The isolates from rat and human urine exhibited similar retention times when chromatographed on the reverse-phase column using a 0–7.5% acetonitrile gradient and on a Zorbax® silica column (4.6 × 250 mm, 10 μm) using a chloroform/methanol/water (93.6:6:0.4) mixture (*ca.* 44.5 and 20.4 min, respectively). Their trimethylsilyl (TMS) derivatives likewise had similar retention times (*ca.* 16.5 and 15.7 min, respectively) using a 2-propanol/methanol/*n*-hexane (20:5:75) mixture. These values coincided with those for synthetic dG–MDA and its TMS derivative, and a mixture of the isolates and their synthetic counterparts co-eluted.

The total ion chromatogram for the TMS derivative of synthetic dG–MDA (TMS–dG–MDA) subjected to GC/MS indicated that it was totally decomposed on the GC column. Ions were seen at *m/z* 187 (Gua–MDA) and at 73 (TMS). When analyzed by DIP-MS, peaks were seen at *m/z* 447 (molecular ion), 187 and 73. The spectrum for the synthetic compound was fully consistent with that found by Seto *et al.* (9). DIP-MS of the isolate from rat urine yielded ions at *m/z* 447 and 187. The presence of these ions is further evidence for the occurrence of dG–MDA in rat urine and for its pyrimidinopurine structure (9). The amount of isolate recovered from human urine (60 ng from 360 mL) was inadequate to obtain an interpretable spectrum.

DISCUSSION

The presence in urine of dG–MDA is consistent with its presence in an hydrolysate of rat liver DNA (4). The urinary compound is presumably a product of DNA repair synthesis. The excretion of dG–MDA by young, growing rats was 70-fold greater than that by adult humans on a body weight basis. Rodents excrete larger amounts of other products of oxidative damage, including thymine glycol and 8-hydroxydeoxyguanosine (8-OHdG) (10). The higher rate of excretion of these metabolites by rats is attributable to increased hydroxyl radical production associated with their high rate of oxygen consumption per unit body weight. As hydroxyl radicals are potent initiators of lipid peroxidation, their higher rate of dG–MDA excretion is attributable to the same cause.

There is other evidence for a higher rate of lipid peroxidation in rats than in humans. A greater proportion of the total MDA in rat urine is excreted in the free form (*ca.* 20 vs. 0–5%), and this fraction is markedly increased by the administration of iron nitrilotriacetate (5). The rate of excretion of dG–MDA found for human adults (404 ± 46 pmol/kg/24 h) is not markedly higher than that reported for 8-OHdG (~220 pmol/kg/24 h) (11). In contrast, the rate of excretion of dG–MDA by five-week-old rats was about 60-fold greater than that observed for 8-OHdG

excretion by two-month-old rats (11). This difference in the relative rates of dG–MDA and 8-OHdG excretion by the two species suggests that, at least in the rat, propagation by a free radical chain reaction, rather than initiation by hydroxyl radicals, is the main mechanism by which lipid peroxidation is driven. However, this explanation assumes that repair synthesis of DNA that has been modified by reactions with hydroxyl radicals and with MDA proceeds at the same rate.

Age is another probable factor in the difference in the dG–MDA content of rat and human urine found in this study. Total MDA excretion per unit body weight decreases progressively with age in rats, from 40 ng/g/24 h at three weeks of age to 25 ng at six weeks and 10 ng at 20–30 weeks (5). This decline is analogous to the decrease in the resting metabolism of growing rats from 260 kcal/kg/d at 40–42 days of age to 155 kcal at 60–64 d and 113 kcal at 100–120 d (12). The difference in dG–MDA excretion between the five-week-old and nine-week-old rats in the present study further indicates that during growth there is a steadily decreasing titer of free MDA in the tissues that is available for reactions with DNA Gua, the lysine residues of proteins and the amino groups of other compounds. Evidence for increased levels of lipid peroxidation products in the tissues of aged animals may be due to an increase in the production of free MDA production in old age or to an accumulation of these products during adult life.

The failure of vitamin E depletion to increase dG–MDA excretion in the rat is noteworthy in view of increases seen in the excretion of free MDA and its lysine derivatives in rats rendered vitamin E-deficient or treated with iron (5). However, it is consistent with a failure to find any change in the dG–MDA content of hydrolysates of DNA isolated from the liver of rats subjected to the same treatments (Draper, Agarwal and Wee, unpublished results). DNA appears to be better protected from peroxidative damage caused by MDA than are tissue proteins, possibly by conservation of vitamin E in the nuclear membrane. Vitamin E depletion of the rats used in this study was verified by liver analysis. The results of the urinalysis for dG–MDA indicate that the excretion of this compound is not a useful index of *in vivo* lipid peroxidation. The cause of significant disparities found in the dG–MDA content of DNA isolated from different rat organs and at different ages (Draper, and Wee, unpublished results) is unknown.

COMMUNICATION

Fatty Acid and Positional Selectivities of Gastric Lipase from Premature Human Infants: *in vitro* Studies

Robert G. Jensen[a,*], Felice A. deJong[b], Lisa G. Lambert-Davis[c] and Margit Hamosh[d]

[a]Department of Nutritional Sciences, University of Connecticut, Storrs, Connecticut 06269-4017, [b]Sigma Aldrich Pty. Ltd., Castle Hill, NSW, 2154, Australia, [c]Chemagnetics, New Castle, California 95658 and [d]Department of Pediatrics, Georgetown University Medical Center, Washington, DC 20007

Gastric lipase activity in aspirates from premature human infants was tested for fatty acid and positional selectivity using racemic diacid triacylglycerols (TG) as substrates. The resulting free fatty acids and monoacylglycerols (MG) were recovered and analyzed. Octanoic acid (8:0) and decanoic acid (10:0) were hydrolyzed with a preference of 61.5:1 and 2.4:1 compared to palmitic acid (16:0) from *rac*-16:0-8:0-8:0 and *rac*-16:0-10:0-10:0, respectively. The ratio of lauric acid (12:0) to oleic acid (18:1) hydrolyzed from *rac*-18:1-12:0-12:0 was 13:1. Myristic acid (14:0), 18:1 and linoleic acid (18:2) were released at similar rates. These data and the composition of the MG suggest that, *in vitro*, the lipase is selective for shorter chain fatty acids and for fatty acids on the primary positions of the TG backbone.
***Lipids* 29, 433–435 (1994).**

The lipase activity in human gastric aspirates was once believed to be of lingual origin. It was also thought that the enzymes that act in the stomach have little effect on dietary triacylglycerols (TG). In the human, the enzyme is now known to be secreted mostly from gastric mucosal cells (1,2). In the newborn, the enzyme hydrolyzes 40–60% of dietary TG (3,4). The lipid globules in milk from humans (4–6) and other species (4,7) are resistant to intestinal lipolysis by either pancreatic lipase (8–10) or bile salt-stimulated lipase from milk (5–7,11), unless first exposed to gastric lipases. Therefore, gastric lipase has a major role in the digestion of dietary TG, but it has received relatively little attention.

Specificity, now more commonly termed selectivity signifying a broader range, is one of the characteristics of lipases. Selectivity controls the digestion of TG and the absorption of the resulting free fatty acids (FFA) and monoacylglycerols (MG) (12). We found that the gastric lipase activity was stereoselective for the *sn*-3 ester over the *sn*-1 ester at a ratio of 4:1 using three enantiomeric TG containing 16:0 and 18:1 as substrates (13). During the present study, selectivity for shorter chain fatty acids was observed when we employed various synthetic TG as substrates. In this paper, we present data that show that, *in vitro*, human infant gastric lipase has a preference for the primary ester groups of TG and in varying degrees for 8:0 through 12:0 fatty acids over 16:0 and 18:1. The implications of our *in vitro* results and their relevance to *in vivo* lipolysis will be discussed. A preliminary report has been published (14).

Abbreviations: FFA, free fatty acids; GLC, gas–liquid chromatography; MG, monoacylglycerols; *rac*-16:0-16:0-18:1, 1,2-dipalmitoyl-3-oleoyl-*rac*-glycerol; TG, triacylglycerols; TLC, thin-layer chromatography.

MATERIALS AND METHODS

Aspirates containing gastric lipase were obtained as part of routine postnatal care at the Georgetown University Hospital (Washington, D.C.). The 0.5–5.0 mL samples were taken from infants whose gestational age was 33–42 wk. The specimens were obtained with the permission of the Georgetown University Institutional Review Board and the informed consent of the infant's parents or guardians. The samples were assayed for lipolytic activity (15), and the 32 samples with the highest activity levels were frozen on dry ice and sent to the University of Connecticut. All samples arrived frozen and were stored in a freezer at –70°C.

The digestion contained 0.1% citrate-Na_2HPO_4 buffer at pH 5.4, 5% bovine serum albumin and 0.1% gum arabic in a final volume of 25–50 mL. Prior to digestion, 2% of the desired TG was added, melted by heating on a steam bath if necessary, and emulsified with a Branson Sonifier (Branson Ultrasonics Corp., Danbury, CT). The mixture was equilibrated at 37°C in a water bath, and the gastric aspirate was added. The amount of aspirate used varied depending on the volume of the sample, but usually two equal portions were employed, one for the TG and one for a control without substrate. This procedure was necessary, as was the later addition of an internal standard, because each aspirate contained some lipid and the risk of denaturing the lipase by extraction of the aspirates with solvent was to be avoided. The incubation time was 30–60 min, depending on the activity of the aspirate. The racemic TG used as substrates were 16:0-8:0-8:0, 16:0-10:0-10:0, 18:1-12:0-12:0, 18:1-14:0-14:0, 18:1-18:2-18:2 and 18:2-18:1-18:1. The TG were synthesized as described by Jensen and Pitas (16). Purity of the TG was ascertained by thin-layer chromatography (TLC) and positional integrity was verified by pancreatic lipolysis (16).

After the desired period of incubation, i.e., upon about 40% hydrolysis, the samples were extracted, the digestion products were separated by TLC, and the fatty acids were analyzed by gas–liquid chromatography (GLC) after conversion to methyl esters (17). The products that contained 8:0 and 10:0 were converted to butyl esters. A known amount of methyl or butyl heptade-

canoate was added to each fraction prior to analysis by GLC. The fatty acids in the aspirate controls were subtracted from those in the respective digestion products after equalizing the internal standards and adjusting the amounts of the other acids accordingly. All data are given as mol%.

We did not attempt to separate the *sn*-1(3)-MG and 2-MG because, under our digestion conditions, acyl migration of the *sn*-2 ester to the *sn*-1(3) ester was observed.

RESULTS AND DISCUSSION

The fatty acid compositions of the original TG and of the MG and FFA from the digestions of the TG by gastric lipase are presented in Table 1. Included for validation of the TG structures are earlier data obtained by pancreatic lipolysis with the appropriate TG acids at *sn*-1(3), in FFA and in *sn*-2 MG. Selectivities for 8:0, 10:0 and 12:0 are clearly seen for gastric lipase. If there was no fatty acid selectivity, and with a 4:1 stereoselectivity for *sn*-3, the FFA from *rac*-16:0-8:0-8:0 would contain a 1:1 ratio of 16:0 and 8:0 (a 1:4 ratio for 16:0 and 8:0 from *sn*-16:0-8:0-8:0, and a 4:1 ratio for 16:0 and 8:0 from *sn*-8:0-8:0-16:0). The MG should be 100% 8:0. These theoretical ratios would apply to the digestion products from all the TG, but they did not for TG containing 8:0, 10:0 and 12:0 fatty acids. The ratios of fatty acids from these TG were 61.5:1 for 8:0/16:0, 2.3:1 for 10:0/16:0 and 13:1 for 12:0/18:1, all indicating selectivity for the shorter chain acids. Myristic acid (14:0) was not preferentially hydrolyzed compared to 16:0, nor was there selectivity between 18:1 and 18:2. The nature of the long-chain fatty acid seems to influence selectivity, e.g., 16:0-10:0-10:0 vs. 18:1-12:0-12:0.

The nature of the fatty acids in the MG (Table 1) suggests that apparent hydrolysis of the *sn*-2 ester occurred after acyl migration to *sn*-1(3). Our digestion conditions, pH 5.4 for 30 to 60 min, favor acyl migration; thus isolation and identification of the MG isomers would not have shed light on the mechanism. Nevertheless, some hydrolysis of 8:0, 10:0 and 12:0 at *sn*-2 probably occurred. We know from past experience with pancreatic lipolyses that acyl migration begins after about 5 min of digestion, which may also have occurred in the present case.

Lack of selectivity for the primary esters in TG of longer chain fatty acids is indicated by the approximately equimolar amounts of 18:1 and 14:0, and 18:1 and 18:2 in the FFA released from 18:1-14:0-14:0, 18:1-18:2-18:2 and 18:2-18:1-18:1. However, the MG again contained *sn*-1(3) fatty acids, which could be caused by either or both *sn*-2 hydrolysis and acyl migration. To differentiate between the two, we could have used triacid TG or, as has been recently described by Rogalska *et al.* (18), shorter digestion times that are less likely to produce MG, followed by high-performance liquid chromatography of the enantiomeric diacylglycerols derivatives. Rogalska *et al.* (18) did not observe any digestion of the *sn*-2 acid in 18:1-18:1-18:1 after 6 min of hydrolysis and confirmed the stereoselectivity of purified human gastric lipase for *sn*-3 of 18:1-18:1-18:1 by their method.

Our results are similar to those reported by other investigators (18,19). Thus, the rates of hydrolysis decreased as the chain length of the fatty acids in monoacid TG increased; the specific activities for 4:0-4:0-4:0 were 1000; for 8:0-8:0-8:0, 470; and for 18:1-18:1-18:1, 0.9 (18). The rates were dependent upon pH, the nature of the substrate and the type of enzyme, with a lower maximum, 4.5 vs. 5.5 for 4:0-4:0-4:0 than for 18:0-18:0-18:0 when homogenates of human gastric mucosa were used as gastric lipase source (19,20). With purified human gastric lipase, activity was only two times higher with 4:0-4:0-4:0 than with 18:1-18:1-18:1, and the pH optima were at 4.0 for Intralipid and at 4 to 6 for 4:0-4:0-4:0 (21). In this study, we did not compare the release of 16:0 and 18:1 from diacid TG containing these

[a]Lipase activity in gastric aspirates; lipolyses were done at pH 5.4 for 30 to 60 min to achieve about 40% hydrolysis.

[b]Porcine pancreatic lipase; lipolyses were done at pH 8.4 for 2 to 5 min.

[c]No fatty acid selectivity would be indicated by a 50:50 ratio, as seen for pancreatic lipase.

[d]X is the fatty acid in the TG, MG or FFA other than 16:0 or 18:1.

acids, but Hamosh *et al.* (22) observed preferential release of 18:1 and 18:2, as well as of 8:0 and 10:0 from infant formulas in the stomach. Further investigation of the apparent selectivity for unsaturated fatty acids is indicated. However, up to 60% of milk TG are hydrolyzed in the stomach of the suckling canine puppy, although canine milk fat contains almost exclusively longer chain fatty acids, none less than 14:0 (4).

Furthermore, there seems to be a temporal relationship to the type of fatty acid released: During short-term digestion (10 min) of human milk fat globules, the amount of 8:0 and 10:0 was higher than that of 18:1 and 18:2, whereas after 30 min of incubation, 18:1 and 18:2 far exceeded the level of medium-chain fatty acids released (23,24).

The extensive hydrolysis of milk fat in the stomach of several species whose milk contains exclusively or predominantly long-chain fatty acids, such as the dog (4), seal (24) and human (3), indicates that, *in vivo*, gastric lipase efficiently releases long-chain fatty acids from milk or formula (4,5,22,25,26). It is possible that the strong product inhibition of gastric lipase by long-chain fatty acids (19,27,28) does not occur under *in vivo* conditions (3,4). Furthermore, some dietary proteins have been shown to bind fatty acids more efficiently than does albumin, which is usually used as a fatty acid sink in *in vitro* studies (28). The presence of short-chain fatty acids at the *sn*-3 position of milk fat TG from the cow (29) explains their possible, but as yet undetermined, preferential release by gastric lipase, an enzyme with a 4:1 stereoselectivity for this position.

Our study, which shows that *in vitro* gastric lipase from premature human infants selectively releases 8:0, 10:0 and 12:0 as compared to 16:0 or 18:1 from racemic TG, emphasizes the need for careful *in vivo* examination of the selectivity of gastric lipolysis. The *in vitro* selectivity of the lipase can be summarized as follows: (i) positionally, primary esters are preferred; (ii) among fatty acids, short-chain fatty acids are preferred; and (iii) sterically, *sn*-3/*sn*-1 are preferred at a 4:1 ratio.

Lymphatic Fatty Acids from Rats Fed Human Milk and Formula Containing Coconut Oil

Matthew E. Roche and **Richard M. Clark***

Department of Nutritional Sciences, University of Connecticut, Storrs, Connecticut 06269-4017

Human milk and infant formula containing coconut/soy oil were infused into the duodenum of rats to determine the incorporation of capric, lauric, myristic and palmitic acids into lymphatic triacylglycerol (TAG). The proportion of capric and lauric acids in the lymphatic TAG reflected the fatty acid composition of the diet. Based on positional analysis, it appears that more than 50% of the capric and lauric acids could have been absorbed from the intestine as *sn*-2 monoacylglycerols. In the rats fed human milk, 50% of palmitic acid in lymphatic TAG was in the *sn*-2 position. Because of the nonrandom distribution of palmitic acid in the lymphatic TAG, the nonspecific lipase in human milk, i.e., bile salt-stimulated lipase, did not appear to be a factor in milk lipid digestion.
***Lipids* 29, 437–439 (1994).**

Human milk and infant formulas containing coconut oil have substantial amounts of capric (10:0), lauric (12:0), myristic (14:0) and palmitic acids (16:0). It is generally accepted that chain length determines the absorption pathway of these fatty acids with 10:0 and 12:0 being transported from the digestive tract in the portal blood while 14:0 and 16:0 are transported in the lymph (1,2). However, it is also known that the structure of the triacylglycerol (TAG) influences the absorption of component fatty acids (3–5). While most of the 10:0 and 12:0 from human milk and infant formula may be taken up into the portal blood, a significant portion may be transported in the lymph if absorbed from the intestinal lumen as *sn*-2 monoacylglycerol (MAG) and resynthesized into lymphatic TAG by the *sn*-2 MAG pathway.

Lipids from human milk contain 20–25% 16:0, which is located predominantly in the *sn*-2 position of the milk TAG (6). Due to the specificity of pancreatic lipase for hydrolysis of fatty acids from the primary positions of TAG, a large proportion of 16:0 from human milk may be absorbed as *sn*-2 MAG (4). However, human milk also contains bile salt-stimulated lipase (BSSL), a nonspecific lipase that is thought to complete digestion of milk lipid by hydrolyzing MAG (7). If BSSL contributes significantly to milk lipid digestion, 16:0 would be hydrolyzed from the *sn*-2 MAG produced by pancreatic lipase, and the final products of digestion would be primarily free fatty acids and glycerol (7). In the absence of *sn*-2 MAG, the phosphatidic acid pathway would be predominant in the enterocyte, and it is assumed that 16:0 would not be preferentially introduced in the *sn*-2 position of TAG by this pathway. Hence, there would be no enrichment of 16:0 in the *sn*-2 position of the lymphatic TAG in animals fed human milk, as was previously suggested (4).

Abbreviations: BSSL, bile salt-stimulated lipase; MAG, monoacylglycerol; TAG, triacylglycerol.

In the present study, human milk and infant formula containing coconut/soy oil were infused into the duodenum of rats to determine incorporation of 10:0, 12:0, 14:0 and 16:0 into lymph and the position of these fatty acids in the lymphatic TAG. One objective of this study was to test the assumption that very little 10:0 or 12:0 is transported in the lymph. A second objective was to determine the position of 16:0 in the lymphatic TAG of rats receiving human milk. If enrichment of 16:0 in the *sn*-2 position is not maintained through digestion and absorption, it would indicate nonspecific lipase activity and support a role for BSSL in digestion of milk lipid. It is assumed that the phosphatidic acid pathway, which would become operative in the absence of 2-MAG, would not preferentially introduce 16:0 in the *sn*-2 position of the lymphatic TAG.

MATERIALS AND METHODS

Animals and surgical procedure. Male Holtzman albino rats obtained from Holtzman Laboratory Animals (Madison, WI) were used in this study. At the time of surgery the rats weighted 275–350 g, and they were consuming a standard laboratory diet (Purina Rodent Chow 5001; Purina Mills, St. Louis, MO) and water *ad libitum*.

The major mesenteric lymph duct was cannulated as described by Warsaw (8). First the rats were anesthetized with methoxyflurane, and a right subcostal incision was made. The major mesenteric lymph duct was located, and a bevelled heparin-filled micro-renathane implantation tube (MRE 040; Braintree Scientific, Braintree, MA) was threaded approximately 3 mm into the lymphatic duct. After a good lymph flow was established, the cannula was secured using cyanobutylacrylate adhesive. Then a feeding tube was placed in the duodenum by passing MRE 040 micro-renathane tubing in a caudal direction through a small gastric puncture and securing it with 4-0 silk. The abdominal wall was closed by suturing the muscle layer with 4-0 silk and then by stapling the skin with Michel wound clips (Harvard Bioscience, South Natick, MA).

Immediately following surgery, the rats were restrained in modified Bollman cages (9), placed in a warm dark environment and allowed to recover for approximately 24 h. During the recovery period the rats had access to water, and a glucose/electrolyte solution (Pedialyte; Ross Laboratories, Columbus, OH) was infused into the duodenum at 2.0 mL/h.

Infusates. Following their recovery, six rats were infused (2.5 mL/h) for 12 h through the feeding tube with human milk (3.3 g lipid/100 mL), and six rats were infused with an infant formula containing coconut/soy oil (3.4 g lipid/100 mL, ProSobee; Mead Johnson, Evansville, IN). Lymph was collected for 12 h in heparinized tubes on ice and stored at −70°C until analyzed.

The human milk was donated by a woman during her eighth month of lactation. Several complete breast ex-

pressions were collected with the aid of an electric breast pump. Milk samples were pooled and stored at –70°C.

Lipid analyses. Total lipids were extracted from aliquots of each diet and each lymph collection was made by a modified Folch procedure (10). The TAG in the lymph were isolated using Silica Gel G thin-layer chromatographic plates developed with hexane/diethyl ether/glacial acetic acid (90:30:2, by vol).

An aliquot of the TAG was used for structural analysis. The fatty acids esterified to the *sn*-2 position were measured directly after hydrolysis of the fatty acids from the *sn*-1,3 positions with porcine pancreatic lipase (11). The fatty acids esterified in the *sn*-1,3 positions were calculated as:

$$(sn\text{-}1,3) = \frac{3(\text{TAG}) - (sn\text{-}2)}{2} \quad [1]$$

Fatty acids associated with total lipid, TAG and *sn*-2 MAG were transmethylated in methanol/hexane (4:1, vol/vol) in the presence of acetyl chloride (12) and fatty acid methyl esters were separated by gas–liquid chromatography on a Supelcowax 10 fused silica capillary column, 30 m × 0.53 mm i.d. (Supelco, Bellefonte, PA).

RESULTS AND DISCUSSION

The fatty acid composition of the infused diets and of the lymph are shown in Table 1. The proportions of 10:0 and 12:0 in lymphatic TAG were approximately the same as those in the diets. This was unexpected as it was assumed that these fatty acids would be transported as albumin-bound free fatty acids in the portal blood (1,2).

One factor that discriminates against transport of 10:0 and 12:0 in the lymph is the preference of acyl-CoA synthetase for fatty acids containing more than 12 carbons (13). When dietary lipid is digested and the fatty acids are absorbed in free form, they must be activated by acyl-CoA synthetase before reesterification into lipid and subsequent transport in the lymph. In the enterocyte, the *sn*-2 monoglyceride pathway is the major pathway for TAG synthesis, and *sn*-2 MAG, a product of pancreatic lipase digestion, serves as the fatty acyl-CoA acceptor (14). Therefore, the fatty acids in the *sn*-2 position of the TAG synthesized by this pathway do not require activation by acyl-CoA synthetase, while fatty acids in the *sn*-1,3 positions do.

A positional analysis was made of lymphatic TAG to determine the distribution of fatty acids in the *sn*-2 and *sn*-1,3 positions (Fig. 1). In the human milk-infused animals, 83% of the 10:0 and 67% of the 12:0 were esterified to the *sn*-2 position of the lymphatic TAG. The TAG in the lymph of the formula-fed animals contained 50% of 10:0 and 54% of the 12:0 in the *sn*-2 position. It appears that a large proportion of the 10:0 and 12:0 from formula and human milk could have been taken up by the enterocyte as *sn*-2 MAG and resynthesized into lymphatic TAG. The 10:0 and 12:0 associated with the *sn*-1,3 positions would have required activation by acyl-CoA synthetase. While medium-chain fatty acids are not the preferred substrate for acyl-CoA synthetase, 10:0 and 12:0 can be activated, as suckling rats are reported to transport considerable 10:0 and 12:0 in the *sn*-1,3 positions of lymphatic TAG (15).

TABLE 1

Fatty Acid Composition of Infusate and Lymph (wt%)[a]

	Human milk		ProSobee[b]	
Fatty acid	Infused	Lymph	Infused	Lymph
10:0	1.0	0.4 ± 0.1	2.2	1.2 ± 0.5
12:0	6.2	3.4 ± 0.7	23.1	19.4 ± 1.4
14:0	7.2	5.8 ± 0.9	11.3	9.0 ± 0.5
16:0	19.9	24.3 ± 2.0	16.3	13.8 ± 1.8
16:1	1.6	2.6 ± 0.5	n.d.[c]	0.1 ± 0.1
18:0	9.4	9.2 ± 0.4	4.6	5.5 ± 0.3
18:1	31.9	29.9 ± 2.2	15.5	17.2 ± 0.8
18:2n-6	16.4	16.4 ± 1.5	25.8	28.4 ± 0.6
18:3n-3	1.1	0.8 ± 0.2	3.1	3.0 ± 0.4
20:4n-6	0.5	3.0 ± 0.5	n.d.	1.3 ± 0.4

[a]Lymph values are means of six observations ± standard deviation.

[b]ProSobee from Mead Johnson (Evansville, IN). The lipid formulation of this infant formula has changed since this study was undertaken.

[c]Fatty acid not detected (less than 0.05 wt%).

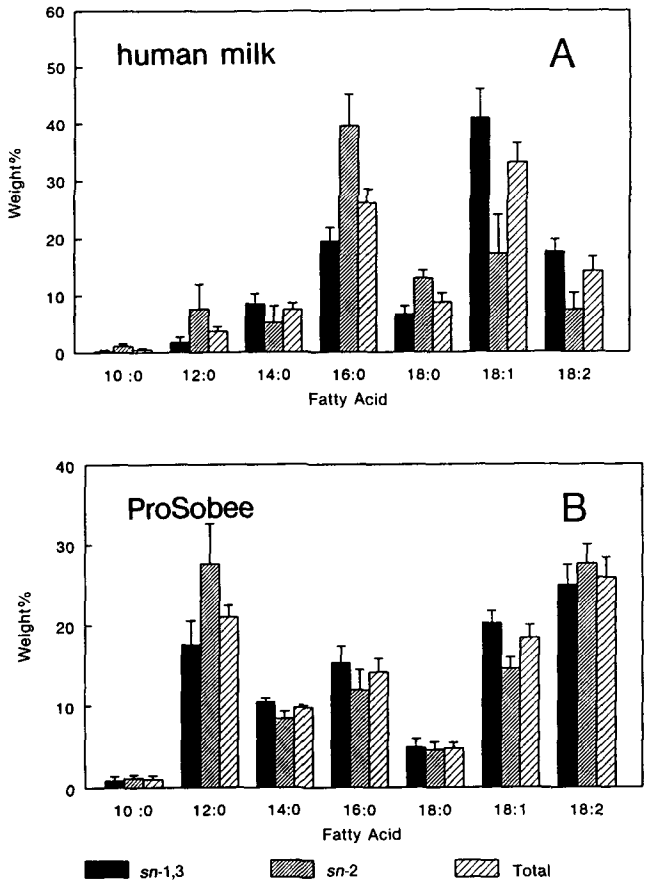

FIG. 1. Distribution of fatty acids (wt%) within each position of lymphatic triacylglycerol from six rats intraduodenally infused with (A) human milk or (B) infant formula (ProSobee; Mead Johnson, Evansville, IN). Results are presented as mean ± standard deviation, n = 6.

Unlike 10:0 and 12:0, the proportion of 14:0 was greater in the *sn*-1,3 positions. Myristic acid is a true long-chain fatty acid, and it is readily activated by acyl-CoA synthetase and incorporated into lymphatic TAG (13).

In the rats infused with human milk, the proportion of 16:0 in the *sn*-2 position of lymphatic TAG was much greater than seen in the rats infused with formula (Fig. 1). This was of interest because one proposed explanation for efficient absorption of milk lipid is the high proportion of 16:0 in the *sn*-2 position of human milk TAG (4). It is thought that 16:0 in the *sn*-2 position would be absorbed as *sn*-2 MAG and not be acted upon by pancreatic lipase and freed. As free 16:0 readily complexes with divalent cations, forming a soap that is poorly absorbed not being in free form would enhance its absorption.

Human milk contains an endogenous lipase, BSSL, i.e., a nonspecific lipase that releases fatty acids from all positions of TAG. It has been proposed that the improved absorption of human milk lipid is due to BSSL in the milk (7). If BSSL were a significant factor in the digestion of milk lipid, it would hydrolyze the product of pancreatic lipase, i.e., 16:0-enriched MAG, and subsequently decrease the proportion of 16:0 in the *sn*-2 position of lymphatic TAG. Because of the large amounts of 16:0 in the *sn*-2 position of lymphatic TAG, BSSL did not appear to be an important factor in the digestion of milk lipid. However, the conditions in this study are not the same as seen in the neonate. In this study, diets were infused into the duodenum so that lipolysis was not initiated by gastric/lingual lipase in the stomach. It has been suggested that circumventing gastric lipolysis in the infant may reduce lipid absorption by 30% (7). Also BSSL may only contribute to milk lipid digestion when bile salts in the intestine are below the critical micelle concentration, and pancreatic lipase is less than optimal (7). These are not conditions in the intestinal lumen of the adult rat. Because of these differences, the results of the present study do not negate a possible role for BSSL in the infant.

In conclusion, significant amounts of 10:0 and 12:0 from human milk and infant formula can be absorbed and transported from the gut *via* the lymph system. The amount of 10:0 and 12:0 found in the lymph is proportional to the amount in the diet with more than 50% esterified to the *sn*-2 position of the lymphatic TAG. The large proportion of 16:0 in the *sn*-2 position of the lymphatic TAG from animals infused with human milk does not support a role for BSSL in the digestion of milk lipid in the adult rat.

Confirmation by Gas Chromatography/Mass Spectrometry of Two Unusual *trans*-3-Monoethylenic Fatty Acids from the Nova Scotian Seaweeds *Palmaria palmata* and *Chondrus crispus*

M. Lamberto[1] and **R.G. Ackman***

Canadian Institute of Fisheries Technology, Technical University of Nova Scotia, Halifax, Nova Scotia, B3J 2X4 Canada

The structures of two unusual fatty acids, the known *trans*-3-hexadecenoic acid and a novel *trans*-3-tetradecenoic acid, both isolated from the Nova Scotian seaweeds *Palmaria palmata* and *Chondrus crispus*, were positively identified. After the extraction of the total fatty acids by saponification, followed by methylation, the monoenoic *trans* fractions were isolated by thin-layer chromatography on silica gel impregnated with silver nitrate. The monoenoic *trans* fractions were derivatized with 2-amino-2-methyl-propanol prior to analysis by gas chromatography/mass spectrometry. The mass spectra showed prominent $[M + 1]^+$ ions but lacked the 12 amu interval useful for identifying the double bond position. Hence, alternative diagnostic peaks were used to confirm the position of the double bond in these two fatty acids. As the *trans*-3-hexadecenoic acid is found in the photosynthetic tissue of all plants, it may also be present in ruminant fats and, presumably, in human adipose tissue.

***Lipids* 29, 441–444 (1994).**

For nearly 30 years (1), *trans*-3-hexadecenoic acid has been known to occur as a component of plant photosynthetic lipids (2,3). This *trans* acid has been found among the fatty acids of numerous North Atlantic macrophytes (4–8), sometimes exceeding 2% of total fatty acids. We have now identified *trans*-3-tetradecenoic acid in several of these algal samples. The rigorous identification of the structure of two homologous fatty acids of this type (14:1, 16:1) from seaweeds by modern gas chromatography/mass spectrometry (GC/MS) is reported here.

MATERIALS AND METHODS

Seaweeds. *Palmaria palmata* and *Chondrus crispus* grown in natural seawater and provided through the courtesy of the Institute for Marine Biosciences of the National Research Council of Canada (Halifax, Nova Scotia, Canada) were the source of the *trans* fatty acids. 2-Amino-2-methyl-propanol (AMP) reagent was obtained from Sigma Chemical Co. (St. Louis, MO). *trans*-3-Hexadecenoic acid for use as a standard was synthesized in our laboratory by a recently published method (9); its structure was confirmed by oxidative ozonolysis (10), MS upon derivatization and infrared (IR) spectroscopy of the free acid (band at 975 cm^{-1}).

Extraction. The total fatty acids from fresh seaweeds were isolated upon saponification by refluxing with a 0.5 N methanolic sodium hydroxide for 2 h (6). After removing the nonsaponifiable components by extraction with hexane, the fatty acids were recovered after acidification by re-extraction with hexane, and then converted to their methyl esters by heating with 8% BF_3 in methanol at 100°C for 60 min (11).

Silver nitrate thin-layer chromatography (TLC). The methyl esters were applied to silica gel TLC plates (Adsorbosil-5; Alltech Associates Inc., Applied Science Laboratories, Deerfield, IL) impregnated with silver nitrate (10% in acetonitrile) (12) and fractionated according to their degree of unsaturation (13) by development in benzene/hexane (2:1, vol/vol). The monoenoic *trans* band (R_f = 0.87) was visible under ultraviolet (UV) light after spraying with 2′,7′-dichlorofluorescein (0.2% in ethanol). The adsorbent band was scraped off, and the silica gel was extracted three times with hexane/chloroform (1:1, vol/vol). The pooled extracts were evaporated to dryness under N_2 and redissolved in hexane for further analysis.

Structural identification as 2-alkenyl-4,4-dimethyloxazoline (DMOX) derivatives. The DMOX derivatives of the fatty acids were prepared by adding 250 μL of AMP to 500 μg of the fatty acid methyl esters in screw-cap vials. After flushing with N_2, the vials were capped and heated at 180°C for 18 h (14). The reaction mixture was cooled, dissolved in 3 mL of dichloromethane and then washed twice with 1 mL of water. After drying the organic phase with anhydrous Na_2SO_4, the solvent was removed under a stream of N_2. The samples were dissolved in hexane prior to analysis by GC/MS.

GC/MS. Electron impact mass spectra were obtained on a model 700 Finnigan MAT Ion Trap Detector (ITD) system (Finnigan MAT, San Jose, CA) interfaced to a Perkin Elmer model 990 gas chromatograph. The gas–liquid chromatography (GLC) fused silica capillary column was fed through a heated transfer line directly into the ITD gas inlet. GC/MS separations were obtained on a flexible-fused silica nonpolar column (DB-1; coating of methyl silicone, 60 m × 0.25 mm i.d., phase thickness 0.25 μ; Chromatographic Specialties Inc., Brockville, Ontario, Canada). The column was operated at 220°C and at 140 kPa helium. The data system consisted of an IBM clone (dtk TECK 1230) interfaced to the internal electronics of the ITD using version 4.0 of the ITD software supplied by the Finnigan Corp. using background subtraction. The ITD was tuned by following the manufacturer's procedure and was operated in the full-scan mode with a 1-s cycle time.

Abbreviations: AMP, 2-amino-2 methyl-propanol; DMOX, 4,4-dimethyloxazolines; ECL, equivalent chain length; GC/MS, gas chromatography/mass spectrometry; GLC, gas–liquid chromatography; ITD, ion trap detector; TLC, thin-layer chromatography.

RESULTS AND DISCUSSION

In seaweeds, in which water is by far the major (90–95%) component, total fatty acids are present only in small amounts. In *C. crispus,* the total fatty acids amounted to 0.41% of the wet weight, and in *P. palmata* came to only 0.34%. *trans*-3-Tetradecenoic acid and *trans*-3-hexadecenoic acid are only minor components of the total fatty acids. The proportion of *trans*-3-tetradecenoic was 0.1% of total fatty acids in both algae, and the proportions of *trans*-3-hexadecenoic acid were 2.4 and 0.9% in *P. palmata* and *C. crispus* acids, respectively. These percentages and those of the other fatty acids were similar to those published earlier and differed only in that *C. crispus* had ~25% 20:4n-6 vs. 1% of this acid in *P. palmata.* Conversely, *C. crispus* had ~25% 20:5n-3, whereas *P. palmata* had ~45%. Neither contained 22:6n-3, and all other fatty acids were ≤6%, except for 16:0, which occurred at about 25% of total fatty acids in both macrophytes.

The mass spectra of the DMOX derivatives obtained with the ITD clearly identified the structures of the *trans*-3-tetradecenoic acid and of the *trans*-3-hexadecenoic acid. A prominent molecular ion and fragments characteristic of fatty acids with the double bond in position 3 were observed (Figs. 1 and 2). It should be emphasized here that a characteristic feature of the ITD is that instead of the molecular ion the protonated ion $[M + H]^+$ occurs (15).

trans-*3-Tetradecenoic acid.* The mass spectrum of the DMOX derivative of *trans*-3-tetradecenoic acid (Fig. 1) showed the protonated molecular ion at *m/z* 280, corresponding to a 14:1 fatty acid derivative with 279 atomic mass units (amu). The base peak was an ion at *m/z* 110, the composition of which is not well known (it appears to be derived from a parent ion fragment at *m/z* 152). This ion, after double bond isomerization and cyclization, produces a configuration that loses a $C(CH_3)_2$ group from the heterocyclic ring with loss of 42 amu (Fig. 3). This ion is typical (16) of the DMOX derivative of a fatty acid with a double bond in position 3, whether *cis* or *trans,* and it is not observed when the double bond is in position 2 or 4.

Another important ion, which appears at *m/z* 264, is due to the loss of a methyl group from the ring, whereas the ion at *m/z* 152 is due to a typical cleavage between the carbons in positions 5 and 6. The ion at *m/z* 113, which is a characteristic of DMOX derivatives of fatty acids, is not very abundant when the double bond is close to the polar end of the molecule. It is usually due to a McLafferty rearrangement and is formed by the migration of the γ-hydrogen followed by cleavage between the carbon atoms 2 and 3.

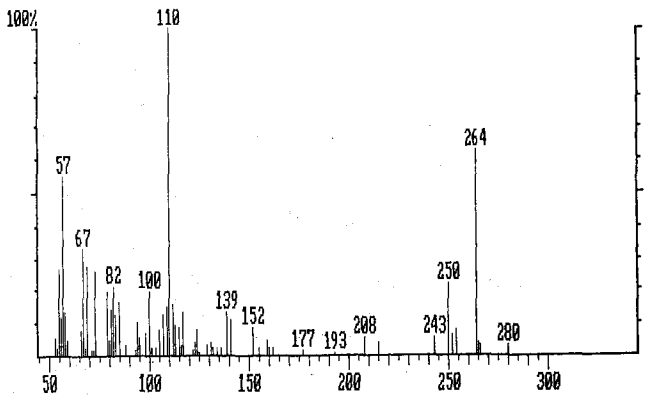

FIG. 1. Electron impact mass spectrum of the 4,4-dimethyloxazoline derivative of natural *trans*-3-tetradecenoic acid.

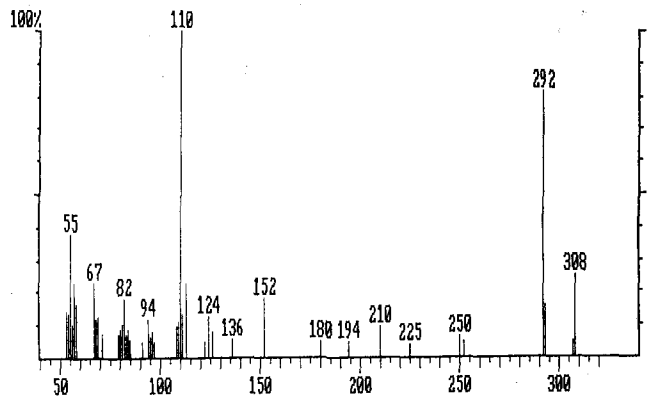

FIG. 2. Electron impact mass spectrum of the 4,4-dimethyloxazoline derivative of natural *trans*-3-hexadecenoic acid.

trans-*3-Hexadecenoic acid.* The electron impact mass spectrum of the DMOX derivative of the *trans*-3-hexadecenoic acid (Fig. 2) was very similar to the spectrum of the *trans*-3-tetradecenoic acid; the protonated molecular ion at *m/z* 308 was as expected. The base peak was at *m/z* 110 whose origin is presumably the same as for the other DMOX derivative discussed previously. A prominent ion at *m/z* 292 due to loss of a methyl group from the ring was also observed. Other important ions include that at *m/z* 152, resulting from a cleavage between carbon atoms 5 and 6, and the ion at *m/z* 113. The ion at *m/z* 126 is a cyclic ion formed by cleavage between carbons 4 and 5 (17).

The mass spectrum of the DMOX derivative of the reference standard *trans*-3-hexadecenoic acid (not shown) had the typical fragmentation pattern observed for the *trans*-3 fatty acids (DMOX derivatives) isolated from the seaweeds.

The mass spectra of the two *trans*-3 fatty acids investigated here permitted investigators to determine their structures, even though the rule of Andersson and Holman (18–20) for identifying ethylenic bond positions by gaps of 12 amu was not applicable. This rule generally applies to the DMOX derivatives of fatty acids with one or more ethylenic bonds but is not applicable to *trans*-3 fatty acids be-

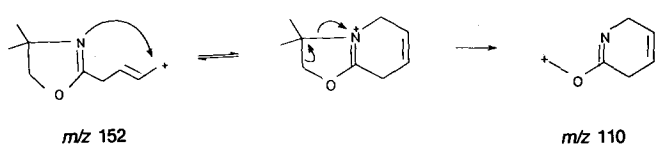

FIG. 3. Proposed mechanism for the formation of ion at *m/z* 110.

cause of the position of the double bond close to the polar end of the molecule. The spectra obtained with the ITD showed, however, a base peak at m/z 110, which is typical of these compounds with a double bond in position 3.

There are six fatty acids that commonly occur (21) in green vegetables, including *trans*-3-hexadecenoic acid. Few vegetables contain much 14:0, whereas the total fatty acids of the two seaweeds contain 4 *(C. crispus)* and 9% *(P. palmata)*. Both contain approximately 25% of 16:0. The *trans*-3 monoenoic contents of the total fatty acids given above do not correlate with the proportions of the corresponding saturated acids. The *trans*-3-tetradecenoic acid is not specific to the red seaweeds, but is also found in brown and green seaweeds.

The equivalent chain length (ECL) of the methyl ester of *trans*-3-hexadecenoic acid for two polyglycol-type liquid phases (SUPELCOWAX-10, Omegawax; Supelco Canada, Oakville, Ontario, Canada) was 16.51 at 185°C. The corresponding ECL value for the ester of *trans*-3-tetradecenoic acid was 14.51. The ECL values for these esters on the methylsilicone liquid phase (DB-1) at 200°C are, respectively, 13.90 (14:1) and 15.91 (16:1). The unique behavior of *trans* acids on cyanosilicone liquid phases (22), eluting earlier than the corresponding *cis* acids, will cause the ECL values to vary with cyano group content (23). One set of ECL values (7) for seaweed 16:1 fatty acid methyl esters separated on a 50 m × 0.25 mm stainless-steel open-tubular column with the cyanosilicone liquid phase SILAR-5CP illustrates this point: *cis*-9-hexadecenoic, 16.38; *trans*-3-hexadecenoic, 16.45; *cis*-13-hexadecenoic, 16.63. On the polyglycol columns, the tentative identification of *trans*-3-hexadecenoic acid in butterfat (24) placed it in the *iso*-17:0 position, approximately at ECL 16.46.

Interestingly, the deposition of *trans*-3-hexadecenoic acid in ruminant fat was forecast (2) as long ago as in 1964, but does not seem to have been addressed in human depot fats. It could be important, in view of current health recommendations to consume more green vegetables, to accurately identify this particular 16:1 fatty acid in total *trans* 16:1 of human adipose tissue. Total *trans* 16:1 levels (by packed column) are purported to be correlated with deaths from coronary heart disease (25,26).

The consumption of seaweeds as human food is common in many countries, especially in Asia (27,28), but there does not seem to be a record of the deposition of *trans*-3-hexadecenoic acid in the depot fats of such populations. Conversely, studies on partially hydrogenated edible oils (22,29) suggest that all *trans*-3 fatty acid isomers, as a result of the mobility of this bond in the proximity of the carboxyl group, would be unlikely to survive hydrogenation to any extent.

In humans, the 16:1 fatty acids of depot fats seem to be in the range of 2–6% of total fatty acids (30,31). These seem to be primarily derived from animal fats. In fish lipids, palmitoleic (*cis*-9-hexadecenoic) acid invariably constitutes an important proportion of the fatty acids (32). As edible vegetable oils are usually low in 16:1, these may be discounted as a source for *trans*-3-hexadecenoic acid originating from partial hydrogenation except if chain shortening (33,34) of the artifactual *trans*-5-octadecenoic acid takes place *in vivo*. However, the latter fatty acid seems rarely present among the isomers formed in the hydrogenation process when applied to vegetable oils (22,35). A chromatogram of methyl esters of fatty acids of human adipose tissue that has been published (30) shows two large 16:1 peaks, allegedly with the smaller n-7 isomer eluting ahead of the n-9 isomer, followed by a cluster of smaller peaks, one of which may represent *trans*-3-hexadecenoate.

LETTER TO THE EDITOR

α-Linolenic Acid in Human Adipose Tissue

Dear Sir:

In a paper on site-specific differences in the fatty acids of human adipose tissue published in *Lipids* (1), the authors make the point that they were unable to detect α-linolenic (18:3n-3) acid in any depot fats from fifteen sites on seven adult males. This is in contrast to three other studies that the authors mention as showing up to 3% of 18:3n-3 in human adipose tissue, although figures of 0.2–0.6% seem to be more common. In view of the increasing interest in ω3 fatty acids in nutrition, vascular biology and medicine (2,3), it is desirable to explain this negative finding. The authors used only OV-1 as liquid phase in gas chromatography (GC). It has long been known that 18:3n-3 acid and linoleic acid (18:2n-6) are not separated effectively on this phase (4–7). This is a general problem with n-3 and n-6 structural analogs when these also differ by one methylene-interrupted ethylenic bond. Thus a good resolution also would not be obtained between the pairs 18:3n-6 and 18:4n-3, 20:4n-6 and 20:5n-3, and 22:5n-6 and 22:6n-3, although the levels of C_{20} and C_{22} fatty acids are usually very low in human adipose tissue (8–10). Two of the latter groups of investigators used polar GC columns and show chromatograms with peaks for 18:3n-6 (γ-linolenic acid) (8,10), which also seems to be present in human adipose tissue in the 0.1–0.3% range. Modern GC with polar, open-tubular columns can resolve the polyunsaturated C_{18}, C_{20} and C_{22} fatty acids mentioned above, as well as 22:4n-6 and 22:5n-3. These polyunsaturated fatty acids should therefore all be reported, even at the low levels found in adipose tissue, as well as for other organs in which these acids are presumed to be functional and important.

α-Linolenic Acid in Human Adipose Tissue—A Reply

Dear Sir:

We recently reported on the fatty acid compositions of fifteen adipose depots from seven adult males (1). None of the depots contained detectable levels of α–linolenic acid (18:3n-3). This finding is in contrast to at least three previous reports (2–4), each of which was discussed in our paper (1). In his letter (5), Dr. Ackman suggests that the reason for the nondetectability of this fatty acid was the type of column used for the separation of fatty acid methyl esters. Indeed, the previous studies all used a more polar gas-chromatographic column than did Calder *et al.* (1), and, as Dr. Ackman indicates, a more polar column would allow better resolution of α–linolenic acid and linoleic acid (18:2n-6). It should be pointed out, however, that the OV-1 column used is able to partially resolve these two fatty acids and that separate peaks are seen; indeed, we have reported α–linolenic acid proportions in lipids isolated from macrophages (6) and lymphocytes (7) cultured *in vitro* in the presence of α–linolenic acid and in animal diets expected to contain this fatty acid.

ARTICLE

Characterization of Lipid Hydroperoxides Generated by Photodynamic Treatment of Leukemia Cells

Gary J. Bachowski[1], Witold Korytowski[2] and Albert W. Girotti*

Department of Biochemistry, Medical College of Wisconsin, Milwaukee, Wisconsin 53226

A new technique, high-performance liquid chromatography with reductive mode electrochemical detection on a mercury drop (HPLC–EC), has been used for analyzing lipid hydroperoxide (LOOH) formation in photooxidatively stressed L1210 leukemia cells. Highly specific and sensitive for peroxides (detection limits <0.5 pmol for cholesterol hydroperoxides and <50 pmol for phospholipid hydroperoxides), this approach allows different classes of LOOH to be separated and determined in minimally damaged cells. L1210 cells in serum-containing growth medium were irradiated in the presence of merocyanine 540 (MC540), a lipophilic photosensitizing dye. Lipid extracts from cells exposed to a light fluence of 0.11 J/cm^2 (which reduced clonally assessed survival by 30%) showed 12–15 well-defined peaks in HPLC–EC. None of these peaks was observed when cells were irradiated without MC540 or when dye/light-treated samples were reduced with triphenylphosphine prior to analysis. Three peaks of relatively low retention time (<12 min) were assigned to the following species by virtue of comigration with authentic standards: 3β-hydroxy-5α-cholest-6-ene-5-hydroperoxide (5α-OOH), 3β-hydroxycholest-4-ene-6β-hydroperoxide (6β-OOH), and 3β-hydroxycholest-5-ene-7α/7β-hydroperoxide (7α/7β-OOH). Formation of 5α-OOH and 6β-OOH (singlet oxygen adducts) was confirmed by subjecting [^{14}C]cholesterol-labeled cells to relatively high levels of photooxidation and analyzing extracted lipids by HPLC with radiochemical detection. Material represented in a major peak at 18–22 min on HPLC–EC was isolated in relatively large amounts by semipreparative HPLC and shown to contain phospholipid hydroperoxides (predominantly phosphatidylcholine species, PCOOH) according to the following criteria: (i) decay of 18–22 min peak during Ca^{2+}/phospholipase A_2 treatment, with reciprocal appearance of fatty acid hydroperoxides; (ii) reduction of peroxide during treatment with reduced glutathione and phospholipid hydroperoxide glutathione peroxidase, but not glutathione peroxidase; and (iii) comigration with PCOOH standards in thin-layer chromatography. HPLC–EC analysis revealed quantifiable amounts of PCOOH and ChOOH at a light fluence that clonally inactivated <10% of the cells, which allows for the possibility that photoperoxidative damage plays a causal role in cell killing.

***Lipids 29,* 449–459 (1994).**

Lipid peroxidation is a prominent manifestation of oxidative stress that has received considerable attention in recent years because of its cytotoxic effects and possible role in pathological conditions such as atherosclerosis, ischemia–reperfusion injury, drug-induced liver damage and carcinogenesis (1–3). Many different enzymatic and nonenzymatic agents can trigger lipid peroxidation in biological systems. Included in the former category are lipoxygenases, cyclooxygenases and cytochrome P450 reductases. Nonenzymatic lipid peroxidation can be triggered by processes such as xenobiotic autoxidation, ozone generation, ionizing radiation and photodynamic action. The surge of biological and biomedical interest in lipid peroxidation has stimulated development of powerful new techniques for separating and detecting peroxidation products and intermediates. Among these are several approaches involving high-performance liquid chromatography (HPLC) of lipid hydroperoxide (LOOH) species, with detection based on measurement of chemiluminescence (4–6), fluorescence (7) or electrochemical (EC) reduction (8–11). A great advantage of these approaches over those employing ultraviolet (UV) absorbance or radiochemical detection is that lipid hydroperoxides can be distinguished from alcohol reduction products that often accompany them in biological samples and tend to coelute with them (10,11). We have reported that HPLC–EC is an excellent approach for determining individual LOOH classes in complex mixtures of cholesterol and phospholipid hydroperoxides (12,13). Using HPLC with a renewable mercury drop electrode, we have achieved detection limits of less than 0.5 pmol for rapidly eluting cholesterol hydroperoxides (13), which exceeds the sensitivity of all other ex-

[1]This paper is based on a dissertation submitted by G.J. Bachowski in partial fulfillment of the requirements for a Ph.D. degree in Biochemistry at the Medical College of Wisconsin (Milwaukee, WI).

isting HPLC methods (5–7). In the work described in this paper, mercury electrode HPLC–EC has been used for analyzing the formation of several different LOOH species in photodynamically-treated leukemia cells. Preliminary findings along these lines have been published recently (13). The ultrahigh sensitivity of the HPLC–EC approach has allowed us to detect significant amounts of phospholipid and cholesterol hydroperoxides in photodamaged cells prior to any large-scale loss of viability.

MATERIALS AND METHODS

Chemicals and reagents. Cholesterol, egg phosphatidylcholine (PC), egg phosphatidylethanolamine (PE), dicetylphosphate (DCP), bovine erythrocytic glutathione peroxidase (GPX), bovine pancreatic phospholipase A_2 (PLA_2), reduced glutathione (GSH), Chelex-100 (50–100 mesh), RPMI-1640 medium, insulin, transferrin, penicillin and streptomycin were obtained from Sigma Chemical Co. (St. Louis, MO). 1-Palmitoyl-2-oleoyl phosphatidylcholine (POPC) and 1-palmitoyl-2-linoleoyl phosphatidylcholine (PLPC) were from Avanti Polar Lipids (Birmingham, AL). Hyclone Laboratories (Logan, UT) supplied the fetal calf serum (FCS). [4-^{14}C]Cholesterol (40–60 mCi/mmol in benzene) was obtained from Research Products International (Mount Prospect, IL). Desferrioxamine (DFO) was supplied by Ciba-Geigy Corp. (Suffern, NY); peroxide-free Triton X-100 by Boehringer-Mannheim Biochemicals (Indianapolis, IN); merocyanine 540 (MC540) by Eastman Kodak (Rochester, NY); and chloroaluminum phthalocyanine tetrasulfonate ($AlPcS_4$) by Porphyrin Products (Logan, UT). HPLC-grade chromatographic solvents were obtained from Burdick and Jackson Corp. (Muskegon, MI) or Mallinckrodt Co. (Paris, KY). Cholesterol hydroperoxide standards [3β-hydroxy-5α-cholest-6-ene-5-hydroperoxide (5α-OOH), 3β-hydroxycholest-4-ene-6β-hydroperoxide (6β-OOH) and 3β-hydroxy-cholest-5-ene-7α/7β-hydroperoxide (7α/7β-OOH) mixture] were prepared and characterized as reported (12). Phospholipid hydroperoxide glutathione peroxidase (PHGPX) was prepared from rat testes as described and stored at –80°C (14,15). The purified enzyme migrated as a single band of molecular weight ~20,000 Da on sodium dodecyl sulfate–polyacrylamide electrophoresis. PHGPX activity was determined by coupled enzymatic assay, using NADPH, GSSG-reductase, GSH and photoperoxidized egg PC (14). All aqueous solutions were prepared with deionized, glass-distilled water.

Cell culture. Murine leukemia L1210 cells (ATCC CLL-219) obtained from the American Type Culture Collection (Rockville, MD) were grown in suspension culture at 37°C under a humidified atmosphere of 95% air/5% CO_2. The growth medium consisted of 1% FCS in RPMI-1640 supplemented with insulin (10 μg/mL), transferrin (5 μg/mL), penicillin (100 U/mL), streptomycin (100 μg/mL), and sodium selenite (5 ng/mL). Cells were reseeded into fresh medium every two days. New cultures were started from frozen stock on a bimonthly basis. All experiments and determinations were carried out on cells in log-phase growth. Cell viability was assessed by 3-(4,5-dimethylthiazoyl-2-yl)-2,5-diphenyltetrazolium bromide (MTT) assay, which is based on metabolic activity (16), and by clonogenic assay (17). Additional details are provided in Reference 18.

Protein and lipid determinations. Total protein in L1210 cells was determined by the method of Lowry *et al.* (19), using bovine serum albumin as the standard; the measured value was 6.4 ± 0.4 mg/10^8 cells (mean ± SD; n = 4).

Total cellular lipid, as determined by gravimetric analysis (18), was found to be 1.43 ± 0.06 mg/10^8 cells (mean ± SD; n = 6). Phospholipid content was measured by phosphate analysis, using a modification of the Bartlett approach (20). Samples containing ~10^7 cells were washed three times with 25 mM Hepes [*N*-(2-hydroxyethyl)-piperazine-*N'*-(2-ethanesulfonic acid)]/125 mM NaCl (pH 7.4). After the addition of 1 mM EDTA, the cell suspension was extracted with 1.6 vol of chloroform/methanol (2:1, vol/vol). The lipid extract was dried under N_2 and dissolved in 0.4 mL of 10 N H_2SO_4. After heating for 2 h at 155°C, 2 drops of 30% H_2O_2 were added, followed by 1 h of additional heating. Ammonium molybdate (0.2 mL of a 2.5% solution) and 1-amino-2-naphthol-4-sulfonic acid (0.1 mL of a 0.2% solution) were then added, along with enough water to bring the final volume to 2.5 mL. The mixture was heated at 100°C for 10 min, after which absorbance at 830 nm was recorded. An extinction coefficient of 23.2 $mM^{-1}cm^{-1}$ at this wavelength (measured with an inorganic phosphate standard) was used for quantitation. Cholesterol content was determined by reverse phase HPLC with UV (212 nm) detection (see HPLC section). Identification and quantitation of cellular cholesterol was based on reference to a cholesterol standard (retention time ~33 min). Triacylglycerol content was determined by ester bond analysis (21) after separation of triacylglycerols from phospholipids. The separation was accomplished by chromatography on 35-mg silica gel minicolumns (Alltech Associates, Deerfield, IL). Lipid samples (in 25–30 μL of isopropanol) were applied to columns that had been prewashed with isopropanol and hexane. The mobile phase solvent systems (applied sequentially by syringe) were as follows: (i) 3.0 mL of chloroform/acetic acid/methanol (97:2:1, by vol), which effected (as established with standards) the complete elution of triacylglycerols and cholesterol, leaving phospholipids behind; and (ii) 2.5 mL of methanol/chloroform/water (20:10:8, by vol), which effected the complete elution of the phospholipids. Recovered fractions were dried in a SpeedVac AS160 Concentrator (Savant Instruments, Farmingdale, NY). Triacylglycerols were treated with hydroxylamine as indicated (21); liberated fatty acyl hydroxamic acids were determined by measuring the absorbance of their ferric complexes at 530 nm. Quantitation was based on an ester group extinction coefficient of 1.02 $mM^{-1}cm^{-1}$ at this wavelength, as established with a dipalmitoyl PC standard. Isolated phospholipids were also subjected to ester bond analysis. Measured values (as wt% of total cellular lipid) were as follows: (i) phospholipid: 69.4 ± 7.5% by phosphate

assay, 72.3 ± 7.8% by ester bond assay; (ii) triacylglycerol: 27.7 ± 2.3%; (iii) cholesterol: 4.0 ± 0.4% (means ± SD; n = 3).

Radiolabeling of cells. Labeling of cholesterol in L1210 cells was accomplished by incubating the cells with unilamellar liposomes containing [4-^{14}C]cholesterol. Before incorporation into liposomes, radioactive cholesterol plus carrier (~0.3 mg total sterol) was separated from any pre-existing oxidation products by silica gel thin-layer chromatography (TLC), using heptane/ethyl acetate (1:1) as the mobile phase (22). The cholesterol zone (located by radioscanning) was removed by scraping and was eluted with chloroform/methanol (2:1, vol/vol). The extract was filtered and dried; recovered lipid (~0.8 μmol; 5–10 μCi) was mixed with 1.0 μmol of egg PC and film-dried under argon. The lipids were resuspended in deaerated, Chelex-treated phosphate buffered saline (PBS) and subjected to five freeze-thaw cycles before being passed through a 200-μm Nucleopore filter in a lipid extruder (Lipex Biomembranes, Vancouver, British Columbia, Canada) (23). Cells were centrifuged, resuspended to a concentration of ~10^7/mL in 10% heat-inactivated FCS/RPMI medium, and mixed with radiolabeled liposomes at a ratio of cellular to liposomal cholesterol of ~4:1 (mol/mol). After 15 h of incubation at 37°C under sterile conditions, the cells were centrifuged, washed extensively with 1% heat-inactivated FCS/RPMI medium to remove the liposomes and resuspended in this medium. A typical incubation as described resulted in a 30–35% exchange (transfer) of [^{14}C]cholesterol.

Photooxidation reactions. Immediately before irradiation, unlabeled or [^{14}C]cholesterol-labeled L1210 cells were centrifuged and resuspended to a concentration of 1.0–3.0 x 10^7/mL in serum-free RPMI medium. The cells were incubated with sensitizer (25 μM MC540) for 30 min in the dark, after which 10-mL aliquots were transferred to 25-cm^2 culture flasks and irradiated on a translucent platform over a twin-bank of cool white 40-W fluorescent tubes. Incident light intensity (fluence rate) at the platform surface was ~7.5 W/m^2, as measured with a radiometer (Yellow Springs Instruments, Yellow Springs, OH). Temperature of the cell suspension was maintained at 25 ± 2°C. After different periods of irradiation (typically no longer than 4 min, corresponding to a fluence of 0.18 J/cm^2), the suspensions were centrifuged; each cell pellet was resuspended in 0.5 mL of PBS containing 1.0 mM EDTA. After extraction with chloroform/methanol (2:1, vol/vol) and drying under argon, the lipid fraction was analyzed iodometrically for peroxide content (see below) and then subjected to analytical HPLC.

For preparing relatively large amounts of cellular LOOH for semipreparative HPLC, the above procedure was scaled-up and $AlPcS_4$ (a more potent singlet oxygen generator; Ref. 24) was used instead of MC540. Typically, 50-mL aliquots of cells (1.0 × 10^7/mL in RPMI medium) were transferred to 165-cm^2 flasks, sensitized with 10 μM $AlPcS_4$, and irradiated for 1 h under a quartz-halogen source at 25°C. The fluence rate was ~2.3 kW/m^2. After irradiation, the cells were pelleted and lipids extracted as described above. Extracts from six of these preparations (corresponding to ~26 mg of lipid from ~3×10^9 cells) were combined and dried under argon. Recovered material was dissolved in 220 μL of isopropanol, which comprised a single injection on semipreparative HPLC.

Iodometric analysis. The LOOH content of standards and experimental samples was determined by iodometric assay, as described (25,26). Hydroperoxides were reduced anaerobically in the presence of excess iodide, with stoichiometric formation of triiodide. The latter was measured spectrophotometrically at 353 nm, quantitation being based on an extinction coefficient of 22.5 mM^{-1}cm^{-1}.

TLC. Cholesterol and phospholipid hydroperoxides were chromatographed on Silica Gel 60 plates of 0.25 mm thickness (EM Science, Cherry Hill, NJ). The mobile phase for cholesterol hydroperoxides was benzene/ethyl acetate (1:1, vol/vol), whereas that for phospholipid hydroperoxides was chloroform/methanol/water (75:25:4, by vol). Peroxides were visualized by spraying with *N,N,N′,N′*-tetramethyl-*p*-phenylenediamine (TMPD). Other details were as described (22,27,28).

HPLC. Liquid chromatography was accomplished with an Isco integrated HPLC system (Isco Inc., Lincoln, NE). Analytical reverse-phase HPLC–EC was carried out at room temperature, using a C18 Ultrasphere column (4.6 × 150 mm; 5 μm particles) from Beckman Instruments (San Ramon, CA) and C18 guard column (4.6 × 45 mm) from Alltech Associates (Deerfield, IL). Except where indicated, the premixed mobile phase consisted of (by vol) 79.5% methanol, 11.5% acetonitrile and 9.0% of an aqueous solution containing 10 mM ammonium acetate and 0.25 mM sodium perchlorate (pH 5.0). Delivered isocratically at a flow rate of 2.0 mL/min, the mobile phase was sparged continuously with high-purity argon that was passed first through an OMI-1 oxygen scrubber from Supelco Inc. (Bellefonte, PA) and then through a presaturating mobile phase scrubber. The column effluent was passed through two detectors in series, an Isco V^4 variable wavelength detector and an EG&G-Princeton Model 420 electrochemical detector with a renewable mercury drop electrode system (Princeton, NJ). A new mercury drop was dispensed and equilibrated for 5–10 min before each injection of analyte; background noise typically dropped to a satisfactory low level during this period. The electrode potential was set at –300 mV vs. an Ag/AgCl reference. Samples were dissolved in isopropanol; immediately before injection, the solutions were sparged for 2–3 min with high-purity helium to minimize O_2 entry into the system. The injection volume for all samples was 10 μL. Data collection, storage and manipulation was accomplished with an on-line AT clone and Isco ChemResearch software. Other details about the methodology have been reported elsewhere (12,13,29). Identification and quantitation of various hydroperoxides detected in cell samples were based on retention times and EC responses of standards, e.g. 5α-OOH, 6β-OOH, 7α/7β-OOH, POPC-OOH, and PLPC-OOH. 5α-OOH and 7α/7β-OOH were found to have the same EC response, which was ~25% higher than that of 6β-OOH; POPC-OOH and PLPC-OOH also

had the same response, but it was about half that of 5α-OOH or 7α/7β-OOH (13).

Semipreparative HPLC–EC was carried out on a Beckman Ultrasphere C18 column (10.0 x 250 mm; 5-μm particles) with an Alltech guard column (4.6 × 45 mm). In this case, the mobile phase consisted of 83% methanol, 10% acetonitrile and 7% aqueous solution containing 10 mM ammonium acetate and 0.25 mM sodium perchlorate (pH 5.0); flow rate was typically 4.0 mL/min.

A Baker silica column (4.6 × 250 mm; 5-μm particles) was used for normal-phase HPLC–RC of lipid extracts from photooxidized [^{14}C]cholesterol-labeled cells. The column was eluted with 97% hexane/3% isopropanol at a flow rate of 1.25 mL/min. ^{14}C-Labeled analytes were detected with a Radiomatic A100 Flow-One\Beta detector equipped with a 2.5-mL flow cell (Radiomatic Instruments, Tampa, FL).

Enzymatic characterization of isolated peroxide fractions. The 18–22 min fraction isolated by semipreparative HPLC–EC was treated with GSH and selenoperoxidases as follows. Samples of the 18–22 min material (~5 nmol of iodometrically determined LOOH) were solubilized in 0.5 mL of Chelex-treated PBS containing 0.1% Triton X-100 and 20 μM DFO. (DFO was included to prevent any iron-catalyzed LOOH degradation.) After addition of GSH alone (1 mM), GSH plus PHGPX (0.1 U/mL), or GSH plus GPX (0.5 U/mL), the mixtures were incubated for 30 min at 37°C, after which lipids were extracted and analyzed by PLOOH-resolving TLC (see above), TMPD being used for peroxide detection.

Phospholipase-A_2 treatment of the 18–22 min fraction was carried out as follows. Samples containing ~5 nmol of total LOOH were film-dried in acid-washed tubes, then vortexed into 0.5 mL of 50 mM Chelex-treated Tris-HCl (pH 7.4) containing 20 μM DFO. After addition of $CaCl_2$ (5 mM) and PLA_2 (60 U/mL), the mixtures were re-vortexed and incubated for periods of up to 1 h at 37°C. A control containing everything except PLA_2 was run alongside. After incubation, lipids were extracted, dried, dissolved in isopropanol and analyzed by HPLC–EC, using the following mobile phase: 85% methanol/9% acetonitrile/6% aqueous solution containing ammonium acetate and sodium perchlorate. The lower polarity of this eluant compared with that used for total LOOH (see preceding section) sharpened the parent peroxide peak by decreasing its retention time, thus permitting hydrolytic decay to be measured with greater sensitivity. For monitoring the formation of fatty acid hydroperoxide (FAOOH) products, a different mobile phase was used, namely a 50% methanol/27.5% acetonitrile/22.5% aqueous solution, which satisfactorily separated FAOOH species without solvent front interference. Identification and quantitation of the FAOOH was based on retention times and EC responses of peroxidized linoleic acid and arachidonic acid standards. The latter were typically prepared by irradiating the fatty acids, 100 mM in chloroform/methanol (1:1, vol/vol), with a quartz-halogen source for 3 h in the presence of 10 μM $AlPcS_4$ at 10°C. After drying, resuspending in PBS/EDTA, extracting and redrying, the standards were determined iodometrically and then chromatographed alongside the unknowns.

RESULTS

HPLC–RC of lipid extracts from photoperoxidized [^{14}C]cholesterol-labeled cells. Total lipid extracted from [4-^{14}C]cholesterol-labeled L1210 cells before and after irradiation in the presence of MC540 was subjected to HPLC–RC analysis. The unirradiated sample (Fig. 1A) shows a major peak of radioactivity at ~5 min, assigned as cholesterol; and a lesser peak at ~3 min, tentatively assigned as cholesteryl ester(s). The apparent transesterification may have been catalyzed by a cellular acyl-CoA/cholesterol acyltransferase, since the serum used in the incubation mixture was heat-treated to inactivate lecithin/cholesterol acyltransferase. The irradiated sample (Fig. 1B) shows at least three distinct product peaks, two of which have been assigned on the basis of matching retention times of standards: 6β-OOH (9.5 min) and 5α-OOH (13.0 min). Product yields relative to total injected radioactivity were ~1.0 and ~2.3%, respectively. Identification of 5α-OOH and 6β-OOH provides unambiguous evidence for singlet oxygen ($^1O_2$) involvement in the photooxidative process (30,31). This is consistent with previous results showing $^1O_2$ intermediacy in

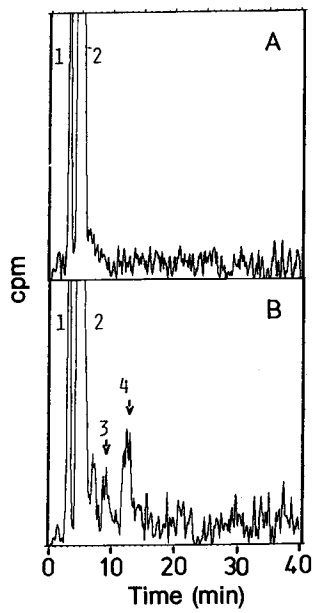

FIG. 1. Normal-phase high-performance liquid chromatography–radiochemical detection (HPLC–RC) of cholesterol hydroperoxides from photooxidized [^{14}C]cholesterol-labeled L1210 cells. Cells (~3.0 × 10^7/mL in medium containing 10% heat-inactivated serum) were radiolabeled by incubating with egg phosphatidylcholine/cholesterol (10:8, mol/mol) liposomes containing ~10 μCi of thin-layer chromatography-purified [4-^{14}C]cholesterol. After washing and resuspending in 1% serum/RPMI medium, the cells were sensitized with 25 μM merocyanine 540 and analyzed by HPLC–RC before (A) and after (B) irradiating for 90 min (fluence ~4.1 J/cm^2). Samples for HPLC–RC contained ~60 μg of total lipid. Peak assignments: 1, unidentified component(s); 2, cholesterol; 3, 3β-hydroxycholest-4-ene-6β-hydroperoxide (6β-OOH); 4, 3β-hydroxy-5α-cholest-6-ene-5-hydroperoxide (5α-OOH). Retention times of separately chromatographed standards (determined by A_{212}) were as follows: 6β-OOH, 9.5 min (arrow); 5α-OOH, 13.0 min (arrow).

model systems, e.g., MC540–sensitized liposomes or erythrocyte membranes (26,32). It should be pointed out that in order to detect product signals by HPLC–RC (cf. Fig. 1B), it was necessary to irradiate cells to extreme limits, killing >99% of the population. The fact that MC540 is a rather modest $^1O_2$ generator (33) and undergoes self-sensitized photobleaching (32), added to the difficulty of measuring cellular photoproducts by HPLC–RC. To improve the sensitivity of LOOH measurement, we switched to reverse-phase HPLC with EC detection. As demonstrated recently (13), subpicomole detection limits can be achieved for ChOOH standards with this approach.

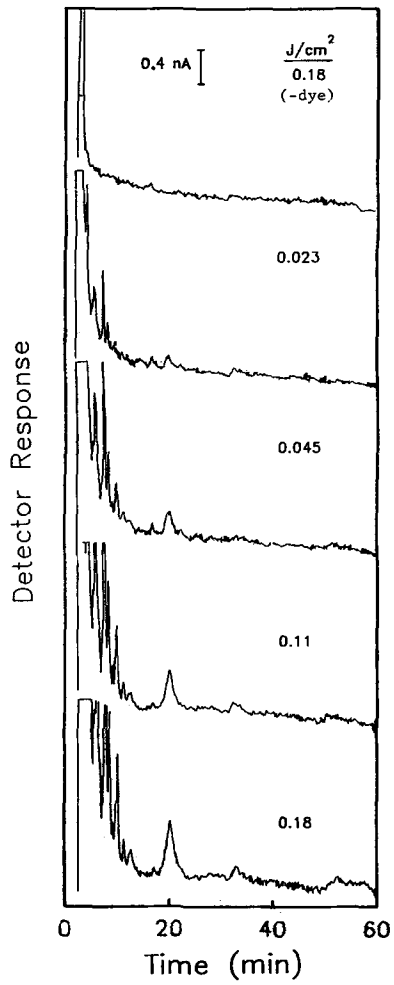

FIG. 2. Reverse-phase HPLC–EC (electrochemical detection) of lipid hydroperoxides from photooxidized L1210 cells. Cells (1.0×10^7/mL in 1% serum/RPMI medium) were irradiated in the absence of sensitizer (top scan) or presence of 25 μM merocyanine 540; at the indicated fluences (J/cm^2) of delivered light, samples containing ~290 μg of total lipid were removed for chromatographic analysis. (The smallest fluence shown, 0.023 J/cm^2, represents 0.5 min of irradiation at a fluence rate of 7.5 W/m^2.) Iodometrically-determined hydroperoxide content of the samples (viewing scans from top to bottom) was as follows: <0.2 nmol; <0.5 nmol; 0.5 nmol; 1.3 nmol; 2.5 nmol. Full-scale detector sensitivity was 2.0 nA for each determination. See Figure 1 for abbreviations.

HPLC–EC of lipid extracts from photoperoxidized cells. HPLC–EC profiles of lipid extracts from cells that had been subjected to modest levels of MC540-sensitized photooxidation are shown in Figure 2. At the lowest delivered light fluence, 0.023 J/cm^2, one can see discrete EC peaks distributed over a 60-min retention time range. The intensity of these peaks increases with increasing fluence up to 0.18 J/cm^2 with no indication of any significant shift in distribution. At least ten major peaks can be distinguished at the 0.18 J/cm^2 level: a tight cluster of five or six peaks in the 5–20-min range, one prominent broad peak centered at ~20 min, and three lesser others at ~33, ~53 and ~57 min. None of these peaks was detected in cells exposed to a 0.18 J/cm^2 fluence in the absence of MC540 (Fig. 2) or in MC540-sensitized cells kept in the dark. Thus, there was no significant background level of species giving EC signals; moreover, these species could not have been generated by light alone or light acting on some endogenous sensitizing agent. Viability assays on cell samples from the Figure 2 experiment showed that cell killing was relatively modest for light fluences that produced substantial EC signals. For example, at 0.045 J/cm^2, cell survival measured by clonal assay was >90% and by MTT assay >95% (Table 1). Even at the highest fluence used in this experiment (0.18 J/cm^2), survival was >10%. Thus, in contrast to radio detection, EC detection allowed us to measure significant levels of photoproducts in minimally damaged cells.

HPLC profiles observed with EC and UV (212 nm) detection were compared for lipid extracts from nontreated and MC540/light-treated cells. As shown in Figure 3, the control (no dye/light) sample exhibited several UV peaks over a 60-min retention time range, but no significant EC peaks. After photooxidation (0.18 J/cm^2 fluence), a characteristic EC profile was observed, whereas the UV profile remained essentially unchanged. When a sample from photooxidized cells was treated with triphenylphosphine (TPP) prior to HPLC, all EC peaks disappeared; once again, the UV profile was unaffected

TABLE 1

Viability of Dye/Light-Treated L1210 Cells[a]

Fluence (J/cm^2)	Clonal assay (viable cells, %)[b]	MTT assay (viable cells, %)[c]
0	100 ± 3	100 ± 4
0.045	91 ± 6	96 ± 6
0.113	65 ± 8	75 ± 1
0.180	12 ± 2	65 ± 2
0.180 (control)[d]	99 ± 6	96 ± 3

[a]Cells (1.0×10^7/mL) were irradiated at 25°C in the presence of 25 μM merocyamine 540 (MC540), except where indicated. Samples are from the experiment described in Figure 2.
[b]Clonal survival is represented as a percentage of colonies formed relative to nonirradiated controls; values are means ± SD (n = 3).
[c]Absorbance at 570 nm in 3-(4,5-dimethylthiazoyl-2-yl)-2,5-diphenyltetrazolium bromide (MTT) assay is represented as a percentage of the absorbance produced by nonirradiated control cells; means ± deviation of values from two determinations.
[d]Cells irradiated in the absence of MC540.

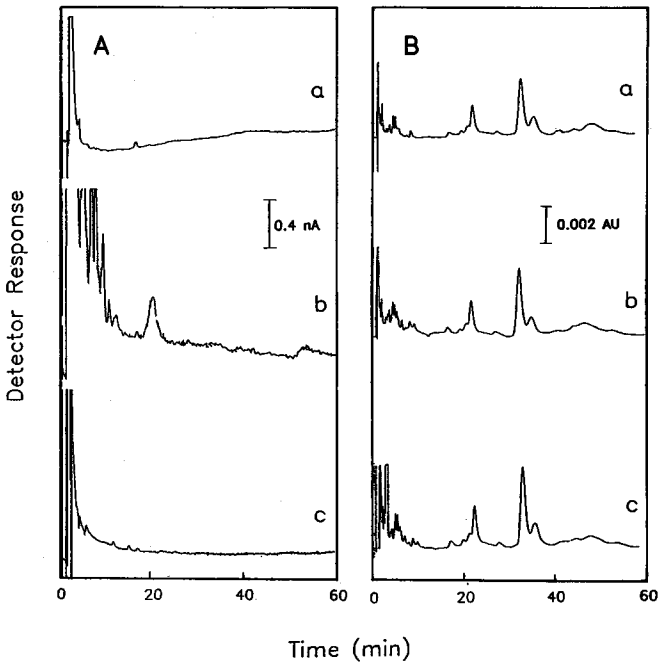

FIG. 3. HPLC analysis of lipid extracts from photoperoxidized L1210 cells. Comparison of profiles obtained with electrochemical detection (panel A) and ultraviolet (A_{212}) detection (panel B). Injected samples, each containing ~290 µg of total lipid, were as follows: (a) extract from nontreated cells; (b) extract from cells exposed to a 0.18 J/cm^2 light fluence in the presence of 25 µM MC540 (~2.5 nmol of total lipid hydroperoxide (LOOH) in injected sample); and (c) extract from photoperoxidized cells (as in b) after treatment with 10 nmol of triphenylphosphine. See Figure 2 for other abbreviation.

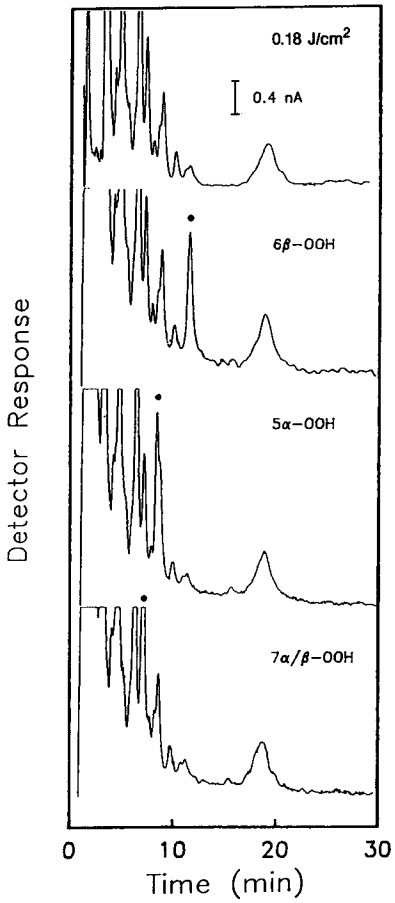

FIG. 4. HPLC–EC profiles of photoperoxidized L1210 cell lipid extracts that were spiked with selected cholesterol hydroperoxide standards. Lipid extracts were spiked with authentic 6β-OOH (11.5 min), 5α-OOH (8.4 min) or 3β-hydroxycholest-5-ene-7α-hydroperoxide/3β-hydroxycholest-5-ene-7β-hydroperoxide (7α/7β-OOH) (7.2 min), as indicated. Injected samples contained ~290 µg of lipid, ~2.5 nmol of LOOH, and 40 pmol of hydroperoxide standard (except for top chromatogram). Peaks corresponding to the added standards are notated by dots. See Figures 1–3 for abbreviations.

except for the appearance of a new peak at ~3 min representing TPP (Fig. 3). TPP is an oxygen-abstracting agent that can effectively reduce hydroperoxides to hydroxides (34). Since the latter are EC-silent, this evidence is consistent with the notion that species giving EC signals are peroxides. As demonstrated previously for simpler (noncellular) systems (12), the contrast in EC and UV responses after reductive treatment highlights the selectivity of EC for peroxide detection under the redox conditions chosen.

Assignment of cholesterol hydroperoxides in HPLC–EC profiles. Realizing that MC540 localizes in the plasma membrane, where most of the cellular cholesterol is located, and that MC540 can sensitize cholesterol peroxidation (Fig. 1), we suspected that some of the EC peaks observed in Figures 2 and 3 (retention times <15 min) represent ChOOH products. As a first attempt at identifying these species, we spiked photooxidized samples with individual standards (5α-OOH, 6β-OOH or 7α/7β-OOH mixture) and located matching positions on HPLC–EC profiles. As shown in Figure 4, a sample peak corresponding to unresolved 7α/7β-OOH (7.2 min) is sharp and distinct. The peak corresponding to 5α-OOH (8.4 min) appears to overlap with that of a more abundant (unidentified) species. Similarly, 6β-OOH appears to be unresolved from another minor species. Whether this might be 6α-OOH, which was shown to be less abundant than the 6β epimer in model systems (12), is presently unknown. Quantitation of cellular 5α-OOH, 6β-OOH and 7α/7β-OOH (collectively referred to as ChOOH; see Table 3) was accomplished by spiking samples with increasing amounts of the respective standards, integrating, and extrapolating to zero addition.

To strengthen our argument about ChOOH identities, we isolated relatively large amounts of these species by semipreparative HPLC–EC and subjected them to alternative TLC analysis along with appropriate standards. As shown in Figure 5 (lane c), a fraction believed to contain 7α/7β-OOH on the basis of spiking results (Fig. 4) actually contained one major peroxide species, which comigrated with authentic 7α/7β-OOH (lane a). Material from the fraction corresponding to 5a-OOH was found to be quite contaminated with other peroxides, as expected (Fig. 5, lane e). However, visualization of a faint spot at the same position as authentic 5α-OOH (lane b) confirms that at least some of this species was present in

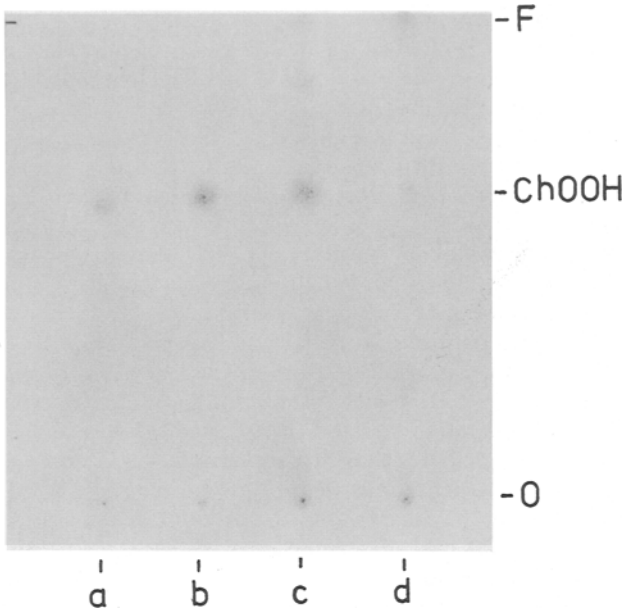

FIG. 5. Thin-layer chromatogram of cholesterol hydroperoxides (ChOOH). Fractions suspected of containing ChOOH (5α-OOH, 6β-OOH and 7α/7β-OOH) were isolated by semipreparative HPLC–EC of lipid extracts from large-scale preparations of photooxidized L1210 cells (see Materials and Methods section). Material from these fractions was analyzed by silica gel thin-layer chromatography (TLC), using benzene/ethyl acetate (1:1, vol/vol) as the mobile phase. Hydroperoxides were visualized by spraying with *N,N,N',N'*-tetramethyl-*p*-phenylenediamine. Sample lanes were as follows: (a) 7α/7β-OOH standard mixture; (b) 5α-OOH standard; (c) HPLC fraction believed to contain 7α/7β-OOH; and (d) HPLC fraction believed to contain 5a-OOH. See Figures 1–4 for other abbreviations; O indicates origin; F indicates solvent front.

mildly photooxidized cells. Although ChOOH species do not separate well from one another on TLC (Fig. 5), diol reduction products do separate satisfactorily (22,28). However, it was not possible to identify and differentiate cell-derived 7α/7β-OOH and 5α-OOH on this basis because sample material was limited and the detection method, spraying with 50% sulfuric acid (27), is not sensitive enough.

Assignment of phospholipid hydroperoxides in HPLC–EC profiles. We have reported elsewhere (13) that photochemically-generated hydroperoxides of two synthetic phospholipids, POPC and PLPC, elute as broad peaks on HPLC–EC, their average retention times being longer than those of ChOOH. These time ranges, particularly the POPC–OOH range, fall close to that of the broad peak appearing at 18–22 min in the present study (Figs. 2 and 3). Suspecting, therefore, that the 18–22-min peak might represent phospholipid hydroperoxides, we used semipreparative HPLC–EC to isolate this material in relatively large amounts for further study. Although this preparation was relatively pure in terms of (putative) hydroperoxide type, it may have contained large amounts of other (EC-silent) species, e.g., unoxidized lipids, making identification by spectroscopic methods, e.g., gas chromatography/mass spectrometry (GC/MS), difficult, if not impossible. We selected two different biochemical approaches as alternatives.

To confirm that the 18–22-min fraction contained hydroperoxides and that they were derived from cellular phospholipids, we treated samples with GSH and two different selenoperoxidases, GPX and PHGPX. PHGPX can catalyze the reduction of membrane lipid hydroperoxides to EC-silent alcohols (35). In addition to PLOOH, the enzyme can act on ChOOH and TGOOH (35,36). GPX can reduce relatively polar peroxides such as H_2O_2 and FAOOH, but does not act on LOOH, whether membrane-bound or solubilized (37). TLC analysis (Fig. 6, lane b) indicated that the 18–22-min fraction contained one major TMPD-reactive compound with mobility matching that of an egg PCOOH standard plus a trace of material migrating as PEOOH (see also Ref. 13). A 30-min incubation of the 18–22-min fraction in the presence of Triton X-100, GSH, PHGPX and DFO resulted in complete disappearance of TMPD-positive spots, including the zone observed at the solvent front (Fig. 6, lane d). (We determined that the latter was generated as an ar-

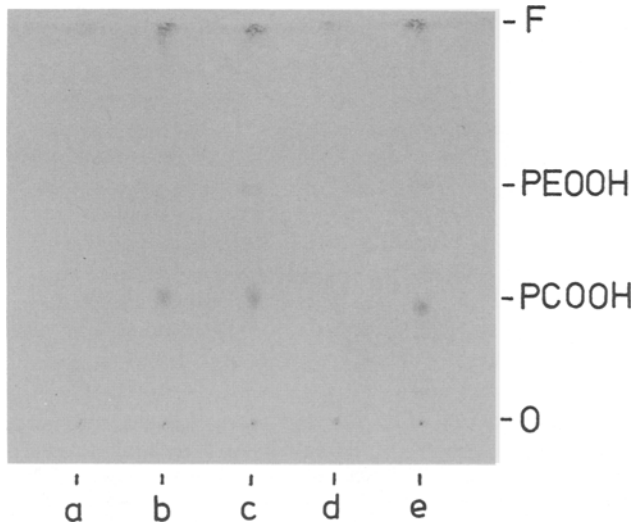

FIG. 6. Thin-layer chromatogram of 18–22-min fraction after treatment with glutathione and selenoperoxidases. Samples of 18–22 min HPLC fraction from a lipid extract of photooxidized L1210 cells were solubilized in Chelex-treated phosphate buffered saline (25 mM sodium phosphate, 125 mM NaCl, pH 7.4) containing 0.1% Triton X-100, 20 μM desferrioxamine (DFO) and 3.0 mM reduced glutathione. Lipids were extracted and analyzed by TLC before incubation (lane b) and after incubation for 30 min at 37°C in the absence of selenoperoxidase (lane c), presence of 0.1 U/mL phospholipid hydroperoxide glutathione peroxidase (lane d), or presence of 0.5 U/mL glutathione peroxidase (lane e). Lane a represents an extract of reaction mixture containing all but the 18–22-min material. Starting material applied in lanes b–e contained ~1.0 nmol of LOOH. Phosphatidylcholine hydroperoxides (PCOOH) and phosphatidylethanolamine hydroperoxides denote positions of photoperoxidized egg phosphatidylcholine and egg phosphatidylethanolamine standards (spots not shown). See Figures 1–5 for other abbreviations.

tifact during sample incubation at 37°C.) No loss of TMPD reactivity was observed when samples were incubated with GSH alone (lane c) or GSH plus GPX (lane e); five-times as many units of GPX were used, yet it was unreactive relative to PHGPX. These results support our contention that the major component observed in the 18–22-min fraction is a phospholipid hydroperoxide, most likely PCOOH.

Additional evidence that the 18–22-min hydroperoxide is derived from phospholipid (mainly PC) was sought by treating samples with Ca^{2+}-dependent PLA_2 to specifically cleave the *sn*-2 fatty acyl groups. Incubation with Ca^{2+}/PLA_2 resulted in a partial decay of the 18–22 min peak on HPLC–EC (Fig. 7A) and appearance of relatively high mobility products (Fig. 7B). Detection of the latter required a separate HPLC–EC run with a more polar mobile phase than used for the parent material. The chosen eluant effected a satisfactory separation of hydrolysis products from the solvent front; a partially resolved doublet appeared at ~4 min and a much smaller shoulder at ~3 min (Fig. 7B). Neither of these was observed in a control incubated with Ca^{2+} alone. Both disappeared when a sample was treated with triphenylphosphine subsequent to Ca^{2+}/PLA_2 (not shown). The EC peaks observed in Figure 7B are ascribed to FAOOH on the basis of matching retention times of photoperoxidized fatty acid standards (not shown), e.g., oleic acid hydroperoxide (~4 min) and linoleic or arachidonic acid hydroperoxide (~3 min). There was a 46% decrease in the amount of starting material after 30 min of incubation with PLA_2 (60 U/mL), and a 56% decrease after an additional 30 min following a second dose of enzyme (Table 2). The observed conservation of total hydroperoxide during Ca^{2+}/PLA_2 treatment (Table 2) indicates that nonenzymatic losses were minor and that all peroxide species were properly accounted for and quantitated. If all hydroperoxides in the 18–22-min fraction existed as PLOOH and occupied the *sn*-2 position of PLOOH, they should have been completely released as FAOOH. That a <60% conversion was actually observed is attributed to the nonideal physical state of the substrate during exposure to PLA_2. Under the conditions used, substrate lipid probably existed in multilamellar form, which could have prevented complete accessibility of peroxidized groups to PLA_2, an enzyme that functions most efficiently on a monolayer or bilayer surface (38). That EC-responsive material in the 18–22-min fraction was converted stoichiometrically, albeit incompletely, to EC-responsive products

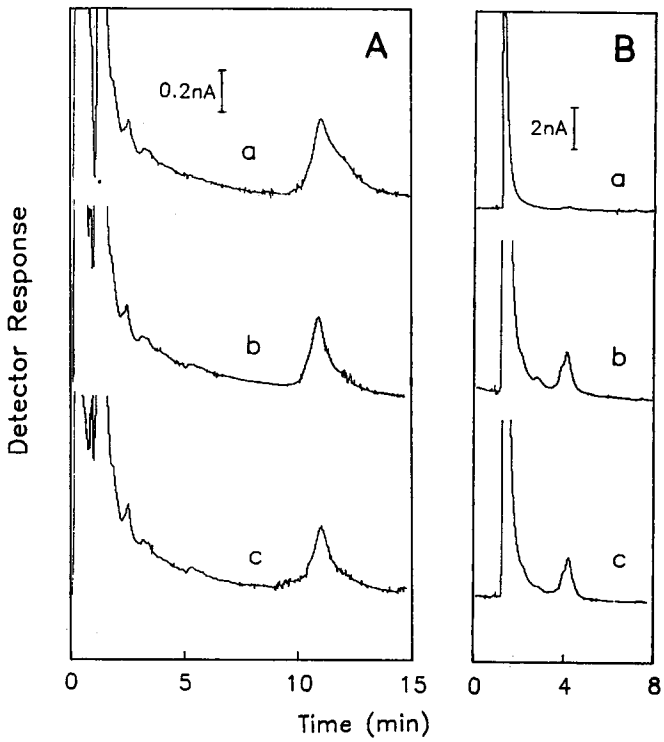

FIG. 7. HPLC–EC of the 18–22-min fraction after Ca^{2+}/phospholipase A_2 treatment. The 18–22-min fraction, isolated by semipreparative HPLC–EC of total lipid extracted from photooxidized cells, was incubated in the presence of Ca^{2+} (5 mM), PLA_2 (up to 120 U/mL) and DFO (20 μM) in 50 mM Tris buffer (pH 7.4) at 37°C. The following samples were chromatographed: (a) a 60-min control sample without PLA_2; (b) material treated with a single dose of PLA_2 (60 U/mL) and incubated for 30 min; (c) material treated with two doses of PLA_2 (60 U/mL), one each at 0 min and 30 min, and incubated for 60 min total. (A) HPLC–EC of the parent material; (B) HPLC–EC of hydrolysis products. Mobile phase in (A) consisted of 85% methanol, 9% acetonitrile, and 6% aqueous solution (pH 5.0) containing 10 mM ammonium acetate and 0.25 mM sodium perchlorate. Retention time for suspected PCOOH is 10–13 min in this system. Mobile phase in (B) consisted of 50% methanol, 27.5% acetonitrile, and 22.5% aqueous solution (see above). The peak at ~4 min in scans b and c (panel B) matches retention of oleic acid hydroperoxide, whereas the shoulder at ~3 min matches retention of arachidonic acid or linoleic acid hydroperoxide. Both of these areas were integrated for quantitation of fatty acid hydroperoxide in Ca^{2+}/PLA_2-treated samples. Integrated values for substrate and product peaks are shown in Table 2. See Figures 1, 2 and 6 for other abbreviations.

TABLE 2

Hydroperoxide Distribution After Ca^{2+}/Phospholipase A_2 (PLA_2) Treatment of the 18–22-min Fraction[a]

Sample	PLOOH (nmol)	FAOOH (nmol)	Total hydroperoxide (nmol)
Control	0.28 ± 0.04[b]	0	0.28 ± 0.04
Ca^{2+}/PLA_2 (30 min)	0.15 ± 0.01	0.16 ± 0.01	0.31 ± 0.02
Ca^{2+}/PLA_2 (60 min)	0.13 ± 0.01	0.18 ± 0.05	0.31 ± 0.06

[a]Analytical high-performance liquid chromatography with mercury drop electrochemical detection data are from the experiment shown in Figure 7. Reaction mixtures included material from the 18–22-min fraction (total iodometric LOOH ~3 μM), 5 mM $CaCl_2$, and 20 μM DFO in 50 mM Tris buffer (pH 7.4) at 37°C. Mixtures were incubated for (i) 30 min in the absence of PLA_2 (control); (ii) 30 min in the presence of PLA_2 (60 U/mL); or (iii) 60 min in the presence of PLA_2 (60 U/mL added at 0 min and again at 30 min). Suspected phospholipid hydroperoxides (PLOOH) in the 18–22-min fraction were quantified by relating their integrated peak area to that of a PLPC–OOH standard; fatty acid hydroperoxides (FAOOH) were determined by relating peak areas to those of arachidonic and linoleic acid hydroperoxide standards.
[b]Values are means ± deviation of two determinations.

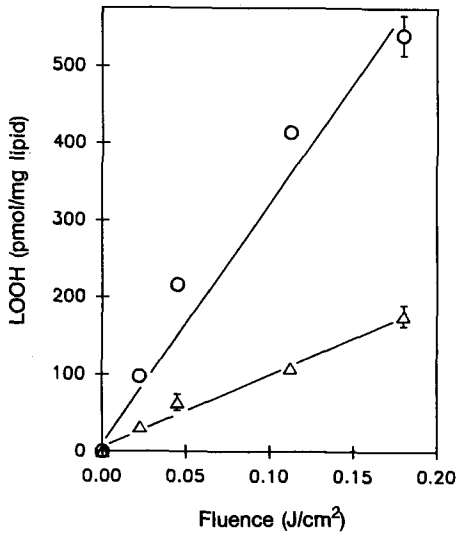

FIG. 8. Accumulation of ChOOH and PCOOH as a function of light fluence. L1210 cells (1.0×10^7/mL) were irradiated in the presence of 25 μM MC540. At the indicated fluence values, lipids were extracted and analyzed by HPLC–EC (~280 μg of total lipid per injected sample). Total ChOOH content (Δ) in each sample is the sum of peak areas for 5α-OOH, 6β-OOH and 7α/7β-OOH. Due to overlap with other species (cf. Fig. 4), 5α-OOH and 6β-OOH were each determined by measuring total peak areas after spiking samples with increasing known amounts of a standard, and extrapolating to zero addition. Total PCOOH content (○) in each sample was determined from the area of the 18–22-min peak. Data points with error bars are means ± SD (n = 4). See Figures 1–6 for abbreviations.

with the mobility of FAOOH is added evidence that the parent material was PLOOH, mainly PCOOH.

Quantitation of cholesterol and PCOOH. A plot of HPLC–EC-determined ChOOH and PCOOH levels as a function of light fluence for MC540-sensitized L1210 cells is shown in Figure 8. As can be seen, each population accumulated in linear fashion over the fluence range used, PCOOH more rapidly than ChOOH by a factor of ~3.5. This is consistent with the fact that cholesterol contains only one double bond, whereas cellular PC would average more than one double bond at the *sn*-2 fatty acyl position, making them intrinsically more oxidizable. It would be difficult to predict the relative rates of PCOOH and ChOOH accumulation in this system, since the actual content of unsaturated fatty acyl groups in PC is unknown. Moreover, additional information (also not available) would be required, making this comparison quite complex, e.g., (i) location of membrane-bound sensitizer relative to PC and cholesterol; (ii) O_2 level in the local environment of PC relative to cholesterol; and (iii) possible differences in the metabolic turnover of PCOOH and ChOOH. Table 3 shows yields of photochemically generated ChOOH and PCOOH expressed as percentages of overall LOOH and as percentages of total lipid in each respective class. As can be seen, ChOOH accounted for 2–3 mol% of the total LOOH over the fluence range used. This is reasonably close to the mol fraction of cholesterol relative to total lipid in our cells (see Materials and Methods section), suggesting that cholesterol and other lipids are similarly accessible to photooxidants. As also shown in Table 3, PCOOH in the 18–22-min fraction accounted for 7–10 mol% of the total LOOH generated at different stages of photooxidation. This value is not far different from the mol% of PC relative to total lipid (39), again suggesting an even distribution of oxidant(s) among reactive lipids. Over a fluence range of 0.045 to 0.18 J/cm^2, ChOOH content expressed as mol% of parent lipid increased from 0.05 to 0.13; PCOOH content expressed as mol% of PC increased by the same amount (Table 3). These data also imply similar accessibility of PC and cholesterol to MC540/light-derived oxidant(s).

TABLE 3

Relative Yields of Lipid Hydroperoxides in MC540/Light-Treated Cells[a]

Fluence (J/cm^2)	Total LOOH nmol/10^8 cells[b]	ChOOH (mol %)[c]		PCOOH (mol %)[d]	
		% LOOH	% Ch	% LOOH	% PC
0	<0.2	—	—	—	—
0.045	0.5	3.0	0.05	10.0	0.05
0.11	1.3	2.2	0.08	7.7	0.10
0.18	2.5	2.5	0.13	8.4	0.13

[a]Cells (1.0×10^7/mL) were exposed to the indicated light fluences in the presence of 25 μM merocyamine 540 (MC540) (see Materials and Methods section).
[b]Total lipid hydroperoxide (LOOH) content was determined by iodometric assay.
[c]Cholesterol hydroperoxide (ChOOH) content of cells was determined by high performance liquid chromatography–electrochemical detection (HPLC–EC). Values are expressed relative to total LOOH and total cholesterol. Cholesterol (Ch) content determined by HPLC with ultraviolet detection was 147 ± 15 nmol/10^8 cells; this translates to 4.0 ± 0.4% (w/w) of total lipid, based on a gravimetrically determined lipid content of 1.42 ± 0.06 mg/10^8 cells.
[d]Phosphatidylcholine hydroperoxide (PCOOH) content of cells was determined by HPLC–EC. The value used for phosphatidylcholine (PC) content was 412 nmol/10^8 cells (Ref. 40).

DISCUSSION

Increasing interest in the cytopathological effects of lipid peroxidation has stimulated the development of highly sensitive and selective approaches for assessing this process. Approaches involving direct measurement of lipid hydroperoxides are especially important because these species can play a central role in cytotoxicity, e.g., by directly perturbing membrane structure and function or by acting as "nuclei" for free radical reactions that exacerbate overall damage. Moreover, identification of certain LOOH (most notably those in the ChOOH family) can provide valuable mechanistic information, e.g., whether a reaction is $^1O_2$-mediated or free radical-mediated. HPLC, with some type of high sensitivity/specificity detection mode such as chemiluminescence, fluorescence or reductive electrochemistry, has become the method of choice for analyzing different LOOH in complex mixtures. Each of these modes has advantages and disadvantages, but it is becoming increasingly clear that EC detection provides the best option in terms of (i) overall cost; (ii) ease of operation and maintenance; and (iii) fewer possibilities of artifactual signals. The latter are less likely to arise in EC because post-column mixing reactions are not required for generating signals. HPLC–EC with a glassy carbon indicator electrode has been used for analyzing PLOOH (8–10) and FAOOH (11). Subsequent work carried out in this laboratory showed that this approach is also suitable for ChOOH products, with detection limits of 25–30 pmol being achieved (12). More recently, we discovered that a renewable mercury drop electrode has several advantages over the glassy carbon electrode, most impressive of which is the 100–200-fold decrease in detection limit for ChOOH. HPLC with mercury electrode EC can be run under conditions that permit baseline separation of ChOOH (5α-OOH, 6β-OOH, 7α/7β-OOH), not only from one another, but also from various PLOOH (e.g., POPC-OOH, PLPC-OOH, egg PCOOH). Preliminary studies (13) demonstrated the feasibility of using this method for monitoring LOOH accumulation in oxidatively stressed cells, e.g., L1210 cells exposed to photodynamic action.

Studying MC540/light-treated cells more extensively in the present work, we have identified and quantified several LOOH species arising during early, minimally lethal, stages of oxidative injury. These include (i) 5α-OOH and 6β-OOH, characteristic products of $^1O_2$ attack on cholesterol (30); (ii) the 7α/7β-OOH epimers, presumed from earlier work (26) to be rearrangement products of 5α-OOH; and (iii) a PLOOH mixture consisting almost exclusively of PCOOH. The extremely high sensitivity of mercury electrode EC permitted measurement of these species at levels that were far below the UV absorbance detection limits at 212 nm (ChOOH) or 233 nm (PLOOH) (13). Although several peaks were observed in the UV detection mode (Fig. 3), these had nothing to do with peroxides, since samples analyzed before and after photooxidation, and also after photooxidation followed by TPP treatment, all had the same UV profile. By contrast, EC peaks appeared only in photooxidized samples and disappeared after incubation with TPP, consistent with what one would expect for reducible LOOH. Definitive identification of the LOOH species, e.g., by spectroscopic techniques such as GC/MS or high resolution nuclear magnetic resonance, was not possible due to low yields, peroxide microheterogeneity, and the presence of co-eluting, nonperoxide contaminants. Large-scale purifications for this purpose were beyond the scope of this work. However, we were able to establish LOOH class identity in other ways, e.g., by using matching standards on HPLC and TLC. In the case of the 18–22-min family, PLOOH (PCOOH) identity was confirmed by demonstrating (i) reactivity with GSH/PHGPX, but not GSH/GPX; and (ii) reactivity with Ca^{2+}-activated PLA_2. The first observation provided proof of general LOOH character, while the second specified that the LOOH is PLOOH with an *sn*-2 peroxyl moiety. Other peroxides, besides the ChOOH and PCOOH described, remain to be identified and quantified. Peroxidized triacylglycerols might be significant products, since triacylglycerols comprise ~28% of total cellular lipid (see Materials and Methods section). Unlike cholesterol and PC, which exist mainly in cell membranes, triacylglycerols are localized in cytosolic lipid vacuoles. Formation of TGOOH would imply that intermediates such as $^1O_2$ generated by MC540 photoactivation in the plasma membrane (26,32) are long-lived enough to cause significant oxidation of cytosolic targets. Some of the unassigned peaks with short retention times (<10 min) could conceivably represent TGOOH (Figs. 2 and 3).

With HPLC–EC, we were able to detect significant levels of LOOH, including ChOOH and PCOOH, at the early stages of dye-sensitized photokilling. These levels were exceedingly low relative to overall lipid. For example, at a fluence of 0.045 J/cm^2, we estimate that the amount of ChOOH plus 18–22-min PCOOH produced was 60–65 pmol/10^8 cells, which translates to ~0.003 mol% of total lipid. These cells appeared to be completely viable by MTT and trypan blue exclusion assays, and >90% viable by clonal assay (Table 1), indicating that LOOH formation is an early event in relation to photokilling. Whether lipid peroxidation is causally linked to cell killing is not clear, but these observations, along with others described recently (18,40), are at least consistent with this possibility. Because damage to other targets may occur coincidentally with lipid peroxidation, the exact role of the latter is difficult to establish. For example, peroxidation-mediated lethality could result from (i) direct membrane damage and lysis, (ii) changes in membrane environments that alter critical protein functions such as ion pumping, or (iii) depletion of vital metabolites such as GSH, NAD(P)H, or ATP as a result of LOOH detoxification/repair.

MC540, the photosensitizing dye used in this study, is under intensive preclinical evaluation as an antitumor agent (41). The dye's phototherapeutic potential is exemplified by the fact that it binds preferentially to neoplastic cells in autologous remission bone marrow grafts and inactivates them when photoexcited by visible light, λ_{max} for the action spectrum and absorption spectrum

being ~568 nm (42). The proximal site of MC540-sensitized photodamage is believed to be the plasma membrane, since the dye localizes principally in this membrane, interacting strongly with lipid constituents (41). Previous studies showed that isolated membranes (liposomes, erythrocyte ghosts) and leukemia cells (L1210, K562) undergo potentially lethal lipid peroxidation when irradiated in the presence of MC540 (18,26,32). Peroxidation was assessed using relatively low-performance methods such as iodometric assay for "bulk" LOOH determination and TLC for preliminary LOOH identification. HPLC–EC represents a major advance in our ability to analyze peroxidized lipids in biological systems and to assess their cytotoxic potential. Further refinements of this approach, e.g., improved product resolution and characterization should enhance our ability to evaluate peroxide cytotoxicity, not only that associated with phototodynamic stress, but other types of oxidative stress as well.

[Received January 10, 1994, and in revised form May 9, 1994; Revision accepted May 14, 1994]

Effect of Dietary Carnosine on Plasma and Tissue Antioxidant Concentrations and on Lipid Oxidation in Rat Skeletal Muscle

Wendy K.M. Chan[a,1], Eric A. Decker[b,*], Ching K. Chow[c] and Gilbert A. Boissonneault[d]

[a]Department of Animal Sciences, [b]Department of Food Science, University of Massachusetts, Amherst, Amherst, Massachusetts 01003, [c]Department of Nutrition and Food Science and [d]Department of Clinical Sciences, University of Kentucky, Lexington, Kentucky 40536

The effect of dietary carnosine supplementation on plasma and tissue carnosine and α-tocopherol concentrations and on the formation of thiobarbituric acid reactive substances (TBARS) in rat skeletal muscle homo-genates was evaluated. Plasma, heart, liver and hind leg muscle was obtained from rats fed basal semipurified diets or basal diets containing carnosine (0.0875%), α-tocopheryl acetate (50 ppm), or carnosine (0.0875%) plus α-tocopheryl acetate (50 ppm). Dietary carnosine supplementation did not increase carnosine concentrations in heart, liver and skeletal muscle. Dietary supplementation with both carnosine and α-tocopherol increased carnosine concentrations in liver 1.56-, 1.51- and 1.51-fold as compared with diets lacking carnosine, α-tocopherol or both carnosine and α-tocopherol, respectively. Dietary supplementation with both carnosine and α-tocopherol also increased α-tocopherol concentrations in heart and liver 1.38-fold and 1.68-fold, respectively, as compared to supplementation with α-tocopherol alone. Dietary supplementation with carnosine, α-tocopherol or both carnosine and α-tocopherol was effective in decreasing the formation of TBARS in rat skeletal muscle homogenate, with dietary α-tocopherol and α-tocopherol plus carnosine being more effective than dietary carnosine alone. The data suggest that dietary supplementation with carnosine and α-tocopherol modulates some tissue carnosine and α-tocopherol concentrations and the formation of TBARS in rat skeletal muscle homogenates.
***Lipids* 29, 461–466 (1994).**

Carnosine (β-alanyl-L-histidine) is an endogenously synthesized dipeptide present in brain (1,2), cardiac muscle, kidney, stomach (1), olfactory bulbs (3) and skeletal muscle, with concentrations in skeletal muscle ranging from 1 to 20 mM (4). Carnosine is synthesized from β-alanine and histidine by carnosine synthetase, which has been found in brain, heart, liver (5), skeletal muscle (6) and olfactory bulb (7). Tissue carnosine concentrations can be influenced by diet. Dietary histidine deficiency reduces skeletal muscle carnosine concentrations in rats (8,9) while high dietary histidine supplementation (5%) has been shown to increase rat skeletal muscle carnosine concentrations (9). Supplementation with high concentrations (1.8–5.0%) of dietary carnosine also increases skeletal carnosine concentrations (9).

The biological function of carnosine is not fully understood, although carnosine has been suggested to act as both an antioxidant and a buffering agent (10). Carnosine has been shown to inhibit lipid oxidation catalyzed by iron (11), hydrogen peroxide-activated hemoglobin (11), singlet oxygen (12,13), lipoxygenase (11), peroxyl radicals (14,15) and hydroxyl radicals (16,17). The antioxidant activity of carnosine has also been demonstrated in oxidation model systems containing phosphatidylcholine liposomes (11), linoleic acid emulsions (14), skeletal muscle microsomes and sarcoplasmic reticulum (18,19). Due to its water solubility, carnosine would provide cells with an antioxidant system that could function in the cytosolic environment where water-soluble oxidation mediators, such as transition metals and oxygen radicals, can be present in high concentrations.

α-Tocopherol is a phenolic lipid-soluble antioxidant present in serum and in the membranes of tissues including heart, liver and skeletal muscle (20). Dietary supplementation of α-tocopherol can increase α-tocopherol concentrations in liver, serum, kidney, heart and skeletal muscle (21–24). An increase in tissue α-tocopherol concentrations has been shown to decrease susceptibility to lipid oxidation reactions, for example, in liver, kidney and skeletal muscle (25,26). α-Tocopherol deficiency in rats has been shown to be associated with a decrease in skeletal muscle carnosine concentrations suggesting that an interrelationship exists *in vivo* between α-tocopherol and carnosine levels (27).

Antioxidants have been postulated to retard various disease conditions including breast cancer, atherosclerosis and aging (28,29). An increase in the levels of endogenous antioxidants, such as α-tocopherol and carnosine through dietary means, may therefore increase the resistance of tissues against oxidation and retard the development of oxidation-related disease conditions. The objective of the present study was to determine how dietary carnosine, at a concentration equivalent to that in a diet containing 20% beef, would affect carnosine, anserine, histidine and α-tocopherol concentrations in both α-tocopherol-deficient and α-tocopherol-adequate rats. The effect of dietary carnosine and α-tocopherol on the formation of thiobarbituric acid reactive substances (TBARS) in rat skeletal muscle homogenates was also determined.

MATERIALS AND METHODS

Chemicals. Hexane and high-performance liquid chromatography (HPLC)-grade methanol were purchased from Curtin Matheson Scientific, Inc. (Houston, TX). Fluoaldehyde *o*-phthalaldehyde (OPA) reagent was from Pierce (Rockford, IL). Carnosine, α-tocopherol, α-tocopheryl acetate and sodium acetate were from Sigma (St. Louis, MO). All other chemicals were reagent-grade or purer.

Abbreviations: HPLC, high-performance liquid chromatography; OPA, *o*-phthalaldehyde reagent; TBARS, thiobarbituric acid reactive substances.

Feeding regimen. Basal semipurified diets fed to rats were prepared as described in Table 1. A 2 × 2 factorial design was used. Groups included: (i) α-tocopheryl acetate (0 ppm) diet without added carnosine (–E–C); (ii) α-tocopheryl acetate (0 ppm) diet with 0.0875% carnosine (–E+C); (iii) α-tocopheryl acetate (50 ppm) diet without added carnosine (+E–C); and (iv) α-tocopheryl acetate (50 ppm) diet with 0.0875% carnosine (+E+C). The carnosine concentration used (0.0875%) in this study was chosen to be equivalent to that of a diet containing about 20% beef. Diets contained 10% stripped corn oil by weight and recommended levels of all other nutrients (including selenium) with the exception of α-tocopherol and carnosine. Diets were prepared monthly and stored at –20°C in sealed plastic bags. Weekly aliquots were stored at 4°C, and the remainder was disposed at week's end. Food was changed daily and remaining food was discarded.

Each group contained 30 animals at the beginning of the experiment. Tissues from eight randomly selected animals from each of the four treatment groups were analyzed. The animals were also the subjects of a mammary cancer study of six months' duration. Rats were treated with 65 mg/kg body weight of 7,12-dimethylbenz[a]anthracene by gavage tube at 55 d of age. Animals were placed on the experimental diets 10 d after gavage treatment for a total of 6 mon. All animals were fed the +E–C diet for a total of 3 wk before switching over to the experimental diets. Food and water were provided *ad libitum.* Mean body weights were not significantly different throughout the experiment (data not shown). Food intake was not measured nor were groups pair-fed as there were no significant differences in body weight.

Rats were exsanguinated by cardiac puncture using a heparinized syringe following metaphane anesthesia. Tissue from heart, liver and leg skeletal muscle, and blood plasma, were frozen immediately after collection and kept at –80°C until use.

Carnosine, anserine and histidine analysis. Heart (0.7 g), liver (2.5 g) and leg skeletal muscle (1.4 g) from six different animals of each dietary group were thawed at 4°C, minced, and homogenized in 3, 10 and 20 mL of 0.36 M perchloric acid, respectively, according to Kasziba *et al.* (1) using a Polytron homogenizer (Brinkmann Instruments Inc., Westbury, NY) at a setting of 4 for 2 min.

TABLE 1

Basal Diet Composition

Ingredient	g/kg Diet
Casein, vitamin-free	200
d,1-Methionine	3
Choline bitartrate	2
AIN-76A vitamin mix[a]	10
AIN-76 mineral mix	35
Cellulose	40
Corn starch	275
Glucose monohydrate	335
Stripped corn oil	100
Vitamin E acetate	± 0.05
Carnosine	± 0.875

[a]Vitamin mix contains no vitamin E.

Homogenates were heated in a boiling water bath for 5 min and centrifuged at 2,000 × *g* for 10 min with a Centrific™ centrifuge (Fisher Scientific, PA). Blood plasma (0.5 mL) was mixed with an equal volume of perchloric acid (0.36 M) and centrifuged at 5,000 × *g* for 10 min with an Eppendorf 5415C microcentrifuge (Madison, WI).

The supernatants from the perchloric acid extractions of heart, liver, skeletal muscle and blood plasma were filtered through a 0.45-μm filter membrane using a syringe. Filtrate (50 μL) was derivatized with 200 μL of OPA reagent for 2 min (30). Carnosine, anserine and histidine concentrations in the derivatized extract (100 μL) were determined by HPLC.

A 5-μm Hypersil ODS high-resolution end-capped column (250 mm × 46 mm) from Alltech Associated Inc. (Deerfield, IL) was utilized for HPLC analysis. The HPLC conditions described by Teahon and Rideout (30) were used. The column was initially equilibrated with 90% Solvent A [10% (vol/vol) methanol in 300 mM sodium acetate adjusted to pH 5.5 with glacial acetic acid] and 10% Solvent B [80% (vol/vol) methanol in 300 mM sodium acetate adjusted to pH 5.5 with glacial acetic acid]. The concentrations of Solvent B were gradually increased during the 25-min run (0 to 5 min, 10 to 20% Solvent B; 5 to 25 min, 20 to 30% Solvent B). The flow rate was 1.5 mL/min and the column temperature was maintained at 30°C. Carnosine, anserine and histidine were quantitated, using an FS 970 Spectrofluoro Monitor (Kratos Analytical Instruments, Ramsey, NJ) at 310 nm for excitation and 375 nm for emission, based on peak areas and standard curves obtained on 10–100 μg/mL of carnosine and histidine and 100–500 μg/mL anserine.

α-Tocopherol analysis. Heart (0.6 g), liver (0.9 g) and leg skeletal muscle (0.6 g) from six different animals of each dietary group were thawed at 4°C, minced and homogenized with 4 mL ethanol (31) using a Polytron homogenizer at a setting 4 for 2 min. Blood plasma (0.5 mL) was mixed with an equal volume of ethanol. The resulting homogenates (1 mL) were mixed with 3.5 mL of hexane and centrifuged at 2,000 × *g* for 10 min. The hexane extract (3 mL) was dried under nitrogen followed by reconstitution in either 0.4 mL (for –E–C and –E+C group samples) or 2.5 mL (for +E–C and +E+C group samples) of hexane before HPLC analysis.

The analytical column used for α-tocopherol measurements was a 5-μm Econosil ODS column (250 mm × 46 mm) from Alltech Associated Inc. Samples (50 μL) were injected into the column using 100% HPLC-grade methanol as the eluting solvent at a flow rate of 1.5 mL/min. α-Tocopherol was detected and quantified at 294 nm with a Waters 490 Multiwavelength Detector (Milford, MA) (32) based on a standard curve obtained on 1–5 μg/mL α-tocopherol standard samples.

Oxidation of skeletal muscle homogenates. Hind-leg skeletal muscles (14 g) from eight different animals from each dietary group were homogenized separately in 100 mL of precooled phosphate buffer (0.1 M, pH 7.4) with a Waring blender for 2 min at 4°C. The homogenates were filtered through three layers of cheesecloth to remove connective tissues, and the filtrates were incubated in a shaking water bath at 37°C for 10 h. The extent of lipid oxida-

tion of the muscle homogenate (3 mL) was determined at various time points by measuring TBARS as described by Sinnhuber and Yu (33). TBARS were expressed as μg malondialdehyde/g muscle. Simultaneously, 0.9 mL of muscle homogenate was mixed with 0.1 mL of butylated hydroxytoluene (BHT; 0.2%) and kept at –80°C until α-tocopherol was measured. Muscle homogenates were mixed with ethanol (1 mL), and α-tocopherol was extracted with hexane and quantitated by HPLC as described above.

Statistical analysis. Carnosine, anserine, histidine and α-tocopherol analyses were done on tissue samples from six different animals on each dietary treatment. Oxidation studies were carried out on muscle from eight different animals on each dietary treatment. TBARS and α-tocopherol concentrations within an oxidation period were compared by analysis of variance utilizing a randomized complete block design to partition the effects of daily variations (34). Statistical analyses were done using the Statistical Analysis System (SAS Institute, Inc., Cary, NC) using the Duncan's multiple range test to determine the significance of difference ($P \leq 0.05$) between mean values.

RESULTS

Carnosine, anserine, histidine and α-tocopherol levels in rat tissues. Carnosine was measurable in heart, liver and skeletal muscle but not in blood plasma (Table 2). Tissue carnosine concentrations were in the order of skeletal muscle > heart > liver in all animals tested. Carnosine concentrations in heart and skeletal muscle were not significantly affected by the dietary treatments (Table 2). Dietary supplementation with carnosine (–E+C) or α-tocopherol (+E–C) did not affect carnosine concentrations in liver; however, supplementation with +E+C increased carnosine concentrations in liver 1.56-, 1.51- and 1.51-fold when compared with the –E–C, –E+C and +E–C diets, respectively (Table 2).

Anserine was detected in skeletal muscle but not in heart, liver or blood plasma (Table 3). None of the dietary treatments significantly affected anserine concentrations in skeletal muscle (Table 3). Histidine was detected in heart, liver, skeletal muscle and plasma with tissue concentrations in the order of heart > liver > skeletal muscle in all animals tested (Table 4). Histidine concentrations in liver and plasma were not significantly affected by the dietary treatments (Table 4). Histidine concentrations in heart were increased 1.46-fold by dietary supplementation with carnosine (–E+C) when compared with tissue values for the unsupplemented diet group (–E–C; Table 4). However, dietary supplementation with tocopherol (+E–C) or both carnosine and α-tocopherol (+E+C) did not affect histidine concentrations in heart (Table 4). Histidine concentrations in skeletal muscle were unaffected by dietary supplementation with carnosine (–E+C) or α-tocopherol (+E–C) when compared with tissue values for unsupplemented rats (–E–C; Table 4). Dietary supplementation with both carnosine and α-tocopherol (+E+C) increased histidine concentrations in skeletal muscle 1.18-, 1.29- and 1.09-fold when compared with the values for animals on the –E–C, –E+C and +E–C diets, respectively (Table 4).

α-Tocopherol was detected in all samples tested, with tissue concentrations in the order of heart > liver > skeletal muscle (Table 5). α-Tocopherol concentrations in heart, liver, skeletal muscle and plasma from rats fed the α-tocopherol-supplemented diet (+E–C) were increased 28.6-, 55.1-, 24.1- and 17.8-fold, respectively, as compared with tissues or plasma from rats on unsupplemented diets (–E–C; Table 5). α-Tocopherol concentrations in heart and liver were increased 1.38- and 1.68-fold, respectively, by carnosine/α-tocopherol supplementation (+E+C) when compared to the values for rats on the +E–C diet. Carnosine/α-tocopherol supplementation did not significantly increase α-tocopherol concentrations in skeletal muscle and serum when compared with the respective +E–C values (Table 5). α-Tocopherol concentrations in heart, liver, skeletal muscle and plasma from rats fed the α-tocopherol-deficient diet (–E–C) were not affected by carnosine supplementation (–E+C; Table 5). The effect of vitamin E deficiency was histologically assessed by Dr. C.B. Hong of the University of Kentucky Livestock Disease Diagnostic Center (Lexington, KY). Examination of liver, skeletal muscle and intestinal sections of vitamin E-adequate (+E–C) and vitamin E-deficient (–E–C) rats revealed no lesions associated with vitamin E or selenium deficiency.

TBARS and α-tocopherol concentrations in incubated skeletal muscle homogenates. Skeletal muscle homogenates obtained from rats fed diets lacking both carnosine and α-tocopherol (–E–C) were the least oxidatively stable ($P \leq 0.05$) of all muscle samples tested with TBARS increasing 8.7-fold between 0 and 10 h of incubation (Fig. 1). Dietary carnosine supplementation (–E+C) significantly ($P \leq 0.05$) decreased the rate of TBARS formation by 14.5 to 27.5% during the oxidation period (0 to 10 h) as compared with TBARS of unsupplemented muscle homogenate (–E–C; Fig. 1). Dietary α-tocopherol supplementation (+E–C) significantly ($P \leq 0.05$) decreased the rate of TBARS formation during the entire incubation when compared with unsupplemented homogenate (–E–C; Fig. 1). Muscle homogenate from rats supplemented with both carnosine and α-tocopherol (+E+C) showed 90.5, 88.8 and 30.1% less TBARS after 6 h of oxidation compared to –E–C, –E+C and +E–C, respectively (Fig. 1). TBARS in

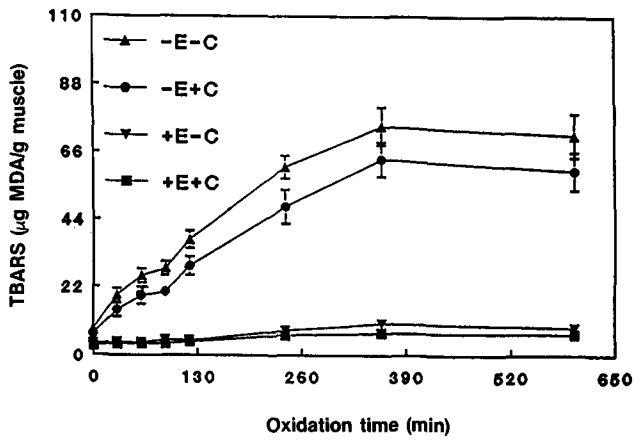

FIG. 1. Thiobarbituric acid reactive substances (TBARS) formation in muscle homogenates from rats fed diets not supplemented with carnosine and α-tocopherol (–E–C), supplemented with carnosine (0.0875%; –E+C), α-tocopherol (50 ppm; +E–C), or both carnosine (0.0875%) and α-tocopherol (50 ppm; +E+C) incubated for the indicated periods of time. Data points and error bars represent means (n = 8) and standard errors. Some standard errors lie within the symbols. MDA, malondialdehyde.

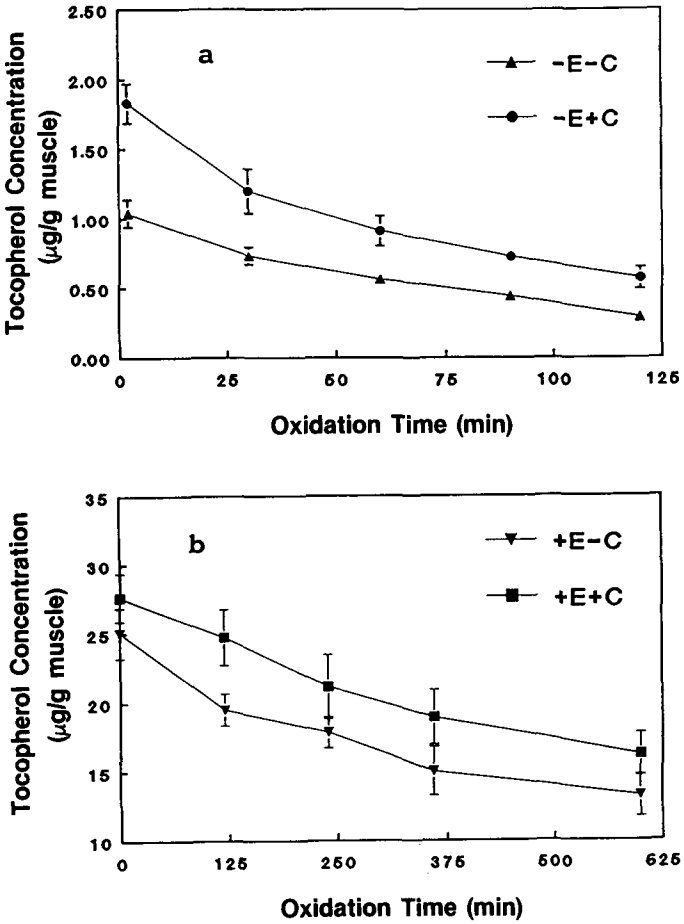

FIG. 2. α-Tocopherol concentrations of muscle homogenates from rat fed diets (a) not supplemented with carnosine and α-tocopherol (–E–C) and supplemented with carnosine (0.0875%; –E+C); (b) supplemented with α-tocopherol (50 ppm; +E+C); incubations were for the indicated periods of time. Data points and error bars represent means (n = 8) and standard errors. Some standard errors lie within the symbols.

muscle homogenates obtained from rats fed the +E+C diets were significantly ($P \leq 0.05$) lower than TBARS in homogenates from +E–C rats at all time points tested.

Muscle homogenates from α-tocopherol-supplemented rats (+E–C and +E+C) had higher α-tocopherol concentrations ($P \leq 0.05$) than homogenates without α-tocopherol supplementation (–E–C and –E+C) for all incubation periods (Fig. 2). Carnosine supplementation resulted in homogenates from rats fed diets with ($P \leq 0.05$; Fig. 2b) or without ($P \leq 0.05$; Fig. 2a) α-tocopherol. α-Tocopherol concentrations decreased over the course of the incubation period. Similar disappearance rates were observed for the –E–C and –E+C homogenates (Fig. 2a) as well as for the +E–C and +E+C homogenates (Fig. 2b).

DISCUSSION

Carnosine and α-tocopherol are antioxidants whose concentrations may be affected by diet (9,22,23). The present studies show that supplementation with 0.0875% carnosine did not increase carnosine concentrations in heart, liver and skeletal muscle (Table 2). Carnosine was not detected in plasma (Table 2), which may be due to the presence of carnosinase that hydrolyzes carnosine into β-Ala and histidine (35). However, plasma histidine concentrations were not elevated in carnosine-supplemented rats (Table 4). It is possible that diet-derived carnosine or the histidine derived from hydrolysis of plasma carnosine may be rapidly removed from plasma. Heart histidine concentrations were observed to increase in rats fed –E+C diets, while skeletal muscle histidine concentrations were observed to increase in rats fed the vitamin E-containing diets (+E–C and +E+C). How these diets were affecting heart and muscle histidine concentrations is unknown. Kasziba *et al.* (1) reported that anserine was present in heart and skeletal muscle of rats; however, in the present study, anserine was only detected in skeletal muscle (Table 3).

Tamaki *et al.* (9) reported that 1.8% dietary carnosine supplementation increased endogenous carnosine concentrations of skeletal muscle of rats fed a histidine-free diet. The absence of changes in carnosine concentrations in skeletal muscle seen in the present study could be due to the low, albeit physiologically relevant, level of carnosine supplementation used (0.0875%). Nevertheless, carnosine concentrations were observed to increase in liver when rats were fed diets containing both α-tocopherol and carnosine. It is not clear why supplemented carnosine was preferentially transported and stored in liver.

Dietary α-tocopherol supplementation increased α-tocopherol concentrations in heart, liver, skeletal muscle and plasma (Table 4) as has been reported by other investigators (21–23). α-Tocopherol concentrations were further increased by carnosine supplementation (+E+C) in heart, liver, skeletal muscle and plasma, although the observed increases in skeletal muscle and plasma were not

significant ($P \geq 0.05$). McManus (27) found that vitamin E deficiency causes over a 60% decrease in skeletal muscle carnosine concentrations in rabbits. Elevated α-tocoperhol concentrations due to carnosine supplementation and decreased carnosine concentrations due to Vitamin E deficiency suggest that an interrelationship between α-tocopherol and carnosine exists *in vivo.*

Diets containing either carnosine (–E+C), α-tocopherol (+E–C) or both carnosine and α-tocopherol (+E+C) were effective in inhibiting lipid oxidation in skeletal muscle when compared to values for the unsupplemented diet (–E–C; Fig. 1). Carnosine concentrations of skeletal muscle from all dietary treatments were similar (Table 2). However, α-tocopherol concentrations of skeletal muscle homogenate from carnosine-supplemented rats were slightly higher than from unsupplemented rats. Therefore, the lower rate of TBARS formation in muscle homogenate from –E+C, +E–C +E+C could be due to higher α-tocopherol concentrations (Fig. 2). α-Tocopherol in –E–C and –E+C (Fig. 2a) as well as in +E–C and +E+C (Fig. 2b) homogenates disappeared in the muscle homogenate at similar rates, suggesting that dietary carnosine supplementation did not increase the stability of α-tocopherol. Although an *in vivo* interrelationship between α-tocopherol and carnosine might exist, carnosine is not thought to be capable of regenerating oxidized α-tocopherol (11,36). Therefore, any increases in antioxidant activity and/or sparing of α-tocopherol by carnosine could be due to differences in the ability of these antioxidants to inactivate lipid- and water-soluble oxidation catalysts.

In conclusion, dietary carnosine supplementation did not affect carnosine concentrations in heart, liver and skeletal muscle. Dietary supplementation with both carnosine and α-tocopherol increased carnosine concentration in liver and α-tocopherol concentrations in liver and heart as compared with diets supplemented with α-tocopherol alone. Dietary supplementation with carnosine, α-tocopherol, or both carnosine and α-tocopherol effectively decreased lipid oxidation in rat skeletal muscle.

Effects of Sodium Butyrate on the Transfer of Arachidonic Acid to Phosphatidylcholine in a Clonal Oligodendrocyte Cell Line (CB-II)

Synthia H. Sun[a,*], Kuo-Chi Chen[b] and Yue-Wen Chen[a]

[a]Institute of Neuroscience and [b]Department of Anatomy, National Yang Ming Medical College, Taipei, Taiwan, Republic of China

The effect of sodium butyrate on membrane phospholipid metabolism in a neonate rat cerebellum derived clonal oligodendrocyte cell line (CB-II) was investigated. Sodium butyrate is an agent known to induce cell differentiation and morphological transformations. A comparison of the *in vivo* phospholipid labeling patterns obtained by incubating CB-II cells with [^{3}H]choline, [^{14}C]myristic acid or [^{3}H]arachidonic acid indicated that butyrate altered the route of acylation–deacylation in phosphatidylcholine (PC) biosynthesis. Using an *in vitro* incubation system containing homogenates of CB-II cells, the largest proportion of radioactivity was found in PC, and addition of sodium butyrate resulted in a further increase in the transfer of arachidonic acid to PC, but not to phosphatidylinositol. Similar results were obtained when this *in vitro* acylation activity was tested using homogenates from sodium butyrate pretreated cells. The butyrate effect was observed regardless of whether or not exogenous lysophosphatidylcholine (LPC) was added to the incubation system. Addition of butyrate did not result in a change in the activity of LPC:acyl-CoA (coenzyme A) acyltransferase (EC 2.3.1.23) in CB-II cells upon incubating cell homogenates with [1-^{14}C]arachidonoyl-CoA and LPC. However, when cell homogenates were incubated with [^{3}H]arachidonic acid in the presence of 2.5–10 mM sodium butyrate, arachidonoyl-CoA synthesis was stimulated. A time course study demonstrated that significant stimulation occurred after three minutes. Taken together, the results suggest that in CB-II cells, sodium butyrate stimulates the transfer of arachidonic acid into PC and that this effect is at least partially due to a stimulation of arachidonoyl-CoA ligase (EC 6.2.1.3).
***Lipids* 29, 467–474 (1994).**

Sodium butyrate is known to stimulate growth and differentiation in a number of cell culture systems (1). For example, the action of butyrate was shown to be associated with the extension of neurite-like processes in a neuroblastoma cell line (2). In C6 glioma cells, the effect of butyrate was related to the ability of butyrate to modulate hormone-mediated induction of glial fibrillary acidic protein and S-100 (3). Butyrate was also shown to induce nerve growth factor gene expression in primary brain monolayer cultures (4) and the expression of *fos* (5,6), *sis* proto-oncogenes, as well as genes of the extracellular matrix protein in F-98 rat glioma cells (6). It is likely that the morphological changes induced by butyrate are associated with changes in membrane lipid compoisition (7,8). Our recent study with a neonate cerebellum-derived clonal oligodendrocyte cell line (CB-II) has correlated the morphological transformation induced by butyrate with changes in membrane phospholipids profiles (9).

It has been well documented that arachidonic acid metabolism in the cell is dependent on the deacylation–reacylation cycle mediated by phospholipase A_2 and lysophopholipid:acyl-CoA (coenzyme A) acyltransferases (10). Reacylation with a fatty acid also depends on the ability of this fatty acid to be converted to acyl-CoA *via* acyl-CoA ligase. Various factors, including detergents and lipid intermediates, such as acyl-CoA and lysophospholipids (11), are known to alter the reacylation process (12,13). The increase in free arachidonic acid and prostanoid in the resident macrophage was shown to be linked to the inhibition of lysophospholipid acyltransferase (14). Phorbol esters and diacylglycerols could also inhibit the incorporation of arachidonate into phospholipids in human platelets through inactivation of both arachidonoyl-CoA ligase and arachidonoyl-CoA:lysophosphatide acyltransferase (15). In rat mesangial cells, stimulation by interleukin-1 of prostaglandin synthesis was related to an increase in both phospholipase A_2 and acyltransferase activities (16). We have previously shown that exposure of CB-II cells to butyrate resulted in an increase in the incorporation of labeled arachidonate into phosphatidylcholine (PC) and a decrease in labeling of phosphatidylethanolamine (PE) (9). However, it is not clear whether the lipid changes are associated with a change in *de novo* biosynthesis or in the acylation–deacylation pathway. In this study, we examined the mechanism underlying the action of sodium butyrate on membrane phospholipids of CB-II cells by incubating cells with lipid precursors and by assaying the arachidonate transfer system *in vitro*. Our results point at a specific effect of butyrate by enhancing the synthesis of arachidonoyl-CoA.

MATERIALS AND METHODS

Materials. Adenosine triphosphate (ATP), bovine serum albumin (BSA; essentially fatty acid free), CoA, bovine brain lysophosphatidylethanolamine (LPE), lysophosphatidylinositol (LPI), lysophosphatidylserine (LPS), 1-myristoyl lysophosphatidylcholine (LPC), palmitic acid, PC, phosphatidylinositol (PI), phosphatidylserine (PS), PE, and ethanolamine plasmalogen (PEpl) and sodium butyrate were purchased from Sigma Chemical Co. (St. Louis, MO). [^{14}C]Arachidonic acid (886 mCi/mmol), [1-^{14}C]arachidonoyl-CoA (46.3 mCi/mmol), [^{3}H]arachidonic acid (240 Ci/mmol), [*methyl*-^{3}H]choline chloride (85.1 Ci/mmol) and [1-^{14}C]myristic acid (58 mCi/mmol) were purchased from NEN/DuPont (Wilmington, DE). DM-160 media were purchased from Kyokuto Pharmaco-

Abbreviations: ATP, adenosine triphosphate; BSA, bovine serum albumin; CB-II, neonate rat cerebellum-derived clonal oligodendrocyte; CoA, coenzyme A; FBS, fetal bovine serum; HPTLC, high-performance thin-layer chromatography; LPC, lysophosphatidylcholine; LPI, lysophosphatidylinositol; LPE, lysophosphatidylethanolamine; LPS, lysophosphatidylserine; PBG, glucose supplemented phosphate buffer; PC, phosphatidylcholine; PE, phosphatidylethanolamine; PEpl, ethanolamine plasmalogen; PI, phosphatidylinositol; PS, phosphatidylserine; TG, triacylglycerol(s).

logical Industrial Co. (Tokyo, Japan); fetal bovine serum (FBS) was obtained from GIBCO (Grand Island, NY) and Hyclone Laboratories Inc. (Logan, UT). Silica gel 60 (10 cm × 10 cm) high-performance thin-layer chromatography (HPTLC) plates and organic solvents were from E. Merck (Darmstadt, Germany). T-25 and T-75 plastic tissue culture flasks and 15- and 50-mL polypropylene centrifuge tubes were purchased from Corning Glass Inc. (Corning, NY). Disposable borosilicate glass culture tubes were from Kimble, a Division of Owen–Illinois (Toledo, OH).

Cell culture. The clonal oligodendrocytes (CB-II) derived from neonate rat cerebellum were cultured in DM 160 medium supplemented with 10% FBS and 50 μg of gentamicin/mL, as described previously (9). These cells had been characterized earlier as glial fibrillary acidic protein negative and galactocerebroside positive and, more recently, as cyclic nucleotide phosphohydrolase positive (data not shown). Cell passages 50–70 were used for the experiments, and cells were normally maintained in T-75 flasks (Corning Glass, Inc.). In a typical experiment, 1.5 to 2 × 10^6 or 2.5 × 10^5 cells were subcultured in T-75 or T-25 flasks, respectively, for three days.

[^{3}H]Arachidonic acid, [^{3}H]choline and [^{14}C]myristic acid incorporation into intact CB-II cells. The incorporation of lipid precursors into intact CB-II cells was followed by subculturing the cells in DM 160 medium supplemented with 10% FBS and 50 μg of gentamicin in T-25 flasks for at least two days. The culture medium was then changed to DM 160 supplemented with 2.5% FBS, in the absence or presence of 2.5 mM sodium butyrate. Labeled precursors, such as 0.5 μCi [^{3}H]arachidonic acid, 4 μCi [^{3}H]choline, or 0.5 μCi [^{14}C]myristic acid, were added and cells were cultured for another 24 h, as described previously (9). At the end of the labeling period, the culture medium was removed, the cells were rinsed once with 0.02 M phosphate buffer (pH 7.4) containing 0.1% glucose (PBG) to remove excess labeled precursors and the reaction was stopped by adding 1.3 mL of ice-cold methanol to the culture. The cells in methanol were transferred to a 13 × 100 mm borosilicate glass test tube, and then 2.7 mL of chloroform and 1 mL of water were added to extract lipids (9).

In vitro *assays of [^{3}H]arachidonic acid transfer.* In the *in vitro* assay system, cells were cultured in T-75 flasks in DM 160 medium supplemented with 10% FBS and 50 μg of gentamicin/mL for at least three days. Subconfluent cultures were removed by trypsinization and aliquots taken for cell counting. After washing with PBG, cells were suspended (2 × 10^6 per mL) in 50 mM Tris-HCl (pH 7.4) and were homogenized with a Potter-Elvehjem homogenizer. A small portion of the cell homogenate was removed for protein assay (17) using BSA as standard. In some experiments, cells were quickly frozen in liquid nitrogen and stored until use. Cells were homogenized with a Potter-Elvehjem homogenizer before the assay. Aliquots of 0.5 mL cell homogenate were incubated in a test tube with 1 μCi of [^{3}H]arachidonic acid, 0.1% fatty acid-free BSA, 0.1 mM CoA, 0.3 mM dithiothreitol, 2.5 mM ATP, 10 mM $MgCl_2$ and 50 mM Tris-HCl (pH 7.4) in the absence or presence of sodium butyrate in a total volume of 1 mL according to the method of Lin *et al.* (18). All incubations were carried out at 37°C for 10 min unless otherwise indicated. In some experiments, 4 μM LPI, 4 μM LPS, 20 μM LPC or 20 μM bovine brain LPE were used according to MacQuarrie *et al.* (13). The lipids, cofactors and sodium butyrate, together with cell homogenates in buffer, were kept in an ice-cold water bath and vortexed vigorously for 20 s prior to incubation. After incubation, the reaction was stopped by adding four volumes of chloroform/methanol (2:1, vol/vol).

Assay of LPC:arachidonoyl-CoA acyltransferase activity. Homogenates from approximately 5 × 10^5 cells were incubated with 50 nCi [1-^{14}C]arachidonoyl-CoA and lysophospholipids in the absence or presence of sodium butyrate and 50 mM Tris-HCl (pH 7.4) in a total of 1 mL at 37°C for 20 min. The amounts of lysophospholipids used were 4 μM LPI, 4 μM LPS, 20 μM LPC or 20 μM bovine brain LPE according to MacQuarrie *et al.* (13). The bovine brain LPE contained 60% alkenyl groups and 40% acyl groups. After incubation, the reaction was stopped by adding four volumes of chloroform/methanol (2:1, vol/vol), and the lipids were extracted and separated by two-dimensional HPTLC (see next section). The radioactivities associated with phospholipids were measured in a Beckman (Palo Alto, CA) scintillation counter and are expressed in pmol/mg protein.

Lipid extraction and separation. For extraction of lipids, four volumes of chloroform/methanol (2:1, vol/vol) were added to the cell suspension. After mixing, the tubes were briefly centrifuged at 2000 rpm to allow phase separation. The lower organic phase was removed and transferred into test tubes. In order to obtain a complete recovery of the acidic phospholipids, the aqueous phase was further extracted by adding two volumes of chloroform/methanol/12N HCl (225:75:0.75, by vol). The acidic organic phase was then removed and neutralized with 4N NH_4OH (about 1 drop) before combining it with the first organic extract. The combined organic extracts were evaporated to dryness, redissolved in chloroform, and applied to HPTLC plates (Kieselgel 60, 10 × 10; E. Merck, Darmstadt, Germany). Phospholipids, namely PI, PS, PC, PEpl and PE, and free fatty acid were separated using a two-dimensional system according to Sun and Horrocks (19) with some modification (9). Briefly, first the plate was developed using chloroform/methanol/acetone/12M NH_4OH (35:20:5:5, by vol). Then the plate was removed from the tank, dried, exposed to HCl fumes for 3 min, and then residual HCl fumes were removed by a stream of warm air for 10 min. The plates were then developed in the second dimension with chloroform/methanol/acetone/glacial acetic acid/0.2 M aqueous ammonium acetate (35:15:14:1:1.75, by vol). After development, the lipid fractions were visualized by exposure to iodine vapor, and the individual phospholipid fractions were scraped into scintillation vials for radioactivity counting. In some experiments, the neutral lipids were removed after separation in the first dimension, extracted and further separated on another HPTLC plate using hexane/diethyl ether/glacial acetic acid (70:30:3.5, by vol). The lipid bands corresponding to triacylglycerols (TG) were used for radioactivity counting.

Assay of arachidonoyl-CoA ligase activity. The synthesis of arachidonoyl-CoA was followed according to the method by Morisaki *et al.* (20), with some modifications. Briefly, homogenates from 5×10^5 cells (approximately 100 μg protein) were incubated with 50 nCi [^{14}C]arachidonic acid, 0.1% fatty acid-free BSA, 0.1 mM CoA, 0.3 mM dithiothreitol, 2.5 mM ATP, 10 mM $MgCl_2$ and 50 mM Tris-HCl (pH 7.4) in the presence and absence of sodium butyrate in a total volume of 250 μL. Incubations were carried out at 37°C for various time periods ranging from 20 s to 10 min. The reaction was terminated by adding 1 mL of Dole's mixture, i.e., isopropanol/heptane/2M H_2SO_4 (40:10:2, by vol) (21). The sample was mixed for 5 min, and then 0.35 mL of water and 0.5 mL of heptane were added. After further mixing, the upper phase was removed, and the lower phase was washed three times with 0.6 mL of heptane containing 5 mg/mL of nonradioactive palmitic acid as carrier (22). Subsequently, the lower phase was taken for radioactivity counting. Levels of arachidonoyl-CoA formed are expressed in nmol/mg protein.

RESULTS

Effect of sodium butyrate on the incorporation of labeled arachidonate, myristate and choline into phospholipids of CB-II cells. When CB-II cells were incubated in the growth medium supplemented with 2.5% FBS containing either [^{3}H]arachidonate or [^{14}C]myristate for 24 h, both labeled fatty acids were incorporated into the cell phospholipids, although each of the labeled fatty acid gave rise to a unique labeling pattern. As shown in Table 1, a greater proportion of labeled myristate was incorporated into PC, whereas labeled arachidonate was incorporated into PC as well as PE and PEpl. With cells labeled with [^{3}H]arachidonate, there was a 25% increase in labeling of PC and a 40% decrease in labeling of PE upon exposure to butyrate (2.5 mM) for 48 h (Table 1). However, this effect of butyrate on PC synthesis was not observed when cells were incubated with [^{14}C]myristic acid (Table 1). In a subsequent experiment, PC biosynthesis in CB-II cells was further probed by incubating cells with [^{3}H]choline. Over 90% of the radioactivity from [^{3}H]choline was found in PC (Table 2). Exposure of cells to butyrate (2.5 mM) for 24 h resulted in a decrease in labeled LPC and sphingomyelin and a small increase in labeled PC.

Effects of sodium butyrate on the incorporation of [^{3}H]arachidonic acid into membrane phospholipids in an in vitro *incubation system.* In this series of experiments, an *in vitro* incubation system was used to assess the incorporation of labeled arachidonate into membrane phospholipids. In the absence of lysophospholipids, [^{3}H]arachidonate was preferentially incorporated into PC of the cell homogenates, but smaller amounts were also found in PI and PE (Fig. 1). Addition of butyrate to the incubation system containing the cell homogenates led to a dose-dependent increase in labeling of PC, but labeling of PI and PE was not altered (Table 3). When exogenous LPC (20 μM) and LPI (4 μM) were added to the *in vitro* incubation system, there was an increase in incorporation of [^{3}H]arachidonate into PC (37%) and PI (80%), respectively (Fig. 2). Nevertheless, further addition of butyrate to systems containing LPC and LPI only enhanced the labeling of PC, but not that of PI (Fig. 2). In a similar experiment, sodium butyrate also enhanced the transfer of arachidonic acid

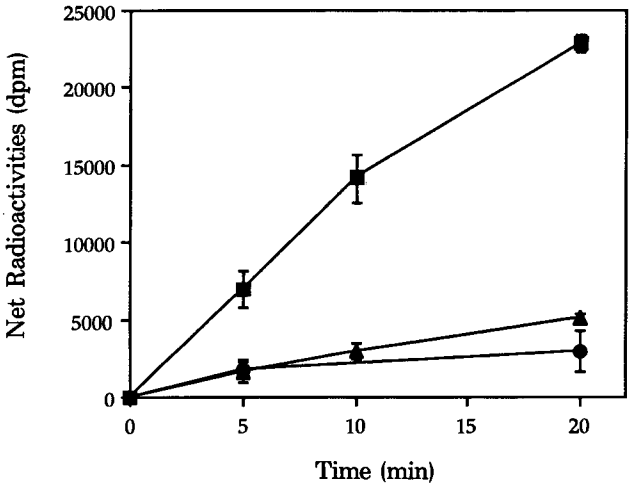

FIG. 1. Time-course of the net radioactivities of [^{3}H]arachidonic acid incorporated into phosphatidylcholine (■), phosphatidylinositol (▲), and phosphatidylethanolamine (●) of neonate rat cerebellum-derived clonal oligodendrocyte cell homogenates using an *in vitro* assay as described in the Materials and Methods section. Homogenates from 1 × 10^6 cells, 1 μCi [^{3}H]arachidonic acid, 0.1 mM coenzyme A, 0.3 mM dithiothreitol, 2.5 mM adenosine triphosphate, 10 mM $MgCl_2$ and 50 mM Tris-HCl (pH 7.4) were incubated at 37°C for the time periods indicated. Radioactivity of the lipids (dpm) is expressed as means ± SD from three determinations; dpm, disintegration per minute.

into TG, whereas LPC inhibited acyl incorporation into TG (Fig. 3). Prior to assay for arachidonoyl transfer activity *in vitro,* CB-II cells were exposed to butyrate for 35 h. Again, there was a significant increase in incorporation of labeled arachidonate into PC in butyrate pretreated cells (Table 4). Under this condition, the butyrate pretreated cells showed a decrease in labeling of TG instead.

Effect of sodium butyrate on lysophospholipid:acyl-CoA acyltransferase. The enzyme activity was assayed by incubating [^{14}C]arachidonoyl-CoA with cell homogenates, as well as in the presence of various classes of lysophospholipids. The results demonstrated that radioactivities were preferentially incorporated into PC (Fig. 4) indicating active LPC:arachidonoyl-CoA acyltransferase activity in CB-II. In the absence of LPC, sodium butyrate alone did not stimulate the incorporation into PC (data not shown). However when LPC (20 μM) was added to the incubation

Total dpm	56418 ± 8278	74495 ± 9056

[a]Radioactivity of the lipids (dpm) is expressed as % of total dpm (mean ± SD) from three determinations. Abbreviations as in Table 1.

[b]Cells were cultured in DM 160 medium supplemented with 10% FBS in the absence or presence of 2.5 mM sodium butyrate for 35 h before obtaining homogenates for arachidonic acid incorporation experiments.

[c]Each incubation contained homogenates from 1×10^6 cells, 0.1 mM coenzyme A, 2.5 mM adenosine triphosphate, 10 mM $MgCl_2$, 0.3 mM dithiothreitol, 1 μCi [^{3}H]arachidonic acid, 50 mM Tris-HCl (pH 7.4) and was kept at 37°C for 10 min. The methods for separation and measurement of the radioactivities of PI, PS, PC, PEpl, PE and triacylglycerols (TG) are described in the Materials and Methods section.

[d]Denotes values that are significantly different ($P \leq 0.05$) comparing butyrate treatment with controls based on nonpaired Student's *t*-test.

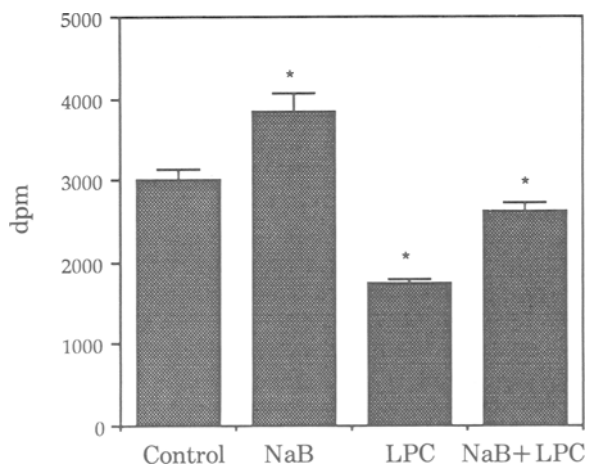

FIG. 3. Effect of NaB and lysophosphatidylcholine (LPC) on the incorporation of [^{3}H]arachidonic acid into triacylglycerols of neonate rat cerebellum-derived clonal oligodendrocyte cell homogenates. Radioactivity of the lipids (dpm) is expressed as means ± SD from three determinations. An asterisk denotes values that are significantly different from controls (no NaB, no LPC) with $P \leq 0.05$ based on nonpaired Student's *t*-test. Homogenates from 1×10^6 cell were incubated with 1 μCi [^{3}H]arachidonic acid, 0.1 mM coenzyme A, 0.3 mM dithiothreitol, 2.5 mM adenosine triphosphate, 10 mM $MgCl_2$ and 50 mM Tris-HCl (pH 7.4) in the presence or absence of 20 μM LPC and in the presence or absence of 2.5 mM NaB at 37°C for 10 min. Other abbreviations as in Figure 1.

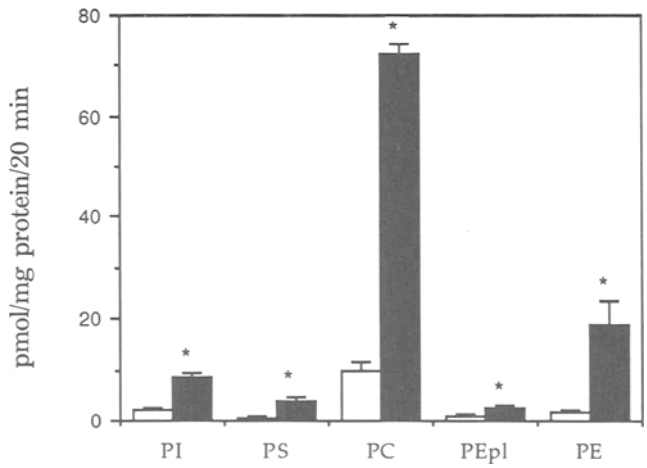

FIG. 4. Effect of lysophospholipids on the incorporation of [1-^{14}C]arachidonoyl-coenzyme A into PI, phosphatidylserine (PS), PC, ethanolamine plasmalogen (PEpl) and phosphatidyl-ethanolamine (PE) of neonate rat cerebellum-derived clonal oligodendrocyte cell homogenates. Homogenates from 1×10^6 cells (approximately 220 μg of protein) were incubated with 50 nCi [1-^{14}C]arachidonoyl-coenzyme A and 50 mM Tris-HCl (pH 7.4) in the absence (□) or presence (■) of 4 μM lysophosphatidylinositol, or 4 μM lysophosphatidylserine or 20 μM lysophophatidylethanolamine, or 40 μM bovine brain lysophosphatidylserine, at 37°C for 20 min. An asterisk denotes values that are significantly different from controls (no LP) with $P \leq 0.05$ based on nonpaired Student's *t*-test. The methods for separation and measurement of the levels of PI, PS, PC, PEpl and PE are described in the Materials and Methods section. Other abbreviations as in Figure 2.

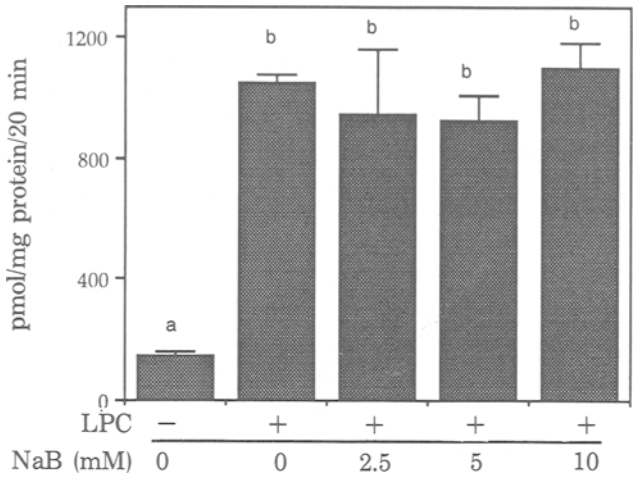

FIG. 5. Effect of NaB and LPC on incorporation of [1-^{14}C]-arachidonoyl-CoA into phosphatidylcholine of neonate rat cerebellum-derived clonal oligodendrocyte homogenates. Homogenates from 1×10^6 cells (approximately 220 μg of protein) were incubated with 50 nCi [1-^{14}C]arachidonoyl-coenzyme A in the absence (–) or presence (+) of 20 μM LPC at the indicated concentrations of NaB at 37°C for 20 min. Bars marked with letter b denote values that are significantly different from controls (bar marked with letter a) (no NaB, no LPC) with $P \leq 0.05$ based on nonpaired Student's *t*-tests. Abbreviations as in Figures 2 and 3.

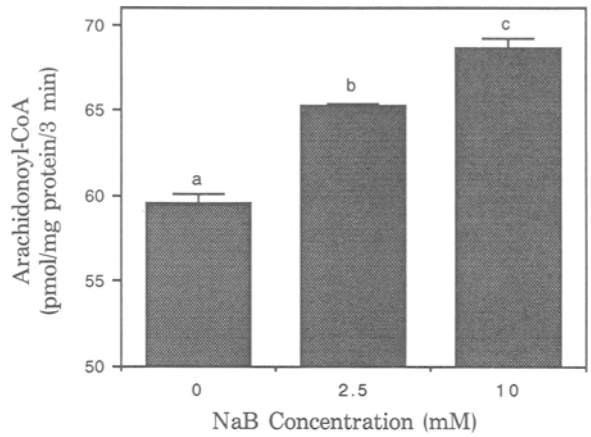

FIG. 7. Dose response relationship of the effect of sodium butyrate on the levels of arachidonoyl-CoA in neonate rat cerebellum-derived clonal oligodendrocyte cell homogenates. Homogenates from 5×10^5 cells were incubated at 37°C with 50 nCi [^{14}C]arachidonic acid, 0.1 mM CoA, 0.3 mM dithiothreitol, 2.5 mM adenosine triphosphate, 10 mM $MgCl_2$ and 50 mM Tris-HCl (pH 7.4) in the absence (0) or presence (2.5–10 mM) of sodium butyrate for three minutes. Arachidonoyl-CoA was extracted and measured as described in the Materials and Methods section. The values are means ± SD from three determinations. Bars marked with different letters differ significantly ($P \leq 0.05$) based on nonpaired Student's *t*-test. Abbreviations as in Figures 2 and 6.

system, there was a fivefold increase in labeling of PC. Interestingly, addition of sodium butyrate (2.5–7.5 mM) to the incubation system did not cause a further increase in labeling of PC (Fig. 5).

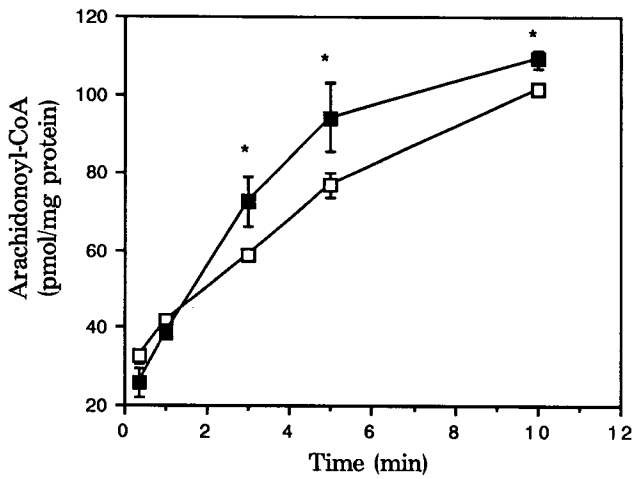

FIG. 6. Time course of synthesis of arachidonoyl-coenzyme A (CoA) in neonate rat cerebellum-derived clonal oligodendrocyte cell homogenates. Homogenates from 5×10^5 cells were incubated at 37°C with 50 nCi [^{14}C]arachidonic acid, 0.1 mM CoA, 0.3 mM dithiothreitol, 2.5 mM adenosine triphosphate, 10 mM $MgCl_2$ and 50 mM Tris-HCl (pH 7.4) in the absence (□) or presence (■) of 2.5 mM sodium butyrate for various time periods. The level of arachidonoyl-CoA at each time point was determined as described in the Materials and Methods section. The values are means ± SD from three determinations. An asterisk denotes values that are significantly different from controls (no butyrate) with $P \leq 0.05$ based on nonpaired Student's *t*-test.

Effect of sodium butyrate on acyl-CoA ligase. The effect of sodium butyrate (2.5–10 mM) on arachidonoyl-CoA synthesis was investigated. Initially, a time course study was carried out in which homogenates from 5×10^5 cells were incubated with [^{14}C]arachidonic acid in the absence or presence of 2.5 mM sodium butyrate at 37°C. As shown in Figure 6, the amount of arachidonoyl-CoA formed increased with time in the presence of sodium butyrate (2.5 mM). In a similar assay system, a dose dependent increase in the synthesis of arachidonoyl-CoA was observed in the incubation system containing 2.5 and 10 mM sodium butyrate (Fig. 7).

DISCUSSION

Although sodium butyrate is known to exert multiple effects on cells, the exact mechanism leading to morphological transformations and concomitant changes in membrane phospholipid profiles had not been elucidated previously. In our earlier study, the effect of butyrate on the morphology of CB-II cells, a clonal oligodendrocyte cell line, correlated with the ability of butyrate to enhance the incorporation of labeled arachidonic acid into PC and decrease its incorporation into PE (9). In the present study, the effect of butyrate on phospholipid metabolism was further studied by examining lysophospholipid acyltransferase and acyl-CoA ligase activities. These studies were prompted by the finding that sodium butyrate altered incorporation of labeled arachidonate. In general, polyunsaturated fatty acids are preferentially transferred into phospholipids by using the acylation–deacylation route, whereas saturated fatty acids are incorporated into phos-

pholipids *via* the *de novo* pathway (12,23). Thus, in agreement with earlier data (24,25), myristate was preferentially incorporated into PC of CB-II cells. Because butyrate did not alter the incorporation of labeled myristate into PC, it was reasonable to assume that butyrate does not affect *de novo* PC biosynthesis. Similarly, butyrate did not alter choline incorporation into PC. However, in experiments in which cells were incubated with labeled choline, butyrate caused a decrease in labeled LPC. As LPC is an intermediate in the acylation–deacylation process, a change in LPC further corroborates the action of butyrate on this cyclic process.

When cell homogenates were incubated with [^{3}H]arachidonate in the absence of exogenous lysophospholipids, there was a time-dependent increase in labeling of PC. This would imply that the membranes contained endogenous LPC as well as acyltransferase to incorporate [^{3}H]arachidonate into PC. The results in Figure 1 further indicate a preference for transfer of arachidonate to LPC, rather than LPI and LPE. This would be in agreement with the recent analyses of the phospholipids of ROC-1 oligodendroglia cells, which showed that more LPC (0.6 mol %) than LPI is present in these cells (26). Earlier studies had also indicated (27,28) that incubation of brain membranes with labeled arachidonic acid resulted in preferential transfer of arachidonic acid to LPC and LPI, rather than LPE and LPS. Although both LPC and LPI acyltransferases are present in CB-II cells, as indicated by the increase in transfer of labeled arachidonic acid into PC and PI in the presence of exogenous LPI and LPC, only the transfer to LPC was affected by butyrate. The reason for the selective effect of butyrate is not clear, but the data are consistent with the notion that different lysophospholipid acyltransferases are involved in the transfer of arachidonate to LPC and LPI (12) and that these acyltransferases respond differently to butyrate.

In the *in vitro* assay system, labeled arachidonic acid is first activated to its acyl-CoA derivative by acyl-CoA ligase prior to being transferred to lysophospholipids *via* lysophospholipid:acyl-CoA acyltransferase. There is evidence that these two enzymes operate in a cooperative manner (12,27). Consequently, it is possible that the effect of butyrate on the transfer of arachidonate to PC is related to a specific effect on one of the two enzymes or on a coupled mechanism between fatty acid activation and transfer of acyl-CoA to the lysophospholipid. By using [^{14}C]arachidonoyl-CoA as substrate, we demonstrated the lack of an effect of butyrate on the lysophospholipid:acyl-CoA acyltransferase.

In one experiment, butyrate also enhanced the incorporation of arachidonic acid into TG, and LPC inhibited the acyltransfer into TG. This agrees with the finding that there is a reciprocal regulatory effect of diacylglycerol and lysophospholipids on acyltransfer to TG and phospholipid in brain membranes (12). It is interesting to note that in homogenates from cells pretreated with sodium butyrate, the increase in labeling of PC was associated with a decrease in labeling of TG (Table 4). It remains to be seen whether the decrease in TG is associated with a decrease in the diacylglycerol pool. To examine whether butyrate-enhanced PC labeling was due to stimulation of CoA-ligase activity conversion of labeled arachidonate to its acyl-CoA derivative was measured in CB-II homogenates. As indicated in Figures 6 and 7, the results showed that the synthesis of arachidonoyl-CoA is stimulated by butyrate.

In conclusion, we have shown that sodium butyrate-induced CB-II cell differentiation and morphological transformations are accompanied by enhanced incorporation of arachidonic acid into PC. Furthermore, enhanced PC synthesis was shown to be due to stimulation of the acylation route. We also showed that butyrate specifically increased acyl-CoA ligase activity. These results provide some novel insights into the role of phospholipids in cell differentiation and growth.

ACKNOWLEDGMENTS

We would like to thank Dr. Alice C. Chang, who established CB-II cell line, for kindly providing the cells and for helpful suggestions. We would also like to thank Dr. Grace Y. Sun at The University of Missouri (Columbia, MO) for constructive suggestions in the preparation of this manuscript and Dr. Samuel H.H. Chan for critical reading of the paper. This work was supported by Research Grant No. NSC-82-0420-B010-006-M10 from National Science Council (Taiwan, Republic of China).

Stimulation of Phosphatidylglycerolphosphate Phosphatase Activity by Unsaturated Fatty Acids in Rat Heart

Shu Guang Cao and **Grant M. Hatch***

Departments of Internal Medicine and Biochemistry and Molecular Biology, University of Manitoba, Winnipeg, Manitoba R3E 0W3, Canada

Phosphatidylglycerolphosphate (PGP) synthase and PGP phosphatase catalyze the sequential synthesis of phosphatidylglycerol from cytidine-5′-diphosphate 1,2-diacyl-*sn*-glycerol (CDP-DG) and glycerol-3-phosphate. PGP synthase and PGP phosphatase activities were characterized in rat heart mitochondrial fractions, and the effect of fatty acids on the activity of these enzymes was determined. PGP synthase was observed to be a heat labile enzyme that exhibited apparent K_m values for CDP-PG and glycerol-3-phosphate of 46 and 20 μM, respectively. The addition of exogenous oleic acid to the assay mixture did not affect PGP synthase activity. PGP phosphatase was observed to be a heat labile enzyme, and addition of oleic acid to the assay mixture caused a concentration-dependent stimulation of PGP phosphatase activity. Maximum stimulation (1.9-fold) of enzyme activity was observed in the presence of 0.5 mM oleic acid, but the stimulation was slightly attenuated by the presence of albumin in the assay. The presence of oleic acid in the assay mixture caused the inactivation of PGP phosphatase activity to be retarded at 55°C. Stimulation of PGP phosphatase activity was also observed with arachidonic acid, whereas taurocholic, stearic and palmitic acids did not significantly affect PGP phosphatase activity. The activity of mitochondrial phosphatidic acid phosphohydrolase was not affected by inclusion of oleic acid in the incubation mixture. We postulate that unsaturated fatty acids stimulate PGP phosphatase activity in rat heart.

***Lipids* 29, 475–480 (1994).**

Phosphatidylglycerol (PG) is an important intermediate in the biosynthesis of cardiolipin (CL); the biosynthetic pathway of PG in mammalian tissues was first elucidated by Kiyasu *et al.* (1). In the isolated rat heart, the biosynthesis of new PG proceeds *via* the cytidine-5′-diphosphate (CDP)-diglyceride pathway (2). Glycerol is taken up by the heart and is phosphorylated to glycerol-3-phosphate (3), which is rapidly acylated to form phosphatidic acid (PA) (2). PA is converted to CDP 1,2-diacyl-*sn*-glycerol (CDP-DG) by PA:CTP cytidylyltransferase (4), the rate-limiting step of PG and CL biosynthesis in isolated rat heart (2). CDP-DG is condensed with glycerol-3-phosphate to form phosphatidylglycerolphosphate (PGP) catalyzed by PGP synthase (1,2). PGP is then dephosphorylated by PGP phosphatase to form PG (1,2). The activities of the latter two enzymes are confined to the mitochondrial fraction in mammalian tissues (1,2,5).

Abbreviations: CDP-DG, cytidine-5′-diphosphate 1,2-diacyl-*sn*-glycerol; CL, cardiolipin; CTP, cytidine-5′-triphosphate; PA, phosphatidic acid; PG, phosphatidylglycerol; PGP, phosphatidylglycerolphosphate.

There are few studies on the regulation of PGP synthase and PGP phosphatase activities in mammalian tissues. PGP synthase was partially purified and characterized from pig liver by McMurray and Jarvis (6). Phosphatidylethanolamine was shown to stimulate the activity of the partially purified enzyme. MacDonald and McMurray (7) partially purified and characterized PGP phosphatase from rat liver. PA (NH_4^+-salt) was shown to inhibit the phosphatase activity whereas PA (Na^+-salt) stimulated the activity. Thus, there is a precedent for lipid modulation of the activity of PGP synthase and PGP phosphatase.

Fatty acids are potent stimulators of several enzymes involved in phospholipid biosynthesis. For example, PA phosphohydrolase, the committed step of DG production, is stimulated by oleic acid (8). In addition, oleic acid stimulates the activity of CTP:phosphocholine cytidylyltransferase, the rate-limiting step of phosphatidylcholine biosynthesis (9,10). This stimulation of enzyme activity was associated with increases in phosphatidylcholine biosynthesis. The heart has a tremendous capacity to take up and utilize fatty acids (11). It is not known if fatty acids modulate PGP synthase and PGP phosphatase activities in the heart. In this paper we provide evidence that rat heart mitochondrial PGP phosphatase activity is stimulated by unsaturated fatty acids.

MATERIALS AND METHODS

Materials. Male Sprague-Dawley rats (200–250 g) were obtained from Charles River Canada Inc. (St. Constante, Quebec, Canada). [^{14}C(*U*)]Glycerol-3-phosphate was purchased from DuPont Canada, Inc. (Mississauga, Ontario, Canada). Phosphatidyl[^{14}C(*U*)]glycerol-3-phosphate was synthesized as described previously (2). Thin-layer plates (silica gel 60, 0.25 mm thick) were obtained from Canlab Division of Baxter Co. (Winnipeg, Manitoba, Canada). Biochemicals used in this study were of analytical grade and purchased from either Sigma Chemical Co. (St. Louis, MO) or Fisher Scientific (Edmonton, Alberta, Canada).

Preparation of rat heart mitochondrial fractions. Animals were sacrificed by decapitation, and the heart was rapidly removed and placed in ice-cold saline. Exogenous blood was removed by perfusion of the heart in the Langendorff mode (12) for 2 min with ice-cold saline. The heart was then cut into small pieces, and a 10% homogenate was prepared in 0.25 M sucrose, 0.145 M NaCl, 5 mM Tris-HCl, pH 7.4, using a Polytron (Model PT10-35; Kinematika, Lucerne, Switzerland) homogenizer. The homogenate was centrifuged at 1,000 × *g* for 5 min (Sorvall RC-5 Superspeed Refrigerated Centrifuge with SS-34 rotor; DuPont Canada Inc.). The pellet was

discarded, and the resulting supernatant was centrifuged at 10,000 × *g* for 15 min. The pellet was resuspended in 1 mL of homogenizing buffer with a tight-fitting Dounce tissue grinder and used as the source of mitochondrial fraction for assay of PGP synthase, PGP phosphatase and PA phosphohydrolase. The supernatant from the 10,000 × *g* separation was centrifuged at 105,000 × *g* for 60 min (Beckman Model L8-70 Ultracentrifuge with Ti 70.1 rotor; Beckman Instruments, Inc., Mississauga, Ontario, Canada). The pellet was resuspended in 1 mL of homogenizing buffer with a tight-fitting Dounce tissue grinder and used as the source of the microsomal fraction. The mitochondrial fraction was contaminated with 10% of microsomal material, and the microsomal fraction contained 5% mitochondrial material (13).

Preparation of fatty acids. A stock 80 mM oleic acid solution was prepared by adding 1.13 g oleic acid to 4.8 mL of 1 M KOH. The mixture was heated to 60°C, and the volume was made up to 50 mL with distilled water. The oleic acid stock solution may be repeatedly frozen for storage at –20°C and upon thawing is a clear liquid. Oleic acid prepared in this fashion was shown to stimulate cytidine-5′-triphosphate (CTP):phosphocholine citidylyltransferase activity *in vitro* (9,10). Sodium taurocholate was dissolved in water, and other fatty acids were dissolved in water with KOH, vortexed and sonicated until a clear suspension was obtained prior to addition to the PGP phosphatase assay mixture.

Assay of PGP synthase, PGP phosphatase and PA phosphohydrolase. PGP synthase was assayed by determining the conversion of [^{14}C(*U*)]glycerol-3-phosphate to phosphatidyl[^{14}C(*U*)]glycerol-3-phosphate (14). The reaction mixture contained 50 mM Tris-HCl, pH 7.0, 10 mM freshly prepared ß-mercaptoethanol, 0.5 mM [^{14}C(*U*)]glycerol-3-phosphate (specific activity, 12,500 dpm/nmol), 0.2 mM CDP-DG dissolved in 10 mM Triton X-100 and 50–100 µg of mitochondrial protein to a final volume of 90 µL. The reaction was initiated by the addition of 10 µL of 0.1 M $MgCl_2 \cdot 6H_2O$. The mixture was incubated at 30°C for 10 min and terminated by the addition of 0.5 mL of 0.1 M HCl in methanol. One mL of chloroform and 1.5 mL of 1 M $MgCl_2 \cdot 6H_2O$ was added to the mixture. The suspension was vortexed and centrifuged for 5 min at full speed in a clinical centrifuge (Model TJ-6; Beckman Instruments Inc.). The upper phase and interphase were removed by suction, and the organic phase was dried under nitrogen gas and resuspended in 50 µL of chloroform/methanol (2:1, vol/vol). A 25-µL aliquot of the resuspended organic phase was placed on an oxalate-treated thin-layer plate with PGP standard and developed in a solvent system containing chloroform/methanol/HCl (87:13:0.2, by vol). The thin-layer plates were prepared by soaking the plates in 0.5 M oxalic acid and air drying overnight prior to use. The iodine stained fractions corresponding to PGP were removed, and radioactivity in these fractions was determined. In some experiments 0.5–2.0 mM oleic acid was included in the incubation mixture.

PGP phosphatase was assayed by determining the conversion of phosphatidyl[^{14}C(*U*)]glycerol-3-phosphate to phosphatidyl[^{14}C(*U*)]glycerol (7). The reaction mixture contained 50 mM Tris-maleate (pH 6.5), 10 mM freshly prepared ß-mercaptoethanol, 0.5–1.5 µM phosphatidyl[^{14}C(*U*)]glycerol-3-phosphate (specific activity, 10,000 dpm/nmol) and 0.1 mg of mitochondrial protein to a final volume of 100 µL. The reaction mixture was incubated at 37°C for 5 min and terminated by the addition of 2 mL of chloroform/methanol/HCl (100:100:0.6, by vol). One mL of chloroform and 1.5 mL of 0.73% NaCl were added to facilitate phase separation. The tubes were centrifuged in a clinical centrifuge as described above, and the organic phase was evaporated under nitrogen gas. The organic phase was resuspended in 25 µL of chloroform/methanol (2:1, vol/vol) and 20 µL placed on a oxalate-treated plate with PG standard and was developed in the solvent system described above for separation of PGP. The iodine stained fractions corresponding to PG were removed and radioactivity in these fractions determined. In some experiments, 0.125 mM albumin (Sigma A-2153, Sigma Chemical Co.) and 0.5 mM fatty acid were added to the incubation mixture.

PA phosphohydrolase was assayed by determining the conversion of 1,2-diacyl-*sn*-[1,3-^{3}H]glycerophosphoric acid to 1,2-diacyl-*sn*-[1,3-^{3}H]glycerol (15). The incubation was performed in tubes which had previously been treated with dimethyldichlorosilane, 2% in 1,1,1-trichloroethane, to prevent the PA substrate from adhering to the glass tubes. The reaction mixture contained 100 mM Tris-HCl, pH 7.4, 1 mM dithioerythritol, 1 mM ethylenediaminetetraacetic acid, 1 mM ethyleneglycoltetraacetic acid, 0.4 mM phosphatidylcholine and 0.6 mM 1,2-diacyl-*sn*-[1,3-^{3}H]glycerophosphoric acid (specific activity, 0.25 µCi/pmol) in a total volume of 90 µL. The reaction mixture was pre-incubated for 5 min at 37°C, then 10 µL of 0.1 M $MgCl_2 \cdot 6H_2O$ was added to start the reaction. The mixture was incubated at 37°C for 60 min and terminated by the addition of 2 mL of chloroform/methanol (2:1, vol/vol). One mL of water was added to facilitate phase separation. The tubes were centrifuged in a clinical centrifuge as described earlier, and the organic phase was evaporated under nitrogen gas. The organic phase was resuspended in 25 µL of chloroform/methanol (2:1, vol/vol) and 20 µL placed on a thin-layer plate with standard 1,2-diacyl-*sn*-glycerol and developed in a solvent system containing petroleum ether/diethyl ether/acetic acid (60:40:1, by vol). The iodine stained fractions corresponding to 1,2-diacyl-*sn*-glycerol were removed and the radioactivity in these fractions determined. In some experiments, 0.2 mg albumin and 0.5 mM oleic acid were added to the incubation mixture.

*Synthesis of 1,2-diacyl-*sn*-[1,3-^{3}H]glycerophosphoric acid.* The 1,2-diacyl-*sn*-[1,3-^{3}H]glycerophosphoric acid was synthesized by perfusing two rat hearts with 100 µCi of 0.1 µM [1,3-^{3}H]glycerol for 15 min and extracting the lipids as described previously (2). PA was separated from other lipids on oxalate-treated plates using the solvent system described for the separation of PGP and PG. The plate was covered with cellophane, except for a standard lane containing PA, and stained with iodine. Silica gel corresponding to the location of the PA

standard was removed, and PA was extracted from the silica gel by the method of Arvidson (16).

Other analytical procedures. Protein was determined by the method of Bradford (17). Radioactivity was determined by liquid scintillation counting (Beckman Model LS 3801 Scintillation Counter; Beckman Instruments Inc.). Student's *t*-test was used for the statistical analysis of data. The level of significance was defined as $P < 0.05$.

RESULTS

Characterization of PGP synthase and PGP phosphatase activities. PGP synthase activity was assayed in mitochondrial fractions isolated from rat heart. PGP synthase activity was linear with time and protein concentration when 10 mM Mg^{+2} was included in the incubation mixture. Product identification revealed approximately 70–75% of radioactivity associated with PG and 20–25% with PGP (data not shown). The conversion of PGP to PG was due to the presence of PGP phosphatase activity in rat heart mitochondria (2). Less than 1% of radioactivity was associated with CL and PA. Mitochondrial fractions were incubated at 55°C for various periods of time prior to assay of PGP synthase activity. As seen in Figure 1A, the PGP synthase lost 26% of its activity by 1 min and 70% of its activity by 5 min of preincubation at 55°C. Thus, cardiac PGP synthase is a heat labile enzyme. When the concentration of CDP-DG was held constant at 0.2 mM and the concentration of glycerol-3-phosphate was varied, PGP synthase activity increased with increasing concentration of glycerol-3-phosphate. A double reciprocal plot of activity *vs.* glycerol-3-phosphate concentration revealed an apparent K_m for glycerol-3-phosphate of 20 μM (Fig. 1B). When the concentration of glycerol-3-phosphate was held constant at 0.5 mM and the concentration of CDP-PG was varied, PGP synthase activity increased with increasing concentration of CDP-DG. The increase was maximum at 0.2 mM CDP-PG. A double reciprocal plot of activity *vs.* CDP-DG concentration revealed an apparent K_m for CDP-DG of 46 μM (Fig. 1C). Less than 10% of the activity of the mitochondrial PGP synthase was observed in the 105,000 × *g* fraction of rat heart homogenates.

PGP phosphatase was assayed in mitochondrial fractions isolated from rat heart. The incubation mixture contained low substrate concentrations because high PGP concentrations (100 μM) are inhibitory to the enzyme (7). With 0.5 μM PGP in the assay, substrate conversion to PG was typically 20–25%. When mitochondrial fractions were incubated in the presence of various concentrations of PGP, the PGP phosphatase activity was increased with increasing concentrations of PGP in the assay mixture (Fig. 2A). Mitochondrial fractions were incubated at 55°C for various periods of time prior to assay of PGP phosphatase activity in the presence of 0.5 μM PGP. By 1, 2.5 and 5 min of preincubation at 55°C, 59, 88 and 95%, respectively, of the enzyme activity was lost (Fig. 2B). Thus, cardiac PGP phosphatase is a heat labile enzyme. Less than 10% of the activity was observed in the 105,000 × *g* fraction of rat heart homogenates.

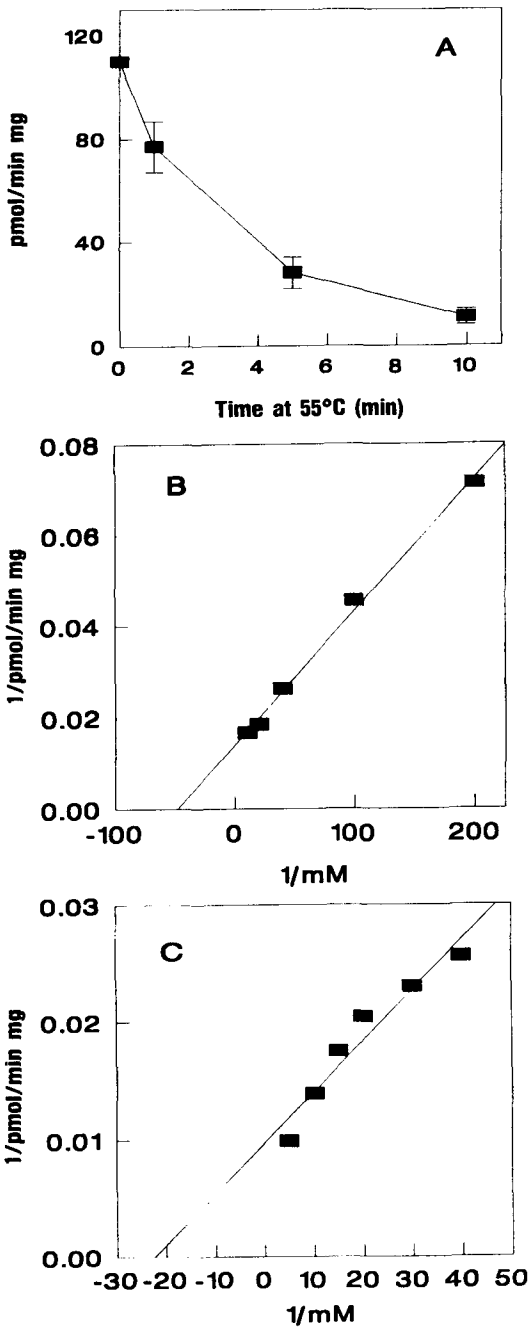

FIG. 1. Heat inactivation profile and kinetics of phosphatidylglycerolphosphate (PGP) synthase. A, A 0.1-mg aliquot of mitochondrial fraction was preincubated for up to 10 min at 55°C and PGP synthase activity subsequently determined. Each value represents the mean ± SD of three separate experiments, each of which was assayed in duplicate. B, PGP synthase activity was determined at various concentrations of glycerol-3-phosphate in the presence of 0.2 mM cytidine-5′-diphosphate 1,2-diacyl-*sn*-glycerol (CDP-DG). A double reciprocal plot of glycerol-3-phosphate concentration *vs.* activity is shown. Each value represents the mean of two separate experiments, each of which was assayed in duplicate. C, PGP synthase was assayed in the presence of various concentrations of CDP-DG in the presence of 0.5 mM glycerol-3-phosphate. A double reciprocal plot of CDP-DG concentration *vs.* activity is shown. Each value represents the mean of two separate experiments, each of which was assayed in duplicate.

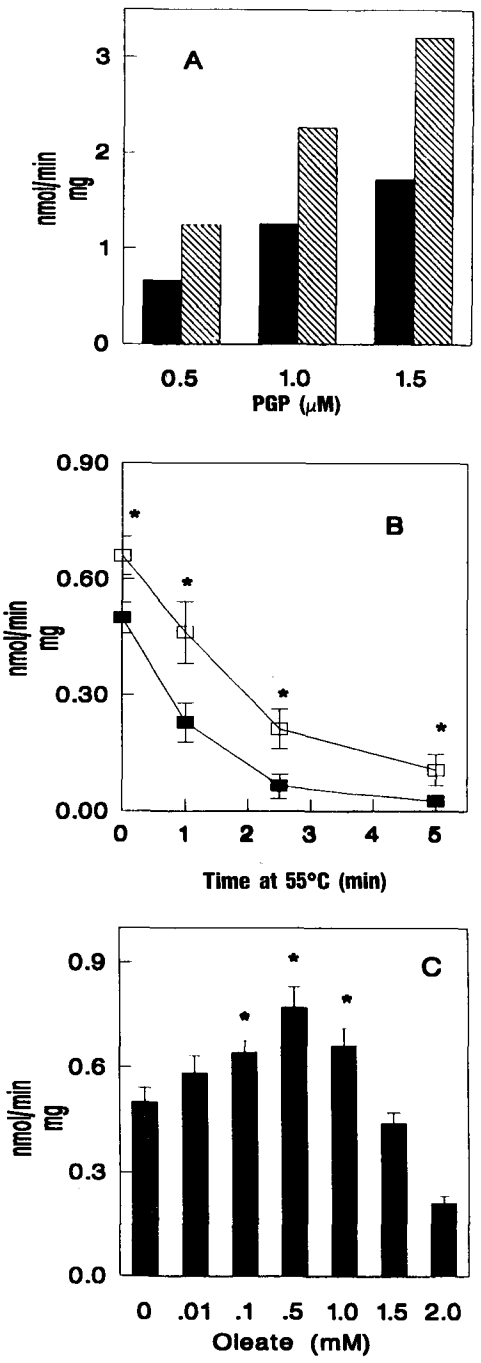

FIG. 2. Heat inactivation profile and effect of oleic acid on phosphatidylglycerolphosphate (PGP) activity. A, PGP phosphatase activity was determined in the absence (solid columns) or presence (hatched columns) of 0.5 mM oleic acid in the incubation mixture at various concentrations of PGP. Each value represents the mean of two separate experiments, each of which was assayed in duplicate. B, A 0.1-mg aliquot of mitochondrial fraction was preincubated for up to 5 min at 55°C, then PGP phosphatase activity was determined in the absence (closed squares) or presence (open squares) of 1.0 mM oleic acid. Each value represents the mean ± SD of three experiments, each of which was assayed in duplicate. C, PGP phosphatase activity was determined in the absence or presence of various concentrations of oleic acid. Each value represents the mean ± SD of three experiments, each of which was assayed in duplicate. *, $P < 0.05$.

Effect of fatty acids on PGP synthase, PGP phosphatase and PA phosphohydrolase activities. To determine if fatty acids affected the activity of PGP synthase, the enzyme activity was determined in isolated rat heart mitochondrial fractions in the absence or presence of 0.5–2.0 mM oleic acid in the assay mixture. PGP synthase activity was unaffected at 0.5–2.0 mM oleic acid concentrations. In addition, oleic acid did not affect the activity of PGP synthase in the presence of low or high glycerol-3-phosphate or CDP-DG concentrations (data not shown).

To determine the effect of fatty acids on PGP phosphatase activity, isolated mitochondrial fractions were incubated in the absence or presence of 0.1–2.0 mM oleic acid in the incubation mixture. The presence of 0.01–1.0 mM oleic acid in the incubation mixture caused a stimulation of PGP phosphatase activity (Fig. 2C). The stimulation was most pronounced at 0.5 mM. Higher concentrations of oleic acid (1.5–2.0 mM) inhibited PGP phosphatase activity. To determine the kinetics of stimulation of PGP phosphatase activity by oleic acid, PGP phosphatase activity was determined in the presence of increasing PGP concentrations in the absence or presence of 0.5 mM oleic acid in the incubation mixture. The presence of oleic acid caused a 1.9-fold stimulation of PGP phosphatase activity at all PGP concentrations (Fig. 2A). To determine if oleic acid altered the heat inactivation of PGP phosphatase, PGP phosphatase activity was determined in the absence or presence of 1.0 mM oleic acid in mitochondrial fractions that were preincubated for various times at 55°C. When 1.0 mM oleic acid was present in the assay mixture, PGP phosphatase activity was decreased only 29, 68 and 83% in mitochondrial fractions that had been preincubated for 1, 2.5 and 5 min at 55°C, respectively (Fig. 2B). Thus, in the presence of oleic acid, the inactivation of PGP phosphatase by heat denaturation was retarded.

Because fatty acids are associated with fatty acid binding proteins *in vivo* (18), we determined the effect of fatty acid bound to albumin on PGP phosphatase activity. A fatty acid/albumin ratio of 4:1 was used as albumin contains six to eight fatty acid binding sites per molecule (19). PGP phosphatase activity was determined in isolated rat heart mitochondrial fractions in the absence or presence of 0.125 mM albumin in the incubation mixture or in the presence of 0.125 mM albumin and 0.5 mM oleic acid. The presence of albumin in the incubation mixture resulted in a 20% decrease in PGP phosphatase activity (Fig. 3A). Thus, the albumin probably removes stimulatory lipids from the membrane. In the presence of 0.5 mM oleic acid and 0.125 mM albumin, PGP phosphatase activity was stimulated 36% compared to incubations that contained albumin alone (Fig. 3A). Thus, oleic acid stimulated PGP phosphatase activity in the presence of a fatty acid binding protein.

The effect of other fatty acids on PGP phosphatase activity was determined. PGP phosphatase activity was assayed in the absence or presence of both saturated and unsaturated fatty acids with differing chainlength and in the presence of the anionic bile salt taurocholic

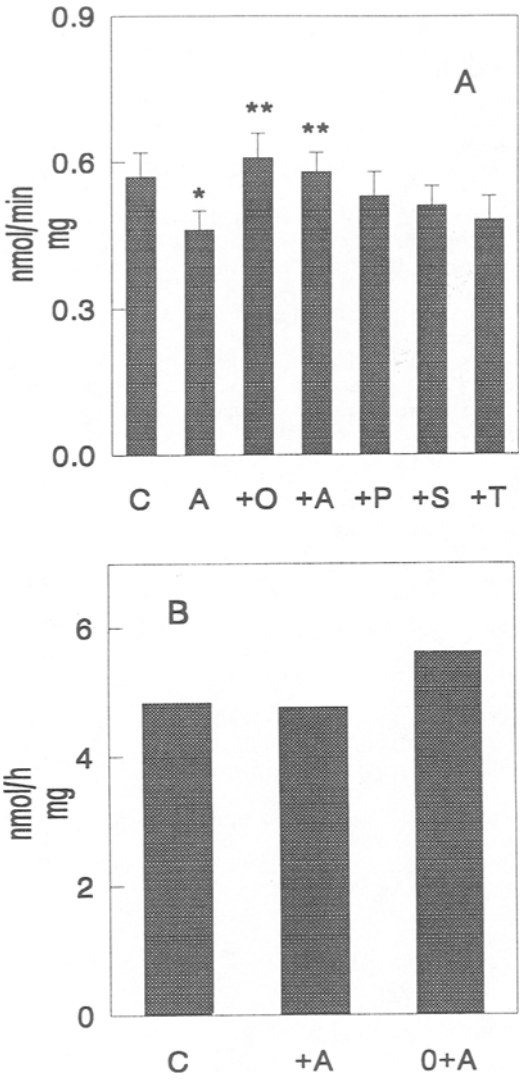

FIG. 3. Effect of albumin and fatty acids on phosphatidylglycerolphosphate (PGP) phosphatase and phosphatidic acid (PA) phosphohydrolase activities. A, PGP phosphatase activity was determined in the absence (C) or presence (A) of albumin or in the presence of albumin plus 0.5 mM oleate (+O), arachidonate (+A), palmitate (+P), stearate (+S) or taurocholate (+T). Each point represents the mean ± SD of three separate experiments, each of which was assayed in duplicate. *, $P < 0.05$, C *vs.* A; **, $P < 0.05$, A *vs.* +O, A *vs.* +A. B, PA phosphohydrolase activity was assayed in the absence (C) or presence (+A) of albumin or 0.5 mM oleic acid bound to albumin (O + A). Each value represents the mean of two separate experiments, each of which was assayed in duplicate. An 11–14% variation was observed between duplicate samples.

acid. Arachidonic acid stimulated PGP phosphatase activity, whereas the presence of taurocholic, stearic and palmitic acids in the assay mixture did not significantly affect PGP phosphatase activity (Fig. 3A).

Fatty acids are known to stimulate PA phosphohydrolase activity by promoting the translocation of the enzyme from the cytosol to the endoplasmic reticulum (8). As a control, we determined the effect of oleic acid on PA phosphohydrolase activity in isolated rat heart mitochondrial fractions. PA phosphohydrolase activity was determined in the absence or presence of 0.2 mg albumin or 0.2 mg albumin and 0.5 mM oleic acid in the incubation mixture. In the presence of albumin or albumin and oleic acid, PA phosphohydrolase activity was not affected (Fig. 3B).

DISCUSSION

The objective of this study was to investigate if the heart PGP synthase and PGP phosphatase activities were modulated by fatty acid. It is clear from this study that unsaturated fatty acids stimulate PGP phosphatase activity in rat heart mitochondria. The stimulation of PGP phosphatase by oleic acid in the absence or presence of albumin coupled with the retarded heat denaturation of the enzyme activity in the presence of oleic acid support this conclusion.

Lipid modulation of enzyme activity has been regarded as a plausible mechanism for the control of phospholipid and triacylglycerol biosynthesis. Oleic acid has been shown to stimulate the activities of PA phosphohydrolase and CTP:phosphocholine cytidylyltransferase, enzymes involved in triacylglycerol and phosphatidylcholine biosynthesis (8–10). In our study, free oleic acid and oleic acid bound to albumin stimulated the activity of heart mitochondrial PGP phosphatase, an enzyme involved in PG and CL biosynthesis. Remarkably, oleic acid appeared to retard the heat inactivation of the PGP phosphatase. However, because the rate of inactivation of PGP phosphatase in control and oleic acid containing incubations was identical, the presence of oleic acid likely promotes enzyme activation. In contrast, high concentrations of free oleic acid inhibited PGP phosphatase activity. This was probably due to an alteration in the enzyme lipid associations required for enzyme catalysis.

The heart PGP phosphatase activity was stimulated by long-chain fatty acids consistent with fatty acid stimulation of other lipogenic enzymes (9,20,21). However, stimulation was significant and most pronounced with unsaturated fatty acids similar to that observed for phospholipase D activation by fatty acids (21). In a previous study, ionic and nonionic detergents were shown to inhibit the partially purified PGP phosphatase from rat liver in the absence of albumin in the incubation mixture (7). In our study, the anionic bile detergent taurocholic acid did not affect the heart PGP phosphatase activity at a concentration in which unsaturated fatty acids were stimulatory when albumin was present in the incubation mixture. This observation suggests that the effect of unsaturated fatty acids on the stimulation of the heart PGP phosphatase was not due to their detergent-like properties. In addition, it was unlikely that low concentrations of oleic acid markedly altered the physical state of the PGP phosphatase and the surrounding membrane structure since the kinetic properties of PGP synthase were not affected by oleic acid.

It was previously postulated that PGP phosphatase and PA phosphohydrolase were the same enzyme in rat lung lamellar fractions (22). However, it was suggested

by Chang and Kennedy (23) that *Escherichia coli* membrane PGP phosphatase activity toward PA may be due to contamination by some other enzyme. In fact, PA phosphohydrolase purified from yeast cell membranes was shown not to dephosphorylate PGP, nor did PA competitively inhibit PGP hydrolysis (24). Rat liver plasma membrane PA phosphohydrolase activity was shown to be stimulated by oleic acid (25). In contrast, oleic acid did not affect the activity of the heart mitochondrial PA phosphohydrolase. Furthermore, the addition of albumin to the incubation mixture did not affect PA phosphohydrolase activity. Thus, the activities of PA phosphohydrolase and PGP phosphatase in rat heart mitochondria appear to be distinct.

Severe diabetes (26) and hypoxia (27) are metabolic conditions that predispose tissues to high concentrations of fatty acids and may affect the regulation of metabolic enzymes. Indeed, rat liver PA phosphohydrolase activity is increased in diabetes, and this may account for the increases in triacylglycerols accumulated in the liver and in the systemic circulation in this disease (8,26). The heart has a large capacity to take up and utilize fatty acids (11). Thus, under altered metabolic conditions, such as severe diabetes or hypoxia, it is possible that the heart PGP phosphatase activity may thus be regulated *in vivo*. Significant levels of PGP have been detected in brain (28,29). However, PGP is found in only limited amounts in other tissues *in vivo* (1). Thus, an important question is whether the heart PGP phosphatase is, indeed, stimulated by unsaturated fatty acids *in vivo*. As low concentrations of free oleic acid and unsaturated fatty acid bound to albumin stimulated the heart PGP phosphatase activity at low PGP concentration, it is possible that modulation of the activity of this enzyme and, thus, heart polyglycerophospholipid biosynthesis at the level of the PGP phosphatase may occur. We are currently investigating this possibility in isolated perfused rat hearts.

This study was designed to examine whether n-3 and n-6 polyunsaturated fatty acids at a very low dietary level (about 0.2%) would alter liver activities in respect to fatty acid oxidation. Obese Zucker rats were used because of their low level of fatty acid oxidation, which would make increases easier to detect. Zucker rats were fed diets containing different oil mixtures (5%, w/w) with the same ratio of n-6/n-3 fatty acids supplied either as fish oil or arachidonic acid concentrate. Decreased hepatic triacylglycerol levels were observed only with the diet containing fish oil. In mitochondrial outer membranes, which support carnitine palmitoyltransferase I activity, cholesterol content was similar for all diets, while the percentage of 22:6n-3 and 20:4n-6 in phospholipids was enhanced about by 6 and 3% with the diets containing fish oil and arachidonic acid, respectively. With the fish oil diet, the only difference found in activities related to fatty acid oxidation was the lower sensitivity of carnitine palmitoyltransferase I to malonyl-CoA inhibition. With the diet containing arachidonic acid, peroxisomal fatty acid oxidation and carnitine palmitoyltransferase I activity were markedly depressed. Compared with the control diet, the diets enriched in fish oil and in arachidonic acid gave rise to a higher specific activity of aryl-ester hydrolase in microsomal fractions. We suggest that slight changes in composition of n-3 or n-6 polyunsaturated fatty acids in mitochondrial outer membranes may alter carnitine palmitoyltransferase I activity.

***Lipids* 29, 481–489 (1994).**

Fish oils (FO) are known to lower the risk of cardiovascular disease partly be reducing plasma triacylglycerols (TAG) (1–3). The effect can be mainly attributed to the amounts of long-chain polyunsaturated fatty acids (PUFA) of the n-3 series, especially eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA) present in marine oils. It was recently demonstrated that rats fed dietary FO rather than olive oil have a lower rate of very low density lipoprotein (VLDL) TAG production in liver and a lower liver concentration of total lipids and TAG (4) suggesting that FO stimulates fatty acid (FA) oxidation and/or impairs TAG synthesis. Indeed, previous studies had shown that n-3 FA are preferentially directed toward β-oxidation pathways in liver cells (5) and mitochondria (6). Moreover, dietary FO has been found to reduce the activity of enzymes involved in FA and TAG synthesis (5,7–10) and to stimulate the FA oxidative pathway in the liver (11).

In rats fed high FO diets, lowered circulating TAG levels have been associated with peroxisome proliferation and a concomitant increase in peroxisomal oxidation (12). However, lower levels of FO consumption (below 15%, w/w of the diet) do not result in significant peroxisomal proliferation (13,14). In Syrian hamsters consuming marine oils at levels below the threshold for hepatic peroxisomal proliferation, the enhanced activity of mitochondrial carnitine palmitoyltransferase (CPT I) has suggested that the decreased hepatic output of TAG may be related to increased mitochondrial FA oxidation (15). In addition, dietary FO have been shown to enhance CPT I activity in rats (14) and mice (16).

The characteristics of FA oxidation are often assessed by measuring series of parameters, including ketone body production and the activity of total CPT (both forms) or CPT I (overt form alone) with either palmitoyl-CoA or palmitate as substrate in animals fed diets containing high amounts of oils (9–11). Since different levels of the same oil in the diet may influence lipogenesis differentially (17,18) and thus have varying effects on mitochondrial FA oxidation (19), the present study was designed to test the validity of previous findings by using diets containing only a moderate percentage of oil mixture (5%, w/w) with the same ratio of n-6/n-3 FA but differing in their contents of PUFA, which were supplied either from FO (n-3 PUFA) or arachidonic acid (AA) concentrate (n-6 PUFA). Obese Zucker rats were chosen because they are known to have a lower rate of hepatic FA oxidation compared to their lean littermates (20,21) and thus were expected to display a relatively greater enhancement of oxidative pathways after feeding the diets enriched in PUFA. It had also been shown that the proportion of 20:4n-6 [which is lower in liver phospholipids (PL) of obese rats] was enhanced after hypolipidemic treatment (22) concomitantly with enhanced mitochondrial FA oxidation (23). These previous observations prompted us to study the effects of direct supplementation of the diet with dietary n-6 and n-3 PUFA on selected mitochondrial activities and on the lipid composition of mitochondrial outer membranes (OM) in which CPT I (which catalyzes a controlling step in the pathway of β-oxidation) resides. In addition, the activity of microsomal aryl-ester hydrolase, which is assumed to control the intracellular pool of acyl-CoA esters (13,14), was monitored, as its induction could reflect increased acyl-CoA levels.

MATERIALS AND METHODS

Materials. L-[*Methyl*-^{3}H]carnitine was obtained from the Amersham Radiochemical Centre (Amersham, Bucks., United Kingdom). Unlabeled L-carnitine was from Dr. C. Cavazza of Sigma-Tau (Pomezia, Italy). Fatty acid-free albumin (Fraction V) used in the homogenization mixture was from Paesel-Lorei (Frankfurt, Germany). Percoll was from Pharmacia LKB Biotechnology (Uppsala, Sweden). Coenzymes, CoA derivatives and other biochemicals were purchased from Sigma Chemical Co. (St. Louis, MO). Standard lipids were obtained from Nu-Chek-Prep (Elysian, MN). The chemicals from Prolabo (Paris, France) and Merck (Darmstadt, Germany) were of analytical grade.

Animals. Obese (fa/fa) male Zucker rats were bred in the Centre de Sélection et d'Elevage d'Animaux de Laboratoire, CNRS (Orléans-la-Source, France). They were five-weeks-old on arrival at the Station de Recherches de Nutrition (INRA-CRJ, Jouy-en-Josas, France) and were housed in stainless-steel cages in a well-ventilated room maintained at 22 ± 2°C on a 12 h light/dark cycle. All animals received a control diet containing (g/kg): casein, 220; DL-methionine, 1.6; sucrose, 218; corn starch, 440; cellulose powder, 20; vitamin mixture, 10 (choline chloride, 0.75 g; thiamine, 10 mg; riboflavin, 10 mg, pyridoxin · HCl, 10 mg; nicotinic acid, 45 mg; Ca pantothenate, 30 mg; biotin, 0.2 mg; folic acid, 0.9 mg; cyanocobalamin, 13.5 µg; inositol, 50 mg; retinoic acid, 45 mg; cholecalciferol, 2.5 mg; ascorbic acid, 450 mg; α-tocopherol, 50 mg; menadione, 22.5 mg; *p*-aminobenzoic acid, 50 mg; and sucrose to 10 g); mineral mixture, 40 [$CaHPO_4 \cdot 2\ H_2O$, 15.2 g; K_2HPO_4, 9.6 g; $CaCO_3$, 7.24 g; NaCl, 2.8 g; MgO, 0.8 g; $MgSO_4 \cdot 7\ H_2O$, 3.6 g; $FeSO_4 \cdot 7\ H_2O$, 0.28 g; $ZnSO_4 \cdot H_2O$, 0.2 g; $MnSO_4 \cdot H_2O$, 0.2 g; $CuSO_4 \cdot 5\ H_2O$, 40 mg; NaF, 40 mg; $Al_2(SO_4)_3K_2SO_4 \cdot 24\ H_2O$, 8 mg; KI, 3.2 mg; $CoCO_3$, 3.2 mg; $Na_2SeO_3 \cdot 5\ H_2O$, 0.4 mg]; and oil mixture, 50 (50% "primor" rapeseed oil, 20% sunflower oil and 30% hydrogenated palm oil). The control diet was provided *ad libitum*. After five weeks, the animals were divided into three groups. One group (control) continued to receive the control diet. The other two groups were fed a similar diet in which the oil mixture was replaced either by one containing FO (35% sunflower oil, 50% hydrogenated palm oil and 15% salmon oil) or containing AA (45% "primor" rapeseed oil, 14% sunflower oil, 35% hydrogenated palm oil and 6% AA concentrate). Table 1 shows that the three oil mixtures had a similar n-6/n-3 FA ratio close to 6. Only the FO and AA oil mixtures contained FA whose carbon numbers were greater than 18, so that the FO mixture was characterized by the presence of n-3 PUFA (20:5 and 22:6) and the AA mixture by the presence of n-6 PUFA (20:4). Animals had free access to tap water. Food intake was limited to 20 g per day (70% of *ad libitum*) to prevent hyperphagia of obese Zucker rats. After seven weeks, the rats were starved for 16 h and exsanguinated (between 0700 and 0800 h) under diethyl ether anesthesia, and the livers were quickly removed (see below).

Preparation of a percoll-purified mitochondrial fraction (PPMF). The liver was transferred to aqueous medium containing 0.25 M sucrose, 10 mM *tris*(hydroxymethyl)aminomethane (Tris)/HCl, pH 7.4, and 1 mM ethyleneglycol-*bis*(β-aminoethyl ether)*N,N'*-tetraacetic acid (EGTA), and kept at 4°C. The liver was cut into small pieces, rinsed several times, blotted with paper and weighed. The tissue was then homogenized in 10 vol of sucrose medium containing, in addition, 1% albumin (24,25) with three strokes of a loose-fitting Teflon pestle at 300 rpm in an ice-cooled Potter–Elvehjem homogenizer (Bioblock, Strasbourg, France). The homogenate was centrifuged at 2,000 × *g* for 2 min (at 3°C in a JA-20 rotor, J-21 Beckman centrifuge; Beckman Instruments, Fullerton, CA), and the first crude mitochondrial pellet (M1) was obtained by centrifugation of the supernatant at 13,000 × *g* for 2 min. The procedure was repeated by homogenization of the low-speed pellet to generate a second crude mitochondrial pellet (M2). A third fraction (M3) was generated from the second low-speed pellet in an identical manner. The three crude mitochondrial pellets were resuspended in the above medium without albumin, pooled and centrifuged at 13,000 × *g* for 2 min to generate the crude mitochondrial fraction (CMF). The CMF was suspended in a mixture of 0.25 M sucrose medium containing 10 mM Tris/HCl buffer, pH 7.4, 1 mM EGTA, and Percoll (31% by volume of the final mixture) as described by Zammit *et al.* (26). This mitochondrial suspension (20 mL) was then layered on top of 20 mL of a Percoll mixture prepared as above, but containing a higher concentration of sucrose (0.3 instead of 0.25 M) using 40 mL centrifuge tubes. After centrifugation at 30,000 x *g* for 20 min in a JA-20 rotor (J-21 Beckman), the mitochondria, which sediment as a fluffy layer, were withdrawn, diluted in buffered 0.25 M sucrose, washed free of percoll by centrifugation at 3,500 × *g* for 10 min, and stored in buffered 0.3 M sucrose as the PPMF.

Isolation of mitochondrial OM. Mitochondrial OM were prepared according to the modified procedure of Parsons *et al.* (27). The PPMF was centrifuged at 13,000 × *g*. The resulting pellet was suspended in hypoosmotic medium containing 20 mM KH_2PO_4, pH 7.4, and 0.02% FA-free albumin (240 to 320 mL) using two mild hand-driven strokes of a Dounce B homogenizer (Bioblock). After 20 min on ice, an amount of ATP (mg) corresponding to 1:5 of the mitochondrial protein content, previously estimated by ultraviolet assay (28), was added and the incubation was left at 0°C for a further 5 min. OM were separated from the inner membrane–matrix fraction by sedimentation at 30,000 × *g* for 8 min, followed by resuspension and centrifugation at 3,500 × *g* for 8 min. The crude OM were recovered from the supernatant by centrifugation at 30,000 × *g* for 8 min. Further purification was achieved on a discontinuous sucrose gradient at 80,000 × *g* for 3 h. OM were collected at the interface of the layers of density 1.1175 and 1.1390, diluted in 3 vol of 20 mM KH_2PO_4, pH 7.4, concentrated by centrifugation at 150,000 × *g* for 30 min, and resuspended in buffered 0.25 M sucrose as the mitochondrial OM fraction.

Microsomal fraction. The supernatant of the first crude mitochondrial pellet (M1) was centrifuged at

18,000 × *g* for 20 min at 3°C to yield a pellet containing mitochondria, peroxisomes and part of the microsomes (not shown). The supernatant was centrifuged at 104,000 × *g* for 40 min at 3°C using a Ti-60 rotor (L8-55 Beckman), and the resulting pellet was suspended in sucrose medium, layered on top of 1.2 M sucrose medium and sedimented as above to remove cytosolic proteins and albumin originating from the homogenization step. The microsomal pellet was easily separated from the lower translucent layer of glycogen by gentle shaking, then stored in buffered 0.25 M sucrose as the microsomal fraction.

Enzyme assays. The presence of mitochondrial, peroxisomal and microsomal organelles was estimated by the activities of monoamine oxidase (29), urate oxidase (30) and aryl-ester hydrolase (31), respectively. The peroxisomal fatty acid-oxidizing system (PFAOS) was determined by CN-insensitive palmitoyl-CoA dependent NAD^+ reduction (32,33) in the presence of 75 μM palmitoyl-CoA. Measurements of CPT I activity were carried out at 30°C according to Bremer (34) with slight modifications (35). Because microsomes have been shown to display carnitine acyltransferase activity (36), the PPMF which were least contaminated by microsomes (Table 4), were preferred over other mitochondrial fractions for CPT I measurements. The sensitivity of CPT I to malonyl-CoA inhibition was estimated by incubating mitochondrial proteins with palmitoyl-CoA (40 μM) and the indicated concentrations of malonyl-CoA for 2 min before addition of L-[^{3}H]carnitine (400 μM, 1 Ci/mol). After 4 min, the reaction was stopped by addition of acid, and the acyl-[^{3}H]carnitine was extracted with *n*-butanol (37). Radioactivity was quantitated using Picofluor 15 (Packard Instrument Co., Meriden, CT) in a Packard 300 C scintillation counter.

Lipid analysis. Total lipids of liver and subcellular fractions were extracted by the procedure of Folch *et al.* (38) and saponified with 10% KOH in methanol (wt/vol) at 100°C for 1 h. Free FA with heptadecanoic acid added as an internal standard were extracted with hexane from the acidified medium and treated, after evaporation of hexane, with H_2SO_4/methanol (5:95, vol/vol) at 100°C for 3 h. The methyl esters were extracted with hexane and analyzed by capillary gas–liquid chromatography (CGLC) on a model 419 Becker–Packard (Downer's Grove, IL) apparatus fitted with a laboratory made 30 m × 0.3 mm i.d. glass capillary column coated with carbowax 20M. CGLC peaks were identified based on their retention time relative to methyl heptadecanoate. Peak areas were measured using a Delsi model Enica 21 computing integrator (Delsi Instruments, Suresnes, France). The separation of PL classes was achieved by high-performance liquid chromatography (39) on a Varian apparatus (Walnut Creek, LA), using a Hibar Merck 250-4 column (Merck) packed with Lichrosorb Si-60 (particle diameter, 5 μm). Mass was estimated by adding a known amount of heptadecanoic acid to each fraction collected. PL FA were directly transesterified with methanol/H_2SO_4 after drying the samples, and were analyzed by CGLC (see above). For measuring TAG, total liver lipids were extracted in the presence of 1,2,3-triheptadecanoylglycerol as an internal standard. TAG were separated by thin-layer chromatography, then saponified, and the FA were methylated and analyzed by CGLC as described above. The cholesterol content of the lipid extracts was measured by CGLC (40) on a model 419 Becker-Packard chromatograph fitted with a 10 m × 0.3 mm i.d. glass capillary column coated with SE-30. Epicoprostanol and α-cholestane were added as internal standards.

Protein. Rapid protein estimations were obtained by spectrophotometry (A280) (28) just before starting the incubations; values were later more accurately determined by the bicinchoninic acid procedure (41).

Statistics. Results are expressed as means ± SE. Statistical comparisons of differences between groups were analyzed by one-way analysis of variance and Fisher's test.

RESULTS AND DISCUSSION

Body and liver weights. An interesting observation that was made in this study is that n-3 PUFA of FO, when present at a level of only 0.2% of the diet (n-3 unsaturated FA constitute 4.1% of the FO mixture; see Table 1), are able to reduce liver weight and liver TAG content of obese Zucker rats (Table 2) whose lipogenesis and esterification pathways are known to be very active (20,21). Values obtained for the rats fed the diet enriched in AA did not differ from those of controls.

TABLE 1

Fatty Acid Composition[a] of the Oil Mixtures Present in the Three Diets[b]

Fatty acids	FO mixture	Control mixture	AA mixture
14:0	1.7	0.8	0.6
16:0	27.2	16.5	16.8
18:0	6.0	4.4	3.9
20:0	0.3	0.4	0.4
22:0	0.4	0.3	0.3
Total saturated	35.6	22.4	22.0
16:1n-7	1.5	—	—
18:1n-9	30.9	43.9	44.7
18:1n-7	1.0	3.2	1.8
20:1n-9	1.1	0.6	0.7
22:1n-11	0.5	—	—
Total monounsaturated	35.0	47.7	47.2
18:2n-6	25.3	25.6	21.5
20:4n-6	—	—	4.2
Total n-6 unsaturated	25.3	25.6	25.7
18:3n-3	0.2	4.3	3.9
18:4n-3	0.3	—	—
20:5n-3	1.6	—	—
22:5n-3	0.4	—	0.4
22:6n-3	1.6	—	—
Total n-3 unsaturated	4.1	4.3	4.3
n-6/n-3 ratio	6.2	6.0	6.0

[a]The composition of fatty acids is given as weight percentage of total fatty acids in the oil mixtures added to the three diets.
[b]FO (fish oil) refers to the oil mixture containing salmon oil. Arachidonic acid (AA) refers to the oil mixture enriched in AA.

TABLE 2

Effects of Diets[a] Enriched in n-3 and n-6 Fatty Acids on Body and Liver Weights[b] and on Lipid Content[b,c] of Liver

	FO	Control	AA
Body weight			
(g)	544 ± 18	550 ± 16	581 ± 30
Liver weight			
(g)	18.5 ± 1.0[d]	21.5 ± 0.9[e]	22.7 ± 1.3[e]
(% of body weight)	3.40 ± 0.15[d]	3.88 ± 0.10[e]	3.89 ±
Liver content in			
Total lipids	122 ± 15[d]	162 ± 19[e]	171 ± 12[e]
Triacylglycerols	77 ± 8[d]	101 ± 12[e]	103 ± 9[e]

[a]FO and AA refer to the diets enriched in n-3 fatty acids with FO and in n-6 fatty acids with the AA concentrate, respectively. See Table 1 for abbreviations.
[b]Results are means ± SE (n = 5). Values in a row with different superscript letters (d,e) are significantly different at $P < 0.05$, as determined by analysis of variance and Fisher's test comparisons.
[c]The contents in total lipids and in triacylglycerols are expressed as mg of fatty acids per gram of liver.

[a]FO and AA as defined in Tables 1 and 2.
[b]Results are means ± SE (n = 5). Values in a row with different superscript letters (d,e,f) are significantly different at $P < 0.05$, as determined by analysis of variance and Fisher's test comparisons.
[c]PFAOS, peroxisomal fatty acid-oxidizing system.

Enzyme activities in liver tissue and mitochondrial fractions. In Table 3, the activities of mitochondrial and peroxisomal enzymes per unit volume of homogenate (corresponding to 1 g liver) are given. The FO diet caused a significant enhancement of mitochondrial (monoamine oxidase) and peroxisomal (urate oxidase and PFAOS) activities per gram liver, but not on a total liver basis (compared to control diet). As the monoamine oxidase specific activity did not differ to any great extent in the purest of the mitochondrial fractions (Table 4), the mitochondrial content should be very similar per whole liver both in FO and control rats. In addition, according to data showing that FO induces an increase in peroxisomal activities when present at a level greater than 15% in the diet (13,14), the results we obtained using a low level of FO (0.75%, because FO represents

[a]Enzyme activities are given in nmoles/min/mg protein. Values are means ± SE (n = 5). Values in a row with different superscript letters (c,d,e) are significantly different at $P < 0.05$, as determined by analysis of variance and Fisher's test comparisons. Microsomal contamination is expressed as mg of microsomal protein per 100 mg of protein of the mitochondrial fraction studied and was calculated as follows: the specific activity of aryl-ester hydrolase in the mitochondrial fraction studied was divided by that in the microsomal fraction of the same liver, and multiplied by 100.
[b]FO and AA as defined in Table 1.

15% of the total oil mixture; see Materials and Methods section) failed to show any enhancement of PFAOS activity per total liver. Consequently peroxisomes were not likely to lower hepatic TAG levels by increasing FA oxidation, as it has been suggested for diets containing FO at higher levels (12,13,42) or only EPA (43). By contrast, the AA diet diminished mitochondrial and peroxisomal enzymatic activities expressed either per gram or total liver (Table 3). These data and the fact that the monoamine oxidase specific activity was similar in the purest of the mitochondrial fractions from AA and control rats (Table 4) would suggest a decrease in mitochondrial mass per gram and total liver of AA rats. Hence, the decreased mitochondrial mass and the lower PFAOS activity should reduce the degree of FA oxidation per total liver in rats fed the AA diet.

Peroxisome and microsome contamination in mitochondrial fractions (Table 4). As monoamine oxidase specific activity was measured in mitochondrial fractions (whole mitochondria or OM) that were not totally pure, it was necessary to assess the amount of the main contaminating organelles that would be likely to influence the specific activity of the mitochondrial enzyme (seen above) and membrane lipid composition. Since urate oxidase specific activities (Table 4) were similar in the liver of rats maintained on any of the three diets (in each fraction) and since urate oxidase specific activity has been reported to be very high in pure peroxisomes, cross-contamination seems unlikely to affect the comparisons between the diets to any extent. For microsomes contaminating the mitochondrial fractions, the specific activity of aryl-ester hydrolase found in mitochondrial and microsomal fractions enabled us to calculate that the crude mitochondrial fractions contained similar amounts of microsomes (between 17 and 21% on a protein basis). In percoll-purified fractions, the values were much lower and corresponded to about 5% of microsomal proteins. Hence, the similar level of contamination of each fraction (for the three diets) by nonmitochondrial organelles would explain the similarity of monoamine oxidase specific activities obtained for the three fractions corresponding to the three diets. In OM fractions, which were devoid of urate oxidase activity, aryl-ester hydrolase activity per mg protein was found to be even greater than in percoll-purified fractions. This microsomal contamination, which represented 11.1 and 15.8% of total protein with the FO and control diets, respectively, could greatly influence the true FA composition and cholesterol content of OM. Attempts to effect a more thorough removal of the microsomes failed, and microsomal membranes already present in percoll-purified fractions seemed to comigrate with OM in the sucrose gradient. The data suggest that microsomal membranes are tightly bound to OM, as has already been suggested (44–47). This also implies that the degree of contamination has to be taken into account when determining the lipid composition of OM. Very long-chain FA are poor substrates for mitochondrial FA oxidation (48) and probably are accumulated as CoA derivatives (49) even when present at low levels in the diet. Since a large part of cellular CoA may be sequestered as long-chain acyl-CoA esters, one role of the aryl-ester hydrolase of the endoplasmic reticulum has been suggested to be to limit the content in acyl-CoA (50). In this respect, the higher specific activity of the aryl-ester hydrolase found in microsomal fractions of rats fed the FO and AA diets would constitute a response to a permanently higher ester content. It could then be expected that accumulated very long-chain acyl-CoA would exert inhibitory effects on enzyme activities related to FA synthesis, as has already been observed in whole animals (51) and in isolated hepatocytes (52).

FA composition of total mitochondrial lipids. It is well documented that dietary FA directly influence the composition of biological membranes and corresponding enzymatic activities (53). Measurements made on whole mitochondria rather reflected the composition of the inner membranes probably because of their extensive surface area. In mitochondria (Table 5), the percentages of 20:4n-6 were 22.2 and 25.3%, while those of 22:6n-3 were 16.9 and 13.1% in FO and control rats, respectively. These differences may not be of great importance in respect to some inner membrane-bound activities since rats fed a diet deficient in α-linolenic acid, 18:3n-3, did not display any change in the activity of the respiratory chain and of F_1F_0-ATPase in spite of a low percentage of 22:6n-3 and a higher percentage of 20:4n-6 (54). However, it is clear that the FO diet favored the accumulation of DHA into mitochondrial membranes in spite of the fact that DHA represented only 1.6% of the FA in the FO mixture. In this respect, Yamaoka *et al.* (55) reported that a diet containing 20% of sardine oil (compared to corn oil) enhanced the proportion of DHA up to two to three times in the various PL of liver mitochondrial membranes. With the FO diet, accumulation of 20:5n-3 cannot be observed (Table 5), but this dietary FA may have been derived through desaturation–elongation reactions to cause the significant enhancement of the level of DHA as shown above. Supplementation of the diet with AA was not accompanied by a corresponding enrichment of mitochondrial lipids with this FA.

TABLE 5

Fatty Acid Composition[a] of Total Lipids of Mitochondrial Fractions[b] Isolated from Liver of Obese Zucker Rats Fed Diets[c] Enriched in Polyunsaturated Fatty Acids

Fatty acids	FO	Control	AA
16:0	16.2 ± 1.8	18.0 ± 1.6	17.1 ± 2.0
16:1	—	—	0.2 ± 0.1
18:0	14.7 ± 0.6[d]	16.0 ± 0.5[e]	15.8 ±
18:1	13.1 ± 0.4[d]	13.0 ± 0.4[d]	11.0 ± 0.3[e]

22:5n-3	0.4 ± 0.2	0.8 ± 0.2	1.1 ± 0.3
22:6n-3	16.9 ± 1.2[d]	13.1 ± 0.7[e]	11.7 ± 0.5[f]

[a]Values are means ± SE (n = 5) and are given in weight percentage relative to total fatty acid mass. Values in a row with different superscript letters (d,e,f) are significantly different at $P < 0.05$, as determined by analysis of variance and Fisher's test comparisons.
[b]Percoll-purified mitochondrial fractions.
[c]FO and AA as defined in Table 2.

This would provide evidence that the requirement for AA was easily met through synthesis starting from 18:2n-6 in animals fed the other two diets.

FA composition of PL in OM fractions. Due to the fact that CPT I is located in the mitochondrial OM and that its activity seems to be influenced by the surrounding PL (56), the FA composition of the major PL classes, phosphatidylcholine (PC) and phosphatidylethanolamine (PE), was determined. Independent of the diet, PC and PE were shown to represent about 57 and 29% of total PL, respectively (Table 6). The FA compositions for both classes of PL appeared qualitatively similar to those obtained for total mitochondria. The FO diet gave rise to the highest percentage of DHA both in PC and PE, while the AA diet led to the lowest percentage of DHA and only to a slightly higher level of 20:4n-6. None of the differences between diets exceeded 6%. In general, it appears that dietary DHA and 20:4n-6 directly enhanced their own presence in OM and conversely diminished each other's level. Since some microsomal membranes were bound to OM membranes, the FA compositions were also determined for PC and PE of the microsomal fractions (Table 7). The percentages of PC and PE in total PL were similar for each, independent of the diet, i.e., they were 63 and 19%, respectively. The FA compositions showed great similarities with those found for the OM fractions. Therefore, the FA composition of pure OM should be very similar to that of OM fractions containing microsomes.

Cholesterol content in mitochondrial and microsomal fractions. The cholesterol content was found to be highest in microsomal fractions and lowest in percoll-purified mitochondrial fractions (Table 8). Cholesterol levels were appreciable in crude mitochondrial fractions and even higher in OM fractions. Since the amount of contaminating microsomes in these fractions was known, the cholesterol content in these fractions devoid of microsomes could be calculated. The corrected values were found to be extremely low and were similar for the three diets in the percoll-purified fractions (about 0.35 µg per mg protein). The OM fractions had the highest cholesterol content (about 11.8 µg per mg protein), so that all mitochondrial cholesterol must essentially be localized in the OM.

CPT I activity and its sensitivity to malonyl-CoA. The specific activity of CPT I in the absence of malonyl-CoA was found to be highest in mitochondria from rats on the control diet and lowest for rats on the AA diet (Fig. 1) The FO diet was shown to reduce the sensitivity of CPT I to malonyl-CoA, in contrast to the AA diet, which clearly enhanced this sensitivity (Fig. 2). Kolodziej and Zammit (57) showed that OM, when exposed to membrane fluidizers such as benzyl alcohol, showed a slightly enhanced CPT I activity and a decreased sensitivity to malonyl-CoA. Therefore, alterations in lipid composition may have an effect on CPT I activity, as has already been shown by Brady *et al.* (58). The similar cholesterol content found in OM of FO and control rats cannot account for any differential effects of this molecule, which is considered to rigidify membrane organization (53). However, the proportion of DHA was always observed to be 4 to 5% higher in PC and PE of OM isolated from rats fed the FO diet. The lower specific activity of CPT I found with the FO diet by comparison to the con-

[a]PC and PE were separated by high-performance liquid chromatography. As a percentage of total phospholipid mass, PC constituted 63.2 ± 0.5, 62.2 ± 0.7, 64.0 ± 0.8, and PE 19.0 ± 0.3, 19.4 ± 0.3, 18.6 ± 0.4 for FO, control, and AA diets, respectively. The fatty acid compositions were analyzed by capillary gas–liquid chromatography. Values are means ± SE (n = 5) and are given in weight percentage relative to total fatty acids. Values in a row for PC or PE with different superscript letters (c,d,e) are significantly different at $P < 0.05$, as determined by analysis of variance and Fisher's test comparisons. The terms total saturated, total n-6, total n-3 and total unsaturated $\geq C_{20}$ refer to the sum of saturated, of n-6, of n-3 and of $\geq C_{20}$ unsaturated fatty acids, respectively.
[b]FO and AA as defined in Table 1. See Tables 2 and 6 for other abbreviations.

trol diet seems to be in disagreement with previous data that had shown no difference in enzyme activities (11) or, oppositely, had shown a more enhanced CPT I specific activity in rats (14) and mice (16) when fed diets containing higher levels of FO. The major differences with respect to our studies were the very low level of FO that we added to the diet and the obesity of Zucker rats we used. The slight difference in FA composition particularly with regard to DHA, between animals fed FO and control diets would be sufficient to alter the environment of the CPT I protein in the OM and to reduce the efficiency of the catalytic site. However, the complexity of characteristics of the enzyme (59), its differential susceptibility to detergents (60), and the additional possibility that the lower activity with the FO diet was due to a change in enzyme mass, makes it difficult to formulate a conclusive explanation at this stage. The most interesting observation concerns the lower sensitivity of CPT I to malonyl-CoA inhibition with FO rats. This is considered more important in the control of FA oxidation than the enzymatic activity itself, at least under some conditions (see, for example, Ref. 61). With the FO diet, the lower sensitivity becomes an even more preponderant factor because of the usually elevated amount of malonyl-CoA in the liver of obese Zucker rats (62,63). Moreover, as mentioned above, some PUFA of FO have been shown to inhibit FA synthesis and related enzyme activities such as acetyl-CoA carboxylase. A lower sensi-

TABLE 8

Effects of Diets[a] on Total Cholesterol Content[b] in Mitochondrial and Microsomal Fractions of Obese Zucker Rat Liver

	FO	Control	AA

Values after correction from microsomal cholesterol contamination			
Percoll-purified fraction	0.35 ± 0.02	0.37 ± 0.02	0.32 ± 0.02
Outer membrane fraction	11.9 ± 0.4	11.5 ± 0.3	11.8 ± 0.3

[a]FO and AA as defined in Table 1.
[b]Results are expressed as μg of total cholesterol per mg protein and are means ± SE (n = 5). The values in a row with different superscript letters (c,d) are significantly different at $P < 0.05$, as determined by analysis of variance and Fisher's test comparisons. Microsomal cholesterol contamination was calculated by multiplying the amount (mg) of microsomal protein contaminating one mg of a mitochondrial fraction (see Table 4) by the cholesterol content of one mg protein of the microsomal fraction isolated from the same liver.

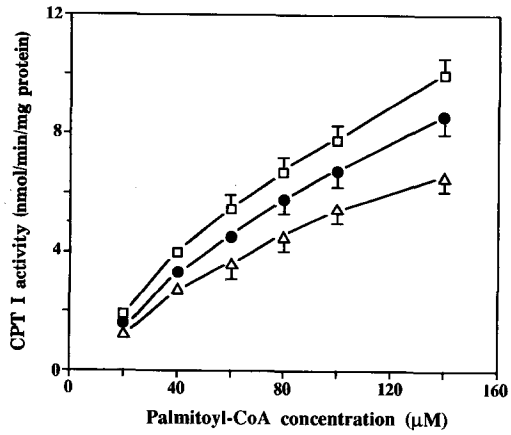

FIG. 1. Effect of increasing palmitoyl-CoA concentrations on the activity of carnitine palmitoyl-transferase I (CPT I) in percoll-purified mitochondrial fractions isolated from liver of obese Zucker rats fed the control diet (□), the fish oil diet (●) or the arachidonic acid diet (△). Assays were performed as described in the Materials and Methods section using 200 μg of mitochondrial protein in the presence of palmitoyl-CoA and L-[^{3}H]carnitine. The radioactivity of the butanolic extract corresponded to carnitine-bound compounds. Results are expressed as nmoles of palmitoyl-carnitine formed per min per mg protein. T-bars show SE (n = 5). Values obtained for 80 to 140 μM palmitoyl-CoA between the groups are significantly different at $P < 0.05$, as determined by analysis of variance and Fisher's test comparisons.

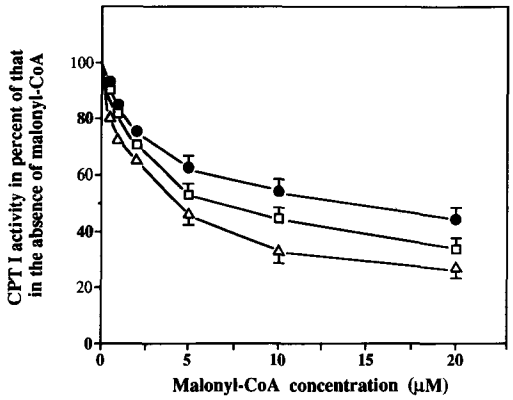

FIG. 2. Inhibitory effect of malonyl-CoA on the activity of carnitine palmitoyl-transferase I (CPT I) in percoll-purified mitochondrial fractions isolated from liver of obese Zucker rats fed the control diet (□), the fish oil (FO) diet (●) or the arachidonic acid (AA) diet (△). Mitochondria were kept 2 min in the presence of 40 μM palmitoyl-CoA and malonyl-CoA before adding labeled L-carnitine. Results are given as percentage of the CPT I activity obtained in the absence of malonyl-CoA. A 50% inhibition by malonyl-CoA was seen at the concentration of 6 μM with the control diet, at 16 μM with the FO diet, and at 4.5 μM with the AA diet. T-bars show SE (n = 5). Values obtained for 10 to 20 μM malonyl-CoA between the groups are significantly different at $P < 0.05$, as determined by analysis of variance and Fisher's test comparisons. See Figure 1 for abbreviation.

tivity to malonyl-CoA associated with a lesser malonyl-CoA synthesis would give rise to a proportionally higher activity of CPT I and a higher rate of FA oxidation.

Results obtained with the AA diet strongly differed from those obtained with the FO diet. AA was present at a level of only 0.2% of the diet (20:4n-6 represented 4.2% of the total AA oil mixture; see Table 1). In contrast to what has been seen for FO rats, liver weights and TAG contents were similar in AA and control rats (Table 2). In rats fed the AA diet, we saw a decrease in PFAOS activity and in mitochondrial protein mass per total liver. Moreover, CPT I specific activity was found to be lowest and its sensitivity to malonyl-CoA inhibition highest from rats on the three diets. A lower rate of FA oxidation by peroxisomes and mitochondria should have favored TAG formation when compared to the control group. At this stage, it is difficult to relate the slightly higher content in 20:4n-6 and/or the lower DHA content of OM PL to the altered characteristics of CPT I enzyme from AA rats compared to controls. However, since rats fed the control and FO diets were capable of producing 20:4n-6 from shorter precursors, it appears that AA was supplied in excess to the cell with the AA diet. As dietary AA (or its acyl-CoA) has been shown to inhibit FA synthetase and acetyl-CoA carboxylase (64,65), less malonyl-CoA synthesis would favor CPT I activity in the intact cell. In addition, the steady intake of AA, which is the major membrane PUFA, should save a large portion of the energy usually required for synthesis. The lower mitochondrial mass per total liver in AA rats might correspond, at least in part, to an adaptive response to less need for energy. In this respect, the amount of AA might represent, by itself and/or through its derivatives, an effective signal to induce metabolic change allowing, in particular, the regulation of mitochondriogenesis.

The major finding of this study was that we could show that the activities that relate to FA oxidation were altered in the liver of obese Zucker rat when the diets contained very low levels of n-3 and n-6 PUFA. The altered composition of mitochondrial OM in n-3 and n-6 PUFA, but not in cholesterol, seems to be sufficient to influence, *via* the kinetic characteristics of CPT I, the pathway of FA oxidation.

Dietary Linoleic, α-Linolenic and Oleic Acids Are Oxidized at Similar Rates in Rats Fed a Diet Containing These Acids in Equal Proportions

Peter J.H. Jones*

Division of Human Nutrition, University of British Columbia, Vancouver, British Columbia, V6T 1Z4 Canada

The objective of this study was to examine whether whole body oxidation rates of dietary linoleic, α-linolenic and oleic acids differ when the acids are provided in identical quantities. Male rats were fed for 10 wk a 15% fat (w/w) diet containing equal amounts of linoleic, α-linolenic and oleic acids (22.7, 23.0 and 23.2% of total fatty acids, respectively). At week 10, after overnight fasting, rats were intragastrically administered 20 μCi of either [1-^{14}C]-labelled linoleic, α-linolenic or oleic acid in a 200-μL bolus of oil containing equal quantities of each fatty acid. The appearance of $^{14}CO_2$ in expired air was then monitored hourly for 12 h for each animal. A preliminary study had shown that growth and food consumption patterns in animals consuming the oil containing equal quantities of each of the fatty acids paralleled the patterns of animals that were self-selecting among separate diets, each of which contained one of the component oils. The appearance of ^{14}C, expressed as percent dose administered, peaked at 2–3 h post-dose for ^{14}C-labelled linoleic (5.28 ± 0.37%/h), α-linolenic (6.92 ± 0.51%/h) and oleic (5.98 ± 0.44%/h) acids. Statistically these values were not significantly different. Cumulative $^{14}CO_2$ excretion rates over 12 h were also similar for linoleic (27.2 ± 0.9%), α-linolenic (26.8 ± 1.2%) and oleic (25.9 ± 1.2%) acids. The results suggest that the rat's capacity to oxidize 18-carbon unsaturated fatty acids is not affected by fatty acid unsaturation when these fatty acids are provided at equal dietary levels.

***Lipids* 29, 491–495 (1994).**

A number of previous studies have indicated that disposal of dietary fat for energy rather than storage depends on the long-chain fatty acid composition of the fat (1–11). Respiratory gas exchange data obtained in animal experiments suggested that greater peroxisomal oxidation (1) and oxygen consumption (2) occurs with consumption of fats rich in polyunsaturated fatty acids (PUFA) compared with fats containing monounsaturated (MUFA) or saturated fatty acids (SAFA). Similarly, energy intake/balance experiments have generally shown that consumption of n-3 PUFA results in lesser weight and energy gains when compared with fats containing other fatty acids (3–5).

Discrimination between various fatty acids in the oxidation process has also been suggested from animal and human experiments with tracer-labelled fatty acids (6–11). In rats fed normal chow diets and given ^{14}C-labelled long-chain fatty acids orally, differences between oxidation rates for α-linolenic acid, oleic acid and linoleic acid were seen over the first 8 h of a 24 h study, with α-linolenic acid being converted to carbon dioxide most rapidly, followed by oleic acid and linoleic acid (6). Arachidonic and γ-linolenic acid exhibited the lowest rates of oxidation. Other studies with labelled fatty acids suggested a similar trend of PUFA toward oxidation rather than retention within body pools (7–10). In humans, expired $^{13}CO_2$ from labelled oleic acid after oral administration appeared more rapidly than from labelled linoleic or stearic acids (11). The general consensus that emerged from these studies is that the blend of fatty acids consumed, which depends on the type of dietary fat or oil selected, can modify an individual's susceptibility to long-term body weight gain.

However, limitations exist in the interpretation of the results from previous experiments when one compares tracer appearance rates in expired CO_2 derived from labelled dietary fatty acids. A major difficulty has often been the vastly different quantity of specific fatty acids consumed. For instance, tracer fatty acids were typically added directly to dietary olive oil (6), or lard and corn oil followed by fasting (7), or were transesterified directly with soybean (8), olive (9) or corn oil (10). Also, tracer fatty acids were added directly to chow diets. Such diets contain, of course, widely varying pools of specific fatty acids. Thus, the quantities of tracee (i.e., the unlabelled fatty acid pool with which the tracer fatty acid became associated varied between experiments and fatty acids tested. Differences in the tracer/tracee ratio imply that it may be erroneous to conclude preferential fatty acid oxidation on the basis of a greater proportion of label excreted, if the tracer was mixed with a fatty acid pool of different size. Moreover, endogenous pools of specific fatty acids which are targeted for oxidation will likely be depleted or expanded in response to the exogenous fatty acid blend delivered by feeding the diet. For these reasons, interpretation of results from many of the earlier tracer studies has remained difficult. Various approaches aimed at controlling the tracer/tracee ratio for specific fatty acids at the time of label administration have previously been used (12); however, animals previously have not been prefed a diet with which internal body pool sizes could be standardized.

To permit the study of the oxidation capacity for specific dietary fatty acids under identical conditions, an approach was chosen here in which equivalent quantities of three important dietary fatty acids, differing in unsaturation, were provided during both the precedent dietary and the comparison phases. The objective was to test the hypothesis that when provided in equal amounts, the capacity of the rat to oxidize dietary linoleic (18:2n-6), α-linolenic (18:3n-3) and oleic acids (18:1n-9) is similar and independent of the degree of unsaturation.

MATERIALS AND METHODS

Animals and diets. Thirty male Sprague Dawley rats (80–100 g; Harlan Sprague Dawley, Indianapolis, IN) were initially fed rodent Purina Laboratory Chow (Purina Mills, St. Louis, MO) and water *ad libitum*. Animals were housed at constant temperature (20°C) and humidity (54–56%) at a 12-h light–dark cycle throughout the experiment. After one week, rats were individually housed in steel cages and switched to an elemental diet containing 15% fat blended to contain equal proportions of linoleic, α-linolenic and oleic acids as triglycerides for ten weeks (Table 1). All oils were obtained from local sources. The equal proportion oil diet was prepared by blending sunflower, flax and olive oil, high in linoleic, α-linolenic and oleic acids, respectively, at a ratio of 1.11:3.00:0.92 (w/w/w). Within individual oils, weight ratios of linoleic, α-linoleic and oleic acids for sunflower, flax and olive oil were 0.456:0.007:0.153, 0.179:0.379:0.180, and 0.116:0.008:0.479, respectively. Overall fatty acid composition of the oil provided was 18:2n-6, 22.69%; 18:3n-3, 23.24%; 18:1n-9, 23.16%; 18:0, 2.48%; and 16:0, 5.88%. Butylated hydroxytoluene was added at a level of 0.02%, and diets were prepared every two to three days. Oils were stored at –5°C. The fatty acid ratio in the final diet was determined by gas–liquid chromatography (GLC). All procedures were approved by the Animal Care Experimentation Committee of the University of British Columbia (Vancouver, British Columbia, Canada).

Fatty acid oxidation. After ten weeks on the blended-oil diet, rats were randomized into three groups on the basis of weight. Food was removed eight hours prior to the experiment. Animals in each group were administered 20 μCi each of either [1-^{14}C]linoleic, α-[1-^{14}C]linolenic or [1-^{14}C]oleic acid (50–60 mCi/mmol; Amersham, Oakville, Ontario, Canada) mixed with 200 μL of the blended oil and given intragastrically *via* an oral catheter. Immediately thereafter animals were placed in a metabolic chamber, and $^{14}CO_2$ was collected for 10 min every hour for 12 h. Carbon dioxide from the metabolic chamber was collected by passing the air from the chamber through a sulfuric acid trap for drying, followed by two collection columns containing a mixture of methoxyethanolamine and ethanolamine (2:1, vol/vol) (6). Samples from the mixture were removed after each collection period and added to scintillation fluid. Radioactivity was assayed using a scintillation counter (Isocap; Nuclear Chicago, Des Plaines, IL).

The trapping efficiency of the methoxyethanolamine/ethanolamine mixture used to collect the CO_2 exhausted from the metabolic chamber was examined in a pilot study. It was determined that the saturation point of the mixture occurred at least 3 min after the 10-min collection period, thus ensuring $^{14}CO_2$ collection without losses.

Gas chromatography. The fatty acid composition of individual oils and of the blended oil diet was determined using a gas–liquid chromatograph (model 5890, Hewlett Packard, Palo Alto, CA) equipped with a flame-ionization detector and a 30 m × 0.2 μm i.d. SP-2330 (10%) capillary column using helium as carrier gas (1 mL/min). Fat was extracted from homogenized aliquots of the blended oil diet using chloroform/methanol (2:1, vol/vol), and the extracts were saponified with KOH and then transesterified with boron trifluoride/methanol (13). Hexane was added, and the mixture was shaken to partition the fatty acid methyl esters (FAME) into the hexane phase. The resulting FAME were injected into the GLC column at 160°C. After 8 min, the column temperature was increased at 2°C/min for 30 min then held constant for an additional 20 min. Chromatographic peaks were identified by comparison of retention data with those of authentic FAME standards (Supelco, Bellefonte, PA).

TABLE 1

Composition of Diet Containing Equal Levels of Linoleic, α-Linolenic and Oleic Acids

Nutrient	Content (g/100 g diet)
Casein	18.00
Sucrose	62.77
Fixed ratio oil[a]	15.00
DL-Methionine	0.23
Mineral mixture[b]	4.00
Vitamin mixture[c]	—[c]

[a]Oil contained equal proportions of linoleic, α-linolenic and oleic acids by combining sunflower, flax and olive oil in a ratio of 1.11:3:0.92, respectively.

[b]Contained calcium carbonate, 38.14%; copper sulfate · $5H_2O$, 0.048%; ferrous sulfate · $7H_2O$, 2.70%; magnesium sulfate · $7H_2O$, 5.73%, manganese sulfate · H_2O, 0.45%; potassium phosphate monobasic (KH_2PO_4), 38.90%; potassium iodide, 0.079%; sodium chloride, 13.93%; zinc chloride, 0.026%; and cobalt chloride · $6H_2O$, 0.002%.

[c]Contained (in g/kg of diet): vitamin A (50,000 IU/g), 0.040; vitamin D (85,000 IU/g), 0.0026; vitamin E (25,000 IU/g), 0.44; choline chloride, 1.65; menadione, 0.049; *p*-aminobenzoic acid, 0.111; nicotinic acid, 0.10; riboflavin, 0.022; pyridoxine hydrochloride, 0.022; thiamin hydrochloride, 0.022; calcium pantothenate, 0.066; biotin, 0.0004; folic acid, 0.002; inositol, 0.111; and vitamin B_{12}, 30 mg.

RESULTS

An initial study was carried out to test the palatability of the blended oil diet compared to diets containing the individual composite oils. Groups of rats (n = 5) consumed either the 15% (w/w) blended oil diet (Table 1) or chose between three food cups containing diets identical in macronutrient content with fats added either as sunflower, flax or olive oil. Figure 1 depicts the growth curves of groups fed both the blended oil and the three optional diets over a 22-d period. Body weight gains were similar across the groups, indicating good acceptability of the blended oil diet by the rat. Food consumption of animals on diets containing the blended oil was also similar to that of animals on diets containing the individual composite oils.

The body weights of the groups given ^{14}C-labelled linoleic (508 ± 22 g, mean ± SEM), α-linolenic (528 ± 23 g) and oleic (518 ± 26 g) acids were similar. Recovery of $^{14}CO_2$ over the 12-h interval post-dose is shown in Figure 2. ^{14}C appeared in expired air within in the first hour of collection with a rapid increase reaching a peak at two to three hours for all three ^{14}C-labelled fatty acids examined. Peak excretion rates for [1-^{14}C]linoleic (5.28 ±

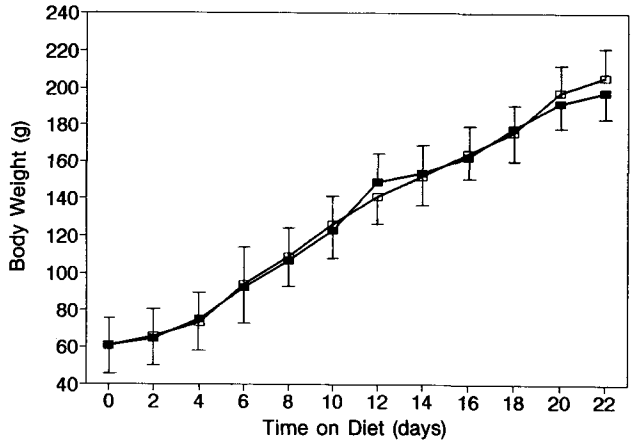

FIG. 1. Body weights of rats given either (*ad libitum*) a choice between three food cups containing identical diets with fat added either as sunflower, flax or olive oil (solid squares) or the blended oil 15% (w/w) fat diet (open squares) over 22 d; data are means ± SEM.

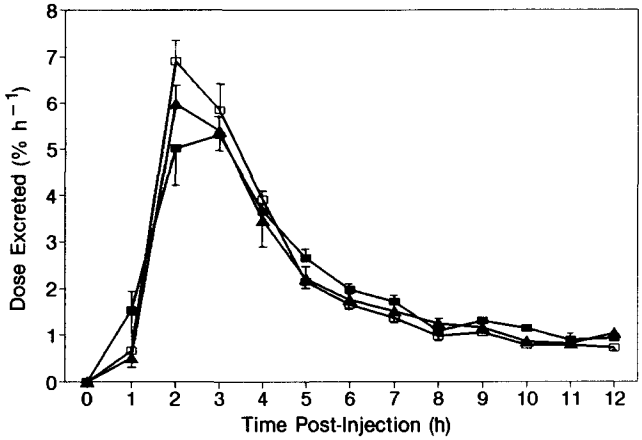

FIG. 3. Cumulative ^{14}C recovery as $^{14}CO_2$ over the 12-h interval post-dose after administration of 1-^{14}C-labelled linoleic (solid squares), α-linolenic (open squares) and oleic (solid triangles) acids; data are means ± SEM.

0.37%/h), α-[1-^{14}C]linolenic (6.92 ± 0.51%/h) and [1-^{14}C]-oleic (5.98 ± 0.44%/h) acids were not significantly different. There were no statistically significant differences in the oxidation rate at two or three hours. Each peak was followed by a gradual decline in excretion rate of label until 12 h; then a levelling off occurred at an excretion rate of about 1%/h.

Cumulative elimination rates for ^{14}C from rats given the labelled fatty acids are shown in Figure 3. There were no differences in cumulative excretion of label among [1-^{14}C]linoleic (27.2 ± 0.9%), α-[1-^{14}C]linolenic (26.8 ± 1.2%) and [1-^{14}C]oleic (25.9 ± 1.2%) acids over the 12-h duration, nor did any differences become significant when data were corrected for body weight.

DISCUSSION

The purpose of this study was to examine whether fatty acid oxidation rates would differ when both dietary and endogenous pool sizes were controlled. In previous studies, pool size often varied when fat oxidation was compared (6–10). The present work demonstrates that when the dietary pool size of the fatty acid examined is maintained at a consistent ratio prior to and during the oxidation period, ^{14}C elimination representative of oxidation rates is virtually identical for the fatty acids tested. These findings contrast results of a number of earlier studies with animals and humans that suggested that differences exist in whole body excretion of labelled fatty acids, but in these previous studies the labelled fatty acids were either provided in tracee pools of varying size, or the pretreatment diet was not standardized.

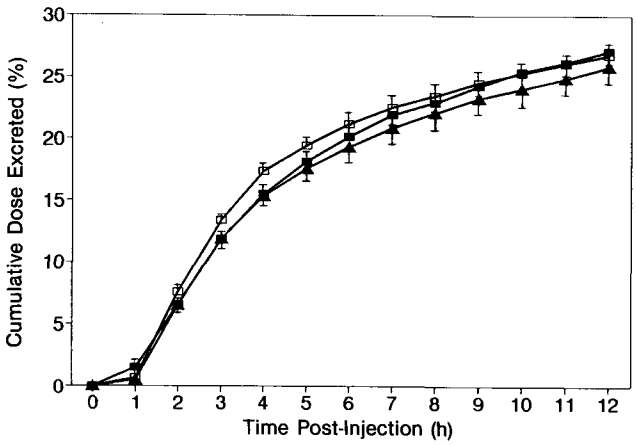

FIG. 2. ^{14}C recovery as $^{14}CO_2$ over the 12-h interval post-dose after administration of 1-^{14}C-labelled linoleic (solid squares), α-linolenic (open squares), or oleic (solid triangles) acid; data are means ± SEM.

In mice given ^{14}C-labelled oleic, linoleic and stearic acids transesterified with linoleic acid-rich corn oil (10), 50% of the administered label in oleic acid was recovered in expired CO_2 at 10-h post-administration, compared with 31 and 19% for linoleic acid and stearic acid, respectively. The comparative oxidation of oleic, palmitic and stearic acids was studied in rats (8) intubated with ^{14}C-labelled fatty acids transesterified with soybean triglyceride. Stearic acid ^{14}C appeared in expired air more slowly allowing 57% recovery after 51 h, compared to 66% from oleic acid. More rapid oxidation of linoleic as compared to stearic acid had been reported in rats fed each ^{14}C-labelled fatty acid mixed with olive oil (9). Similar studies in rats fed diets containing 15% of calories as triolein, trilinolein or tripalmitin, labelled with the respective ^{14}C-labelled fatty acid, had shown that 64, 52 and 51% of the dietary oleate, linoleate and palmitate, respectively, was oxidized after 72 h (14). Overall, these findings suggested differences in oxidation between MUFA, PUFA and SAFA; however, pool sizes of unlabelled (tracee) fatty acids likely varied widely between the fatty acids that were compared.

A similar oxidation pattern had been observed in humans (11). Subjects fed ^{13}C-labelled fatty acids mixed with a breakfast meal, exhibited greater 9-h cumulative $^{13}CO_2$ excretion in expired air from absorbed oleate (15.1%) than from absorbed linoleate (10.2%) or stearate (2.9%) (11). Data from fat malabsorption studies had shown that

orally ingested [^{13}C]triolein was converted to $^{13}CO_2$ more rapidly than [^{13}C]palmitic acid when given under the same conditions (15). Six hours after administration to healthy subjects, of each labelled fatty acid mixed in 0.7 g/kg of lipomul, 11.3 and 6.6% of label from triolein and palmitic acid, respectively, had appeared in breath. Other work has shown that triolein was oxidized more rapidly than tripalmitin when these ^{14}C-labelled fats were administered to healthy humans (16). However, when a comparison was made between whole body oxidation of orally fed ^{14}C-labelled oleic, linoleic and α-linolenic acids in healthy individuals after 24 h, no significant differences in $^{14}CO_2$ recoveries were observed (17). As with animal studies, the tracer/tracee ratio of specific fatty acids varied within the fat bolus fed. Thus, the findings of tracer studies carried out both in animals and in humans indicate that the shift of long-chain fatty acids toward oxidation, rather than storage, varies depending on the degree of unsaturation. However, without controlling fatty acid pool size, interpretation of the results of these studies remains difficult.

In other approaches aimed at examining whether fatty acid oxidation is related to structure, the tracer was directly introduced into the bloodstream, bypassing digestive and absorptive processes. When comparing whole body fatty acid oxidation, direct injection can compensate for potential variations in gastrointestinal absorption and dietary pool size between the various fatty acids tested. In rats maintained on formula diets and injected with ^{14}C-labelled linoleic, oleic and stearic acids, the oxidation rate as determined from cumulative $^{14}CO_2$ production was found to be highest for linoleic acid and lowest for stearic acid (18). The same group later reported increased oxidation of linoleic acid over palmitic acid (19), postulating that production of a highly metabolizable gluconeogenic propionyl-CoA from linoleic acid during oxidation explained the elevated rate of oxidation of linoleic acid. The oxidation rates of infused albumin bound [^{14}C]palmitic and [^{14}C]oleic acids were similar in dogs (20). Conversely, in humans, oxidation rates of injected ^{14}C-labelled palmitic, oleic and linoleic acids were 9.4, 10.0 and 6.3% of the dose administered, respectively, after one hour (7).

Although direct injection of tracer bypasses digestive processes, data interpretation in studies using injection when comparing dietary fatty acid oxidation can be difficult as the amount of injected label appearing in CO_2 represents the fraction of the plasma pool oxidized, not the absolute amount. Net or absolute oxidation measurement depends on the plasma pool size as well as the fractional turnover rate. Markedly smaller plasma pools of linoleic acid in comparison with palmitic acid have been reported (21). Thus, whether the appearance rate of a tracer directly corresponds to net fatty acid oxidation remains to be determined.

By contrast, other investigators have noted no difference in fatty acid oxidation rates. Awad *et al.* (22) found no difference in energy deposition between rats fed PUFA vs. MUFA/SAFA containing diets at 20% of energy for four weeks. Similarly, no difference was observed in humans in $^{14}CO_2$ excretion after oral administration of ^{14}C-labelled palmitic, stearic, oleic, linoleic and α-linolenic acids in healthy individuals after 24 h (17). Toorop *et al.* (12) controlled both the specific activity and net quantity of dietary linoleate and palmitate given to rats and found that, expressed relative to fatty acid absorbed, the oxidation rates of each of the fatty acids were similar. In other studies, such as those of Leyton *et al.* (6), enhanced conversion of α-[^{14}C]linolenic acid to $^{14}CO_2$, when compared to other fatty acids, would be expected given the very small pool size of linolenic acid within the olive oil carrier. In this case, although the proportion of α-[^{14}C]linolenic acid oxidized from the carrier oil was large, net oxidation would have been minimal.

During movement between gut and site of oxidation, labelled fatty acids must cross several transport and metabolite pools, the size of which will be at least partially dependent on prior dietary intake. Given two different labelled fatty acids entering this network of pools from the gut at equal rates, the fatty acid traversing a series of larger pools before arriving at the site where it is oxidized will become more diluted when compared to a fatty acid crossing smaller pools. This dilution will result in a diminished rate of labelled CO_2 expiration. Our findings suggest that a pretreatment diet containing equal fatty acid pools may correct for differences in oxidation due to variability across these internal fatty acid pools. When the labelled fatty acid is then delivered in an oil of equal fatty acid pools, each fatty acid behaves in a similar manner from the absorptive to the oxidative stages of metabolism. Previous work has suggested that absorption efficiencies of different MUFA and PUFA are similar in rats (23,24) and in humans (25), although transport from gut to liver may vary depending on chain length (26). Thus, it cannot be ruled out that absorption and oxidation kinetics varied between the fatty acids tested in a self-compensating manner. However, the similarity in the shape of the curves across the three fatty acids tested suggests similar kinetics.

In summary, the present data suggest that the capacity to oxidize fatty acids varying in degree of saturation is similar when rats are both prefed equal quantities of each fatty acid over a prolonged period and are administered the fatty acid at equivalent tracer/tracee ratios in a fat bolus. The results suggest that differences previously observed in fatty acid oxidation were due to the particular blend of fatty acids provided in the diet and not to the capacity of the organism to oxidize different fatty acids at different rates.

Fatty Acid Turnover Rates in the Adipose Tissues of the Growing Chicken *(Gallus domesticus)*[1,2]

T.A. Foglia*, A.L. Cartwright[3], R.J. Gyurik[4] and J.G. Philips

USDA, ARS, ERRC, Philadelphia, Pennsylvania 19118 and Poultry Research Laboratory, Georgetown, Delaware 19947

The purpose of this study was to investigate the mobility of fatty acids in adipose tissue of the chicken and to determine whether adipose tissue dynamics are altered by dietary repartitioning agents. To this end, the turnover rates of fatty acids and triglycerides were estimated in adipose tissue of growing chicks by using isopentadecanoic acid (IPDA) and elaidic acid (EA) as marker dietary fatty acids. The half-life of IPDA in abdominal and sartorial adipose tissues of birds over 6 to 10 wk of age were 20 ± 4 and 23 ± 6 d, respectively. The half-life for the remaining total carcass lipids was 23 ± 3 d. The corresponding half-life for EA in abdominal fat tissue of birds over 2 to 7 wk of age was 18 ± 3 d, a half-life not significantly different from the IPDA half-lives. On the other hand, a thyromimetic repartitioning agent (L-94901) fed to birds at the 2 ppm level from 2 to 7 wk of age significantly decreased the half-life of EA in abdominal fat tissue to 6 ± 2 d. The data suggest that fatty acids were released from a more labile adipose site and subsequently reincorporated into abdominal and sartorial tissues and that fat mobilization occurred at the same time as did adipose tissue deposition in the growing chicken.
***Lipids* 29, 497–502 (1994).**

Differences in fat deposition among breeds and strains of chickens point at the effects of genetic factors on body composition. Animals selected for fast growth and feed efficiency often show a propensity to deposit excessive amounts of fat (1–3), and genetic factors often affect body weight and tissue and plasma lipid composition. Also, the activities of lipogenic and lipolytic enzymes have been shown to significantly correlate with the genetic factors that favor high or low body weight (4–6). More recently, lipoprotein lipase activity and lipid content of abdominal fat tissue were used to predict the degree of fatness of broiler chickens (7).

Nutritional factors and the age of the birds also affect patterns of fat deposition and lipid metabolism (8–11). Other factors that control fatness in animals include feed restriction to slow fat deposition, and the use of growth promoters and partitioning agents to depress fattening and to enhance muscle accretion (12).

Triglyceride dynamics, such as fatty acid turnover, clearance, oxidation or uptake by adipose tissue have been investigated in humans and animals (13–15). Adipose tissue from the chicken serves as an excellent model for the study of direct incorporation and release of dietary fatty acids. The liver accounts for 90% of *de novo* fatty acid synthesis in young chickens (16), and other studies confirm that in birds hepatic lipogenesis is much greater than adipose tissue lipogenesis. Accordingly, nearly all fat that accumulates in broiler adipose tissue either evolves from synthesis in the liver or derives from the diet (17).

Among the methods used to measure lipid turnover, *in vivo* techniques using structurally isomeric fatty acids that occur naturally in trace amounts have often been used. To this end, we reported in a preliminary account of this work that isopentadecanoic acid (IPDA) is a suitable fatty acid marker for triglyceride turnover rates in the adipose tissues of growing chickens (18). While this work was in progress, Lemarchal *et al.* (19) reported the use of elaidic acid (EA) for determining triglyceride turnover rates in 11- to 21-week-old chickens that had been selected for either fatness or leanness. Aside from our earlier report (18), no measures of fat turnover have been published for young chickens when adipose growth rate is most rapid.

This study reports the half-life of the fatty acid markers, IPDA and EA in adipose depots of growing chickens between 6 and 10 wk and 2 to 7 wk of age, respectively. The effect of the thyromimetic repartitioning agent, L-94901 on the turnover rate of elaidic acid in abdominal tissue of the growing chick from 2 to 7 wk of age also was measured.

MATERIALS AND METHODS

Synthesis of labeled oils. The method for large-scale synthesis of triisopentadecanoin [(tri-13-methyltetradecanoyl)-glycerol; 13-MTDG)] by acid-catalyzed condensation of 13-methyltetradecanoic acid (IPDA) with glycerol has been published (20). Trielaidin (TE) was prepared similarly from EA obtained by the isomerization of oleic acid (21). 13-MTDG (400 g) was blended with a commercially available unhydrogenated soybean oil (1 kg). Fatty acyl chains were randomized by heating the oil mixture to 80°C for 2 h in the presence of 0.4% sodium methoxide under a nitrogen atmosphere (22,23). Similarly, EA-labeled oil was prepared starting with TE. The randomized oils had the fatty acyl compositions reported in Table 1.

Animals and diets. In Experiment 1, forty female broiler chicks (Shaver Poultry Breeding Farms Ltd., Ontario, CA) were tagged with wing bands and fed commer-

cial starter ration until the diet was changed to unlabeled diet formulation at eight days of age. The unlabeled diet (3.1 kcal/g; 23.1% crude protein; 11.9% moisture; 4.1% crude fat; 5.8% ash; 50.9% nitrogen-free extract; 2.3% crude fiber) was given *ad libitum*. At 25 d of age, birds were weighed and housed in individual cages equipped with individual feeder trays. At 28 d of age, birds were weighed and given individual feeders containing a fatty acyl-labeled diet (Diet A). The composition of the two diets was the same, except that labeled diet was formulated with 2% soy oil containing 22.2% of its triglyceride fatty acids as IPDA (soy oil and IPDA), which replaced 2% unlabeled soy oil in the unlabeled diet (Table 1). After two weeks of feeding the labeled diet, feeders were weighed and replaced with clean feeders containing unlabeled diet.

Experiment 2 was designed similarly to Experiment 1 with the exceptions that younger birds were used, and EA was the label. Two groups of 35 birds each were raised as described in Experiment 1 until birds were placed in individual cages at 14 d of age. A control group of 35 birds was given feeder trays containing a diet (Diet B) that was formulated as the unlabeled diet except that 2% soy oil was replaced with 2% soy oil that contained 18.0% of its triglyceride fatty acids as EA. Fatty acyl composition of the labeled oil (soy oil and TE) and the lipid isolated from the unlabeled and EA-labeled diet (Diet B) are given in Table 1. Feeders for the treated group contained the same labeled diet to which was added 2 ppm thyromimetic repartioning compound L-94901 (Smithkline Beecham Animal Health Products, West Chester, PA). Feeders of control and treated birds were removed after two weeks of feeding the labeled diet. Control birds subsequently were given feeders that contained unlabeled diet while treated birds were given feeders containing unlabeled diet with 2 ppm of L-94901.

Experimental design. In the IPDA study, Experiment 1, four birds were killed at 28, 33, 38, 42, 49, 56, 63 and 70 d of age. These ages correspond to 0, 5, 10 and 14 d of consumption of labeled diet and 7, 14, 21 and 28 d of subsequent consumption of unlabeled diet. Birds were killed by exsanguination after electrical stunning. Carcasses were chilled for 1 h in ice water immediately after scalding, defeathering and weighing. Abdominal and sartorial fat depots were excised and frozen at –20°C before lipid analysis. After removal of ingesta from the gastrointestinal tract, residual carcasses (defeathered carcasses without the removed adipose tissues) were ground with a meat grinder, and homogeneous samples were frozen for lipid analysis.

For both the treated and control birds of Experiment 2, feed consumption and body weight were recorded at least every other day from 14 d of age until death. Three birds from each group were killed at day 14, 18, 21, 28, 35, 39, 42 and 49 of age. These ages correspond to 0, 4, 7, and 14 d of consumption of labeled diet with (treated) or without (control) L-94901 and 7, 11, 14, and 21 d of unlabeled diet with (treated) or without (control) L-94901. Abdominal adipose tissues were collected and stored using the procedures described in Experiment 1.

Lipid isolation and analyses. Lipids were extracted from the diets with diethyl ether in a Soxhlet apparatus. Lipids were extracted from samples of abdominal (2 g) and sartorial (1 g) fat tissues, and residual carcass (5 g) by the method of Marmer and Maxwell (24). All tissue samples were analyzed in duplicate. Lipid extracts were stored in dichloromethane, and aliquots taken for percent lipid determination (wt/wt) and fatty acid composition.

Fatty acid compositions (Table 1) were determined by gas–liquid chromatography (GLC) of the fatty acid methyl esters (FAME). FAME were prepared and quantitated by the procedure of Slover and Lanza (25). FAME were separated on a Hewlett-Packard (Avondale, PA) Model 5890 gas chromatograph equipped with a split capillary injector, a flame-ionization detector and a fused silica capillary column, 60 m × 0.25 mm i.d., coated with SP-2340 (Supelco, Bellefonte, PA). He served as carrier gas (linear velocity of methane, 22.9 cm/s) at a split ratio of 80:1. FAME were separated by oven temperature programming: initial temperature, 140°C; then 0.5°C/min to 150°C; then 2°C/min to 200°C; hold for 20 min. Methyl heneicosanoate (21:0) served as internal standard. Signal analysis was accomplished by routing the detector output to a Hewlett-Packard Model 3396A integrator and a Hewlett-Packard Model 9122C mass storage unit for subsequent statistical analyses. The described chromatographic conditions gave complete baseline separation of all the fatty acids listed in Table 1.

Statistical analyses. The weight percent label found in the various tissues were analyzed by analysis of covariance using body weight as a covariate to determine the effect of diet and age. Unadjusted means for each combination of diet and age were then subjected to a nonlinear regression analysis using an exponential decay model. Half-lives ($t_{1/2}$, the time required for label content to

decline by one-half) of IPDA or EA for each tissue were calculated from the coefficients of the exponential decay model (19) of the form $Y = Ae^{-bt}$, where Y is the amount of IPDA or EA at time t in days, A is the amount of IPDA or EA at the apex value, and b is the rate of decline of IPDA or EA. Statistical comparison of data from experiments were made by analysis of variance (ANOVA). All analyses were performed using the SAS software system (26).

RESULTS AND DISCUSSION

IPDA and EA were used to determine fatty acid turnover rates in adipose tissues of growing chickens. In Experiment 1, four-week-old chicks were fed an IPDA-labeled diet for two weeks and subsequently fed an unlabeled diet for a four-week period. In Experiment 2, two-week-old birds were fed an EA-labeled diet for two weeks and subsequently fed an unlabeled diet for a three-week period. Chicks in the EA study were also fed the triiodothyronine analog L-94901 to determine if thyromimetic effects could be detected in fatty acyl turnover rates (27,28). All formulated diets had 4% total lipid content with fatty acid compositions as listed in Table 1. Unlabeled diets had no detectable amounts of IPDA or EA. Fatty acyl profiles were similar for each diet except for the impact of IPDA and EA substitution. Nearly 12% of the acyl residues in Diet A were IPDA, while approximately 8.5% of the fatty acyl residues in Diet B were EA.

The abdominal adipose depot was selected for study since it is the largest discrete depot and is an early developing adipose site (29). A second fat depot studied in the IPDA experiment was the sartorial fat pad. Like the abdominal depot, it is a discrete, though smaller adipose site that is well-defined at hatch but is a later developing fat depot (30). Lipids extracted from the defeathered carcass with the abdominal and sartorial depots excised were also analyzed. Lipids extracted from the residual carcass were analyzed to follow fatty acid turnover in lipids throughout the chicken, predominantly skin-associated, intermuscular and liver lipids.

Carcass weight, adipose depot weight and total lipid content of depots increased with growth of the birds during the IPDA (Table 2) and EA (Table 3) experiments. The general trend was for the residual carcass, and for the abdominal and sartorial fat tissues to increase in absolute mass during the IPDA study (Experiment 1). In each case, proportional lipid content remained constant as the absolute amount of lipid increased with age and body weight of the birds. Fatty acid marker analysis was designed to account for this dilution of the label with increasing tissue size by using body weight as a covariant in the data analyses.

The concentration of IPDA in fat depots (Table 2) increased from an undetectable level at the start of Experiment 1 (28 d of age) to a maximum of 19.3 mg/g of tissue for abdominal fat pad, 13.0 mg/g of tissue for sartorial fat pad, and 2.0 mg/g residual carcass after 14 d of feeding the IPDA diet (42 days of age). During this time, the total amount of IPDA in the tissues increased until 508, 43 and 2,351 mg was present in the abdominal, sartorial and residual carcass depots, respectively. However, the maximum amount of IPDA in the depots was reached at a tissue collection time subsequent to IPDA-diet withdrawal. The total amount of IPDA increased to 652 mg in abdominal fat, 57.6 mg in sartorial fat and 2,695 mg in residual carcass at 49 d of age or 7 d after labeled-diet withdrawal. The percentage total IPDA increase between 42 and 49 d of age was larger for abdominal (28%) and sartorial (35%) depots than for carcass (15%). These data suggest differences in mobilization and deposition rates among fat depots. However, for all tissues, total IPDA content consis-

[a]Data presented are means and SEM of at least three birds.
[b]The 14-day-old birds were fed EA labeled diet for two weeks followed by three weeks on unlabeled diet.
[c]Fed as control birds except that EA diet and unlabelled diet contained 2 ppm thyromimetic L-94901.
[d]Paired (control-treated) values within a column with the same superscript are significantly different at $P < 0.10$ level using analyais of variance (ANOVA).
[e]Paired (control-treated) values within a column with the same superscript are significantly different at $P < 0.05$ level using ANOVA.

tently declined after the peak IPDA content was determined at 49 d until the end of the study.

The occurrence of maximal IPDA content at 49 d indicated that incorporation of IPDA from ingesta in the digestive tract after removal of labeled diet was significant. Labeled feed was removed from all birds in the experiment before they were killed at 42 d. Ingesta were removed from gastrointestinal tracts before 42-d birds were processed for analysis. Birds remaining on the study for observations beyond 42 d (49, 56, 63 and 70 d) were allowed to digest and adsorb ingested labeled diet. The increased IPDA content can be explained by this factor when combined with the variation associated with individual birds killed at these times. Approximately 12% of fatty acids in the 5% crude fat of the labeled diet was IPDA. The average daily feed intake for broilers at 42 d of age is over 100 g per day. Accordingly, digestive tract contents can include substantial amounts of feed stored in the crop. This residual absorption potential when considered with the size of standard errors relative to the amount of IPDA increase between 42 and 49 d supports this explanation. The delay in maximal IPDA content perhaps also includes loss of dietary fat in transport to the liver and lipoprotein particles during exsanguination (31).

Gross trends of abdominal adipose mass, lipid content and label incorporation data from Experiment 2 were similar to those of Experiment 1 (Table 3). Carcass weight, adipose tissue mass and total lipid content generally increased from the start, two weeks of age, to the end, seven weeks of age, of the study for both control and thyromimetic-treated (2 ppm L-94901) birds. There were no significant differences in body weight or feed intake between control and treated birds. However, significant ($P < 0.10$) decreases in the size of the fat pads were detected for thyromimetic-treated birds as compared to control birds at 28, 35 and 39 d of age, which correspond to 14, 21 and 25 d of exposure to thyromimetic (Table 3). The triiodothyronine analog L-94901 was observed to markedly decrease the abdominal adipose tissue mass in broilers (Gyurik, R.J., unpublished results) but the mechanism of this effect has not been published. Since thyromimetic compounds increase lipid mobilization and tissue turnover, they should also up-regulate fatty acid turnover rates. Moreover, increased thyroid hormone-like activity decreases relative abdominal adipose tissue mass in chickens (32).

EA incorporation into control birds exhibited characteristics similar to those observed for IPDA incorporation in Experiment 1. The concentration of EA in the abdominal adipose tissue of control chicks increased to an apex of 11.5 mg/g at 28 d of age (Table 3). This apex of EA concentration occurred at the time of EA diet withdrawal and is consistent with the data from all fat depots from IPDA Experiment 1. On the other hand, the apex at an EA concentration of 14.6 mg/g was not reached in thyromimetic-treated birds until 35 d of age. This anomalous observation suggests that fatty acid adipose tissue dynamics are altered by thyromimetic treatment.

In general, there were no significant differences in the total amount of EA deposited into the abdominal depot of treated birds relative to the amount deposited in control birds over 14 days of feeding the labeled diet. However, significant ($P < 0.05$) differences in total EA content were found after removal of the label that also suggested altered adipose tissue dynamics. The maximal total amount of EA incorporated into the abdominal adipose tissue was seen in 35 days of age for both control and treated birds (270 and 357, respectively). These maxima of total EA content are significantly different ($P < 0.05$) (Table 3) and followed cessation of feeding fatty acid-labeled diet, just as observed in the IPDA experiment.

The previously emphasized differences in responses between thyromimetic-treated birds and control birds from Experiment 2, and the repletion data from Experiment 1 can be explained by altered lipid and tissue dynamics. The increased EA concentration that was seen later in thyromimetic-treated birds than in control birds would result from a reduced dilution rate of EA with unlabeled fatty acids that occurs as a normal consequence of growth. An increased turnover of deposited triglyceride in treated birds would be consistent with this observation. However, the greater accumulation of total EA in thyromimetic-treated birds relative to control birds (357 vs. 270 mg) suggests that thyromimetic-stimulated fat mobilization was followed by a disproportionate redeposition of fat in abdominal adipose tissue from other more labile pools. This phenomenon also was observed in Experiment 1 where higher proportional increases of IPDA incorporation after label withdrawal (42 vs. 49 d of age) occurred in abdominal and sartorial depot lipid relative to the higher incorporation observed in carcass lipid (28, 35 and 15%, respectively). These site differences could result either from modifications of the dietary fatty acid profile and the effect of *de novo* fatty acid synthesis by the liver before subsequent delivery to fat depots (33) or from mobilization of fatty acids from labile depots and redeposition in less labile depots. The thyromimetic triiodothyronine analog L-94901 also may have suppressed *de novo* triglyceride synthesis (28).

The depletion rates of IPDA and EA from adipose depots and carcass lipids were measured as a decline in total fatty acid marker content. The $t_{1/2}$ of fatty acids, IPDA and EA, were determined from functions of total mg fatty acid label in the tissue over the age of the birds. These data are presented graphically in Figures 1 and 2 for Experiments 1 and 2, respectively. Two stages of IPDA content are depicted in Figure 1. An IPDA loading phase occurred from 28 to 49 d corresponding to 7 d beyond which the IPDA-labeled diet was fed. A depletion phase followed from day 49 to 70 d of age when birds were fed the IPDA-free, unlabeled diet. Similar repletion (14 to 35 d) and depletion (35 to 49 d) phases were observed for EA over the course of Experiment 2 (Fig. 2). Measures of fatty acid dynamics can be obtained from data collected during the depletion phase (13–15) since IPDA and EA are used as energy sources like normal constituent saturated and unsaturated fatty acids.

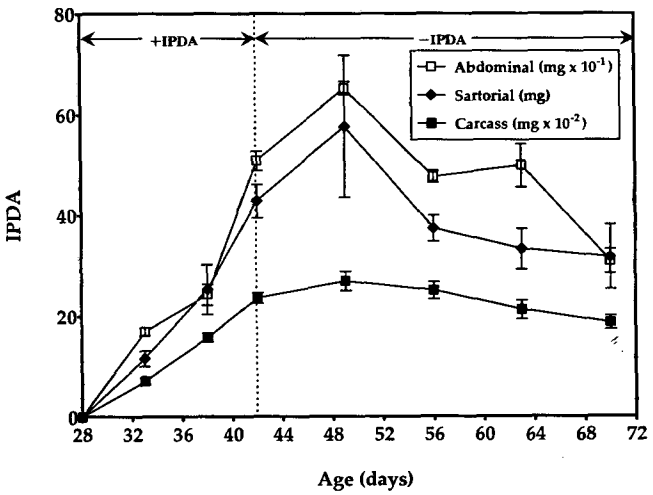

FIG. 1. Total isopentadecanoic acid (IPDA) content of adipose tissues (n = 3) as function of time for birds fed an IPDA-labeled diet from 4 to 6 wk of age followed by unlabeled diet to 10 wk of age.

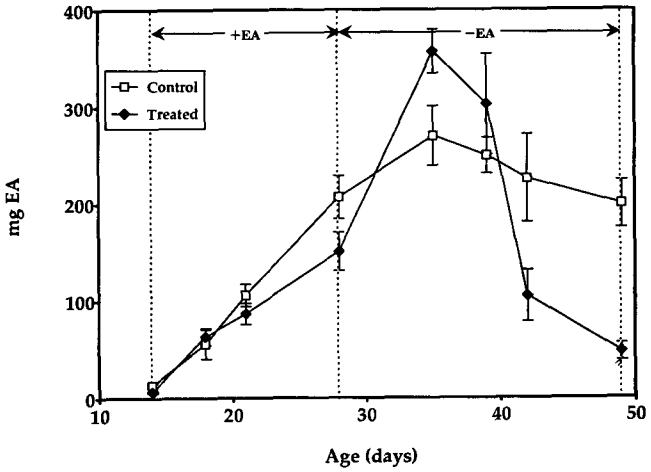

FIG. 2. Total elaidic acid (EA) content of abdominal fat pad (n = 3) as function of time. Control birds were fed an EA-labeled diet from 2 to 4 wk of age followed by 3 wk on unlabeled diet. Treated birds were fed the same diet as controls but containing 2 ppm of the thyromimetic L-94901.

The $t_{1/2}$ of IPDA and EA are listed in Table 4. For the abdominal and sartorial fat depots, $t_{1/2}$ of IPDA were 20 ± 4 and 23 ± 6 d, respectively. These values are not statistically different. For total carcass lipids, the $t_{1/2}$ of IPDA

TABLE 4

[e]Data for 14-day-old birds fed EA-labeled diet for two weeks followed by three weeks on unlabeled diet.
[f,g]Mean values within the same column with a letter in common are significantly different ($P < 0.05$) using analysis of variance contrasts.
[h]Birds fed as control except that EA-labeled diet and unlabeled diet contained 2 ppm of the tyromimetic L-94901.

was 27 ± 2 d, which is not significantly larger than the former half-lives. The $t_{1/2}$ for EA in abdominal adipose tissue of growing birds was 18 ± 3 and 6 ± 2 d for control and thyromimetic-treated birds, respectively. These $t_{1/2}$ are significantly ($P < 0.05$) different, which suggests that the thyromimetic L-94901 affects adipose tissue dynamics. The $t_{1/2}$ for IPDA determined in the adipose depots and carcass lipids of Experiment 1 are comparable to those reported for the rat in epididymal fat ($t_{1/2}$ = 18 d) (13) and for adipose tissue using other structurally isomeric fatty acids (34). In Experiment 2, the $t_{1/2}$ of elaidic acid found in abdominal tissue of control birds (18 d) was lower than the reported $t_{1/2}$ of EA in abdominal tissue for 11- to 21-week-old-chickens (29 d) reported by another laboratory (19). This difference may be due to the more rapid development and tissue turnover rates of fat depots in two- to seven-week-old birds as compared with older birds.

Turnover times (T), defined as the time required for a given amount of given fatty acid triglyceride to be removed from an adipose site, were calculated from the relationship $T = t_{1/2}/\ln 2 = 1/b$ where b is the slope of the exponential curve used to determine the $t_{1/2}$ of the fatty acid. This relationship assumes no exogenous source of the fatty acid during the measurement of the depletion phase of the study. Under this condition, T for IPDA and EA were measured as reported in Table 4. As with $t_{1/2}$, no differences in T for IPDA in the adipose tissues studied were observed with T on average being 30 d (Table 4). The T for EA in abdominal adipose tissue were statistically different ($P < 0.05$) for untreated and treated birds (20 ± 2 vs. 9 ± 3 d, respectively). These times are shorter than those found (18) for older birds where a T of 43 and 46 d was reported. The data indicate that coincident with rapid growth and fat depostion, significant amounts of triglyceride are mobilized in the growing chick. The data also suggest that the T3 analog L-94901 significantly affects the turnover rates of fatty acids in abdominal adipose tissue and affects fat pad growth.

Effects of Dietary Fat and Fatty Acids on Sterol Balance in Hamsters

Bertram I. Cohen*, Nariman Ayyad, Takahiro Mikami[1], Yasuko Mikami[1] and Erwin H. Mosbach

Departments of Surgery, Beth Israel Medical Center and the Mount Sinai School of Medicine of the City University of New York, New York, New York 10003

Sterol balance studies, using both isotopic and chromatographic techniques, were carried out in hamsters fed semipurified diets to detect changes in sterol metabolism during the early period of the lithogenic stimulus. The balance studies examined animals in the first two weeks on the experimental lithogenic diets. The variables were as follows: dose of cholesterol (group 1, 0.05% vs. group 2, 0.2%); dietary fat (fatty acid) (group 2, butterfat vs. group 4, palmitic acid); source of hamster [group 2, Sasco (Omaha, NE) vs. group 3, Charles River (Wilmington, MA)]; average weight of animals (group 4, 60 g vs. group 5, 119 g). Animals in groups 1, 2, 3 and 5 maintained almost constant weight throughout the two-week balance study. Liver and plasma cholesterol levels increased in groups 2–5 with increasing dose of dietary cholesterol. The highest levels were found in group 4 (liver cholesterol, 32.7 mg/g; plasma cholesterol, 367 mg/dL). Sterol balance measurements showed that bile acid synthesis remained low (range 0.55–1.01 mg/d) for all groups regardless of the intake of dietary cholesterol (range, 3.27–20.90 mg/d). The dietary cholesterol absorbed from the intestine (range, 2.91–18.91 mg/d) was stored in the liver; this storage was reflected in the negative values for cholesterol balance for all groups (range, –0.70 to –14.97 mg/d). These studies did not reveal any correlations between parameters of sterol balance and cholelithiasis.

***Lipids* 29, 503–508 (1994).**

The etiology of cholesterol cholelithiasis is probably multifactorial–metabolism of biliary lipids and proteins, the gallbladder and, indirectly, the diet all play a role in producing supersaturated bile, nucleating factors, vesicles, cholesterol crystals and stones (1–9). The systematic examination of factors believed to be important for the initiation/propagation of cholesterol cholelithiasis requires an effective and reliable animal model. Our laboratory has used the Sasco hamster (Omaha, NE), fed a nutritionally adequate semipurified diet (SPD) containing corn oil plus 4% butterfat and 0.3% cholesterol, for several reasons. First, animals fed this diet consistently had a cholesterol gallstone incidence of 50–60%, remained healthy and continued to grow (10–13). This was in contrast to animals fed fat-free lithogenic diets, which also form stones; however, many animals developed diarrhea, became ill and died during the experiment (14).

We have reported that cholesterol gallstones can be influenced by several factors, including (i) the intake of various dietary fats (12,13) and (ii) the source of hamster. A group of Sasco hamsters fed the SPD plus 0.3% cholesterol and 4% butterfat had a gallstone incidence of 63% (12). Replacement of butterfat with either olive oil, corn oil, menhaden oil or safflower oil prevented gallstone formation, whereas substitution of palmitic acid for butterfat intensified cholelithiasis (12). Animals from Charles River (Wilmington, MA), fed the identical lithogenic diet and treated in a similar manner, formed significantly fewer gallstones (10). The cholesterol metabolism/sterol balance in the hamsters from these two sources might be different, and this difference could alter cholelithiasis.

The sterol balance method was developed to provide a reliable estimate of cholesterol absorption, synthesis and turnover in the steady or near-steady state (15–23). The present study extends our preliminary sterol balance studies in hamsters (23) and examines in detail the effect of various factors as follows: (i) the effect of dose of cholesterol (0.05% vs. 0.2%) (group 1 vs. group 2), (ii) differences between strains (source) of hamster (group 2 vs. group 3), and (iii) cholesterol metabolism in animals with weights (ages) similar to those at the beginning (group 4) and at the end (group 5) of our gallstone prevention studies. Emphasis was placed on initial events (a two-week balance study) of our dietary manipulations prior to the development of cholesterol gallstones in this model. The data suggest that dietary fat (butter or palmitic acid) can produce an increase in plasma and liver cholesterol with little enhancement in endogenous bile acid synthesis. Cholesterol balance was a negative value, suggesting accumulation of dietary cholesterol in this model.

MATERIALS AND METHODS

Animals and diets. Male golden Syrian hamsters *(Mesocricetus auratus),* weighing either 57–66 g or 102–124 g, were purchased from Sasco, Inc. or from Charles River Breeding Lab. Animals were quarantined for one week after arrival. All animals (five per group) were placed in individual metabolic cages (Acme Research Products, Cincinnati, OH) for four days prior to the experiment, and fed powdered chow and water *ad libitum.* The cages used allow for quantitative recovery of feces from each hamster.

The methods were those commonly used for humans or rats, but with certain modifications necessary for the hamster (15–18). All food was finely ground and weighed every two days to allow accurate measure of food intake. On day 1 of the experiment, each hamster was injected intraperitoneally with 5 μCi of *R*-[2-^{14}C]mevalonolactone in sterile saline. Feeding of the experimental diet was begun immediately after the injection. All animals were maintained under similar conditions, using a 12-h light/dark cycle for the duration of the 14-d experiment. Feces were collected quantitatively on days 6, 8, 11 and 14 after isotopic labeling. Blood to measure the specific activity of serum cholesterol could not be collected *via* the tail vein as reported earlier (23), but was obtained by cannulation

Abbreviations: GLC, gas–liquid chromatography; PAD, palmitic acid diet; SPD, semipurified diet.

(under local anesthesia) of the jugular vein (days 8 and 11) (followed by electrocautery to minimize bleeding) and by cardiac puncture (day 14). At sacrifice (day 14), samples of bile and liver were obtained for determination of biliary cholesterol specific activity, liver cholesterol concentration and liver cholesterol specific activity.

Labeled compound. *R*-[2-^{14}C]Mevalonolactone (Amersham Corp., Arlington Heights, IL) in toluene was found to be greater than 98% pure by thin-layer chromatography on silica gel 60 using acetone/benzene (1:1, vol/vol). Solvents were evaporated under nitrogen, and the mevalonolactone was redissolved in sterile saline (5×10^6 dpm/0.5 mL).

Reference compounds. Cholesterol (Sigma Chemical Co., St. Louis, MO) was recrystallized from boiling ethanol. The material was dried *in vacuo* and stored under nitrogen. 5α-Cholestane (Alltech Associates, Inc., Deerfield, IL) was used as the internal standard for gas–liquid chromatography (GLC) when separating the neutral sterols and acidic steroids after preparation of the trimethylsilyl derivatives.

GLC. The methods and conditions were similar to those described earlier, with certain modifications (15,16). All analyses were carried out on a Hewlett-Packard (Palo Alto, CA) 5890A gas chromatograph equipped with a flame-ionization detector. The column used was a capillary Econo Cap SE-30 (30 m, 0.32 mm) (Alltech). Conditions for the analyses, including injector (265°C), detector (265°C) and oven temperature (245°C) were identical to those used for packed columns (15,16).

Preparation of diets. The diets fed to all groups were purchased from Dyets Inc. (Bethlehem, PA). They contained the following basic components: 43.7% corn starch, 20% casein, 14.6% dyetrose (soluble starch), 10% fiber (cellulose), 5% salt mix (modified U.S.P. XIV salt mix no. 200951), 2% corn oil, 0.5% vitamin mix (no. 300000), 0.2% choline chloride and 4% butterfat. This diet is defined as semipurified diet + 4% butterfat, or butterfat diet. Cholesterol and 1.2% palmitic acid (in place of butterfat) was added and the groups/diets defined as follows: group 1, butterfat diet + 0.05% cholesterol; groups 2 and 3, butterfat diet + 0.2% cholesterol; groups 4 and 5, palmitic acid diet (PAD) + 0.3% cholesterol.

Methods for the isolation and quantitation of neutral and acidic steroids. The analyses were carried out using procedures described earlier (17). Fecal samples (0.8–1.0 g) were dried, powdered and extracted with ethanol for 48 h. After evaporation to 20 mL, 2 mL of 10 N NaOH was added, and the samples were refluxed for 1 h. Water was added, and the neutral sterols were extracted with hexane (50 mL, 2×). The neutral sterols were quantitated by GLC using 5α-cholestane as an internal standard after preparation of the trimethylsilyl derivatives. The weight of each neutral sterol component was directly proportional to the area of the 5α-cholestane (17).

The aqueous solution containing the acidic steroids was evaporated to dryness, redissolved in 18 mL of water and brought to 2 N in respect to NaOH by addition of 10 N NaOH. The acidic steroids were hydrolyzed at 14–16 psi in an autoclave for 3 h. Each sample was cooled and the pH adjusted to 1–2 by addition of HCl. The bile acids were extracted once with 50 mL of Folch mixture, $CHCl_3$/MeOH (2:1, vol/vol), followed by 50 mL of chloroform. All samples were evaporated to dryness. Bile acid methyl esters and trimethylsilyl derivatives were prepared using conditions as described earlier (17,18). Total bile acids were quantitated by capillary GLC using conditions similar to those for packed columns. The helium flow rate was 35 mL/min. 3α,7α-Dihydroxy-12-keto-5β-cholanoic acid was used as quantitative internal standard.

Calculations (Refs. 19,23). Fecal neutral sterols and fecal acidic steroids (mg/g, mg/d) were determined by GLC. Cholesterol in the diet was assayed following extraction of the food (1–2 g) with ethanol using procedures similar to those used for fecal neutral sterols. Endogenous neutral sterols (mg/d) were calculated from the value for the total radioactivity in the neutral sterol fraction divided by the specific activity of the plasma cholesterol determined two days earlier. Cholesterol absorption was determined by the difference between the intake of dietary cholesterol (determined from analyses of food) and the unabsorbed neutral sterols. Cholesterol turnover was the total of endogenous neutral sterols (mg/d) plus total (endogenous) bile acids (mg/d). Cholesterol balance was the difference between cholesterol turnover and cholesterol absorption.

Statistics. The numerical data are expressed as mean ± SD. Differences between data in experimental groups were calculated using analysis of variance to determine the F statistic. When the F statistic was significant, the level of significance was determined by Student's *t*-test (24).

RESULTS

Sterol balance studies were undertaken to determine whether diets that were used for gallstone formation (containing either butterfat or palmitic acid, a major fatty acid component of butterfat) altered cholesterol absorption/synthesis in the hamster. We fed nutritionally adequate semipurified diets that were altered to examine various parameters as follows: (i) cholesterol absorption by varying the amounts of cholesterol (0.05% and 0.2%), group 1 vs. group 2; (ii) cholesterol absorption by varying dietary fat (fatty acid) and dose of cholesterol, group 2 vs. group 4; (iii) comparison of a hamster in which stones form readily (Sasco) to one in which few stones form (Charles River), group 2 vs. group 3; and (iv) comparison of cholesterol balance in Sasco hamsters that are four weeks old (and weigh about 60 g) to those that are eight weeks old (and weigh about 120 g), group 4 vs. group 5. Groups 4 and 5 were studied because gallstone incidence was significantly higher in younger vs. older hamsters fed identical diets for six weeks. It would be important to determine whether factors affecting cholesterol metabolism were related to this difference. The balance period in these studies was for two weeks (in which stones and crystals had not yet formed) vs. six weeks for our gallstone formation studies. Our goal was to evaluate early changes in cholesterol metabolism using diets that affect stone incidence. Animals in all groups maintained almost constant weight throughout the experiment; daily food intake ranged from an average of 7.1 g/d (group 2) to 11.0 g/d

TABLE 1

Effect of Dietary Cholesterol and Fatty Acids on Animal Weight, Food Intake and Fecal Output[a]

Group	Source	Diet	Initial weight (g)	Final weight (g)	Food intake[b] (g/d)	Fecal output[c] (g/d)
1	Sasco[d] (four weeks old)	Semipurified diet + 4% butterfat + 0.05% cholesterol	106 ± 10 (99–116)	105 ± 11 (94–120)	7.8 ± 1.3 (5.5–9.8)	1.1 ± 0.2 (0.7–1.5)
2	Sasco (four weeks old)	Butterfat diet + 0.2% cholesterol	87 ± 8 (76–96)	95 ± 10 (86–104)	7.1 ± 1.9 (1.0–9.1)	1.0 ± 0.3 (0.4–1.3)
3	Charles River[d] (four weeks old)	Butterfat diet + 0.2% cholesterol	86 ± 4 (83–94)	84 ± 12 (66–96)	8.4 ± 2.3 (5.5–12.1)	1.2 ± 0.3 (0.6–2.1)
4	Sasco (four weeks old)	Palmitic acid diet + 0.3% cholesterol	60 ± 4 (57–66)	80 ± 20 (59–102)	8.5 ± 2.8 (2.7–13.0)	1.0 ± 0.3 (0.4–1.5)
5	Sasco (eight weeks old)	Palmitic acid diet + 0.3% cholesterol	119 ± 7 (112–124)	124 ± 12 (106–134)	11.0 ± 2.4 (6.7–14.0)	1.2 ± 0.4 (0.3–1.8)

[a]Numbers are averages ± SD; numbers in parentheses represent the range. Butterfat diet = semipurified diet + 4% butterfat; palmitic acid diet = semipurified diet + 1.2% palmitic acid. See Materials and Methods section for components of the semipurified diet.

[b]A daily average for the 14-day experimental period.

[c]Determined from the feces collected on days 6, 8, 11 and 14 of the experiment.

[d]Hamsters from Sasco (Omaha, NE) or Charles River (Wilmington, MA).

(group 5). Daily fecal outputs were almost identical in all five groups (range of 1.0–1.2 g/d) (Table 1). The specific activities of cholesterol in liver, plasma and bile were similar in each group on the day of sacrifice (day 14). Neither cholesterol crystals nor stones were present in the bile of any of the animals. Animals fed butterfat (groups 1–3) had similar weight gain, food intake, and fecal output and remained as healthy as animals fed the PAD (groups 4 and 5).

Tissue cholesterol levels are summarized in Table 2. Plasma cholesterol was similar in hamsters fed diets containing either 0.05% cholesterol (group 1) or 0.2% choles-

TABLE 2

Effect of Dietary Cholesterol and Fatty Acids on Cholesterol Concentration in Body Tissues and Gallstone Formation[a]

terol (group 2, 192 vs. 208 mg/dL, respectively). There was no significant difference in plasma cholesterol for Sasco vs. Charles River animals (group 2 vs. group 3). Plasma cholesterol levels increased significantly with the addition of 1.2% palmitic acid plus 0.3% cholesterol to the diet; the increase in plasma cholesterol (compared to animals fed 0.05% cholesterol) was similar when the starting weights were either 60 g (group 4) or 119 g (group 5; 367 vs. 361 mg/dL, respectively). Animals fed palmitic acid plus 0.3% cholesterol had plasma cholesterol levels higher than those fed butterfat + 0.2% cholesterol, regardless of age (367 and 361, groups 4 and 5 vs. 208 and 212, groups 2 and 3, respectively). Liver cholesterol levels increased significantly in groups 2–5 vs. group 1 ($P < 0.01$), with several interesting differences and similarities between groups. Young Sasco hamsters (group 4) had significantly higher cholesterol levels compared to older animals (group 5) given the identical diet. Liver weights were similar and ranged from 4.9 g (group 1) to 6.1 g (group 3). These weights tended to be higher in the cholesterol-fed groups (groups 2–5). No significant difference in liver cholesterol was observed in Sasco or Charles River hamsters fed the identical diet and treated under identical conditions. The incidence of cholesterol gallstones (after six weeks of feeding) was different depending on fat, source of hamster, as well as the amount of dietary cholesterol. We previously studied animals similar to those of groups 1 and 3 (10,13); these animals were given 0.1 and 0.3% cholesterol instead of 0.05 and 0.2% cholesterol.

The effect of the various diets on sterol balance is summarized in Table 3. Dietary cholesterol (g/d) was 3.27 (group 1), 11.70 and 11.90 (groups 2 and 3), and 18.70 and 20.90 (groups 4 and 5). These doses were chosen to enable us to detect differences in cholesterol absorption that could (after six weeks) affect stone incidence. Regardless of the amount of dietary cholesterol absorbed, daily acidic steroid output remained low for all animals in all groups (range 0.55–1.01 mg/d). Quantitation of acidic steroids was obtained from GLC measurements as no exogenous bile acids were included in the diet. Daily endogenous fecal neutral sterols were determined isotopically using the specific activity of plasma cholesterol two days prior to feces collection. In all cases, endogenous neutral sterols exceeded acidic sterol output 1.5- to 4-fold. This value was highest in older male Sasco hamsters (group 5, 3.13 mg/d) fed palmitic acid and lowest in Sasco males fed 0.05% cholesterol (group 1, 1.42 mg/d) or young Sasco males fed palmitic acid (group 4, 1.42 mg/d). Endogenous neutral sterols were similar in groups fed butterfat (groups 1–3) vs. palmitic acid (groups 4 and 5).

Cholesterol absorption ranged from 67% (groups 2 and 3) to 89–90% (groups 1 and 5). No differences in cholesterol absorption were noted based on source (groups 2 and 3 vs. group 1) or age of hamster (group 4 vs group 5). Animals fed the palmitic acid diets (group 5) absorbed more of the dietary cholesterol (18.91 mg/d, 91% of total dietary cholesterol) than other groups.

Cholesterol turnover (measured by combined isotopic and chromatographic methods) ranged from 1.84 mg/d to 3.94 mg/d. Cholesterol balance was a negative value in all groups, indicating a net absorption and storage of cholesterol in body pools.

DISCUSSION

The sterol balance technique was originally designed to estimate daily cholesterol synthesis in humans (15,16). The methods were modified so that they could be used in

TABLE 3

Effect of Dietary Cholesterol and Fatty Acids on Sterol Balance in Hamsters[a]

Group	Source	Diet	Daily acidic steroid output (mg/d)	Daily neutral sterol output (mg/d)	Daily endogenous sterol output (mg/d)	Daily cholesterol absorption (mg/d)	Daily cholesterol intake (mg/d)	Daily cholesterol turnover (mg/d)	Daily cholesterol balance (mg/d)
1	Sasco (four weeks old)	Semipurified diet + 4% butterfat + 0.05% cholesterol	0.86 ± 0.37 (0.35–1.66)	1.39 ± 0.36[b] (0.62–2.06)	1.42 ± 0.49 (0.77–2.28)	2.91 ± 0.39[c] (2.52–3.64)	3.27 ± 0.54[c] (2.29–4.12)	2.21 ± 0.60 (1.17–3.56)	−0.70 ± 0.40[c] [+0.52–(−6.25)]

various animal models, such as the rat (17,18) and hamster (23). These animal models are useful for testing various synthetic and natural compounds using dietary modifications and administering new drugs in situations where human studies cannot be carried out. Our laboratory has reported that the hamster can form cholesterol gallstones in a reproducible and reliable manner in only 2–6 wk (10–13). The effect of the cholesterol diets (similar to those used to induce cholelithiasis) on total sterol balance has not been determined. The differences in stone formation observed between different hamsters might have their origin in differences in cholesterol metabolism. Consequently, we used the sterol balance method (modified for hamsters) to determine cholesterol absorption, endogenous sterol production and cholesterol balance in hamsters fed two lithogenic diets (butterfat + 0.2% cholesterol and palmitic acid + 0.3% cholesterol). The incidence of gallstones (after six weeks) when using butterfat + 0.2% cholesterol was almost identical to one using butterfat + 0.3% cholesterol (13). We felt it would be preferable to examine sterol balance at the lowest dose of dietary cholesterol where we could measure cholesterol absorption by using the methods of Quintão *et al.* (16).

Measurements of sterol balance are dependent on the following conditions (16)—constant plasma cholesterol concentration, unchanging fecal steroid output and constant body weight. All animals in our experiments fulfilled the first two criteria; constant body weight was maintained in all groups except in group 4 (the youngest of all groups at the start of the experiment). Nevertheless, group 4 is important for comparison because animals in this group are identical to those in which gallstone formation occurs within six weeks (10).

The measurement of endogenous neutral sterols required that we determine the specific activity of plasma cholesterol at three time points. In human studies, as well as in sterol balance studies in rats (where blood was obtained from the tail vein), this measurement is simple and required no special surgical procedures. However, we were unable to obtain blood from the tail vein of either Sasco or Charles River hamsters. Cardiac puncture frequently proved fatal. We abandoned these approaches and obtained blood via dissection of the jugular vein (under anesthesia) followed by electrocauterization to stop any excessive bleeding. No hamsters became ill or died as a result of this new procedure. The blood we obtained by this method was analyzed for cholesterol concentration and radioactivity in the usual manner. As in the rat, the specific activities of cholesterol in liver, plasma and bile were similar in all animals at sacrifice.

The balance studies were carried out for 14 d; this time frame enabled us to evaluate "early" changes in sterol metabolism and correlate these changes to stone development seen in previous studies (at six weeks) (10). Animals ingested an average of 8.6 g of food per day. Our earlier balance studies were carried out in rats (19) rather than in hamsters. There are several important differences between these two species—presence of a gallbladder in hamsters vs. none in rats, and ability of hamsters to absorb higher amounts of dietary cholesterol (24) and store this cholesterol in the liver as cholesteryl ester. In this regard, hamsters absorb more cholesterol per unit body weight than rats (19).

Animals in group 2 (Sasco males) and group 3 (Charles River males) were compared to determine whether source of hamster, which dramatically affected cholesterol cholelithiasis (10), also affected sterol balance. Acidic steroid output (mg/d) was higher in Sasco male hamsters compared to Charles River hamsters fed the identical diet (1.01 vs. 0.64 mg/d, $P < 0.02$). This value represents the daily bile acid synthesis in animals fed no exogenous bile acids and maintaining almost constant weight (25). When bile acid synthesis was calculated, values of 1.06 and 0.76 (mg/100 g animal/day), respectively, were obtained. The lower bile acid output in feces was associated with a lower biliary lipid concentration observed for the Charles River (Lakeview) hamster (10). The fecal bile acid output in the hamsters in this experiment fed SPD was considerably lower than that for the rat (17,18) and hamsters fed chow diets (23). The daily fecal output averaged 4–6 g/d for rats (17,18) and 2–3 g/d for hamsters fed chow diets. Fecal output in the current experiment averaged 1.0–1.2 g/d for hamsters fed SPD. We suggest that an increased absorption of bile acids in hamsters fed SPD resulted in an increased return of bile acids to the liver with decreased synthesis (as compared to chow diets) to maintain bile acid balance. The explanation, however, for the lower incidence of cholelithiasis in Charles River vs. Sasco hamsters was not immediately evident from differences in sterol balance.

Hamsters in all groups, with the possible exception of group 1, responded to the increased load of dietary cholesterol by absorbing this cholesterol and storing most of it in the liver. As a result, cholesterol balance (mg/d) was a negative value, reflecting no net synthesis but rather the storage of this dietary cholesterol. Presumably, cholesterol synthesis in groups 2–5 was completely inhibited by the doses of exogenous cholesterol fed to these animals. Interestingly, liver cholesterol levels were significantly lower for eight-week-old (group 5) vs. four-week-old (group 4) hamsters. This is reflected in the increased excretion of total neutral sterols and increased turnover of cholesterol in the older (group 5) animals. Because cholesterol absorption is higher for the older animals, it suggests increased mobilization of cholesterol prior to cholesterol excretion.

The balance studies attempted to elucidate any differences between animals fed palmitic acid + 0.3% cholesterol vs. those fed butterfat + 0.2% cholesterol. Daily acidic steroid output (synthesis in our studies) was significantly reduced with 1.2% palmitic acid in the diet (group 4) vs. animals where this component was not added (group 2) even though cholesterol absorption was almost doubled for group 2 vs. group 4. Interestingly, animals in group 4 excreted the least amounts of acidic steroids, neutral sterols and had the smallest cholesterol turnover (compared to animals in group 3 and in group 5). Animals in group 4, studied earlier under identical conditions and fed for six weeks, had the highest incidence of cholesterol stones (95%) (13). We have reported that animals fed palmitic acid + 0.3% cholesterol have elevated biliary cholesterol levels (when stones are present at week 6) com-

pared to animals fed butterfat + 0.2% cholesterol (4.99 vs. 3.70 mg/mL, respectively) (13). This suggests that the inability of the animals to compensate for the increased cholesterol load (by either fecal excretion or bile acid synthesis) may be a factor responsible for stone development.

In conclusion, the sterol balance method elucidated several important differences between the experimental groups, such as acidic steroid and neutral sterol output, and cholesterol turnover. Cholesterol absorption was greater than 50% (of cholesterol intake) in all animals. Net cholesterol balance was negative, showing an influx of cholesterol into body pools. There were no significant differences in sterol balance measurements in hamsters from Sasco as compared to those from Charles River. Whether observable differences exist with other fats or fatty acids remains to be elucidated.

The tropical marine sponge *Amphimedon terpenensis* (family Niphatidae, order Haplosclerida) has previously been shown to possess unusual lipids, including unusual fatty acids. The biosynthetic origin of these fatty acids is of interest as the sponge supports a significant population of eubacterial and cyanobacterial symbionts. The total fatty acid composition of the sponge was analyzed by gas chromatography/mass spectrometry of the methyl esters. Among the most abundant of the fatty acids in intact tissue were 16:0, 18:0 and 3,7,11,15-tetramethylhexadecanoic (phytanic) acid. In addition, three brominated fatty acids, (5*E*,9*Z*)-6-bromo-5,9-tetracosadienoic acid (24:2Br), (5*E*,9*Z*)-6-bromo-5,9-pentacosadienoic acid (25:2Br) and (5*E*,9*Z*)-6-bromo-5,9-hexacosadienoic acid (26:2Br) were also present. The three brominated fatty acids, together with phytanic acid, were isolated from both ectosomoal (superficial) and choanosomal (internal) regions of the sponge. Analysis of extracts prepared from sponge/symbiont cells, partitioned by density gradient centrifugation on Ficoll, indicated that phytanic acid and the three brominated fatty acids were associated with sponge cells only. Further, a fatty acid methyl ester sample from intact tissue of *A. terpenensis* was partitioned according to phospholipid class, and the brominated fatty acids were shown to be associated with the phosphatidylserine and phosphatidylethanolamine fractions that are commonly present in marine sponge lipids. The phosphatidylcholine and phosphatidylglycerol fractions were rich in the relatively shorter chain fatty acids (16:0 and 18:0). The association of brominated long-chain fatty acids (LCFA) with sponge cells has been confirmed. The findings allow comment on the use of fatty acid profiles in chemotaxonomy and permit further interpretation of LCFA biosynthetic pathways in sponges. The assignment of the sponge studied, which is currently placed as *A. terpenensis*, is being supported to some extent, but the species is unusual in having C_{25} fatty acids as the major constituent in this group. Other factors, such as season or microenvironmental conditions, may influence observed fatty acid composition which tends to reduce the usefulness of fatty acid profiles as markers in sponge chemotaxonomy.

***Lipids* 29, 509–516 (1994).**

Marine sponges have attracted the attention of lipid chemists because they frequently contain unconventional sterols with nuclear or side chain modifications, or possess high levels of fatty acids characterized by very long chains (VLFA, C_{24}–C_{34}). A number of the fatty acids isolated possess unusual functional groups such as hydroxy, methoxy, acetoxy or halogen substituents. The physiological role of such unusual lipid constituents is unclear, but they certainly separate sponges from other eukaryotes (1–4). The tropical marine sponge *Amphimedon terpenensis* (family Niphatidae, order Haplosclerida), which has been the subject of extensive chemical and biochemical study by our group in recent years (5–9), possesses a lipid composition unique even by sponge standards. Three features distinguish this species: (i) the presence of bioactive diterpene isonitriles, notably the major metabolite diisocyanoadociane (**1**) (10); (ii) the presence of low levels of Δ5,7-sterols, with conventional side chains, relative to terpene levels (7,8); and (iii) the presence of brominated long-chain fatty acids (LCFA), e.g., **2–4**, which we identified by two-dimensional nuclear magnetic resonance (NMR) spectroscopy (9). The structures of lipids **1–4** are all summarized in Figure 1. The absence of unusual sterols, together with the novel terpenes, suggested that the terpenes may play a primary role in membrane function in this sponge. This hypothesis is supported by observations that the terpene **1** was found to be associated with sponge cell membranes isolated from *A. terpenensis* and purified by differential centrifugation (8). This association is, however, complex and the degree to which the terpene substitutes for sterols appears to be related to sponge cell type. Larger archaeocytes and spherulocytes, in particular, exhibited higher membrane terpene concentrations relative to the smaller pinacocytes and collencytes. A unicellular cyanobacterium, possibly *Aphanocapsa feldmanni*, and numerous strains of eubacteria were also present within the sponge, and in varying concentrations in separated cell lines, although no correlations of bacterial density with terpene concentration were evident.

Abbreviations: CMF–ASW, calcium magnesium free artificial sea water; FAME, fatty acid methyl ester(s); GC, gas chromatography; GC/MS, gas chromatography/mass spectrometry; HPLC, high-performance liquid chromatography; LCFA, long-chain fatty acid; MS, mass spectrometry; NMR, nuclear magnetic resonance; PC, phosphatidylcholine; PE, phosphatidylethanolamine; PI, phosphatidylinositol; PS, phosphatidylserine; TEM, transition electron microscopy; VLFA, very long-chain fatty acid.

The association of bacterial symbionts with marine sponges represents a major problem in utilizing sterol (11–13) and terpene (14) profiles in sponge chemotaxonomy. The continued discovery of novel terpene and sterol components is, however, of great physiological and pharmacological significance and generates intriguing hypotheses concerning their possible biosynthetic origin. The lipid content of *A. terpenensis* is interesting in a chemotaxonomic sense as it does not clearly distinguish the species affiliation. It was therefore deemed prudent to confirm the origin of the unusual brominated fatty acids **2–4** as being associated with sponge or symbiont cells. The membrane structure of *A. terpenensis* is perhaps unique and, therefore, this sponge is deserving of a more detailed fatty acid compositional analysis. The fatty acid content of the differing sponge and microbial cell types in *A. terpenensis* was therefore evaluated by the following three experimental methods: (i) separation of cyanobacteria by dissection of surface tissue; (ii) separation of phospholipid types according to class; and (iii) separation of dissociated cells, using methods recently developed for marine sponges (9,15–18) to yield preparations of low and high density sponge cell types. The results of these studies are reported in this paper.

MATERIALS AND METHODS

Sponge collection. Seasonal variation in fatty acid content has been reported (4,19,20); therefore, all the samples used in this study were collected at the same time of year. Specimens of *A. terpenensis* (Australian Museum No. 4978) were collected near Townsville at -15 m from John Brewer Reef in November 1987 for intact tissue fatty acid analysis and preliminary cell separation. *A. terpenensis* was collected from Davies Reef in November 1989 for intact tissue fatty acid analysis, cell separation experiments and preparative isolation of fatty acids, and in November 1991 for analysis by phospholipid class. Sponges collected in November 1987 were place in aerated sea water maintained at ambient temperature while transported to the Sir George Fisher Centre for Tropical Marine Studies (Townsville, Australia), then placed in a small aquarium overnight at 18°C prior to the cell separation procedure. Samples selected for whole animal analysis were frozen for examination a few days later. Sponges collected in November 1989 were maintained in a flowing aquarium system at ambient temperature and with a normal light/dark regime at the Australian Institute of Marine Science for two days prior to cell separation. Unfortunately, this coincided with heavy sedimentation problems in this aquarium which effectively cut out all incident light. Sponges collected in November 1991 were maintained in a flowing aquarium system at ambient temperature and with a normal light/dark regime at the Australian Institute of Marine Science overnight before workup.

Chemicals and materials. Proteinase enzyme (No. P-2143), Ficoll type 400 and 14% BF_3-MeOH were purchased from Sigma Chemical Co. (St. Louis, MO). Calcium magnesium free artificial sea water (CMF–ASW) was prepared from doubly distilled water and contained 462 mM NaCl, 8.4 mM Na_2SO_4, 11 mM KCl and 2.1 mM $NaHCO_3$. All solvents were distilled prior to use or were of high-performance liquid chromatography (HPLC) grade (Mallinckrodt, Melbourne, Australia).

Cell separation. Method A: Dissection of whole sponge. Sponge tissue collected in November 1989 was carefully cleaned of all debris and separated into ectosomal tissue (66 g wet weight) and choanosomal tissue (70 g wet weight). A sample of intact animal tissue (380 g) was also retained for analysis. The three tissue samples were freeze-dried, then extracted and analyzed by gas chromatography (GC) for fatty acid methyl esters (FAME) as described previously (9).

Cell separation. Method B: Cell dissociation and density gradient separation. Cell separation of *A. terpenensis* was carried out on a sponge specimen (500 g wet weight, collected in November 1989) using previously described methods (8). The heavy sponge cell pellet (H_1) obtained by centrifugation of a dissociated sponge cell preparation at 600 × *g* at 10°C for 5 min (Damon IEC B-20A preparative centrifuge; Damon, Needham Heights, MA) was resuspended in a minimum volume of CMF–ASW and repelleted at 600 × *g* at 10°C for 5 min to remove bacterial and low density sponge cell contaminants prior to Ficoll treatment. The sponge cell pellet (H_2) obtained was divided into two portions; the major portion (90%) was resuspended in CMF–ASW, and cells were separated according to density by centrifugation (600 × *g* at 10°C) across discontinuous Ficoll gradients for 5 min. The bands of cells which accumulated at the interface between successive Ficoll fractions were isolated by pipette according to Figure 2, washed with CMF–ASW to remove Ficoll and pelleted (600 × *g* at 10°C for 5 min), then samples were taken for transmis-

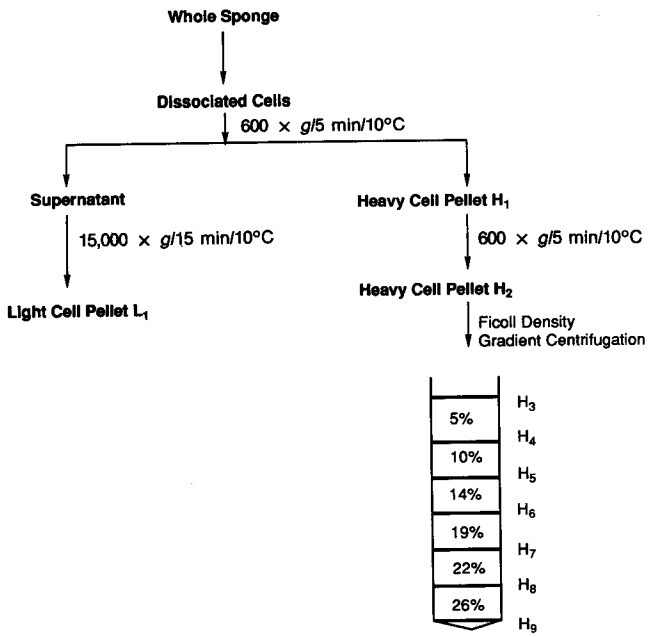

FIG. 2. Cell separation scheme using discontinuous Ficoll gradients. Capital letters with subscripts refer to cell pellets cited in text. Ficoll concentrations are weight percentage in calcium magnesium free artificial sea water.

sion electron microscopy (TEM). The two supernatants from H_1 and H_2 were combined and centrifuged at 15,000 × *g* at 10°C for 15 min to isolate a pelleted low density cell fraction L_1. The pellets H_3–H_9 and L_1 were lyophilized prior to chemical analysis. The minor portion of the sponge cell pellet H_2 (10%) was also lyophilized and then analyzed. Each pellet (approximate weight, 5–10 mg, except for H_7, <1 mg) was extracted with 3 × 1 mL of $CHCl_3$/MeOH (1:1, vol/vol). The soluble material was separated from other cellular debris by filtration through a small plug of glass wool and sand. The extract was dried under a stream of nitrogen, then treated with HCl-MeOH (1.4N; 1 mL) in screw-capped vials for 1 h at reflux. Solvents and reagents were azeotropically removed with toluene under a stream of nitrogen and the resulting material dissolved in toluene (0.25 mL) and passed through a 0.5 g florisil column eluting with toluene (3 mL). After evaporation of the solvent, the straw-colored extract was dissolved in hexane (0.25 mL) and passed through a 0.5 g silica (Anasil) column eluting with hexane (10 mL). The resulting clear solution was evaporated prior to GC analysis as before.

Analysis of sponge tissue by phospholipid class. A $CHCl_3$/MeOH (1:1 vol/vol) extract, prepared from 9 g of diced whole sponge (collected in November 1991), was concentrated *in vacuo*, dried azeotropically, and diluted to 15 mL with $CHCl_3$/MeOH. An aliquot (2 mL) was separated by preparative silica thin-layer chromatography under conditions ($CHCl_3$/MeOH/H_2O, 65:35:4, by vol) in which standard samples of phosphatidylethanolamine (PE), phosphatidylcholine (PC), phosphatidylserine (PS) and phosphatidylinositol (PI) gave R_f values of 0.76, 0.18, 0.55 and 0.46, respectively, using molybdenum blue for detection (18,21,22). Each phospholipid class was transmethylated with 1.4M HCl in MeOH and the resulting FAME mixture purified by Florisil chromatography, as described above, then analyzed by GC/mass spectrometry (GC/MS) using a Hewlett-Packard (Palo Alto, CA) 5890A instrument equipped with a 25 m (0.22 mm i.d.) bonded phase (BP_5) column (SGE, Melbourne, Australia) and a Hewlett-Packard 5970 series mass selective detector with helium as carrier gas.

Preparation of thin sections and electron microscopy. Whole animal tissue, ectodermal and choanodermal tissue, and cell pellets L_1 and H_2–H_9 were examined by TEM using methods detailed by Lawson *et al.* (22,23).

TABLE 1

Major Fatty Acids from the Phospholipids of *Amphimedon terpenensis*[a]

ECL	Fatty acid	Abundance	
14.00	Tetradecanoic (14:0)	0.3[b]	0.7[c]
14.62	13-Methyltetradecanoic (*iso*-15:0)	1.1	1.4

22.64[e]	21-Methyldocosanoic (*iso*-23:0)	[d]	0.6
22.74[e]	20-Methyldocosanoic (*anteiso*-23:0)	[d]	1.2
23.61[e]	5,9-Tetracosadienoic (24:2)	1.3	2.1
24.64[e]	5,9-Pentacosadienoic (25:2)	1.9	2.5
25.64[f]	5,9-Hexacosadienoic (26:2)	0.3	0.3
26.35[e]	6-Bromo-5,9-tetracosadienoic (24:2Br)	2.9	0.7
27.31[e]	6-Bromo-5,9-pentacosadienoic (25:2Br)	19.0	2.7
28.34[e]	6-Bromo-5,9-hexacosadienoic (26:2Br)	5.2	1.2

[a]By equivalent chain length (ECL). Minor peaks at ECL 17.06, 23.40, 24.30, 25.99, 26.80, 26.85 and 27.03 were not identified. Me16:0 and Me18:0 refer to mixtures of monomethyl-branched C_{17} and C_{19} fatty acids.
[b]November 1987 collection; HCl-MeOH.
[c]November 1989 collection; BF_3-MeOH.
[d]Less than 0.2% abundance.
[e]By ECL, nuclear magnetic resonance and mass spectrometry.
[f]By ECL and mass spectrometry.

RESULTS

Fatty acid analysis. The major FAME (C_9–C_{20}) were identified in standard fashion by establishing GC equivalent chain length values and by reference to the Hewlett-Packard Peak Library AEROBE, used previously for sponge fatty acid analysis (17,18,22,24). LCFA, >C_{20}, together with 3,7,11,15-tetramethylhexadecanoic acid (phytanic acid), were also isolated by HPLC, and the methyl esters and *N*-acyl pyrrolides were analyzed by NMR and MS (9,25). A summary of the fatty acids detected in *A. terpenensis* is presented in Table 1. In November 1987, the most abundant fatty acids were found to be 16:0 (5.9%), 18:0 (2.4%), phytanic acid (10.1%), the brominated fatty acids (24:2Br, 2.9%; 25:2Br, 19.0%; 26:2Br, 5.2%) and branched chain acids such as Me16:0 (1.9%) and Me18:0 (3.1%). A FAME sample, prepared using BF_3-MeOH rather than HCl-MeOH, from sponge material collected in November 1989, gave much lower abundances for the brominated fatty acids.

Distribution of fatty acids—dissection of whole sponge. Tables 2–4 show the percentage abundance of fatty acids between whole animal, superficial and choanosomal tissue. The data shown in Table 2 indicate that the two major acids in *A. terpenensis* are 25:2Br and phytanic acid, respectively, and brominated acids 24:2Br and 26:2Br are also present in significant quantity. All three brominated acids **2–4,** together with phytanic acid, are

TABLE 2

Distribution of Major Fatty Acids in *Amphimedon terpenensis*[a,b]

Fatty acid methyl esters	Whole animal (%)		Surface tissue (%)		Internal tissue (%)	
	HCl-MeOH[a]	BF_3-MeOH[b]	HCl-MeOH[b]	BF_3-MeOH[b]	HCl-MeOH[b]	BF_3-MeOH[b]
16:0	5.9	13.9	9.4	17.5	11.6	9.7
18:0	2.4	2.7	1.7	2.7	2.6	1.8
Phytanic	10.1	10.3	11.7	9.2	21.7	11.2
24:2Br	2.9	0.7	1.7	1.2	3.7	0.6
25:2Br	19.0	2.6	10.0	5.7	26.9	5.6
26:2Br	5.2	1.2	3.6	2.3	8.2	1.4

[a]November 1987 collection. [b]November 1989 collection.

found in both superficial and choanosomal tissue. The brominated fatty acids are sensitive to the use of BF_3-MeOH, as indicated by their much lower abundances (contrasted with higher abundances for the saturated fatty acids) in extracts prepared with this reagent as compared to use of 1.4M HCl in methanol. The percentages listed should be taken as minimum estimates of brominated fatty acid in samples prepared with BF_3-MeOH.

Table 3 lists the percentage abundances in *A. terpenensis* of fatty acids normally attributable to cyanobacteria (26,27), in particular C_{16} and C_{18} saturated and unsaturated acids. *Amphimedon terpenensis* whole tissue contains high levels of C_{16} acids, both saturated and unsaturated, and the ratio of 16:0 to 18:0 is >1, as expected for a sponge rich in cyanobacterial symbionts (17). The major unsaturated acid present is 16:1n-7, in accordance with our identification of a unicellular cyanobacterial symbiont similar to *Aphanocapsa* sp. (7,8). If the data are normalized to a percentage abundance of 10% for phytanic acid [c.f. method of Gillan *et al.* (26)], the relative abundances of acids such as 16:0, 18:0 and 16:1n-7, which characterize the cyanobacterial symbiont of *A. terpenensis*, are seen to be more prevalent in the superficial tissue, where the cyanobacteria are localized, than in the choanosomal tissue.

Table 4 lists the distribution of fatty acids in *A. terpenensis* which are normally attributed to bacterial symbionts in marine sponges (26,28–30). Apart from the monomethyl-branched fatty acids Me16:0 and Me18:0, none of the fatty acids characteristic of bacteria are present in significant amounts in whole animal tissue of *A. terpenensis*; most are present in amounts less than those of the typical cyanobacterial acids described above. The low levels of individual bacterial acids are not unexpected, given the diversity of bacterial types detected within the sponge in our previous TEM study. The branched chain FAME, other than *iso*-15:0, *iso*-16:0 and *iso*-19:0, were evenly distributed between superficial and choanosomal tissue, consistent with our previous work which had demonstrated the presence of bacteria in both tissue types (9). Bacterial symbionts are therefore not present in large enough quantities to dominate the fatty acid composition of *A. terpenensis*. During the HPLC purification of brominated fatty acid esters, a number of branched LCFA, such as *iso*-21:0, *anteiso*-21:0 and their 22:0 and 23:0 homologues, were isolated in small quantity and characterized by NMR and MS.

Distribution of fatty acids according to phospholipid class. The major phospholipids in *A. terpenensis* were PE, PC, PS and PI. The PC fraction, characteristic of eucaryotes (18), contained the standard fatty acids 16:0, 18:0 and 18:1, but no LCFA. The PE fraction and, to a lesser extent, the PI fraction contained the triad of brominated acids, while phytanic acid was located in the PE and PI fractions, but not in the PS or PC fractions.

TABLE 3

Distribution of Fatty Acids in *Amphimedon terpenensis* Which Are Normally Attributed to Cyanobacterial Symbionts

Fatty acid methyl esters	Whole animal (%)		Surface tissue[a] (%)		Internal tissue[a] (%)

No attempt was made to separate a phosphatidylglycerol fraction [characteristic of cyanobacteria and also the major phospholipid of gram positive bacteria (18)] from the PE fraction.

Distribution of fatty acids by cell type—cell dissociation and density gradient separation. Dissociation of sponge tissue and cell separation on the basis of density was accomplished using methods previously applied to *A. terpenensis* (8). As in the earlier work, the experimental conditions used damaged many cells, and small pellet samples were routinely obtained. Electron microscopy indicated that the dissociation process had yielded intact cells independent of the collagenous, extracellular matrix together with many cell fragments and other debris resulting from the dissociation process. Bacterial contamination of H_2, the dense sponge cell fraction, was low (less than 1%), whereas the low density cell fraction, L_1, was enriched in bacteria (6.4 ± 2.2%; mean ± SD) but also contained small sponge cells. After Ficoll separation of H_2, bacteria were located in H_3 (<1%) and H_5 (15.8 ± 1.3%). The specimen of *A. terpenensis* used contained lower levels of cyanobacteria than expected from previous work, possibly as a result of the sample having been stressed under the abnormal aquarium conditions. As a result, none of TEM samples H_1–H_9 showed significant levels of cyanobacteria; traces only were detected in H_2, H_6, and H_8. The fate of individual sponge cell types could not be determined completely as many of the pellets (H_3–H_9) contained much cell debris (10–30%, except for H_3 45%, H_5 66% and H_7 75%), most likely as a result of sponge cell lysis in the presence of proteinase in addition to disruption when in contact with Ficoll. The few intact cells in H_3–H_9 did not fix well, a problem that was also encountered in our previous work. Small rounded cells were noted in L_1, H_3 and H_4 (including unidentified vacuolated cells, possibly small spherulous cells) whereas H_6, H_8 and H_9 contained larger spherulous cells and archaeocytes. H_4 also contained archaeocytes. The only two fractions which were significantly different from those seen in our previous cell separation work were H_5 (containing many bacteria, no sponge cells, but possibly cell organelles and membrane material) and H_7 (with no sponge or symbiont types discernible).

Detailed chemical analysis was possible for all pellets created from Ficoll density gradient separation except H_7, for which the amount of pellet remaining after TEM sampling was very small. Extracts were methylated with MeOH-HCl and analyzed sequentially by GC using an automatic sampling program. Table 5 shows the percentage abundance of the major FAME in each cell preparation. The major fatty acid phytanic acid was present in all samples. There were larger amounts of phytanic acid in the denser sponge cell preparation (8.4% of FAME extract for H_2) as compared with the lighter cell preparation (5.1% of FAME extract for L_1); the highest

amounts of phytanic acid were located in H_3 and H_4 (11.8 and 15.4% of FAME extract as compared with 8.4% for H_2). The brominated fatty acids were also present in all cell preparations (percentages ranged from 20.8% of FAME extract for L_1 to 2.4% of FAME extract for H_6). The amounts of brominated acids in L_1 (for example, 20.8% for 25:2Br) were higher than the amounts in H_2 (11.2%), suggesting that the small rounded sponge cells in L_1 might contain these acids; when H_2 was partitioned by density gradient centrifugation, significant amounts of brominated fatty acid were present in fractions H_3–H_5. The pellets H_3 and H_4 had been identified by TEM as containing small rounded sponge cells. The electron micrographs also showed that H_3 contained insignificant numbers of eubacteria, H_4 was bacteria-free, while H_5 contained large quantities of bacteria. It is notable (Table 5) that cell pellet H_8, identified by TEM as a fraction containing archaeocytes, contained high levels of brominated fatty acids (7.3% for 25:2Br); therefore, heavier sponge cells may also contain these novel fatty acids. We attach little significance to the increased levels of brominated fatty acid in cell pellet H_9 as much of the material in this fraction represents reaggregated cells.

The amounts of 16:0, 18:0 and of other fatty acids, such as 16:1n-7, normally associated with cyanobacteria increased notably in H_5–H_8. Pellets H_6 and H_8 contained cyanobacteria as judged by TEM. The presence of cyanobacteria in H_5 and H_7 was not indicated by TEM, although the dark colors observed for these pellets (compared with cell preparations H_3 and H_4) was consistent with them containing cyanobacteria. The distribution of fatty acids usually attributed to bacteria in the sponge cell-enriched fractions H_3–H_9 was then compared with that in the bacteria-rich fraction L_1 (Table 5), and with the fatty acid composition of the whole animal (Table 4). Fraction L_1 contained amounts of typical bacterial fatty acids similar to those in whole animal, whereas these acids are generally present in smaller quantities in the dense cell preparation H_2, the only significant exception being *anteiso*-15:0, *anteiso*-17:0 and *anteiso*-19:0. The levels of Me16:0 and Me18:0 remained quite high in all the heavy cell pellets, but were not present in the same quantities as in whole animal.

DISCUSSION

There is now substantial evidence that marine sponges are sources of unusual fatty acids which are generally associated with the phospholipid fractions rather than other lipid fractions (1). In some recent cases, unusual fatty acids from marine sponges have been identified as membrane components (16,22–24). There have, however, been few studies on the lipid distribution according to cell type (16–18), even though an understanding of the cellular location of fatty acids is central to understanding their biosynthesis, their usefulness as chemotaxonomic markers and the physiological role of membrane constituents which potentially differentiate sponge cell membranes from other eukaryotic membranes. The major focus of our work was to determine whether the unusual triad of brominated LCFA were of sponge or symbiont origin. Cyanobacteria are not known to produce LCFA, and bacteria do not generally produce fatty acids with chain length >22:0 (28). Other possible symbionts, such as fungi or algae, were excluded from consideration as they were not apparent in light or TEM examination of sponge samples. The pigment patter for *A. terpenensis* is consistent with that elicited by a unicellular cyanobacterial symbiont and does not conform to any other algal type. Furthermore, brominated fatty acids have not yet been isolated from algae, although they have been isolated from a number of sponges of the orders Nepheliospongida, Haplosclerida, Halichondrida and Axinellida (25,31–41), each presumably with a different symbiont population. Sponges contain greater quantities of odd and branched fatty acids than do other plant or animal species, and contain the greatest range of unusual fatty acids of any phylum (1,19,20). All the brominated fatty acids isolated in our work possessed the Δ5,9*cis,cis* substitution pattern, which is characteristic of the VLFA ascribed to marine sponges (1,42). Therefore we hypothesized that brominated acids are located in sponge cells on both chemotaxonomic and phylogenetic grounds.

The experimental work described in this paper confirms that the suite of brominated fatty acids found in *A. terpenensis* are located in sponge cells rather than the diverse symbiont cell types associated with this sponge. Firstly, all three brominated acids were shown to be major components of both superficial and choanosomal tissues. The two tissue types both contain sponge cells, but differ in the nature of their symbiont populations. Fatty acids ascribed to cyanobacteria predominated in the superficial tissue whereas the range of fatty acids usually ascribed to eubacteria were present in low quantities in both superficial and choanosomal tissue, consistent with our previous electron microscopic identification of several morphologically distinct strains of eubacteria, each of which presumably has its own characteristic fatty acid composition. Secondly, the brominated fatty acids were found to be uniquely associated with the PE and PS classes. Lam *et al.* (25) isolated the C_{26} acid (**4**) from a Californian *Hymeniacidon* sp. and found that it was also a major component of the PE fraction. The association between sponge VLFA and amino-containing headgroups has been noted by other investigators (1,42,43). Finally, sponge cell preparations which were bacteria-free by TEM contained high levels of brominated acids. Fatty acids which are considered characteristic of bacterial or cyanobacterial symbionts showed distributions that were markedly different from those of the brominated acids in the cell preparations obtained; the fatty acid profile was generally consistent with the presence or absence of symbionts as determined by TEM.

The highest levels of brominated acids were associated with preparations (fractions L_1, H_3 and H_4) containing small sponge cells. Dissociated sponge cells commonly take on a more rounded shape than when present in whole tissue; this fact, together with the poor fixation which we have routinely encountered in our work on

A. terpenensis, prevented thorough morphological assignment of the cell types present. However, our earlier work has shown that these fractions might be expected to contain choanocytes and vacuolated cells (8), which together with the detection of increased levels of brominated acids in choanosomal tissue suggests that choanocytes may be the cell type which contains the brominated fatty acids. Although further analysis is required to confirm this possibility, our preliminary data are consistent with other reports in which purified choanocyte cells from *Tethya aurantia* and from *Pseudaxinyssa* sp. were shown to contain LCFA (17,18).

Biosynthetic experiments have shown that marine sponges can synthesize LCFA by chain elongation, followed by desaturation, of shorter chain (C_{14}, C_{16}) acids obtained from dietary sources or from symbionts (1). Precursor incorporation experiments by Lam *et al.* (25) on **4** established that bromination occurs at a late stage in the biosynthetic pathway, and this is consistent with the observation that brominated acids are of sponge origin as the chain elongation of short carbon chain fatty acid precursors is known to be carried out by the sponge host (1). The ability to introduce bromine into fatty acyl chains therefore appears to be a specific metabolic characteristic of sponge rather than of cyanobacterial or eubacterial cells. Bromination is most likely carried out on the preformed VLFA (perhaps by addition of Br_2 across a double or triple bond followed by elimination of HBr).

Phytanic acid is an isoprenoid fatty acid frequently isolated from marine sponges, but which has also been isolated from halophilic bacteria and is known to be transferred through marine food webs (43,44). In *A. terpenensis*, phytanic acid was shown to be a major constituent of the PE fraction. As aminophospholipids, such as PE and PS, have been found to predominate in sponge phospholipids (1,25), this suggested to us that phytanic acid is stored in sponge cells rather than in, or associated with, symbiont cells. Three other isoprenoid fatty acids have been isolated from marine sources. The fatty acid 4,8,12-trimethyltridecanoic acid has been demonstrated to be a component of the sponge cell population of *Pseudaxinyssa* sp., where it plays a structural role in membranes (17,22). This acid has also been useful as a taxonomic marker for sponges of the family Spirastrellidae (45). Carballeira and Maldonado (46) isolated a third isoprenoid acid, 3,7,11-trimethyldodecanoic acid, while Barnathan *et al.* (47) reported the isolation of 5,9,13-trimethyltetradecanoic acid. The increasing number of reports on the isolation of isoprenoid fatty acids from diverse sponge taxa with differing symbiont populations constitutes circumstantial evidence that these isoprenoid acids may be considered as a true component of sponge cells.

The use of fatty acids as a chemotaxonomic marker for sponges has been evaluated by Bergquist *et al.* (19), but is limited by seasonal, geographic and environmental variation (4,19,20). Furthermore, as our work, and that of others has shown, the fatty acid profile may be related to symbiont levels (18,26,42), although in many sponges the influence of symbionts may be minimal (19,48). Brominated fatty acids have been isolated previously from sponges of the families Nepheliospongidae (order Nepheliospongida), Hymeniacidonidae (order Halichondrida) and Agelasidae (order Axinellida) (25,31–41). The precise taxonomic status of the sponge used in this study is unclear as it shows certain taxonomic characteristics of the closely-related orders Nepheliospongida and Haplosclerida, but current information places the sponge as closest to the genus *Amphimedon* (order Haplosclerida) (49). Haplosclerid sponges are characterized by higher than average C_{27}–C_{30} acid levels, whereas sponges of the order Nepheliospongida are characterized by high levels of unsaturated LCFA, and by high C_{16} levels (19,20); some species are low in C_{17}–C_{23} acids (19). In its fatty acid composition, *A. terpenensis* shows many characteristics closely identified with nepheliospongids, but the sponge differs from other nepheliospongid species by having C_{25} as its major LCFA and in not containing measurable quantities of C_{27} acids. The levels of C_{25} acids in nepheliospongid species are usually lower than those of C_{27} acids (20). The recent report of brominated fatty acids from a Caribbean *Agelas* sp. (40) is of interest given that other sponges from this order contain isonitrile metabolites, as does *A. terpenensis*.

In an analysis of sponges of the genus *Amphimedon* from the Caribbean, Carballeira's group (50,51) found novel α-hydroxylated C_{22} and C_{23} acids, C_{23}, C_{25} and C_{27} monounsaturated acids together with C_{29} and C_{30} trienoic acids in *A. compressa*, while *A. complanata* was found to be rich in diunsaturated acids and in the rare eicosadienoic acids 6,11-20:2 and 11,15-20:2 (52). These two analyses differ significantly from those reported for the Australian *A. terpenensis*, highlighting the continued need to verify chemotaxonomic data with classical taxonomy and to examine further ecological influences on fatty acid variation within marine sponges.

ACKNOWLEDGMENTS

Financial assistance from the Australia Research Council (to Drs. Garson and Murphy), from the Royal Society (Marine Sciences grant to Dr. Garson), from the University of Wollongong (to Dr. Garson) and from NIH grants no. GM06840 and AM04257 (to Professor Carl Djerassi) is gratefully acknowledged. We thank Max Hoberg (Stanford University) and Karel Klika (The University of Queensland) for assistance with GC and GC/MS analyses, Rundi Larsen for preliminary cell separation work, Professor Carl Djerassi, Professor Pat Bergquist and Dr. Jane Fromont for useful discussions, and the Australian Institute of Marine Science for access to ship time.

[Received April 2, 1993, and in revised form May 14, 1994; Revision accepted May 16, 1994]

METHOD

Spectrophotometric Assay of 2,4-Dienoyl Coenzyme A Reductase with 5-Phenyl-2,4-pentadienoyl-Coenzyme A as Substrate

Mohamed A. Nada[1], **Khaled Shoukry** and **Horst Schulz***

Department of Chemistry, City College of the City University of New York, New York, New York 10031

The spectrophotometric assay of 2,4-dienoyl coenzyme A (CoA) reductase (EC 1.1.1.34) was modified to improve the linearity and sensitivity of this method. 5-Phenyl-2,4-pentadienoyl-CoA, which has an absorbance maximum at 340 nm with an extinction coefficient of 44,300 M^{-1} cm^{-1}, was synthesized and used as substrate. This compound is reduced by nicotinamide adenine dinucleotide phosphate (NADPH)-dependent 2,4-dienoyl-CoA reductase to 5-phenyl-3-pentenoyl-CoA. When a tissue homogenate serves as an enzyme source, the product is further metabolized by Δ^3,Δ^2-enoyl-CoA isomerase (EC 5.3.3.8) to 5-phenyl-2-pentenoyl-CoA, which is hydrated to 5-phenyl-3-hydroxypentanoyl-CoA by enoyl-CoA hydratase (EC 4.2.1.17). The modified assay method, which measures the decrease in absorbance at 340 nm due to the reduction of 5-phenyl-2,4-pentadienoyl-CoA and the oxidation of NADPH, is linear for a longer period of time and is twice as sensitive as the conventional assay with 2,4-decadienoyl-CoA as substrate.

***Lipids* 29, 517–521 (1994).**

2,4-Dienoyl coenzyme A (CoA) reductase (EC 1.3.1.34) functions in the β-oxidation of unsaturated fatty acids by reductively removing even-numbered double bonds such as, for example, the 12-*cis* double bond of linoleic acid (1). Linoleoyl-CoA is chain-shortened by β-oxidation to 4-*cis*-decenoyl-CoA, which is converted by medium-chain acyl-CoA dehydrogenase (EC 1.3.99.3) to 2-*trans*-4-*cis*-decenoyl-CoA. The latter compound is reduced by nicotinamide adenine dinucleotide phosphate (NADPH)-dependent 2,4-dienoyl-CoA reductase to 3-*trans*-decenoyl-CoA which, after conversion to 2-*trans*-decenoyl-CoA by Δ^3,Δ^2-enoyl-CoA isomerase (EC 5.3.3.8), can be completely degraded *via* the β-oxidation spiral. More recently, evidence was presented in support of a pathway by which odd-numbered double bonds, the 15-*cis* double bond of linolenic acid, for example, are also removed by 2,4-dienoyl-CoA reductase (2).

Further studies of 2,4-dienoyl-CoA reductase require a simple and sensitive assay method, especially as the specific activity of this enzyme in tissue extracts is low. The first report of a disorder of unsaturated fatty acid oxidation due to a deficiency of 2,4-dienoyl-CoA reductase (3) prompted the design of a sensitive radioactive assay of 2,4-dienoyl-CoA reductase (4). However, the need to synthesize [4*S*-^{3}H]NADPH for this assay limits its use. We therefore decided to improve the available spectrophotometric assay method, which is based on the measurement of NADPH oxidation at 340 nm, with either 2,4-decadienoyl-CoA or sorboyl-CoA as a substrate (5). By using 5-phenyl-2,4-pentadienoyl-CoA as a substrate, which has an absorbance maximum at 340 nm, the sensitivity and also the linearity of the assay method was improved.

EXPERIMENTAL PROCEDURES

Materials. Acyl-CoA oxidase from *Athrobacter* species, NADPH, CoA and other standard biochemicals were purchased from Sigma Chemical Co. (St. Louis, MO). Aldrich (Milwaukee, WI) was the source of 2-*trans*-4-*trans*-decadienal, *trans*-cinnamaldehyde and 4-*cis*-decenal. The following enzymes were purified or partially purified by the indicated procedures: enoyl-CoA hydratase or crotonase (4.2.1.17) from bovine liver (6), 2,4-dienoyl-CoA reductase from rat liver (7) and peroxisomal trifunctional enzyme from rat liver (8,9). 4-*cis*-Decenal and 2-*trans*-4-*trans*-decadienal were oxidized with Ag_2O to 4-*cis*-decenoic acid and 2-*trans*-4-*trans*-decadienoic acid, respectively, by a general procedure for the oxidation of aldehydes to acids that are sensitive to strong oxidizing agents (10). 5-Phenyl-2,4-pentadienoic acid was synthesized by reacting *trans*-cinnamaldehyde with malonic acid in the presence of pyridine using a general procedure described by Linstead *et al.* (11). In brief, 2.5 g of *trans*-cinnamaldehyde were mixed with 2 g of dry pyridine and then combined with 2 g of dry malonic acid. The mixture was kept for 48 h at 25°C and then heated at 80°C for approximately 8 h until CO_2 ceased to evolve. The reaction mixture was acidified with 50% (vol/vol) H_2SO_4 and extracted with diethyl ether. The ether phase was extracted several times with 10% (wt/vol) Na_2CO_3. The aqueous solution was acidified with 50% (vol/vol) H_2SO_4 and extracted with diethyl ether. After drying the ether phase over anhydrous Na_2SO_4, the ether was removed under reduced pressure. 5-Phenyl-2,4-pentadienoic acid was obtained in approximately 50% yield. The acid crystallized at –20°C from petroleum ether (b.p. 37–52°C)/diethyl ether in the form of white needles with an m.p. of 166–168°C (literature m.p. 166–167°C) (12). CoA thioesters of 2-*trans*-4-*trans*-decadienoic acid, 4-*cis*-decenoic acid and 5-phenyl-2,4-pentadienoic acid were prepared by the mixed anhydride procedure as detailed by Fong and Schulz (13). Acyl-CoA compounds used for spectral or high-performance liquid chromatography (HPLC) analyses were purified by HPLC, whereas their use as substrates in enzyme assays did not require any purification. The concentrations of all acyl-CoA solutions,

Abbreviations: A, absorbance; CoA, coenzyme A; HPLC, high-performance liquid chromatography; NADPH, nicotinamide adenine dinucleotide phosphate, reduced form; P_i, phosphate; U, unit; UV, ultraviolet.

including 5-phenyl-2,4-pentadienoyl-CoA, were determined by quantifying free CoA by the Ellman procedure (14) after completely cleaving the thioester bond with 1M hydroxylamine at pH 7 (13). 2-*trans*-4-*cis*-Decadienoyl-CoA was prepared from 4-*cis*-decenoyl-CoA by acyl-CoA oxidase under aerobic conditions as described previously (15), except that catalase was omitted from the incubation mixture. The ultraviolet (UV) spectrum of HPLC-purified 5-phenyl-2,4-pentadienoyl-CoA showed two broad peaks centered around 260 and 340 nm. The ratio of A_{340}/A_{260} was 1.95. The extinction coefficient of the absorbance peak at 340 nm was 44,300 M^{-1} cm^{-1}. Liver mitochondria were isolated according to a general procedure (16). For the preparation of a soluble extract, rat liver mitochondria were sonicated ten times for 8 s each with a Heat Systems (Plainview, NY) sonifier (Model W-385) equipped with a microtip and centrifuged at 105,000 × *g* for 1 h. The supernatant served as a source of soluble mitochondrial enzymes.

Assays of 2,4-dienoyl-CoA reductase and protein. 2,4-Dienoyl-CoA reductase was assayed spectrophotometrically by measuring the absorbance change at 340 nm with a Gilford (Oberlin, OH) Model 250 recording spectrophotometer at 25°C. Absorbance scans of the UV region were recorded with a microprocessor-controlled Gilford 2600 UV-VIS spectrophotometer equipped with a graphics plotter. The assay mixture (1 mL) contained 0.2 M KP_i (P_i, phosphate) (pH 8), 0.1 mM NADPH, 25 μM 2-*trans*-4-*trans*-decadienoyl-CoA or 25 μM 2-*trans*-4-*cis*-decadienoyl-CoA or 25 μM 5-phenyl-2,4-pentadienoyl-CoA and partially purified 2,4-dienoyl-CoA reductase (4–10 μg of protein), or a soluble extract of rat liver mitochondria (40–100 μg of protein) to give an absorbance change of 0.01 to 0.025 A/min. The assay was started by the addition of enzyme. One unit (U) of enzyme activity is defined as the amount of enzyme that catalyzes the conversion of 1 μmol of substrate to product per min. Protein concentrations were determined by the dye binding assay as described by Bradford (17), with bovine serum albumin as standard.

HPLC analysis and purification of acyl-CoA. Prior to analysis by HPLC, incubations were terminated by acidification to pH 1–2 with conc. HCl. Samples were filtered through 0.22 μm (pore size) membranes, after which the pH was adjusted to 5 with 4N KOH. The filtrates were applied to a Waters (Milford, MA) μBondapak C_{18} reverse-phase column (30 cm × 3.9 mm) attached to a Waters gradient HPLC system. The absorbance of the effluent was monitored at 254 nm. Separation was achieved by linearly increasing the acetonitrile content of the 25 mM ammonium P_i elution buffer (pH 5.5) from 20 to 80% in 20 min at a flow rate of 2 mL/min. When acyl-CoA was purified by HPLC, fractions containing the compound of interest were concentrated at room temperature on a rotary evaporator under reduced pressure generated by a water aspirator.

RESULTS AND DISCUSSION

2,4-Dienoyl-CoA reductase, which is an essential enzyme for the β-oxidation of unsaturated fatty acids, is routinely assayed by measuring the substrate-dependent oxidation of NADPH spectrophotometrically at 340 nm. Because the specific activity of this enzyme in tissue extracts is as low as 13 mU/mg in human liver (3), 4.6 mU/mg in human muscle (3) and 3.4 mU/mg in bovine liver (4), the sensitivity of the spectrophotometric assay with 2,4-decadienoyl-CoA as a substrate is frequently insufficient, especially when only small tissue samples are available. In an attempt to increase the sensitivity of the convenient spectrophotometric assay method, we set out to design and synthesize a substrate with an absorbance maximum close to that of NADPH at 340 nm and with a large extinction coefficient. 2,4,6-Octatrienoyl-CoA, which has an absorbance maximum at 337 nm with an extinction coefficient close to 50,000 M^{-1} cm^{-1}, was previously shown to be a substrate of 2,4-dienoyl-CoA reductase (7). However, this compound is not very stable and, hence, it was decided to synthesize and evaluate (as a reductase substrate) a compound that has a phenyl group in conjugation with the basic 2,4-dienoyl-CoA chromophore. These considerations prompted the synthesis of 5-phenyl-2,4-pentadienoyl-CoA, which has an absorbance maximum at 340 nm with an extinction coefficient of 44,300 M^{-1} cm^{-1} and which was found to be more stable than the commonly used substrate 2,4-decadienoyl-CoA. 5-Phenyl-2,4-pentadienoic acid was conveniently synthesized from *trans*-cinnamaldehyde and malonic acid in the presence of pyridine (11). Because the condensation reaction results in the formation of a *trans* double bond, 5-phenyl-2,4-pentadienoic acid prepared by this method was expected to have a *trans,trans* configuration. This assumption was confirmed by its melting point of 166–167°C, which is close to that reported for the *trans,trans* isomer (12).

When 5-phenyl-2,4-pentadienoyl-CoA was incubated with NADPH in the presence of 2,4-dienoyl-CoA reductase, the absorbance at 340 nm due to both substrates with a combined extinction coefficient of 50,500 M^{-1} cm^{-1}

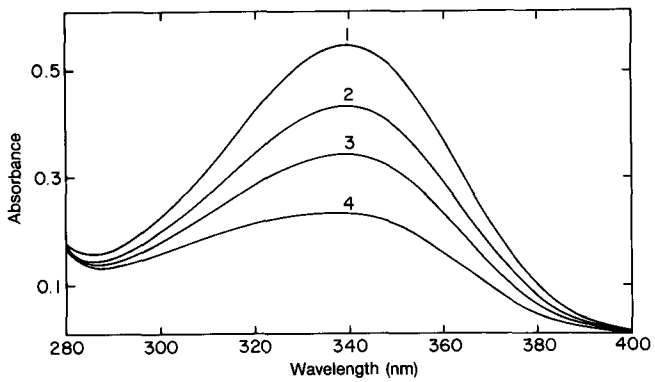

FIG. 1. Spectral changes associated with the reduction of 5-phenyl-2,4-pentadienoyl-coenzyme A (CoA) by nicotinamide adenine dinucleotide phosphate (NADPH) catalyzed by 2,4-dienoyl-CoA reductase. Curve 1, prior to the addition of 2,4-dienoyl-CoA reductase; curve 2, 3 min; curve 3, 8 min; curve 4, 30 min after initiation of the reaction. The reaction mixture contained 0.2 M KP_i (pH 8.0), 0.1 mM NADPH, 12.5 μM 5-phenyl-2,4-pentadienoyl-CoA, and partially purified 2,4-dienoyl-CoA reductase (15 μg/mL). The reference cuvette contained the same mixture, except that 5-phenyl-2,4-pentadienoyl-CoA was omitted.

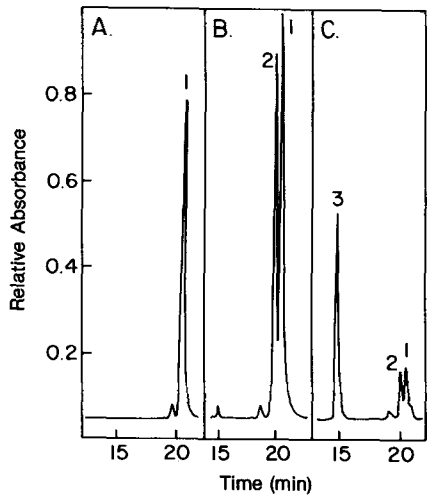

FIG. 2. High-performance liquid chromatography analysis of metabolites formed from 5-phenyl-2,4-pentadienoyl-CoA by 2,4-dienoyl-CoA reductase or by a soluble extract of rat liver mitochondria. A, 5-Phenyl-2,4-pentadienoyl-CoA; B, product formed from 5-phenyl-2,4-pentadienoyl-CoA by partially purified 2,4-dienoyl-CoA reductase in the presence of NADPH; C, metabolites formed when 5-phenyl-2,4-pentadienoyl-CoA was incubated with a soluble extract of rat liver mitochondria in the presence of NADPH. Peak 1, 5-phenyl-2,4-pentadienoyl-CoA; peak 2, 5-phenyl-3-pentenoyl-CoA or 5-phenyl-2-pentenoyl-CoA; peak 3, 5-phenyl-3-hydroxypentanoyl-CoA. For details about the assay, see Experimental Procedures section. Abbreviations as in Figure 1.

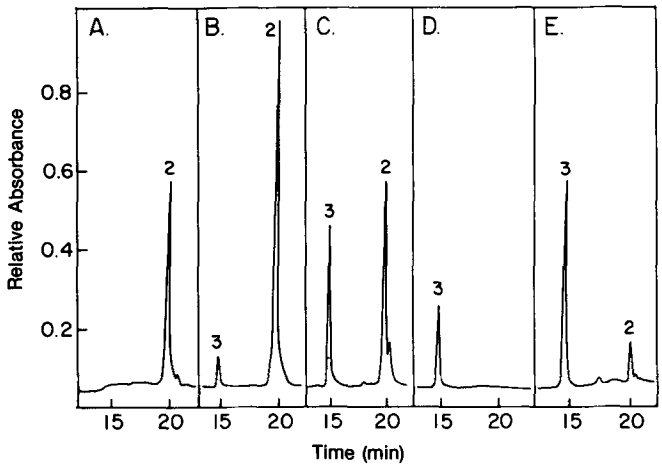

FIG. 3. High-performance liquid chromatography (HPLC) identification of metabolites formed from 5-phenyl-2,4-pentadienoyl-CoA by enzymes of β-oxidation. A, HPLC-purified 5-phenyl-3-pentenoyl-CoA formed from 5-phenyl-2,4-pentadienoyl-CoA by partially purified 2,4-dienoyl-CoA reductase in the presence of NADPH; B, after incubation of 5-phenyl-3-pentenoyl-CoA with purified crotonase (0.25 μg/mL); C, after incubation of 5-phenyl-3-pentenoyl-CoA with peroxisomal trifunctional enzyme (3.5 μg/mL); D, HPLC-purified 5-phenyl-3-hydroxypentanoyl-CoA; E, after incubation of 5-phenyl-3-hydroxypentanoyl-CoA with purified crotonase. Peak 2, 5-phenyl-3-pentenoyl-CoA or 5-phenyl-2-pentenoyl-CoA; peak 3, 5-phenyl-3-hydroxypentanoyl-CoA. Abbreviations as in Figure 1.

decreased in a time-dependent manner (Fig. 1). When partially purified 2,4-dienoyl-CoA reductase was used, only one product was identified by HPLC (Fig. 2B). This compound, which was eluted slightly ahead of the substrate 5-phenyl-2,4-pentadienoyl-CoA (Fig. 2B), was assumed to be 5-phenyl-3-pentenoyl-CoA because both mitochondrial isoforms of the reductase catalyze the reduction of 2,4-dienoyl-CoA to 3-*trans*-enoyl-CoA (1,18). When a soluble extract of rat liver mitochondria served as a source of 2,4-dienoyl-CoA reductase, most of the product was a more polar compound (Fig. 2C). This compound was presumed to be 5-phenyl-3-hydroxypentanoyl-CoA, because 5-phenyl-3-pentenoyl-CoA would be converted to 5-phenyl-3-hydroxypentanoyl-CoA by the sequential actions of Δ^3,Δ^2-enoyl-CoA isomerase and enoyl-CoA hydratase (crotonase) present in the mitochondrial extract. The product formed from 5-phenyl-2,4-pentadienoyl-CoA by partially purified 2,4-dienoyl-CoA reductase was purified by HPLC (Fig. 3A). When this compound, presumably 5-phenyl-3-pentenoyl-CoA, was incubated with enoyl-CoA hydratase (crotonase), most of it remained unchanged except for a small amount that was converted to the more polar compound (Fig. 3B). The formation of the latter compound was most likely due to the presence of a residual amount of Δ^3,Δ^2-enoyl-CoA isomerase in the preparation of purified crotonase. However, when the reduction product was incubated with the peroxisomal trifunctional enzyme, which contains enoyl-CoA hydratase, 3-hydroxyacyl-CoA dehydrogenase and Δ^3,Δ^2-enoyl-CoA isomerase activities (8,9), a significant part of the compound was converted to the polar compound (Fig. 3C). Together, these observations support the conclusion that the product formed by reduction of 5-phenyl-2,4-pentadienoyl-CoA is 5-phenyl-3-pentenoyl-CoA, which cannot be hydrated by enoyl-CoA hydratase. However, if the reduction product is first isomerized to 5-phenyl-2-pentenoyl-CoA by Δ^3,Δ^2-enoyl-CoA isomerase present in the mitochondrial extract or associated with the trifunctional enzyme, it can be hydrated to 5-phenyl-3-hydroxypentanoyl-CoA by the enoyl-CoA hydratase activity present in the extract or associated with the trifunctional protein. The identity of the polar reaction product, presumed to be 5-phenyl-3-hydroxypentanoyl-CoA, was established by purifying (Fig. 3D) and incubating it with crotonase. Part of the compound was dehydrated to 5-phenyl-2-pentenoyl-CoA, which was eluted from the HPLC column at the same position where 5-phenyl-3-pentenoyl-CoA emerged (compare Fig. 3A and 3E). The relative intensities of peaks 3 and 2 (Fig. 3E) agree with the equilibrium ratio of 3.2 reported for hydrated vs. dehydrated forms of 2-enoyl-CoA (19).

The above characterization of products establishes that the NADPH-dependent reduction of 5-phenyl-2,4-pentadienoyl-CoA (Fig. 4, compound **1**) by 2,4-dienoyl-CoA reductase present in a soluble extract of rat liver mitochondria initially yields 5-phenyl-3-pentenoyl-CoA (Fig. 4, compound **2**). However, as other β-oxidation enzymes are present in the tissue homogenate, 5-phenyl-3-pentenoyl-CoA will be converted to 5-phenyl-2-pentenoyl-CoA (Fig. 4, compound **3**) by Δ^3,Δ^2-enoyl-CoA isomerase, and the latter compound will be partially hydrated by enoyl-CoA hydratase to 5-phenyl-3-hydroxypentanoyl-CoA (Fig. 4, compound **4**). None of the reactions subsequent to

METHOD

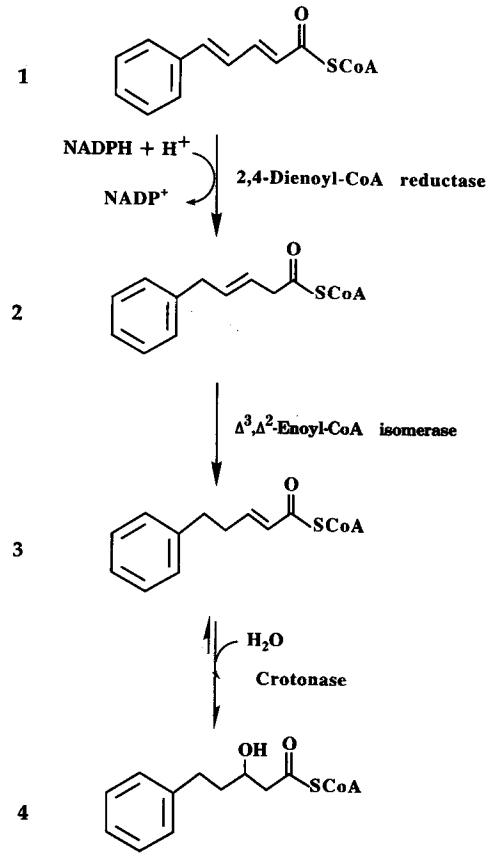

FIG. 4. NADPH-dependent reduction of 5-phenyl-2,4-pentadienoyl-CoA and subsequent β-oxidation reactions catalyzed by a soluble extract of rat liver mitochondria. 1, 5-Phenyl-2,4-pentadienoyl-CoA; 2, 5-phenyl-3-pentenoyl-CoA; 3, 5-phenyl-2-pentenoyl-CoA; 4, 5-phenyl-3-hydroxypentanoyl-CoA. Abbreviations as in Figure 1.

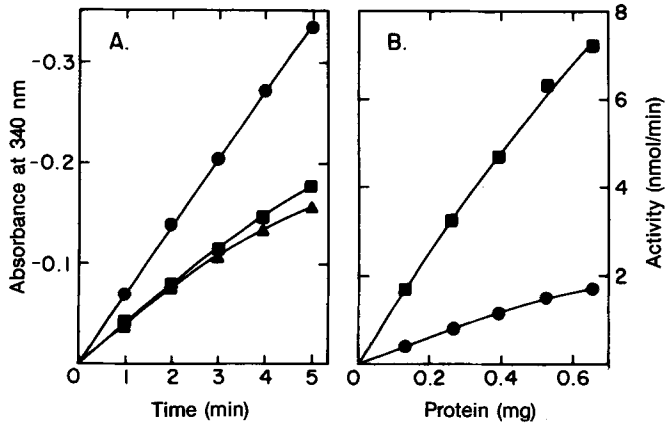

FIG. 5. NADPH-dependent reduction of 5-phenyl-2,4-pentadienoyl-CoA or 2,4-decadienoyl-CoA by 2,4-dienoyl-CoA reductase present in a soluble extract of rat liver mitochondria. A, absorbance change at 340 nm as a function of time. The reaction mixture (1 mL) contained 0.2 M KP_i (pH 8), 0.1 mM NADPH, 0.12 mg of mitochondrial protein and either 25 μM 5-phenyl-2,4-pentadienoyl-CoA (●), or 25 μM 2-*trans*-4-*cis*-decadienoyl-CoA (■), or 25 νM 2-*trans*-4-*trans*-decadienoyl-CoA (▲); B, activity of 2,4-dienoyl-CoA reductase as a function of soluble mitochondrial protein from rat liver, with 2-*trans*-4-*cis*-decadienoyl-CoA (■) or 5-phenyl-2,4-pentadienoyl-CoA as substrate (●). Assay conditions were identical to those given under A. Abbreviations as in Figure 1.

the reduction of 5-phenyl-2,4-pentadienoyl-CoA are contributing to the absorbance change at 340 nm. If NAD^+ were present in the incubation mixture, 5-phenyl-3-hydroxypentanoyl-CoA might be oxidized by 3-hydroxyacyl-CoA dehydrogenase to yield NADH, and thereby give rise to an increase in the absorbance at 340 nm.

When 2,4-dienoyl-CoA reductase, present in a soluble extract from rat liver mitochondria, was assayed with 5-phenyl-2,4-pentadienoyl-CoA and for comparison with 2-*trans*-4-*trans*-decadienoyl-CoA or 2-*trans*-4-*cis*-decadienoyl-CoA as substrates, the results shown in Figure 5 were obtained. With 5-phenyl-2,4-pentadienoyl-CoA as substrate, the change in absorbance at 340 nm as a function of time was linear for at least 5 min. By contrast, the progress curves obtained with the other two substrates deviated from linearity almost immediately after the reaction was initiated. Consequently, reliable values for initial velocities could not be obtained with 2,4-decadienoyl-CoA thioesters as substrates. The decline in rates seen toward the end of the reaction (Fig. 5A) was due to substrate depletion. The greater linearity of the novel assay is partly due to the greater absorptivity of the substrate. Thus, the amount of 5-phenyl-2,4-pentadienoyl-CoA that must be converted to product to obtain a certain absorbance change is only one-eighth of the amount of 2,4-decadienoyl-CoA. This situation greatly reduces the likelihood that nonlinear progress curves will be obtained with the modified assay method. Another advantage of the novel assay procedure is that under identical conditions the absorbance change with 5-phenyl-2,4-pentadienoyl-CoA as substrate is twice the change obtained with either of the isomeric 2,4-decadienoyl-CoA thioesters (Fig. 5A). However, when reductase activities are calculated from absorbance changes, a different picture is obtained. As shown in Figure 5B, the reductase activity with 2-*trans*-4-*cis*-decadienoyl-CoA as substrate is almost four times higher than with 5-phenyl-2,4-pentadienoyl-CoA. The apparent difference between the results shown in Figure 5 (A and B) is due to different extinction coefficients at 340 nm associated with the reduction of 5-phenyl-2,4-pentadienoyl-CoA by NADPH (ε = 50,500 M^{-1} cm^{-1}) and of 2,4-decadienoyl-CoA by NADPH (ε = 6,220 M^{-1} cm^{-1}). What is crucial, when the sensitivity of the assay method is considered, is the greater absorbance change with 5-phenyl-2,4-pentadienoyl-CoA as a substrate as compared to the conventional assay with either isomer of 2,4-decadienoyl-CoA. Kinetic parameters (K_m, V_{max}) were determined for the reduction of 5-phenyl-2,4-pentadienoyl-CoA and 2-*trans*-4-*cis*-decadienoyl-CoA by 2,4-dienoyl-CoA reductase at a fixed concentration of 0.1 mM NADPH. The apparent K_m values for 5-phenyl-2,4-pentadienoyl-CoA (9.5 μM) and 2-*trans*-4-*cis*-decadienoyl-CoA (9.1 μM) were virtually identical, whereas the maximal velocity with the new substrate was eight times slower (0.1 U/mg) than the V_{max} (0.8 U/mg) of the conventional assay.

The modified spectrophotometric assay of 2,4-dienoyl-CoA reductase described in this report represents an im-

provement over the currently used method due to the greater absorbance change that remains linear for a longer period of time. As 5-phenyl-2,4-pentadienoyl-CoA and 2,4-decadienoyl-CoA are prepared by two-step syntheses of equal difficulty, the modified method is recommended for routine assays of 2,4-dienoyl-CoA reductase.

COMMUNICATION

Positional Distribution of Octadecadienoic Acids in Sponge Phosphatidylethanolamines

Néstor M. Carballeira*, Anastacio Emiliano and **Reginald Morales**

Department of Chemistry, University of Puerto Rico, San Juan, Puerto Rico 00931-3346

The distribution of C14–C22 fatty acids in the phosphatidylethanolamines isolated from the sponges *Agelas* sp. and *Spongia tampa* was investigated. Selective changes with phospholipase A_2 (from *Agkistrodon halys blomhoffii*) followed by thin-layer chromatographic separation of the resulting lysophosphatidylethanolamines and free fatty acids and subsequent methylation with HCl/MeOH and diazomethane, respectively, revealed that the 5,9-octadecadienoic acid and the 9,12-octadecadienoic acid present showed no preference for either position *sn*-1 or *sn*-2 in these phosphatidylethanolamines. The other saturated and unsaturated fatty acids with chains between 14 and 22 carbons long were also found to be equally distributed between positions *sn*-1 and *sn*-2 in the phosphatidylethanolamines in these sponges. The results contrast with what is known about the distribution in most mammalian phospholipids, such as the phosphatidylcholines from human erythrocytes, where octadecadienoic acid typically occupies the *sn*-2 position.

***Lipids* 29, 523–525 (1994).**

There is little information available on the positional distribution of fatty acids (FA) in the phospholipids of marine organisms (1). However, some interesting species differences in the distribution of individual phospholipid FA have been reported. For example, docosahexaenoic acid has been shown to exclusively occupy the *sn*-2 position in the phospholipids from whale and lobster (1), while in phosphatidylcholines (PC) from muscle of salmon and tuna, more than 40% of this acid was found at the *sn*-1 position (2). Oleic acid has also been found in some species of whale to occupy the *sn*-1 position in PC whereas in cod and scallop muscle, oleic acid seems to prefer the *sn*-2 position (2). In fish and other animal PC, 9,12-octadecadienoic acid (18:2) is typically found at the *sn*-2 position (1).

Sponge phospholipids with very long-chain FA (C_{26}–C_{30}) have a random FA distribution between *sn*-1 and *sn*-2 (3). For example, 1,2-di-(5*Z*,9*Z*)-5,9-hexacosadienoyl-*sn*-glycero-3-phosphoethanolamine was isolated from the sponges *Microciona prolifera* and *Parasperella psila* and characterized by fast-atom bombardment and tandem mass spectrometry (4). The sponge *Aplysina fistularis* was found to contain 1,2-di-5,9,23-triacontatrienoyl-*sn*-glycero-3-phosphoethanol-amine (5). Phospholipids with polyunsaturated FA (e.g., 20:4 and 22:6) have also been found in sponges. For example, the sponge *Higginsia tethyoides* contains 1,2-di-5,8,11,14-docosatetraenoyl-*sn*-glycero-3-phosphocholine (5), whereas *M. prolifera* synthesizes 1,2-di-(4*Z*,7*Z*,10*Z*,13*Z*,16*Z*,19*Z*)docosahexaenoyl-*sn*-glycero-3-phosphocholine as the major PC molecular species (4). Phospholipid molecular species found in higher organisms, such as those found in human erythrocytes, possess a more ordered FA distribution (6). Thus, saturated FA are normally found at the 1-position, and unsaturated FA normally occupy the 2-position (6,7).

The positional distribution of octadecadienoic acids, including linoleic acid, in phospholipids from marine sponges has not been studied previously. In the present work, we determined the positional distribution of two octadecadienoic acids, namely 5,9-octadecadienoic acid and 9,12-octadecadienoic acid, in phosphatidylethanolamines (PE) isolated from the sponges *Agelas* sp. and *Spongia tampa*.

MATERIALS AND METHODS

Agelas sp. was collected August 1, 1992, near Mona Island, Puerto Rico, at a depth of 25 m. *Spongia tampa* was collected in July 1992 at a depth of 1 ft from the mangroves of La Parguera, Puerto Rico. The sponges were freeze-dried in a Labconco Freeze Dryer 4.5 (Model 77510; Labconco, Kansas City, MO). The sponges (30–50 g) were then carefully cleaned of all nonsponge debris and cut into small pieces. Extraction with 250 mL of chloroform/methanol (1:1, vol/vol) yielded the total lipids. The neutral lipids, glycolipids and phospholipids (20 mg) were separated by column chromatography on silica gel (60–200 mesh) using the procedure of Privett *et al.* (8). The phospholipid classes were fractionated by thin-layer chromatography (TLC) on silica gel 60 using chloroform/methanol/NH_4OH (65:35:5, by vol) as solvent. Spray reagents such as molybdenum blue (phospholipids) and ninhydrin (amino groups) were used for the identification of the phospholipids. PE was isolated by preparative TLC under the conditions described above. The TLC fraction identified as PE was scraped from the plate, and the phospholipids were extracted from the silica gel with $CHCl_3$/MeOH/H_2O (50:45:5, by vol).

PC from human erythrocytes was isolated as follows. Duplicate samples of 1.0 mL of a 25% cell suspension in tris [tris(hydroxymethyl)aminomethane] buffered saline (1.2 μmol total phospholipid) were extracted according to Folch *et al.* (9). The total extract was applied to a 5 × 20 cm Whatman pre-coated silica gel plate and developed with $CHCl_3$/MeOH/H_2O (64:32:5, by vol), which contained 0.01% butylated hydroxytoluene as antioxidant. Lipid was visualized with 2′,7′-dichlorofluorescein, and the band corresponding to PC was scraped off.

Abbreviations: FA, fatty acid(s); GC/MS, gas chromatography/mass spectrometry; PC, phosphatidylcholine(s); PE, phosphatidylethanolamine(s); TLC, thin-layer chromatography; tris, tris(hydroxymethyl)aminomethane.

Phospholipids were enzymatically cleaved by dissolving the purified phospholipid fraction (1.2 μmol) in 1.0 mL of diethyl ether/MeOH (95:5, vol/vol) together with 10 μg of neutral phospholipase A_2 (purified from *Agkistrodon halys blomhoffii*) containing 140 mM tris-HCl (pH = 7.4) and 10 mM $CaCl_2$ (10–12). The reaction mixture was thoroughly mixed by vortexing and incubated at room temperature for 10 min. The reaction time was kept short to minimize acyl migration. The lipids were extracted according to Folch *et al.* (9), and the resulting free FA, unreacted phospholipids and lysophospholipids were separated by preparative TLC on silica gel using $CHCl_3$/MeOH/H_2O (65:35:5, by vol) as solvent. The resulting free FA from the *sn*-2 position of the phospholipids were esterified with diazomethane by adding 200 μL of a saturated solution of diazomethane in ether. The ethereal layer was washed with H_2O (2 × 0.5 mL) and dried under a stream of nitrogen. The fatty acyl components of the lysophospholipids were analyzed as methyl esters by reaction with methanolic hydrogen chloride (13) followed by chromatographic purification on a small column and elution with hexane/diethyl ether (9:1, vol/vol). The resulting methyl esters were analyzed by gas chromatography/mass spectrometry (GC/MS) using a Hewlett-Packard 59970 MS ChemStation (Hewlett-Packard, Palo Alto, CA) equipped with a 30 m × 0.32 mm nonpolar fused silica column (Supelco, Bellefonte, PA) with SPB™-1 as the bonded phase.

GC/Fourier transform infrared (FTIR) spectra were recorded on a Nicolet (Madison, WI) 740 FTIR spectrometer. The double bonds of the monoenoic and dienoic methyl esters were localized by preparing the corresponding dimethyl disulfide derivatives by dissolving the esters (2 mg) in dimethyl disulfide (0.2 mL), adding a solution (0.05 mL) of iodine in diethyl ether (60 mg/mL), and heating the solution at 50°C for 24 h as described previously (14).

RESULTS AND DISCUSSION

The total phospholipid FA composition of the sponge *Agelas* sp. was previously reported (15), and a series of novel brominated FA from the phospholipids of this sponge was isolated. The total phospholipid FA from *S. tampa* have not been reported previously. In the present study, we identified the 5,9-pentacosadienoic acid and 5,9-hexacosadienoic acid as the more prominent phospholipid FA of *S. tampa*. We also identified, in trace amounts, the 9- and 16-pentacosenoic acids as well as the 9-, 15- and 16-hexacosenoic acids, which had previously been found in sponge phospholipids (3). We were able to isolate (by TLC) a pure PE fraction, which contained C_{14}–C_{22} FAs and was free of contaminants. PC was only found in minor amounts in the sponges, and we were not able to isolate a pure PC fraction that was free of other lipids.

The purified PE, from both *Agelas* sp. and *S. tampa*, afforded C_{14}–C_{22} FA after MeOH/HCl transesterification. The principal saturated FA in the isolated PE were tetradecanoic acid (14:0), hexadecanoic acid (16:0) and

[a]The experimental error was calculated to be about 1%. No alkyl ethers or alkenyl ethers were identified in these phospholipids.

[b]The data were obtained on phosphatidylcholines from human erythrocytes when analyzed under the same conditions as the sponge phosphatidylethanolamines. Other fatty acids exclusively identified at the *sn*-2 position of the phosphatidylcholines from human erythrocytes were: 20:3 (4.2%), 20:4ω6 (21%), 22:4ω6 (2.2%), 22:5ω6 (0.9%), 22:5ω3 (0.9%) and 22:6ω3 (3.8%). No polyunsaturated fatty acids were detected at the *sn*-1 position.

[c]*i, iso; ai, anteiso.*

octadecenoic acid (18:0). These acids were identified by GC/MS and by GC co-injection with authentic standards (Table 1). The saturated FA accounted for 28–41% of the total FA in PE from both sponges. The principal FA in the PE were monounsaturated acids of the n-9 family, i.e., 9-octadecenoic acid (18:1Δ9) and 13-docosenoic acid (22:1Δ13), which together accounted for more than half of the total acids in this phospholipid (38–51%). Other monounsaturated FA belonging to the n-7 family were also found, namely 9-hexadecenoic acid (16:1Δ9) and 11-octadecenoic acid (18:1Δ11), which accounted for 6–10% of the total FA observed. The only octadecadienoic acid in *Agelas* sp. was characterized as 5,9-octadecadienoic acid (18:2Δ5,9) by MS of its methyl ester and dimethyl disulfide derivative, and based on GC retention times (4). On the other hand, the sponge *S. tampa* contained the 9,12-octadecadienoic acid as the only dienoic acid in the isolated PE.

The positional distribution of the C_{14}–C_{22} FA in the PE from *Agelas* sp. and *S. tampa* was examined by means of enzymatic digestion with neutral phospholipase A_2 from *A. halys blomhoffii*, which releases FA from the *sn*-2 position (10–12). The purified enzyme was obtained from *A. halys blomhoffii* as previously reported (12), and it showed a single band on sodium dodecyl sulfate gel electrophoresis, excluding contamination with lipase or phospholipase A_1 (12). The FA composition at the *sn*-1 and *sn*-2 positions, as determined by this method, is presented in Table 1. It is apparent that the FA distribution between *sn*-1 and *sn*-2 is quite similar. For example, the saturated FA 14:0, 16:0 and 18:0 were equally found at positions *sn*-1 and *sn*-2, with a slight preference for position *sn*-1 in both sponges. The typical odd-chain branched FA *iso*- and *anteiso*-15:0 and 17:0 were also found to occupy both positions, with no clear preference for *sn*-1 or *sn*-2. The most abundant FA in the mixture, namely 18:1Δ9 and 22:1Δ13, were also found both at positions *sn*-1 and *sn*-2, but a slight preference for *sn*-2 was observed in *Agelas* sp. Thus, in these sponges saturated and monounsaturated FA can equally occupy the *sn*-1 and *sn*-2 positions in PE. Such lack of positional specificity has been observed before in several bacteria (16,17).

The lysoPE and free FA formed after PLA_2 hydrolysis in the present study were produced in an approximately 1:1 molar ratio. We estimated that the extent of hydrolysis was *ca.* 60%. The FA compositions of the PE before hydrolysis and of the residual PE after hydrolysis were shown to be similar. As a control, we also applied the methodology we used to PC isolated from human erythrocytes. We selected these phospholipids because the positional distribution of FA, and specifically that of the 9,12-octadecadienoic acid, has been thoroughly studied (6). As can be seen from Table 1, no significant 1,2-acyl migration occurred in the method we used.

One interesting finding in these sponges was the lack of any positional specificity for the octadecadienoic acids, i.e., for example in *Agelas* sp. the 5,9-octadecadienoic acid was equally found at positions *sn*-1 and *sn*-2 in the PE. This may imply the presence of the identically substituted 1,2-di-(5*Z*,9*Z*)-5,9-octadecadienoyl-*sn*-glycero-3-phosphoethanolamine, similar to what has been reported for the longer chain "demospongic" FA of sponges (3). In *S. tampa*, a similar observation was made with the methylene-interrupted 9,12-octadecadienoic acid, present both at positions *sn*-1 and *sn*-2 of PE.

This study represents the first effort to elucidate the positional distribution of C_{14}–C_{22} FA in the phospholipids of sponges. The PE studied have FA similar to cyanobacteria (blue-green algae) as the 16:1Δ9 acid is considered a major cyanobacterial acid (18). However, the 18:2(Δ5,9) and 18:2(Δ9,12) acids are not common in bacteria (18). In particular, the 18:2(Δ5,9) acid has not been found in bacteria. Thus, the PE we isolated could originate from microbial symbionts and sponge cells. It is also interesting to note that the two sponges collected from two different habitats have a very similar PE FA distribution.

ACKNOWLEDGMENTS

We thank Dr. Abimael Rodríguez as well as Jaime Rodríguez and Edgardo Rodríguez for their help with the expedition to Mona Island, Puerto Rico. Dr. Vance Vicente from the United States Department of the Interior Fish and Wildlife Service classified the sponge. This work was supported by the National Science Foundation under Grant No. CHE-8715649 and the National Institutes of Health (NIH-MBRS Program) under Grant No. S06 GM08102-20.

Production of Docosahexaenoic Acid by Marine Bacteria Isolated from Deep Sea Fish

Yutaka Yano*, Akihiko Nakayama, Hiroaki Saito and **Kenji Ishihara**

National Research Institute of Fisheries Science, Kanagawa 236, Japan

Five bacterial strains isolated from the intestine of deep sea fish were shown to produce docosahexaenoic acid (22:6n-3; DHA) at a level of 6.4 to 11.6% of total fatty acids when incubated in DHA-free medium. In all of the strains examined, other polyunsaturated fatty acids were barely detectable, except for eicosapentaenoic acid (20:5n-3). A typical strain, such as T3615, produced DHA at a concentration of about 0.8 mg/L within six days of aerobic incubation at 5°C and under atmospheric pressure. The T3615 strain, belonging to the genus *Vibrio*, is rod-shaped, Gram-negative, motile and facultatively anaerobic.

***Lipids* 29, 527–528 (1994).**

It is now commonly believed that docosahexaenoic acid (22:6n-3; DHA) has some beneficial health effects. Hence, DHA has attracted considerable scientific, as well as public, attention (1,2). DHA is also known to be essential for the normal growth of fish at the larval stage (3). DHA concentrates are currently produced from fish oils. However, it is still difficult to obtain highly pure DHA preparations, which is partly due to the fact that the DHA content of fish oils fluctuates widely depending on the species of fish used, as well as the season.

Other sources of DHA are being sought among algae and fungi (4,5). Bacterial production of DHA would be of interest because of the ease with which bacteria can be cultured in modern biotechnology equipment. Only one study dealing with the bacterial production of DHA has been published so far (6), although there are some papers describing bacteria that can produce other polyunsaturated fatty acids, such as eicosapentaenoic acid (20:5n-3; EPA) (7–10). We now found that out of nine bacterial strains isolated from the intestine of deep sea fish, five produced DHA.

MATERIALS AND METHODS

Isolation and cultivation of microorganisms. The bacterial strains were isolated from the intestines of two species of deep sea fish, *Histiobranchus* sp. and *Coryphaenoides yaquinae,* which were caught at depths of 3,200–5,300 m during crab-pot fishing. Diluted intestinal contents were spread on marine agar 2216 (Difco Laboratories, Detroit, MI) plates and incubated at 5°C for two months. Colonies were purified by being streaked in a series of three transfers onto the plates. Nine strains isolated in this manner were further analyzed, lipids were recovered and the fatty acid composition was determined. The strain numbers, species names of the fish specimens and the depths at which the fish were caught are given in Table 1. Bacterial growth was monitored by counting 4,6-diamidino-2-phenylindole-stained cells by epifluorescence microscopy. Strains were classified by taxonomic tests following an established identification scheme (11).

TABLE 1

Strains of Bacteria and the Fish Species from Which the Bacteria Were Isolated

Strain number	Fish number	Species name of fish	Depth (m)[a]
T3602	36	*Histiobranchus* sp.	4,700
T3615	36	*Histiobranchus* sp.	4,700
T4607	46	*Coryphaenoides yaquinae*	4,300
T4609	46	*C. yaquinae*	4,300
T4714	47	*C. yaquinae*	3,200
T4715	47	*C. yaquinae*	3,200
T5301	53	*C. yaquinae*	5,300
T5603	56	*C. yaquinae*	5,200
T5611	56	*C. yaquinae*	5,200

[a]The depth at which the fish were caught.

Lipid analyses. The strains were grown in marine broth 2216 (Difco Laboratories) at 5°C and under atmospheric pressure while shaking. Cells were harvested by centrifugation, and the lipids were extracted according to the procedure of Folch *et al.* (12). Extraction of the same medium before use served as control. Fatty acids were transmethylated in 2.5% methanolic HCl by heating at 85°C for 3 h. The fatty acid methyl esters were analyzed by gas chromatography using an Omegawax 250 capillary column (25 m × 0.25 mm i.d.; Supelco, Bellefonte, PA) and helium as carrier gas. The oven temperature was 180°C. The samples were further analyzed using a SP-2330 capillary column (30 m × 0.25 mm i.d.; Supelco) with the oven temperature at 150°C. The fatty acid methyl esters were identified by comparison with known standards (Sigma, St. Louis, MO). Tricosanoic acid was used as internal standard. The fatty acid methyl esters were also confirmed by gas chromatography/mass spectrometry using a JMS-DX303 instrument (JEOL, Tokyo, Japan) with an Omegawax 320 column (30 m × 0.32 mm i.d.). The oven temperature was 200°C. Electron impact mass spectra were measured at 70 eV.

RESULTS AND DISCUSSION

The fatty acid compositions of nine of the strains examined are given in Table 2. Five strains out of the nine strains examined produced DHA. The DHA produced by the strains accounted for 6.4 to 11.6% of the total fatty acids when incubated in marine broth 2216. Small amounts (<0.01 mg/L) of palmitic acid (16:0), palmitoleic acid (16:1n-7) and oleic acid (18:1n-9) were present in the medium before use. Polyunsaturated fatty acids, such as

Abbreviations: DHA, docosahexaenoic acid; EPA, eicosapentaenoic acid.

TABLE 2

Fatty Acid Compositions of Cultured Bacteria Originally Isolated from Intestinal Contents of Deep Sea Fish

Fatty acids	Strain number of fish				
	T3615	T4714	T4715	T5603	T5611
14:0	17.8	6.9	9.0	16.8	15.8
14:1n-5	12.2	2.0	2.4	4.2	5.2
15:0	trace[a]	0.5	0.6	1.0	0.8
16:0	10.7	16.8	16.9	15.7	16.4
16:1n-7	45.3	53.4	56.9	48.3	49.8
18:0	trace	0.5	0.5	trace	trace
18:1n-9	trace	1.2	0.9	trace	trace
18:1n-7	0.6	2.8	2.2	trace	trace
18:3n-6	trace	nd	nd	0.9	0.6
20:3n-3	nd[b]	trace	trace	nd	nd
20:4n-3	0.6	0.8	0.5	trace	trace
20:5n-3	1.1	2.7	1.9	2.5	2.6
22:6n-3	9.4	11.6	8.1	9.4	6.4

[a]Trace, <0.5%. [b]nd, Not detectable.

EPA and DHA, were not detected (not listed in Table 2). The results indicated that the bacterial strains synthesized DHA *de novo*. The other major fatty acids in the five strains were myristic acid (14:0), myristoleic acid (14:1n-5), palmitic acid and palmitoleic acid. EPA was also detected in all strains, although DHA-producing bacteria were not shown to produce EPA in an earlier study (6). Other polyunsaturated fatty acids were barely detectable. This simple fatty acid composition would suggest that the purification of DHA from bacterial lipids should be much easier than from other DHA sources, including fish oils or fungal lipids.

The growth curve for a typical strain, T3615, is shown in Figure 1. The cell count reached a maximum of 1.5×10^8 cells/mL after six days during aerobic incubation at 5°C and under atmospheric pressure while shaking. Under these conditions, 122 mg of dry cells and 11.9 mg of total lipids per L of culture were obtained. The DHA yield was 0.8 mg/L. The strain was shown to be barophilic as it grew to 1.2×10^8 cells/mL after three days at 5°C at higher pressure (41.4 MPa). The strain also produced DHA under high pressure, but a quantitative comparison of DHA yields obtained at atmospheric pressure and at high pressure is different because other factors affecting growth, such as the supply of oxygen, cannot be kept constant.

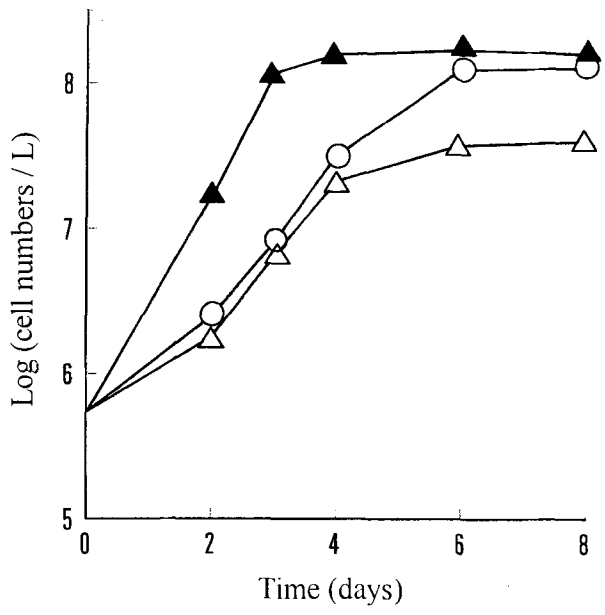

FIG. 1. Growth curves of the strain T3615 at 5°C under atmospheric pressure and at 41.4 Mpa. ○, Atmospheric pressure with shaking; △, atmospheric pressure without shaking; and ▲, 41.4 Mpa without shaking.

Cells of the strain T3615 were 1–2 μm in diameter and 2–3 μm in length, although the size was somewhat dependent on culture conditions. The strain is rod-shaped, motile and Gram-negative, and not luminous. It produced acids but not gas from glucose, and required sea water or artificial sea water for growth. These characteristics indicate that the strain belongs to the genus *Vibrio*.

The results suggest that bacteria may become useful for the production of DHA, although the productivity of the strains studied here seems lower than that of algae or fungi (4, 5). EPA synthesis has already been reported for *Escherichia coli* that carry part of the DNA of EPA-producing bacteria (13). As the cultivation of *E. coli* is much easier and requires less energy, bacterial DHA production could be improved by using biotechnological approaches and gene manipulation and, for example, DNA of the isolates described in this study.

ACKNOWLEDGMENTS

This study was supported by grant "BRP" from the Ministry of Agriculture, Forestry and Fisheries. We thank Dr. S. Konagaya and K. Yoshida for valuable advice and comments. We thank the officers and crew of R/V *Soyo* for collecting fish samples.

ARTICLE

Distribution of Cholesterol Among Its Carriers in the Bile of Male and Female Hamsters

Takahiro Mikami[1], Bertram I. Cohen, Yasuko Mikami[1], Nariman Ayyad and **Erwin H. Mosbach***

Department of Surgery, Beth Israel Medical Center, New York, New York 10003

The distribution of cholesterol among its carriers was studied in the bile of male and female hamsters. Sasco hamsters (Sasco Inc., Omaha, NE) were fed a semipurified diet with 0.0% cholesterol and 4% butterfat (group 1, males; group 4, females); a semipurified diet with 0.3% cholesterol and 1.2% palmitic acid (group 2, males; group 5, females); and a semipurified diet with 0.3% cholesterol and 4% safflower oil (group 3, males; group 6, females). At the end of six weeks, gallstones were found only in male hamsters receiving both cholesterol and dietary fat (fatty acid) (incidence of cholesterol stones: 90% in group 2; 22% in group 3). The biliary cholesterol carriers were separated and isolated from the bile of the hamsters by gel filtration chromatography, using the method of Pattinson [Pattinson, N.R., Willis, K.E., and Frampton, C.M. (1991) *J. Lipid Res. 32*, 205–214]. In those male hamsters that formed cholesterol gallstones, significant amounts of cholesterol were present in the void volume which contained large cholesterol phospholipid vesicles (void volume vesicles) (23% in group 2 and 15% in group 3). Smaller cholesterol/phospholipid vesicles were eluted next (fractions 30–45) and contained 15% of biliary cholesterol in group 2 and 21% in group 3. The remainder of the cholesterol was associated with mixed cholesterol/phospholipid/bile salt micelles. The cholesterol/phospholipid ratio was larger in both the void volume vesicles and small vesicles (2.40 and 1.48 in group 2; 2.56 and 1.33 in group 3, respectively) compared to the micelles (about 0.3 in groups 2 and 3). In contrast, the bile of the female hamsters contained few vesicles (3% small vesicles in group 5) and the cholesterol/phospholipid ratio of these vesicles was lower (0.94). Hamsters fed cholesterol-free diets (groups 1 and 4) had no biliary cholesterol/phospholipid vesicles; all cholesterol was present in micelles. The results suggest that both the gender and the diet of the hamsters affected the distribution of biliary cholesterol between vesicles and micelles. The development of cholelithiasis in this animal model appears to depend on the rapid nucleation of cholesterol-rich phospholipid vesicles in bile.

***Lipids* 29, 529–534 (1994).**

Cholesterol/phospholipid vesicles and cholesterol/phospholipid/bile salt mixed micelles are the main cholesterol carriers in gallbladder bile (1–3). It has recently become apparent that the vesicles play an important role in cholesterol gallstone formation (4–8). Nucleation of cholesterol, the initial step in cholelithiasis, is a consequence of vesicular aggregation, and rapid cholesterol nucleation is associated with high cholesterol/phospholipid ratios of vesicles (4,7–9).

A hamster model of cholesterol cholelithiasis has been in use in our laboratory for a number of years (10–16). Lithogenesis in this model is a function of several factors, particularly of dietary constituents and source, age and sex of the experimental animals (11,14–16). Recently, we reported that under standard conditions (lithogenic diet fed for six weeks) gallstones were formed in male hamsters but not in female hamsters of either the Sasco (Sasco Inc., Omaha, NE) or Charles River (Charles River Laboratories, Wilmington, MA) "strains" (16). We hypothesized that lithogenesis might occur more rapidly in male hamsters as compared to female hamsters after a six-week feeding if (i) the bile of the former contains biliary cholesterol in the form of vesicles, and (ii) in the males, the vesicular cholesterol/phospholipid ratio is relatively higher than in females. To test this hypothesis, we studied the effect of the gender of the experimental animals on gallstone incidence, the distribution of biliary cholesterol between vesicles and micelles and the vesicular cholesterol/phospholipid ratio in bile.

As observed previously, only the male hamsters developed gallstones in response to the standard lithogenic diet. In these animals, a relatively large amount of cholesterol was carried in void volume vesicles with high cholesterol/phospholipid ratios. These results suggest that the observed sex difference in our hamster model of cholesterol cholelithiasis is due, at least in part, to differences between cholesterol carriers in bile.

MATERIALS AND METHODS

Animals. Male and female golden Syrian hamsters (28 males and 32 females) were obtained from Sasco Inc. Male and female animals were each divided into three groups of nine to eleven animals; their weights averaged 75 g (average age, six weeks). The basal, semipurified diet (SPD) purchased from Dyets, Inc. (Bethlehem, PA) contained 43.7% corn starch, 20% casein, 14.6% dyetrose (soluble starch), 10% fiber (cellulose), 5% salt mix (modified U.S.P. XIV salt mix, no. 200951), 2% corn oil, 0.5% vitamin mix (no. 300000) and 0.2% choline chloride. To this diet was added 4% butterfat (group 1, males; group 4, females); 0.3% cholesterol, 1.2% palmitic acid and 2.5% cornstarch (group 2, males; group 5, females); or 0.3% cholesterol and 4% safflower oil less 0.3% cornstarch (group 3, males; group 6, females). These diets were fed for a period of six weeks. An additional 25 animals (8–9 animals/group) were fed the SPD with 0.3% cholesterol and 1.2% palmitic acid (for two weeks) in order to obtain sufficient bile to

check the reproducibility of the gel filtration technique (groups A–C).

At the end of the experimental period, the hamsters in each group were fasted for 24 h and anesthetized with 20 mg of ketamine hydrochloride (Aveco Co., Inc., Fort Dodge, IA). The gallbladder was examined for the presence of gallstones, and bile was removed with a 100-μL Hamilton syringe and examined by polarized light microscopy (Olympus MCHAP microscope; Olympus Corp., Lake Success, NY) for the presence of cholesterol stones or cholesterol crystals. The remaining fresh bile of each group was combined and centrifuged in 1.5-mL microfuge tubes using an Eppendorf 5415C centrifuge (Brinkmann Instruments, Westbury, NY) at 2000 rpm for 30 min. The fresh supernatant solution was used immediately for separation of the vesicles and micelles by gel filtration chromatography.

Column chromatography. A toluene solution of 0.25 μCi [1α,2α(n)-^{3}H]cholesterol (45.6 Ci/mmol) and a chloroform/methanol (1:1, vol/vol) solution of 0.15 μCi 1-palmitoyl-2-[1-^{14}C]oleoyl-*sn*-glycero-3-phosphocholine (53 mCi/mmol) (Amersham Life Science, Arlington Heights, IL) were mixed and evaporated under N_2. The bile samples were added to the labeled compounds and incubated for 1 h at 37°C with shaking. The labeled bile samples (200 μL) were applied to Sepharose CL-4B-200 (Sigma Chemical Co., St. Louis, MO) columns (20 cm × 1.5 cm i.d.) and eluted with saline buffered with 0.01 M phosphate (pH 7.4) containing 0.04% sodium azide and 6 mM sodium taurocholate as described by Pattinson *et al.* (17); the flow rate was 15.5 mL/h. Fractions of 500 μL each were collected, and an aliquot (100 μL) of each fraction was counted in a Beckman LS 3801 liquid scintillation system (Beckman Instruments, Fullerton, CA) with automatic quench correction, using Aquasol-2 (NEN Research Products, Boston, MA) as the scintillation fluid.

Chemical analyses. After hydrolysis, bile acids were determined as the methyl ester acetates by capillary gas–liquid chromatography as described previously (18). Biliary phospholipids were determined enzymatically using the Wako phospholipid B kit (Wako Pure Chemical Industries, Ltd., Osaka, Japan). Biliary cholesterol was determined as the trimethylsilyl ether by capillary gas–liquid chromatography (11). The cholesterol saturation indices (CSI) of the bile were calculated as reported previously (19,20).

After gel filtration chromatography, the percentage of cholesterol and phospholipid in vesicles and micelles was calculated by determining the total radioactivity of the area under each peak (shown later in Figs. 1 and 2). The cholesterol/phospholipid ratio of vesicles and micelles was calculated using the above percentages.

Statistics. The data for the distribution of cholesterol among vesicles and micelles in animals maintained with SPD, containing 0.3% cholesterol and 1.2% palmitic acid for two weeks, were obtained in triplicate and are summarized as the mean ± SD (Table 5 later in text). Differences in gallstone incidence between groups were determined by chi square.

RESULTS

All hamsters remained healthy during the six-week feeding period, and the animals in all six groups gained similar amounts of weight. The incidence of cholesterol gallstones and biliary cholesterol crystals is shown in Table 1. The groups (1 and 4) receiving the cholesterol-free diet had no gallstones. Male hamsters maintained with 0.3% cholesterol plus 1.2% palmitic acid (group 2) had a 90% incidence of gallstones; those receiving 0.3% cholesterol plus 4.0% safflower oil (group 3) had an incidence of only 22%. In contrast, female hamsters fed the identical diets (groups 5 and 6) did not form gallstones or biliary cholesterol crystals. None of the animals in any group had pigment stones.

Molar proportions of biliary lipids, CSI and cholesterol/phospholipid ratios in bile are summarized in Table 2. In the cholesterol-fed groups, the male hamsters had higher CSI and cholesterol/phospholipid ratios than the females (groups 2 and 3 vs. groups 5 and 6); the CSI of stone-forming groups 2 and 3 was greater than unity—1.27 in group 2 and 1.13 in group 3. The total lipid concentrations of the six groups were similar.

The biliary bile acid composition of the six experimental groups is shown in Table 3. As observed previously (11), cholesterol feeding increased the chenodeoxycholic acid (CDCA)/cholic acid ratio in both male and female hamsters. The biles of male animals contained higher proportions of hyodeoxycholic acid and lower proportions of lithocholic acid and deoxycholic acid as compared with the corresponding groups of female animals.

Figure 1 illustrates the elution patterns of the combined biles of each of the six groups as determined by gel filtration chromatography. In groups 2 and 3, which form cho-

[a]See Materials and Methods section for details of the hamster diets. SPD, semipurified diet; CSI, cholesterol saturation index.

lesterol gallstones (see Table 1), significant amounts of cholesterol were present in the void volume vesicles, fractions 20–35, and small vesicles, fractions 35–45. In all groups, a considerable proportion of the labeled cholesterol was eluted in fractions 45–75 (micelles). The percent of cholesterol in the combined vesicular fractions (void volume vesicles and small vesicles) amounted to 38.3% in group 2 and 35.9% in group 3 (Table 4). In groups 1, 4, 5 and 6, the biliary cholesterol was practically all in the micellar fraction, and none of the animals had cholesterol gallstones. The cholesterol/phospholipid ratio of the void volume vesicles and small vesicles in groups 2 and 3 exceeded unity (2.40 and 1.48, group 2; 2.56 and 1.33, group 3) (Table 4). The bile of the female hamsters receiving the lithogenic diet (group 5) appeared to contain some small vesicles (2.9%); the cholesterol/phospholipid ratio of this fraction was less than 1 (0.94). In the bile of animals receiving cholesterol-free diets (groups 1 and 4), cholesterol appeared to be present solely in the form of micelles. The cholesterol/phospholipid ratio of the micelles ranged from 0.17 (group 4) to 0.35 (group 5).

In order to determine the reproducibility of the gel filtration technique, we performed column chromatography in triplicate using the bile of hamsters fed the SPD with 0.3% cholesterol and 1.2% palmitic acid for two weeks. Figure 2 shows the elution profile of the combined bile of these three groups. All groups (A–C) had similar amounts of void volume vesicles and small vesicles in bile and the cholesterol/phospholipid ratio of the vesicles was also similar in these groups (Table 5).

DISCUSSION

Male Sasco hamsters fed an SPD with added 0.3% cholesterol and 1.2% palmitic acid had a high incidence of cholesterol gallstones; cholelithiasis was reduced, but not abolished when 4% safflower oil was substituted for the palmitic acid (14). Female hamsters fed the same diets developed neither biliary cholesterol crystals nor gallstones. No cholesterol gallstones were formed without exogenous cholesterol regardless of whether 4% butterfat or 1.2% palmitic acid were incorporated into the diet (14).

The formation of cholesterol gallstones and crystals is believed to occur from nucleation of vesicles of high cholesterol content (7–9). We hypothesized that in the stone-forming groups vesicles were present in bile. It was necessary to isolate and quantitate the amount of vesicles and micelles to confirm this hypothesis. Consequently, we car-

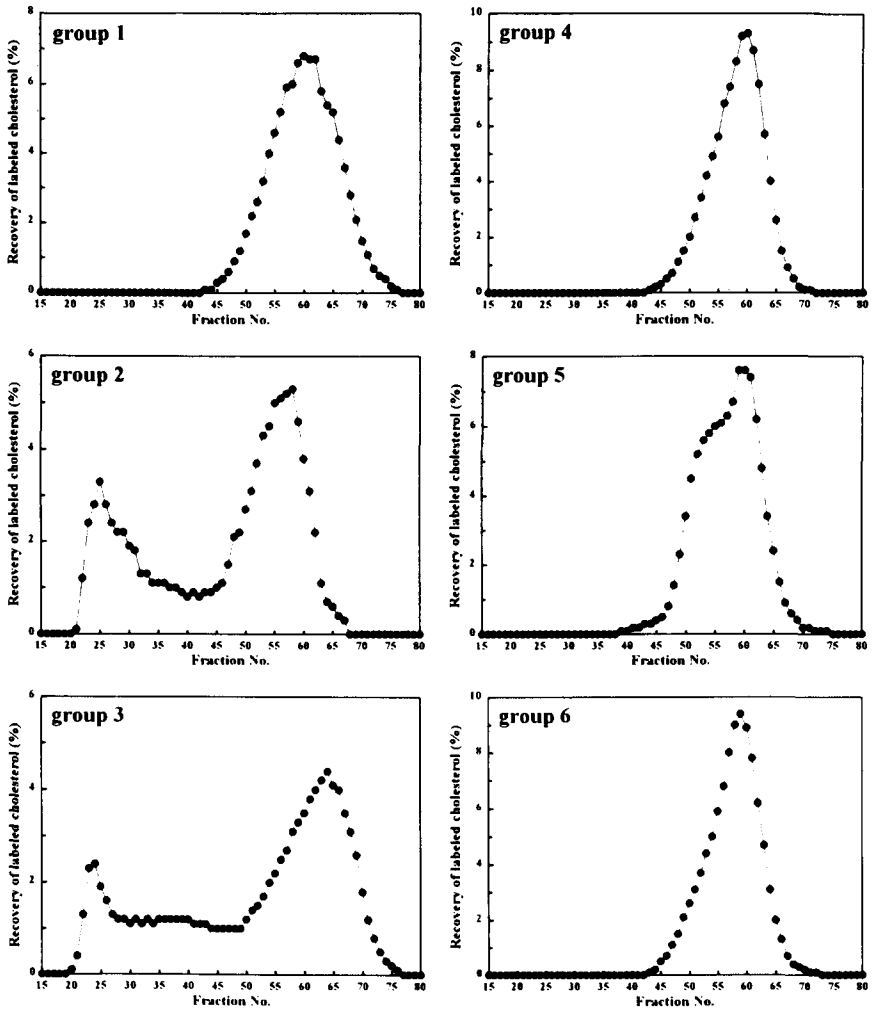

FIG. 1. Gel filtration chromatography of hamster gallbladder bile on Sepharose CL-4B-200 (Sigma Chemical Co., St. Louis, MO). The elution profiles show percent recovery of [^{3}H]cholesterol (●). 1) Male, semipurified diet (SPD) with 0.0% cholesterol and 4% butterfat (group 1); 2) male, SPD with 0.3% cholesterol and 1.2% palmitic acid (group 2); 3) male, SPD with 0.3% cholesterol and 4% safflower oil (group 3); 4) female, SPD with 0.0% cholesterol and 4% butterfat (group 4); 5) female, SPD with 0.3% cholesterol and 1.2% palmitic acid (group 5); 6) female, SPD with 0.3% cholesterol and 4% safflower oil (group 6). The biles of groups 1, 4 and 6 contain micelles only (fractions 45–75). The bile of group 2 contains both void volume vesicles and micelles. The bile of group 3 contains void volume vesicles, small vesicles (fractions 35–45) and micelles. The bile of group 5 contains largely micelles with a small vesicular shoulder. See Table 4 for quantitation.

ried out gel filtration chromatography to obtain these data. The method employed was that of Pattinson *et al.* (17), using Sepharose CL-4B-200. The biles of 9–11 hamsters in each group had to be combined. The small quantities of bile obtained from the individual animals made it necessary to pool bile samples in order to have sufficient material for column chromatography. It would be ideal to carry out column chromatography on individual samples of bile using the exact bile acid concentration and bile acid species in the eluting buffer. However, this is impractical when dealing with the relatively minute quantities of bile available from each hamster (20–50 μL/animal). The use of 6 mM sodium taurocholate, pH 7.4, as the eluting buffer was identical to that of Pattinson *et al.* (17). The choice of 6 mM sodium taurocholate is an estimate based on previous data (17). Because hamster bile and human gallbladder bile are similar (but not identical in composition), we used the same bile acid concentration for our elution buffer (6 mM sodium taurocholate). It would have been ideal to determine the intermicellar bile acid concentration (21), but the small amounts of bile available made this impossible. We verified the reproducibility of our column method using three groups of animals (8–9 animals/group), each fed the SPD containing 0.3% cholesterol and 1.2% palmitic acid for two weeks. The vesicle fractions (%) were very similar in all cases (Table 5 and Fig. 2). It

[a]Vesicles and micelles were separated by gel filtration chromatography (Ref. 17). See Materials and Methods section for details. Ves, void-volume vesicles; s-Ves, small vesicles; Mic, Micelles; SPD, semipurified diet.

seems highly plausible that the results of the other gel filtration chromatographic separations (Table 4) would also be reproducible if larger groups of animals were used for each study. However, the cost of each experiment because of the large number of animals required limits our ability to obtain this additional data.

Pattinson *et al.* (17) reported three types of cholesterol carriers in bile, namely, vesicles (eluted in the void volume), small vesicles and mixed micelles. Only gallstone patients, but not the stone-free control subjects, had vesicles in their gallbladder bile. In addition, Schriever and Jüngst (6) also reported that biliary vesicles were present in 18 of 19 gallbladder biles of stone-containing patients but in only 3 of 14 biles of control subjects. In the present study, vesicles were detected in those groups of animals (groups 2 and 3) in which gallstones were formed. Presumably, cholesterol nucleates from vesicles with high cholesterol/phospholipid ratios (7,9). Table 4 shows that the vesicles in groups 2 and 3 had high cholesterol/phospholipid ratios (2.40 and 2.56, respectively). In contrast, in the female animals in groups 5 and 6, no vesicles were detected in the gallbladder bile and no gallstones formed. These results seem to confirm that a relationship between the presence of vesicles and cholelithiasis in these animals may well exist.

Both total biliary lipid concentration and the cholesterol saturation of bile play an important role in modifying the relative concentrations of biliary cholesterol carriers (6,9,22). In the present study, the total biliary lipid concentration of males and females was similar. The cholesterol saturation indices of groups 2 and 3 exceeded unity, and vesicles were present in only these two groups. Although stone incidence in groups 2 and 3 differed, the bile of both groups contained considerable proportions of biliary cholesterol in vesicles. It appears that a high CSI is only one of the factors determining vesicle stability and cholesterol nucleation. However, bile is a complex mixture of lipids, electrolytes, mucus, proteins and other substances, all of which can play a role in promoting or inhibiting the nucleation of cholesterol from cholesterol-rich vesicles. In the other four groups, the CSI were less than unity, and vesicles were not detected. However, high cholesterol saturation of bile alone does not account for the presence of vesicles in these animals. Recently, Chijiiwa *et al.* (22) reported that in the bile of gallstone patients, a high concentration of cholesterol in biliary vesicles was associated with high CSI and a high biliary total protein concentration. Halpern *et al.* (4) discussed the possibility that factors promoting nucleation may affect biliary vesicle formation and aggregation. In the present study, we measured neither biliary protein concentration nor nucleation time. Again, the small volume of bile (20–50 µL) obtained from each hamster makes it difficult to perform such experiments.

The bile acid composition of the animals was affected by gender. There was an increased proportion of 6-hydroxylated bile acids [hyodeoxycholic acid (HDCA) and murideoxycholic acid (MDCA)] in the bile of male hamsters, compared to females. Although hamster bile contains small concentrations of ß-muricholic acid (23,24), the 7-dehydroxylation of the latter seems quantitatively inadequate to account for the presence of MDCA and [*via* bac-

[a]The data represent results from three groups of hamsters receiving identical diets. Vesicles and micelles were separated by gel filtration chromatography (Ref. 17). See Materials and Methods section for details. See Table 4 for abbreviations.

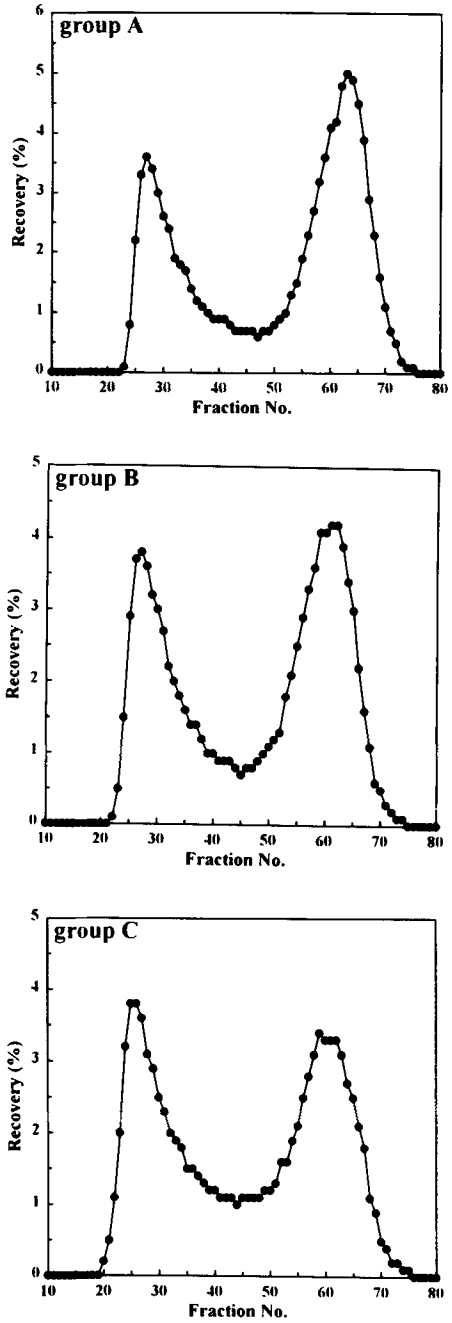

FIG. 2. Gel filtration chromatography of three samples of hamster gallbladder bile on Sepharose CL-4B-200, demonstrating reproducibility of the procedure. The elution profiles show percent recovery of [^{3}H]cholesterol (●). Hamsters were fed the semipurified diet with 0.3% cholesterol and 1.2% palmitic acid for two weeks (groups A–C). See Table 5 for quantitation. See Figure 1 for company source address.

terial action (12)] of HDCA. Further, it seems unlikely that these 6-hydroxylated bile acids arise *via* the 7-dehydroxylation of CDCA followed by 6-hydroxylation of the resulting lithocholic acid. Further studies are needed to elucidate the differences and origin of 6-hydroxy bile acids in our hamsters.

In conclusion, total biliary cholesterol concentration and the distribution of cholesterol between vesicles and micelles in bile was affected by the gender of the hamsters. Cholesterol gallstone formation (in the males) was strongly associated with the presence of vesicles in gallbladder bile. Such vesicles were absent in the females, possibly because their rates of biliary cholesterol secretion were inherently lower. These results suggest that the sex difference observed in this animal model may be related to the formation (in males) or lack of formation (in females) of vesicular cholesterol carriers. Additional studies will be needed to define the mechanism(s) underlying this difference.

Arachidonic Acid and Eicosapentaenoic Acid Stimulate Type II Pneumocyte Surfactant Secretion

Richard Carleton Baybutt[a], John Edgar Smith[a], Mark N. Gillespie[b], Terry G. Newcomb[c] and Yu-Yan Yeh[a,*]

[a]Nutrition Department, The Pennsylvania State University, University Park, Pennsylvania 16802 and [b]Division of Pharmacology and Experimental Therapeutics, College of Pharmacy and [c]Microbiology and Immunology Department, University of Kentucky, Lexington, Kentucky 40536

Arachidonic acid and its leukotriene metabolites have been shown to stimulate surfactant secretion by alveolar type II cells. The present study was undertaken to determine the effects of various unsaturated fatty acids, including eicosapentaenoic acid, on surfactant secretion. Surfactant secretion was expressed as the percent of [^{3}H]choline-derived phospholipids released into culture medium by type II pneumocytes of adult rats. Consistent with the earlier findings, arachidonic acid stimulated secretion in a concentration-dependent fashion (3.5–21 μM), doubling baseline secretion at 21 μM. Eicosapentaenoic acid was found to be equally effective as arachidonic acid in stimulating secretion. A comparison with palmitic, oleic and linoleic acids revealed that highly unsaturated fatty acids stimulated secretion to the greatest extent. This was supported by a positive correlation between degree of unsaturation (i.e., 0, 1, 2, 4 and 5 double bonds) and stimulation of surfactant secretion. In the present study, exogenous leukotriene E_4 (10^{-13}–10^{-6}) did not stimulate surfactant secretion. Neither nordihydroguaiaretic acid (0.1 μM) nor indomethacin (0.1 μM) affected arachidonic acid-stimulated secretion. The stimulatory effects of arachidonic acid and eicosapentaenoic acid on surfactant secretion were related to the highly unsaturated nature of the fatty acids and were not mediated by increased levels of cyclic adenosine monophosphate or calcium.

***Lipids* 29, 535–539 (1994).**

Surfactant is a lipoprotein complex that reduces the surface tension of water lining the lumen of the alveoli enabling respiration (1). It is synthesized, stored and secreted by the alveolar type II cells (2). Deficiency of surfactant can cause respiratory distress syndrome in premature infants and adults (3,4).

Fish oil rich in n-3 fatty acids [i.e., eicosapentaenoic (EPA) and docosahexaenoic acids] may have beneficial effects on the treatment and/or prevention of cardiovascular disease (5), cancer (6), psoriasis (7), arthritis (8) and atherogenesis (9). Despite these potential benefits, fish oil could also exert adverse effects, such as those associated with high intake of cholesterol and vitamin A and D (10), and prolonged bleeding times (5). Surfactant secretion by alveolar type II cells has been shown to be stimulated by arachidonic acid (11). One proposed mechanism underlying such stimulation involves leukotrienes derived from arachidonic acid (12). In other tissues, EPA perturbs leukotriene formation from arachidonic acid (AA) and thereby hinders the metabolic effects of AA (6–8,13,14). However, it is not known whether EPA antagonizes AA action leading to impairment of surfactant secretion. The present study was undertaken to compare the effects of EPA and AA on surfactant secretion by alveolar type II cells. The study showed that EPA is as effective as AA in stimulating surfactant secretion by alveolar type II cells.

Abbreviations: AA, arachidonic acid; ATP, adenosine triphosphate; cAMP, cyclic adenosine monophosphate; C-DMEM, complete Dulbecco's modified Eagle's medium; CMF–PBS, calcium-/magnesium-free phosphate-buffered saline; EPA, eicosapentaenoic acid; LTE_4, leukotriene E_4; OA, oleic acid; PA, palmitic acid.

MATERIALS AND METHODS

Cell isolation and culture. Pathogen-free, male Sprague-Dawley rats, weighing approximately 300 g, were used to isolate type II pneumocytes according to the procedure of Mason *et al.* (15) with minor modifications (16). The final step of the purification used cell differential adherence in culture. The purity of the adhering cells was 86 ± 1% (n = 4) as determined by tannic acid staining (17). The viability of the cells was 95 ± 1% (n = 10) as judged by trypan blue exclusion.

A 2-mL aliquot of cell suspension in C-DMEM (complete Dulbecco's modified Eagle's medium) supplemented with 10% fetal bovine serum, penicillin (100 μU/mL) and streptomycin (100 μg/mL) was plated at a density of 2.0×10^6 cells/well on six-well plates and incubated for 18–20 h under an atmosphere of 5% CO_2 and 95% air saturated with water at 37°C in the presence of 0.1 mL [*methyl*-^{3}H]choline chloride (specific activity, 2.5 μCi/μmol). Lower than typical amounts of radioactivity could be used because the siliconized glassware employed minimized losses.

Immediately after the 18–20 h incubation, surfactant secretion was measured according to the procedure previously described (11,18). The adhering cells were washed three times with 2 mL of C-DMEM and then incubated at 37°C in 1.3 mL of serum-free and antibiotic-free DMEM for 30 min prior to addition of the test compounds. The cultured cells were incubated for 3 h after the test compounds had been added. In a preliminary study, a linear rate of the secretion was observed between 1 and 4 h of incubation.

The measurement of ^{3}H-labeled total lipids released into the medium is an established marker of surfactant secretion (19). Surfactant secretion was expressed as percent of the radioactivity of [^{3}H]lipid recovered in the medium over the sum of the radioactivity found in cells plus the medium multiplied by 100. Lactate dehydrogenase activity was measured (20) in the cultured cells and in the incubation media to determine if cell injury or lysis had occurred.

Preparation of test compounds. AA, EPA, linoleic acid, nordihydroguaiaretic acid and indomethacin were dissolved in ethanol, while leukotriene E_4 (LTE_4) and the

sodium salts of palmitic acid (PA) and oleic acid (OA) were dissolved in distilled water as stock solution. The solutions were diluted in serum-free and antibiotic-free DMEM prior to adding to cells. The concentration of ethanol introduced in all experiments was less than 0.05%. Ethanol at this concentration neither induced cell lysis nor stimulated surfactant secretion (unpublished data).

Measurement of cyclic adenosine monophosphate (cAMP) and intracellular calcium. The cAMP levels were measured using Amersham's cAMP[^{125}I]assay kit (Amersham Corp., Arlington Heights, IL). The cells were prepared and treated as before using two concentrations of the fatty acids, i.e., 7 and 21 μM. After the 3-h fatty acid treatment, the cells were washed with phosphate-buffered saline, and the cellular cAMP content determined.

Intracellular calcium was measured with a bioluminescent photoprotein as described elsewhere (21). The cells were preloaded with aequorin (a calcium-sensitive luminescent probe) prior to the experiment. Approximately 4–5 × 10^6 adhering cells, on a 100-mm Corning dish, were washed twice with 10 μM ethyleneglycol-*bis*(β-aminoethyl ether)*N,N,N′,N′*-tetraacetic acid in Ca^{2+}- and Mg^{2+}-free phosphate-buffered saline (CMF–PBS) and twice with CMF–PBS. The cells were scraped using a rubber policeman in the presence of 50 μL of 1.0 mg/mL aequorin (Friday Harbor Photoproteins, Friday Harbor, Washington). After 5 min, the cells were diluted with phenol red-free DMEM to a concentration of 1–2 × 10^6 per mL, and 0.8 mL of this cell suspension was injected into Sykes-Moore chambers (Bellco, Vineland, NJ). After a 3-h adhering time, the floating cells along with the cell debris, were washed away. The cells were then treated with the various fatty acids, and luminescence was recorded for 5 min. An established intracellular calcium mobilizer, adenosine triphosphate (ATP), was used as a positive control (22).

Culture media and chemicals. DMEM, fetal bovine serum and antibiotics were purchased from Gibco Labs (Grand Island, NY). [*Methyl*-^{3}H]choline chloride was obtained from Amersham Corporation. Ecoscint counting solvent was from National Diagnostics (Manville, NJ). LTE_4 was a gift from Merck Frosst Centre for Therapeutic Research (Pointe Claire, Dorval, Quebec, Canada). Organic solvents were reagent grade and purchased from Fisher Scientific (Pittsburgh, PA). All other chemicals and compounds were from Sigma Chemical Co. (St. Louis, MO).

Data and statistical analysis. For each cell isolation, the type II cells from two to three lungs were combined and distributed in culture plates consisting of six wells (4-cm diameter). The control and treatment groups were analyzed in triplicate for each isolation. The number of isolations for each of the different experiments are reported along with the mean and standard error, and were analyzed statistically. A one-way analysis of variance was used (Minitab Statistical Software Program, State College, PA). In a series of experiments evaluating the effects of saturated and unsaturated fatty acids on surfactant secretion, the error variance was tested by Bartlett's test for homogeneity (23), and the error variance was found to be heterogeneous. Therefore, a $\log_{10}$ transformation of the data was performed before the analysis of variance. This was followed by Fisher's least significant test (24) to determine where the difference existed.

To establish a linear relationship between the independent and dependent variables in some of the experiments, a regression analysis was performed and the correlation coefficient was obtained. Covariate analysis was used to test the difference between the slope and intercept of two regression lines (Minitab Statistical Software Program).

RESULTS

AA, EPA and surfactant secretion. The type II pneumocytes isolated and maintained in culture under the experimental conditions were responsive to known secretagogues. When treated with 10 μM ATP and 1 mM adenosine, the rates of surfactant secretion were stimulated by 178 and 82%, respectively. These results are similar to those reported by Gilfillan and Rooney (25). Under the same experimental conditions, both AA and EPA stimulated secretion in a concentration dependent fashion with a correlation coefficient of 0.73 and 0.79 for AA (four experiments) and EPA (three experiments), respectively (Fig. 1). A significant linear regression line was found for both fatty acids at a level of $P < 0.001$ for the individual experiments as well as when combined. A polynomial model did not significantly improve the fit of the data, suggesting that a linear relationship best represents the data. A saturation effect could not be observed for these fatty acids as concentrations at approximately 50 μM or greater caused cell lysis, as was indicated by cell detachment and

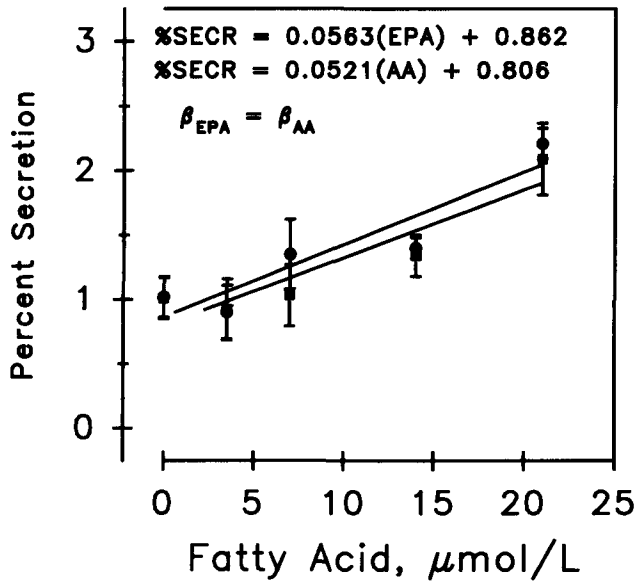

FIG. 1. A comparison of the effect of arachidonic acid (AA) and eicosapentaenoic acid (EPA) on surfactant secretion. Values are means ± SE of data from three and four cell isolations for EPA (●) and AA (■), respectively. Data from each isolation were determined in triplicate. The slope and intercept for the two regression lines are not different. Percent secretion (%SECR) is defined as the amount of [^{3}H]lipid radioactivity recovered in the media divided by the radioactivity of [^{3}H]lipid found in the cells plus the media multiplied by 100.

permeation of trypan blue into the nuclei. Lactate dehydrogenase release at the lower fatty acid concentrations used in these experiments was not different from control values (i.e., 2.6 ± 0.5% of total cellular enzyme activity, mean ± SE, n = 3), suggesting that release of surfactant was by a secretory process and did not result from cell lysis.

A further comparison of the regression lines derived from the secretory responses of AA and EPA by covariate analysis revealed that the two response curves shared the same slope and intercept (F = 0.029). This indicates that AA and EPA are equally effective in promoting surfactant secretion.

Effects of other fatty acids. In order to determine whether the stimulation of surfactant secretion is specific to highly unsaturated fatty acids, the effects of linoleic acid, OA and PA at 21 μM concentrations were also investigated (Fig. 2). Consistent with observations made in the preceding experiments, EPA and AA stimulated surfactant secretion. The stimulation by the polyunsaturated fatty acids, EPA, AA and linoleic acid, were 116, 85 and 50% above baseline, respectively. The stimulatory effect of these fatty acids was significantly greater than that caused by PA. It should be noted that the percent stimulation caused by EPA was significantly higher than that caused by linoleic acid which, in turn, was significantly higher than that elicited by PA.

Eicosanoids and surfactant secretion. AA-derived LTE_4 has previously been shown to stimulate surfactant secretion (12). The results shown in Figure 3 appeared to indicate an inhibition of surfactant secretion by LTE_4 ranging from pM to μM concentrations. However, because the slope of the regression line did not significantly differ from that for the untreated group, the data suggested that lipid secretion by the type II pneumocytes was not affected by LTE_4.

A comparison was made between groups of cells treated with AA (21 μM) alone or in combination with 0.1 μM nordihydroguaiaretic acid or 0.1 μM indomethacin. The concentration of nordihydroguaiaretic acid chosen for this experiment has been previously shown to impair AA-stimulated secretion (11). The indomethacin concentration used in this experiment has been shown to inhibit prostaglandin synthesis in other cells (26). At higher concentrations, indomethacin inhibits both prostaglandin and leukotriene synthesis (26). Therefore, we only tested indomethacin at the lower concentration. Neither the lipoxygenase nor the cyclooxygenase inhibitor altered AA-stimulated surfactant secretion at these concentrations (Fig. 4).

The roles of cAMP and calcium. When the cells were treated for 3 h with fatty acids at 7 or 21 μM concentration, there was no consistent trend of the effect of fatty acid on the respective cAMP level (Fig. 5). At the lower concentration, PA increased cellular cAMP content,

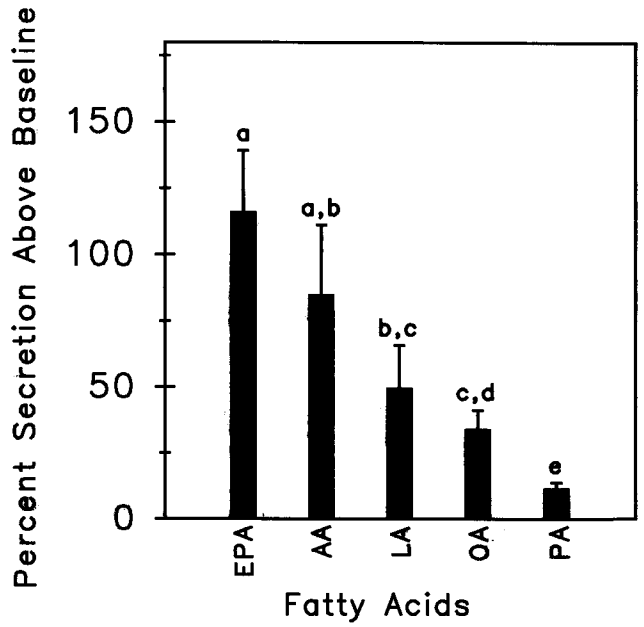

FIG. 2. The effects of different fatty acids on surfactant secretion. The concentration of fatty acids were 21 μM. Values are means ± SE for three to five cell isolations. Data from each isolation was determined in triplicate. Percent secretion above baseline was calculated by the equation: difference in percent secretion between tested and control group/percent secretion of control group × 100. The average baseline secretion was 0.93 ± 0.27%. An analysis of variance was performed with transformed data followed by a Fisher's least significant difference test (see Materials and Methods). Unshared superscript letters indicate significant differences among the responses of fatty acids to surfactant secretion. Abbreviations as in Figure 1; LA, linoleic acid; OA, oleic acid; PA, palmitic acid.

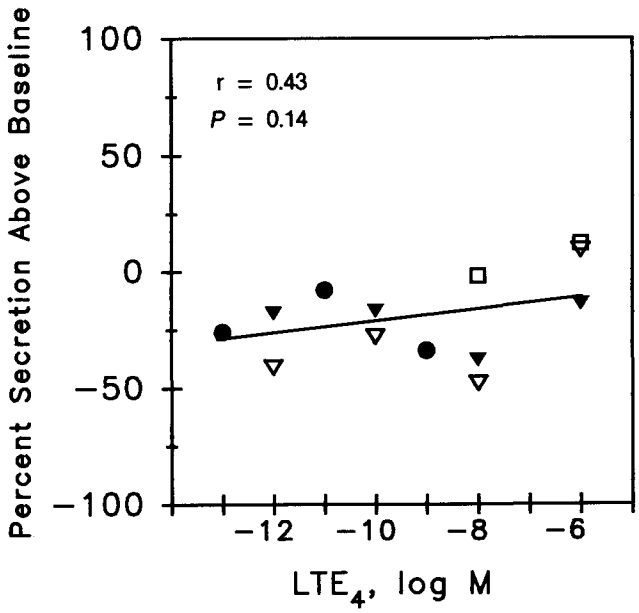

FIG. 3. The effect of leukotriene E_4 (LTE_4) on surfactant secretion. The four different symbols represent four different cell isolations. Each point represents a mean of triplicate measurements for each isolation. Percent secretion above baseline was calculated by the equation: difference in percent secretion between experimental and control group/percent secretion of control group × 100. The *P* and r represent the *P* value and correlation coefficient of the regression line, respectively.

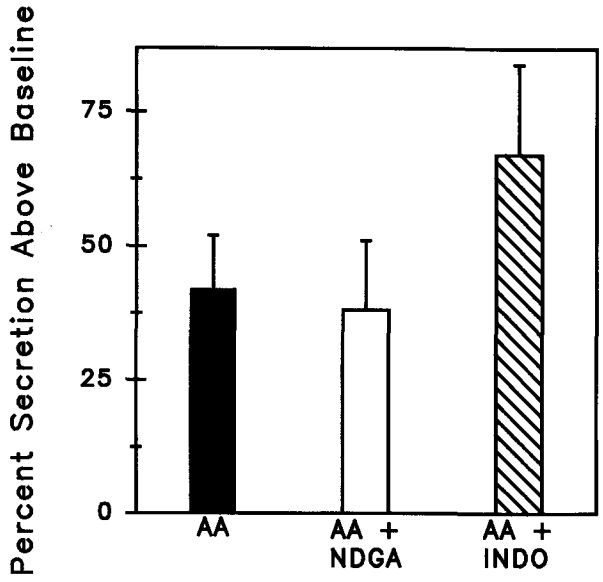

FIG. 4. The effect of a lipoxygenase inhibitor and cyclooxygenase inhibitor on arachidonic acid (AA)-stimulated surfactant secretion. The cells were incubated with 21 μM AA in the absence or presence of either 0.1 μM nordihydroguaiaretic acid (NDGA) or 0.1 μM indomethacin (INDO). Values are means ± SE for three cell isolations. Data from each isolation were determined in triplicate. Percent secretion above baseline was calculated by the equation: difference in percent secretion between experimental and control group/percent secretion of control group × 100. The average baseline secretion was 0.93 ± 0.16%.

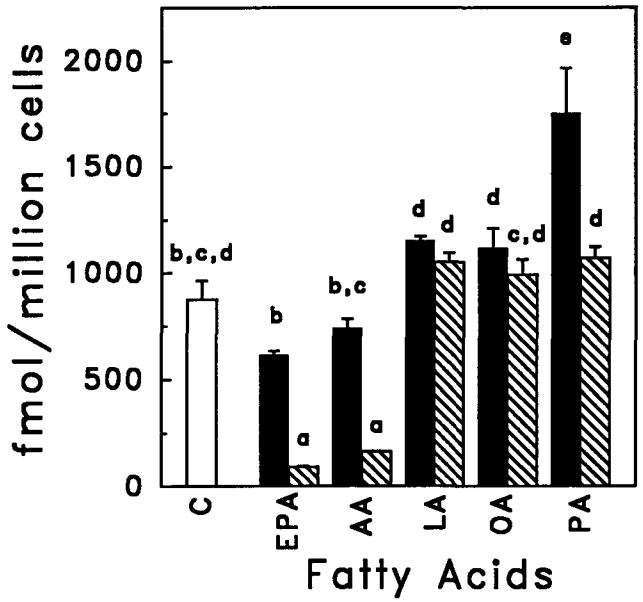

FIG. 5. The effects of different fatty acids on cyclic adenosine monophosphate (cAMP) levels. Values are means ± SE for triplicate samples from one experiment. Unshared superscript letters indicate significant difference in levels of cAMP among the cells treated with various fatty acids. Black and striped bars indicate cells treated with 7 and 21 μM fatty acid, respectively. Abbreviations as in Figure 2; C, control.

whereas the highly unsaturated fatty acids slightly decreased it. However, at the higher concentration, the highly unsaturated fatty acids (i.e., EPA and AA) markedly reduced cAMP, while no effect was noted for the other fatty acids.

The cells treated with ATP as a positive control had cytoplasmic-free calcium increased to 463 from 73 nM at baseline level. The extent of the stimulation was comparable to that reported by Dorn *et al.* (22). Despite the apparent response of the cells to ATP, the cellular-free calcium level was not altered by any of the fatty acids tested (data not shown).

DISCUSSION

Surfactant secretion is known to be regulated by a number of secretagogues, including calcium (27), β-adrenergic agonists (28) and purines (29,30). The role of AA in modulating the secretion, however, has not been fully established. Gilfillan and Rooney (11) first reported a stimulation of surfactant secretion by AA in alveolar type II cells, but such stimulatory effects were not observed by Sano *et al.* (18). Consistent with the former study, we found a significant increase in surfactant lipid secretion by AA in the cultured alveolar type II cells, and the stimulatory action of AA was found to be concentration-dependent. In view of the known antagonistic action of n-3 and n-6 fatty acid in metabolic processes (6–8,13,14), the present study was expanded to investigate the effect of EPA on surfactant secretion. Contrary to our expectations, EPA was as effective as AA in enhancing surfactant secretion in the cultured type II cells.

The mechanisms underlying stimulation of secretion by EPA and AA are not fully understood. AA-stimulated secretion has been partly attributed to lipoxygenase products derived from AA (11,12). This mechanism, however, is not supported by the data of the present study for the following reasons. First, despite a wide range of concentrations tested, exogenous LTE_4 did not alter the baseline secretion of surfactant lipid. This finding is consistent with the results of an earlier study, which had shown that leukotriene C_4 and leukotriene D_4 were ineffective in stimulating surfactant secretion (18). Second, in the present study, AA-stimulated secretion was not affected by lipoxygenase nor cyclooxygenase inhibitors. Furthermore, if leukotrienes were involved, one should have seen opposing effects of EPA and arachidonic acid since five-series leukotrienes derived from EPA are known to be less biologically active than the four-series leukotrienes generated from AA (31,32). However, because other eicosanoid inhibitors and concentrations were not thoroughly investigated, a role of leukotrienes and/or prostaglandins cannot be entirely ruled out. The reason for the discrepancy between our findings and those of Gilfillan and Rooney (11,12) in regard to the role of leukotrienes in surfactant secretion by alveolar type II cells is not clear, although they also found that indomethacin at the concentrations used in our experiments did not affect secretion (11). It should also be noted that eicosanoid-independent AA-stimulated secretion has been demonstrated in GH_3 pituitary cells (33). In these secretory cells, AA-stimulated

prolactin secretion was not reduced by leukotriene or prostaglandin inhibitors (33).

The most important finding of the present study was the differential stimulatory effect on surfactant secretion exhibited by fatty acids varying in chain length and in the number of double bonds. The level of stimulation produced was highest for highly unsaturated fatty acids (EPA and AA), lowest for the saturated PA, and intermediate for monounsaturated (oleic) and diunsaturated (linoleic) fatty acids. Thus, the stimulation of surfactant secretion is dependent on the degree of unsaturation of the fatty acids as supported by an analysis of the data which revealed a positive correlation ($r = 0.71$, $P < 0.01$) between the degree of unsaturation (e.g., 0, 1, 2, 4 and 5 double bonds) and the stimulation of secretion. This is consistent with the earlier finding by Kolesnick *et al.* (33) which showed that prolactin secretion by pituitary cells was stimulated to a greater extent by AA followed, in decreasing order, by linolenic acid, linoleic acid, OA and steric acid. However, our data do not exclude the possibility that the stimulation may also be related to carbon chain length, as there was a significant correlation ($r = 0.67$, $P < 0.01$) between chain length (e.g., 16, 18 and 20 carbons) and stimulation.

The physiological significance of fatty acid-enhanced release of surfactant is not known. Tissue fatty acid composition is susceptible to modification by dietary fat. In a recent study, we demonstrated that menhaden oil supplementation in diet increased the levels of highly unsaturated fatty acids, e.g., EPA and docosahexaenoic acid, in type II pneumocyte phospholipids (34). If polyunsaturated fatty acids enhance surfactant release relative to saturated fats, the composition of the diet may be an important factor to consider for those who have problems with surfactant production and/or release.

The precise mechanism by which highly unsaturated fatty acids stimulate surfactant secretion is unclear. Calcium and cAMP are known to enhance surfactant secretion (27,28,35), but changes in cellular levels of these two mediators are not likely to be responsible for the observed stimulation. The mechanism may rather be related to changes in membrane fluidity, which, when increased, may facilitate fusion of surfactant with the cell membrane. In fact, highly unsaturated fatty acids, such as AA, have been demonstrated to facilitate fusion of secretory vesicles into cell membranes (36). Conversely, when AA was replaced by OA, the rate of fusion was markedly reduced (36). Whether enhanced fusion of vesicles within the alveolar type II cells by highly unsaturated fatty acids promotes surfactant secretion remains to be determined.

ACKNOWLEDGMENTS

The authors wish to thank Drs. C. Channa Reddy, John F. Kavanaugh, Penny M. Kris-Etherton and John L. Beard for their comments and suggestions. The technical advice and assistance of Dr. Jesse E. Sisken and Dr. Yuzhang Cao, and the professional secretarial assistance of Nancy Hopkins and Shelly Bynum, are greatly appreciated. Evidence That Palmitic Acid Is Absorbed as *sn*-2 Monoacylglycerol from Human Milk by Breast-Fed Infants

Sheila M. Innis*, Roger Dyer and **Carolanne M. Nelson**

Department of Pediatrics, University of British Columbia, Vancouver, British Columbia, V5Z 4H4 Canada

Milk fatty acids consist of about 20–25% palmitic acid (16:0), with about 70% of 16:0 esterified to the *sn*-2 position of the milk triacylglycerols. Hydrolysis of dietary triacylglycerols by endogenous lipases produces *sn*-2 monoacylglycerols and free fatty acids, which are absorbed, reesterified, and then secreted into plasma. Unesterified 16:0 is not well absorbed and readily forms soaps with calcium in the intestine. The positioning of 16:0 at the *sn*-2 position of milk triacylglycerols could explain the high coefficient of absorption of milk fat. However, the milk lipase, bile salt-stimulated lipase, has been suggested to complete the hydrolysis of milk fat to free fatty acids and glycerol. These studies determined whether 16:0 is absorbed from human milk as *sn*-2 monopalmitin by comparison of the plasma triacylglycerol total and *sn*-2 position fatty acid composition between breast-fed and formula-fed term gestation infants. The human milk and formula had 21.0 and 22.3% of 16:0, respectively, with 54.2 and 4.8% 16:0 in the fatty acids esterified to the 2 position. The plasma triacylglycerol total fatty acids had 26.0 ± 0.6 and 26.2 ± 0.6% of 16:0, and the *sn*-2 position fatty acids had 23.3 ± 3.3 and 7.4 ± 0.7% of 16:0 in the three-month-old exclusively breast-fed (n = 17) and formula-fed (n = 18) infants, respectively. Marked differences were found in the plasma total and the 2 position phospholipid percentage of 20:4ω6, i.e., 11.6 ± 0.3 and 6.9 ± 0.6 (total), 17.7 ± 1.4 and 9.7 ± 0.6 (*sn*-2 position) and percentage of 22:6ω3, 4.6 ± 0.3 and 2.1 ± 0.3 (total), 5.6 ± 0.6 and 2.0 ± 0.2 (*sn*-2 position) for the breast-fed and formula-fed infants, respectively. These studies provide convincing evidence that 16:0 is absorbed from human milk as *sn*-2 monoacyl-glycerol. The metabolic significance of the differences in positional distribution of fatty acids in the plasma lipids of breast-fed and formula-fed infants is not known.

***Lipids* 29, 541–545 (1994).**

Palmitic acid (16:0) usually represents 20–25% of human milk fatty acids, and about 70% of 16:0 is esterified to the *sn*-2 position in the triacylglycerols (1–3). The reason for the preferential esterification of 16:0 to the 2 position of glycerol during triacylglycerol synthesis in the mammary gland, and any potential physiological significance of this to infant nutrition, is not yet clear. It is known that the products of gastric and pancreatic colipase-dependent lipase hydrolysis of dietary fat are free fatty acids, released from the *sn*-1,3 positions and *sn*-2 monoacylglycerols (4). The efficiency of absorption of unesterified 16:0 by infants is relatively low, only about 63% compared to over 90% for the unsaturated fatty acids oleic acid (18:1ω9) and linoleic acid (18:2ω6) (5). This is believed to be due in part to a melting point above body temperature (63°) and a tendency for rapid formation of hydrated fatty acid soaps at the pH of the intestine (4). Consistent with this, studies have been reported that showed that fat absorption is higher in infants fed fats with 16:0 esterified to the triacylglycerol *sn*-2 rather than the *sn*-1,3 positions (6–8). This supports the hypothesis that the high efficiency of human milk fat absorption may be the result of the specific positioning of milk 16:0 at the *sn*-2 position of the triacylglycerol moiety (8).

The significance of *sn*-2 monoacylglycerol absorption in infants fed fresh human milk is, however, controversial because of the hypothesized role of the milk lipase, bile salt-stimulated lipase, in milk fat digestion. This enzyme is synthesized in the mammary gland, survives the acid environment of the stomach, and, at least *in vitro*, is able to complete the hydrolysis of milk triacylglycerols to form glycerol and free fatty acids (9–13). Additional hydrolysis of the products of endogenous lipase digestion of milk fat by bile salt-stimulated lipase has been suggested to explain the high efficiency of absorption of human milk (9–13). Hydrolysis to release 16:0 from *sn*-2 monoacylglycerols formed by endogenous lipase activity, however, does not seem consistent with the specific positioning of 16:0 at the *sn*-2 position of human milk triacylglycerols, the low coefficient of absorption of unesterified 16:0, or the high coefficient of absorption of human milk fat in infants.

In contrast to human milk, 16:0 in vegetable oils and nonmilk-derived animal fats, other than lard, is predominantly esterified to the triacylglycerol *sn*-1,3 positions, and unsaturated fatty acids occupy the *sn*-2 position (2). Since endogenous lipases do not hydrolyze the *sn*-2 ester bond of dietary fats (4,9), it is reasonable to assume that infants fed formula will absorb *sn*-2 monoacylglycerols containing unsaturated fatty acids. The composition of monoacylglycerols absorbed from the intestinal lumen is important to the fatty acid distribution of circulating lipids because about 70% of the fatty acids absorbed as *sn*-2 monoacylglycerols are conserved in the original position during reesterification to form triacylglycerols in the intestinal cells (4). Several studies have shown that the rate of hydrolysis and composition of remnant particles formed by lipoprotein and hepatic lipase is influenced by the plasma triacylglycerol fatty acid composition and positional distribution (4,14,15). It is possible, therefore, that the distribution of fatty acids in milk or formula triacylglycerols could have important metabolic effects beyond that on fat absorption. As a first step in understanding the metabolic significance of the fatty acid distribution in milk fat, the present studies sought to determine if *sn*-2 monoacylglycerol containing 16:0 is absorbed from human milk. This was done by the comparing of the composition of total and *sn*-2 position fatty acids in plasma lipids between breast-fed infants and infants fed formula containing

Abbreviation: LCAT, lecithin:cholesterol acyltransferase.

similar amounts of 16:0 to milk but predominantly esterified to the formula fat *sn*-1,3 positions.

MATERIALS AND METHODS

Subjects and methods. Infants were eligible for this study if they were full-term (>37 wk gestation at birth), appropriate weight for gestational age, and if the mother had chosen to exclusively breast-feed or feed formula for at least 3 mon. The infants were enrolled into the study by 14 d of age following written, informed parental consent prior to 14 d of age. Infants assigned to the formula group were fed a ready-to-feed liquid formula (Enfalac; Mead Johnson Nutritionals, Evansville, IN) containing amounts of 16:0 similar to those in human milk (Table 1). Body weight, length, head circumference and skin-fold thickness (subscapular, abdominal and triceps) were recorded for all infants at 14 d and at 1,2 and 3 mon of age. Breast-feeding mothers provided a mid-feed sample of breast milk at 14 d and 3 mon *postpartum*. Blood samples were obtained by venipuncture from each infant at 3 mon (90 ± 4 d) of age during an out-patient visit to the BC's Children's Hospital. Infants were not fasted, and had been fed between 1 and 3 h prior to blood sampling. The protocol and procedures involving the infants were approved by the University of British Columbia Screening Committee for Research Involving Human Subjects, and by the Research Screening Committee of the BC's Children's Hospital.

Following collection, blood samples were immediately placed on ice and transferred to the research laboratory no more than 15 min after collection. Plasma was separated by centrifugation, total lipids were extracted, and triacylglycerols, phospholipids and cholesteryl esters were separated by thin-layer chromatography (16,17). Analysis of the composition of fatty acids at the *sn*-2 position of the plasma phospholipids and triacylglycerols, and of the formula and milk fat was based on the methods published by Kuksis (18) and Christie (19), as described elsewhere (17). The enzymatic hydrolysis utilized pig pancreatic lipase (EC 3.1.1.3, type II) for the milk and formula fat and plasma triacylglycerols, and phospholipase A_2 (EC 3.1.1.4) (Sigma Chemical Co., St. Louis, MO) for plasma phospholipids. After hydrolysis, 17:0 monoacylglycerol was added as an internal standard, the sample was extracted, and the monoacylglycerols separated by thin-layer chromatography. Monoacylglycerol recovery and the composition of the fatty acids in the *sn*-2 position of the milk and formula diet, and in the plasma lipid fractions was determined by fatty acid methyl ester analysis on the monoacylglycerol fraction. The fatty acid compositions of the milk and formula fat were analyzed by the method of Lepage and Roy (20) without solvent extraction. Fatty acid methyl esters were analyzed using a Varian 3400 gas–liquid chromatograph equipped with an RTx 2330 capillary column, 30 m x 25 mm i.d. (Restek Corporation, Bellefonte, PA) and a Varian Star data system (Varian Canada Inc., Georgetown, Ontario, Canada) as described elsewhere (17). The flow rate of the carrier gas (helium) was 1 mL/min; the injector and flame-ionization detector were maintained at 240 and 260°C, respectively. The samples were injected with the column oven at 80°C. The temperature of the oven was programmed to increase to 170°C at 10°C/min after 2 min, then increase to 195°C at 20°C/min after 25 min, and to increase to 245°C at 20°C/min after 18 min. The fatty acid methyl esters were identified by comparison of their retention times with those of authentic standards.

Statistical analysis. Comparisons of results to determine the effect of breast-feeding vs. formula-feeding on the fatty acid compositions of the infants' plasma lipids were conducted using Student's *t*-test with a $P < 0.05$ as statistically significant. All calculations were performed using the GLM procedure in the Number Cruncher Statistical System, version 5.01 (Kaysville, UT).

TABLE 1

Composition of Human Milk and Infant Formula Fat Total and *sn*-2 Position Fatty Acids (wt%)[a]

Fatty acid (wt%)	Human milk		Formula	
	Total	*sn*-2 Position	Total	*sn*-2 Position
12:0	4.1 ± 0.4	2.5 ± 0.4	8.9	4.5

22:6ω3	0.2 ± 0.0	0.4 ± 0.0	nd	nd

[a]Values given are percentage of total fatty acids and for human milk represent means ± SEM (range) of mid-feed milk collected when the infants were 3 months old. Values for formula are the average of three separate analyses; <0.1 indicates value >0.00 and <0.10%; nd, not detected.

RESULTS

Formula and milk triacylglycerol composition and fatty acid distribution. The fatty acid composition of the human milk samples was similar to that reported in other recent studies (2) with mean levels of 21.0% 16:0, 13.3% 18:2ω6, 0.5% 20:4ω6 and 0.2% 22:6ω3 (Table 1). The fatty acids at the *sn*-2 position of the milk fat had 54.2% 16:0, indicating that over 80% of the milk total 16:0 was esterified to the *sn*-2 position. This result is consistent with the value of 51.2% 16:0 in fatty acids at the *sn*-2 position of mature human milk triacylglycerols reported by Martin *et al.* (3). In contrast to 16:0, only about 14% of the total 18:1 and 20% of the total 18:2ω6 in the milk fat was esterified to the *sn*-2 position (Table 1). The longer chain ω6 and ω3 fatty acids, 20:4ω6 and 22:6ω3, were approximately equally distributed between the *sn*-2 and the *sn*-1/-3 positions, with about 46%

of the 20:4ω6 and 66% of the 22:6ω3 being recovered in the *sn*-2 monoacylglycerols (Table 1). Martin *et al.* (3) used chemical degradation to show that about 49% of the 20:4ω6 and 66% of the 22:6ω3 was in the *sn*-2 position, and about 45% of the 20:4ω6 and 33% of the 22:6ω3 was esterified to the *sn*-3 position of human milk triacylglycerols. The infant formula contained an amount of 16:0 (22.3%) similar to that in human milk. The formula, however, contained predominantly 18:1 and 18:2ω6, and had only 4.8% of 16:0 in the fatty acids esterified to the 2 position of the formula fat.

Total and sn-2 *fatty acid composition of plasma triacylglycerols from breast-fed infants and infants fed formula.* These studies provide unambiguous evidence that 16:0 esterified to the *sn*-2 position of human milk is absorbed intact by human infants and re-esterified to triacylglycerols for secretion into plasma (Table 2). The triacylglycerol total fatty acids of the breast-fed infants had significantly higher levels of 14:0, 16:1, 18:0, 20:4ω6, 20:5ω3 and 22:5ω6 and lower levels of 18:2ω6 than the formula-fed infants. The significantly higher percentage of 16:0 in the triacylglycerol *sn*-2 position fatty acids of the three-month-old breast-fed compared to formula-fed infants (23.3 ± 3.3 and 7.4 ± 0.7% 16:0, respectively) was accompanied by significantly lower levels of 18:1 and 18:2ω6. The formula-fed infants also had significantly lower levels of 16:1, 20:3ω6, 20:4ω6, 20:5ω3, 22:5ω3 and 22:6ω3 in their plasma triacylglycerol *sn*-2 position fatty acids than did the breast-fed infants.

Total and sn-2 *fatty acid composition of plasma phospholipids from breast-fed infants and infants fed formula.* The plasma phospholipid total fatty acids of the breast-fed infants had significantly lower levels of 16:0 and 18:2ω6, but higher levels of 18:0, 20:2ω6, 20:3ω6, 20:4ω6, 20:5ω3, 22:4ω6, 22:5ω3 and 22:6ω3 than those of infants who were fed formula (Table 3). Similarly, the phospholipid *sn*-2 position fatty acids of the breast-fed infants had significantly lower levels of 18:2ω6 and 18:3ω3 and higher 20:4ω6, 20:5ω3, 22:5ω3 and 22:6ω3 than those of the formula-fed infants.

Fatty acid composition of plasma cholesteryl esters from breast-fed infants and infants fed formula. The major difference in the plasma cholesteryl ester fatty acid composition due to feeding formula rather than breast feeding was in the percentage of 20:4ω6 and 22:6ω3. Levels of 20:4ω6 and 22:6ω3 in the plasma cholesteryl esters of the infants who were fed formula were approximately one-third of the levels in the infants who were breast-fed. The cholesteryl ester percentages of 14:0, 16:0, 16:1 and 20:5ω3 were also significantly lower, whereas the percentage of 18:2ω6 and 18:3ω3 were significantly higher in the formula-fed than breast-fed infants.

TABLE 2

Composition of Plasma Triacylglycerol Total and *sn*-2 Position Fatty Acids in Three-Month-Old Breast-Fed and Formula-Fed Gestation Infants[a]

Fatty acid (wt%)	Triacylglycerol total		*sn*-2 Position	
	Breast-fed	Formula-fed	Breast-fed	Formula-fed

DISCUSSION

The results of these studies provide convincing evidence that 16:0 esterified to the *sn*-2 position of human milk is conserved throughout digestion and absorption, and the conversion to triacylglycerols in the enterocyte, and then secreted into plasma as lipoprotein triacylglycerols. *In vitro* studies have shown that the milk lipase, bile salt-stimulated lipase, can complete the digestion of *sn*-2 monoacylglycerols formed by gastric acid colipase-dependent lipase hydrolysis of triacylglycerols to give unesterified fatty acids and glycerol (9,13). Information

on the extent of hydrolysis of *sn*-2 monoacylglycerols with 16:0 *in vivo* in young infants has not been published. Strong circumstantial evidence that bile salt-stimulated lipase does not quantitatively hydrolyze 16:0 from the *sn*-2 position of human milk fat is provided by the results of these studies that show approximately 26% of 16:0 in fatty acids esterified to the plasma triacylglycerol *sn*-2 position of breast-fed infants compared to only about 7.4% 16:0 in infants fed a formula containing comparable amounts of 16:0 to the milk, but predominantly esterified to the glycerol *sn*-1,3 positions. These results are evidence in support of the hypothesis (8) that the preferential esterification of 16:0 to the *sn*-2 position of human milk triacylglycerols is one of the reasons for the high coefficient of absorption of human milk fat. Although the studies reported here indicate that bile salt-stimulated lipase does not quantitatively complete the hydrolysis of milk triacylglycerols to free fatty acids and glycerol in infants *in vivo*, other studies have suggested a possible role in the hydrolysis of milk long-chain ω6 and ω3 fatty acids. The positioning of a substantial proportion of the 20:4ω6 and 22:6ω3 at the *sn*-3 position in milk triacylglycerols (3) is believed to render these fatty acids relatively resistant to hydrolysis by pancreatic colipase-dependent lipase (21,22). Whether or not bile salt-stimulated lipase is important in the digestion of long-chain ω6 and ω3 fatty acids from human milk has still to be fully clarified.

The plasma phospholipid levels of 20:4ω6 and 22:6ω3 are known to be lower in infants fed formula than in infants fed human milk (23,24). The analyses reported here show that this difference involves substantially lower 20:4ω6 and 22:6ω3 levels, but much higher 18:2ω6 levels in the fatty acids esterified to the *sn*-2 position of plasma phospholipids in infants fed formula rather than breast-fed (mean ± SEM 18:2ω6, 40.2 ± 1.6 and 25.0 ± 1.4%, 20:4ω6, 9.7 ± 0.6 and 17.7 ± 1.4%; 22:6ω3, 2.0 ± 0.2 and 5.6 ± 0.6%; for the formula and breast-fed infants, respectively). The higher levels of 18:2ω6 at the *sn*-2 position of plasma phospholipids in the formula-fed compared to breast-fed infants seems to reflect the higher amount of 18:2ω6 at the 2 position of the formula compared to the human milk fat (27.1 and 8.1% 18:2ω6 for the formula and human milk, respectively), and not the small difference in 18:2ω6 between the formula and milk total fatty acids (17.7 and 12.8% 18:2ω6, respectively). Although recent studies have shown that phospholipid synthesis in intestinal cells may proceed *via* the monoacylglycerol pathway (25), it is not clear to what extent this occurs *in vivo* in young infants. It may also be of relevance that recent studies have shown that the incorporation of 20:4ω6 into rat lymph phospholipids was higher when 20:4ω6 was given with 18:1 and monopalmitin than when given with 18:2ω6 and monoolein (26). This may suggest that absorption of monopalmitin following hydrolysis of human milk fat could facilitate incorporation of 20:4ω6 into intestinal lipoprotein phospholipids of breast-fed infants. Future studies on the fatty acid composition and structure of intestinal chylomicron and very low density lipoprotein would provide more specific information on this.

In recent studies, higher levels of 16:0 were found in plasma cholesteryl esters of piglets fed milk or formula containing 16:0 esterified to the 2 position of the fat than in piglets fed formula with 16:0 predominantly esterified to the triacylglycerol 1,3 positions (17). A similar, but smaller difference was found in the present studies with infants; that is, the percentage of 16:0 was about 15% higher in the cholesteryl esters of the breast-fed than of the formula-fed infants. Neither the origin nor metabolic significance of the relatively high amounts of cholesteryl palmitate in plasma seems to be known. Recent studies have suggested that lecithin:cholesterol acyltransferase (LCAT) from human plasma preferentially uses the *sn*-1 acyl group from phosphatidylcholines when 20:4ω6 or 22:6ω3 is esterified to the *sn*-2 position (26). Since molecular species of phosphatidylcholines containing 20:4ω6 and 22:6ω3 in the *sn*-2 position have 16:0 and 18:0 in the *sn*-1 position, this could explain the origin of 16:0 in plasma cholesteryl esters. The higher proportions of 20:4ω6 and 22:6ω3 in the plasma cholesteryl esters of infants who are breast-fed rather than fed formula (Table 4), however, suggests LCAT is able to use these fatty acids as substrates and form cholesteryl esters. Whether or not cholesteryl esters are quantitatively important in the transfer of fatty acids to tissues, possibly *via* low density lipoprotein receptors or *via* high density lipoprotein transfer, and the significance of the fatty acid composition to cholesteryl ester metabolism is not known.

The studies reported here provide *in vivo* data to show that the distribution of saturated and unsaturated fatty acids in human milk and infant formula is a determinant of the fatty acid distribution of infant plasma triacylglycerols and phospholipids. The high amount of 16:0 in the *sn*-2 position of plasma triacylglycerols in breast-fed infants shows that 16:0 is absorbed as *sn*-2 mono-

TABLE 4

Composition of Plasma Cholesteryl Ester Fatty Acids (wt%) in Infants Fed Human Milk or Formula[a]

Fatty acid (wt%)	Breast-fed	Formula-fed
12:0	0.2 ± 0.0	0.2 ± 0.0
14:0	1.1 ± 0.0	0.8 ± 0.0[b]
16:0	17.2 ± 0.5	15.0 ± 0.6[b]
16:1	2.6 ± 0.1	1.9 ± 0.1[b]
18:0	3.1 ± 0.3	3.2 ± 0.2
18:1	25.4 ± 0.6	27.1 ± 0.7
18:2ω6	40.1 ± 0.7	45.8 ± 0.8[b]
18:3ω3	0.4 ± 0.0	0.5 ± 0.0[b]
20:2ω6	0.1 ± 0.0	0.1 ± 0.0

[b]Values significantly different from respective values for breast-fed infants.

palmitin by infants fed human milk. In contrast, it is probable that 16:0 is absorbed predominantly as an unesterified fatty acid from conventional infant formula. It is likely that analyses of isolated chylomicrons will show higher amounts of 16:0 in the triacylglycerol *sn*-2 position than were found in plasma total triacylglycerols. Lipoprotein lipase is stereospecific and is known to hydrolyze triacylglycerols with saturated fatty acids at the *sn*-2 position more slowly than triacylglycerols with unsaturated fatty acids at the *sn*-2 position (4,14,15). Whether or not hydrolysis of plasma triacylglycerols proceeds at similar rates in infants fed formula and infants fed human milk is not known. Future work, possibly involving analysis of the complete positional distribution of fatty acids in triacylglycerols and phospholipids in separated lipoproteins may help elucidate the implications of human milk fat structure to fatty acid metabolism and tissue delivery in the infant.

To understand how dietary fatty acids differentially modulate mouse skin tumorigenesis, the ability of specific fatty acids and their derivatives to activate murine epidermal protein kinase C (PKC) *in vitro* was investigated. Total PKC from untreated female SSIN mouse skin was partially purified and incubated with specific fatty acids at concentrations up to 300 μM in the presence of Ca^{2+} and phosphatidylserine. The *cis*-unsaturated fatty acids tested, ranging from 16:1 to 22:6, stimulated PKC activity in a similar dose-dependent manner with an approximate threefold maximum increase over control. Neither the number of *cis*-double bonds nor the chainlength of these fatty acids affected their relative ability to activate PKC. *trans*-Fatty acids, with the exception of linoelaidic acid (*t,t*-18:2n-6), exhibited about half of the potency of their corresponding *cis*-isomers in stimulating PKC at the plateau concentration (200 μM) or lower. Substitutions close to the double bond on *cis*-fatty acids abolished their ability to activate PKC. The hydroxylated metabolites of arachidonic acid (20:4n-6) and linoleic acid (*c,c*-18:2n-6), i.e., the hydroxyeicosatetraenoic acids (HETE) and hydroxyoctadecadienoic acids (HODE), also activated mouse skin PKC *in vitro*, but only about half as effectively as did the respective parent fatty acids. The results suggest that both hydroxyl substitution and *trans*-configuration of HETE and HODE are responsible for their reduced ability to activate PKC. Overall the data suggests that the reduced skin tumor yield observed in mice fed diets high in *c,c*-18:2n-6 is not likely to be due to differences in the ability of *c,c*-18:2n-6 or 20:4n-6, or their metabolites, to activate PKC.

***Lipids* 29, 547–553 (1994).**

Protein kinase C (PKC) is a crucial enzyme in cellular signal transduction, and it is also a target receptor protein for phorbol ester (1). *In vitro* studies have shown that PKC phosphorylates a broad range of endogenous proteins containing seryl and threonyl residues (1,2). Numerous physiological functions of PKC have been determined, such as its involvement in cell secretion, exocytosis, smooth muscle contraction, gene expression and cell proliferation (3). Ten isozymes of PKC have been identified in mammalian tissues thus far; the characteristics and tissue specificity of several PKC isozymes have been reviewed by Nishizuka (4). PKC isozymes α, β, γ, δ, ε and ζ have been identified in mouse epidermal cells by different groups (5–9). PKC was first described as a Ca^{2+}- and phospholipid-dependent enzyme that could be activated by diacylglycerol (1). Various studies have shown that unsaturated fatty acid and some of their oxygenated metabolites can activate PKC isozymes from rat brain (10,11) or human placental cytosol (12) *in vitro* and in intact human platelets (13). The phorbol ester, 12-*O*-tetradecanoylphorbol-13-acetate (TPA), which has a diacylglycerol-like structure, can increase the affinity of PKC for Ca^{2+} and activates PKC (1).

Arachidonic acid (20:4n-6) and other fatty acids can be released from phospholipids by phospholipase A_2 in many tissues and may subsequently activate PKC (1,4). Numerous studies have also shown that the composition of membrane phospholipids can be altered by modifying dietary fat composition (14–17). As shown previously, linoleic acid can compete with arachidonic acid for incorporation into epidermal cell membranes in mice fed a diet rich in corn oil (18). This, in turn, would alter the composition of the free fatty acids liberated from phospholipids by phospholipases. Fan *et al.* (13) reported that arachidonic acid and linoleic acid exhibited a similar potential to activate rat brain PKC *in vitro*; however, arachidonic acid showed a much greater ability to stimulate the phosphorylation of a 43-kDa protein than did linoleic acid in intact human platelets.

Both 20:4n-6 and *c,c*-18:2n-6 are substrates of lipoxygenase and can be metabolized to hydroxy metabolites (19). In a previous study, we have demonstrated that approximately 20% of 20:4n-6 was metabolized by lipoxygenase in mouse epidermal cells, which resulted in the *in vitro* formation of four major monohydroxy metabolites (5-,8-,12- and 15-hydroxyeicosatetraenoic acid, HETE) (20). We also tentatively identified 9- and 13-hydroxyoctadecadienoic acid (HODE) as the major metabolites when [1-^{14}C]*c,c*-18:2n-6 was incubated with mouse epidermal cells. Therefore, in addition to 20:4n-6 and *c,c*-18:2n-6, we studied the ability of the hydroxylated metabolites of 20:4n-6 and *c,c*-18:2n-6 (HETE and HODE) to activate PKC in mouse skin.

Previous work in our laboratory has demonstrated that diets high in *c,c*-18:2n-6 caused changes in the fatty acid composition of epidermal phospholipids such that *c,c*-18:2n-6 levels increased while 20:4n-6 levels decreased. The high *c,c*-18:2n-6 diets also inhibited TPA-induced skin tumor promotion, when compared to low *c,c*-18:2n-6 diets (20). While the direct activation of PKC by TPA is believed to be responsible for most, if not all, the effects of TPA, including promotion (1), other nonphorbol ester promoters, such as chrysarobin, do not directly activate PKC but do cause loss of PKC activity (21). This apparent down-regu-

Abbreviations: ATP, adenosine 5′-triphosphate; DEAE-cellulose, diethyl-aminoethyl cellulose; 5,6-DHT, 5,6-dihydroxyeicosatrienoic acid; DTT, dithiothreitol; EDTA, ethylenediaminetetraacetic acid; EGTA, ethyleneglycol-*bis*(β-aminoethyl ether)-*N,N,N′,N′*-tetraacetic acid; 12,13-EODE, 12(13)-epoxyoctadienoic acid; HETE, hydroxyeicosatetraenoic acid; HpETE, hydroperoxyeicosatetraenoic acid; HODE, hydroxyoctadecadienoic acid; HpODE, hydroperoxyoctadecadienoic acid; PKC, protein kinase C; PMSF, phenylmethylsulfonyl fluoride; PS, phosphatidylserine; TPA, 12-*O*-tetradecanoylphorbol-13-acetate.

lation of PKC is likely to be due to the activation of PKC by ligands produced in response to chrysarobin (22). It was therefore the goal of this study to compare the relative ability of different fatty acids to activate epidermal PKC and to determine whether the activation observed correlated with the known effects of these dietary fatty acids on carcinogenesis.

MATERIALS AND METHODS

Materials. 5(*S*)-, 8(*S*)-, 12(*S*)- and 15(*S*)-HETE, 9(*S*)- or 13(*S*)-HODE, 5,6-dihydroxyeicosatrienoic acid (5,6-DHT) and 12(13)-epoxyoctadecadienoic acid (12,13-EODE) were purchased from Cayman Chemical (Ann Arbor, MI). All fatty acids tested (see Table 1), histone (Type III-S), adenosine 5′-triphosphate (ATP), phosphatidylserine (PS), phenylmethylsulfonyl fluoride (PMSF), dithiothreitol (DTT), ethylenediaminetetraacetic acid (EDTA), ethyleneglycol-*bis*(β-aminoethyl ether)-*N,N,N′,N′*-tetraacetic acid (EGTA), diethylaminoethyl (DEAE) cellulose, and the protease inhibitors aprotinin, leupeptin and pepstatin were purchased from Sigma Chemical Co. (St. Louis, MO). Whatman phosphocellulose paper, grade p81, was purchased from Fisher Scientific (Houston, TX). [γ-^{32}P]ATP (specific activity, 25 Ci/mmol; concentration 10 mCi/mL) was purchased from ICN Biomedicals, Inc. (Irvine, CA).

PKC preparation. Untreated female SSIN (SENCAR) mice (from The University of Texas M.D. Anderson Cancer Center, Science Park Veterinary Division breeding colony, Smithville, TX), each 6–12 weeks old and weighing 25–40 g were used in all experiments. Mice were shaved and then killed by cervical dislocation. The dorsal skin was removed immediately and placed on ice. Epidermal cells were scraped and placed in homogenization buffer (20 mM Tris, pH 7.4, 2 mM EDTA, 2 mM EGTA, 1 mM DTT, 1 mM PMSF, 20 μg/mL aprotinin, 50 μg/mL leupeptin, 10 μg/mL pepstatin and 0.5% Triton X-100). Skin scrapings were homogenized and centrifuged at 540,000 × *g* (100,000 rpm) for 10 min at 4°C using a Beckman TL-100 ultracentrifuge (Beckman Instruments, Fullerton, CA). The protein concentration of the supernatant was determined by the Coomassie blue reaction (Bio-Rad, Richmond, CA). Protein (2 mg) was loaded onto a 1-mL DEAE-cellulose column, partially purified PKC was eluted with 0.12 M NaCl.

PKC activity assay. Total PKC activity was determined as described by Ashendel *et al.* (23) and as modified by Fischer *et al.* (24). In brief, PKC activity was measured by comparing the transfer of [^{32}P]phosphate from [γ-^{32}P]ATP to histone (Type III-S) in the presence (plus) and absence (minus) of Ca^{2+} (0.5 mM) and PS (20 μg/mL). Ten μL of ethanol, or various concentrations of HETE and HODE or fatty acids in 10 μL of ethanol, were added into tubes containing 75 μL of assay mixture. Assay mixtures consisted of 20 mM Tris, pH 7.6, 10 mM $MgCl_2$, 375 μg/mL histone, and 20 μM ATP along with 20 μCi/mL [γ-^{32}P]ATP. For each assay, 25 μL of PKC eluate (elution buffer for background samples) was added into each tube at 15-s intervals and incubated at 30°C for 10 min, after which 25 μL of reaction mixture was spotted on grade p81 phosphocellulose paper (1 square inch) and then immersed into 75 mM phosphoric acid solution (10 mL per sample). After three subsequent washes with distilled water, the radioactivity of each sample was counted in 5 mL of scintillation cocktail using a Beckman LS-1801 Liquid Scintillation Counter. The specific activity of PKC was calculated as pmol phosphate incorporated/min/mg protein in the PKC eluate.

To minimize variations in the actual PKC activities between different experiments, the PKC activity of each compound was normalized using the activity induced by arachidonic acid at 300 μM as 100% activity. Data were standardized as percentage of PKC activity relative to that observed in the presence of 300 μM arachidonic acid.

Statistical analysis. Results are expressed as means ± standard errors (n = 9); data were analyzed by Fisher PLSD analysis performed at a 95% confidence level.

TABLE 1

Nomenclature of Fatty Acids

Common name of fatty acid	Shorthand	*cis/trans*[a]
Stearic acid	18:0	
Palmitoleic acid	*c*-16:1n-7	*Z*
Palmitelaidic acid	*t*-16:1n-7	*E*
cis-Vaccenic acid	*c*-18:1n-7	*Z*
trans-Vaccenic acid	*t*-18:1n-7	*E*
Oleic acid	*c*-18:1n-9	*Z*
Elaidic acid	*t*-18:1n-9	*E*
Linoleic acid	*c,c*-18:2n-6	*Z,Z*
Linoelaidic acid	*t,t*-18:2n-6	*E,E*
Linolenic acid	18:3n-3	*all Z*
γ-Linolenic acid	18:3n-6	*all Z*
Methyl γ-linolenate	Me-18:3n-6	*all Z*
Arachidonic acid	20:4n-6	*all Z*
Eicosapentaenoic acid	20:5n-3	*all Z*
Docosatrienoic acid	22:3n-3	*all Z*
Adrenic acid	22:4n-6	*all Z*
Docosahexaenoic acid	22:6n-3	*all Z*

[a]*Z*, double bond with a *cis*-configuration; *E*, double bond with a *trans*-configuration.

RESULTS

Basal PKC activity in the presence of Ca^{2+} (0.5 mM) and PS (20 μg/mL), without any addition of fatty acid, was approximately 30 pmol/min/mg protein (Fig. 1). The maximum PKC activity observed in the presence of 20:4n-6 at 200 and 300 μM was about 100 pmol/min/mg protein (Fig. 1). Stearic acid (18:0) only activated PKC minimally in that the maximum PKC stimulation caused by 18:0 was less than 40% of that caused by 20:4n-6 at 300 μM (Fig. 1).

Fatty acids differing in the number of *cis*-double bonds, namely, oleic acid (*c*-18:1n-9), *c,c*-18:2n-6, γ-linoleic acid (18:3n-6), 20:4n-6, eicosapentaenoic acid (20:5n-3) or docosahexaenoic acid (22:6n-3), activated PKC in a similar dose-response manner (Fig. 1). PKC activity reach a plateau at a concentration of 200 μM for

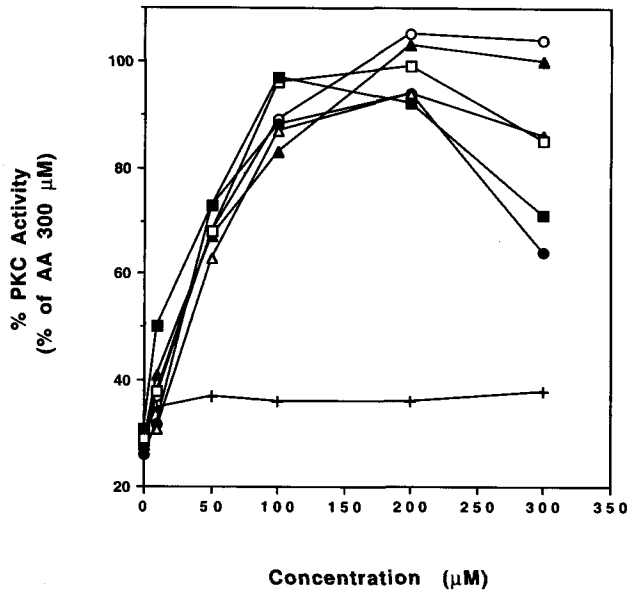

FIG. 1. A dose-response comparison of protein kinase C (PKC) activity induced by a saturated fatty acid, 18:0 (cross) or unsaturated fatty acids with different numbers of double bonds: *c*-18:1n-9 (open circles), 18:2n-6 (closed circles), 18:3n-6 (open triangles), 20:4n-6 (closed triangles), 20:5n-3 (open squares) or 22:6n-3 (closed squares). An internal standard, arachidonic acid (AA) (20:4n-6) 300 μM, was included in each assay. The PKC activity of each compound is expressed as the percentage of activity induced by 20:4n-6 at 300 μM. Three separate experiments for each fatty acid were performed, with triplicates for each concentration.

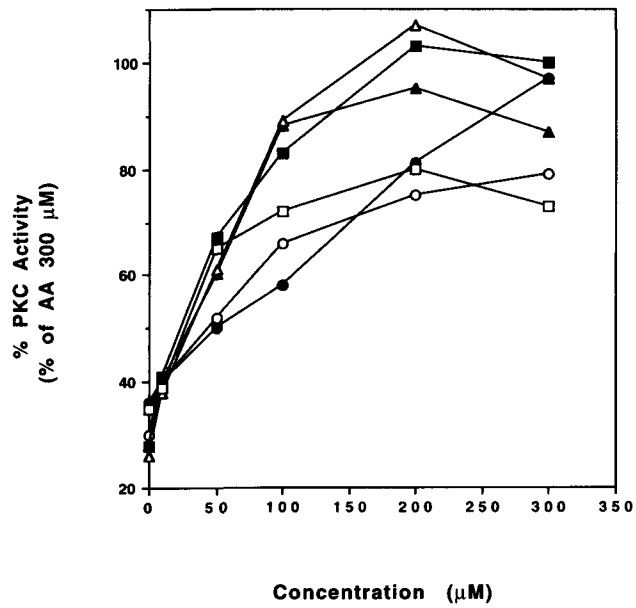

FIG. 2. Effect of chain length on the potency of *cis*-fatty acids to activate PKC. Three pairs of *cis*-fatty acids with the same number of double bonds but different chainlength were tested: *c*-16:1n-7 (closed triangles), *c*-18:1n-7 (open triangles); 18:3n-3 (closed circles), 22:3n-3 (open circles); 20:4n-6 (closed squares), 22:4n-6 (open squares). The PKC activity for each compound is expressed as the percentage of activity induced by 20:4n-6 at 300 μM. Three separate experiments for each fatty acid were performed, with triplicates for each concentration. See Figure 1 for abbreviations.

most of the *cis*-fatty acids followed by a decline in activity at 300 μM (Fig. 1). There was no significant difference between the maximum PKC activities attained in the presence of these different fatty acids. This suggested that the presence of a *cis*-double bond is essential for fatty acids to activate PKC and that the presence of additional double bonds in these fatty acids does not further affect their potency.

Comparison of the PKC-activating potency of three pairs of *cis*-fatty acids having the same number of double bonds but differing in chainlength, namely, palmitoleic acid (*c*-16:1n-7) and *cis*-vaccenic acid (*c*-18:1n-7), linolenic acid (18:3n-3) and docosatrienoic acid (22:3n-3), and arachidonic acid (20:4n-6) and adrenic acid (22:4n-6), suggested that there is no apparent correlation between the length of the chain and the potency of the *cis*-fatty acid (Fig. 2).

To define the effect of the configuration of the fatty acid double bond on the activation of PKC, four pairs of fatty acids were examined. Of four *trans*-fatty acids, namely palmitelaidic acid (*t*-16:1n-7), *trans*-vaccenic acid (*t*-18:1n-7), elaidic acid (*t*-18:1n-9), and linoelaidic acid (*t,t*-18:2n-6), all except *t,t*-18:2n-6 exhibited a much reduced ability to activate PKC compared to their corresponding *cis*-fatty acids, i.e., palmitoleic acid (*c*-16:1n-7), *cis*-vaccenic acid (*c*18:1n-7), oleic acid (*c*-18:1n-9) and linoleic acid (*c,c*-18:2n-6), respectively (Fig. 3). At the plateau concentration for *cis*-fatty acid (200 μM) or lower (50 and 100 μM), PKC activity in the presence of most *cis*-fatty acids was about twice that seen for the corresponding *trans*-fatty acids (Fig. 3). When the concentration was increased from 200 to 300 μM, most *cis*-fatty acids showed a slight decease in PKC activation, whereas *trans*-fatty acids exhibited a continuing increase in PKC activity. Even though the *trans*-fatty acids showed a different dose response from the *cis*-fatty acids, the maximum PKC activity cause by *trans*-fatty acids did not exceed the value attained by the corresponding *cis*-fatty acids within the dose range tested (10–300 μM). However, linoelaidic acid (*t,t*-18:2n-6), containing two *trans*-double bonds, caused a dose response and a maximum PKC activity similar to that of its *cis*-analog linoleic acid (*c,c*-18:2n-6) (Fig. 3).

A substituent on the chain markedly reduced the ability of *cis*-fatty acid to activate PKC. Two substituted fatty acids were chosen to examine the substituent effect, namely, 5,6-DHT, a dihydroxylated 20:3 *cis*-fatty acid which represents a 20:4n-6 with its C-5 double bond replaced by two hydroxyl substituted carbons, and 12,13-EODE, a 12(13)-epoxy oleic acid. Both substituted fatty acids gave the same dose-response curve with the maximum activity reaching approximately 50% of that caused by 20:4n-6 at 300 μM (Fig. 4).

Changes on the carboxyl group of a *cis*-fatty acid, such as the methyl ester of 18:3n-6 (Me-18:3n-6), completely abolished its ability to activate PKC (Fig. 4).

All HETE tested were capable of activating PKC at a dose of 100 μM or higher (Fig. 5). In general, all HETE

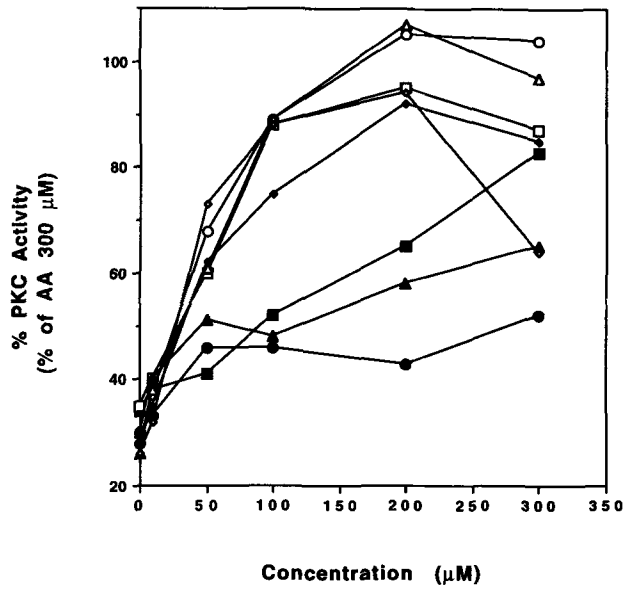

FIG. 3. Comparison of PKC activities induced by *cis*- or *trans*-fatty acids. Four pairs of *cis*- and *trans*-fatty acids were used: *c*-16:1n-7 (open squares), *t*-16:1n-7 (closed squares); *c*-18:1n-7 (open triangles), *t*-18:1n-7 (closed triangles); *c*-18:1n-9 (open circles), *t*-18:1n-9 (closed circles); *c,c*-18:2n-6 (open diamonds), *t,t*-18:2n-6 (closed diamonds). All *cis*-fatty acids are represented by open symbols; all *trans*-fatty acids are represented by closed symbols. The PKC activity for each compound is expressed as the percentage of activity induced by 20:4n-6 at 300 μM. Three separate experiments for each fatty acid were performed, with triplicates for each concentration. See Figure 1 for abbreviations.

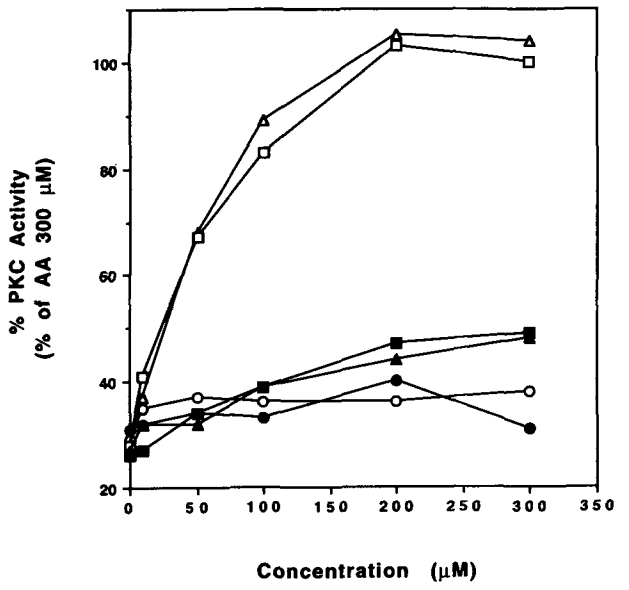

FIG. 4. Comparison of PKC activities induced by *cis*-fatty acids and their derivatives. Stearic acid (open circles), *c*-18:1n-9 (open triangles), 20:4n-6 (open squares), 5,6-dihydroxyeicosatrienoic acid, 20:3n-6 (closed squares), 12(13)-epoxyoctadienoic acid, 18:1n-9 (closed triangles) and Me-18:3n-6 (closed circles) were used. The PKC activity for each compound is expressed as the percentage of activity induced by 20:4n-6 at 300 μM. Three separate experiments for each fatty acid were performed, with triplicates for each concentration. See Figure 1 for abbreviations.

isomers activated PKC to a similar extent, namely, between 150 and 200% of control values or between 35 and 55% of the activation caused by 20:4n-6 at 300 μM (Fig. 5). Although 9- and 13-HODE activated PKC at doses of 200 and 300 μM (Fig. 6), 9-HODE caused a higher maximal PKC activity than did the 13-HODE or 4 HETE isomers, which was about 60% of that induced by 20:4n-6 at 300 μM (Fig. 6). All hydroxylated metabolites of 20:4n-6 and *c,c*-18:2n-6 were capable of minimally activating PKC at concentrations above 100 μM.

DISCUSSION

In general, the potencies of the fatty acids and their derivatives to activate untreated mouse skin PKC can be ranked in decreasing order as follows: *cis*-fatty acids > *trans*-fatty acids ≥ substituted *cis*-fatty acids ≥ HETE and HODE > saturated fatty acids and methyl esters of *cis*-fatty acids.

Neither the saturated fatty acid 18:0 nor the methyl ester of a *cis*-fatty acid, Me-18:3n-6, activated PKC to any appreciable extent; both stimulated PKC less than 30% above control levels while 20:4n-6 at 300 μM resulted in an at least 300% increase over controls. These findings are in agreement with the results of studies done on rat brain (10,13). Seifert *et al.* (10) and Fan *et al.* (13) showed that 18:0 did not activate PKC in rat brain

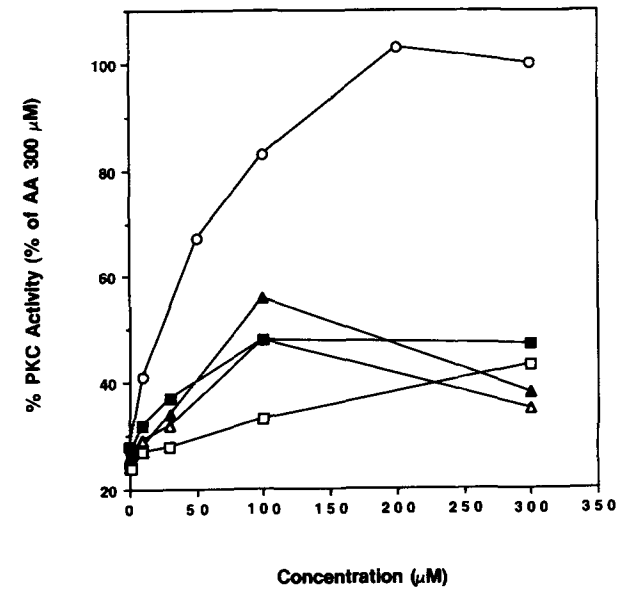

FIG. 5. Comparison of PKC activation induced by 20:4n-6 and its hydroxylated metabolites, hydroxyeicosatetraenoic acid (HETE). AA (20:4n-6) (open circles) and four HETE, i.e., 5(*S*)-HETE (closed triangles), 8(*S*)-HETE (open triangles), 12(*S*)-HETE (closed squares) and 15(*S*)-HETE (open squares) were used in this comparison. The PKC activity for each compound is expressed as the percentage of activity induced by 20:4n-6 at 300 μM. See Figure 1 for other abbreviations.

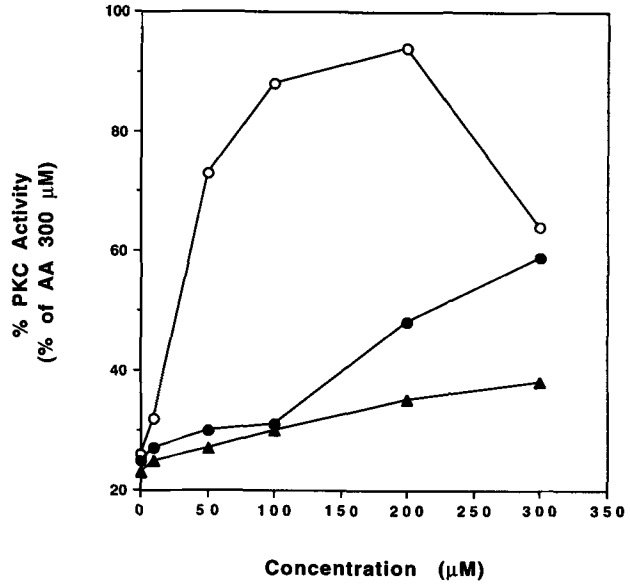

FIG. 6. Comparison of PKC activation induced by *c,c*-18:2n-6 and its hydroxylated metabolites, hydroxyoctadecadienoic acid (HODE). Linoleic acid (open circles) and two HODE, i.e., 9(*S*)-HODE (closed circles) and 13(*S*)-HODE (closed triangles), were used in the comparison. The PKC activity for each compound is expressed as the percentage of activity induced by 20:4n-6 at 300 µM. See Figure 1 for other abbreviations.

at 100 or 500 µM, respectively. Shinomura *et al.* (25) reported that at 50 µM concentration neither palmitic acid (16:0) nor 18:0 activated PKC in rat brain cytosol, whereas 20:4n-6 stimulated PKC activity to at least 200% of control levels. Seifert *et al.* (10) also showed that methyl arachidonate at 100 µM did not activate PKC while the parent fatty acid, 20:4n-6, stimulated PKC activity three- to fourfold above basal levels. Fan *et al.* (13) reported that methyl esters of *c*-18:1n-9, *c,c*-18:2n-6, 18:3n-3 and 20:4n-6 at 500 µM caused very little PKC activation (less than 20% of their parent fatty acids) in rat brain *in vitro* (13). Thus, at least one fatty acid double bond and the carboxyl group appear to be required to induce activation of PKC.

The number of double bonds and the chainlength of the fatty acids do not appear to be important factors in influencing activating potency, since most fatty acids containing one or more *cis*-double bonds gave virtually identical dose-response curves at concentrations between 10 and 200 µM. These findings are different from those reported by McPhail *et al.* (26) or Seifert *et al.* (10). McPhail *et al.* (26) indicated that the ability of fatty acids to activate PKC increased to some degree with an increase in the number of *cis* double bonds. The PKC activating potential of the three fatty acids studied by McPhail *et al.* (26) in decreasing order was found to be 18:3n-6 > *c,c*-18:2n-6 > *c*-18:1n-9. The dose response curves for *c,c*-18:2n-6 and *c*-18:1n-9 reported by McPhail *et al.* (26) were almost identical between 30 and 300 µM and the maximum PKC activity induced by 18:3n-6 was not much higher than that induced by either *c,c*-18:2n-6 or *c*-18:1n-9 in the presence of diolein. Also, 18:3n-6 appeared to be a less potent stimulator than *c,c*-18:2n-6 and *c*-18:1n-9 at concentrations other than the optimal one. Seifert *et al.* (10) reported that the maximum PKC activity induced by fatty acids increased with chainlength; however, among four *cis*-fatty acids, namely myristoleic acid (*c*-14:1n-5), *c*-16:1n-7, *c*-18:1n-7, *c*-18:1n-9, *c*-16:1n-7 induced the same maximum PKC activity as did *c*-18:1n-9, and *c*-16:1n-7 caused a higher PKC activity than either of the 18:1 fatty acids at 100 µM. The differences observed between different laboratories might be due to tissue-specific PKC isozyme distribution and activity. Studies on the activation of three types of PKC isozymes (α, β and γ) by fatty acids, including 20:4n-6, *c,c*-18:2n-6 and *c*-18:1n-9, clearly indicated isozyme specificity with regard to fatty acid-stimulated activation (27). The decreasing order of PKC activity induced by fatty acids for PKC α and β isozymes was 20:4n-6 > *c,c*-18:2n-6 > *c*-18:1n-9; however, the order was reversed with PKC γ. Wang *et al.* (5) demonstrated that mouse epidermal PKC isozymes exhibited different dose responses to treatment with 20:4n-6. They reported that PKC α, β, and δ showed one- to threefold increases in PKC activity when the concentration of 20:4n-6 was increased from 25 to 400 µM in the presence of PS and Ca^{2+}. PKC γ and ζ, on the other hand, exhibited high activity when stimulated with 20:4n-6 at 25 µM; at 400 µM concentration, 20:4n-6 almost completely inhibited the activity of PKC γ and ζ. Even though different potencies for *cis*-fatty acids were seen in rat brain in other studies and in mouse skin in our study, the effective dose ranges found in our study were in agreement with those observed by Seifert *et al.* (10) and McPhail *et al.* (26) (approximately 50 to 300 µM).

As discussed above, numerous studies have suggested that at least one *cis*-double bond is essential for activation of PKC. Leach and Blumberg (28) reported that saturated fatty acids such as butyric (4:0), lauric (12:0), myristic (14:0) and palmitic (16:0) acids showed very low ability to activate PKC, and they did not inhibit [^{3}H]phorbol 12,13-dibutyrate ([^{3}H]PDBu) binding activity in mouse brain cytosol (with the exception of lauric acid). On the other hand, *c,c*-18:2n-6, 18:3n-3 and 20:4n-6 markedly inhibited [^{3}H]PDBu binding in a concentration-dependent manner in the presence of phosphatidylcholine and PS. Leach and Blumberg (28) suggested that fatty acids may interact with PKC at a hydrophobic site which in turn allows the binding of [^{3}H]PDBu and the activation of PKC.

cis-Unsaturated fatty acids are known to perturb the lipid membrane and to increase membrane fluidity to a much greater extent than do saturated fatty acids or *trans*-unsaturated fatty acids (10,13,29,30). Although these rules cannot necessarily be applied to *in vitro* conditions, they suggest that configurational difference between *cis*- and *trans*-fatty acids could play a role in the ability of a fatty acid to interact with PKC. Seifert *et al.* (10) suggested that PKC activity stimulated by fatty acids might relate to fatty acid hydrophobicity and might not be due to a detergent effect. We found that fatty acids containing one *trans*-double bond exhibited

lower potencies than did the corresponding *cis*-fatty acids in activating PKC at the doses tested. These results were not in complete agreement with the observation made on rat brain by Seifert *et al.* (10) who found that *trans*-fatty acids containing 16 or 18 carbons, with the exception of *t*-18:1n-9, induced the same PKC activities as their *cis*-isomers. Ashendel *et al.* (31) had reported that PKC activity in mouse brain is much higher than in epidermis. Also, the differential distribution and activities of isozymes in tissues do probably contribute to the differences observed between brain and epidermal PKC activation.

The PKC activities induced by the two substituted *cis*-fatty acids, 5,6-DHT and 12,13-EODE, were even lower than those induced by *trans*-fatty acids. This gives further credence to the suggestion that the *cis*-configuration might be very important in the interaction between fatty acid and the hydrophobic site of PKC which would, in turn, modulate the PKC active site. The carbon chain of a *cis*-fatty acid exhibits a minimal 44° bend at the site of the double bond (32); this exposes the double bond far more than it does in a *trans*-fatty acid which essentially resembles a straight carbon chain. Substitution with a hydroxyl or epoxy group in the vicinity of the *cis*-double bond would provide stearic hindrance near the double bond. Thus, both *trans*-configuration and substitution close to the *cis*-double bond would reduce exposure of the double bond of the fatty acid and reduce interaction with PKC.

All HETE and HODE exhibited much lower potencies in activating PKC than did their parent *cis*-fatty acids, i.e., 20:4n-6 and *c,c*-18:2n-6, respectively. The hydroxylation of 20:4n-6 or *c,c*-18:2n-6 *via* lipoxygenase introduces one hydroxyl group at the site of one of the *cis*-double bonds; the *cis*-double bond is then shifted to the adjacent position and is converted into *trans*. The results of our study suggest that both the substituent effect and the configurational change make HETE and HODE much less potent PKC activators than are their parent fatty acids 20:4n-6 and *c,c*-18:2n-6. O'Brian *et al.* (11) reported that hydroperoxy metabolites of 20:4n-6 and *c,c*-18:2n-6, i.e., 15-hydroperoxyeicosatetraenoic acid (15-HpETE) and 13-hydroperoxyoctadecadienoic acid (13-HpODE), respectively, induced slightly reduced maximum activity but higher affinity to PKC than did 20:4n-6 or *c,c*-18:2n-6. On the other hand, 13-HODE exhibited both lower affinity and induced lower maximum activity. O'Brian *et al.* (11) suggest that oxidation of a component of PKC by hydroperoxy metabolites might be involved, rather than simply the binding to PKC. This would also explain why hydroperoxy metabolites of 20:4n-6 or *c,c*-18:2n-6 could possess the same structures as HETE and HODE yet exhibit potencies similar to those of their parent compounds.

In conclusion, the hydroxylated metabolites of 20:4n-6 and *c,c*-18:2n-6 produced *via* the lipoxygenase pathway were much less able to activate mouse skin PKC than were their parent compounds. Therefore, the ability of 20:4n-6 or *c,c*-18:2n-6 to activate PKC would be reduced once they were metabolized in the skin, and the possible role of 20:4n-6 or *c,c*-18:2n-6 in mouse skin tumor promotion *via* PKC activation would be less important. Furthermore, there was no significant difference in PKC activation between either 20:4n-6 and *c,c*-18:2n-6 or between HETE and HODE, which suggests that the inhibitory effect of *c,c*-18:2n-6 in mouse skin tumor promotion is not mediated by the activation of PKC by these fatty acids.

Lymphatic Absorption of Oxidized Cholesterol in Rats

Kyoichi Osada[a], Eiji Sasaki[a] and Michihiro Sugano[b,*]

[a]Laboratory of Nutrition Chemistry and [b]Laboratory of Food Science, Kyushu University School of Agriculture 46-09, Hakozaki, Fukuoka 812, Japan

The absorption of cholesterol and of cholesterol oxidation products (oxidized cholesterols) was compared in lymph-cannulated rats. We found that the lymphatic absorption of an intragastrically administered, emulsified lipid meal containing 25 mg of cholesterol or 25 mg of oxidized cholesterols, within 24 h, was approximately 67 and 30%, respectively. The absorption rate of individual oxidized cholesterols differed considerably and was approximately 30% for 7α-hydroxycholesterol, 42% for 7β-hydroxycholesterol, 32% for 5β-epoxycholesterol, 28% for 5α-epoxycholesterol, 15% for cholestanetriol and 12% for 7-ketocholesterol. Moreover, cholesterol oxidation products delayed the absorption of oleic acid as triolein. Approximately 35 and 48% of cholesterol was recovered in chylomicrons (CM) and very low density lipoprotein (VLDL), respectively. In contrast, 54 and 40% of the oxidized cholesterols was recovered in CM and VLDL, respectively, although there was a significant difference in the distribution of individual oxidized cholesterols. The results of the present study indicate that oxidized cholesterols are absorbed to a lesser extent than is cholesterol, that they disturb fat absorption and that they distribute differently between lymphatic lipoproteins.
***Lipids* 29, 555–559 (1994).**

Cholesterol is a common component of most diets and undergoes autoxidation when exposed to heat, air, light and oxidizing agents. Processed foods are known to contain a variety of oxidized sterols including hydroperoxycholesterol, hydroxycholesterol, epoxycholesterol and ketocholesterol (1–6). Cholesterol oxidation products (oxidized cholesterols) exhibit diverse biological activities including cytotoxicity (7), mutagenicity (8), carcinogenicity (9) and atherogenicity (10). This has been concluded mainly from observations made *in vitro* whereas the *in vivo* effects of oxidized cholesterols are still less understood. Recently, Kendall *et al.* (11) demonstrated that dietary oxidized cholesterols moderately enhance colon carcinogenesis when compared to cholesterol in mice, and Berezov *et al.* (12) reported on the immunodepressive activity of oxidized cholesterols. To better appreciate the physiological effects of oxidized cholesterols, it is necessary to understand the extent and the mode of their absorption from the intestine. At present, only minimal information is available in regard to the absorption of oxidized cholesterols (13–16).

In the present study, the pattern of absorption of oxidized cholesterols and their effect on fat absorption were investigated in lymph-cannulated rats. The distribution of oxidized cholesterols between lymph lipoproteins was also determined.

Abbreviations: ACAT, acyl coenzyme A:cholesterol acyltransferase; CM, chylomicron; EDTA, ethylenediaminetetraacetic acid, disodium salt; GC, gas chromatography, HDL, high density lipoprotein; LDL, low density lipoprotein; VLDL, very low density lipoprotein.

MATERIALS AND METHODS

Materials. Cholesterol [purity, 99.7% by gas chromatography (GC); no oxidized cholesterols were detected] and sodium taurocholate (purity > 98%) were purchased from Nacalai Tesque Co. (Kyoto, Japan). Triolein (purity > 99%), pentadecanoic acid and 5α-cholestane were from Sigma Chemical Co. (St. Louis, MO). Fatty acid-free bovine serum albumin was from Miles Inc. (Kankakee, IL).

Preparation of cholesterol oxidation products. Cholesterol was melted and kept in an electric oven at 150°C for 12 h. The oxidized cholesterols formed (17) were then applied onto a silicic acid column (24 mm × 700 mm; silica gel 60, 70–230 mesh; E. Merck, Darmstadt, Germany) and fractionated by successive elution with 200 mL of *n*-hexane, 200 mL of diethyl ether, and finally 300 mL of methanol. An aliquot of the polar fraction eluted with methanol was dried on an rotary evaporator and then *in vacuo*. The composition of the oxidized cholesterol-rich fraction thus obtained is shown in Table 1. The preparation consisted of more than 85% oxidized cholesterols.

Animal treatment. Male Sprague-Dawley rats (Seiwa Experimental Animals, Fukuoka, Japan) weighing 300–340 g were given a commercial nonpurified diet (type NMF, Oriental Yeast Co., Tokyo, Japan) for 2 d after arrival and drinking water *ad libitum*. Rats under nembutal anesthesia were subjected to cannulation of the left thoracic lymph channel, and an indwelling catheter was placed in the stomach (18). An osmotically normal solution containing 139 mM glucose and 85 mM NaCl was infused continuously during lymph collection at a rate of 3 mL/h through the gastric tube (19). After surgery, animals were placed in restraining cages in a warm recovery room and allowed free access to drinking water containing 139 mM glucose and 85 mM NaCl. On the next morning, after collecting lymph for 2 h (blank lymph) to

5α-Epoxycholesterol	6.0
Cholestanetriol	4.7
7-Ketocholesterol	30.2
Unknowns[a]	23.0

[a]Composed of more than 20 components.

determine the amounts of endogenous cholesterol and oleic acid secreted per hour in lymph, each animal was administered 3 mL of a test emulsion through the gastric tube, and the lymph was collected for 24 h beginning at 10:00 a.m. The 3-mL test emulsion contained 200 mg of sodium taurocholate, 50 mg of fatty acid-free albumin, 200 mg of triolein and 25 mg of either cholesterol or cholesterol oxidation products. The emulsions were prepared by sonication at room temperature using an Ultrasonic Disruptor Model UR-200P (Tomy Seiko Co. Ltd., Tokyo, Japan). The lymph was collected in tubes containing ethylenediaminetetraacetic acid disodium salt (EDTA; 50 mg) for 3-h periods during the first 9 h after administration of the test emulsion and in a single collection from 9–24 h thereafter.

Lipids analysis. Lymph lipids were extracted with 20 vol of chloroform/methanol (2:1, vol/vol) according to the method of Folch *et al.* (20), and then saponified in ethanolic 1 N KOH at 70°C for 1 h (21). Although some studies (22,23) have suggested that hot alkaline saponification can decompose oxidized cholesterols, the standards we used were stable under the conditions employed. The unsaponifiable fraction was extracted with *n*-hexane and converted to trimethylsilyl ethers by reaction with a mixture of trimethylchlorosilane, 1,1,1,3,3,3-hexamethyldisilazane and anhydrous pyridine (1:3:9, by vol) at room temperature. The trimethylsilyl ethers were separated by capillary GC using 5α-cholestane as internal standard. The fatty acid composition was determined by GC of the methyl esters that were prepared by transmethylation of the lipids extracted with BF_3/methanol in the presence of pentadecanoic acid as internal standard (24). Total and free sterols were measured by the method of Sperry and Webb (25). Free and esterified cholesterols were separated by thin-layer chromatography (silica gel 60, 0.25 mm thick layers; E. Merck) using hexane/diethyl ether (60:40, vol/vol) as developing solvent. The sterols were eluted with methanol and analyzed by capillary GC as described above.

The absorption rates of each of the sterols and of triolein were determined by subtracting the amounts of sterols and oleic acid in blank lymph from those found in the experimental lymph, and the resulting values were divided by the amounts of sterols or oleic acid administered to obtain absorption rates.

Isolation of lymph lipoproteins. Lymph collected in ice-cooled tubes was separated into the major lipoprotein fractions by ultracentrifugation (26). Chylomicrons (d < 1.006 g/mL) were collected at 23,000 × *g* for 40 min and very low density lipoprotein (VLDL) (d < 1.006 g/mL) at 50,000 × *g* for 16 h.

GC. Trimethylsilyl derivatives of oxidized cholesterols in lymph were separated by capillary GC (GC-7AG; Shimadzu Co., Kyoto, Japan) using a flame-ionization detector, a fused silica capillary ULBON HR-1 column with a liquid phase thickness of 0.25 μm (0.25 mm × 50 m; Shinwa Chemical Industries, Kyoto, Japan), and a Shimadzu C-R6A integrator. The oven and injector temperatures were 280 and 300°C, respectively, and the helium flow rate was 2.2 mL/min. Individual oxidized cholesterols were identified as described previously (27). Methyl esters of fatty acids were analyzed using a Shimadzu gas chromatograph (GC-8A) equipped with a flame-ionization detector, a 10% Silar 10C column (3 mm × 2 m), and a C-R5A integrator. The oven and injector temperatures were 210 and 250°C, respectively. The flow rate of nitrogen gas was 25 mL/min.

Statistical analysis. Duncan's new multiple-range test (28) and Student's *t*-test (29) were used to define the differences between values.

RESULTS

There were significant differences in lymph flow rates between the rats that received cholesterol and of those that received the oxidized cholesterols, and the flow rates were significantly lower in the latter (Table 2).

Figure 1 shows the chromatographic patterns of the cholesterol oxidation products administered and of those recovered in lymph. Figure 2 illustrates the lymphatic absorption of cholesterol and of the various oxidized cholesterols. As can be seen, cholesterol was absorbed within 24 h at a higher rate than were the oxidized cholesterols, i.e., 66.8 ± 4.5% vs. 30.0 ± 2.6%, respectively. However, the rate of absorption of cholesterol in the presence of the cholesterol oxidation products was significantly lower than that in rats that received cholesterol alone (50.9 ± 4.2% vs. 66.8 ± 4.5%, respectively). The absorption rates within 24 h of cholestanetriol (15.2 ± 3.6%) and 7-ketocholesterol (12.0 ± 2.6%), in turn, were significantly lower than those of the other oxidized cholesterols, while those of 7α-hydroxycholesterol, 5α-epoxycholesterol and 5β-epoxycholesterol were quite similar (30.4 ± 3.2, 27.5 ±2.5 and 32.3 ± 6.7%, respectively). 7β-Hydroxycholesterol (41.5 ± 5.6% 24 h) was absorbed at a higher rate than were the other oxidized cholesterols.

As shown in Figure 3, the cholesterol oxidation products interfered with the lymphatic absorption of oleic acid

TABLE 2

Body Weight and Lymph Flow[a]

Groups	Body weight (g)	Lymph flow (mL) 0–3 h	3–6 h	6–9 h	9–24 h	0–24 h
Cholesterol	332 ± 16	25.8 ± 1.4[b]	24.1 ± 2.4[b]	24.4 ± 2.0[b]	102 ± 11[b]	176 ± 16[b]
Cholesterol oxidation products	320 ± 3	10.8 ± 1.4	8.9 ± 1.0	9.1 ± 0.8	42.6 ± 2.2	71.4 ± 4.0

[a]Values are means ± SE of 5–7 rats. [b]Significantly different from the corresponding cholesterol oxidation products group at $P < 0.001$ (Student's *t*-test).

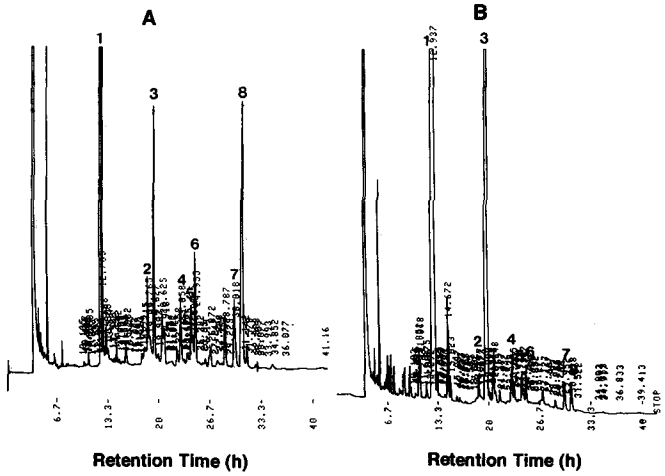

FIG. 1. Gas chromatography of the cholesterol oxidation products administered (A) and of the oxidized cholesterols recovered in lymph (B). Peaks: 1, 5α-cholestane (internal standard); 2, 7α-hydroxycholesterol; 3, cholesterol; 4, 7β-hydroxycholesterol; 5, 5β-epoxycholesterol; 6, 5α-epoxycholesterol; 7, cholestanetriol; and 8, 7-ketocholesterol.

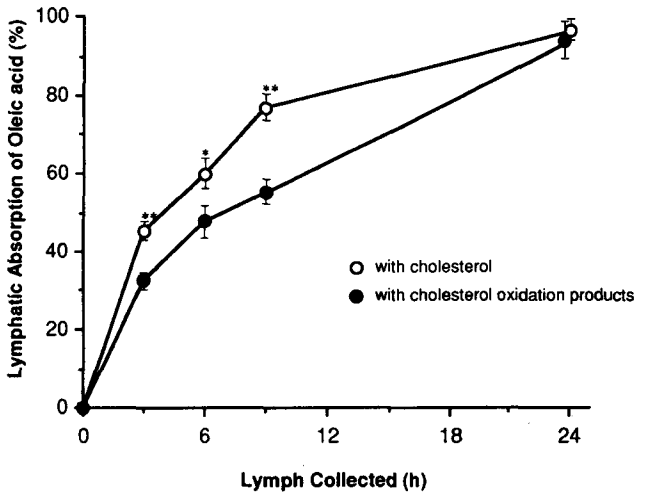

FIG. 3. Lymphatic absorption of oleic acid administered as triolein. Thoracic duct lymph was cannulated as described in the Materials and Methods section and cholesterol or cholesterol oxidation products was administered by stomach catheter. Lymph was collected periodically for 24 h. The percentage shows the rate of the oleic acid recovered in lymph to the oleic acid administered in the test emulsion. Values are means ± SE for five rats. Values are significantly different for the corresponding oxidized cholesterol group at *$P < 0.05$ and **$P < 0.01$ (Student's t-test).

when administered as triolein during the first 6 h after administration, but the difference disappeared after 24 h (96.3 ± 5.7 and 95.8 ± 5.2% for the cholesterol and the cholesterol oxidation products groups, respectively).

The distribution of cholesterol and of oxidized cholesterols between lymph lipoproteins is shown in Figure 4. A differential distribution between lymph lipoproteins is seen between cholesterol and oxidized cholesterols. Approximately 35% of cholesterol was carried in chylomicrons (CM) while 48% was associated with VLDL. In contrast, more oxidized cholesterols than cholesterol were generally associated with CM, whereas the levels associ-

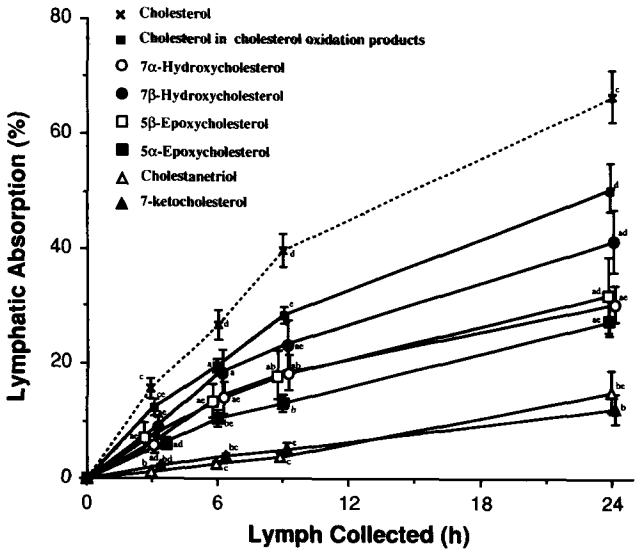

FIG. 2. Lymphatic absorption of cholesterol and of various oxidized cholesterols. Thoracic duet lymph was cannulated as described in the Materials and Methods section and cholesterol or the cholesterol oxidation products was administered by stomach catheter. Lymph was collected periodically for 24 h. Absorption in percentage is the percentage of the dose. Values are means ± SE for five rats. Values at each point not sharing a common letter are significantly different at $P < 0.05$ (Duncan's new multiple-range test).

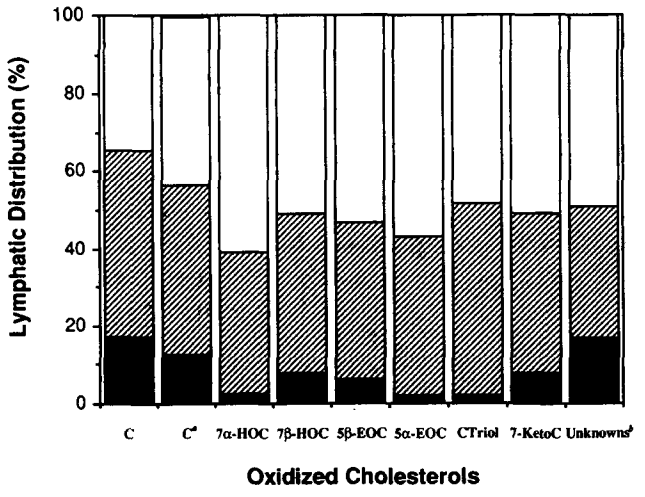

FIG. 4. Distribution of cholesterol and oxidized cholesterols between lymph lipoproteins. Lymph lipoproteins were separated as described in the Materials and Methods section. Open bar represents chylomicrons, hatched bar represents very low density lipoprotein, closed portion of bar represents bottom fraction (d < 0.06). Oxidized Cholesterols in Esterified and Nonesterified Sterol Fractions of Lymph[a]

Sterols	Sterol fraction	
	Esterified	Nonesterified
	(weight %)	
7α-Hydroxycholesterol	1.1 ± 0.3[c]	4.3 ± 0.3
Cholesterol	80.7 ± 1.6[c]	54.5 ± 1.5
7β-Hydroxycholesterol	1.6 ± 0.4[c]	14.5 ± 0.5
5β-Epoxycholesterol	2.1 ± 0.3	2.5 ± 0.7
5α-Epoxycholesterol	5.1 ± 0.3[c]	3.0 ± 0.7
Cholestanetriol	0.2 ± 0.1[c]	1.5 ± 0.2
7-Ketocholesterol	2.3 ± 0.1[c]	1.4 ± 0.1
Unknowns[b]	1.2 ± 0.5[c]	18.1 ± 0.8

[a]Values are means ± SE of five rats.
[b]Composed of more than 20 compounds.
[c]Significantly different from the corresponding nonesterified fraction at $P < 0.05$ (Student's *t*-test).

ated with VLDL tended to be low except for cholestanetriol. Lesser amounts of oxidized cholesterols than of cholesterol were present in lipoprotein fractions heavier than CM and VLDL.

The degree of sterol esterification in rats given cholesterol oxidation products was lower than in those given cholesterol (68.4 ± 0.9 and 79.6 ± 6.0% for oxidized cholesterols and cholesterol, respectively). The compositions of cholesterol and of the oxidized cholesterols in the nonesterified and esterified sterol fractions of lymph are shown in Table 3. The esterified sterol fraction contained about 81% cholesterol while the free sterol fraction contained approximately 55% cholesterol. The oxidized cholesterols were also not evenly distributed between the esterified and the nonesterified sterol fractions. Thus, for example, considerably higher amounts of 7β-hydroxycholesterol were present in the free rather than the esterified sterol form.

DISCUSSION

Oxidized cholesterol derivatives occur in many food products. They have been identified in butter (1), dairy products (2), egg products (1,3), heated tallow (4), pancakes (5), French fries (5) and various meat products (6). We also showed that oxidized cholesterols are present in processed marine foods (30). The *in vivo* absorption of oxidized cholesterols is still not very well understood. Peng *et al.* (13) have previously analyzed the composition of various cholesterol oxidation products in serum after gastric administration to rabbits, and they assumed that the rate of absorption of oxidized cholesterols is not significantly different from that of cholesterol. Bascoul *et al.* (14) have shown that 5α-epoxycholesterol after oral administration to rats was largely absorbed (about 90%) by the intestinal mucosa. Moreover, available data on the absorption of oxidized cholesterols have shown that their absorption appears to be similar to that of cholesterol based on tracer studies and that dietary oxysterols are absorbed from the gastrointestinal tract quite rapidly (16,31). The present study suggests that considerable differences exist in the degree of absorption of various oxidized cholesterols, and that less of the oxidized cholesterols was absorbed than of the cholesterol administered.

Several mechanisms could explain the lower rates of absorption of oxidized cholesterols. Firstly, it is possible that the oxidized cholesterols are less soluble as micelles than is cholesterol, as it has been shown that lower micellar solubility results in lower cholesterol absorption (17,32). The higher polarity of the oxidized cholesterols may, indeed, interfere with micelle formation. We found that lipid emulsions containing the cholesterol oxidation products were much less stable than those containing cholesterol, and precipitates formed when such emulsions were kept at room temperature. Secondly, it would also be possible that the lower degree of lymphatic absorption of oxidized cholesterols could be attributed to their lesser susceptibility to esterification in the small intestinal mucosal cells. Esterification is a mandatory step in the sterol absorption process. Thirdly, since oxidized cholesterols can exert strongly cytotoxic effects (7), they may injure the mucosal cells, which could explain the reduced lymph flow in rats given cholesterol oxidation products. Reduced lymph flow, in turn, may reduce the absorption of oxidized cholesterols. However, the lymph flow rates and absorption rates did not necessarily parallel each other in the present study, suggesting that the reduced flow rate may only be a contributing cause of the observed differences.

Most of oxidized cholesterols appeared in the nonesterified sterol fraction of lymph. This may be one of the reasons for the poor absorption of the oxidized cholesterols as has previously been shown for ß-sitosterol, which is a poorly absorbable plant sterol (33). Although our results would suggest inhibition by oxidized cholesterols of the acyl coenzyme A:cholesterol acyltransferase (ACAT) reaction, it has been shown in cell culture studies (34) that ACAT activity is actually stimulated by oxidized cholesterols. Nevertheless, the lower rate of esterification of oxidized sterols and their poor absorption may still be due to the fact that oxidized cholesterols serve as structurally poor substrates for the esterification reaction because of the presence of hindering hydroxy-, keto- and epoxy groups.

Our study also showed that cholesterol oxidation products interfered with the lymphatic absorption of cholesterol and of oleic acid given as triolein (Figs. 2 and 3). The mechanisms of these effects are presently unknown.

Furthermore, the distribution of the oxidized cholesterols between the lymphatic lipoproteins was found different than that of cholesterol. Ikeda *et al.* (33) had shown that both β-sitosterol and cholesterol were exclusively associated with CM. Since more of the oxidized cholesterols were carried in CM than was cholesterol (Fig. 4), their metabolic fate may also differ. Peng *et al.* (13,35) had reported that cholestanetriol, 7α-hydroxycholesterol, 7β-hydroxycholesterol and 7-ketocholesterol showed a preference for being transported in VLDL, whereas most of the 25-hydroxycholesterol was associated with low density lipoprotein (LDL) of the sera of rabbits or squirrel monkeys. Also, Brooks *et al.* (36) had found that, for example, α- and β-epoxides of cholesterol, 7-ketocholesterol and 26-hydroxycholesterol were predominantly carried by VLDL and LDL in serum of type II hypercholesterolemic pa-

tients. Moreover, Emanuel *et al.* (15) had reported that some oxidized cholesterols may be selectively absorbed and transported *via* CM. Thus, oxidized cholesterols are predominantly distributed in the serum lipoproteins of lower densities including CM, VLDL and LDL, whereas only minute amounts are associated with high density lipoproteins (HDL). Oxidized cholesterols have been found in human aortic tissues and plaques (37), and the selective transport of oxidized cholesterols by CM, VLDL and LDL may contribute in part to their atherogenicity (10).

Oxidized cholesterols have been implicated in the initiation and/or progression of atherosclerosis due to their toxicity to arterial endothelial and smooth muscle cells both *in vitro* (38) and *in vivo* (39). The presence of oxidized cholesterols in oxidized human LDL has been reported (40). Also Baranowski *et al.* (41) reported that oxidized cholesterols including 25-hydroxycholesterol, 5β-epoxycholesterol and cholestanetriol promoted tissue inflammation and necrosis and also caused cell death in cultures. Since a relatively large amount of oxidized cholesterols was absorbed from the intestine, they may exert various secondary effects *in vivo*.

In conclusion, the present study has demonstrated that lymphatic absorption of oxidized cholesterols occurs to a considerable degree in rats. Approximately 30% of the oxidized cholesterols was absorbed. Nakatsugawa and Kaneda (42,43) had shown that 0.23 and 0.5–0.6% of the methyl linoleate hydroperoxides administered were found in the lymph of rabbits and rats in unchanged form, respectively. Thus, oxidized cholesterols appear to be absorbed more readily than are autoxidized fatty acids. The oxidized cholesterols used in this study may not be altogether like naturally autoxidized cholesterol present in foods. However, our preceding study (30) had shown that the composition of oxidized cholesterols in fish products did not differ depending on the source. Since cholesterol in foods is quite easily oxidized when oxidizable fats are present, particularly during high-temperature cooking (30), more attention should be paid to oxidized cholesterols present in the diet. In fact, the concentration of oxidized cholesterols was found increased in human plasma CM after consumption of a powdered egg meal containing 30–90 ppm oxidized cholesterols (15). Also, Jacobson (44) inferred that dietary oxidized cholesterols from ghee may be responsible for the high frequency of atherosclerotic complications in Indian immigrant populations. More studies are needed to elucidate the effect of various dietary cholesterol oxidation products on metabolic processes.

Menhaden fish oil (FO) containing n-3 fatty acids dramatically extends the life span and delays the onset and progression of autoimmune disease in (NZB×NZW)F_1 (B/W) female mice as compared to those fed corn oil (CO) rich in n-6 lipids. As an inefficient antioxidant defense system has been linked to autoimmune diseases, the present study was undertaken to determine whether the protective action of n-3 lipids is mediated through their antioxidant defense system. Weanling B/W mice were fed a nutritionally adequate, semipurified diet containing CO or krill oil (KO) or FO at 10% level (w/w) *ad libitum* until the mice were 6.5 months old. All diets contained the same level of vitamin E (21.5 mg/100 g diet). We compared the effects of feeding n-6 and n-3 lipids on survival, kidney disease, hepatic microsomal lipid composition, peroxidation, and on the activity and mRNA expression of the antioxidant enzymes catalase, glutathione peroxidase (GSH-Px) and superoxide dismutase (SOD) in 6.5-month-old B/W mice. The results showed that when compared to livers from CO-fed mice, livers from KO- and FO-fed mice showed: (i) significantly higher ($P < 0.001$) activities and expression of CAT, GSH-Px and SOD; (ii) significantly lower ($P < 0.001$) arachidonic acid (20:4n-6) and linoleic acid (18:2n-6) and higher ($P < 0.001$) eicosapentaenoic acid (20:5n-3) and docosahexaenoic acid (22:6n-3) levels in hepatic microsomes; and (iii) significantly lower ($P < 0.001$) estimated peroxidation indices and thiobarbituric acid reactive substances generation. The data indicate that one of the mechanisms through which the n-3 lipids delay the onset of autoimmune diseases in B/W mice may be through maintenance of higher activities and expression of hepatic antioxidant enzymes.

***Lipids* 29, 561–568 (1994).**

Autoimmune-prone (NZB×NZW)F_1 (B/W) female mice spontaneously develop severe lupus nephritis as they age. At an early age they also exhibit vascular lesions resembling systemic lupus erythematosus (SLE) in humans, and these mice die between 6 and 12 months of age (1). Earlier studies had shown that caloric restriction and the source of dietary fat can have a profound effect on autoimmune SLE in mice (2–5). Our ongoing studies have indicated that n-3 fatty acid-rich menhaden fish oil (FO) dramatically extends the life span and delays the onset of autoimmune disease, whereas corn oil (CO), rich in n-6 fatty acids, significantly shortens the life span and accelerates autoimmune processes in these mice (6,7). We also observed that feeding *ad libitum* a diet containing 20% FO and/or moderate caloric restriction inhibited autoimmune disease in these mice. The beneficial effects observed have been primarily attributed to the increased eicosapentaenoic acid (20:5n-3) and docosahexaenoic acid (22:6n-3) contents and to the markedly decreased 20:4n-6 levels in the FO-fed animals.

The deleterious effects of oxidative stress have previously been associated with various pathological conditions (8–10), but the role of an impaired or defective antioxidant defense system in autoimmune diseases has been explored only to a limited extent (11–13). Our recent study on MRL/*lpr* mice indicated that along with other immunological abnormalities, these mice clearly showed a defective antioxidant defense system as the expression of hepatic antioxidant enzymes was significantly lower when compared to that of an MRL/+ strain (14). It is not yet known, however, whether the n-3 dietary lipids of FO, which are known to ameliorate autoimmune disease, are also able to modulate the liver antioxidant defense system in animals prone to developing autoimmune disease. The susceptibility of an organism to oxidative damage is affected by the efficiency of the antioxidative defense system to cope with the oxidative stress which, in turn, can be influenced by nutritional intervention with antioxidants (15). Antioxidant enzymes, such as glutathione peroxidase (GSH-Px), catalase (CAT) and superoxide dismutase (SOD), as well as antioxidant nutrients, such as vitamin E, vitamin A, vitamin C and selenium, can participate in controlling lipid peroxidation (16–18). Because antioxidant enzymes play an important role in the protection against free radical damage, a decrease in the activities or expression of these enzymes may predispose tissues to free radical injury (19,20).

The present study was undertaken to compare the effects of dietary CO, krill oil (KO) and FO on hepatic microsomal lipid composition, peroxidation and the expression of mRNA for three antioxidant enzymes (CAT, GSH-Px and SOD) in B/W female mice. In addition, we also tested crude krill lecithin (KO) as an alternate source of n-3 lipids. The data we obtained indicate that besides having a decreased survival rate, the CO-fed B/W mice exhibited lower activities and lower mRNA expression of the three antioxidant enzymes, as well as higher levels of 20:4n-6, and increased peroxidation in liver tissue. Our

Abbreviations: B/W mice, (NZB×NZW) F_1 mice; CAT, catalase; CO, corn oil; EDTA, ethylenediaminetetraacetic acid; FO, fish oil; GAPDH, glyceraldehyde 3-phosphate dehydrogenase; GSH, glutathione reduced form; GSH-Px, glutathione peroxidase; KO, krill oil; NADPH, β-nicotinamide adenine dinucleotide phosphate, reduced form; SDS, sodium dodecylsulfate; SLE, systemic lupus erythematosus; SOD, superoxide dismutase; SSC, sodium chloride/sodium citrate buffer; TBARS, thiobarbituric acid reactive substances.

present data also show that with adequate antioxidant supplements, FO can restore or enhance the antioxidant defense system and prolong the life span of autoimmune prone B/W mice.

MATERIALS AND METHODS

Experimental animals and diets. B/W female mice were purchased from the Jackson Laboratories (Bar Harbor, ME). The weanling mice (20/group; 15 mice for survival study and 5 mice/group for cross sectional study at 6.5 months) were fed *ad libitum* nutritionally adequate, semipurified diets prepared weekly containing 10% (w/w) CO (ICN, Irvine, CA), crude KO (a generous gift from Itano Refrigerated Food Co., Ltd., Tokushima, Japan) or odor-free FO (U.S. Department of Commerce, National Marine Fisheries Service, Charleston, NC). The fatty acid composition of the three oils is given in Table 1. The current AIN diet formula contains the following diet ingredients: casein, 20%; dextrose, 30%; starch, 31%; oil, 10%; cellulose, 3.5%; AIN salt mixture, 3.5%; AIN vitamin mixture, 1.5%; DL-methionine, 0.3%; and choline, 0.2%. All three oils had equal levels of antioxidants, i.e., 1.3 g (1300 I.U.) α-tocopherol per kg oil, 1.2 g (13.2 I.U.) γ-tocopherol/kg and 1 g/kg *tert*-butylhydroquinone, as recommended by the National Institutes of Health (NIH) to prevent peroxidation during storage. The FO and KO diets also contained 1% CO to meet essential fatty acid requirements. The final concentration of vitamin E (DL-α-tocopheryl acetate, γ-tocopherol and α-tocopherol) was ~215 I.U./kg diet. Fresh food was provided daily in the evening, and precautions were taken to prevent oxidation of lipids and diets. The mice were maintained in plastic cages under a 12-h light/dark cycle. The body weights and proteinuria were recorded once a month. NIH guidelines were strictly followed. The animals (5 mice/group) were sacrificed at 6.5 months of age by cervical dislocation, livers were collected in ice-cold physiological saline, and part of the livers was frozen in liquid nitrogen and stored at –80°C for RNA isolation.

TABLE 1

Fatty Acid Composition of the Oils[a]

Fatty acid	Corn oil (%)	Fish oil (%)	Krill oil (%)
14:0	0.03	8.40	9.67
16:0	10.33	13.97	17.00
18:0	1.99	2.51	1.07
20:0	—	0.14	0.07
16:1	0.16	11.17	6.40
18:1	24.00	10.00	15.40
18:2n-6	52.60	0.66	1.64
18:3	0.09		
20:4n-6	—	1.45	0.52
20:5n-3	—	13.37	11.14
22:4n-6	—	0.11	—
22:5n-6	—	0.39	—
22:5n-3	—	2.06	0.38
22:6n-3	—	8.60	6.77
Others	10.80	27.20	29.40

[a]The analysis was carried out by the U.S. Department of Commerce, NOAA, National Marine and Fisheries Service, Southeast Fisheries Center, Charleston Laboratory (Charleston, SC).

Preparation of liver cytosol and microsomes. The livers were rinsed in ice-cold physiological saline and minced with scissors. A 10% homogenate of livers was prepared in 0.15 M KCl buffer (pH 7.4) and centrifuged at 12,000 × *g* for 10 min. The pellet was discarded, and the supernatant was collected and centrifuged at 105,000 × *g* for 90 min. The supernatant was the cytosolic fraction that was saved for determining the activities of the antioxidant enzymes. The pellet was resuspended in the buffer and centrifuged at 12,000 × *g* for 15 min to wash and collect the microsomal pellet. The microsomal pellets then were resuspended in the homogenization buffer. The protein content of the microsomes was measured using the BCA Protein Assay Reagent (Pierce, Rockford, IL). Fatty acid analyses and lipid peroxidation analyses were carried out on the liver microsomal fractions.

Measurement of thiobarbituric acid reactive substances (TBARS). TBARS in liver homogenates were measured using a modification of the thiobarbituric acid assay by Laganiere and Yu (21). A 10-min centrifugation at 2000 × *g* replaced the lengthy organic solvent extraction of pigments. Malondialdehyde (as tetraethyl acetal; Aldrich Chemical Company, Milwaukee, WI) was used as standard.

Fatty acid analyses of liver microsomal total lipids. Lipids from liver microsomes were extracted with chloroform/methanol (2:1, vol/vol). Fatty acid methyl esters were obtained by transesterification with borontrifluoride/methanol reagent (90°C, 2 h) as described previously (22). The methyl esters were extracted with hexane and analyzed on a Perkin Elmer (San Jose, CA) 8420 gas chromatograph equipped with a fused silica capillary column (22). Chromatographic conditions included an oven temperature of 205°C, a flame-ionization detector set at 250°C, and helium as carrier gas at a flow rate of 0.9 mL/min. Mixtures of fatty acid methyl ester standards (Nu-Chek-Prep, Elysian, MN) were used for peak identification.

Expression of hepatic antioxidant enzymes (CAT, GSH-Px, SOD) mRNA. Total RNA was isolated from the frozen livers using the acid/guanidinium isothiocyanate/phenol/chloroform extraction procedure (23), and the RNA was quantified spectrophotometrically. Twenty micrograms of total RNA was electrophoresed in 0.8% agarose/2.2 M formaldehyde gel. The gel contained ethidium bromide (0.5 μg/mL) in order to verify RNA integrity and loading equivalency. RNA was electroblotted onto nitrocellulose (Schleicher & Schuell, Keene, NH) and fixed to the membrane by cross-linking, using Stratagene UV crosslinker-1800 (Stratagene, La Jolla, CA). The blots were prehybridized, hybridized and then washed following the procedure described in detail by Korc *et al.* (24). In brief, the blots were prehybridized overnight at 42°C in a buffer containing 50% formamide/0.1% sodium dodecylsulfate (SDS)/0.5X sodium chloride/sodium citrate buffer (SSC) (1X SSC = 150 mM NaCl, 15 mM sodium citrate, pH 7.0)/2X Denhardt's (1X Denhardt's = 0.02% each of Ficoll, polyvinylpyrrolidone and bovine serum albumin)/250 μg/mL sonicated, denatured salmon sperm DNA and

50 mM sodium phosphate, pH 6.5. The blots were then hybridized at 42°C for 18 h in the same buffer to which 10% dextran sulfate and the ^{32}P-labeled cDNA probe (1×10^6 cpm/mL) were added. The blots were then washed at 23°C three times for 5 min each in a buffer containing 2X SSC/1.0% SDS, followed by three washes in 0.1X SSC/1% SDS (high stringency). The blots were exposed at –80°C to Kodak XAR-5 film with Dupont intensifying screens. The intensity of the autoradiographic bands was semi-quantified by videoimage analysis using NIH Image 1.4 program, and the values were expressed in fold change as a ratio of the densitometric value of CAT, GSH-Px and SOD to that of glyceraldehyde 3-phosphate dehydrogenase (GAPDH). GAPDH was used as an internal control. The size of mRNA was determined by its relative positions to that of ethidium bromide-stained 28S and 18S ribosomal RNA and 0.24-9.5 kb RNA ladder (Gibco-BRL, Grand Island, NY). The cDNA used in this study were CAT (1.3 kb *Bam* HI/*Sph*I fragment) (25), GSH-Px (0.55 kb *Eco*RI fragment) (26), SOD (0.65 kb *Pst* I fragment) (27) and GAPDH (1.0 kb *Bam* H1-*Pst* I fragment) (28). The cDNA probes (CAT, SOD, GAPDH) were obtained from American Type Culture Collection (Rockville, MD). The cDNA were labeled with [α-^{32}P]dCTP (3000 Ci/mmol; Amersham, Arlington Heights, IL) by random prime labeling (Boehringer Mannheim, Indianapolis, IN) to obtain a specific activity of $0.8–1.2 \times 10^9$ cpm/μg.

Measurement of SOD, GSH-Px and CAT enzyme activities in the cytosolic fractions. The chemicals used in the enzyme assays were obtained from Sigma Chemical Company (St. Louis, MO). All three enzyme activities in the cytosolic fraction of livers were measured in a Shimadzu UV-Visible recording spectrophotometer UV-265 (Shimadzu Scientific Instruments, Houston, TX). CAT (EC 1.11.1.6) activity was measured by monitoring the decomposition of H_2O_2 at 240 nm as described by Aebi (29). The reaction mixture (3 mL) consisted of 50 mM phosphate buffer (pH 7.0) and 1 mL 30 mM H_2O_2 in phosphate buffer and suitably diluted cytosol. CAT activity was expressed as μmoles of hydrogen peroxide reduced/min/mg protein. GSH-Px (EC 1.11.1.9) activity was measured using the coupled-enzyme system as previously described (30). The reaction mixture consisted of 0.5 mL potassium phosphate buffer (pH 7.0) containing 1 mM ethylenediaminetetraacetic acid (EDTA), 0.1 mL of 10 mM GSH and 0.1 mL of 2.4 U/mL glutathione reductase. The mixture was preincubated for 10 min at 37°C. Thereafter, 0.1 mL of 1.5 mM β-nicotinamide adenine dinucleotide phosphate, reduced form (NADPH) was added, and hydroperoxide-independent consumption of NADPH was monitored for three min. The overall reaction was started by adding 0.1 mL of 12 mM *t*-butyl hydroperoxide solution, and the decrease in absorption at 340 nm was monitored at 25°C. GSH-Px activity was calculated based on the equation described by Flohe and Gunzier (31). SOD (EC 1.15.1.1) activity in the cytosolic fraction was determined as described by McCord and Fridovich (32) using the xanthine oxidase/cytochrome C system. The reaction mixture consisted of 2.4 mL of 0.05 M potassium phosphate buffer (pH 7.8) containing 0.1 mM EDTA, 0.3 mL of 0.1 mM ferricytochrome C, 0.1 mL of 1% deoxycholate, 0.1 mL of 1.5 mM potassium cyanide, 0.3 mL of 0.5 mM xanthine and 20 μL of appropriately diluted xanthine oxidase to produce a rate of reduction of ferricytochrome C at 550 nm of 0.025 absorbance unit/min at 25°C. One unit of SOD was defined as the amount of SOD required to inhibit the rate of reduction of cytochrome C by 50%.

Statistical analyses. The data shown are means ± SEM. Data were statistically analyzed using Student's *t*-test with Bonferroni adjustment (33), and $P < 0.05$ was considered significant.

RESULTS

Survivial, body weight and proteinuria levels. The body weights of B/W mice on all three diets showed a steady increase until four months, after which time the body weights plateaued (Table 2). The mice on the 10% CO diet showed slightly lower body weights after four months as compared to the mice on the KO or FO diets. The mice on 10% CO developed severe proteinuria relatively early (by seven months) compared to the mice on the n-3 lipid-based diets (Table 3). The three types of dietary lipids fed at the 10% level had a significant effect on the survival rates of these mice. The percent survival of B/W mice on the three dietary treatments is compiled in Table 4. At eleven months, all mice in the CO group had died, and 20% of the mice in the KO group and 47% of the mice in the FO group were still alive.

Fatty acid composition of microsomal fraction. In order to study the effect of dietary lipids on the membrane lipid composition of liver, microsomal membranes were isolated

TABLE 2

Effect of 10% (w/w) Corn Oil-, Krill Oil- or Fish Oil-Based Diets on Body Weights of (NZB×NZW) F_1 Mice

Age (months)	(body weights in grams)[a] Corn oil	Krill oil	Fish oil
1.0	20.2 ± 0.4	20.5 ± 0.4	20.0 ± 0.4
2.5	31.9 ± 0.7	33.7 ± 0.7	32.9 ± 0.5
4.5	40.8 ± 0.8	42.2 ± 1.0	41.8 ± 0.8
6.5	42.4 ± 1.6	46.1 ± 1.0	45.9 ± 0.9

TABLE 3

Effect of 10% (w/w) Corn Oil-, Krill Oil- or Fish Oil-Based Diets on Proteinuria Levels in (NZB×NZW) F_1 Mice

Age (months)	Diet	Number of mice	Proteinuria levels[a] + (30 mg/dL)	++ (100 mg/dL)	+++ (500 mg/dL)
6.5	Corn oil	15	9	1	5
6.5	Krill oil	15	8	4	3
6.5	Fish oil	15	11	4	0
10	Corn oil	5	0	0	5
10	Krill oil	11	3	1	7
10	Fish oil	14	5	2	7

[a]Proteinuria was determined by using Chemstrip (Boehringer Mannheim, Indianapolis, IN).

TABLE 4

Effect of 10% (w/w) Corn Oil-, Krill Oil- or Fish Oil-Based Diets on Survival Rate in (NZB×NZW) F_1 Mice

Diets	Survival (at 11 months)	
	Number of mice alive	Percent survival
Corn oil	0/15	0
Krill oil	3/15	20.0
Fish oil	7/15	46.7

[a]Both fish oil and krill oil significantly ($P < 0.01$) increased the survival rate of B/W mice.

and analyzed for fatty acid composition. KO and FO had generally similar effects on the fatty acid composition of the microsomal fractions, whereas the effect of CO was different (Table 5). The levels of 16:0 and 16:1 were significantly lower ($P < 0.001$), and the 18:0 level was higher in the CO-fed group compared to the KO- and FO-fed groups. The levels of 18:2 and 20:4n-6 fatty acids were significantly higher ($P < 0.001$) in the CO-fed group, and 20:5 and 22:6 were significantly higher ($P < 0.01$–0.001) in the n-3 lipids-fed groups. When comparing the KO and FO groups, we found that the levels of 18:1 ($P < 0.01$) were significantly lower and that the 22:6 levels were higher ($P < 0.01$) in the FO-fed group.

TBARS. To determine whether the different microsomal lipid composition affected the susceptibility of the microsomal lipids to peroxidation, we measured the generation of TBARS. We found that both the KO-fed and FO-fed groups showed significantly lower levels of TBARS values compared to the CO-fed group (Fig. 1).

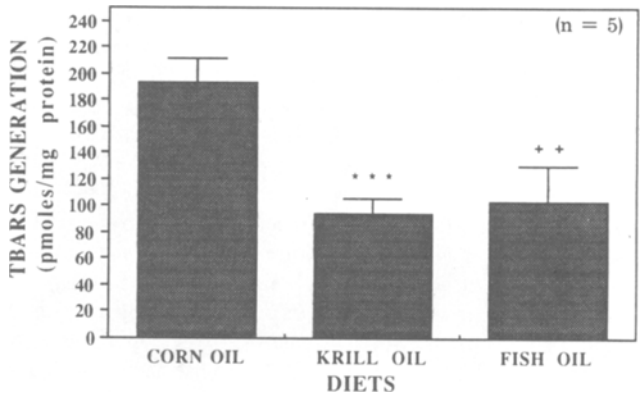

FIG. 1. Effect of 10% (w/w) corn oil-, krill oil- or fish oil-based dietary treatments on thiobarbituric acid reactive substances (TBARS) generation by liver microsomal membrane lipids of B/W mice. Values are means ± SEM of five mice/group. Values not denoted by the same superscripts are significantly different. TBARS generation was significantly higher in the corn oil-fed group compared to the groups fed fish oil ($^{++}P < 0.01$) or krill oil ($^{***}P < 0.001$).

mRNA Expression of antioxidant enzymes. The effect of the three dietary treatments on the expression of hepatic antioxidant enzyme mRNA patterns was examined by Northern blot analysis. Our data indicate that the three key antioxidant enzyme (CAT, GSH-Px and SOD) mRNA levels were lower in the livers of the CO-fed group com-

[a]Values are expressed as percent w/w. Values are mean ± SEM of four mice/group. Abbreviation as in Table 4.
[b–d]Values with different superscripts in the same row are significantly different at $P < 0.05$ as revealed by Student's t-test with Bonferroni adjustment.

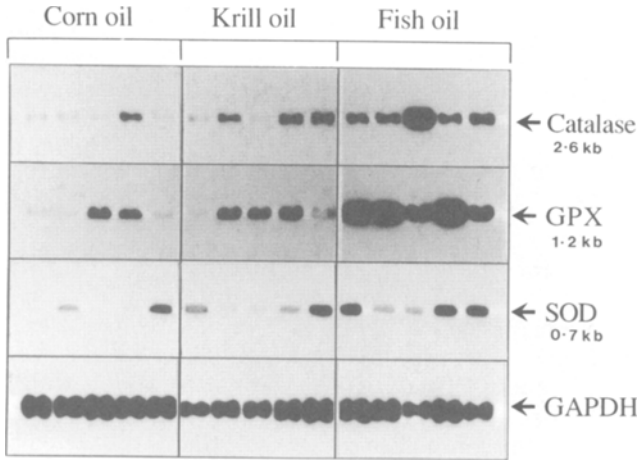

FIG. 2. Northern blot analysis of mRNA expression of antioxidant enzymes in the livers of B/W mice treated with 10% (w/w) corn oil-, krill oil- or fish oil-based diets. Each lane represents an RNA sample from one animal. Twenty micrograms of total RNA was denatured, electrophoresed through 0.8% agarose/formaldehyde gel, electroblotted on to nitrocellulase, and probed with random primed ^{32}P-labeled cDNA probes. The autoradiographic exposure time was eight days [catalase, glutathione peroxidase (GPX) and superoxide dismutase (SOD)] and 36 h for glyceraldehyde 3-phosphate dehydrogenase (GAPDH).

pared to those in the KO- and FO-fed groups (Fig. 2). FO feeding resulted in a higher expression of these enzymes compared to KO feeding. The differences in mRNA levels were not due to variation in RNA loading, as GAPDH levels did not vary significantly. Loading equivalency was also confirmed by ethidium bromide-stained 18S and 28S. Densitometric analysis of the autoradiographic bands, after standardization relative to GAPDH, revealed (Fig. 3) a significantly increased expression of the antioxidant enzymes in the FO group compared to the CO group ($P < 0.01$ level). However, when comparing the FO and the KO groups, CAT mRNA expression was significantly higher ($P < 0.05$) in the FO group.

Enzymatic activities of cytosolic CAT, GSH-Px and SOD. The mice fed the KO- and FO-based diets expressed significantly higher enzyme activities ($P < 0.001$) for CAT (9–9-fold), GSH-Px (4-fold and SOD (1.4-fold) in the liver cytosols when compared to the group given the CO-based diet (Table 6). The enzyme activities were similar in the KO and FO groups suggesting that n-3 lipids have a more favorable effect on antioxidant status than does CO.

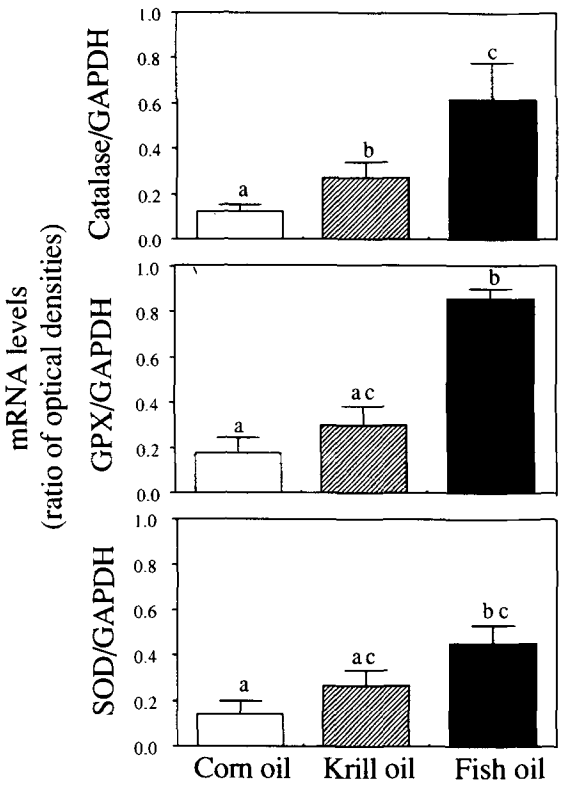

FIG. 3. Densitometric analysis of the autoradiographic bands seen in Figure 2. For the analysis, video image analysis was done utilizing the National Institutes of Health Image 1.4 program, and the results are expressed as a ratio of the specific message to the constitutively expressed GAPDH message. The values were tested for significance using Student's *t*-test. Any values in the figure not denoted by the same superscript are significantly different. The statistical significance of the values tested were as follows: CAT–CO vs. KO: $P < 0.05$; CO vs. FO: $P < 0.01$; KO vs. FO: $P < 0.05$; GSH-Px–CO vs. FO: $P < 0.01$; KO vs. FO: $P < 0.01$; SOD–CO vs. FO: $P < 0.01$. Abbreviations as in Figure 2; CAT, catalase; CO, corn oil; KO, krill oil; FO, fish oil; GSA-Px, glutathione peroxidase.

TABLE 6

Effect of 10% (w/w) Corn Oil-, Krill Oil- or Fish Oil-Based Diets on the Activities of Hepatic Cytosolic Antioxidant Enzymes in B/W Mice[a]

Enzyme	Corn oil	Krill oil	Fish oil
Catalase[b]	59.1 ± 4.4[c]	529.9 ± 27.5[d]	472.0 ±
GSH-Px[e]	25.5 ± 2.0[c]	98.7 ± 5.9[d]	106.0 ± 3.4[d]
SOD[f]	7.2 ± 0.3[c]	9.9 ± 0.4[d]	10.2 ± 0.2[d]

[a]Values are means ± SEM of five mice/group. Abbreviation as in Table 4.
[b]Catalase activity is expressed as μmol H_2O_2 reduced/mg protein/min.
[c,d]Values with different superscript letters (c,d) in the same row are significantly different at $P < 0.05$ level as analyzed by Student's *t*-test with Bonferroni adjustment.
[e]GSH-Px (glutathione peroxidase) activity expressed as μmol β-nicotinamide adenine dinucleotide phosphate oxidized/g protein/min.
[f]SOD (superoxide dismutase) activity is expressed in units/mg protein.

DISCUSSION

Along with several therapeutic approaches aimed at delaying the pathology of autoimmune diseases, nutritional intervention is now also being recognized as having a major effect in the treatment of several of these diseases (5,34–36). Our extensive work on dietary intervention in autoimmune mice suggests that both dietary restriction and an n-3 lipid diet administered without reducing the caloric intake can dramatically prolong the life span and delay the onset of immunological abnormalities in B/W mice (37–39). The exact mechanism(s) involved in delaying autoimmune disease either by food restriction or by FO, is presently not clear, although several possibilities have been suggested (4,5,9,34,35). It is well established that autoimmune diseases have multifactorial etiologies (1,12). Along with genetic, hormonal, viral, immunological and other factors, the inability of the antioxidant defense system to cope with oxidative stress has been proposed as one possible cause. More direct evidence, however, has not yet been forthcoming (39,40).

The role of antioxidant nutrients in membrane-related and cellular immune functions has been addressed by several investigators (41–44). Our earlier work on enzyme-dependent and nonenzymatic *in vitro* lipid peroxidation in B/W mice fed high levels of CO or FO has indicated that vitamin E supplementation can significantly reduce peroxidation in liver mitochondrial and microsomal membranes (45). We thus become interested in testing whether the degree of peroxidation in subcellular membrane lipids in autoimmune mice was due to defects in the antioxidant defense system. Furthermore, it would be important to establish whether different lipids have a differential effect on the antioxidant defense system at the molecular level. In the present study, we examined the effects of feeding n-6 and n-3 lipid-enriched diets on the activities and the mRNA expression of three key antioxidant enzymes, on microsomal lipid composition, and on the extent of lipid peroxidation. Our data show that the activities and the mRNA levels of these antioxidant enzymes were higher in the livers of B/W mice on the KO and FO diets, i.e., fed

lipids enriched with n-3 fatty acids. The degree of peroxidation and the levels of 20:4n-6 were also found to be significantly lower in the liver microsomal fractions of the n-3 lipids-fed B/W mice.

The effect of n-6 and n-3 lipids on subcellular membrane composition and function, including immune-related functions, has been reported by various investigators (46–48). Although several studies have pointed toward protective effects of FO, no information is available on the effectiveness of KO as an anti-inflammatory lipid. In recent years, consumption of krill has increased steadily in Japan and in some neighboring countries. Our present data indicate that crude KO may also have some anti-inflammatory potential, although insufficient information is available to compare its value to that of menhaden FO. The menhaden oil that was used in the present study was extensively purified and was odor-free, and it is currently used as n-3 lipid source in several experimental and clincial studies (5,34,49–51). As the three dietary lipids we used in the present study were supplemented with equal levels of antioxidants, the results we obtained could not have been compromised because of differences in dietary antioxidant levels.

Recent studies have clearly established that the source of nutrients and the caloric intake can both play an important role in determining the expression of certain genes (19,52,53) and in determining the cellular antioxidative defense mechanism (15,43,54,59,60). As the antioxidant enzymes GSH-Px and CAT detoxify hydroperoxides and SOD detoxifies superoxide radicals, they all play along with antioxidant nutrients, a key role in the antioxidant defense system. The antioxidant enzymes constitute a major cell defense against acute oxygen toxicity, and they protect membrane components against damage caused by free radicals. Nutritional intervention, including food restriction, preserves the enzyme activities and the mRNA expression of these antioxidant enzymes, as well as cytochrome P450 mRNA levels (10,38,57,59,60). Both the quantity of the dietary fat and its composition affect the hepatic H_2O_2-metabolizing systems, the activities of NADPH-generating enzymes and lipid peroxidation (58). Interestingly, both CAT and GSH-Px activities were found to increase when polyunsaturated fatty acids in the diet were increased (20). Yamazaki *et al.* (61) found that feeding FO to animals increased the activities of peroxisomal enzymes, fatty acyl-CoA, CAT and GSH-Px and also lowered plasma triglycerides when compared to safflower oil-fed animals. The results of the present study strongly suggest that the mRNA levels of the three key enzymes involved in the antioxidant defense are lower in the livers of CO-fed B/W mice (at 6.5 months of age) than in the livers of FO- or KO-fed mice. The findings suggest that the defect may be at the transcriptional level. Decreased antioxidant mRNA levels were observed with progressive renal disease in these mice. It is not clear at present at what time point the antioxidant enzyme mRNA levels begin to decline in CO-fed mice compared to FO-fed mice, and this still needs to be established. Additional studies are required to clarify the exact role of specific lipids and the levels that would affect antioxidant enzyme mRNA levels both in autoimmune disease-prone strains and in resistant strains. Increased levels of antioxidant enzymes, including SOD and CAT as well as of other antioxidants are closely linked to preserving health and longevity in both mice and rats (10,14,57).

Reactive oxygen species have also been implicated as possible effectors of oxygen-mediated changes in gene expression (61). Although intracellular CAT is thought to protect macrophages from the toxic effects of high doses of H_2O_2, GSH-Px is thought to be more important than CAT in hydroperoxide catabolism (63). It is quite possible that certain abnormal immune functions in CO-fed B/W mice could be caused by increased peroxidative damage that occurs in cellular membranes due to changes in the activities of antioxidant enzymes causing increased oxidative stress to cells.

A very interesting observation made in the present study is the significant difference in steady-state mRNA levels for the key antioxidant enzymes found in the livers of mice on two different lipid diets. Recent studies have suggested that n-6 fatty acids are more susceptible to lipid peroxidation than are n-3 fatty acids. Fatty acids of the n-6 type appear to be oxidized rapidly under conditions under which n-3 fatty acids were not oxidized at any detectable rate (64,65). Although the type of dietary lipid and the degree of unsaturation of membrane phospholipids have a strong effect on lipid peroxidation (66), additional factors, including free radical chain breaking antioxidants such as vitamin E, initiators of lipid peroxidation such as mixed function oxidase system, and inherent antioxidant defense system (16–18), may also be involved.

Earlier studies on MRL/*lpr* mice have indicated that, in addition to immunological abnormalities, these mice exhibited altered membrane phospholipid fatty acid composition in subcellular fractions, including in liver nuclear envelopes and liver mitochondria (67). Also, the genotype had a definite effect on splenocyte phospholipid fatty acid composition (68), suggesting that higher levels of 20:4n-6 and of some longer chain fatty acids could make certain membranes more susceptible to peroxidation, for example, by decreasing fluidity and thereby affecting the activity and expression of enzymes (73). Although hepatic antioxidant enzyme expression and activities and microsomal fatty acid compositions of mice were similar in the KO and FO groups, the survival rate was higher in the FO group, suggesting FO may be more effective in preventing the onset of autoimmune disease by acting more effectively on target tissues, such as kidneys, and by modulating other immune factors (69,70).

In the present study, the three dietary oils used were supplemented with 2.5 g vitamin E/kg of oil to prevent peroxidation, as recommended by the NIH. Each diet therefore contained ~215 mg vitamin E/kg (vitamin E from oil and vitamin mixture). Although the vitamin E levels in plasma or hepatic microsomes were not determined in the present study, this issue had previously been addressed by us. For instance, we had compared the effects of 75 and 500 I.U. of vitamin E in FO- and CO-based diets on the vitamin E levels in plasma and hepatic microsomal and mitochondrial membranes and on lipid peroxidation. We found that in FO-fed mice, 75 I.U. of vitamin E is inadequate to restore the loss of plasma and membrane-

bound vitamin E, and 500 I.U. was sufficient to replenish both serum and hepatic vitamin E levels and to reduce free radical generation (45).

Several studies have indicated that tissue lipid peroxidation may result from lowered antioxidant enzyme activities (19,71) as well as from low tissue vitamin E levels (18,72). However, by increasing dietary vitamin E levels, peroxidation of hepatic microsomes could be prevented (18,72). Also, by increasing dietary vitamin E levels from 35 to 180 I.U., increased tissue vitamin E levels in the FO group similar to those in the CO group were noted, whereas liver and kidney vitamin E levels were unaffected by dietary lipids (18). Although hepatic vitamin E levels were not measured in the present study, our earlier observations (45) and studies reported by others suggest that tissue vitamin E levels could be increased with an increase in dietary vitamin E levels. It is possible, however, that the high level of dietary vitamin E used in the present study may have protected the target tissues of autoimmune-prone B/W mice from peroxidative damage, especially in FO-fed mice. In addition, the high dietary vitamin E supplementation and the well-designed feeding and storage practices followed for oils in the present study may have contributed further to preserving the enzyme activities and the mRNA expression of enzymes involved in the antioxidant defense system far better in FO- and less so in CO-fed mice. Further work is required to measure the effects with and without different levels of vitamin E on tissue vitamin E levels and lipid peroxidation as well as on antioxidant enzyme activities.

In summary, our data indicate that a diet containing marine lipids with very long-chain n-3 fatty acids may delay the onset of autoimmune disease in mice. It appears that alteration of the membrane fatty acid composition due to n-3 lipids may enhance the efficiency of the antioxidant defense system at the molecular level and may prevent the susceptibility of membranes to peroxidation. Further studies are needed to establish the role of various lipids in maintaining an antioxidant defense system and in assuring an extended life span in long-lived inbred strains of mice and rats. As FO contains highly unsaturated and potentially unstable n-3 fatty acids, concerns have been raised in the past about their tendency to peroxidize during storage, as animals fed FO have been reported to excrete higher levels of TBARS in urine (74). Our data, however, would indicate that by supplementing FO with adequate levels of antioxidants, it is possible to enhance the antioxidant defense system, especially in autoimmune-prone mice. This may be one of the mechanisms by which the FO diet significantly increases the survival rate and delays the onset of autoimmunity in autoimmune prone B/W mice. The findings are encouraging in view of utilizing FO in therapeutic applications.

ACKNOWLEDGMENTS

This research was supported by NIH grants RO1-AG 03417 and DE 10863. The authors wish to thank V. Tomar for his excellent technical assistance, Dr. Arlan G. Richardson, The Audie L. Murphy Veteran's Memorial Hospital and the University of Texas Health Science Center at San Antonio, for a generous gift of GSH-Px cDNA, Itano Refrigerated Food Co., Ltd. (Tokushima, Japan) for providing krill oil, and the U.S. Department of Commerce, National Marine Fisheries Service (Charleston, NC) for supplying menhaden fish oil.

Serum Fatty Acid Profiles in Cystic Fibrosis Patients and Their Parents

A.B. Christophe[a], W.J. Warwick[b] and R.T. Holman[a,*]

[a]Department of Endocrinology and Metabolic Diseases, Division of Nutrition, University of Ghent, Ghent, Belgium B9000, [b]Cystic Fibrosis Research Center, University of Minnesota Hospital, Minneapolis, Minnesota 55455 and [c]The Hormel Institute, University of Minnesota, Austin, Minnesota 55912

Fatty acid compositions of the major serum lipid classes from 43 cystic fibrosis (CF) homozygotes (CF patients), 36 obligate heterozygotes (parents of CF patients) and 34 controls were determined by capillary gas chromatography. Fatty acid compositions of the homozygote CF patients were skewed in the direction of relative essential fatty acid deficiency in comparison with the controls. Less pronounced, but similar deviations from normal, were observed in the heterozygotes. Homozygotes with normal fatty acid compositions and heterozygotes with considerably disturbed fatty acid profiles were found.
***Lipids* 29, 569–575 (1994).**

In several studies of the fatty acid (FA) composition of serum lipid classes in cystic fibrosis (CF) patients (cited in Ref. 1), CF seems associated with some form of essential fatty acid (EFA) deficiency. Studies of FA in CF patients have been related to age (1,2), presence of pancreatic insufficiency (1,3) or degree of fat malabsorption (1). Polyunsaturated fatty acid (PUFA) profiles of a series of CF patients previously studied in this laboratory revealed distortions of PUFA pattern in serum lipids, indicating linoleic acid deficiency and probable abnormalities of PUFA metabolism (4).

FA compositions of the serum lipids of small groups of obligate heterozygotes (parents of CF patients) have been reported (3,5). Because biochemical differences or abnormalities may occur in heterozygotes due, among other causes, to the presence of certain mutations of the CF gene, a large group of heterozygotes was investigated in comparison with homozygotes and healthy controls, using capillary gas chromatography, which is more discriminating and sensitive than the packed columns used in earlier studies.

Lower linoleic acid (18:2ω6) in serum phospholipids (PL) of CF patients has been found in most studies, but subdivision of CF patients on the basis of this measure had not been done. We chose this criterion for study of CF patients and of obligate heterozygotes because it should reveal changes in other FA in relation to linoleate level, and reveal whether these relationships were dissimilar in CF homozygotes, CF heterozygotes, and healthy controls.

MATERIALS AND METHODS

Serum. Blood was obtained in the morning from nonfasting individuals who gave informed consent. Sera were frozen at –30°C and analyzed within a week. This study was approved by the Human Subjects Committee of the University of Minnesota (Austin, MN).

CF homozygotes. CF patients (24 males and 19 females, ranging in age from 4 to 44 years with a mean age of 20.2 years) were outpatients who visited the University of Minnesota Cystic Fibrosis Center. Diagnosis was based on clinical criteria and multiple sweat tests showing chloride concentrations greater than 60 mmol/L with the Gibson–Cooke sweat test (6). Their weight for height ranged from 70.4 to 128.1% of the predicted value (mean ± SD = 101.3 ± 13), their forced vital capacity from 33.1 to 117.6% (average 85.0 ± 23.6) and forced expiratory volume from 16.8 to 121.4% (average 69.2 ± 29.9). The CF patients were instructed to consume normal diets and to adjust their pancreatic enzyme therapy to have one or two bowel movements a day. All were encouraged to increase their dietary fat intake, but none were on medium chain triglycerides (TG). (See Table 1 later for details.)

Heterozygotes. Twenty-three mothers and 14 fathers of CF patients volunteered for this study. They ranged in age from 25 to 59 years of age (with a mean age of 38.7 years; all asymptomatic and in good health).

Controls. This group consisted of 17 males and 17 females, all healthy and without a family history of CF, with an average age of 33.6 years and a range of 21–45 years. This group included healthy parents of children with other diseases, as well as volunteers from the University of Minnesota staff.

Assay. Serum lipids were extracted and separated into PL, cholesteryl esters (CE), TG and nonesterified fatty acids (NEFA). From each lipid class, methyl esters were prepared in methanol by boron trifluoride catalysis (7). Methyl esters were separated and analyzed by gas chromatography using a 15 m × 0.1 mm i.d. CPS 1 capillary column (Scientific Glass Engineering, Inc., Austin, TX), in a Packard (Palo Alto, CA) 428 gas chromatograph equipped with a glass splitter and a flame-ionization detector. The split ratio was 1:100, the column flow 0.11 mL/min and, after an initial delay of 10 min at 160°C, the temperature was programmed from 160 to 200°C at 2°C/min and held at 200°C for 35 min to complete an analysis in 65 min. Identification of the methyl esters was made by comparing their retention times with those of authentic standards.

Data handling. Content of an FA is expressed as percent of total FA of a lipid class, which is most appropriate for expressing concentration of an FA within a lipid substrate (8–12). Data were entered into a computer by group and lipid class. The content of linoleic acid in the serum PL (18:2ω6) was used to assign each individual into subgroups with low (<15%), intermediate (15–20%) and "normal" linoleic acid content (>20%). Programs, written to

Abbreviations: CE, cholesteryl esters; CF, cystic fibrosis; DBI, double bond index; EFA, essential fatty acid(s); FA, fatty acid(s); NEFA, nonesterified fatty acid; NR, normalcy ratio(s); PL, phospholipids; PUFA, polyunsaturated fatty acids; TG, triglycerides.

calculate and plot profiles of normalcy ratios (NR) (equivalent to Z scores) to evaluate EFA status of one group compared to its control group (9,10), were modified to present profiles of homozygotes and heterozygotes together. Significance of differences between two groups was evaluated by Student's *t*-test. One-way analysis of variance was used for comparisons of the three subgroups differing in PL-18:2ω6.

RESULTS

The characteristics of the three groups and their three subgroups are listed in Table 1. Only one individual (3%) in the control group (n = 34) had less than 20% linoleic acid in her serum PL. This occurred for 46% of the parents of CF patients (n = 37) (43% in males, n = 14; and 48% in females, n = 23) and for 70% of the CF patients (n = 43) (67% in males, n = 24; and 74% in females, n = 19). Thus, 30% of the patients and 54% of the carriers of the CF gene had normal serum levels of linoleic acid. Table 1 also shows that a few heterozygotes had lower PL-18:2ω6 than some CF patients.

In contrast to control individuals with no known metabolic disease (13), the percentage of 18:2ω6 in the PL of CF patients appeared to increase with age. This was confirmed by linear regression analysis of 18:2ω6 in PL vs. age, for which the equation was found to be:

$$\text{PL-18:2}\omega6 = 15.34 + 0.13\,(\text{yr}) \quad R = 0.35\ (0.01 < P < 0.05) \qquad [1]$$

No correlation was found between PL-18:2ω6 and the relative weight for height of the patients.

The FA composition of serum PL of the control group ± SE is given in Table 2. Values for PL for CF patients and parents of CF patients may be estimated from these control values and the NR shown in Figure 1.

FA profiles in CF. Although some FA and parameters calculated from them have been used as measures of EFA status, we consider that the whole profile is more revealing. It graphically depicts the FA composition of a tissue lipid by comparing it with control values, and permits differentiation of many PUFA defects occurring in disease. Profiles of serum PL and NEFA of CF homozygotes and heterozygotes are given in Figures 1 and 2.

The FA profile of PL in CF patients (Fig. 1, upper bars of each pair) showed low 18:2ω6 and 20:0 in serum PL, and high 16:1ω7, 18:1ω9, 20:3ω6, 22:5ω3 and 24:1ω9. The indicator of nutritional EFA deficiency, 20:3ω9, did not differ significantly from normal value. Loss of 18:2ω6 was largely replaced by monoenoic acids and minor significant increments of 20:3ω6 and 22:5ω3. Total ω6 PUFA were significantly suppressed in homozygotes, whereas total ω3 PUFA were normal. Despite these changes, a composite indicator of lipid "fluidity," the double bond index (DBI) of the FA of PL (8), did not vary significantly from normal (1.36 ± 0.03 vs. 1.37 ± 0.03).

Parents of CF patients (Fig. 1, lower bars of each pair) showed most of these changes but with less significance. Thus, 18:2ω6 was significantly less than normal ($P < 0.001$), although it was not as low as for homozygotes. Although the heterozygote profile had few significant abnormalities or dramatic features, the contour was similar to that of homozygotes. The DBI of the FA of PL was slightly but significantly less in the heterozygotes than in the controls.

The CE profile for CF patients revealed low 18:2ω6 but elevated 18:3ω6 and 20:3ω6. The major compensation for the low 18:2ω6 was by 18:1, 16:0 and 16:1. No 20:3ω9 could be detected in this lipid class. DBI was decreased (1.55 ± 0.02 vs. 1.68 ± 0.001; $P < 0.001$), and branched-chain and odd-chain acids increased. Parents of CF patients had less 18:2ω6 and elevated levels of 18:1 and saturated acids. Data for CE are not shown.

The TG profile (data not shown) for CF patients had low 18:2ω6. Paucities of 18:3ω3 and its end product, 22:6ω3, occurred in this lipid class only, perhaps reflecting deficient intake of ω3 PUFA. Increased 20:3ω9, usually taken as evidence of EFA deficiency, occurred only in this lipid.

TABLE 1

Description of the CF Patients, Parents of CF Patients and Control Groups and Their Subgroups Studied[a]

Groups/subgroups	n	%	Male	Female	Mean	SD	Age range (yr)
CF patients	43	100	24	19	20.2	8.5	4–44
Low <15% PL-18:2ω6	8	19	4	4	16.6	5.7	11–24

18:0	12.1 ± 0.24	20:3ω6	2.98 ± 0.11	24:1ω9	0.77 ± 0.06
18:1i	1.68 ± 0.17	20:3ω9	0.46 ± 0.05		

[a]Weight %. Branched isomers are identified by Br, positional monoenoic acid isomers different from ω9 by i. FA, fatty acids.

Branched-chain acids were elevated 5.8-fold, but odd-chain acids were normal. The 16:1 was elevated, total PUFA were low and the DBI was 88% of normal. Parents of CF patients presented a pattern similar to CF patients, with diminished magnitudes and significances.

The NEFA profile for CF patients (Fig. 2, upper bars) showed low 18:2ω6, total ω6, PUFA and 20:0, as well as significantly elevated 20:3ω6, 16:0, 18:0, and odd-chain FA. The profile for parents of CF patients was similar (Fig. 2, lower bars), with lesser changes and significances. The unique feature of these profiles was that in both homozygotes and heterozygotes, 20:3ω6 was elevated to four times the normal, suggesting that the eicosanoid pattern may be skewed, affecting metabolic control.

Studies comparing subgroups. With decreasing proportion of 18:2ω6 in the PL of the three subgroups of CF patients, there was a decrease of this FA in CE, TG and NEFA as well. A regression analysis between PL-18:2ω6 and CE-18:2ω6 was made, and the result is shown graphically in Figure 3.

When the subgroup of CF patients with highest normal PL-18:2ω6 content was compared with controls, those differences characteristic of CF were much less pronounced (data not shown). Eleven patients with normal values for PL-18:2ω6 could be matched with 11 individuals from the control group having very similar PL-18:2ω6 values. There were no significant differences with respect to other FA when comparing these two groups. That is, patients

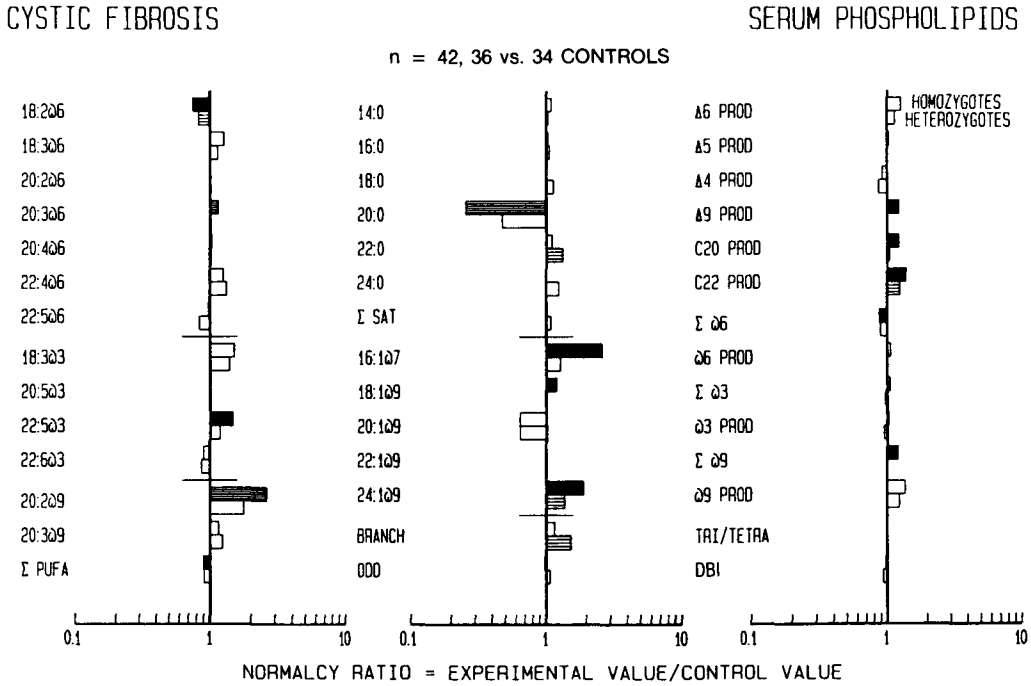

FIG. 1. Fatty acid profile of serum phospholipids from cystic fibrosis (CF) patients (top bars) and parents of CF patients (lower bars) as compared with controls. Normalcy ratio, the experimental value divided by control value, is plotted on a logarithmic scale. Black bars $P < 0.001$, closely-striated $P < 0.01$, widely-striated $P < 0.05$, open bars nonsignificant.

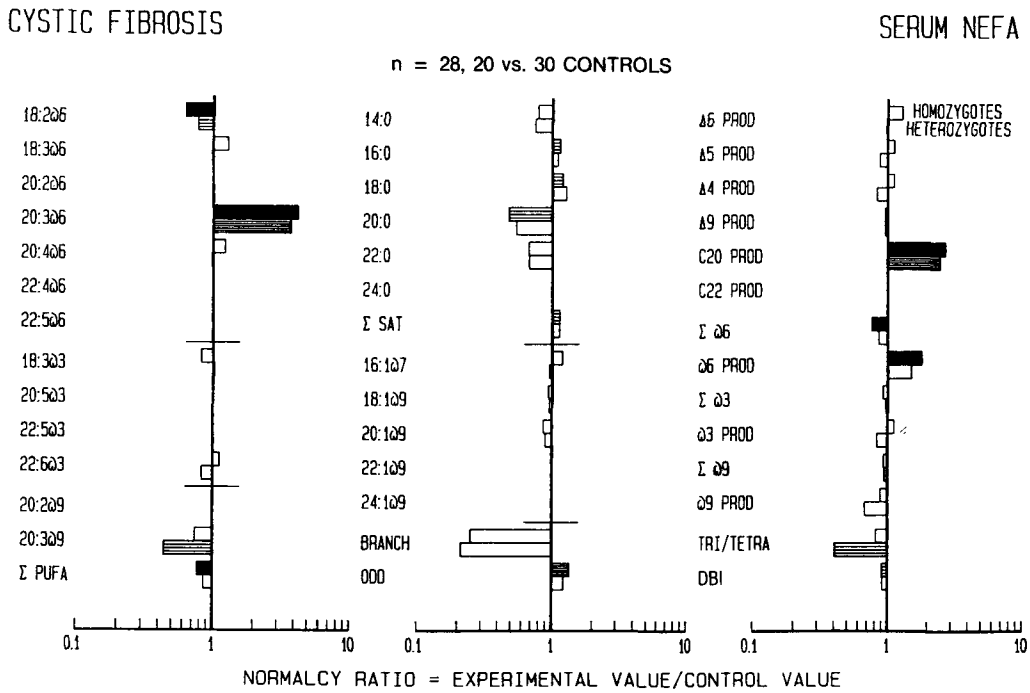

FIG. 2. Fatty acid profiles of fatty acids of serum nonesterified fatty acids from CF patients (upper bars) and from parents of CF patients (lower bars). See Figure 1 for legends and abbreviations.

who were normal in 18:2ω6 were normal in all other FA in the PL fraction. With stepwise decreases in 18:2ω6 in the homozygote subgroups, 14:0, 15:0, 16:0, 16:1ω7, 18:1ω9, 18:3ω3, 20:2ω9 and 24:1 increased, whereas 17:0, 18:0Br, 20:0 and 20:1ω9 decreased. In going from the subgroup with normal 18:2ω6 to the intermediate group, increases in 18:3ω6, 20:3ω9, 20:3ω6, 20:4ω6, 22:5ω6 and 22:6ω3 were observed, whereas with further decrease in 18:2ω6, these decreased. Reversed nonlinear changes were observed for 16:1*t*, 22:0 and 24:0. All the fatty acids of the former group have in common a Δ6 desaturase step in their metabolism.

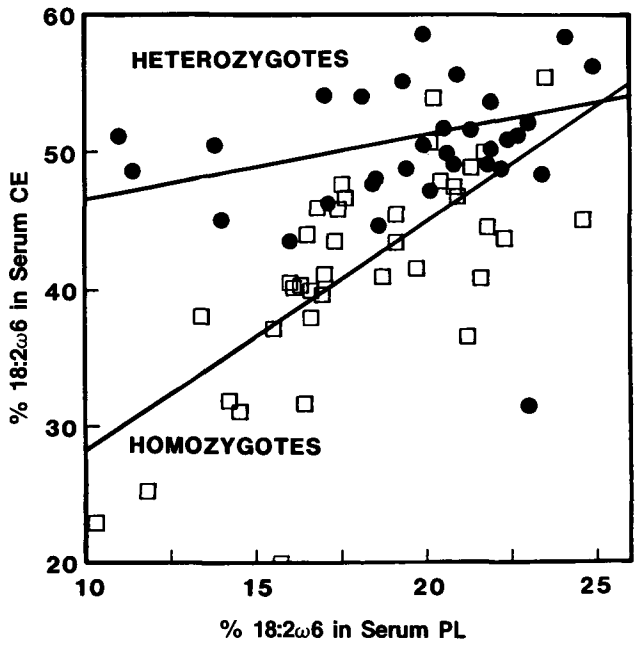

FIG. 3. Correlation between the content of linoleic acid in serum phospholipids and serum cholesteryl esters (CE) in cystic fibrosis (CF) patients (□—□) and in parents of CF patients (●—●).

With decreasing proportion of 18:2ω6 in the CE of the three subgroups of CF patients, there was an increase in 16:0, 16:1ω7, 18:1ω9 and 18:1 isomers. In TG, the 16:0 and 16:1ω7 increased as the 18:2ω6 decreased. In the NEFA fraction, 16:1ω7 increased only in the subgroup with severely reduced 18:2ω6 content.

When the homozygote and heterozygote subgroups with normal PL-18:2ω6 were compared, no significant differences were found for any FA or calculated parameter. When the subgroups with subnormal PL-18:2ω6 were compared, the homozygotes with low PL-18:2ω6 had a deficit in 18:2ω6 of about 11% of the total FA in this lipid class, largely compensated for by a 7% increase in monoenoic acids and about a 1.5% increase in saturated FA. In contrast, in the heterozygotes with low PL-18:2ω6, the 11% deficit of 18:2ω6 in the PL was compensated for by an equal increase in saturated FA, but not by a change in monoenoic acids. A regression analysis between oleic acid and linoleic acid in serum PL of CF patients of CF heterozygotes is shown in Figure 4. In these low PL-18:2ω6 subgroups, the lowered 18:2ω6 in the CE was compensated for by an increase in saturated FA and by an increase in monoenoic acid which was more pronounced in the homozygote subgroup than in the heterozygote subgroup. In the TG, only 18:2ω6 was significantly different in the low PL-18:2ω6 subgroups. There was no significant difference in composition of the NEFA between the homo-

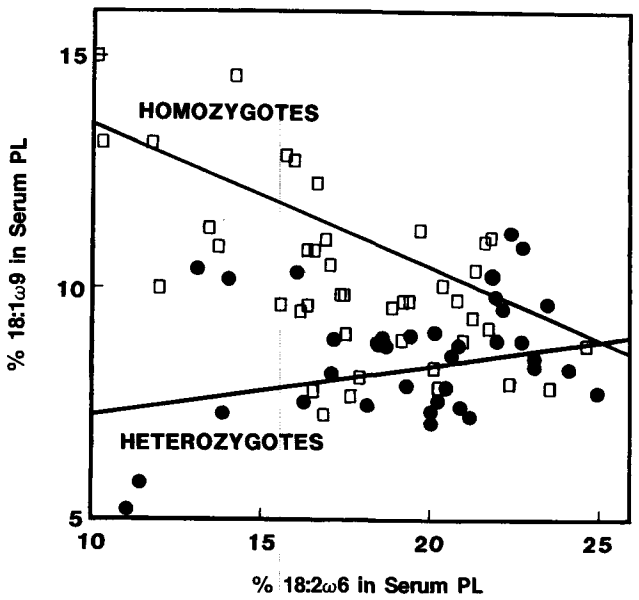

FIG. 4. Correlation between the content of oleic and of linoleic acids in serum phospholipids (PL) in cystic fibrosis (CF) patients (□—□) and in parents of CF patients (●—●).

zygote and heterozygote subgroups with low PL-18:2ω6. These observations indicate that homozygote and heterozygote conditions modify the acylation-deacylation reactions differently.

DISCUSSION

Methodology. It was not feasible to obtain blood in the fasting state because most patients and their accompanying parent(s) were required to travel a considerable distance to reach the clinic. The FA composition of PL and CE are not influenced in the postprandial state (14). The FA composition of the TG and NEFA, on the contrary, change toward that of the fat fed before returning to fasting values in a time- and dose-dependent matter (14). Nevertheless, valuable information can be obtained from these lipid classes. Indeed, an increase in 20:3ω6, as seen in the NEFA fraction, cannot be due to fat consumption because neither this FA nor its precursor, 18:3ω6, is present in a Western type diet to any significant extent (15), and fat feeding would tend to reduce its level in these lipids.

"Two flag" profiles, as introduced here, are extremely useful to visualize similarities and dissimilarities of deviations of two groups from the norm. FA profiles, especially of the PL, indicate EFA status of a group. We subdivided the entire group of patients and CF-heterozygotes into three subgroups. The lower limit of the group with "normal" PL-18:2ω6 was chosen as 20% PL-18:2ω6 because all control individuals except one (who was 2.6 SD lower than the mean and may have been an unknown carrier, *vide infra*) fell in this group. The upper limit of the "low-linoleic acid group" was chosen as 15% PL-18:2ω6. When subclassification was done in this way, the average of PL-18:2ω6 of the total group was almost identical to that of the intermediate subgroup.

CF patients. The 18:2ω6 in PL is reduced in CF (1–4, 16,17). When subgroups with decreasing proportions of PL-18:2ω6 were examined, they also exhibited decreasing proportions of 18:2ω6 in CE, TG and NEFA. Thus, the four lipid classes reveal rather parallel phenomena. Ninety-seven percent of those in the normal group had PL-18:2ω6 > 20% (Table 1). The only control person of 34 to have low PL-18:2ω6 may be an unknown CF heterozygote. Indeed, the carrier frequency is about 1:20 in a Caucasian population (18), and reduced PL-18:2ω6 occurs in 47% of the carriers (this study). In contrast, 70% of the CF patients had less than this proportion of 18:2ω6 in their PL. This proportion is close to the 85% of CF patients with malabsorption found to have reduced levels of 18:2ω6 in total plasma lipids (1). The increase in PL-18:2ω6 with age observed here in the CF patients is in contrast with the very slight decrease with age observed in control individuals (13), suggesting that a selection among the patients may have taken place, permitting a higher survival of those with a higher, more normal PL-18:2ω6 content. The basis of this hypothetical selection could possibly be that this group may contain more patients with pancreatic sufficiency. Indeed, normal levels of 18:2ω6 in PL and better survival rates have been found in subgroups of patients without pancreatic insufficiency (3) and without malabsorption (1), but not in patients with fat malabsorption corrected by administration of lipases (2,19). Much larger groups and prospective studies will be required to decide whether 18:2ω6 of PL is a good predictor of survival in CF patients. Higher PL-18:2ω6 may be the reflection of better nutritional status (20). Nutritional rehabilitation in CF has been shown to result in a catch-up weight, sustained improvement in linear growth and fewer pulmonary infections, as well as a significant reversal of the trend for deteriorating lung function (21). On the other hand, interventions aimed at correcting linoleic acid deficiency in CF without change in caloric intake also resulted in enhanced growth (22). Farrell *et al.* (1) found no correlation between age and content of 18:2ω6 in plasma total lipids of CF patients. Their observation is not necessarily at variance with our finding because changes in the content of 18:2ω6 in nonfasting total lipids do not necessarily parallel changes of 18:2ω6 in PL. Improvement of linoleic acid status after administration of extra calories as carbohydrates (20) or after administration of linoleic acid-rich diets (16,21,22) has been documented. Monoene acids are increased in the PL of CF patients (1,4,20). Some authors (4,23) found decreased levels of 20:4ω6 in the PL fraction of patients with CF, whereas others did not (1–3). Whether 20:4ω6 is normal may depend on several factors including the plasma zinc level (24) and the extent of fat malabsorption (19) and liver involvement (23). Normal (4,25), as well as significantly increased (26), levels of 20:3ω9 have been described in PL of CF as well as slightly decreased (4,25) to increased levels of 20:3ω6 (26,27). Our present findings suggest that when 18:2ω6 is slightly low, 20:3ω6 and 20:4ω6 may increase in compensation and that when 18:2ω6 is reduced more markedly, synthesis and incorporation of its metabolites may be subnormal. Lower levels of 18:2ω6 than found in this study group may be required to get an increase in 20:3ω9, as is the case in

CF infants (17). CF infants were not included in this study. An increase of PL-20:4ω6 with less severely reduced PL-18:2ω6, and a decrease of 20:4ω6 with sharply reduced 18:2ω6 was described in a patient with fat malabsorption maintained by intravenous alimentation preparations with different 18:2ω6 contents (28). The change of 20:4ω6 with decreasing 18:2ω6 seems related not to CF but to the degree of EFA deficiency.

NEFA, although the least abundant of the four lipid classes, vary with prandial state, have the highest rate of turnover and include many eicosanoid precursors important to metabolic control. This lipid class changes drastically in some diseases, with major changes of pattern and concentration of PUFA. In Reye's Syndrome, NEFA are elevated, and the proportions of PUFA may reach ten times normal values (11). In cirrhosis, 20:2ω6, 20:4ω6 and 22:6ω3 increase 2–3-fold (12). These observations suggest release of PUFA from PL to NEFA.

The deviations from normal composition of TG, CE and NEFA in CF are similar to those reported by others (2–5), and similar, but more severe, deviations have been reported for patients with EFA deficiency (10,28–30). The content of 18:2ω6 in the lipids of CF patients is not as low as in severe EFA deficiency. In the latter condition, there are high levels of 20:3ω9. A marked increase of 20:3ω9 was not found in this study, thus not indicating defective EFA metabolism as reported earlier (4,31). Our present study indicates a moderate deficiency of 18:2ω6 for the group as a whole. The difference between our earlier study (4) and the present one may be due to improved management of the disease over the years.

The FA profile of PL in CF was found to be different in the different subgroups (results not shown). Thus, the profile of the total group will critically depend upon the abundance of the different subgroups or more generally on the percentage of 18:2ω6 distribution of the total group. This implies that in comparisons of FA profiles in different diseases and attempted correlations of other FA with 18:2ω6, the distributions of 18:2ω6 should be the same in the compared groups. Moreover, comparison of FA profiles in different diseases may be complicated by minor differences due to age and sex distribution (13), and to larger differences due to differences in eating habits.

With these reservations in mind, we compared some features of the FA profile of the CF subgroup with intermediate linoleic acid content with those of some other groups with a similar NR for linoleic acid. In chronic malnutrition, which is generally believed to be largely caloric, and protein deficiencies (32), reduced PL-18:2ω6 (NR = 0.79) was accompanied with significantly ($P < 0.001$) reduced 20:3ω6 (NR + 0.64) and 20:4ω6 (NR = 0.72). In anorexia nervosa (33), where energy intake is reduced but protein intake is normal, reduced PL:18:2ω6 (NR = 0.78) was accompanied with essentially normal 20:3ω6 (1.03) and 20:4ω6 (NR = 0.95). In healthy individuals put on a diet with 0.6 to 1.3 energy % linoleic acid (34), reduced PL-18:2ω6 (NR = 0.73) was associated with increased 20:3ω6 (NR = 1.46) and 20:4ω6 (NR = 1.20). In the CF subgroup with identically reduced PL-18:2ω6 (NR = 0.73), there was significant increase ($P < 0.001$) in 20:3ω6 (NR = 1.09). Thus, deviations in the abundance of the major ω6 FA in serum PL of this CF group most resemble those seen in those in the normal group with low-linoleic acid intake. Several factors, such as incomplete correction of fat malabsorption, reduced energy intake, increased arachidonic acid turnover (35) and increased energy expenditure (36), may increase linoleic acid requirement in CF. Thus, suboptimal intake of linoleic acid could explain these results.

Parents of CF patients. An early study found no differences between the FA compositions of the major serum lipid classes of those in the normal group and of five obligate CF heterozygote (3). We found the same in our subgroup of heterozygotes with normal 18:2ω6 in PL (results not shown) who comprised 54% of our heterozygotes (Table 1). We also found heterozygotes with subnormal 18:2ω6 in PL in whom abnormal FA compositions of the other serum lipids were observed. In a study on the NEFA pattern of CF patients and their parents, opposing deviations from normal were found for 16:0 and 18:2ω6 (5). The authors suggested that increased 18:2ω6 in parents of CF, observed in that study, might be due to a higher dietary intake of PUFA (5). Differences in lipoprotein composition between non-CF siblings and those in the normal group have been described (37). Comparisons between homozygote and heterozygote subgroups with similar PL-18:2ω6 content indicate that changes in compensation for the paucities of EFA differ for homozygotes and heterozygotes.

Reduced content of linoleate in serum lipids in CF patients may be secondary to malabsorption (1), but fat malabsorption has not been found in heterozygotes. Our finding that some heterozygotes have reduced 18:2ω6 content in their serum lipids could suggest that at least in some CF gene carriers, the reduced 18:2ω6 levels have other causes than fat malabsorption. Specific mutations are associated with increased energy expenditure (36) which, in turn, could affect linoleate levels. Heterozygotes may differ from the control group because parents may adapt their diet to that of their sick child. Because our CF patients were instructed to eat normal diets, this possibility seems unlikely. Heterozygotes with severely disturbed FA compositions have no clinical signs of the disease, whereas homozygotes with normal FA composition display clinical signs of the disease. Disturbed FA compositions do not seem to be strongly related to the clinical symptoms.

This does not mean that normalizing FA compositions of plasma lipids in CF (16,20,22,38) is not beneficial, although improvement in clinical status of the patients in response to linoleate intake has not been uniform (1,4,39,40). In our present study, we found no evidence for the deficiencies of long-chain PUFA observed ten years previously (4), and we suspect that generally improved care and nutrition may have exerted an influence. From the regression lines in Figure 4, it is apparent that differences found between CF homozygotes and heterozygotes are greatest at low levels of PL-18:2ω6, and that they vanish for individuals with normal PL-18:2ω6 levels as the regression lines converge. Thus, this abnormality may be corrected nutritionally.

Homozygotes compared to heterozygotes. The profiles of the FA composition of serum lipid classes of CF homozygotes and heterozygotes are similar, but are less pronounced in the latter. Similar deviations from normal

have also been found in the FA composition of platelet lipids of CF homozygotes and heterozygotes (41). In the PL fraction, heterozygotes and homozygotes compensate for reduced 18:2ω6 in different ways. None of our controls had 18:2ω6 levels as low as those found in CF, and how such individuals might compensate for low 18:2ω6 in their lipids could not be determined. In individuals with similarly reduced 18:2ω6 in PL due to intravenous alimentation without EFA (13), malabsorption (28) or septicemia, chronic bronchitis and other illnesses unassociated with malabsorption (42), compensation was by marked increase in monoenoic fatty acids and by a lesser increase in saturated FA. We find similar compensation in CF patients (Fig. 4). In contrast, low 18:2ω6 in parents of CF patients was compensated for entirely by increased saturated acids without any increase in monounsaturated FA. Thus, deviation from the expected pattern in EFA deficiency is found in heterozygotes but not in homozygotes.

The CF gene has recently been identified, and different mutations of this gene have been documented (42–44). These could lead to different subgroups of CF patients with different clinical and biochemical patterns (44). The putative CF gene product has been described (42), and it has been suggested that it could be an ion channel or may serve to regulate ion channel activities. The sequellae which link reduced ion channel activity with disturbed FA composition of tissue lipids, if such a link exists, is currently unknown. The heterogeneity in genetic make up of patients and carriers, due to different mutations, could contribute to the wide range in severity of FA disturbances found. The newly acquired possibility to identify different mutations enables investigation of these possibilities.

ACKNOWLEDGMENTS

Financial support for this study was provided by Program Project Grant HL08214, NIH grant NS14304, Scotia Pharmaceuticals, and The Hormel Foundation. Assistance with analysis and computation by Susan B. Johnson is gratefully acknowledged.

The Lipid Composition of Selected Tissues from a Mediterranean Monk Seal, *Monachus monachus*

R. James Henderson[a,*], **Nick Kalogeropoulos**[b] and **Maria N. Alexis**[b]

[a]N.E.R.C. Unit of Aquatic Biochemistry, Department of Biological and Molecular Sciences, University of Stirling, Stirling FK9 4LA, Scotland and [b]National Centre for Marine Research, Aghios Kosmas, Helleniko, 16604, Athens, Greece

The lipid composition of blubber, brain, muscle and heart from a Mediterranean monk seal *Monachus monachus* (an endangered species) were examined to allow comparisons with more common species of seals. Only neutral lipids (mainly triacylglycerols) were detectable in the blubber lipids, whereas polar lipids predominated in the heart and in the brain. Neutral and polar lipids comprised almost equal proportions in both liver and muscle. Choline glycerophospholipids (CGP) were the major polar lipids, followed by ethanolamine glycerophospholipids (EGP) in the liver, heart and muscle. Cerebrosides accounted for 28.8% of the brain lipids. All lipid classes of the liver contained high levels (31–47%) of polyunsaturated fatty acids (PUFA), with the exception of phosphatidylserine. The total proportion of n-6 PUFA exceeded that of n-3 PUFA in all lipid classes of the liver, due mainly to the high levels of 20:4n-6. The highest level of 20:4n-6 occurred in phosphatidylinositol, where it comprised 32.4% of the total fatty acids. The CGP and EGP of the brain contained lower levels of PUFA than those of the liver, muscle and heart. Alkenyl ethers accounted for 35.8% of the total long-chain moieties in brain EGP. The fatty acid composition of blubber triacylglycerols differed from those of the lipid classes from other tissues in that it had a very low ratio of n-6 to n-3 PUFA (0.3) as a result of a lower content of 20:4n-6.

***Lipids* 29, 577–582 (1994).**

The Mediterranean monk seal, *Monachus monachus* (Hermann 1779), is one of the world's rarest mammals (1). Only a few hundred individuals remain and the species is faced with extinction (2,3). Because of its low abundance and the danger of genetic deterioration due to isolation, the monk seal is under protection in the European Community, and a seal park has been established in the Northern Aegean Sea for this purpose.

Although data exist concerning the biology, behavior and feeding habits of the Mediterranean monk seal (4), the lipid composition of its tissues has not been reported previously. In contrast, a substantial amount of information is available concerning the fatty acid composition of commercial oils, as well as tissue and milk lipids from several species of seals from Arctic and temperate waters (5–12). Most previous studies of seal lipids have concentrated on the total lipids from blubber, while the lipid composition of other tissues has not been examined in detail.

*To whom correspondence should be addressed.

Abbreviations: CGP, choline glycerophospholipids; CL, cardiolipin; DMA, dimethyl acetal; EGP, ethanolamine glycerophospholipids; HPTLC, high-performance thin-layer chromatography; PG, phosphatidylglycerol; PI, phosphatidylinositol; PS, phosphatidylserine; PUFA, polyunsaturated fatty acids; TAG, triacylglycerols.

Although data obtained to date suggest that general similarities exist in fatty acid composition between oils from different species of seal, it is known that the fatty acid composition of oils obtained from marine mammals is strongly influenced by that of the dietary lipids (7,9,11,12). The species of organisms that comprise the food webs in the Mediterranean Sea differ from those found in colder waters, and it may be expected that these differences are reflected in the lipid composition of the monk seal. For this reason, the analysis of the lipid composition of tissues from the monk seal was undertaken in the present study when the rare opportunity arose of obtaining tissues from a fresh corpse.

MATERIALS AND METHODS

Samples were collected in March 1990 from an adult (6+ years old) male *M. monachus* that was found strangled in a fisherman's net near the southern coast of Santorini Island in the Southern Aegean Sea (36°20′ N, 25°22′ E) (13). The animal was recovered about 15 h after its death and was kept surrounded by ice until its subsequent dissection at the National Centre for Marine Research (Athens, Greece). The length of the body from the tip of the snout to the tip of the tail was 218 cm, and the circumference at the navel was 121 cm. Apart from the presence of a few parasitic worms in the intestine, the seal showed no obvious indications of disease and appeared to be a healthy individual in good condition. The stomach was almost full, mainly with fish taken from the net in which it had become entangled (13). Samples of liver, brain, heart, muscle and blubber were weighed and immediately stored at −20°C in chloroform/methanol (2:1, vol/vol) under an atmosphere of nitrogen in glass vials sealed with Teflon-lined caps. Samples of blubber, taken from the belly region where the blubber was about 4 cm thick, were treated similarly. For the extraction of lipids, the samples were homogenized in chloroform/methanol (2:1, vol/vol) with subsequent washing of the organic phase with 0.88% (wt/vol) KCl, essentially as described by Christie (14). The amount of lipid recovered was determined gravimetrically after removal of the solvent by evaporation under a stream of nitrogen.

Lipid class composition was determined by subjecting aliquots of the lipid extract to high-performance thin-layer chromatography (HPTLC) alongside known standards using glass plates coated with silica gel 60 without fluorescent indicator (E. Merck, Darmstadt, Germany). Plates were first developed to half final distance with methyl acetate/propan-2-ol/chloroform/methanol/0.25% (wt/vol) aqueous KCl (25:25:25:10:9, by vol) and then developed fully using hexane/diethyl

ether/glacial acetic acid (80:20:2, by vol) (15). Separated lipid fractions were detected by spraying the developed chromatogram with 3% cupric acetate in 8% phosphoric acid (16), followed by charring at 160°C for 20 min, and were quantitated by optical scanning densitometry using a Shimadzu CS-930 dual wave length scanner (Anachem, Luton, United Kingdom) linked to Shimadzu DR-2 data recorder (15).

For the analysis of fatty acid composition, aliquots of total lipid extracts were separated into component lipid classes by TLC on 20 × 20 cm glass plates coated with silica gel G60 (E. Merck) using the double development system described previously. Developed chromatograms were sprayed with 0.01% (wt/vol) 2′,7′-dichlorofluorescein in methanol containing 0.05% (wt/vol) butylated hydroxytoluene and viewing under ultraviolet light. Bands of adsorbent containing lipid classes were marked and scraped from the glass plate into test tubes. The fatty acyl moieties of the lipid classes were converted to their methyl esters by transesterification directly on the adsorbent using 1% (vol/vol) sulfuric acid in methanol for 16 h at 50°C under an atmosphere of nitrogen (14). The resultant fatty acid methyl esters were purified by HPTLC using hexane/diethyl ether/glacial acetic acid (80:20:2, by vol) as the developing solvent and were recovered from the adsorbent by elution with hexane containing 0.05% (wt/vol) butylated hydroxytoluene as antioxidant.

Fatty acid methyl esters were analyzed by gas–liquid chromatography using a Packard 439 gas chromatograph equipped with a flame-ionization detector and fitted with a fused silica capillary column (50 m × 0.22 mm i.d.) coated with FFAP (S.G.E., Milton Keynes, United Kingdom) as the stationary phase. Hydrogen was employed as the carrier gas, and sample application was by on-column injection. The temperature of the oven was programmed to rise from 50 to 225°C during each analysis. Separated components were identified by reference to authentic standards and a well-characterized fish oil, and were quantitated by means of a Shimadzu CR6A integrator attached to the gas chromatograph.

RESULTS

The lipid contents and lipid class compositions of several tissues from the individual monk seal examined are presented in Table 1. Of the tissues analyzed other than blubber, brain had the highest lipid content (15.8%), followed in descending order by liver, muscle and heart. Only neutral lipids, mainly triacylglycerols (TAG), were detected in blubber lipid. Neutral and polar lipids comprised almost equal proportions in both liver and muscle, whereas polar lipids predominated in the brain and in the heart. TAG were the predominant neutral lipid of muscle, and in the lipids of both liver and heart, the proportions of TAG and steryl esters were similar. Cholesterol was the most abundant nuetral lipid in brain. Free fatty acids were present at a level of 10.5 to 17.0% in the total lipid extracted from all tissues except brain.

More than 70% of the lipids from the brain were polar lipids, and cerebrosides, which comprised 28% of the total lipids, were the principal lipids of this organ. Ethanolamine glycerophospholipids (EGP) were the only other class of polar lipids to comprise more than

TABLE 1

Lipid Content and Lipid Class Composition of Tissues of Mediterranean Monk Seal, *Monachus monachus*

[a]n.d., Not determined.

10% of the brain lipids, and the proportion of sphingomyelin in the brain lipids (6%) was notably higher than in other tissues. Choline glycerophospholipids (CGP) were the major polar lipids, followed by EGP, in the liver, heart and muscle. The highest level of phosphatidylglycerol/cardiolipin (PG/CL) was observed in the lipids from heart, and phosphatidylinositol (PI) and phosphatidylserine (PS) accounted for small proportions of the lipids from all tissues except blubber. Low levels of lysophosphatidylcholine were also present in the lipids of all tissues except brain and blubber, in which they were not detectable.

High levels (31–47%) of polyunsaturated fatty acids (PUFA) were present in all liver lipids examined, with the exception of PS, in which they comprised only 19.5% of the total fatty acids (Table 2). The proportion of total n-6 PUFA always exceeded that of n-3 PUFA, due mainly to the presence of 20:4n-6 as the principal PUFA of all lipid classes except PS. A particularly high level of 20:4n-6 was observed in PI, where it accounted for over 30% of the total fatty acids. Other n-6 PUFA were only minor components of all lipid classes, with the exception of the PG/CL fraction in which 18:2n-6 comprised 30.5% of the fatty acids. This feature, combined with a low content of n-3 PUFA, conferred this fraction with a very high n-6/n-3 ratio (15.8). The principal n-3 PUFA of all lipid classes in the liver was 22:6n-3, which was most abundant in TAG (12.8%) and EGP (13.5%). Although the level of 22:5n-3 exceeded that of 20:5n-3 in all classes, both these PUFA were still only minor components. Other notable features of the liver lipid classes were the formation from EGP of around 1% each of 16:0 dimethyl acetal (DMA) and 18:0 DMA produced by transmethylation of 1-*O*-alk-1′-enyl linked ether chains and the occurrence in sphingomyelin of the highest observed level (5.4%) of 24:1n-9.

[a]TAG, triacylglycerols; CGP, choline glycerophospholipids; EGP, ethanolamine glycerophospholipids; PS, phosphatidylserine; PI, phosphatidylinositol; PG, phosphatidylglycerol; CL, cardiolipin; SM, sphingomyelin; sat., saturated; monounsat., monounsaturated; DMA, dimethyl acetal.

The TAG of muscle and heart were generally similar in fatty acid composition to those of liver although, unlike the latter, they both contained 20:5n-3 (Table 3). The level of PUFA in the CGP of muscle (21.2%) was lower than that of both the liver and heart due mainly to a lower content of 20:4n-6. The EGP of muscle was very similar to that of the liver in terms of PUFA content and n-6/n-3 ratio but had a higher content of alkenyl ethers as more than 18% of the long-chain moieties in muscle EGP formed 16:0 DMA, 18:0 DMA, 18:1n-7 DMA and 18:1n-9 DMA. Similar values were found for the DMAs derived from heart EGP, which was also characterized by a very high PUFA content (51%).

The fatty acid compositions of the CGP and EGP from the brain were notably different from those of the same phospholipids from other tissues (Table 4). In particular, the PUFA contents of the two brain phospholipids were much lower. Only 4.4% of the total fatty acids in brain CGP were PUFA, with the remainder comprising almost equal proportions of saturated and monounsaturated fatty acids, particularly 16:0 and 18:1n-9. The EGP of brain contained 19.9% PUFA, within which 20:4n-6 and 22:6n-3 each accounted for around 6%. The brain EGP was also characterized by its high content of alkenyl ethers. Thus, the 16:0 DMA, 18:1n-9 DMA and 18:1n-7 DMA produced 10.6, 7.1 and 12.4%, respectively, of the total long-chain moieties produced by transmethylation of this phospholipid fraction.

Of all the classes examined, the fatty acids of blubber TAG had the lowest n-6/n-3 ratio (0.3). This low ratio resulted from the fact that 20:4n-6 accounted for only 2.0% of the fatty acids in blubber TAG, whereas 22:6n-3 comprised 15.5%, the highest content of any class. The proportion of 22:5n-3 (3.4%) exceeded that of 20:5n-3 (2.0%).

DISCUSSION

The data presented in this study were obtained on only one monk seal, and, consequently, caution must be ap-

plied when extrapolating the patterns of lipid composition to this species in general. The results, however, do allow a representative comparison of the lipid compositions of different tissues within an individual monk seal, a subject for which comparative data are surprisingly rare as previous studies of seal lipids have concentrated on blubber (5,6,12).

The lipid contents of blubber, heart and liver of the individual monk seal examined here are all consistent with those reported previously for other species of seal (5,6), and the high lipid content of the brain is typical of brain tissue of mammals in general (17). With the exception of the brain, all the tissues of the monk seal contained significant amounts of free fatty acids in their total lipid. Because fatty acids are not usually found to any great extent in tissues in their free, nonesterified form, this suggests that some hydrolysis of lipids had occurred *post mortem,* and, consequently, the lipid compositions of the tissues in the living animal may have been slightly different from those recorded here. Nevertheless, tissue-specific patterns of lipid class composition were still discernible, as exemplified by the high levels of cerebrosides and PG/CL observed in the lipids of the heart and brain tissues, respectively. As CL is a specific component of inner mitochondrial membranes (18), the overall lipid class composition of the heart presumably reflects the involvement of large numbers of mitochondria for the supply of energy for contraction.

The brain lipids of the monk seal examined here have many of the characteristic feature found in other mammals (17), as well as in fish (19). The fact that the value found here for the cerebroside content of seal brain

lipids (28.8%) is actually higher than that found in other mammals may be due to the sample of brain analyzed, which consisted largely of white matter, as this tissue contains a much higher concentration of cerebrosides than does gray matter (17). Further evidence in support of this statement comes from the observation that the PUFA contents of the CGP and EGP are very similar to those observed for the same phospholipids in the white matter of normal human brain (20), and, overall, the fatty acid compositions of the seal CGP and EGP more closely resemble those of human white matter than gray matter (17).

The PUFA content of the blubber TAG from the monk seal (29%) examined in the present study is similar to values that have been reported for the blubber lipids of grey seals (*Halichoerus grypus*) (5) and harbor seals (*Phoca vitulina*) (6) from Nova Scotia, and oils prepared from harp seals (*Pagophilus groenlandica*) (7) and Uruguayan fur seals (*Arctocephalus australis* Zimmermann) (10). Higher levels of PUFA have been observed in the blubber lipids of phocid seals from the Bering Sea (12) and the Baltic (11). The proportions of 20:4n-6 and 22:5n-6 observed in the blubber lipids of the monk seal examined here are, however, notably higher than those commonly found in other seal species.

When the fatty acid compositions of lipids of different tissues from the monk seal are compared, it is apparent that the blubber TAG are richer in n-3 PUFA and poorer in n-6 PUFA, particularly 20:4n-6, than the lipids of the other tissues examined. It has been shown previously that the blubber lipids of the harbor seal also contain lower levels of 20:4n-6 than the phospholipids and TAG of heart and lung (8), and that 20:4n-6 accounts for around 17% of the fatty acids in the liver of the Baltic ringed seal (*P. hispida botanica*) (11), but is almost absent in the blubber lipid. Such observations, along with the data obtained in the present study, suggest that a general pattern exists for seals in which blubber TAG are characterized by very low ratios (0.3 or less) of n-6 to n-3 PUFA, whereas in the TAG and phospholipid of internal organs the ratio is much higher, reflecting the general predominance of n-6 PUFA in these lipids. This marked difference in PUFA composition between the TAG of blubber and those of the other tissues may reflect a situation in which the bulk of fatty acids present in blubber are those that have been absorbed from the diet and transported directly in chylomicrons to the blubber for deposition without modification. At the same time, the PUFA in the lipids of other tissues may have been processed by the liver and undergone desaturation and elongation prior to their esterification. Given such a situation, the high levels of n-3 that occur in the blubber lipids of seals in these ecosystems (7) can be expected as n-3 PUFA predominate by far over those of the n-6 series in the lipids of phytoplankton, zooplankton and fish that constitute the marine food webs in temperate and polar latitudes (21). In evolutionary terms, seals are related to terrestrial mammals and as such are presumably capable of converting dietary 18:2n-6 to 20:4n-6. Such a conversion might account for the high levels of 20:4n-6 observed in the lipids of seal tissues other than the blubber. However, it is notable that the liver and muscle TAG of the monk seal examined in this study contained higher levels of 20:4n-6, but lower levels of 18:2n-6, than those of terrestrial mammals fed plant or fish oils (22,23). Assuming that the blubber fatty acid composition is a direct reflection of that of the dietary lipids, then the low level of 18:2n-6 present in the blubber lipid would suggest that large levels of this PUFA had not been available in the diet of the monk seal as a precursor of 20:4n-6. This may also imply that the monk seal had been very active in the specific conversion of 18:2n-6 to 20:4n-6. It is also possible that the monk seal had received preformed 20:4n-6 in its diet. The level of 20:4n-6 observed here for the blubber TAG suggests that the diet consumed by the individual studied contained higher levels of this PUFA than seals from more northerly latitudes. The diet of *M. monachus* in the Mediterranean Sea normally consists of fish, cephalopods and marine plants, including zostera and sargassum (4). Although the lipids of fish in general are characterized by high levels of n-3 PUFA, 20:4n-6 is more common in the lipids of both freshwater and marine fish from Australian and other tropical inshore waters (24–26). Particularly high levels of 20:4n-6 have been noted in the lipids of omnivorous fish, which consume macroalgae in these locations as part of their diet (27). It is known that 20:4n-6 is the predominant PUFA in the lipids of *Sargassum* species of algae from different parts of the world (28), and, assuming this holds true for *Sargassum* species in the Mediterranean Sea, then this macroalgae may be a direct source of this fatty acid for the monk seal. The extent to which high levels of 20:4n-6 are characteristic of organisms at all trophic levels in the Mediterranean remains to be examined.

It must be stressed that no definite conclusions should be drawn in regard to the lipid composition of a species in general from the analysis of a single animal as analyzed in this study. Nevertheless, the results obtained here indicate that the fatty acid compositions of blubber and other tissues of the Mediterranean monk seal may differ somewhat from those of seals from more temperate waters, particularly with regard to the ratio of n-6 to n-3 long-chain PUFA.

ACKNOWLEDGMENTS

The authors would like to thank Daniel Cebrian Menckero for supplying the samples of monk seal tissues and Moira Park for technical assistance in their analysis.

Metabolism of Long-Chain Fatty Acids, Alcohols and Alkylglycerols in the Fish Parasite *Paratenuisentis ambiguus* (Acanthocephala)

Christin Filipponi[a], Horst Taraschewski[b] and Nikolaus Weber[c,*]

[a]Lehrstuhl für Spezielle Zoologie und Parasitologie der Ruhr-Universität, D-44801 Bochum, [b]Zoologisches Institut der Universität, D-76128 Karlsruhe and [c]Institut für Biochemie und Technologie der Fette, H.P. Kaufmann-Institut, BAGKF, D-48006 Münster, Germany

Specific differences between the acyl composition of lipids of the helminth *Paratenuisentis ambiguus* and its host eel, as shown previously, prompted us to study the lipid metabolism in this intestinal fish parasite. Adults and larvae of *P. ambiguus* were fed various lipid precursors, e.g., fatty acids, long-chain alcohols and 1-*O*-alkylglycerols, which may occur as common nutrients of intestinal parasites. Incorporation of [1-^{14}C]palmitic acid into neutral and polar lipids was found to be similar under aerobic and near-anaerobic conditions. In adult parasites maintained in culture medium supplemented with glucose, [1-^{14}C]palmitic acid was incorporated mainly into triacylglycerols and phosphatidylcholines, whereas [1-^{14}C]oleic acid was incorporated preferentially into triacylglycerols. In fasted adults, as well as in larvae, [1-^{14}C]oleic acid was mainly transferred to phosphatidylcholines. Lipolytic activity was detected in adult parasites that had been incubated with radioactive trioleoylglycerol. [1-^{14}C]Hexadecan-1-ol was oxidized in *P. ambiguus* at a high rate to labeled palmitic acid, which was incorporated into various lipid classes of *P. ambiguus*. Small but significant proportions of radioactivity from hexadecan-1-ol were incorporated into ether glycerolipids of the parasite. A more direct precursor in ether glycerolipid metabolism, i.e., *rac*-1-*O*-[1′-^{14}C]hexadecylglycerol, was incorporated into alkyl and 1′-alkenyl moieties of choline and etha-nolamine etherglycerophospholipids of *P. ambiguus* in high yield. High proportions of labeled diacylglycerols, triacylglycerols and steryl esters were detected in surface lipids as well as lipid extracts of the culture media after incubation of *P. ambiguus* with [1-^{14}C]palmitic or [1-^{14}C]oleic acids. The results suggest that palmitic acid and oleic acid are incorporated into neutral and polar lipids of *P. ambiguus* maintained in glucose medium quite differently with oleic acid showing a strong preference for triacylglycerols. However, the incorporation of palmitic acid in glucose-fed parasites was similar to that of oleic acid in fasted parasites, as well as in larvae. This may be explained by partial fatty acid depletion in fasted worms and rapid cell division in larvae, respectively.

***Lipids* 29, 583–589 (1994).**

Paratenuisentis ambiguus (Acanthocephala) is a helminth that resides in the intestine of the American and the European eel (1–3). The parasites attach themselves to the wall of the intestine where they cause inflammatory reactions. This inflammation, together with the high worm burdens, is harmful to the eel leading to retarded growth of this commercially important fish. The growing interest in fish parasitology resulting from the expanding commercial aquaculture of edible fish prompted us to study the lipids of *P. ambiguus* in comparison with infected eel intestine (4,5) in order to establish differences between the lipids of parasite and host.

Helminths are able to absorb fatty acids and other lipids and to incorporate them into various lipid classes (6–8). As a consequence, the acyl compositions of the lipids of the parasites would be expected to resemble those of the host tissue. The composition of the acyl moieties of various lipids of *P. ambiguus*, however, was found to be remarkably different from that of infected eel intestine (4,5). In particular, much higher proportions of saturated long-chain fatty acids, as well as eicosapentaenoic acid, have been found in neutral and polar lipid classes of the parasite when compared to those of eel. The reason for these differences is presently not known.

In the present investigation, we have fed both adult and larval forms of *P. ambiguus* various lipid precursors which may occur as common nutrients inside the eel gut and in the coelum of the larva's host, i.e., *Gammarus tigrinus* (Amphipoda) (1), respectively, in order to shed light on lipid biosynthesis and metabolism at different developmental stages of this helminth. Studies on the regulation of lipid metabolism in *P. ambiguus* could be a useful first step toward the control of acanthocephalans in fish and of endoparasites in general.

MATERIALS AND METHODS

Chemicals, preparation of substrates and derivatization. High-performance liquid chromatography (HPLC)-grade solvents were purchased from E. Merck (Darmstadt, Germany). Fatty acid methyl ester standards were products of Nu-Chek-Prep (Elysian, MN). Methyl esters derived from acyl lipids were prepared by transmethylation using methanol/benzene/sulfuric acid (84:10:4, by vol) (9); free fatty acids (FA) were converted to their methyl esters using diazomethane (9,10). 1-*O*-Alkylglycerols were prepared following the procedure of Baumann and Mangold (11). Acetylations were carried out in acetic anhydride/pyridine (10).

Radiochemicals and preparation of radioactive substrates. [1-^{14}C]Palmitic acid (2.18 GBq/mmol), [1-^{14}C]-oleic acid (2.07 GBq/mmol), and tri[1-^{14}C]oleoylglycerol (2.07 GBq/mmol) were purchased from Amersham-Buchler (Braunschweig, Germany). Methyl [1-^{14}C]-palmitate (1.0 GBq/mmol) was derived from palmitic acid by reaction with diazomethane. [1-^{14}C]Hexadecan-1-ol

*To whom correspondence should be addressed at Institut für Biochemie und Technologie der Fette, H.P. Kaufmann-Institut, BAGKF, P.O. Box 1705, D-48006 Münster, Germany.

Abbreviations: CPL, choline glycerophospholipids; EPL, ethanolamine glycerophospholipids; FA, free fatty acids; HPLC, high-performance liquid chromatography; MEM, minimum essential medium; NAD+, nicotinamide adenine dinucleotide, oxidized; RP-HPLC, reverse-phase high-performance liquid chromatography; TLC, thin-layer chromatography.

(1.0 GBq/mmol) was prepared from methyl [1-^{14}C]palmitate by reduction with lithium aluminum hydride (10). *rac*-1-*O*-[1′-^{14}C]Hexadecylglycerol (0.97 GBq/mmol) was prepared from [1-^{14}C]hexadecan-1-ol and *rac*-isopropylideneglycerol (Aldrich, Steinheim, Germany) as mentioned previously (11).

Biological materials. Eels (*Anguilla anguilla*) naturally infected with *P. ambiguus* were caught in the Weser river; they were free of other intestinal helminths. *Paratenuisentis ambiguus* worms were obtained and maintained as described previously (4). In all experiments, pooled samples of the whole organisms of *P. ambiguus*, males as well as females, were used for incubations. To study lipid metabolism in fasted parasites, *P. ambiguus* worms from eels were kept for three days in modified minimum essential medium (MEM) (Flow Laboratories, Meckenheim, Germany) without glucose and serum. *Paratenuisentis ambiguus* worms survived for about one week when starved under these conditions. Larvae of *P. ambiguus* were obtained from experimentally infected *G. tigrinus* as described previously (12). At 40 d post infection, the amphipods were squashed, and the infective larvae were washed with MEM and used for assay.

Time course of [1-^{14}C]palmitic acid incorporation into the lipids of adult parasites. About 225 *P. ambiguus* worms (average fresh weight 2.5 mg/animal) were incubated at room temperature with 2 μCi (20 mCi/mmol) [1-^{14}C]palmitic acid (ammonium salt) in 10 mL modified MEM, either under aerobic or nearly anaerobic (nitrogen atmosphere) conditions. Aliquots of worms were removed from the medium after 1, 6 and 24 h and washed with MEM. After homogenization of the worms (around 200 mg fresh weight, each) in dichloromethane/methanol (1:2, vol/vol), using an Ultra-Turrax blender (IKA-Werke, Staufen, Germany), total lipids were extracted as described below.

Incubation of P. ambiguus, *adults and larvae, as well as fasted worms, with various ^{14}C-labeled substrates.* Adult and larval parasites, about 100 animals each, were incubated in 5 mL modified MEM with 2 μCi (20 mCi/mmol) radioactively labeled substrates, i.e., [1-^{14}C]palmitic and [1-^{14}C]oleic acids (ammonium salts), tri[1-^{14}C]oleoylglycerol, [1-^{14}C]hexadecan-1-ol or *rac*-1-*O*-[1′-^{14}C]hexadecylglycerol, for 24 h under aerobic conditions. Substrates were added in ethanolic solution (50 μL). Fasted worms were incubated in modified MEM without glucose and serum. Total lipids of adult worms and larvae were extracted as described in the next paragraph(s).

Isolation of surface lipids. After incubation with various substrates, e.g., radioactive fatty acids, *P. ambiguus* worms were taken from the medium by forceps and washed with MEM. Adhering medium was removed with tissue paper, and the surface lipids were extracted by gentle shaking for about 20 s in dichloromethane/methanol (98:2, vol/vol) according to a method adapted from Holloway (13).

Extraction of total lipids. Paratenuisentis ambiguus worm tissue (200–300 mg fresh weight, freed of surface lipids as described above, was homogenized in 4 mL dichloro-methane/methanol (1:2, vol/vol). The total lipid extract was obtained as described previously (4). Total lipids from culture media were extracted in a similar manner with 4 mL of dichloromethane/methanol (1:2, vol/vol) per mL medium.

Lipid analysis. Aliquots of total lipids were separated into various lipid fractions, e.g., wax esters, steryl esters, triacylglycerols, long-chain aldehydes, FA, choline (CPL) and ethanolamine glycerolipids (EPL), as well as sphingomyelins, by preparative thin-layer chromatography (TLC) on Silica Gel H (E. Merck), and the various lipid fractions were purified and derivatized as described previously (4,5). The fraction of long-chain aldehydes isolated from *P. ambiguus* after incubation with [1-^{14}C]hexadecan-1-ol (see Table 3 later) was purified by re-chromatography on Silica Gel H layers (0.3 mm) with hexane/diethyl ether (85:15, vol/vol) as solvent and identified by co-chromatography with a standard. The aldehyde fraction was isolated and reduced with $LiAlH_4$ (as already described). The resulting long-chain alcohols were acetylated (10) and the alkyl acetates identified by radio-reverse-phase (RP) HPLC, as described later. All lipid fractions on TLC plates were identified by co-chromatography with standards and detected by brief exposure to iodine vapors. In addition, the fractions of phospholipids were detected by staining with specific reagents as described previously (5).

Triacylglycerol fractions derived from incubations of *P. ambiguus* with tri[1-^{14}C]oleoylglycerol, as well as the fatty acid methyl esters derived from total lipids of parasites after incubation with [1-^{14}C]palmitic or [1-^{14}C]oleic acids, were fractionated according to their number of double bonds by argentation-TLC (10) on layers of Silica Gel G (E. Merck) containing 25% $AgNO_3$. The plates were developed three times with toluene at 5°C for the separation of fatty acid methyl esters and with dichloromethane/methanol (99:1, vol/vol) for the separation of triacylglycerols.

Aliquots of triacylglycerols were subjected to hydrolysis with lipase from porcine pancreas (Boehringer-Mannheim, Mannheim, Germany), and the resulting reaction products were separated by TLC (10). The radioactivity in the various fractions, i.e., mono- and diacylglycerols as well as FA was determined by scanning. The fractions of 2-acylglycerols (representing the *sn*-2 fatty acids) and the FA (from *sn*-1 plus *sn*-3 positions) were used for the determination of the positional distribution of labeled fatty acids. Labeled fatty acid methyl esters were prepared from the various hydrolysis products as described above and analyzed by radio-RP-HPLC.

Aliquots of CPL and EPL were hydrolyzed by phospholipase A_2 from porcine pancreas (Boehringer-Mannheim), and the resulting reaction products were separated by TLC (10). The products of hydrolysis, i.e., FA of *sn*-2 position as well as 1-acyl-2-lysophospholipids (representing the *sn*-1 fatty acids), were isolated, derivatized to the corresponding methyl esters and analyzed by radio-RP-HPLC as described below. Aliquots of total lipids were reduced with $LiAlH_4$. The resulting mixtures of long-chain alcohols and 1-*O*-alkylglycerols plus 1-*O*-(1′-alkenyl)glycerols were separated as described previously (4) and finally analyzed by radio-RP-HPLC as described below.

Determination of radioactivity. The distribution of radioactive fractions on thin-layer chromatograms was de-

termined with a Berthold LB 2832 Automatic TLC-Linear Analyzer in combination with an LB 500 data system (EG&G Berthold, Wildbad, Germany). Solutions were mixed with Toluene Scintillator (Packard, Frankfurt/M., Germany) or Aquasol-2 (NEN, Dreieich, Germany), and radioactivity was determined by liquid scintillation counting using an LKB-Wallac 1214 Rackbeta instrument (LKB, Stockholm, Sweden).

A Merck-Hitachi L-6200 pump equipped with an ACS mass detector model 750/14 (Applied Chromatography Systems, Macclesfield, United Kingdom) and with a Berthold LB 506 B HPLC Radioactivity Monitor in combination with a Splitter Mixer LB 5034 (EG&G Berthold) was used for radio-HPLC; and a Merck-Hitachi D-2500 Chromato Integrator for monitoring mass and radioactivity traces. Labeled lipids and lipid derivatives were analyzed by RP-HPLC on two LiChrospher 100 RP-18 (5 µm) columns (E. Merck) in sequence (125 × 4 mm, each) using acetonitrile or acetonitrile/acetone mixtures as eluents. Toluene scintillator (Packard) was continuously added to the solvent stream in a ratio of 3:1 (vol/vol). Triacylglycerols were resolved with acetonitrile/acetone (62:38, vol/vol) at a flow rate of 1.0 mL/min (14). Fatty acid methyl esters and alkyl acetates were separated with acetonitrile at a flow rate of 0.6 mL/min. 1-*O*-Alkyldiacetylglycerols dissolved in acetone were injected for ether glycerolipid analysis. The mixtures of 1-*O*-alkyldiacetylglycerols derived from total lipids of *P. ambiguus* tissue were separated with acetonitrile at a flow rate of 0.8 mL/min. Synthetic standards were used for comparison.

RESULTS AND DISCUSSION

The various lipid precursors with which the adult *P. ambiguus* endoparasites were incubated *in vitro* can be expected to occur in eel intestine as possible nutrients for the parasites. For example, fatty acids and alkylglycerols are formed by intestinal lipolysis of acyl glycerolipids and alkyl glycerolipids (ether lipids), respectively, while long-chain alcohols are known to be common constituents of aquatic animals (15) that fall prey to eel. In a similar manner, fasted adults, as well as larvae of *P. ambiguus*, were incubated with fatty acids in order to study lipid metabolism at different physiological and developmental stages of this parasite. To our knowledge, the biosynthesis of neutral and polar lipids in acanthocephalans by use of labeled fatty acids and other lipid precursors, except for [1-^{14}C]acetate (16,17), has not been reported previously.

Metabolism of [1-^{14}C]palmitic and [1-^{14}C]oleic acid in P. ambiguus. The time course of incorporation of radioactivity from [1-^{14}C]palmitic acid into the lipids of adult *P. ambiguus* parasites was studied under aerobic and nearly anaerobic conditions, the latter being similar to the intestinal environment. Table 1 shows that in both incubations the incorporation of radioactivity into the total lipids, as well as the distribution of radioactivity in the various lipid classes, were similar. After a period of 24 h, most of the radioactivity was concentrated in phosphatidylcholines (around 40%) and triacylglycerols (around 20%), whereas minor proportions of radioactivity were detected in diacylglycerols and phosphatidylethanol-amines as well as steryl esters and wax esters. These data show that the metabolism of palmitic acid in adult *P. ambiguus* parasites is not specifically affected by oxygen. Similar results have been obtained for the incorporation of radioactive acetate into the neutral and polar lipids of the cestodes *Hymenolepsis diminuta* and *Spirometra mansonoides* under aerobic and anaerobic conditions (16,17).

When the incorporation of radioactivity from [1-^{14}C]-palmitic acid was compared to that from [1-^{14}C]oleic acid, different patterns were observed for the incorporation of palmitoyl and oleoyl moieties into the various lipid classes of adult *P. ambiguus* (Table 2). Again, palmitic acid was esterified predominantly into triacylglycerols and phosphatidylcholines, whereas oleic acid was incorporated mainly into triacylglycerols (81%). Small proportions of radioactivity of both labeled fatty acids were found to be channelled into diacylglycerophosphoethanolamines as well as steryl esters. Moreover, it is obvious from the incorporation of radioactivity into total lipids as well as from the relatively high concentration of unmetabolized [1-^{14}C]palmitic acid and the low concentration of [1-^{14}C]oleic acid that oleic acid was esterified into various lipid classes more extensively than was palmitic acid (Tables 1 and 2).

[a]Abbreviations as in Table 1. [b]Excluding radioactivity of FA. [c]Substrate. [d]Trace (<2%).

The metabolism of [1-^{14}C]oleic acid in parasites of different physiological status, i.e., maintained in glucose-supplemented or glucose- and serum-free modified MEM ("fasted"), was found to be completely different (Table 2). In *P. ambiguus* worms that were kept in glucose-supplemented medium, [1-^{14}C]oleic acid was incorporated almost exclusively into triacylglycerols. In parasites that were maintained in glucose- and serum-free modified MEM, however, labeled oleoyl moieties were found predominantly in both triacylglycerols (33%) and phosphatidylcholines (33%), as well as in a number of other neutral and polar lipids, e.g., steryl esters, wax esters, sphingomyelins and phosphatidylethanolamines.

In larvae of *P. ambiguus*, [1-^{14}C]oleic acid was esterified mainly into polar lipids, particularly phosphatidylcholines (66%), whereas only small proportions of radioactivity were found in triacylglycerols (9%) (Table 2). Thus, the incorporation of labeled oleic acid into the lipids of larvae is similar to that in fasted adult parasites.

Wax esters are widely distributed in the animal and plant kingdom and occur in high proportions in many aquatic and predominantly in marine animals. Small proportions of wax esters have been detected in *P. ambiguus* as well (4), whereas infective larvae of the acanthocephalan *Polymorphus minutus* were found to contain high proportions of these apolar lipids (18).

Both adults and larvae of *P. ambiguus* incorporated only small proportions (<2–6% of incorporated radioactivity) of labeled palmitic and oleic acid into wax esters (Tables 1 and 2). Even when adult *P. ambiguus* worms were incubated with [1-^{14}C]hexadecan-1-ol, which is a direct precursor of wax ester biosynthesis, only 8% of the label incorporated was recovered in wax esters (Table 3). From these data it may be concluded that wax ester biosynthesis is of minor importance in both adults and larvae of *P. ambiguus*. In this context, it is of interest that wax esters do not play a striking role as surface lipids of the parasite either.

The observation that palmitic acid and oleic acid were esterified into the lipids of *P. ambiguus* in a different manner is interesting. Fasted worms and larvae have low amounts of surplus fatty acids at their disposal because of the minor nutrient supply and rapid cell division, respectively, as compared to adult parasites maintained under standard conditions. This may explain the preferred incorporation of exogenous fatty acids into membrane lipids, e.g., phosphatidylcholines and phosphatidylethanolamines, as compared to storage lipids (triacylglycerols), at these two physiologically or developmentally different stages of *P. ambiguus* (Table 1).

Stereospecific distribution of acyl moieties in various glycerolipids. Table 4 shows the stereospecific distribution of radioactively labeled acyl moieties between the different positions of the glycerol backbone of triacylglycerols and phosphatidylcholines of *P. ambiguus*, adults and larvae, after incubation with [1-^{14}C]palmitic and [1-^{14}C]oleic acid, respectively. The data indicated that labeled palmitic acid was incorporated mainly into the *sn*-1 or *sn*-3 positions of triacylglycerols and into the *sn*-1 position of phosphatidylcholines of adult parasites. Similar results have been obtained for saturated long-chain fatty acids in endogenous phosphatidylcholines from *P. ambiguus* (N. Weber, K. Aitzetmüller, and H. Taraschewski, unpublished data).

TABLE 3

Incorporation of Radioactivity into Various Lipid Classes of Adult *Paratenuisentis ambiguus* Worms After Incubation with [1-^{14}C]Hexadecan-1-ol and *rac*-1-*O*-[1-^{14}C]Hexadecylglycerol[a]

Labeled oleoyl moieties, however, were almost equally distributed between the *sn*-1,3 and *sn*-2 positions of triacylglycerols, as well as the *sn*-1 and *sn*-2 positions of phosphatidylcholines in adult *P. ambiguus* worms. Our results are in agreement with the stereospecific distribution of palmitoyl and oleoyl moieties found in the lipids, particularly phospholipids, of vertebrates (19,20).

In contrast to the above pattern of stereospecific distribution in adult parasites, [1-^{14}C]oleoyl moieties were preferentially transferred to the *sn*-1 and/or *sn*-3 positions of triacylglycerols in fasted adults (maintained in glucose- and serum-free modified MEM), as well as in larvae of *P. ambiguus*. The incorporation of labeled oleic acid into the phosphatidylcholines of larvae, however, was similar to that found in adult *P. ambiguus* worms which had been incubated under standard conditions (glucose-supplemented MEM).

These results also show that physiologically or developmentally different stages of *P. ambiguus*, such as fasted adults as well as larvae, are able to esterify oleic acid into specific positions of the glycerol backbone. Similar results are known from experiments with fish, indicating that both the quantity of fatty acids transferred to, as well as their stereospecific distribution at the glycerol molecule, depend on the diet offered to the animals (20).

Metabolism of [1-^{14}C]hexadecan-1-ol and rac-*1-O-[1-^{14}C]hexadecylglycerol: Formation of ether glycerolipids.* In animal tissues, acyl-CoA thioesters are reduced to the corresponding long-chain alcohols *via* long-chain aldehyde intermediates (21). Saturated and monounsaturated long-chain alcohols are precursors of ether glycerolipids (22,23). They can also be acylated to yield wax esters or can be reoxidized to fatty acids which, in turn, can be incorporated into various ester lipids (24). Adult *P. ambiguus* worms were incubated with [1-^{14}C]hexadecan-1-ol in order to study the metabolism of this long-chain alcohol and in particular, its use in the formation of ether glycerolipids. After a 24-h incubation under aerobic conditions, most of the radioactive substrate was oxidized to the corresponding fatty acid, i.e., palmitic acid, which was incorporated into various ester lipids in a similar manner as found in the incubations with [1-^{14}C]palmitic acid. Only small proportions of radioactivity from hexadecan-1-ol were found to be incorporated into ether glycerolipids

[b]Trace (<2%).

(Table 5). For example, the proportion of radioactive 1-*O*-alkyl moieties in the fraction of triradylglycerols was 23%, whereas CPL and EPL contained 7 and 14% of 1-*O*-[1-^{14}C]alkyl moieties, respectively. The radioactivity in the alkyl moieties was almost equally distributed between neutral and polar ether lipids. Relatively high proportions of labeled steryl esters and wax esters were detected in the lipids of parasites incubated with [1-^{14}C]hexadecan-1-ol. The occurrence of small proportions of radioactivity (4%) in the fraction of long-chain aldehydes (Table 3), which are known to be intermediates of the oxidation of long-chain alcohols in vertebrates, confirms the involvement of this intermediate (21,25). The extent of ether lipid formation from [1-^{14}C]hexadecan-1-ol was in a similar range as it was found for the incubations with [1-^{14}C]palmitic acid (Table 5). Incubations of adult and larval *P. ambiguus* parasites with [1-^{14}C]oleic acid, however, led to ether glycerolipids only in small proportions (Table 5).

In vertebrates, the oxidation of long-chain alcohols to the corresponding fatty acids *via* long-chain aldehydes depends on the concentration of nicotinamide adenide dinucleotide (NAD^+) in the cells (21). The reactions are catalyzed by a long-chain alcohol: NAD^+ oxidoreductase, and the sequence of reactions is reversible in the presence of surplus NADH (NAD^+, reduced) (25). An enzyme having similar activities may be responsible for the metabolism of long-chain alcohols in *P. ambiguus*. It is of interest that various oxidoreductase activities were reported of two acanthocephalans, i.e., *P. minutus* and *Moniliformis moniliformis* (26,27). However, the specificity of the latter enzymes for long-chain alcohols had not been previously investigated. Oxygen which is necessary for the maintenance of the reaction may be present in eel intestine in sufficient concentration or may be available for the parasite from the host's blood.

1-*O*-Alkylglycerols are more direct precursors of complex ether lipid biosynthesis than are long-chain alcohols; *rac*-1-*O*-[1-^{14}C]hexadecylglycerol was therefore fed to adult *P. ambiguus* worms. In contrast to long-chain alcohol, the latter substrate was converted predominantly to 1-*O*-hexadecyl-2-acylglycerophosphocholines (Table 5). In addition, small proportions of radioactivity were found in 1-*O*-hexadecyl-2-acylglycerophosphoethanolamines and 1-*O*-hexadecyl-2,3-diacylglycerols. Only trace amounts of the substrate were oxidized to fatty acids during the 24-h incubation period. It is of interest that high proportions of labeled plasmalogens were detected in the two ether phospholipid classes after incubation with radioactive 1-*O*-hexadecylglycerol.

Surface lipids and lipid extracts from culture medium. The distribution of radioactivity in the surface lipids isolated from *P. ambiguus*, in adults and larvae, after incubation with [1-^{14}C]palmitic acid, [1-^{14}C]oleic acid and [1-^{14}C]hexadecan-1-ol, is shown in Table 6. After deduction of radioactive substrates, surface lipids usually contributed 1–2% of radioactivity of total lipids. Highest incorporation of radioactivity was detected in the neutral lipid fractions, e.g., di- and triacylglycerols, as well as in steryl esters, which were the predominantly labeled lipids of the surface coat of *P. ambiguus*. It is well known that weakly polar lipids typically occur in the surface lipids of many organisms, including helminths (28). For example, a variety of such apolar lipids form the lipid coat of parasitic nematodes (29). Labeled wax esters, however, which are known to be typical surface lipids of plants and animals were found in *P. ambiguus*, even after incubation with [1-^{14}C]hexadecanol, in trace amounts only. It is suggested that these lipids do not play an important role as surface lipids in *P. ambiguus*.

In this context it was of interest to investigate the distribution of radioactivity in lipids that had been extracted from culture media after incubation of *P. ambiguus*, adults and larvae, with various radioactive substrates. Only small proportions of lipid metabolites, predominantly neutral lipids, such as diacylglycerols, triacylglycerols and steryl esters, were detected in the culture media (Table 6). Little is known about the excretion of lipids by acanthocephalans; most probably it occurs predominantly in the region of the presoma where the incorporation of radioactive triolein has also been observed (3,8). It is not presently clear whether or not the radioactive lipids extracted from the culture media can be regarded as excretion products of *P. ambiguus* or whether they may be derived from the surface coat of the parasites.

Lipolytic activities in P. ambiguus. *Paratenuisentis ambiguus* parasites are able to hydrolyze triacylglycerols, as is evident from incubation with tri[1-^{14}C]oleoylglycerol. After an incubation period of 24 h, about 42% of the substrate had been hydrolyzed, i.e., 55 pmoles/animal. The

resulting labeled oleoyl moieties were incorporated predominantly into triacylglycerols, as was shown for the incubations with [1-^{14}C]oleic acid. After the incubation of *P. ambiguus* worms with [^{14}C]triolein, labeled triacylglycerols were fractionated by argentation-TLC, followed by radio-RP-HPLC analysis. The results of these chromatographic analyses revealed that radioactive dioleoylpalmitoylglycerol (15%) was the main triacylglycerol species formed, together with small proportions (4%) of triacylglycerol species containing polyunsaturated acyl moieties. Triacylglycerol hydrolase activity had been found in other endoparasites, such as *Schistosoma japonicum* and *S. mansoni* (Trematoda), as well (30,31).

In conclusion, we found that the fish parasite *P. ambiguus* can absorb fatty acids from the surrounding medium and esterify them into various lipid classes, predominantly triacylglycerols and phosphatidylcholines. The pattern of fatty acid incorporation into the various lipid classes depends on the individual fatty acid substrate (saturated/monounsaturated) as well as on the developmental stage (larva/adult) and nutritional condition (glucose fed/starved) of *P. ambiguus*. Other lipid substrates, such as hexadecanol and 1-*O*-hexadecylglycerol, are also absorbed by the parasite and incorporated into ether lipids. Under aerobic conditions, 1-hexadecanol was extensively oxidized to palmitic acid. Triacylglycerol lipase activity, which may be involved in the formation of individual molecular species of glycerolipids as well as in catabolic reactions, was found in the parasite. From these results it is obvious that *P. ambiguus* is able to synthesize complex acyl and alkyl glycerolipids from fatty acids, long-chain alcohols and alkylglycerols that occur in fish intestine. Specifically, the parasite seems to channel saturated long-chain fatty acids into the phospholipids. This is consistent with the results on the acyl composition of phosphatidylcholines, phosphatidylethanolamines and phosphatidylserines of *P. ambiguus* (5). Chain elongation, particularly of palmitic acid, has also been observed in *P. ambiguus* (N. Weber, K. Aitzetmüller, and H. Taraschewski, unpublished data).

METHOD

An Improved Spectrophotometric Triiodide Assay for Lipid Hydroperoxides

Robert A. Darrow* and **Daniel T. Organisciak**

Department of Biochemistry and Molecular Biology, Wright State University, Dayton, Ohio 45435

A spectrophotometric method is described for the measurement of lipid hydroperoxides, to a lower limit of 0.5 nmoles, based on the formation of triiodide ions measured at the absorbance maximum of 365 nm. The assay mixture, which was modified from an earlier published procedure [El-Saadani, M., Esterbauer, H., El-Sayed, M., Goher, M., Nassar, A.Y., and Jürgens, G. (1989) *J. Lipid Res. 30*, 627–630], contains 18% methanol together with nonionic and cationic detergents, and is designed so that the hydroperoxides to be measured can be added in either water or methanol. By incubating the reaction mixture at 50°C for 30 min, less-reactive hydroperoxides can be measured with the same fidelity as more-reactive ones. Under these conditions, the assay can be carried out under ordinary room lighting and without special protection from ambient oxygen with absorbance values being stable up to 15 h. Enzymatic standardizations showed that the triiodide method gave comparable results for H_2O_2, cumene hydroperoxide, linoleic acid hydroperoxide, phosphatidylcholine hydroperoxide, and a photooxidized tissue extract containing a mixture of hydroperoxides. The triiodide assay is recommended primarily for measuring purified hydroperoxides.
***Lipids 29*, 591–594 (1994).**

Standard methods for the iodometric assay of hydroperoxides normally require careful exclusion of air and the use of special glassware, making it difficult and time-consuming to process multiple samples (1,2). The speed and convenience offered by the iodometric method described by El-Saadani *et al.* (3) for assaying aqueous samples of peroxidized lipoproteins prompted us to try to use it with a wide range of organic hydroperoxides. We found that within the recommended incubation time of 30 min at ambient temperature, samples of H_2O_2 gave values of absorbance at 365 nm that were consistent with the quoted molar absorptivity of I_3^- (3), but that samples of cumene hydroperoxide (CuOOH) or *t*-butyl hydroperoxide required up to 24 h of incubation time. However, by incubating samples at 50°C, as used by Gebicki and Guille (2) in their oxygen-sensitive iodometric method, the reaction was complete with a wide variety of hydroperoxides within thirty minutes.

*To whom correspondence should be addressed.

Abbreviations: BHT, butylated hydroxytoluene; CuOOH, cumene hydroperoxide; EDTA, ethylenediaminetetraacetic acid; GPX, glutathione peroxidase; GR, glutathione reductase; GSH, glutathione; HPLC, high-performance liquid chromatography; Lin, linoleic acid; LinOOH, linoleic acid hydroperoxide; NADPH, reduced nicotinamide adenine dinucleotide phosphate; PC, phosphatidylcholine; PCOOH, phosphatidylcholine hydroperoxide; PHGPX, phospholipid hydroperoxide glutathione peroxidase; TLC, thin-layer chromatography.

Additional modifications we made include the use of a more concentrated color reagent (3), in order to allow a larger sample volume, the elimination of butylated hydroxytoluene (BHT) and ethylenediaminetetraacetic acid (EDTA) from the incubation mixture, and the incorporation of a standard volume of methanol which serves as a convenient solvent for measuring more lipophilic hydroperoxides.

MATERIALS AND METHODS

Materials. Peroxide-free Triton X-100 was from Calbiochem (La Jolla, CA), CuOOH was from Fluka AG (Buchs, Switzerland), dichloromethane of high-performance liquid chromatography (HPLC) grade was from Burdick and Jackson (Muskegon, MI), triphenylmethyl hydroperoxide was from Aldrich (Milwaukee, WI), hydroxylapatite was from Biorad (Hercules, CA), and silica gel HL thin-layer chromatography (TLC) plates were from Analtech (Newark, DE). Linoleic acid (Lin), soybean phosphatidylcholine (PC), rose bengal, reduced nicotinamide adenine dinucleotide phosphate (NADPH), reduced glutathione (GSH), yeast glutathione reductase (GR) and bovine glutathione peroxidase (GPX) were from Sigma (St. Louis, MO). Other chemicals were from standard commercial sources. Methanol and chloroform were redistilled in glass before use.

Preparation of lipid hydroperoxides. Lipids were photooxidized in a stoppered glass cell using a modification of the procedure of van Kuijk *et al.* (4). The stirred reaction mixture contained 1.85 mL methanol, 0.1 mL rose bengal stock solution (1.25 mg Na rose bengal/mL methanol) and 0.05 mL PC stock solution (100 mg PC/mL chloroform). Illumination was for 16 h at room temperature with white light from a Tungsten-Halogen lamp focused with a glass lens onto the edge of the reaction cell. The incident energy was measured to be 2,000 W/m^2 at the surface of the cell. After illumination, the hydroperoxides were separated from the rose bengal sensitizer by adding 4 mL of dichloromethane and 2 mL of water, and the resulting lower phase was retained. The lower phase was then reextracted 2 times with 4 mL of water/methanol (1:1, vol/vol) and dried at 45°C under a stream of nitrogen. The PC hydroperoxide (PCOOH) preparations were stable for at least 6 mon when dissolved in methanol and stored at –40°C.

The PCOOH reaction product appeared as a single fraction at an R_f of 0.14 on silica gel TLC plates when developed with chloroform/methanol/water (65:35:3.5, by vol) (5) and stained for lipids (5) or peroxides (6). The hydroperoxide of linoleic acid (LinOOH), prepared and analyzed in the same way, migrated at an R_f of 0.93. The ab-

sence of a rapidly-migrating impurity in the PCOOH preparations indicated that the procedure did not result in significant hydrolysis of the fatty acid peroxides from the phospholipid. For PCOOH, the molar ratio of hydroperoxide to organic phosphate (5) was between 0.5 and 1.0, depending on the duration of illumination and on light intensity.

Enzymatic procedures. Enzymatic assay of hydroperoxides followed the procedure of Heath and Tappel (7) which is based on NADPH oxidation, monitored at 340 nm, coupled with GR to the reduction of peroxides by GSH catalyzed by either GPX (7) or phospholipid hydroperoxide glutathione peroxidase (PHGPX; Ref. 8). The reaction mixture for GPX was kept at pH 7.0, as described (9), except that the incubation was done at room temperature. Incubations using PHGPX were carried out at pH 7.4 at 35°C as described (8). Concentrations of hydroperoxides differing by a factor of two were used for all enzymatic determinations, and all assays gave proportional values. Absorbance at 340 nm was monitored until the rate of change of the experimental samples equalled that of a control containing no added hydroperoxide. The value of $6.0 \times 10^3\ M^{-1} \times cm^{-1}$ (10) was assumed for the molar absorptivity of NADPH. Partially-purified PHGPX was isolated from pig liver by acetone precipitation of a 100,000 $\times g$ aqueous supernatant, followed by column chromatography on Sephadex G-10, hydroxyl apatite and Sephadex G-75. The preparation was free of GPX, and of GSH *S*-transferase as assayed with H_2O_2 (9) and chlorodinitrobenzene (11) as substrates, respectively.

Iodometric assay. In our standard procedure, up to 30 nmoles of hydroperoxide, in either water or in methanol, were added to 10 × 75-mm glass tubes. Samples dissolved in water were brought to 0.4 mL by addition of water, followed by addition of 0.2 mL of methanol; samples dissolved in methanol were diluted to a volume of 0.2 mL, followed by 0.4 mL of water. Color reagent (0.5 mL) was added, and the contents were mixed by vortexing within 1 min after the addition. The tubes were capped with parafilm and incubated in a water bath at 50°C for 30 min. After cooling to room temperature, the absorbance at 365 nm was determined by subtracting the absorbance of a blank containing only color reagent and solvent. A stock color reagent was made up by combining 9.3 mL 1M K_2HPO_4, 30.7 mL 1M KH_2PO_4, 1.5 mL 0.02M NaN_3, 4 mL 10% peroxide-free Triton X-100, 2 mL 1% benzalkonium chloride and 4 mL of 0.5 mM $(NH_4)_6Mo_7O_{24} \cdot 4H_2O$. The stock mixture was diluted to 100 mL with water and stored at 4°C where it was stable for 6 mon. Forty mg of KI per mL of reagent was added just before use.

RESULTS AND DISCUSSION

Excellent proportionality between added hydroperoxide and absorbance at 365 nm was attained by the present procedure as is evident from the standard curve obtained with PCOOH (Fig. 1). No significant deviation from linearity was seen as judged by linear least squares analysis. Although we normally measured less than 30 nmoles of hydroperoxide, we observed that proportionality was maintained up to 70 nmoles using a wide range of hydroperoxides. This is in contrast to iodometric assays of hydroperoxides based on starch iodine complex formation (12,13). These assays are about as sensitive as the present method when using small volumes (13) but depart significantly from linearity above 15 nmoles of hydroperoxide. They suffer further disadvantages due to possible variability in the quality of the soluble starch. In the present assay, the molar absorptivity at 365 nm (see inset, Fig. 1) for I_3^- derived from enzymatically standardized H_2O_2 was $2.48 \times 10^4 \times M^{-1} \times cm^{-1}$ which is in good agreement with the value of $2.46 \times 10^4 \times M^{-1} \times cm^{-1}$ obtained by El-Saadani *et al.* (3) who directly added I_2 to the assay mixture. This shows that 18% methanol, which is present in our assay but was absent from the original, does not affect the absorbance of the reaction product. While testing the tolerance of the assay system to methanol, using either H_2O_2 or PCOOH, we found no effect of methanol up to 20%, but decreased color development was seen at 30% methanol. When freshly prepared with peroxide-free Triton X-100, our reagent gives a blank absorbance of about 0.01, but the method can still be used with blanks up to 0.2, as we noted when using Triton X-100 that had not been especially purified.

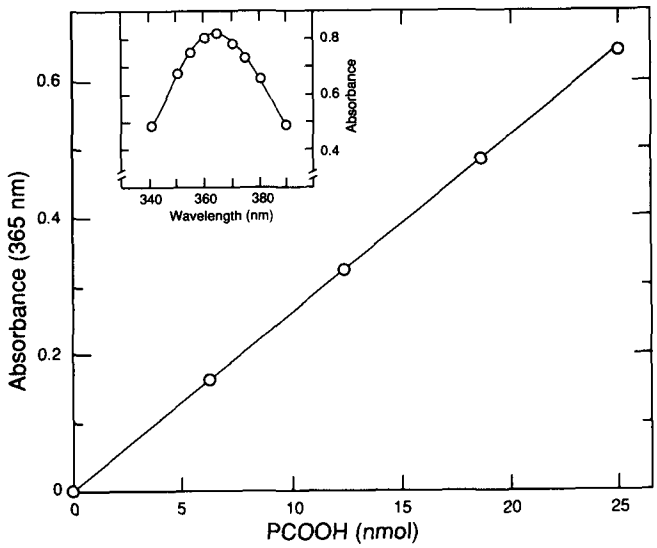

FIG. 1. Standard curve for phosphatidylcholine hydroperoxide (PCOOH) and absorbance maximum for triiodide ions. The mean absorbances from duplicate samples of PCOOH obtained as described in Materials and Methods are plotted vs. nmoles of PCOOH added. The maximum range of the duplicates was less than 1% of the mean at each point. The curve of absorbance vs. wavelength (inset) was obtained from a sample containing 36 nmoles of H_2O_2 using a single-beam spectrophotometer calibrated to within 0.5 nm with a holmium oxide filter.

The kinetics of I_3^- formation from representative hydroperoxides of various types are shown in Figure 2. PCOOH and LinOOH showed similar reactivities with both essentially complete within the recommended 30 min incubation time at 50°C. Hydrogen peroxide went to completion in all samples except for the two shortest incubation times at 30°C. CuOOH was the least reactive, reaching 87% of its maximum value within 30 min at 50°C. Thus, when applying the method to hydroperoxides of un-

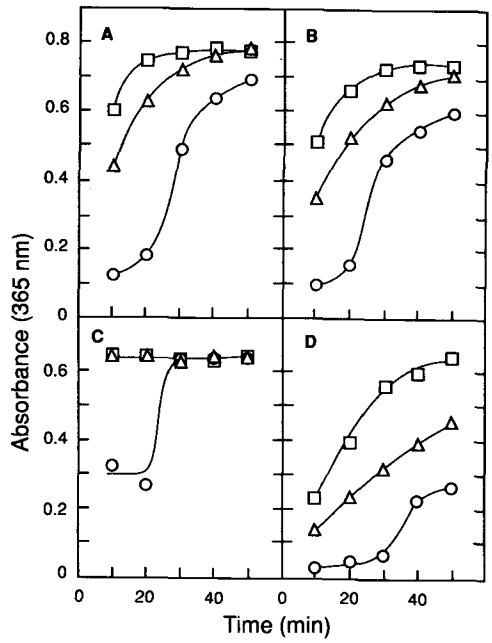

FIG. 2. Effect of temperature on color development for various hydroperoxides. Reactions were set up at 5 times the usual volume, containing, A, 32 μM phosphatidylcholine hydroperoxide; B, 30 μM linoleic acid hydroperoxide; C, 26 μM H_2O_2; D, 25 μM cumene hydroperoxide, and incubated in a water bath at 30°C (○), 40°C (△) and 50°C (□). Timing began with the addition of color reagent, and 1.0-mL samples were removed at various times and held on ice for no longer than 3 min when all samples for a particular time point were read against water. The absorbance of the reagent blank (*ca.* 0.01) did not change with time at any of the temperatures.

known reactivity, it is important to ensure that an appropriate incubation time is chosen.

El-Sadaani *et al.* (3) had observed that interference from molecular oxygen in the assay was minimal; blank values measured immediately after mixing were the same as those measured after 30 min at ambient temperature. However, these authors recommended that the 30-min color development proceed in the dark. We have made no attempt to exclude normal room lighting or oxygen and have found the method to be very forgiving in this respect. Table 1 shows the stability of absorbance when a series of assay tubes was processed with the recommended 30-min incubation time at 50°C and then allowed to stand on the bench top for up to 15 h before measurement. Samples included PC, PCOOH, Lin, LinOOH and a reagent blank, all with and without EDTA/BHT at the levels originally recommended (3). In each sample, the absorbance values were exceptionally stable, indicating that autoxidation of I^- does not occur, even without exclusion of air, nor was there any significant peroxide formation from the unoxidized lipids or from Triton X-100 in the color reagent. Although not shown, $FeCl_3$ (5 μM) in the absence of EDTA/BHT had no effect on the assay of the samples listed in Table 1. $CuCl_2$ (5 μM) caused an increase in the absorbance of the reagent blank equivalent to 3 nmoles of hydroperoxide, but subtraction of this blank value brought the assay of added lipid hydroperoxides into line.

TABLE 1

Stability of Absorbance of Samples at 365 nm with Time, Plus and Minus EDTA/BHT[a]

[a]Replicate samples were prepared as described in Materials and Methods with or without 20 μM butylated hydroxytoluene (BHT) added in methanol and 24 μM ethylenediaminetetraacetic acid (EDTA) added in water. After 30 min at 50°C, samples were read at once against a water blank, or left at room temperature for the specified time before reading, with the absorbance at 365 nm being converted to nmoles of hydroperoxide using the molar absorptivity given in the text. PCOOH, phosphatidylcholine hydroperoxide; PC, phosphatidylcholine; LinOOH, linoleic acid hydroperoxide; Lin, linoleic acid.

[b]Approximately 20 nmoles of each lipid was added per tube.

Although we normally add KI to the color reagent just before use, reagent stored for 48 h at room temperature and unprotected from light gave indistinguishable results from those obtained with fresh reagent.

Table 2 shows that the iodometric method described here gives uniform results with various hydroperoxides. Five different preparations of hydroperoxide were assayed iodometrically, and the same preparations were assayed enzymatically using both GPX and PHGPX. Good agreement among the three methods was obtained for the apparent concentrations calculated from the raw data, representing a range of sample sizes and dilutions. As expected from the known specificity of the two peroxidases (8), PCOOH could not be detected with GPX but was detectable with PHGPX. A photooxidized crude extract of retinal lipids, containing a mixture of hydroperoxides, was also unreactive with GPX but reacted with PHGPX.

We have found the present assay useful for relatively pure samples of various hydroperoxides, but less useful for direct measurement of endogenous hydroperoxides in crude tissue extracts. When either rat brain or rat retina was extracted, partitioned into dichloromethane and redissolved in methanol, essentially as described by van Kuijk *et al.* (4), no positive iodometric assay could be obtained on these samples. Furthermore, the presence of such tissue extracts prevented the normal development of color from added H_2O_2 or CuOOH. However, when similar samples were first photooxidized in the presence of rose bengal, no interference with the reaction was seen (Table 2). The interfering material has not been identified, but vitamin E is present in crude lipid extracts and known to interfere with another oxidation/reduction assay for

TABLE 2

Comparison of the Iodometric Method with Enzymatic Methods for Estimating Various Hydroperoxides[a]

	Iodometric method[b]	Enzymatic methods[c]	
		GPX	PHGPX
	Calculated concentration of hydroperoxide (mM)		
H_2O_2	1.82 ± 0.01	1.82 ± 0.01	1.83 ± 0.01
CuOOH	2.09 ± 0.06	2.22 ± 0.06	2.25 ± 0.09
LinOOH	1.73 ± 0.01	1.67 ± 0.04	1.81 ± 0.01
PCOOH	1.70 ± 0.08	0	1.50 ± 0.05
Retinal lipid hydroperoxides	0.90 ± 0.006	0	0.83 ± 0.09

[a]Each number was calculated from the mean of two determinations plus and minus the observed range. H_2O_2 and cumene hydroperoxide (CuOOH) were commercial samples. PCOOH was made by dye-catalyzed photooxidation as described in Materials and Methods. LinOOH and retinal lipid hydroperoxides were made by subjecting linoleic acid, and a lipid-rich extract of rat retina, respectively, to similar photooxidation procedures. See Table 1 for other abbreviations.

[b]Samples were analyzed iodometrically in duplicate as described in this paper. The concentration of H_2O_2, as evaluated enzymatically, served as the standard value for the iodometric assays.

[c]Samples were analyzed enzymatically by coupling reduction of the hydroperoxides by glutathione catalyzed by commercial glutathione peroxidase from bovine erythrocytes (GPX) or by phospholipid hydroperoxide glutathione peroxidase (PHGPX; Ref. 8) to the oxidation of NADPH by oxidized glutathione catalyzed by yeast glutathione reductase. For further details of the enzymatic procedure, see Materials and Methods section.

hydroperoxides (14). Added α-tocopherol inhibited our present assay stoichiometrically, causing a mole-for-mole decrease in the absorbance expected from added hydroperoxide standards. Furthermore, adding increasing amounts of H_2O_2 to a reaction mixture containing an excess of α-tocopherol caused a proportional decrease in absorbance at 292 nm and also in fluorescence emitted at 340 nm after excitation at 295 nm, suggesting alteration of the conjugated ring of α-tocopherol. It may be that the conjugated ring of vitamin E in fresh tissue extracts reacts with the newly-produced I_2 under our assay conditions, making it unavailable to form the I_3^- chromophore. Unsaturated fatty acid side chains are another potential target for iodination. However, we observed no interference with the estimation of 30 nmoles of H_2O_2, LinOOH or PCOOH, from adding 400 nmoles of Lin or 200 nmoles of PC, quantities near the solubility limit for our standard reaction mixture. Additional work will be required to adapt this method for general application to hydroperoxide measurements in crude tissue extracts.

ACKNOWLEDGMENTS

This work was supported by NIH grant EY-01959 to D.T.O. We thank Darrell Fleischman for providing the apparatus for photooxidation and for measuring the fluence.

A Microprecipitation Technique Suitable for Measuring α-Lipoprotein Cholesterol

Donald L. Puppione* and **Sarada Charugundla**

Molecular Biology Institute and the Department of Chemistry and Biochemistry, University of California, Los Angeles, California 90024

A semi-automated method has been developed for determining α-lipoprotein cholesterol values. Precipitation of apolipoprotein B containing lipoproteins takes place in wells of microtiter plates after 100 μL of serum are mixed with 20 μL of a heparin/$MnCl_2$ solution. A Beckman (Fullerton, CA) Biomek 1000 work station is used to transfer sera, supernatants and reagents between tubes and microtiter plates. Supernatant cholesterol is determined enzymatically, and absorbances are read at 490 nm using a Molecular Devices Corporation (Palo Alto, CA) plate reader. Values obtained on both fresh and frozen serum samples agreed with corresponding data obtained at the Centers for Disease Control (CDC; Atlanta, GA). For the fresh samples, the average bias was 2.87%. The within-run coefficients of variations were between 2.2 and 0.6% for the data obtained on CDC frozen control pools. The results indicate that the semi-automated method is suitable for obtaining accurate and precise data for α-lipoprotein cholesterol. The method lends itself to the analysis of large numbers of samples and is particularly suited for the study of lipoproteins of small mammals.

***Lipids* 29, 595–597 (1994).**

With advancements in the design of plate readers, microtiter plates can be used to measure concentrations of both total plasma cholesterol and triacylglycerol (1–3). Utilizing the Biomek 1000 (Beckman, Fullerton, CA) work station in conjunction with the V_{max} Microplate Reader (Palo Alto, CA), it was possible to use microtiter plates to precipitate apolipoprotein (apo) B containing lipoproteins and to measure α-lipoprotein cholesterol. The general term "α-lipoprotein cholesterol" is used throughout this paper instead of high density lipoprotein (HDL) cholesterol because the procedures were developed to study the lipoproteins of a variety of mammals in which α-lipoproteins can be highly polydisperse, being present in both the low density lipoprotein (LDL) and HDL ultracentrifugal classes (4–6).

A variety of polyanions in association with divalent cations can be used to precipitate apo B-containing lipoproteins (7) that, in mammalian plasma, can contain either apo B100 (molecular weight, 545,000) or apo B48 (molecular weight, 260,000) (8). On the surface of the triacylglycerol-rich lipoproteins, either one of the two forms of apo B is present, and apo B100 is on the surface of β-migrating LDL. Heparin/$MnCl_2$ was selected as the precipitant in this method because in studies of various mammalian species (9), including humans (7,9,10), it has been shown to be selective in precipitating apo B-containing lipoproteins.

Abbreviations: apo, apolipoprotein; CDC, Centers for Disease Control; HDL, high density lipoprotein(s); LDL, low density lipoprotein(s); PIPES, piperazine-*N,N'-bis*(2-ethanesulfonic acid).

The present paper describes how α-lipoprotein cholesterol values can be determined after 20 μL of a heparin/$MnCl_2$ solution and 100 μL of serum are mixed in wells of microtiter plates. Enzymatic reagents are used to measure α-lipoprotein cholesterol with analyses done on 20 μL of supernatant. The absorbance of each of the 96 wells of the microtiter plates is read within 5 s. Data on fresh and frozen serum samples compared with values obtained at the Centers for Disease Control (CDC; Atlanta, GA) indicate that the semi-automated method is both accurate and precise.

MATERIALS AND METHODS

Frozen serum samples. Frozen samples consisting of one of three pools, A, B and C, were obtained from the CDC Lipid Standardization Laboratory (Atlanta, GA). On separate days, six vials of a given pool were analyzed.

Fresh serum samples. Fasting serum samples were obtained from ten individuals at the Medical College of Virginia (Richmond, VA) and sent refrigerated overnight to UCLA (Los Angeles, CA) where analyses were done the day after the blood was drawn.

Enzymatic cholesterol reagent. The reagent, 50 mM piperazine-*N,N'-bis*(2-ethanesulfonic acid) (PIPES) buffer (Sigma; St. Louis, MO), pH 6.9, was prepared as described by Warnick (11) with the following modifications. Lyophilized enzymes (International Bioproducts, Streamwood, IL) were dissolved in 3 M NaCl and stored at –20°C. Enzymes were added on the day of the assay to give the following concentrations: horseradish peroxidase, 10 U/mL; cholesterol esterase 0.2 U/mL; and cholesterol oxidase, 0.2 U/mL. Phenol was replaced by 1.5 mM sodium 2-hydroxy-3,5-dichlorobenzenesulfonic acid (Research Organic, Inc., Cleveland, OH).

Initial set-up of the Biomek 1000. Because the Biomek 1000 moves rapidly during programmed maneuvers, 96-hole plastic racks (Bremshield Corp., Van Nuys, CA) were specially designed both to keep the racks in position on the movable tray and to maintain 1 mL polystyrene tubes (DBM Scientific, Valencia, CA) tightly in a vertical position. The spacing of holes in the rack was identical to the spacing of wells in a standard 96-well plate. For all of the programmed maneuvers, the MP 200 tool with eight tips was used to aspirate, to dispense and to mix the sera, solutions and supernatants.

Heparin/$MnCl_2$ precipitation protocol. The micromethod for precipitating apo B containing lipoproteins was based on modification (12) of the procedure of Burstein *et al.* (7). Before each run, serum sufficient for the analysis was transferred with Pasteur pipettes into 1 mL tubes arranged in columns in a Bremshield rack. The remaining steps were done with the Biomek. First, preselected wells of 96 round-bottom well plates (Costar, Cam-

bridge, MA) were filled, eight at a time, with 20 μL of a solution of sodium heparin (1099 U/mL, Liquaemin Sodium; Organon, W. Orange, NJ) and 0.275 M $MnCl_2$. Then, from each tube 100 μL of serum was transferred to a well containing the heparin/$MnCl_2$ solution. This step was done by transferring sera from a column of eight tubes at a time to the corresponding column of eight wells. To mix the sample with the precipitating reagent, plates were vibrated for 15 s in the V_{max} Microplate Reader and then incubated for 20 min at 4°C. Using a plate holder that fits the TH-4 rotor, plates were spun at 4°C and 1500 × *g* for 20 min in a Beckman TJ-6 centrifuge.

Measurement of α-lipoprotein cholesterol. The Biomek 1000 was programmed to aspirate 20 μL of supernatant from wells, eight in a column, and to dispense this volume into a corresponding column of tubes in a Bremshield rack. Next, 600 μL of enzymatic reagent were dispensed manually with an 8-tipped Titertek Multistepper (ICN Flow Labs., Costa Mesa, CA). The Bremshield rack containing the tubes was incubated in a 37°C water bath for 15 min. Then, the rack was returned to the Biomek 1000, which first mixed the solution in each tube by aspirating and dispensing twice 180 μL and then transferred three, 175-μL aliquots into wells of a 96 flat-bottom well plate (Costar). Routine monitoring of these plates at 490 nm has revealed that the optical path lengths of the wells are quite uniform. However, the plates were not used if visible scratches were observed. Saline blanks were prepared by adding 100 μL of solution (0.19 M NaCl) to 20 μL of heparin/$MnCl_2$ solution. A 20-μL aliquot of a 50-mg/dL Sigma calibrator without any precipitating reagent was included in each run as a standard. Using this standard, the concentrations were calculated on an IBM PS/2 computer using software from Molecular Devices after plates were read at 490 nm in the V_{max} Microplate Reader. A dilution correction of 1.20, resulting from precipitant addition, was incorporated into the calculations. The values reported in the Results section in Tables 1 and 2 for each sample were determined from the means of readings of three wells.

RESULTS

High blank values have previously been reported when enzymatic reagents prepared with phosphate buffer were used to analyze heparin/Mn^{2+} supernatants (13,14). However, with the enzymatic reagent prepared with PIPES buffer, difference in absorbance at 490 nm between the saline/heparin/Mn^{2+} blank and the reagent blank in this study was never greater than 0.004. This difference amounted to a correction that varied between 0.7 and 0.2 mg/dL for the various runs. Analyses of the CDC pools indicated that the assay was linear for absorbances between 0.160 and 0.450. Each value in Table 1 consists of the mean of three separate measurements obtained using one of the vials containing a specific control pool. The coefficient of variation for any one of these sets of three measurements was never greater than 2.39%. Moreover, the data for the mean of the means for these sets of measurements resulted in coefficients of variation being less than 2.2%. Comparing the data to the CDC target values, the bias was positive and ranged between 1.24 and 6.34%. All of the values fell within the range limits, ±10% from the target value, as required by the CDC (15). The upper limits for standard deviations required by the CDC are 2.50 for pool A, 3.00 for pool B and 3.50 for pool C.

Table 2 lists the cholesterol values when fresh serum was used to obtain heparin/Mn^{2+} supernatants at our laboratory and at the CDC. The set of samples sent to the CDC were frozen at −70°C, and the precipitation and analyses were done a week later. The data obtained in both laboratories agreed quite well. The highest bias among the ten samples was 7.59%. Data were also obtained on a diluted control pool. All of the data obtained with the semi-automated method were well within the CDC limit of ±10% from their observed value (15).

DISCUSSION

Throughout the Lipid Research Clinic studies, heparin/$MnCl_2$ was the precipitating reagent used to

determine the distribution of cholesterol among lipoprotein classes (12). A 3-mL volume was used for precipitation in these studies (12). Using microtiter plates, we were able to reduce this volume to 100 μL. Although sample volume is usually not a concern when dealing with human plasmas, such protocols are indispensable when characterizing the plasma lipids of a small mammal. Increasingly, microtiter plates are being used to determine plasma lipid concentrations because of the savings in time and reagents. All of the 96 wells can be read in 5 s, and the data can be stored in a personal computer and processed. The reagent volume is reduced almost two- to fourfold. Further savings can be attained by preparing the enzymatic reagents instead of using commercial kits.

Incomplete precipitation is a problem common to precipitating procedures when analyzing hypertriglyceridemic samples. In our laboratory, such samples are identified by first measuring plasma triacylglycerol concentrations. If the concentration is greater than 400 mg/dL, precipitation only is done on the ultracentrifugally isolated 1.006 g/mL bottom fraction. If the plasma is observed to be turbid or if the triacylglycerol concentration is between 150 and 400 mg/dL, the plasma is diluted twofold before precipitation. In lieu of these steps, careful inspection of the 96 well plates following their centrifugation has enabled us to identify any contaminated supernatants.

In conclusion, we describe here how 100 μL of plasma or serum can be used for a rapid and precise determination of α-lipoprotein cholesterol using heparin/Mn^{2+} as the precipitant. With the Biomek 1000, the initial loading of serum in all 96 wells can be done in less than eight minutes. The combination of the work station with the rapid reading capability of the plate reader provides the ability to determine over 380 α-lipoprotein cholesterol values in approximately four hours. Based on the values reported here, it is possible with this system to obtain data with a precision and accuracy suitable for CDC standardization. Finally, preparing the enzymatic reagent with PIPES buffer does not give rise to any of the problems (13,14) encountered when phosphate buffered reagents are used to analyze heparin/Mn^{2+} supernatants.

ACKNOWLEDGMENTS

This work was supported by research grant HL-28481 from the National Institutes of Health. The authors wish to acknowledge Dr. Parvin Waymack of the CDC for analyses done in his laboratory and Dr. Craig Laughton of the Syntex Corporation (Palo Alto, CA) for his helpful comments and suggestions during the initial phase of this work.

Trp89 in the Lid of *Humicola lanuginosa* Lipase Is Important for Efficient Hydrolysis of Tributyrin

Mats Holmquist[a], Mats Martinelle[a], Ib Groth Clausen[b], Shamkant Patkar[b], Allan Svendsen[b] and Karl Hult[a,*]

[a]Department of Biochemistry and Biotechnology, Royal Institute of Technology, S-100 44 Stockholm, Sweden, and [b]Novo-Nordisk A/S, 2880 Bagsvaerd, Denmark

To determine whether Trp89 located in the lid of the lipase (EC 3.1.1.3) from *Humicola lanuginosa* is important for the catalytic property of the enzyme, site-directed mutagenesis at Trp89 was carried out. The kinetic properties of wild type and mutated enzymes were studied with tributyrin as substrate. Lipase variants in which Trp89 was changed to Phe, Leu, Gly or Glu all showed less than 14% of the activity compared to that of the wild type lipase. The Trp89Glu mutant was the least active with only 1% of the activity seen with the wild type enzyme. All Trp mutants had the same binding affinity to the tributyrin substrate interface as did the wild type enzyme. Wild type lipase showed saturation kinetics against tributyrin when activities were measured with mixed emulsions containing different proportions of tributyrin and the nonionic alkyl polyoxyethylene ether surfactant, Triton DF-16. Wild type enzyme showed a $V_{max} = 6000 \pm 300$ mmol · min^{-1} · g^{-1} and an apparent $K_m = 16 \pm 2\%$ (vol/vol) for tributyrin in Triton DF-16, while the mutants did not show saturation kinetics in an identical assay. The apparent K_m for tributyrin in Triton DF-16 was increased as the result of replacing Trp89 with other residues (Phe, Leu, Gly or Glu). The activities of all mutants were more sensitive to the presence of Triton DF-16 in the tributyrin substrate than was wild type lipase. The activity of the Trp89Glu mutant was decreased to 50% in the presence of 2 vol% Triton DF-16 compared to the activity seen with pure tributyrin as substrate. Wild type lipase and all mutants except Trp89Glu had the same affinity for the substrate interface formed by 15.6 vol% tributyrin in Triton DF-16. The Trp89Glu mutant showed a lower affinity than all the other lipase variants for the interface of 15.6 vol% tributyrin in Triton DF-16. The study showed that Trp89 located in the lid of *H. lanuginosa* lipase is important for the efficient hydrolysis of tributyrin and that this residue plays a role in the catalytic steps after adsorption of the lipase to the substrate interface.

***Lipids* 29, 599–603 (1994).**

Triglyceride lipases (EC 3.1.1.3) are enzymes that catalyze the hydrolytic digestion of neutral lipids. Triglyceride lipases are activated at the lipid/water interface formed by their water-insoluble substrates (1–3). The activation process was early suggested to be associated with a conformational change of the enzyme (2,4). The three-dimensional structures of the lipases from *Rhizomucor miehei* (5,6), human pancreas (7) and *Geotrichum candidum* (8,9) all show an active site that is covered by one or more surface loops. The three-dimensional structures of *R. miehei* lipase-inhibitor complexes (10,11) have served as a model for the interfacial activation of that lipase. The α-helical lid (surface loop), which covers the active site of the free lipase, was displaced in the lipase-inhibitor complexes, providing access for the substrate to the active site of the enzyme. The activation of human pancreatic lipase (12), *G. candidum* (8,9) and *Candida rugosa* (13) lipases involves structural rearrangements of more than one surface loop. The amphiphilicity of the lid covering the active center of human lipoprotein lipase has been shown to be important for substrate specificity (14). A specific single-site modification of the lids of *R. miehei* and *Humicola lanuginosa* lipases has been shown to alter the activity and the specificity of the enzymes (15,16).

The two homologous lipases from the filamentous fungi *R. miehei* and *H. lanuginosa* have similar active sites (16), and the amino acid sequences of the lids covering the active site show high homology (17). The present investigation is focused on the conserved Trp residue in the lid of the two lipases (17). Chemical modification of Trp residues in the lipases from *H. lanuginosa* (18) and *Rhizopus delemar* (19) has shown that some Trp residues are important for enzyme activity, but the exact modification sites were not determined. Analyses of the three-dimensional structures of the *R. miehei* lipase (5,6) and lipase-inhibitor complexes (10,11) have shown that in the closed conformer the Trp residue located in the lid blocks the position at the active site where the inhibitor is bound in the open-lid structure. In the open-lid structure, the Trp residue covers part of the entrance to the active site and the Trp residue takes part in the formation of a large exposed hydrophobic surface upon activation (10,11).

In the present paper we demonstrate the importance of Trp89 in the lid of *H. lanuginosa* lipase to obtain a fully active enzyme for the hydrolysis of tributyrin. This was shown by site-directed mutagenesis and by following enzyme kinetics. The possible functional role of Trp89 in the lid is discussed.

MATERIALS AND METHODS

Chemicals. Tributyrin, Triton DF-16 (nonionic ethoxylate polyoxyethylene ether of linear primary alcohols), 3-(*N*-morpholino)propanesulfonic acid (MOPS), tris(hydroxymethyl)aminomethane (TRIS)-acetate and gum arabic were purchased from Sigma (St. Louis, MO). Calcium chloride and ammonium acetate were obtained from

*To whom correspondence should be addressed at Department of Biochemistry and Biotechnology, Royal Institute of Technology, Teknikringen 34, S-100 44 Stockholm, Sweden.

Abbreviations: DEAE, diethyl aminoethyl; MOPS, 3-(*N*-morpholino)propanesulfonic acid; OD_{280}, optical density measured at 280 nm; PCR, polymerase chain reaction; SDS–PAGE, sodium dodecylsulfate polyacrylamide gel electrophoresis; TRIS-acetate, tris(hydroxymethyl)aminomethane acetate.

Merck (Darmstadt, Germany). All chemicals used were of analytical grade.

Cloning and expression of the H. lanuginosa *lipase.* The gene from *H. lanuginosa* encoding the triglyceride lipase was cloned, sequenced and expressed as described by Boel and Huge-Jensen (20), and the lipase produced was isolated from the culture medium.

Site-directed mutagenesis. The method used for the mutation of Trp89 in the lipase gene has been described by Nelson and Long (21). A polymerase chain reaction (PCR) fragment containing the desired mutation was generated by using a chemically synthesized DNA-strand as one of the primers in the PCR reactions. From the PCR generated fragment, a DNA fragment carrying the mutation was isolated after cleavage with restriction enzymes and then inserted into the expression plasmid. The correct mutation was verified by DNA sequencing.

Lipase purification. About 200 mL of supernatant from the culture medium was centrifuged, and the precipitate was discarded by decantation. Ice-cold ethanol was slowly added to the supernatant which was cooled in an ice bath. The solution was centrifuged, and the precipitate was discarded. The pH of the supernatant was adjusted to 7 with NaOH, and the ionic strength was adjusted by dilution with water to be lower than that of 50 mM TRIS-acetate buffer, pH 7.

Ion exchange step I: The supernatant containing 70% ethanol was applied onto a 200 mL diethylaminoethyl (DEAE) Fast Flow Sepharose column (Pharmacia, Uppsala, Sweden) equilibrated with 50 mM TRIS-acetate buffer, pH 7. The column was washed at a flow rate of 5 mL/min until the optical density measured at 280 nm (OD_{280}) of the eluate was less than 0.05. The bound protein was subsequently eluted with a linear NaCl gradient (five column volumes) up to 0.5 M NaCl in 50 mM TRIS-acetate buffer, pH 7. Lipase activity was eluted between 0.1 and 0.15 M NaCl.

Hydrophobic interaction chromatography step: The fractions containing lipase activity were pooled, and ammonium acetate was added to a final concentration of 0.8 M. The solution was applied on a 100-mL Toyopearl™ Butyl-650C column (TosoHaas, Montgomeryville, PA). The column was equilibrated with 0.8 M ammonium acetate at a flow rate of 5 mL/min and was washed until OD_{280} was below 0.05. The bound activity was eluted with distilled water. The fractions with lipase activity were pooled, and the conductivity of the solution was adjusted by dilution with water to be less than that of 50 mM TRIS-acetate buffer, pH 7.

Ion exchange step II: The lipase solution was applied onto a 30-mL Q-Sepharose High Performance column (Pharmacia) equilibrated with 50 mM TRIS-acetate buffer, pH 7. The bound activity was eluted with a linear salt gradient up to 1 M NaCl at a flow rate of 1 mL/min.

No contaminants could be detected in the purified lipase after sodium dodecylsulfate polyacrylamide gel electrophoresis (SDS–PAGE) and Commassie Blue staining.

Protein quantitation. Protein concentrations were determined spectrophotometrically at 280 nm (wild type *H. lanuginosa* lipase, $\varepsilon = 4.3 \times 10^4\ M^{-1}cm^{-}$; Trp mutants, $\varepsilon = 3.6 \times 10^4\ M^{-1}cm^{-1}$).

Enzyme activity assay. Tributyrin (0.5 mmol) was added to a water solution (5 mL) of gum arabic [5% (wt/vol)] and calcium chloride (0.2 M), pH 7.5. The mixture was emulsified by sonication for one minute. The enzyme was dissolved in 10 mM MOPS buffer, pH 7.5. The reaction was started by the addition of enzyme solution to the stirred, thermostatted (25°C) substrate solution (1.5 mL). The pH was maintained automatically with sodium hydroxide (10–100 mM), using a Radiometer pH-stat equipped with an ABU91 autoburette (1 mL) connected to a VIT90 videotitrator. The reactions were run for 5 min under nitrogen. In experiments with Triton DF-16, tributyrin and Triton DF-16 were mixed before being added to the water solution and then sonicated. The total volume of tributyrin plus Triton DF-16 was kept constant at 32 mL/L of water (for 100% tributyrin equal to 0.1 M).

RESULTS

Hydrolysis of emulsified tributyrin. The enzyme variants in which Trp89 had been changed to Phe, Leu, Gly or Glu, all showed less than 14% of the activity obtained with the wild type enzyme in a standard tributyrin assay, pH 7.5 (Table 1). The same activities were obtained with 0.1 or 0.2 M tributyrin. The Trp89Glu mutated enzyme was the least active, expressing only 1% of the activity of wild type enzyme. A different activity-pH dependence was seen for the Trp89Glu mutant compared to those of the Trp89Gly mutant and the wild type enzyme (Fig. 1).

The apparent interfacial $K_{m,i}$ values (3,22) of the wild type and the Trp89 mutants of the lipase were the same, $K_{m,i} = 12\ m^2/L$ (0.017 M) for the interface obtained with pure tributyrin as a substrate (Fig. 2). The tributyrin droplet radius in the emulsion was estimated by microscopy to be r = 1.3 μm (distribution, r = 0.7–2 μm).

Hydrolysis of mixed emulsions of tributyrin and Triton DF-16. Wild type lipase showed saturation kinetics when the tributyrin concentraton was increased from 0 to 100% in Triton DF-16. The total volume of tributyrin plus Triton DF-16 was kept constant at 32 mL/L of water (for 100% tributyrin this amounted to 0.1 M, or in substrate surface to 68 m^2/L emulsion). Wild type enzyme showed a $V_{max} = 6000 \pm 300\ mmol \cdot min^{-1} \cdot g^{-1}$ and an apparent $K_m = 16 \pm 2$ vol% tributyrin in Triton DF-16. These results were obtained by fitting experimental data directly (non-

TABLE 1

Activity of Wild Type and Trp89 Mutants of *Humicola lanuginosa* Lipase in a Standard Tributyrin Assay at pH 7.5 and 25°C

Enzyme	Activity[a] (mmol/min · g)
Wild type	5400 ± 200
Trp89Phe	750 ± 50
Trp89Leu	415 ± 15
Trp89Gly	295 ± 15
Trp89Glu	63 ± 5

[a]Standard deviations are based on three separate measurements.

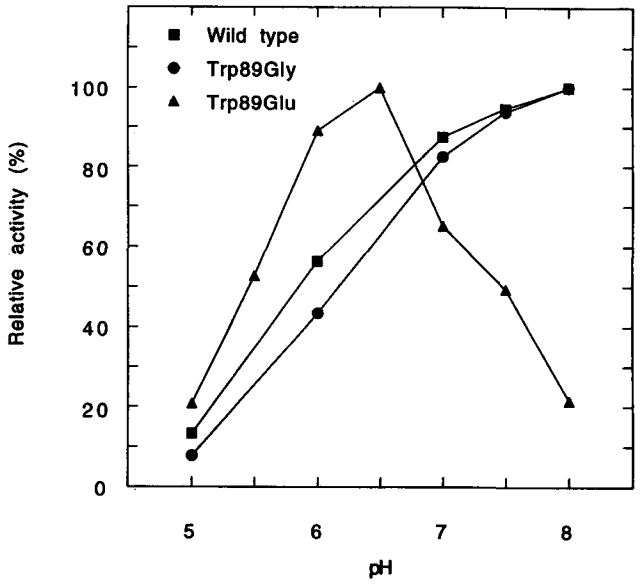

FIG. 1. Activity of wild type and Trp89 mutants of *Humicola lanuginosa* lipase as a function of pH in the hydrolysis of 0.1 M tributyrin at 25°C. A relative activity of 100% corresponds to the highest activity obtained for each enzyme variant in the pH interval 5 to 8.

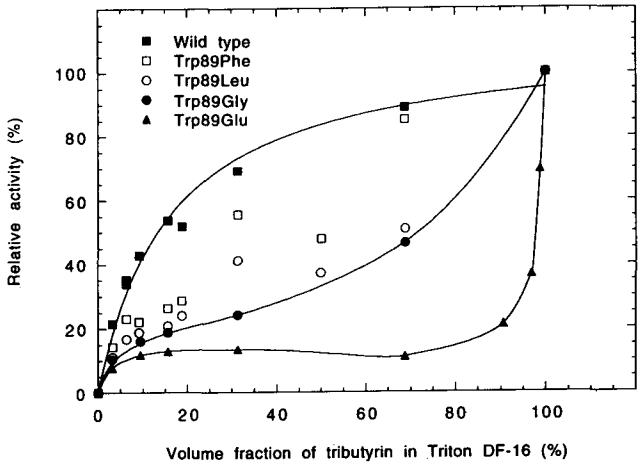

FIG. 3. Activities of wild type and Trp89 mutants of *Humicola lanuginosa* lipase in mixed emulsions of tributyrin and Triton DF-16. The volume of tributyrin plus Triton DF-16 was kept constant at 32 mL/L water in all experiments. The volume fraction 100% corresponds to 0.1 M tributyrin, and 100% activity was defined as that obtained with 0.1 M tributyrin as a substrate. Activities were measured at pH 7.5 and 25°C.

linear regression) to a Michaelis-Menten type curve (Fig. 3). The enzymes in which Trp89 had been mutated to Phe, Leu, Gly or Glu did not show saturation kinetics under the same experimental conditions and did not fit a Michaelis-Menten type curve. Instead, more complex nonlinear relationships between the activity and the volume fraction of tributyrin in Triton DF-16 were seen (Fig. 3). The activities of all mutants tested were more sensitive to the presence of Triton DF-16 in the tributyrin substrate than was the wild type enzyme. The activity of the Trp89Glu mutated lipase plateaued at a concentration of 10% tributyrin in Triton DF-16 (Fig. 3). When the tributyrin concentration was further increased (90–100%), the activity increased to 100%. Only 2 vol% Triton DF-16 was needed to reduce the activity to 50% compared to the activity obtained with pure tributyrin.

Wild type enzyme and all Trp mutants except Trp89Glu had the same apparent interfacial $K_{m,i}$ value (3,22), namely 2 m^2/L for the interface formed by 15.6% tribu-

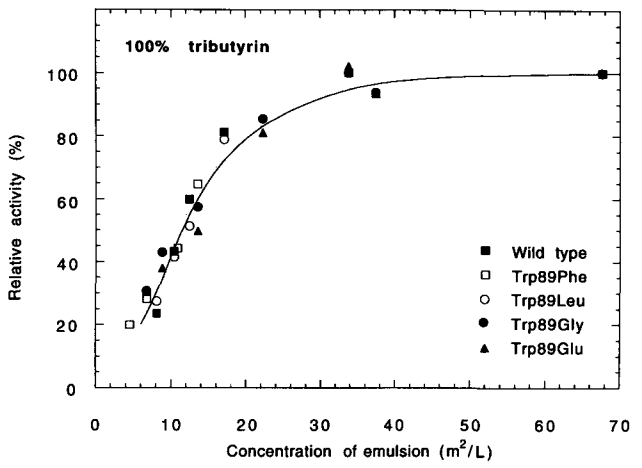

FIG. 2. Activities of wild type and Trp89 mutants of *Humicola lanuginosa* lipase as a function of the emulsion concentration (substrate surface). Experiments were performed by dilution of a stock emulsion of tributyrin (0.1 M tributyrin or in substrate surface, 68 m^2/L emulsion). The 100% activity corresponds to the activity obtained with the stock emulsion. Activities were measured at pH 7.5 and 25°C.

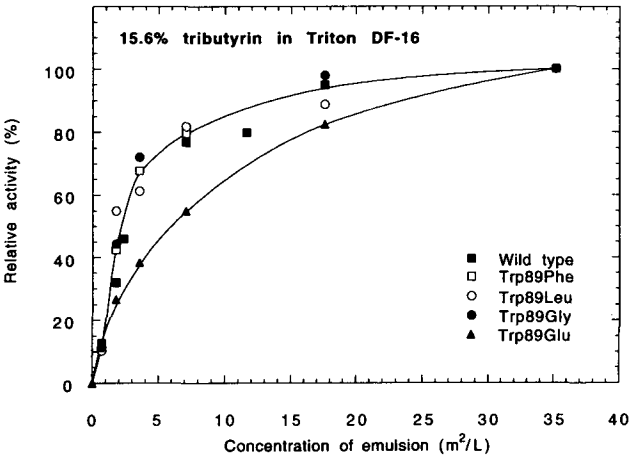

FIG. 4. Activities of wild type and Trp89 mutants of *Humicola lanuginosa* lipase as a function of the emulsion concentration (substrate surface). Experiments were performed by dilution of a stock emulsion of 15.6% tributyrin in Triton DF-16 (the total volume of tributyrin plus Triton DF-16 was 32 mL/L water or in substrate surface, 35 m^2/L emulsion). The 100% activity corresponds to the activity obtained with the stock emulsion. Activities were measured at pH 7.5 and 25°C.

tyrin in Triton DF-16 (Fig. 4). The Trp89Glu mutant had a lower affinity for the substrate than did the wild type enzyme. The apparent interfacial $K_{m,i}$ of the Trp89Glu mutant was about 7 m^2/L (Fig. 3). The droplet size obtained with the mixed emulsion of 15.6% tributyrin in Triton DF-16, r = 2.5 μm (distribution, 0.7–7 μm), was greater than the one obtained with pure tributyrin.

DISCUSSION

The ability of the lipase to hydrolyze emulsified tributyrin, either pure or mixed with Triton DF-16, was considerably decreased when Trp89 was changed to other residues (Table 1, Fig. 3). The activities of the lipase mutants were determined with an excess of substrate surface. The differences between the lipases should therefore originate from the catalytic steps occurring at the substrate interface (Fig. 5). The mutants where Trp89 had been changed to the smaller hydrophobic amino acids, Phe, Leu or Gly, showed 5–14% of the activity seen with wild type enzyme. Consequently the size and/or hydrophobicity of the residue at position 89 is important for high enzyme activity. In the Trp89Glu mutant, in which an ionizable side chain had been introduced, only 1% of the activity remained. The negatively charged residue in the lid might be unfavorable for efficient catalysis. In fact, this was seen by the different activity-pH dependence for the Trp89Glu mutant compared to those of the Trp89Gly mutant and the wild type enzyme (Fig. 1). The negatively charged Glu residue could affect the electrostatic stabilization of the position of the lid (15,16) resulting in an open conformation of the enzyme which is not optimal for catalysis. In addition, the charged Glu residue in the lid is close to the ionized fatty acid generated by the hydrolysis of the acyl-enzyme intermediate. Perhaps Glu89 prevents efficient interfacial penetration of the enzyme into the lipid phase.

Lipase bound to the substrate interface might have different conformations with different specific activities. Once the lipase has adopted its open active conformation(s), the efficiency of the catalysis depends on the ability of the enzyme to extract substrate from the lipid phase into the active site (K_m) and to subsequently convert substrate to product (V_{max}) (Fig. 5). With a standard tributyrin assay, these different steps, occurring at the substrate interface, cannot be separately investigated since the concentration of tributyrin at the interface cannot be varied. To gather further insights into the mechanism behind the considerably decreased activities seen as the result of changing Trp89 in the lid into other residues, a complementary activity assay was used in which the accessibility of tributyrin at the interface was altered by the presence of the Triton DF-16 surfactant. The results obtained show that the activities of the mutants are more sensitive to the dilution of tributyrin with Triton DF-16 than that of the wild type enzyme. Since the experiments were performed with an excess of emulsion surface, the activities reflected the steps in catalysis at the substrate interface (Fig. 5). Lipase activity has been shown to depend on the interfacial quality and/or the interfacial pressure of the substrate (23). The mixed emulsions of tributyrin and Triton DF-16 represent a complex system in which the quality of the interface and the interfacial pressure might depend on the molar ratio of the two components tributyrin and Triton DF-16. Nevertheless, the qualitative results obtained in the tributyrin/Triton DF-16 assay clearly illustrate the importance of Trp89 in the lid to obtain a functional enzyme for triglyceride digestion in the presence of Triton DF-16. The ability of a lipase to efficiently degrade lipid substrates in the presence of detergents is a desirable property of an enzyme to be used in, for instance, washing powder.

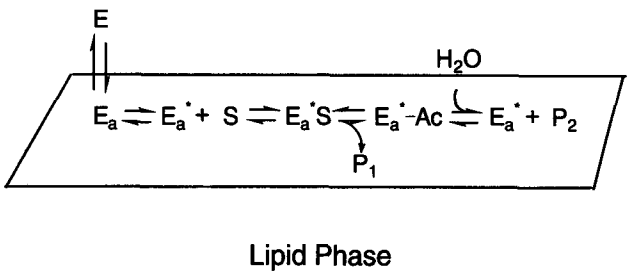

FIG. 5. Schematic model of lipolysis. E, enzyme in bulk water; E_a, enzyme adsorbed at the lipid interface; E_a^*, active enzyme adsorbed at the lipid interface; S, triglyceride substrate; E_a^*S, Michaelis-Menten complex; E_a^*-Ac, acyl-enzyme; P_1, diacylglycerol; P_2, fatty acid.

It is not clear if the steps leading to acylation or deacylation of the enzyme are rate-determining in the hydrolysis of tributyrin. Data obtained with wild type enzyme and other substrates have indicated that the acylation process is rate-determining with triglycerides as substrates (Martinelle, M., Holmquist, M., Clausen, I.G., Patkar, S., Svendsen, A., and Hult, K., manuscript in preparation). It therefore seems as if the Trp89 residue plays a role during the formation of the acyl-enzyme intermediate (Fig. 5). The ability of the lipase to efficiently form the acyl-enzyme intermediate at the interface is dependent on a number of separate steps: i) the active open-lid conformation must be formed, ii) the lipase has to penetrate the lipid interface and iii) the active site has to be saturated with substrate. From the data obtained in this investigation, we cannot determine which of these steps were affected by the mutation of Trp89 into other residues.

The lipases from *Rhizopus* species *(Rh. delemar, Rh. niveus, Rh. javanicus)* have molecular structures similar to that of the lipase from *R. miehei* (24). The Trp residue in the lid of *R. miehei* lipase corresponds to an Ala in the lipases from the *Rhizopus* species. It has been suggested that the Trp residue is unimportant for the function of the lid (22). Since other amino acid residues in the lid of the *Rhizopus* species lipases and *R. miehei* lipase are different, the importance of a particular residue in different lipase lids is difficult to estimate. Therefore, our finding that Trp89 in the *H. lanuginosa* lipase lid is important for activity should not be generalized to other lipases. The continued work toward a detailed understanding of lipase catalysis will assist in the efforts of engineering lipases with desirable properties.

Dietary Fat Composition and Age Affect Synaptosomal and Retinal Phospholipid Fatty Acid Composition in C57BL/6 Mice

Carl D. McGee[a,1], **Carol E. Greenwood**[a,b,*] and **Bernhard Cinader**[a]

[a]Departments of Nutritional Sciences and Immunology, Faculty of Medicine, University of Toronto, Toronto, Ontario M5S 1A8, Canada and [b]Department of Food and Nutrition Services, Baycrest Centre for Geriatric Care, North York, Ontario M6A 2E1,Canada

The purpose of this study was (i) to determine whether dietary fat-induced differences in neural and retinal membranes occur when dietary fat treatment is implemented in aged animals and (ii) to characterize the effect of long-term differences in dietary fat on neural and retinal membrane composition. For the first objective, young (six-week-old) and old (95-week-old) mice were randomly assigned to beef tallow (TAL) or soybean oil (SBO) diets for eight weeks. For the second objective, young (four-week-old) mice consumed either TAL or SBO diets for 99 weeks. Young and old mice challenged with a change in dietary fat for an eight-week period showed both diet and age effects on neural and retinal phospholipid fatty acid composition ($P < 0.05$). In addition, significant diet by age interactions were evident. In mice that consumed TAL and SBO diets throughout their life, only retinal phosphatidylethanolamine (PE) 18:2n-6 and neural phosphatidylserine 22:5n-6, PE 18:2n-6 and phosphatidylcholine 18:2n-6 differed between dietary treatments ($P < 0.05$). Neither the unsaturation index nor the n-6/n-3 ratio was affected by diet. Neural and retinal phospholipid fatty acid composition were responsive to changes in dietary fat even when the treatment was implemented beyond developmental or post-weanling stages. In contrast, when mice consumed TAL or SBO diets throughout their life, fewer differences in phospholipid fatty acid composition were detected, suggesting that the effect of the dietary treatment was mitigated by aging.

***Lipids* 29, 605–610 (1994).**

Although the lipid composition of brain is less responsive to changes in dietary fat than that of peripheral tissues (1), dietary fat can affect neural membrane fatty acid composition, particularly during development when cell differentiation and rapid accretion of neural lipids occur (2). In addition, dietary fat affects the composition of brain lipids in post-weanling animals (3–5) because of turnover of phospholipid fatty acids, synaptogenesis and arborization. Notably, this effect is manifested over a relatively short period of time (four weeks) and occurs with diets that are nutritionally complete (i.e., not essential fatty acid-deficient) (4,5).

Like the brain, retinal tissue has a high concentration of long-chain polyenoic n-3 fatty acids that can be altered by dietary manipulation. Imposition of an n-3 fatty acid deficiency in a developmental model has demonstrated the sensitivity of retinal phospholipid fatty acid composition to changes in the availability of dietary n-3 fatty acids (6,7). As with neural phospholipid composition, the composition of retinal lipids in post-weanling animals responds to differences in dietary fat composition that occur in normal diets (8).

Phospholipid metabolism and fatty acid composition of neural and retinal tissues are also affected by aging (9–12). Differences in both the amount of phospholipid and phospholipid fatty acid composition occur as animals age. In general, the most notable effect is the diminution of long-chain polyenoic n-3 fatty acids, particularly 22:6n-3 (11).

Changes in the lipid composition of electrically active tissues may have important biological effects. Alterations in phospholipid fatty acid composition have been associated with changes in the activities of membrane-bound enzymes (13,14), electroretinograms (6,7) and measures of cognitive performance (15,16).

Current dietary guidelines advocate quantitative and qualitative changes in dietary fat by broad segments of the population. The impact of such changes in dietary fat on the composition of electrically active tissues in aged animals is unknown. The purpose of the present study was (i) to determine whether neural and retinal tissues of aged mice were sensitive to changes in dietary fat composition when they were initiated late in life and (ii) to determine if lifelong consumption of diets that varied in their fatty acid composition resulted in differences in fatty acid composition of phospholipids in the brain and retina of aged mice.

MATERIALS AND METHODS

Animals and diets. Female C57BL/6 mice (Jackson River Laboratories, Bar Harbor, ME) were housed in plastic cages (4–5 animals/cage) under constant environmental conditions (room temperature 22–24°C; 12-h light/dark cycle). All animals were checked daily for health problems; unhealthy animals (skin lesions, tumors, *etc.*) were excluded from the study.

Tallow (TAL) and soybean oil (SBO) diets were nutritionally adequate, purified granular mixtures containing 40% carbohydrate, 24% protein, 5% nonnutritive fiber, 2.5% vitamin mix and 5.1% mineral mix. A detailed description of diet ingredients has been published previously (17). TAL and SBO diets were isoenergetic with 20% (wt/wt) dietary fat. The fatty acid composition of the diets is described in Table 1.

Diets were designed to have adequate levels of vitamin E as an antioxidant (4400 I.U. α-tocopheryl acetate/kg diet). Levels of thiobarbituric acid reactive substances detected in diets after 48 h at room temperature were 2.1 and 3.2 μmol/kg diet for TAL and SBO, respectively (18).

TABLE 1

Fatty Acid Composition of Experimental Diets[a]

Fatty acid	(% of total fatty acids) TAL	SBO
14:0	3.9	0.3
16:0	27.8	10.8
16:1n-7	2.4	0.1
18:0	20.1	3.4
18:1n-9	35.4	20.5
18:2n-6	9.7	56.4
18:3n-3	1.1	8.8

[a]Fat was extracted from premixed diets and fatty acid profiles determined by gas chromatography. TAL, beef tallow; SBO, soybean oil.

Our previous work showed an increased mortality in mice fed 20% (wt/wt) fat diets *ad libitum* (Cinader, B., unpublished data); therefore, mice consuming TAL and SBO diets had access to food only on alternate days. All animals had *ad libitum* access to water.

Experimental design. The effect of the composition of dietary fat and age on membrane fatty acid composition was examined with a 2×2 factorial design. At either six weeks or 95 weeks of age, mice that had consumed chow diets throughout their life were randomly assigned to 20% (wt/wt) TAL or SBO diets. Diets were fed for eight weeks.

To determine if lifelong consumption of diets that differed in their fatty acid composition resulted in differences in phospholipid fatty acid composition, four-week-old animals were randomly assigned to 20% (wt/wt) TAL or SBO diets for 99 weeks. At the end of the experiments, fasted mice were decapitated, and tissues were immediately removed and frozen on dry ice. Tissues were stored at –70°C until analysis. Retinae were dissected from frozen tissue under a light microscope.

Isolation of synaptosomal plasma membrane. Synaptosomal plasma membranes were isolated according to the method of Whittaker and Barker (19). Whole brains were homogenized in 0.32 M sucrose and centrifuged. The supernatant was decanted and recentrifuged to obtain a pellet containing mitochondria, synaptosomes and myelin. This pellet was applied to a discontinuous sucrose gradient and centrifuged at 100,000 × *g* for 60 min at 1°C. Synaptosomes were removed quantitatively from the 0.8–1.2 M interface and were osmotically shocked by suspension in distilled water for 1 h. The synaptosomal fraction was reapplied to a discontinuous sucrose gradient and recentrifuged as just described. Following centrifugation, plasma membranes were collected quantitatively from the 0.8–1.2 M sucrose interface. The purity of the fraction was verified by measuring the enrichment of 5′-nucleotidase (EC 3.1.3.5) (20) and by the removal of monoamine oxidase (EC 1.4.3.4) (21).

Fatty acid analysis. Lipids were extracted from membrane preparations by the method of Folch *et al.* (22). Phospholipids were separated by thin-layer chromatography (23,24), and fatty acid methyl esters were prepared by methylation with boron trifluoride in methanol (25). Fatty acid methyl esters from phosphatidylethanolamines (PE), phosphatidylcholines (PC), phosphatidylserines (PS) and phosphatidylinositols (PI) were analyzed by gas–liquid chromatography using flame-ionization detection (Vista 402; Varian, Palo Alto, CA). Fatty acids were identified by comparing their retention times with those of authentic standards (Nu-Chek-Prep, Elysian, MN). Results are expressed as percent of total fatty acids.

Statistical analyses. Data were analyzed using the SAS 6.03 (SAS Institute, Inc., Cary, NC) program. Factorial data were subjected to two-way analysis of variance with diet (TAL and SBO) and age (14 and 103 weeks) as main effects (26). Data comparing membrane fatty acid composition in mice that were exposed to different dietary treatments for 99 weeks were analyzed by Student's *t*-test (24). For all analyses the acceptable level of significance (Type 1 error) was 5%.

RESULTS

Effects of diet and age on synaptosomal phospholipid fatty acid composition. Both dietary fat composition and age affected synaptosomal plasma membrane phospholipid fatty acid composition. Among PE fatty acids (Fig. 1), 18:2n-6 was affected by diet alone, whereas 18:1 and 22:5n-6 were affected only by age. Diet and age each had

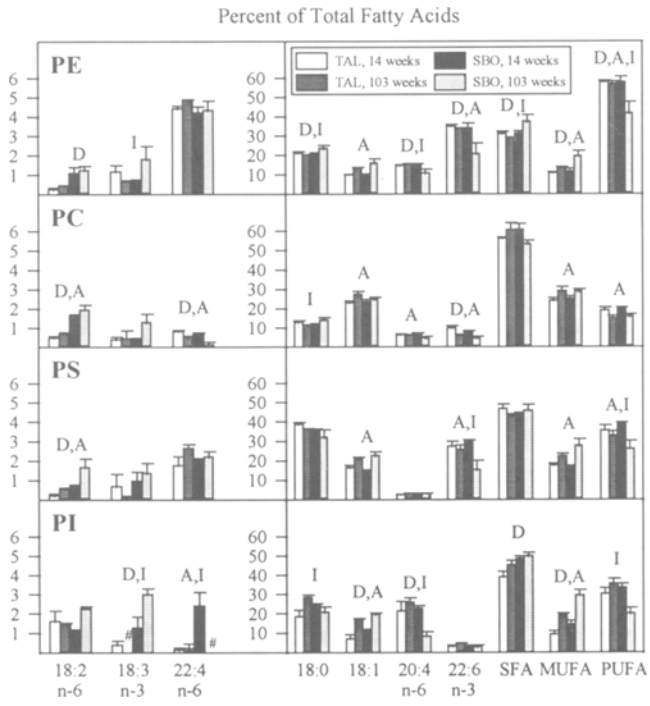

FIG. 1. Fatty acid composition of synaptosomal plasma membrane phospholipids. The inset label indicates the age at which the animals were killed. Mice were fed chow diets for six or 95 weeks, then were randomly assigned to 20% (wt/wt) beef tallow (TAL) or soybean oil (SBO) diets for eight weeks. Values are mean ± SE; n = 4–6/treatment; # indicates that the fatty acid was not detected. Letters indicate: D, significant effect of diet; A, significant effect of age; I, significant diet × age interaction ($P < 0.05$). PE, phosphatidylethanolamine; PC, phosphatidylcholine; PS, phosphatidylserine; PI, phosphatidylinositol; SFA, saturated fatty acids; MUFA, monounsaturated fatty acids; PUFA, polyunsaturated fatty acids.

independent effects on 22:6n-3 and monounsaturated fatty acids (MUFA). There was a primary effect of diet in addition to a significant interaction term for 18:0, 20:4n-6 and saturated fatty acids (SFA). Main effects of diet and age, as well as a significant interaction term, were observed for polyunsaturated fatty acids (PUFA). The interaction of dietary fat and age was a determinant of PE 18:3n-3. The unsaturation index and the ratio of n-6/n-3 fatty acids in PE were also affected by diet and age (Table 2). There was a main effect of diet and age for both outcomes, as well as a significant interaction term for the unsaturation index.

Age was an independent factor for levels of 18:1, 20:4n-6, MUFA and PUFA in membrane phospholipids among PC fatty acids (Fig. 1). Both diet and age were independent factors for 18:2n-6, 22:4n-6 and 22:6n-3. There was a significant interaction term for 16:0 and 18:0. Age had an effect on the unsaturation index of PC fatty acids, whereas diet and age both affected the n-6/n-3 fatty acid ratio (Table 2).

Only the PS 18:2n-6 and n-6/n-3 fatty acid ratio were affected by dietary treatment (Fig. 1, Table 2). There was an independent effect of age for 18:1, 18:2n-6, 22:6n-3, MUFA, PUFA, the unsaturation index and the n-6/n-3 fatty acid ratio. A significant interaction between dietary treatment and age was observed for 16:0, 22:6n-3, PUFA, the unsaturation index and the n-6/n-3 fatty acid ratio.

Among PI fatty acids, there was a main effect of diet on 16:0, 18:1, 18:3n-3, 20:4n-6, SFA, MUFA and the n-6/n-3 ratio (Fig. 1, Table 2). Age was an independent factor for 16:0, 18:1, 20:4n-6, MUFA and the n-6/n-3 ratio. There was a significant interaction term for 16:0, 18:0, 18:3n-3, 20:4n-6, 22:4n-6, PUFA, the unsaturation index and the n-6/n-3 ratio.

When the dietary treatment was implemented in four-week-old mice and continued till senescence, dietary fat composition resulted in lesser differences in synaptosomal fatty acid composition than when the dietary treatment was implemented with 95-week-old mice for the final eight weeks of life (Fig. 2). Mice fed TAL diets throughout their life had a lower percentage of 18:2n-6 in PE, PC and PI than did mice fed SBO diets. In addition, PS 22:5n-6 was affected by diet (data not shown). Diet had no effect on either the unsaturation index or the n-6/n-3 ratio (data not shown).

Effect of diet and age on retinal phospholipid fatty acid composition. Among retinal PE fatty acids, there was an independent effect of diet on 18:2n-6, 20:4n-6, 22:6n-3, SFA and PUFA (Fig. 3). Age had an independent effect on 18:2n-6, 20:4n-6 and the n-6/n-3 fatty acid ratio (Table 2). There was a significant interaction term for 20:4n-6. Analysis of PC fatty acid composition showed a diet effect only for 18:2n-6.

When the fatty acid composition of retinal membranes from mice fed their respective diets for 99 weeks were analyzed, only PE 18:2n-6 differed between dietary fat treatments (0.24 ± 0.04% vs. 0.88 ± 0.05% of total fatty acids, TAL and SBO, respectively). Neither the unsaturation index nor the n-6/n-3 ratio was affected by diet (data not shown).

DISCUSSION

An extensive body of literature has documented the effects of aging on the lipid composition of the brain (see Ref. 27 for a review), and recent studies have examined possible mechanisms by which aging alters phospholipid fatty acid composition in brain (9,10,12) and in retina (11). Although studies on peripheral tissues have examined the combined effect of dietary fat and aging on phospholipid fatty acid composition (28,29), to our knowledge there are no data

TABLE 2

Unsaturation Index and Ratio of n-6/n-3 Fatty Acids in Synaptosomal Plasma Membrane and Retinal Phospholipids from Young and Old Mice[a]

		Unsaturation index		n-6/n-3 Ratio	
		TAL	SBO	TAL	SBO
Synaptosomal phospholipids					
PE	14 weeks	309 ± 6[bcd]	305 ± 15	0.60 ± 0.1[b,c]	0.64 ± 0.02
	103 weeks	305 ± 2	218 ± 37	0.66 ± 0.02	0.92 ± 0.13
PC	14 weeks	119 ± 6[c]	107 ± 3	0.89 ± 0.12[bc]	1.27 ± 0.04
	103 weeks	97 ± 5	91 ± 4	1.43 ± 0.15	1.66 ± 0.16
PI	14 weeks	127 ± 22[d]	148 ± 6	7.20 ± 0.69[bcd]	6.37 ± 0.90
	103 weeks	160 ± 10	102 ± 12	7.02 ± 0.66	2.29 ± 0.04
PS	14 weeks	211 ± 16[cd]	226 ± 5	0.26 ± 0.03[bcd]	0.27 ± 0.02
	103 weeks	208 ± 12	155 ± 24	0.33 ± 0.03	0.65 ± 0.14
Retinal phospholipids					
PE	14 weeks	277 ± 15	195 ± 18	0.28 ± 0.03[c]	0.47 ± 0.07
	103 weeks	256 ± 25	243 ± 12	0.48 ± 0.03	0.52 ± 0.05
PC	14 weeks	93 ± 13	108 ± 8	0.78 ± 0.16	0.61 ± 0.04
	103 weeks	89 ± 16	96 ± 21	0.79 ± 0.07	1.77 ± 0.74

[a]Mice were fed chow diets during six and 95 weeks of age, then randomly assigned to 20% (wt/wt) TAL or SBO diets for eight weeks. The label shows the age at which animals were killed. The unsaturation index was calculated from percent fatty acid data determined by gas chromatography. Values are mean ± SE, n = 4–6/treatment. Superscript letters indicate: b, significant effect of diet; c, significant effect of age; d, significant diet × age interaction ($P < 0.05$). Abbreviations as in Table 1; PE, phosphatidylethanolamine; PC, phosphatidylcholine; PI, phosphatidylinositol; PS, phosphatidylserine.

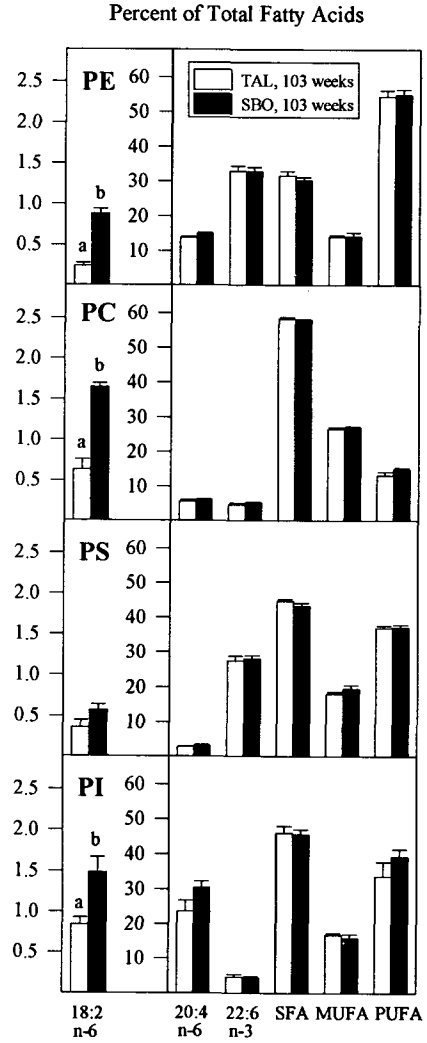

FIG. 2. Fatty acid composition of synaptosomal plasma membrane phospholipids. Mice were randomly assigned to dietary fat treatment at four weeks and consumed diets for 99 weeks. Values are mean ± SE; n = 6–8/dietary fat treatment. Values not sharing a common superscript letter are significantly different ($P < 0.05$). Abbreviations as in Figure 1.

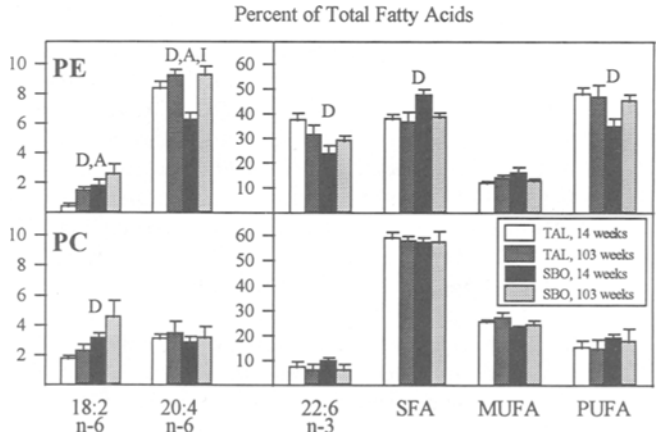

FIG. 3. Fatty acid composition of retinal PE and PC fractions. The inset label indicates the age at which the animals were killed. Mice were fed chow diets for six or 95 weeks, then were randomly assigned to 20% (wt/wt) TAL or SBO diets for eight weeks. Values are mean ± SE; n = 4–6/treatment. Letters indicate: D, significant effect of diet; A, significant effect of age; I, significant diet × age interaction ($P < 0.05$). Abbreviations as in Figure 1.

regarding the interaction of these factors on composition and function of electrically active tissues. Accordingly, the first objective of this research was to determine if diet-induced differences in neural and retinal fatty acid composition previously described in post-weanling animals also occur when the dietary treatment is implemented late in life. Mice that consumed chow diets for six or 95 weeks were subjected to a change in the amount and type of dietary fat during the final eight weeks of life. In addition to assessing the susceptibility of neural and retinal membranes in aged mice to changes in dietary fat, it was possible to determine if dietary fat and aging exerted independent and/or interactive effects on fatty acid composition of these tissues.

Our second objective was to determine if long-term consumption of diets with different fatty acid profiles resulted in differences in the composition of phospholipid fatty acids in the brain and retina of aged mice. Tissue fatty acid composition was examined in mice with a lifetime exposure (99 weeks) to different dietary fat regimens.

For both objectives, fat comprised 20% (wt/wt) of the diets, or approximately 40% of energy. This amount of fat is comparable to estimates of dietary fat as a percentage of energy in North American human populations (30,31). Because TAL and SBO were used as the source of dietary fat, the diets represent extreme points on the continuum of dietary polyunsaturated/saturated fatty acid ratios (0.21 and 4.4, TAL and SBO, respectively).

The results of the first experiment suggest that the response of electrically active tissues to a dietary fatty acid challenge is dependent upon the age of the animal when the dietary change is made. When the effect of a short-term change in dietary fat composition was examined in post-weanling (six-week-old) and old mice (95-week-old), differences due to age and dietary fat treatments were apparent in synaptosomal plasma membrane and retinal phospholipid fatty acid composition (Figs. 1 and 3). In addition to the main effects of diet and age, however, there was a dietary fat by age interaction for a number of tissue fatty acids, indicating that young and old mice did not respond in the same way to identical dietary fat treatments. Consistent with our previous observations in post-weanling rats (17), changes in the percentage of neural fatty acids in response to dietary fat treatment were most pronounced in PE and PC, whereas PI was most resistant. Differences tended to exist among the 20- and 22-carbon fatty acids.

In the second experiment, fewer differences in the percent fatty acid composition of synaptosomal plasma membrane and retinal phospholipids were evident despite lifetime exposure to qualitative differences in dietary fat (Fig. 2). These data suggest that there may be physiologic mechanisms that override the impact of prolonged differences in dietary fat. The critical exposure period is un-

known; however, data from Dyer and Greenwood (4) indicated that cardiolipin stabilized after four weeks with no change for up to 12 weeks. In contrast, differences in the ratio of n-6/n-3 22-carbon fatty acids continued to increase up to 12 weeks (5).

One factor which may have contributed to the results observed with lifetime exposure to dietary fat sources is that mice were fed on alternate days. Other studies have demonstrated changes in membrane fatty acid composition in both peripheral (32,33) and neural tissues (34) with food restriction. In addition, differences in physicochemical properties of cellular membranes have been demonstrated between *ad libitum* and restricted-fed rats; membrane viscosity of splenic lymphocytes and β-adrenergic receptor density were greater in rats with restricted food intake compared to rats fed *ad libitum* (32).

Our results cannot be directly compared with these studies because the manner in which the restricted feeding paradigm was implemented differed. Our study used an every-other-day feeding regimen because our previous work had shown an increased mortality in mice fed high fat diets on an *ad libitum* basis (Cinader, B., unpublished data). Although Pieri (32) restricted animals by feeding on alternate days, the diets contained only 6% (wt/wt) dietary fat, whereas the TAL and SBO diets used in this study contained 20% (wt/wt) dietary fat. In contrast, Tacconi *et al.* (34) food restricted their rats by diluting the energy density of diets with dietary fiber. The degree to which the differences in feeding regimens may account for differences in the results is unknown.

The effect of diet and age on the amounts of phospholipid n-3 fatty acids in electrically active tissues is of interest because of their abundance in these tissues and because they are desaturation and elongation products of 18:3n-3, an essential fatty acid. Rotstein *et al.* (11) described levels of 22:6n-3 in retina from rats 2–3 and 26–27 months old. They reported a decline with age in PC and PS 22:6n-3, as well as very long-chain polyenoic fatty acids (11). Moreover, they noted that there was no compensation by shorter chain PUFAs for this decrease, suggesting that an overall diminution in membrane fluidity occurred consequent to alterations in fatty acid composition. Neural data for young and old mice fed diets with different fatty acid composition during the final eight weeks of life revealed an age-related decrease in PE, PC and PS 22:6n-3, as well as an effect of age on the unsaturation index for each of these phospholipids. However, the effect of age on the unsaturation index was dependent on dietary fat treatment in all phospholipids except PC. These results suggest that an overall decrease in membrane fluidity occurs with aging, but the effect may be mitigated by the type of dietary fat.

The functional importance of such changes in membrane fatty acid composition has not been resolved. Developmental studies have shown that a decrease in n-3 fatty acids in retinal membrane is coincident with visual impairment in both rats and monkeys (6,7); however, a definitive link between visual function and retinal membrane composition has not been established (7,35). Studies with post-weanling animals have associated changes in dietary fat composition with a wide range of behaviors, including cognition (15,16), temperature regulation (36), pain sensitivity (36) and feeding behavior (14,17). Although differences in neural fatty acid composition have been shown to occur in a time-frame consistent with the appearance of differences in feeding behavior (17), subsequent studies failed to demonstrate causality (37). Thus, the functional significance of differences in neuronal fatty acids composition of the magnitude described is tentative as definitive mechanisms linking the biochemical and physicochemical changes with alterations in behavior have been elusive.

In summary, electrically active tissues are responsive to differences in dietary fat composition even when the treatment is implemented well beyond developmental or post-weanling stages. However, young and old mice presented with identical changes in dietary fat do not respond in the same manner due to significant diet by age interactions. Consequently, differences in fatty acid profiles previously reported in post-weanling animals may not be predictive of the magnitude or direction of change when similar dietary fat regimens are implemented with aged animals. In contrast, data from animals that consumed their respective diets from weanling to senescence indicate that electrically active tissues are more refractory to diet, suggesting that the effect of the dietary treatment is mitigated by aging.

Central Nervous System Demyelinating Diseases and Increased Release of Cholesterol into the Urinary System of Rats

Harold J. Nicholas[a,*] and **John Taylor**[b]

[a]The Edward A. Doisy Department of Biochemistry and Molecular Biology and the [b]Department of Anatomy, St. Louis University School of Medicine, St. Louis, Missouri 63104

The question of what happens to cholesterol in the adult central nervous system during its slow turnover has been addressed using rats with brain and spinal cord labeled with [4-^{14}C]cholesterol upon intracerebral injection of labeled cholesterol into rats at 10–12 days of age. At six months after injection, ^{14}C was found only in the brain and spinal cord and was slowly released *via* the rat's urine. When labeled rats were given demyelinating agents (triethyl tin chloride, hexachlorophene, sodium cyanide) and when experimental allergic encephalomyelitis was induced, a measurable increase in urinary ^{14}C label above control levels was found. It was concluded that there is a direct relationship between the experimental demyelination induced and the increased release of cholesterol metabolites into urine. The study suggests that a clinical method could be developed to determine the rate of central nervous system demyelination by measuring the amount of urinary cholesterol metabolites.

***Lipids* 29, 611–617 (1994).**

We earlier reported (1) that when [4-^{14}C]cholesterol was injected intracerebrally (IC) into immature rats, ^{14}C was excreted through the urine throughout the rats' life span. Additional evidence is now presented which indicates that six months after injection of labeled cholesterol, rats excrete ^{14}C derived from their brain and spinal cord, and it is surmised that this excretion reflects the slow turnover of cholesterol in the central nervous system (CNS), and specifically in myelin. The main purpose of the present investigation was to determine whether demyelinating agents would influence the urinary excretion of ^{14}C label derived from cholesterol. Therefore, mature labeled rats (at least six months of age) were given triethyl tin chloride [TET(Cl)], hexachlorophene (HCP) or sodium cyanide. In addition, experimental allergic encephalomyelitis (EAE) was induced in similarly prepared rats, and the ^{14}C urinary content was measured daily.

The specificity of CNS demyelination induced in young rats by oral feeding of triethyl tin sulfate makes it an appropriate tool for study of toxin-induced demyelination (2,3). Administration of small amounts of triethyl tin sulfate (5–10 mg/L) into the drinking water of rats causes a devastating loss of myelin in CNS. The demyelination occurs in the presence of severe edema and without intervention of macrophage activity (3,4).

Abbreviations: CNS, central nervous system; EAE, experimental allergic encephalomyelitis; HCP, hexachlorophene; IC, intracerebral; TET(Cl), triethyl tin chloride.

In our studies we used TET(Cl) on the assumption that tin and not the associated ion was the critical agent. Since use of TET(Cl) has not been reported in the literature, the pathological effects of this tin salt were studied by light and electron microscopy. HCP administered to rats in their food is also known to induce CNS (5) and peripheral nerve (6) demyelination. Likewise, subcutaneously injected cyanide produces demyelinated lesions in the CNS (7). In addition to these studies, it seemed a reasonable corollary to extend them to EAE, which is considered to be a reasonable working model for certain aspects of the human disease multiple sclerosis. EAE is classified as a demyelinating disease in rodents and is characterized by a marked flaccid paralysis of the hind limbs, in the rat a decreasing tendency of the tail to curl around the examiner's finger, waddling gait, incontinence and death in the most severely affected animals (8).

MATERIALS AND METHODS

Preparation of rats and determination of urinary ^{14}C. IC injection of [4-^{14}C]cholesterol into 10- to 12-day-old Sprague-Dawley rats and collection of urine for ^{14}C determination have been described (1). The Lewis rats used in the present experiments were similarly treated. ^{14}C was determined on a Packard Tricarb Model 3320 scintillation counter (Packard Instrument Co., Downers Grove, IL) with an efficiency of 85% for ^{14}C. Samples containing 0.5 mL of urine and 10 mL of Instagel (Packard Instrument Co.) were used for measurements. [4-^{14}C]Cholesterol IC injected Lewis rats were used for the EAE studies, and Sprague-Dawley rats were used for all other experiments. All rats were subjected to demyelination experiments only when they reached six months of age or more, and all weighed 250 g or more at the beginning of the experimental period. All animals showed weight loss by the time of sacrifice. The age of the rats used to determine the distribution of ^{14}C in tissues is indicated in the appropriate tables. All rats were maintained on Purina rat chow (Ralston-Purina, St. Louis, MO) and water *ad libitum*.

Chemicals and other materials. TET(Cl) was purchased from KKK Pharmaceuticals (Plainview, NY). HCP was purchased from the Aldrich Chemical Company (Milwaukee, WI). Sodium cyanide, analytical grade, was purchased from Fisher Scientific Company (St. Louis, MO). Soluene-350 was purchased from Packard. Sprague-Dawley rats were purchased from the St. Louis University School of Medicine, and Lewis rats were purchased from Charles River Laboratories (Wilmington, ME). *Myobacterium tuberculosis* H37RA and Freund's Incomplete Adjuvant were obtained from Difco

Laboratories (Detroit, MI). Guinea pig spinal cord was obtained from locally purchased animals.

Administration of chemical demyelinating agents. TET(Cl) [$Sn(C_2H_5)_3Cl$] was presented to rats in their drinking water at 5 mg/L initially, then at 10 mg/L to accelerate the pathological process. HCP was pulverized and mixed with finely ground rat chow at a concentration of 50 mg or 100 mg/100 g of chow. The mixture was pounded into 2 × 10 cm rods and placed in troughs in metabolic cages to minimize contamination of food with urine. Sodium cyanide was subcutaneously injected into the abdomen as either 1.0 mg or 2.0 mg in 0.5 mL water.

Induction of EAE. Lewis rats age 10- to 12-d were injected IC with [4-^{14}C]cholesterol as previously described (1). Six months after labeling, the rats were placed into metabolic cages for urine collection. Prior to induction of EAE, a somewhat longer than usual control period was allowed for collection of urine. The rats were injected intradermally into both hind feet pads with a suspension of 5.0 mg (wet weight) of whole guinea pig spinal cord plus 3.0 mg of *M. tuberculosis* per mL of Incomplete Freund's Adjuvant. Each rat received a total of 0.25 mL of the mixture at six sites on the hind foot pads.

Examination of tissue for ^{14}C. CNS tissues were suspended in distilled water by homogenization in a close-fitting Teflon-glass pestle, and aliquots were taken for ^{14}C determination. Two methods were used to examine other body tissue. In the first method, the tissues were dried *in vacuo* over potassium hydroxide pellets and then ground as thoroughly as possible using a mortar and pestle (or, for larger organs, a Waring Blender). The ground tissues were then extracted overnight in a Soxhlet extractor with chloroform/ethanol (2:1, vol/vol). The volume of the extracts was reduced (nitrogen, water bath), and an aliquot (evaporated to dryness) was taken for ^{14}C determination. In the second method, the organs or tissues were blotted, weighed and macerated using a mortar and pestle. A weighed portion was dissolved in Soluene-350 (0.5N quaternary ammonium hydroxide) either by standing at room temperature or by heating on a steam bath. Aliquots of the solution (0.5 mL) were added to 10 mL Instagel and counted for ^{14}C. Soluene-350 (0.5 mL) in 10 mL Instagel served for background counts.

Light and electron microscopy. The rats, when received for these studies, were extremely lethargic or moribund. They were anesthetized intraperitoneally with a lethal dose of Diabutal (veterinary sodium barbital). Because of the need for biochemical assay of CNS tissues, it was not possible to perfuse the rats with fixative. The calvarium was opened rapidly and tissue samples were taken from the cortex, cerebellum and spinal cord. This was somewhat difficult because of the markedly edematous condition of the CNS. The tissue samples were placed in 3% glutaraldehyde in Millonig's phosphate buffer for electron microscopic studies and in 10% neutral buffered formalin for light microscopic examination. The tissue for electron microscopy was post-fixed in 1% 0.05 M osmic acid in Millonig's phosphate buffer and processed for Epon p12 embedding. Thin sections were double-stained with lead citrate and uranyl acetate. Tissue for light microscopy was embedded into paraffin and stained by the Weil technique to show myelin. The tissues from two normal Sprague-Dawley rats were compared for control.

Urinary ^{14}C excretion controls. It is difficult to distinguish on routine daily assays between urinary ^{14}C and the radioactive potassium (^{40}K) normally excreted in urine (9). Although there is no indication that ^{40}K urinary excretion is elevated during demyelinating conditions, proper controls seemed advised. Therefore, two Sprague-Dawley rats and two Lewis rats each weighing 250+ g, that were not injected with ^{14}C, were treated with the demyelinating agents. These rats were placed into metabolic cages and fed Purina rat chow *ad libitum*, and their urine was collected daily and counted for ^{14}C. Each rat showed the characteristic pathological indications anticipated for the treatment administered. As an additional control, one Sprague-Dawley rat labeled with ^{14}C was placed in a metabolic cage and given one subcutaneous injection of 0.5 mL saline in the abdomen, and urine was collected and counted for ^{14}C in the manner described.

RESULTS

Experiments with TET(Cl). The urinary ^{14}C excretion patterns of four previously injected rats that were given drinking water containing TET(Cl) are shown in Figure 1. (For comparison, the urinary excretion pattern of a control rat will later be shown in Figure 7A.) The clinical signs we observed with progressing disease were as described by Eto *et al.* (3). The rats at sacrifice were in extremely poor condition, severely emaciated and nearly comatose, with partial or complete paralysis of the hind limbs. Urine excretion was reduced, but not completely eliminated, and there was little or no fecal excretion. Light microscopic examination of CNS tissue revealed edema and vacuolation varying from slight to marked. The myelin stained tissue appeared pale in the white matter with swelling of the glial cells. This picture seemed consistent with spongy degeneration of neural tissue. Electron microscopy showed rather severe splitting at the myelin laminae, with concomitant bleeding or vacuolation of the nerve fibers as well as marked edema and swelling of the astrocytes (light and electron microscope pictures were taken but are not shown). In short, the microscopic picture matched that observed after administration of triethyl tin sulfate (2,3). Figure 1 clearly shows a marked increase in urinary ^{14}C excretion following administration of the demyelinating chemical. (The ^{14}C excretion pattern for a control rat will be shown in Fig. 7A.) As can be noted from Figure 1A, the average daily total counts per minute (cpm) for the two peaks for days 37–46 is 1,090, as compared to the average daily total cpm for days 2–36 of 475 cpm. This represents an increase of 56%. Similarly, in Figure 1C the average daily total cpm of the two peaks for days 37–46 is 1,188 as opposed to the average for days 1–36 of 447, an increase of 62%. If one considers the peaks for days 43–46 (6,879 cpm), the increase amounts to 81%.

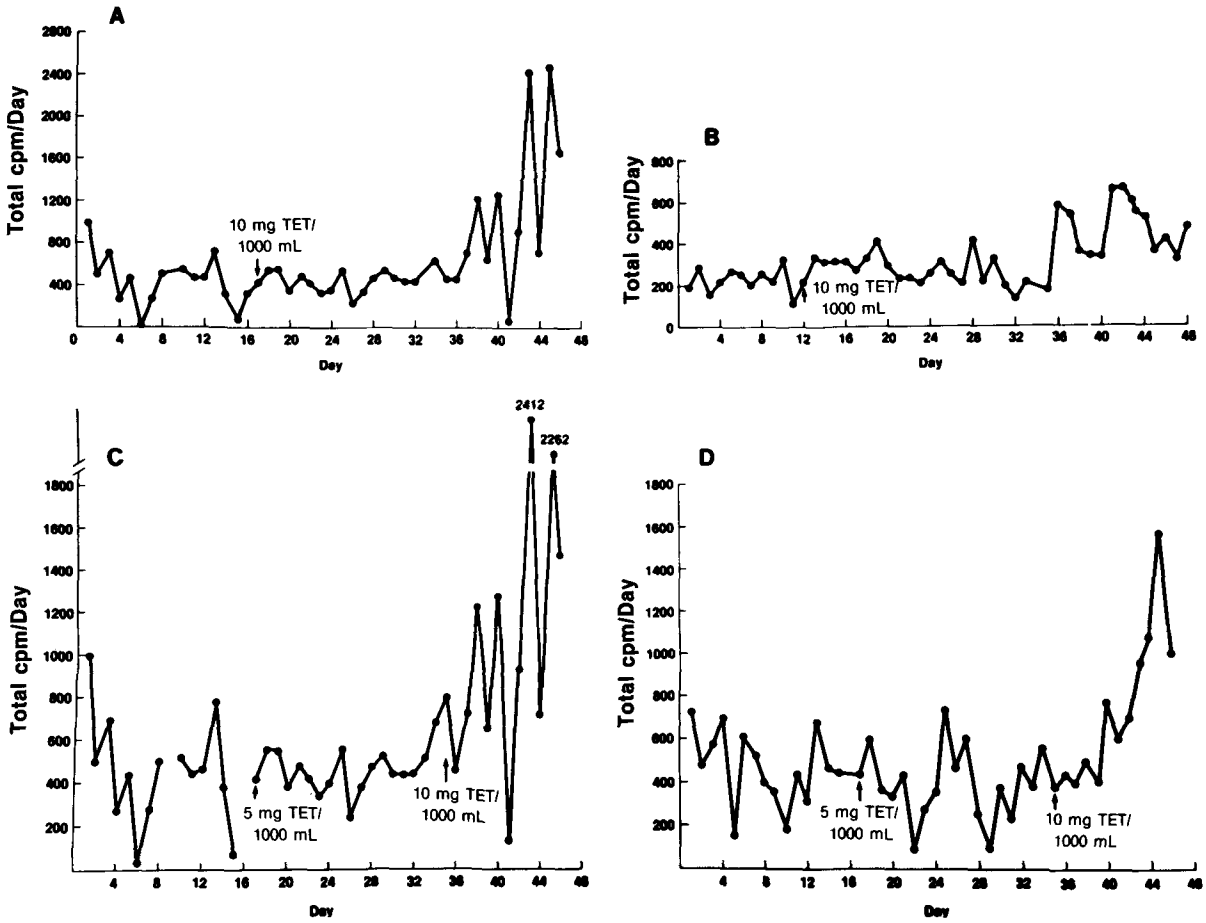

FIG. 1. ^{14}C Urinary excretion pattern of four adult rats each given 5 μCi of [4-^{14}C]cholesterol intracerebrally one year previously, and receiving triethyl tin (TET) chloride in their drinking water as indicated; cpm, counts per minute.

Experiments with HCP. Two rats with CNS prelabeled with [4-^{14}C]cholesterol were given HCP mixed with their chow in the amount of 5 or 10 mg per 100 g of chow. These rats responded as expected (6) with characteristic symptoms (weight loss, general weakness, partial paralysis of the hind limbs). The urinary ^{14}C excretion patterns of the two experimental rats are shown in Figure 2. (For comparison, the urinary excretion pattern of a control rat will be shown later in Fig. 7C.) The excretion pattern for the rat shown in Figure 2B is probably the weak link of all the groups. We suggest, in retrospect, that this is due to the fact that a longer "control period" should have been used, and that less demyelinating agent was taken in by the rat due to the method of administration [eating as opposed to drinking as in the case of the TET(Cl)-treated rats]. Nevertheless, the peak shown for days 22–31 constitutes a 27% increase in ^{14}C urinary excretion over the entire previous period (days 2–21).

Experiments with sodium cyanide. The effects of subcutaneously injected sodium cyanide were investigated using two rats with their CNS prelabeled with [4-^{14}C]-cholesterol. These rats exhibited the characteristic physical responses reported in the literature (7) and showed increased urinary ^{14}C excretion as shown in Figure 3. A massive release of ^{14}C into the urine, beginning several days after injection of NaCN, is apparent. This excretion continued for at least two weeks after administration of NaCN had ceased, subsequently diminished, but did not return to normal levels. Since these rats did not appear to be in pain, the injections were reinstated at 2 mg per day. Several days later there was another marked increase in ^{14}C excretion, and the rats were sacrificed upon showing severe symptoms characteristic of cyanide injection. (The urinary excretion pattern of one control rat is depicted in Fig. 7B.)

Experiments involving induction of EAE. Four Lewis rats with CNS cholesterol labeled with ^{14}C and in which EAE had been induced showed characteristic microscopic lesions in multiple sections of the brain and spinal cord. In addition, all exhibited the extreme hind leg paralysis associated with the disease. The urinary ^{14}C excretion patterns of these rats are shown in Figure 4. In each case a marked increase in ^{14}C excretion was observed following the induction of EAE, analogous to that following the administration of the chemical demyelinating agents previously discussed. The excretion of a control EAE rat will be shown in Figure 7D.)

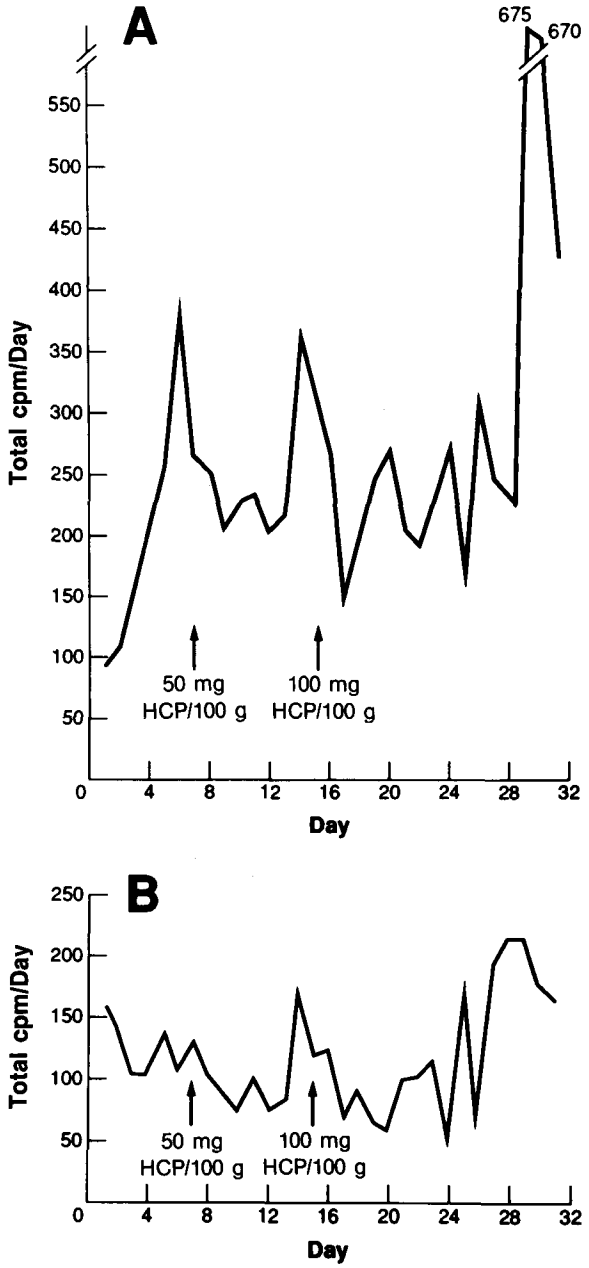

FIG. 2. ^{14}C Urinary excretion pattern of two adult rats given 5 µCi of [4-^{14}C]cholesterol one year previously and hexachlorophene (HCP) in their chow as indicated; cpm, counts per minute.

Distribution of ^{14}C in rats injected IC with [4-^{14}C]cholesterol. The distribution of ^{14}C in CNS subcellular fractions of adult rats injected IC with [4-^{14}C]cholesterol at 10 d of age was reported in an earlier paper (1). Most of the ^{14}C (87%) was associated with myelin. All rats in the current study exhibited approximately the same subcellular distribution of ^{14}C in brain and spinal cord (data not shown). For the present studies and for future work, it seems of interest to present data also showing the distribution of ^{14}C in the total rat.

TABLE 1

Distribution of ^{14}C Label in Central Nervous System (CNS) Sections of an Adult Rat After Intracerebral Injection of [4-^{14}C]Cholesterol (at 12 d of age)

CNS section	Total dpm per region[a]	dpm/mg
Right cerebrum	263,700	1,290
Left cerebrum	292,200	1,328
Cerebellum	152,900	725
Medulla	234,300	1,143
Spinal cord[b]	60,000	517

[a]Measured by suspension of whole region in water with a close-fitting Teflon-glass hand homogenizer from which a 0.5-mL aliquot was taken for ^{14}C determination.
[b]Represents only 0.116 g of upper spinal cord.

Although the initial injections of ^{14}C were into one cerebral hemisphere, the ^{14}C permeated the CNS (see Table 1). Two months after IC injection of [4-^{14}C]cholesterol, there was still a considerable amount of ^{14}C in the major organs (Table 2). However, six months after IC injection, only the intestine and liver (other than the CNS) showed evidence of ^{14}C, and this only in traces (Table 2). Two years after IC injection, no ^{14}C was detected in any organ tissue except the CNS (also Table 2). The trace

[b]Data taken from one of two rats injected intracerebrally with 5 µCi of [4-^{14}C]cholesterol at 12 d of age.
[c]Work-up of tissues for ^{14}C determination given in Materials and Methods section (Soluene-350 method).
[d]Determined after chloroform/methanol (2:1, vol/vol) extraction. See Materials and Methods section for details.
[e]Results believed to be due to residual central nervous system tissue not removed from spinal cord and skull.
[f]Five-mL sample taken at time of sacrifice.

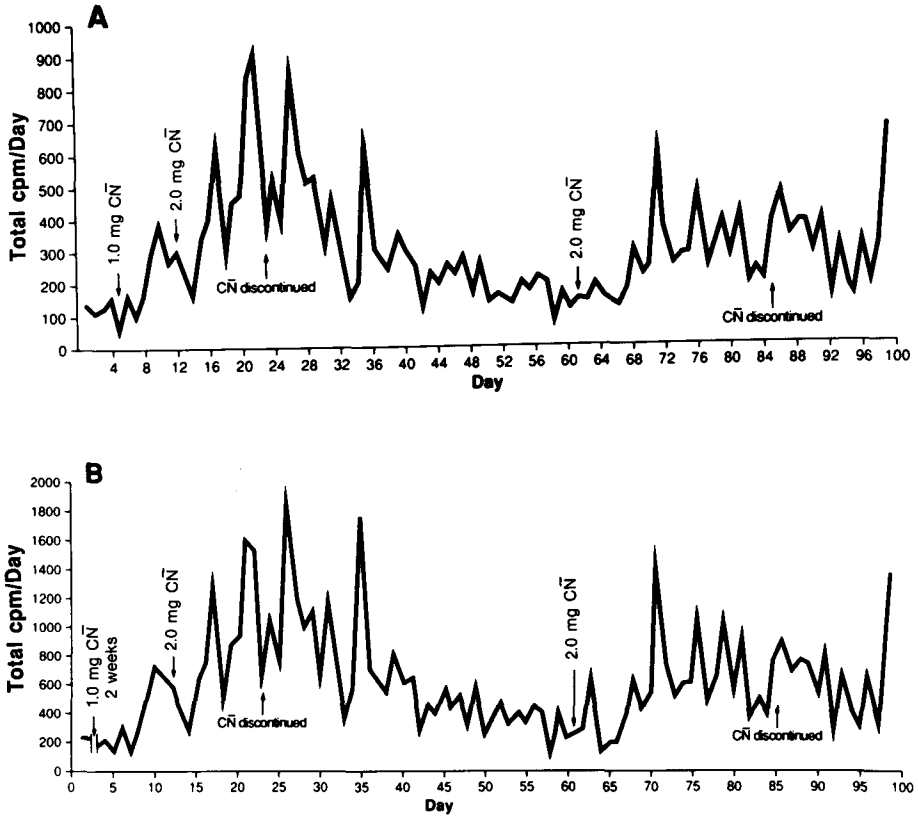

FIG. 3. ^{14}C Urinary excretion pattern of two adult rats given 5 μCi of [4-^{14}C]cholesterol intracerebrally one year previously and sodium cyanide (CN̄) subcutaneously as indicated. Despite the remarkable similarity of the two patterns, the data are from two different rats (e.g., see ordinate values); cpm, counts per minute.

amount detected in the carcass was negligible. The absence of ^{14}C in the kidney six months after injection illustrates the transient role of this organ in the excretory process. Therefore, from the data shown, it is apparent that the urinary ^{14}C measured must have come from the CNS, at least initially.

The effect of starvation and subcutaneous injection on the urinary excretion of ^{14}C. As the work progressed, the question arose as to whether other experimental conditions might influence the excretion of urinary ^{14}C. While we could not cover every contingency, two were considered for this study. For example, we wondered whether the single subcutaneous injection as used in the cyanide experiments might have an effect. Figure 5 suggests that it does not, since there was no change in urinary ^{14}C level after subcutaneous injection of 0.5 mL of saline. This also serves as an additional baseline control. More critical, however, was the potential effect of lowered food intake common to all of the animals in these experiments, resulting in measurable weight loss. The effect of starvation, which is readily reproducible, is shown for one rat in Figure 6. Instead of an increase in urinary ^{14}C excretion, there was an immediate drop. Whether this is in response to the CNS or the kidneys (or both) is presently not known.

Controls and ^{14}C baselines. Controls for each demyelinating experiment, using nonlabeled rats, are shown in Figure 7. There was no increase in urinary ^{14}C under any of the demyelinating conditions tested. It should be noted that the baselines for all of these controls are considerably lower than that seen for the rats with ^{14}C-labeled brain and spinal cord. This is because the nonlabeled rats excreted only ^{40}K. Urinary ^{14}C excretion in labeled rats is characterized by peaks even in the pretreatment periods and is markedly increased in the experimental periods. This suggests some rhythmic type of excretion, the significance of which is unknown at this time.

DISCUSSION

A large number of chemicals are known to be toxic to the CNS by causing demyelination (10). Of these we chose three for the present study because they are easily administered to animals *via* diet or by injection. EAE was chosen because of its analogy to multiple sclerosis.

Although a small amount of ^{14}C is eliminated from the CNS *via* the biliary route (Nicholas, H.P., Elliott, W.H., and Hsu, F., manuscript in preparation), the major route of excretion from brain and spinal cord, as determined by our tracer studies, is the urinary route.

There are several important points that can be made based on our studies. First, a large increase in urinary cholesterol metabolites results when CNS demyelina-

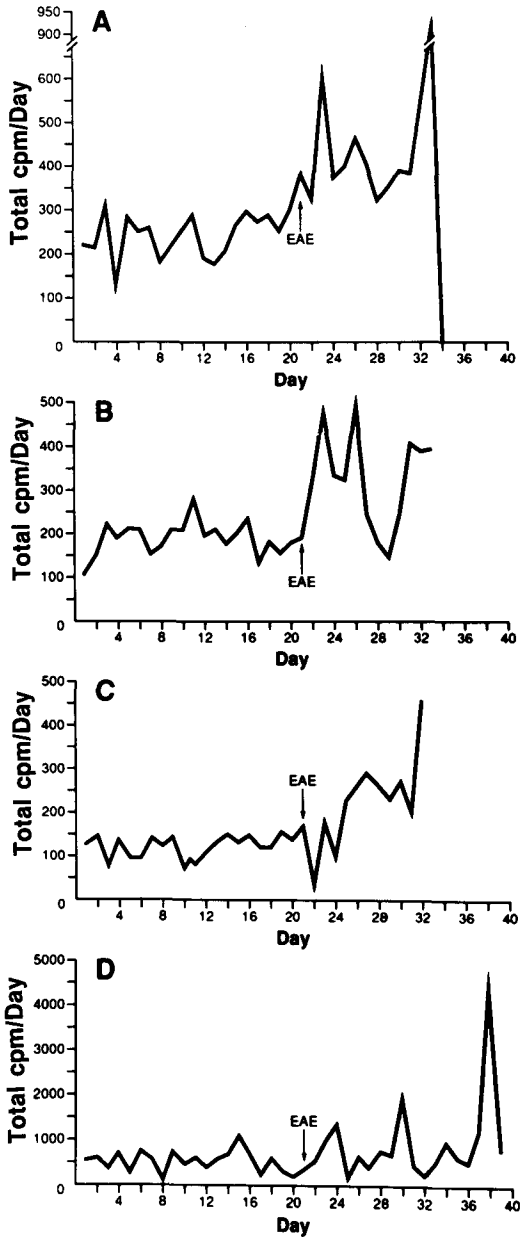

FIG. 4. ^{14}C Urinary excretion pattern of four adult rats given 5 µCi of [4-^{14}C]cholesterol intracerebrally one year previously and experimental allergic encephalomyelitis (EAE) as indicated. The arrows shown indicate the day they were injected intradermally in both hind feet pads with whole guinea pig spinal cord plus *Myobacterium tuberculosis* in Incomplete Freund's Adjuvant; cpm, counts per minute.

FIG. 5. ^{14}C Urinary excretion pattern of an adult rat given 5 µCi of [4-^{14}C]cholesterol intracerebrally one year previously and a single subcutaneous injection of 0.5 mL saline in the abdomen as indicated; cpm, counts per minute.

FIG. 6. ^{14}C Urinary excretion pattern of an adult rat given 5 µCi of [4-^{14}C]cholesterol intracerebrally one year previously, with food removed as indicated; cpm, counts per minute.

tion occurs. Therefore, this reflects the degree of CNS demyelination and can probably be determined quantitatively by chemical means in nonlabeled species (e.g., humans). Secondly, the metabolites, if formed within the CNS, could have considerable physiological (or pathological) significance because they are excreted in greater quantity under demyelinating conditions. One of these constituents is an acidic steroid that could by itself be responsible for demyelination (11–13).

One group of urinary metabolites has been described (1). A second group of the same type, but differing in solubility and polarity, has been identified (manuscript in preparation). The precise nature of the metabolites may differ with the demyelinating agent. Additional studies are necessary to determine this.

ACKNOWLEDGMENTS

The authors wish to thank Ralph Abernathy for care and treatment of the rats used in this work. Many useful comments on the induction of EAE were received from Dr. Marion E. Smith of the Veterans Administration Medical Center (Palo Alto, CA).

Dietary Lipids Modify the Fatty Acid Composition of Cartilage, Isolated Chondrocytes and Matrix Vesicles

Hui Xu[a], **Bruce A. Watkins**[a,*] and **Huston D. Adkisson**[b]

[a]Department of Food Science, Lipid Chemistry and Metabolism Laboratory, Purdue University, West Lafayette, Indiana 47907 and [b]Division of Rheumatology, Washington University School of Medicine, St. Louis, Missouri 63110

The effects of dietary lipids on the fatty acid composition of hyaline cartilage, epiphyseal chondrocytes (EC) and matrix vesicles (MV) were evaluated in chicks. A basal semipurified diet was fed to chicks containing one of the following lipid sources at 70 g/kg: soybean oil, butter + corn oil, margarine + corn oil or menhaden oil + corn oil (MEC). Articular and epiphyseal growth cartilage were isolated from the proximal tibiotarsus; EC and MV were subsequently released by trypsin (EC 3.4.21.4) and collagenase (EC 3.4.24.3) digestion followed by ultracentrifugation. The fatty acid composition of polar lipids in chick epiphyseal cartilage at three and six weeks, as well as articular cartilage, EC and MV at eight weeks of age revealed the presence of high levels of saturated and monounsaturated fatty acids (up to 85.5%) but low levels of n-6 polyunsaturated fatty acids (PUFA) (2.6–10.2%). Mead acid (20:3n-9, >3%) was also present in cartilage, EC and MV lipids, and was unaffected by the dietary lipid treatments. Total n-3 PUFA concentrations were the highest in cartilage, EC and MV of chicks consuming MEC. Feeding MEC lowered the levels of 20:4n-6 in cartilage, but increased 20:5n-3 levels. The data are consistent with those reported previously which showed that cartilage tissues are low in n-6 PUFA and that they contain 20:3n-9. We furthermore demonstrated that the PUFA composition of cartilage can be modified by dietary lipids.
***Lipids 29,* 619–625 (1994).**

Matrix vesicles (MV) are believed to be responsible for initiating *de novo* mineralization in most calcifying tissues (1). The membrane-bound acidic phospholipids located within the MV structure facilitate mineralization by forming lipid–Ca^{2+}–protein complexes (2). High alkaline phosphatase (AP) activity is present in isolated MV (3), and this activity is much higher than that found in chondrocytes.

Peress *et al.* (4) first studied the lipid composition of the MV fraction isolated from epiphyseal cartilage of fetal calves. Wuthier (5) then reported the fatty acid composition of lipids of epiphyseal chondrocytes (EC) and MV obtained from chicken growth plate cartilage. Polyunsaturated fatty acids (PUFA) are structurally and physiologically important for mineralizing tissues in bone and for locally regulating bone modeling. Fatty acids serve as precursors for the synthesis of the phospholipids present in MV, and PUFA also serve as substrates for prostaglandin (PG) E_2 biosynthesis. PGE_2 produced in bone tissue acts as a potent bone resorbing agent and appears to regulate the activity of cytokines and growth factors in bone (6). Recently, Adkisson *et al.* (7) discovered high concentrations of 20:3n-9 and low concentrations of n-6 PUFA in normal cartilage tissues of several vertebrates, including in humans and in chicken. However, the impact of dietary lipids on bone, cartilage and MV function and metabolism is presently unknown, even though it is well established that dietary lipids can modulate n-6 and n-3 PUFA levels in *Aves* (8).

In the present study, various dietary lipids varying in PUFA composition were evaluated in chicks to determine their effects on the fatty acid composition of cartilage, EC and MV. A basal semipurified diet which contained varying amounts of n-6 or n-3 PUFA, saturated fatty acids or *trans*-18:1 fatty acids was fed to chicks.

MATERIALS AND METHODS

Animals and diets. One-day-old Hubbard Cockerel broiler chicks obtained from a commercial hatchery were fed a semipurified diet (Table 1) formulated to meet all of the nutrient requirements for chick growth (9). One of four dietary lipid treatments were given at 70 g/kg of diet: soybean oil (SBO) (Bunge Foods Inc., Bradley, IL), butter (75%) + corn oil (25%) (BC), margarine (80%) + corn oil (20%) (MAC) or menhaden oil (57%) + corn oil (43%) (MEC). Menhaden oil was donated by Zapata Haynie Co. (Reedville, VA); butter (Weaver Brothers Inc., Roanoke, IN), margarine (Scot Lad Foods Inc., Pewaukee, WI) and corn oil (Best Foods, CPC International Inc., Englewood Cliffs, NJ) were purchased locally. Corn oil was added to all lipid treatments (except SBO) to supplement linoleic acid. Each diet was given to four replicate pens of ten chicks. Diets and water were provided *ad libitum.*

Collection of cartilage and isolation of chondrocytes and MVs. Three-, six- and eight-week-old chicks were killed by exsanguination. Tibiotarsal bones with intact articular and epiphyseal cartilage and liver were collected, chilled on ice, and stored at –20°C. EC and MV from epiphyseal cartilage were isolated immediately after collecting tibiotarsal bones from eight-week-old chickens following the method described by Genge *et al.* (10). Briefly, the growth cartilage tissues were finely sliced (0.1–0.3-mm thick) and digested in ice-cold, synthetic cartilage lymph (SCL), as described by Majeska and Wuthier (11), containing 0.1% trypsin (EC 3.4.21.4; 4 mL/g tissue; Sigma Chemical Co., St. Louis, MO) at 37°C for 15 min. After removing the trypsin buffer, cartilage tissues were digested in SCL buffer containing crude collagenase (EC 3.4.24.3; 500 units/g tissue; Sigma) at 37°C for 5 h with shaking. The

[a]The semipurified basal diet contained (g/kg): isolated soybean protein, 250; corn starch, 283.75; dextrose, 283.75; lipid, 70; cellulose, 30; $CaHPO_4 \cdot 2H_2O$, 25; $CaCO_3$, 15; DL-methionine, 7.5; mineral premix, 30; vitamin premix, 5. The diet was formulated to contain 22.5% crude protein and 3557 kcal/kg metabolizable energy. The analyzed crude protein was 23.5%, and lipid content was 6.5–7.8% for the four dietary treatments. SBO, soybean oil diet; BC, butter + corn oil diet; MAC, margarine + corn oil diet; MEC, menhaden oil + corn oil diet; SAT, saturated fatty acids; MONO, monounsaturated fatty acids; PUFA, polyunsaturated fatty acids.

[b]Mineral premix provided (mg/kg diet): ZnO, 90; $MgSO_4 \cdot 7H_2O$, 6000; $MnSO_4 \cdot H_2O$, 300; $CuSO_4 \cdot 5H_2O$, 60; $FeSO_4 \cdot 7H_2O$, 500; KIO_3, 6; $Na_2MoO_4 \cdot 2H_2O$, 10; $CoCl_2 \cdot 6H_2O$, 5; Na_2O_3Se, 0.43; KCl, 1500; K_2HPO_4, 6000; NaCl, 6000.

[c]Vitamin premix provided per kg of diet: vitamin A palmitate, 4500 IU; cholecalciferol, 4500 ICU; menadione sodium bisulfite, 1.5 mg; DL-α-tocopherol, 50 IU; thiamine hydrochloride, 15 mg; riboflavin, 15 mg; sodium pantothenate, 50 mg; niacin, 50 mg; pyridoxine hydrochloride, 6 mg; folic acid, 6 mg; cyanocobalamin, 0.02 mg; *d*-biotin, 0.3 mg; choline chloride, 600 mg; butylated hydroxytoluene, 200 mg.

[d]ND, not detected.

digest was gently vortexed for 3 min to release unbound chondrocytes and then filtered through nylon mesh to remove debris. The filtrate was centrifuged at 250 × *g* for 20 min, and the pellet containing the chondrocyte fraction was resuspended with *N*-tris(hydroxymethyl)-methyl-2-aminoethanesulfonic acid (TES) buffer (50 mM TES, 1.4 mM $MgCl_2$, 10% sucrose, pH 7.5). The supernatant was centrifuged at 13,000 × *g* for 30 min to remove the membrane fragments and mitochondria, and then at 100,000 × *g* for 60 min to sediment the MV. The MV pellet was resuspended in TES buffer.

Total protein measurement. Total protein was determined using a protein assay kit (purchased from Sigma, P 5656) which is based on the method of Lowry *et al.* (12).

AP assay. AP activity in EC and MV was measured as described by Tietz *et al.* (13). *p*-Nitrophenyl phosphate (USB Co., Cleveland, OH) was used as substrate to assay AP activity. AP specific activity was defined as μmol of *p*-nitrophenyl phosphate hydrolyzed/mg protein/min.

Fatty acid analysis. Lipids in the diet, in liver, in tibiotarsal articular and epiphyseal cartilages, as well as in EC and MV were extracted with chloroform/methanol (2:1, vol/vol). The polar lipids from liver and cartilage were isolated by solid-phase extraction (14). Lipids (except from articular cartilage) were saponified, and fatty acid methyl esters (FAME) prepared using 14% boron trifluoride in methanol (Alltech Associates Inc., Deerfield, IL). FAME were analyzed using a gas chromatograph (HP 5890 series II, autosampler 7673, HP 3365 ChemStation; Hewlett-Packard Co., Avondale, PA) which was equipped with a DB 23 column (length 30 m, i.d. 0.53 mm, film thickness 0.5 μm; J&W Scientific Co., Folsom, CA) and was operated at 170°C for 10 min, with the temperature programmed 1°C/min to 210°C and held for 5 min. The injector and flame-ionization detector temperatures were 225 and 250°C, respectively. FAME were identified by comparison of their retention times with those of standards (GLC 422, Nu-Chek-Prep, Elysian, MN) and of FAME prepared from menhaden oil (18:4n-3 and 20:5n-3). Fatty acid compositions are given as weight or area percentages. *Cis* and *trans* 18:1 FAME were quantified after separation on silver-nitrate impregnated thin-layer chromatography (TLC) plates followed by capillary gas–liquid chromatography (GLC) (15). Mead acid was isolated in the triene band by argentation TLC (16), recovered, and quantified by capillary GLC. The polar lipids of articular cartilage were saponified (10% KOH in methanol), and fatty acid pentafluorobenzyl esters were prepared (17) and quantified by capillary GLC (SP-2380, length 30 m, i.d. 0.32 mm, film thickness 0.20 μm; Supelco, Inc., Bellefonte, PA). The gas chromatograph (HP Model 5890) was held at 160°C for 2 min, temperature programmed at 10°C/min to 200°C, and then held for 10 min. Both injector and electrochemical detector temperatures were set at 225°C.

Statistical analysis. Data were subjected to analysis of variance, and where significant differences were found a Duncan's multiple range test at a probability of $P < 0.05$ was performed (18). Variation within treatments is expressed as the pooled standard deviation (SD) or pooled standard error of the mean (SEM).

RESULTS

Chick growth and tibiotarsal bone length were not affected by the different dietary lipid treatments. The MV were characterized by high AP activity (12 μmol/mg protein/min) as compared to the activity found in EC (0.4 μmol/mg protein/min) and confirmed by transmission electron microscopy. The AP activities in the EC and MV were not affected by the different dietary lipid treatments.

The fatty acid compositions of the tibiotarsal epiphyseal cartilage in three- and six-week-old chicks, and of EC, MV and articular cartilage in eight-week-old chicks showed that in polar lipids the total saturated and monounsaturated fatty acids were high (>80%) and the total n-6 PUFA were very low (<10.2%). The 18:1 peak seen in GLC represented primarily *c*18:1n-9 and *c*18:1n-7.

The fatty acid compositions of polar and neutral lipids of epiphyseal cartilage of chicks were affected by the lipids fed (Tables 2 and 3). Chicks consuming the MEC diet had the highest amounts of total n-3 PUFA and the highest n-3/n-6 PUFA ratios in polar and neutral lipids at three and six weeks of age. The amounts of 20:5n-3, 22:5n-3 and 22:6n-3 in polar and neutral lipids of epiphyseal cartilage seemed to increase from three to six weeks in chicks fed MEC as compared with chicks fed the other diets. At six weeks, chicks given MEC had the lowest levels of 20:4n-6 and 22:4n-6 in their polar lipids (Table 3). The amounts of 14:0, 16:0 and 18:1 were higher in polar lipids of epiphyseal cartilage of chicks consuming BC compared to the values obtained from chicks given SBO. The amounts of 18:0 were highest in the neutral lipids of cartilage of chicks fed BC at three weeks, and the total amounts of stearic acid in cartilage decreased from three to six weeks independent of the dietary treatment. At six weeks, the total amounts of PUFA (n-6 and n-3) were lowest in cartilage neutral lipids of chicks fed BC, reflecting the fatty acid composition of the BC diet (Table 3).

When cartilage lipids were analyzed by GLC, a major peak was observed having a retention time identical to that of 20:2n-6. Further characterization by TLC followed by GLC of the diene and triene bands revealed that 20:3n-9 greatly exceeded the amount of 20:2n-6 present in this location. As the components co-eluted, we report here the combined value. The amount of 20:3n-9 in cartilage polar lipids decreased between three and six weeks in all chicks. Neutral lipids of cartilage contained 20:2n-6 and 20:3n-9, but the amounts were higher in chicks at six weeks (Table 3).

The amounts of saturated fatty acids and n-6 PUFA (mainly linoleate) appeared to increase in cartilage lipids

[a,b,c]Mean values (n = 4) within rows having different superscripts are significantly different ($P < 0.05$).
[d]ND, not detected; for other abbreviations, see Table 1.
[e]Includes 20:2n-6 and 20:3n-9 (Mead acid).

in chicks between three and six weeks. The amount of 18:2n-6 in cartilage neutral lipids of all chicks increased nearly twofold independent of the dietary lipid treatment. Chicks fed BC, which was lowest in 18:2n-6, had the lowest n-6 PUFA levels in neutral lipids (Table 3).

The concentrations of 20:5n-3, 22:5n-3 and total n-3 PUFA, and the n-3/n-6 PUFA ratios were greatest in EC and MV of chicks fed MEC as compared to the values seen for chicks fed the other dietary lipids (Table 4). Chicks fed MEC had a lower concentration of 20:4n-6 and total n-6 PUFA in EC. The MV from chicks fed MEC maintained the lowest amounts of 18:2n-6, and the amounts of 20:4n-6 in MV were lower than for chicks given SBO. Consistent with what was seen for the polar lipids in epiphyseal cartilage of six-week-old chicks (Table 3), the predominant saturated fatty acid in EC and MV was 16:0, followed by 18:0. Appreciable amounts (3%) of 20:3n-9 were also found in cartilage, EC and MV. The Mead acid concentrations in epiphyseal cartilage, EC and MV were unaffected by the dietary lipid treatments.

The articular cartilage of eight-week-old chicks was dramatically affected by the levels of n-3 and n-6 PUFA present in the MEC and SBO diets, respectively (Table 5). The MEC treatment lowered the amounts of 20:4n-6, total PUFA and n-6 PUFA, but elevated the amount of n-3 PUFA (20:5n-3 and 22:6n-3) and the n-3/n-6 PUFA ratio in chick articular cartilage polar lipids. Additionally, the SBO and MEC treatments lowered 20:3n-9 to less than 3% of the total fatty acids. The concentration of 18:2n-6 was greatest in the polar lipids of articular cartilage in chicks fed SBO, reflecting the composition of soybean oil. Interestingly, the 18:2n-6 increase did not result in a parallel increase in 20:4n-6.

Although a considerable amount of *trans*-18:1 fatty acids was present in the MAC diet (14.85% of *t*18:1) (Table 1), and *trans*-18:1 was found in the growth carti-

lage of three-week-old chicks (1.5% of total FAME) fed MAC, no *trans*-18:1 was detected in the EC and MV of these chicks. Also, no *trans*-18:1 was found in growth cartilage of three-week-old chicks that consumed the BC diet (2.19% dietary *t*18:1).

Figure 1 illustrates the changes in the concentrations of n-3 and n-6 PUFA in liver polar lipids of chicks at three and six weeks of age. The values for fatty acids are presented as standardized differences (STD) based on statistical analysis (number of standard error of the mean units). The STD for n-3 and n-6 PUFA show that chicks fed MEC had lower amounts of 18:2n-6 and 20:4n-6 but higher amounts of 20:5n-3 and 22:6n-3 in liver polar lipids compared to chicks given the other treatments. Changes in n-3 and n-6 PUFA concentrations in liver polar lipids were similar to those found in chick cartilage polar lipids.

DISCUSSION

AP is one of many membrane-bound enzymes found in isolated MV, and its high activity is crucial for proper MV function in mineralization (19). We observed high AP specific activity in MV as compared to EC isolated from chick tibiotarsal growth cartilage, which agrees with the literature (3). The activity of AP was not affected by the dietary lipid treatments, although short chain fatty acids have been reported to alter AP activity in certain biological membranes (20).

It was important to note that chicken cartilage tissues, chondrocytes and MVs all contained large amounts of saturated and monounsaturated fatty acids (>80%) and low levels of n-6 PUFA (<10.2%). In contrast to cartilage lipids, liver polar lipids from these chicks contained

22–41% n-6 PUFA, whereas the saturated and monounsaturated fatty acids comprised 50–60% of the total fatty acids (data not shown). The total amounts of saturated fatty acids and PUFAs in epiphyseal cartilage polar lipids, EC and MV of chicks were affected by the different dietary treatments. However, the amounts of monounsaturated fatty acids (16:1 and 18:1) were higher in polar lipids of epiphyseal cartilage of three-week-old chicks fed BC and MEC and in articular cartilage of eight-week-old chicks fed MEC.

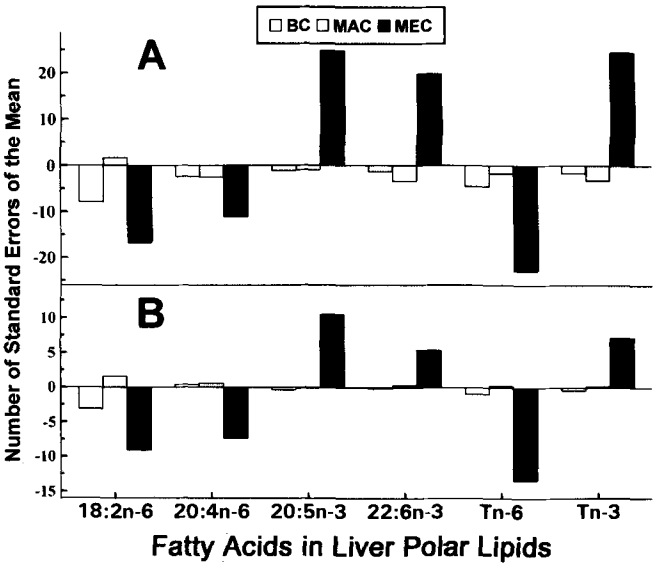

FIG. 1. Polyunsaturated fatty acids (PUFA) in liver polar lipids of chickens at three weeks of age (panel A) and six weeks of age (panel B) presented as standardized differences (STD). The STD for PUFA values were calculated as a difference in treatment mean (butter + corn oil diet; margarine + corn oil diet; or menhaden oil + corn oil diet) from the mean for soybean oil diet (SBO) divided by the pooled SEM (n = 4). An STD value of 2.5 (+ or −) is significantly different ($P < 0.05$) from the SBO treatment.

The fatty acid analyses of articular and epiphyseal cartilages, EC and MV obtained from chicks fed MEC demonstrated that dietary n-3 PUFA are readily incorporated into these tissues and accumulate in neutral lipids of growth cartilage. Interestingly, when chicks were fed a high level of dietary linoleate, 18:2n-6 accumulated in the neutral lipids of chick epiphyseal cartilage. In a study with rats, Lippiello *et al.* (21) found that a menhaden oil diet significantly decreased n-6 PUFA but elevated 20:5n-3 and 22:6n-3 concentrations in articular cartilage.

In the present study, the fatty acid composition of MV was close to that of EC, which is similar to the results reported by Wuthier (5). The low levels of n-6 PUFA in chondrocytes and MV may be related to the involvement of n-6 PUFA in PG biosynthesis in growth cartilage (7).

PGE_2 is known to participate in bone resorption and bone formation (22) and is involved in regulating the activity of cytokines and growth factors in bone (6). Some data (23,24) suggest that altered PUFA metabolism may affect bone and cartilage development by a PG dependent mechanism.

In addition to confirming the presence of Mead acid in growth cartilage, which was first described by Adkisson *et al.* (7), we now quantified high levels of Mead acid in the EC and MV cartilage fractions of chicks on all the dietary treatments.

During early bone development, rapid depletion of arachidonic acid occurs to support eicosanoid biosynthesis (24). The reduction in n-6 PUFA results in lower concentrations of 18:2n-6, which decreases the competition between 18:2n-6 and 18:1n-9 for the Δ6 desaturase and enhances Mead acid formation. Another explanation for the unusual fatty acid composition of cartilage may be that the tissue is sensitive to n-6 PUFA and eicosanoids and, thus, accumulates less n-6 PUFA. Interestingly, our data demonstrate that feeding SBO, a rich source of linoleic acid, had no effect on Mead acid concentrations in growth cartilage, EC or MV. However, we did note a general trend toward a decrease in the concentration of Mead acid in epiphyseal cartilage between three and six weeks, which was independent of the dietary treatment. This agrees well with the findings of Adkisson *et al.* (25), who reported a marked depletion in Mead acid content of phospholipids in human costal and articular cartilages as a function of aging.

Although dietary *trans*-18:1 were reported to be incorporated into liver, lung and abdominal fat pads of chicks (26), as well as into tibiotarsal growth cartilage (27), *trans*-18:1 was not detectable in EC and MV of chicks fed the *trans*-18:1 diet (MAC). Perhaps the amounts of *trans*-18:1 in MAC and BC were insufficient to cause their accumulation in EC as their levels were 14.85 and 2.19%, respectively, compared to the 44.44% used in a previous study (27).

Total n-3 PUFA levels and the n-3/n-6 ratios were the greatest in cartilage, EC and MV of chicks consuming MEC as compared to those fed SBO, BC and MAC. Feeding MEC to chicks lowered the concentrations of 20:4n-6 but increased those of 20:5n-3 and 22:6n-3 in EC and MV.

The rapid enrichment of n-3 PUFA in EC and MV isolated from growth cartilage may imply that the avascularity of cartilage may not be the main reason for the lower n-6 PUFA and higher 20:3n-9 levels as explained by Adkisson *et al.* (7). The effect of enriched n-3 PUFA on the cellular functions of EC and MV in growth cartilage tissue is not presently clear.

The data from our present experiments confirm previous reports that normal cartilage tissues are low in n-6 PUFA and contain 20:3n-9 (Mead acid), and they demonstrate that the concentration of Mead acid appears to be unaffected by the level of dietary essential fatty acids (18:2n-6 and 18:3n-3). *Trans*-18:1 fatty acids did accumulate in epiphyseal cartilage of the proximal tibiotarsus of chicks fed margarine. The data also indicate that n-3 PUFA levels can be increased in cartilage tissue and cells by a diet enriched with n-3 PUFA.

The Immunosuppressive Substance 2-Chloro-2-deoxyadenosine Modulates Lipoprotein Metabolism in a Murine Macrophage Cell Line (P388 cells)

Monika Lechleitner[a,*], Bernhard Auer[b], Udo Zilian[a], Fritz Hoppichler[a], Michael Schirmer[a], Bernhard Föger[a], Francoise Geisen[a], Josef R. Patsch[a] and Günther Konwalinka[a]

[a]Department of Internal Medicine and [b]Department of Biochemistry, University of Innsbruck, A-6020 Innsbruck, Austria

A recently developed immunosuppressive substance, 2-chloro-2-deoxyadenosine (2-CdA), was reported to inhibit monocyte functions at low concentration. Because macrophages play a key role in the formation of atherosclerotic plaques, it was of interest to study the effect of 2-CdA on cellular lipid metabolism. For this purpose we have used a macrophage cell line (P388) to perform incubation studies in the presence of acetylated low density lipoprotein (Ac-LDL) and 2-CdA. The addition of 2-CdA, in concentrations ranging from 5–20 nM, induced a dose-dependent decrease in cellular cholesterol content and in the amount of extracellular [^{14}C]oleic acid (OA) incorporated into the cholesteryl ester (CE) fraction. The effect was maximized at 20 nM 2-CdA with an 86% reduction in cholesterol esterification compared to controls ($P < 0.008$). To evaluate the mechanism of interaction of 2-CdA with cellular lipid metabolism, deoxycytidine (dCyt) and 3-methoxybenzamide (3-MOB), substances known to antagonize the effect of 2-CdA in different ways, were co-administered with 2-CdA. dCyt, a competitive inhibitor of dCyt kinase, which catalyzes phosphorylation to the active metabolite, antagonized the effects of 20 nM 2-CdA, producing significantly greater incorporation of extracellular [^{14}C]OA into the CE fraction than in the presence of 2-CdA alone ($P < 0.0086$). Co-incubation with 2-CdA and the poly-ADP-ribose synthetase inhibitor 3-MOB, which is known to render cells resistant to 2-CdA toxicity by preventing cellular nicotinamide adenine dinucleotide (NAD)- and adenosine triphosphase-depletion, also reversed the effect of 2-CdA on lipid accumulation. However, incubation of P388 cells with 20 nM 2-CdA did not result in a decrease in cellular NAD content. As 20 nM 2-CdA showed no effect on intracellular cholesterol synthesis based on measurement by 3-hydroxy-3-methylglutaryl coenzyme A reductase activity, the decrease in cellular cholesterol content and in [^{14}C]OA incorporation seems to be primarily due to an interference with Ac-LDL metabolism.

***Lipids* 29, 627–633 (1994).**

Monocyte-derived macrophages play a central role in atherogenesis and constitute the major source of foam cells in atherosclerotic lesions (1–3). Accumulation of cholesteryl esters (CE) in macrophages occurs by the uptake of modified lipoproteins *via* the scavenger receptor pathway (4–6). Several factors have been reported to modulate these receptor activities in human monocytes (3,7), peritoneal murine macrophages (4) and in macrophage cell lines (8). Bacterial endotoxin (9) and lymphocyte conditioned medium (10) were shown to inhibit scavenger receptor activities. Maturation of monocytes to macrophages (11), macrophage conditioned medium and increased plating density all enhance receptor activities (12,13). Based on these results, it has been suggested that the activity of scavenger receptors reflects macrophage differentiation and/or activation. Activation of macrophages was found to be initiated by a lymphokine, interferon γ, which is released by stimulated T-lymphocytes within the atherosclerotic lesion (14). The primed macrophage is susceptible to endotoxins and other stimulatory factors and exhibits increased phagocytotic activity (14,15).

The complex interactions between macrophage activity and the magnitude of acetylated low density lipoprotein (Ac-LDL) degradation is demonstrated by the inhibition reported of scavenger receptor expression by interferon γ (10,14), whereas interferon γ appeared to increase Ac-LDL degradation in another system (16). Dexamethasone, an agent known to depress a number of macrophage inflammatory and immune functions, augments scavenger receptor activity in human monocytes–macrophages (17).

2-Chlorodeoxyadenosine (2-CdA), a new drug with strong immunosuppressive properties (18–20), inhibits macrophage functions like phagocytosis and IL-6 release at low concentrations (20). To investigate a potential effect of 2-CdA on cellular lipid metabolism, we used the murine macrophage line P388, which is considered to be a suitable model for foam cell formation, including studies of the scavenger receptor pathway (8). 2-CdA is a 2-chloro analog of deoxyadenosine, which is resistant to degradation by adenosine deaminase (21). For its biological effects, 2-CdA requires intracellular phosphorylation by deoxycytidine (dCyt) kinase (21). The phosphorylated metabolite chlorodeoxy adenosine triphosphate (cdATP) accumulates in cells rich in this enzyme and poor in 5-nucleotidase (22). It has been suggested that the chlorodeoxyadenosine nucleotides rapidly cause DNA strand breaks in nondividing lymphocytes and monocytes, and that the free ends of DNA activate the enzyme poly(ADP-ribose) polymerase, resulting in NAD and ATP depletion of cells and, consequently, in cell death (23,24). Toxicity of 2-CdA is abolished in lymphocytes and macrophages by dCyt, which acts as a competitive inhibitor of dCyt kinase and thus prevents accumulation of chlorodeoxyadenosine nucleotides (21). The lymphocytotoxic effects of 2-CdA are also blocked by co-incubation of the cells with the ADP

Abbreviations: ACAT, acyl coenzyme A:cholesterol acyltransferase; Ac-LDL, acetylated low denstiy lipoprotein; ADP, adenosine diphosphate; AMP, adenosine–monophosphate; 2-CdA, 2-chloro-2-deoxyadenosine; cdATP, chlorodeoxy adenosine triphosphate; CE, cholesteryl ester; dCyt, deoxycytidine; EDTA, ethylenediaminetetraacetic acid; HMG–CoA, 3-hydroxy-3-methylglutaryl coenzyme A; LDL, low density lipoprotein; 3-MOB, 3-methoxybenzamide; NAD, nicotinamide adenine dinucleotide; OA, oleic acid.

ribosylation inhibitor 3-methoxybenzamide (3-MOB) (25,26).

Because 2-CdA initiates a sequence of well-defined biochemical events in monocytes that can be blocked at enzymatic sites by dCyt and 3-MOB, this drug appeared to be ideal for investigating the effects of immunosuppression on cellular lipid metabolism.

MATERIALS AND METHODS

Lipoprotein preparation. LDL was obtained from the ethylenediaminetetraacetic acid (EDTA)-anticoagulated blood of healthy donors, after overnight fasting, using zonal ultracentrifugation (27). The lipoproteins were dialyzed against saline-EDTA (0.9% NaCl, 1 mM EDTA). Ac-LDL was prepared by acetylating LDL with acetic anhydride as described by Basu *et al.* (28). LDL and Ac-LDL were stored at 4°C under nitrogen and used within one week after preparation. Protein was determined by the method of Lowry *et al.* (29).

Chlorodeoxyadenosine, dCyt and 3-MOB. Chlorodeoxyadenosine was kindly provided by E. Beutler (Scripps Clinic, La Jolla, CA). dCyt was purchased from Sigma (St. Louis, MO). Drugs were stored as dry powder at –20°C and dissolved in sterile 0.9% NaCl prior to use.

Cell lines. The murine macrophage cell line P388 (lymphoid neoplasm of DBA/2 mice treated with 3-methylcholanthrene) was obtained from the Salk Institute Cell Repository (San Diego, CA). The cell culture medium was Hepes-buffered RPMI-1640 supplemented with 1 mM glutamine, 10% heat-inactivated fetal calf serum, 100 μg/mL penicillin and 100 units/mL streptomycin. Cells were maintained in 100-mm dishes in a humidified incubator (5% CO_2) at 37°C.

Cell cultures. For the experiments, 1×10^6 cells/dish (10-mm dishes) were seeded in 1 mL complete medium in triplicate. Cell viability was greater than 90% as assessed by Trypan Blue dye exclusion. Cultures were re-fed 24 h later, when they usually had reached about 70% confluency, with 1 mL of serum-free medium containing the desired concentration of Ac-LDL (10–100 μg/mL) or 25-hydroxycholesterol (Sigma) (25 and 100 μg/mL), to which 2-CdA (5–80 nM) and/or dCyt (10^{-3}–10^{-6} M), 2-CdA and/or 3-MOB (2.5 and 5 mM) and 2-CdA and/or aminophylline (10 and 20 μM) were added, as indicated in the figures.

Time-course studies. In pre-incubation studies, 1×10^6 cells/dish were seeded in 1 mL complete medium in triplicate. After the cells had reached about 70% confluency, cultures were re-fed with complete medium (to which 2-CdA was added), and subsequently incubated for 4, 8 and 24 h. After incubation with 2-CdA, the cells were washed twice with phosphate-buffered saline and then incubated again with 1 mL serum-free medium (RPMI-1640) containing 100 μg/mL Ac-LDL.

To determine whether the 2-CdA antagonizing effect of dCyt is time-dependent, two sets of experiments were used. In one the competitive inhibitor of the 2-CdA activating enzyme dCyt kinase, dCyt and 2-CdA were added simultaneously to the confluent cell cultures in complete medium and incubated for 24 h. Cell monolayers were then washed and incubated with serum-free medium containing Ac-LDL. In the second set of experiments, dCyt was added after treatment of cell cultures with 2-CdA. The cultures were then washed with saline solution and incubated with medium containing Ac-LDL and dCyt.

Cholesterol esterification assay. [^{14}C]Oleic acid (OA) (55 mCi/mmol; Amersham, Arlington Heights, IL), was complexed with bovine serum albumin. Cells were incubated with Ac-LDL and 0.01 M albumin complexed with [^{14}C]OA. After an incubation period of 24 h, cell monolayers were washed and extracted with hexane/isopropanol (3:2, vol/vol) containing 10 μg/mL carrier cholesterol, cholesteryl oleate and [^{3}H]cholesterol to assess recovery. Labeled lipids were taken to dryness, re-dissolved in hexane and separated by thin-layer chromatography on Whatman MK-F microslides using heptane/diethyl ether/acetic acid (75:25:2, by vol) as developing solvent. Lipid fractions were visualized with iodine vapor and scraped into vials for counting (8). Cell monolayers were dissolved in 0.1N NaOH for protein determination according to Lowry *et al.* (29).

Determination of total amounts of cholesterol. Cultures were washed and extracted with hexane/isopropanol (3:2, vol/vol). After solvent removal, total cholesterol, free cholesterol and triglyceride mass were assayed using an enzymatic kit (Cholesterol CHOD-PAP, Triglycerides GPO-PAP; Boehringer Mannheim, Mannheim, Germany).

3-Hydroxy-3-methylglutaryl coenzyme A (HMG–CoA) reductase activity. The rate limiting enzyme in *de novo* cholesterol synthesis, HMG–CoA reductase, was assayed in P388 cells incubated for 24 h with or without 20 nM 2-CdA, according to the method described by Harwood *et al.* (30). HMG–CoA reductase activity in HEPG2 cells served as control in evaluating the assay.

Measurement of intracellular NAD. Cellular NAD content was determined in P388 cells 24 h after plating and subsequent incubation for 4, 8 and 24 h, either with 20 nM 2-CdA and 10^{-3} M dCyt, or alternatively with 20 nM 2-CdA and 2.5 mM 3-MOB. At above time points, samples were also assessed for cell viability. NAD content was quantified by high-performance liquid chromatography (31).

Statistical methods. Data are expressed as mean ± SD for triplicate determinations. The Mann-Whitney U test was used to evaluate differences in the lipid content of the cells treated with and without 2-CdA.

RESULTS

Influence of 2-CdA on [^{14}C]OA incorporation into the CE fraction and on cellular cholesterol and triglyceride levels. The addition of 2-CdA at various concentrations (from 5 to 80 nM) to 1×10^6 P388 cells exposed to different concentrations of Ac-LDL (10–100 μg/mL) resulted in a dose-dependent reduction of the amount of extracellular [^{14}C]OA incorporated into the CE fraction, as compared to control cultures treated with Ac-LDL alone. At 5 nM, 2-CdA caused only a slight reduction in [^{14}C]OA incorporation, but at 10 nM there was a significant decrease compared to controls ($P < 0.009$) as is shown in Figure 1. A further reduction to 86% ($P < 0.008$) was achieved at 20 nM 2-CdA; however, increasing the concentrations to 40 or

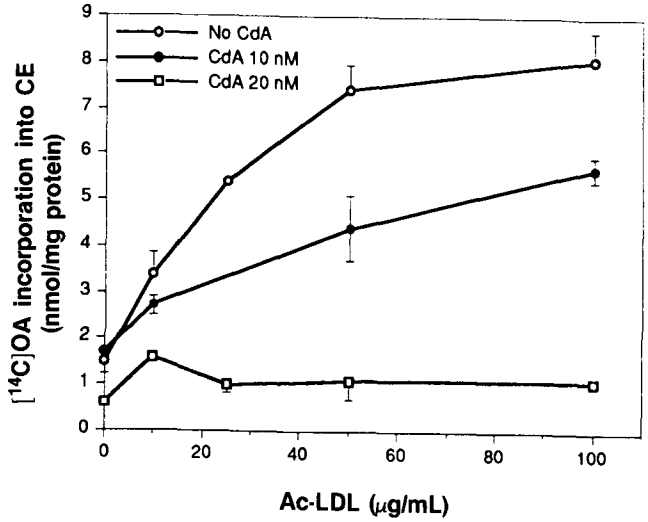

FIG. 1. Cultures grown for 24 h in complete medium were washed and re-fed with serum-free medium supplemented with acetylated low density lipoprotein (Ac-LDL) alone (10, 50 and 100 μg/mL), or Ac-LDL and 2-chloro-2-deoxyadenosine (2-CdA) (5, 10, 20 40 or 80 nM). For cholesteryl ester (CE) determination, 0.1 mM [^{14}C]oleic acid (OA) complexed with bovine serum albumin was added to the cultures. After 24 h, lipids were extracted with hexane/2-propanol (3:2, vol/vol), and the CE content was calculated as described in the Materials and Methods section.

80 nM produced no additional decrease ($P < 0.009$). By contrast, a dose-dependent decrease in total cellular cholesterol content was found with increasing 2-CdA concentrations up to 80 nM (Fig. 2). Concentrations above 80 nM 2-CdA were toxic to P388 cells (data not shown).

Cellular-free cholesterol content did not decrease significantly during 2-CdA incubation (without 2-CdA, 52 ± 9 μg/mg protein; with 2-CdA at 10 nM, 49 ± 10 μg/mg protein, $P < 0.6$; with 2-CdA at 20 nM, 41± 8 μg/mg protein, $P < 0.2$). These results indicate that the decrease in cellular total cholesterol results from a decrease in the amount of cellular CE. Incubation with 2-CdA revealed no significant effect on cellular triglyceride content (without 2-CdA, 127 ± 11 μg/mg protein; with 2-CdA at 10 nM, 115 ± 12 μg/mg protein, $P < 0.4$; with 2-CdA at 20 nM, 108 ± 9 μg/mg protein, $P < 0.07$).

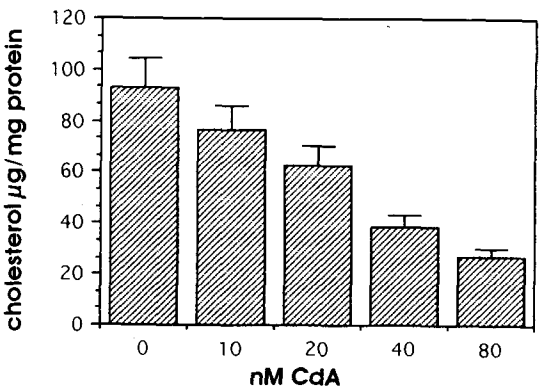

FIG. 2. Cell cultures grown for 24 h in complete medium were re-fed with serum-free medium containing 100 μg/mL Ac-LDL and 2-CdA at concentrations of 10, 20, 40 and 80 nM. After 24 h, lipids were extracted with hexane/2-propanol and the cholesterol content determined enzymatically as described in the Materials and Methods section. Abbreviations as in Figure 1.

When P388 cells were incubated with 25-hydroxycholesterol, which is known to act as a stimulus for CE synthesis by increasing acyl coenzyme A:cholesterol acyltransferase (ACAT) activity (32), the presence of 2-CdA at 20 nM had no influence on extracellular [^{14}C]OA incorporation into the CE fraction (25-hydroxycholesterol, 25 μg/mL: without 2-CdA. 2.3 ± 0.5 nmol/mg protein; with 2-CdA, 2.2 ± 0.3 nmol/mg protein, $P < 0.4$; 25-hydroxycholesterol, 100 μg/mL: without 2-CdA, 3.7 ± 0.5 nmol/mg protein; with 2-CdA, 3.5 ± 0.3 nmol/mg protein, $P < 0.3$).

Cell protein content usually varied by less than 12% within each experiment in the cell cultures exposed to 2-CdA at concentrations between 5 and 80 nM. No significant difference in cell viability was found between cultures without 2-CdA and those incubated with 2-CdA at 20 nM for 24 h (95.7 ± 1.5% and 94.0 ± 1.7% viable cells, respectively). As 20 nM 2-CdA did not affect the viability of P388 cells and produced a plateau for the reducing effect, this dose of 2-CdA was routinely used in the following experiments.

Pre-incubation studies. Previous *in vitro* studies on the effect of 2-CdA on lymphocytes and monocytes have shown that a minimal exposure of 8 h is required for initiation of a sequence of metabolic changes ultimately leading to cell death (22). We performed pre-incubation studies in order to determine the length of time cells need to be exposed to 2-CdA for the optimal effect on lipid metabolism to occur, and to exclude simple interactions of 2-CdA with Ac-LDL or the plasma membrane lipid matrix.

P388 cells were pre-incubated with 2-CdA (20 nM) for 4, 8 and 24 h for this purpose. After incubation, 2-CdA was removed by careful washing, and cells were again incubated with Ac-LDL for 24 h, after which time [^{14}C]OA incorporation into the CE fraction and total cholesterol content were determined. As seen in Table 1, a 24-h exposure to 2-CdA was required for a significant reduction of cellular cholesterol content and cholesterol esterification to occur ($P < 0.008$). Furthermore, a simple 2-CdA/lipoprotein interaction was excluded.

TABLE 1

Effect of Exposure Time of 2-CdA on Cellular Lipid Content[a]

Exposure time	[^{14}C]OA incorporation into CE ± SD (nmol/mg protein)	Total cholesterol ± SD (mg/mg protein)
No CdA	8.1 ± 0.9	96 ± 0.6
4 h	7.7 ± 0.6	88 ± 2.6
8 h	5.3 ± 0.5	78 ± 4.9
24 h	1.1 ± 0.1	67 ± 2.0

[a]Cells (1×10^6 mL) were seeded in complete medium. After 24 h, cells were re-fed with complete medium containing 20 nM 2-chloro-2-deoxyadenosine (2-CdA) for various exposure times (4, 8 and 24 h). After careful washing, serum-free medium containing acetylated low density lipoprotein 100 μg/mL was added. For cholesteryl ester (CE) determination, 0.1 mM [^{14}C]oleic acid (OA) complexed with bovine serum albumin was added to the culture medium. Again after 24 h, lipids were extracted and results calculated as described in the Materials and Methods section.

The role of dCyt kinase. Previous studies have shown that the toxic effects of 2-CdA on monocytes and lymphocytes require phosphorylation catalyzed by dCyt kinase and are prevented by dCyt in cells with low 5′-nucleotidase activity (20,24). In order to examine whether the lipid-lowering effect of 2-CdA also depends on intracellular phosphorylation by dCyt kinase, dCyt, a competitive inhibitor of dCyt kinase, was added simultaneously with both 2-CdA and Ac-LDL to the cell cultures. Up to 10^{-3} M, dCyt alone had no effect on lipid accumulation in foam cells in the presence of 100 μg/mL Ac-LDL; at this concentration [^{14}C]OA incorporation into CE was 7.7 ± 0.6 nmol/mg protein and total cholesterol content was 99 ± 1.0 μg/mg protein. However, when 10^{-3} M dCyt was co-administered with 2-CdA to Ac-LDL-containing cultures, the effect of 2-CdA on cholesterol content and [^{14}C]OA incorporation could be completely reversed (Figs. 3 and 4). [^{14}C]OA incorporation into the CE fraction under these experimental conditions was significantly higher as compared to cultures treated with 2-CdA alone ($P < 0.0086$). This suggests that dCyt kinase plays a role in the effects of 2-CdA on cellular lipid metabolism.

In further experiments dCyt was co-administered with Ac-LDL 24 h after the addition of 2-CdA. the results (Table 2) show that a delayed addition of dCyt could not reverse the lipid-lowering effect of 2-CdA, further indicating that the 2-CdA effect is mediated by a metabolic sequence of events.

Effect of 3-MOB. Previous studies have shown that cellular NAD is preserved by 3-aminobenzamide in 2-CdA treated lymphocytes and monocytes (20). To assess the relationship of ADP-ribosylation to the effect of 2-CdA on cellular cholesterol content and [^{14}C]OA incorporation, P388 cells were treated with 3-MOB, an inhibitor of ribosylation, both alone and in combination. The results show (Figs. 5 and 6) that nontoxic concentrations of 3-MOB administered alone had no effect on lipid metabolism (for 2.5 and 5 mM concentrations, [^{14}C]OA incorporation into CE was 8.7 ± 0.6 and 8.3 ± 0.6 nmol/mg protein, respectively; cholesterol content was 100 ± 1.5 μg/mg protein and 96 ± 0.6 μg/mg protein, respectively), whereas a simultaneous exposure of cells to 3-MOB and 2-CdA prevented the ef-

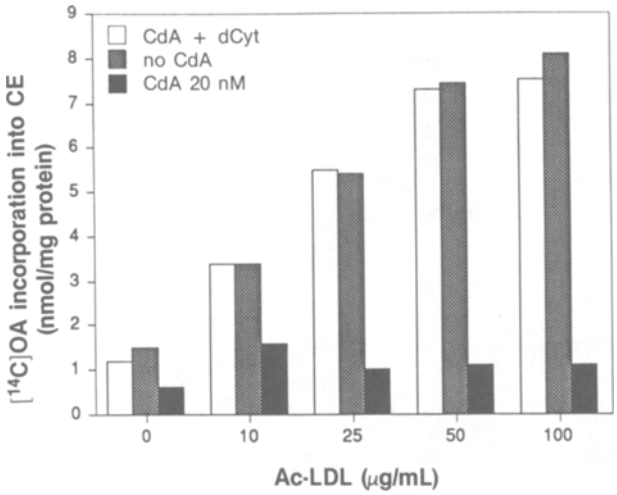

FIG. 3. Cultures grown for 24 h in complete medium were re-fed with serum-free medium containing Ac-LDL alone (10, 25, 50 and 100 μg/mL), Ac-LDL (10, 25, 50 and 100 μg/mL) and 20 nM 2-CdA or Ac-LDL (10, 25, 50 and 100 μg/mL) together with 20 nM 2-CdA and 10^{-3} M deoxycytidine (dCyt). For CE determination, 0.1 mM [^{14}C]OA complexed with bovine serum albumin was added to the cultures; after 24 h, lipids were extracted and results calculated as described in the Materials and Methods section (20 nM 2-CdA vs. 20 nM 2-CdA and 10^{-3} M dCyt; $P < 0.0086$). Abbreviations as in Figure 1.

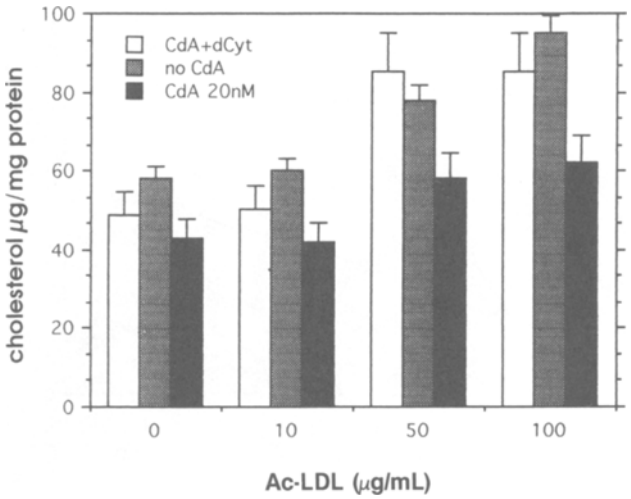

FIG. 4. Cultures were grown for 24 h in complete medium and re-fed with serum-free medium containing Ac-LDL alone (10, 50 and 100 μg/mL), Ac-LDL and 20 nM 2-CdA, or Ac-LDL together with 20 nM 2-CdA and 10^{-3} M dCyt. After 24 h, lipids were extracted and the cholesterol content measured as described in the Materials and Methods section. Abbreviations as in Figures 1 and 3.

TABLE 2

Effects of Delayed dCyt Addition on the Cellular Lipid Content of 2-CdA-Treated Cells[a]

Treatment	[^{14}C]OA incorporation into CE ± SD (nmol/mg protein)	Total cholesterol ± SD (mg/mg protein)
2-CdA	1.1 ± 0.1	67 ± 2.1
2-CdA and dCyt simultaneously	7.3 ± 0.6	85 ± 3.6
2-CdA followed by dCyt	1.7 ± 0.6	72 ± 3.0
dCyt	7.7 ± 0.6	99 ± 1.0

[a]Cells were grown for 24 h in complete medium and re-fed with serum-free medium containing 100 μg/mL acetylated low density lipoprotein (Ac-LDL). 20 nM 2-CdA, 20 nM 2-CdA together with 10^{-3} M deoxycytidine (dCyt), or 10^{-3} M dCyt alone was added to these cultures with Ac-LDL. In an equivalent number of plates, cells were pre-incubated with 20 nM 2-CdA in complete medium for 24 h. After this pre-incubation period, cells were carefully washed and incubated in serum-free medium containing 100 μg/mL Ac-LDL and 10^{-3} M dCyt. For determination of CE, 0.1 mM [^{14}C]OA complexed with bovine serum albumin was added to the cultures. After 24 h lipids were extracted and results calculated as described in the Materials and Methods section. Abbreviations as in Table 1.

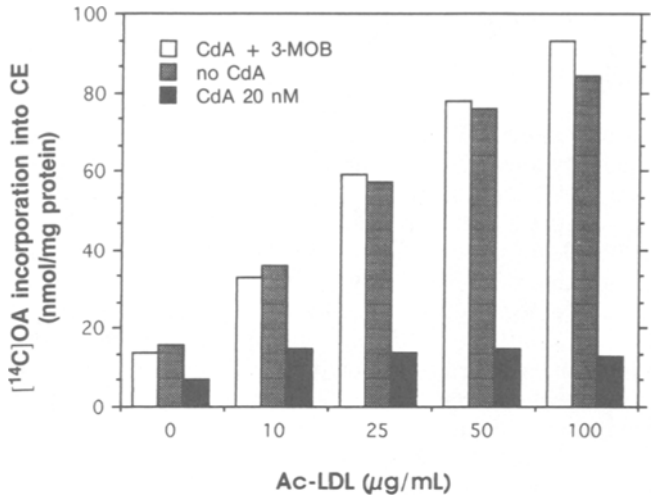

FIG. 5. Cultures were grown in complete medium for 24 h and re-fed with serum-free medium containing Ac-LDL alone (10, 25, 50 and 100 μg/mL), Ac-LDL and 20 nM 2-CdA, or Ac-LDL together with 20 nM 2-CdA and 5 nM 3-methoxybenzamide (3-MOB). For CE determination, 0.1 mM [^{14}C]OA complexed with bovine serum albumin was added to the cultures. After 24 h, lipids were extracted and results calculated as described in the Materials and Methods section. Abbreviations as in Figure 1.

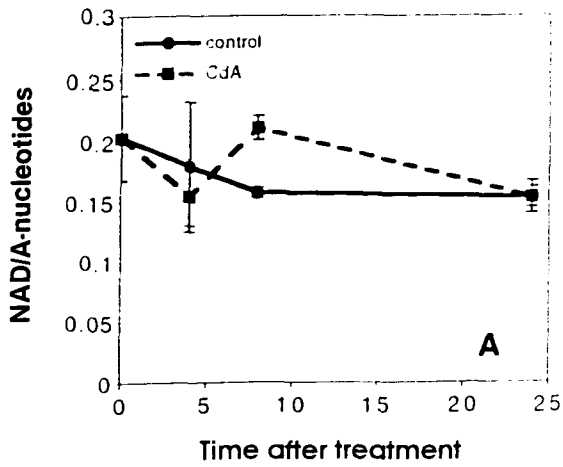
fect of 2-CdA on cellular cholesterol levels and cholesterol esterification.

Effect of aminophylline. To investigate whether the 2-CdA effect depends on intracellular cyclic-AMP levels, which have recently been shown to stimulate LDL receptor activity and hydrolysis of lysosomal cholesterol (33), the xanthine derivative aminophylline (10 and 20 μM) was added to cell cultures incubated with Ac-LDL and 2-CdA. Aminophylline could antagonize the lipid-lowering effect of 2-CdA—the amount of [^{14}C]OA incorporated into the CE fraction increased to 84 and 94% of the values obtained without 2-CdA (10 μM aminophylline, 7.6 ± 0.6 nmol/mg protein; 20 μM aminophylline, 8.3 ± 0.2 nmol/mg protein).

HMG–CoA reductase activity. The addition of 20 nM 2-CdA to P388 cells showed no effect on cellular cholesterol synthesis as measured by HMG–CoA reductase activity (4.8 ± 0.75 nM mevalonate/min/mg protein in 2-CdA treated cells; 4.6 ± 0.2 nM mevalonate/min/mg protein in controls).

Cellular NAD content. In contrast to the previously described decline in cellular NAD content in monocytes treated with high doses of 2-CdA (1 μM) (24), NAD content in P388 cells did not decrease after incubation with



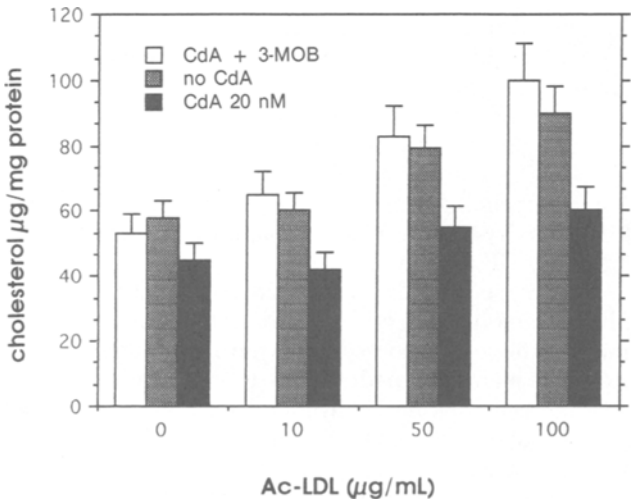


FIG. 6. Cultures were grown for 24 h in complete medium and re-fed with serum-free medium containing Ac-LDL alone (10, 50 and 100 μg/mL), Ac-LDL and 20 nM 2-CdA, or Ac-LDL together with 20 nM 2-CdA and 5 mM 3-MOB. After 24 h, lipids were extracted and total cholesterol was measured as described in the Materials and Methods section. Abbreviations as in Figures 1 and 5.

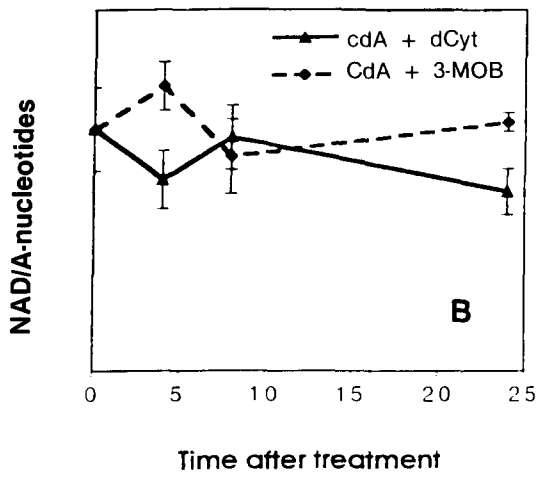

FIG. 7. Cell cultures were plated in complete medium for 24 h. Thereafter, (A) 2-CdA (to a final concentration of 20 nM), and (B) 20 nM 2-CdA and 10^{-3} M dCyt and 20 nM 2-CdA and 2.5 mM 3-MOB were added. After the incubation period indicated, cells were harvested and nucleotide content determined by high-performance liquid chromatography. The values for NAD content per sum of nucleotides are given. Abbreviations as in Figures 1, 3 and 5.

20 nM 2-CdA, as is seen in Figure 7A. The NAD concentrations of the cell cultures without treatment, of those treated with CdA alone, and of those treated with a combination of 2-CdA and dCyt, were similar. Co-incubation of cell cultures with 2-CdA and 3-MOB, an inhibitor of ADP-ribosylation, led to slightly elevated levels of NAD after 4 and 24 h (Fig. 7B).

DISCUSSION

The murine cell line P388 was originally derived from a lymphoid neoplasm of mice treated with 3-methylcholantrene (8). Like monocytes, P388 cells express scavenger receptors, and uptake of Ac-LDL by their scavenger receptor results in foam cell formation.

We now report that 2-CdA, a drug with immunosuppressive properties, modulates lipoprotein metabolism, in that it reduces, in a dose-dependent manner, cholesterol content and incorporation of [^{14}C]OA into the CE fraction of P388 cells incubated with Ac-LDL. Maximal inhibition of up to 86% occurred at a 2-CdA concentration of 20 nM after 24 h. Based on our viability studies and measurement of the total protein content in cultures with and without 2-CdA, the reduced CE content of P388 is not related to increased cell death.

Furthermore, our investigations demonstrate that sequential metabolic changes, similar to those described for normal human monocytes and lymphocytes, must be responsible for the effects of 2-CdA on lipid metabolism in P388 cells. In order to evaluate the mode of action of 2-CdA that is operative, dCyt and 3-MOB, which are known to antagonize the effect of 2-CdA in two different ways, were co-administered with 2-CdA to the cultures.

2-CdA, like deoxypurinenucleosides, enters cells through an efficient transport system and is phosphorylated by deoxycytidine kinase to the corresponding mononucleotide (23). The observed reversal of the effect of 2-CdA by simultaneous addition of dCyt implicates dCyt kinase activity and phosphorylation of 2-CdA to the active metabolite as responsible for the observed modulation of lipid metabolism. A 24-h delay of dCyt addition could not reverse the reduced Ac-LDL metabolism caused by 2-CdA. These results exclude a simple nonspecific interaction of 2-CdA with Ac-LDL or the plasma membrane lipid matrix. Deoxynucleotides can only accumulate in cells rich in deoxycytidine kinase and poor in 5-nucleotidase (22), which seems to be the case in P388 cells.

The nucleotide metabolite of 2-CdA is incorporated into DNA of nondividing monocytes and lymphocytes and rapidly causes DNA strands to break (20,24). The DNA damage is followed by progressive decrease in RNA synthesis and by accelerated consumption of NAD for poly-ADP-ribose synthesis. Ultimately, these biochemical events lead to a decline in ATP levels and cell death.

Based on these observations, it seemed reasonable to speculate that NAD-consumption for poly-ADP-ribose synthesis might also be involved in the altered Ac-LDL metabolism in P388 cells. Our *in vitro* results showed that 3-MOB, an inhibitor of ADP-ribosylation, preserved the cholesterol content and the amount of [^{14}C]OA incorporated into the CE fraction of P388 cells during exposure to 2-CdA. However, the measurement of NAD in P388 cells after a 2-CdA incubation period for 4, 8 and 24 h did not reveal a decline of intracellular NAD levels when compared to untreated cells. This could be explained by the lower amount of DNA strand breakage caused by the significantly lower 2-CdA concentration in our experiments, namely, 20 nM CdA instead of 1 μM CdA (19). Therefore, we suggest that the preservation of cholesterol content and cholesterol esterification in P388 cells by the ribosylation inhibitor 3-MOB is not primarily the result of maintenance of intracellular NAD levels, but might be mostly due to inhibition of ADP-ribosylation of chromosomal proteins. Poly-ADP-ribosylation of specific groups of chromosomal proteins has been observed during DNA repair, gene expression and cell differentiation (34).

Cyclic AMP-elevating agents have been reported to stimulate LDL receptor protein synthesis, as well as hydrolysis of lysosomal CE (33). The xanthine amine derivative aminophylline effectively antagonized the effect of 2-CdA on cellular CE synthesis. These results could indicate an association between the CE-lowering effect of 2-CdA and intracellular cyclic AMP levels.

The low 2-CdA concentrations used in our experiments did not reduce the viability of the P388 cells. This is in agreement with previous studies, which demonstrated that these low 2-CdA concentrations inhibit monocyte phagocytosis and reduce interleukin-6 release, but only higher 2-CdA concentrations led to a dose-dependent loss of monocyte viability (20). Our data provide evidence for another effect of low 2-CdA concentration on cell function which results in reduced cellular cholesterol contents and [^{14}C]OA incorporation into the CE fraction. As 2-CdA did not show an effect on intracellular cholesterol synthesis, the modulation in lipid metabolism seems to depend primarily on an altered Ac-LDL metabolism. Co-incubation of 2-CdA with 25-hydroxycholesterol, a substance known to increase ACAT activity (32), revealed no significant effect on the amount of extracellular [^{14}C]OA incorporated into the CE fraction. The effect of 2-CdA on Ac-LDL metabolism might be due to a decreased scavenger receptor activity, a decreased rate of lipoprotein internalization, a change in the intracellular pathway after internalization of Ac-LDL, or might be due to increased retroendocytosis (3,7,28). However, co-incubation studies of 2-CdA with 25-hydroxycholesterol, a substance known to increase ACAT activity (32), revealed no significant effect of 2-CdA on cellular CE synthesis.

An increase in Ac-LDL degradation during incubation of human monocytes with the immunosuppressant dexamethasone was reported elsewhere (17). The effects of dexamethasone are mediated by the intracellular glucocorticoid receptor, and involve increased cellular RNA levels and protein synthesis. Whereas stimulation of cellular protein synthesis could explain why dexamethasone augments scavenger receptor activity and thus Ac-LDL degradation, 2-CdA might reduce cellular lipid content by causing DNA strand breakage, leading to decreased RNA and protein synthesis (22).

The immunosuppressive 2-CdA, which, at a low concentration, affects several monocyte functions, including cellular lipid metabolism, could possibly provide a tool

to analyze various steps in the development of the atherosclerotic plaque, as the action of 2-CdA on lipid metabolism can be abolished by the competitive inhibitor dCyt and by the ADP ribosylation inhibitor 3-MOB. Further investigations will be necessary to define the exact mechanism of 2-CdA on cellular lipoprotein metabolism.

Dietary Polyunsaturated Fat Decreases Interaction Between Low Density Lipoproteins and Arterial Proteoglycans

James M. Manning[b], Abraham K. Gebre[a], Iris J. Edwards[a], William D. Wagner[a], Lawrence L. Rudel[a] and John S. Parks[a,*]

[a]Department of Comparative Medicine, Bowman Gray School of Medicine of Wake Forest University, Winston-Salem, North Carolina 27157 and [b]Department of Exercise and Movement Science, The William Paterson College of New Jersey, Wayne, New Jersey 07470

Polyunsaturated dietary fat (n-3 and n-6) results in less atherosclerosis in monkeys compared to lard (Parks, J.S., Kaduck-Sawyer, J., Bullock, B.C., and Rudel, L.L., *Arteriosclerosis 10,* 1102–1112; Rudel, L.L., Parks, J.S., Johnson, F.L., and Babiak, J., *J. Lipid Res. 27,* 465–474, 1986). We hypothesized that this was due, in part, to a decreased reactivity of low density lipoproteins (LDL) with arterial proteoglycans (PG). To test this hypothesis, cynomolgus monkeys were fed diets containing lard, safflower oil (n-6 polyunsaturated; Poly), menhanden fish oil (FO), or oleic acid-rich safflower oil (oleinate; Mono) for 14 mon, and plasma LDL were isolated and characterized. Several properties of LDL thought to be important in the interaction of LDL with arterial PG were measured including LDL particle size, chemical composition, sialic acid content, density distribution, apolipoprotein E (apoE) content and cholesteryl ester transition temperature. Plasma LDL cholesterol concentrations (mg/dL) after 14 mon of diet consumption averaged (mean ± SEM): FO (366 ± 45), Lard (352 ± 27), Poly (279 ± 24), and Mono (230 ± 43). The composition of LDL was similar among diet groups except that FO LDL were relatively depleted of cholesteryl ester and enriched in protein and were smaller in size. LDL sialic acid content was similar among diet groups (4.5–5.0 μg/mg LDL protein). The LDL apoE/B molar ratio, a measure of the apoE content per LDL particle averaged: Mono (3.0 ± 1.0), Poly (2.0 ± 0.1), Lard (1.8 ± 0.5), and FO (1.0 ± 0.2). The FO group had a lower proportion (13%) of the apoE enriched d = 1.015–1.025 g/mL subfraction of LDL than did the other diet groups (31–45%). The transition temperature of the LDL cholesteryl esters was below body temperature for the FO and Poly groups (36°C) and above for the Lard and Mono groups (40–44°C). The percentage of LDL cholesterol that formed insoluble complexes with arterial chondroitin sulfate PG averaged: Mono (29 ± 4%), Lard (18 ± 3%), Poly (14 ± 3%), and FO (7 ± 2%). Among all diet groups, there was a significant positive correlation (r = 0.54) between LDL–PG complex formation and LDL apoE/B molar ratio. We conclude that dietary FO and Poly result in LDL that are less reactive with arterial PG compared to Lard or Mono fats. While FO appears to decrease PG binding by decreasing the apoE content and amount of the largest LDL subfraction, Poly fat appears to affect LDL–PG interactions by other mechanisms. Decreased LDL–PG interactions may lead to decreased atherosclerosis in animals fed polyunsaturated dietary fat. *Lipids 29,* 635–641 (1994).

Isocaloric substitution of fish oil (FO) for saturated fat in the diet of nonhuman primates results in less coronary artery (1) and abdominal aorta (2) atherosclerosis. In general, diets enriched in n-3 fatty acids result in lower low density lipoprotein (LDL) cholesterol concentrations in nonhuman primates (1,2), but in some cases, LDL cholesterol concentrations are unchanged compared to more saturated fat dietary groups (3). However, dietary FO in African green and cynomolgus monkeys consistently results in LDL that are smaller, contain less cholesteryl ester (CE) and more polyunsaturated CE species, and have a lower CE liquid crystalline-to-liquid transition temperature (3–5). Additional studies in cynomolgus monkeys have demonstrated a relative depletion of LDL apolipoprotein E (apoE) and an increased proportion of denser LDL subfractions in animals fed FO vs. Lard-containing diets (6). These studies illustrate that significant changes in LDL particle composition can occur with n-3 fatty acid-rich diets with little effect on plasma LDL cholesterol concentrations and that these changes in LDL particle composition may affect progression of atherosclerosis.

Several studies have shown a strong positive correlation between coronary artery or abdominal aorta atherosclerosis and LDL size, CE fatty acid composition and apoE content in nonhuman primates (1,7,8). One of the first steps of arterial lipid accumulation in atherosclerosis is thought to involve trapping of LDL in the arterial wall, presumably through interaction with arterial proteoglycans (PG) (9–11). PG are electronegative macromolecular glycoconjugates composed of sulfated glycosaminoglycan chains covalently linked to a protein core and are ubiquitous components of the extracellular matrix (12). In the presence of divalent cations, arterial PG bind to LDL, presumably through the interaction of the sulfated glycosaminoglycan chains of the PG with regions of apoB protein that bind to the glycosaminoglycan heparin (13). ApoE also contains two regions that bind heparin (14). Once formed, LDL–PG complexes formed *in vitro* or isolated from atherosclerotic arteries are capable of stimulating CE accumulation in cultured macrophages (15–17).

To determine whether any of the atherogenic properties of LDL that correlate with atherosclerosis development also influence LDL binding to arterial PG, we studied the interaction of LDL with arterial chondroitin sulfate proteoglycans. LDL from animals fed an FO diet were smaller, more dense and contained less apoE compared to

Abbreviations: ACAT, acyl-CoA:cholesterol acyltransferase; apoA-I, apolipoprotein A-I; apoB, apolipoprotein B; apoE, apolipoprotein E; CE, cholesteryl ester(s); EDTA, ethylenediaminetetraacetic acid; ELISA, enzyme-linked immunosorbent assay; FO, fish oil; HDL, high density lipoprotein(s); HDL-C, high density lipoprotein-cholesterol; LCAT, lecithin:cholesterol acyltransferase; LDL, low density lipoprotein(s); Mono, monounsaturated fat (i.e., oleinate); PG, proteoglycan(s); Poly, polyunsaturated fat (i.e., safflower oil); TPC, total plasma cholesterol.

those from animals fed a Lard diet (3,6). FO LDL also bound less avidly to the arterial PG *in vitro* (6,18) consistent with the decreased atherosclerosis development in FO-fed nonhuman primates (1,2). In addition, there was a positive correlation between LDL–PG complex formation and the apoE content of the d = 1.015–1.025 g/mL subfraction (6). However, it is unclear whether the decreased PG interaction with FO LDL was due to a specific effect of n-3 fatty acids, *per se,* or whether a similar result would have been observed with dietary polyunsaturated fat enriched in n-6 fatty acids.

The purpose of the present study was to compare and contrast the effects of dietary n-3 and n-6 polyunsaturated fat relative to more saturated dietary fats (Lard and oleinate) on LDL composition, density subfraction heterogeneity, and PG binding. Based on our previous study (6), we hypothesized that both n-6 as well as n-3 dietary polyunsaturated fat would decrease the amount of LDL apoE, resulting in less PG binding compared to more saturated dietary fats.

MATERIALS AND METHODS

Experimental design. A subset of 25 feral adult male cynomolgus monkeys *(Macaca fascicularis)* from Indonesia were chosen for these studies from a larger group of 52 monkeys. The monkeys were purchased and placed in quarantine for 14 wk, during which time they received a monkey chow diet (Ralston Purina Co., St. Louis, MO). The animals were then fed for 12 wk an atherogenic challenge diet containing 40% of calories from fat and 0.45 mg/kcal cholesterol to assess the dietary responsiveness of each animal. After the challenge phase, the animals were fed monkey chow for a 14-week "washout" period to allow plasma lipids to return to baseline concentrations. This was followed by an experimental phase in which animals were assigned to one of four diet groups [Lard, monounsaturated fat (mono), polyunsaturated fat (poly) or FO] based on the challenge phase data so that each group had equivalent total plasma cholesterol (TPC), high density lipoprotein (HDL)-cholesterol (HDL-C) and body weight values. For this study, a subgroup of 6–7 animals from each diet group was chosen so that TPC and HDL-C concentrations of the subgroup were not significantly different from the parent group for each of the dietary fats.

Diets. The experimental diets contained 35% of calories as fat and 0.40 mg cholesterol/kcal. The four experimental fats included Lard, oleic acid-rich safflower oil (oleinate), safflower oil (n-6 polyunsaturated) and menhaden fish oil (n-3 polyunsaturated). Detailed compositions of the diets will appear in a separate publication (Thornburg, J.T., Parks, J.S., and Rudel, L.L., manuscript in preparation). The oleinate oil was provided by the Institute of Shortening and Edible Oils, Inc. (Washington, D.C.). Fish oil from the Southeast Fisheries Center (Charleston, SC) was isocalorically substituted for half of the Lard calories while the parent fat was used for the other three diets. β-Sitosterol and cholesterol content were made equivalent among the four diets. The α- and δ-tocopherols and Tenox 20A (*tert.*-butylhydroquinone; Eastern Chemical Products, Kingsport, TN) were added to the diets to balance the amounts contained in the FO diet.

LDL isolation and chemical characterization. Blood samples were taken from the animals after at least 14 mon of experimental diet consumption and following an overnight fast. Following the administration of ketamine hydrochloride (10 mg/kg), 25 mL of blood was drawn from the femoral vein into chilled tubes (4°C) containing 0.1% ethylenediaminetetraacetic acid (EDTA) and 0.02% NaN_3 (final concentrations) at pH 7.4. Plasma was isolated from each sample by low-speed centrifugation. Lipoproteins were isolated from plasma by ultracentrifugation and were fractionated by size using a Superose 6B high-performance liquid chromatography column as described previously (3). Cholesterol distribution of the isolated lipoproteins was assayed using enzymatic methods (19). LDL sialic acid content was determined by the method of Codington *et al.* (20) and the results were normalized to mg LDL protein. The thiobarbituric acid reactive substances assay was used to determine the extent of lipid peroxidation among LDL samples from the four diet groups (21). LDL samples were stored at 4°C under an argon atmosphere.

Density gradient subfractionation of LDL. Isolated LDL samples were subfractionated by density gradient centrifugation using 5 mg of LDL protein. Discontinuous salt gradients were set up using 39-mL quick-seal centrifuge tubes by first adding 10 mL of a d = 1.006 g/mL solution and then successively underlayering 19 mL of a d = 1.030 g/mL solution (including the LDL sample) and 10 mL of a d = 1.060 g/mL solution. LDL was subfractionated using a VTi-50 vertical rotor at 242,000 × *g* at 15°C for 6 h (22). Individual tubes were pooled to give three density fractions of LDL: d = 1.015–1.025 g/mL, d = 1.025–1.035 g/mL and d = 1.035–1.045 g/mL. These subfractions were dialyzed against 0.9% NaCl, 0.01% EDTA, 0.01% NaN_3, pH 7.4, and concentrated to 2 mL for chemical analyses. LDL and LDL subfraction chemical compositions were determined as described previously (23). Plasma LDL and LDL subfraction apolipoproteins E and B_{100} were assayed using an enzyme-linked immunosorbent (ELISA) assay (24,25).

LDL–PG binding studies. LDL binding to isolated arterial chondroitin sulfate PG was investigated as described previously (18). Briefly, 100 μg of LDL cholesterol was incubated with 1 μg PG (measured as hexuronic acid) in buffer containing 5 mM Tris, 6 mM KCl, 15 mM $CaCl_2$, 1 mM $MgSO_4$, pH 7.2, at 26°C for 30 min. The insoluble LDL–PG complexes that formed were isolated by low-speed centrifugation. The supernatant was removed, the pellet was resuspended and LDL cholesterol was measured enzymatically (19). Data are presented as percentage of total LDL cholesterol present as insoluble PG complex.

Data analysis. Data are presented as mean ± standard error of the mean. Statistical analyses were done using the Statview™ SE+ program for the Macintosh computer. One-way analysis of variance was used to detect a main effect of diet. Analysis of covariance was used to adjust PG binding data for differences in LDL cholesterol to apoB ratio and LDL apoE content. When a significant effect was

disclosed, Fisher's least significant difference test was used to compare individual diet group differences.

RESULTS

Total plasma and lipoprotein cholesterol concentrations for animals consuming the four experimental diets are shown in Table 1. TPC and very low density lipoprotein and intermediate-size LDL cholesterol concentrations were not significantly different among the dietary groups. Average LDL cholesterol concentrations for animals fed FO and Lard diets were higher than those consuming the Mono or Poly diets. The HDL cholesterol concentrations were significantly lower for the FO and Poly groups compared to the Mono and Lard groups. The animals consuming the FO diet had significantly smaller LDL particles, measured as LDL molecular weight, than those consuming the other three experimental diets. The LDL cholesterol/apoB ratio, an independent estimate of LDL size, followed the same trend as LDL molecular weight among diet groups.

Because of the observed differences in LDL cholesterol concentration and LDL size among the experimental diet groups, LDL subfraction heterogeneity was investigated by density gradient ultracentrifugation. Representative density gradient profiles for one animal from each diet group are shown in Figure 1. The LDL from the animal fed the FO diet was more dense and distributed predominantly in the lower half of the gradient while the LDL from animals fed the Lard, Mono, or Poly diets were less dense and distributed predominantly in the upper half of the gradient. LDL density heterogeneity was apparent for all animals regardless of diet group. Three density fractions from the LDL gradients were pooled for subsequent analysis.

The LDL apoB and cholesterol subfraction distribution for the three density cuts is shown in Table 2. As suggested from the density gradient profiles in Figure 1, the proportion of apoB in the d = 1.015–1.025 g/mL subfraction of LDL for the FO group was less than one-third that of the other three diet groups ($P < 0.0028$). There was a correspondingly higher proportion of apoB in the d = 1.035–1.045 d/mL subfraction for the FO group compared to the other three diet groups ($P < 0.016$). LDL cholesterol density distribution followed similar trends as LDL apoB.

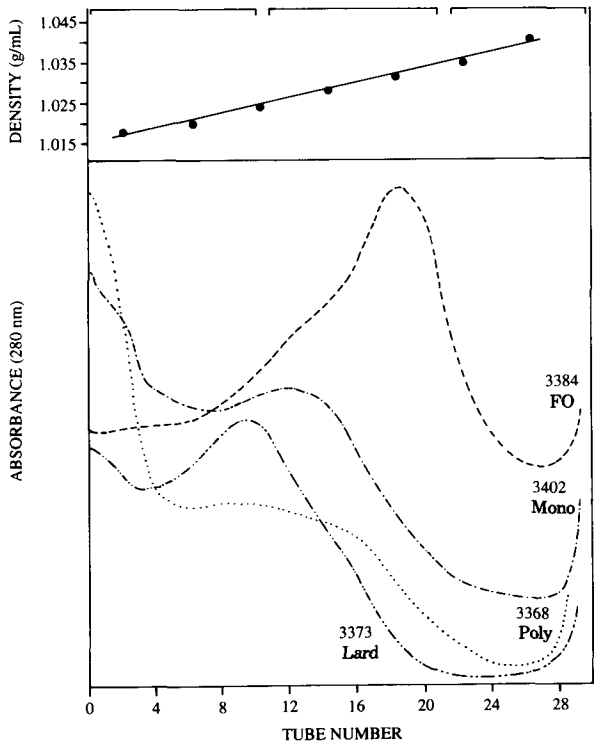

FIG. 1. Density gradient profile of low density lipoprotein (LDL) isolated from plasma by ultracentrifugation and column chromatography. Profiles shown represent one animal from each diet group that had an LDL cholesterol concentration near the group mean. Brackets indicate where subfractions were pooled for subsequent analyses. FO, fish oil; Mono, monounsaturated fat (i.e., oleinate); Poly, polyunsaturated fat (i.e., safflower oil).

Previous studies have shown that much of the apoE in the plasma of cynomolgus monkeys fed atherogenic diets is bound to LDL particles (7,26). To determine the effect of dietary fat type on the LDL subfraction distribution of apoE, the amount of apoE and apoB among the three LDL density subfractions was quantified by ELISA. The values

were then converted to an apoE/B molar ratio, a measure of apoE per LDL particle, since each LDL particle contains only one molecule of apoB. The data are shown in Table 3. The average E/B molar ratio was ordered: Mono (3.0 ± 0.9) > Poly (2.0 ± 0.1) > Lard (1.8 ± 0.5) > FO (1.0 ± 0.2). The effect of diet was of borderline significance ($P = 0.059$). The d = 1.015–1.025 g/mL subfraction had a significantly higher apoE/B molar ratio for the Mono and Poly diet groups compared to the FO and Lard diet groups ($P = 0.0306$). The apoE/B molar ratio was not significantly different among diet groups for the d = 1.025–1.035 g/mL or the d = 1.035–1.045 g/mL subfraction.

The chemical composition of the LDL subfractions and total LDL for the four diet groups is shown in Table 4. LDL from the FO group contained relatively more protein and less CE compared to the other three diet groups, consistent with the smaller size of the FO LDL (i.e., decreased LDL molecular weight and LDL cholesterol/apoB ratio; Table 1). A similar trend was also observed for the d = 1.015–1.025 g/mL subfraction, although the compositional differences did not reach statistical significance. Overall, the compositional differences of LDL subfractions among diet groups were small.

To determine whether the type of dietary fat had modified the LDL CE liquid crystalline-to-liquid transition temperature, a differential scanning calorimetric study was performed; the results are shown in Table 5. The mean transition temperatures for LDL were ordered: Lard > Mono > Poly = FO. The mean transition temperature for both of the polyunsaturated diet groups (i.e., Poly and FO) was below body temperature, whereas it was above body temperature for the Lard and Mono groups. These data confirmed that the different types of dietary fat had altered the CE fatty acid composition of LDL consistent with results of previous studies (3,4).

The results of the PG binding assay are shown in Figure 2. Each point represents data from an individual animal. On average, the percentage of LDL forming an insoluble complex with PG was ordered: Mono (29 ± 4%) > Lard (19 ± 3%) > Poly (14 ± 3%) > FO (7 ± 2%). The mean LDL–PG binding for the FO group was significantly lower than means for the other three diet groups ($P < 0.05$). If data were pooled and analyzed as polyunsaturated (n-3 plus n-6) vs. Lard plus Mono, there was also a significantly lower percentage of LDL cholesterol complexed with PG for the combined polyunsaturated group ($P <$

0.002; Student's *t*-test). The same statistically significant trend in LDL binding to PG was observed after analysis of covariance to adjust for differences in LDL cholesterol/apoB ratio among diet groups.

Our previous study suggested that part of the difference in LDL–PG complex formation between Lard and FO LDL could be explained by the decreased apoE content of FO LDL (6). To determine whether LDL apoE content influenced diet-induced difference in LDL–PG complex formation, the average LDL apoE/B molar ratio was plotted against LDL–PG complex formation (Fig. 3). There was a positive relationship between LDL apoE content and the ability of LDL to form insoluble complexes with PG. The correlation coefficient (r) for the same plot of individual animal data was 0.54 ($P < 0.05$). However, analysis of covariance revealed that significant differences in LDL–PG binding remained after adjusting for differences in LDL apoE/B molar ratio among diet groups.

Previous studies suggested an inverse relationship between LDL sialic acid content and LDL–PG binding. To determine whether differences in sialic acid content among diet groups was related to the differences in LDL–PG complex formation, the sialic acid content of plasma LDL was measured (Table 6). The sialic acid content of the plasma LDL averaged 4.5–5.0 μg/mg LDL protein and was not significantly different among diet groups.

The thiobarbituric acid reactive substances assay was used to determine whether lipid peroxidation was different among LDL samples from the four diet groups. In a subset of three animals from each diet group, there was

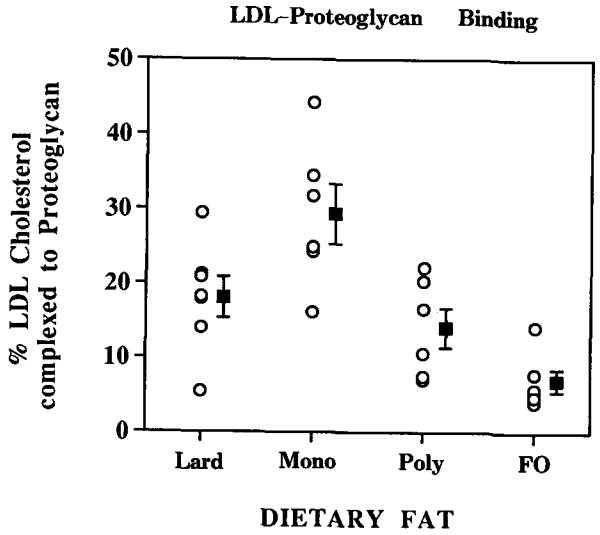

FIG. 2. Formation of particulate complexes between arterial chrondroitin sulfate proteoglycans (PG) (1 μg as hexuronate) and plasma LDL (100 μg as cholesterol). Plasma LDL were isolated from the plasma of cynomolgus monkeys in the four diet groups. Incubations of LDL and PG were performed in 5 mM Tris, 6 mM KCl, 15 mM $CaCl_2$ and 1.5 mM $MgSO_4$ (pH 7.2) for 30 min at 26°C. Formation of particulate PG–LDL complexes was measured as cholesterol in a 1,500 × *g* pellet, which is represented as the percentage of total LDL cholesterol in the incubation. Each open circle represents data from an individual animal; the closed squares represent the mean ± SEM for each diet group. See Figure 1 for other abbreviations.

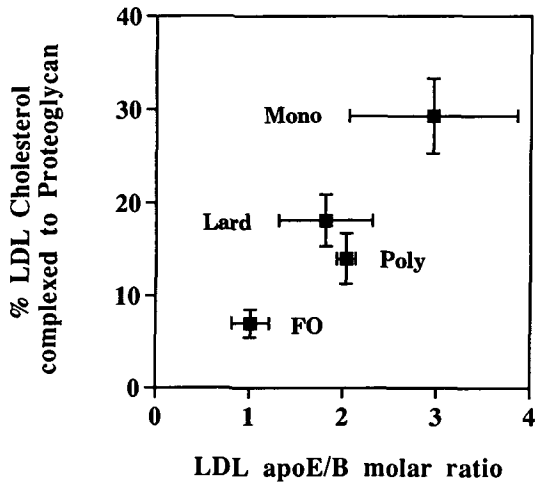

FIG. 3. A plot of LDL apoE/B molar ratio, determined by enzyme-linked immunosorbent assay vs. LDL–PG complex formation assayed as described in Figure 2 legend. Symbols represent the mean ± SEM for each diet group; apoE/B, apolipoprotein E and B. See Figures 1 and 2 for other abbreviations.

<1.1 nmol thiobarbituric acid reactive substances/mg LDL cholesterol, and there was no significant difference, by analysis of variance, among the diet groups.

DISCUSSION

Previous studies have demonstrated that isocaloric substitution of polyunsaturated fat for saturated fat resulted in less coronary artery and aortic atherosclerosis in several nonhuman primate species (1,2,8,27). This has been observed regardless of whether the polyunsaturated dietary fat was enriched in n-6 or n-3 fatty acids. However, the exact mechanism for the reduced atherogenicity of polyunsaturated fat is unknown and is likely to be multifactorial. Since LDL and PG have been co-localized in atherosclerotic lesions of human beings and experimental animals (9–11) and LDL–PG complexes can lead to CE accumulation in macrophages *in vitro* (15,16), we hypothesized that one mechanism by which polyunsaturated dietary fat diminishes atherosclerosis progression might involve a decrease in LDL–PG interaction.

The results of the present study support this hypothesis. FO LDL was significantly less reactive with PG than LDL from the other three diet groups. Poly LDL was significantly less reactive with PG than Mono LDL and, on average, was less reactive than Lard LDL (Fig. 2). Since all other experimental variables except the source of LDL were constant, the data suggest that one or more of the properties of LDL important in the interaction with PG were affected by polyunsaturated fat.

One property of LDL that is thought to be important in atherosclerosis progression and LDL–PG interaction is the apoE content (6). The apoE content of plasma LDL is highly correlated with coronary artery atherosclerosis in nonhuman primates (7). ApoE also contains two sites that bind to the glycosaminoglycan, heparin (14). In a previous study, the apoE content of LDL and the density distribution of LDL subfractions appeared to be related to the decreased interaction of FO LDL with PG compared to Lard LDL (6). However, the results from the present study show that Poly LDL was similar to Lard LDL and Mono LDL in chemical composition (Table 4), density distribution (Table 2) and apoE content (Table 3). The data taken together suggest that FO decreases PG binding *in vitro* by decreasing the apoE content and amount of the d = 1.015–1.025 g/mL subfraction, whereas Poly appears to affect LDL–PG interactions by other mechanisms.

A possible explanation for differences in LDL–PG interaction may relate to LDL particle charge. LDL sialic acid content varies among LDL subfractions (28) and among individuals (29,30). The sialic acid content of LDL also influences PG interaction (29). We are aware of no data that suggest that the type of dietary fat modifies the sialic acid content of LDL, and we found no difference in LDL sialic acid content among the four diet groups in this study (Table 6). Therefore, the observed differences in LDL–PG interaction among diet groups cannot be explained by differences in sialic acid content.

In the present study, the type of dietary fat had little effect on the chemical composition, density distribution, size and apoE content of plasma LDL, except in the FO group. FO LDL were smaller (Table 1), more dense (Table 2) and contained less apoE (Table 3) and less CE (Table 4) compared to LDL from the other three diet groups. The decrease in size and CE content of FO LDL likely resulted from decreased CE input into plasma LDL by the two CE-generating enzymes, lecithin:cholesterol acyltransferase

(LCAT) and acyl-CoA:cholesterol acyltransferase (ACAT). Previous studies have shown that phospholipids containing n-3 fatty acids in the *sn*-2 position are poor substrates for LCAT regardless of whether the phospholipid is in a recombinant substrate particle or a monolayer film (31,32). In addition, livers from nonhuman primates fed FO diets secrete less cholesterol than those from animals fed lard diets (33), and hepatic microsomal ACAT activity is reduced compared to animals fed lard and safflower oil diets (23). HDL phospholipids purified from the plasma of cynomolgus monkeys fed the FO diet and made into recombinant substrate particles are less reactive with LCAT than plasma HDL phospholipids isolated from the Lard, Poly or Mono diet groups (Thornburg, J.T., Parks, J.S., and Rudel, L.L., manuscript in preparation). Taken together, these data suggest that FO LDL are smaller, more dense and contain fewer CE molecules per particle because n-3 fatty acids are poor substrates for CE synthesis by LCAT and ACAT.

The decreased apoE content of FO LDL and LDL subfractions with respect to the other diet groups may be related to a decreased association of apoE with the LDL particle surface. Relative to Lard LDL, FO LDL are enriched in sphingomyelin and relatively poor in phosphatidylcholine, and the phosphatidylcholine species are enriched in n-3 fatty acids. These FO-induced changes in the LDL particle surface may limit apoE binding. In support of this hypothesis, we have found that apoA-I binds more poorly to phosphatidylcholine monolayers containing n-3 fatty acids vs. oleic acid in the *sn*-2 position (34). In addition, Ibdah *et al.* (35) have demonstrated that the increased sphingomyelin content of LDL vs. HDL may prevent apoA-I binding to LDL. If apoE binding to lipoprotein surfaces is influenced by FO in a manner similar to that for apoA-I, then the FO-induced changes in LDL phospholipids may reduce apoE binding to LDL. Studies are currently underway to test this possibility.

The LDL apoE/B molar ratio was greater in this study compared to our previous study (6). Although the explanation for this difference is unknown, it likely relates to the amount of dietary cholesterol consumed by the animals. Diets containing 0.26 mg cholesterol/kcal were used in the previous study compared to 0.4 mg cholesterol/kcal in the present one. This may have contributed to the nearly twofold greater concentration of apoE in whole plasma in the present study compared to that observed previously. In addition, different animals were used for the two studies. In spite of the difference in apoE enrichment of LDL between the studies, the effect of dietary FO on LDL size, composition, density distribution and PG interaction was similar compared to the Lard group in both studies.

ACKNOWLEDGMENTS

The authors gratefully acknowledge Linda Odham for her assistance in manuscript preparation, Karen Klein for editorial comments, Dr. Ed Hunter of Procter & Gamble and The Institute of Shortening and Edible Oils, Inc. for helping obtain the oleinate oil, and the Southeast Fisheries Center (Charleston, SC) for the processed fish oil. This work was supported, in part, by grants from The National Institutes of Health, National Heart, Lung and Blood Institute, HL 49373, HL 25161, and HL 08373 (National Research Service Award), and a grant from the Center for Research, School of Science and Health, William Paterson College of New Jersey (JMM).

Fatty Acid Composition of Lung, Macrophage and Surfactant Phospholipids After Short-Term Enteral Feeding with n-3 Lipids

John D. Palombo*, Erin E. Lydon, Pei-Linn Chen, Bruce R. Bistrian and R. Armour Forse

Laboratories of Surgical Metabolism/Nutrition, Departments of Surgery and Medicine, New England Deaconess Hospital, Harvard Medical School, Boston, Massachusetts 02215

Utilization of enteral feeding modalities may prove clinically relevant for rapid modulation of lung phospholipid polyunsaturated fatty acids (PUFA) that serve as substrates for the formation of vasoactive dienoic eicosanoids. We compared the effects of short-term enteral feeding with formulations enriched with either fish (n-3) or corn (n-6) oil PUFA on the fatty acid composition of rat lung, alveolar macrophage and surfactant phospholipids. The diets were infused continuously for 72 h through a surgically placed gastroduodenal feeding catheter by a syringe pump. The n-3 PUFA derived from the fish oil enriched diet were readily incorporated into the phospholipid membranes of the alveolar macrophages, lung tissue and pulmonary surfactant. The relative percentages of the n-3 PUFA were significantly higher and individual and total n-6 PUFA significantly lower in the macrophage, lung and surfactant phospholipids from the n-3-supplemented rats in comparison with those present in the rats infused enterally with the n-6 diet or untreated, chow-fed rats (baseline). In contrast, there was a significant increase in linoleic acid (18:2n-6) without modification of arachidonic acid (20:4n-6) in the alveolar macrophages, lung tissue and surfactant from rats enterally receiving the n-6 diet relative to levels measured in the rats at baseline. The results suggest that short-term continuous delivery of n-3-enriched enteral preparations can foster rapid modification of membrane phospholipid PUFA composition of lung tissue, alveolar macrophages and lung surfactant. Utilization of similar infusion modalities to deliver n-3-enriched enteral formulations may prove beneficial to critically ill or postoperative patients with persistent lung inflammation secondary to uncontrolled formation of vasoactive eicosanoids derived from arachidonic acid.
***Lipids* 29, 643–649 (1994).**

Arachidonic acid (20:4n-6, AA), an n-6 fatty acid derived from the essential dietary fatty acid linoleic acid (18:2n-6; LA), serves as the primary precursor of vasoactive eicosanoids formed *via* cyclooxygenase and 5′-lipoxygenase within immune cell (e.g., macrophage) membrane phospholipids. The resulting leukotrienes and dienoic series of prostanoids are potent mediators of lung injury and inflammation promoting platelet aggregation, arteriolar vasoconstriction, capillary permeability and neutrophil (PMN) chemotaxis (1,2). Given the extensive capillary vasculature and large population of marginating PMN that are normally adherent to lung endothelium (3), the lung is particularly vulnerable to tissue damage by PMN and capillary occlusion by activated platelets after trauma or sepsis. Persistent lung inflammation, with or without infection, further compromises pulmonary endothelial integrity, impairs gas exchange and predisposes the development of adult respiratory distress syndrome (ARDS) (4). In theory, then, critically ill patients at risk of developing ARDS may derive some benefit from treatment modalities that reduce lung generation of, or exposure to, AA-derived eicosanoids.

Clinical and experimental studies conducted during the past decade have revealed that the structural and functional properties of host immune cells can be modified by nutritional supplementation with marine oil (n-3) polyunsaturated fatty acids (PUFA), e.g., eicosapentaenoic acid (20:5n-3; EPA) (5,6). Studies from this laboratory have shown that displacement of n-6 PUFA, i.e., 20:4n-6 and 18:2n-6, from plasma phospholipids by n-3 PUFA in endotoxin-challenged guinea pigs was associated with reduced pulmonary leukosequestration, improved lung morphology and increased survival (7,8). Others have reported that P_aO_2 and blood pressure were significantly higher and that plasma thromboxane A_2 was lower during an infusion of live *Escherichia coli* in pigs prefed an n-3-enriched diet relative to corresponding values in corn oil-fed animals (9). These studies indicate that nutritional modulation of cell membrane PUFA with marine oil n-3 fatty acids appears to confer an advantage with respect to maintenance of pulmonary function during septic complications.

In the clinical setting, critically ill or surgical patients often require enteral nutrition support secondary to anorexia and/or a postoperative incapacity (e.g., upper gastrointestinal surgery) to consume adequate amounts of nutrients. Unfortunately, the majority of commercially available enteral nutrient preparations are enriched with 18:2n-6, thus predisposing incorporation of 20:4n-6 within macrophage membrane phospholipids. Therefore, utilization of novel enteral formulations containing marine oil PUFA to modulate the phospholipid PUFA composition and function of immune cells is now being explored. We, and others, have demonstrated that continuous enteral delivery of n-3-enriched formulations promotes significant displacement of 18:2n-6 and 20:4n-6 from liver Kupffer and endothelial cells and plasma phospholipids in animals (10) as well as from erythrocyte phospholipids in humans (11,12) within 4–7 d, irrespective of concurrent endotoxemic or septic complications. Recent studies of the effects of infusion time have shown that the modification of macrophage phospholipid PUFA achieved after three days of contin-

Abbreviations: AA, arachidonic acid; ANOVA, analysis of variance; ARDS, adult respiratory distress syndrome; CSP, crude surfactant pellet; DHA, docosahexaenoic acid; DPA, docosapentaenoic acid; DPPC, dipalmitoyl phosphatidylcholine; EPA, eicosapentaenoic acid; LA, linoleic acid; LPS, lipopolysaccharide; MUFA, monounsaturated fatty acids; PBS, phosphate buffered saline; PMN, polymorphonuclear neutrophil; PUFA, polyunsaturated fatty acids; SFA, saturated fatty acids.

uous enteral delivery of diets containing fish and borage oil PUFA was not enhanced by feeding for three additional days (13). Other studies from this laboratory have confirmed that systemic levels of dienoic prostanoids elicited after endotoxin (lipopolysaccharide; LPS) exposure were significantly lower in rats enterally fed with a fish oil-enriched formulation than in LPS-challenged rats infused with a safflower oil-based diet (14).

The extent to which short-term infusions of enteral formulations enriched with fish oil modify lung tissue, alveolar macrophages and surfactant phospholipid PUFA has not been addressed. The ability to induce dietary modifications of surfactant PUFA may also prove important, given that the relative percentage of 20:4n-6 in surfactant phospholipids increases in patients with ARDS (15,16). The objectives of the present study were to determine changes in the individual n-3 and n-6 PUFA within the phospholipid fractions of these lung components from rats fed enterally for 72 h with fish or corn oil-enriched formulations containing moderate (27%) amounts of lipid.

MATERIALS AND METHODS

Animal surgery. The study design was approved by the Deaconess Animal Care and Use Committee. The methods and diets were identical to those described previously (10). Briefly, male (200–250 g) Sprague-Dawley rats (Harlan, Altamont, NY) were allowed standard chow pellets (Prolab RMH 3000; Agway Inc., Cornell, NY) *ad libitum* for five days prior to study entry. One group of rats (n = 8) was then sacrificed to provide baseline levels of lung tissue, alveolar macrophage and surfactant phospholipid PUFA. The remaining rats (n = 16) underwent aseptic surgical placement of an enteral feeding catheter. After anesthetization with diethyl ether (08:30 h of day 0), a 0.030″ × 0.065″ medical silastic catheter was advanced into the duodenum through an ostomy in the fundus of the stomach and anchored to the stomach wall with a purse string suture. The proximal end of the catheter was tunneled subcutaneously, exteriorized at the midscapular region and attached to a flow-through swivel to permit freedom of movement. Each rat was housed individually in a wire-bottomed cage during enteral feeding and allowed water *ad libitum* for the duration of the study.

Enteral feeding. After recovery from surgery, the rats received either a fish oil- or a corn oil-enriched enteral formulation based upon preoperative randomization (n = 8/group). The enteral diets consisted of a complete basal formulation (Vital HN; Ross Laboratories, Columbus, OH) with which an isocaloric quantity of either fish oil concentrate (Omegacaps Ltd., St. Louis, MO) or corn oil (Best Foods, Union, NJ) was blended. The fatty acids from the fish oil concentrate were primarily in the form of ethyl esters. The absorption of fish n-3 PUFA given as ethyl esters has been shown to be similar to that of fish n-3 PUFA given as triglycerides (17). The corn oil was supplemented with α-tocopherol to equal the total vitamin E activity present in the fish oil concentrate (1 U/g oil). Each enteral diet provided 1.4 g N/kg/d and 250 kcal/kg/d. Lipids accounted for 27% of the total dietary energy in the enteral formulations. The calories derived from lipid in the chow pellets constituted 14.5% of total dietary energy. The relevant fatty acids of the enteral formulations and chow pellet (baseline) triglycerides were determined by gas chromatography and expressed as relative percentage of the total fatty acids present (Table 1). The enteral diets were infused continuously by a programmable syringe pump (Model 42; Harvard Apparatus, Natick, MA) at a constant rate for 72 h beginning at 13:00 h of day 0.

Tissue procurement. Each rat was anesthetized with an intraperitoneal injection of pentobarbital (80 mg/kg B.W.) at 13:00 of day 3. The thoracic cavity was exposed and the lung vasculature flushed with 5 mL saline *via* the superior *vena cava*. A 14-gauge angiocatheter was inserted through a tracheostomy, and the lungs were lavaged eight times with 5 mL of cold phosphate buffered saline (PBS); gentle chest massage facilitated lavage recovery (>90%). The cumulative lavage fluid was kept on ice during this procedure. Following lavage, lung tissue samples (free of bronchial tissue) were excised, minced, washed with PBS and stored under N_2 at −20°C until analysis. Frozen lung tissue was homogenized in saline immediately before lipid extraction, as described in the next paragraph.

The lavage fluid was spun at 400 × *g* for 10 min at 4°C. The cell-free supernatant was then respun at 40,000 × *g* at 4°C for 60 min to obtain a crude surfactant pellet (CSP) (18). The supernatant was removed, and the CSP was resuspended in 200 µL of saline containing 5 mM $CaCl_2$ for total phospholipid fatty acid analysis. The cell pellet containing alveolar macrophages after the first centrifugation at 400 × *g* was resuspended in PBS and centrifuged at 110 × *g* for 10 min at 4°C. The washed cell pellet was then resuspended in PBS, layered on Ficoll Paque (Pharmacia, Piscataway, NJ) and centrifuged at 500 × *g* at 22°C for 35 min to isolate the alveolar macrophages. The macrophage layer was removed, washed with PBS, centrifuged at 110 × *g* for 10 min at 4°C and resuspended in PBS. Purity and viability (trypan blue exclusion) were >95% under light microscopy. Alveolar macrophages (5–7 × 10^6) were stored in PBS at −20°C for total phospholipid fatty acid analysis.

TABLE 1

Fatty Acid Composition of Baseline and Enteral Diets[a]

Fatty acid	Baseline	Corn oil-enriched	Fish oil-enriched
<14:0	2.1	4.3	6.7
16:0	20.2	9.3	2.5
18:0	8.7	1.8	2.0
18:1n-9	29.7	24.4	6.8
18:2n-6	34.6	54.4	12.9
18:3n-3	0.3	0.7	0.6
20:5n-3	1.2	0.2	21.7
22:5n-3	0.1	0.1	4.2
22:6n-3	1.1	0.1	16.2

[a]The baseline diet was chow pellets. The corn oil- and fish oil-enriched diets were enteral formulations. Relative percent of total fatty acids as determined by gas chromatography.

Phospholipid fatty acid analysis. Sixteen identifiable fatty acids (12–24 carbons in length) in the phospholipid fraction of lung tissue homogenate, CSP and alveolar macrophages were determined by methods described previously (10). Diheptadecanoyl phosphatidylcholine was used as an internal standard and was added prior to lipid extraction. After lipid extraction in chloroform/methanol (2:1, vol/vol), the phospholipid fraction was isolated on silica gel H (Analtech, Newark, DE) thin-layer plates using a mobile phase of petroleum ether/diethyl ether/glacial acetic acid (80:20:1, by vol) and identified relative to the migration of a phospholipid standard using dichlorofluorescein spray. The phospholipid band was isolated and the fatty acids were transmethylated with 14% BF_3 in methanol. In a few instances, smaller bands of surfactant phospholipids from identically treated rats were combined to improve yield. The fatty acid methyl esters were separated and quantified on a Hewlett-Packard (Palo Alto, CA) 5890 Series II gas chromatograph equipped with a 50-m fused silica capillary column containing SP-2330 as the stationary phase with a 0.20 mm film thickness (Supelco, Bellefonte, PA). The relative mole percentages of individual fatty acids were determined using Chem Station software (Hewlett-Packard) based upon the relative responses of an external standard of pure fatty acid methyl esters (Nu-Chek-Prep, Elysian, MN).

Statistics. Computer-based statistical programs were used (BMDP Software, Inc., Los Angeles, CA). Statistical tests included analysis of variance (ANOVA) by diet. Levene's test provided a test of equal variability among diet groups. If the Levene's test was significant, the Brown–Forsythe test was used to allow for unequal group variances at the expense of a loss of degrees of freedom. If the overall ANOVA or Brown–Forsythe test was significant ($P < 0.05$), *post hoc* comparisons of means were determined using Bonferroni comparison tests.

RESULTS

The enteral formulations used were well tolerated by all the rats. There were no signs of physical stress or diarrhea during the enteral feeding. Spleen weights and overall morphologic appearance of the major organs were similar to the baseline group given chow pellets *ad libitum*. There were no significant differences between the two groups of enterally fed rats with respect to either initial (overall mean ± SD = 230 ± 7 g) or final (231 ± 8 g) body weights.

Lung phospholipid PUFA. The relative mole percentage of the principal fatty acids present in the phospholipids of the lung homogenate are listed in Table 2. Despite the fact that the enteral diets contained relatively lower levels of 16:0 than the chow pellets (Table 1), a trend toward an increased relative percentage of 16:0 and total saturated fatty acids (SFA) in the enterally-fed rat lungs relative to that in the baseline group was evident. This rise in the relative percentage of 16:0 was slightly offset by a reduction of lung phospholipid 18:0 after enteral feeding in comparison to the relative percentage of 18:0 in the baseline group of rats. The relative percentage of total phospholipid PUFA in the lungs was similar among the three diet groups. Total monounsaturated fatty acids (MUFA), the bulk of which is rep-

[c]NS, not significant.

resented by 18:1n-9, differed significantly between the fish and chow groups only (12.5 vs. 14.2%, respectively).

Provision of the fish oil PUFA enriched diet for 72 h induced significant changes in the individual and total n-3 and n-6 PUFA in the lung phospholipids relative to those present in the baseline (chow) group or those infused with the corn oil PUFA diet (Table 2). Both 18:2n-6 and 20:4n-6, as well as total n-6 PUFA, were significantly lower in the lung phospholipids of the rats given the fish oil PUFA diet than in those measured in the lungs from either the corn oil group or baseline group. The mean relative percentage of 18:2n-6 in lungs from the fish group was 6.5% as compared with 10.3 and 7.9% in lungs from the corn and baseline groups, respectively. The relative percentage of 20:4n-6 in the lung phospholipids of the fish oil group was 8.6%, in comparison to 12.4% in the corn oil group ($P < 0.001$) or 13.4% in the baseline group ($P < 0.001$). In conjunction with these reductions, the relative percentage of individual n-3 PUFA, the 20:5n-3/20:4n-6 ratio, the n-3/n-6 ratio, and the sum of n-3 PUFA were significantly higher ($P < 0.001$) in the fish group relative to those of either the corn or baseline group. The mean 20:5n-3 in the lung phospholipids of the rats given the fish oil-enriched diet enterally was 5.0% as compared to 1.3% at baseline and 0.1% in the corn oil-enriched groups, respectively. Lung phospholipid docosapentaenoic (DPA; 22:5n-3) acid (3 vs. 1.4%) and docosahexaenoic (DHA; 22:6n-3) acid (3.2 vs. 1.4%) were also higher in the group given the fish oil diet relative to the rats given the corn-oil-enriched diet.

It was also observed that the baseline rats had a significantly higher relative percentage of lung phospholipid 20:5n-3 and total n-3 PUFA than the corn group; this difference was presumably due to the presence of fish meal in the chow pellets used. These results also suggest that continuous enteral feeding for 72 h with the corn-oil-enriched diet, which was devoid of n-3 PUFA, promoted rapid loss of phospholipid 20:5n-3 and 22:6n-3 originally present after the baseline feeding period.

Alveolar macrophage phospholipid PUFA. The effects of enteral infusion of the fish- or corn oil-enriched formulations on the fatty acid composition of alveolar macrophage phospholipids (Table 3) paralleled those observed in the lung tissue. There were no differences among the three diet groups with respect to the relative percentage of individual SFA. However, the relative percentage of total SFA in alveolar macrophages from the enterally infused rats tended to be higher than the total SFA at baseline (65 vs. 61%). Concurrently, the total PUFA in alveolar macrophage phospholipids from both groups of enterally fed rats were lower than those measured at baseline. Total MUFA were similar among the three dietary groups. As observed in the lung tissue analyses (Table 2), the alveolar macrophages from the fish group had significantly lower relative percentage of 18:2n-6 and 20:4n-6 and greater relative percentage of 22:6n-3 than the macrophages from either the baseline rats or those infused with the corn oil-enriched formulation. The rats receiving the fish oil-enriched diet also had significantly higher 20:5n-3/20:4n-6 and n-3/n-6 ratios and total n-3 PUFA in the alveolar macrophage phospholipids than those in the rats at baseline or after enteral feeding with the corn oil-enriched diet. Rats given the corn oil-enriched diet for 72 h had significantly higher ($P < 0.001$) relative percentage of 18:2n-6 than baseline rats (8.9 vs 6.8%, respectively). As observed in the lung

[c]NS, not significant.

tissue phospholipids, concomitant levels of alveolar macrophage phospholipid 20:4n-6 and total n-6 PUFA in the rats infused with the corn oil-enriched diet remained similar to those seen in the baseline group (Table 3).

Surfactant phospholipid fatty acids. In general, compositional changes in the fatty acid profiles of the (SP) phospholipids (Table 4) after enteral feeding followed the trends observed for both the lung tissue (Table 2) and the alveolar macrophages (Table 3). The relative percentage of 16:0, the primary fatty acid associated with phosphatidylcholine, the main surfactant phospholipid, was comparable among the three diet groups. Although the baseline diet contained a higher relative percentage of 18:0 than either enteral diet (Table 1), surfactant phospholipids from the enterally fed rats, particularly those receiving the fish oil diet, had significantly higher levels of this SFA. The increase in surfactant SFA in the enteral fish group relative to the baseline rats was matched by a corresponding decrease in total MUFA, similar to the changes observed in lung tissue (Table 2). The relative percentage of both 18:2n-6 and 20:4n-6 were significantly lower in the surfactant phospholipids from the rats receiving the fish oil enteral formulation in comparison to surfactant from either the rats at baseline or the rats fed enterally with the corn oil formulation. The relative percentage of 20:5n-3, 22:6n-3 and total n-3 PUFA changed inversely to the relative percentage of individual and total n-6 PUFA. Significant displacement of n-6 PUFA from the phospholipids by n-3 PUFA was exemplified by the increased ratios of both 20:5n-3/20:4n-6 and n-3/n-6. However, the total PUFA in surfactant phospholipids remained similar among the diet groups.

DISCUSSION

Novel enteral formulations containing n-3 PUFA derived from marine and plant oils are currently being evaluated for potential utilization in critically ill or postoperative patients (11–13). Recent clinical studies have revealed that surgical (11,19) or burn (20) patients provided with fish oil-enriched formulations experienced reductions in the number of infections per patient and/or lengths of stay relative to patients that received standard formulations enriched with LA. The efficacy of long-chain n-3 PUFA to attenuate a post-traumatic inflammatory response is partly due to their capacity to displace n-6 PUFA from immune cell membrane phospholipids. In addition, EPA (20:5n-3), the principal fish oil n-3 PUFA, attenuates the formation of proinflammatory dienoic eicosanoids by competing with 20:4n-6 for cyclooxygenase binding sites (21). The eicosanoids derived from 20:5n-3 have reduced inflammatory properties relative to those derived from 20:4n-6. EPA also retards the conversion of 18:2n-6 to 20:4n-6 by inhibiting the rate-limiting enzyme, Δ6 desaturase. Other studies have demonstrated that cytokine release was lower from stimulated mononuclear cells that were enriched with n-3 PUFA than in cells containing higher relative percentage n-6 PUFA (5). However, the efficacy of n-3-enriched enteral diets for attenuating lung injury or inflammation in the clinical setting remains unresolved. Moreover, the extent of dietary n-3 PUFA uptake by lung tissue and alveolar components has not been assessed in patients nutritionally supported with n-3-enriched enteral preparations.

The present study was conducted to characterize the incorporation of n-3 and n-6 PUFA by rat lung, alveolar macrophage and surfactant phospholipids after short-term enteral infusion of diets enriched with fish or corn oil. The results revealed that continuous enteral feeding with a fish oil-enriched formulation fostered significant modulation of the PUFA composition of rat lung parenchymal tissue (Table 2), macrophage (Table 3) and surfactant (Table 4) phospholipids within 72 h. The generalized effects were that n-6 PUFA (i.e., 18:2n-6 and 20:4n-6), which are potential precursors of the vasoactive dienoic eicosanoids and leukotrienes, were displaced by longer chain n-3 PUFA (i.e., 20:5n-3, 22:5n-3 and 22:6n-3). The rapidity of these changes paralleled those previously observed in the plasma pool, as well as liver sinusoidal cells of rats after short-term enteral feeding with identical formulations (10). These findings may have clinical relevance given that equations formulated to predict tissue incorporation of dietary n-3 PUFA at specific intake ratios of n-3/n-6 PUFA are similar for rats and humans (22). Moreover, we have also observed that the incorporation of n-3 fatty acids into rat liver or lung macrophages during continuous enteral feeding is not impaired during concurrent endotoxemia (10,13). Evidence from clinical trials supports these findings. Other investigators (12) have shown that the relative percentage of EPA and n-3/n-6 ratios in both plasma and erythrocytes from critically ill patients were increased significantly above baseline within seven days after continuous enteral administration of a fish oil-enriched formulation.

In contrast to the rats infused with the n-3-enriched diet in the present study, rats infused with the corn oil-enriched formulation exhibited significant increases of 18:2n-6 with concomitant reductions of 20:5n-3 and total n-3 PUFA in lung (Table 2) and alveolar macrophage (Table 3) phospholipids relative to initial levels measured in the baseline rats given chow pellets. The importance of these results is underscored in that the majority of moderate- to high-fat enteral formulations currently used in the clinical setting have percentages of 18:2n-6 similar to that present in the corn oil-enriched formulation. The relative percentage of 20:4n-6 in both lung and alveolar macrophage phospholipids after enteral treatment with the corn oil diet remained unchanged from levels measured at baseline. The results from this study support the concept that significant displacement of 20:4n-6 from phospholipids by dietary PUFA is negligible unless: (i) the exogenous dietary PUFA have a carbon length or degree of unsaturation similar to 20:4n-6, and (ii) the relative n-3/n-6 ratio of the dietary PUFA is favorably weighted to enhance exchange with endogenous PUFA (23,24). With regard to the first conditional requirement, we had previously observed that liver sinusoidal cell and plasma phospholipid 18:2n-6, but not 20:4n-6, could be displaced by 18:1n-9 in rats infused with an enteral formulation enriched with olive oil (10).

The data from rats given the diet enriched with fish oil PUFA suggest that alveolar macrophages may be more capable of metabolizing 20:5n-3 (EPA) and/or 22:5n-3 (DPA) to 22:6n-3 (DHA) than lung tissue. Using the mean values listed in Tables 2 and 3, rough estimates of the EPA/DHA ratios for lung tissue and alveolar macrophages are 1.6 and 0.4, respectively. Further examination of the data reveals that the corresponding ratios of EPA/DPA are 1.7 and 1.0, respectively, and the ratios of DPA/DHA are 0.9 and 0.4, respectively, for lung and alveolar macrophage phospholipids. These ratios suggest that the alveolar macrophage appears to possess relatively higher elongase (i.e., for conversion of EPA to DPA) as well as $\Delta 4$ desaturase activity (i.e., for conversion of DPA to DHA) than the lung. However, such estimates based upon relative percentage of substrate do not take into account any potential differences that may exist between lung tissue and alveolar macrophages with regard to their individual capacities to incorporate DPA and/or DHA present in the diet (Table 1). With this *caveat* in mind, alveolar macrophages appear to be similar to peritoneal macrophages with respect to elongase activity (25). However, the $\Delta 4$ desaturase activity of peritoneal macrophages has been reported to be low (26). Further studies are required to determine any actual differences in enzyme activities between these two types of macrophages.

An interesting finding in the present study was that although alveolar macrophages and surfactant are not in direct physical contact with the plasma pool, displacement of their respective phospholipid n-6 PUFA by dietary n-3 PUFA during the 72 h infusion period was remarkable. Whether these alveolar components acquired n-3 PUFA transported directly from the plasma or through an intermediary cell source, e.g., type I or II pneumocytes, has not been resolved. In support of the latter concept, other investigators have recently reported that incorporation of dietary n-3 PUFA into type II pneumocytes, which synthesize surfactant, readily occurred *in vivo* in rats given chow enriched with fish oil (27). Moreover, an earlier study documented the transfer of radiolabeled 20:4n-6 from alveolar type II cells to alveolar macrophages *in vitro* (28). Alternatively, some portion of the alveolar macrophage phospholipid 22:5n-3 and/or 22:6n-3 may have been derived from elongation and/or desaturation of 20:5n-3 (as discussed earlier) within the macrophage or by the type II cell. Presumably, these latter cells also served as the direct source of the n-3 PUFA that were present in the surfactant phospholipids.

Although the possibility exists that the alveolar macrophages were newly recruited from the vascular pool of monocytes enriched with n-3 PUFA, an earlier study of bone marrow transplant patients indicated that replacement of resident alveolar macrophages by those derived from the transplanted marrow had occurred over several months (29). Alternatively, a source of n-3 PUFA for alveolar macrophages may, in part, arise from the surfactant phospholipid pool (Table 4). Phospholipids account for 80% of the composition of pulmonary surfactant. Moreover, these macrophages actively phagocytose surfactant as a regulatory mechanism for surfactant clearance (30,31). However, surfactant turnover would have to proceed at a rate high enough to en-

able uptake of significant amounts of n-3 PUFA by the macrophages. In this regard, earlier investigations indicated that >90% of radiolabelled surfactant phosphatidylcholine was cleared from the alveolar space within 24 h in adult rabbit lungs *in vivo* (32). Unfortunately, the metabolic complexity of and potential interactions among the lung's alveolar cells and components obviate identification of the immediate source(s) of n-3 PUFA present in the alveolar macrophages at this time.

We were unable to measure surfactant surface tension, precluding detection of potential dietary effects arising from n-3 PUFA on this functional parameter. Dipalmitoyl phosphatidylcholine (DPPC) is the primary surfactant phospholipid involved in the reduction of alveolar surface tension (31,33). In this regard, the relative percentage of palmitic acid (16:0) present in the surfactant total phospholipids was similar among the treatment groups (Table 4). However, it is not known whether changes in surfactant DPPC concentration occurred. A recent study of rats fed a fish oil-enriched diet for four weeks revealed that the amount of DPPC present in the surfactant was similar to that present in rats given a corn oil-enriched diet (27); however, DPPC associated with lung tissue from the fish oil group was increased relative to that in the corn oil group in that study. Another recent study (34) indicated that pretreatment of pigs with an n-3-enriched diet did not alter the minimum surface tension of pulmonary surfactant after endotoxin challenge relative to that measured in pigs fed an n-6-enriched diet. Given these findings, it appears unlikely that modification of the unsaturated fatty acid profile of surfactant phospholipids by dietary treatment with n-3 PUFA would alter or impair the surface tension properties of lung surfactant.

In summary, significant displacement of both LA and AA from rat lung, alveolar macrophage and surfactant phospholipids was achieved within 72 h by continuous delivery of an enteral formulation enriched with fish oil PUFA. The capacity of enteral feeding modalities to rapidly modulate the PUFA composition of these lung components may facilitate timely attenuation of eicosanoid-driven inflammatory processes in critically ill or postoperative patients at risk of developing ARDS.

[a]Department of Cell Biology and Human Anatomy, University of California, School of Medicine, Davis, California 95616-8643 and [b]Molecular and Cell Biology Section, Department of Animal Science, Texas A&M University, College Station, Texas 77843-2471

Diets that contain high levels of n-3 fatty acids from fish oil have been shown to significantly effect macrophage cytolytic capacity, tumor necrosis factor alpha production and eicosanoid production. The present study was undertaken to determine whether n-3 fatty acids from vegetable origin [linseed oil (LIN)] would have the same effects on murine macrophage tumoricidal capacity and eicosanoid production as would fish oil. Mice were fed for three weeks diets that contained 10% (wt/wt) of either LIN, which is high in linolenic acid (18:3n-3), menhaden fish oil (MFO), which is high in eicosapentaenoic (20:5n-3) and docosahexaenoic (22:6n-3) acids, or safflower oil (SAF), which is high in linoleic acid (18:2n-6). *In vivo*- or *in vitro*-activated macrophages were assessed for select functions. As expected, macrophages from mice fed LIN and MFO produced significantly lower levels of both prostaglandins and leukotriene C_4 when compared with macrophages from mice fed SAF. In addition, LIN and MFO macrophages were able to synthesize leuko-triene C_5, which could not be produced by macrophages from mice fed SAF. The effects of LIN, however, were not as pronounced as those of MFO. With respect to specific functions, macrophages from mice fed LIN did not have altered cytolytic capacity when compared with macrophages from mice fed SAF and activated *in vitro* with either lipopolysaccharide (LPS) alone for 24 h or with LPS plus interferon gamma (IFNγ) for 5 h. Diet did not significantly alter tumoricidal capacity of macrophages activated completely *in vivo* either. Specific binding of macrophages to tumor targets, nitric oxide production and the production of tumor necrosis factor alpha were found to be unaltered by LIN when compared with SAF. The results are not consistent with a general n-3 effect, as LIN could not effect the functions comparable to MFO. The results also suggest that a change in eicosanoid production may not be sufficient to modulate tumoricidal activity in macrophages.

***Lipids* 29, 651–655 (1994).**

Dietary n-3 fatty acids have attracted much attention of late as it has been shown that they can modulate the immune system and, in particular, macrophage function (1–5). Fish oil, which contains high levels of the n-3 fatty acids, eicosapentaenoic (20:5n-3) and docosahexaenoic (22:6n-3) acids, is a major source of n-3 fatty acids. Another source of n-3 fatty acids is linseed oil (LIN), which contains high levels of the n-3 fatty acid, α-linolenic acid (18:3n-3). Although there are numerous reports on the effects of fish oil on immune and, specifically, macrophage function, only very few have focused on the effects of LIN. One report (6) described the effect of LIN on macrophage phagocytosis of yeast and carbon particles and on macrophage arginase activity; however, no differences in phagocytic capacity were observed among the diets tested (LIN and corn oil), although arginase activity was decreased with LIN feeding. The authors (6) suggested the decreased arginase activity was due to a decrease in prostaglandin E (PGE) production caused by the LIN diet. The effects of dietary LIN on macrophage tumoricidal capacity have not been studied. We, and others, have reported, however, on the effects of menhaden fish oil (MFO) on macrophage cytolytic capacity (7), peroxide production and Iα expression (3,8), as well as on tumor necrosis factor alpha (TNFα) production (5,9–11). These studies showed that n-3 fatty acids from MFO could have contrasting effects on macrophage function. For example, although MFO was shown to decrease macrophage responsiveness to interferon gamma (IFNγ), and thus, cytolytic capacity (7), it was shown to increase macrophage capacity for TNFα production (4,5,10). In the present study, we show the effects of dietary LIN, which is also high in n-3 fatty acids, on macrophage tumoricidal activity and eicosanoid production. We used two populations of macrophages that have a high capacity for cytolytic activity. One population, thioglycollate-elicited macrophages, have been well-characterized but must be stimulated *in vitro* before they can kill tumor cells. The other population of macrophages are elicited with maleic anhydride divinyl ether (MVE-2) and lipopolysaccharide (LPS) and do not require activation *in vitro* as they are fully activated for tumor cell kill *in vivo* (12).

MATERIALS AND METHODS

Diets and animals. Female C57BL/6NCr mice, five weeks of age, were obtained from Charles River (Kingston, NY). Animals were housed in autoclaved cages in a laminar flow hood and given sterilized water to minimize "spontaneous" activation of macrophages (13). Mice were fed standard chow upon arrival, but were switched to the experimental diets after 48 h. Mice were fed the semipurified diets for at least three weeks before experiments were performed. The diets tested were adequate in all nutrients and varied only in the type of oil fed, i.e., either LIN (Seymour Organic Foods, Seymour, IL), safflower oil (SAF; California Oils, Richmond, CA), or MFO, which made up 10% of the diet by weight. The basic compositions of the semipurified diets have been described previously in detail (7); the diets contained casein, 20%; DL-methionine, 0.3%; corn starch, 15%; sucrose, 44%; cellulose, 5%; AIN-76 mineral mix, 3.5%; AIN-76 vitamin mix, 2%;

Abbreviations: HBSS, Hank's balanced salt solution; IFNγ, interferon gamma; MEM, minimum essential medium; PEC, peritoneal exudate cells; PGE, prostaglandin E; LIN, linseed oil; LPS, lipopolysaccharide; LT, leukotriene; MFO, menhaden fish oil; MVE-2, maleic anhydride divinyl ether; SAF, safflower oil; SDS, sodium dodecylsulfate; TNFα, tumor necrosis factor alpha.

choline chloride, 0.2%; and the dietary oil, 10%. The major fatty acids of the SAF diet were (in wt%): 16:0, 7.0%; 18:0, 2.5%; 18:1n-9, 10.7%; 18:2n-6, 78.2%; and others, 1.6%. The LIN diet contained 16:0, 6.5%; 18:0, 3.9%; 18:1n-9, 22.1%; 18:2n-6, 17.0%; 18:3n-3, 47%; and others, 3.5%. The MFO diet contained 14:0, 7.7%; 16:0, 16.0%; 18:0, 2.8%; 18:1n-9, 10.5%; 18:2n-6, 1.2%; 18:3n-6, 0.6%; 20:4n-6, 0.6%; 20:5n-3, 16.9%; 22:5n-3, 2.5%; 22:6n-3, 12.0%; and others, 29.2%. The powdered diets were mixed and stored at –20°C under N_2. Animals were allowed free access to both food and water. Neither body weights nor food intake differed significantly ($P > 0.05$) between the three dietary groups (data not shown).

Macrophages. Thioglycollate-elicited macrophages were obtained 3–5 d after peritoneal injection of 2.0 mL sterile fluid thioglycollate medium (prepared to manufacturer's specifications; Difco, Detroit, MI). For fully activated macrophages, mice were injected with 500 μg MVE-2 (Hercules, Inc., Wilmington, DE) plus 10 ng/mL LPS 5 d prior to use. Peritoneal exudate cells (PEC) were harvested from no less than three mice for each experiment with Hank's balanced salt solution (HBSS; BioWhittaker, Walkersville, MD) and ones from similar diet groups were pooled, centrifuged at 500 × *g* for 5 min, and resuspended in Eagle's minimum essential medium (MEM; BioWhittaker) containing 5% heat-inactivated calf serum (Hyclone, Logan, UT). Macrophage concentrations were adjusted after differential staining. There were no dietary fat effects on the percentage of PEC that were macrophages, regardless of the elicitation method or PEC yield (data not shown). Following 90 min of adherence in Eagle's MEM plus 5% serum, nonadherent cells were removed by rinsing with HBSS, and macrophage monolayers were further incubated in serum-free Eagle's MEM with or without activating agents, as described next. Macrophages made up more than 98% of the final adherent cell population as judged by phagocytosis and morphology. There were no differences in the adherence efficiency between the dietary groups (data not shown). The endotoxin level of the serum was <0.06 ng/mL, as determined by the supplier; all other reagents were negative for endotoxin as determined by the *Limulus* amebocyte lysate assay (BioWhittaker) which was sensitive to <0.1 ng/mL. All glassware was heat-sterilized at 180°C for 4 h to degrade residual endotoxin.

Analysis of eicosanoid production. For the measurement of leukotrienes (LT) produced, thioglycollate-elicited macrophages were isolated from PEC as described previously by adherence to 100-mm tissue culture plates. Cells were rinsed, then incubated in serum-free MEM (alpha modification; BioWhittaker) supplemented with 20 mM [*N*-2-hydroxyethyl]piperazine-*N'*-2-ethanesulfonic acid], 2 mM L-glutamine, 5 μg/mL gentamicin and 5 mM reduced glutathione for 2 h (14). After purification, macrophages were stimulated with 5 μM calcium ionophore A23187 for 40 min, and supernatants were immediately frozen at –75°C. Leukotrienes were analyzed essentially as previously described (15). Briefly, frozen supernatants were thawed and extracted using BakerBond reversed-phase C18 extraction columns (J.T. Baker, Phillipsburg, NJ). Extracted samples were dried under nitrogen and resuspended in a small aliquot of methanol/water (1:1, vol/vol). Samples were separated on a Waters 600E high-performance liquid chromatography using a Resolve C18 reversed-phase column (Waters, Milford, MA) and a mobile phase of methanol/5 mM ammonium acetate (3:1, vol/vol) run at 0.55 mL/min. Peaks were compared with authentic standards and verified by spectral analysis using an on-line photodiode array detector (Waters). Leukotrienes were quantitated by peak comparison with that of a prostaglandin B_2 standard. Levels of PGE_2 produced were measured in macrophage supernatants using an enzyme immunoasay kit (Cayman Chemical Co., Ann Arbor, MI). Protein was measured using the Biorad protein assay (Biorad, Hercules, CA).

Cytolysis assay and nitric oxide production. Thioglycollate-elicited macrophages from mice fed the experimental diets were plated in 96-well dishes and were either activated 24 h with LPS (*Escherichia coli* serotype 0111:B4, phenol extract, 0-1000 ng/mL; Sigma, St. Louis, MO), or 5 h with LPS, IFNγ (0–25 U/mL; Gibco, Gaithersburg, MD), or LPS + IFNγ in serum-free Eagle's MEM. Fully activated macrophages were plated in the same manner, but because they were completely activated *in vivo* for cytolysis, they received no additional treatment. Monolayers of *in vitro*- or *in vivo*-activated macrophages were overlaid with ^{51}Cr-labeled P815 cells as described (7). Briefly, P815 targets in midlog phase of growth (5×10^5/mL) were incubated for 60 min in 0.5 mL Eagle's MEM + 5% CS with 100 μCi/mL $Na_2{}^{51}CrO_4$ (NEN, Boston MA) with frequent gentle agitation. The cells were washed with HBSS, then resuspended to 10^5 cells/mL in Eagle's MEM + 5% serum. Aliquots were added to macrophage monolayers to give an effector/target ratio of 10:1, and the cultures were incubated for 18 h. To assess cytolysis, cell-free supernatant was removed from each well and placed into a glass tube for counting in a gamma spectrophotometer. Spontaneous release of label was determined from wells containing tumor cells alone, and total incorporated radioactivity was released by lysis with 0.5% sodium dodecylsulfate (SDS). Nitric oxide produced was measured in the supernatants of the cytolysis experiments using Greiss reagent (16). Briefly, macrophage supernatants were reacted with equal parts of 1% sulfanilamide (Sigma) and 0.1% naphthylethylenediamine (Sigma). The spectral change was determined on a microplate spectrophotometer at 550 nm, and the sample concentrations (nmoles nitrite/10^6 cells) calculated using a standard curve created with known concentrations of pure nitrite. Cytolysis and nitric oxide studies were done in triplicate, and each experiment was repeated three times. The results presented come from one representative experiment. Other experiments showed similar trends.

Selective binding. Thioglycollate-elicited macrophage monolayers in 96-well plates were treated with LPS, IFNγ or LPS + IFNγ as in the cytolysis assay described previously. Radiolabeled P815 cells were then added for various periods of time from 15 to 90 min, after which nonadherent P815 cells were removed by vigorous rinsing. Monolayers with adherent P815 cells were then lysed with 0.5% SDS and an aliquot counted in the gamma counter.

TNFα bioassay. Thioglycollate-elicited macrophages from diet mice were plated in 96-well dishes and treated

with LPS, as just described. After the activation period, supernatants of monolayers were tested for TNFα content by using a bioassay with the TNFα-sensitive cell line L929, as described (2,17). For the bioassay, sample supernatants or rTNFα standard were added in triplicate to 96-well plates containing 2–3 × 10^4 adherent L929 cells. Twofold serial dilutions were made, and the wells were then overlaid with Eagle's MEM containing 10% serum and 5 μg/mL actinomycin D (Sigma). The plates were incubated for 20 h, rinsed and stained with 0.2% crystal violet in 2% EtOH, dried, treated with 0.5% SDS, and quantitated at 570 nm. TNFα activity was calculated as the reciprocal dilution at 50% lysis of L929 cells. Sensitivity of the assay for TNFα was tested by treating some samples containing TNFα with a polyclonal rabbit anti-mouse TNFα antibody for neutralizing (Genzyme) which, at a dilution of 1:100, completely inhibited cytolysis of L929 targets. All bioassays were repeated at least three times.

Statistical analyses. Statistical analysis was performed using a two-tailed Student's *t*-test. Differences were judged as statistically significant when the *P* value was less than 0.05. The number of mice used for each experiment depended upon the number of cells required, the eliciting agent and the peritoneal macrophage yield.

RESULTS

Eicosanoid production. Eicosanoids were measured: (i) to allow evaluation of the extent to which dietary fat could modulate macrophage fatty acid composition; (ii) to compare the modulation seen with that observed previously with dietary fish oil; and (iii) to help in elucidating the mechanism by which dietary fat affects macrophage functions, many of which are modulated by eicosanoids. To address the changes caused by LIN feeding, we tested LT and PGE production by thioglycollate-elicited macrophages before and after stimulation with calcium ionophore A23187. Feeding mice LIN significantly decreased ($P < 0.05$) A23187-stimulated thioglycollate-elicited macrophage leukotriene C_4 (LTC_4) production when compared to macrophages from mice fed SAF (Table 1). Moreover, although there was no production of leukotriene C_5 (LTC_5) in macrophages from mice fed SAF, LIN macrophages produced relatively small amounts of LTC_5 that were significantly ($P > 0.05$) greater than those produced by SAF macrophages (Table 1). This alteration of LT production by LIN, however, was not as great as that seen with MFO (Table 1 and Ref. 15). Linseed oil feeding also altered PGE production by thioglycollate-elicited macrophages when compared with macro-phages from mice fed SAF. Upon stimulation with A23187, LIN macrophages produced 3–4 times less PGE when compared with A23187-stimulated SAF macrophages (Table 2). Macrophages from mice fed MFO showed further decreased PGE production compared with both LIN and SAF mice. We and others have previously shown that MFO feeding significantly decreased PGE production by macrophages (7,10). Basal levels of PGE were not significantly ($P > 0.05$) altered by dietary fat.

Cytolysis. Other n-3 fatty acids have been shown to alter macrophage cytolytic capacity (7). It has not been resolved, however, whether the effects of dietary MFO are directly due to alterations in eicosanoid metabolism, or to some other mechanism. Because LIN can also alter macrophage eicosanoid production (results above), we first tested the effects of LIN on *in vitro* activation of similar thioglycollate-elicited macrophages for tumoricidal activity against P815 mastocytoma cells. LIN feeding did not alter cytolysis after short-term *in vitro* activation with LPS and IFNγ (Fig. 1) or long-term *in vitro* activation with LPS only (data not shown). MFO feeding, however, significantly ($P < 0.05$) altered cytolysis when macrophages were incubated with relatively low levels of IFNγ and LPS (10 ng/mL). At higher levels of IFNγ, the cytolytic capacity of macrophages from mice fed MFO was similar to that of LIN and SAF macrophages. The results of cytolysis with MFO macrophages are consistent with our previously published data (7). Because fatty acids may be secreted from the macrophages and because culture conditions may alter cellular lipid levels during activation, macrophages were also activated *in vivo* with MVE-2/LPS. Tumoricidal macrophages obtained directly from mice fed LIN, SAF or MFO were cytolytic but did not differ in their capacity to kill tumor cells (data not shown).

TABLE 1

Effect of Dietary Fat on Leukotriene Production in Thioglycollate-Elicited Murine Macrophages[a]

Dietary fat	LTC_4	LTC_5
	(ng · mg protein^{-1} · h^{-1})	
Linseed oil	38 ± 7[b]	9 ± 2
Safflower oil	82 ± 11	ND[c]
Menhaden fish oil	40 ± 3[b,d]	24 ± 6[d]

[a]Measured leukotriene levels represent means ± SEM, and are based on triplicate samples from separate mice. Leukotriene production was stimulated *in vitro* with A23187 (5 μM).
[b]Significantly ($P < 0.05$) decreased as compared to levels from safflower oil-fed group.
[c]ND, not detected.
[d]Published data (Ref. 15) are presented here for comparison only.

TABLE 2

Effect of Dietary Fat on Prostaglandin E (PGE) Production in Thioglycollate-Elicited Murine Macrophages[a]

Dietary fat	Unstimulated	Stimulated
	(pg · mg protein^{-1} · h^{-1})	
Linseed oil	350 ± 80	1000 ± 160[b,c]
Safflower oil	290 ± 30	3550 ± 860[b]
Menhaden fish oil[c]	300 ± 30	520 ± 70[b–d]

[a]The enzyme immunoassay kit (Cayman Chemical Co., Ann Arbor, MI) used is for PGE_2 and cross-reacts minimally with PGE_1 and 100% with PGE_3. Macrophages were stimulated with calcium ionophore A23187 for 40 min and the supernatants tested directly using the kit.
[b]Significantly ($P < 0.05$) greater when compared with unstimulated cells.
[c]Significantly ($P < 0.05$) lower when compared with stimulated cells from the safflower oil-fed group.
[d]Significantly ($P < 0.05$) lower when compared with stimulated cells from the linseed oil-fed group.

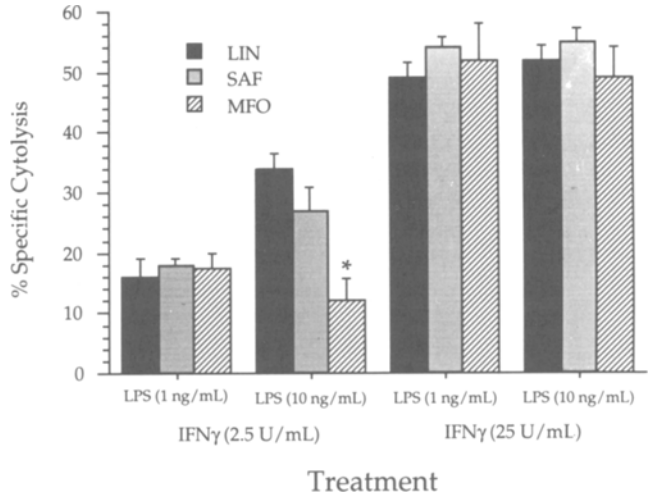

FIG. 1. Effect of dietary fat on *in vitro* activation of thioglycollate-elicited macrophages for specific tumor cell cytolysis. Macrophages from mice fed the different diets were activated with interferon gamma (IFNγ) and lipopolysaccharide (LPS) for 5 h in serum-free medium. *Significantly ($P < 0.05$) decreased compared to the other diets at that treatment. LIN, linseed oil; SAF, safflower oil; MFO, menhaden fish oil.

Nitric oxide production and selective binding. It is possible that while functional macrophage cytolysis was not affected by LIN feeding, some of the capacities required for cytolysis, such as tumor cell binding or nitric oxide production, may be differentially affected such that the sum of their alteration may add up to no effect. Our results, however, show this not to be the case as dietary fat did not alter the production of nitric oxide, a cytolytic mediator elaborated by macrophages (Fig. 2). To bring about cytolysis, activated macrophages must first specifically bind to target cells (18). When radiolabeled P815 cells were added to macrophages activated with 1 ng/mL LPS and 25 U/mL

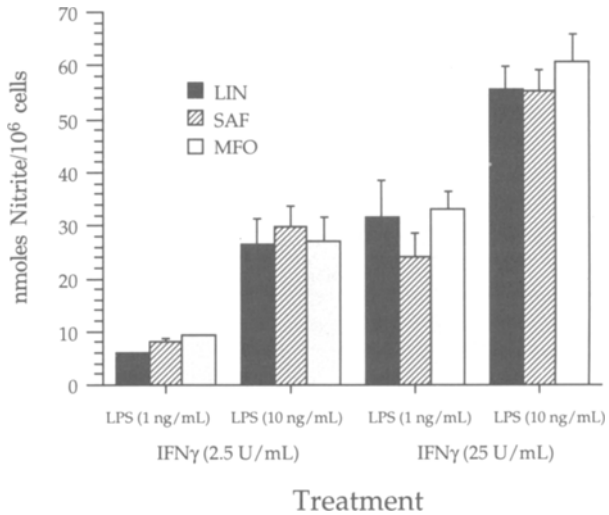

FIG. 2. Effect of dietary fat on *in vitro* activation of thioglycollate-elicited macrophages for nitric oxide production. Macrophages from diet mice were treated with IFNγ and LPS for 5 h, then overlaid with the tumor targets for 18 h. Nitric oxide was measured from the supernatants after that time period. No significant ($P > 0.05$) differences among the diets were observed. Abbreviations as in Figure 1.

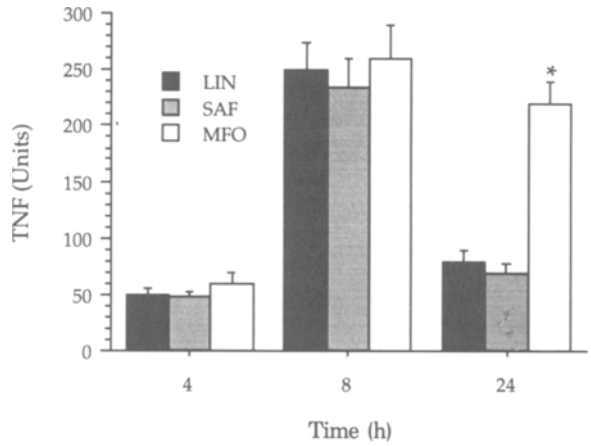

FIG. 3. Effect of dietary fat on the production of tumor necrosis factor alpha (TNFα) by LPS-stimulated (10 ng/mL) thioglycollate-elicited macrophages. TNFα bioactivity was calculated as the reciprocal dilution at 50% lysis of L929 cells. *Significantly ($P < 0.05$) increased as compared to the other diets at that time point. Abbreviations as in Figure 1.

IFNγ, no significant differences ($P > 0.05$) were observed between the dietary groups in the percentage of tumor targets that were specifically bound (LIN = 16 ± 3; SAF = 21 ± 4). No differences were observed at other levels and combinations of LPS and IFNγ, such as 10 and 100 ng/mL LPS, and 0.25 and 2.5 U/mL IFNγ (data not shown).

TNFα production. Dietary MFO has been shown to modulate TNFα production, which may be due to alterations in eicosanoid production (5,11). When we tested the effects of LIN-feeding, which alters eicosanoid production, on bioactive TNFα levels in LPS-stimulated (10 ng/mL) thioglycollate-elicited macrophages, we found that there were no significant ($P > 0.05$) differences as compared to the SAF group (Fig. 3). MFO, in contrast, was able to alter macrophage TNFα production at 24 h, which is consistent with our previous data (5).

DISCUSSION

In the present study, we have shown that feeding 10% LIN significantly altered eicosanoid production, but was unable to alter specific macrophage cytolytic capacity against P815 mastocytoma cells or TNFα production. These results suggest that the mechanism of the effects on macrophage function due to dietary fat may be independent of altered eicosanoid synthesis, as LIN does alter eicosanoid synthesis, but does not alter cytolysis. It is well established that feeding animals fish oil can alter the production of eicosanoids by macrophages and other cells. In general, fish oil feeding suppresses PGE_2 production and four-series leukotriene production in macrophages while stimulating the synthesis of new five-series leukotrienes. Few studies prior to this report have sought to evaluate the effects of other n-3 fatty acid sources on eicosanoid production (19–21). In one study (19), a diet containing 18:3n-3 was shown to decrease peritoneal macrophage production of leukotriene B_4 (LTB_4) and LTC_4, as well as PGE_2. Recently it was also shown that a diet containing 18:3n-3 can induce *in vivo* peritoneal macrophages stimu-

lated with zymosan to synthesize leukotriene E_5 (20,21). In our study, we showed that thioglycollate-elicited macrophages from mice fed LIN, which contains relatively high levels of 18:3n-3 (47%), were able to produce LTC_5 after stimulation with calcium ionophore A23187. Although a limited number of studies have begun to define the roles of LTB_4 and PGE_2 in the immune system, the effects of LTC_4 and LTC_5 have not been clarified. The mechanism by which dietary fat alters eicosanoids and its relationship to macrophage function has yet to be determined, although it may be due to altered tissue levels of arachidonate, the precursor for eicosanoids.

Three previous studies (22–24) have reported on the effects of dietary LIN on the production of TNFα by macrophages. In one, LIN feeding was shown to increase TNFα production in rat resident macrophages as compared to macrophages from animals fed corn oil (22). However, in that same study, no differences were observed among the diets with respect to TNFα production by complete Freund's Adjuvant-elicited macrophages. In another study (23), resident and casein-elicited, but not thioglycollate-elicited, peritoneal macrophages from mice fed diets containing high levels of 18:2n-3 produced greater amounts of TNFα compared with macrophages from mice fed diets containing high levels of 18:2n-6. Neither did we see an enhancement of TNFα production by thioglycollate-elicited macrophages with LIN feeding. It has been shown that PGE can significantly down-regulate production of TNFα by macrophages, whereas inhibition of PGE synthesis has the opposite effect (5,10,25). Therefore, a possible mechanism for the effect of fish oil on TNFα production by macrophages may be related to an alteration in eicosanoid synthesis. LIN feeding, however, does not have the same capacity to affect TNFα production in thioglycollate-elicited macrophages, perhaps because it does not decrease PGE production to the same extent as MFO.

Besides modifying the production of TNFα in macrophages (4,5,10), dietary MFO can significantly alter activation of thioglycollate-elicited macrophages for cytolysis of tumor targets (7). These effects may have been due to the levels of n-3 fatty acids in the fish oil. One possible mechanism for the effects of dietary fat on tumoricidal activity may be an alteration of eicosanoid synthesis, as others have shown that PGE is responsible for down-regulating resident macrophage tumoricidal capacity (26–28). In the present study, however, we did not observe an alteration in cytolysis with LIN feeding after either *in vitro* activation with IFNγ and LPS or *in vivo* activation with MVE-2. Perhaps LIN did not alter eicosanoid production to the extent required for down-regulation.

In the present study we have attempted to clarify whether n-3 fatty acids have a general effect on macrophage function. Because LIN contains significant levels of 18:3n-3, and 18:3n-3 can be converted to 20:5n-3, we expected to observe effects similar to those previously reported for fish oil. With respect to eicosanoid production, LIN did have an effect similar to that of MFO. However, with respect to macrophage tumoricidal capacity, LIN feeding followed the pattern of the SAF (n-6) effects. Thus, the relationship between the effects of n-3 fatty acids and macrophage function may be specific for the type of n-3 fatty acid, or may be responsive to the balance between n-3 and n-6 fatty acids.

COMMUNICATION

Inhibition of Cytolytic T Lymphocyte Activity by Oxysterols

Ömer Küçük[a,*], Jeanette Stoner-Picking[a], Stanley Yachnin[b], Leo I. Gordon[c], R. Michael Williams[c], Leonard J. Lis[a] and Maxwell P. Westerman[a]

[a]Section of Hematology/Oncology, Chicago Medical School and the Veterans Affairs Medical Center, North Chicago, Illinois 60064, [b]Section of Hematology/Oncology, University of Chicago, Chicago, Illinois 60637 and [c]Section of Hematology/Oncology, Northwestern University Medical School, Chicago, Illinois 60611

The objective of this study was to investigate the effects of oxysterols (OS), namely 5α-hydroxy-6-ketocholestanol, 6-ketocholestanol and 25-hydroxycholesterol, on specific cell-mediated cytotoxicity by C57BL/6 spleen cells against P815-X2 (a DBA/2 mastocytoma) target cells. Cytolytic T lymphocytes (CTL) were generated by intraperitoneally injecting C57BL/6 mice with P815-X2 tumor cells 10 d prior to the cytotoxicity experiments. Preincubation of CTL with 10^{-5} M 5α-hydroxy-6-ketocholestanol and 6-ketocholestanol for 45 min in lipoprotein-depleted medium resulted in an inhibition of cytolytic activity (73 and 43%, respectively) as measured by 4-h ^{51}Cr release. At a concentration of 5×10^{-6} M, 5α-hydroxy-6-ketocholestanol inhibited CTL activity by 65%, whereas 6-ketocholestanol did not elicit any inhibition. By contrast, 25-hydroxycholesterol did not inhibit CTL at either concentration, although it is known to be a potent inhibitor of 3-hydroxy-3-methyl-glutaryl-coenzyme A reductase, the rate-limiting enzyme in the cholesterol biosynthetic pathway. When CTL were preincubated with OS in lipoprotein-replete medium, there was no inhibition of CTL activity at the respective concentrations. The results suggest that the inhibition of CTL activity upon short-term incubation with OS is not due to the inhibition of cholesterol synthesis, but may be due to the insertion of OS into the plasma membrane to replace cholesterol and alteration of membrane physical properties.
***Lipids* 29, 657–660 (1994).**

Oxysterols (OS) are cholesterol oxidation products which may be produced under a variety of conditions that are associated with oxidant stress (1–7). Increased generation of OS has been reported to occur in the cell membrane under prooxidant conditions (6). Cholesterol oxidation products have been found in skin exposed to ultraviolet light (3,4), which is known to have immunosuppressive effects. Grever *et al.* (8) observed that after exposure to highly reactive oxygen compounds human lymphocytes were significantly impaired in both antibody-dependent and nonantibody-mediated cytotoxicity against a human lymphoblast target cell. As OS have been shown to inhibit cellular immunity (9–11), it is possible that the oxidant induced inhibition of cell-mediated toxicity observed by Grever *et al.* (8) may be due to generation of OS in the cell membrane. OS taken up by diet may also be immunosuppressive, as was shown by Heiniger *et al.* (12), who observed that a diet containing 0.25% 7-ketocholesterol had a suppressive effect on the secondary immune response in C57BL/6 mice.

We have previously reported the inhibitory effect of OS on natural killer (NK) cell activity (11). In the present report, we describe the effects of short term *in vitro* incubation with three OS, namely 25-hydroxycholesterol, 6-ketocholestanol and 5α-hydroxy-6-ketocholestanol, on tumor cell killing by cytolytic T lymphocytes (CTL) specifically generated *in vivo* against the target allogeneic tumor cells. We chose two OS that are oxidized at the sterol nucleus and one OS that is oxidized at the alkyl side chain, in order to determine if the location of the oxygenated group influences the effects of OS on CTL activity. We also chose to study these OS because they are among the oxidation products of cholesterol (1) and because their effects on other systems have been studied (11,13).

MATERIALS AND METHODS

Animals. Normal 4–6-week-old male C57BL/6 (H-2^b) mice were obtained from Harlon (Frederick, MD). The animals were age-matched (6–10 weeks old) at the onset of each experiment.

OS. 6-Ketocholestanol (3β-hydroxy-5α-cholestan-6-one) was obtained from Sigma (St. Louis, MO) and 5α-hydroxy-6-ketocholestanol (3β,5-dihydroxy-5α-cholestan-6-one) and 25-hydroxycholesterol (cholest-5-ene-3β,25-diol) were obtained from Steraloids (Wilton, NH). The OS were added to lymphocyte suspensions as ethanolic stock solutions with 100 times the desired final concentration.

Target cells. P815-X2 mastocytoma cells (DBA/2 origin, H-2^d) were maintained in tissue culture flasks containing RPMI-1640 medium with Hepes (MA Bioproducts, Walkersville, MD), 5% heat-inactivated fetal calf serum (GIBCO, Grand Island, NY), 0.1 mg/mL gentamycin and 5 mM L-glutamine in a 5% CO_2 humidified incubator. Cultures were passaged twice weekly and periodically tested for mycoplasma contamination.

Preparation of lymphocytes. Ten days after an intraperitoneal inoculation of 20×10^6 viable P815-X2 cells, spleens were removed from C57BL/6 mice immediately after cervical dislocation. Single cell suspensions of spleen cells were made in ice-cold RPMI-1640 with gentle teasing of cells out of the spleens by using a scalpel blade. After enrichment of the lymphocyte fraction using an Isolymph (Gallard-Schlesinger Chemical, Carle Place, NY) gradient, the cells were washed, and 2×10^6 cells in 4 mL of RPMI-1640 were placed in tubes for incubation.

Incubation with OS. One mL of lipoprotein-depleted serum (LPDS) or normal human AB serum (ABS) was added to 4 mL of lymphocyte suspension, resulting in 20% lipoprotein-depleted medium (LPDM) or lipoprotein replete medium. LPDS was prepared as previously de-

Abbreviations: ABS, human blood group AB serum; CTL, cytolytic T lymphocyte; H-2, mouse major histocompatibility complex; HMG–CoA, 3-hydroxy-3-methylglutaryl coenzyme A; LPDM, lipoprotein-depleted medium; LPDS, lipoprotein-depleted serum; NK, natural killer; OS, oxysterol.

scribed (11) by ultracentrifugational flotation of lipoproteins of a density <1.25 g/mL. The residual bottom fraction was dialyzed extensively against phosphate buffered saline, heated to 56°C for 45 min, and sterilized by membrane filtration prior to use. Fifty μL of an ethanolic solution of OS was added, resulting in a final OS concentration ranging from 2.5×10^{-6} M to 10^{-5} M. Because OS were added in ethanol, all incubations contained a final concentration of 1% (vol/vol) ethanol. Incubations were carried out at 37°C for 45 min with gentle rocking in a water bath. Viability of lymphocytes was assessed by trypan blue dye exclusion both before and after incubation.

^{51}Cr release assay. P815-X2 target cells (10^6 cells) were labeled with 100 μCi $Na_2{}^{51}CrO_4$ for 90 min at 37°C and were washed three times. The desired concentration of lymphocytes (100 μL) and 100 μL of ^{51}Cr-labeled target cells (5,000) were added into triplicate wells of a 96-well, U-bottomed microtiter plate (Corning, Corning, NY) to obtain the desired effector/target cell ratios. The plates were centrifuged at $300 \times g$ for 2 min and then incubated for 4 h at 37°C under a 5% CO_2 atmosphere in a humidified incubator. The plates were then centrifuged at $500 \times g$ for 10 min, and 100 μL of supernatant was transferred to tubes for radioactivity counting. The percentage of specific ^{51}Cr release was calculated by using the formula:

$$\frac{\text{cpm experimental release} - \text{cpm spontaneous release}}{\text{cpm maximal release} - \text{cpm spontaneous release}} \times 100 \quad [1]$$

in which maximal release refers to the cpm obtained after adding Triton X-100 (0.5%) to the target cells just before centrifugation of the plates, and spontaneous release refers to the cpm released by target cells in the absence of effectors. All experimental and control values were the means of three replicates.

Percent inhibition of CTL activity by OS was calculated by using the formula:

$$\frac{\%\ \text{specific}\ ^{51}\text{Cr release with control medium} - \%\ \text{specific}\ ^{51}\text{Cr release with OS}}{\%\ \text{specific}\ ^{51}\text{Cr release with control medium}} \times 100 \quad [2]$$

Control medium contained 1% ethanol and 20% LPDM with no OS added. Percent inhibition values shown on Table 1 are the results of four experiments expressed as mean % inhibition ± standard error.

RESULTS

Table 1 shows the inhibition of cytolytic T cell activity by the OS used in this study. At a concentration of 2.5×10^{-6} M in the preincubation medium, none of the OS resulted in an inhibition of CTL activity. At a concentration of 5×10^{-6} M, 5α-hydroxy-6-ketocholestanol resulted in a 65% inhibition of CTL activity. When the concentration of OS in the incubation medium was increased to 10^{-5} M, 6-ketocholestanol resulted in a 43% inhibition of CTL activity, and the inhibition with 5α-hydroxy-6-ketocholestanol increased to 73%. 25-Hydroxycholesterol resulted in little or no inhibition of CTL activity at any of the above concentrations used in these experiments. The viability of lymphocytes after incubation with OS at these concentrations was more than 90%, excluding the possibility of OS toxicity.

TABLE 1

Concentration-Dependent Inhibition of Specific Cytolytic T Lymphocyte (CTL) Activity by 5α-Hydroxy-6-ketocholestanol and 6-Ketocholestanol

	% of inhibition[a] of CTL by OS at different concentrations		
Oxysterols (OS)	2.5×10^{-6} M	5.0×10^{-6} M	1.0×10^{-5} M
5α-Hydroxy-6-ketocholestanol	8 ± 6[b]	65 ± 20	73 ± 15
6-Ketocholestanol	10 ± 6	8 ± 4	43 ± 20
25-Hydroxycholesterol	4 ± 3	4 ± 3	0

[a]% Inhibition = [(% specific ^{51}Cr release with control medium − % specific ^{51}Cr release with OS)/(% specific ^{51}Cr release with control medium)] × 100.
[b]Results of four experiments are expressed as percentage of inhibition (mean ± SE). Effector cell to target cell ratio is 50:1.

TABLE 2

Presence of Lipoproteins (ABS) in the Incubation Medium Prevents Inhibition of CTL Activity by 5α-Hydroxy-6-ketocholestanol (5×10^{-6} M)[a]

Percentage specific ^{51}Cr release (mean ± SE)[b]		
20% LPDS + ethanol	20% LPDS + OS	20% ABS + OS
57 ± 2	29 ± 14	51 ± 4

[a]Abbreviations as in Table 1. LPDS, lipoprotein-depleted serum; ABS, human blood group AB serum.
[b]Results of four experiments are expressed as mean percentage of specific ^{51}Cr release ± SE. Effector cell to target cell ratio is 50:1.

The inhibitory effect of 5α-hydroxy-6-ketocholestanol on CTL activity was prevented by the presence of lipoproteins in the incubation medium, which was achieved by using normal human ABS instead of lipoprotein-depleted serum in the incubation medium (Table 2). At 5×10^{-6} M 5α-hydroxy-6-ketocholestanol in the preincubation medium, % specific ^{51}Cr release was 29 ± 14% in the presence of 20% LPDM and 51 ± 4% (mean ± standard error) in the presence of 20% ABS. Control incubation with 20% LPDM and 1% ethanol in the absence of 5α-hydroxy-6-ketocholestanol resulted in a % specific ^{51}Cr release of 57 ± 2%. Results are the means ± standard errors of four experiments under each condition at an effector/target cell ratio of 50:1.

DISCUSSION

In the present study we have examined the effects of OS on specific CTL activity. The nature of inhibition of specific CTL activity by OS was similar to the previously reported (11) inhibition of NK cell activity by these compounds, i.e., OS oxidized at the C-5 and C-6 positions of the sterol nucleus inhibited CTL activity, whereas 25-hydroxycholesterol being oxidized at C-25 of the alkyl side chain had little or no inhibitory effect (Table 1). However,

CTL appear to be less sensitive to the inhibitory effects of OS as compared to NK cells, which were inhibited more profoundly under similar experimental conditions (11). When the insertion of OS into the plasma membrane of CTL was reduced due to the presence of lipoproteins in the incubation medium, there was little inhibition of CTL activity (Table 2). This finding supports the hypothesis that OS inhibit CTL lytic function by inserting themselves into the plasma membrane and altering its physical properties. This phenomenon of lipoprotein competition with plasma membrane for OS binding was also observed in the OS-induced inhibition of NK cell activity (11).

OS may influence cellular functions either by altering the physical properties of the membrane (e.g., fluidity) due to their presence in the lipid bilayer as cholesterol analogues, or by inhibiting 3-hydroxy-3-methylglutaryl CoA (HMG–CoA) reductase, the key regulatory enzyme in the cholesterol biosynthetic pathway (13–15), or by other yet unknown means. Heiniger *et al.* (9) have shown that preincubation of CTL generated in secondary C57BL/6 anti-DBA/2 mixed lymphocyte cultures with an OS inhibitor of cellular cholesterol biosynthesis (25-hydroxycholesterol) for 24 h strongly depressed cytolytic activity. In other studies involving similar long-term incubations with OS, Humphries and McConnell (16) have observed inhibition of plaque-forming cell response by 25-hydroxycholesterol, and Spangrude *et al.* (10) observed inhibition of differentiation and function of tumor specific cytotoxic T lymphocytes by 25-hydroxycholesterol, 20α-hydroxycholesterol, 7β-hydroxycholesterol and 7α-hydroxycholesterol. Although 20α-hydroxycholesterol and 25-hydroxycholesterol caused a parallel depression in lymphocyte proliferation, CTL activity and endogenous sterol biosynthesis, 7β-hydroxycholesterol and 7α-hydroxycholesterol abrogated CTL activity without depressing proliferative responses and endogenous sterol biosynthesis (10). We have previously found that oxidation of cholesterol at C-5, C-6 and C-7 of the sterol nucleus results in OS which are potent inhibitors of NK cell-mediated cytotoxicity (11).

The mechanism of inhibition of CTL activity by OS is unlikely to be due to inhibition of cholesterol synthesis in these experiments, because: (i) CTL activity was not inhibited by 25-hydroxycholesterol (Table 1), which is a potent inhibitor of HMG–CoA reductase, the rate-limiting enzyme in cholesterol biosynthesis; and (ii) the duration of exposure to OS was too short (45 min) to attribute the inhibition of CTL to decreased cholesterol synthesis. Previously observed morphologic and fluidity changes in red cell membranes (6,13,15,17) and the functional membrane changes in lymphocytes (18) and granulocytes (19) induced by OS suggest that the inhibition of CTL may be due to alterations in the physical properties of CTL plasma membrane caused by OS. Figure 1 depicts the OS used in this study. The presence of OS in a cell membrane would be expected to affect the packing of phospholipid molecules. Model membrane (20,21) and red blood cell membrane (6,15,22) studies have shown that OS influence membrane fluidity and lipid packing. The inhibition of CTL activity by OS oxidized at the C-5 and C-6 positions, but not by OS oxidized at C-25 position, appears to be consistent with the hypothesis that inhibition of CTL by OS

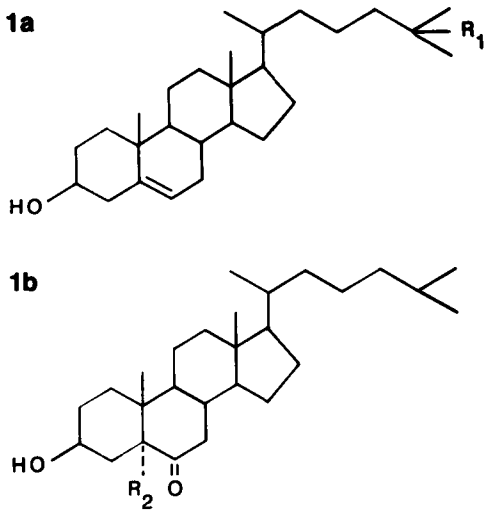

FIG. 1. Schematic representation of the sterols used. (1a) Cholesterol: R_1 = H; 25-hydroxycholesterol: R_1 = OH; (1b) 6-ketocholestanol: R_2 = H; 5α-hydroxy-6-ketocholestanol: R_2 = OH.

is due to its effects on fluidity and/or packing of the plasma membrane, which would be expected to be affected more profoundly by OS oxidized at the sterol nucleus (i.e., C-5, C-6), as compared to OS oxidized at the alkyl side chain (i.e., C-25) (15,22).

The dynamics of membrane proteins play an important role in cellular functions. Fluidity of the lipid matrix appears to be a major mechanism whereby the dynamics of membrane proteins are controlled (23,24). Thus, the function of membrane carriers, receptors and enzymes can be markedly affected by changes in lipid microviscosity (25–28). Borochov and Shinitzky (29) have shown that cholesterol depletion, which reduces membrane microviscosity, resulted in masking of membrane proteins and, conversely, an increase in membrane microviscosity, through cholesterol enrichment in red cell membranes resulted in an increase of protein exposure to the aqueous surrounding. Insertion of OS into the red cell membrane has also been shown to alter lipid fluidity and protein conformation (15).

Although the inhibition of HMG–CoA reductase by OS as a mechanism of OS-induced modulation of cell functions has been extensively investigated, relatively little attention has been directed to the possible effects of OS on the membrane physical properties (6,13). OS, being cholesterol analogues, are readily incorporated into lipid bilayers (13) and thus affect the structural and functional integrity of the mammalian plasma membrane (15). Under *in vivo* conditions, OS may accumulate in the plasma membranes of T cells, which have a long life span, resulting in cellular dysfunction and leading to immunosuppression. This would be expected to occur particularly when the organism is exposed to increased oxidant stress. The alteration of cell membrane structure and the inhibition of cholesterol biosynthesis by OS may both play a role in the pathogenesis of OS-induced immunosuppression *in vivo*.

In conclusion, the results show that C-5 and C-6 oxidation products of cholesterol inhibit CTL activity, and the

C-25 oxidation product does not inhibit CTL under the short-term *in vitro* exposure conditions used in these experiments. Our results suggest that the observed inhibitory effects of OS on CTL lytic function may be partly due to modulation of lymphocyte plasma membrane fluidity and structure induced by insertion of OS into the membrane. The position of the oxygen group(s) on the OS molecules appear to influence the degree of their effect on membrane physical and functional properties.

Sterols of Eustigmatophytes

G.W. Patterson[a,*], E. Tsitsa-Tzardis[a,1], G.H. Wikfors[b], P. Ghosh[a], B.C. Smith[b] and P.K. Gladu[c]

[a]Department of Botany, University of Maryland, College Park, Maryland 20742, [b]NOAA, National Marine Fisheries Service, Northeast Fisheries Science Center, Milford, Connecticut 06460 and [c]Department of Biology, Frostburg State University, Frostburg, Maryland 21532

The oyster cannot synthesize sterols from smaller molecules but must obtain them from its diet, which consists of detritus and small organisms, i.e., mostly single-celled algae. Algae differ widely in their effectiveness as oyster food. Small (<5 μm) algae which are abundant in sterols and polyunsaturated fatty acids appear to be most effective. Recent studies have shown the occurrence of cholesterol in strains of the unicellular algae *Tetraselmis, Chaetoceros* and *Skeletonema,* sometimes in large quantities. In the study reported here, six isolates of a recently constructed algal class, the Eustigmatophyceae, have been examined for sterols and fatty acids by gas chromatography and gas chromatography/mass spectrometry. All strains were shown to contain cholesterol as the principal sterol. Two isolates contained large amounts of total sterol (400–1000 fg/cell), and one (Sticho 0–18) also contained large amounts of eicosapentaenoic acid (20:5n-3). These biochemical characteristics are desirable in a potential food source for oysters.
***Lipids* 29, 661–664 (1994).**

The need to improve the productivity of the eastern United States oyster fisheries and our capabilities in oyster aquaculture has stimulated research into finding an optimal diet for the oyster (1,2). Most oyster diets are composed of single-celled algae, but algae differ widely in their ability to support oyster growth (2). Although representatives of most unicellular algal groups have been examined for their ability to support oyster growth, the Eustigmatophyceae has not been systematically evaluated as oyster food. This class was first proposed by Hibberd and Leedale (3) who differentiated it from other algal taxa chiefly based on ultrastructural features. Possession of unique pigment characteristics, i.e., chlorophyll a as the only chlorophyll pigment and violaxanthin as the dominant xanthophyll, was later ascribed to the class (4). As most eustigmatophycean vegetative stages are small (1–5 μm) and nonmotile unicells, identification beyond the class level is difficult, and eustigmatophytes often have been misidentified as xanthophytes or chlorophytes. Established cultures can be assigned to the Eustigmatophyceae by the absence of chlorophyll b and c and the presence of violaxanthin and/or vaucherioxanthin as the main accessory pigments. The strains analyzed in the present study were determined to be eustigmatophytes by these criteria, although all had been misidentified previously in several chlorophyte genera. Strain designations used are those assigned by the isolator.

There is little information on the effectiveness of eustigmatophytes as bivalve feed. *Nannochloropsis salinia* (strain Sticho-GSB) has been used successfully to rear larvae of the hard clam, *Mercenaria mercenaria,* through metamorphosis (Wikfors, G.H., unpublished data). One marine eustigmatophyte, *N. oculata* ("marine chlorella"), is widely used in fish aquaculture as a feed for rotifers and brine shrimp, which are subsequently given as live prey to larval marine fish (5). Recent studies have shown that oyster growth is positively correlated with several biochemical components of its diet (1,6), with sterols and polyunsaturated fatty acids being of major importance. As all available data indicate that the oyster is unable to synthesize cholesterol (its major sterol) (7) or sufficient amounts of polyunsaturated fatty acids to meet metabolic demands (8,9), algal strains containing cholesterol (or closely related sterols) and polyunsaturated fatty acids offer excellent potential as oyster food. Therefore, our recent work has involved examination of numerous phytoplanktons for their sterol and fatty acid compositions (10,11).

Only five isolates of Eustigmatophytes have been examined for sterol and fatty acid composition (12,13). Suen *et al.* (12) reported the sterol of *Nannochloropsis* sp. QII to be cholesterol, and the major polyunsaturated fatty acid to be 20:4. Volkman *et al.* (13) examined four eustigmatophyte isolates and found 20:5n-3 to be the major polyunsaturated fatty acid and cholesterol the major sterol in each isolate. The present paper reports on the sterol composition and on the major fatty acids in six isolates of the Eustigmatophyceae.

MATERIALS AND METHODS

Eustigmatophyte cultures analyzed were from the Milford Microalgal Culture Collection; strain designations and sources are given in Table 1. Most isolates are unidentified, or had been misidentified as various chlorophyte taxae; they were shown to be eustigmatophytes by spectrophotometric pigment analysis (14), which revealed that chlorophyll a was the sole chlorophyll (Table 2). High-performance liquid chromatography of xanthophyll pigments (15) confirmed the presence of violaxanthin and the absence of neoxanthin, antheraxauthin and lutein, demonstrating that each of these isolates is a eustigmatophyte. All cultures were axenic. Biomass for sterol analysis was provided by 1500 mL E medium (16) cultures in 2800-mL Fernbach flasks. Flasks were inoculated with late-log cultures, incubated at 20°C with a 12 h light/dark cycle (600 $\mu E\ m^{-2}\ s^{-1}$), and harvested, after 30 d growth, in a stationary phase characterized as N-limited (Wikfors, G.H., unpublished data). Harvested cells were concentrated by cold (5°C) centrifugation (2000 × *g*), washed with sterile NaCl solution isotonic to the growth medium, transferred to glass lyophilizer vials, frozen in a cold (–25°C) methanol bath, and lyophilized with a Virtis Unitrap 100 Freeze-dryer (American Optical Company, Buffalo, NY).

[a]*Chlorella autotrophica*, strain 580, is included for comparison of chlorophyte pigment composition; ratio of A/B or A/C < 0.1 is not significantly different from 0.

The number of cells contained within each lyophilizer vial was determined microscopically with an Improved Neubauer Hemocytometer (American Optical Company) containing a subsample of a volumetrically diluted cell concentrate. For dry weight measurements, cells were collected on a glass-fiber filter, rinsed with isotonic ammonium formate solution, dried for 8 h at 80°C, and weighed.

Lyophilized samples were extracted overnight in a Soxhlet with chloroform/methanol (2:1, vol/vol). The form of sterols present in the phytoplankton was determined by fractionating the total lipids on a Biosil A column. Free sterols were generated from esters and glycosides (17), followed by sterol identification and quantitative analysis by capillary gas chromatography (GC) on SPB-1 (18). Sterols were identified by comparing their relative retention times vs. those of cholesterol in capillary GC with those of authentic standards. Identifications were confirmed by GC/mass spectrometry (GC/MS) (18). Major fatty acids (over 10% of total) were identified by capillary GC on a 0.25 mm × 100 m column coated with a 0.2 μm film of SPB-2560.

RESULTS AND DISCUSSION

The major sterol in all Eustigmatophyte isolates was cholesterol, with amounts ranging from 52–80% of total sterol. Smaller amounts of 24-ethylcholesterol and isofucosterol were also present in many of the isolates (Scheme 1, Table 3). From their sterol compositions, four isolates (Sticho-GSB, U-106, U-112 and Sticho-M) were essentially indistinguishable from each other, having a total sterol content of 13–30 fg/cell. Strain U-113C had high total sterol content (480 fg/cell) with 79% of the total sterol being present as cholesterol. Isolate Sticho 0–18 was distinguishable from all the other isolates by its higher dry weight (26 pg/cell), its very high total sterol content (1000 fg/cell), and by the fact that the companion sterols of cholesterol were 24-methylcholesta-5,22-dienol and 24-ethylcholesta-5,22-dienol (Scheme 1). GC/MS data and GC relative retention times of the sterols identified were identical to those of authentic standards. Although most algal sterols with asymmetry at C-24 have 24β alkyl groups (9), the C-24 stereochemistry was not determined in this work. The sterols in all six isolates were present almost exclusively as free sterols. Steryl esters and steryl glycosides were present at less than 5% of total sterol.

The major fatty acid of the strains Sticho-GSB, U-106, U-112 and U-113C was palmitic acid (16:0); only small

[b]As % of total sterol; CHOL, cholesterol; MC5,22, 24-methyl-cholesta-5,22-dienol; EC5,22, 24-ethylcholesta-5,22-dienol; EC, 24-ethylcholesterol; FUCO, fucosterol; ISOFUCO, isofucosterol.

quantities (less than 10% of total fatty acid) of long-chain polyunsaturated fatty acids were present (Table 4). Isolates of Sticho-M and Sticho 0–18 contained eicosapentaenoic acid (20:5n-3) as the major fatty acid. Thus, Sticho-M can be differentiated from the other three strains with similar sterol compositions, which have 16:0 rather than 20:5 as the major fatty acid. Biochemical similarities among strains U-106, U-112 and Sticho-GSB suggest that all these strains may be isolates of *N. salinia.*

Interestingly, Suen *et al.* (12) detected 20:4, but not 20:5n-3 or 22:6n-3, in *Nannochloropsis* sp. II, but all strains examined by the Volkman group (19,20) had large amounts of 20:5n-3. None of the isolates analyzed in our study had both sterol and fatty acid compositions consistent with *N. oculata,* the species frequently used in aquaculture (5).

Cholesterol is the major sterol in all eustigmatophytes studied in this and in previous work, although the quantity of cholesterol varies greatly among isolates. About half the strains appear rich in long-chain polyunsaturated fatty acids (12,13). The early work of Dupuy (21) had shown that oysters can be grown on a mixed diet, which included one eustigmatophyte. Because Sticho 0–18 is rich in 20:5n-3 and very high in sterol content, it appears to have the greatest potential as oyster food of the eustigmatophyte isolates studied to date.

The purpose of this study was to investigate the temporal relationships of the transport of β-carotene in human lipoproteins. We administered 60 mg β-carotene with breakfast to nine fasting subjects, then blood samples were collected at intervals of up to 75 h, lipoproteins were isolated, and β-carotene was quantitated. β-Carotene concentrations in chylomicrons and very low density lipoproteins (VLDL) peaked at 6 and 9 h, respectively. Nonetheless, at all time points the majority of plasma β-carotene was contained in low density lipoproteins (LDL), while high density lipoproteins (HDL) carried a smaller portion (at 24 h, 73 ± 8% in LDL as compared with 23 ± 5% in HDL). In three subjects, transport of β-carotene was compared with the results of earlier studies on the transport of stereoisomers of α-tocopherol. Unlike plasma *RRR*-α-tocopherol concentrations, which are maintained by the preferential incorporation of *RRR*-α-tocopherol into VLDL by the liver, β-carotene increased and decreased in VLDL similarly to *SRR*-α-tocopherol, a stereoisomer whose concentrations are not maintained in plasma. In conclusion, β-carotene is primarily transported in the plasma in LDL, but its incorporation by the liver into lipoproteins does not appear to be enhanced.

***Lipids* 29, 665–669 (1994).**

In intestinal cells, β-carotene can either be secreted directly in chylomicrons, or it can be converted by intestinal cells to retinol, which is esterified with palmitic acid for export in chylomicrons (1). For the purpose of calculating the recommended dietary allowance for vitamin A, it has been assumed that 33% of a dose of β-carotene is absorbed, and 50% is converted to retinol (2). Most (75–79%) of the plasma carotenoids are associated with low density lipoproteins (LDL), with the remainder being carried by high density lipoproteins (HDL) (3–7).

We have been studying the transport of α-tocopherol in lipoproteins using deuterium-labeled tocopherols, both α- and γ-tocopherols, as well as two stereoisomers of α-tocopherol (*RRR*- and *SRR*-) (8–12). These studies have demonstrated that there is little discrimination between tocopherols during absorption and secretion in chylomicrons, but, subsequently, there is a preferential incorporation of *RRR*-α-tocopherol, the naturally occurring stereoisomer, into very low density lipoproteins (VLDL) (13). During catabolism of the triglyceride-rich lipoproteins (both chylomicrons and VLDL), there is rapid transfer of tocopherols between the lipoproteins.

β-Carotene is more hydrophobic than α-tocopherol; therefore, it may not be transferred to lipoproteins during chylomicron catabolism in a manner similar to tocopherols. Furthermore, available evidence suggests that a tocopherol binding protein is required for the preferential incorporation of *RRR*-α-tocopherol into nascent VLDL (9,14). Although a hepatic carotenoid binding protein, which could be involved in the incorporation of β-carotene into VLDL, has been described in a preliminary report by Okoh and Lakshman (15), β-carotene may behave more like γ- or *SRR*-α-tocopherols, which are not efficiently resecreted in VLDL into the plasma (16). The purpose of this study was to evaluate the temporal relationships of the transport of β-carotene in human plasma lipoproteins.

EXPERIMENTAL DESIGN AND METHODS

Experimental protocols. This study was carried out within the guidelines of the Institutional Review Board of New York University Medical Center (New York, NY). Ten subjects gave written informed consent and had no abnormalities of lipid or lipoprotein metabolism. The subjects were instructed to consume a gelatin capsule containing 60 mg β-carotene beadlets [Hoffman La Roche, Nutley, NJ; beadlets are a formulation of β-carotene that are especially bioavailable (17)] following an overnight fast, along with a suggested breakfast consisting of 1 cup whole milk, 1 cup vanilla ice cream, 1 banana, 1 serving of cereal (Cheerios) and 1 cup of coffee. Subsequent meals were the subject's choice, but the subjects were instructed to avoid carrots, yellow squash, pumpkin, broccoli and spinach a week before the study as well as during the course of the study. The characteristics of the nine subjects reported here are shown in Table 1.

Blood samples (15 mL/time point) were collected in ethylenediaminetetraacetic acid (EDTA) tubes (Becton-Dickinson, Rutherford, NJ) at 0, 3, 6, 9, 11, 28, 53 and 76 h after the subjects consumed the β-carotene. Plasma was separated from blood cells by centrifugation; a 1.0 mL aliquot of plasma was used for β-carotene quantitation, and the remainder was used for isolation of the lipoprotein fractions. Samples were protected from light at all times.

Lipoprotein isolation. Chylomicrons and lipoproteins were isolated as described previously (8). Briefly, chylomicrons were isolated from duplicate samples of 4 mL plasma overlayed with 2 mL saline (0.15 M NaCl, 0.3 mM EDTA, pH 7.4) by centrifugation for 8 min at 40,000 rpm

[a]HDL, high density lipoproteins. [b]ND, not determined.

using a swinging bucket rotor (TLS 55) and a TL 100 ultracentrifuge (Beckman Instruments, Inc., Palo Alto, CA). The remaining lipoprotein fractions were isolated in two sequential steps by ultracentrifugation for 2 h at 435,680 × *g* using a fixed angle rotor (TLA 100.2) with density changes achieved by adding solid KBr. The density ranges used were: VLDL d < 1.006, LDL 1.006 < d < 1.063 and HDL 1.063 < d < 1.21.

β-Carotene analysis. β-Carotene was analyzed using a modification of the method of Stacewicz-Sapuntzakis *et al.* (18). Briefly, upon isolation, the lipoprotein fractions and the plasma samples were saponified with alcoholic potassium hydroxide in the presence of 1% ascorbic acid, then were extracted with hexane, and an aliquot of the extract was dried under nitrogen. The samples were resuspended in 50 μL chloroform and diluted to 200 μL with mobile phase (methanol/acetonitrile/tetrahydrofuran, 50:45:5, by vol) containing 100 mg ammonium acetate per L of mixture. Aliquots containing between 1 and 50 mg β-carotene were injected into a high-pressure liquid chromatography system (Waters, Milford, MA) equipped with a C18 column (Waters) at a flow rate of mobile phase of 2 mL/min, and detected at 450 nm using a Waters variable wavelength ultraviolet detector. β-Carotene is not stable enough to use purified standards for daily use as calibrators. Therefore, β-carotene for use as a standard was extracted daily from beadlets (a stabilized form with added antioxidants). β-Carotene in plasma or lipoproteins was quantitated by comparison of peak areas with those of a β-carotene standard.

Deuterated tocopherol study. Three of the study subjects (numbers 2, 3 and 4) had previously participated in studies using deuterated tocopherols (12); results of various concentrations of deuterated α-tocopherols are reported here for comparison with the β-carotene values. Briefly, each subject consumed a capsule containing 50 mg each of d_6-*RRR*-α-tocopheryl acetate, d_3-*SRR*-α-tocopheryl acetate and d_2-*RRR*-γ-tocopherol, with a breakfast following an overnight fast. Blood samples were drawn into EDTA tubes at approximately 0, 3, 6, 9, 12, 27, 51 and 75 h after consumption of the tocopherols. Subjects were allowed to eat *ad libitum*.

Plasma was immediately separated from blood cells by centrifugation. An aliquot (1.0 mL) was frozen for subsequent tocopherol analysis, and the remainder was used for isolation of the lipoprotein fractions, as described in a previous paragraph. Frozen plasma and lipoprotein fractions were shipped on dry ice to the National Research Council of Canada where they were kept frozen at –80°C until analyzed. The amounts of d_2-γ-tocopherol, d_3-, d_6-, d_9-α-tocopherols and unlabeled (d_0-)α- and γ-tocopherols in the collected tocopherol fraction were determined by gas chromatography/mass spectrometry after conversion to their trimethylsilyl ethers. The absolute concentrations of d_0-, d_3- and d_6-α-tocopherols and d_0- and d_2-γ-tocopherols in the plasma and lipoprotein samples were obtained by comparing their respective peak areas with the peak areas of the corresponding d_9-α- and d_{17}-γ-tocopherols added (8,9,19).

Data analysis and statistical methods. Calculations were carried out using a Macintosh II computer (Apple Computers, Cupertino, CA). The concentrations of lipoprotein β-carotene were summed and compared with the plasma concentrations of β-carotene for each time point. The total lipoprotein concentrations ranged from 80–120% of the plasma concentrations. The plasma concentration was used as the total amount of β-carotene, and the sum of the lipoprotein β-carotene was corrected to this value. The lipoprotein β-carotene distribution was based on the actual measurements. The mean ± standard deviations were calculated for each time point for the plasma and each of the lipoprotein fractions for the nine subjects. The area under the curve (AUC) was calculated for the plasma carotenoids by summing the trapezoids estimated from the X–Y data points using KaleidaGraph (Synergy Software, PCS Inc., Reading, PA). The statistical significance of the differences was determined using the statistical analysis program, Super Anova (Abacus Concepts, Berkeley, CA), using analysis of variance and least square means comparisons. Results of the statistical tests were considered to be significant at the 95% confidence level ($P < 0.05$).

RESULTS

The concentrations of β-carotene in the plasma and lipoproteins from nine subjects are shown in Figure 1. One of the ten subjects studied had almost undetectable plasma β-carotene levels; his data are not included. Previously, Prince and Frisoli (20) reported that dietary fat is necessary for β-carotene absorption; likely the omitted subject did not consume breakfast with the dose. Plasma β-carotene of the other nine subjects increased up to 27 h and then remained relatively constant for the remainder of the study. The AUC ranged from 8 to 116 nmol/mL · h with a mean ± standard deviation of 51 ± 33 nmol/mL · h. Despite the wide range of β-carotene concentrations, in all subjects β-carotene was observed to peak first in the chylomicrons, and then in the VLDL (Fig. 1). HDL β-carotene concentrations appeared to increase only during triglyceride-rich lipoprotein catabolism (up to 11 h) and then reached a plateau, whereas LDL β-carotene concentrations increased for a longer period of time (up to 48 h).

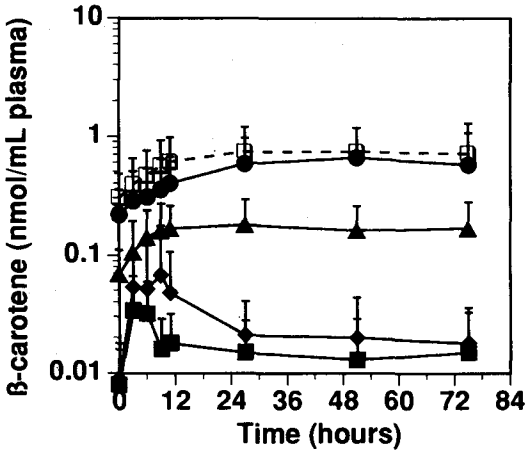

FIG. 1. Plasma and lipoprotein β-carotene concentrations. Following an overnight fast, nine subjects each consumed a gelatin capsule containing 60 mg β-carotene beadlets (Hoffmann La Roche, Nutley, NJ) along with breakfast. Blood samples (15 mL/time point) were collected in EDTA tubes (Becton-Dickinson, Rutherford, NJ) at 0, 3, 6, 9, 11, 28, 53 and 76 hours. Plasma was separated from blood cells by centrifugation; chylomicrons and lipoprotein fractions were isolated as described in the Experimental Design and Methods section. The density ranges of the lipoproteins were: very low density (VLDL) d < 1.006, low density (LDL) 1.006 < d < 1.063, and high density (HDL) 1.063 < d < 1.21. Shown are means + SD of the β-carotene concentrations in plasma and each of the lipoprotein fractions. Key: ❑, plasma; ●, LDL; ▲, HDL; ◆, VLDL; ■, chylomicrons.

The percentage distribution of plasma β-carotene in the lipoprotein fractions throughout the study are shown in Figure 2. Early on, increases in proportion of plasma β-carotene were observed in the triglyceride rich-lipoproteins (in chylomicrons a statistically significant increase compared to baseline was observed at 3 h, $P < 0.001$), while the VLDL showed significant increases at 3 h ($P < 0.001$), 6 h ($P < 0.01$) and 9 h ($P < 0.01$). During triglyceride-rich lipoprotein catabolism from 0 to 9 h, HDL β-carotene increased 6% (22 ± 5 to 28 ± 8%, $P < 0.03$). At the outset of the study, 72 ± 6% of the plasma β-carotene was found in LDL, which contained most of the plasma β-carotene at all time points. However, because the other lipoproteins transported β-carotene during the initial part of the study, the proportion of plasma β-carotene in LDL decreased from 3 to 11 h and significantly smaller fractions of plasma β-carotene were present in LDL at 3 h ($P < 0.01$), 6 h ($P < 0.001$), 9 h ($P < 0.01$) and 11 h ($P < 0.05$). By 27 h, the distribution of β-carotene in all lipoprotein fractions had returned to baseline values.

Three of the subjects (numbers 2, 3 and 4) studied had previously participated in studies using deuterated α-tocopherols (12). For purposes of comparison of α-tocopherol with β-carotene (because β-carotene was unlabeled), the increase in β-carotene concentrations is compared with the deuterated α-tocopherol concentrations. As shown in Figure 3, the plasma concentrations of both labeled stereoisomers of α-tocopherol were about fivefold greater than those of β-carotene at 3 h. By 24 h, the concentrations of β-carotene reached those of *SRR*-α-tocopherol. Subsequently, the concentrations of β-carotene and *SRR*-α-tocopherol decreased at a similar rate.

Examination of the lipoprotein patterns of β-carotene and of the α-tocopherols in these three subjects shows marked differences in the transport of β-carotene and α-tocopherol (Fig. 4). It appears that the peak in chylomicron β-carotene precedes that of α-tocopherol; however, because the data are from separate studies, the temporal relationship between the chylomicron transport of α-tocopherol and β-carotene cannot be stated with certainty. In

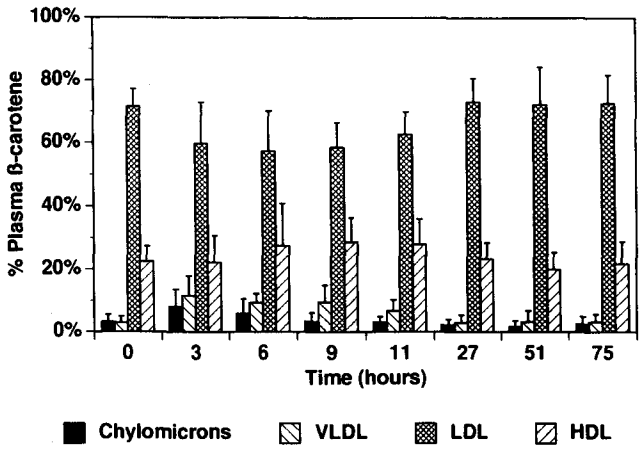

FIG. 2. Percentage distribution of β-carotene in lipoprotein fractions. The percentage distribution of plasma β-carotene in each of the lipoprotein fractions described in Figure 1 was calculated for each subject. Shown are the means + SD for each fraction. Abbreviations as in Figure 1.

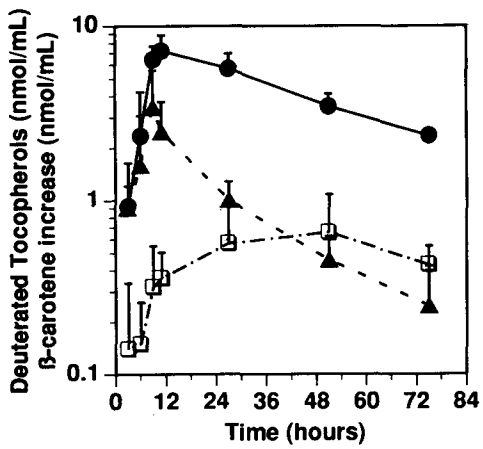

FIG. 3. Comparisons of plasma concentrations of labeled α-tocopherol stereoisomers with increases in β-carotene concentrations. Three subjects (numbers 2, 3 and 4) had previously participated in a study on the transport of vitamin E by consuming a dose containing 50 mg of each *RRR*- and *SRR*-α-tocopherols labeled with 6 or 3 atoms of deuterium, respectively (12). The concentrations of β-carotene in the plasma of these subjects in response to the dose of β-carotene beadlets were estimated by subtracting the concentration of β-carotene at time 0. Shown are the means + SD of the concentrations of deuterated tocopherols (*RRR*-α-tocopherol and *SRR*-α-tocopherol) and the increases in β-carotene above background. Key: ▲, d_3-*SRR*; ●, d_6-*RRR*; ❑, β-carotene increase.

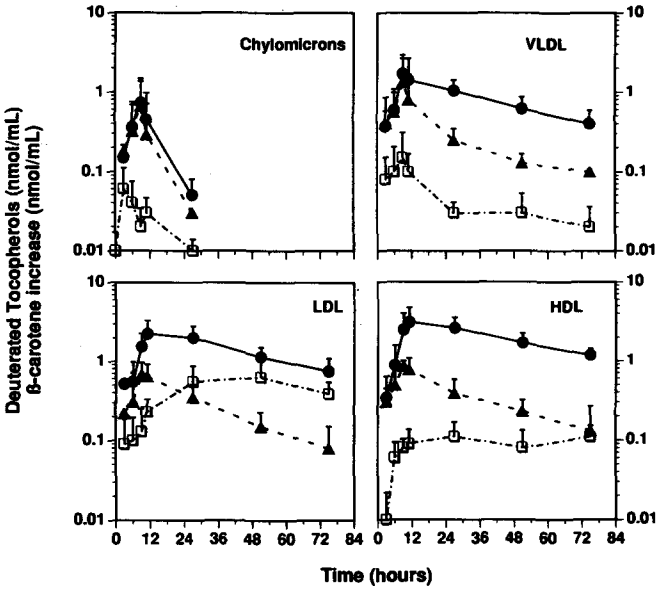

FIG. 4. Lipoprotein concentrations of β-carotene increases and labeled stereoisomers of α-tocopherol. Lipoprotein (as described in Figure 1) concentrations of deuterium-labeled *stereoisomers of α-tocopherol* and *β-carotene increases* are shown from the three subjects described in Figure 3. Key as in Figure 3; abbreviations as in Figure 1.

VLDL, β-carotene concentrations (although fivefold lower) parallel those of *SRR*-α-tocopherol. In LDL, the concentrations of β-carotene increased, nearly reaching those of *RRR*-α-tocopherol at 48 h, unlike those of *SRR*-α-tocopherol, which began to decrease at 9 h. In HDL, β-carotene concentrations essentially reach their maxima by 11 h.

DISCUSSION

This study demonstrates that β-carotene is absorbed and secreted by the intestine in chylomicrons and is subsequently secreted by the liver in VLDL. Increases in HDL β-carotene were observed during the catabolism of these two triglyceride-rich lipoproteins in the plasma. Unlike HDL β-carotene, which increased only during the first 12 h of the study, LDL β-carotene transport in LDL concentrations increased up to 48 h. These increases are likely the result of the conversion of VLDL to LDL.

The comparisons between the transport of α-tocopherol and β-carotene provide further insights in the transport of these two hydrophobic nutrients. Similar amounts of deuterated α-tocopherols and unlabeled β-carotene were administered, but increases in plasma concentrations of β-carotene were almost tenfold lower (Fig. 3). It is likely that the lower plasma concentrations of β-carotene result from a combination of low absorption rates and low plasma incorporation. With respect to absorption, although both β-carotene and α-tocopherols are transported in chylomicrons, the greater hydrophobicity of β-carotene may limit its intracellular transport and thus its incorporation into chylomicrons. Additionally, some β-carotene is converted to retinol and is absorbed, as retinyl palmitate (1).

With respect to plasma transport, we have previously demonstrated that *RRR*-α-tocopherol is preferentially enriched in plasma by 24 h following an oral dose containing various labeled tocopherols (10,12). The preference for incorporation of *RRR*-α-tocopherol into nascent VLDL by the liver (11) likely results from the selection of this form of vitamin E by the tocopherol transfer protein (21–24). The catabolism of VLDL enriched in *RRR*-α-tocopherol in the plasma and the continued preferential secretion of *RRR*-α-tocopherol in VLDL by the liver are probably responsible for maintaining plasma α-tocopherol concentrations (13,25). In VLDL, β-carotene concentrations paralleled those of *SRR*-α-tocopherol, suggesting that β-carotene is incorporated into VLDL in a nonspecific manner. Further, the differences in the α-tocopherol and β-carotene concentration curves in LDL and HDL demonstrate differences in transport of these two nutrients. Because of its hydrophobicity, β-carotene is likely to be located in the hydrophobic lipoprotein core, which would be consistent with the preference of β-carotene for LDL rather than those for HDL. In contrast, HDL β-carotene increased during the first few hours of the experiment, suggesting that during the transfer of surface components from chylomicrons to HDL there is also transfer of some core lipids. Furthermore, HDL β-carotene represents a relatively small fraction of β-carotene, suggesting that β-carotene does not readily exchange between lipoproteins *in vivo* or *in vitro* (26).

In conclusion, this study demonstrates that the plasma and lipoprotein transport of two hydrophobic nutrients, β-carotene and *RRR*-α-tocopherol, are dissimilar. β-Carotene does not readily exchange between lipoproteins, and it appears to concentrate in LDL, whereas *RRR*-α-tocopherol is present in all of the lipoprotein fractions. It has been suggested that β-carotene might function as an antioxidant and protect LDL from peroxidative damage during oxidative stress. However, recent studies have suggested that β-carotene supplementation does not necessarily increase the resistance to oxidative stress (6). Thus, the beneficial effects of elevated LDL β-carotene remain to be demonstrated.

ACKNOWLEDGMENTS

David Fry and Nora Lagmay provided excellent technical assistance. This study was supported in part by grants from the U.S. public Health Service, HL 30842, and from Hoffmann La Roche, which also supplied β-carotene beadlets.

Rat liver microsomes, when fortified with NADPH, Fe^{3+} and phosphate, can catalyze the oxidative decarboxylation (α-oxidation) of 3-methyl-substituted fatty acids (phytanic and 3-methylheptadecanoic acids) at rates that equal 60–70% of those observed in isolated hepatocytes (Huang, S., Van Veldhoven, P.P., Vanhoutte, F., Parmentier, G., Eyssen, H.J., and Mannaerts, G.P., 1992, *Arch. Biochem. Biophys. 296*, 214–223). In the present study we set out to identify and compare the products and possible intermediates of α-oxidation formed in rat hepatocytes and by rat liver microsomes. In the presence of NADPH, Fe^{3+} and phosphate, microsomes decarboxylated not only 3-methyl fatty acids but also 2-methyl fatty acids and even straight chain fatty acids. The decarboxylation products of 3-methylheptadecanoic and palmitic acids were purified by high-performance liquid chromatography and identified by gas chromatography/mass spectrometry as 2-methylhexadecanoic and pentadecanoic acids, respectively. Inclusion in the incubation mixtures of glutathione plus glutathione peroxidase inhibited decarboxylation by more than 90%, suggesting that a 2-hydroperoxy fatty acid is formed as a possible intermediate. However, we have not yet been able to unequivocally identify this intermediate. Instead, several possible rearrangement metabolites were identified. In isolated rat hepatocytes incubated with 3-methylheptadecanoic acid, the formation of the decarboxylation product, 2-methylhexadecanoic acid, was demonstrated, but no accumulation of putative intermediates or rearrangement products was observed. Our data do not allow us to draw conclusions on whether the reconstituted microsomal system is representative of the cellular α-oxidation system. However, the results we obtained with [3-^{3}H]-labelled fatty acids indicate that during α-oxidation in intact cells the hydrogen at carbon-3, which carries the methyl branch, is not attacked.

***Lipids* 29, 671–678 (1994).**

Phytanic acid (3,7,11,15-tetramethylhexadecanoic acid) is an isoprenoid-derived fatty acid that accumulates in the body fluids and tissues of patients suffering from Refsum's disease, a rare inherited metabolic disorder affecting the nervous system (1). Due to the presence of a methyl group at carbon-3, phytanic acid cannot be degraded *via* the classical β-oxidation pathway. Instead, it is first oxidatively decarboxylated by α-oxidation, yielding CO_2 and a 2-methyl-substituted fatty acid, pristanic acid (1), which can then be degraded *via* peroxisomal β-oxidation (2).

The mechanism of phytanic acid α-oxidation has remained elusive for many years. Earlier studies, by Steinberg's group and others (3–7), had suggested that phytanic acid α-oxidation involved an unusual α-hydroxylation step to yield 2-hydroxyphytanic acid as an intermediate and that the enzymatic activity was located in the mitochondria. In recent years, there have been a number of reports (8–12) that showed that phytanic acid accumulation also occurs in the body fluids and tissues of patients with general peroxisomal disorders, e.g., Zellweger syndrome, infantile Refsum disease, neonatal adrenoleukodystrophy and rhizomelic chondrodysplasia punctata, suggesting that peroxisomes may play a role in phytanic acid α-oxidation. However, cell fractionation studies have produced contradictory results—the highest α-oxidation activity was found in either mitochondrial (7,13,14) or combined mitochondrial plus cytosolic fractions (15). Very recently, Wanders and van Roermund (16) suggested that α-oxidation involves the sequential action of mitochondria and peroxisomes, and Singh *et al.* (17) concluded that α-oxidation is located in mitochondria in the rat, but it is in the peroxisomes in humans. Reports on the cofactor requirements of phytanic acid α-oxidation have also been inconsistent. Tsai *et al.* (7) postulated that α–oxidation requires O_2, NADPH and Fe^{3+}, whereas others found that, besides O_2, the only cofactors necessary are adenosine triphosphate (ATP) and Mg^{2+} (13–16) or ATP, Mg^{2+} and CoA (17). A further complication in interpreting the above studies is the fact that the α-oxidation rates obtained in these broken cell systems were extremely low as compared with those obtainable in intact cells (18).

In a recent report (18), we have demonstrated that the maximal rates of α-oxidation in isolated rat hepatocytes amounted to 7 and 10 nmol/min × 10^8 cells with phytanic acid and 3-methylheptadecanoic acid, respectively. In rat liver homogenates, optimal rates of α-oxidation, which equalled 60–70% of those observed in the intact hepatocytes, required O_2, NADPH, Fe^{3+} and phosphate ions. Subcellular fractionation revealed that under our assay conditions α-oxidation is located in the endoplasmic reticulum. Using the same assay conditions, we now find that rat liver microsomes decarboxylate not only 3-methyl fatty acids but also 2-methyl fatty acids, and even straight chain fatty acids. We furthermore attempted to identify and purify the decarboxylation products and the putative reaction intermediate(s).

Abbreviations: ATP, adenosine triphosphate; BSTFA–TMCS, *bis*(trimethylsilyl)trifluoroacetamide containing 1% trimethylchlorosilane; EI, electron impact; GC, gas chromatography; HPLC, high-performance liquid chromatography; MS, mass spectrometry; TLC, thin-layer chromatography; TMS, trimethylsilyl.

MATERIALS AND METHODS

Chemicals. Collagenase, superoxide dismutase, catalase, glucose-6-phosphate, and glucose-6-phosphate dehydrogenase were purchased from Boehringer Mannheim (Heidelberg, Germany). Glutathione peroxidase, cytochrome C and metyrapone were from Sigma (St. Louis, MO). Glutathione was from Merck (Darmstadt, Germany). Palmitic acid was from Janssen Chimica (Beerse, Belgium). Phytanic acid, [1-^{14}C]phytanic acid (specific radioactivity, 54 mCi/mmol, initial radiochemical purity 99.2%), 3-methylheptadecanoic acid, 3-methyl-[1-^{14}C]heptadecanoic acid (specific radioactivity, 54 mCi/mmol, initial radiochemical purity 99.8%), 2-methylpalmitic acid and 2-methyl-[1-^{14}C]palmitic acid (specific radioactivity, 35 mCi/mmol, initial radiochemical purity 98.8%) were synthesized as described previously (2,18). [1-^{14}C]Palmitic acid (specific radioactivity, 57 mCi/mmol, stated radiochemical purity 97.7%) and [9,10-^{3}H]palmitic acid (specific radioactivity, 51.6 Ci/mol, stated radiochemical purity 98.4%) were obtained from New England Nuclear (Bad Homberg, Germany). [^{3}H]$NaBH_4$ (specific radioactivity 32 Ci/mmol) was from Amersham International (Amersham, England) and [1,2-^{13}C]palmitic acid (isotopic purity>99%) was purchased from Isotec Inc. (Miamisburg, OH). *Bis*(trimethylsilyl)trifluoroacetamide containing 1% trimethylchlorosilane (BSTFA–TMCS) was obtained from Alltech Associates (Laarne, Belgium). Ethereal diazomethane was prepared from Diazald^{R} as recommended by the manufacturer (Aldrich, Brussels, Belgium).

Synthesis of 3-methyl-[3-^{3}H]heptadecanoic acid. Tritiated 3-methylheptadecanoic acid was prepared from [2-^{3}H]hexadec-2-yl methanesulfonate, similarly to the previously described synthesis of cold 3-methylheptadecanoic acid (18). [2-^{3}H]Hexadec-2-yl methanesulfonate was obtained from 2-hexadecanol as follows. 2-Hexadecanol (245 mg, 1 mmol) was dissolved in 20 mL of hexane and oxidized by adding 35 mL of 2.7 M CrO_3/4.3 M H_2SO_4. After vigorous stirring for 30 min at room temperature, 2-hexadecanone was extracted into hexane. The hexane phase was washed twice with saturated $NaHCO_3$, thrice with water, and analyzed by thin-layer chromatography (TLC) using hexane/diethyl ether/acetic acid (60:40:1, by vol). Visualization by iodine or ultraviolet-illumination revealed only one spot with an R_f value of 0.82. In the next step, 2-hexadecanone (48.2 mg, 0.2 mmol, dissolved in 2 mL of tetrahydrofuran) was reduced by adding 50 μmol of [^{3}H]$NaBH_4$ (10 mCi), which was dissolved in 0.47 mL of 0.1 N NaOH. After 5 h, another aliquot of $NaBH_4$ was added (60 μmol, dissolved in 1 mL of 0.2 N NaOH), and the reaction was stirred further at room temperature (65 h in total) to ensure complete reduction. The reaction mixture was diluted to 10 mL with water, NaCl was added to a final concentration of 1 M, and the mixture was extracted thrice with diethyl ether. The combined organic phases, after washing with 0.1 M NaOH, contained 4.6 mCi of tritium. Most of label (76%) was associated with 2-hexadecanol (R_f 0.52). Without further purification, the crude 2-hexadecanol was mesylated (R_f 0.58), and then converted to diethyl-2-(1′-methylpentadecyl)malonic acid and decarboxylated (18). Following purification by preparative TLC, 3-methyl-[3-^{3}H]heptadecanoic acid (R_f 0.50) was obtained with a yield of 33% and a specific radioactivity of 6.93 mCi/mmol (radiochemical purity, 99.8%). Upon further analysis either as fatty acid or methyl ester by TLC or high-performance liquid chromatography (HPLC), no difference was observed between the tritiated compound and 3-methylheptadecanoic acid or 3-methyl-[1-^{14}C]heptadecanoic acid, which were synthesized by different routes (18).

Preparation of rat hepatocytes and liver microsomes. Male Wistar Albino rats (100–120 g body weight) were maintained on a standard laboratory diet until sacrifice. Isolated hepatocytes were prepared as described by Zahlten and Stratman (19). For the preparation of liver microsomes, livers were removed immediately after decapitation and homogenized in 0.25 M sucrose containing 5 mM 3-[*N*-morpholino]propanesulfonic acid, buffer pH 7.4. The homogenates (12.5%, wt/vol) were centrifuged at 10,000 × *g* for 24 min. The resulting postmitochondrial supernatants were then centrifuged at 100,000 × *g* for 1 h. The microsomal pellets were resuspended in the homogenization buffer and stored at –20°C. The microsomes were used within one month without significant loss of activity. Protein content was measured by the method of Peterson (20) using bovine serum albumin as standard.

Incubation of substrates and extraction of metabolic products. Incubations of radiolabelled substrates with isolated rat hepatocytes or liver microsomes and the measurement of $^{14}CO_2$ production were done essentially as described previously (18), except that the radiolabelled substrates were always purified by reverse-phase HPLC prior to the start of the incubations. In microsomal incubations, the reactions were terminated after 15 min by acidifying with 1 M HCl (final pH around 2), and the incubation mixtures were immediately transferred to extraction tubes. The fatty acids were extracted thrice with three volumes of ethyl acetate, and the combined organic extracts were dried in a stream of nitrogen and stored at –20°C before HPLC analysis. In hepatocyte incubations, the reactions were stopped by acidification with 6% (wt/vol) $HClO_4$, and the mixtures were extracted with 3.75 volumes of chloroform/methanol (1:2, vol/vol). The mixtures were left on ice for 2 h and then were centrifuged at 2,000 × *g* for 20 min at 4°C. The pellets were discarded, and the supernatants were transferred to tubes containing 1.25 volumes of water and 1.25 volumes of chloroform. After mixing, the two phases were separated by centrifugation at 2,000 × *g* for 10 min at 4°C. The upper aqueous phase was discarded, and the lower phase was dried in a stream of nitrogen. The residues were dissolved in 2 mL hexane/diethyl ether (95:5, vol/vol) and applied to a silica Sep-Pak column (9 × 20 mm, Analytichem International, Harbor City, CA). The fatty acids and the polar metabolites were eluted with 15 mL of diethyl ether. The eluates were taken to dryness under nitrogen and stored at –20°C before HPLC analysis.

Reverse-phase HPLC. The dried organic extracts were dissolved in 100 μL of methanol, and 75 μL was applied to a reverse-phase HPLC column (Nova-Pak ODS C_{18}, 4 μm, 3.9 × 150 mm; Waters, Milford, MA). The fatty acid substrates and the polar metabolites were separated with a

methanol gradient in water (containing 0.1% vol/vol, acetic acid) (see Fig. 1B), at a constant flow rate of 1 mL/min. The radioactivity was either constantly monitored with an on-line Flo-One/β HPLC radioactivity detector (Radiomatic A505; Canberra Packard, Zurich, Switzerland) or the fractions were collected and counted for radioactivity in a liquid scintillation counter. Fractions of interest were collected, taken to dryness under nitrogen, derivatized with ethereal diazomethane, and further separated by reverse-phase HPLC using the same gradient program. The radioactive fractions were collected, taken to dryness under nitrogen, and the residues were dissolved in hexane for gas chromatography/mass spectrometry (GC/MS) analysis or derivatized with BSTFA–TMCS as recommended by the manufacturer before GC/MS analysis.

Gas–liquid chromatography/MS. A Hewlett-Packard (Palo Alto, CA) 5890 gas chromatograph was directly coupled to a Finnigan MAT (San Jose, CA) TSQ70 triple quadrupole mass spectrometer. Chromatography was done on a 25 m × 0.32 mm i.d. RSL 200 chemically bonded (FSOT) fused-silica capillary column (Alltech), film thickness 0.25 μm, using splitless injection and helium as carrier gas. The column oven temperature was held at 80°C for 2 min, then increased to 150°C at a rate of 20°C/min, held at 150°C for 1 min, then increased to 200°C at a rate of 2°C/min, held at 200°C for 1 min, and then increased to 300°C at a rate of 20°C/min. The injection port and GC/MS interface were maintained at 250°C. Electron impact (EI) spectra were obtained with an ionization energy of 70 eV and a source temperature of 150°C.

RESULTS

Cofactor requirements and substrate specificity of α-oxidation. As can be seen from Table 1, in the presence of the necessary cofactors rat liver microsomes decarboxylated not only 3-methyl-substituted fatty acids, but also 2-methyl-substituted fatty acids and straight chain fatty acids.

In agreement with earlier data (18), the formation of CO_2 was clearly dependent on the presence of Fe^{3+} ions, as omission of Fe^{3+} from the incubation mixtures resulted in an almost complete suppression of CO_2 production. The stimulation of α-oxidation by phosphate and NADPH varied according to the substrate used. The reason for this variation is presently not known.

Addition of CoA to the incubation mixtures, fortified with Fe^{3+}, NADPH and phosphate, did not affect the decarboxylation rates. When CoA was added together with ATP, CO_2 production decreased, suggesting that fatty acid activation shunted the fatty acids away from the α-oxidation pathway. Why the decarboxylation of 3-methyl substituted fatty acids was affected more than that of palmitate and its 2-methyl derivative is not clear. In order to exclude the possibility that the CO_2 production from palmitate and 2-methylpalmitate, which can be degraded *via* β-oxidation, was derived from β-oxidation by contaminating mitochondria and/or peroxisomes, CO_2 production was measured in the presence of the cofactors required for β-oxidation. Under these conditions, hardly any CO_2 production could be detected.

Reverse-phase HPLC separation of α-oxidation products and intermediates. In an attempt to identify the reaction products and putative reaction intermediates of α-oxidation, we chose 3-methyl-[1-^{14}C,3-^{3}H]heptadecanoic and [1-^{14}C, 9,10-^{3}H]palmitic acids as the substrates for further experiments. The reverse-phase HPLC chromatograms of the ethyl acetate extracts from incubations of rat liver microsomes with double-labelled substrates are shown in Figure 1 (A and B). In each incubation, one single-labelled tritiated peak (P and P′) and several double-labelled peaks (A, B, C and I, II, III) were detected. In addition, we also detected a single ^{14}C-labelled peak, designated as D in Figure 1A. These peaks were all dependent on the presence of the cofactors and of protein and were not observed at zero time or upon incubation with boiled microsomes. The results suggest that the single-labelled tritiated peaks represent the decarboxylated α-oxidation products and that the double-labelled peaks may represent reaction intermediates. The peaks designated S and S′are the

TABLE 1

Cofactor Requirements and Substrate Specificity of α-Oxidation[a]

	Complete system[b]	$-Fe^{3+}$	$-P_i$[c]	$-NADP^+$[d]	+CoA[e]	+CoA + ATP[f]	β-Oxidation[g]
3-Methylheptadecanoate	89.4	0	0	2.52	92.1	5.05	0
Phytanate	73.2	1.26	8.65	4.68	72.3	5.95	0.36
Palmitate	100.7	0.54	39.3	18.6	107.8	52.6	1.80
2-Methylpalmitate	91.4	0	23.6	14.4	93.7	37.3	0.18

[a]The results are all expressed as pmoles of CO_2 produced per mg protein per min.
[b]The complete reaction mixture (final volume, 1 mL) consisted of 200 mM Tris buffer, pH 7.4; 0.1 mM $FeCl_3$; 4.0 mM phosphate buffer; 1.2 mM NADP; 5.0 mM glucose-6-phosphate; 2 units of glucose-6-phosphate dehydrogenase; 0.2 mM [1-^{14}C]fatty acid; and 0.5 mg microsomal protein. Incubations were carried out at 37°C for 15 min.
[c]In incubations listed in this column, the NADPH generating system was replaced by NADPH.
[d]$NADP^+$ was omitted from the complete system.
[e]CoA (0.5 mM) was added to the complete system.
[f]CoA (0.5 mM) and 4 mM ATP were added to the complete system.
[g]The incubation media contained in addition to the Tris buffer only the β-oxidation cofactors: 0.5 mM CoA, 0.5 mM carnitine, 4 mM ATP, and 2 mM NAD^+.

unreacted substrates. The peaks labelled P_{450} and P'_{450} probably correspond to ω-oxidation products as they almost completely disappeared when the incubations contained cytochrome C, which competes with cytochrome P_{450} for electrons from NADPH cytochrome P_{450} reductase, or an inhibitor of cytochrome P_{450}, such as metyrapone.

Identification of the decarboxylation products. The single-labelled tritiated fractions P and P'of Figure 1 (A and B) were further purified by reverse-phase HPLC after methylation with ethereal diazomethane. In a subsequent step the tritiated methyl esters were subjected to GC and combined GC/MS. Only one major peak, whose elution time corresponded to that of methylated 2-methylhexadecanoic and pentadecanoic acid, was observed in the GC profiles (data not shown). Also, the EI mass spectra of these fractions corresponded to those of 2-methylhexadecanoic and pentadecanoic acid methyl ester. Intense ions were associated with the typical McLafferty rearrangement fragments of 2-methyl fatty acid (*m/z* 88) and of straight chain fatty acid (*m/z* 74) methyl esters. Other ions that were identified belonged to the carboxymethoxy series, starting at *m/z* 101 (115, 143, 157, 185, 213, 227 and 241) for methylated 2-methylhexadecanoic acid and at *m/z* 87 (101, 129, 143, 157, 171, 199 and 213) for methylated pentadecanoic acid. The signals at *m/z* 227 (M – 57) and at 213 (M – 43) reflected the formation of another typical fragment of the methyl esters of 2-methyl fatty acids and straight chain fatty acids, respectively (data not shown).

Identification of 5-oxo-, 4-oxo-, 5-hydroxy- and 3-hydroxy-3-methylheptadecanoic acids. The lipids present in the fractions corresponding to peaks A, B, C, and D of Figure 1A were methylated with ethereal diazomethane and further purified by reverse-phase HPLC (data not shown). Subsequent treatment with BSTFA–TMCS did not affect the polarities of the methyl ester of fractions A, B and D but substantially reduced the polarity of the methyl ester of C as revealed by TLC analysis (silica gel 60, hexane/diethyl ether/acetic acid, 70:30:1, by vol); data not shown, indicating that peak C represented a hydroxylated fatty acid. Further analysis by GC of the BSTFA–TMCS-treated purified methyl esters showed in each instance only one major peak, the EI mass spectra of which are given in Figure 2.

As illustrated in Figure 2A, peak A of Figure 1A was identified as being due to 5-oxo-3-methylheptadecanoic acid (expected molecular mass of the methyl ester at *m/z* 312). The base peak located at *m/z* 158 is formed by cleavage between carbons 6 and 7 and transfer of a proton from carbon 7 to the 5-oxo group by a typical McLafferty rearrangement. Ions at *m/z* 143 and 197 represent the two ions formed by an α-cleavage to the 5-oxo group. Other ions identified include *m/z* 126 (158 – CH_3OH), 171 (157 + 14), 101 and 239 (the two cleavage ions α to the 3-methyl group), 253 (M^+ – $COOCH_3$) and 281 (M^+ – OCH_3).

Based on the fragmentation pattern in Figure 2B, peak B was identified as 4-oxo-3-methylheptadecanoic acid. Identified ions of the methyl ester include *m/z* 144 (McLafferty ion after cleavage β to the 4-oxo group), *m/z* 129 and 211 (cleavage ions α to the 4-oxo group), *m/z* 112 (144 –

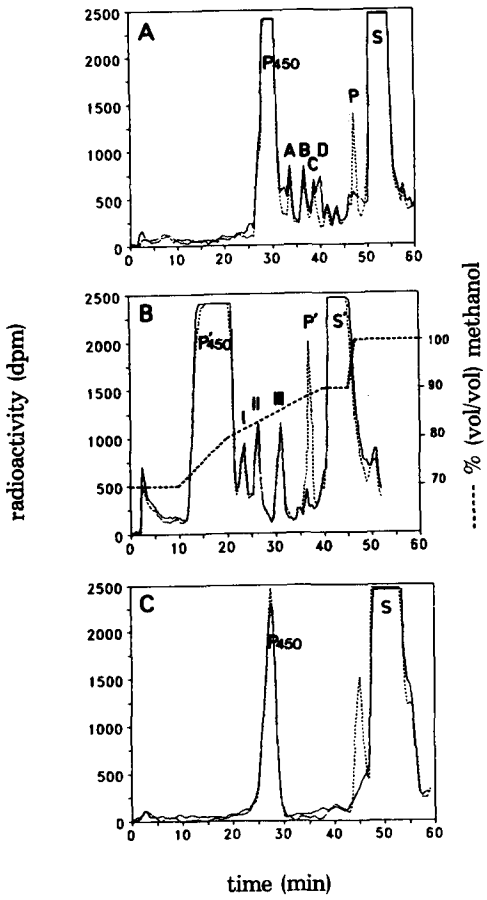

FIG. 1. Reverse-phase high-performance liquid chromatography (HPLC) separation of α-oxidation products and putative intermediates formed by liver microsomes and in rat hepatocytes. Rat liver microsomes (1 mg of protein) were incubated in capped siliconized vials at 37°C for 15 min in a mixture (final volume of 2 mL) consisting of 200 mM Tris buffer (pH 7.4), 12.5 mM sucrose, 0.25 mM 3-[*N*-morpholino]propanesulfonic acid, (pH 7.4), 0.1 mM $FeCl_3$, 1.2 mM NADP, 5 mM glucose-6-phosphate, 2 U glucose-6-phosphate dehydrogenase and 0.25 mM double-labelled fatty acid substrates. Reactions were terminated by the addition of 1 M HCl, and media were extracted with ethyl acetate as described in the Materials and Methods section. Isolated hepatocytes (5×10^6 cells) were incubated at 37°C in 2 mL Krebs-Henseleit buffer, pH 7.4, containing 2% (wt/vol) defatted albumin and 0.25 mM double-labelled 3-methylheptadecanoic acid. Reactions were stopped with $HClO_4$, and the fatty acid and its polar metabolites were extracted with chloroform/methanol and separated as described in the Materials and Methods section. The fatty acid substrates and the reaction products and intermediates were separated by reverse-phase HPLC using a methanol gradient in water containing 0.1% (vol/vol) acetic acid as shown in part B. The eluates were monitored for radioactivity (solid line, 14C; dashed line, 3H). A, Microsomes incubated with 3-methylheptadecanoic acid (3-methyl-[1-^{14}C]heptadecanoic acid; specific radioactivity, 1.5 μCi/μmol; 3-methyl-[3-^{3}H]heptadecanoic acid; specific radioactivity, 1.5 μCi/μmol). B, Microsomes incubated with palmitic acid ([1-^{14}C]palmitic acid; specific radioactivity, 1.5 μCi/μmol; [9,10-^{3}H]palmitic acid; specific radioactivity, 1.5 μCi/μmol) C, Hepatocytes incubated with 3-methylheptadecanoic acid (3-methyl-[1-^{14}C]heptadecanoic acid; specific radioactivity, 1.5 μCi/μmol; 3-methyl-[3-^{3}H]heptadecanoic acid, specific radioactivity, 1.5 μCi/μmol).

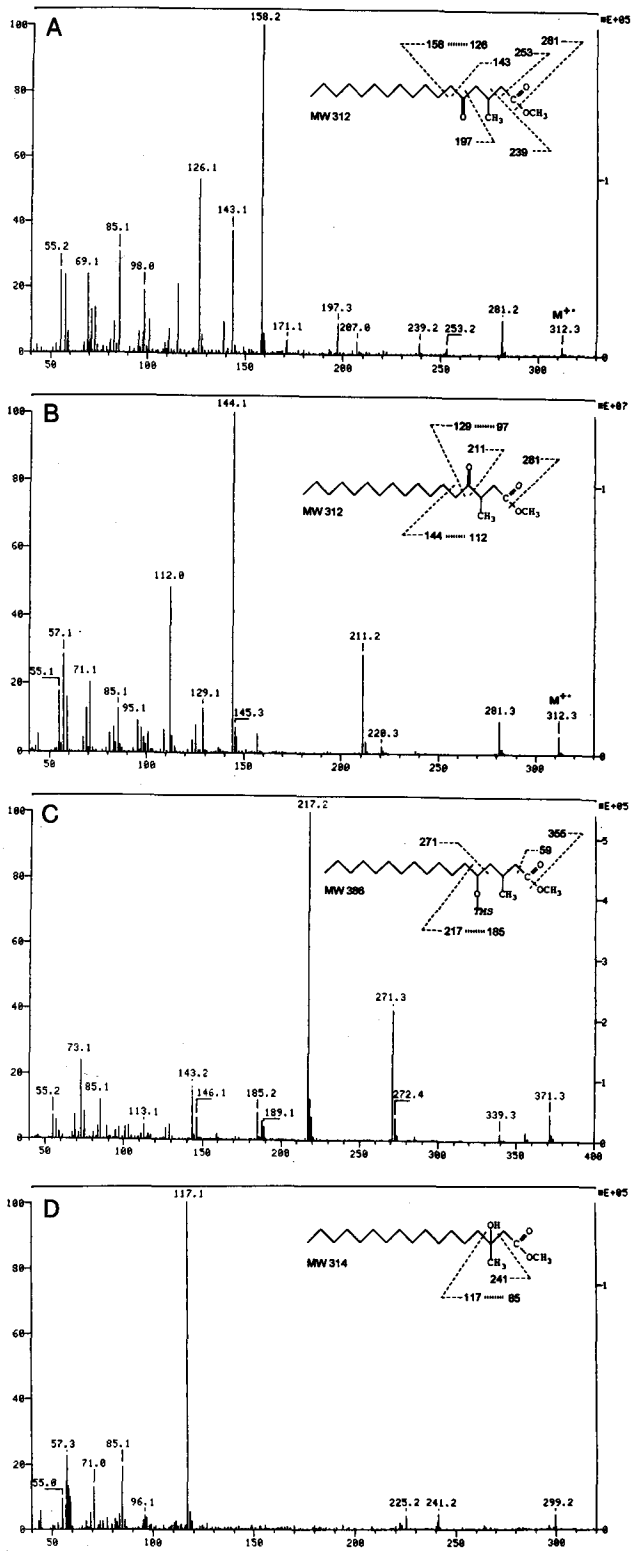

FIG. 2. Electron impact (EI) mass spectra of fractions A, B, C and D shown in Figure 1A after treatment with diazomethane and *bis*(trimethylsilyl)trifluoroacetamide containing 1% trimethylchlorosilone (BSTFA–TMCS). Fractions A, B, C and D shown in Figure 1A were collected, methylated and further resolved by reverse-phase high-performance liquid chromatography, followed by gas chromatography/mass spectrometry after BSTFA–TMCS treatment of the purified methyl esters. EI mass spectra of peaks A (A), B (B), C (C) and D (D) are shown. MW, molecular weight.

CH_3OH), *m/z* 157 (143 + 14), 101 and 239, 281 and 312 (M^+).

As noted above, the differential mobility of the methyl ester of fraction C during TLC upon treatment with BSTFA–TMCS indicated that it was a hydroxylated fatty acid derivative. Based upon the EI spectrum, peak C was identified as 5-hydroxy-3-methylheptadecanoic. The highest ion mass is observed at *m/z* 371, which is due to a loss of a CH_3 group from a molecular ion of 386 (M^+), the methyl ester/trimethyl silyl (TMS) ether of a monohydroxylated 3-methylheptadecanoic acid. The base ion at *m/z*

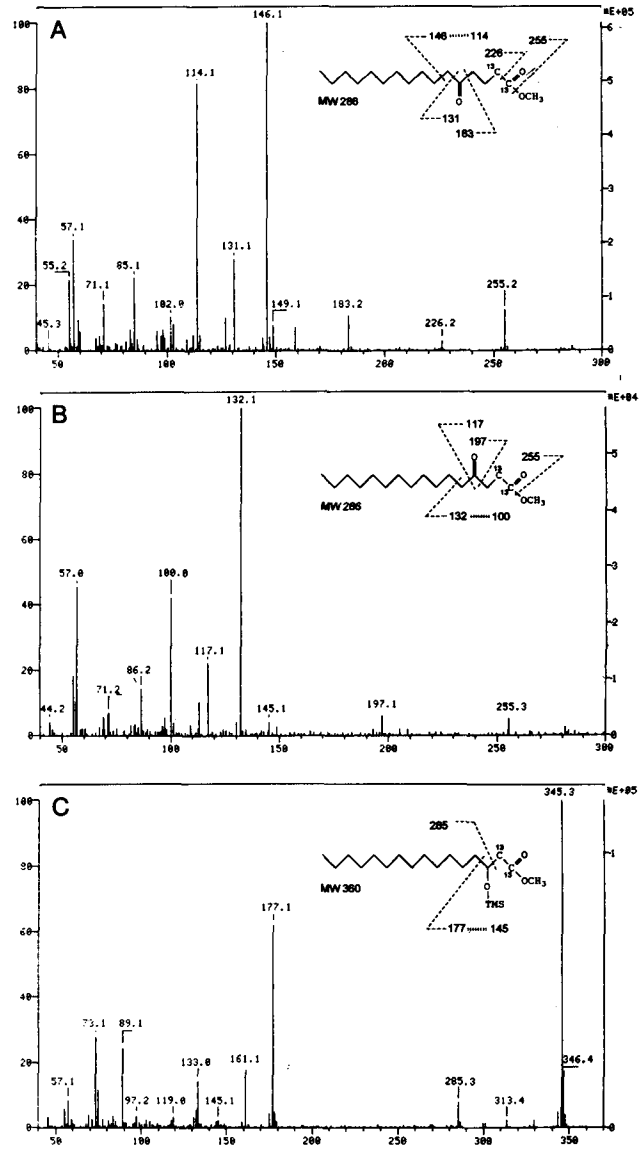

FIG. 3. EI mass spectra of fractions I, II and III shown in Figure 1B after treatment with diazomethane and BSTFA–TMCS. Fractions I, II and III shown in Figure 1B were collected, methylated and further resolved by reverse-phase high-performance liquid chromatography, followed by gas chromatography/mass spectrometry after BSTFA–TMCS treatment of the purified methyl esters. EI mass spectra of peaks I (A), II (B) and III (C) are shown. Abbreviations as in Figures 1 and 2.

217 is formed by a cleavage α to the OTMS group at the carbon 5 position, the other α-cleavage ion being observed at *m/z* 271. Other ions identified are at *m/z* 73 (TMS), 185 (217 – CH_3OH), 285 (271 + 14), 339 (371 – CH_3OH) and 355 (M^+ – OCH3).

Peak D in Figure 1A is only ^{14}C-labelled, suggesting that some chemical modification occurred at the carbon-3 position resulting in the loss of the ^3H label. TLC analysis indicated that the compound could not be silylated by treatment with BSTFA–TMCS after methylation with diazomethane (see above). The highest ion mass is observed at *m/z* 299 (Fig. 2D), which is in agreement with the molecular mass of a monohydroxylated 3-methylheptadecanoic acid methyl ester after loss of a methyl group (314 – 15). Therefore, this compound is easily identified as 3-hydroxy-3-methylheptadecanoic acid methyl ester. Such a tertiary alcohol cannot be silylated by treatment with BSTFA–TMCS due to steric hindrance. The base ion at *m/z* 117 and the ion at *m/z* 241 represent the two ions formed by cleavage α to the methyl and hydroxyl groups. Other ions identified are *m/z* 85 (117 – CH_3OH) and 225 (241 – 17 + 1).

Identification of 5-oxo-, 4-oxo- and 3-hydroxyhexadecanoic acids. The lipids associated with peaks I to III (Fig. 1B) were methylated with diazomethane and further purified by reverse-phase HPLC. GC analysis of these putative reaction intermediates derived from palmitic acid sometimes revealed more than one peak (data not shown). In order to facilitate the identification of the correct compound by MS, we decided in this particular experiment to incubate the microsomes with double-labelled palmitic acid diluted with [1,2-^{13}C]palmitic acid instead of the unlabelled palmitic acid. Figure 3 shows the EI mass spectra of the peaks corresponding to fractions I, II and III of Figure 1B, after treatment with diazomethane and BSTFA–TMCS. Preliminary TLC analysis indicated that fractions I and II did not contain a hydroxyl group, whereas fraction III appeared to be a hydroxylated fatty acid (data not shown).

Fraction I appeared to be 5-oxopalmitic acid (expected molecular ion at *m/z* 286) (Fig. 3A). The base ion is observed at *m/z* 146 (145 + 1, McLafferty ion after cleavage β to the 5-oxo group). The α-cleavage ions appear at *m/z* 131 and 183. Other ions identified include *m/z* 114 (146 – CH_3OH), 159 (145 + 14), 226 (M^+ – $^{13}COOCH_3$) and 255 (M^+ – OCH_3).

Based upon the fragmentation pattern, fraction II was identified as 4-oxopalmitic acid (Fig. 3B). The base ion at *m/z* 132 is a McLafferty ion after cleavage β to the 4 oxo group. Other ions identified include *m/z* 100 (132 – CH_3OH), 145 (131 + 14), and 255 (M^+ – OCH_3). Ions at *m/z* 117 and 197 represent the two ions formed by a cleavage α to the 4-oxo group.

The EI spectrum of the methyl ester/TMS ether of fraction III (Fig. 1B), identified as 3-hydroxypalmitic acid, is shown in Figure 3C. The expected molecular mass at *m/z* 360 is missing, which is not uncommon with the TMS derivatives of hydroxy fatty acids. The highest ion mass is observed at *m/z* 345 (360 – 15, a loss of methyl group). The hydroxyl group is identified at carbon-3, with one α-cleavage ion at *m/z* 177 and the other at *m/z* 285. Other ions identified include *m/z* 73 (TMS), 89 (OTMS), 145 (177 – CH_3OH), 313 (345 – CH_3OH) and 329 (M^+ – 31).

TABLE 2

Effects of Glutathione and Glutathione Peroxidase on Fatty Acid Decarboxylation[a]

	(pmole CO_2/min·mg·protein)	
	Palmitic acid	3-Methylheptadecanoic acid
Control	65.78	95.27
+ GSH (1 mM)	51.44	58.79
+ GPx (5 units)	73.40	88.55
+ GSH/GPx (1 mM/5 units)	5.30	6.61

[a]Incubations were carried out in the complete incubation mixture described in Table 1. GSH, glutathione; GPx, glutathione peroxidase.

Effects of glutathione and glutathione peroxidase on fatty acid decarboxylation by rat liver microsomes. The results of these experiments suggested that the compounds identified by GC/MS are not direct reaction intermediates. One possibility that we envision was that they might have been formed as rearrangement products of an unstable hydroperoxy fatty acid intermediate.

Therefore, in a subsequent experiment we examined the effects of glutathione and glutathione peroxidase on the decarboxylation of palmitic and 3-methylheptadecanoic acids by liver microsomes. Table 2 shows that glutathione plus glutathione peroxidase almost completely inhibited the decarboxylation reaction, again suggesting that a hydroperoxy fatty acid intermediate is formed during the reaction. Reverse-phase HPLC analysis of the ethyl acetate extracts revealed the disappearance of the tritiated decarboxylation products as well as of the double-labelled fractions A, B, C, I, II and III and the ^{14}C-labelled fraction D (Fig. 1). However, we did not detect the appearance of a hydroxy fatty acid, expected to be formed from the putative hydroperoxy fatty acid by glutathione peroxidase (data not shown).

Experiments with isolated hepatocytes. The results from these experiments did not allow for the identification of reaction intermediates. We therefore decided to carry out experiments with freshly isolated intact hepatocytes as enzyme source and 3-methylheptadecanoic acid as the substrate. The extracts from the incubations with hepatocytes were separated by reverse-phase HPLC, and the results are shown in Figure 1C. The single-labelled tritiated fraction was methylated, further purified by reverse-phase HPLC, and identified by GC/MS as the decarboxylation product 2-methylhexadecanoic acid (data not shown). The peak, designated S, represents unreacted 3-methylheptadecanoic acid. Only one other double-labelled peak, designated P_{450}, was observed. This peak completely disappeared after preincubation of the cells with metyrapone, indicating that the peak represents ω-oxidation products formed by cytochrome P_{450}.

DISCUSSION

This study demonstrates that, in the presence of the necessary cofactors, rat liver microsomes are capable of de-

carboxylating not only 3-methyl-branched fatty acids but also 2-methyl-branched fatty acids and even straight chain fatty acids. This is not surprising, as it has been shown that plant leaves as well as mammalian brain microsomes can catalyze the decarboxylation of straight chain fatty acids (21–23).

The main purpose of this study was the identification of the reaction products and putative reaction intermediates of α-oxidation. Tsai *et al.* (6,7) identified 2-hydroxyphytanic acid as a reaction intermediate in the α-oxidation of phytanic acid to pristanic acid. Ten Brink *et al.* (24) observed the accumulation of 2-hydroxyphytanic acid in plasma from patients with peroxisomal disorders, suggesting that in these patients, who also accumulate phytanic acid, the main defect lies in the conversion of 2-hydroxyphytanic acid to pristanic acid. However, Skjeldal and Stokke (25) have questioned the formation of a 2-hydroxy intermediate in α-oxidation.

In the present work, we have identified the decarboxylation products of palmitic and 3-methylheptadecanoic acids as pentadecanoic and 2-methylhexadecanoic acids, respectively, but we failed to find any evidence for the formation of a 2-hydroxy-fatty acid intermediate in our microsomal assay systems as well as in intact hepatocytes. Instead, in our microsomal system we identified the formation of 5-oxo-, 4-oxo-, 5-hydroxy- and 3-hydroxy-fatty acids. Obviously, these compounds are difficult to integrate in a mechanistic scheme of α-oxidation, producing a fatty acid one carbon shorter than the original molecule. Although their molecular structures seem to rule out a role as intermediates, their formation appears to be closely related to the decarboxylation process as studied under our assay conditions. Although their molecular structures seem to rule out a role as intermediates, their formation appears to be closely related to the decarboxylation process under our assay conditions. Like the production of CO_2 and of fatty acids shortened by one carbon atom, the formation of these intermediates was dependent on the presence of Fe^{3+}, NADPH and P_i, and it was strongly suppressed by the addition of glutathione and glutathione peroxidase. The fact that glutathione and glutathione peroxidase strongly inhibited fatty acid decarboxylation suggests that a 2-hydroperoxy fatty acid was formed as an intermediate in the decarboxylation reaction. The formation of a 2-hydroperoxy intermediate has also been suggested by others for fatty acid α-oxidation in plant leaves and mammalian brain microsomes (21–23, 26,27). Why we have not been able to detect the accumulation of a hydroxy fatty acid, which is formed from a hydroperoxy fatty acid by glutathione peroxidase, after addition of this enzyme to microsomes, is unclear unless one assumes that the putative hydroxy fatty acid remains tightly bound to the enzyme(s) involved in α-oxidation thus keeping its concentration low. In any case, at least in the microsomal system, the putative hydroxy fatty acid does not seem to function as an intermediate, because fatty acid decarboxylation was almost completely suppressed by glutathione peroxidase. On the other hand, if a hydroperoxy fatty acid is formed as an intermediate, this unstable compound might be rearranged to some stable oxygenated products, as has been reported for other hydroperoxy fatty acids (28–30). Such chemical rearrangement reaction, which is facilitated by the presence of iron ions (28,29), might explain the observed accumulation of the oxo and hydroxy fatty acids. The possibility that these oxygenated fatty acids were formed by reactive oxygen species, such as H_2O_2, superoxide anions or hydroxyl radicals, seems remote as their accumulation was not affected by inclusion in the reaction mixtures of catalase (H_2O_2 scavenger), superoxide dismutase (superoxide anion scavenger) and mannitol or dimethyl sulfoxide (hydroxyl radical scavengers) (data not shown).

The fact that we did not find any evidence for the accumulation of intermediates in isolated hepatocytes, suggests that in the intact cell the concentrations of intermediates must be low and that, if a hydroperoxy intermediate is formed, it must be rapidly converted by the α-oxidation system before significant chemical rearrangement can occur.

Because we have been unable to detect similar intermediates in incubations with microsomes and intact hepatocytes, our results do not allow us to conclude that the microsomal fatty acid decarboxylation system, as described here, represents the true α-oxidation process as it occurs in the intact cell. Although the different steps in this process are still unclear, our data show that the hydrogen at carbon-3 carrying the methyl branch is not involved in these steps, excluding a 2,3-desaturation as a potential reaction step.

Upregulation of Low Density Lipoprotein Receptor Activity by Tumor Necrosis Factor, a Process Independent of Tumor Necrosis Factor-Induced Lipid Synthesis and Secretion

Wei Liao* and **Claes-Henrik Florén**

Department of Internal Medicine, Lund University, Malmö General Hospital, S-214 01 Malmö, Sweden

It has been shown that tumor necrosis factor (TNF) rapidly upregulates expression of the low density lipoprotein (LDL) receptors on Hep G2 cells and acutely stimulates hepatic lipid synthesis and secretion *in vivo*. It may thus be possible that TNF-induced expression of LDL receptors is secondary to a decrease in cellular cholesterol content caused by TNF-stimulated lipid secretion. In order to know whether TNF upregulates LDL receptors by depletion of the cellular cholesterol content, the present experiments were designed to study the temporal relationship between TNF-stimulated expression of LDL receptor activity and TNF-induced changes in lipid synthesis and secretion in an *in vitro* setting by using Hep G2 cells (a highly differentiated human hepatoma cell line) as a hepatocyte model. Hep G2 cells were incubated with TNF (usually 2.5 nmol/L) for certain periods, and LDL receptor activity was evaluated by measuring [^{125}I]LDL binding at 4°C; lipid synthesis and secretion were assayed by measuring [^{3}H]glycerol incorporation into triglycerides and phospholipids as well as [^{14}C]acetate incorporation into cholesterol. We found that a 30-h exposure of the cells to TNF was needed for the effect of TNF to be seen on lipid synthesis and secretion as measured by incorporation of [^{3}H]glycerol into triglycerides and phospholipids, whereas TNF rapidly (in several hours) upregulated LDL receptor activity. TNF stimulated triglyceride synthesis, but did not stimulate phospholipid synthesis. On the other hand, TNF stimulated phospholipid secretion, but did not stimulate triglyceride secretion. Exposure of the cells to TNF for 16 or 24 h neither decreased cholesterol synthesis nor stimulated cholesterol secretion as measured by [^{14}C]acetate incorporation into cholesterol. Upregulation of LDL receptor activity through inhibition of cellular cholesterol synthesis with compactin (a competitive inhibitor of the 3-hydroxyl-3-methylglutaryl-CoA reductase) was augmented by TNF, whereas downregulation of LDL receptor activity through stimulation of cellular cholesterol synthesis with mevalonolactone almost completely blocked the upregulatory effect of TNF. In conclusion, TNF-stimulated expression of LDL receptor activity is not secondary to a depletion of cellular cholesterol content through TNF-stimulated lipid secretion or inhibition of cholesterol synthesis.

***Lipids* 29, 679–684 (1994).**

Cytokines are believed to mediate various pathophysiologic responses to endotoxin and to infectious agents, of which tumor necrosis factor (TNF) is one of the most important (1–5). TNF is a mediator essential for the expression of most biological activities of endotoxin. Endotoxemia and gram-negative bacterial infection cause profound changes in metabolism, including hyperlipidemia. Administration of cytokines, such as TNF and interleukin (IL) 1, into experimental animals can also lead to a hyperlipidemic response (6–10; for reviews, see Refs. 11,12). TNF-induced hyperlipidemia occurs mainly through an acute stimulation of hepatic lipogenesis with a subsequent release of very low density lipoproteins (VLDL) into the bloodstream (6–8). Earlier studies have shown that TNF directly stimulates hepatic lipogenesis in Hep G2 cells (13). We and others have previously reported that TNF rapidly upregulates expression of the low density lipoprotein (LDL) receptors on Hep G2 cells (14,15). Thus, TNF may upregulate LDL receptor expression by decreasing hepatic cholesterol content through stimulation of VLDL secretion or by other mechanisms. The present study was carried out to elucidate the temporal relationship between TNF-stimulated expression of LDL receptors and TNF-induced changes in hepatic lipid synthesis and secretion in Hep G2 cells.

MATERIALS AND METHODS

Materials. Recombinant human TNF was supplied by Boehringer Ingelheim (Vienna, Austria). [1(3)-^{3}H]Glycerol (2.8 Ci/mmol), [9,10(n)-^{3}H]oleic acid (5 Ci/mmol) and [1-^{14}C]acetic acid (sodium salt, 53.4 mCi/mmol) were purchased from Amersham (Buckinghamshire, United Kingdom). Oleic acid, triolein, cholesterol, cholesteryl oleate, fatty acid-free bovine serum albumin (BSA), human serum albumin (HSA; fraction V) and mevalonolactone were purchased from Sigma (St. Louis, MO). Compactin was a kind gift from Dr. Akira Endo (Fermentation Research Laboratories, Sankyo Co. Ltd., Tokyo, Japan). Fetal calf serum was purchased from Flow Laboratories (Irvine, United Kingdom). RPMI-1640 with glutamine and 0.05% trypsin/0.02% ethylenediaminetetraacetic acid (EDTA) were purchased from Life Technologies Ltd. (Paisley, United Kingdom). Plastic Petri dishes (35-mm) and 80-cm^2 flasks were purchased from NUNCLON (Roskilde, Denmark). Thin-layer chromatography (TLC) silica gel 60 plates were purchased from E. Merck (Darmstadt, Germany). OptiPhas HiSafe II liquid scintillation cocktails were purchased from Wallac Oy (Turku, Finland).

Cell culture. The human hepatoma cell line Hep G2 was obtained from the American Tissue Type Culture Collection (Rockville, MD). The cells were cultured in 80-cm^2 flasks and seeded into 35-mm Petri dishes for the experiments as described previously (16,17).

Lipoprotein isolation and labeling. LDL was isolated

Abbreviations: apo, Apolipoprotein; BSA, bovine serum albumin; EDTA, ethylenediaminetetraacetic acid; HSA, human serum albumin; IL, interleukin; LDL, low density lipoproteins; PBS, phosphate-buffered saline; TLC, thin-layer chromatography; TNF, tumor necrosis factor; VLDL, very low density lipoproteins.

from human plasma from normocholesterolemic subjects by sequentional preparative ultracentrifugation (18) as described earlier (16,17). A narrow density range (1.034–1.054 g/mL) was used in the experiments to minimize contamination of LDL with apolipoprotein E.

LDL was iodinated with ^{125}I by the monochloride method (19) as modified for lipoproteins (20). Unbound ^{125}I was removed by chromatography on a Sephadex G-25 column PD10 (Pharmacia, Uppsala, Sweden), followed by extensive dialysis against 0.15 M NaCl with 1 mM EDTA, pH 7.4. The specific activity of the LDL was between 150 and 400 cpm/ng LDL protein.

Cellular lipid biosynthesis. To measure triglyceride and phospholipid synthesis, we used the [^{3}H]glycerol incorporation technique under essentially the same experimental conditions as cited by Grunfeld *et al.* (13). In brief, the effect of TNF on lipid biosynthesis in Hep G2 cells was studied after the cells had reached subconfluency. The cells were then incubated in RPMI 1640 containing 0.5% HSA in the presence or absence of TNF as described in the legends to the figures (shown later). For the last 6 h, the medium was replaced with RPMI 1640 containing 0.5% HSA, 1 mmol/L oleic acid (bound to albumin) and 2.5 μCi/mL [^{3}H]glycerol with or without TNF. Oleic acid was included during the incubation to enhance the synthesis of triacylglycerols. Glycerol incorporation was stopped by removing the medium and washing the cells three times with cold phosphate-buffered saline (PBS). The cellular lipids and the lipids secreted into the medium were then extracted with chloroform/methanol (1:2, by vol) (21). The chloroform phase was dried under nitrogen, after which the lipids were separated by TLC as described earlier (22). The triglyceride band was recognized by exposure to iodine vapor, using triolein as an internal standard, whereas phospholipids did not migrate from the origin. The triglyceride and phospholipid bands were then cut from the plates and counted in 10 mL scintillation fluid in a beta counter (Packard 300 CD liquid scintillation spectrometer; Packard Instruments, Groningen, The Netherlands).

To measure cholesterol synthesis, we used [^{14}C]acetate as precursor. Hep G2 cells were used when the cells had reached subconfluency. The cells were then incubated in RPMI 1640 containing 0.5% HSA in the presence or absence of TNF (2.5 nmol/L). For the last 16 h, [^{14}C]acetate (sodium salt, 2 μCi/mL medium) was added. [^{14}C]Acetate incorporation was stopped by removing the medium and washing the cells three times wth cold PBS. The cellular lipids and the lipids secreted into the medium were then extracted and separated by TLC as described in the above paragraph. The cholesterol band was cut from the plates and counted in 10 mL scintillation fluid in the beta counter. Radioactivity associated with the cholesterol band was taken as index of the overall cholesterol biosynthetic activity.

LDL receptor activity assay. The LDL receptor activity assay was carried out at 4°C by measuring LDL binding as described earlier (14,22). In brief, after exposure of the cells to TNF (2.5 nmol/L), the cells were washed twice with 1 mL PBS containing 0.2% BSA. Ice-cold medium (1 mL) containing 0.5% HSA was added to each dish. The cells were then precooled for 20 min at 4°C. Next, [^{125}I]LDL (2 μg LDL protein/mL medium) was added to each dish for a 2-h incubation at 4°C. The cells were then washed once with 1 mL of cold PBS containing 0.2% BSA and twice with 1 mL PBS, and then scraped into 1 mL of 0.5 mol/L NaOH for cell protein assay and for measuring radioactivity in a gamma-counter (LKB model 1271 automatic gamma counter; Wallac, Turku, Finland).

Cholesterol esterification assay. The cells were incubated with RPMI 1640 containing 0.5% HSA in the presence or absence of TNF (2.5 nmol/L), with increasing amounts of LDL added, for 24 h. For the last 4 h, [^{3}H]oleic acid complexed with BSA (2 μCi/mL medium) was added to measure cholesterol esterification as described previously (22). The radioactivity recovered in the cholesteryl ester band was taken as a measure of the cellular cholesteryl ester synthetic activity.

Statistics. Data are presented as means ± SD. Experimental results were analyzed for their statistical significance by Student's *t*-test. The paired data were analyzed by Student's paired *t*-test, as indicated in the text. A P value of less than 0.05 was considered significant.

RESULTS

Effect of TNF on cellular triglyceride and phospholipid synthesis. Incubation of Hep G2 cells with TNF (2.5 nmol/L or 42.5 ng/mL) did not acutely stimulate lipid synthesis, but after 30-h exposure of the cells to TNF, [^{3}H]glycerol incorporation into triglycerides was increased by 15–27% (Fig. 1A). An optimal effect of TNF on triglyceride synthesis was seen after 78 h. The cells were then exposed to increasing amounts of TNF for 78 h. The data show that TNF stimulated triglyceride synthesis in a dose-dependent manner (Fig. 2A). Thus 1.56 nmol/L of TNF induced an increase in triglyceride synthesis by about 21%. At concentrations over 3.125 nmol/L, the level of increased triglyceride synthesis (by 35–48%, $P < 0.05$ or less) remained quite constant. By contrast, TNF did not seem to stimulate phospholipid synthesis (Figs. 1A and 2A).

Effect of TNF on cellular triglyceride and phospholipid secretion. TNF did not stimulate triglyceride secretion, but caused a time- and dose-dependent stimulation of secretion of phospholipids into the medium (Figs. 1B and 2B). During shorter incubation (up to 16 h) with TNF (2.5 nmol/L), there was no increase in the secretion of newly synthesized lipids. After 30 h of incubation, TNF-treated cells seemed to secrete more labeled phospholipids into the medium than did control cells (a 19–31% increase) (Fig. 1B). Longer incubations with TNF led to a progressive increase in phospholipid secretion into the medium (Fig. 1B). TNF stimulated [^{3}H]glycerol incorporation into phospholipids in a dose-dependent manner (Fig. 2B). Thus, 0.78 nmol/L of TNF cause a 42% increase ($P < 0.02$) in phospholipid secretion. At concentrations over 1.56 nmol/L, the increase in phospholipid secretion (by 67–84%, $P < 0.001$) remained quite constant. It should also be noted that only relatively small amounts of newly synthesized lipids were secreted (see legends to Figs. 1 and 2).

Effect of TNF on cholesterol synthesis and secretion. After 16 or 24 h of exposure of cells to TNF (2.5 nmol/L),

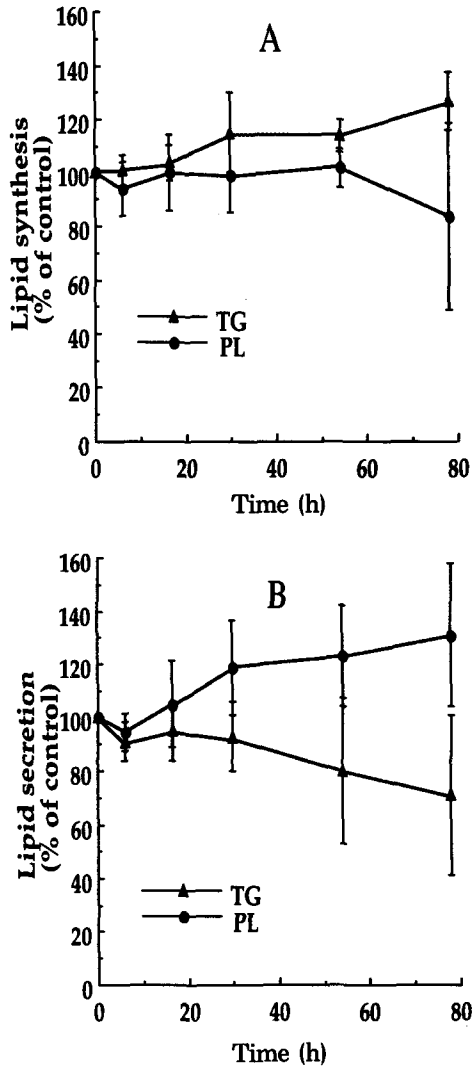

FIG. 1. Time course of the effect of tumor necrosis factor (TNF) on [^{3}H]glycerol incorporation into cellular lipids (synthesis) and into medium lipids (secretion). Hep G2 cells were cultured in 2 mL RPMI 1640 containing 10% fetal calf serum until subconfluent. Medium was then changed to 1 mL medium containing 0.5% human serum albumin (HSA) for 78 h. During this period of incubation, TNF was added at various time points at a concentration of 2.5 nmol/L. Total exposure time to TNF is indicated in the figure. For the last 6 h, medium was replaced with 1 mL medium containing 0.5% HSA, 1 mmol/L oleic acid (bound to albumin) and 2.5 μCi [^{3}H]glycerol with or without TNF. The cellular lipids and the secreted lipids were extracted and analyzed as described in the Materials and Methods section. The data are means ± SD of three separate experiments, each done at least with triplicate dishes and are expressed as percentages of controls. The control values for [^{3}H]glycerol incorporation into the cellular triglycerides (TG) and phospholipids (PL) (lipid synthesis) are 202.7 and 31.5 pmol/dish, respectively. The control values for [^{3}H]glycerol incorporation into the medium TGs and PLs (lipid secretion) are 1.1 and 1.3 pmol/dish, respectively.

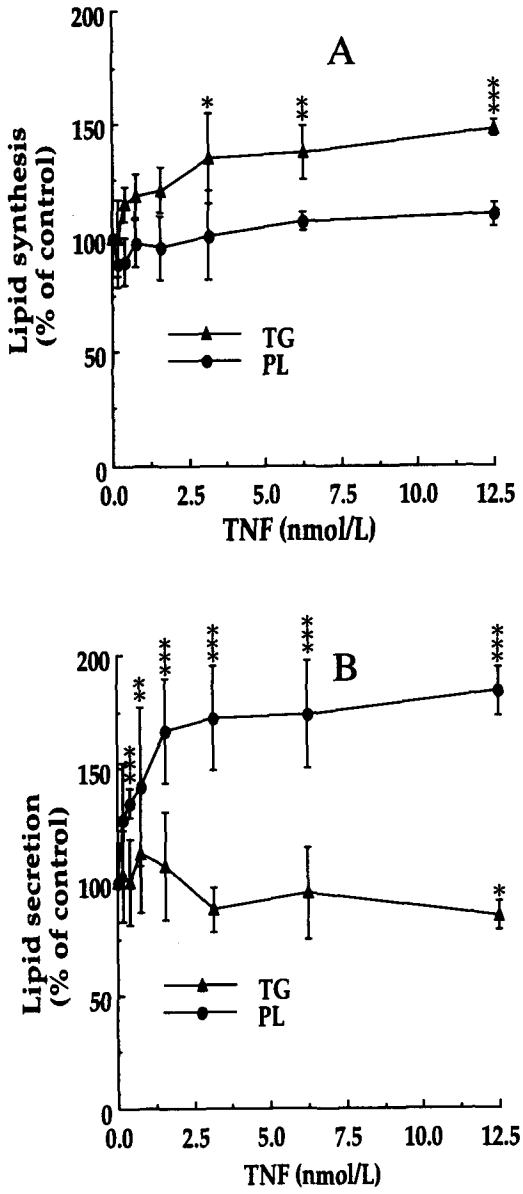

FIG. 2. Dose response of the effect of TNF on [^{3}H]glycerol incorporation into cellular lipids (synthesis) and into medium lipids (secretion). Hep G2 cells were cultured in 2 mL RPMI 1640 containing 10% fetal calf serum until subconfluent. Medium was then changed to 1 mL medium containing 0.5% HSA with increasing amounts of TNF for 78 h. For the last 6 h of the incubation, medium was replaced with 1 mL medium containing 0.5% HSA, 1 mmol/L oleic acid (bound to albumin) and 2.5 μCi [^{3}H]glycerol with increasing amounts of TNF. The cellular lipids and the secreted lipids were extracted and analyzed as described in the Materials and Methods section. The data are means ± SD of triplicate determinations and are expressed as percentages of controls. The control values for [^{3}H]glycerol incorporation into the cellular TGs and PLs (lipid synthesis) are 160.5 and 25.5 pmol/dish, respectively. The control values for [^{3}H]glycerol incorporation into the medium TGs and PLs (lipid secretion) are 0.9 and 1.3 pmol/dish, respectively. One, two and three star(s) show that *P* values are less than 0.05, 0.02 and 0.001, respectively. Abbreviations as in Figure 1.

no significant changes could be seen in [^{14}C]acetate incorporation into cellular cholesterol (98 ± 10% of the control for a 16-h exposure in three separate experiments each done with triplicate dishes; 98 ± 12% of the control for a

24-h exposure in four separate experiments each done with triplicate dishes). The data indicate that TNF does not acutely inhibit cellular cholesterol synthesis. However, a 48-h exposure to TNF seemed to slightly inhibit cellular cholesterol synthesis (85 ± 8.2% of the control in three separate experiments each done with triplicate dishes). On the other hand, after exposure to TNF for 16, 24, or 48 h the cells did not secrete more ^{14}C-labeled cholesterol into the medium (data not shown).

Comparison of TNF-stimulated lipid synthesis and secretion with its effect on expression of LDL receptors. Exposure of the cells to TNF caused a time-dependent increase in LDL receptor activity in Hep G2 cells. After 16 h of incubation, TNF-stimulated LDL binding seemed to reach a maximal level (14). Because TNF does not increase nonspecific binding of [^{125}I]LDL to Hep G2 cells (determined in the presence of a 40-fold excess of unlabeled LDL), the increase in binding exclusively reflects increased specific binding (calculated by subtracting nonspecific binding from total binding) i.e., increased LDL receptor activity (14). Consequently, in the present study only total binding was measured. The results from eight separate experiments (including three matched experiments in which LDL receptor activity and lipid synthesis and secretion were measured simultaneously) are shown in Table 1. After a 16-h exposure of the cells to TNF (2.5 nmol/L), LDL binding increased by 49% ($P < 0.005$, Student's paired t-test), whereas no significant changes could be seen in lipid synthesis and secretion (see Table 1). In fact, TNF-stimulated LDL receptor activity became apparent earlier (after a 2-h exposure of the cells to 2.5 nmol/L TNF, an increase of 16 ± 9.9%, $P < 0.025$, Student's paired t-test, five separate experiments; after a 12-h exposure of the cells to 2.5 nmol/L TNF, an increase of 43 ± 15%, $P < 0.001$, Student's paired t-test, eighteen separate experiments). After longer exposure to TNF (48 h), TNF increased LDL binding by 62% ($P < 0.05$, Student's paired t-test), increased triglyceride synthesis by 15% ($P < 0.005$, Student's paired t-test), and increased phospholipid secretion by 27% ($P < 0.025$, Student's paired t-test), respectively (see Table 1).

Effect of TNF on LDL-stimulated cholesterol esterification. One of the consequences of LDL receptor-mediated cellular LDL catabolism is the activation of acyl-coenzyme A:cholesterol acyltransferase. LDL-induced cholesterol esterification reflects LDL receptor activity. Exposure of Hep G2 cells to TNF (2.5 nmol/L) caused a significant increase in LDL-stimulated cholesterol esterification, but had no effect on basal cholesterol esterification (in the absence of LDL) (Table 2). This implies that TNF-stimulated LDL receptor activity leads to an increase in cellular endocytosis of LDL followed by hydrolysis of cholesteryl ester into free cholesterol in lysosomes.

Modulation of cellular cholesterol content and its effect on TNF-induced upregulation of LDL receptor activity. We used compactin, a competitive inhibitor of 3-hydroxy-3-methylglutaryl-CoA reductase, to inhibit cholesterol synthesis. We used mevalonolactone, which enhances cellular cholesterol synthesis by supplying an intermediary in the cholesterol biosynthetic pathway beyond the rate-limiting step, to stimulate cholesterol synthesis. We then observed the effect of variation in cellular cholesterol content on TNF-stimulated expression of LDL receptor activity. As expected, exposure of the cells to mevalonolactone for 48 h led to a marked reduction of LDL binding by 69–75% ($P < 0.001$), whereas exposure to compactin caused an increase in LDL binding by 156–173% ($P < 0.001$) (Table 3). Moreover, upregulation of LDL receptor activity with compactin showed a synergistic effect with the upregulation by TNF, whereas downregulation of LDL receptor activity with mevalonolactone almost completely blocked the upregulatory effect of TNF (Table 3).

DISCUSSION

TNF is a mediator responsible for most *in vivo* endotoxic activity (1–5). TNF may mediate endotoxin-induced hyperlipidemia by suppression of lipoprotein lipase (23,24), an enzyme which hydrolyzes triglycerides in VLDL and chy-

[a]Hep G2 cells were used when the cells reached subconfluency. The cells were incubated with RPMI 1640 containing 0.5% human serum albumin in the presence or absence of TNF (2.5 nmol/L) with increasing amounts of LDL added for 24 h. For the last 4 h, [^{3}H]oleic acid complexed with bovine serum albumin was added for the cholesterol esterification assay as described in the Materials and Methods section. The data are means ± SD of triplicate determinations. Numbers in parentheses are percentages of the corresponding control values. NS, not significant. Abbreviations as in Table 1.

TABLE 3

Effect of Variation of Cellular Cholesterol Content on TNF-Induced Upregulation of LDL Receptor Activity[a]

Additives	LDL binding (% of control)	
	Experiment 1	Experiment 2
None (control)	100 ± 13	100 ± 13
Mevalonolactone (10 mM)	25 ± 3.3[b]	31 ± 3.8[b]
Compactin (20 μM)	273 ± 22[b]	256 ± 24[b]
TNF (2.5 nM)	195 ± 17[c]	177 ± 26[d]
Mevalonolactone (10 mM) + TNF (2.5 nM)	29 ± 4.2[b]	33 ± 2.3[b]
Compactin (20 μM) + TNF (2.5 nM)	395 ± 59[c,e]	350 ± 31[b,f]

[a]Hep G2 cells were cultured in RPMI1640 containing 10% fetal calf serum until subconfluent. Medium was then changed to RPMI 1640 containing 0.5% human serum albumin with or without mevalonolactone or compactin for 48 h. For the last 24 h, TNF (2.5 nmol/L) was added to the dishes as indicated. After the incubation, LDL binding was measured as described in the Materials and Methods section. The data are means ± SD of triplicate determinations and expressed as percentages of the controls. The control values were 15.6 ng LDL protein/mg cell protein (experiment 1) and 15.5 ng LDL protein/mg cell protein (experiment 2), respectively. Abbreviations as in Table 1.
[b]$P < 0.001$, compared with the corresponding control values.
[c]$P < 0.005$, compared with the corresponding control values.
[d]$P < 0.02$, compared with the corresponding control values.
[e]$P < 0.05$, compared with the addition of compactin alone, and $P < 0.001$, compared with the addition of TNF alone.
[f]$P < 0.02$, compared with the addition of compactin alone, and $P < 0.005$, compared with the addition of TNF alone.

lomicrons, and/or by stimulation of hepatic lipid synthesis with a subsequent release of endogenous triglycerides as VLDL particles into the bloodstream (6–8). Current data show that TNF increases serum triglyceride levels primarily by stimulation of hepatic lipid synthesis and secretion of VLDL, rather than by suppression of lipoprotein lipase (6–9,12). Administration of TNF leads to an acute hypertriglyceridemic response, which can be seen as early as 2 h after TNF administration (6–8). We and others have previously reported that TNF rapidly upregulates LDL receptor activity *in vitro* (14,15). Thus TNF may upregulate LDL receptor expression *via* depletion of hepatocytic cholesterol content secondarily caused by stimulation of VLDL secretion. Therefore, we compared the effects of TNF on lipid synthesis and secretion and on expression of LDL receptor activity in Hep G2 cells.

Although the use of Hep G2 cells has some limitations, for example, these cells secrete only scarce amounts of lipoproteins which also applies, to some extent, to hepatocytes in primary cultures (25–27), Hep G2 cells have been used extensively as a model for studying hepatic lipid metabolism (28). Grunfeld *et al.* (13) showed that TNF and other cytokines (IL 1 and interferon α) stimulate lipid synthesis and secretion in Hep G2 cells by measuring [^{3}H]glycerol incorporation into lipids. They found that a 24-h exposure of Hep G2 cells to TNF is needed for TNF to stimulate lipid synthesis and secretion (13), although data were mostly given as incorporation of [^{3}H]glycerol into total lipids. By using the same experimental conditions, the present study confirms that TNF can directly stimulate lipid synthesis and secretion. The response patterns of Hep G2 cells to TNF exposure found in the present study are basically consistent with the data by Grunfeld *et al.* (13), i.e., TNF stimulates lipid synthesis and secretion in a dose- and time-dependent manner, but long-term exposure is needed for the effect to appear. We further found that TNF stimulated incorporation of [^{3}H]glycerol into triglycerides in Hep G2 cells, but did not stimulate phospholipid synthesis, and that TNF caused an increase in phospholipid secretion, but did not stimulate triglyceride secretion. This suggests that TNF may cause triglyceride accumulation in hepatocytes. One recent *in vitro* study showed that after exposure of Hep G2 cells to cytokines (TNF, IL 1 and IL 6) for 24 h, the concentrations of apolipoproteins (apo) A-I and B in the medium were decreased and cellular apoA-I mRNA, but not apoB mRNA, was decreased (29). In *in vivo* studies, it was found that the levels of hepatic mRNA for apoB and apoE did not increase 24 h after a single administration of TNF (30), but hepatic lipid (fatty acids, triglycerides and cholesterol) synthesis and secretion were markedly increased (6–8). *In vivo* stimulation of triglyceride synthesis by TNF is fast compared to its stimulation of cholesterol synthesis (6–8). Hence, TNF may relatively delay secretion of triglycerides *in vivo,* resulting in hepatic accumulation of triglycerides, a process involved in fatty liver formation, which is also observed in endotoxemia (31).

The lipogenetic response of Hep G2 cells to TNF in *in vitro* studies carried out by us and others (13) is significantly different from that which is seen in an *in vivo* setting. TNF administration to intact animals causes an acute response of lipid synthesis and secretion by the liver as early as 2 h after administration (6–8), whereas many hours are needed for the lipogenetic effect of TNF to appear in Hep G2 cells. What causes this difference is not clear. This is also the case with other biological activities of TNF, i.e., serum zinc levels and amino acid transport, which are rapidly modulated when TNF is given to rats

in vivo, but TNF increases zinc and amino acid transport only after 16 to 20 h of exposure in hepatocytes *in vitro* (32,33).

LDL receptor expression is believed to be largely controlled at the level of transcription and has been linked inversely to intracellular cholesterol levels (34,35), whereas little is known about the regulatory mechanisms for LDL receptor activity independent of cholesterol pathways. The current study shows that TNF acutely stimulates LDL receptor activity, whereas at this point, it neither increases lipid secretion nor decreases cholesterol synthesis. These findings suggest that TNF upregulates LDL receptor activity *via* a pathway independent of cholesterol homeostasis. One recent study has shown that TNF upregulates LDL receptors by inducing LDL receptor gene transcription in Hep G2 cells (15). Inhibition of protein synthesis blocks the stimulatory effect of TNF on expression of LDL receptor activity and LDL receptor gene (14,15), suggesting that TNF induces synthesis of protein factor(s) which then activate(s) LDL receptor gene transcription. It was found that TNF simultaneously induced expression of the genes for the LDL receptor and its positive transcription factor SP-1 in human endothelial cells (36), suggesting a possible role of SP-1 in TNF-induced expression of the LDL receptor. Other macrophage-derived factors, including oncostatin M, IL 6, IL1 and transforming growth factor β, have recently been reported to also have the ability to upregulate LDL receptor activity in Hep G2 cells (37,38).

We previously showed that incubation of Hep G2 cells with LDL for 12 h before exposure to TNF completely abolished the upregulatory effect of TNF on LDL receptor activity (14). In the present study, we further show that downregulation of LDL receptor activity *via* stimulation of cholesterol synthesis by using mevalonolactone also completely blocked the upregulatory effect of TNF on LDL receptor activity, whereas upregulation of LDL receptor activity *via* inhibition of cholesterol synthesis by using compactin showed a synergistic effect with TNF. One recent study also showed that LDL blocked the stimulatory effect of TNF on the expression of the LDL receptor gene (15).

The present study further shows that exposure of Hep G2 cells to TNF causes a significant increase in LDL-stimulated cholesterol esterification, suggesting that TNF-stimulated LDL receptor activity leads to an increase in cellular endocytosis of LDL followed by hydrolysis of cholesteryl ester into free cholesterol in lysosomes.

In summary, TNF-stimulated expression of LDL receptor activity is not secondary to a depletion of cellular cholesterol content caused by TNF-stimulated lipid secretion or by inhibition of cellular cholesterol synthesis, but rather an effect on LDL receptor gene expression. TNF-stimulated LDL receptor expression may be one example of non-cholesterol-mediated modes for the regulation of hepatic LDL receptors.

Lipid Composition of Glucose-Stimulated Pancreatic Islets and Insulin-Secreting Tumor Cells

Ingo Rustenbeck*, Alexander Matthies[1] and Sigurd Lenzen[2]

Institute of Pharmacology and Toxicology, University of Göttingen, D-37075 Göttingen, Germany

The effect of glucose stimulation (25 mM for 5 min) on the phospholipid and neutral lipid composition of isolated pancreatic islets was studied to find out whether there is a change in the mass of potential lipid mediators or modulators of insulin secretion. For comparison, the lipid compositions of homogenates and subcellular fractions from RINm5F insulin-secreting tumor cells and of glucose-stimulated streptozotocin/nicotinamide-induced islet cell tumors were analyzed. After separation of the lipid extract into a neutral and an acidic fraction by anion-exchange chromatography, lipids were separated by high-performance thin-layer chromatography and quantitated by *in situ* densitometry of the cupric sulfate-charred bands. In glucose-stimulated islets, the molar percentages of phosphatidic acid (PA) and of phosphatidylinositol were significantly increased (3.1 vs. 4.7 mol% and 8.6 vs. 11.8 mol%), while those of all other phospholipids and neutral lipids, including 1,2-diacylglycerol, were not significantly changed. In stimulated islet cell tumors, an increase of PA was visible in the microsomal fraction, and there was an increase of lysophosphatidylcholine in the mitochondrial fraction. However, in both tumoral tissues, particularly in RINm5F cells, the lipid distribution pattern showed abnormalities which can be regarded as a loss of differentiation and which limit the usefulness of these tissues for the study of the physiological regulation of lipid metabolism during glucose stimulation. In conclusion, the data are in accordance with a role of PA early in stimulus-secretion coupling. The well-known stimulation of phospholipid synthesis in pancreatic islets during glucose-induced insulin secretion does not result in an increase in the total phospholipid mass.

***Lipids* 29, 685–692 (1994).**

The role of pancreatic B cell lipid metabolism in the course of insulin secretion has remained elusive in spite of the considerable research efforts that have been made (for recent reviews, see Refs. 1 and 2). Stimulation of lipid metabolism during glucose-induced insulin secretion has been known for a number of years (3,4), and two, not mutually exclusive,views of its role have evolved: (i) lipid metabolism provides the pancreatic B cell with additional fuel resulting in a potentiation of glucose-induced insulin secretion (5–8); and (ii) lipid and, particularly, phospholipid metabolism generates second messengers which activate the secretory machinery (9–11). Following the discovery of phospholipase C-generated inositol-1,4,5-trisphosphate as Ca^{2+}-mobilizing second messenger (12) and of 1,2-diacylglycerol (1,2-DG) as an endogenous activator of protein kinase C (13), both of which are involved in stimulus-secretion coupling in a number of tissues, the second view also prevailed in studies on lipid metabolism in endocrine pancreatic tissue. However, there is a fundamental difference between stimulus-secretion coupling in pancreatic B cells and other secretory cells: The physiological induction of secretion in pancreatic islet B cells is strictly dependent on metabolism of the secretagogues ("substrate site" or "fuel" hypothesis of insulin secretion). It now appears that activation of phospholipase C is restricted to a cholinergic enhancement of glucose-induced insulin secretion or is only secondary to Ca^{2+} entry into the B cell during glucose-induced secretion (14). The physiological importance of lysophospholipid (15,16) and arachidonic acid liberation (17) due to phospholipase A_2 (PLA_2) activity in pancreatic islets (18) is still uncertain. The same applies to the recent description of a phospholipase D (PLD) activity (19), which results in the production of phosphatidic acid (PA).

Thus, in recent years a wealth of data has accumulated on the actions of putative lipid-derived second messengers and on their relative turnover rates, as measured by the incorporation of radioactively labeled precursors, but there is comparatively little information on the mass of phospholipids and neutral lipids in pancreatic islets and none on their subcellular distribution because comparatively large amounts of tissue are required. Some studies on this topic have been published (Refs. 3, 20–22; and see Table 1 for an overview), but only one of these has dealt with stimulated islets for a limited number of phospholipids (21). Mass measurements are particularly necessary to assess the role of lysophospholipids and of PA. Because both compounds are obligate intermediates in phospholipid metabolism, they are likely to become more intensively labeled during stimulation when determined by the incorporation of a radioactively labeled precursor. However, it is not clear whether an accumulation occurs that might enable these compounds to influence cellular functions, i.e., to exert a second messenger role. We therefore determined a detailed pattern of phospholipids and neutral lipids of resting and glucose-stimulated islets. As it is also desirable to study the subcellular distribution of the lipids, a similar pattern was determined for the homogenates and crude subcellular fractions of RINm5F cells and of a number of streptozotocin/nicotinamide (STZ/NA)-induced islet cell tumors to assess whether these tumoral tissues might be useful tools to study the

Σ (nmol/mg)	230	220	152	320

[a]The data are given as mol% for easier comparison between the different sets of data. The sums (Σ) have been recalculated on the basis of a protein content corresponding to half of the dry weight (Ref. 3) or an islet protein content of 0.5 μg (Refs. 20–22). In References 21 and 22, data on the neutral lipid content were also given, the sum being 4–6 pmol/islet [about 10 nmol/mg, excluding cholesterol (CHOL)] in Ref. 21, and 1043 ng/islet (about 3500 nmol/mg, including CHOL and cholesteryl ester) in Reference 22. PA mass in islet tissue was determined by Dunlop *et al.* (10) and can be recalculated to correspond to 65–130 nmol/mg protein. n.d., Not determined. LPC, lysophosphatidylcholine; SPH1, denotes the low R_f of sphingomyelin; SPH2, denotes the high R_f of sphingomyelin; PC, phosphatidylcholine; LPE, lysophosphatidylethanolamine; PE, phosphatidylethanolamine; PI, phosphatidylinositol; PS, phosphatidylserine; PG, phosphatidylglycerol; PA, phosphatidic acid; CL, cardiolipin.

relation between stimulus-secretion coupling and lipid metabolism in pancreatic islets.

MATERIALS AND METHODS

Chemicals. Phospholipids and neutral lipids which were used as standards for chromatography were obtained from Sigma (St. Louis, MO), Calbiochem (San Diego, CA) or Serdary (London, Ontario, Canada). The purity was checked before use by high-performance thin-layer chromatography (HPTLC). Solvents were of high-performance liquid chromatography grade from Merck (Darmstadt, Germany), Baker (Deventer, The Netherlands) or Fluka (Buchs, Switzerland), as purissimum grade or as Burdick and Jackson brand. Sephadex media were obtained from Pharmacia (Uppsala, Sweden). HPTLC $60F_{254}$ plates were from Merck.

Tissue preparation and incubation. Pancreatic islets from fasted ob/ob mice (50–60 g) were isolated from the pancreas following collagenase digestion in Krebs-Ringer bicarbonate medium (23) and collected under a stereomicroscope. Due to the high yield of islets from the pancreas of these mice and the particularly large size of these islets, a tissue mass could be attained that was sufficient for a detailed analysis of phospholipids and neutral lipids of the homogenate, but was still insufficient for comparable analyses of subcellular fractions. An additional advantage of these islets is the high content (>90%) of B cells (24). After preincubation for 30 min in an *N*-(2-hydroxyethyl)-piperazine-*N'*-2-ethanesulfonic acid (HEPES)-buffered Krebs-Ringer bicarbonate medium containing 5 mM glucose, batches of 750–1000 islets were incubated for 5 min in the same medium, containing either 5 or 25 mM glucose. After the incubation, the islets were homogenized in ice-cold homogenization medium [210 mM mannitol, 70 mM sucrose, 20 mM HEPES and 0.5 mM ethyleneglycol-*bis*(2-aminoethyl ether)*N,N,N',N'*-tetraacetic acid, adjusted to pH 7.0 with KOH], and the homogenate was extracted with hexane/2-propanol.

The RINm5F rat islet tumor cell line, which responds abnormally to glucose stimulation (25), was cultivated in Hams F12 medium supplemented with 10% fetal calf serum under an atmosphere of 95% O_2 and 5% CO_2 at 37°C. After trypsination, the cells (*ca.* 5×10^7) were washed in homogenization medium (see previous paragraph) and homogenized.

Pancreatic islet cell tumors with a high content of B cells (>90%) were induced in Wistar rats by STZ/NA treatment as described by STZ/NA treatment as described previously (26,27). After 15–18 mon, pancreatic islet tumors of variable size had developed in six rats. The pancreases were removed, and the tumors were isolated by microdissection under a stereomicroscope. After preincubation for 30 min at 5 mM glucose, three STZ/NA-induced tumors (wet weight 3.8, 14 and 71 mg) were stimulated with 25 mM glucose for 30 min, while the other three tumors (wet weight 6.8, 98 and 500 mg) served as controls. In view of the much larger tissue mass as compared to islets, this longer incubation time was chosen to ensure complete diffusion of glucose.

Subcellular fractionation. Crude subcellular fractions from RINm5F cells and islet cell tumors were obtained by differential centrifugation at 4°C. After centrifuging twice at $660 \times g$, the mitochondrial fraction was isolated from the supernatant by sedimentation at $4{,}000 \times g$ for 15 min. The pellet obtained after a $100{,}000 \times g$ centrifugation was the microsomal fraction, and the $100{,}000 \times g$ supernatant was the cytosolic fraction. By this centrifugation protocol, a fivefold enriched mitochondrial fraction was obtained, as only 10% of the B cell mitochondria were not pelleted by the $4{,}000 \times g$ step according to the determination of the mitochondrial marker enzymes, monoamine oxidase, succinic acid dehydrogenase and glutamic acid dehydrogenase (S. Lenzen, unpublished data). Secretory granules were mainly present in the microsomal fraction, but were also present in the mitochondrial fraction, as was visible from the insulin content (S. Lenzen, unpublished data). There is a close similarity between the subcellular composition of normal islets and STZ/NA tumors according to the determination of subcellular marker enzymes (27).

Lipid analysis. Lipids were extracted from the homogenates or the subcellular fractions by vortex-mixing and sonicating the samples with a twentyfold volume of hexane/2-propanol (3:2, by vol) (28). Centrifugation at $2{,}500 \times g$ pelleted the lipid-insoluble compounds. The supernatant was concentrated in a vacuum centrifuge (aRVC; Sigma-Zentrifugen, Osterode, Germany). This

total lipid extract was separated into a neutral and an acidic fraction by passage through a diethylaminoethyl-Sephadex minicolumn (1 mL gel volume, acetate as counter-ion). The neutral lipids and the zwitterionic phospholipids were eluted with 1.5 mL of Solvent A (chloroform/methanol/water, 30:60:8, by vol) (30), and the acidic phospholipids were eluted with 5 mL of Solvent B (chloroform/methanol/0.8 M sodium acetate, 30:60:8, by vol) (30). Both fractions were concentrated, redissolved in 300 µL of Solvent A and desalted by application onto a Sephadex G15 minicolumn (1.6 mL gel volume) and elution with 1.3 mL of Solvent A. The effluent of this column was concentrated again and aliquots applied to a HPTLC plate by use of a motorized Hamilton syringe. The neutral fraction (Fig. 1) was chromatographed with chloroform/methanol/triethylamine/water (30:35:34:8, by vol), while the acidic fraction (Fig. 2) was chromatographed with chloroform/methanol/triethylamine/2.6 M ammonia (30:37:34:8, by vol). The plates had previously been impregnated with boric acid from 40–100 mm for the development of the neutral fraction and from 10–100 mm for the development of the anionic fraction. The neutral lipids of the pancreatic islets (Fig. 3) were separated by chromatography of a desalted total lipid extract using a modification of a unidimensional multiple development system according to Yao and Rastetter (31) consisting of chlorobenzene/diethyl ether/ethanol/acetic acid (60:40:1:0.05, by vol), hexane/diethyl ether (94.6, by vol), and pure hexane. After development, the lipid bands were charred at 175°C with a cupric sulfate reagent (32). Quantification of the charred bands was performed in a Desaga CD60 densitometer by comparison with peak areas of standards run on the same plate. The precision of the standard curve, calculated as a polynomial of second degree, was of particular importance for the lower limit of determination of low abundance compounds, such as phosphatidylglycerol (PG), PA or 1,2-DG. Hexadecylphosphocholine, a synthetic phospholipid (synthesized and provided by Dr. H.J. Eibl, Max-Planck-Institute of Biophysical Chemistry, Göttingen), could be used as an internal standard due to its migration between LPC (L designates the 2-lysoform of a phospholipid; PC, phosphatidylcholine) and sphingomyelin (SPH) in HPTLC (33); its recovery was 89% in this system. Standard phospholipids, when processed through the different separation and concentration steps, suffered a loss of 10–15%. All determinations were made in duplicate. [For further details see Rustenbeck and Lenzen (33), Rustenbeck *et al.* (34), and references therein.] The mass of each class of lipid was determined as nmol per mg protein. To describe the phospholipid composition, the molar mass of an individual phospholipid class was expressed as percentage of the total phospholipid mass (mol%) of the respective

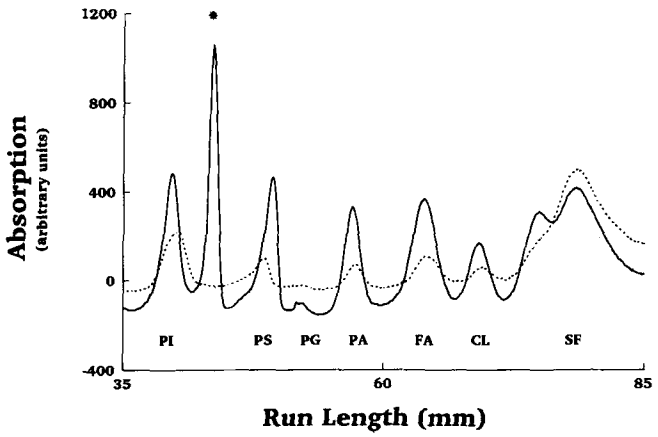

FIG. 2. High-performance thin-layer chromatogram of anionic phospholipids and fatty acids (FA) of the homogenate from pancreatic islets. The asterisk denotes an artifactual splitting of the phosphatidylinositol (PI) peak due to residual salt contamination. At lower sample loads, only the basic PI peak was observed (dotted chromatogram). Abbreviations as in Figure 1; PS, phosphatidylserine; PG, phosphatidylglycerol; PA, phosphatidic acid; CL, cardiolipin.

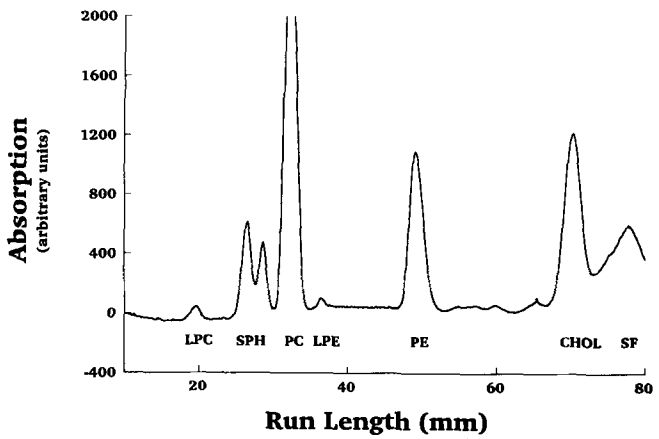

FIG. 1. High-performance thin-layer chromatogram of phospholipids and neutral lipids of the homogenate from glucose-stimulated pancreatic islets. FIG. 3. High-performance thin-layer chromatogram of neutral lipids of the homogenate from glucose-stimulated pancreatic islets. The profile for the standards is given in the dotted chromatogram. The asterisk denotes 1,3-diacylglycerol (DG). The tailing of the triacylglycerol (TG) peak is caused by the multiple development system. Abbreviations as in Figure 1; CE, cholesteryl ester.

homogenate or subcellular fraction. Protein was determined according to McKnight (35) in aliquots which had not been subjected to lipid extraction. Values are presented as means ± SEM and were tested for statistical significance by Student's unpaired *t*-test.

RESULTS

Phospholipid and neutral lipid composition of homogenates of glucose-stimulated pancreatic islets in comparison with controls. The total phospholipid and neutral lipid content of pancreatic islets did not change significantly during a 5-min stimulation with 25 mM glucose as compared with islets maintained at a nonstimulatory glucose concentration (5 mM). Phospholipids represented 68.2% of the total lipid mass in unstimulated and 62.4% in stimulated islets; the respective values for neutral lipids were 31.8 and 37.6% (Table 2). Among the phospholipids, the molar percentage of two anionic phospholipids showed significant changes (Table 3): Phosphatidylinositol (PI), the most abundant anionic phospholipid, increased from 8.6 to 11.8 mol% ($P < 0.05$), and PA increased from 3.1 to 4.7 mol% ($P < 0.005$). Lysophospholipids, which are regarded by some authors as potential mediators in the induction of insulin secretion (2), showed no change in abundance during this short-term incubation. LPC, lysophosphatidylethanolamine (LPE), lysophosphatidylinositol (LPI) and lysophosphatidic acid (LPA) were resolved chromatographically. In both stimulated and resting islets, LPE and LPC represented 5% of their parent compounds, whereas LPI and LPA could not be found in any of the samples. In view of the increase in PA, a simultaneous increase in LPA might have indicated whether *de novo* synthesis was responsible for the increase in PA mass. However, the LPA peak in the standard chromatograms was not baseline-separated from the peak of phosphatidylserine (PS), and, therefore, small amounts of LPA (<10% of the PS peak area) may have escaped detection. LPG was also not separated from PS. However, in view of the low abundance (0.2 mol%) of PG, it appears unlikely that LPG was present in amounts similar to those of LPC and LPE. PC and PE were the most abundant phospholipids. In accordance with earlier reports on the phospholipid composition of pancreatic islets (see Table 1), the content of PC was 49.9 mol% and that of PE 21.2 mol%. The molar percentages were not significantly different in glucose-stimulated islets (48.4 and 18.6 mol% for PC and PE, respectively). SPH was resolved into two subfractions. The component with the lesser R_f value comprised 64% of the total SPH mass. The slower migration of this component probably reflects the presence of a hydroxyacyl group (2-hydroxylignoceric acid and 2-hydroxynervonic acid), as is known to occur in sphingolipids (31,36). The mitochondrial phospholipid, cardiolipin (CL), comprised only 1 mol% in the islet homogenates. This very low value is consistent with earlier data published on CL abundance in pancreatic islets (Table 1).

Among the neutral lipids of pancreatic islets, cholesterol (CHOL) was by far the major component (73 mol% of the neutral lipids). The contents of CHOL, triacylglycerol (TG) and unesterified fatty acids (FA) were unchanged after glucose stimulation. As the intensity of charring depends on acyl chain length and unsaturation, comparatively large SEM values were observed in the FA determinations. The sensitivity of the charring reaction permitted the detection of small amounts of DG present in pancreatic islets (Fig. 3). The peak areas of 1,2-DG were sufficient for quantitation, and no change could be seen in the glucose-stimulated islets (Table 4). 1,3-DG was present only in trace amounts.

Phospholipid and neutral lipid composition of homogenates and subcellular fractions of RINm5F cells. In homogenates of RINm5F cells, the relative contribution of phospholipids (71.6%) and neutral lipids (28.4%) relative to the total lipid mass (Tables 5 and 6) was the same as in resting pancreatic islets (68.2 and 31.8%, respectively). However, the lipid/protein ratio was significantly ($P < 0.01$) lower than in pancreatic islet tissue (136.5 vs. 228.9 nmol/mg). Although the pattern of the phospholipids in the homogenate of the RINm5F cells was similar to the one of the homogenates of pancreatic islets, three lipid

TABLE 2

Total Contents of Phospholipids and Neutral Lipids in Homogenates from ob/ob Mouse Pancreatic Islets After Incubation for 5 min at Low or High Glucose Levels[a]

	(nmol/mg protein)	
	Phospholipid content	Neutral lipid content
5 mM glucose	156.0 ± 7.2 (68.2)	72.9 ± 7.1 (31.8)
25 mM glucose	140.2 ± 6.3 (62.4)	84.6 ± 6.1 (37.6)

[a]The contents of phospholipid and neutral lipid represent the sum of each type of lipid determined. The numbers in parentheses denote the respective percentage of the total lipid mass. The data are means ± SEM of four (5 mM glucose) or six (25 mM glucose) experiments. Neither the phospholipid nor the neutral lipid content is significantly different between the two groups.

TABLE 3

Composition of Phospholipids in Homogenates from ob/ob Mouse Pancreatic Islets After Incubation for 5 min at Low or High Glucose Levels[a]

	(mol% of total phospholipid)	
	5 mM Glucose	25 mM Glucose
LPC	2.7 ± 0.3	2.3 ± 0.4
SPH1	5.4 ± 0.3	5.3 ± 0.4
SPH2	3.0 ± 0.2	2.8 ± 0.2
PC	49.9 ± 1.0	48.4 ± 1.1
LPE	1.1 ± 0.1	1.0 ± 0.1
PE	21.2 ± 1.0	18.6 ± 0.6
PI	8.6 ± 0.8	11.8 ± 1.1[b]
PS	4.1 ± 0.6	4.1 ± 0.2
PG	0.2 ± 0.0	0.2 ± 0.0
PA	3.1 ± 0.2	4.7 ± 0.3[c]
CL	0.9 ± 0.1	1.0 ± 0.1

[a]The data are means ± SEM of four (5 mM glucose) or six (25 mM glucose) experiments. Where indicated, values are significantly different to those obtained on islets incubated at low glucose levels ([b]$P < 0.05$), [c]$P < 0.005$). To calculate the mass of individual phospholipids, the tabulated mol% is to be multiplied by the phospholipid content of each group (see Table 2). For abbreviations, see Table 1.

TABLE 4

Composition of Neutral Lipids in Homogenates from ob/ob Mouse Pancreatic Islets After Incubation for 5 min at Low or High Glucose Levels[a]

	(mol% of total neutral lipid)	
	5 mM Glucose	25 mM Glucose
FA	17.2 ± 3.6	18.3 ± 2.5
CHOL	73.7 ± 4.3	72.9 ± 3.4
TG	7.8 ± 1.6	7.7 ± 1.2
1,2-DG	0.22 ± 0.06	0.18 ± 0.05
1,3-DG	Trace	0.0
CE	0.31 ± 0.10	0.22 ± 0.08

[a]The data are means ± SEM of four (5 mM glucose) or six (25 mM glucose) experiments. To calculate the mass of individual lipids, the tabulated mol% is to be multiplied by the neutral lipid content of each group (see Table 2). TG, triacylglycerol; DG, diacylglycerol; FA, unesterified fatty acids; CHOL, cholesterol; CE, cholesteryl esters.

TABLE 6

Composition of Neutral Lipids in Homogenates and Subcellular Fractions from RINm5F Cells[a]

	(nmol/mg protein)			
	Homogenate	Mitochondrial fraction	Microsomal fraction	Cytosolic fraction
FA	2.0 ± 0.4	17.2 ± 3.5	23.1 ± 2.2	3.4 ± 1.1
CHOL	30.8 ± 2.5	145.2 ± 13.8	78.2 ± 8.3	4.4 ± 0.9
TG (+ DG + CE)	6.0 ± 1.2	16.4 ± 4.9	12.3 ± 4.4	5.8 ± 1.6
Σ	38.8 (28.4)	178.8 (46.1)	113.6 (51.9)	13.6 (76.8)

[a]The data are means ± SEM of 4–5 experiments. The TG value also includes DG and CE. The numbers in parentheses denote the percentage of neutral lipids relative to the total lipid content. For abbreviations, see Table 4.

classes showed clear differences (Table 5): CL and PG were present at higher percentages (4.7 and 2.0 mol% in RINm5F cells vs. 0.9 and 0.2 mol% in islets), whereas PA was present only in trace amounts in RINm5F cells. As in pancreatic islets, SPH was resolved into two subclasses, and the component with the lesser R_f value was again predominant (74% of total SPH mass).

Among the subcellular fractions, the phospholipid/protein ratio was highest in the mitochondrial fraction and amounted to 208.9 nmol/mg, which is similar to the mitochondrial phospholipid content in other, nontumorous tissues (37,38). In the mitochondrial and microsomal fractions of the RINm5F cells, the neutral lipid percentage was higher than in the homogenates (46.1 and 51.4% vs. 28.4%), which was mainly due to a high CHOL content in these fractions (Table 6). Another interesting feature in addition to the high CHOL content was the high percentage of SPH in the mitochondrial fraction (total SPH 15.8 mol%), as mitochondrial membranes usually have a very low SPH content (39). The CL content of the mitochondrial fraction was 2.8-fold increased when compared to that of the homogenate (13.1 mol% vs. 4.7 mol%). The increased percentage of CL in the mitochondrial fraction was paralleled by a similar increase in PG from which CL is synthesized in mitochondria (Table 5). The mitochondrial fraction was the only one in which PA could be quantitated; in the homogenate and in the microsomal fraction, PA was present only in trace amounts (Table 5).

TABLE 5

Composition of Phospholipids in Homogenates and Subcellular Fractions from RINm5F Cells[a]

	(mol% of total phospholipid)			
	Homogenate	Mitochondrial fraction	Microsomal fraction	Cytosolic fraction
LPC	1.9 ± 0.3	2.6 ± 0.6	4.2 ± 1.0	6.1 ± 2.4
SPH1	5.7 ± 0.7	11.2 ± 0.6	14.2 ± 2.6	20.7 ± 3.7
SPH2	2.0 ± 0.2	4.6 ± 0.6	6.3 ± 1.4	8.4 ± 2.2
PC	52.5 ± 4.7	40.8 ± 5.7	39.2 ± 8.3	42.8 ± 6.3
LPE	2.7 ± 0.4	2.3 ± 0.8	3.8 ± 1.2	3.4 ± 1.8
PE	18.1 ± 1.3	10.5 ± 1.8	12.3 ± 3.9	4.8 ± 1.1
PI	6.5 ± 0.3	2.9 ± 0.6	4.1 ± 0.6	trace
PS	3.9 ± 0.5	6.1 ± 1.9	10.8 ± 3.6	8.9 ± 0.2
PG	2.0 ± 0.6	5.5 ± 1.7	1.0 ± 0.5	0.0
PA	trace	0.5 ± 0.3	trace	0.0
CL	4.7 ± 0.4	13.1 ± 2.6	4.1 ± 0.8	4.8 ± 2.3
Σ (nmol/mg)	97.7 (71.6)	208.9 (53.9)	105.1 (48.1)	4.1 (32.2)

[a]The data are means ± SEM of 4–5 experiments. The numbers in parentheses denote the percentage of phospholipids relative to the total lipid content. To calculate the mass of individual phospholipids, tabulated mol% is to be multiplied by the phospholipid content of each group. An amount was termed "trace" when the peaks were regularly visible, but below the limit of determination. For abbreviations, see Table 1.

Phospholipid and neutral lipid composition of homogenates and subcellular fractions of glucose-stimulated STZ/NA-induced islet cell tumors in comparison with controls. In most determinations of the lipid composition of the STZ/NA-induced islet cell tumors, the standard errors were larger than in the corresponding determinations with RINm5F cells or islets (Tables 7 and 8). The different sizes of the tumors, resulting in less homogenous samples are likely to contribute to this. Similar to the lipid distribution in RINm5F cells, a low content of PA in the homogenate (0.2 mol%) was seen. Considerable amounts of CHOL and SPH in the mitochondrial fraction were also reminiscent of the results obtained with RINm5F cells, even though the mass of CHOL in the mitochondrial fraction was clearly lower (71.8 nmol/mg in STZ/NA tumors vs. 145.2 nmol/mg in RINm5F cells). As in both other insulin secretory tissues, SPH consisted of two subfractions, of which the low-R_f component was predominant (65% of total SPH mass). A glucose stimulus (25 mM for 30 min) affected the molar percentages of three phospholipids, but none of the neutral lipids (Tables 7 and 8). The PC content in the homogenate was significantly lowered by 20% ($P < 0.05$). Practically the same reduction (25%; $P < 0.05$) was seen in the microsomal fraction (Table 7). Such a reduction may reflect PLA_2 activation in the course of insulin secretion (2), but no accumulation of LPC was seen in the homogenate and the microsomal fraction. However, there was a significant increase in LPC in the mitochondrial

TABLE 7

Composition of Phospholipids in Homogenates and Subcellular Fractions from STZ/NA Tumors[a]

	(mol% of total phospholipid)			
	Homogenate	Mitochondrial fraction	Microsomal fraction	Cytosolic fraction
LPC	4.2 ± 1.3	3.0 ± 0.5	4.2 ± 1.0	6.9 ± 1.0
LPC		5.0 ± 0.5[b]		
SPH1	8.3 ± 2.2	4.2 ± 0.9	6.0 ± 1.6	7.3 ± 2.7
SPH2	5.4 ± 0.9	3.2 ± 0.7	4.7 ± 1.4	5.4 ± 1.4
PC	51.2 ± 2.2	41.7 ± 2.5	52.8 ± 3.1	39.0 ± 7.2
PC	41.1 ± 2.5[b]		39.4 ± 2.6[b]	
LPE	1.4 ± 0.4	1.7 ± 0.2	1.9 ± 0.3	0.6 ± 0.3
PE	23.1 ± 4.8	29.0 ± 6.1	24.8 ± 5.1	24.7 ± 9.5
PI	7.6 ± 1.5	8.7 ± 1.9	7.7 ± 1.9	8.6 ± 1.2
PS	1.9 ± 0.4	2.5 ± 0.6	3.3 ± 0.7	4.2 ± 0.7
PG	0.2 ± 0.1	0.3 ± 0.1	0.2 ± 0.1	0.0
PA	0.1 ± 0.1	0.5 ± 0.1	0.2 ± 0.1	3.1 ± 1.7
PA			0.9 ± 0.2[b]	
CL	3.2 ± 0.4	4.8 ± 0.6	0.1 ± 0.1	0.2 ± 0.2
Σ (nmol/mg)	136.8 (67.4)	281.1 (73.4)	203.6 (56.0)	18.8 (52.5)

[a]The values that were not significantly different between stimulated (25 mM glucose for 30 min) and control tumors were treated as one group and are means ± SEM of six experiments. The numbers in parentheses denote the percentage of phospholipids relative to the total lipid content. To calculate the mass of individual phospholipids, the tabulated mol% is to be multiplied by the phospholipid content of each group. For abbreviations, see Table 1.
[b]Where significant differences occurred ($P < 0.05$), the value of the stimulated tumors is given in the line below the value of the control tumors; in that case each value is a mean ± SEM of three experiments.

fraction. Apparently due to the small size of the mitochondrial fraction and the comparatively low abundance of LPC, a similar change was not detectable in the homogenate. The same reasoning applies to the 4.5-fold increase in PA in the microsomal fraction ($P < 0.05$), which was not reflected in a significant change in PA in the homogenate.

TABLE 8

Composition of the Neutral Lipids in Homogenates and Subcellular Fractions from STZ/NA Tumors[a]

	(nmol/mg protein)			
	Homogenate	Mitochondrial fraction	Microsomal fraction	Cytosolic fraction
FA	14.7 ± 3.1	17.8 ± 4.4	27.3 ± 5.3	5.5 ± 1.2
CHOL	42.2 ± 5.3	71.8 ± 8.9	103.0 ± 18.4	9.6 ± 3.7
TG (+ DG + CE)	9.3 ± 2.3	12.5 ± 2.3	29.7 ± 9.3	1.8 ± 0.6
Σ	66.2 (32.6)	102.1 (26.6)	160.0 (44.0)	16.9 (47.6)

[a]There were no significant differences between the values from stimulated (25 mM glucose for 30 min) and control tumors; therefore, the mean values ± SEM for all six tumors are given. The TG value also includes DG and CE. The numbers in parentheses denote the percentage of neutral lipids relative to the total lipid content. For abbreviations, see Table 4.

DISCUSSION

The central observation in experiments conducted with pancreatic islets was the increase in PA and PI mass after a 5-min stimulation at a maximally effective glucose concentration (25 mM). The magnitude of the change in PA (+52%) was similar to the increase of radioactively-labeled palmitic acid in PA after a 30 min stimulation with 28 mM glucose reported recently by Konrad and colleagues (40). The paucity of data on the mass of PA (Table 1) is due to the low abundance of PA and the difficulty of separating PA from other phospholipids, particularly PE. The value for PA mass in islet tissue reported by Dunlop *et al.* (10) appears surprisingly high when recalculated on a nmol/mg basis (see Table 1). In conjunction with the increase in PA, the increase in PI mass in stimulated islets may indicate *de novo* synthesis of these lipids. *De novo* synthesis of PA and PI early in glucose stimulation has been proposed to occur by Farese *et al.* (41) and Dunlop and Larkins (42). However, generation of PA from PC through hydrolytic cleavage by a PLD is also possible, as recently shown by Metz and Dunlop (19).

De novo synthesis of PA and PI appears to be an attractive mode in view of the physiological role of pancreatic islets as fuel-sensors. PA synthesis connects glycolysis and FA metabolism and can relate both pathways to the generation of a second messenger. This may be 1,2-DG generated from PA by the action of a phosphohydrolase, but PA may also act as a signal transducer in its own right (43,44). It is conceivable also that PA through its mitogenic action (43) might act as a mediator of the proliferative effect of glucose on pancreatic B cells (45). Although the lack of a change in 1,2-DG noted in our study does not rule out a second messenger role for DG, it may suggest that PA could play a role in signal transduction rather than simply being a precursor of 1,2-DG. Constant levels of 1,2-DG during glucose-induced insulin secretion have also been reported by Wolf and colleagues (46) who measured 1,2-DG up to 20 minutes after the initiation of glucose stimulation using a DG-kinase assay. Most of the 1,2-DG measured in this study is likely to be located in the endoplasmic reticulum due to its role as an intermediate in the synthesis of phospholipids and TG (47). It is not clear whether a significant amount of 1,2-DG is available to serve as a second messenger at the plasma membrane level (48). Products of PLA_2 reactions form a second group of potential lipid mediators in glucose-induced insulin secretion (2,15). These include lysophospholipids and polyunsaturated FA, in particular arachidonic acid.

In the present study, we did not analyze FA compositions but only determined unesterified FA as a class. The amount of total FA we measured (12 nmol/mg protein) did not change upon glucose stimulation. The mass of arachidonic acid was earlier determined by Wolf and colleagues (17) and was found to be 2 pmol/islet after glucose stimulation, which is roughly equivalent to 4 nmol/mg protein. HPTLC resolved all relevant lysophospholipids, but the mass of one of the most abundant compounds, LPC, was found unchanged. This is somewhat in contrast to data by Turk and colleagues (21) who reported a decline in LPC mass from a rather high initial value of 5.5 to 0.5

pmol/islet during glucose stimulation. However, an increase in LPC that is confined to only one specific subcellular compartment can be overlooked when only homogenates are examined. In pancreatic B cells, the mitochondria represent only a minor compartment as the mitochondrial volume accounted for only 4% of the total B cell volume, as opposed to more than 20% in hepatocytes (49). The small size of the mitochondrial compartment in pancreatic B cell can also explain the low content of CL in the homogenate (1 mol%), as CL is exclusively located in the inner mitochondrial membrane.

The observation that the total phospholipid mass was not increased in stimulated islets may appear surprising in view of the numerous reports on enhanced phospholipid and neutral lipid synthesis during glucose-induced insulin secretion (3,5,6,8,41). However, the data are in accordance with those of Montague and Parkin (9), who found that the phospholipid (230 nmol/mg) and cholesterol (60 nmol/mg) contents of guinea-pig islets were unchanged after glucose stimulation. Turk *et al.* (21) also found a slightly reduced content of PC (150 vs. 130 pmol/islet as determined by FA mass) after 30 min of glucose stimulation, whereas all other major phospholipids were slightly, but not significantly, reduced. Thus, activation of a particular lipid metabolic pathway during glucose stimulation does not necessarily result in an accumulation of a presumptive mediator. Alternatively, the analyses of the lipid pattern in homogenates may not be sufficient to elucidate transient changes restricted to one subcellular compartment. The larger amounts of tissue available from the RINm5F insulinoma cell line or from STZ/NA-induced tumors permit the analysis of lipids from subcellular fractions. The large amounts of SPH and CHOL, as well as of unesterified FA, found in the mitochondrial fraction are consistent with observations made on hepatoma cells (39,50,51), indicating a loss of the typical pattern of biosynthesis and intracellular translocation of these lipids. The predominance of hydroxyacyl species of SPH, which was most marked in RINm5F cells, was a common characteristic of all the insulin secretory tissues studied here. By contrast, liver, kidney and erythrocytes contained only low levels of the hydroxylated SPH species (I. Rustenbeck, unpublished data). Compared to normal islets in the resting state, RINm5F cells contained much less PA and larger amounts of CL and of its precursor, PG, in the homogenates. More detailed comparisons between the three types of tissues should only be made with caution, as the different methods used to prepare the tissues (collagenase digestion vs. trypsination vs. microdissection) may affect observed lipid patterns. Bearing this in mind, it nevertheless appears that the abovementioned similarities between the lipids of RINm5F cells and those of other tumorous tissues somewhat limit the usefulness of this cell line to further investigate the possible role of lipid mediators in insulin secretion. One could even speculate that the alterations in the lipid metabolism might actually contribute to the defective secretory responsiveness of these cells in addition to the well-known defective recognition of glucose (25).

In contrast to RINm5F cells, STZ/NA tumors are responsive to changes in glucose concentration in the physiological range, although the insulin secretory responsiveness decreases with increasing tumor size (27). The subcellular distribution of lipids appeared to be less deranged than in the RINm5F cells. The localization of the increase in PA in the microsomal fraction would be consistent with *de novo* synthesis of PA. The increase in LPC in the mitochondrial fraction might result from an accumulation of Ca^{2+} in the mitochondria during prolonged glucose stimulation (52), leading to an activation of mitochondrial PLA_2 (53). These changes need not necessarily be related to stimulus–secretion coupling, but they demonstrate that activation of PLA_2 or PLD in a small subcellular compartment may not be detectable in tissue homogenates. Therefore the data obtained with islet homogenates suggest a second messenger role for PA, but at the same time do not rule out such a role for 1,2-DG or LPC.

Effect of Dietary Fat on Colonic Protein Kinase C and Induction of Aberrant Crypt Foci[1]

Lynne M.Z. Lafave[a], Prem Kumarathasan[b] and Ranjana P. Bird[a,*]

[a]The University of Manitoba, Department of Foods and Nutrition, Winnipeg, Manitoba, R3T 2N2, Canada and [b]The Division of Chemistry, Environmental Health Centre, Health Protection Branch, Ottawa, Ontario, K1A OC6, Canada

A major objective of the present study was to determine whether a high-fat diet affects early events during colon carcinogenesis. Female Sprague-Dawley rats were injected with saline or azoxymethane (20 mg/kg) and fed either a normal (5% corn oil w/w) or a high (5% corn oil and 15% beef tallow w/w) fat diet. To assess the effect of a known tumor-promoting diet on the early events of neoplastic transformation, Study 1 examined the induction and growth of aberrant crypt foci (ACF) as well as of proliferative indices. The total number of ACF were similar in both groups even after 8 wk of dietary treatment; however, ACF with accelerated growth characteristics (≥4 crypts/focal lesion) were more prevalent ($P \leq 0.05$) in the colons of animals fed the high-fat diet. Metaphase arrest cells and 5′-bromo-2′-deoxyuridine labelled cells showed no appreciable response to dietary changes. To determine whether changes in colonic signal transduction pathways represent an early response to dietary modification, Study 2 evaluated the activity of protein kinase C (PKC), proliferative indices and changes in phospholipid fatty acid profiles. In comparison to the normal fat group, the colons of high-fat fed animals exhibited higher ($P \leq 0.05$) membranes and lower soluble PKC activity; however, proliferation patterns of these colons were not altered. Changes in the membrane lipid composition were minor; however, an increase in the phosphatidylcholine/phosphatidylethanolamine ratio and in 20:4n-6 was noted. Our results demonstrate that in comparison to a normal-fat diet, a high-fat diet stimulated the growth of a population of ACF, i.e., preneoplastic lesions leading to advanced growth characteristics. In addition, a high-fat diet exerted a marked influence on total, cytosolic and membrane associated PKC activities. The findings suggest that modulation of PKC may play a critical role at the early stages of colon carcinogenesis.

***Lipids* 29, 693–700 (1994).**

Epidemiological and animal studies have contributed a great deal to our understanding of the role of dietary components in the etiology and prevention of colon cancer (1–6). Several studies have demonstrated that rodent diets containing 20% fat by weight or more from sources such as corn oil, safflower oil, beef fat, lard or a combination thereof, have a promotional effect on chemically-induced colon carcinogenesis (3–6). However, this promotional effect is not seen when the dietary fat is derived from fish oil or coconut oil (4,7).

Although the effect of fat has been well-documented, the exact mechanism by which the high-fat diet exerts this promotional effect on colon carcinogenesis remains poorly understood. Several mechanisms have been offered to explain the tumor-modulating effect of high-fat diets. One such mechanism suggests that a high-fat diet increases the level of luminal free fatty acids and bile acids that may reach the colon and irritate the mucosa, thus enhancing proliferation of colonic epithelial cells (8–10).

It has also been proposed that membrane phospholipid composition may regulate the activity of protein kinase C (PKC), an enzyme known to play a pivotal role in cell growth and differentiation (11,12). Alterations in PKC activity may thus affect the carcinogenic process (13).

The main objectives of the present investigation were to assess the effect of a high beef tallow diet with known tumor-promoting activity on the number and growth features of aberrant crypt foci (ACF) which are considered preneoplastic lesions. We also assessed the effect of this diet on phospholipid composition, proliferative indices and PKC activity of rat colonic mucosa. Feeding a high beef tallow diet to rats resulted in an increased number of aberrant crypt foci which exhibited advanced growth features compared to those seen with animals on a normal fat diet. In addition, the high beef tallow diet exerted a distinct effect on the membrane lipid composition and PKC activity of rat colonic mucosa.

MATERIALS AND METHODS

Animals. Female Sprague-Dawley rats (Campus Breeding, Department of Animal Care, University of Manitoba, Winnipeg, Canada), approximately 5–6 weeks old, were acclimated for one week prior to the experiments. The animals were housed in wire cages using a 12:12 h light/dark cycle. Temperature and humidity were controlled at 22°C and 50%, respectively. Animals had access to food and water *ad libitum*. All animals were cared for according to the guidelines of the Canadian Council of Animal Care.

Diets. The formulated diets were based on a modified AIN-76A diet (14,15) as described in Table 1. For the high-fat diet, an additional 15% fat by weight was added as beef tallow at the expense of carbohydrate. The nutrients per kilocalorie density of the diets were identical except for fat and carbohydrate.

Study 1: Preneoplastic lesions and proliferative patterns. Animals were injected with a single dose of azoxymethane (AOM), 20 mg/kg (Sigma Chemical Co.,

% Calories from linoleic acid	7.1	7.0

[a]Modified AIN-76A diet composition.
[b]Diet based on modified AIN-76A adapted for a high-fat intake.

St. Louis, MO) and placed on the normal fat (control) diet for 1 wk. Animals were randomly allocated into dietary groups (8 animals/group) and fed either the high or normal fat diet for 8 wk. Two hours and one hour prior to termination by carbon dioxide asphyxiation, animals received an i.p. injection of colchicine, 1 mg/kg body weight (Sigma) or 5′-bromo-2′deoxyuridine (BrdU), 30 mg/kg body weight (Sigma). Colons were removed immediately after termination and flushed with phosphate buffered saline (PBS), slit open from caecum to anus, and fixed in 70% ethanol. Colons were assessed for ACF and proliferative indices.

Quantification of ACF. Following the protocol established by Bird (16), the fixed colons were stained in a 0.02% solution of methylene blue (Sigma); then using a light microscope, colons were assessed for the number and growth of ACF. The criteria used to identify a focus of ACF included: (i) increased size, (ii) thicker epithelial cell lining and (iii) increased pericryptal zone relative to normal crypts (17). Visualization and quantification of the number and crypt multiplicity of ACF in the entire colon were done as previously described (16,18). In order to determine crypt multiplicity, the number of crypts in each focus was recorded. To determine the distribution of ACF, the colon was divided into three sections. R represented the first 4 cm from the rectal end, M was the next 4 cm and C was the next 3–4 cm from M.

Measurement of mitotic and BrdU indices. Colonic tissue was processed for histology and mitotic proliferation as assessed by scoring crypt sections for colchicine (Sigma) arrested mitotic figures. BrdU immunohistochemistry was performed as described for proliferating cell nuclear antigen (PCNA) immunohistochemistry with the additional step of DNA digestion by 2N HCl treatment for 1 h following rehydration. The anti-BrdU monoclonal antibody (Becton-Dickinson, San Jose, CA) 1:40 dilution in antibody diluting buffer was applied to tissues for 1 h. For determination of the BrdU labeling index or mitotic index, ten well-orientated crypts were evaluated in which the base, lumen, and top of the crypts could be seen displaying a U-shaped configuration. The number and the position of the positively identified cells in each crypt column were recorded in terms of serial position counting upwards from position 1, at the base of the crypt up to the mouth of the crypt. The BrdU labelling index and mitotic index were calculated as the number of positive cells per crypt divided by the total number of cells per crypt multiplied by 100.

Study 2: Colonic PKC activity, cells exhibiting PCNA and mucosal lipid composition. Animals received a single saline injection and were then placed on the normal fat diet for one week. Animals were randomly allocated into dietary groups (10 animals/group) and fed either the high or the normal fat diet for 4 wk, after which time they were killed by carbon dioxide asphyxiation.

Extraction, separation and assay of PKC from rat colonic tissue. Rat colonic PKC activity was measured according to the PKC assay previously described (19) with some modifications. Briefly, colons were removed, flushed with cold Krebs Ringer solution, slit longitudinally and placed on a 0°C cooled surface to collect colonic mucosal scrapings. The tissue was homogenized in 25 mM Tris buffer (pH 7.5) containing 0.25 mM phenylmethylsulfonyl fluoride, 15 mM ethyleneglycol-*bis*(ß-aminoethyl ether)-*N,N,N′,N′*-tetraacetic acid, 0.25 M sucrose and 10 µg/mL trypsin inhibitor. The homogenized mixture was centrifuged at 100,000 × *g* for 60 min. The supernatant, which represents the soluble fraction, was applied to a pre-equilibrated DEAE-sephacel column. The column was washed with two bed volumes of Buffer A (lacking Triton-X 100) and eluted with a 25 mM Tris Buffer B containing 0.25 mM PMSF, 15 mM mercaptoethanol and 0.15 mM NaCl. The pellet was resuspended and homogenized in Buffer A with 0.5% Triton-X 100, centrifuged at 100,000 × *g* for 60 min, and its supernatant, which represents the particulate fraction, was partially purified as described for the soluble fraction. All column procedures were carried out at 4°C unless otherwise noted. Activity was determined by comparing the transfer of ^{32}P from γ-[^{32}P]adenosine triphosphate (ATP) (NEN, Mississauga, Ontario, Canada) to a histone protein in both the presence and absence of phosphatidylserine (PS) and diacylglycerol (DAG). All reaction mixtures contained 25 mM Tris buffer (pH 7.5) with 10 mM $MgCl_2$, 740 µg/mL histone, 2 mM $CaCl_2$, with (PS–DAT and calcium-dependent] or without (non-PS–DAG-dependent) 80 µg/mL PS and 8 µg/mL DAG. A 75-µL aliquot of the reaction mixture was added to 25 µL of column eluate; the reaction was then initiated by addition of 10 µL of γ-[^{32}P]ATP (0.45 µCi/10 µL) and allowed to incubate at 37°C for 5 min. Reactions were then quenched in an ice bath, and then 50 µL of the mixture was spotted onto small squares of P81 phosphocellulose paper. The paper was immersed in 75 mM phosphoric acid, washed with ddH_2) and the dried squares were counted for radioactivity on a Beckman LS6000TA Liquid Scintillation Counter (Beckman Instruments, Fullerton, CA). Protein content was assayed using the Coomasie Blue protein assay (Sigma).

Measurement of PCNA indices. Colonic tissue was embedded in paraffin wax, and 5-µm thick sections were

processed for immunohistochemistry employing the unlabelled antibody bridge method and the Universal Peroxidase kit from Signet Laboratories (ID Labs Inc., London, Ontario, Canada); the method is similar to that described by Richter *et al.* (20). Tissue sections were deparaffinized and then flooded with normal goat serum and incubated for 20 min to block nonspecific binding. The anti-PCNA monoclonal antibody (Dimension Laboratories, Inc., Mississauga, Ontario, Canada) diluted with antibody diluting buffer (1:40) was applied to tissue sections, and the slides were subsequently incubated for 1 h. Each tissue section was then sequentially incubated with anti-mouse IgG (antibody bridge) and mouse IgG peroxidase (labeling agent). The peroxidase reaction was initiated by immersing the slides in 0.06% 3,3′-diaminobenzidine tetrahydrochloride (Sigma) in PBS to which 0.03% H_2O_2 had been added immediately prior to use. Finally, the slides were lightly counterstained with hematoxylin, dehydrated, and mounted with Permount (Fisher Scientific, Ottawa, Ontario, Canada). All incubations were carried out in a humidified chamber at room temperature, and between incubations slides were extensively washed with PBS. The PCNA labelling index was determined by identifying ten well-orientated crypts in which the base, lumen and the top of the crypts could be seen displaying a U-shaped configuration. The number and the position of the labelled cells in each crypt column were recorded in terms of serial position counting upward from position 1, at the base of the crypt up to the mouth of the crypt. The PCNA labelling index was calculated at the number of positive cells per crypt divided by the total number of cells per crypt multiplied by 100.

Analysis of colonic lipids. Animals were killed by CO_2 asphyxiation and their colons removed rapidly and rinsed in ice-cold PBS. Colons were slit open longitudinally, freed from all contents, laid flat, and mucosa was scraped with a microscope glass slide. Lipids were extracted as described by Folch *et al.* (21) using chloroform/methanol (2:1, vol/vol). Phospholipids were separated by thin-layer chromatography using Silica Gel Merck 60 (BDH Inc., Toronto, Ontario, Canada) precoated plates. All major phospholipids were clearly separated following development of the plates in chloroform/methanol/acetic acid/water (50:37.5:3:1.5, by vol). Lipid bands were visualized with 2′7′-dichlorofluorescein and identified by comparison of their migration rate with those of standard phospholipids (Serdary Research Laboratories Inc., London, Ontario, Canada). Bands corresponding to phosphatidylcholine (PC) and phosphatidylethanolamine (PE) were scraped from the plates and the lipid fractions were directly transmethylated with 6% sulfuric acid in methanol for 2 h at 80°C in the presence of heptadecenaoic acid (17:0) as internal standard. Following incubation, the reaction mixture was cooled and diluted with water (1 mL) and petroleum ether (2 mL). The upper phase containing the fatty acid methyl esters was removed, dried under pure nitrogen, and reconstituted in small volumes of hexane. Reconstituted fatty acid methyl esters were analyzed by gas–liquid chromatography (Varian Star 3400; Varian Instruments, Palo Alto, CA) using a fused Omega Wax capillary column (30 × 0.25 μm) held at 160°C for 1 min, then ramped to 220°C at 2°C per min, and then held for 20 min using helium as the carrier gas.

Statistical analyses. Statistical analysis of the data was by Student *t*-test to compare group means using the SAS statistical software for microcomputers (SAS Institute, Inc., Cary, NC). A P value of <0.05 was considered significant.

RESULTS

The body weights of normal-fat and high-fat fed animals were similar throughout the experiment in both carcinogen and saline treated animals (Fig. 1); however, after 4 wk of dietary treatment, the body weight of animals fed the high-fat diet was greater, though not statistically significant, from the normal-fat diet (carcinogen: 273.1 ± 12.9 vs. 243.4 ± 5.9; saline: 220.0 ± 5.5 vs. 194.4 ± 11.2, respectively).

Study 1: Preneoplastic lesions and proliferative patterns. Dietary changes did not alter crypt height or the size of the proliferative zone in either metaphase arrest or BrdU labelling identification (results not shown). Although the number of cells in S-phase as measured by the BrdU labelling index were slightly greater in the high-fat fed animals both in the mid (3.7 ± 0.7 vs. 3.1 ± 0.6) and rec-

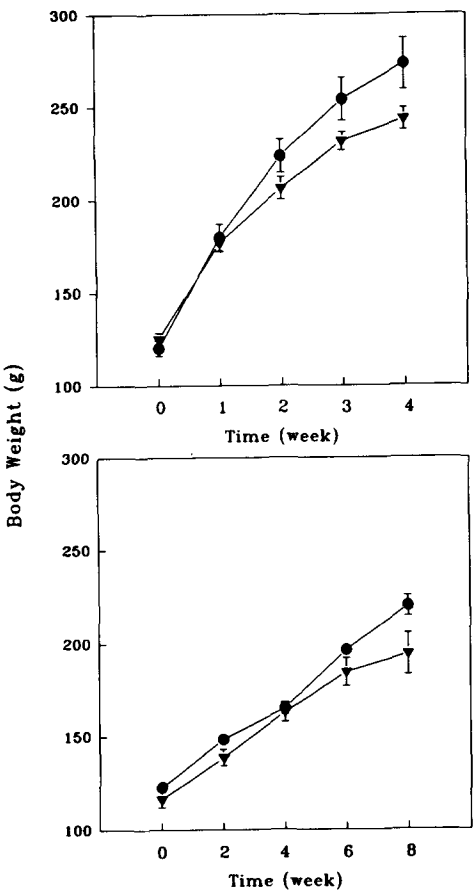

FIG. 1. Initial body weight and body weight gained in rats fed the high-fat (circle) or the normal fat (triangle) diets, and injected with saline in Study 2 (top panel) or AOM in Study 1 (bottom panel). Data represent mean ± SEM.

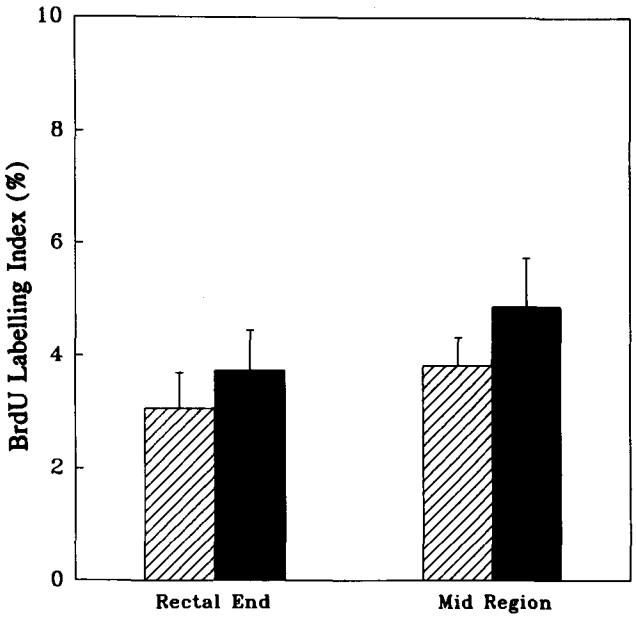

FIG. 2. Comparison of S-phase cells in carcinogen-treated colons between normal-fat at (hatched bar) and high-fat (filled bar) diets in the mid and in the rectal colonic regions as measured by the 5′-bromo-2′-deoxyuridine labelling index (BrdU). Column and bar represent the mean ± SEM.

tal (4.9 ± 0.9 vs. 3.8 ± 0.5) region, the changes did not reach statistical significance (Fig. 2). Similarly, mitotic activity, as measured by the number of cells arrested in metaphase, was greater, though not significantly, in the rectal (7.4 ± 1.6 vs. 5.4 ± 1.2) and mid (6.0 ± 0.9 vs. 5.6 ± 1.1) colonic mucosa of animals fed the high-fat diet (Fig. 3).

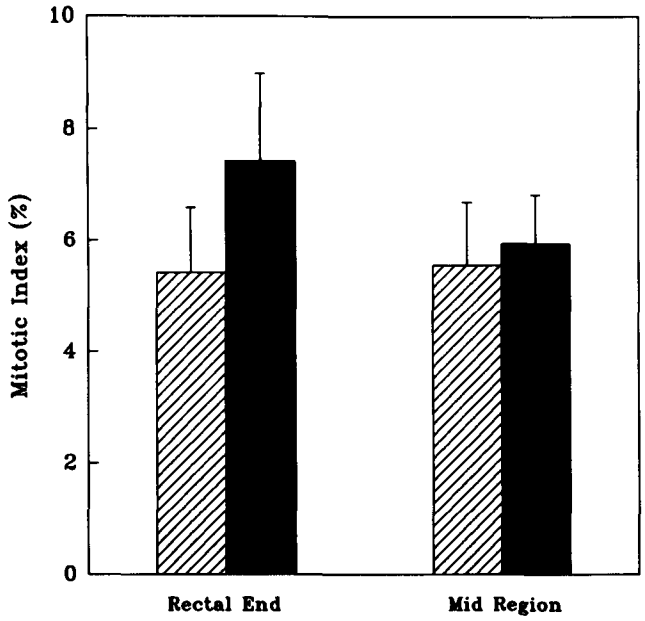

FIG. 3. Comparison of metaphase cells in carcinogen-treated colons between normal fat (hatched bar) and high-fat (filled bar) diets in the mid and in the rectal colonic regions as measured by the mitotic index. Column and bar represent the mean ± SEM.

The total number of ACF per colon (no. foci/colon) did not significantly differ between the two dietary groups although the mean multiplicity (no. AC/focus) was elevated in animals fed the high-fat diet (Table 2). The number of foci with crypt multiplicities of 1, 2 or 3 were not significantly altered by increased dietary fat intake. Interestingly, a significant increase in the population of ACF with advanced growth features (AC ≥ 4) was noted in response to high-fat consumption. A comparative distribution of these advanced lesions along the colon is shown in Table 2. In spite of an increase in the number of ACF with advanced growth features in the high-fat group, the relative distribution of ACF along the length of the colon was not affected by dietary treatment (Table 2).

Study 2: Colonic PKC activity, cells exhibiting PCNA, and mucosal lipid composition. The effect of the high-fat diet on the PCNA labelling index was not significantly different from that of the normal-fat diet in either the rectal or mid region of the colon (22.9 ± 1.1 vs. 19.2 ± 1.5; 22.0 ± 1.3 vs. 18.8 ± 1.0). However, a trend toward an elevated labelling index in the crypts of high-fat fed animals was observed which was similar in both the rectal and mid region of the colon (Fig. 4).

The activity of membrane (particulate) PKC was significantly higher (1.7 ± 0.4 vs. 0.7 ± 0.1) in the colonic mucosa of animals fed the high-fat diet (Fig. 5). Conversely, the PKC activity measured in the cytosolic (soluble) fraction was significantly lower (0.1 ± 0.0 vs. 4.0 ± 1.4) in the high-fat relative to the normal-fat fed animals. Total PKC activity was not significantly altered (normal; 4.6 ± 1.4 vs. high; 1.8 ± 0.3) by dietary changes.

The two major phospholipid classes of colonic mucosa were also quantified. Compared to the normal-fat diet group, the colons from animals fed the high-fat diet contained less PE resulting in a greater PC-to-PE ratio

DISCUSSION

In the present investigation we explored the possibility that PKC plays an important role in colon carcinogenesis and that the activity of this enzyme is affected by a high-fat diet which is known to exert a tumor-promoting effect. In Study 1, we found that a high-fat diet that stimulated the growth of a select population of ACF did not enhance proliferative indices of the colonic epithelium measured by two different procedures. Study 2 was conducted to determine whether the high-fat diet would affect PKC activity, phospholipid composition and proliferative indices measured by assessing cells exhibiting PCNA. Our data show that feeding a high-fat diet increased the colonic

membranous (particulate) PKC activity and decreased the cytosolic (soluble) PKC activity when compared to animals fed a normal fat diet. A major effect of the high-fat diet on the lipid composition of the colonic mucosa was a decreased PE content and an increased percentage of 20:4n-6 in both the PC and PE fractions.

It is recognized that colon carcinogenesis is a multistep process which includes sequential selection and propagation of preneoplastic lesions. Aberrant crypt foci are present in carcinogen-treated rodent colons as well as in human colons with colon cancer in patients at high risk for colon cancer development (22–26). Several studies aimed at investigating the genotypic, morphologic and growth features of ACF have supported the contention that ACF are preneoplastic lesions (23–25,27). Moreover, a colon harboring a greater number of ACF with advanced growth features is at greater risk for developing the disease than one with fewer advanced ACF (28–30). The ability of the high-fat diet to increase the number of ACF with higher crypt multiplicity is compatible with the notion that this diet enhances the carcinogenic process; in the present investigation the high-fat diet exerted this effect by eight weeks of dietary treatment.

The high-fat diet did not significantly alter the proliferative activity of the colonic epithelium as compared to the normal-fat diet in either study regardless of the assessment used. Generally, assessment of S-phase cells either by enumerating the cells which incorporated BrdU or [^{3}H]thymidine has been advocated to estimate the risk of colon cancer development (31,32). It is known that cell replication is a complex multistep process that can be interrupted or stagnated at several stages by endogenous and exogenous factors (33,34) and that depending on the method of assessment different stages of the cell cycle are enumerated. We employed three different methods to evaluated proliferation of the colonic mucosa. The BrdU labelling index assesses the percentage of cryptal cells engaged in DNA synthesis, whereas the metaphase arrest technique allows enumeration of cells actually undergoing mitosis (35,36). There are only a few studies which have measured both parameters in the same colon. In the present study we found that both parameters were slightly increased in the high-fat fed animals. The assessment of cells exhibiting PCNA allows the identification of cycling cells. The antigens detected include various naturally occurring cell cycle related proteins (35). As a result, PCNA labelling indices tend to be greater than the BrdU labelling indices, and it has been suggested that this may be due to the gradient in PCNA expression that enlarges the window of reactivity (37). Although this method of assessment is in its early stages of development, several studies have reported excellent correlations between BrdU, [^{3}H]thymidine and PCNA proliferative indices (17,37). It has been suggested that PCNA immunohistochemistry may be a superior technique for determining proliferative status as this technique circumvents the use of radioactive ([^{3}H]thymidine) or cytotoxic (colchicine, BrdU) chemicals while still providing spatial and conformational information not available with flow cytometric analysis. The PCNA methodology is therefore ideal in situations where enzymatic and proliferative measurements are to be evaluated on the same specimen. In our experiments it was apparent that the PCNA labelling index tended to be greater in the colons of animals fed the high-fat diet, which was in accordance with the trends in the BrdU and mitotic indices assessed in the carcinogen-treated colons. The inability of the high-fat diet to significantly increase the proliferative indices of the colonic epithelium and its ability to accelerate the growth of a selected ACF suggests that the high-fat diet may be exerting a promotional effect on colon carcinogenesis by mechanisms other than stimulating colonic cell proliferation.

PKC is known to exist in various isoforms which exhibit differences in co-factor dependence and activator specificity (38,39). The ability of PKC to remain associated with the membrane as the active form may depend on the lipid composition of that membrane. It was apparent that membrane PKC activity was higher in the colonic mucosa of animals fed the high-fat diet suggesting that this diet may have increased the turnover rate of PKC. The lower amount of cytosolic PKC activity may demonstrate enhanced translocation of the enzyme to the membrane. This observation is compatible with the findings of others who have reported that tumor promoters appear to increase the translocation of cytosolic PKC to the particulate fraction (40). Furthermore, a study investigating the role of dietary fat and PKC in skin carcinogenesis found that activity in the particulate fraction increased twofold, and the soluble PKC activity decreased dramatically in animals consuming a high-fat diet (41). PKC has been recognized as having an important role in the regulation of cell growth and

differentiation (11,12). It has been established that PKC is a receptor for phorbol ester tumor promoters (42), and activation of this enzyme has been reported in response to bile acids, which are known to promote colon carcinogenesis (43). The enzyme has been implicated in imparting drug resistance (44) and is thought to play a role as a tumor suppressor gene (45). These findings taken together illustrate the possible importance of this enzyme in the pathogenesis of colon cancer. This has also led to the suggestion that PKC may serve as a convenient intermediate marker in the evaluation of intervention studies (43,46). However, studies have yielded somewhat conflicting results as downregulation of PKC activity has been observed in cancerous tissue of chemically induced rat colon carcinogenesis (47,48) and human colonic carcinomas (49,50), while others have found no differences (51). It is now recognized that PKC may translocate to the nucleus (52) and thus participate in biological responses.

In the present investigation, PKC activity in the cytosolic and particulate fractions was measured using a method similar to those employed by others for studying colonic epithelium (13,16,43,46,53). Considerable advances have been made in the biochemical and molecular approaches to study various PKC isoforms and their role in cellular processes. In our view, the observation that PKC activity was modulated in the normal mucosa by dietary fat and that the level of various PKC isoforms may differ in normal vs. neoplastic colonic tissue (53,54) does lend support to the notion that PKC plays an important role in colon carcinogenesis. How a tumor-promoting environment affects PKC activity and its isoforms in normal and neoplastic tissue remains to be seen and should be explored in future studies.

The ability of the high-fat diet to increase the PC/PE ratio in the colonic mucosa is similar to findings reported for the colonic mucosa of mice fed a high corn oil or beef tallow diet (55). Although the initial activation of PKC is dependent on the hydrolysis of phosphatidylinositol, Nishizuka (11) proposed that this transient stimulation is frequently followed by a more sustained increase in DAG derived through the hydrolysis of PC. It is, therefore, plausible that the increased PKC activity observed in the high-fat fed animals may in part be attributable to an increased PC/PE colonic mucosal ratio. Whether it is the increased PC/PE ratio or the decreased PE content of the cellular membranes which affects PKC directly still remains to be established. The consistent increase in the percentage of 20:4n-6 in response to the high-fat diet in both the PC and PE fractions is worth noting and may be of biological importance. Arachidonic acid and its metabolites have been associated with neoplastic events and have been proposed to affect signal transduction by affecting the PKC activation pathway (55).

In summary, our results demonstrate that a high-fat diet rich in saturated fatty acids markedly affects the preneoplastic state of the colonic epithelium. Moreover, although this diet exerted minor effects on the lipid composition of the tissue, it exerted a distinct modulating effect on the activity of PKC, an enzyme critically associated with cell growth and differentiation and the carcinogenic process.

Linoleic Acid Uptake by Isolated Enterocytes: Influence of α-Linolenic Acid on Absorption

Jacques Goré[a,*], Claude Hoinard[a] and Charles Couet[b]

[a]Laboratoire de Physiologie et Biophysique Cellulaires, Faculté de Pharmacie and [b]Laboratoire de Nutrition, Faculté de Médecine, Université de Tours, 37032 Tours Cedex, France

In a previous study we showed that intestinal uptake of α-linolenic acid (18:3n-3) was carrier-mediated and we suggested that a plasma membrane fatty acid protein was involved in the transport of long-chain fatty acids. To further test this hypothesis, the mechanism of linoleic acid (18:2n-6) uptake by isolated intestinal cells was examined using a rapid filtration method and 20 mM sodium taurocholate as solubilizing agent. Under these experimental conditions transport of [1-^{14}C]linoleic acid monomers in the concentration range of 2 to 2220 nM was saturable with a V_m of 5.1 ± 0.6 nmol/mg protein/min and a K_m of 183 ± 7 nM. Experiments carried out in the presence of metabolic inhibitors, such as 2,4-dinitrophenol and antimycin A, suggested that an active, carrier-mediated mechanism was involved in the intestinal uptake of this essential fatty acid. The addition of excess unlabeled linoleic acid to the incubation medium led to a 89% decrease in the uptake of [1-^{14}C]linoleic acid, while D-glucose did not compete for transport into the cell. Other long-chain polyunsaturated fatty acids added to the incubation mixture inhibited linoleic acid uptake by more than 80%. The presence of α-linolenic acid (18:3n-3) in the incubation medium caused the competitive inhibition (K_i = 353 nM) of linoleic acid uptake. The data are compatible with the hypothesis that intestinal uptake of both linoleic, and α-linolenic acid is mediated by a membrane carrier common to long-chain fatty acids.

***Lipids* 29, 701–706 (1994).**

Linoleic acid (18:2n-6) and α-linolenic acid (18:3n-3) are essential fatty acids that share the same desaturation and chain elongation pathways (1–3) and produce metabolites that are incorporated into membrane phospholipids and body tissues (4). The two fatty acids compete with each other particularly at the limiting Δ6 desaturase step (1–3). Several authors have investigated the effects of the n-6/n-3 fatty acid ratio in the diet with focus on the metabolic steps leading to the synthesis of eicosanoids (5–9). On the other hand, few studies have addressed the possibility that high levels of 18:2n-6 in the diet may interfere with 18:3n-3 uptake by intestinal cells, and *vice versa* (10,11). There is increasing evidence showing that cellular uptake of long-chain fatty acids occurs by a process of facilitated membrane translocation involving a membrane-bound fatty acid binding protein (12–14).

In a previous study we observed that α-linolenic acid uptake by intestinal cells was carrier-mediated and that addition of linoleic acid to the incubation medium led to a decrease in the initial rate of α-linolenic acid uptake (15). Based on these observations, we hypothesized that the parent essential fatty acids were transported by the same transport protein. This hypothesis could be questioned in the light of the facilitated (16–18) or passive (19) diffusion mechanism of linoleic acid across membrane enterocytes reported by others. Indeed, the mechanism of α-linolenic acid uptake that we observed in the presence of linoleic acid could be related to an allosteric inhibition of the transport protein without any concomitant uptake of linoleic acid *via* the same carrier. In order to address this point, it was necessary (i) to determine the kinetic parameters of the initial rate of uptake of linoleic acid and (ii) to examine whether the intestinal uptake of these essential fatty acids is linked by a competitive or noncompetitive inhibition mechanism.

In the present study we examined the kinetics of linoleic acid uptake by isolated hamster intestinal cells using sodium taurocholate as solubilizing agent. The effect of other long-chain fatty acids, in particular α-linolenic acid, on linoleic acid uptake was also determined. The results show that linoleic acid uptake is active and carrier-mediated and that α-linolenic acid added to the incubation medium leads to the competitive inhibition of linoleic acid uptake by intestinal cells.

MATERIALS AND METHODS

Chemicals and solutions. Taurocholic acid sodium salt, cholesterol, D-glucose, antimycin A, 2,4-dinitrophenol, collagenase type IA, bovine serum albumin essentially fatty acid free, *N*-2-hydroxyethylpiperazine-*N'*-2-ethanesulfonic acid (HEPES), Hanks' medium, free fatty acids (linoleic, α-linolenic, γ-linolenic, linolelaidic, arachidonic, eicosatrienoic, eicosapentaenoic, docosatetraenoic), linoleic anhydride and linolenic acid methyl ester were obtained from Sigma Chimie (St. Quentin Fallavier, France). [1-^{14}C]Linoleic acid (1.9 GBq/mmol) was purchased from New England Nuclear (DuPont de Nemours, Paris, France). The scintillation liquid Optiphase 'Hisafe' II was from LKB (Pharmacia, St. Quentin en Yvelines, France). Solutions of labeled linoleic acid were prepared by isotopic dilution. For the uptake studies, the fatty acids and all other reagents were solubilized at room temperature in Hanks' medium containing 20 mM taurocholate by sonication for 5 min in a Ney 300 water-bath sonicator (Bioblock Scientific, Illkirch, France).

Preparation of intestinal cells. Intestinal cells were isolated as previously described (15,20). Briefly, male hamsters weighing 100–120 g (Elevage Dépré, Saint Doulchard, France) were killed by overexposure to diethyl ether. The entire small intestine was removed, rinsed with oxygenated buffer solution containing sodium citrate and incubated for 10 min in the same buffer at 37°C. The intestine was then emptied, filled with oxygenated buffer solution containing ethylenediaminetetraacetic acid, incubated for 3 min at 37°C, and then gently palpated with

Abbreviation: HEPES, *N*-2-hydroxyethylpiperazine-*N'*-2-ethanesulfonic acid.

the fingers for 2 min. This treatment was repeated twice. The buffer containing intestinal cells was recovered in Hanks' solution. After centrifugation ($765 \times g$), the isolated cells were resuspended in Hanks' medium containing collagenase type IA (37°C, 15 min with stirring). The intestinal cells were then washed twice and resuspended in Hanks' medium (cellular stock solution containing about 5 mg protein/mL). Light microscopy of the suspension showed that about 90% of the cells displayed the typical features of villus-tip cells. Viability was assessed by trypan blue exclusion and by lactate dehydrogenase release assay using the lactate dehydrogenase (EC 1.1.1.27) optimized kit DG 1340-K (Sigma Chimie). Protein concentration was assayed by the method of Lowry *et al.* (21).

Determination of linoleic acid monomer concentration. Ultrafiltration and polyethylene partitioning were used to measure monomer concentrations. (i) Ultrafiltration method: Linoleic acid monomers in the micellar solution were determined by ultrafiltration through a 1,000-molecular weight cut-off membrane YM1 (Grace SA, Amicon Division, Epernon, France) as described previously (15). Radioactivity was determined in the initial micellar solution, the filtrate, and in the retained solution after ultrafiltration. The recovery of the radioactivity initially present in the micellar solution was found to be complete, thus no adsorption occurred on the ultrafiltration membrane. Linoleic acid molar concentration was calculated from the specific activity of [1-^{14}C]linoleic acid. The percentage of monomer fatty acid in the micellar solution was calculated as the ratio of concentration in the filtrate against the concentration in the retained fraction. (ii) Polyethylene partitioning system: This technique is based upon the partitioning of fatty acids between the aqueous solution and a solid organic phase, namely a polyethylene disc. Using this method, Sallee (22) demonstrated that monomer activities of solutions of long-chain fatty acids dissolved in 20 mM bile acid were linearly dependent on the total fatty acid concentration in the incubation medium. Polyethylene discs, 1.2 cm in diameter, were punched from polyethylene film, 0.16 mm thick, manufactured by Roth Sochiel (Lauterbourg, France). To remove any oil and debris, the discs were washed in methanol and distilled water and were dried before use. After equilibration of two discs in 3 mL of fatty acid test solutions for 24 h (shaking waterbath, 37°C), the discs were removed, rinsed in Hanks' medium and the radioactivity associated with the discs was determined.

Determination of linoleic acid uptake. Uptake of [1-^{14}C]linoleic acid was measured by the rapid vacuum filtration assay. One mL of cellular stock suspension was incubated for 1 min in a 37°C waterbath with stirring, and uptake was started by the addition of 1 mL of fatty acid solution (Hanks' medium plus 20 mmol/L sodium taurocholate) containing [1-^{14}C]linoleic acid at 37°C. At various time points, 200-μL sample aliquots (about 0.5 mg protein) were pipetted into 3 mL of 5 mg albumin/mL Hanks' medium (4°C) to stop cellular influx and to remove bound fatty acids. In separate experiments it was found that resuspending the cells in 5 mg albumin/mL at 4°C stopped uptake after a rapid reequilibration period of 1 min. During this time about 10% of cell-associated radioactivity was removed, and no further change in radioactivity was detected during the next 10 min. The stop solution containing cells was pipetted onto the center of Whatman GF/C glass microfibre filter (Poly Labo, Strasbourg, France), and filtered under 8×10^4 P_a vacuum pressure using a filtration apparatus (Hoefer model FH225V; Bioblock). Cells were washed with 5 mL of 5 mg albumin/mL solution (4°C) and thereafter with 20 mL of Hanks' medium (4°C). Filters were placed in scintillation vials, 4 mL of scintillation liquid were added and radioactivity was determined in a LKB-1215 Rackbeta liquid scintillation counter (Pharmacia). Nonspecific radioactivity binding to filters and cells was measured in each experiment by adding 5 mg albumin/mL Hanks' medium (4°C) before the addition of corresponding aliquots of cells and [1-^{14}C]-linolenic acid working solutions. The value of each sample was the net radioactivity after subtraction of this blank.

The effect of the metabolic inhibitor antimycin A or 2,4-dinitrophenol (final concentrations 25 and 250 μM, respectively) was studied by adding the inhibitor to the cells 10 min before linoleic acid solubilized in taurocholate was added. In studies on the effect of Na^+ depletion, NaCl was replaced by isoosmotic choline chloride. Cells were first washed twice in the Na^+ depleted medium and then incubated for 10 min at 37°C in the same medium. One mL of [1-^{14}C]linoleic acid was then added to 1 mL of cell suspension (final concentration 100 μM linoleic acid in 20 mM taurocholate), and uptake was determined as described above. The experimental protocol was changed somewhat in studies on the effect of other unlabeled substrates (100 μM or 1 mM final concentration) on linoleic acid uptake. Nine hundred μL of unlabeled substrate solubilized in 20 mM taurocholate was added to 1 mL of cell suspension. After 30 s at 37°C with stirring, 100 μL of [1-^{14}C]-linoleic acid was added (final concentration 100 μM in 20 mM taurocholate), and the initial rate of uptake was determined as described above.

Statistical analysis. Initial rates of uptake were calculated by the least-squares method which allows an estimation of simple linear regression parameters and their standard deviations. Comparisons of ordinates at origin with zero value were evaluated by Student *t*-test. Curves characterizing the intracellular uptake of linoleic acid were calculated with Microsoft® Excel solver (Les Ulis, France) and P.C.S.M. program (Deltasoft, Grenoble, France). The program provides the kinetic parameters (V_m, K_m) of a nonlinear function (Michaelis-Menten equation) with the least-squares method. Comparisons between group means were evaluated by unpaired *t*-test. Statistical significance of differences among more than two groups were determined by analysis of variance.

RESULTS

Determination of the concentration of linoleic acid monomers in the incubation medium. Linoleic acid transport by intestinal cells was studied in the concentration range of 1 to 1000 μM. When the fatty acid was solubilized in the incubation medium containing a bile salt (sodium

taurocholate), a mixture of mixed micelles of fatty acid/taurocholate and free fatty acids (monomer) was obtained. The micelles cannot readily pass through cell membranes due to their higher molecular weight, and it is generally accepted that only fatty acids present as monomers can participate in the absorption process (23). The membrane ultrafiltration method we used made it possible to determine the quantity of monomeric fatty acid in the solution studied (1 to 1000 μM linoleic acid in 20 mM sodium taurocholate). Figure 1 shows that the monomer concentration was proportional to the quantity of linoleic acid present in the incubation medium. The Y-intercept of this line was not significantly different from zero, and the partition coefficient between fatty acids in the extra- and intramicellar phase was constant ($K = 2.22 \times 10^{-3}$).

Another estimation of the monomer activities was based on the polyethylene disc method (see Materials and Methods section). Figure 2 shows the relationship between the linoleic acid concentration in the incubation medium and the quantity of fatty acid taken up by the polyethylene discs. The relationship between these two parameters was linear as long as the linoleic acid concentration in the incubation medium was lower than 400 μM.

Kinetics of intracellular uptake of linoleic acid. Figure 3 is an example of uptake kinetics by isolated intestinal cells of linoleic acid at 200 μM solubilized in 20 mM taurocholate. Uptake was maximal and linear during the first 20 s of incubation, and then decreased progressively. The initial uptake rate of the fatty acid (V_0) corresponds to the slope of the line obtained by fitting the experimental values measured during the first 20 s of incubation to a linear model. The example of Figure 3 gives $V_0 = 3.57$ nmol/mg protein/min (mean $V_0 = 3.67 \pm 0.57$ nmol/mg protein/min).

A reduction in linoleic acid transport of more than 80% was observed when the temperature of the incubation medium was decreased from 37 to 4°C (Fig. 3). A lower level of uptake was also noted when intestinal cells were incubated for 10 min at 37°C in the presence of metabolic inhibitors. In comparison to controls, 2,4-dinitrophenol, an uncoupler of oxidative phosphorylation (250 μM), and antimycin A, an inhibitor of the mitochondrial electron transport system (25 μM), caused a considerable decrease in the initial rate of uptake of 100 μM linoleic acid (2.18 ± 0.22, 0.66 ± 0.21, 0.32 ± 0.20 nmol/mg protein/min, respectively). This drop in fatty acid uptake was much greater than the decrease in intestinal cell viability seen due to these metabolic inhibitors (<7%).

Influence of linoleic acid concentration on initial rate of uptake. The initial rates of fatty acid uptake were measured for different concentrations (1 to 1000 μM) of linoleic acid solubilized in 20 mM taurocholate. When initial rates were plotted as a function of monomer concentration as

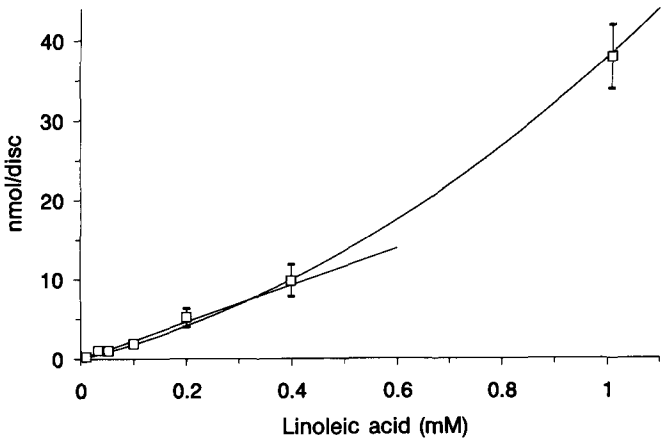

FIG. 2. Characteristics of partitioning of linoleic acid into polyethylene discs and apparent monomeric activity of linoleic acid in 20 mM taurocholate micellar solutions. Values are means ± SE of four experiments. Absent error bars indicate that errors fell within symbol.

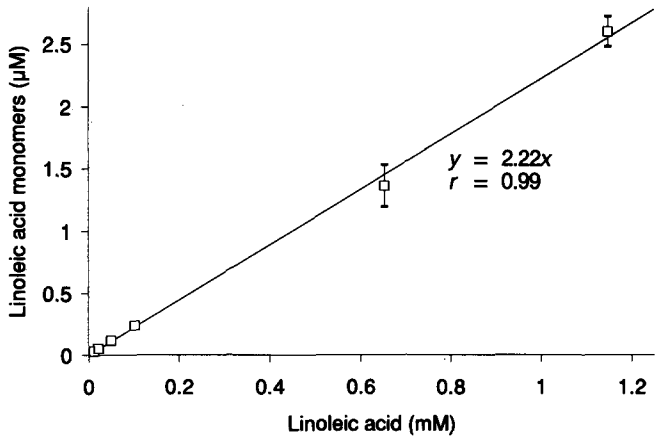

FIG. 1. Effect of the level of linoleic acid solubilized in 20 mM taurocholate on linoleic acid monomer concentration. Monomers were separated from micellar aggregates by ultrafiltration as described in the Materials and Methods section. Values are means ± SE of three experiments. Absent error bars indicate that errors fell within symbol.

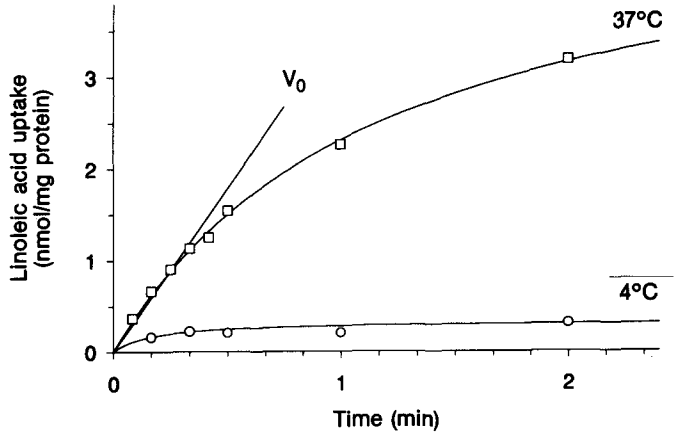

FIG. 3. Time course of linoleic acid uptake by isolated enterocytes at 37 and 4°C. Linoleic acid (200 μM) was solubilized in 20 mM taurocholate. The initial uptake rate (V_0) was calculated by the least-squares method from the uptake obtained over the initial 20-s incubation period. Values are means ± SE of four experiments. All error bars fell within the symbols.

determined by ultrafiltration (2 to 2220 nM), saturation of uptake was observed (Fig. 4). When the experimental values were fit to the Michaelis-Menten model, V_m = 5.1 ± 0.6 nmol/mg protein/min and K_m = 183 ± 7 nM were calculated.

Effect of long-chain fatty acids and other substrates on the uptake of linoleic acid. In order to determine whether the uptake of linoleic acid by intestinal cells was modified by the presence of other substrates in the incubation medium, long-chain polyunsaturated fatty acids, certain derivatives of linoleic acid, or D-glucose, each at 1 mM, were added to the micellar solution containing 100 μM [1-^{14}C]linoleic acid and 20 mM taurocholate. The addition of long-chain fatty acids reduced the uptake of linoleic acid by more than 80% (Table 1). This inhibition was observed for fatty acids with different chain lengths or different degrees of unsaturation. On the other hand, changes in the uptake of [1-^{14}C]linoleic acid induced by linoleic acid analogues were dependent on the type of derivative used. When the terminal carboxyl group of linoleic acid was blocked (linoleic acid methyl ester, linoleic anhydride), the inhibition of uptake was attenuated. Finally, when the incubation medium was supplemented with a molecule that is actively transported by intestinal cells, but is unrelated to a fatty acid (D-glucose), there was no change in linoleic acid uptake. The inhibition of linoleic acid influx observed in the presence of unlabeled fatty acids was not related to a decrease in the monomer concentration of [1-^{14}C]linoleic acid in the incubation medium. The polyethylene disc technique indicated no statistically significant difference between linoleic acid monomers present in the incubation medium before and after the addition of 1 mM unlabeled substrate (Table 2).

Effect of α-linolenic acid on the uptake of linoleic acid. The initial rate of [1-^{14}C]linoleic acid uptake (50 to 500 μM solubilized in 20 mM taurocholate) was measured with and without the addition of a constant quantity of α-linolenic acid (100 μM solubilized in 20 mM taurocholate) to the incubation medium. A Lineweaver-Burk plot of the data (Fig. 5) shows that the addition of α-linolenic acid to the incubation medium changed the slope that characterizes [1-^{14}C]linoleic acid uptake (K_m/V_m), but had no significant effect on the Y-intercept ($1/V_m$). In other words, addition of α-linolenic acid caused a change in K_m without modifying V_m for [1-^{14}C]linoleic acid. The decreased uptake observed coincided with competitive inhibition, with an apparent K_i of 157 μM, corresponding to an α-linolenic acid monomer concentration of 353 nM.

Effect of extracellular sodium on linoleic acid uptake. The effect of extracellular sodium on the uptake of 100 μM linoleic acid dissolved in 20 mM taurocholate was tested by replacing the sodium chloride in the incubation medium by an isoosmotic concentration of choline chlo-

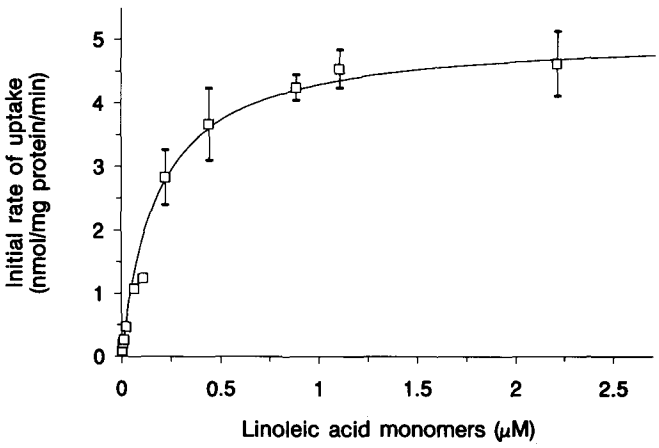

FIG. 4. Relationship between linoleic acid monomer concentration in the incubation medium and initial uptake rate. Values are means ± SE of four separate experiments. Kinetics parameters were generated from weighted least-square fits of the individual data points from each experiment to a rectangular hyperbola (V_m = 5.1 ± 0.6 nmol/mg protein/min; K_m = 183 ± 7 nM).

[c]Linoleic acid content of polyethylene disc is expressed as pmol/disc. There is no statistical difference ($P > 0.05$) between the means (analysis of variance).

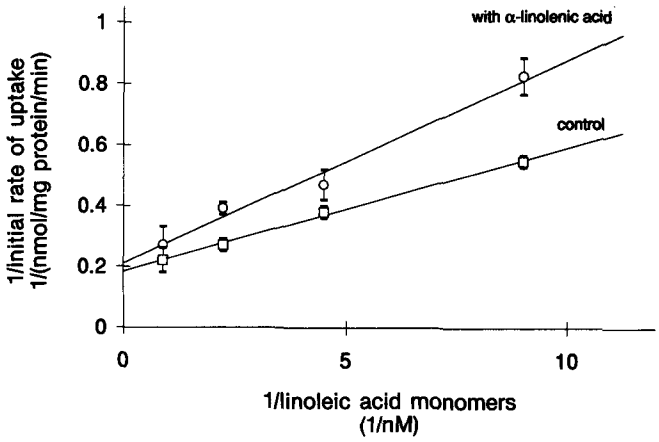

FIG. 5. Lineweaver-Burk plot of cellular [1-^{14}C]linoleic acid uptake in the presence (circles, Y = 0.2097 + 0.0303 X, r = 0.973) and absence (squares, Y = 0.1839 + 0.0185 X, r = 0.984) of 100 μM α-linolenic acid in the incubation medium. The addition of α-linolenic acid changed the K_m value without changing the V_m value of linoleic acid uptake, revealing a predominantly competitive type of inhibition by α-linolenic acid. Values are means ± SE of four experiments.

ride. Nevertheless, the presence of sodium taurocholate as solubilizing agent requires a minimum of 20 mM Na^+ in the incubation medium. In Na^+-depleted medium, uptake of linoleic acid was reduced (1.05 ± 0.07 nmol/mg protein/min) compared with the presence of Na^+ (1.82 ± 0.06 nmol/mg protein/min, this control value was lower than usually seen due to additional washes used in this protocol). The decreased uptake was associated with a decrease in monomer activity of linoleic acid in the incubation medium (839 ± 16 pmol/disc in the Na^+-depleted medium and 1940 ± 74 pmol/disc in presence of Na^+) probably because of changes in the ionic strength in the incubation medium. Taking into account this decrease in monomer concentration, we arrived at an initial rate of uptake of 0.99 nmol/mg protein/min. This calculated value for V_i was quite similar to that reported for Na^+-depleted medium. Thus, a direct relationship between Na^+-depleted medium and reduced linoleic acid uptake seems unlikely.

DISCUSSION

Prior work in our laboratory had shown that the uptake of α-linolenic acid (18:3n-3) by isolated hamster intestinal cells was carrier-mediated (15). This was concluded based on results obtained utilizing rapid filtration through glass microfiber filter with a bile salt present as solubilizing agent. Appropriate dispersion of fatty acids in the incubation medium is indispensable when studying fatty acid absorption by intestinal cells. Several authors have used bovine serum albumin to complex fatty acids, and the proportion of unbound fatty acid (monomers) in the incubation medium could thus be modulated by varying the fatty acid/albumin ratio (11,24,25). This approach is thought to be physiologically appropriate for cells that are naturally in contact with circulating plasma, e.g., liver cells. In intestinal absorption, however, fatty acids are solubilized by bile salts, and to mimic physiological conditions, the fatty acids used in this study were solubilized by the addition of 20 mM sodium taurocholate. We have shown that sodium taurocholate had no effect on the viability or permeability of intestinal cells when the incubation time was shorter than 1 min (15), as used in the present study. Membrane ultrafiltration (1,000 molecular weight cut-off) showed that the monomer concentration increased proportionally to the total concentration of linoleic acid solubilized in the incubation medium (Hanks' medium plus 20 mM sodium taurocholate). The partition coefficient between monomers and micelles observed for linoleic acid ($K = 2.22 \times 10^{-3}$) was similar to that found for α-linolenic acid ($K = 2.25 \times 10^{-3}$) (15).

The results obtained in the present study indicate that linoleic acid uptake by isolated hamster intestinal cells depends on an active and carrier-mediated mechanism. Several points argue in favor of this type of transport:

(i) The initial rate of linoleic acid uptake was not proportional to the monomer concentration in the incubation medium. The initial rate of fatty acid uptake reached a plateau when the monomer concentration was higher than 1000 nM. Kinetics were saturable, and the Michaelis-Menten model led to the calculation of V_m = 5.1 ± 0.6 nmol/mg protein/min and K_m = 183 ± 7 nM. This saturable transport mechanism excludes the simple diffusion mechanism proposed for this fatty acid by Ling *et al.* (19) and agrees with results obtained *in vitro* (16) and *in vivo* (17) by Chow and Hollander and by Molina *et al.* (18) using everted intestinal sacs. With respect to intestinal uptake, the data obtained for oleate (13), α-linolenate (15) and linoleate (this study), strongly support the carrier-mediated transport of C18 fatty acids.

(ii) Lowering the temperature of the incubation medium from 37 to 4°C caused a considerable reduction in the initial rate of linoleic acid uptake. This may in part be due to a decrease in monomer concentration. However, the action of metabolic inhibitors, such as 2,4-dinitrophenol and antimycin A, caused a considerable drop in fatty acid uptake. This suggests that the process of linoleic acid uptake by intestinal cells requires cellular energy. The uptake of linoleic acid, as that of α-linolenic acid, is thus dependent on active transport. With respect to the role of energy in linoleic acid transport, our results disagree with work published by others (16–18). As we mentioned earlier (15), however, the previous authors (16–18) studied the absorption of linoleic acid using models and experimental conditions that did not permit them to assess the effect of temperature and metabolic inhibitors on the initial rate of fatty acid uptake.

(iii) Involvement of an active, carrier-mediated mechanism presupposes the existence of a transport protein. In order to clarify this point, we determined the effect of several polyunsaturated fatty acids, including linoleic acid itself, on the uptake of labeled linoleic acid. The separate addition of fatty acids to the incubation medium resulted in a significant decrease in the initial rate of linoleic acid uptake. This considerable decrease in linoleic acid uptake was apparently not related to the type of fatty acid added in large excess to the incubation medium. The terminal carboxyl group of the fatty acid, on the other hand, played

an important role in the recognition of linoleic acid by the transporter.

The decreased uptake of linoleic acid we observed could nevertheless be related to a disturbance in the monomer/micelle balance induced by addition of a high concentration of fatty acids to the incubation medium (16,26). Although this cannot be ruled out, it seems improbable since the monomer concentration of linoleic acid remained unchanged after the addition of different substrates, based on data obtained by the polyethylene disc method.

Both the active and carrier-mediated uptake of linoleic acid, and the inhibitory effect of other fatty acids, argue in favor of the presence of a membrane transport protein that can be shared by several long-chain fatty acids. In our previous work (15) the existence of this common carrier was stipulated based on the inhibition of α-linolenic acid uptake induced by large amounts of several polyunsaturated fatty acids, particularly linoleic acid. It was not clear, however, whether the inhibition observed was competitive or noncompetitive. In the present study, this point was examined for the parent essential fatty acids, α-linolenic and linoleic acids. The addition of α-linolenic acid to micellar solutions of linoleic acid changed the K_m characterizing the uptake without significantly changing V_m. When α-linolenic acid was added to the incubation medium, a competitive inhibition of linoleic acid uptake was seen. The inhibition constant we calculated (K_i = 353 nM) is very close to the K_m we reported for α-linolenic acid (15).

Our results suggest that uptake of the two essential fatty acids, linoleic and α-linolenic acids, by intestinal cells is brought about by the same transport protein, probably the 40 kDa plasma membrane fatty acid binding protein described by Stremmel *et al.* (12) to occur in intestinal cells (12) and which was subsequently also found in other tissues (27). Within the C_{18} fatty acids, the K_m differs for different fatty acids. A K_m of 93 nM was reported for oleic acid (13), of 183 nM for linoleic acid (present study) and of 382 nM for α-linolenic acid (15). These differences suggest that for fatty acids of the same carbon-chain length, the number and/or the position of double-bounds can modulate the affinity to the common membrane transport protein.

Uncommon *cis* and *trans* fatty acids can be desaturated and elongated to produce unusual C_{18} and C_{20} polyunsaturated fatty acids in animal tissues. In the present study we examined the formation of such metabolites derived from *cis* and *trans* isomers of oleic and linoleic acids of partially hydrogenated vegetable oil origin in rats. For two months, adult male rats were fed a partially hydrogenated canola oil diet containing moderately high levels of *trans* fatty acids (9.6 energy%) and an adequate level of linoleic acid (1.46 energy%). Analysis of the phospholipid (PL) fatty acids of liver, heart, serum and brain showed no new C_{18} polyunsaturated fatty acids, except for those uncommon 18:2 isomers originating from the diet. However, minor levels (each <0.3% PL fatty acids) of six unusual C_{20} polyunsaturated fatty acids were detected in the tissues examined, except in brain PL. Identification of their structures indicated that the dietary 9*c*,13*t*-18:2 isomer, which is the major *trans* polyunsaturated fatty acid in partially hydrogenated vegetable oils, was desaturated and elongated to 5*c*,8*c*,11*c*,15*t*-20:4, possibly by the same pathway that is operative for linoleic acid. Furthermore, dietary 12*c*-18:1 was converted to 8*c*,14*c*-20:2 and 5*c*,8*c*,14*c*-20:3; dietary 9*c*,12*t*-18:2 metabolized to 11*c*,14*t*-20:2 and 5*c*,8*c*,11*c*14*t*-20:4, and dietary 9*t*,12*c* to 11*t*,14*c*-20:2. These results suggested that of all the possible isomers of oleic and linoleic acids in partially hydrogenated vegetable oils, 12*c*-18:1, 9*c*,13*t*-18:2, 9*c*,12*t*-18:2 and 9*t*,12*c*-18:2 are the preferred substrates for desaturation and elongation in rats. However, their conversions to C_{20} metabolites were not as efficient as that of oleic or linoleic acids.

***Lipids* 29, 707–714 (1994).**

Partially hydrogenated vegetable oils (PHVO) contain a range of *cis* and *trans* isomers of oleic (9*c*-18:1) and linoleic (9*c*,12*c*-18:2) acids (1–5). Studies with rodents have shown that some of these isomers are desaturated and elongated to unusual C_{18} and C_{20} polyunsaturated fatty acids (PUFA) (6–8).

Cis-9,*trans*-13-octadecadienoic acid (9*c*,13*t*-18:2) is the major *trans* polyunsaturated isomer in PHVO (2,5,9). During gas chromatographic analysis, this isomer co-elutes with 8*t*,12*c*-18:2, which is a very minor component in PHVO (2). Therefore, the amounts of these two isomers are generally listed together in reports giving the fatty acid composition of dietary fats. Canadian margarines contain 0.5–2.6% of the two isomers (2), and many bakery products contain similar levels (10). Levels as high as 9% were reported for some partially hydrogenated soybean oil stocks (5). Information on the metabolism of the two mono-*trans* geometrical isomers of linoleic acid, 9*c*,12*t*-18:2 and 9*t*,12*c*-18:2 (5–7,11,12), which are also present in appreciable quantities in PHVO, is available, but nothing is known about the metabolism of 9*c*,13*t*-18:2. The Δ6 desaturase is active only on fatty acids with a *cis*-9 double bond, and, hence, it may be expected that the 9*c*,13*t*-18:2 is converted to a *t*-20:4 isomer, similar to the conversion of 9*c*,12*t*-18:2 to a *trans* isomer of arachidonic acid in rodents (5–7,12).

The present study, therefore, examined the possible formation of PUFA metabolites of 9*c*,13*t*-18:2 in rats. Because 9*c*,13*t*-18:2 is not commercially available, a mildly hydrogenated canola oil, with 9*c*,13*t*-18:2 + 8*t*,12*c*-18:2 content of 1.9%, was used as the dietary source of this acid. In addition, we report the occurrence of other unusual C_{20} PUFA and the compositions of 18:2 and 18:1 isomers in the rat. The fatty acid data were compared to a reference group of rats fed an unhydrogenated canola oil diet.

MATERIALS AND METHODS

Fatty acid methyl esters (FAME) standards were purchased from Sigma Chemical Company (St. Louis, MO). Several unsaturated FAME required for the identification of unusual C_{18} and C_{20} PUFA were prepared from 9*c*,12*c*-18:2, 9*c*,12*c*,15*c*-18:3, 11*c*,14*c*-20:2, 8*c*,11*c*,14*c*-20:3 and 5*c*,8*c*,11*c*,14*c*-20:4 standards, through partial reduction with hydrazine, geometrical isomerization with *p*-toluenesulfinic acid and fractionation of the products by $AgNO_3$–thin-layer chromatography (TLC) (2,13–15).

The partially hydrogenated canola oil (PHCO) (iodine value 94) used in the rat diet was supplied by Canamara Foods (Toronto, Ontario, Canada). Unhydrogenated canola oil was purchased from a supermarket in Ottawa.

Animals and diets. Male Sprague-Dawley rats (Charles River, Quebec, Canada), weighing 244 ± 3 g, were housed individually in metal cages in an air-conditioned room maintained at 22°C and 60% relative humidity with a 12-h day/12-h night cycle. The rats were randomly assigned to two groups of ten rats per group. The animals were fed isocaloric (468 Kcal/100 g diet), semisynthetic diets containing either 20% PHCO or 20% canola oil. The other ingredients in the diet were, in g/100 g diet, vitamin-free ca-

sein, 22.0; cornstarch, 27.0; sucrose, 22.8; alphacel, 3.0; mineral mixture-AIN 76, 3.5; vitamin mixture-AIN 76A, 1.0; choline bitartrate, 0.4; and DL-methionine, 0.3 (Teklad, Madison, WI). The diets were prepared weekly and stored at −4°C. Food and water were available to the animals *ad libitum*. The animals were killed after 60 d of feeding; liver, heart, brain and blood (aorta) were collected and immediately frozen in liquid nitrogen and stored at −80°C under nitrogen until analyzed for fatty acids.

Analytical procedures. Total lipids from the tissues were extracted with chloroform/methanol (2:1, vol/vol) (16). Phospholipids (PL) were isolated by TLC with development in hexane/diethyl ether/acetic acid (80:20:1, by vol). FAME of the PL and dietary oils were obtained following treatment with BF_3/MeOH (Sigma Chemical Company).

The FAME from liver PL of the ten rats fed the PHCO diet were pooled for determination of the 18:1 isomer composition and for characterization of the unusual C_{18} and C_{20} PUFA. The FAME were initially fractionated by semi-preparative high-pressure liquid chromatography (HPLC) on a Waters (Milford, MA) Bondapak C_{18} column using MeOH/H_2O (95:5, vol/vol) as mobile phase. Each HPLC fraction (four in all) was further fractionated by preparative $AgNO_3$–TLC with development either in toluene at −25°C (for separation of the fractions containing three or less double bonds) or hexane/diethyl ether (2:3, vol/vol) at room temperature (for separation of fractions containing four or more double bonds). This produced various fractions enriched with 18:1*c*, 18:1*t*, 18:2*tt*, 18:2*ct*/*tc* (methylene interrupted, MI) 18:2*ct*/*tc* (nonmethylene interrupted, NMI), 18:2*cc* (MI), 18:2*cc* (NMI), 20:2*ct*/*tc* (MI), 20:2*cc* (MI), 20:3*ccc* (NMI) 20:3*ccc* (MI), 20:4 (all isomers) and 20:5 + 22:4 + 22:5 + 22:6. Each step of the isolation procedure was monitored by gas chromatography (GC). The HPLC and $AgNO_3$–TLC fractionations were repeated several times to obtain sufficient material for structural characterization.

For the determination of the composition of the 18:1 and 18:2 isomers in the dietary PHCO, the FAME were fractionated by $AgNO_3$–TLC with development in toluene at −25°C (2).

The isomer distribution of the isolated 18:1*c* and *t* fractions was determined through oxidative ozonolysis (17). The structures of the various 18:2 isomer fractions were identified from the previous work at this laboratory (2).

The structures of C_{20} PUFA were initially identified by comparison of their GC retention times with those of authentic standards. The structures of some isomers were confirmed through partial hydrazine reduction followed by identification of the resultant *cis*- and *trans*-monounsaturated FAME. Finally, the double bond positions of all the PUFA were confirmed by GC/mass spectrometry (GC/MS) analysis of their 2-alkenyl-4,4-dimethyloxazoline (DMOX) derivatives (18–20).

Silica gel plates (Whatman K5, 250 μm layer, 20 cm × 20 cm; Whatman Laboratory Division, Clifton, NJ) were impregnated by dipping in a 10% solution of $AgNO_3$ in acetonitrile for 30 min. The bands were detected under ultraviolet light at 254 nm, after spraying with a 0.2% solution of 2′,7′-dichlorofluorescein in ethanol, and scraped into glass centrifuge tubes. A 1% solution of NaCl in 90% MeOH was added until the silver-dichlorofluorescein complex disappeared. Water was added, and the methyl esters were extracted with hexane.

FAME were analyzed by GC using a SP-2560 flexible fused silica capillary column (100 m × 0.25 mm i.d., 20 μm film thickness; Supelco, Inc., Bellefonte, PA) in a Hewlett-Packard 5890 Series II gas chromatograph (Palo Alto, CA). The column was operated isothermally (180°C), or the oven temperature was programmed. After 10 min at an initial temperature of 160°C, the temperature was increased at a rate of 1°C per min to 210°C and held at the final temperature for 20 min. The injector and detector temperatures were 250°C. Hydrogen was used as the carrier gas at a pressure of 20 psi. The equivalent chain length (ECL) values of the unsaturated fatty acids were calculated according to the method described by Ackman (21).

For GC/MS analysis, the isolated fractions or the total FAME from the liver PL were saponified and acidified to the free acids and then converted to the DMOX derivative by treating with 2-amino-2-methylpropanol in a microvial at 170°C for 1 h, according to the procedure of Zhang *et al.* (18). Mass spectra of the DMOX derivatives were obtained on a VG Analytical MS system (Model 7070EQ; VG Analytical, Manchester, England), equipped with an 11/250 data system interfaced to a Varian GC (Model Vista 6000; Varian Associates, Palo Alto, CA) operated at an ionization energy of 70 eV. GC separation of the DMOX derivatives was performed on the same SP-2560 capillary column described for the FAME analysis. Helium was the carrier gas. The GC column oven temperature was programmed from 70 to 120°C at 50°C/min and from 120 to 220°C at 1.5°C/min.

RESULTS

Fatty acid composition of dietary fats. The fatty acid composition of the two diets is summarized in Table 1. Both diets contained comparable amounts of saturated fat as well as total *c*-18:1. However, the PHCO diet contained lower proportions of essential fatty acids (EFA) (3.8% vs. 30.3%) and higher proportions of *trans* fatty acids (26.6% vs. 0.2%). The *t*-18:1 isomers of PHCO ranged from Δ8 to Δ16, whereas the *c*-18:1 isomers ranged from Δ6 to Δ16. In contrast, unhydrogenated canola oil contained only two *c*-18:1 isomers, oleic (*c*-9) and *cis*-vaccenic (*c*-11), and there were no *t*-18:1 isomers.

The unusual 18:2 isomer content in PHCO was 7.6% of the total fatty acids. The 18:2 fraction consisted of several isomers, of which 9*c*,13*t*-18:2 was the major component. *trans*-PUFA were also present in the unhydrogenated canola oil, but at much lower levels, derived from the mono-*trans* geometrical isomers of linoleic and α-linolenic acids.

Food consumption, body and organ weights. Rats fed different diets consumed similar amounts of food (20:4 ± 3.1 g/rat/d), showed no sign of EFA deficiency and appeared healthy throughout the experimental period. The body, liver, heart and kidney weights of the PHCO group were 574.4 ± 34.9, 16.2 ± 2.9, 1.4 ± 0.2 and 3.1 ± 0.4 g, respectively, and did not differ from those of the reference group.

[a]PHCO, partially hydrogenated canola oil; EFA, essential fatty acid.
[b]A mixture of mono-*trans* geometric isomers of 18:3n-3.
[c]Others include 16:1, 20:1, 22:1, 24:1 and 18:2 conjugated fatty acids.

Tissue PL fatty acids. The fatty acid composition of liver, heart, brain and serum PL is shown in Table 2. The gas chromatographic trace of the FAME profile of liver PL is shown in Figure 1. Feeding PHCO rats led to the incorporation of *c*- and *t*-18:1 and 18:2 isomeric fatty acids in liver, heart and serum. However, no dietary isomeric fatty acids were incorporated into brain. Generally, the fatty acid composition of brain PL was unaffected by that of the diet. Compared to the canola oil group, the liver, heart and serum PL of PHCO fed rats contained higher percentage of saturated fatty acids, 5*c*,8*c*,11*c*-20:3 and lower percentages of 18:2n-6, 22:5n-3 and 22:6n-3. Another noticeable difference was that although the content of 22:5n-6 in tissues of rats fed PHCO was quite large, it was almost absent in the canola oil group. In rats fed PHCO, as compared to the canola oil group, the content of 20:4n-6 was low in liver and serum PL. In contrast, the 20:4n-6 content of heart PL of PHCO was significantly higher than that in heart PL of canola oil group.

Comparison of the c- and t-18:1 isomer patterns of dietary PHCO (Table 1) with those in tissues of rats fed PHCO (Table 2) shows that isomers ranging from Δ11 to Δ16, especially the Δ12, were enriched in the tissue PL, relative to the lower Δ value isomers. This increase was accompanied by large decreases in the proportions of both 10c- and 10t-isomers. In the cis series, the proportion of 9c-18:1 was also lower in the tissue PL than in dietary PHCO. In the tissue PL of rats fed the canola oil, the 11c-18:1 isomer was the only significant component besides oleic acid.

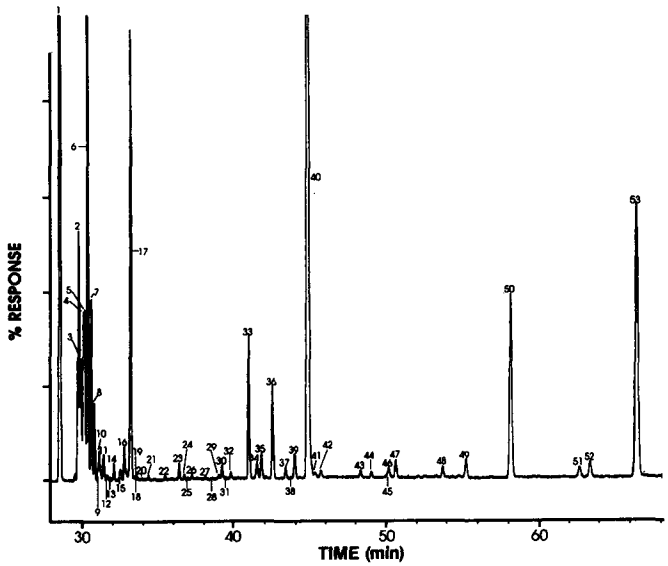

FIG. 1. The C_{18}, C_{20} and C_{22} regions of a gas chromatogram obtained on an SP-2560 capillary column (100 m × 0.25 mm) of the fatty acid methyl esters from liver phospholipids of rats fed partially hydrogenated canola oil. Peak identifications: (peak no., fatty acid) 1, 18:0; 2, 8c-9c-18:1; 3, 10t-18:1; 4, 11t-18:1; 5, 12t-18:1; 6, 13t-15t-18:1 + 6c-10c-18:1; 7, 11c-18:1; 8, 12c-18:1; 9, tt-18:2; 10, 13c-18:1; 11, 14c-18:1 + 16t-18:1; 12, tt-18:2 + 15c-18:1; 13, 9t,12t-18:2; 14, 9c,13t/8t,12c-18:2; 15, 9c,12t-18:2 + 8c,13c-18:2 + 9t,13c-18:2; 16, 9t,12c-18:2 + 10t,15c/9t,15c-18:2 + 9c,13c-18:2; 17, 18:2n-6; 18, 9c,14c-18:2; 19, 9c,15c-18:2; 20, unknown; 21, 12c,15c-18:2; 22, 20:0; 23, 11c-20:1; 24, 12c-20:1; 25, 18:2 conjugates; 26, 13c-20:1; 27, 18:2 conjugates; 28, 18:2 conjugates; 29, 11c,14t-20:2; 30, 8c,14c-20:2; 31, 11t,14c-20:2; 32, 20:2n-6; 33, 20:3n-9; 34, 5c,8c14c-20:3; 35, 5c,11c,14c-20:3; 36, 20:3n-6; 37, 5c,8c,11c,15t-20:4; 38, unknown; 39, 5c,8c,11c,14t-20:4; 40, 20:4n-6; 41, 22:1; 42, 22:1; 43, 22:2; 44, 22:2; 45, 20:5n-3; 46, unknown; 47, unknown; 48, 24:0; 49, 24:1; 50, 22:5n-6; 51, 22:5n-3; 52, t-22:6n-3; and 53, 22:6n-3.

[a]Abbreviations as in Table 1. PUFA, polyunsaturated fatty acids. Trace, <0.01%. Values are mean ± standard deviation (n = 10).

Linoleic acid was the only 18:2 isomer in the PL in rats fed canola oil (Table 2). The 18:2 from liver PL of rats fed PHCO was largely linoleic, but it contained minor proportions (<0.8%) of several unusual isomers. The HPLC/$AgNO_3$–TLC and GC analyses suggested that all the unusual isomers originated from dietary PHCO. No new unusual isomers were detected. However, some pronounced quantitative differences in the individual isomers were observed. Among the unusual isomers, the relative proportions of 9c,12t-18:2, 8t,13c-18:2, 10t,15c/9t,15c-18:2 and 9c,15c-18:2 in particular were substantially lower in the tissue PL than in the dietary PHCO. On the other hand, 9t,12c was found in much higher proportions in the liver PL, and 9c,13t appeared to remain unchanged.

Feeding of PHCO diet to rats led to the formation of minor levels of six unusual C_{20} metabolites (peaks 29, 30, 31, 34, 37 and 39 in Fig. 1). They were identified as 11c,14t-20:2 (peak 29), 8c,14c-20:2 (peak 30), 11t,14c-20:2 (peak 31), 5c,8c,14c-20:3 (peak 34), 5c,8c,11c,15t-20:4 (peak 37) and 5c,8c,11c,14t-20:4 (peak 39). The mass spectra of the DMOX derivatives of those C_{20} PUFA fatty acids were consistent with the structures proposed for them. As an illustration, the mass spectrum of the DMOX derivative of 5c,8c,11c,15t-20:4, a hitherto unknown PUFA, is shown in Figure 2. Table 3 summarizes the results obtained for the other five unusual C_{20} PUFA. Only the diagnostic fragments, locating the double bond positions, are presented.

The mass spectrum of the DMOX derivative of 5c,8c,11c,15t-20:4 (Fig. 2) gave very intense ions at m/z 113 and 126, which are characteristic of the DMOX derivatives of fatty acids (18–20). The molecular ion appeared at m/z 357, which is in agreement with the molecular weight for the DMOX derivative of 20:4. The Δ5 double was localized by appearance of the prominent ion at m/z 153. This ion is a diagnostic ion in the spectra of DMOX derivatives with their first double bond at the Δ5 position (18–20). In DMOX derivatives of unsaturated fatty acids, a mass interval of 12 atomic mass units (amu) instead of the regular 14 amu, between two neighboring even-mass homologous fragments containing n-1 and n carbon atoms in the acid moiety indicates a double bond between n and n + 1 in the chain (18–20). Thus Δ8, Δ11 and Δ15 double bonds in 5c,8c,11c,15t-20:4 were clearly located by ions (m/z 180 vs. 192, m/z 220 vs. 232 and m/z 274 and 286) which differed by 12 amu. The prominent ion at m/z 260 confirms the presence of allylic bonds at the Δ11 and Δ15 positions. As shown in Table 3, the positions of the double bonds in the other unusual C_{20} were clearly localized by ions which differed by 12 amu and the Δ5 bond by a prominent ion at m/z 153.

The geometry of the double bonds in 5c,8c,11c,15t-20:4 could be deduced by comparison of the experimental and calculated ECL values. This approach has been success-

fully applied to the identification of C_{20} *all cis*-polyunsaturated fatty acids (22), geometrical isomers of 20:5n-3 (23), as well as to some *cis* and *trans* C_{18} isomers (24). The observed ECL value for the FAME of the 5*c*,8*c*,11*c*,15*t*-20:4 isomer on the SP-2560 column was 22.46. It was possible to verify the ECL value of 22.46 for this isomer as the sum of the fractional chain length values of FAME of authentic 5*c*,8*c*,11*c*-20:3 and 15*t*-20:1, *ca.* 1.80 and 0.66, respectively, on the same GC column, plus the ECL base of 20.00, as there is no additional increment for interaction of the ethylenic bonds (25). Authentic 15*t*-20:1 (or 20:1n-5*t*) is not readily available. Therefore, its ECL value was estimated by extrapolating the retention time data of 13*t*-18:1 (or 18:1n-5*t*) using semi-log plots of retention time vs. carbon number, as described by Ackman (21). From all these data, the novel minor unusual 20:4 isomer was identified as 5*c*,8*c*,11*c*,15*t*-20:4. The structures of the other five unusual C_{20} PUFA were also identified using similar techniques.

The unusual C_{20} PUFA were mostly concentrated in the serum PL followed by liver and heart PL (Table 2). They were not detected in the brain PL nor in any of the tissues of rats fed canola oil. No unusual C_{22} metabolites were detected in any of the tissues examined.

DISCUSSION

The incorporation of dietary *c*- and *t*-18:1 isomers into tissue PL (except brain) indicates a preferential accumulation of high Δ value isomers, irrespective of their geometry. This phenomenon was also reported in rats fed hydrogenated soybean oil (26). Thus, the specificity for accumulation of 18:1 isomers appears to be more a matter of position of the double bond rather than of geometry. The observed large amounts both 12*c* and 12*t* isomers in tissue PL may indicate that the accumulation is more specific for the Δ12 position. None of the uncommon 18:1 isomers, except for 12*c*-18:1, were converted to C_{18} or C_{20} PUFA 18:2 (as discussed next). This suggests that all the uncommon 18:1 isomers, except for 12*c*-18:1, are not suitable substrates for chain elongation and/or desaturation. Furthermore, the specific accumulation of high Δ value isomers may indicate that high Δ value isomers are less readily subjected to β-oxidation than are low Δ value isomers. Within the series of *c*-18:1, the ratio of oleic acid to *cis*-vaccenic acid was lower in the tissues of rats fed PHCO than in rats fed canola oil. This may indicate that the incorporation of *c*-18:1 isomers into tissue PL is at the expense oleic acid rather than *cis*-vaccenic acid.

All the 18:2 isomers in the liver PL of rats fed PHCO originated from the diet, and no new isomers were detected. The isomer pattern was quite different from that reported by Holman *et al.* (8) for liver PL of rats fed partially hydrogenated soybean oil (PHSO). Almost all the unusual 18:2 isomers in that study were formed from the uncommon 18:1 isomers, either through Δ5 or Δ6 desaturation. The differences in the types and levels of the uncommon C_{18} PUFA in the two studies were most certainly due to the differences in the dietary levels of linoleic acid (5). The PHSO diet used by Holman *et al.* (8) was deficient in EFA and provided only about 0.16 energy% (en%) as linoleic acid. This allowed the uncommon isomers to act as substrates for chain desaturation. In the present study, this biochemical process was suppressed, probably because the linoleic acid content (1.46 en%) in the PHCO diet was adequate and above the EFA requirement of 0.6 en% for male rat (27).

The uncommon isomers of 18:2 also differ in the degree of their accumulation in tissue PL, with 9*t*,12*c*-18:2 and, to a lesser extent, 9*c*,13*t*/8*t*,12*c*-18:2 being more readily deposited than other dietary isomers. The selective accumulation of 9*t*,12*c* isomer over the 9*c*,12*t* isomer has also been reported by previous investigators (6,7,12). In studies with deuterated isotopes, the 9*t*,12*c* isomer became enriched in mouse liver 2–4 times more than the 9*c*,12*t* isomer (7). Of all the uncommon 18:2 isomers, only 9*t*,12*c*, 9*c*,13*t* and 9*c*,12*t* produced C_{20} PUFA metabolites (as discussed later). Thus, the lower accumulation of all the other isomers is indicative of their faster catabolic rates. We have also found a similar distribution of 18:2 isomers in adipose tissue of Canadian men (Chen, Z.Y., and Ratnayake, W.M.N., unpublished data) and in breast milk of lactating women (Chen, Z.Y., Pelletier, G., Hollywood, R., and Ratnayake, W.M.N., unpublished data).

Previous studies, using large amounts of synthetic 9*c*,12*t*-18:2 and linoleic acid, have shown that 9*c*,12*t*-18:2 is elongated to 5*c*,8*c*,11*c*,14*t*-20:4 similar to the conversion of linoleic acid to arachidonic acid (6,7,12). Furthermore, these reports have shown that *trans,trans* and the *trans,cis* geometric isomers of linoleic acid are not readily converted to isomers of arachidonic acid. The results of the present study confirm these metabolic pathways of the three geometrical isomers of linoleic acid. The 5*c*,8*c*,11*c*,14*t*-20:4 was the only geometrical isomer of arachidonic acid detected in all the tissue PL examined, except for brain PL. Beyers and Emken (7), using deuterated fatty acids, estimated that the rates of conversion of 9*c*,12*t*-18:2 and linoleic acid to 14*t*-20:4 and arachidonic acid were identical. In the present study, however, the 14*t*

geometrical isomer was a minor component in the tissue PL and a rapid desaturation and chain-elongation of 9c,12t-18:2 was not apparent. The ratio of 9c,12t-18:2 to linoleic acid in PHCO was 0.29, but the ratios of their products in the tissue PL were extremely low, i.e., 0.03, 0.02 and 0.03 for liver, heart and serum, respectively. This indicates that conversion of 9c,12t-18:2 to t-20:4 is lower than that of linoleic to arachidonic acid and that the reaction rates established using deuterated fatty acids (7) may not be applicable to diets containing an assortment of isomers, such as those present in PHVO. Although there was no large difference in the proportions of 9c,12t-18:2 and linoleic acid in the PHCO diet, they were not proportionately incorporated into the tissue PL. Linoleic acid was a major component, whereas 9c,12t-18:2 was only a minor component in the tissue PL. This may indicate that 9c,12t-18:2 was rapidly catabolized or was not absorbed as readily as was dietary linoleic acid. In any event, the higher proportion of linoleic acid in tissues provides a higher substrate level for the desaturase and elongase enzyme systems, which may partly explain the higher arachidonic level and lower 14t-20:4 level in tissues.

This is the first report that demonstrates the occurrence of 5c,8c,11c,15t-20:4 in animals fed PHVO. This unusual PUFA most likely derives from dietary 9c,13t-18:2 *via* an alternating sequence of desaturation, chain elongation and desaturation (Fig. 3) similar to the conversions of 9c,12t-18:2 to 5c,8c,11c,14t-20:4 (6,7,12) and 9c-18:1 to 5c,8c,11c-20:3 (28). Such a common biochemical pathway seems possible because the three precursors, 9c-18:1, 9c,12t-18:2 and 9c,13t-18:2, share some common structural features. The first double bond in these three fatty acids is at the Δ9 position and is in *cis* configuration. Thus, all three fatty acids seem to be ideal substrates for Δ6 desaturase (5). The *trans* double bond in both the 18:2 isomers is located between the Δ9c double bond and the methyl terminus, which imparts an extended structure toward the distal part of the fatty acid chain. Thus, the distal parts of the two 18:2 isomers share characteristics of a saturated hydrocarbon chain and thus are geometrically related to each other, as well as to 9c-18:1. We therefore suggest that 9c,12t-18:2 and 9c,13t-18:2 could biochemically mimic 9c-18:1, and that the three fatty acids could share a mutual metabolic pathway and produce structurally similar end products (Fig. 3). A similar explanation has been given by Wolff *et al.* (29) to rationalize the metabolical similarities between 9c,12c,15t-18:3 and 9c,12c-18:2. The intermediate metabolites shown in Figure 3 were not detected in the present study, suggesting transitory existence of the intermediate metabolites during the chain elongation and desaturation process of the three dietary fatty acids.

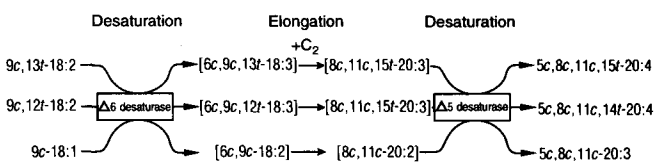

FIG. 3. Scheme showing the probable biochemical pathways for the formation of 5c,8c,11c,15t-20:4, 5c,8c,11c,14t-20:4 and 5c,8c,11c-20:3.

The two unusual mono-*trans* C_{20} diethylenic fatty acids, 11c,14t and 11t,14c, detected as trace components in tissues, were likely derived from the two mono-*trans* geometric isomers of linoleic acid, which were present in the dietary PHCO in almost equal quantities. In contrast to our findings, Beyers and Emken (7) found only 11c,14t-20:2, but not the other geometric isomer, in mice fed deuterated isotopes of the two mono-*trans* geometrical isomers. These authors suggested that 9t,12c-18:2, but not 9c,12t-18:2, is a good substrate for chain elongation. Our study, on the other hand, indicates that both are good substrates for chain elongation. Thus, it appears that the metabolism of the two mono-*trans* geometrical isomers of linoleic acid may be species dependent. Rats may have a greater capacity to metabolize isomeric fats from dietary sources than do mice. Other factors, such as the age of the animals and the duration of the experiments, could also have been responsible for the observed differences.

The two *all cis* NMI C_{20} PUFA, 8c,14c-20:2 and 5c,8c,14c-20:3, detected in the present study are structurally related to each other and, therefore, both PUFA may have originated from dietary 12c-18:1. Thus, 8c,14c-20:2 may arise by Δ6 desaturation of 12c-18:1, followed by 2-carbon chain elongation and subsequent Δ5 desaturation of 8c,14c-20:2 could give 5c,8c,14c-20:3. However, 6c,12c-18:2 was not present in the tissue PL, suggesting that the 2-carbon chain extension is the fastest step in the proposed metabolic pathway for 12c-18:1. The conversion of 8c,14c-20:2 to 5c,8c,14c-20:3 is probably similar to the conversion of 11c,14c-20:2 to 5c,8c,14c-20:3 (28). The latter two C_{20} PUFA are metabolites of the "dead end" metabolic pathway of linoleic acid (7). The levels of these four C_{20} PUFA are low in tissue PL, indicating that the previously mentioned pathways of 12c-18:1 and linoleic acid do not play a major biosynthetic role.

The amount of dietary linoleic acid has been implicated to exert a profound influence on the formation of unusual C_{20} PUFA in animals fed PHVO. Holman *et al.* (8) reported the formation of high levels of several C_{20} PUFA derived from isomeric fatty acids of oleic acid in rats fed an EFA-deficient PHSO diet. On the other hand, Zevenbergen *et al.* (30) did not report the occurrence of unusual PUFA in rats given PHSO containing 2 en% linoleic acid and various levels of *trans* fatty acids. The present study, however, shows the formation of unusual PUFA, even at adequate dietary levels of linoleic acid. Thus, it appears that linoleic acid at a dietary level of slightly greater than 1.46 en% is required to completely inhibit the formation of unusual C_{20} PUFA in rats. The presence of high levels of 22:5n-6 in tissue PL in the PHCO group indicated that the PHCO diet was deficient in the n-3 fatty acids, but not in n-6 fatty acids (31). The PHCO diet contained only trace levels of α-linolenic acid (<0.01% of total fatty acids), whereas the α-linolenic acid requirement in rats has been suggested to be 0.4% of the total dietary energy (33). This deficiency may have also exacerbated the formation of unusual PUFA, as all the dietary fatty acids compete with each other for the same desaturation and elongation enzymes. Future studies should focus on the optimal dietary

levels of linoleic and α-linoleic acids required to completely inhibit the formation of unusual PUFA. From the present study, it is apparent that of the various uncommon isomers of 18:1 and 18:2 in partially hydrogenated fats, 12*c*-18:1, 9*c*,12*t*-18:2, 9*t*,12*c*-18:2 and 9*c*,13*t*-18:2 are the preferred substrates for desaturation and chain elongation to C_{20} PUFA metabolites in the rat. However, their conversion to the C_{20} PUFA is not as efficient as that of oleic or linoleic acid.

It is well established that geometrical isomers of linoleic acid are incorporated, desaturated and elongated in the developing brain of mouse (7) and rat (11). Formation of *trans* long-chain n-3 PUFA has also been shown in the brain PL of developing rats (32). However, in the present study the dietary 18:1 and 18:2 isomers and their C_{20} PUFA metabolites were not detected in the brain PL. Furthermore, the PHCO diet had no overt influence on the fatty acid composition of the brain. In contrast to other studies, the present study was done on adult rats. Thus, it appears that the adult brain selectively excludes isomeric fatty acids, whereas the developing brain is less selective (11). In a separate study, we found significant amounts of *trans* and 18:2 isomeric fatty acids of PHVO origin in breast milk of lactating Canadian women (Chen, Z.Y., Pelletier, G., Hollywood, R., and Ratnayake, W.M.N., unpublished data). Future studies should investigate the possible incorporation of the isomeric fatty acids into the brain of infants and evaluate the physiological effects of such incorporation.

ACKNOWLEDGMENTS

The technical assistance of L. Samara and D. Paltry is greatly appreciated. T. Mag of Canamara Foods Ltd., Toronto, is thanked for supplying partially hydrogenated canola oil. Drs. R. Peace and R. Mongeau are thanked for reviewing the manuscript and for their valuable suggestions. Z.Y. Chen was a T.K. Murray Post-Doctoral Fellow of the National Institute of Nutrition, Canada.

To shed light on the question whether the phospholipids present in chromatin are native or are due to contamination from nuclear membranes, we labeled the phospholipids of isolated nuclei and determined the amount of phospholipids (PL) and PL fatty acid composition in nuclei and chromatin. The hepatocyte nuclei were isolated and radioiodinated by the lactoperoxidase method under saturating and nonsaturating conditions, and the radioactivity associated with chromatin extracted from these nuclei was monitored. Whereas 97% the label was recovered in the nuclear membranes, only 0.08–0.6% was found in chromatin. The PL present in chromatin were relative to the amounts present in the entire nuclei and calculated as percentage of total, phosphatidylethanolamine (10%), phosphatidylserine (22%), phosphatidylinositol (19%) phosphatidylcholine (14%), and sphingomyelin (35%). In sphingomyelin of chromatin-associated PL an enrichment in polyunsaturated fatty acids was seen. The data indicated that the PL found in isolated chromatin do not seem to be due to contamination from the nuclear membrane.
***Lipids 29,* 715–719 (1994).**

The presence of lipids inside the nuclei has been demonstrated in plant and animal cells using the acid hematein method (1). These results have been confirmed using autoradiography on semi-thin sections of plant cells incubated with [^{3}H]ethanolamine (2). Rees *et al.* (3) have shown that in liver nuclei, after complete destruction of the nuclear membrane, the fraction heavily labeled with [^{14}C]orotic acid contains phospholipids (PL) and probably corresponds to the etherochromatin attached to the nucleoli of whole nuclei. The presence of PL in chromatin was confirmed by Cocco *et al.* (4) after treatment with Triton X-100 and digestion of the nuclei with micrococconuclease. The results suggest that the PL are part of nuclear matrix and serve as anchorage for DNA during replication or are involved in the transport of mRNA within the nuclei (4). In blood lymphocytes, PL are linked to the nonhistonic fraction (5), and this complex has a stimulating effect on inactive chromatin extracted from thymus lymphocytes (6). A specific role has been attributed to sphingomyelin (SP), present in high concentrations in the nonhistonic fraction (5), which stimulates DNA polymerase activity *in vitro* (7) and inhibits RNA polymerase, which, in turn, is stimulated by phosphatidylserine (PS) (8). Changes in the concentration of SP have also been observed in tumor cells (9,10).

Abbreviations: DNase, deoxyribonuclease; EDTA, ethylenediaminetetraacetic acid; GO, glucose oxidase; LPO, lactoperoxidase; PBS, phosphate buffered saline; PC, phosphatidylcholine; PE, phosphatidylethanolamine; PL, phospholipid(s); PMSF; phenylmethylsulfonylfluoride; PS, phosphatidyl-serine; SP, sphingomyelin; TLC, thin-layer chromatography.

These results have been criticized by Tata *et al.* (11) who showed that the presence of PL depends in part on cytoplasmic and in part on internal nuclear membrane contamination since their turnover is equal to that of the nuclei. Therefore, in spite of some evidence, the presence of PL in chromatin has often been considered a marker of incomplete purification (12). Nevertheless, the presence of PL in chromatin was corroborated using a method for separating chromatin from Triton X-100-treated hepatocyte nuclei, since chromatin had a PL and fatty acid composition different from that of the Triton X-100-treated whole nuclei (2). Turnover and synthesis of this fraction also differed from those of the nuclei and the microsomes (13). Autoradiography and electron microscopy have furthermore suggested the presence of PL inside the nuclei (14,15). Using gold-complexed phospholipase A_2 and RNAse, it has been shown that PL and RNA are present in noncondensed chromatin in hepatocyte nuclei (14) and in erythroleukemic cells (15). It has been demonstrated that during hepatic regeneration, chromatin PL are synthesized in parallel with DNA synthesis, whereas no modifications have been observed in the nuclear PL (16). There are also differences in the composition of nuclear and chromatin PL in proliferating rat liver cells after partial hepatectomy (17). The composition of PL furthermore changes in relation to changes in gene expression, as has been shown during hepatocyte maturation in newborns (18).

In view of the possible functional role of PL in chromatin (7–10), it is essential to demonstrate that they are not contaminants derived from nuclear membrane. This question was addressed in the present study in which the lactoperoxidase (LPO)-catalyzed radioiodination assay for lipids was employed. This method, initially used to study cell surface proteins (19), exclusively labelled the hydrophobic core of PL constituting the outer leaflet of liposomes or the surface of cultured cells (20,21). Therefore, labelling intact liver nuclei and following the radioactivity during chromatin preparation and PL extraction appears to be a suitable methodological approach to demonstrate whether the PL present in liver chromatin are derived from nuclear membrane contamination or not. Furthermore, comparison of the fatty acid patterns of the main PL classes found in chromatin with those of nuclear PL would provide further evidence of the specificity of chromatin-associated PL.

MATERIALS AND METHODS

Animals. Thirty-day-old Sprague-Dawley rats of either sex were used. They were kept on a natural light–dark cycle and had free access to pelleted food and water *ad libitum* prior to killing between 9 and 10 a.m.

Nuclei preparation and chromatin isolation (Procedure I). Rats were anesthetized, and livers were perfused

via the portal vein with 0.25 M sucrose containing 3 mM $CaCl_2$ and 1 mM phenylmethylsulfonylfluoride (PMSF; Sigma, St. Louis, MO) adjusted to pH 7.4 with concentrated Tris. The livers were then quickly removed and washed in the same solution. Hepatic nuclei were isolated according to the procedure of Bresnick *et al.* (22) which yields 95–98% of isolated hepatocyte nuclei. After washing in the solution described by Barnes *et al.* (23), the nuclei were gently suspended in 10 mM Tris containing 0.25 M sucrose, 1 mM PMSF and 0.3% (vol/vol) Triton X-100 (Sigma) adjusted to pH 7.4 with 0.1 N NaOH, and were centrifuged for 5 min at 5,000 × *g* at 4°C. Swelling of the nuclei and chromatin extraction were done according to Shaw and Huang (24). The nuclei were then washed four times with hypotonic solution containing 0.075 M NaCl, 0.024 M ethylenediaminetetraacetic acid (EDTA), and 1 mM PMSF adjusted to pH 8 with 0.1 N NaOH, and again washed with Tris solution of decreasing concentrations (from 50 to 0.4 mM) containing 1 mM PMSF, pH 8. The entire procedure was carried out at 0–4°C. Finally, the material was suspended in 1 mM PMSF (100 mL for 20 g of liver), brought to pH 8 with NH_4OH, and stirred overnight at 4°C. The solution was then centrifuged at 90,000 × *g* for 30 min at 4°C. The chromatin-containing sediment was resuspended in 10 mM Tris, pH 8. During purification, the preparations were monitored at each step by light microscopy following methylene blue staining to check the swelling of nuclei and the chromatin separation; and also by measuring biochemical markers as previously described (2).

Preparation of nuclei and isolation of nuclear membranes (Procedure II). Rats were killed by cervical dislocation and livers were rapidly removed, chopped, and then nuclei isolated according to the procedure of Widnell and Tata (25). Briefly, tissue was homogenized in 0.32 M sucrose containing 3 mM $MgCl_2$, pH 7.4, and then centrifuged at 700 × *g* for 10 min at 4°C. The pellet was resuspended in the same medium, and centrifugation was repeated. The final pellet was resuspended in 2.4 M sucrose containing 1 mM $MgCl_2$, pH 7.4, and the suspension was centrifuged at 50,000 × *g* for 60 min at 4°C. The nuclei were then washed with 0.25 M sucrose containing 1 mM $MgCl_2$, pH 7.4, and the suspension was centrifuged at 700 × *g* for 5 min at 4°C. This procedure, although suitable for the preparation of membranes is not suitable for the isolation of chromatin. The nuclei isolated by this method are being referred to as liver nuclei.

Nuclear membranes were isolated according to Kay and Johnston (26). The isolated nuclei were lysed in 8 mM Tris HCl, pH 8.5, containing 0.1 mM $MgCl_2$, 4 mM 2-mercaptoethanol (Merck, Darmstadt, Germany), 8% sucrose, 1 μg/mL deoxyribonuclease I (DNase I) (Sigma). After 15 min of incubation at 22°C, the reaction was stopped by diluting the lysate with cold water (1:1, vol/vol). The lysed nuclei were centrifuged at 38,000 × *g* for 15 min at 4°C, and the sediment was resuspended in 10 mM Tris HCl, pH 7.4, containing 0.1 mM $MgCl_2$, 5 mM 2-mercaptoethanol, 10% sucrose and 1 μg/mL DNase I. Digestion was carried out for 20 min and stopped as described. The final nuclear envelope pellet was obtained after centrifugation at 38,000 × *g* for 15 min at 4°C.

LPO-catalyzed radioiodination of nuclei and chromatin. The LPO reaction (27,28) was used to radiolabel lipid moieties. For this purpose, hepatocyte nuclei (isolated by Procedure I) were suspended in Ca^{2+} and Mg^{2+}-free phosphate buffered saline (PBS), pH 7.2, and liver nuclei (obtained by Procedure II) were suspended in 0.25 M sucrose containing 1 mM $MgCl_2$. In both experiments the nuclear suspension contained 5 mg protein, 1.1–1.2 mg DNA and 0.6–0.7 mg RNA. Under nonsaturating conditions, the reagents were added to 1 mL of nuclei suspension which included 400 μCi $Na^{125}I$ (212 pmol) free of carrier (15 mCi/μg ^{125}I; Amersham, Buckinghamshire, United Kingdom) in 400 μL PBS, 50 μg LPO [EC 1.11.1.7.] (Sigma) in 50 μL PBS, and 50 mU of glucose oxidase (GO) [EC 1.1.3.4.] (Sigma) in 50 μL PBS. The reaction was initiated by adding 45 μg D(+)glucose (Merck) in 50 μL PBS and then allowed to proceed for 10 min at room temperature. Under saturating conditions, the carrier-free radioactive iodide was mixed with 240 nmol KI Analar grade (Prolabo, Paris, France) and 100 μg LPO (in 50 μL PBS) and 500 mU GO (in 50 μL) were added. The reaction was initiated by adding 450 μg D(+)glucose and continued for 30 min at room temperature.

After radioiodination the lipids of 100 μL of the nuclear suspension were extracted. The remaining labeled nuclei were diluted with unlabeled nuclei for other assays. All experiments were repeated three times for each of the isolation procedures.

The method was also used for chromatin, except that the LPO and GO concentrations were increased five- and twofold, respectively, in respect to the amount of protein used.

Lipid extraction. Lipids were extracted from nuclei (8 mg/mL) and chromatin (2.5 mg/mL) with 20 vol of chloroform/methanol (2:1, vol/vol). The organic phase was washed with 0.2 vol 0.74% KCl, and after phase partition the organic phase was washed with 0.4 vol of chloroform/methanol/water (3:48:47, by vol) according to Folch *et al.* (29). When radioiodinated PL were extracted, the washing phases contained 1 mM KI.

Radioiodinated lipid fractionation. The organic phase was evaporated under a nitrogen stream and fractionated on silica H 60 (Merck) columns (35 mm high, 3 mm diameter; bed volume, 0.3 mL). The silica was washed once with chloroform/methanol (1:1, vol/vol), twice with methanol, and then activated at 110°C. From the silica equilibrated in chloroform, the neutral lipids, the neutral glycolipids, and the PL were eluted successively with 4 volumes of chloroform, acetone, and methanol, respectively. The radioactivity of each of the fractions was determined.

PL identification and fatty acid analysis. PL were separated on thin-layer chromatography (TLC) plates (Whatmann LK5, Maidstone, United Kingdom) according to Leray *et al.* (30). The plates were pretreated with 2.3% boric acid in ethanol and activated for 15 min at 110°C. Chloroform/ethanol/water/triethylamine (30:35:7:35, by vol) was used as solvent. The plates were air-dried and sprayed with primulina (5 mg/100 mL acetone/water, 4:1, vol/vol), and the PL were identified under ultraviolet light relative to standards. The PL were then subjected to

boron trifluoride (Sigma)-catalyzed methanolysis without prior elution according to Morrison and Smith (31). Fatty acid methyl esters dissolved in *n*-hexane were analyzed using a Perkin-Elmer Sigma I gas chromatograph (Palo Alto, CA) equipped with a 50-m bonded fused silica open tubular column (0.32 mm diameter × 50 m, superox; Altech Associates Inc., Deerfield, IL) with helium gas as carrier (23 psi) and at a column temperature of 200°C. The split/splitless injector and the flame-ionization detector were maintained at 230°C. The amounts of PL were estimated using methylheptadecanoate as internal standard and are expressed as nmol PL/mg DNA. Abundances of individual fatty acids are given in mole percent relative to total fatty acid methyl esters.

Other assays. Protein, DNA and RNA contents were determined according to Lowry *et al.* (32), Burton (33) and Schneider (34), respectively. Since the RNA values were not corrected for the presence of DNA, the RNA values are overestimated about 1.4-fold when the DNA concentration is five times that of RNA, as it is in chromatin (34).

RESULTS

Criteria of purity for isolated chromatin and nuclear membranes. Rat liver tissue contains hepatocytes as well as other cell types, including Kupffer and endothelial cells and connective tissue which represent about 40% of the total (35). When using Procedure I, 95–98% of the nuclei recovered were from hepatocytes, whereas Procedure II yielded 60% hepatocyte and 40% nonhepatocyte nuclei. Therefore nuclei from Procedure I are being referred to as hepatocyte nuclei, those from Procedure II as liver nuclei, although no significant differences in DNA and RNA contents, expressed in μg/mg protein were seen between the preparations (Table 1). The isolated nuclear membrane was found to contain approximately the same amount of DNA and RNA/mg protein (Table 1), which is in agreement with data reported by Kay and Johnston (26).

Chromatin isolated from hepatocyte nuclei contained a significantly greater amount of DNA/mg protein than did hepatocyte and liver nuclei preparations (Table 1). This difference is also evident when one compares the percentages of total DNA (Table 1). Our present results are similar to those obtained in a previous study (2) on hepatocyte chromatin of rats of different age (28–32% DNA, 5–7% RNA, 60–65% protein and 0.2% PL). In the hepatocyte nuclei, the RNA/DNA ratio was 0.32 and decreased by 35% to 0.21 upon chromatin isolation. This decrease is similar to that reported by Tata *et al.* (11) and gives additional credence to the purity of the preparations.

LPO-catalyzed radioiodination. Table 2 shows that a 1100-fold dilution of radioactive iodide ($Na^{125}I$) with KI reduced the amount of label associated with nuclear PL (8-fold and 6-fold in nuclei isolated by Procedures I and II, respectively). Thus, under saturating conditions, all PL accessible to the radioiodination system appeared labelled. Under nonsaturating conditions, at least 10% of the sites accessible to LPO were labelled. The high specific radioactivity allowed for a more accurate identification of the label in the course of the chromatin and nuclear preparations. It is noteworthy that the labelling of nuclei isolated according to Procedure II was 96% lower than for nuclei isolated according to Procedure I. The low labeling yield could be explained by the fact that the nuclei were labeled in unbuffered medium containing Mg^{2+} (4 mM), which is known to inhibit LPO (36).

Table 2 also shows that the label associated with nuclear PL was almost entirely recovered in the nuclear membranes, while only minute quantities of radioactivity were found in the PL extracted from chromatin (0.08–0.6%). Extraction of labeled PL from either nuclei or nuclear membranes, followed by TLC separation and autoradiography, indicated that all the major PL classes were radioiodinated. Since the amounts of labeling seen in chromatin are very similar, irrespective of whether saturating or nonsaturating radioiodination conditions were used with intact nuclei, the minute quantities of labeling are probably due to adsorbed free radioactive iodine which migrates with the solvent front on the chromatogram. When chromatin was isolated from unlabeled nuclei and

TABLE 1

Comparison of DNA and RNA Contents of Hepatocyte Nuclei, Chromatin, Liver Nuclei and Nuclear Membranes[a]

	Hepatocyte nuclei	Chromatin	Liver nuclei	Nuclear membranes
DNA	210.7 ± 22.8[b] (16.4 ± 1.5)	351.7 ± 67.5[b] (24.4 ± 3.5)	230.5 ± 70.0[c] (17.3 ± 3.9)	55.2 ± 30.4[c] (7.0 ± 1.4)
RNA	69.0 ± 30.0 (5.3 ± 2.1)	77.6 ± 21.7 (5.4 ± 1.3)	93.8 ± 44.8 (10.5 ± 3.1)	54.0 ± 37.2 (7.0 ± 1.0)

[a]Values are expressed as μg/mg protein and indicate means ± SD of ten experiments for hepatocyte nuclei, 15 for chromatin, 3 for liver nuclei and 3 for nuclear membranes. Values given in parentheses are percentage of total nuclear content.
[b]$P < 0.05$ for difference between hepatocyte nuclei and chromatin.
[c]$P < 0.05$ for difference between liver nuclei and nuclear membranes.

TABLE 2

Distribution of ^{125}I-Label Associated with Phospholipids Extracted from Nuclei, Nuclear Membranes and Chromatin[a]

	Hepatocyte nuclei	Chromatin	Liver nuclei	Nuclear membranes
Nonsaturating conditions[b]	7084×10^3	6×10^3 (0.08%)	208×10^3	202×10^3 (97%)
Saturating conditions[c]	873×10^3	5×10^3 (0.6%)	38×10^3	36×10^3 (95%)

[a]Values for a typical experiment are given in cpm/mg protein. The recoveries of label associated with phospholipids that were extracted from chromatin and from nuclear membranes are given in parentheses. The experiment was repeated four times. Nuclei were separated according to the method of Bresnick *et al.* (22) for hepatocytes and of Kay and Johnston (26) for liver nuclei. Nuclei were radioiodinated using lactoperoxidase under saturating and nonsaturating conditions. Chromatin was extracted according to the method of Shaw and Huang (24).
[b]1.6×10^{-3} mol Na ^{125}I/mol phospholipid.
[c]Footnote c as footnote b + 1.8×10^{-3} mol K ^{125}I/mol phospholipid.

TABLE 3

Comparison of the Amounts of Total Phospholipid (PL) and of Individual PL Classes in Hepatocyte Nuclei and Chromatin[a]

	PL	PE	PS	PI	PC	SP
Nuclei	123.9 ± 10.1	25.6 ± 2.3	3.2 ± 0.5	14.5 ± 2.4	68.5 ± 13.2	6.5 ± 0.5
Chromatin	12.5 ± 3.6	2.5 ± 0.8	0.7 ± 0.3	2.8 ± 0.7	9.5 ± 0.5	2.4 ± 1.0
	(10)	(9.8)	(22)	(19)	(14)	(35)

[a]Values are given in nmol/mg DNA. Values in parentheses give the percentage of individual chromatin PL classes relative to total nuclear PL. PE, phosphatidylethanolamine; PS, phosphatidylserine; PI, phosphatidylinositol; PC, phosphatidylcholine; SP, sphingomyelin.

then radioiodinated, intense labeling was seen which is contrary to the results obtained with chromatin extracted from radioiodinated nuclei.

As the data show that chromatin PL extracted from labelled nuclei are unlabelled, and PL are labelled only when the radioiodination is done directly on chromatin, the chromatin PL cannot be due to lipid contamination of the nuclear membrane PL.

Principal PL distribution and fatty acid pattern of nuclei and chromatin. The total PL content of hepatocyte nuclei was 124 nmol/mg DNA as illustrated in Table 3. PL in the chromatin amounted to 12.5 nmol/mg DNA (Table 3), which was about 10% of the amount present in the nuclei and is in agreement with previous data (2).

If the nmoles of individual chromatin PL classes are divided by the respective nuclear total PL (considered as equal to 100), phosphatidylethanolamine (PE) amounts to 9.8%, PS to 22%, phosphatidylinositol (PI) to 19%, phosphatidylcholine (PC) to 14% and SP to 35% (Table 3). This clearly shows that compared to nuclei PL, chromatin PL are particularly rich in SP, but are deficient in PE.

Fatty acid analyses showed a high unsaturated/saturated fatty acid ratio for chromatin PE largely due to a low 16:0 level (Table 4). PS showed a decrease in 18:1, but an increase in 20:4 and 22:6 relative to PS of the nuclei. Large differences were observed for chromatin SP, which was rich in polyunsaturated fatty acids.

The data taken together are consistent with the idea that chromatin-associated PL have specific fatty acid profiles.

DISCUSSION

LPO-catalyzed radioiodination of liver nuclei and localization of the label showed a 97% recovery in nuclear membrane PL and of 0.08–0.6% in chromatin PL. A compari-

	Chromatin	1.19 ± 0.04	1.00 ± 0.10	1.45 ± 0.50	1.07 ± 0.13	0.69 ± 0.15

[a]Results are expressed as mole percentage of total fatty acid methyl esters; only major components are listed. For abbreviations see Table 3.

son of data obtained under nonsaturating and saturating labeling conditions showed that chromatin labeling was due to free iodide rather than to contamination by nuclear membrane. Since chromatin PL amounted to 10% of the total nuclear PL and contamination was less than 1%, this would support the conclusion that the PL extracted from chromatin are genuine chromatin PL and are not due to PL contamination. These data are in agreement with electron microscopic evidence for the presence of PL inside the nuclei based on gold labelling (14,15). The lipids appear largely localized in the active chromatin (6), and their distribution seems similar to that of RNA (14,15). The PL appear more concentrated near the nucleolus and, according to Cocco *et al.* (4), are likely to be anchored close to the nuclear matrix.

Contamination can also be excluded because of the decreases seen in RNA and PL with respect to the nuclei. In fact, the RNA/DNA ratio seen in chromatin was 35% lower than that in the nuclei, a difference similar to that reported by Tata *et al.* (11). Previous studies on PL composition, synthesis and turnover (2,16,13) had indicated that the PL found in chromatin are not contamination artifacts, but constituents of chromatin. Moreover, nuclear membrane or cytoplasmic contamination does not fit the time course for ^{32}P incorporation into chromatin (13). Our present data provide direct and independent evidence in support of our previous findings based on different methodologies.

Analyses of the PL composition of the nuclei show that chromatin is particularly rich in SP which confirms the earlier observation by Chayen and Gahan (37). Fatty acid analyses confirm that chromatin PL differ from whole nuclei PL. In particular, SP is rich in polyunsaturated fatty acids and all PL being components of chromatin have specific profiles.

In regard to the role of chromatin PL, several hypotheses about their potential function in relation to DNA structure and translational activity have been proposed (7). However, at present there is no clear evidence for their specific role *in vivo*. During rat liver regeneration, *de novo* synthesis of chromatin-associated PL was correlated with DNA replication, whereas this was not the case for nuclear PL (16). Changes in PL composition were observed, especially during the first days of life (18) at the onset of hepatocyte maturation (38).

In regard to PL synthesis, the kinetics of ^{32}P incorporation in chromatin were shown to be similar to those found in microsomes, except that its peak was delayed by three hours (13), suggesting that PL are synthesized in microsomes from where they are transferred to chromatin (13). Experiments are presently under way to explore these questions.

METHOD

Preparation of Defined Molecular Species of Lactosylceramide by Chemical Deacylation and Reacylation with *N*-Succinimidyl Fatty Acid Esters

Hiroko Kadowaki* and **Marianne A. Grant**

Department of Medicine, Boston University School of Medicine, Boston, Massachusetts 02118 and Division of Lipid Metabolism, Boston Veterans Administration Medical Center, Boston, Massachusetts 02130

A procedure for the preparation of specific molecular species of D-*erythro*-lactosylceramide involving deacylation and reacylation of lactosylceramide prepared from bovine brain gangliosides is described. Lactosylceramide was *N*-deacylated by alkaline hydrolysis and the resulting four lysolactosylceramides, which contained d18:1, d20:1, d18:0 and d20:0 long-chain bases, were simultaneously re-*N*-acylated with the *N*-succinimidyl ester of either 16:0, 18:0, 20:0, 22:0, 24:0, 20:1, 22:1 or 24:1 fatty acid. The resulting lactosylceramide contained four molecular species of lactosylceramides, i.e., d18:1, d20:1, d18:0 and d20:0 long-chain bases coupled with the fatty acid that was introduced. Lactosylceramides prepared in this manner were separated into four individual molecular species by high-performance liquid chromatography (HPLC). Each of the purified molecular species of lactosylceramide was quantitated by HPLC after derivatization with benzoylchloride and was characterized by mass spectrometry. The yields of reacylated lactosylceramide were 38–58% relative to the starting lactosylceramide; the purity of each of the molecular species of lactosylceramide was greater than 95%.

***Lipids* 29, 721–725 (1994).**

The ceramide molecular species composition of various glycosphingolipids has been shown to affect the biological activity of glycosphingolipids (3–5). In the case of the intrinsic Golgi membrane enzyme CMP-*N*-acetylneuraminate:lactosylceramide α2,3-sialyltransferase (LacCerα2,3-ST) [EC 2.4.99.9], which catalyzes the synthesis of (*N*-acetylneuraminosyl)-galactosylglucosylceramide (GM3) from lactosylceramide (LacCer), it has been shown that the enzyme displays a distinct molecular species specificity for the lipophylic substrate LacCer (6,7) and that the molecular species specificity of the enzyme is highly dependent on the lipid composition of the Golgi membrane (8). To determine the basis for this effect, it became necessary to obtain a wide range of pure molecular species of LacCer containing specific combinations of long-chain base and fatty acid. It is difficult to isolate individual pure molecular species of LacCer from natural sources because the LacCer content is generally very low and the molecular species composition of most LacCer is highly complex. LacCer can be prepared from other glycosphingolipids by stepwise enzymatic hydrolysis or by mild acid hydrolysis, but it is still not possible to isolate more than a few individual molecular species of LacCer from natural sources. It therefore became necessary to chemically synthesize the specific LacCer molecular species required to shed light on the molecular species specificity of LacCerα2,3-ST. The present paper describes the synthesis of pure molecular species of LacCer by *N*-deacylation of LacCer (derived from bovine brain gangliosides) followed by re-*N*-acylation of the resulting lyso-LacCer with the *N*-succinimidyl ester of one of several fatty acids.

EXPERIMENTAL PROCEDURES

Materials. Octadecanoic, eicosanoic, docosanoic, tetracosanoic, *cis*-11-eicosenoic, *cis*-13-docosenoic and *cis*-15-tetracosenoic acids were obtained from Nu-Chek-Prep (Elysian, MN); *N,N'*-dicyclohexylcarbodiimide, *N*-hydroxysuccinimide, palmitic acid *N*-hydroxysuccinimide ester, psychosine (1-β-D-galactosylsphingosine) and triethylamine were from Sigma Chemicals (St. Louis, MO); silica gel 60 (particle size 0.063–0.100 mm) and precoated high-performance thin-layer chromatography (HPTLC) plates coated with silica gel 60 were from EM Separations (Gibbstown, NJ); DEAE-Sephadex A25 was from Pharmacia Fine Chemicals (Piscataway, NJ); analytical and HPLC-grade solvents, and Nylon membrane filter (pore size 0.45 μm) were from Fisher Scientific (Medford, MA); bovine brain was from Pel-Freez Biologicals (Rogers, AR). Globotetraosylceramide ($GbOse_4Cer$) was prepared from human red blood cells (9).

Synthesis of N-succinimidyl ester of fatty acid. The *N*-succinimidyl ester of each of the fatty acids used (i.e., 18:0, 20:0, 22:0, 24:0, 20:1, 22:1 and 24:1) was synthesized by reacting the fatty acid with *N*-hydroxysuccinimide in

Abbreviations: HPLC, high-performance liquid chromatography; HPTLC, high-performance thin-layer chromatography; LacCerα2,3-ST, CMP-*N*-acetylneuraminate:lactosylceramide α2,3-sialyltransferase; NeuAc, *N*-acetylneuraminic acid.

The glycosphingolipid nomenclature is as recommended by the IUPAC-IUB Commission on Biochemical Nomenclature (1). GalCer, galactosylceramide, Gal(β1-1)Cer; GlcCer, glucosylceramide, Glc(β1-1)Cer; LacCer, lactosylceramide, Gal(β1-4)GlcCer; $GbOse_3Cer$, globotriaosylceramide, Gal(α1-4)Gal(β1-4)GlcCer; $GbOse_4Cer$, globotetraosylceramide, GalNAc(β1-3)Gal(α1-4)-Gal(β1-4)GlcCer; $GgOse_3Cer$, gangliotriaosylceramide, GalNAc-(β1-4)Gal(β1-4)GlcCer; $GgOse_4Cer$, gangliotetraosylceramide, Gal(β1-3)GalNAc(β1-4)Gal(β1-4)GlcCer; GM3, (NeuAcα2-3)-Galβ1-4GlcCer; GM1, Galβ1-3GalNAcβ1-4(NeuAcα2-3)Galβ1-4-GlcCer.

The molecular species abbreviations suggested by Breimer *et al.* (2) are used. For example, in the notation d18:1-18:0, the d18:1 represents the long-chain base sphingosine (D-*erythro*-1,3-dihydroxy-2-amino-*trans*-4-octadecene) and 18:0 represents the fatty acid (octadecanoic acid).

the presence of *N,N'*-dicyclohexylcarbodiimide according to the method of Lapidot *et al.* (10). The purity of each of the recrystallized *N*-succinimidyl fatty acid esters was determined by HPTLC (10). Only a single spot corresponding to the *N*-succinimidyl fatty acid ester was observed in HPTLC.

Preparation of LacCer. LacCer was prepared from both gangliosides and $GbOse_4Cer$. Gangliosides were isolated from bovine brain as described by Ledeen and Yu (11) and Kadowaki *et al.* (12).

Approximately 100 mg of gangliosides are incubated with 6 mL of 0.05 N sulfuric acid in water at 80°C for 2 h, and the resulting hydrolysate is neutralized with sodium hydroxide. Chloroform and methanol are then added to bring the final solvent proportion to Folch partitioning conditions (13). After vigorous mixing, the two phases are separated by centrifugation. The upper phase contains gangliosides (predominantly GM1). The lower phase contains two major glycosphingolipids, i.e., gangliotriaosylceramide ($GgOse_3Cer$) and gangliotetraosylceramide ($GgOse_4Cer$), and two minor ones, i.e., glucosylceramide (GlcCer) and LacCer. The lower phase is evaporated to dryness, redissolved in chloroform, and applied to a silica gel 60 (acid-washed) column (3 × 25 cm) to isolate LacCer. The column is eluted successively with 1 L each of chloroform, chloroform/methanol (96:4, vol/vol), (94:6), (92:8), (90:10), (86:14) and finally methanol. The glycosphingolipid composition of each fraction is monitored by applying an aliquot to an HPTLC plate which is developed in chloroform/methanol/water (60:35:8, by vol) and on which fractions are visualized with orcinol spray (14). The fractions containing LacCer as the major component are combined, evaporated to dryness, dissolved in chloroform, and then re-applied to a silica gel 60 column (1 × 25 cm). The column is eluted successively with 100 mL of mixtures of chloroform and methanol (from 6 to 14% methanol in 1% increments). The glycosphingolipid composition of these fractions is also monitored by HPTLC as described above. The fractions containing only LacCer are combined and used for the deacylation procedure. Fractions from the silica gel 60 column that contain $GgOse_3Cer$ and $GgOse_4Cer$ are combined and subjected to further acid hydrolysis. Gangliosides in the upper phase are also subjected to further acid hydrolysis. LacCer obtained from these fractions is purified as described above. After several cycles of acid hydrolysis, approximately 25 mg of LacCer is obtained. LacCer was also prepared from human red blood cell $GbOse_4Cer$ by enzymatic cleavage of the sugars as previously described (15).

Preparation of lysoLacCer. LysoLacCer was prepared by a modified procedure developed for the preparation of lysocerebrosides by Radin (16). For this purpose, LacCer (10 μmol) is dissolved in 3.6 mL of *n*-butanol in a culture tube (20 × 150 mm) with a Teflon-lined cap, and 0.4 mL of 12.5 M potassium hydroxide in water is added. The reaction mixture is sealed under nitrogen and heated at 125°C for 4 h. After cooling, 10.4 mL of chloroform, 1.2 mL of methanol and 2.4 mL of water are added to the reaction tube. The tube is shaken vigorously and then centrifuged at 1,000 × *g* to separate the two phases. The lower phase (containing lysoLacCer) is washed twice with 2.5 mL of saline/methanol (1:1, vol/vol) and dried under a stream of nitrogen.

Re-N-acylation of lysoLacCer and purification of the product LacCer. LysoLacCer is re-*N*-acylated with *N*-succinimidyl fatty acid ester in the presence of triethylamine by a modification of the procedure for the reacylation of lysoGM1 ganglioside as reported by Neuenhofer *et al.* (17). *N*-Succinimidyl fatty acid ester (50–200 μmol) and lysoLacCer (derived from 10 μmol of the original LacCer) are dissolved in 10 mL of chloroform/methanol/water (60:40:9, by vol) in a culture tube (16 × 125 mm) with a Teflon-lined cap, and 100 μL of triethylamine is added. The tube is sealed under nitrogen, and the reaction is allowed to proceed overnight at room temperature. To the reaction mixture, 2 mL of chloroform and 2 mL of water are added, mixed vigorously, and then centrifuged at 1,000 × *g* for 10 min. The lower phase containing reacylated lysoLacCer is washed twice with 2 mL of saline/methanol (1:1, vol/vol), dried under nitrogen, and redissolved in 5 mL of chloroform. The sample is applied to a silica gel 60 column (1 × 25 cm) equilibrated with chloroform. The column is eluted (approximately 1 mL/min) successively with 100 mL mixtures of chloroform and methanol (from 4 to 14% methanol in 2% increments). Excess *N*-succinimidyl fatty acid ester elutes from the column in the 4% methanol fraction. Lac-Cer elution is monitored in an aliquot of each fraction by HPTLC, and the fractions that contain LacCer are combined.

Separation of individual molecular species of LacCer. Underivatized LacCer was separated (6) into individual molecular species by high-performance liquid chromatography (HPLC) on a C18 reversed-phase (5 μm, Ultrasphere ODS; Beckman, San Ramon, CA) column (4.6 × 250 mm) using a mobile phase of metha-nol/water (96:4, vol/vol) at 30°C at a flow rate varying from 1 mL/min to 1.5 mL/min depending on the carbon chain length of the reacylated fatty acid (the longer the carbon chain, the faster the flow rate) with the effluent being monitored at 205 nm. Each fraction is collected, dried under nitrogen, and Folch partitioned. The lower phase containing LacCer is used for the molecular species identification.

Identification of LacCer molecular species. The individual molecular species of LacCer isolated by HPLC are converted to *O*- and *N*-benzoyl derivatives by reaction with benzoylchloride in pyridine (18) and identified by HPLC on a C18 reversed-phase (3 μm, Spherisorb ODS-2; Metachem Technologies, Redondo Beach, CA) column (2 × 250 mm) using a mobile phase of acetonitrile/2-propanol (8:2, vol/vol) at 30°C at a flow rate of 0.3 mL/min with the effluent being monitored at 230 nm. Peaks are identified by their retention times relative to those of known molecular species of perbenzoylated LacCer (d18:1-16:0, d18:1-18:0, d18:1-24:0 and d20:1-18:0) used as standards, and also by HPLC–mass spectrometry.

Quantitation of LacCer. The perbenzoylated LacCer is quantitated by HPLC on a LiChrospher Si 500 (10 μm; EM Science, Cherry Hill, NJ) column (4.6 × 250 mm) using a mobile phase of hexane/dioxane (88:12, vol/vol) at room temperature at a flow rate of 1 mL/min with the effluent being monitored at 230 nm. The perbenzoylated

LacCer species elute between 14 and 26 min and are quantitated by digital integration.

RESULTS AND DISCUSSION

Bovine brain gangliosides contain primarily d18:1 and d20:1 long-chain bases while d18:0 and d20:0 long-chain bases are present as minor components (19,20). Therefore, when LacCer is prepared from brain gangliosides, the ceramide molecular species of the LacCer reflect the original ganglioside molecular species. It was observed that as the gangliosides were repeatedly reprocessed by mild acid hydrolysis, the proportion of d20:1 long-chain base in the resulting LacCer fraction increased from approximately 30 to over 60%. Thus, it appears that glycosphingolipids containing a d18 long-chain base were more readily hydrolyzed under mild acidic conditions than glycosphingolipids containing a d20 long-chain base.

Procedures for deacylating glycosphingolipids have been reported for cerebrosides (16), GM3 (21), GM1 (22,23), GM3 and GM1 (24), and a number of other gangliosides (17). The alkaline hydrolysis procedure for cerebrosides using potassium hydroxide in *n*-butanol/water with refluxing at 125°C for 4 h (16) and for gangliosides using potassium hydroxide in methanol with refluxing at 102°C for 25 h (17) both hydrolyzed LacCer to lysoLacCer equally well. The procedure for GM1 ganglioside using tetramethylammonium hydroxide in *n*-butanol/water with refluxing at 100°C for 13 h (22) resulted in more by-products and lower recovery of lysoLacCer. Because of the shorter reflux time, the procedure developed for cerebrosides by Radin (16) was used to prepare lysoLacCer. However, after the reaction, the potassium hydroxide and the hydrolyzed fatty acids were removed by repeated solvent partitioning. Figure 1A shows the results of alkaline hydrolysis of LacCer as monitored by HPTLC. The amount of the unknown by-product detected above lysoLacCer (lane 3) increased when the lysoLacCer was stored for a few days. A similar observation was made in the HPTLC analysis of psychosine (data not shown). We did not identify the structure of these by-products.

Procedures have been reported for the re-*N*-acylation of long-chain bases (25) and of lysoGM1 (17) using *N*-succinimidyl esters of fatty acids, and of lysoGM1 using free fatty acids (22). For reacylation of lysoLacCer, the methods using *N*-succinimidyl fatty acid esters in tetrahydrofuran (25) or in chloroform/methanol/water/triethylamine (17) resulted in equally high yields. The method using free fatty acids (22) did not give good yields. The method for reacylation developed by Neuenhofer *et al.* (17) was used in the present study because it was simpler to purify the products. The lysoLacCer prepared from brain ganglioside LacCer was reacylated with *N*-succinimidyl 16:0, 18:0, 20:0, 22:0, 24:0, 20:1, 22:1 and 24:1 fatty acid esters. Reacylated lysoLacCer was purified on a silica gel 60 column and separated into individual molecular species by HPLC as described in Experimental Procedures section. As an

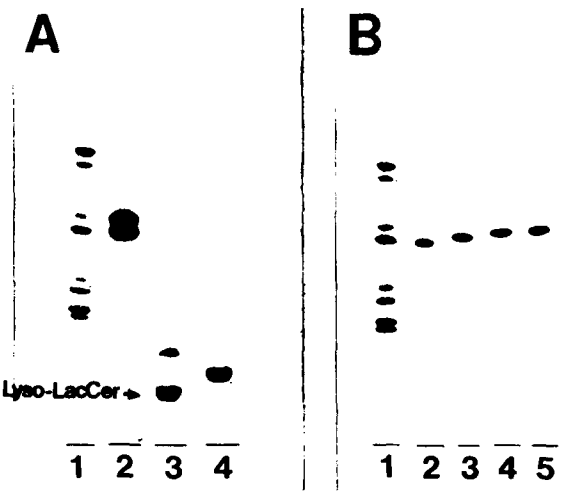

FIG. 1. Thin-layer chromatogram of LacCer and lysoLacCer. LacCer prepared from red blood cell $GbOse_4Cer$ was deacylated as described in Experimental Procedures section. A. Lane 1, neutral glycosphingolipid standards (from top are GlcCer, LacCer, $GbOse_3Cer$ and $GbOse_4Cer$); lane 2, LacCer prepared from $GbOse_4Cer$; lane 3, lysoLacCer; and lane 4, psychosine (lysoGalCer). B. Lane 1, neutral glycosphingolipid standards; lane 2, LacCer deacylated and reacylated with 16:0; lane 3, reacylated with 20:0; lane 4, reacylated with 22:0; lane 5, reacylated with 22:1. High-performance thin-layer chromatography plates were developed in chloroform/methanol/water (60:35:8, by vol) and visualized with orcinol spray and heating at 130°C (14).

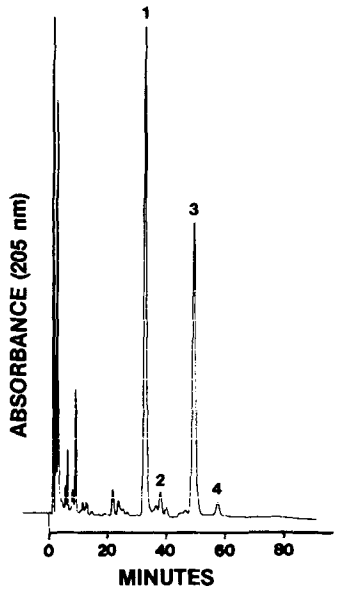

FIG. 2. Molecular species separation of LacCer after deacylation followed by reacylation. LacCer prepared from brain gangliosides was deacylated and then reacylated with *N*-succinimidyl 20:0 fatty acid ester and purified on a silica gel 60 column as described in Experimental Procedures section. Underivatized LacCer was separated into individual molecular species by high-performance liquid chromatography on a C18 reversed-phase column (5 μm, Ultrasphere ODS, 4.6 × 250 mm) at 30°C. The mobile phase was methanol/water (96:4, vol/vol) at a flow rate of 1.2 mL/min. The sample was injected in ethanol. The effluent was monitored at 205 nm with an attenuation of 0.16 absorbance unit full scale. Peak 1, d18:1-20:0; peak 2, d18:0-20:0 (approximately 70%); peak 3, d20:1-20:0; and peak 4, d20:0-20:0.

example, the molecular species pattern of LacCer reacylated with 20:0 fatty acid is presented in Figure 2. The major molecular species of reacylated LacCer were d18:1-20:0 (peak 1) and d20:1-20:0 (peak 3), and the minor molecular species were d18:0-20:0 (peak 2) and d20:0-20:0 (peak 4).

An aliquot of each of the LacCer molecular species was perbenzoylated, and purity was determined by HPLC using an acetonitrile-containing mobile phase. With this mobile phase, it is possible to separate molecular species containing a saturated fatty acid from a molecular species that contains a monounsaturated fatty acid with two more carbons but the same long-chain base, e.g., d18:1-22:0 from d18:1-24:1 (26). Moreover, using a mobile phase of acetonitrile/2-propanol (8:2, vol/vol) and a 3 μm C18 reversed-phase column, perbenzoylated LacCer molecular species which have the same number of carbons and the same number of double bond, e.g., d18:1-20:0 and d20:1-18:0, could also be resolved into two peaks (data not shown). As seen in Figures 3 and 4, all molecular species of LacCer prepared were single molecular species. It appears, however, that lysoLacCer reacylated with unsaturated fatty acids (Fig. 4) are less pure than those reacylated with saturated fatty acids (Fig. 3). For d18:1 and d20:1 long-chain bases, over 95% of the reacylated LacCer were one molecular species. It was difficult to obtain relatively pure molecular species of LacCer containing d18:0 long-chain base coupled with the fatty acid introduced (Fig. 2, peak 2) due to contamination with other minor components. Because of the small amount of these contaminants, we were not able to identify them. On the other hand, the LacCer molecular species containing d20:0 long-chain base coupled with the fatty acid introduced (Fig. 2, peak 4) was relatively pure (approximately 90%). The identity of each molecular species of LacCer was confirmed by HPLC–mass spectrometry (data not shown).

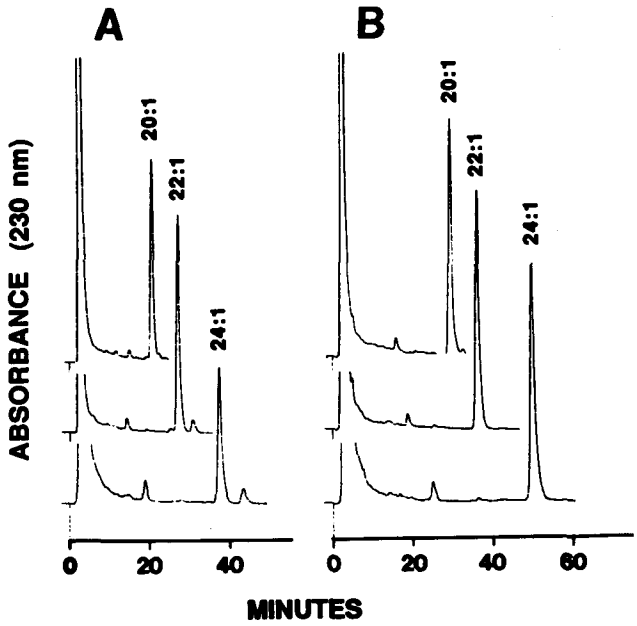

FIG. 4. Determination of the purity of LacCer molecular species reacylated with unsaturated fatty acid. LacCer reacylated with *N*-succinimidyl 20:1, 22:1 or 24:1 fatty acid ester was separated into individual molecular species and the purity was determined by high-performance liquid chromatography as described in Figure 3. A, LacCer containing d18:1 long-chain base; B, LacCer containing d20:1 long-chain base. The fatty acid moiety is identified above each peak.

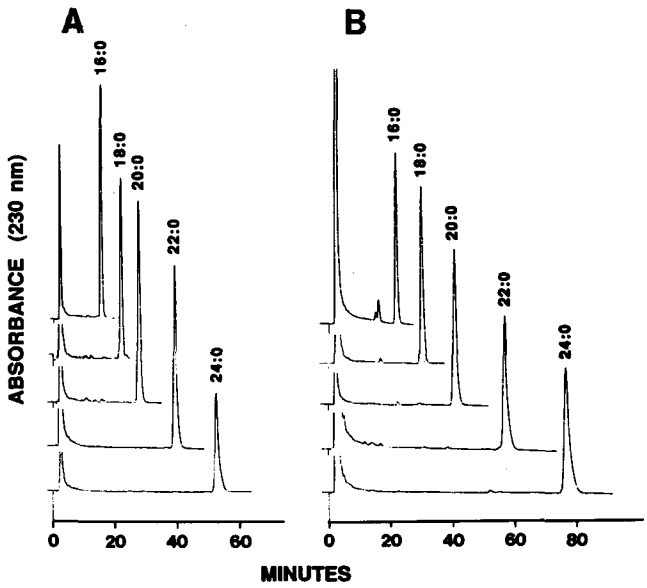

FIG. 3. Determination of the purity of LacCer molecular species reacylated with saturated fatty acid. LacCer prepared from brain gangliosides was deacylated and then reacylated with *N*-succinimidyl 16:0, 18:0, 20:0, 22:0 or 24:0 fatty acid ester, and separated into individual molecular species as shown in Figure 2. Major peaks were collected, perbenzoylated, and their molecular species and purity were determined by high-performance liquid chromatography on a C18 reversed-phase column (3 μm, Spherisorb ODS-2, 2 × 250 mm) at 30°C. The mobile phase was acetonitrile/2-propanol (8:2, vol/vol) at a flow rate of 0.3 mL/min. The sample was injected in the mobile phase. A, LacCer containing d18:1 long-chain base; B, LacCer containing d20:1 long-chain base. The fatty acid moiety is identified above each peak.

The recovery of reacylated lysoLacCer was determined relative to the original LacCer used as starting material. For this determination, the original LacCer was prepared from $GbOse_4Cer$ because the LacCer prepared from red blood cell $GbOse_4Cer$ contains only d18:1 as long-chain base, and that the product LacCer after de/reacylation contains only a single molecular species. In the present study, *N*-succinimidyl 16:0, 20:0, 22:0 or 20:1 fatty acid ester was used for reacylation. Each newly synthesized LacCer showed a single band in HPTLC (Fig. 1B, lanes 2–5) and gave a single peak in HPLC (data not shown). The yields of LacCer relative to the original LacCer (650 nmol) used as starting material upon reaction with *N*-succinimidyl 16:0, 20:0, 22:0 or 22:1 fatty acid ester were 290 nmol (45%), 376 nmol (58%), 277 nmol (43%) and 245 nmol (38%), respectively. Thus, it appears that reacylation with saturated fatty acids results in higher yields.

As seen in Figures 3 and 4, the L-isomer, which can clearly be resolved from the D-isomer by HPLC (data not shown), was not observed. Moreover, as reported by Neuenhofer *et al.* (17), the *threo*-sphingoid configuration

was not formed in the course of the deacylation and reacylation procedures. The methods described here are therefore useful for preparing a variety of pure D-*erythro*-LacCer molecular species.

ACKNOWLEDGMENTS

This investigation was supported by the National Institutes of Health Grant NS 23354. We also thank James E. Evans (Division of Biochemistry, Eunice Kennedy Shriver Center, Waltham, MA) for performing mass spectrometry.

Apolipoprotein A-I, A-IV and E Synthesis in the Liver of Copper-Deficient Rats

Fatiha Nassir[a], Andrzej Mazur[a,*], Elyett Gueux[a], Colette Sérougne[b] and Yves Rayssiguier[a]

[a]Centre de Recherches en Nutrition Humaine, Laboratoire des Maladies Métaboliques, INRA, Theix, 63122 St. Genès Champanelle and [b]Laboratoire de Physiologie de la Nutrition, Université Paris Sud, 91405 Orsay Cédex, France

Copper deficiency induces hypercholesterolemia in the rat. This hypercholesterolemia is mainly due to an increase in apo E-rich high density lipoproteins (HDL_1). The present study was undertaken to determine whether the HDL increase could be explained by altered low-molecular weight apolipoprotein (apo) synthesis in the liver. The effect of copper deficiency on apo A-I, apo A-IV and apo E concentrations in plasma, as well as on respective mRNA levels and synthesis in the liver, were therefore investigated. We observed that the increased HDL_1 levels in the plasma of copper-deficient rats were associated with a significant rise in plasma apo E concentrations; however, plasma apo A-I and apo A-IV concentrations remained unchanged. Liver apo synthesis and respective apo mRNA levels were not significantly altered in copper-deficient animals when compared to control rats. No changes in apo E mRNA levels in various tissues from copper-deficient, as compared to control rats, were noted. Based on the data obtained, it was concluded that the observed changes in plasma lipoprotein and apo concentrations are not related to changes in low-molecular weight apo synthesis in the liver. The mechanisms of the impaired catabolism of HDL_1 should be further evaluated to possibly explain the observed increase in this fraction in copper-deficient rats.

***Lipids* 29, 727–729 (1994).**

Copper deficiency has been shown to induce hypercholesterolemia in humans and in various experimental animals (1,2). It was suggested that hypercholesterolemia in copper-deficient rats may be the result of an increased rate of cholesterol synthesis in the liver (1–3). Recently Kim *et al.* (4) proposed that copper deficiency-induced hypercholesterolemia and elevated 3-hydroxy-3-methyl-glutaryl coenzyme A reductase activity may be due to elevated hepatic glutathione. The authors (4) have shown that inhibition of elevated hepatic glutathione abolishes the increase in plasma cholesterol concentration. Copper deficiency-induced hypercholesterolemia is associated with changes in lipoprotein concentration and composition (2,5,6). We have recently shown that increased apolipoprotein (apo) B synthesis in the liver accompanies copper deficiency induced hyperlipemia and an increase in plasma apo B concentration (7). Moreover, the specific rise in apo B100 synthesis suggested that this increase may contribute to the elevated plasma low density lipoprotein concentrations. The induction of apo B synthesis through copper deficiency may be related to the increased production of fatty acids and cholesterol in the liver for both the assembly and the secretion of triglyceride-rich lipoproteins (2). However, in copper-deficient rats, increases in plasma lipid and apo levels are mostly associated with high density lipoprotein (HDL) (5,6,8). In the present study, we therefore investigated whether the increase in HDL could be explained by changes in low-molecular weight apo synthesis in the liver. We followed the effect of copper deficiency on apo A-I, apo A-IV and apo E concentrations in plasma as well as on the respective mRNA levels and synthesis in the liver.

Abbreviations: apo, apolipoprotein; HDL, high density lipoproteins; TCA, trichloroacetic acid.

MATERIALS AND METHODS

Weanling male Wistar rats (Iffa-Centre des Recherches et d'Elevage des Oncins, L'Arbresle, France) were randomly divided into copper-deficient and control groups. Rats were housed in wire-bottomed cages in a temperature-controlled room (22°C) with a 12-h light/dark cycle and were pair-fed appropriate diets for six weeks. The semi-purified diets contained (g/kg): casein, 200; sucrose, 650; corn oil, 50; alphacel, 50; DL-methionine, 3; choline bitartrate, 2; modified AIN-76 mineral mix, 35; and AIN 76A vitamin mix, 10 (ICN Biomedicals, Orsay, France). Cupric carbonate was omitted from the AIN-76 mineral mix in the copper-deficient diet. As assessed by atomic spectrophotometric analysis (model 560; Perkin Elmer, Norwalk, CT), the copper concentrations of the two diets were 0.4 mg/kg (deficient) and 6 mg/kg (control). Animals were anesthetized with sodium pentobarbital (40 mg/kg body weight i.p.) and then killed. Blood was collected into tubes containing ethylenediaminetetraacetic acid or heparin, and plasma was obtained by low-speed centrifugation ($2,000 \times g$). Copper in plasma was determined by atomic absorption analysis. Total cholesterol (BioMérieux, Charbonnières-les-Bains, France) in plasma was determined enzymatically. Apo were determined by radial immunodiffusion using sheep anti-rat apo antisera; plasma samples were diluted with Nonidet P40 (0.5% final concentration) for apo E assay and with urea (7M final concentration) for apo A-I and apo A-IV assays (9,10).

Lipoprotein fractions were separated from plasma by continuous gradient ultracentrifugation in an L8.70 Beckman (Beckman Instruments, Palo Alto, CA) centrifuge using a SW 41 rotor as described previously (11). Twenty-two fractions were collected from the meniscus of the tubes, and total cholesterol content in these fractions was assayed.

Total cell RNA was isolated from tissues using the guanidinium/phenol/chloroform method described by Chomczynski and Sacchi (12). Northern and dot blots of total cellular RNA, labeling of probes, hybridization and washing of filters were done as described previously (13,14). The cDNA probe for rat apo E (kindly provided by P. Cardot, URA-CNRS 1283, Paris, France) and oligonucleotide probes for apo A-I and apo A-IV were used to de-

tect specific mRNA (13,14). A mouse 18S rRNA cDNA clone was used as control probe (kindly provided by G. Veyssière, Université Blaise Pascal, Clermont Ferrand, France). Quantification of specific mRNA was performed on autoradiograms of filters by densitometric analysis using a laser densitometer (Ultroscan XL; LKB, Bromma, Sweden), and values were expressed in absorbance units relative to the level for control animals.

Apo synthesis rates were determined in the liver of copper-adequate and copper-deficient rats after intraportal vein injection of 1.0 mCi L-[4,5-^{3}H]leucine (specific activity 5.29 TBq/mmol; Amersham, Buckinghamshire, United Kingdom), as described by Baum *et al.* (15). Quantitative immunoprecipitation of apo was done on liver homogenates using polyclonal rabbit antisera directed against rat apo E, A-I and A-IV. The immune complexes obtained were washed extensively and separated on denaturing sodium dodecylsulfate polyacrylamide gel electrophoresis disc gels (7.5% acrylamide). Gels were sliced and radioactivity was determined by liquid scintillation spectrometry (Kontron, St-Quentin-en-Yvelines, France) following the addition of 3% Protosol-Econofluor (NEN, Boston, MA) to gel slices. Data are expressed as percent of total [trichloroacetic acid (TCA)-insoluble] radioactivity.

Values are given as means ± SEM. Data were analyzed by Student's *t*-test.

RESULTS AND DISCUSSION

As previously noted in other laboratories (1,16), as well as in our own (7,17,18), we observed, in addition to reduced plasma copper concentrations, a number of changes that are usually associated with copper deficiency (Table 1). As shown in Table 1, significantly lower body weights and higher relative heart and liver weights were seen in rats fed the copper-deficient diets when compared to controls. In agreement with previous works (2,17,18), plasma cholesterol concentrations were significantly elevated in copper-deficient rats when compared to those of controls (Table 1). As is shown by density gradient ultracentrifugational analysis of plasma lipoproteins (Fig. 1), hypercholesterolemia is mainly due to an increase in the concentration of HDL, and particularly HDL_1. This is consistent with earlier observations (4,19) when plasma lipoproteins were analyzed by polyacrylamide gradient gel electrophoresis and by gel filtration. In the present study, we have clearly shown that the changes in lipoprotein distribution in copper-deficient rats are associated with an increase in plasma apo E concentration. However, copper deficiency had no significant effect on plasma apo A-I and apo A-IV levels (Table 2).

Studies on apo A-I, A-IV and apo E synthesis in the liver have shown (Table 2) that the synthesis of these apo is not significantly altered by copper deficiency. Total protein

TABLE 1

Effect of Copper Deficiency on Body Weight, Relative Organ Weights and Plasma Copper and Cholesterol Concentrations[a]

	Control	Copper-deficient
Body weight (g)	289 ± 3	242 ± 8[b]
Relative liver weight (g/100 g)	3.8 ± 0.1	6.1 ± 0.2[b]
Relative heart weight (g/100 g)	0.33 ± 0.01	0.73 ± 0.05[b]
Plasma copper (μmol/L)	14.60 ± 0.50	0.60 ± 0.08[b]
Plasma total cholesterol (mmol/L)	1.55 ± 0.06	1.98 ± 0.11[b]

[a]Means of 12 animals per group ± SEM.
[b]Significant difference from control rats, $P < 0.001$.

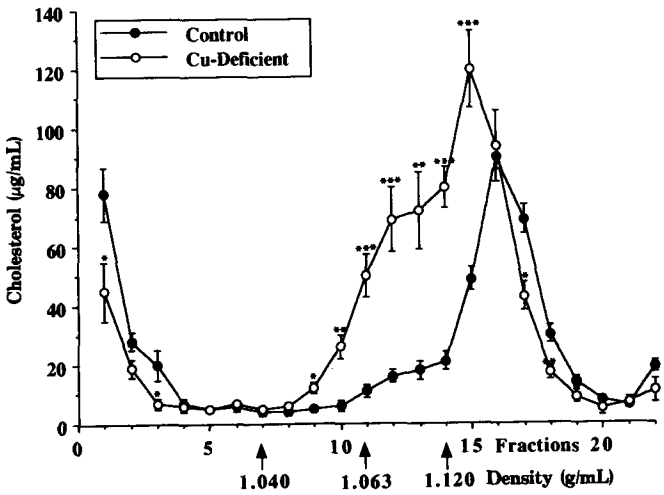

FIG. 1. Effect of copper deficiency on cholesterol distribution in lipoprotein fractions separated by density gradient ultracentrifugation. The results represent the mean (± SEM) of six determinations for control and of five determinations for copper-deficient rats. The points that were significantly different between control and copper-deficient rats are designated with an asterisk (*$P < 0.05$; **$P < 0.01$; ***$P < 0.001$).

TABLE 2

Effect of Copper Deficiency on Apolipoprotein A-I, A-IV and E Concentrations in the Plasma and on Their Synthesis and mRNA Levels in the Liver[a]

	Control	Copper-deficient
Apo A-I		
Plasma (mg/100 mL)	27.8 ± 1.7	29.1 ± 1.8
Synthesis in liver (% of TCA-insoluble radioactivity)	0.19 ± 0.02	0.16 ± 0.02
Liver mRNA (AU)	100 ± 5	93 ± 3
Apo A-IV		
Plasma (mg/100 mL)	16.6 ± 0.7	17.5 ± 1.0
Synthesis in liver (% of TCA-insoluble radioactivity)	0.21 ± 0.03	0.18 ± 0.03
Liver mRNA (AU)	100 ± 6	87 ± 2
Apo E		
Plasma (mg/100 mL)	17.5 ± 0.3	23.2 ± 0.8[b]
Synthesis in liver (% of TCA-insoluble radioactivity)	0.98 ± 0.03	0.88 ± 0.17
Liver mRNA (AU)	100 ± 7	96 ± 7

[a]Means of 12 animals per group ± SEM for plasma apolipoproteins, and of six animals ± SEM per group for apolipoprotein mRNA levels and synthesis. TCA, trichloroacetic acid; AU, absorbance unit.
[b]Significant difference from control rats, $P < 0.001$.

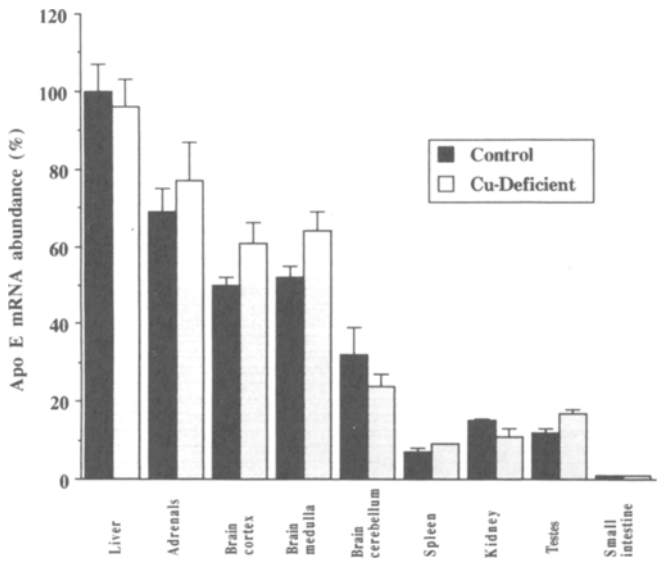

FIG. 2. Effect of copper deficiency on apolipoprotein (apo) E mRNA abundance in various tissues. The amount of apo E mRNA in each tissue is expressed relative to the amount in the liver of control rats (taken as 100%). Values are mean ± SEM of six rats per groups. There was no significant difference ($P > 0.05$) between both groups.

synthesis in the liver, as indicated by [^{3}H]leucine incorporation into TCA-insoluble material, was similar between both groups (control, 118 ± 10 cpm/μg protein; copper deficient, 110 ± 13 cpm/μg protein; $P > 0.05$). Copper deficiency did not significantly change apo A-I, apo A-IV and apo E mRNA levels in the liver either (Table 2). As apo E is synthesized not only by hepatocytes but by a wide variety of mammalian cells (20), we studied the effect of copper deficiency on apo E mRNA levels in several tissues from control and copper-deficient rats. Consistent with results of previous studies done in the rat (20), apo E mRNA was most abundant in the liver, but substantial amounts of apo mRNA were also found in adrenals and in brain (Fig. 2). Copper deficiency did not significantly alter the apo E mRNA levels in all tissues studied (Fig. 2).

In summary, one can conclude from the present work that copper-deficiency does not affect apo E, apo A-I and apo A-IV synthesis in the liver. However, since the liver weight and, in particular, the relative liver weight increase in copper-deficient rats, the possibility exists that the increase in liver mass may contribute to the apparent absolute increase in apo synthesis by this organ. On the other hand, the increase in plasma volume in copper-deficient animals may have an effect on plasma apo concentration independent of changes in apo metabolism. This will need to be considered in future work. Furthermore, as the specific increase in apo E plasma concentration, without changes in apo A-I and apo A-IV concentrations, occurs in copper deficiency, the mechanisms of the impaired catabolism of HDL_1 should be evaluated to pinpoint the cause of the increase in this lipoprotein fraction.

1-*O*-Hexadecylglycerol (chimyl alcohol), 1-*O*-heptadecylglycerol and 1-*O*-octadecylglycerol (batyl alcohol) have been identified as the major native constituents of a mixture of free alkyl glycerol ethers isolated from the contained water and the methanolic extract of the sponge *Desmapsamma anchorata*. Minor components were the free C_{14}, C_{15}, C_{19}, C_{20} and C_{21} alkyl glycerol monoethers. The alkyl glycerol monoethers were analyzed and identified by gas chromatography/mass spectrometry of their isopropylidene derivatives. This is the first report on the occurrence of free C_{15}, C_{19}, C_{20} and C_{21} alkyl glycerol monoethers in a sponge.
***Lipids* 29, 731–734 (1994).**

The saturated monoalkyl ethers of glycerol, 1-*O*-hexadecyl-*sn*-glycerol(**1c**; chimyl alcohol) (see Fig. 1); and 1-*O*-octadecyl-*sn*-glycerol(**1e**; batyl alcohol) commonly occur esterified to fatty acids in a wide variety of marine organisms (1–5). They have also been found in some marine sponges in the unesterified form (6–11). Thus, free chimyl alcohol **1c** was recently found in *Stylopus australis* (Poecilosclerida:Hymedesmiidae) (6), *Tethya aurantia* (Hadromerida:Tethyidae) (7) and *Tedania ignis* (Poecilosclerida:Myxillidae) (8), while batyl alcohol **1e** was found in *Ulosa ruetzleri* (Axinellida:Axinellidae) (9) and *T. ignis* (8). The first report on the occurrence of a free alkyl glycerol monoether in a sponge was that on 1-*O*-tridecyl-*sn*-glycerol (**1i**) from a sponge of the family Plocamiidae (10). At about the same time, the branched-chain alkyl glycerol monoesters **5a** and **5b** were isolated from a Taiwanese marine sponge of genus *Aaptos* (Hadromerida:Suberitidae) (11) and **1j** and **1k** from *T. aurantia* (7).

Desmapsamma anchorata (Poecilosclerida:Esperiopsidae) first described by Carter in 1882 (12) and more recently by Green *et al.* (13), is a *Desmapsamma* ramose sponge erected on an encrusting base. Alive, it is pale pink externally and dark orange internally, and it is smooth and "spongy." *Desmapsamma anchorata* inhabits its hexacoralia plates and *Acropora* cemeteries on the leeward side of coral reefs in the Gulf of Mexico and Caribbean Sea. It has previously been shown that the Caribbean *D. anchorata* contains interesting fatty acids with unusual unsaturation and methyl branching as well as the common C_{14} to C_{26} fatty acids and common sponge sterols; but no free alkyl glycerol ethers were found (14). We report here on the isolation of free saturated monoalkyl ethers of glycerol from *D. anchorata* harvested in the Gulf of Mexico.

EXPERIMENTAL PROCEDURES

Sponge collection. Approximately 30 specimens of *D. anchorata* were collected at depths of 2 to 15 m and at a water surface temperature of 28°C near the La Anegada de Afuera reef (Veracruz, Ver., Mexico) in June 1989. A voucher specimen is being kept at the Laboratorio de Farmacología Marina, Instituto de Ciencias del Mar y Limnología (UNAM). *Desmapsamma anchorata* is a shallow water species which shows no association with symbiotic algae but considerable affinity for *Holopsamma helwigi* at the same location. *Desmapsamma anchorata* is a very abundant species near the reefs of Veracruz, Mexico.

Isolation. The sponge (6.0 kg) was squeezed, and the water from the sponge was filtered through a Büchner funnel using a celite layer as filter aid to remove insoluble materials. The filtrate was extracted with ethyl acetate (4 × 500 mL). The insoluble material was washed from the celite layer first with petroleum ether (4 × 2 L) and then with methanol (4 × 2 L). The ethyl acetate extract and the petroleum ether and methanol washings were taken to dryness *in vacuo* to yield 1.42, 0.43 and 0.94 g of material, respectively. The residues were then combined as they were found to be similar as judged by thin-layer chromatography (TLC) using the developing solvent dichloromethane/acetone (9:1, vol/vol).

To the remaining sponge material (545.5 g dry wt), methanol (5 × 2.5 L) was added, and the mixture was filtered through celite. The aqueous methanol phase was brought to dryness and then extracted with dichloromethane and ethyl acetate (4 × 2 L each). The organic extracts were concentrated *in vacuo* to yield a reddish-brown oil (35 g). The residue from the aqueous phase of the sponge was chromatographed on a column (4.5 × 35.0 cm) of 60 g of silica gel, while the residue from the remaining sponge material was separated on a column (6.0 × 35.0 cm) containing 170 g of silica gel, and the columns were eluted with petroleum ether, petroleum ether/ethyl acetate mixtures, and methanol. Elution with petroleum ether yielded 135 mg of a mixture of fatty acid methyl esters which were likely formed during methanol extraction. Gas chromatography/mass spectrometry (GC/MS) analysis of the mixture indicated the presence of C_{14} to C_{21} fatty acids which had previously been identified in this species (14). Petroleum ether/ethyl acetate (9:1, vol/vol) yielded 4.2 g of a mixture of sterols (m.p. 134–140°C). Acetylation of the

sterol mixture (60 mg) gave the corresponding acetates. GC/MS of the acetates confirmed the presence of the sterols previously identified in this species (14), i.e., desmosterol (3.9%), cholesta-5,22-dienol (9.2%), cholesterol (44.6%), 24-methylcholesta-5,22-dienol (18.3%), 24-methylcholesterol (6.2%), stigmasterol (4.4%) and sitosterol (11.1%). Elution with petroleum ether/ethyl acetate (4:1 and 3:1, vol/vol) yielded a mixture of the monoalkyl ethers of glycerol (10 mg from aqueous phase, and 300 mg from sponge) as an amorphous solid (**1a–h**). The compounds found in the aqueous and sponge residues were similar.

Optical rotations were measured on $CHCl_3$ solutions using a Jasco DIP-360 Digital polarimeter (Japan Spectroscopic Co., Tokyo, Japan). ^1H and ^{13}C nuclear magnetic resonance (NMR) spectra on $CDCl_3$ solutions, with tetramethylsilane (TMS) as internal standard, were recorded at 300 MHz or 200 MHz, either on a Varian VXR-300S instrument or a Varian Gemini-200 instrument (Varian, Palo Alto, CA). Mass spectra (MS) were recorded using a Hewlett-Packard MS5985B mass spectrometer (Palo Alto, CA). GC/MS was done using a PAS-1701 (ECD tested 1701 silicone) column (25 × 0.32 mm × 0.25 μm) in a Hewlett-Packard 5890 Series II gas chromatograph linked to a JEOL JMS-AX505HA mass spectrometer with a data system (Tokyo, Japan). Samples were analyzed using temperature programming: first isothermal at 100°C for 1 min, then increased at 10°C/min to 280°C, and finally kept at 280°C for 10 min. TLC was done on silica gel plates impregnated with fluorescent dye (Merck Silica Gel 60 F_{254}; Merck, Darmstadt, Germany).

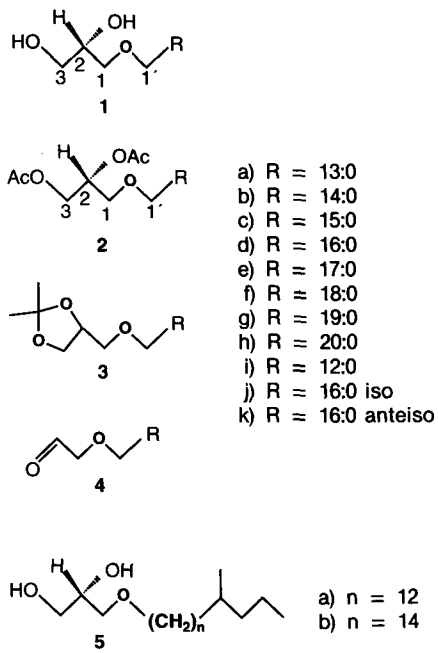

FIG. 1. Structures of alkyl glycerol monoethers (1a–h) from *Desmapsamma anchorata* and of some structural analogs (2a–h, 3a–h) as well as of some related compounds from other sponges (1i–k, 5a–b).

*Monoalkyl ethers of glycerol (Fig. 1, **1a–h**).* ^1H NMR ($CDCl_3$, 300 MHz) δ 0.88 *t*, *J* = 6.7 Hz, CH_3; 1.26, *s*, $(CH_2)_n$, aliphatic chain; 1.57, *quint*, *J* = 6.9 Hz, H-2′; 3.46, AB *m*; *apparent td*, *J* = 6.6 Hz, *J* = 1.2 Hz, H-1′; 3.48, *dd*, *J* = 9.6 Hz, *J* = 6.0 Hz, H-1a; 3.53, *dd*, *J* = 9.6 Hz, *J* = 4.2 Hz, H-1b; 3.63, *dd*, *J* = 11.7 Hz, *J* = 5.4 Hz, H-3a; 3.71, *dd*, *J* = 11.7 Hz, *J* = 3.9 Hz, H-3b; and 3.86, *pseudo quint*, *J* = 5.4 Hz, H-2. ^{13}C NMR δ ($CDCl_3$, 75 MHz) δ 14.13, 22.70, 26.08, 29.36, 29.47, 29.58, 29.59, 29.62, 29.67, 29.70, 31.92, 64.23, 70.48, 71.83, 72.43. The chemical shifts for H-1 and H-3 are reverse compared to those described in Ref. 15. Assignments for H-2 and H-3 were confirmed by the downfield shifts of the signals in the ^1H NMR spectrum of the acetylation product.

Acetylation of the monoalkyl ethers of glycerol. An aliquot of monoalkyl ethers (10 mg) was treated with Ac_2O (0.2 mL) and pyridine (0.1 mL) at room temperature overnight. The excess reactants were removed on a rotary evaporator under reduced pressure. The residue was chromatographed on a column of silica gel to yield the diacetates (Fig. 1, **2a–h**) (5 mg) as a yellowish oil. ^1H NMR ($CDCl_3$, 300 MHz) δ 0.89, *t*, CH_3; 1.26, *s*, CH_2, aliphatic chain; 1.56, *quint*, H-2′; 2.07, *s*, AcO; 2.10, *s*, AcO; 3.44, AB *m*, H-1′; 3.56, *d*, *J* = 5.3 Hz, H-1; 4.16, *dd*, *J*= 11.5 Hz, *J* = 5.8 Hz, H-3b; 4.34, *dd*, *J* = 11.5 Hz, *J* = 4.0 Hz, H-3a; and 5.19, *m*, H-2. ^{13}C NMR δ ($CDCl_3$, 75 MHz) 14.15, 20.81, 21.08, 22.71, 26.03, 29.37, 29.46, 29.53, 29.62, 29.64, 29.72, 31.94, 62.99, 68.82, 70.31, 71.76.

Isopropylidene derivatives of monoalkyl ethers of glycerol. To a solution of monoalkyl ethers of glycerol (20 mg) in dry acetone (12 mL), dry $CuSO_4$ was added in excess and refluxed with stirring for 2 h. The reaction was monitored by TLC. The mixture was filtered, and the filtrate was directly subjected to silica gel column chromatography. Elution with petroleum ether/CH_2Cl_2 (4:1, vol/vol) yielded the isopropylidene derivatives (Fig. 1, **3a–h**). ^1H NMR ($CDCl_3$, 300 MHz) δ 0.88, *t*, CH_3; 1.26, *s*, CH_2, aliphatic chain; 1.37, *s*, 3H, 1.43, *s*, 3H, gem dimethyl; 1.56, *quint*, H-2′; 3.41 and 3.52, *dd*, *J* = 9.8 Hz, *J* = 5.6 Hz, H-1b and H-1a; 3.46, AB *m*, H-1′a and H-1′b; 3.73 and 4.07, *dd*, *J* = 8.2 Hz, *J* = 6.4 Hz, H-3b and H-3a; and 4.28, *pseudo quint*, *J* = 6.2 Hz, H-2. ^{13}C NMR ($CDCl_3$, 175 MHz) δ 14.07, 22.65, 25.38, 26.01, 26.73, 29.33, 29.43, 29.56, 29.65, 29.99, 31.89, 66.93, 71.81, 71.89, 74.75, 109.37.

Periodate oxidation of the monoalkyl ethers of glycerol. A solution of monoalkyl ethers of glycerol (50 mg) in diethyl ether was treated with 38% periodic acid (10 mL) at room temperature overnight, and the reaction mixture was purified by column chromatography to yield the respective glycolaldehyde ethers (Fig. 1, **4a–h**) (10 mg). ^1H NMR ($CDCl_3$, 200 MHz) δ 0.9, *t*, CH_3, *J* = 7.0 Hz; 1.25, *s*, CH_2, aliphatic chain; 1.57, *m*, H-2′; 3.53 *t*, *J* = 6.5 Hz, H-1′; 4.05, *d*, *J* = 1.0 Hz, H-1; and 9.74, *t*, *J* = 1.0 Hz, H-2.

RESULTS AND DISCUSSION

The monoalkyl ethers of glycerol were isolated as a waxy solid (m.p. 57–58°C; $[\alpha]_D$ + 2.0° at c = 0.2 in $CHCl_3$) and

were identified by ^1H NMR and GC/MS of the isopropylidene derivatives. The ^1H NMR spectrum exhibited signals for an aliphatic long chain and signals associated with the presence of the glycerol monoether moiety. Three methylenes and one methine were observed attached to oxygen atoms: a two proton AB multiplet (an apparent triplet of doublets, J = 6.6 Hz, J = 1.2 Hz H-1′) at 3.46 ppm, two AB doublets of doublets centered at 3.48 ppm (J = 9.6 Hz, J = 6.0 Hz, H-1a) and 3.53 ppm (J = 9.6 Hz, J = 4.2 Hz, H-1b), two AB doublets of doublets centered at 3.63 ppm (J = 11.7 Hz, J = 5.4 Hz, H-3a) and 3.71 ppm (J = 11.7 Hz, J = 3.9 Hz, H-3b) and a pseudo quintuplet at 3.86 ppm ($J \approx 5.4$ Hz) for the methine proton (H-2). The ^{13}C NMR spectrum was in agreement with this structure and showed three methylene carbons at 72.43 (C-1), 71.83 (C-1′) and 64.23 (C-3), and a methine at 70.48 (C-2). These assignments are based on multipulse APT and 2D ^1H-^{13}C correlation experiments.

Proton assignments were confirmed by converting the diols to the corresponding diacetates. The ^1H NMR showed two sharp singlets at 2.07 and 2.10 ppm corresponding to the acetyl protons, as well as a downfield shift of the two H-3 doublets of doublets (4.16, J = 11.5 Hz, J = 5.8 Hz, H-3a; 4.34, J = 11.5 Hz, J = 4.0 Hz, H-3b) and the methine proton (H-2, 5.19 ppm).

Oxidative cleavage of the diols with periodic acid gave the corresponding glycoaldehyde alkyl ethers confirming the presence of a 1,2-diol group. The ^1H NMR spectrum exhibited the aldehydic proton at 9.74 ppm as a triplet (J = 1.0 Hz) coupled with the methylene doublet at 4.05 ppm (J = 1.0 Hz).

The above assignments are in good agreement with those published for chimyl and batyl alcohol (**1c, 1e**) as well as other monoalkyl ethers of glycerol **1j, 1k** (7,15,16).

Although useful anomalous ion peaks at one mass unit above the molecular weight [M + 1] have been reported to occur in the spectra of various ethers, alcohols, glycols, amines and nitriles (17), the presence of such a peak has not been reported previously for alkylglycerol ethers (6–11,15). We noted that the electron impact mass spectrum measured at 70 eV on the mixture of monoalkyl ethers of glycerol isolated from *D. anchorata* showed a useful [M + 1] peak at *m/z* 317 (0.9%) and other significant peaks at *m/z* 285 $[M - CH_3O]^+$ (0.6%), 255 $[M - C_2H_5O_2]^+$ (0.9%) and 225 $[M - C_3H_7O_3]^+$ (3.1%) characteristic of chimyl alcohol **1c** as the major component. The mass spectrum also showed additional weak [M + 1] ion peaks at *m/z* 331 (0.2%) and 345 (0.1%) indicative of the presence of C_{17} and C_{18} analogs. Similar results were obtained at 12 eV and in the chemical ionization mode (data not shown).

While mass spectrometry using the direct insertion mode, of the intact alkyl glycerol monoethers indicated the presence of glycerol ethers with 16:0, 17:0 and 18:0 hydrocarbon chains as major constituents, GC/MS of the isopropylidene derivatives identified glycerol ethers with hydrocarbon chain lengths from C_{14} to C_{21}. GC/MS of the isopropylidene derivatives did not give molecular ion peaks, but it showed the $[M - 15]^+$ ion and the characteristic base peak at *m/z* 101 (18). The major saturated 1-*O*-alkyl glycerol ethers in decreasing order of abundance were: C_{16} (56.48%), C_{17} (21.98%), and C_{18} (17.24%), followed by C_{14} (1.65%), C_{15} (1.44%), C_{19} (0.77%), C_{20} (<0.5%) and C_{21} (<0.5%). GC/MS furthermore indicated the presence of two C_{16}, four C_{17}, three C_{18} and two C_{19} saturated alkyl isomers, suggesting the presence of iso, anteiso, and/or other branched structures. It was not possible to identify the position of the methyl branching in the hydrocarbon side chain. It should be noted that GC/MS of the methyl esters of the fatty acids isolated from this sponge also indicated the presence of carbon chain lengths from C_{14} to C_{21} and the presence of saturated branched isomers (14).

Sponges such as *D. anchorata* have been shown to be a good source of phospholipids with fatty acids having unusual unsaturation and methyl branching which is typically not found in terrestrial systems (14). Chimyl alcohol (**1c**), batyl alcohol (**1e**) and their unsaturated analogs are widely distributed in nature and have been found in elasmobranch fish, human milk and bone marrow, atherosclerotic human aorta, pig spleen, in the fat of neonatal calves, in colostrum and milk of cows, goats, pigs and sheep (9), and more recently in reptile skin gland secretions (18). Unesterified alkyl glycerol monoethers have been isolated from marine sponges, although screening of several marine sponges of the class Demospongiae has shown that this type of ether lipid is not widely distributed among sponges (7). Studies on the antimicrobial activity of alkyl glycerol ethers have shown that these compounds inhibit bacterial growth (19). Their role in sponges is still uncertain, although it has been proposed that alkyl glycerol monoethers may play some part in the defense mechanism in the life of the sponge (7).

ACKNOWLEDGMENTS

Specimens were collected with the help of L.M. Mitchell and J.A. Mercado. We also thank R. Patiño for optical rotation measurements, R Gaviño for 200 MHz NMR spectra, I. Chávez for 300 MHz NMR measurements; and L. Velasco and F.J. Pérez for mass spectra and GC/MS. The authors thank the International Foundation for Science (IFS) Stockholm, Sweden, for financial support (F. Cruz), Research Grant Agreement No. F/1684-1.

ARTICLE

HDL_3-Mediated Cholesterol Efflux from Cultured Enterocytes: The Role of Apoproteins A-I and A-II

Gerhard Herold*, Uta Hesse, Frank Wisst, Carl Fahr, Milena Fahr, Gerhard Rogler[1], Irmlind Geerling and Eduard F. Stange[2]

Department of Internal Medicine I, University of Ulm, 89070 Ulm, Germany

High density lipoproteins (HDL) were recently demonstrated in an enterocyte model (CaCo-2 cells) to mediate reverse cholesterol transport by retroendocytosis. The present study was carried out to define the role of the major HDL apoproteins (apo) A-I and apo A-II in this pathway. HDL_3 was fractionated by heparin affinity chromatography into the two main fractions containing either apo A-I only (fraction A) or both apo A-I and apo A-II (fraction B). In addition, liposomes were reconstituted from purified apo A-I or apo A-II and dimyristoyl phosphatidylcholine. The cell binding properties and cholesterol efflux potential were studied in the lipoprotein fractions and the liposomes. Both fractions exhibited similar maximal binding capacities of 4427 (A) and 5041 (B) ng/mg cell protein, but their dissociation constants differed (40.5 and 167.7 μg/mL, respectively). Fraction A induced cholesterol efflux and stimulated cholesterol synthesis more than did fraction B. Fraction A mobilized both cellular free and esterified cholesterol, whereas fraction B preferentially mobilized cholesteryl esters. Liposomes, containing either apo A-I or apo A-II, showed specific binding, endocytosis and endosomal transport, and were released as intact particles. Apo A-I liposomes also mediated cholesterol efflux. In conclusion, there is evidence that the HDL_3 subfractions A and B, as well as reconstituted liposomes containing either apo A-I or apo A-II, were specifically bound and entered a retroendocytosis pathway which was directly linked to cholesterol efflux. Quantitatively, the apo A-I subfraction appeared to play the dominant role in normal enterocytes. The apo A-II content of fraction B was related to the mobilization of cholesteryl esters.

***Lipids* 29, 735–745 (1994).**

Current understanding of cholesterol transport *in vivo* suggests a primary role for high density lipoproteins (HDL) in the reverse cholesterol transport (1) from peripheral tissues to the liver (2). HDL represent a series of dynamically changing HDL populations differing in density, size and composition (3). HDL contains various apolipoproteins (4), most importantly apoprotein A-I (apo A-I) and apoprotein A-II (apo A-II). Specific binding of HDL_3 has been observed in a variety of different cell systems (5–10), as well as in freshly isolated or cultured intestine-derived cells (11–17). Two principally different cellular pathways were suggested for HDL_3-mediated cholesterol efflux: (i) a docking receptor promoting cholesterol translocation (5,18), or (ii) a receptor-mediated intracellular endosomal pathway termed "retroendocytosis" (6,17,19). Both are associated with subsequent efflux of predominantly intracellular as opposed to plasma membrane cholesterol (20). Therefore, a compartmentation of structural and kinetic domains of cholesterol (21–23), as well as a role of the functional intracellular compartmentation of enterocyte cholesterol (24–28), seems feasible. Furthermore, the identification of HDL binding proteins (29–32) has made some progress, but the exact receptor structure is still unclear.

Previous work suggested a different efflux potential of HDL_3 fractions, dependent on the molar ratio of the major apoproteins, apo A-I to apo A-II. In several studies it was shown that apo A-I predominantly promoted cholesterol efflux from adipose cells (33,34) and macrophages (35). In contrast, similar effects of apo A-I and apo A-I/apo A-II particles of different ratios were observed not only in another macrophage system (36), but also in rat hepatoma cells, normal human skin fibroblasts and rabbit aortic smooth muscle cells (37). In bovine aortic endothelial cells (38), the binding affinity and capacity were found to be similar in apo A-I HDL_3 and apo A-II HDL_3. In another study, the particles containing only apo A-I were bound to the membranes of these cells with higher capacity and lower affinity (39). Specific binding and mediation of cholesterol efflux by apo A-IV-containing particles was also recently shown (40). These particles also bind to the apo A-I/apo A-II receptor site of adipose cells (40).

We previously reported that HDL_3 mediates cholesterol efflux from intestinal cells by a retroendocytosis pathway (16,17). The present work defines the role of HDL_3 subfractions containing either apo A-I or apo A-I and apo A-II, as well as the role of reconstituted liposomes of apo A-I or apo A-II, using a previously described culture system of differentiating intestinal cells (17). These cells, derived from a adenocarcinoma of the colon (CaCo-2), are regarded as a valid enterocyte model (41).

MATERIALS AND METHODS

Cell culture system. CaCo-2 cells were obtained from the American Type Culture collection (HTB 37, Rockville, MD) (42). Cells were subcultured and then grown as monolayers on 30-mm Millicell HA filters (Millipore GmbH, Eschborn, Germany) as described previously (17,43). Cells were maintained in 10% (vol/vol) Dulbecco's minimal essential medium (DMEM) (Gibco, Eggenstein, Germany) supplemented with L-glutamine (2 mmol/L), 1% nonessential amino acids, 1% Pen Strep (Gibco) and 20% (vol/vol) fetal calf serum (FCS) (Biochrom, Berlin, Germany) in an atmosphere containing 8% CO_2. Depending on the experimental design, FCS was removed and DMEM was supplemented either with 10% lipoprotein-deficient (LPD) FCS or with fatty acid-free albumin (Sigma Chemicals, Deisenhofen, Germany) as detailed later.

The cells displayed polarized morphology characterized by apical microvilli and a basolateral membrane covering the filter membranes. Confluence of the cell layers was observed around day five after plating. Although the cells partially differentiated during the initial rapid proliferation, a burst of differentiation was primarily observed after day 11 of culture (17). Confluence was observed by light microscopy as well as in a series of electron microscopic studies. Experiments were mainly performed in the postconfluent proliferating phase of cells. Gold-labeled and [^{125}I]labeled HDL_3 fractions and liposomes were exclusively added to the basolateral medium compartment. For efflux measurements, designed with the label [^{14}C]mevalonolactone (MVL) or [^{14}C]octanoate, the fractions and particles used were present basolaterally.

Lipoprotein preparation and isolation. Human plasma was obtained from healthy blood donors. Plasma lipoprotein fractions were separated by ultracentrifugation as described earlier (44). Using potassium bromide for density adjustment, the fractions were isolated at the respective densities of d < 1.006 g/mL for very low density lipoproteins, d 1.019–1.063 for low density lipoproteins (LDL), d 1.063–1.130 for HDL_2 and d 1.130–1.210 for HDL_3. Apo E was removed from the HDL_3 obtained by heparin-Sepharose (CL-6B; Pharmacia, Uppsala, Sweden) affinity chromatography (45) as checked by sodium dodecylsulfate polyacrylamide gel electrophoresis (SDS–PAGE). The fractions were detected as distinct homogeneously shaped peaks. The first and quantitatively most important peak (fraction A) only contained apo A-I. The second peak (fraction B) contained apo A-I, slightly lesser amounts of apo A-II and a trace of apo E. To check the purity and the apolipoprotein pattern of the fractions, the lipoproteins were delipidated and the apo residue was incubated with 0.03% SDS and 125 mM mercaptoethanol solution. Subsequently, SDS–PAGE and Coomasie blue staining were used to identify the apo bands. The protein content of the particles was determined using bicinchoninic acid (BCA)(Sigma) as described in the method by Smith *et al.* (46). The lipoprotein concentrations refer to their protein contents. LPD–FCS was prepared from the bottom layer of unfrozen FCS (obtained from Gibco) ultracentrifuged at a density of 1.210 g/mL.

Isolation of the apo A-I and A-II. HDL_3 separated by ultracentrifugation was subjected to the guanidine procedure (47) and repeated dialysis, using a procedural modification (A. Steinmetz, Marburg, Germany, personal communication). The sample was centrifuged at a KBr density of 1.21 g/mL for 24 h at 50,000 rpm. A separation into two phases, an aqueous bottom layer and a lipid containing top layer, was achieved with this procedure. The top layer contained all the lipids, part of apo A-I and most of apo A-II, and the bottom layer mainly contained apo A-I. Compared to apo A-I, only a small quantity of apo A-II could be isolated. To delipidate the lipid containing layer, the phase was incubated several times with diethyl ether/ethanol (1:3, vol/vol) at -20°C for 24 h. The incubation mixture was centrifuged at 2000 rpm for 10 min, and the turbid, lipid-containing supernatant was removed. Then, top and bottom layers were each mixed with a buffer containing 30 mM Tris and 6 M urea at pH 8, and each other was eluted separately over a diethylaminoethyl sephacel column (Pharmacia) using an NaCl gradient up to 125 mM. Subsequently, the samples were dialyzed against 5 mM ammonium bicarbonate. Finally, apo A-I and apo A-II were shown to be pure by SDS–PAGE, were lyophilized, and then stored at -20°C.

Preparation of dimyristoyl phosphatidylcholine (DMPC) A-I and A-II liposomes (Lip A-I and Lip A-II). The liposomes were prepared as previously described (40). Apo and DMPC (Sigma) were mixed in a molar ratio of 1:150. For 10 mg of apo A-I, 36.6 mg of DMPC in chloroform (-20°C) were dispersed in a glass tube and the apo was added. Next, 850 µL of cholic acid (Sigma) [750 mM in phosphate buffered saline (PBS)] were added, mixed and incubated for 30 min at 24°C. To remove excess cholate, the suspension was dialyzed against PBS (40). The protein content of liposomes was measured as described above (46); the liposome concentrations used refer to their protein content.

Colloidal gold preparation and lipoprotein labeling. Preparation of colloidal gold as well as the labeling procedure were essentially done as previously described (17). According to the method of Frens (48), a particle size of 20–40 nm was used in the studies. For the conjugation to HDL_3 fractions and liposomes, the method originally described for LDL (17,49) was used. Gold labeled liposomes were characterized by negative staining. Similar to earlier studies with HDL_3 (16,17), colloidal gold was used as a control, but no specific binding and no internalization were detected.

[^{125}I]Labeling of HDL_3 fractions and liposomes. Using sodium [^{125}I]iodide (Amersham Buchler GmbH, Braunschweig, Germany), Bilheimer *et al.*'s modification (50) of the iodine monochloride method was utilized, arriving at a final specific radioactivity in the range of 200–500 cpm/ng protein for HDL_3 and 100–300 cpm/ng protein for the liposomes. Studies with iodinated and gold labeled lipoproteins and liposomes were performed as previously described (16,17), with minor modifications. Briefly, the cells were incubated in a medium con-

taining 20% FCS until day five and 100 μg/mL LDL (to enrich the cells with cholesterol) between days three and five. The incubation time for binding was 2 h at 4°C. Then, DMEM medium, containing 2 mg/mL albumin, was added, containing increasing concentrations (10–200 μg lipoprotein protein/mL) of [^{125}I]HDL_3 fractions or [^{125}I]liposomes. Specific binding was determined as the difference between total and nonspecific binding, measured with a 50-fold excess of unlabeled HDL_3.

Studies with [^{14}C]labeling of cellular cholesterol. In this set of experiments, procedures and methods were used identical to those described previously (17). Briefly, cells were cultured in DMEM with 20% FCS until day seven and medium was changed every two days. Between days seven and nine, the culture medium contained DMEM, 10% LPD-FCS and 0.5 mM unlabeled octanoate. Newly synthesized cholesterol was labeled using the precursor [^{14}C]octanoate [Du Pont GmbH (NEN), Dreieich, Germany; specific activity 11,600 dpm/nmol], which was also present in the medium between days seven and nine. The HDL_3 subfractions were added to the medium at day eight for a 24-h period. The labeling procedure was done according to a previously described method (25), which had shown comparable results using both [^{3}H]water or [^{14}C]octanoate. Following the incubation, the cells were chilled on ice, and the medium was collected separately, together with three portions of buffer (PBS + 1 mg/mL albumin). Lipids were extracted separately from cells and medium, and free and esterified cholesterol were isolated by thin-layer chromatography (25). Cholesteryl esters were separated and saponified to remove labeled fatty acids (25). Initially, internal standards were routinely added to cell homogenates and medium, to correct for cholesterol loss. Cholesterol synthesis was calculated from the C_2-flux from [^{14}C]octanoate into cholesterol (51).

In a set of time course experiments, DMEM medium containing 20% FCS was present until day five of culture. For cholesterol loading of the cells, cells were incubated in 5 mM MVL (Sigma) between days four and five of culture. FCS was replaced by 10% LPD-FCS to minimize the availability of exogeneous unlabeled cholesterol and the label [^{14}C]MVL [Du Pont GmbH (NEN)] was added from day five to six. The labeling incubation was carried out at 37°C for 24 h. The specific activity was identical in all subsequent sets of experiments (1.5 μCi/filter, 0.5 μCi/mL). To prevent the esterification of labeled nascent cholesterol, 5 μg/mL of Sandoz-Compound 58035 (gift of Sandoz Research Institute, East Hanover, NJ) was added only during the labeling incubation. The labeling procedure was stopped by chilling the cells on ice. Unspecific membrane-associated radioactivity was removed by intensively washing the cells (PBS + 1mg/mL albumin). Subsequently, the medium was changed to DMEM-supplemented with 1 mg/mL albumin, as well as with the different HDL_3 fractions (present only in the basolateral compartment), and efflux of preformed sterols was measured during a 24-h incubation at 37°C. In aliquots of 200 μL of medium, the cell detritus was removed by centrifugation, and the released radioactivity was determined and calculated per mg cell protein. Cellular protein content was determined as described above (46).

Statistics. For statistical analysis, the Student's *t*-test for paired or unpaired samples was used as applicable (* = $P \leq 0.05$; ** = $P \leq 0.01$).

RESULTS

Binding of [^{125}I]labeled HDL_3 subfractions A and B. The HDL_3 density class represents a mixture of particles differing in their apo pattern. The further separation by heparin–sepharose affinity chromatography revealed two main fractions, alternatively containing apo A-I (fraction A) or apo A-I plus apo A-II (fraction B,) which both were used for further experiments. Specific binding of [^{125}I]labeled HDL_3 fractions A and B was saturable and concentration-dependent (Fig. 1). Compared to fraction A, the apo A-II containing fraction B showed a lower level of specific binding at all concentrations tested (Fig. 1). The maximal binding capacity (B_{max}) for fraction A, as derived from Scatchard analysis of the mean values, amounted to 4427 ng/mg cell protein, and the dissociation constant (K_D) was 40.5 μg/mL (correla-

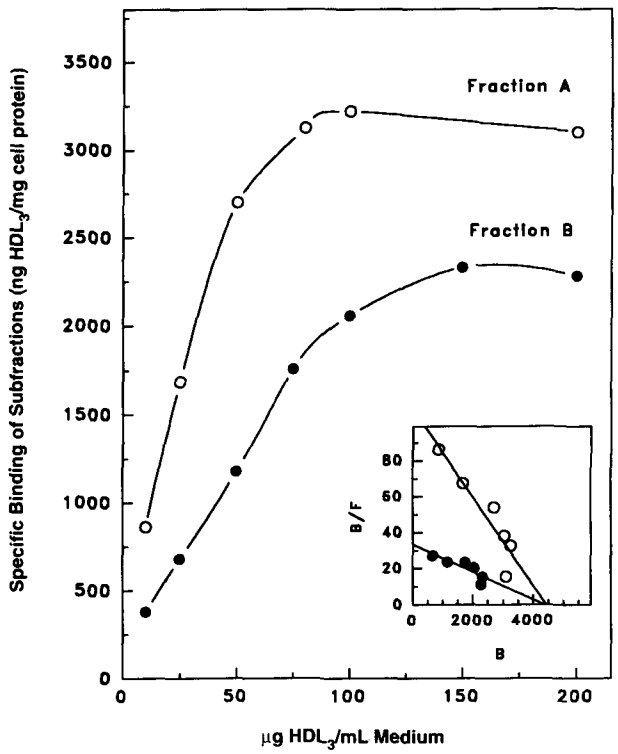

FIG. 1. Binding of HDL_3 subfractions A and B. CaCo-2 cells were cultured with 20% fetal calf serum until day five, 100 μg/mL low density lipoprotein were added from days three to five, and binding was measured at 4°C for 2 h as described in the Materials and Methods section. The curves show specific binding and the corresponding Scatchard analysis, which was calculated from the mean values. The data represent the mean values of two separate experiments (which varied by less than ±8%). Abbreviations: HDL, high density lipoprotein.

tion coefficient r = 0.927). The corresponding values for fraction B were 5041 ng/mg cell protein and 167.7 μg/mL (K_D) (r = 0.832).

Cholesterol synthesis from [^{14}C]octanoate and HDL$_3$ subfraction A- and B-mediated efflux. In this set of experiments, cholesterol synthesis was measured with small amounts of octanoate which did not effectively enhance cellular cholesterol content. The labeling process included prelabeling as well as continuous labeling during the efflux phase of the incubation. The synthesis rate of cholesterol in controls ranged from 20.7 to 38.8 nmol C_2-flux/mg/48 h (n = 8) with a mean value of 26.9 nmol C_2-flux/mg/48 h. Newly synthesized cholesteryl esters of controls varied between 5 and 10% of total cholesterol with a mean value of 6%. With both HDL$_3$ fractions, total cholesterol synthesis was induced and increased moderately, but dose dependently, from 28.8 ± 3.9 up to 39.7 ± 9.5 nmol C_2-flux/mg/48 h (fraction A) and from 30.5 ± 1.1 up to 36.7 ± 1.4 nmol C_2-flux/mg/48 h (fraction B) (Fig. 2).

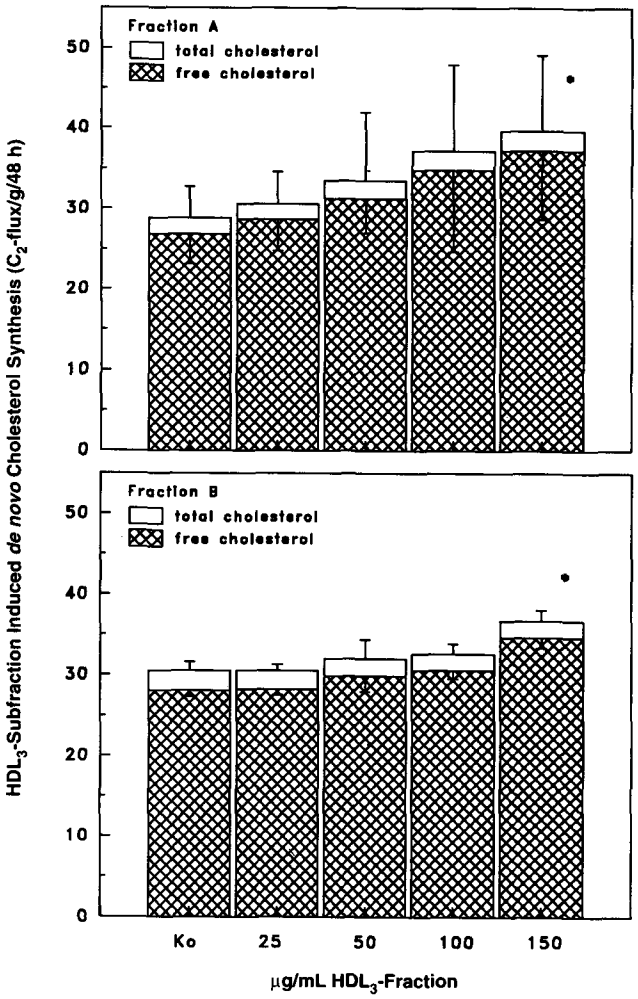

FIG. 2. HDL$_3$ subfraction induced changes in free, esterified and total cholesterol. Cells were treated as described in Table 1. Free and esterified cholesterol of cells and medium were extracted as described in the Materials and Methods section, and the values for cells and medium were combined. The data represent nmol C_2-flux/mg/48 h of three separate experiments ± 1 SEM *$P \leq 0.05$; abbreviations as in Figure 1.

Interesting changes in cholesterol distribution between cells and medium were also observed. The intracellular cholesterol moiety varied only minimally, but most of the HDL$_3$-induced, newly synthesized cholesterol was found in the culture medium. Compared to medium controls, the labeled free cholesterol in the medium was stimulated up to 173% (fraction A) and up to 143% (fraction B) (Table 1). This stimulation was found to be significant for both fractions at the highest concentration tested (Table 1), but remained just below the significance level, if both fractions were compared to each other.

Notably, both fractions predominantly effected an efflux of free as compared to esterified cholesterol into the medium. The C_2-flux into the ester portion in control cells did not exceed 8.7% of total cholesterol flux, and in the medium a maximal value of 6.8% of total was reached. Therefore, changes in esterified cholesterol affected only a very small amount as compared to free cholesterol. Nevertheless, a somewhat distinct distribution profile was observed for esters. With fraction A, total esterified cholesterol synthesis was slightly enhanced to 117 ± 20.5% of controls, whereas esterified cholesterol in

TABLE 1

HDL$_3$ Subfraction Mediated Changes of Labeled Free and Esterified Cholesterol[a]

HDL$_3$ (μg/mL)	Free cellular cholesterol	Free medium cholesterol	Esterified cell cholesterol	Esterified medium cholesterol
HDL$_3$ (fraction A)				
25	106.3 ± 4.1	109.7 ± 7.0	94.0 ± 12.1	105.3 ± 14.1
50	112.2 ± 3.1	123.5 ± 8.9	100.4 ± 3.0	126.8 ± 10.1
100	106.3 ± 7.4	155.6 ± 20.8	105.4 ± 4.0	132.1 ± 19.9
150	104.7 ± 8.3	173.3 ± 24.6[b]	95.6 ± 21.0	147.8 ± 31.2
HDL$_3$ (fraction B)				
25	103.1 ± 3.2	97.8 ± 5.4	88.3 ± 16.2	101.5 ± 4.0
50	103.4 ± 7.8	109.3 ± 8.8	88.0 ± 3.8[c]	89.4 ± 15.8
100	97.5 ± 2.8	120.8 ± 9.8	76.1 ± 6.9[c]	98.9 ± 25.7
150	104.7 ± 2.6	143.3 ± 13.1[c]	67.4 ± 13.1[b]	118.2 ± 24.7

[a]The data show changes in percentage of their corresponding control values measured separately in cells and in medium. Cells were grown in Dulbecco's minimal essential medium with 20% fetal calf serum (FCS) until day seven. Between days seven and nine, FCS was replaced by 10% lipoprotein deficient-FCS and only [^{14}C]octanoate was present for these 48 h. High density lipoprotein (HDL)$_3$ subfractions were added only for the last 24 h until day nine, without medium change. Free and esterified cholesterol of cells and medium were extracted separately as described in the Materials and Methods section. The C_2-fluxes (nmol/mg/48 h) are given as percent of controls ± SEM. For free cell cholesterol, the flux into controls was 12.79 ± 1.55 (fraction A) and 14.66 ± 0.85 (fraction B). For medium cholesterol the controls were 12.90 ± 2.45 (fraction A) and 13.46 ± 0.13 (fraction B). For esterified cell cholesterol, the controls refer to 1.16 ± 0.04 (fraction A) and 1.39 ± 0.19 (fraction B). For esterified medium cholesterol, the controls amounted to 0.84 ± 0.19 (A) and 0.98 ± 0.13 (B). The data represent the mean of three separate experiments.
[b]$P \leq 0.01$.
[c]$P \leq 0.05$.

the medium rose not significantly, up to 148% of controls, and the intracellular portion remained essentially constant (Table 1). With fraction B, total esterified cholesterol fell to 88 ± 11.1% of control values, whereas the esters in the medium reached 118%, and the cellular ester portion significantly decreased to 67% of controls (Table 1).

Kinetics of the HDL subfraction A- and B-mediated efflux. In this set of experiments, MVL was used as a precursor as well as [^{14}C]MVL as label, to bypass the regulatory enzyme hydroxymethylglutaryl coenzyme A (HMG–CoA) reductase and to effectively load the cells with cholesterol. In a separate experiment it was shown that CaCo-2 cells normally contained about 38.5 ± 4.1 µg cholesterol/mg protein (30.3 ± 2.0 µg/mg of free and 8.2 ± 2.0 µg/mg of esterified cholesterol, n = 6). The cholesterol content could be effectively enhanced by the incubation with MVL up to values of 52.9 ± 12.9 µg/mg (36.9 ± 12.5 µg/mg of free and 16.0 ± 4.0 µg/mg of esterified cholesterol, n = 4). Compared to albumin, which was present in controls and acted as an unspecific cholesterol acceptor, fraction A actively enhanced the basal cholesterol efflux dose dependently ($P \leq 0.05$) (Fig. 3A). It showed similar kinetics in cholesterol loaded cells, but with higher efficiency (Fig. 3C). The inhibition of cholesterol esterification during the labeling incubation reduced the induced efflux of label to the level of nonloaded cells (Fig. 3E), but remained significantly ($P \leq 0.05$) above that of controls. In contrast, fraction B enhanced the efflux in nonloaded cells significantly only at the highest concentration tested ($P \leq 0.05$) (Fig. 3B). Its effect on loaded cells was more pronounced (Fig. 3D), but did not reach the efficiency of fraction A. Compared to fraction A, its efflux potential could be completely blocked by the simultaneous inhibition of the esterification of the nascent labeled cholesterol (Fig. 3F).

Binding of [^{125}I]labeled liposomes, reconstituted from DMPC and apo (Lip A-I and Lip A-II). According to a previously described procedure (17) to characterize binding and the fate of HDL_3 (fraction A), similar experiments were performed with the apo A-containing liposomes. Labeled liposomes, Lip A-I and Lip A-II, exhibited specific binding to CaCo-2 cells at 4°C with saturation kinetics (Figs. 4 and 5). Equilibrium of binding at 4°C was reached after nearly 2 h for both Lip A-I and Lip A-II (data not shown). Derived from Scatchard analysis of the mean values, the binding characteristics of the liposomal particles were calculated. The B_{max} of Lip A-I amounted to 7445 ng/mg cell protein and the binding affinity K_D was 99.9 µg/mL (r = 0.920) (Fig. 4). The corresponding values for Lip A-II showed a B_{max} of 5024 ng/mg cell protein and a K_D of 47.3 µg/mL (r = 0.972) (Fig. 5).

In a separate series of experiments, Lip A-I and Lip A-II were prebound to the cells at 4°C, and their fate was followed during subsequent warm-up at 37°C (Fig. 6). The amount of the specifically membrane bound Lip A decreased rapidly to approximately half of the initial value within 1 h for Lip A-I and within 2 h for Lip A-II. Simultaneously, the medium release of intact particles showed a complementary rise (Fig. 6).

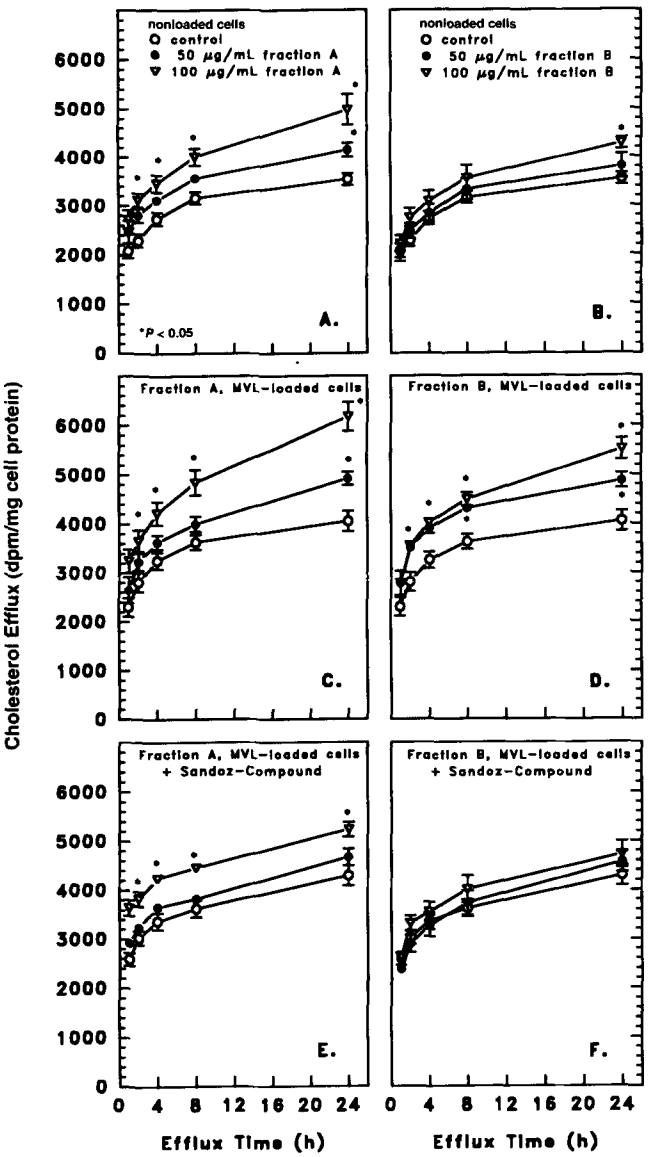

FIG. 3. Efflux kinetics mediated by HDL_3 subfractions A and B after cholesterol prelabeling. Cells were prepared as described in the Materials and Methods section. A + B demonstrate the efflux in nonloaded, prelabeled cells, C + D the efflux after preincubating of the cells with 5 mM mevalonolactone (MVL), E + F show changes after the additional supplementation with 5 µg/mL Sandoz-Compound 58035 during the labeling process to inhibit the esterification of newly formed cholesterol. The data represent the mean values of three to five separate experiments ± SEM. Significance levels are relative to controls. *$P \leq 0.05$; abbreviation as in Figure 1.

Studies with gold labeled Lip A-I and Lip A-II. The artificial liposomes reacted with gold similarly to the native HDL_3, as described previously (16,17). The labeled liposomes were identified by negative staining (Figs. 7 and 8). The particle volumes were comparable to native HDL_3 and resembled the native fraction A (data not shown). The membrane associated, labeled particles were predominantly found basolaterally. For both, internalization was shown by the membrane areas forming coated pits

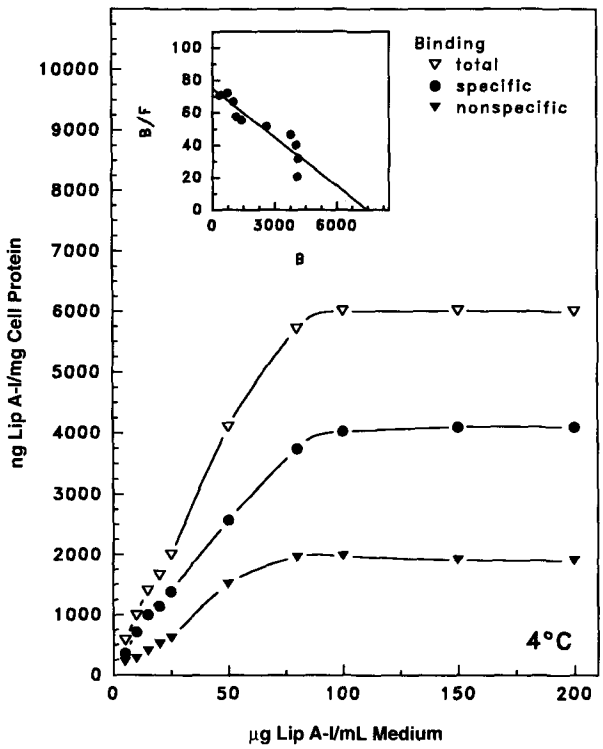

FIG. 4. Concentration dependent binding of liposome A-I (Lip A-I) at 4°C. Specific and unspecific binding were measured, and the Scatchard plot was calculated from the mean values. The data represent the mean values of two separate experiments (which varied by less than ±9%).

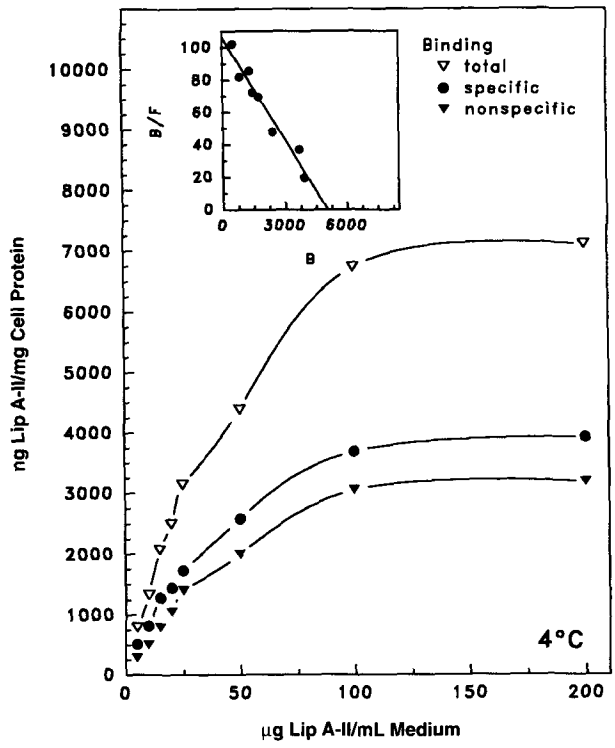

FIG. 5. Concentration dependent binding of liposome A-II (Lip A-II) at 4°C. Specific and unspecific binding were measured, and the Scatchard plot was calculated from the mean values. The data represent the mean values of two separate experiments (which varied by less than ±15%).

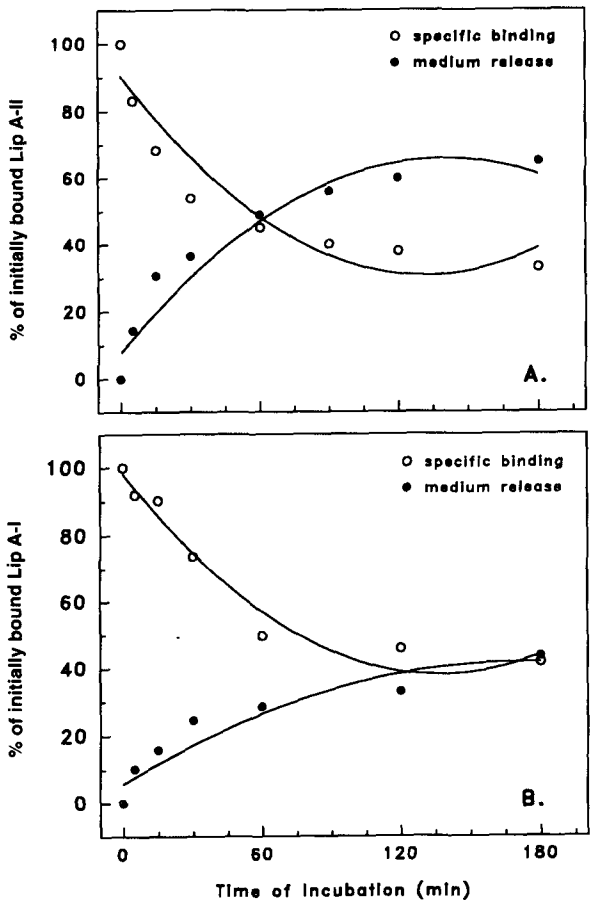

FIG. 6. Medium release of prebound liposome A-I (Lip A-I) and liposome A-II (Lip A-II). At day five, cells were incubated with 10 µg/mL [^{125}I]Lip A-I or [^{125}I]Lip A-II for 2 h at 4°C, to allow specific binding. Subsequent warm-up to 37°C after removing the medium and intensively washing the cells led to a time-dependent reduction of membrane bound [^{125}I]Lip A-I (A) and [^{125}I]Lip A-II (B) and a simultaneous appearance of intact labeled particles in the medium. The data represent the mean values of two separate experiments (which varied by less than ±13%).

as well as by internalized endosomal gold-labeled particles (Figs. 7 and 8). Lip A-I also was detected close to partially dissolved lipid droplets (Fig. 7D). Both liposomal particles were found in normal as well as in bloated endosomes, containing curled membrane fragments.

Efflux kinetics of Lip A-I-mediated efflux after cholesterol prelabeling. Lip A-I were used to monitor the efflux capacity of liposomal particles. Similar to the native lipoprotein fractions, Lip A-I was added after prelabeling the cells as described above. Interestingly, both concentrations of the liposomal fraction used resulted in a similar efflux efficiency (Fig. 9), which was slightly higher than that observed with fraction A. This was true for non- and MVL-loaded cells (Fig. 9A,B). The cells, additionally incubated with Sandoz-Compound 58035, also showed a very high efflux (Fig. 9C), much higher than that observed with fraction A.

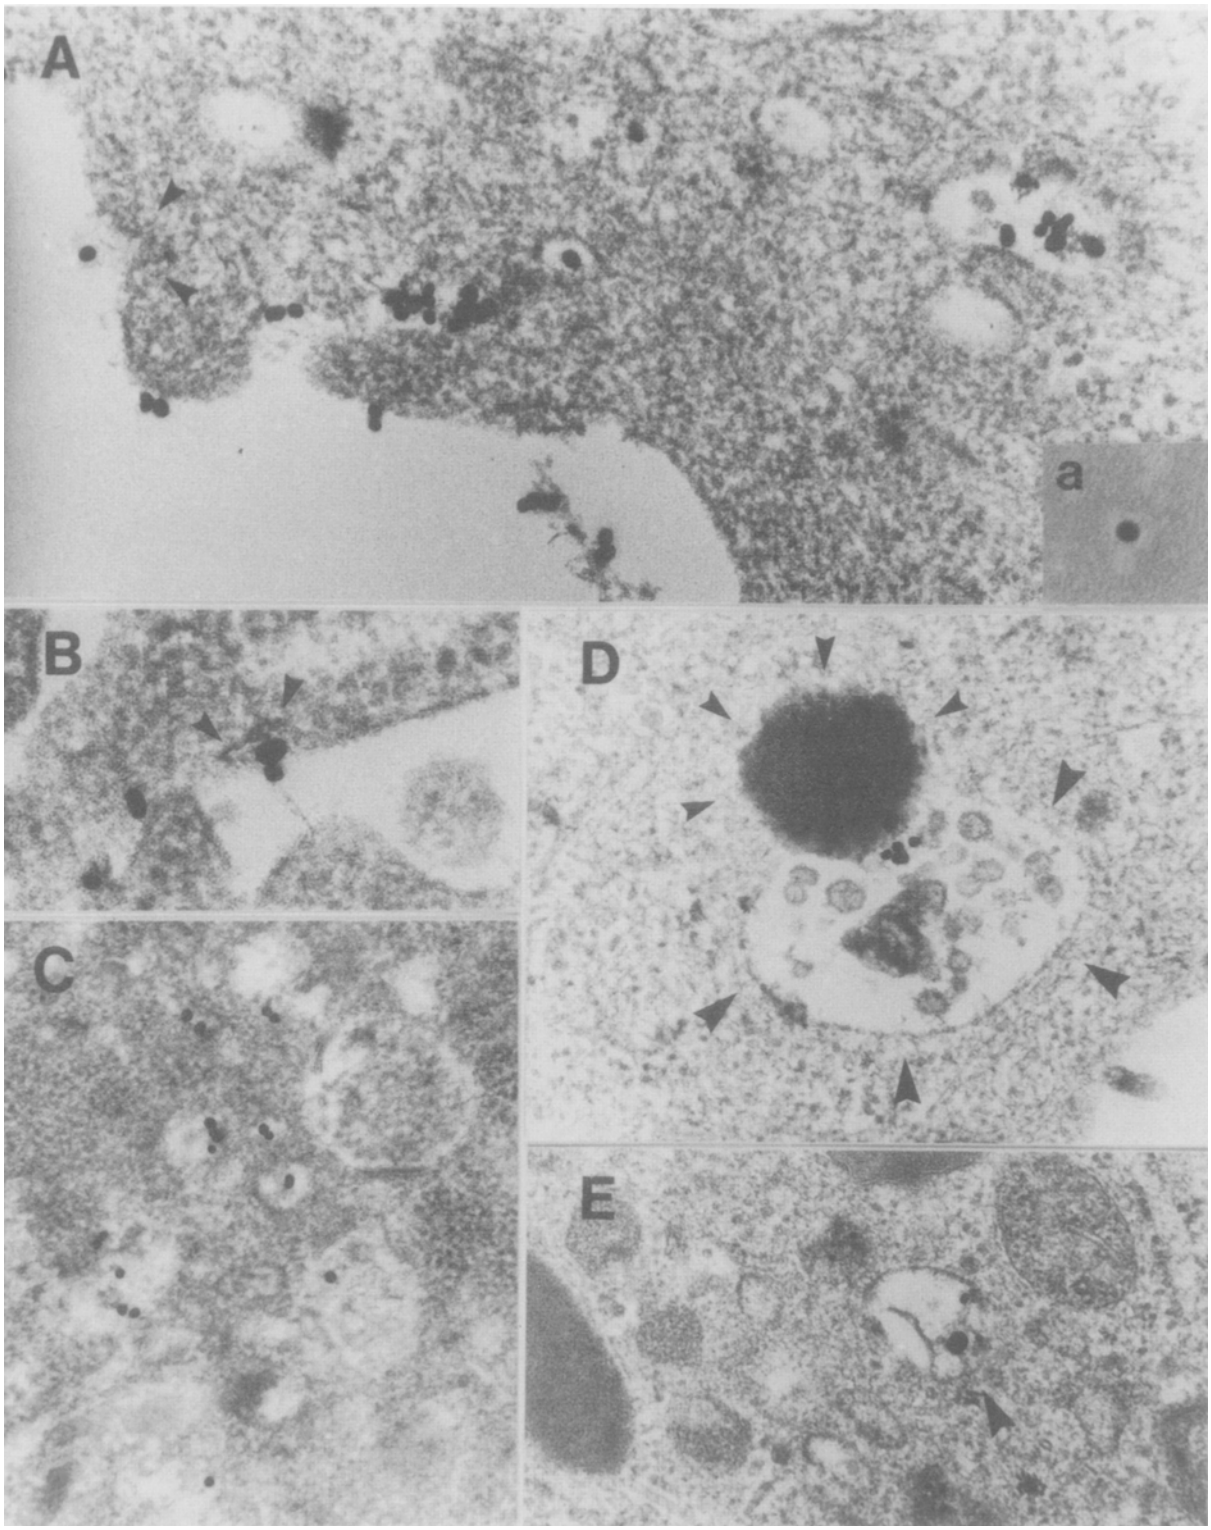

FIG. 7. Electron microscopy of gold labeled liposome A-I (Lip A-I). The fate of gold-labeled liposomes was followed after a 2-h incubation at 37°C, washing the cells and subsequent fixation. Basolateral binding as well as internalization was seen. (A) Electron micrograph shows binding, formation of a coated pit (small arrow heads), and endosomal uptake and intracellular transport (arrows) of the gold-labeled liposomes; magnification (M), 80,000-fold. The right lower corner shows the gold-liposome complex by negative staining (a). (B) Membrane binding site, forming a coated pit, M, 110,000-fold. (C) Multiple endosomal structures, containing the gold label; M, 60,000-fold. (D) Bloated endosome (small arrow heads) in direct contact with the remainder of a lipid droplet (small arrows). The endosome contains curled membrane fragments; M, 60,000-fold. (E) Another gold label in an endosomal structure, also containing residual membrane fragments; M, 60,000-fold.

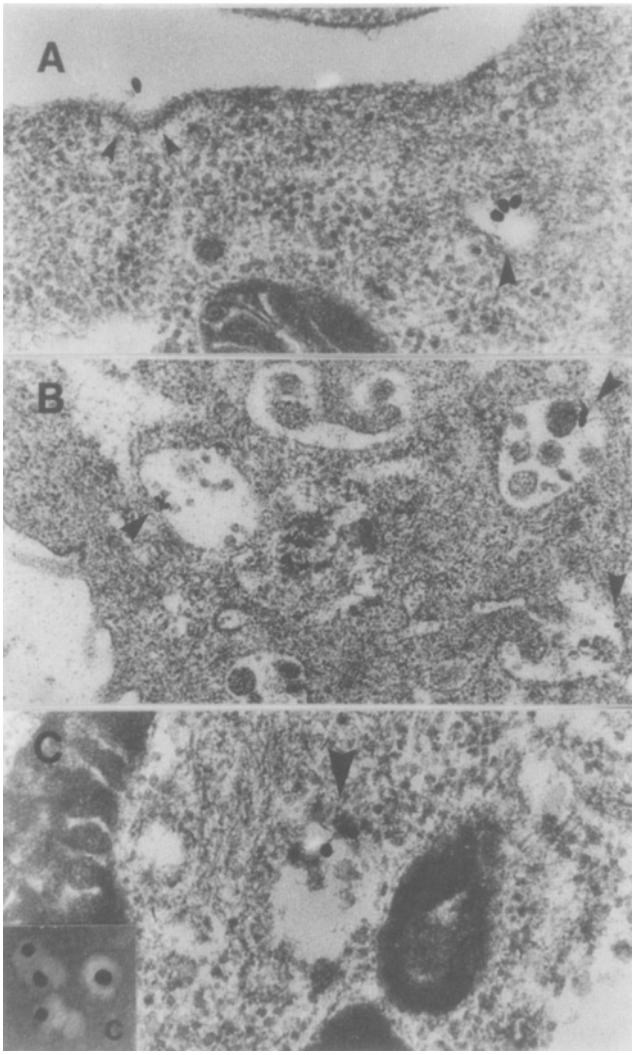

FIG. 8. Electron microscopy of gold-labeled liposome A-II (Lip A-II). The fate of gold-labeled liposomes was followed after a 2-h incubation at 37°C, washing the cells, and subsequent fixation. Basolateral binding as well as internalization was seen. (A) Membrane associated gold label, inducing the formation of a coated pit (small arrow heads) and gold-labeled Lip A-II located in an endosome; magnification (M) 80,000-fold. (B) Some bloated endosomal structures, containing membrane fragments, as shown for Lip A-I; M 40,000-fold. (C) Demonstration of such an endosomal structure in greater detail; M 80,000-fold. Left lower corner, negative staining of the gold-liposome complex (c).

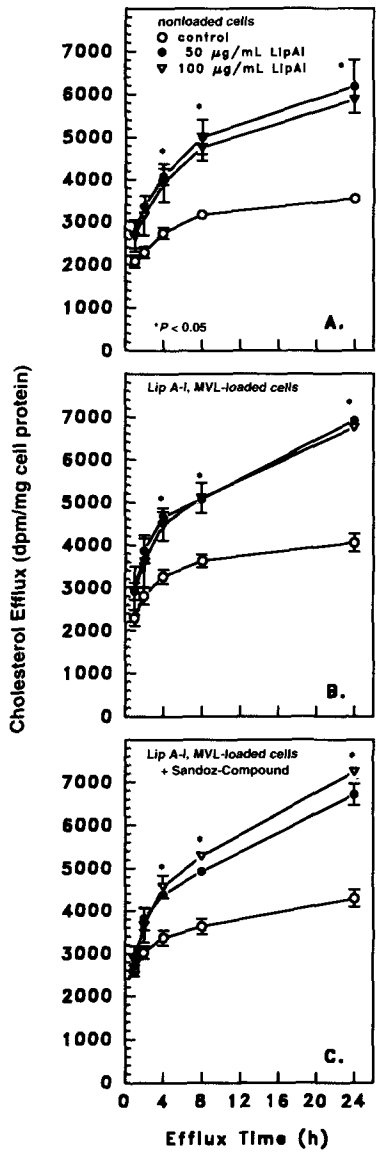

FIG. 9. Efflux kinetics of liposome A- (Lip A-I) after cholesterol prelabeling. Cells were prepared and treated as described in the Materials and Methods section. The experimental design corresponded to that in Figure 3. (A) shows the efflux in nonloaded cells; (B) the efflux after preloading of the cells with 5 mM MVL; (C) shows changes after additional supplementation with 5 µg/mL Sandoz-Compound 58035 during the labeling process to inhibit the esterification of newly formed cholesterol. The data represent the mean values of three separate experiments ±1 SEM. Significance levels refer to controls. *$P \leq 0.05$. See Figure 3 for abbreviation.

DISCUSSION

In cultured enterocytes, HDL-mediated efflux was recently shown to involve a complicated pathway of cell surface binding, endosomal internalization and lysis of lipid droplets, followed by retroendocytosis of the particles (16,17). Thus, unlike HDL_2, which delivers cholesterol to cells in a similar manner to LDL (25,27,28), HDL_3 has its own receptor pathway (11–17) and acts as a cholesterol acceptor. During the previous studies, the HDL_3 subfraction used was equivalent to fraction A in the present study, i.e., it contained only apo A-I. However, because HDL_3 prepared by ultracentrifugation contains other apo, in particular A-II, it was of interest to compare fractions differing in their apo composition. The apo and lipid compositions clearly depend on the method of isolation and have been shown to affect binding and probably cholesterol efflux (33–36,38,39). However, studies in macrophages with particles differing in the apo A-I/apo A-II ratio obtained by preparative isoelectric focusing (36) or isotachyphoresis (35) gave opposite results. When different particle populations containing either apo A-I or apo A-I plus apo A-II were ob-

tained by immunoaffinity chromatography (34), only the apo A-I containing fraction promoted cholesterol efflux. Nevertheless, both particles displayed specific binding within the same range of concentrations. Another approach used the substitution of apo A-I by apo A-II in intact HDL_3 (38) or a combination of immunological methods and apo A-II enrichment of HDL_3 (39). These well designed binding experiments led us to postulate that the mechanisms involved probably differ between apo A-I and apo A-II containing particles. The lack of agreement in the respective literature is probably due to differences in particle preparation resulting in variable particle compositions. Therefore, it seemed appropriate to use native particles of different apo compositions obtained by a method which was able to clearly separate two quantitatively important subfractions, a pure apo A-I fraction from the mixed fraction. The characterization of the binding properties of the two fractions described above revealed a higher specific binding affinity of the apo A-I particles (fraction A) as compared to the apo A-I/apo A-II containing fraction B, but the maximal binding capacity of both fractions was similar. An inverse affinity pattern between distinct apo A-I and apo A-I/apo A-II containing particles was reported for endothelial cells (39). No differences, depending on the apo composition, were observed in adipose cells (34) and macrophages (36). Thus, intestinal epithelial cells appear to differ with respect to these binding patterns from most other cell types.

Considering the differences in binding of both fractions, it was of interest to study the efflux characteristics. In one experiment, cholesterol synthesis was labeled before (24 h) and during (24 h) the incubation with the HDL_3 subfractions. With the use of the label [^{14}C]octanoate, the mechanisms of feedback regulation remained intact and accumulation of excess cholesterol could be avoided. The amount of labeled cellular cholesteryl esters did not exceed 10% of the total cholesterol label. Both fractions mainly stimulated the synthesis of free cholesterol dose dependently in these nonloaded cells, whereas the ester portion remained nearly unchanged. Fraction A was more effective in releasing cholesterol particularly at lower concentrations. Interestingly, the excess cholesterol was completely found in the medium, whereas the portion of cellular free cholesterol remained unchanged. Changes of the very small amount of esterified cholesterol were quantitatively less important, although a significant reduction in the amount of labeled cellular esters by fraction B was noted. The results indicated a net loss of free cholesterol, which was apparently balanced by the induction of synthesis. The findings were compatible with a HMG–CoA reductase (EC 1.1.1.34) induction by unfractionated HDL_3 observed in rat intestinal crypt cells (27) and CaCo-2 cells (52). Simultaneously, an inhibition of acyl-CoA:cholesterol acyltransferase (ACAT; EC 2.3.1.26) was observed, which explains decreased cholesteryl ester formation (52).

At any rate, simple cholesterol exchange mechanisms (53) simulating the observed net efflux of labeled cholesterol may be excluded. A reduction of cellular cholesterol mass (free and esterified) was observed previously in cholesterol and cholesteryl ester loaded cells (17) and recently also in normal cells (unpublished data). Loading with MVL effectively enhanced total cellular cholesterol, mainly in the esterified form, and enlarged the efflux sensitive cholesterol pool. As recently shown, cholesterol enriched cells displayed more HDL receptors because they are subject to up- and downregulation, depending on the cellular cholesterol content (6,17). This may explain why the amount of cholesterol efflux, particularly by fraction A, was related to the intracellular cholesterol excess.

The medium cholesterol detected in control experiments may be due to serum proteins, especially albumin acting as potential acceptors (54, and unpublished data). In addition, CaCo-2 cells synthesize and secrete lipoproteins basolaterally as has been shown previously (43,55). Compared to the secretion of triglycerides and phospholipids, the amount of secreted cholesteryl esters was low, especially when the medium contained LPD-FCS (43). Because the ester portion in our medium was also very low, it seems possible that small amounts of cholesteryl esters were actively secreted by lipoprotein formation. However, such a contribution is unlikely to be specifically induced by HDL_3 and therefore does not explain the differential between controls and under HDL_3 supplemented conditions.

To further discriminate the observed relationship in cholesterol synthesis and efflux, efflux was studied in normal and cholesterol-enriched cells which had been labeled with [^{14}C]MVL. Although the kinetics of efflux in the presence of HDL_3 were quite similar in nonloaded and loaded cells, the efflux efficiency in loaded cells was higher for both fractions. Compared to fraction A, fraction B was less effective in promoting efflux from nonloaded cells which were low in cholesteryl esters. Fraction A also mediated efflux of labeled cholesterol in mevalonolactone loaded cells if the esterification of the labeled, newly synthesized cholesterol was blocked by an ACAT-inhibitor, whereas fraction B did not. The total amount of fraction A-induced efflux was reduced as compared to loaded but untreated cells, suggesting that accessible pools of cholesteryl esters were reduced. These findings provide evidence that the apo A-II containing fraction B predominantly mobilized esterified cholesterol and was less effective, compared to fraction A, in mediating efflux of excess free cholesterol. Electron microscopic observations demonstrated a direct interaction between endosomes, containing labeled fraction A (16,17) or labeled liposomes and lipid droplets. It may be hypothesized that these cholesteryl ester stores and their hydrolysis represent the cholesterol substrate for efflux. Recent work had also demonstrated intracellular traffic of HDL (56), involvement of the trans-Golgi system (56,57), and possibly exocytosis as HDL_2-like, apo E enriched particles (58).

Previous results reported for other cells in regard to cholesterol efflux mediated by lipoprotein particles either containing apo A-I or apo A-I and apo A-II have been controversial. With native lipoprotein fractions of varying apo A-I/apo A-II ratios, a predominant role of

apo A-I had been demonstrated in adipose cells, whereas efflux was inhibited with increasing apo A-II concentrations (34). Another study on the same cell line showed that cholesterol efflux was promoted only by native HDL_3 particles containing apo A-I (33). Artificial liposomes of different apo A-I/apo A-II ratios also had an efflux potential which decreased with an increase in apo A-II content (33). The preparation of six distinct subpopulations of HDL, differing in their apo A-I/apo A-II ratios, had comparable effects on the efflux from peritoneal macrophages (36), while other macrophage studies (35) identified apo A-I as the predominant apo. Johnson *et al.* (37) found either normal or cholesterol loaded, no particle specific differences in three cell types. From these data it could be concluded that apo A-I plays the dominant role in mediating efflux (4, 33–35), whereas apo A-II may even be antagonistic to the process (33,34). The present results in enterocytes are consistent with a reduced efflux potential of apo A-II, but for the first time suggest cholesteryl ester efflux by apo A-II containing particles.

For further characterization, the binding of apo A-I and of apo A-II was studied separately, using previously described liposomal preparations (33,59). These liposomes mainly differed in their lipid composition from native or apo A-II enriched HDL_3 and less so in size. Compared to the apo A-I subfraction A, the apo A containing liposomes differed with respect to binding affinity and maximal binding capacity. Lip A-I showed a higher B_{max} and lower affinity than the corresponding native particle, whereas Lip A-II resembled fraction A in affinity. Similar but lower binding affinities were found with apo A-I and apo A-II liposomes in rat ovaries (60). It remains to be clarified why the measured K_D values of native and reconstituted particles were somewhat higher as compared to other experimental systems (34–36) dealing with different particles derived from plasma. Both gold-labeled liposome particles displayed endocytosis, intracellular endosomal packing and contacts to lipid droplets, as shown for HDL_3 (17). Prebound Lip A-I and Lip A-II were released as intact particles, similar to the native particles (17). Taken together, these findings also support the retroendocytosis concept for liposomal particles.

Finally, the liposomal binding and uptake studies were complemented by experiments demonstrating that Lip A-I induced efflux. Lip A-I induced an efflux of cholesterol at a maximal rate, which was slightly above that of fraction A. Unlike fractions A and B, efflux was not reduced if esterification was inhibited, suggesting that accessible pools of free cholesterol were depleted.

In conclusion, efflux efficiency was influenced by the cholesterol and ester content of the cells and by the apo pattern of the HDL_3 particles. There is evidence that both apo, A-I and A-II, were bound specifically and were retroendocytosed. Apo A-I played the dominant role for the receptor mediated cholesterol efflux in cultured enterocytes, but the apo A-II content did not prevent efflux. The apo A-II content may preferentially account for the mobilization of cellular cholesteryl esters, therefore mainly promoting efflux from cholesterol-enriched cells.

The Effects of Clofibrate and Bezafibrate on Cholesterol Metabolism in the Liver of the Male Rat

J.H. Shand and **D.W. West***

Hannah Research Institute, Ayr, KA6 5HL, Scotland

Fibric acid derivatives are used to treat hyperlipidemia and have wide ranging effects on lipid metabolism. The action of these compounds on cholesterol esterification, catalyzed by acyl-coenzyme A:cholesterol acyltransferase (ACAT), has been quite widely studied, but their effect on cholesteryl ester hydrolysis and the enzyme neutral cholesteryl ester hydrolase (nCEH) has been largely ignored. Male rats were therefore fed for 10 d on a standard chow diet supplemented with either clofibrate or bezafibrate, to study their effects on plasma lipid levels and hepatic cholesterol metabolism. Plasma triacylglycerols were not significantly altered by these diets, but bezafibrate significantly lowered plasma cholesterol levels (29.7%, $P < 0.01$). When expressed per unit weight of DNA, both fibrates reduced the hepatic content of triacylglycerol, cholesterol and cholesteryl esters (40, 18.7, 16.5 and 66.7, 28.6, 34.2% for clofibrate and bezafibrate, respectively). ACAT activity was significantly reduced by both drugs, but clofibrate (65% inhibition) was more effective than bezafibrate (35% inhibition). The most dramatic effect of the diets was a marked increase in the activity of both the microsomal and the cytosolic nCEH. When expressed on a whole liver basis, the effect of bezafibrate on the cytosolic enzyme (13.6-fold increase in activity) was much greater than that of clofibrate (4.8-fold increase). Increases in the activity of a cytosolic protein that inhibits the activity of nCEH were also noted, but these changes were relatively small. The results suggest that the activation of nCEH, in combination with the inhibition in ACAT activity, contributes to a decrease in the cholesteryl ester content of the liver which may influence the secretion of very low density lipoprotein.
***Lipids* 29, 747–752 (1994).**

The fibric acid derivatives clofibrate and bezafibrate are used in the treatment of hyperlipidemia in patients at risk from coronary artery disease and in some diabetics whose hyperlipidemia cannot be controlled by other means. Despite their wide use, the mechanisms by which these compounds exert their hypolipidemic effects are not yet clear but seem to involve both increased clearance of very low density lipoprotein (VLDL), through activation of lipoprotein lipase, and, to a lesser extent, to a decreased production of triglycerides (1–3). In addition, these agents cause substantial reductions in plasma cholesterol (4–6) although again the mechanism of this effect is unknown.

The hepatic metabolism of cholesterol involves four key enzymes as well as receptors, controlling the uptake of lipoprotein particles from plasma. The synthesis of cholesterol is catalyzed by 3-hydroxy-3-methylglutaryl coenzyme A (HMG-CoA) reductase while cholesterol 7α-hydroxylase governs the catabolism of cholesterol to bile acids. The formation of cholesteryl esters, the storage form of cholesterol in the liver, is catalyzed by acyl-coenzyme A:cholesterol acyltransferase (ACAT) (7,8) while the hydrolysis of the esters back to free cholesterol is due to the action of a neutral cholesteryl ester hydrolase (nCEH) (9). Most of the fibric acid derivatives appear to inhibit ACAT (4,5,9) while the more potent derivatives, such as bezafibrate, also inhibit HMG-CoA reductase and cholesterol 7α-hydroxylase (4,5,10) and, at the same time, stimulate cholesterol excretion by increasing the biliary output of the sterol (11,12).

An important aspect of hepatic cholesterol metabolism that appears to have been largely neglected is the possible involvement of nCEH in the mechanism of action of these hypolipidemic agents. It may, nevertheless, have a major role since its substrate, the pool of cholesteryl esters, will be influenced by the decline in ACAT activity. Such an effect has been suggested to explain the fibrate-induced loss of cholesteryl esters from cultured 3T3 fibroblasts (13,14).

In addition to possible variations in the activity of the nCEH, we have also shown that the activity of a hepatic protein inhibitor of this enzyme can be varied under a variety of hormonal and nutritional conditions (15,16). It is possible, therefore, that these hypolipidemic agents would also affect the activity of this protein, so altering nCEH activity.

In the present study we have fed clofibrate and bezafibrate to male rats and have demonstrated that, in addition to inhibiting ACAT and altering the cholesterol content of the liver, a major effect of these drugs was to cause a marked increase in the activity of hepatic nCEH, both cytosolic and microsomal. Minor changes in the activity of the cytosolic inhibitor of nCEH were also noted.

MATERIALS AND METHODS

[9,10(n)-^{3}H]Oleic acid (370 GBq/mmol), [9,10(n)-^{3}H]triolein (370 GBq/mmol), [1-^{14}C]oleic acid (2 GBq/mmol) and cholesteryl [1-^{14}C]oleate (2 GBq/mmol) were obtained from Amersham (Little Chalfont, United Kingdom). Cholesteryl [9,10(n)-^{3}H]oleate and [9,10(n)-^{3}H]oleoyl CoA were synthesized as described (15,17). Dithiothreitol was purchased from Calbiochem (Nottingham, United Kingdom). All other biochemicals were from Sigma (Poole, United Kingdom).

Animals and diets. Male Wistar rats, weighing about 120 g at the start of the experiment, were kept on a constant light/dark cycle (lights on 08.00–20.00 h) and were fed for 10 d on crushed CRM(X) breeding diet (Special Diet Services, Manea, Cambridgeshire, United Kingdom) containing 2.4% (w/w) fat and less than 0.01% (w/w) cholesterol. One group of rats was fed the control diet while two other groups were fed the same basic diet supplemented with either clofibrate or bezafibrate (0.3% w/w). These

Abbreviations: ACAT, acyl-coenzyme A:cholesterol acyltransferase; C, cholesterol; CE, cholesteryl ester; nCEH, neutral cholesteryl ester hydrolase; HMG-CoA, 3-hydroxy-3-methylglutaryl coenzyme A; SEM, standard error of the mean; TRIS, tris(hydroxymethyl)-aminomethane; VLDL, very low density lipoprotein.

agents were incorporated by mixing an acetone solution with the crushed diet and then allowing the solvent to evaporate for at least 48 h. The control diet was treated in the same way but with acetone alone. The rats were fed at 08.30 h at a rate of 30 g per rat per day and were weighed at daily intervals. At the end of the experimental period, the animals were killed by cervical dislocation at 09.30 h, i.e., 25 h after their last feed, and the livers were excised, weighed, and frozen in liquid nitrogen. Blood samples were centrifuged immediately (10,000 × *g*) in heparinized tubes and the clear plasma samples stored at -20°C.

Tissue processing. Livers were homogenized as described (17) in 4 vol of ice-cold buffer consisting of 50 mM 2-(*N*-morpholino)ethanesulfonic acid, 50 mM tris(hydroxymethyl)aminomethane (TRIS)/HCl buffer, pH 7.2, containing 1 mM ethylenediaminetetraacetic acid, 1 mM ethyleneglycol-*bis*(2-aminoethyl)tetraacetic acid, 1 mM dithiothreitol and proteinase inhibitors (1 μg/mL each of pepstatin A, leupeptin and antipain). Microsomal and cytosolic fractions were then prepared according to the method of Shand *et al.* (18) and stored in aliquots at -80°C.

Enzyme assays. The activity of ACAT was assayed in microsomes (150 μg protein) by measuring the rate of conversion of [9,10(n)-^{3}H]oleoyl CoA (20 nmol, 250,000 dpm) to cholesteryl [9,10(n)-^{3}H]oleate as previously described using endogenous cholesterol as the substrate in a total volume of 0.2 mL (17). In addition, parallel assays were performed in the presence of exogenous cholesterol (200 μg/mL) added as a suspension of liposomes, prepared as described by Batzri and Korn (19) using cholesterol and phosphatidylcholine in a molar ratio of 1:2. All assays were preincubated for 30 min before addition of substrate and incubation time was limited to 5 min to ensure linearity. Cholesteryl [1-^{14}C]oleate was used as an internal standard to correct for recovery.

The activity of nCEH was measured, essentially according to Shand and West (15) using 50 μg of either microsomal or cytosolic protein in a total volume of 0.2 mL. The reaction was initiated by addition of an ethanolic solution of cholesteryl [9,10(n)-^{3}H]oleate (20 nmol, 1 × 10^6 dpm) and terminated after 45 min. [1-^{14}C]Oleic acid was then added as a recovery standard, and the rate of hydrolysis of the substrate was measured by estimation of the released [9,10(n)-^{3}H]oleic acid.

Triacylglycerol lipase in cytosols was assayed in an identical manner to nCEH using [9,10(n)-^{3}H]triolein as substrate.

Assay of the nCEH inhibitor protein. The liver cytosols were assayed for inhibitory activity against rat mammary gland microsomal nCEH essentially as described (15) using 30–40 μg of cytosolic protein. The quantity of cytosolic protein required to produce 50% inhibition of the nCEH was then calculated. Controls, without mammary gland microsomes, were incubated at the same time to allow correction for the activity of cytosolic nCEH.

Estimation of cholesterol and cholesteryl esters. Lipids, extracted (20) from the liver homogenates and microsomal suspensions, were redissolved in ethanol while those extracted from plasma lipids were resuspended, by sonication, in buffer containing 50 mM TRIS pH 7.9, 100 mM KCl, 20 mM KF and 0.05% (wt/vol) Triton X-100. The extracts were then assayed, with and without cholesteryl esterase, according to the fluorimetric method of Gamble *et al.* (21), to give the microsomal contents of total and free cholesterol, respectively. Esterified cholesterol could then be estimated by difference.

Estimation of triacylglycerols. Triacylglycerols were estimated directly in the liver homogenates and in the aqueous suspensions of the extracted plasma lipids by a modification of the method of McGowan *et al.* (22) using assay kit number 339-10 as supplied by Sigma.

Protein and DNA measurements. Protein concentrations were assayed by the dye-binding method of Bradford (23), using bovine serum albumin as standard, and DNA as described by Labarca and Paigen (24).

RESULTS

Body weight, liver weight and hepatic and plasma lipid levels. Neither of the dietary supplements affected the rate of body weight gain in the course of the experiment, but, in agreement with previous reports, liver weight was significantly increased by both clofibrate (21%; $P < 0.05$) and bezafibrate (50%; $P < 0.01$) by the end of the experiment (Table 1). The concentration of cholesterol in the plasma tended to be lower in the animals treated with the fibrates (Table 1), but only with bezafibrate did this achieve significance ($P < 0.05$). Both drugs also tended to decrease plasma triacylglycerol levels but neither produced a significant effect. The triacylglycerol levels in the liver, whether expressed on a cellular (i.e., related to DNA concentration) or whole liver basis, were significantly lowered by the dietary treatments (Table 2). Bezafibrate was more effective than was clofibrate since it reduced cellular and whole liver triacylglycerol by 63% ($P < 0.001$) and 32% ($P < 0.01$), respectively, compared with 38% ($P < 0.001$) and 15% ($P < 0.05$) for clofibrate.

The dietary supplementation with the fibric acid derivatives caused significant reductions in the levels of both free and esterified cholesterol in the liver when expressed on a DNA basis (Table 2), the most effective again being bezafibrate. However, when expressed on a whole liver basis, the differences disappeared.

TABLE 1

The Effect of Treatment with Clofibrate and Bezafibrate on Liver Weight and Plasma Lipid Levels[a]

Treatment	Liver weight (g)	Plasma	
		Triacylglycerol (mg/100 mL)	Total cholesterol (mg/100 mL)
Control (11)	8.4 ± 0.4	50.0 ± 2.6	44.1 ± 2.9
Clofibrate (6)	10.2 ± 0.5[b]	45.9 ± 2.5	40.0 ± 5.2
Bezafibrate (5)	12.6 ± 1.0[c]	45.5 ± 3.3	31.0 ± 2.1[c]

[a]Plasma triacylglycerols and total cholesterol were estimated in lipid extracts of plasma resuspended in buffer as described in the Materials and Methods section. The results are the means ± SEM for the number of animals given in parentheses. Significant differences from control values were determined using the Student's *t*-test.
[b]$P < 0.05$.
[c]$P < 0.01$.

TABLE 2

The Effect of Treatment with Clofibrate and Bezafibrate on Liver Lipid Levels[a]

Treatment	Triacylglycerol		Cholesterol		Cholesteryl esters	
	mg/mg DNA	mg/total liver	μg/mg DNA	mg/total liver	μg/mg DNA	mg/total liver
Control (11)	1.5 ± 0.1	77.8 ± 2.4	261.4 ± 15.0	15.5 ± 0.7	168.0 ± 7.6	10.7 ± 0.6
Clofibrate (6)	0.9 ± 0.06[d]	66.5 ± 4.4[b]	212.5 ± 3.9[c]	15.8 ± 0.3	140.2 ± 8.9[b]	10.4 ± 0.7
Bezafibrate (5)	0.5 ± 0.06[d]	53.2 ± 4.4[c]	186.6 ± 6.8[d]	19.1 ± 1.9	110.6 ± 4.8[d]	11.1 ± 0.7

[a]Liver triacylglycerol levels were determined directly in the tissue homogenates whereas liver cholesterol and cholesteryl esters were measured by means of a fluorimetric assay in lipid extracts dissolved in ethanol as described in the Materials and Methods section. The results are the means ± SEM for the number of animals given in parentheses. Significant differences from control values were determined using the Student's *t*-test. [b]$P < 0.05$. [c]$P < 0.01$. [d]$P < 0.001$.

ACAT and microsomal cholesterol and cholesteryl esters. The effects of dietary fibric acid derivatives on ACAT activity are shown in Table 3. When assayed using the cholesterol endogenous to the microsomes, clofibrate reduced the activity of ACAT by about 65% ($P < 0.001$) and in this instance was more effective than bezafibrate which caused only a 35% ($P < 0.01$) reduction in the activity of the enzyme. When exogenous cholesterol was included in the assay, the difference between the controls and the clofibrate-treated animals was maintained whereas the effect of bezafibrate became insignificant. The total ACAT activity in the whole liver was not significantly changed by bezafibrate but was reduced by about 56% ($P < 0.001$) by clofibrate.

A similar result was observed in relation to the levels of microsomal free and esterified cholesterol (Table 4) where clofibrate reduced these values to a greater extent than did bezafibrate. The ratio of free to esterified cholesterol in the microsomes was not affected by clofibrate treatment but was significantly raised by bezafibrate.

TABLE 3

The Effect of Treatment with Clofibrate and Bezafibrate on ACAT Activity[a]

Treatment	ACAT activity		
	pmol CE formed per min/mg microsomal protein		nmol CE formed per min/total liver
	Endogenous cholesterol	Exogenous cholesterol	
Control (11)	231.6 ± 19.5	597.9 ± 65.9	23.0 ± 1.8
Clofibrate (6)	79.9 ± 12.3[c]	226.8 ± 34.9[c]	10.1 ± 1.4[c]
Bezafibrate (5)	151.2 ± 14.1[b]	435.6 ± 52.1	20.0 ± 2.9

[a]Acyl-CoA:cholesterol acyltransferase (ACAT) activities were assayed using 150 μg microsomal protein incubated with [9,10-^{3}H]oleoylCoA for 5 min. Activity was measured using the cholesterol endogenous to the microsomes and in the presence of saturating amounts of exogenous cholesterol added as cholesterol/phosphatidylcholine liposomes as described in the Materials and Methods section. The "total liver" figures are based on the assay using endogenous cholesterol. The results are the means ± SEM for the number of animals given in parentheses. Significant differences from control values were determined using the Student's *t*-test. CE, cholesteryl ester.
[b]$P < 0.01$.
[c]$P < 0.001$.

The changes in ACAT activity showed a positive correlation with the levels of both free (r = 0.60) and esterified cholesterol (r = 0.54) in the microsomal membranes (Fig. 1).

Microsomal and cytosolic cholesteryl ester hydrolase (nCEH). The most dramatic effects produced by the fibrate-supplemented diets were changes in the activities of both microsomal and cytosolic nCEH (Table 5). On a protein basis, clofibrate led to a 4.5-fold increase in the cytosolic nCEH while bezafibrate increased the enzyme activity by a factor of 8.6. When the increase in liver weight was taken into account, it was apparent that the increases in cytosolic nCEH activity were even greater. The microsomal nCEH was also increased by the fibric acid derivatives although the differences were not quite as marked as seen with the cytosolic enzyme with both drugs causing a 3- to 4-fold increase in enzyme activity. There was a significant, negative correlation (r = 0.91) between the microsomal nCEH activities and the levels of microsomal cholesteryl esters (Fig. 2). In contrast, the levels of cytosolic triacylglycerol lipase were unaffected by any of these diets (data not shown).

Cytosolic inhibitory protein. Table 6 shows the effects of the dietary treatments on the activity of the liver cytosolic inhibitor of nCEH. Whereas clofibrate caused no significant changes in the activity of the inhibitor when expressed on a protein basis, bezafibrate treatment led to a decrease in inhibitory activity of 22% ($P < 0.01$). When ex-

TABLE 4

The Effect of Treatment with Clofibrate and Bezafibrate on the Microsomal Contents of Cholesterol and Cholesteryl Esters[a]

Treatment	Cholesterol (μg/mg protein)	Cholesteryl esters (μg/mg protein)	C/CE ratio
Control (11)	31.4 ± 1.3	19.0 ± 1.0	1.63 ± 0.05
Clofibrate (6)	19.3 ± 0.9[d]	11.3 ± 0.8[d]	1.73 ± 0.07
Bezafibrate (5)	26.0 ± 0.8[c]	13.2 ± 0.7[d]	2.00 ± 0.15[b]

[a]Cholesterol (C) and cholesteryl ester (CE) concentrations were measured by means of a fluorimetric assay on ethanolic solutions of the extracted microsomal lipids. The results are the means ± SEM for the number of animals given in parentheses. Significant differences from control values were determined using the Student's *t*-test.

[c]$P < 0.01$.
[d]$P < 0.001$.

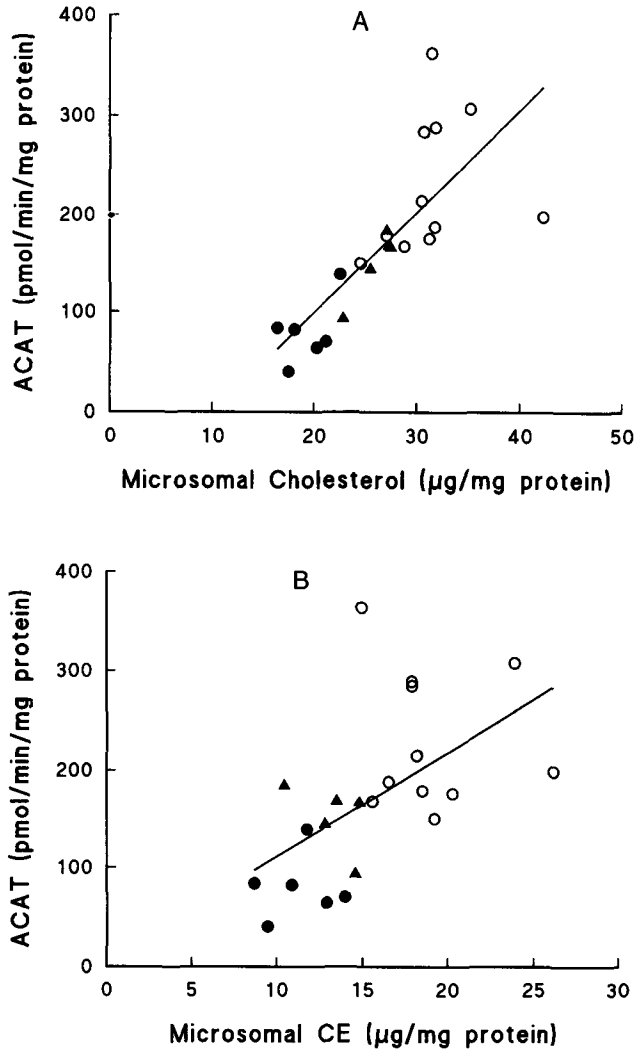

FIG. 1. Scatter diagram relating acyl-CoA:cholesterol acyltransferase (ACAT) activities to the microsomal contents of cholesterol (A) and cholesteryl esters (CE) (B) in the livers of control rats (○) and animals treated with clofibrate (●) and bezafibrate (▲). Regression analysis was performed and showed the relationships to be linear for both ACAT vs. cholesterol (y = 10.28x - 105.99, r = 0.77) and ACAT vs. CE (y = 10.64x + 4.75, r = 0.56).

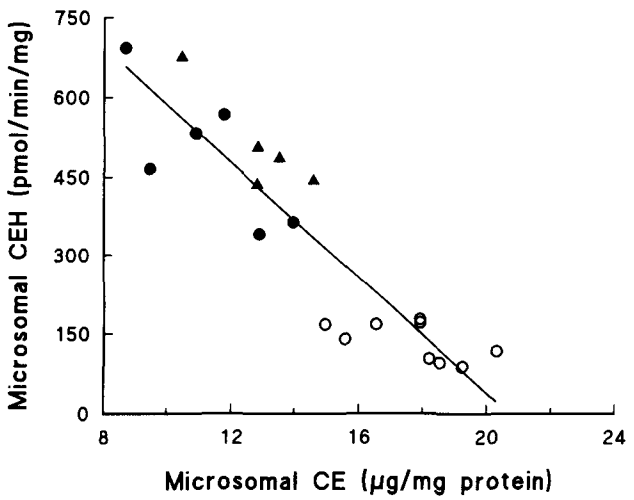

FIG. 2. Scatter diagram relating microsomal neutral cholesteryl ester hydrolase (nCEH) activities to the microsomal contents of cholesteryl esters (CE) in the livers of control rats (○) and animals treated with clofibrate (●) and bezafibrate (▲). Regression analysis was performed and showed the relationship to be linear (y = -54.71x + 1133.34, r = -0.91).

pressed on a whole liver basis, however, it was apparent that both fibrates had increased the total amount of inhibitor present in the tissue by around 21% ($P < 0.05$). In general, however, there appeared to be little or no correlation between the activities of the cytosolic inhibitor and those of the microsomal or cytosolic nCEH enzymes.

DISCUSSION

The inhibition of ACAT activity recorded in the present study confirms the observations of other workers (4,9). The level of ACAT activity is normally dependent on the availability of cholesterol substrate, and there was a good correlation between ACAT activity and microsomal cholesterol content suggesting that a decrease in the availability of substrate contributed to the effect. However, ACAT activity in isolated microsomes can also be increased by the provision of exogenous cholesterol, and with such treatment the ACAT activity in the microsomes

TABLE 5

The Effects of Treatment with Clofibrate and Bezafibrate on the Activities of the Microsomal and Cytosolic Cholesteryl Ester Hydrolases (CEH)[a]

	Microsomal CEH		Cytosolic CEH	
Treatment	pmol/min/mg protein	nmol/min/liver	pmol/min/mg protein	nmol/min/liver
Control (11)	139.8 ± 10.3	13.9 ± 0.8	11.7 ± 1.5	12.2 ± 1.6
Clofibrate (6)	494.2 ± 49.3[b]	63.3 ± 5.8[b]	52.6 ± 7.8[b]	68.8 ± 8.7[b]
Bezafibrate (5)	509.8 ± 38.9[b]	66.9 ± 7.0[b]	100.9 ± 11.3[b]	166.7 ± 25.5[b]

[a]CEH activities were assayed on 50 μg of microsomal or cytosolic protein incubated with cholesteryl [9,10-^{3}H]oleate for 45 min. The results are the means ± SEM for the number of animals given in parentheses. Significant differences from control values were determined using the Student's *t*-test.

TABLE 6

The Effects of Treatment with Clofibrate and Bezafibrate on the Activity of the Cytosolic Protein Inhibitor of Cholesteryl Ester Hydrolase (CEH)[a]

Treatment	CEH inhibitor activity	
	% Inhibition by 40 μg cytosolic protein	50% Inhibitory units/liver ($\times 10^3$)
Control (9)	37.0 ± 1.5	19.0 ± 0.9
Clofibrate (5)	35.3 ± 1.5	23.8 ± 1.5[b]
Bezafibrate (5)	28.8 ± 2.2[c]	23.0 ± 1.1[b]

[a]The activity of the neutral CEH inhibitor protein was assayed in the liver cytosols by incubation of 30–40 μg of cytosolic protein with rat mammary gland microsomes. The percentage inhibition of the CEH activity due to 40 μg was then determined. The activity in whole liver is expressed as 50% inhibitory units where 1 unit is the amount (μg) of cytosolic protein required to inhibit the mammary microsomal CEH by 50%. The results are the means ± SEM for the number of animals given in parentheses. Significant differences from control values were determined using the Student's *t*-test.
[b]$P < 0.05$.
[c]$P < 0.01$.

from the bezafibrate-treated animals was seen to be similar to that of the controls. The remaining small difference between the two groups of animals could be accounted for by the increased nCEH activity in the bezafibrate-treated microsomes, even though nCEH activity recorded under the conditions of the ACAT assay was reduced by 50% in the absence of exogenous cholesterol, and by 80% when cholesterol was added. This suggests that the levels of ACAT enzyme in the two sets of animals are the same and that the apparent differences were a reflection of substrate availability in the microsomes, a conclusion supported by the total liver ACAT measurements (Table 3). However it was apparent that, for the clofibrate-treated animals, ACAT activity in the presence of exogenous cholesterol was still considerably less than that seen in the controls. This indicates that in those animals the reduction in ACAT activity arose from a decrease in the amount of the enzyme as well as a decrease in the availability of cholesterol. Again this conclusion is supported by the results obtained when ACAT activity was calculated for the whole liver (Table 3).

A reduced level of cholesteryl esters in the livers of clofibrate-treated rats has been reported by Turley and Dietschy (11) while Stahlberg *et al.* (4,5) observed a lowered hepatic microsomal content of esterified cholesterol. Reduced accumulation of cholesteryl esters was also recorded by Hudson and Day (13) when 3T3 fibroblasts were incubated with fibric acid derivatives. Although this could have been an effect of the reduction in ACAT activity, they also found that the large accumulation of cholesteryl esters, induced in fibroblasts by incubation with modified low density lipoprotein, was rapidly lost when either clofibrate or bezafibrate was added to the medium. They concluded that this could not arise solely from inhibition of ACAT and, since esterified cholesterol must be hydrolyzed prior to removal from the cell, speculated that increased hydrolysis of the esters may have been involved (13).

Although the fibrates were shown to have no direct effect on the lysosomal CEH (14), the results presented in the current paper confirm this hypothesis by demonstrating that nCEH in both the microsomal and cytosolic fractions was markedly increased in the livers of rats treated with either clofibrate or bezafibrate. The combination of increased nCEH and decreased ACAT could thus account for the reduced hepatic cholesteryl ester content.

Although liver nCEH has been shown to be activated *in vitro* by cAMP-dependent protein kinase, the maximum activation recorded was around 140% (25). This makes it unlikely that the increases in nCEH activity reported in the present work were due to phosphorylation of the enzyme, although such a covalent modification could make a contribution. Increases have been reported in a number of other cellular proteins, e.g., carnitine acyltransferase (26,27), fatty acid binding protein (28,29), and peroxisomal β-oxidation (30), following fibrate treatment of rats, and the extent of the increase in nCEH activity is comparable with these. The increases have been suggested to occur, *via* induction of the genes for these proteins, by activation of a group of specific transcription factors (31). It is probable that the enhanced nCEH activity can be ascribed to the same cause, although this would have to be ascertained by the appropriate investigation.

The increased nCEH activity may be a consequence of other changes in cellular metabolism resulting from fibrate treatment. There is a higher rate of peroxisomal (30) and mitochondrial (27) fatty acid oxidation in the livers of such animals, as well as an increase in the activity of acyl-CoA synthetase (32), both of which impose an enhanced requirement for long-chain fatty acids. This cannot be met by increased synthesis because the fibrates also cause inhibition of hepatic acetyl-CoA carboxylase (33), the rate-limiting enzyme in the synthesis of fatty acids. The increased hydrolysis of cholesteryl esters, combined with decreased esterification, may be a response to this increased demand for long-chain fatty acids.

In contrast to the large increases in nCEH activity, the much smaller changes in the activity of the cytosolic inhibitor of this enzyme (15,16), produced by bezafibrate, would not be expected to have major effects. Nevertheless, the reductions observed were such as to accentuate the effect of the changes in nCEH activity.

It is of interest to consider the clinical implications of the fibrate-induced changes in hepatic ACAT and nCEH activity. Hyperlipidemic patients treated with fibric acid derivatives exhibit a reduction in the circulating levels of VLDL which is due to a combination of increased catabolism, through stimulation of lipoprotein lipase activity (1,2), and a reduction in VLDL synthesis and secretion (3). The latter has been confirmed in studies using HepG2 cells (34). Although this has been suggested to be due to limitations in the supply of fatty acid substrate for VLDL secretion (3,35), incubation of HepG2 cells with fenofibrate also caused a reduction in cholesteryl esters as well as in triacylglycerols and free fatty acids (35).

Intracellular stores of cholesteryl ester have been shown to be necessary for VLDL secretion (36), and studies in which these stores have been depleted by inhibition of either HMG-CoA reductase (36) or ACAT (37) have revealed decreased triacylglycerol secretion. The serum triacylglycerol levels recorded in this study were in general

lower than literature values (26,38,39). This, and the lack of significant effect in the animals given fibrates, may result from the feeding regime where animals were given food at the start of the light period and sacrificed 24 h later. Nevertheless, similarly nonsignificant effects of fibrates on serum triacylglycerol levels have been reported by Stahlberg *et al.* (4). The activity of ACAT in human liver is unaffected by fibrate treatment (5) and bezafibrate failed to modulate HMG-CoA reductase activity either directly or indirectly in human mononuclear cells (40). If the reduction in VLDL secretion seen in patients, given fibric acid derivatives, and in fibrate-treated HepG2 cells is a consequence of a decrease in the cholesteryl ester content of the cells, our observations suggest that this could result from an increase in the nCEH activity of human liver similar to that occurring in rat liver.

Furthermore, treatment of hyperlipidemic patients with fibrates commonly causes an increase in the cholesterol content of bile, leading to supersaturation and the concomitant formation of gallstones (11,41). Although the mechanism of this hypersecretion of biliary cholesterol has not been fully explained, the results presented here may help to clarify the situation. There is considerable evidence that different pools of cholesterol exist within the hepatocyte and that specific pools control the secretion of cholesterol into bile (for a review, see Ref. 42). Inappropriate increases in the supply of cholesterol to such a pool has been shown to lead to enhanced biliary sterol secretion (43). The free cholesterol resulting from the combination of reduced ACAT and increased nCEH could also feed into such a pool leading to increased secretion of cholesterol into bile. Such an interrelationship between hepatic cholesterol esterification and biliary cholesterol output has been previously studied by Nervi *et al.* (44) and Stone *et al.* (45). They showed that inhibition of ACAT by various dietary and pharmacological manipulations was associated with enhanced secretion of cholesterol into bile. Continual removal of cholesterol to bile may then result in the reduction of cell cholesterol to the levels observed in this study.

Liver, Serum and Adipose Tissue Fatty Acid Composition in Suckling Zucker Rats

Margot P. Cleary*, **Frederick C. Phillips** and **Ruth A. Morton**

The Hormel Institute, University of Minnesota, Austin, Minnesota 55912

Young adult obese Zucker rats have altered tissue fatty acid (FA) composition. The present study was aimed at determining whether such changes were seen in either liver, serum or adipose tissue obtained from 17-day-old obese (fafa) rats in comparison to both homozygous (FaFa) and heterozygous (Fafa) lean rats. Body weights of obese pups (30.3 g) were significantly greater than those of homozygous lean rats (25.2 g) ($P < 0.05$). Liver weight and lipid content were similar in all groups. Inguinal fat pad weight and lipid content were greatest in obese pups (573 mg) followed by heterozygous lean pups (303 mg); homozygous lean pups (146 mg) had the lowest values. There were no differences among the groups in hepatic FA composition in either triacylglycerol (TG) or phospholipid fractions. Serum TG was similar among the groups, while serum phospholipid was greater ($P < 0.05$) in obese (269 mg/dL) than in homozygous lean pups (184 mg/dL); heterozygous lean pups had an intermediate value not significantly different from either homozygous group. On a percent basis, there were no differences in FA composition in either serum lipid fraction among the three groups. There were a number of significant differences in adipose tissue FA composition between the groups on a percent basis. The adipose tissue FA composition on a percent basis reflected that of maternal milk. The results indicate that suckling obese Zucker rats do not have tissue FA profiles that are characteristic of essential FA deficiency.

***Lipids 29,* 753–758 (1994).**

Many metabolic abnormalities are seen in the genetically obese Zucker rat, including hyperinsulinemia (1) and hyperlipidemia (2,3). Excessive lipid synthesis in liver and adipose tissue has been documented (4–7), and cellular insulin resistance has been shown to develop as the rats age (8,9). Recent studies have been aimed at establishing a molecular basis for some of these effects (10–12), but the genetic lesion responsible for the obesity *per se* has not been identified.

Establishing the order of appearance of these metabolic disturbances in the Zucker rat will assist in delineating the defects that are responsible for the obesity. However, investigations on young, suckling rats have been limited because techniques for genotyping suckling rats have been lacking. Lavau and Bazin (13) described a relatively simple means for separating lean from obese pups at 16–17 d of age. This technique utilizes inguinal fat pad weights and fat pad-to-body weight ratios to distinguish suckling homozygous obese (fafa) pups from their heterozygous lean (Fafa) littermates when the pups were taken from litters with heterozygous lean (Fafa) mothers and homozygous obese (fafa) fathers. The suckling pups that became obese as adults had greater fat pad weights and pad-to-body weight ratios at 16–17 d of age. We have recently reported similar findings (14). The method allows for quick assessment of the pups' genotype and allows the use of animals at a time when the body weights of lean and obese pups are similar and the pups consume similar quantities of milk (15).

Milk intake has been reported to be similar for lean and obese pups (15). However, suckling obese pups have elevated adipose tissue lipid synthesis (14,16,17) and greater adipose tissue mass (13,14,16,17) compared to lean pups (14,16,17). Since polyunsaturated fatty acid (FA) intake is limited by dietary intake, one could hypothesize that altered tissue FA profiles may be an early characteristic of obesity. A number of studies (18–20) have previously shown that postweaning obese rats, compared to lean rats, shows altered FA composition indicative of early essential FA deficiency in several tissues.

In the present study, the FA composition of liver and serum triacylglycerol (TG) and phospholipid (PL) fractions and of inguinal adipose tissue total lipid were determined in 17-day-old rat pups. We used obese (fafa) pups and lean Zucker rats of two genotypes, FaFa and Fafa. This was done to determine if there was an effect of the "fa" gene in young lean rats, as other studies had shown that the presence of this gene in lean rats had some impact (14,21,22). The composition of mother's milk was also determined.

MATERIALS AND METHODS

Animals. Rats were obtained from a colony maintained at the Hormel Institute (Austin, MN). Rooms were temperature (21°C) and humidity (50%) controlled and maintained at a 12-h light/dark cycle. The study was approved by the University of Minnesota Animal Care and Use Committee. The Hormel Institute Animal Facility is accredited by the American Association for Accreditation of Laboratory Animal Care.

From 5 wk of age, the female rats designated to be mothers in this experiment were fed a low-fat diet consisting, on a g/100 g basis, of: cornstarch, 58; casein, 20.5; celufil, 9.0; sucrose, 5.0; salt mixture, 4.0; vitamin mixture, 1.0; methionine, 0.5; and corn oil, 2.0 (all components were from United States Biochemical Corporation, Cleveland, OH). FA composition of the diet on a percent basis was 14:0, 0.2; 16:0, 12.1; 18:0, 2.3; 18:1ω9, 26.4; 18:2ω6, 57.4; 18:3ω3, 1.0; 20:0, 0.3; and 21:0, 0.3. Upon reaching 200 g body weight and/or 10 wk of age, female rats were bred to male rats. The female rats were housed in plastic cages with wood shavings throughout mating, pregnancy and lactation. Specially designed food cup holders were used to prevent the pups from eating their mother's food.

Two types of breeding crosses were used. Homozygous (FaFa) lean male and female rats were bred to provide homozygous (FaFa) lean pups, and homozygous (fafa) obese

Abbreviations: FA, fatty acid; FID, flame-ionization detector; PL, phospholipids; TG, triacylglycerol.

male rats were mated with heterozygous (Fafa) lean female rats to provide heterozygous (Fafa) lean and homozygous (fafa) obese pups.

At 17 d of age, pups were killed by decapitation, and blood was collected for serum preparation. Livers as well as left and right inguinal fat depots were removed and weighed. When pups were obtained from the obese male/heterozygous lean female crosses, fat depot weight and fat pad-to-body weight ratio were used to identify lean and obese pups. Liver and adipose tissue were processed as described below. Each mother rat was separated from her pups for one hour and then injected intraperitoneally with 2 IU of oxytocin. Under mild diethylether anesthesia, approximately 2 mL of milk were expressed by gentle manipulation of teats with thumb and forefinger. Milk droplets were collected using mild suction.

Adipose tissue total lipid extraction. Total adipose tissue lipid was extracted using a modification of the method by Dole and Meinertz (23). The tissue (100–700 mg) was homogenized with 5 mL Dole's reagent (isopropanol/hexane/1 N H_2SO_4, 40:10:1, by vol). Next, 3 mL water and 3 mL hexane were added, and the tube was shaken for 30 s. The layers were allowed to separate for 15 min, and the hexane phase was removed. The lower phase was reextracted twice with 3 mL of hexane. After the hexane had been evaporated with N_2, the total lipid was dissolved in a known volume of methylene chloride, and aliquots were taken for lipid determination.

Liver tissue total lipid extraction. Total liver lipids were extracted using the method developed by Phillips and Privett (24). Tissue (0.5 g) and 5 mL of hot acetic acid (0.05 N) were heated in a water bath (95°C) for 30 min. The sample was homogenized and centrifuged at 12,000 rpm for 15 min. The acetic acid was decanted and the pellet resuspended in 5 mL acetic acid (0.05 N) and centrifuged, and the acetic acid phase was decanted. The pellet was transferred to a 40-mL glass tube containing 12.5 mL methanol, then 12.5 mL of chloroform was added before the mixture was homogenized for 30 s. After standing for 15 min at room temperature, the sample was centrifuged for 5 min at 3,000 rpm. The chloroform/methanol extract was decanted, and the pellet was reextracted first with 20 mL of chloroform/methanol (1:1, vol/vol) and then with 20 mL of chloroform/methanol (1:2, vol/vol). The combined extracts were evaporated under vacuum. The dried lipid extract was dissolved in a known volume of methylene chloride, and aliquots were taken for lipid determination.

Milk and serum total lipid extraction. Each sample (200 μL) was added dropwise to stirred ice-cold methanol (3.4 mL). The sample was placed in an ice bath for 10 min, followed by addition of 3.4 mL of ice-cold chloroform. After an additional 10 min, 6.8 mL of ice-cold chloroform/methanol (1:1, vol/vol) was added, and the sample was centrifuged for 3 min at 3,000 rpm. The lipid-containing chloroform/methanol layer was decanted into a 15-mL screw-cap tube and evaporated under N_2. The lipid extract was dissolved in a known volume of methylene chloride, and aliquots were taken for lipid determination.

Isolation of serum TG and PL. The total lipid extract (0.5–5 mg) was spotted onto a thin-layer chromatographic plate (silica gel H, 0.3 mm layer). The plate was developed in a paper-lined chamber using hexane/diethyl ether/acetic acid (200:50:2, by vol) as solvent. After development, the TG and PL zones were identified under an ultraviolet lamp after spraying the plates with 0.2% 2,7-dichlorofluorescein in methanol and drying with N_2. The TG and PL zones were scraped into glass screw-cap tubes, and 0.5 mL methylene chloride was added. Samples were transesterified as described below.

FA analysis. The isolated TG and PL fractions and the fat tissue lipids were transesterified by adding 2 mL of 3N HCl/methanol reagent, flushing with N_2, and heating at 90°C for 1 h for the TG and for 2 h for the PL fractions. The tubes were cooled, and an equal volume of water was added. The methyl esters were extracted twice with 5 mL hexane. The hexane was evaporated, and the esters were dissolved in methylene chloride. Samples were analyzed using a Hewlett-Packard 5840A gas–liquid chromatograph equipped with a 30 m × 0.26 mm DB225 (0.25 μm film) capillary column (J&W Scientific, Folsom, CA) and flame-ionization detector (FID) using helium as the carrier gas. The temperature was programmed from 160 to 225°C at 2°C/min.

Statistics. Data are presented as means ± SEM. FA data are given in area percent unless otherwise noted. Five pups were used in each group. Statistical comparisons were made by one-way analysis of variance followed by Least Significant Difference test to determine significance between specific groups. A total of 27 FA between 10:0 and 24:1ω9 were analyzed. For values obtained that were greater than 0.5%, all data are presented whether or not there were significant differences. For values less than 0.5%, only those data are presented for which statistically significant differences were seen.

Fourteen samples of mother's milk were obtained (seven homozygous and seven heterozygous females). There were no differences in fatty acid composition of the milk between the two genotypes; therefore, the results for these two groups were combined.

RESULTS

At 17 d of age, obese pups weighed significantly more than homozygous lean pups (Table 1). The heterozygous lean pups had an intermediate body weight that was not significantly different from that of either of the other two groups. Liver weights and amounts of liver lipids were similar among the three groups (Table 1). Inguinal fat pad weight was greatest in obese pups followed by that of heterozygous lean pups (Table 1); homozygous lean pups had the lightest fat pads. Fat pad lipids followed a similar pattern. The fat pad-to-body weight ratio was higher in obese compared to lean pups. Serum TG concentrations were similar in all three groups. Serum PL concentrations were greater in obese compared to homozygous lean rats, and heterozygous lean pups had an intermediate value not significantly different from either homozygous group.

As can be seen in Table 2, there were minor differences in hepatic FA composition among the three groups in both the TG and PL fractions when results were expressed on a percent basis. No significant differences were seen when

TABLE 1

Body Weight, Liver Weight, Liver Lipid Weight, Inguinal Fat Pad Weight, Fat-to-Body Weight Ratio and Serum Lipid Levels in 17-day-old Zucker Rat Pups[a]

	Homozygous (FaFa) lean	Heterozygous (Fafa) lean	Homozygous (fafa) obese
Body weight (g)	$25.2^{b} \pm 0.6$	$27.7^{b,c} \pm 2.3$	$30.3^{c} \pm 1.0$
Liver weight (mg)	$764^{b} \pm 14$	$888^{b} \pm 77$	$895^{b} \pm 48$
Liver lipid weight (mg)	$30.9^{b} \pm 0.8$	$35.7^{b} \pm 3.4$	$36.8^{b} \pm 2.0$
Inguinal pad weight (mg)	$146^{b} \pm 6$	$303^{c} \pm 33$	$537^{d} \pm 48$
Fat pad lipid weight (mg)	$83^{b} \pm 2$	$211^{c} \pm 27$	$408^{d} \pm 41$
Fat pad-to-body weight	$0.0058^{b} \pm 0.0002$	$0.0075^{b} \pm 0.0005$	$0.0144^{c} \pm 0.0015$
Serum triacylglycerol (mg/dL)	$163^{b} \pm 5$	$180^{b} \pm 21$	$203^{b} \pm 15$
Serum phospholipid (mg/dL)	$184^{b} \pm 5$	$229^{b,c} \pm 27$	$269^{c} \pm 20$

[a]Values are mean ± SEM; n = 5 per group.
[b,c,d]Across a row, numbers with different superscripts are significantly different; $P < 0.05$.

FA were grouped by saturation level. Although no statistical comparisons were made, it can be seen that there were distinct differences in FA composition between the two lipid classes. Since liver weights and lipid contents were similar, there were no differences among the groups when absolute (mg/g) amounts of individual FA were determined (data not shown).

On a percent basis, there were essentially no differences in either serum TG or PL FA profiles among the three groups of 17-day-old rat pups (Table 3). As in the liver, there were differences between the two lipid fractions with respect to the distribution of the FA by the degree of unsaturation. As shown in Table 1, obese pups did have significantly higher serum PL concentrations compared to

[a]Values are means of five rats/group ± SEM. A total of 27 fatty acids between 10:0 and 24:1ω9 were assayed. Results were included when at least one experimental group had a value of 0.5% or greater for either the triacylglycerol or phospholipid fraction or when values were significantly different. Fatty acids with values less than 0.5% where there were no significant differences were 10:0, 14:1ω5, 15:0, 20:1ω9, 20:5ω3, and 24:1ω9.
[b,c]Values with different superscripts are significantly different at $P < 0.05$ for that lipid fraction.

Sum of:						
Saturated	57.7[b] ± 1.6	54.2[b] ± 1.1	55.4[b] ± 2.3	46.1[b] ± 0.2	45.2[b] ± 0.3	44.8[b] ± 0.1
Monounsaturated	19.7[b] ± 0.7	21.7[b] ± 0.5	21.2[b] ± 1.0	5.3[b] ± 0.1	5.4[b] ± 0.2	5.9[b] ± 0.2
Polyunsaturated	23.6[b] ± 0.9	25.4[b] ± 1.4	24.7[b] ± 2.5	48.8[b] ± 0.2	49.6[b] ± 0.2	49.4[b] ± 0.2

[a]Values are means of five rats/group ± SEM. A total of 27 fatty acids between 10:0 and 24:1ω9 were assayed. Results were included when at least one experimental group had a value of 0.5% or greater for either the triacylglycerol or phospholipid fraction or when values were significantly different. Fatty acids with values less than 0.5% where there were no significant differences were 14:1ω5, 18:3ω6, 18:3ω3, 20:1ω9, and 20:5ω3.

[b,c]Values with different superscripts are significantly different at $P < 0.05$ for that lipid fraction.

homozygous lean pups, and also showed a trend toward higher serum TG levels. When serum FA composition was expressed as mg/dL, significant differences were noted between obese and homozygous lean pups for several FA in the TG fraction, but there were no differences in the sums for saturated, monounsaturated or polyunsaturated FA (results not shown). In the PL fraction, most levels of individual FA calculated as mg/dL were significantly higher in obese than in homozygous lean rats (results not shown). Of particular interest is that 18:2ω6 and 20:4ω6 levels were 50% higher in obese rats compared to homozygous lean rats. The heterozygous lean rats tended to have intermediate values for most FA that were not consistently and statistically different from those of the other two groups.

Adipose tissue FA composition as a percent of total lipids is presented in Table 4. Compared to either serum or liver, fewer FA were identified at >0.5% in adipose tissue. However, a number of statistically significant differences were found for these FA present in low amounts. In general, obese and heterozygous lean rats had significantly higher values for ω6 and ω3 FA when they were present at low levels. However, 18:2ω6 values were similar in all three groups. Obese rats had slightly higher levels of several medium chain FA, particularly when compared to homozygous lean rats. Both homozygous and heterozygous lean rats had higher levels of 18:0, 18:1ω9 and 18:1ω7 in adipose tissue than did obese rats. There were no differences among the groups for the sum of saturated FA. The summed monounsaturated FA levels were highest in homozygous lean rats, intermediate in heterozygous lean rats, and lowest in obese rats. Heterozygous lean rats had higher total polyunsaturated FA levels than did homozygous lean rats, and obese rats had an intermediate value that was not significantly different from that of the two lean groups. In general, significant differences found among the groups were minor. The composition of mother's milk is also included in Table 4. Adipose tissue FA composition on a percent basis was similar to that of maternal milk obtained on the seventeenth day of lactation. As expected due to differences in fat pad weights, large significant differences in the amounts of FA were found among the three groups when FA composition was presented on a per depot basis (results not shown). For all FA,

TABLE 4

Adipose Tissue Fatty Acid Composition by Percent of 17-day-old Rat Pups and Rat Milk at 17 Days of Lactation (area %)[a]

	Homozygous (FaFa) lean	Heterozygous (Fafa) lean	Homozygous (fafa) obese	Mother's milk

[a]Values are means of five rats/group ± SEM (except for mother's milk n = 14). A total of 27 fatty acids between 10:0 and 24:1ω9 fatty acids were assayed. Results were included when at least one experimental group had a value of 0.5% or greater or when values were significantly different. Fatty acids with values less than 0.5% where there were no significant differences were 15:0, 16:1ω9, 17:0, 20:1ω9, 20:3ω9, 20:5ω3, 24:0, and 24:1ω9; n.d., not detected.

[b,c,d]Values with different superscripts are significantly different at $P < 0.05$.

obese Zucker rats had the highest levels, heterozygous lean rats had intermediate levels, and homozygous lean rats had the lowest levels. This correlation was also seen when FA were grouped by saturation level (results not shown).

DISCUSSION

In general, the results indicate that suckling obese Zucker rats do not manifest patterns of altered polyunsaturated FA levels in either serum, liver or adipose tissue. These findings contrast with previously reported studies in which tissue FA compositions of older obese and lean Zucker rats were compared (18–20). Earlier, Wahle (19) had reported that adipose tissue from 90–120-day-old Zucker obese rats had higher levels of 16:0 and 16:1, similar amounts of 18:0 and 18:1, but dramatically lower 18:2 levels than did adipose tissue from lean rats. Results for liver were similar except that 18:0 tended to be lower in obese rats than in lean rats. The general conclusion was that monounsaturated FA replaced/substituted for the polyunsaturated FA the levels of which were limited by dietary content and intake in the obese rats.

In a more extensive study, Guesnet *et al.* (18) evaluated more tissues and identified more FA in PL using three-month-old rats. Few differences in FA composition in tissues related to the nervous system were reported between lean and obese rats. However, in serum, liver, kidney and heart, n-6 polyunsaturated FA were lower in the tissues of obese rats than in lean rats, except for the liver, where they were similar.

The general conclusion drawn by several investigators (18,25) has been that obese rats have decreased Δ5 desaturase activity. However, Phinney *et al.* (26) found that supplementing obese Zucker rats with black currant seed oil, which is rich in γ-linolenic acid (18:3ω6), elevated 20:4n-6 tissue levels. This finding as well as the fact that products of the desaturase/elongase pathways were found in nonsupplemented obese rats led to the conclusion that the Δ6 and Δ5 desaturase systems were capable of producing sufficient amounts of product. This led to the hypothesis (26) that there is a loss of substrate specificity for 18:2ω6 and/or that there is enhanced catabolism of 20:4ω6 in obese rats.

In young obese suckling rats, however, we did not find evidence of an altered polyunsaturated FA pattern that would suggest a deficient state. In fact, obese rats had identical FA patterns when compared to lean rats when the results are presented on a percent basis. In agreement with this, Guerre-Millo *et al.* (27) recently reported on the

FA composition of PL of adipocyte plasma membranes from 30-day-old lean and obese Zucker rats. The authors found no differences between lean and obese rats except for a significant increase in 22:6n-3 in obese rats.

When results for adipose tissue FA composition were calculated on a depot basis, obese rats had five times more 18:2ω6 and almost seven times more 20:4ω6 than did homozygous lean rats. Clearly at 17 d of age, obese Zucker rats did not have lowered polyunsaturated FA tissue levels compared to lean pups. This would indicate that an adequate supply of these nutrients can be supplied by mother's milk. Milk fat content in the present study was 12.87 ± 0.59 (mean ± SEM g/dL). This value agrees with previously published data (15,28–30), and the FA composition of the milk agrees, in general, with results obtained on rats fed standard type diets (31,32).

In summary, (i) in suckling obese rats there was no evidence of polyunsaturated FA deficiency in liver, adipose tissue or serum, and (ii) adipose tissue FA composition reflected milk FA composition. Thus, the changes in polyunsaturated FA metabolism in Zucker rats must occur postweaning and are not involved in the early stages of obesity.

Composition and Structure of Triacylglycerols in Brown Adipose Tissue of Rats Fed Fish Oil

Thierry Raclot, René Groscolas and **Claude Leray***
Centre d'Ecologie et Physiologie Energétiques, 67087 Strasbourg, France

This study examines the incorporation of highly unsaturated n-3 fatty acids (HUFA) into triacylglycerols (TAG) of brown adipose tissue (BAT), and their effect on the positional distribution of saturated (SFA) and of unsaturated (UFA) 16- or 18-carbon fatty acids. To this end, rats were fed a fish oil diet for up to four weeks. The stereospecific analysis of TAG was based on generation of *sn*-1,2- and *sn*-2,3-acylglycerols by Grignard degradation, followed by synthesis of phosphatidic acid and specific hydrolysis with phospholipase A_2. From the end of the first week of fish oil feeding, a steady-state in the fatty acid composition of TAG in BAT was reached. HUFA concentration increased 30-fold, mainly at the expense of n-9 UFA and of SFA. The amount of SFA decreased selectively at position 3, where these fatty acids were progressively replaced by n-3 HUFA. By contrast, the amount of UFA decreased at all positions, and their positional distribution was not affected. About 60% of HUFA was incorporated at position 3. Nearly twice as much 22:6n-3 was incorporated into TAG than had been previously observed in white adipose tissue (WAT) [Leray, C., Raclot, T., and Groscolas, R. (1993)*Lipids 28*, 279–284]. At the steady-state, the distribution of HUFA was characterized by high proportions of 22:6n-3 and 20:5n-3 in position 3. Moreover, in each position of TAG, a steady level was reached rapidly (within 1 wk). It is concluded that, during fish-oil feeding, fatty acids in TAG of BAT show characteristic time-course changes that lead to a characteristic composition and a tissue-specific positional distribution. This suggests that adipose tissue has its own specificity in controlling the build-up of TAG stores, which is likely to be regulated by the specificity of acylating enzymes as well as molecular rearrangements.
***Lipids 29*, 759–764 (1994).**

Fatty acids are stored mainly as triacylglycerols (TAG) in adipose tissues where they comprise from about 50% (brown adipose tissue, BAT) to 90% (white adipose tissue, WAT) of tissue weight. Whereas the overall mechanisms of synthesis and degradation of TAG have been adequately described (1), the finer aspects of metabolic regulation at the molecular level are only poorly understood. In particular, only limited information is available on the control of the fatty acid distribution between the three sites of the glycerol moiety. Several reports (reviewed in Ref. 1) have provided evidence that esterifying enzymes tend to place the saturated fatty acids (SFA) at the *sn*-1 position of triacylglycerols, the unsaturated 16- and 18-carbon fatty acids (UFA) at the *sn*-2 position, and the highly unsaturated 20- and 22-carbon fatty acids (HUFA) at the *sn*-3 position. The 20- and 22-carbon HUFA of the n-3 series are abundant in fish oil and have been shown to be stored after ingestion by rats in adipose tissue (2–4). HUFA have been shown to play important roles as antagonists in eicosanoid biosynthesis (5) and are known to prevent or to alleviate various pathological conditions (6). Recently, HUFA have been shown to limit the hypertrophy of abdominal depots in growing rats fed high-fat diets (7). It is thus of interest to gain a better understanding of the action of exogenous n-3 HUFA on storage tissues and, conversely, of the influence of these fatty acids on the structure of the TAG stored. The two types of adipose tissue found in mammals, the WAT and the BAT, are well known for their physiologically distinct functions. Whereas WAT is the reserve of fat energy for other tissues (8), BAT is the main site of nonshivering thermogenesis (9) with its stored fatty acids being mainly oxidized in mitochondria. Because of its distinct size and metabolic activity, BAT may be expected to accumulate TAG by processes and with time-dependencies different from those in WAT (2). Until now, this aspect of TAG storage has not been examined in BAT.

The purpose of the present study was to examine the time-course changes of the quantitative and stereospecific incorporation of n-3 HUFA into TAG of BAT in rats fed for up to four weeks a diet supplemented with fish oil. Concurrently, the stereospecific distribution of the other stored fatty acids, both of exogenous and endogenous origin, was also investigated. This made it possible to compare the fate of the fatty acids in the two types of adipose tissue.

MATERIALS AND METHODS

Animals and diet. Thirty-five male Wistar rats, individually housed under a 12-h light/dark cycle at 25°C, were fed a basal diet (AO, Usine d'Alimentation Rationnelle, Villemoisson, France) containing 3% total lipids by weight. The small amount of phospholipids present in this diet (17% of the total lipid moiety) had a fatty acid composition similar to that of TAG. When animals reached 225 g mean live body weight, they were given *ad libitum* a semisynthetic diet supplemented with fish oil (MaxEPA; R.P. Scherer, Beinheim, France; 19% in the diet). The fatty acid composition of the fish oil diet is given in Table 1. The dietary treatment used here was the same as that described previously (2).

Extraction and analysis of lipids. All animals were killed by cervical dislocation at 9 a.m. Five rats fed the basal diet were killed at the onset of the experimental feeding period. Groups of animals fed the fish oil diet were killed after feeding periods of 1 and 3 d, and 1, 2, 3 and 4 wk (five rats in each group). BAT samples were immediately extracted (10), and TAG were isolated by thin-layer chromatography using hexane/diethyl ether/acetic acid

(70:30:1, by vol) as the developing solvent. The stereospecific analysis of TAG was done on samples from three rats killed at the onset and after feeding periods of 3 d, 1 and 4 wk as described previously (2). Briefly, representative *sn*-1,2- and *sn*-2,3-acylglycerols were generated by Grignard degradation, and *rac*-phosphatidic acids were chemically synthesized. Fatty acids at the *sn*-2 position from *sn*-1,2-phosphatidic acids were released by phospholipase A_2. This allowed the direct determination of the fatty acids at positions 1 and 2 and the calculation of the fatty acids acylated at position 3. Fatty acids were determined directly following thin-layer chromatography by gas–liquid chromatography of the methyl esters (11) on a Chrompack 9000 chromatograph equipped with an AT-WAX capillary column (0.25 mm i.d. × 60 m; Alltech, Templeuve, France). All solvents contained 25 mg/L ethyl gallate as an antioxidant, and reactions were carried out under nitrogen.

Although reproducible results were obtained even when low levels of fatty acids were present, figures for minor fatty acids are not reported. Results are given as means ± SEM. The Student's *t*-test was used to establish significant differences among means.

RESULTS

TAG fatty acid composition. The fatty acid composition of TAG of BAT changed markedly during the first week of fish oil feeding. Thereafter (week 1 to week 4), no significant changes were observed. Based on these results, four time points were selected: time 0 (basal diet), after 3 d (about half the final steady level of HUFA concentration), and after 1 and 4 wk (final steady-state) (Table 1). There was a rapid and very significant increase (30-fold) in the concentration of HUFA in TAG of BAT, 88% of HUFA belonging to the n-3 series. After one week, HUFA reached a steady level corresponding to 15%, which was about half that in the fish oil diet. All individual n-3 HUFA reached a steady but different level after the same period. The final concentration of 22:6n-3 was significantly higher than that of 20:5n-3 (+60%, $P < 0.05$); thus the concentration of these HUFA was found in a proportion inverse to that in the fish oil diet (22:6n-3, 8.4%; 20:5n-3, 15.9%). The observed increase in HUFA was compensated for by a progressive decrease in UFA (mainly of the n-9 series; from 31.5 to 22.1% at 0 and 28 d, respectively; $P < 0.05$) and by a similar decrease in SFA (from 48.5 to 37.6% at 0 and 28 d, respectively; $P < 0.01$). Both UFA and SFA groups reached a steady level after 1 wk, as was also observed for HUFA.

Fatty acid distribution in TAG. The positional distribution of the main fatty acids in the BAT TAG of rats fed the basal and the fish oil diets is given in Table 2. In rats fed the basal diet, each position of TAG was characterized by a specific fatty acid pattern. Fatty acids at position 1 were highly saturated (about half of the total SFA were in this position), whereas positions 2 and 3 were mainly acylated with UFA (80% of the total amount). Only trace amounts of HUFA were found at each of the three positions. Among UFA, monoenoic acids of the n-7 series were evenly distributed, those of the n-9 series were distributed mainly at position 2 and 3, and 18:2n-6 was mainly acylated to

[a]Fatty acid composition in mole%. For each fatty acid or group of fatty acids the sum of the three positions equals its total amount in triacylglycerols. Means ± SEM of three experimental values. See legend to Figure 1 for other explanations and abbreviations.

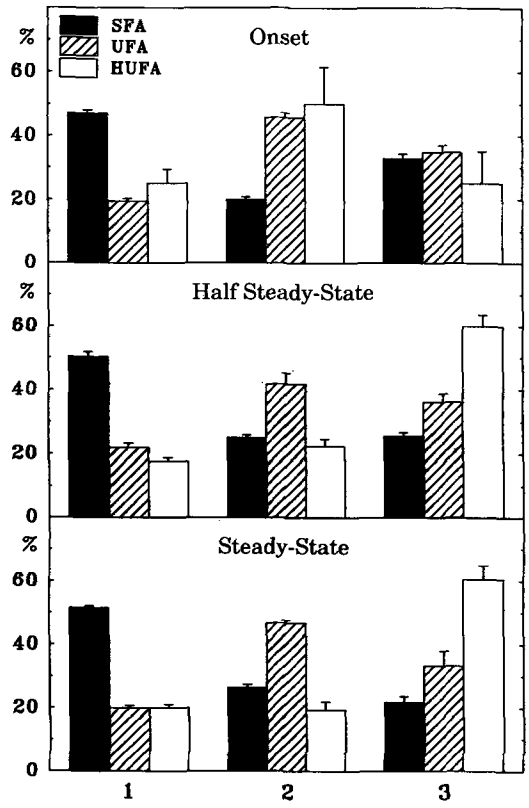

FIG. 1. Time-course of the changes in the positional distribution of the three fatty acyl groups in triacylglycerols of brown adipose tissue during fish oil feeding. Results are expressed in mole% for each series in each of the three position, the sum of the three positions being 100. Onset, basal diet; half steady-state, stage at which half changes in the 20- and 22-highly unsaturated fatty acids (HUFA) content were reached (day 3); Steady-state, mean value at the two last stages (weeks 1 and 4). Values are means (n = 3) and T-bars show SEM. SFA, saturated fatty acids; UFA, 16- and 18-unsaturated fatty acids.

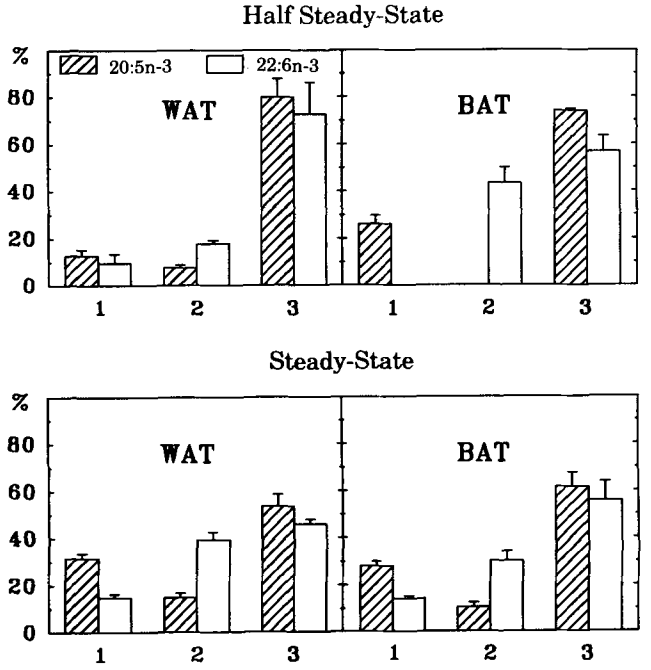

FIG. 2. Positional distribution of 20:5n-3 and 22:6n-3 in triacylglycerols of white (WAT) and brown (BAT) adipose tissues during fish oil feeding. Results are expressed in mole% for each series in each of the three positions, the sum of the three positions being 100. Half steady-state, day 7 for WAT and day 3 for BAT; steady-state, weeks 2–4 in WAT and weeks 1–4 in BAT. Data for WAT are computed from (1). Values are means (n = 3) and T-bars show SEM.

position 2 (about 60% of the total amount). In rats fed the fish oil diet, a significant decrease of the amount of both SFA and UFA at position 3 was observed after 3 d for the former ($P < 0.01$) and after 1 wk ($P < 0.05$) for the latter. The amount of UFA also decreased significantly at position 2 ($P < 0.01$), but this was not reflected in significant changes in the distribution of n-7 and n-9 fatty acids and of 18:2n-6. The rapid enrichment of HUFA in BAT was characterized by the rapid acylation of HUFA in position 3, where they mostly replaced SFA (after 3 d) and UFA (after 1 wk). To a lesser extent, HUFA were also acylated in positions 1 and 2, with the time courses of these changes being similar. The changes led to a 2.5-fold increase in the proportion of HUFA at position 3 ($P < 0.05$) at the expense of position 2, whereby the HUFA proportion at position 1 remained nearly steady (Fig. 1). When a half steady-state was reached, the distribution patterns of 20:5n-3 and 22:6n-3 were clearly distinct (Fig. 2). If one considers only relative values higher than 0.5 mol%, 22:6n-3 was found at positions 2 and 3 in roughly similar proportions, whereas 20:5n-3 was found at positions 1 and 3, its abundance being about three times lower at position 1 than at position 3 ($P < 0.01$). At the end of the feeding period (steady-state of HUFA content), about 60% of the total 20:5n-3 and 22:6n-3 were found acylated at position 3, with some 20:5n-3 present at position 2 (10% of the total), and with 22:6n-3 at position 1 (16%) (Fig. 2). The two other n-3 fatty acids, 18:4n-3 and 22:5n-3, were found only at position 3 (Table 2).

DISCUSSION

In the present study, the composition of the n-3 HUFA enriched diet differed greatly from that of BAT at the onset of fish-oil feeding (Table 1). The fatty acid supply through the intestine, liver and plasma was thus maintained at a high level that allowed the TAG pools to reach steady-states rapidly. Since a drastic dietary change was made, the data can primarily be interpreted in fatty acid metabolic terms. Thus, as suggested previously (12), the known selectivity of the acylating enzymes enabled us to distinguish the fatty acids between three primary groups (SFA, UFA and HUFA).

To our knowledge, this study is the first to examine TAG structure in BAT. In rats fed the basal diet, TAG of BAT contained almost exclusively SFA and UFA, and their distribution pattern appeared similar to that previously reported in WAT of the rat and other mammals (2,13–15). The preferential incorporation of SFA into position 1 and of 18:2n-6 into position 2 in BAT, as in WAT, is likely to result from a similar substrate affinity in the first two acy-

lating steps in phosphatidic acid biosynthesis. However, it is also possible that acyl-CoA concentrations could influence the site of fatty acid acylation in phosphatidic acid and help in overcoming the intrinsic specificities of acyltransferases (16,17).

Feeding of the fish oil diet induced different trends in fatty acid content and distribution in TAG of BAT (Figs. 1 and 2) in comparison with TAG of WAT (Fig. 2; Ref. 2). The SFA content progressively decreased in BAT, mainly at position 3, whereas it increased slightly in WAT without causing noticeable changes in distribution. The total amount of UFA decreased less in BAT than in WAT, but UFA positional distribution, including that of 18:2n-6, was unaffected in either fat depot. The HUFA enrichment in TAG was greater and more rapid in BAT than in WAT, but the distribution patterns of these exogenous fatty acids were similar.

Despite the increasing interest in the effect of n-3 fatty acids under various pathological conditions (6), the metabolic fate of the fatty acids involved has only been insufficiently investigated, especially with respect to their storage in and their mobilization from adipose tissues (18). Knowledge of the stereochemistry of stored TAG seems not only important with regard to the acylation steps but also with regard to the lipolysis processes. Indeed, the hormone-sensitive lipase from WAT is known to have a marked preference for the primary ester bond of TAG (19). This lipase was also shown to preferentially release polyunsaturated fatty acids from TAG in WAT (20). Similar positional specificity may be expected for the hormone-sensitive lipase of BAT, but fatty acid release cannot be assessed without knowledge of TAG structure. Noticeable differences are detected when the distribution of the two main n-3 HUFA in BAT (Fig. 2) is compared with that previously reported for TAG of WAT (2). At the steady-state, the higher enrichment of 20:5n-3 and 22:6n-3 in position 3 of TAG of BAT when compared to WAT suggests tissue-specific differences in stereospecificity at the level of the three acylating steps. This is corroborated by the observation of a delayed acylation of 20:5n-3 at position 2 and of 22:6n-3 at position 1. Unfortunately, in previous studies on these acylation processes in adipose tissue (21,22), the specificity for n-3 fatty acids was not considered. When comparing the time-dependent distribution of the two main n-3 fatty acids in TAG of BAT to that of WAT, some differences appear mainly at the level of 22:6n-3. In BAT, the proportion of this fatty acid decreased at position 2 and increased at position 1, whereas the proportion at position 3 was maintained. In WAT, the proportion of 22:6n-3 increased at positions 1 and 2 at the expense of position 3. This suggests that subtle mechanistic controls exist in the stepwise acylation of 22:6n-3 onto glycerol-3-phosphate. In particular, the early acylation of 22:6n-3 at position 2 in BAT suggests some tissue-dependent specificity of the 2-acylglycerophosphate acyltransferase. On the other hand, similarities between the two tissues were also observed. Thus, an early acylation of 20:5n-3 and 22:6n-3 at position 3 was found both in BAT and in WAT. This observation suggests that in both tissues the last step of TAG biosynthesis, controlled by the diacylglycerol acyltransferase, has a higher affinity for these fatty acids than that seen along the phosphatidic acid pathway. Molecular remodeling and differential acyltransferase specificities are likely responsible for the decreasing amount of 22:6n-3 at position 2 in BAT as well as for the delayed acylation in WAT of 20:5n-3 and of 22:6n-3 at positions 1 and 2, respectively. Important remodeling processes are likely to take place in BAT following the synthesis of phosphatidic acid since the enrichment of 22:6n-3 relative to 20:5n-3 in TAG was not observed in adipocyte choline or ethanolamine glycerophospholipids (Leray, C., Andriamampandry, M., Raclot, T., and Groscolas, R., unpublished data). The progressive changes that we observed in BAT fatty acid composition may furthermore result from selective hydrolysis of storage lipids and/or reesterification of n-3 HUFA taken up from blood. A similar hypothesis has been brought forward for WAT (23) and liver (24) TAG in fed and starved rats, respectively. The higher enrichment of BAT TAG in 22:6n-3 may involve a preferential release of 20:5n-3 over that of 22:6n-3, as has been suggested for WAT (18,25). The relative importance of these mechanisms in the build-up of fat depots during fish-oil feeding remains to be determined. Another explanation for the observed remodeling of TAG molecules in BAT leading to a difference in enrichment of 22:6n-3 relative to 20:5n-3 may be that the availability of specific fatty acids is altered by selective fatty acid oxidation. Since the dietary fat level is known to modulate the thermogenic activity of BAT (26–28), the high-fat diet used in this study is likely to have increased its mitochondrial oxidative capacity and peroxisomal metabolism. Although the importance of these two fatty acid degradation pathways has not yet been evaluated, a number of data suggests that they contribute efficiently to the oxidation of different fatty acids on the basis of their relative affinities (29). This is supported by observations of increased hepatic fatty acid oxidation in rats fed n-3 fatty acids (30–33) as well as observed differential oxidation of fatty acids (34). Thus, complex regulatory mechanisms are likely to be involved in promoting the synthesis of characteristic TAG molecular species in BAT when rats are fed a fish oil enriched diet. Conversely, it can be postulated that the fatty acids stored may modulate BAT thermogenic activity. Since the role of specific fatty acids as uncouplers for BAT adipocyte respiration remains unclear (9,27), future experiments with n-3 fatty acids are needed to advance our understanding of the regulation of this important physiological mechanism.

When comparing fatty acid metabolism in BAT and WAT in the course of dietary treatment, the relative weights of the two fat stores and their vascularization should also be considered. The rapid attainment of a steady-state fatty acid composition, as we observed here in BAT, may be due in part to its small size (about 0.25 g TAG vs. about 5 g in a rat retroperitoneal depot). Although the rate of *de novo* TAG formation in BAT was shown to be less than that in WAT (35), a high overall turnover rate of lipids in BAT could adequately explain the faster incorporation of n-3 HUFA into BAT compared to WAT.

In conclusion, it appears that BAT has a higher affinity than WAT for n-3 HUFA (2) when animals are fed a fish oil diet, although a contribution from intracellular fatty acid interconversion should not be ruled out. Our study of

the time-related acylation of n-3 HUFA in BAT shows specific patterns when compared to WAT. Our data suggest the existence of several regulatory steps (which may be sensitive to dietary manipulations) in the build-up of BAT fat depots. This process may include diet-induced changes in the thermogenic capacity of BAT. Further studies are required to determine whether the major function of this highly specialized tissue is affected by the stereochemistry of the TAG stored.

Absorption of Isomeric, Palmitic Acid-Containing Triacylglycerols Resembling Human Milk Fat in the Adult Rat

Nanneke J. de Fouw[a,*], Gerard A.A. Kivits[a], Paul T. Quinlan[b] and Wim G.L. van Nielen[a]

[a]Unilever Research Laboratorium Vlaardingen, 3133 AT Vlaardingen, The Netherlands and [b]Unilever Research Laboratories Colworth House, Bedford, England

The effect of the positional distribution of palmitic acid (16:0) in triacylglycerols (TAG) on 16:0 apparent absorption in adult rats was investigated. The rats were fed two diets which contained 30 energy % as fat with identical total fatty acid compositions, both containing 30% 16:0. The Betapol diet contained TAG with 73% of total 16:0 in the *sn*-2 position, the control diet contained TAG with 6% of total 16:0 in the *sn*-2 position. After six weeks on these diets, the rats were killed two or six hours after the last meal, and the small intestine was removed, cut into 10-cm segments, and the fatty acid composition of the segment's contents was determined. At both time points the amount of 16:0 in the intestinal segments starting at 40 cm from the stomach was much lower in the animals fed Betapol than in the animals fed the control diet. Overall absorption of 16:0 and stearic acid was significantly greater in the Betapol group. Absorption of oleic and linoleic acid from the small intestine was similar in both groups, although the overall absorption was significantly greater in the animals fed Betapol. Total fat absorption was significantly higher in the Betapol-fed rats than in the control-fed rats. No effect on calcium and nitrogen absorption, on plasma total cholesterol and TAG levels, and on bodyweights (growth) was seen. The data demonstrate that the positional distribution of the fatty acids in the TAG molecule affects the site of absorption in the small intestine and particularly the net absorption of saturated fatty acids.

***Lipids* 29, 765–770 (1994).**

The fat components of milk formulas used for bottle-feeding infants are usually based on vegetable oils which are either used alone or in combination with butterfat or other animal fats. The fat components are often formulated to approximate the total saturated fatty acid (FA) composition of human milk. Studies have demonstrated that human milk fat is better absorbed than infant formulas, particularly in the premature and newborn infant (1–7). Human milk fat typically contains 20–25% palmitic acid (16:0) (5), and most (>70%) of the 16:0 is esterified to the *sn*-2 position of the triacylglycerols (TAG). It has been suggested that this, together with the lipases present in human milk, accounts for its high absorption (8,9). In contrast, vegetable fat-based infant formulas containing similar 16:0 levels as human breast milk consist predominantly of *sn*-1,3 16:0 TAG, which are less readily absorbed than human breast milk even when residual bile salt-stimulated lipase activity is eliminated by sterilization (10). The apparent nutritionally beneficial effect of *sn*-2 16:0 TAG is thought to be related to the way saturated FA are absorbed by the intestine.

Little information is available on the apparent absorption of TAG with similar total FA composition but with different FA positional distribution. Previous studies on infants, as well as on laboratory animals, on TAG absorption have either compared animal vs. vegetable fats, fats with different FA compositions, or the effect of chemical randomization on fat absorption. The goal of the present study was to investigate the effect of FA positional distribution in TAG on TAG lipolysis and FA absorption. We have therefore prepared two structured fats with identical total FA composition but differing only in the positional distribution of 16:0, with the latter either being predominantly esterified to the *sn*-1,3 positions or the *sn*-2 position. The TAG were used to study the effect of FA positional distribution on TAG hydrolysis in the small intestine, the rate and extent of absorption of the lipid hydrolysis products, and the nature of the excreted products in the feces of adult rats.

MATERIALS AND METHODS

Chemicals. All solvents and chemicals (Merck, Darmstadt, Germany) used were at least analytical grade. Methyl heptadecanoate (99% pure) was obtained from Merck.

Diets. The composition of the 30 energy % semisynthetic diets is given in Table 1. The diets were prepared in one batch for the entire experimental period and were stored in small portions at −22°C. The animals were provided with demineralized drinking water starting from day five after their arrival.

TABLE 1

Composition of the Semisynthetic Diets

Ingredients	g/1000 kcal
Calcium caseinate	60.7
Vitamin mixture (Vit'70)[a]	1.0
Mineral mixture (RMH'88)[a]	3.6
Cellulose	15.0
Fat blend (control or test)	32.3
Maize starch	134.3
Total	246.9

[a]Amounts of minerals and vitamins in the purified diets per 1000 kcal: Ca, 846 mg; P, 728 mg; K, 601 mg; Na, 167 mg; Cl, 167 mg; Mg, 133 mg; Fe, 8.3 mg, I, 0.04 mg; Mn, 16.7 mg; Zn, 4.0 mg; Cu, 1.65 mg; choline chloride, 250 mg; myoinositol, 25 mg; vitamin B_{12}, 0.0129 mg; vitamin B_1 (thiamine mononitrate), 1.5 mg; calcium pantothenate, 5 mg; niacin, 5 mg; vitamin B_2 (riboflavin), 1.5 mg; vitamin B_6 (pyridoxin), 1.58 mg; folate (folic acid), 0.25 mg; vitamin K_3 (menadion, concentration 22.7%), 0.227 mg; biotin, 0.05 mg; vitamin A, 2500 IU; vitamin D_3, 250 IU; and vitamin E (concentration, 500 IU/g), 20 mg.

Abbreviations: FA, fatty acids; FAME, fatty acid methyl esters; GC, gas chromatography; Ln, linoleic acid; O, oleic acid; S, saturated fatty acid; TAG, triacylglycerol; TC, total cholesterol; TLC, thin-layer chromatography.

TABLE 2

Fatty Acid (FA) Composition of the Fat Blends[a]

FA	Overall		*sn*-2 Position[b]	
	Control	Betapol	Control	Betapol
14:0	0.9	1.0	0.4	1.9
16:0	29.9	30.4	5.9	72.7
16:1	0.3	0.1	0.2	[c]
18:0	3.4	3.2	0.5	6.9
18:1n-9	50.0	51.5	68.2	14.7
18:2n-6	13.4	13.3	24.2	3.6
18:3n-3	0.3	0.1	0.4	[c]

[a]Percentages of individual FA are expressed relative to total FA methyl esters. The control blend was a mixture of natural oils (87.5% palmolein, 11% high oleic acid sunflowerseed oil, 1.5% sunflowerseed oil). Betapol was prepared by enzymic interesterification.
[b]To calculate the proportion of an FA esterified to the *sn*-2 position, the following formula applies: *sn*-2 position (%)/3 × overall FA methyl esters (%), e.g., for 16:0 in the test blend: 72.7/3 × 30.4 = 0.8 (80% of total 16:0 is esterified to the *sn*-2 position); or for 16:0 in the control blend: 5.9/3 × 29.9 = 0.066 (6.6% of total 16:0 is esterified to the *sn*-2 position).
[c]Less than 0.1%.

Fats. The *sn*-1,3 16:0 rich fraction was obtained by solvent fractionation of palm oil, followed by blending with 11% high-oleate sunflowerseed oil, and 1.5% sunflowerseed oil. The Betapol-rich fat was obtained by *sn*-1,3 enzymic interesterification of a palm fraction with sunflower FA, followed by solvent fractionation of the resultant TAG. Both fats were fully refined before use. FA and TAG compositions are shown in Tables 2 and 3, respectively.

Animals and feeding regimen. Forty male rats (Wistar WU; Charles River Wiga, Sulzfeld, Germany), seven weeks of age were housed individually in steel cages and had free access to food and drinking water. After an acclimatization period of two days, the animals were divided according to body weight into two groups of 20 animals each (Group 1 and Group 2). They were trained to eat their daily food in two separate meals, each during a 30 min time span, at 700 and 1900 hours. During this meal-type feeding period, the rats were randomly subdivided into two additional groups: half the animals of Group 1 were killed 2 h after the last morning meal (Group 1 or 2, 2 h) and the other half 6 h after the last morning meal (Group 1 or 2, 6 h). Each subgroup consisted of 10 animals. To ensure that the animals consumed the entire meal on the day of sacrifice, the animals were provided with a meal that was 90% of the usual amount.

TABLE 3

Silver-Phase Triacylglycerol (TAG) Analysis of Fat[a]

TAG[b]	Control	Betapol
SSS	0.3	0.3
SOS	12.0	0.9

>3 Double bonds/TAG	4.4	4.2
sn-2 Saturated FAME relative to total FAME	5.5	86.9

[a]Fat composition is given a weight percent relative to total TAG.
[b]S, saturated acid; O, oleic acid; Ln, linoleic acid; FAME, fatty acid methyl ester.
[c]Less than 0.2%.

Serum total cholesterol levels. A commercially available kit from Boehringer Mannheim (Boehringer Testcombination Cholesterol CHOD-PAP; Mannheim, Germany) was used to determine total cholesterol (TC). Cholesteryl esters in serum were hydrolyzed with cholesterol esterase to free cholesterol which, with cholesterol oxidase, formed hydrogen peroxide which was measured spectrophotometrically using a Vitatron Programmable Analyser PA 800 (Dieren, The Netherlands).

Serum TAG levels. Total glycerol was determined using the GPO-PAP method (Boehringer Mannheim). Free glycerol was determined enzymatically [using the Boehringer Mannheim ultraviolet (UV) method, omitting the KOH hydrolysis step]. TAG was defined as the difference between total glycerol and free glycerol.

Preparation of intestinal segments and collection of intestinal contents. The animals were decapitated either two or six hours after their last meal. The stomach was ligated just below the end of the oesophagus and just below the pylorus. The duodenum and ileum were ligated and cut into 10-cm pieces. The intestinal contents were collected as quickly as possible using blunt metal needles and placed into glass tubes containing cold methanol and Tris/HCl buffer (pH 4) (1:1, by vol). The mixtures were thoroughly agitated and placed on ice until further analysis within the same day. The entire intestinal content of each of the segments was thoroughly mixed with 4 mL cold methanol, immediately followed by addition of 1 mL of Michaelis buffer (containing sodium acetate and sodium barbital, pH 3) to stop any residual lipase activity. After mixing, 2 mL of chloroform and 50 µL of internal standard solution (methyl heptadecanoate, 17:0 methyl ester, 10 µg/µL) was added. After vortexing for 10 s, the mixture was left at room temperature for at least 15 min, and was then centrifuged for 10 min at 1500 × *g*. After centrifugation, the supernatant was collected, and the sediment was washed with 4 mL of chloroform/methanol (2:1, vol/vol), mixed well using a Vortex mixer, and again centrifuged for 10 min at 1500 × *g*. Two mL chloroform and 2 mL distilled water were added to the combined supernatants, and the mixture was cautiously shaken and subsequently centrifuged for another 10 min at 1500 × *g*. The chloroform layer was removed and washed with 8 mL methanol/water (1:1, vol/vol), carefully mixed, and centrifuged again. The extract was evaporated under a stream of nitrogen. Finally, 2 mL of chloroform were added, and the extract was stored under nitrogen at -20°C.

Preparation of fatty acid methyl esters (FAME) from the lipid extracts. An appropriate amount of lipid extract was concentrated under a stream of nitrogen in a screw-capped vial. After addition of 4 mL of methanolic HCl, the mixture was placed in a waterbath at 65°C for 2 h. After cooling to room temperature, 8 mL of 5% (wt/vol) aqueous

NaCl was added, and the reaction mixture was extracted with 6 mL of hexane/diethyl ether (1:1, vol/vol). The extraction was repeated twice with 3 mL of hexane/diethyl ether (1:1, vol/vol) under the same conditions, and the combined hexane/diethyl ether extracts were concentrated under a stream of nitrogen. The residue containing the FAME was purified by thin-layer chromatography (TLC) (DC Fertigplatten, Kieselgel 60; Merck) using hexane/diethyl ether (80:20 vol/vol) as developing solvent; detection was with 0.01% primuline under UV (254 nm) light. The zone corresponding to FAME was scraped off and extracted three times with hexane/diethyl ether (1:1, by vol/vol). After evaporation of the solvent, the residue was dissolved in 100 μL of *n*-heptane and transferred to gas chromatography (GC) vials and stored.

GC analysis. FAME were analyzed on a Varian 3700 chromatograph (Walnut Creek, CA) equipped with an automatic sampler and flame-ionization detector, employing a wall coated open tubular fused silica capillary column coated with 0.20 μm Chrompack (CP) Sil-88 (Fused Silica, Chrompack, Middelburg, The Netherlands) (length 50 m, i.d. 0.25 mm). The injector and detector temperature were set at 230°C. After an initial isothermal period of 8 min at 170°C, the temperature was raised to 220°C at 2°C/min, followed by a hold at 220°C for 10 min. Nitrogen was used as the carrier gas.

Silver-phase high-performance liquid chromatography. This method was used according to Jeffrey (11) to identify the specific TAG species present in the blend.

Feces collection and extraction of total fat in dried feces. Feces were collected and pooled from study days 20–27. The samples were stored under nitrogen at -70°C until further analysis. The freeze-dried feces (1.5–2 g) was placed into a 100-mL glass beaker. Five mL of 20% aqueous HCl was added per gram of feces and mixed. After 2 h, approximately 40 g of calcium sulfate was added, and the mixture was well stirred. The mixture was then quantitatively transferred to a Whatman thimble (Whatman, Maidstone, Kent, United Kingdom). The mixture was extracted with petroleum ether for 8 h, using a Soxhlet extractor (Whatman) and a preweighed 100 mL-flask. The petroleum ether was evaporated, and the extracted lipid was dried with acetone. The amount of extractable lipid was determined gravimetrically. After addition of a known amount of 17:0 as internal standard, the extracts were methylated and analyzed by GC.

Gross energy determination of feces (Parr adiabatic bomb). Gross energy in feces was determined by the International Standards Organization method (12).

Protein determination in feces using a Kjelfoss automatic instrument. The method used was that described by Smith (13).

Mineral determination in feces. Feces samples were dry-ashed, and the minerals were converted to their chlorides by fusing with concentrated HCl and then diluted with an equal volume of water. The metal chlorides were extracted with 3M aqueous HCl, and the resulting solutions were analyzed by atomic absorption spectroscopy or colorimetry.

Calcium determination in feces using atomic absorption spectroscopy. Calcium was determined according to the *AOAC Official Methods of Analysis* (14). The following formula was used to calculate the calcium content in the sample:

$$\text{Ca (wt\%)} = (c \times \text{dilution} \times 100)/(w \times 10^4) \quad [1]$$

in which c is the concentration in the diluted solution (μg/mL) and w the sample weight.

Statistical analysis. The Student's *t*-Test was used to analyze the rat feces data, food consumption and growth, utilizing the SAS statistical analysis package (version 6.4; SAS Institute, Cary, NC). The fatty acid analysis data of the intestinal segment contents were log-transformed prior to statistical analysis.

RESULTS

Fatty acid composition of the fat blends. Tables 2 and 3 show the composition of the fat blends used. The total FA compositions of the control and Betapol blends were identical. However, the blends substantially differed in the positional distribution of the FA on the TAG glycerol backbone. In the Betapol blend, 80% of 16:0 was esterified to the *sn*-2 position; in the control blend, it was only 6.6%. This affected the positional distribution of oleic acid—in the control blend oleic acid was predominantly esterified to the *sn*-2 position (44.6% of total), and in the Betapol it was only 9.5%.

The results of the silver-phase analysis (Table 3) show that in the control blend the major TAG were SOO (saturated–oleic–oleic) and SOLn (saturated–oleic–linoleic), as compared to the Betapol blend, in which OSO and OSLn predominated.

Bodyweight, growth and food consumption. The bodyweights at the start of the experiment of the different groups did not differ statistically and were as follows (g ± SEM): control (2 h), 201.6 ± 6.3 g; control (6 h), 202.8 ± 11.7 g; Betapol (2 h), 203.3 ± 6.5 g; Betapol (6 h), 199.4 ± 12.3 g. At the end of the experiment, the bodyweights also did not differ significantly and were: control (2 h), 266.7 ± 22.2 g; control (6 h), 255.5 ± 21.6 g; Betapol (2 h), 264.4 ± 15.4 g, Betapol (6 h), 261.4 ± 21.9 g.

No statistically significant differences between the rats fed the different diets in respect to food consumption or growth were seen. The mean total food intake (g ± SEM) over study days 20–26 was for the Betapol-fed animals (74.8 ± 1.25 g) and for the control-fed animals (70.5 ± 1.76 g). The mean growth (g ± SEM) from the start of the experiment up to study day 27 was for the Betapol-fed animals (65.6 ± 3.47 g) and the control-fed animals (58.9 ± 3.47 g).

Plasma TC and TAG levels of the rats at the end of the feeding period. Table 4 shows the plasma TC and TAG levels of the rats at the end of the feeding period, 2 and 6 h after the last meal. No significant differences were seen between the rats fed the different diets.

Rat feces analysis. Table 5 shows the overall fat and FA absorption during the feeding period of the different diets. The rats on the Betapol diet absorbed significantly more fat than those on the control diet—97.2% vs. 95.6% ($P < 0.001$), respectively. The mean FA absorption of the rats

TABLE 4

Total Plasma Cholesterol (TC) and Triacylglycerol (TAG) Levels of Rats[a]

	TC (mM)		TAG (mM)	
Group	2 h	6 h	2 h	6 h
Control	1.78 ± 0.5	1.79 ± 0.3	2.3 ± 0.5	2.14 ± 0.8
Betapol	1.84 ± 0.4	1.88 ± 0.3	2.48 ± 0.8	2.92 ± 1.1

[a]At the end of the feeding period 2 and 6 h after the last meal (n = 10, mean ± SD).

fed the Betapol diet was significantly higher (99.2%) compared to that of the control-fed rats (97.9%, $P < 0.001$). The increased fat absorption also resulted in a small but significant increase in the total energy absorption from the Betapol diet and, consequently, in an increase in digestible energy.

No statistically significant differences were seen in respect to nitrogen and calcium excretion.

In Table 5 data are shown on the individual FA excreted in the feces during a 5-day period. Palmitic acid, oleic acid, linoleic acid and stearic acid were all significantly better absorbed by the rats fed the Betapol blend than by the rats fed the control blend. The greatest difference in excretion between the two diets was found for 16:0.

Fatty acid analysis of the intestinal segment contents. Figure 1 shows the results of the FA analyses of the different intestinal segments contents. It appears that, in particular 16:0, when fed as Betapol, required a much smaller portion of the intestine to be absorbed when compared to the control blend; this was seen both at 2 and 6 h

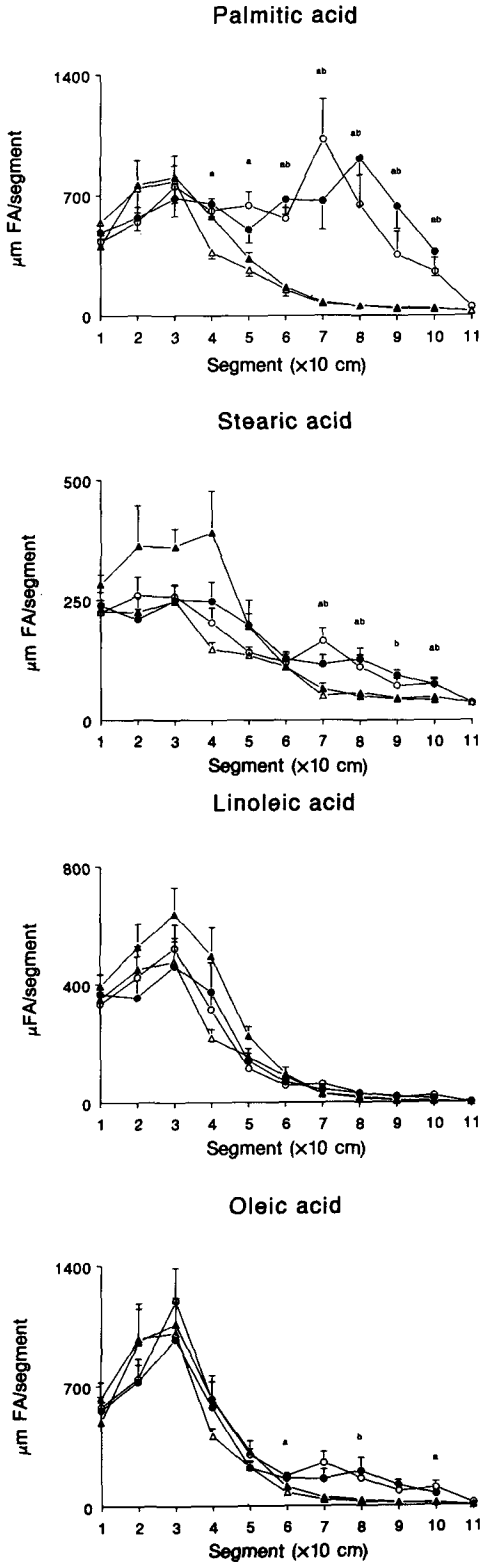

FIG. 1. Nonabsorbed fatty acids, palmitic, stearic and linoleic and oleic (µg/segment ± SEM) in intestinal segments. The data were log-transformed before statistical analysis. Level of significance, $P < 0.05$. Open symbols, 2 h after the last meal; closed symbols, 6 h after the last meal. Triangles, Betapol blend, circles, control blend; n = 6 rats per group. a, Betapol differs significantly from control at two hours after the last meal; b, Betapol differs significantly from control at six hours after the last meal. FA, fatty acid.

after the last meal. Furthermore, oleic acid was significantly better absorbed from segment 6 onward by the rats fed Betapol compared to the animals fed the control diet both at 2 and 6 h after the last meal; the differences, however, are small. The same holds true for the absorption of stearic acid. From segment 6 onward, stearic acid present in the Betapol blend was better absorbed than stearic acid present in the control blend. No explanation can be given for the observed increase in stearic acid in the first four segments at 6 h after the last meal of the control blend compared to the other blend and other time points. The absorption patterns for linoleic acid and oleic acid did not differ between the two diets.

DISCUSSION

In the present study, we investigated the effect of the positional distribution of FA in dietary TAG on the rate of apparent digestion and absorption in the rat. The two fat blends used had identical FA compositions but differed in the positional distribution of 16:0 and oleic acid. In the control blend, most of the total 16:0 (93.4%) was esterified to the *sn*-1,3 positions of the TAG, whereas in the test blend (Betapol) 16:0 was predominantly esterified to the *sn*-2 position of TAG.

The total fat excretion of the rats was significantly lower on the Betapol diet than on the control diet. This is mainly due to the decreased excretion of 16:0 on the Betapol blend. Tomarelli *et al.* (4) found that the relative absorption of 16:0 was linearly related to its proportion at the *sn*-2 position of the TAG molecule, which agrees with our results.

Furthermore, our data clearly demonstrate that both at 2 and 6 h after the last meal, 16:0 fed to the rats as Betapol appeared to be more rapidly absorbed in the upper part of the intestine as compared to 16:0 of the control diet. This more rapid disappearance of 16:0 was related to a more efficient absorption overall. For 18:1, preferentially esterified to the *sn*-2 position in the control blend as compared to the Betapol blend, no differences in the absorption patterns between control and Betapol blend were seen. The absorption of the other FA (stearic and linoleic acid) required about the same intestinal length for both fat blends. These results indicate that the positional distribution of saturated FA in dietary TAG is more critical in determining absorption efficiency than it is for unsaturated FA.

The differences in intestinal length required to absorb 16:0 located at the *sn*-2 vs. the *sn*-1,3 positions can be explained as follows. First, TAG containing unsaturated FA at the *sn*-1,3 positions are more readily hydrolyzed than TAG bearing saturated FA at these positions, and thus they are absorbed earlier (15–17). Second, after TAG hydrolysis, the products released are for the Betapol blend oleic acid and *sn*-2-palmitoylglycerol, and for the control blend 16:0, oleic acid and *sn*-2-oleoylglycerol. The absorption of unsaturated monoacylglycerol is strongly favored due to its relatively greater hydrophilicity as compared to saturated monoacylglycerols (18). Third, 16:0 (melting point, 63°C) is not as well absorbed as are fatty acids with a lower melting point, and it requires more bile acids to maintain it in micellar solution, which is a prerequisite for lipid absorption to occur. Finally, FA soaps can be formed, especially in the absence of a micellar phase. Calcium soaps have been shown to be about six times less soluble in the intestinal lumen than are the corresponding free FA (19). Calcium and magnesium soaps of unsaturated FA are more soluble in the intestinal fluid and can be solubilized to a greater extent by the products of fat digestion and thus are better absorbed (20,21). Furthermore, calcium soaps are in general much more soluble in unsaturated FA micelles than in saturated FA micelles.

To get some insights on the amount of FA soaps and free FA present in the feces, an attempt was made to differentiate between the two forms by solvent-extracting the feces samples before and after acidification. It was found that 70–75% of the total FA present could be extracted only after acidification of the sample (data not shown). This suggests that the bulk of the FA excreted in the feces was present as FA soaps. That this did not result in significantly altered calcium excretion is perhaps not surprising, because of the very low levels of fat being excreted in comparison to fecal calcium. Of the latter, as little as 20% may have been associated with FA as soaps (assuming a 2:1 molar ratio for FA/calcium), making it very difficult to detect changes in calcium associated with this pool. Mattson and co-workers (20) reported that the excretion of stearic acid in feces was affected by the amount of calcium present in the diet and by the positional distribution of stearic acid in the TAG. In their experiments they used 6 mg calcium per g of diet, whereas our diets contained 3.4 mg/g diet.

Our results do not suggest that differences in FA positional distribution lead to differences in plasma TC and TAG levels in the rat. Several papers have been published on the possible effect of FA positional distribution in the TAG molecule on cholesterol metabolism in rabbits and in humans (22,23). It has been reported by Ockner and coworkers (24) and Ockner and Jones (25) that differences in intestinal absorption could account for the physiological characteristics of chylomicrons in rats. In the light of our findings, it is thus possible that the positional distribution of FA in the TAG could affect some aspects of chylomicron metabolism. Zampelas *et al.* (26) have studied the effect of a liquid meal containing either the Betapol blend or the control blend on postprandial lipid responses. They reported that the positional distribution of palmitic acid on TAG did not effect the postprandial lipemia in adult male subjects. However, their results do not exclude the possibility that different responses may be seen when these TAG are given for a longer period of time.

In conclusion it is clear that feeding TAG enriched in *sn*-2 16:0 (Betapol) to rats as compared to *sn*-1,3 16:0 TAG results in increased total fat absorption. In addition, the length of intestine required to achieve this absorption is reduced. These results were obtained on adult rats having a well developed intestinal system. In weanling animals, and in premature or newborn infants, the uptake systems are not as well developed (lower levels of lipases and bile acids), and it appears reasonable to hypothesize that under these conditions the *sn*-2 16:0 fat blend will have even greater beneficial effects (27,28).

n-3 Fatty Acids Inhibit Defects and Fatty Acid Changes Caused by Phenytoin in Early Gestation in Mice

Kim A. High and **Stan Kubow***

School of Dietetics and Human Nutrition, McGill University, Ste. Anne de Bellevue, Québec, H9X 3V9 Canada

Our previous work has shown that n-3 fatty acids exert a protective effect against phenytoin-induced cleft palate when phenytoin was administered midgestation [gestational days (GD) 12 and 13] to CD-1 mice. The effects of dietary n-3 fatty acids on phenytoin teratogenicity were investigated at an earlier gestational period (GD 9) to examine whether n-3 fatty acids could exert protective action against other teratogenic effects of phenytoin apart from cleft palate. The effect of phenytoin exposure on maternal hepatic polyunsaturated fatty acid composition was also studied since Δ6 desaturase activity has been shown to be modified by pharmacological action. Female CD-1 mice were fed a standard laboratory diet (SLD), safflower oil (SAFF) or a cod liver/linseed oil (CLO/LO)-based diet for three weeks prior to impregnation and throughout pregnancy. Pregnant mice were administered a single i.p. dose of phenytoin on GD 9, and teratological assessments were performed on GD 19. Tissues were harvested on GD 10 for maternal hepatic phospholipid fatty acid analysis from another group of phenytoin-treated mice. The CLO/LO and the SLD mice, as compared to the SAFF-fed animals, showed a reduction in total malformations and fetal growth retardation due to phenytoin. Open eye defect was the only anomaly induced by phenytoin in the CLO/LO fetuses while phenytoin produced a variety of malformations in the SAFF fetuses such as tail defects, cleft palate, open eye and absence or blockage of the ureter. Dietary n-6/n-3 fatty acid ratios were reflected in maternal hepatic phospholipids; however, phenytoin exposure appeared to inhibit the conversion of 18:2n-6 to 20:4n-6 in the SAFF dams only. These results indicate that the overall protective effects of dietary n-3 fatty acids on phenytoin embryo-toxicity are observed at an early gestational period.

***Lipids* 29, 771–778 (1994).**

Phenytoin (5,5-diphenylhydantoin, Dilantin), an extensively used anticonvulsant, is a suspected human teratogen (1–3) and is teratogenic in mice (4–9). The Fetal Hydantoin Syndrome (FHS) describes a particular set of anomalies in children born to women taking hydantoin anticonvulsants during pregnancy, primarily phenytoin (1). This syndrome of defects includes craniofacial anomalies, cardiac defects, and growth and mental retardation (1). Mouse models have been used frequently to investigate issues related to the teratogenic actions of phenytoin. Chronic *in utero* phenytoin exposure resulting in a mouse hydantoin syndrome similar to FHS has been reported (9). In various mouse strains, acute phenytoin administration during organogenesis results primarily in the induction of cleft palate, cardiac defects, open eyelid and fetal weight reduction (4–9). As with other classic teratogenic agents, the type of defect produced by acute phenytoin administration depends upon the stage during pregnancy when phenytoin exposure occurs.

A number of possible mechanisms of phenytoin teratogenicity have been suggested including: (i) drug-induced folate deficiency; (ii) a glucocorticoid-mediated mechanism; and (iii) metabolism to a reactive intermediate and binding to embryonic macromolecules (10). The mechanism of phenytoin teratogenicity under investigation in our laboratory is the prostaglandin H synthase (PGS)-mediated bioactivation of phenytoin to a reactive intermediate (11). Indication of a teratogenic role for reactive intermediates of phenytoin has come from *in vivo* studies showing that covalent binding of phenytoin to embryonic proteins was positively and highly correlated with phenytoin-induced malformations (12). As PGS occurs in high concentrations in embryonic tissues (13), it may play an important role in the metabolic activation of phenytoin to a reactive intermediate. Evidence for a teratogenic role for a reactive free radical intermediate generated from PGS-mediated metabolism of phenytoin includes studies demonstrating that: (i) inhibition of PGS activity by administration of acetylsalicylic acid in CD-1 mice resulted in a 50% reduction in phenytoin-induced cleft palates and a 43% reduction in covalent binding of phenytoin to embryonic proteins (14); (ii) addition of either antioxidants or the PGS inhibitor, indomethacin, inhibited arachidonic acid (20:4n-6)-dependent covalent binding of phenytoin to microsomal proteins from ram seminal vesicles (a rich source of PGS) and various murine tissues (11); and (iii) pretreatment with either the antioxidant caffeic acid or the free radical spin trapping agent, α-phenyl-*N*-*t*-butyl-nitrone, caused dose-related decreases in phenytoin-induced cleft palates and resorptions (14).

The present study represents a follow-up to our previously published report (12) which demonstrated that a semipurified diet rich in n-3 fatty acids fed for three weeks prior to gestation was associated with a lowered frequency of cleft palate due to phenytoin exposure on gestational days (GD) 12 and 13 in CD-1 mice. Additionally, on GD 12, embryonic production of prostaglandin $F_{2\alpha}$ ($PGF_{2\alpha}$) and covalent binding of radiolabeled phenytoin to embryonic proteins were reduced, and the embryonic n-3/n-6 phospholipid fatty acid ratio was increased in animals fed the n-3 fatty acid-enriched diet. The results of these studies led to the hypothesis that an underlying mechanism of the protective effects of the n-3 fatty acids was an inhibition of embryonic PGS-mediated bioactivation of phenytoin. Since phenytoin-induced cleft palate was the sole defect

Abbreviations: ANOVA, analysis of variance; BHT, butylated hydroxytoluene; CLO/LO, cod liver oil/linseed oil; FAME, fatty acid methyl esters; FHS, Fetal Hydantoin Syndrome; GD, gestational day; $PGF_{2\alpha}$, prostaglandin $F_{2\alpha}$; PGS, prostaglandin H synthase; PUFA, polyunsaturated fatty acids; SAFF, safflower oil; SLD, standard laboratory diet; TBA, thiobarbituric acid; TBARS, thiobarbituric acid reactive substances.

observed following phenytoin treatment on GD 12 and 13, it was unclear whether the protective effects of n-3 fatty acids were primarily mediated against phenytoin-induced cleft palate or whether n-3 fatty acids could exert protective action against a variety of teratogenic effects of phenytoin. Before any specific conclusions can be drawn, it is necessary to determine if the protective effect of n-3 fatty acids against phenytoin-induced malformations in the CD-1 mouse exists on a continuum from an earlier period of organogenesis (GD 9) to the time of palatal shelve closure on GD 12 and 13. Administration of phenytoin on GD 9 was chosen in the present study since phenytoin administration in mice during this period of organogenesis has been associated with an increased incidence of open eyelid and tail defects (15).

Animals lack the enzymes necessary to form n-3 or n-6 polyunsaturated fatty acids (PUFA) and thus require these essential fatty acids in the diet. Microsomal fractions from the brain, and other animal tissues are capable of elongation and desaturation of the n-3 and n-6 essential fatty acids. Two of the endproducts of the elongation and desaturation pathway, eicosapentaenoic acid (20:5n-3) and 20:4n-6, each generate a separate family of prostaglandins *via* PGS metabolism. Of major significance for essential fatty acid nutrition is the competitive desaturation of the n-3 and n-6 series by Δ6 desaturase as this is the rate-limiting step of the elongation–desaturation pathway (16). As a consequence, supplementation of diets with rich n-3 sources, such as fish oils, results in the selective incorporation of 20:5n-3 and docosahexaenoic acid (22:6n-3) into various lipid classes while concomitantly reducing the content of 20:4n-6 in several tissues as has been seen in humans and experimental animals (12, 17,18). The increased tissue n-3 fatty acid content can directly inhibit PGS activity by causing a decreased peroxide tone (19). Additionally, recent studies have shown that tissue PUFA content and composition may be profoundly altered by pharmacological modification through inhibition of Δ6 desaturase with possible functional implications (20). As eicosanoids derived from n-3 or n-6 PUFA in maternal and fetal tissues play a vital role in fetal growth (13), research is needed to determine whether phenytoin treatment alters tissue PUFA levels during pregnancy and whether this is affected by the family of PUFA concurrently consumed.

In the present study we have extended our previous investigation (12) and have addressed these important issues. A set of reproductive endpoints as well as maternal phospholipid fatty acid profiles were determined so that the impact of dietary n-3 fatty acids on the relationship of phenytoin exposure with (i) reproductive toxicity during an early period of pregnancy (GD 9), and (ii) PUFA metabolism could be studied at the level of the individual animal.

MATERIALS AND METHODS

Animals and mating procedure. Virgin female (20–25 g) CD-1 mice (Charles River Canada, St. Constant, Quebec, Canada) were housed in a temperature-controlled room (24 ± 1°C) with a 12-h light–dark cycle (light cycle 0700 to 1900 h). The mice were housed in polypropylene shoebox cages with chrome-plated wire lids and heat-treated hardwood bedding (Beta-Chip; Northeastern Products Corp., Warrensburg, NY). They were randomly housed four per cage, and food and tap water were provided *ad libitum*. For mating purposes, one to three females from the same cage were housed with a male from 1700 to 0830 h. Food was removed from the cages during this period. The presence of a vaginal plug the following morning confirmed insemination and this date was designated as GD 1. Females were returned to their dietary treatment cages where they remained until sacrifice.

Diets. The semipurified diets used in these experiments were modified versions of the AIN-76 diet (21) consisting of the following ingredients (g/kg diet): dextrose, 489; vitamin-free casein, 182; D,L-methionine, 3; cellulose, 51; vitamin mix, 12; mineral mix, 63; lipid, 200. The lipid component was either 200 g safflower oil (SAFF) or a mixture of 20 g SAFF, 90 g codliver oil (CLO) and 90 g linseed oil (LO). The 20 g SAFF in the CLO/LO diet was included to provide a sufficient amount of linoleic acid (18:2n-6) to prevent essential fatty acid deficiency (21). All dietary components were obtained from ICN Biomedicals (Cleveland, OH). Vitamin and mineral mixes formulated for the increased requirements of these compounds during pregnancy were adapted from Fergusson and Koski (22). As CLO contained additional amounts of vitamins A and D, retinyl palmitate (102150 IU/kg diet) and cholecalciferol (9000 IU/kg diet) were added to the SAFF diet to match the vitamin concentrations in the CLO/LO diet. Additional *dl*-α-tocopheryl acetate was added to increase the overall concentration of vitamin E activity to 2000 IU/kg diet to protect the mice from an increased risk of *in vivo* lipid peroxidation and vitamin E insufficiency demonstrated previously in mice fed elevated concentrations of fish oil (23,24). The synthetic antioxidant butylated hydroxytoluene (BHT; ICN Biomedicals) was added to the dietary oils (0.01%, w/w) to protect against oxidation of PUFA. A standard laboratory diet (SLD; Mouse Chow® No. 5015; Purina Mills Inc., St. Louis. MO) was used as a control diet. The fatty acid composition of the diets is described in Table 1.

Semipurified diets were mixed before the beginning of each experimental period, aliquoted and stored under N_2 at -20°C. Aliquots contained sufficient food for approximately three weeks and were stored at 4°C under N_2. Female mice consuming semipurified diet were provided fresh diet on alternate days for three weeks prior to mating and throughout pregnancy. This feeding protocol has previously been shown to increase the ratio of n-3 to n-6 fatty acids in embryonic and maternal tissue phospholipids in mice fed 10% (w/w) of CLO/LO (1:1, w/w) (12). Food consumption and body weight data were recorded three times per week for the semipurified diet groups.

Samples of uneaten semipurified diet were removed from feed containers after each 48 h feeding period and stored at -20°C, under N_2 until analysis for thiobarbituric acid reactive substances (TBARS) to obtain an index of lipid peroxidation. A modification of the thiobarbituric acid (TBA) assay by Dahle *et al.* (25) was used. The lipids of each of the diet samples were extracted with chloro-

[e]UI (unsaturation index) = Σ (% FAME × number of double bonds in the FAME).

form/methanol (2:1, vol/vol) by the method of Folch *et al.* (26). Chloroform extracts were evaporated to dryness under N_2 and reconstituted with 40% ethanol to a final concentration of 0.5 mg/mL. To the reaction mixture was added 2.0 mL of 0.1 N sodium phosphate buffer (pH 6.0), 1.0 mL of 20% trichloroacetic acid and 2.0 mL of a 0.67% aqueous solution of TBA. After incubation for 15 min at 100°C, TBARS were measured spectrophotometrically at 535 nm on a Beckman DU-40 spectrophotometer. Analysis of the uneaten semipurified diet samples for TBARS yielded values that are indicative of relatively low levels of dietary lipid peroxidation (23,27), i.e., below 20 nmol of reference standard (malonaldehyde *bis*diethyl acetal); Sigma Chemical Co., St. Louis, MO) per g diet.

Experiment 1. A teratogenic dose of phenytoin (65 mg/kg) (5,12) was given to five SLD dams and ten mice each in the SAFF and CLO/LO groups as a single intraperitoneal (i.p.) injection on GD 9, employing a standard injection volume of 10.0 mL/kg body weight. A single dose regimen of phenytoin was given to decrease the likelihood of maternal toxicity or excessive embryo lethality which could mask the teratogenic effects of phenytoin (28). An equivalent number of dams in each dietary group received an identical volume of pH-matched vehicle (saline). Phenytoin (sodium diphenylhydantoin; Sigma) was dissolved in normal saline containing 0.002 M NaOH (Malinckrodt, Paris, KY) to achieve a final pH of 10.5. All solutions were prepared immediately prior to administration. Dams were killed on GD 19 by cervical dislocation. Following laparotomy, the uterus was exteriorized and the number, location and weight of fetuses and resorptions noted. All fetuses were weighed, sexed and examined for the presence or absence of major external anomalies (e.g., exencephaly, spina bifida, hydrocephaly, eye defects, hairlip and limb defects). Fetuses that died during a 2 h observation period after caesarian section were distinguished from live fetuses and resorptions in order to serve as an indication of postpartum mortality. Fetuses were also examined under a dissecting microscope for cleft palates. The frequency of malformations or of a specific defect was calculated as the number of affected fetuses divided by the total number of fetuses examined for a particular group and then multiplied by 100. The resorption incidence was determined as the number of resorptions divided by the number of implantation sites (fetuses plus resorptions) and expressed as a percentage.

Experiment 2. To examine the effects of dietary and phenytoin treatment on maternal hepatic phospholipid fatty acid composition, a second study was done in which phenytoin was administered to four mice from each dietary regime on GD 9 as described above. An additional four mice from each dietary group were injected with pH-matched vehicle. Maternal livers were extracted between 18 and 24 h after phenytoin or vehicle exposure on GD 9, rinsed with ice-cold 1.15% KCl and frozen at -80°C until phospholipid fatty acid analysis.

Tissue phospholipid fatty acid analysis. Lipid extracts from maternal liver homogenates were prepared as described previously (12) and separated into neutral lipid and phospholipid fatty acid fractions according to the method of Juaneda and Rocquelin (29). As described previously (12), fatty acid methyl esters (FAME) of total phospholipids were prepared and gas–liquid chromatography was used to separate and quantify FAME. FAME were identified by comparing retention times with those of authentic standards (Nu-Chek-Prep, Elysian, MN) and were quantified relative to heptadecanoic acid (17:0) used as internal standard.

Statistical analyses. Analyses of continuous variables were done as a three-by-two factorial design for two-way analysis of variance (ANOVA). The effects of diet and GD 9 phenytoin treatment on mean fetal weight were determined by nested ANOVA. As there were differences among the treatments in terms of litter size, statistical comparisons on fetal weight were performed using litter size as a covariate. When significant differences occurred, treatment mean differences were identified by Tukey's (equal cell sizes) or Bonferroni's (unequal cell sizes) multiple comparison tests. Statistical evaluations of postpartum mortality, the frequency of anomalies and specific types of malformations on a per-fetus basis were done by chi-square with Yates correction. All analyses were performed using the Statistical Analysis System for personal computers (Version 6.04, 1992; SAS Institute, Cary, NC). A probability of $P < 0.05$ was accepted *a priori* as the minimal level of significance for all analyses.

RESULTS

Maternal indices. Average feed consumption per cage of mice, either before or during pregnancy, was unaffected

by the type of semipurified diet (data not shown). Greater weight gain observed in the SLD mice during pregnancy as compared to the SAFF and CLO/LO dams may partially be explained by the larger litter size and the greater number of implantation sites of the SLD dams (Table 2). Litter sizes, expressed as the average number of live fetuses per litter, for the phenytoin-treated and control CLO/LO groups were lower than those for the SLD groups, whereas only the SAFF control dams had a smaller mean litter size relative to the SLD groups. Although the mean litter size of the phenytoin-treated SAFF diet group was larger than that of the control SAFF group, this may be partially explained by the greater number of implantation sites in the phenytoin-treated SAFF group compared to its control group. Comparison of implantation sites per dam gave the same results as those obtained for litter size with the additional observation that the mean number of implantation sites was greater in the phenytoin-exposed SAFF group vs. the phenytoin-exposed and control CLO/LO groups. Despite the differences between groups in terms of the average number of live fetuses and implantations per litter, neither drug nor dietary treatment affected the incidence of resorptions (Table 2). This result supports the idea that differences detected between the phenytoin-exposed SAFF group and both of the CLO/LO groups in terms of implantation sites were not likely due to treatment effects.

Fetal indices. Phenytoin exposure reduced mean fetal weight only in SAFF fetuses, whereas the fetuses from the n-3 fatty acid supplemented mice and the SLD group were unaffected by phenytoin treatment (Table 3). Although comparisons between the diet and drug groups in terms of postpartum mortality were not statistically significant, a clear trend was observed for an increased postpartum mortality due to phenytoin exposure in each of the dietary treatments (Table 3). When the phenytoin-treated groups were pooled, however, phenytoin was observed to exert a significant effect upon postpartum lethality relative to the groups receiving dietary treatment alone. Cleft palate, a defect characteristically induced by exposure to phenytoin on GD 11 through 13, was present following phenytoin treatment in SAFF fetuses but absent in fetuses from the SLD and CLO/LO groups (Table 3). In contrast to the presence of cleft palates observed in SAFF fetuses, the frequency of open eye defect was increased significantly by phenytoin treatment only in the CLO/LO diet group (Table 3). Although open eye defect was observed in phenytoin-exposed SAFF fetuses (2.6%), those fetuses affected were within one litter, whereas fetuses with open eye defect were distributed among four litters in the CLO/LO diet group.

Phenytoin exposure on GD 9 increased the frequency of malformations in each diet group (Table 3), although this increase was not statistically significant in the SLD group. The frequency of phenytoin-induced malformations was 2.5 times higher in SAFF offspring (16.2 %) as compared to CLO/LO fetuses exposed to phenytoin (6.4%). Malformations observed in the SAFF fetuses exposed to phenytoin on GD 9 included tail defects (8.5%), cleft palate (4.3%), open eye (2.6%) and absence or blockage of the ureter (1.7%). In contrast, open eye defect was the only malformation exhibited by the CLO/LO phenytoin-exposed fetuses. Anomalies observed in SLD offspring exposed to phenytoin included open eye (3.9%), tail defects (2.6 %) and one fetus with an atrophied hind region. The incidence of abnormalities did not differ significantly among the groups receiving dietary treatments alone and was within the norm for CD-1 mice fed either standard laboratory diets (5) or semipurifed diets (12).

Maternal hepatic phospholipid fatty acids. Dietary fat composition did not affect feed intake, prior to mating or during pregnancy, nor did it affect net weight gain in mice used for this analysis (data not shown). Phenytoin treatment on GD 9 decreased weight gain within each diet group, although the decrease was only significant within the CLO/LO group. The decrease in weight gain following

TABLE 2

Effects of Dietary Fat and Phenytoin Treatment on Pregnancy Outcome in Mice[a,b]

Treatment		Maternal	Live fetuses	Implantations	Resorption

[f]Number of fetuses affected (% of fetuses affected within the treatment group).
[g]Significantly greater than SAFF control group ($P < 0.01$) and phenytoin-treated CLO/LO group ($P < 0.05$) by continuity-adjusted chi-square analyses.
[h]Significantly greater than CLO/LO control group ($P < 0.05$) by continuity-adjusted chi-square analysis.

phenytoin exposure could be due to a sedative-like effect of the drug. There were no effects of diet or drug exposure on the average number of live embryos or on implantation sites per litter (data not shown). In contrast to mice in Experiment 1, phenytoin caused a significant increase in the incidence of resorptions in the CLO/LO animals. This increase may have been due to an unusually low number of resorptions in the CLO/LO control group.

Individual fatty acid levels (% wt of total FAME per group) of the maternal liver phospholipid fraction are shown in Figure 1. The livers of control SLD and CLO/LO dams had a higher content of 16:0 and lower concentrations of 18:0 and 18:1n-9 as compared to SAFF control livers. The hepatic phospholipid concentrations of 18:2n-6 were the highest in the vehicle-control SLD group while the CLO/LO dams receiving vehicle showed higher hepatic phospholipid levels of 18:2n-6 than the SAFF control livers. The SAFF livers of control dams contained the highest amount of 20:4n-6, more than fourfold higher concentrations than were observed in control CLO/LO livers. The livers of SLD mice receiving saline vehicle also had higher levels of 20:4n-6 than did the CLO/LO control livers. The CLO/LO liver phospholipids contained the only detectable concentrations of 20:5n-3. The longer chain 22:6n-3 was seen in all dietary treatments but was dramatically affected by dietary treatment as CLO/LO livers contained more than five times and almost twice the concentrations in SAFF and SLD livers, respectively.

Phenytoin exposure also induced differences in the fatty acid composition of maternal liver phospholipids. Phenytoin treatment increased 18:2n-6 concentrations in SAFF and SLD maternal hepatic phospholipids. In contrast, phenytoin exposure did not affect hepatic phospholipid fatty acid composition in the CLO/LO group. The ratio of hepatic phospholipid 20:4n-6 to 18:2n-6 (Fig. 2) in livers from the SAFF dams was decreased as a result of phenytoin exposure, suggesting an inhibition in the conversion

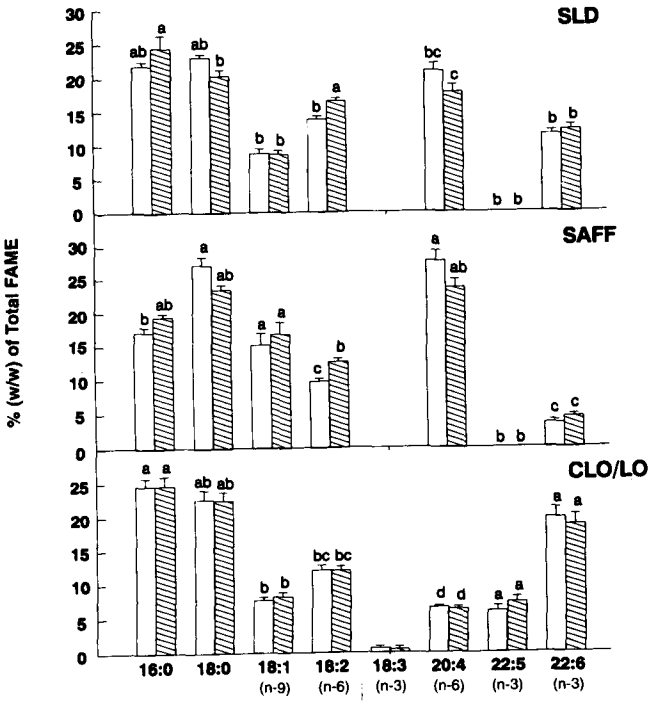

FIG. 1. Maternal hepatic phospholipid fatty acid composition in pregnant mice. Dams were fed either standard laboratory diet (SLD), safflower oil (SAFF) or codliver oil/linseed oil (CLO/LO) based diet for 3 wk prior to mating and through gestational day (GD) 10. On GD 9 dams were injected i.p. with saline (control) or with 65 mg/kg phenytoin. Dams were killed 24 h later and maternal livers were dissected, rinsed with ice-cold 1.15% KCl, and frozen at −80°C until fatty acid analysis. Data are expressed as the mean ± SEM (n = 4). Open bars represent vehicle controls and cross-hatched bars represent phenytoin-treated dams. Differences in the mean amounts for a particular fatty acid between diets and drug treatment are indicated by different letters as determined by Tukey's multiple comparisons test ($P < 0.05$). FAME, fatty acid methyl esters.

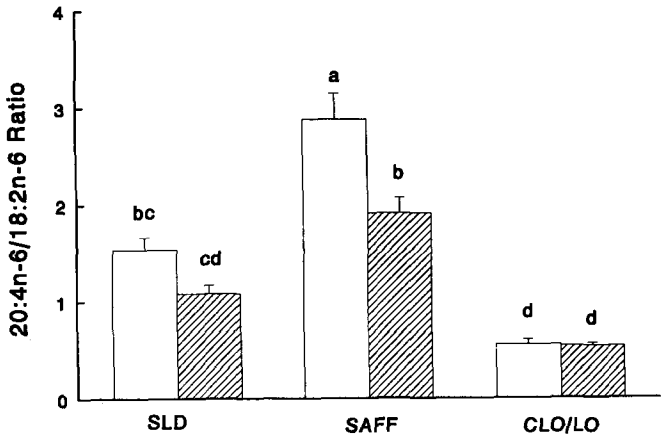

FIG. 2. Ratio of 20:4n-6/18:2n-6 in hepatic phospholipid fatty acids in pregnant mice. Mice were treated as described in Figure 1. Data are expressed as the mean ± SEM (n = 4). Open bars represent vehicle-controls and cross-hatched bars phenytoin-treated dams. Different letters indicate significant differences between means among all treatment groups by Tukey's multiple comparisons test ($P < 0.05$). See Figure 1 for abbreviations.

of 18:2n-6 to 20:4n-6 by phenytoin. Phenytoin treatment also decreased the ratio of n-6:n-3 hepatic phospholipid fatty acids in the SAFF group (Table 4) whereas the SLD and CLO/LO groups were unaffected by phenytoin in this regard. As expected, the CLO/LO groups exhibited the lowest phospholipid fatty acid n-6:n-3 ratio, and the n-6/n-3 ratio for the SLD mice was between those for the other two diet groups. Dams fed the SAFF diet had the lowest unsaturation index, likely due to the low amount of 22:6n-3 in the hepatic phospholipids (Table 4). The highest unsaturation index for hepatic phospholipid fatty acids came from those mice fed the CLO/LO diet while mice from the SLD groups yielded intermediary values.

DISCUSSION

As expected, acute phenytoin exposure on GD 9 in CD-1 mice produced adverse effects on fetal growth and morphological development that were similar to those previously observed in *in vivo* murine studies (5–9,12). The effects were evidenced by a decrease in fetal weight and an increased incidence of cleft palate, open eyelid and tail defects. Although phenytoin increased the frequency of malformations in CLO/LO fetuses (6.4%), there were 2.5 times more phenytoin-induced defects observed in fetuses from the SAFF group (16.2%). The lowered incidence of phenytoin-induced anomalies in the CLO/LO fetuses as compared to SAFF fetuses demonstrates that dietary n-3 fatty acids can decrease teratogenicity caused by phenytoin exposure at an early gestational period (GD 9), and these findings parallel earlier results (12) obtained on n-3 fatty acid-fed mice exposed to phenytoin with midgestation. Since resorption incidence was not affected by dietary treatment, the CLO/LO dietary treatment caused a decrease in phenytoin teratogenicity rather than a repartitioning of the type of outcome. Although phenytoin treatment was associated with an increase in anomalies in both of the semipurified diet groups and the SLD group (7.9%), the increase in SLD mice was not statistically significant. This latter finding was likely due to the relatively smaller number of dams in the SLD groups. The reduction in fetal weights observed in the SAFF diet group due to phenytoin exposure early during gestation is in agreement with other reports of phenytoin-mediated growth reduction (5–9,12,30). The phenytoin-mediated fetal growth retardation was suppressed in the CLO/LO group demonstrating that dietary n-3 fatty acid supplementation can also protect against this aspect of phenytoin fetotoxicity. This latter finding, however, contrasts our earlier work (12) which showed no protective action of n-3 fatty acids against fetal growth retardation induced by phenytoin. The lack of protection of the CLO/LO diet in our previous study could be related to the later gestational times (GD 12 and 13) of phenytoin administration. The earlier period of phenytoin treatment in the present study is also likely responsible for the relatively low incidence of phenytoin-induced cleft palate among the treatment groups, and this has also been observed in mice treated with phenytoin on GD 9 in other studies (15). Previous work by Lum and Wells (5) has indicated that the period of maximal sensitivity to phenytoin-induced cleft palate in the CD-1 mouse occurs on GD 12 and 13. On the other hand, in this study the total malformation incidence in the phenytoin-treated safflower oil group was relatively high at 16% and is similar to the total malformation incidences of approximately 10% seen in previous studies using CD-1 mice following phenytoin treatment on GD 12 and 13 (5,14).

TABLE 4

Unsaturation Index and n-6/n-3 Ratio of Maternal Hepatic Phospholipids (wt% of total FAME)[a]

	SLD		SAFF		CLO/LO	
	Control	Phenytoin	Control	Phenytoin	Control	Phenytoin
UI[b]	189 ± 4.95[c,d,e]	185.6 ± 6.83[d,e]	165.5 ± 5.93[e]	162.5 ± 4.85[e]	208.0 ± 8.86[d]	206.9 ± 9.69[d]
n-6/n-3	3.06 ± 0.16[f]	2.84 ± 0.15[f]	10.87 ± 0.94[d]	8.23 ± 0.38[e]	0.71 ± 0.06[g]	0.70 ± 0.04[g]

[a]CD-1 dams were fed either SLD or a SAFF or CLO/LO based semipurified diet, from 3 wk prior to implantation until gestational day (GD) 10. Dams were injected i.p. with either 65 mg/kg phenytoin or saline (control) on GD 9. Dams were killed on GD 10 and livers were immediately dissected, rinsed with ice-cold 1.15% KCl and frozen at -80°C until phospholipid fatty acid analysis. See Tables 1 and 2 for abbreviations.
[b]UI = Σ (% FAME × number of double bonds in the FAME).
[c]Means ± SEM.
[d-g]Means not sharing a common superscript, within a row, are significantly different ($P < 0.05$) by Tukey's multiple comparison test.

Dietary fat also affected the type of defects observed following phenytoin exposure on GD 9. Malformations observed in fetuses from the phenytoin-treated SAFF dams affected the tail, palate, eyes and the external opening of the urogenital system. Open eye defect, on the other hand, was the only gross defect induced by phenytoin in the CLO/LO group. Acute phenytoin exposure by single injections on GD 9 through 15 has shown that treatment on GD 9 alone leads to phenytoin-induced open eye defect in Swiss Webster mice (31). Phenytoin may affect the production of a precursor involved in eyelid formation and/or eyelid fusion since eyelid growth does not occur until GD 13–15 (32). Formation of the peridermal cells of the developing eyelid region begins on about GD 10 (33), and phenytoin treatment on GD 9 may interfere with the formation of this group of cells which are important in temporary fusions, such as those between the eyelids of a neonatal mouse (34).

The overall protection of n-3 fatty acids against phenytoin-induced growth retardation and the decreased incidence of overall malformations in the CLO/LO fetuses supports the idea that n-3 fatty acids exert a generalized protective action against phenytoin teratogenicity. The mechanisms involved could include an enhanced balance of bioactivation to detoxification of phenytoin in the SAFF-fed animals at the level of the embryo as our previous findings showed enhanced concentrations of covalently bound phenytoin to protein in embryos from SAFF-fed dams relative to CLO/LO embryos (12). This effect was attributed to the relatively higher level of embryonic activity of prostaglandin H synthase in SAFF embryos which can bioactivate phenytoin to a reactive intermediate. Differences among the dietary treatments in terms of distribution, conjugation and excretion pathways of phenytoin could also alter the plasma halflife and embryonic exposure to phenytoin, thereby modifying teratogenic outcome.

It is unlikely that the high intake of n-6 fatty acids contributed to the increased teratogenic action of phenytoin. Our earlier work (12) showed that mice fed either a saturated fat diet or a safflower oil-based diet demonstrated a similar incidence of phenytoin-induced cleft palate that was relatively higher in comparison to mice fed a CLO/LO diet. Moreover, studies have consistently shown that increasing the intake of 18:2n-6 above approximately 1–2% of energy does not lead to a further increase in 20:4n-6 tissue levels (35). Our previous findings showed no increase in embryonic, placental or hepatic levels of 20:4n-6 with 12% (w/w) safflower oil intake vs. 10% (w/w) hydrogenated coconut oil + 2% (w/w) safflower oil (12). These observations support our contention that the n-3 fatty acid-based diets exerted a protective effect on phenytoin teratogenicity as opposed to an enhancement of phenytoin teratogenicity by the n-6 fatty acid-based SAFF diet.

In our study, the CLO/LO diet produced changes in hepatic phospholipids consistent with the expected effect of CLO/LO, namely an increase in 20:5n-3 and 22:6n-3 contents and a reduction in 20:4n-6. This is in agreement with other reports (17–19) which indicate that the decrease in 20:4n-6 is the result of the competitive replacement of n-6 PUFA by n-3 PUFA and/or the inhibition of the Δ6 desaturase and elongase enzymes. Differences in the dietary ratio of n-6/n-3 between the SAFF (49) and CLO/LO (0.3) diets also resulted in a 15-fold reduction in this ratio for hepatic phospholipids from dams fed the CLO/LO diet relative to SAFF dams.

The present study provides new information on the effects of phenytoin on fatty acid composition during gestation. Phenytoin exposure increased 18:2n-6 concentrations in liver phospholipids from the SLD and SAFF mice but not in the CLO/LO hepatic phospholipids. The conversion of 18:2n-6 to 20:4n-6 was also reduced in the SAFF group exposed to phenytoin as compared to the SAFF control group as determined by calculating the ratio of product (20:4n-6) to precursor fatty acid (18:2n-6). This result is similar to the findings of Cunnane *et al.* (36), who found that phenytoin treatment of children with epidermolysis bullosa dramatically increased 18:2n-6 while simultaneously decreasing 20:4n-6 in plasma and erythrocyte phospholipids. These findings implied that Δ6 and/or Δ5 desaturation of 18:2n-6 was inhibited by phenytoin. Other studies had shown that microsomal Δ5 and Δ6 desaturase activity can be decreased upon exposure to xenobiotics. For example, hepatocarcinogenic treatment in rats, in the form of diethylnitrosamine and 2-acetylaminofluorene, was shown to result in a similar decreased 20:4n-6/18:2n-6 ratio in the hepatic phospholipids (20). In the present study, the possible inhibitory effect of phenytoin on the 18:2n-6 to 20:4n-6 conversion was not observed in hepatic phospholipids from the SLD or CLO/LO dams. This may have been due to the higher degree of affinity of the desaturases for the n-3 fatty acids (16). The higher amounts of n-3 fatty acids (i.e., lower ratios of n-6/n-3 fatty acids) in the hepatic phospholipids of the SLD and CLO/LO groups as compared to the SAFF dams, in conjunction with the higher affinity of the desaturase enzymes for the n-3 fatty acids, could have contributed to the lack of effect of phenytoin on the conversion of 18:2n-6 to 20:4n-6 observed in these groups. This idea is supported by the fact that 18:3n-3 conversion to 20:5n-3 and 22:6n-3 was not affected in the SAFF hepatic phospholipids.

In summary, the results from this study have shown that animals receiving a diet in the form of CLO/LO had a lower incidence of malformations as compared to SAFF-fed mice when treated with phenytoin in early gestation. Although further study is required, the protective effects of the CLO/LO diets could be attributed to its lower n-6/n-3 fatty acid ratio. The present findings, together with our previous work (12), indicate that semipurified diets containing n-3 fatty acids can strongly protect against a variety of malformations induced by phenytoin during two substantially different developmental periods of susceptibility to major phenytoin-induced defects. The PUFA composition of maternal liver phospholipids can be manipulated *in vivo* by administration of phenytoin and by administration of specific dietary oils. The present study revealed that the incorporation of long-chain n-3 PUFA into tissue phospholipids appears to influence the efficacy of phenytoin in depressing maternal liver phospholipid PUFA composition. Further work is needed, however, to fully evaluate the effect of linseed oil and fish oil feeding on the mechanisms of the phenytoin-induced alterations of hepatic PUFA metabolism.

Effects of Low Casein and Fish Oil on Hyperlipidemia and Proteinuria in Nephritic Rats

Kiyohito Fujisawa, Kazumi Yagasaki* and **Ryuhei Funabiki**

Department of Applied Biological Science, Tokyo Noko University, Fuchu, Tokyo 183, Japan

The effects of amino acid-fortified low casein and fish oil (FO) diets on hyperlipidemia and proteinuria were studied in rats with nephrotoxic serum nephritis. After an antiserum injection, rats were maintained for 14 d on four different experimental diets: a 20% casein diet containing corn oil (CO) or FO, or an 8% casein diet supplemented with cystine plus threonine containing CO or FO. The 8% casein diets reduced urinary protein excretion in nephritic rats without inducing severe growth retardation or fatty liver compared with the basal 20% casein diets. Both the 8% casein diet and the FO diet decreased serum cholesterol, triglyceride and phospholipid levels in nephritic rats, and nonesterified fatty acid levels were decreased by FO feeding. In nephritic animals, hepatic cholesterol synthesis was decreased by the 8% casein diets compared with the 20% casein diets, and tended to be reduced by FO feeding between groups at the same casein levels. No effect of diet was observed on fatty acid synthesis among the nephritic rats. FO administration to the nephritic animals suppressed fecal steroid excretion. While lipoprotein lipase activity was unchanged among the nephritic rats, hepatic triglyceride lipase activity was reduced by either the 8% casein or FO diet. The results suggest that the hypolipidemic action of low casein diets may, at least in part, be due to reduced hepatic cholesterol synthesis and suppressed triglyceride secretion from the liver. They also suggest that the hypolipidemic action of FO may, at least in part, be due to reduced hepatic cholesterol synthesis and decreased fatty acid mobilization from peripheral adipose tissue.

***Lipids 29,* 779–783 (1994).**

Renal injuries such as puromycin aminonucleoside nephrotic syndrome (1) and nephrotoxic serum nephritis (NSN) (2) are known to be accompanied by severe hyperlipidemia. These types of hyperlipidemias need to be remedied as they are believed to cause further deterioration of kidney function (3,4).

Brenner *et al.* (5) suggested that injury of the glomerulus is caused by increased permeability of the glomerular capillary to plasma proteins and that high protein intake enhances the hyperfiltration of glomeruli causing progressive damage. It has been reported that low protein diets ameliorate proteinuria in nephrotic patients (6) and in rats (7). Protein malnutrition can occur after a long period of low protein intake, even if low protein diets have beneficial effects on symptoms of renal diseases. We demonstrated that low protein diets suppressed hyperlipidemia and proteinuria incident to NSN (8) and that the supplementation of limiting amino acids to diets low in proteins alleviated growth retardation due to low protein intake (9).

Dietary fish oil (FO) rich in n-3 polyunsaturated fatty acids has been shown to bring about greater hypolipidemic effects in rats through reduced hepatic lipogenesis (10) than corn oil (CO) which is rich in linoleate (18:2n-6). FO-enriched diets have also been reported to weaken the progression of autoimmune diseases in NZB/NZW (11) and MRL-1pr (12) mice by altering several immunological functions (13). The effects of FO diets on nephrotoxic serum nephritis, which is one of the immune-mediated models, remain ambivalent. There have been reports that FO alleviated this type of nephritis compared to beef tallow (14), while a high α-linolenate diet has been shown to exacerbate it when compared to a high linoleate diet (15).

In the present study, we examined the effects of dietary FO and of an amino acid-fortified low casein diet, individually and in combination, on the incidence of hyperlipidemia and proteinuria in NSN.

MATERIALS AND METHODS

Animals and diets. Male Wistar rats (three weeks old) were obtained from Charles River Japan (Kanagawa, Japan). The rats were kept on a stock pellet diet (CE-2; CLEA Japan, Tokyo, Japan) for 3 d. On the fourth day of preliminary feeding, rats were divided into two groups with equal body weights and were fed a basal 20% casein diet containing either 10% CO or FO for another three weeks. The rats were kept in an air-conditioned room at a temperature of 22 ± 2°C and at a relative humidity of 60 ± 5% using an 8:00 a.m. to 8:00 p.m. light cycle. All the animals were moved on the twenty-first day of preliminary feeding from individual cages with wire bottoms into metabolism cages to collect urine. The composition of the basal 20% casein diet was as follows: 20% casein (Oriental Yeast Co., Tokyo, Japan), 10% CO (Hayashi Chemicals Co., Tokyo, Japan) or FO (Sanomega EPA-S18GA, the generous gift of NOF Corporation, Tokyo, Japan), 63.3% α-corn starch (Nihon Nosan Kogyo Co., Yokohama, Japan), 3.5% mineral mixture (AIN composition; Nihon Nosan Kogyo Co.), 1% vitamin mixture (AIN composition; Nihon Nosan Kogyo Co.), 0.2% choline bitartrate (Wako Pure Chemical Industries, Osaka, Japan) and 2% cellulose powder (Oriental Yeast Co.). The composition of CO and FO is shown in Table 1. The FO contained 0.3% vitamin E. Separately from the vitamin mixture, the CO diet was therefore supplemented with extra vitamin E (Riken E Oil 800, Riken Vitamin Co., Tokyo, Japan) to adjust to the vitamin E content (350 mg/kg diet) of the FO diet. No side effects have been noted at this dose of vitamin E in rats (16). On the twenty-fourth day of preliminary feeding

(day 0), rats of the CO and FO groups were further divided into two groups of equal body weight; they received a single intravenous injection in the tail vein of anti-rat kidney glomerular basement membrane (GBM) rabbit antiserum (0.5 mL/rat), which was produced by immunizing rabbits with the supernatant of trypsin-digested rat GBM (17,18). On the following day (day 1), the animals were subcutaneously immunized with rabbit γ-globulin (8 mg/rat; Sigma Chemical Co., St. Louis, MO) in 0.2 mL of Freund's complete adjuvant (Wako Pure Chemical Industries) in the hind foot pads as described previously (19,20). Immediately after the injection of antiserum (day 0), rats of each group were kept for 14 d on a particular experimental diet. Rats previously maintained on the CO diet were successively fed either a 20% casein diet containing CO (20-C) or an 8% casein diet supplemented with 0.3% L-cystine (Nippon Rikagakuyakuhin Co., Tokyo, Japan) and 0.36% L-threonine (Ajinomoto Co., Inc., Tokyo, Japan) containing CO (8-C), while those on the FO diet were fed either a 20% casein diet containing FO (20-F) or an 8% casein diet supplemented with 0.3% L-cystine and 0.36% L-threonine containing FO (8-F). Fats given no anti-serum injection were regarded as the normal group and maintained on the 20-C diet throughout the experiment. Each experimental diet was adjusted to 100% by changing the amount of α-corn starch to keep all the diets isocaloric. Water and all diets were available *ad libitum*. Urine excreted during the preceding 24 h by the rats individually housed in metabolism cages was collected at 9:00 a.m. each day. The animals were deprived of their diets at 9:00 a.m. on day 14, but allowed free access to water until sacrifice by decapitation 4 h later. Blood was collected and left to clot at room temperature to obtain serum. Liver, kidney and epididymal adipose tissue were quickly removed, washed with cold 0.9% NaCl, blotted on filter paper, and weighed. Aliquots of the liver and adipose tissue were frozen in liquid nitrogen and stored at -80°C until analyzed.

Lipid analyses. From the liver, total lipids were extracted according to the procedure of Folch *et al.* (21). After aliquots of the chloroform phase had been dried, cholesterol (Ch) (22), triglyceride (TG) (23) and phospholipid (PL) (24) levels were determined as described previously (8). The serum TG and PL levels were also determined as described above. Serum total Ch levels were enzymatically determined using a commercial kit (Wako Pure Chemical Industries). Serum nonesterified fatty acid (NEFA) levels were also determined as described previously (25).

Serum albumin and urinary protein determination. Serum albumin was determined with a commercial kit (Wako Pure Chemical Industries). Urinary protein was measured by the Bradford method (Bio-Rad Protein Assay; Bio-Rad Laboratories, Richmond, CA) (26).

Cholesterol and fatty acid syntheses from [^{14}C]acetate in liver slices. Liver slices weighing 100–120 mg were incubated for 2 h in 1 mL of Krebs-Ringer phosphate buffer (pH 7.4) containing 37 kBq/μmol of [1-^{14}C]acetate (2.04 MBq/μmol; Amersham International plc, Buckinghamshire, United Kingdom). Total fatty acid (FA) and Ch syntheses were estimated as described previously (27,28).

Fecal steroid excretion. Feces were collected individually for 2 d before rats were sacrificed. Neutral sterols (NS) and bile acids (BA) were extracted according to the method of Yamanaka *et al.* (29). BA and NS were enzymatically determined with commercial kits (Wako Pure Chemical Industries) as described (30).

Tissue lipolytic activities. Heparin-releasable TG lipases were obtained from epididymal fat pads (lipoprotein lipase, LPL) and liver (hepatic TG lipase, HTGL). Each of the fresh tissues weighing 300 mg was homogenized in 0.2 M Tris-HCl buffer (pH 8.5) containing 10 U/mL of sodium heparin (Wako Pure Chemical Industries) according to the method of Noguchi *et al.* (31). Lipases were incubated for 1 h in 0.2 M Tris-HCl buffer (pH 8.0 and with adequate apolipoprotein C-II as an activator of LPL for LPL assay and pH 8.5 for HTGL) containing 925 Bq/μmol of [*carboxyl*-^{14}C]triolein (925 MBq/mmol; NEN Research Products, Boston, MA), and lipase activities were estimated as described (32,33).

Statistical analysis. Statistical analyses were carried out using Student's *t*-test (normal 20-C vs. nephritic 20-C) and Duncan's multiple-range test (among the nephritic groups); a P value of <0.05 was considered significant.

RESULTS

As shown in Table 2, nephritis caused growth retardation, enlargement of the liver and kidney, and hypoalbuminemia (normal 20-C vs. nephritic 20-C). Food intake tended to be decreased by inducing nephritis. In the nephritic state, body weight gain of the 20-F and 8-C groups was comparable to that of the 20-C group, but the growth of the 8-F group was significantly suppressed when compared with that of the 20% casein (20-C, 20-F) groups. Food intake was almost the same among the four nephritic groups except for the 8-C group in which rats consumed the greatest amount. A nephritis-induced enlargement of the liver was not affected by any dietary manipulation, but that of the kidney was reduced by feeding the 8-C diet. No dietary effect was noted on the serum albumin level in any of the four nephritic groups.

While urinary protein excretion in normal rats remained constant at low levels during the experimental period, that of nephritic control (20-C) rats rapidly and linearly increased up to day 3 and remained at a high rate until day 14 (data not shown). The excretion rate of the 8% casein (8-C, 8-F) groups commenced to significantly de-

TABLE 2

Body Weight Gain, Food Intake, Tissue Weights and Serum Albumin Level[a]

crease on day 7, and FO, in contrast to CO, showed no lowering effect on urinary protein excretion at either the 20 or the 8% casein level (Fig. 1).

Table 3 shows serum and liver lipid levels. Hyperlipidemia characterized by elevations in Ch, TG and PL was confirmed in nephritic control rats (20-C) as compared with normal rats, and the hyperlipidemia was reduced by feeding either low casein (20-C vs. 8-C, 20-C vs. 8-F) or FO containing (20-C vs. 20-F) diets. The serum NEFA level tended to decrease upon nephritis induction, and FO feeding (20-F, 8-F) further decreased the level significantly in nephritic rats compared with CO feeding (20-C, 8-C). Induction of nephritis significantly reduced liver Ch and TG

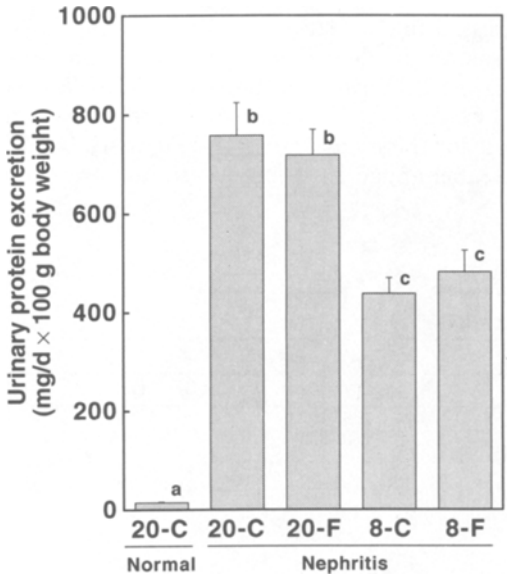

FIG. 1. Urinary protein excretion on day 7. Each value and vertical bar represents the mean of six rats and standard error, respectively. (a) Significantly different from the nephritic 20% casein diet containing corn oil (20-C) group at $P < 0.05$ by Student's t-test. (b,c) Values not sharing a common letter are significantly different at $P < 0.05$ by Duncan's multiple-range test; 20-F, a 20% casein diet containing fish oil; 8-C, an 8% casein diet, supplemented with cystine and threonine, containing corn oil; 8-F, an 8% casein diet, supplemented with cystine and threonine, containing fish oil.

levels. The Ch level was unchanged among the four nephritic groups. The TG level was increased, but the PL level was decreased by feeding the 8% casein diets.

As seen in Table 4, hepatic Ch synthesis accelerated by nephritis was suppressed by feeding the 8% casein diets compared with the 20% casein diets, and tended to be reduced by FO feeding between the groups at the same casein levels (20-C vs. 20-F and 8-C vs. 8-F). Although hepatic FA synthesis was significantly stimulated by inducing nephritis, no dietary effect was observed in nephritic rats. Nephritis induction did not influence fecal steroid excretion. Administration of FO to the nephritic rats (20-F, 8-F) caused a suppression of NS excretion when compared with CO (20-C, 8-C) feeding. BA excretion was significantly suppressed in the 20-F group compared with the other three groups. No significant nephritic or dietary effects were observed on epididymal adipose tissue LPL activity. Though HTGL activity was unchanged by the nephritis induction, the activity was slightly but significantly lower in the 20-F, 8-C and 8-F groups than in the 20-C group.

DISCUSSION

In the present study, we examined both the individual and the concurrent effects of dietary FO and of an 8% casein diet supplemented with cystine and threonine, which are limiting amino acids of casein, on hyperlipidemia and proteinuria in rats with NSN. Protein malnutrition as manifested in growth retardation and severe fatty liver was not seen when rats were administered the 8% casein diets supplemented with the limiting amino acids (8-C, 8-F). Proteinuria, hypoalbuminemia and hyperlipidemia were caused by nephritis induction. Proteinuria was reduced by feeding the 8% casein diets (8-C, 8-F) irrespective of the dietary oil used. The hyperlipidemia was caused, at least in part, by stimulated hepatic Ch and FA syntheses (Table 4), which is in good agreement with our own data (9) and earlier studies by others (34). A reduction of hypercholesterolemia and hypertriglyceridemia was observed in nephritic animals fed the 8-C compared with those fed the 20-C diet (Table 3). FO also had a noticable hypolipidemic effect at the 20% casein level (20-C vs. 20-F); however, at the 8% casein level, the hypolipidemic effect was no longer seen (8-C vs. 8-F and 20-F vs. 8-F). Interestingly, liver TG

and PL contents were affected by the dietary casein level but not by the dietary oil type. The effect of low casein level observed here is not due to a deficiency in essential amino acid for growth, since the 8-C actually induced the same growth as the 20-C.

The hypocholesterolemic action of low casein diets may, at least in part, be due to a reduced hepatic Ch synthesis, which was stimulated by nephritis induction. In contrast, the hypotriglyceridemic action of low casein diets may be partly due to suppressed TG secretion from the liver, since the liver TG accumulated in low casein groups (8-C, 8-F) when compared with the 20% casein groups (20-C, 20-F). The hypocholesterolemic action of FO may also, at least in part, be due to reduced hepatic Ch synthesis, and the hypotriglyceridemic action of FO may partly be due to a lower FA mobilization from peripheral adipose tissue. As reported previously for normal rats, it is possible that FO may increase FA oxidation and reduce intestinal absorption of TG (35). Although the serum Ch level was lowered by FO treatment at the 20% casein level, hepatic Ch synthesis was slightly reduced and fecal steroid excretion was decreased. There have been reports that FO reduced serum Ch levels, due to a reduced secretion of Ch from the liver (10) and an increased biliary excretion of Ch compared with CO (36), and a higher binding affinity of low density lipoprotein receptors compared with coconut oil feeding (37) to normal rats. The FO effects observed in normal rats might occur in nephritic rats fed the FO diet. Interestingly, FO suppressed fecal NS excretion. It has to be considered that FO might induce changes in the gastrointestinal flora of the rats, although the cause of this suppression is unclear. The CO and FO used here are actually in the TG form, and there was little NS in both the CO and FO, so that NS in the diets are unlikely to be responsible for the results. In the present study, LPL activity was unchanged by nephritis induction, which is in

TABLE 4

Hepatic Lipogenesis, Fecal Steroid Excretion and Tissue Lipolytic Activities[a]

Measurement	Normal	Nephritis			
	20-C	20-C	20-F	8-C	8-F
Hepatic lipid syntheses (dpm × 10^{-4}/2 h/g liver)					
Ch	2.9 ± 0.7	5.5 ± 1.4[c]	4.8 ± 1.0[c,d]	2.8 ± 0.8[c,d]	1.9 ± 0.5[d]
FA	3.2 ± 0.5[b]	6.6 ± 1.1[c]	6.3 ± 1.6[c]	7.7 ± 1.3[c]	4.1 ± 0.8[c]
Fecal steroid excretion (μmol/2 d/100 g body weight)					
NS	17 ± 1	16 ± 1[c]	8 ± 1[d]	20 ± 2[c]	8 ± 1[d]
BA	9 ± 1	11 ± 1[c]	7 ± 1[d]	11 ± 1[c]	10 ± 2[c]
Tissue lipolytic activities (μmol FFA/h/g tissue)					
LPL	4.8 ± 1.0	4.3 ± 0.4[c]	4.5 ± 1.0[c]	4.2 ± 1.0[c]	4.9 ± 0.4[c]
HTGL	0.3 ± 0.0	0.3 ± 0.0[c]	0.2 ± 0.0[d]	0.2 ± 0.0[d]	0.2 ± 0.0[d]

[a]Values are means ± SEM for six rats. Rats were treated as described in the Materials and Methods section; Ch, cholesterol; FA, fatty acid; NS, neutral sterols; BA, bile acids; FFA, free fatty acid; LPL, lipoprotein lipase; HTGL, hepatic triglyceride lipase. See Table 2 for other abbreviations.
[b]Significantly different from the nephritic 20-C group at $P < 0.05$ by Student's *t*-test.
[c,d]Values not sharing a common letter are significantly different at $P < 0.05$ by Duncan's multiple-range test.

agreement with the results by others (38,39). Neither low protein nor FO intake influenced LPL activity, and HTGL activity was decreased by low protein or FO feeding. It has been reported that abnormalities in lipoprotein components rather than LPL activity were observed in nephrosis (38,39). Thus, there is a possibility that abnormalities in the lipoprotein components in the present study may have been normalized by the low protein intake. Hepatic TG lipase activity was unchanged between the normal and nephritic 20-C groups, although HTGL activity was reported to decrease in nephrosis (40). The reason for this discrepancy is not clear at present. In the present study, the dietary vitamin E level was the same among four diets (350 mg/kg diet). No side effects and no effects on lipid metabolism have been noted at the dose of vitamin E used here (16).

Scharschmidt *et al.* (14) reported that FO decreased the syntheses of glomerular thromboxane (TX) A_2, a vasoconstrictor, and prostaglandin E_2, a vasodilator, and that FO had beneficial effects on NSN. They examined urinary protein excretion and insulin clearance before and 48 to 72 h after anti-GBM antiserum injection, and antiserum injection induced a low level of proteinuria (about 1.5 mg/d × rat in normal vs. 15 mg/d × rat in nephritis). The rats we used were maintained for 14 d and showed a high excretion rate for urinary protein (15 mg/d × 100 g body weight in normal vs. 758 mg/d × 100 g body weight in nephritis, Fig. 1); this suggests that the nephritis seen by Scharschmidt and her colleagues (14) was in an earlier stage than ours. Watanabe *et al.* (15) showed that high α-linolenate intake complicated symptoms of NSN compared to high linoleate intake, although a previous study by Suzuki *et al.* (19) had demonstrated that TXA_2 synthetase inhibitors improved NSN. These findings suggest that the effectiveness of vasodilatory and vasoconstrictive eicosanoids may be different depending on the stage of nephritis (15). Further experiments including survival studies and histologic analyses are needed to clarify these aspects.

In conclusion, we have shown that amino acid-fortified low casein diets improved hyperlipidemia and proteinuria without retarding growth in NSN. The hypolipidemic action of FO might be different from that of low protein diets. FO might maintain the abovementioned hypolipidemic effects in the nephritic state as well as in the normal state.

Adipose Monoacylglycerol:Acyl-Coenzyme A Acyltransferase Activity in the White-Throated Sparrow (*Zonotrichia albicollis*): Characterization and Function in a Migratory Bird

Nadia Mostafa, B. Ganesh Bhat and **Rosalind A. Coleman***

Departments of Nutrition and Pediatrics, The University of North Carolina at Chapel Hill, Chapel Hill, North Carolina 27599-7400

Although migrating birds use stored triacylglycerol as their primary fuel for flight, they must retain sufficient stores of ω6 and ω3 fatty acids to sustain reproduction after the spring migration. Hepatic monoacylglycerol:acyl-coenzyme A acyltransferase (EC 2.3.1.22) (MGAT) activity is associated with physiological periods in which lipolysis and ß-oxidation are prominent, and it may also play a role in the selective retention of certain essential fatty acids. Therefore, we characterized MGAT activity in adipose tissue from the white-throated sparrow (*Zonotrichia albicollis*), a migratory bird. MGAT specific activity from adipose tissue and liver, respectively, was 22.2 ± 7.27 and 0.79 ± 0.35 nmol/min/mg of total particulate protein. Activity did not vary seasonally or between male and female birds. Specific activity increased 4.3-fold in the presence of 75 µg of phosphatidylcholine and phosphatidylserine (1:1, w/w). MGAT acylated *sn*-1(3)-monooleoylglycerol, *sn*-2-monooleylglycerol ether and *sn*-1(3)-monooleylglycerol ether at 7.5, 5.7 and 1.7%, respectively, of the rate observed with *sn*-2-monooleoylglycerol. An initial lag phase observed at low concentrations of palmitoyl-CoA was corrected by adding 2 mM $MgCl_2$, $Mg(NO_3)_2$ or $CaCl_2$, suggesting a requirement for divalent cations. MGAT acylated *sn*-2-monolinolenoylglycerol and *sn*-2-monolinoleoylglycerol in preference to *sn*-2-monooleoylglycerol. Specificity of MGAT for *sn*-2-monoacylglycerols and the probable enhanced affinity for *sn*-2-monoacylglycerols of specific acyl chains may allow selected ω6 and ω3 fatty acids to be retained within the adipocyte, while nonessential fatty acids are released for β-oxidation in flight muscles.

***Lipids* 29, 785–791 (1994).**

Seasonal migration is characteristic for many birds that breed at middle and high latitudes. Sparrows, small birds with relatively high metabolic rates (1), avoid winters by migrating to warmer regions. During migratory flight, replenishing energy reserves may be difficult or impossible (2–4). Thus, triacylglycerol stored in adipose tissue serves as the primary fuel for flight muscles during migration by providing fatty acids for oxidation (1,5–7).

Although studies of the metabolism and action of ω3 and ω6 fatty acids and their derivatives in migrating birds are limited, their importance in poultry is clear (8,9–13). Linoleic acid deficiency results in poor growth, reduced resistance to disease, fatty liver and reduced gonadal size. Reproductive failure, probably the result of eicosanoid deficiency, is manifested by decreased egg weight and embryo viability. The ω3 fatty acid, α-linolenic acid, is probably required for the synthesis of phospholipids in nervous tissue and retina in the developing chick (8).

When normal food supplies are absent or diminished, the massive oxidation of stored fatty acids during migration could deplete endogenous stores of ω3 and ω6 fatty acids, and lead to impaired reproductive capacity when birds arrive at their breeding sites. Studies in chickens have suggested that a mechanism exists to prevent the loss of ω3 and ω6 fatty acids from endogenous stores. In chicks, ω3 and ω6 fatty acids accumulate in tissue glycerolipids out of proportion to their relative amounts in egg yolk (9,14), and one might hypothesize that selected essential fatty acids might be similarly retained during migration in order to preserve eicosanoid precursors that are critical for reproduction. The tissue content of fatty acid species varies seasonally, but differences in fatty acid composition of foods consumed have confounded most studies of free-living and migrating birds (15–19).

We have suggested that animals that undergo normal physiological states characterized by massive lipolysis and β-oxidation might selectively retain ω3 and ω6 fatty acids, and that the monoacylglycerol pathway of glycerolipid synthesis could provide a mechanism for their retention (20). The monoacylglycerol pathway is defined by the presence of the monoacylglycerol:acyl-CoA (coenzyme A) acyltransferase (MGAT) (EC 2.3.1.22), a microsomal enzyme activity that stereospecifically acylates *sn*-2-monoacylglycerols to form *sn*-1,2-diacylglycerols (21,22). Since ω3 and ω6 fatty acids are predominantly found in the *sn*-2 position of most glycerolipids (23,24), reacylation of *sn*-2-monoacylglycerols would tend to conserve these acyl species, particularly if MGAT were selective in the monoacylglycerol species that are reacylated.

We have hypothesized that hepatic MGAT provides a mechanism by which essential fatty acids may be retained during physiological states of exaggerated lipolysis and β-oxidation. Such states occur in neonatal rats, chick embryos, fetal guinea pigs and hibernating marmot (20). The enhanced expression of hepatic MGAT activity in streptozotocin-induced diabetes in adult rats is consistent with a role for this microsomal activity in causing or maintaining the different essential fatty acid composition that characterizes membrane lipids in the diabetic animal (25).

Because migrating birds undergo a prolonged state of accelerated lipolysis in order to provide fatty acids to power flight muscles, we wondered whether migration was associated with changes in MGAT activity in adipose

Abbreviations: AMP, adenosine monophosphate; ATP, adenosine triphosphate; CoA, coenzyme A; EDTA, (ethylenedinitrilo)tetraacetic acid; MGAT, monoacylglycerol acyl-coenzyme A acyltransferase; NAD, nicotinamide adenine dinucleotide (oxidized form); NADH, nicotinamide adenine dinucleotide (reduced form); PC, phosphatidylcholine; PS, phosphatidylserine; Tris-HCl, (hydroxymethyl)aminomethane hydrochloride.

tissue or liver. We found very high MGAT activity in adipose tissue, but not in liver, of the white-throated sparrow. In order to determine whether adipose MGAT activity might play a role in the selective retention of essential fatty acids in migrating birds, we characterized the activity and tested its ability to utilize monoacylglycerols that contain different acyl groups.

MATERIALS AND METHODS

Materials. Phosphatidylcholine (PC; from egg lecithin), phosphatidylserine (PS; from beef brain), *sn*-2- and *sn*-1(3)-monooleoylglycerols, *sn*-1(3)- and *sn*-2-monooleylglycerol ethers, trilinolenin and trilinolein were obtained from Serdary Research Laboratories, Inc. (London, Ontario, Canada). Bovine serum albumin (essentially fatty acid-free) and Type VI-S porcine pancreatic lipase were from Sigma (St. Louis, MO). Cytoscint was from ICN Pharmaceuticals (Cleveland, OH). [^{3}H]Palmitic acid was obtained from New England Nuclear (Boston, MA). [^{3}H]Palmitoyl-CoA was synthesized enzymatically (26). Scored 250 micron silica gel G and plates impregnated with 10% $AgNO_3$ or with 3% borate were from Analtech, Inc. (Newark, DE).

Synthesis of monoacylglycerols. sn-2-Monolinoleoylglycerol and *sn*-2-monolinolenoylglycerol were synthesized from trilinolein and trilinolenin, respectively, by incomplete enzymatic hydrolysis with Type VI-S procine pancreatic lipase (27). The reaction products were extracted with diethyl ether, and the *sn*-2-monoacylglycerols were separated from 1(3)-monoacylglycerols and other lipids on 3% borate silica gel G plates developed with chloroform/acetone/methanol/acetic acid (90:5:2:0.5, by vol). Monoacylglycerols were stored in hexane at -20°C until use within a few days of synthesis. Butylated hydroxytoluene (0.05%) was present during enzymatic hydrolysis and storage. The *sn*-2- and *sn*-1(3)-monoacylglycerols were quantified colorimetrically (28). To minimize acyl migration, commercially obtained monoacylglycerols were kept in small aliquots at -20°C.

Collection and preparation of tissue samples. White-throated sparrows (*Zonotrichia albicollis*) arrive from their breeding localities in southern Ontario by late October and remain in North Carolina until the onset of their vernal migration in early April. Birds were captured in Durham, North Carolina. At Duke University, Durham, each sparrow was caged individually. A natural light/dark photoperiod was maintained. The laboratory diet consisted of 70% canary and 30% large black rapeseeds (G.W. Hill Co., Inc., Florency, KY) and was supplemented with worms and hard-boiled eggs with shells. Preparations of liver and fat were obtained within 5 d of capture from seven birds and at 5, 7 and 10 mon after capture of five birds that had been maintained in cages. Liver and adipose tissue fatty acids were not measured because of the inconsistencies in the bird's previous diets (natural and laboratory). Birds (about 25 g) were anesthetized with methylflurane (metaphane) and dissected. Adipose tissue was collected from the furcular (clavicule-coracoid) fossa and abdominal depots from all birds (n = 12), and liver was obtained from seven birds. Fat depots were minimal in July and November (four samples), low in January (four samples), and greatest in April and May (four samples). Tissue was homogenized in Medium I consisting of 0.25 M sucrose, 1 mM (ethylenedinitrilo)tetraacetic acid (EDTA), 10 mM tris(hydroxymethyl)aminomethane hydrochloride (Tris-Cl), pH 7.4 in a Teflon-glass homogenizing vessel with 10 up and down strokes at medium speed. Total particulate preparations were pelleted by centrifuging each homogenate in Medium I at 100,000 × *g* for 1 h. Protein was measured by the method of Lowry *et al.* (29) using bovine serum albumin as standard.

Assay of MGAT activity. MGAT activity was assayed at 23°C under conditions that measured initial rates, in a final volume of 200 µL, by modifying a previously described method (22). The reaction mixture contained 100 mM Tris-Cl, pH 8.0, 1 mg/mL bovine serum albumin, 25 µM [^{3}H]palmitoyl-CoA and 50 µM *sn*-2-monooleoylglycerol dispersed in acetone. The final acetone concentration was 2.5%. The reaction was initiated by adding 2 to 6 µg of total particulate protein and was terminated after 5 min by adding 1.5 mL of propanol-2/heptane/water (80:20:2, by vol) and mixing on a Vortex mixer. After adding 1 mL heptane and 0.5 mL water, the heptane layer was removed and washed twice with 2 mL 0.5 N NaOH/ethanol/water (10:50:50, by vol). Aliquots of the final heptane phase were counted in 4 mL of Cytoscint. The remaining portion of the heptane phase was concentrated in a Savant Speed Vac concentrator and chromatographed with carrier lipids on 10-cm silica gel G plates using heptane/isopropyl ether/acetic acid (60:40:4, by vol). Lipids were made visible by exposure to I_2 vapor, and the bands corresponding to diacylglycerol and triacylglycerol were scraped off and counted. MGAT specific activities were calculated by subtracting one-half the counts per minute which appeared in triacylglycerol.

Monoacylglycerol specificity. Total particulate preparations from sparrow adipose tissue (2.5 µg protein) were incubated with 20 µM each of 2-monooleoylglycerol and 2-monolinolenoylglycerol. Diacylglycerols and triacylglycerols were separated on silica gel G plates using heptane/isopropyl ether/acetic acid (60:40:4, by vol), and were eluted with $CHCl_3$. The mono- and triunsaturated diacylglycerols and triacylglycerols were separated on 10% $AgNO_3$-impregnated plates using hexane/diethyl ether (15:85, vol/vol) for diacylglycerols and (70:30, vol/vol) for triacylglycerols (30).

RESULTS

MGAT activity. In order to determine whether MGAT activity in migrating birds might play a role in the selective retention of essential fatty acids, we examined hepatic and adipose tissue MGAT activity in the white-throated sparrow. All studies were performed under conditions that measured initial rates. No differences were observed in the activities between males and females or in birds that had been kept in captivity compared to those studied immediately after capture. MGAT specific activity was 22.2 ± 7.27 nmol/min/mg of protein (range 9.3–34) in total particulate fractions from twelve independent preparations of sparrow adipose tissue. Even though MGAT was as-

sayed in total particulate fractions from whole adipose tissue, the mean activity found was 5-fold higher than the activity comparably assayed in rat adipose tissue microsomes (31). In liver from seven independent preparations, MGAT specific activity was 0.79 ± 0.35 nmol/min/mg of protein (range 0.39–1.35). The low hepatic activity was similar to that observed in adult rat liver (21). Despite seasonal changes in the amount of adipose tissue, the specific activities of MGAT in both fat and liver did not change (data not shown).

Because our previous studies suggested that the high MGAT activity observed in liver under conditions of enhanced lipolysis might be related to selective retention of ω3 and ω6 fatty acids, the high adipose MGAT activity was characterized further. The activity was proportional to the concentration of protein employed up to 10 μg at 5 min and with time to 11.5 min when 2 μg of protein was used (data not shown). More than 96% of the labeled product was identified by thin-layer chromatography as diacylglycerol and triacylglycerol. Unlike the products of MGAT activity from rat (21) and chick liver (32), the relative amounts of diacylglycerol and triacylglycerol products varied minimally with time; at each time point, about 40% of the product was diacylglycerol and about 50% was triacylglycerol (data not shown).

Effect of phospholipids and bovine serum albumin. Addition of 0.3 mg/mL of PC/PS (1:1, w/w) stimulates rat intestinal and neonatal hepatic MGAT activities as much as 4- and 2-fold, respectively (22), but inhibits the activity from adult liver (25). In sparrow adipose tissue, a maximal 4.3-fold increase was observed with 0.375 mg/mL of the PC/PS mixture (Fig. 1).

The effect of bovine serum albumin on adipose tissue MGAT activity was examined because the activity is stimulated in its presence in microsomes from liver and intestinal mucosa (22) and rat adipocytes (31). In sparrow adipose tissue, however, the addition of up to 1.0 mg/mL bovine serum albumin did not affect adipose tissue MGAT activity. Bovine serum albumin inhibited MGAT activity about 15% at 1.25 mg/mL (data not shown).

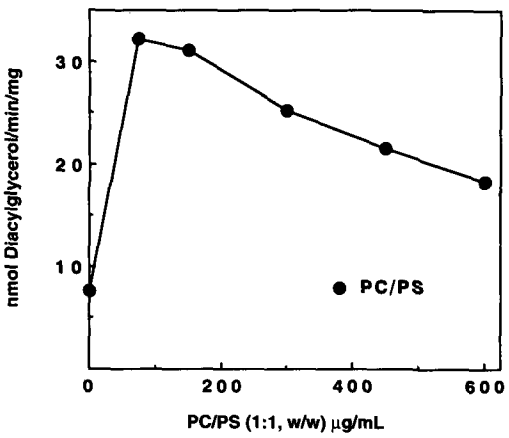

FIG. 1. Dependence of monoacylglycerol:acylCoenzyme A acyltransferase activity on phosphatidylcholine/phosphatidylserine (PC/PS) (1:1, w/w). Assays were performed with 2 μg of protein as described in the Materials and Methods section except that the amount of added phospholipid was varied as indicated. Without added PC/PS, the specific activity was 12.7 nmol/min/mg. This figure is representative of two independent studies using different preparations.

Monoradylglycerol specificity. The hepatic MGAT activity from suckling rats and chick embryos is highly specific for *sn*-2-monoacylglycerols and acylates monoalkylglycerol ethers poorly. In contrast, MGAT activity from rat intestine readily acylates monoalkylglycerols, perhaps for the purpose of allowing monoalkylglycerol ethers from the diet to enter chylomicra triradylglycerols (33). To determine whether the MGAT activity of sparrow adipose tissue shared the specificity of that of the liver, we tested its ability to acylate various monoradylglycerols. The activity from adipose tissue was highly specific for *sn*-2-monoacylglycerols and had a diminished ability to acylate either 1(3)-monoacylglycerol or monoalkylglycerols. At a concentration of 50 μM of each of the substrates, MGAT acylated 1(3)-monooleoylglycerol, *sn*-2-monooleylglycerol ether and 1(3)-monooleylglycerol ether at 7.5, 5.7 and 1.7%, respectively, of the rate observed with *sn*-2-monooleoylglycerol. These results suggest that the MGAT activity of adipose tissue, like that of liver, is highly selective in its substrate specificity. In fact, the low activity observed with 1(3)-monoacylglycerol may have been due to the presence of small amounts of *sn*-2-monoacylglycerol due to acyl migration.

We have previously shown that hepatic MGAT from three different species has a greater affinity for *sn*-2-monoacylglycerols that contain 18:2 or 18:3 fatty acids than for those containing 18:1 or 20:4 (20). In order to determine whether MGAT from sparrow adipose tissue exhibits a similar acyl-chain preference, we tested its ability to acylate monoacylglycerols that contain different fatty acids at the *sn*-2 position. The enzyme activity seen with *sn*-2-18:1-glycerol monoester was compared with the activity seen with the more unsaturated *sn*-2-18:2 and *sn*-2-18:3-glycerol monoesters (Fig. 2). We found that MGAT acylated *sn*-2-18:3-glycerol monoester and *sn*-2-18:2-glycerol monoester in preference to *sn*-2-18:1-glycerol monoester. An increased rate of acylation of *sn*-2-18:2 and *sn*-2-18:3-glycerol monoesters was observed at each of the concentrations of monoacylglycerols examined. Although the apparent K_m values were 20, 47 and >1000 μM for *sn*-2-18:3-glycerol monoester, *sn*-2-18:2-glycerol monoester and *sn*-2-18:1-glycerol monoester, respectively, Michaelis-Menten kinetics cannot be universally applied to this microsomal system with hydrophobic and amphipathic substrates. The apparent K_m value for *sn*-2-18:1-glycerol monoester with MGAT from liver was <50 μM (21,32). We hypothesized that the preference shown by MGAT for *sn*-2-acylglycerols would tend to ensure the relative conservation of essential fatty acids which predominate in the *sn*-2 position of glycerolipids (20). In addition, the apparent increase in affinity for *sn*-2-acylglycerols containing 18:2 and 18:3 may enable MGAT to play a role in conserving specific ω3 and ω6 fatty acids during periods of accelerated lipolysis. The increased apparent affinity is particularly evident at low monoacylglycerol concentrations. Low amounts of monoacylglycerol are likely to be present normally in the endoplasmic reticulum (20). Although the concentration of *sn*-2-monoacylglycerol in

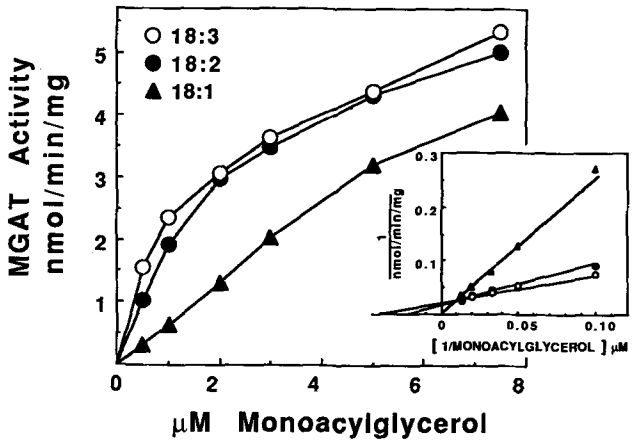

FIG. 2. Dependence of monoacylglycerol acyltransferase activity on *sn*-2-monoacylglycerols with different acyl chains. Each monoacylglycerol substrate was added in 5 μL acetone as described in the Materials and Methods section. The amount of total particulate protein present in each assay was 2.5 μg. The inset shows the double reciprocal plot of the data (Ref. 34). The regression coefficients were all >0.996. With 50 μM *sn*-2-18:1-glycerol monoester, the specific activity was 21.0 nmol/min/mg. Each point is the average of duplicate determinations that varied by less than 5%.

adipocyte endoplasmic reticulum is not known, we have calculated that, in liver, the normal concentration would be less than 1 mol% or about 2 μM (20). This concentration is well within the range at which MGAT exhibits differential affinity for monoacylglycerols having different acyl chains (Fig. 2).

To test directly the effect of the more unsaturated species on MGAT activity, 20 μM each of *sn*-2-18:1- and 18:3-glycerol monoesters were added to the assays, and the products were resolved by argentation chromatography according to their degree of unsaturation (30). Analyses of the products indicated that MGAT acylated 39.5% of the *sn*-2-monooleoylglycerol and 60.5% of the *sn*-2-monolinolenoylglycerol, consistent with a preference for the more unsaturated monoacylglycerols.

Dependence on palmitoyl-CoA and the effect of divalent cations and salts. The dependence of sparrow adipose tissue MGAT on palmitoyl-CoA showed an initial lag phase between 5 and 20 μM, was concave upward between 20 and 40 μM, and reached a plateau at about 40 μM (Fig. 3). The sigmoidal shape of the palmitoyl-CoA dependence curve is typical of allosteric enzymes which are regulated by specific effector molecules (35–37). To determine whether any of a variety of possible effectors might eliminate the lag in the dependence curve, we examined the effect of adding various possible effectors to the enzyme assay. Addition of 5 mM adenosine triphosphate (ATP), 2 mM adenosine monophosphate (AMP), 1 mM nicotinamide adenine dinucleotide (NAD), 1 mM nicotinamide adenine dinucleotide (reduced form) (NADH), 1 mM CoA, or 1 mM citrate to the assay mixture had no effect on the initial lag period. However, the lag phase observed at 5 and 10 μM palmitoyl-CoA was corrected by adding 2 or 10 mM $MgCl_2$, $Mg(NO_3)_2$ or $CaCl_2$ (Fig. 3). Although, in each case, 10 mM salt was more stimulatory, each of the

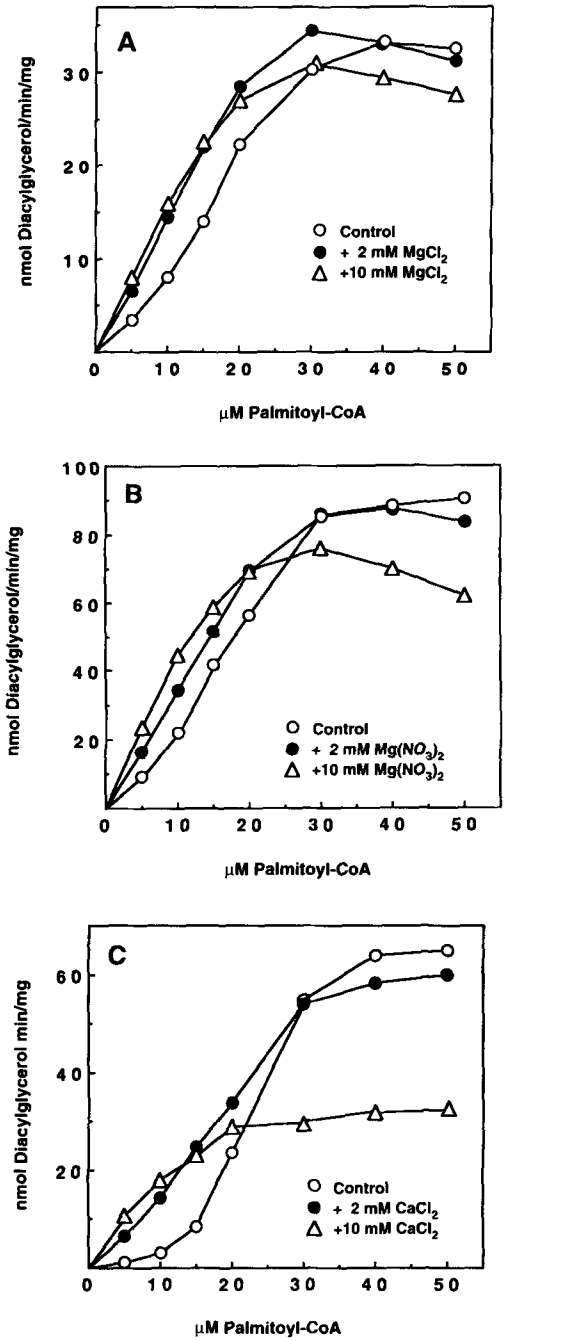

FIG. 3. Dependence of monoacylglycerol acyltransferase activity on palmitoyl-coenzyme A in the absence or presence of A) $MgCl_2$, B) $MgNO_3$, and C) $CaCl_2$. Divalent cations were present in the assay mixture at 0, 2, or 10 mM as indicated. Each of the experiments used a different adipose tissue preparation. The study with $MgCl_2$ was representative of two other studies using independent adipose tissue preparations.

salts at 10 mM inhibited MGAT activity when the palmitoyl-CoA concentration was greater than 20 to 30 μM. These results suggested a requirement for divalent cations when a low concentration of the palmitoyl-CoA substrate was present. The lack of a lag at higher concentrations of palmitoyl-CoA was unlikely to be due to a con-

taminating salt in the palmitoyl-CoA preparation itself since the addition of 10 mM EDTA did not alter the palmitoyl-CoA dependence at any of the concentrations of palmitoyl-CoA (data not shown).

A number of enzymes are activated by incubation with Mg^{2+}, unrelated to an ATP cofactor requirement (35–37). Enzyme activation by metal ions may be related to polymerization, to a change in enzyme conformation, to involvement in enzyme catalysis or to an alteration in substrate binding. Since MGAT has not been purified to homogeneity, mechanistic conclusions cannot be drawn. However, in order to determine whether the divalent cations might be exerting their effect by stabilizing MGAT, we tested the ability of $MgCl_2$ to enable MGAT activity to withstand thermal denaturation. With either 10 or 40 μM palmitoyl-CoA present, MGAT activity decreased 62% after 4 min of heating at 56°C in both the presence or absence of 2 or 10 mM $MgCl_2$ (data not shown). These results suggest that Mg^{2+} does not enhance activity by stabilizing the enzyme in a functional state.

We tested a variety of salts at 2.5 and 10 mM in order to determine whether other divalent cations and salts stimulated MGAT activity. The palmitoyl-CoA concentration was maintained at 10 μM (Table 1). MGAT activity was stimulated greatly in the presence of Mg^{2+}, Ca^{2+} and Ba^{2+}, was minimally stimulated by Na^+, was unaffected by Li^+, and was inhibited by Co^{2+}, Fe^{2+} and Zn^{2+}. $CuCl_2$ stimulated MGAT activity at 2.5 mM and inhibited it at 10 mM. Thus, the stimulatory effect was not universal for divalent cations or salts.

Previous studies of MGAT from liver have not shown an initial lag in the palmitoyl-CoA dependence, nor was MGAT stimulated by the addition of salts to the enzyme assay (21,32). In the presence of 25 μM palmitoyl-CoA, $CaCl_2$ and $MgCl_2$ inhibited MGAT activity. In a detailed study of MGAT from rat adipocytes, however, 5 mM $MgCl_2$, $CaCl_2$ or $BaCl_2$ stimulated MGAT activity when an optimum concentration (25 μM) of palmitoyl-CoA was present (31).

TABLE 1

Effect of Different Metal Ions on MGAT Activity at Low Palmitoyl-CoA Concentrations[a]

	Percent of control					
Concentration	$MgCl_2$	$MgSO_4$	$Mg(NO_3)_2$	$CaCl_2$	NaCl	Ba acetate
2.5 mM	276	318	369	384	104	183
10.0 mM	543	541	573	491	137	307

	Percent of control					
Concentration	LiCl	$CoCl_2$	$CuCl_2$	$FeCl_3$	$FeSO_4$	$ZnCl_2$
2.5 mM	83	80	114	11	6	3
10.0 mM	120	21	22	3	1	16

[a]Assays were performed as described in the Materials and Methods section except that 10 μM [^{3}H]palmitoyl-coenzyme A (CoA) was used and salts were present in the incubation mixture at 2.5 or 10 mM, as indicated. All assays were performed on the same day using 2 μg protein from the same enzyme preparation. The control monoacylglycerol acyl-coenzyme A acyltransferase (MGAT) specific activity with 10 μM palmitoyl-CoA was 1.16 nmol/min/mg. Results shown are the averages from duplicate assays. Two other enzyme preparations gave qualitatively similar results.

DISCUSSION

Our data show that the level of MGAT specific activity in sparrow adipose tissue is similar to that of liver from suckling rat, marmot, and chick embryo (20,21,32). In these animals, the presence of high hepatic MGAT activity correlates with developmental periods in which β-oxidation of fatty acids provides the primary source of the animal's energy while, concomitantly, essential fatty acids must be retained for normal development.

As previously reported for other nonpurified MGAT activities, a mixture of PS and PC markedly stimulated adipose MGAT activity (21,32). In Triton X-100/phospholipid/mixed micelles, very low concentrations of anionic phospholipids are known to stimulate partially purified MGAT from rat liver as much as 11-fold (38). Full activation requires about 11 molecules of PS per micelle (38). The data on sparrow fat suggest that adipose MGAT may have similar requirements for anionic phospholipids.

In contrast to other reported MGAT activities, the sparrow activity's dependence on palmitoyl-CoA showed an initial lag that could be abolished by adding one of several divalent cations to the reaction mixture. Magnesium, calcium, and barium were effective activators. Although this type of response is typically observed with allosterically regulated enzymes, conclusions about MGAT's mode of regulation must await the availability of a purified enzyme preparation. In contrast to the divalent ion activators, sodium and lithium had little or no effect, and cobalt, iron (Fe^{2+}), and zinc were inhibitory.

At low concentrations of the *sn*-2-monoacylglycerol substrate, *sn*-2-monolinoleoyl- and *sn*-2-monolinolenoylglycerol were acylated in sparrow fat more readily than *sn*-2-monooleoylglycerol. We have calculated that the concentration of monoacylglycerol in hepatic membranes is about 2 μM, well within the range in which MGAT exhibits a preference for the more unsaturated species (20). This preference is not the result of changes in membrane fluidity conferred by the more unsaturated monoacylglycerols because, when incubated with equal amounts of *sn*-2-monooleoylglycerol and *sn*-2-monolinolenoylglycerol, twice as much of the 18:3 species was acylated. Similar findings were reported for three hepatic MGAT activities (20). Taken as a whole, the data suggest that MGAT may play a physiological role in helping to retain essential fatty acids within these tissues.

During migration, lipids serve as the primary fuel for flight muscles (1,39–41). Among various species of migrating birds, the amount of stored fat correlates roughly with the distance migrated and with the speed of migration (1,42). Seasonal differences in the fatty acid species in avian adipose tissue have been attributed both to the fatty acid composition of available foods, including foods consumed during the migration itself (15,18) and to innate metabolic processes (16,17,19). Although the reported increase in unsaturated species in some migrating birds was attributed to a need for greater mobility of lipid stores (42), there is little evidence that saturated fatty acid

species are mobilized poorly from adipose depots. Although the relative content of linoleate and linolenate in goose adipose triacylglycerol changed very little during migration, the content of these fatty acids after reproduction differed markedly in male and female geese, suggesting that unsaturated fatty acids were used in egg production (18).

The roles of ω6 and ω3 fatty acids in physiology, development and metabolism are less well understood in avian than in mammalian tissue. However, one would anticipate, during spring migration, that birds need to retain ω6 and ω3 fatty acids because these fatty acids will be required for reproduction and for the formation of membranes of the retina and brain in the developing chick (8–13). The question arises how ω6 and ω3 fatty acids can be retained in the face of high ongoing rates of lipolysis and β-oxidation. We hypothesize that, unlike other species in which physiologic periods of lipolysis are associated with high MGAT activity in liver (20), the migrating bird must recapture the ω6 and ω3 fatty acids before they leave the adipose stores. In this way, ω6 and ω3 fatty acids can be selectively retained within the adipocyte. Since ω6 and ω3 fatty acids are predominantly found in the *sn*-2 position of glycerolipids, including triacylglycerols (23,24), high MGAT activity in adipocytes would allow reacylation of *sn*-2-monoacylglycerols and, thereby, prevent loss of ω6 and ω3 fatty acids as muscle fuels. The increased affinity for monoacylglycerols that contain ω6 and ω3 may provide a further mechanism for selective retention.

Lipolysis and reesterification occur continuously in adipocytes, even under conditions when lipolysis is not hormonally stimulated. Under nonstimulated conditions in human adipocytes, as much as 40% of triacylglycerol is reesterified within adipocytes (43). Thus, during the nonmigratory state, adipose MGAT may also reacylate monoacylglycerols. This process might be particularly prominent during premigratory fattening and hyperphagia. After human adipocytes are stimulated by β-adrenergic drugs, as much as 8–21% of triacylglycerol is reesterified within adipocytes (43). Thus, during migration, although hormone-sensitive lipase is reesterified within adipocytes (43). Thus, during migration, although hormone-sensitive lipase is stimulated to hydrolyze adipose triacylglycerol, MGAT may provide a means of recycling *sn*-2-monoacylglycerols.

Figure 4 shows possible pathways of fatty acid metabolism in the sparrow. We hypothesize that the flux of specific fatty acids is regulated within adipose tissue. There, the specificity of adipose MGAT for *sn*-2-monoacylglycerols and the enhanced affinity for 2-monoacylglycerols that contain specific acyl chains, would allow adipocytes to retain selected ω6 and ω3 fatty acids. Other, predominantly nonessential fatty acids would be released for β-oxidation in flight muscles. Although liver is also likely to take up some fatty acid and reesterify it, MGAT activity is relatively low in adult sparrow liver, and little further conservation of ω6 and ω3 fatty acids would occur.

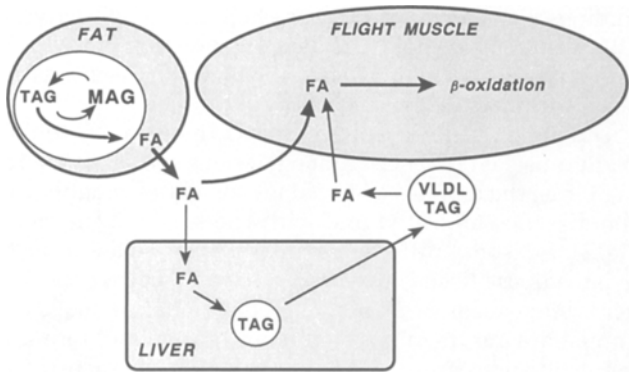

FIG. 4. Postulated pathways of avian fatty acid (FA) metabolism during migration. VLDL, very low density lipoproteins; MAG, monoacylglycerol; TAG, triacylglycerol.

ACKNOWLEDGMENTS

These studies were supported by a grant from the National Institutes of Health HD 19068. We are grateful to Dr. Susan Peters and Dr. Steven Nowicke, Duke University, for tissue samples and for helpful discussions.

Structural and Functional Role of Lipids in Yeast and Mycelial Forms of *Candida albicans*

Sawraj Goyal and **G.K. Khuller***

Department of Biochemistry, Postgraduate Institute of Medical Education and Research, Chandigarh 160012, India

The levels of total lipids, sterols and phospholipids were found to be significantly higher in the mycelial form (log phase) of *Candida albicans* than in the yeast form. Increased phospholipid levels in the mycelial form were due to higher levels of phosphatidylcholine, phosphatidylserine and phosphatidylinositol. Analyses of fatty acid composition also revealed higher levels of myristic acid (40%) in the yeast form, resulting in higher levels of saturated lipids than in the mycelial form. The changes in the lipid composition were also manifested in altered thermotropic phase behavior as gel-to-liquid crystalline phase transitions were observed at 36 and 27°C for the lipids of the yeast and mycelial forms, respectively. These changes coincided with higher uptake rate, i.e., Km and Vmax values, for the transport of L-proline and with a higher sensitivity of the mycelial form against antifungal drugs.

***Lipids* 29, 793–797 (1994).**

Candida albicans, a fungal pathogen responsible for candidiasis, exists either as yeast or as filamentous mycelia. Both growth forms are found in tissues affected by candidiasis, but the mycelial form is considered to be more pathogenic (1). Because lipids play a role in pathogenicity and are the potential targets for many antifungal drugs, immense interest has been generated in the diverse effects of lipids in respect to membrane organization, permeability properties and sensitivity toward antifungal drugs (2–8). Studies on the lipid composition of the dimorphic forms of *C. albicans* are particularly important as the pathogenicities of the two morphological forms differ (1).

The objective of the present investigation was to compare the lipid composition and its effect on membrane transport, gel-to-liquid crystalline phase transition and sensitivity toward antifungal drugs.

MATERIALS AND METHODS

Organism and culture conditions. Candida albicans 3153, obtained from the Mycological Reference Laboratory (Central Public Health Laboratory, Colindale, London, England), was maintained in Sabouraud glucose broth and cultivated in defined mineral salt solution containing (per liter) 8 g $(NH_4)_2SO_4$, 3.6 g KH_2PO_4, 1.2 g $Na_2HPO_4 \cdot 2H_2O$, 0.2 g $MgSO_4 \cdot 7H_2O$ and 0.1 µg D-biotin on a gyratory shaker (200 rpm, Model G2; New Brunswick Scientific Co. Inc., Edison, NJ) at 37°C. Yeast and mycelial forms were obtained at pH 4.5 and 6.8, respectively. Cells were harvested in mid log phase (16-h growth) and processed further as follows.

Quantitation of lipids. Lipids were extracted by the method of Folch *et al.* (9). Total lipids were measured gravimetrically. Phospholipids were quantified by the method of Marinetti (10). Individual phospholipids were separated by one-dimensional thin-layer chromatography on Silica Gel H (11) impregnated with 0.18% ammonium sulfate in chloroform/methanol/7 N aqueous ammonia (65:25:4, by vol). Standard phospholipid markers were run side-by-side with samples, and fractions were visible by exposure to iodine vapors and identified by spraying with specific reagents (11). Phospholipid classes were quantified by phosphorus assay according to the method of Marinetti (10). Sterols were estimated by the method of Zlatkis *et al.* (12). Phospholipids were separated from total lipids by acetone precipitation, and fatty acid methyl esters were prepared as described previously (13). Fatty acid methyl esters were then analyzed by gas–liquid chromatography in an AIMIL-Nucon gas chromatograph (Delhi, India) fitted with a glass column (1.83 m × 3 mm i.d.) packed with 15% diethyleneglycolsuccinate on 80–100 mesh. Fatty acids were identified by comparison of their retention times with those of authentic standards. Peak areas were quantified by triangulation.

Enzyme assays. The activity of glycerol kinase was determined as described earlier (14). The assay for the activity of glycerol-3-phosphate acyltransferase was carried out as described by Okuyama *et al.* (15). For the separation of the product, the filter disc method of Goldfine (16), as modified by van den Bosch and Vagelos (17), was used. The homogenate for the acyltransferase assay was prepared by harvesting and sonicating the cells at 4°C in 40 mM Tris-HCl buffer, pH 7.5. For the glycerol kinase assay, the homogenate was prepared in 10 mM Tris-HCl buffer, pH 8.0. The homogenate was centrifuged at 5000 × *g* for 20 min to remove cell debris, and the supernatant was used for the assays.

Uptake studies. Log phase cells were washed with 0.85% NaCl and resuspended in medium under sterile conditions. Cells were preincubated at 37°C for 30 min with shaking. Ten µCi of [^{14}C]acetate/g of cells was then added in 50 mL of medium, and at different time points 3 mL of sample from each culture was transferred into tubes containing 0.5 mL 1 M KCN (18). The tubes were centrifuged at 2700 × *g* for 15 min, the cell pellet was recovered and lipids were extracted. Radioactivity was counted in an LKB Wallace liquid scintillation counter (Turku, Finland) using a toluene-based scintillation fluid.

Liposome preparation. Liposomes were prepared by the method of Alving *et al.* (19). Briefly, lipids, extracted from log phase yeast and mycelial forms, were dissolved separately in chloroform/methanol (2:1, vol/vol) and transferred to pear-shaped flasks. Under a gentle flow of nitrogen, the solvent was evaporated to dryness to form a thin lipid film on the walls of the flasks. The flasks were then kept in a high vacuum dessiccator for 2 h to remove resid-

Abbreviations: ANS, 1-anilinonaphthalene-8-sulfonate; DPH, 1,6-diphenyl-1,3,5-hexatriene; LPC, lysophosphatidylcholine; MIC, minimum inhibitory concentration; PC, phosphatidylcholine; PE, phosphatidylethanolamine.

ual organic solvents. Liposomes were prepared by dispersing the lipids in 10 mM Tris-HCl buffer, pH 7.4, containing 145 mM NaCl and 0.025% ethylenediaminetetraacetate, followed by vortexing for 10 min in the presence of glass beads. To the final liposome preparation, 1,6-diphenyl-1,3,5-hexatriene (DPH) was added to obtain a phospholipid to probe ratio of 750:1. The final DPH concentration was 1 μM.

Steady-state fluorescence polarization. Fluorescence polarization was measured on a Kontron (Zürich, Switzerland) SFM-25 fluorescence spectrofluorimeter (excitation wavelength, 360 nm; emission wavelength, 430 nm). Polarization values (P) were determined as described earlier (20):

$$P = \frac{I_{\parallel} - I_{\perp}}{I_{\parallel} - I_{\perp}} \quad [1]$$

where $I_{\parallel}$ and $I_{\perp}$ are the intensities of parallel and perpendicular polarized light, respectively. The standard deviation of polarization values was 0.02. Temperature was maintained within ±0.5°C.

Preparation of spheroplasts. Spheroplasts were prepared according to the method of Jayakumar *et al.* (21). Formation of spheroplasts was monitored microscopically. The incubation mixture was centrifuged at 1,000 × *g* for 10 min, and the supernatant containing the cell wall degrading enzymes was discarded. The pellet was washed twice with the buffer, and the spheroplasts were purified by centrifugation on a Ficoll-opaque gradient (Uppsala, Sweden) at 400 × *g* for 10 min. The purified spheroplasts that were free of cell debris recovered from the supernatant were used for further studies.

1-Anilinonaphthalene-8-sulfonate (ANS) binding studies. A fluorescent probe, ANS, was used for determining the number of binding sites in membranes of yeast and mycelial spheroplasts. The assay mixture consisted of a total volume of 2.0 mL with 10 mM citrate phosphate buffer, pH 6.5, containing 0.7 M sodium chloride, 50 μM ANS and 50–200 μg spheroplast protein. Fluorescence emission was recorded on a Kontron SFM-25 spectrofluorimeter. The numbers of binding sites were calculated from Scatchard plot analyses (22).

Transport assay. Spheroplasts (150–200 μg protein/mL) were preincubated at 37°C for 10 min after addition of cycloheximide (200 μg/mL) to inhibit protein synthesis. The reaction was initiated by addition of L-[^{3}H]proline (sp. act., 24 Ci/mmol). At the time points indicated, 0.1-mL aliquots were removed and added to 5.0 mL of chilled normal saline. The diluted suspension was rapidly filtered through 0.45 μm millipore filters, and radioactivity retained was counted in an LKB liquid scintillation counter using a toluene-based scintillation fluid.

Protein estimation. Protein was measured by the method of Lowry *et al.* (23).

Determination of minimum inhibitory concentration (MIC) of antifungal drugs. MIC values for amphotericin B, nystatin and miconazole were determined for yeast and mycelial forms of *C. albicans* over a 48-h growth period at 37°C using the standard agar dilution method. MIC was the concentration of the drug that inhibited growth by more than 90%. Stock solutions of these drugs were prepared in dimethylsulfoxide.

Statistical analysis. Student's t-test was used to assess levels of significance. Values of $P < 0.05$ were considered significant.

RESULTS AND DISCUSSION

Total lipid, phospholipid and sterol contents of log phase (16-h growth) mycelial cells were significantly higher than those of yeast cells. Lipids constituted 3.8 and 4.3% of the dry weight of the yeast and mycelial forms, respectively. The mycelial forms contained significantly higher levels of phosphatidylcholine (PC), phosphatidylserine, phosphatidylinositol and lysophosphatidylcholine (LPC), and lower levels of phosphatidylethanolamine (PE) compared to the yeast form (Table 1). PC levels increased to 104% while PE levels decreased to 33% in the mycelial form as compared to those in the yeast form, suggesting that the PC in the mycelial form may possibly be formed by the methylation pathway.

Analysis of the fatty acids of the total phospholipids revealed higher levels of saturated fatty acids, particularly of myristic acid (14:0) in the yeast form, and the mycelial phospholipids were found to contain higher levels of palmitic acid (16:0), palmitoleic acid (16:1) and linoleic acid (18:2). The higher levels of saturated fatty acids in the yeast form could cause a decrease in membrane fluidity which, in turn, may affect permeability properties. The ratio of unsaturated to saturated fatty acids was about threefold higher in the mycelial form of *C. albicans* than it was in the yeast cells, similar to what had been observed by Ghannoum *et al.* (24).

Incorporation of [^{14}C]acetate as precursor of lipid biosynthesis was linear up to four minutes, and was significantly higher in the mycelial form (data not presented). Phospholipid biosynthesis in the yeast form of *C. albicans*

TABLE 1

Lipid Composition of Log Phase Cells of Yeast and Mycelial Forms of *Candida albicans* ATCC 3153[a]

Lipids	(mg/g dry wt) Yeast form	Mycelial form	Percentage change[d]
Total lipids	37.67 ± 1.53	42.76 ± 1.24[b]	13.5
Total phospholipids	9.84 ± 0.61	14.82 ± 0.21[c]	50.6
Total sterols	4.90 ± 0.20	8.07 ± 0.81[c]	64.7
Lysophosphatidylcholine (LPC)	0.91 ± 0.05	1.46 ± 0.04[c]	60.4
Phosphatidylserine	1.12 ± 0.16	1.60 ± 0.05[b]	42.9
Phosphatidylinositol	0.91 ± 0.16	1.55 ± 0.07[b]	70.3

TABLE 2

Specific Activities of Phospholipid Biosynthetic Enzymes in Yeast and Mycelial Forms of *Candida albicans*[a]

Enzyme	Specific activity (nmol/mg protein/h)	
	Yeast form	Mycelial form
Glycerol kinase	7.47 ± 0.40	11.23 ± 0.40[b]
Glycerol-3-phosphate acyltransferase	5.10 ± 0.76	8.90 ± 0.80[b]

[a]Values are mean ± SD of four different batches.
[b]$P < 0.01$.

had been studied earlier (25), but no report is available so far on the activities of phospholipid enzymes in the mycelial form. Our data revealed that the activities of glycerol kinase and glycerol-3-phosphate acyltransferase, two of the initial enzymes in phospholipid biosynthesis, were significantly higher in the mycelial form (Table 2). The mycelial form of *C. albicans* has previously been shown to possess lower activities of phospholipid degrading enzymes than did the yeast form (26). Thus, the higher/lower activities of phospholipid biosynthetic/degrading enzymes in the mycelial form of *C. albicans* are consistent with the higher levels of phospholipids in the mycelial form.

Fluorescence polarization studies revealed that the lipids of the mycelial form were more fluid as discontinuities were observed in the fluorescence polarization plots at 36 and 27°C for the yeast and mycelial forms, respectively (Fig. 1). The discontinuity in fluorescence polarization suggests a gel-to-liquid crystalline phase transition. The nature of the fatty acyl chains of phospholipids is a most important factor in determining membrane fluidity,

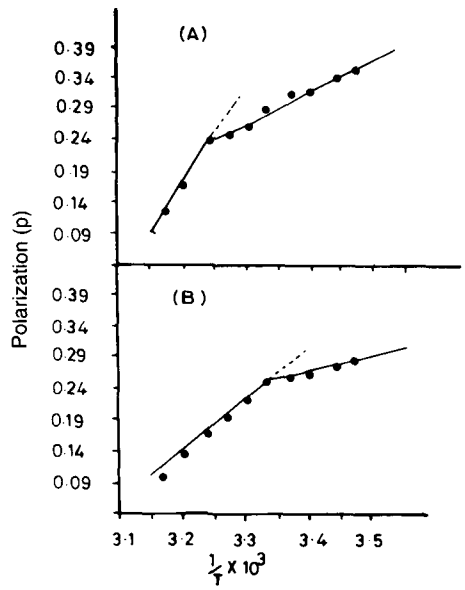

FIG. 1. Fluorescence polarization plots of liposomal membranes prepared from lipids of *Candida albicans*. (A) Yeast form; (B) mycelial form. Fluorescence polarization measurements were carried out as described in the Materials and Methods section.

TABLE 3

Composition of Phospholipid Fatty Acids of Log Phase Cells of Yeast and Mycelial Forms of *Candida albicans*[a]

Fatty acid	(relative percentage)	
	Yeast form	Mycelial form
14:0	40.5	7.4
15:0	13.4	3.6
16:0	16.6	33.9
16:1	12.0	26.8
18:0	2.5	4.8
18:1	11.5	14.4
18:2	3.2	9.2

which is consistent with the observed increase in the degree of unsaturation in the mycelial form as compared to the yeast form (Table 3). Furthermore, the polarization values decreased with increasing temperature, indicating an increase in probe mobility with increasing temperature. As a decrease in fluorescence polarization is a measure of disorder, the present study suggests mycelial lipids to be more fluid. Membrane fluidity has been reported to play an important role in various cellular functions including permeability (27), regulation of enzyme activity (28) and transport of various nutrients (29).

In addition to the generally accepted role of fatty acids in modulating the fluidity of membranes, the phospholipid head groups, their charge and structure, can also affect fluidity. Previous studies have supported that PE molecules are more closely packed than are PC molecules (30). Because, in the present investigation, the PC/PE levels were found to be high/low in the mycelial form compared to the yeast form of *C. albicans,* a fluorescent probe, ANS, was employed to examine structural changes arising due to modulation of membrane surface charge. Because ANS is not transported into the cells, but remains predominantly bound onto the cell surface, spheroplasts of yeast and mycelial forms were prepared by enzymatically removing the cell wall. Removal of the cell wall did not result in loss of lipids as the lipid content and composition of spheroplasts were the same as those of whole cells (unpublished observation). The analysis of our results from Scatchard plot suggested that the number of phospholipid binding sites was significantly higher in the mycelial form (Table 4), consistent with the presence of higher levels of

LPC and PC and lower levels of PE in the mycelial form than in the yeast form.

To explore the effect of altered lipid composition on biochemical functions, the transport of L-[^{3}H]proline was studied in yeast and in mycelial forms. The Km and Vmax values for the uptake of proline were significantly higher for the mycelial form (Table 5), suggesting that the permeases responsible for the uptake of proline are affected to different degrees by the changes in lipid composition in the yeast and mycelial forms. These results agree with the findings of others suggesting that fluctuations in phospholipid and sterol levels can lead to a change in membrane permeability and membrane associated functions, including the activities of membrane bound enzymes (31–33).

To examine the effect of altered lipid composition on the behavior of antifungal drugs, MIC of amphotericin B, nystatin (polyenes) and miconazole (azole antifungal drug) to dimorphic forms of *C. albicans* were examined. The sites of action of polyenes and miconazole are different (34). The mycelial form was found to be more susceptible to these drugs (Table 6), which may be due to the presence of higher levels of phospholipid unsaturated fatty acids (Table 3) and sterols (Table 1) close to the target sites for the polyene antifungal drugs (35,36). Whereas in the case of miconazole the higher susceptibility of the mycelial form may be due to greater accumulation of methylated sterols, miconazole inhibits P-450 dependent 14α-demethylase in the ergosterol biosynthetic pathway (8), leading to accumulation of methylated sterols possibly resulting in the leakage of essential metabolites (37), and ultimately in cell death.

Taken together, the results of this study indicate that the yeast and mycelial forms of *C. albicans* differ in their phospholipid and fatty acid composition, and that the changes in lipid composition are accompanied by changes in structural and functional properties.

ACKNOWLEDGMENT

[a]Department of Chemistry, Faculty of Science, Ehime University, Matsuyama 790 and [b]Developing Center Section No. 1, Konica Co., Ltd., Sakura 1, Hino 191, Japan

Quenching reactions of singlet oxygen and scavenging reactions of free radicals by α-, β-, γ- and δ-tocopheramines (Toc-amines) were investigated spectrophotometrically in ethanol and Triton X-100 micellar dispersions. The rate constants of quenching of singlet oxygen (k_Q) by α-, β-, γ- and δ-Toc-amines increased as the total electron donating capacity of the methyl groups at the aromatic ring increased. A plot of logk_Q vs. peak oxidation potential (E_p) was found to be linear and the slope was negative. Similar results were obtained for scavenging of a phenoxyl radical (PhO·). The results suggest that charge transfer plays an important role in these reactions. The k_Q values were found to be 1.30–2.57 times as large as k_Q for α-tocopherol (α-Toc). Although α-Toc has the highest antioxidant activity among natural tocopherols and related phenols, Toc-amines also can serve as antioxidants.

***Lipids* 29, 799–802 (1994).**

It is well known that vitamin E (α-, β-, γ- and δ-tocopherol) inhibits the autoxidation of organic molecules in liquid phase. The mechanism involved has been studied extensively by several investigators (1–4). Vitamin E is present in cellular membranes and in edible oils and acts as an antioxidant by protecting polyunsaturated lipids from peroxidation.

The antioxidant properties of tocopherols (Toc) have been ascribed to hydrogen transfer from the OH group in Toc to a peroxyl radical (LOO·). The hydrogen transfer produces a tocopheroxyl radical (Toc·), which combines with another LOO· (Reactions 1 and 2) (5,6).

$$\text{LOO}\cdot + \text{Toc} \xrightarrow{k_1} \text{LOOH} + \text{Toc}\cdot \quad [1]$$

$$\text{LOO}\cdot + \text{Toc}\cdot \rightarrow \text{nonradical products} \quad [2]$$

Abbreviations: DPBF, 2,5-diphenyl-3,4-benzofuran; EP, 3-(1,4-epidioxy-4-methyl-1,4-dihydro-1-naphthyl)propionic acid; E_p, peak oxidation potential; k_d, rate constant of deactivation of singlet oxygen in pure solvent; k_{obsd}, pseudo-first-order rate constant for reaction between 2,6-di-*t*-butyl-4-(4-methoxyphenyl)phenoxyl and antioxidant; K_Q, rate constant of quenching of singlet oxygen by antioxidant; k_s, second-order rate constant for reaction between 2,6-di-*t*-butyl-4-(4-methoxyphenyl)phenoxyl and antioxidant; LOO·, lipid peroxyl radical; PhO·, 2,6-di-*t*-butyl-4-(4-methoxyphenyl)phenoxyl; SCE, saturated calomel reference electrode; S_s, slope of first-order plots of disappearance of 2,5-diphenyl-3,4-benzofuran in presence of antioxidant; S_0, slope of first-order plots of disappearance of 2,5-diphenyl-3,4-benzofuran in absence of antioxidant; Toc, tocopherol and its analogues; Toc·, tocopheroxyl radical and its analogues; Toc-amine, tocopheramine.

In a previous study (7), we measured the reaction rates, k_s, of α-, β-, γ- and δ-Toc with 2,6-di-*t*-butyl-4-(4-methoxyphenyl)phenoxyl (PhO·) in ethanol (EtOH) solution (Reaction 3) using stopped-flow spectrophotometry. PhO· can be regarded as a model for active oxygen radicals (LOO· and others) in biological systems.

$$\text{PhO}\cdot + \text{Toc} \xrightarrow{k_s} \text{PhOH} + \text{Toc}\cdot \quad [3]$$

The second-order rate constants, k_s, obtained were 5.12×10^3 (α-Toc), 2.24×10^3 (β-Toc), 2.42×10^3 (γ-Toc) and 1.00×10^3 (δ-Toc) $M^{-1}s^{-1}$ in EtOH at 25.0°C. The relative rates (α/β/γ/δ, 100:44:47:20) agreed well with those obtained in studies on the reactivity of Toc toward poly(peroxystyryl)peroxyl radicals (100:41:44:14) using the O_2 consumption method (Reaction 1, Ref. 8). The result suggests that the relative reactivity of Toc in solution probably does not depend on the type of oxyradicals (PhO· and LOO·) used. It appears that both a charge transfer and proton tunneling play an important role in the antioxidant reaction of Toc (9,10).

Lipid peroxidation is also induced by the reaction of a singlet oxygen with unsaturated lipids, and Toc can act as efficient quencher of singlet oxygen (11–13). α-Toc quenches singlet oxygen by both physical quenching and chemical reaction (Reaction 4, Refs. 11–13).

$$^1O_2 + \text{Toc} \xrightarrow{k_Q} \text{physical quenching} + \text{chemical reaction} \quad [4]$$

In reactions of Toc, plots of k_Q vs. k_s show a linear relationship (14).

Tocopheramines (Toc-amines) can also act as antioxidants (15–17). In fact, in the rat red cell hemolysis test Toc-amines show activity equal to or greater than Toc (15). In order to clarify the antioxidant activity of Toc-amine derivatives, we have measured in the present study the rates (k_s) of scavenging of PhO· by α-, β-, γ- and δ-Toc-amines in EtOH solution and in micellar dispersion at 25°C. We have also measured the rate (k_Q) of singlet oxygen quenching at 35°C, and compared the observed rates, k_s and k_Q, with those of α-Toc. The structures of the molecules used in this work are shown in Figure 1.

MATERIALS AND METHODS

α-, β-, γ- and δ-Toc-amines were prepared according to published methods (18). Ethanol, diethyl ether, benzene, cyclohexane, hexane, toluene and methanol were purified by distillation prior to use. Triton X-100 was purchased

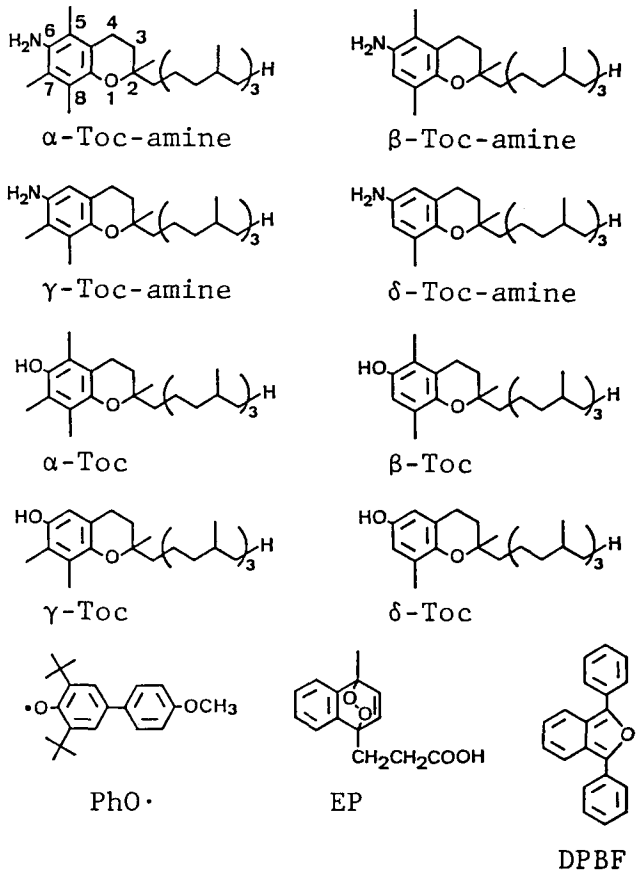

FIG. 1. Structures of molecules used in this work. PhO·, 2,6-di-*t*-butyl-4-(4-methoxyphenyl)phenoxyl; EP, 3-(1,4-epidioxy-4-methyl-1,4-dihydro-1-naphthyl)propionic acid; DPBF, 2,5-diphenyl-3,4-benzofuran.

from Nacalai Tesque (Kyoto, Japan) and was used as such. The aqueous solution (5.0 wt%) was buffered at pH 7.0 with KH_2PO_4/$NaHPO_4$.

The experimental setup and procedures used for the measurement of k_s have been described in detail previously (19). Briefly, the kinetic data were obtained with a UNISOKU stopped-flow spectrophotometer Model RS-450 (Hirakata, Japan) by mixing equal volumes of solutions or micellar dispersions of a Toc-amine and PhO· under a nitrogen atmosphere. All measurements were made at 25.0 ± 0.5°C. The pseudo-first-order rate constant for the reaction [3] (k_{obsd}) was determined by following the decrease in absorbance of PhO· (375 or 580 nm). The rate constant k_{obsd} is given by Equation 5:

$$k_{obsd} = k_0 + k_s[\text{Toc-amine}] \quad [5]$$

k_0 denotes the rate constant for the natural decay of PhO·; [Toc-amine] refers to the molar concentration of Toc-amine. The rate parameters were obtained by plotting k_{obsd} against [Toc-amine].

The experimental setup and the procedures for the measurement of k_Q have also been described in detail (14). Briefly, the kinetic data were obtained with a Shimadzu UV-2100S spectrophotometer (Kyoto, Japan). Singlet oxygen was generated by the thermal decomposition of 3-(1,4-epidioxy-4-methyl-1,4-dihydro-1-naphthyl)propionic acid (EP; 20,21). 2,5-Diphenyl-3,4-benzofuran (DPBF) was used as standard. The value for k_Q was determined according to Young *et al.* (22). EtOH solutions or micellar dispersions of EP, DPBF and Toc-amine in EtOH were reacted at 35°C. The disappearance of DPBF was measured at 411 nm. The value for k_Q was determined following Equation 6:

$$S_0/S_s = 1 + (k_Q/k_d)[\text{Toc-amine}] \quad [6]$$

where S_0 and S_s denote slopes of the first-order plots of disappearance of DPBF in the absence and presence of Toc-amine, respectively. The value for k_0 can be calculated by using the value of the rate of deactivation of singlet oxygen in pure solvent (k_d), while k_d in EtOH was found to be 8.3×10^4 s^{-1} (23). Since k_d in micellar dispersion is not known, the rate of Reaction 4 in micellar dispersion was estimated to be k_Q/k_d.

The peak oxidation potential (E_p) of Toc-amine was obtained by cyclic voltammetry. Cyclic voltammetry was performed at room temperature under an atmosphere of nitrogen using a Yanaco cyclic voltammetric analyzer Model P-1000H (Kyoto, Japan). The electrodes used were platinum and saturated calomel reference electrodes (SCE) in acetonitrile (dried over P_2O_5) containing 40 mM tetrabutylammonium perchlorate. Under these conditions, ferrocene as a standard sample has a half-wave oxidation potential of +400 mV.

In micellar dispersion, the reactions occur entirely in the hydrophobic phase rather than the bulk phase. Toc-amine, PhO·, EP, DPBF, and singlet oxygen move freely between micelles. Accordingly, the values for k_s and k_Q should be calculated in the micellar volume. However, since the micellar volume is not well known, we calculated the values in the bulk volume. The values for k_s and k_Q thus obtained in the micellar dispersion should be considered relative.

RESULTS AND DISCUSSION

The values of k_s for the reactions of Toc-amine with PhO· in EtOH and micellar dispersion are listed in Table 1 together with E_p and the Toc data. Figure 2 shows plots of $\log k_s$ vs. E_p of Toc-amine and Toc. The k_s of Toc-amine in micellar dispersion and the k_s of Toc in EtOH and micellar dispersion increased as the total electron-donating capacity of the alkyl substituents at its aromatic ring increased and E_p decreased. In Figure 2, the plot for each of these samples indicates a linear relationship. The results suggest that the electron transfer from Toc-amine to LOO· (or PhO·) plays an important role in Reactions 1 and 3 as proposed in the case of Toc (7,9,10); similar to Toc (9,10), both electron transfer and proton tunneling play an important role in the antioxidant reaction of Toc-amine. This electron transfer corresponds to the "normal" region in the Marcus theory (24–26; 27 and references therein) and/or the Rehm–Weller equation (28,29; 30 and references therein).

However, the linear relationship cannot be seen in the reaction of Toc-amine in EtOH; k_s of α-Toc-amine is

TABLE 1

The k_s and k_Q Values for Toc-amine and Toc in EtOH and Micellar Dispersion as Well as E_p[a]

Compounds	k_s[b] ($M^{-1}s^{-1}$) EtOH	k_s[b] ($M^{-1}s^{-1}$) Micellar dispersion	k_Q[b] ($M^{-1}s^{-1}$) EtOH	k_Q/k_d[b] (s^{-1}) Micellar dispersion	E_p[c] vs. SCE (mV)
α-Toc-amine	3.62×10^2	8.76×10^2	5.30×10^8	4.82×10^3	490
β-Toc-amine	8.57×10^2	7.33×10^2	4.25×10^8	5.97×10^3	520
γ-Toc-amine	9.44×10^2	3.97×10^2	3.85×10^8	3.87×10^3	510
δ-Toc-amine	8.35×10^2	1.97×10^2	2.67×10^8	4.16×10^3	570
α-Toc	5.12×10^3[d]	4.53×10^5	2.06×10^8[e]	2.20×10^3	860[f]
β-Toc	2.24×10^3[d]	1.22×10^5	1.53×10^8[e]	1.70×10^3	920[f]
γ-Toc	2.42×10^3[d]	1.19×10^5	1.38×10^8[e]	1.65×10^3	930[f]
δ-Toc	1.00×10^3[d]	1.04×10^4	0.53×10^8[e]	1.38×10^3	990[f]

[a]E_p, peak oxidation potential; k_d, rate constant of deactivation of singlet oxygen in pure solvent; k_Q, rate constant of quenching of singlet oxygen by antioxidant; k_s, second-order rate constant for reaction between 2,6-di-*t*-butyl-4-(4-methoxyphenyl)phenoxyl and antioxidant; SCE, saturated calomel reference electrode; Toc, tocopherol and its analogues; Toc-amine, tocopheramine. [b]Experimental errors <±5%. [c]Experimental errors <±10 mV. [d]Reference 7. [e]Reference 14. [f]Reference 19.

smaller than the k_s of other Toc-amines. This result is somewhat surprising since the "expected" relative trend is observed in micellar dispersion. It was therefore of interest to make these measurements in other solvents, especially nonprotic ones. The k_s values for the reactions of Toc-amine with PhO· in diethyl ether, benzene, cyclohexane, hexane, toluene, and methanol are listed in Table 2. As in the case of EtOH, k_s for α-Toc-amine is smaller than for the other Toc-amines in diethyl ether, benzene, and hexane. Thus these results are unlikely due to hydrogen bonding and protic solvation and can generally be found in various solvents. At present, we cannot offer an unambiguous explanation, but it is possible that the electron transfer from α-Toc-amine to PhO· in EtOH corresponds to the "inverted region" in the Marcus theory (24–27) and/or the "activationless region" in the Rehm–Weller equation (28–30).

The k_Q values for the reactions of Toc-amine with singlet oxygen in EtOH and micellar dispersion are also listed in Table 1, together with the data for Toc. Figure 3 shows plots of logk_Q vs. E_p of Toc-amine and Toc. The k_Q of Toc-amine and Toc in EtOH and micellar dispersion increased as the total electron-donating capacity of the alkyl substituents at its aromatic ring increased and E_p

TABLE 2

The k_s Values ($M^{-1}s^{-1}$) for Toc-amine in Various Solvents[a,b]

	α-Toc-amine	β-Toc-amine	γ-Toc-amine	δ-Toc-amine
Diethyl ether	3.85×10^2	6.82×10^2	6.82×10^2	4.06×10^2
Benzene	6.91×10^2	1.03×10^3	1.13×10^3	8.57×10^2
Cyclohexane	8.15×10^2	9.71×10^2	1.14×10^3	6.82×10^2
Hexane	6.04×10^2	8.47×10^2	1.22×10^3	8.63×10^2
Toluene	6.13×10^2	—	—	—
Methanol	6.76×10^2	—	—	—

[a]k_s, second-order rate constant for reaction between 2,6-di-*t*-butyl-4-(4-methoxyphenyl)-phenoxyl and tocopheramine; Toc-amine, tocopheramine.
[b]Experimental errors <±5%.

decreased. In Figure 3, the plot for each of these samples shows a linear relationship, although the slope for Toc-amine in micellar dispersion is very small. The reaction of singlet oxygen with phenols is known to be an electron-transfer reaction (20,31).

It would be worthwhile to compare the relative activity in the rat erythrocyte hemolysis test (15,32) with the relative ratio of both k_s and k_Q of Toc-amines and Toc in EtOH and micellar dispersion. Although the activity of Toc-amine was similar to that of the corresponding Toc in the rat erythrocyte hemolysis test (data not shown), k_s of Toc-amine is much smaller than that of the corresponding Toc. On the other hand, the k_Q values of Toc-amines were found to be 1.30–2.57 times larger than k_Q of α-Toc, which has the largest k_Q among natural Toc and related phenols. Thus, Toc-amines have properties that make them useful as antioxidants.

ACKNOWLEDGMENTS

We thank Professor Kenzo Inoue and Dr. Kunihiko Tajima of Ehime University for kindly helping S.I. in his work. Our thanks are also due to Yuji Okauchi of Ehime University for his measurements of k_s values of tocopherols in micellar dispersion (Table 1).

ARTICLE

Effects of Site-Directed Mutagenesis on the Serine Residues of Human Lecithin:Cholesterol Acyltransferase

Shi-Jing Qu, Hui-Zhen Fan, Francisco Blanco-Vaca, and **Henry J. Pownall***

Department of Medicine, Baylor College of Medicine and The Methodist Hospital, Houston, Texas 77030

Lecithin:cholesterol acyltransferase (LCAT) is a serine protease-type enzyme that esterifies cholesterol in human plasma and is activated by apolipoprotein A-I in high-density lipoproteins. LCAT contains 22 serine residues, including Ser181, which is thought to be part of the catalytic site. In order to determine the importance of these serine residues in LCAT, we prepared six LCAT mutants: LCAT (Ser19 → Ala), LCAT (Ser181 → Gly), LCAT (Ser208 → Ala), LCAT (Ser216 → Ala), LCAT (Ser225 → Ala) and LCAT (Ser383 → Ala). We also replaced the adjacent asparagine residues in two additional mutants, LCAT (Ser19 → Ala, Asn20 → Thr) and LCAT (Ser383 → Ala, Asn384 → Thr), in order to ascertain the effect of the serines on *N*-glycosylation. The mutant complementary DNA (cDNA) were subcloned into a eukaryotic expression vector (pSG5) and expressed in COS-6 cells. By polymerase chain reaction analysis, LCAT-specific messenger RNA (mRNA) was found in all mutant and wild-type transfectants. Western blot analysis revealed LCAT-specific bands in media and lysates of the transfected cells. With two exceptions, the amounts of LCAT mass secreted by the transfectants were similar to that of the wild type (mean, 90% mass of wild type; range, 34–138%). Except for LCAT (Ser181 → Gly), which was inactive, the specific activities of the remainder of the mutant enzymes were also similar (mean, 95% activity of wild type; range, 65–169%). These results indicate that Ser181 is part of the catalytic site and that stereoconservative substitutions for serines have minor effects on the synthesis, secretion and specific activities of human LCAT.

***Lipids* 29, 803–809 (1994).**

Lecithin:cholesterol acyltransferase (LCAT;EC 2.3.1.43), which catalyzes the transfer of an acyl group from phosphatidylcholine (PC) to the 3β position of cholesterol, is a key enzyme in reverse cholesterol transport (1,2). Protein and DNA sequencing of LCAT (3,4) reveal a 416-residue glycoprotein containing a mixture of β-structure, α-helix and random coil. The hexapeptide Ile 178-Gly179-His180-Ser181-Leu182-Gly183 was first implicated in catalysis because of its reactivity with an active site reagent (5) and its homology with pancreatic and lingual lipases (3,4). A recent report of mutagenesis *in vitro* supported the role of Ser181 in the active site of LCAT (6). Ser216, which appears in a tripeptide sequence (Gly-X-Ser) similar to that of Ser181, is another residue which has been proposed as a part of the active site (7). Moreover, Ser208 and Ser216 are close to the active site region, where small changes in structure might be expected to modify enzyme activity. Thus, it was of interest to determine whether nearby serines play an important role in LCAT activity and to confirm the importance of Ser181 in catalysis. Because serine residues are adjacent to two asparagine residues, Asn20 and Asn384, *N*-glycosylation might be one process that the proximity of serines could affect. A change in glycosylation could, in turn, influence the secretion and activity of LCAT (8,9). In order to assess the importance of the serine residues in LCAT synthesis, secretion and activity, eight mutants were prepared by site-directed mutagenesis, expressed in COS-6 cells, and tested *in vitro*.

Abbreviations: cDNA, complementary deoxyribonucleic acid; DAPC, 1,2-diarachidonoyl phosphatidylcholine; dATP, deoxyadenosine triphosphate; DEAE, diethylaminoethyl; DMEM, Dulbecco's modified Eagle's medium; IgG, immunoglobulin G; LCAT, lecithin:cholesterol acyltransferase; mRNA, messenger RNA; PC, phosphatidylcholine; PCR, polymerase chain reaction; POPC, 1-palmitoyl-2-oleoyl phosphatidylcholine; R-HDL, reassembled high density lipoprotein.

MATERIALS AND METHODS

Materials. Restriction enzymes were purchased from Promega (Madison, WI). The Sequenase Version 2.0 DNA Sequencing Kit was obtained from United States Biochemical (Cleveland, OH). Amersham (Arlington Heights, IL) was the source for [α-^{35}S]deoxyadenosine triphosphate (dATP) (1,000 Ci/mmol), [α-^{32}P]ATP (5,000 Ci/mmol) and Na^{125}I. The rabbit anti-goat immunoglobulin G (IgG) was purchased from BioRad (Hercules, CA), ^{3}H-labeled cholesterol from DuPont (Wilmington, DE) and the phospholipids from Avanti Polar Lipids (Alabaster, AL). A full-length cDNA (complementary DNA) clone of human LCAT (pUCLCAT.10) spliced into the *Eco*RI/*Bam*HI sites of pUC19 was kindly provided by Richard Lawn of Genentech Inc. (South San Francisco, CA) (4). The insert contained 102 nucleotides in the 5′-untranslated region, the entire coding region, and 68 nucleotides in the 3′-untranslated region. Both ends were bound by multiple linkers.

Construction of the mutant clones. The cloning and expression strategies were essentially those of Qu *et al.* (9,10). The oligonucleotides used as the primers for mutagenesis (Table 1) were synthesized on a Cyclone Plus DNA synthesizer (Burlington, MA) and purified by an Oligo-pak oligonucleotide purification column (MiliGen/BioSearch; Burlington, MA). Before use, the oligonucleotides were phosphorylated at the 5′ position by T_4 polynucleotide kinase. After digestion by *Eco*RI and *Bam*HI, the pUCLCAT.10 was subcloned into M13mp18 and M13mp19. Single-stranded DNA containing uracil was prepared by using *Escherichia coli* host strain CJ236 (ung$^-$) to culture the M13mp18 or M13mp19 LCAT clones (11). The single-stranded DNA was used as a template and hybridized to the oligonucleotides, which contained mismatched nucleotides coding for the mutant amino acids. After hybridization, the

[a]Mutagenesis primers are the antisense strands; the substituted nucleotides are underlined.

second strand was synthesized using T_7DNA polymerase and T_4ligase. The double-stranded DNA was transformed into an ung$^+$ *E. coli* strain, DH-5α′. The plaques of mutant cDNA were identified by the dideoxynucleotide method (12). After digestion by *Eco*RI and *Bam*HI, the wild-type and mutant cDNA were subcloned into a eukaryotic expression vector, pSG5 (13). They were then transformed into *E. coli* AG1. The positive clones were checked by restriction enzyme mapping and direct sequencing. The selected mutant cDNA were prepared using a kit (Qiagen Midi, Chatsworth, CA) to create larger quantities for expression in mammalian cells.

In vitro *expression of LCAT.* A modified diethylaminoethyl (DEAE)–Dextran method (14) was used to transfect wild-type and mutant cDNA of LCAT into COS-6 cells. Cells were grown in high-glucose Dulbecco's modified Eagle's medium (DMEM) with 10% heat-inactivated fetal bovine serum and 1× antibiotic–antimycotic liquid (Gibco BRL; Gibco, Gaithersburg, MD) in 75-cm^2 flakes. After exceeding 90% confluence, the cells were subcultured at a 1:4 to 1:6 ratio and incubated for 24–48 h. The cells were transfected with 20 μg of plasmid per flask, incubated for 3 h with chloroquine and the DNA–DEAE–medium stock, and then shocked with 10% dimethylsulfoxide for 2 min. In each experiment, two flasks containing COS-6 cells plus pSG5 plasmids and COS-6 cells only were used as controls. After 72 h of incubation, the media were collected, centrifuged and immediately tested for LCAT activity using model reassembled high density lipoprotein (R-HDL) as the substrate.

RNA preparation, cDNA synthesis and polymerase chain reaction. After the collection of the media for LCAT assays, the transfected COS-6 cells were used to prepare total RNA. Extraction of RNA with guanidinium thiocyanate (15) was followed by centrifugation in cesium trifluoroacetate (16) and precipitation in ethanol. The PCR was performed on the RNA using the GeneAmp RNA PCR Kit (Cetus Perkin-Elmer, Norwalk, CT). PCR was initially conducted for 2 min at 94°C, followed by 30 cycles of 1 min at 94°C, 1 min at 55°C and 1 min at 72°C. These cycles were followed by 10 additional min of PCR at 72°C and an overnight soak at 4°C.

Quantification of LCAT mass and activity. R-HDL was prepared by a detergent removal technique (17): 1-palmitoyl-2-oleoyl phosphatidylcholine (POPC) or 1,2-diarachidonoyl phosphatidylcholine (DAPC), 2 mol% cholesterol and a trace of ^{3}H-labeled cholesterol (7,500 dpm/pmol) were mixed and the organic solvent removed under a stream of N_2. The lipids were vortexed, suspended in tris(hydroxymethyl)aminomethane-buffered saline at pH 7.4, and combined with human apolipoprotein A-I at a lipid protein ratio of 100:1 (M/M). Sodium cholate (10%) was added until the turbidity disappeared. The resulting solution was exhaustively dialyzed against the same buffer, and the LCAT assays were performed as previously described (18). Substrate saturation curves were obtained similarly, except that the substrate concentration was varied as needed.

A solid-phase radioimmunoassay using a goat polyclonal antibody to human LCAT was used to determine LCAT mass; purified human plasma LCAT was the standard. Isolated human LCAT, media from transfected COS-6 cells and the controls (COS-6 cells untransfected or transfected with only the expression vector pSG5) were concentrated tenfold with a Centriprep-30 (Amicon, Beverly, MA). This solution was then applied to a nitrocellulose membrane in a dot-blot apparatus, incubated with antiserum and rabbit anti-goat ^{125}I-labeled IgG, and washed extensively. The dots were cut and the radioactivity was measured by gamma counting.

For the Western blot analysis, electrophoresis was conducted using a 12% sodium dodecylsulfate–polyacrylamide gel, after which the proteins were transferred to a nitrocellulose membrane and reacted with goat antiserum to human LCAT. The bands were visualized using a rabbit anti-goat IgG (heavy and light chains) horseradish peroxidase-conjugated IgG kit (BioRad, Hercules, CA).

RESULTS

Mutagenesis strategy and construction of the expression vector. Alanine and glycine were selected to replace the serines located at residues 19, 181, 208, 216, 225 and 383 of LCAT. These residues were chosen so that the mutated site would retain the same charge. Based on its homology with other lipases (3,4), LCAT's active site has

been assigned to the hexapeptide Ile178-Gly179-His180-Ser181-Leu182-Gly183. We substituted a glycine residue at Ser181 to confirm that it is the likely acceptor of the acyl group transferred from PC to cholesterol during catalysis. Ser208 and Ser216 also contain a portion of the active site structure, Ser-X-Gly, and are close to the putative active site. Moreover, Ser216 reacts with an active site reagent and was once thought to be part of the catalytic site (5). Mutants in which each of these two sites was replaced by alanine were also prepared.

Human LCAT contains four sites of *N*-glycosylation; two of these sites, Asn20 and Asn384, are adjacent to serine residues (3,4). Two mutants, LCAT (Ser19 → Ala) and (Ser383 → Ala), were prepared and tested to determine whether LCAT synthesis, secretion or activity was affected by serine residues vicinal to glycosylation sites. Also, two compound mutants in which an asparagine and the adjacent serine were replaced by threonine and alanine, respectively, were prepared to identify interactions between serines and asparagines that might influence these processes in LCAT. In all, eight cDNA mutants of LCAT were prepared and tested. The oligonucleotide primers used for mutagenesis are listed in Table 1. After mutation, the mutant cDNA were subcloned into a eukaryotic expression vector, pSG5 (11,12,15). The coding regions corresponding to the mutated amino acids were confirmed by DNA sequencing. Sequences of wild-type and mutant LCAT cDNA bracketing the mutation sites are compared in Figure 1. The mutant and wild-type cDNA were expressed in COS-6 cells (11,12).

PCR analysis. Using the primers listed in Table 1, the total RNA of COS-6 cells transfected by pSG5, with and without the inserted LCAT cDNA, were analyzed by PCR. LCAT-specific mRNA (messenger RNA) is indicated by the presence of a 561-bp fragment as a result of agarose gel electrophoresis; this fragment was not found in the cells with pSG5 vector control (Fig. 2). In contrast, the wild-type and all of the mutants contained the 561-bp fragment. Thus, we established that all the cloned cDNA had transcribed their respective mRNA.

Western blot analysis of secreted and intracellular LCAT. Cell lysates from the transfected COS-6 cells were tested by Western blot analysis using a goat anti-

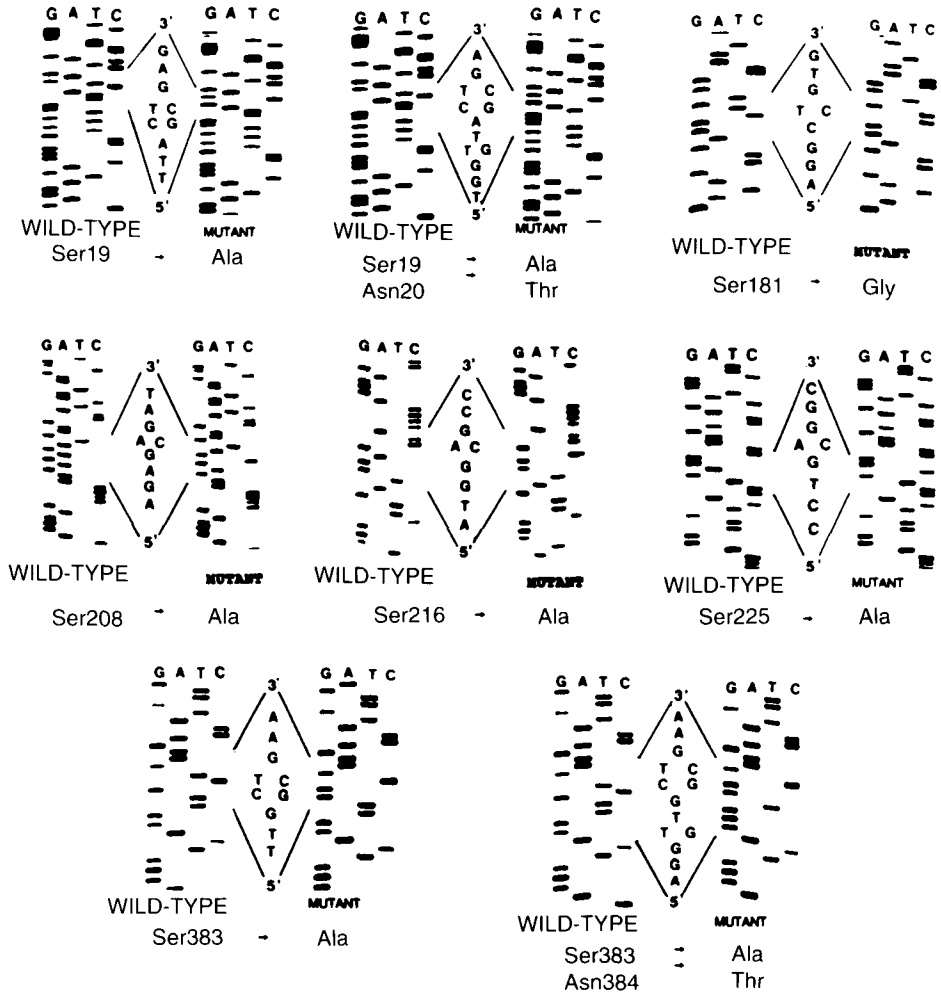

FIG. 1. Comparison of complementary DNA sequences of lecithin:cholesterol acyltransferase (LCAT) from wild-type and mutants. Each pair of autoradiograms contains the sequence of interest of both wild-type LCAT and the site-directed mutant. All sequences are the antisense strand.

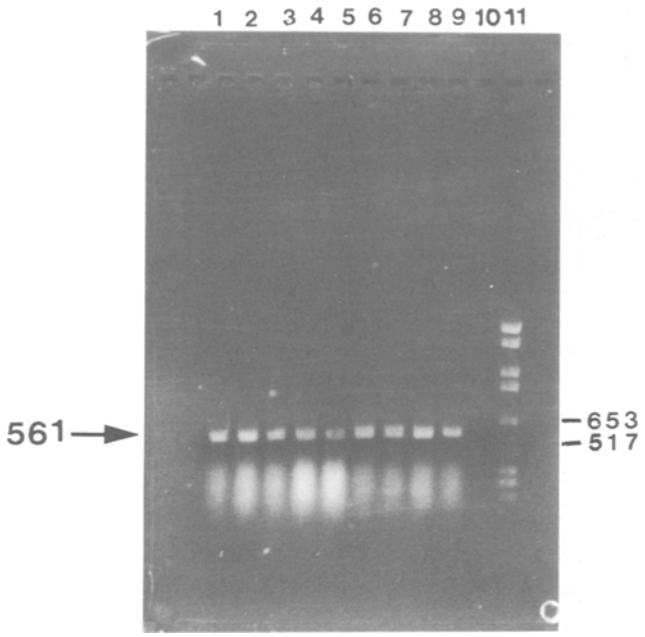

FIG. 2. Polymerase chain reaction amplification of complementary DNA from total RNA. The total RNA sample from COS-cells was subjected to polymerase chain reaction (PCR). Electrophoresis was performed on a 1.2% agarose gel. From the 100 μL of resulting PCR mixture, 5 μL was applied to each lane. Lane assignments were as follows: 1, wild-type LCAT; 2, LCAT (Ser19 → Ala); 3, LCAT (Ser19 → Ala, Asn20 → Thr); 4, LCAT (Ser181 → Gly); 5, LCAT (Ser208 → Ala); 6, LCAT (Ser216 → Ala); 7, LCAT (Ser225 → Ala); 8, LCAT (Ser383 → Ala); 9, LCAT (Ser383 → Ala, Asn384 → Thr); 10, cells transfected by pSG5; 11, marker. Abbreviation as in Figure 1.

human LCAT serum as the first antibody (Fig. 3). Control tests of cell lysates with pre-immune goat serum demonstrated that the additional band corresponding to a molecular weight of about 40kD was due to nonspecific binding. LCAT-reactive bands with molecular weights similar to that of human plasma LCAT were observed when the lysates from cells transfected with the wild-type or mutant cDNA were tested. Lysates from control cells transfected by pSG5 lacking the LCAT insert were negative. These results suggest that all of the cells that contained the mutant and wild-type inserts synthesized LCAT. The lysates from cells transfected with LCAT (Ser19 → Ala, Asn20 → Thr) and LCAT (Ser383 → Ala, Asn 384 → Thr) migrated further than wild-type LCAT. In contrast, no difference was found between LCAT (Ser19 → Ala) and LCAT (Ser383 → Ala) cell-transfected lysate migrations and that of the wild-type LCAT. The media from the transfected cells were also tested by Western blot analysis (Fig. 4). In most cases a single intense band corresponding to the molecular weight of human plasma LCAT was found. However, a number of differences were noted. Although the same volumes of media were applied to the each gel, bands for LCAT (Ser181 → Gly) and (Ser383 → Ala, Asn20 → Thr) were less intense than the others. The bands from the cells transfected with LCAT (Ser19 → Ala, Asn20 → Thr) and LCAT (Ser383 → Ala, Asn384 → Thr) exhibited a greater migration distance, which was consistent with the result that would be given by an LCAT-positive product with a molecular weight lower than that of human plasma LCAT.

Quantification of secreted LCAT mass and activities. Wild-type and mutant cDNA of LCAT cloned into pSG5 were transfected into COS-6 cells. After incubating at 37°C for 72 h, the media were screened for LCAT activity using R-HDL as the substrate. No measurable LCAT activity was found in the media collected from the cells that were not transfected or that were transfected by the pSG5 plasmids lacking the LCAT insert. The media from the COS-6 cells transfected by wild-type and mutant LCAT cDNA exhibited different levels of expression. The media were replaced with DMEM and incu-

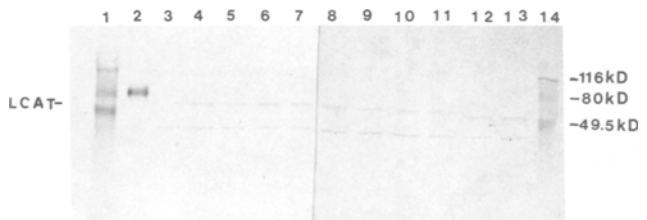

FIG. 3. Western blot analysis of transfected COS-6 cell lysates from control, wild-type and mutants. After incubating for 72 h, cells were washed with phosphate buffered saline and trypsinized. Cells from each 75-cm^2 flask were homogenized using 1 mL of solubilizing buffer (1.6% Triton X-100, 0.3 mM leupeptin, 5.0 M urea and 1.5 mM phenylmethanesulfonyl fluoride). For each sample, 10 μg of protein was used for the analysis. Lane assignments were as follows: 1, marker; 2, standard LCAT; 3, cells transfected by pSG5; 4, wild-type LCAT; 5, LCAT (Ser181 → Gly); 6, LCAT (Ser19 → Ala); 7, LCAT (Ser208 → Ala); 8, wild-type LCAT; 9, LCAT (Ser216 → Ala); 10, LCAT (Ser225 → Ala); 11, LCAT (Ser383 → Ala); 12, LCAT (Ser19 → Ala, Asn20 → Thr); 13, LCAT (Ser383 → Ala, Asn384 → Thr); 14, marker. Abbreviation as in Figure 1.

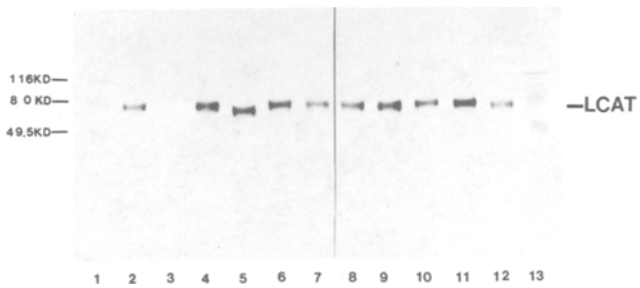

FIG. 4. Western blot analysis of isolated human LCAT, and wild-type or mutant transfected COS-6 cell culture media. The media from COS-6 cells were concentrated tenfold, and 5 μL was applied to each lane. Lane assignments were as follows: 1, marker; 2, standard LCAT; 3, cells transfected by pSG5; 4, wild-type LCAT; 5, LCAT (Ser19 → Ala, Asn20 → Thr); 6, LCAT (Ser19 → Ala); 7, LCAT (Ser181 → Gly); 8, LCAT (Ser208 → Ala); 9, LCAT (Ser216 → Ala); 10, LCAT (Ser225 → Ala); 11, LCAT (Ser383 → Ala); 12, LCAT (Ser383 → Ala, Asn384 → Thr); 13, marker. Abbreviation as in Figure 1.

TABLE 2

Enzyme Activity, Mass and Specific Activity of COS-6 Cell Media Transfected by Wild-Type and Complementary DNA Mutants of Serine[a]

	Activity (nmol cholesteryl ester/mL medium/h)	Mass (μg/mL medium)	Specific activity (nmol cholesteryl ester/μg protein)
Wild-type	6.24 ± 0.21 (1.00)[b]	1.41 ± 0.22 (1.00)	4.46 ± 0.15 (1.00)
Ser19 → Ala	7.82 ± 0.58 (1.20)	1.42 ± 0.12 (1.00)	5.50 ± 0.41 (1.23)
Ser19 → Ala, Asn20 → Thr	4.44 ± 0.51 (0.71)	1.45 ± 0.10 (1.00)	2.92 ± 0.35 (0.65)
Ser181 → Gly	0.03 ± 0.01 (0.005)	0.48 ± 0.01 (0.34)	0.06 ± 0.02 (0.01)
Ser208 → Ala	10.50 ± 0.90 (1.68)	1.40 ± 0.19 (1.00)	7.50 ± 0.64 (1.69)
Ser216 → Ala	13.12 ± 0.44 (2.10)	1.95 ± 0.21 (1.38)	6.73 ± 0.22 (1.51)
Ser225 → Ala	4.29 ± 0.50 (0.83)	1.46 ± 0.25 (1.00)	2.94 ± 0.34 (0.66)
Ser383 → Ala	6.70 ± 0.39 (1.07)	1.50 ± 0.28 (1.00)	4.47 ± 0.26 (1.00)
Ser383 → Ala, Asn384 → Thr	2.91 ± 0.32 (0.46)	0.75 ± 0.01 (0.50)	3.88 ± 0.42 (0.87)

[a]Results from triplicate transfections performed with each plasmid. After 72 h of incubation, the medium was centrifuged in a Beckman J2-21 centrifuge at 1200 rpm for 10 min; 10 μL was then used to estimate lecithin:cholesterol acyltransferase (LCAT) activity. Mass quantification was performed using a dot-blot method. For each well, 4 μg/mL standard LCAT (10, 20, 40, 80 and 100 μL per well) or the sample medium concentrated twofold (20, 40 and 80 μL per well) was applied to nitrocellulose membranes. LCAT was detected by reaction with goat anti-human LCAT serum and ^{125}I-labeled rabbit anti-goat immunoglobulin G.
[b]Values in parentheses indicate the ratio of the mutant value to that of the wild-type LCAT.

bated for another 48 h. LCAT mass was analyzed by a solid-phase immunoassay using a goat anti-LCAT serum raised by purified plasma LCAT as the first antibody and ^{125}I-labeled rabbit anti goat IgG as the second antibody (Table 2). LCAT activity was measured as well.

With the exception of LCAT (Ser181 → Gly), the secreted masses and activities of the various mutant LCAT species were easily detected (Table 2). If LCAT (Ser181 → Gly) is excluded, the total secreted activity from the transfectants was not greatly different from that of the wild-type (mean, 113% of that of the wild-type; range, 46–210%). Secreted LCAT mass was almost identical to that of the wild-type (mean, 90%; range, 34–138%). In contrast, secretion of LCAT (Ser181 → Gly) was only 34% of that of the wild type. Small but significant differences among the other mutants were observed. The secreted masses of LCAT (Ser216 → Ala) and LCAT (Ser383 → Ala, Asn384 → Thr) were 138 and 50%, respectively, of that of the wild-type.

Excluding LCAT (Ser181 → Gly), the specific activities of the mutants were similar to that of the wild-type (mean, 109%; range, 65–169%). The specific activities of two simple mutants which contain a portion of the consensus active site sequence, LCAT (Ser208 → Ala) and LCAT (Ser216 → Ala), were significantly higher than that of the wild-type; LCAT (Ser225 → Ala) had a lower specific activity. Addition of an Asn → Thr point mutation adjacent to existing Ser → Ala substitutions at Ser19 and Ser 383 further reduced the specific activities by 13 and 47%, respectively.

Substrate specificities. The substrate specificities of wild-type and mutant LCAT were compared using the R-HDL prepared from POPC and DAPC. According to the apparent V_{max} obtained with POPC substrates (Table 3), LCAT (Ser208 → Ala) and LCAT (Ser216 → Ala) were approximately 1.6 and 2 times as active as the wild-type. The activities of LCAT (Ser19 → Ala), LCAT (Ser225 → Ala) and LCAT (Ser383 → Ala) were 82, 34 and 68%, respectively, of the activity of the wild-type. LCAT (Ser19 → Ala, Asn20 → Thr) displayed 28% of the activity of the wild-type, while LCAT (Ser383 → Ala, Asn384 → Thr) displayed 43% of the wild-type activity. The R-HDL containing DAPC had a much lower reactivity for all of the mutants, giving results in a pattern similar to that of the substrate containing POPC. The values for the ratio of the apparent V_{max} using POPC to the

TABLE 3

Kinetic Constants for Wild-Type Lecithin:Cholesterol Acyltransferase and Serine Mutants

	POPC		DAPC		
	V_{max}[a]	$K_m \times 10^{8}$[b]	V_{max}	$K_m \times 10^{6}$	R[c]
Wild type	16.0	22.0	2.6	49	6.8
Ser19 → Ala	13.0	19.0	2.0	110	6.7
Ser19 → Ala, Asn20 → Thr	4.4	22.0	0.8	34	7.5
Ser208 → Ala	27.0	22.0	5.4	85	5.0
Ser216 → Ala	35.0	25.0	9.0	110	3.9
Ser225 → Ala	5.6	19.0	0.6	85	9.3

Ser383 → Ala, Asn384 → Thr	6.8	8.0	0.8	30	8.5

[a]Apparent V_{max} is expressed in nmol cholesteryl esters formed/mL/h.
[b]Apparent K_m is expressed in moles phosphatidylcholine/L.
[c]R is the ratio of V_{max} using 1-palmitoyl-2-oleoyl phosphatidylcholine (POPC) to V_{max} using 1,2-diarachidonoyl phosphatidylcholine (DAPC).

V_{max} using DAPC were similar for both the wild type and the mutants.

The affinities of the mutants for the substrate as measured by the apparent K_m were a function of the mutation and the fatty acid composition of the substrate. With POPC as the acyl donor, the apparent K_m values for most of the mutants were close to the value given by the wild-type. The exception was LCAT (Ser383 → Ala, Asn384 → Thr), which had a lower apparent K_m that indicated a higher affinity for the substrate. When DAPC was used as a donor lipid, the affinity of the mutants was similar to or greater than that of the wild-type (mean, 144% of wild type; range, 61–224%). The LCAT mutated at residues 19, 208, 216 and 225 had high apparent K_m values and therefore lower affinity for the substrate. In all cases, consistently lower apparent K_m values demonstrated that the affinity for the substrate was greater with POPC than DAPC.

DISCUSSION

Previous studies of LCAT structure and function, particularly those of fish-eye disease and familial LCAT deficiency (19,20), have shown that a small change in the primary structure involving a single amino acid residue remote from the active site serine can be associated with a large decrease in the rate of secretion and specific activity. In contrast, all but one of the mutations that we prepared resulted in the synthesis of secretion-competent LCAT with a specific activity comparable to that of the wild-type. The LCAT (Ser181 → Gly) mutant was poorly secreted by COS-6 cells and was the only mutant studied that did not catalyze cholesterol esterification. From this result we conclude that this serine is required for catalytic activity. These data provide direct evidence that LCAT is a serine protease-type enzyme and confirm the report of Francone and Fielding (6), who prepared similar mutations in Chinese hamster ovary cells.

A significant enhancement of enzyme activity was observed when Ser208 or Ser216 was replaced by an alanine residue. However, the magnitude of this enhancement was considerably lower than that reported by Francone and Fielding (6), who investigated the effects of mutations at Ser216, but not at Ser208. The segment of LCAT that includes Ser208 and Ser216 is adjacent to the active site region and is not as hydrophobic as the eleven-residue segment containing Ser181 and the five residues on either side. The cause of the higher catalytic activity of LCAT (Ser208 → Ala) and LCAT (Ser216 → Ala) is not known. One possible explanation is that Ser208 and Ser216 may be part of the domain to which a phospholipid molecule binds. Because serine residues are more hydrophilic than alanine residues, the mutation at the serine site may facilitate the hydrophobic binding of substrate molecules. However, a large number of additional mutations would be necessary to make this assignment with certainty.

Two double mutants in which a serine and an adjacent asparagine were replaced by alanine and threonine, respectively, gave rise to secretion-competent proteins. As expected, elimination of the *N*-glycosylation sites (Asn20 and Asn384) was associated with a lower molecular weight due to a lower carbohydrate content. There were no significant differences in the secretion and specific activities of double mutants. We conclude that replacement of serine residues with alanine does not affect the *N*-glycosylation of adjacent asparagine residues and that there is a only a small effect of either mutation or the combination of mutations on LCAT secretion and activity.

The LCAT from different animal species vary considerably in their relative activities against common PC structures, such as POPC, and large, bulky PC molecules, such as DAPC (21–24). This variation has been assigned to possible structural differences, which create steric hindrance to prevent the entry of DAPC into the active site for some molecular species. As with native plasma LCAT, the reactivity of the wild-type enzyme using POPC was about seven times that using DAPC. From this we conclude that selective substitution of alanine residues for serines does not affect the molecular species specificity of human LCAT, and that these residues are likely to be remote from the region of LCAT that binds to PC molecules.

Replacement of serine residues did not greatly change the synthesis, secretion, specific activity or molecular specificity of human plasma LCAT. The one exception was LCAT (Ser181 → Gly), which was poorly secreted and inactive, thereby confirming previous reports that this residue is the active site acceptor of an acyl group from PCs. Thus, our overall conclusion is that the hydrophilic character of serine residues is not essential to the normal functioning of LCAT. Substitution for more than one serine may, however, give different results.

The presence of plasma cholesteryl ester transfer protein (CETP) activity may be atherogenic, and, therefore, strategies to inhibit its activity or production may result in a beneficial effect on lipoprotein profiles and the disease process. The current report describes 4-phenyl-5-tridecyl-4H-1,2,4-triazole-3-thiol (PD 140195), a novel CETP inhibitor. The concentration-dependent inhibition of CETP by PD 140195 and the inhibitory monoclonal antibody (Mab) TP2 is demonstrated in a variety of *in vitro* assay systems. Molecular models of PD140195 suggest a spatial mimicry of the cholesteryl ester structure. Despite the structural similarity, kinetic studies with a fluorescent cholesteryl ester analog suggest that the inhibition of transfer is not competitive. PD 140195 also selectively inhibited cholesteryl ester but not triglyceride transfer, while the Mab TP2 blocked CETP transfer of both. Studies were carried out to determine whether CETP inhibition observed *in vitro* could also be demonstrated *in vivo*. When PD 140195 was intravenously infused to anesthetized rabbits (up to 20 mg/kg), only transient CETP inhibition was observed. *In vitro* reconstitution studies in the presence of bovine serum albumin resulted in marked reduction of PD 140195 inhibitory activity. Thus, the low activity of PD 140195 in whole plasma probably results from binding to other plasma proteins.

***Lipids* 29, 811–818 (1994).**

Cholesteryl ester transfer protein (CETP) is a 74 kDa plasma glycoprotein responsible for the reciprocal exchange of neutral lipids between circulating lipoproteins (1–10). Net alteration in lipoprotein core lipid composition is a complex process. The modifications are influenced by lipoprotein concentration, lipoprotein residence time and the activities of lecithin:cholesterol acyltransferase (LCAT), hepatic lipase, lipoprotein lipase and CETP (11,12). In general, in species lacking CETP activity, and humans genetically-deficient in CETP, the equilibrium favors elevation of antiatherogenic (high density lipoproteins, HDL) and diminution of atherogenic (low density lipoproteins, LDL) lipoproteins (5, 13–22). Therefore, plasma CETP inhibition could be an advantageous pharmacological target for the treatment of dyslipidemic patients at risk for coronary heart disease.

Recent studies of a Japanese family with deficiency in plasma CETP have shown that the deficiency was associated with marked elevation of HDL, its associated apolipoproteins (A-I, E, A-IV) and a rarity of coronary artery disease (13,15–18,23). The defect has been identified as a G to A substitution in the fourteenth intron of CETP pre-messenger RNA (16). This splice donor defect is also the cause of the deficiency in additional Japanese families identified (17,18,20). In a more recent study, the deficiency (both homozygous and heterozygous) has been shown to be associated with a large proportion of Japanese with hyperalphalipoproteinemia (20,24). More recently, a missense mutation at nucleotide 1506 (G for A) has been identified in exon 15 of the CETP gene, resulting in a substution of a glycine for aspartic acid at amino acid 442 (25). The two subjects heterozygous for the missense mutation had three times the normal HDL levels. Overall, these studies suggest that even partial reduction in CETP levels, as found in heterozygous individuals, is associated with elevated HDL. This apparently benign condition (CETP deficiency) has been coined the "longevity syndrome" (13).

A variety of species, which lack CETP activity, including, mice, rats and dogs, have HDL as their major lipoprotein (5). When fed atherogenic diets, transgenic mice expressing human or cynomologus monkey CETP develop atherogenic lipoprotein profiles, including elevation of apolipoprotein B (apoB) containing lipoproteins (very low density lipoproteins, VLDL; and beta migrating cholesteryl ester-enriched very low density lipoproteions, β-VLDL) and reduction of HDL (14,21). These mice also develop atherosclerotic lesions (26). In the transgenic mice, CETP plasma activity has also been shown to be directly correlated with apoB and inversely correlated with apolipoprotein A-I (apoA-I) levels. Infusion of antibodies to CETP into rabbits (27,28) results in a more favorable lipoprotein profile, including elevated HDL cholesterol and particle size. Conversely, infusion of CETP into rats (29,30) results in a less favorable lipoprotein profile, including elevation of VLDL and LDL cholesterol and apoB, and diminution of apolipoprotein E (apoE)-rich HDL cholesterol and HDL size.

Overall, the data suggest that plasma CETP levels contribute to the atherogenicity of plasma. This effect, in part, may be related to the redistribution of core lipids, and alterations in their clearance. Therefore, our focus has been directed to the inhibition of CETP syn-

Abbreviations: apo, Apolipoprotein; BODIPY-CE, cholesteryl 4,4-difluoro-5,7-dimethyl-4-bora-3α,4α-diaza-3-indacenedodecanoate; CETP, cholesteryl ester transfer protein; DMA/PEG 200, dimethylacetamide/polyethylene glycol 200; DMSO, dimethylsulfoxide; DTNB, 5,5′-dithio-*bis*(2-nitrobenzoic acid); EDTA, ethylenediaminetetraacetic acid; FCIA, fluorescent cholesteryl ester transfer protein inhibition assay; HDL, high density lipoproteins; HDL_3, high density lipoproteins isolated between the densities of 1.11–1.21 g/mL; LCAT, lecithin:cholesterol acyltransferase; LDL, low density lipoproteins; Mab, monoclonal antibody; PD 140195, 4-phenyl-5-tridecyl-4H-1,2,4-triazole-3-thiol; VLDL, very low density lipoprotein; 1XDB, 50 mM Tris, 150 mM NaCl, 2mM ethylenediaminetetraacetic acid, pH 7.4 buffer; β-VLDL, beta migrating very low density lipoproteins; [^{3}H]CL-HDL_3, high density lipoproteins isolated between the densities of 1.11–1.21 g/mL containing [1,2-^{3}H]cholesteryl linoleate; [^{3}H]TO-HDL_3, high density lipoproteins isolated between the densities of 1.11–1.21 g/mL containing [9,10-^{3}H]triolein.

thesis or activity. The present report describes a novel inhibitor of CETP activity. The activity of this compound on the inhibition of purified and crude CETP preparations is documented. However, when 4-phenyl-5-tridecyl-4H-1,2,4-triazole-3-thiol (PD 140195) was infused in rabbits at high levels only a transient inhibition of CETP activity was observed.

MATERIALS AND METHODS

Preparation of CETP. The d > 1.21 g/mL fraction was isolated from rabbit (Pel-Freez Biologicals, Rogers, AR) or human plasma and dialyzed against 50 mM Tris, 150 mM NaCl, 2mM ethylenediaminetetraacetic acid (EDTA), pH 7.4, buffer (1XDB, pH 7.4). Aliquots were stored frozen at −20°C. Chinese hamster ovary cells transfected with human recombinant CETP (31) were obtained by license agreement (Columbia University, NY). Medium from these cells grown in 10% fetal bovine serum in Hams F-12 was used as a source of human CETP without further purification. The human CETP inhibitory Mab (monoclonal antibody) TP2 was a kind gift from Drs. Ross Milne and Yves Marcel (University of Ottawa Heart Institute, Canada). Mab TP2 is also known to inhibit rabbit CETP (27).

Radioisotopic whole plasma CETP assays. The method for preparation of radiolabeled HDL is an adaptation of the methods previously described by Morton and Zilversmit (32). Briefly, egg phosphatidylcholine in chloroform (5.08 nmol), 100 μCi [1,2-^{3}H]cholesteryl linoleate (1 nmol) in toluene, and butylated hydroxytoluene (0.022 nmol) in chloroform were combined and dried under a stream of N_2, and then lyophilized to remove residual solvent. The dried lipids were resuspended in 2 mL of 50 mM Tris-HCl, 0.01% EDTA, 1 mM dithiothreitol, pH 7.4 by vortexing (10 min), followed by sonication (Cole-Parmer Model 8851) for 2 × 20 min. Fifty mL of a human d > 1.063 g/mL fraction in 1XDB, 5.8 mL of 15 mM 5,5′-dithio-*bis*(2-nitrobenzoic acid) (DTNB) in 1XDB, and 1 mL of 0.2 M EDTA containing 2% NaN_3 were added, and the mixture was incubated 16–18 h at 37°C under nitrogen. The HDL_3 fraction (d = 1.11–1.21 g/mL) was isolated following removal of the 1.063–1.11 g/mL fraction by sequential ultracentrifugation. This [1,2-^{3}H]cholesteryl linoleate-HDL_3 fraction ([^{3}H]CL-HDL_3) was dialyzed against 1XDB and used in whole plasma CETP assays. In some preparations, we used 100 μCi of [9,10-^{3}H]triolein for incorporation into HDL_3 ([^{3}H]TO-HDL_3) by essentially the same method used for the incorporation of [1,2-^{3}H]cholesteryl linoleate. Typically, about 25% of [1,2-^{3}H]cholesteryl linoleate and 38% 9,10-[^{3}H]triolein were incorporated into HDL_3 preparations.

Inhibitor screens were performed in 102.5 or 205 μL total volumes in deep 96-well polypropylene plates (1.2 mL capacity/well) or glass tubes, respectively. Compounds (final concentrations up to 100 μM) were added in 2.5 or 5.0 μL dimethylsulfoxide (DMSO) and preincubated for 1 h at 37°C with previously frozen human plasma (25 or 50 μL). [^{3}H]CL-HDL_3 (20,000 or 40,000 dpm) in 75 or 150 μL of 1XDB, pH 8.0, was added and incubated at 37°C. Wells were harvested periodically up to 24 h by the addition of a 1.0 mL solution (per 102.5 μL incubation) containing 10 mg/mL bovine serum albumin, 1.29 mg/mL bovine intestinal mucosa heparin (Sigma Chemical Co., St. Louis, MO) in 0.14 M $MnCl_2 \cdot 4H_20$ in 1XDB pH 8.0 (33). Samples were mixed, and after 10 min centrifuged at 2200 rpm for 30 min at 10°C in an IEC PR-6000 centrifuge (International Equipment Co., Needham Heights, MA) to precipitate apoB-containing lipoproteins. Supernatant aliquots were counted by liquid scintillation spectroscopy to determine radioactivity remaining in HDL_3.

Fluorescent microemulsion assays. Inhibition of CETP activity in rabbit d > 1.21 g/mL or media from Chinese hamster ovary cells secreting recombinant human CETP was assessed in a defined component system by a microemulsion assay utilizing a fluorescent cholesteryl ester analog (BODIPY-CE) containing 4,4-difluoro-5,7-dimethyl-4-bora-3α,4α-diaza-3-indacenedodecanoate in place of the normal fatty acid as previously described in detail elsewhere (34). Studies with BODIPY-CE labeled emulsions were done in flat-bottom 96-well plates (Costar Corporation, Cambridge, MA) containing up to 255 μL of sample per well. The 96-well plates were covered and kept in a humidified 37°C incubator in the time intervals between plate scans. BODIPY-CE fluorescence was detected with a Titertek Fluoroskan II 96-well plate reader (Labsystems, Inc., Research Triangle Park, NC) equipped with a 485 and 538 nm band pass filters in the excitation and emission paths, respectively.

For fluorescent assays, maximal initial transfer velocity was first determined with donor BODIPY-CE containing microemulsions (77 pmol BODIPY-CE in 770 pmol total core lipids) and acceptor microemulsions (7.7 nmol core lipids) by titration with recombinant human CETP or rabbit d > 1.21 g/mL fraction in a total volume of 200 μL 1XDB containing 2.5% DMSO. Inhibitor screens were performed with CETP concentrations representing approximately one-half maximal velocity.

To determine albumin effects on sequestration or inactivation of inhibitors, assays also were performed at various bovine serum albumin concentrations with recombinant human CETP, BODIPY-CE containing microemulsions (144 pmol BODIPY-CE) and tenfold excess acceptor microemulsions in a total volume of 250 μL 1XDB containing 2% DMSO.

For other fluorescent CETP inhibitory assays, BODIPY-CE containing microemulsions (0.3, 0.6 or 1.2 nMol BODIPY-CE) were added to 200 μL whole plasma in the absence or presence of inhibitors in a total volume of 255 μL 1XDB containing 2% DMSO. Inhibition data were linear up to 6 h and essentially identical independent of the three different trace amounts of BODIPY-CE containing microemulsion added.

CETP kinetic assay. To assess the inhibition kinetics, we utilized the BODIPY-CE microemulsion assay with increasing amounts of acceptor Intralipid emulsions. Compounds at various concentrations were incubated with variable amounts of Intralipid, a constant amount of BODIPY-CE microemulsion (0.385 nmol BODIPY-CE) and a rabbit CETP source (20 μL plasma or d > 1.21

g/mL). Fluorescence yield was periodically measured to determine initial velocity.

Infusion studies Male Kuiper rabbits (1.7 kg average weight) anesthetized with Rompum (15 mg/kg) and Ketamine · HCl (50 mg/kg) were used to study the *in vivo* effects of PD 140195. Pretreatment blood samples were obtained from a marginal ear vein. PD 140195 (20 mg/mL) solubilized in a dimethylacetamide/polyethylene glycol 200 (DMA/PEG 200) (25:75, vol/vol) vehicle was intravenously infused at 0.1 mL/min to obtain dosages of 10 or 20 mg/kg. Additional blood samples were taken 0.5, 1, 2 and 4 h following initiation of dosing for *ex vivo* CETP activity determinations.

Plasma aliquots (5, 10, 20 and 30 µL) were incubated in a humidified chamber at 37°C with Intralipid (678 nmol triglyceride) and BODIPY-CE microemulsion (1.15 nmol BODIPY-CE in 13.39 nmol total core lipids) in a total incubation volume of 240 µL 1XDB. Fluorescence yields were periodically determined up to 20 h to determine initial transfer rates for *ex vivo* CETP activity under Vmax conditions as previously described (34).

Synthesis of PD 140195. Tetradecanoyl chloride and 4-phenyl-3-thiosemicarbazide were obtained from Aldrich Chemical Co. (Milwaukee, WI). Tetradecanoyl chloride (51 mL, 0.19 mol) was added dropwise at 0°C to a mechanically stirred solution of 4-phenyl-3-thiosemicarbazide ($PhNHCSNHNH_2$; 31.4 g, 0.19 mol) in tetrahydrofuran (1L) and triethylamine (26 mL, 0.19 mol). The solution was allowed to warm to room temperature and stirred for 18 h. The mixture was filtered, the filtrate concentrated *in vacuo,* and then triturated with 50% ethyl acetate/hexane (0.5L) with ice cooling. The resultant precipitate was filtered, washed with 50% ethyl acetate/hexane (2 × 200 mL) and dried for 12 h *in vacuo* to yield tetradecanoic acid, 2-(*N*-phenylaminothioxomethyl)hydrazide (44.4 g) which without further purification was dissolved in a mechanically stirred solution of sodium hydroxide (14.1 g, 0.35 mol) in water (0.5 L). The resultant mixture was allowed to stir until all solid had dissolved, and then for an additional 4 h. The mixture was acidified with 1M HCl (0.5 L) and the precipitate filtered, dried *in vacuo,* and recrystallized from acetonitrile to yield PD 140195 as needles (40.6 g, 59%). Melting point (96–97°C) was determined on a Thomas-Hoover melting point apparatus (Philadelphia, PA) and is uncorrected. ^1H nuclear magnetic resonance (DMSO): δ 13.69 (*s,* 1H), 7.62–7.48 (*m,* 3H), 7.43–7.36 (*m,* 2H), 2.43 (*t,* 3H), 1.50–1.35 (*m,* 2H), 1.28–1.09 (*m,* 20H), 0.85 (*t,* 3H) was obtained on a Bruker AM250 MHz instrument (Billerica, MA). Elemental analyses, ($C_{21}H_{32}N_3S$) C, H, N, S, was determined on a Perkin-Elmer Model 240C elemental analyzer (Madison, NJ), and were within 0.4%.

RESULTS

Random screening of the chemical inventory of Parke-Davis resulted in the identification of several compounds with apparent CETP inhibitory activity. In these initial studies, we incubated whole human plasma with human [^3H]CL-HDL_3 in the presence of DMSO vehicle, CETP inhibitory Mab TP2 (7), or 100 µM compounds for 16 to 24 h. Transfer of cholesteryl linoleate radioactivity to apoB containing lipoproteins was assessed by heparin–manganese precipitation followed by determination of radioactivity remaining in the supernatant (i.e., apoE-free HDL). CETP inhibition by PD 140195 was identified in this manner. Utilizing this whole plasma assay, the time course and concentration dependent CETP inhibition by PD 140195 were determined (Fig. 1). We constructed a molecular model of PD 140195 using the SYBYL molecular modeling system (Tripos Associates, St. Louis, MO) and compared this to the crystal structure of cholesteryl oleate, one of the natural substrates in the transfer process mediated by CETP (Fig. 2). It was interesting to note that PD 140195 could be aligned to mimic either the cholesterol or oleic acid portion of the ester. Both of these alignments position the polar functions of the inhibitor along those of the cholesteryl ester moiety in such a manner as to match the interaction with potential H-bonding recognition sites on the transfer protein. When this is done, PD 140195 was found to mimic almost exactly the length of either the cholesterol moiety or the oleic acid moiety in its extended form. Common putative H-bond donor or acceptor interactions are depicted.

Although the crystal structure of CETP is unknown, the similarities between PD 140195 and cholesteryl

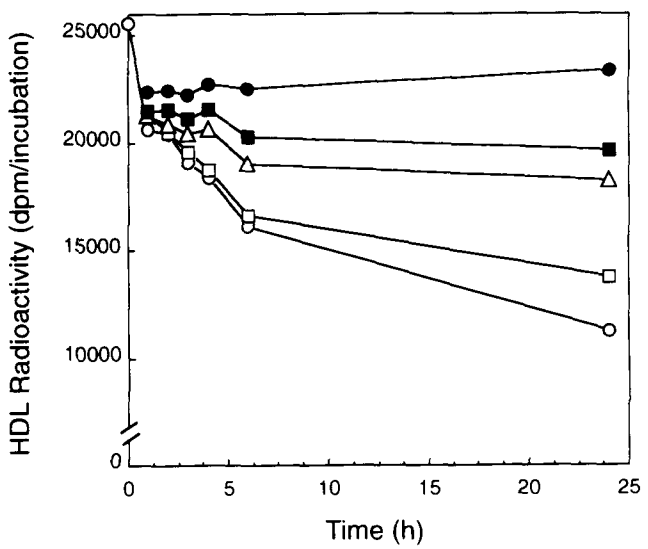

FIG. 1. Inhibition of cholesteryl ester transfer protein (CETP) in whole human plasma by PD 140195. Whole human plasma (50 µL) was incubated with high density lipoproteins (HDL) isolated between the densities of 1.11–1.21 g/mL containing [1,2-^3H]cholesteryl linoleate ([^3H]CL-HDL_3) (40,000 dpm) in the presence of 5 µL dimethylsulfoxide (DMSO) vehicle (○), 5 µg/mL CETP inhibitory monoclonal antibody TP2 (●), or 10 µM (□), 30 µM (△) or 100 µM (■) PD 140195 in a total volume of 205 µL. At intervals up to 24 h, the amount of radioactivity remaining in the supernatant following heparin/manganese precipitation of apolipoprotein (apo) B and apoE containing lipoproteins was determined as described in Materials and Methods. Data represent the average of triplicate incubations for each time point and are representative of a typical experiment.

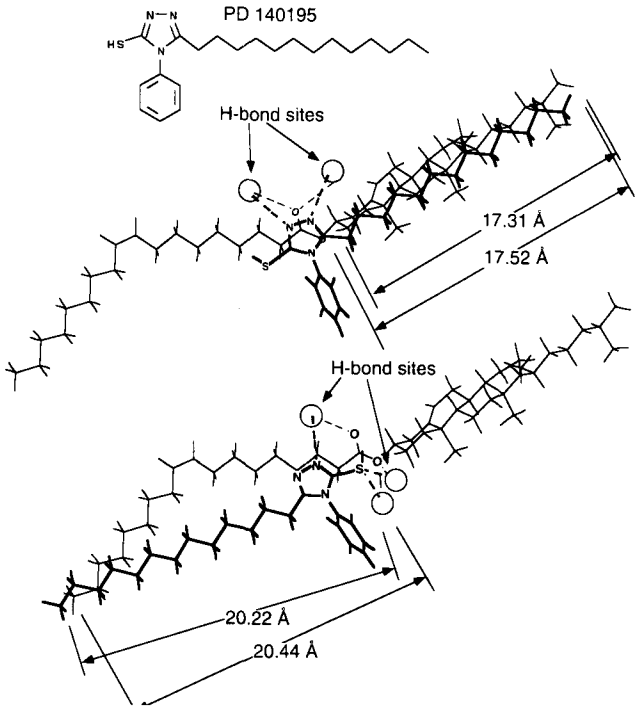

FIG. 2. Structure of PD 140195 and similarity to a cholesteryl ester. PD 140195 (top) is overlayed on cholesteryl oleate in a "side chain-cholesterol mode" (middle) and "side chain-side chain mode" (bottom). Mimicry of potential hydrogen sites for both PD 140195 and cholesteryl oleate are shown for both overlays.

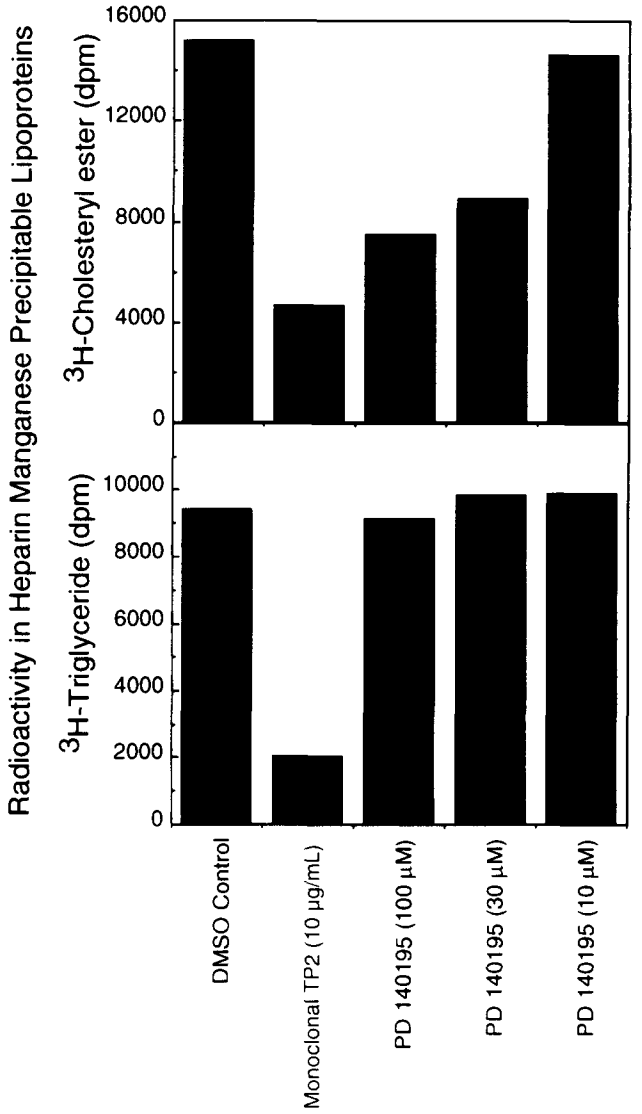

FIG. 3. Effect of monoclonal (Mab) TP2 and PD 140195 on cholesteryl ester transfer protein (CETP) facilitated transfer of cholesteryl oleate and triolein in human plasma. Human plasma (50 µL) was preincubated with Mab TP2 (10 µg/mL), PD 140195 (10–100 µM) or dimethylsulfoxide (DMSO) vehicle (5 µL) for 1 h at 37°C prior to addition of either high density lipoproteins isolated between the densities of 1.11–1.21 g/mL containing [1,2-^{3}H]cholesteryl linoleate ([^{3}H]CL-HDL$_3$) (41,000 dpm) or [9,10-^{3}H]triolein ([^{3}H]TO-HDL$_3$) (45,000 dpm) in a total incubation volume of 205 µL 1XDB. Incubation continued for an additional 17 h at 37°C prior to heparin/manganese precipitation and determination of supernatant radioactivity as described in Materials and Methods. Data show radioactivity transferred to precipitated acceptor lipoproteins (2 to 6 tubes for each condition) and are representative of a typical experiment.

ester suggests transfer inhibition might involve occupation of the cholesteryl ester binding domain. Although triglycerides and cholesteryl esters appear to transfer in an equimolar fashion (35), it is unclear whether a separate or shared domain facilitates this process. CETP site-directed mutations (31) and whole immunoglobulin inhibitory Mab TP2 (36) block both triglyceride and cholesteryl transfer, suggestive of a single site. However, unlike whole immunoglobulin, Fab fragments of Mab TP2 dissociated the transfer rates of cholesteryl ester and triglyceride (36), which is suggestive of independent lipid binding sites. In support of separate lipid binding domains are the studies of Morton and Zilversmit (37) that demonstrated selective inhibition of triglyceride exchange with mercurial compounds. Furthermore, Busch and Harmony (38) demonstrated selective cholesteryl ester inhibition with short-chain cholesteryl esters. Consistent with the data of Swenson *et al.* (36), who utilized [^{3}H]CL-HDL$_3$ or [^{3}H]TO-HDL$_3$ in whole plasma assays, Mab TP2 (whole immunoglobulin) inhibited both cholesteryl ester and triglyceride exchange, while PD 140195 inhibited only cholesteryl ester transfer (Fig. 3).

Although the whole plasma assay was useful in identifying CETP inhibitors, we found utilization of precipitation assays for CETP activity somewhat problematic in that endogenous apoE can rapidly equilibrate to the surface of the added [^{3}H]CL-HDL$_3$ (34,39). This exchange would facilitate [^{3}H]CL-HDL$_3$ precipitation with the apoB containing lipoproteins. In our experience, approximately 10–20% of added HDL radioactivity precipitated with heparin–manganese at zero time. Zero time recovery was further compromised (not shown) when [^{3}H]CL-HDL$_3$ was added to plasma of species containing large amounts of HDL associated apoE (mouse plasma for example). Other assays dependent on physi-

cal separation of donor and acceptor, such as gel filtration (Fig. 3) or ultracentrifugation, are not practical for assessing transfer activity in multiple samples at various time points. Therefore, we developed a fluorescent assay for determination of CETP activity (34). Utilizing this fluorescent CETP inhibition assay (FCIA), the concentration-dependent PD 140195 effects on BODIPY-CE transfer from microemulsions were assessed in whole plasma and component systems and are compared to precipitation assays that utilized [^{3}H]CL-HDL$_3$ as donor in whole human or rabbit plasma (Fig. 4). It should be noted that a significant increase in inhibition was observed in the reconstituted component system that contained recombinant CETP. This apparent difference between reconstituted and whole plasma systems will be addressed.

To assess *in vivo* inhibitory activity, anesthetized rabbits were intravenously infused with PD 140195 in a DMA/PEG 200 vehicle over 10–15 min, resulting in a dosage of 10 or 20 mg/kg. At intervals, blood was obtained for *ex vivo* CETP activity utilizing BODIPY-CE microemulsions under conditions that determine maximal transfer velocity (34). Under these conditions, a transient and concentration-dependent inhibition of CETP was observed, which returned to control levels by 4 h (Fig. 5). In a separate experiment, performed without anesthesia, the duration of the drug effect was considerably shorter (not shown). These observations were somewhat puzzling, in that robust inhibition was observed with the *in vitro* component systems (e.g., Figs. 1 and 3), although, with the various *in vitro* systems, a marked difference (approximately 30-fold) in inhibitory capacity was noted. However, a direct comparison of the *in vitro* systems is not rigorous, since multiple components vary between each system. However, qualitatively, rabbit d > 1.21 g/mL fractions and whole plasmas ap-

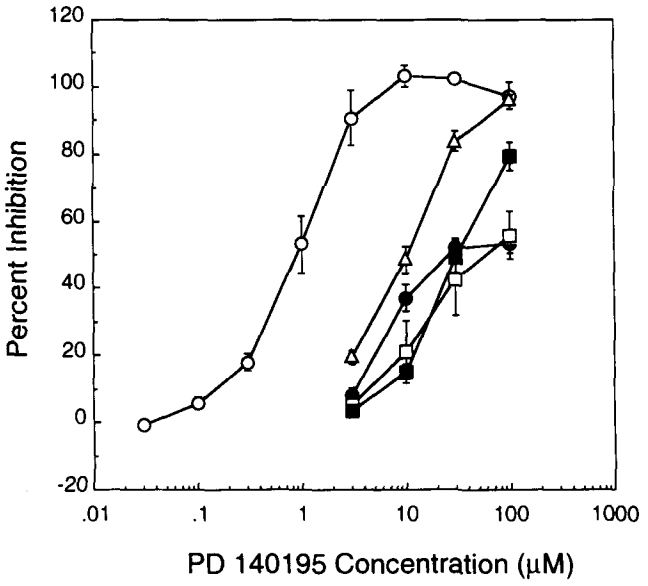

FIG. 4. Inhibition curves for PD 140195 utilizing various assays and cholesteryl ester transfer protein (CETP) sources. Typical PD 140195 inhibitory data utilizing high density lipoproteins (HDL) isolated between the densities of 1.11–1.21 g/mL containing [1,2-^{3}H]cholesteryl linoleate ([^{3}H]CL-HDL$_3$) as the donor lipoprotein in whole plasma CETP assays or cholesteryl 4,4-difluoro-5,7-dimethyl-4-bora-3α,4α-diaza-3-indacenedodecanoate (BODIPY-CE) containing microemulsions as donor in fluorescent assays. Transfer inhibition of [^{3}H]cholesteryl linoleate from human [^{3}H]CL-HDL$_3$ to human (●) or rabbit (□) plasma heparin-mangenese precipitable lipoproteins was determined after an overnight incubation (16–18 h). Fluorescent assays utilized either recombinant human CETP (○) or rabbit d > 1.21 g/mL fraction (■) as a source of CETP, BODIPY-CE microemulsions as donors, and excess nonfluorescent microemulsions as a BODIPY-CE acceptors as described in Materials and Methods. Fluorescent assays were also performed with BODIPY-CE microemulsions (0.3, 0.6 or 1.2 BODIPY-CE) in 200 μL whole rabbit plasma (△), as a source of CETP and acceptor (endogenous lipoproteins). For fluorescent assays, inhibition was determined at 1–2 h (recombinant human or rabbit d > 1.21 g/mL as CETP source) or 6 h (whole rabbit plasma). Data represent CETP transfer inhibition ± SEM for 3 to 23 experiments at each PD 140195 concentration.

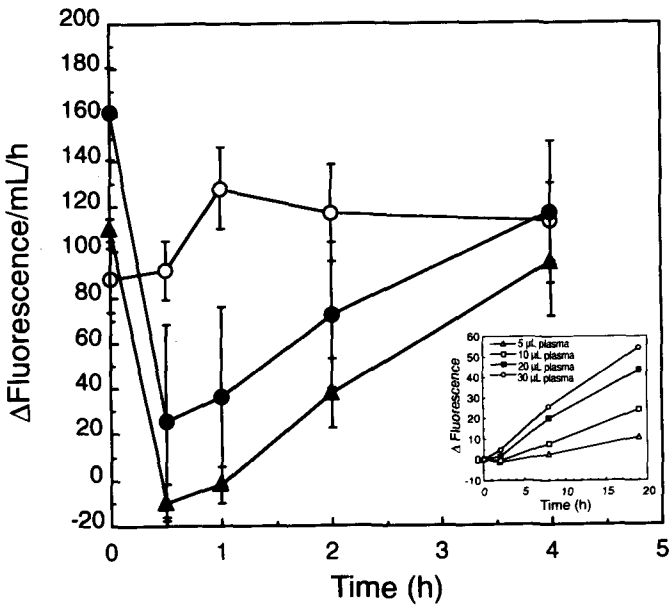

FIG. 5. *Ex vivo* inhibition of cholesteryl ester transfer protein (CETP) facilitated transfer of cholesteryl 4,4-difluoro-5,7-dimethyl-4-bora-3α,4α-diaza-3-indacenedodecanoate (BODIPY-CE) in microemulsions in plasma from rabbits treated with PD 140195. Anesthetized male Kuiper rabbits were intravenously infused (over approximately 10–15 minutes with a peristaltic pump) with vehicle (○, n = 5), 10 mg/kg PD 140195 (●, n = 4), or 20 mg/kg PD 140195 (▲, n = 4). Blood samples were taken prior to and periodically following the start of infusion. To determine *ex vivo* CETP activity, plasma (5, 10, 20 or 30 μL) from each time point were incubated at 37°C with Intralipid and cholesteryl 4,4-difluoro-5,7-dimethyl-4-bora-3α,4α-diaza-3-indacenedodecanoate (BODIPY-CE) containing microemulsions in a total volume of 240 μL in microtiter plates. Under these conditions initial transfer velocity is determined under Vmax conditions. Fluorescent yields were periodically determined for up to 21 h (34). A typical assay to determine initial transfer velocity using dilutions of preinfusion plasma is shown (inset). Data shown in large figure represent change in fluorescent yields ± SEM (i.e., *ex vivo* CETP activity in blood samples taken before and up to 4 h following PD 140195 treatment) utilizing duplicate determinations made at 19 or 21 h for 10 μL plasma.

peared to be more refractory to inhibition than recombinant human CETP (Fig. 3). The multiple variables in the whole plasma assays, including the ratio of PD 140195 to CETP and lipoproteins, and that of BODIPY-CE microemulsion levels to lipoproteins, made loss of PD 140195 inhibitory activity difficult to define. These observations suggest that this compound was either competitive with endogenous lipids for CETP or that other plasma components were inactivating PD 140195. The reduced effectiveness of PD 140195 was further investigated in component systems.

To determine if the inhibition was competitive, rabbit plasma or d > 1.21 g/mL was incubated with BODIPY-CE microemulsions with Mab TP2 (2.5–10 μg/mL) or PD 140195 (0.3–3 μM) at various amounts of Intralipid acceptor (Fig. 6). Under these conditions, competitive inhibition was not demonstrable. Possibly, a lack of competition was observed since triglyceride transfer (the major component of Intralipid) is not inhibited by PD 140195. In this regard, we have found that PD 140195 has little or no effect on triglyceride transfer from [^{3}H]TO-HDL$_3$ (Fig. 3). Whether cholesteryl ester emulsions could restore activity in the presence of PD 140195 was not further studied. In a separate assay in which rabbit plasma represented the bulk of the incubation volume, the time course of BODIPY-CE transfer during PD 140195 inhibition was determined and shown to result in a significant decrease in the effectiveness of PD 140195 (Fig. 7). Thus, a component of whole plasma appeared to neutralize this inhibitor.

Next, we investigated the role albumin might play on PD 140195 CETP inhibition. Utilizing, a component system consisting of recombinant CETP, BODIPY-CE microemulsions, and a 10-fold microemulsion acceptor excess in the absence or presence of bovine serum albumin, CETP inhibitory activity was assessed for PD 140195 and Mab TP2 (Fig. 8). Albumin had no inhibitory effect on Mab TP2 inhibition of CETP. In contrast, albumin addition resulted in a concentration-dependent abolition of the inhibitory effects of PD 140195.

DISCUSSION

Whether CETP plays a role in the inhibition or progression of atherosclerosis has been controversial (10). It has

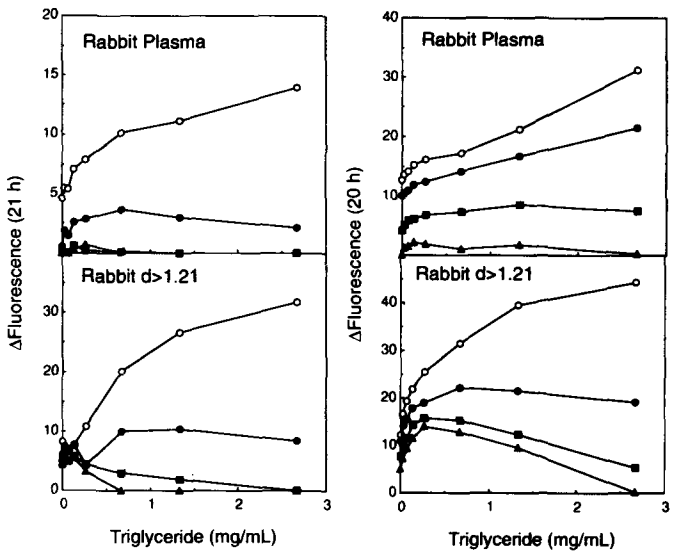

FIG. 6. Effect of triglycerides on PD 140195 inhibition of cholesteryl ester transfer protein (CETP) facilitated transfer. Rabbit plasma (20 μL) or d > 1.21 g/mL (from 20 μL of rabbit plasma) was incubated at 37°C with 2.5 μg/mL (●), 5 μg/mL (■), 10 μg/mL (▲) CETP inhibitory monoclonal antibody (Mab) TP2 (left side graphs), 0.3 μM (●), 1.0 μM (■), 3.0 μM (▲) PD 140195 (right side graphs) or 5 μL dimethylsulfoxide (DMSO) vehicle alone (○) (all graphs) in the presence of a constant amount of cholesteryl 4,4-difluoro-5,7-dimethyl-4-bora-3α,4α-diaza-3-indacenedodecanoate (BODIPY-CE) containing microemulsion (0.385 nmol BODIPY-CE) and varying amounts of triglyceride emulsion (Intralipid) as indicated in a total incubation volume of 225 μL. Fluorescence was determined at time zero and at 21 h or 20 h, for Mab TP2 and PD 140195, respectively. Data represent the change in fluorescence for duplicate incubations for each condition.

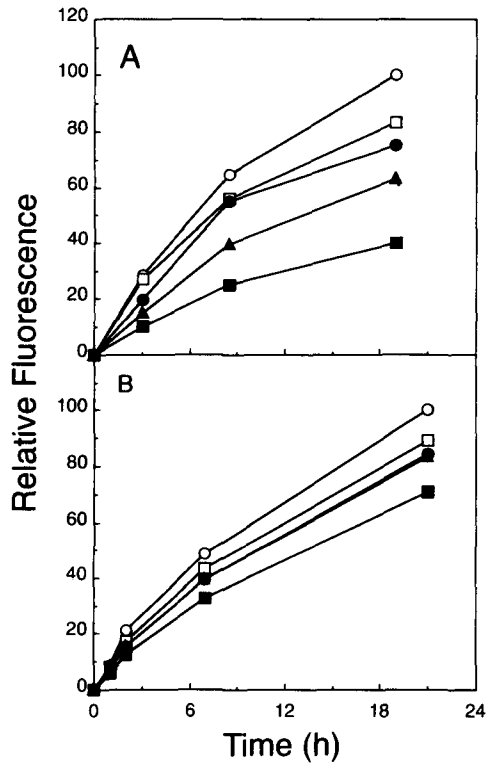

FIG. 7. Cholesteryl ester transfer protein (CETP) activity under conditions in which whole plasma is the predominant assay component. Rabbit plasma (200 μL) was incubated at 37°C with cholesteryl 4,4-difluoro-5,7-dimethyl-4-bora-3α,4α-diaza-3-indacenedodecanoate (BODIPY-CE) containing microemulsions (20 μL), and 10 μg/mL (●), 20 μg/mL (▲), 40 μg/mL (■) CETP inhibitory monoclonal antibody (Mab) TP2 (panel A), 0.3 μM (●), 3.0 μM (▲), 30 μM (■) PD 140195 (panel B) or 5 μl dimethylsulfoxide (DMSO) vehicle alone (○) in a total volume of 225 μL. Incubations in the absence of DMSO (□) to control for possible nonspecific effects of the vehicle (present with added Mab TP2 and PD 140195) were also performed. Fluorescence was periodically determined up to 21 h. Data are shown as fluorescence change relative to the highest DMSO control values.

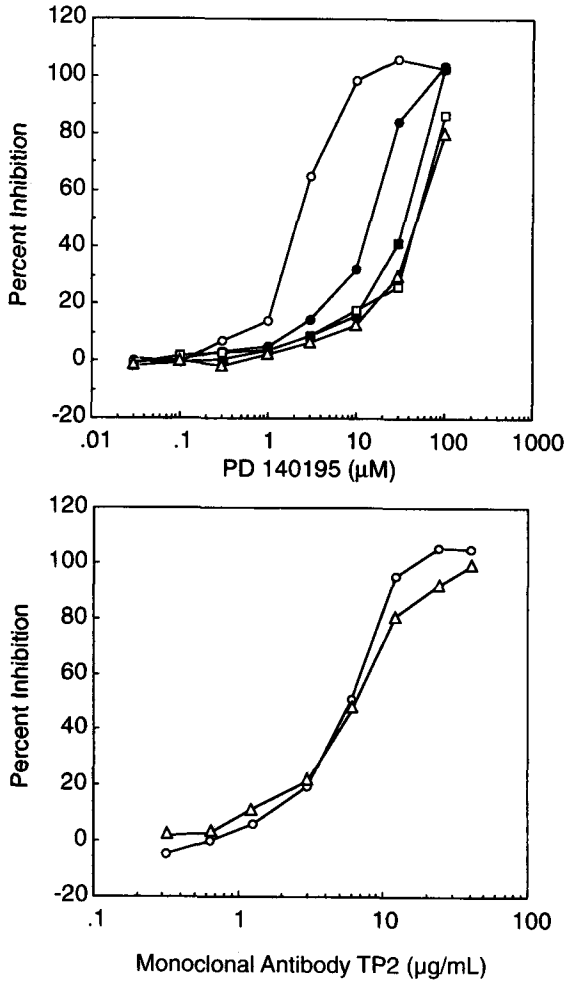

FIG. 8. Effect of albumin on PD 140195 inhibition of cholesteryl ester transfer protein (CETP). PD 140195 (top graph) or monoclonal antibody (Mab) TP2 (bottom graph) was incubated at 37°C with recombinant human CETP (100 μL conditioned media), cholesteryl 4,4-difluoro-5,7-dimethyl-4-bora-3α,4α-diaza-3-indacenedodecanoate (BODIPY-CE) microemulsions (donors), a 10-fold excess of nonfluorescent microemulsion (acceptors) in the absence (○) or presence of 0.5 (●), 1 (■), 2 (□) or 3 (△) percent bovine serum albumin in a total volume of 250 μL. CETP activity was monitored by the loss of fluorescence quenching after 1 h. Data are typical of a represenative experiment.

been hypothesized that CETP plays a central role in reverse cholesterol transport and therefore its inhibition might be atherogenic. However, a direct link between elevated CETP levels and an antiatherosclerotic effect has not been demonstrated. In fact, enhanced delivery of periperial tissue cholesterol to LDL from HDL *via* CETP might reduce hepatic LDL receptor levels and result in an atherosclerotic plasma profile and disease (40). In contrast, CETP reduction appears to be beneficial for inhibiting atherosclerosis progression or enhancing atherosclerosis regression. In humans, homozygous and heterozygous CETP deficiencies are associated with elevated apoE, apoA-I, HDL cholesterol and longevity, and a reduction in LDL cholesterol and coronary heart disease. In general, with the exception of the pig, species that lack CETP activity (i.e., rats, mice and dogs) are resistant to dietary cholesterol induced atherosclerosis; while dietary cholesterol results in atherosclerosis progression in species with CETP activity including CETP-transgenic mice, rabbits, nonhuman primates and humans.

Thus, the inhibition of CETP activity is an intense area of research. Earlier studies have demonstrated that infusion of inhibitory monoclonal or polyclonal CETP antibodies into rabbits results in the appearance of an antiatherosclerotic profile (27,28). More recently, preliminary data have shown that corticosterone administration to CETP-transgenic mice results in decreased plasma CETP levels and reduced hepatic CETP mRNA levels (10). Thus, strategies to inhibit circulating CETP or its synthesis may have beneficial affects on elevating HDL, reducing LDL, and preventing atherosclerosis.

In the current study we describe, in part, our efforts to find simple organic compounds to inhibit circulating CETP. To our knowledge, this is the first report that demonstrates a pharmacologic approach to inhibit CETP. We have described various assays used to monitor CETP activity for the discovery of inhibitors and also have described some of the pitfalls in this discovery process. The major obstacle in this discovery process at this point is movement from an *in vitro* reconstituted system to the whole plasma and to animal systems. Although we found that many inhibitors block CETP activity in reconstituted systems, their specificity to CETP appears to be low in the complex milieu of plasma and in whole animals. In general, the compounds discovered are hydrophobic and might partition into lipoproteins or cellular membranes, thus losing their effectiveness. In addition, binding of PD 140195 and other compounds to other plasma protein components, such as albumin, will also reduce their effectiveness. It should be noted, that albumin (4 g/dL) is in 20,000–40,000-fold molar excess to that of CETP (0.1–0.2 mg/dL) in human plasma. To this end, we have separated inhibitors into those that are and are not (not shown) inactivated by albumin. Some of these compounds not inhibited by albumin are, however, inactive in whole plasma, suggesting that they are bound by other plasma components (Bisgaier, C.L., Essenburg, A.D., Minton, L.L., and White, A., unpublished data). Since antibody studies have demonstrated the feasibility of inhibiting plasma CETP and modulating plasma lipids and lipoproteins, identifying specific CETP inhibitors by novel chemical synthesis will likely result in CETP inhibition in whole plasma and the organism.

Other approaches to CETP inhibition include transcription and translational inhibition. However, much less is known about these processes. Recently, work of Pape *et al.* (41) and Rea *et al.* (42) have suggested that a major source of this protein in nonhuman primates and rabbits is the hepatic nonparenchymal cells, suggesting them as likely targets of pharmacologic intervention. The establishment of stable cell lines to express CETP with its endogenous promoter should enhance pharmacologic strategies for inhibition of CETP production.

ACKNOWLEDGMENTS

The authors gratefully acknowledge Drs. Michael Pape and Roger Newton for their critical review of the manuscript. The authors

also thank Michelle Buroker for technical contributions to these studies. We are also grateful to Drs. Ross Milne and Yves Marcel and their associates of the Universtiy of Ottawa Heart Institute for providing us with CETP Mab TP2, and to Dr. Alan Tall and his associates of Columbia University for providing us with Chinese hamster ovary cells transfected with human recombinant CETP.

Interactions of MDL 29,311 and Probucol Metabolites with Cholesteryl Esters

Larry R. McLean*, Nick Brake and **Karen A. Hagaman**
Marion Merrell Dow Research Institute, Cincinnati, Ohio 45215

The hypothesis that the efficacy of hydrophobic antioxidants in animal models of atherogenesis may, in part, be related to physical effects on cholesteryl esters in cells was probed with analogs and metabolites of probucol. The interactions of an effective *bis*-thiomethane analog (MDL 29,311) and selected metabolites of probucol with cholesteryl oleate were examined by differential scanning calorimetry and polarized light microscopy. Like probucol, MDL 29,311 and the bisphenol metabolite decrease the liquid-crystalline phase transition enthalpy of cholesteryl oleate with increasing concentrations. At 20 mol%, no transition is detectable. By contrast, the spiroquinone metabolite of probucol and the diphenoquinone metabolite common to both molecules have minimal effects on the liquid-crystalline transitions of cholesteryl oleate. At 20 mol%, neither compound has as great an effect as 1 mol% MDL 29,311. Consistent with their effects on dry cholesteryl oleate, MDL 29,311 and the bisphenol metabolite convert lipid inclusions in cells supplemented with cholesterol to an isotropic physical state similar to that observed with probucol. The number of anisotropic inclusions in the cells decreases with increasing concentration in the medium in the range of 50 to 250 μg/mL. In cells fed with the spiroquinone or diphenoquinone metabolites, the lipid inclusions are liquid-crystalline and resemble those observed with cholesterol-fed controls. These data are interpreted in terms of a model in which hydrophobic antioxidants closely related to probucol disrupt the packing of cellular cholesteryl esters.
***Lipids* 29, 819–823 (1994).**

An early event in the progression of atherosclerosis is the intimal deposition of lipids, including cholesterol and cholesteryl esters (1). This deposition arises from a combination of extracellular and intracellular processes and has been shown in some animal models of atherogenesis to be inhibited by hydrophobic antioxidants such as probucol [*bis* (3, 5-di-*tert*-butyl-4-hydroxyphenylthio) propane] (2). Part of the efficacy of probucol in animal models may be due to modulation of the assembly and molecular interactions of lipoproteins (3). In addition, probucol has been shown to disrupt packing of cholesteryl esters in cells and model lipoproteins on the basis of thermal and microscopic measurements (4). This may contribute to its antioxidant activity in the lipid phase as the rate of oxidation of lipids depends strongly on acyl chain packing (5). The consequence of this fluidizing effect in cells is that the rate of lipid clearance from cholesteryl ester-rich lipid droplets is increased by probucol in the presence of a cholesterol acceptor in the medium (4). These data suggest that hydrophobic antioxidants have both physical effects and antioxidant activities that may be important to the mechanisms by which they inhibit lipid deposition. The present report examines whether such fluidization is common to analogs of probucol that are effective in animal models of cholesterol deposition.

The primary cell types which contribute to lipid deposition in the arterial wall are macrophages and smooth muscle cells. Both cell types accumulate cholesteryl esters to form the foam cells characteristic of atherosclerotic lesions. In cultured cells, cholesteryl ester deposition may be achieved by addition of cholesterol-rich phospholipid liposomes, cholesterol-enriched medium or low density lipoproteins (LDL) that have been modified by acetylation (4,6). Fu5AH rat hepatoma cells are a useful model for studies of the physical properties of the cholesteryl esters deposited in cultured cells. In the presence of cholesterol-enriched medium, Fu5AH hepatoma cells accumulate lipid in an ordered physical state within droplets that exhibit characteristic birefringence cross-patterns when observed through polarized optics. Addition of oleic acid to the medium increases the triglyceride content of the lipid deposits and results in a disordered physical state (6). This increase in fluidity of the lipid droplets increases the rate by which cholesterol may be removed from the cells in the presence of a cholesterol acceptor in the medium.

In LDL receptor-deficient rabbits, an analog of probucol (MDL 29,311) which contains a *bis*-thiomethane rather than the *bis*-thiopropane of probucol (Fig. 1) is effective in reducing aortic surface lesions, but does not significantly reduce plasma cholesterol concentrations (7). The closely related structure of this analog suggested that it may have cholesteryl ester fluidizing activity similar to that of probucol. This activity may be an additional contribution that supplements antioxidant activity in reducing the incidence of fatty lesions in receptor-deficient animals. However, some of the activity of probucol and MDL 29,311 may be the result of their common metabolites. On the basis of studies in monkey liver and adipose tissue (8), probucol has three primary metabolites: the spiroquinone, diphenoquinone and bisphenol (Fig. 1). The present study examines the interactions of MDL 29,311 and the probucol metabolites on cellular cholesteryl esters and the liquid crystalline transitions of cholesteryl oleate.

MATERIALS AND METHODS

Cholesteryl ester loading of cells in culture. The Fu5AH rat hepatoma cell line was graciously provided by J.M. Glick (Philadelphia, PA). Stock cultures were grown in minimal essential medium (MEM) supplemented with basal medium Eagle vitamins, 50 μg/mL of gentamycin,

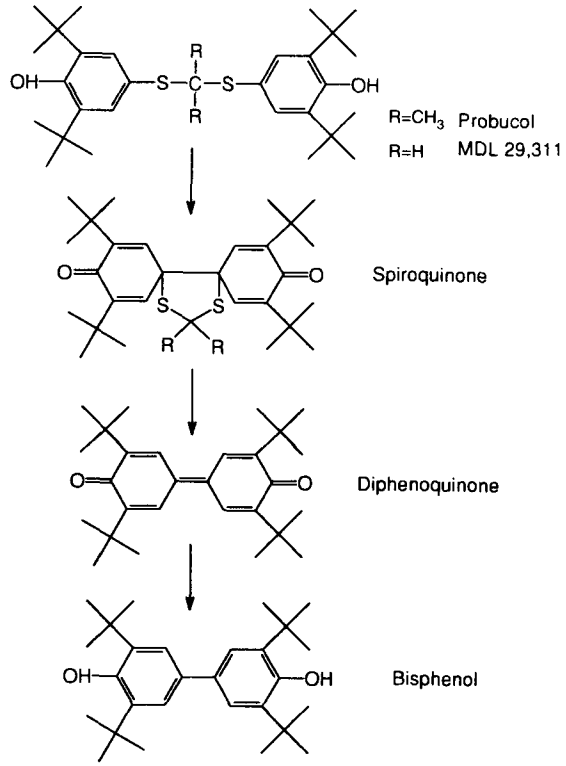

FIG. 1. Structures of probucol, MDL 29,311 and the spiroquinone, diphenoquinone and bisphenol metabolites.

and 5% calf supreme serum (Gibco, Grand Island, NY). Cells were maintained in an atmosphere containing 5% CO_2. Cells were grown in 2-well glass bottom chamber slides (Nunc, Lab-Tek, Naperville, IL) in 2 mL of MEM containing 5% serum for observation of the phase state of lipid inclusions. Loading medium was made by dissolving cholesterol (Calbiochem, La Jolla, CA) in warm (~75°C) absolute ethanol at 10–20 mg/mL and injecting it into warm calf supreme serum while swirling. The mixture was immediately diluted with MEM to a final serum concentration of 10%. Probucol, MDL 29,311, spiroquinone, diphenoquinone and bisphenol were added to serum with cholesterol in a similar manner. The final ethanol concentration was less than 2%. After growth of cells to 70–80% confluence in the chamber slides, the growth medium was replaced with 2 mL of the appropriate loading medium. After loading for 48–72 h, the cells were washed three times with Dulbecco's phosphate buffered saline. Cells were inspected and photographed with a Nikon Microphot-FX microscope. (Melville, NY) equipped with a 10× eye-piece, a 10× objective and polarizing optics.

Differential scanning calorimetry (DSC). DSC scans of dry mixtures of cholesteryl oleate (Nu-Chek-Prep, Elysian, MN) with probucol, MDL 29,311 and the metabolites were made on a Perkin-Elmer DSC-7 (Norwalk, CT). The samples were prepared by mixing in chloroform. A measured aliquot of the solution was transferred to a DSC pan, dried by gentle warming and placed under vacuum overnight. The samples were stored for 10 d at –80°C to promote formation of crystalline material. The samples were scanned at a rate of 2°C/min. Heat capacities and enthalpies were calculated with the software provided by Perkin-Elmer. Transition temperatures correspond to the onset temperatures.

Hydrophobicity estimations. Two high-performance liquid chromatographic (HPLC) systems were used to estimate the hydrophobicity of the molecules. Both employed a C-8 column (5 cm × 4.6 mm id Chromegabond Octyl, 5 μm; Es Industries, Berlin, NJ) and a flow rate of 1.0 mL/min. The dead volume of the column was 0.68 mL. Peaks were monitored at 230 nm with an ABI model 783A detector (Foster City, CA). A Beckman CALS Peak Pro data system (Fullerton, CA) was used for determination of peak retention times and integrations. Mobile phases A and B were mixed by two Waters model 510 pumps (Milford, MA) interfaced with a Waters model 680 controller. In both systems, mobile phase A contained 0.02 M morpholinepropanesulfonic acid and 0.0075 M ethylamine in water adjusted to pH 7.4. In the first system, mobile phase B contained 0.25% octanol in methanol, and a series of isocratic elutions with methanol fractions of 0.98, 0.95, 0.90, 0.85, 0.80 and 0.75 were run. Values in water [log k'(w)] were calculated by extrapolation of the log k' values linearly to zero methanol In the second system, mobile phase B contained 0.25% octanol in tetrahydrofuran, and the sample was eluted with tetrahydrofuran fractions of 0.70, 0.65, 0.60, 0.55, 0.50 and 0.45. An average elution time (midpoint) was calculated for all six runs to give the best estimate of the elution time at 57.5% tetrahydrofuran.

RESULTS

Rat Fu5AH hepatoma cells accumulate lipid droplets that consist primarily of cholesteryl oleate (6). This cell line thus serves as a model system to study the basic features of lipid fluidizing by hydrophobic antioxidants *in vitro*. The propensity of the Fu5AH cell line to deposit lipids in an ordered array when the medium is supplemented with additional cholesterol allows facile manipulation of culture conditions to effect modulation of the physical properties of cellular lipids. Numerous droplets in an ordered anisotropic liquid-crystalline state can be seen in cells observed at room temperature by optical microscopy with crossed polarizers (Fig. 2). The anisotropic liquid crystals appear as bright regions, and the isotropic lipid is dark.

In the experiments shown in Figures 2–4, the cell medium was supplemented with cholesterol (250 μg/mL) and incubated for two days. Probucol, MDL 29,311 and the probucol metabolites were added to the cholesterol-supplemented medium at concentrations of 50, 100 and 250 μg/mL. With the spiroquinone and the diphenoquinone at concentrations up to 250 μg/mL, the cells resemble the cholesterol-fed control cells, with large numbers of birefringent, anisotropic liquid-crystalline droplets (data not shown). With increasing concentrations of probucol, MDL 29,311 or the bisphenol metabolite, a decrease in the number of anisotropic cholesteryl ester droplets was observed at room temperature. At a concentration of 250 μg/mL, the cells contain primarily

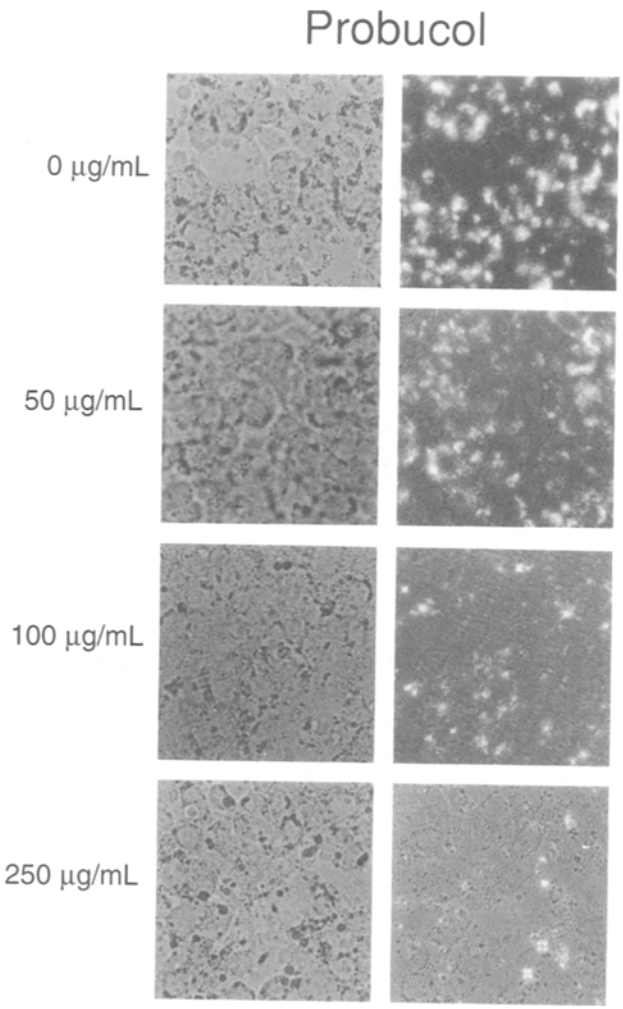

FIG. 2. Light micrographs of living cells fed media enriched with 250 μg/mL cholesterol and varying amounts of probucol observed without (left panels) and with (right panels) crossed polarizers at room temperature.

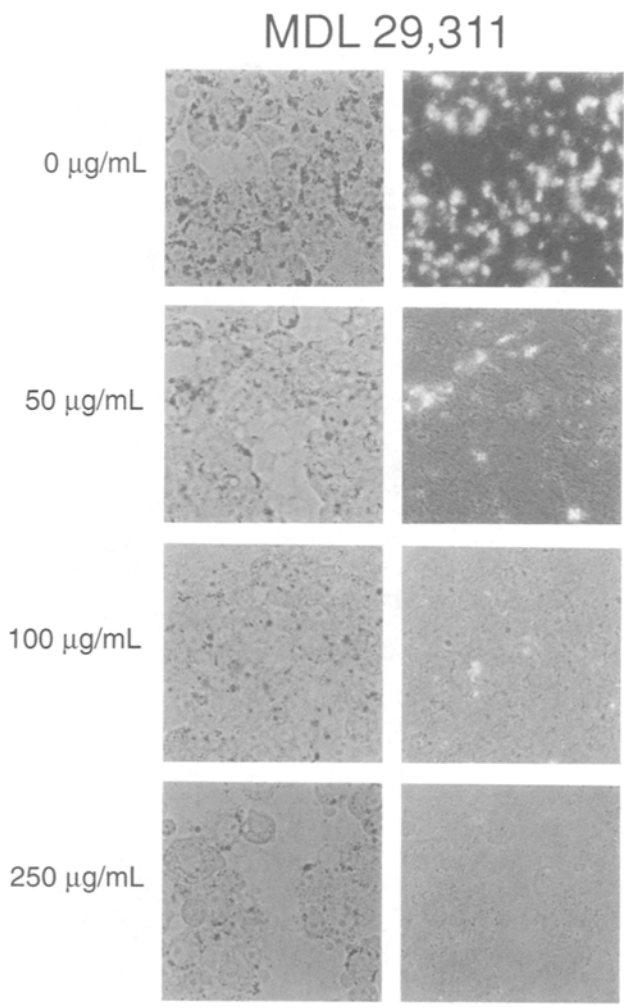

FIG. 3. Light micrographs of cells incubated with cholesterol and increasing amounts of MDL 29,311.

liquid cholesteryl ester droplets which remain dark (isotropic) when observed though crossed polarizers.

To determine whether the effects on cells were due primarily to physical interactions of the analog and metabolites with cholesteryl esters, the effects on dry cholesteryl oleate liquid-crystalline transitions were examined by DSC. This lipid was chosen because of its prevalence in lipid droplets in Fu5AH cells (6). Two sharp phase transitions were observed in pure cholesteryl oleate corresponding to the transformation from isotropic to cholesteric and from cholesteric to smectic phases. The transitions in pure cholesteryl oleate correspond in enthalpy and transition temperatures to those previously reported (4). Due to the overlap of the two transitions, especially in the presence of the analog and the metabolites, only total enthalpies were calculated.

The diphenoquinone metabolite decreased the phase transition temperatures of cholesteryl oleate at concentrations of 20 mol%, with some broadening of the transition and a minimal decrease in the total enthalpy (Table 1). The spiroquinone metabolite broadened the transitions somewhat more at 20 mol%, but the effect was comparable to 1 mol% of the bisphenol metabolite. By contrast, both the bisphenol and MDL 29,311 have a significant effect on the liquid-crystalline phase transitions, even at low concentrations. With this metabolite and the analog at 1 mol%, the cholesteryl oleate liquid-crystalline transitions are significantly broadened, and the phase transition temperatures are depressed by ~4°C. Further broadening of the phase transitions of cholesteryl oleate is observed with increasing concentrations of both MDL 29,311 and the bisphenol metabolite. No discernible phase transition is observed with either compound at concentrations of 20 mol%. The phase behavior and the shapes of the transitions for both MDL 29,311 and the bisphenol metabolite are similar to those previously reported for probucol in the same system (4).

The hydrophobicity of the molecules was examined by HPLC in a series of solvent mixtures on a C-8 column. The retention times of probucol, MDL 29,311 and the bisphenol metabolite are nearly equivalent with methanolic eluants. The calculated log k'(w) values were 10.2 for probucol, 9.4 for MDL 29,311 and 8.9 for the bisphenol metabolite. By contrast, the quinone metabolites are

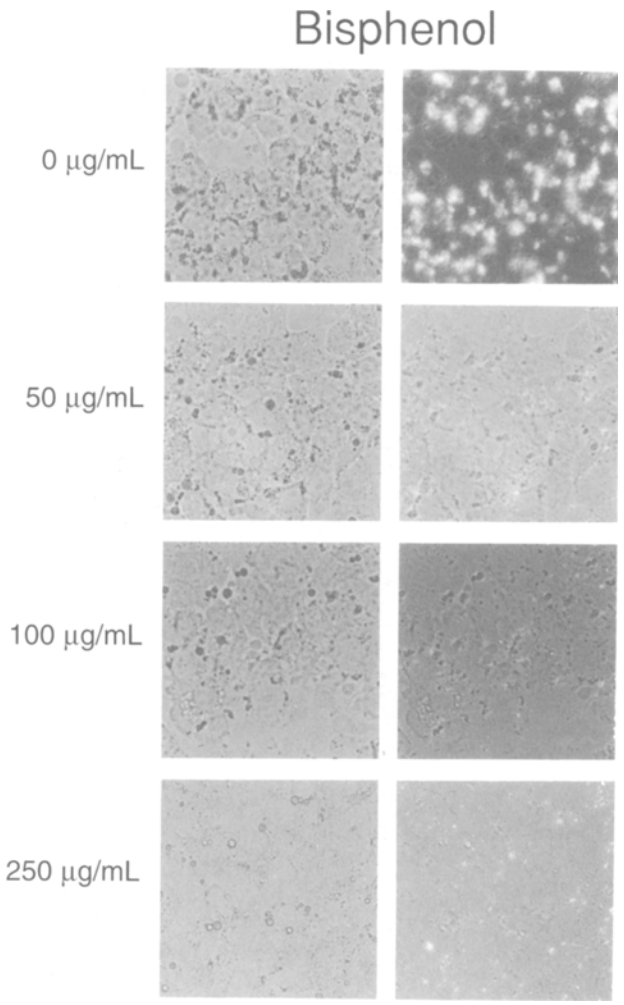

FIG. 4. Light micrographs of cells incubated with cholesterol and increasing amounts of the bisphenol metabolite.

strongly retained on C-8 columns and are not eluted with concentrations <85% methanol. Thus, extrapolation to zero methanol concentration yields misleading results. A second system employing a range of tetrahydrofuran concentrations and calculation of the elution time at 57.5% tetrahydrofuran was also used to give more accurate data for the later-eluting molecules. In this system, the log k′ values relative to probucol were 1.11 for diphenoquinone, 1.04 for the spiroquinone, 0.97 for MDL 29,311 and 0.91 for the bisphenol. These data are consistent with previous HPLC data that indicate that the quinones elute at higher concentrations of organic solvent in gradient systems. (7).

DISCUSSION

Contributions of physical effects to the activities of potentially antiatherogenic compounds have recently been suggested for both probucol (4) and lovastatin (9). Although it is difficult at this point to separate the contributions of physical effects, the data of the present report are consistent with a general phenomenon in which hydrophobic antioxidants fluidize lipids deposited in cells

TABLE 1

Effect of MDL 29,311 and Probucol Metabolites on the Enthalphy and Phase Transition Temperatures of Cholesteryl Oleate

		ΔH (J/g)[a]	T_m (°C)	
Addition	mol%	Total	Smectic	Cholesteric
None		3.4	38.6	44.2
MDL 29,311	1	1.8	34.2	39.5
MDL 29,311	5	0.9	28.9	38.3
MDL 29,311	10	0.3	27.4	
MDL 29,311	20		no transitions	
Bisphenol	1	2.4	36.2	42.0
Bisphenol	5	1.1	31.8	37.2
Bisphenol	10	0.6	27.3	30.9
Bisphenol	20		no transitions	
Spiroquinone	20	3.1	36.2	41.2
Diphenoquinone	20	2.4	33.2	35.5

[a]Standard errors of the enthalpies are ±0.2, and of the transition temperatures are ±0.3

in the presence of excess cholesterol. Vitamin E has a similar effect on both dry cholesteryl oleate and in cells (L.R. McLean, unpublished data). With probucol and related molecules, one must also take care to consider the effects of their metabolic products, which may accumulate to a substantial extent *in vivo*.

The present data show that probucol, a closely related analog, and their common bisphenol metabolite have similar physical effects on cholesteryl ester droplets in cells and in dry mixtures with cholesteryl oleate. In dry cholesteryl esters, this is achieved by decreasing the cooperativity of chain melting during the liquid-crystalline phase transitions. The observed decreases in phase transition temperatures correspond closely to the ~5°C decrease observed with probucol (4). The loss of an observable liquid-crystalline phase transition at concentrations of 20–25 mol% of MDL 29,311 and the bisphenol metabolite is also indistinguishable from the effects of probucol on cholesteryl oleate. These observations in a pure model system are consistent with the effects of the molecules on cellular lipid deposits. By contrast, the diphenoquinone and the spiroquinone metabolites have minimal effects on the phase transition enthalpies of dry cholesteryl esters or the number of anisotropic droplets in cells.

The data are consistent with one of two mechanisms. The first is an alteration in the composition of the intercellular lipid droplets. This possibility has not been ruled out in the present set of experiments. The second is that probucol and the effective analogs act through physical effects on lipid packing. The similarities of the effects of MDL 29,311, probucol and their common bisphenol metabolite on cellular lipid inclusions and on pure cholesteryl oleate are consistent with the latter hypothesis.

Comparison of the structures of the five compounds examined for their effects on cholesteryl ester physical state reveals several important differences. All of the molecules contain two di-*tert*-butyl aromatic rings (Fig. 1). The three active compounds are phenols; the inactive compounds are quinones. The higher hydropho-

bicity of the quinones may explain, in part, their relative lack of efficacy in cell experiments, wherein the molecules may either not readily enter the cells or not be metabolized intracellularly to the bisphenol.

However, it is unlikely that the increased hydrophobicity of the quinones limits their interaction with cholesteryl esters. The quinones, by virtue of the constraints imposed by either the sulfur-containing ring system of the spiroquinone or the double bond of the diphenoquinone, have limited rotational mobility of the aromatic rings and are expected to form a relatively rigid planar system. We propose that the flexibility conferred upon probucol, MDL 29,311 and the bisphenol metabolite by virtue of the unconstrained linkage between their two phenol groups allows rotation of the phenolic rings relative to each other and promotes disruption of the ordered packing of the cholesteryl esters. This hypothesis is also supported by the conformational flexibility that is expected to be retained with a single bond, as is the bisphenol metabolite, which is also active.

The data suggest that physical effects, coupled with the antioxidant activity of MDL 29,311 (7), may contribute to the decrement of fatty lesions in receptor-deficient rabbits without significantly lowering plasma cholesterol levels. One plausible mechanism is that the dynamic turnover of cholesteryl esters in cells is promoted by increasing the fluidity of the lipids. Such a hypothesis is consistent with the proposal that the physical state of the lipids in atherosclerotic plaque is important in determining the rate of turnover of the components of a fatty lesion (10). This fluidizing effect, common to probucol, its bisphenol metabolite and a selected analog, may be an important mechanism of action in reducing arterial fatty lesions in animal models.

ACKNOWLEDGMENT

We thank Klaus Haegele for valuable comments and suggestions.

Differential Effects of Eicosapentaenoic Acid and Docosahexaenoic Acid on Human Skin Fibroblasts

Eric R. Brown and **Papasani V. Subbaiah***

Departments of Biochemistry and Medicine, Rush Medical College, Chicago, Illinois 60612

To better understand the mode of action of ω3 fatty acids in cell membranes, human foreskin fibroblasts were grown in serum-free medium supplemented with 50 μM oleic acid linoleic acid, eicosapentaenoic acid (EPA) or docosahexaenoic acid (DHA), and the effects on membrane composition, fluorescence polarization and enzyme activities were followed. The cells were enriched with EPA and DHA up to 7 and 13% of total lipids, respectively, of which >95% was associated with phospholipids. In addition, the concentration of 22:5n-3 increased with both EPA and DHA to 7.5, and 2.1% of the total fatty acids, respectively. When compared to controls (oleic acid), cells treated with DHA showed a decrease in cholesterol, phospholipids, arachidonic acid (AA) and free cholesterol/phospholipid ratio ($P < 0.05$). In the presence of EPA, only decreases in AA and cholesterol were significant ($P < 0.05$). Membrane fluidity, assessed by fluorescence anisotropy, was increased 16% in cells enriched with DHA ($P < 0.05$), but showed no change with EPA or linoleic acid. There was an increase in membrane-associated 5′-nucleotidase (+27%) and adenylate cyclase (+19%) activities ($P < 0.05$), in DHA-enriched, but not in EPA-enriched cells, when compared with oleate controls. The studies show that incorporation of DHA, but not EPA, into cell membranes of fibroblasts alters membrane biophysical characteristics and function. We suggest that these two major n-3 fatty acids of fish oils have differential effects on cell membranes, and this may be related to the known differences in their physiological effects.

***Lipids* 29, 825–829 (1994).**

Epidemiological and clinical studies have shown that ingestion of n-3 polyunsaturated fatty acids (PUFA) is associated with decreased incidence and progression of atherosclerosis-related disorders (1–4). However, the mechanisms by which these n-3 fatty acids exert their beneficial effects are not completely clear.

It is believed that eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA) present in marine oils are mostly responsible for the observed beneficial effects (4). As the two n-3 fatty acids are found at varying ratios in different marine oils (5), the relative advantage of one fatty acid over the other has been difficult to assess. Kobatake *et al.* (6) found that EPA selectively lowered triglycerides, whereas DHA selectively lowered cholesterol in rats. Childs *et al.* (7) found that, although all fish oils lowered triglycerides in humans, only DHA-rich tuna and salmon oils reduced low density lipoproteins (LDL) and apoprotein B. Moreover, our laboratory recently reported a differential incorporation of EPA and DHA into plasma lipids (8). We found that relatively more EPA was incorporated into cholesteryl esters, and DHA was preferentially incorporated into phospholipids. These studies suggest that DHA and EPA may be differentially metabolized.

It is well established that the activities of membrane-associated enzymes and receptors can be modulated by changes in membrane lipid composition and in biophysical characteristics (9). It has also been shown that the fatty acids of marine oils are readily incorporated into membrane phospholipids (10). Thus, there has been increased interest in the role n-3 PUFA play in modulating membrane function (11,12). Although several *in vivo* studies have been published on the effects of these marine oils on membrane-associated enzyme activities (13–15), such studies have not been carried out in cultured cells to compare the effects of EPA and DHA on membrane-bound enzymes.

In the present study, we examined the effects of EPA and DHA on the lipid composition and biophysical properties of cell membranes and on the activities of two membrane-associated enzymes, namely adenylate cyclase and 5′-nucleotidase of human skin fibroblasts grown in culture. The results presented here show that EPA and DHA have differential effects on membrane fluidity, as measured by fluorescence polarization, and on the activities of those membrane-bound enzymes.

MATERIALS AND METHODS

Cell culture. Human newborn foreskin fibroblasts (passages 5′–10) were purchased from ViroMed (Minnetonka, MN), and were grown in 75-cm^2 stock flasks in Dulbecco's modified Eagle medium (DMEM) supplemented with 10% fetal calf serum (Biologos, Naperville, IL), penicillin (100 U/mL) and streptomycin (100 μg/mL). On Day 0 of the study, confluent monolayers of cells from stock flasks were dissociated with 0.05% trypsin 0.02% ethylenediaminetetraacetate (EDTA) solution and were seeded at a concentration of 2×10^5 cells per 75-cm^2 flask containing 10 mL of growth medium supplemented with 10% fetal calf serum. Cells were grown in this medium overnight to allow attachment of cells. The medium was then removed, and the monolayer was washed twice with phosphate buffered saline (PBS). Serum-free medium containing equal volumes of DMEM and F-12 medium, 200 mM glutamine, 2 g/L $NaHCO_3$, 100 μg/mL bovine serum albumin (BSA), 5 μg/mL iron saturated transferrin, 3×10^{-8} M Na_2SeO_3, 15 mM Hepes, 10 ng/mL epidermal growth factor and 5

* To whom correspondence should be addressed at Section of Endocrinology, Rush Medical College, 1653 West Congress Parkway, Chicago, IL 60612.

Abbreviations: AMP, adenosine 5′-phosphate; ATP, adenosine triphosphate; BSA, bovine serum albumin; cAMP, adenosine 3′,5′-monophosphate; DG, diacylglycerol; DHA, docosahexaenoic acid; DMEM, Dulbecco's minimal essential medium; EDTA, ethylenediaminetetraacetate; EPA, eicosapentaenoic acid; GLC, gas–liquid chromatography; LDL, low density lipoproteins; PBS, phosphate buffered saline; PC, phosphatidylcholine; PE, phosphatidylethanolamine; Sph, sphingomyelin; TLC, thin-layer chromatography; TMA-DPH, 4′-trimethylammonio-1,6-diphenyl-1,3,5-hexatriene.

μg/mL insulin (Sigma Chemicals, St. Louis, MO) was added along with 50 μM of either oleic acid, linoleic acid, EPA or DHA complexed with human serum albumin (molar ratio fatty acid/albumin, 4:1), together with 20 μM butylated hydroxytoluene (Cayman Chemicals, Ann Arbor, MI). The cells were grown in fatty acid-supplemented medium for four days. Cell numbers and viability were determined by hemocytometer and Trypan Blue exclusion test, respectively.

Fluidity measurements. Cells grown as described above in the presence of various fatty acids were washed with PBS and trypsinized. Approximately 5×10^6 cells were suspended in 1 mL of buffer containing 136 mM NaCl, 11.9 mM $NaHCO_3$, 5.6 mM glucose, 5 mM Hepes, 2.7 mM KCl, 2 mM MgCl and 0.42 NaH_2PO_4 (pH 7.4). The fluorescent probe 4′-trimethylammonio-1,6-diphenyl-1,3,5 hexatriene (TMA-DPH) (Sigma) was added to the mixture to give a final concentration of 2 μM. Samples were immediately subjected to polarization analysis at 37°C (excitation wavelength, 366 nm; emission, 450 nm) using a spectrofluorometer with polarization attachment (SLM Instruments, Urbana, IL) (16). The cells were stirred with a magnetic stirrer. Anisotropy (r) was calculated by the equation: $r = 2 \times P/3\text{-}P$, where P is the polarization value. The limiting hindered anisotropy (the static component of steady-state anisotropy) was calculated as: (4 r/3) – 0.1 (17,18).

Lipid analysis. Total cellular lipids were extracted by the method of Bligh and Dyer (19). For gas–liquid chromatography (GLC), the fatty acids were methylated in 1 mL of petroleum ether and 1 mL BF_3 in methanol (14% wt/vol), by heating at 85°C for 15 min and occasional vortexing. The fatty acid methyl esters were dried down under nitrogen, resuspended in hexane for GLC analysis on a Shimadzu GC-9 instrument (Columbia, MD) employing a Supelcowax 10 fused-silica capillary column (8). Authentic fatty acid methyl esters were used for the identification of GLC peaks based on retention times.

For phospholipid analysis, total lipid extracts were applied onto silica gel thin-layer chromatography (TLC) plates (Whatman; American Scientific Products, McGaw Park, IL), and the plates were developed with chloroform/methanol/acetic acid/0.15 M aqueous NaCl (50:25:8:2.5, by vol). This procedure separates lysophosphatidylcholine (R_f 0.1), sphingomyelin (Sph) (R_f 0.2), phosphatidylcholine (PC) (R_f 0.32), phosphatidylinositol plus phosphatidylserine (R_f 0.55), and phosphatidylethanolamine (PE) (R_f 0.8). The phospholipid fractions were visualized by exposure to iodine vapors and scraped from the TLC plate, and lipid phosphorus was estimated by the modified Bartlett procedure (20).

Total cholesterol was measured using an enzymatic kit (Boehringer-Mannheim, Indianapolis, IN) containing cholesterol esterase and cholesterol oxidase. Free cholesterol was measured using a similar assay except that cholesterol esterase was omitted.

Plasma membrane preparation and determination of enzyme activities. Fibroblasts were grown as described above, washed twice with PBS, trypsinized, and centrifuged at $125 \times g$ for 10 min. The cells were washed again, then resuspended in 0.3 M sucrose in a 1:10 dilution of PBS containing 0.15 mM EDTA. The resulting suspension was homogenized and centrifuged according to the procedure of Perdue and Sneider (21) to pellet the plasma membranes.

The assay of 5′-nucleotidase was performed according to the procedure of Lange and Steck (22). Ten μg of cell membrane protein was incubated for 30 min at 37°C in a final volume of 0.75 mL containing 50 mM glycine (pH 9.0), 0.4 mM $MgCl_2$, and 0.16 mM 5′-adenosine monophosphate (AMP). The reaction was stopped by chilling the mixture on ice and adding $ZnSO_4$ and $Ba(OH)_2$ to a final concentration of 37.5 mM each to precipitate unreacted substrate. The mixture was spun at 3000 rpm for 5 min after 10 min on ice. The supernatant was brought to 70 mM $ZnSO_4$ and $Ba(OH)_2$, centrifuged again, and its absorbance was measured at 260 nm. The enzyme activity was expressed as change in absorbance/30 min/mg protein.

Adenylate cyclase activity of the membranes was determined by estimating the formation of 3′,5′ cyclic adenosine monophosphate (cAMP) from adenosine triphosphate (ATP) at 37°C (23). One hundred μg of membrane protein was incubated with 0.2 mL of assay solution consisting of 50 mM Tris-HCl, pH 7.6, 5 mM $MgCl_2$, 250 μM [^{3}H]ATP (ICN Radiochemicals, Irvine, CA), 10 mM creatine phosphate, 0.2 mg/mL creatine kinase, 0.2 mg/mL BSA and 10 mM NaF for 20 min. The reaction was stopped by the addition of 0.1 mL solution of cAMP (50 mM) and ATP (75 mM). The solution was heated at 100°C for 1 min, and after cooling, the cAMP was isolated by the addition of 0.2 mL of 0.25 mM $ZnSO_4$ and 0.2 mL 0.25 mM $Ba(OH)_2$. The radioactivity remaining in the supernatant was counted in a liquid scintillation counter after the addition of 10 mL of scintillation fluid. The enzyme activity was expressed as pmol of cAMP formed/20 min/mg protein.

Protein and DNA determination. The protein content of prepared membranes was determined according to the procedure of Lowry and colleagues (24) using bovine serum albumin (BSA) as a reference standard, after solubilization of membrane preparations in 0.1 N NaOH and 1% sodium dodecylsulfate. The DNA content of cells was determined fluorometrically, using bibenzimidazole dye and calf thymus DNA as a reference standard, according to the procedure of Cesarone *et al.* (25).

Statistics. All results are reported as means ± SEM. The significance of the difference between the means was analyzed with paired and unpaired Student's *t*-test using StatPackets program (Walonick Associates, Minneapolis, MN).

RESULTS

Cellular lipid composition. Table 1 shows that there is no significant difference in cell protein content or DNA content of linoleate-, EPA- or DHA-enriched cells when compared to oleate-enriched controls. No difference in cell growth and viability was observed, as measured by cell counts and Trypan Blue exclusion assay, respectively, upon enrichment with any of the fatty acids (results not shown).

TABLE 1

Cell Viability and Protein and DNA Determination of Fatty Acid-Enriched Cells[a]

Fatty acid enrichment	Protein	DNA	Viability[b] (%)
Oleic	203 ± 30	9.4 ± 1.4	93.7 ± 2.2
Linoleic	201 ± 29	9.3 ± 1.3	93.1 ± 2.0
EPA[c]	211 ± 26	9.8 ± 1.5	92.5 ± 1.9
DHA[c]	208 ± 25	10.0 ± 1.0	93.4 ± 1.6

[a]Values are means ± SEM and are expresed as $\mu g/10^6$ cells. All experiments were done in duplicate (n = 6).
[b]Viability was determined by Trypan Blue exclusion.
[c]EPA, eicosapentaenoic acid; DHA, docosahexaenoic acid.

Cells treated with EPA contained 6.8% of the total fatty acids as EPA, and 7.5% as its elongation product 22:5. The DHA-treated cells contained 13% of total fatty acids as DHA, and 2.1% as 22:5n-3 (Table 2). The increase in the total n-3 fatty acid concentration (20:5 + 22:5 + 22:6) over the oleate control was similar with EPA- and DHA-treated cells (12.1 and 12.9%, respectively). Analysis of the fatty acid composition of total phospholipids and neutral lipids (triglycerides, fatty acids and cholesteryl esters) following their separation on silica gel TLC revealed that over 95% of total EPA or DHA was associated with the phospholipid fraction (results not shown). When compared to oleate-enriched cells, the linoleate-enriched cells showed a significant decrease in 16:0 and 18:1n-7 and an increase in 18:2, 18:1n-7 and 20:3n-6. Both EPA-and DHA-enriched cells showed significant decreases in 16:0, 18:1n-9 and 20:4n-6. The DHA-enriched cells also showed a significant decrease in 18:0. There was some retroconversion of 22:6 to 22:5 and 20:5. However, there was no increase in 22:6 in EPA-treated cells, even though 22:5 was increased. The phospholipid analysis revealed that only DHA enrichment resulted in significant decreases in Sph, PC, and PE (Table 3). The concentration of cholesterol decreased in both EPA- and DHA-treated cells. However, only DHA-enrichment resulted in a significant decrease in the free cholesterol/phospholipid ratio (Table 4). Although the absolute concentrations of all phospholipids decreased in DHA-enriched cells, there was no significant change in the Sph/PC ratio for either EPA- or DHA-enriched cells when compared to controls.

TABLE 2

Fatty Acid (FA) Composition of Total Membrane Lipids (wt%)[a]

Membrane	FA supplemented in the medium

[a]Values are means ± SEM; each experiment (n = 7) was analyzed in duplicate; nd, not detected.
[b]$P < 0.05$, compared to 18:1 control.
[c]$P < 0.001$, compared to 18:1 control.

TABLE 3

Phospholipid Analysis of Fatty Acid-Enriched Membranes[a]

Fatty acid enrichment	Sphingomyelin	PC	PE	PI + PS
Oleic	44.8 ± 2.0	164.9 ± 8.1	103.5 ± 3.4	46.1 ± 1.6
Linoleic	43.1 ± 1.7	161.3 ± 4.7	95.2 ± 3.0	46.5 ± 1.7
EPA	45.1 ± 1.4	165.3 ± 5.3	103.9 ± 3.7	46.4 ± 1.6
DHA	40.1 ± 1.6[b]	143.3 ± 4.0[b]	90.0 ± 3.5[b]	44.1 ± 3.3

[a]Values are means ± SEM, expressed as nmol/mg cell protein. All experiments were done in duplicate (n = 7). PI, phosphatidylinositol; PS, phosphatidylserine. The amount of lysoPC present was negligible in all cells. Other abbreviations as in Table 1.
[b]$P < 0.05$ compared to oleate controls.

Membrane fluidity. The fluidity of fatty acid-enriched plasma membranes was assessed by measuring the rotational mobility of TMA-DPH. As this probe does not enter the cells, it is believed to be specific for the outer leaflet of the plasma membrane of intact cells (16). Our results show that the fluorescence anisotropy as well as its static component, the limiting hindered anisotropy (17), of DHA-enriched membranes were significantly decreased when compared to oleate controls (Table 5). There were no significant changes in the linoleate- or EPA-treated cells.

Adenylate cyclase and 5′-nucleotidase activities. Adenylate cyclase activity was determined by the formation of cAMP from ATP after stimulation with fluoride, which specifically stimulates the regulatory protein subunit (22). Results presented in Table 6 show that there was no significant change in the basal activity upon linoleate, EPA or DHA enrichment. However, the NaF-stimulated activity was increased 20% upon DHA enrichment when compared to controls, but not with linoleate or EPA enrichment.

The activity of 5′-nucleotidase of plasma membranes was assayed by measuring the generation of adenosine from 5′-AMP. We observed a 27% increase in the activity of this enzyme in DHA-treated cells as compared to

TABLE 4

Cholesterol Levels (free cholesterol) and Lipid Ratios of Fatty Acid-Enriched Cells[a]

Fatty acid enrichment	FC	FC/PL	Sph/PC
Oleic	20.4 ± 1.1	0.40 ± 0.03	0.27 ± 0.02
Linoleic	19.4 ± 0.9	0.39 ± 0.05	0.26 ± 0.02
EPA	19.0 ± 1.0[b]	0.37 ± 0.04	0.27 ± 0.01
DHA	15.6 ± 0.8[c]	0.34 ± 0.03[b]	0.28 ± 0.02

[a]All values are means ± SEM. Free cholesterol (FC) values are expressed as μg/mg cell protein. Ratios are expressed as mol/mol. Experiments (n = 6) were done in duplicates. PL, phospholipids; Sph, sphingomyelin; PC, phosphatidylcholine.
[b]$P < 0.05$, compared to oleate controls.
[c]$P < 0.001$ compared to oleate controls.

TABLE 5

Fluorescence Anisotropy of Fatty Acid-Enriched Membranes at 37°C[a]

Fatty acid enrichment	Anisotropy (r)	Limiting hindered anisotropy
Oleic	0.244 ± 0.013	0.219 ± 0.008
Linoleic	0.240 ± 0.012	0.220 ± 0.008
EPA	0.238 ± 0.015	0.218 ± 0.010
DHA	0.210 ± 0.012[b]	0.184 ± 0.009[b]

[a]Anisotropy (r) was calculated following the equation: $r = 2 \times P/3-P$; where P is the polarization value. Limiting hindered anisotropy was determined by the equation: $r = (4r/3) - 0.1$. Values represent means ± SE of six experiments done in duplicates (at least six measurements of each). Abbreviations as in Table 1.
[b]$P < 0.05$ compared to oleate controls.

TABLE 6

Adenylate Cyclase and 5′-Nucleotidase Activities of Fatty Acid-Enriched Membranes[a]

Fatty acid enrichment	Adenylate cyclase		5′-Nucleotidase
	Basal	+NaF	
Oleic	94 ± 21	638 ± 84	64 ± 13
Linoleic	88 ± 21	600 ± 92	70 ± 12
EPA	86 ± 19	672 ± 109	73 ± 14
DHA	90 ± 22	780 ± 94[b]	86 ± 11[b]

[a]Values are means ± SEM for nine experiments done in duplicate. Adenylate cyclase activity is expressed as pmol adenosine 3′,5′-monophosphate formed/20 min/mg protein. 5′-Nucleotidase activity is expressed as change in absorbance units at 260 nm/30 min/mg protein ($\times 10^2$). Abbreviations as in Table 1.

oleate controls (Table 6). No significant change was observed upon linoleate or EPA enrichment.

DISCUSSION

Although both EPA and DHA belong to the n-3 family of fatty acids, and are interconverted in mammalian systems, they exhibit significantly different physical characteristics *in vitro*. Although its "helical structure" allows DHA to behave more like a saturated fatty acid, DHA is still more fluidizing than EPA (26). Studies have also shown that these fatty acids are differentially incorporated into various tissues (9). Taken together, it thus also seemed possible that they have different metabolic effects at the cellular level.

The results presented here show that EPA and DHA do, indeed, have differential effects on membrane structure and function in human skin fibroblasts. Analysis of the fatty acid composition of both EPA- and DHA-enriched cells revealed a significant decrease in arachidonic acid (20:4) content. This is in agreement with previous studies (27) and supports the view that the n-3 PUFA either compete with 20:4 for the *sn*-2 position of membrane phospholipids or inhibit the formation of 20:4 from linoleic acid (18:2) (27). As we found no significant decrease in 18:2 upon either EPA or DHA enrichment, it appears that both mechanisms are active in fibroblasts. Treatment of cells with EPA resulted in a 7.5% enrichment of the membrane with 22:5, suggesting elongase activity in our system.

Only DHA enrichment resulted in a significant decrease in Sph, PE and PC. Because there was no difference in the growth of DHA-treated cells when compared to oleate- or linoleate-enriched cells, it appears that DHA specifically inhibited phospholipid synthesis. It is well established that ω3 fatty acids inhibit cytidinetriphosphate:phosphocholine cytidylyltransferase (28) and phosphatidate phosphohydrolase (29), two key enzymes in phospholipid synthesis. Thus, it is likely that this mechanism was active upon DHA-, but not EPA enrichment.

Cells enriched with DHA showed a significant increase in membrane fluidity as measured by TMA-DPH anisotropy. Other indicators of membrane fluidity were also altered upon DHA enrichment. These include decreases in membrane cholesterol and 18:0 levels and a reduction in the free cholesterol/phospholipid ratio. Although we observed a significant decrease in the cholesterol content of EPA-enriched cells, there was no change in their membrane fluidity. This may have several reasons. First, the membranes were enriched with EPA only up to 6.8% of total membrane fatty acids, compared with 13% for DHA observed upon DHA treatment. Second, there was no significant decrease in 18:0 concentration or in the free cholesterol/phospholipid ratio upon EPA enrichment. Finally, the elongation product of EPA, docosapentaenoic acid (22:5), which comprised 7.5% of the total fatty acids, confers relative rigidity to the membrane when compared to either 20:5 or 22:6 (26). Our observation of no change in membrane fluidity upon linoleate enrichment is at variance with some studies (30) and in agreement with others (31). Possible reasons for the disparate findings include differences in cell types, extent of incorporation of linoleate, and the techniques employed to determine membrane fluidity. Computer modelling of various diacylglycerols (DG) showed that the oleate-containing DG are less orderly packed than those containing linoleate (32). This too would suggest theoretically that the fluidity of oleate- and linoleate-enriched membranes may be different. However, we observed no change in the cholesterol content or free cholesterol/phospholipid ratio of linoleate-treated cells when compared to oleate controls. These factors most likely account in part for the lack of change in fluidity observed upon linoleate enrichment.

It has been suggested that the activity of 5′-nucleotidase depends on the Sph or PC content of the membrane (33). Interestingly, we observed an increase in the activity of this enzyme despite a reduction in these phospholipids upon DHA enrichment. This would suggest that another mechanism, such as changes in the biophysical properties of the membranes, was responsible for the observed increased activity. For example, an increase in the lipid disorder would allow the enzyme more conformational freedom, and increase its activity by decreasing the energy of activation. It is also possible that a modified lipid environment can lead to stabilization of a more active conformation of the enzyme.

The activity of fluoride-stimulated adenylate cyclase was also increased upon DHA enrichment. The activity of this enzyme is believed to be dependent upon the

membrane cholesterol content (33). Our observations of increased activity of this enzyme and a concomitant decrease in the free cholesterol/phospholipid ratio upon DHA enrichment is at variance with some reported work (34), but in agreement with some other investigations (15). It has been suggested that an optimal lipid environment is necessary for the maximal activity of this enzyme (34), and it is possible that DHA treatment, which decreases both the free cholesterol/phospholipid ratio and membrane viscosity, provides such an environment. The increased disorder in membrane lipids would probably allow a more efficient coupling of adenylate cyclase's regulatory proteins and catalytic subunits. Our observation of no change in the basal activity of the enzyme is in agreement with other studies, as it has been postulated that the basal activity is very resistant to changes in membrane lipid composition (9,15,35).

In conclusion, EPA and DHA have differential effects on membrane lipid composition, fluidity and function of human skin fibroblasts. Recently Bates *et al.* (36) reported that treatment of neutrophils with DHA, but not with EPA, increased the neutrophil-mediated endothelial detachment, showing that these fatty acids exert differential effects on neutrophils also. Our recent work also showed a significant increase in LDL receptor function in DHA- but not in EPA-enriched fibroblasts (E. Brown and P.V. Subbaiah, unpublished observations). Furthermore, recent studies from our laboratory suggested that the positional specificity of plasma lecithin:cholesterol acyltransferase is altered in the presence of 16:0/22:6 PC, but not in the presence of 16:0/20:5 PC, resulting in the synthesis of saturated cholesteryl ester in the presence of the former (37). These differential effects of EPA and DHA on membrane and lipoprotein metabolism may contribute to the known differences in their anti-atherogenic properties (6,7).

Comparison of Linoleic Acid and Eicosapentaenoic Acid Incorporation into Human Breast Cancer Cells

Mary Ann Hatala*, Jodie Rayburn and **David P. Rose**

Division of Nutrition and Endocrinology, American Health Foundation, Valhalla, New York 10595

To gain some insight into the mechanisms involved in the opposing effects of linoleic acid (LA) and eicosapentaenoic acid (EPA) on the growth and invasiveness of MDA-MB-435 human breast cancer cells, the dynamics of the uptake by cells and the incorporation of [^{14}C]LA and [^{14}C]EPA into major lipid and phospholipid pools, as well as the effects of unlabeled EPA or LA on the uptake and distribution of [^{14}C]LA or [^{14}C]EPA, respectively, were examined. Cells were exposed to [^{14}C]LA (1.28 μg/mL) or [^{14}C]EPA (1.0 μg/mL) and unlabeled EPA or LA, respectively, at 0, 1, 4 and 16 μg/mL for 24 h in serum-free media. The uptake of each fatty acid (FA) was linear over time and was not affected by the presence of the opposing FA. For both FA, 80–90% was incorporated into the phospholipid fraction with the remaining 10–20% in neutral lipids. The relative distribution profile of [^{14}C]LA among the phospholipid classes indicated a preferential incorporation into phosphatidylcholine (65%), whereas [^{14}C]EPA was mostly found in phosphatidylethanolamine (58%). In the presence of unlabeled EPA or LA at various concentrations, corresponding dose-dependent shifts of [^{14}C]LA or [^{14}C]EPA from the phospholipid to the neutral lipid pool were noted, which did not alter the relative distribution of the FA among the phospholipid classes. Exogenous exposure to EPA or LA increased its content in membrane phospholipids while concurrently decreasing LA or EPA content, respectively, in a dose-dependent manner. Arachidonic acid content of membrane phospholipids remained constant. The divergent distribution profiles of LA and EPA within the phospholipid compartment provides some insight into the mechanisms of their opposing effects on MDA-MB-435 cell growth and invasiveness. Also, the effects of LA and EPA on the uptake and distribution of their opposing FA shed some light on the mechanisms mediating their competitive effects.

***Lipids* 29, 831–837 (1994).**

Modulation of chemically-induced mammary carcinogenesis by both the level and type of dietary fatty acids (FA) has been demonstrated in rodent models (1–4). Moreover, the growth of transplantable rodent mammary carcinomas has been shown to be stimulated by feeding diets rich in n-6 FA and to be suppressed by n-3 FA-rich diets (5–8). Although several mechanisms may be involved in these dietary effects, most investigators have emphasized a role for prostaglandins and leukotrienes derived from linoleic acid (LA) in stimulating carcinoma development and progression and an inhibitory influence of n-3 FA on eicosanoid biosynthesis (2,4,7).

Studies from our laboratory have indicated (9–15) that FA also influence the growth of human breast cancer cells, as well as expression of the metastatic phenotype. Growth of human breast cancer cell lines in culture was stimulated by LA, an n-6 FA, whereas the n-3 FA eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA) exerted inhibitory effects (9,10); these two classes of FA also had corresponding effects on the capacity of MDA-MB-435 human breast cancer cells to invade through a reconstituted basement membrane in an *in vitro* assay (11). In both situations, these opposing effects of the n-6 and n-3 FA have been associated with inhibition of lipoxygenase-mediated eicosanoid synthesis by the tumor cells (10–12).

Furthermore, a high-fat diet rich in LA stimulated the growth and metastasis of MDA-MB-435 cells when injected into the mammary fat pads of athymic nude mice (13,14), and a high dietary intake of menhaden oil, rich in n-3 FA, suppressed the growth and metastasis of this cell line in the nude mouse model (15).

In addition to direct inhibitory effects on enzymes involved in arachidonate metabolism, the divergent effects of n-6 and n-3 FA on breast cancer growth and metastasis may directly involve the cell membrane phospholipids which play key roles in intracellular signalling, including the generation of eicosanoids (16). Moreover, changes in the FA composition of the cell membrane phospholipids can alter these pathways (17) and, as membrane composition is influenced by dietary FA (18,19), nutritional factors are capable of influencing cell signalling pathways.

The present study was undertaken to define and compare the cellular uptake and the incorporation of LA and EPA into the major phospholipid and neutral lipid pools of MDA-MB-435 cells *in vitro*. The influence of EPA and LA on the uptake and distribution profiles of LA and EPA, respectively, was also established as a preliminary investigation of the competitive effects between n-6 and n-3 FA.

MATERIALS AND METHODS

Materials. [1-^{14}C]Linoleic acid (55 mCi/mmol) and [1-^{14}C]eicosa-5,8,11,14,17-pentaenoic acid (58 mCi/mmol) were purchased from Amersham Corp. (Arlington Heights, IL). Lipid and phospholipid standards and insulin were purchased from Sigma Chemical Company (St. Louis, MO), and delipidized bovine serum albumin (BSA) from Collaborative Biomedical Products (Bedford, MA). Thin-layer chromatography (TLC) plates were

Abbreviations: AA, arachidonic acid; ANOVA, analysis of variance; BSA, bovine serum albumin; DHA, docosahexaenoic acid; EPA, eicosapentaenoic acid; FA, fatty acid(s); FBS, fetal bovine serum; HETE, hydroxyeicosatetraenoic acid; IMDM, Iscove's modified Dulbecco's medium; LA, linoleic acid; PC, phosphatidylcholine; PE, phosphatidylethanolamine; PI, phosphatidylinositol; PLA_2, phospholipase A_2; PS, phosphatidylserine; TLC, thin-layer chromatography.

from Whatman Inc. (Clifton, NJ); Triton X-100 (scintillation grade) and Budget-Solve scintillation fluid were obtained from Research Products International Corporation (Mount Prospect, IL). For cell culture, Iscove's modified Dulbecco's medium (IMDM) was obtained from Gibco (Grand Island, NY), fetal bovine serum (FBS) from Upstate Biotechnologies Inc. (Lake Placid, NY) and cell culture plates from Corning (Corning, NY). Solvents were of high purity high-performance liquid chromatography grade.

Cell culture. The MDA-MB-435 human breast cancer cell line, which is estrogen-independent and estrogen receptor negative (20), was provided by J.E. Price (M.D. Anderson Cancer Center, Houston, TX). Cells were cultured in IMDM supplemented with 5% FBS, penicillin (100 U/mL), and streptomycin (100 µg/mL) in a 95% air/5% CO_2 incubator. Cell passages from 5 to 28 were used.

Experimental conditions. Cells were plated in 60-mm culture plates at a density of 2.0×10^4 cells/cm^2 and cultured for 24 h in 5% FBS-supplemented IMDM. The medium was then changed to serum-free IMDM containing insulin (10 µg/mL) and delipidized BSA (1.25 mg/mL). For the first experimental set, 1.0 µCi of [^{14}C]LA (final concentration 1.28 µg/mL) was added to each plate. Duplicate plates also received unlabeled EPA at a final concentration of 0.0, 1.0, 4.0 or 16.0 µg/mL. For the second experimental set, a mixture of 0.1 µCi of [^{14}C]eicosa-5,8,11,14,17-pentaenoic acid and unlabeled EPA was added to each plate to yield a final concentration of 1.0 µg/mL. Duplicate plates also received unlabeled LA at a final concentration of 0.0, 1.0, 4.0 or 16.0 µg/mL. Cells were exposed to the FA for 24 h. All FA were prepared in USP ethanol (200 proof), and the final ethanol concentration in the culture media was 0.1%.

For the preparation of cells for FA analysis by gas chromatography, cells were plated in 100-mm culture plates at 2.0×10^4 cells/cm^2 and received unlabeled FA at concentrations stated in the above protocols. Five plates of cells per condition were treated, washed as described later, scraped, and pooled into 500 µL phosphate buffered saline. Aliquots (10 µL) were removed for protein determination (Bio-Rad, Richmond, CA).

Cellular uptake of [^{14}C]fatty acids. Aliquots of media from labeled cells were removed and counted at various time points from 0–24 h to determine FA uptake. Percent uptake was calculated as:

$$\frac{(\text{cpm at time 0}) - (\text{cpm at time point})}{\text{cpm at time 0}} \times 100$$

Results represent the mean ± SE of three experiments performed in duplicate.

Analysis of [^{14}C]fatty acid distribution among cellular phospholipids and neutral lipids. Cells were washed once with serum-free IMDM containing insulin (10 µg/mL) and delipidized BSA to remove unincorporated FA, and twice with PBS. Cells were scraped into 500 µL PBS, and lipids were extracted with 2.25 mL of $CHCl_3$/MeOH (1:2, vol/vol), 0.1 mL distilled H_2O, 0.75 mL $CHCl_3$ and 0.75 mL 4M KCl, according to the method of Bligh and Dyer (21). The $CHCl_3$/MeOH (1:2, vol/vol) solvent mixture contained phosphatidylcholine (PC), phosphatidylethanolamine (PE), phosphatidylinositol (PI), and phosphatidylserine (PS) standards. The extract was dried under N_2, resuspended in 200 µL $CHCl_3$/MeOH (1:2, vol/vol) and applied to a 60A silica gel TLC plate. Phospholipids, neutral lipids and a triglyceride standard were separated using the solvent system chloroform/methanol/acetic acid (65:45:4, by vol) (22). The following R_f values were determined in this solvent system: PC (0.07), PE (0.42), PI/PS (0.22), and triglyceride (neutral lipid; 0.85). Lipids were made visible by exposure to iodine vapors, scraped from the plate, eluted from the silica gel with methanol/Triton X-100 (6:1, vol/vol), and quantitated by scintillation counting. Results represent the mean ± SE of three independent experiments performed in duplicate.

FA analysis by gas chromatography. Lipids were extracted according to the method of Folch *et al.* (23). Briefly, 0.2 volumes of 0.12 M KCl and 4.5 mL of $CHCl_3$/MeOH (2:1, vol/vol) containing 50 µg/mL dipentadecanoyl phosphatidylcholine as internal standard were added to 0.5 mL of cell suspension. The mixture was vortexed for 2 min, centrifuged at $1000 \times g$ for 10 min, and the lower phase containing the lipids was evaporated to dryness under N_2. The residue was reconstituted in 6 mL of acetone saturated with $MgCl_2$ and stored overnight at –20°C. The acetone phase containing neutral lipids was discarded, and the remaining precipitate (phospholipid phase) was redissolved in methanol/benzene (4:1, vol/vol). Transesterification of FA was performed as described by Lepage and Roy (24). The FA methyl esters were separated and quantified by gas chromatography (Hewlett Packard 5890A; Hewlett-Packard, Palo Alto, CA) on a 30 m × 0.25 mm capillary column (Supelco, Bellefonte, PA). Helium was used as carrier gas, and the temperature was programmed from 145 to 181°C at 1°C/min. Individual FA methyl esters were identified by comparison with known standards (Nu-Chek-Prep, Elysian, MN). Single determinations from two independent experiments are presented.

Statistics. Data were analyzed using the SigmaStat program and one-way analysis of variance (ANOVA) or, when necessary, the Kruskal-Wallis ANOVA on Ranks, followed by the Student Newman Keuls Test. Values of $P < 0.05$ were considered significant.

RESULTS

Time-course studies were performed to establish a profile for the uptake of LA and EPA by MDA-MB-435 cells and to determine the effect of competition between the two FA on their respective uptakes. MDA-MB-435 cells steadily accumulated [^{14}C]LA and [^{14}C]EPA during the first 8–16 h of exposure, after which little further accumulation was noted (Fig. 1). The initial rate of cellular uptake was greater for [^{14}C]EPA with 3-fold and 1.6-fold higher rates from 0–4 h and 4–16 h, respectively, as compared to [^{14}C]LA. Uptake was nearly maximal (~90%) at 16 h for both FA; for convenience, the 24-h time point was chosen for subsequent FA incorporation experiments. [^{14}C]LA (1.28 µg/mL) uptake was not af-

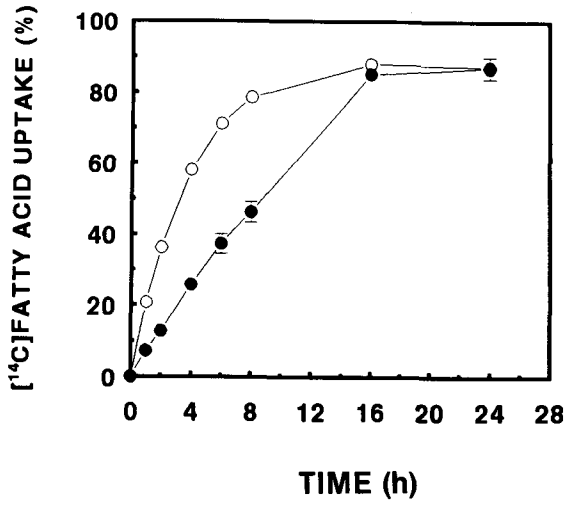

FIG. 1. Time-course of uptake of [^{14}C]linoleic acid (LA) and [^{14}C]eicosapentaenoic acid (EPA) into MDA-MB-435 cells. Cells (2×10^4 cells/cm^2) were treated with 1.0 μCi of [^{14}C]LA (●) or 0.1 μCi of [^{14}C]EPA (○) for 24 h in serum-free media. Aliquots of media were counted as described in the Materials and Methods section to determine percent fatty acid uptakes. Data are expressed as mean ± SE of three experiments performed in duplicate.

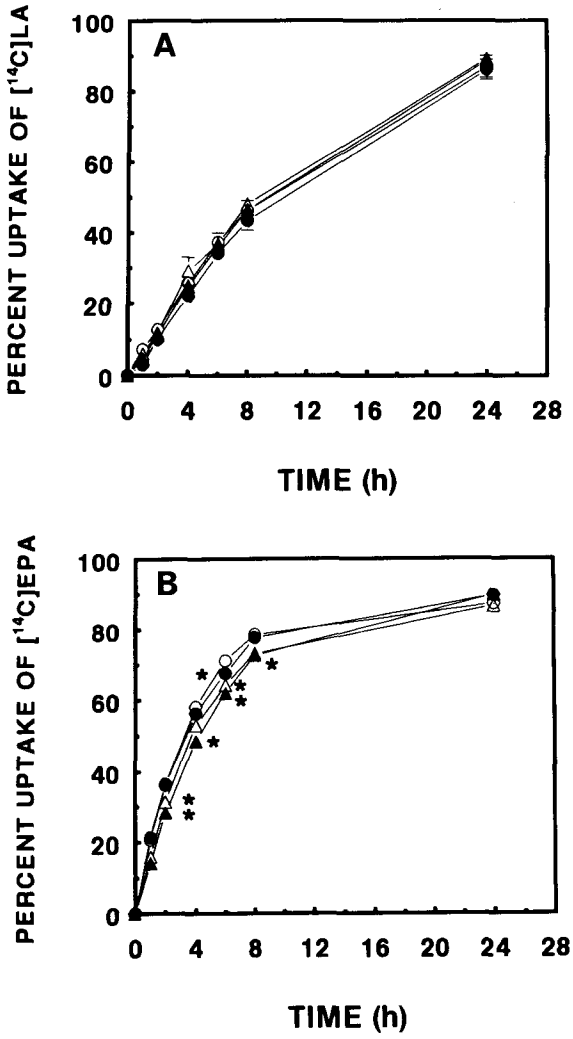

FIG. 2. A. Effect of EPA on the uptake rate of [^{14}C]LA into MDA-MB-435 cells. Cells were exposed to 1.0 μCi of [^{14}C]LA (1.28 μg/mL final concentration) plus 0 (○), 1 (●), 4 (△) or 16 (▲) μg/mL unlabeled EPA for 24 h in serum-free media. Aliquots of media were counted to determine percent [^{14}C]LA uptake. B. Effect of LA on the uptake rate of [^{14}C]EPA into MDA-MB-435 cells. Cells were exposed to 0.1 μCi of [^{14}C]EPA (1.0 μg/mL final concentration) plus 0 (○), 1 (●), 4 (△) or 16 (▲) μg/mL unlabeled LA for 24 h in serum-free media. Aliquots of media were counted to determine percent [^{14}C]EPA uptake. Data represent mean ± SE of three experiments performed in duplicate; *$P < 0.05$ vs. 0 μg/mL LA. Abbreviations as in Figure 1.

fected by exogenous supplementation of EPA at concentrations of 1, 4 or 16 μg/mL (Fig. 2A). Similarly, LA did not substantially reduce the [^{14}C]EPA uptake rate, although a slight dose-dependent inhibition reached statistical significance (Fig. 2B).

Comparison of the degree of esterification of the labeled FA into the two lipid classes revealed similar profiles with 80% of [^{14}C]LA and 93% of [^{14}C]EPA incorporated into phospholipids and 20 and 7% into neutral lipids, respectively (Fig. 3A). However, the relative distribution of incorporated [^{14}C]LA and [^{14}C]EPA differed substantially among the phospholipid fractions. Of the phospholipid-associated [^{14}C]LA, 65% of [^{14}C]LA was incorporated into PC, and 21% and 14% into the PE and PI/PS fractions, respectively. For [^{14}C]EPA, the major phospholipid incorporation site was PE with 58% incorporation, followed by PC with 25% and PI/PS with 17% (Fig. 3B). These proportional distributions for [^{14}C]LA and [^{14}C]EPA within the phospholipid compartment of MDA-MB-435 cells were not altered by concurrent exposure to graded concentrations of unlabeled EPA or LA, respectively (data not shown). Free FA accounted for only 1–3% of the total lipids under all experimental conditions.

The effects of unlabeled EPA and LA on the incorporation of [^{14}C]LA and [^{14}C]EPA, respectively, into the lipid pools of MDA-MB-435 cells were examined next. Exposure of cells to [^{14}C]LA plus graded concentrations of unlabeled EPA (1, 4 and 16 μg/mL) significantly reduced [^{14}C]LA incorporation into the phospholipid fraction in a concentration-dependent manner (Fig. 4A). However, the sensitivity of the effect of EPA on [^{14}C]LA incorporation into phospholipids was not relatively marked since 4-fold and 16-fold greater amounts were required to produce 25 and 60% reductions, respectively. A similar profile was obtained for the effect of unlabeled LA on the incorporation of [^{14}C]EPA into the phospholipid fraction (Fig. 4B), which may suggest that LA and EPA are equally sensitive to the effects of its opposing FA. For both experimental sets, the decreases in phospholipid incorporation were accompanied by corresponding increases of the [^{14}C]FA into the neutral lipid compartment.

Further analyses of the effects of unlabeled EPA and LA on the distribution of [^{14}C]LA and [^{14}C]EPA, respectively, among the three phospholipid fractions (PC, PE, PI/PS) were performed to determine the specific phospholipid involved in attenuation of [^{14}C]FA incorpora-

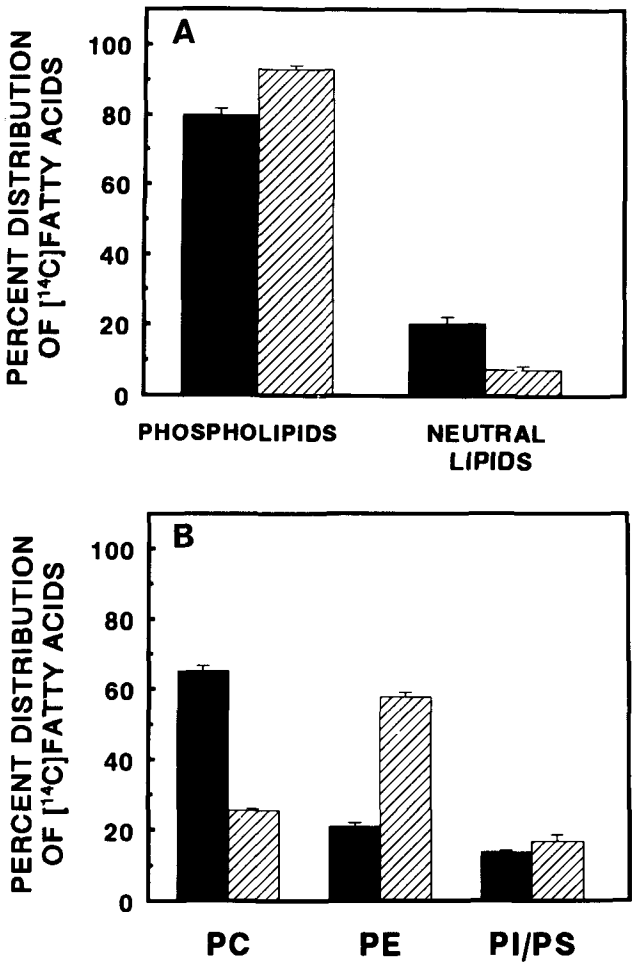

FIG. 3. A. Incorporation of [^{14}C]LA and [^{14}C]EPA into the phospholipid and neutral lipid compartments of MDA-MB-435 cells. Cells were exposed to 1.0 μCi of [^{14}C]LA (solid bar) or 0.1 μCi of [^{14}C]EPA (hatched bar) for 24 h in serum-free media. Lipids were extracted, separated by thin-layer chromatography, and counted to determine the percent incorporation of [^{14}C]LA and [^{14}C]EPA into phospholipids and neutral lipids. B. Percent distribution of [^{14}C]LA (solid bar) and [^{14}C]EPA (hatched bar) among the phospholipid fractions. Data are presented as a percentage of total phospholipids. Values represent mean ± SE of three experiments performed in duplicate. Abbreviations as in Figure 1; PC, phosphatidylcholine; PE, phosphatidylethanolamine; PI/PS, phosphatidylinositol/phosphatidylserine.

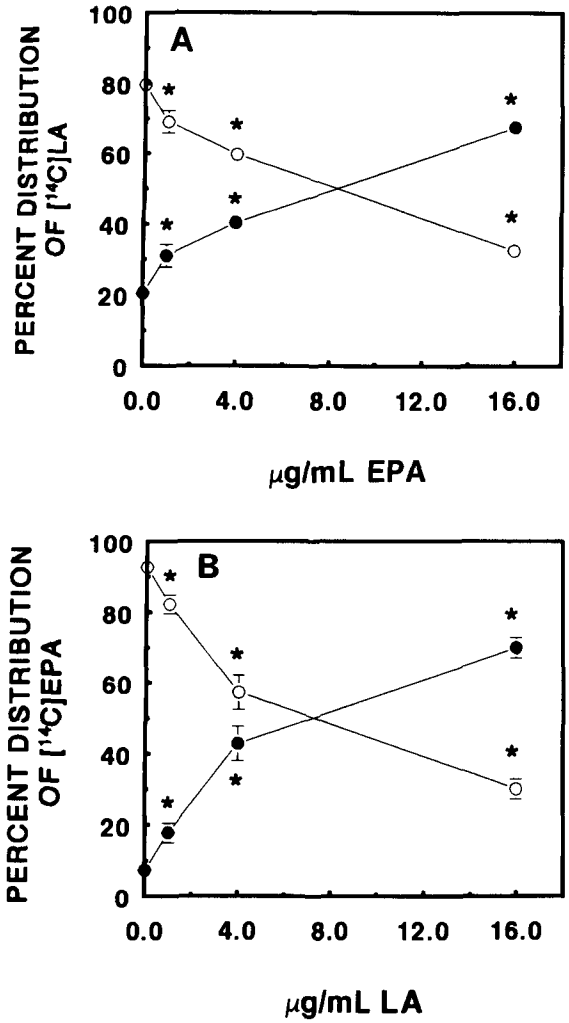

FIG. 4. A. Effect of EPA on [^{14}C]LA incorporation into phospholipid and neutral lipid compartments of MDA-MB-435 cells. Cells were exposed to 1.0 μCi of [^{14}C]LA and unlabeled EPA as described in the Materials and Methods section. Lipids were extracted, separated by TLC, and counted to determine percent incorporation of [^{14}C]LA into phospholipid (○) and neutral lipids (●); *$P < 0.05$ vs. 0 μg/mL EPA. B. Effect of LA on [^{14}C]EPA incorporation into phospholipid and neutral lipid compartments of MDA-MB-435 cells. Cells were exposed to 0.1 μCi of [^{14}C]EPA and unlabeled LA as described in the Materials and Methods section. Lipids were extracted, separated by TLC, and counted to determine percent incorporation of [^{14}C]EPA into phospholipid (○) and neutral lipids (●). Values represent the mean ± SE of three experiments performed in duplicate; *$P < 0.05$ vs. 0 μg/mL LA. Abbreviations as in Figure 1.

tion. Unlabeled EPA dose-dependently decreased [^{14}C]LA incorporation into PC, PE and PI/PS; at the highest dose (16 μg/mL EPA), [^{14}C]LA incorporation was reduced to ~40% (Fig. 5A). Similarly, [^{14}C]EPA incorporation into PC, PE and PI/PS was reduced by unlabeled LA (Fig. 5B) although [^{14}C]EPA appeared more sensitive to the effects of LA as less incorporation (~25%) was observed in the presence of 16 μg/mL LA. For both [^{14}C]LA and [^{14}C]EPA, the decrement of incorporation by its respective opposing FA was relatively equal in each phospholipid fraction.

Table 1 depicts the FA profile of the phospholipid fraction of MDA-MB-435 cells exposed to graded concentrations of LA and EPA. Exposure of cells to 1.3 μg/mL LA, plus increasing concentrations of EPA, resulted in a dose-dependent decrease in the LA content of membrane phospholipids and a corresponding increase in EPA content. Conversely, treatment of cells with 1.0 μg/mL EPA plus graded concentrations of LA produced a dose-related reduction of EPA composition of membrane phospholipids and a corresponding increase in LA content. In both experimental sets, no significant changes in arachidonic acid (AA) content of the phospholipids were noted. Also, the contents of palmitic and stearic acids were not altered. Representation of the data normalized

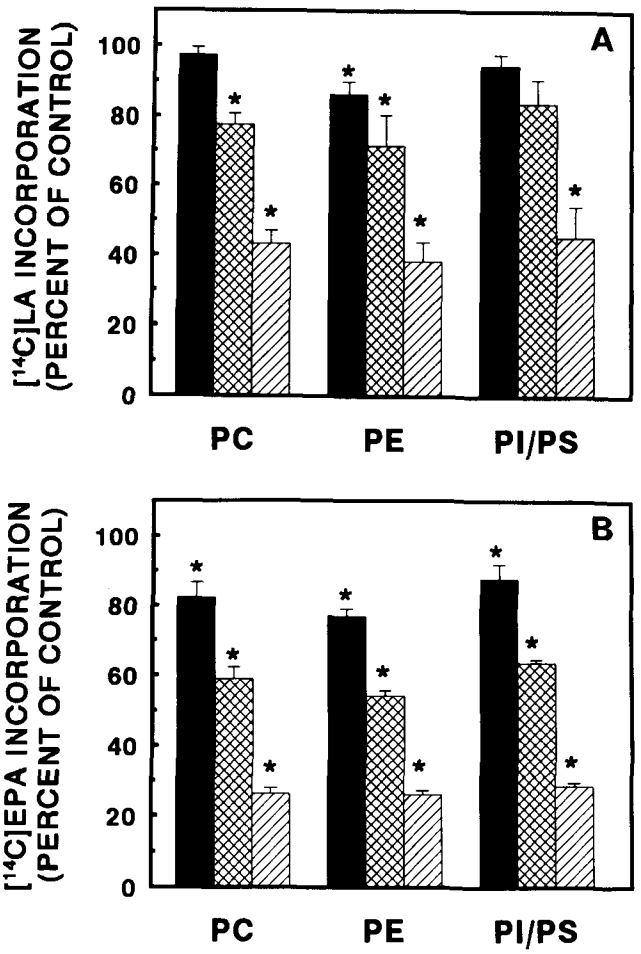

FIG. 5. A. Effect of EPA on the incorporation of [^{14}C]LA into phosphatidylcholine (PC), phosphatidylethanolamine (PE), and phosphatidylinositol/serine (PI/PS) fractions of MDA-MB-435 cells. Cells were exposed to 1.0 μCi of [^{14}C]LA and 1 (solid bar), 4 (double hatched-bar) or 16 (single-hatched bar) μg/mL unlabeled EPA as described in the Materials and Methods section. The incorporation into each phospholipid fraction is expressed as a percentage of the control (no EPA exposure) set at 100%. B. Effect of LA on [^{14}C]EPA incorporation into PC, PE and PI/PS fractions of MDA-MB-435 cells. Cells were exposed to 0.1 μCi of [^{14}C]EPA and 1 (solid bar), 4 (double-hatched bar), or 16 (single-hatched bar) μg/mL unlabeled LA as described in the Materials and Methods section. The incorporation into each phospholipid fraction is expressed as a percentage of the control (no LA exposure) set at 100%. to protein yielded the same trends as illustrated in Table 1 (data not shown).

DISCUSSION

As far as we are aware, analyses of the distribution profiles of LA and EPA in cultured human breast cancer cells have not been reported previously. The present study documents the incorporation of LA and EPA into the major lipid pools of MDA-MB-435 cells and demonstrates that this incorporation is altered by the competing FA. LA and EPA were found to be preferentially esterified to phospholipids, which is consistent with the phospholipid pool constituting the major site of FA incorporation in both cultured normal and transformed human cells (25–30).

The primary difference in the distribution profiles of LA and EPA was that LA was preferentially esterified to PC whereas EPA was mostly incorporated into PE. This pattern of distribution may suggest a possible biochemical mechanism for their opposing biological effects, which involve the substrate specificity of phospholipase A_2 (PLA_2), the rate-limiting enzyme in the biosynthesis of eicosanoids. If PC is the preferential substrate for PLA_2 in MDA-MB-435 cells, and PC the primary incorporation site for LA, then PLA_2 activity would result in release of free LA, which would be subsequently converted to AA and ultimately metabolized to series two eicosanoids. Alternatively, if PLA_2 exhibits substrate specificity for PE, the phospholipid which incorporates EPA, then PLA_2-mediated release of EPA would generate series three eicosanoids with their different effects. Therefore, the distinct phospholipid esterification sites of the two FA can potentially lead to the generation of a differing spectrum of eicosanoids with divergent biological actions.

The uptake of the n-6 and n-3 FA was not suppressed by up to 16-fold greater concentrations of the opposing FA, indicating that interference of cellular uptake does not account for the competitive effects of LA and EPA. However, EPA was effective in channeling LA from the phospholipid to the neutral lipid pool; LA similarly altered the distribution of EPA. These results concur with earlier reports of competition between FA for esterification into phospholipids. For example, in cultured fibroblasts, EPA and AA have been shown to independently inhibit incorporation of LA into the total phospholipid fraction while concurrently shunting LA into triacylglycerols (28). Likewise, in neuroblastoma cells, LA incorporation into triacylglycerols increased markedly, and incorporation into phospholipids decreased in the presence of increasing concentrations of 18:3n-3, 18:3n-6, and 20:3n-6 FA (25). It has been suggested that the competition for FA esterification into phospholipids is consistent with a relatively restricted phospholipid acceptor pool which does not expand in response to an influx of exogenous FA (25,28). However, the neutral lipid pool does appear to enlarge to store the excess FA, thereby serving as a cytoplasmic lipid storage site for the displaced FA. In the present study, the shunting of LA or EPA by its opposing FA from the phospholipid compartment, a site involved in intracellular signaling, to a neutral lipid reserve pool suggests an alternate mechanism for the competitive effects of LA and EPA.

A number of investigators have examined the LA and EPA content of chemically-induced mammary carcinomas or transplantable tumor cells in rodents fed diets of differing FA composition; in general, the tumor FA profiles reflected the dietary intakes (2–4,7,31). Jurkowski and Cave (3) reported that tumorigenesis was suppressed as the level of menhaden oil in the diet increased and that levels of EPA and DHA also increased in *N*-nitrosomethylurea-induced rat mammary carcino-

[a]Cells were plated at 2×10^4 cells/cm^2 (100-mm plates) and treated for 24 h with unlabeled LA and EPA at the indicated concentrations. For each experiment (Expt.), five plates of cells per condition were treated and pooled for fatty acid analysis. Results are reported as μg fatty acid per five plates of cells. Single determinations from two separate experiments are presented. ND, not detected.

mas; there were also corresponding slight decreases in LA and AA. Similarly, Gabor and Abraham (8) demonstrated that feeding fish oil to mice bearing a transplantable mammary adenocarcinoma suppressed tumor growth; also, there was a reduction in the proportion of AA in the tumor total FA content as the n-3 FA increased. In the present study of cultured MDA-MB-435 cells, the relative proportions of LA and EPA in the membrane phospholipids were determined by their concentrations in the medium. Yet, there were no changes in AA, an n-6 FA, which is produced from LA. The relatively short exposure time (24 h) of the cells to the FA may be responsible for the lack of change in AA content. In contrast to this result of a short-term *in vitro* study, we have reported that solid tumors formed by this breast cancer cell line in the mammary fat pads of nude mice show significant reductions in both phospholipid LA and AA, together with prostaglandin E_2, when dietary n-3 FA were increased by feeding a 17% menhaden oil/5% corn oil diet for 12 wk (32).

Growth of estrogen-independent human breast cancer cell lines *in vitro* are stimulated by LA, an effect which is associated with enhanced biosynthesis of lipoxygenase products, principally 12- and 15-(*S*)-hydroxyeicosatetraenoic acids (HETE), and is blocked by esculetin, a selective lipoxygenase inhibitor (10; and Liu, X.-H., Connolly, J.M., and Rose, D.P., manuscript submitted for publication). Moreover, the growth and metastasis of MDA-MB-435 cell solid tumors in athymic nude mice is inhibited by feeding EPA or DHA, and here there are also highly significant reductions in tumor tissue 12-HETE and 15-HETE, together with prostaglandin E_2, concentrations (Rose, D.P., Connolly, J.M., Rayburn, J., and Coleman, M., manuscript submitted for publication). While these observations imply the involvement of the eicosanoids in the opposing effects of dietary n-6 and n-3 FA *in vivo* (14,15), other mechanisms must also be considered. For example, the FA composition of the membrane can alter the activity of membrane-bound enzymes (33), some of which play key roles in intracellular signalling. Also, the cell membrane FA composition determines its fluidity (34) which, in turn, may influence the accessibility of protein hormones (33,35), and perhaps growth factors, to their membrane-associated receptors.

In conclusion, this study establishes the distribution profiles of LA and EPA in a human breast cancer cell line and also defines preliminary competitive effects of the two opposing FA on cellular uptake and phospholipid incorporation. These data provide a first step toward future investigations which will be designed to elucidate the biochemical mechanisms responsible for the divergent effects of LA and EPA on the growth and invasiveness of human breast cancer cells.

Levels of Polyunsaturated Fatty Acids in Tissues from Zinc-Deficient Rats Fed a Linseed Oil Diet

Klaus Eder and **Manfred Kirchgessner***

Institut für Ernährungsphysiologie, Technische Universität München, 85350 Freising, Germany

The effect of zinc deficiency on the levels of n-6 and n-3 polyunsaturated fatty acids (PUFA) in lipids from tissues of rats fed a diet containing linseed oil was investigated. Rats were fed either a control diet (25 mg Zn/kg) or a zinc-deficient diet (0.8 mg Zn/kg) for 10 d. To avoid energy and nutrient deficiency, 11.6 g of diet per day was administered by gastric tube. At the end of the experiment, rats fed the zinc-deficient diet had drastically reduced plasma zinc concentration and alkaline phosphatase activity consistent with severe zinc deficiency in these rats. Zinc-deficient rats had higher levels of n-3 PUFA, in particular eicosapentaenoic acid (EPA), and lower levels of n-6 PUFA, in particular linoleic acid, in liver and plasma phosphatidylcholine (PC) and in erythrocyte membrane total lipids than did control rats. By contrast, the levels of n-3 PUFA in PC from testes and heart, and in phosphatidylethanolamine (PE) from liver, testes and heart, were only slightly different between zinc-deficient and control rats. The study suggests that desaturation of α-linolenic acid is not inhibited by zinc deficiency, and that in zinc-deficient rats, n-3 PUFA preferentially incorporated into phospholipids at the expense of n-6 PUFA, especially EPA into PC. The study also shows that the effect of zinc deficiency on PUFA levels is different for PC and PE in rat tissues.

***Lipids* 29, 839–844 (1994).**

Zinc deficiency has been shown to accentuate essential fatty acid (EFA) deficiency in rats, and an interaction between zinc and EFA metabolism has been proposed (1). A number of studies on the role of zinc in EFA metabolism have been undertaken to examine the effects of zinc deficiency on the fatty acid composition of phospholipids, neutral lipids and total lipids in various tissues (2–10). In some of these studies, zinc deficiency was shown to elevate linoleic acid levels and to lower arachidonic acid levels in rat tissue lipids (3–5,9), and it was thus concluded that zinc plays a role in the desaturation of linoleic acid. This would also be consistent with reports on lowered *in vitro* Δ5 and Δ6 desaturase activities in several tissues of zinc-deficient rats (3,4,11). By contrast, other investigators have reported that arachidonic acid levels were not lowered (6,7), or even elevated (8), in tissues of zinc-deficient rats. The latter studies suggested that zinc would not play a significant role in fatty acid desaturation.

In previous studies interest mainly focused in the effects of zinc on the desaturation of linoleic acid, and thus in most of these experiments rats were fed diets containing oils rich in linoleic acid, such as corn oil (2–6,9) or safflower oil (7). However, fatty acid desaturases do not only catalyze desaturation of fatty acids of the n-6 series, but also catalyze desaturation of n-3 fatty acids. Yet, to our knowledge, the effect of zinc deficiency on the desaturation of fatty acid of the n-3 series has not been investigated. In the present study, rats were fed a zinc-deficient diet containing linseed oil which contains nearly 60% α-linolenic acid, and the levels of n-3 very long chain polyunsaturated fatty acids (PUFA) were examined in various tissue lipids to monitor the effect of zinc deficiency on the desaturation of α-linolenic acid. Thus, the present study should help in clarifying whether zinc deficiency impairs desaturation or not.

It is a common difficulty when studying that rats after a few days on a zinc-deficient diet reduce food intake (12,13). Thus, the effect of zinc deficiency is confounded by undernourishment in experiments in which rats are expected to voluntarily consume zinc-deficient diets (14–17). Reduced food intake is also known to affect desaturation of PUFA (7). In the present study, rats were therefore force-fed by gastric tube to control food intake. Force-feeding has been shown to be a practical approach when studying the effect of short-term zinc deficiency without having results confounded by insufficient nutrient intake (14–18). In a previous study (19) rats were force-fed either a zinc-deficient diet with coconut oil, or a zinc-deficient diet with fish oil. In that study, zinc-deficient rats fed the coconut oil diet developed a fatty liver whereas those fed the fish oil diet did not. This finding suggested that the effect of zinc deficiency on liver lipid levels depends on the dietary fat. Thus, the effect of zinc deficiency on liver lipid levels in rats which were force-fed a diet containing linseed oil was also investigated.

MATERIALS AND METHODS

Animals, diets and tube feeding. Twenty-five male SPF Sprague-Dawley rats weighing 123 ± 6 g (Savo GmbH, Kisslegg, Germany) were divided into two groups. The control group consisted of 12 rats; the depletion group consisted of 15 rats because of the higher risk of mortality. The rats were housed individually in Macrolon cages. A daily 12-h light/dark cycle and a temperature of 23°C and 60% relative humidity were maintained.

All rats were force-fed a semisynthetic diet by gastric tube four times a day (0800, 1300, 1800, 2300) as earlier described in detail (17). The composition of the basic experimental diet is shown in Table 1. The depletion diet contained 0.8 mg Zn/kg, the control diet was supplemented with zinc sulfate to give a zinc concentration of 25 mg/kg. The composition of the linseed oil was as follows (in g/100 g fatty acids): palmitic acid (16:0), 5.3; stearic acid (18:0), 3.7; oleic acid (18:1), 19.7; linoleic acid (18:2n-6), 14.5; and α-linolenic acid (18:3n-3), 56.8; other fatty acids were present only in traces

Abbreviations: DHA, docosahexaenoic acid; DPA, docosapentaenoic acid; EFA, essential fatty acids; EPA, eicosapentaenoic acid; HPLC, high-performance liquid chromatography; MUFA, monounsaturated fatty acids; PC, phosphatidylcholine; PE, phosphatidylethanolamine; PUFA polyunsaturated fatty acids; SFA, saturated fatty acids.

TABLE 1

Composition of the Experimental Diet

Ingredient	Amount (g/kg)
Casein	200
Corn starch	328
Sugar	300
Fiber (cellulose)	30
Linseed oil	80
Mineral mixture[a]	40
Vitamin mixture[b]	20
DL-Methionine	2

[a]Minerals per kg diet: $Na_2HPO_4 \cdot 2\ H_2O$, 8.80 g; KH_2PO_4, 8.20 g; KCl, 6.00 g; $MgCl_2 \cdot 6\ H_2O$, 3.40 g; $CaCO_3$, 13.6 g; $FeSO_4 \cdot 7\ H_2O$ 248.8 mg; $CuSO_4 \cdot 7\ H_2O$, 47.2 mg; $MnSO_4 \cdot 5\ H_2O$, 123.1 mg; KI, 9.0 mg; $NiSO_4 \cdot 6\ H_2O$, 4.48 mg; $NaMoO_4 \cdot 2\ H_2O$, 0.50 mg; $SnCl_2 \cdot 2H_2O$, 0.57 mg; $Na_2SeO_3 \cdot 5\ H_2O$, 0.67 mg; $CrCl_3 \cdot 6\ H_2O$, 0.51 mg; NH_4VO_3, 0.23 mg; $Na_2SiO_3 \cdot 5\ H_2O$, 1.51 mg.
[b]Vitamins per kg diet: 1.7 mg all-*trans* retinol; 7.5 µg cholecalciferol; 150 mg all-*rac*-α-tocopherol; 5 mg menadione sodium bisulfite; 5 mg thiamin · HCl; 10 mg riboflavine; 6 mg pyridoxine · HCl; 50 mg Ca pantothenate; 20 mg nicotinic acid; 1000 mg choline chloride; 0.2 mg folic acid; 0.025 mg cyanocobalamin; sugar to 20 g.

(<0.1 g/100 g fatty acids). Diet slurries were freshly prepared before each feeding by mixing the dry dietary components (92 g) with linseed oil (8 g) and 60 mL of doubly distilled water (with or without zinc sulfate). Immediately before feeding, the slurry was heated in a glass bottle at 50°C for a few minutes. The gastric tube consisted of a 5-mL syringe connected to a slide catheter. During tube feeding, the rats were conscious and held by hand. The catheter was inserted into the stomach of the rats, and the slurry was slowly injected. To avoid contamination, zinc-deficient rats were always fed before the control rats. Each rat received 4 mL of slurry per feeding (equal to 11.6 g of food per day). The rats had free access to drinking water (doubly distilled water, supplemented with 0.14 g/L sodium chloride to adjust osmolarity to that of tap water).

After 8 d, the rats fed the depletion diet showed symptoms of zinc deficiency such as sparse and coarse hair, skin lesions around the mouth, eyes and paws, ataxy, and lethargy; the rats appeared severely ill. At days 9 and 10 of the experiment, two rats fed the zinc-deficient diet died. Therefore, the experiment had to be terminated. At day 11 of the experiment 12 h after the last feeding, all rats were killed by decapitation after light diethyl ether anesthesia. Blood was collected from the neck into heparinized tubes, and liver, heart, testes and the mesentery of the small intestine were excised. Plasma and tissue samples were stored at −80°C until analyzed.

Lipid analyses. Lipids of liver, heart, testes, erythrocyte membranes, mesentery of small intestine, and plasma were extracted with *n*-hexane/isopropanol (3:2, vol/vol; containing butylated hydroxytoluene as antioxidant) according to Hara and Radin (20). Prior to extraction, erythrocytes were washed three times with sodium chloride solution (9 g/L), and hemolyzed. Erythrocyte membrane fragments were washed three times with hypotonic Tris buffer, pH 7.4 (21).

Phospholipids of the extract were separated by high-performance liquid chromatography (HPLC) (22) using a Merck-Hitachi (Darmstadt, Germany) system consisting of a gradient pump (L-6200), a diode array (L-3000), a 25 cm x 0.4 cm (internal diameter) Si 60 (5 µm) cartridge (LiChroCART, Merck), an integrator (D-2000), and a fraction collector (Model 201; Gilson, Villiers-le-Bel, France). The gradient system consisted of the mobile phases (i) acetonitrile, (ii) acetonitrile/85% phosphoric acid (99.8:0.2, vol/vol), and (iii) methanol/85% phosphoric acid (99.8:0.2, vol/vol). This method allowed base line separation of all major phospholipid classes. In the present study, phosphatidylcholine (PC) includes all subclasses of choline glycerophospholipids and phosphatidylethanolamine (PE) all ethanolamine glycerophospholipids. All lipids to be analyzed for their fatty acid composition were transmethylated with boron trifluoride/methanol (100 g/L) reagent (23). Fatty acid methyl esters were separated by capillary gas chromatography (Sichromat 2-8; Siemens, Karlsruhe, Germany) using a programmed temperature vaporizing injection system, a flame-ionization detector and a 50 m CP-Sil 88 WCOT capillary column (Chrompack, Middleburg, The Netherlands). Fractions were identified by comparing their retention times with those of individual pure standards, and were quantified relative to heptadecanoic acid methyl ester used as internal standard (24).

For measurement of liver total cholesterol and triglycerides, extracted lipids were dissolved in Triton X-100 as described by De Hoff *et al.* (25). Total cholesterol and triglycerides were determined using enzymatic reagent kits obtained from Boehringer (Mannheim, Germany). Concentrations of liver phospholipids were calculated by the amount and the mean molecular mass of its bound fatty acids after separation of phospholipids by HPLC and gas chromatographic fatty acid analysis (22).

Zinc analyses and activity of alkaline phosphatase. The zinc concentration of blood plasma was measured directly by aspirating a dilute solution (1:5, vol/vol) into a flame of an atomic spectrophotometer (model 5100; Perkin-Elmer, Überlingen, Germany). The activity of alkaline phosphatase (E.C. 3.1.3.1) in plasma was measured using commercial kit reagents (Boehringer) and an auto analyzer (Hitachi, Model 704; Boehringer).

Data analysis. Treatment effects were evaluated by analysis of variance using Minitab (release 7.2) software (MINITAB, Inc., State College, PA).

RESULTS

Growth and zinc status. The initial body weight was 122.5 ± 6.7 g (mean ± SD) for the control rats and 123.2 ± 5.6 g for the rats fed the zinc-deficient diet. During the first eight days of the experiment, the weight gain of the rats fed the two diets was similar; the body weight at day 8 was 154.4 ± 7.2 g for the control rats and 152.1 ± 4.7 g for the zinc-deficient rats. Thereafter, the zinc-deficient rats ceased to grow, whereas the control rats continued their weight gain. The final body weight at day 11 was 169.5 ± 6.6 g for the control rats and 152.0 ± 6.6 g for the zinc-deficient rats ($P < 0.05$). The zinc concentration in plasma was 15.3 ± 2.0 µmol/L in the control rats and 4.4 ± 0.6 µmol/L in the zinc-deficient rats. The

activity of alkaline phosphatase in plasma was 397 ± 71 Units/L in the control rats and 163 ± 48 Units/L in the zinc-deficient rats.

Fatty acid composition of lipids. The fatty acid composition of PC from liver and plasma is shown in Table 2. The effect of zinc deficiency on fatty acid composition was similar in liver and plasma PC. Total monounsaturated fatty acids (MUFA), linoleic acid (18:2n-6), dihomo-γ-linolenic acid (20:3n-6), docosapentaenoic acid (DPA, 22:5n-3) and total n-6 PUFA were lower in liver and plasma PC of zinc-deficient rats; α-linolenic acid (18:3n-3), eicosapentaenoic acid (EPA, 20:5n-3) and total n-3 PUFA were elevated in liver and plasma PC of zinc-deficient rats. In plasma PC, total saturated fatty acids

(SFA) were also higher in zinc-deficient rats than in control rats, and zinc-deficient rats had a decreased total n-6/n-3 PUFA ratio in liver and plasma PC.

The fatty acid composition of PC from testes and heart is shown in Table 3. The effects of zinc deficiency on the fatty acid composition of testes and heart PC were less pronounced than the effects on the fatty acid composition of liver and plasma PC. Total MUFA, EPA (20:5n-3) and DPA (22:5n-3) were significantly elevated in testes PC of zinc-deficient rats, whereas arachidonic acid (20:4n-6) and total n-6 PUFA were lower. The total n-6/n-3 PUFA ratio in testes PC was lower in zinc-deficient rats than in control rats. The only effect of zinc deficiency on heart PC seen was an elevation of linoleic acid (18:2n-6) and α-linolenic acid (18:3n-3).

The fatty acid composition of PE from liver, testes and

Total cholesterol	2.49 ± 0.53[b]	2.01 ± 0.42[c]
Phosphatidylcholine	12.1 ± 1.2[b]	13.6 ± 1.1[c]
Phosphatidylethanolamine	7.37 ± 0.79	7.06 ± 1.02

[a]Mean ± SD (n = 12 for control group; n = 13 for zinc-deficient group). Values with different superscripts (b, c) are significantly different ($P < 0.05$).

heart is shown in Table 4. In general, the effects of zinc deficiency on PE were less pronounced than those on PC. Total SFA, γ-linolenic acid (18:3n-6) and α-linolenic acid (18:3n-3) were elevated in liver PE of zinc-deficient rats, whereas linoleic (18:2n-6), dihomo-γ-linolenic acid (20:3n-6), docosatetraenoic acid (22:4n-6) and total n-6 PUFA were lower. Testes PE from zinc-deficient rats contained higher levels of total MUFA, EPA (20:5n-3) and total n-3 PUFA and lower levels of linoleic acid (18:2n-6), dihomo-γ-linolenic acid (20:3n-6), docosatetraenoic acid (22:4n-6) and total n-6 PUFA than that from control rats. Zinc-deficient rats also had a lower total n-6/n-3 PUFA ratio for testes PE. In heart PE, the only change seen due to zinc deficiency was a slight elevation of α-linolenic acid.

The fatty acid composition of total lipids from erythrocyte membranes and the mesentery of small intestine is shown in Table 5. In erythrocyte membrane total lipids of zinc-deficient rats, linoleic acid (18:2n-6) was lower, but total n-3 PUFA and, in particular, α-linolenic acid (18:3n-3) and EPA (20:5n-3) were elevated. Zinc-deficient rats also had a lower total n-6/n-3 PUFA ratio for erythrocyte membrane lipids. In contrast, zinc deficiency did not change the fatty acid composition of total lipids from mesentery of small intestine.

Liver lipids levels. Control rats and zinc-deficient rats had similar liver triglyceride and PE concentrations (Table 6). By contrast, total cholesterol was lower in zinc-deficient rats than in control rats, and PC was higher in zinc-deficient rats than in control rats.

DISCUSSION

The present study was undertaken to investigate the effect of zinc deficiency on the fatty acid patterns of rats fed a diet rich in α-linolenic acid. For this purpose, a rat model was used that permits induction of a severe zinc deficiency without having the observed effects due to zinc deficiency distorted by changes due to energy and nutrient intake. The disadvantage of the model is that it can only be used for short-term studies because rats force-fed a diet containing extremely low zinc concentrations cannot survive beyond 10 or 12 d. In zinc-deficient rats that consumed the diet *ad libitum,* plasma alkaline phosphatase activity, which is an approximate indicator of the zinc state (26,27), was greatly reduced already after 2 to 4 d on a zinc-deficient diet (28,29). This means that a zinc-deficient state existed only for approximately 6 to 8 d. Although the model we used may be physiologically less relevant, it is useful to study the effects of very severe zinc deficiency. In physiologically more relevant models, the effects of zinc deficiency on fatty acid metabolism are typically being investigated using moderately zinc-deficient rats (9), which typically consume adequate quantities of food. However, effects due to severe zinc deficiency might remain hidden when using these models.

In the present study the effect of zinc deficiency on fatty acid metabolism was examined by following its effect on the fatty acid composition of PC and PE. These two phospholipid classes represent approximately 80% of the total phospholipids in rat liver, heart and testes and approximately 90% of total phospholipids in rat plasma (30), and most of the PUFA is associated with there phospholipid fractions (31). In general, fatty acid compositions can be modified by a variety of processes (31), and changes in fatty acid compositions alone do not allow specific conclusions to be drawn about any of the individual processes. Nevertheless, the observation that the levels of EPA in liver phospholipids were unchanged or even elevated suggests that zinc deficiency does not affect Δ5 and Δ6 desaturation of α-linolenic acid, at least not within the time frame of the present study. This disagrees with the results of some earlier studies which showed that zinc deficiency inhibited Δ5 and Δ6 desaturation (3–5,9,11) in rats fed diets containing oils rich in n-6 fatty acids. In the present study, the effects of zinc deficiency on the fatty acid composition of phospholipids were more pronounced in liver and plasma than in other tissues investigated. This might be due to the higher turnover rates of phospholipids in liver than in other tissues (32).

An interesting observation in the present study was that zinc-deficient rats had elevated levels of EPA in PC but not in PE. This could indicate that zinc deficiency may alter the incorporation of EPA into PC. Increased levels of EPA in PC were recently also observed in zinc-deficient rats which had been force-fed a fish oil diet (19). By contrast, the levels of α-linolenic acid were higher in both PC and PE. However, in this and recent studies (18,19), independent of the dietary fat, the levels of linoleic acid were reduced in rats which had been force-fed with zinc-deficient diets. This is in contrast to results obtained on rats that consumed a zinc-deficient diet *ad libitum* (4,5,9,33). The lower levels of linoleic acid we observed in the present study may be due to increased oxidation. The increased levels of linoleic acid which have been reported in the literature were suggested to be due to reduced desaturation (4,5,9,33).

The level of arachidonic acid, which is often used as a measure of desaturation (5,9,33), was not changed by zinc deficiency in either PC or PE. However, it should be noted that feeding a diet rich in α-linolenic acid is known to suppress the desaturation of linoleic acid (34) which is reflected by lower levels of arachidonic acid compared with rats fed diets containing fats with lower levels of n-3 fatty acids (3–9,33).

In a previous study, rats which were force-fed a zinc-deficient diet based predominately on coconut oil developed fatty livers, whereas rats fed a zinc-deficient diet based predominately on fish oil did not (19). In the present study, total lipid and triglyceride levels in liver were not different between control and zinc-deficient rats. This suggests that linseed oil, like fish oil, can prevent the formation of fatty liver which has been observed in rats force-fed zinc-deficient diets based on coconut oil.

The n-3 Polyunsaturated Fatty Acid Levels in Rat Tissue Lipids Increase in Response to Dietary Olive Oil Relative to Sunflower Oil

Maria D. Navarro, José L. Periago, Maria L. Pita and **Paloma Hortelano***

Department of Biochemistry and Molecular Biology, Faculty of Pharmacy, University of Granada, 18071 Granada, Spain

In the present study, changes in phospholipid compositions of liver microsomes, erythrocyte membranes, platelets, aorta, cardiac muscle and brain of rats fed olive oil were compared with those of rats fed sunflower oil. Four groups of rats starting at weaning were fed for four weeks a basal diet containing 5 or 25% olive oil or sunflower oil. We found that oleic acid was higher and linoleic acid was lower in membrane phospholipids of olive oil fed rats compared to sunflower oil fed rats. Polyunsaturated fatty acids of the n-3 series were markedly elevated in all tissues of rats on the olive oil diets relative to those on the sunflower oil diets. The results are consistent with a lower linoleic/linolenic acid ratio induced by the olive oil diets, suggesting a positive correlation between olive oil ingestion and n-3 polyunsaturated fatty acid levels in cell and tissue lipids. The study suggests that an adequate intake of olive oil may enhance the conversion of n-3 fatty acids.

***Lipids* 29, 845–849 (1994).**

Long-chain polyunsaturated fatty acids (PUFA) of the n-3 and n-6 series are of much current interest. The intake of PUFA of both series has been correlated with a decreased risk of cardiovascular disease due to the hypolipemic, antithrombotic and antiarrhythmic effects of PUFA (1–3). Furthermore, specific roles for n-3 PUFA have been recognized in specialized tissues, such as brain and retina (4–6).

Changes in cell membrane lipid composition induced by dietary supplementation with unsaturated fats have been repeatedly described (7–13). Nevertheless, there is a growing concern that habitual intake of large quantities of PUFA may be unhealthy, as PUFA are quite susceptible to peroxidation, and thus may promote carcinogenesis and possibly reduce high density lipoprotein levels (14,15).

Recently, attention has been paid to the intake of olive oil with its high oleic acid (18:1n-9) and moderate linoleic acid (18:2n-6) levels. Olive oil is an important component of the so-called Mediterranean diet. Numerous studies have noted that the incidence of cardiovascular disease in the Mediterranean area is one of the lowest of the Western hemisphere (16,17), which has focused renewed interest on olive oil. Decreased plasma cholesterol levels, lower levels of low density lipoprotein (LDL)-cholesterol and thromboxane A_2 (TXA_2), and increased plasma levels of prostacyclin have been reported by us and others after olive oil ingestion (18–22).

A recent study by our group, in which we observed an increase in long-chain n-3 PUFA in liver microsomal fractions from rats fed an olive oil diet rather than a corn oil diet (8) has prompted us to further focus on this olive oil effect. Results of others have also shown increases in LDL n-3 PUFA in individuals on a monounsaturated diet as compared to individuals on a PUFA diet (9). Thus, the aim of the present study was to evaluate the effect of feeding olive oil to rats on the phospholipid (PL) fatty acid compositions of liver microsomes, erythrocyte membranes, platelets, aorta, cardiac muscle and brain. Sunflower oil added to the diet at the same percentages served as reference oil.

Abbreviations: LDL, low density lipoprotein; O-5, 5% olive oil diet; O-25, 25% olive oil diet; PC, phosphatidylcholine; PE, phosphatidylethanolamine; PL, phospholipid; PUFA, polyunsaturated fatty acids; S-5, 5% sunflower oil diet; S-25, 25% sunflower oil diet; TXA_2, thromboxane A_2.

MATERIALS AND METHODS

Animals and diets. Male weanling Wistar rats (Interfauna, Barcelona, Spain) weighing 50–55 g were housed in wire-bottom cages using a 12-h light/dark cycle. Animals were housed and handled in compliance with our Institution's guidelines for animal research.

Rats were randomly assigned to four groups, each containing ten animals. Two groups were fed similar low-fat diets supplemented with 5% sunflower oil (S-5) or 5% olive oil (O-5). The other two groups were fed high-fat diets that were isocaloric with the low-fat diets, but were supplemented with 25% sunflower oil (S-25) or 25% olive oil (O-25) (Table 1) (22,23). The fatty acid composition of the diets is shown in Table 2. Diets were stored at 4°C, and the rats were fed fresh food daily. Food and water were provided *ad libitum*.

Sample collection. Rats were killed by decapitation under light diethyl ether anesthesia. Blood was collected separately for the isolation of erythrocyte membranes and for the preparation of platelet suspensions. For the former, blood was collected in heparinized tubes, and for the latter

TABLE 1

Composition of the Basal Diets[a]

Component	Low-fat diets	High-fat diets
	(g/100 g diet)	
Cellulose	5.0	30.0
DL-Methionine	0.3	0.3
Casein	20.0	20.0
Starch	49.09	14.63
Sucrose	15.0	4.46
Vitamin mix	1.0	1.0
Mineral mix	4.5	4.5
Choline chloride	0.11	0.11
Olive oil[b]	5.0 (diet O-5)	25.0 (diet O-25)
Sunflower oil[c]	5.0 (diet S-5)	25.0 (diet S-25)

[a]Abbreviations: O-5, olive oil 5%; S-5, sunflower oil 5%; O-25, olive oil 25%; S-25, sunflower oil 25%. The composition of the diets was adjusted so that all animals in all dietary groups would consume the same amounts of protein, minerals, vitamins and calories. An inert ingredient (cellulose) was added to high-fat diets to facilitate diet elaboration.

20:3n-6	—	0.6
18:3n-3	1.0	0.3
18:2n-6/18:3n-3	8.3	222.3

[a]Values are percent distributions of fatty acid methyl esters.

it was collected in 3.8% sodium citrate (1:9, vol/vol) as described by Hashimoto *et al.* (24).

Aorta, brain and heart ventricles were washed in 0.15M NaCl, frozen in liquid nitrogen, and stored at –80°C until analyzed. Liver was washed in 0.15M NaCl and homogenized in phosphate buffer to isolate microsomes.

Analytical methods. To obtain erythrocyte membranes, blood samples were centrifuged at 3000 × *g* for 10 min to separate plasma from cells. Erythrocyte membranes were obtained according to the method described by Hanahan and Ekholm (25). Liver microsomes were isolated according to Philipp and Shapiro (26).

Total lipids were extracted (27) with chloroform/methanol (2:1, vol/vol) containing the antioxidant butylated hydroxytoluene (50 mg/L).

PL were separated by thin-layer chromatography on Silica Gel G 60 (Merck, Darmstadt, Germany) using two different solvent systems, namely hexane/diethyl ether/acetic acid (80:20:1, by vol) (28) to isolate total PL and ethyl acetate/chloroform/*n*-propanol/methanol/0.25% KCl (25:25:25:10:9, by vol) (29) to isolate the phosphatidylcholine (PC) and phosphatidylethanolamine (PE) fractions from liver microsomes.

Fractions were detected by exposure to iodine vapors. The areas of silica gel containing PL, PC and PE were immediately (after iodine evaporation) scraped from the plates, eluted with chloroform, and analyzed for fatty acid composition. Fatty acids were transmethylated according to Morrison and Smith (30).

Fatty acid methyl esters were separated on a 30 m × 0.15 μm (i.d.) fused silica capillary column (DB23 30N; J&W Scientific, Folsom, CA) attached to a Konik 3000 HRGC chromatograph (Barcelona, Spain) equipped with a Spectraphysics SP4290 integrator (San Jose, CA). Fatty acids were identified by comparing retention times with those of standards (Sigma Química, Barcelona, Spain). Fatty acid compositions are expressed as the percent distribution of fatty acid methyl esters.

Statistical analysis. All results are shown as means ± SEM. Analysis with Bonferroni's test for multiple pairwise comparisons was performed. Analyses were done using the BMDP Computer Software Program (BMDP Statistical Software, Cork, Ireland).

RESULTS

The relative fatty acid compositions of the PL of erythrocyte membranes, platelets, cardiac muscle, brain, aorta, liver microsomes and of the two major PL fractions, PE and PC, of liver microsomes are shown in Tables 3 to 6.

The saturated fatty acid compositions are shown in Table 3. Rats fed the sunflower oil diets showed, in general, the highest levels of total saturated fatty acids especially in the high-fat fed group.

The respective figures for oleic and linoleic acids are shown in Table 4. The percentages of oleic acid were markedly greater in animals fed olive oil diets than those of the other two groups, except for brain where there was no effect of diet. Rats fed high-fat diets showed higher oleic acid levels in platelet PL when compared to rats fed low-fat diets; conversely, oleic acid was significantly lower in PL, PC and PE of liver microsomes and cardiac muscle from high-fat vs. low-fat fed rats. The two groups of rats fed sunflower oil diets showed increases in linoleic acid levels which were significant relative to those in the olive oil groups in all the cell sources. Linoleic acid was very low

	18:2n-6	3.7 ± 0.5[d]	3.9 ± 0.3	8.7 ± 0.5	16.8 ± 2.0[c,d]

[a]Results are mean percent distributions ± SEM of fatty acid methyl esters measured on ten animals. See Table 3 for abbreviations. [b]See Table 1 for diet abbreviations. [c]$P < 0.05$, significance relative to O-25 group. [d]$P < 0.05$ significance relative to S-5 group.

in brain PL (<1.5%). In erythrocyte membrane, platelet, brain and aorta PL, animals fed the S-25 diets showed higher linoleic acid levels than animals fed the S-5 diet.

Arachidonic acid (20:4n-6) and long-chain n-6 PUFA values are shown in Table 5. Rats fed the S-5 diet showed higher levels of 20:4n-6 than rats fed the O-5 diet in erythrocyte membrane and platelet PL and in PL, PC, and PE from liver microsomes, and lower levels of 20:4n-6 in heart PL. Brain 20:4n-6 was unaffected by the diet.

The changes seen for n-6 PUFA with carbon chains of more than 18 carbon atoms (n-6 PUFA > C_{18}) (Table 5) were similar to those seen for 20:4n-6 except for heart PL which showed higher levels of n-6 PUFA > C_{18} in sunflower oil fed rats compared to olive oil fed rats; this was largely due to the increase in docosatetraenoic acid (22:4n-6) and docosapentaenoic acid (22:5n-6) which we found in heart PL (data not shown).

Linolenic acid (18:3n-3), the precursor of n-3 PUFA, was found at low levels (<1.5%) and was not affected by the diet (data not shown). Table 6 shows the data we obtained for 22:6n-3 and for n-3 PUFA longer than C_{18} (n-3 PUFA > C_{18}). The two profiles are similar, as 22:6n-3 is the fatty

acid contributing to the greatest extent to total PUFA. These fatty acids were found at higher levels in olive oil fed animals (5 and 25% fat diets), with the levels being always higher in the 25% olive oil fed group.

DISCUSSION

The aim of the present study was to evaluate the effect of an olive oil diet, rich in monounsaturated fatty acids, on the fatty acid compositions of different tissue PL, with a sunflower oil diet serving as reference diet.

Animals fed the olive oil diets showed the lowest total saturated fatty acid levels. These results are similar to those previously seen by our group in plasma and erythrocytes from rats fed olive oil diets as compared to those in corn oil fed rats (7); others have also reported this effect in endothelial cell cultures supplemented with oleic acid (12).

Oleic acid levels were higher in rats fed olive oil diets than in rats fed sunflower oil, except for brain PL in which similar levels were seen. This could be attributed to the high 18:1 content of the diet as well as to an increase in Δ9 desaturase activity due to olive oil feeding as we have previously described (8). It is also relevant to point out that platelets, which are deprived of desaturating capacity (31,32), showed a higher oleic acid content in high-fat fed than in low-fat fed rats, consistent with the increased intake of this fatty acid and the absence of Δ9 desaturase activity.

Linoleic acid was elevated in the two groups fed the sunflower oil diets corresponding with its high levels in the diet. Linoleic acid levels in brain were very low as has been described by others (33,34) and consistent with the effectiveness of its desaturation by this organ (33).

Arachidonic acid levels of PL are normally dependent upon the desaturating capacity of the tissue and the mode of its incorporation into cell PL (35,36). In humans, 20:4n-6 levels are greatly dependent on the diet, as Δ6 desaturation is slow and rate-limiting. In fact, under certain pathologic conditions, in which Δ6 desaturation is affected, arachidonic acid must be supplemented to the diet (37,38). In certain cell types, including erythrocytes and platelets, due to a lack in desaturating capacity, arachidonic acid levels decreased as the percentage of fat increased in the diet. By contrast, tissues with regulated desaturase activity incorporated less linoleic acid into PL and more arachidonic acid as the percentage of fat increased in the diet. In brain, the elevated levels of n-6 PUFA > C_{18} in PL, together with the low levels of linoleic acid, may indicate that dietary 18:2n-6 taken up by the brain is rapidly desaturated and elongated to long-chain PUFA. Animals fed sunflower oil diets incorporated more n-6 PUFA > C_{18} into PL of cells with desaturating capacity than did animals fed olive oil diets.

Fatty acids of the n-3 series were always elevated in olive oil-fed rats compared to sunflower oil-fed rats. The reason for this increase could be the competition between linoleic acid and α-linolenic acid for desaturases (35) which would depend on the fatty acid ratio of the diet. When the 18:2n-6/18:3n-3 ratio decreases, desaturation of 18:3n-3 is favored. In sunflower oil, the ratio of 18:2n-6/18:3n-3 is greater than in olive oil because of the high content in linoleate in the former, resulting in lower levels of long-chain n-3 PUFA found in rats fed sunflower oil as compared to olive oil fed animals.

Nevertheless, the 18:2n-6/18:3n-3 ratio might not be the only factor contributing to this increase in n-3 fatty acids, as the fat percentage in the diet also induces changes in n-3 PUFA content; rats fed the O-25 diet had, in general, higher levels of n-3 PUFA in their PL than rats fed the O-5 diet, whereas the situation in S-5 and S-25 fed rats was reversed.

The results in regard to n-3 fatty acids are of great potential interest. We have recently obtained data (22) which indicated that olive oil diets alter eicosanoid metabolism and diminish TXA_2 formation; availability of the direct precursor is an important factor in the regulation of the biosynthesis of eicosanoids in animal tissues, and precursor availability is greatly dependent on the ratio of the fatty acids in diet (39). In addition, experimental evidence indicates that n-3 fatty acids are essential for normal functional development of the retina and brain, particularly in premature infants (40–42); in various animal models, n-3 fatty acids have been shown to decrease the number and size of tumors and to increase the time elapsed before reappearance of tumors (43,44). Also, n-3 fatty acids can decrease the tendency to thrombus formation (45) and lower LDL-cholesterol (4,5), thus having potential beneficial effects in respect to coronary heart disease.

Over the past hundred years, Western diet has suffered absolute and relative changes in n-6/n-3 fatty acid ratios. There has been an increased consumption of animal fat with an imbalance in n-6/n-3 ratios as Western diets have become deficient in n-3 fatty acids (39). Appropriate n-6/n-3 ratios need to be considered when making dietary recommendations, as their balance is important in regulating homeostasis and normal development. Our data also suggest that an adequate intake of olive oil should prove beneficial in the prevention of coronary heart disease.

Dietary ω3 Fatty Acids and Cholesterol Modify Enterocyte Microsomal Membrane Phospholipids, Cholesterol Content and Phospholipid Enzyme Activities in Diabetic Rats

Division of Gastroenterology and Nutrition and Metabolism Research Group, Departments of [a]Medicine, [b]Foods and Nutrition, University of Alberta, Edmonton, Alberta, T6G 2C2 Canada

Diabetes-associated changes in intestinal uptake of nutrients are modified by isocaloric variations in the type of dietary lipids, and are associated with alterations in the phospholipid and fatty acyl content of the intestinal brush border membrane. The present study was designed to test the hypothesis that diet- and diabetes-associated changes in enterocyte microsomal membrane phospholipids are due to variations in the activity of two phospholipid metabolizing enzymes, 1,2-diacylglycerol:CDPcholine cholinephosphotransferase (CPT) and phosphatidylethanolamine methyltransferase (PEMT). Adult female Wistar rats were fed one of four semisynthetic diets—beef tallow low in cholesterol (BT), beef tallow high in cholesterol (BTC), fish oil low in cholesterol (FO) or fish oil high in cholesterol. In half of the animals, diabetes mellitus was produced by injection of streptozotocin. Jejunal and ileal enterocyte microsomes (EMM) were isolated and analyzed for cholesterol and phospholipids, as well as for CPT and PEMT activities. In control animals, feeding FO reduced EMM total phospholipids including phosphatidylcholine (PC), phosphatidylethanolamine (PE) and phosphatidylinositol. Feeding FO resulted in a greater than 95% reduction in the activity of CPT. Diabetes was associated with increased jejunal EMM total phospholipids including sphingomyelin (SM) and PE, without associated changes in CPT or PEMT. Dietary cholesterol supplementation did not affect EMM total cholesterol or phospholipid composition in control rats fed BT or FO, but was associated with an increase in EMM cholesterol in diabetic rats fed BT or FO. A decrease in total phospholipids due to a decline in SM, PC and PE in diabetic rats fed FO was not associated with changes in the activities of CPT or PEMT in EMM. Thus (i) enterocyte microsomal membrane cholesterol and phospholipid contents are influenced by diabetes, dietary cholesterol and the type of fatty acid in the diet, and (ii) changes in phospholipid composition are not fully explained by alterations in the activities of CPT and PEMT.

***Lipids* 29, 851–858 (1994).**

The absorption of nutrients is increased in streptozotocin-induced diabetes in the rat (1–11), which is associated with an increase in phospholipid content of the intestinal brush border membrane (BBM) (12,13). Diabetes-associated changes in BBM phospholipid composition were also observed, notably, a large increase in phosphatidylcholine (PC) and phosphatidylethanolamine (PE) (13). The presence of cholesterol or the fatty acid composition of the diet (saturated beef tallow or polyunsaturated ω3 fatty acids of fish oil) influences intestinal uptake of D-glucose and lipids (14,15), and also modifies BBM phospholipid and cholesterol levels (15,16). The mechanisms which control the phospholipid composition of the BBM have not yet been elucidated.

PC represents the major BBM phospholipid comprising approximately 40–45% of total BBM phospholipids (13). *De novo* PC synthesis has been described in the intestine (17–20), and a high fat diet is known to increase the activity of intestinal 1,2-diacylglycerol:CDPcholine choline phosphotransferase (CPT), the enzyme catalyzing the final step in the synthesis of PC (21). Diabetes has been shown to increase CPT activity in rat liver microsomes by 92% over that in control animals (22). The effect of diabetes or of altering the quality of the dietary fat on the activity of the rate-limiting enzyme of enterocyte *de novo* PC synthesis, CTP:phosphocholine cytidylyltransferase is not known, although changes in CPT activity have been reported to parallel those observed in CTP:phosphocholine cytidylyltransferase activity (23).

In rat liver microsomes, phosphatidylethanolamine methyltransferase (PEMT) activity was shown to be reduced by almost 50% in diabetic as compared to control rats (22). PEMT catalyzes the conversion of PE to PC with *S*-adenosylmethionine serving as the methyl donor. PEMT activity has also been observed in the BBM of the small intestine (24), although alterations that may result from diabetes or diet have not been reported.

BBM phospholipids are synthesized at the enterocyte microsomal membrane (EMM), specifically at the endoplasmic reticulum (17). The activity of PEMT or CPT in EMM may be influenced by diet and/or diabetes, thereby resulting in alterations in EMM and, subsequently, in BBM phospholipid composition. The trafficking of lipids to the BBM after synthesis in the EMM is not well understood. The BBM PC/PE ratio may also be altered by PEMT activity present in BBM.

The present study will therefore examine the effect of diet and diabetes on EMM lipid composition and will focus on two enzymes involved in the synthesis of PC. We hypothesize (i) that changes in dietary ω3 fatty acids or cholesterol affect cholesterol levels and the amounts and types of phospholipids in EMM of control and diabetic rats, and (ii) that these changes are the result of altered CPT and PEMT activities in the EMM.

Abbreviations: BBM, brush border membrane; BT, beef tallow with low cholesterol diet; BTC, beef tallow with high cholesterol diet; CPT, 1,2-diacylglycerol:CDPcholine cholinephosphotransferase; EMM, enterocyte microsomal membranes; FO, fish oil with low cholesterol diet; FOC, fish oil with high cholesterol diet; PC, phosphatidylcholine; PE, phosphatidylethanolamine; PEMT, phosphatidylethanolamine methyltransferase; PI, phosphatidylinositol; SM, sphingomyelin.

METHODS AND MATERIALS

Animals and diets. The guiding principles in the care and use of laboratory animals, approved by the Canadian Federation of Biological Societies, and reviewed by the Animal Policy and Welfare Committee at the University of Alberta (Edmonton, Alberta, Canada), were observed in the conduct of this study. Female Wistar rats weighing 200–250 g were divided into two groups. The first group was rendered hyperglycemic by the intravenous injection of streptozotocin (65 mg/kg body weight). The second group was injected with saline and served as nondiabetic control. Both groups were initially fed a standard Purina® rat chow (Ralston Purina, St. Louis, MO) diet for two weeks. Then the control and diabetic groups were subdivided further into four groups of 20 rats each, and were fed one of four semisynthetic diets for two weeks—beef tallow with low (0.06%) cholesterol (BT), beef tallow with high (1%) cholesterol (BTC), fish oil with low (0.06%) cholesterol (FO), or fish oil with high (1%) cholesterol (FOC). These semisynthetic diets were nutritionally adequate, meeting known essential nutrient requirements. The composition of the diets is detailed in Tables 1 and 2.

Food intake was monitored every two to three days. Animals were weighed weekly. Blood glucose concentrations were determined one week post-injection and at the time of sacrifice. Animals were allowed access to food and water *ad libitum* until they were killed. Diet composition, food intake, weight gain and blood glucose levels have been reported (16).

Membrane preparation and analysis. EMM were prepared by a modification of the methods described by Lindeskog *et al.* (25). Intestinal mucosal scrapings were homogenized in a buffer (containing 0.25 M sucrose, 0.1 M KH_2PO_4, 1 mM ethylenediaminetetraacetic acid, 1 mM dithiothreitol, 66.7 mM NaF and 0.2% trypsin inhibitor), and were centrifuged for 10 min at 800 × *g* to remove cellular debris. The supernatant was centrifuged for 30 min at 15,000 × *g* to remove mitochondrial membranes. The resultant supernatant was then centrifuged for 30 min at 48,000 × *g* to remove brush border and basolateral membranes. The final supernatant was centrifuged for 60 min at 105,000 × *g* to pellet the microsomal membranes. Glucose-6-phosphatase activity was determined to assess the purity of the microsomal preparation which was enriched approximately tenfold over homogenate (26).

Lipids of the isolated EMM were extracted immediately after preparation according to a modification of the method of Bowyer and King (27) and Folch *et al.* (28). Aliquots of the chloroform layer were removed for determining free and esterified cholesterol (29,30) and total phospholipid (31), as well as phospholipid composition (32,33).

Intestinal CPT activity was determined according to the method of Hoffman *et al.* (22). PEMT activity was assayed according to the methods of Dudeja and Brasitus (24) and Fonlupt *et al.* (34).

Expression of data. All data are expressed as mean ± SEM. Each of the eight groups consisted of 20 rats, and each sample represented material pooled from two animals, such that each group provided ten samples. The results were tested statistically by analysis of variance and by Student Neuman-Keul multiple range test.

TABLE 1

Macronutrient Composition of the Semisynthetic Diets[a]

Diet composition	g/kg
Casein	270.00
Starch	200.00
Glucose	207.65
Cellulose	50.00
Vitamin mix	10.00
Mineral mix	50.85
Choline	2.75
Inositol	6.25
L-methionine	2.50
Fat	200.00

[a]All diets were nutritionally adequate for 18:2 and 18:3. BT (beef tallow) contains 16:0 and 18:0 prepared with 18% beef tallow plus 2% safflower oil. FO (fish oil) contains 20:5ω3 and 22:6ω3 prepared with 10% fish oil plus 8% beef tallow plus 2% safflower oil. BTC (beef tallow plus cholesterol) and FOC (fish oil plus cholesterol) were prepared as above with 1% cholesterol added to the diets. Fish oil contains cholesterol (0.6% w/w), and therefore no additional cholesterol is added to the FOC diet. Thus, the final cholesterol content of FO and FOC diets was 0.06% (w/w) and 2.06% (w/w), respectively.

TABLE 2

Fatty Acid Composition of Experimental Diets[a]

Fatty acid	BT	FO
	(g/kg total diet)	
14:0	3.8	5.6
15:0	0.6	0.4
16:0	27.5	17.9
16:1ω7	0.6	6.3
17:0	2.1	0.9
18:0	52.3	25.2
18:1ω9	5.3	7.1
18:1ω7	0.1	1.3
18:2ω6	6.9	7.6
18:3ω3		3.2
20:5ω3		15.1
22:5ω3		1.3
22:6ω3		5.6

[a]Abbreviations as in Table 1.

RESULTS

EMM lipid composition. In the jejunal EMM of control rats, feeding fish oil (FO or FOC) was associated with a 42–50% decline in total phospholipid content, no change in the cholesterol content and a resultant 46–48% decline in phospholipid/cholesterol ratio as compared to animals fed beef tallow (BT or BTC) (Table 3). In diabetic rats, jejunal EMM total phospholipid content was lowered 43% and cholesterol content was unchanged; thus the phospholipid/cholesterol ratio was also lower when animals were fed FOC compared to animals fed

[a]The composition of the diets is given in Tables 1 and 2. For abbreviations, see Table 1. [b]$P < 0.05$, fish oil vs. beef. [c]$P < 0.05$, cholesterol supplementation. [d]$P < 0.05$, diabetic vs. control.

BTC. Cholesterol supplementation did not significantly alter the jejunal EMM phospholipid and cholesterol levels of control animals fed beef tallow or fish oil, although small changes resulted in a 20% decline in the phospholipid/cholesterol ratio in animals fed beef tallow (BTC vs. BT). By contrast, in the jejunal EMM of diabetic animals, cholesterol supplementation decreased the phospholipid content by 28% in animals fed fish oil, and increased the cholesterol content by 46% in animals fed either beef tallow or fish oil, which resulted in a phospholipid/cholesterol ratio that was reduced by 30 and 52%, respectively. Diabetes was associated with an increase in jejunal EMM total phospholipid content in animals fed BTC (32%), FO (78%) and FOC (50%), and an increase in total cholesterol content in animals fed BTC (32%) and FOC (22%) as compared with controls. The phospholipid/cholesterol ratio was not significantly altered in diabetes except for the twofold increase in the diabetic compared with the control animals fed FO.

Ileal EMM phospholipid and cholesterol content was unaffected by fish oil feeding in both control and in diabetic animals (Table 4). Although ileal EMM phospholipid content and the phospholipid/cholesterol ratio were unchanged, the cholesterol content was significantly increased (by 36%) when control animals fed beef tallow were supplemented with cholesterol. In diabetic animals fed fish oil, cholesterol supplementation did not significantly affect phospholipid content, but increased ileal EMM cholesterol content 42% and reduced the phospholipid/cholesterol ratio by 45%. Cholesterol supplementation did not alter the ileal EMM phospholipid and cholesterol content of control animals fed fish oil, or diabetic animals fed beef tallow. Although diabetes was associated with a 19% increase in ileal EMM cholesterol content in animals fed FOC, the total phospholipid levels and the phospholipid/cholesterol ratio remained unchanged when compared with controls fed FOC. Diabetes did not significantly alter the ileal EMM phospholipid and cholesterol content of animals fed BT, BTC or FO as compared with controls.

EMM phospholipid composition. Feeding FO was associated with a decline in sphingomyelin (SM), PC and PE in jejunal EMM of control animals, as compared with those fed BT, by 37, 54 and 35%, respectively. Feeding FOC was associated with a 53% reduction in PE and a 63% reduction in phosphatidylinositol (PI) compared with feeding BTC (Table 5). In the jejunal EMM of diabetic animals, feeding FO was also associated with a 57% decrease in SM when compared with feeding BT, whereas feeding FOC was associated with a decline in SM (56%) and PE (46%) when compared with feeding BTC. Cholesterol supplementation did not alter the phospholipid composition of jejunal or ileal EMM in control animals fed either beef tallow or fish oil. In the jejunal EMM of diabetic animals, cholesterol supplementation was associated with an increase in SM (24% and PE

[a]The composition of the diets and the abbreviations are given in Tables 1 and 2. [b]$P < 0.05$, fish oil vs. beef.

(27%) in animals fed beef tallow, whereas in diabetic animals fed fish oil, cholesterol supplementation was associated with a reduction in PC (42%) and PE (29%). Diabetes was associated with an increase in jejunal EMM SM (28–55%) and PE (22–34%) in animals fed beef tallow (BT or BTC). In animals fed FO, diabetes was associated with an increase in jejunal EMM PC (167%) and PE (81%) with a resultant 68% reduction in SM/PC ratio, and in animals fed FOC only PE was increased (94%).

In the ileal EMM of control animals, feeding FOC did not alter phospholipid composition compared with feeding BTC, although feeding FO was associated with a 54% reduction in PI compared with feeding BT (Table 6). In diabetic rats, feeding FO did not alter the ileal EMM phospholipid composition compared with diabetic rats fed BT, while feeding FOC was associated with a decline in SM (34%) and a 92% increase in PC/PE ratio compared with feeding BTC. Ileal EMM phospholipid composition was unaffected by cholesterol supplementation in diabetic animals fed either beef tallow or fish oil.

CPT and PEMT activities. Feeding fish oil (FO or FOC), when compared with feeding beef tallow (BT or BTC), was associated with a marked decline in jejunal EMM CPT activity of control (94–95%) and diabetic rats (74–82%), whereas the decline in ileal CPT activity in control (63–70%) and in diabetic (74–76%) rats did not reach statistical significance ($P < 0.05$) (Table 7). CPT was not significantly affected by adding cholesterol to the diet, or by diabetes. The general decline in jejunal and ileal EMM PEMT activity observed with diabetes in the absence of dietary cholesterol did not reach statistical significane. PEMT activity was not significantly affected by dietary ω3 fatty acids or by cholesterol supplementation.

DISCUSSION

Feeding a polyunsaturated fatty acid diet may reduce the enhanced uptake of glucose and lipids in diabetic rats (16,35,36). Alterations in the lipid composition and properties of the BBM have been postulated to explain this decline in nutrient absorption (16,37). Diabetes is associated with an increase in BBM total phospholipids due to an increase in PC and PE (13). This diabetes-associated increase in BBM PC and PE, and the fish oil-associated decline in BBM PC and PE led to the hypothesis that the synthesis of phospholipids in the enterocyte is influenced by diet and diabetes. The next step was to examine the site of lipid synthesis and membrane assembly, namely the EMM.

Diabetes was found to be associated with an increase in jejunal EMM total phospholipid content in rats fed BTC, FOC and FO, with this increase being primarily due to an increase in PE content in all groups, although SM was also increased in animals fed BTC (Tables 3–6). The increase in PE was not associated with any changes in the activity of PEMT (Table 7), but may be due to changes in the enzymes involved in *de novo* PE synthesis. The increase in EMM SM levels with diabetes in animals fed beef tallow suggests that future studies should

[a]The composition of the diets and abbreviations are given in Tables 1 and 2. [b]$P < 0.05$, fish oil vs. beef.

also consider examining the activity of sphingomyelinase. Insulin increases sphingomyelinase activity (38), and therefore diabetes may be associated with a decline in the activity of this enzyme and thereby lead to increased EMM SM levels.

The total cholesterol content of jejunal EMM was approximately 45% higher in diabetic than in control rats, but only when they were fed a high cholesterol diet (BTC or FOC). Cholesterol absorption is known to be increased in diabetes (39). Control animals appear to maintain a constant EMM cholesterol content even in the face of a high dietary content of cholesterol. This homeostatic regulation appears to fail in diabetes. The inability of the diabetic rat jejunal EMM to cope with an increased dietary load of cholesterol may be related to the known changes in cholesterol metabolism that are observed in diabetes. Intestinal *de novo* synthesis of cholesterol has been shown to be increased 2–3-fold in streptozotocin-diabetic rats (40) associated with an increase in 3-hydroxy-3-methylglutaryl-CoA reductase activity (41–43). Cholesterol feeding did not alter cholesterol synthesis in control animals, but markedly inhibited cholesterol synthesis in the diabetic small intestine (44). In control rats, feeding a diet enriched in ω3 polyunsaturated fatty acids is associated with an increase in acyl-CoA:cholesterol acyltransferase activity and is not increased further with dietary cholesterol supplementation (45,46). The mechanism by which jejunal EMM cholesterol is increased in diabetic rats on a high cholesterol diet is unknown, but may be related to the possible increased availability of dietary cholesterol for membrane synthesis resulting from exceeding the capacity of the increased lipoprotein transport from the intestine to the circulation observed with diabetes (47).

BBM phospholipid content is reduced by fish oil feeding (16), although the mechanism of this alteration is not clear. Feeding fish oil also reduced the total phospholipid content of control jejunal EMM (Table 3), which resulted in a decrease in the phospholipid-to-cholesterol ratio, with changes also occurring in individual phospholipids including SM, PC and PI (Table 5). Fish oil feeding does not appear to alter membrane cholesterol content compared to feeding beef tallow. In diabetic animals, feeding fish oil reduced the total phospholipid content of jejunal EMM of animals fed the high cholesterol diet (FOC), but not those fed the low cholesterol diet (FO). This decline in total phospholipids was a consequence of the reduction in SM and PE (Table 5). The data suggest that feeding ω3 polyunsaturated fatty acids is associated with a decrease in phospholipid synthesis.

The decrease in EMM PC observed with fish oil feeding (Table 5) led us to postulate that enterocyte microsomal PC synthesis may be affected by the CPT and the PEMT pathways. The decrease in PC observed in jejunal EMM of control rats fed FO was associated with a marked reduction in the activity of EMM CPT (Table 7), the enzyme catalyzing the last step in the PC synthesis by the CDPcholine pathway. The decline in PE in control rats fed FO or FOC, and in diabetic rats fed FOC (Table 5), cannot be explained by differences in microsomal PEMT activity (Table 7) and may involve a decrease in the *de novo* synthesis of PE. The marked reduction in EMM SM content with fish oil feeding may be due to a decline in *de novo* synthesis or an increase in sphingomyelinase activity.

Cholesterol supplementation did not alter jejunal or ileal EMM total phospholipid content or composition in control animals (Tables 3 and 5). In diabetic rats, cholesterol feeding did not alter the jejunal EMM total phospholipid content when fed beef tallow (BTC vs. BT), but was associated with a decline in total phospholipids when fed fish oil (FOC vs. FO) due to a reduction in PE. Thus, dietary cholesterol may influence the regulation of *de novo* phospholipid synthesis in the rat small intestine, as it does in rat liver (48).

Whereas the jejunal EMM was responsive to the effects of dietary fatty acids and cholesterol, and to diabetes, the ileal EMM showed relatively few changes, namely a decline in SM and an increase in PC/PE ratio with fish oil feeding in diabetes (FOC vs. BTC), an increased cholesterol content, and reduced phospholipid/cholesterol ratio with cholesterol feeding in diabetes (FOC vs. FO) (Tables 4 and 6). Except for an increase in cholesterol content with diabetes in animals fed FOC, diabetes was not associated with any change in phospholipid, cholesterol and phospholipid composition. The activities of CPT and PEMT in ileal EMM did not respond to fish oil feeding (Table 7). It is possible that the EMM are inherently different for the ileum and for the jejunum, as is the case for microsomal desaturase activities (49). Alternatively, the dietary signal to adapt is likely much stronger in the jejunum than in the ileum, and when ileal EMM composition is modified, the change is qualitatively similar to that in the jejunum. Whether the variable responses between jejunum and ileum are on the basis of qualitative or quantitative differences remains the subject of future study.

Alterations in membrane fluidity arise from changes in membrane lipid composition and may play a role in the regulation of membrane-bound enzymes (50). Diabetes was associated with a decrease in BBM fluidity and an increase in sodium-dependent D glucose transport (51,52). Hepatic desaturase activity is also influenced by hepatic microsomal membrane lipid composition (53). Diabetes and dietary lipid-associated changes in EMM cholesterol and phospholipid content may be associated with a variety of changes in EMM fluidity which, in turn, may have influenced the activity of intrinsic membrane proteins such as CPT and PEMT. However, in addition to membrane cholesterol content, phospholipid content and phospholipid composition, phospholipid fatty acid composition is also an important determinant of membrane fluidity. The decline in CPT activity observed with fish oil feeding may be related to a change in fluidity resulting from feeding a diet enriched with ω3 polyunsaturated fatty acids. Future studies may examine the effect of diabetes and diet on EMM fluidity and phospholipid fatty acid composition.

Until the actual signals for EMM adaptation in response to diabetes and dietary manipulation are identified, the mechanisms responsible for the control of mem-

brane composition and adaptation remain the subject of further investigation.

To test if linolenic acid (18:3n-3) from vegetable oils would affect bleeding times and platelet counts in newborns, piglets were used as a model fed milk replacer diets containing 25% (by wt) vegetable oils or oil mixtures for 28 d and compared to sow-reared piglets. The oils tested included soybean, canola, olive, high oleic sunflower (HOAS), a canola/coconut mixture and a mixture of oils mimicking canola in fatty acid composition. All piglets fed the milk replacer diets showed normal growth. Bleeding times increased after birth from 4–6 min to 7–10 min by week 4 ($P < 0.001$), and were higher in pigs fed diets containing 18:3n-3, as well as in sow-reared piglets receiving n-3 polyunsaturated fatty acids (PUFA) in the milk, as compared to diets low in 18:3n-3. Platelet numbers increased within the first week in newborn piglets from 300 to 550 $\times 10^9$/L, and remained high thereafter. Milk replacer diets, containing vegetable oils, generally showed a transient delay in the rise of platelet numbers, which was partially associated with an increased platelet volume. The oils showed differences in the length of delay, but by the third week of age, all platelet counts were >500 $\times 10^9$/L. The delay in rise in platelet counts appeared to be related to the fatty acid composition of the oil, as the effect was reproduced by a mixture of oils with a certain fatty acid profile, and disappeared upon the addition of saturated fatty acids to the vegetable oil. There were no alterations in the coagulation factors due to the dietary oils. Blood plasma, platelets and red blood cell membranes showed increased levels of 18:3n-3 and long-chain n-3 PUFA in response to dietary 18:3n-3. The level of saturated fatty acids in blood lipids was generally lower in canola and HOAS oil-fed piglets as compared to piglets fed soybean oil or reared with the sow. The results suggest that consumption of milk replacer diets containing vegetable oils rich in 18:3n-3 does not represent a bleeding risk, and that the transient lower platelet count can be counterbalanced by the addition of saturated fatty acids to the vegetable oils.

Abbreviations: ANOVA, analysis of variance; APTT, activated partial thromboplastin time; C, cholesterol; CE, cholesteryl ester; EDTA, ethylenediaminetetraacetic acid; Hb, hemoglobin; HEAR, high erucic acid rapeseed; HOAS, high oleic acid sunflower; MCH, mean corpuscular hemoglobin; MCHC, mean corpuscular hemoglobin concentration; MPV, mean platelet volume; PC, phosphatidylcholine; PCV, packed cell volume; PE, phosphatidylethanolamine; PS, phosphatidylserine; PT, prothrombin time; PUFA, polyunsaturated fatty acids; RBC, red blood cell; SP, sphingomyelin; TAG, triacylglycerol; WBC, white blood cell.

While larger intakes of long-chain n-3 polyunsaturated fatty acids (PUFA) from fish oil in human diets have been shown to be associated with a number of favorable effects, such as reduced coronary heart disease, improved serum lipid profiles and decreased platelet aggregation (1–4), there have also been some concerns, for example with respect to prolonged bleeding times (3,5–14) and a decrease in platelet counts (3,5,6,8–10,14–17). These changes are believed to be due to the incorporation of eicosapentaenoic (20:5n-3) and docosahexaenoic (22:6n-3) acids into platelet phospholipids, resulting in alterations in platelet and hemostatic function.

Based on the metabolic conversion of dietary linolenic acid (18:3n-3) to 20:5n-3 and 22:6n-3 in animals and in humans (1,18,19), one might expect the same effects from vegetable oils containing 18:3n-3. A number of studies have shown that the consumption of diets containing 18:3n-3 increased the long-chain n-3 PUFA in blood lipids (20–27), but the increases were less than those seen with the inclusion of fish oils containing 20:5n-3 and 22:6n-3 (20,28). The possibility that vegetable oils containing substantial amounts of 18:3n-3 might affect bleeding times or platelet counts was recently investigated. In three studies with humans, bleeding times were either moderately increased (25,29) or remained the same (27) with the consumption of canola oil, but changes in platelet counts were not investigated. In a study on newborn piglets, a reduction in platelet count was observed after 18 d when oil/fat mixtures were fed containing about 33% canola oil or high oleic acid safflower or sunflower oil (28), but bleeding times were not measured.

The possible risk of increased bleeding and thrombocytopenia due to dietary n-3 fatty acids would be of particular concern to infants because of their greater susceptibility to injury, their higher intake of food per unit body weight and their often restricted choice in diet. The recent interest to improve the n-3 fatty acid contents of infant formulas (4,30,31) might lead to the inclusion of increased 18:3n-3 from vegetable oils to satisfy the n-3 requirement. The increased 18:3n-3 content in infant formulas needs to be evaluated in the light of the apparent risks involved.

In the present study, the risk factors of increased bleeding and decreased platelet counts were assessed in newborn piglets fed milk replacer diets containing various vegetable oils with different levels of 18:3n-3 as the sole source of fat in the diet. The pig was chosen because it is believed to be a suitable model for hematological studies in humans (32). The oils tested included soybean

oil and canola oil which, in addition to 18:3n-3, contained high levels of either linoleic acid (18:2n-6) or oleic acid (18:1n-9), respectively. Oils high in 18:1n-9 and low in 18:3n-3, i.e., high oleic acid sunflower (HOAS) oil and olive oil, were used for comparison. Sow-reared groups were included which received preformed C_{20} and C_{22} n-6 and n-3 PUFA from maternal milk. Canola oil was included in order to compare its effects with those of the other oils. Canola oil is presently excluded from infant formulas (33) in the United States, as its safety has not been conclusively documented.

MATERIALS AND METHODS

Animals and housing. Newborn Yorkshire male and female piglets were left with the sow for one day to permit consumption of colostrum. Littermates were allocated randomly to the diets so that the diets were balanced for litter and sex. Piglets were housed individually in stainless steel cages, arranged in banks of six (34), which were equipped with a common milk replacer reservoir and an automatic feed dispensing system. Animals were fed every two hours at a rate of solid intake equivalent to 7% of body weight/day. Body weights were recorded every three days and feed was adjusted accordingly.

Diets. The oils used in these studies, alone or in mixtures, included: soybean oil (CanAmera Foods Inc., Toronto, Ontario, Canada), HOAS oil and olive oil (Loblaws Ltd., Ottawa, Ontario, Canada) canola and high erucic acid rapeseed (HEAR) oils (CanAmera Foods, Inc., Altona, Manitoba, Canada), and linseed oil (gift from Dr. J.D. Jones, Ottawa, Ontario, Canada). The fatty acid composition of the test oils and oil mixtures are shown in Table 1. Small amounts of HEAR oil were added to canola oil to bring the level of erucic acid (22:1n-9) to about 2%, which is the maximum permissible level of 22:1n-9 in canola oil in the United States (33). A mixture of oils was prepared from HOAS oil, soybean oil and linseed oil to mimic the fatty acid composition of canola oil, except without 22:1n-9. Only sow milk contained long-chain n-6 and n-3 PUFA.

TABLE 1

Fatty Acid Composition of Sow Milk and Oils Used in Milk Replacer Diets

Fatty acids	Sow milk[a]	Soybean oil	HOAS[b] oil	Canola oil[c]	Mixture of oils[d]
≤14:0	2.1	0.1	0.1	0.1	0.1

24:0	0.1	0.1	0.4	0.2	0.2
24:1n-9	0.1	0	0	0.2	0

[a]Sow milk contained 1.8% 14:0, 1.6% n-6 PUFA (polyunsaturated fatty acids; 20:3n-6, 20:4n-6, 22:4n-6 and 22:5n-6), and 0.7% n-3 PUFA (20:5n-3, 22:5n-3 and 22:6n-3).
[b]HOAS, high oleic acid sunflower.
[c]Mixture of canola oil (0.8%, 22:1n-9) and high erucic acid rapeseed oil (42.9%, 22:1n-9) in the ratio of 98:2.
[d]Mixture of HOAS oil, soybean oil and linseed oil in a ratio of 55:31:14.

Milk replacer diets were stored at -20°C and prepared daily to include 21% solids of which dietary oil was 25% by weight (~50% of calories) and γ-globulin was 16% (35). Formalin (40% solution) was added as a preservative at 0.1% of total milk replacer. The digestible energy content of the final milk replacer was 953 kcal/L (35).

The level of vitamin E (α-tocopherol) included was 22 IU/kg diet, or 37% more than the National Research Council (NRC) requirements given for newborn piglets (36). This level appears to be too low as assessed by liver vitamin E concentrations of vitamin E, which ranged from 1–4 ng/mg wet weight. The vitamin E in the diet was therefore increased to 100 (one canola group, Experiment I) and 150 IU/kg (all diets, Experiment II) with a corresponding increase to about 7 and 14 ng/mg wet weight of liver for Experiments I and II, respectively. Sow milk contains about 2 μg/mL α-tocopherol.

Bleeding time measurements. Bleeding measurements were taken at one day of age and every week thereafter by the same person. Piglets were placed in a harness, a small area of the shoulder was cleaned and shaved, and an incision was made using a Simplate II device (Organon Teknika, Scarborough, Ontario, Canada) which gave two cuts 5 mm in length and 1 mm deep. Every 30 s a filter paper disc was carefully placed near the cut without disturbing it. The bleeding time was recorded as the time between the incision and when the filter paper no longer stained.

Blood sampling and measurements. Blood for hematological measurements was taken by orbital sinus puncture (37), and 0.5 mL was collected in each of two tubes, one containing sodium citrate (for coagulation studies), the other ethylenediaminetetraacetic acid (EDTA, for complete blood counts) as anticoagulant. The blood was thoroughly mixed with the anticoagulants and transported immediately for analysis. Complete blood count including a platelet count and mean platelet volume (MPV) and differential were measured using a Technicon H-2 analyzer (Technicon Instrument Corp., Tarrytown, NY).

Lipid analyses. For lipid analyses, about 15 mL of blood was obtained from the jugular vein using vacutainer tubes containing EDTA. The blood was taken from three piglets/diet at time of slaughter. Whole blood was separated into plasma, platelets and red blood cell (RBC) membranes as follows: the blood was centrifuged as soon as possible at 150 × *g* for 15 min. The plasma was removed, adjusted to pH 6.5 with 1 M citric acid, and two drops of EDTA were added. The plasma was centrifuged again at 150 × *g* to remove traces of red and white cells, and then at 2500 × *g* for 15 min to remove the platelets. The plasma was stored at –70°C until analyzed for lipids. The platelets were suspended in 1 mL of buffer (20 mM

Na_2HPO_4, 130 mM NaCl and 2 mM EDTA at pH 6.5) containing inhibitors (10 µL of 4 mM iodoacetamide, 20 µL of 4 mM *N*-ethylmaleimide in 50% ethanol, and 10 µL of aprotinin containing 10,000 units/mL) and centrifuged at 2500 × *g* for 15 min. The platelets were then resuspended in 1 mL of buffer plus inhibitors and stored at –70°C. For lipid analyses, the platelets from the three piglets/diet were combined. The RBC membranes were prepared from RBC as described (38).

Platelets and RBC membranes were taken up in chloroform/methanol/water (1:2:0.8, by vol) and thoroughly mixed. More chloroform and water was then added to give a final volume ratio of 2:2:1.8 for chloroform/methanol/water (39). The chloroform layer contained the total lipids. The total lipids from serum were extracted as described (40). Lipid classes were separated by thin-layer chromatography using silica gel H coated plates (41), and observed under ultraviolet light after spraying the plates with 2′,7′-dichlorofluorescein. Fractions were scraped off, methyl heptadecanoate was added as internal standard, and the lipids were transmethylated in the presence of silica gel using anhydrous HCl/methanol (5% by wt). The resulting methyl esters and dimethyl acetals were analyzed by gas–liquid chromatography (42).

Bone marrow examination. Sections of femoral bone marrow were taken at 28 d in Experiment II. Samples were fixed in formalin, embedded in paraffin and 5-µm thick sections were stained with hematoxylin and eosin and examined by light microscopy.

Statistics. Data from each age set were examined separately using analysis of variance (ANOVA). The terms in the model for the milk replacer-fed piglets were litter and treatment. The data were reanalyzed using the 0 d data as a covariate. The inferences were very similar from this analysis, and therefore only the results from the ANOVA are presented. To examine patterns during each experiment, the data were reanalyzed using a repeated measures ANOVA, thereby allowing differences over time to be evaluated on a within-piglet basis. For none of the parameters analyzed was diet × age interaction significant ($P > 0.05$). The litter effect was not significant ($P > 0.05$) for the parameters considered here, and, therefore, the hematological data and the lipid and fatty acid composition data (three piglets chosen at random from diet groups in Experiment II) were examined using a one-way ANOVA with treatments as the only term in the model. Results were considered to be statistically significant whenever $P < 0.05$. Data presented in Tables 2 and 3 are least square means because some values are missing; mean significant levels were based on the least significant difference test.

RESULTS

Diets and growth. The fatty acid composition of the dietary oils used in the studies is shown in Table 1. There were no significant differences in growth among piglets fed the different artificial milk replacers, and, for that reason, the results of the four diets in Experiment II were combined in Figure 1. The body weights of piglets left nursing the sow were significantly greater during the first week compared to piglets fed the milk replacer diets, but by the fourth week this was reversed. When milk replacers were fed at 7% of body weight, there were no significant differences in milk consumption among the different diets (Fig. 1).

Bleeding times. The bleeding times of one-day-old piglets ranged from 4–6 min and increased significantly ($P < 0.001$) with age on all milk replacer diets (Fig. 2). Generally, oils containing 18:3n-3 (soybean oil, canola oil, mixture of oils) gave longer bleeding times than oils low in 18:3n-3 (HOAS oil) (Experiment II, 28 d). There were no significant differences in bleeding times between canola and soybean oil-fed piglets and between the mixture of oils (similar to canola oil in fatty acid composition) and canola oil (Experiment II).

Platelets. The platelet results from two additional unpublished studies (III and IV) are included in Table 2. One-day-old piglets had a relatively low platelet count ranging from 200 to 450 × 10^9/L (mean 320 × 10^9/L). For nursing piglets, the platelet counts increased significantly ($P < 0.01$) within one week to 500–630 × 10^9 counts/L and remained high thereafter (Experiments II and III). Canola oil caused a significant and consistent two-week delay in the rise of platelet counts. The transfer of piglets to solid diets at 28 d had no effect (Experiment III) and neither did increasing the level of vitamin E in the diet (Experiment I). To test whether the delay in platelet counts might be related to 22:1n-9 in canola oil, a mixture of oils was fed having a fatty acid composition similar to canola oil but devoid of 22:1n-9 (Table 1). Erucic acid at the level of ~2% did not appear to affect the delay in platelet counts, as piglets fed the mixture of oils and canola oil had a similar pattern in platelet counts (Experiments II and IV, Table 2). On the other hand, adding saturated fatty acids in the form of coconut oil to canola oil (in a 2:3 ratio) caused disappearance of the delay (Experiment III). HOAS oil also caused a two-week delay in the rise of platelet counts similar to that caused by canola oil (Experiment II).

The results with soybean oil were not consistent. In Experiments I, II and IV, soybean oil showed high platelet counts after about one week, but not in Experiment III, in which there was a one-week delay. Olive oil showed a similar inconsistency. In Experiment III, the platelet count was high after 10 d, whereas in Experiment IV the platelet count was low.

In the one-day-old piglet, the distribution of platelet size was generally biphasic, but by the second week a more bell-shaped distribution was observed. This was associated with a significant reduction in MPV in sow-reared piglets (Table 3). By the third and fourth week, sow-reared piglets had a significantly reduced MPV compared to those fed the milk replacer diets high in oleic acid (HOAS, canola and mixture of oils), but there was no significant correlation of MPV to platelet counts.

Other hematological variables. The hematological data from Experiment II are presented in Table 3. In general, the major changes in many of the parameters were related to the age of the piglets. These included a significant increase in hemoglobin (Hb), RBC counts and mean corpuscular hemoglobin concentration (MCHC),

[a]Piglets were one day of age when placed on experiment. Values are means of six piglets/diet. SEM, pooled standard error of the mean between diets (horizontal values) and within animals (vertical values). ANOVA, analysis of variance testing for effect of diet (column) and time on diet (row); NS, $P > 0.05$; *$P < 0.05$; **$P < 0.01$. See Table 1 for other abbreviations.

[b–g]Values within an experiment and time period (column) having different superscripts *b–d*, and within a diet (row) having different superscripts *e–g*, are significantly different ($P < 0.05$).

[h]Canola oil diets contained 22 IU vitamin E per kg.

[i]Canola oil diet contained 100 IU vitamin E per kg.

or an increase in mean corpuscular volume followed by a decrease. The packed cell volume (PCV), the MPV and mean corpuscular hemoglobin (MCH) values did not change significantly throughout the four-week feeding trial, while the white blood cell (WBC) counts showed wide variation from one week to another.

In general, there were several diet differences at the one and two week measurements, but by the fourth week, all the diet differences disappeared. The values for the soybean oil-fed group were similar to sow-reared piglets, except at a few time periods in WBC, MCH and MCHC. On the other hand, compared to sow-reared piglets, the three milk replacer diets high in oleic acid (canola oil, HOAS oil and the mixture of oils) showed decreased values of PCV, Hb and RBC counts within the first two weeks, and retained higher MPV values even at four weeks on the diets.

The prothrombin time (PT) and activated partial thromboplastin time (APTT) values were high at one day of age, decreased significantly after one week, and did not change significantly thereafter (Table 3). Piglets fed soybean oil and HOAS oil showed significantly higher PT values at two and three weeks, but by the fourth week there were no significant differences between diets. The APTT values in piglets fed the milk replacer diets remained constant after the first week, while the sow-reared piglets showed some variation which, however, was not significant.

Bone marrow. The bone marrow sections of all piglets (Experiment II) were normal with the exception of three

$^{a-f}$Values within a hematological variable and time period (column) having different superscripts *a, b, c,* and within a diet (row) having different superscripts *d, e, f,* are significantly diffrent ($P < 0.01$). Piglets were one day of age when placed on experiment. Values are means of six piglets/diet. SEM, pooled standard error of the mean between diets (horizontal values) and within animals (vertical values). ANOVA, analysis of variance testing for effect of diet (column) and time on diet (row); NS, $P > 0.05$; *$P < 0.05$; **$P < 0.01$. PCV, packed cell volume; Hb, hemoglobin; RBC, red blood cell; WBC, white blood cell; PT, prothrombin time; MCV, mean corpuscular volume; MCH, mean corpuscular Hb; MCHC, mean corpuscular Hb concentration; MPV, mean platelet volume; APTT, activated thromboplastin time.

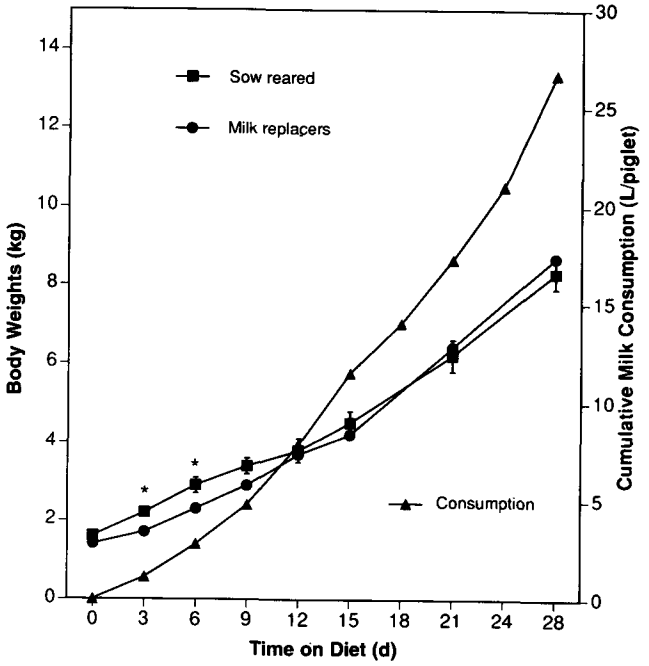

FIG. 1. Body weights of piglets left with the sow (●) or fed milk replacer diets (■) (25% by wt oil) from 1 to 28 d (Experiment II). For each time period, the pooled SEM (error bar) and significance (no label, $P > 0.05$; *$P < 0.05$) are indicated. The four milk replacer diets in Experiment II are combined because there were no significant differences between them. The average cumulative milk consumption per piglet (▲) fed milk replacer for 28 d is shown on the right side.

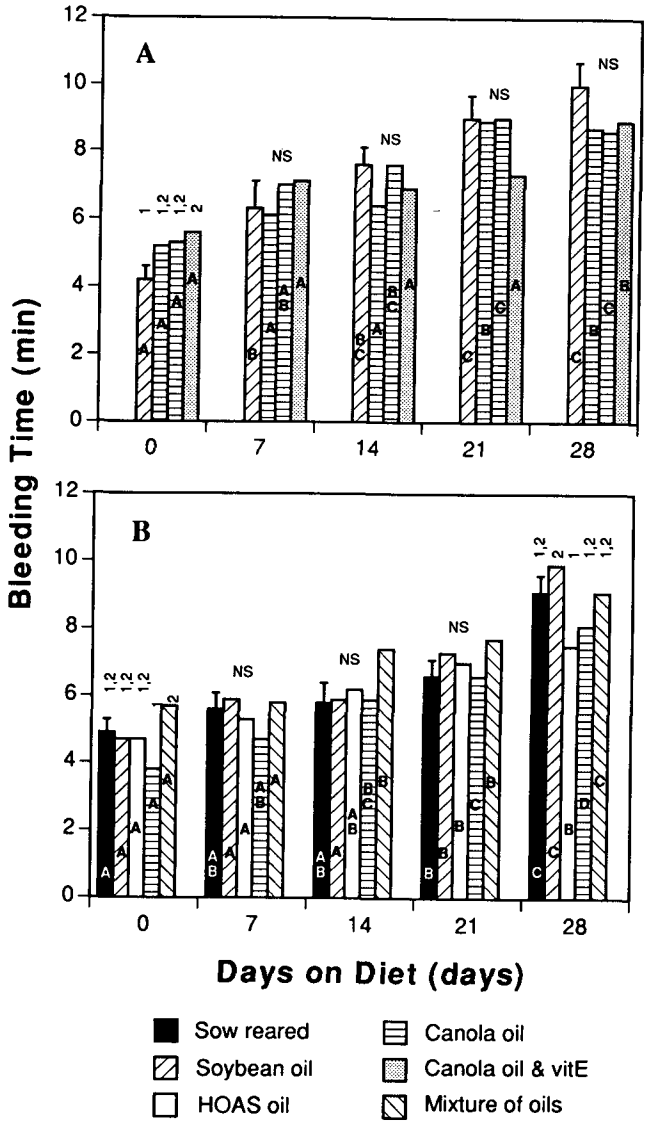

FIG. 2. Bleeding times of piglets left with the sow or fed milk replacer diets (25% by wt oil) from 1 to 28 d. For each time period and experiment, the pooled SEM is indicated as an error bar above the column. Differences between diets ($P < 0.01$) are indicated by different numbers above the columns. Differences within a diet with time are shown by different capital letters within the bars. High oleic acid sunflower (HOAS); mixture of oils, HOAS oil/soybean oil/linseed oil (55:31:14). Results of Experiments I (A) and II (B).

piglets (two fed canola oil and one fed soybean oil) which showed somewhat hypercellularity in the marrows with increased numbers of megakaryocytes at 28 d. These piglets also showed a high (>600 × 10^9/L) platelet count.

Blood lipid changes. There were characteristic differences in the plasma, RBC membrane and platelet lipids, but no differences between diets. While plasma was rich in cholesteryl esters (CE; ~36%), phosphatidylcholine (PC; ~30%), sphingomyelin (SP; ~15%) and triacylglycerol (TAG; ~11%), the RBC membranes were composed mainly of cholesterol (C; ~27%), phosphatidylethanolamine (PE; ~19%), PC (~18%), SP (~14%) and phosphatidylserine (PS; ~12%). The platelet lipid profile was generally similar to that of the RBC membrane lipids except for higher PS (~16%), TAG (~9%) and CE (~5%), and lower SP (~11%) values.

The fatty acid composition of plasma, RBC membrane and platelet PC (Table 4) and PE (Table 5) of Experiment II were selected for diet comparisons. Piglets fed soybean or canola oils, which contained appreciable amounts of 18:3n-3, showed significantly higher levels of both 18:3n-3 and its C_{22}n-3 PUFA metabolites in all three blood fractions as compared to piglets fed HOAS oil which contained little 18:3n-3. On the other hand, piglets nursing the sow received preformed C_{22}n-3 PUFA and little 18:3n-3 in their milk (Table 1), which was reflected in their relative high abundance of the n-3 PUFA and low 18:3n-3 content in the blood fractions. The concentration of 20:5n-3 in canola oil-fed piglets was significantly higher than in any of the other diets, including the nursing piglets. In plasma and RBC membrane PC and PE, the ratio of n-6 to n-3 long-chain PUFA was lowest in canola oil-fed piglets, followed by soybean oil, sow-reared, and HOAS oil-fed piglets (Tables 4 and 5). Generally, the n-6/n-3 ratio for each diet group was similar between plasma and RBC membranes within each phospholipid, and higher for PC than for PE. In platelet PC and PE, the ratio of n-6 to n-3 long-chain PUFA for all diet groups was much higher as compared to plasma and RBC membrane lipids. The n-6/n-3 PUFA ratios were

[a–d]For footnotes *a* to *d* see Table 4. [e]All dimethylacetal values are percent of total dimethylacetal and fatty acid methyl ester responses, while the fatty acid data are expressed as percent of total fatty acid methyl esters only. Other abbreviations as in Table 4.

highly correlated (0.97–0.99) to the dietary n-6/n-3 ratios (calculations not shown).

The relative concentration of 18:2n-6 in the PC and PE was proportional to that present in the diet (calculations not shown). The concentration of arachidonic acid (20:4n-6) in plasma and RBC membranes, but not in platelets, was significantly higher in sow-reared piglets compared to those fed the milk replacer diets because this acid was present in sow milk. Among the milk replacer diets, there were few differences in 20:4n-6; generally, canola oil was on the low side and HOAS on the high side.

The monounsaturated fatty acids generally paralleled those found in the diet, and the incorporation of 22:1n-9 was minimal (Tables 4 and 5). The relative concentration of the saturated fatty acids was generally lower in the canola and HOAS oil-fed piglets compared to the soybean oil-fed and sow-reared piglets. The alkenyl ether content, measured as dimethylacetals, was greatest in platelet PE; on the milk replacer diets their levels were reduced significantly.

DISCUSSION

In this study, newborn piglets were fed milk replacers containing soybean or canola oils at 25% by weight of dry matter content providing each piglet with 1.5 g/d 18:3n-3 at 3 d, 4.9 g/d at 15 d and 5.8 g/d at 28 d of age, or approximately 1 g/d/kg body weight (calculated from results in Fig. 1). This consumption of 18:3n-3 from canola or soybean oils by the newborn piglet is approximately ten times greater per kg body weight than is provided in adult human trials (in Ref. 29, canola oil was fed at 7.5 g/d or 0.1 g/d/kg body weight for a 75 kg person). Based on the increased consumption relative to body weights of a newborn compared to an adult, there is certainly a need to test the newborn using dietary oils containing 18:3n-3. Furthermore, the newborn is undergoing a rapid transition from oxidizing glucose (in the fetal state) to oxidizing fatty acids as the main source of energy (43), and may therefore be more sensitive to dietary changes.

The results of these studies show that the bleeding times increased with age over the first four weeks on all diets. Piglets fed about 1 g/d/kg 18:3n-3 from canola or soybean oil diets, or those nursing the sow, which received preformed long-chain n-3 PUFA, showed prolonged bleeding times after four weeks compared to HOAS oil feeding (Fig. 2). The increased bleeding times in the canola and soybean oil groups would appear to be due to the piglet's ability to convert dietary 18:3n-3 into 20:5n-3 and 22:6n-3, as evidenced by the higher levels of these n-3 PUFA in blood lipids of these piglets compared to those fed HOAS oil (Tables 4 and 5). The increase in long-chain n-3 PUFA in blood lipids in response to dietary 18:3n-3 has been observed by other investigators (20,22,24,27), but because all but one group (24,29) did not measure bleeding times concurrently, the possible risk could not be assessed. Furthermore, this is the first study in which bleeding has been tested in the newborn.

Three studies with adult humans were reported recently in which diets were formulated to contain substantial amounts of canola oil (about 10% 18:3n-3) that provided subjects with 3 (25) and 7.4 g/d (27,29) 18:3n-3, or 0.04 and 0.1 g/d/kg body weight, respectively. In two studies a significant increase in bleeding time was observed, namely from 4.3 to 6.7 min (25) and 3.9 to 4.9 min (29). The latter group (29) did not confirm increased bleeding times in their repeat study (27). However, it should be noted that all these bleeding times are within the normal range accepted for humans (11,44). One would conclude from these results that consumption of vegetable oils with about 10% 18:3n-3 as sole source of fat in the diet appears to provide a low risk of excessive bleeding in adults (25,27,29). A similar conclusion can be made from the results of the present study of feeding canola oil or soybean oil as sole source of fat to newborn piglets. The bleeding times increased significantly ($P < 0.001$) from about 4 to 6 min to 7 to 10 min, but the risk for bleeding would appear to be low, except possibly for hemophiliacs.

Piglets fed milk replacer diets often showed a transient delay in the normal rise of platelet counts within the first week of life compared to sow-reared piglets. This delay in the rise of platelet counts was consistent and more prolonged for canola and HOAS oil-fed piglets compared to soybean oil and olive oil-fed piglets. It would appear that this phenomenon was related to the fatty acid composition of the oil in the milk replacer, as the delay was reproduced by mimicking the fatty acid profile of canola oil, and eliminated by the addition of saturated fatty acids in the form of coconut oil to canola oil. A low level of dietary 16:0 was recently shown to be one of the factors associated with lower platelet counts in piglets even in the presence of high levels of shorter chain saturated fatty acids (20%) in the diet (28). If the effects of saturated fatty acids on platelet number can be verified, it would alleviate the concern of reduced platelet counts in the newborn fed diets containing vegetable oils, all of which are generally low in saturated fatty acids. It is of interest to note that *de novo* synthesis of fatty acids in piglets during the first three weeks after birth is negligible (45,46), which coincides with the time of reduced platelet counts. A low availability of saturated fatty acids, both from the diet and *de novo* synthesis, would lead to lower levels of total saturated fatty acids in membrane lipids, which was in fact observed in all three blood components from canola and HOAS oil-fed piglets (Tables 4 and 5). As cell membranes contain approximately 40% saturated fatty acids (47), a reduction in this level could lead to altered function and/or physical characteristics.

Diets high in 22:1n-9 have been associated with reduced platelet counts in humans (48–50). The results of the present study show that the delay in the rise of platelet counts is associated with fatty acids other than 22:1n-9 as a similar pattern was observed with oils and oil mixtures devoid of 22:1n-9 as with canola oil. The question of whether 22:1n-9 at levels in excess of that permitted in canola oil, i.e., 2% (33), will cause a further reduction in platelet counts in the newborn, remains to be investigated.

There was no correlation between increased bleeding

and decreased platelet counts in this study, as was observed by others (5,10,50). Furthermore, we observed no increase in PT and APTT in response to increased bleeding in agreement with studies with fish oil (5,7,14,15,16) and 22:1n-9 (50). A number of hematological parameters showed temporary changes (PCV, Hb and RBC counts) which appeared to be related to diets high in 18:1n-9, but these differences disappeared by the fourth week on the diet. Most hematological values were within the normal range reported for piglets (32,51).

The Lipids of Slugs and Snails: Evolution, Diet and Biosynthesis

Ning Zhu*, **Xiaonan Dai, Don S. Lin** and **William E. Connor**

Division of Endocrinology, Metabolism and Clinical Nutrition, Department of Medicine, Oregon Health Sciences University, Portland, Oregon 97201

There is a considerable gap in current knowledge of the lipid composition of snails and slugs, both of which belong to the phylum Mollusca. We have therefore analyzed the sterol and fatty acid compositions of three species of slugs and three species of snails. The sterols of slugs included eight different sterols: cholesterol contributed 76-85% of the total sterols, brassicasterol accounted for 4-13%; other sterols we identified were lathosterol, 24-methylene cholesterol, campesterol, stigmasterol, sitosterol and sitostanol. In contrast, snails contained two additional sterols, desmosterol and cholestanol. Of the polyunsaturated fatty acids in slugs, linoleic (18:2n-6) and arachidonic acids (20:4n-6) were the major n-6 fatty acids, while linolenic (18:3n-3) and eicosapentaenoic acids (20:5n-3) were the predominant n-3 fatty acids. Docosahexaenoic acid (22:6n-3), the end product in the n-3 fatty acid synthetic pathway and an important membrane fatty acid of mammals, fish and birds, was absent in both slugs and snails. However, the analogous product of n-6 fatty acid synthesis, 22:5n-6, was found in both snails and slugs. This raises speculation about preference for n-6 fatty acid synthesis in these species. Our data show the unique sterol and fatty acid compositions of slugs and snails, as well as similarities and differences in sterol composition between the two. The results between the two land mollusks are contrasted with those of marine mollusks, such as oysters, clams and scallops.

***Lipids 29,* 869–875 (1994).**

Mollusks as a group have a unique sterol and fatty acid composition. Previously, we reported that oysters, clams and scallops contain many other sterols besides cholesterol, including 24-methylene cholesterol and brassicasterol (1,2). These shellfish sterols are variably absorbed by the human intestine (1). Shellfish also have a high concentration of the biologically important longer chain n-3 fatty acids (3). However, detailed information about the sterol and fatty acid composition of slugs and snails is lacking, especially for slugs (3–14). Both are members of the same phylum, Mollusca, with slugs having evolved from snails (15).

In the present study, we have analyzed the sterol and fatty acid composition of three species of slugs and three species of snails. These land mollusks had quite different fatty acids and sterols than the mollusks of the sea such as clams, oysters and scallops. The nutrition of the marine mollusks is derived from phytoplankton, the plants of the sea, and zooplankton, whereas the diet of slugs and snails consists of land-based vegetation. In both species, cholesterol synthetic precursors were found, desmosterol in snails and lathosterol in slugs, and in both we observed the complete absence of the n-3 docosahexaenoic acid.

Abbreviation: TLC, thin-layer chromatography.

MATERIALS AND METHODS

Three species of slugs were collected from local gardens in Portland, Oregon, between May and June of 1992–1993, and were classified according to "Plants and Animals of the Pacific Northwest" (15). They included *Prophysaon andersoni*, *Arion ater* (coal-black phase and reddish-brown phase) and *Limax maximus*. *Prophysaon andersoni* was 5–6 cm long and weighed 0.2–0.5 g, with lemon-yellow color. In the coal-black phase, *A. ater* was 5–7 cm, 0.8–2.1 g. In the reddish-brown phase, *A. ater* had the same length as in the coal-black phase, but was heavier (1.2–2.8 g). *Limax maximus*, a gray color, was the longest and heaviest among the different species of slugs studied (length, 8–11 cm; weight, 2.3–7.8 g). We also analyzed three different species of snails: one species of canned snail (*Helix* sp., from France) and two species of live snails collected in the local gardens (*Vespericola columbiana and Hapotrema sportella*). They differed in weight and color of the shell. *Helix* sp., the heaviest among them (7.2–10.0 g without the shell), had a light-brown shell with dark-brown strips. *Vespericola columbiana* was the lightest (0.4–0.6 g) with a nearly black shell. *Haplotrema sportella* weighed 2.0–2.9 g, with a brown shell color.

The slugs and snails were killed by exposure to diethyl ether vapor. The entera and slime were removed. The tissues were freeze-dried and then ground. The lipids were extracted by a modified method of Folch *et al.* (16). The sterol composition was determined by saponification, extraction, digitonin precipitation and gas–liquid chromatography, as has been described (17). Briefly, slug lipids were saponified with alcoholic KOH. Free sterols were precipitated with digitonin (18). Digitonin precipitable sterols were then converted to trimethylsilyl ethers and subjected to gas–liquid chromatography using cholestane as an internal standard. The analyses were performed by gas–liquid chromatography on an instrument equipped with a hydrogen flame-ionization detector (model Sigma 3B; Perkin-Elmer, Norwalk, CT) and a 30-m SE-30 fused silica capillary column. Temperatures of column, detector and injection port were 260, 300 and 300°C, respectively. Helium was used as the carrier gas. [4-^{14}C]Cholesterol (New England Nuclear, Boston, MA) was used as internal standard to monitor any losses. The recovery varied between 80–90%.

The fatty acid compositions of slug and snail lipids were analyzed by methods described previously (19). Aliquots of lipid extracts were saponified with alcoholic KOH. Neutral lipids were removed by hexane extraction. Fatty acids were recovered by acidifying the aque-

ous phase, and extracting with hexane. Free fatty acids were then methylated with boron trifluoride in methanol (20). To analyze the fatty acid compositions of phospholipids, another aliquot of lipid extract was subjected to thin-layer chromatography (TLC) using the solvent system hexane/chloroform/diethyl ether/acetic acid (80:10:10:1, by vol) (21), and lipid classes (phospholipids, free fatty acid, triglycerides and cholesteryl esters) were separated. The fatty acids of phospholipids were transmethylated with boron trifluoride in methanol as described. Methyl ester of fatty acids were analyzed by gas–liquid chromatography on an instrument equipped with a hydrogen flame-ionization detector (Perkin-Elmer model 8500) and a 30-m SP-2330 fused silica capillary column. Temperatures of column, detector and injection port were 184, 250 and 250°C, respectfully. Helium was used as the carrier gas. The retention time and area of each peak were measured on a dedicated chromatography station running Omega (Perkin-Elmer). A mixture of fatty acid standards was run daily for calibration purposes.

RESULTS

Sterol composition. The sterol compositions of the three species of slugs are given in Table 1. Eight different sterols were found which contained 63 to 104 mg sterols per 100 g wet tissue. Cholesterol was the major sterol (76–85% of total sterols). Brassicasterol was the next most common sterol (4–13%). Three to five percent of the slug sterols were plant sterols in which campesterol, a 28 carbon sterol, predominated. Plant sterols included campesterol, stigmasterol and sitosterol, which are the three most abundant sterols in higher plants (22). Other sterols, e.g., brassicasterol, are found in a few land plants (23). The sterol compositions were similar between different species of slugs although small differences did exist. For example, *P. andersoni* had a lower cholesterol content than the other two species of slugs.

The sterol compositions of the three species of snails are shown in Table 2. Although the sterols were similar among the different species, snails differed from slugs in containing cholestanol (1.4 to 4.1 mg/100 g wet tissue) and desmosterol (0.5 to 9.1 mg/100 g wet tissue), both of which were absent in slugs. 24-Methylene cholesterol was more consistently present in the snails. On the other hand, slugs had a higher brassicasterol content than snails. Another sterol in the pathway of cholesterol biosynthesis, 7-dehydrocholesterol, was not found.

In Table 3, the sterol compositions of slugs are compared to those of other mollusks from the sea. Although the total sterol contents were similar, the sterol compositions of slugs and snails were vastly different from those of marine shellfish. In slugs and snails, nearly 90% of the sterols were cholesterol. The other sterols included brassicasterol, campesterol, sitosterol, cholestanol, desmosterol and small amounts of lathosterol and 24-methylene cholesterol. In contrast, the cholesterol only amounted to about 40% of total sterols in filter-feeding mollusks such as scallops, oysters and clams. The other sterols were a C_{26} sterol, 22-dehydrocholesterol, brassicasterol, 24-methylene cholesterol and a C_{29} sterol. Only cholesterol was present in crab, shrimp and lobster.

Fatty acid composition. When the lipid classes (phospholipids, free fatty acids, triglycerides and steryl esters) of slugs and snails were fractionated, only the phospholipid and sterol bands were clearly seen on the TLC plate. The phospholipid fraction contained the same fatty acid compositions as did the total lipid fraction (data not shown). This suggested that the phospholipids constituted the predominate lipids in slugs and snails.

The fatty acid compositions of slugs and snails were similar among different species (Tables 4 and 5). Slug lipids contained a particularly high level of polyunsaturated fatty acids (51–57%), but docosahexaenoic acid, offer an important membrane n-3 fatty acid, was not detected in slugs although its immediate precursor, 22:5n-3, was present. Slugs contained 19–24% of saturated and 17–20% of monounsaturated fatty acids. Palmitic and stearic acids were the major saturated

TABLE 1

The Sterol Content and Composition of Different Species of Slugs

Sterol (mg/100 g wet wt)	*Prophysaon andersoni* (n = 18)	*Arion ater* (n = 18)	*Limax maximus* (n = 6)
		(means ± SD)

fatty acids. Oleic acid was the most prevalent monounsaturated fatty acid. Seventy-seven to eighty-one percent of the polyunsaturated fatty acids were of the n-6 family and 19–23% were of the n-3 family. The arachidonic acid content was especially high (13.5–14.4%) and was higher than the content of linoleic acid (11.6–15.2%). Linolenic and eicosapentaenoic acids were the predominant n-3 fatty acids.

The fatty acid compositions of slug and snail lipids showed small but significant differences. Slugs had a higher concentration of n-3 fatty acids and a lower n-6 fatty acid concentration than snails. The major n-3 and n-6 fatty acids which contributed to this difference were linolenic acid (18:3n-3) and arachidonic acid (20:4n-6). As a result, the slug lipids had a lower n-6/n-3 ratio than snail lipids. Of interest was that both species had n-6 fatty acids with a chain length of 22 carbons, i.e., 22:4n-6 and 22:5n-6.

The fatty acid compositions of slugs and snails are compared with marine mollusks and other shellfish in Table 6 and Figures 1 and 2. The most striking difference was the presence of docosahexaenoic acid in all of the shellfish from 8–27% of total fatty acids. In contrast, slugs and snails contained no docosahexaenoic acid. Slugs and snails had 3–4% eicosapentaenoic acid (20:5n-3) which was 20–30% of total fatty acids in shellfish . Both slugs and snails had a much higher content of linoleic acid (18:2n-6) and arachidonic acid (20:4n-6) than shellfish (about 4–7 times higher). Overall, slugs and snails had higher levels of n-6 fatty acids and lower levels of n-3 fatty acids than shellfish (Figs. 1 and 2) as might be expected from land based animals (n-6 predominant) compared to sea animals with predominant n-3 fatty acids.

DISCUSSION

In the present study, we have, for the first time, fully characterized the sterol and fatty acid compositions of slugs and added information about the lipids of snails. Several unique features of their lipid composition were observed. The absence of docosahexaenoic acid and the presence of other highly polyunsaturated, long-chain fatty acids in the membrane phospholipids were remarkable. A second finding was the presence of cholesterol biosynthetic precursors, desmosterol and lathosterol.

Docosahexaenoic acid is an important component of membrane phospholipids of most animals, birds and

TABLE 3

The Comparison of the Content of Major Sterols of Slugs, Snails and Marine Shellfish[a]

	Cholesterol	C_{26} Sterol	22-Dehydrocholesterol	Brassicasterol	24-Methylene cholesterol	C_{29} Sterol	Other sterols[b]	Total sterols
Slugs[c]	86.6			5.9	0.1		10.4	102.8

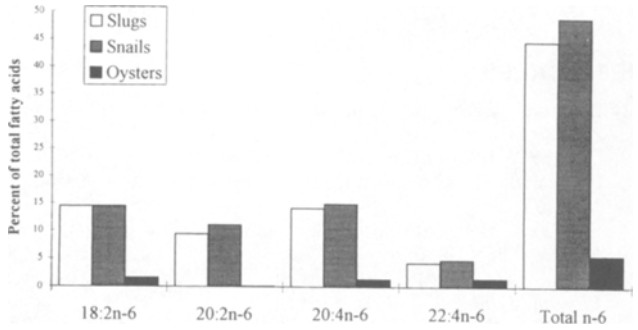

FIG. 2. The n-6 fatty acids of slugs, snails and oysters.

sea-life and is present in high concentration in organs such as brain, retina and sperm of the primates (19,24, 25). The reason for the absence of docosahexaenoic acid in slugs and snails is not known. Long-chain n-3 polyunsaturated fatty acids can be synthesized from dietary linolenic acid (18:3n-3) through a series of desaturation and chain elongation steps. In slugs, the synthesis of the very long-chain and highly polyunsaturated fatty acids proceeded through 20:5n-3 and 22:5n-3, but the further desaturation step to 22:6n-3 did not occur. There was a relative block also for 22:6n-3 synthesis in the mature and full-term human infants fed formulas containing linolenic acid (18:3n-3) (26). In that instance, too, synthesis to 22:5n-3 proceeds well, but the final step, the synthesis of 22:6n-3, occurs but seems to proceed very slowly. Even in adult humans, the feeding of flaxseed, a rich source of 18:3n-3, yields within a few days considerable increases in 20:45n-3 and 22:5n-3, but not in 22:6n-3 (Connor, W.E., unpublished observations).

In slugs there was a relatively high content of the n-6 long-chain polyunsaturated fatty acids such as 20:4n-6, 22:4n-6 and 22:5n-6. Slugs can synthesize linoleic acid from acetate (27). The presence of 22:5n-6 in slugs indicated synthesis from dietary linoleic acid (18:2n-6). Since linoleic and linolenic acids share a common enzymatic system for desaturation and elongation, the presence of 22:5n-6, the last elongation and desaturation product from 18:2n-6, and the absence of 22:6n-3, the last elongation and desaturation product from 18:3n-3, in the slugs suggested that the last step of desaturation and elongation seems to favor n-6 fatty acids synthesis. It is commonly accepted that docosahexaenoic acid is formed from the action of a Δ4 desaturase on 22:5n-3, a precursor fatty acid found in both slugs and snails. Since this enzyme has not been actually identified, an alternative pathway for docosahexaenoic acid synthesis was proposed recently by Voss *et al.* (28).

The absence of docosahexaenoic acid and the presence of an analogous n-6 fatty acid (22:5n-6) in both slugs and snails is in contrast to the mammalian brain and retina that show a decided preference for n-3 fatty acids of their cellular membranes (24). Docosahexaenoic acid is the most abundant polyunsaturated fatty acid in these nervous tissues, whereas 22:5n-6 is conspicuous by very low concentrations except under unusual circumstances. If there is a deficiency of n-3 polyunsaturated fatty acids in the diet (i.e., α-linolenic acid), then 22:5n-6 becomes the predominate fatty acid replacing 22:6n-3 (19,24). The brain of the newborn rabbit also seems to show a preference for 22:5n-6 (29). Since neither 22:6n-3 or 22:5n-6 is present in the diet of slugs and snails so far as known, clearly all of the more polyunsaturated and longer chain fatty acids are derived by synthesis from 18:2n-6 and 18:3n-3, which are richly present in the diet. Despite there being no deficiency of n-3 fatty acids in the diet, the synthetic pathway to an n-6, 22-carbon fatty acid is preferred and is even exclusive. In contrast to slugs and snails, the shellfish mollusks from the sea contain docosahexaenoic acid in quantity. This docosahexaenoic acid probably originated from the phytoplankton of their diet which are rich in both eicosapentaenoic acid and docosahexaenoic acid (30).

Although in our analyses of the three species of slugs and three species of snails in the present study there was a consistent absence of docosahexaenoic acid, Fried *et al.* (12) did find a very small quantity of docosahexaenoic acid (less than 1%), in *Helisoma trivolvis*. Furthermore, free sterols and phospholipids were the two major lipid components in the snails and slugs of this study. Fried *et al.* (10,11) found free sterols and triglycerides were the predominant lipids in *H. trivolvis* snails and *Succinea ovalis* snails. Since analytical methodology was similar between these authors and ours, the difference in results must have occurred from the different species of snails analyzed.

Of the eight sterols found in the slugs, cholesterol was the predominant sterol (76–85% of total sterols) in slugs. This cholesterol could come from dietary intake or *de novo* synthesis. However, slugs are vegetarians and do not consume cholesterol. It is not known whether slugs can synthesize cholesterol from acetate or from the other sterols present in the diet. Among the invertebrates, insects and crustaceans were found unable to synthesize cholesterol from acetate (31). The finding of lathosterol in slugs, and intermediate precursor of cholesterol biosynthesis, suggests the possibility that slugs may be able to synthesize cholesterol. However, direct evidence is needed to verify this point. Interestingly, slug lipids contained significant amounts of brassicasterol (4–13% of total sterols). A high content of brassicasterol was also found in shellfish and phytoplankton. However, the diet of slugs provided abundant plant sterols such as campesterol, sitosterol and stigmasterol

and could provide some other sterols such as brassicasterol. In slug lipids, sterols of possible plant origin contributed only 3–5% of the total sterols. Structurally, brassicasterol is similar to campesterol with one more double bond, at the 22 position. However, these two sterols have an opposite configuration at the 24 position. Brassicasterol differs from stigmasterol only by having a methyl group at the 24 position instead of an ethyl group. In view of this similarity of structure between brassicasterol and the other plant sterols, the high content of brassicasterol found in the slugs may result from dietary sources or from its conversion from dietary plant sterols. In a previous study, we demonstrated that there was dealkylation of sitosterol to form cholesterol in Florida land crab (32).

The results of these analyses provided more detailed information about the sterol and fatty acid composition of the snails although some information is available in the literature (3–12). Similar to our results, Furlong and Caulfield (9) found that cholesterol is the major sterol in the snails. They also found desmosterol, campesterol, stigmasterol and sitosterol in the hepatopancreas of snails. In our study, we found five additional sterols—cholestanol, brassicasterol, lathosterol, 24-methylene cholesterol and sitostanol—in snails. The difference in our two studies may be due to different species of snails analyzed or the higher sensitivity and resolution power of the capillary gas–liquid chromatography we used for our analyses. Snails had the same sterol composition as earthworms (*Lumbricus terrestis*) (33). Slugs had a sterol composition similar to snails and earthworms except for the absence of cholestanol and desmosterol. The reason for these differences is not known. The finding of a high content of desmosterol in snails, (9.1% in *V. columbiana*) and in the earthworm (8.6%) is interesting because usually only trace amounts of desmosterol are present in tissues. Recently, we found a large quantity of desmosterol in the sperm of primates (25). The presence of considerable but variable quantities of desmosterol in the sterols of snails suggest an active cholesterol biosynthesis. While it is true that desmosterol is found in a very limited number of plants, these are plants of the sea such as red algae (34). Desmosterol has not been identified in land plants which constitute the diet of the snails. It seems likely then that snails, in particular, must have the capacity to synthesize cholesterol. Both slugs and snails have a very different sterol composition from the marine mollusks, which contain other unique sterols such as a C_{26} sterol and 22-dehydrocholesterol (1). It is likely that these shellfish obtain their sterols form their diet of phytoplankton (35).

In conclusion, slugs which have evolved from snails (15) have sterol and fatty acid compositions similar but not identical to snails. Relatively high amounts of two biologically important fatty acids, arachidonic and eicosapentaenoic acids, were found in both the slugs and snails. Docosahexaenoic acid (22:6n-3) was completely absent in both slugs and snails. If the n-3 and n-6 fatty acid share the same enzyme system for elongation and desaturation, it is not clear why there was such a complete preference for the synthesis of 22:5n-6 over 22:6n-3. The sterol content of these two land mollusks is quantitatively similar to ocean shellfish but qualitatively quite different. The presence of cholesterol precursors, lathosterol and desmosterol, in snails and lathosterol in slugs suggests that cholesterol synthesis may occur in these mollusks. In view of the unique absence of docosahexaenoic acid and presence of lathosterol and desmosterol, snails and slugs offer fascinating models for the further study of both fatty acid and sterol synthesis.

Peroxidation Reactions in Plant Membranes: Effects of Free Fatty Acids

Katherine D. Barclay[1] and **Bryan D. McKersie***

Department of Crop Science, University of Guelph, Guelph, Ontario N1G 2W1, Canada

Free fatty acids accumulate in plant membranes after exposure of plants to environmental stress, such as freezing and desiccation. Fatty acid accumulation has been linked to various biophysical changes and to the occurrence of lipid peroxidation, but the relationships appear complex and inconsistent. The interactions between oxygen free radicals, free fatty acids and lipid peroxidation in plant membranes were examined further by studying peroxidation reactions in a model membrane system composed of a complex mixture of plant phospholipids, including various free fatty acids. Multilamellar liposomes were treated with oxygen free radicals generated from iron ascorbate. Increased concentrations of free palmitic acid up to 10 mol% (fatty acid/phospholipid) reduced the production of aldehydes detected by the thiobarbituric acid assay, but enhanced the production of fluorescent products. By contrast, increased concentrations of free linolenic acid increased aldehyde production and reduced the formation of fluorescent products. The two free fatty acids both enhanced the susceptibility of phospholipids to degradation as shown by the reduced recovery of esterified polyunsaturated fatty acids (linoleic and linolenic). The free radical reactions with or without free fatty acid additions catalyzed the selective degradation of phospholipids in the order phosphatidylethanolamine > phosphatidylcholine > phosphatidylinositol > phosphatidylglycerol. Selective degradation of phospholipids is often observed after periods of environmental stress or during senescence of plants, and has been cited as evidence for the involvement of phospholipases in these degenerative processes. The results indicate that selectivity is not a criterion for eliminating the involvement of oxygen free radicals in these degenerative processes. Furthermore, the results suggest that modifications of lipid composition during a plant's acclimation to adverse environments may determine the types of free radical reactions that occur due to stress.

***Lipids* 29, 877–882 (1994).**

In plants, increased production of oxygen free radicals and the accumulation of lipid peroxidation products have been associated with a variety of environmental types of stress and with various developmental processes which involve membrane catabolism. For example, lethal freeze–thaw stress of winter wheat has been shown to produce superoxide in a microsomal membrane fraction, promote loss of microsomal lipid-P, increase free fatty acids and increase lipid phase transition temperatures (1,2). Similarly, germinating soybean seeds which had lost desiccation tolerance showed similar physical and compositional changes in a microsomal membrane fraction after drying (3). Plants chilled in high light produced superoxide and singlet oxygen which initiated lipid peroxidation reactions in thylakoids (4). In developmental processes such as senescence, oxygen free radicals have been shown to mediate degradative reactions leading to selective catabolism of phospholipids and formation of gel phase domains (5). The accumulation of free fatty acids in stressed plant tissue can be very high, and values of 20% relative to phospholipid have been reported in aged pollen samples (6).

The peroxidation reactions that occur in plant membranes, however, do not follow the classical reactions which have been detailed so well in model lipid systems (7). For example, treatment of isolated microsomal membranes from winter wheat crowns, or from soybean seeds, with superoxide *in vitro* initiated phospholipid degradation but did not cause a selective degradation of polyunsaturated fatty acids (PUFA) (2,8,9). Under these circumstances, superoxide-initiated deacylation reactions lead to the accumulation of free fatty acids (2,3). The tertiary carbon of the glycerol backbone of phospholipids has been proposed to be the predominant site of free radical attack leading to the deacylation of the phospholipid and accumulation of free fatty acids (10).

Alternatively, phospholipid deacylation and free fatty acid accumulation may be a consequence of enhanced phospholipase activity. This has been the classical interpretation of the results of several studies on membrane catabolism during environmental stress and senescence (11–13). Regardless of whether free fatty acids are produced by oxygen-based radical reactions or by phospholipases, the accumulation of free fatty acids in the membrane bilayer has been linked to a variety of biophysical changes, such as altered lipid microviscosity, elevated lipid phase transition temperatures, and the formation of gel phase domains (14,15). Free fatty acids may also act as fusogens (16–18), promoting membrane fusion within injured cells. Many environmental stresses involve changes in the water status of the plant and in the hydration level of the membrane; two notable examples are desiccation and freezing (19). Sucrose and trehalose are effective membrane-stabilizing agents which prevent the formation of hexagonal and gel phases at low levels of hydration in both model and biological membranes (20). However, if the bilayer contains even trace amounts of free palmitic acid, the stabilizing effect of the sugar is reduced (21). It is also interesting to note that perturbed or destabilized membrane bilayers, such as those containing free fatty acids, are more susceptible to further degradation (5).

Thus, oxygen-based free radicals, phospholipid catabolism, lipid peroxidation and free fatty acid accumulation seem to play a common role in membrane catabolism during senescence or environmental stress, and these factors interact in a complex manner that cannot be fully explained based on current knowledge of free radical reactions in plant membranes.

Abbreviations: BHT, butylated hydroxytoluene; EDTA, ethylenediaminetetraacetic acid; MDA, malondialdehyde; PA, phosphatidic acid; PC, phosphatidylcholine; PE, phosphatidylethanolamine; PG, phosphatidylglycerol; PI, phosphatidylinositol; PUFA, polyunsaturated fatty acids; TBA, thiobarbituric acid; TBARS, thiobarbituric acid reactive substances.

In the present study, the effects of free fatty acids on both the susceptibility of plant membrane phospholipids to lipid peroxidation, as well as the types of degradative products formed in a model membrane system have been investigated in an attempt to better understand these interactions. Liposomes composed of soybean asolecithin, a complex mixture of plant phospholipids, and various free fatty acids were exposed to free radicals generated by Fe^{3+}, ethylenediaminetetraacetic acid (EDTA) and ascorbate, which is a variation on the Fenton reaction producing hydroxyl, perferryl and superoxide radicals.

MATERIALS AND METHODS

Treatment of model membranes. Soybean asolecithin (Fluka, Buchs, Switzerland) was dissolved in chloroform (30 mg/mL), bound to a sep-pak silica column and sequentially eluted with 10 mL chloroform, 20 mL acetone and 20 mL methanol. Only the methanol fraction containing the purified phospholipids was used to prepare liposomes. Free fatty acids (Sigma, St. Louis, MO) were added, without further purification, to the methanolic phospholipid fraction prior to formation of the multilamellar liposomes. In most experiments, free fatty acids were added to the phospholipids to a final concentration of 0, 2.5, 5 or 10 mol% (fatty acid/phospholipid) in chloroform. This fraction was dried under vacuum, resuspended in 10 mM KH_2PO_4 (pH 6.8) buffer, and vortexed to form multilamellar liposomes.

To treat the liposomes with oxygen free radicals, 2-mL samples of the liposomes were added to 2 mL 10 mM KH_2PO_4 buffer, 0.5 mL 10 mM Fe^{2+}–EDTA and 0.5 mL 20 mM ascorbate as described previously (9). Because the free radical reactions proceeded so quickly, the time 0 samples were taken without the addition of the free radical generating system, but simply with the addition of phosphate buffer. Treated samples of 0.5 mL were removed in most experiments at 30, 60, 90 and 120 min. The reaction was stopped by the immediate addition of either the chemical reagents for a specific assay or by chloroform/methanol addition.

Lipid analysis. To analyze the lipid composition of the initial or the free radical-treated liposome preparations, liposomes were partitioned against two volumes of chloroform/methanol (1:1, vol/vol). The extracted phospholipids were separated by thin-layer chromatography using a solvent system consisting of chloroform/methanol/water (65:35:5, by vol). The phospholipids were extracted from the silica with chloroform/methanol (1:1, vol/vol), dried, and resuspended in 4 mL methanolic KOH, capped under nitrogen, and heated at 70°C for 15 min for transmethylation (9). Diheptadecanoyl phosphatidylcholine was added prior to transmethylation to serve as an internal standard in phospholipid quantitation.

To assay aldehyde reaction products, 2 mL thiobarbituric acid (TBA) reagent (0.375% TBA, 15% trichloroacetic acid) was added to the reaction mixture, immediately heated at 100°C for 15 min, cooled, and a glacial acetic acid/chloroform (1:3, vol/vol) mixture was added to clear the emulsion. Absorbance of the aqueous layer was measured at 532 nm. To quantify hydroperoxides, the same procedure was followed except that 25 μL of 1 g of butylated hydroxytoluene (BHT) in 2 mL acetone was added to the TBA reagent (22). Fluorescent peroxidation products were quantified in the reaction solutions by scanning at an excitation wavelength of 360 nm and an emission range of 370–550 nm (23).

Experimental design and statistical analysis. Multilamellar liposomes were formed from mixtures of phospholipid and various free fatty acids. The free fatty acid concentrations chosen were intended to span the concentrations observed previously in plant microsomal membranes (1–3,5,6), but based on the preliminary experiments, we chose only one unsaturated (linolenic acid) and one saturated (palmitic acid) fatty acid. The liposomes were treated in aqueous solution with oxygen free radicals from a mixture of iron ascorbate, and the products were usually measured at 2 h after the addition of the iron.

All experiments were conducted in a randomized complete block design replicated at least three times over time. The data for thiobarbituric acid reactive substances (TBARS) were statistically evaluated by analysis of variance using a two-way factorial design. The data were also analyzed as a power regression:

$$y = ax^b \ (a > 0) \qquad (1)$$

All other experiments were statistically analyzed using a pooled *t*-test for comparison of the free fatty acid treatments to the control at 95% confidence levels.

RESULTS

The soybean asolecithin used in this study to prepare the liposomes was composed primarily of four phospholipids, i.e., phosphatidylcholine (PC), phosphatidylethanolamine (PE), phosphatidylinositol (PI) and phosphatidylglycerol (PG) at concentrations of 44, 22, 18 and 11% of the total phospholipids, respectively (Table 1). Phosphatidic acid (PA) was found to be present in quantities of 6% of the total phospholipid fraction. The fatty acid composition of each of the phospholipid classes was similar for PC, PI, PG and PE. Linoleic and palmitic acids were the predominant fatty acids in each of these phospholipids. PA was the exception, with higher levels of linolenic acid and lower levels of linoleic acid than the others. The preparation is similar in composition to lipid extracts from microsomal membranes of seed and cotyledon tissues (3,6,8), and

represented a convenient means of modelling the effects of free fatty acids in a plant membrane.

The addition of various free fatty acids to the soybean asolecithin model membrane system altered the free radical reactions according to a number of assays measuring both the products and fatty acid substrates of the peroxidation reaction.

The TBA assay typically measures a variety of aldehyde products produced in lipid peroxidation (22,23). TBARS rapidly increased upon treatment of the soybean asolecithin vesicles with free radicals. Aldehyde product formation increased rapidly in the first 30 min of the reaction and more slowly later. The addition of free palmitic acid to the soybean asolecithin vesicles significantly ($P = 0.05$) decreased TBARS accumulation (Table 2). For example, after 2 h the TBARS seen in liposomes containing 10 mol% free palmitic acid were reduced to approximately 50% compared to those seen in liposomes without free fatty acid addition. In contrast, addition of free linolenic acid significantly ($P = 0.05$) increased TBARS at all reaction times. For example, liposomes containing 5 mol% free linolenic acid after 2 h free radical treatment had TBARS values of 169% relative to that of the control (Table 3).

The kinetics of TBARS formation in these reactions were fitted to the power regression equation, and all free fatty acid additions had r^2 values of not less than 0.98, with the exception of 5 mol% free linolenic acid ($r^2 = 0.89$). Therefore, there did not seem to be major changes in the reaction kinetics with the addition of the free fatty acids, indicating that the reactions were uniformly promoted or inhibited at all sampling times.

The addition of free stearic acid to the soybean asolecithin liposomes had no effect on the formation of TBARS as a result of free radical treatment (data not shown). Therefore, the addition of free fatty acids to the soybean asolecithin increased, decreased or had no effect on the formation of aldehydes during free radical mediated peroxidation, depending upon the type of free fatty acid added to the liposome. This phenomenon was followed in more detail using two of the free fatty acids which differed most dramatically in their effects, namely palmitic and linolenic acids.

Peroxidation reactions also produce hydroperoxides, which can react in the TBA assay. Adding BHT to the TBA assay prevents hydroperoxides from contributing to the estimation of TBARS (22). The TBA assay measured all aldehyde peroxidation products, TBA with BHT measured the aldehyde products excluding the hydroperoxides, and the difference between the two assays gave an indication of the amount of hydroperoxides produced. In the liposomes without free fatty acid addition, relatively low levels of hydroperoxides were present after 2 h of reaction (Table 4), presumably because they were consumed in reactions with Fe^{2+}–EDTA. Increasing mol% of free palmitic acid in the liposomes reduced hydroperoxides, but this was not statistically significant because of the low initial values. With addition of free linolenic acid to the soybean asolecithin liposomes, greater amounts of hydroperoxides were formed at increasing concentrations of free linolenic acid.

Schiff-base structures, formed from the reaction of malondialdehyde (MDA) and other aldehydes with amino groups, are fluorescent products of the peroxidation reaction (23). The addition of 2.5 and 5 mol% free palmitic acid produced significantly ($P = 0.05$) greater concentrations of fluorescent products (Table 5). However, no significant differences were noted in the fluorescent intensities among the three different free fatty acid concentrations. With addition of free linolenic acid to the soybean asolecithin liposomes, lesser amounts of fluorescent peroxidation products were produced. The formation of these products in soybean asolecithin liposomes increased with reaction time up to 2 h following the power regression with r^2 val-

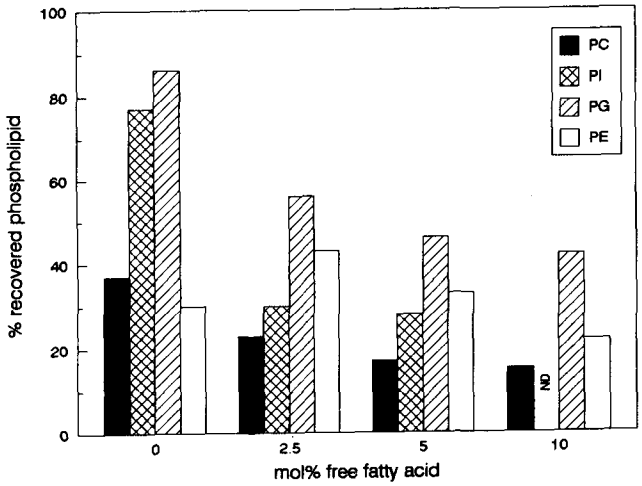

FIG. 1. Recovery of individual phospholipids after Fe-ascorbate treatment of multilamellar liposomes containing varying amounts of free palmitic acid. Percent recovery measures the quantity of a phospholipid after treatment (t = 2 h) relative to the quantity before treatment (t = 0 h). ND, not detected. PC, phosphatidylcholine; PI, phosphatidylinositol; PG, phosphatidylglycerol; PE, phosphatidylethanolamine.

ues of not less than 0.99, with the exception of 5% free linolenic acid ($r^2 = 0.94$). This indicates that like the formation of TBARS, the reaction kinetics for the formation of fluorescent products were not changed with the addition of free fatty acids, and that the reactions were uniformly promoted or inhibited at all sampling times.

The major source of substrate for the free radical-mediated peroxidation reactions is the esterified PUFA in the phospholipids of the soybean asolecithin liposomes. Only 56% of all esterified fatty acids were recovered after the 2-h free radical exposure, indicating that 44% of the phospholipids had been degraded. The proportion of PUFA in the esterified fatty acid fraction decreased from 67 to 48% (Table 6). This seems to be the result of the preferential degradation of PUFA and the proportional increase in saturated fatty acids. With the addition of either palmitic or linolenic acid, the degradation of all phospholipids increased (data not shown), and the selective degradation of PUFA increased slightly, reducing the proportion of PUFA to approximately 32% with the addition of 10 mol% of either free fatty acid.

Without the addition of free fatty acids, there was selective degradation of specific phospholipid classes during the free radical-mediated peroxidation reactions. After 2 h incubation, 30% of PE, 38% of PC, 78% of PI and 88% of PG were recovered. The addition of free palmitic acid or free linolenic acid enhanced the degradation of PC, PG and PI, but had relatively little effect on PE (Figs. 1 and 2).

The recovery of esterified PUFA in each phospholipid class followed a similar pattern. After 2 h of free radical exposure, 77% of the PUFA from PE and 60% from PC were degraded, but the PUFA in PI and PG were rela-

tively more resistant to degradation (Table 7). All concentrations of free palmitic acid and free linolenic acid significantly amplified the loss in esterified PUFA.

DISCUSSION

In the model membrane system of soybean asolecithin liposomes, addition of free fatty acids increased the susceptibility of the lipids to free radical-mediated degradation as shown by reduced recovery of PUFA and phospholipid. However, the type of free fatty acid present affected the types of peroxidation products formed. Increasing concentrations of free palmitic acid in the liposomes increased formation of fluorescent peroxidation products, but reduced hydroperoxides and TBARS. In contrast, increasing concentrations of free linolenic acid in the liposomes caused no change to the amount of fluorescent peroxidation products, and increased hydroperoxides and TBARS.

These differences in the type of peroxidation product formed as a result of the inclusion of different free fatty acids in the liposome may indicate that the free fatty acid was acting either chemically as a substrate in the peroxidation reactions, or physically as a perturbing agent altering the packing, fluidity, and/or physical arrangement of the phospholipids in the multilamellar liposome. Free linolenic acid containing three double bonds is highly susceptible to free radical attack. Thus, 18:3 is likely a substrate in the peroxidation reactions resulting in the formation of TBARS and hydroperoxides from the direct peroxidation of the free fatty acid itself. On the other hand, free palmitic acid containing no double bond is not an immediate substrate in peroxidation reactions.

The liposomes used in this study were multilamellar, and the radicals were generated in the aqueous compartment outside the liposome. Unilamellar vesicles have been shown to react to this free radical treatment differently than multilamellar vesicles (9). It is therefore conceivable that the presence of the free fatty acids altered fluidity (14), thereby changing the susceptibility of lipids to the free radical reactions. These changes are perhaps associated with the closer apposition of the fatty acid chains imposed by the presence of free palmitic acid.

Furthermore, compounds such as dihydropyridines may be formed by reaction of MDA with amines, such as ethanolamine, producing fluorescent structures (23). Of the individual classes of phospholipids, PE was most sensitive to the peroxidation reaction, especially in the absence of free fatty acids. Therefore, it is likely that a considerable proportion of the fluorescent peroxidation products was Schiff-base structures formed by reaction of the amine group of PE with aldehyde peroxidation products. However, as more free palmitic acid was added, the production of fluorescent products increased but the extent of PE degradation did not. In this instance, the rise in fluorescent intensity noted may be solely due to the production of fluorescent aldehyde polymers.

The selective degradation of specific phospholipid classes has been observed in several systems undergoing membrane catabolism, and has since been attributed to the selectivity of the phospholipase degradation (11–13). In the soybean asolecithin liposomes, sensitivity to degradation by the free radical reactions followed the order PE > PC > PI > PG. The differences in susceptibility are not due to differences in the proportion of PUFA present in each phospholipid class because their initial PUFA composition ranged from only 69 to 56% and followed the order PI > PC > PE > PG. The involvement of PE in the formation of Schiff-base structures may explain its greater sensitivity to degradation. Differences in molecular species and the relative lateral distribution of the phospholipids in the liposome may influence exposure of the individual PUFA to the free radical reactions. The selective loss of PC has been seen in tissues of nonhardy plants exposed to freezing temperatures (11), as well as in plants during senescence (12,13). In both cases, degradation was attributed to increased phospholipase activity. In the model membranes used in this study, no proteins or enzymes were present, simply lipid, Fe and ascorbate. Therefore, the selective degradation of phospholipid can be attributed solely to free radical reactions. Consequently, selective degradation of phospholipid is not a good criterion for phospholipase and other hydrolytic enzyme activities, especially in plant cells under conditions which are known to highly favor free radical reactions such as freezing (2) and senescence (5).

In summary, the presence of free fatty acids in a model membrane increased lipid degradation and altered the formation of peroxidation products. Therefore, the accumulation of free fatty acids in plant cell membranes during periods of environmental stress, whether the result of phospholipase activity or free radical mediated deacylation, would be expected to have a number of deleterious consequences, but the effect on the membrane will differ depending on the type of free fatty acid that accumulates. Therefore, the initial fatty acid composition of the membrane is very important in determining the membrane's response, not only because it will influence its susceptibility to free radical attack, but also because it will determine the type of free fatty acid liberated by deacylation reactions. Furthermore, the phospholipid headgroup appears to play a significant role in determining a phospho-

lipid's susceptibility to free radical attack. During acclimation to environmental stress, plants alter the lipid composition of their membranes (24). This has been interpreted almost exclusively in terms of membrane fluidity and lipid phase changes (24). Acclimation also causes the membranes and plants to become increasingly resistant to free radical attack (2,25). The degree to which changes in fatty acid unsaturation and in phospholipid class are responsible for this difference in resistance has yet to be determined.

METHOD

Reactions of Diazomethane with Glycerolipids in the Presence of Serum or Inorganic Salts[1]

Patricia C. Schmid* and **Harald H.O. Schmid**

The Hormel Institute, University of Minnesota, Austin, Minnesota 55912

Diazomethane is widely used for the selective methylation of nonesterified fatty acids in the presence of other lipids. However, when the reaction is carried out directly with plasma or serum, substantial methanolysis of phospholipid acyl groups occurs. Because of the importance of rigorous selectivity in the assay of unesterified fatty acids which are present only in trace amounts in cells and body fluids, we have investigated the diazomethane procedure in detail and reached the following conclusions: (i) When diazomethane reacts with lipid extracts in organic solvent, no ester hydrolysis occurs. (ii) In the presence of serum or plasma, diazomethane reacts with water and inorganic salts, causing the solution to become basic ($CH_2N_2 + NaCl + HOH \rightarrow CH_3Cl + Na^+ + OH^- + N_2$); methoxide ions are formed from methanol ($CH_3OH + OH^- \rightarrow CH_3O^- + HOH$) causing extensive methanolysis ($CH_3O^- + RO\text{–}CO\text{–}R' \rightarrow CH_3O\text{–}CO\text{–}R' + RO^-$). An analogous reaction takes place with ethanol. All esters of glycerol are transesterified in aqueous salt solution by this mechanism. It is therefore essential to prepare a lipid extract prior to the assay of unesterified fatty acids when using the diazomethane procedure.

***Lipids* 29, 883–887 (1994).**

Diazomethane is an extremely versatile reagent that has been used in synthetic organic chemistry for more than a century (1–3). In the lipid field, diazomethane is employed for the selective methylation of unesterified fatty acids (4) in the presence of other lipids. We have used this method extensively over the past 15 years (5–9). In the usual procedure, a dilute solution of diazomethane in diethyl ether is added to a lipid extract dissolved in diethyl ether/methanol (9:1, vol/vol). It has been shown that under these conditions the methyl group of the fatty acid methyl ester is derived from diazomethane (see Equation 1). The methanol in the solvent does not participate in the reaction (4). Experiments with ^{18}O-labeled fatty acids have shown that both fatty acid oxygens are retained in the methyl ester (6).

$$R\text{–}COOH + CH_2N_2 \rightarrow R\text{–}COOCH_3 + N_2 \qquad [1]$$

In a method developed for the rapid estimation of unesterified fatty acids in human blood plasma through "extractive methylation," Pace-Asciak (10) added ethereal diazomethane directly to a 1:1 (vol/vol) mixture of plasma and methanol. However, Lin *et al.* (11) later reported that diazomethane caused extensive methanolysis of phospholipid acyl groups under the conditions described by Pace-Asciak (10), and they questioned the selectivity of fatty acid methylation by diazomethane in the presence of other lipids. Unfortunately, Lin *et al.* (11) did not offer a hypothesis regarding the mechanism of the reaction and certain ambiguities in the reported experimental details could lead to confusion about the selectivity of the diazomethane reaction in organic solvent as well. Because of the importance of such selectivity for the methylation of unesterified fatty acids, which are often present only in trace amounts, and because we have never observed (5–9) transesterification or hydrolysis of ester bonds induced by diazomethane, we investigated possible causes for the results reported by Lin *et al.* (11).

The data presented here confirm the conclusions of Schlenk and Gellerman (4) that diazomethane does not react with lipid ester bonds in organic solvents. However, we found that diazomethane in the presence of water, inorganic salts and methanol causes extensive methanolysis of glycerolipids. The same sequence of reactions occurs if plasma is substituted for the inorganic salt solution.

MATERIALS AND METHODS

Diazald™ (*N*-methyl-*N*-nitroso-*p*-toluenesulfonamide), dipalmitoyl phosphatidylethanolamine (DPPE) and dimyristoyl phosphatidylcholine (DMPC) were from Sigma Chemical Company (St. Louis, MO). 1-Palmitoyl lysophosphatidylcholine and 1-stearoyl-2-oleoyl phosphatidylcholine (SOPC) were from Avanti Polar Lipids (Birmingham, AL). Heptadecanoic acid, methyl heptadecanoate, arachidonic acid, cholesteryl oleate (CE) and tripentadecanoylglycerol (TAG) were from Nu-Chek-Prep (Elysian, MN).

Diazomethane was prepared from Diazald essentially as described by Schlenk and Gellerman (4) and as used routinely in our laboratory (5–9). The diazomethane produced from one gram of Diazald was recovered in approximately 30 mL of diethyl ether to give a solution with an estimated concentration of less than 150 mM. This solution was stored in tubes with Teflon-lined screw caps at –20°C for up to three weeks. All operations that necessitated opening a vessel containing diazomethane were conducted in a fume hood. Diethyl ether, containing ethanol as a preservative, was freshly distilled in an all-glass system before use. Citrated plasma was prepared from blood drawn from a healthy, nonfasting volunteer.

Methanolysis/methylation in plasma.[2] In the procedure described by Pace-Asciak (10), 0.2 mL of plasma is mixed

[1]We dedicate this paper to Dr. Hermann Schlenk on the occasion of his 80th birthday.

Abbreviations: BSA, bovine serum albumin; CE, cholesteryl ester (cholesteryl oleate); DMPC, dimyristoyl phosphatidylcholine; DPPE, dipalmitoyl phosphatidylethanolamine; GC, gas chromatography; HEPES, *N*-2-hydroxyethylpiperazine-*N'*-2-ethanesulfonic acid; LPC, lysophosphatidylcholine (1-palmitoyl lysophosphatidylcholine); SOPC, 1-stearoyl-2-oleoyl phosphatidylcholine; TAG, triacylglycerol (tripentadecanoylglycerol); TLC, thin-layer chromatography.

[2]Methylation is defined as the addition of a methyl group from diazomethane to an unesterified fatty acid; methanolysis (or transesterification) means alcoholysis with methanol, in which methoxide ion reacts with a glycerol ester to form a methyl ester.

with 0.2 mL of methanol, 12 μg of pentadecanoic acid and 1 mL of ethereal diazomethane (derived from about 0.1 g of Diazald). After 10 min at room temperature, an 800 μL aliquot of the upper (diethyl ether) phase is transferred to another tube, taken to dryness and the residue is dissolved in hexane for analysis by gas chromatography (10).

We used 10 μg of heptadecanoic acid as internal standard. In order to conserve reagents, our standard reaction mixture usually consisted of 0.1 mL of plasma (or salt solution), 0.1 mL of methanol and 0.5 mL of ethereal diazomethane. Samples were vortexed and then reacted for 10 min at room temperature in open tubes in a fume hood. The diethyl ether and residual diazomethane were quickly removed under a stream of nitrogen, and the methyl esters were extracted from the aqueous phase into 5 mL of hexane/diethyl ether (4:1, vol/vol) or into 2 mL of chloroform/methanol (2:1, vol/vol).

In later experiments the volume of methanol was increased to 0.3 mL to form a single phase with the ether and water.

Lipid extraction before methylation. Plasma aliquots of 0.1 mL were mixed with 10 μg of heptadecanoic acid as internal standard, extracted with 4 mL of chloroform/methanol (2:1, vol/vol) and partitioned with 1 mL of 2.5% NaCl in small, screw-cap test tubes (12). The tubes were centrifuged, the organic layer was removed and blown to dryness under nitrogen. The lipids were redissolved in 1 mL of diethyl ether/methanol (9:1, vol/vol), and 0.5 mL of diazomethane was added. After 10 min at room temperature, the diethyl ether and diazomethane were removed under a stream of nitrogen.

Purification of methyl esters. When diazomethane was added to a lipid mixture, the methyl esters were usually purified before gas chromatography (GC). After reaction with diazomethane, the lipids were dissolved in 1 mL of hexane and applied to a small column of silicic acid (about 1 g) in a disposable glass transfer pipette. The test tube was rinsed with an additional 2 mL of hexane that was also applied to the column. Methyl esters were eluted with 4 mL of hexane/diethyl ether (9:1, vol/vol). Cholesterol and polar lipids remained on the column. The elution scheme was checked for recovery of methyl esters by analyzing one of the samples by GC before and after purification.

GC of methyl esters. GC was performed with a Packard Model 428 GC equipped with dual flame-ionization detectors and a Spectra-Physics 4270 integrator. Methyl esters were separated on a 12 ft × 1/8 in. aluminum column packed with 10% SP-2330 on 100/120 Chromosorb W AW (Supelco, Bellefonte, PA), with the temperature programmed from 180 to 230°C at a rate of 3°C per min.

RESULTS

Unesterified fatty acids in human plasma. In a direct comparison of the two methods, aliquots of fresh citrated plasma were treated following the procedure of Pace-Asciak (10), or the plasma lipids were extracted before reaction with diazomethane. Each group of assays included six replicates. The results of the GC analyses of methyl esters are given in Table 1. As expected (11), the Pace-Asciak procedure (10) yielded a concentration of methyl esters ten times the amount detected after lipid extraction, with a large standard deviation. There was also a difference in the composition of the methyl esters. Long-chain polyunsaturated fatty acid comprised more than 15% of the fatty acid methyl esters obtained by the Pace-Asciak procedure (10) but were not present in the methyl esters recovered from the lipid extracts. The extracts contained a higher percentage of methyl oleate.

TABLE 1

Comparison of Plasma Unesterified Fatty Acids Determined by the Pace-Asciak Procedure (Ref. 10) and After Extraction[a]

	Pace-Asciak (Ref. 10)		Extract	
	(Methyl esters recovered)			
Fatty acid	μg/mL	wt%	μg/mL	wt%
16:0	76.8 (±22.7)	28.5	7.5 (±0.9)	26.2
16:1	3.7 (±1.5)	1.4	0.6 (±0.2)	2.2
18:0	38.8 (±12.2)	14.4	3.4 (±0.4)	11.9
18:1	50.5 (±12.4)	18.8	12.1 (±1.2)	42.3
18:2n-6	57.7 (±18.4)	21.4	5.0 (±1.0)	17.4
20:3n-6	5.45 (±2.05)	2.0	n.d.	
20:4n-6	23.8 (±8.45)	8.8	n.d.	
22:5n-3	1.45 (±0.70)	0.5	n.d.	
22:6n-3	11.0 (±2.95)	4.1	n.d.	
Total μg/mL	269.0 (±80.6)		28.6 (±3.6)	
μM	960		100	

[a]Aliquots of fresh citrated plasma from a nonfasting volunteer were mixed with methanol and diazomethane/diethyl ether (Ref. 10) or were extracted with chloroform/methanol (2:1, vol/vol) and the lipid extracts were treated with diazomethane (Extract). Methyl esters were quantitated by gas chromatography using an internal standard (heptadecanoic acid, added before extraction or before treatment with diazomethane) as described in the Materials and Methods section. Values are mean ± SD of six replicates in each group. n.d., Not detected.

Because we found only traces of unesterified arachidonic acid in the lipid extracts, whereas it is reported to be a prominent component in other assays (11,13), we checked its recovery by adding known amounts of arachidonic acid to serum before lipid extraction and analysis. As little as 0.7 μg added to 0.1 mL of serum before extraction could be measured with complete recovery (data not shown).

Conditions that affect the methanolysis of complex lipids. Figure 1 shows that the amounts of methyl esters formed by "extractive methylation" (10) increased with time and with increasing concentrations of diazomethane.

In order to determine which components of the mixture are necessary for methanolysis of plasma lipids, 0.1 mL aliquots of plasma were incubated with methanol, methanol plus diethyl ether or ethanol plus diethyl ether for 20 min before lipid extraction. The yield of methyl esters was the same as after extraction alone (Table 2).

Because the reaction was catalyzed by an interaction between diazomethane and one or more of the plasma components, plasma lipids were extracted from 0.1 mL aliquots, redissolved in 0.1 mL methanol and mixed with 0.1 mL of solutions of bovine serum albumin (BSA), BSA in 1 M NaCl or 1 M NaCl. Upon treatment with diazomethane, methanolysis was extensive in the solutions

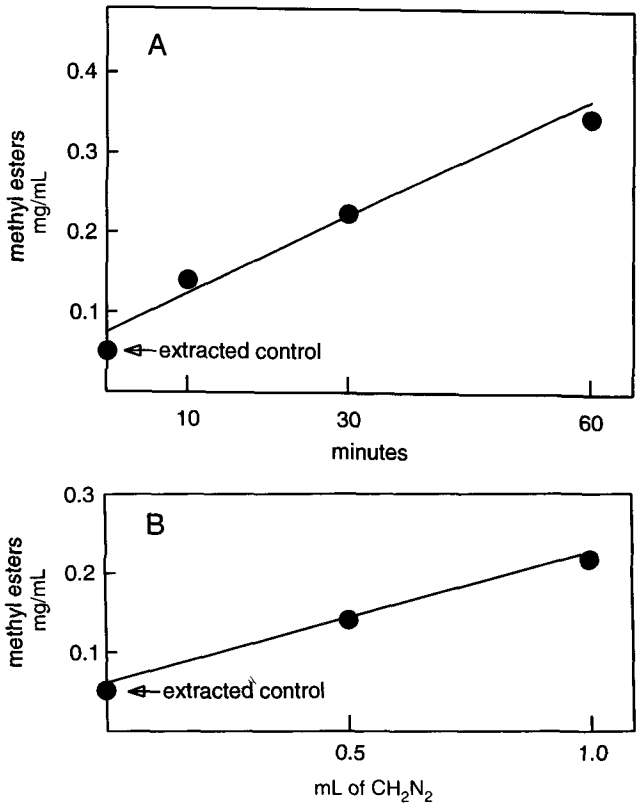

FIG. 1. Plasma (0.1 mL), methanol (0.1 mL) and ethereal diazomethane (0.5 mL) were incubated for different periods of time (A) and for 10 min with different amounts of diazomethane (B). Methyl esters were analyzed as described in the Materials and Methods section.

containing NaCl and did not increase when protein was present. Protein in the absence of NaCl did not cause methanolysis, nor did water alone. NaCl in the absence of diazomethane had no effect (Table 3).

Methanolysis of different lipid classes. In order to quantify the reaction of various lipid classes, we used mixtures of synthetic lipids containing different fatty acids, i.e., CE, TAG, DMPC, 1-palmitoyl lysophosphatidylcholine (LPC),

TABLE 2

Preincubation of Plasma Before Extraction[a]

Treatment (0.1 mL plasma)	Total methyl esters (μg/mL plasma)
Methanol (0.1 mL, 20 min)	30.3
Methanol (0.1 mL) and diethyl ether (0.5 mL, 20 min)	29.0
Ethanol (0.1 mL) and diethyl ether (0.5 mL, 20 min)	28.4
No additions	24.8
Methanol (0.1 mL) and ethereal diazomethane (0.5 mL)	139.1

[a]Plasma was incubated with the indicated additions, followed by extraction with chloroform/methanol (2:1, vol/vol) and reaction with diazomethane as described in the Materials and Methods section. Methyl esters were quantitated by gas chromatography in the presence of an internal standard.

TABLE 3

Methanolysis of Lipids Extracted from 0.1 mL Plasma and Mixed with Protein Solutions Plus Methanol and Ethereal Diazomethane[a]

Addition (0.1 mL)	Methyl esters (μg)
Albumin in 1 M NaCl	50.4
1 M NaCl	69.7
Plasma	34.2
Albumin, no NaCl	7.3
No additions (extracted control)	4.6
1 M NaCl, no diazomethane (extracted)	5.3

[a]Bovine serum albumin was dissolved in 1 M NaCl or in water at a concentration of 70 mg/mL. These solutions were added to the lipid extracts (from 0.1 mL plasma) dissolved in 0.1 mL of methanol. Ethereal diazomethane (0.5 mL) was added and after 10 min the methyl esters were extracted and quantitated by gas chromatography as described in the Materials and Methods section.

SOPC and DPPE. GC analysis of methyl esters in the presence of an internal standard was used to quantify the degree of methanolysis of each lipid class. Mixtures did not include more than one palmitate-containing lipid.

A lipid mixture (CE, TAG, DMPC and LPC) was incubated with diazomethane and several different salt solutions ($CaCl_2$, NaBr, KCl, Na_2SO_4) in *N*-2-hydroxyethylpiperazine-*N'*-2-ethanesulfonic acid (HEPES) at pH 7.4. All salts tested were equally effective in promoting the methanolysis of DMPC and LPC, but CE and TAG were not affected. Twenty-five mM HEPES also caused some methanolysis, but water alone did not. There was no difference in the rate of methanolysis between the *sn*-1 and *sn*-2 position of SOPC when incubated with 1 M NaCl. DPPE reacted at about the same rate as DMPC and SOPC (data not shown).

When a mixture of PC, LPC and TAG was reacted with increasing concentrations of NaCl, LPC was preferentially hydrolyzed, DMPC reacted at a slower rate, and TAG was not affected (Fig. 2A). Under these conditions, the reactants formed a two-phase system. However, when the volume of methanol was increased to 0.3 mL, a single phase was formed and all lipids tested, with the exception of cholesteryl esters, were substrates for the reaction (Fig. 2B). The data were explained by considering that in the two-phase system, LPC readily partitions into the aqueous/methanol phase, DMPC partitions less readily, and TAG remains in the ether phase, with the reaction taking place in the aqueous/methanol phase.

In the one-phase system of 0.3 mL methanol, 0.1 mL aqueous NaCl and 0.5 mL ethereal diazomethane, as little as 1 mM NaCl was sufficient to cause measurable methanolysis (data not shown). At 1 M NaCl, methanolysis of DMPC, LPC and TAG was complete.

When ethanol replaced methanol, ethyl esters were produced, proving that the mechanism involves transesterification or alcoholysis and that diazomethane is not directly involved in the methylation. Substituting isopropranol did not result in the production of isopropyl esters, probably for steric reasons, but led to a slight increase in the recovery of methyl esters. Presumably, in this case acyl groups were hydrolyzed due to the increase in pH and the

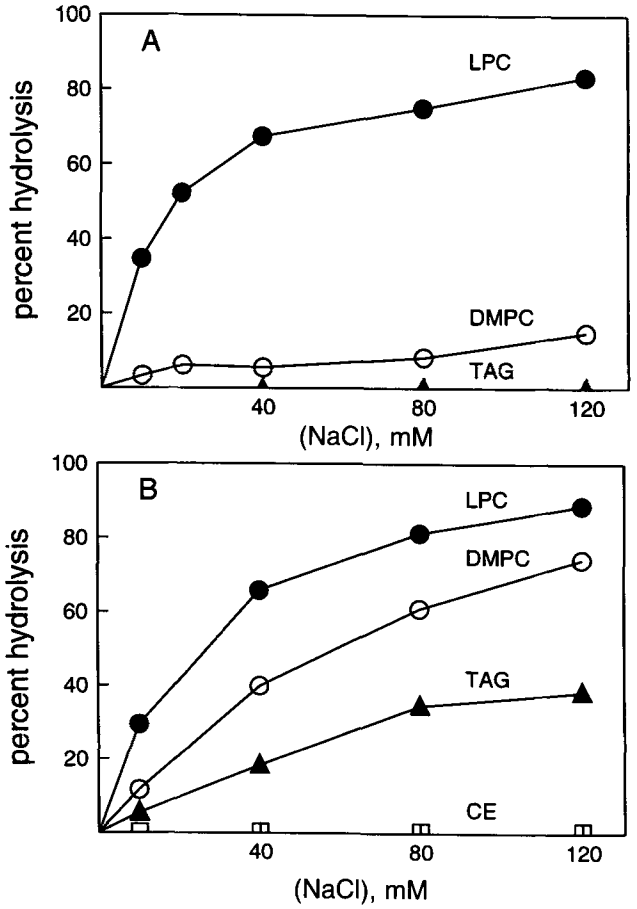

FIG. 2. Mixtures of 1-palmitoyl lysophosphatidylcholine (LPC) (●), dimyristoyl phosphatidylcholine (DMPC) (○), tripentadecanoylglycerol (TAG) (▲) and cholesteryl oleate (CE) (□) were incubated for 10 min with 0.5 mL of ethereal diazomethane and 0.1 mL of the indicated solutions of NaCl. Panel A, 0.1 mL methanol; Panel B, 0.3 mL methanol. Methyl esters were analyzed as described in the Materials and Methods section.

resulting fatty acids were methylated with diazomethane (data not shown).

DISCUSSION

The mechanism for the observed hydrolysis of lipid acyl groups by mixtures of diazomethane and aqueous inorganic salts is based on the observation by Kuhn and Ruelius (14), later reviewed by Huisgen (15), that diazomethane can methylate the anion of an inorganic salt, freeing the cation and thereby causing the aqueous solution to become basic (Equation 2):

$$CH_2N_2 + NaCl + HOH \rightarrow CH_3Cl + Na^+ + OH^- + N_2 \quad [2]$$

In the presence of methanol, this is sufficient to cause the formation of methoxide ion (Equation 3), a nucleophile that attacks the carbonyl carbon atom of the ester bond in a classic transesterification reaction (Equation 4):

$$CH_3OH + OH^- \rightarrow CH_3O^- + HOH \quad [3]$$

$$CH_3O^- + RO\text{–}CO\text{–}R' \rightarrow CH_3O\text{–}CO\text{–}R' + RO^- \quad [4]$$

It has been shown that methanolysis occurs faster than hydrolysis in methanol/water mixtures (16). Therefore, reaction in aqueous salt solutions, including plasma (10), will result in transesterification as described here. Higher salt concentrations probably stimulate the reaction through primary or secondary salt effects. Because free fatty acids are not esterified in basic medium by methoxide ions (17), it appears that in plasma the free fatty acids and the internal standard are methylated by diazomethane in the usual way and lipid acyl groups undergo methanolysis as outlined above, with the extent of reaction depending on specific conditions. When the Pace-Asciak procedure (10) was followed, the reaction occurred substantially faster with lysophosphatidylcholine than with other lipids, most likely because lysophosphatidylcholine partitions more readily into the aqueous/methanol phase.When sufficient methanol was present to effect a single phase, all lipids except cholesteryl esters were transesterified. In the two-phase system, triacylglycerols were not transesterified to any major extent, as was also reported by Lin *et al.* (11), but TAG participated readily in the reaction in single phase.

Trace amounts of unesterified fatty acids are found in serum, plasma, tissues and cells in the presence of overwhelming amounts of other lipids. Therefore a method for their analysis must be absolutely specific. Even a reaction of less than 1% of the bulk of the complex lipids would introduce significant errors. No matter how carefully conditions are controlled, use of a reagent such as methanol/acetyl chloride (13), that also transesterifies acyl groups (18), leads to overestimation of unesterified fatty acids accompanied by errors in their composition (19).

Some of the problems of nonspecificity of reagents such as methanol/acetyl chloride and methanol/HCl can be overcome by first isolating the unesterified fatty acids from the lipid extract, preferably by thin-layer chromatography (TLC). However, this is a time-consuming procedure and such small amounts of lipid are difficult to accurately localize on and to quantitatively isolate from a TLC plate. If the unesterified fatty acid fraction is contaminated with other trace lipids, such as diacylglycerols, there will be a corresponding overestimation due to methanolysis. Also, care must be taken to prevent oxidation of polyunsaturated fatty acids during chromatography. In contrast, methylation with diazomethane assures that the assay is specific for unesterified fatty acids. After methylation, small columns of silicic acid or commercial solid-phase extraction cartridges can be used to remove complex lipids that can cause problems if they are injected into the gas chromatograph.

Because of its somewhat basic character, diazomethane can also react with methanol to form methoxide, and can catalyze methanolysis of acetates in concentrated solutions at extended reaction times (48 h; Ref. 20). We have found no evidence that this reaction occurs at the concentrations and times employed for the methylation of fatty acids in lipid mixtures. Reaction of unsaturated fatty acids with ethereal diazomethane in the absence of methanol will lead to the generation of side products (21). Thus it

was shown that α,β-unsaturated fatty acids and α-keto acids, compounds unlikely to be encountered in usual lipid analyses, react with diazomethane not only at the carboxyl group but also at the double bond and the oxo group (22).

Our present data clearly show that diazomethane, when used as originally described (4), selectively methylates unesterified fatty acids and does not cause any transesterification of acyl groups. It is advisable to follow the procedure exactly, i.e., to use a reaction medium of diethyl ether/methanol (9:1, vol/vol) (4), or to carefully confirm that modifications to the method do not alter the results.

Although diazomethane is toxic and can explode under certain conditions, when in dilute solution and used in a functioning fume hood, it presents no greater hazard or inconvenience than do many other reagents that are in routine use in the laboratory. In our experience, diazomethane in diethyl ether/methanol solution is the only reagent that specifically methylates unesterified fatty acids and should therefore be used for the assay of free fatty acids in the presence of other lipids.

Ultrasound in Fatty Acid Chemistry: Synthesis of a 1-Pyrroline Fatty Acid Ester Isomer from Methyl Ricinoleate

Marcel S.F. Lie Ken Jie*, M.S.K. Syed-Rahmatullah, C.K. Lam and P. Kalluri

Department of Chemistry, The University of Hong Kong, Hong Kong

A novel 1-pyrroline fatty acid ester isomer [*viz.* 8-(5-hexyl-1-pyrrolin-2-yl)octanoate] has been synthesized from methyl ricinoleate by two routes with an overall yield of 42 and 30%, respectively. Most of the reactions are carried out under concomitant ultrasonic irradiation (20 KHz, *ca.* 53 watts/cm^2). Under such a reaction condition, the reaction time is considerably shortened, and product yields are high. Dehydrobromination under concomitant ultrasonic irradiation of methyl 9,10-dibromo-12-hydroxyoctadecanoate with KOH in EtOH furnishes methyl 12-hydroxy-9-octadecynoate (66%) within 15 min. Hydration of the latter under ultrasound with mercury(II)acetate in aqueous tetrahydrofuran yields exclusively methyl 12-hydroxy-9-oxo-octadecanoate (95%) in 30 min. The hydroxy group in the latter compound is transformed to the azido function *via* the mesylate, and treatment of the azido-oxo intermediate (methyl 12-azido-9-oxooctadecanoate) with Ph_3P under ultrasonic irradiation furnishes the requisite 1-pyrroline fatty acid ester (77%). The same azido-oxo intermediate has also been obtained by the oxidation of methyl 12-azido-9-*cis*-octadecenoate using benzoquinone and a catalytic amount of Pd(II)chloride in aqueous tetrahydrofuran under concomitant ultrasonic irradiation (90 min) to give the product in 45% yield. The latter reaction does not take place even under prolonged silent stirring of the reaction mixture.

***Lipids* 29, 889–892 (1994).**

2,5-Dialkyl pyrrolines and pyrrolidines have been identified in the venom of the fire ant *(Solenopsis punctaticeps)* (1,2) and have been shown to possess necrotizing and hemolyzing properties (3,4). A number of synthetic procedures have been reported for the preparation of dialkyl pyrrolines with emphasis on the subsequent production of 2,5-disubstituted pyrrolidines for entomological studies (5–9).

We have reported earlier the synthesis and properties of a long-chain fatty ester derivative [methyl 8-(5-hexyl-2-pyrrolin-1-yl)octanoate, **1**] containing a 1-pyrroline nucleus in the alkyl chain from methyl *iso*-ricinoleate (methyl 9-hydroxy-12-*cis*-octadecenoate) (10). In the present paper we describe the transformation of the very readily available methyl ricinoleate (methyl 12-hydroxy-9-*cis*-octadecenoate) from castor oil to a novel 1-pyrroline isomer [methyl 8-(5-hexyl-1-pyrrolin-2-yl)octanoate, **2**] with the imine bond (C=N) of the pyrroline nucleus linked to the C-9 position instead of to C-12 (see Scheme 1). The requisite 1-pyrroline fatty ester isomer (**2**) was synthesized by two different approaches from methyl ricinoleate. Both approaches make use of ultrasound irradiation during the various synthetic steps to accelerate the formation of key intermediates. The synthetic routes are illustrated in Figure 1.

(2), R = $(CH_2)_7COOCH_3$; R' = $CH_3(CH_2)_5$

SCHEME 1

MATERIALS AND METHODS

Ricinoleic acid was obtained from castor oil by the partition method described by Gunstone (11). Petroleum ether refers to the fraction with b.p. 40–60°C. Thin-layer chromatographic (TLC) analysis was done on microscope glass plates coated with silica gel (type 60, silica gel GF_{254}, 0.1 mm layer; Merck, Darmstadt, Germany). Column chromatographic separation was achieved on silica gel (type 60, 70–230 mesh; Merck) by gradient elution using mixtures of petroleum ether/diethyl ether ranging from

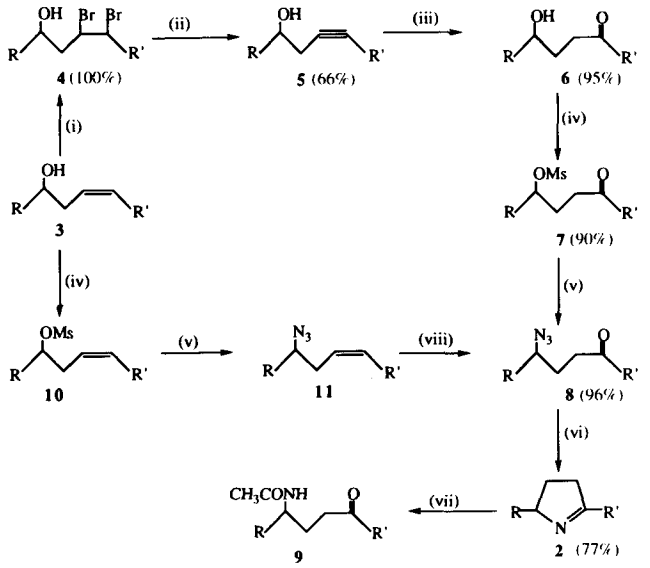

FIG. 1. Synthesis of 1-pyrroline fatty ester. Reagents and conditions: (i) Br_2, Et_2O, 20°C, 15 min; (ii) KOH, EtOH, ultrasound, 30 min; (iii) Hg $(OAc)_2$, tetrahydrofuran (THF), H_2O, ultrasound, 25 min; (iv) MsCl, Et_3N, CH_2Cl_2, –5°C, 30 min; (v) NaN_3, DMF, 80°C, 2 h; (vi) PPh_3, THF, ultrasound, 30 min; (vii) Ac_2O, 90°C, 1 h; (viii) $PdCl_2$, benzoquinone, THF, H_2O, ultrasound, 90 min.

Abbreviations: ECL, equivalent chain length; GLC, gas–liquid chromatography; IR, infrared; MS, mass spectrometry; NMR, nuclear magnetic resonance spectroscopy; R_f, retardation factor; THF, tetrahydrofuran; TLC, thin-layer chromatography.

1:0 to 2:3, vol/vol, depending on the polarity of the product. Gas–liquid chromatographic (GLC) analysis was carried out on a Hewlett-Packard model 5970 gas chromatograph (Hewlett-Packard, Palo Alto, CA) fitted with a microbore SE-30 (0.53 mm diameter, 2.65 μm film thickness, 10 m length) or SPB1 column (0.20 mm diameter, 0.20 μm film thickness, 30 m length) (Supelco, Bellefonte, PA) using nitrogen (20 mL/min) as the carrier gas at a column temperature of 190°C with the flame-ionization detector set at 210°C. External standards of methyl myristate, palmitate and stearate were used as reference compounds, and equivalent chain length (ECL) values were calculated for each component (12). Infrared (IR) spectra were obtained on liquid films on a Shimadzu model IR-470 photospectrometer (Shimadzu Corp., Kyoto, Japan). Nuclear magnetic resonance (NMR) spectra (in $CDCl_3$) were obtained on a JEOL FX90Q (90 MHz) or JEOL GSX-270 (270 MHz) instrument (JEOL Ltd., Tokyo, Japan). Ultrasonication was carried out using a 20 KHz (*ca.* 53 W/cm^2) ultrasound horn (Undatim Ultrasonic S.A., Louvain-la-Neuve, Belgium) with the reaction mixture contained in a water-jacketed cell. Low-resolution mass spectra were recorded using a Hewlett-Packard gas chromatograph fitted with a Mass Selective Detector™. High-resolution mass spectra were recorded on a Finnigan Mat 95 mass spectrometer (Finnegan Mat Corp., San Jose, CA).

Methyl 9,10-dibromo-12-hydroxyoctadecanoate (**4**). Bromine (5.6 g, 3.5 mmol) was added to a solution of methyl ricinoleate (**3,** 2.0 g, 6.4 mmol) in diethyl ether (30 mL) and stirred for 15 min. The reaction mixture was successively washed with aqueous sodium thiosulfate solution (5%, 10 mL), water (20 mL), and dried over anhydrous sodium sulfate. The ethereal mixture was filtered and the filtrate evaporated to give crude methyl 9,10-dibromo-12-hydroxyoctadecanoate (**4,** 3.0 g, 100%) as a viscous liquid (13,14). TLC, retardation factor (R_f) 0.6 (petroleum ether/diethyl ether, 7:3, vol/vol); IR (cm^{-1}): 3450 (*br*), 1740(*s*), 840(*m*), 760(*m*) and 720 (*s*); ^{1}H NMR ($CDCl_3$, δ): 0.88(*t*, 3H, C*H*$_3$), 1.2–1.8(*m*, 20H, C*H*$_2$), 1.9–2.1(*m*, 4H, C*H*$_2$), 2.2(*s*, 1H, CH-O*H*), 2.3(*t*, 2H, 2-*H*), 3.6(*s*, 3H, COOC*H*$_3$), 3.8(*m*, 1H, C*H*-OH), 4.6(*m*, 2H, C*H*-Br).

Methyl 12-hydroxy-9-octadecynoate (**5**). A mixture of compound **4** (3.0 g, 6.3 mmol), ethanol (95%, 30 mL) and KOH (5.3 g, 9.5 mmol) was sonicated for 30 min using a 20 KHz ultrasound horn at 20°C. The reaction mixture was acidified with HCl (6M, 20 mL) and extracted with diethyl ether (3 × 30 mL). The ethereal extract was washed with water (30 mL) and dried over anhydrous sodium sulfate. The solvent was evaporated, and the residue was refluxed with borontrifluoride/methanol (14%, w/w, 5 mL) in absolute methanol (30 mL) for 10 min. Water (50 mL) was added and the reaction mixture was extracted with diethyl ether (2 × 50 mL). The solvent was evaporated, and silica column chromatographic purification of the residue using a mixture of petroleum ether and diethyl ether (85:15, vol/vol) as eluent gave pure methyl 12-hydroxy-9-octadecynoate (**5,** 1.3 g, 66%). TLC, R_f 0.5 (petroleum ether/diethyl ether, 7:3, vol/vol); IR (cm^{-1}): 3450 (*br*), 1740 (*s*), 1460 (*m*), 1435 (*m*), 1360 (*m*) and 1170(*m*). ^{1}H NMR ($CDCl_3$, δ): 0.88 (*t*, 3H, C*H*$_3$), 1.2–1.6 (*m*, 20H, C*H*$_2$), 2.04 (*s*, 1H, CH-O*H*), 2.2 (*m*, 4H, 8-*H* and 11-*H*), 2.3 (*t*, 2H, 2-*H*), 3.66 (*s*, 3H, COOC*H*$_3$) and 3.69 (*m*, 1H, C*H*OH); ^{13}C NMR ($CDCl_3$, ppm): 14.1 (C-18), 18.7 (C-8), 22.6 (C-17), 24.9 (C-3), 25.2 (C-14), 27.7 (C-11), 28.6 (C-7), 28.9, 29.3, 31.8 (C-16), 33.9 (C-2), 36.2 (C-13), 51.4 (COO*C*H$_3$), 70.3 (C-12), 76.2 (C-10), 83.1 (C-9) and 174.3 (C-1).

Methyl 12-hydroxy-9-oxooctadecanoate (**6**). A mixture of compound **5** (2.0 g, 6.4 mmol), tetrahydrofuran (30 mL), water (30 mL) and mercury(II)acetate (4.1 g, 12.8 mmol) was sonicated for 25 min at 20°C. The reaction mixture was acidified with dilute HCl (2M, 20 mL) and extracted with diethyl ether (2 × 50 mL). The ethereal extract was washed with water (2 × 20 mL) and dried over anhydrous sodium sulfate. The solvent was evaporated and silica column chromatography afforded pure methyl 12-hydroxy-9-oxo-octadecanoate (**6,** 2.0 g, 95%). TLC, R_f 0.4 (petroleum ether/diethyl ether, 7:3, vol/vol); IR (cm^{-1}): 3500 (*br*), 1740 (*s*), 1700 (*s*), 1460 (*m*), 1380 (*m*); ^{1}H NMR ($CDCl_3$, δ): 0.88 (*t*, 3H, C*H*$_3$), 1.2–1.6 (*m*, 22H, C*H*$_2$), 2.10 (*s*, 1H, CH-O*H*), 2.30 (*t*, 2H, 2-*H*), 2.5 (*t*, 4H, 8-*H*, 10-*H*), 3.4–3.6 (*m*, 1H, C*H*-OH) and 3.6 (*s*, COOC*H*$_3$); ^{13}C NMR ($CDCl_3$, ppm): 14.03 (C-18), 22.59 (C-17), 23.83 (C-7), 24.86 (C-3), 25.67 (C-14), 28.98, 29.30, 30.98 (C-11), 31.85 (C-16), 34.07 (C-2), 37.80 (C-13), 39.10 (C-10), 42.89 (C-8), 51.40 (COO*C*H$_3$), 71.48 (C-12), 174.22 (C-1) and 212.00 (C-9).

Methyl 12-mesyloxy-9-oxooctadecanoate (**7**). A mixture of compound **6** (1.0 g, 3.0 mmol), methanesulfonyl chloride (0.8 g, 7.0 mmol), triethylamine (1.0 mL) and dichloromethane (10 mL) was stirred at 0–5°C for 30 min. The reaction mixture was diluted with dichloromethane (50 mL) and successively washed with dilute HCl (2M, 4 mL), water (20 mL), and dried over anhydrous sodium sulfate. The mixture was filtered and the filtrate evaporated to give crude methyl 12-mesyloxy-9-oxooctadecanoate (**7,** 1.1 g, 90%) as a viscous oil. TLC, R_f 0.4 (petroleum ether/diethyl ether, 1:1, vol/vol), IR (cm^{-1}): 2960, 2850, 1740, 1710, 1355, 1180, 970, 900, 760, 740 and 700; ^{1}H NMR (CDCl, δ): 0.9 (*t*, 3H, C*H*$_3$), 1.2–1.4 (*m*, 18H, C*H*$_2$), 2.0 (*m*, 4H, 11-*H*, 13-*H*), 2.3 (*t*, 2H, 2-*H*), 2.45 (*t*, 4H, 8-*H*, 10-*H*), 2.90 (*s*, 3H, C*H*$_3$ of OMs), 3.6 (*s*, 3H, COOC*H*$_3$) and 4.70 (*quintet*, 1H, C*H*-OMs); ^{13}C NMR ($CDCl_3$, ppm): 14.03 (C-18), 22.53 (C-17), 23.67 (C-7), 24.54 (C-14), 24.92 (C-3), 28.22, 29.03, 29.36, 29.68 (C-11), 31.74 (C-16), 34.02 (C-2), 34.86 (C-13), 37.74 (C-10), 38.62 (*C*H$_3$ of OMs), 42.74 (C-8), 51.30 (COO*C*H$_3$), 82.94 (C-12), 174.06 (C-1) and 209.65 (C-9).

Methyl 12-azido-9-oxooctadecanoate (**8**). A mixture of compound **7** (1.1 g, 2.7 mmol), sodium azide (0.4 g, 6 mmol) and dimethylformamide (10 mL) was stirred at 80°C for 2 h. Water (20 mL) was added, and the reaction mixture was extracted with diethyl ether (2 × 40 mL). The ethereal extract was washed with water (30 mL) and dried over anhydrous sodium sulfate. The solvent was evaporated, and silica column chromatographic purification gave methyl 12-azido-9-oxooctadecanoate (**8,** 0.8 g, 96%). TLC, R_f 0.4 (petroleum ether/diethyl ether, 4:1, vol/vol); GLC, ECL 19.6 (SPB1), IR (cm^{-1}): 2930, 2857, 2098, 1741, 1714; ^{1}H NMR ($CDCl_3$, δ): 0.88 (*t*, 3H, C*H*$_3$), 1.2–1.5 (*m*, 14H, C*H*$_2$), 1.6–1.8 (*m*, 6H, C*H*$_2$), 1.9 (*m*, 2H, 11-*H*), 2.30 (*t*, 2H, 2-*H*), 2.41 (*t*, *J* = 7.0 Hz, 2H, 8-*H*), 2.54 (*t*, *J* = 7.0 Hz, 2H, 10-*H*), 3.25 (*m*, 1H, 12-*H*), 3.60 (*s*, 3H, COOC*H*$_3$); ^{13}C NMR ($CDCl_3$, ppm): 14.03 (C-18), 22.57 (C-17), 23.76 (C-7),

24.88 (C-3), 26.04 (C-14), 28.18, 28.94, 29.03, 29.08, 29.31 (C-11), 31.69 (C-16), 34.04 (C-2), 34.53 (C-13), 38.90 (C-10), 42.95 (C-8), 51.46 ($COOCH_3$), 62.36 (C-12), 174.25 (C-1) and 210.20 (C-9).

Compound **8** was also obtained from methyl 12-azido-9-*cis*-octadecenoate (**11**) as follows. A mixture of methyl 12-azido-9-*cis*-octadecenoate (**11**, 0.4 g, 1.2 mmol), benzoquinone (0.19 g), palladium(II)chloride (59% Pd content, 0.018 g), tetrahydrofuran (20 mL) and water (5 mL) was sonicated at 20°C for 90 min. Dilute HCl (2M, 50 mL) was added, and the reaction mixture was extracted with diethyl ether (2 × 40 mL). The ethereal extract was successively washed with dilute NaOH (0.5 M, 15 mL), water (30 mL), and brine (20 mL), and dried over sodium sulfate. The ethereal mixture was filtered, and the solvent of the filtrate was evaporated. The residue was purified by silica column chromatography to yield compound **8** (0.2 g, 45%).

Methyl 8-(5-hexyl-1-pyrrolin-2-yl)octanoate (**2**). A mixture of compound **8** (0.8 g, 2.3 mmol), triphenylphosphine (0.8 g, 3.0 mmol), and anhydrous tetrahydrofuran (20 mL) was sonicated at 80°C for 30 min. Water (40 mL) was added, and the reaction mixture was extracted with diethyl ether (2 × 30 mL). The ethereal extract was washed with water (30 mL) and dried over anhydrous sodium sulfate. The solvent was evaporated, and silica column chromatographic purification of the residue using a mixture of petroleum ether and diethyl ether (2:3, vol/vol) as the eluent furnished the 1-pyrroline derivative **2** (0.5 g, 77%). TLC, R_f 0.5 (petroleum ether/diethyl ether, 3:2, vol/vol); GLC, ECL 18.6 (SPB1); IR (cm^1): 2926, 2854, 1741, 1644 (C=N, cyclic), 1463, 1197 and 1171; ^1H NMR ($CDCl_3$, δ): 0.89 (*t*, 3H, CH_3), 1.20–1.50 (*m*, 14H, CH_2), 1.50–1.80 (*m*, 6H, CH_2), 2.02 (*m*, 2H, ring CH_2, 11-*H*), 2.30 (*t*, 4H, 2-*H*, 8-*H*), 2.45 (*t*, *J* = 7.0 Hz, 2H, 10-*H*), 3.65 (*s*, 3H, $COOCH_3$) and 3.90 (*m*, *br*, 1H, N-C*H*, 12-*H*); ^{13}C NMR ($CDCl_3$, ppm): 14.09 (C-18), 22.64 (C-17), 24.92 (C-3), 26.65 (C-7, C-14), 28.66 (C-11), 29.04, 31.91 (C-16), 33.90 (C-8), 34.08 (C-2), 36.73 (C-13), 37.00 (C-10), 51.36 ($COOCH_3$), 72.59 (C-12), 174.17 (C-1) and 176.88 (C-9); mass spectrometry (MS) [*m/z* (relative intensity)]: M^+ 309.2664 (calc. 309.2667); 309 (4), 280 (19), 278 (25), 236 (14), 236 (14), 224 (12), 180 (56), 168 (12), 167 (100), 166 (14), 152 (11), 110 (13), 97 (12), 96 (31), 83 (27), 82 (66) and 55 (15).

Methyl 12-acetamido-9-oxooctadecanoate (**9**). A mixture of compound **2** (0.34 g, 1.1 mmol) and acetic anhydride (3.5 mL) was stirred at 90°C for 1 h. The reaction mixture was cooled and ice-water (15 mL) was added. The precipitate was collected by suction filtration, washed with cold water (5 × 10 mL) and recrystallized from a mixture of diethyl ether and ethyl acetate (1:3, vol/vol) to give compound **9**. TLC, R_f = 0.5 (hexane/diethyl ether/methanol, 1:3:1 by vol); ^1H NMR ($CDCl_3$, δ): 0.89 (*t*, 3H, CH_3), 1.20–1.50 (*m*, 14H, CH_2), 1.5–1.8 (*m*, 8H, CH_2), 1.95 (*s*, 3H, CH_3CONH), 2.30 (*t*, 2H, 2-*H*), 2.4 (*t*, *J* = 7.0 Hz, 2H, 8-*H*), 2.5 (*t*, *J* = 7.0 Hz, 2H, 10-*H*), 3.6 (*s*, 3H, $COOCH_3$), 3.9 (*m*, 1H, C*H*-$NHCOCH_3$) and 5.3 (*d*, *J* = 9.0 Hz, 1H, N*H*$COCH_3$); ^{13}C NMR $CDCl_3$, 14.07 (C-18), 22,58 (C-17), 23.5 ($NHCOCH_3$), 23.76 (C-7), 24.86 (C-3), 25.85 (C-14), 28.9 (C-11), 29.02, 31.76 (C-16), 34.04 (C-2), 35.81 (C-13), 39.59 (C-10), 42.95 (C-8), 49.48 (C-12), 51.48 ($COOCH_3$), 169.82 ($NHCOCH_3$), 174.28 (C-1) and 211.49 (C-9); MS [*m/z* (relative intensity)]: 69 (11), 99 (19), 114 (95), 128 (40), 156 (66), 157 (21), 168 (18), 170 (100), 185 (16), 242 (22), 266 (17), 278 (21), 284 (29), 296 (22), 310 (52), 326 (41), 338 (11), 339 (2), 369 (3).

RESULTS AND DISCUSSION

In our first reported synthesis of a 1-pyrroline fatty acid ester derivative, *iso*-ricinoleic acid (9-hydroxy-12-*cis*-octadecenoic acid, isolated from the seeds of *Wrightia tinctoria*) was used as the starting substrate (10). The presence of two methylene groups between the unsaturated center and the hydroxy function in the alkyl chain of this natural, unsaturated hydroxy fatty acid provided the suitable retrosynthetic steps for obtaining the target molecule (**1**) through a key intermediate (a 1,4-azido-oxo derivative). The 1-pyrroline fatty acid ester (**1**) synthesized was shown to have the C=N of the pyrroline nucleus attached to the C-12 of the alkyl chain of the substrate (*iso*-ricinoleic acid). As *W. tinctoria* seed oil is not readily available as compared to castor oil (a ready source of ricinoleic acid, 12-hydroxy-9-*cis*-octadecenoic acid), the focus of this project was therefore to obtain 1-pyrroline fatty acid derivatives from ricinoleic acid. The key intermediate in this synthesis plan was to obtain a similar 1,4-azido-oxo intermediate. Cyclization of the latter would therefore lead to the requisite 1-pyrroline fatty acid derivative. However, employing ricinoleic acid as the starting substrate, the position of the azido and oxo function are in the reversed order as compared with the 1,4-azido-oxo intermediate derived from *iso*-ricinoleic acid. Hence, the 1-pyrroline fatty acid product (**2**) is anticipated to have the C=N bond attached to C-9 of the alkyl chain of the fatty acid instead of the C-12.

Two synthetic routes leading to the target molecule (**2**) were envisaged. The first route involved the bromination of methyl ricinoleate (**3**) to give the corresponding dibromo derivative (**4**), which under concomitant ultrasound treatment (30 min) with KOH in ethanol furnished methyl 12-hydroxy-9-octadecynoate (**5**) in 66% yield. Hydration of compound **5** with mercury(II)acetate in aqueous tetrahydrofuran (THF) was also carried out under ultrasonic irradiation for 25 min to yield exclusively methyl 12-hydroxy-9-oxooctadecanoate (**6**) in almost quantitative yield (95%). The above debromination and hydration experiments normally required 6 h of reflux and 4 d of stirring at room temperature, respectively, for the reactions to be complete. Conversion of the hydroxy function in compound **6** to the azido group was achieved *via* the mesylate (**7**) to give the key intermediate **8** (methyl 12-azido-9-oxooctadecanoate). Subsequent cyclization according to the method described by Lambert *et al.* (15) of compound **8** with PPh_3 but under concomitant ultrasonic irradiation (30 min) furnished the requisite 1-pyrroline derivative (**2**) in 92% yield.

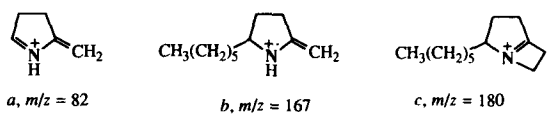
The second route leading to the target molecule (**2**) followed a similar approach as that reported for methyl 8-(5-hexyl-2-pyrrolin-1-yl)octanoate (compound **1**) from methyl *iso*-ricinoleate (10). Methyl ricinoleate was first transformed to the mesylate (**10**) and then converted to methyl 12-azido-9-*cis*-octadecenoate (**11**). The latter was then oxi-

dized with benzoquinone in the presence of palladium(II)chloride in aqueous THF under concomitant ultrasonic treatment (90 min) to yield exclusively the required key intermediate **8**. When this reaction was carried out by stirring at room temperature for 7 d, a very low yield of compound **8** (12%) was obtained. Increasing the temperature of the reaction caused large amounts of side products to be formed due to overoxidation. The use of ultrasound at room temperature provided not only the optimum condition for this chemical transformation, but also allowed for regiospecific oxidation. Reaction of compound **8** with Ph_3P gave the requisite 1-pyrroline derivative **2.** Both routes made use of ultrasound where reactions were expected to require long reaction times.

The final product (compound **2**) was characterized by a combination of physical methods, and the position of the imine (C=N) bond in the ring system was established by ring opening reaction of compound **2** to the acetamido derivative followed by mass spectral analysis.

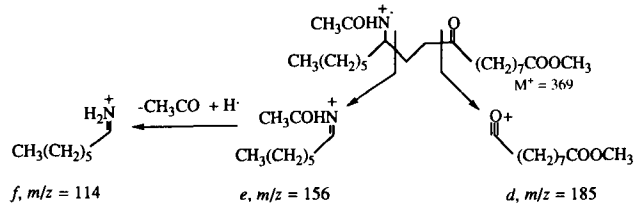
From the IR spectral analysis of compound **2,** the strong absorption bands at 1644 and 1741 cm^{-1} indicated the presence of the imine (C=N) and ester (C=O) function, respectively. The presence of the 1-pyrroline ring system was further supported by the signals at δ 2.02 and 2.45 for the methylene protons of the ring and the characteristically broad multiplet at δ 3.90 for the pyrroline ring CH proton adjacent to the nitrogen atom. Confirmation of the 1-pyrroline nucleus was further obtained from the ^{13}C NMR spectrum of compound **2**. The chemical shift of the imino (C=N) carbon atom of the 1-pyrroline system appeared at 176.88 (C-9) and the ring methine carbon atom at 72.59 (C-12) ppm. The C=N bond of the pyrroline system caused deshielding of the adjacent methylene carbon atoms with signals appearing at 33.90 and 36.73 for the C-8 and C-13 carbon atom, respectively. The shift of the remaining methylene carbon atom of the five-membered heterocyclic system appeared at 28.66 (C-11) ppm. The shielding γ-effect of the nitrogen atom of the pyrroline ring caused the shifts of the C-7 and C-14 carbon atoms to appear at 26.65 ppm.

The ^1H and ^{13}C NMR spectra of compound **2** were very similar to those obtained on compound **1** (10). The mass spectral analysis of compound **2** further confirmed the presence of the pyrroline nucleus from the peak at *m/z* 82 (Scheme 2, ion *a*, 66%), and the position of the pyrroline ring system between C-9 and C-12 was implied by the peaks at *m/z* 167 (*b*, 100) and 180 (*c*, 56). The only remaining doubt was the position of the imine bond. To determine



a, *m/z* = 82 *b*, *m/z* = 167 *c*, *m/z* = 180

SCHEME 2



f, *m/z* = 114 *e*, *m/z* = 156 *d*, *m/z* = 185

SCHEME 3

the position of the C=N linkage, compound **2** was converted to the corresponding acetamido-oxo derivative (**9**) by reaction with acetic anhydride. The mass spectral analysis of compound **9** confirmed the oxo function at the C-9 position from the peak at *m/z* 185 (Scheme 3, ion *d*, 16%). The linkage of the acetamido group was confirmed from the peak at *m/z* 156 (*e*, 66%) and the subsequent cleavage of the $CH_3C{\equiv}O^+$ moiety from this ion fragment to give the characteristic ion fragment at *m/z* 114 (*f*, 95%) (16). These results confirmed the linkage of the imine bond (C=N) at the C-9 carbon atom. In the case of compound **1,** the mass spectrum of the acetamido derivative did not give an ion fragment at *m/z* 114, as the acetamido group was linked to the C-9 carbon atom (10).

This study reports the structural elucidation of diunsaturated 5- or 6-membered ring cyclic fatty acid monomers (CFAM) isolated from heated flaxseed oil by complementary gas chromatography (GC)–mass spectrometry (MS) and GC–matrix isolation–Fourier transform infrared spectroscopy (MI–FTIR). Infrared measurements of CFAM were carried out on methyl ester derivatives as well-resolved chromatograms were obtained on a polar 100% cyanopropyl polysiloxane capillary GC column. By contrast, electron ionization MS of methyl ester derivatives was of limited value because of double bond migration during the ionization process in the mass spectrometer. This communication reports definitive MS fragmentation patterns that can confirm ring position and double bond position along the fatty acid chain in 1,2-disubstituted CFAM determined as 2-alkenyl-4,4-dimethyloxazoline derivatives. Double bond configuration (*cis, trans,* or conjugated *cis,cis*) in CFAM was confirmed by GC–MI–FTIR. The presence of CFAM, degradation products found in used frying oils, is a potential source of dietary toxicity.

***Lipids* 29, 893–896 (1994).**

Several decades ago, it was suspected that unsaturated cyclic fatty acid monomers (CFAM) are formed in frying oils. Consequently, several attempts were made to elucidate their structures by various analytical techniques (1–10). CFAM, which are reported to be potentially toxic (6,11–13) and are readily absorbed by the digestive system (14,15), were found at levels up to 0.5% in frying oils collected from restaurants in the United States (16).

Electron ionization (EI) mass spectrometry (MS) is of limited value in identifying unsaturation sites in CFAM methyl esters because in the EI mode double bonds tend to migrate along the aliphatic hydrocarbon chain (17,18). Hence, EI mass spectra of methyl esters cannot distinguish between closely related CFAM structures, and more suitable derivatives had to be found. Recent developments in the identification of CFAM isolated from seed oils (19) and heated sunflower oil (20) have been reported. The nature of the cyclic monoenoic fatty acids formed from linoleic acid in sunflower oil heated to 275°C was determined by gas chromatography–mass spectrometry (GC–MS) of the picolinyl ester derivatives following isolation by silver ion high-performance liquid chromatography (20). Compared to CFAM methyl ester derivatives, picolinyl ester derivatives inevitably suffer some loss of resolution during GC separation (20), and it is rarely possible to interpret mass spectra from mixtures satisfactorily (20). Although several derivatives have been proposed for locating double bonds (21), 2-alkenyl-4,4-dimethyloxazoline was selected because it has been successfully used to characterize unsaturated fatty acids with a terminal (monosubstituted) 5-membered ring (22). Moreover, in contrast to picolinyl ester derivatives, the resolution obtained in the GC separation of CFAM oxazoline derivatives was as good as that of methyl esters under identical GC conditions.

In the present study, a complex mixture of diunsaturated CFAM methyl esters was successfully converted to 2-alkenyl-4,4-dimethyloxazoline derivatives (21,22). The resulting CFAM oxazolines exhibited definitive EI mass spectra with distinctive fragmentations; thus the location of double bonds along the fatty acid chain of all components of the CFAM mixture could be determined. Matrix isolation–Fourier transform infrared spectroscopy (MI–FTIR) (23,24) offered equally unequivocal and complementary information on double bond configuration.

By using capillary GC–EIMS and GC–MI–FTIR, it was possible to rapidly establish the location of double bonds along the hydrocarbon chains in cyclic dienoic fatty acid monomers, the double bond configuration, the molecular weight, the location of the ring along the fatty acid chain, the ring size and the degree of unsaturation of diunsaturated C_{18} CFAM in complex mixtures isolated from heated flaxseed (linseed) oil.

MATERIALS AND METHODS

Materials were obtained from the following sources: refined linseed oil from Cargill (Riverside, ND); silica gel from Mallinckrodt (St. Louis, MO); urea from International Biotechnologies, Inc. (New Haven, CT); solvents (reagent grade) from Fisher (Pittsburgh, PA); Wilkinson's catalyst [tris(phenylphosphine)rhodium(I) chloride] from Strem Chemical Co. (Newburyport, MA); and deuterium from Alpha Products (Ward Hill, MA).

[1]This work was presented in part at the 84th American Oil Chemists' Society Annual Meeting held in Anaheim, CA, in April 1993.

[2]Physical sciences aide, 1991–1992; currently a medical student at the University of Maryland, Baltimore, MD.

Abbreviations: AMP, 2-amino-2-methyl-1-propanol; CFAM, cyclic fatty acid monomers; EI, electron ionization; FAME, fatty acid methyl esters; FTIR, Fourier transform infrared spectroscopy; GC, gas chromatography; MI, matrix isolation; MS, mass spectrometry; PFK, perfluorokerosene.

A test portion of oil was heated at 275°C under nitrogen for 12 h as previously described (25).

Refined linseed oil was saponified with potassium hydroxide, and the unsaponifiables were removed as detailed in the American Oil Chemists' Society official method Ca 6a 40 (26). The fatty acids recovered were converted to methyl esters as described previously (27). Published procedures (25) were followed for the separation of fatty acid methyl esters (FAME) from polar lipids by silicic acid column chromatography and for the isolation of CFAM methyl esters by urea fractionation of the nonpolar FAME fraction. The urea fractionation step was carried out twice, and the optimum ratio of urea to FAME was 3:1.

A portion of the isolated mixture of CFAM methyl esters was catalytically hydrogenated over platinum oxide by using a microhydrogenator (Supelco, Inc., Bellefonte, PA) as described earlier (9). Unsaturated FAME were deuterated by the method of Rakoff and Emken (28).

The method of Fay and Richly (21) for derivatizing FAME to oxazolines was modified as follows. About 150 μL 2-amino-2-methyl-1-propanol (AMP) was added to 24 mg of neat methyl esters in a 2-mL reaction vial. The vial was suspended in a wax bath held at 175°C for 6 h. The content of the vial was cooled and transferred with 5 mL methylene chloride to a 250-mL separatory funnel containing 40 mL petroleum ether. The funnel content was shaken, and the petroleum ether layer was washed with 40 mL deionized water and then dried with sodium sulfate. The solution was evaporated under a stream of argon, and the residue was dissolved in isooctane.

Low resolution GC–EIMS analyses were obtained using a Hewlett-Packard (Avondale, PA) 5890 series II gas chromatograph coupled to a Fissons VG (Wytheshawe, United Kingdom) Autospec Q mass spectrometer and OPUS 2000 data system. Version 1.6C software was used for the GC–MS system. The capillary GC column used (CP-Sil-88; Chrompack, Inc., Bridgewater, NJ), 50 m × 0.22 mm (i.d.), was coated with 0.19-μm stationary phase film. Adjusting the capillary GC column head pressure to 10 psi gave chromatographic profiles comparable to those obtained with a flame-ionization detector. GC–MS conditions were as follows: splitless injection with helium sweep restored 1 min after injection; injector and transfer lines held at 230°C; oven temperature program, 75°C for 2 min after injection, 20°C/min to 185°C, hold for 15 min, 4°C/min to 225°C, hold for 5 min. The mass spectrometer was tuned to a resolution of 1000 (5% valley) by observing *m/z* 305 in the EI mass spectrum of perfluorokerosene (PFK). The mass scale was calibrated with PFK for magnet scans from 440 to 44 daltons at 1 s/decade. Filament emission was 200 μA at 70 eV. Ion source temperature was 250°C.

Gas-chromatographic separations with MI–FTIR detection were performed on a Hewlett-Packard Model 5890 instrument. A Mattson Cryolect MI–FTIR system (Madison, WI) was used as detailed earlier (29).

RESULTS AND DISCUSSION

The total ion chromatogram obtained for the mixture of CFAM is shown in Figure 1. The oxazoline mass spectra confirmed the molecular weight of unsaturated C_{18} CFAM, the ring size, the degree of unsaturation, the position of the ring, and the location of double bonds along the chain. The CFAM oxazoline EI mass spectra consisted mainly of an even-mass homologous series in which the most intense peak in each cluster was at *m/z* 126 + 14*n* (*n* = 0, 1, 2, etc.). The pattern of peaks 14 mass units apart, occurring as a result of the cleavage of methylene groups (22), was interrupted when a double bond and/or a ring was present along the hydrocarbon chain. A double bond between carbons n and n+1 in a given hydrocarbon chain was indicated by an interruption of 12 mass units between fragments with n and n–1 carbon atoms (30). Rings caused large gaps of 68 (cyclopentyl), 82 (cyclohexyl), 66 (cyclopentenyl) or 80 (cyclohexenyl) mass units.

Typical examples of mass spectra for diunsaturated CFAM extracted from the heated flaxseed oil include two spectra of compounds that have a cyclopentenyl ring and either a *trans* double bond in the oxazoline 2-alkenyl substituent (Fig. 2A) or a *cis* double bond in the hydrocarbon (*n*-butene) substituent (Fig. 2B). The signal at *m/z* 113 arises from a McLafferty rearrangement involving the dimethyl oxazoline ring (30), whereas *m/z* 126 is reportedly formed *via* a cyclization displacement reaction induced by the nucleophilic center (30). The double bond configuration for these compounds was assigned on the basis of the position of infrared bands. Specifically, a cyclopentenyl

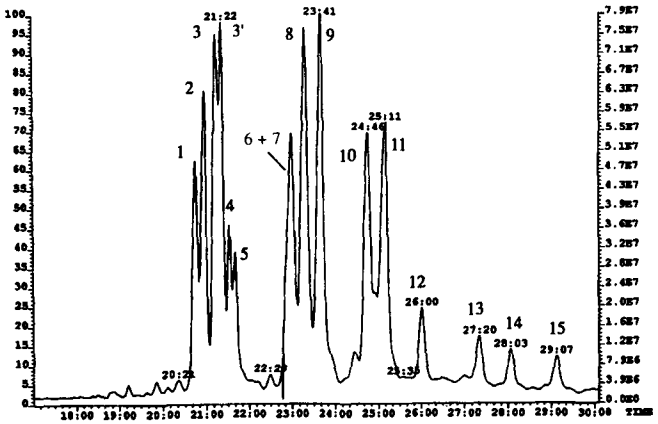

FIG. 1. Total ion chromatogram for the mixture of diunsaturated C_{18} cyclic fatty acid monomers (CFAM) oxazolines isolated from heated flaxseed (linseed) oil. CFAM having a cyclopentenyl ring (peaks 1–4, 6 and 7) eluted before those with a six-membered ring (peaks 8–13) on a 100% cyanopropyl polysiloxane capillary gas chromatography (GC) column. Peak 5 is due to the oxazoline derivative of linoleic acid. The structures that gave rise to peaks 14 and 15 are being investigated further. The identities of the alkenyl substituents at C-2 in 2-alkenyl-4,4-dimethyloxazolines that gave rise to the different GC peaks are as follows: 1, 8-(2-but-*trans*-1-enyl-cyclopentenyl)octyl; 2 and 4, 9-(2-propyl-cyclopentenyl)non-*trans*-8-enyl; 3, 9-(2-propyl-cyclopentenyl)non-*cis*-7-enyl; 3′ and 6, 8-(2-but-*cis*-1-enyl-cyclopentenyl)octyl; 7, 9-(2-propyl-cyclopentenyl)non-*cis*-8-enyl; 8 and 9, 8-(2-propyl-cyclohex-*cis*-4-enyl)oct-*trans*-7-enyl; 10 and 11, 8-(prop-*trans*-1-enyl-cyclohex-*cis*-4-enyl; 12 and 13, 8-(2-propyl-cyclohexa-*cis,cis*-3,5-dienyl)octyl. It is noted that the numbering of carbon atoms n and n+1 in the original fatty acid chain corresponds to carbons n–1 and n, respectively, along the 2-alkenyl chain of the oxazoline derivative.

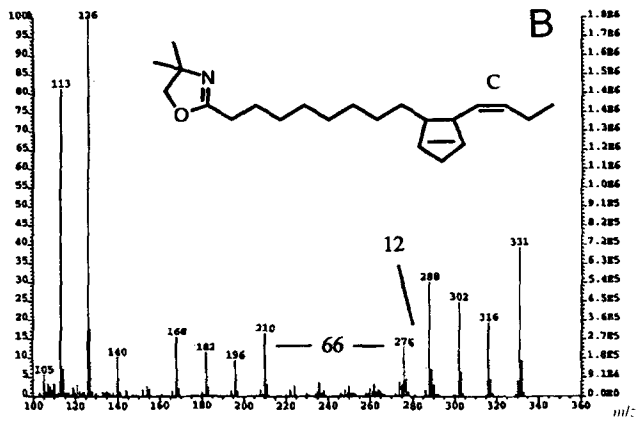
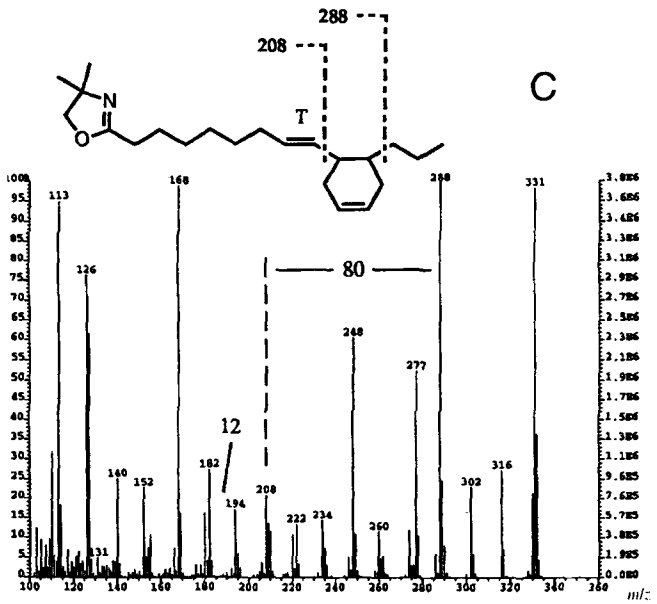
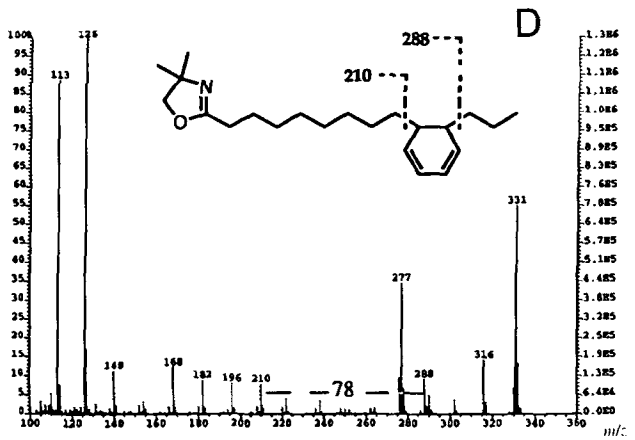
ring *cis* double bond gave rise to bands near 3061 cm^{-1} (=C–H stretch) and 716 cm^{-1} (=C–H deformation) (8,31). A *trans* unsaturation site in a hydrocarbon chain produced weak features near 3035 and 3003 cm^{-1} (stretch) and a relatively strong band at 970 cm^{-1} (deformation) (32); a *cis* double bond in a chain produced a band of medium intensity near 3006 cm^{-1} (stretch) (32). The synthesis of standard C_{18} mono- or diunsaturated CFAM with a cyclohexenyl ring was reported (4,33,34), but CFAM with a cyclopentenyl ring (with two *cis* hydrogen atoms on the ring double bond) have yet to be prepared (10). The ring 1,2-disubstitution pattern was previously established for several cyclopentenyl (3,10) and cyclohexenyl (1,2,4,6,7) CFAM isolated from heated linseed oil by analyzing their oxidation products.

Mass spectra for a mono- and a diunsaturated six-membered ring CFAM are shown in Figures 2C and 2D, respectively. The odd-mass peak at *m/z* 277 (M-54), probably due to a retro Diels-Alder reaction, was not observed after hydrogenation (Fig. 2E). The compounds exhibited two sharp infrared bands of interest at 3032 (stretch) and 664 (deformation) cm^{-1} that are characteristic of a *cis* double bond in







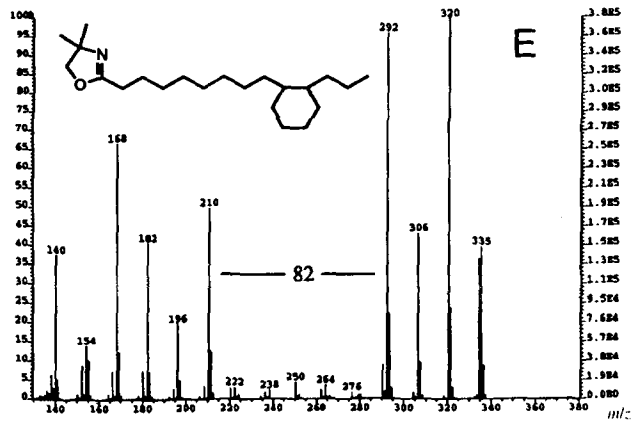


FIG. 2. A. Electron ionization (EI) mass spectrum for 2-[9-(2-propyl-cyclopentenyl)non-*trans*-8-enyl]-4,4-dimethyloxazoline indicating the location and degree of unsaturation in the ring and the position of the double bond in the chain. The location of the *cis* double bond in a 1,2-disubstituted five-membered ring could be either between C-3 and C-4, or between C-4 and C-5, B. EI mass spectrum for 2-[8-(2-but-*cis*-1-enyl-cyclopentenyl)octyl]-4,4-dimethyloxazoline. C. EI mass spectrum for 2-[8-(2-propyl-cyclohex-*cis*-4-enyl)oct-*trans*-7-enyl]-4,4-dimethyloxazoline. D. EI mass spectrum for 2-[8-(2-propyl-cyclohexa-*cis*,*cis*-3,5-dienyl)octyl]-4,4-dimethyloxazoline. Conjugation was deduced from Fourier transform infrared data (see text). E. EI mass spectrum for the saturated CFAM 2-[8-(2-propyl-cyclohexyl)octyl]-4,4-dimethyloxazoline. See Figure 1 for other abbreviation.

a six-membered ring (1,2,8); the latter species (Fig. 2D) gave rise to an additional feature at 723 cm^{-1} which indicated that two conjugated *cis* double bonds were present in the cyclohexadienyl ring. A similar pair of bands (near 655 and 740 cm^{-1}) was reported (31) for a 1,3-cyclohexadiene standard in the condensed phase at room temperature. It is noted that for a retro Diels-Alder reaction to occur (*m/z* 277) for this cyclohexadiene CFAM (Fig. 2D), isomerization of the ring double bonds would have to take place.

The combination of GC–EIMS and GC–MI–FTIR proved to be a powerful method for the rapid elucidation of the structure, and particularly for determining the double bond configuration and position along the fatty acid chain in mixtures of diunsaturated CFAM.

CORRECTIONS

Tissue Phospholipid Fatty Acid Composition in Genetically Lean (Fa/-) or Obese (fa/fa) Zucker Female Rats on the Same Diet
Ph. Guesnet, J.-M. Bourre, M. Guerre-Millo, G. Pascal and G. Durand
Lipids 25, 517–522 (1990)

In this paper, in Table 4, the values for 20:3n-6 for kidney should read 1.0 ± 0.2 for lean rats and 1.3 ± 0.2[b] for obese rats (rather than 0.5 ± 0.2 and 0.3 ± 0.1), and for heart 0.3 ± 0.1 for lean rats and 0.7 ± 0.2[c] for obese rats (rather than 0.7 ± 0.2 and 0.5 ± 0.1).

In Table 6, the obese/lean ratios for brain for the Δ6-desaturase index should be 1.25 (and not 0.80), and for the Δ5-desaturase index 0.75 (and not 1.32).

Study on the Lipid Composition of Aging Fisher-344 Rat Lymphoid Cells: Effect of Long-Term Calorie Restriction
Serge Laganiere and Gabriel Fernandes
Lipids 26, 472–478 (1991)

In Table 2 of this paper, the value for 20:4 for long-term calorie restricted rats (LCR) at 12 months should be 17.98 ± 0.61 (rather than 7.98 ± 0.61). Similarly in Figure 3, upper right panel, the shaded LCR bar at 12 m for 20:4 should extend to 17.98 ± 0.61 (rather than to 7.98 ± 0.61).

Effects of *bis* Homoallylic and Homoallylic Hydroxyl Substitution on the Olefinic ^{13}C Resonance Shifts in Fatty Acid Methyl Esters
Philip E. Pfeffer, Philip E. Sonnet, Daniel P. Schwartz, Stanley F. Osman and David Weisleder
Lipids 27, 285–288 (1992)

Because of the recent unambiguous assignment of the C-9 and C-10 carbon-13 signals of *cis*- and *trans*-12-hydroxy-9-octadecenoic acids (*Nat. Prod. Lett. 3*, 65–69, 1993), the authors wish to make the following corrections:

In Table 3 (p. 287), column 5 (*cis* Ia) should be exchanged with column 6 (*cis* Ib), and column 7 (*trans* Ia) should be exchanged with column 8 (*trans* Ib).

On page 288, equation [3] should be exchanged with equation [4].

Reference 8 should read:

8. Lie Ken Jie, M.S.F., and Cheng, A.K.L. (1993) *Nat. Prod. Lett. 3*, 65–69.

Effects of Sodium Butyrate on the Transfer of Arachidonic Acid to Phosphatidylcholine in a Clonal Oligodendrocyte Cell Line (CB-II)
Synthia H. Sun, Kuo-Chi Chen and Yue-Wen Chen
Lipids 29, 467–474 (1994)

In this paper, in Table 2, the standard error for the last entry was inadvertently deleted. The value for total dpm in the presence of sodium butyrate should be 113201 ± 10825.

Thermal Adaptation Affects the Fatty Acid Composition of Plasma Phospholipids in Trout
Charlotte Wallaert and Patrick J. Babin
Lipids 29, 373–376 (1994)

In this paper, the first footnote to Table 1, line 9, should read "22°C-summer- and 8°C-winter-acclimated trout" (instead of "2°C-summer- and 8°C-winter-acclimated trout").

In addition Figures 1 and 2 were inadvertently transposed. The illustration at the right is Figure 1; the illustration at the left is Figure 2.

Editorial

When I decided to step down as Editor-in-Chief of *Lipids* by the end of this year, it was gratifying to know that I would leave the helm of a journal that is strong and healthy and that has earned the respect of the scientific community. The past ten years as *Lipids* Editor have been both challenging and rewarding. Looking back, I believe, we can be proud of what we accomplished.

To produce a quality scientific journal each month requires the special efforts of many, as well as cooperation and mutual trust. Authors, referees, editors, and production staff must work together and pool their efforts to assure success.

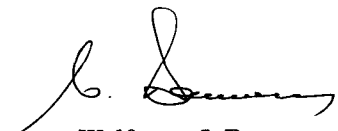
I wish to thank, first of all, our authors who have shown their confidence in our peer review and have submitted some of their most interesting work to our journal. Given an opportunity to further improve their papers after review, most authors have cooperated conscientiously and enthusiastically, and most were not even deterred by green ink.

It is with a deep sense of gratitude that I wish to specifically acknowledge the input and efforts of the many who served *Lipids* as referees over the years. A first-class journal is dependent on first-class reviewers. We have been fortunate, indeed, as we could count on the cooperation and advice of our many loyal referees, including some of the world's foremost experts in their respective fields. My special thanks to each and every one of them for volunteering their precious time and for letting us benefit from their knowledge and insights.

I also wish to express my appreciation to our Associate Editors for their tireless efforts and their help in keeping manuscripts moving along in the review process, and to the members of the *Lipids* Editorial Advisory Board for their encouragement and advice. I would also like to specifically thank my colleague and friend, Dr. Barbara Malewicz, who has served as Assistant to the Editor-in-Chief and as Index Editor. She kept the lines open to authors, referees and associate editors, and she did it efficiently and with grace. My cordial thanks to Barbara for her dedication, unparalleled hard work, encouragement, and support. She also kept our research program vigorous, thus allowing me to attend to my philanthropic editorial pursuits.

With the exception of the first volume of *Lipids*, which was edited by our Founding Editor, A. Richard Baldwin, all volumes of *Lipids* published since 1967 were edited at The Hormel Institute. With my stepping down as Editor-in-Chief, this 28-year tradition will come to an end. It is thus most appropriate to thank The Hormel Institute and its Board of Directors for making a home for *Lipids* throughout these years and for generously supporting its *Lipids* editors and the journal.

Looking back over the past ten years as *Lipids* Editor, I must say that I thoroughly enjoyed my daily excursions into the many areas of basic lipid science. I also very much cherished my personal contacts with authors, referees and associate editors from around the globe, many of whom I think of now as good friends. Serving as Editor-in-Chief of *Lipids* has been a special privilege, and it has been a most memorable and most rewarding experience. I am looking back with gratitude and pride. I trust I served the scientific community well.



Wolfgang J. Baumann
Editor-in-Chief
