of monoolein (Sigma) and 50 mg of oleic acid (Sigma) in 5 mL of phosphate-buffered (pH 7) isotonic saline (PBS) using standard procedures (8).

Recirculating *in vitro* liver perfusion was performed by the technique of Mortimore (9). Cholesterol-rich livers were perfused at 2.5 mL/min/g with 3.5% bovine serum albumin and 10% canine erythrocytes in 200 mL Krebs bicarbonate buffer (pH 7.4) at 37°C. The erythrocytes were washed extensively with saline prior to use.

Abbreviations: Apo E, apolipoprotein E; FBS, fetal bovine serum; HDL, high density lipoproteins; LDL, low density lipoprotein; MEM, minimal essential medium; PBS, phosphate buffered saline; P/C, phosphatidylcholine/cholesterol; P/C-E, P/C-apoE; VLDL, very low density lipoprotein.

Bile flow was measured to monitor the functional state of the liver, and values ranged from 0.4–0.6 mL/h for the 6-h perfusion. Two hours prior to the perfusion, some of the rats were injected with 20 mg of triolein in the form of an egg lecithin/triolein emulsion in 2 mL PBS, while controls received 2 mL PBS. In other liver perfusions, 20 mg of the triolein emulsion and 2 mg of rat apolipoprotein E (apo E) were added to the perfusate 2 h after the perfusion was begun. Aliquots of the perfusate were obtained at half-hour intervals to assay cholesterol mass and lipoprotein distribution.

Cell culture. Hepatocytes and Kupffer cells were obtained from cholesterol-fed rats by a modified (10) collagenase perfusion of the liver as previously described (11). After perfusion of 250 mL of calcium-free [2-hydroxyethyl]piperazine [2-ethanesulfonic acid] (pH 7.4) buffer and 250 mL of 0.05% collagenase, cells were freed and filtered at 4°C. The cells were spun in a Sorvall RC2-B centrifuge (Newton, CT) using an SS-34 rotor at 500 rpm for 2 min at 4°C and then washed three times with calcium-free buffer. An aliquot of the cells was applied to 45% Percoll and centrifuged at 16,000 rpm for 20 min in the Sorvall centrifuge to generate a d 1.1016–d 1.139 gradient. Banding of cells occurred according to cell cholesterol contents ranging from 160 to 20 µg/mg cell protein. The cells were centrifuged out of Percoll into Eagle's minimal essential medium (MEM) with 5% fetal bovine serum (FBS), counted in a hemocytometer, and assayed for viability (11).

Approximately 1.2×10^6 hepatocytes were plated per 35-mm collagen-coated tissue culture dish. The culture medium was 1 mL of MEM containing nonessential amino acids, 10% FBS, 10^{-7} M insulin and 2 µg gentamycin sulfate. Cultures were changed after 2 h to MEM without FBS and maintained in a 95:5% O_2/CO_2 atmosphere at 37°C for up to two days prior to study. Experiments were initiated only after it was demonstrated that apo E enhanced the entry of chylomicrons into the cells (11).

Experiments were initiated by adding chylomicrons, or triolein emulsions, to the MEM at a concentration of 200 µg/mL with or without rat apo E (100 µg/mL), or by adding rat apo E alone (100 µg/mL). The medium was changed after 2 h and assayed for free and total cholesterol. After these initial 2-h incubations, the medium was changed to MEM at 2 h, and again at 12 h, and assayed for free and total cholesterol mass and for radioactivity. Cells were also harvested and assayed for free and total cholesterol, as well as protein.

Apolipoprotein preparation. Apo E was prepared from rat plasma d < 1.21 lipoprotein (12) that had been delipidated with 150 mL of ethanol/diethyl ether (3:1, vol/vol) after dialysis against 0.1% ethylenediaminetetraacetic acid and lyophilization. The nitrogen-dried residue was dissolved in 0.05 M NaCl, 2 mM phosphate pH 7.4 and 5 M urea, and then applied to a heparin affinity column to separate apo E from the other apo-lipoproteins, as previously described (13). Rat apo-lipoproteins A-I and C-III were prepared from the heparin-unbound fraction by sequential molecular sieving (4 M guanidine Sephacryl 300) and diethylaminoethyl cellulose chromatography (14). The purity of the isolated apoproteins was verified by sodium dodecylsulfate–polyacrylamide gel electrophoresis (15). Triolein emulsions, egg lecithin and egg lecithin/free cholesterol (1:1 molar ratio) liposomes were prepared by sonication as previously described (16).

Chemical assays. Total cholesterol mass was determined in media and hepatocytes by both a colorimetric method (17) and by a modified enzymatic assay (Wako Chemicals, Dallas, TX). Free cholesterol was also determined by a modified enzymatic assay (Wako Chemicals). The media and cells were extracted by the Dole method (18), and the organic phases dried under N_2. The residues were then reconstituted with 10 µL of isopropanol and 1 mL of 0.15 M Tris (pH 7.0) 0.1% *p*-chlorophenol containing 0.13 U of both cholesterol ester hydrolase and cholesterol oxidase with 2.4 U of peroxidase, and 4-aminoantipyrine. A standard curve for cholesteryl ester ranging from 2.5–20 µg cholesterol was run in each series along with a laboratory standard. The mixture was incubated for 5 min at 37° and then read at room temperature in a Gilford 230 spectrophotometer at 505 nm. Free cholesterol mass was assayed similarly without use of cholesterol ester hydrolase.

Plasma, perfusate and media lipoproteins were separated into very low density (VLDL; d < 1.006), (LDL; d 1.006–d 1.063), and high density (HDL; d 1.063–d 1.21) by a previously described (12) ultracentrifugation method. After dialysis with PBS, the total d < 1.21 lipoproteins were separated into supernatant and lower fractions by heparin/Mn^{++} precipitation (19). The total d < 1.21 lipoproteins were also separated into heparin/Sepharose-bound and -unbound fractions, as previously described (13). All data are expressed as means ± standard errors; significances were determined by two-tailed Student's *t*-test.

RESULTS

After intravenous injection of 15 mg of chylomicron triacylglycerols into fasted (10 h) male rats, which had been fed cholesterol for six weeks, plasma cholesterol levels increased to more than twice the baseline level (Fig. 1, top panel). Chylomicron clearance was followed by a 5–6 h latency period with stable plasma cholesterol levels prior to the subsequent increase. At least 7.5 mg of cholesterol must have been transferred to plasma (assuming a plasma volume corresponding to 4.5% body weight) to produce the observed increase. Prior to injection, 76 ± 7% of total plasma cholesterol was in ester form, and at the peak plasma level 69 ± 11% (not significantly different). A 15-mg intravenous bolus of an egg phosphatidylcholine dispersion, equivalent to about five times the injected chylomicron phospholipid amount, did not produce the chylomicron effect (Fig. 1, bottom panel). Only a significant gradual increase in free cholesterol occurred, with no change in total cholesterol.

Cholesterol-fed rats (8 wk) were given 20 mg of chylomicron triacylglycerols or an equal volume of PBS through the penile vein 2 h prior to the subsequent *in vitro* liver perfusion. For the first 2 h of perfusion, the

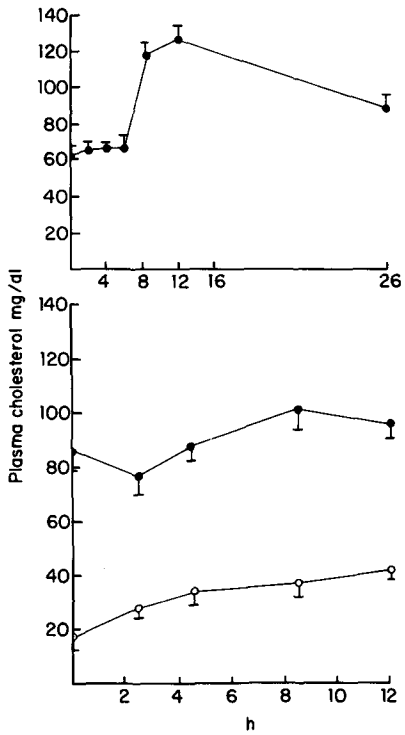

FIG. 1. Top panel: plasma total cholesterol concentration (±SE) in five rats fed a 2% cholesterol supplemented diet for six weeks following intravenous chylomicron administration (15 mg triglyceride) at 0 h. All concentrations after 6 h are significantly ($P < 0.02$) greater than the preinjection (0 h) values. Bottom panel: plasma total (●) and free (○) cholesterol concentrations (±SE) in four of the cholesterol-fed rats used for the chylomicron studies (top) following 15 mg of intravenous egg phosphatidylcholine. All free cholesterol concentrations after the phospholipid injection were greater ($P < 0.05$) than the preinjection (0 h) values.

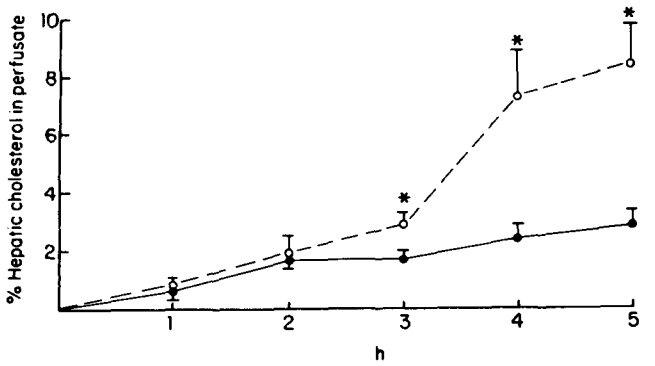

FIG. 2. The fraction of hepatic cholesterol appearing in the perfusate of an isolated *in vitro* perfused liver 2 h after intravenous chylomicron administration (20 mg triglyceride) (○) (n = 5); or buffer (●) (n = 6). The mean (SE) hepatic cholesterol was 34 (12) mg/g liver for the chylomicron injection and 29 (10) mg/g liver for the buffer injection. A significantly ($P < 0.02$) greater fraction of hepatic cholesterol was recovered in the perfusate of the chylomicron-injected than the buffer-injected group at 3, 4, and 5 h (*).

increase in perfusate cholesterol was similar (Fig. 2) for chylomicron and PBS injected rats. In the final 3 h, the perfusates of chylomicron-injected rats were significantly richer in cholesterol than were the controls. After 5 h, cholesteryl esters amounted to 68 ± 8% of the perfusate total cholesterol in the chylomicron-injected rats (n = 5) which was similar to the value (71 ± 4%) found in controls (n = 5). In both, after 5 h, more than 78% of the perfusate cholesterol was associated with heparin/Mn^{++}-precipitable lipoproteins. These 5-h perfusate lipoproteins were ultracentrifuged at d 1.006, d 1.063 and d 1.21. The mean (±SE) percentage distributions of perfusate lipoprotein cholesterol in buffer-injected rats (n = 3) was 16 ± 7, 39 ± 11 and 44 ± 12%, which was similar to the values measured for the perfusates of chylomicron-injected rats (n = 3), i.e., 14 ± 6, 47 ± 13 and 39 ± 14% in HDL, LDL and VLDL, respectively. The LDL and VLDL of both groups of rats had broad beta electrophoretic mobility.

Monolayer cultures of cholesterol-rich hepatocytes from rats fed a cholesterol-enriched diet responded to a soy triacylglycerol emulsion supplemented with rat apo E (Table 1). A significant increase in media cholesterol levels was observed during the 2-h incubation with the apo E-supplemented triacylglycerol emulsion when compared to cells maintained in unsupplemented media, or cells in media that contained only the emulsion, apo E or Na oleate. After the media were removed, the cells were washed with PBS and incubated with MEM alone for 12 h. The cells exposed to the apo E/triacylglycerol emulsions had significantly more media cholesterol than con-

TABLE 1

Induction of Cholesterol Secretion by Hepatocytes in Monolayer Culture[a]

Additions	μg Medium cholesterol/mg cell protein	
	2 h	14 h
None	2.5 (0.4)	5.7 (0.8)
Emulsion 200 μg triacylglycerol (TG)/mL	2.9 (0.3)	6.4 (1.1)
Emulsion 200 μg TG/mL plus apo E 100 μg/mL	5.7 (0.9)[b]	16.3 (2.0)[c]
Apo E 100 μg/mL	2.1 (0.2)	4.0 (0.3)
Na oleate 0.75 mM	3.6 (0.4)	4.5 (0.6)

[a]The results are the means (SE) of quadruplicate determinations of medium total cholesterol at 2 and 14 h after incubating monolayer cultures of cholesterol-rich hepatocytes [88 ± 18 μg/mg (n = 8) cell protein] from rats fed a 2% cholesterol diet for seven weeks, with the triacylglycerol-rich fraction of a commercial soy oil emulsion and/or rat apolipoprotein E (apo E) in minimal essential medium (MEM). The added emulsion contained less cholesterol than was detectable by the assay. The monolayers were maintained on fetal bovine serum for 36 h before apo E response was seen (Ref. 11).

[b]The media of the hepatocytes exposed to emulsion and apo E contained significantly more cholesterol at 2 h than the unsupplemented media (at $P < 0.02$), or the solely emulsion ($P < 0.05$) or apo E ($P < 0.01$) exposed hepatocytes.

[c]The 14-h media (which had been changed to MEM after the initial 2 h incubation) of hepatocytes exposed to emulsion and apo E contained significantly more cholesterol than controls or emulsion exposed cells ($P < 0.01$) or cells solely exposed to apo E ($P < 0.001$). The percentages of free cholesterol (29 ± 7) in this media was not different from those in the 14-h control media (35 ± 9) without additions.

TABLE 2

Changes in Perfusate Cholesterol Levels upon Infusion of an Apo E-Rich Triolein Emulsion[a]

Perfusion	μg Cholesterol/mL/h	
	Before	After
1	1.88 (0.09)	2.68 (0.13)[b]
2	0.92 (0.22)	2.00 (0.22)[c]
3	1.23 (0.41)	2.43 (0.74)
4	0.46 (0.14)	1.00 (0.10)[d]
Control	0.88 (0.24)	0.94 (0.34)

[a]Cholesterol-rich liver (28–76 mg/g liver) was perfused with 100 mL of Krebs-Ringer bicarbonate buffer containing 30 mg bovine serum albumin/mL and a 10% hematocrit of washed canine erythrocytes. For the initial 2-h perfusate, total cholesterol was assayed each 0.5 h, and means (SE) were calculated (before). At 2 h, 20 mg of a triolein emulsion along with 2 mg rat apolipoprotein E (apo E) was added. Perfusate was assayed 2 h after the addition and at 0.5-h intervals upon concluding the perfusion at 6 h (after). Two mL of phosphate-buffered saline was added to the control perfusion at 2 h. Each data point represents means of four 0.5-h time points. Significance of changes is indicated by $^bP < 0.01$, $^cP < 0.02$, and $^dP < 0.05$.

trols with cholesterol being in the free and esterified form. Incubations of the cholesterol-rich hepatocytes in monolayers with 200 μg of egg phosphatidylcholine/free cholesterol (P/C) in a 1:1 molar ratio supplemented with apo E (100 μg) (P/C-E) revealed no differences in media cholesterol following incubation when compared with the unsupplemented P/C [P/C-E; 2 h, 3.8 (0.2); 14 h, 3.5 (0.1); P/C; 2 h, 3.5 (0.3); 14 h, 4.0 (0.2) μg cholesterol/mg cell protein; n = 4 (SE)].

TABLE 3

Media Cholesterol of Different Cholesterol-Rich Liver Cells After Exposure to Triolein-Rich Emulsions and/or Apo E[a]

Additions	Light hepatocytes	Heavy hepatocytes	Kupffer cells
	(μg media cholesterol/mg cell protein)		
None	3.8 (0.1)	2.8 (0.6)	3.0 (0.8)
Triolein emulsion (200 μg TG/mL)	4.4 (0.6)	2.6 (0.4)	3.0 (0.4)
Triolein emulsion (200 μg TG/mL plus apo E 100 γ/mL)	9.6 (0.2)[b]	6.4 (0.4)[b]	3.9 (0.2)
Apo E 100 μg	3.6 (0.1)	4.4 (0.4)	

[a]The results are the means (SE) of triplicate 12-h MEM incubations after an initial 2-h exposure of the cells to the indicated media additions in MEM. Cultured cells isolated from a Percoll gradient and plated for more than 24 h were incubated in MEM with the additions indicated. After the 2-h incubation, the cells were washed and the medium changed to MEM and assayed for cholesterol after 12 h. The light and heavy hepatocytes had cholesterol contents of 83 (SE 8; n = 10) and 48 (SE 12; n = 8) μg cholesterol/mg cell protein, respectively. Abbreviations as in Table 1.
[b]Significantly greater than any of the other media at $P < 0.001$. The percent distribution of cholesterol in the media high density lipoprotein, low density lipoprotein and very low density lipoprotein of the light hepatocytes following apo E-triolein addition was 34, 38 and 28, and for the light hepatocytes with no addition 46, 24 and 31, respectively.

TABLE 4

Cholesterol Secretion of Hepatocytes in Monolayers Following Exposure to Apoprotein Supplemented Triolein Emulsions[a]

Additions	μg Media cholesterol/mg protein	
	2 h	14 h
None	1.92 (0.07)	2.34 (0.19)
Apo E (50 μg)	2.38 (0.17)[b]	3.21 (0.09)[c]
Apo C-III (50 μg)	1.95 (0.02)	2.45 (0.13)
Apo A-I (50 μg)	1.85 (0.02)	2.59 (0.24)

[a]The data are the means of quadruplicate determinations for each point after an initial 2-h incubation of cholesterol-rich hepatocytes (44 ± 13 μg/mg) with 200 μg of a triolein emulsion and the indicated apolipoproteins. The data are significantly different than the incubation without apoproteins at $^bP < 0.05$ and $^cP < 0.01$.

Addition of 20 mg of triolein emulsion and 2 mg of rat apo E to the perfusate of an isolated perfusion of a cholesterol-rich liver resulted in higher perfusate cholesterol levels (Table 2). The emulsion was cleared within 30 min, and the cholesterol increase became apparent 2–3 h thereafter. A control perfusion did not show such a difference. The perfusate cholesterol was essentially all (>93%) in the d < 1.063 fraction both before and after infusing the apo E-supplemented triacylglycerol emulsion. The percentage of free cholesterol (mean ± SE) was not significantly different before (34 ± 9%, n = 12) and after the addition (37 ± 11%, n = 10).

The cholesterol-loaded hepatocytes were fractionated according to their density into hepatocytes with higher or lower cholesterol contents, and into Kupffer cells. In the 12-h interval following the initial 2-h incubation upon media supplementation, significantly more cholesterol was found in the media of both the lighter and heavier hepatocytes exposed to apo E-triolein emulsions than after any other treatment (Table 3). The hepatocytes containing relatively more cholesterol (lighter cells) showed a more active secretion into the medium than did the heavier cells. The fraction of cell cholesterol secreted by both the less dense and the more dense cells was similar (less dense, 11.4 ± 2.8%; more dense 13.1 ± 3.1%). As was observed in the hepatic perfusions (Fig. 2), most of the medium cholesterol was associated with the VLDL and LDL fractions following exposure of the lighter hepatocytes to the apo E-triolein. Kupffer cells were not responsive to triolein emulsions with or without apo E. The substitution of apo E by apolipoprotein C-III or A-I in the triolein emulsions incubated with the cholesterol-rich cells did not provoke an increase in media cholesterol levels either at the early (2 h) or the late (14 h) time points (Table 4).

DISCUSSION

Rats on cholesterol-supplemented diets acquire appreciable hepatic cholesteryl ester levels within weeks. If the animals are then exposed to the influx of plasma chylomicrons, either following a lipid-rich meal (6) or in-

travenous triacylglycerol injection, they respond with an appreciable increase in plasma cholesterol levels. An increase in plasma apo B and apo E parallels this cholesterol rise, which is predominantly associated with LDLs and VLDLs (7).

Anhepatic cholesterol-fed rats lack this response to either chylomicrons or triglyceride emulsions (6), suggesting that the liver may be the source of increased plasma cholesterol levels. The data presented here are consistent with this. When cholesterol-rich livers are challenged with chylomicrons or triacylglycerol emulsions in the presence of apo E, they respond by secreting lower density cholesterol-rich lipoproteins. This was shown in isolated hepatic perfusions and in cultures of hepatocytes obtained from rats fed 2% cholesterol for at least four weeks to increase the content of cholesteryl esters in the liver.

Hepatic secretion of cholesterol following plasma clearance of particulate triacylglycerols could have several causes. The clearance of chylomicrons or emulsified triacylglycerols invariably (20,21) results in a free fatty acid influx, which could stimulate hepatic VLDL production. However, the fact that intravenous infusion of equal or greater amounts of free fatty acids failed to provoke this response in the cholesterol-fed rat rules out this possibility (6). The LDLs that increase in plasma also do not resemble VLDL (7).

Plasma clearance of particulate triacylglycerols is also followed by the accumulation of residual plasma phosphatidylcholines from the particles. Infusion of phosphatidylcholine into chow-fed rats is known (22) to recruit free cholesterol from tissue, which is then acylated by plasma lecithin: cholesterol acyltransferase. In cholesterol-fed rats with more tissue cholesterol, this process could be accentuated. The inability of phosphatidylcholine liposomes to generate a response similar to that of chylomicrons makes this mechanism unlikely, as does the fact that chylomicron phosphatidylcholine is primarily transferred to HDL and not to LDL.

The lack of a similar plasma cholesterol increase in chow-fed rats upon chylomicron influx re-emphasizes the importance of the hepatic cholesterol pool. This lack of a response in chow-fed rats could either be due to: (i) an inappropriate hepatic stimulus, (ii) an appropriate stimulus with little hepatic response or (iii) both an appropriate stimulus and response but insufficient hepatic cholesterol mass to alter plasma levels. We favor the final explanation for a number of reasons. When triacylglycerols are given to rats on a fat-free diet, an impressive increase in acetate incorporation into cholesterol is observed after a latent phase similar to that seen in the plasma response in cholesterol-fed rats (23). When hepatocytes from chow-fed rats are given labelled cholesterol before being placed in monolayer culture, the cholesterol label can be provoked to appear in the medium, without an increase in cholesterol mass, by exposure to apo E-supplemented triacylglycerol emulsions (manuscript in preparation). These observations suggest that the hepatocytes from chow-fed rats, without stored cholesterol, are affected by the influx of chylomicron remnants but do not generate a sufficient level of lipoprotein cholesterol secretion to produce an increase in plasma cholesterol.

The mechanism by which the apo E-rich emulsions or chylomicrons induce the secretion of cholesterol-rich lipoproteins is unknown. Previous studies (7) have shown an increase in both plasma apo B and apo E with cholesterol, so it is not simply cholesterol enrichment of existing lipoproteins but the formation of new lipoproteins. The plasma cholesterol increase was mainly due to stored hepatic cholesterol with a lesser synthetic component. This may also be the case for the apoprotein B and E increments. The entry of the chylomicron remnant into the liver produces a considerable influx of apo E. This apoprotein may have an endosomal transit different than that of apo B dissociating from the chylomicron lipid, with routing to the golgi similar to transferrin. This apo E cycle may actually provoke secretion of hepatic cholesterol upon exiting the cell. This mechanism is currently under study.

The observation that the clearance of triacylglycerol-rich particles provokes an increase in lower density lipoprotein cholesterol may also be relevant to humans. The conventional Western diet contains significant amounts of cholesterol, and individuals on such a diet have shown a dramatic effect (4) of lipid restriction on plasma LDL cholesterol levels. This may not be totally due to cholesterol intake and LDL receptor activity (3), but may be partly in response to the increase in particulate triacylglycerol clearance occurring on lipid-rich diets. The reciprocal relationship noted for triacylglycerol-rich lipoproteins and LDL may also be attributable to this. An aberration in triglyceride-rich lipoprotein clearance, even as observed in dysbetalipoproteinemia (Type III), may not provide the appropriate stimulus for LDL cholesterol production and may result in lowering LDL cholesterol levels.

A Cross-Species Comparison of Neutral Lipid Composition of Milk Fat of Prosimian Primates

J.J. Myher[a], A. Kuksis[a,*], C. Tilden[b] and O.T. Oftedal[c]

[a]Banting and Best Department of Medical Research, University of Toronto, Toronto, M5G 1L6 Canada, [b]Department of Biological Anthropology and Anatomy, Duke Primate Center, Duke University, Durham, North Carolina 27705 and [c]Department of Zoological Research, National Zoological Park, Smithsonian Institution, Washington, D.C. 20008

The fatty acid composition of milk fat is known to be affected by dietary and genetic differences, while the milk triacylglycerol structure is believed to be attuned to the needs of the subsequent lipolysis during gastrointestinal passage. The availability of milk samples from eight species of prosimian primates, whose milk triacylglycerol structure had not been analyzed, offered an opportunity to further assess these ideas. The milk samples were collected by manual expression and the lipids extracted with chloroform/methanol (2:1, vol/vol). The lipid classes were resolved by thin-layer chromatography, and the neutral lipids subjected to detailed analyses by capillary gas–liquid chromatography of fatty acids and molecular species of triacylglycerols using nonpolar and polarizable liquid phases. The milk samples were found to differ greatly in total fat content (4–73%) and in the composition of the neutral lipid classes and molecular species. The concentration of triacylglycerols ranged from 88–95%, free fatty acids from 0.5–10%, alkyldiacylglycerols from 0.5–5.0%, and diacylglycerols, monoacylglycerols and free and esterified cholesterol made up the remainder. The fatty acid chain length ranged from C_8–C_{24}, with palmitic (16–31%) and oleic (13–40%) acids being the major components in most of the species. In all instances, the molecular association of the fatty acids differed from random distribution by a higher proportion of the monoacid (trioleoyl) and diacid (dipalmitoyloleoyl) glycerols. The phylogenetic influences on neutral milk lipid composition, however, remained unclear, as some of the differences between closely related species were greater than those between more distantly related ones.

***Lipids* 29, 411–419 (1994).**

Triacylglycerols (TG) compose 98–99% of the milk fat of most mammals (1). In nonruminants, the TG are largely comprised of long-chain fatty acids of various degrees of unsaturation. About 20 different species of acids are generally present in larger than trace amounts. It has been suggested that the TG fatty acids in milk are largely derived from dietary fat and plasma TG, although the mammary gland is also know to synthesize fatty acids (2–4). The composition and molecular association of the fatty acids in the TG molecules are genetically influenced (1,4). Recent work has suggested (5) that the milk TG structure is tailored for rapid hydrolysis by the concerted actions of lingual and gastrointestinal lipases. The availability of the milk samples from eight species of prosimian primates provided an opportunity to examine the hypothesis further.

TG composition had been previously determined only in the catarrhine primates, such as macaques (6), baboons (7) and humans (8,9), but very little is known about the milk fats of the prosimian primates. Constituent fatty acids have been studied, however, in two closely-related prosimian species (6,10). The present data show that the neutral milk fats of the prosimian species are similar to those of other primates considering their diet and physiological state.

MATERIALS AND METHODS

Animal species studied. Milk samples were collected from eight species of prosimians (Prosimii: Primates) housed at the Duke University Primate Center. These species were: (i) *Eulemur fulvus* (brown lemur); (ii) *E. macaco* (black lemur); (iii) *E. mongoz* (mongoose lemur); (iv) *E. rubriventer* (red-bellied lemur); (v) *Hapalemur griseus* (gentle bamboo lemur); (vi) *Varecia variegata* (ruffed lemur); (vii) *Nycticebus coucang* (slow loris); and (viii) *Otolemur garnettii* (greater bushbaby or greater galago).

Milk collection and storage. Mothers and offspring were separated one to three hours prior to milking to allow accumulation of milk in the glands. Milk samples were obtained by manual expression following intramuscular injection of oxytocin (approximately 4 g/kg) to stimulate milk ejection. Each teat was evacuated as fully as possible, and any discernible contaminants were removed manually before storing at –80°C for subsequent analysis.

An attempt was made to collect samples near mid-lactation when milk composition is likely to be relatively stable. For lemuroids, samples were collected between 40 and 75 d *postpartum*; the sample for *N. coucang* was collected 32 d after parturition. Unfortunately, only an early lactation sample collected four days *postpartum* was available for *O. garnettii* when milk lipid analysis was initially undertaken. However, a subsequent cross-check for free fatty acid content and TG carbon distribution using an *O. garnettii* milk sample collected seventeen days *postpartum* revealed a similar lipid composition. Samples collected from *V. variegata, N. coucanq* and *E. mongoz* were shipped on dry ice for analysis. Some thawing of these samples may have occurred during shipment, as not all samples arrived frozen.

Diets. All animals were fed once daily and provided water *ad libitum* from drip-water bottles. The lemuroid diet consisted of dry biscuits (Purina Monkey Chow 5037; Purina Mills, St. Louis, MO) and various types of cut fruit, except for the diets of *E. mongoz* and *H.*

Abbreviations: ADG, alkyldiacylglycerol(s); CE, cholesteryl ester(s); GC/MS, gas chromatography/mass spectrometry; GLC, gas–liquid chromatography; L, linoleoyl; La, lauroyl; M, myristoyl; O, oleoyl; P, palmitoyl; Po, palmitoleoyl; S, stearoyl; TG, triacylglycerol(s); TLC, thin-layer chromatography. Triacylglycerol structures are abbreviated by listing their three constituent fatty acids in sequence, e.g., PPP, LaOL.

griseus, which contained less fruit but a variety of fresh vegetables. *Hapalemur griseus* were also provided with bamboo, part of their native diet, and the bamboo leaves were eaten readily by the subjects. Different fruits and vegetables were provided daily.

Otolemur garnettii and *N. coucanq* were both fed cracked high-protein biscuits (Purina Monkey Chow) and fruit. The diet of *O. garnettii* was supplemented once a week with mineral oil-soaked crickets, and a hard-boiled egg once every two weeks. The diet of *N. coucanq* was also regularly supplemented with crickets.

Lipid extraction. Milk samples (0.1–0.5 mL) were lyophilized and then transferred to 1 × 15 mL centrifuge tubes with 1 mL water. The dispersed milk samples were diluted with 3 mL methanol and vortexed, followed by addition of 2 mL chloroform containing 1 mg tridecanoylglycerol as internal standard and vortexing. After addition of 4 mL chloroform and 1.25 mL saline, the tubes were vortexed and centrifuged. The lower chloroform layer was collected and dried by passing through an anhydrous sodium sulfate column and the eluate evaporated under nitrogen. The dry residue was redissolved in a small amount of chloroform and an aliquot of the total lipid extract used for the determination of total lipid profile by capillary gas–liquid chromatography (GLC) with a nonpolar liquid phase (11). The samples were rerun after trimethylsilylation.

Isolation of TG. The TG fraction was recovered from each milk lipid extract by thin-layer chromatography (TLC) on Silica Gel H (Merck, Darmstadt, Germany). The plates (20 × 20 cm, 250 μm thick layer) were developed with hexane/diethyl ether (150:30, vol/vol), which retained free fatty acids close to the origin (R_f = 0.16). The TG were resolved (11) into two bands—a small upper zone (R_f = 0.61–0.75) containing alkyldiacylglycerols (ADG) and a large lower zone (R_f = 0.29–0.61) containing TG. Some milk samples contained a minor band (R_f = 0.88) running ahead of ADG, which was due to cholesteryl esters (CE). The purified neutral lipid bands were recovered from the TLC plates by extraction with chloroform and were saved for further analysis.

Determination of fatty acids. Samples were transmethylated with sodium methoxide (12), neutralized with dilute acetic acid in hexane and extracted with a small portion of chloroform. The organic phase was washed once with water and once with water containing one drop of aqueous ammonia. The lower phase was dried by passing through a short column of anhydrous sodium sulfate. The eluate was directly injected into an SE-54 capillary GLC column using an on-column injector, and the carbon chain length of the fatty acids was determined (12). The remainder of the fatty acid methyl ester sample was brought to dryness and redissolved in hexane. The fatty acid methyl esters were then re-analyzed on a 15-m RTx 2330 polar capillary GLC column (Restek Corp., Port Matilda, PA) using a 7:1 split injection system (13). The carrier gas was hydrogen at 2 psi, and the column temperature was programmed from 80 to 130° at 20°C/min and then to 220°C at 5°C/min (13). The results from nonpolar and polar GLC columns were used together to calculate the final composition.

Determination of TG. The molecular weight distribution of the purified TG and ADG was determined using an 8-m DB-5 (SE-54 equivalent) capillary GLC column (J&W Scientific, Folsom, CA) as described previously (13). The molecular association of fatty acids in the TG and ADG was determined by GLC of the intact molecules on a polarizable capillary column (25 m × 0.25 i.d.) coated with 65% phenylmethylsilicone film (OV-22 equivalent; Quadrex, New Haven, CT) (14) using hydrogen as carrier gas (20 psi). Samples were injected on-column at 40°C and, after elution of the solvent, the oven was ballistically heated to 220°C, when the integration mode was initiated and the column temperature was programmed at 10°C/min to 320°C and then at 2°C/min to 360°C. The data from the GLC analyses on both the nonpolar and polar capillary columns were used for the final calculations.

Determination of ADG. Alkylglycerols and fatty acid methyl esters were prepared from ADG by transmethylation with 1 N sodium methoxide. Alkylglycerol diacetates were prepared with acetic anhydride/pyridine (1:1, vol/vol) and analyzed along with the fatty acid methyl esters by GLC using both nonpolar (SE-54) and polar (SP-2380) capillary columns, as previously described (13). The identities of the peaks were confirmed by gas chromatography/mass spectrometry (GC/MS) using an HP 5989 mass spectrometer and an HP 5890 Series II gas chromatograph (Hewlett-Packard, Palo Alto, CA). Injections were made *via* a splitless injector port set at 290°C and a 12 m × 0.2 mm capillary column coated with 0.33 μm HP-1 (Hewlett-Packard) was used. The oven temperature was initially held at 100°C for 0.5 min and then programmed to 190°C at 20°C/min, to 240°C at 5°C/min, and finally to 290°C at 10°C/min. Electron impact mass spectra (*m/z* 50–500) were acquired every two seconds using 70 eV ionization energy. The alkylglycerol diacetates were identified primarily on the basis of the $[M - 103]^+$, $[M - 60]^+$, $[alkyl]^+$ and *m/z* 159 ions (15).

RESULTS

Figure 1 shows a representative GLC profile of the neutral lipid fractions isolated from milk samples (*E. macaco*). The even carbon numbered TG (C_{38}–C_{54}) constituted the bulk of the neutral lipids. There were also small amounts of odd carbon numbered TG, along with overlapping ADG (see below), which emerged between the even carbon numbered TG and possessed a normal distribution curve (C_{39}–C_{49} on the TG scale). The diacylglycerol peaks were resolved into saturated and unsaturated fractions, which varied in proportion with chain length (C_{26}–C_{36}). The next largest fraction was due to free fatty acids, which ranged from C_8–C_{18}, and also yielded partial resolution between saturated and unsaturated species. Free cholesterol and monoacylglycerols were present in the lowest amounts. Table 1 gives the quantitative composition of the neutral lipid classes of the various milk samples. The fat concentration of the samples varied from 0.29 to 7.3%, consistent with previous analyses employing gravimetric methods (16,17).

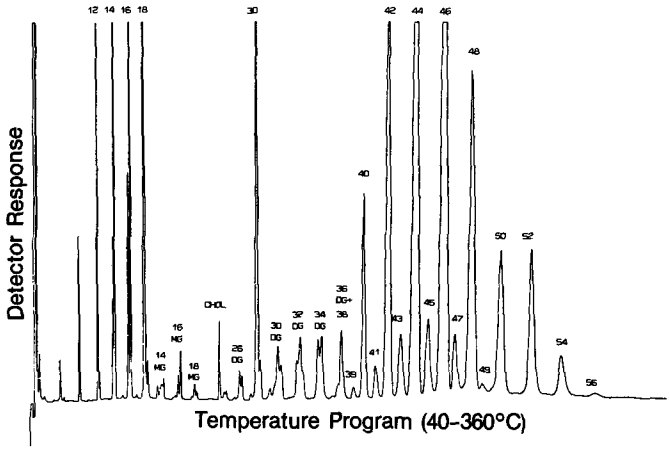

FIG. 1. Total neutral lipid profile of a representative prosimian (*Eulemur macaco*) milk sample as obtained for the trimethylsilyl ethers by capillary gas-liquid chromatography on a nonpolar liquid phase. Peak identification: 8–18, free fatty acids of 8–18 acyl carbons; 14–18, monoacylglycerols (MG) with 14–18 acyl carbons; CHOL, free cholesterol; 26–36, diacylglycerols (DG) with 26–36 acyl carbons; 38–56, triacylglycerols with 38–56 acyl carbons; 39–49, alkyldiacylglycerols with 40–50 carbons in the chains. GLC conditions as described previously (Ref. 12).

Proportionally, the TG made up 70–95% of total lipid. The major nonglycerolipid component was free fatty acid (1–16%) with a nearly constant proportion of free diacylglycerols (3–10%). Monoacylglycerols were absent. On the basis of the molecular weight distribution, the diacylglycerols were largely made up of the 14–16, 16–16 and 16–18 combinations of saturated and unsaturated fatty acids. The peak identity was confirmed by TLC/GLC analysis and by cochromatography with standards. The presence of the ADG was confirmed by a GC/MS identification of the alkylglycerol moieties as the diacetates.

Table 2 gives the carbon number distribution of the neutral lipid classes as obtained by GLC on nonpolar capillary columns for the eight milk samples. The carbon numbers were consistent with the free fatty acid composition, although a random distribution did not appear to be present. The odd carbon numbered TG, ADG, and CE were combined and recorded under the odd carbon number of TG. Separate estimates for the ADG are given below.

Figure 2 compares the carbon number distribution for the TG and ADG purified from a milk sample especially rich in the alkyl ethers (*E. rubriventer*). The ADG were made up of mixed fatty acid esters of C_{16} (28%), C_{18} (48%) and $C_{18:1}$ (23%) alkylglycerols ranging in total nonglycerol carbon number from C_{38} to C_{58}. The ADG were estimated to make up about 0.5% of the total TG fraction in this sample. Other milk fat samples contained less ADG, but possessed similar carbon number distributions.

Table 3 shows considerable variation in the fatty acid composition of the purified TG samples, although nearly all contained 8:0–24:1 acids. Palmitic acid was a major fatty acid, comprising over 20 mole percent in all milks except that of *E. fulvus*, which contained myristic and lauric as the major fatty acids. *Varecia variegata, O. garnettii* and *E. mongoz* contained oleic acid as the major component. All samples contained significant amounts (7–14%) of linoleic acid, but only traces of 20:4 and other long chain polyunsaturated fatty acids. The fatty acids of the purified ADG fractions contained, on average, 14:0 (22%), 16:0 (30%), 18:1n-9 (17%) and 18:2 (11%) as major components and 12:0 (7%), 16:1 (8%), 18:0 (3%) and 18:1n-7 (1.4%) as minor components.

Figure 3 gives the polar capillary GLC profiles of intact TG from two milk samples from *E. rubriventer* (Fig. 3A) and *V. variegata* (Fig. 3B), which differed greatly in

[a]Primate species as in Table 1. Single determinations from a series of calibrated runs.

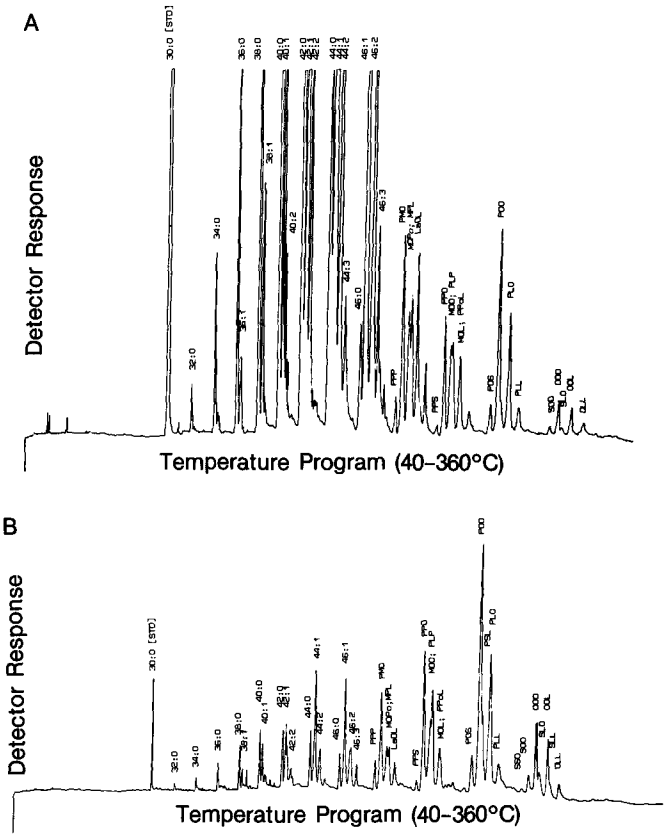

FIG. 3. Polarizable capillary gas–liquid chromatography (GLC) profiles of two prosimian milk samples exhibiting extremes in carbon number distribution. A, *Eulemur rubriventer*; B, *Varecia variegata*. Peak identification as given in the figure and in text; 30:0, tridecanoylglycerol internal standard; 32:0 to 46:3, triacylglycerols with a total of 32–46 acyl carbons and 0–3 double bonds. P, palmitic; M, myristic; S, stearic; O, oleic; L, linoleic acids. GLC conditions were as given in text for the polarizable column GLC of lipids.

respect to the carbon number and degree of unsaturation. Similar patterns were recorded for the TG prepared from the other milk samples. Table 4 gives the quantitative molecular species composition of the milk TG as calculated by utilizing the results obtained on polar and nonpolar capillary columns. The molecular species of the TG reflected the composition of the major fatty acids, but differed from a random distribution by a higher proportion of monoacid (trioleoyl) and diacid (dipalmitoyloleoyl) TG than calculated on basis of random distribution.

Figure 4 illustrates the polarizable capillary GLC resolution of the ADG isolated from one of the milk samples (*E. rubriventer*). The peaks were identified by reference to the fatty acid and alkylglycerol compositions, the distribution of the carbon numbers obtained by nonpolar capillary GLC, and by reference to standards. There was one saturated (both medium and long chain) or one monounsaturated chain per molecule. Table 5 gives the quantitative composition for two of the ADG samples resolved on the polarizable capillary GLC column. The proportions of the various ADG reflected the fatty acid and alkylglycerol compositions, but differed significantly from the distributions anticipated from a strictly random combination of the respective chains.

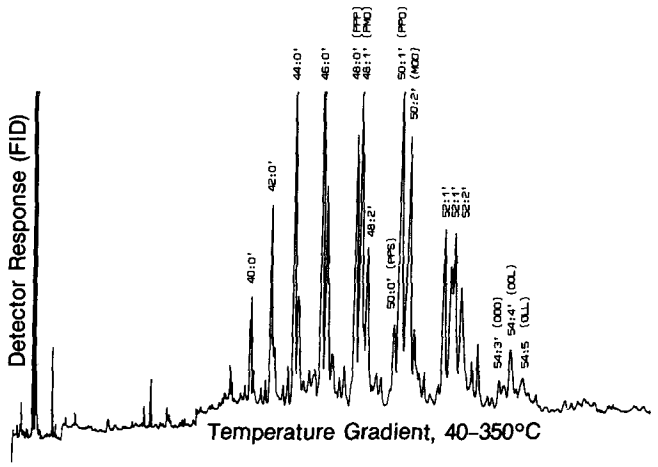

FIG. 4. Polarizable capillary GLC profile of the purified alkyldiacylglycerol fraction from a prosimian milk sample (*Eulemur rubriventer*). Peak identification and abbreviations as in Figure 3. GLC conditions as in text and in Figure 3.

DISCUSSION

The availability of milk samples from eight species of prosimian primates, which previously had not been analyzed, offered an opportunity to examine the validity of some current hypotheses about the purposeful design of milk fat TG structure. *Eulemur* species, *Varecia* and *Hapelemur* are members of a monophyletic group, the Lemuroidea, who range in size from approximately one to three kilograms, and are only found today on the island of Madagascar. Recent work has confirmed the close relationships among the separate *Eulemur* species and suggested that the *Hapalemur* species, along with *Lemur catta*, form a sister group to *Eulemur* (19–23). The relationship of *Varecia* to the other lemurs is more distant still. Recently, the inclusion of *Varecia* with *Eulemur*, *Lemur* and *Hapalemur* in the family Lemuridae has been questioned (Refs. 20, 22; J.M. Macedonia and K.F. Stanger, 1993, unpublished results).

Nycticebus coucang and *O. garnettii* are representatives of two major sister taxa within the suborder Lorisidea. The slow loris, *N. coucang*, represents the Lorisoidea (lorises), and *O. garnettii* represents the Galagidae (galagos). Lorisoids are continentally-distributed, small (0.2–1.2 kg), nocturnal prosimians. Lorises are found in both Africa and Asia; the slow loris, *N. coucang*, is widely distributed throughout southeast Asia. Galagos, including *O. garnettii*, are found on the African continent.

Fatty acid composition. In common with many other mammalian species, the studied prosimians produced milk fat containing large proportions of palmitic and oleic acids. Short chain fatty acids (less than C_8) were absent. The odd carbon numbered fatty acids, which constitute a significant proportion of total fatty acids in ruminant milk fats (13), were also largely absent. Fatty acid chains of C_8 were present in significant amounts only in *E. rubriventer* and *H. griseus*. Milks of *Eulemur* species generally contained high levels of medium chain (C_{10} to C_{15}) acids (40.5–54.3%), except for *E. mongoz*, which had the lowest (10.5%). The milk fats of *E. fulvus*,

[a]Primate species as given in Table 1. Single determinations from a series of calibrated runs.

[b]Total number of acyl carbons:total number of double bonds in a triacylglycerol molecule; L, linoleoyl; La, lauroyl; M, myristoyl; O, oleoyl; P, palmitoyl; Po, palmitoleoyl; S, stearoyl; C_{56}, C_{58} and C_{60}, triacylglycerols of 56, 58 and 60 acyl carbons, respectively, and unspecified degree of unsaturation.

E. macaco and *E. rubriventer* were very similar to each other and were characterized by a high proportion of C_{12} and C_{14} acids. *Eulemur fulvus* represented the extreme, having a higher percentage of medium chain acids than of C_{16} and C_{18} fatty acids. *Eulemur mongoz* had moderate levels of medium chain acids and greater quantities of C_{18} acids, as did the lorisoid primates and, to some extent, *H. griseus* and *Varecia*. Palmitic acid was prominent in milks of most species, but was particularly high in *N. coucang*. In many respects, the milk of *E. mongoz* resembles that of *H. sapiens*, with similar levels of palmitic, oleic and linoleic acids and smaller quantities of longer chain fatty acids, such as 20, 22 and 24 acyl carbon homologues.

To some extent the differences in fatty acid composition observed among species may be a consequence of dietary differences. The diet of the lactating mother has been shown among human subjects to have a

[a](4) *Eulemur rubriventer*; (6) *Vareca variegata*; abbreviations as in Table 4. Single determinations from a series of calibrated runs.

predictable relationship with milk composition (4). Human mothers on high-carbohydrate/low-fat diets have been reported to produce milk enriched in medium chain fatty acids (4), which appear to be synthesized *de novo* in the mammary gland rather than being derived from blood or dietary precursors (24). Thus, the high levels of medium chain fatty acids in most *Eulemur* spp. (except *E. mongoz*) may reflect low-fat intakes and relatively increased mammary synthesis. It is possible that the inclusion of vegetables in the diet of *E. mongoz* (not offered to other *Eulemur* species) may partly explain higher levels of long chain fatty acids in the milk of this species as compared to other *Eulemur* species. However, *Varecia* consumes a diet that is comparable to that of the other *Eulemur*, but produces milk more similar in fatty acid composition to that of *E. mongoz*.

The relatively high proportion of free fatty acids in some of the milk samples is reminiscent of that seen in the milk of a human Type I hyperlipoproteinemia patient (11,25), who presumably synthesize much of the fatty acid fraction in the mammary gland due to an inability to clear plasma TG because of a lack of lipopro-

tein lipase (26). Alternatively, the free fatty acids could have come from lipolysis of the milk TG, to which they correspond in composition. However, those samples (*V. variegata, N. coucang* and *E. mongoz*), which had thawed, did not have higher free fatty acid concentration than samples that remained frozen at -80°C prior to analysis.

TG composition and structure. The milk TG of *Eulemur* species tended to have the lowest average acyl carbon number. *Eulemur fulvus* was extreme among the lemuroids, as it had much greater proportions of C_{36} and C_{38} TG in relation to C_{40} to C_{46} TG. *Varecia* species differed from others by having very little C_{40} and little C_{42}. *Eulemur* species (excluding *E. mongoz*) had little or no TG with C_{50} or higher acyl carbons, while the C_{52} TG made up about 40% of the total in *E. mongoz* and 30% in *V. variegata*. Among lorisoids, TG with the longer chains were more prominent, as would be expected from the fatty acid composition. Thus, C_{44}–C_{52} TG were major components of both *N. coucang* and *O. garnettii*. The longer chain TG in all instances were made up mainly of PMO, MPoO, PPO, PLP, POO, PLO, OOO and OOL TG in varying proportions.

The work of Hansen *et al.* (27) has shown that the monoacylglycerol pathway of TG synthesis is absent from the mammary gland of the goat, in which case TG have to be formed exclusively *via* the phosphatidic acid pathway. This pathway proceeds *via* long chain diacylglycerol intermediates with mono- and diunsaturated fatty acids in the *sn*-2 position. Because medium chain fatty acids (C_8–C_{12}) are not readily incorporated into the phosphatidic acid and thus into the diacylglycerol intermediates, it would be anticipated that the short and medium chain fatty acids would occupy mainly the *sn*-3 position, as has already been shown for human (9) and ruminant (28–30) milk fats. In such a case, the biosynthetic diacylglycerol intermediates isolated from the milk fat would contain only long chain species, mainly C_{32}, C_{34} and C_{36} derivatives. As the neutral lipid profiles indicated the presence of both medium and long chain length diacylglycerols (Table 2), as well as small amounts of long chain monoacylglycerols, it would appear that the diacylglycerols were predominantly formed by hydrolysis due to lipoprotein lipase present in fresh milks. This enzyme attacks the *sn*-1 position, preferentially producing medium and long chain diacylglycerols of the *sn*-2,3 configuration (31,32). Alternatively, tissue damage during manual expression of the milk may have led to release of lipases, resulting in lipolysis.

ADG composition and structure. ADG have been detected in milk samples of ruminants (33,34) and in a healthy human female (34). Although the origin of the alkylglycerol moiety of these glycerolipids is not known, dietary alkylglycerols would appear to be the most likely precursors. The *sn*-1 monoalkylglycerols released from food glycerophospholipids in the intestinal lumen are readily absorbed and incorporated into tissue lipids (35,36). Therefore, the alkyl group in the ADG would be anticipated to be located in the *sn*-1 position.

Although the prosimian primates were not maintained on rigidly controlled dietary regimens, the differences in the fatty acid and neutral glycerolipid composition were consistent with dietary influences within the limits of the experimental controls. The phylogenetic influence on neutral milk lipid composition, however, remained unclear as some of the differences between closely related species were greater than those between more distantly related ones.

ACKNOWLEDGMENTS

These studies were supported by funds from the Medical Research Council of Canada (Ottawa, Canada); the Heart and Stroke Foundation of Ontario (Toronto, Canada); the Brookfield Zoo/Chicago Zoological Society (Chicago, Illinois); the Duke Primate Center and Graduate School of Duke University (Durham, North Carolina); and by a Grant-in-Aid of Research from Sigma Xi, the Scientific Research Society. We would like to extend our appreciation to Elwyn Simons and the Duke Primate Center staff for their support and assistance with data collection.

Sterol and Fatty Acid Composition of Neutral Lipids of *Paratenuisentis ambiguus* and Its Host Eel[1]

Nikolaus Weber[a,*], Klaus Vosmann[b], Kurt Aitzetmüller[b], Christin Filipponi[c] and Horst Taraschewski[d]

[a]Institut für Biochemie und Technologie der Fette, [b]Institut für Chemie und Physik der Fette, BAGKF, 48147 Münster, [c]Institut für Spezielle Zoologie und Parasitologie, Ruhr Universität Bochum, 44801 Bochum and [d]Zoologisches Institut der Universität, 76128 Karlsruhe, Germany

The sterol composition of free sterol and steryl ester fractions of the fish parasite *Paratenuisentis ambiguus* was determined. In addition, the fatty acid composition of various neutral lipid classes, i.e., wax esters, steryl esters, triacylglycerols and free fatty acids, as well as the composition of the 1-*O*-alkyl moieties of total ether glycerolipids of the parasite, were investigated. The results of these studies were compared with those obtained on the intestinal tract tissue of its host, the eel (*Anguilla anguilla*). Cholesterol is the major sterol in both *P. ambiguus* and *A. anguilla*. However, the sterols of *P. ambiguus* contain high proportions (>20%) of other sterols, such as campesterol and various dehydrosterols. [e.g., 7-dehydrocholesterol and cholesta-5,22(*E*)-dienol]. The presence of these minor sterols agrees with the known biotransformations of exogenous sterols in various helminths. Considerable differences are found in the fatty acid composition of neutral lipid fractions, as well as the total lipid extract from the endoparasite as compared to the host tissue. In particular, eicosapentaenoic acid (20:5n-3), other polyunsaturated fatty acids, such as 20:4n-6, 22:5n-3 and 22:6n-3, as well as long-chain saturated fatty acids, such as 20:0, are generally enriched in the neutral lipid fractions of the parasite as compared to those of infected eel intestine. The analysis of ether glycerolipids revealed that 1-*O*-hexadecyl (16:0) and 1-*O*-hexadecenyl (16:1) moieties were present in similar proportions in the ether lipids of both *P. ambiguus* and eel intestine, whereas 1-*O*-octadecyl (18:0) moieties are more prominent in the parasite and 1-*O*-octadecenyl (18:1) moieties in the eel. The results of these studies show that *P. ambiguus* has specific mechanisms for the regulation of the sterol and fatty acid composition of its neutral lipids.

***Lipids* 29, 421–427 (1994).**

Lipid composition and metabolism have not been extensively studied in Acanthocephala. Some earlier histochemical studies have shown that lipid deposits occur in various tissues of these endoparasites (1). The total lipid content, as well as the ratio of neutral lipids to phospholipids, was found to vary among some acanthocephalans, e.g., *Moniliformis moniliformis, Macracanthorhynchus hirudinaceus* and *Sphaerirostris pinguis* (2,3). In addition, differences in total lipid contents have been shown between male and female organisms of the same species (2). On the other hand, the composition and biosynthesis of lipids in various species of fish are now established (4,5). In fish, dietary lipids play an important role as a source of essential fatty acids (EFA) such as 18:2n-6 or 18:3n-3, and of long-chain polyunsaturated fatty acids, i.e., 20:5n-3 and 22:6n-3 (6). The extent to which the acyl moieties are altered by dietary lipids is, however, different in different lipid classes. Generally, neutral lipids of fish, such as triacylglycerols, are affected by feeding an EFA-deficient diet to a larger extent than are phospholipids, whereas the latter are changed preferentially by EFA (6). Little is known about the lipid content and the fatty acid composition of whole intestinal tissue of fish and specifically in the case of the North Atlantic eel, *Anguilla anguilla* (5).

Paratenuisentis ambiguus (Van Cleave, 1921) Bullock et Samuel 1975 (Eoacanthocephala, Tenuisentidae) is an endoparasite found in the intestine of the American (*A. rostrata*) and the European eel (*A. anguilla*) (7,8). Taraschewski (9) observed that the worm's presoma, which is surrounded by intestinal tissue of the eel, apparently collects host lipids at its surface. On the other hand, an osmiophilic substance seemed to be excreted by the parasite through perforations of its proboscis hooks (9). In addition, it was shown that lipids such as tritiated triolein can be absorbed by *P. ambiguus* and other acanthocephalans through the tegument of the presoma (10). Little information is available on the composition and biochemistry of lipids in Acanthocephala, including *P. ambiguus* (1).

There is increasing interest in fish parasitology because of the increasing use of commercial aquaculture and because of the significant financial losses that can be caused by the pathogenic effects of parasitic worms. This prompted us to study the lipids of *P. ambiguus* in comparison with the lipids of infected tissue of eel intestine. Endoparasites are known to have only a very limited lipid metabolism (11). Thus, the aim of our studies was to find differences in the lipid composition between parasite and host that could be utilized to design means to control acanthocephalans and other parasites of eel.

MATERIALS AND METHODS

Chemicals. High-performance liquid chromatography (HPLC)-grade solvents (acetonitrile, acetone) were purchased from E. Merck (Darmstadt, Germany). Fatty acid methyl ester standards were from Nu-Chek-Prep (Elysian, MN); the fish oil standards "PUFA 1" and "PUFA 3" were from Matreya (Pleasant Gap, PA); "CPL Fish Oil 30" was from Larodan (Malmö, Sweden). Acetylations were carried out in acetic anhydride/pyridine (1:1, vol/vol) at 80°C for 1 h. Methyl esters derived from acyl lipids were prepared by transmethylation using

Abbreviations: EFA, essential fatty acids; GC, gas chromatography; GC/MS, gas chromatography/mass spectrometry; HPLC, high-performance liquid chromatography; RP-HPLC, reverse-phase high-performance liquid chromatography; RRT, relative retention time; TLC, thin-layer chromatography.

methanol/benzene/conc. sulfuric acid (84:10:4, by vol); free fatty acids were esterified with diazomethane (12).

Biological materials. Eels (*A. anguilla*) from the Weser river that were naturally infected with *P. ambiguus* were used for the analyses; they were free of other intestinal helminths. The eels were killed and dissected immediately. Intestinal tissues were excised and the attached parasites removed. The parasites were kept overnight at 7°C in minimum essential medium (MEM; Flow Laboratories, Meckenheim, Germany) supplemented with glucose (1 g/L) as well as streptomycin (100 µg/mL) and penicillin (100 U/mL). In addition, sections of infected intestinal tissue were excised from different parts of the anterior eel gut, pooled and then deep-frozen. Both *P. ambiguus* (whole organisms, males and females combined) and eel intestine were used for lipid extraction.

Extraction procedures. Paratenuisentis ambiguus, 5.7 g worm tissue (average weight 2.5 mg/animal) and *A. anguilla*, 6.1 g intestinal tissue, were homogenized in 4 mL of dichloro-methane/methanol (1:2, vol/vol) per gram fresh weight using an Ultra-Turrax blender (IKA-Werke, Staufen, Germany). After centrifugation, pellets were reextracted twice with 10 mL, each, of dichloromethane/methanol (2:1, vol/vol). The combined extracts were diluted with dichloromethane and water, and the phases were separated by centrifugation (13,14). The organic phases were dried and concentrated, and the total lipids of both tissues determined gravimetrically.

Lipid analysis. Aliquots of total lipids were fractionated by preparative thin-layer chromatography (TLC) on Silica Gel H (E. Merck) with hexane/diethyl ether/acetic acid (80:20:1, by vol) as solvent. Fractions containing wax esters plus steryl esters, triacylglycerols, free fatty acids and sterols were isolated and extracted from silica gel using water-saturated diethyl ether. The fractions of polar lipids at the origin of the plates were isolated and extracted with dichloromethane/methanol/water (1:2:0.8, by vol) (13). The polar lipid extracts obtained as described were kept in dichloromethane/methanol (2:1, vol/vol) for further analyses. The fractions consisting of wax esters plus steryl esters were resolved on layers of magnesium oxide with hexane/diethyl ether/ethyl acetate (75:25:1, by vol) as solvent (15). Aliquots of steryl ester fractions were subjected to alkaline hydrolysis (16). The liberated sterols were extracted from the reaction mixture and purified by TLC on Silica Gel H using hexane/diethyl ether (3:2, vol/vol) as solvents. The fractions of free sterols, as well as sterols derived from steryl esters by alkaline hydrolysis, were acetylated for gas chromatography (GC) and gas chromatography/mass spectrometry (GC/MS) as described previously. All lipid fractions on silica plates were detected by charring after spraying with chromic sulfuric acid and heating at 200°C; fractions were identified by co-chromatography with standards. Lipid fractions on magnesium oxide plates were detected by exposure to iodine vapors. All lipids were quantified by weighing. Aliquots of total lipids as well as of acyl lipid fractions were converted to the methyl esters by methanolysis as described. Fatty acid methyl esters and steryl acetates were purified by TLC on Silica Gel H with hexane/diethyl ether (4:1, vol/vol) as developing solvent, isolated and then analyzed by GC as described next.

Aliquots of total lipid extracts were subjected to hydrogenolysis with $LiAlH_4$ (17). The resulting mixtures of long-chain alcohols and alkylglycerols were separated on layers of Silica Gel H with diethyl ether and identified by co-chromatography with standards. The fraction of alkylglycerols was treated with conc. HCl in order to remove plasmalogenic ether lipids from the alkylglycerol fraction by cleavage of the vinyl ether bond (18). The resulting reaction products, i.e., long-chain aldehydes, and the remaining 1-*O*-alkylglycerols were separated by TLC on Silica Gel H using hexane/diethyl ether (1:4, vol/vol), and identified by co-chromatography with standards. The fraction of 1-*O*-alkylglycerols was isolated and acetylated, and the resulting 1-*O*-alkyl-2,3-diacetylglycerols were analyzed by reverse phase (RP) HPLC as described in an upcoming section.

GC of fatty acid methyl esters and steryl acetates. GC of fatty acid methyl esters and steryl acetates was carried out using a Hewlett-Packard (Böblingen, Germany) HP-5890 Series II gas chromatograph. Fatty acid methyl esters were separated on a 0.24 µm Silar 5 CP WCOT fused silica column (Chrompack, Middelburg, The Netherlands), 50 m × 0.25 mm i.d., and steryl acetates on a 0.29 µm OV-1 fused silica column (Macherey & Nagel, Düren, Germany), 25 m × 0.32 mm i.d. Fatty acid methyl esters were separated using nitrogen (1.13 mL/min) as carrier gas initially at 165°C for 1 min, followed by linear programming from 165 to 205° at 1°C per min. The split ratio was 1:100, the injector temperature 230°C and the flame-ionization detector temperature 260°C. GC peaks were assigned by comparison of their retention times with those of known standards and by calculating equivalent chain lengths and relative retention times (relative to 16:0 = 1.00). Steryl acetates were separated under similar conditions using a linear temperature program from 228 to 252°C at 4°C per min. The final temperature was kept constant for 30 min.

GC/MS of steryl acetates. GC/MS of the steryl acetates was performed using the electron ionization mode (70 eV) and the chemical ionization mode (methane as reagent gas) on a Hewlett-Packard instrument Model 5890 Series II/5989 A. The GC instrument was equipped with a Permabond OV-1 fused silica capillary column (25 m × 0.32 mm i.d.; 0.23 µm film thickness). The carrier gas was He at a flow rate of 1.5 mL/min. The column temperature was initially kept at 225°C for 5 min and then programmed from 225 to 255°C at 4°C/min. The final temperature was held for 45 min. Other operating conditions were split/splitless injector in splitless mode (temperature 300°C), interface temperature 280°C and ion source temperature 200°C.

RP-HPLC of 1-O-alkyl-2,3-diacetylglycerols. A Merck-Hitachi (E. Merck) L-6200 pump equipped with an ACS 750/4 mass detector was used in combination with an integrator for monitoring HPLC separations and analysis of peak areas. 1-*O*-Alkyl-2,3-diacetylglycerols derived from ether glycerolipids were analyzed by RP-HPLC on

two LiChrospher 100 RP-18 (5 μm) columns (E. Merck), 125 × 4 mm each, in sequence using acetonitrile at a flow rate of 1.0 mL/min. Detector signals of the mass detector were quantified by calibration with synthetic standards.

RESULTS AND DISCUSSION

We have determined the total lipids of *P. ambiguus* (28 mg/g wet weight) and infected eel intestine (77 mg/g wet weight), as well as the triacylglycerols, which are the major neutral lipids of *P. ambiguus* (60 mg/g total lipids) and eel intestine (270 mg/g total lipids). In both organisms all other neutral lipid classes studied, such as wax esters, free fatty acids, sterols and steryl esters, were present only in minor proportions (Table 1). The fatty acid compositions of total lipids and various neutral lipid fractions, as well as the sterol compositions of free sterol and steryl ester fractions of *P. ambiguus*, were determined and compared with the corresponding lipid fractions of infected intestinal tissue of its host *A. anguilla*. The results we obtained on phospholipids will be reported in a subsequent paper (Aitzetmüller, Taraschewski, Filipponi, Werner and Weber, *Lipids*, to be published).

Sterols and steryl esters. Gas chromatographic analysis revealed that the major free and esterified sterol from both *P. ambiguus* and eel intestine is cholesterol. However, *P. ambiguus* has a much higher content of minor sterols than eel intestine and, consequently, a lower proportion of cholesterol (Table 2). Both intermediates of sterol metabolism and/or dietary phytosterols are found in the minor sterol fraction of the parasite, as was shown by GC/MS of their acetates. These minor steryl acetates show prominent $M^+ - 60$ (acetic acid) fragments that indicate the presence of the Δ^5-sterol structure. Molecular ions of 3-acetoxy derivatives are usually not detected in the mass spectra of Δ^5-unsaturated sterols because of the preferential formation of $\Delta^{3,5}$-diene derivatives by the loss of acetic acid (19). The most important mass spectral data are presented in Table 3.

The two compounds with retention times shorter than cholesterol have nearly identical mass spectra (Table 3). Beside the Δ^5 double bond of the sterol backbone, a second double bond must be present in the side-chain; this is evident from the fragment *m/z* 255, which is characteristic for a monounsaturated steryl backbone. It is known from the investigations of Itoh *et al.* (20) that only one pair of geometrical isomers of C_{27}-sterols exists with relative retention times (RRT) shorter than that of cholesterol (RRT = 1.00), i.e., Δ^{22}-dehydrocholesterols with a double bond having *E* or *Z* configuration at C-22 of the side-chain. Therefore, our results and the data given in the literature suggest the presence of both cholesta-5,22(*Z*)-dienol and cholesta-5,22(*E*)-dienol as constituents of *P. ambiguus* sterols.

The sterol with RRT 1.05 was identified as 7-dehydrocholesterol (Table 3), which has been frequently detected in the sterol fractions of various nematodes, e.g., *Caenorhabditis elegans* and *Turbatrix aceti* (21). The compound with RRT 1.07 was identified as a Δ^5-C_{28}-sterol with a further double bond in the side chain. These data agree, for example, with a dehydrocampesterol having one double bond in the side chain, whereas the sterol with RRT 1.16 was characterized as having a Δ^5-C_{28}-steryl moiety with a saturated side chain. One may speculate that this compound is a dehydrocampesterol with an additional double bond in the sterol nucleus. The mass spectrum of the compound with RRT 1.18 corresponds to that of a reference standard of campesteryl acetate (Table 3).

It is generally believed that acanthocephalans (1) and various other endoparasites (11) are not able to synthesize sterols *de novo*, particularly cholesterol. Obviously, cholesterol, which is the major sterol found in Acanthocephala, is absorbed from host intestinal contents together with other sterols, such as phytosterols. For example, Barrett *et al.* (22) have shown that cholesterol accounts for 57.5% of total sterols in *M. hirudinaceus* and 84% in *M. moniliformis*. In both parasites it is accompanied by appreciable proportions of campesterol (1–16%) and sitosterol (10–21%), as well as by trace amounts of stanols (dihydro sterols). The occurrence of various other sterols has been reported from a number of plant parasitic and free-living nematodes, e.g., *C. elegans* (21,23). These worms are able to metabolize exogenous sterols, e.g., by the introduction and isomerization of double bonds. The various sterols detected in the lipid extract of *P. ambiguus* most probably result from both nutrient uptake and metabolic changes. In contrast, the lipids of higher animals, such as eel, contain almost ex-

clusively cholesterol as the sterol component (>93–95%; Table 2).

Acyl lipids and free fatty acids. From studying the total lipids (Table 4), it was not clear whether the differences observed were simply due to different ratios of neutral lipids to phospholipids in parasite and host. For example, the data presented here show that the proportion of neutral lipids, in particular triacylglycerols, is higher by far in eel intestine than in the parasite. The results of fatty acid analyses of total lipids, wax esters, steryl esters, triacylglycerols and free fatty acids are summarized in Table 4. A number of GC peaks were believed to be minor fatty acids, including double bond positional isomers, and were not further identified (they are not included in Table 4). The figures represent area% (uncorrected) of the fatty acid methyl ester peaks.

There is a striking difference between the acyl moieties of steryl esters of eel gut, which contained predominantly 16:0 and 18:0 saturated fatty acids, and the acyl moieties of steryl esters of *P. ambiguus*, in which saturated fatty acids are present in minor proportions only. Major unsaturated fatty acids detected in the steryl ester fraction of *P. ambiguus* are 18:1n-9, 18:1n-7, 18:2n-6 and 20:5n-3 (Table 4).

The fatty acid compositions of wax esters isolated from *P. ambiguus* and eel intestine are also different in many respects (Table 4). Monounsaturated n-7 fatty acids (16:1n-7, 18:1n-7) are prominent acyl moieties in the parasite wax esters, but are present in low proportions only in wax esters of eel intestine. In *P. ambiguus* wax esters, part of which may originate from the parasite's surface coat, we found 20:1n-7 and 20:1n-11 acyl moieties that are not observed in the corresponding eel lipids. The same is true for 20:2n-6. The long-chain saturated fatty acids 20:0 and 24:0 are present in wax esters and steryl esters of both species.

Palmitoleic acid (16:1n-7) is a major fatty acid in all the *P. ambiguus* lipid classes and is present in amounts similar to those of 16:0. The ratio of peak areas of 16:0 to 16:1n-7 was fairly constant and close to 1 in all the parasite neutral lipid classes. This ratio was approximately 27 in the eel wax esters and 5.6 in the eel steryl esters. However, in the eel triglycerides, 16:0 and 16:1n-7 were again present at similar levels (11–12% of total fatty acids each). The critical pair 20:5n-3/22:0 (not separated on the Silar GC column) was estimated to be predominantly 20:5n-3, with the exception of *P. ambiguus* wax esters, where 20:5n-3 and 22:0 were present at a ratio of 2:1.

Among acanthocephalans, steryl esters and wax esters have been detected in *Polymorphus minutus* (24) and may be ubiquitously distributed in fish (25,26). However, little is known on the fatty acid composition of these lipid classes in acanthocephalans, except that the wax esters of *P. minutus* cystacanths, which reportedly occur in extremely high proportions, may be used as storage lipids by the larvae of this parasite (24).

The triacylglycerols of both parasite and host also show a complex pattern of acyl moieties. Although the two species contain triacylglycerols with remarkably high proportions of long-chain acyl moieties, it is obvious that peaks representing unsaturated fatty acids of chain lengths 16, 18 and 20 are more prominent in triacylglycerols of *P. ambiguus* than of eel intestine. Similar results have been found for the neutral lipid fractions of *M. moniliformis* (Acanthocephala) and *Oochoristica agamae* (Cestoda) (27,28).

To our knowledge, this is the first report on the fatty acid composition of triacylglycerols in adult acanthocephalans, whereas more information on the composition of triacylglycerols of various fish species, including eel, is available (4,6,29). It is evident from the studies on

fish lipids that the fatty acid composition of triacylglycerols and other lipids is significantly affected by dietary lipids as well as environmental conditions, in particular, temperature (5,6,30).

In the free fatty acid fraction, as in wax esters, the proportions of fatty acids in the 18:4 to 20:2 range are clearly increased in *P. ambiguus* as compared to eel intestine (Table 4). The fatty acid composition of the *P. ambiguus* free fatty acid fraction apparently contains several fatty acids, e.g., 18:4n-3, 20:0, 20:1n-7 and 20:1n-11, which are not present or present only in much smaller amounts in host intestinal tissue. Eicosapentaenoic acid was found to be a major fatty acid of total lipids as well as of steryl esters, triacylglycerols and free fatty acids.

It might have originated from aquatic diet (5) and/or from bacteria of the intestine (31). Relatively high proportions of myristic acid were detected in the fractions of triacylglycerols and free fatty acids of both *P. ambiguus* and infected eel intestine. In both acanthocephalans and fish, little is known so far on the composition of free fatty acid fractions; although some information is available on the composition of free fatty acids of *P. minutus* cystacanths, which were found to contain large proportions of saturated long-chain fatty acids (24). In the endoparasitic acanthocephalans, it is also possible that the free fatty acid fraction, at least in part, may originate from fatty acids of eel intestinal contents that have been adsorbed onto the parasite's surface coat.

Ether lipids. Ether glycerolipids are ubiquitous in the animal kingdom (32–34). Although the contents of neutral ether lipids and ether phospholipids have been determined extensively in a great variety of fish (35), little is known about the occurrence of ether lipids in Acanthocephala (1,11). Beames and Fisher (2) identified small proportions of plasmalogens in both *M. hirudinaceus* and *M. moniliformis*. We have determined the composition of alkyl moieties of ether glycerolipids in total lipid extracts isolated from *P. ambiguus* and eel intestine. The most abundant alkyl moiety in *P. ambiguus* is 16:0 (38%), followed by 16:1 and 18:1 (25.5% each). In eel intestine, a similar distribution of these alkyl moieties has been detected (16:0, 37.7%; 16:1, 22.6%; 18:1, 37.7%). 1-*O*-Octadecyl moieties (18:0), which are found in remarkably high proportions (9.5%) in the parasite, are low in eel intestine (2%); smaller proportions (1.5%) of 1-*O*-eicosenyl moieties (20:1) are detected in *P. ambiguus* but not in eel intestine. Only traces of plasmalogens, if any, have been detected in the ether lipid fraction of *P. ambiguus*.

In conclusion, we have found that, compared to eel intestine, the sterol and steryl ester fractions of *P. ambiguus* are characterized by the occurrence of remarkably high proportions of phytosterols as well as by dehydro sterols. The neutral acyl lipid fractions of both *P. ambiguus* and eel intestine contain large proportions of unsaturated and, in particular, polyunsaturated fatty acids. The chain lengths of these polyunsaturated fatty acids are found to be predominantly $\geq C_{20}$. In comparison with eel intestine, the neutral lipids of the endoparasite contain higher proportions of polyunsaturated fatty acids. The principles that regulate the metabolism, as well as the absorption and distribution of individual fatty acids, in *P. ambiguus* are not known. It has been shown in aquatic animals that, besides membrane lipids, the fluidity of storage lipids, such as triacylglycerols and wax esters, was increased at lower temperatures due to accumulation of mono- and polyunsaturated long-chain moieties in these lipids (4). Similarly, differences in the composition of the 1-*O*-alkyl moieties of ether glycerolipids from *P. ambiguus* and eel intestine have been found; it is noteworthy that the ether lipids of the parasite contain higher proportions of the 1-*O*-octadecyl moiety.

Finally, it should be noted that neutral lipids, such as wax esters, steryl esters, triacylglycerols and free fatty acids, usually are components of the surface coat (36) that protects endoparasites from the host environment. Such lipids have been shown to be released by human blood flukes (*Schistosoma* ssp.) (37–39). Studies on the biophysical properties of these lipids show that they are able to diffuse within the plane of the surface of endoparasites (40). Surface lipids may also play an important role in the resistance of *P. ambiguus* to host cellular defense mechanisms which are characterized by an increase in leukocyte numbers in the infected intestinal wall (41,42).

ACKNOWLEDGMENTS

The authors are indebted to Dr. E. Homberg and B. Bielefeld for sterol analyses, and to G. Werner for fatty acid analyses. Fisherman M. Reiter (Petershagen, Germany) provided the infected eels.

In an ongoing study, rat and human urine have been examined for the presence of malondialdehyde (MDA) derivatives as indicators of the nature of lipid peroxidative damage caused by this compound *in vivo*. MDA in urine was found to be present mainly in the form of two lysine adducts, one acetylated and the other unacetylated, reflecting *in vivo* reactions with tissue proteins. Two minor metabolites were identified as adducts with the phospholipid bases serine and ethanolamine and a third one as an adduct with the nucleic acid base guanine. The identification of an MDA adduct with deoxyguanosine (dG–MDA) among the products of hydrolysis of rat liver DNA suggested the possible occurrence of this compound in urine. In the present study dG–MDA was identified in rat and in human urine, and a high-performance liquid chromatographic method utilizing fluorescence detection was developed for its estimation. The method is sensitive to 1 pmol of dG–MDA and requires a minimum of 1 mL of rat urine or 5 mL of human urine. Its rate of excretion by five-week-old rats (28.54 ± 2.28 nmol/kg/24 h) (mean ± SEM) was higher than that for nine-week-old rats (6.29 ± 1.02) and much higher than that for adult humans (0.40 ± 0.05). The results indicate that, as reported for 8-hydroxy-deoxyguanosine, dG–MDA excretion is related to metabolic rate. Excretion of dG–MDA by the rat, like the excretion of total MDA, declines during growth on a body weight basis at a rate similar to the decrease in resting energy metabolism. In contrast to other MDA derivatives excreted in rat urine, vitamin E deficiency had no effect on the excretion of dG–MDA. Together with evidence that the dG–MDA content of rat liver DNA likewise is unaffected by vitamin E depletion or by administration of catalysts of *in vivo* lipid peroxidation, these findings indicate that DNA is protected from lipid peroxidative damage, possibly through conservation of the vitamin E associated with the lipids of the nuclear membrane.

***Lipids* 29, 429–432 (1994).**

In an ongoing study, the forms in which malondialdehyde (MDA) is excreted in rat and in human urine have been investigated as a source of information on the nature of its reactions with macromolecules *in vivo*. About 75% of the MDA in urine collected from rats fed an MDA-free diet was found to be present as two lysine adducts, one acetylated and the other unacetylated, reflecting *in vivo* reactions with tissue proteins (1). Three minor metabolites were identified as adducts with the phospholipid bases serine and ethanolamine, and the nucleic acid base guanine. Of the total MDA in rat urine, only 10–20% is normally present in the free form. Human urine contains similar metabolites, but the excretion of total MDA (free and acid hydrolyzable) is much smaller on a body weight basis, and little or no MDA (0–5%) is excreted in the free form. Over half of the lysine derivatives excreted in human urine originate in the diet, where MDA generated by the peroxidation of food lipids reacts with the lysine residues of food proteins from which it is released during protein digestion and absorbed as a lysine adduct (2). Unlike free MDA, the lysine adduct is not mutagenic.

The identification of guanine–MDA (Gua–MDA) in urine (3) and of an MDA adduct with deoxyguanosine (dG–MDA) in a hydrolysate of rat liver DNA (4) suggested the possible occurrence of this adduct in urine. In this paper, evidence is presented for the presence of dG–MDA in rat and human urine, and estimates are given for its rate of excretion.

EXPERIMENTAL PROCEDURES

Animal experiments. Twenty-four-hour urine samples were collected from five five-week-old rats (body weight about 100 g) that had been fed a purified diet containing 10% corn oil (5) supplemented with a high level of vitamin E (100 IU ppm dl-α-tocopheryl acetate) for two weeks postweaning. The samples were collected under toluene twice daily, filtered and stored at –20°C prior to analysis.

In a second experiment, a group of five weanling rats was fed the vitamin E-supplemented diet and another group was fed the same diet, except that vitamin E was deleted and natural corn oil was replaced with molecular-distilled corn oil (5). After six weeks, vitamin E depletion in the second group was confirmed using an autohemolysis test (6) (81% hemolysis vs. 17% in the controls). Both groups then were switched for 72 h to an MDA-free diet containing 10% hydrogenated coconut oil, and urine was collected for the final 48 h.

Twenty-four-hour urine samples were obtained from five healthy, middle-aged women consuming free-choice diets, and aliquots were frozen as described.

Urinalysis for dG–MDA. Three mL of rat urine was mixed with an equal volume of ethanol and stored overnight at 4°C. After centrifuging, a volume of supernate equivalent to 2 mL of urine was freeze-dried, and the residue was dissolved in 1 mL of water.

The sample was applied to a chromatographic system composed of an AG 1-X8 anion exchange membrane in the chloride form (Bio-Rad, Richmond, CA), an AG 50W-X8 cation exchange membrane in the sodium form (Bio-Rad)

and a C_{18} μBondapak reverse-phase SEP-PAK® capsule (Waters, Millipore Corp., Milford, MA). These components were mounted, in tandem, on a 10 mL syringe. The system was developed with 2 mL water, and the anion exchange membrane was removed. The remaining components were washed with 7 mL saturated KCl solution, and the cation exchange membrane was removed. The reverse-phase capsule then was washed with 2 mL water followed by 3 mL methanol. The methanolic fraction, containing dG–MDA, was dried at 40°C under a stream of air, and the residue was dissolved in 500 μL of water.

Further purification was achieved using an isocratic high-performance liquid chromatography (HPLC) system (Waters) that included a reverse phase C_{18} μBondapak analytical steel column, a scanning fluorescence detector (Model 470) and an absorbance detector (Model 440). For fluorescence analysis, the excitation and emission wavelengths were set at 340 and 518 nm, respectively. Aliquots (100–200 μL) of the partially purified sample were injected onto the column, and the system was developed with 10% methanol in water at a flow rate of 1 mL per min. Major fluorescence peaks were observed during the first 10 min, followed by a 12–15 min peak that coincided with that of pure synthetic dG–MDA (R_t 10.9 min) and was collected for further characterization. Recovery of standard dG–MDA added to the sample. This fraction was collected, evaporated to dryness, and the residue was taken up in 500 μL of water. Aliquots (100–200 μL) were re-injected, and the column was developed with 15% methanol in water at a flow rate of 1 mL per min. A 7–10 min fraction was collected, dried, and the residue was dissolved in 500 μL water. Two fluorescent compounds present in the fraction were resolved by rechromatography on the same column using 30% methanol in water at a flow rate of 0.5 mL per min. One compound co-eluted with synthetic dG–MDA (R_t 10.9 min) and was collected for further characterization. Recovery of standard dG–MDA injected onto the column was essentially quantitative over the operational range, and overall recovery was 89%.

The amounts of dG–MDA found in human urine were markedly lower than those for rat urine, necessitating the use of a larger starting sample (10–15 mL). In addition, human urine samples varied unpredictably in their content of fluorescent compounds, probably of dietary origin, that interfered in the isolation and quantification of dG–MDA using HPLC with fluorescence detection. Absorbance detection gave a well-defined peak for dG–MDA, but was ten times less sensitive than fluorescence detection. In contrast to urine samples obtained from rats fed a standard diet, each sample of human urine presented a different analytical challenge.

Isolation of dG–MDA from urine. Rat urine (100 mL in two 50-mL aliquots) was chromatographed on a 2.3 × 45 cm, 200–400 mesh AG 1X8 anion exchange column as described previously (7). The column was developed using a linear salt gradient provided by 1 L of 0–1 M NaCl solution. Fractions 60–120 (5 mL each) were pooled and reduced to 10 mL *in vacuo* at 37°C. The concentrated eluate was applied to a C_{18} μBondapak reverse-phase glass column (2 × 10 cm, 55–105 μm) and washed with 50 mL water, followed by 50 mL of 10% methanol to remove residual salt. The column then was developed with 25% methanol in water, and 10-mL fractions were collected.

Fractions 5–7 were combined, evaporated to dryness *in vacuo* at 37°C, and the residue was dissolved in 2 mL chloroform/methanol/water (85:14:1, by vol). This mixture was used as the mobile phase for further purification of the sample on a Zorbax® silica gel glass column (1.2 × 14 cm, 55–105 μm). Fractions 6–10 (4 mL each) were pooled, dried as before, and the residue was taken up in 300 μL water. Ten 30-μL aliquots (each equivalent to 10 mL urine) were injected onto a reverse-phase C_{18} μBondapak column (3.9 × 300 mm, 10 μm) fitted with a Guard-Pak Holder® (Waters) charged with C_{18} inserts. The column was developed for 50 min using a linear gradient of 0–7.5% acetonitrile at a flow rate of 1.0 mL per min. Eluates were detected by absorption (254 nm) and fluorescence (340, 518 nm) detectors, and the isolation procedure was monitored throughout by co-chromatography of the eluates with pure synthetic standard. Based on its retention time (45 min), the 44–46 min fractions were collected.

Human urine (600 mL) was freeze-dried and the residue dissolved in 120 mL distilled water. After standing overnight in the cold, the sample was centrifuged for 15 min at 2,000 rpm, and 100 mL of the supernatant fraction, equivalent to 500 mL of urine, was used for the isolation of dG–MDA by the procedure described for rat urine.

Preparation of silyl derivatives. The fractions collected from the silica gel column were dried and derivatized in acetonitrile using *O-bis*(trimethylsilyl)trifluoroacetamide + 1% trimethylchlorosilane. The reaction mixture was dried *in vacuo,* and the residue was subjected to HPLC, gas chromatography/mass spectrometry (GC/MS) and direct input probe-mass spectrometry (DIP-MS) analysis.

RESULTS

The chromatograms obtained for a sample of synthetic dG–MDA, for the eluate equivalent to 20 μL of rat urine collected from the reverse-phase column and for the com-

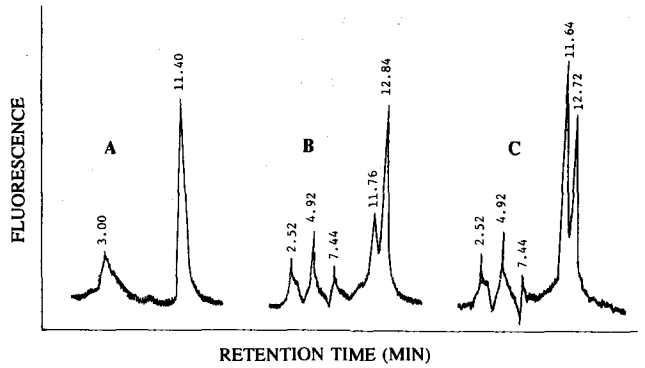

FIG. 2. High-performance liquid chromatography tracings obtained for 7.3 pmol of synthetic deoxyguanosine–malondialdehyde adduct (A), isolate equivalent to 100 μL of human urine (B), and the combination of A and B (C).

bined samples are illustrated in Figure 1. The analogous chromatograms for an eluate from human urine are shown in Figure 2. The fluorescence peak at *ca.* 12.5 min represented the only significant contaminant of dG–MDA found in the isolates from both rat and human urine and could not be consistently separated using reverse-phase HPLC. It did not appear in the absorption chromatograms, in which a single peak corresponding to that for synthetic dG–MDA was observed when a larger sample of urine was used.

The identity of the eluate from rat urine (Fig. 1B) was further investigated by examining its acid and thermal hydrolysis products. An aqueous solution of the compound was heated in a boiling water bath at pH 3 for 30 min in the presence of thiobarbituric acid (TBA), and the reaction products were analyzed for TBA–MDA complex by a procedure that is specific for MDA (8). The amount of isolate consumed in the reaction was quantified in terms of dG–MDA equivalents from a regression line for fluorescence peak area vs. pmoles of synthetic dG–MDA injected onto the column. The fluorescence response was linear over the range employed (1–10 pmol). The molar ratio of the amount of dG–MDA estimated by fluorescence analysis and found by MDA analysis was 1:0.98.

Another sample of isolate, estimated by fluorescence analysis to contain 44.16 pmol of dG–MDA, was partially hydrolyzed by heating in 100 μL of aqueous HCl in a boiling water bath for 30 min. The products were chromatographed on the C_{18} μBondapak column using 10% methanol in water as solvent. Absorbance peaks were recorded using a detector set at 254 nm and at maximum sensitivity. The amounts of Gua, deoxyguanosine (dG) and Gua–MDA in the hydrolysate were determined from standard curves prepared using pure compounds. The analysis yielded 23.76 pmol Gua, 5.26 pmol dG and 11.78 pmol of Gua–MDA (recovery 40.8 pmol or 92.4%).

Analysis of 24-h urine samples collected from five-week-old rats averaging 99 g in body weight yielded a value for dG–MDA of 28.54 ± 2.28 nmol/kg/24 h (mean ± SEM) (n = 5). The corresponding value for five 24-h samples of adult human urine was 0.40 ± 0.05 nmol/kg/24 h. The minimum operational sample size was 1 mL for rat urine and 5 mL for human urine.

Analysis of urine collected from five nine-week-old rats fed the vitamin E-deficient diet for the previous six weeks yielded a value of 6.29 ± 1.02 nmol dG–MDA/kg/24 h. The value for the positive controls was not significantly different (6.07 ± 0.69 nmol/kg/24 h). There was also no difference in final body weights (*ca.* 170 g). As found previously (5), the excretion of total MDA in the urine was higher in the deficient group (13.9 vs. 8.1 μg/24 h; $P < 0.05$).
