Very Long Chain Fatty Acids in Higher Animals—A Review

Alf Poulos*

ABSTRACT: Fatty acids with greater than 22 carbon atoms (very long chain fatty acids, VLCFA) are present in small amounts in most animal tissues. Saturated and monoenoic VLCFA are major components of brain, while the polyenoic VLCFA occur in significant amounts in certain specialized animal tissues such at retina and spermatozoa. Biosynthesis of VLCFA occurs by carbon chain elongation of shorter chain fatty acid precursors while β-oxidation takes place almost exclusively in peroxisomes. Mitochondria are unable to oxidize VLCFA because they lack a specific VLCFA coenzyme A synthetase, the first enzyme in the β-oxidation pathway. VLCFA accumulate in the tissues of patients with inherited abnormalities in peroxisomal assembly, and also in individuals with defects in enzymes catalyzing individual reactions along the β-oxidation pathway. It is believed that the accumulation of VLCFA in patient tissues contributes to the severe pathological changes which are a feature of these conditions. However, little is known of the role of VLCFA in normal cellular processes, and of the molecular basis for their contribution to the disease process. The present review provides an outline of the current knowledge of VLCFA including their biosynthesis, degradation, possible function and involvement in human disease.
Lipids 30, 1–14 (1995).

Interest in very long chain fatty acids (i.e., fatty acids with greater than 22 carbon atoms, VLCFA) has increased greatly over the last few years since the recognition that this group of fatty acids is associated with certain disorders of peroxisomal structure and/or function. Indeed, the measurement of plasma and tissue VLCFA levels has formed the basis for a biochemical test for peroxisomal function. These studies have confirmed that VLCFA are components of most human tissues, indicating that they play a physiological role in many different cell types. More recent reports of an involvement of VLCFA in the biosynthesis of polyunsaturated fatty acids have stimulated further interest. In this review it is proposed to focus on the VLCFA in higher animals. Readers are referred to earlier reviews on VLCFA in animals and plants, and the involvement of VLCFA in human disease (1,2).

Abbreviations: ABC, ATP-binding cassette; ALD, adrenoleukodystrophy; ATP, adenosine triphosphate; CoA, coenzyme A; FABP, fatty acid binding protein; TCA, tricarboxylic acid; TNFα, tumor necrosis factor α; VLCFA, very long chain fatty acids.

STRUCTURE AND OCCURRENCE OF VLCFA

Like the shorter chain fatty acids, VLCFA which occur in nature can be divided broadly into three different classes—saturated, monoenoic and polyenoic. These may be subdivided further into hydroxylated and nonhydroxylated, and branched and unbranched chain derivatives.

Saturated and monoenoic VLCFA. The richest source of saturated and monoenoic VLCFA in most higher animals is the brain, and particularly myelin. The brain contains high amounts of 24 and 26 carbon saturated and monoenoic fatty acids and significant amounts of odd-chain 23, 25 and 27 carbon fatty acids. Smaller amounts of fatty acids with 28 and 30 carbon atoms are also found in brain. The monoenoic fatty acids in brain are *cis* configuration and contain predominantly two isomeric forms, n-7 and n-9 homologues (3,4). The relative proportions of the two monoenoic homologues vary quite significantly with carbon chain length. It is interesting to note that the shorter chain, odd-numbered monoenoic fatty acids (i.e., 17, 19 and 21 carbon fatty acids) comprise a mixture of n-8 and n-10 homologues, indicating that they are not precursors for the monoenoic VLCFA. The concentration of VLCFA in the brain increases with development (5,6). In addition to the developmental changes, there is an increase in VLCFA with aging (7). Significant levels of a wide variety of saturated and monoenoic VLCFA also occur in meibomian glands (and their secretions) of cattle, rabbits, mice, rats and humans (8–12). VLCFA comprise up to 23% of the fatty acids of human meibomian glands and their secretions (8). Odd- and even-numbered fatty acids with up to 32 carbon atoms were reported in these glands. Of particular interest is the presence of appreciable amounts of branched chain iso- and anteiso-fatty acids (13). Saturated and monenoic VLCFA occur in small amounts in most tissues and in body fluids. They are trace components of human plasma (14), the two principal plasma VLCFA (24:0 and 24:1) normally constituting less than 1.0%, while 26:0 and 26:1 make up less than 0.1% of the total fatty acid complement. In general, the VLCFA with >26 carbon atoms are not detected in tissues other than brain, skin or in certain glands. However, labeled VLCFA can be detected when cells are incubated with high specific activity [^{14}C]acetate (15), so it is likely that they occur in most tissues.

Saturated and monoenoic fatty acids occur as α-hydroxy derivatives in kidney, stomach (16,17) and, particularly, in

Copyright © 1995 by AOCS Press

mammalian brain (6). α-Hydroxy VLCFA (mainly 24:0, 25:0, 26:0 and 27:0 and their corresponding monenoic derivatives) occur in large amounts in brain, and ω-hydroxy monenoic VLCFA with up to 34 carbon atoms are found in epidermal lipids (18,19).

Only a small proportion of the saturated and monenoic VLCFA occurs unesterified. However, it is difficult to know whether the small amounts of unesterified VLCFA found, for instance in tissue such as brain (Poulos, A., and Sharp, P., unpublished observations), are simply the result of post-mortem changes. Depending on the tissue, VLCFA are joined either in ester or amide linkage, in a number of different lipid species including cholesterol esters, gangliosides, galactocerebroside, sphingomyelin, and phosphatidylcholine (20–23). α-Hydroxy VLCFA are bound almost exclusively in amide linkage in cerebroside sulfate and galactocerebroside (6,24), while ω-hydroxy VLCFA are bound to unusual acylglucosyl ceramide and acylceramide species (19,25). More recent reports indicate that significant amounts of saturated and monoenoic VLCFA are bound in thioester linkage to myelin proteolipid protein (26–28). Covalently-bound lipids containing VLCFA are also found in human stratum corneum lipids (29,30).

Unsaturated VLCFA. The occurrence of polyenoic VLCFA (mainly 24:4n-6 and 24:5n-6) in rat testis was reported over twenty years ago (31,32). Later studies confirmed the presence of a homologous series of n-6 polyenoic VLCFA with up to 30 carbon atoms in rat and mouse testis (33–35). More recently, polyenoic VLCFA have been detected in mature spermatozoa of a number of mammalian species including man (36,37), in rat epididymal spermatozoa (38) and in rat seminiferous tubules (39). Mammalian spermatozoa contain polyenoic VLCFA with up to 34 carbon atoms and from 3–6 methylene-interrupted double bonds. In some species the polyenoic VLCFA comprise up to 5% of the total fatty acids. Both n-3 and n-6 fatty acids have been detected in spermatozoa, although in individual species there is a predominance of one series or the other. Ram and bull spermatozoa, which contain significant amounts of both n-3 and n-6 series acids, are particularly rich in the longer chain polyenoic VLCFA, i.e., 30–34 carbon n-3 series hexaenoic acids. The n-6 series fatty acids with 3–5 double bonds predominate in human, boar and rat spermatozoa, while boar and rat contain unusual fatty acids with an odd number of carbon atoms (36,39). The testis and spermatozoa of the latter two species also contain unusual 2-hydroxylated n-6 tetra- and pentaenoic fatty acids with very long carbon chains (40). These fatty acids are joined in amide linkage to sphingomyelin in ram spermatozoa (37). However, in the rat, polyenoic VLCFA are also found esterified in triacylglycerols and cholesterol esters, as well as in sphingomyelin (39). Alkyl diacylglycerols, which are only minor components of rat testis, are particularly rich in polyenoic VLCFA. Around 34% of the total alkyl diacylglycerols fatty acids are fatty acids with carbon chain lengths >22 (39). Rat spermatozoa are also unusual in that they contain appreciable amounts of n-9 series polyenoic fatty acids, including 22:4n-9 and a novel VLCFA, 24:4n-9. These fatty acids appear to be concentrated in choline plasmalogen (41).

Another particularly rich source of polyenoic VLCFA is the retina. The occurrence of polyenoic VLCFA in the retina of diverse vertebrates (fish, birds and mammals) was first reported in the late 1980s (42–45). These fatty acids contain up to 36 carbon atoms and from 4–6 methylene-interrupted *cis* double bonds, and they comprise around 2% of the total fatty acids of retina and up to 13% of the rod outer segments (42). Representatives of both n-3 and n-6 series are present. As observed with testis and spermatozoa, the longer chain fatty acids (30–36 carbon atoms) predominate. Much of the polyenoic fatty acids are present in dipolyunsaturated molecular species of phosphatidylcholine. For example, VLCFA-containing phosphatidylcholines of bovine retina include 30:4n-6/22:6n-3, 32:4n-6/22:6n-3, 34:4n-6/22:6n-3, 30:5n-3/22:6n-3, 32:5n-3/22:6n-3, 34:5n-3/22:6n-3, 30:6n-3/22:6n-3, 32:6n-3/22:6n-3, 34:6n-3/22:6n-3 (43,45), highly hydrophobic species with up to 56 carbon atoms (not including the glycerol moiety) and with as many as 12 olefinic centers. The VLCFA are esterified almost exclusively in the *sn*-1 position of the glycerol molecule (44). The structure of some of these molecular species has been confirmed by fast atom bombardment mass spectrometry (45).

Polyenoic VLCFA were first reported in human brain in patients with the rare inherited disorder, Zellweger's syndrome (46,47). However, later studies demonstrated the presence of VLCFA with up to 38 carbon atoms and from 3–6 methylene-interrupted double bonds in normal young human brain (20,45). The longer chain fatty acids (30–38 carbon atoms) are largely, but not exclusively, tetra- and pentaenoic n-6 series acids, with 34:4n-6 and 34:5n-6 predominating. The polyenoic VLCFA are also components of rat brain. Although 24:4n-6 and 24:6n-3 are the major VLCFA in adult rat brain, there are significant amounts of 34:4n-6 and 36:4n-6 (48). However, there are marked changes in both the concentration and composition of the polyenoic VLCFA with development in rat and human brain. The content of these fatty acids declines with increasing age in the rat. Concomitantly, there is a marked reduction in the levels of pentaenoic VLCFA with age and an increase in the proportion of longer chain VLCFA. For example, 34:4n-6 and 34:5n-6 are the major longer chain polyenoic VLCFA in neonatal rat brain, and 36:4n-6 predominates in adult brain. A similar change with development is observed in human brain (20). Thus n-6 pentaenoic VLCFA predominate in the fetus and in neonates, while the n-6 series tetraenoic acids are major components in older children.

As in the retina, most of these fatty acids are found esterified to the *sn*-1-position of the glycerol moiety in phosphatidylcholine (2,20,45). However, brain differs from retina in that the fatty acids esterified to the *sn*-2 position include arachidonic, oleic and palmitoleic acids. These molecular species are similarly hydrophobic with up to 58 carbon atoms (excluding glycerol) and nine olefinic centers. Whereas the longer chain VLCFA (>32 carbon atoms) are concentrated al-

most exclusively in phosphatidylcholine, those with <32 carbon atoms are also found in the unesterified fatty acid and cholesterol ester fractions (49).

Trace amounts of 24 to 28 carbon tetraenoic n-6 fatty acids (<0.1%) have been reported in human neutrophils (50), and 24:4n-6 is present in human platelets (Robinson, B.S., Ferrante, A., and Poulos, A., unpublished data) and human plasma (51). Studies using labeled fatty acid precursors indicate that 24:4n-6, 24:5n-6, 24:5n-3 and 24:6n-3 are normal components of liver (52), retinoblastoma, fibroblasts (53,54) and cultured endothelial cells (55). It is likely that polyenoic VLCFA are normal components of most animal cells, but sensitive analytical procedures may be required to detect them in some tissues.

BIOSYNTHESIS

Saturated and monenoic VLCFA. Three different pathways are involved in the biosynthesis of saturated fatty acids; a soluble cytoplasmic system which generates fatty acids, mostly palmitic acid, from acetyl coenzyme A (CoA) *via* malonyl CoA, and mitochondrial and microsomal systems. The latter system also uses malonyl CoA as donor while mitochondrial fatty acid synthesis requires acetyl CoA (56,57). It is believed that the microsomal and mitochondrial elongation pathways generate fatty acids with carbon chain lengths >16. Early reports indicated that there were three microsomal pathways involving the elongation of palmitoyl CoA, stearoyl CoA and arachidoyl CoA (16:0, 18:0 and 20:0, respectively) in mouse brain (58), and this has received some recent support (59,60). Inhibitor studies indicate that different processes may be involved in the elongation of 20:0 CoA to 22:0 CoA, and 20:0 CoA to 24:0 CoA in pig neutrophils (60). One possible explanation for these findings is that there may be a specific enzyme system required for the generation of saturated VLCFA from 20:0.

Biosynthesis of monenoic VLCFA proceeds *via* the same elongation pathways except, of course, the precursor fatty acids are the corresponding monenoic rather than the saturated fatty acids (61–63). There is no evidence that monenoic VLCFA are formed by the desaturation of the corresponding saturated VLCFA (54,64). Monenoic fatty acids depress the synthesis of saturated VLCFA (63,65–67), possibly by competing with the saturates for the elongases. Active synthesis of fatty acids with up to 34 carbon atoms occurs even in tissue which contains small amounts of endogenous monenoic VLCFA, indicating that the longer chain fatty acids are probably formed in most tissues (15).

Polyenoic VLCFA. Synthesis of polyenoic VLCFA has been described in a number of different mammalian tissues using either radiolabeled polyenoic fatty acids or acetate as precursors. Labeled polyenoic VLCFA are formed from [^{14}C]acetate and [^{14}C]arachidonic acid, respectively, by isolated rat spermatocytes and spermatids (33,34). [1-^{14}C]-Arachidonic acid injected into rat testis was also elongated *in vivo* to form n-6 tetra- and pentaenoic VLCFA with up to 30 carbon atoms (35). The longer chain fatty acids are formed by the sequential two carbon elongation of polyenoic fatty acid precursors, probably in much the same way as shorter chain fatty acids are synthesized. Rosenthal and Hill (55) reported the synthesis of n-6 polyenoic VLCFA from 20:3n-6 in endothelial cells in culture. These authors observed that most of the synthesized polyenoic VLCFA were in the culture medium in which the cells had been grown. Penta- and hexaenoic n-3 VLCFA synthesis from [1-^{14}C]acetate has also been reported in bovine retina (68).

Labeled 24 carbon fatty acids are formed from [^{14}C]-22:5n-3 and 22:4n-6 by skin fibroblasts and retinoblastoma cells (53,69). Tetraenoic fatty acids with up to 28 carbon atoms are synthesized from 20:4 and 24:4 by rat seminal tubules, but 32:4 is not elongated (39). Labeled tetra- and pentaenoic VLCFA with up to 30 carbon atoms are also detected when [U-^{14}C]acetate is used as the label. Surprisingly, labeled odd-chain tetraenoic VLCFA (21, 23, 25 and 27 carbon compounds) are also formed from [U-^{14}C]acetate (39). It has been speculated that the odd-chain compounds are formed by the α-oxidation of the corresponding precursor even-chain fatty acid. Synthesis of polyenoic VLCFA has also been observed in isolated human neutrophils. The carbon chains of [1-^{14}C]20:4n-6 and 24:4n-6 are extended by up to four carbon atoms (50) by these cells, but there is no extension in the carbon chain length of a longer chain tetraenoic fatty acid (30:4).

Apart from elongation of the carbon chain, tetraenoic VLCFA are also desaturated to form the corresponding pentaenoic fatty acids. Indeed, it is now believed that the desaturation of 24 carbon polyenoic fatty acids plays a pivotal role in the synthesis of 22 carbon n-3 hexaenoic fatty acids (52). Thus, the synthesis of 22:6n-3 takes place *via* a 4-desaturase-independent process as follows: 22:5n-3 → 24:5n-3 → 24:6n-3 → 22:6n-3, involving a desaturation of a polyenoic VLCFA (24:5n-3) by 6-desaturase followed by a subsequent oxidative step to generate the 22 carbon hexaenoic fatty acid. Studies of Aveldano *et al.* (39) provide evidence that 22 carbon n-6 fatty acids are formed by a similar pathway, i.e., 22:4n-6 → 24:4n-6 → 24:5n-6 → 22:5n-6 in rat seminal tubules, and may also apply in other tissues. These authors observed a very rapid synthesis of 24:5n-6 from [1-^{14}C]-24:4n-6. A number of odd- and even-chain tetra- and pentaenoic fatty acids with up to 30 carbon atoms were detected in the incubation mixtures, probably formed by elongation of 24:4 and 24:5 and chain shortening of the products.

Because of the presence of n-6 hexanoic, and even heptaenoic, VLCFA in some tissues, some desaturation of polyunsaturated fatty acids with >24 carbon atoms may also occur (20,46). The 11,14,17,20[1-^{14}C]26:4 injected intracerebrally into rats was elongated to form VLCFA with up to 36 carbon atoms (70). However, significant amounts of label were detected in 26:5n-6 and 28:5n-6, indicating that desaturation of the 26 carbon fatty acid can take place in brain. While it is possible that the labeling of pentaenoic VLCFA reflected the β-oxidation of 26:4 and subsequent incorporation of released

acetate into fatty acids, this seems unlikely in view of the relatively low β-oxidation activity observed in these tissues. It was not clear from this report where in the fatty acid molecule the desaturation had occurred. If the product formed was 8,11,14,17,20[1-^{14}C]26:5 [and this was not confirmed, but seems likely in view of the fact that the unlabeled fatty acid is a normal component of human and rat brain (20,48)], the enzyme acting on the fatty acid had 8-desaturase activity. However, as the identity of the product was not unambiguously determined, the possibility that the double bond was introduced at some other site in the carbon chain by another desaturase cannot be discounted. More recent metabolic studies in neutrophils and seminal tubules using even longer chain polyenoic VLCFA (i.e., 30:4n-6 and 32:4n-6) indicate that these fatty acids are poor substrates for desaturases (39,50). It is likely, therefore, that the final desaturation step in the synthesis of n-6 hexaenoic VLCFA in tissues such as brain involves either a 26 or 28 carbon pentaenoic acid. The product is then elongated to give VLCFA with 30–38 carbon atoms.

DEGRADATION

Saturated and monenoic fatty acids. Saturated fatty acids with up to 22 carbon atoms are degraded in mitochondria and peroxisomes. The movement of fatty acids across the double membranes of mitochondria and into the matrix where the oxidative process takes place is determined by a complex series of reactions involving acyl CoA synthetases (ligases), carnitine acyltransferase 1 (CPT1), translocase and CPT2 (71,72). The first enzyme in this sequence, acyl CoA synthetase, is specific for fatty acids with less than 24 carbon atoms (73,74) and is membrane-bound (75). Acyl CoA synthetase activity toward shorter chain saturated fatty acids, such as palmitic and lauric acids, is present in peroxisomal membranes (76), indicating that conversion of the fatty acid to its thioester may be necessary for peroxisomal import. Although Miyazawa *et al.* (77) reported that the acyl CoA synthetase activities in peroxisomes and mitochondria are due to the same enzyme protein, doubts remain as to whether the two organelles share the same enzyme.

On the other hand, there is now clear evidence that rat liver peroxisomes and microsomes contain an acyl CoA synthetase activity which acts on saturated VLCFA (73,74). Whereas the microsomal activity plays an integral role in lipid biosynthesis, the peroxisomal activity is an essential component of the peroxisomal β-oxidation pathway. It is not clear at present whether this enzyme (VLCFA CoA synthetase) is specific for saturates or whether it is capable of acting on monenoic and polyenoic VLCFA. The inability of highly purified rat liver mitochondria to oxidize VLCFA is believed to be due to the absence of this enzyme from the organelle (73,74). However, isolated rat liver peroxisomes, which contain VLCFA CoA synthetase activity, efficiently oxidize lignoceric acid. Other studies carried out with human liver and fibroblasts indicate that the oxidation of saturated VLCFA occurs in peroxisomes in human tissues as well (78,79). However, Veerkamp and Moerkerk (80) and Reubsaet *et al.* (81) have produced some evidence for the mitochondrial oxidation of lignoceric acid by rat and human tissues. These data were generated using homogenates and measuring lignoceric acid oxidation in the presence and absence of mitochondrial inhibitors. One possible explanation for the inhibitory effect of rotenone and antimycin on the oxidation of lignoceric acid by the tissue homogenates used by this group is that the fatty acid was converted to its CoA thioester by the microsomal VLCFA CoA synthetase present in their preparations. In contrast to the free acid, VLCFA CoA is oxidized by peroxisomes and mitochondria of rat liver and human skin fibroblasts (78,82).

While the data for the peroxisomal localization of VLCFA oxidation in rat liver and human skin fibroblasts is convincing, the subcellular site of VLCFA oxidation in brain remains unclear. H. Singh *et al.* (83) observed lignoceric acid oxidation activity in two distinct subcellular fractions isolated from rat brain. Analysis of various enzymological markers in these fractions indicated that both mitochondria and peroxisomes were able to oxidize lignoceric acid. Moreover, the specific activity of VLCFA CoA synthetase was similar in both subcellular compartments. More recent reports by I. Singh's group (84,85) and by Lageweg *et al.* (86) have not confirmed these findings. The former have observed that mitochondria isolated from rat brain have much lower lignoceric acid oxidation and VLCFA CoA synthetase activities, while Lageweg *et al.* (86) found that inhibition of mitochondrial palmitoyltransferase activity had little effect on lignoceric acid oxidation. It has been suggested that the lignoceric acid oxidation observed by H. Singh *et al.* (83) in mitochondrial fractions was due to the presence of myelin in these fractions (85), and that VLCFA was oxidized by mitochondria after conversion to its thioester by myelin VLCFA CoA synthetase. It is worth noting, however, that despite the apparently negligible contamination of I. Singh's mitochondrial fractions with myelin, substantial amounts of lignoceric acid oxidation activity still remained in their mitochondrial fractions. Furthermore, their data were generated using young rats instead of the adult rats used by H. Singh *et al.* (83). The possibility that there are differences in mitochondrial lignoceric acid oxidation with development cannot be discounted.

While it is now generally accepted that there is a peroxisomal synthetase specific for saturated VLCFA, there is little information as to whether the other enzymes which take part in the peroxisomal oxidation of VLCFA, i.e., acyl CoA oxidase, the bifunctional protein, and 3-ketothiolase, have a broad substrate specificity and are capable of acting on shorter chain fatty acids as well as VLCFA, or whether there are separate enzymes capable of acting only on VLCFA (87–90). There is evidence for the existence of three separate enzymes with acyl CoA oxidase activities toward long-chain fatty acids, 2-methyl chain fatty acids, and bile acids in rat liver (91–93). Interestingly, the two oxidases which act on fatty acids are able to act on lignoceric acid (93,94). In contrast, it is believed that there are only two acyl CoA oxidases in human liver—one enzyme is specific for long-chain fatty

acids and the other for 2-methyl fatty acids and bile acids (92). Data obtained from patients with isolated defects in acyl CoA oxidase indicate that the human enzyme can handle both long-chain and VLCFA. The available evidence suggests that there is a single peroxisomal bifunctional protein in rat liver (95). It is generally believed that this enzyme has a broad substrate specificity toward fatty acids and is capable of acting on VLCFA. There are two genes for 3-ketothiolases in rat liver coding for separate enzyme proteins (96), but, as yet, there is no indication that there is a separate 3-ketothiolase for VLCFA. Recently, a novel acyl CoA dehydrogenase with some activity toward longer chain fatty acids has been isolated from rat liver mitochondria (90). Although the enzyme has been referred to as a very long chain acyl CoA dehydrogenase to distinguish it from other mitochondrial acyl CoA synthetases, it is most active toward 16 and 18 carbon fatty acids. While the enzyme appears capable of acting on lignoceroyl CoA, its activity toward this substrate is much less (about 10%) than that observed with palmitoyl CoA (90). Moreover, because isolated rat liver mitochondria are unable to oxidize lignoceric acid (73), the metabolic role of this dehydrogenase is unclear.

Topographical studies on the localization of the active site of peroxisomal VLCFA synthetase have produced conflicting results. I. Singh's group (97) has proposed that the active site of the enzyme is on the lumenal surface of peroxisomes, while Lageweg *et al.* (98) have claimed that the enzyme is on the cytoplasmic side. The localization of VLCFA CoA synthetase is of considerable importance because of its implications in VLCFA oxidation. Because the peroxisomal oxidation of fatty acids is not enhanced by the addition of carnitine (99), it is believed that carnitine acyl CoA transferases are not necessary for the uptake of fatty acids into the organelle. Carnitine octanoyl CoA transferase has been reported to occur in peroxisomes, but it is thought to be involved in the elimination of octanoyl CoA, a product of fatty acid oxidation, from peroxisomes (100). However, the finding that the active site for VLCFA CoA synthetase is located on the lumenal side of the peroxisomal membrane (97) indicates that some mechanism for uptake of the free VLCFA must exist. This hypothesis is further supported by a report that uptake of VLCFA into peroxisomes from human skin fibroblasts is much greater than the uptake of the corresponding thioester (101). Moreover, the oxidation of unesterified lignoceric acid by isolated rat liver peroxisomes is also much greater than the oxidation of lignoceroyl CoA (101). It is tempting to speculate that VLCFA entry into peroxisomes is regulated by a peroxisomal membrane factor, possibly after the binding of the fatty acid to a binding protein. Fatty acid binding proteins (FABP) have been found in many different tissues (102,103). Peroxisomal proliferators induce the expression of FABP in rat liver and intestine (104) as well as in cultured rat hepatocytes, and also induce an increase in peroxisomal oxidation (105,106). Although a number of FABP have been described, there is, as yet, no evidence for the occurrence of a FABP which is specific for VLCFA.

Recent studies by Aubourg's group (107,108) have led to the identification of a protein which is involved in the oxidation of VLCFA. This protein belongs to the ATP-binding cassette (ABC) transmembrane transporter superfamily (109) and may be necessary for normal uptake of VLCFA into peroxisomes. However, it is doubtful that the protein is involved in this process as adenosine triphosphate (ATP) is normally required for normal function of other ABC transporter proteins, but is not required for VLCFA uptake into peroxisomes (101). It would seem more likely that the protein may play a role in the transport of enzyme proteins which take part in VLCFA oxidation.

There have been few reports on the degradation of monoenoic VLCFA. Human skin fibroblasts oxidize erucic (110, 111), tricosenoic and tetracosenoic (22:1, 23:1 and 24:1, respectively) acids (61,112), a large part of this process probably occurring in peroxisomes (110).

Polyenoic VLCFA. The number of studies on the oxidation of polyenoic VLCFA has been limited. Street *et al.* (54) observed that [1-^{14}C]24:4n-6 was oxidized by human skin fibroblasts. A number of radioactive products were detected including carbon dioxide, various water-soluble products and short-chain fatty acids. It was proposed that the main product of oxidation was acetate which was either oxidized by mitochondria or entered the Krebs cycle. Some of the acetate produced also appeared to take part in the *de novo* synthesis of fatty acids. Because of the reduced oxidation activity of peroxisome-deficient cells, it was speculated that the oxidation took place in peroxisomes. However, more recent studies in our laboratory have demonstrated that peroxisome-deficient fibroblasts in suspension can oxidize 24:4n-6, but not 24:0, indicating that the oxidation of 24:4 can take place in either peroxisomes or mitochondria (Table 1). The most likely explanation for the differences between 24:0 and 24:4n-6 oxidation is that 24:4n-6 can be converted to 24:4n-6 CoA at the mitochondrial outer membrane and can therefore enter mitochondria to take part in β-oxidation. Preliminary experiments in our laboratory have confirmed that rat liver mitochondrial

[a]$^{14}CO_2$ produced from [1-^{14}C] fatty acids by suspensions of skin fibroblasts was measured as described by Street *et al.* (64). The assays were performed in duplicate, and the data in control cells are presented as mean ± standard deviation. The data for Zellweger syndrome are an average of two observations. The range of values are shown in parentheses.

outer membranes are able to convert 24:4 to its corresponding thioester, although the identity of the ligase catalyzing this reaction has not been characterized (Singh, H., Beckman, K., and Poulos, A., unpublished observations). There are a number of possibilities: (i) the enzyme is specific for polyenoic VLCFA (and not for the shorter chain polyenoic fatty acids) and therefore essential for the degradation of this class of fatty acids; (ii) the enzyme may be specific for all VLCFA including saturated and polyenoic derivatives (although this seems unlikely in view of our findings that 24:4, but not 24:0, is a substrate for mitochondrial acyl CoA synthetase; and (iii) 24:4n-6 is a substrate for arachidonoyl CoA synthetase, an enzyme which has been reported to be quite distinct from the one acting on saturated long-chain fatty acids (113) and which acts on other tetraenoic fatty acids. Mitochondrial outer membranes are able to convert 24:4 CoA to the carnitine ester of 24:4 (Singh, H., and Poulos, A., unpublished data). These data are strongly suggestive of a mitochondrial role in the oxidation of 24:4, although it is still not known whether the longer chain polyenoic VLCFA (>24 carbons) can also be oxidized in this organelle. A polyenoic VLCFA such as 24:4 can be oxidized in both mitochondria and peroxisomes, but as the carbon chain length of a fatty acid increases, the role of peroxisomes probably becomes more important.

Some studies have been carried out with polyenoic VLCFA with carbon chain length greater than 24. Robinson *et al.* (70) injected [1-^{14}C]26:4 intracerebrally into rats and observed the formation of small amounts (0.5–1.6% of the total recovered label) of water-soluble products, indicating that some oxidation of the substrate had occurred. 24:4n-6 and 32:4n-6 have also been shown to be oxidized to carbon dioxide and water-soluble products by rat seminal tubules (39). However, oxidation of exogenous 32:4n-6 is much slower than 24:4n-6, possibly because of the limited uptake of the former into cells (39; Poulos, A., Beckman, K., and Singh, H., unpublished observations using cultured skin fibroblasts). Because of this difference in uptake, it cannot be concluded that 32:4n-6 is less metabolically active than 24:4n-6. As determined by measuring carbon dioxide and water-soluble metabolite formation, the oxidation of 24:4n-6 is greater than the oxidation of the shorter chain tetraenoic acid, arachidonic acid (39). One possible explanation is that a greater proportion of the arachidonic acid than of 24:4n-6 is incorporated into cellular phospholipids (and much of this into phosphatidylinositol) which, presumably, leaves less arachidonic acid available as a substrate for catabolic processes. In contrast, most of the exogenous 24:4n-6 was incorporated into triacylglycerol rather than into phospholipids. The triacylglycerol-linked fatty acid may be more likely to take part in degradative processes than the phospholipid-bound fatty acid. The lower incorporation of the longer chain polyenoic VLCFA has also been observed in human neutrophils (50).

Polyenoic fatty acids with long and very long chains having an odd number of carbon atoms occur as endogenous components of reproductive tissue lipids (36,37,39). Labeling experiments using [U-^{14}C]acetate have demonstrated that rat seminal tubules are able to generate these peculiar VLCFA *in situ* (39). The metabolic origin of the odd-chain polyenoic VLCFA remains to be determined. It has been proposed that they may arise by the one carbon shortening of even carbon chain fatty acids, presumably by an α-oxidative process. Despite intensive study over the last thirty years, the mechanism of α-oxidation has not yet been elucidated (114–119). The possibility that the oxidation of some of the polyenoic VLCFA of a given tissue proceeds *via* α-oxidation is intriguing and worthy of further investigation.

Additional enzymes, such as Δ^3, Δ^2-enoyl-CoA isomerase and 2,4-dienoyl CoA reductase, are required for the breakdown of polyenoic fatty acids (120,121). The peroxisomal bifunctional protein has been shown to have trifunctional activity possessing Δ^3, Δ^2-enoyl isomerase, as well as 2-enoyl CoA hydratase and 3-hydroxyacyl CoA dehydratase activities (121). It is likely that the isomerase and reductase are also necessary for the oxidation of the corresponding polyenoic VLCFA.

THE INVOLVEMENT OF VERY LONG CHAIN FATTY ACIDS IN HUMAN DISEASE

Saturated VLCFA. Igarashi *et al.* (122,123) were the first to report on the apparent link between VLCFA and human disease. They observed the accumulation of saturated VLCFA in post-mortem tissues of patients with X-linked adrenoleukodystrophy (ALD), a rare neurodegenerative disorder affecting young males. Brain cholesterol esters and gangliosides, and adrenal cholesterol esters, were found to have large amounts of odd- and even-carbon chain length saturated VLCFA, in particular 25:0 and 26:0 fatty acids. These findings were later confirmed by other groups (124–126). These VLCFA are also present in many other ALD tissues or body fluids including plasma (14), muscle (127), cultured skin fibroblasts (128), cultured aminocytes (129), erythrocytes (23) and leukocytes (130). More recent investigations have revealed that the fatty acids which accumulate in brain are mixtures of saturated and monenoic derivatives with carbon chain lengths up to 34 (20,131), the monenoic fatty acids comprising both n-7 and n-9 derivatives. While the saturated VLCFA occur largely in cholesterol esters, the monenoic VLCFA are found mainly in molecular species of phosphatidylcholine which are partially separable by thin-layer chromatography from other molecular species of the phospholipid occurring in brain (20).

Because of the belief that the inflammatory response which leads to the extensive demyelination observed in ALD brain (132,237) is in some way related to the accumulation of saturated VLCFA, attempts have been made to correlate the pathological changes with VLCFA levels. Reinecke *et al.* (133) reported that the severity of the pathological changes in the different parts of the brain appeared to correlate with the saturated VLCFA levels in the cholesterol ester fraction, and speculated that the VLCFA changes preceded the inflammatory response. A similar study was conducted by Theda *et al.*

(131) who reported that there was an increase in the levels of VLCFA-containing glycerolipids, and particularly phosphatidylcholine (VLCFA–PC), in the actively demyelinating edge of the lesions and, apparently, in regions of the brain. They suggested that these molecular species of VLCFA–PC may be antigenic and could therefore provide a focus for an immunological attack of the brain (133).

The accumulation of VLCFA is paralleled by the reduced ability of ALD patients to oxidize VLCFA to acetate and carbon dioxide (82,134–137). The decrease in fatty acid oxidation appears to be related to a reduced activity of peroxisomal VLCFA CoA synthetase activity (138,139). More recently, the primary defect in ALD has been found to be in a gene coding for peroxisomal protein which belongs to the ABC superfamily of transporters (107,108). The relationship between the defect in a transporter protein and an abnormality in VLCFA oxidation has yet to be determined. As mentioned earlier, the protein may be involved in the transport of VLCFA into peroxisomes. Alternatively, it may be required either for the appropriate insertion of VLCFA CoA synthetase into peroxisome membranes, or to stabilize the synthetase once it has been inserted into the peroxisomal membrane. Using immunofluorescent techniques, it has been shown that the ALD protein is located in peroxisomes (Aubourg, P., private communication).

In addition to the impairment in VLCFA oxidation, ALD skin fibroblasts show an increase in fatty acid elongation activity (64,140–143). However, the biochemical basis for this remains unknown. It has been suggested that the increased elongation simply reflects the greater availability of VLCFA due to the impaired oxidation activity (64). These findings are consistent with a possible role of peroxisomes in the regulation of microsomal fatty acid elongation, but precisely how this regulation occurs is not known.

The presumed involvement of saturated VLCFA in the pathogenesis of ALD raised the possibility of treatment of the disease by restriction of the dietary intake of these fatty acids, particularly as it was shown that a significant proportion of the VLCFA which accumulates in ALD brain is of dietary origin (144). The use of a VLCFA-restricted diet (145) was unsuccessful in reducing the plasma levels of these fatty acids, and did not offer any clinical benefits (146). This suggested that considerable synthesis of saturated VLCFA, presumably by elongation of shorter chain fatty acid precursors, takes place in patient tissues. Oleic acid was later shown to inhibit the synthesis of saturated VLCFA in skin fibroblasts in culture, possibly by competing with the endogenous shorter chain saturated fatty acids for the microsomal elongases involved in fatty acid synthesis (66). However, oleic acid (as glycerol trioleate) was not totally effective in reducing plasma levels of saturated VLCFA (147,148). A much greater reduction in saturated VLCFA levels was achieved by supplementing the diet with glycerol trioleate and glycerol trierucate (glycerol esterified to erucic acid, 22:1n-9), the so-called "Lorenzo's Oil" (65,67,149), but the clinical benefits, at least for patients with neurological signs, do not appear to be very significant (150,151). Plasma and liver of ALD patients who have received dietary supplementation with "Lorenzo's Oil" show increased levels of erucic acid and its elongation products (24:1 and 26:1). However, while an early study indicated that erucic acid was able to cross into the brain (67), these findings have not been confirmed (152–154) and raise serious doubts as to the capacity of the diet to alter the VLCFA composition of the brain and thereby produce clinical benefits. Whether greater amounts of erucic acid would be able to cross into the brain in younger, neurologically-intact patients is under current investigation.

In the last few years a number of other peroxisomal disorders which are also characterized by accumulation of saturated VLCFA in plasma and cultured skin fibroblasts have also been described. These patients may be divided into those who have normal numbers of morphologically-normal peroxisomes, but who have an abnormality in any one of a number of peroxisomal enzymes involved in β-oxidation (group 1), and those whose tissues show a greatly reduced number and/or morphologically-abnormal peroxisomes (group 2). The former group includes X-linked ALD and also includes patients with acyl CoA oxidase, bifunctional protein and 3-ketothiolase deficiency states (155–159). The latter group includes patients with Zellweger's syndrome, the neonatal autosomal recessive form of ALD, infantile Refsum's disease and various other conditions (160–166).

Unsaturated VLCFA. Saturated VLCFA are increased in the plasma of group 1 and 2 patients, but the latter in particular also show elevations in monounsaturated VLCFA (136,167). These are mainly 25, 26 and 28 carbon fatty acids and are a mixture of the n-7 and n-9 series. Some patients with group 2 disorders, notably those with Zellweger's syndrome, also accumulate polyenoic VLCFA in plasma (51). Elevated amounts of 24:5n-6, 26:5n-6, 28:5n-6, 30:5n-6 and 30:6n-6 have been detected in the plasma of Zellweger's syndrome patients, and in the brain of this and other diseases of group 2 (20,46). These studies indicated that polyenoic VLCFA accumulate only in the plasma of patients with defects in peroxisomal assembly, and specifically in those individuals who have the clinical features of Zellweger's syndrome. However, somatic cell hybridization studies have demonstrated that there are at least eight different genes involved in peroxisomal assembly (168). Mutations in any one of these genes can affect peroxisomal assembly and cause disease. Zellweger's syndrome may result from an abnormality in any one of at least five of these genes. Recently, it has been shown that one of these genes codes for a 35 kDa peroxisomal integral membrane protein (238). The involvement of a gene coding for a 70 kDa protein, a member of the ATP-binding transporter family, in the most common complementation group, is not so clear-cut (239). Zellweger's syndrome patients may belong to the same complementation groups (i.e., have different abnormalities in the same gene) as other peroxisome-deficient patients (e.g., neonatal ALD and infantile Refsum's disease) whose clinical presentations are quite different. Plasma polyenoic VLCFA are not normally increased

in neonatal ALD and infantile Refsum's disease patients, although there is an increase in the levels of polyenoic VLCFA in the brain of these patients (20). It is not known why these fatty acids do not accumulate in non-Zellweger's syndrome plasma. One likely explanation is that the plasma polyenoic VLCFA levels are only increased in the most severely affected patients, a hypothesis which has received some support from ultrastructural studies showing the virtually complete absence of peroxisomes in the liver of many Zellweger's syndrome patients and some peroxisomal structures in non-Zellweger's syndrome patients (166). The difference may also be related to the fact that Zellweger's syndrome patients are generally diagnosed in the first few days or weeks of life, while, for other phenotypes, diagnosis may not be made until later in infancy (169–171).

Studies carried out on the brains of patients with peroxisomal assembly defects have demonstrated that the most pronounced change occurs in the hexaenoic VLCFA. These fatty acids are not detected in normal infant or adult brain, but occur in trace amounts in fetal brain (20). Hexaenoic VLCFA are also found in small amounts in the brains of very young rats (one-day-old), but, as in human brain, they are undetectable in older animals (48). The accumulation of the very long chain polyenes in peroxisomal disease may be, at least in part, a consequence of the reduced capacity of the brain to oxidize them.

The increased activity of microsomal fatty acid carbon chain elongation may also contribute to the accumulation of unsaturated VLCFA in group 2 patients. Radiolabeled monenoic VLCFA with up to 34 carbon atoms are formed from [2-^{14}C]acetate in greater amounts than those observed in control cell lines (15). They probably arise by elongation of shorter chain (monoenoic) fatty acids. While the synthesis of the monenoic VLCFA may have been increased because of the decreased β-oxidation activity, microsomal elongation activity is also increased in these cells (141).

The observation that the levels of polyenoic VLCFA are not greatly altered in X-linked ALD brain is surprising, particularly in view of the reported increased elongation activity in ALD tissue (141,143). As monenoic VLCFA are increased in ALD, it is probable that the increased elongation activity is specific for saturates and monounsaturates and does not act on polyunsaturates. This is consistent with the normal elongation of 24:4n-6 observed in ALD fibroblasts (64). One interpretation of these data is that a specific elongase (or elongases) take part in the biosynthesis of polyenoic VLCFA. The normal elongation of 24:4n-6 by ALD fibroblasts would tend to support this view.

FUNCTION

Little is really known about the possible function of VLCFA in animal tissues. However, while recent studies have not provided all, or even most, of the answers, they have been particularly useful in better defining the metabolic role of these lipids. These studies have, in turn, provided a firmer theoretical basis for speculation about function.

Structural role. A structural role for VLCFA was inferred many years ago with the recognition of the presence in very high abundance of saturated and monenoic VLCFA in the myelin sheath (6,172,173). It has been suggested that the VLCFA increase the stability of myelin (56). Similarly, a structural role has been suggested for the n-3 and n-6 polyenoic VLCFA (which are esterified to the *sn*-1 position of phosphatidylcholine) in the photoreceptor membranes of vertebrate retina (44). The importance of fatty acids such as docosahexaenoic acid in the maintenance of normal visual function has been established (174), but the role of the polyenoic VLCFA has not yet been studied. It has been proposed that the thermal behavior of the retinal rod inner outer segments reflects the asymmetric distribution of lipids in these membranes (175). Presumably the interaction of lipids with the various protein elements in membranes contributes to the properties of the membrane structures. Certainly, there is good evidence for the ability of lipids to influence the conformation of peptides (176). Because the molecular species of polyenoic VLCFA-containing phosphatidylcholine remains associated with rhodopsin even after repeated extraction with hexane, it has bene postulated that they may partially surround the α-helix of rhodopsin, thereby providing an environment necessary for normal function of the photoreceptor membranes (44). VLCFA are also highly concentrated in spermatozoa, only in that case they are bound to sphingomyelin. Experiments in our laboratory indicate that such sphingomyelins are distributed in the head, tail and midpiece, as well as in the lipoprotein coat in ram spermatozoa. As the sequential actions of sphingomyelinase and ceramidase are probably involved in the release of the VLCFA from sphingomyelin (177), and as the activity of ceramidase in comparison to other lysosomal enzymes is generally low in mammalian tissues (178,179), the turnover of sphingomyelin is probably slower than that of glycerophospholipids, which supports the idea of a structural role for VLCFA-containing sphingomyelins. However, recent reports of the distribution of polyenoic VLCFA in glycerolipids, and the identification of hydroxylated polyenoic VLCFA in rat spermatozoa (39), suggest that VLCFA may have multiple functions in spermatozoa.

Another possible structural role for VLCFA has been suggested from their presence in the lipids of meibomian glands, skin and hair of mammals. The meibomian glands are located within the eyelids of mammals, producing an oily secretion which forms a layer on the surface of the aqueous tear film and believed to contribute to its stability (180–182). The lipids in the secretions from the meibomian glands are thought to act as a barrier to the entry of skin surface lipids which could disrupt the tear film, prevent the spillover of the tear film, reduce evaporation, and may have some limited function as a lubricant (180). The VLCFA in the skin may also act as a barrier, although in this case it seems likely that they are involved in the prevention of transepidermal water loss (183). The unusual epidermal lipids, O-acylceramide and O-acylglucosyl ceramide, which contain linoleic acid moi-

eties esterified to the ω-hydroxyl groups of ω-hydroxyl monoenoic VLCFA, are thought to be necessary to ensure the maintenance of an adequate hydrophobic barrier to the movement of water (19,25). The importance of these lipids is suggested by the transepidermal loss of water in individuals who are essential fatty acid-deficient (184–185).

Metabolic role. A possible metabolic role, particularly for the 24 carbon n-6 tetraenoic and 24 carbon n-3 pentaenoic fatty acids, in biosynthesis of the important 22 carbon polyenoic fatty acids (52) (22:5n-6 and 22:6n-3) has been discussed earlier. It has also been demonstrated that the terminal two carbons of the saturated, and particularly the polyenoic VLCFA, once cleaved can be used for the cytoplasmic *de novo* synthesis of shorter chain fatty acids (54,64), although it is possible that some synthesis of fatty acids may occur in peroxisomes (186). As labeled amino acids may be formed from carboxy-labeled VLCFA (54,64), it is probable that acetate formed by β-oxidation enters the tricarboxylic acid (TCA) cycle where it is utilized for various biosynthetic processes. Acetate is also converted to acetoacetate in peroxisomes and utilized for the synthesis of sterols (187,188). In this context it is worth noting that both sterol carrier protein-2, which participates in cholesterol and bile acid biosynthesis (189,190), and 3-hydroxy-3-methylglutaryl CoA reductase (191), the key regulatory enzyme in cholesterol biosynthesis, are also present in peroxisomes. Presumably some of the acetate derived from the peroxisomal β-oxidation of fatty acids is transported in some form either to the cytosol where it takes part in fatty acid synthesis, or to the endoplasmic reticulum where it is used for carbon chain elongation of fatty acids, or into the mitochondria where it joins the TCA cycle. How this is done, and what determines where the released acetate is sent in the cell remains a mystery. The further issue of whether the acetate formed from VLCFA has some other, as yet unknown function, is not known. Certainly, a defect along the peroxisomal β-oxidation pathway affecting the metabolism of VLCFA appears to have devastating clinical effects on patients seemingly out of all proportion to the plasma levels of VLCFA (155,157). While it is plausible that the clinical effects relate to the toxicity of the VLCFA (192,149), the possibility that VLCFA β-oxidation has some other critical cellular function cannot be discounted. Cell lines which are deficient in peroxisomal β-oxidation also have disturbances in other parts of the cell. For example, the activities of microsomal fatty acid elongases are increased (141), and there may also be disturbances in desaturase activity (193,194). Moreover, there are morphological changes in mitochondria from some patients (160,195,196).

VLCFA can be precursors of other molecules such as alkanes (197), alcohols, or aldehydes. As yet, however, there is no indication that such products contribute to the pathology of peroxisomal disease. Because of the possibility that polyenoic VLCFA are converted into oxygenated metabolites in a manner similar to that observed for the shorter chain polyenoic fatty acids (198–200), and these oxygenated VLCFA may induce some of the pathological changes observed in peroxisomal disease, we have analyzed the products formed by incubating polyenoic VLCFA with different cells. Human neutrophils are able to convert 24:4n-6 into its 9-hydroxylated derivative in a reaction presumably catalyzed by 5-lipoxygenase (50,201), but cyclooxygenases do not act on this fatty acid. However, the longer carbon chain length VLCFA (e.g., 30:4n-6) are not substrates for neutrophil lipoxygenases. Our data indicate that 30 and 32 carbon tetraenoic fatty acids are poorly taken up into cells. They are mainly incorporated into diacylglycerol and triacylglycerols in fibroblasts (Poulos, A., Beckman, K., and Singh, H., unpublished data), neutrophils (50) and seminal tubules (39).

Signal transduction. The role of lipids in cellular signalling has received increasing attention since the important discoveries of Nishizuka (202) and Majerus *et al.* (203) in the mid-1980s. These workers reported the release of diacylglycerol and inositol phosphates in response to the binding of an agonist to its membrane receptor and the subsequent activation of phospholipase C. Diacylglycerol and inositol phosphates act as second messengers, activating protein kinase C and releasing intracellular stores of calcium, respectively. In the last few years it has become apparent that agonist-induced hydrolysis of phosphatidylcholine (204–206) and phosphatidylethanolamine (207–209) also occur. It has also become clear that agonists may induce the release of phosphatidic acid *via* the activation of phospholipase D. Phosphatidic acid is believed to produce its effect after conversion to diacylglycerol by phosphatidic acid phosphohydrolase (210–212) or lysophosphatidic acid (213), or it may be active in its own right (214). In addition to the involvement of the glycerophospholipids, it has become apparent that sphingolipids also play a role in cellular signalling (215). The binding of an agonist such as tumor necrosis factor α (TNFα) to its membrane induces the hydrolysis of sphingomyelin and the concomitant release of ceramide, an important second messenger of the sphingolipid cycle (216–218). Ceramide induces its effect *via* its action on ceramide-activated protein phosphatase (219,220) or protein kinase (221). Other sphingolipids, including ceramide-1-phosphate, sphingosine-1-phosphate and sphingosine itself, also take part in cellular signalling processes (215). As phospholipases A_2, C and D, and sphingomyelinase have all been reported to be activated in response to the binding of various agonists to membrane receptors (202,210,215,222), it is likely that VLCFA-containing second messenger lipids may be formed, particularly in cells (such as those of brain, retina and testis) which are rich in VLCFA. As yet it is not known whether any of the above cellular signalling processes can be influenced by the introduction of VLCFA ester or amide functions into the various lipid second messenger molecules. However, fatty acid structure can also influence the diacylglycerol and phosphatidylcholine-induced *in vitro* activation of protein kinase C (223), and lipid structure is also an important factor in the ability of protein kinase C to bind to lipid vesicles (224). If unique molecular species of lipid second messengers are indeed formed, it remains to be determined whether they play a role in signal transduction.

Unesterified fatty acids have also been shown to have potent physiological effects on cells. For example, the n-6 and n-3 polyunsaturated fatty acids such as arachidonic acid and docosahexaenoic acid activate certain cellular functions such as the oxygen-dependent respiratory burst in neutrophils (225–227) and macrophages (228), leukocyte chemotaxis (229), and neutrophil adhesion (230) by mechanisms which are not believed to involve eicosanoids. These effects indicate that fatty acids are able to modulate cellular signalling processes, and, indeed, they have been considered to be potential second messengers (231), but their mechanisms of action are not understood. The n-3 and n-6 polyenoic VLCFA, but not the corresponding saturates and monounsaturates, are able to activate the neutrophil respiratory burst (226,232), their activity declining with increasing carbon chain length. Although they appear to be less active than the shorter chain analogues, this may simply reflect their slower cellular uptake (39,50,232). It is unlikely that these effects are mediated by hydroxylated products because the longer carbon chain fatty acids (30 and 32 carbon fatty acids) are active although they are not substrates for neutrophil lipoxygenases and cyclooxygenases (50). We have recently observed that 30 carbon polyenoic fatty acids are able to induce calcium mobilization in isolated human neutrophils (Hardy, S.J., Robinson, B.S., Ferrante, A., Johnson, D.W., Poulos, A., and Murray, A.W., unpublished observations). As the 30 to 34 carbon polyenoic fatty acids are also very effective *in vitro* activators of protein kinase C, it is tempting to speculate that they may be involved in modulating the activity of this important regulatory enzyme (233).

CONCLUSIONS

The recognition of the involvement of VLCFA in human disease has prompted a renewed interest in this class of fatty acids. The inference to be drawn from the clinical observations is that VCLFA are important cellular components and that disturbances in their metabolism can have devastating consequences. Future studies of these intriguing lipids are likely to be fruitful in a number of different areas. Two of the most interesting questions concern the involvement of VLCFA in the neuropathology of peroxisomal disease and, in particular, in the severe demyelination which is a characteristic feature of X-linked ALD, and the role of the ALD protein in VLCFA oxidation. Other questions which will be addressed relate to the existence of enzymes and binding proteins which are specific for VLCFA. Thus far, there is evidence for the existence of at least one enzyme which is specific for VLCFA, e.g., VLCFA CoA synthetase, but it is probably that other enzymes will be identified in the future. The relationship between the mitochondrial and peroxisomal roles in the oxidation of VLCFA, and the precise mechanisms by which the products of these oxidative processes are channeled to the endoplasmic reticulum, presumably for use in biosynthetic processes, will also be explored. Finally, the exciting discoveries in signal transduction in the last few years have raised the possibility that the VLCFA, or VLCFA-containing lipids, have a role as messenger lipids. The development of greatly improved methods for the solubilization of VLCFA (234), and the availability of unlabeled and radiolabeled VLCFA (235,236), will provide a stimulus for these future investigations.

ARTICLE

Trans Fatty Acid Isomers in Canadian Human Milk

Z.-Y. Chen*, G. Pelletier, R. Hollywood and W.M.N. Ratnayake

Nutrition Research Division, Food Directorate, Health Protection Branch, Health Canada, Ottawa, Ontario, K1A 0L2 Canada

ABSTRACT: The fatty acid composition, total *trans* content (i.e., sum of all the fatty acids which may have one or more *trans* double bonds) and geometric and positional isomer distribution of unsaturated fatty acids of 198 human milk samples collected in 1992 from nine provinces of Canada were determined using a combination of capillary gas–liquid chromatography and silver nitrate thin-layer chromatography. The mean total *trans* fatty acid content was 7.19 ± 3.03% of the total milk fatty acids and ranged from 0.10 to 17.15%. Twenty-five of the 198 samples contained more than 10% total *trans* fatty acids, and thirteen samples contained less than 4%. Total *trans* isomers of linoleic acid were 0.89% of the total milk fatty acids with 18:2Δ9*c*,13*t* being the most prevalent isomer, followed by 18:2Δ9*c*,12*t* and 18:2Δ9*t*,12*c*. Using the total *trans* values in human milk determined in the present study, the intake of total *trans* fatty acids from various dietary sources by Canadian lactating women was estimated to be 10.6 ± 3.7 g/person/d, and in some individuals, the intake could be as high as 20.3 g/d. The 18:1 *trans* isomer distribution differed from that of cow's milk fat but was remarkably similar to that in partially hydrogenated soybean and canola oils, suggesting that partially hydrogenated vegetable oils are the major source of these *trans* fatty acids. *Lipids 30,* 15–21 (1995).

Partially hydrogenated fats contain an assortment of geometric and positional isomers of unsaturated fatty acids, of which the *trans* isomers have been reported to raise serum low-density lipoprotein cholesterol (1,2) and lower high-density lipoprotein cholesterol (1). Recent epidemiological and clinical studies have suggested that intake of *trans* fatty acids may be a risk factor in cardiovascular disease (3,4). Some other reports, however, have indicated no such health risk associated with *trans* fatty acids (5,6). *Trans* fatty acids may also interfere with biosynthesis of long-chain polyunsaturated fatty acids during development (7–10). In essential fatty acid deficiency, some of the isomeric fatty acids, particularly the mono-*trans* geometrical isomers of linoleic acid (18:2n-6), are desaturated and elongated to produce unusual longer chain polyunsaturated fatty acid metabolites in rodents (10–12). The major *trans* isomer of 18:2n-6 in partially hydrogenated vegetable oils is 18:2Δ9*c*,13*t* (13,14). Recently, we have shown that 18:2Δ9*c*,13*t* and three other isomeric fatty acids in partially hydrogenated vegetable oils, *viz.*, 18:Δ12*c*, 18:2Δ9*c*,12*t* and 18:2Δ9*t*,12*c*, are metabolized to unusual C_{20} polyunsaturated fatty acid isomers even under sufficient intake of 18:2n-6 (1.46% energy; Ref. 15). *Trans* fatty acids have been reported to occur in human milk (16–19). Distribution of *trans* and *cis* isomers has been determined in human tissues (20), but similar data are not yet available for human milk. These *trans* isomers must be of dietary origin, because they cannot be synthesized by mammals. Dietary *trans* fatty acids have also been shown to depress the milk fat content in mice regardless of total fat intake or the dietary level of 18:2n-6 (21,22), but not in swine (23).

To determine the relative contribution of *trans* fatty acid isomers from dietary sources, the present study compared the isomer distribution profile in human milk fat with that in partially hydrogenated vegetable oils and also that in cow's milk. We also sought to ascertain whether dietary *trans* fatty acids inhibit human milk fat production. This was done by correlating the milk fat content with total milk *trans* fatty acid content, which is defined as the sum of all the fatty acids with one or more double *trans* double bonds. Furthermore, *trans* fatty acid consumption of Canadian lactating women was estimated based on the *trans* fatty acid content in their milk.

MATERIALS AND METHODS

Materials. The human milk samples used in this study were from the 1992 collection of Health Protection Branch's ongoing monitoring program of chlorinated hydrocarbon contaminants in the breast milk of Canadian women (unpublished work of Dr. W.H. Newsome, Health Protection Branch, Ottawa, Canada). Samples of "mature milk" (3 to 4 wk after parturition) were collected from donors from nine provinces of Canada (20–25 samples/province) who had resided in Canada for at least 5 yr. Donors were requested to express their milk manually several times during each feeding, alternating between right and left breast. The sample from each donor thus represented the accumulated milk collection of one day. A total of 198 samples was collected in residue-free bottles shipped and stored as reported earlier (24).

Twelve basestocks. Partially hydrogenated canola (PHCO) and soybean (PHSO) basestocks with different contents of *trans* fatty acids and iodine values were supplied by CanAmera Foods, Inc. (Toronto, Ontario, Canada), which is one of the largest edible oil processors. It also supplies their basestocks to most of the major food chains in Canada. We therefore believe that the basestocks analyzed are representative of what are in the Canadian market. Homogenized cow's milk was purchased locally.

Milk lipid extraction. Milk samples were thawed at room temperature (25°C). Fat from a 5 g sample was extracted using 25 vol of $CHCl_3$/MeOH (2:1, vol/vol) containing 0.02% butylated hydroxytoluene (Sigma Chemicals, St. Louis, MO) as an antioxidant and triheptadecanoin (1 mg/mL; Sigma Chemicals) as an internal standard to quantitate total milk fat (25). Another 5 g sample was extracted with the same solvent system but without addition of triheptadecanoin to determine the content of endogenous heptadecanoic acid in milk. Cow's milk fat was similarly extracted.

Fatty acid analysis. The extracted lipids were converted to fatty acid methyl esters (FAME) using 14% BF_3/MeOH reagent (Sigma Chemicals) at 90°C for 50 min under nitrogen. FAME were analyzed by gas–liquid chromatography (GLC) using an SP-2560 flexible fused silica capillary column (100 m × 0.25 mm i.d., 20 μm film thickness; Supelco, Inc. Bellefonte, PA) in a Hewlett-Packard 5890 series II gas chromatograph equipped with a flame-ionization detector (Palo Alto, CA). Column temperature was programmed from 150 to 180°C at a rate of 0.5°C/min, and then to 210°C at a rate of 3°C/min. Injector and detector temperatures were 250 and 300°C, respectively. Hydrogen was used as the carrier gas at a head pressure of 20 psi.

The gas chromatographic trace of the FAME profile of human milk is shown in Figure 1. Single step, direct GLC cannot determine the total 18:1 *trans* due to overlap of high delta 18:1 *trans* isomers (18:1Δ12*t* to 18:1Δ16*t*) with 18:1 *cis* isomer peaks (26). We found that an average of 20.8% of total 18:1 *trans* were actually overlapped with 18:1 *cis* fraction. The extent of overlap primarily was dependent on the total *trans* content and ranged from 9–30%. The higher the total 18:1 *trans*, the greater the overlap. Therefore, the total 18:1 *trans* and total 18:1 *cis* contents in the milk samples were de-

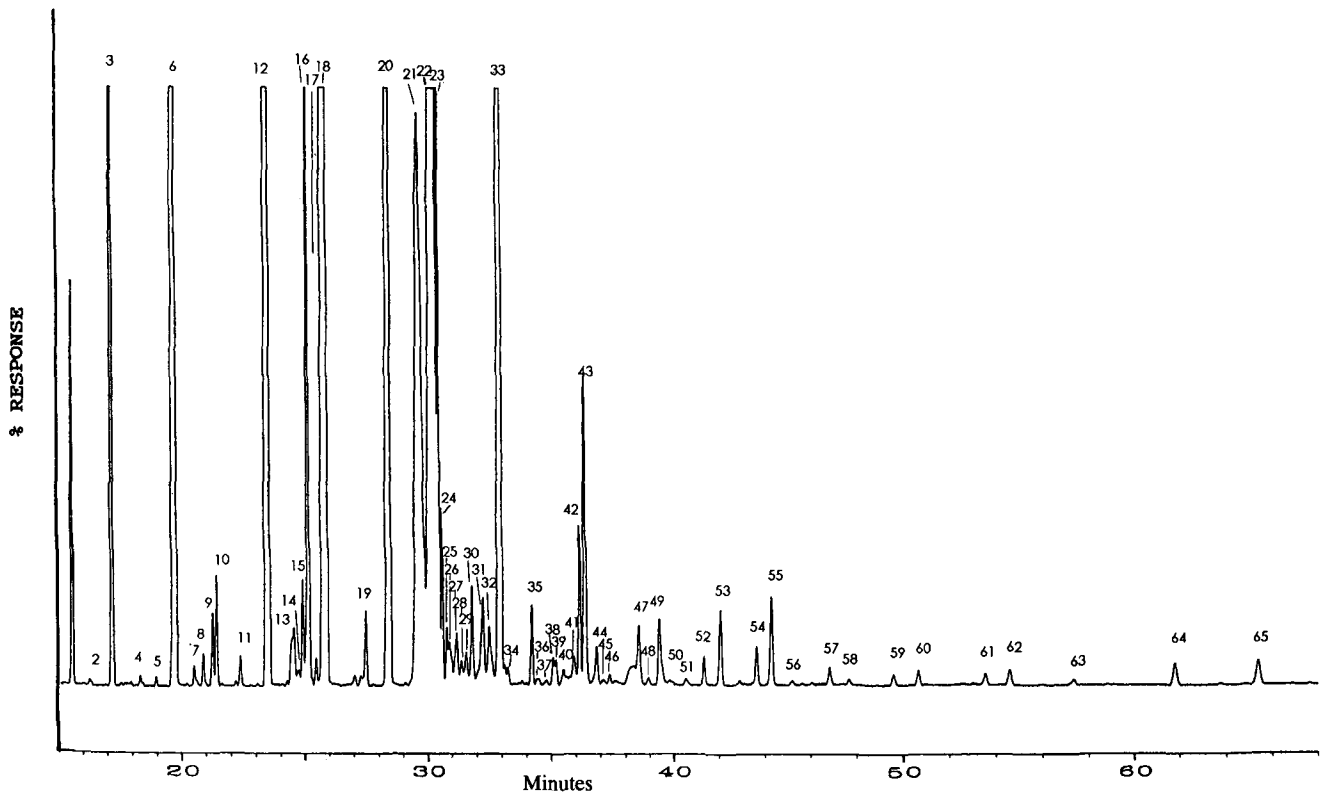

FIG. 1. A typical chromatogram of the C_{10} to C_{22} region of fatty acid methyl esters from a sample of Canadian human milk total lipids on an SP-2560 capillary column (100 m × 0.25 mm). Peaks were identified as: 1, 10:0; 2, 11:0; 3, 12:0; 4, 13:0; 5, 14:0 *br*; 6, 14:0; 7, 14:1Δ9*t*; 8, 14:1Δ7*c*; 9, 14:1Δ9*c*; 10, 15:0; 11, 16:0 *br* + 15:1 ?; 12, 16:0; 13, 16:1Δ7*t*; 14, 16:1Δ9t; 15, 16:1Δ7*c*; 16, 16:1Δ9*c*; 17, unknown; 18, 17:0 (internal standard); 19, 17:1Δ10*c*; 20, 18:0; 21, 18:1(Δ7–Δ11)*t*; 22, 18:1(Δ7–Δ10)*c* + 18:1(Δ12–Δ15)*t*; 23, 18:1Δ11*c*; 24, 18:1Δ12*c*; 25, 18:1Δ13*c*; 26, 18:2*tt*; 27, 18:1Δ14*c* + 18:1Δ16*t*; 28, 18:1Δ15*c*; 29, 18:1Δ16*c* + 18:2Δ9*t*,12*t*; 30, 18:2Δ9*c*,13*t* + 18:2Δ8*t*,12*c*; 31, 18:2Δ9*c*,12*t*; 32, 18:2Δ9*t*,12*c*; 33, 18:2n-6; 34, 18:2Δ9*c*,15*c*; 35, 20:0; 36, unknown; 37, unknown; 38, 18:3n-6; 39 + 40 + 41, 18:3*t*; 42, 20:1Δ11*c*; 43, 18:3n-3; 44, 20:1Δ13*c*; 45+46, 18:2 conjugates; 47, 20:2Δ8*c*,14*c*; 48, 18:2 conjugate; 49, 20:2n-6; 50, 18:2 conjugate; 51, 20:3Δ5*c*,8*c*,11*c*; 52, 20:3Δ5*c*,11*c*,14*c*; 53, 20:3n-6; 54, 22:1Δ13*c*; 55, 20:4n-6; 56, 20:4n-3; 57, unknown; 58, unknown; 59, 20:5n-3; 60, 24:0; 61, 24:1*c*; 62, 22:4n-6; 63, 22:5n-6; 64, 22:5n-3; 65, 22:6n-3.

termined using silver nitrate thin-layer chromatography ($AgNO_3$–TLC) in conjunction with capillary GLC (26). Preparative $AgNO_3$–TLC plates were prepared as described previously (26). FAME (~15 mg) were applied to the plates in hexane solution using a TLC streaker (Applied Science Laboratories, State College, PA). The plates were developed in toluene at –20°C for 3 h. The separated bands were visualized under ultraviolet light (254 nm) after spraying with 0.2% dichlorofluorescein in ethanol. The 18:1 *trans* band was scraped off the plate and extracted with hexane/$CHCl_3$ (1:1, vol/vol). After drying under nitrogen, the 18:1 *trans* fraction was redissolved in hexane, and analyzed by GLC using an SP-2560 capillary column. The proportion of 18:1 *trans* isomers (the high delta value *trans* isomers) that overlapped with the 18:1 *cis* isomer peaks were calculated by comparing the 18:1 region of the GLC chromatogram of the isolated 18:1 *trans* fraction with that of the parent FAME mixture prior to $AgNO_3$–TLC fractionation. For this purpose, the 18:1 *trans* isomer peaks (18:1Δ7*t* to 18:1Δ11*t*) that were well separated from the *cis* peaks served as the internal standard. The total 18:1 *trans* content was then calculated, by summing up the proportions of the 18:1 *trans* isomers (18:1Δ12*t* to 18:1Δ16*t*) that overlapped with the *cis* isomers and the well separated 18:1 *trans* isomers.

The distribution of 18:1 *trans* and *cis* isomers isolated by $AgNO_3$–TLC was determined by BF_3/MeOH oxidative ozonolysis (27). Ozone was generated in a Model T-408 Polymetrics Laboratory Ozonator (Polymetrics, Inc., San Jose, CA). Calculation of individual monounsaturated isomers was based on the proportion of the corresponding dimethyl ester products. The dimethyl esters were identified according to Ratnayake and Pelletier (14).

The geometric and positional isomers of 18:2n-6 in human milk were identified and determined as described previously (14).

Statistics. Data were expressed as mean ± standard deviation. Analysis of variance followed by Student's *t*-test (two-tailed) where applicable was used for statistical evaluation of significant difference between groups.

RESULTS

The fatty acid data of Canadian breast milk are given in Tables 1 and 2. The mean fat content of the samples, calculated using triheptadecanoin as the internal standard (25), was 31.6 ± 9.4 g/L. A correlation between the fat content and percentage of total *trans* fatty acids was not observed; however, 18:2n-6 and α-linolenic acid (18:3n-3) were inversely related to the total *trans* fatty acids and 18:1 *trans* isomers (Fig. 2). In addition, total 18:1 *trans* isomers were positively correlated to stearic acid (18:0; $P < 0.01$) but it was negatively correlated with oleic acid (18:1n-9; $P < 0.05$; data not shown). The saturated fatty acids comprised 38.5% total milk fatty acids, approximately half of which was palmitic acid (16:0). The second major group was n-9 monounsaturated fatty acids, of which oleic acid (18:1Δ9) contributed the most (30.7%); 18:2n-6 varied

TABLE 2
Total Content (g/L) and Fatty Acid Composition (wt% of total fatty acids) of Canadian Human Milk Determined by Ag–TLC Plus GC[a]

Fatty acid class	% of total fatty acids
Total saturated fatty acids	38.50 (2.94)
Total C_{10}–C_{13} saturated fatty acids	7.11 (2.53)
Total C_{14-16} saturated fatty acids	24.77 (3.26)
Total n-6 fatty acids	11.39 (3.18)
Total n-3 fatty acids	1.49 (0.44)
Total n-6 long-chain fatty acids	0.83 (0.28)
Total n-3 long-chain fatty acids	0.33 (0.24)
Total *trans* fatty acids	7.19 (3.03)
Total 18:1 *trans* fatty acids	5.87 (2.52)
Total 18:1 *cis* other than 18:1n-9	4.22 (0.96)
Total milk fat (g/L)	31.58 (9.37)

[a]Data are mean (SD); n = 198. Abbreviations as in Table 1.

from 5.8 to 21.4% with an average value of 10.5%; 18:3n-3 accounted for 1.2% total milk fatty acids with a range of 0.6 to 1.9%. The longer-chain products of 18:2n-6 and 18:3n-3 represented 0.8 and 0.3% of total fatty acids, respectively. A correlation between both 18:2n-6 and 18:3n-3 and their corresponding long-chain metabolites was not observed.

Trans fatty acids were found in all the samples and ranged from 0.1 to 17.2% with a mean of 7.2 ± 3.0%. Twenty-five out of the 198 samples contained more than 10% total *trans* fatty acids. Furthermore, more than 15% *trans* fatty acids was found in 2% of the samples.

As expected, 18:1 *trans* was the major *trans* isomer group. It ranged from 0.1 to 15.4% of total fatty acids with a mean value of 5.9%. The average 18:1 *trans* isomer distribution is illustrated in Figure 3. In addition, the average 18:1 *trans* isomer distributions for PHSO, PHCO and cow's milk fat are also presented in Figure 3 for comparison. In the human milk samples analyzed, the most prevalent isomer was Δ11*t*, followed by Δ10*t*, Δ9*t*, Δ12*t* and Δ13*t* in a decreasing order. The 18:1 *trans* isomer distribution closely resembled that of PHSO, and to a lesser extent to the pattern in PHCO, but differed from that of cow's milk fat. In contrast to human milk fat and partially hydrogenated vegetable oils, cow's milk fat was characterized by having as much as 43% of total 18:1 *trans* isomers represented by 18:1Δ11*t* and low proportions of other isomers.

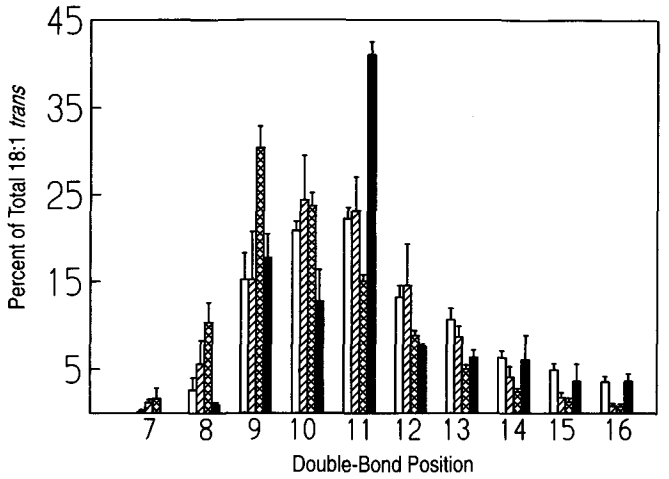

FIG. 3. Distribution of individual 18:1 *trans* isomer in human milk lipids (open bar, n = 198), partially hydrogenated soybean oil (hatched bar, n = 6), partially hydrogenated canola oil (cross-hatched bar, n = 6) and in cow's milk fat (solid bar, n = 6). Data are mean ± standard deviation. Total 18:1 *trans* isomers (wt% of total fatty acids) were 5.87% in human milk, 31.17% in partially hydrogenated soybean, 32.51% in partially hydrogenated canola oil and 2.10% in cow's milk fat.

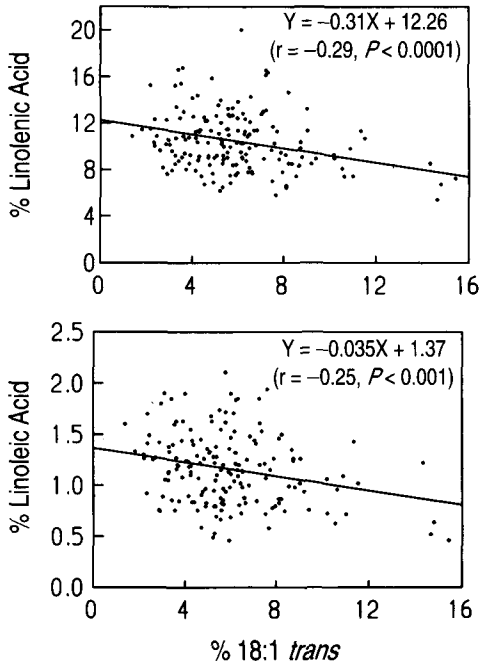

FIG. 2. Correlation of percent 18:2n-6 and percent 18:3n-3 with percent 18:1 *trans* in human milk lipids (n = 198).

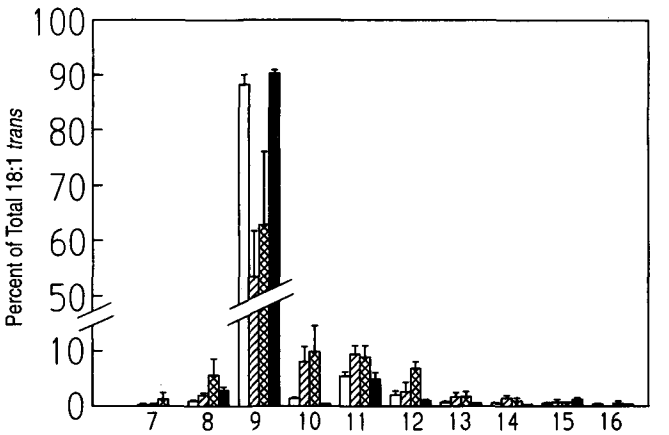

FIG. 4. Distribution of individual 18:1 *cis* isomer in human milk lipids (open bar, n = 198), in partially hydrogenated soybean oil (hatched bar, n = 6), in partially hydrogenated canola oil (cross-hatched bar, n = 6) and in cow's milk fat (solid bar, n = 6). Data are mean ± standard deviation. Total 18:1 *cis* isomers (wt% of total fatty acids) were 36.88% in human milk, 38.04% in partially hydrogenated soybean, 44.19% in partially hydrogenated canola oil and 22.91% in cow's milk fat.

TABLE 3
Fatty Acid Composition (wt%) of High *Trans* Milk, Low *Trans* Milk and Medium *Trans* Milk Determined by Ag–TLC Plus GC[a]

Fatty acid	High *trans* (n = 25)	Medium *trans* (n = 155)	Low *trans* (n = 18)
18:2n-6	9.12 ± 1.96[a]	10.50 ± 2.51[a,b]	11.70 ± 2.51[b]
18:3n-3	0.97 ± 0.27[a]	1.19 ± 0.36[a,b]	1.28 ± 0.32[b]
18:1*t*	10.35 ± 2.21[a]	5.42 ± 1.32[b]	2.64 ± 1.18[c]
18:1Δ9*c*	29.41 ± 3.47	30.75 ± 3.66	30.52 ± 3.59
Total other 18:1*c*	3.93 ± 0.46	4.24 ± 0.49	4.08 ± 0.48
18:2Δ9*c*,13*t*/8*t*,12*c*	0.51 ± 0.14[a]	0.36 ± 0.13[a]	0.13 ± 0.11[b]
18:2Δ9*c*,12*t*	0.42 ± 0.15[a]	0.28 ± 0.13[a]	0.12 ± 0.11[b]
18:2Δ9*t*,12*c*	0.37 ± 0.11[a]	0.24 ± 0.12[a]	0.07 ± 0.07[b]
20:4n-6	0.33 ± 0.06	0.35 ± 0.13	0.36 ± 0.12
22:6n-3	0.13 ± 0.06	0.14 ± 0.12	0.16 ± 0.07
Total *trans*	12.40 ± 2.41[a]	6.92 ± 1.50[b]	3.10 ± 0.97[c]

[a]Data are mean ± SD. Means in the same row with different superscripts (a, b, c) differ, $P < 0.01$. Total other 18:1*c* is the sum of 18:1 *cis* isomers excluding 18:1Δ9*c*. Abbreviations as in Table 1.

The distribution patterns of 18:1 *cis* isomers in human milk fat, partially hydrogenated vegetable oil and cow's milk fat were not comparable (Fig. 4). In human milk, the total 18:1 *cis* isomer group was largely oleic acid (Δ9*c*; 88.2%), followed by *cis*-vaccenic acid (Δ11*c*; 5.5%) with a small amount of other isomers ranging from Δ8 to Δ16. This is in contrast to PHSO and PHCO, where 18:1Δ9*c* accounted for 54–63% of total 18:1 *cis* isomers followed by Δ12*c* (7–18%), Δ11*c* (8–9%) and Δ10*c* (7–8%). In cow's milk, the Δ9*c* isomer represented 90% of the total 18:1 *cis* isomers with Δ11*c* and Δ8*c* being less than 5 and 3%, respectively (Fig. 4).

Trans isomers of 18:2n-6 amounted to 0.9% of total milk fatty acids (Table 1). This group primarily was composed of four isomers, 18:2Δ9*c*,13*t*/8*t*,12*t* (0.4%), 18:2Δ9*c*,12*t* (0.3%) and 18:2Δ9*t*,12*c* (0.2%). In the partially hydrogenated vegetable oils analyzed in the present study, these isomers accounted for 2.0, 1.1 and 1.0% of total fatty acids, respectively. The 18:2Δ9*c*,13*t* and 18:2Δ8*t*,12*c* are not separable by GLC or silver TLC, and hence are listed together (Tables 1 and 3). Of these two isomers, however, 18:1Δ9*c*,13*t* is the major one in PHSO and PHCO; and 18:2Δ8*t*,12*c* normally presents at extremely low level (14).

DISCUSSION

Significant regional differences in the average fatty acid composition data of Canadian human milk samples were not observed in this study (data not shown). However, within this population there were wide variations in the content of *trans* fatty acid in breast milk. Thus, we have reclassified the human milk samples into three categories (Table 3) according to the content of *trans* fatty acids; high-*trans* milk (HTM) for samples containing >10% *trans*, medium-*trans* milk (MTM) for samples containing ≥4% but ≤10% *trans*, and low-*trans* milk (LTM) for samples containing <4% *trans*. The high content of *trans* fatty acids in HTM was associated with lower levels of 18:2n-6 and 18:3n-3 than in MTM and LTM (Fig. 2; Table 3).

The total number of HTM accounted for 12% of total samples analyzed, and MTM accounted for 78%. This may indicate that the diet of a very large (~90%) segment of Canadian lactating women contains moderate to high levels of *trans* fatty acids. The fatty acid composition of milk from lactating women reflects to a certain extent the fatty acid composition of diets from previous days. This is particularly applicable to 18:1 *trans* fatty acids which fluctuate in human milk lipids according to their amount in the diet (18,28). Craig-Schmidt *et al.* (28) have reported a linear correlation between 18:1 *trans* in milk and in the diet among eight lactating women consuming different levels of partially hydrogenated fats. Using their linear equation, $Y = 1.49 + 0.42X$ [where Y and X represent the percentage 18:1 *trans* in total milk fat and dietary fat, respectively (28)], total *trans* intake can be estimated provided total *trans* fatty acids in diet and milk have similar relationship as 18:1 *trans*. Application of this equation indicates that HTM lactating women consumed diets in which 26.0% of fat was *trans* fatty acids. Thus, the total *trans* fatty acid intake for HTM women, ingesting a total energy of 2350 kcal in which 30% of the energy is derived from fat (29), could be estimated to be 7.7% of the total dietary energy or 20.3 g/person/d. Similarly, total *trans* fatty acid intake for MTM women could be estimated to be 3.9% total energy or 10.1 g/person/d, whereas total *trans* intake for LTM lactating women could be 1.1% total energy or 3.0 g/person/d. If the calculation is based on the mean *trans* fatty acid content (7.2%) for all the 198 human milk samples, then the mean total *trans* fatty acid intake for Canadian lactating women could be estimated to be 4.0% total energy or 10.6 g/person/d. This value is 16.5% higher than the value of 9.1 g/person/d estimated for the Canadian general population in 1981 (30). From data reported in four studies involving up to 57 breast milk samples (16,18,31,32), a mean value of 4.5 g/person/d can be deduced for lactating women in the United States. A similar *trans* fatty acid consumption has been estimated for British women (33). Thus, these data may suggest that Canadian women are consuming more *trans* fatty acids than are women in the United States or Britain. However, the estimated *trans* intake for women in the United States is far below the recent estimates of 12.5–15.2 g (34) or 8.1 g/person/d (35,36) for the general United States population.

In the present study a correlation between total *trans* fatty acids and total milk fat content was not found, which may indicate that dietary *trans* fatty acids do not suppress milk fat production in humans. This suggestion is consistent with the findings of Jensen *et al.* (37) for United States women. These findings with humans are also consistent with those in a laboratory study of ours in which partially hydrogenated canola oil did not suppress percent fat in lactating rats (Chen and Ratnayake, unpublished data). Similar observation was found in swine (23). Contrary to these findings, suppression of milk fat percentage by dietary *trans* fatty acids has been reported in mice (21,22). Thus, it appears that the influence of dietary

trans fatty acids on fat production in milk may be species-dependent.

The 18:1 *trans* isomer distribution was remarkably similar to that of partially hydrogenated vegetable oils. Since *trans* fatty acids are not *de novo* synthesized, the *trans* isomer distribution is a reflection of that in the diet. Under conditions of energy deficiency, lactating women produce milk which resembles the fatty acid pattern of their adipose tissue, but when energy is adequate, the dietary fatty acids are the major influence (38). The fatty acid composition of adipose tissue has also been suggested to reflect the long-term fatty acid profile of the diet (39–43). We have found a similar 18:1 *trans* isomer pattern between partially hydrogenated vegetable oil and adipose tissue in Canadian subjects (Chen, Ratnayake, Fortier, Ross, and Cunnane, unpublished data). A similar observation was also made by Ohlrogge *et al.* (20) for the United States population. Although complete dietary records were unavailable in the present study, this close correlation between the distribution of individual 18:1 isomers in partially hydrogenated vegetable oils and in human milk fat or adipose tissue, suggests that the major source of these fatty acids in the Canadian population is partially hydrogenated vegetable oil, whereas contribution from dairy products is relatively minor.

It is difficult to compare the pattern of 18:1 *cis* isomers in human milk with that in the diet because of the *de novo* synthesis of Δ9*c* and Δ11*c* isomers. However, comparison of the relative proportions of Δ8*c*, Δ9*c* and Δ12*c* isomers in partially hydrogenated vegetable oils with those in human milk indicates that Δ10*c* isomer is preferentially metabolized or discriminated by mammary gland. The low incorporation or apparent selective metabolism of the Δ10*c* isomer in human milk fat was also observed in human (20,44) and animal tissues (45,46).

Chappell *et al.* (19) studied the influence of margarine on fatty acid composition and found a significant elevation in milk 18:2n-6 levels with a depression in 18:1 *trans* following ingestion of margarine containing lower levels 18:1 *trans* fatty acids. This pattern in milk fatty acid was reversed by feeding margarine high in *trans* fatty acids and low in 18:2n-6 (19). We also found a similar inverse relationship between 18:2n-6 and 18:1 *trans* in human adipose tissue (Chen, Ratnayake, Fortier, Ross, and Cunnane, unpublished data). The linear inverse relationship between 18:2n-6 or 18:3n-3 and 18:1 *trans* isomers observed in this study indicates the elevation of *trans* fatty acids in Canadian human milk is at the expense of 18:2n-6, 18:3n-3 because high *trans* products contain less 18:2n-6 and 18:3n-3.

Many geometric and positional isomers of 18:2n-6 are formed during partial hydrogenation of vegetable oils (13,14) or during the deodorization of oils (47,48), 18:2Δ9*c*,13*t*, 18:2Δ9*c*,12*t* and 18:2Δ9*t*,12*c* are the major 18:2 isomers. Significant levels of these isomers are present in margarine and other dietary fats (13,14). The interest in these 18:2 isomers is related to their possible chain-elongation and desaturation to unusual 20:4 isomers (11,12,15). In essential fatty acid-deficient rats fed partially hydrogenated soybean oil, the formation of 20:4 isomers was extensive and was even more than the arachidonic acid produced (11). We have studied the relationship between chain-elongation and desaturation of the 18:2 isomers and dietary level of 18:2n-6 in rats. Our data have shown that elongation and desaturation of these isomers are inversely related to the level of 18:2n-6 in the diet (49). In another study (15), we found that 18:2Δ9*c*,13*t* and 18:2Δ9*c*,12*t* were metabolized to 20:4Δ5*c*,8*c*,11*c*,15*t* and 20:4Δ5*c*,8*c*,11*c*,14*t*, respectively, even under sufficient intake of 18:2n-6 (1.46% energy). Although these unusual 20:4 isomers were less than 0.4% of the total liver phospholipids, it is conceivable that they might exert some physiological effects. For example, a *trans* isomer of docosahexaenoic acid (DHA) derived from a mono *trans* isomer of 18:3n-3 has been found to incorporate into the retina of rats (50) and consequently altered the electroretinograph (51). We found that several milk samples in the present study had as much as 1.7% of total fat as 18:2 isomers. It is generally believed that dietary *trans*/*cis* isomers of 18:2n-6 and 18:3n-3 are not elongated and desaturated to C_{20} and C_{22} polyunsaturated fatty acids in humans, under conditions of adequate intake of essential fatty acids (5,6,32,52). Contrary to this, Chardigny *et al.* (53) found *trans* isomers of eicosapentaenoic acid and DHA in human platelets. Although 20:4 *trans* isomers are not present in human milk (present study), future studies should focus on the possible formation of C_{20} and C_{22} *trans* isomers in infants ingesting HTM. It will also be necessary to determine whether or not incorporation of such *trans* isomers into infants tissues may have physiological implications.

In addition to the possible chain-elongation and desaturation of 18:2 isomers, some 18:1 *cis* isomers may also be metabolized to unusual C_{20} isomers. For example, our previous study showed that 18:1Δ12*c* was desaturated/elongated subsequently to 20:2Δ8*c*,14*c* and 20:2Δ5*c*,8*c*,14*c* in rats fed the partially hydrogenated oils under sufficient intake of 18:2n-6 (15). In the human milks we analyzed, 18:1Δ12*c* accounted for 2.0% of total 18:1 *cis* fatty acids (Fig. 4). In addition, its two corresponding C_{20} metabolites were found to account for 0.2% of total milk fat (Table 1). The presence of the two metabolites in human milk suggests that the metabolic pathway of 18:1Δ12*c* may be similar in rats and humans.

In conclusion, it is clear that *trans* fatty acid isomers present in partially hydrogenated vegetable oils are transferred to human milk through maternal diets and, subsequently, to infants. Feeding diets high in *trans* fatty acids to newborn animals led to rapid accumulation of *trans* fatty acids in adipose tissue, liver and heart (54–56). The significance of an early supply of *trans* fatty acids in large amounts to human neonates is still unknown.

ACKNOWLEDGMENTS

Z.Y. Chen was a T.K. Murray Fellow of the National Institute of Nutrition. The authors thank Bureau of Field Operations and Dr. W.H. Newsome for procuring the samples. Thanks are also due to the

mothers who donated milk samples. T. Mag of CanAmera Food, Inc. (Toronto, Ontario, Canada) is thanked for supplying partially hydrogenated canola and soybean oil basestocks.

ABSTRACT: The effect of a long-term adaptation of rainbow trout to 8 and 18°C combined with a corn oil- or a fish oil-supplemented diet on the characteristics of the spermatozoan plasma membrane was investigated. The experiment lasted up to 22 mon during which spermatozoa were collected from the mature males. Spermatozoan plasma membranes were isolated by nitrogen cavitation, and the cholesterol content, phospholipid composition and fatty acid pattern were investigated. Membrane viscosity was assessed on whole cells by electron spin resonance using spin-labeled phospholipids. Neither diet nor rearing temperature influenced the cholesterol content of the plasma membrane nor the phospholipid class distribution. The rearing temperature of the broodstock only slightly affected the phospholipid fatty acids. A minor decrease in 18:0 and increase in monounsaturated fatty acids was observed for the cold-adapted fish. These modifications were not sufficient to affect membrane fluidity, and we conclude that trout spermatozoa do not display any homeoviscous adaptations in these conditions. On the contrary, the dietary fatty acid intake greatly modified the fatty acid profile of plasma membrane phospholipids. The fish oil-fed trout displayed a much higher n-3/n-6 fatty acid ratio than did the corn oil-fed ones, but the 22:6n-3 levels remained unchanged. Modifications in plasma membrane composition by the diet were obtained although neither of the two diets was deficient in essential fatty acids. The enrichment in n-3 fatty acids, however, did not affect plasma membrane fluidity which was unchanged by the diets.
Lipids 30, 23–33 (1995).

The quality of the spermatozoan plasma membrane in rainbow trout is a key factor in protecting the cell from the extracellular environment, be it the hypo-osmotic water into which milt is ejaculated or the media and extenders used in artificial fertilization. The importance of trout sperm plasma membrane integrity in resistance to stress such as osmotic shock or cold shock was confirmed by Maléjac *et al.* (1). Lipids, particularly phospholipids and cholesterol, are important structural elements of the cell membrane. It has been demonstrated in many vertebrate species that the resistance of sperm to cold shock depends on their cholesterol content (2–4), the cellular level of unsaturated fatty acids (5), and the phase transition temperature of spermatozoan glycolipids (6). In artificial membrane vesicles, the fatty acid composition has been shown to affect bilayer permeability and the ability of the membrane to fuse (7,8). Fatty acid composition also influences the osmotic fragility of erythrocytes, which additionally depends on the nature of phospholipid polar head groups (9,10). Several reviews have extensively covered the relationships between membrane composition (i.e., fatty acid unsaturation and acyl chain length, cholesterol, phospholipids, and proteins) and the physical parameter often referred to as "membrane fluidity" (11–13).

In mammals, changes in plasma membrane composition through dietary manipulation are well documented (reviewed in Ref. 11). In fish, many studies have shown that the fatty acid composition of the diet influences tissue lipids, particularly the fatty acid pattern in phospholipids (for review, see Refs. 14,15). The lipid composition of the broodstock diet has been reported to affect the fatty acid profile of trout eggs and spermatozoa (16,17) and of gilthead sea bream eggs (18). These studies, however, compared essential fatty acid (EFA)-deficient and non EFA-deficient diets and concerned whole cells. To our knowledge, the only data available in fish membranes concern the brush border membrane of trout and carp intestine (19–21).

The temperature at which fish are reared also affects the lipid composition of the cells. Cold acclimation of these poikilothermic animals has been shown to increase the proportions of unsaturated fatty acids and phosphatidylethanolamine and to decrease the proportions of saturated fatty acids, phosphatidylcholine, sphingomyelin, and cholesterol (13). These

modifications were assumed to increase membrane fluidity and to maintain normal cellular functions at low environmental temperature.

It is not known how the rearing temperature and changes in the dietary fatty acid profiles affect the lipids in the membranes of rainbow trout spermatozoa. The present study was undertaken to investigate the combined effects of temperature and dietary lipids on the cholesterol content, phospholipids, and fatty acid composition of phospholipid classes in the plasma membranes of rainbow trout spermatozoa. To this end, broodstock were reared at two water temperatures (8 and 18°C), and the diets were enriched with either linoleic acid or n-3 polyunsaturated fatty acids (PUFAs). For each set of rearing conditions, the biophysical state of the spermatozoan membrane was assessed by electron spin resonance (ESR) to estimate membrane fluidity.

MATERIALS AND METHODS

Animals, rearing temperatures and diets. One-year-old juvenile rainbow trout (*Oncorhynchus mykiss*) specimens of a winter strain, weighing about 100 g and reared at the INRA experimental farm at Donzacq, France (18°C water), were divided into four groups. Two groups were transferred to the INRA experimental farm at Lees-Athas, France (8°C water). In each farm, the trout were fed one of two experimental isoenergetic diets, in the form of pellets. Diet compositions are shown in Table 1. The relative percentages of n-3 fatty acids (0.5% in the corn oil diet and 1.1% in the cod liver oil diet) and n-6 fatty acids (3.7 and 1.36% respectively) met the known EFA requirements of broodstock fish. The corn oil diet was enriched in linoleic acid (three times more than in the cod liver oil diet), the cod liver oil diet in n-3 fatty acids (2.3-fold with respect to the former). The ratio of highly PUFA (at least four unsaturations) to saturated fatty acids was 2-fold lower in the corn oil diet (0.21) than in the cod liver oil diet (0.40). To obtain the same growth rate at both rearing temperatures, the fish reared at 18°C were rationed.

The first sexual maturity of the fish occurred 9 mon after the beginning of the experiment. Their mean weight was 1 kg and they were then two years old. Sperm was collected by hand stripping. For each rearing condition, sperm from six to nine fish were pooled. Each fish contributed the same sperm volume in the pool. This year, we obtained one to two pools of sperm, depending on the group. These pools were used for the determination of the lipid composition of plasma membrane. After another year under these rearing conditions (total of 22 mon), fish reached their second sexual maturity as they became three years old. Sperm was collected again and pooled in the same conditions. The two pools obtained this year were used for both the lipid composition and the fluidity studies on the plasma membrane. Since no difference in the lipid composition appeared between the two breeding seasons, the corresponding data were not separated in Tables 3 to 7.

Membrane preparation. Pure spermatozoan plasma membranes were prepared as previously described (22). Briefly, washed spermatozoa were subjected to a 900 psi nitrogen pressure for 20 min. Sperm extrusion lasted one minute, and a crude membrane preparation was collected after centrifuging (500 × *g* for 20 min) on a 1M sucrose cushion. Plasma membranes were separated from contaminating nuclear membranes, mitochondria, and flagella by sucrose density ultracentrifugation (54,000 × *g* for 2 h) on a subcontinuous gradient (1.8 to 0.25 M). The purity of the plasma membrane fraction was assessed by electron microscopy and by enzyme marker assays (22). The plasma membrane fraction showed a 4- to 5-fold enrichment in 5′-nucleotidase (EC 3.1.3.5; plasma membrane marker) activity, and no succinic dehydrogenase (EC 1.3.99.1; mitochondrial marker) activity was detected.

TABLE 1
Composition of Experimental Diets

Ingredients (wt%)[a]	Corn oil diet	Cod liver oil diet
Fish meat	45	45
Wheat starch (native)	20	20
Soybean LTI	18	18
Pre-gelatinized starch	5	5
Mineral mix (INRA[b], France)	2	2
Vitamin mix (INRA[b], France)	2	2
Sodium alginate	2	2
Corn oil	6	0
Cod liver oil	0	6
Antioxidant (ethoxyquin, ppm)	100	100
Protein (%)	43	43
Lipid (%)	11	11
Digestible energy (kJ/g)	15.5	15.5
Major fatty acids (molar % of the total)		
14:0	2.0	6.0
16:0	17.6	24.6
16:1	2.2	8.1
18:0	2.9	4.0
18:1	23.8	22.3
18:2n-6	44.8	15.2
18:3n-3	1.7	2.2
18:4n-3	0.3	1.3
20:1	0.2	2.3
20:4n-6	0.2	0.4
20:4n-3	—	0.3
20:5n-3	2.0	5.5
22:1	—	1.6
22:5n-3	0.2	0.5
22:6n-3	2.0	5.8
Total n-3	6.3	15.5
Total n-6	45.0	15.6
n-3/n-6	0.1	1.0
UI	139.3	128.6

[a]LTI, Low Trypsin Inhibiteur extruded full fatty soybean; UI, unsaturation index = relative percentage of each unsaturated fatty acid times the number of double bonds for that particular fatty acid.
[b]Mineral mix contained the following ingredients (g/kg mix):calcium carbonate, 215; magnesium hydroxide, 124; KCl, 90; ferric citrate, 20; KI, 0.4; NaCl, 40; calcium hydrogen phosphate ($CaHPO_4$), 500; copper sulfate, 3; zinc sulfate, 4; cobalt sulfate, 0.2; manganese sulfate, 3.
[c]Vitamin mix contained the following diluted in cellulose (g/kg mix):vitamin A (500,000 IU/g), 1.5; vitamin D_3 (100,000 IU/g), 1.5; vitamin E (500 IU/g), 6; vitamin K, 0.25; thiamine, 0.75; riboflavin, 1.5; pyridoxine, 0.75; nicotinic acid, 8.75; vitamin C, 25; folic acid, 0.25; vitamine B_{12} (1000 mg/kg), 2.5; inositol, 50; biotin (2%), 6.25; calcium pantothenate, 2.5; choline (50%), 200.

Lipid extraction and analysis. One volume of plasma membrane suspension was vigorously mixed with four volumes of chloroform/methanol (2:1, vol/vol) (23) containing 0.02% butylated hydroxytoluene (BHT) as an antioxidant. The lower phase was carefully separated, dried, and dissolved in chloroform with 0.02% BHT. Total cholesterol was determined enzymatically (Biochemica test combination; Boehringer, Mannheim, Germany) in 96-well plates after lipid extraction. Phospholipids were quantitated by colorimetric determination of phosphorus according to Bartlett (24) after hydrolysis with sulfuric acid. Phospholipids were separated from neutral lipids and glycolipids according to Linard (25). After adsorption of the sample to the Sep-Pak silica columns (Waters Associates, Millipore Corporation, Milford, MA), 20 mL chloroform were pushed through the cartridge, followed by 10 mL acetone and 20 mL methanol. Phospholipid classes were separated by high-performance liquid chromatography (HPLC) on a Zorbax silica column (250 mm length, 4.6 mm internal diameter, 5 μm particle size, Societe Francaise de Chromatographie, Eragny, France) on line with a LCD/Milton Roy 3000 detector (Riviera Beach, CA) at 205 nm. The mobile phases were: Solvent A, *n*-hexane/2-propanol (3:2, vol/vol), and Solvent B, *n*-hexane/2-propanol/water (3:2:0.275, by vol) at a flow rate of 1.5 mL/min. After injection of phospholipids, the column was eluted for 9 min with 50% A:50% B. The proportion of B was increased in 5 min to 78%, maintained for 9 min, increased to 100% in 2 min, and maintained for another 14 min. Finally, the proportion of B was decreased to 50% in 4 min, maintained for 9 min, and elution was stopped. Under these conditions, the various classes of phospholipids eluted within 50 min. Quantitation of these classes was performed by phosphorus assay.

Fatty acid distribution in the phospholipid classes was determined by gas–liquid chromatography of the fatty acid methyl esters obtained after transmethylation (26). For each class, 1 mg phospholipid in 1 mL methanol and 8 mL 12 N hydrochloric acid chloroform/2,2-dimethoxypropane (9.87:86.25:3.95, by vol) with 0.02% BHT were mixed in screw-cap vials which were then closed under a flush of nitrogen and heated at 65°C. The reaction was carried out for 3 h for total phospholipids, 4 h for phosphatidylethanolamine and phosphatidylcholine, 4.5 h for phosphatidylinositol, and 5 h for phosphatidylserine. After the tubes had cooled, fatty acid methyl esters were extracted in 4 mL *n*-hexane, dried and dissolved in isooctane.

Á Chrompack CP 9000 gas chromatograph (Les Ullis, France) equipped with a splitter injector, a flame-ionization detector, and a CP wax 52 CB bonded fused silica capillary column (50 m ¥ 0.25 mm internal diameter) was used for fatty acid methyl ester analysis. The carrier gas was hydrogen, at a flow rate of 1.5 mL/min. The injector and detector were set at 250 and 270°C, respectively, and the oven temperature was increased from 180 to 225°C at a rate of 4°C/min. Peaks were identified by comparing their retention times with those of authentic fatty acid methyl esters, and areas were calculated on a Spectra-Physics integrator (SP4400, Chrompack, Les Ullis, France).

Spermatozoan spin-labeling. The spin-labeled analogues of phospholipids used in these experiments are 1-palmitoyl-2-(4-doxylpentanoyl)phosphatidylcholine (SL-PC) and -phosphatidylserine (SL-PS) (see Ref. 27 for their synthesis description). The required amount of spin-labeled analog (corresponding to 1.6% of total membrane phospholipids) from a chloroform solution was deposited in a tube and dried under nitrogen. The dried film was resuspended in one volume of seminal-fluid-like mineral medium (28) consisting of 110 mM NaCl, 28.3 mM KCl, 1.1 mM $MgSO_4$, 1.8 mM $CaCl_2$ and 20 mM tris buffer (pH 9). One volume of spermatozoa in suspension ($2 \cdot 10^{10}$ cells/mL) and one volume of diisopropyl fluorophosphate (DFP) 5 mM were mixed with the spin-labeled phospholipid. Cell suspension was incubated for 30 min at room temperature to allow SL-PS to equilibrate in the membrane inner leaflet. ESR spectra were recorded at 4, 8, 13, 18 and 24°C after re-oxidation of nitroxides by 12 mM potassium ferricyanide. All ESR measurements were performed with a Varian E-109 spectrometer (Palo Alto, CA) equipped with a temperature control device. To compare the mobility of the spin probe in the different conditions, the apparent rotational correlation time was estimated as described (29).

Protein content. Membrane suspensions were digested in 1 M sodium hydroxide overnight at room temperature, and the protein content was determined according to Smith *et al.* (30) using the Pierce bicinchoninic acid (BCA) protein assay reagent (Rockford, IL).

Statistical analysis. Sperm from six to nine fishes were pooled for each individual analysis. Unless otherwise mentioned, the results shown are the means of three to four of these analyses ± standard error (SE). The statistical significance of differences between different groups was determined by the Mann-Whitney test (rank-sum test) (31). This test was performed by comparing the two diets, irrespective of the rearing temperature, and the two temperatures, irrespective of the diet in order to increase the sample number (from 3–4 to 6–8) and to allow this kind of analysis. The total number of fish involved in each group varied from 17 to 34.

RESULTS

Neither the lipid content of the two diets nor the rearing temperature had any significant effect on the phospholipid or cholesterol contents (relative to protein) of the spermatozoan plasma membrane (Table 2). The high SEs are due to high individual variations and made it difficult to assess the statistical significance of small differences between groups.

The different broodstock rearing conditions did not result in significantly different phospholipid class distributions in spermatozoan plasma membranes (Table 3). Whatever the diet or rearing temperature, phosphatidylcholine was the major phospholipid (46.5 to 54%), followed by phosphatidylethanolamine (29.5 to 33%) and phosphatidylserine (9.5 to 10.3%). Sphingomyelin was present in minor proportions (1.0 to 2.7%), and diphosphatidylglycerol was hardly detected (1.0%).

[a]Values are means of three to four pools ± SE of six to nine fish sperm. No statistical significance was observed between the groups (Mann-Whitney test).

We investigated the fatty acid profiles of the four main phospholipid classes: phosphatidylcholine, phosphatidylethanolamine, phosphatidylserine, and phosphatidylinositol (Tables 4 to 7). Palmitic acid was present in high amounts in trout spermatozoan plasma membrane, accounting for 40% of the total fatty acids in phosphatidylcholine (Table 4), 20% in phosphatidylethanolamine (Table 5), and over 10% in phosphatidylserine (Table 6) and phosphatidylinositol (Table 7). Oleic acid was also a major fatty acid in all four classes. In phosphatidylserine, 25% of the total fatty acids was 18:1n-9, and in the remaining classes the percentage was 12 to 20%. Phosphatidylserine was characterized by high proportions of 22:6n-3 (25%), and this fatty acid accounted for 10 to 15% of the total fatty acids in phosphatidylinositol, phosphatidylcholine and phosphatidylethanolamine. Of the four classes, phosphatidylcholine, the major phospholipid, had the lowest unsaturated fatty acid (UFA) to saturated fatty acids (SFA) ratio and the lowest unsaturation index. The high UFA to SFA ratio in phosphatidylserine is due to the fact that half of the phosphatidylserine fatty acids were 18:1n-9 and 22:6n-3 (Table 6).

The four phospholipid classes all exhibited the same general pattern of fatty acid change in response to reduced water temperature and to dietary modifications. In phosphatidylcholine, the proportion of 18:0 was lower at a rearing temperature of 8°C while the proportion of monounsaturated fatty acids (MUFA) was higher (Table 4). This slightly but significantly increased the MUFA to PUFA ratio but did not influence the UFA to SFA ratio or the unsaturation index. The effect of diet on phosphatidylcholine was as follows: the high amounts of 18:2n-6 in corn oil increased not only the plasma membrane 18:2n-6 levels (2-fold) but also the proportions of all n-6 PUFA (20:2n-6, 20:4n-6, and 22:5n-6 2-fold), the greatest difference between the two dietary groups being the 4-fold enrichment in 20:3n-6 in corn oil-fed trout (Table 4). The high proportions of 18:2n-6 and 20:4n-6 in trout fed corn oil as compared to trout fed cod liver oil resulted in a lower MUFA to PUFA ratio in the former. The corn oil diet had only one-third as much 14:0 and one-fourth as much 16:1 as did the cod liver oil diet (Table 1), but the plasma membrane phosphatidylcholines in corn oil-fed trout contained two-thirds as much 14:0 as found in that from fish oil-fed trout. The high proportion of n-3 PUFAs in the cod liver oil diet (two times more 20:5n-3 and 22:5n-3 than in the corn oil diet) resulted in a similar enrichment of spermatozoan membrane phosphatidylcholine in these fatty acids. Surprisingly, the 22:6n-3 levels were the same in both groups, although the cod liver oil-coated pellets were 3-fold richer in this fatty acid. Thus, phosphatidylcholine is the phospholipid class for which the difference in the n-3/n-6 ratio between the two diets is the highest and for which the UFA/SFA ratio is most affected by the diets. The resulting unsaturation index was slightly higher in the cod liver oil-fed fish, mainly due to the proportion of 20:5n-3, but this difference was observed mainly in fish reared at 18°C and was not significant.

Phosphatidylethanolamine was more unsaturated than phosphatidylcholine, the UFA/SFA ratio being about two times higher in phosphatidylethanolamine. The effects of di-

etary n-3 and n-6 enrichment were about the same as for phosphatidylcholine. The proportion of 22:6n-3 was not affected. In phosphatidylethanolamine, however, the high proportion of 20:5n-3 in cod liver oil-fed trout resulted in an increased unsaturation index despite the high levels of 20:4n-6 and 18:2n-6 in corn oil-fed groups. Rearing at 18°C resulted in higher 18:0 and lower 16:0 levels than observed in 8°C reared trout, leading to a lower MUFA/PUFA ratio in the latter.

Phosphatidylserine is the phospholipid class in which fatty acids, excluding 18:0, were the most strongly influenced by the rearing temperature (Table 6). Amounts of all SFA possessing 14 to 17 carbons were higher in 18°C acclimated trout, resulting in a lower UFA/SFA ratio in this group. Palmitoleic acid levels were higher in the 18°C reared groups. The two diets affected the fatty acid profile of phosphatidylserine as described for phosphatidylcholine, with 22:6n-3 unchanged whatever the rearing conditions. Contrary to phosphatidylcholine, phosphatidylserine exhibited a lower MUFA/PUFA ratio in the cod liver oil-fed groups. The unsaturation index was unaffected by the rearing conditions.

In phosphatidylinositol, the five fatty acids, 16:0, 18:1n-9, 20:4n-6, 20:5n-3, and 22:6n-3, were present in proportions approaching 10% or more. The high levels of 16:0 and 18:0 made this phospholipid class very saturated, a fact reflected in the low unsaturation index. The diet mainly affected 20:4n-6 and 20:5n-3 levels, the 22:6n-3 level remaining unchanged. As observed for phosphatidylcholine and phosphatidylethanolamine, 18:0 levels were higher in the fish reared at 18°C, leading to a lower UFA/SFA ratio. As in phosphatidyl-serine and phosphatidylcholine, the unsaturation index was not affected by the rearing conditions.

The fact that 20:3n-9 was not detectable in all four phospholipid classes confirms that neither of the diets was EFA-deficient (32).

Membrane viscosity. Membrane viscosity was measured on sperm from each of the four experimental groups. ESR spectra were recorded with SL-PC and SL-PS at five different temperatures, namely at 4°C, the temperature at which spermatozoa are stored after collection; 8 and 18°C, the two rearing temperatures before spawning; 13°C, the temperature at which trout are usually reared in our laboratory; and at 24°C, the temperature used for thawing and fertilization after cryopreservation. The SL-PC reflected the microviscosity in the outer monolayer, and the SL-PS reflected that of the inner

monolayer. This distribution was determined by their properties of transmembrane movement. For a given sample, the apparent correlation times calculated from the ESR spectra revealed that the higher the recording temperature, the lower the membrane microviscosity surrounding the spin label. The rearing temperature, however, did not affect membrane viscosity. The correlation times recorded at a given temperature (8 or 18°C) were the same for fish reared at 8 or 18°C (Fig. 1). This means that no adaptation of spermatozoan membranes of cold-acclimated trout compensated for the cold-induced increase in viscosity. Dietary lipids also had no effect on plasma membrane microviscosity as assessed by ESR. In addition, for any sperm cell sample, the microviscosity of the inner monolayer was always lower than that of the outer monolayer since the apparent correlation time of SL-PS was shorter than that of SL-PC.

DISCUSSION

Plasma membrane characteristics. Teleostean spermatozoa have no acrosome, and fertilization of the eggs occurs after the spermatozoa have passed through the micropylar canal to reach the egg plasma membrane. Prior to this study, no information was available on the phospholipid composition of the plasma membranes of such spermatozoa. Our results show that by comparison with mammals (33–37), levels of sphingomyelin in trout spermatozoan plasma membrane are very low. This low sphingomyelin content was also observed in trout erythrocyte plasma membranes (2.8%) (38). Phosphatidylserine levels, on the contrary, are higher in trout spermatozoan plasma membrane than in mammalian ones. The distribution of phosphatidylcholine and phosphatidylethanolamine in trout spermatozoan membrane is quite similar to that found in vertebrate membranes of other cell types, where these classes predominate. Phosphatidylethanolamine is more abundant, however, in trout spermatozoa than in mammalian ones. One could expect that the high phosphatidylethanolamine levels in trout plasma membranes would contribute to enhancing their fusion capacity as unsaturated phosphatidylethanolamines are thought to show a tendency toward forming nonbilayer-type configurations due to their "cone-shaped" structure (39,40). Surprisingly, we observed

that trout spermatozoan plasma membranes contain about 1% of diphosphatidylglycerol. This phospholipid is thought to be almost exclusively localized in the inner mitochondrial membrane (41). Such a contamination in our plasma membrane fraction is unlikely since no succinic dehydrogenase (mitochondrial marker) activity was detected (22). A mitochondrial contamination leading to add 1% of diphosphatidylglycerol to the total plasma membrane phospholipids would surely be detectable by enzymatic marker assay. We can then reasonably assume that trout spermatozoan plasma membrane contains diphosphatidylglycerol. In mammals, some authors have reported its presence in plasma membranes of ram epididymal or ejaculated spermatozoa (42,37).

Of the four phospholipid classes studied here, phosphatidylcholine was the most saturated, due to very high levels of 16:0. Such a preeminence of 16:0 in phosphatidylcholine is often described, whether in whole cells or in plasma membrane. Examples include cod (*Gadus morhua*) erythrocytes (43), cod and trout muscle, liver, gill, heart, kidney, and spleen (44,45), buffalo fish (*Jotiobus cyprinellus*) sperm (46), and brush border membrane from rainbow trout intestine (20). In the present study, phosphatidylinositol also displayed very saturated profiles as compared to phosphatidylethanolamine and phosphatidylserine, which contained more PUFAs. The plasma membranes of mammalian spermatozoa differ markedly from trout spermatozoan membranes in regard to fatty acid saturation in the various classes of phospholipids. In goat and boar caudal epididymis, phosphatidylethanolamine fatty acids are more saturated than those of phosphatidylcholine (35,34). In these species, furthermore, phosphatidylinositol and phosphatidylserine are the most saturated phospholipids (SFA percentages for boar caudal epididymis are respectively 98 and 64%). In phosphatidylinositol of trout spermatozoan plasma membrane, arachidonic and stearic acids predominate. This is also true in trout gill, spleen, and kidney (47) and in mammals. Phosphatidylinositol may be the primary source of arachidonate for lipoxygenase and cyclooxygenase reactions in fish sperm as postulated for gonad cell lines (48), since prostaglandins have been identified in the testes and milt of numerous fish, including trout (14,15).

Dietary effects. The dietary fats affected the various phospholipid classes differently. The n-3/n-6 ratio was much less affected in phosphatidylserine (1.5-fold) than in the other phospholipids (2.5 to 2.7-fold). This was due, however, to the

constant high level of 22:6n-3 in this phospholipid, irrespective of the diet. This persistence of 22:6n-3 raises questions as to its physiological importance for trout spermatozoa. Yu and Sinhuber (49) showed that an EFA-deficient diet in trout induced only a 30% decrease in 22:6n-3 content of body phospholipids over a 3.5-month period. Casteldine and Buckley (32,50) reported the same phenomenon, i.e., maintenance of the 22:6n-3 levels in trout that received diets devoid of EFAs. This could be linked to slow catabolism of long-chain PUFAs or to an efficient system for recycling 22:6n-3 during lipid metabolism (32). The rate of ß-oxidation of 22:6n-3 in the mitochondria of different fish tissues is limited or null (15). This, coupled with the apparent retention of 22:6n-3 during lipid mobilization, might ensure that this fatty acid is specifically retained to fulfill its role as a major constituent of biomembrane phospholipids (15). In whole trout spermatozoa, however, Watanabe *et al.* (16) have shown that when 18:2n-6 was available in an (n-3)-deficient diet, a 50% drop in 22:6n-3 was compensated by a 4-fold increase in 20:4n-6 and 22:5n-6. Whole spermatozoa from trout fed an EFA-deficient diet for one year displayed a decrease in 22:6n-3 levels although these levels were maintained in erythrocytes (17). It has been proposed that this PUFA could play a role in controlling membrane fluidity (51) or could be a substrate of lipoxygenases (15). Our study suggests a major role for 22:6n-3 in the phospholipids of trout spermatozoan plasma membrane, since levels remain constant even when most of the available fatty acids in the diet are of the n-6 series.

Temperature effect. The temperature at which the fish were reared appears to affect neither the cholesterol and phospholipid contents of spermatozoan plasma membrane nor its phospholipid class distribution. Maintenance of cholesterol levels was somewhat surprising, considering that a correlation between cholesterol content and temperature is often described in membranes of poikilothermic animals (13). However, most of these studies dealt with short-term adaptation of the fish (less than one month), and mitochondria were the structures described to be most commonly affected by temperature. Membranes of cold-adapted poikilotherms usually possess higher proportions of phosphatidylethanolamine and, less commonly, lower proportions of phosphatidylcholine than membranes formed at higher growth temperatures. This increases the proportion of nonbilayer-forming lipids at cold temperatures. Like the cholesterol decrease, this adaptation is

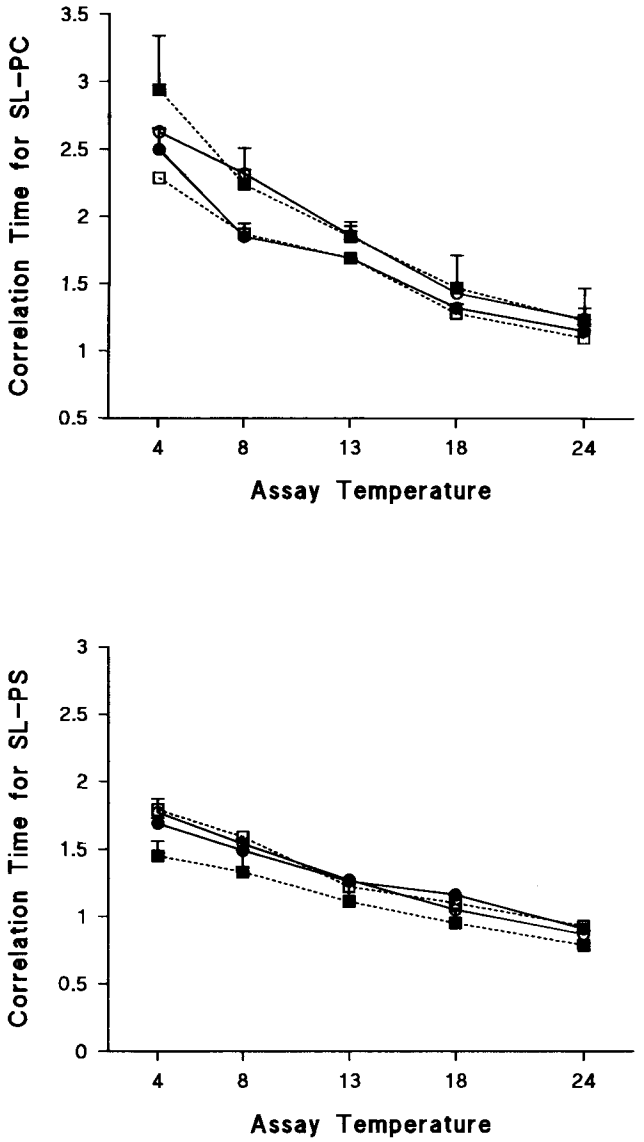

FIG. 1. Correlation time (in ns) as a function of temperature (in °C) for spin labeled-phosphatidylcholine (SL-PC) and -phosphatidylserine (SL-PS) incorporated in trout spermatozoan plasma membrane; ○, 8°C-reared trout fed with corn oil diet; ●, 8°C-reared trout fed with cod liver oil diet; □, 18°C-reared trout fed with corn oil diet; ■, 18°C-reared trout fed with cod liver oil diet. Values reported are the result of two different pools (± SE) of five to eight individual sperms. No significant differences appeared between the two diets and the two rearing temperatures.

believed to maintain a constant viscosity of the membrane. From the insignificant variations obtained for each phospholipid class in spermatozoan plasma membranes from trout reared at 8 or 18°C, it appears that this type of adaptation to low temperature did not operate in these cells. This lack of change with long-term adaptation to a different temperature is in agreement with previous observations on flounder (*Platichthys fletus*) erythrocyte plasma membranes (52). If changes in the cholesterol and phospholipid contents are merely short-term responses to thermal stress, the fact that the fish were transferred to the colder temperature prior to spermatogenesis and remained at that temperature until the process was complete could explain the apparent lack of thermal adaptation in trout spermatozoa.

A nearly ubiquitous response to exposure to a cold environment, as judged from most studies, is a drop in the proportion of SFAs and a corresponding rise in the proportion of UFAs. The introduction of double bonds in the phospholipid fatty acids disturbs the molecular packing of the membrane. Upon adaptation to a warmer temperature, conversely, an increase in the saturation level of fatty acids increases membrane viscosity. This "homeoviscous adaptation" (53) is thought to maintain a constant fluidity in biological membranes whatever the rearing temperature, in order to maintain membrane functions. We, conversely, have shown that long-term adaptation of trout to two very different rearing temperatures has little effect on the phospholipid fatty acids of trout spermatozoan plasma membranes. This is at variance with most studies on short-term adaptation of fish tissues (13): trout hepatocytes, liver plasma membranes, and mitochondria, carp liver and muscle mitochondrial membranes, and cod and carp erythrocytes (43,54). In all these cases, production of UFAs was stimulated by a sharp drop in the rearing temperature. A long-term adaptation of the fish does not always result in an acclimatory response. Although a long-term temperature adaptation resulted in slight but significant changes of the fatty acid composition in flounder erythrocyte plasma membrane (45,52), it was not the case in Atlantic salmon (*Salmo salar*) liver (55). The margin of 10°C between the two acclimation temperatures employed in our study is somewhat smaller than is commonly employed in such experiments (margins of 15 to 20°C). However, Malak *et al.* (56) showed that a six-week acclimation of trout to 11 and 21°C notably affected the fatty acid pattern of several tissues. This allows us to think that the rearing temperatures we used are of sufficient importance to trigger an acclimation response in trout. The *in vitro* experiments on trout and carp hepatocytes have shown that prolonged exposure to cold diminished the capacity for UFA production and that the total capacity to produce saturated or unsaturated species clearly did not correlate with growth temperatures (57). These observations could be one explanation for the apparent lack of response to a long-term temperature adaptation we observed in trout sperm.

The viscosity of trout spermatozoan plasma membranes as assessed by ESR appeared unaffected by the rearing temperature of the broodstock. In a previous paper (58), we showed that phosphatidylcholine is located mainly on the outer leaflet of the plasma membrane while most of the phosphatidylserine is inside. The two spin-labels used here should thus provide information on microviscosity in each bilayer leaflet. That the viscosity of neither leaflet is affected by the rearing temperature of the broodstock is in good agreement with the very slight variations observed in the fatty acid profile of each phospholipid class. Such a lack of a homeoviscous adaptation has been described for the sarcoplasmic reticulum of goldfish white muscle (59) and for the brush border membrane of carp intestinal mucosa (60). Homeoviscous adaptation is not a

property of all cellular membranes, but occurs selectively in situations where compensations maintaining membrane order serve to maintain membrane function and hence, to some extent, tissue function as well (60). The trout spermatozoan is a highly differentiated cell, but one whose metabolic activity is low and whose viability in the genital tract before spawning does not seem to depend on the molecular order of its plasma membrane. Membrane viscosity assessed by ESR with spin-labeled phospholipid gives information at the interfacial level of the membrane, since the doxyl group is located at the third carbon level. Adjustments of viscosity in the hydrophobic core cannot be detected by this probe. Hazel *et al.* (61) observed in trout hepatic plasma membranes that compensatory fluidity changes in response to temperature are more important in the hydrophobic moiety of the membrane than at the interface.

In conclusion, the fatty acid profile of phosphatidylcholines, phosphatidylethanolamines, phosphatidylinositols, and phosphatidylserines in trout spermatozoan plasma membranes was affected by the fatty acid profiles of the broodstock diet. This indicates the ability of the plasma membrane to incorporate most available fatty acids. This ability is, however, limited by the need for n-3 fatty acids as shown by the higher n-3/n-6 ratio in the plasma membrane than in the food pellets and by the constancy of the 22:6n-3 levels. As judged from the results of long-term adaptation to two different temperatures before and during spermatogenesis, the rearing temperature had little effect on the lipid composition of the plasma membranes of mature spermatozoa. This agrees with the fact that no difference in membrane viscosity was observed between the two groups and supports the hypothesis that rainbow trout spermatozoa do not display any homeoviscous adaptation.

ACKNOWLEDGMENTS

This work was supported by the Institut National de la Recherche Agronomique, by the Centre National de la Recherche Scientifique (URA 256), and by a grant from the "Région Bretagne" (Développement de Biotechnologies appliquées à l'aquaculture). K. Müller was a recipient of a short-term EMBO fellowship. We are grateful to Drs. G. Corraze, L. Frémont and X. Pelletier for kind and helpful discussions and advice. We thank Mr. Monasz for care with the fish and Mrs. Heydorff for skillful assistance.

ABSTRACT: The aim of our work was to determine whether fatty acid modifications in smooth muscle cell phospholipids affect cholesterol efflux and desorption. [^{3}H]Cholesterol was used to label cholesterol pools in the whole cell or selectively in the plasma membrane. Cells were incubated for 12 h in order to increase oleate, linoleate, arachidonate, eicosapentaenoic acid (EPA) or docosahexaenoic acid (DHA) in phospholipids. Cholesterol efflux was monitored using native or tetranitromethane modified high-density lipoprotein$_3$ (HDL_3). When all cholesterol pools were labeled, the efflux from cells treated with different fatty acids were not different. Plasma membrane cholesterol efflux remained unchanged after oleate, linoleate or arachidonate treatments, but was markedly increased after EPA and DHA enrichment, both with native HDL_3 and with tetranitromethane–high-density lipoprotein. These results suggest that the positive effects of n-3 fatty acid consumption on the atherosclerotic process could be linked in part to an increase in plasma membrane cholesterol efflux from vascular smooth muscle cells. *Lipids 30,* 35–41 (1995).

Aortic smooth muscle cells play a key role in the atherosclerotic process particularly by accumulating cholesterol before they are transformed into foam cells (1–3). The mechanisms of foam cell transformation remain uncertain but involve abnormalities of cholesterol transport. Cholesterol efflux is widely believed to be an important factor in regulating cell cholesterol homeostasis (4), and the rate-limiting step of this process was shown to be the desorption of cell membrane cholesterol into the culture medium (5). Cholesterol desorption involves lipid–lipid interactions between membrane cholesterol and lipoproteins, and the extraction of cholesterol from its hydrophobic environment depends on membrane physicochemical characteristics (6). Membrane physical properties and membrane fluidity have been reported to be strongly dependent on the membrane composition, particularly the phospholipid fatty acid profile (7).

The aim of this study was to induce changes in membrane phospholipid unsaturated fatty acid content in order to modify desorption and exchange of cell membrane cholesterol. Five different fatty acids were added to the media of confluent cultured aortic smooth muscle cells (SMC) and incorporated into cell membrane phospholipids during short time incubations.

ω-3 Fatty acids were of particular interest in regard to atherosclerosis prevention (8), as many studies have shown an inverse correlation between n-3 fatty acid consumption and the prevalence of coronary heart disease. The influence of fatty acid enrichment on cholesterol desorption was examined by selectively labelling the membrane cholesterol pool before efflux experiments were performed with different cholesterol acceptors.

MATERIALS AND METHODS

Cell culture. Aortic SMC were obtained from 6–10-week-old rats, as previously described (9). Briefly, the media layer of thoracic aorta was dissected out and SMC dispersed into single cells by collagenase (2 mg/mL, CLSI; Worthington Biochemical Corp., Freehold, NJ) and elastase (0.4 mg/mL, Type III; Biosys, Compiègne, France). Cells were seeded in Petri dishes (35 mm) or 6-multiwell plates ($3–5 \times 10^4$ cells/cm^2). Cells were grown in minimum Eagle's medium (MEM) supplemented with 10% newborn calf serum, penicillin/ streptomycin (100 units/mL and 50 μg/mL, respectively) and glutamine (2 mM). Medium was renewed three times a week. Secondary cultures were carried out in 25 cm^2 Falcon flasks using trypsin (0.08%). Cells were reseeded at 2.10^5 cells per flask and studied between 2 and 4 passages. For experiments, cells in Falcon flasks were used during the post-confluent phase.

Fatty acid enrichment procedure. Cells were incubated with fatty acid–bovine serum albumin (BSA) complexes during 12 h (10). The fatty acids used were oleic acid, linoleic acid, arachidonic acid, eicosapentaenoic acid (EPA), and docosahexaenoic acid (DHA), all from Sigma Chemical Corp. (St. Louis, MO).

The 50-mM fatty acid stock solutions were prepared as previously described (10) by drying fatty acids under N_2, on ice.

The dried fatty acids were dissolved in methanol containing 12.5 μg/mL butylated hydroxytoluene. MEM without calf serum containing 0.1 mM fatty acid and 2 mg BSA/mL was used for fatty acid enrichment procedures. Control medium consisted of MEM without calf serum containing 2 mg/mL BSA.

Fatty acid composition of SMC phospholipids. Lipids were extracted according to the method of Folch *et al.* (11). Fatty acid composition of cell phospholipids was studied by gas–liquid chromatography (GLC) after separation of neutral lipids by thin-layer chromatography (TLC) using a petroleum ether/diethyl oxide/acetic acid solvent system (90:30:2). Phospholipids were scraped and re-extracted as described previously (10). Phospholipid fatty acids were methylated according to the technique of Morrison and Smith (12). Methylated fatty acids were analyzed in an Intersmat IGC 120 DFL using a flame-ionization detector and a 30 m × 0.53 mm DB 23 column (J&W Scientific, Folsom, CA). The oven temperature was 128°C at injection and maintained during 10 min, then increased at a rate of 2°C/min for 6 min, and finally raised at a rate of 4°C/min up to 235°C. Injector and detector temperatures were 150 and 250°C, respectively. Helium was used as carrier gas under a pressure of 0.8 bars.

Lipoproteins and modified lipoproteins. High-density lipoproteins $_3$ (HDL_3; density range 1.125–1.21 g/mL) were isolated by precipitation and standard sequential ultracentrifugation of healthy donor human plasma (13). For 1 mL of plasma, very low density lipoprotein and low-density lipoprotein (LDL) were precipitated with 100 μL of 4% phosphotungstic acid (PTA) and 25 μL of 2 M $MgCl_2$. The supernatant fraction containing immunoglobulins and HDL was collected. Immunoglobulins were precipitated with 900 μL of 4% PTA. After a 3500 rpm centrifugation, the supernatant phase was collected and HDL were precipitated with 175 μL of 2 M $MgCl_2$. The HDL pellet was dissolved in 0.5 M Na_2CO_3. The density was adjusted to 1.125 for a 24 h ultracentrifugation, and the HDL_2 and HDL_3 fractions were separated. The density of the infranatant containing HDL_3 fraction was adjusted to 1.21, and HDL_3 were then re-isolated by flotation after a further 24 h ultracentrifugation. Lipoproteins were dialyzed for 48 h in standard buffer with 150 mM NaCl and 10 mM ethylenediaminetetraacetate (EDTA). Protein amounts were determined by the method of Bradford (14). HDL_3 were treated with 3 mM tetranitromethane (TNM) (15) (Sigma). A stock solution of 3 M of TNM was made at room temperature in 95% ethanol. The reaction mixture included 3 mM of TNM, 150 mM NaCl and 5 mM EDTA. The incubation was performed during 1 h at room temperature with the 0.5–1.5 mg/mL HDL_3 solution. The TNM–HDL were isolated by gel filtration chromatography on Sephadex G25 column (Pharmacia, Uppsala, Sweden) and extensively dialyzed. Apolipoprotein E containing HDL_3 were eliminated by the PTA/$MgCL_2$ precipitation procedure. Apolipoprotein profiles of HDL were controlled by sodium dodecyl sulfate–polyacrylamide gel electrophoresis (15) using the Mini Protean Cell System (Biorad, Richmond, CA). Native and modified lipoprotein sizes were determined by PAGE in 4–30% native polyacrylamide gels (Pharmacia-LKB, Uppsala, Sweden). The identical migration observed excluded possible aggregation.

Labeling of intracellular cholesterol pools before fatty acid incubations. The different intracellular cholesterol pools were labeled (16) before fatty acid enrichment by incubating the cells 48 h with MEM containing 10% newborn calf serum, without previous cholesterol depletion of the cells. The calf serum was previously labeled 24 h with 5 μCi/mL of [^{3}H]cholesterol (specific activity 48.4 Ci/mmole) without lecithin cholesterol acyl transferase (LCAT) inhibition in order to allow esterification of radiolabeled cholesterol in the LDL fraction. Using this procedure, [^{3}H]cholesterol was allowed to equilibrate within the different cellular pools but was predominantly recovered within the intracellular pools. After the labeling period, 60% of the cell radioactivity was recovered in the intracellular pool, 14% in the plasma membrane and 26% in the cholesteryl ester fraction, as assessed by the cholesterol oxidase procedure (see below). The degree of [^{3}H]cholesterol labeling was measured at the end of the fatty acid enrichment period and was taken as 100% for efflux measurements.The [^{3}H]cholesterol present in the cells at the end of the cholesterol labelling period was measured in separate dishes for each experiment. Before the fatty acid enrichment period, 83540 ± 1860 cpm were recovered in the cells. After the fatty acid enrichment period, 79120 ± 2130, 80340 ± 1860, 78350 ± 2200, 78980 ± 3170, 77520 ± 3080 and 79610 ± 2490 cpm were recovered in the cells for control, oleate-, linoleate-, arachidonate-, EPA- and DHA-treated cells, respectively. Only a slight efflux was observed during the fatty acid enrichment period, and it was the same for all the fatty acid-enriched cells. This is consistent with the finding that most of the label remains in the intracellular pools after the labeling period.

Labeling of plasma membrane cholesterol after fatty acid incubations. After fatty acid incubations as described above, SMC were incubated for 45 min at 10°C with serum free medium containing 2 μCi/mL of [^{3}H]cholesterol (Amersham, Amersham, United Kingdom) added in ethanol. With this procedure, labeled cholesterol is known to be selectively incorporated in the plasma membrane pool as previously shown (17–19). The 100% values were 30350 ± 2130, 29120 ± 2440, 32730 ± 1870, 28550 ± 2260, 30480 ± 2500 and 29890 ± 2135 cpm for control, oleate-, linoleate-, arachidonate-, EPA- and DHA-treated cells, respectively. In order to assess whether membrane cholesterol was specificaly labeled, cells were washed five times with cold Hank's buffer and fixed with 1 mL of 1% cold glutaraldehyde (10 min, 0°C). Cells were rinsed three times with cold sucrose buffer (310 mM sucrose, 0.5 mM NaH_2PO_4; pH 7.4) and were then incubated in the same buffer with 2 U of cholesterol oxidase (Boehringer, Ingelheim, Germany) for 2 h at 37°C. Cells were washed three times with cold Hank's buffer and then scraped with a rubber policeman. The cell suspension was collected, and lipids were extracted with 25 mL of hexane/isopropanol (3:2) and 5 mL 88% KCl 0 for 12 h. The lipid phase was dried under N_2, and the labeled lipids were separated in TLC (20 ×

20 Gel silica plates; Merck, Darmstadt, Germany) with chloroform/methanol (100:2). Cholesterol, cholestenone and cholesteryl esters were identified using the appropriate standards. Each silica gel spot was removed, and the radioactivity of each lipid fraction was quantitated by liquid scintillation counting. Under these conditions, more than 95% of cholesterol was selectively oxidized to cholestenone.

Competitive binding studies. Binding assays were carried out at 4°C in order to prevent internalization of HDL_3 or TNM–HDL. Cells were incubated for four hours with 20 μg/mL ^{125}I-HDL_3 labeled by the iodine monochloride procedure of MacFarlane (20). Briefly, 4 mg of native HDL_3 was added to glycine buffer 1M in NaCl 0.9% and mixed with 1 mCi NaI (10 μL) + 13 μL ICl (from a stock solution 0.033 M) added to 200 μL glycine buffer 1 M in NaCl 0.9%. HDL_3 was separated by gel filtration chromatography on Sephadex G25 column. ^{125}I-HDL_3-labeled cells were pulse-chased by 100, 200 and 300 μg of unlabeled HDL_3 or TNM–HDL in MEM without calf serum medium. Cells were washed three times with NaCl 0.9%/(2-amino-2-hydroxymethylpropane-1,3-diol)/BSA and three times with the same buffer without BSA. In order to assess the influence of fatty acid preincubations on the number of HDL_3 high affinity binding sites expressed by the cells, competitive binding experiments were performed between fatty acid preincubated cells and control cells using the same procedure as described earlier.

Efflux assays. After the fatty acid incubations and the labeling procedure, cells were rinsed five times with cold Hank's buffer and 200 μg/mL of HDL_3 or TNM–HDL. Media conditions for control cells were identical as for treated cells except that lipoproteins were replaced by 200 μg/mL of BSA. Cells were incubated at 37°C. At each indicated time, the culture medium was collected, centrifuged and counted in 8 mL of scintillating liquid (Beckmann, Fullerton, CA). Data are expressed as the percentage of the initial cell [^{3}H]cholesterol radioactivity (after fatty acid enrichment period) per well appearing in the medium. Phospholipid fatty acid composition was measured in trypsinized cells by GLC after lipid extraction with 25 mL of dichloromethane/methanol (2:1) and 5 mL KCl 0.88% overnight and phospholipid separation by TLC as described previously.

Cellular cholesterol and protein assays. Cellular cholesterol was assayed according to the colorimetric method of Omodeo Sale (21). Cellular protein content was determined as previously described by Lowry (22).

Statistical analysis. A one-way analysis of variance was used to compare values obtained under different experimental conditions, followed by pair-wise comparisons among means using the unpaired Student's *t*-test.

RESULTS

SMC fatty acid phospholipid composition after preincubation with the different free fatty acids. Table 1 shows the fatty acid profile of confluent SMC after the different fatty acid treatments. Preincubation with oleic acid (18:1n-9) resulted in a 7% increase in oleic acid content in the phospholipid fraction (40.77 ± 1.64 vs. 33.27 ± 2.52 for control cells). No major change was observed in the other fatty acids. The percentage of total monounsaturated fatty acids increased in oleic treated cells vs. control cells (46.68 ± 1.44 vs. 41.12 ± 1.56). The percentage of n-9 fatty acids increased significantly (10%): 47.57 ± 1.96 vs. 37.8 ± 2.67 in control cells.

Linoleic acid (18:2n-6) treatment led to a twofold increase in linoleic acid content (9.73%) in treated cells and a slight increase in the polyunsaturated fatty acids (PUFA) percentage (21.82 ± 1.56 vs. 17.91 ± 0.61) and in n-6 content (14.75 ± 0.92 vs. 12.45 ± 0.85).

Arachidonic acid (20:4n-6) treatment gave the highest percentage in phospholipid arachidonic acid (13.1 ± 1.71 vs. 3.51 ± 0.57 in controls), in PUFA acids (26.73 ± 1.30 vs. 17.91 ± 0.61) and in n-6 fatty acids (20.06 ± 1.26 vs. 12.45 ± 0.85 in controls).

EPA (20:5n-3) incubations resulted in 7.94 ± 1.52 in EPA vs. 2.46 ± 0.33 in control cells, 26.23 ± 4.53 in PUFA vs. 17.91 ± 0.61 in controls, 18.6 ± 5.03 in n-3 fatty acids vs. 4.71 ± 0.62 in controls.

DHA (22:6n-3) treatment produced 9.55 ± 0.73% DHA (vs. 0.62 ± 0.17 for control cells) in phospholipids, 22.84 ± 0.82 (vs. 17.91 ± 0.61 for control cells) in PUFA and 16.74 ± 2.97 in n-3 fatty acids vs. 4.71 ± 0.62 in controls.

Measurement of unsaturation in each group of treated cells was expressed using an unsaturation index calculated as follows (10):

$$\text{unsaturated index} = \sum(\%\ \text{of each fatty acid} \times \text{amount of double bonds per fatty acid}) \quad [1]$$

According to this formula, both EPA- and DHA-treated cells showed a significant increase in unsaturation index (171.05 and 140.03, respectively) as compared to control cells or to other fatty acid treatments. In summary, the five fatty acid treatments resulted in five different SMC phospholipid profiles, characterized by a different PUFA percentage and n-3 percentage.

HDL_3 and TNM-modified HDL-mediated efflux. Efflux of cell cholesterol was measured using two different protocols. A: The intracellular cholesterol pools were labeled by incubating confluent cells during 48 h with [^{3}H]cholesterol radiolabeled MEM before fatty acid enrichment procedure because fatty acid incubations were shorter in time in regard to cholesterol labelling procedure. If fatty acids had been incubated first, 48 h of cholesterol labeling might have allowed fatty acid transformations. Efflux experiments were performed after different incubation delays with 200 μg HDL_3/mL. No significant differences could be found in HDL_3 mediated efflux within the different fatty acid treated cells (data not shown). B: Plasma membrane cholesterol was selectively labeled after prior incubations with the different fatty acids. Before incubation with the lipoproteins, no difference could be observed in the amount of labeled cholesterol incorporated in the plasma membrane of the different fatty acid treated cells (data not shown).

[a]Values are mean ± SD weight % of total fatty acids in the phospholipid fraction from six typical experiments: For one experiment, six 75 cm^2 flask of cells were used for each fatty acid pre-incubation, and the experiments were renewed six times. At the end of the pre-incubation time, the cells were trypsinized and the lipids were extracted according to Folch *et al.* (11); phospholipids were separated and samples were methylated for gas–liquid chromatography. DMA, dimethyl acetal; PUFA, polyunsaturated fatty acid; MUFA, monounsatured fatty acid; unsat., unsaturated.
[b]$P < 0.05$ vs. controls.
[c]$P < 0.01$ vs. controls.
[d]$P < 0.001$ vs. controls.

In oleic, linoleic and arachidonic acid-treated cells, no significant differences could be observed in TNM-modified HDL-mediated efflux, nor in HDL_3-mediated efflux, compared to control cells. In EPA- and DHA-treated cells, TNM- modified HDL-mediated efflux and native HDL_3-mediated efflux were greatly increased (Figs. 1 and 2)—+30% for EPA- and DHA-treated cells vs. control cells after 5 h incubation with 200 μg TNM-modified HDL; and +25% for EPA- and +35% for DHA-treated cells after 5 h incubation with 200 μg HDL_3.

Competition of ^{125}I-labeled HDL_3 binding by unlabeled native and TNM-modified HDL_3 showed that TNM-modified HDL could not displace labeled HDL_3, as native HDL_3 did (98.8 vs. 68.5% binding, with 300 μg protein/mL, respectively; Table 2). Furthermore, competition of ^{125}I-labeled HDL_3 binding by unlabeled native HDL_3 in n-3 fatty acid-treated cells and control cells showed no difference (Table 3).

Taken together, these different results indicate that the increase in plasma membrane cholesterol efflux observed in n-3 fatty acid-treated cells could not be attributed to an enhancement in the number of HDL_3 cell binding sites: TNM-modified HDL-mediated efflux, as well as HDL_3-mediated efflux, were increased in n-3 fatty acid-treated cells and n-3 fatty acid-treated cells did not present any increase in the number of high affinity binding sites for HDL_3.

Free cholesterol content of SMC after 12 h incubation with EPA and DHA. Cholesterol was assayed according to the method of Omodeo Sale (21), and protein content was determined following the method of Lowry (22). No difference in cholesterol content could be found between EPA- or DHA-treated cells and control cells after fatty acid enrichment procedures (Table 4). No difference in labeled cholesterol partitioning between cell membrane and intracellular pools could be found between EPA- or DHA-treated cells and control cells after fatty acid enrichment procedures and before cholesterol efflux experiments (95 ± 4, 94 ± 3 and 92 ± 5% of cholesterol was oxidized to cholestenone for control cells, EPA-incubated cells and DHA-incubated cells, respectively) (Table 4).

DISCUSSION

The purpose of the present work was to induce significant changes in phospholipid fatty acid profile of SMC in order to determine whether various types of unsaturated fatty acids used could affect the rate of cholesterol efflux from cells. A series of 12-h incubations with MEM without calf serum containing BSA or oleic, linoleic, arachidonic, EPA or DHA resulted in different SMC fatty acid profiles.

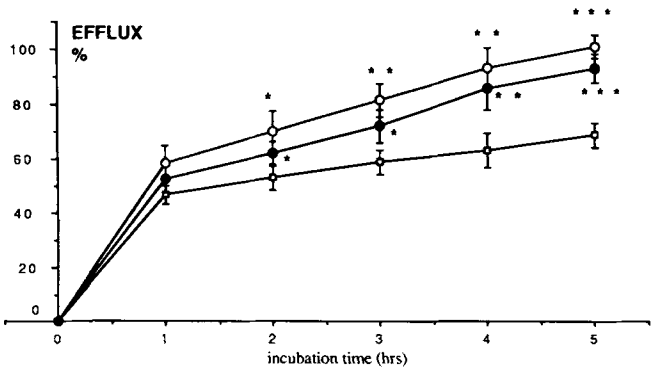

FIG. 1. Time course efflux of plasma membrane cholesterol after 12 h of incubation with eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA) and 5 h of incubation with 200 μg/mL of native high-density lipoprotein $_3$ (HDL_3). Plasma membrane cholesterol was labeled and cells were incubated with fatty acids as described. Cells were then incubated with 200 μg of native HDL_3 or with 200 μg/mL of bovine serum albumin during 5 h. The medium was collected at each indicated time. The cells were washed and trypsinized for cell counting or digested with NaOH 0.1 N in order to determine cell protein content. For the different fatty acid treatments, cell number and cell protein amounts were not significantly different. Data are values of radiolabeled cholesterol in the medium expressed as the percentage of the initial cell [^{3}H]radioactivity per well appearing in the medium. Values are means ± SD and n = 6 wells for each treatment at each time; data represent one of three identical experiments. Control (□); EPA treatment (●); DHA treatment (○). 100% value represents 30480 ± 2500 and 29890 ± 2135 cpm for EPA- and DHA-treated cells, respectively. Different from control at: $*P < 0.05$; $**P < 0.01$; $***P < 0.001$.

When the intracellular cholesterol pools were labeled and the fatty acid enrichment procedure was used, no significant differences in cholesterol efflux could be detected between the different groups. The membrane enrichment in the different unsaturated fatty acids seemed to have no physical or metabolic effect on the cholesterol translocation process under our conditions. These results prompted us to specifically label the plasma membrane cholesterol pool to magnify the desorption of cholesterol from cell membrane to the medium acceptors. This step is known to be a rate-limiting factor for efflux (4,5), and the translocation from intracellular pools seemed to be unaffected by the different fatty acid incubations in our conditions. When plasma membrane cholesterol was selectively labeled, pre-incubation with n-3 fatty acids increased HDL_3-mediated cholesterol efflux and TNM–HDL-mediated cholesterol efflux. These results show that increasing EPA and DHA in cell phospholipids increased the plasma membrane cholesterol desorption from the cell membrane bilayer into the phospholipid bilayer of an acceptor particle.

As both native and TNM-treated HDL gave similar results, this process appears to involve lipid–lipid interactions rather than apoprotein-mediated cholesterol movements. Furthermore, pulse chase studies provided evidence that n-3-treated cells did not express more high affinity HDL_3 binding sites than did control cells. Taken together, these different findings clearly indicate that the increase in plasma membrane cholesterol efflux observed in n-3 fatty acid-treated cells could not be attributed to an alteration of, or enhancement in, the number of HDL_3 cell binding sites. In addition, cell cholesterol

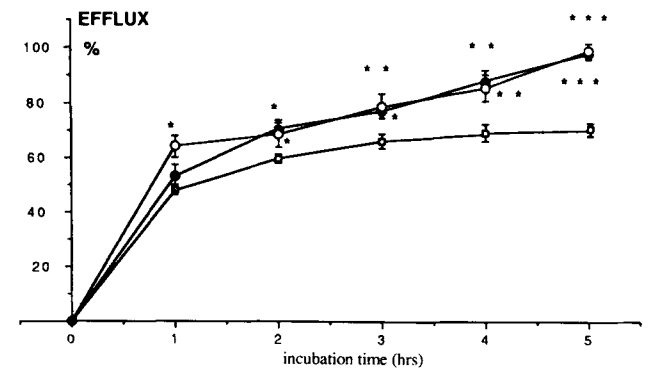

FIG. 2. Time course efflux of plasma membrane cholesterol after 12 h of incubation with EPA and DHA and 5 h of incubation with 200 μg/mL of tetranitromethane (TNM)-modified HDL. Plasma membrane cholesterol was labeled and fatty acids were incubated as previously described. Efflux of plasma membrane cholesterol was measured under the same experimental conditions as in Figure 1, except that native HDL_3 were replaced by TNM–HDL. Control (□); EPA treatment (●); DHA treatment (○). 100% value represents 30480 ± 2500 and 29890 ± 2135 cpm for EPA- and DHA-treated cells, respectively. *, **, *** and abbreviations as in Figure 1.

TABLE 2
Competition of ^{125}I-Labeled HDL_3 Binding by Unlabeled Native HDL_3 or TNM-Modified HDL[a]

Competitor concentration	% ^{125}I-labeled HDL_3 bound	
μg prot/mL	Native HDL_3	TNM-modified HDL
0	100.0 ± 2.23	100.0 ± 2.23
100	68.77 ± 4.32	97.78 ± 1.97
200	62.09 ± 1.71	100.6 ± 4.48
300	68.48 ± 1.58	98.76 ± 3.50

[a]Binding was measured with 20 μg of ^{125}I-labeled high-density lipoprotein $(HDL)_3$/dish and 0–300 μg of unlabeled native HDL_3 or tetranitromethane (TNM) modified HDL. Data are expressed as % of the amount of binding without competitors (means ± SD; six wells for each concentration). Data are from one of two similar experiments.TNM-modified HDL were unable to displace ^{125}I-labeled HDL_3 as native HDL_3 did.

TABLE 3
Competition of ^{125}I-Labeled HDL_3 Binding by Unlabeled Native HDL_3 in ω-3 Fatty Acid Treated Cells and Control Cells[a]

Competitor concentration	% ^{125}I-labeled HDL_3 bound		
μg prot/mL	Control cells	EPA-treated cells	DHA-treated cells
0	100.0 ± 2.16	100.0 ± 2.16	100.0 ± 2.16
100	56.52 ± 0.56	45.65 ± 2.11	45.53 ± 1.76
200	44.03 ± 1.10	41.22 ± 2.51	40.81 ± 1.34
300	33.37 ± 0.68	32.27 ± 1.35	34.58 ± 0.75

[a]Binding was measured with 20 μg of ^{125}I-labeled HDL_3/dish for each fatty acid pretreatment and control cells and 0–300 μg of unlabeled native HDL_3/mL. Data are expressed as % of the amount of binding without competitors (means ± SD; six wells for each concentration). Data are from one of two similar experiments. ^{125}I-labeled HDL_3 binding without unlabeled HDL_3 was identical for each fatty acid pretreated cells and control cells. The binding values were the same for ω-3 fatty acid-treated cells and control cells, for each unlabeled HDL_3 incubation. Abbreviations as in Table 2; EPA, eicosapentaenoic acid; DHA, docosahexaenoic acid.

TABLE 4
Free Cholesterol Distribution and Content of Smooth Muscle Cell After 12 h Incubation with Different Fatty Acids[a]

Treatment	Control cells	Oleate	Linoleate	Arachidonate	EPA	DHA
μg cholesterol/mg cell protein	39.25 ± 0.28	38.30 ± 1.5	41.60 ± 0.9	42.75 ± 1.3	40.05 ± 0.72	38.20 ± 0.13
% Cholesterol oxidizable	95 ± 4	93 ± 3	93 ± 4	95 ± 5	94 ± 3	92 ± 5

[a]Results are the mean ± SD of four independent determinations. Cholesterol was assayed according to (21) and protein content was determined by method (22). Membrane cholesterol was determined according to the cholesterol oxidase procedure. See Table 3 for abbreviations.

content was unaffected by n-3 fatty acid incubations. In contrast to the incubations with n-3 fatty acids, cells pre-incubated with oleic, linoleic or arachidonic acid had HDL_3-mediated cholesterol efflux and TNM–HDL-mediated cholesterol efflux similar to control cells.

The fatty acid incubations resulted in characteristic unsaturation patterns for each cell group (Table 1). It is difficult to determine the real efficiency of 18:1n-9 to change plasma membrane physical properties because of the relatively modest changes found. The 18:1n-9 homeostasis seems to be strongly maintained in phospholipids of SMC in culture under our conditions. Linoleic, arachidonic, EPA and DHA incubations gave a similar rise in cell PUFA percentages but provided very different patterns of fatty acid increase, suggesting that phospholipid n-3 fatty acid content is the main factor in the differences in membrane cholesterol extraction by phospholipids of acceptor particles that we found. Abundant evidence exists that dietary fatty acid consumption influences plasma lipids and lipoproteins in both human and animals (23).

Although consumption of n-3 PUFA is associated with a reduced incidence of coronary arterial diseases (8,24) and modifications of cholesterol metabolism (25,26), little is known about the influence of cellular enrichment in unsaturated fatty acids on the cholesterol metabolism of nonvascular cells (27,28). The effect of lipid modification of the membrane phospholipid pool may be to alter the conformation of proteins, which are sensitive to lipid environment (7), rather than to directly perturb bulk lipid fluidity (29) or specific lipid domains (6,30) and the physical and biochemical functions controlled by the membrane lipids.

Although effects of phospholipid fatty acid composition on cholesterol efflux rates have been studied on the human endothelial EA.hy 926 cell line (10), modifications of phospholipid fatty acids by n-3 PUFAs were studied in very few reports on SMC (31,32). Morisaki *et al.* (32), using a 16-h incubation procedure with 90 μM of 20:5n-3 and 22:6n-3 obtained results similar to ours: n-3 content was increased 1.8-fold and 2.6-fold after incubation with EPA and DHA, respectively, whereas in our study we found a 4-fold increase with EPA and 3.5-fold increase with DHA. In a previous similar work, Kilsdonk *et al.* (10) showed that in EA.hy 926 cells after cholesterol enrichment, palmitate incubation was the most efficient in increasing cholesterol efflux in an HDL_3 binding-independent manner, whereas EPA was less efficient. Such discrepancies between our results and Kilsdonk *et al.*'s (10) study could be due to differences in the two protocols: First, the two cell types used were very different. SMC were used between 2–4 passages and EA.hy 926 cells were issued from a continuous transformed cell line. Second, the efflux measurement protocols were not the same; Kilsdonk *et al.* (10) assayed cholesterol remaining in the cells after lipoprotein incubations, whereas we measured the appearance cholesterol in the medium specifically from the plasma membrane pool. Third, in our study, efflux was measured after short-time incubations with lipoproteins whereas Kilsdonk *et al.* (10) performed incubations for 12 h and more. Taking Kilsdonk *et al.*'s (10) results into account, it can be assumed that palmitate incubation in EA.hy 926 cells is more efficient for cholesteryl ester palmitate enrichment than for phospholipid palmitate enrichment and that palmitate effects on cholesterol efflux must be rather related to a modification of the different kinetic pools of membrane cholesterol. Thus, fatty acids might influence cholesterol efflux in at least two different manners—directly by incorporating into the phospholipid fraction and indirectly by affecting cholesterol distribution. On the other hand, a faster cholesterol HDL-mediated efflux was found with n-3 enriched HDL from n-3 fed rabbits (33), suggesting that n-3 in lipoproteins had a positive effect on efflux.

According to our present findings and a previous study showing that DHA increased permeability and decreased phase transition temperature of cells (34), it may be concluded that in SMC, n-3 fatty acids promoted cholesterol efflux because of the increased unsaturation they produced in the phospholipid bilayer. The increased unsaturation index found in our study might account in part for the effect of n-3 fatty acid on promoting desorption of plasma membrane cholesterol. Incorporation of EPA and DHA in phospholipids of plasma membrane increases the membrane unsaturation, much more than does oleic, linoleic or arachidonic acid incorporation. Alterations in membrane fluidity or lipid domain structures are possibly responsible for the effects observed.

The previous work of Sweet and Schroeder (35) showed that PUFA could alter transbilayer sterol localization, and it is possible that such a mechanism was involved in the enhanced plasma membrane cholesterol efflux seen with n-3 fatty acid enrichment. Mechanisms of cell cholesterol efflux remain controversial; binding site interactions are not well defined (36–38), but the fatty acid profiles of HDL (39) or cells (35,40) are greatly involved in cholesterol diffusion. The cholesterol transport through membranes involves specific pools or domains (30,41), particularly transbilayer domains within the cytofacial (inner) and exofacial (outer) leaflets. The cytofacial leaflet is known to be more rigid and contains more sterol. PUFA, incorporated into the membrane phospholipids in culture, alter the transbilayer difference in fluidity (41,42), and can result in an apparent reversal of membrane transbilayer

cholesterol distribution; more than 70% of the membrane sterol can become exofacial (35). Thus, regulation of the size of the exofacial cholesterol pool probably results in a bigger cholesterol pool available for diffusion and efflux; n-3 fatty acids in SMC phospholipids likely affect the size of this pool by a mechanism that remains to be elucidated. ω-3 Fatty acids and particularly DHA can adopt unique, closely packed arrays in lipid bilayers and thus can affect plasma membrane physical properties (43). These conformations were predicted on the basis of molecular dynamics calculations. Recently, surface pressure area experiments have indicated that there was no evidence to suggest that the average area per molecule for ω-3 fatty acids was different from the ω-6 fatty acid at high surface pressure (19). The most interesting finding about the role of ω-3 fatty acids in plasma membranes comes from a recent work of Knapp *et al.* (44). This study demonstrates that dietary n-3 fatty acids are selectively incorporated into phospholipid species that are concentrated in the erythrocyte membrane inner leaflet. If ω-3 fatty acids in our experiments have been incorporated in the inner leaflet of the smooth muscle cells, EPA and DHA could have adopted closely packed arrays and excluded cholesterol molecules from the inner to the outer leaflet of the membrane by negative association (43). Then, cholesterol in the outer layer could be picked up by the lipoproteins and plasma membrane cholesterol efflux increased. Nevertheless, this mechanism remains to be corroborated. Further studies are needed for complete elucidation of the n-3 fatty acid metabolism in cells and particularly for *in vivo* evaluation of dietary n-3 benefits, which must be confronted with the other physiological actions of n-3, and particularly the eicosanoid mediated cellular physiology (45).

Studies on Linoleic Acid 8*R*-Dioxygenase and Hydroperoxide Isomerase of the Fungus *Gaeumannomyces graminis*

Chao Su, Irene D. Brodowsky* and Ernst H. Oliw

Department of Pharmaceutical Biosciences, Division of Pharmacology, Uppsala University
Biomedical Center, S-751 24 Uppsala, Sweden

ABSTRACT: Linoleic acid is sequentially converted to 7*S*,8*S*-dihydroxy-9*Z*,12*Z*-octadecadienoic acid by the 8*R*-dioxygenase and hydroperoxide isomerase of the fungus *Gaeumannomyces graminis*, which is a common pathogen of wheat. The objective of this study was to separate and characterize the two enzyme activities. The isomerase activity was found mainly in the microsomal fraction of the mycelia and the 8*R*-dioxygenase in the cytosol. The 8*R*-dioxygenase could be partially purified by ammonium sulfate precipitation, gel filtration, ion exchange chromatography or isoelectric focusing. The 8*R*-dioxygenase was unstable during purification, but it could be stabilized by glutathione, glutathione peroxidase and ethylenediaminetetraacetic acid. Several protease inhibitors reduced the enzyme activity. Gel filtration with Sephacryl S-300 showed that most 8*R*-dioxygenase activity was eluted with the front with little retention. Isoelectric focusing in the presence of ethylene glycol (20%) indicated an isoelectric point of pI 6.1–6.3. The enzyme was retained on strong anion exchange columns at pH 7.4 and could be eluted with 0.3–0.5 M NaCl. Incubation of the enzyme with 0.1 mM linoleic acid led to partial inactivation, which may indicate product inhibition. Paracetamol and the lipoxygenase inhibitor ICI 230,487 at 30 μM inhibited the 8*R*-dioxygenase by 44 and 58%, respectively. 8*R*-hydroperoxy-9*Z*,12*Z*-octadecadienoic acid was isolated from incubations of linoleic acid with the partially purified enzyme or with the cytosol in the presence of *p*-hydroxymercuribenzoate. The hydroperoxide was rapidly converted by the hydroperoxide isomerase in the microsomal fractions to 7*S*,8*S*-dihydroxy-9*Z*,12*Z*-octadecadienoic acid. The isomerase was neither inhibited by carbon monoxide nor by ketoconazole (100 μM). The isomerase was active over a broad pH range. It could be separated from the 8*R*-dioxygenase by differential centrifugation, by ammonium sulfate precipitation and by gel filtration. We conclude that the linoleic acid 8*R*-dioxygenase and the hydroperoxide isomerase are two separate enzymes.

Lipids 30, 43–50 (1995).

Lipoxygenases metabolize linoleic acid and other polyunsaturated fatty acids with a 1*Z*,4*Z*-pentadienyl functionality to hydroperoxy fatty acids by hydrogen abstraction from the methylene carbon and antarafacial insertion of molecular oxygen (1,2). With few exceptions, the known sequences of lipoxygenases of plants and mammals show a common central motif, His-X_4-His-X_4-His-X_{17}-His-X_8-His, with at least five other conserved residues in this region (3,4). This central area is believed to bind the catalytically active iron. The three-dimensional structure of soybean lipoxygenase-1 and its iron-binding amino acid residues were recently reported (5,6). The catalytic iron is bound to three histidines and the carboxyl group of the C-terminal isoleucine. The iron is the target of many lipoxygenase inhibitors (7).

Two fungi, *Gaeumannomyces graminis* and *Laetisaria arvalis*, have been found to contain a fatty acid dioxygenase that shows both catalytic similarities and differences with lipoxygenases (8–10). This enzyme, linoleic acid 8*R*-dioxygenase, transforms linoleic acid to 8*R*-hydroperoxy-9*Z*,12*Z*-octadecadienoic acid (8*R*-HPODE) by hydrogen abstraction and antarafacial insertion of molecular oxygen at C-8 (11). In contrast to lipoxygenases, the 8*R*-dioxygenase accepts oleic acid as a substrate. It can metabolize many C_{18} fatty acids with a saturated C-2 to C-8 carboxyl side chain and with a *cis* double bond at position 9–10 (9). Linoleic acid 8*R*-dioxygenase and lipoxygenases are both inhibited by hydroxamic acid derivatives and by some other agents, indicating a similar oxygenation mechanism (12).

Hydroperoxides of fatty acids can be further metabolized. *Gaeumannomyces graminis* has been found to metabolize linoleic acid to 7*S*,8*S*-dihydroxy-9*Z*,12*Z*-octadecadienoic

acid (7*S*,8*S*-DiHODE) (9). Experiments under oxygen-18 gas and with glutathione peroxidase indicated that 7*S*,8*S*-DiHODE was formed from 8*R*-HPODE by an intramolecular hydroxylation by the distal hydroperoxide oxygen (9). The hydroxylation at C-7 of 8*R*-HPODE, which is catalyzed by this hydroperoxide isomerase, occurs by suprafacial hydrogen abstraction and oxygen insertion, resulting in a *threo* 1,2-diol (12). A similar hydroperoxide isomerase has also been described in the red alga, *Gracilariopsis lemaneiformis*, which can metabolize hydroperoxides to *erythro* 1,2-diols, e.g., 12*S*-hydroperoxyeicosatetraenoic acid to 12*R*,13*S*-dihydroxyeicosatetraenoic acid (13,14). Another example of a hydroperoxide metabolizing enzyme is the allene oxide synthase from flaxseed. This enzyme was recently cloned, and it belongs to a new gene family of cytochrome P450 (P450) (CYP74) (15,16).

The objectives of the present study were to determine whether the 8*R*-dioxygenase and hydroperoxide isomerase activities could be separated and to study some properties of the two enzymes. We describe methods to prepare linoleic acid 8*R*-dioxygenase, hydroperoxide isomerase and 8*R*-HPODE. Measures to increase the stability of the 8*R*-dioxygenase are also described.

MATERIALS AND METHODS

Materials. Gaeumannomyces graminis var. graminis was from Centraalbureau voor Schimmelcultures (Baarn, The Netherlands). Linoleic acid (99%), ketoconazole, N-tosyl-L-phenylalanine chloromethyl ketone (TPCK), *p*-hydroxymercuribenzoate, superoxide dismutase and glutathione (GSH) peroxidase (both from bovine erythrocytes) were from Sigma (St. Louis, MO). [1-^{14}C]Linoleic, [1-^{14}C]arachidonic and [1-^{14}C]eicosapentaenoic acids (55 Ci/mol) were purchased from Amersham Int. (Amersham, Buckshire, United Kingdom). Fatty acids were checked by thin-layer chromatography (TLC) and purified if necessary. SepPak-C_{18} was from Waters (Milford, MA). Precoated TLC plates (0.25 mm silica gel 60A, 10 or 20 cm long) were from Merck (Darmstadt, Germany) and from Whatman (Maidstone, United Kingdom). 8*R*-HODE, 7*S*,8*S*-DiHODE, 18*R*-hydroxy-5*Z*,8*Z*,11*Z*,14*Z*-eicosatetraenoic acid and 19*R*-hydroxy-5*Z*,8*Z*,11*Z*,14*Z*-eicosatetraenoic acid were prepared as described (8,9,17). 13*S*-Hydroxy-9*Z*,11*E*-octadecadienoic acid (13*S*-HODE) was obtained by biosynthesis and used as internal standard (12). 9*S*-Hydroperoxy-10*E*-12*Z*-octadecadienoic acid (9*S*-HPODE) was prepared as described (18). Sephacryl S-300 HR, Sephadex G-50, PD-10 and Q-Sepharose FF were from Pharmacia (Uppsala, Sweden). Ampholyte (3:10 and 5:8) and strong anion exchange columns (Econopak Q) were from BioRad (Stockholm, Sweden). Paracetamol was obtained locally. ICI 230,487, which is the N-ethyl analogue of the 5-lipoxygenase inhibitor ICI D2138 (*cf.* Ref. 7), was a gift from Zeneca Pharmaceuticals (Cheshire, United Kingdom). BW A4C (7) was a gift from the Wellcome Foundation (Beckenham, United Kingdom). Aprotinin was from Bayer AG (Leverkusen, Germany). Emulgen 911 was a generous gift from KAO Corp. (Tokyo, Japan). 4-Aminobenzamidine dihydrochloride and most other chemicals were from Merck.

Preparation of subcellular fractions of mycelia. Gaeumannomyces graminis was cultivated for about one week as described (9). The mycelia were filtered under vacuum, washed with saline and stored at –80°C. The following steps were performed at 4°C. The frozen mycelia (10 g) were homogenized with alumina type A-5 (10 g; Sigma) and 20 mL 50 mM potassium phosphate buffer (pH 7.4; buffer A) with 0.75 M sorbitol, by grinding in a mortar on ice. Addition of GSH (2 mM), ethylenediaminetetraacetic acid (EDTA; 5 mM) and [ethylene-*bis*(oxyethylenenitrilo)]tetraacetic acid (EGTA; 1–2 mM) to the buffer was found to improve enzyme stability. The white slurry was centrifuged at 10,000 × *g* for 20 min. The supernatant was saved, and the alumina pellet was ground in 10–15 mL buffer and recentrifuged. The clear supernatants were pooled and subjected to ultracentrifugation (100,000 × *g*; 60 min). The 100,000 × *g* supernatant and the pellet, which was suspended in buffer A, are referred to as the cytosol and the microsomal fraction, respectively. The cytosol and the microsomes were either used directly or stored at –80°C.

Assay of linoleic acid 8R-dioxygenase. All incubations were performed on ice. The cytosol was diluted to a protein concentration of about 0.5 mg/mL (with buffer A or 10 mM triethanolamine, pH 7.4) and incubated with 2 to 100 μM [^{14}C]18:2(n-6). An enzyme unit of 8*R*-dioxygenase was defined as biosynthesis of 1 pmol of 8*R*-HODE per min upon incubation with 100 μM [^{14}C]linoleic acid (3–4 Ci/mol), GSH-peroxidase (1 U/mL) and GSH (1 mM) for 10 min [reverse-phase high-performance liquid chromatography (RP–HPLC) assay]. This concentration of GSH–peroxidase inhibited formation of 7*S*,8*S*-DiHODE (9). The cytosol typically contained 400–1000 units per mg of protein. The 8*R*-dioxygenase activity was followed during enzyme purification by incubation of 0.2–0.3 mL of the fractions with 60 nCi of [^{14}C]linoleic acid (20 min, TLC assay). All incubations were terminated by addition of four volumes of ethanol, and precipitates were removed by centrifugation. The material in the supernatant was extracted and analyzed by RP–HPLC or TLC.

Drugs were added to the cytosol (with GSH and GSH-peroxidase) and preincubated on ice for 20 min. The substrate was then added (0.1 μCi of [^{14}C]linoleic acid, 2 μM). The drugs were dissolved in ethanol (ICI 230,487), dimethyl sulfoxide (BW A4C) or distilled water (paracetamol), and these solvents (0.6% final concentration) were added to the controls. Samples were incubated in duplicate and analyzed by RP–HPLC. The effects of detergents, protease inhibitors and solvents on 8*R*-dioxygenase activity were assayed by TLC.

Assay of hydroperoxide isomerase. The microsomes were suspended in buffer A (to 2 mg protein/mL) and incubated with ^{14}C-labeled 8*R*-HPODE (3–5 μCi) in duplicate or triplicate (20 min, on ice). All incubations were terminated by the addition of 4 vol of ethanol. The effect on variation of buffer

pH on isomerase activity was assessed by adding 5 μL of the microsomal suspension to 95 μL 0.1 M buffer of different pH values. The buffers were citrate–phosphate (pH 3–7), potassium phosphate (pH 6–8), sodium borate (pH 8–9) in one series of experiments and glycine–NaOH (pH 9–12) in a second experiment. The buffered enzyme was incubated with [^{14}C]8*R*-HPODE for 10 min. In order to approximate the useful incubation times for the isomerase at our experimental conditions, the microsomal suspension was incubated with [^{14}C]8*R*-HPODE, and duplicate samples were removed at different time points. To determine if ketoconazole inhibited the isomerase, the microsomal suspension was pretreated for 20 min with 100 μM ketoconazole (in 0.07 M HCl). To establish whether CO inhibits the isomerase, buffer A (7 vol) on ice was saturated with CO or N_2, mixed with the microsomes (1 vol) and incubated directly. Formation of [^{14}C]7*S*,8*S*-DiHODE was determined by RP–HPLC and liquid scintillation, using 13*S*-HODE as an internal standard.

Separation of metabolites. After extractive isolation with SepPak-C_{18} cartridges (8), the metabolites formed from [^{14}C]linoleic acid were analyzed by RP–HPLC using 13*S*-HODE (1 μg) as internal standard or by TLC. The RP–HPLC columns (5-μm Nucleosil-C_{18}, 150 × 4.6 mm) were eluted with methanol/water/acetic acid (75:25:0.01, by vol) at 1 mL/min. Ultraviolet (UV) absorption at 235 nm was followed for quantification of the internal standard (8). Equipment for RP–HPLC was as described (8). TLC was usually performed with toluene/dioxane/acetic acid/formic acid (82:14:1:1; by vol; system A). The R_f values for linoleic acid, 8*R*-HPODE, 8*R*-HODE and 7*S*,8*S*-DiHODE were 0.54, 0.42, 0.32 and 0.13, respectively. For quantification, the TLC plates were scanned for radioactivity (model II; Berthold Dünnschichtscanner, Hässleby, Sweden). The area of the ^{14}C-labeled peaks on the chart was usually estimated by weighing the peaks. Initially, authentic 8*R*-HODE and 7*S*,8*S*-DiHODE were used as TLC references and stained with phosphomolybdic acid (Merck). Methyl esters were prepared by treatment with an excess of ethereal diazomethane (9). 7*S*,8*S*-DiHODE methyl ester was analyzed by TLC (ethyl acetate/hexane/acetic acid, 5:5:0.05; by vol). The R_f values for 7*S*,8*S*-DiHODE methyl ester and 8*R*-HODE methyl ester were 0.46 and 0.66, respectively.

*Preparation of ^{14}C-labeled 8*R*-HPODE.* A partially purified preparation of 8*R*-dioxygenase was used to biosynthesize 8*R*-HPODE. The low-speed supernatant was desalted (by gel filtration on Sephadex G-50 or PD-10 columns in buffer A with 0.75 M sorbitol), and the active fractions were subject to anion exchange chromatography (three Econopac Q cartridges in a series). The latter were eluted with a linear gradient of 0–1 M NaCl in 30 min (flow rate 1 mL/min) in buffer A. The active fractions (0.3 to 0.5 M NaCl) were incubated with [^{14}C]linoleic acid (10 μCi) on ice.

Alternatively, 18 mL of buffer A with 0.75 M sorbitol was bubbled with oxygen gas for 5 min on ice. [^{14}C]Linoleic acid (7 μCi in 50 μL ethanol) was added together with 0.2 mL 100 μM *p*-hydroxymercuribenzoate, followed by 2 mL of cytosol (containing 40 mg of protein and 28,000 units of 8*R*-dioxygenase). After mixing, the sample was incubated for 15 min under a stream of oxygen gas. After acidification and extractive isolation, the products were purified by TLC (system A). The band with [^{14}C]8*R*-HPODE was scraped from the TLC plate and eluted with ethyl acetate.

Partial purification of 8R-dioxygenase. Ammonium sulfate precipitates were prepared by mixing equal volumes of cytosol and a 3.6 M (90% saturation) ammonium sulfate solution in buffer A (pH 7.4), containing 2 mM GSH and 5 mM EDTA. After mixing, the suspension was centrifuged (10,000 × *g*, 20 min) and the pellet was either resuspended in phosphate buffer with 2 mM GSH and 5 mM EDTA or stored at –80°C.

Sephacryl S-300 (1.9 × 49 cm) was used for gel filtration. Protein elution was followed by UV absorption at 280 nm. The column was usually eluted with 40 mM potassium phosphate buffer (pH 7.4, flow 2.2 mL/min) containing 5 mM EDTA and 2 mM GSH (buffer B). In some experiments, ethylene glycol (20%) or sorbitol (14%) were added. A more diluted buffer was used (5 mM potassium phosphate) in connection with isoelectric focusing.

The active fractions from gel filtration were diluted with water and subjected to isoelectric focusing with 1% ampholyte (3:10 or 5:8) and 20% ethylene glycol. A preparative scale isoelectric focusing cell (Rotofor; BioRad) was used. Ethylene glycol reduced precipitations in the Rotofor cell and allowed electrofocusing at a low temperature. The power was increased stepwise: 3W (0.5 h), 9W (0.5 h) and 12W (2 h). Refocusing was performed with fractions of pH 4–9. The 20 fractions obtained were adjusted to pH 7.0–7.5 with buffer, and enzyme activity was analyzed by TLC assessment of products.

Ion exchange chromatography was performed with strong anion exchangers, Econopac Q cartridges (see above) or a Q-Sepharose FF column (1.6 × 7 cm). The latter was equilibrated with buffer B and eluted with 3 mL/min. The column was typically loaded with 20 mg protein, washed with buffer B for 15 min and then eluted with a concave gradient of 0–1 M NaCl in buffer B.

Assay of cytochrome P450 metabolites. The microsomes and cytosol were incubated with [^{14}C]arachidonic acid or [^{14}C]eicosapentaenoic acid (1.2 μCi/mL) for 30 min at 30°C in the presence of 1 mM NADPH. After extractive isolation, the metabolites of arachidonic acid and eicosapentaenoic acid were analyzed by RP–HPLC or methylated and analyzed by TLC (8,9). Sonication of microsomes was performed as described (8).

Other analyses. Gas chromatography/mass spectrometry (GC/MS) analysis was performed as described (9). Radioactivity was determined by liquid scintillation using EcoScint (Hintze, Lidingö, Sweden). Sodium dodecyl sulfate–polyacrylamide gel electrophoresis (SDS–PAGE) was performed according to the manufacturer of electrophoresis equipment (Miniprotean II; BioRad). Protein concentrations were determined as described (19) with gamma-globulin as standard or by UV analysis (280 nm).

RESULTS

*Stability and partial purification of linoleic acid 8*R*-dioxygenase.* Purification of 8*R*-dioxygenase was hampered by the instability of the enzyme. Storage for 24 h at 4°C usually led to loss of all or almost all enzyme activity. Addition of mM concentrations of GSH stabilized the enzyme. In many experiments, half of the activity of the cytosol could be preserved for 3 d in the presence of 2 mM GSH, while the control showed no enzyme activity after this time. Addition of glutathione peroxidase (2 U/mL) further increased the stability for a few days (Fig. 1). Superoxide dismutase (2 mg/mL) or cysteine (1 mM) appeared to be without effect. ATP (2 mM) and calcium (about 2 mM free concentration) did not stimulate the enzyme.

Some protease inhibitors were evaluated. EDTA (5 mM) stabilized the enzyme in comparison with the control. However, 1 mM TCPK or 1 mM 4-aminobenzamidine inhibited the 8*R*-dioxygenase activity by over 70%, and aprotinin (100 U/mL) was without beneficial effects.

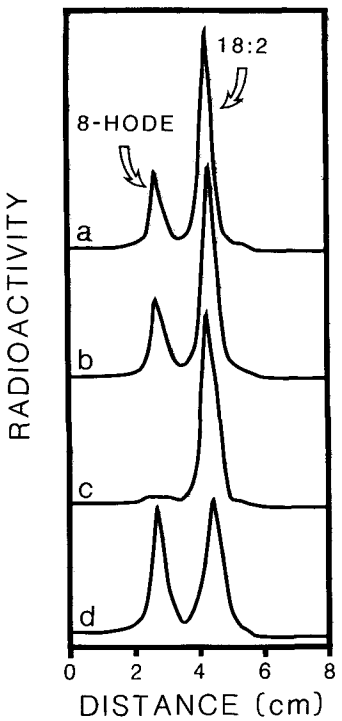

FIG. 1. Effect of glutathione peroxidase on the stability of linoleic acid 8*R*-dioxygenase. The cytosolic fraction of *Gaeumannomyces graminis* was kept on ice for 7 d (a–c) or incubated on the first day with [^{14}C]linoleic acid (d). The products were analyzed by thin-layer chromatography (system A; toluene/dioxane/acetic acid/formic acid, 82:14:1:1; by vol). Trace a: analysis of products from proteins stored for 7 d in the presence of glutathione (GSH) peroxidase (2 U/mL) and superoxide dismutase (2 mg/mL); trace b: analysis of products from proteins stored for 7 d with GSH peroxidase; trace c: analysis of products from proteins stored for 7 d without additions; d: analysis of products from proteins incubated on day 1 without GSH peroxidase and superoxide dismutase. Ethyldiaminetetraacetic acid, 5 mM, and GSH, 3 mM , were present in all four samples. This preparation apparently did not contain hydroperoxide isomerase activity.

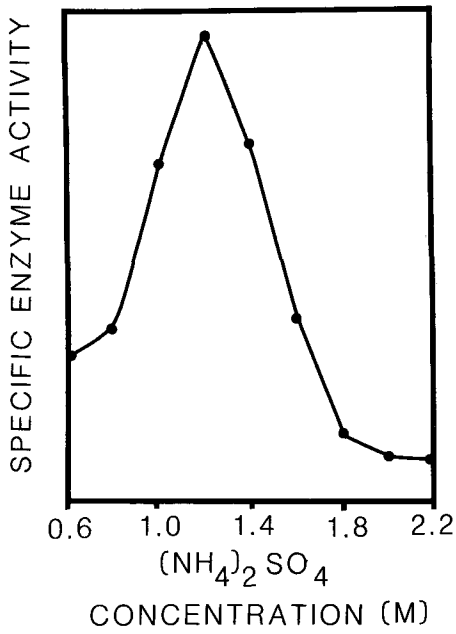

FIG. 2. Ammonium sulfate precipitation of linoleic acid 8*R*-dioxygenase in the cytosol of *Gaeumannomyces graminis*. The curve shows specific enzyme activity in the precipitates, taken from zero to the indicated concentration of ammonium sulfate.

Sorbitol (0.75M, 14%), glycerol (15%) and ethylene glycol (25%) did not inhibit the enzyme. Sorbitol appeared to increase the yield of 8*R*-dioxygenase during grinding of mycelia. Detergents and organic solvents, such as 0.5% of Triton X-100, Emulgen 911, Tween 80 and 20, sodium deoxycholate or polyoxyethylene-10-lauryl ether, 10% isopropanol, and 10% acetonitrile, inactivated the enzyme. Urea (1–4 M) and glycine (2%) also inhibited the enzyme, while ampholyte (1%) was without effect.

The precipitation of 8*R*-dioxygenase from the cytosol by increasing concentrations of ammonium sulfate is illustrated in Figure 2. Most enzyme activity was precipitated between 20 and 45% saturation, i.e., between 0.8 and 1.8 M ammonium sulfate. Routinely, the 0 to 45% ammonium sulfate cut was used for further purification. The recovery of enzyme activity was 75%, and the specific activity was 0.5 nmol/min/mg of protein before and 0.6 nmol/min/mg of protein after precipitation.

Gel filtration of the ammonium sulfate precipitate showed that most of the enzyme activity eluted with the front with only little retention relative to the bulk of proteins while the isomerase activity appeared to elute with the front and with no retention relative to the bulk proteins (Fig. 3). Virtually all enzyme activity eluted before bovine serum albumin. SDS–PAGE showed that the active fractions contained proteins of various sizes. Gel filtration was therefore performed under different conditions to reduce formation of aggregates of proteins, e.g., with 20% ethylene glycol (20). However, the elution of proteins and enzyme activity appeared to be un-

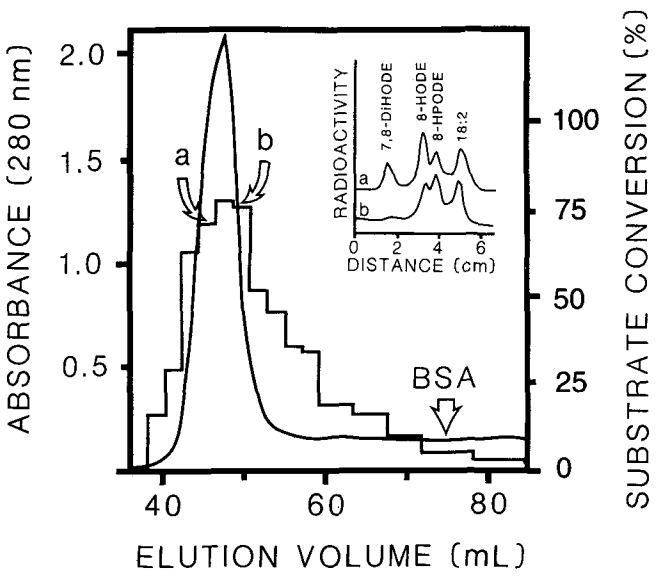

FIG. 3. Gel filtration of 8*R*-dioxygenase. The ordinates show the elution of protein (ultraviolet 280 nm; smooth curve) and 8*R*-dioxygenase activity from the column (Sephacryl-300; Pharmacia, Uppsala, Sweden). The enzyme activity of the fractions is given as the conversion of [^{14}C]linoleic acid to polar products in percent [7*S*,8*S*-DiHODE and 8*R*-H(P)ODE; thin-layer chromatographic (TLC) analysis]. The elution volume of bovine serum albumin (BSA) is marked with the arrow. The inserted TLC chromatograms of fractions marked a and b indicate a partial separation of the 8*R*-dioxygenase from the isomerase.

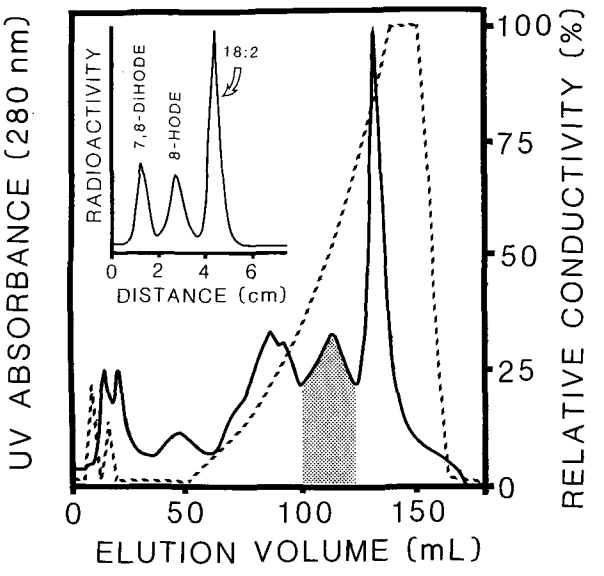

FIG. 4. Chromatography of linoleic acid 8*R*-dioxygenase on a strong anion exchange column. The column (Q-Sepharose FF) was eluted with a gradient of 0–1 M NaCl as shown by the dotted line (relative conductivity). Elution of proteins and other ultraviolet (UV)-absorbing material is shown by the solid line. Linoleic acid 8*R*-dioxygenase activity eluted with 100–125 mL (shaded area). The inserted TLC analysis shows that these fractions were associated with hydroperoxide isomerase activity, at least in some experiments. Abbreviations as in Figure 3.

changed. After gel filtration, the specific activity was not increased (0.5 nmol/min/mg of protein).

Most of the enzyme activity was retained on strong anion exchange columns (Econopac Q, Q-Sepharose FF) when dissolved ammonium sulfate precipitate was applied. The bound enzyme could be eluted with a gradient of 0–1 M NaCl. A chromatogram from a column with Q-Sepharose FF is illustrated in Figure 4. As shown by the insert in Figure 4, the fractions with 8*R*-dioxygenase in some experiments also contained hydroperoxide isomerase. The isomerase activity was not analyzed *per se*, but formation of [^{14}C]7*S*,8*S*-DiHODE from [^{14}C]linoleic acid or [^{14}C]8*R*-HPODE indicated its presence. Anion exchange chromatography was also associated with significant loss of enzyme activity. The specific activity was not determined.

Isoelectric focusing of active fractions from gel filtration was performed in the presence of 20% ethylene glycol. About 5 mg of protein could be loaded without significant protein precipitation. The apparent isoelectric point of 8*R*-dioxygenase was about pI 6.1 to 6.3, as judged from refocusing. The active fractions from the isoelectric focusing appeared to be without hydroperoxide isomerase activity. Other fractions were not checked for isomerase activity. SDS–PAGE showed that the active fractions from isoelectric focusing were not homogeneous. Isoelectric focusing led to a major loss of enzyme activity. The specific activity was not determined.

Inhibition of linoleic acid 8R-dioxygenase by linoleic acid and by drugs. Many lipoxygenases are inactivated by their products (21). We investigated whether 8*R*-dioxygenase exhibited this phenomenon. Unlabeled linoleic acid (0.1 mM) was first added to the cytosol (0.3 mL) and incubated for 1 h. Radiolabeled linoleic acid (0.1 μCi) was then added, and the samples were further incubated for 1 h. The controls were preincubated without substrate for 1 h, and the two substrates were then added and incubated for 1 h.

Preincubation of the cytosol with 0.1 mM linoleic acid for 1 h on ice led to loss of enzyme activity. The conversion of the radiolabeled substrate with the preincubated cytosol was 53 ± 4% (SD, n = 4) vs. 100 ± 5% in the control (n = 4). In the presence of 1 mM GSH, the corresponding figures were 48 ± 7% (n = 6) vs. 100 ± 6% (n = 6) in the control. Preincubation with linoleic acid thus reduced the enzyme activity to half, and GSH had no stabilizing effect during this short time period.

Preliminary experiments showed that 8*R*-dioxygenase was inhibited dose-dependently by paracetamol and by ICI 230,487. In the presence of 30 μM of paracetamol the 8*R*-dioxygenase activity was 56 ± 9% (SD, n = 7). In the presence of 30 μM of ICI 230,487 the dioxygenase activity was 42 ± 7% (n = 5) of the controls (100 ± 7%, n = 11). For comparison, another lipoxygenase inhibitor, BW A4C, caused over 90% inhibition of this preparation at 3 μM (*cf.* Ref. 12).

Preparation of 8R-HPODE. Incubation of the cytosol with linoleic acid usually led to formation of 8*R*-HODE as the

main product rather than 8*R*-HPODE. In the presence of 1 mM *p*-hydroxymercuribenzoate, the yield of 8*R*-HPODE increased. Under these conditions, ^{14}C-labeled linoleic acid was converted to ^{14}C-labeled 8*R*-HPODE as the major product as shown on the TLC chromatogram in Figure 5A. Alternatively, 8*R*-HPODE was prepared by incubation of linoleic with 8*R*-dioxygenase that had been partly purified by anion exchange chromatography. In the latter case, TLC afforded 18:2, 8*R*-HPODE and 8*R*-HODE in a ratio of 1:2:1.

Properties of hydroperoxide isomerase. The microsomal fraction of the mycelia contained relatively little 8*R*-dioxygenase, but a prominent hydroperoxide isomerase activity. Incubation of the microsomal fraction with [^{14}C]linoleic acid led to conversion of the substrate to one major, polar metabolite with little accumulation of 8*R*-H(P)ODE. The structure of this metabolite was confirmed by GC/MS to be 7*S*,8*S*-DiHODE [analyzed as the $(CH_3)_3Si$ ether methyl ester derivative]. The C value was 20.9, and the mass spectrum was identical with that previously reported for 7*S*,8*S*-DiHODE (9). Incubation of [^{14}C]8*R*-HPODE with the microsomal fraction resulted in biosynthesis of [^{14}C]7*S*,8*S*-DiHODE as the major product as judged from RP–HPLC (Fig. 5B). No conversion was noted by heat-inactivated preparations (2 min in boiling water). Hydroperoxide isomerase activity was also found in some preparations of cytosol as previously reported (9,12). Neither CO nor ketoconazole (100 μM) inhibited the microsomal metabolism of [^{14}C]8*R*-HPODE to [^{14}C]7*S*,8*S*-DiHODE.

As shown by Figure 5C, [^{14}C]8*R*-HPODE was rapidly converted to [^{14}C]7*S*,8*S*-DiHODE. The effect of pH on the isomerase activity is shown by the insert in Figure 5C. The isomerase appeared to have a broad pH optimum with the enzyme being active between pH 7 and 10.

The methyl ester of [^{14}C]8*R*-HPODE was also investigated as a substrate. TLC showed that the methyl ester was partly converted to [^{14}C]7*S*,8*S*-DiHODE methyl ester (product and substrate in a ratio of about 1:3), while the free acid was converted more efficiently by the microsomes under the same conditions [7*S*,8*S*-DiHODE and 8*R*-H(P)ODE in a 2:1 ratio]. These results suggested that the methyl ester of 8*R*-HPODE was a rather poor substrate for the isomerase. Finally, [^{14}C]9*S*-HPODE was not metabolized to diols by the microsomes.

P450 in microsomal and cytosolic fractions. Both the cytosolic and the microsomal fractions metabolized radiolabeled arachidonic acid and eicosapentaenoic acid in the presence of 1 mM NADPH to polar products. Only small amounts of products were formed without this cofactor. TLC analysis indicated that arachidonic acid was metabolized to 18*R*- and 19*R*-hydroxy-5*Z*,8*Z*,11*Z*,14*Z*-eicosatetraenoic acids in a 2:3 ratio. Eicosapentaenoic acid was mainly metabolized to a more polar product than these hydroxy fatty acids (presumably 17,18-dihydroxy-5*Z*,8*Z*,11*Z*,14*Z*-eicosatetraenoic acid, *cf.* Refs. 8,17). The P450-catalyzed oxygenation of arachidonic acid was about eight times greater per mg of protein in the microsomal fraction than in the cytosol. However, sonication of washed microsomes and recentrifugation appeared to increase the enzyme activity in the supernatant about four times.

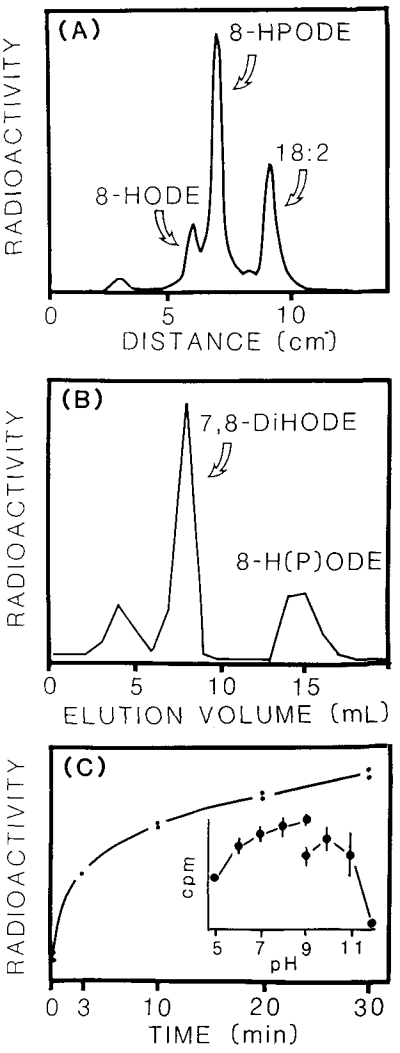

FIG. 5. Isolation and metabolism of 8*R*-HPODE. A, TLC analysis of an incubation of cytosol (10 mg protein) with [^{14}C]linoleic acid (7 μCi, 37 μg) and 1 mM *p*-hydroxymercuribenzoate (see text for details). The main peak of material corresponded to [^{14}C]8*R*-HPODE. B, reversed-phase high-performance liquid chromatography analysis of products from an incubation of [^{14}C]8*R*-HPODE (2 nCi, 10 ng) with microsomes of mycelia of *Gaeumannomyces graminis* (0.2 mg protein). C. Time curve for the formation of [^{14}C]7*S*,8*S*-DiHODE from [^{14}C]8*R*-HPODE (2 nCi, 10 ng) by microsomes of mycelia (0.2 mg protein). DISCUSSION

The present report shows that the linoleic acid 8*R*-dioxygenase and hydroperoxide isomerase activities can be separated by differential centrifugation, by ammonium sulfate precipitation and by gel filtration chromatography. The 8*R*-dioxygenase is present mainly in the cytosol and the hydroperoxide isomerase in the microsomal fractions. The isomerase is more sensitive to salting out by ammonium sulfate than the 8*R*-

dioxygenase, and the activities can be partially separated by this method. Furthermore, the 8*R*-dioxygenase activity is retained somewhat on a gel filtration column relative to the isomerase activity and the bulk proteins.

The purification of 8*R*-dioxygenase was not straightforward due to its instability. Many lipoxygenases share this feature (22,23). The reason for loss of enzyme activity is unknown, but proteolysis and loss of the catalytic iron after exposure to oxygen in the absence of reducing agents have been implicated. Some lipoxygenases are therefore purified under anaerobic conditions. We tried to purify 8*R*-dioxygenase under partly anaerobic conditions in preliminary experiments, but the yield did not improve. Many lipoxygenases (21) can be inactivated by their products, possibly *via* formation of peroxyl radicals. The latter can be reduced to inert alcohols by GSH, other reducing agents and glutathione peroxidase. Incubation of the 8*R*-dioxygenase with 0.1 mM linoleic acid also resulted in loss of enzyme activity (Fig. 5). We found that GSH improved the stability of 8*R*-dioxygenase significantly, while two other reducing agents, dithiothreitol and β-mercaptoethanol, were previously found to inhibit the enzyme (12). Glutathione peroxidase also partly stabilized the cytosolic linoleic acid 8*R*-dioxygenase, while superoxide dismutase had little beneficial effect (Fig. 1). It may be added that recombinant 5-lipoxygenase was found to be stabilized in the presence of glutathione peroxidase and superoxide dismutase (24).

8*R*-Dioxygenase could be partially purified by ultracentrifugation, ammonium sulfate precipitation, gel filtration, ion exchange chromatography and isoelectric focusing. The recovery after ammonium sulfate precipitation was reasonable (75%), but the specific activity was almost unchanged. During gel filtration, the main enzyme activity eluted with the front and with only some retention relative to the void volume. Formation of protein aggregates may occur during gel filtration. This step was therefore performed in the presence of 20% ethylene glycol (20). However, SDS–PAGE and gel filtration in the presence of 4 M urea showed that aggregates of proteins nevertheless were present. Since it cannot be excluded that the 8*R*-dioxygenase eluted in aggregates, the molecular weight could not be estimated from gel filtration.

Preparative-scale isoelectric focusing was described as a very efficient step for purification of rabbit reticulocyte 15-lipoxygenase (22). In our hands, the method was complicated by protein precipitation even with the addition of 20% ethylene glycol and could only be used for analytical purposes. Under the conditions used, the 8*R*-dioxygenase showed an isoelectric point between pI 6.1–6.3.

Isoelectric focusing as well as anion exchange chromatography were associated with loss of enzyme activity. It seemed possible that proteolysis may explain the rather low yield of 8*R*-dioxygenase during these purification steps. Unfortunately, linoleic acid 8*R*-dioxygenase was found to be inhibited by common serine protease inhibitors, e.g., by mM concentrations of 4-aminobenzamidine and TCPK. Phenylmethanesulfonyl fluoride also inhibits 8*R*-dioxygenase (12). EDTA was the only protease inhibitor which enhanced the stability of the dioxygenase. Stabilizing agents in addition to EDTA, GSH and GSH peroxidase should be helpful for further purification.

8*R*-Dioxygenase was recently found to be inhibited by some 5-lipoxygenase inhibitors. In this report, we investigated the effects of paracetamol and ICI 230,487, a hydroxamic acid derivative, on the 8*R*-dioxygenase. Both drugs appeared to be equally potent with an IC_{50} of about 30 μM. The effect of paracetamol appeared to be dose-dependent and occurred within the clinical concentration (about 60 μM; Ref. 25). The inhibition caused by paracetamol is of interest since the mechanism of its analgesic actions is largely unknown (25). It may therefore be of interest to determine whether 8*R*-dioxygenase-like enzymes occur in mammals.

Many P450 enzymes catalyze hydroxylations with suprafacial hydrogen abstraction and oxygen insertion and can use hydroperoxides as oxygen donors (11,26,27). The microsomal hydroperoxide isomerase converted radiolabeled 8*R*-HPODE to 7*S*,8*S*-DiHODE. Like P450, it showed a suprafacial relationship of hydrogen abstraction and oxygen insertion which may indicate that the isomerase could be related to P450 (11). On the other hand, it was neither inhibited by carbon monoxide nor by ketoconazole. The microsomal fraction also contained a putative P450, which catalyzed ω2 and ω3 hydroxylation of arachidonic acid and ω3 epoxygenation of eicosapentaenoic acid. This enzyme was previously found in the cytosol and was NADPH-dependent (8).

The physiological functions of 8*R*-HODE, 8*R*-HPODE and 7*S*,8*S*-DiHODE are unknown, but it is possible that these oxylipins may have biological activity. Racemic 8*R*-HODE has been found to induce hyphal lysis of some fungi (28). In pursuit of a signal substance that induced sexual sporulation, 8*R*-HODE was detected in a mutant of the fungus *Aspergillus nidulans* and found to induce premature sexual sporulation (29,30). Interestingly, 5*S*,8*R*-dihydroxylinoleic acid was also identified as a metabolite of *A. nidulans* with a similar biological effect. It will be interesting to determine whether this compound is derived from 8*R*-HPODE.

Recently, a novel linoleic acid ω6-lipoxygenase of infected rice was sequenced by methods based on the sequence homology of lipoxygenases (31). Sequences of at least 14 different plant and mammalian lipoxygenases thus display, *inter alia,* a characteristic motif of 38 amino acids, including four conserved histidines within and one histidine outside this motif (3,4,32). If linoleic acid 8*R*-dioxygenase contains this homologous region, it is possible that the enzyme might be cloned and sequenced in analogy with the rice lipoxygenase. Otherwise, the purification of 8*R*-dioxygenase must be pursued in order to obtain a pure enzyme, which can be used as a starting point for cloning methods. *Gaeumannomyces graminis* grows rapidly and contains large amounts of 8*R*-dioxygenase that can be stabilized as described here. The present study provides a basis for further purification and structural characterization of the 8*R*-dioxygenase for comparison with lipoxygenases and other dioxygenases.

ABSTRACT: The aim of this investigation was to determine whether chain-breaking antioxidants able to prevent lipid peroxidation can inhibit lipoxygenase-1 (EC 1.13.11.12). Therefore, the effects of ascorbic acid, 6-palmitoylascorbic acid and trolox on the enzyme activity were analyzed by means of Lineweaver–Burk double reciprocal plots and Yoshino's graphical method. The effect of these compounds on the formation of free radicals during lipoxygenase-1 reaction was investigated as well, by monitoring the enzymic formation of oxodienes. We present evidence that the chain-breaking antioxidants ascorbic acid, 6-palmitoylascorbic acid and trolox inhibit soybean lipoxygenase-1 in the micromolar concentration range (Ki 27, 3 and 18 μM, respectively). The inhibition is competitive, complete and reversible. All three compounds trap the free radicals formed during the lipoxygenase-catalyzed reaction, which might substantially contribute to their inhibitory ability. These findings can have physiological significance in the light of the lipoxygenase involvement in biomembrane remodelling.
Lipids 30, 51–54 (1995).

Lipoxygenases (linoleate:oxygen oxidoreductase, EC 1.13.11.12) are nonheme, nonsulfur–iron dioxygenases which act on fatty acids containing one or more 1,4-*Z,Z*-pentadiene moieties to form *Z,E*-conjugated hydroperoxides. Lipoxygenases from both animal and plant tissues have been purified and characterized (*cf.* Refs. 1–3 for reviews). These enzymes play several physiological roles (1–3), in particular the product hydroperoxides are precursors of specific regulatory molecules, such as leukotrienes and lipoxins in animals (3,4), and jasmonic acid and traumatin in plants (2,5). Since the discovery of the role of lipoxygenases in the biosynthesis of potent effectors critical in animal and plant physiology, extensive research was done to find efficient inhibitors of their activity. Most studies have used soybean lipoxygenase-1 (LOX), a homologue of mammalian lipoxygenases whose three-dimensional structure (6,7) and catalytic mechanism (8,9) have been characterized in detail. LOX activity is suppressed by several compounds, which act in different ways on the LOX-catalyzed reaction (10, 1). This paper describes the ability of the antioxidants ascorbic acid (12,13), 6-palmitoylascorbic acid (13) and trolox (a water-soluble analogue of α-tocopherol) (12) to competitively inhibit LOX activity. Keeping in mind the role of LOX in biomembrane alteration (14–16), it is suggested that chain-breaking antioxidants can protect cell membranes from lipid peroxidation (12,13,17) through the inhibition of the LOX-catalyzed oxygenation of polyenoic fatty acids.

Abbreviation: LOX, lipoxygenase-1.

MATERIALS AND METHODS

Chemicals were of the purest analytical grade. Linoleic acid, ascorbic acid and sodium dithionite were from Sigma (St. Louis, MO). 6-o-Palmitoyl-L-ascorbic acid was purchased from Fluka (Buchs, Switzerland) and trolox (6-hydroxy-2,5,7,8-tetramethylchroman-2-carboxylic acid) was from Janssen (Geel, Belgium).

LOX was purified from soybean [*Glycine max* (L.) Merrill, var. Williams] seeds according to Finazzi Agrò *et al.* (18). The purified enzyme showed a single band on sodium dodecyl sulfate–polyacrylamide gel electrophoresis and had a specific activity of 200 μmoles O_2.min^{-1}.mg $protein^{-1}$, assayed polarographically (19). In the inhibition experiments, LOX activity was determined spectrophotometrically by recording the formation of conjugated hydroperoxides at 234 nm (19). A stock solution of linoleic acid (30 μM), dissolved in 1% Tween-20 in water, was diluted to the appropriate final concentration in 0.1 M sodium phosphate buffer, pH 6.8, according to Lomnitski *et al.* (20). Dehydroascorbic acid was biosynthesized by incubating ascorbic acid with an excess of ascorbate oxidase, as reported Maccarrone *et al.* (21). The incubation mixture was filtered through centricon 30 microconcentrators (Amicon, Lexington, MA), in order to remove the enzyme molecules.

The effect of inhibitors on linoleic acid oxygenation by LOX was analyzed by Lineweaver–Burk double reciprocal plots (20). Enzyme inhibition was also analyzed by Yoshino's graphical method (22) in order to distinguish partial from complete inhibitors. We observed that the residual activity, when related to the activity in the absence of the inhibitor, was independent of the sequence of reagents addition. Therefore, the reaction was started by addition of the substrate (in the range 15–120 μM) to the reaction mixture containing 15 nM LOX and different inhibitor concentrations, namely 0–350 μM ascorbic acid, 0–35 μM 6-palmitoylascorbic acid, 0–50 μM trolox or 0–100 μM sodium dithionite. Reversibility of inhibition (11) was assessed by assaying residual LOX activity after dialysis of the enzyme/inhibitor mixtures (1 mL) against 0.1 M sodium phosphate buffer, pH 6.8 (100 mL), at 4°C. The pH dependence of LOX inhibition was determined as reported (20,23), using 90 μM linoleic acid and 15 nM LOX. Progress curves of the oxygenation of 30 μM linoleic acid catalyzed by 15 nM LOX were recorded by following the formation of the hydroperoxide products at 234 nm (19). Polarographic measurements of LOX activity (19) always confirmed the spectrophotometric data.

The effect of inhibitors on the formation of side products of linoleic acid oxygenation was assessed by following the formation of total oxodienes (i.e., 13-oxo-octadeca-9,11-dienoic plus 13-oxo-trideca-9,11-dienoic acids) at 285 nm (10,24). The standard reaction mixture contained 90 μM linoleic acid, 15 nM LOX and different amounts of inhibitors, in 0.1 M sodium phosphate buffer, pH 6.8. The data reported in this paper are the mean of three independent determinations (coefficient of variation <7%).

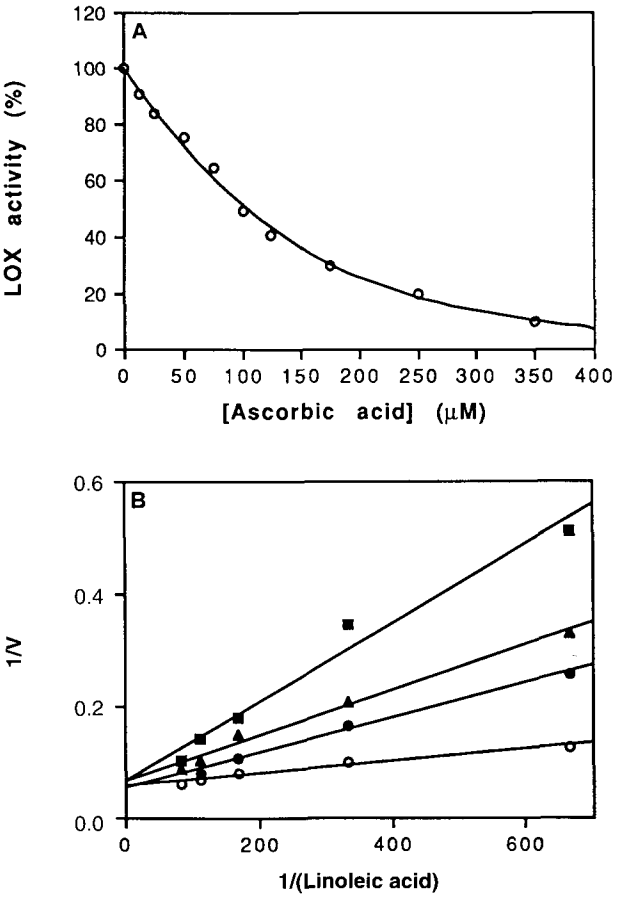

FIG. 1. A. Concentration-dependence of lipoxygenase-1 (LOX) inhibition by ascorbic acid. B. Lineweaver–Burk plots of linoleic acid oxygenation by LOX in the absence of inhibitors (open circles) or in the presence of 30 μM trolox (closed circles), 100 μM ascorbic acid (closed triangles) or 10 μM 6-palmitoylascorbic acid (closed squares). 1/V and 1/(Linoleic acid) values are expressed as $\mu M^{-1}.min$ and $\mu M^{-1} \times 10^4$, respectively.

RESULTS

Ascorbic acid suppressed LOX-catalyzed oxygenation of linoleic acid in a concentration-dependent manner (Fig. 1A). Double reciprocal plots for LOX in the presence and absence of ascorbic acid are shown in Figure 1B.

The Michaelis constant was found to be 19 μM for linoleate in the absence of inhibitor, a value which agrees well with previous determinations (8). Ascorbic acid proved to be a competitive inhibitor of LOX (Fig. 1B), its inhibition constant, Ki, being 27 μM. In order to ascertain whether ascorbic acid inhibition was complete or partial, Yoshino's fractional-velocity plot was drawn (22). This plot (not shown) was consistent with a complete competitive inhibition. Moreover, ascorbic acid acted as a reversible inhibitor, with LOX regaining full activity after four minutes of dialysis of enzyme/inhibitor mixtures (15 nM/100 μM) at 4°C. The ability of ascorbic acid to inhibit linoleic acid oxygenation by LOX was dependent on the pH of the reaction, increasing from pH 5.5 to pH 7.0, and then dropping down between pH 7.0 and 9.0 (Fig. 2A). Finally, ascorbic acid inhibited the formation of oxodienes during the LOX-catalyzed reaction in a concentration-dependent way (Fig. 2B).

The inhibition of oxodiene formation was greater than the inhibition of linoleic acid oxygenation (compare Fig. 1A with Fig. 2B). At variance with ascorbic acid, dehydroascorbic acid was unable to inhibit oxodiene formation and inhibited LOX activity to a lesser extent. In fact, 150 μM dehydroascorbic acid reduced linoleic acid oxygenation to 70% of the control value, compared to 38% obtained with 150 μM ascorbic acid. The same inhibition studies performed with ascorbic acid were done with the chain-breaking antioxidants 6-palmitoylascorbic acid and trolox. Both compounds were found to be complete, reversible and competitive inhibitors of LOX activity (Fig. 1B), Ki values being 3 and 18 μM, respectively (Table 1). Sodium dithionite, a nonspecific reductant, slowed down LOX-catalyzed reaction by acting as a noncompetitive inhibitor, with a Ki of 49 μM (Table 1).

Interestingly, sodium dithionite inhibition resulted in a lengthening of the lag phase (9,19) of linoleic acid oxygenation (Fig. 3A), at variance with ascorbic acid (Fig. 3B) and the other chain-breaking antioxidants (data not shown).

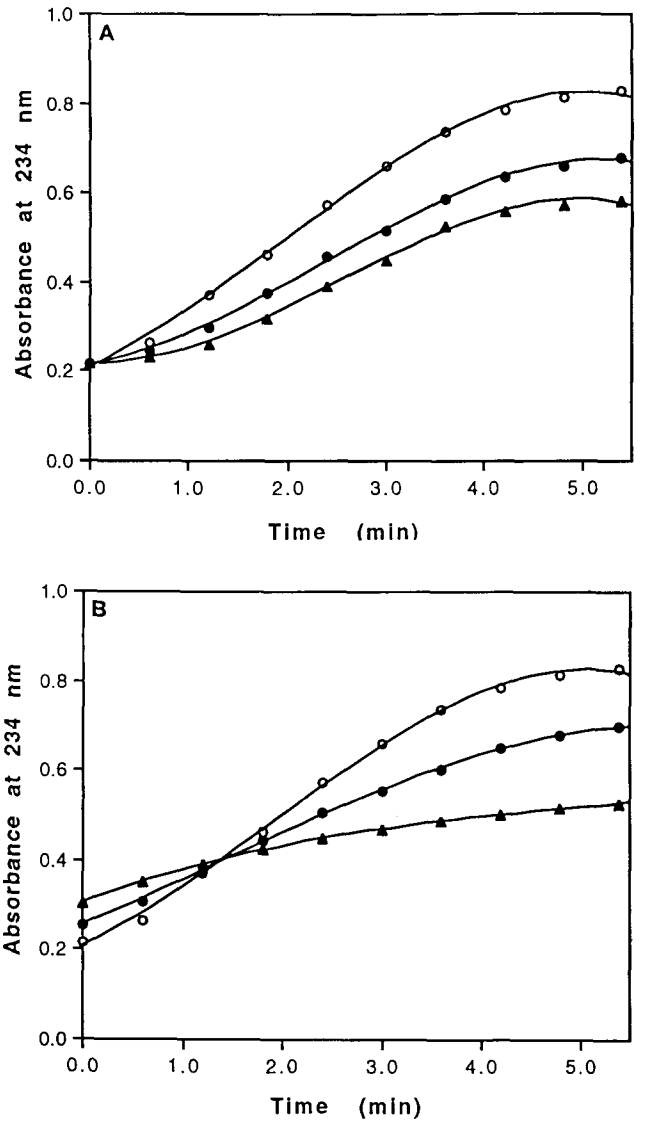

FIG. 3. A. Progress curves of LOX-catalyzed reaction, in the absence (open circles) or in the presence of 25 μM (closed circles) and 50 μM (closed triangles) sodium dithionite. B. Progress curves of LOX reaction in the absence (open circles) or in the presence of 50 μM (closed circles) and 100 μM (closed triangles) ascorbic acid. Abbreviation as in Figure 1.

TABLE 1
Inhibition of Lipoxygenase-1 by Chain-Breaking Antioxidants and Sodium Dithionite

Inhibitor	Inhibition type	Inhibition constant (Ki, μM)
Ascorbic acid	Competitive	27
6-Palmitoylascorbic acid	Competitive	3
Trolox	Competitive	18
Sodium dithionite	Noncompetitive	49

DISCUSSION

Oxygenation of linoleic acid catalyzed by soybean LOX is most effective at pH 9.0–10.0 (8,19). However, there was no inhibition of LOX under alkaline conditions (Fig. 2A). Conformational changes in the enzyme molecule might be responsible for the pH dependency of inhibition, a finding already reported for LOX (20,25). Therefore, experiments were performed at pH 6.8, where LOX retained high activity (26) and maximal inhibition was observed (Fig. 2A).

Several studies on soybean LOX showed that inhibitors can act through a number of mechanisms, e.g., by binding to sites other than the active site of the enzyme molecule (20), by preventing the formation of the activated Fe(III) form of LOX (27) or by reducing the catalytically active ferric enzyme to its inactive ferrous form through the formation of free radical metabolites (26). Here, ascorbic acid, 6-palmitoylascorbic acid and trolox are shown to act as competitive, complete and reversible inhibitors of LOX. Unlike other antioxidant inhibitors of LOX (26), the compounds under study did not reduce Fe(III) to inactive Fe(II), in fact the lag phase of the reaction (Fig. 3B) was not prolonged (9,10,19). Electron paramagnetic resonance spectroscopy (not shown) confirmed this finding, clearly indicating the lack of radical formation from the inhibitor molecules during LOX inhibition. At variance with the chain-breaking antioxidants, sodium dithionite acted as a noncompetitive inhibitor and caused a lengthening

of the lag phase of the reaction (Fig. 3A). This is consistent with sodium dithionite being a nonspecific reductant, which turns LOX into the inactive Fe(II) form (27). It can be suggested that the chain-breaking antioxidants might interact with the interior of the "funnel" leading to the active site (6), because enhancing the lipophilicity of the inhibitor made it more effective (Table 1). This hypothesis is in line with previous work on the competitive inhibition of LOX by *n*-alcohols, where longer alkyl chains were shown to increase the affinity of these compounds for the enzyme (28). Furthermore, ascorbic acid, 6-palmitoylascorbic acid and trolox are powerful radical-trapping antioxidants (12,13). Ascorbic acid strongly suppressed the formation of oxodienes (Fig. 2B), side products of linoleic acid oxidation which are indicative of the dissociation of free radicals from the active site (10,24). The same was found with 6-palmitoylascorbic acid and trolox (data not shown). These results suggest that the inhibitors can trap the radical intermediates escaping from LOX after hydrogen abstraction from linoleic acid, before enzymic oxygen insertion has occurred (8,10). Such radical-trapping ability might substantially contribute to the inhibition power of the compounds, as suggested also by the pH dependence (Fig. 2A). In fact, at neutral pH values, LOX produces more radicals than at pH 9.0, and trapping of these radicals, together with conformational changes of the enzyme (20), might improve LOX inhibition. The hypothesis that both hindrance of the active site and trapping of free radicals can contribute to LOX inhibition is also corroborated by the experiments with dehydroascorbic acid. The oxidized form of ascorbic acid was unable to reduce oxodiene formation (i.e., to trap radical intermediates), which resulted in a weaker inhibition of the LOX-catalyzed reaction. Finally, it seems noteworthy that trolox acted as competitive inhibitor of soybean LOX, at variance with its water-insoluble analogue α-tocopherol which inhibited the enzyme in a noncompetitive way (20). This difference resembles that of other compounds, e.g., retinol and β-carotene (20), and can be attributed to the different polarity of the two molecules.

In conclusion, evidence is presented that ascorbic acid, 6-palmitoylascorbic acid and trolox act as competitive inhibitors of soybean LOX. Thus, the effects of these chain-breaking antioxidants in protecting cell membranes by preventing lipid peroxidation can occur through the formation of an inactive complex with LOX, besides the trapping of free radicals. These results might have physiological significance in the light of lipoxygenase involvement in biomembrane alteration, both in animals (14) and in plants (15,16).

A Microsomal Membrane Component Associated with Iron Reduction in NADPH-Supported Lipid Peroxidation

Yoshiko Tampo and Masanori Yonaha*

Division of Environmental Hygiene, Hokkaido Institute of Pharmaceutical Sciences, Otaru, Hokkaido 047-02, Japan

ABSTRACT: This study was conducted to determine whether a factor responsible for reduced nicotinamide adenine dinucleotide phosphate (NADPH)-supported lipid peroxidation in rat liver microsomes is involved in iron reduction by cooperation with NADPH-cytochrome P450 reductase. Under anaerobic conditions, NADPH-dependent reduction of ferric pyrophosphate in microsomes was not dependent on cytochrome P450 levels and was not inhibited by carbon monoxide (CO). All of the iron complexes with chelators such as adenosine 5′-diphosphate, pyrophosphate, nitrilotriacetate, oxalate or citrate were reduced in microsomes, although in the reconstituted system containing purified NADPH-cytochrome P450 reductase little or no iron reduction was found. A cytochrome P450-free fraction from a cholate-solubilized preparation of microsomes after passage through a laurate sepharose column was required for reduction of iron pyrophosphate in the reconstituted system leading to lipid peroxidation. The iron reduction was not inhibited by CO and was destroyed by heat treatment or trypsin digestion of the fraction. All iron complexes were reduced in the presence of the fraction, using a reducing equivalent of NADPH *via* NADPH-cytochrome P450 reductase. The results indicate that a heat-labile component, which is probably a protein distinct from cytochrome P450, is associated with iron reduction responsible for lipid peroxidation in microsomes.
Lipids 30, 55–62 (1995).

Lipid peroxidation in biomembranes is mediated by free radical reactions leading to membranous degeneration. Reduced nicotinamide adenine dinucleotide phosphate (NADPH)-supported lipid peroxidation occurs in subcellular fractions of various tissues and has been extensively studied in rat hepatic microsomes (1–7). The peroxidation system requires iron chelates with a chelator such as adenosine 5′-diphosphate (ADP) or pyrophosphate (PPi) (1,2). The involvement of NADPH-cytochrome P450 reductase in the NADPH-supported lipid peroxidation was shown with the use of antibodies (3,8). The reduction of the iron complex is believed to be associated with initiation of lipid peroxidation. In the microsomes, the Fe^{3+}-ADP reduction occurs on the addition of NADPH alone (9). However, Fe^{3+}-ADP is not capable of interaction with isolated NADPH-cytochrome P450 reductase, and no iron reduction and no NADPH oxidation occur in the absence of exogenous Fe^{3+}-ethylenediaminetetraacetate (EDTA) (10).

In microsomes, ferric cytochrome P450 has been proposed to function as a propagator of lipid peroxidation much as is Fe^{3+}-EDTA in the reconstituted system consisting of Fe^{3+}-EDTA, Fe^{3+}-ADP, purified NADPH-cytochrome P450 reductase, microsomal lipids and NADPH (4). Recently, some evidence has also been provided showing that cytochrome P450 functions as a O_2^- generator resulting in reduction of the iron complex in the reconstituted peroxidation system (11), or is directly involved in reduction of the iron complex mediated *via* NADPH-cytochrome P450 reductase (12,13). NADPH oxidation that was accompanied by reduction of ferric iron, such as Fe^{3+} without a chelator, Fe^{3+}-ADP, and Fe^{3+}-citrate, was inhibited by carbon monoxide (CO), indicating involvement of cytochrome P450 (14). In contrast, some reports indicated noninvolvement of cytochrome P450 in NADPH-supported lipid peroxidation in microsomes, not inhibited by CO (7,15,16). Moreover, a different enzyme other than cytochrome P450 for the peroxidation has been suggested (8,16). Although traces of the hemoprotein were contained in the fraction used in one study (17), the involvement of another factor instead of cytochrome P450 in lipid peroxidation has also been suggested.

In this study, the cholate-solubilized fraction of microsomes was subjected to a laurate sepharose column to remove cytochrome P450. We report that the partially purified fractions, distinct from cytochrome P450, caused lipid peroxidation by reducing iron complexes through NADPH-cytochrome P450 reductase.

MATERIALS AND METHODS

Materials. NADPH was purchased from Oriental Yeast Co., Ltd. (Tokyo, Japan), and 2-thiobarbituric acid and sodium cholate were obtained from E. Merck (Darmstadt, Germany) and Sigma Chemical Company (St. Louis, MO), respectively. Sodium cholate was washed with ethanol on a Buchner funnel to remove a yellow pigment prior to use. Bathophenanthroline disulfonic acid 2Na salt (BPT) was obtained from

Wako Pure Chemicals Ind. Ltd (Osaka, Japan). The L-α-phosphatidylcholine (β-arachidonoyl-γ-stearoyl), trypsin (bovine pancreas, Type I), trypsin inhibitor (soybean, Type II-s) and phenylmethylsulfonyl fluoride were purchased from Sigma Chemical Company. The levels of peroxides in phosphatidylcholine, estimated by iodometry (18), were less than 0.5 mol%. All other chemicals employed were of commercial reagent-grade quality. Fe^{3+} was used as $FeCl_3$. Fe^{3+}-nitrilotriacetate (NTA) was prepared by dissolving NTA in dilute NaOH and adjusting to pH 7 followed by dissolution of $FeCl_3$. The other ferric chelates were prepared by dissolving $FeCl_3$ and chelator in H_2O. Concentration of iron complexes was expressed as iron in all experiments.

NADPH-cytochrome P450-reductase and microsomal lipids. NADPH-cytochrome P450 reductase was purified from rat liver microsomes according to the method of Yasukochi and Masters (19). Microsomal lipids were extracted from liver microsomes as described previously (17).

Cholate-solubilized microsomal fraction. Male Sprague-Dawley rats weighing about 250 to 300 g were killed by decapitation; the livers were removed, perfused with ice-cold saline, and homogenized in 10 vol of 0.25 M sucrose containing 1 mM phenylmethylsulfonyl fluoride, a protease inhibitor. Microsomes were prepared by the calcium chloride aggregation method (20). The microsomal pellets from 4.5 g of livers were suspended by homogenizing in 45 mL of 0.15 M KCl containing 5 mM EDTA, and the suspension was centrifuged at 25,000 × *g* for 15 min. To remove EDTA and contaminated cytosol, the pellets were washed twice with 45 mL of 10 mM Tris-HCl buffer (pH 7.5) containing 0.15 M KCl and finally suspended in 50 mM Tris-HCl buffer (pH 7.5). Microsomal protein was estimated by the Biuret method (21). Differential solubilization of microsomes between 0.4 and 1.2% of sodium cholate was carried out as described previously (17), and the fraction was referred to as the cholate-cut fraction. Eight mL of the fraction was applied on a laurate AH-sepharose 4B column (1.5 × 21 cm) prepared by the method of Gibson and Schenkman (22), equilibrated with 5 mM sodium phosphate buffer (pH 7.5) containing 1.4% sodium cholate, 0.05 mM dithiothreitol and 20% (vol/vol) glycerol, and eluted with the equilibrating buffer. Protein in the eluates was measured by the method of Lowry *et al.* (23).

Preparation of lipid liposomes. All operations were carried out after purging with Ar, and sonication was done in ice-cold water. A solution of 3.5 mg microsomal lipids or phosphatidylcholine in chloroform was added to a small bottle, the chloroform removed, and the bottle sealed after inclusion of 1 mL of 0.1 M Tris-HCl buffer (pH 7.5) containing 0.25 M NaCl purged with Ar. The bottle was placed in a Bransonic bath, and the lipids were dispersed by sonication for 0.5 min. Then the suspension was transferred to a thin-walled polycarbonate tube (1.6 × 7.9 cm), sealed with parafilm, and sonicated for 3 min. Sonication was repeated once again to yield an opalescent liquid. The levels of peroxides in phosphatidylcholine liposomes after sonication were 1.5 ± 0.4 mol% (n = 6).

Lipid peroxidation. NADPH-supported phospholipid peroxidation in the reconstituted systems was conducted as follows: The incubation mixture consisted of an aliquot (80 μL/mL) of eluate, liposomes of microsomal lipids (0.5 mg/mL) or 50 μM phosphatidylcholine, NADPH-cytochrome P450 reductase (0.06 nmol/mL), 0.2 mM Fe^{3+}-PPi (1:0.9, mol/mol), 0.15 M KCl and 25 mM Tris-HCl buffer, pH 7.5. After a 2-min temperature equilibration at 37°C, the reaction was initiated by adding 0.1 mM NADPH and was run at 37°C. Oxygen consumption was measured in a 1.5 mL cell at 37°C with a Clark electrode in a YSI Model 5300 Biological Oxygen Monitor (Yellow Springs, OH) and was calibrated by the method of Misra and Fridovich (24). Thiobarbituric acid-reactive substances (TBARS) were quantified by the method of Ottolenghi (25), using the extinction coefficient at 535 nm of 156 $mM^{-1}cm^{-1}$(26), and were expressed in terms of malondialdehyde (MDA) production.

Reduction of iron complex. The incubation mixture contained iron complex, NADPH-cytochrome P450 reductase (0.06 nmol/mL), 0.1 mM NADPH, 0.15 M KCl, and 25 mM Tris-HCl buffer, pH 7.5. Reduction of iron was monitored by measuring an increase in absorbance at 534 nm on adding BPT (0.6 μmol) 20 s after the reaction was stopped with 0.1 mM *p*-chloromercuribenzoate. Ferrous was estimated using the extinction coefficient of 22,140 $M^{-1}cm^{-1}$ for Fe^{2+}-BPT (27).

Other assay. NADPH oxidation was monitored by measuring a decrease in absorbance at 340 nm at 37 °C. NADPH-cytochrome P450 reductase activity was measured using the extinction coefficient of 19.6 $mM^{-1}cm^{-1}$ of Yonetani (28). Cytochrome P450 and cytochrome b_5 were estimated by the methods of Omura and Sato (29) and Raw and Mahler (30), respectively.

RESULTS

Reduction of iron complexes in microsomes and by purified NADPH-cytochrome P450 reductase is shown in Table 1. In microsomes, all of the iron complexes were reduced, except Fe^{3+} without a chelator, consistent with the previous observation of little or no lipid peroxidation without chelator (2,7). Additionally, different reducibilities of iron complexes were found. No iron reduction of Fe^{3+}-ADP and Fe^{3+}-PPi occurred in the reconstituted system, which included the same levels of NADPH-cytochrome P450 reductase activity as that in microsomes, but Fe^{3+} without a chelator was reduced to some extent. Under the reconstituted conditions, Fe^{3+}-NTA, Fe^{3+}-citrate and Fe^{3+}-oxalate were also reduced, but these activities were much lower than those in the microsomes. In the presence of Fe^{3+}-NTA, the rates of lipid peroxidation for phosphatidylcholine liposomes in the reconstituted system were 44 ± 4 nmol O_2 /min/mL (oxygen consumption, n = 7) and 2.2 ± 0.5 nmol MDA/min/mL (TBARS production, n = 4), but Fe^{3+}-oxalate and Fe^{3+}-citrate showed little peroxidation activity (data not shown). Cholate treatment of microsomes diminished the cytochrome P450 content to 27% of the control, and

Reduction of Iron or Iron Complexes in Microsomes and in the Reconstituted System[a]

System	Iron complex	Iron reduction (nmol Fe^{2+}/min/mL incubation mixture)
Microsomes	Fe^{3+}	n.d.[b] (6)[c]
	Fe^{3+}-ADP (1:17)	5.1 ± 0.7 (5)
	Fe^{3+}-PPi (1:0.9)	3.6 ± 0.5 (5)
	Fe^{3+}-NTA (1:1.1)	12.4 ± 1.7 (6)
	Fe^{3+}-oxalate (1:5)	1.6 ± 0.3 (4)
	Fe^{3+}-citrate (1:5)	9.4 ± 1.3 (5)
Reconstituted	Fe^{3+}	0.5 ± 0.1 (4)
	Fe^{3+}-ADP (1:17)	n.d. (6)
	Fe^{3+}-PPi (1:0.9)	n.d. (6)
	Fe^{3+}-NTA (1:1.1)	1.1 ± 0.4 (3)
	Fe^{3+}-oxalate (1:5)	0.2 ± 0.0 (3)
	Fe^{3+}-citrate (1:5)	0.2 ± 0.0 (3)

[a]The incubation mixture contained microsomes (0.5 mg protein/mL) or reduced nicotinamide adenosine dinucleotide phosphate (NADPH)-cytochrome P450 reductase (0.06 nmol/mL) in the reconstituted system. All incubations contained 0.2 mM NADPH, 0.1 mM iron complex, 0.15 M KCl and 25 mM Tris-HCl buffer, pH 7.5 in a final volume of 1 mL. Iron reduction was measured as decribed in the Materials and Methods section. Data represent the means ± S.D. PPi, pyrophosphate; NTA, nitrilotriacetate; ADP, adenosine 5'-diphosphate.
[b]n.d., Not detected (lower than 0.05).
[c]The values in parentheses represent the number of determinations.

TABLE 2
Reduction of Fe^{3+}-PPi in Cholate-Treated Microsomes[a]

Treatment	Cytochrome P450 (nmol/mL incubation mixture)	Iron reduction) (nmol Fe^{2+}/min/mL incubation mixture)	
		Ar	CO
None	0.45 ± 0.01 (100)[b]	3.9 ± 0.3	3.9 ± 0.3
Cholate	0.12 ± 0.02 (27)	4.0 ± 0.3	3.9 ± 0.1
Cholate + glycerol	0.37 ± 0.03 (82)	4.1 ± 0.4	3.9 ± 0.2

[a]Aliquots of 20% sodium cholate were added to microsomes (20 mg/mL) suspended in 50 mM Tris-HCl buffer, pH 7.5, to yield a final concentration of 1.4% sodium cholate and 10 mg protein per mL, and the suspension was homogenized. The concentration of glycerol added was 20%. The incubation mixture contained 0.5 mg protein/mL, 0.2 mM NADPH, 0.1 mM Fe^{3+}-PPi (1:0.9, mol/mol), 0.15 M KCl and 25 mM Tris-HCl buffer (pH 7.5). Iron reduction was measured under a stream of Ar or CO, as described in the Materials and Methods section. Data represent the means ± S.D. of three determinations. Abbreviations as in Table 1; CO, carbon monoxide.
[b]The figures in parentheses indicate percent relative to "None."

the addition of glycerol reversed the content to 82% of the control (Table 2). Regardless of differences in the cytochrome P450 content in these microsomes, the reducing rates of Fe^{3+}-PPi under Ar were not altered, and no inhibition of the iron reduction by CO was observed. These findings strongly suggest that a component responsible for iron reduction, which is distinct from cytochrome P450 and exhibits different susceptibilities to CO, may be present in the microsomes.

The cholate-cut fraction of microsomes between 0.4 and 1.2% of sodium cholate was chromatographed on a laurate AH-sepharose 4B column, and the elution profile is given in

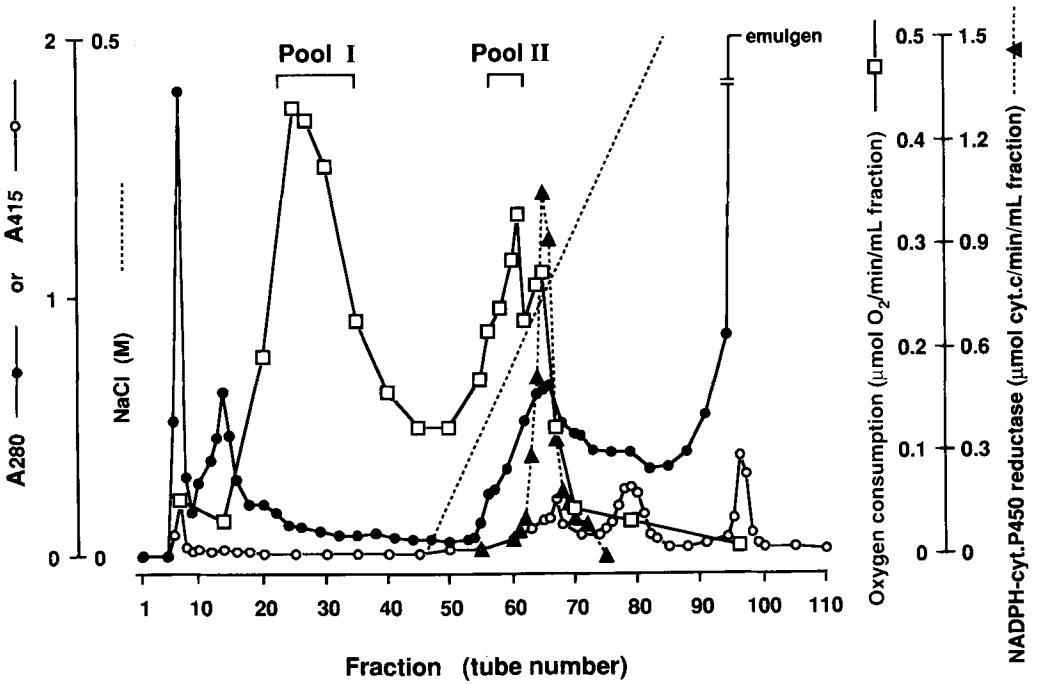

FIG. 1. Elution profile of the cholate-solubilized microsomes from a laurate AH-sepharose 4B column. Cholate solubilization of microsomes and laurate sepharose column chromatography were carried out as described in the Materials and Methods section. Volume of fractions was 3.4 mL. NADPH-supported lipid peroxidation was assayed in the reconstituted system containing 120 μL of eluate, 0.1 mM NADPH, 0.75 mg of microsomal lipid liposomes, 0.09 nmol NADPH-cytochrome P450 reductase, 0.2 mM Fe^{3+}-PPi (1:0.9), 0.15 M KCl and 25 mM Tris-HCl buffer, pH 7.5, in a final volume of 1.5 mL. Oxygen consumption was measured at 37°C. PPi, pyrophosphate; NADPH, reduced nicotinamide adenosine dinucleotide phosphate; Cyt.P450, cytochrome P450.

Fe^{3+}-oxalate (1:5)	0.7 ± 0.2 (3)
Fe^{3+}-citrate (1:5)	1.2 ± 0.2 (3)

[a]The incubation mixture contained 80 μL of pool I, 0.06 nmol NADPH-cytochrome P450 reductase, 0.2 mM NADPH, 0.1 mM iron complex, 0.15 M KCl and 25 mM Tris-HCl buffer, pH 7.5 in a final volume of 1 mL. Iron reduction was measured as described in the Materials and Methods section.
[b]The values in parentheses represent the number of determinations. Data represent the means ± S.D. Abbreviations as in Table 1.

Figure 1. An aliquot of each fraction was added to the reconstituted system consisting of microsomal lipids, Fe^{3+}-PPi, NADPH-cytochrome P450 reductase, and NADPH, and lipid peroxidation was monitored. The first peak (pool I) exhibiting the principal activity was eluted with the equilibrating buffer, and subsequently, a lesser activity (pool II) was eluted with a linear 0–0.5 M NaCl gradient in the equilibrating buffer. The active peak eluting later than pool II appears to be produced by contaminating NADPH-cytochrome P450 reductase in the fraction. The same result of active peaks was seen when microsomes were not washed with EDTA, suggesting that a removable metal is not involved. The column was finally treated with 5 mM sodium phosphate (pH 7.5), containing 20% glycerol, 0.8% (wt/vol) Emulgen 911 and 1 M NaCl. About 70% of the protein loaded on the column was eluted prior to treatment with the last buffer. Four peaks of absorption at 415 nm, indicative of heme proteins, appeared over the total elution. The first peak contained neither cytochrome P450 nor cytochrome b_5, the second peak and the fourth peak contained both cytochrome P450 and a minor amount of cytochrome P420, and the third peak contained cytochrome b_5. NADPH-cytochrome P450 reductase, cytochrome P450, and cytochrome b_5 were not detected in pool I, and pool I revealed high specific activities of both oxygen consumption and TBARS production in the reconstituted system and low concentration of protein as compared with those in pool II or in the cholate-cut fraction (Table 3).

In the presence of Fe^{3+}-PPi and NADPH-cytochrome P450 reductase, NADPH oxidation was greatly stimulated by the addition of pool I to the reaction medium (Fig. 2A) and was accompanied by autoxidation of the Fe^{2+}-PPi formed (Fig. 2C). After further inclusion of phosphatidylcholine, lipid peroxidation monitored by O_2 consumption and TBARS production was highly promoted (Fig. 2D), but NADPH oxidation was not stimulated at all (Fig. 2B). After a 10-min incubation, the NADPH oxidation was somewhat reduced (Fig. 2B). This decrease may be due to partial inactivation of NADPH-cytochrome P450 reductase and/or a component in pool I by radicals generated during lipid peroxidation.

Phospholipid peroxidation activity of pool I completely disappeared on heat treatment at 90°C for 10 min and on trypsin digestion but not by treatment with heated trypsin (data not shown). Also, full phospholipid peroxidation occurred with trypsin in the presence of trypsin inhibitor. The result shows that a component exhibiting phospholipid peroxidation activity in pool I may be a heat-labile protein, in accord with the results of lipid peroxidation in microsomes and in the reconstituted system employing the fraction eluted from the Sephadex G-150 column (17).

Fe^{3+}-PPi was linearly reduced under a stream of Ar in the presence of NADPH-cytochrome P450 reductase, pool I, and NADPH, but the reduction was not caused without the addition of pool I (Fig. 3A). Reduced iron was not detected under air at all (data not shown). The iron reduction under Ar showed a dose-related response with an increase in added pool I, and the response was similarly observed under CO (Fig. 3B). Pool I was not replaced by the buffer employed in elution of pool I to reduce iron. Heat treatment and trypsin digestion of pool I caused no iron reduction. As compared with the reducing rates in the absence of pool I (Table 1), the addition of pool I enhanced Fe^{3+} reduction with or without chelators (Table 4).

DISCUSSION

Végh *et al.* (9) demonstrated iron reduction in microsomes in the reaction medium evacuated with Ar and suggested that the integrity of microsomal membranes was essential to NADPH-cytochrome P450 reductase activity to reduce ADP-Fe^{3+}, because the activity was greatly decreased by detergents. Cytochrome P450 has been proposed by some investi-

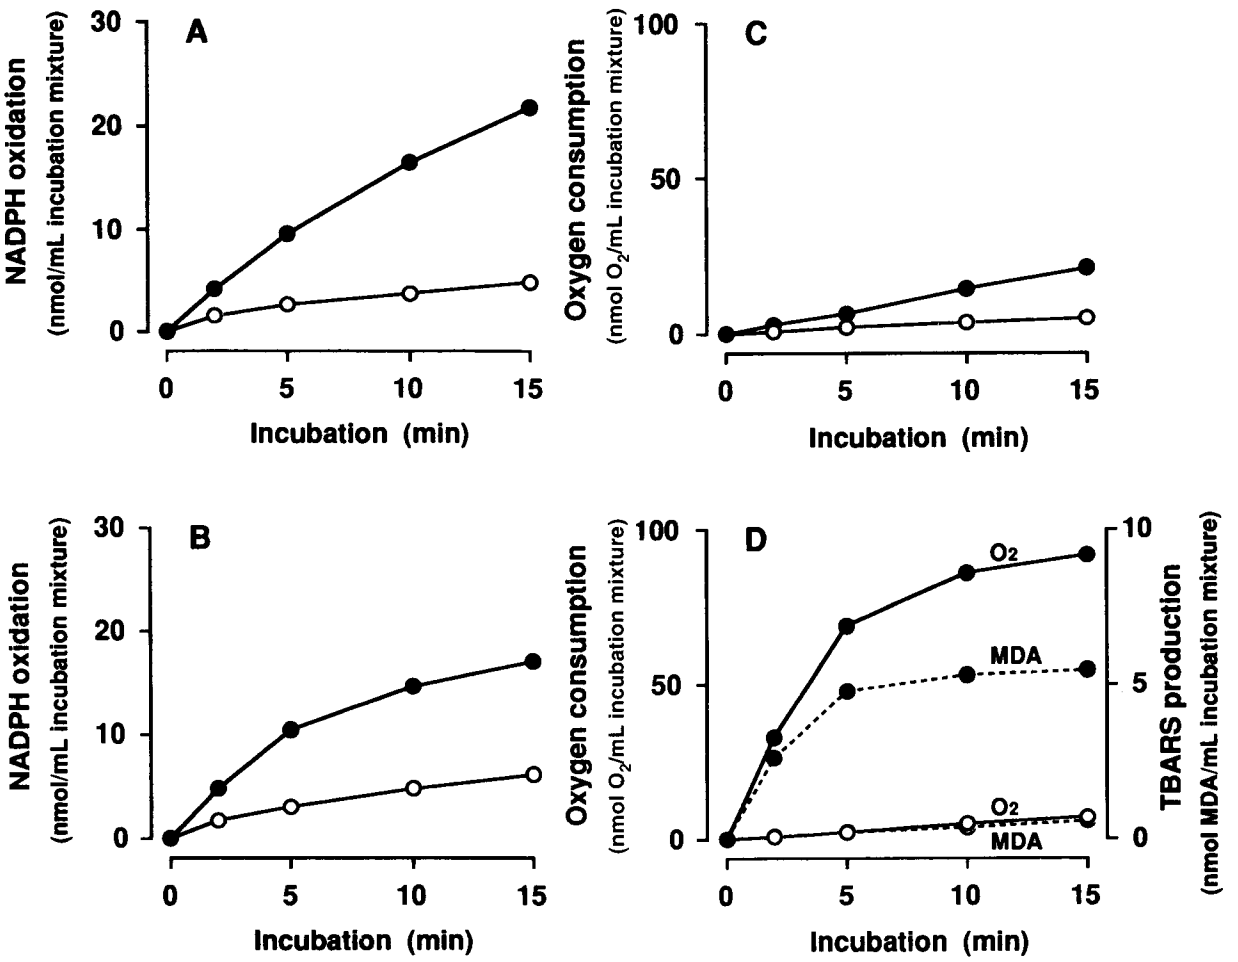

FIG. 2. NADPH oxidation and phospholipid peroxidation in the reconstituted systems. Complete incubation system contained 120 μL of pool I, 50-μM phosphatidylcholine liposomes, 0.1 mM NADPH, 0.09 nmol NADPH-cytochrome P450 reductase, 0.2 mM Fe^{3+}-PPi (1:0.9), 0.15 M KCl and 25 mM Tris-HCl buffer, p H 7.5, in a final volume of 1.5 mL. NADPH oxidation, oxygen consumption and malondialdehyde (MDA) production were assayed at 37°C as described in the Materials and Methods section. A and C, without phosphatidylcholine; B and D, with phosphatidylcholine. Data represent the means of four determinations for NADPH oxidation and the means of six determinations for oxygen consumption. ●, in the presence of pool I; ○, in the absence of pool I. TBARS, thiobarbituric acid-reactive substances; other abbreviations as in Figure 1.

gators (12,13) to be involved in iron reduction accompanied by lipid peroxidation in microsomes. Vile and Winterbourn (14) reported that NADPH oxidation in the presence of Fe^{3+} or Fe^{3+}-ADP at low levels in microsomes was inhibited by CO and the inhibition was reversed by an increase in added iron leading to competition with cytochrome P450 and suggesting involvement of the hemoprotein in the iron reduction. In the current study, iron reduction of Fe^{3+}-PPi in microsomes was not inhibited by CO and not influenced by alteration of cytochrome P450 content modulated by cholate and glycerol in microsomes. Thus, the direct assay of reduced iron appears to indicate no involvement of cytochrome P450.

Based on a study using the active fraction of lipid peroxidation in the reconstituted system, it has been demonstrated that NADPH-dependent iron reduction requires a component in pool I in the presence of NADPH-cytochrome P450 reductase. Some investigators (11-13) have studied the involvement of cytochrome P450 in phospholipid peroxidation in the reconstituted system composed of the iron complex, phospholipid liposomes, NADPH-cytochrome P450 reductase and NADPH; they added approximately 0.3 nmol cytochrome P450 to 1 mL of the reaction mixtures. The current assay of phospholipid peroxidation in the reconstituted system was conducted by the addition of 80 μL of pool I per mL of the reaction mixture. Since the detection limit of cytochrome P450 was 0.05 nmol per mL of pool I, the hemoprotein content corresponded to 0.004 nmol even at the maximum level in 1 mL of incubation mixture. Accordingly, even if present, the cytochrome P450 in the incubation mixtures is too low to promote lipid peroxidation.

Under a stream of Ar, purified NADPH-cytochrome P450 reductase alone could not reduce Fe^{3+}-PPi, in agreement with the result for Fe^{3+}-ADP described by others (10). Further addition of pool I, which was separated by a laurate sepharose column from cytochrome P450 and NADPH-cytochrome P450 reductase, was capable of reducing Fe^{3+}-PPi. The re-

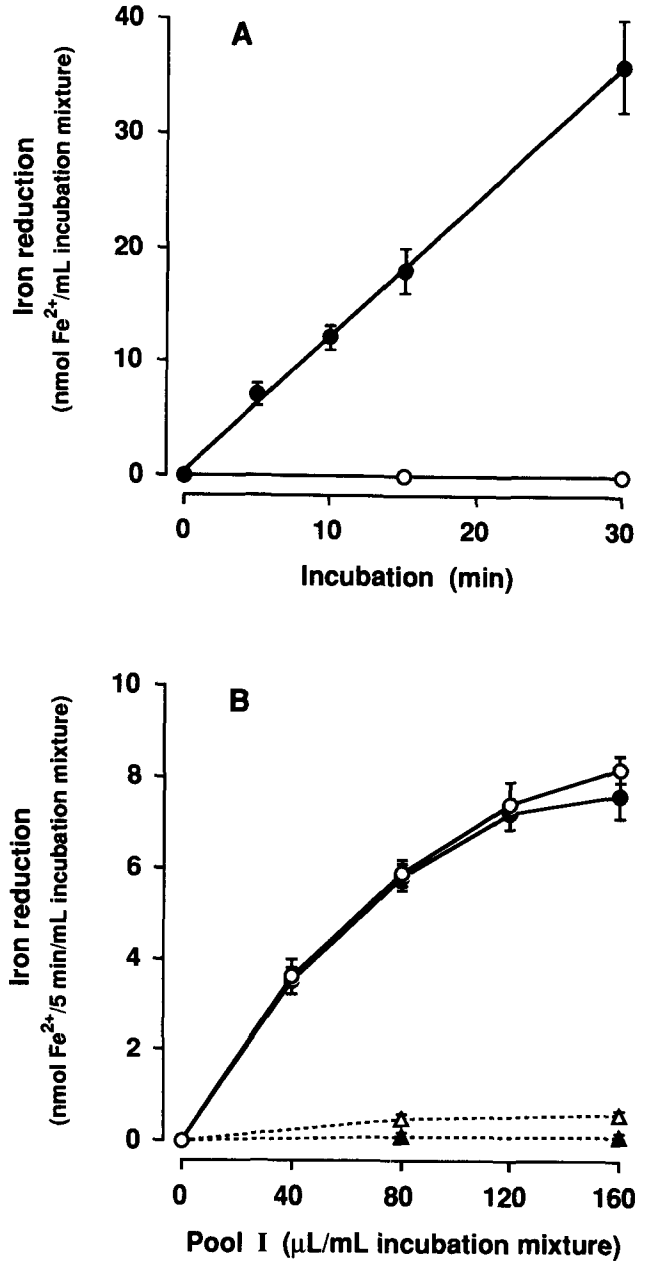

FIG. 3. Iron reduction under anaerobic conditions in the reconstituted systems. Complete system contained 80 μL of pool I, 0.1 mM NADPH, 0.06 nmol NADPH-cytochrome P450 reductase, 0.2 mM Fe^{3+}-pyrophosphate (1:0.9), 0.15 M KCl and 25 mM Tris-HCl buffer, pH 7.5, in a final volume of 1 mL. Heat treatment of pool I was carried out at 90°C for 10 min. Treatment of pool I (300 μL) with trypsin (5 μg) was conducted at 30°C for 25 min and stopped by adding trypsin inhibitor (10 μg). Iron reduction was measured as described in the Materials and Methods section. Data represent the means ± SD of four determinations. A, Time course under Ar. ●, complete system; ○, without Pool I. B, Dose response of pool I on iron reduction. ○, under Ar (pool I); ●, under carbon monoxide (CO) (pool I); △, (under Ar) trypsin digested pool I; ▲, (under Ar) heated pool I or the buffer employed in elution of pool I. Abbreviation as in Figure 1.

ducing activity of Fe^{3+}-PPi was destroyed by heat treatment or trypsin digestion of pool I and was not influenced by CO. The peroxidizing activity of pool I in the reconstituted system was also eliminated by heat treatment or trypsin digestion. These results indicate that a component in pool I is probably a protein, but clearly obviate the involvement of cytochrome P450 in iron reduction and phospholipid peroxidation in a NADPH-supported reconstituted system. The component in pool I was concentrated to about 8.5 times with cellulose acetate membrane (Ultracent-30; Tosoh Co. Ltd., Tokyo, Japan) (data not shown). The nature of the partially purified component has not been further determined. On the other hand, there are many enzymes in liver microsomes, other than cytochrome P450, which require NADPH-cytochrome P450 reductase and NADPH to function, e.g., cytochrome b_5 (31), fatty acyl coenzyme A desaturases (32), fatty acid elongase (33), homeoxygenase (34) or squalene epoxidase (35). However, no cytochrome b_5 was detected in pool I. Furthermore, since some of the above enzymes are solubilized with a detergent, such as deoxycholate (32) or Triton X-100 (35), without the loss of the enzyme activity, their possible involvement in iron reduction and phospholipid peroxidation may be excluded. For NADPH-dependent lipid peroxidation, the detergents are inhibitory in concentrations as low as 0.03% (36). Phospholipase A has been suggested to be involved at some stage in the alloxan- or copper-induced propagation of lipid peroxidation in rat liver microsomes (37). However, it has been shown that lipid peroxidation, catalyzed by a purified microsomal preparation in the presence of NADPH-cytochrome P450 reductase, NADPH and Fe^{3+}-PPi, was inhibited by *p*-bromophenacyl bromide, but inhibition of phospholipase A_2 required other reagents for inhibition (17). Thus, from the inhibitory effect of *p*-bromophenacyl bromide, it is conceivable that one or more nucleophilic functional group was involved.

The inclusion of *o*-phenanthroline or EDTA in the system containing NADPH-cytochrome P450 reductase and Fe^{3+}-ADP greatly stimulates NADPH oxidation which suggests iron reduction, although the absence of these chelators causes only a very slow rate of oxidation (38). The effect of these chelators is considered to be due to a newly formed iron chelate, which is an acceptable reducing equivalent *via* NADPH-cytochrome P450 reductase through NADPH. In the present experiments, free Fe^{3+} was poorly reduced in the system containing NADPH and NADPH-cytochrome P450 reductase, but under the conditions, Fe^{3+}-NTA was reduced highly to promote lipid peroxidation, whereas other chelators abolished or diminished the reducing rates of iron (Table 1). Thus, it appears that the effect of chelators on iron reduction causes production of the specific form of iron complex for interaction with the reductase. For instance, in the presence of NADPH-cytochrome P450 reductase and NADPH, Fe^{3+}-PPi or Fe^{3+}-ADP is markedly reduced in the presence of EDTA, to give rise to PPi (or ADP)-Fe^{3+}-EDTA complex, as compared with the reduction rate of Fe^{3+}-EDTA alone (39). In a manner similar to the effect of EDTA, it is conceivable that a component in the pooled fraction may cause a preferable configuration with the iron moiety to undergo interaction with reductase.

There was no evidence for reduction of free Fe^{3+} in microsomes, although free Fe^{3+} was reduced by NADPH-cy-

tochrome P450 reductase with or without pool I. This may reveal the occurrence of a component in microsomes which prevents interaction of free Fe^{3+} with NADPH-cytochrome P450 reductase and is not susceptible to chelated iron.

NADPH-supported lipid peroxidation in microsomes is promoted by the presence of iron chelates through an initiation reaction and a subsequent propagation reaction. The perferryl ion complex (1,4) has been proposed for the initiation of lipid peroxidation, but there is an argument, based on thermodynamic considerations, against its ability to abstract doubly allylic hydrogen (40). The ferrous dioxygen ferric complex (41) has also been proposed for the initiation. In this case, the 1:1 ratio of Fe^{2+} to Fe^{3+} is important (42). However, the mechanism may not always be supported by the fact that the effect of ferric ion is displaced by Al^{3+}, Pb^{2+} or Ca^{2+} (43,44). Recently, it has been suggested that an iron species appears to interact with anionic oxygen on phosphate moieties in phospholipids to promote lipid peroxidation which is competitively inhibited by Co(II) (45) or Mn(II) (46). In this case, a ferrous iron species would catalyze hydroperoxide breakdown by a site-specific mechanism on liposomal membranes producing alkoxyl radicals resulting in chain reactions (47). No stimulation of NADPH consumption was caused by the inclusion of phosphatidylcholine in the incubation system resulting in promotion of lipid peroxidation (Fig. 2), indicating that the Fe^{3+}-PPi reduction step is rate-limiting. Furthermore, phospholipid peroxidation in microsomes ceased rapidly when NADPH was depleted by addition of an α-ketoglutarate/glutamate dehydrogenase system (16). These findings provide evidence that the phospholipid peroxidation is greatly dependent on the iron reducing step.

Lipid peroxidation promoted in biomembranes may be not always associated with tissue degeneration. Vladimirov *et al.* (48) have proposed two effects of lipid peroxidation in normal tissues: membrane lipid exchange and cell division control. Some investigators reported that the peroxidized lipids formed may contribute to the turnover and remodeling of membranous phospholipids (49) and to the metabolizing of drugs (50). Thus, the occurrence of a component associated with iron reduction in microsomal membranes appears to suggest that phospholipid peroxidation *in vivo* may function in some physiological roles.

Zinc Deficiency and Activities of Lipogenic and Glycolytic Enzymes in Liver of Rats Fed Coconut Oil or Linseed Oil

Klaus Eder and Manfred Kirchgessner*

Institut für Ernährungsphysiologie der Technischen Universität München Weihenstephan, 85350 Freising, Germany

ABSTRACT: In previous studies, zinc-deficient rats force-fed a diet with coconut oil as the major dietary fat developed a fatty liver, whereas zinc-deficient rats force-fed a diet with linseed oil did not. The present study was conducted to elucidate the reason for this phenomenon. In a bifactorial experiment, rats were fed zinc-adequate or zinc-deficient diets containing either a mixture of coconut oil (70 g/kg) and safflower oil (10 g/kg) ("coconut oil diet") or linseed oil (80 g/kg) ("linseed oil diet") as a source of dietary fat, and activities of lipogenic and glycolytic enzymes in liver were determined. In order to ensure adequate food intake, all the rats were force-fed. Zinc-deficient rats on the coconut oil diet developed a fatty liver, characterized by elevated levels of triglycerides with saturated and monounsaturated fatty acids. These rats also had markedly elevated activities of the lipogenic enzymes acetyl-CoA carboxylase, fatty acid synthase (FAS), glucose-6-phosphate dehydrogenase (G6PDH), 6-phosphogluconate dehydrogenase (6PGDH), and citrate cleavage enzyme, whereas activities of malic enzyme and glycolytic enzymes were not different compared with zinc-adequate rats on the coconut oil diet. In contrast, rats receiving the linseed oil diet had similar triglyceride concentrations regardless of zinc status, and activities of lipogenic enzymes and glycolytic enzymes were not different between the two groups. Zinc-deficient rats fed either type of dietary fat exhibited statistically significant correlations between activities of FAS, G6PDH, 6PGDH and concentrations of saturated and monounsaturated fatty acids in liver. The concentrations of serum lipids were elevated in zinc-deficient rats fed either type of dietary fat. These results demonstrate that fatty liver in zinc-deficient rats on the coconut oil diet is caused by elevated activities of lipogenic enzymes, and not by disturbed lipid secretion from liver. Dietary linseed oil prevents both the elevation of lipogenic enzyme activity and fatty liver in zinc-deficient rats.
Lipids 30, 63–69 (1995).

A general problem in conventional zinc deficiency experiments is that only a few days after a zinc-deficient diet is administered rats largely reduce voluntary food intake (1–3). Therefore, rats fed a zinc-deficient diet suffer not only from zinc deficiency but generalized malnutrition. Thus, energy deficiency confounds the effects of zinc deficiency even in experiments including pair-fed control rats, particularly on parameters of lipid metabolism. In order to investigate the effects of zinc deficiency without distortion by the confounding effect of very low food intake, we fed rats a zinc-deficient diet by gastric tube (4–8). This force-feeding technique allows provision of sufficient nutrients and guarantees identical food intake and periodicity of feeding in control and zinc-deficient rats. In one of those studies, it was observed that rats force-fed a zinc-deficient diet containing predominately coconut oil as a source of dietary fat developed a fatty liver characterized by high concentrations of triglycerides with saturated and monounsaturated fatty acids (5), whereas rats force-fed a zinc-deficient diet containing oils rich in n-3 polyunsaturated fatty acids (PUFA) such as fish oil (5) or linseed oil (6) did not. The most likely reasons for the development of a fatty liver would be enhanced lipogenesis or disturbed secretion of lipids from liver into blood. Since concentrations of lipids in serum were elevated rather than reduced in rats force-fed zinc-deficient diets containing either type of fat (7,8), it is unlikely that disturbed secretion of lipids from liver into blood is the reason for fatty liver in the rats fed coconut oil. Therefore, we hypothesized that the rate of lipogenesis is enhanced in zinc-deficient rats fed a diet containing coconut oil but is not enhanced in rats fed a diet containing fish oil or linseed oil. To test this hypothesis, a bifactorial experiment was performed containing four groups of rats force-fed either zinc-deficient or zinc-adequate diets with a coconut oil/safflower oil mixture or linseed oil as source of dietary fat. To achieve information about the rate of lipogenesis, activities of hepatic enzymes involved in lipogenesis were determined: acetyl-CoA carboxylase (AcCx; E.C. 6.4.1.2) which provides malonyl-CoA for fatty acid synthesis, and fatty acid synthase (FAS) which is involved in chain elongation; glucose-6-phosphate dehydrogenase (G6PDH; E.C. 1.1.1.49), 6-phosphogluconate dehydrogenase (6PGDH; E.C. 1.1.1.44) and malic enzyme (ME; E.C. 1.1.1.40) which provide NADPH; citrate cleavage enzyme (CCE; E.C. 4.1.3.8) which provides cytoplasmatic acetyl-CoA, and α-glycerophosphate dehydrogenase (αGPDH, E.C. 1.1.1.8) which provides α-glycerophosphate. Moreover, activities of two key

enzymes of glycolysis [phosphofructokinase (PFK), E.C. 2.7.1.11; pyruvate kinase (PK), E.C. 2.7.1.40] were determined to achieve information about glycolytic production of acetyl-CoA, which is the substrate for fatty acid synthesis.

MATERIALS AND METHODS

Animals and diets. Thirty-six male Sprague-Dawley rats weighing 121 ± 4 g were divided into four groups of nine rats each: zinc-adequate/coconut oil diet; zinc-deficient/coconut oil diet; zinc-adequate/linseed oil diet; zinc-deficient/linseed oil diet. The rats were housed individually in Macrolon cages. A daily 12-h light/dark cycle, a temperature of 23°C and 60% humidity were maintained. All the rats were fed four times per day (0800, 1300, 1800, 2300) by intragastric tube (5). The composition of the semisynthetic diets is given in Table 1. The basal diet contained 0.5 mg Zn/kg. The zinc-adequate diets were supplemented with 30 mg/kg Zn (as zinc sulfate). The coconut oil diets also contained safflower oil to provide essential fatty acids. The fatty acid composition of the dietary fats is given in Table 2. Diet slurries were freshly prepared before each feeding by mixing dry diet (92 g) with oil (8 g) and double distilled water (60 mL, with or without added zinc sulfate). Immediately before feeding, the slurry was warmed in a glass bottle at 50°C for a few minutes. The intragastric tube consisted of a 5-mL syringe connected with a slide catheter. During tube feeding, the conscious rat was handheld. The catheter was then inserted into the stomach of the rat, and the slurry was slowly injected. To avoid contamination, zinc-deficient rats were always fed before the control rats. Each rat received 4 mL of slurry per feeding (representing 2.9 g of food dry matter per feeding and 11.6 g of food dry matter per day). The rats had free access to drinking water [double-distilled water, supplemented with 0.14 g/L sodium chloride (suprapure) to adapt osmolarity to that of tap water].

TABLE 1
Composition of the Experimental Diets (g/kg diet)

Component	Coconut oil diet	Linseed oil diet
Casein (EDTA purified)	200	200
Corn starch	328	328
Sucrose	300	300
Coconut oil	70	—
Safflower oil	10	—
Linseed oil	—	80
Fiber (cellulose)	30	30
Mineral mixture[a]	40	40
Vitamin mixture[b]	20	20
DL-methionine	2	2

[a]Minerals per kg diet: Na_2HPO_4 • 2 H_2O 10.74 g; KH_2PO_4 8.20 g; KCl 6.00 g; $MgCl_2$ • 6 H_2O 3.40 g; $CaCO_3$ 13.6 g; $FeSO_4$ • 7 H_2O 248.8 mg; $CuSO_4$ • 7 H_2O 47.2 mg; $MnSO_4$ • 5 H_2O 46.1 mg; KI 9.0 mg; $NiSO_4$ • 6 H_2O 4.48 mg; Na_2MoO_4 • 2 H_2O 0.50 mg; $SnCl_2$ • 2H_2O 0.57 mg; Na_2SeO_3 • 5 H_2O 0.67 mg; $CrCl_3$ • 6 H_2O 0.51 mg; NH_4VO_3 0.23 mg; Na_2SiO_3 • 5 H_2O 1.51 mg; sugar to 40 g. EDTA, ethylenediaminetetraacetic acid.
[b]Vitamins per kg diet: 1.7 mg all-*trans* retinol; 7.5 µg cholecalciferol; 150 mg all-*rac*-α-tocopherol; 1 mg menadione sodium bisulfite; 5 mg thiamine • HCl; 10 mg riboflavin; 6 mg pyridoxine • HCl; 40 mg Ca pantothenate; 50 mg nicotinic acid; 1,000 mg choline chloride; 0.2 mg folic acid; 0.025 mg cyanocobalamin; sugar to 20 g.

TABLE 2
Fatty Acid Composition of the Dietary Fats (g/100 g fatty acids)

20:0	0.10	—
20:1n-9	0.10	—

[a]Each value represents the mean of five analyses.
[b]Indicates that fatty acid exists only in traces (< 0.1 g/100 g).

After 9 d, rats fed both types of zinc-deficient diet showed symptoms of zinc deficiency such as sparse and coarse hair, skin lesions around mouth, paws and eyes, ataxia and lethargy; they were obviously severely ill. Therefore, the experiment had to be terminated after 10 d of feeding. On the last day of the experiment, the rats were fed four times according to the regular schedule and were then additionally fed in the night (0500) to stimulate activity of lipogenic enzymes. Rats were then killed exactly 3 h after that feeding by decapitation under light anesthesia with diethyl ether.

Lipid analyses. Liver lipids were extracted with a hexane/isopropanol mixture (3:2, vol/vol, containing butylated hydroxytoluene as antioxidant) (9). For determination of total liver lipids, the solvent of a portion of the extract was evaporated, and the lipid mass was determined gravimetrically. For determination of liver total cholesterol and triglycerides, extract was dissolved in Triton X-100 as described (10). Total cholesterol and triglycerides were determined using enzymatic reagent kits obtained from Boehringer (Mannheim, Germany). Phospholipids of the extract were separated by high-performance liquid chromatography and quantified by their bound fatty acids (11).

Fatty acids of liver total lipids and dietary fats were converted into methyl esters by transesterification with boron fluoride/methanol reagent (12). Fatty acid methyl esters (FAMEs) were separated by gas chromatography using a Sichromat 2–8 gas chromatographic system (Siemens, Karlsruhe, Germany), fitted with a programmed temperature vaporizing injection system, a flame-ionization detector and a 50 m CP-Sil 88 capillary column (Chrompack, Middleburg, The Netherlands). FAMEs were identified by comparing retention times with those of individual purified standards, and quantified with heptadecanoic acid methyl ester as internal standard (11,13). Serum lipids (total cholesterol, triglycerides, phospholipids) were determined using an auto analyzer (Model 704; Hitachi, Tokyo, Japan) and commercial available enzymatic kit reagents (Boehringer).

Activities of liver enzymes. Approximately 4 g of liver was homogenized in 10 mL of 0.25 M Sucrose buffer (in 0.1 M phosphate buffer, pH 7.4) using a Potter-Elvehjem-homoge-

nizer. Homogenates were centrifuged (105,000 *g* for 1 h at 4°C), and the supernatants were used for enzyme assays. All the enzymes were assayed by spectrophotometric methods. G6PDH (14), 6PGDH (15) and ME (16) were determined by the rate of NADP reduction. In the assay of G6PDH, activity of 6PGDH was inhibited by maleimide (14). FAS was determined from the rate of malonyl-CoA-dependent NADPH oxidation (17), and AcCx was determined from NADH oxidation in an assay coupled with PK and lactate dehydrogenase (18). CCE was determined from NADH oxidation in an assay coupled with malate dehydrogenase (19). αGPDH was determined from α-glycerophosphate-dependent reduction of NAD (20). PFK determination was based upon the coupling of fructose-1,6-diphosphate formation to the oxidation of NADH with the use of aldolase, triosephosphate isomerase, and α-GPDH (21). PK was determined from NADH oxidation in an assay coupled with lactate dehydrogenase (22).

Zinc analysis and activity of alkaline phosphatase. Zinc concentration of serum was measured directly by aspirating a dilute solution (1:5) into the flame of an atomic absorption spectrophotometer (model 303; Perkin-Elmer, Überlingen, Germany). The activity of alkaline phosphatase in serum was determined using a commercial reagent kit (Boehringer) in an auto analyzer.

Statistical analysis. Treatment effects were analyzed by two-way analysis of variance (ANOVA) using the SPSS/PC + V3.0 software (SPSS, Chicago, IL). Classification factors were zinc supply and source of dietary fat, as well as interaction between those factors. Means of the four treatment groups were compared by the Student-Newman-Keuls multiple range test.

RESULTS

Weight gain and zinc status of the rats. Weight gain as well as activity of alkaline phosphatase and zinc concentration in serum are shown in Table 3. During the first 8 d of the experiment, the weight gain was nearly identical in the rats of all groups. Growth of the rats receiving the zinc-deficient diets then stopped, whereas weight gain of the rats receiving the zinc-adequate diets continued during the remainder of the experiment. The dietary fat did not influence mean daily growth rates which were higher for zinc-adequate rats than for zinc-deficient rats. Activity of alkaline phosphatase in serum was 65% lower in zinc-deficient rats fed the coconut oil diet than in zinc-adequate rats fed the coconut oil diet and 56% lower in zinc-deficient rats fed the linseed oil diet than in zinc-adequate rats fed the linseed oil diet. Serum zinc concentration was 78% lower in zinc-deficient rats fed the coconut oil diet than in equivalent control rats and 79% lower in zinc-deficient rats fed the linseed oil diet than in the equivalent control rats. Surprisingly, serum zinc concentration was significantly lower in zinc-adequate rats fed the linseed oil diet than in zinc-adequate rats fed the coconut oil diet, and there was a significant interaction between the factors zinc and fat on serum zinc concentration.

Liver and serum lipids. The effect of zinc deficiency on dry matter content and concentrations of total lipids and triglycerides was dependent on the type of dietary fat (Table 4). The zinc-deficient rats fed the coconut oil diet had a higher dry matter content and higher concentrations of total lipids and triglycerides in the liver than the control rats fed the coconut oil diet. In contrast, dry matter content and concentrations of total lipids and triglycerides in the zinc-deficient rats fed the linseed oil diet were not significantly different from those of the zinc-adequate rats fed the linseed oil diet. Concentration of total cholesterol in liver was not different between the four groups. Concentration of phosphatidylcholine was higher in zinc-deficient rats fed the coconut oil diet than in zinc-adequate rats fed the coconut oil diet, but was not significantly different between the two groups fed the linseed oil diet. Concentrations of phosphatidylethanolamine were not different between zinc-deficient and adequate rats fed both types of dietary fat.

TABLE 3
Weight Gain of the Rats During the Experiment, Activity of Alkaline Phosphatase and Zinc (Zn) Concentration in Serum at the End of the Experiment[a,b]

Parameter	Coconut oil diet		Linseed oil diet	
	Zn-adequate	Zn-deficient	Zn-adequate	Zn-deficient
Weight (g)				
Day 1	121 ± 4	121 ± 3	121 ± 4	121 ± 4

TABLE 6
Activity[a] of Lipogenic and Glycolytic Enzymes in Liver[b,c]

Enzyme	Coconut oil diet		Linseed oil diet	
	Zn-adequate	Zn-deficient	Zn-adequate	Zn-deficient
Acetyl-CoA-carboxylase[f]	9.86 ± 5.28[d]	20.6 ± 11.5[e]	8.62 ± 3.23[d]	13.0 ± 2.6[d,e]
Fatty acid synthase[f]	2.30 ± 1.63[d]	5.59 ± 2.38[e]	3.22 ± 2.11[d]	4.02 ± 1.94[d,e]
Glucose-6-phosphate dehydrogenase[f]	14.2 ± 8.3[d]	29.1 ± 17.3[e]	11.2 ± 3.6[d]	20.3 ± 9.9[d,e]
6-Phosphogluconate dehydrogenase[f]	26.2 ± 6.3[d]	40.3 ± 11.6[e]	26.4 ± 6.9[d]	33.7 ± 7.2[d,e]
Malic enzyme	16.6 ± 2.5	14.5 ± 3.5	16.8 ± 4.0	15.1 ± 2.4
Citrate cleavage enzyme[f,g,h]	23.3 ± 4.3[d]	35.8 ± 9.6[e]	22.0 ± 4.9[d]	26.4 ± 3.2[d,e]
α-Glycerophosphate dehydrogenase[f]	184 ± 24[d]	150 ± 21[e]	185 ± 22[d]	169 ± 17[d,e]
Phosphofructokinase[f]	10.2 ± 1.45	11.3 ± 1.2	10.4 ± 1.0	11.3 ± 1.0
Pyruvate kinase[g]	1022 ± 193	971 ± 173	851 ± 170	847 ± 139

[a]Acetyl-CoA carboxylase and fatty acid synthase are expressed as nmoles NADPH oxidized/mg protein • min at 25°C; glucose-6-phosphate dehydrogenase, 6-phosphogluconate dehydrogenase and malic enzyme are expressed as nmoles NADP reduced/mg protein • min at 25°C; citrate cleavage enzyme, phosphofructokinase and pyruvate kinase are expressed as nmoles NADH oxidized/mg protein • min at 25°C; α–glycerophosphate dehydrogenase is expressed as nmoles NAD reduced/mg protein • min at 25°C.
[b]Values represent means ± SD with n = 9 for each group. Means with different superscript letters (d,e) within one row differ significantly by Student-Newman-Keuls test ($P < 0.05$).
[c]Significance of factors: Zinc (Zn): $P < 0.05$, [g]fat: $P < 0.05$, [h]Zn x fat: $P < 0.05$.

All the rats had high concentrations of triglycerides in serum because they were fed 3 h before killing (Table 4). However, zinc-deficient rats fed the coconut oil diet had higher triglyceride concentrations than zinc-adequate rats fed the coconut oil diet whereas in the groups fed the linseed oil diet there was no difference between zinc-deficient and zinc-adequate rats. Concentration of total cholesterol was higher in both groups of zinc-deficient rats than in the equivalent control rats. Similarly, concentration of phospholipids in serum was higher in both groups of zinc-deficient rats than in the equivalent control rats. There was a significant effect of fat type and a significant interaction between the factors zinc and fat type on concentrations of triglycerides and phospholipids.

The effect of zinc deficiency on the concentrations of total fatty acids and most of the individual fatty acids in the liver was also dependent on the type of dietary fat (Table 5). The zinc-deficient rats fed the coconut oil diet had greatly elevated concentrations of saturated and monounsaturated fatty acids compared to the zinc-adequate rats fed the coconut oil diet, whereas concentrations of these fatty acids in the zinc-deficient rats fed the linseed oil diet were largely unchanged relative to the zinc-adequate rats fed the linseed oil diet. Zinc-deficient rats fed the coconut oil diet had also slightly elevated concentrations of n-6 PUFA relative to the zinc-adequate rats, while concentrations of n-3 PUFA were unchanged. In contrast, zinc-deficient rats fed the linseed oil diet had neither higher concentrations of total n-6 PUFA nor higher concentrations of total n-3 PUFA than zinc-adequate rats fed the linseed oil diet. However, concentration of eicosapentaenoic acid was higher in zinc-deficient rats than in zinc-adequate rats fed the linseed oil diet.

Activity of lipogenic and glycolytic enzymes. Zinc-deficient rats fed the coconut oil diet had significantly higher activities of AcCx, FAS, G6PDH, 6PGDH and CCE than zinc-adequate rats fed the coconut oil diet (Table 6). Activities of these enzymes were elevated in zinc-deficient rats fed the coconut oil diet in the range between 54 and 143%. In contrast, activities

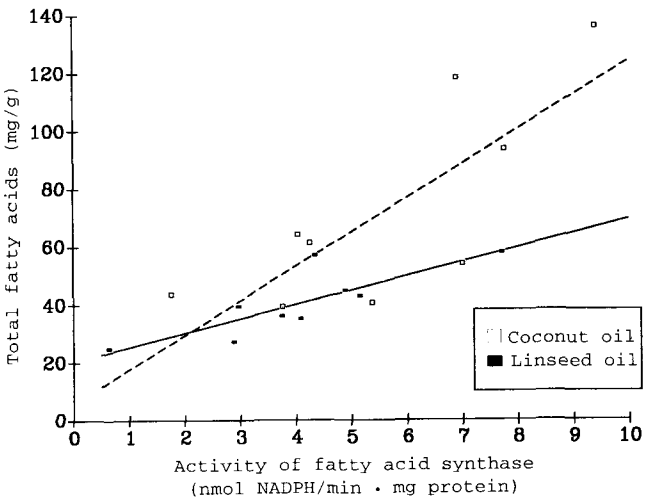

FIG. 1. Linear regression analysis between activity of fatty acid synthase and concentration of total fatty acids in liver of zinc-deficient rats fed coconut oil diet (....., Y = 6.0 + 11.80 • X, r = 0.61) and in zinc-deficient rats fed linseed oil diet (———, Y = 20.6 + 4.89 • X, r = 0.67).

of ME, PFK and PK were not different between these groups, and activity of αGPDH was lower in zinc-deficient rats fed the coconut oil diet than in the equivalent control rats.

In contrast, activity of none of the enzymes measured was significantly different between zinc-deficient rats fed the linseed oil diet and zinc-adequate rats fed the linseed oil diet. However, nominal values were higher in zinc-deficient rats than in zinc-adequate rats fed the linseed oil diet for AcCx (51%), FAS (25%), G6PDH (81%), 6PGDH (28%) and CCE (20%). ANOVA showed that the dietary fat influenced the activities of CCE and PK but not the activities of the other enzymes. There existed no statistical significant interaction between the factors zinc and fat on activity of any enzyme.

In the zinc-deficient rats fed both types of dietary fat, there existed significant ($P < 0.05$) linear correlations between activities of G6PDH, 6PGDH, FAS and concentrations of saturated and monounsaturated fatty acids in liver. In contrast, ac-

tivities of those enzymes did not correlate with concentrations of PUFA. There were no correlations between activities of ME, CCE and AcCx and concentrations of saturated, monounsaturated or PUFAs. Figure 1 shows the correlation between activity of FAS and concentration of liver total fatty acids in zinc-deficient rats fed both types of dietary fat.

DISCUSSION

The present study agrees with former studies (5,23) showing that rats force-fed a zinc-deficient diet with predominately saturated fatty acids accumulate triglycerides in liver, whereas rats fed a zinc-deficient diet with a highly polyunsaturated fat did not. Elevated activities of lipogenic enzymes in liver observed in the present study as well as elevated serum lipid concentrations in this and former studies (7,8) demonstrate that triglyceride accumulation is due to increased lipogenesis and not to disturbed secretion of lipids. Activity of AcCx, the key enzyme in lipogenesis (24), was twice as high in liver of zinc-deficient than in control rats fed the coconut oil diet. Unchanged activities of two key enzymes involved in glycolysis demonstrate that increased triglyceride concentration in liver is not due to enhanced production of acetyl-CoA by glycolysis.

There may be a connection between increased hepatic lipogenesis of zinc-deficient rats fed a highly saturated fat diet and disturbed metabolism of essential fatty acids. Zinc deficiency has been shown to produce similar clinical features in the rat as essential fatty acid (EFA) deficiency (25). Fatty liver that has been demonstrated in the present study in zinc-deficient rats fed a diet with a high saturated fat is also a symptom that occurs in EFA-deficient rats (26,27). Rats fed fat-free diets or diets containing hydrogenated fats also exhibit elevated activities of lipogenic enzymes in liver (28–30).

Oxygenation products derived from arachidonic acid were suggested to have a function in regulating activities of lipogenic enzymes (29,31). This was indicated by the observation that addition of safflower oil to a fat-free diet suppresses the activity of FAS and AcCx as well as G6PDH and 6PGDH in rat liver, whereas addition of safflower oil plus eicosa-5,8,11,14-tetraynoic acid (which inhibits many oxygenation reactions of arachidonic acid including cyclooxygenase, lipoxygenase and P-450 metabolism) did not (29,31). Fatty liver observed in zinc-deficient rats is not due to biochemical processes related to inhibited desaturation of linoleic acid because in the experiment presented here, zinc deficiency did not lower *in vitro* activity of Δ5- and Δ6-desaturases as well as levels of arachidonic acid in liver phospholipids and microsomes in the rats fed both types of dietary fat (Eder and Kirchgessner, unpublished data). On the other hand, the reason for the observation that zinc-deficient rats fed the linseed oil diet did not develop a fatty liver could be that feeding diets with a high level of α-linolenic acid causes synthesis of n-3 derived oxygenation products. The effects of those products are in several ways different from those derived from arachidonic acid (32). Because α-linolenic acid has been shown to be a more potent inhibitor of lipogenic enzymes (33) than linoleic acid, it is possible that 18:3 n-3 derivatives have a higher activity on inhibition of lipogenic enzymes than 18:2 n-6 derivatives.

One point that should be noted with respect to interpretation of fatty liver is that the ratio between feed intake and body weight at the end of the experiment was higher in zinc-deficient rats than in control rats. However, for two reasons it is likely that fatty liver is not the result of a higher relative feed intake. First, if higher relative feed intake would be the reason, fatty liver would be expected in zinc-deficient rats fed both dietary fats. Second, rats that voluntarily consume a higher quantity of diet than the rats of the present experiment do not gain a fatty liver (34).

In contrast with the present study, in zinc deficiency experiments in which rats voluntarily consumed the diet, with one exception (35) zinc deficiency did not elevate lipid concentrations in liver (36–39). This might be due to anorexia associated with zinc deficiency. Fasting or low food intake has been shown to markedly decrease activity of lipogenic enzymes (40). Moderately zinc-depleted rats that voluntarily consumed similar quantities of diet as the rats of the present study did not gain a fatty liver (39). This indicates that only severe zinc deficiency and high food intake at the same time increase lipogenesis in liver. Therefore, it can be concluded that fatty liver is not a physiologically-relevant effect because it is prevented by reduction of food intake in zinc deficiency.

Another point worthy of mention is that control rats fed the saturated fat diet and the highly unsaturated fat diet had similar activities of lipogenic enzymes in liver. This disagrees with studies indicating that PUFA are more potent in suppressing lipogenic enzyme activity than saturated fats (28,41). Possibly, the disparity in results is due to different feeding regimes because the eating period greatly influences lipogenesis in liver and adipose tissue. Meal-feeding, which is widely used in studies demonstrating the effect of fats on lipogenesis, has been shown to increase activity of lipogenic enzymes in comparison with *ad libitum* feeding (42). However, there have been no studies published on the effects of different dietary fats on lipogenic enzymes in rats force-fed the diet four times daily. As in the present study, rats fed diets high in either polyunsaturated or saturated fats were found to have equal degrees of inhibition of fatty acid synthesis (43).

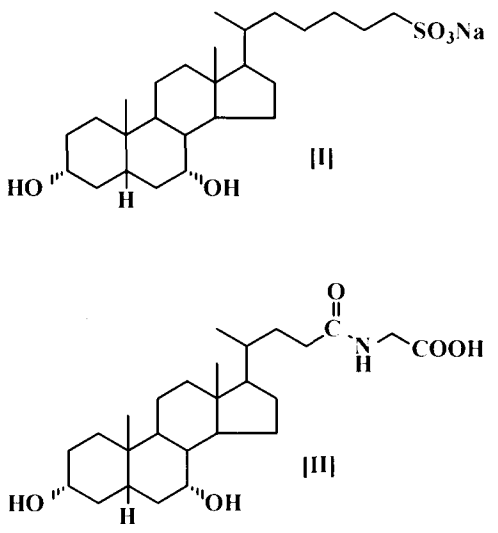
ABSTRACT: This paper reports the chemical synthesis of a new bile acid analogue, namely sodium 3α,7α-dihydroxy-25,26-bishomo-5β-cholane-26-sulfonate (bishomoCDC-sul) from chenodeoxycholic acid and describes its metabolism in the hamster. The structure of the new compound was confirmed by proton and carbon-13 nuclear magnetic resonance spectroscopy. After intravenous infusion of [^{3}H]-labeled sulfonate into bile fistula hamsters, it was extracted by the liver and secreted into the bile; more than 65% of the radioactivity was recovered in the bile within 1 h. Following intraduodenal administration of the [^{3}H]sulfonate and [^{14}C]chenodeoxycholyltaurine, both compounds were excreted into the bile more slowly; only 41 and 43% of the radioactivity, respectively, were recovered in the bile during the four-hour experimental period. In contrast, when the labeled compounds were injected into the terminal ileum, both the sulfonate and chenodeoxycholyltaurine were rapidly absorbed and secreted into the bile; 84 and 97%, respectively, of the radioactivity were recovered during a four-hour period. Chromatographic analysis demonstrated that in these short-term experiments most (>95%) of the sulfonate was secreted into the bile without biotransformation regardless of the route of administration. When infused intravenously at increasing doses, bishomoCDC-sul induced cholestasis at an infusion rate of 1 μmol/min/kg. These results suggest that sodium 3α,7α-dihydroxy-25,26-bishomo-5β-cholane-26-sulfonate was absorbed from the terminal ileum by active transport, extracted by the liver, and secreted into the bile in a manner similar to that of the natural bile acids.
Lipids 30, 71–78 (1995).

We have synthesized and studied sulfonate analogues of the natural bile acids (1–6) in order to develop cholelitholytic agents that might be safe and have more persistent effects than chenodeoxycholic acid (CDCA) and ursodeoxycholic acid (UDCA). These therapeutic agents are currently in use to dissolve cholesterol gallstones (7–9). In animal experiments, sulfonate analogues of CDCA (CDC-sul; sodium 3α,7α-dihydroxy-5β-cholane-24-sulfonate), UDCA (UDC-sul; sodium 3α,7β-dihydroxy-5β-cholane-24-sulfonate) and norursodeoxycholic acid (norUDC-sul) were efficiently absorbed from the terminal ileum by active transport and secreted into the bile in a manner similar to the natural bile acids (2,5). Orally-administered CDCA and UDCA are 7-dehydroxylated by intestinal microorganisms to form lithocholic acid (LCA) (10,11). This results in the loss of active drug from the enterohepatic circulation. It is also known that LCA is a hepatotoxic agent (12,13) and a promoter of colon cancer (14,15). In contrast, CDC-sul, UDC-sul and norUDC-sul were completely resistant to bacterial biotransformation (2,5).



Recently, using sulfonate analogues of norchenodeoxycholic acid (norCDC-sul) and homochenodeoxycholic acid (homoCDC-sul), we demonstrated that side chain length affected the biological properties of the sulfonates. In dose response studies, intravenously infused homoCDC-sul produced cholestasis at a lower dose (0.75 μmol/min/kg) than norCDC-sul (2.0 μmol/min/kg) (4). It is known that bile acid hydrophobicity influences their cholestatic properties (16,17). By high-performance liquid chromatography (HPLC), homoCDC-sul is more hydrophobic than norCDC-sul. However, even though chenodeoxycholyltaurine (CDC-tau) is more hydrophobic than norCDC-sul, only the latter was cholestatic under the conditions employed (4). Sulfonate analogues do not possess a peptide bond in the side chain. In addition, the side chains of both sulfonates (norCDC-sul, homoCDC-sul) are shorter than that of CDC-tau. Therefore, we hypothesized that the cholestatic effect of sulfonate analogues will be reduced in compounds possessing the same side chain length as the natural conjugated bile acids. To test this hypothesis, we synthesized the sulfonate analogue of bishomochenodeoxycholic acid (bishomoCDCA), namely sodium 3α,7α-dihydroxy-25,26-bishomo-5β-cholane-26-sulfonate (bishomoCDC-sul) (Scheme 1), in which the

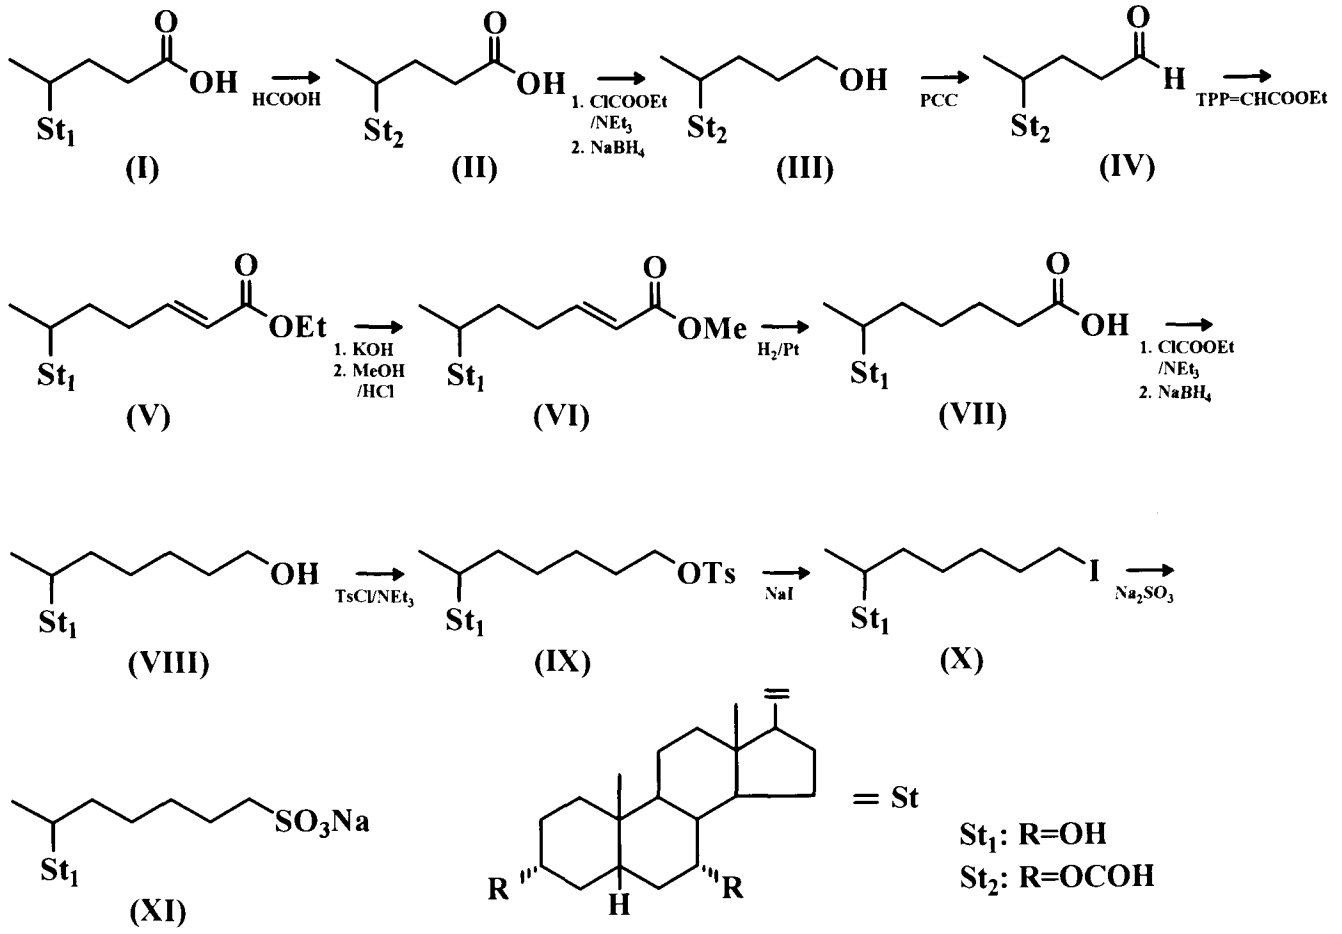
SCHEME 1

length of the side chain is the same as that of chenodeoxycholylglycine (CDC-gly) (Scheme 1), and studied its metabolism and cholestatic properties in the hamster.

MATERIALS AND METHODS

General. Melting points were determined on a Thermolyne melting point apparatus (Dubuque, IA) and are not corrected. Proton nuclear magnetic resonance (^{1}H NMR) and carbon-13 nuclear magnetic resonance (^{13}C NMR) spectra were determined on a JEOL (Tokyo, Japan) JMN-FX-400 spectrometer (400 MHz) in CD_3OD solution using tetramethylsilane as internal standard. Thin-layer chromatography (TLC) was performed on precoated silica gel 60 F_{254} plates (0.2 mm thickness; EM Science, Darmstadt, Germany); a 10% ethanolic solution of phosphomolybdic acid was used to visualize the spots. HPLC was carried out on a Varian (Palo Alto, CA) model 5020 liquid chromatograph with a refractive index detector (HP1047A; Hewlett-Packard, Avondale, PA) and an ultraviolet detector (Waters 480 variable wavelength detector; Millipore, Milford, MA). A NOVA-C_{18} 4μ column (Waters Associates) was used in a Waters Z-module (solvent; methanol/water, 75:25, pH adjusted to 5.37 with phosphoric acid, flow rate 1.0 mL/min). Radioactivity was measured on a Beckman LS 3801 liquid scintillation system (Beckman Instruments, Fullerton, CA) with automatic quench correction, using Aquasol-2 (NEN Research Products, Boston, MA) as the scintillation fluid.



Synthesis. 3α,7α-Diformoxy-5β-cholan-24-ol (Scheme 2, **III***).* 3α,7α-Diformoxy-5β-cholan-24-oic acid (Scheme 2, **II**) was synthesized from CDCA (Scheme 2, **I**) as described previously (18). Triethylamine (15 mL) and 10 mL of ethyl chloroformate were added to a tetrahydrofuran (150 mL) solution of (II) (20.0 g). This solution was stirred at 0°C for 2 h. One-hundred and fifty mL of a 10% aqueous solution of sodium borohydride were added and stirred at room temperature for three hours. The solution was diluted with water, acidified with 1 N HCl and extracted with ethyl acetate. After evaporation, the residue was purified on a silica gel G 60 column (300 g, 35–70 mesh; ASTM; Merck, Darmstadt, Germany) using increasing proportions of ethyl acetate in benzene as eluent. The fractions containing 3α,7α-diformoxy-5β–cholan-24-ol (Scheme 2, **III**) were collected and evaporated; 12.7 g of an oily residue (**III**) was obtained.

3α,7α-Diformoxy-5β-cholan-24-al (Scheme 2, **IV***).* Sodium acetate (1.2 g) and 8.6 g of pyridinium chlorochromate were added to a solution of 3α,7α-diformoxy-5β-cholan-24-ol (Scheme 2, **III**) (12.7 g) in methylene chloride (150 mL). This solution was stirred at room temperature for two hours. The reaction mixture was diluted with 250 mL of ether and applied to a Florisil (150 g) column. After elution with ether, evaporation of the appropriate fractions gave 9.5 g of 3α,7α-diformoxy-5β-cholan-24-al (Scheme 2, **IV**). This residue was used for the next reaction without purification.

Methyl 3α,7α-dihydroxy-27-nor-5β-cholest-24-en-26-oate (Scheme 2, **VI***).* 3α,7α-Diformoxy-5β-cholan-24-al (Scheme 2, **IV**) (9.5 g) was dissolved in 50 mL of dry benzene and added to a solution of (carbethoxymethylene)triphenylphosphorane (11.5 g) in 25 mL of dry benzene. The reaction mixture was refluxed for 7 h. After dilution with water and acidification with 1 N HCl, the reaction mixture was extracted with ethyl acetate. The residue (Scheme 2, **V**) was dissolved in 100 mL of 5% methanolic KOH, and the solution was refluxed for 1.5 h. The hydrolyzate was extracted with ethyl acetate after dilution with water and acidification with 1 N HCl. The methyl ester was prepared by addition of 100 mL of methanol/HCl (100:3). The solution was diluted with water and extracted with ethyl acetate. The residue was purified on a silica gel G 60 column (300 g) using increasing proportions of ethyl acetate in benzene. The fractions containing methyl 3α,7α-dihydroxy-27-nor-5β-cholest-24-en-26-oate (Scheme 2, **VI**) were collected and evaporated; 2.0 g of (**VI**) were obtained. ^{1}H NMR 0.69(3H, *s*, 18–CH_3), 0.92(3H, *s*, 19-CH_3), 0.95(3H, *d*, J = 6.6 Hz, 21-CH_3), 3.37(1H, *m*, 3β-H), 3.70(3H, *s*, –$COOCH_3$), 3.79(1H, *m*, 7β-H), 5.83(1H, *dt*, J = 15.6 Hz and 1.7 Hz, 25-H), 6.69(1H, *dt*, J = 15.6 Hz and 6.8 Hz, 24-H).

3α,7α-Dihydroxy-25,26-bishomo-5β-cholan-26-oic acid (Scheme 2, **VII***).* Methyl 3α,7α-dihydroxy-27-nor-5β-cholest-24-en-26-oate (Scheme 2, **VI**) (4.6 g) was reduced with H_2 in 50 mL of methanol for 1.5 h using 5% platinum on activated carbon (500 mg) as a catalyst and a hydrogen pressure of 40 psi. After filtration and evaporation, the residue was dissolved in 100 mL of 5% methanolic KOH and refluxed for 1.5 h. The reaction mixture was extracted with ethyl acetate after dilution with water and acidification with 1 N HCl. The residue was crystallized from methanol/ethyl acetate, and colorless crystals of 3α,7α-dihydroxy-25,26-bishomo-5β-cholan-26-oic acid (Scheme 2, **VII**) (3.2 g) were obtained (m.p. = 189–191°C [lit. 191–192°C (19)].

25,26-Bishomo-5β-cholane-3α,7α-26-triol (Scheme 2, **VIII***).* Triethylamine (2.0 mL) and 1.5 mL of ethyl chloroformate were added to a tetrahydrofuran solution (40 mL)

SCHEME 2

of 3α,7α-dihydroxy-25,26-bishomo-5β-cholan-26-oic acid (Scheme 2, **VII**) (2.0 g). This solution was stirred at 0°C for 2 h. Twenty mL of a 10% aqueous solution of sodium borohydride were added, and the reaction mixture was stirred at room temperature for 3 h. The solution was diluted with water, acidified with 1 N HCl and extracted with ethyl acetate. Evaporation gave a residue of 25,26-bishomo-5β-cholane-3α,7α,26-triol (Scheme 2, **VIII**), 1.4 g. ^{1}H NMR 0.69(3H, *s*, 18-CH_3), 0.92(3H, *s*, 19-CH_3), 0.95(3H, *d*, J = 6.6 Hz, 21-CH_3), 3.37(1H, *m*, 3β–H), 3.53(2H, *t*, J = 6.6 Hz, 26-CH_2-OH), 3.79(1H, *m*, 7β-H).

*25,26-Bishomo-26-*p*-toluenesulfoxy-5β-cholane-3α,7α-diol (Scheme 2,* **IX**). To a solution of 25,26-bishomo-5β-cholane-3α,7α,26-triol (Scheme 2, **VIII**) (3.4 g) in tetrahydrofuran (75 mL), there were added 3 mL of triethylamine and 3.4 g of *p*-toluenesulfonyl chloride. This solution was kept at 4°C for 14 d. After dilution with water and acidification with 1 N HCl, the reaction mixture was extracted with ethyl acetate. The residue was purified on a silica gel G 60 column (200 g, 35–70 mesh) using increasing proportions of ethyl acetate in benzene. The fractions containing 25,26-bishomo-26-*p*-toluenesulfoxy-5β-cholane-3α,7α-diol (Scheme 2, **IX**) were collected and evaporated; 1.5 g of (**IX**) was obtained as an oily residue. ^{1}H NMR 0.67(3H, *s*, 18-CH_3), 0.89(3H, *d*, J = 6.6 Hz, 21-CH_3), 0.92(3H, *s*, 19-CH_3), 2.45(3H, *s*, CH_3-phenyl), 3.38(1H, *m*, 3β–H), 3.79(1H, *m*, 7β-H), 4.01(2H, *m*, 26-CH_2-OTs), 7.75 and 7.77(4H, phenyl protons).

25,26-Bishomo-26-iodo-5β-cholane-3α,7α-diol (Scheme 2, **X**). To a solution of 25,26-bishomo-26-*p*-toluenesulfoxy-5β-cholane-3α,7α-diol (Scheme 2, **IX**) (1.5 g) in acetone (15 mL), there were added 15 mL of 10% sodium iodide in acetone. The reaction mixture was allowed to stand at 40°C for 4 h. The solution was diluted with water and extracted with ether. Evaporation gave an oily residue of 25,26-bishomo-26-iodo-5β-cholane-3α,7α-diol (Scheme 2, **X**) (1.4 g). ^{1}H NMR 0.69(3H, *s*, 18-CH_3), 0.93(3H, *s*,19-CH_3), 0-95(3H, *d*, J = 6.6 Hz, 21-CH_3), 3.23(2H, *t*, J = 7.0 Hz, 26-CH_2-I), 3.37(1H, *m*, 3β-H), 3.79(1H, *m*, 7β-H).

Sodium 3α,7α-dihydroxy-25,26-bishomo-5β-cholane-26-sulfonate (Scheme 2, **XI**). 25,26-Bishomo-26-iodo-5β-cholane-3α,7α-diol (Scheme 2, **X**) (1.4 g) was dissolved in an ethanolic solution of sodium sulfite (20 mL of ethanol plus 20 mL of 10% aqueous sodium sulfite). The solution was refluxed for 8 h. The ethanol was evaporated, and the residue was dissolved in methanol and filtered. The filtrate was evaporated, and the residue was dissolved in a small amount of water and applied to a 100 g column of Diaion resin (Nippon

Rensui Co., Tokyo, Japan) which is similar to SepPak C_{18}. After washing with 500 mL of water to remove sodium sulfite, the column was eluted with increasing amounts of methanol in water (50 to 80%). The fractions containing sodium 3α,7α-dihydroxy-25,26-bishomo-5β-cholane-26-sulfonate (Scheme 2, **XI**) were collected and evaporated. The residue was crystallized from methanol–ethyl acetate, and colorless crystals of (**XI**) (1.1 g) were obtained: m.p. 278–281°C. ^{1}H NMR: 0.67(3H, *s*, 18-CH_3), 0.92(3H, *s*, 19-CH_3), 0.95(3H, *d*, J = 6.4 Hz, 21-CH_3), 2.78(2H, *m*, 26-CH_2-SO_3-Na), 3.36(1H, *m*, 3β-H), 3.79(1H, *m*, 7β-H).

Labeled compounds. [24,25-^{3}H]BishomoCDC-sul (sp. act. 2.6 × 10^6 dpm/mg) was prepared from [24,25-^{3}H]-bishomoCDCA by the method described above for the unlabeled compound. The tritium label was introduced by NEN Research Products by reduction of compound VI with ^{3}H/Pt. The labeled compound was purified to constant specific radioactivity by repeated preparative TLC on silica gel H using the solvent system isooctane/ethyl acetate/acetic acid, 10:10:2, by vol. [24-^{14}C] CDC-tau (sp. act. 9.5 × 10^4 dpm/mg) was synthesized from [24-^{14}C] CDCA (NEN Research Products, Wilmington, DE) by the method of Tserng *et al.* (20). Radiopurity of the labeled compounds was better than 95% as determined by radio-TLC. Each labeled compound was dissolved in 0.9% aqueous NaCl solution for the biological studies.

Liver uptake and intestinal absorption of bishomoCDC-sul. Male golden Syrian hamsters (Sasco, Omaha, NE), weighing 108 ± 4 g, were fed Purina chow (Purina, St. Louis, MO) and water *ad libitum,* and kept under a controlled 12-h light/dark cycle for 1 wk prior to surgery. All animals were operated on between 8:30 and 9:30 a.m. The hamsters were anesthetized by intraabdominal injection of ketamine (Ketaset, Bristol Labs, Syracuse, NY), 20 mg/animal. Injections of ketamine (10 mg/dose) were employed to maintain anesthesia, as required.

A polyethylene catheter (PE-10, 0.28 mm i.d., Clay Adams, Parsippany, NJ) was inserted into the left femoral vein, and saline was infused at a rate of 1.1 mL/h using a Harvard syringe pump (Harvard Apparatus, South Natick, MA). The abdomen was opened by a midline incision, the cystic duct was ligated with a hemostatic clip (Hemo Clip, Edward Weck & Co., Inc., Research Triangle Park, NC), and an external biliary fistula was constructed using PE-10 polyethylene tubing. The urethra was ligated to allow urine to accumulate in the bladder.

In the intravenous infusion study, saline was infused into the femoral vein for 40 min prior to the administration of the [^{3}H]bishomoCDC-sul. The labeled sulfonate was then infused for 20 min at a dose of 50 μg/min (total amount administered, 1 mg); saline was again infused until the end of the experiment. Bile samples were collected in weighed tubes every 20 min for a total period of 4 h.

In the intraduodenal injection experiments, after cannulation of the bile duct and the femoral vein as described above, the labeled sulfonate (0.5 mg) and CDC-tau (0.5 mg) were injected as one bolus into the duodenum. For intraileal injection, the distal end of the ileum was ligated, and the labeled compounds were injected as a bolus into the terminal ileum. Bile samples were collected every 20 min for 4 h. At the end of the experiment, blood and urine were obtained by cardiac puncture and by aspiration from the urinary bladder, respectively, and the liver was excised. All biological specimens were stored at –20°C.

Cholestatic effect of bishomoCDC-sul. In order to estimate the effect of bishomoCDC-sul on bile flow, a dose response experiment was performed as follows: after a 2-h control period, during which saline was infused intravenously, bishomoCDC-sul was administered at increasing rates (0.1, 0.25, 0.5, 0.75, 1.0, 1.5, 2.0 and 3.0 μmol/min/kg). These doses were infused for consecutive 40-min periods; bile samples were collected at 20-min intervals.

Analytical techniques. In the metabolic experiments, bile samples were collected every 20 min. Two aliquots were taken from each sample to determine the fate of the administered labeled compounds as follows: (i) The radioactivity of the first aliquot (10 μL) was determined by liquid scintillation counting and (ii) the second aliquot (3 μL) was analyzed by TLC to detect the metabolites of the administered labeled compounds using solvent system CMAW (chloroform/methanol/acetic acid/water, 13:4:2:1). The bile was spotted directly on a TLC plate along with reference compounds. After development (15 cm) and detection of the spots, each TLC plate was cut into segments (1 cm) from the origin to the solvent front, and the radioactivity of each segment was measured as described previously (4).

Aliquots of serum and urine were checked for radioactivity. Bile salts in the liver were analyzed according to the method of Yanagisawa *et al.* (21), and their radioactivity was measured as described above.

Calculation. The numerical data are expressed as mean ± SEM.

RESULTS

Synthesis of bishomoCDC-sul. The synthetic route to bishomoCDC-sul is shown in Scheme 2. BishomoCDCA (Scheme 2, **VII**) was obtained from CDCA (Scheme 2, **I**) *via* the Wittig reaction. After protection of the nuclear hydroxy groups as formyl esters (18), CDCA was reduced to 3α,7α-diformoxy-5β-cholan-24-ol (Scheme 2, **III**) and oxidized to 3α,7α-diformoxy-5β-cholan-24-al (Scheme 2, **IV**) with pyridinium chlorochromate. BishomoCDCA (Scheme, **VII**) was obtained by the reaction of the C_{24}-aldehyde with (carbethoxymethylene)-triphenylphosphorane and hydrogenation of methyl 3α,7α-dihydroxy-27-nor-5β–cholest-24-en-26-oate (Scheme 2, **VI**). BishomoCDCA was treated with ethyl chloroformate in the presence of triethylamine and sodium borohydride to form 25,26-bishomo-5β-cholane-3α,7α,26-triol (Scheme 2, **VIII**). The terminal hydroxy group of the bishomo-cholane triol was selectively converted to the *p*-toluenesulfonyl ester, 25,26-bishomo-26-*p*-toluenesulfoxy-

5β-cholane-3α,7α-diol, by treatment with *p*-toluenesulfonyl chloride in anhydrous tetrahydrofuran solution using triethylamine as a catalytic base. Selective tosylation of the terminal hydroxy group was confirmed by ^{1}H NMR. The signal of the terminal methylene protons was shifted 0.48 ppm downfield by tosylation. The signals of the 18- and 21-methyl protons were shifted upfield by 0.02 and 0.06 ppm, respectively. The tosyl ester (Scheme 2, **IX**) was converted quantitatively into the iodide, 25,26-bishomo-26-iodo-5β-cholane-3α,7α-diol (Scheme 2, **X**). In the C_{26}-iodide derivative (Scheme 2, **X**), the terminal methylene protons were observed at 3.23 ppm. The iodide derivative (Scheme 2, **X**) was refluxed with ethanolic sodium sulfite to give the desired bishomoCDC-sul (Scheme 2, **XI**). The presence of the sulfonic acid at the end of the side chain was confirmed by ^{1}H NMR and ^{13}C NMR (Table 1). The signal of the protons of the terminal methylene was observed at 2.78 ppm, and the signal of the terminal carbon which was bonded directly to the sulfur atom was observed at 52.8 ppm (3,4).

Hepatic uptake and intestinal absorption of bishomoCDC-sul. [^{3}H]-Labeled bishomoCDC-sul was administered intravenously, intraduodenally and intraileally into bile fistula hamsters. The fate of the administered label in bile, liver, blood and urine is summarized in Table 2. Following intravenous administration, 94% of the labeled compound was recovered in bile during the 4-h collection period. In the intraduodenal experiment, only 41% of the label was recovered in bile during the same period. In contrast, after intraileal injection of labeled bishomoCDC-sul, 84% of the radioactivity was recovered in the bile. Radioactivity in blood and urine was below detectable limits.

After intravenous infusion of [^{3}H]-labeled bishomoCDC-sul, the compound appeared rapidly in the bile and more than 60% of the radioactivity was recovered within 1 h. The half time ($t_{1/2}$) of biliary recovery was 45 min.

Biliary secretion of radioactivity after intraduodenal injection of [^{3}H]-labeled bishomoCDC-sul and [^{14}C]-labeled CDC-tau is shown in Figure 1. Both compounds were secreted into the bile more slowly than they were after intravenous administration, and the time course of the recovery of bishomoCDC-sul in the bile closely resembled that of CDC-tau. Figure 2 illustrates the biliary recovery of radioactivity after intraileal injection of the labeled compounds. Both appeared in bile more rapidly than after intraduodenal injection. With CDC-tau, more than 70% of the radioactivity was recovered within 1 h. In contrast, only 40% of labeled bishomoCDC-sul was secreted into the bile during the same period.

TABLE 2
Fate of Radioactivity After Intravenous (iv), Intraduodenal (id) and Intraileal (ii) Administration of [^{3}H]-Labeled BishomoCDC-sul into Bile Fistula Hamsters[a]

Number of animals	Administration	Isotopic recovery (%)				
		Bile	Liver	Blood	Urine	Total
3	iv	94.02 ± 3.46[b]	1.78 ± 1.06	n.d.[c]	n.d.	95.80 ± 4.20
3	id	41.47 ± 3.56	1.32 ± 0.06	n.d.	n.d.	42.79 ± 3.58
3	ii	84.37 ± 1.85	2.81 ± 1.09	n.d.	n.d.	87.18 ± 2.23

[a]The [^{3}H]-labeled bishomoCDC-sul was infused iv into bile fistula hamsters at a rate of 50 μg/min for 20 min. id and ii administration were *via* bolus injection of 0.5 mg. Bile samples were collected for 4 h, and liver, blood and urine samples were then obtained to determine their radioactivity.
[b]The data are expressed as mean ± SEM.
[c]n.d., Not detected.

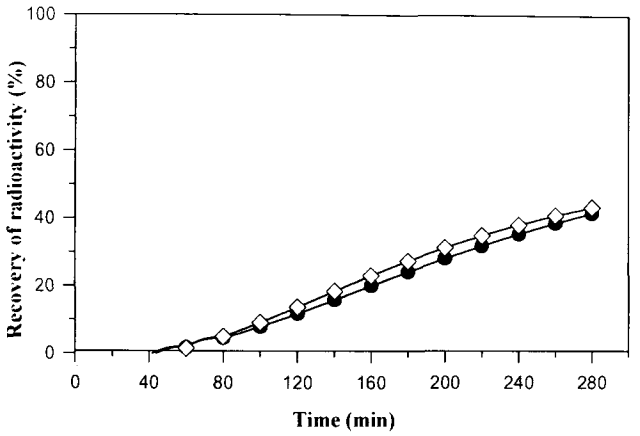

FIG. 1. Cumulative biliary recovery of radioactivity in bile fistula hamsters after intraduodenal injection of [^{3}H]-labeled bishomoCDC-sul and [^{14}C]-labeled chenodeoxycholytaurine. After a 40-min control period, the compounds were injected as a bolus (0.5 mg). The curves represent the means of three hamsters in each group.

From the data of Figure 2, it can be calculated that the $t_{1/2}$s of biliary recovery of CDC-tau and bishomoCDC-sul were 31 and 86 min, respectively.

Figure 3 shows the semi-quantitative analysis by radio-TLC of the bile after intravenous or intraduodenal administration of [^{3}H]labeled bishomoCDC-sul. In these acute experiments, bishomoCDC-sul was secreted into the bile without detectable biotransformation by the liver. The same result was obtained after intraileal administration of bishomoCDC-sul.

Cholestatic effect of bishomoCDC-sul. In order to study the cholestatic properties of bishomoCDC-sul, infusion experiments were performed with the unlabeled compound. Bile flow during intravenus infusion of increasing doses of bishomoCDC-sul is shown in Figure 4. Bile flow remained constant when bishomoCDC-sul was infused at a dose of 0.1

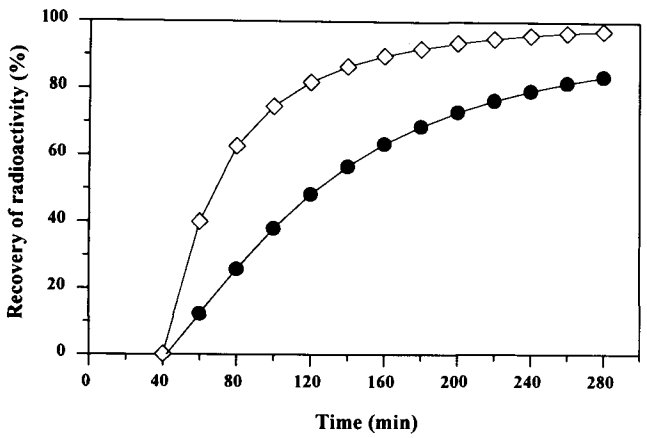

FIG. 2. Cumulative biliary recovery of radioactivity in bile fistula hamsters after intraileal injection of [^{3}H]-labeled bishomoCDC-sul and [^{14}C]-labeled chenodeoxycholytaurine. After a 40-min control period, the compounds were injected as a bolus (0.5 mg). The curves represent the means of three hamsters in each group.

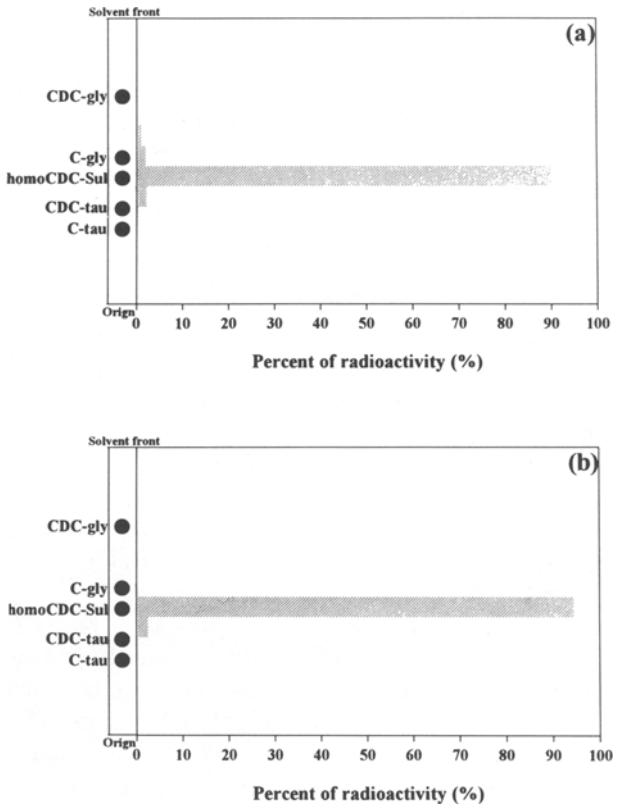

FIG. 3. Thin-layer chromatographic analysis of radioactivity recovered in the bile from bile fistula hamsters after (a) intravenous (iv) and (b) intraduodenal (id) administration of [^{3}H]-labeled bishomoCDC-sul. The bile samples were analyzed by thin-layer chromatography (solvent system CMAW, see Methods section). Reference compounds were as follows: C-tau, cholyltaurine; CDC-tau, chenodeoxycholyltaurine; bishomoCDC-sul, sodium 3α,7α-dihydroxy-25,26-bishomo-5β-cholane-26-sulfonate; C-gly, cholylglycine; CDC-gly, chenodeoxycholylglycine. The administered compound was recovered unchanged in the bile. Similar results were obtained following intraileal injection.

to 0.5 μmol/min/kg. An infusion rate of 1 μmol/min/kg of bishomoCDC-sul induced cholestasis.

DISCUSSION

Conjugation of a bile acid with taurine greatly increases its hepatic extraction (22). Bile acid sulfonates are structurally similar to taurine conjugated bile acids and have similar polarities. Therefore, it might be expected that following i.v. infusion bishomoCDC-sul would be extracted by the liver and secreted into the bile, and this was indeed the case. The natural glycine conjugated dihydroxy bile acids are absorbed in the upper small intestine by passive diffusion and by active transport in the terminal ileum. Highly polar taurine conjugates are absorbed poorly by passive diffusion but are transported rapidly by the ileal active transport system (23,24). Figure 1 shows that after intraduodenal injection, bishomoCDC-sul (and CDC-tau) was absorbed relatively slowly, while after intraileal injection the rate of appearance in the bile was much more rapid (Fig. 2). These results indicate that

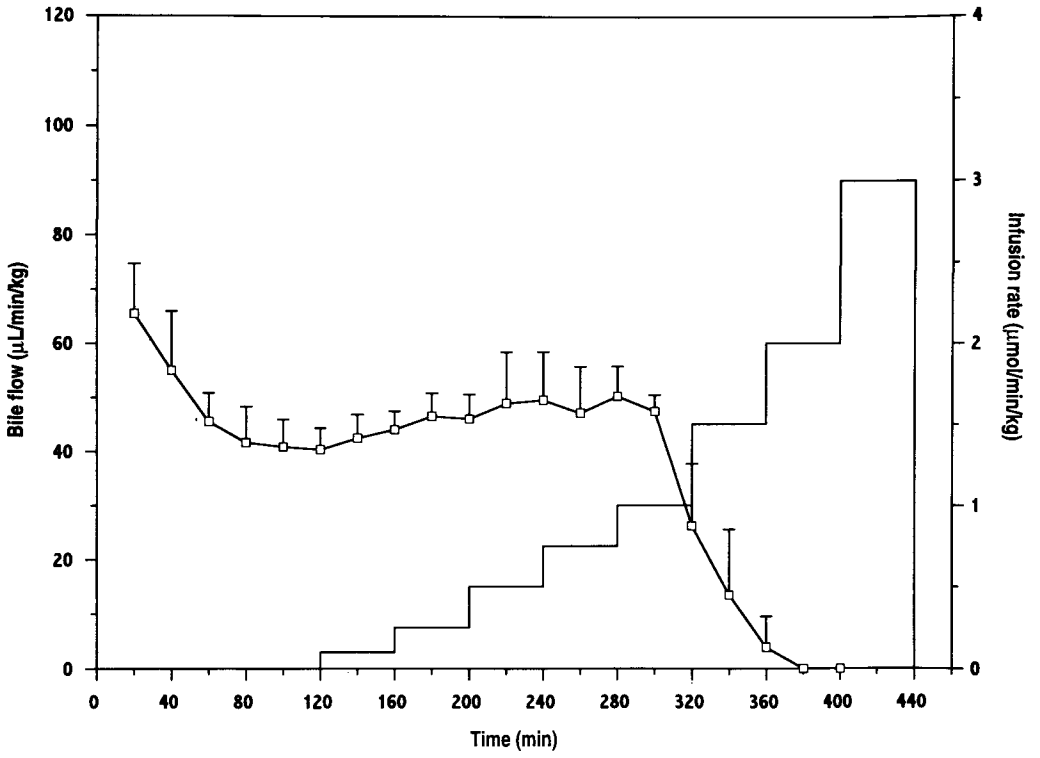

FIG. 4. Effect of bishomoCDC-sul on bile flow in bile fistula hamsters. After a 2-h control period (saline infusion), bishomoCDC-sul was infused intravenously at increasing rates (0.1, 0.25, 0.5, 0.75, 1.0, 1.5, 2.0 and 3.0 µmol/min/kg). Each dose was administered for consecutive periods of 40 min, and bile samples were collected every 20 min. (Mean of three hamsters. The vertical lines at each data point represent 1 SEM.)

bishomoCDC-sul is absorbed from the terminal ileum by active transport, just like the natural bile acids, although at a somewhat slower rate. We recently demonstrated that norCDC-sul was absorbed as efficiently as CDC-tau; however, homoCDC-sul was absorbed more slowly than CDC-tau (4). We ascribe these differences to the different polarities of the bile acid sulfonate analogues—by HPLC, the polarity of norCDC-sul was similar to that of CDC-tau, and homoCDC-sul was less polar than CDC-tau. The polarity of bishomoCDC-sul was considerably lower than that of all of the above bile acids, and this may explain, in part, its slower rate of ileal absorption. However, the cholestatic effect of bishomoCDC-sul is related, at least in part, to its relatively slow hepatic clearance. Blood levels of bishomoCDC-sul were not measured during the infusion experiment so that we can only state that the analogue was not present in blood at the end of the infusion period.

In order to define the cholestatic potential of bishomoCDC-sul, we infused the compound at increasing doses. BishomoCDC-sul produced cholestasis at a dose of 1.0 µmol/min/kg. This dose was higher than that of homoCDC-sul (0.75 µmol/min/kg) and lower than that of norCDC-sul (2.0 µmol/min/kg) (4). It is known that hydrophobic bile acids are more hepatotoxic and more cholestatic than hydrophilic bile acids (16,17,24–26). BishomoCDC-sul is more hydrophobic than homoCDC-sul because the former has one more methylene moiety in the side chain. In addition, we demonstrated that CDC-tau was less cholestatic than norCDC-sul even though CDC-tau was more hydrophobic than norCDC-sul (4). These findings suggest that the cholestatic properties of bile acids are a function of their hydrophobicity, the length of the side chain of the bile acid and the presence or absence of a peptide bond in the side chain. BishomoCDC-sul possesses the same side chain length as the glycine conjugated bile acid, CDC-gly. This may explain why bishomoCDC-sul was less cholestatic than homoCDC-sul, even though it was more hydrophobic.

In summary, we synthesized the sulfonate analogue of bishomoCDC, namely bishomoCDC-sul. BishomoCDC-sul was absorbed from the terminal ileum by active transport, efficiently extracted by the liver, and secreted into the bile. In acute experiments, bishomoCDC-sul underwent negligible biotransformation. BishomoCDC-sul was cholestatic in the hamster but to a lesser extent than homoCDC-sul. More studies are needed to decide whether certain sulfonate analogues can serve as long-acting cholelitholytic agents.

Chemical and Enzymatic Preparation of Acylglycerols Containing C_{18} Furanoid Fatty Acids

Marcel S.F. Lie Ken Jie* and M.S.K. Syed-Rahmatullah

Department of Chemistry, The University of Hong Kong, Hong Kong

ABSTRACT: C_{18} furanoid triacylglycerol [glycerol tri-(9,12-epoxy-9,11-octadecadienoate)] was prepared by chemical transformation of triricinolein isolated from castor oil. The procedure involved oxidation, epoxidation and cyclization of the epoxy-keto intermediate with sodium azide and ammonium chloride in aqueous ethanol. The furanoid triacylglycerol was also obtained by esterification of C_{18} furanoid fatty acid with glycerol using Novozyme 435 (Novo Nordisk A.S., Bagsvaerd, Denmark) as biocatalyst. When Lipozyme (Novo Nordisk A.S.) was used, a mixture of the furanoid 1(3)-*rac*-monoacylglycerol and 1,3-diacylglycerol was obtained. In order to obtain the C_{18} furanoid 1,2(2,3)-diacylglycerol, selective hydrolysis of the furanoid triacylglycerol was achieved using porcine pancreatic lipase in *tris*(hydroxymethyl) methylamine buffer. Interesterification of triolein with methyl C_{18} furanoid ester in the presence of Lipozyme showed maximum incorporation of 34% of furanoid fatty acid. Extension of the interesterification to vegetable oils (olive, peanut, sunflower, corn and palm oil) allowed a maximum of 24% furanoid acid incorporation to be achieved.
Lipids 30, 79–84 (1995).

A considerable number of long-chain fatty acids containing a furan ring system as part of the alkyl chain have been isolated from a seed oil (1), the latex of the rubber plant (2,3), algal species (4) and from many other plant tissues (5). Such furanoid fatty acids are also found in the liver of some freshwater and marine fishes (6–12), in the crayfish (13–15), and in sponges (16) and soft corals (17). Furanoid fatty acids have also been isolated from the lipid extracts of higher animals (18), including human (19). Furanoid fatty acids are found acylated to glycerol as part of the triacylglycerol pool in seed oils (2,3) and in fish liver (12), but are esterified to cholesterol in the testes of fish (12). The role and function of these unusual fatty acids remain to be determined. In our continuing effort to study the properties of furanoid fatty acids and their derivatives, we describe the synthesis of C_{18} furanoid acylglycerols (mono-, di- and triacylglycerols) by partial chemical synthesis and by the incorporation of a C_{18} furanoid fatty acid into triolein and other vegetable oils by enzymatic esterification and interesterification methods.

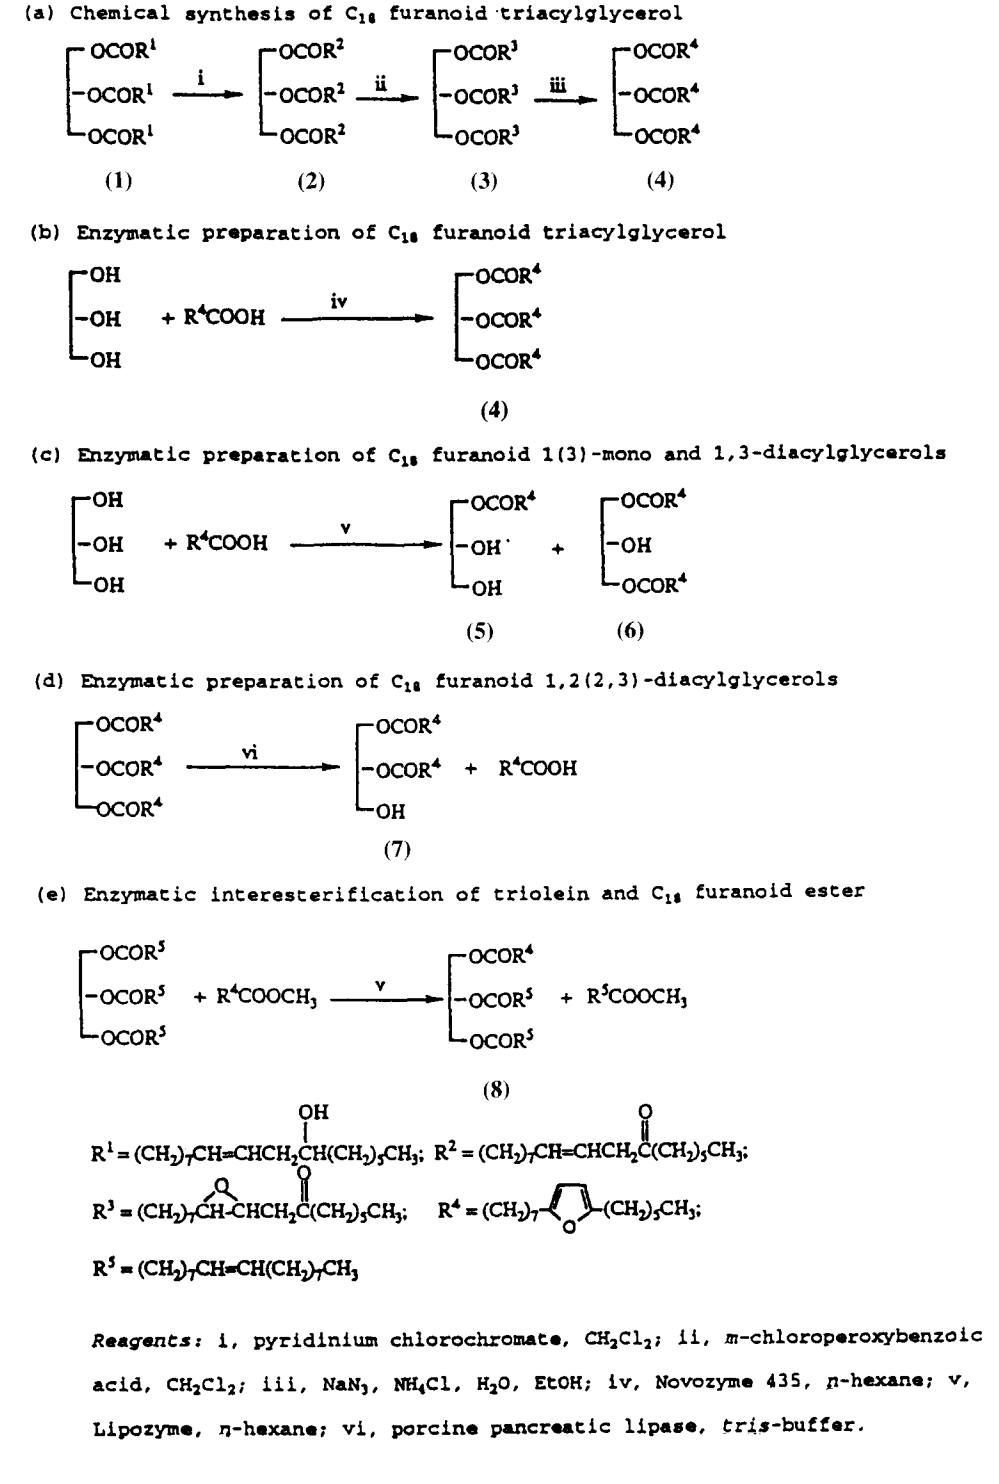
Abbreviations: IR, infrared spectroscopy; NMR, nuclear magnetic resonance spectroscopy.

MATERIALS AND METHODS



Castor, palm, olive, peanut, corn and sunflower oil were purchased from local supermarkets. All solvents were distilled before use. Petroleum ether refers to the fraction with b.p. of 40–60°C. Triolein was synthesized by enzymatic (Novozyme 435) esterification of glycerol with oleic acid. Pyridinium chlorochromate was purchased from Aldrich Chemical Co. (Milwaukee, WI). Lipozyme [lipase isolated from *Rhizomucor miehei* and immobilized on anion exchange resin, activity 24 BIU (BIU—Batch Interesterification Unit, *viz.* 1 μmol of palmitic acid incorporated into triolein per min under standard conditions as defined by the manufacturer)] and Novozyme 435 (lipase isolated from *Candida antarctica* and immobilized on macroporous acrylic resin, activity 40 BIU/g are gifts from Novo Nordisk A.S. (Bagsvaerd, Denmark). Porcine pancreatic lipase (type II, 179 units/mg protein) was purchased from Sigma (St. Louis, MO). Thin-layer, column and gas–liquid chromatographic analyses were performed as described elsewhere (20). Melting points were determined on a hot stage microscope apparatus and values are uncorrected. Methyl 9,12-epoxy-9,11-octadecadienoate was prepared by a previously described method (21). Infrared, ^1H and ^{13}C nuclear magnetic resonance (NMR) spectra were recorded as described elsewhere (20).

Triricinolein [glycerol tri-(12-hydroxy-9-*cis*-octadecenoate)] was obtained from castor oil as follows: castor oil (10.0 g) was dissolved in a mixture of petroleum ether/diethyl ether (5:2, vol/vol) (100 mL). The solution was passed through a silica (100 g) column. The column was eluted with a mixture of petroleum ether/diethyl ether (7:3, vol/vol; 200 mL) to remove triacylglycerols containing two ricinoleic acids and a nonhydroxylated fatty acid. The column was further eluted with a mixture of petroleum ether/diethyl ether (2:3, vol/vol; 400 mL), which furnished pure triricinolein (7.0 g) on evaporation of the solvent.

EXPERIMENTAL PROCEDURES

Chemical synthesis of C_{18} furanoid triacylglycerol by the oxidation of triricinolein (**1**) *(Scheme 1a).* A solution of pyridinium chlorochromate (2.0 g, 9.3 mmol) in dichloromethane (50 mL) was added to triricinolein (**1**, 2.0 g, 2.15 mmol) and stirred for 4 h at room temperature. Diethyl ether (100 mL) was added to precipitate the chromium salts, and the reaction mixture was filtered through a column of Florisil (50 g). The adsorbed reaction product was further eluted with diethyl ether (200 mL). The solvent of the eluate was evaporated to give a residue (1.9 g), which was purified by silica (30 g) col-

SCHEME 1

umn chromatography using a mixture of petroleum ether/diethyl ether (7:3, vol/vol; 150 mL) as the eluent to give pure glycerol tri-(12-oxo-9-*cis*-octadecenoate) (**2**, 1.7 g, 85%) as a viscous liquid. Infrared (cm^{-1}) film: 3010, 1740(C=O, ester), 1715(C=O, oxo). ^1H NMR ($CDCl_3$, δ) 0.84(*t*, 9H, CH_3), 1.2–1.5(*m*, 48H, CH_2), 1.5–1.9(*m*, 12H, CH_2), 1.9–2.0(*m*, 6H, CH_2-CH=CH), 2.3(*t*, 6H, 2-*H*), 2.44(*t*, 6H, 13-*H*), 3.16(*d*, 6H, 11-*H*), 4.24(*m*, 4H, glyceryl CH_2), 5.3(*m*, 1H, glyceryl C*H*), 5.6(*m*, 6H, C*H*=C*H*). ^{13}C NMR ($CDCl_3$, ppm) 13.98(C-18), 22.5(C-17), 23.84(C-14), 24.87(C-3), 27.52(C-8), 28.93, 29.09, 29.31, 31.64(C-16), 34.02(C-2 of 1-acyl, 2C), 34.18(C-2 of 2-acyl, 1C), 41.71(C-11), 42.36(C-13), 62.14(glyceryl, CH_2), 69.02(glyceryl, *C*H), 121.13(C-10), 133.49(C-9), 172.76(C-1 of 2-acyl, 1C), 173.14(C-1 of 1-acyl, 2C) and 209.01(C-12, C=O oxo).

*Epoxidation of glycerol tri-(12-oxo-9-*cis*-octadecenoate)* (**2**). A mixture of the keto-ene triglyceride intermediate (**2**, 1.0 g, 1.1 mmol), dichloromethane (25 mL and *m*-chloroperoxybenzoic acid (1.2 g, 50% purity, 3.5 mmol) was stirred for 8 h at room temperature. Aqueous sodium sulfite (10%, 20 mL) was added and the organic phase was isolated. The organic phase was successively washed with aqueous $NaHCO_3$ (5%, 15 mL), water (2 x 20 mL), and dried (Na_2SO_4). Evaporation of the filtrate furnished crude glycerol tri-(9,10-epoxy-12-oxo-octadecanoate) (**3**, 0.9 g, 82%), which was purified by recrystallization from a mixture of petroleum ether/diethyl ether (1:1, vol/vol) to yield pure glycerol tri-(9,12-epoxy-12-oxo-octadecanoate) (**3**, 0.7 g, 73%). m.p. 73°C; IR (cm^{-1}) film 1740(C=O, ester), 1700(C=O, oxo), 842(C-H, epoxy ring). ^1H NMR ($CDCl_3$, δ) 0.88(*t*, 9H, CH_3), 1.2–1.8(*m*, 60H, CH_2), 2.2–2.45(*m*, 12H, 2-*H*, 13-*H*), 2.64(*d*, 6H, 11-*H*), 2.95(*m*, 3H, epoxy C-*H*, 9-*H*), 3.3(*m*, 3H, epoxy C-*H*, 10-*H*), 4.0–4.4(*m*, 4H, glyceryl CH_2), 5.24(*m*, 1H, glyceryl C*H*). ^{13}C NMR ($CDCl_3$, ppm) 14.03(C-18), 22.48(C-17), 23.62(C-14), 24.81(C-3), 26.49(C-8), 28.01(C-7), 28.29, 28.98, 29.20, 29.31, 31.58(C-16), 34.02(C-2 of 1-acyl, 2C), 34.18(C-2 of 2-acyl, 1C), 41.71(C-11), 43.39(C-13), 52.39(C-10), 56.50(C-9), 62.14(glyceryl CH_2), 69.12(glyceryl *C*H), 172.82(C-1 of 2-acyl, 1C), 173.20(C-1 of 1-acyl, 2C), 208.41(C-12, C=O oxo, 3C).

Cyclization of epoxy-keto triglyceride (**3**). A mixture of compound **3** (0.5 g, 0.5 mmol.), sodium azide (0.9 g, 14 mmol), ammonium chloride (0.75 g, 14 mmol), water (3.0 mL) and ethanol (20 mL) was refluxed for 40 min. The reaction mixture was cooled and extracted with diethyl ether (2 x 50 mL). The ethereal extract was washed with water (2 x 20 mL) and dried (Na_2SO_4). Silica column chromatographic purification using a mixture of petroleum ether/diethyl ether (9:1, vol/vol) as eluent gave pure glycerol tri-(9,12-epoxy-9,11-octadecadienoate) (**4**, 0.3 g, 66%) as a viscous liquid. IR (cm^{-1}) film 3100(C-H furan), 1740(C=O ester), 1610, 1560, 1010(C-O-C furan), 780. ^1H NMR ($CDCl_3$, δ) 0.88(*t*, 9H, CH_3), 1.2–1.4(*m*, 36H, CH_2), 1.6–1.8(*m*, 24H, CH_2), 2.3(*t*, 6H, 2-*H*), 2.55(*t*, 12H, 8-*H*, 13-*H*), 4.1–4.4(*m*, 4H, glyceryl CH_2), 5.26(*m*, 1H, glyceryl C*H*) 5.83(*s*, 6H, furan C*H*). ^{13}C NMR ($CDCl_3$, ppm) 14.09(C-18), 22.60(C-17), 24.83(C-3, 1-acyl), 24.86(C-3, 2-acyl), 28.04, 28.09, 28.91, 29.03, 31.61(C-16), 34.01(C-2 of 1-acyl, 2C), 34.18(C-2 of 2-acyl, 1C), 62.11(glyceryl CH_2), 68.90(glyceryl *C*H), 104.81(C-10), 104.87(C-11), 154.43(C-9), 154.69(C-12), 172.85(C-1 of 2-acyl, 1C), 173.26(C-1 of 1-acyl, 2C).

Enzymatic method: enzymatic esterification of glycerol with furanoid fatty acid (9,12-epoxy-9,11-octadecadienoic acid) in the presence of Novozyme 435 (Scheme 1b). A mixture of 9,12-epoxy-9,11-octadecadienoic acid (0.3 g, 1.0 mmol), glycerol (53 mg, 0.06 mmol), Novozyme 435 (35 mg) and *n*-hexane (2 mL) was stirred at 60°C for 2 h. Molecular sieve (4 Å, 0.5 g) was added (to remove co-produced water), and the mixture was stirred for a further 6 h. The mixture was centrifuged to separate the molecular sieve and enzyme from the reaction mixture. The supernatant liquid was isolated and silica column chromatographic separation by gradient elution using mixture of petroleum ether/diethyl ether (9:1 to 3:2, vol/vol) as eluent gave: glycerol tri-(9,12-epoxy-9,11-octadecadienoate) (**4**, 0.16 g, 47%) and glycerol 1,3-di-(9,12-epoxy-9,11-octadecadienoate) (0.06 g, 10%).

*Preparation of C_{18} furanoid 1(3)-*rac*-monoacylglycerol* (**5**) *and 1,3-diacylglycerols* (**6**) *(Scheme 1c): Enzymatic esterification of glycerol with 9,12-epoxy-9,11-octadecadienoic acid in the presence of Lipozyme.* A mixture of methyl 9,12-epoxy-9,11-octadecadienoic acid (0.4 g, 1.3 mmol), glycerol (60 mg, 0.6 mmol), Lipozyme (46 mg), silica gel (TLC grade) (60 mg) and *n*-hexane (4 mL) was stirred at 60°C for 2 h. Molecular sieve (0.5 g) was added and the reaction mixture stirred for a further 10 h. Isolation and silica column chromatographic separation by gradient elution with mixtures of petroleum ether/diethyl ether (9:1 to 7:3, vol/vol) as eluent yielded: (a) glycerol 1(3)-*rac*-(9,12-epoxy-9,11-octadecadienoate) (**5**, 70 mg, 20%). ^1H NMR ($CDCl_3$, δ) 0.88(*t*, 3H, CH_3), 1.2–1.5(*m*, 12H, CH_2), 1.6–1.8(*m*, 6H, CH_2), 2.3(*t*, 2H, 2-*H*), 2.55(*t*, 4H, 8-*H*, 13-*H*), 3.0(*s*, 2H, O-*H*), 3.65(*d*, glyceryl CH_2-OH), 3.93(*m*, glyceryl C*H*), 4.19(*d*, 2H, glyceryl CH_2), 5.83(*s*, 2H, furan C*H*). ^{13}C NMR ($CDCl_3$, ppm) 14.09(C-18), 22.59(C-17), 24.92(C-3), 28.12(C-7, C-8, C-13, C-14, 4C), 28.98, 31.64(C-16), 34.18(C-2), 63.49(glyceryl CH_2-OH), 65.23(glyceryl CH_2-O-CO-), 70.37(glyceryl, *C*H-OH), 104.94(C-10, C-11, furan), 154.45(C-9, C-12, furan) and 174.28(C-1); (b) glycerol 1,3-di(9,12-epoxy-9,11-octadecadienoate) (**6**, 150 mg, 45%). ^1H NMR ($CDCl_3$, δ) 0.88(*t*, 6H, CH_3), 1.1–1.5(*m*, 24H, CH_2), 1.6–1.8(*m*, 12H, CH_2), 2.0(*s*, 2H, O-H), 2.3(*t*, 4H, 2-*H*), 2.55(*t*, 8H, 8-*H*, 13-*H*), 4.1–4.15(*m*, 5H, glyceryl C*H* and CH_2), 5.8(*s*, 4H, furan C*H*). ^{13}C NMR ($CDCl_3$, ppm) 14.09(C-18), 22.63(C-17), 24.84(C-3), 28.02(C-8/C-13), 28.08(C-8/C-13). 28.90, 29.11, 29.17, 29.34, 29.70, 31.61(C-16), 34.07(C-2), 65.05, 68.33, 104.81, 104.88(furan, *C*-H), 154.42, 154.68(furan, *C*) and 173.87(C-1); and (c) glycerol tri-(9,12-epoxy-9,11-octadecadienoate) (**4**, 17 mg, 5%).

*Preparation of glycerol 1,2(2,3)-*rac*-di-(9,12-epoxy-9,11-octadecadienoates by pancreatic lipase hydrolysis of glycerol tri-(9,12-epoxy-9,11-octadecadienoate)* (**4**) *(Scheme 1d).* Glycerol tri(9,12-epoxy-9,11-octadecadienoate) (**4**, 0.2 g)

was suspended in *tris*(hydroxymethyl) methylamine buffer (2 mL, 1M, pH 8.0) in a screw-capped test tube. Aqueous calcium chloride (0.4 mL, 22 g in 100 mL) and sodium cholate (1 mL, 0.1% solution) were added and the mixture kept at 40°C for 5 min. A suspension of porcine pancreatic lipase (40 mg) in *tris*(hydroxymethyl) methylamine buffer (1 mL) at 40°C was added, and the mixture was stirred at 40°C for 10 min. Dilute HCl (6M, 1.0 mL) and diethyl ether (2 mL) were added, and the mixture was centrifuged. The ethereal layer was isolated and the aqueous solution was re-extracted with diethyl ether (2 x 2 mL). The combined ethereal extract was dried (Na_2SO_4) and the filtrate was evaporated under a stream of nitrogen. The residue was quickly separated on a silica (10 g) column using a mixture of petroleum ether/diethyl ether (1:1 to 0:1, vol/vol) as the eluent by gradient elution to give glycerol 1,2(2,3)-*rac*-di-(9,12-epoxy-9,11-octadecadienoate) (**7**, 80 mg, 35%). ^{1}H NMR ($CDCl_3$, δ) 0.88(*t*, 6H, CH_3), 1.2–1.5(*m*, 24H, CH_2), 1.55–1.8(*m*, 17H, CH_2 and O-*H*), 2.30(*t*, 4H, 2-*H*), 2.6(*t*, 8H, 8-*H* and 13-*H*), 3.70 (*d*, 2H, glyceryl CH_2-OH), 4.3(*m*, 2H, glyceryl CH_2), 5.10(*m*, 1H, glyceryl C*H*) and 5.82(*s*, 4H, furan C*H*). ^{13}C NMR ($CDCl_3$, ppm) 14.03(C-18), 22.59(C-17), 24.76 and 24.86(C-3), 28.12, 28.60, 29.04, 31.64(C-16), 34.08 and 34.29(C-2), 61.49(glyceryl CH_2OH), 62.19(glyceryl CH_2), 72.1(glyceryl C*H*), 104.90(furan C*H*), 154.45(C-9), 154.72(C-12), 173.30 and 173.68(C-1).

Incorporation of 9,12-epoxy-9,11-octadecadienoic acid into triolein by enzymatic interesterification using Lipozyme (Scheme 1d). A mixture of triolein (0.2 g, 0.23 mmol), methyl 9,12-epoxy-9,11-octadecadienoate (0.2 g, 0.68 mmol), Lipozyme (40 mg) and *n*-hexane (2 mL) was stirred at 60°C for 4 h. The mixture was centrifuged, and the supernatant liquid was eluted through a silica column using a mixture of petroleum ether/diethyl ether (4:1, vol/vol) as the eluent to give glycerol 1(3)-*rac*-(9,12-epoxy-9,11-octadecadienoate)-2,3(1,2)-dioleate (**8**, 0.12 g, 60%). IR (cm^{-1}) film 3100(C-H) furan), 1740(C=O, ester), 1610, 1560 and 1010 (C-O-C, furan). ^{1}H NMR ($CDCl_3$, δ): 0.84(*t*, 9H, CH_3), 1.2–1.5(*m*, CH_2), 2.0(*m*, 8H, CH_2CH=CH), 2.30(*t*, 6H, 2-*H*), 2.50(*t*, 4H, CH_2-furan), 4.2(*m*, 4H, glyceryl CH_2), 5.36(*m*, 1H, glyceryl C*H*) and 5.74(*s*, 2H, furan C*H*). ^{13}C NMR ($CDCl_3$, ppm) 14.08(C-18, furanoyl), 14.12(C-18, oleoyl), 22.59(C-17, furanoyl), 22.70(C-17, oleoyl), 24.83(C-3, furanoyl), 24.86(C-3, 1-oleoyl), 24.90(C-3, 2-oleoyl), 27.19, 27.22, 27.24, 28.04, 28.09, 28.11, 28.91, 29.03, 29.07, 29.11, 29.13, 29.15, 29.21, 29.33, 29.34, 29.54, 29.67, 29.73, 29.78, 31.61(C-16, furanoyl), 31.92(C-16, oleoyl), 34.02(C-2, furanoyl), 34.05(C-2, 1-oleoyl), 34.21(C-2, 2-oleoyl), 62.18(glyceryl CH_2), 68.90(glyceryl C*H*), 104.80(C-10, furanoyl), 104.86(C-11, furanoyl), 129.69(C-9, 2-oleoyl), 129.72(C-9, 1-oleoyl), 130.03(C-10, 1-oleoyl), 130.04(C-10, 2-oleoyl), 154.43(C-9, furanoyl), 154.69(C-12, furanoyl), 172.86(C-1, 2-oleoyl), 173.24(C-1, furanoyl) and 173.27(C-1, 1-oleoyl).

The same interesterification procedure was repeated using different vegetable oils (olive, peanut, sunflower, corn and palm oil). In each case the triacylglycerol fraction was isolated by silica column chromatography. The extent of the incorporation of the furanoid fatty acid into the various seed oils was reflected by the amount of furanoid fatty acid present in the total fatty acid composition of the interesterified seed oils as given in Table 1.

RESULTS AND DISCUSSION

To synthesize C_{18} furanoid triacylglycerol (**4**), two approaches were investigated (Scheme 1, a and b). Starting from triricinolein (**1**) isolated from castor oil, oxidation of the hydroxy function in high yield was achieved by using commercially available pyridinium chlorochromate in CH_2Cl_2. This method was preferred to the low-yield two-phase (diethyl ether/water) chromic acid procedure often employed in the synthesis of the furanoid fatty ester from methyl ricinoleate (22), which caused overoxidation of the substrate. Subsequent epoxidation of the keto-ene triacylglycerol (**2**) was successfully accomplished with *m*-chloroperoxybenzoic acid. Using the high yield and efficient NaN_3/NH_4Cl/EtOH method de-

veloped by us (21), the keto-epoxy triacylglycerol intermediate was cyclized to the requisite C_{18} furanoid triacylglycerol (**4**) in good yield (66%).

Novozyme 435 and Lipozyme are reported to be efficient biocatalysts for esterification and interesterification, respectively (23,24). To obtain the same C_{18} furanoid triacylglycerol (**4**) by enzymatic (biocatalytic) means, the C_{18} furanoid fatty acid was first prepared by well-established methods (21). Enzymatic esterification of C_{18} furanoid fatty acid to glycerol was conducted using Novozyme 435 (Scheme 1b) or Lipozyme at 60°C in *n*-hexane (Scheme 1c). Molecular sieve was added to the reaction mixture during incubation to remove the water liberated during the process and to direct the course of reaction toward esterification. When Novozyme 435 was used as the biocatalyst, the C_{18} furanoid triacylglycerol (**4**) was obtained in 47% yield together with 1,3-diacylglycerol (10%). The C_{18} furanoid triacylglycerol (**4**) obtained by both chemical transformation of triricinolein or by enzymatic esterification of glycerol with C_{18} furanoid fatty acid was characterized by the signals at δ 4.1–4.4(*m*), 5.26(*m*) for the glyceryl protons and 5.83(*s*) for the furan protons in the ^{1}H NMR spectrum. These assignments were based on the intensities of the signals and from the reported chemical shift values of methyl C_{18} furanoid fatty ester (22). The signals at 62.11 and 68.90 for the glyceryl carbon shifts, and 104.81, 104.87, 154.43 and 154.69 ppm for the furan carbon shifts in the ^{13}C NMR spectrum confirmed the structure of compound **4**.

When Novozyme 435 was replaced by Lipozyme, the esterification process was poor in producing triacylglycerol. Instead the reaction furnished mainly the 1(3)-*rac*-(9,12-epoxy-9,11-octadecadienoate) (**5**, 20%) and glycerol 1,3-di(9,12-epoxy-9,11-octadecadienoate) (**6**, 45%), due to its specific ability to esterify fatty acids to the 1- and 3-positions of the glycerol molecule. Only a small amount of the triacylglycerol (**4**, 5%) was produced (Scheme 1c). From these results, Novozyme 435 is the choice biocatalyst to be used for esterification of fatty acids to glycerols to yield triacylglycerols, whereas Lipozyme is best used for obtaining 1(3)-*rac*-mono- and 1,3-diacylglycerols.

The C_{18} furanoid 1,2(2,3)-*rac*-diacylglycerol (**7**) was also prepared by selectively hydrolyzing the 1(3)-position of the corresponding C_{18} furanoid triacylglycerol (**4**) with porcine pancreatic lipase according to the IUPAC method (25) with minor modification (Scheme 1d). Rapid silica column chromatographic separation of the product furnished unreacted C_{18} furanoid triacylglycerol (**4**, 10%) and glycerol 1,2(2,3)-*rac*-di(9,12-epoxy-9,11-octadecadienoate) (**7**, 35%). However, the latter compound isomerized readily to the 1,3-diacylglycerol on standing at room temperature.

The incorporation of C_{18} furanoid fatty ester to triacylglycerols was investigated by the interesterification reaction with triolein (Scheme 1e) and some vegetable oils. Lipozyme was selected as the biocatalyst for this purpose. The experimental conditions were first optimized by using triolein as a model substrate. The reaction temperature was kept constant at 60°C for 4 h during each trial. The amount of furanoid fatty acid incorporation into the triolein at the 1- and 3-positions of the glycerol backbone depended on the ratio of the amount of the triolein to furanoid fatty ester used. When a 1:1 ratio of triolein and furanoid fatty ester was used, only 14.5% of furanoid fatty acid was incorporated. By changing the ratio of triolein and furanoid fatty ester to 1:3, a 34% incorporation of furanoid fatty acid into the triolein molecule was observed. But when a ratio of 1:9 of triolein to furanoid ester was tried, the rate of interesterification was not improved as the incorporation of the furanoid fatty acid remained at a constant level of 34%. By extending the reaction time from 4 to 8 h, increased amounts of diacylglycerols, monoacylglycerols and free fatty acids were obtained, but the amount of furanoid acid incorporation decreased with time.

From the interesterification study of vegetable oils (olive, peanut, sunflower, corn and palm oil), it became apparent that the incorporation of the C_{18} furanoid fatty ester into the various natural triacylglycerols could only be achieved to a maximum of 24.3% (Table 1). Increasing the incubation period of the biocatalyzed interesterification process did not improve the degree of incorporation of the C_{18} furanoid ester into the triacylglycerols of the vegetable oils.

The ^{13}C NMR spectral results of the interesterified triacylglycerol product of triolein showed that the C_{18} furanoid fatty acid was esterified to the 1(3)-position of the glycerol backbone only. This was deduced by referring to the ^{13}C NMR result obtained for glycerol tri-(9,12-epoxy-9,11-octadecadienoate). The carbon shifts of the olefinic carbon atoms of oleic acid moieties in this product also showed that the oleic acid occupied both the 1- and 2-positions of the triacylglycerol molecule from the signals at: 129.72(C-9, 1-acyl), 129.69(C-9, 2-acyl), 130.03(C-10, 1-acyl) and 130.04(C-10, 2-acyl). Signals associated with the furan nucleus appeared at 104.80, 104.86, 154.43 and 154.69 ppm. It can be concluded from this study that enzymatic interesterification using Lipozyme allowed only the 1-acyl chain of the triacylglycerol to be replaced by the C_{18} furanoid ester.

This study confirms that Lipozyme, Novozyme and porcine pancreatic lipase do not discriminate the synthetic C_{18} furanoid fatty acid over other common natural fatty acids in the process of esterification, interesterification or hydrolysis involving such biocatalysts.

ABSTRACT: The utility of reverse-phase high-performance liquid chromatography (HPLC), desorption chemical-ionization mass spectrometry (DCI–MS) and tandem mass spectrometry (MS/MS) for the characterization of triacylglycerols in complex mixtures has been further explored. Triacylglycerols of anhydrous bovine milk fat were separated by using two reverse-phase C_{18} HPLC columns, and eluents were monitored with an evaporative light-scattering detector. Fifty-eight fractions were resolved and analyzed by positive ion isobutane DCI–MS. The formation of protonated molecules and of major fragments corresponding to the random loss of any one of the constituent fatty acids readily identified acyl carbon numbers and the number of double bonds within each fatty acid. MS/MS was only required when the original mass spectra indicated the presence of more than one triacylglycerol or of impurities in a fraction. Protonated molecules produced by DCI were fragmented using high energy collisional activation, and the resulting ions were detected by MS/MS. Odd-chain triacylglycerols were also readily distinguished using this methodology. The positive ion DCI and MS/MS techniques described here demonstrate the usefulness of this approach for the characterization of triacylglycerols in complex mixtures.

Lipids 30, 85–90 (1995).

Milk fat contains an unusually wide range of fatty acids (1–5). Because of this complexity, the structural elucidation of milk fat triacylglycerols is a formidable task (6). Triacylglycerols can typically be analyzed by high-performance liquid chromatography (HPLC) or gas–liquid chromatography (GLC) (7). However, the low volatility of triacylglycerols requires very high GLC column temperatures (350–375°C), which can cause degradation (8), particularly with polyunsaturated triacylglycerols (9). The recent availability of evaporative light-scattering detectors (ELSD) has brought about a major advance in the detection of lipids upon HPLC separation relative to earlier types of detectors (refractive index, ultraviolet). ELSD also permits elution with solvent gradients, as is required to resolve triacylglycerol mixtures as complex as those found in milk fat (10).

A number of excellent studies have been reported which have demonstrated reverse-phase HPLC separations (11–17), as well as the application of ELSD (18–21) for triacylglycerol analysis. Only quite recently have these chromatographic methods, as well as tandem mass spectrometry (MS/MS), been used to structurally characterize mixtures of triacylglycerols (22,23). It is known that mass spectrometry (MS) of triacylglycerols using positive ion chemical ionization (CI) or desorption chemical ionization (DCI) produces protonated molecules $[M + H]^+$, as well as fragment ions corresponding to random elimination of an acyl group from the triacylglycerol, $[MH - RCOOH]^+$ (24–26). Alternatively, negative ion DCI MS/MS has been used to characterize triglyceride structures (22,23). MS/MS following collisional activation can provide fragment ions of selected protonated molecules formed during CI or DCI, thus simplifying the identification of fragments ions when more than one $[M + H]^+$ species is present.

The aim of this study was (i) to fractionate milk fat triacylglycerols by HPLC–ELSD and (ii) to characterize the triacylglycerol species present by DCI–MS and MS/MS techniques.

EXPERIMENTAL PROCEDURES

Materials. Anhydrous milk fat (butter oil) was donated by Danish Maid Butter Co. (Chicago, IL). It contained no less

than 99.6% butter fat and no more than 0.4% moisture. 1,2-Dimyristoyl-3-lauroyl-glycerol, 1,2-dipalmitoyl-3-myristoyl-glycerol, 1,3-dioleoyl-2-stearoyl-glycerol, cholesterol, cholesterol myristate, cholesterol palmitate, cholesterol oleate and cholesterol arachidate were obtained from Sigma (St. Louis, MO). Acetonitrile, methylene chloride, acetone, hexanes and methyl-*tert*-butyl ether were purchased from Fisher (Fair Lawn, NJ). Propionitrile (PCN) was obtained from Fluka (Ronkonkoma, NY) and was purified by distillation. Ethanol was purchased from Midwest Grain Product Co. (Weston, MI). All HPLC solvents were filtered through a 0.45 μm membrane filter (Micron Separations Inc., Westboro, MA).

HPLC analysis of triacylglycerols. The HPLC setup consisted of a three-pump system, Model 510 and 501 pumps, a Gradient Controller, a U6K injector (Waters Associates, Milford, MA) and a Model ELSD-MK IIA ELSD (Varex Corp., Burtonsville, MD). Chromatograms were processed using a Dynamax HPLC Method Manager (Rainin, Woburn, MA). The analytical columns (5 μm, 25 cm × 4.6 mm i.d.) were a Spherisorb ODS-2 (Alltech Associates, Deerfield, IL) and a Zorbax C_{18} (Mac-Mod Analytical Inc., Chadds Ford, PA) connected in tandem with a Spherisorb ODS-2 precolumn (5 μm, 3.5 cm × 4.6 mm; Anspec, Ann Arbor, MI). Triacylglycerols were eluted using acetonitrile, Solvent A; PCN, Solvent B; and PCN/methylene chloride (72:28, vol/vol), Solvent C. The elution involved two linear gradient steps at a flow rate of 0.7 mL/min. The first step was from 30% Solvent A and 70% Solvent B to 5% Solvent A and 95% Solvent B in 50 min.The second step was from 5% Solvent A and 95% Solvent B to 0% Solvent A, 0% Solvent B and 100% Solvent C in 70 min. The detector drift tube temperature was 130°C, inlet pressure of nitrogen nebulizing gas was 32 psi and the detector exhaust temperature was 81–82°C. Typical milk fat separations involved 50-μL injections of milk fat solution (5 μg of milk fat per μL of PCN/methylene chloride; 3:2, vol/vol).

Isolation of triacylglycerols. Approximately 900 μg of milk fat was injected for each HPLC analysis. A flow splitter (Varex Corp.) was utilized to divide the column effluent between a fraction collector (ISCO Retriever II; ISCO, Lincoln, NE) and the detector at a split ratio of 9:1. Solvent was evaporated under a stream of N_2, fractions were reconstituted in PCN/methylene chloride (2:1, vol/vol), and aliquots were reinjected onto the HPLC to check peak purity. The remaining portion of each triacylglycerol isolate was dried (N_2 stream) and kept at −18°C until mass spectrometric analysis.

MS. Isobutane positive ion DCI mass spectra were obtained using a JEOL (Tokyo, Japan) JMS-HX110HF double-focusing mass spectrometer, equipped with a JMA-DA5000 data system and a DCI direct insertion probe. Samples were dissolved in methylene chloride (1–5 μg/μL), and 10 μL was loaded onto the tungsten DCI filament. The solvent was then evaporated and the probe inserted into the ionization source. The filament was heated at 0.25 μA/min in isobutane reagent gas so that molecules were protonated immediately upon desorption. The ion source temperature was 150°C, and the resolution was 1000 for all measurements. Based on the total ion chromatogram, 4–8 scans containing the most abundant sample ions over the region *m/z* 100–1,200 were averaged using the data system. MS/MS analyses were obtained by collisional activation of selected $[M + H]^+$ precursors, followed by linked scanning at constant magnetic field strength/electrostatic analyzer voltage (B/E), whereby the magnetic field (B) was scanned at a constant ratio to the electrostatic analyzer voltage (E). Helium was used as the collision gas in the first field-free region, and the pressure was adjusted so that the abundance of the $[M + H]^+$ precursor ion was attenuated by 70%.

RESULTS

A chromatogram showing the HPLC separation and ELSD of milk fat triacylglycerols is shown in Figure 1. The milk fat triacylglycerols were resolved into 58 peaks. Because few milk fat triacylglycerols that could be used as standards are commercially available, assignment of peaks to specific triacylglycerols is a complex task. In the present study we used positive ion DCI–MS and MS/MS with isobutane as the reagent gas to characterize the triacylglycerol(s) associated with each peak.

Although the use of isobutane as reagent gas in CI–MS has been reported to result in protonated molecules of low abundance (24,26), in our experiments DCI–MS with isobutane resulted in $[M + H]^+$ ions for all the triacylglycerols analyzed in this study. In our preliminary DCI–MS analyses of triacylglycerol standards, the relative abundances of the $[M + H]^+$ ions from 1,2-dipalmitoyl-3-myristoyl-glycerol, 1,2-dimyristoyl-3-lauroyl-glycerol and 1,3-dioleoyl-2-stearoyl-glycerol were 5, 15 and 51%, respectively.

Table 1 lists the total acyl carbon number, the number of double bonds, and the fatty acids contained in each triglyceride eluted by HPLC (peaks 1 to 58; Fig. 1). Examples of

DCI mass spectra and tandem mass spectra are shown in Figures 2–4. The DCI–MS spectrum of HPLC peak 12 (Fig. 2) shows a protonated molecule *m/z* 611 representing a triacylglycerol structure with a total acyl carbon number of 34. The ion *m/z* 649 was formed by addition of a potassium cation to the intact molecule which facilitated the assignment of *m/z* 611 as the protonated molecule. The glass tubes in which the triacylglycerol fractions were collected and stored are the most probable source of the potassium. Fragment ions *m/z* 523, 383 and 355 were formed from the protonated molecule by loss of butyric, myristic and palmitic acid, respectively. The positions of each of the acyl groups on the glycerol backbone could not be determined from these data. Because only one triacylglycerol was detected in HPLC peak 12 and abundant fragment ions provided adequate structural information, MS/MS analyses were not obtained.

When two or more triacylglycerols or impurities, such as cholesterol or cholesteryl ester, were detected in an HPLC fraction, collisional activation of each triacylglycerol $[M + H]^+$ followed by MS/MS analysis was required to identify

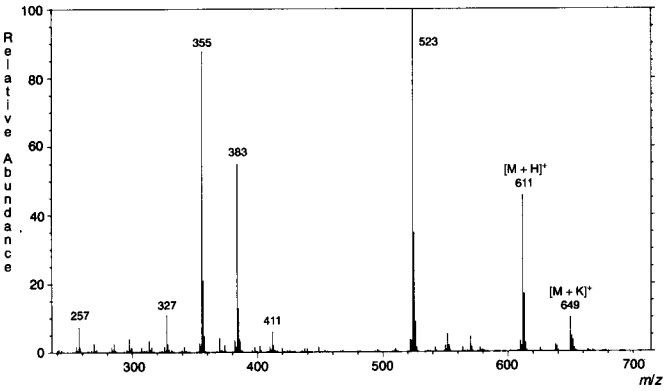

FIG. 2. Positive ion desorption chemical-ionization mass spectrum of fraction 12 (see Fig. 1) showing the presence of a single triacylglycerol (34:0). Fragment ions correspond to elimination of butyric (*m/z* 523), myristic (*m/z* 383) or palmitic (*m/z* 355) acid from the protonated molecule.

structurally significant fragment ions specific to that compound. For example, the DCI mass spectrum of peak 16 (Fig. 3) showed two protonated molecules *m/z* 665 and 639, of approximately equal abundance. MS/MS analysis of the $[M + H]^+$ ion of *m/z* 665 (Fig. 4a) showed $[MH - RCOOH]^+$ fragment ions at *m/z* 577, 409 and 383, which identified this triacylglycerol as 4,16,18:1. MS/MS analysis of the $[M + H]^+$ ion of *m/z* 639 (Fig. 4b) showed fragment ions corresponding to loss of C_6, C_{14} or C_{16} fatty acid. Therefore, the protonated ion *m/z* 639 was identified as being due to a 6,14,16 triacylglycerol.

Triacylglycerols with branched-chain, odd-acyl carbon numbers were readily identified and characterized by MS/MS. For example, MS/MS of the $[M + H]^+$ ion *m/z* 653 (37:0 triacylglycerol; peak 18) gave ions *m/z* 565, 537, 397 and 369, which were formed by elimination of 4, 6, 16 or 18 carbon fatty acids from a mixture of isomeric triacylglycerols. The fragment ions *m/z* 411 and 383 represented branched, odd-chain fatty acids with 15 and 17 carbons, respectively.

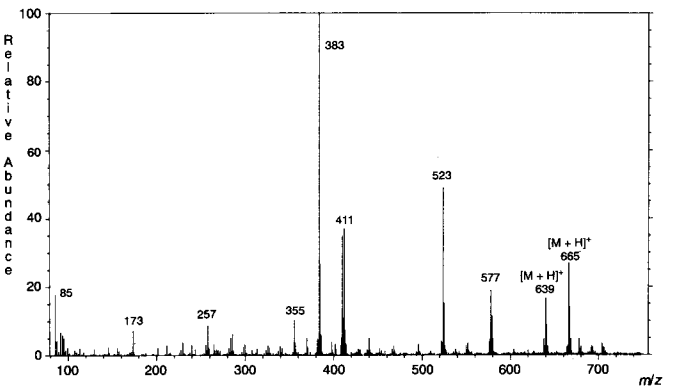

FIG. 3. Positive ion desorption chemical-ionization mass spectrum of fraction 16 (see Fig. 1) showing the protonated ions of two triacylglycerols (38:1 and 36:0).

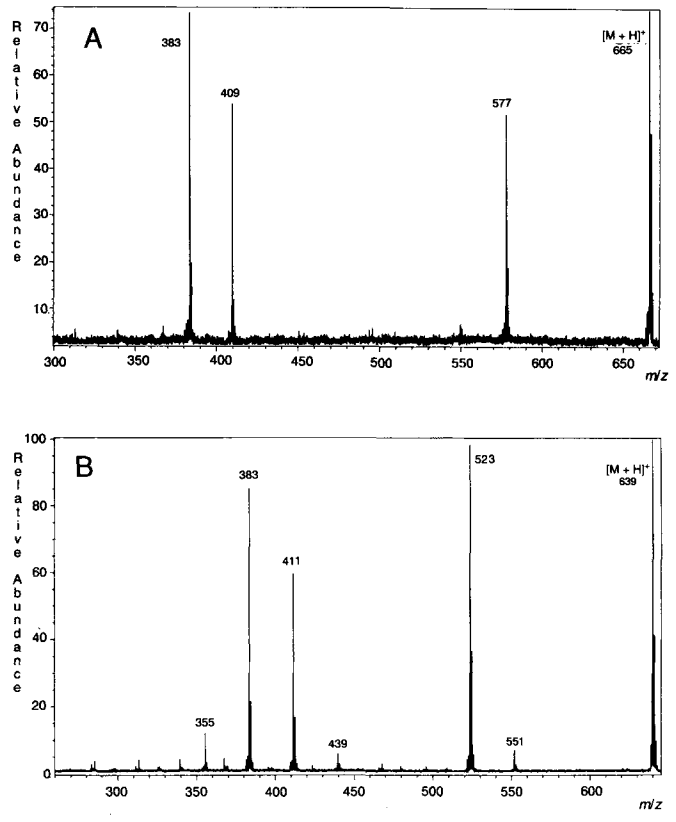

FIG. 4. Tandem mass spectrum of the $[M + H]^+$ precursor ion of *m/z* 665 (Panel A) and of *m/z* 639 (Panel B) shown in Figure 3. Fragment ions of the 38:1 triacylglycerol (Panel A) correspond to a fatty acid composition of 4,16,18:1. Fragment ions of the 36:0 triacylglycerol (Panel B) correspond to elimination of C_6 (*m/z* 523), C_{14} (*m/z* 411) and C_{16} (*m/z* 383) fatty acids from $[M + H]^+$.

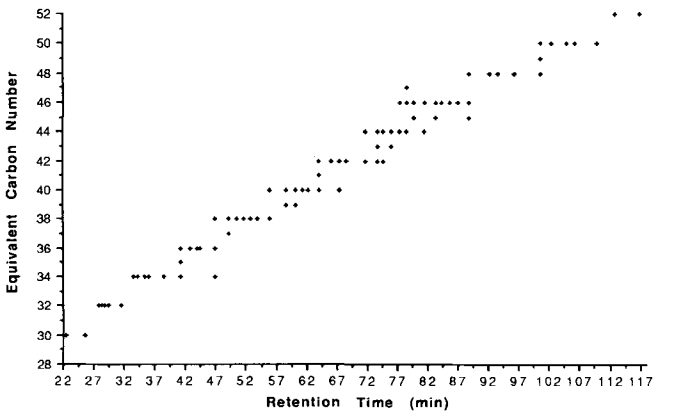

FIG. 5. Plot of retention times vs. equivalent carbon numbers (ECN) of milk fat triacylglycerols.

Based on the relative abundances of these fragment ions, most of the triacylglycerols in this mixture were 6,15,16 and 4,16,17, while 4,15,18 and 8,14,15 were present only as minor components.

Figure 5 shows the relationship between HPLC retention times and equivalent carbon numbers (ECN) of milk fat triacylglycerols. Triacylglycerols that differed by more than one ECN were typically resolved. Triacylglycerols of equal ECN eluted over a 5–10 min range.

DISCUSSION

Although HPLC separations of milk fat triacylglycerols have previously been carried out successfully (14,17), GLC methods have typically been used to characterize the fatty acid profiles of triglycerides upon enzymatic hydrolysis rather than analyze the triglyceride molecules themselves. Only quite recently have milk fat triglyceride structures been directly elucidated using MS/MS techniques (22). In earlier studies based on electron impact (EI) ionization of triacylglycerols, molecular ions of sufficient intensity to provide molecular weight information were usually not obtained (24,26). However, $[M + H]^+$ ions of high abundance can be obtained for both low- and high-molecular weight triacylglycerols by DCI–MS. The DCI fragmentation patterns of triacylglycerols are different from those seen upon EI ionization. For example, typical EI–MS fragment ions such as $[RCO]^+$ and $[RCO + 74]^+$ (27) are not observed in the DCI mass spectra. Ions corresponding to protonated fatty acids are sometimes detected. The most intense $[RCOOH_2]^+$ ions were observed at *m/z* 257, 283 and 285 (corresponding to palmitic, oleic and stearic acid, respectively), whereas protonated butyric acid was rarely seen. Because $[RCOOH_2]^+$ ions were not observed in tandem mass spectra of protonated triacylglycerols, these ions are probably formed by loss of neutral fatty acids from triacylglycerols in the ion source, followed by protonation by the reagent gas.

In the DCI mass spectra of HPLC peaks 25 through 58 (see Fig. 1), abundant ions were detected at *m/z* 369 and 391. Peaks 44 through 49 contained ions *m/z* 387 which correspond to protonated cholesterol. The DCI mass spectra of cholesteryl ester standards, including cholesteryl myristate, cholesteryl palmitate, cholesteryl oleate and cholesteryl arachidate, showed protonated molecules as base peaks at *m/z* 369, but no other abundant ions. Chromatography of these cholesteryl esters showed that these compounds eluted within the range of retention times between peaks 25 through 58.

In other CI or DCI mass spectrometric investigations, ammonia has been most widely used as reagent gas in triacylglycerol analysis. In positive ion CI and DCI mass spectra, abundant $[M + H]^+$ and $[M + NH_4]^+$ ions were detected (24,26), but the ion signal intensity was divided between $[M + H]^+$ and $[M + NH_4]^+$ species, thereby reducing sensitivity. Therefore, isobutane is preferred over ammonia as a positive ion DCI reagent gas for triacylglycerol analysis.

In negative ion DCI, ammonia has been used to facilitate the formation of deprotonated triacylglycerols with little or no fragmentation, thereby resulting in high sensitivity (22,23). However, in the absence of fragmentation in negative ion DCI, a second analysis by collisional activation in MS/MS is required to obtain diagnostically significant fragment ions. When using positive ion DCI, as used in this in-

vestigation, MS/MS measurements are only necessary if the sample contains several triacylglycerols or impurities.

The location of fatty acid double bonds in the carboxylate ions can be determined by using high energy collisional activation to induce charge-remote fragmentation followed by MS/MS analysis, such as linked scanning at constant B/E (28,29). However, because of the great number of HPLC fractions we obtained and due to limitations in mass spectrometer time, a systematic characterization of the acyl groups to locate the sites of unsaturation was not carried out.

Within each cluster of HPLC peaks with the same ECN (Fig. 5), triacylglycerols containing polyunsaturated fatty acids eluted earlier than less unsaturated or saturated triacylglycerols. Nevertheless, the ECN model cannot provide a comprehensive description of the milk fat triacylglycerol profile, when a gradient chromatographic elution system of high selectivity is employed. Other models (i.e., theoretical carbon number), attempting to relate the elution order with the triacylglycerol structure, were not evaluated in this study.

After careful examination of peak purity, possible carry over, and of the DCI–MS and MS/MS spectra, our data suggest that the 4,10,18:1 triacylglycerol of peak 1 is different from the 4,10,18:1 structure of peak 2. Other examples include the 14,16,18:1 triacylglycerol of peaks 44 and 45 and the 16,18,18:1 structure of peaks 54 and 55. Because all these triacylglycerols contain unsaturated fatty acids, different chromatographic retention times for isomer pairs might represent differences in the location or geometry of double bonds rather than in the positional distribution of fatty acids on the glycerol backbone. This is most likely the case for the 18:1,18:1,18:1 triacylglycerols appearing in both the 45 and 46 HPLC peaks. Other examples of HPLC separations of positional isomers of triacylglycerols have been reported (25,26).

Recently, the composition of triacylglycerols of butterfat fractions obtained by an industrial melt crystallization process were characterized (30). Triacylglycerol structures of the fractions were determined by using a combination of chromatographic techniques including both HPLC and gas chromatographic analyses. Profiles of milk fat that were presented (30) were similar and complementary to those reported in the present investigation. The advantages of the methodology we report here include the structural characterization of purified triacylglycerols directly by DCI–MS and MS/MS techniques without prior modification or derivatization.

Comparative Studies of Metabolism of 4-Desmethyl, 4-Monomethyl and 4,4-Dimethyl Sterols in *Manduca sexta*

James A. Svoboda[a,*], Samir A. Ross[b] and W. David Nes[c]

[a]Insect Neurobiology & Hormone Laboratory, ARS, USDA, Beltsville, Maryland 20705, [b]Department of Pharmacy, University of Mississippi, Oxford, Mississippi 38677 and [c]Department of Chemistry & Biochemistry, Texas Tech University, Lubbock, Texas 79409

ABSTRACT: To investigate the metabolism and possible deleterious effects of 4-methyl and 4,4-dimethyl steroids in *Manduca sexta*, the 4,4-dimethyl sterols lanosterol and cycloartenol, the 4-methyl sterol obtusifoliol and the 4,4-dimethyl pentacyclic triterpenoid α-amyrin were fed in an artificial agar-based diet at various concentrations. Utilization and metabolism of these four compounds were compared with sitosterol, stigmasterol, brassicasterol, ergosterol and 24-methylenecholesterol, 24-alkyl sterols that are readily dealkylated and converted to cholesterol in *Manduca* and in most phytophagous insects. None of the 4-methylated compounds significantly inhibited development except at very high dietary concentrations. The Δ^{24}-bonds of lanosterol and cycloartenol were effectively reduced by the *Manduca* Δ^{24}-sterol reductase enzyme, as is the Δ^{24}-bond of desmosterol which, in most phytophagous insects, is an intermediate in the conversion of sitosterol, stigmasterol and other C_{28} and C_{29} phytosterols to cholesterol. On the other hand, the 24-methylene substituent of obtusifoliol was not dealkylated. Each of the 4-desmethyl C_{28} and C_{29} sterols was readily converted to cholesterol, and a significant amount of 7-dehydrocholesterol was derived from ergosterol metabolism. The reason for the differences in substrate specificity of these sterols is not clear, but the information may be useful in the development of new, specific, mechanism-based inhibitors of sterol metabolism.

Lipids 30, 91–94 (1995).

A considerable body of literature on the utilization and metabolism of 4-desmethyl sterols in insects exists, and several reviews provide thorough discussion of this area (1–3). This knowledge is based primarily on studies on metabolism of C_{28} and C_{29} phytosterols (e.g., campesterol, sitosterol and stigmasterol), which are the most prevalent sterols in plant material and comprise the majority of sterols ingested by phytophagous insects (4). Insects are unable to biosynthesize sterols, and most species utilize cholesterol as a biosynthetic precursor for the steroid molting hormones, the ecdysteroids (5). As little or no cholesterol is present in most plant material, the majority of phytophagous insects rely on their ability to dealkylate the one- or two-carbon alkyl groups attached to C-24 on the sterol side chain of phytosterols to produce the necessary cholesterol (1).

The sterols of wheat seedlings treated with the systemic fungicide fenpropimorph consisted mainly of 9ß,19-cyclopropyl sterols. Feeding *Locusta migratoria* with treated wheat seedlings having this greatly altered sterol composition produced deleterious effects on larval development and reduced the ecdysteroid content of eggs (6,7). Also, feeding impure lanosterol in a well-defined diet to *Heliothis zea* greatly limited larval development (8). Genetically manipulating sterol biosynthesis in selected crop plants could possibly limit the availability of utilizable sterols for phytophagous insects and thus provide a new approach for insect control. Because 4,4-dimethyl and 4-methyl sterols are involved in phytosterol biosynthesis, it was of interest to determine whether certain 4-methylated sterols had adverse effects when fed at high concentrations to a phytophagous insect, as well as the extent to which the insect metabolized them. To this end, several highly purified 4-methylated compounds, including cycloartenol, lanosterol and obtusifoliol and the pentacyclic α-amyrin, were each fed as the sole added sterol in an artificial diet to the tobacco hornworm, *Manduca sexta*. Their metabolism and effects on insect development were compared with the well-studied 4-desmethyl sterols sitosterol, stigmasterol, brassicasterol and 24-methylenecholesterol, each of which is readily converted to cholesterol in *Manduca* (9,10). Cholesterol was also included as a control supplement, and the metabolism of ergosterol, previously not studied as a dietary sterol in *Manduca*, was examined.

MATERIALS AND METHODS

Manduca sexta larvae were reared on an artificial diet prepared in 100 mL portions as previously described (11), ex-

cept that brewer's yeast was not included and the casein was extracted six times rather than three in order to minimize endogenous sterol content as much as possible. Thus, wheat germ, which is necessary at a minimum concentration of 3 g per 100 mL of diet to obtain satisfactory larval growth, is the only significant source of sterol in the artificial diet. Three grams of wheat germ contain *ca.* 10 mg of sterol, the equivalent of 100 ppm of endogenous sterols composed mainly of sitosterol (~60%) and campesterol (~25%), about 1% cholesterol and several other minor components. Test compounds were coated on the dry diet ingredients in dichloromethane to provide the desired concentration in the complete diet. For metabolic studies and sterol analysis, newly hatched larvae were fed each of the compounds at a concentration of 260 ppm (26 mg/100 mL) of added compound. Six larvae were included in each test. After the gut was purged, prepupae were weighed and stored in methanol at –20°C until analyzed. To the extent that the supply of the compounds allowed, each 4-methylated sterol was included in the diet at increasing concentrations of 520, 1040 and 2080 ppm in order to observe possible effects on larval growth and development. All test compounds except sitosterol (synthesized in our laboratory) were isolated from natural sources, and the purity of each was as follows: cholesterol (99%), sitosterol (99%), stigmasterol (98%), brassicasterol (100%), ergosterol (100%), 24-methylenecholesterol (97%), cycloartenol (97%), lanosterol (100%), obtusifoliol (95%) and α-amyrin (100%). [2-^{3}H]Lanosterol (2.17×10^5 dpm/mg sp. act.) was also fed in one experiment to provide additional verification of any metabolism that might occur. [2-^{3}H]Lanosterol was prepared according to the method of Le and Nes (12).

Prior to sterol analysis, insects were minced and homogenized in CH_3OH/H_2O/5% KOH (80:10:10, by vol) and refluxed for three hours. An equal volume of H_2O was added and the nonsaponifiable material was extracted four times with ether; the ether fractions were combined and the solvent was removed on a rotoevaporator. 4-Desmethyl, 4-monomethyl and 4,4-dimethyl sterols were purified and separated by preparative thin-layer chromatography (TLC) on Analtech (Newark, DE) silica gel plates (250 μm) developed in benzene/ether (85:15, v/v). The respective bands were scraped from the plate and eluted with CH_3OH. The fractions were analyzed isothermally at 245°C by gas–liquid chromatography (GLC) on a packed 3% SE-30 column on an HP 5890 gas chromatograph (Hewlett-Packard, Palo Alto, CA). High-performance liquid chromatograph (HPLC) analysis of these fractions was performed on a 25 cm C_{18}-Whatman (Clifton, NJ) reversed-phase column (0.5 μm) at 40°C with a solvent system of CH_3OH/H_2O (96:4, v/v) flowing at 1.5 mL/min. Gas–liquid chromatography/mass spectrometric (GC/MS) analysis of each free sterol peak was performed on a table-top Hewlett-Packard model 5870 mass detector equipped with a DB-1-coated 15 m × 0.32 mm capillary column (0.25 μm film). Electron impact spectra were collected at 70 eV.

RESULTS

The analyses of sterols and triterpenoid from *Manduca* prepupae isolated from larvae fed the various sterols added at 260 ppm in the artificial diet are summarized in Table 1. Normal growth occurred with each compound at this concentration. In the cholesterol-fed controls, 87% of the sterols was cholesterol. As expected, cholesterol was the major component of the sterols from insects fed diets supplemented with the 4-desmethyl 24-alkyl sterols sitosterol, stigmasterol, brassicasterol, ergosterol and 24-methylenecholesterol. 7-Dehydrocholesterol (cholesta-5,7-dienol) comprised 18.2% of the sterols from ergosterol-fed insects. In the lanosterol-fed insects, lanosterol (31.3%) and dihydrolanosterol (40.4%) were the major sterols. The presence of 18.7% cholesterol in the sterols from these insects indicates an efficient uptake and dealkylation of the endogenous 4-desmethyl dietary sterols, such as sitosterol and campesterol. Verification of the conversion of [^{3}H]lanosterol to [^{3}H]dihydrolanosterol provided further evidence for the reduction of the Δ^{24}-bond of lanosterol by *Manduca* (45% conversion). No other product of [^{3}H]-lano-sterol metabolism was detected by TLC or HPLC, indicating only the Δ^{24}-bond was transformed by the insect. Similarly, in the cycloartenol-fed insects, the Δ^{24}-bond was efficiently reduced to provide cycloartanol as a major sterol (16.0%), with cycloartenol comprising 51.0% of the total sterols. The 24-methylenecycloartenol identified (1.7%) was from the starting material. Again, cholesterol was the major (20.1%) 4-des-methyl sterol, as was the case with lanosterol-fed insects.

Obtusifoliol was the major sterol (46.6%) isolated from insects fed that sterol, and cholesterol (35.8%) was the most abundant 4-desmethyl sterol. The Δ^7-obtusifoliol came from the starting material. There was no indication of metabolism of obtusifoliol by *Manduca*. α-Amyrin constituted only 33.5% of the total "sterols" in the insects fed this triterpenoid, suggesting that it was not absorbed as well as the endogenous 4-desmethylsterols. Cholesterol (35.2%) was the major sterol in these insects.

The differences in levels of 4-desmethyl sterols in the 4-methyl- and 4,4-dimethyl sterol-fed insects are worth noting. In the lanosterol- and cycloartenol-fed insects, the total desmethyl sterols were 26.2 and 29.6% of the total sterols, respectively. In contrast, desmethyl sterols comprised 44.6% of the total sterols in obtusifoliol-fed insects and 66.5% of the total in α-amyrin-fed *Manduca*.

Insufficient obtusifoliol was available to examine the possible effects on development at concentrations higher than 260 ppm. Cycloartenol was fed at dietary concentrations of 520 and 1040 ppm, and, although some slowing of larval growth occurred at 1040 ppm, normal prepupae and pupae resulted. Sufficient material was available to test α-amyrin up to 2080 ppm. Larval growth was delayed at 1040 ppm, but four normal pupae were obtained from the six larvae, and three normal adults emerged. When fed 2080 ppm α-amyrin, larval development was greatly inhibited, two prepupae were

[a]Analysis of each compound made by gas–liquid chromatography and verified by gas chromatography/mass spectrometry.
[b]Trivial and systematic names: Cholesterol, cholest-5-en-3ß-ol; desmosterol, cholesta-5,24-dien-3ß-ol; campesterol (24*R*)-24-methylcholest-5-en-3ß-ol; sitosterol, (24*R*)-24-ethylcholest-5-en-3ß-ol; stigmasterol, (24*S*)-24-ethylcholesta-5,22-*E*-dien-3ß-ol; 7-dehydrocholesterol, cholesta-5,7-dien-3ß-ol; ergosterol, (24*R*)-24-methylcholesta-5,7,22-*E*-trien-3ß-ol; brassicasterol, (24*R*)-24-methylcholesta-5,22-*E*-dien-3ß-ol; 24-methylenecholesterol, 24(*E*) methylenecholest-5-en-3ß-ol; lanosterol, 4,4,14- trimethyl-5α-cholesta-8,24-dien-3ß-ol; dihydrolanosterol, 4,4,14-trimethyl-5α-cholest-8-en-3ß-ol; cycloartenol, 4,4,14-trimethyl-9ß,19-cyclo-5α-cholest-24-en-3ß-ol; cycloartanol, 4,4,14-trimethyl-9ß,19-cyclo-5α-cholestan-3ß-ol; obtusifoliol, 4α,14α-dimethyl-24-methylene-5α-cholest-8-en-3ß-ol (Ref. 13).

obtained, but no adults emerged. With adequate material available, lanosterol was the most extensively tested of the 4-methylated compounds. In three tests at 1040 ppm, some delay of larval development was noted, but pupae and some adults were obtained. At 2080 ppm, larval development was greatly retarded in each of six tests, but in only one test were no prepupae obtained. However, no adult emergence occurred in any of the six experiments with lanosterol at 2080 ppm.

DISCUSSION

As expected, cholesterol was the major sterol in *Manduca* prepupae from larvae fed 4-desmethyl sterols. In ergosterol-fed insects, occurrence of 7-dehydrocholesterol as a major metabolite (18.2%) reflected the additional nuclear double bond. 7-Dehydrocholesterol has been identified as a major sterol in the flour beetle (*Tribolium confusum*), regardless of dietary sterol tested (14). 7-Dehydrocholesterol is a precursor

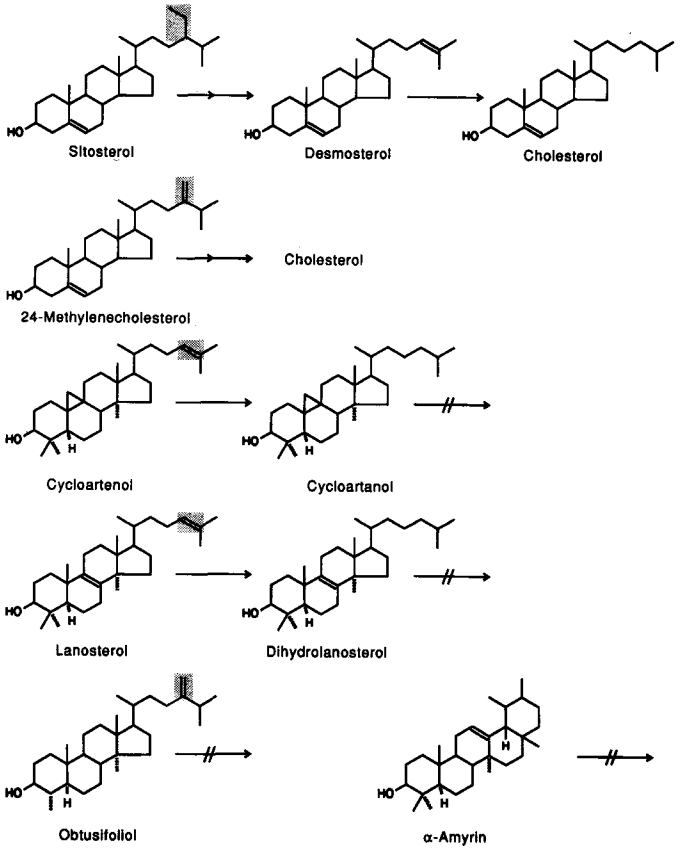

FIG. 1. Metabolism of representative 4-desmethyl, 4-methyl and 4,4-dimethyl sterols in *Manduca sexta*.

for the molting hormones (ecdysteroids), and outside of the prothoracic glands, is usually only present in *Manduca* in trace amounts (15).

The analyses of sterols from *Manduca* prepupae reared on diet supplemented with 260 ppm of the 4-methylated sterols revealed that metabolism of 4-methylated sterols does occur, but is limited to reduction of the Δ^{24}-bonds of cycloartenol and lanosterol. Even with the 4,4,14-trimethyl structures, the Δ^{24}-sterol reductase enzyme is quite effective in reducing these side-chain double bonds. No further metabolism of these two sterols was apparent. On the other hand, although 24-methylenecholesterol is readily dealkylated and converted to cholesterol in this insect, the 24-methylene of obtusifoliol was not dealkylated. It is interesting to note that the Δ^{24}-reductase enzyme is able to reduce the Δ^{24}-bond of 4,4-dimethyl sterols, but the enzymes that dealkylate 24-methylene groups are unable to dealkylate this group from a 4-monomethyl sterol. In addition, the pentacyclic triterpenoid α-amyrin was incorporated unchanged by *Manduca*. The comparative metabolism of the steroids used in this study is illustrated in Figure 1.

The differences in total desmethyl sterols found in *Manduca* fed the various 4-methyl steroids indicate that lanosterol and cycloartenol are most readily absorbed and incorporated in the tissues. The insect more readily takes up the endogenous 4-desmethyl sterols (sitosterol, campesterol) than obtusifoliol or α-amyrin. The reason for these differences is not clear, but certainly it appears that a pentacyclic triterpenoid is least preferred, and that the sterols with a side chain most similar to the cholesterol side chain are preferentially absorbed.

It has been well documented that certain insects are capable of selective sterol uptake from the diet (16). Likewise, egg production can be affected when adult locusts are fed wheat seedlings in which the sterol content has been greatly altered from the usual C_{28} and C_{29} phytosterols to mostly 9ß,19-cyclopropylsterols (6,7). In the present study, lanosterol, which differs from cycloartenol only by lacking the 9ß,19-cyclopropyl group, was inhibitory at the highest concentration tested. Perhaps, if the accumulation of the normal plant sterol intermediate cycloartenol, or another related compound, could be induced in the plant by altering specific enzyme activity *via* genetic engineering or by other means such as a steroid metabolism inhibitor, development of larvae of certain phytophagous plant pests could be disrupted.

Hypothesis: An Amino Acid Sequence in Lipoprotein Lipase Codes for Its Degradation by Ca^{2+}-Dependent Proteases

Dear Sir:

Lipoprotein lipase (E.C. 3.1.1.34; LPL) is a glycosylated homodimer bound to the intraluminal surface of capillaries in most extrahepatic tissues and is responsible for the hydrolysis of circulating triacylglycerols into fatty acids and monoacylglycerol. Its activity is particularly high in adipose tissue and muscle, corresponding to their use of triacylglycerol-derived fatty acids for storage and/or oxidation. The regulation of LPL is tissue-specific. The enzyme activity is high in adipose tissue in the postprandial state and low during fasting, whereas the converse occurs in muscle (1). The degradation of LPL could be a key regulatory mechanism of the level of tissue LPL activity. Four pathways of LPL degradation have been suggested: (i) newly synthetized LPL is degraded in the lysosome before its secretion; (ii) the secreted enzyme can be re-internalized by parenchymal cells to enter the lysosomes and be degraded; (iii) the endothelium-bound enzyme can be detached and can reach the liver through the circulation; and (iv) the degradation of LPL can occur in the endoplasmic reticulum (2). Little is known, however, about the possible molecular mechanisms involved in these processes.

It has been found that LPL contains a sequence rich in the amino acids proline (P), glutamate (E), serine (S) and threonine (T), which is known to modulate protein degradation (3). The PEST-rich sequence of LPL spans 23 to 52 amino acids depending on the species and contains as much as 50% of PEST residues, which is about twice their frequency in the whole protein. In addition, the basic residues arginine, lysine and histidine are absent in the PEST-rich region but more frequent in the flanking regions than in the whole LPL sequence (4,5) (Fig. 1). Thus LPL meets the criterion of a protein characterized as having a PEST sequence. A PEST-rich sequence is a typical feature of rapidly degraded proteins (3), so it is not surprising that LPL contains one, since this enzyme has a half-life in various cell lines of about one hour (2). A PEST sequence is present in some proteins that are not rapidly degraded, but it has been suggested that, in these few cases, it is absent from the surface of the protein when it assumes its normal tertiary structure (3). The tertiary structure of LPL is not known, but it is frequently compared with human pancreatic lipase which is very homologous to LPL and has been crystallized (4). Based on this crystal structure, a model of the homodimeric LPL has recently been published in which one side of the carboxy-terminal region of one monomer is near the n-terminal region of the other (6). Such an arrangement, if confirmed, would allow the interaction of the PEST sequence with proteases. The sequence of LPL we describe is located in its carboxy-terminal region at the junction of exons 8 and 9. Except in the guinea pig, the sequence ends at a site of N-glycosylation (residue 359 in the human LPL). No other function has been attributed to this sequence (4). Moreover, no mutation of LPL causing enzyme deficiency has yet been reported for this PEST-rich region (7).

Proteins containing a PEST sequence may be sensitive to several proteolytic pathways (8). The Ca^{2+}-dependent proteases, calpains, are especially good candidates because apolipoprotein B, 3-hydroxy-3-methylglutaryl coenzyme A reductase and c-Fos contain PEST-rich sequences and are hydrolyzed by calpains (3,9,10). Moreover, the calpains I and II, and their specific inhibitor calpastatin, which is also Ca^{2+}-dependent, are distributed in a tissue-specific manner in accordance with the tissue-specific regulation of LPL. For instance, calpastatin is found in high concentration in the heart where LPL activity is the highest of all tissues (2,11). The content of calpastatin exceeds that of calpains I and II in rat heart and skeletal muscles, but not in adipose tissue (11). Calpains I and II are widely distributed cellular proteases active at μM and mM concentrations of Ca^{2+}, respectively. Higher concentrations of Ca^{2+} activate calpastatin (11). It is difficult to define the site at which Ca^{2+} might alter the degradation rate of LPL because Ca^{2+} metabolism is under the control of many organelles in addition to its transport across the plasma membrane (12). Moreover, Ca^{2+} can be sequestered at the surface of cell membranes by heparan sulfate proteoglycans (13). This is noteworthy because the proteoglycans that anchor LPL at the vascular endothelium modulate its secretion and lysosomal degradation and are effectively degraded by calpains *in vitro* (2,13).

Many agents that alter Ca^{2+} homeostasis have been shown to modify the activity of LPL. Indeed, the stimulatory effect of insulin on adipose LPL activity is mimicked or potentiated by the Ca^{2+} ionophore A23187, whereas blockade of transcription with cordicepin and alpha-amanitin do not alter it

FIG. 1. The PEST-rich sequence of lipoprotein lipase (LPL) is found in the six species in which the protein has been cloned (panel A). Panel B shows that the frequency of the amino acids proline (P), glutamate (E), serine (S) and threonine (T) is high in the sequence in comparison with the whole LPL, whereas the flanking regions are enriched in the basic residues arginine (R), lysine (K) and histidine (H). Numbers refer to the amino acid position in the aligned sequences as published by Wang *et al.* (4) and Brault *et al.* (5).

(14). Moreover, LPL stimulation by insulin is abolished by depletion of cellular Ca^{2+} with EGTA (14). Thus, it may be that because insulin increases the cytosolic cellular Ca^{2+} content, the degradation rate of LPL in adipose tissue is decreased in the postprandial state (15,16). This mechanism does not exclude modulation of LPL at the transcriptional level, but Ca^{2+} could also inactivate the Ca^{2+}-dependent proteases acting on the PEST-rich sequence of LPL. This hypothesis is concordant with the fact that adipose LPL is chronically increased in obese subjects, who may also have a chronic increase in cytosolic Ca^{2+} concentration (1,17). In this situation, degradation of LPL might be blunted during the transition from the postprandial to the fasting state. Moreover, the absence of an acute insulin effect in adipose tissue of these subjects has been reported for both cytosolic Ca^{2+} and LPL activity (1,17). Such a mechanism of adipose LPL modulation by Ca^{2+}-dependent proteases is further supported by the observation that vanadate, which blocks the intracellular sequestration of Ca^{2+}, normalizes the lowered adipose LPL activity in streptozotocin-treated rats (18,19). In addition, epinephrine increases the Ca^{+} efflux from adipocytes and has been shown to increase the degradation of LPL (20,21).

It can also be argued that Ca^{2+}-dependent proteases modulate the activity of muscle LPL. Indeed, there is a large body of evidence suggesting that glucose uptake is Ca^{2+}-dependent (22). On the other hand, it has been shown *in vivo* that when glucose uptake is high, muscle LPL activity is low, such as during an insulin infusion (23). Thus, it can be hypothesized that Ca^{2+} is involved in the reciprocal modulation of LPL activity and glucose transport in muscles. That Ca^{2+} would be associated with divergent effects on adipose tissue and muscle LPL could stem from the tissue-specific relative abundance of calpains and their inhibitor calpastatin.

In summary, the PEST-rich sequence of LPL and a number of observations suggest a physiological role for Ca^{2+}-dependent proteases in the degradation of LPL. This means of controlling LPL activity could partly explain its tissue-specific regulation during the postprandial and fasting states.

ANNOUNCEMENTS

1995

June

2nd International Congress of the International Society for the Study of Fatty Acids and Lipids, June 7–10, National Institutes of Health, Bethesda, Maryland, USA. Information: A.P. Simopolous, ISSFAL, 2001 S St., N.W., Suite 530, Washington, DC 20009 USA.

18th Nordic Lipid Symposium, June 18–21, Reykjavik, Iceland. Information: G. Lambertsen, Lipidforum Secretariat, Breistølen 1, N-5035 Bergen, Norway (Fax: 4755-325724).

August

36th International Conference on the Biochemistry of Lipids, Aug. 8–11, Georgetown University, Washington, D.C., USA. Information: Ms. Hattie Johnson, Georgetown University, Office of Continuing Professional Education, 2233 Wisconsin Ave., NW, Suite 333, Washington, DC 20007-2197 USA (Phone: 202-687-8735; Toll-Free: 800-382-3613; Fax: 202-687-3019).

September

5th International Congress on Platelet-Activating Factor and Related Lipid Mediators, Sept. 12–16, Berlin, Germany. Information: Dr. S. Nigam, Dept. of Gyn., University-Klinikum Steglitz, Hindenburgdamm 30, 12200 Berlin, Germany (Fax: 8155510).

October

21st World Congress and Exhibition of the International Society for Fat Research, Oct. 1–5, The Hague, The Netherlands. Information: 21st ISF Congress Secretariat, P.O. Box 3489, Champaign, IL 61826-3489 USA (Fax: 1-217-351-8091).

EDITORIAL

A Southward Move for *Lipids*

This month *Lipids* celebrates its twenty-ninth birthday and moves its Editorial Office southward, albeit only 135 miles. Since its inception, the journal has had only four Editors and has firmly established itself as a premier source of new information on basic lipid research. Our founding Editor, A. Richard Baldwin, wrote a prescient editorial in the first issue of January 1966 in which he said: "The discovery of a possible relationship between the fat in the diet and cholesterol in the blood, and the development of new analytical techniques, have together breathed new life into what only a few years ago was considered a relatively exhausted and uninteresting field of research." Since that time, the awarding of a series of lipids-related Nobel prizes, the development of many new drugs targeting the metabolism or actions of lipid species, and the emergence of entire disciplines centered on lipid autacoids, hormones, protein modifiers, and gene regulators illustrate the enormous advance in our understanding of the importance of lipid molecules in biology.

The changes that led to the lipid renaissance have included not only technical improvements in chromatography, mass spectrometry, NMR, and other physical methods, but also the publication of definitive clinical trials verifying the importance of diet and cholesterol metabolism in human vascular disease. Epidemiologic evidence of the role of dietary fat in cancer, an appreciation of the importance of polyunsaturated fatty acids in human development, and of lipid oxidation in a number of disease processes has greatly increased research funding and activity in lipid-related fields during the past twenty-nine years. The regulation of gene expression by fatty acids, retinoids and other lipids, post-translational regulation of protein function by attachment of fatty acids and isoprenyl alcohols, and utilization of drugs altering lipid metabolism in experimental cancer therapy are only a few of the many "cutting edge" areas of lipid research.

Lipids has, indeed, adapted to the changing face of basic lipid research over nearly three decades. It is of interest that the first issue of *Lipids* included not only new analytical methods and lipid composition studies, but also papers presenting lipid–protein interactions, X-ray diffraction and mathematical modelling approaches. Studies published in recent issues, and those currently in press deal with molecular modelling based upon mathematical manipulation of X-ray crystallographical data, new mass spectrometric methods, and the molecular biology of lipid–protein interactions in both carrier proteins and enzymes. Also represented are works using a new generation of biophysical methods to provide novel perspectives on membrane structure and function. The realization that different families of polyunsaturated fatty acids may have different biological functions has led to numerous papers debating what makes particular fatty acids "essential" for a given species, and whether increasing the n-6 or n-3 fatty acid (or decreasing the *trans* fatty acid) content of the diet in industrial countries may provide health benefits. Thus, the papers published in *Lipids* now utilize a broad array of new and traditional techniques to explore areas of lipidology that are of great importance in medicine and biology. *Lipids* will continue to provide an expanding forum for basic and mechanistic work involving lipid research; as Dr. Baldwin described it in 1966, this includes studies on metabolism, nutrition, physiology, analytical methodology, natural products, and biomedical applications.

Many changes are taking place in the publishing field as well as in science. Our tax returns and NIH grants can now be submitted electronically, and contributors to *Lipids* are now usually submitting their final text on computer disk. Scientific journals are dealing with the problems of CD-ROM and on-line editions and their attendant copyright issues. *Lipids* will adapt to this new environment by bringing our readership the latest information as rapidly as an electronically enhanced peer-review system will allow, and a variety of new options are under study. To increase publication quality and efficiency, there will be a new font and some changes in article format. We will continue the practice of having timely Review Articles on a regular basis, and we welcome Letters-to-the-Editor on speculative or controversial topics. Portions of selected issues may be devoted to presenting peer-reviewed papers from significant lipids meetings, and our Announcements page will include mention of meetings and other special items pertinent to workers in lipid research. Although the field of lipid research was "considered a relatively exhausted and unimportant" one in 1960, our perspective 35 years later is that it will only continue to expand in the decades ahead and that we will make every effort to have *Lipids* serve as an integral part of that expansion.

The guiding philosophy of *Lipids* has remained the same throughout the tenure of my four predecessors. As stated by Dr. Wolfgang Baumann in his 1986 editorial, "a journal's success is measured by its appeal to contributors and readers," and "the editorial philosophy of *Lipids* will be guided by the desire to reach beyond past accomplishments." Last month's issue included a tribute to Dr. Baumann's extraordinary efforts to serve the journal and the scientific community, and

these efforts have continued in his assuring a smooth editorial transition. I am especially grateful for his many words of advice and encouragement. To continue the level of excellence achieved by my predecessors, I am also fortunate to have the support of Mary Lane and her staff at AOCS Press, our distinguished group of Associate Editors and Editorial Advisory Board members, and the continued cooperation of our excellent reviewers. In an era of rapid change on many fronts, it is essential that we receive the suggestions and perspectives of many lipid researchers in addition to their other contributions, and these are always welcome. The importance of any journal, after all, lies in its usefulness and responsiveness to the scientific community it serves.

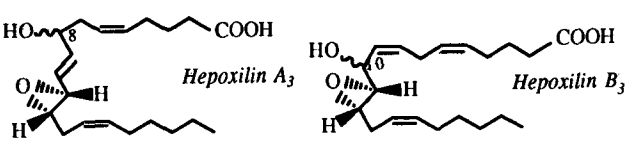
Howard R. Knapp
Editor-in-Chief

Hepoxilins: A Review on Their Enzymatic Formation, Metabolism and Chemical Synthesis

C.R. Pace-Asciak[a,b,*], Denis Reynaud[a] and Peter M. Demin[a]

[a]Research Institute, Hospital for Sick Children, Toronto, Ontario, M5G 1X8 Canada and [b]Department of Pharmacology, Faculty of Medicine, University of Toronto, Toronto, Ontario, M5S 1A8 Canada

ABSTRACT: This article reviews published evidence describing the enzymatic and nonenzymatic formation and the routes of metabolism of the hepoxilins. Also treated are the major approaches used for the chemical synthesis of these compounds and for some of their analogs.
Lipids 30, 107–114 (1995).



The hepoxilin pathway was discovered over a decade ago (1–5), and considerable research since has shown a variety of interesting biological activities, the basis of which appears to relate to the release of intracellular calcium (6) and to the opening of potassium channels (7,8). Hepoxilins appear to have pro-inflammatory actions in the skin (9–11), but appear to inhibit the actions of inflammatory agents in the human neutrophil (12). Hepoxilin receptors have recently been identified which are coupled to G-proteins (13). For reviews on the cellular actions of the hepoxilins, the reader is referred to recent reviews (14,15). This brief article reviews evidence for the enzymatic formation and metabolism of the hepoxilins. Also addressed is a review of the diverse approaches used for the chemical synthesis of these compounds, as well as several stable analogs which also possess biological activity.

NOMENCLATURE

Hepoxilins are monohydroxy-epoxide derivatives of arachidonic acid formed from the initial unstable product of 12-lipoxygenase, 12(*S*)-hydroperoxy-5*Z*,8*Z*,10*E*,14*Z*-eicosatetraenoic acid [12(*S*)-HPETE] (2). The term hepoxilin was coined to combine structure (Hydroxy EPOXide) with their first reported biological activity (release of InsuLIN) (4). Two hepoxilins have been isolated, i.e., 8(*S/R*)-hydroxy-11(*S*),12(*S*)-*trans*-epoxyeicosa-5*Z*,9*E*,14*Z*-trienoic acid (hepoxilin A_3, HxA_3) and 10(*S/R*)-hydroxy-11(*S*),12(*S*)-*trans*-epoxyeicosa-5*Z*,8*Z*,14*Z*-trienoic acid (hepoxilin B_3, HxB_3). This terminology is consistent with that used in the prostaglandin field where the subscript denotes the number of double bonds in the molecule. The "A" and "B" designation relates to the carbon position of the hydroxyl group; A refers to a hydroxyl group at C8, B denotes one at C10. As the epoxide group is relatively unstable biologically with further metabolic reactions taking place (see section on metabolism), the designated metabolites are referred to the initial hepoxilin, e.g., the glutathione conjugate is referred as hepoxilin A_3-C, by analogy with the leukotriene system of naming these conjugates. Hydrolysis of the epoxide generates trihydroxy metabolites, 8(*S/R*),11(*R*),12(*S*)-trihydroxy-eicosa-5*Z*,9*E*,14*Z*-trienoic acid (trioxilin A_3, $TrXA_3$) and 10(*S/R*),11(*R*),12(*R*)-trihydroxy-eicosa-5*Z*,8*Z*,14-trienoic acid (trioxilin B_3, $TrXB_3$). As mentioned above, these products are derived from arachidonic acid. Similar products have been isolated from eicosapentaenoic acid (16).

Scheme 1 describes the structures of HxA_3 and HxB_3.

Isolation. Indirect evidence for the formation of hepoxilins was first obtained by Jones *et al.* in 1978 (17) when a trihydroxy metabolite of arachidonic acid was reported formed by washed human platelets. That product, 10,11,12-trihydroxy-eicosatrienoic acid, was proposed to be derived from a 10-hydroxy-11,12-epoxide intermediate. Subsequently, these authors isolated a hydroxy-epoxide (18) which was later called hepoxilin B_3 (14). Bryant and Bailey (19) later reported the structure of two trihydroxy metabolites formed by human platelets bearing hydroxyl groups at C8, C11 and C12, and C8, C9 and C12 also proposing their formation through an epoxide intermediate. It is now known that these compounds arise from hepoxilin A_3 during its stereo-uncontrolled acid-catalyzed hydrolysis (20). Interestingly, formation of these metabolites was stimulated by glucose in the incubation

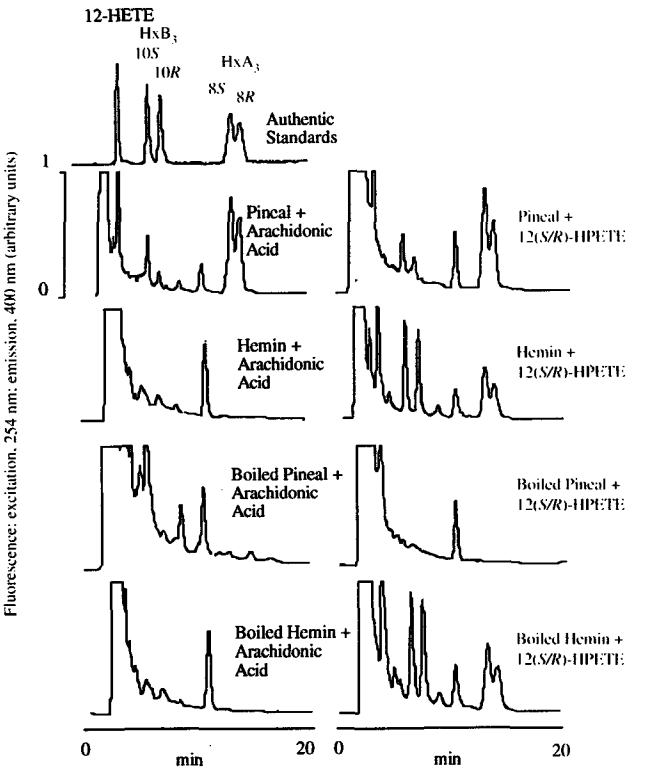
medium (21). These compounds were later found to be formed in rat lung (1). Pace-Asciak *et al.* isolated from rat lung the two hydroxy-epoxide intermediates that yielded the above mentioned trihydroxy metabolites, and their structures were determined to be the isomeric 8-hydroxy and 10-hydroxy-11,12-epoxide derivatives of arachidonic acid (2), later called hepoxilins A_3 and B_3 (4). It was also recognized that the epoxide ring was acid labile, providing a reason why previous reports isolated only the trihydroxy products. The epoxide group of each epimer (8*S* or 8*R*) of hepoxilin A_3 is also subject to enzymatic hydrolysis to yield one trihydroxy product, 8(*S* or *R*),11(*R*),12(*S*)-trihydroxyeicosa-5*Z*,9*E*,14*Z*-trienoic acid. As biological testing on pancreatic islets demonstrated that the isolated hydroxy-epoxides potentiated the glucose-evoked release of insulin (4), the products were named "hepoxilins" to combine structural features with their insulin secretory properties (4).

Formation of the hepoxilins has been reported in human platelets and lung, liver, pancreas, brain, aorta and pineal gland of the rat (for review see Refs. 14 and 15). They are also formed by the *Aplysia* brain (22), and a report by Moghaddam *et al.* (23) indicates that they are also formed in tropical marine algae. Hepoxilin A_3 has been identified as the endogenous factor regulating volume decrease in human platelets (7,8). Trioxilin B_4 has been identified as the hatching factor in barnacles (24), whereas trioxilin A_4 was isolated from fish gills (25).

BIOSYNTHESIS

Hepoxilins are formed from 12(*S*)-HPETE (2). Early work with 12(*S*)-HPETE in which the hydroperoxide group was labeled with ^{18}oxygen, derived from experiments involving the reaction of platelet 12(*S*)-lipoxygenase with d_8-arachidonic acid, demonstrated the complete retention of ^{18}oxygen in both the hydroxyl and epoxide moieties in the resulting hepoxilins when the 12-HPETE was incubated with a lung homogenate (26). These experiments demonstrated that hepoxilins are formed from 12-HPETE and that the oxygen atoms in hepoxilins are derived through an intramolecular isomerization involving an intermediate which excludes external oxygen from the incubation medium. Such an internalized isomerization is typical of enzymatic catalysis, except that the retention of oxygen from the hydroperoxide is observed both with a rat lung preparation as well as with hemin or hemoglobin as catalyst (5), indicative of a pseudo-enzymatic reaction (26). This type of transformation suggested that hepoxilin synthesis may be nonenzymatic, even though it typified an enzymatic-type transformation from 12-HPETE. Only recently, through use of rapid nonacidic extraction methods and derivatization into stable fluorescent ester derivatives, has unequivocal information been obtained to demonstrate the presence of a heat-inactivatable protein in the rat pineal gland that forms hepoxilin A_3 (27). In these studies, a racemic mixture of 12(*S*)- and 12(*R*)-HPETE, formed through the light-induced autoxidation of arachidonic acid, was incubated with intact (slices of) pineal glands, and the products were characterized by high-performance liquid chromatography (HPLC) after appropriate derivatization (and stabilization) into fluorescent ester derivatives. Several important findings were observed in these experiments. First, hepoxilin A_3 was the major hepoxilin formed with the intact tissue, little hepoxilin B_3 was found. In contrast, when hemin was used as catalyst in the absence of the tissue, both hepoxilin A_3 and B_3 were formed from the 12-HPETE racemic mixture, in approximately equal amounts. Boiling of the pineal gland abolished all hepoxilin formation, whereas boiling of hemin did not affect hepoxilin formation. A similar conversion of arachidonic acid by the pineal gland into mostly hepoxilin A_3 of the native 11(*S*),12(*S*)-configuration of the epoxide is observed, indicating the presence of 12(*S*)-lipoxygenase in the pineal gland (28,29), which is coupled to hepoxilin A_3 synthase. Arachidonic acid is not converted into products when incubated with hemin. As with 12-HPETE, boiling of the pineal tissue abolished all enzymatic conversion of arachidonic acid (see Fig. 1). Second, when 12-hydroxy-5*Z*,8*Z*,10*E*,14*Z*-eicosatetraenoic acid (12-HETE) was purified from both the fresh pineal experiments and the



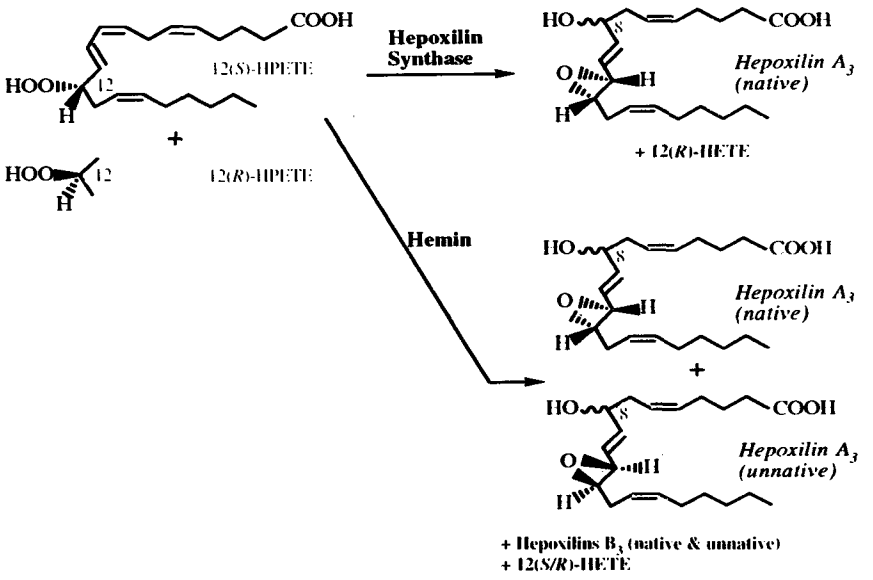


FIG. 1. Experiments to show the enzymatic nature of hepoxilin synthesis in the pineal gland in contrast to the nonenzymatic formation by hemin. Note the different ratio of hepoxilin A_3 (HxA_3) vs. hepoxilin B_3 (HxB_3) formed by the pineal in contrast to hemin catalysis. Also note the total abolition of hepoxilin synthesis by boiling the pineal [both from arachidonic acid as well as 12-HPETE (hydroperoxy-5*Z*,8*Z*,10*E*,14*Z*-eicosatetraenoic acid) substrates—second panels from bottom] in contrast to the lack of effect during hemin catalysis (bottom right panel). These experiments provide strong support for an enzymatic pathway in the formation of HxA_3. HETE, hydroxy-5*Z*,8*Z*,10*E*,14*Z*-eicosatetraenoic acid.

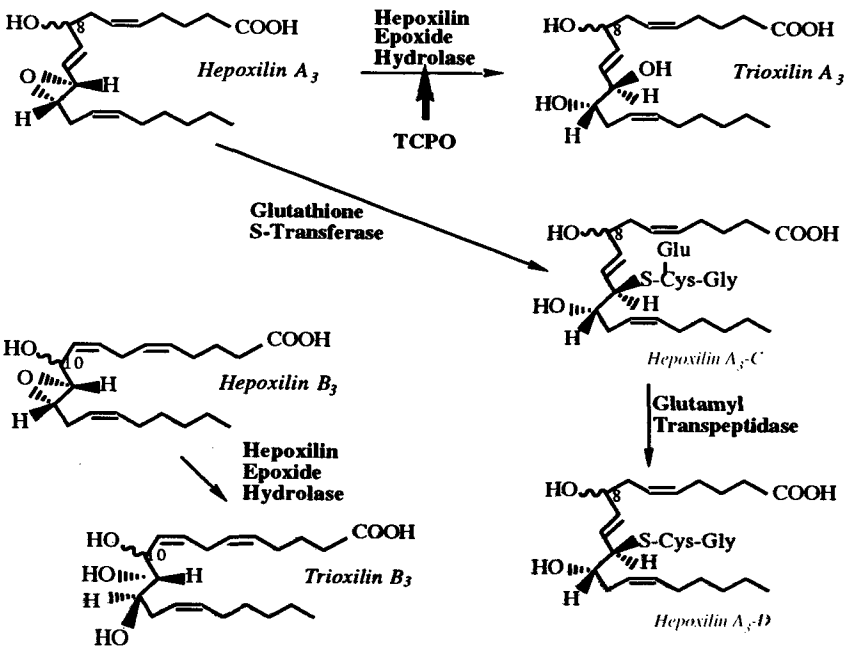
SCHEME 2

hemin experiments and analyzed by chiral phase HPLC, it was found that the 12(*S*)-HETE was absent in the pineal gland experiments, only 12(*R*)-HETE was present because all the 12(*S*)-HPETE in the epimeric substrate was used up in the formation of hepoxilin A_3. In contrast, in the hemin experiments both 12(*S*)- and 12(*R*)-HETEs were found in the same epimeric proportion as the starting HPETE because hemin was not substrate selective.



These experiments indicate a stereoselection of 12(*S*)-HPETE by the pineal gland, but not by hemin, in the formation of hepoxilin A_3. Third, chiral phase analysis of hepoxilin A_3 formed by the pineal gland confirmed the natural *S,S-trans* configuration of the epoxide group, while both the (11*S*,12*S*)- and the (11*R*,12*R*)-*trans* hepoxilins A_3 were formed during hemin catalysis, further demonstrating the nonselectivity of hemin. The nonenzymatic isomerization of HPETEs in the linoleic acid series has been previously observed (30–32). These important new findings are summarized in Scheme 2.

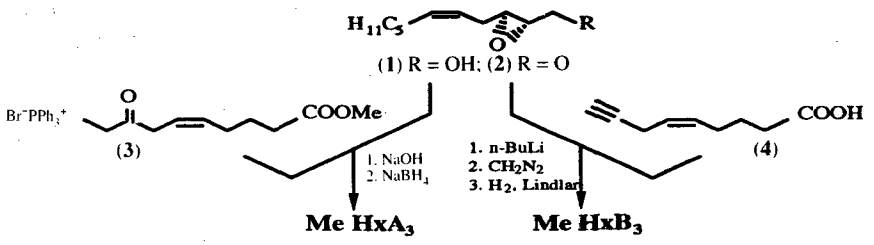
These experiments demonstrate that hepoxilin A_3 formation is carried out by a specific heat-labile protein (hepoxilin A_3 synthase) which catalyzes the transformation of 12(*S*)-HPETE almost exclusively into the 8(*S*)- and 8(*R*)-epimers of hepoxilin A_3 with only minor amounts of hepoxilin B_3 formed. It seems that hepoxilin B_3 may not be an enzymatic product as it is formed only to a small extent by the intact pineal gland and may in fact be due to catalysis by some hemoprotein. Hepoxilin A_3 synthase appears to be a cytosolic protein whose characterization is in progress. Transformation of 12(*S*)-HPETE by this protein does not seem to require any cofactors.

METABOLISM

Two pathways have been described for the metabolism of hepoxilin A_3 (33,34). Hepoxilin B_3 is more chemically stable than hepoxilin A_3, although it is also metabolized (2). Scheme 3 describes the two metabolic pathways for hepoxilin A_3 metabolism. The first pathway involves solvolysis of the epoxide by water, the new hydroxyl group entering at C11 with inversion of configuration, i.e., (11*R*). The newly formed trihydroxy metabolite is termed trioxilin A_3. The responsible enzyme appears to be selective for the hepoxilin structure as the partially purified protein appears to prefer hepoxilin A_3 as substrate in comparison to leukotriene A_4 or styrene oxide (35). In contrast, the acid-catalyzed hydrolysis of hepoxilin A_3 leads to a mixture of trioxilin epimers with hydroxyl groups at C8, C11 and C12, as well as C8, C9 and C12 (20). In contrast to the metabolism of hepoxilin A_3, hepoxilin B_3 is metabolized with epoxide ring opening through an attack of the hydroxyl group at C12, as well as with inversion of configuration, i.e., (12*R*) (2). The second pathway described for the metabolism of hepoxilin A_3 involves the addition of glutathione at C11 of the epoxide moiety to afford an 11(*R*)-glutathionyl-8(*R/S*),12(*S*)-dihydroxy metabolite of hepoxilin A_3 (hepoxilin A_3-C, HxA_3-C) (33,36). The reaction is carried out by a glutathione S-transferase (GST). Work with purified isozymes of rat liver GST has shown that the reaction is best carried out by a homodimer containing the Y_{b2} subunit while isozymes containing the Y_a or the Y_c subunits showed marginal activity (37). The same subunit converts leukotriene A_4 into C_4 (38). In contrast, the conversion of the prostaglandin endoperoxide PGH_2 into PGE_2 and PGF_{2a} requires the Y_a subunit (39). Chemical opening of the epoxide by glutathione gives by analogy with chemical hydrolysis, a mixture of 11(*R*)- and 9(*S/R*)-glutathionyl adducts (40).

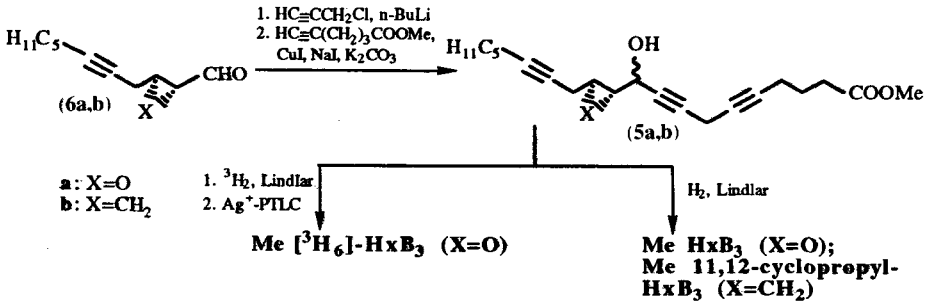
Hepoxilin epoxide hydrolase is inhibited by trichloropropene oxide (TCPO), a general epoxide hydrolase inhibitor (36). In the presence of TCPO, HxA_3 metabolism is shunted toward glutathione conjugation with the formation of HxA_3-C (36). HxA_3-C formation has been shown to occur in rat aorta (41) and in rat brain (36). HxA_3-C shares with its precursor

SCHEME 3



some of the biological activity in some systems. Specifically, HxA_3-C is capable of potentiating the norepinephrine-induced contraction of the rat aorta (42), portal vein (42) and the guinea pig trachea (43), and the bradykinin-induced vascular permeability in rat skin (10). The compound also shows an enhancing action of electrical potentials in rat hippocampal CA1 neurons (44,45), specifically the resting membrane potential, post spike train after-hyperpolarization and the inhibitory postsynaptic potential but not the excitatory postsynaptic potential. The former two actions of HxA_3-C are epimer-specific, with the (8*R*) epimer showing activity exclusively in the vascular reactivity assay, whereas the (8*S*) epimer is the active species on vascular permeability. These epimer-specific actions suggest receptor-mediation. In fact HxA_3-specific binding proteins have been described in human neutrophils which appear to be intracellular in localization, and mediated through G-protein interaction (13).

CHEMICAL SYNTHESIS OF HEPOXILINS AND SOME STABLE ANALOGS



Several different approaches have been described for the chemical synthesis of the hepoxilins. These different approaches will be looked at through the key intermediates used by different groups from which the hepoxilin structure was generated.

The first total synthesis of HxB_3 and HxA_3 was developed by Corey *et al.* (46,47) on the basis of methods used for the synthesis of other acyclic eicosanoids. Both types of hepoxilins were obtained using a common epoxy alcohol **1**, readily available *via* Sharpless asymmetric epoxidation of the corresponding (*E*)-allylic alcohol. After oxidation of **1** into the aldehyde **2**, it was condensed with either **3** as its triphenylphosphonium salt or lithium derivative of terminal acetylene **4** creating γ- or α-hydroxy epoxy fragments of HxA_3 and HxB_3 (Scheme 4).

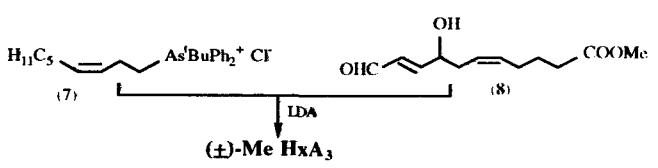
The C8- and C10-epimeric mixtures of HxA_3 and HxB_3 obtained were finally separated as individual diastereomers, and their chromatographic and spectral properties were in agreement with compounds isolated from natural sources. The use of acetylenic fragments has led to the synthesis of deuterium- or tritium-labelled analogs of hepoxilins. The triacetylenic analog of HxB_3 **5a** allowed the preparation of hepoxilins (A and B) with high specific activity (48). The relatively unstable triacetylene **5a** was synthesized by Vasiljeva and co-workers (49) in high yield through the condensation

SCHEME 4

SCHEME 5

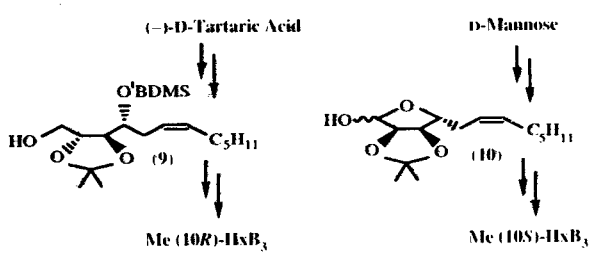
of the acetylenic epoxyaldehyde **6a** with the Li-derivative of propargylchloride and methyl 5-hexynoate (49). Partial catalytic hydrogenation of **5a** in Lindlar conditions secured high selectivity of the three (*Z*)-double bonds (Scheme 5). Starting from the cyclopropyl aldehyde **6b**, cyclopropyl analogs of HxB_3 have been prepared (50).

Chabert *et al.* (51) developed a new approach to create the γ-hydroxy epoxy fragment of HxA_3 using arsonium ylides to lead to the formation of the epoxide. A stable readily available arsonium salt **7** was condensed with γ-hydroxy vinylic aldehyde **8** to give the (±)-methyl ester of HxA_3 (Scheme 6).



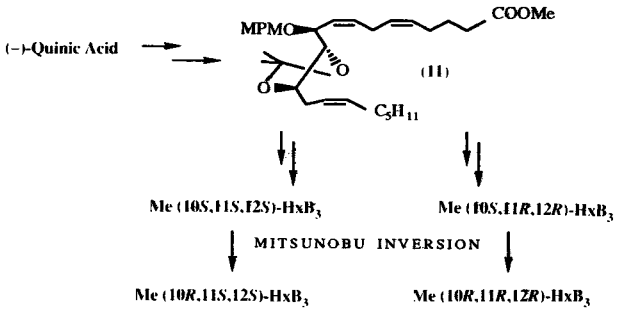
A number of approaches to optically active HxB_3 employed available natural chirones. Wu and Wu (52,53) used isopropilydene derivatives of *vic*-triols **9** and **10** obtained from (−)-D-tartaric acid and D-mannose, to prepare HxB_3 (52,53). Wittig condensations of **9** and **10** with corresponding synthons led to the protected 10,11,12-triols; C10 individual epimers of HxB_3 were obtained by subsequent tosylation/deprotection/epoxide ring closure (Scheme 7).

These synthetic schemes permitted the preparation of individual optical isomers of $TrxB_3$, the trihydroxy metabolite, which might be useful in studies investigating the naturally occurring products of hydrolysis of HxB_3. Hence, in another synthesis (−)-quinic acid was utilized as a source of chirality to prepare the triol **14** with differentiated hydroxyl groups (54). This approach afforded all possible four stereoisomers of HxB_3 derived from the *trans*-epoxide as well as $TrxB_3$, including the unnatural (11*R*,12*R*)-enantiomers of hepoxilins that would be formed from (12*R*)-HPETE (Scheme 8).

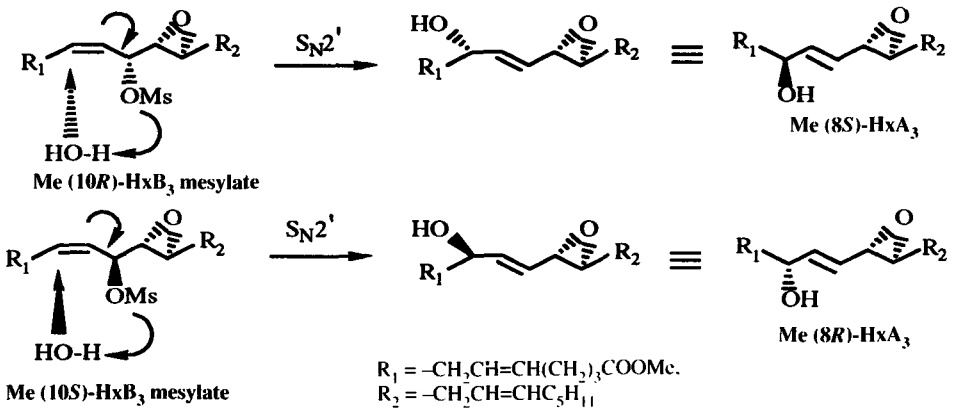


Transformations of hepoxilins. Because HxB_3 is more chemically stable than HxA_3, and as both are allylic isomers, methods for the interconversion of HxB_3 into HxA_3 through allylic transposition of the hydroxyl group have been investigated (Scheme 9). Demin *et al.* (55) developed an approach to HxA_3 synthesis from HxB_3 based on the solvolysis of unstable HxB_3 mesylates leading to a mixture of HxA_3 and B_3. This allylic rearrangement involves an S_N2' mechanism with a moderate (1.6:1) preference of C8-epimer of HxA_3 arising from the *syn*-attack of H_2O as a neutral nucleophile to afford the C8-epimer with an *anti* configuration of the C8 hydroxyl group. The C8-configuration of the individual epimers of HxA_3 was assigned according to this mechanism. The configuration of the carbinolic centres of HxA_3 was also established on the basis of products of ozonolysis of HxA_3 acetates (40).

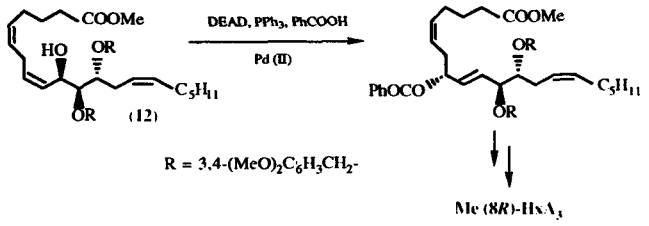
Stable cyclopropyl analogs of HxB_3 were similarly transformed to cyclopropyl-HxA_3 as their acetates *via* standard Pd (II)-promoted mechanism (50). Lumin *et al.* (56) improved this Pd (II)-dependent process and developed a Pd (II)-directed allylic Mitsunobu displacement to rearrange protected triol **12** into its C8-isomer including Pd(II) interception of an oxyphosphonium intermediate. Subsequent deprotection/ring closure led to (8*R*)-HxA_3 in high yield and diastereoselectivity. Its (8*S*)-epimer was obtained in a similar manner (Scheme 10).



It was also shown that the classic Mitsunobu inversion of carbinolic centers of hepoxilins is accompanied by allylic rearrangement to some degree (Scheme 11). This was used in



SCHEME 6



SCHEME 7

SCHEME 8

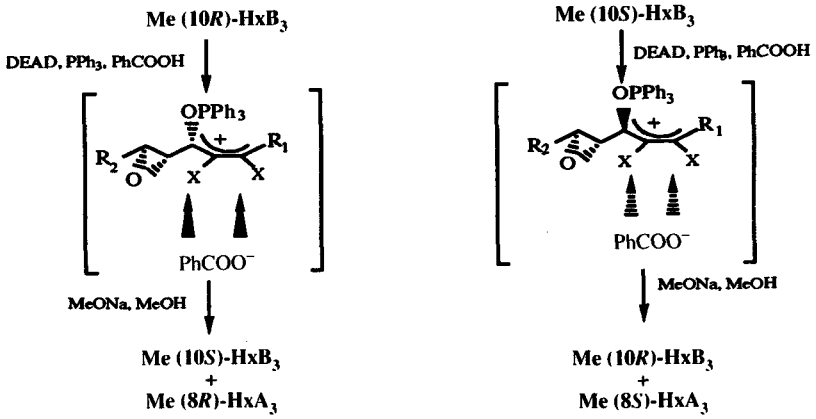
SCHEME 9

SCHEME 10

the preparation of tritium-labeled HxA_3, using labeled HxB_3 as a starting material. Very mild conditions permitted the handling of highly radioactive material (48). Employing this method, all possible regio- and stereo-isomers of hepoxilins were prepared (57).

By analogy with peptido-leukotrienes, chemical opening of the epoxide in hepoxilins by *N*-trifluoroacetate of glutathione was achieved, and glutathione adducts of HxA_3 (40) and HxB_3 (54) were synthesized. In case of HxA_3, C11 (*R*) thioether conjugate, as well as two C9 (*R/S*) thioether conjugates, were obtained as a separable mixture, whereas for HxB_3 a sole product of glutathione attack at C12 was isolated (Scheme 12).

CONCLUSIONS



This review is intended to summarize literature available to date on the biochemistry and chemistry of the hepoxilins, a rapidly emerging area of eicosanoid research. This review may prove helpful in view of the recent demonstration of the existence of an enzyme system which forms HxA_3 specifically from 12(*S*)-HPETE, and in view of the demonstration of receptor-mediated actions. Stable analogs of the hepoxilins may prove useful in furthering this research.

Nuclear Magnetic Resonance Spectroscopic Analysis of Homoallylic and *bis* Homoallylic Substituted Methyl Fatty Ester Derivatives

Marcel S.F. Lie Ken Jie* and K.L. Cheng

Department of Chemistry, The University of Hong Kong, Pokfulam Road, Hong Kong

ABSTRACT: Using a combination of selective irradiation ^{1}H nuclear magnetic resonance experiments and two-dimensional ^{1}H–^{13}C correlation spectroscopy spectral analysis of homoallylic and *bis* homoallylic substituted (azido, acetoxy, chloro and oxo) fatty ester derivatives, the carbon shifts of the ethylenic carbon atoms were determined. In the case of methyl 12-azido-9*Z*-octadecenoate (homoallylic), the carbon chemical shifts of the ethylenic C-9 and C-10 carbon nuclei are 133.092 and 124.596 ppm, respectively. In methyl 9-azido-12*Z*-octadecenoate (*bis* homoallylic), the carbon chemical shift of the ethylenic C-12 and C-13 carbon nuclei are 128.118 and 131.243 ppm, respectively.

Lipids 30, 115–120 (1995).

A survey of the chemical literature shows conflicting assignments of the ^{13}C carbon chemical shifts of the ethylenic carbon atoms of homoallylic substituted unsaturated fatty esters. Methyl ricinoleate (methyl 12-hydroxy-9*Z*-octadecenoate, **1a**) and *iso*-ricinoleate (methyl 9-hydroxy-12*Z*-octadecenoate, **1b**) are typical examples of oxygenated unsaturated fatty esters, which contain a homoallylic and a *bis* homoallylic hydroxy function in the alkyl chain, respectively. Wenkert *et al.* (1) have assigned the signal at 133.9 ppm to the shift of the C-9 ethylenic carbon nucleus, and the more upfield olefin signal at 125.8 ppm to the shift of the C-10 carbon atom of methyl ricinelaidate. Similar trends in the assignments of the shifts of such ethylenic carbon atoms with a hydroxy function at the homoallylic position have been reported by Bascetta and Gunstone (2), Dauzonne *et al.* (3), Radeglia *et al.* (4) and Bernassau and Fetizon (5).

Pfeffer *et al.* (6) have carried out an intensive study on the effects of homoallylic and *bis* homoallylic hydroxyl substitution on the olefinic ^{13}C resonance shifts in fatty esters. However, these investigators have used ^{13}C nuclear magnetic resonance (NMR) data from various literature sources, including those reported by Rakoff *et al.* (7), to make their assignments of olefinic resonances. Rakoff *et al.'s* (7) assignment of the carbon shifts of the C-9 and C-10 ethylenic carbon nuclei of methyl ricinoleate are in a reversed order, where the signals at 125.5 and 133.0 ppm have been assigned to the carbon shifts of the C-9 and C-10 ethylenic carbon atoms, respectively. This trend is supported by Carlson *et al.* (8) and Husain *et al.* (9). A further search of the chemical literature reveals that many authors concur with this reversed trend of assignment. For example, the shifts of C-3 and C-4 carbon atoms of 3*Z*-hexadecen-1-ol are assigned by Camps *et al.* (10) as 133.6 and 124.9 ppm, respectively. Barabas *et al.* (11) assign the shifts of C-3 and C-4 carbon atom of 3*Z*-hexen-1-ol as 135.3 and 125.3 ppm, respectively. The C-3 and C-4 carbon atoms in 3-octen-1-ol are also assigned in this order by Disselnkotter *et al.* (12). Gunstone (13) has acknowledged the ethylenic carbon shifts of methyl ricinoleate in this reversed order in his latest review.

We have recently addressed this anomaly by studying the two-dimensional ^{1}H–^{13}C correlation spectroscopy (COSY) NMR spectroscopic properties of the carbon chemical shifts of the ethylenic carbon atoms of methyl ricinoleate and methyl ricinelaidate (14). In this preliminary study, we have shown that the assignment of the shifts of the C-9 and C-10 ethylenic carbon atoms agree with those reported by Wenkert *et al.* (1). To substantiate our results, we consider it necessary to conduct additional NMR experiments on selected derivatives of methyl ricinoleate to confirm beyond all doubts the assignment of the ethylenic carbon atoms in molecules containing a homoallylic substituent. To achieve this goal, the hydroxy function of methyl ricinoleate is chemically transformed to an azido, acetoxy, chloro or oxo function. With this range of functional groups in the homoallylic position, it is possible to examine the different neighboring shift effects on the ethylenic carbon atoms and to observe the connectivities between the ^{1}H and ^{13}C shifts in the two-dimensional COSY spectra of these molecules. And, to extend our study to the *bis* homoallylic substituents on the carbon shifts of the ethylenic carbons, the azido, acetoxy, chloro and oxo derivatives of methyl *iso*-ricinoleate (methyl 9-hydroxy-12*Z*-octadecenoate) are also included in this investigation. Pfeffer *et al.*

(15) have recently published an amendment to their publication on the effects of *bis* homoallylic and homoallylic substitution on the olefin carbon resonance shifts in fatty acid methyl esters.

MATERIALS AND METHODS

The isolation of ricinoleic acid from castor oil and *iso*-ricinoleic acid from the seed oil of *Wrightia tinctoria*, and the procedures for the transformation of methyl ricinoleate (**1a**) and *iso*-ricinoleate (**1b**) to the corresponding azido (**2a, 2b**), acetoxy (**3a, 3b**), chloro (**4a, 4b**) and oxo (**5a, 5b**) derivatives are described elsewhere (16–19). NMR spectra were recorded on $CDCl_3$ solutions (0.2 mmol) with a JEOL (Tokyo, Japan) GSX-270 (270 MHz) spectrometer with proton observation at 270.00 MHz and carbon observation at 67.94 MHz. Chemical shifts are reported relative to tetramethylsilane (TMS) as internal standard. Connectivities in the ^{1}H–^{13}C NMR spectra were established at 270.05 MHz using a combination of spin–spin decoupling, COSY and double quantum filter experiments. Carbon atom types were established in ^{13}C NMR using a combination of broad-band proton decoupling and DEPT (distortionless enhancement by polarization transfer) experiments.

RESULTS AND DISCUSSION

The case of methyl 12-azido-9*Z*-octadecenoate (**2a**) is taken as an example to illustrate the detail NMR investigation leading to the confirmation of the assignment of the C-9 and C-10 ethylenic carbon atoms in this homoallylic substituted fatty ester derivative.

Focussing on the shifts of the protons of the α-methylene groups (8-*H* and 11-*H*) adjacent to the olefinic system, the ^{1}H NMR spectrum of methyl 12-azido-9*Z*-octadecenoate (Fig. 1a) shows the shift of the 8-*H* protons appearing at δ 2.04 as a multiplet. The shift of the 11-*H* protons also appears as a multiplet at δ 2.27. This slightly more downfield signal than that exhibited by the 8-*H* proton is due to the combined effects of the azide function and the olefinic bond. The methine proton (12-*H*) gives a quintet at δ 3.20. The olefinic protons (9-*H* and 10-*H*) appear as two multiplets centered at δ 5.40 and 5.53. To confirm the shifts of the olefinic protons, a selective double irradiation of the ^{1}H NMR spectrum was carried out at δ 2.2745 (the shift center of the 11-*H* proton), which caused the multiplet at δ 5.40 to collapse to a doublet (Fig. 1b). This result confirms the shift of the 10-*H* olefinic protons at δ 5.40. A similar selective irradiation experiment was carried at δ 2.0432 (the shift center of the 8-*H* proton), which caused the multiplet at δ 5.53 to collapse into a doublet (Fig. 1c). This observation confirms the multiplet at δ 5.53 as arising from the shift of the 9-*H* olefinic proton.

In the ^{13}C NMR spectrum of methyl 12-azido-9*Z*-octadecenoate, the carbon chemical shift of the C-8 and C-11 carbon nuclei appeared at 27.412 and 32.298 ppm, respectively. The shift of the olefinic carbon atoms were found at 124.596 and 133.092 ppm from TMS. From the two-dimensional ^{1}H–^{13}C COSY NMR spectrum (Fig. 2) the connectivities between the 8-*H*/C-8, 11-*H*/C-11 were readily established. With the proton shifts of the 9-*H* and 10-*H* protons already established through the selective irradiation experiments as described above, the carbon shift of the C-9 and C-10 carbon nuclei were therefore readily determined from the two-dimensional spectrum. The carbon shift of the C-9 carbon atom corresponded to the signal at 133.092 ppm, and that of the C-10 carbon atom to the signal at 124.596 ppm. The results of the ^{1}H and ^{13}C NMR of these derivatives are presented in Tables 1 and 2, respectively.

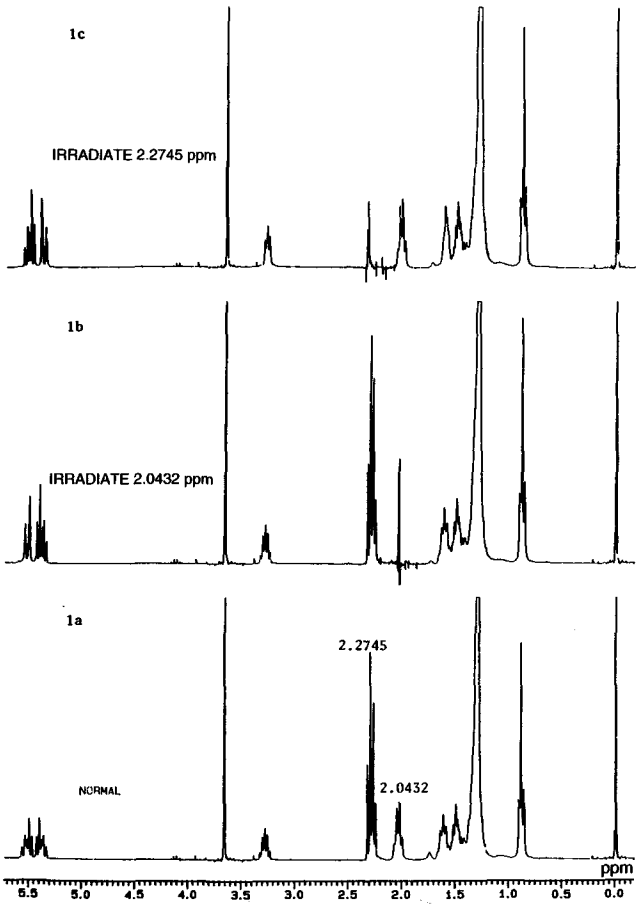

FIG. 1. ^{1}H nuclear magnetic resonance spectrum of methyl 12-azido-9*Z*-octadecenoate (**2a**).

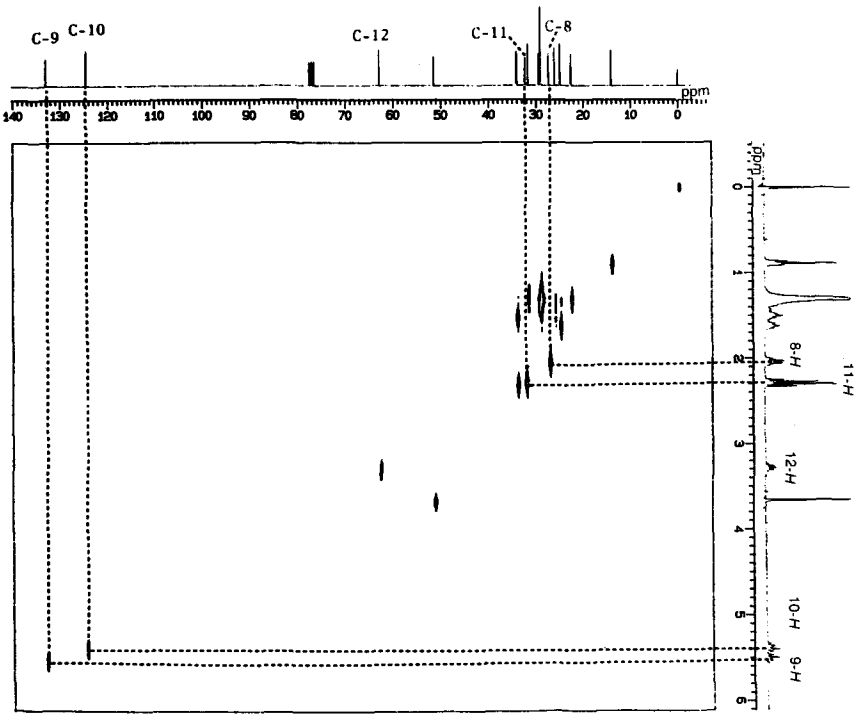
Similar selective double irradiation experiments and two-dimensional ^{1}H–^{13}C COSY spectral analyses were carried out for the other derivatives [12-acetoxy (**3a**), 12-chloro (**4a**), 12-oxo (**5a**)] of methyl ricinoleate. In the ^{1}H NMR spectrum of methyl 12-acetoxy-9*Z*-octadecenoate, the resolution of the shifts of the olefinic protons was very distinct. In the case of the 12-chloro and 12-oxo derivatives, the signals (multiplets) for the olefinic protons were partially overlapped. Nevertheless, the selective irradiation experiments at the corresponding shift position of the 8-*H* and 11-*H* protons gave clear and distinct collapse of the associated signals in the olefinic re-



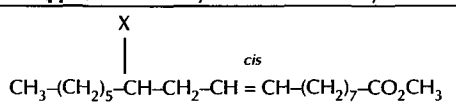


FIG. 2. ^{1}H–^{13}C correlation spectroscopy nuclear magnetic resonance spectrum of methyl 12-azido-9*Z*-octadecenoate (**2a**).

gion of the spectrum. This enabled the precise shift positions of the 9-*H* and 10-*H* olefinic protons in each case to be determined. By making use of the interconnectivities of the ^{1}H–^{13}C NMR COSY spectra of these derivatives, the carbon chemical shifts of the olefinic carbon atoms in each case were confirmed. The results of the ^{1}H and ^{13}C NMR spectral analysis of the acetoxy-, chloro- and oxo-derivatives of methyl ricinoleate are shown in Tables 1 and 2, respectively. The results of the ^{1}H and ^{13}C NMR spectroscopic analysis of methyl ricinoleate are also included in the tables for reference purpose. It can be concluded from this study that in the ^{1}H NMR spectroscopic analysis of homoallylic substituted unsaturated fatty ester derivatives, the effect of the substituent or function (such as hydroxy, azido, acetoxy, chloro and oxo) causes a more shielding effect on the γ-positioned than the δ-positioned olefinic proton. However, in the ^{13}C NMR analysis, the effect of the same substituents at the homoallylic position causes a significant shielding effect on the γ-olefinic carbon atom, but a deshielding effect on the more distally positioned δ-olefinic carbon atom.

In the *bis* homoallylic fatty ester derivatives of *iso*-ricinoleic acid, the substituent [9-azido (**2b**), 9-acetoxy (**3b**), 9-chloro (**4b**) and 9-oxo (**5b**)] is separated from the olefinic system by two methylene groups. The carbon chemical shifts of the α-methylene groups (C-11 and C-14) adjacent to the olefinic bond were readily distinguished and identified (Table 3). By making use of the two-dimensional ^{1}H–^{13}C COSY spectra of these derivatives, it was possible to establish the

precise proton chemical shifts of the 11-*H* and 14-*H* protons. The sample was subjected to selective irradiation at the corresponding shift positions of 11-*H* and 14-*H*. From these experiments, the proton chemical shifts of the olefinic protons in the *bis* homoallylic system were determined by observing the collapse or simplification of the olefinic proton signals. As an example, the shifts of the 11-*H* and 14-*H* of methyl 9-azido-12*Z*-octadecenoate (**2b**) appeared at δ 2.144 and 2.041, respectively. Selective irradiation at δ 2.144 caused the olefinic signal at δ 5.334 to collapse, which determined the shift of the 12-*H* olefinic proton. Likewise, by irradiating at δ 2.041, the shift of the 13-*H* olefinic proton was found at δ 5.399. Referring to the two-dimensional COSY spectrum, the interconnectivities allowed the carbon shifts of C-12 and C-13 to be established at 128.118 and 131.243 ppm. From this study, it can be concluded that a *bis* homoallylic substituent (hydroxy, azido, acetoxy, chloro or oxo) causes a greater shielding effect on the δ-positioned olefinic carbon atom than on the more distally ε-positioned olefinic carbon atom. The results of the ^{1}H and ^{13}C NMR analysis of the various derivatives of methyl *iso*-ricinoleate are presented in Tables 3 and 4, respectively. The assignment of the shifts of the olefinic carbons of methyl *iso*-ricinoleate agrees with those reported by Pfeffer *et al.* (6).

It can be concluded that for a $C_n=C_{n+1}$ bond, the carbon chemical shift of the C_n is always greater than that of the C_{n+1} in a homoallylic [$C_n=C_{n+1}$-CH_2-CH(X)-, where X = OH, N_3, OAc, Cl or oxo] or *bis* homoallylic [$C_n=C_{n+1}$-CH_2-CH_2-CH(X)-] system.

Phase Properties of Mixtures of Ceramides

Chien-Hsuan Han[a], Ronald Sanftleben[b] and Timothy S. Wiedmann[a,*]

[a]Department of Pharmaceutics, College of Pharmacy, University of Minnesota, and [b]CIMA Laboratories, Minneapolis, Minnesota 55455

ABSTRACT: Ceramides have been proposed to have a central role in the function of the stratum corneum. Ceramides also influence the phase properties of model skin lipid mixtures, but the relevance of this to the stratum corneum function is controversial. Because the stratum corneum contains several classes of ceramides, the type of ceramides used in model mixtures of stratum corneum lipid lamellae may be important. Thus, the properties of α-hydroxy fatty acid containing (HFAC) and nonhydroxy fatty acid containing (NFAC) ceramides and their mixtures have been investigated. Ceramides were obtained by the conversion of purified bovine brain cerebrosides. Isolated, anhydrous HFAC underwent an endothermic solid to liquid transition at 92°C. With hydration, an endothermic transition at 71.8°C was observed which was accompanied by a reduction in the birefringence. The enthalpy increased from 66 to 89 J/g with a 20-d storage time. These thermal properties are very similar to those observed with hydroxy fatty acid containing cerebrosides. In contrast, anhydrous nonhydroxy fatty acid containing ceramides underwent a broad endothermic transition over the temperature range of 50–90°C. When hydrated, the initial endothermic transition was interrupted by an exothermic transition that was followed immediately by a second endothermic transition. During these thermal changes, there was a loss of birefringence, and with completion of the second endothermic transition, a nonbirefringent liquid was observed. NFAC samples, stored at 70°C for 5 min, cooled, and then rescanned, displayed only one endotherm at 75°C. The thermal behavior of mixtures of HFAC and NFAC was relatively simple, with a progressive decrease and broadening in the temperature of the phase transition as the proportion of NFAC increased up to weight fractions of NFAC of 0.7. At lower weight fractions, a plateau in the transition temperature as a function of weight fraction was observed. Even at a weight fraction of 0.1 HFAC, no transition to a nonbirefringent liquid state was observed. The high enthalpic changes observed with mixtures of HFAC and NFAC are consistent with the proposed central role that ceramides have in the mechanical and permeability properties of the skin. Moreover, the marked difference in the properties of these two similar lipids may help to explain some of the properties of the stratum corneum.

Lipids 30, 121–128 (1995).

Abbreviations: FID, flame-ionization detector; HFAC, hydroxy fatty acid containing ceramides; HFA–CER, hydroxy fatty acid containing cerebrosides; NFAC, nonhydroxy fatty acid containing ceramides; NFA–CER, nonhydroxy fatty acid containing cerebrosides; TLC, thin-layer chromatography.

Ceramides are N-acyl linked sphingolipids which are found only in abundance in the stratum corneum (1). Following isolation from the skin, the ceramides have been separated by thin-layer chromatography (TLC) into five to seven classes based on the number of hydroxyl moieties and acyl chain-length (2–4). Aside from the unusual acyloxy derivative which is present at a level of 10%, the remaining ceramides are characterized by a relatively small polar head group of two to four hydroxyl moieties and an amide linkage connecting the fatty acid to the sphingolipid base (4). The common acyl chains are 16 and 24 to 28 carbons in length.

Ceramides have been suggested to have a central role in the function in the skin by contributing to the water impermeability of the stratum corneum (5–8). In addition, ceramides have been implicated in controlling epidermal turnover (5). The multiple hydroxyl moieties could form an extensive hydrogen-bonded network which contributes to the interbilayer attractive interactions (9–12). The asymmetric chainlengths coupled with the terminal hydroxyl groups may also form an interdigitated multilamellar arrangement and thereby provide cohesive links in the intercellular region of the stratum corneum (8,13,14).

While ceramides are evidently important to the skin, the details of their role in the phase behavior and how this relates to the function of the stratum corneum remain unresolved (15–18). Part of the difficulty may lie in the use of different model lipid mixtures as well as various sources of ceramides. In particular, type III ceramides derived from bovine brain sphingomyelin have been commonly used as the sole ceramide which only has two hydroxyl moieties. It would seem that a better understanding of the properties of ceramides would prove useful as the first step in resolving the controversy regarding the role of ceramides in the stratum corneum. Therefore, in this study, the thermotropic phase behavior of nonhydroxy fatty acid containing (NFAC) ceramides and hydroxy fatty acid containing ceramides (HFAC) has been determined. In addition, the phase properties of the ceramide mixtures have been investigated to obtain the fundamental basis of the role of ceramides in the lipid lamellae of the stratum corneum.

MATERIALS AND METHODS

Isolation of ceramides. Cerebrosides were isolated from bovine brain following a modified procedure of Radin (19).

Copyright © 1995 by AOCS Press

Briefly, brains were dehydrated by blending twice with acetone (4 mL/g). The dispersion was allowed to settle and then was filtered through Whatman filter paper in a Buchner funnel. The cakes were further dried overnight in a dessicator attached to the house vacuum system. The dried mass was dispersed in 85% ethanol in water by blending and then refluxed for 30 min. The solids were collected by filtration and refluxed again with 85% ethanol. The combined supernatants were placed in a refrigerator. The resulting precipitate was collected by filtration, dissolved in a minimum volume of warm ether, and precipitated with acetone (6:1 volume ratio to ether). After storing overnight in the refrigerator, a Folch extraction ($CHCl_3/CH_3OH/H_2O$, 4:2:1) was introduced. This minimized the clogging of the subsequent dichloromethane/methanol solvent gradient column (Bio-Sil A, 100–200 mesh; BIO-RAD, Richmond, CA) that was used to purify the cerebrosides. The cerebrosides eluted at 10% methanol in dichloromethane.

The isolated cerebrosides were then converted to ceramides by cleaving the carbohydrate moiety from the sphingosine base by the procedure of Carter *et al.* (20). The resulting ceramides were separated into two groups according to the absence or presence of hydroxy fatty acids by silica column chromatography in a dichloromethane/methanol solvent gradient. The NFAC fraction began to elute at 4% methanol with the HFAC fraction following.

The acyl chain composition of NFAC was determined by reacting the dried fraction with 10% BCl_3 in methanol for 20 min at 80°C. The resulting fatty acid methyl esters were extracted into hexane, dried under argon, and reconstituted with carbon disulfide. The solution was injected on a gas chromatograph (model 5830A; Hewlett-Packard, Avondale, PA) equipped with a flame-ionization detector (FID) and 18850A GC terminal for automatic peak integration. The solid phase consisted of 10% DEGS-PS on 80/100 Supelcoport (Supelco, Inc., Bellefonte, PA) packed in a ⅛″ × 30 cm column. The carrier gas was N_2 at a flow rate of 20 mL/min and the injector, column and detector temperatures were 250, 200 and 275°C, respectively. The composition was determined by comparing the retention times with known standards, and the integrated areas were corrected for the differences in response of the FID. Other peaks were assigned by interpolation of plots of the log of the retention time as a function of carbon number.

Optical microscopy/birefringence. Visual changes occurring in the samples with fixed and programmed temperature variations were viewed with a hot stage microscope. A WILD (Heerbrugg, Switzerland) M3Z stereomicroscope, MPW51 shutter piece, and Photoautomat MPS45 using center-weighted integrated metering were coupled to a Mettler (Highstown, NJ) FP800 Thermosystem. Also included was a Mettler FP80 central processor for programmed temperature control and a Mettler FP82HT hot stage. Birefringence was viewed by placing Tiffen 49 mm SR polarizing lenses (Hauppauge, NY) above and below the sample. The angle between the direction of the polarizers was visually set at right angles by minimizing the transmitted light. Photographs were taken with Kodak ASA 400 black and white 35 mm film (Rochester, NY). Typical exposure times were 30 to 60 s for the low birefringent samples.

Thermal analysis. Ceramides were first lyophilized from cyclohexane to obtain a dry powder. Accurately determined weights of HFAC and NFAC were combined to generate the entire range of compositions. The mixtures were dissolved in 10–30% methanol in dichloromethane and the appropriate volume was placed into preweighed coated aluminum differential scanning calorimeter pan (DuPont, Wilmington, DE). The solution was dried overnight under high vacuum and excess distilled water was added to bring the solid content to less than 33 wt%. The pans were then hermetically sealed. Uniform hydration was achieved by heating in a steam bath (85°C) for 20 min. Due to the presence of metastability, variable incubation conditions were used. TLC failed to indicate any chemical stability problems with these procedures (21).

Calorimetric scans were usually performed at 5°/min on a DuPont 910 differential scanning calorimeter (Wilmington, DE). The phase transition was determined by extrapolation to the baseline of the most rapid rise in the excess heat capacity as a function of temperature curve. This value is more reproducible than the maximum value of the excess heat capacity as a function of temperature curve and compensates for the rapid scan rate. The enthalpy was determined by integrating the area under the curve from a plot of the excess heat capacity as a function of temperature. For the phase diagram, onset and completion temperatures were corrected by the method of Mabrey and Sturtevant (22) using the endotherm obtained with pure HFAC.

RESULTS

Both fractions of the isolated ceramides yielded a single spot with TLC in a solvent system of 9:1 chloroform/methanol. The fatty acid composition of the NFAC are given in Table 1. Also included are the results from nonhydroxy fatty acid containing and hydroxy fatty acid containing cerebrosides (NFA–CER and HFA–CER, respectively) as reported by O'Brien and Rouser (23). The major fatty acids are stearic, lignoceric and nervonic, which make up about 60% of the fatty acids on NFAC.

In Figure 1, the differential scanning calorimetric results of anhydrous and hydrated samples of HFAC are given. HFAC underwent a solid to liquid phase change at 92°C. The transition was independent of whether the solid was a lyophilized powder or cooled from a liquid state. With hydration, the transition temperature was 71.8 ± 0.4°C, which is in good agreement with that reported for HFAC obtained with the unmodified Radin procedure (21). Because the enthalpy increased with storage time, further study was needed as described in the following.

HFAC were viewed with optical microscopy while heating. HFAC were nearly transparent both above and below the phase transition temperature. The birefringence was also determined, and the results are given in Figure 2. At 40°C, HFAC was found

to be brightly birefringent (Fig. 2A). With heating, there was a reduction in the birefringence over the temperature range of 65–75°C. After completion of the thermal changes, the sample still remained somewhat birefringent (Fig. 2B). As can be noted, considerable heterogeneity with regard to the intensity of the birefringence is evident for HFAC.

When the storage time of HFAC was increased, neither the overall shape of the curve nor the position of the peak temperatures changed. However, the integrated area under the curve progressively increased over a 20-d period as is shown in Figure 3. Immediately rescanning the sample after rapid cooling from 90°C resulted in an enthalpy change of about 66 J/g. After 20 d of storage, the enthalpy change for the thermal transition appeared to reach a plateau value of 89 ± 11 J/g.

A similar series of experiments was also conducted with the NFAC. The solid-to-liquid phase change of a lyophilized powder of NFAC occurred over a broad temperature range (Fig. 4A). With hydration, relatively complicated thermal changes were observed (Fig. 4B). At 55°C, NFAC began to undergo an endothermic transition. This was interrupted by an exothermic transition that had a peak occurring at 72°C. Thereafter, a second endothermic transition was recorded which had a peak temperature of about 79°C. Other samples prepared with NFAC displayed similar behavior although the peak temperatures were variable.

Hydrated NFAC was also nearly transparent at 40°C. As the temperature was increased, melting to a transparent liquid

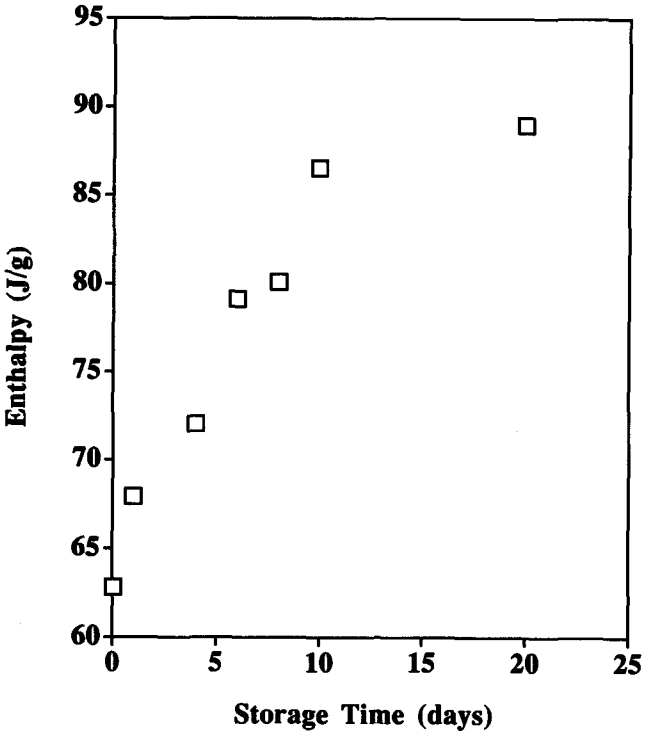

FIG. 3. The change in enthalpy of hydroxy fatty acid ceramides determined as a function of room temperature storage time.

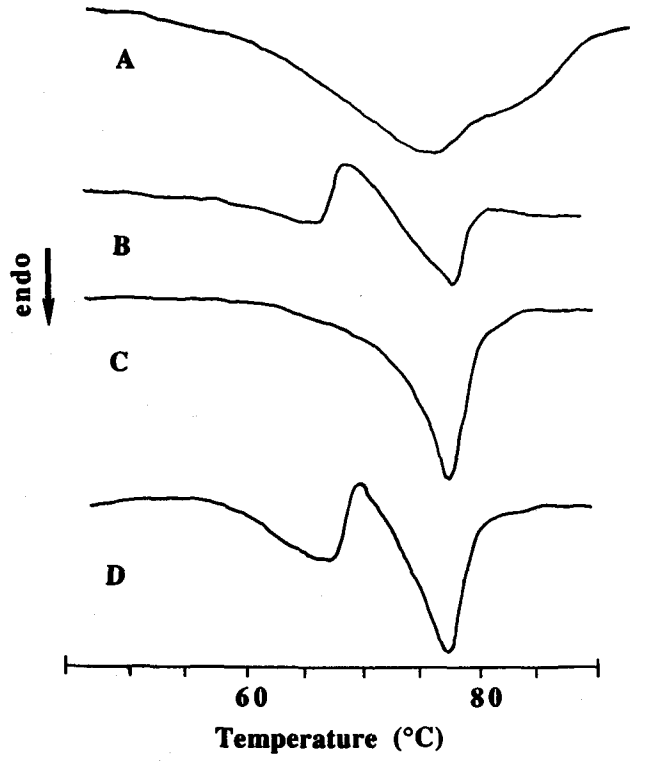

FIG. 4. Calorimetric scans at 5°C/min of (A) anhydrous nonhydroxy fatty acid ceramide and (B) hydrated nonhydroxy fatty acid ceramide (66 aqueous wt%). Calorimetric scans of hydrated nonhydroxy fatty acid ceramide obtained with the following sequential conditions: (C) heated to 70°C, cooled to 40°C and then scanned at 5°C/min and (D) cooled from 90°C and then immediately scanned at 5°C/min.

occurred over the temperature range of 75–80°C. In addition, NFAC was brightly birefringent at 40°C as is evident in Figure 5A. The birefringence remained intense until a temperature of 70°C (Fig. 5B), after which there was a loss in intensity. This corresponded to the formation of a nonbirefringent liquid (Fig. 5C). The birefringence was partially recovered with cooling to 40°C, although reappearance of the bright birefringence took a longer time.

The thermograms observed for NFAC are indicative of metastability, and thus the effect of sample history on the thermal response was determined. NFAC was scanned at 5°C/min

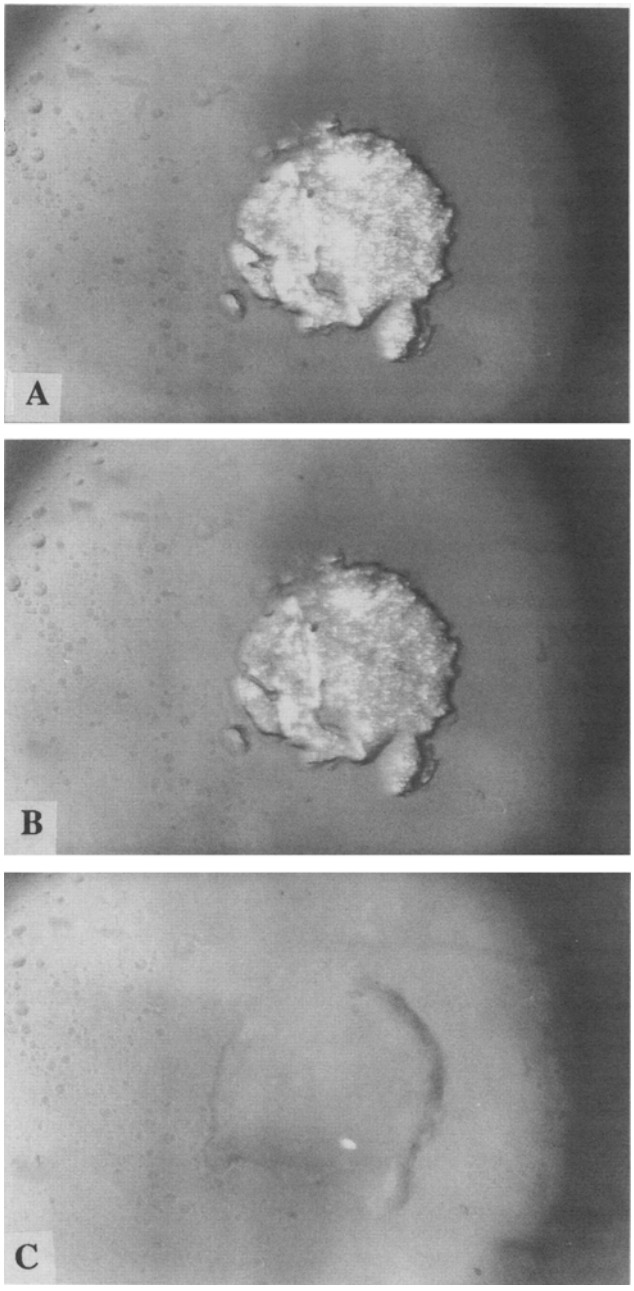

FIG. 5. Photographs of hydrated nonhydroxy fatty acid ceramide taken with cross-polarizers at temperatures of (A) 40°C, (B) 70°C and (C) 85°C.

to a temperature of 90°C which yielded the result shown in Figure 4B. After cooling to room temperature, the sample was heated at 5°/min to 70°C, held at this temperature for 5 min, and then cooled to room temperature. The sample was then scanned at 5°C/min to a final temperature of 95°C with the resulting thermogram given in Figure 4C. Only one endothermic transition was observed which had a temperature of 75°C. Finally, the sample was cooled to 40°C and scanned to 90°C, and the metastability was again observed (Fig. 4D).

Finally, thermal analysis of HFAC and NFAC mixtures was conducted. In Figure 6, the endothermic transitions are given for samples that were stored for 7 d. The top scan shows the trace of pure HFAC which produced a single endotherm. Incorporation of NFAC into HFAC caused a broadening of the curves and a slight reduction in the onset and completion temperatures. At small weight fractions of HFAC, the value of the peak temperature of the transition reached a plateau. The bottom trace was obtained with pure NFAC. This was the only sample where an exothermic peak was observed and which formed a liquid. Samples containing 0.7 and 0.22 weight fraction HFAC had time-dependent enthalpy changes and time-independent transition temperatures comparable to that observed with pure HFAC.

In Figure 7, the corrected onset and completion temperatures are given as a function of the weight fraction of HFAC. The progressive decrease in onset and completion temperature with increasing amounts of NFAC is clearly seen. At low HFAC weight fractions, there is a plateau in the onset and completion temperatures. Overall, HFAC and NFAC evidently do not exhibit complex phase behavior over most of the composition range.

DISCUSSION

This study represents the first investigation into the thermal behavior of mixtures of HFAC and NFAC. Each class still contains many different chemical species, due to the variability in the fatty acid chain with respect to the length and degree of unsaturation. Nevertheless, rather simple thermal behavior is observed. Thus, in this respect it shares commonality with lipid mixtures, such as egg phosphatidylcholines and bovine brain cerebrosides.

The modified procedure for isolating the ceramides is straightforward. The use of the acetone dehydration step followed by the ethanol extraction is much easier than the chloroform/methanol extractions suggested by Carter *et al.* (20). Moreover, the Folch extraction introduced before the column purification of the cerebrosides apparently removed polar impurities that contributed to the precipitation on the column. The fatty acid composition of the nonhydroxy containing ceramides is in very good agreement with that reported for the nonhydroxy containing cerebrosides. This suggests the minor modification does not influence the resulting composition of ceramides. Moreover, the fatty acid composition of the HFAC is expected to closely follow that of the HFA–CER also given in Table 1.

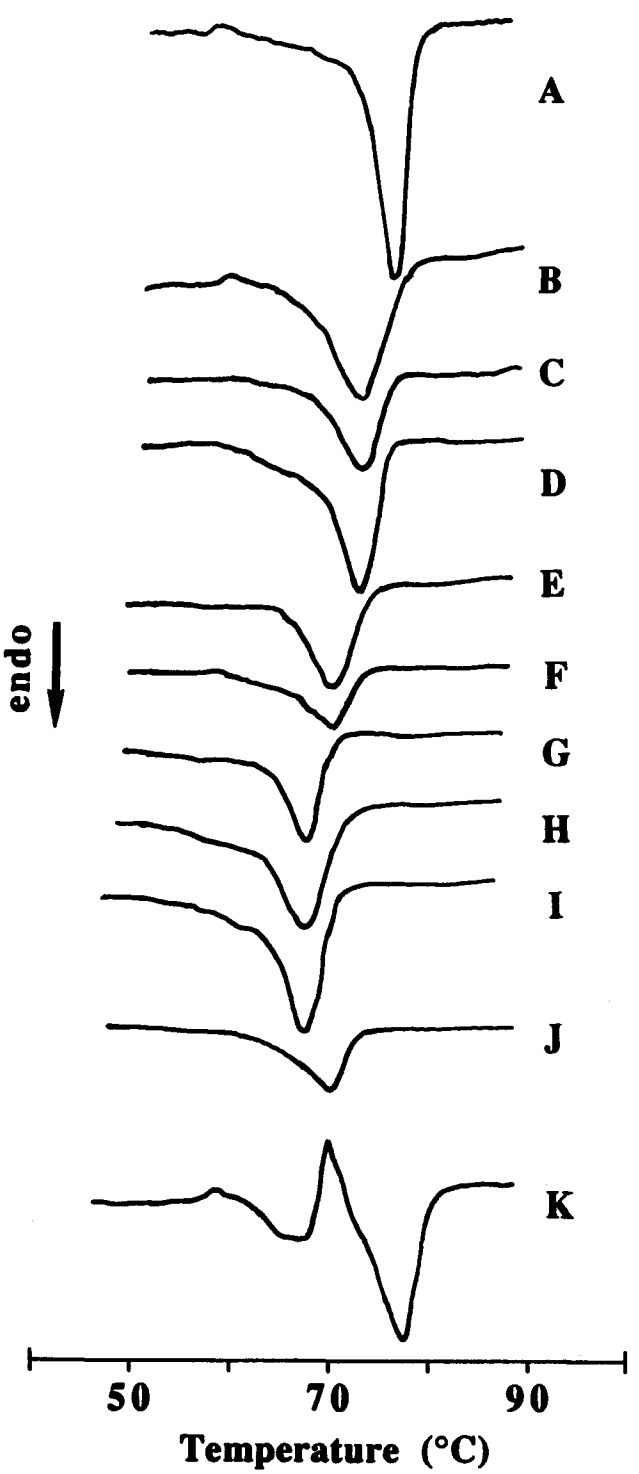

FIG. 6. Calorimetric scans at 5°C/min of mixtures of hydroxy fatty acid ceramides and nonhydroxy fatty acid ceramides stored for 7 d at room temperature with weight fractions of hydroxy fatty acid ceramides of (A) 1.0, (B) 0.90, (C) 0.80, (D) 0.74, (E) 0.60, (F) 0.50, (G) 0.39, (H) 0.29, (I) 0.21, (J) 0.10 and (K) 0.0.

The thermal behavior of the anhydrous and hydrated samples coupled with the measurement of the birefringence suggests that hydrated HFAC samples undergo a gel-to-liquid crystalline phase transition. The temperature and enthalpy of

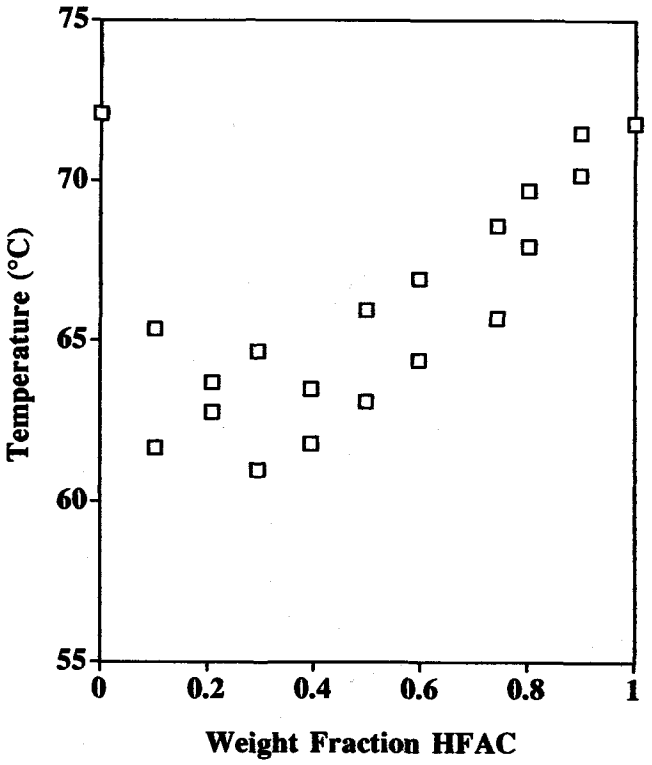

FIG. 7. Corrected onset and completion temperatures given as a function of weight fraction of hydroxy fatty acid ceramides. HFAC, hydroxy fatty acid containing ceramides.

the thermal transition of HFAC are in reasonable agreement with Shah *et al.* (24) who reported values of 80.0°C and 8.5 kcal/mol. However, they indicated that there was a gel to inverted hexagonal phase transition. Until more details become available, it is not possible to determine the source of this discrepancy.

While the temperature of the transition of HFAC remained constant, the enthalpy change continued to increase for at least 20 d. Analogous results have been reported for bovine brain HFA-CER (25,26). However, the enthalpy for the gel to liquid crystalline phase transition was still increasing after six months (26).

Curatolo and Jungalwala (26) suggested that the time-dependent enthalpy change of HFA-CER was the result of the slow formation of a stable gel state from a metastable state. They further speculated that the difference in these two states lay in the extent of order of the acyl chain. That is, the presence of the α-hydroxyl moiety on the acyl chain retarded the rate of formation of a highly ordered chain. A similar phenomenon may be occurring with the HFAC.

Alternatively, there may be a slow dehydration occurring in the interbilayer aqueous space as has been suggested for phospholipids (26,27). This would in turn have significance for the role of ceramides in the function of the lipid lamellae of the stratum corneum. X-ray diffraction studies of intact stratum corneum have revealed that the lipid lamellar spacing does not appreciably change with increasing water content (28). This suggests that the lipid lamellae have sufficiently strong attractive interactions to prevent the swelling which may in part be due to the presence of ceramides.

The magnitude of the enthalpy change is also noteworthy. Using the reported acyl chain composition to calculate the average molecular weight, the enthalpy change after storage is about 15 kcal/mol (25,26). Therefore, the enthalpy change of the transition is almost twice as high as that observed for phosphatidylcholines which typically is 8 kcal/mol. For HFA-CER, Curotolo and Jungalwala (26) observed an enthalpy change of 66.5 J/g after 3 months of storage. This is about two-thirds of the value measured for HFAC. Thus, there is a significant energetic contribution from disruption of the intermolecular hydrogen bonding between the lipid head groups with generation of liquid crystalline state.

Overall, the time independence of the transition temperature and the magnitude and time dependence of the enthalpy change of HFAC are similar to cerebrosides. This similarity has the implication that the functional groups common to both lipids dominate the phase behavior. Therefore, it may be that the neutral carbohydrate moiety of cerebrosides does not significantly change the nature of the phases above and below the transition temperature. This argument is corroborated by Curotalo's observations that the phase transition temperatures and enthalpies were largely independent of fatty acid chain-length (26).

For NFAC, evidently a metastable gel phase is readily produced. No estimate of the enthalpy change was obtained due to the proximity of the exothermic transitions. Shah *et al.* (24) reported similar complicated thermal behavior of their NFAC. From X-ray diffraction, it appears that NFAC exists as a lamellar crystalline structure at low temperatures, but above the thermal transitions only reflections at 30 and 4.6 Å remain. An earlier report of the X-ray crystallography performed with N-palmitoyl-galactosyl-sphingosine may also be relevant (29). With this lipid, a low-temperature metastable phase was produced by cooling from the liquid crystalline phase. The actual metastability was postulated to arise from the presence of water about the head groups of the lipids. The stable state was characterized as a dehydrated lamellar phase. Bovine brain NFA–CER also displayed analogous metastable behavior (25,26,30–32). Thus, there may be a connection between the metastable behavior of NFAC and the extent of hydration.

It is of particular interest that HFAC undergoes a transformation to an ordered phase while NFAC does not. NFAC differs from HFAC by a single hydroxyl group in the head group. As has been established for some time, the stereochemistry (D-isomer) of the naturally occurring α-hydroxy moiety on fatty acids is such that only intermolecular hydrogen bonding is allowed (10). The intermolecular hydrogen bonding could provide a stabilizing effect for the lamellar phase. Furthermore, the additional hydroxyl group may also interact with water to maintain a hydrated head group. The cerebrosides contain an additional carbohydrate moiety in comparison to NFAC and undergo a gel-to-liquid crystalline phase transition. The presence of only an amide and two hy-

droxy moieties on NFAC may be insufficient to maintain the hydration of the head group, and thus there is a loss of the lamellar structure at high temperatures.

In spite of the complexity of the thermal response of HFAC and NFAC, mixtures of NFAC and HFAC yield relatively simple thermograms. Here again, the behavior of ceramides appears to mirror that observed with mixtures of cerebrosides (25,26). While progressively more complicated thermograms were obtained with fractionation and purification of individual cerebrosides, the crude mixtures yielded single endothermic transitions. The fairly high enthalpy change, even in the presence of such a diverse chemical mixture, suggests that ceramides can readily participate in the formation of a highly ordered lipid matrix. Thus, the physical chemical properties of isolated ceramides support the contention that ceramides have a pivotal role in controlling the mechanical and permeability properties of the stratum corneum of the skin.

Finally, the results from this study have implications for investigations into the role of ceramides in the function of the stratum corneum (14–18,33). The replacement of dipalmitoyl phosphatidylcholine by isolated stratum corneum ceramides in mixtures of cholesterol, 2-^{2}H-palmitic acid, and cholesterol sulphate led to the appearance of an isotropic peak in the ^{2}H NMR spectrum (14). These isolated ceramides would contain about 40% nonhydroxy fatty acids and 20% hydroxy fatty acids. Another 10% are the unusual ω-acyloxy ceramide, and the remainder are ceramides with the trihydroxy, phytosphingosine base (2–4). Because the dihydroxy ceramide, NFAC, readily formed a nonlamellar phase, the nonhydroxy fatty acid–containing ceramides fraction of the stratum corneum may energetically contribute to the formation of the isotropic phase.

For the studies involving model lipid mixtures, it is important to consider the composition of the ceramides of the skin and the model system. The bulk of the ceramides in the stratum corneum contain three or more hydroxy moieties in the head group. With respect to the fatty acid composition of the stratum corneum, less can be said. It appears that even in the most careful studies either the presence of hydroxylation or the presence of unsaturation was not determined (2–4). However, the most common acyl chainlengths are 16, 24 and 26 carbons. For model skin lipid mixtures, a number of different ceramide fractions have been used including type III and type IV bovine brain ceramides and synthetic palmitoyl sphingosine (14,15). Type III ceramides are obtained from enzymatic cleavage of sphingomyelin and do not contain any hydroxy fatty acids. The fatty acid composition of type III ceramide is not too different from the cerebrosides in that stearic acid and nervonic acid are prevalent. Type IV are derived from bovine brain cerebrosides and thus are comparable to the HFAC used in this study. Again, stearic and especially lignoceric and nervonic acids are present in appreciable quantities.

Although ceramides from the stratum corneum obviously are the most relevant for *in vitro* studies, the low abundance and difficulty in labeling severely limits spectroscopic investigations. It would seem that the use of a mixture of type III and type IV bovine brain ceramides would lead to the closest mimic of the stratum corneum ceramides (33). However, because the stratum corneum ceramides also contain phytosphingosine base, the average number of hydroxy groups of this mixture will be less than that of the stratum corneum. In addition, the brain ceramides have 60% of their acyl chains of either 18 or 24 carbons, while the stratum corneum appears to be more evenly distributed and with longer chains. Thus, there is perhaps greater asymmetry in the acyl chains of the stratum corneum ceramides in comparison to bovine brain model systems.

A modified procedure for obtaining hydroxy fatty acid and nonhydroxy fatty acid ceramides has been used for the study of the thermotropic behavior of ceramides. Whereas HFAC has a time-dependent enthalpy of transition, NFAC has a more complicated thermogram due to the ease in which it enters a metastable state. Mixtures of NFAC and HFAC have simple thermal properties for most compositions. Only with pure NFAC was a transition to a nonbirefringent liquid observed, indicating the profound effect of the introduction of a single hydroxy moiety on the resulting phase. The metastability of NFAC and time-dependent enthalpy of HFAC are qualitatively similar to NFA–CER and HFA–CER, respectively. This has the implication that the common functional groups of the ceramides and cerebrosides control the phase behavior of these lipids. Finally, the marked difference in the behavior of HFAC and NFAC allows for greater possibilities for the function of ceramides in the stratum corneum.

ACKNOWLEGDMENTS

We acknowledge the suggestions of Dr. Amir Salmon in improving the lipid isolation. We also appreciate the preliminary DSC studies carried out by Vincent Wong and Audrey Cheng and the assistance of Darasa Thumchai in performing the acyl chain analysis. We thank the reviewers for providing excellent comments and suggestions. Work was supported by a Grant-in-Aid from the University of Minnesota Graduate School and a gift from 3M Biosciences Laboratory.

Analysis of Lipoxygenase Kinetics by High-Performance Liquid Chromatography with a Polymer Column

Alberto Nuñez* and George J. Piazza

ERRC, ARS, USDA, Wyndmoor, Pennsylvania 19118

ABSTRACT: Soybean lipoxygenase (LOX; EC 1.12.11.12) catalyzes the oxygenation of polyunsaturated fatty acids, acylglycerols and phosphoglycerols, producing a regio- and enantiospecific hydroperoxide product. The goal of this work was to measure the relative rate of LOX-catalyzed oxidation of mixtures of lipids containing linoleate, using high-performance liquid chromatography (HPLC) and a light-scattering detector (LSD). Previous literature suggested that reversed-phase HPLC with silica-based columns could be used for the separation of individual fatty acids, acylglycerols, phosphoglycerides and their oxidation products. However, these columns produced ineffective separations of phosphoglycerides unless choline chloride and a strong base, such as KOH, are present in the mobile phase. Such modifiers precluded the use of the LSD. It was found that a reversed-phase column based upon an organic polymer support, rather than on silica, was able to separate these mixtures with a ternary solvent gradient of methanol/water/acetonitrile without the need for the addition of modifiers. The oxidation time course of a mixture of linoleic acid, trilinolein and 1-linoleoyl-2-stearoyl-*sn*-glycero-3-phosphocholine was followed using the developed HPLC method. The results showed that trilinolein and phosphatidylcholine reacted at one-tenth the rate of linoleic acid. The diacylglycerol, 1,3-dilinolein, was oxidized at a rate that was approximately 40% that of linoleic acid, with the formation of mono- and dihydroperoxides as well as other unidentified products.

Lipids 30, 129–133 (1995).

The enzyme, lipoxygenase (LOX; EC 1.13.11.12), catalyzes the oxidation of polyunsaturated fatty acid containing a *cis, cis*-1-4-pentadiene moiety, producing fatty acid hydroperoxides. It is known that LOX from a variety of natural sources produces a single major product (1,2). For example 13(*S*)-hydroperoxy-9,11-octadecadienoic acid results from the action of soybean LOX upon linoleic acid (LA) (3). Recently it was shown that immobilization of LOX enhances its stability, thereby increasing its potential as a synthetic reagent for the selective oxidation (4,5). In addition to free fatty acid substrates, early studies showed that polyunsaturated acylglycerols undergo oxidation with soybean LOX (6–8). More recently, it was shown that this enzyme catalyzes the oxidation of phosphatidylcholine, provided that a bile salt surfactant is present (9). Structural analysis of the products illustrated the high positional and stereochemical specificity of this reaction (10). Although prior work has shown that LOX acts upon fatty acids, acylglycerols and phosphoglycerides, the substrate specificity of LOX has never been determined with a bile salt present in the reaction medium.

To measure enzyme specificity, Schellenberger *et al.* (11) have developed a statistical method for the analysis of reactions of competitive substrates. To use this method, the relative concentrations of all substrates or products must be followed over time by an analytical technique. For the analysis of LOX substrates and products, high-performance liquid chromatography (HPLC) is an excellent option. There is a vast volume of HPLC methodologies published for the separation of neutral and polar acylglycerols using normal-phase (NP) and silica-based reversed-phase (RP) columns (12). Although NP-HPLC is used for the separation of lipid classes, separation of the components of each class is usually accomplished by RP-HPLC. Fatty acids and neutral acylglycerols can be separated with an RP-HPLC method that uses a quaternary stepped mobile phase gradient (13). However, the successful separation of phosphoglycerides requires the inclusion of a modifying salt in the mobile phase. For example, an RP-HPLC method described by Patton *et al.* (14) used 20 mM choline chloride in methanol/water/acetonitrile as the mobile phase. More recently, it was shown that inclusion of ammonium acetate in the mobile phase greatly increased peak sharpness (15,16).

For monitoring the elution of acylglycerols and phosphoglycerides ultraviolet (UV) detection at 205 nm is often used. However, there are two significant disadvantages to the use of a UV detector. First, solvents with significant absorption above 200 nm cannot be used in the mobile phase and, second, the degree of unsaturation in the sample strongly affects detector sensitivity. A detector that does not have these deficiencies is the light-scattering detector (LSD). On the other hand, its use is limited when salts or buffers are used in the mobile phase. Although 0.1% ammonium acetate may be

used with an LSD, the addition of choline chloride results in unacceptable baseline noise. It occurred to us that a polymer-based RP column would adsorb the polar functionalities of phosphoglycerides less tightly than a silica-based RP column, alleviating the necessity for the addition of mobile phase salts and buffers. This would be an important advance, as it would allow the utilization of an LSD for the quantitation of all lipids species. Therefore, a polymer-based RP-HPLC method was developed for the analysis of mixtures of free LA, phosphoglycerides and acylglycerols containing linoleate using a mobile phase that was free of salt. This method was utilized to determine the relative rate of oxidation by LOX of these lipid classes.

MATERIALS AND METHODS

Materials. Soybean LOX (lipoxidase, Type 1-B), LA, trilinolein (TL), 1,3-dilinolein (1,3-DL) and 1,3-diolein (DO) were purchased from Sigma (St. Louis, MO). Avanti Polar Lipids, Inc. (Alabaster, AL) supplied 1-palmitoyl-2-linoleoyl-*sn*-glycero-3-phosphoethanolamine (1P-2L-PE) and 1-linoleoyl-2-stearoyl-*sn*-glycero-3-phosphocholine (1L-2S-PC). All HPLC solvents (hexane, acetonitrile and methanol) were obtained from Burdick and Jackson (Muskegon, MI). Water was purified to a resistance of 18 MΩ-cm using a Barnstead (Dubuque, IA) NANOpure system. All other reagents were of the highest purity available.

Formation of hydroperoxide. An aliquot of the substrate (6 μmol linoleate) and 2 μmol of DO (as internal standard) dissolved in chloroform was placed in a 10-mL Erlenmeyer flask, and the solvent removed under a stream of dry nitrogen. In addition to the substrate, the reaction medium contained 0.2 mg LOX, 0.2 mL 100 mM deoxycholate and 1.8 mL aqueous buffer, consisting of an equal 0.1 M mixture of the buffers AMP, TRICINE, HEPES and MES (respectively, 2-amino-2-methyl-1-propanol hydrochloride, N-tris(hydroxymethyl)-methylglycine, N-(2-hydroxyethyl)piperazine-N′-(2-ethanesulfonic acid, and 2-N-morpholino)ethanesulfonic acid). Oxidation was conducted at 15°C with agitation at 250 rpm for an indicated time. Reactions were quenched with 400 μL 1M citric acid and extracted within 1 h with two 1.5 mL aliquots of chloroform/methanol (2:1, vol/vol). The solvent was removed under a stream of nitrogen, and the sample was redissolved in 0.5 mL of methylene chloride.

HPLC. Liquid chromatographic analysis was performed with a Hewlett-Packard (Palo Alto, CA) Model 1050 HPLC equipped with a gradient program and autosampler. Detection of analytes was by a variable wavelength UV detector, HP 1050 Series, connected in series with a Varex IIA Universal Evaporative Light-Scattering Detector (ELSD, Rockville, MD) operated at 100°C with nitrogen (40 psi) as the nebulizer gas. All analyses were accomplished with a HEMA-RP C18 10 micron column (250 mm × 4.6 mm) at programmed flow rate (1 to 1.5 mL/min). Also, the studies included an ADSORBOSPHERE C18 5-micron (250 mm × 4.6 mm) column. Both columns were obtained from Alltech (Deerfield, IL). Other types of silica-based columns (CHROMSPHER Si, 5μ, 200 mm × 3 mm, and Chrompack Chromsep 5μ LICHROSORB DIOL, 5μ, 200 mm × 3 mm, both supplied by Chrompack, Raritan, NJ) were evaluated but were found to give inferior separations.

Time course and relative rate analysis. A typical reaction time course consisted of seven time points taken at five-minute intervals. The data for each time point was derived from a separately prepared reaction mixture. Each data point represents the mean of at least three injections of 20 μL of the reaction extract. Oxidations were followed by monitoring with both a UV detector (205 nm) and an LSD. Comparable results were obtained with both detectors. The analysis of the data from the mixtures of substrates to obtain the relative rate of oxidation was accomplished using the computer program developed by Schellenberger *et al.* (11).

RESULTS AND DISCUSSION

HPLC analysis. Preliminary studies on the separation of a mixture of free fatty acid, acylglycerols and phosphoglycerides were made with a silica-based ADSORBOSPHERE RP column. Although several gradient shapes, and combinations of solvents (e.g., isopropanol, acetonitrile, methanol, 1% ammonium acetate in methanol, water) were tried, phosphoglycerides eluted as significantly tailed peaks, and quantitation was not possible. Addition of 20 mM choline chloride to the mobile phase reduced tailing noticeably, as described previously (10,14). However, it was found that the concentration of choline chloride in the mobile phase could be reduced to 1 mM if the column was first equilibrated with 20 mM choline chloride for 1–2 h. Total removal of this modifier resulted in slowly increasing peak tailing of the phosphoglyceride with time. In addition to choline chloride, it was found that the addition of base was needed to obtain completely symmetrical phosphoglyceride peaks. Trimethylamine, ammonium hydroxide and KOH were tested as bases, and the best performance was obtained with 5 mM KOH as a component of the elution system. The best mobile phase gradient that was found is shown in Table 1. Using this gradient, the

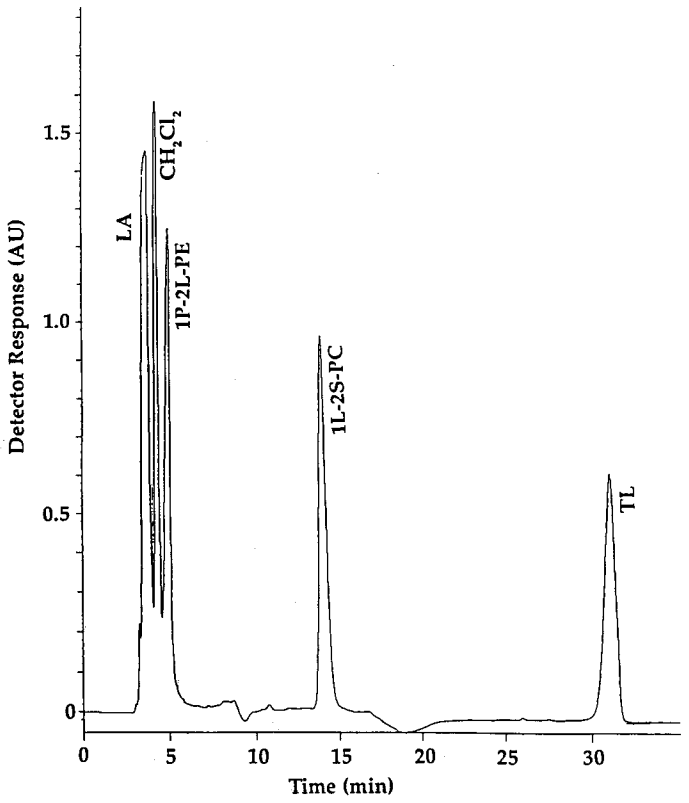

FIG. 1. Elution profile of the injection of 20 µL of a mixture of linoleic acid (LA), 1-palmitoyl-2-linoleoyl-*sn*-glycero-3-phosphoethanolamine (1P-2L-PE), 1-linoleoyl-2-stearoyl-*sn*-glycero-3-phosphocholine (1L-2S-PC) and trilinolein (TL) (2 mg/mL in methylene chloride) with silica-based reversed-phase high-performance liquid chromatography using the solvents and modifiers described in Table 1. An Alltech (Deerfield, IL) 5 micron ADSORBOSPHERE C18 column (250 mm × 4.6 mm) was used, with ultraviolet detection at 205 nm.

separation of LA, 1P-2L-PE, 1L-2S-PC and TL was attempted. The elution profile is shown in Figure 1, and it can be seen that the peaks corresponding to the LA, the injecting solvent, methylene chloride and 1P-2L-PE were not satisfactorily resolved. Due to the presence of an unsatisfactory level of baseline noise in the LSD, only the UV detector was used. The inclusion of KOH in the mobile phase also rapidly cleaves the organic layer from the silicate particles and causes damage to the silica structure of the column, decreasing its resolution and lifetime (17). For these reasons this method was abandoned. Other silica-based columns (CHROMSPHER Si, 5µ, and LICHROSORB DIOL, 5µ) were also tested but were found to be unsatisfactory for the separation of this mixture of components.

Because of problems encountered with the silica-based RP column, a polymer-based (hydroxyethyl methacrylate/dimethacrylate copolymer) HEMA-RP C18 column was evaluated. This column is resistant to bases and lacks the interactions associated with the free silanols in the silica-based RP column. After trying different mobile phases, the best separation was achieved with a ternary gradient of water/methanol/acetonitrile, without the need for inclusion of salt, buffer or base (Table 2). Figure 2 shows the chromatogram for the separation of the mixture of LA, 1P-2L-PE, 1L-2S-PC, 1,3-DL, DO and TL with the HEMA-RP C18 column. All components, including phosphoglycerides, eluted as sharp peaks. The solvent gradient shown in Table 2 was used for elution and detection was by the LSD.

Comparative kinetic study. A mixture of LA, 1L-2S-PC and TL was prepared in the presence of 10 mM deoxycholate and was subjected to the action of LOX. The concentrations of substrates over time were determined by HPLC using both

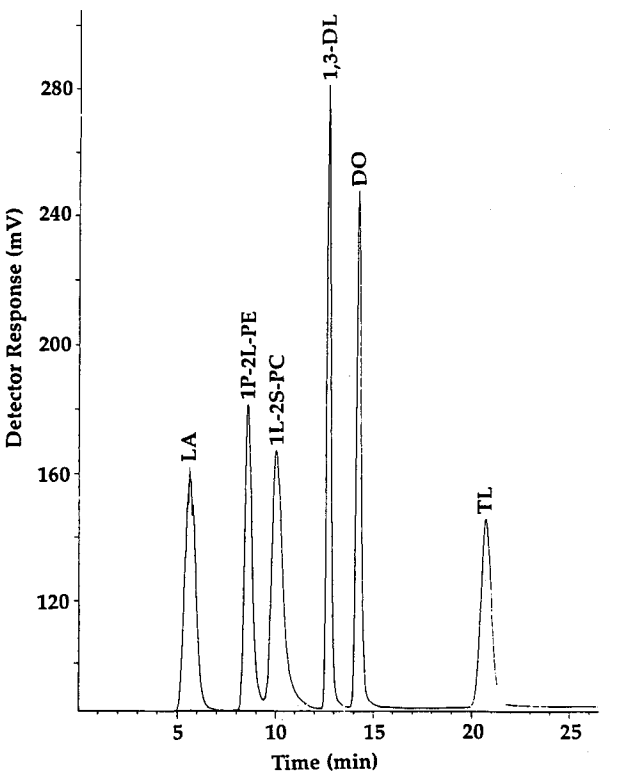

FIG. 2. Elution profile of the injection of 20 µL of mixture of LA, 1P-2L-PE, 1L-2S-PC, 1,3-dilinolein (1,3-DL), 1,3-diolein (DO) and TL (2 mg/mL in methylene chloride) with polymer-based reversed-phase high-performance liquid chromatography using the solvents described in Table 2. An Alltech 10 micron HEMA-RP C18 column (250 mm × 4.6 mm) was used, with light-scattering detection. Abbreviations and company source as in Figure 1.

the LSD and the UV detector. However, at the longer time points the concentration of LA became very low, and only the UV detector was sensitive enough to measure the remaining LA. Figure 3 shows the chromatogram of the substrates and hydroperoxides formed from a mixture of LA, 1L-2S-PC and TL after 30 min of reaction. Peaks B, D and G correspond to LA, 1L-2S-PC and TL, respectively. Peaks A, C and F are the corresponding hydroperoxide products. Peak E is the internal standard (DO). The assignment of each hydroperoxide was made by oxidation of each substrate separately. Figure 4 shows a typical time course of LOX-catalyzed oxidation of LA, 1L-2S-PC and TL. The relative rate of oxidation of the multiple substrates was calculated by the method of Schellenberger *et al.* (11), and the results are presented in Table 3. As expected, LA was oxidized at the fastest rate, and the rates of oxidation of 1L-2S-PC and TL were only 10% of that of LA. Control experiments showed that nonenzymatic oxidation did not occur over the time-span of the experiment.

The competitive oxidation of LA and 1,3-DL by LOX was also monitored by HPLC. Surprisingly, 1,3-DL was oxidized at a rate that was 40% as fast as LA (Table 3). The relatively high rate of oxidation of 1,3-DL as compared to TL and 1L-2S-PC suggests that steric factors strongly influenced the ability of LOX to promote hydroperoxide formation. The oxidation of 1,3-DL by LOX led to the formation of mono- and dihydroperoxides as major products, with small amounts of other unidentified products as determined by HPLC.

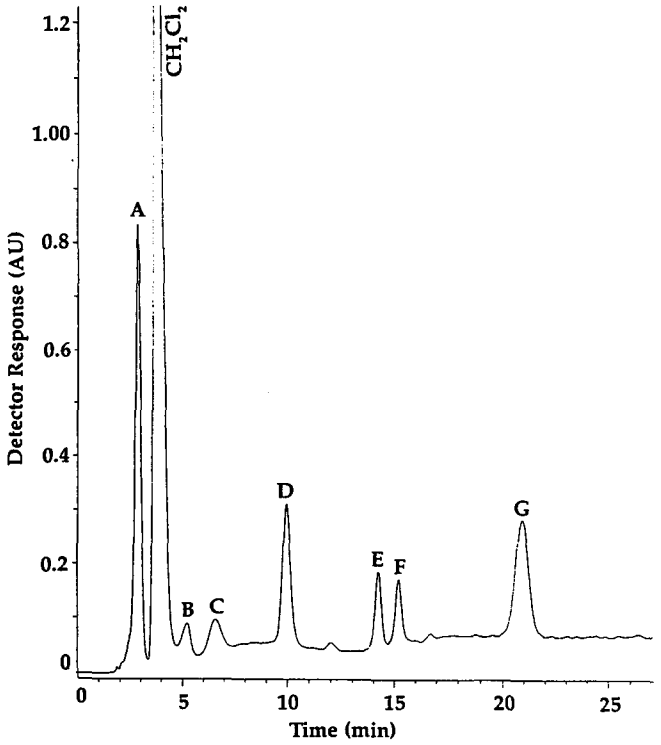

FIG. 3. Elution profile of a mixture of LA, 1L-2S-PC and TL after 30 min of incubation with lipoxygenase, with polymer-based reversed-phase high-performance liquid chromatography using the solvents described in Table 2. An Alltech 10-micron HEMA-RP C18 column (250 mm × 4.6 mm) was used, with ultraviolet detection at 205 nm. A, peroxide of LA (B); C, peroxide of 1L-2S-PC (D); E, DO (internal standard); F, peroxide of TL (G). Abbreviations and company source as in Figures 1 and 2.

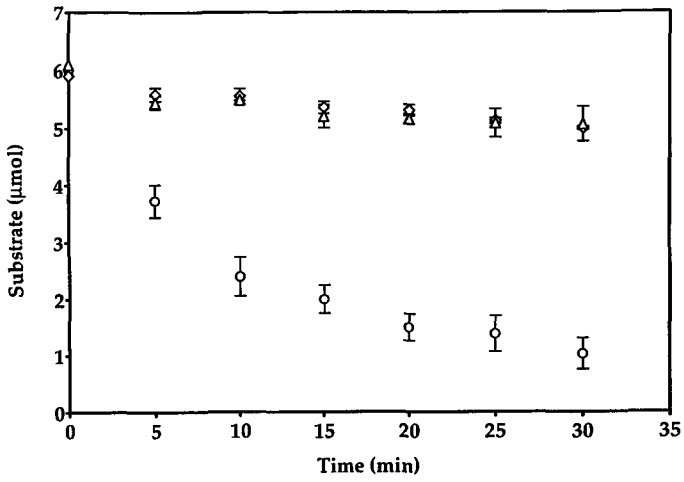

FIG. 4. Time course of the oxidation by lipoxygenase of a mixture of LA (○); TL (◇) and 1L-2S-PC (△), as determined by reversed-phase high-performance liquid chromatography. The chromatographic conditions are described in Table 2. Abbreviations as in Figure 1.

TABLE 3
Relative Rate of Oxidation of Linoleic Acid (LA), 1L-2S-PC, Trilinolein (TL) and 1,3-DL by Lipoxygenase[a]

Substrates	Relative rate (%)[b]
LA	100
1L-2S-PC	11 ± 1
TL	10 ± 3
LA	100
1,3-DL	36 ± 2

[a]Each determination consisted of seven samples containing 6 µmol linoleate for each substrate, 10 mM deoxycholate, and 0.2 mg lipoxygenase at pH 8 and 15°C. Samples were analyzed every 5 min from time 0 to 30. Abbreviations as in Table 1.
[b]The data are the means ± SD (n = 6).

In conclusion, the use of the HPLC with a polymer-based column allowed for the separation and quantitation of a mixture of free fatty acid, acylglycerols and phosphoglycerides without the need of modifiers in the mobile phase. Detection by both LSD and UV can be made. The utility of this HPLC method was demonstrated using chemically pure substrates. However, this method should be useful for analyzing the extent of oxidation in many fats and oils.

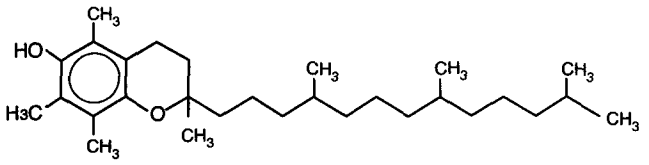
Effect of *d*-α-Tocopherol Analogues on Lipoxygenase-Dependent Peroxidation of Phospholipid–Bile Salt Micelles

Hirofumi Arai[a], Akihiko Nagao[b], Junji Terao[b,*], Tetsuya Suzuki[a] and Kozo Takama[a]

[a]Department of Food Science and Technology, Faculty of Fisheries, Hokkaido University, Hokkaido 041, Japan and [b]National Food Research Institute, Ministry of Agriculture, Forestry and Fisheries, Ibaraki 305, Japan

ABSTRACT: In order to know whether or not vitamin E acts as an effective antioxidant in lipoxygenase-dependent peroxidation of phospholipids, the effect of vitamin E and vitamin E analogues, 2,2,5,7,8-pentamethyl-6-hydroxychroman (PMC) and 6-hydroxy-2,5,7,8-tetramethylchroman-2-carboxylic acid (Trolox C), was investigated in enzymatic lipid peroxidation of bile salt micelles of pig liver phosphatidylcholine (PC) using soybean lipoxygenase. 15-Hydroperoxy-5,8,11,13-eicosatetraenoic acid was exclusively produced by the reaction with the PC molecular species containing arachidonic acid moiety, indicating that the hydroperoxidation of pig liver PC entirely progresses through the enzymatic reaction. PMC suppressed the accumulation of PC-hydroperoxides (PC–OOH) more efficiently than either *d*-α-tocopherol (α-Toc) or Trolox C, and 50% inhibition concentration by PMC was close to that of quercetin, a known lipoxygenase inhibitor from natural origin. The antioxidant activity of PMC was also superior to that of either α-Toc or Trolox C in ferrous ion-induced nonenzymatic oxidation of PC micelles in the presence of a trace amount of PC–OOH, although the radical-scavenging activities of these compounds in solution were similar or comparable to one another. In conclusion, PMC is more effective than α-Toc as an inhibitor of lipoxygenase reaction with phospholipids and of autoxidation in phospholipids. The phytyl chain of α-Toc seems to be unfavorable for exerting an inhibitory effect on lipoxygenase reaction with phospholipid–bile salt micelles.
Lipids 30, 135–140 (1995).

It has been suggested that lipid peroxidation is one of the significant pathophysiological factors in the oxidative stress leading to various diseases, including atherosclerosis (1,2). Although a large number of studies have been carried out using a variety of model systems, the mechanism of lipid peroxidation occurring *in vivo* is still not entirely clarified. In particular, the mechanism of its initial reaction remains equivocal in many cases. In recent years, mammalian lipoxygenase (EC 1.13.11.12) has received much attention as a possible initiator for propagating lipid peroxidation in the process of oxidative modification of low-density lipoprotein (3) and biomembranes (4,5).



Human tissues possess a well-organized defense system against oxidative stress (6), and *d*-α-tocopherol (α-Toc) is considered to act as a primary antioxidant in the suppression of the propagation reaction of nonenzymatic lipid peroxidation by trapping chain-propagating lipid peroxyl radicals (7). On the other hand, it has also been reported that α-Toc plays an important role in the modulation of lipoxygenase pathway in arachidonic acid metabolism (8,9). Thus, it is of much interest to know the antioxidant activity of α-Toc against lipoxygenase-dependent lipid peroxidation, when this enzymatic reaction is involved in the initiation of propagating lipid peroxidation *in vivo*.

We studied whether or not α-Toc acts as an effective inhibitor of the enzymatic peroxidation of unsaturated phospholipids using soybean lipoxygenase, because soybean lipoxygenase can oxidize phospholipids directly in the presence of bile salt (10,11). Also, phospholipids are recognized as a major target of oxidative damage induced by lipid peroxidation. The role of the phytyl side chain on the antioxidant activity of α-Toc has been frequently discussed in peroxidation of membranous phospholipids (12–15). Thus, the inhibitory effects of α-Toc and α-Toc analogues [**1**], 2,2,5,7,8-pentamethyl-6-hydroxychroman (PMC) [**2**] and 6-hydroxy-2,5,7,8-tetramethylchroman-2-carboxylic acid (Trolox C) [**3**] (Scheme 1), on this enzymatic reaction system were compared to those of nonenzymatic ferrous ion-induced phospholipid peroxidation in order to understand the role of the phytyl side chain in the inhibition. The results strongly suggest that an α-Toc analogue, PMC, is superior to α-Toc in the inhibition of lipoxygenase-dependent phospholipid peroxidation.

SCHEME 1

MATERIALS AND METHODS

Materials. Soybean lipoxygenase (Type I-B, 94,000 units/mg protein) and 1-stearoyl-2-arachidonyl phosphatidylcholine (SA–PC; 99%) were purchased from Sigma (St. Louis, MO). α-Toc and PMC were supplied by Eisai Pharmaceutical Co. (Tokyo, Japan). Trolox C was purchased from Aldrich (Milwaukee, WI). β-Carotene was purchased from Merck (Darmstadt, Germany). Butylated hydroxyanisole [2(3)-*tert*-butyl-4-methoxyphenol; BHA] and caffeic acid (3,4-dihydroxycinnamic acid) were purchased from Nacalai Tesque Inc. (Kyoto, Japan). Quercetin was obtained from Wako Pure Chem. (Osaka, Japan). Pig liver phosphatidylcholine (PC) was purchased from Funakoshi Co. (Tokyo, Japan) and purified by reversed-phase column chromatography (16). The fatty acid composition of pig liver PC was determined by gas chromatography after transmethylation as follows: 16:0, 27.6%, 18:0; 17.0%, 18:1; 27.5%, 18:2; 18.0%, 20:4; 7.7%. PC–hydroperoxides (PC–OOH) were prepared from egg yolk PC (Sigma; 99%) by photooxidation (17) and purified by reversed-phase column chromatography (16). All other chemicals and solvents were of analytical grade.

Preparation of PC micelles. Pig liver PC (1 μmol) in chloroform solution and an appropriate amount of antioxidant in a methanol solution were mixed in a round-bottom test tube and evaporated to a thin lipid film under nitrogen and finally *in vacuo*. The lipid film was rapidly dispersed in 900 μL HEPES buffer (20 mM, pH 7.4) containing 20 mM sodium deoxycholate by vigorous shaking on a vortex mixer for 1 min and sonicated with a BRANSON B-12 ultrasonifier (55 kHz) for 1 min.

Lipoxygenase reaction of PC micelles. Lipid peroxidation of PC micelles was induced by the addition of 2.8×10^4 units of soybean lipoxygenase in 100 μL HEPES buffer (20 mM, pH 7.4). The mixture was incubated with continuous shaking at 37°C in the dark. At regular intervals, PC–OOH in the mixture was determined by reversed-phase high-performance liquid chromatography (HPLC) with ultraviolet (UV) detection according to the method reported previously (18), in which the mixture of methanol/water (95:5, vol/vol) was used as an eluting solvent.

HPLC analysis of the products obtained from the lipoxygenase reaction with SA–PC. SA–PC micelles without antioxidants were prepared and oxidized by soybean lipoxygenase for 60 min in the same condition described above. The lipid fraction was extracted from the reaction mixture and was treated with phospholipase A_2 from bee venom by the method of Hughes *et al.* (19). Then the extracted products were analyzed by reversed-phase HPLC with UV detection according to the method reported previously (20). Authentic 15-hydroperoxy-5,8,11,13-eicosatetraenoic acid (15-HPETE) was prepared by enzymatic oxidation of arachidonic acid using soybean lipoxygenase (21). The isomeric mixture of HPETE was prepared from autoxidized arachidonic acid (20).

Nonenzymatic oxidation of PC micelles induced by ferrous ion–ascorbate system. PC micelles with or without antioxidants were prepared by the same method as described in the preparation for lipoxygenase reaction, except for the addition of PC–OOH before preparation of the micelles. The lipid peroxidation was induced by the addition of $FeSO_4$ dissolved in an aqueous solution of ascorbic acid. The assay mixture consisted of 1 mM PC, 0.01 mM PC–OOH, appropriate concentration of antioxidant, 0.1 mM $FeSO_4$, 1 mM ascorbic acid and 20 mM sodium deoxycholate in 20 mM HEPES buffer (pH 7.4). The mixture was incubated with continuous shaking at 37°C in the dark. At regular intervals, samples were subjected to thiobarbituric acid assay (22), and the amount of thiobarbituric acid reacting substances (TBARS) were expressed as μM malondialdehyde.

Measurement of peroxyl radical-scavenging activity in solution. Peroxyl radical-scavenging activities of α-Toc, PMC and Trolox C in solution were determined according to the method described previously (23). Briefly, 100 mM of methyl linoleate in a solution of *n*-hexane/2-propanol/ethanol (8:3:1, by vol) containing each antioxidant was subjected to radical chain oxidation by the addition of 10 mM of 2,2′-azobis-(2,4-dimethylvaleronitrile) (AMVN) at 37°C in the dark. The resulting methyl linoleate hydroperoxides (MeL–OOH) were quantified by normal-phase HPLC technique (24). The rate of oxidation during the induction period (R_{inh}) and the rate of oxidation after the induction period, that is, the rate of propagation (R_p), were obtained from the slope of the curve of MeL–OOH formation. The apparent induction period (t_{inh}) could be calculated from the intersecting point of the curve for R_{inh} and that for R_p. We applied the method by Burton and Ingold (25) for the calculation of kinetic parameters of each antioxidant.

RESULTS

Effect of α-Toc and its analogues on lipoxygenase reaction. The bile salt micelles of PC were rapidly oxidized by soybean lipoxygenase, although neither its multilamellar liposomes nor large unilamellar liposomes were oxidized after incubation for 2 h as previously reported by Eskola and Laakso (data

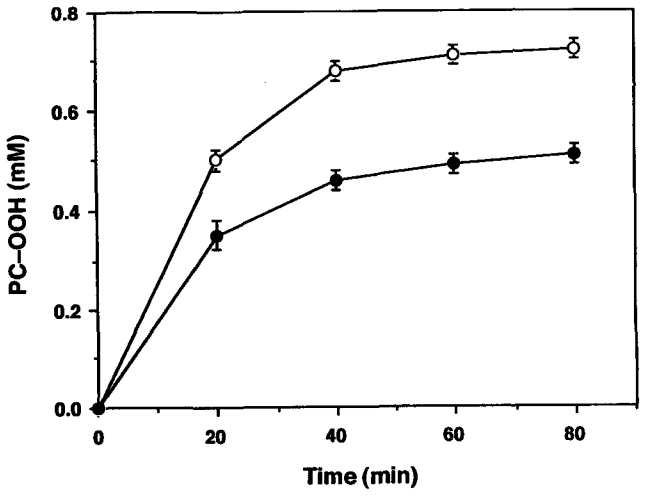

FIG. 1. Effect of α-Toc on lipoxygenase-dependent peroxidation of PC micelles. The concentration of PC–OOH was determined by reversed-phase HPLC with ultraviolet detection (Ref. 18). The reaction system consisted of pig liver PC (1 mM), soybean lipoxygenase (2.8×10^4 units) and 20 mM sodium deoxycholate in 20 mM HEPES buffer (1.0 mL, pH 7.4). No addition (○), 0.1 mM α-Toc (●). α-Toc, *d*-α-tocopherol; PC, phosphatidylcholine; PC–OOH, phosphatidylcholine–hydroperoxides; HPLC, high-performance liquid chromatography.

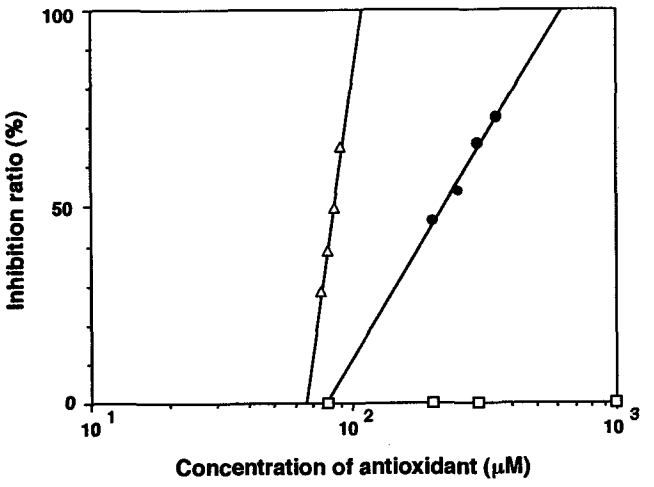

FIG. 2. The relationship between the inhibition by α-Toc (●), 2,2,5,7,8-pentamethyl-6-hydroxychroman (PMC) (△), and 6-hydroxy-2,5,7,8-tetramethylchroman-2-carboxylicacid (Trolox C) (□) on lipoxygenase reaction of PC micelles and their concentrations. The reaction system was the same as that described in the legend in Figure 1. Abbreviations as in Figure 1.

are not shown here) (10). Figure 1 shows the time course of the accumulation of PC–OOH by the reaction of PC micelles with soybean lipoxygenase in the presence and the absence of α-Toc. In the absence of α-Toc, PC–OOH accumulation progressed rapidly in the initial stage and terminated after 40 min incubation because of the exhaustion of substrate. Both the rate of PC–OOH accumulation and its maximum amount were suppressed in the presence of 0.1 mM α-Toc. Figure 2 shows the relationship between the concentration of α-Toc or α-Toc analogues and the inhibition ratio of PC–OOH accumulation after 60 min incubation. The 50% inhibition concentrations (IC_{50}) of α-Toc and PMC were 220 and 80 μM, respectively. Trolox C did not exert any inhibitory effect in the range from 80 μM to 1 mM. Inhibition ratio (%) of α-Toc, PMC and Trolox C were calculated from the following equation:

$$\text{inhibition ratio (\%)} = ([B] - [A])/[B] \times 100 \qquad [1]$$

where [*A*] and [*B*] are the concentration of PC–OOH after 60 min incubation in the presence of either α-Toc or α-Toc analogues (PMC and Trolox C) and that in the absence of them, respectively.

Effect of lipophilic antioxidants on lipoxygenase reaction. The inhibitory effect of some lipophilic antioxidants on the lipoxygenase reaction was also measured by the same procedure shown in the case of α-Toc and its analogues (Table 1). The IC_{50} of butylated hydroxyanisole (BHA) and quercetin were comparable to that of PMC. The inhibition by caffeic acid was weaker than that of α-Toc, whereas β-carotene showed no inhibitory effect even at the concentration of 1 mM.

Product specificity of lipoxygenase reaction. We investigated the product specificity of the reaction of PC micelles with lipoxygenase by using SA–PC to confirm that the reaction proceeds through enzymatic mechanism. It is known that autoxidation of SA–PC produces several isomers of HPETE at the arachidonic acid moiety (26). Figure 3 shows HPLC chromatograms of authentic 15-HPETE (A), phospholipase A_2-mediated hydrolyzed products from SA–PC after incubation with soybean lipoxygenase (B) and the isomeric mixture of HPETE from autoxidized arachidonic acid (C). The chromatogram of HPETE of SA–PC with lipoxygenase reaction was coincident with that of 15-HPETE. Thus, it was found that oxygen molecule exclusively attacked the 15-position of arachidonic acid moiety in the reaction of SA–PC with soybean lipoxygenase at neutral pH, similarly to the reaction at pH 9.0 reported by Brash *et al.* (11). Consequently, it seems that hydroperoxidation of pig liver PC in this reaction system also progresses through the enzymatic reaction.

Inhibition by α-Toc and its analogues on ferrous ion-dependent peroxidation in micelles. We investigated the effect

TABLE 1
The 50% Inhibition Concentrations (IC_{50}) of Antioxidants on Lipoxygenase Reaction of Phosphatidylcholine Micelles

Antioxidants	IC_{50} (μM)[a]
d-α-Tocopherol	220
PMC	80
Trolox C	no effect
β-Carotene	no effect
BHA	70
Quercetin	90
Caffeic acid	610

[a]IC_{50} of each antioxidant was determined by the procedure shown in Figure 3. BHA, butylated hydroxyanisole; PMC, 2,2,5,7,8-pentamethyl-6-hydroxychroman; Trolox C, 6-hydroxy-2,5,7,8-tetramethylchroman-2-carboxylic acid.

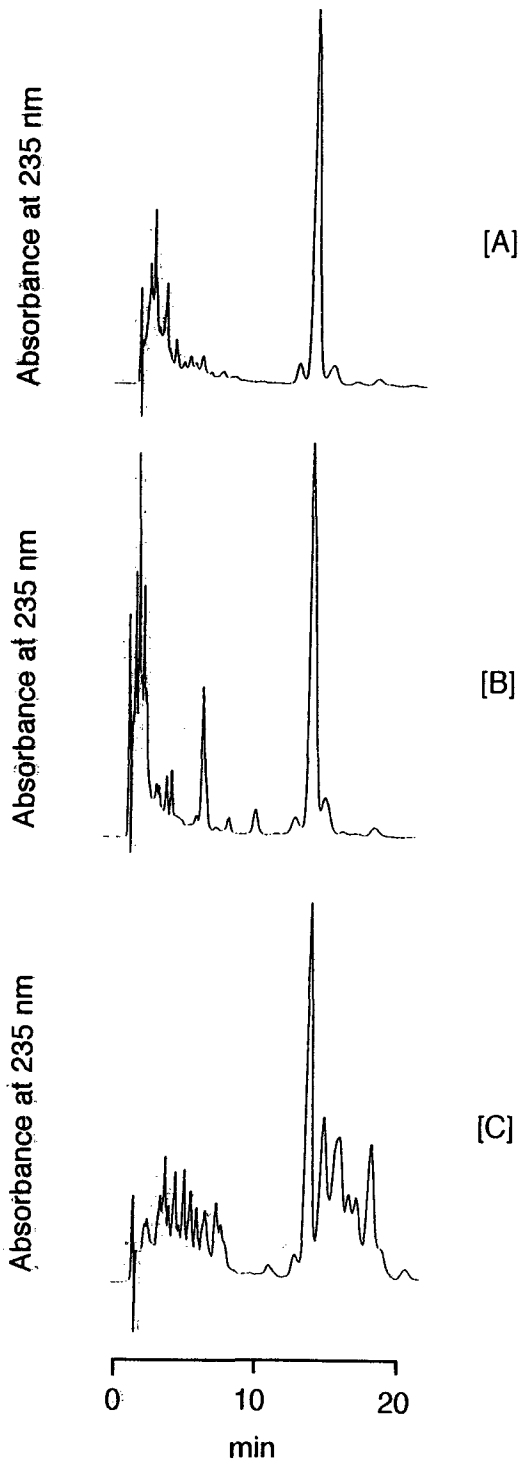

FIG. 3. HPLC chromatograms of the 15-hydroperoxy-5,8,11,13-eicosatetraenoic acid (HPETE) (A), phospholipase A_2-mediated hydrolyzed products from 1-stearoyl-2-arachidonylphosphatidylcholine after incubation with soybean lipoxygenase (B) and the isomeric mixture of HPETE from autoxidized arachidonic acid (C). Abbreviation as in Figure 1.

of α-Toc and its analogues on the ferrous ion-dependent peroxidation of PC micelles to determine the effect of these antioxidants on nonenzymatic lipid peroxidation in the phospholipid micelles. Figure 4 shows the relationship between the inhibition ratio of TBARS accumulation and various concentrations of α-Toc or its analogues. IC_{50} of α-Toc, PMC and Trolox C were 0.9, 0.3 and 7.4 μM, respectively. Inhibition ratio of α-Toc, PMC and Trolox C were calculated from the following equation:

$$\text{inhibition ratio (\%)} = ([B] - [A])/[B] \times 100 \quad [2]$$

where [*A*] and [*B*] are TBARS value after 36 h incubation in the presence of either α-Toc or α-Toc analogues (PMC and Trolox C) and that in the absence of them, respectively. Thus, the activity of these antioxidants during ferrous ion-dependent peroxidation of PC micelles was decreased in the order of PMC > α-Toc > Trolox C.

Peroxyl radical-scavenging activity of α-Toc and its analogues in solution. The peroxyl radical-scavenging activities of α-Toc and its analogues in solution were measured at their different concentrations. The ratio of the rate constant for the inhibition of oxidation during the induction period (k_{inh}) to the rate constant for chain propagation (k_p) can be determined by the following equation (27):

$$k_{inh}/k_p = [LH]/R_{inh} \cdot t_{inh} \quad [3]$$

in which [*LH*] signifies the concentration of methyl linoleate. Figure 5 shows a plot of k_{inh}/k_p vs. concentrations of antioxidants ranging from 41.7 to 166.7 μM. The value of k_{inh}/k_p for each antioxidant decreased with the increase of concentration. However, the values of k_{inh}/k_p for α-Toc and PMC were not significantly different from each other (1500–2500) at each concentration. On the other hand, the values of k_{inh}/k_p for Trolox C were slightly lower (1000–2000) than those of α-Toc and PMC. Stoichiometric numbers of radicals (*n*) trapped by PMC and Trolox C, a function of t_{inh}, were also obtained, indicating that α-Toc traps two chain-propagating lipid peroxyl radicals. The *n* values of PMC and Trolox C were calculated at different concentrations to be 1.8–2.1 and 1.9–2.3, respectively.

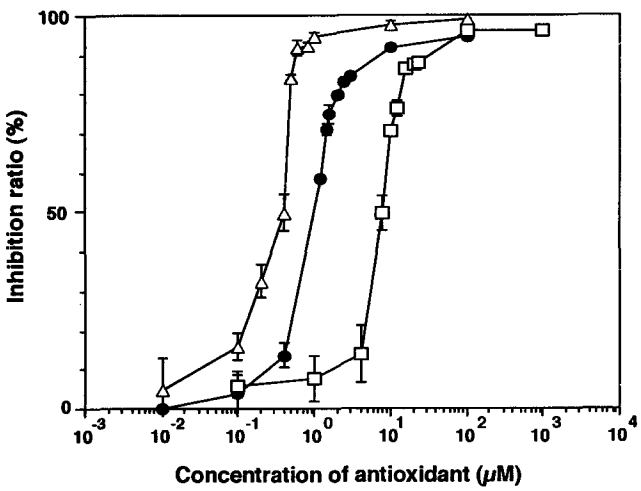

FIG. 4. The relationship between the inhibition by α-Toc (●), PMC (△) and Trolox C (□) on ferrous ion ascorbate-dependent peroxidation of PC micelles and their concentrations. Abbreviations as in Figures 1 and 2.

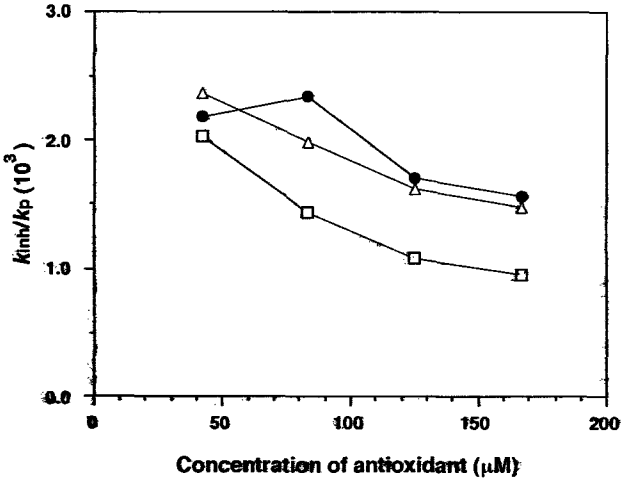

FIG. 5. The concentration-dependent rate constant for the inhibition of oxidation during the induction period and rate constant for chain propagation (k_{inh}/k_p) values of α-Toc and α-Toc analogues (PMC and Trolox C) on 2,2'-azobis-(2,4-dimethylvaleronitrile)-initiated oxidation of methyl linoleate in solution. α-Toc (●), PMC (△), Trolox C (□). Abbreviations as in Figures 1 and 2.

DISCUSSION

It has been suggested that lipoxygenase from plant and animal sources can oxidize directly fatty acids esterified in phospholipids (3–5,10,11,28–30). We selected a reaction system consisting of soybean lipoxygenase and pig liver PC in bile salt micelles to investigate the inhibitory effect of α-Toc and its analogues on the reaction of lipoxygenase with phospholipids. This simplified system will assist in studying the effect of α-Toc on lipoxygenase reaction in phospholipid bilayers.

Although the Sigma enzyme preparation was possibly a mixture of isozymes, L-1 probably predominates because it is the most stable of the isozymes. Because the 15-position of arachidonic acid moiety was exclusively oxidized from SA–PC, this demonstrates that isozyme L-1 is likely to be responsible for the hydroperoxidation because of its known specificity (21). It has been reported that α-Toc serves as an effective inhibitor of the oxidation of free fatty acids by purified lipoxygenase from plant or animal sources (31–33). However, this study is the first to report that vitamin E inhibits lipoxygenase-dependent hydroperoxidation of phospholipids as far as we know. In addition, the effectiveness of α-Toc as lipoxygenase inhibitor for phospholipids has not been compared to that of PMC or Trolox C, although Panganamala *et al.* (34) have shown that α-Toc inhibits the lipoxygenase reaction more efficiently than Trolox C in the oxidation of free fatty acids in ethanol/water solution.

Our results clearly show that PMC, an α-Toc analogue possessing a methyl group instead of phytyl side chain, exerts an inhibitory effect more efficiently than α-Toc. The efficacy of the inhibition by PMC (IC_{50}) was nearly the same as that of a synthetic antioxidant, BHA, and a known lipoxygenase inhibitor from natural origin, quercetin (35,36). Trolox C, another α-Toc analogue possessing a carboxyl group instead of phytyl side chain, exerted no inhibitory effect even at the same concentration as that of substrate PC. Interestingly, β-carotene did not act as lipoxygenase inhibitor in this reaction system although Lomniski *et al.* (37) pointed out that β-carotene inhibits lipoxygenase activity in the oxidation of free fatty acids.

In general, the inhibition of lipoxygenase reaction seems to be derived from inactivation of the active site of the enzyme or scavenging of free radicals at the active site. Niki *et al.* (13) concluded that the phytyl side chain does not affect the peroxyl radical-scavenging activity by showing that the rate constant for the inhibition (k_{inh}) by PMC was the same as that by α-Toc in the radical chain reaction of unsaturated lipids in solution. We revealed that the k_{inh}/k_p was nearly the same for α-Toc and PMC at different concentrations. The ratios obtained from Trolox C were also comparable to those obtained from α-Toc and PMC. Stoichiometric numbers of radicals (n) trapped by PMC and Trolox C were also similar to that trapped by α-Toc at different concentrations. Therefore, it is unlikely that their inherent radical-scavenging activities are the determinant for the effectiveness of inhibition on the lipoxygenase reaction of PC micelles. Thus, the localization of each compound in heterogeneous environment of the reaction system definitely affects the inhibitory effect. It seems that the localization of α-Toc, PMC and Trolox C in micelles is different from one another depending on the structure at their 2-positions. Fukuzawa *et al.* (12) and Niki *et al.* (13) have suggested that PMC has a higher motility than α-Toc in PC liposomes. It is also likely that PMC can move more freely than α-Toc in the PC micelles resulting in the superiority of PMC in inhibiting the lipoxygenase reaction. On the other hand, our results demonstrated that Trolox C has no effect on the lipoxygenase reaction. Barclay and Vinqvist (38) indicated that Trolox C is negatively charged at neutral pH because the pKa of its carboxyl group was 3.89. Therefore, negatively charged Trolox C would not enter the negatively charged bile salt micelles because of the electrostatic repulsion, and little effect of Trolox C was observed on the lipoxygenase reaction.

Once lipid hydroperoxides are formed by an enzymatic reaction, nonenzymatic chain oxidation may also occur through the generation of alkoxyl and peroxyl radicals from preformed hydroperoxides by the reaction with contaminant metal ions. It was observed that the antioxidant activity of PMC on the oxidation of PC micelles induced by ferrous ion in the presence of trace amount of PC–OOH was also superior to that of α-Toc or Trolox C. It is therefore apparent that PMC is more effective than α-Toc or Trolox C in the prevention of lipoxygenase-induced phospholipid peroxidation. Lipoxygenase-induced phospholipid peroxidation has attracted much attention in relation to the formation of oxidized low-density lipoprotein in the process of atherosclerosis (2,3) and the destruction of reticulocyte membrane structures in their maturing process (39,40). This study implies that PMC is a potent antioxidant of enzymatic peroxidation of phospholipids, although the micellar system in this experiment does not reflect directly the event of lipid peroxidation occurring *in vivo*.

Protective Effect of Estrogens and Catecholestrogens Against Peroxidative Membrane Damage *in vitro*

Mercedes Lacort*, Ana M. Leal, Mariana Liza, César Martín, Rosa Martínez and M. Begoña Ruiz-Larrea

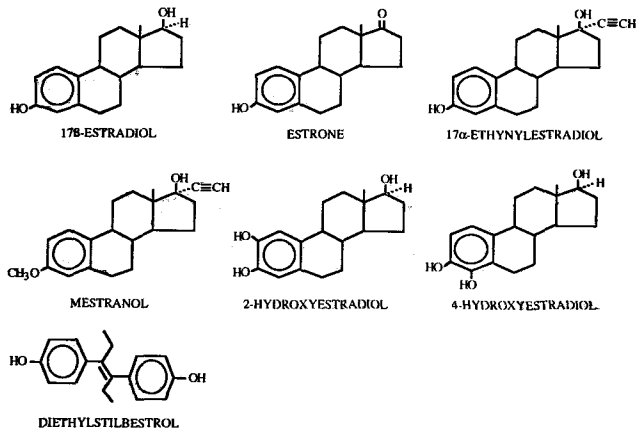
Departamento de Fisiología, Facultad de Medicina, Universidad del Pais Vasco, Bilbao, Spain

ABSTRACT: The antioxidant effects of natural estrogens (estrone, E_1; 17β-estradiol), synthetic estrogens (17α-ethynylestradiol, EE_2; mestranol, MES; diethylstilbestrol, DES) and catecholestrogens (2-hydroxyestradiol; 4-hydroxyestradiol, 4-OHE_2) on lipid peroxidation induced by different means in rat liver microsomes were investigated. The extent of lipid peroxidation was determined by measuring thiobarbituric acid reactive substances. Prooxidants included Fe^{3+}/ADP/reduced NADPH, Fe^{2+}/ascorbate, *tert*-butyl hydroperoxide (*t*-BOOH) and 2,2′-azo*bis*(2-amidinopropane) (AAPH). Estrogens and catecholestrogens decreased lipid peroxidation in all four systems tested. In the iron/ascorbate model it was shown that (i) 4-OHE_2 and DES had analogous patterns of inhibition, irrespective of the presence of NADPH or the functional integrity of the microsomes, and (ii) the antioxidant activities of E_1, EE_2 and MES were dependent on the assay conditions with the activity being markedly higher when estrogen metabolism was favored. When peroxidation was initiated by the peroxyl radical generator AAPH, the inhibitory effects observed were least pronounced. Our data also showed that, in each of the systems, all inhibitors displayed the same order of inhibitory potency with DES and catecholestrogens being the most potent antioxidants under all experimental conditions used. The present results confirm earlier findings and point toward a link between estrogen metabolism and estrogen antioxidant activity. The data also indicate that estrogens and catecholestrogens interact with the peroxidative process at different levels with their interactions with iron or the metal-derived species being the most important modes of inhibition.
Lipids 30, 141–146 (1995).

Natural and synthetic estrogens have been reported to produce prooxidant and cytotoxic effects, which have been attributed to reactive intermediates generated during their microsomal metabolism (1–4). Estrogens are hydroxylated by a reduced NADPH cytochrome P-450 monooxygenase and mainly converted into catecholestrogens. Catecholestrogens and diethylstilbestrol (DES) are precursors of quinones that undergo reversible oxidation-reduction reactions (5), yielding semiquinones and reactive oxygen species (O_2^-, H_2O_2). These compounds in the presence of transition metals are a source of hydroxyl radicals, which are stimulators of lipid peroxidation. Various *in vivo* studies have demonstrated increased peroxidation in chicken erythrocytes (6) and hamster kidney (7) after estrogen treatments. Yet, other studies have shown antioxidant actions of estrogens against peroxidation induced by either ultraviolet irradiation and various prooxidant systems (8–11). We earlier found that the addition of 17β-estradiol (E_2) to fresh hepatocyte incubations protected the cells against spontaneous peroxidation (12). More recently, we have shown that E_2 and 2-hydroxyestradiol (2-OHE_2) inhibit iron-stimulated peroxidation in microsomal lipids (13). We found that E_2 was only a moderately efficient inhibitor, while inhibition increased markedly when the estrogen was incubated with microsomes (13).

The present experiments were aimed at further investigating the antioxidant action of various natural and synthetic estrogens, and catecholestrogens, on peroxidative damage to rat liver microsomes. The involvement of their metabolic transformations on these effects was also investigated. Peroxidation was induced by different types of prooxidants in order to gain a more precise view of the mechanism of inhibition. Malondialdehyde (MDA) formation was measured to monitor the extent of lipid peroxidation. The antioxidant potency of each compound with all the initiator systems was also determined by calculating the half inhibitory concentration (IC_{50}) values from the respective concentration-dependent curves (Scheme 1).

MATERIALS AND METHODS



Chemicals. DES, E_2, estrone (E_1), 17α-ethynylestradiol (EE_2), 2-OHE_2, 4-hydroxyestradiol (4-OHE_2), mestranol (MES) and *tert*-butyl hydroperoxide (*t*-BOOH) (70% aqueous solution) were from Sigma (St. Louis, MO), and 2,2′-azo*bis*(2-amidinopropane) (AAPH) was from Polysciences Inc. (Warrington, PA). All other chemicals were of the highest grade available.

Preparation of microsomal fractions. Liver microsomes were isolated from male Sprague-Dawley rats weighing about

SCHEME 1

180 g. Rats were allowed food and water *ad libitum*. The animals were anesthetized, and the livers were perfused with saline and homogenized in 250 mM sucrose. Microsomes were prepared as previously described (14), washed once in 150 mM Tris/HCl buffer, pH 8, and suspended in 150 mM Tris/HCl buffer, pH 7.4. Denaturation of microsomes was accomplished by heat treatment (30 min at 80°C). Microsomal protein concentrations were determined by the method of Bradford (15) using bovine albumin as standard.

Incubation of microsomes. Microsomes (0.3–0.6 mg of protein) were resuspended in Tris/HCl buffer, pH 7.4, and preincubated for 10 min with the agents (10 μM) dissolved in 1% dimethylsulfoxide (DMSO) in a final volume of 1 mL. Control experiments were done using the same amount of the organic solvent. Incubations were carried out at 37°C in a shaker bath under air. At zero time, lipid peroxidation was initiated using one of the following systems: (i) Fe/ADP/NADPH: 2 μM $FeCl_3$ and 200 μM ADP (previously complexed) and 200 μM NADPH as cofactor; (ii) Fe/ascorbate: 25 μM $FeSO_4$, 100 μM ascorbate and 10 mM KH_2PO_4; in some experiments 200 μM NADPH was also added together with the estrogens; (iii) *t*-BOOH (1.5 mM) and (iv) the water-soluble azo derivative AAPH (25 mM). All additions are expressed as final concentrations. Incubations were stopped at selected time points by adding 5% trichloroacetic acid (TCA) and then centrifuged to pellet the protein.

Lipid peroxidation assay. Lipid peroxidation was measured by monitoring thiobarbituric acid reactive substances (TBARS) formation according to Fee and Teitelbaum (16). A 350-μL portion of the supernatant was added to 700 μL of a thiobarbituric acid (TBA) solution in 5% TCA, and the mixture was heated at 100°C for 15 min. After cooling, the absorbance of the sample was measured at 535 nm. Microsomal lipid peroxidation was expressed as nanomoles of MDA per milligram of protein. MDA values were calculated using a molar extinction coefficient of 156 $mM^{-1}cm^{-1}$ at 535 nm. IC_{50} values were obtained from the concentration-response curves and converted to micromolar concentrations by using a GraphPAD programme (Institut for Scientific Information, San Diego, CA).

RESULTS

We have investigated the effects of various natural and synthetic estrogens and catecholestrogens on microsomal lipid peroxidation. TBARS formation was determined in both iron-dependent and iron-independent systems. In each case, optimal reaction conditions had previously been established. DMSO itself had no effect on the peroxidative processes. None of the steroids interfered with the measurement of the TBA assay.

Figure 1 shows the time-course of TBARS formation in the Fe/ADP/NADPH system in microsomes incubated with or without the estrogens. 4-OHE_2, EE_2 and DES proved to be strong antioxidants at supraphysiologic concentrations. E_1, with a keto group at C-17, had a lower antioxidant activity. Substitution of the C-3 hydroxyl group of EE_2 by a methoxyl group (changing EE_2 to MES) greatly reduced its ability to inhibit TBARS formation. Other steroids tested (testosterone, progesterone and cholesterol) had no effects on lipid peroxidation (data not shown).

When microsomes were incubated with Fe/ascorbate, DES and 4-OHE_2 markedly suppressed MDA formation (Fig. 2a). EE_2 provoked an intermediate inhibition, whereas little or no inhibitory effects were observed in the presence of E_1 and MES, respectively. When NADPH was included during the

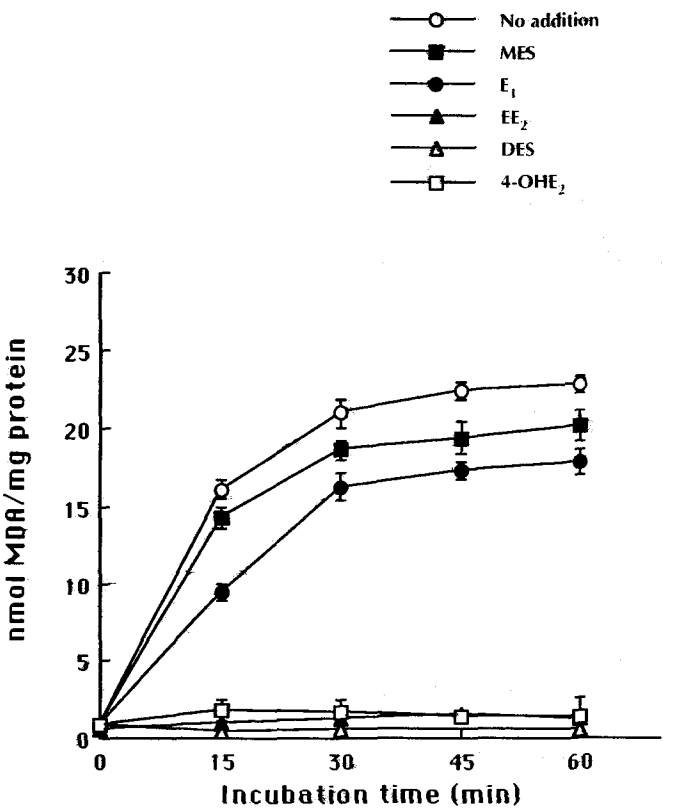

FIG. 1. Antioxidant effects of estrogens (10 μM) on microsomal lipid peroxidation induced by Fe^{3+}/ADP/NADPH. Values are the means ± SE (n = 3). MDA, malondialdehyde; MES, mestranol; E_1, estrone; EE_2, 17α-ethynylestradiol; DES, diethylstilbestrol; 4-OHE_2, 4-hydroxyestradiol.

preincubation period, thus favoring the metabolic transformation of the estrogens, all the molecules completely inhibited lipid peroxidation (Fig. 2b). Additional experiments were carried out with heat-denatured microsomes (Fig. 3); under these conditions, the patterns of inhibition of estrogens and 4-OHE_2 were similar to those obtained with functional microsomes without NADPH (Fig. 2a).

We also evaluated the kinetics of MDA formation stimulated by 1.5 mM *t*-BOOH. In comparison to iron-containing systems, the capacity of the organic hydroperoxide to promote lipid peroxidation was markedly (about 5-fold) lower (Fig. 4). Catecholestrogens and DES were the most efficient compounds, whereas MES was the least active inhibitor.

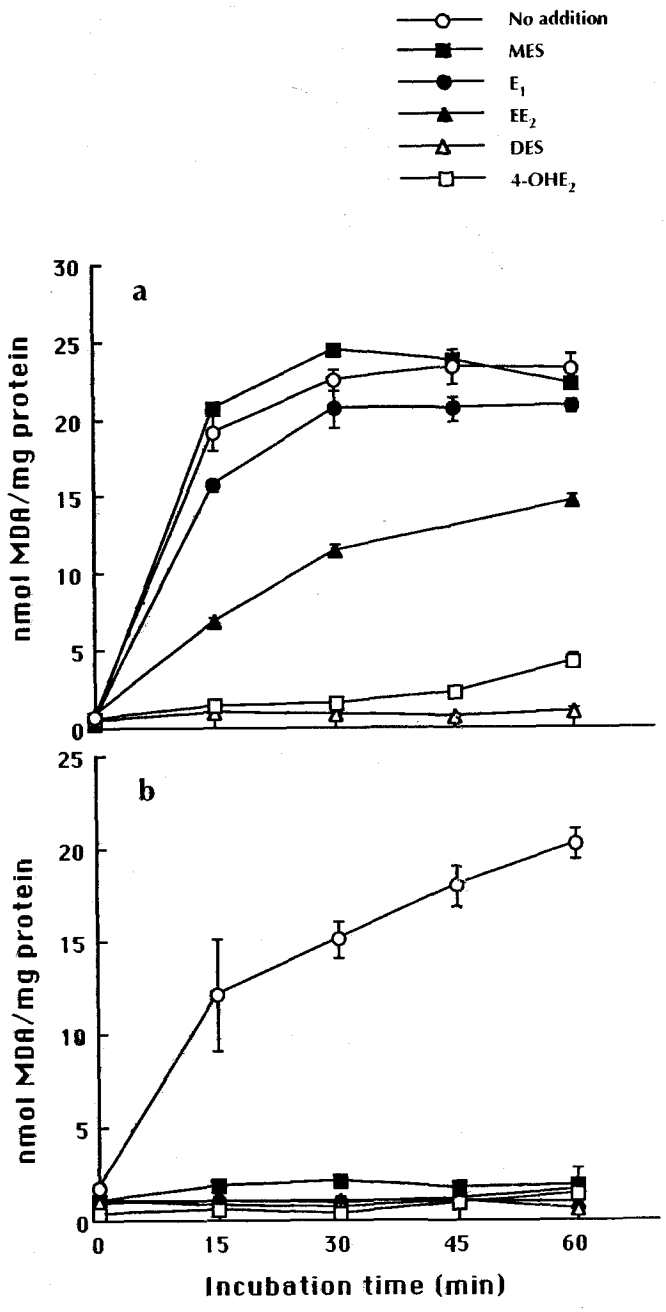

FIG. 2. Effects of estrogens on Fe^{2+}/ascorbate induced lipid peroxidation in microsomes incubated in the absence (a) or presence (b) of NADPH. Values are the means ± SE (n = 3). See Figure 1 for other abbreviations.

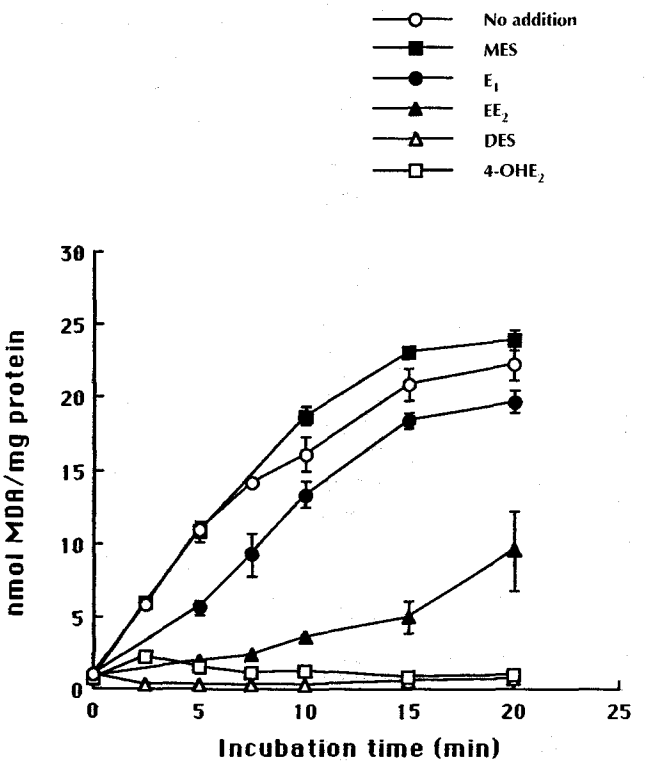

FIG. 3. Effects of estrogens on Fe^{2+}/ascorbate induced lipid peroxidation in denatured microsomes. Values are the means ± SE (n = 3). See Figure 1 for abbreviations.

Lipid peroxidation induced by the water-soluble azo compound AAPH (25 mM) was also investigated. In this model, some lipoperoxidation similar to that found with *t*-BOOH was observed in controls. The 2-OHE_2 exerted complete protection, and the other agents showed different degrees of inhibition, steroidal estrogens being the least efficient, while DES and 4-OHE_2 gave intermediate protection (Fig. 5).

In studies with denatured microsomes, only DES and catecholestrogens decreased the rates of lipid peroxidation initiated by both *t*-BOOH and AAPH, although the values of TBARS production in control incubates (without additions) were extremely low (data not shown).

We have quantified the antioxidant potential of estrogens and catecholestrogens by determining the concentration of these compounds which inhibited control MDA production by 50% (IC_{50}). Figure 6 shows curves that are typical for the agents assayed in the Fe/ADP/NADPH system. Half maximal inhibition values were calculated from these curves (or similar ones), and the results obtained are summarized in Table 1. As can be seen, the efficiencies of the compounds tested against microsomal lipid peroxidation were dependent on the initiator system, generally in the following order: Fe/ADP/NADPH > Fe/ascorbate = *t*-BOOH > AAPH. All the molecules displayed a similar order of inhibitory potency in

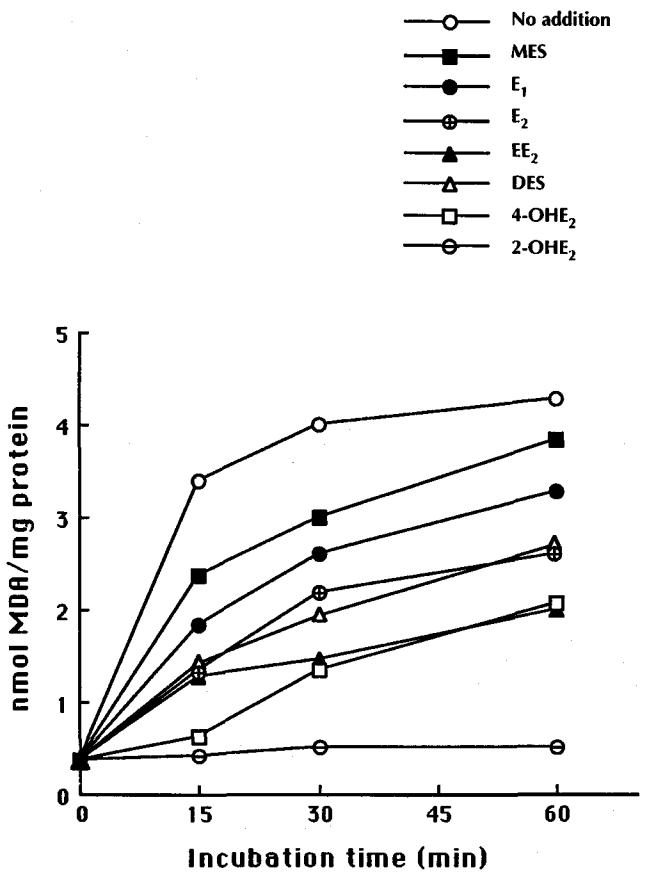

FIG. 4. Effects of estrogens and catecholestrogens on *tert*-butyl hydroperoxide induced lipid peroxidation. Values are the means from three sets of experiments with mean errors less than 5%. 2-OHE_2, 2 hydroxyestradiol; E_2, 17β-estradiol. See Figure 1 for other abbreviations.

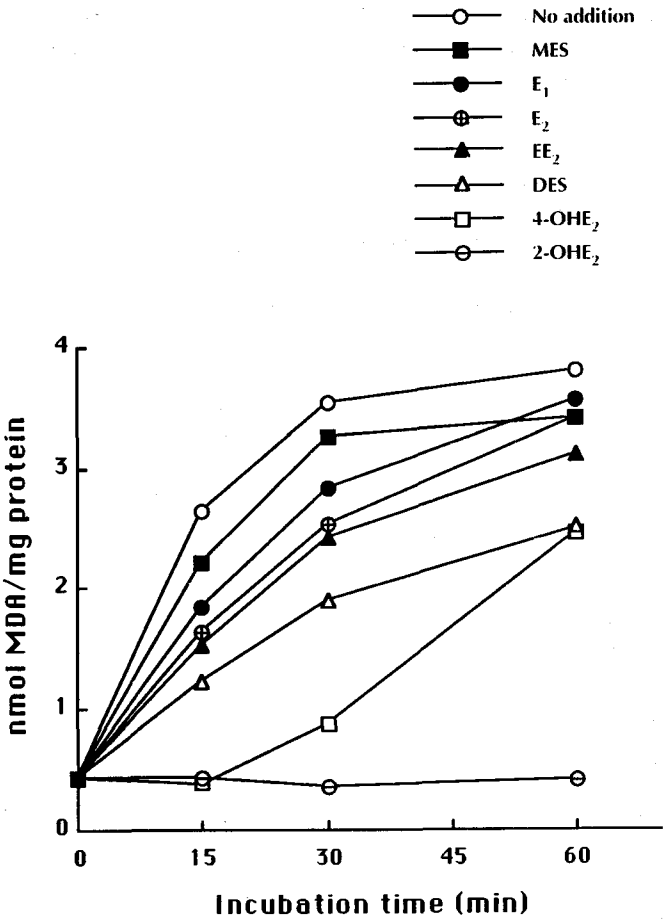

FIG. 5. Time-course of thiobarbituric acid reactive substances formation during 2,2′-azo*bis*(2-amidinopropane) (25 mM) induced lipid peroxidation in microsomes incubated with estrogens and catecholestrogens. Values are means of two experiments with mean errors less than 5%. See Figures 1 and 4 for abbreivations.

each of the systems. The catecholestrogens, with IC_{50} between 0.11–5.80 μM, were the most effective inhibitors in our systems. E_1 was found to be the least active; 50% inhibition in the AAPH model could not be achieved (Table 1).

In the Fe/ascorbate system, the efficiencies of steroidal estrogens were similar to those found with *t*-BOOH (Table 1). However, when NADPH was included in the incubates, the IC_{50} values for E_1, E_2, and EE_2 decreased to 3.6 ± 0.6 (n = 6), 2.3 ± 0.5 (n = 5) and 2.5 ± 0.5 (n = 3), respectively.

DISCUSSION

The present results provide evidence that supraphysiologic concentrations of estrogens and catecholestrogens are effective inhibitors of *in vitro* microsomal lipid peroxidation under a variety of conditions. The degrees of inhibition shown by estrogens and catecholestrogens were variable and dependent on the peroxidative model. In all cases, 2-OHE_2 was the most potent inhibitor with an IC_{50} in the range of 0.11–1.21 μM.

Several conclusions can be drawn from results obtained on the Fe/ascorbate model. 4-OHE_2 and DES showed analogous antioxidant profiles; they strongly inhibited lipid peroxidation irrespective of the functional integrity of microsomes or the presence of NADPH in the incubations. The steroidal estrogens, however, behaved differently, dependent on the assay conditions. They required preincubation with NADPH and the full activity of microsomal transforming enzymes to exert substantial inhibition. This peculiarity was likewise seen in our preliminary study dealing with E_2 effects (13), while it was not seen in other studies on estrogen antioxidant actions. The enhanced effects seen with metabolically active microsomes (Fig. 2b) are surely due to the introduction of OH groups to the steroidal structures during their transformation into catechols. Phenolic compounds have antioxidant properties because of their capacity to bind with iron (17–19) and/or to reduce peroxyl or alkoxyl radicals by donating a hydrogen atom from their OH group (20,21). Compared to the phenoxyl radical, the catechol-derived radical is resonance-stabilized and, thus, shows a higher scavenging activity. The phenolic structure of E_1 could account for the slight protective action of the estrogen seen in incubates without NADPH or when denatured microsomes were used. In this regard, the lack of an effect by MES, whose 3-OH group is blocked by methylation, is of interest. The fact that EE_2 was a better antioxidant than E_2 (Table 1) can be related to the ethynyl group at C-17 in EE_2.

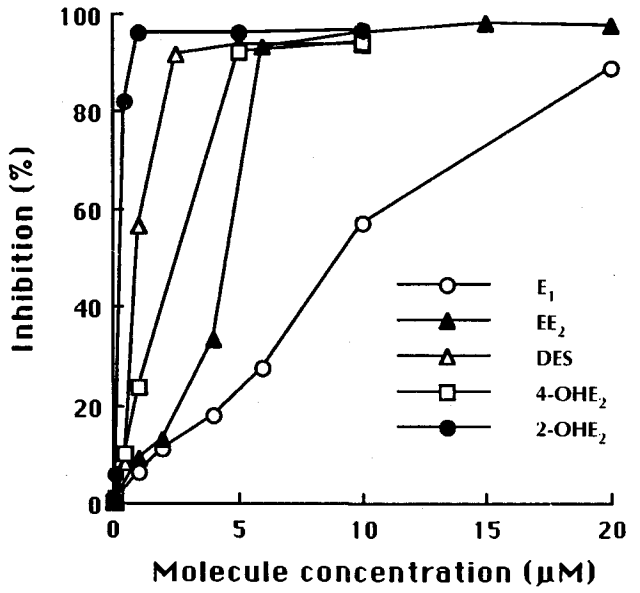

FIG. 6. Concentration-dependent inhibition of Fe^{3+}/ADP/NADPH-induced lipid peroxidation by estrogens and catecholestrogens. Microsomes were incubated for 30 min under the conditions described in the text. Results are the means of triplicate determinations. See Figures 1 and 4 for abbreviations.

Addition of Fe^{3+}/ADP/NADPH increases microsomal lipid peroxidation through the reduction of Fe^{3+} to Fe^{2+} catalyzed by NADPH cytochrome P-450 reductases. Under these conditions, estrogens may inhibit peroxidation by diverting reducing equivalents away from the iron-reduction process toward their own metabolism. The strong antioxidant action of 4-OHE_2 and DES at the concentrations used in this study makes it difficult to know whether enzymic competition is involved in the effects of these agents.

In iron-containing models, hydroxyl and perferryl radicals (22,23) and ferric/ferrous complexes (24) have been proposed as initiator species. All of them are very strong oxidants and can readily react with membrane lipids. When *t*-BOOH or AAPH were used as prooxidants, the amounts of MDA produced were much lower than those from iron-induced peroxidation. Both *t*-BOOH and AAPH generate peroxyl radicals, which are not potent oxidants (25). AAPH forms carbon-centered radicals, that rapidly react with O_2, yielding peroxyl radicals *via* an iron-independent mechanism (26,27). *t*-BOOH decomposes by heterolytic or homolytic scission, also generating peroxyl radicals, and thus accelerates propagation reactions. However, scission reactions of the hydroperoxide also produce reduced or perferryl forms of cytochrome P-450 (28) and, in this way, induce some iron-dependent peroxidation. Using *t*-BOOH as prooxidant, the antioxidant effects of the estrogens were similar to those found with Fe^{2+}/ascorbate. The inhibitory effects of these agents decreased considerably when AAPH was used as initiator. In fact, the estrogens produced the lowest inhibition in this case (Table 1).

In summary, our results corroborate preliminary reports in which a relationship between the metabolism of estrogens to catechols and their antioxidant properties was postulated. Data also show that the estrogen-protective effects on membranes depend on the chemical structure of the agent, the prooxidant used, and the availability of iron. The effects of estrogens and catecholestrogens are greater when peroxidation is initiated by complexes containing iron and less so when peroxidation involves peroxyl radicals. These results imply that there is a complex mechanism of action in the protective effects of these molecules. Estrogens and catecholestrogens seem to interact with the peroxidative process at different stages, not only by stopping free radical chain reactions at the propagation step, but also, and even more efficiently, by interacting with iron and/or the initiation species derived from the transition metal.

TABLE 1
Half Inhibitory Concentrations (IC_{50}, μM) of Estrogens and Catecholestrogens on Lipid Peroxidation Induced by Different Initiators[a]

Compound	IC_{50} (μM)			
	Fe^{2+}/asc	Fe^{3+}/ADP/NADPH	*t*-BOOH	AAPH
E_1	54.6 ± 2.9	10.8 ± 0.8	49.5 ± 2.9	NR[b]
E_2	19.3 ± 2.9	4.3 ± 0.2	18.7 ± 3.8	32.2 ± 5.7

Effect of Exercise on the Plasma Nonesterified Fatty Acid Composition of Dogs and Goats: Species with Different Aerobic Capacities and Diets

Grant McClelland[a,1], Georges Zwingelstein[b], C. Richard Taylor[c] and Jean-Michel Weber[a,*]

[a]Biology Department, University of Ottawa, Ottawa, Ontario, K1N 6N5 Canada, [b]Institut Michel Pacha, Université de Lyon, 83500 La Seyne sur Mer, France and [c]Concord Field Station, Museum of Comparative Zoology, Harvard University, Cambridge, Massachusetts 02138

ABSTRACT: The goals of this study were to determine: (i) whether mammals mobilize particular nonesterified fatty acids (NEFA) preferentially during locomotion, (ii) if differences in aerobic capacity or diet can affect the pattern of NEFA mobilization and (iii) which individual NEFA are most representative of total NEFA concentration changes, to use them as tracers for turnover studies. Individual NEFA were measured in trained dogs and goats (VO_2max dog/VO_2max goat = 2.2; where VO_2max = maximal oxygen consumption) during treadmill exercise at 40 and 60% VO_2max. Important interspecies differences in individual NEFA concentrations could be attributed to differences in aerobic capacity. The more aerobic species (dog) had much higher plasma NEFA concentrations for all but one NEFA (18:0), when compared with the low-aerobic species (goat). In addition, exercise caused a large increase in concentration of individual NEFA in the dogs, with the largest increases seen in 18:1 (150% above resting values) and 16:0 (60% increase), but it had no effect in goats. Therefore, the aerobic species has a much higher ability for mobilizing and transporting NEFA in plasma than its low-aerobic counterpart. Two NEFA accounted for more than half total plasma NEFA in both species, 18:1 (about 35% total NEFA) and 16:0 (20%). Calculation of variability in percent composition reveals that oleate and palmitate also closely reflect changes in total NEFA and are therefore the most appropriate tracers for *in vivo* kinetic studies in exercising mammals. Differences in diet and digestion physiology explained some differences in the plasma NEFA composition of the two species; this was reflected in the percent contributions of individual fatty acids to total NEFA: in dogs 18:1 > 16:0 > 18:2 > 18:0, while in goats 18:1 > 16:0 > 18:0 > 18:2. Also, only goats had 18:3 (6% total NEFA), a fatty acid of plant origin, while only dogs had 16:1 (7% total NEFA). Overall, however, the plasma NEFA composition of goats did not exactly reflect that of their diet due to preabsorptive modification of unsaturated fatty acids, while in dogs there was a good correlation between dietary and plasma NEFA.

Lipids 30, 147–153 (1995).

Fatty acids represent a crucial source of oxidative fuel for muscle contraction, and vertebrates are known to store enough triacylglycerol to sustain exercise for several days (1,2). Mammals adapted for prolonged locomotion can oxidize nonesterified fatty acids (NEFA) at much higher rates than sedentary, low-aerobic species (3,4), in part because of their increased capacity to mobilize NEFA from adipose tissue (5), but also because of their higher rates of circulatory NEFA transport (4). At equivalent exercise intensities (same percentage VO_2max; where VO_2max = maximal oxygen consumption), endurance-adapted mammals transport NEFA at much higher rates than do low-aerobic species, possibly because the plasma albumins of such species allow them to maintain a much higher total NEFA concentration in plasma (4). Major changes in total plasma concentration occur during and after exercise (4,6), but it is not clear whether all individual NEFA change in parallel, or if there is preferential mobilization or use of certain fatty acids (7).

Dogs and goats were chosen as representative species of endurance-adapted and sedentary mammals for this and other studies (3–5,8) because their aerobic capacities (VO_2max) differ by a factor of 2.2. In addition, these species show major differences in diet and digestive physiology (9,10). In nonruminant mammals, including dogs and humans, plasma NEFA patterns closely reflect the fatty acid composition of adipose tissue triacylglycerol (7), and the composition of stored triacylglycerol is itself closely related to dietary fatty acid patterns (10,11). In contrast, ruminant species, such as the goat, show important preabsorptive modifications of NEFA. For example, a significant portion of 18 carbon polyunsaturated NEFA are hydrogenated to stearate (9). These significant differences in energy metabolism, diet and digestion suggest that dogs and goats should differ in their plasma NEFA patterns, and that exercise should have a different effect on the two species.

Preferential mobilization and oxidation of particular NEFA also influence the choice of a proper fatty acid tracer for *in vivo* kinetics studies of lipid fluxes in mammals, and the same individual NEFA may not be an appropriate tracer for all species. NEFA turnover rate is usually measured by

continuous infusion of a labelled fatty acid, and this technique is based on the assumption that the individual NEFA used as a tracer is representative of the total NEFA pool (12). Traditionally, palmitate and oleate have been chosen almost exclusively because they are the most abundant in human plasma (13,14). However, it is not known whether these particular NEFA can be used interchangeably in other species or if other acids would be more suitable. As a first attempt to address this issue, and because concentration and flux are usually correlated (13,15), we have quantified changes in percent composition for each plasma NEFA and calculated its coefficient of variation (CV) throughout conditions of extreme fluctuations in total concentration (i.e., exercise and recovery). Theoretically, the NEFA whose percentage composition shows the lowest CV is the best representative of the total NEFA pool. The goals of this study were, therefore, to measure the concentration of individual NEFA in the plasma of exercising dogs and goats: (i) to determine whether particular NEFA are mobilized or used preferentially during locomotion, (ii) to determine whether differences in diet or aerobic capacity can have an effect on the pattern of NEFA mobilization and (iii) to find the most appropriate NEFA tracer(s) for *in vivo* kinetic studies by establishing which NEFA best represents the total plasma NEFA pool in the two species.

MATERIALS AND METHODS

Animals, training and experimental protocols. All experimental procedures were approved by the Animal Care Committee of Harvard University (Cambridge, MA). Five months before the experiments, three African pygmy goats *(Capra hircus,* two females and one male, body mass 31.0 ± 1.3 kg) and three dogs *(Canis familiaris,* all females, 24.9 ± 1.8 kg) were started on a training schedule using a motorized treadmill at different speeds. Animals were trained at least four times weekly until their oxygen consumption (VO_2) was reproducible at each speed. VO_2 was measured with an open flow system as described by Fedak *et al.* (16). All training and experiments were performed at 18 and 29% incline for goats and dogs, respectively. To allow meaningful comparisons, exercise intensities were standardized according to maximal oxygen consumption (VO_2 max), and the two species were always measured at the same percentage of their VO_2max. The VO_2max of the individual animals used here had been measured previously (3), and each animal was specifically trained to run for 2 h at 40% VO_2max and 1 h at 60% VO_2max. In the present study, 60% VO_2max was chosen as the highest intensity because lipolysis (5) and circulatory fatty acid delivery (4) are both maximized at this work rate. Recovery was also monitored because the highest plasma fatty acid concentrations are known to occur shortly after the end of exercise in several species including dogs (4) and humans (6,17).

Goats were fed hay (NEFA composition: 25.5% 16:0, 0.4% 16:1, 3.1% 18:0, 14.2% 18:1, 27.4% 18:2 and 26.5% 18:3) and they were housed in a large outdoor paddock with shelter. The dogs were fed dry dog chow (5% fiber, 25% protein and 10% fat with the following composition: 24.5% of total NEFA as 16:0, 0.3% 16:1, 14.6% 18:0, 42.1% 18:1 and 15.5% 18:2), and they were housed in a large indoor-outdoor run. Food was withheld for 18 h before measurements, but the animals had unlimited access to water. One day before each experiment, a PE-50 catheter was placed in the aorta *via* the carotid artery as described previously (5). Blood samples (2 mL each) were drawn 15, 10 and 5 min before exercise, and at times 0, 2, 5, 10, 20, 40, 60, 80, 100 and 120 min during exercise at 40% VO_2max. At 60% VO_2max, samples were taken at times 0, 2, 5, 10, 20, 30, 40, 50 and 60 min. Additional samples were drawn 2, 5, 10, 20, 30, 40, 50 and 60 min after exercise had ended (recovery period). Samples were spun, and the plasma was separated and frozen immediately. The two exercise intensities were measured in different experiments, and two experiments on the same animal were separated by at least one week.

NEFA concentrations. Individual NEFA concentrations were measured on a Hewlett-Packard 5890 series II gas chromatograph (Mississauga, Canada) equipped with an automatic injection system (HP 7673) and flame-ionization detector. NEFA extraction and methylation were performed with the method of Tserng *et al.* (18) modified by increasing methylation time to 20 min. Preliminary thin-layer chromatography (TLC) and gas chromatography (GC) analyses using plasma and standard polyunsaturated fatty acids, including 20:4ω6, showed that 20 min were necessary for near complete methylation. One-hundred µL of plasma were methylated with 1 mL 2,2-dimethoxypropane (Sigma, St. Louis, MO) after adding 20 µL of conc. HCl. The reaction was stopped after 20 min by the addition of 10 µL pyridine, and the NEFA methyl esters were recovered by two extractions with 750 µL isooctane (BDH, Toronto, Ontario, Canada). Analyses were performed on a 30-m fused silica capillary column (DB-23; J&W Scientific, Folsom, CA) kept at 170°C for 35 min after injection, raised to 220°C at a rate of 50°C/min, and kept at that temperature up to 46 min. The injection port temperature was 210°C and the detector was kept at 250°C. NEFA standards (Supelco, Bellefonte, PA) were injected for GC calibration, and heptadecanoic acid (12 µg/100 µL, in methanol) was used as an internal standard. This internal standard was added to plasma before methylation, and recovery ranged between 95 and 98%.

Statistical analysis. Results were analyzed with one- and two-way analyses of variance (ANOVA) after percentages were arcsine transformed. In cases where the data failed tests for normality (Kolmogorov–Smirnov), a nonparametric Kruskal–Wallis one-way ANOVA on ranks was used. Bonferroni's *t*-test for multiple comparisons was used to compare mean NEFA concentrations during exercise and recovery with those at rest, and to compare the different phases in Table 1. A Dunn's multiple comparison was performed when sample sizes were unequal. Linear regressions were performed on all exercise values for each species separately to see if NEFA concentrations changed significantly over time.

[a]Values are averages of two determinations in each of three animals.
[b]See Figure 2 and Results section for definition of phases a through e. Animals were exercised at 40 and 60% VO_2max (VO_2max = maximal oxygen consumption).
[c–i]Within each column and each treatment, means for phases sharing the same superscript are significantly different from each other at $P < 0.05$.

CVs (19) were calculated separately in each species for each NEFA throughout exercise and recovery. Data for the two exercise intensities were combined to calculate these coefficients. All values presented are means and their standard errors (SEM).

RESULTS

NEFA concentrations. Plasma concentrations of palmitic, oleic and linoleic acids were always much higher in dogs than in goats before, during and after exercise at 40 and 60% VO_2max ($P < 0.001$, Fig. 1). Stearic acid concentration was not different between the two species (263 ± 6 nmoles/mL) and remained at resting levels throughout exercise at both intensities and during recovery. In dogs, with the exception of stearate, the concentration of all NEFA showed a steady increase during exercise at both intensities (linear regressions, $P < 0.01$), and an overshoot in concentration occurred after the end of work (Fig. 1). NEFA concentrations were maximal during the overshoot when they reached levels more than twice resting values shortly after exercise ended ($P < 0.05$). Dog 16:0 reached maximal concentrations of 690 ± 47 and 649 ± 78 nmol/mL shortly after exercise at 40 and 60% VO_2max, respectively. In the same species, 18:1 concentration increased throughout exercise and reached maximum values of 1495 ± 153 and 1479 ± 109 nmol/mL, 20 min after ending exercise at 40 and 60% VO_2max, respectively. Recovery overshoot values for 18:2 were 678 ± 23 nmol/mL (20 min after the 40% VO_2max run) and 614 ± 76 nmol/mL (10 min after the 60% VO_2max run) (Fig. 1). In sharp contrast to the response observed in dogs, the NEFA concentrations of goats never increased above resting values ($P > 0.05$). Palmitic acid remained at an average level of 153 ± 8 nmol/mL, oleic acid stayed at 227 ± 13 and linoleic acid at 66 ± 5 for both, 40 and 60% VO_2max runs ($P > 0.05$, Fig. 1). Within each species, the overall patterns of changes in NEFA concentration were similar at the two exercise intensities.

NEFA composition. Palmitic, stearic, oleic and linoleic acids were present in both species. Significant amounts of 16:1 were only found in dog plasma (7% of total NEFA), and 18:3 was present only in goat plasma (6%). Changes in the distribution of individual NEFA over time are presented in

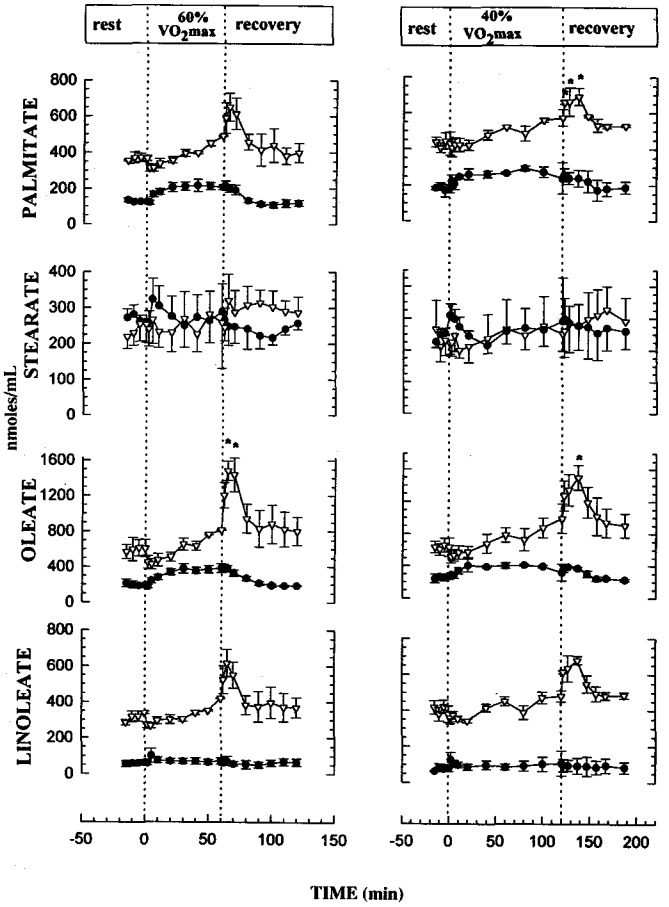

FIG. 1. Mean concentrations of individual nonesterified fatty acid in the plasma of dogs (▽, n = 3) and African pygmy goats (●, n = 3) before, during and after a 1-h run at 60% maximal oxygen consumption (VO_2max) and a 2-h run at 40% VO_2max.

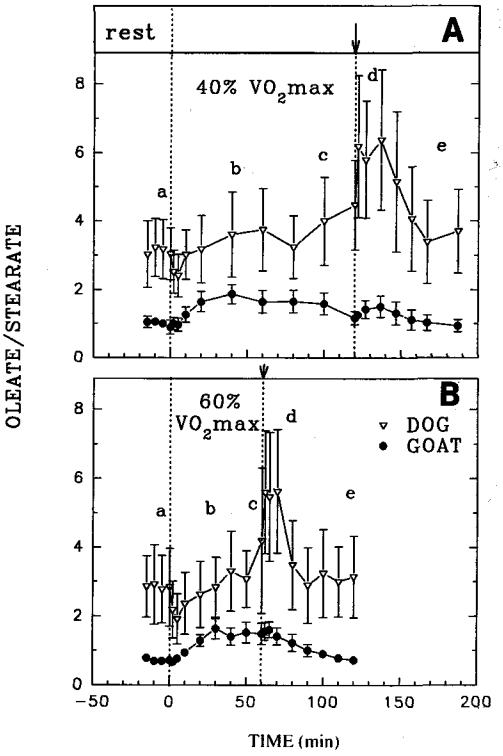

FIG. 2. Ratio of oleic to stearic acid concentration in the plasma of dogs (▽, n = 3) and goats (●, n = 3), before, during and after exercise (A) a 2-h run at 40% VO_2max and (B) a 1-h run at 60% VO_2max. Arrows indicate when exercise was terminated. See Figure 1 for abbreviation.

Table 1 as percentages of total NEFA concentration. Experimental protocols were divided in five phases to facilitate comparison: Phase a was the preexercise control period. Phase b was the onset of exercise (average value between 20 and 40 min of exercise at 40% VO_2max, and between 20 and 30 min at *60%* VO_2max). Phase c was the end of exercise (average value between 100 and 120 min at 40% VO_2max, and between 50 and 60 min at 60% VO_2max). Phase d was the beginning of recovery (127 to 137 min at 40% VO_2max and 65 to 70 min at 60% VO_2max). Finally, phase e was the end of recovery (167 to 187 min at 40% VO_2max and 110 to 120 min at 60% VO_2max). The five phases are illustrated in Figure 2, and significant differences between phases are indicated by superscripts in Table 1. Oleic acid was the most abundant NEFA, representing on average over 35% of total NEFA in both species. Similarly, the relative importance of 16:0 was the same in dogs and goats; averaged throughout exercise and recovery at both intensities, 16:0 accounted for 21% of total NEFA concentration. Together, therefore, 18:1 and 16:0 represented more than half of total NEFA in both species. At 40% VO_2max, the percentages of 18:1 and 16:0 were not different between species ($P > 0.05$). However, at 60% VO_2max, the percentages of 18:1 and 16:0 were both significantly higher in dogs than in goats ($P < 0.01$) (39 vs. 34% for 18:1, and 22 vs. 20% for 16:0). The percentage of 18:0 was almost two times higher in goats than in dogs (goats: 24 and 27% vs. dogs: 13 and 16% at 40 and 60% VO_2max, respectively). The situation was reversed for 18:2 because this NEFA accounted for 20% in dogs, but only 9% in goats.

To emphasize important interspecies differences in the effect of exercise on plasma NEFA composition, the concentration ratio of 18:1 to 18:0 was calculated for both species (Fig. 2). This ratio was always much higher in dogs than in goats ($P < 0.001$). The difference between the two species varied during and after exercise at both intensities, but it was most pronounced early in recovery. At rest, the ratio was more than 2-fold higher in dogs than in goats (over 2.5 vs. 0.9). The ratio in goats doubled during exercise before returning progressively to resting levels during the recovery period. In dogs, the ratio increased slowly during exercise before a much sharper rise in the first 20 min of recovery. High maximal values of 5.4 and 5.0 were reached after ending the runs at 40 and 60% VO_2max, respectively (Fig. 2).

CVs for individual NEFA composition. Mean CVs for all exercise and recovery values at both 40 and 60% VO_2max were calculated for the percent composition of each NEFA (Table 2). Palmitic and oleic acids had the lowest and second lowest CV in both species, respectively. The variability in composition of all the other NEFA was clearly higher than for

TABLE 2
Mean Coefficients of Variation for Individual Fatty Acid Composition (% total nonesterified fatty acid concentration) Throughout Exercise and Recovery in Trained Goats and Dogs[a]

	Goat	Dog
16:0	9.06	8.86
16:1	—[b]	22.21
18:0	13.07	19.11
18:1	12.30	10.09
18:2	16.70	16.43
18:3	15.63	—[b]

[a]Values for two exercise intensities were combined (40 and 60% maximal rate of oxygen consumption or aerobic capacity). [b]Not detected.

16:0 or 18:1, and the highest CVs were observed for 16:1 in dogs and 18:2 in goats.

DISCUSSION

The present study shows that exercise has a very different effect on the concentration of individual plasma NEFA in sedentary animals, such as goats, than in highly aerobic, endurance-adapted animals, such as dogs. It also reveals that important differences in plasma NEFA composition between these two species can be attributed to dietary NEFA and differences in digestion. Moreover, variability in percent composition for individual NEFA shows that, as in humans, changes in plasma 16:0 and 18:1 most closely reflect changes in total NEFA concentration of dogs and goats, suggesting that these two fatty acids are most appropriate as tracers for NEFA kinetic studies in mammals in general.

Except for stearic acid, plasma NEFA concentrations were much higher in dog than in goat (Fig. 1), allowing the species with high aerobic capacity (dog) to deliver this important oxidative fuel to working muscles at much higher rates than the sedentary species with low aerobic capacity (goat). The high concentrations found in dogs may be possible because this species possesses a plasma albumin with higher NEFA binding capacity than goat albumin. We have recently suggested this higher albumin binding capacity for fatty acids in dogs as an adaptation for endurance locomotion (4).

Another major difference between the two species lies in the fact that exercise causes a large increase in NEFA concentration in dogs (except for 18:0), but has no effect in goats, where it stays at resting levels throughout work and recovery (Fig. 1). Humans have a similar response to that described here for dogs: except for 18:0, their plasma NEFA concentration increases by 25% after exercising at moderate intensity for 30 min (21). These results clearly show that dogs and humans mobilize NEFA reserves during exercise, because, in these species, concentrations of individual NEFA are known to be well correlated with rates of turnover (13,15) and oxidation (15,20). Therefore, in dogs and humans, increases in concentration can be used as an index of NEFA mobilization. In contrast, the lack of change in plasma NEFA concentration of exercising goats reveals that they are able to increase NEFA flux while keeping plasma concentration constant. In goats, NEFA mobilization and oxidation are kept closely balanced throughout exercise and recovery. This observation shows that concentration and turnover of 16:0 and 18:1 are not correlated in goats because they do increase oxidation during exercise, even though lipid utilization is not stimulated as much as in dogs (4).

In dogs, 18:1 and 16:0 have the highest concentrations at rest and show the greatest relative increase during the onset of exercise. These results indicate that dogs mobilize these two NEFA preferentially compared with other NEFA, and probably at much higher rates than do goats. However, these conclusions must remain tentative because percent extraction in locomotory muscles may change with exercise and between species. For example, stearic acid does not follow the typical pattern observed for all other NEFA, and it does not appear to contribute to the overall increase in oxidative fuel use associated with exercise in mammals studied to date. It has been proposed that the fractional uptake of 18:0 may increase in exercising humans (21), suggesting that rates of release from adipose tissue and uptake by working muscles may both increase in parallel and stay exactly matched during physical work (17). This would make stearic acid flux independent of its plasma concentration, and an increase in 18:0 mobilization/oxidation would only be discernible by flux measurements. Stearic acid kinetics should be investigated thoroughly in exercising mammals to determine whether the scenario proposed above actually occurs. In goats, the absence of NEFA mobilization throughout exercise may be the consequence of high plasma glucose availability. Recent experiments on the same animals reveal that glucose concentration increases progressively during exercise in goats, but is very steady in dogs (Weber, Roberts and Taylor, unpublished results). Hyperglycemia can decrease fatty acid turnover by as much as 30% in humans (22), and glucose could therefore be an important inhibitor of lipid mobilization in exercising goats.

Dogs (Fig. 1) and humans (6,17) show a very large post-exercise increase in NEFA concentration. Fifteen min after the 40% VO_2max run, dog 16:0 and 18:1 concentrations reached maximal values 60 and 150% above resting levels, respectively. In striking contrast, no change was observed in recovering goats. The large concentration overshoots seen in dogs and humans indicate that both these species, unlike goats, probably lack rapid control mechanisms for lipolysis (5,6,17). High plasma NEFA concentrations after exercise may play a role in the regulation of fuel oxidation by inhibiting muscle glycolysis through the glucose–fatty acid cycle, and by promoting muscle glycogen resynthesis through an increase in glucose availability (17). In goats, the absence of NEFA overshoot is consistent with the fact that their lipolytic rate returns to resting levels immediately and rapidly after the end of exercise (5).

Plasma NEFA compositions of the two species investigated can be explained by differences in diet, incorporation of individual NEFA in triacylglycerols, and *in situ* modifications of NEFA in adipose tissue and liver triacylglycerol reserves. The composition of NEFA in plasma is known to reflect differen-

tial NEFA incorporation into adipose tissue triacylglycerol, and it has been reported that under conditions of enhanced lipolysis, the composition of plasma NEFA approaches that of adipose tissue (7). *In vivo* dog experiments and *in vitro* measurements on rat epididymal fat pads show that the rate of release of each individual NEFA is correlated with its relative concentration in adipose tissue (7). For nonruminants, both adipose tissue triacylglycerol and plasma NEFA reflect dietary composition (11) due to little preabsorptive modification (10). Indeed, the composition of plasma NEFA in dogs (Table 1) closely reflects that of their diet (see Materials and Methods section). In ruminant mammals, NEFA composition of adipose tissue triacylglycerol may also be influenced by postabsorptive modifications of dietary NEFA. For example, the much higher proportion of 18:1 found in goat plasma (Table 1) than in their diet may be the consequence of high activities for the enzymes fatty acid elongase and stearoyl-CoA desaturase in adipose tissue (23,24).

Stearic acid represents a greater proportion of total dietary NEFA in dogs than in goats, but the opposite is true for total plasma NEFA (Table 1). This discrepancy can be accounted for by differences in digestive physiology between ruminants and nonruminants. In ruminants, dietary unsaturated fatty acids are hydrogenated in the rumen, and little polyunsaturated NEFA reach absorption sites in the small intestine (9,25). For example, higher than expected levels of stearic acid are probably found in plasma because a large proportion of dietary 18 carbon polyunsaturated NEFA is hydrogenated to 18:0 prior to absorption (9). Given that goats and other ruminants absorb lower amounts of polyunsaturated NEFA than predicted from their diet (25), availability from digestion rather than differential rate of esterification between NEFA in adipose tissue triacylglycerol likely dictates the composition of adipose tissue and ultimately plasma (23).

Figure 2 shows that the concentration ratio of 18:0/18:1 is very different between dogs and goats, before, during and after exercise. This observation may be partly explained by interspecific differences in the activities of enzymes responsible for NEFA incorporation in adipose tissue triacylglycerol; lower incorporation of particular NEFA may result in their lower contribution to total plasma NEFA. Except for stearic acid, rates of incorporation in adipose tissue increase linearly with plasma concentration (23). In experiments by Lin *et al.* (23), 18:0 had the lowest rate of esterification in bovine adipose tissue while 16:0 had the highest. Incorporation of 18:0 in adipose tissue triacylglycerol may differ between dogs and goats due to discrepancies in the activities of fatty acyl-CoA synthetase. Low incorporation of stearic acid into bovine adipose tissue is thought to be caused by fatty acyl-CoA synthetase's low affinity for 18:0 (23). As in dogs, 18:0 does not contribute to the increase in total plasma NEFA of humans, and the 18:1/18:0 ratio increases from 3.3 at rest (compared to 2.7 in dogs) to a maximum of 4.5 (5.4 in dogs) after 50 min of exercise (21).

Additional differences between dogs and goats may be more directly attributed to differences in diet, and the composition of plasma NEFA found here in goats is comparable with values reported previously (25). Only goat plasma contained 18:3, a NEFA of plant origin especially abundant in grass lipids (25,26), and represented a relatively large proportion of total FA in the goat diet of our study (see Materials and Methods section). Palmitoleic acid was only found in dog plasma, although this NEFA has also been reported to be present in small amounts in goat plasma (25). We did not detect it in goats with the methods used in the present study.

Palmitic and oleic acids have the lowest variability in percent composition throughout exercise and recovery (Table 2). Therefore, changes in their concentrations are the most representative of changes in total plasma NEFA, and they should be the preferred labeled fatty acids for flux measurements in dogs and goats. Also, both of these acids are relatively abundant, making the measurement of their specific radioactivity or enrichment easier than with other much less concentrated NEFA. Palmitic and oleic acids have been used extensively in NEFA kinetics studies in humans (12,13,27), and the present study suggests that they are also suitable for such studies in other mammalian species, even during exercise.

Effect of Reproductive States on Lipid Mobilization and Linoleic Acid Metabolism in Mammary Glands

Gautam K. Bandyopadhyay, Le-Young Lee, Raphael C. Guzman and Satyabrata Nandi*

Cancer Research Laboratory, Department of Molecular and Cell Biology, University of California, Berkeley, California 94720

ABSTRACT: Effects of pregnancy and lactation on lipid metabolism in mouse mammary fat pads and nonmammary adipose tissues have been studied. In order to address the question whether the influence of hormonal milieu on lipid metabolism in mammary epithelial cells during pregnancy and lactation is the same as in fat cells, we have studied the mobilization of lipids and metabolism of fatty acids in the intact mammary glands, parenchyma-free mammary fat pads and in the perimetrial fat tissues of virgin, pregnant and lactating mice. Compared to parenchyma-free mammary fat pads, the perimetrial adipose tissues accumulated 5-fold higher levels of triglycerides during pregnancy. Mammary fat cells maintained overall lipid levels during pregnancy and lactation (16–20 μg/fat pad). In contrast, lactation depleted total lipid stores from 108 ± 5 to 24 ± 4.5 μg/fat pad in perimetrial fat pads. Results of comparative analysis of fatty acid composition of mammary fat pads, with and without epithelial tissue, from virgin and lactating mice showed stimulation of 18:2ω6 metabolism leading to 130% increase in the ratio 20:4ω6 to 18:2ω6 in the epithelial compartment. Pregnancy and lactation resulted in the elevation of 20:4ω6 levels probably due to a 4-fold increase in Δ5 desaturase activity and a decrease in oxidative degradation of 18:2ω6. These results suggest that, unlike other adipose tissues, the metabolic pathways in mammary fat cells are not dedicated to sequestration and accumulation of dietary lipids during pregnancy. Lactation favors mammary epithelial cell-stimulated production of precursors of eicosanoids which are known to have agonist-like effect on mammary epithelial cells.

Lipids 30, 155–162 (1995).

The production of milk by the mammary glands is controlled by multiple hormones (1,2). These lactogenic hormones not only regulate the expression of mammary-specific products, but also prepare other organs and tissues to support milk production (3). In response to the preparations for lactation, mammary tissues undergo metabolic changes, many of which are reciprocal to the corresponding changes in the adipose tissues.

During lactation, the uptake of circulating lipids and carbohydrates and the synthesis of lipids in mammary tissue are increased, whereas the converse is true for nonmammary adipose tissue. During pregnancy and before parturition, adipose tissue accumulates more lipids than mammary glands; however, as lactation ensues, the metabolic pattern is switched (3–9). It has been suggested (see Ref. 3 for a review) that the modulation of insulin sensitivity of tissues by progesterone and prolactin plays a role in this regulation.

The metabolic interaction between mammary and adipose tissues may help in supplying essential fatty acids (EFA) and other nutrients from the depot fat to the mammary glands. Dietary EFA can be received from the circulation, but these fatty acids are turned over and metabolized. By comparison, adipose tissues can store EFA (10–12), and, therefore, these fatty acids will be available even when the dietary supply is reduced. It has been shown previously that dietary EFA deficiency affects the maintenance and induction of prolactin receptors in liver (13) and arrests mammary development in young mice (14). Dietary linoleate, but not saturated fats, can accelerate the growth and branching of mammary ducts in young mice (15). Such influences of EFA on mammary gland development are partly dependent on age and maturation of the ovary (16).

What is not clear from most of these studies is the role of mammary fatty tissue of the gland, which surrounds the epithelial tissue but is separated from it by the basement membrane. Previous studies have demonstrated that mammary epithelial tissue can develop and function normally when transplanted to other white adipose tissue (17–19). Results from two laboratories have also suggested that local stromal environment has the capacity to influence mammary epithelial response to hormones and that estrogen stimulated mammary epithelial growth may be mediated through its actions on surrounding adipocytes (20–22). While the fat cells in a gland can influence the functions of epithelial cells, the presence of epithelial cells in a fat pad can also modify the response of fat cells to some agonists. Thus, in pregnant swine, response to norepinephrine leading to fatty acid release was found to be higher in mammary fat pads than that in peritoneal fat pads (23).

In this context, our interests were to study (i) the paracrine role of lipids in the interactions between stromal adipocytes and epithelial cells of mammary glands, and (ii) the fate of

linoleic acid, which is stored in the fat cells and can be transported into the epithelial cells, in response to hormonal changes during pregnancy and lactation. Earlier studies from our and other laboratories have demonstrated that EFA, such as 18:2ω6 and 20:4ω6, can directly influence the epidermal growth factor and hormonal effects on mammary epithelial proliferation and differentiation (24–27). In the present study we have used mammary fat pads free of epithelial tissue as representative of mammary fat cells in mice. By comparing the lipid composition of cleared fat pads and intact mammary glands under different reproductive states, we report here that, unlike other adipose tissues, mammary fat cells do not accumulate lipids during pregnancy. Lactation-induced biochemical changes in the mammary glands allow mammary tissues to maintain higher levels of 18:2ω6 and 20:4ω6 compared to mammary tissues in virgin mice.

MATERIALS AND METHODS

Materials. Reference fatty acids were purchased from Biomol (Plymouth Meeting, PA) and Ocean Organics Inc. (Peace Dale, RI). [1-^{14}C]18:2ω6 and [1-^{14}C]20:3ω6 were purchased from New England Nuclear (Boston, MA). High-performance liquid chromatography (HPLC)-grade solvents and other chemical reagents were bought from Fisher Scientific (Pittsburgh, PA) and Sigma Chemical Co. (St. Louis, MO), respectively. Culture media were obtained from GIBCO-BRL (Gaithersburg, MD). Ovine prolactin (NIAMDD o-Prl) was a gift from the National Institutes of Health (Bethesda, MD).

Animal procedures. Female Balb/C mice were obtained from the animal colony maintained by the Cancer Research Laboratory, University of California (Berkeley, CA). One group of 6-week-old and another group of 8-week-old virgin female mice, 12 mice in each group, were allowed to mate with males, and the formation of vaginal plugs was examined each morning to determine pregnancy. The older pregnant mice were sacrificed by cervical dislocation on day 11 of pregnancy (midpregnant). The younger group of pregnant mice were allowed to give birth to pups (after 18–19 d of pregnancy) and lactate. At day 10 of lactation, pups were removed and mothers were sacrificed. Virgin mice of same age served as control. At the time of sacrifice, virgin, pregnant and lactating mice were 70–72 days old. For collection of number 4 inguinal mammary fat pads, the mice were killed by cervical dislocation, the lymph nodes were removed and tissues were collected in a tube containing medium 199 (GIBCO-BRL). Mammary tissues were sliced with a scalpel to 1–2 mm thickness and washed free of fluids (e.g., milk from the lactating tissue) by incubation (each time for 10 min) and rinsing five times with medium 199. Abdominal fat pads were obtained from the fatty tissues surrounding the uterus (perimetrial fat pad) and were similarly sliced and washed. The perimetrial adipose tissue was used as a representative of abdominal fat pads.

All mice were fed *ad libitum* with food pellets (Wayne rodent blox 8656) which contained 5% (w/w) fat contributed by dry yeast, soybean oil, animal liver and fish meal. The fatty acid composition of this diet is given in Table 1.

Mammary parenchyma from one of the two number 4 inguinal fat pads was removed from eighteen 3-week-old mice following a procedure described in detail by DeOme *et al.* (28). Mice were anesthetized by injecting (10 μL/g body weight) a 10% (vol/vol) Nembutal solution (Abbott Laboratories, Chicago, IL) prepared in a solvent mixture composed of normal saline/propylene glycol/ethanol (6:2:1, vol/vol). An inverted Y-shaped skin incision (1 inch long) was made along the midline of the abdomen and between the inguinal and perianal nipples along the hind legs (½ inch long). The exposed inguinal nipple of one number 4 mammary fat pad and the large blood vessel running from the lymph node were cauterized. The areas of the number 4 fat pad containing growing ductal elements are dissected free of skin and discarded. The

[a]Results are presented as the mean SE for five replicate samples. Abbreviations: AFP, abdominal fat pad; CMEP, cleared mammary fat pad; IMFP, intact mammary fat pad. [b]The other fatty acid components of the diet are 18:3ω3 (2.5 ± 0.3) and 20-5ω3 (1.1 ± 0.2). [c]Significantly different ($P < 0.05$) from the corresponding tissues in virgin mice. [d]Difference from virgin mice was not significant.

remaining gland-free mammary fat pad, called cleared mammary fat pad, is filled with fat cells (along with other stromal components) but is devoid of mammary epithelial tissue. The two types of contralateral number 4 fat pads from the same animal, one with and the other without the epithelial tissue, and exposed to the same hormonal milieu, offer a good system for comparison of the effects of hormones on epithelial vs. fatty tissues of the mammary glands. Twelve mice with cleared mammary fat pads were mated to produce pregnant and lactating mice. In all experiments, five mice were used for each experimental group representing a physiological state. Tissues from each mouse were analyzed separately.

Explant culture and incorporation of labeled fatty acids. Fragments of number 4 inguinal mammary fat pads (*ca.* 1.0 cubic mm in size and *ca.* 1.0 mg in weight) were prepared by following the procedure described by Topper *et al.* (29). Mammary explants were transferred onto triangular-shaped steel-wired grids (15 explants per grid) and placed inside 6-well culture plates covered with medium (3 mL). Corners of the grids were bent so that the grids could stand as raised platforms, and explants on them could remain close to the air/liquid interface. Explants were cultured for 2 d in Dulbecco's modified Eagle's medium (DMEM)/F12 (1:1, vol/vol; GIBCO-BRL) containing delipidated bovine serum albumin (1 mg/mL), soybean trypsin inhibitor (5 μg/mL), transferrin (5 μg/mL), Vitamin E (1 μg/mL), amphotericin B (2 μg/mL), penicillin (30 μg/mL), streptomycin sulfate (50 μg/mL) and a trace element cocktail composed of (final concentration) 1 nM $MnCl_2$, 10 nM H_2SeO_3, 50 μM Na_2SiO_3, 1 nM $(NH_4)_6Mo_7O_{24}$, 5 nM NH_4VO_3, 0.5 nM $NiCl_2$, and 0.5 nM $SnCl_2$. During the first 24 h in culture, the medium was supplemented with insulin (100 ng/mL). For the next 24 h, explants were cultured in the presence of radiolabeled fatty acids (as bovine serum albumin conjugates, 2.0 μg Ci/mL) in medium supplemented with insulin (100 ng/mL), prolactin (1 μg/mL) and cortisol (100 nM). After 24 h of incubation, the labeled media were removed, and the explants were washed with chilled unlabeled medium and then frozen.

Lipid extraction, separation and analysis. The detailed procedures for lipid extraction and separation by thin-layer chromatography (TLC) have been described previously (25). Tissues were first homogenized by Polytron (Brinkmann Instruments, Switzerland) in 0.8 ml ± HCl (0.1 N) and then blended with 3 mL of a mixture of chloroform/methanol (1:2, vol/vol). The monophasic mixture was centrifuged, and the clear supernatant was mixed with an equal volume of 1% NaCl solution and chloroform. The mixture was vortexed and centrifuged to separate two solvent layers. The lower organic layer containing tissue lipids was collected, and the extraction was repeated with the top aqueous layer. The organic phase was dehydrated by anhydrous sodium sulfate and concentrated by blowing nitrogen gas. An aliquot was subjected to TLC analysis for neutral lipids (developed inside a fume hood using a solvent mixture: hexane/diethyl ether/acetic acid, 70:30:1, by vol) and phospholipids (developing solvent: chloroform/methanol/acetone/acetic acid/water, 6:2:8:2:1, by vol). Another aliquot of the lipid extract was digested in 5% methanolic KOH solution and then acidified to generate free fatty acids. Free fatty acids were converted to bromophenacyl derivatives and analyzed by HPLC as described previously (30). Quantitations of total triglycerides, diglycerides and phospholipids were done by assaying total glycerol (after saponification), acyl esters (31,32) and organic phosphates (33) in the extracts of TLC separated lipids. Glycerol was assayed by using a kit from Boehringer Mannheim (Indianapolis, IN).

Determination of Δ5 desaturase activity. Microsomes were prepared and conversion of [1-^{14}C]20:3ω6 to [1-^{14}C]-20:4ω6 by microsomal Δ5 desaturase activity was determined by following the procedure described by Mandon *et al.* (34). Labeled fatty acids were analyzed by HPLC and monitored by Flow-One Beta radiodetector (Radiomatic Instruments, Tampa, FL).

Presentation of results. To compare the effect of reproductive states on lipid metabolism in three different tissues, groups of virgin, pregnant and lactating mice (five mice per group maintained on the same diet) were sacrificed when they were 70–72 days old. The group of virgin mice served as control. Data are presented as means ± SE for five replicate samples, each obtained from one mouse. Two such experiments were carried out, and the results from one experiment are presented. The significance of the differences in the data was tested by Wilcoxon's rank sum test at the 5% level. In some experiments, duplicate samples were analyzed and mean of the duplicates was presented. In these cases, data from two separate experiments were pooled for analysis of significance of differences in the data.The data obtained from the glands under one physiological state have been compared with the glands from another physiological state on the basis of differences observed in the total levels during the change of physiological states. This comparison reflects the total amount of change that occurred per gland when virgin mice went through pregnancy and lactation. Since the wet weight, DNA and protein contents of mammary glands and adipose tissues did not remain constant during these changes in physiological states, the normalization of data with respect to these parameters did not represent the true comparison of the metabolic alterations.

RESULTS

Pregnancy and lactation in mice caused an increase in the amount of total DNA and protein in intact mammary fat pads (IMFP). Compared to nonpregnant tissue, there was a 2-fold increase in DNA and protein content at midpregnancy, and a 6- to 7-fold increase in DNA and an 8-fold increase in protein by the tenth day of lactation (Table 2). The DNA content in the epithelial tissue alone was estimated by subtracting the total amount of DNA in cleared mammary fat pads (CMFP) from that of IMFP. The increase in total DNA content in the epithelial tissue of IMFP of lactating mice was 10-fold higher than IMFP of virgin mice. This value was lower than the previously reported estimation where the increase was 20- to 25-

TABLE 2
Total Protein and DNA Levels of Mammary and Adipose Tissues of Mice Under Different Reproductive Conditions[a]

Physiological condition	Tissue	DNA (μg/fat pad)	Protein (mg/fat pad)
Virgin	IMFP	60 ± 7	2.34 ± 0.5
	CMFP	23 ± 3	1.6 ± 0.15

	AFP	53 ± 14	4.3 ± 0.47

[a]Results are presented as the mean ± SE per fat pad to indicate the extent of changes that occurred in the whole tissue. Five replicate samples per group were analyzed. Five mice, each providing one sample fat pad for analysis, were used per group. For other details, see the legend of Figure 1 and the Materials and Methods section. For abbreviations, see Table 1.

fold (35). CMFP and abdominal fat pads (AFP) under similar conditions did not show these changes. Rather, a significant decrease in DNA content was observed which cannot be explained at this stage. However, lipid accumulation was different in CMFP and AFP. While lipid levels in AFP increased dramatically during pregnancy, CMFP and IMFP did not show such trends (Fig. 1A). In lactating mice, the lipid content of IMFP was 2- to 3-fold higher than CMFP (Fig. 1A), suggesting that lipogenesis was taking place in the epithelial compartment of IMFP. These increases in lipid content were contributed by triglycerides (TG) in AFP (Fig. 1B) and by triglycerides and phospholipids (PL) in IMFP (Fig. 1B and D). The higher diglyceride (DG) levels in AFP (Fig. 1C) may have contributed to increased accumulation of TG. Lactation caused depletion of TG store in AFP (Fig. 1B), but TG levels in the lactating IMFP were similar to AFP. Probably, lactating IMFP channeled most of the TG into secreted milk and could not store more TG than other tissues. The rise in PL in the lactating IMFP (Fig. 1D) corresponded to the increased number of epithelial cells containing higher levels of endoplasmic reticulum and secretory vesicles.

The results of the analyses of fatty acid composition of lipids from mammary and adipose tissues are shown in Tables 1 and 3. The fatty acid profile of lactating IMFP, which actually represents epithelial tissue plus residual milk lipids, showed an expected rise in the level of medium-chain fatty acids (10:0,12:0,14:0) probably due to the induction of medium-chain acyl thioesterase activity (5,6). A comparison of the levels and the composition of fatty acids in the tissues showed that, compared to virgin mice, there was a 50% and a 130% rise in the ratio 20:4ω6 to 18:2ω6 in pregnant and lactating mice, respectively (Table 3). The rise in 20:4ω6 level was not observed in CMFP and AFP (Tables 1 and 3) under similar hormonal and physiological conditions.

Pregnancy increased the total lipid content in AFP and led to the building up of a large store of 16:1ω7, 18:1ω9 and

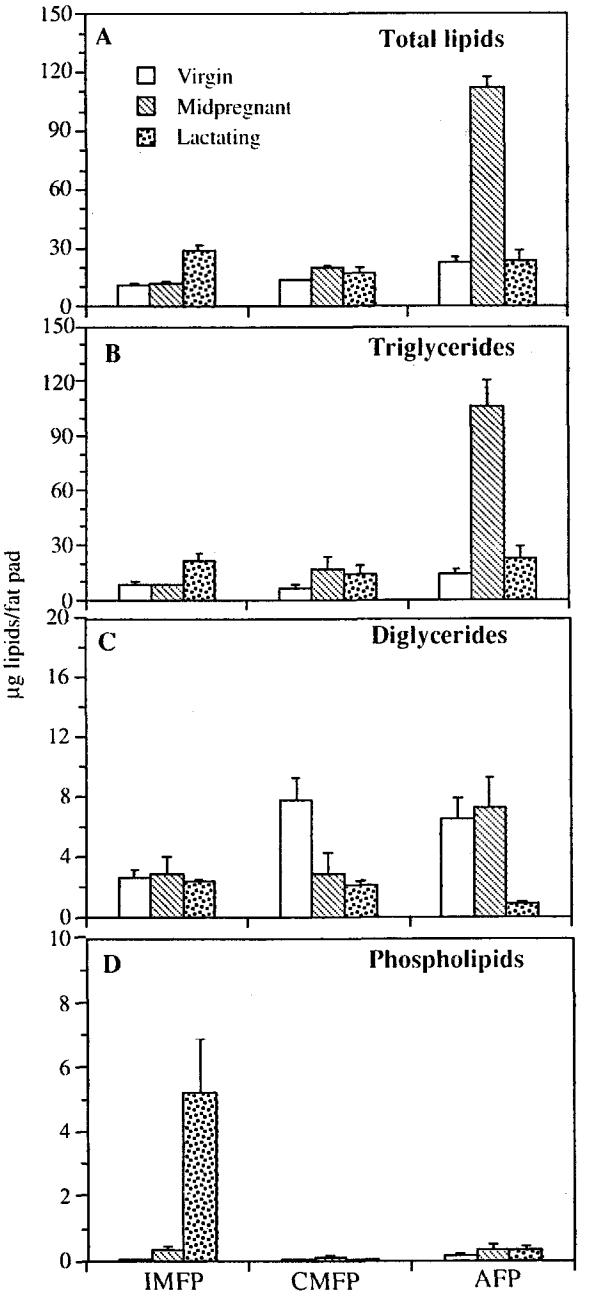

FIG. 1. Changes in total lipid, triglyceride, diglyceride and phospholipid levels in intact mammary fat pads (IMFP), cleared mammary fat pads (CMFP) and abdominal fat pads (AFP) from virgin, pregnant and lactating mice. Results are presented as mean ± SE per fat pad to indicate the extent of changes that occurred in the whole tissue. The entire number 4 inguinal mammary fat pads and perimetrial fat pads (representing abdominal fat pads) were collected for analysis. Five replicate samples per group were analyzed. Five mice, each providing one sample fat pad for analysis, were used per group. For analytical details, see the Materials and Methods section.

18:2ω6. This supply was depleted during lactation, bringing the level down to that similar to virgin mice (Table 3). In this respect, the metabolic response of CMFP was different from that of AFP. There was neither a decrease in the saturated fatty acid composition nor an increase in the accumulation of

[a]Results from one of the two experiments are presented as the mean ± SE for five replicate samples, each obtained from one mouse. The two experiments showed similar trends. For abbreviations, see Table 1.
[b]The amounts of 18:2ω6 and 20:4ω6 in lactating mice were significantly ($P < 0.05$, Wilcoxon test) higher than in virgin or pregnant mice.

unsaturated fatty acids in CMFP of pregnant mice or the mobilization of unsaturated fatty acids in CMFP of lactating mice (Tables 1 and 3).

It should be noted that the results in Table 3 are presented as nmol per fat pad to indicate the level of fatty acids, and those in Table 1 are presented as mol% composition. A comparison of the composition of dietary and tissue fatty acids demonstrated that the proportion of monounsaturated fatty acids in the mammary and adipose tissues was higher than that of the diet, whereas the opposite was true for 18:2ω6 except in AFP of pregnant mice where the percentage of 18:2ω6 was comparable to that in the diet. The proportions of saturated fatty acids in AFP of pregnant mice were considerably lower than those in other tissues (Table 1) mainly due to a decrease in the percentage of 16:0. In pregnant mice, the mobilization of 18:2ω6 in IMFP was similar to that of lactating mice, but CMFP maintained a similar proportion of 18:2ω6 as in virgin mice. The percentage of 18:2ω6 in the lactating mice was significantly ($P < 0.05$) lower than that of virgin mice. IMFP and CMFP of lactating mice showed a similar pattern and differed from AFP where the proportion of 18:2ω6 was not significantly different from that of virgin mice. Although the percent composition of 16:0 in AFP of pregnant mice and 18:2ω6 in IMFP and CMFP of lactating mice were lower than that of virgin mice (Table 1), the total level of these fatty acids in those tissues did not show any decrease (Table 3).

The metabolism of 18:2ω6 in the IMFP explants *in vitro* demonstrated that, compared to the explants from virgin mice, there were 100 and 300% increases in the production of 20:3ω6 and 20:4ω6, respectively, from labeled 18:2ω6 by the mammary explants of pregnant and lactating mice (Table 4). Parallel to these changes in linoleate metabolism, microsomal Δ5 desaturase activity was also found to be 4-fold higher in the tissues from pregnant and lactating mice compared to virgin mice (Table 4). In mouse liver lipids, the ratio of 20:4ω6 to 18:2ω6 in the pregnant tissues (0.75 ± 0.2) was not significantly different from virgin tissue (0.6 ± 0.1), suggesting that pregnancy did not affect linoleate metabolism in liver dramatically (results not shown).

In contrast to their lower capacities for desaturation, the IMFP of virgin mice had a much higher capacity for oxidative degradation of incorporated [1-^{14}C]18:2ω6 than the IMFP of lactating mice (Table 4). While the IMFP of lactating mice actively desaturated and chain-elongated 18:2ω6 to produce 18:3ω6, 20:3ω6 and 20:4ω6, there was little radioactivity in the saturated and monounsaturated fatty acids. On the other hand, when virgin IMFP explants were incubated under similar conditions, labeling of saturated fatty acids occurred but remained restricted to 10:0 and 12:0 fatty acids (Table 4). In addition, 18:3ω6, 20:3ω6 and some 20:4ω6 were also produced.

DISCUSSION

Pregnancy and lactation change the pattern of lipid metabolism as a whole in adipose tissue and mammary gland. During pregnancy, adipose tissue has the highest accumulation of TG, but the TG store is depleted during lactation, as we have observed in AFP. Our results demonstrated that fat cells from AFP and CMFP behaved differently during pregnancy. In contrast to AFP, pregnancy and lactation did not cause dramatic changes in the lipid levels in CMFP. Since changes in the concentration of DG and TG in CMFP were moderate and reciprocal in nature, overall levels of esterified lipids were maintained during pregnancy and lactation.

A number of factors, including the elevated levels of circulating progesterone (36–38) and insulin (39,40) and higher

TABLE 4
Incorporation and Metabolism of [1-^{14}C]18:2ω6 in the Explant Cultures of Mammary Glands Obtained from Virgin, Pregnant and Lactating Mice[a]

Reproductive states	Incorporation into cellular lipids (% of labeled fatty acid added)[a]	Major labeled fatty acids					Microsomal Δ5 desaturase activities (units)[c]
		Saturated[b]	18:2ω6	18:3ω6	20:3ω6	20:4ω6[e]

[a]The results from the two incorporation experiments, each carried out in duplicate, have been presented as a mean of the duplicate assays. Both mean values from two experiments are shown. The four datum points (from two duplicate assays) in one category were compared with the others, and the significance of differences was tested. Incorporations were normalized against 15 mg wet weight for each tissue (total tissue weight per well).
[b]Saturated fatty acids represent $C_{10.0}$–$C_{12.0}$ region of the HPLC chromatogram.
[c]1 unit = p mols of [1-^{14}C]20:3ω6 converted to [1-^{14}C]20 4ω6/mg microsomal protein/15 min at 30° ± SE (three experiments).
[d]Significantly different ($P < 0.05$) from pregnant and lactating mice.
[e]Differences from midpregnant mice are not significant.

lipoprotein lipase (LPL) activity (41,42) in the tissue, have been found to contribute to the accumulation of TG in adipose tissue. During lactation, lipogenesis in the mammary gland is stimulated with a corresponding decline in nonmammary adipose tissue (3,6,43,44). It appears that the effect of progesterone on CMFP is different from that on AFP and the lack of LPL activity in the fat cells of mammary tissues, as shown by Camp *et al.* (45), may be responsible for a lower level of TG accumulation in CMFP during pregnancy. Our data suggest that mammary fat cells may differ from nonmammary fat cells (or other adipose tissues) in sequestering dietary lipids and delivering them to lactating mammary epithelial tissue.

The fatty acid composition revealed that pregnancy caused a large accumulation of monounsaturated fatty acids and 18:2ω6 in the lipid stores of AFP which were mobilized during lactation. Unlike AFP, the level of 18:2ω6 in CMFP of pregnant mice was same as in virgin mice. But the fat cells of mammary tissue can transport free fatty acids (produced by lipolysis of TG by hormone sensitive lipase and released extracellularly due to lack of reesterification) directly across the basement membrane into the epithelial tissue without going into circulation. Therefore, stored linoleate of mammary fat cells, even though the store is not as large as in AFP, can be an important source of EFA for mammary epithelial cell functions.

The percentage of 18:2ω6 in the IMFP of lactating mice was low compared to virgin mice due to higher desaturation and chain elongation of 18:2ω6 and accumulation of medium chain fatty acids in the lactating mice. However, as the level of total lipids in the IMFP of lactating mice was much higher than that of virgin mice, the total amount of 18:2ω6 was also maintained at a higher level in the lactating mice. It appears that the decrease in percent composition of fatty acids was compensated for by an increase in accumulation of total lipids (therefore, higher total fatty acid levels) in respective tissues.

The contribution of 18:2ω6 in the development, proliferation and differentiation of mammary epithelial cells has been documented (24–27). Dietary 18:2ω6, stored mostly as TG in the fat cells, can be released into circulation under the influence of hormones and utilized by mammary epithelial cells. The metabolism of 18:2ω6 by the mammary cells is influenced by physiological conditions. Proliferating epithelial tissue in the pregnant and lactating mice has elevated levels of Δ5 desaturase activity, and, as a result, the IMFP of lactating mice are able to maintain a higher level of 20:4ω6. Cleared mammary fat pads in the lactating mice (contralateral to IMFP) did not show higher 20:4ω6 levels. Therefore, it can be inferred that increased metabolism of linoleate through Δ5 desaturation occurred in the epithelium compartment. Work by others has demonstrated that fat-free diets cause decreased Δ5 desaturase activity in liver microsomes and that supplementation of ω6-unsaturated fatty acids in the diet restored the activity level (46,47). Our results emphasize that in the mammary glands under similar dietary regimen, differentiation of epithelial tissue (as in pregnancy and lactation) raises Δ5 desaturase activity in the epithelial compartment of IMFP.

Although the higher desaturase activity may be partly accounted for by higher epithelial cellularity in the mammary tissues of pregnant and lactating mice (thus contributing higher amounts of epithelial proteins) compared to virgin mice, calculations based on protein content show that while the amount of protein in the IMFP of pregnant mice was two times higher than that of virgin mice, there was a 4-fold increase in Δ5 desaturase activity in the tissues of pregnant mice over virgin mice. This suggests an induction or activation of desaturase activity during pregnancy. Similar consideration for accounting desaturase activity in the IMFP of lactating mice cannot be made because IMFP of lactating mice contains a large amount of casein vesicles. This contributes to IMFP of lactating mice having seven times more protein than that of virgin mice, whereas Δ5 desaturase activity was 4-fold higher. Because microsomal preparations from IMFP of lactating mice are likely to contain large proportions of secretory casein resides, true comparisons of specific activities

of Δ5 desaturase between IMFP of virgin and lactating mice are difficult to make. However, it may be assumed that if the contribution by caseins to the microsomal proteins could be discounted, the calculated specific activity of Δ5 desaturase in the IMFP of lactating mice is likely to be higher than the observed value. It should be noted here that protein content of CMFP did not increase during pregnancy and lactation.

The mammary tissue explants from lactating mice have been shown to be poor in β oxidation of fatty acids (48,49). In our experiments, the same has been found to be true with linoleate. However, the explants from IMFP of virgin mice can cause appreciable oxidation of 18:2ω6. As a result, a large percentage of saturated fatty acids in the virgin tissue becomes radiolabeled by [^{14}C]acetyl-CoA produced by oxidation of [1-^{14}C]18:2ω6. Therefore, it appears that the enzymatic activities in the differentiated tissues are regulated in favor of mobilization of stored linoleate, generation of 20:4ω6, and protection of available linoleate from oxidative degradation. These changes in linoleate metabolism seem to be compatible with the essential role of linoleate in mammary functions. Since all explants were cultured in the same hormone-supplemented medium, the differences in fatty acid metabolism observed in the mammary explants of virgin, midpregnant and lactating mice were not caused by the incubation conditions. Rather, they probably represent biochemical characteristics of the tissues concerned.

In conclusion, it appears that the hormonal conditions during pregnancy bring about striking differences in metabolic response between mammary fat cells and other fatty tissues. Lactation allows mammary tissues to preserve dietary linoleate (without much oxidative degradation), a precursor of eicosanoids which act like agonists for mammary functions.

ABSTRACT: The present study was aimed at answering the question why feeding rats an oligofructose (OFS) supplemented diet could cause a significant reduction in plasma lipid levels. Daily administration of a 10% (w/w) OFS-containing diet to normolipidemic male rats resulted in a decrease in plasma triglycerides, phospholipids and cholesterol. The triglyceride-lowering effect was observed after one week and lasted for at least 16 wk and was associated with a reduction in plasma very low density lipoproteins, indicating that the hypolipidemic effect of OFS may be due to changes in liver lipid metabolism. We therefore tested whether OFS feeding modified the capacity of the liver to synthesize triglycerides from free fatty acids. Hepatocytes isolated from livers of control and OFS-fed rats were incubated in the presence of [1-^{14}C]palmitate, and both intracellular and extracellular [^{14}C]triglyceride formation were quantified. We found that chronic feeding of an OFS-supplemented diet to rats significantly reduced the capacity of isolated hepatocytes to synthesize triglycerides from palmitate. The results suggest that, like other soluble dietary fibers, OFS significantly alters liver lipid metabolism, resulting over time in a significant reduction in plasma triglyceride, phospholipid and cholesterol levels.

Lipids 30, 163–167 (1995).

Oligofructose (OFS) is an oligomer of ß-D-fructose containing two to nine monomeric units which are linked by ß (2-1) glycosidic bridges. OFS is resistant to hydrolysis by pancreatic amylase and saccharidases (1,2). OFS thus belongs to the class of nondigestible oligosaccharides (NDO) which share many properties with fermentable dietary fibers (3). Being nondigestible, OFS reaches the colon intact where it is fermented mostly by *Bifidobacterium* (4). This process produces energy for bacterial proliferation, short-chain fatty acids (SCFA) such as acetate, propionate and butyrate, as well as lactate, which all feed the host. Mostly gaseous by-products (CO_2, CH_4 and H_2) are excreted (5).

In an earlier study, we had shown that feeding rats a diet containing 20% OFS for 30 d led to a significant decrease in the concentration of both serum and liver triglyceride levels (6). This suggested that the capacity of OFS-fed rats to esterify and secrete fatty acids as very low density lipoproteins (VLDL) may be reduced when compared to isocalorically fed control rats.

Similar effects of nondigestible, but fermentable, carbohydrates (including the synthetic fructooligosaccharides that are chemically similar to OFS) on serum triglycerides have been reported (7). It has been hypothesized that some SCFA, in particular propionate and possibly acetate, could be the mediators of this systemic modulation of the metabolism of triglycerides and of other lipids due to dietary fiber. However, the biochemical mechanism of this modulation remained largely undefined and may also vary for different food ingredients. Moreover, it may not be limited to the synthesis of triglycerides or the secretion of VLDL.

We have therefore followed the time course of the hypolipidemic effect of OFS under conditions that would exclude any changes in body weights. Furthermore, the lipid compositions of serum lipoproteins during OFS feeding were compared to those of control rats. Finally, an *ex vivo* protocol was developed to study the influence of OFS feeding on the capacity of hepatocytes isolated from these rats to incorporate [1-^{14}C]palmitate into triglycerides.

MATERIALS AND METHODS

Chemicals. OFS (purity ≥98%) was supplied as Raftilose®P95 by Raffinerie Tirlemontoise Inc. (Tienen, Belgium). It contains at least 95% (w/w) fructooligosaccharides with a mean degree of polymerization of 4.8. Collagenase and Dulbecco's medium were purchased from Boehringer-

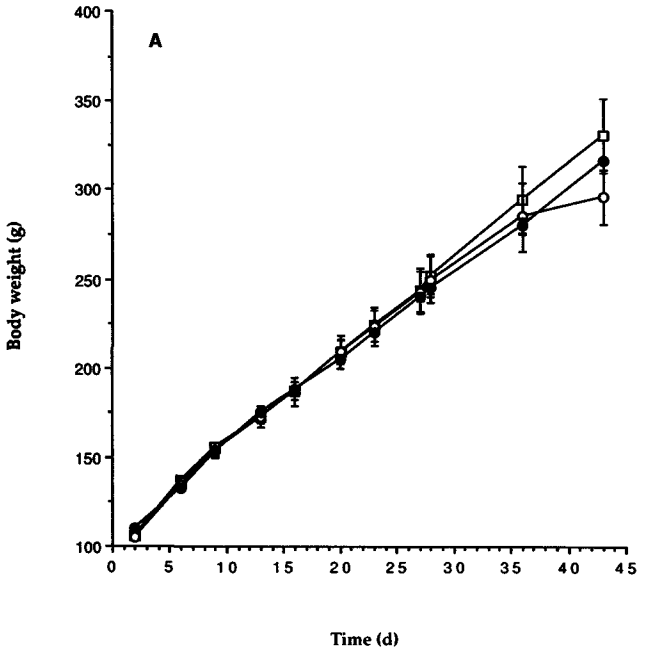
Mannheim (Mannheim, Germany) and Flow Laboratories (Irvine, Scotland), respectively. Bovine serum albumin (BSA) (fraction V) was from the Sigma Chemical Company (St Louis, MO); [1-^{14}C]palmitic acid (710 μCi/mmol) was from New England Nuclear Research Products (Boston, MA); Carbo Sorb and Permafluor scintillation mixtures were from Beckman (Los Angeles, CA). All other chemicals were of the purest grade available.

Animals and diets. Male Wistar rats ICO-WY IOPS from Iffa Credo (Les Oncins, France) initially weighing about 100 g were housed individually in grill-bottom metal wire cages in a room maintained under a 12 h light/dark cycle at 21 ± 3°C. The animals were acclimatized for one week prior to the experiment. All animals had free access to food and water.

The powdered basal diet A04 was purchased from UAR (Villemoisson-Sur-Orge, France). It contained 58% (w/w) carbohydrates, including starch 33% (w/w) and fiber (3% w/w), 17% (w/w) proteins, 12% (w/w) water, 4% (w/w) cellulose, 3% (w/w) lipids and 5% (w/w) minerals. Vitamin A and D3 levels were 7500 and 1500 UI/kg, respectively.

The diets used for the experiments were: (i) the control diet, corresponding to the A04 diet (caloric value, 2.9 Kcal/g); (ii) the sucrose-supplemented diet (5% wt/ wt) prepared by adding 5 g of dry saccharose to 95 g of AO4 diet (caloric value, 2.9 Kcal/g); (iii) the OFS-enriched diet (10% w/w) prepared by adding 10 g of dry OFS to 90 g of AO4 diet (caloric value, 2.8 Kcal/g, assuming that the OFS caloric value is 2 Kcal/g; Ref. 8).

Animal experiments were performed consistent with the rules for humane care according to Belgian State Directives.



Experimental protocols. Experiment 1 compared food intake and body weight of rats fed control and OFS-containing (10% w/w) diets. However, as the OFS supplement not only diluted the diet but also slightly modified its caloric content, a diet was prepared which was supplemented with 5% w/w sucrose. This assumed that OFS had ≤50% the caloric content of sucrose (8). Following the acclimatization period, 15 rats were weight matched and assigned to three groups which received one of the three diets for up to 7 wk. Body weight, 24-h food intake and fecal excretion were measured twice weekly. The feces collected on week 6 were frozen, lyophilized and then used for lipid analysis. Experiment 2 used two groups of ten rats and was designed to monitor the time course (up to 12 wk) of the effect of OFS feeding on serum triglycerides, which was measured once every week and then at the end of the treatment (week 16). Experiment 3 was the *ex vivo* protocol in which two groups of ten rats fed either a control or an OFS-containing (10% w/w) diet for 5–6 wk were used to prepare hepatocytes according to the following procedure: after feeding, rats were anesthetized at 10:00 a.m.; the liver was excised; and hepatocytes were isolated by the collagenase perfusion technique of Berry and Friend (9) as adapted by Krack *et al.* (10). Hepatocytes (≥90% viability as measured by Trypan blue exclusion) were then incubated at a final concentration of 0.5 10^6 cells/mL in Dulbecco's medium containing 5×10^{-5}M [1-^{14}C]palmitate (0.7 mCi/mmol) bound to BSA and prepared according to Capuzzi *et al.* (11). The reaction was carried out for 150 min in an incubation vessel with a rotating helix (40 rpm) as previously described (12). At 30-min intervals, samples of the suspension were removed for biochemical and radiochemical analysis. Each assay was carried out in duplicate, and at least eight separate experiments were performed.

Analytical procedures. For the enzymatic measurement of serum triglycerides, post-prandial blood samples were collected through the caudal vein. For the separation of lipoproteins, blood was collected from the vena cava of rats that had been fasted for 18 h. Serum was then ultracentrifuged on a density gradient (rotor SW41, 40 000 rpm, 18 h) according to Chapman *et al.* (13). Triglycerides, phospholipids and total and esterified cholesterol were assayed in total serum and in each lipoprotein fraction using Boehringer kits. The feces collected on week 6 in protocol 2 were frozen, then dried and powdered. Total lipids were extracted with chloroform/methanol 1:1. The organic phase was evaporated under nitrogen, and the residue was solved in ethanol. Total (free and esterified) fatty acids were measured using a kit from Boehringer-Mannheim. The synthesis of triglycerides and secretion of lipoproteins by isolated hepatocytes were assayed radiochemically. Both the incorporation of [1-^{14}C]palmitate into cellular triglycerides and the increase in [^{14}C]lipids in the culture medium were measured as described by Deboyser *et al.* (12). The activity of palmitoyl coenzyme A synthetase in isolated hepatocytes was measured by the spectrophotometric method of Ichara and Shibasaki (14). All results of the *ex vivo* experiment were expressed per mg of cellular protein which was determined by the method of Lowry *et al.* (15).

Statistical analysis. Data are expressed as mean ± standard error (SEM). To compare the time course of the effect of OFS feeding on body weight and food intake (Experiment 1) or the *in vitro* incubation of hepatocytes on [1-^{14}C]palmitate incorporation (Experiment 3), analysis of variance (ANOVA) using a two-way ANOVA program was performed, followed by a Sheffe test to analyze time/treatment interaction on food intake. Statview^{TM} 512^{+} software was used. To compare the lipid composition of lipoproteins and the concentration of serum triglycerides in Experiment 2, Student's *t*-tests were performed. In all statistical analyses, $P < 0.05$ was used as the significance level to analyze OFS effects.

RESULTS

Body weight growth and food intake (Experiment 1). The rats fed the diet supplemented with OFS gained weight each day at a similar rate (variance analysis; $P > 0.05$) as did the controls and sucrose-supplement fed rats (Fig. 1A). Food consumption was not significantly different (variance analysis; $P > 0.05$) between experimental groups (Fig. 1B), despite a tendency for OFS-fed rats to eat more than did the rats of the other groups. All animals fed OFS over time appeared healthy and behaved normally.

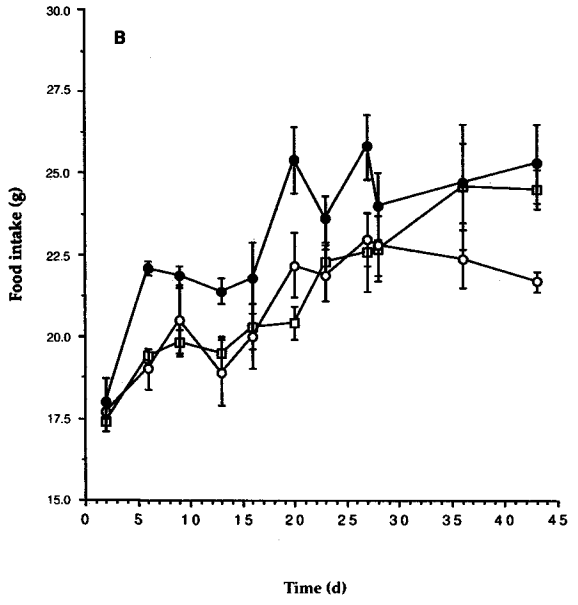


FIG. 1. Body weight (A) and food intake (B) of rats fed a control diet (□) or a diet supplemented with either 5% w/w sucrose (○) or 10% w/w oligofructose (OFS) (●). The values represent means ± SEM of five rats in each group. Variance analysis based on a two-way analysis of variance was used to test for time/treatment interaction. No statistically significant effect ($P > 0.05$) of OFS feeding was apparent.

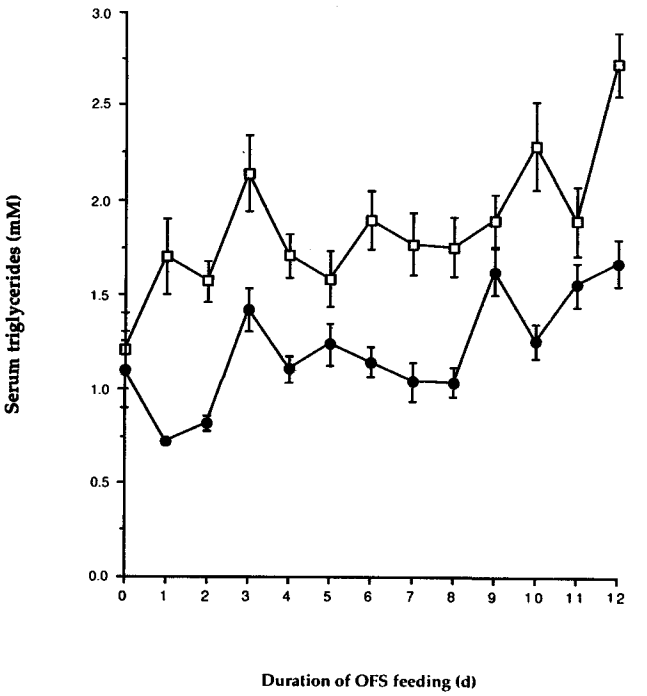

FIG. 2. Time course of serum triglycerides (mmol/L) of rats fed a standard (□) or an oligofructose (OFS)-supplemented (●) diet. The values represent means ± SEM of five animals in each experimental group. Variance analysis based on a two-way analysis of variance was used to test for time/treatment interaction. It showed a statistically significant effect ($P < 0.05$) of OFS feeding.

Serum lipids and lipoproteins (Experiment 2). Chronic administration of OFS to the rats caused a significant ($P < 0.05$) reduction in serum triglyceride levels (Fig. 2). The triglyceride-lowering effect was significant ($P < 0.05$) after one week of feeding and lasted for up to 16 wk ($P < 0.05$). Such a decrease in serum triglycerides was unlikely to be due to changes in fecal excretion of lipids. Indeed, fecal analysis at week 6 showed no statistically significant differences in 24-h excretion of esterified fatty acids between standard and OFS-supplement fed rats (15.8 ± 2.4 μmol vs. 14.9 ± 1.1 μmol esterified fatty acids for control and treated rats, respectively). Table 1 shows that OFS-feeding for 16 wk caused a significant ($P < 0.05$) reduction in serum triglycerides (25% decrease), phospholipids (15% decrease) and total cholesterol (15% decrease). This was exclusively due to the reduction of lipids in the VLDL fraction with the composition of both LDL and HDL remaining unchanged. Moreover, the effect of OFS on VLDL was likely to be due to a reduction in the number rather than a change in the composition of VLDL particles. Indeed, neither the composition nor the size estimated [according to Fungwee *et al.* (16)], by calculating the ratio of the sum of phospholipids plus free cholesterol over the serum triglycerides and esterified cholesterol, showed a statistically significant difference (Table 2).

Effect of OFS on the synthesis and secretion of triglycerides in isolated hepatocytes (Experiment 2). The incorporation of [1-^{14}C]palmitate into cellular triglycerides, as a function of incubation time, in hepatocytes isolated from OFS-fed rats was lower than in control cells ($P < 0.05$) (Fig. 3A). After 150 min of incubation, the incorporation of [1-^{14}C]palmitate into cellular triglycerides was reduced by 40% ($P < 0.05$). Apart from this reduction in the cellular incorporation of [1-^{14}C]palmitate, the accumulation over time of [^{14}C]triglyc-

[a]Values represent means ± SEM; numbers in parentheses are the number of samples analyzed, each sample being from one rat. Abbreviations: OFS, oligofructose; VLDL, very low density lipoprotein; LDL, low-density lipoprotein; HDL, high-density lipoprotein; n is the number of samples.
[b]$P < 0.05$ for difference between control and treated rats.

TABLE 2
Composition and Size of Serum VLDL Particles in Rats Fed Standard or OFS-Supplemented Diets[a]

	Experimental group	
VLDL	Controls (n = 9)	OFS (n = 8)
	(composition%)	
Triglycerides	68 ± 1	65 ± 1
Phospholipids	12 ± 0.1	13 ± 0.4
Total cholesterol	6 ± 0.3	7 ± 0.4
Total free cholesterol	3.7 ± 0.4	3.3 ± 0.2
Protein	13 ± 0.4	15 ± 1
Size (calculated)	0.30 ± 0.03	0.30 ± 0.04

[a]Values represent means ± SEM; n is the number of samples analyzed. Student's *t*-test was used to compare the experimental data, which showed no statistical difference. See Table 1 for abbreviations.

erides in the incubation medium was not statistically different ($P > 0.05$) under the two experimental conditions (Fig. 3B).

Palmitoyl-CoA synthetase activity. The rate of activation to acyl-CoA is limiting in the incorporation of fatty acids into cellular triglycerides (17). As adaptive changes in the activity of the enzyme involved in this activation may reflect alterations in the metabolic flux, we examined whether palmitoyl-CoA synthetase activity was altered after OFS feeding. However, the activity was not statistically different ($P > 0.05$) in homogenates of hepatocytes isolated from controls and OFS-fed rats (2.5 ± 0.2 and 2.5 ± 0.1 mmol/min/mg protein), respectively.

DISCUSSION

Our data show that feeding rats a diet supplemented with 10% OFS had no significant effect on body weight gain. Besides a slight but not significant increase in macro- and micronutrient intake, the chronic feeding of OFS significantly reduced serum triglycerides when measured in both fed and fasted rats. Moreover, in the fasted state, serum phospholipids and total and esterified cholesterol were also significantly reduced. These data confirm and extend our previous observations (6) and the findings of others (7) that the OFS-like synthetic fructo-oligosaccharides called Neosugar®, similarly reduce triglyceridemia by 30% after feeding to rats for a 6-wk period of a supplemented (10 to 20% w/w) diet. Our data also agree with previous observations that fermentable dietary fibers, such as pectins, are effective nondigestible carbohydrates that reduce serum and liver triglycerides (18,19).

Using an *ex vivo* protocol, we have also shown that OFS feeding results in a reduced capacity of isolated hepatocytes to incorporate free fatty acids into cellular triglycerides. Within the period of observation, no effect on secretion of newly synthesized triglycerides occurred.

The observation that reduced serum triglyceride, phospholipid and cholesterol levels were mainly due to a decrease in the number of VLDL particles, together with the results of our *ex vivo* experiments, supports the hypothesis that OFS feeding, like that of other fermentable dietary fibers (20), significantly alters the metabolism of lipids in the liver with, as a likely consequence, a reduction in VLDL production. Such an effect has also been demonstrated for lovastatin treatment (21). However, an increase in the catabolism of VLDL by lipoprotein lipase, as observed with fibrates, cannot, as yet, be discounted.

The observation that hepatocytes isolated from OFS-fed rats had a lower capacity than those from control rats to incorporate [1-^{14}C]palmitate into cellular triglycerides still needs to be explained. Since the activity of palmitoyl-CoA synthetase was not changed, we postulate that the availability of acyl-CoA is modified in the hepatocytes of OFS-fed rats. Two possibilities could be explored: either the pattern of esterification of acyl-CoA could be altered or the catabolism of acyl-CoA to ketone bodies could be stimulated. In the latter case, regulation of the key enzyme carnitine acyltransferase would likely be involved. Whatever metabolic change is responsible for the hypolipidemic effect, however, one must still explain how a nondigestible carbohydrate can regulate systemic lipid metabolism if, as shown in this study, it has no significant effect on the fecal excretion of lipids. The most likely mediators of such an effect may be the SCFA and/or lactate which are produced in significant amounts by fermenting bacteria. These carboxylic acids are absorbed through the intestinal membrane and reach the liver. Moreover, they have already been shown to act as regulators of key hepatic meta-

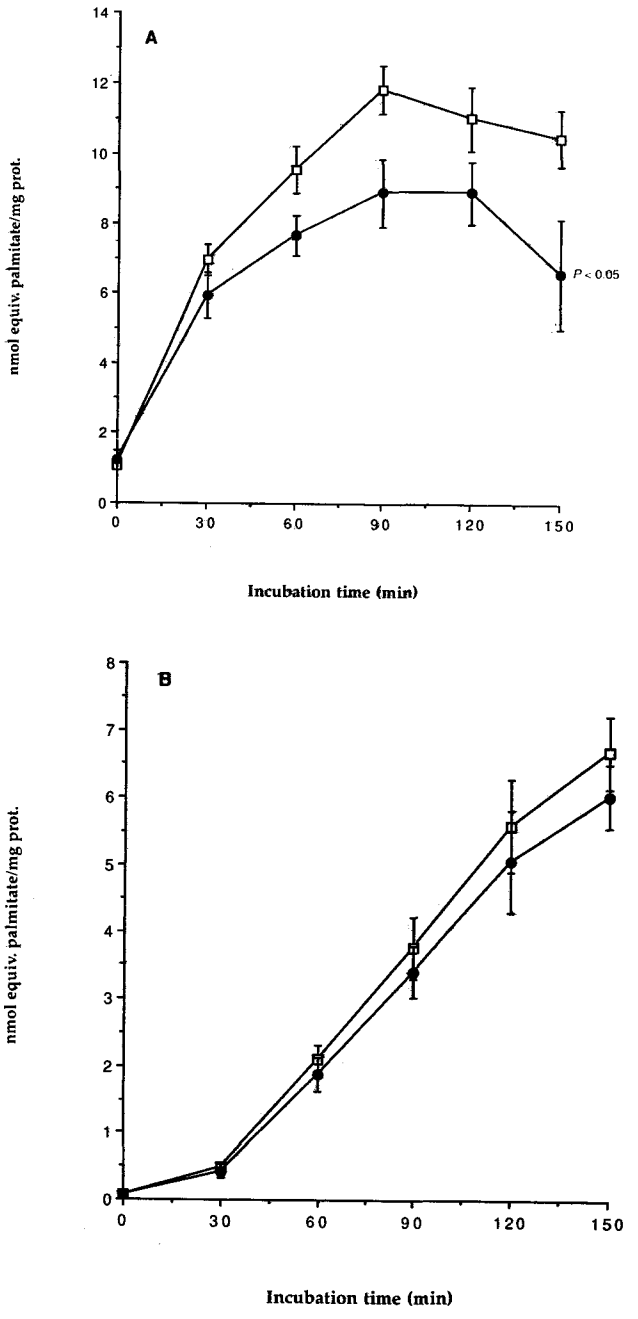

FIG. 3. Effect of oligofructose (OFS) feeding on the capacity of isolated hepatocytes to incorporate [1-^{14}C]palmitate into cellular triglycerides (A) and to secrete [^{14}C] very low density lipoprotein (VLDL) into the culture medium (B). Hepatocytes from control (□) or OFS-fed rats (●) were incubated for 150 min in Dulbecco's medium and analyzed as described in the Materials and Methods section. Variance analysis based on a two-way analysis of variance was used to test time/treatment interaction which showed statistically significant changes ($P < 0.05$) for OFS feeding for incorporation into cellular triglycerides (A) but not for VLDL release (B).

bolic pathways (22). Studies are in progress to test these hypotheses and, in particular, the role of the liver in mediating the hypolipidemic effect.

ABSTRACT: A neutral lipid class was isolated by thin-layer chromatography from the skin surface lipids of the hairless mouse. The fraction migrated faster than triglycerides and had a migration rate similar to that of diacyl alkanediols (diester wax). Upon deacylation, however, the long-chain diols were identified as 1-alkylglycerol ethers based on their chromatographic properties and on the mass spectra of their nicotinylidene derivatives. Thus, the skin lipid fraction was identified as 1-*O*-alkyldiacylglycerol. The alkyl moieties were all saturated and even-numbered and ranged in chainlength from C_{16} to C_{22} with 1-*O*-hexadecylglycerol amounting to 34% of the total glycerol ether moieties. The fatty acids derived from this lipid fraction were mostly monoenoic with chainlengths ranging from C_{16} to C_{24}. The major acyl component was eicosenoic acid (20:1) representing 61% of the total fatty acids.
Lipids 30, 169–172 (1995).

A number of studies have been undertaken to characterize the skin surface lipids of mammalian species (1–6). In the course of our study on the lipid and fatty acid compositions of the skin surface lipids of the hairless mouse, a neutral lipid fraction was isolated by thin-layer chromatography (TLC). The neutral lipid migrated closely with diacylated glycerol ethers and showed a somewhat lower mobility than diester wax.

Downing and Sharaf (6) had described the presence of alkyldiacylglycerols in the skin surface lipid of guinea pig. On the basis of its migration rate on TLC, the unidentified lipid we isolated from the skin surface of the hairless mouse appeared to be similar to alkyldiacylglycerol. The present study was undertaken to confirm the presence of these neutral glycerol ether lipids in the skin surface of the hairless mouse.

MATERIALS AND METHODS

Chemicals. 1-*O*-Hexadecyl-2,3-dipalmitoyl-*rac*-glycerol and 1,2-di-*O*-hexadecyl-3-palmitoyl-*rac*-glycerol were purchased from Sigma Chemical Company (St. Louis, MO); 3-pyridine carboxaldehyde was from Aldrich Chemical Company (Milwaukee, WI). Other reagents used were all guaranteed grade and were purchased from Nacalai Tesque (Kyoto, Japan).

Extraction of the skin surface lipids of the mouse. Hairless mice (21–45 weeks old) were purchased from Japan SLC, Inc. (Shizuoka, Japan), and housed in stainless-steel cages at 25 ± 2°C under a 12-h light/dark cycle with light from 0800 to 2000 h. The animals were anesthetized with diethyl ether, and the skin surface lipids were extracted as described previously in detail (7). Briefly, reagent grade ethanol (20 mL) was poured over the back of the animals in such a manner that as little solvent as possible flowed over the ears, mouth and anal regions. The back was then repeatedly rinsed with ethanol which was collected in Petri dishes. After removing hair and other debris by filtration, the extract was brought to dryness on a rotary evaporator, redissolved in hexane, and stored at –20°C.

TLC. For the preparation of alkyldiacylglycerol, the skin surface lipids were applied to precoated silica gel plates (Merck, Darmstadt, Germany), and the plates were developed successively with hexane, benzene and hexane/diethyl ether/acetic acid (70:30:1, by vol). Lipid fractions were extracted from the silica gel with chloroform/methanol (2:1, vol/vol).

For analytical purposes, high-performance thin-layer chromatography (HPTLC) plates (Merck) were used. Chromatograms were sprayed with 50% sulfuric acid and were visualized by charring at 120°C for 15 min.

Gas chromatography/mass spectrometry (GC/MS). Alkyldiacylglycerols isolated by TLC were hydrolyzed in ethanolic alkali (0.5 N KOH in 94% ethanol) at 40°C for 60 min. The fatty acids derived were methylated by heating with 5% anhydrous hydrogen chloride in methanol. The fatty acid methyl esters (5 to 10 μg) were analyzed on a gas chromatograph (GC 14A; Shimadzu, Kyoto, Japan) equipped with a flame-ionization detector. A fused silica capillary column (CBP1-M50-025, 0.2 mm inner diameter × 50 m length; Shimadzu) was used with nitrogen serving as carrier gas at a flow rate of 0.35 mL/min. The column temperature was programmed from a hold at 50°C for 1 min, to 100°C at a rate of 10°C/min, and then further raised to the final temperature of 270°C at a rate of 5°C/min.

The fatty acids derived from alkyldiacylglycerols were also characterized by MS of their picolinyl esters. Picolinyl esters

of fatty acids were prepared as described previously (8). Fatty acids (200 μg) were dissolved in 0.1 mL of thionyl chloride and left to stand at room temperature for 1 min. The reagent was then evaporated to dryness under a nitrogen stream. A dilute solution of pyridyl carbinol (0.1 mL,1%) in acetonitrile was added, and the mixture was allowed to stand for 1 min. The mixture was then brought to dryness, and the reaction products were extracted into 20 μL of ethyl acetate. Aliquots of this extract were injected into the gas chromatograph.

The deacylation products obtained from alkyldiacylglycerols were converted into their nicotinylidene derivatives as described previously (9,10). For the present purpose, the non-saponifiable lipid extract containing alkylglycerol (about 300 μg) was evaporated to dryness. The sample together with 0.2 mL of *p*-toluenesulfonic acid (2 mg/mL acetonitrile) and 0.3 mL of freshly prepared pyridine-3-carboxyaldehyde (4 mg/mL acetonitrile) was kept at 90°C overnight, cooled, and diluted with 1 mL of water. The products were extracted with 1 mL ethyl acetate, the extract washed successively with water (1 × 1 mL) and saturated aqueous sodium chloride solution (2 × 1 mL), and dried over anhydrous sodium sulfate.

Both picolinyl and nicotinylidene derivatives were then analyzed by GC/MS. The mass spectrometer used was a Shimadzu GC/MS-QP1000EX. The column used was the same as described above and was operated with helium as carrier gas at a flow rate of 0.38 mL/min. The column temperature was programmed from a hold at 50°C for 1 min, to 100°C at a rate of 10°C/min, and then further raised to the final temperature of 300°C at a rate of 5°C/min. Ionization of samples was by electron impact at 70 eV.

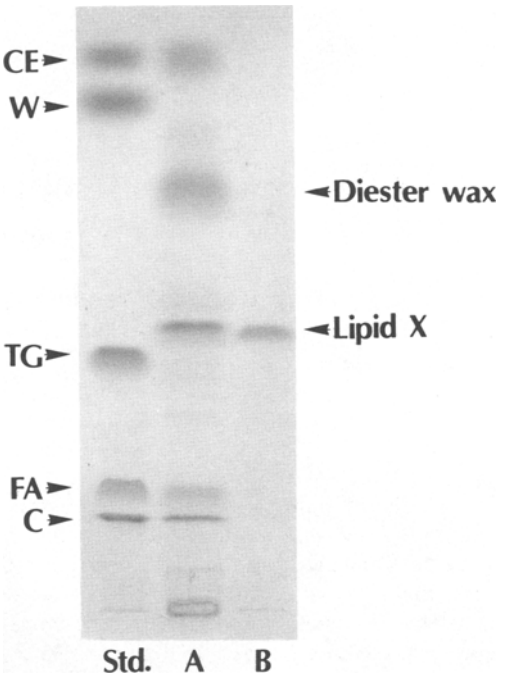

FIG. 1. High-performance thin-layer chromatography chromatogram of the skin surface lipids of the hairless mouse (lane A), 1-*O*-hexadecyl-2,3-dipalmitoyl-*rac*-glycerol (lane B), and of standards (Std.). The plates were developed successively with hexane, then with benzene to the top, and finally to half plate height with hexane/diethyl ether/acetic acid (70:30:1, by vol). The chromatogram was sprayed with 50% sulfuric acid and charred at 120°C for 15 min. Standards used were C, cholesterol; FA, fatty acid (oleic acid); TG, triglyceride (triolein); W, wax (stearyl oleate); CE, cholesteryl ester (cholesteryl oleate).

RESULTS

Figure 1 shows the HPTLC pattern of the skin surface lipids of the hairless mouse (lane A) together with alkyldiacylglycerol (lane B) and standards (Std.). A lipid fraction is seen in the region where alkylglycerides migrate, and it was tentatively named lipid X. This lipid accounted for about 15% of the total skin surface lipids of the hairless mouse as determined densitometrically.

Figure 2 shows the gas chromatogram of the nicotinylidene derivatives of the diols derived from lipid X (A) and diester wax (B). Consistent with previous observations, the nicotinylidene derivatives of alkanediol and monoalkylglycerols exhibited pairs of peaks due to the presence of diastereomers (*cis*- and *trans*-form, see Ref. 9). The isomer eluting earlier would be expected to be the *cis*-form due to its more compact nature. The nicotinylidene derivatives of the diols derived from lipid X were clearly distinguishable from those derived from diester wax. The peaks shown in the figure were identified by comparison of their retention times with those of authentic standards and based on their mass spectra as discussed in the following paragraphs.

Figure 3 shows the mass spectrum of fraction a1 (see Fig. 2A) in panel A and of the nicotinylidene derivative of 1-*O*-hexadecylglycerol in panel B, confirming the identity of the two compounds. The diagnostic ions of ether compounds are the fragment ions X, Y and Z. The formation of these fragments is illustrated in Figure 4A. The mass spectra of fractions b and c in Figure 2 showed similar fragmentation patterns and also exhibited the abundant diagnostic ions X, Y and Z. Thus, the peaks a–c were identified as the nicotinylidene derivatives of monoalkylglycerols with alkyl chains of 16, 18 and 20 carbons long.

Ions separated by 14 mass units are seen in the region between the molecular ion (M^+, m/z = 405) and the ion at m/z = 194. The ion at $[M - 15]^+$ had been of minimal intensity in the previous study (9) and was not seen in the present study. The mass spectrum shown in Figure 3A thus reflects the straight chain structure of 1-hexadecylglycerol. The base peak was the fragment at m/z = 57. The ratios of the intensities for the fragment X, Y and Z to that of peak m/z = 108 were 0.52, 0.20 and 0.44, respectively.

The mass spectra of peak c1 in Figure 2B and of the nicotinylidene derivative of hexadecane-1,2-diol are given in Figures 5A and B, respectively. The fragmentation pattern of peak c1 was quite similar to that of the nicotinylidene derivative of hexadecane-1,2-diol except for the presence of parent ion M^+ at m/z = 403. Peak c1 was therefore identified as the nicotinylidene derivatives of eicosane-1,2-diol (M^+, m/z = 347). A mechanism for the formation of these ions is proposed

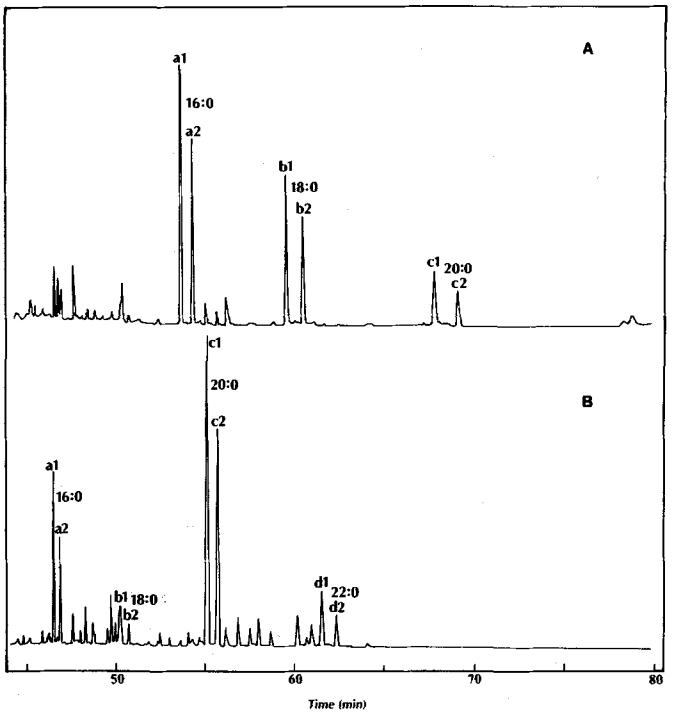

FIG. 2. Gas chromatograms of the nicotinylidene derivatives of the deacylated products derived from lipid X (A) and diester wax (B). The chainlengths for the alkyl ether group (A) and the diol (B) were determined by gas chromatography/mass spectrometry. Fractions a, b and c in panel A are the nicotinylidene derivatives of alkylglycerols with alkyl chainlengths of 16, 18 and 20 carbon atoms, respectively. Fractions a, b, c and d in panel B are the nicotinylidene derivatives of alkanediols with chainlength of 16, 18, 20 and 22 carbon atoms, respectively.

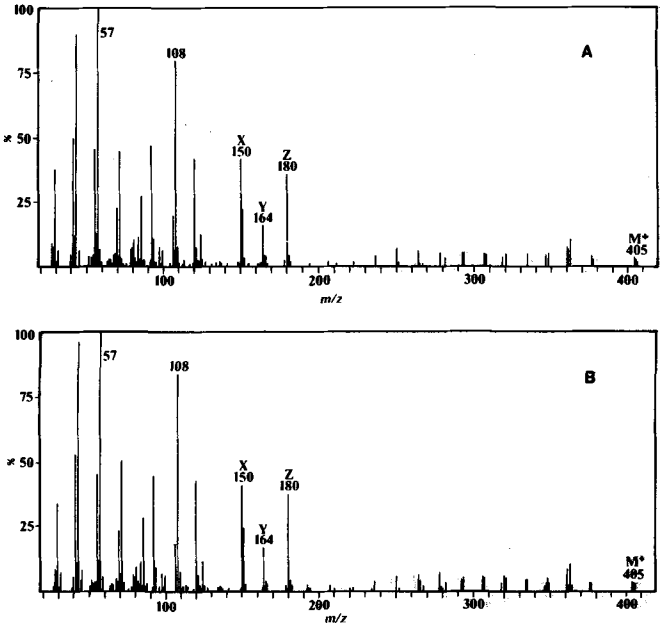

FIG. 3. Mass spectra of fraction a1 in Figure 2A (A) and the nicotinylidene derivative of 1-hexadecylglycerol (B). The ordinate is the abundance relative to the base peak (m/z = 57).

in Figure 4B. In this case, the fragment Z (m/z = 180) was not detectable. The relative intensity to that of the base peak m/z = 108 was 0.1 for fragment X (m/z = 150) and 0.02 for fragment Y (m/z = 164). The spectrum thus did not contain the diagnostic ions for alkylglycerol. As was the case for alkylglycerol, no evidence for the presence of methyl substitution in *iso*-position was apparent from the spectrum. A series of straight-chain alkane-1,2-diols with chainlengths of C_{16}–C_{22} were identified, as is shown in Figure 2B.

Table 1 lists the alkylglycerol and fatty acid composition of lipid X which is now identified as a mixture of monoalkyldiacylglycerols. The *O*-alkyl moieties of this lipid were mainly saturated, straight chains of C_{16}–C_{22}. The picolinyl esters of the fatty acids were analyzed by GC/MS and identified as shown in Table 1. The monoalkyldiacylglycerols contained fatty acids with chainlengths of C_{16}–C_{24}. The sum of the monoenoic fatty acids was about 73%, with 61% consisting of 20:1. Appreciable amounts of *iso*-fatty acids were present whereas only traces of *anteiso*-fatty acids were detectable.

Table 2 presents the diol and fatty acid composition of the diester wax. All the alkanediols identified had saturated and straight carbon chain structures with chainlengths of C_{16}–C_{22}. The most prominent component was eicosane-1,2-diol amounting to 48% of total alkanediols. The fatty acids of the diester wax showed less unsaturation than those of the alkyldiacylglycerols. The sum of monoenoic fatty acids was about 38%. In contrast to the alkyldiacylglycerols, the diol diester wax contained branched-chain fatty acids in significant proportions. The *iso*-series of branched-chain fatty acids (20%) predominated over the *anteiso*-series (2%) in this lipid class.

DISCUSSION

The presence of monoalkyldiacylglycerol has been shown here in the skin surface lipids of the hairless mouse for the

first time. Skin surface lipids have previously been analyzed in several mammalian species, including the mouse. Nicolaides *et al.* (11) had reported that there are two types of diol diester waxes in the skin surface lipids of the mouse, namely a slower and a faster migrating fraction in TLC, although no structural evidence was presented. The lesser mobility of the slower migrating fraction was attributed to the abundance of unsaturated fatty acids and branched-chain alkanediol.

The skin lipid profile of the hairless mouse shown in the present study is quite similar to that described by Nicolaides *et al.* (11) for the mouse. On the basis of its mobility in TLC, the lipid identified as alkyldiacylglycerol in the present study appeared to correspond to the lower mobility diester wax

which the earlier authors considered a subclass of diacyl alkanediol. It has been noted that a certain diversity exists in the skin surface lipids between different animal species (11,12). Reevaluation of these data suggests that the skin surface lipids of several animals seem to contain the lipid class with a mobility in TLC similar to that of diacylated glycerol ethers. Thus, glycerol ether diesters may be rather common on the skin surface of animals.

Although little is known about the physiological significance of the ether lipid, the presence of an ether linkage in its structure may hinder hydrolysis by the bacterial enzymes present on the skin surface. The relative stability of these compounds, would also explain the lower levels of free fatty acids in the skin surface lipids of animals.

Analysis of Triglycerides Using Atmospheric Pressure Chemical Ionization Mass Spectrometry

Wm. Craig Byrdwell* and Edward A. Emken

FQS, NCAUR, ARS, USDA, Peoria, Illinois 61604

ABSTRACT: Atmospheric pressure chemical ionization (APCI) mass spectrometry was investigated as a new method for analysis of a mixture of triglycerides separated by reverse-phase high-performance liquid chromatography. A mixture of homogeneous (monoacid) triglyceride standards containing fatty acids with zero to three double bonds was analyzed to demonstrate the quality of mass spectra obtained by using the APCI interface. The mass spectra showed that minimal fragmentation occurs, resulting primarily in diglyceride $[M - RCOO]^+$ ions and $[M + 1]^+$ protonated molecular ions. The degree of unsaturation within the acyl chains had a marked effect on the proportion of diglyceride ions vs. the $[M + 1]^+$ ions formed in the APCI source. The mass spectra of triglycerides containing fatty acids with two or three double bonds showed predominantly protonated triglyceride ions, with diglyceride peaks representing 13 to 25% of the base peak. The triglycerides containing singly unsaturated fatty acids gave diglyceride ions as the base peak, and $[M + 1]^+$ ions with an intensity 20 to 28% that of the base peak. Only diglyceride ions were observable in the spectra of triglycerides containing saturated fatty acids.

Lipids 30, 173–175 (1995).

Separated (1–6), fractionated (7–9) and unseparated (10–20) mixtures of triglycerides (TG) have been analyzed using direct inlet introduction (1–4,6), desorption chemical ionization (9,19, 20), direct insertion probe introduction (7,8,10–14), electrospray (18) and other (5,15–17) mass spectrometric methods. The use of electron impact ionization methods for analysis of TG generally results in spectra containing low-molecular weight fragments, with no quasimolecular ions present. Spectra of TGs obtained using desorption chemical ionization methods show increased amounts of quasi-molecular ions, while retaining moderate fragmentation, which can be useful for structural assignment. Desorption chemical ionization, however, is not amenable to use for direct detection in a high-performance liquid chromatography (HPLC) flow system. Direct insertion probe methods can provide spectra containing minimal fragmentation, with primarily diglyceride and TG ions. These spectra may readily allow identification of a number of molecular species of TG. However, direct probe introduction is also not amenable to direct detection in a flow system. Direct inlet introduction allows direct detection in an HPLC system and also produces spectra that contain sizeable quasimolecular ions and minimal fragmentation. It has been demonstrated to be an effective interface for TG analysis (1–4,6). Electrospray ionization (ESI) has been used for analysis of a mixture of TGs infused *via* syringe pump (18). Spectra obtained using ESI contained only quasimolecular ions, with no fragmentation. This lack of fragmentation can result in ambiguity in structural assignments for TG of identical molecular weight. Tandem mass spectrometry/mass spectrometry (MS/MS) could provide the additional structural information necessary to uniquely identify TG species. Collision-induced dissociation can also be used to produce lower molecular weight ions. The flow rates used for syringe pump infusion are very low compared to those in a conventional HPLC flow system. The necessity of an ionic buffer in the effluent for ESI will affect the types of columns and solvents which may be used. Alternatively, a sheath liquid may be used to provide the necessary ionic buffer. In either case, the ESI–MS detectability is based on the ability to ionize the neutral TG in solution. So, while preliminary results of use of ESI for detection of nonpolar TG are encouraging, further data will be necessary for a thorough comparison of ionization methods in an HPLC system.

Atmospheric pressure chemical ionization (APCI), like ESI, is an atmospheric pressure ionization method (21). However, unlike ESI, APCI uses a corona needle discharge to impart charge onto vaporized molecules which are sprayed from a capillary inlet. These are swept into the high vacuum region of the mass spectrometer through a capillary bleed. Also unlike ESI, APCI requires no buffers in solution in order to produce efficient fragmentation. This lack of need of a buffer allows neutral, nonpolar molecules to be analyzed as easily as more polar molecules which are ionizable in solution. An APCI interface allows direct introduction of HPLC column effluent at a rate of up to 2 mL/min.

Presented here is the first report of an APCI interface for the direct mass spectrometric analysis of TG standards. We demonstrate that, because of minimal fragmentation, APCI is

an effective method for identification of TG species separated by reverse phase HPLC (RP-HPLC).

MATERIALS AND METHODS

TG. Individual TG standards were obtained from Nu-Chek-Prep (Elysian, MN). A TG mixture was made by dissolving 25–37 mg of each TG (liquid or solid) in 5 mL of tetrahydrofuran, for a total concentration of 57.0 mg/mL. The following homogeneous (monoacid) TG were included in the mixture: tripalmitin (tri 16:0, PPP), tripalmitolein (tri 16:1, PoPoPo), tristearin (tri 18:0, SSS), triolein (tri 18:1, OOO), trilinolein (tri 18:2, LLL), trilinolenin (tri 18:3, LnLnLn), triarachidin (tri 20:0, AAA), trigadolein (tri 20:1, GGG) and trierucin (tri 22:1, EEE).

Chromatography. All solvents were purchased from Aldrich Chemical Co. (Milwaukee, WI). Solvents were HPLC grade or the highest available quality and were used without further purification. The HPLC pump was an LDC 4100 MS (Thermo Separation Products, Schaumburg, IL) quaternary pump system with membrane degasser. The columns used were an Adsorbosphere C18 (Alltech Associates, Deerfield, IL), 25 cm × 4.6 mm, 5 μm (12% carbon load) in series with an Adsorbosphere UHS C18 25 cm × 4.6 mm, 10 μm (30% carbon load). A gradient solvent program with propionitrile (PrCN) and hexane (Hex) was used to accomplish the separations. The gradient used was as follows: initial 88% PrCN, 12% Hex; linear from 10 to 15 min to 75% PrCN, 25% Hex, held until 25 min; linear from 25 to 30 min to 50% PrCN, 50% Hex, held until 40 min. The flow rate was 1 mL/min. The flow was split so that ~600 μL/min went to an evaporative light-scattering detector (ELSD) and ~400 μL/min went to the APCI interface. 5 μL of the TG mixture was injected, which resulted in ~114 μg of total TG mixture (10 to 15 μg of each component) going to the APCI interface. High signal-to-noise ratios in the mass spectra indicate that usable spectra may be obtainable using perhaps a hundred-fold less sample. However, the total ion chromatographic signal-to-noise ratio is much lower, so smaller samples necessitate greater reliance upon the ELSD chromatogram.

The ELSD was an ELSD MKIII (Varex, Burtonsville, MD). The drift tube was set at 140°C, the gas flow was 2.0 standard liters per minute. High-purity N_2 was used as the nebulizer gas.

MS. A Finnigan MAT (San Jose, CA) SSQ 710C fitted with an APCI source was used to acquire mass spectral data. The vaporizer was operated at 240°C; the capillary heater was operated at 250°C. The corona voltage was set at 5 μA. High-purity nitrogen was used for the sheath and auxiliary gases, which were set to 55 psi and 5 mL/min, respectively. Spectra were obtained from 400 to 1100 amu, with a scan time of 2.5 s. Preliminary data showed no substantial ions below 400 amu. The total ion chromatogram was processed using the data system's automatic seven-point smoothing and peak label functions. A peak threshold of 1% intensity was applied to the mass spectra.

RESULTS AND DISCUSSION

The reconstructed ion chromatogram (RIC) of the separated TG mixture is presented in Figure 1. The chromatogram obtained from the ELSD is similar to the RIC and is not presented here. Representative mass spectra of monoacid TG containing 3, 2, 1 and 0 sites of unsaturation in the acyl chains are shown in Figure 2. The mass spectra of the TG showed very little fragmentation. The most significant fragments present in these spectra arose from the protonated molecular ion $[TG + 1]^+$ and the diglyceride (DG) ion $[M - RCOO]^+$, or $[DG]^+$. The TG that contained two or more sites of unsaturation (LnLnLn and LLL) in the fatty acyl chains gave a $[TG + 1]^+$ base peak. The $[DG]^+$ peak of those TG had an intensity of approximately 20 to 35% that of the base peak. Those TG containing less than two sites of unsaturation in each acyl chain showed a base peak arising from the DG ion. TG that contained one site of unsaturation in each of the acyl chains (PoPoPo, OOO, GGG, EEE) showed a $[DG]^+$ base peak, with a $[TG + 1]^+$ peak intensity which was 15 to 20% that of the base peak. Completely saturated TG produced no detectable $[TG + 1]^+$ peak. The spectra of these TG consisted solely of $[DG]^+$ fragments. Spectra of most TG showed minor peaks representing the addition of water to the DG and/or TG ion, $[DG + 18]^+$ and/or $[TG + 1 + 18]^+$. Adduct formation of some TG with the propionitrile solvent was also observed with the appearance of $[TG + 1 + 55]^+$ ions.

The variation with respect to molecular ion and fragment ion abundances that we observed in these spectra due to varying degrees of unsaturation has been observed using other ionization methods (1,2,8,11,19). This variation in ion intensities has necessitated the use of response factors, or calibration factors, for quantitation. Quantitation from spectra obtained with APCI will likewise require the use of calibration factors. For qualitative analysis, however, APCI spectra allowed direct identification of numerous TG species.

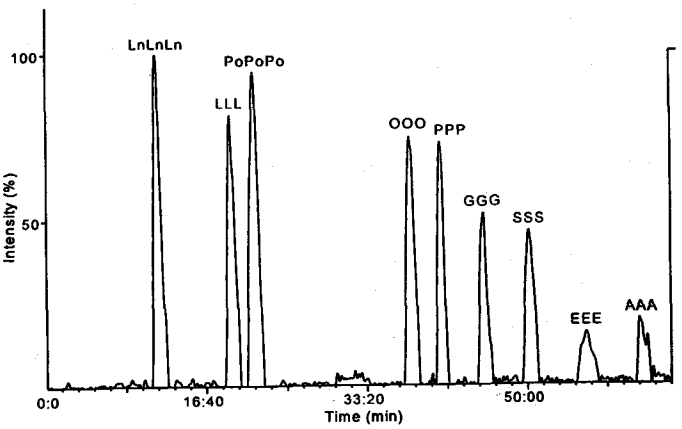

FIG. 1. Total ion chromatogram of triglyceride mixture. Order of elution: trilinolenin (LnLnLn), trilinolein (LLL), tripalmitolein (PoPoPo), triolein (OOO), tripalmitin (PPP), trigadolein (GGG), tristearin (SSS), trierucin (EEE), triarachidin (AAA).

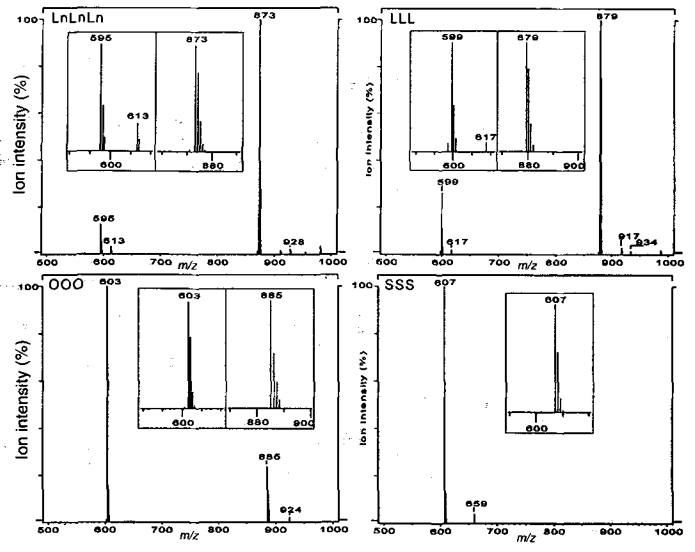

FIG. 2. Mass spectra of LnLnLn, LLL, OOO and SSS. See Figure 1 for abbreviations.

These results clearly show the utility of APCI as an ionization method for TG analysis. The compatibility of APCI with a nonpolar chromatographic solvent system allows an expanded range of molecules to be analyzed, compared to the other widely used atmospheric pressure ionization method, ESI. While the APCI source did not give molecular ions as does ESI for trisaturated TG, the simple fragmentation pattern of all species allowed identification by the DG fragments.

Incorporation of *all-trans*- or 9-*cis*-β-Carotene into Mixed Micelles *in vitro*

Galit Levin and Shoshana Mokady*

Department of Food Engineering and Biotechnology, Technion—Israel Institute of Technology, Haifa 32000, Israel

ABSTRACT: Various studies suggest that *all-trans*- and 9-*cis*-β-carotene are absorbed in the intestine to different extents. The present study was undertaken to evaluate the degree of *in vitro* incorporation of the two isomers into intestinal mixed micelles, which is an essential early step in the absorption process. The micelles were designed to simulate those present during fat digestion in the lumen of the human small intestine with respect to bile salts, lipids, pH and temperature. Solutions of *all-trans*- and 9-*cis*-β-carotene at various ratios were added to the lipid mixture. A direct correlation was seen between the 9-*cis*-β-carotene level in the mixture and the degree of total β-carotene incorporation into micelles. An increased level of *all-trans*-β-carotene in the system led to a decrease in the percentage of β-carotene incorporated into the micelles. In contrast, when carotene mixtures enriched with the 9-*cis* isomer were used, an increase in the level of total carotene in the solution was accompanied by a constant or even enhanced carotene incorporation. The results indicate that the differences in the absorption of β-carotene isomers might be the result of their different ability to be incorporated into the lipid micelles of the intestinal lumen. In addition, the results point toward the possibility that ingestion of 9-*cis*-β-carotene by humans may increase carotene availability.

Lipids 30, 177–179 (1995).

In recent years β-carotene has been suggested to be an important antioxidant and anticancer agent (1). Due to its hydrophobic nature, β-carotene is incorporated in the intestine into the lipid mixed micelles, and then absorbed (2). The efficiency of *all-trans*-β-carotene absorption in humans is quite low (10–15%) (3).

Fruits and vegetables are known to contain, in addition to *all-trans*-β-carotene, varying amounts of the 9-*cis* isomer (4). In our laboratory, the metabolism of the 9-*cis*-β-carotene stereoisomer in living organisms is being studied using the alga *Dunaliella bardawil* as a source of 9-*cis*-β-carotene (5–7). We have recently shown that the 9-*cis* isomer may possess better antioxidant properties than the *all-trans* isomer (8). Therefore, its absorption characteristics in the small intestine, especially in humans, is of considerable interest.

Abbreviations: HPLC, high-performance liquid chromatography; THF, tetrahydrofuran.

Previous studies had indicated that there are species-specific differences in the ability to absorb various carotenoids (9). It is now well accepted that the solubilization of carotenoids in intestinal lipid micelles is a prerequisite for their absorption. The species differences in carotenoid absorption might therefore be due to the ability in a given species to form a suitable micellar solution in the intestinal lumen with one carotenoid but not with the other (9). We recently suggested (7) that there are differences between rats and chicks in the absorption pattern of *all-trans*- and 9-*cis*-β-carotene. However, no information is available in regard to these luminar events in humans.

In the present study, the incorporation of *all-trans*- and 9-*cis*-β-carotene into mixed micelles was examined *in vitro.* Conditions were maintained similar to those thought to be present in the lumen of the human small intestine during fat digestion and absorption with respect to bile salts, Na^+, lipid concentration, pH and temperature (10).

MATERIALS AND METHODS

Carotene extraction and purification. Spray-dried *D. bardawil* (NBT, Eilat, Israel) was extracted with a mixture of 30% ethanol (95%) and 70% hexane (vol/vol), followed by three additional extractions with hexane. Following evaporation of the solvents and saponification, the pigments were transferred into hexane, washed with water, and the extract was filtered to remove crystals of *all-trans*-β-carotene. The extract was further purified (8) by high-performance liquid chromatography (HPLC) on a C18 reverse-phase preparative column and a guard column (218TP1022 and 201FSK54 respectively; Vydac, The Separation Group, Hesparia, CA). The product obtained was composed of 85.7% 9-*cis*- and 14.3% *all-trans*-β-carotene. The carotenes were taken up in tetrahydrofuran (THF) and brought to 1.6 mM. Synthetic *all-trans*-β-carotene (Type I; Sigma, St. Louis, MO) was dissolved in THF at the same concentration. Mixtures of the two β-carotene solutions with 9-*cis*-β-carotene concentrations of 5, 23, 47.5, 62.5 and 85.7% (wt/vol) were prepared.

Preparation of mixed micelles. Mixed micelles containing the β-carotenes were prepared by the method of Canfield *et al.* (11). Briefly, a solution of triolein, monoolein, oleic acid and dipalmitoyl phosphatidylcholine in hexane was mixed

Copyright © 1995 by AOCS Press

with one of the above carotene solutions. The levels of total β-carotene in the solutions were 40, 80, 120, 160, 200 and 240 μM. Following evaporation of the solvent, a mixture of bile acids in Krebs-Ringer bicarbonate buffer (pH 7.4) was added. Sonication was carried out at 37°C for 2 h using a bath sonicator (E/MC Fisher, Scientific International, Springfield, NJ). The solution was then centrifuged (106000 × *g*) for 2 h using a Centricon T-2055 ultracentrifuge (Kontron Analytical, Zurich, Switzerland). Solubilization of β-carotene in the lower aqueous phase was taken as evidence for micelle formation (11).

Carotene analysis. Carotene was extracted from the micelles with hexane/ethanol (3:1, vol/vol) (11). The concentration of total β-carotene was determined spectrophotometrically at 472 nm ($E^{1\%}_{1\ cm} = 2262$). The isomeric β-carotene composition in the micelles was assayed by HPLC using an analytical column as described before (7).

Statistical analysis. Differences between group means were determined by Student's *t*-test.

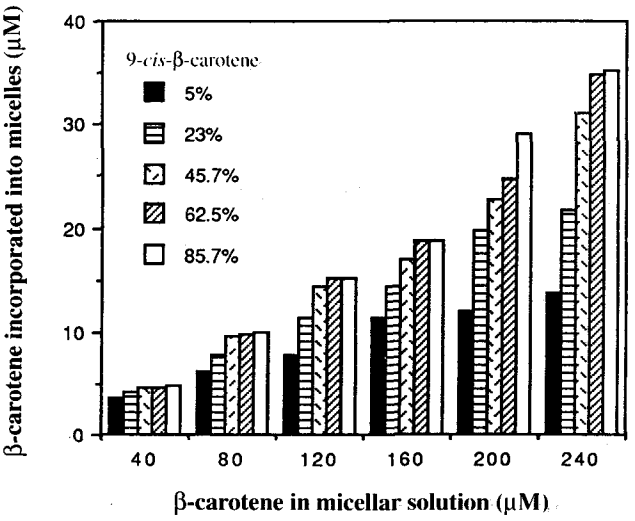

FIG. 1. Effect of 9-*cis*-β-carotene concentration in systems containing various amounts of total β-carotene on the level of total β-carotene incorporated into mixed micelles *in vitro*.

RESULTS

The level of incorporation of β-carotenes into lipid mixed micelles was studied in an *in vitro* system. Larger amounts of β-carotene were incorporated into the micelles when the carotene mixtures contained 85.7% rather than 5% 9-*cis*-β-carotene (Table 1). The differences observed were highly significant at all β-carotene concentrations tested. This enhancement, due to the higher level of 9-*cis*-β-carotene in the solution, was also seen in systems containing identical amounts of total carotene (Fig. 1).

When *all-trans*-β-carotene (5% 9-*cis*-β-carotene) was used at higher levels, the amount of β-carotene that was incorporated into the micelles reached a plateau at approximately 14 μM. However, when carotene mixtures with increasing concentrations of the 9-*cis* isomer were used, a maximal carotene level in the micelles was not reached. On the contrary, an increase in micellar carotene content was observed. This enhancement was most pronounced at the two highest total carotene levels (Fig. 1).

Increased levels of *all-trans*-β-carotene in the solution led to a decrease in the percentage of β-carotene incorporated into the micelles (Fig. 2). In contrast, when the various carotene mixtures enriched with the 9-*cis* isomer were used, an increase in the level of total carotene in the solution was accompanied by a constant or even an enhanced efficiency of β-carotene incorporation.

The isomeric compositions of the micellar β-carotenes was found to be identical to those of the carotene mixtures in the solutions (Fig. 3).

TABLE 1
Incorporation of Total β-Carotene into Mixed Micelles as a Function of Isomeric Composition

β-Carotene concentration in micellar solution (μM)	β-Carotene in micelles (μM)[a]	
	5% 9-*cis*-β-carotene	85.7% 9-*cis*-β-carotene
80	5.85 ± 0.63	9.42 ± 0.37[b]
200	13.73 ± 1.56	26.39 ± 1.58[b]
240	16.28 ± 1.77	37.36 ± 2.64[b]

[a]Mean ± SD of three samples.
[b]Statistically significant effect ($P < 0.01$) of 9-*cis*-β-carotene concentration.

DISCUSSION

In the present study we found that the isomeric composition of the β-carotene mixtures affected the amount of total carotene incorporated into the lipid mixed micelles, simulating those formed in human small intestine. Specifically, the level of incorporation was found to increase in relation with the amount of 9-*cis*-β-carotene in the mixture.

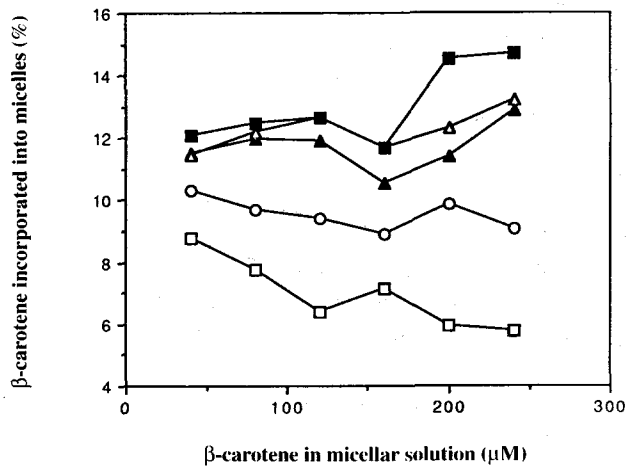

FIG. 2. Efficiency (%) of incorporation of β-carotene into mixed micellar solutions in systems containing various amounts of total β-carotene as a function of 9-*cis*-β-carotene concentration: 5% (□); 23% (○); 45.7% (▲); 62.5% (△); or 85.7% (■).

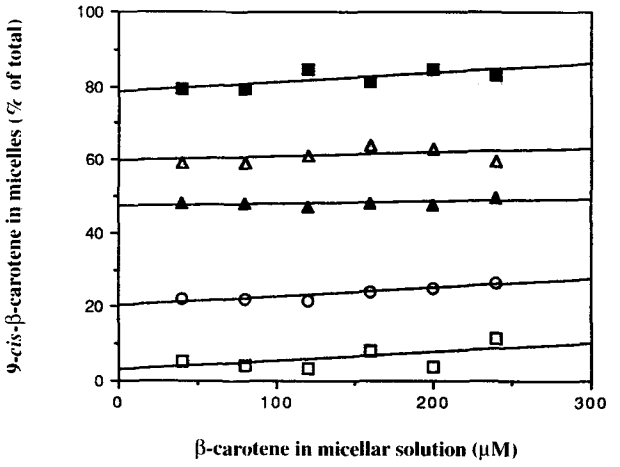

FIG. 3. Isomeric composition of micellar β-carotene in systems containing various amounts of total β-carotene as a function of 9-*cis*-β-carotene concentration: 5% (□); 23% (○); 45.7% (▲); 62.5% (△); or 85.7% (■).

The incorporation of β-carotene into mixed micelles has previously been studied only with *all-trans*-β-carotene. Thus, Canfield *et al.* (11) have shown that the incorporation efficiency decreased with higher amounts of β-carotene in the solution, reaching an upper level of 15 μM, which is in good agreement with the value of 14 μM obtained in the present study.

In experiments with rats and chicks, it was shown that a higher concentration of 9-*cis*-β-carotene in the diet was associated with a reduction in the hepatic carotene levels in rats, while in chicks an increase was observed (7). This was explained by possible differences between the two animal species in the micellar composition, and consequently in the ability to incorporate the various β-carotene isomers, which resulted in differences in the extent of absorption of the isomers. Since a species difference apparently exists, it was not possible to predict the efficiency of the absorption of the two isomers in humans. The present *in vitro* study suggests that 9-*cis*-β-carotene in the human diet might bring about an increase in the amount of total carotene incorporated into micelles, and thus cause an increase in carotene absorption similar to what has been observed in chicks. However, in contrast to chicks in which the hepatic and possibly the micellar 9-*cis* isomer concentration was higher than in the diet, in the micelles simulating those formed in the human intestine, the level of the 9-*cis* isomer was similar to that in the solution.

Although the present study suggests that 9-*cis*-β-carotene can be incorporated into intestinal micelles quite efficiently, it is of importance to note that the absorption of 9-*cis*-β-carotene in the human small intestine has previously been questioned. Jensen *et al.* (12) studied the levels of *all-trans*- and 9-*cis*-β-carotene in human serum following ingestion of *Dunaliella* carotene extract, or carrot extract which contained mostly the *all-trans* isomer. In both dietary treatments, the major isomer found in the serum was *all-trans*-β-carotene, and the ratio between the two isomers was identical. These researchers thus concluded that in humans there is a preferential absorption of the *all-trans*-β-carotene over that of the 9-*cis* isomer. Stahl *et al.* (13) in a more recent study was not able to show the presence of 9-*cis*-β-carotene in human serum following *Dunaliella* consumption. However, analyses of β-carotene isomeric composition in human livers revealed the presence of substantial amounts of 9-*cis*-β-carotene (14). This observation might point to the possibility that 9-*cis*-β-carotene is absorbed in humans but is immediately transferred to and accumulated in tissues and thus is not found in the serum (14). The results of the present study, in which mixed micelles were shown to contain substantial amounts of 9-*cis*-β-carotene, are consistent with this hypothesis. Nonetheless, further experiments are needed to clarify these points.

Effect of Growth Temperature on the Positional Distribution of Eicosapentaenoic Acid and *trans* Hexadecenoic Acid in the Phospholipids of a *Vibrio* Species of Bacterium

R.J. Henderson*, R.-M. Millar and J.R. Sargent

N.E.R.C. Unit of Aquatic Biochemistry, Department of Biological and Molecular Sciences, University of Stirling, Stirling FK9 4LA, Scotland

ABSTRACT: Phosphatidylethanolamine (PE) and phosphatidylglycerol (PG) were isolated from a *Vibrio* species of bacterium, known to produce eicosapentaenoic acid (20:5n-3) and *trans*-hexadecenoic acid (16:1n-7), and subjected to phospholipase A_2 degradation to determine the positional distribution of component fatty acids. At the two growth temperatures studied (20 and 5°C), both 20:5n-3 and *trans* 16:1 n-7 were located mainly at position *sn*-2 in PE. Increases in the proportions of 20:5n-3 and *trans* 16:1n-7 in position *sn*-2 with decreasing growth temperature were balanced mainly by decreases in the level of *iso*-15:0. In PG, *trans* 16:1n-7 was located predominantly in position *sn*-1, although the difference between the two positions was not as great as in PE. Eicosapentaenoic acid was preferentially located in position *sn*-2 of PG, particularly at 5°C when it comprised 29.9% of the total fatty acids in this position. It is concluded that *trans* 16:1n-7/20:5n-3 is not a major molecular species of phospholipid in this species of *Vibrio* and that changes in the levels of molecular species of PE containing *iso*-15:0 may feature in thermal acclimation.

Lipids 30, 181–185 (1995).

It is well established that alterations in membrane lipid composition occur in poikilothermic organisms as an adaptation to changes in the temperature of their environment (1,2). An increase in the level of polyunsaturated fatty acids (PUFA) in phospholipids is an almost ubiquitous response in poikilothermic eukaryotes to a decrease in temperature. Bacteria do not, in general, contain PUFA (3). Temperature-induced adaptations in the fatty acid profile of bacteria that have been noted include increases in the proportions of monounsaturated fatty acids, shorter chain fatty acids and branched-chain fatty acids, as well as changes in the ratio of *anteiso*- to *iso* acids (4–6). Some strains of bacteria contain *trans*-monounsaturated fatty acids in addition to the more common *cis* isomers, and it has been shown that in the psychrophilic bacterium *Vibrio* sp. strain ABE-1, the relative proportion of *trans* 16:1n-7 decreases as a response to a decrease in environmental temperature (7,8).

We have recently reported the simultaneous occurrence of eicosapentaenoic acid (20:5n-3) and *trans* hexadecenoic acid (16:1n-7) in a *Vibrio* species of bacterium isolated from fish intestines and have shown that the level of both these fatty acids in the cellular phospholipids is higher at a growth temperature of 5 than 20°C (9). This increase in the level of *trans* 16:1 with decreasing growth temperature contrasts with the decrease observed with *Vibrio* ABE-1 species (7,8). In the latter species the *trans* fatty acid is known to be located mainly in position *sn*-2 of phosphatidylethanolamine (PE) (8). Although position *sn-2* of the phospholipids of most eukaryotes is characteristically enriched in PUFA (10,11), the C_{18} PUFA of photosynthetic cyanobacteria are known to be specifically located in the *sn*-1 position of phosphatidylglycerol (PG) (12). No information is available for the positional distribution of 20:5n-3 in the phospholipids of bacteria. We have previously postulated that the observed increase in both *trans* 16:1n-7 and 20:5n-3 in the *Vibrio* species with decreasing temperature results from the specific increase in a molecular species of phospholipid containing both these two fatty acids (9), a suggestion which implies that the fatty acids occupy different positions within the phospholipid. The study described here was undertaken to determine the positional distribution of 20:5n-3 and *trans* 16:1n-7 in the phospholipids of the *Vibrio* species of bacterium, which contains both these fatty acids. In addition to determining how the two fatty acids are distributed within the two constituent phospholipids of the *Vibrio* species, PE and PG (9), it was intended to establish whether specific changes in positional distribution occur in response to changes in growth temperature.

MATERIALS AND METHODS

Chemicals. Inorganic chemicals were of AnalaR grade and were supplied by BDH (Lutterworth, Leics., United Kingdom). Solvents were of glass-distilled or high-performance

liquid chromatography (HPLC) grade and were obtained from Rathburn Chemicals (Walkerburn, United Kingdom). Phospholipase A_2 (E.C. 3.1.1.4) prepared from *Naja naja* venom was purchased from Sigma Chemical Co. (Poole, Dorset, United Kingdom).

Growth of bacteria. The bacterium studied was the *Vibrio* species originally isolated from the gut of Arctic char *(Salvelinus alpinus* L.) (13). Cultures of the bacterium were grown under sterile conditions in defatted, freshwater medium in the dark at 20 and 5°C as described previously (9), and harvested during late log phase (24 h and 5 d for cultures at 20 and 5°C, respectively) by centrifugation at 7,000 × *g* for 10 min. Cultures were grown sequentially and did not arise from the same inoculating culture.

Phospholipid analysis. Lipid was extracted from pellets of bacterial cells by blending with chloroform/propan-2-ol (2:1, vol/vol) as described previously (9). All lipid extracts and fractions were maintained at −70°C under an atmosphere of oxygen-free nitrogen between analytical operations. PE and PG were isolated by thin-layer chromatography (TLC) of total lipid extracts on 20 × 20 cm glass plates precoated with silica gel G (E. Merck, Darmstadt, Germany) using chloroform/methanol/water (65:25:4, by vol) as developing solvent. Developed chromatograms were sprayed lightly with 0.01% (wt/vol) 2′,7′-dichlorofuorescein in methanol and viewed under ultraviolet (UV) light. Bands of adsorbent containing PE and PG were scraped separately from the plates and the phospholipids eluted from the adsorbent with chloroform/methanol/water (5:5:1, by vol). After removal of the solvent by evaporation and desiccation under vacuum, the phospholipids were redissolved in chloroform/methanol (2:1, vol/vol) and the purity of aliquots checked by high-performance TLC (HPTLC) on silica gel using chloroform/methanol/water (65:25:4, by vol) as developing solvent.

For the enzymatic hydrolysis of phospholipids, 2.5 mg PE or PG were dissolved in 0.75 mL diethyl ether, and 0.25 mL 0.1M Tris HCl, pH 7.5 containing 4 mM $CaCI_2$ and 20 units of phospholipase A_2, was added. The mixture was stirred vigorously at 30°C for 4 h. Lipids were then extracted from the assay with chloroform/methanol (2:1, vol/vol). After reduction of solvent volume by evaporation, lipid extracts were applied to HPTLC plates which were subjected to single-dimension, double development with methyl acetate/propan-2-ol/chloroform/methanol/0.25% KCl (25:25:25:10:9, by vol) followed by hexane/diethyl ether/glacial acetic acid (80:20:2, by vol) (14). Developed chromatograms were sprayed lightly with 0.01% (wt/vol) 2′,7′-dichlorofluorescein in methanol and viewed under UV light. Bands corresponding to lysoPE or lysoPG and free fatty acids were marked, scraped from the HPTLC plates into test tubes and subjected to acid-catalyzed transesterification with 1% sulfuric acid in methanol to produce the methyl ester derivatives of the constituent fatty acids (15). Aliquots of PE and PG were also subjected directly to acid-catalyzed transesterification. Fatty acid methyl esters were purified by HPTLC on silica gel plates using hexane/diethyl ether/glacial acetic acid (85:1 :1, by vol) as developing solvent and recovered from the adsorbent by elution with hexane/diethyl ether (1:1, vol/vol).

Analyses of fatty acid methyl esters were carried out by gas chromatography using a fused silica capillary column (25 m × 0.32 mm i.d. coated with BPX 70; S.G.E., Milton Keynes, United Kingdom). Sample application was by on-column injection, H_2 was used as carrier gas and the oven temperature was programmed to increase from 50 to 180°C during the course of an analysis. Separated methyl esters were identified by reference to authentic standards and by comparison with previously characterized samples of total fatty acids from the same species (9). The molar amounts of fatty acids were calculated by multiplying the area of each chromatographic peak by the appropriate arithmetic factor (15). The fatty acid compositions of the free fatty acid fraction and the lysophospholipid were considered to represent that of positions *sn-2* and *sn*-1, respectively, of the original intact phospholipid. The accuracy of the positional analysis was considered acceptable when the sum of the concentrations of a given fatty acid in positions *sn*-1 and *sn*-2, divided by two, was within 2% of the value for the fatty acid in the original phospholipid.

Statistical evaluation. Student's *t*-test was used for the statistical analysis of data, and the level of significance was defined as $P < 0.05$.

RESULTS

PE. The fatty acid composition of PE, the major phospholipid of the *Vibrio* (9), was significantly influenced by the temperature at which the bacteria were grown (Table 1). PE of bacteria grown at 5°C contained significantly higher levels of 20:5n-3 and *trans* 16:1n-7 and, conversely, lower levels of *iso*-14:0, *iso*-15:0, 17:0, 18:1n-9 and 18:1n-7 than that isolated from bacteria grown at 20°C. At both growth temperatures, more than half of the fatty acids esterified in position *sn*-1 of PE were saturated, whereas position *sn*-2 contained mainly monounsaturated fatty acids. The bulk of 20:5n-3 was always located in position *sn*-2, which also contained most of the *trans* 16:1n-7 present in PE.

Growth temperature influenced the fatty acid composition of both positions of PE. Bacteria grown at 5°C contained approximately threefold higher levels of both 20:5n-3 and *trans* 16:1n-7 in position *sn*-1 of PE than bacteria grown at 20°C, although these fatty acids together still accounted for only 2.7% of the fatty acids in this position at 5°C. In position *sn*-2, 20:5n-3 and *trans* 16:1n-7 comprised 9.6 and 17.7% of the fatty acids in this position at 5°C as compared to the lower corresponding values of 2.5 and 6.4% at 20°C. Conversely, the level of saturated fatty acids, particularly *iso*-15:0, in position *sn*-2 was lower at 5 than 20°C. The level of the major fatty acid in position *sn*-2, *cis* 16:1 n-7, was not significantly changed by growth temperature although its level in position *sn*-1 was higher at 5 than 20°C (13.8% vs. 7.7%).

PG. As with PE, the overall fatty acid composition of PG was influenced by growth temperature (Table 2). In particu-

[a]Values are mol% and are means ± SD of six cultures. Values at 5°C with superscripts are significantly different from the corresponding 20°C value; [b]$P < 0.05$; [c]$P < 0.02$; [d]$P < 0.01$; [e]$P < 0.002$; [f]$P < 0.001$. *i-, iso; a-, anteiso;* sat., saturated fatty acids; mono.. monounsaturated fatty acids; PUFA, polyunsaturated fatty acids.

lar, the level of monounsaturated and polyunsaturated fatty acids were lower and higher, respectively, at 5 than 20°C. The level of saturated fatty acids, around 28% of total PG fatty acids, was not significantly affected by growth temperature.

Regardless of growth temperature, position *sn*-1 of PG was characterized by a high content of saturated fatty acids, particularly 16:0, and the monounsaturated fatty acids *cis* 16:1n-7 and 18:1n-7. Position *sn*-2 contained less saturated fatty acids than position *sn*-1, but had a higher content of PUFA, in the form of 20:5n-3, and was richer in *cis* 16:1n-7. More *trans* 16:1n-7 was located in position *sn*-2 than in position *sn*-1.

A higher level of 20:5n-3 was present in the *sn*-1 position of PG from the *Vibrio* grown at 5°C (5.6%) than in that of the same phospholipid of bacteria grown at 20°C (1.2%). The level of *trans* 16:1n-7 in position *sn*-1 was also higher at 5 than 20°C (4.2 vs. 1.6%). The fatty acid profile of position *sn*-2 was markedly influenced by growth temperature. In PG of bacteria grown at 5°C, *cis* 16:1n-7 accounted for 24.8% of the fatty acids in position *sn*-2, and this proportion increased to 43.6% at 20°C. In contrast, the content of 20:5n-3 decreased from 29.9% at 5°C to 8.2% at 20°C. The level of 17:1n-8 in position *sn*-2 also increased significantly with increasing growth temperature, and the overall content of monounsaturated fatty acids in this position was substantially higher at 20 than at 5°C. The level of *trans* 16:1n-7 in position *sn*-2 was not significantly influenced by growth temperature. Overall, the temperature-related changes in fatty acid composition of PG were more obvious in position *sn*-2 than in position *sn*-1.

DISCUSSION

It is well established that position *sn*-1 of bacterial phospholipids contains predominantly saturated fatty acids, whereas the *sn*-2 position is enriched in monounsaturated fatty acids (3,5). The data obtained in the present study confirm this pattern and further establish the unsaturated nature of position *sn*-2 by demonstrating that 20:5n-3 is located mainly in this position in both PE and PG in a *Vibrio* species of bacterium containing this PUFA. This is in keeping with the positional distribution patterns observed in eukaryotic phospholipids, where position *sn*-2 generally contains the highest proportion of PUFA (10,11), but is in contrast to the situation in cyanobacteria where C_{18} PUFA are concentrated in position *sn*-1 (12). It is likely that the preferential location of PUFA in the *sn*-2 position of bacterial phospholipids extends to 22:6n-3 in those species of bacteria which can produce this PUFA (16), although this remains to be established.

The finding that most of the *trans* 16:1n-7 in PE of the species of bacterium analyzed here is esterified to the *sn*-2 position of the glycerol moiety is in agreement with a previous

[a]Values are mol% and are means ± SD of six cultures. Values at 5°C with superscripts are significantly different from the corresponding 20° value; [b]$P < 0.05$: [c]$P < 0.02$; [d]$P < 0.01$; [e]$P < 0.002$; [f]$P < 0.001$. *i-, iso; a-, anteiso;* sat., saturated fatty acids; mono., monounsaturated fatty acids; PUFA, polyunsaturated fatty acids.

study of the ABE-1 strain of *Vibrio,* which also contains this *trans*-monounsaturated fatty acid but no PUFA (8). In the species examined here, both *trans* 16:1n-7 and 20:5n-3 are located predominantly in the same position of PE with the level of the *trans* fatty acid exceeding that of the PUFA. It is notable that although the proportions of both fatty acids increased in position *sn*-2 with a reduction in growth temperature, the ratio of *trans* 16:1n-7 to 20:5n-3 was lower at 5°C (1.8) than at 20°C (2.6). This demonstrates that the magnitude of increase in 20:5n-3 in response to decreases in growth temperature is greater than that observed in the *trans* fatty acid.

The increase in the level of 20:5n-3 observed in bacterial phospholipids in response to a decreased growth temperature is in keeping with the frequently reported increases in the degree of unsaturation of phospholipids which occur during the adaptation of poikilothermic animals and plants to a reduced environmental temperature (1,2). However, in marked contrast to the situation observed here, the level of *trans* 16:1n-7 has been reported to be lower at 5°C than at 20°C in the *Vibrio* sp. strain ABE-1 (7,8). This difference in response between the two species of *Vibrio* may be related to differences in the other fatty acids present in PE. In comparison with the species of *Vibrio* examined here, *Vibrio* strain ABE-1 contains a more restricted pattern of fatty acids and, within its PE, changes in *trans* 16:1n-7 are reciprocated almost exclusively by changes in the level of *cis* 16:1n-7 (7,8). In contrast, the *Vibrio* in this study contains a wide range of fatty acids, and the levels of several fatty acids are influenced by growth temperature. In particular, it is notable that the increase in *trans* 16:1n-7 (11 mol%) observed when the bacteria were grown at 5°C compared to 20°C was matched by an almost equivalent decrease in the level of *iso* 15:0. Although the melting point and phase transition temperature of *iso*-15:0 are lower than those of saturated C_{14}–C_{18} straight chain fatty acids, the melting point of *iso* 15:0 (51.7°C) (5) is still higher than that of *trans* 16:1n-7 (32–33°C) (17). Consequently, it may be expected that an increase in the proportion of the latter fatty acid with a lowering of growth temperature would assist in maintaining membrane fluidity.

The observed positional distribution patterns refute our previous suggestion that a *trans* 16:1n-7/20:5n-3 molecular species of phospholipid is involved in temperature adaptation of membranes in this species of bacterium (9). Although the relative amounts of individual molecular species of PE which occurred at the two growth temperatures were not measured directly, it can be deduced from the positional distribution of fatty acids that the principal molecular species of PE at 20°C probably contained 16:0 or *iso*-15:0 in the *sn*-1 position coupled with *iso*-15:0 or *cis* 16:1 n-7 at position *sn*-2. At 5°C, higher proportions of molecular species containing *cis* 16:1n-7 at position *sn*-1 and *trans* 16:1n-7 or 20:5n-3 at position *sn*-2 would have been present. Thus, a *trans*

16:1n-7/20:5n-3 molecular species, if present, would only have been a minor molecular species at both temperatures.

The positional distribution of *trans* fatty acids in PG of bacteria has not been previously reported. Although the present results demonstrate that position *sn*-2 of PG contained more *trans* 16:1n-7 than position *sn*-1, as in PE, the difference between the two positions was not so great as observed with PE. At the same time, the position *sn*-2 of PG was much richer in 20:5n-3 than the same position of PE, and the proportion of 20:5n-3 always exceeded that of *trans* 16:1n-7 regardless of temperature. Because PE and PG both arise from CDP-diacylglycerol in Gram negative bacteria, similarities in fatty acid composition might be expected. However, PG is known to be a highly active substrate in the lipid metabolism of bacteria and has more potential than PE for changing its fatty acid composition (3).

The positional data suggest that the biggest temperature-induced changes in molecular species composition of PG involve those containing 20:5n-3 rather than *trans* 16:1n-7. Thus, at 20°C molecular species of PG containing 16:0 or a *cis* monounsaturated fatty acid coupled with *cis* 16:1n-7 at position *sn*-2 are major molecular species, while a decrease in growth temperature results in an increase in molecular species with 20:5n-3 at position *sn*-2. At the same time, however, small amounts of di-20:5n-3 molecular species may also be formed. Analysis by HPLC of the molecular species of PE and PG is of obvious interest in elucidating thermal adaptation effects in this *Vibrio* species but presents a challenge on account of the constituent levels of odd-chain and branched fatty acids.

In *Vibrio* sp. strain ABE-1, the increase in *trans* 16:1n-7 observed during adaptation to growth at a high temperature is matched closely by the decrease in *cis* 16:1n-7, and the conversion of *cis* to *trans* isomers by an isomerase has been demonstrated when the bacterium adapts to growth at higher temperature in the presence of inhibitors of *de novo* fatty acid synthesis (7,8). However, it is notable that, in the *Vibrio* species studied here, the levels of *cis* and *trans* 16:1n-7 show no inverse relationship in either PE or PG during temperature adaptation, and it remains to be established whether the bacterium can adopt the isomerization of preexisting *cis* 16:1n-7 to its *trans* isomer as a strategy for adaptation to growth at low temperature.

It has been recently shown that, in the phospholipids of some species of lower fungi, n-3 PUFA are located predominantly in position *sn*-1, whereas n-6 PUFA mainly occupy position *sn*-2 (18). This specific positional distribution has been attributed to the Δ15 desaturase having a specificity for the acyl group in position *sn*-1. Although the preferential esterification of 20:5n-3 in position *sn*-2 of *Vibrio* suggests that such a positional specificity of desaturases does not operate in this bacterium, very little is known of the mechanisms of PUFA biosynthesis in bacteria. It remains to be established whether intact phospholipids, as in fungi, plants and protozoa, or acyl thioesters as in animals, serve as substrates for desaturase enzymes in bacteria.

ANNOUNCEMENTS

1995

June

2nd International Congress of the International Society for the Study of Fatty Acids and Lipids, June 7–10, National Institutes of Health, Bethesda, Maryland, USA. Information: A.P. Simopolous, ISSFAL, 2001 S St., N.W., Suite 530, Washington, DC 20009 USA.

18th Nordic Lipid Symposium, June 18–21, Reykjavik, Iceland. Information: G. Lambertsen, Lipidforum Secretariat, Breistølen 1, N-5035 Bergen, Norway (Fax: 4755-325724).

August

36th International Conference on the Biochemistry of Lipids, Aug. 8–11, Georgetown University, Washington, D.C., USA. Information: Ms. Hattie Johnson, Georgetown University, Office of Continuing Professional Education, 2233 Wisconsin Ave., NW, Suite 333, Washington, DC 20007-2197 USA (Phone: 202-687-8735; Toll-Free: 800-382-3613; Fax: 202-687-3019).

September

5th International Congress on Platelet-Activating Factor and Related Lipid Mediators, Sept. 12–16, Berlin, Germany. Information: Dr. S. Nigam, Dept. of Gyn., University-Klinikum Steglitz, Hindenburgdamm 30, 12200 Berlin, Germany (Fax: 8155510).

October

21st World Congress and Exhibition of the International Society for Fat Research, Oct. 1–5, The Hague, The Netherlands. Information: 21st ISF Congress Secretariat, P.O. Box 3489, Champaign, IL 61826-3489 USA (Fax: 1-217-351-8091).

7th Asian Congress of Nutrition, Beijing, China, Oct. 7–11, 1995. Information: Mr. Ma Shi-liang, Chinese Academy of Preventive Medicine, 27 Nan Wei Road, Beijing 100050, China (Phone: 86-1-3022960; Fax: 86-1-3170892).

Regulation of Biosynthesis and Function of Isopentenoids: An Introduction

W. David Nes[a,*] and Edward J. Parish[b]

[a]Department of Chemistry and Biochemistry, Texas Tech University, Lubbock, Texas and [b]Department of Chemistry, Auburn University, Auburn, Alabama

During the AOCS Annual Meeting & Expo at the Atlanta Marriott Marquis in Atlanta, Georgia, which took place May 8–12, 1994, a two-day symposium was held on the "Regulation of Biosynthesis and Function of Isopentenoids." The topics ranged from studies on molecular biology, pathway sequencing and regulation of sterol biosynthesis and function in plants, animals and bacteria, to conformational analyses and the synthesis of biorationally designed, mechanism-based inactivators of sterol production. The four sessions on isopentenoids, including sterols and sterol-like structures, involved more than a dozen invited plenary lectures by experts from academia, industry, and federal laboratories [*INFORM* 5:469–470, 485–486, 493–494, 508–509 (1994)].

This was the ninth AOCS-sponsored symposium held on the topic; the first was organized by the late Henry Kircher and was held during the 1970 AOCS Annual Meeting & Expo in New Orleans. The proceedings of one of these meetings were published as an AOCS monograph in 1991, and six of the symposia were published as units of peer-reviewed papers in *Lipids*. The level of participation over the years at these meetings has been most impressive, and many of the symposia papers that appeared in *Lipids* are frequently cited in the scientific literature. The present issue of *Lipids* contains eleven papers based on Atlanta symposium presentations. They include seven reviews and four original research articles.

We wish to thank Wolfgang J. Baumann, then Editor-in-Chief of *Lipids*, for his special efforts in peer-reviewing and editing the papers and for his willingness to publish this symposium as a unit publication in *Lipids*. His personal attention to each of the papers of this and of the earlier symposia is much appreciated. Finally, we also wish to thank AOCS, Dupont, Marion Merrell Dow, and Johnson & Johnson for their support.

Some New Aspects of Isoprenoid Biosynthesis in Plants—A Review[1]

Thomas J. Bach*

C.N.R.S.-I.B.M.P., Département d'Enzymologie Cellulaire et Moléculaire, Institut de Botanique, Université Louis Pasteur, F-67083 Strasbourg, France

ABSTRACT: Plants are capable of synthesizing a myriad of isoprenoids and prenyl lipids. Much attention has been focused on 3-hydroxy-3-methylglutaryl-CoA reductase (HMGR), the enzyme that synthesizes mevalonate and is generally considered responsible for the regulation of substrate flux to isoprenoids. In contrast to vertebrates, where there seems to exist only one HMGR gene, in plants a small family of isogenes appears differentially expressed in regard to location and time. Much less is known in plants about the preceding steps, *viz.* the conversion of acetyl-CoA to HMG–CoA. An enzyme system has been isolated from radish that can catalyze this transformation, and which shows some unusual properties *in vitro*. The intracellular localization of the early steps of isoprenoid biosynthesis in plant cells is still a matter of debate. The various observations and hypotheses derived from incorporation and inhibition studies are somewhat contradictory, and an attempt is being made to rationalize various findings that do not at first seem compatible. There are good arguments in favor of an exclusively cytoplasmic formation of isopentenyl pyrophosphate (IPP) via mevalonic acid, but other studies and observations suggest an independent formation in plastids. Other possibilities are being considered, such as the existence of independent (compartmentalized) biosynthetic pathways of IPP formation *via* the so-called Rohmer pathway. Substrate channeling through the formation of end product-specific multienzyme complexes (metabolons) with no release of substrate intermediates will also be discussed.

Lipids 30, 191–202 (1995).

A myriad of natural products are derivatives of a common C_5 isoprene unit and are thus classified as isoprenoids. As it is impossible to cover the broad field of plant isoprenoid biosynthesis, I will focus on some recent aspects, which, at first sight, seem incompatible or even in conflict with each other, and may be clarified by being looked at from a new angle. The intracellular localization of enzymes, especially of those at the entry of the multibranched isoprenoid pathway, is still a matter of debate and will be discussed in light of new findings. Recently, evidence also has been presented for the existence of alternate pathways of mevalonate and/or isopentenyl pyrophosphate (IPP) formation in plants, the latter one being reminiscent of the so-called Rohmer pathway that is operative in certain bacteria. The possible existence of two independent and strictly compartmentalized biosynthetic routes for the formation of a single intermediate would explain some contradictory results that have been obtained and that suggested the partial or complete segregation of organelles from cytoplasmic enzymes, as was deduced from incorporation and inhibition studies as well as through determination of enzyme activities in subcellular fractions. Moreover, such an alternate pathway would explain the obviously close relationship between isoprene production and the Calvin cycle in certain plants, as well as the unequal labeling of certain isoprenoids from various precursors.

GENERAL IMPORTANCE OF THE MULTIBRANCHED ISOPRENOID PATHWAY IN PLANTS

To date, some 22,000 isoprenoids (terpenoids, isopentenoids) have been characterized (1), most being of plant origin. For instance, from tobacco alone, more than 470 isoprenoid derivatives had been identified by 1985 (2). It is apparent that the multibranched isoprenoid pathway in plants represents one of the most complicated biosynthetic pathways known (Fig. 1). There exists hardly a metabolic process in plants that does not require the biochemical or physiological involvement of isoprenoids, be it "pure" isoprenoids consisting only of isoprene units, or "mixed" isoprenoids, with only part of the molecule being derived *via* the isoprenoid pathway. Besides their function in photosynthesis (carotenoids, chlorophylls, phylloquinone, plastoquinone), respiration (ubiquinone, cytochrome a), membrane architecture (sterols and triterpenoids), regulation of growth and development (gibberellic acids, abscisic acid, brassinosteroids, certain cytokinins), defense against pathogen attack (numerous isoprenoid phytoalexins), exchange of signals and so forth, prenylation of proteins might be thought of as one important

[1]Based in part on a paper presented at the Symposium on the "Regulation of Biosynthesis and Function of Isopentenoids," Atlanta, Georgia, May 1994.

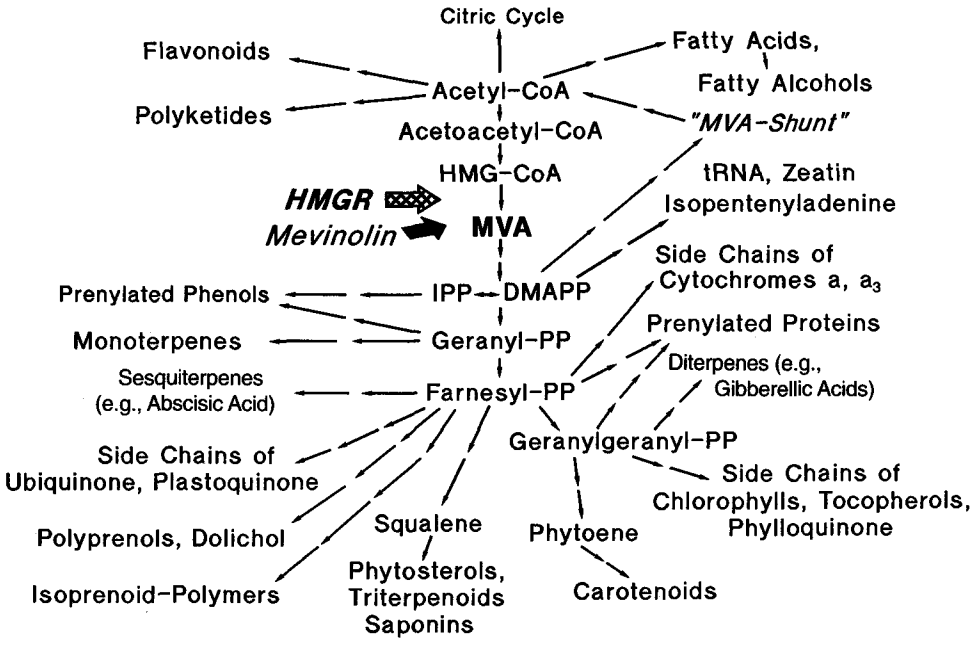

FIG. 1. The multibranched isoprenoid pathway in plants. The position of the key enzyme 3-hydroxy-3-methylglutaryl–CoA (HMG–CoA) reductase and its specific inhibitor mevinolin is indicated. MVA, mevalonic acid; HMGR, HMG–CoA reductase; IPP, isopentenyl pyrophosphate; PP, pyrophosphate; DMAPP, dimethylallyl pyrophosphate.

mechanism of membrane targeting and cell cycle regulation. However, in view of the new findings discussed below, this "classical" scheme may need some modification.

Mevalonic acid (MVA) as specific precursor of isoprenoids. With the discovery of MVA isolated from distillates of brewers yeast as an acetate-replacing growth factor in the culture broth of *Lactobacillus acidophilus* (3), and with its excellent incorporation into cholesterol in rat liver homogenates (4,5), the "true" committed precursor for isoprenoid biosynthesis has been identified. By monitoring the incorporation of labeled MVA into various plant isoprenoids (see Refs. 6–10, and references therein) the principle that *(R)*-MVA serves as precursor of isoprenoids became accepted. The degree of radiolabeling from MVA found in isoprenoids other than sterols or sterol precursors, such as squalene, cycloartenol etc., can be rather negligible (Refs. 7, 10, 11, and literature cited therein). The radiochemical purity of the MVA-derived, radiolabeled compound has not been proven in every case. This also holds true for the incorporation of acetate (or of precursors that can be easily metabolized to acetate) into isoprenoids. Since this substrate serves as a precursor in various syntheses, including the biosynthesis of fatty acids and their derivatives, contamination by other lipophilic compounds can cause serious problems. For example, long-chain fatty alcohols are known to migrate on thin-layer chromatography plates with R_f values similar to that of sterols (12), and complete purification of sterols requires several steps of column chromatography and repeated recrystallization. Thus, the radiochemical purity of the radiolabeled products of the multibranched isoprenoid pathway was not really proven in each case, nor had the time of exposure to radiolabeled precursors such as ^{14}C- or ^{3}H-labeled MVA excluded metabolic degradation and, consequently, reuse of breakdown products, e.g., of acetate, in the *de novo* biosynthesis of isoprenoids. Further, as already discussed by Banthorpe *et al.* (7) and by Goad (10), the unavoidable introduction of unphysiologically large quantities of MVA might result in the degradation of the additive to products that may also act as enzyme inhibitors or lead to the induction of salvage degradation pathways. On the other hand, a poor incorporation of MVA, due to its limited uptake and transport, does not prove *per se* that it is not an obligate intermediate in the biosynthesis of a certain isoprenoid.

Properties of plant R-*mevalonate: NADP$^+$ oxidoreductase, CoA-acylating, EC 1.1.1.34 (3-hydroxy-3-methylglutaryl–CoA; HMGR).* It is widely accepted that HMGR, catalyzing the NADPH-dependent double-reduction of 3-hydroxy-3-methylglutaryl–CoA (HMG–CoA) to MVA, plays a crucial role in the part of the isoprenoid pathway leading to phytosterols (13–16). Treatment of seedlings with mevinolin (lovastatin), a natural antibiotic and HMGR inhibitor (17–21), as well by its natural and artificial analogues leads to severe disturbances in plant growth (16,18,22,23–25), due to the specific block of *de novo* sterol biosynthesis. A further argument in favor of a regulatory role of HMGR in phytosterol accumulation was derived from the observation that in triazole-resistant tobacco mutant cells overproducing sterols (26), HMGR activity had increased 3- to 4-fold (27). Overproduced sterols, largely in the form of biosynthetic precursors, such as cycloartenol, appear as fatty acyl esters in lipid

droplets of the cytoplasm, but not in membranes (28,29). The same phenotype is present in transformed tobacco cells overexpressing the soluble part of hamster HMGR (30) or overexpressing rubber tree HMGR (H. Schaller, M.-L. Chye, and P. Benveniste, personal communication). Apparently, plants derived from tobacco mutants or from transformed cells overexpressing HMGR genes exhibit a normal phenotype and growth rate, without significant changes in pigment composition. Furthermore, feeding of exogenous MVA to alfalfa seedlings and cell cultures (31) led to the accumulation of phytosterol intermediates, further underlining the central regulatory role of HMGR in the control of substrate flux from acetyl-CoA to phytosterols as discussed earlier (13).

Hydrophobicity plots according to Kyte and Doolittle (32) predict that all plant HMGR isozymes sequenced so far (33–48) should contain a highly conserved membrane domain consisting of two hydrophobic amino acid sequences, separated from the soluble and highly conserved domain bearing the catalytic site by a linker region without any significant homology (Refs. 49,50). In plants it appears that HMGR isozymes are encoded by a small family of genes, and evidence is emerging that these genes and gene products are placed under developmental or environmental control by factors such as light, xenobiotics, or microbial elicitors (41,43, 51–66; see Refs. 16,53,66–68 for additional references), somehow reflecting the greater diversity of mevalonate derivatives in the realm of plants.

In contrast to the sequence areas coding for the sites of catalytic activity, found to be highly conserved in all eukaryotic HMGR enzymes (see Refs. 59,69, and literature cited therein), the regions of the membrane anchor and especially the neighboring linker are characterized by evolutionary sequence diversity. Animal and yeast HMGR types contain eight such hydrophobic regions in the membrane anchor (70,71). When two radish HMGR isogenes (cDNA derived from *HMG1* and *HMG2*) were expressed in an MVA-auxotrophic yeast mutant, however, we could show that the two membrane-spanning amino acid sequences are sufficient to direct the targeting of nascent radish HMGR into yeast membranes. Western blot analyses revealed that, in the heterologous system, proteins of the correct size (about 63 kDa) had been integrated into the membrane(s) (for details, see Ref. 72). It must be noted, however, that there exists a considerable controversy as to the exact intracellular localization of HMGR in plants (see Refs. 11,14,16,50,51,53,73–78, and literature cited therein). As known so far, all plant HMGR sequences are characterized by the absence of a typical leader peptide indicative of a translocation from the cytoplasm into organelles. Recent *in vitro* transcription/translation experiments with two rather divergent isogenes encoding *Arabidopsis* HMGR showed a co-translational insertion of plant HMGR protein into endoplasmic reticulum-derived microsomes (50), similar to the situation in vertebrate cells. However, for the import of proteins destined for the outer chloroplast envelope, apparently no ATP-hydrolysis, no transit sequence, and no protease-sensitive envelope surface components are needed (79). Thus, a localization of an isozyme of HMGR in the outer plastid envelope as suggested by Wilson and Russell (63) cannot be ruled out. Boronat *et al.* (80) have recently reported the use of alternative promoters in the *Arabidopsis HMG1* gene, which results in the synthesis of two HMGR1 forms that differ in their *N*-terminal end. However, in an *in vitro* transcription/translation system, all forms of *Arabidopsis* HMGR isozymes were equally incorporated into microsomes, as in an SRP-dependent manner (N. Campos, and A. Boronat, personal communication). In tomato, where four HMGR isogenes have been identified which show differences in their temporal expression programs and inducibility by arachidonic acid, synthesis of MVA is essential for the development of green fruits (cell division and expansion), but is also linked to the conversion of chloroplasts to chromoplasts in parallel with lycopene accumulation (81; W. Gruissem, personal communication). Different HMGR isozymes might therefore direct the synthesis of different end products of the isoprenoid pathway. .

Conversion of acetyl-CoA to HMG–CoA. Following the pioneering work of Rudney and Lynen and their associates with yeast and mammalian tissue, it has been well documented (*cf.* Ref. 16, and literature cited therein) that the conversion of three units of acetyl-CoA to HMG–CoA is catalyzed by two distinct enzymes: (i) AACT (acetyl-CoA acetyltransferase, EC 2.1.3.9) catalyzing a Claisen-type condensation, and (ii) HMGS (*S*-3-hydroxy-3-methylglutaryl-coenzyme A:acetoacetyl-coenzyme A lyase, CoA acylating, EC 4.1.3.5), catalyzing an aldol condensation. Little was known until recently as to the situation in plants (11,14–16). We have purified and characterized a membrane-associated enzyme system from four-day-old etiolated radish seedlings (*Raphanus sativus* L.), capable of converting acetyl-CoA to HMG–CoA (82). This enzyme system, apparently catalyzing both partial reactions, is being referred to as AACT/HMG–CoA synthase (HMGS). The quite unusual *in vitro* properties of this enzyme system led us to believe that plants might have developed an additional mechanism of HMG–CoA synthesis different from that of other eukaryotes. The most puzzling feature of radish AACT/HMGS is its apparent activation by redox-cycling as mediated by the artificial redox couple Fe(II)/pyrroloquinoline quinone (PQQ), or alternatively by Fe(II) and higher concentrations of H_2O_2, suggesting the involvement of hydroxyl radicals formed by a Fenton-Haber-Weiss reaction [$Fe^{2+} + H_2O_2 \rightarrow Fe^{3+} + OH^- + {}^{\bullet}OH$]. This effect can be seen with crude solubilized radish AACT/HMGS, but it is more pronounced with purified enzyme and it can be further enhanced by addition of PQQ (83). It is evident that during the purification we remove a heat-stable cofactor system (that remains yet to be identified), which cannot only partially replace the PQQ but also, to a certain extent, Fe^{2+}. However, at present, we cannot exclude that this new system represents a multifunctional enzyme or even an intrinsic side-activity of a plant-specific enzyme, which might be less specific than we thought earlier. Although on sodium dodecyl sulfate gels we detected only a prominent band of about 56 kDa (82), in good agree-

ment with values obtained by gel filtration on various materials (16,42), an underlying impurity cannot yet be excluded. Conclusive proof of the existence of the so-called AACT/HMGS enzyme system will need to await the isolation of the respective genes. However, we have been able to complement a yeast *erg*-mutant, deficient in temperature-stable AACT with a radish cDNA and have thus isolated a gene that encodes a soluble form of AACT with a molecular weight of about 42 kDa (84; EMBL accession number X78116). This latter observation would support the conclusions by van der Heijden *et al.* (85,86), although their purification scheme, using cell-free preparations of *Catharanthus roseus* cell cultures, has apparently not yet resulted in a separation of AACT and HMGS activities. A method for the simultaneous determination of all intermediates of the isoprenoid pathway, starting with acetyl-CoA, has recently been developed (87). While all other intermediates could be found, depending on the substrate fed, in no case was free acetoacetyl-CoA detected in isolated cells capable of synthesizing monoterpenes. In our test system for AACT/HMGS, we could not trap free acetoacetyl-CoA as a putative intermediate (16). Thus, the situation is still far from being clear. Furthermore, the exact intracellular localization of HMG–CoA synthesis (i.e., cytoplasm vs. plastids and/or mitochondria) remains obscure unless corresponding genes have been cloned.

BRANCHED-CHAIN AMINO ACIDS AS PRECURSORS OF PLANT ISOPRENOIDS

L-Leucine and L-valine, when fed to germinating pea seeds (*Pisum sativum*) were incorporated into squalene and β-amyrin (88). Chemical degradation by ozonolysis of the radioactive squalene revealed an equal distribution of the radioactivity in the IPP-derived (four portions per molecule) and the dimethylallyl pyrophosphate (DMAPP)-derived moieties (two portions per molecule). However, an unbalanced distribution in favor of the DMAPP-derived moiety of monoterpenoids was found after feeding radioisotopically labeled L-leucine, L-valine, DL-alanine, acetate, and *R,S*-MVA to intact plants of *Cinnamomum camphora* and of *Pelargonium roseum* (89). The relatively low incorporation of amino acids was explained in several ways: (i) the radioactivity of amino acids is scattered into metabolites other than monoterpenoids; (ii) there is a substantial pool of amino acids which leads to dilution of radioactivity; and (iii) there is little permeation of the amino acids into the biosynthetic site of monoterpenoids (90). The DMAPP-derived moiety of monoterpenoids, biosynthesized from [*U*-^{14}C]leucine and [*U*-^{14}C]valine was labeled with more than 64% of the incorporated tracers, while this moiety when derived from [2-^{14}C]MVA contained less than 32% of the tracers (89). This lends support to the interpretation that both amino acids are incorporated not *via* MVA, but by an alternate route, e.g., a combination of the well known mammalian leucine degradation pathway and a reversal of the MVA shunt (see below). The distribution pattern in monoterpenoids after administration of [2-^{14}C]alanine was similar to that after incorporation of MVA, which indicates that alanine is first metabolized to acetyl-CoA, which then constructs preferentially the IPP-derived moiety of the monoterpenoids *via* MVA (89).

Contradictory results were obtained by Anastasis *et al.* (90) when they studied the incorporation of [2-^{13}C]- and [3-^{13}C]-leucines into sesquiterpenoid paniculides by tissue cultures of *Andrographis paniculata*. Apparently, HMG–CoA from leucine breakdown was not incorporated intact but was broken down to acetyl-CoA and subsequently incorporated *via* HMG–CoA and MVA. The same seems to hold true for phytosterols labeled under the same conditions (91). However, the incorporation time was 7 d, which might result in degradation of precursors and products, while in the studies summarized by Suga *et al.* (88) and Tange (89), incorporation times ranged from 12 to 72 h. From the incorporation pattern in bakuchiol, a meroterpene from *Psoralea corylifolia*, derived from leucine, valine, and isovaleric acid, it was concluded that these substrates are metabolized to CO_2, which is then incorporated (92).

Evidence for the occurrence of a MVA shunt pathway in plants. Evidence has been presented for the occurrence of a mevalonate shunt pathway in higher plants (12), with HMG–CoA as an intermediate, as it is most likely true for the degradation of leucine. Given the fact that the membrane fraction used to isolate AACT/HMGS from radish is also a major source for HMG–CoA lyase (HMGL) (EC 4.1.3.4), a key enzyme of the MVA shunt (93), its presence could indicate that in plants AACT/HMGS plays a role in a ketogenic cycle. However, to our knowledge, there is no clear information as to the metabolic fate in plants of acetoacetate generated by the HMG–CoA lyase (HMGL) reaction. However, though the activity of 3-methylcrotonyl-CoA carboxylase (EC 6.4.1.4) has been demonstrated in plants (94–98), and also that of *trans*-3-methylglutaconyl-CoA hydratase (3-hydroxy-3-methylglutaryl-CoA hydrolyase, EC 4.2.1.18) (85,86), further evidence of an alternative peroxisomal pathway of leucine degradation has been presented by Gerbling (99), including free acids rather than CoA esters. At present the interdependence of those intervening and/or scavenging pathways is not yet known, nor is their regulation.

ISOPRENE EMISSION BY PLANTS

Many plants produce considerable amounts of isoprene (see Ref. 100, and literature cited therein) which can cause air pollution problems in some areas. Isoprene emission from plants may account for half of the total nonmethane hydrocarbon emissions from the biosphere to the troposphere, thereby influencing the oxidative capacity and generating tropospheric ozone and carbon monoxide (see Ref. 101, for literature). Environmental stimuli or wounding affect the rate of synthesis (100,102). This high amount of isoprene, derived from the IPP isomer DMAPP (103), can hardly be explained by the quite limited substrate flow from acetyl-CoA to MVA, because cellular HMGR activity, at least from what has been

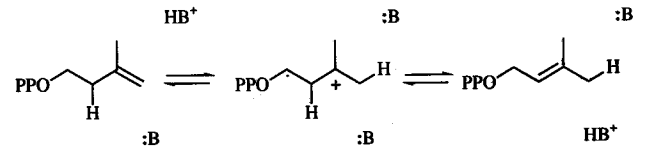

FIG. 2. Isopentenyl pyrophosphate isomerization to dimethylallyl pyrophosphate. The reaction proceeds *via* an acid-base catalyzed carbocationic mechanism. :B, basic amino acid residue involved in enzymatic catalysis; HB^+ protonated form (from Ref. 111). PPO, pyrophosphate esterified with hydroxyl groups of Δ^2- and Δ^3-isopentenol.

found in all plants studied so far, would not be sufficient to saturate such a rate of synthesis. Furthermore, it appears that there is a rather direct coupling to photosynthetic activity, *viz.* intermediates of the Calvin cycle (100,101,104–108). Most likely, pyruvate derived from 3-phosphoglyceric acid as the primary product of CO_2 fixation is a close precursor (see below for possible biosynthetic consequences). Isoprene is also a normal constituent of human breath (see Ref. 109, and literature cited therein), but in this case a clear coupling to the rate of cholesterol and mevalonate biosynthesis was shown. Blockade of MVA biosynthesis by the hypocholesterolemic drug mevinolin (lovastatin) leads to a decrease in cholesterol synthesis in liver, and to the same degree to a diminished production of isoprene (109).

Isoprene production might be explained by the enzymatic mechanism of IPP isomerization to DMAPP: Reardon and Abeles (110) and Muehlbacher and Poulter (111) have elegantly shown that IPP isomerase (isopentenyl-diphosphate Δ-isomerase, EC 5.3.3.2) catalyzes a reaction with an intermediate carbocation (Fig. 2). This isomerization involves an antarafacial transposition of a proton, suggesting that a conjugate acid-base pair works in tandem to catalyze the reaction (111). A similar carbocation intermediate occurs in the acid-catalyzed nonenzymatic conversion of DMAPP to isoprene in liver (112; Fig. 3). Elimination of diphosphate from DMAPP could result in the formation of a delocalized carbocation intermediate followed by the loss of a single proton,

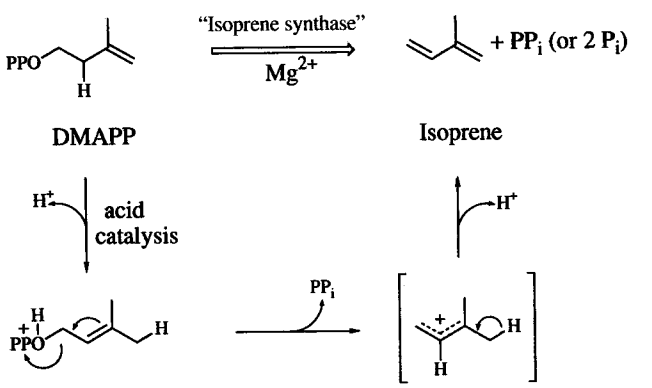

FIG. 3. The "isoprene synthase reaction." Comparison to the probable mechanism for the acid-catalyzed conversion of DMAPP to isoprene as proposed by Silver and Fall (103). The enzymatic and acid-catalyzed reactions may proceed *via* a delocalized carbocation intermediate (redrawn from Ref. 103). See Figures 1 and 2 for abbreviations.

which would yield isoprene (103). It might be speculated that the Mg^{2+}-dependent reaction is in fact identical to that catalyzed by the so-called isoprene synthase partially purified by Silver and Fall (103), and that the plant enzyme cannot closely control the isomerization, ultimately leading to an abortion of enzyme-bound substrate and hence to the production of isoprene (see Refs. 109,112).

THE ROHMER PATHWAY

Bacterial isoprenoid biosynthesis. Current biosynthetic evidence indicates that the steps from IPP to isoprenoids in Eubacteria are the same as those in eukaryotes (113–123; see Refs. 122–128 for further literature). The incorporation of ^{13}C-labeled precursors into ubiquinone-8 (123), and especially into prokaryotic hopanoids (128–131), sterol surrogates in bacterial membranes but also in the thylakoids of the cyanobacterium *Synechocystis* sp. (132), has revealed that the classical pathway of IPP formation starting from acetyl-CoA *via* acetoacetyl-CoA, HMG–CoA, MVA, mevalonate phosphate (MVAP), and mevalonate pyrophosphate (MVAPP) does not exist in a great variety of bacteria, including *Escherichia coli, Zymomonas mobilis, Methylobacterium organophilum* (133), and *Rhodopseudomonas palustris, R. acidophila, Acetobacter aceti* ssp. *xylinum* (134).

Zhou and White (123) argued that label from acetate could be incorporated after being metabolically "scrambled," i.e., *via* the glyoxylate cycle: The condensation of acetate (as acetyl-CoA) with glyoxylate by action of malate synthase (EC 4.1.3.2) would form malate, which could then be converted into pyruvate by malic enzyme (L-malate: $NADP^+$ oxidoreductase [oxalacetate-decarboxylating], EC 1.1.1.40). The incorporation of the C-3 and C-2 unit of the resulting pyruvate into IPP and hence into hopanoids is better explained by the model as proposed by Rohmer *et al.* (125; Fig. 4): The formation of the structure C-5 of IPP (better: of the structure "isoprene unit") would proceed in a way similar to the biosynthesis of L-valine. A TPP-activated acetaldehyde generated by pyruvate decarboxylation would be added to the C-2 carbonyl group of a dihydroxyacetone derivative (such as dihydroxyacetone, monohydroxyacetone, or their mono- or diphosphates, methylglyoxal, etc.), followed by a transposition reaction. The following reactions (reduction, isomerization, elimination of water) remain speculative, but the authors argue that they could again be similar to those found in L-valine biosynthesis. However, at least in the case of the ethanol-producing bacteria *Z. mobilis*, they could exclude L-valine or one of its precursors as substrate of IPP formation (see Ref. 125 for details).

An alternative IPP synthesis in plants akin to the bacterial Rohmer pathway? Hano *et al.* (135,136) have used callus and cell suspension cultures of *Morus alba* L. to study the biosynthesis of optically active prenylchalcones such as chalcomoracin. [2-^{13}C]MVA was not incorporated into the prenyl moiety of chalcomoracin, while it was incorporated into

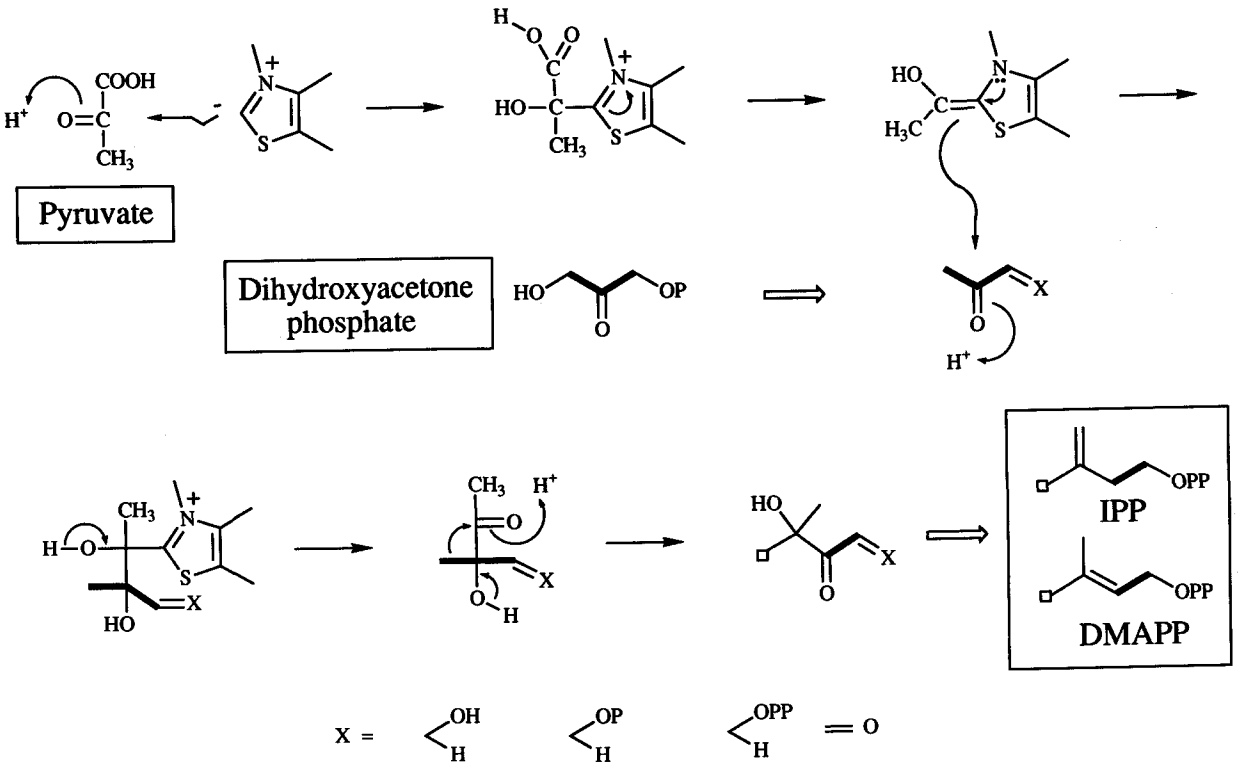

FIG. 4. The biosynthetic pathway of bacterial IPP formation as proposed by Rohmer *et al.* (125) (redrawn from Ref. 125). OPP, pyrophosphate esterified with hydroxyl group of Δ^2- and Δ^3-isopentenol. See Figure 1 for other abbreviations.

β-sitosterol. The labeling pattern of chalcomoracin from [2-^{13}C]-L-leucine was the same as from [1-^{13}C]acetate. Feeding D-[U-$^{13}C_6$]glucose, [1,3-$^{13}C_2$]- and [2-^{13}C]glycerol (which formed [1,3,4,6-$^{13}C_4$]- and [2,5-$^{13}C_2$]glucose, respectively) demonstrated that of the three acetate units composing the hemiterpene moiety, the starter acetate unit is of glycolytic origin, whereas the second and third acetate units originate from the pentose phosphate cycle. Triose phosphates such as dihydroxyacetone phosphate and glyceraldehyde-3-phosphate are postulated to occupy the junction of this chimeric hemiterpene pathway with glycolysis and the pentose phosphate cycle (see Fig. 5). The major difference in the isotopic enrichments between the Rohmer pathway and the mechanism proposed by Hano *et al.* (135,136) is that ^{13}C-label coming from [1-^{13}C]acetate appears in C-4 of IPP, while the hemiterpene moieties of prenylchalcones were not enriched, and second in *M. alba* cell cultures, label from [1,3-$^{13}C_2$]- and [2-^{13}C]glycerol labeled the C-1 and C-5 positions, or the C-2, C-3, and C-4 positions of IPP, respectively. Although the nuclear magnetic resonance data are quite conclusive, it is still difficult to rationalize in this model how acetyl-CoA units can be distinguished in the formation of HMG–CoA as an intermediate (135,136), if not assuming intermediates that are recognizable through tight binding to proteins/enzymes. This work needs to be complemented by (i) incorporation studies using specifically ^{13}C-labeled glucose (see below), and in particular (ii) the application of inhibitors of the mevinolin type, which should be capable of affecting the synthesis of chalcomoracin if the model is true.

In an independent study, presented at a previous isoprenoid meeting at Strasbourg/Bischenberg, Cartayrade *et al.* (137) compared the biosynthesis of β-sitosterol and of diterpenoid ginkgolides in embryos of *Ginkgo biloba*. (Ginkgolides act apparently as antagonists of platelet-activating factors and are thus of high pharmaceutical interest for the treatment of thrombosis, inflammatory reactions and cardiovascular disorders; for literature see Ref. 138.) In *G. biloba*, the IPP precursor of β-sitosterol is assembled *via* MVA formed by the classical pathway from acetyl-CoA *via* acetoacetyl-CoA, HMG–CoA. In contrast, the IPP units used for formation of ginkgolides are apparently assembled through decarboxylative condensation of pyruvate with a triose phosphate, similar or identical to the Rohmer pathway (137,139). Further, these two independent biosynthetic machineries are compartmentalized. However, there seems to exist some "leakage" at the C-15 level such that a small quantity of farnesyl-pyrophosphate (PP) made in the cytoplasm as for β-sitosterol synthesis, is linked then by action of geranylgeranyl-PP synthase to an IPP unit made by the alternative pathway, most possibly in the plastid (137,139). Soler *et al.* (140) presented evi-dence of an IPP translocator in the plastid envelope, but the K_m of about 500 μM with respect to IPP does not convincingly show that it is really a very specific protein. It might function as a (pyro)phosphate translocator that

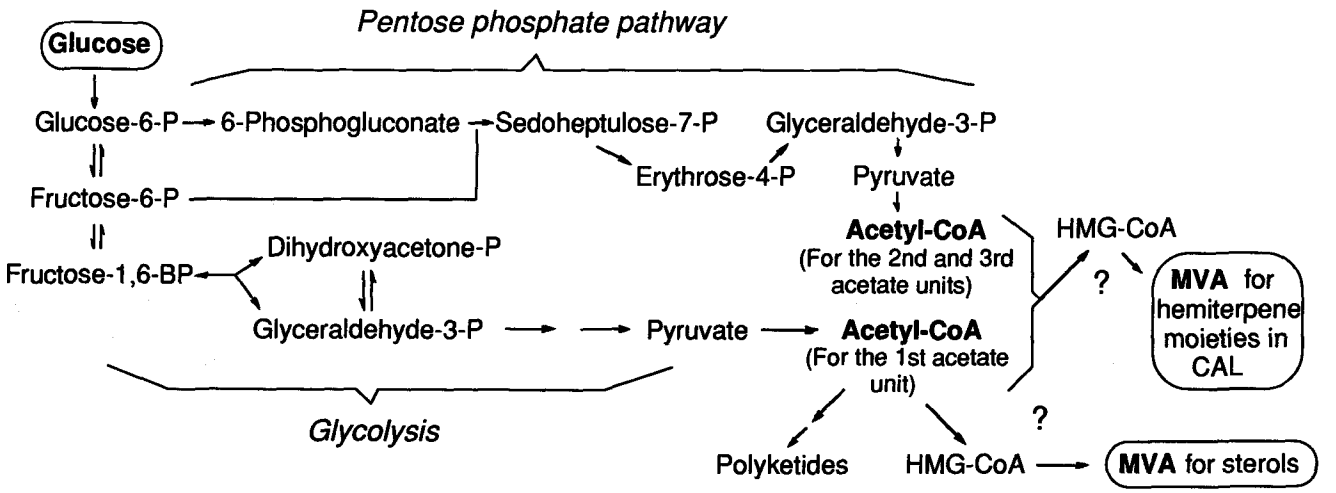

FIG. 5. Biosynthetic routes from glucose to the hemiterpene moiety of chalcomoracin (CAL) and to sterols in *Morus alba* cells as proposed by Hano *et al.* (135,136). For details, e.g., labeling patterns, see References 135,136. Note that differential mechanisms are proposed for the synthesis of HMG–CoA and of MVA used for CAL and sterols, respectively. Question marks denote uncertainties as to the enzyme systems involved (see text for discussion). See Figure 1 for other abbreviations.

could perhaps also accept higher IPP homologs such as farnesyl-PP.

Evidence of an enzymatic machinery for the Rohmer pathway? A crucial point in this new model of IPP formation in bacteria and eukaryotes as well is the fact that until now individual enzyme reactions have not yet been identified. An exception could be the initial reaction, the formation of thiamine diphosphate (TPP)-acetaldehyde, catalyzed by pyruvate decarboxylase (PDC, 2-oxoacid carboxylase, EC 4.1.1.1), an enzyme that is not present in animal tissues, but has been isolated from yeast (see Ref. 141, and literature cited therein) and also from some plants such as maize (142). Yeast PDC can also catalyze an aldol-type condensation reaction between two molecules of acetaldehyde to form the α-ketol acetoin in a concerted reaction mechanism (141). It seems reasonable to assume a similar reaction pathway for the reaction of the TPP-bound "acetaldehyde" [2-(1-hydroxyethyl)TPP] with the dihydroxyacetone derivative as postulated by Rohmer *et al.* (125). Given the fact that the hyperbolic kinetic properties and apparent molecular weights of the yeast (iso-)enzyme(s) (tetramers, native mass of 242 kDa) and the maize enzymes (kernels: 61 and 60 kDa subunits, roots: 59 and 58 kDa subunits), tetrameric structure for both isozymes (142) are so similar, then it would be no surprise if both enzymes could catalyze the same condensation reaction as well. However, PDC is a typical enzyme of anaerobic metabolism (see Ref. 143 and literature therein), and corresponding mRNA are induced anaerobically (144,145). It should be therefore difficult for acetaldehyde to "escape" the action of alcohol dehydrogenase (EC 1.1.1.1), which is also specifically enhanced under anaerobic conditions. Maize PDC, having a sharp pH optimum of 5.8, is inactive at the pH >7 of aerobically metabolizing tissues (142). However, as an alternative, it could be speculated that the entry reaction of the pyruvate dehydrogenase complex, pyruvate decarboxylation, which is mechanistically identical, could give rise to the same intermediate 2-(1-hydroxyethyl) derivative of the thiazol ring of TPP, which somehow would escape the subsequent dehydrogenation and the resulting esterification of the acetyl unit to coenzyme A. Plant cells contain two pyruvate dehydrogenase complexes, one in the mitochondria and the other in the plastids (see Ref. 146, and literature cited therein). If such a "side reaction" would exist, then incorporation data using pyruvate as a precursor of plastid isoprenoids and fatty acids (76,78,147) might be reinterpreted so that pyruvate decarboxylation could lead to a reactive intermediate exclusively used for IPP synthesis, while full conversion of pyruvate to acetyl-CoA would yield a pool that is exclusively used for fatty acid biosynthesis. In this way, the problem of two independent acetyl-CoA pools in the same subcellular compartment with little or no exchange, as postulated by Schultz and co-workers (76,78), could be easily circumvented.

In thiamine-deficient mutants of *Nicotiana sylvestris,* the synthesis of carotenes and chlorophylls, but not of fatty acids is blocked (148). Since thiamine (in the form of TPP) is a mandatory cofactor for the decarboxylation of pyruvate, the interruption of pigment synthesis in its absence might further indicate the tight linkage to the activity of the pyruvate dehydrogenase complex or to PDC. In this case the contribution of acetyl-CoA formed from pyruvate to fatty acid synthesis would be negligible as compared to acetate imported from outside of the chloroplast (148). Acetolactate synthase (ALS, EC 4.1.3.18, also commonly referred to as acetohydroxy acid synthase) is also capable of converting pyruvate to the abovementioned 2-(1-hydroxyethyl)-TPP intermediate (149). Competition between pyruvate and ketobutyrate for this intermediate defines the partitioning ratio with respect to the two physiological reactions, *viz.* one specific to isoleucine formation and the other specific to valine or leucine biosynthesis (149). The oxygenase side reaction of ALS is explained by the competition between molecular oxygen and pyruvate or ketobutyrate for the hydroxyethyl-TPP intermediate (149).

Although the fixed-time colorimetric assay for ALS employed by these authors would not distinguish between acetolactate and acetoin formation, it seems rather unlikely that an enzyme that is capable of closely controlling the partitioning ratio between the structural homologs pyruvate and ketobutyrate would accept further substrates for condensation, such as triosephosphates. Thiamine thiazolone pyrophosphate, a transition state analog of the reaction intermediate hydroxyethyl-TPP, has been shown to indiscriminately inhibit enzymes using a thiamine cofactor (150); however, for the study of entry reactions of the Rohmer pathway, such compounds might be useful as molecular probes.

CONSEQUENCES FOR THE SO-CALLED SEGREGATION MODEL OF ISOPRENOID BIOSYNTHESIS

Kleinig and his associates (11,151,152) have speculated on the presence of a synthetic pathway leading to IPP and not requiring the intermediate HMG–CoA. We (16) discussed the existence of a pathway as proposed by Emmanuel and Robblee (153), starting from propionate, that was incorporated into cholesterol in rat liver (154). According to these authors' hypothesis, propionyl-CoA could condense with propionaldehyde in a reaction analogous to the formation of malate from acetyl-CoA and glyoxylate, followed by the mutation of a methyl group catalyzed by a mutase in analogy to the conversion of L-glutamate to *threo*-β-methyl-L-aspartate. Oxidation of this hypothetical intermediate would yield MVA. Some conversion of propionate into 3-hydroxypropionate (and traces of acetate) in lima beans (*Phaseolus limensis*) with acrylic acid as an intermediate has been described (155). However, a vitamin B_{12}-dependent mutase activity, which would have led to the formation of a methylmalonyl derivative and finally to succinate, could not be detected. Thus, we should probably abandon those alternative models and return to the Rohmer pathway (125) as outlined above, or, alternatively, to the pathway proposed by Hano and his colleagues (135,136).

Similarly, the presence of the Rohmer pathway in plants could provide a further explanation for the observations obtained with the HMGR inhibitor mevinolin, *viz.* its great efficiency in blocking cytoplasmic sterol biosynthesis, but its low efficiency in affecting ubiquinone biosynthesis, and its practically complete inefficiency in blocking the accumulation of isoprenoids and prenyl lipids of the chloroplast, as summarized and discussed earlier (16, 23). It could also explain the puzzling observation that, in contrast to phytosterols, prenyl-substituted coumarins were not labeled from [2-^{14}C]acetate nor from [2-^{14}C]MVA in elicitor-treated cultures of *Ammi majus*, suggesting that the DMAPP needed as substrate for the (plastid?) umbelliferone: dimethylallyl transferase is formed from IPP synthesized *de novo* within the plastid, rather than from IPP imported into the plastid from the cytosol (156). Elicitor-induced inhibition of phytosterol biosynthesis should occur by specific inhibition of one of the enzymes on the cytosolic pathway from MVA to DMAPP (156). IPP was similarly accepted as an effective substrate for prenyl lipid synthesis as CO_2 when testing isolated chloroplasts from the unicellular green alga *Acetabularia* (77), whereas "conventional" IPP precursors were not. This observation can easily be explained by the existence of an alternative pathway.

MVA and IPP were more rapidly taken up by proplastid-like plastids from 70S ribosome-deficient, bleached leaves of rye seedlings grown at a nonpermissive temperature of 32°C (157), than by chloroplasts from green seedlings cultivated at 22°C. But in contrast to IPP, MVA was not incorporated into lipids by either type of isolated organelle. However *in vivo*, MVA was incorporated into prenyl lipids such as plastoquinone, phylloquinone, and lutein in leaf sections of rye seedlings (157). In bleached leaves the rate of incorporation was strikingly higher than in green leaves. If any interpretation is to be made of such discrepancies between the situation *in vitro* and *in vivo*, these data seem to indicate that divergent types of plastid differentiation might be associated with fundamental changes of the metabolite flow of isoprenoid precursors between different products and compartments and with changes of import into the plastid compartment (157). The presence of plastidic MVA kinase and MVAP kinase in addition to cytosolic activities has been claimed from latency experiments using immature chloroplasts from barley (158). However, the cloning of a cDNA from *Arabidopsis thaliana* encoding MVA by complementation of a yeast mutant (159), and corresponding Southern blot analyses have not yet provided any evidence for the existence of a further MVA kinase gene, for instance coding for a organelle-specific isozyme. The cloning of corresponding genes from evolutionarily distant plants is therefore highly desirable in order to possibly detect isogenes. (For literature on early controversies on the presence of MVA kinase isoforms in plant cell, see Ref. 14.) Single MVA kinase genes have also been cloned from rat liver (160), human tissue (161), and from yeast (162). However, recently, evidence has been presented of a predominant localization of a 42 kDa MVA kinase in rat peroxisomes, immunologically distinct from a cytosolic 40 kDa enzyme, as well as from a 46 kDa enzyme in mitochondria (163). Thus, it cannot be excluded that evolutionarily distinct isozymes of MVA kinase exist in eukaryotes.

In a recent report, Albrecht and Sandmann (164) have used maize etioplasts to study the light-stimulated biosynthesis of carotenoids. Enzyme activities downstream from MVA were determined. It appears as if exclusively IPP isomerase is affected by light (164). Unfortunately, absolute values for plastidic activities of MVA kinase, MVAP kinase, and MVAPP decarboxylase were not given (164). From their incorporation data using acetate and pyruvate as precursors, Heintze *et al.* (165), concluded that genes encoding the chloroplast MVA pathway might be expressed only at an early stage of chloroplast development (which, however, does not resolve the abovementioned dilemma of having no HMGR gene coding for a protein with a leader peptide typical of translocation into plastids). Future work might reveal that, depending on the plant species and their developmental stage, different strate-

gies might be used to ensure a sufficient IPP synthesis in the cytoplasm and in the organelles. If such anaplerotic and/or compartmentalized pathways coexist, then we have to look for some molecular switch or sensor responsible for activating genes for different biosynthetic routes.

In order to explain such contradictory observations, it might also be possible to consider substrate channeling with no relase or access of intermediates (and of inhibitors), for instance, through a close arrangement of enzymes into metabolons within an end-product specific reaction sequence, like in carbohydrate metabolism (143), e.g., at the surface of membranes. This could be envisaged to occur even in the same subcellular compartment. A synthesis of products finally localized in plastids and mitochondria outside of the organelle has been proposed (166). The Golgi apparatus has recently been discussed as such a subcellular site of synthesis for prenylquinones (166); this is somewhat different from (167), or even in sharp contrast (168) to earlier findings (see Refs. 11,14 for further literature). This would require the presence of specific transport systems in the envelope membranes of plastids and mitochondria as well. No clear evidence of their existence has been presented yet.

CONCLUSION

From the observations discussed above, which are partially in conflict with each other, it should become obvious that we are still quite a long way from completely understanding how the individual enzymes/genes of the multibranched isoprenoid pathway in plants are compartmentalized or are interacting. In some way, we have to revise well established textbook knowledge which, as far as plant biochemistry is concerned, was not always experimentally proven, but rather deduced by analogy from results obtained with animal tissue or yeast. The co-existence of alternative machineries for the synthesis of one and the same isoprenoid precursor, be it IPP or MVA, is an even more intriguing challenge for future studies in biochemistry, molecular biology and physiology. This possibly extends to evolutionary aspects (169,170), for instance, to the symbiotic origins of organelles (171,172) and to the conservation of (prokaryotic?) pathways in higher plants. Sometimes things are not as simple as they look at first sight!

ACKNOWLEDGMENTS

Previous work in the author's laboratory at the University of Karlsruhe was generously supported by the Deutsche Forschungsgemeinschaft. Ongoing studies at the Institut de Biologie Moléculaire des Plantes (Strasbourg) are made possible by the support of the C.N.R.S. The helpful discussions with Prof. Michel Rohmer (Mulhouse, France), Drs. Alain Cartayrade and Matthias Schwarz (Zürich), Dr. Robert van der Heijden (Leiden), Prof. Albert Boronat (Barcelona), Prof. Wilhelm Gruissem (Berkeley), Prof. Pierre Benveniste and Dr. Hubert Schaller (Strasbourg), and Prof. Shinichi Ueda (Kyoto) on their partially unpublished work are greatly appreciated. Special thanks are given to Prof. W. David Nes and Prof. Ed Parish for the invitation to the AOCS symposium on sterols, and to Dr. Jean-Caude Kader and Prof. Paul Mazliak for the opportunity to present a major part of this article to the participants of the 11th International Plant Lipid Meeting.

Developmental Regulation of Sterol Biosynthesis in *Zea mays*[1,2]

De-an Guo[3], M. Venkatramesh and W. David Nes*

Department of Chemistry and Biochemistry, Texas Tech University, Lubbock, Texas 79409

ABSTRACT: Sixty-one sterols and pentacyclic triterpenes have been isolated and characterized by chromatographic and spectral methods from *Zea mays* (corn). Several plant parts were examined; seed, pollen, cultured hypocotyl cells, roots, coleoptiles (sheaths), and blades. By studying reaction pathways and mechanisms on plants fed radiotracers ([2-^{14}C]mevalonic acid, [2-^{14}C]acetate, and [2-^{3}H]acetate), and stable isotopes (D_2O), we discovered that hydroxymethylglutaryl CoA reductase is not "the" rate-limiting enzyme of sitosterol production. Additionally, we observed an ontogenetic shift and kinetic isotope effect in sterol biosynthesis that was associated with the C-24 alkylation of the sterol side chain. Blades synthesized mainly 24α-ethyl-sterols, sheaths synthesized mainly 24-methyl-sterols, pollen possessed an interrupted sterol pathway, accumulating 24(28)-methylene-sterols, and germinating seeds were found to lack an active *de novo* pathway. Shoots, normally synthesizing (*Z*)-24(28)-ethylidine-cholesterol, after incubation with deuterated water, synthesized the rearranged double-bond isomer, stigmasta-5,23-dien-3β-ol. Examination of the mass spectrum and ^{1}H nuclear magnetic resonance spectrum of the deuterated 24-ethyl-sterol indicated the Bloch-Cornforth route originating with acetyl-CoA and passing through mevalonic acid to sterol was not operative at this stage of development. An alternate pathway giving rise to sterols is proposed.

Lipids 30, 203–219 (1995).

The sterol compositions of *Zea mays* anatomy have been studied extensively (1–23). Sitosterol, stigmasterol, campesterol, and 24-epicampesterol were the major sterols isolated from the plant (8–10,20). Phytosterol production was found to involve irreversible carbon flux from acetyl-CoA to hydroxymethylglutaryl CoA (HMG–CoA) to mevalonic acid to isopentenoids (Bloch-Cornforth pathway) and then into a criss-crossing grid of sterol transforming enzymes of low sterol specificity until equilibrium (sterol homeostasis) was established (24,25). Sitosterol production was shown to be controlled by cycloartenol availability (Fig. 1), which presumably was controlled by the enzyme regulating conversion of HMG-CoA to mevalonic acid (HMG–CoA reductase) (24–26). The stereochemistry of C-24 alkylation was studied and found to involve multiple reaction pathways (Fig 2): 24β-methyl-sterols were formed by either the Δ^{23}- or Δ^{25}-transmethylation route whereas 24α-methyl-sterols were formed by the $\Delta^{24(28)}$-transmethylation route (18,20). Thus far, the Δ^{23}-transmethylation pathway has been demonstrated only in corn.

In our previous studies on phytosterol distribution and biochemistry (27–32), we recognized a phenomenon different from that reported for corn. That is, phytosterol genesis may be controlled during plant development at two levels of carbon flux: (i) cycloartenol production, which may be influenced either by mevalonic acid availability or carbon flux *via* the "Popják shunt" (27). This novel shunt, which we demonstrated for the first time in plants, allows for amino acids (33) and sugars (34) to be introduced into isopentyl pyrophosphate by a route that by-passes mevalonic acid as an intermediate; and (ii) cycloartenol transformation to 24-alkyl-sterols (sitosterol). This latter pathway may be controlled by the turnover rate and function of the Δ^5-sterol end products and the stoichiometry of sterol and cofactor (oxygen, *S*-adenosyl-L-methionine; and NADPH) associated with enzymes that act selectively on the sterol substrate (35,36). Both aspects of control regulate the activity of enzymes and the ordering of sterol intermediates that give rise to taxa-specific pathways from cycloartenol to 24-alkyl-sterols (35). That corn should be different from other plants in its sterol synthetic capabilities was puzzling, which led us to reinvestigate the composition and biosynthesis of sterols from corn in more detail.

In the present study, we examined the sterol compositions of several anatomical parts of *Zea mays*. Using high-performance liquid chromatography (HPLC) methods not available to earlier investigators studying corn, we identified most of the sterols reported by them and several new ones. One of the new sterols, 24β-ethyl-clerosterol, is generally thought to be synthesized only by primitive plants (37). We confirmed that changes occurred in sterol content during germination and seedling development (8–12). We also studied sterol biosynthesis using a variety of radiotracers and stable isotopes. Our

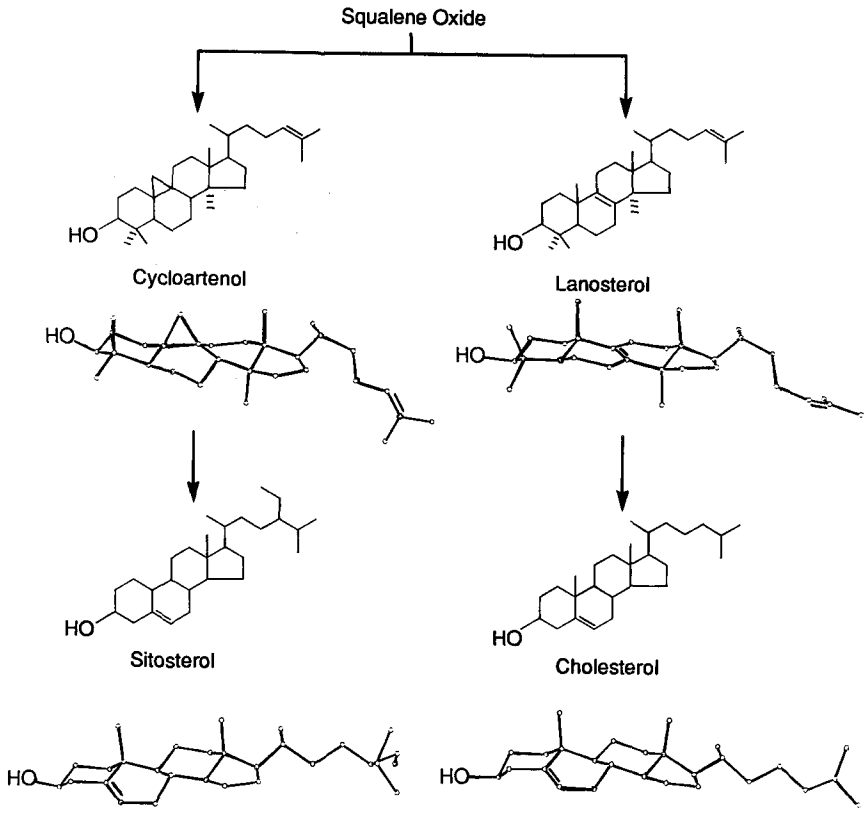

FIG. 1. Two-pathway model of sterol transformation. Both the conventional and conformational view (X-ray crystallographic structures are from Griffin and Nes, unpublished) of the sterol molecules are shown.

results indicate that synthesis of 24-ethyl-sterols is kinetically favored over 24-methyl-sterols at some, but not at all, stages of corn development; seeds do not synthesize sterols *de novo*, but they provide as much as 70% of the shoot sterol for early seedling growth. A strong kinetic isotope effect (KIE) was observed in the C-24 alkylation pathway of early maturing shoots after incubation of germinating seeds with deuterated water. This result indicates that structurally related 24-alkyl-sterol isomers are, in fact, generated by a single C-24 methyl-transferase and that C-24 alkylation may be a key regulatory step in phytosterol synthesis. Pulse labeling experiments using eight-day blades and sheaths confirmed the regulatory importance of C-24 alkylation pathways in sterol transformation. These experiments also demonstrated that the $\Delta^{24(28)}$-methylene-sterol pathway is kinetically favored in blades whereas the $\Delta^{23(24)}$-24-methyl-sterol pathway is kinetically favored in sheaths. The deuterated water incubations also indicated the Bloch-Cornforth pathway (37) involving the conversion of acetyl-CoA to HMG–CoA to sterols was down-regulated in early maturing shoots and some alternate pathway operated in the shoot to enable carbon flux into sterol.

The trivial naming and systematic nomenclature for sterols continue to be an area of much debate (reviewed in Ref. 36). Two sets of rules are now in use; one that is based on a combination of historical, chemical, and biosynthetic reasoning, the Nes system (Fig. 3) (36,37); the other follows an archaic numbering system that establishes priorities based on revised IUPAC recommendations (38).

The structural features characteristic of phytosterols include supernumerary alkyl groups at C-24 with both α and β chirality. In the Nes system (36,37), the cholestane skeleton (as the hydrocarbon) is used as the building block onto which substituents are added or are removed. The α/β-nomenclature of the nucleus is different from the one used in the side chain (36). The A/B-ring junction is assumed to be *trans* oriented (5α-H and 10β-CH_3). The α/β-system and the hydroxyl group at C-3 is β-oriented (equatorial) and is preferred to the R/S-system for distinguishing relative stereochemistry. Thus sitosterol [not β-sitosterol, β is dropped in common usage (37)] is 24α-ethyl-cholest-5-en-3β-ol [alternatively 24(*R*)-24-ethyl-cholest-5-en-3β-ol] or simply 24α-ethyl-cholesterol. Two other sterol skeletons may be used as necessary, ergostane (24-methyl-cholestane) and stigmastane (24-ethyl-cholestane). Neither the configuration at C-24 nor the presence of the Δ^{22}-bond is implied when using the ergostane or stigmastane nomenclature, even though ergosterol has a Δ^{22}-bond and 24β-methyl group and stigmasterol has a Δ^{22}-bond and 24α-ethyl group. The 4,4-dimethyl-sterol intermediates, such as cycloartenol (trivial name), have been viewed as triterpenoids by IUPAC recommendations and natural prod-

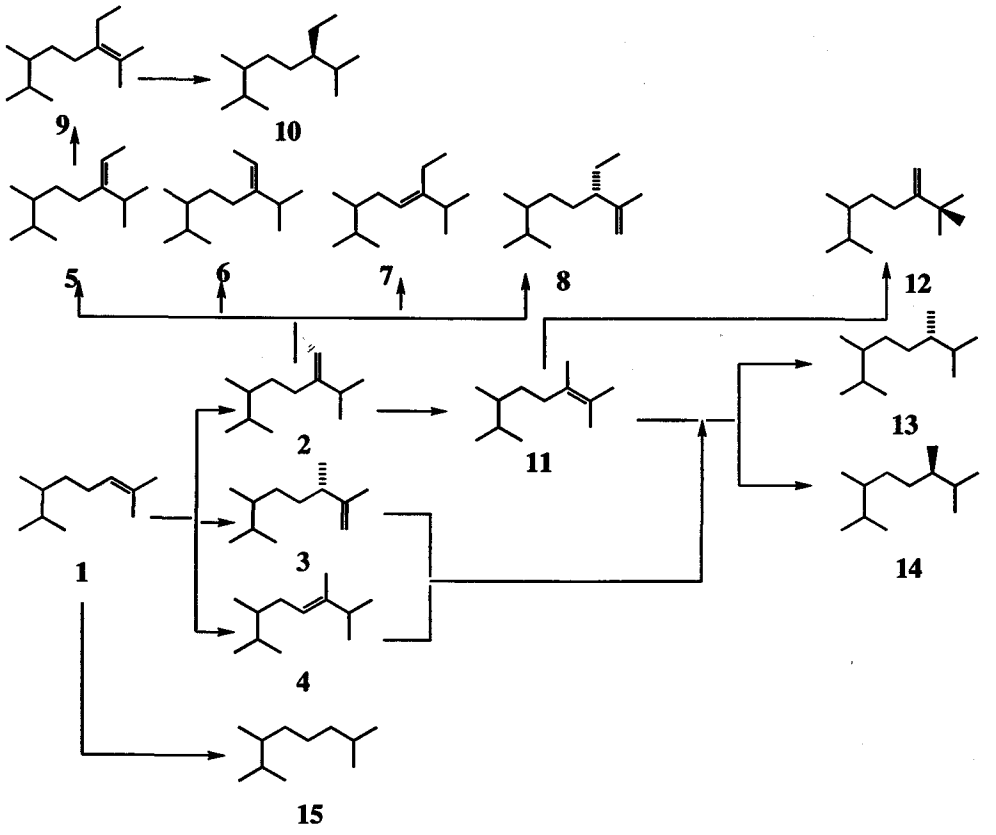

FIG. 2. Pathways of C-24 alkylation and reduction in sterol side-chain transformations; alkylation pathway involving structures **1** and **2** is operationally defined as the $\Delta^{24(28)}$-methylene pathway; alkylation pathway involving structures **1** and **3** is operationally defined as the $\Delta^{23(24)}$-pathway; alkylation pathway involving structures **1** and **4** is operationally defined as the $\Delta^{25(27)}$-pathway.

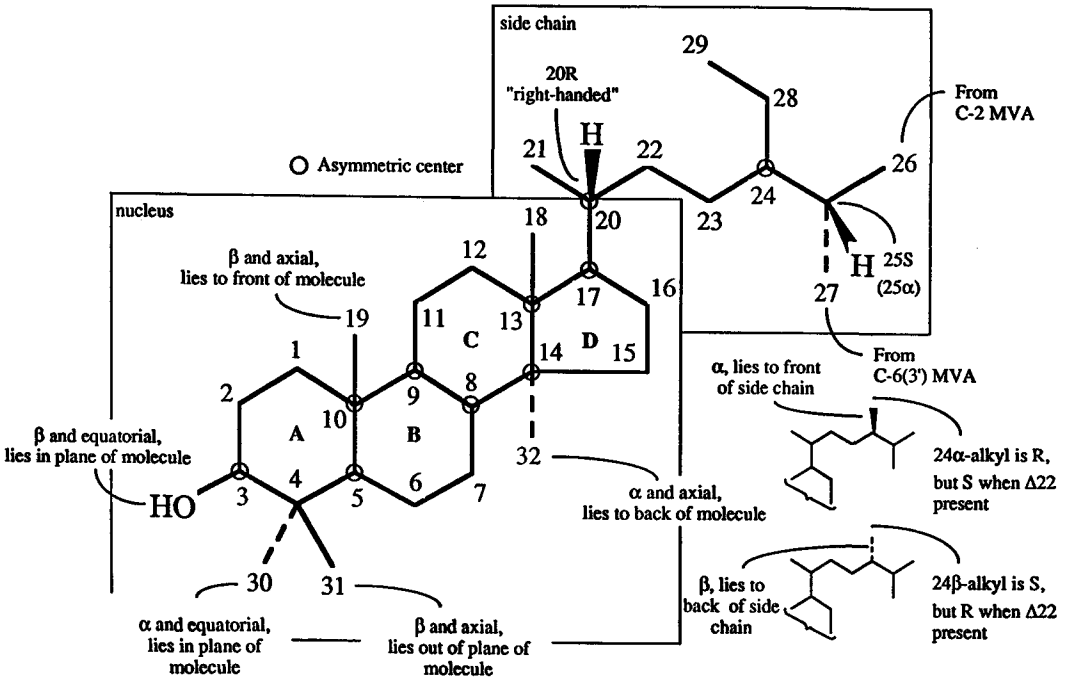

FIG. 3. Nes system (modified from Fieser and Fieser, *cf.* Ref. 37) for the numbering of carbon atoms in the sterol constitution. MVA, mevalonic acid.

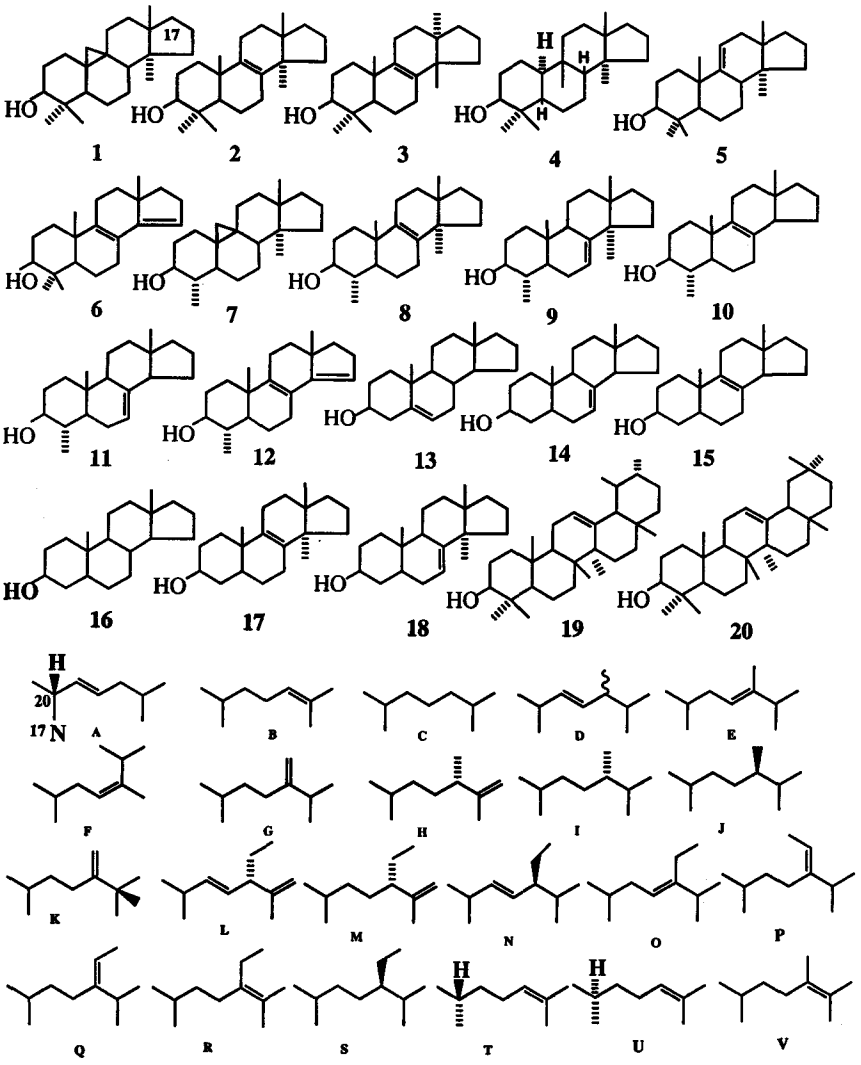

FIG. 4. Structures of sterols and triterpenoids discussed in text.

ucts chemists. We view cycloartenol as a sterol on biosynthetic grounds and refer to it formally as 4,4,14-trimethyl-9β,19- cyclo-5α-cholest-24-en-3β-ol. Alternatively, euphol is a triterpenoid, even though chemically it may be considered a structural isomer of cycloartenol. In order to save space, sterol structures are shown in Figure 4 by a number (nucleus) and letter (side chain).

MATERIALS AND METHODS

Zea mays (Lot No. 7054; Asgrow Seed Co., Stonington, IL) seeds were surface sterilized by soaking in 10% Chlorox bleach for 30 min. Seeds were then soaked in running tap water for 16 h. Seeds were germinated in trays of moistened paper towels overlaid with a second tray. The seedlings were grown in the dark for up to eight days. Seedlings with shoots and roots of similar lengths (±0.5 mm) were harvested from each tray. Three-day shoots were excised at their base. Four-day shoots were cut at the first node, and the top parts were then dissected into sheaths (coleoptiles) and blades. Four-day roots were cut 3–4 mm from the tip and at the base of the root connecting to the seed, producing two parts: the root cap and the mature root system. Eight-day shoots were dissected in a similar manner as four-day shoots. Eight-day roots were dissected at the base of the root. Friable corn cells used for tissue culture were derived from seedling hypocotyl tissue and grown on M&S medium supplemented with 3% sucrose, 2 mg/L 2,4-D, and 7 g/L agar to produce calli, and were transferred once a month onto fresh agar plates. Calli were used as inoculum for cells cultured in 1L-Erlenmeyer flasks on a shaker platform at 160 rpm, as described (39).

Incubations with labeled substrates were performed as follows. Typically fifty eight-day seedlings were grown in the dark. The blades and sheaths were separated from the seed and each group incubated in Petri dishes containing either 7 mL water or 5 mL phosphate buffer (0.1 M KH_2PO_4 and 0.1 M Na_2HPO_4 adjusted to pH 7.4). The blades and sheaths were placed in a gentle draft to enhance transpiration and up-

take of the solution during the incubation period. Additional water was supplied to the Petri dish as necessary. We observed that the addition of phosphate buffer promoted uptake of mevalonic acid into the plants. DL-[2-^{14}C]Mevalonic acid as the *N,N'*-dibenzylethylenediammonium salt (2–10 mCi/mmol) and [2-^{14}C]acetic acid as the sodium salt (40–60 mCi/mmol) were purchased from Amersham (Chicago, IL). [^{3}H]Acetic acid as the sodium salt (2–5 Ci/mmol) was purchased from NEN (Boston, MA), and D_2O (99.9% D) was purchased from Cambridge Isotopes (Andover, MA).

Sterols were isolated and analyzed in the same manner as described previously (40–42). In our experiments, we now routinely saponify the plant material directly in methanolic KOH (rather than extract the plant material in organic solvent e.g., with acetone prior to saponification). We compared the protocols reported in the literature (24) for isolating sterols from corn with our method and found that there was no quantitative difference in the amount of sterol released from the plant; also, we found that saponification of cultured cells and yeast was necessary to release most of the sterol from the cells (39,43).

The instrumentation and techniques for HPLC and gas–liquid chromatography (GLC) have been described earlier (41,44,45). GLC/mass spectrometry (MS) was performed by Dr. Robert A. Norton (USDA, Peoria, IL) on a Hewlett-Packard 5890 series II gas chromatograph (San Fernando, CA) with 5970 MSD at 70 ev. The capillary column for GLC was a 15-m DB5MS (J&W Scientific, Folsom, CA) column. The temperature program was as follows: 170°C for 1 min ramping to 270°C at 20°C/min, isothermal at 270°C for 3 min, ramping to 280°C at 2°C/ min, then isothermal at 280°C for 6 min. The scan range was 50–550, the injector port was kept at 250°C, and the transfer line at 280°C. ^{1}H nuclear magnetic resonance (NMR) spectroscopy was performed on samples dissolved in $CDCl_3$ at ambient temperature on either a Bruker AF-300 or Bruker AF-200 NMR spectrometer (Billerica, MA) with tetramethylsilane as internal standard.

Key to our developmental and kinetic studies on phytosterol biosynthesis was our ability to isolate sterols from corn plants in pure form. To that end, we developed a series of chromatographic steps using thin-layer chromatography (TLC) and reversed-phase HPLC methods (41,44,45). TLC will separate compounds based on the degree of substitution at C-4. TLC was used first to produce three classes of sterols: 4,4-dimethyl-, 4-monomethyl-, and 4-desmethyl-sterols (41). HPLC was used next to separate sterols based on the size and stereochemistry of the molecule (41,45). GLC may be used to provide preliminary characterization of the sterol and of its purity (41,45). Table 1 shows the various constitutional, geometric and diastereoisomeric features of the sterol molecule that may be distinguished by using a combination of chromatographic systems. The instrumental conditions used in Table 1 are as follows: reverse-phase HPLC; A—operated on a 25 cm Whatman partisphere C-18 column (5 mm par-

ticle size, 4.6 mm i.d.) eluted with MeOH/H_2O (96:4, vol/vol) at 40°C at a flow rate of 1.5 mL/min; B—operated on a 25 cm TSK gel C-18 column (Toya Soda Manufacturing Co., Tokyo, Japan; 5 mm particle size, 4.6 mm i.d.) eluted with MeOH/*i*-PrOH (4:1, vol/vol) at room temperature at a flow rate of 1.00 mL/min; C—operated on a 25 cm Zorbax C-18 column (Dupont, Boston, MA; 5 mm particle size, 4.6 mm i.d.) eluted with 100% MeOH at room temperature at a flow rate of 1.00 mL/min. GLC; A—performed on a three-foot spiral 3% SE-30 packed column operated isothermally at 245°C; B—performed on a capillary 15 M HP-50 column operated isothermally. Cycloartenol may be separated from β-amyrin by use of a Whatman C-18 column operated at low temperature (10°C) at a flow rate of 1.00 mL/min eluted with MeOH/H_2O (96:4, vol/vol).

RESULTS AND DISCUSSION

Sterol composition. The first studies were designed to establish the sterol composition of corn. We germinated several batches of seeds for four to nine days and pooled the plants. The seedlings were anatomically dissected into sheaths, blades, and roots. From this material, trace compounds could be isolated and characterized. As shown in Table 2, we identified approximately sixty sterols. The identity of each sterol was confirmed by matching their GLC behavior and mass spectra with data obtained on authentic specimens. There were several sterols occurring at trace levels that we were unable to identify. Table 2 showed that we isolated many of the same sterols identified earlier by others (1–23). Several sterols isolated by us were new corn sterols: for instance, 24(28)-methylene-25-methyl-cholesterol, cholesta-5,22-dienol, and 22-dehydroclerosterol (stigmast-5,22,25-trienol). Ergost-23-enol was a new naturally occurring sterol (Table 3). The ^1H NMR data of selected sterols isolated from corn are given in Table 3. The assignments of the ^1H NMR signals for C-26, C-27, C-28, and C-29, reported in Table 3, are based on recent labeling experiments with stable isotopes (39,46,47). The ^{13}C NMR spectrum in Figure 5 shows that the configuration of the C-24 alkyl group may be distinguished by the chemical shift of C-29. The 24-methyl-cholesterol samples were shown to be epimeric mixtures by HPLC and ^1H NMR (Fig. 6). The ratio of 24α- to 24β-methyl cholesterol varied depending on the stage of seedling development. We could not detect cyclolaudenol (limit of detection, 0.001% of the total sterol) in any plant part. However, we detected codisterol and two doubly bioalkylated $\Delta^{25(27)}$-24-ethyl-sterols. The β-configuration of the 24-ethyl group was confirmed by ^1H NMR (Table 3). We isolated several other unusual 24-ethyl sterols, including fucosterol (24*E*-ethylidene-cholesterol) and 24-ethyl-desmosterol. These results indicated the existence of multiple transmethylation pathways, operating at both the first and second stage of C-24 alkylation. The detection of 24(28)-methylene-25-methyl-cholesterol and 24-methyl-desmosterol indicated that the two sterols might be in a unique precursor–product relationship, as

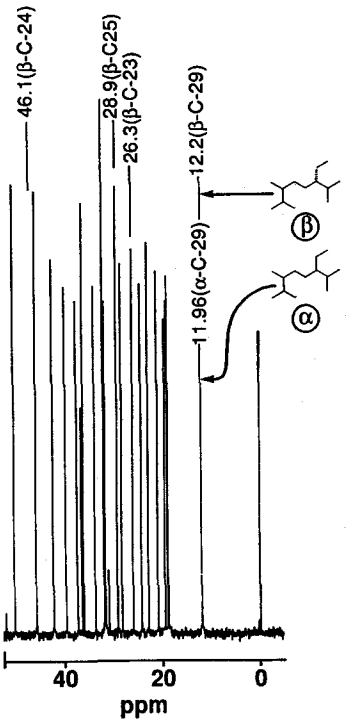

FIG. 5. ^{13}C Nuclear magnetic resonance spectrum of sitosterol isolated from corn sheaths. The relevant chemical shift for C-29 that characterize sitosterol and 24-episitosterol (clionasterol) is highlighted in the figure.

shown elsewhere in Kalinowska *et al.* (28). The detection of fucosterol and clereosterol [24β-ethyl-cholesta-5,25(27)-dienol] in corn along with isofucosterol was significant in terms of sterol phylogenesis, since only isofucosterol was thought to be synthesized by highly advanced plants such as corn (28,47). Rendell *et al.* (24) found that corn "sitosterol" contained a few percent of its 24-epimer as judged by ^1H NMR. Our samples of sitosterol were analyzed by ^{13}C NMR, a spectroscopic technique that is better suited than ^1H NMR to distinguish the chiral purity of C-24 alkyl sterols, because of the signal-to-noise ratio. All of our sitosterol samples were found to be epimerically pure 24α-ethyl-cholesterol. From the 4,4-dimethyl sterol fraction, we isolated two pentacyclic triterpenoids, α- and β-amyrin along with cycloartenol and 24-alkylated cycloartenols. For kinetic studies on sterol biosynthesis, we developed HPLC methods to separate the amyrins from cycloartenol and 24-alkylated cycloartenols (see Materials and Methods, and Table 1).

Changes in sterol content and distribution. Figure 7 shows that in the first eight days following seed germination, total sterol content of roots and shoots increased in parallel with increased body length. The rate of daily sterol production was found to be *ca.* 4 to 5 μg/day. Koops and Groeneveld (33) reported similar rates of sterol production for etiolated *Euphorbia lathyris* seedlings. The results indicated active sterol synthesis in the seedling to meet the demands of new plant growth. There was no significant change in the sterol profile of the seed during imbibition (sterol content remained at *ca.*

118 μg/seed for day 1 following imbibition). Kemp *et al.* (8) reported that during the first two weeks of corn seedling development, sterol increased in the shoot and root, as we reported here. Kemp *et al.* (8) found that the sterol composition of the shoot did not change qualitatively during seedling maturation whereas the root sterol composition did. In the root, the sitosterol levels decreased whereas stigmasterol levels increased. Alternatively, in our study we observed that the sterol composition changed in subtle ways qualitatively and quantitatively in the root and shoot (notably when the shoot is separated into blade and sheath) during seedling development. Table 4 shows the sitosterol/stigmasterol ratio and 24α–/24β-methyl-cholesterol ratio changes during physiological aging. The level of ergosta-5,23-dienol increased during development of dark-grown coleoptiles (sheaths). Actively growing tissues, such as root caps, tissue cultures, and blades, produced mainly 24-ethyl-sterols, and sitosterol predominated the sterol mixture. Pollen sterols were unusual both qualitatively and quantitatively. Pollen accumulated 24(28)-methylene-sterols, including the Δ^7-sterols, 24(28)-methylene-lophenol, and cholesta-7,24(28)-dienol. Of the plant parts studied, pollen produced the most sterol (3,904 μg sterol/g fresh weight) whereas the three-day shoot possessed the least sterol (94 μg sterol/g fresh weight).

Relative rates of sterol biosynthesis and transformation. Table 5 shows the incorporation of [2-^{3}H]acetate into sheath and blade sterols after 24-h incubation. When the blade 4,4-desmethyl-sterol fraction was purified into individual sterols by HPLC, the bulk of the radioactivity was found to be with six Δ^5-sterols: as percent of total activity, ^{3}H was associated with 24(28)-methylene-cholesterol (9%), campesterol (4%), 24-epicampesterol (5%), isofucosterol (28%), sitosterol (43%), and stigmasterol (7%). When the sheath 4,4-desmethyl-sterols were purified by HPLC (Fig. 8), it was clear that neither stigmasterol, sitosterol, nor 24-epicampesterol incorporated significant label from [2-^{3}H]acetate whereas 24(28)-methylene-cholesterol, ergosta-5,23-dienol, and campesterol were labelled significantly. These results suggested that sheath and blade produce many of the same sterols, but that their production rates differ.

Figure 9 shows that [2-^{14}C]mevalonic acid uptake was linear up to about 10 h. There was much greater incorporation of [2-^{14}C]mevalonic acid into 4,4-desmethyl-sterols in blades than in sheaths. These results were consistent with the [2-^{3}H]acetate feeds to eight-day seedlings. From [2-^{14}C]-mevalonic acid experiment, the relative rate of 4,4-desmethyl-sterol synthesis in the blade was found to be *ca.* 1.0 pmol/h/100 shoots and the ratio of relative rates of synthesis of 24-methyl- and 24-ethyl-sterols about 4:1, which is in good agreement with the data observed by Rendell *et al.* (24), who studied kinetics of sterol synthesis in etiolated corn shoots. Scheid *et al.* (18) studied the kinetics of sterol biosyn-

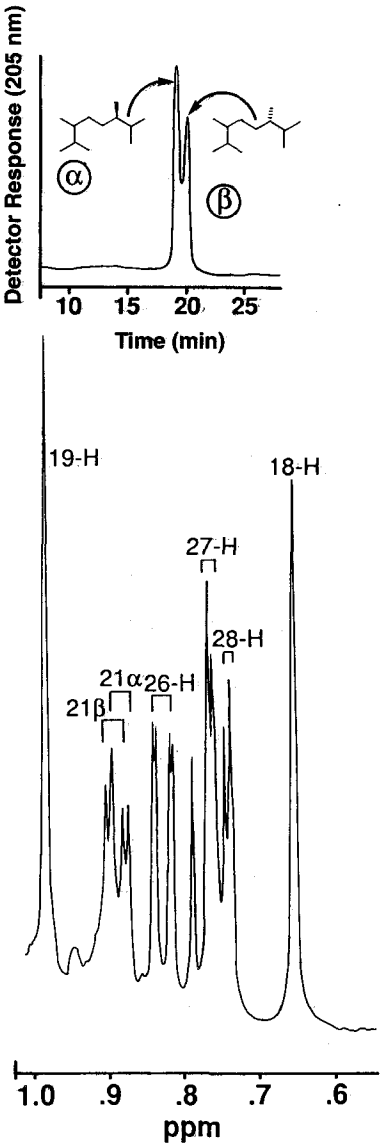

FIG. 6. High-performance liquid chromatography chromatogram [sample chromatographed on a TSK gel column (Toya Soda Manufacturing Co., Tokyo, Japan)] (top) and ^{1}H nuclear magnetic resonance spectrum (300 MHz) (bottom) of a diastereoisomeric mixture of 24-methyl-cholesterol isolated from eight-day corn sheaths.

thesis in the sheath of etiolated corn seedlings. They found that neither sitosterol, stigmasterol, nor 24-methyl-sterols were labeled significantly from incubation with [2-^{14}C]acetate, whereas ^{14}C label was incorporated into 24(28)-methylene-cholesterol and ergosta-5,23-dienol. Rendell *et al.* (24) reported that 24-ethyl-sterols were labeled significantly in etiolated corn shoots.

We were puzzled by the different results. However, as our results on the separated anatomical parts, i.e., sheaths and blades, clearly show, the blade is biosynthetically more active in producing sterols than is sheath. Thus, Rendell *et al.* (24) seem to have quantified blade sterol synthesis in the shoots.

Pulse chase experiments. Figure 10 shows an experiment that involved an eight-hour equilibrium-labeling period using [2-^{14}C]mevalonic acid as substrate followed by a period for up to three hours when mevalonic acid was chased into cycloartenol. Table 6 shows the product analysis upon chasing the label into 4,4-desmethyl-sterols. Regardless of whether the tissue was blade or sheath, cycloartenol was turned over rapidly: 24 pmol/h/mg protein during the chase whereas the turnover rates of the 4,4-desmethyl-sterols were an order of magnitude lower than those of cycloartenol (data not shown). There were no significant differences in cycloartenol synthesis in blades and sheaths during the three-hour chase, whereas significant differences were found in the relative rates of individual sterol end products. As shown in Table 6, sitosterol was synthesized slowly whereas ergosta-5,23-dienol was synthesized rapidly. Stigmasterol synthesis was very low, as reported by others studying corn (24), and by us studying sorghum (30). Stigmastanol, which appears just after sitosterol in HPLC, was not synthesized actively, in contrast to the findings of Misso and Goad (20) who reported active synthesis of stanols. The high rate of 24(28)-methylene-cholesterol turnover shown in Table 6 is consistent with its playing a role as an intermediate rather than an end product of cycloartenol transformation to Δ^5-sterol end products (31). To explain the differences in the kinetics of sitosterol and stigmasterol synthesis, Rendell *et al.* (24) proposed a two-pool model. This model might also explain the labeling kinetics of stanols. However, the model will not adequately explain the differences in 24-methyl- and 24-ethyl-sterol synthesis. Our hypothesis is that cycloartenol was channeled into two C-24 alkylation pathways, the $\Delta^{24(28)}$-methylene and Δ^{23}-methyl pathway. The sheath operated both pathways whereas the blade operated only the $\Delta^{24(28)}$-methylene pathway. We assume differences in rates of Δ^5-sterol synthesis in sheaths and blades are not based on differences in carbon flow from mevalonic acid metabolism, because cycloartenol synthesis was equally active in both tissues. We hypothesize that the rate of Δ^5-sterol synthesis is controlled by cycloartenol turnover, which is controlled by the activity of the C-24 methyl transferase (35).

At this point we thought the blades and sheaths synthesized most of the sterol present in the tissue. However, when we calculated the relative rate of sterol synthesis from the data obtained in Figure 6 to be 30 nmol sterol produced/h/100 shoots, we concluded that there was a discrepancy between the natural product and biochemical determinations in estimating rates of sterol production. There was obviously too little sterol synthesized from exogenous acetate or mevalonate by the Bloch-Cornforth pathway to account for the level of sterol actually accumulating in the maturing seedlings. The question arose whether the sterol present in early maturing shoots was derived partly from *de novo* synthesis of some alternative pathway (e.g., the Popják shunt), or from translocation of sterol stored in the seed, or both. To answer this question, additional experiments were needed, as discussed next.

KIE. Table 5 shows the incorporation of label from [2-^{14}C]mevalonic acid and [2-^{14}C]acetic acid into the nonsaponifiable lipid fraction and into sterol fractions purified by

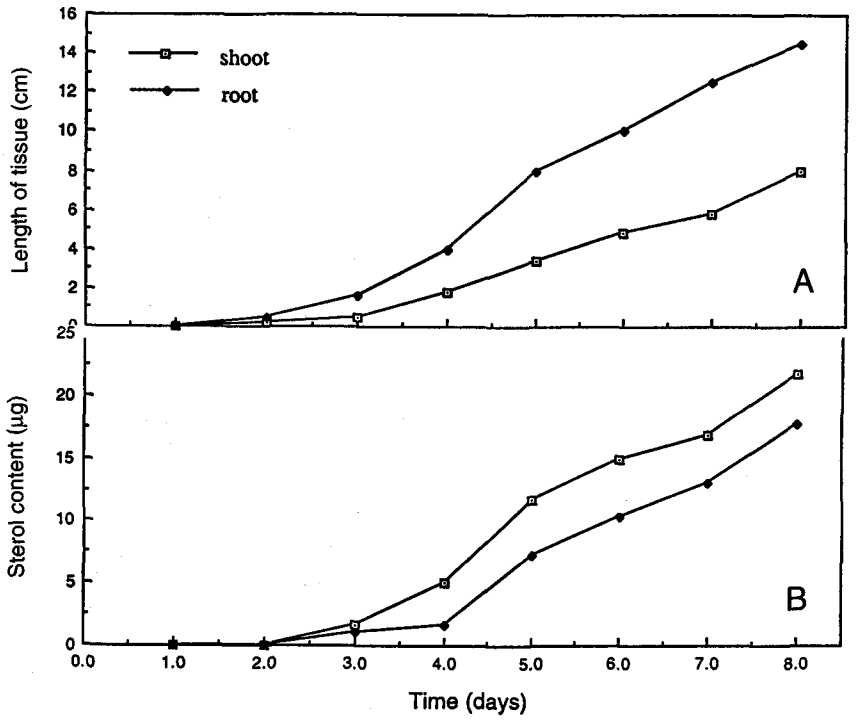

FIG. 7. A: Plot of root and shoot growth and B: changes in sterol content relative to time of seedling maturation. The day one value is the time following imbibition of water.

TLC. Whereas label from mevalonic acid was incorporated into 4-desmethyl-sterols, label from acetic acid was not. The results proved that seeds do not synthesize sterols *de novo* from acetate. To confirm further that the mevalonate to sterol pathway was not active in germinating seeds, corn seeds were imbibed with deuterated water. The seeds were slow to germinate, but after ten days, the seeds developed shoots of approximate length to three-day germinated plants incubated with normal water. The GLC/MS of the seed sterols confirmed that none were labeled with deuterium.

The three-day shoots from normal water germinated seeds were found to possess five main sterols by GLC. They were, based on their retention times in GLC (Fig. 11), ergosta-

5,23(24)-dienol, 24-methyl-cholesterol, stigmasterol, sitosterol, and isofucosterol. The shoot sterol composition from seeds germinated in D_2O was different from the sterol composition of seeds germinated in H_2O (Fig. 11). A new peak appeared in the GLC corresponding to the relative retention time, measured relative to cholesterol (RRT_c), of stigmasta-5,23(24)-enol, and the peak for isofucosterol disappeared. A second novel compound, which was not readily evident in the GLC chromatogram of 4-desmethyl-sterols from the D_2O-treated shoots, was detected during HPLC fractionation of the 4-desmethyl-sterol mixture. Based on HPLC, the two new sterols represented about 30% of the total sterol mixture of the shoot. Shoot 4-desmethyl-sterols from the D_2O treatment were examined by GLC/MS. Two of the sterols were found to be labeled with deuterium, ergosta-5,23(24)-dienol and stigmasta-5,23(24)-dienol, whereas the other sterols were not labeled, e.g., sitosterol (Fig. 12). The apparent molecular weights of the two labeled sterols, M^+ 446 and 432 amu, respectively, indicated that 34 hydrogens were introduced into the sterol molecule from deuterium (in the form of deuterium introduced from NADPH and medium in the form of H^+). This number contrasts with the value of *ca.* 24 hydrogens previously hypothesized (48,49) as the number of hydrogens normally introduced into phytosterol synthesis (assuming complete equilibration of NADPH with D_2O) (48). The 14 mass unit difference between ergosta-5,23-dienol and stigmast-5,23-dienol indicated that the methyl on *S*-adenosyl-L-methionine was not labeled with deuterium, and therefore the amino acid must have been translocated along with sterols from the seed to the developing shoot. We were concerned with the character of the mass spectra of the deuterated sterols obtained by the GLC/MS (spectra obtained on a table top HP model GLC/MS). Therefore, we prepared 24,24-dideuterated 24-methyl-cholesterol by deuteration and 24-methyl-cholesterol by hydrogenation from 24-methyl-desmosterol, as described (50). As shown in Figure 13, protium-deuterium exchange occurred in GLC that affected the distribution of ions in the high mass region. The sample of deuterated 24-methyl-cholesterol was examined by ^1H and ^{13}C NMR and found to incorporate deuterium in place of hydrogen at C-24 and C-25 completely. We observed this exchange phenomenon with several other deuterated sterols (unpublished). We observed that as the number of deuterium atoms incorporated into the sterol increases, the molecular ion cluster becomes more prominent. It is important to note that the ions thought to represent endogenous substrate are due to protium/deuterium exchange resulting from the sample passing through chromatographic column which operates at high temperatures. The identities of the two deuterated sterols isolated from shoots were confirmed by purifying them by HPLC, and by then examining the pure sample by ^1H NMR. Both sterols showed NMR spectra consistent with the proposed structures (ergosta-5,23-dienol and stigmasta-5,23-dienol). Specifically, for the deuterated sample of ergosta-5,23-dienol, the spectra showed a characteristic olefinic proton resonating at δ 3.513 ppm (multiplet) for H-3 and at δ 5. 318 ppm for H-6 (doublet). The signal for the H-23 proton was observedat δ 5.109 ppm (partial triplet) (Fig. 14). There was also a small chemical shift and a change in the character of the signals for H-3, H-6, and H-23 in the ^1H NMR spectra of the deuterated compared to normal sample. The signals corresponding to H-3, H-6, and H-23 shifted due to an apparent β-deuterium isotope effect of (+) 0.016 ppm and (−) 0.014 ppm and (+) 0.005 ppm, respectively. The methyl region of the ^1H NMR spectra was complex. From the shoot 4,4-dimethyl TLC band, several sterols and triterpenes were isolated. Cycloartenol was labeled with deuterium (M^+ 460 amu) whereas none of the triterpenes nor 24(28)-methylene-cycloartanol were labeled. Lakshmann and Veech (48), studying cholesterol synthesis in the rat using ^3H_2O as the labeled intermediate, hypothesized on biosynthetic grounds (i.e., the Bloch-Cornforth pathway) that H-3, H-6, and H-23 on cholesterol should contain tritium.

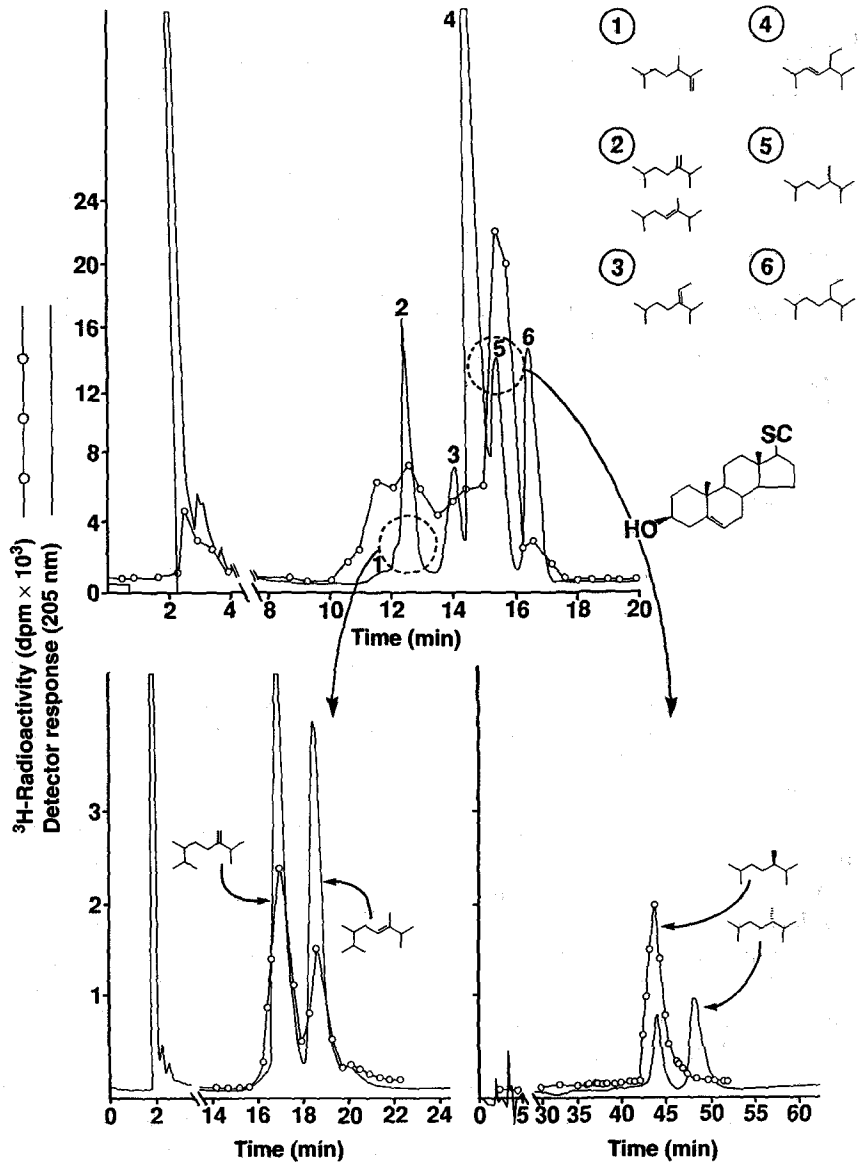

FIG. 8. Reversed-phase high-performance liquid chromatography (HPLC) (Zorbax C-18 column; Dupont, Boston, MA) mass and radioactivity analysis of the total 4-desmethyl-sterol fraction (top) isolated from sheaths of eight-day seedlings. Selected HPLC fractions, which were known to contain a mixture of sterols, were eluted from the Zorbax column and rechromatographed using a TSK gel C-18 column (Table 1), as shown in the bottom figure. See Figure 6 for company source.

The tritium at C-6 and C-23 should be derived from hydrogens derived from NADPH incorporated into mevalonic acid (48). The tritium incorporated into H-3 should be derived from reduction of a 3-keto sterol formed during the C-4 demethylation step of lanosterol. Our spectroscopic data on the deuterated Δ^{23}-alkyl-sterols do not support the Bloch-Cornforth labeling pattern for sterols. The signals in the ^{1}H NMR demonstrated that deuterated ergosta-5,23-dienol retained hydrogens at C-3, C-6, and C-23, which shows that mevalonic acid was not a precursor of the deuterated sterols.

The synthesis of deuterated ergosta-5,23-dienol and stigmasta-5,23-dienol suggests that the first and second methyl transfer at C-24 should be sensitive to a KIE. Most likely, there were originally a hydrogen and a deuterium at C-23, since the methyl cation has been shown to possess three hydrogen atoms. An induced KIE occurs when a primary deuterium isotope effect accelerates the rate of formation of one transmethylation product by suppressing the rate of formation of another transmethylation product. Isotopically sensitive branching describes the rate enhancement in the formation of one product of a multiple product enzyme caused by a reduction of the rate constant for the formation of a second

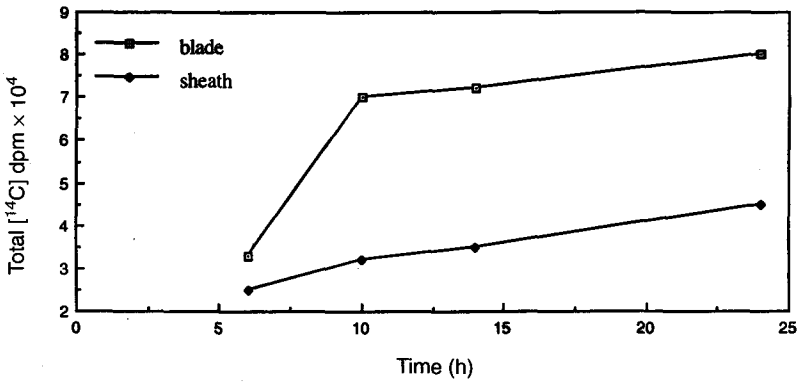

FIG. 9. Curves relating time of incubation of [2-^{14}C]mevalonic acid with the extent of [2-^{14}C]mevalonic acid incorporation into 4-desmethyl-sterols of blades and sheaths of eight-day seedlings (*cf.* Table 5).

product due to isotopic substitution in the substrate. Observations of this kind indicate that the two products arise from a common intermediate formed by the same enzyme (51). Goad *et al.* (52), studying sterol side-chain alkylation mechanisms in an alga, observed a KIE in the first and second transmethylation. From our data on the sterol composition of corn, we found that the plant produced several C-24 alkylated isomers, all of which may be described as originating mechanistically from the same reaction involving the same enzyme. The KIE operating during transmethylation favors abstraction of a proton from H-23 rather than from the incoming methyl cation (H-28) or from H-27. Assuming that a single C-24 methyltransferase mediates the production of several C-24 methylated alternatives, then the course and rate of methylated products formation should be affected, which is what was observed here. It follows that the deuterated Δ^{23}-24-alkyl-sterols were formed by disturbed methylation equilibria involving either cycloartenol giving rise to cyclosadol (first transmethylation) which is turned over to ergosta-5,23-dienol, or 24(28)-methylene-lophenol, giving rise to 4α-methyl-stigmasta-7,23-dienol which then is turned over to stigmasta-5,23-dienol.

In both deuterated samples of stigmasta-5,23-dienol and ergosta-5,23-dienol, H-6 and H-3 were labeled with hydrogen rather than deuterium. This was unexpected and suggests that the Bloch-Cornforth pathway (37), which may lead to the formation of the two deuterated 24-alkyl-sterols, might be downregulated during early shoot development. The unusual labeling pattern indicated either sugar (*via* pyruvate) or amino acid (possibly derived from pyruvate) was transformed into a 5-carbon molecule that entered into the isopentenoid pathway *via* the Popják shunt, effectively by-passing mevalonic acid. The 5-carbon molecule then could be phosphorylated and converted into isopentenyl pyrophosphate. Studies with stable isotopes are planned to shed light on this novel plant lipid pathway.

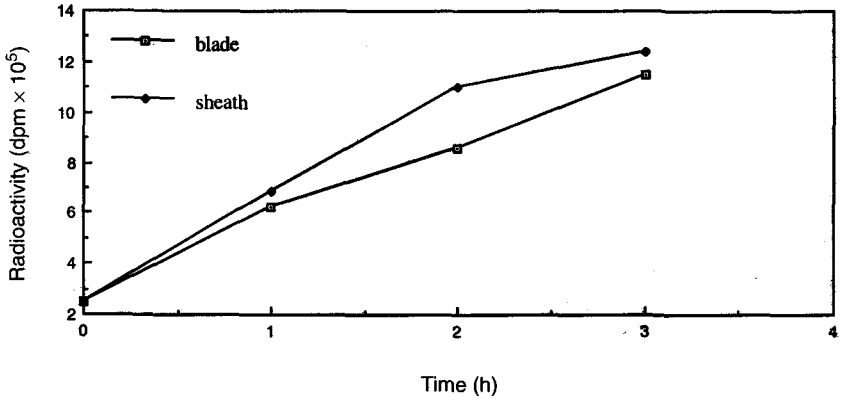

FIG. 10. Pulse-chase experiments which involved preequilibration of [2-^{14}C]mevalonic acid in a phosphate buffer with eight-day blades and sheaths, then chasing the label for up to 3 h into cycloartenol (purified by thin-layer chromatography and high-performance liquid chromatography) (*cf.* Table 6 for results of the chase of radioactivity into 4-desmethyl-sterol end products).

[a]SA, specific activity in dpm/nmol; 5.0 μCi of [2-^{14}C]mevalonic acid was supplied to fifty seedlings and incubated for 8 h. The seedlings were rinsed with water and placed into fresh buffer for 1, 2, and 3 h. Only the 8-h (zero-h chase time point) and 11-h (3-h chase time point) are reported.
[b]This pathway was not operational in blades.

CONCLUSIONS

It is well known that the activity of HMG–CoA reductase is important in regulating carbon flux from acetate to sterol. Nevertheless, for some time we have questioned whether HMG–CoA reductase is "the" rate-limiting enzyme in phytosterol transformation, a biochemistry which may be viewed as the "post-cycloartenol" pathway (32,36). We believe the search for the critical rate-limiting step in phytosterol transformation (which is distinct from steps that lead to cycloartenol production) should be directed to enzymes that act on the tetracyclic structure (36). In this study we discovered that the C-24 alkylation step was a rate-limiting step in sterol transformations. We define the start of the sterol pathway with the formation of cycloartenol (4,4-dimethyl-sterol) and ending with the formation of Δ^5-sterols (4-desmethyl-sterol) (36). Stanols, such as stigmastanol (sitostanol), might be considered the end products of cycloartenol metabolism. They are likely formed by conversion of the Δ^5,3-OH compound to a Δ^4,3-one, and reduced to produce the Δ^0-compound as shown chemically (53). Stanols, unlike Δ^5-sterols, do not accumulate in membranes (54); therefore by definition (36) they cannot be end products equivalent functionally to sitosterol. They either accumulate as ferculate esters in corn seeds (55) or form part of the surface wax (unpublished observations). We hypothesized that the steady-state concentration and structure of the end product are important in ways that go beyond their role as membrane inserts (36). In sunflower we found that the end product may feed back on the transformation process by binding competitively with other sterols that may be viewed as the natural (preferred) substrates (56,57). Thus it appeared that the precise outcome of cycloartenol transformation to 24-alkyl-sterols depended on substrate availability and structure of sterols. Additionally important are the corresponding rate constants (kinetic control) for binding and catalysis by the C-24 methyltransferase and thermodynamic control where product utilization promotes the different kinetically favored pathways. A similar pathway appears to be operating in corn.

As shown by our kinetic studies and confirmed by the sterol composition data of maturing seedlings, carbon from cycloartenol flows into sitosterol first. Then secondly, as tissues age, carbon flows into 24-methylene- and 24-methyl-sterols. The accumulation of 24-methyl-sterols in some tissues means the activity of the C-24 methyltransferase was affected. Figure 15 shows our hypothetical kinetically favored 24-alkylation pathway in actively growing tissues (albeit that involving active cell proliferation). There are important branch points in the pathway which are controlled by C-24 alkylation.The critical slow step, or the first committed step in the corn sterol pathway, appears to be methylation of cycloartenol. However, by the regulating of C-24 methyltransferase activity, e.g., of cycloartenol transmethylation, the kinetics of the pathway may be shifted from one that produces 24(28)-methylene-sterols giving rise to sitosterol to one which gives rise to Δ^{23},24-methyl-sterols, such as cyclosadol and ergosta-5,23-dienol. If there is sufficient preformed sterol available for transmethylation, as was the case in the developing shoot (*via* translocation from the seed), the second alkylation step may become rate-determining. Here enzyme activity may be regulated by conformational control resulting from structurally similar sterols competing for the same sites on the C-24 methyltransferase. The inability for the deuterated Δ^{23},24-alkyl sterols to be turned-over in the shoot may indicate that the side-chain reductase is regiospecific for the 24,25-bond or that a KIE was operating with respect to the 23,24-reductase.

The novel labeling pattern in the deuterated sterols isolated from the shoots of seeds germinated in D_2O water indicates that carbon flux into the isopentenoid pathway and into sterols

may involve novel pathways that require participation of the Popják shunt.

ABSTRACT: Research on the ergosterol biosynthetic pathway in fungi has focused on the identification of the specific sterol structure required for normal membrane structure and function and for completion of the cell cycle. The pathway and its end product are also the targets for a number of antifungal drugs. Identification of essential steps in ergo-sterol biosynthesis could provide new targets for the development of novel therapeutic agents. Nine of the eleven genes in the portion of the pathway committed exclusively to ergosterol biosynthesis have been cloned, and their essentiality for aerobic growth has been determined. The first three genes, *ERG9* (squalene synthase), *ERG1* (squalene epoxidase), and *ERG7* (lanosterol synthase), have been cloned and found to be essential for aerobic viability since their absence would result in the cell being unable to synthesize a sterol molecule. The remaining eight genes encode enzymes which metabolize the first sterol, lanosterol, to ultimately form ergosterol. The two earliest genes, *ERG11* (lanosterol demethylase) and *ERG24* (C-14 reductase), have been cloned and found to be essential for aerobic growth but are suppressed by mutations in the C-5 desaturase (*ERG3*) gene and *fen1* and *fen2* mutations, respectively. The remaining cloned genes, *ERG6* (C-24 methylase), *ERG2* (D8Æ7 isomerase), *ERG3* (C-5 desaturase), and *ERG4* (C-24(28) reductase), have been found to be nonessential. The remaining genes not yet cloned are the C-4 demethylase and the C-22 desaturase *(ERG5).*
Lipids 30, 221–226 (1995).

Sterol biosynthesis in eucaryotic cells has been intensely studied for decades. The biosynthetic pathways of animal, plant, and fungal sterols are now well-defined, and the regulation of cholesterol biosynthesis in animal cells has been well documented (1). Much of the interest in the cholesterol pathway has resulted from the association of poorly regulated cholesterol synthesis and cardiovascular disease.

Research on the fungal sterol pathway which produces the C_{28} sterol, ergosterol, as its end product has followed two major lines of investigation. The first of these is directed to answer fundamental questions concerning the role or roles of sterol in membrane structure and function. Using a variety of systems, sterols have been shown to play critical roles in maintaining appropriate membrane fluidity (2,3), regulating membrane permeability (4,5), influencing the activity of membrane-bound enzymes (6), and altering cell growth rate (7). Beyond these membrane-related functions, sterols have been implicated in providing an essential function in the cell cycle. In this capacity, a sterol of specific structural features is required at hormonal levels (10 nM) to allow cell cycle completion. This phenomenon has been demonstrated in yeast (8) and animal cells (9,10). The elucidation of this sterol function as well as the sterol molecule responsible have been subjects of recent research. The second focus of fungal sterol research is driven by the need to develop new antifungal agents for use in medicine and agriculture. There has been an alarming recent rise in the number of human fungal infections (11) resulting from several factors that include both increases in the incidence of immunosuppressive disease and increases in immunosuppression resulting from technological advances in areas of science and medicine that have modified clinical practices.

As eucaryotes, fungal pathogens possess few potential therapeutic targets that would leave the host unaffected. The rise in microbial resistance to currently available therapeutic agents has been cited in publications varying from basic scientific journals to the lay press (12,13). Although the major emphasis of many of these articles is bacterial resistance, all officially approved antifungal agents have major deficiencies that limit their effective use. Of additional consequence here is the fact that some of the best fungal antibiotics are fungistatic rather than fungicidal. Coupled with immunosuppressive disease and medical advances in chemotherapy and transplantation, all of which result in or require immunosuppression, a fungistatic compound merely retards the pathogen which must then be controlled by a nonfunctional immune response. Human immunodeficiency virus infection is a particularly important area in which currently available antifungals have

been of limited efficacy (14,15). Thus, the identification of essential or required steps in sterol synthesis might provide ideal targets for new drugs that could have improved antifungal activity.

The major targets for antifungal compounds include ergosterol and its biosynthesis. There are a number of drugs that specifically block ergosterol biosynthesis with little effect on host cholesterol synthesis. Specificity is based upon differential enzyme susceptibility or differences in cell permeability. In many cases, adverse side effects result from inhibition of host enzymes. The allylamines inhibit squalene epoxidase (16), an enzyme appearing in the pathway just before the synthesis of the first sterol molecule (Fig. 1). These compounds are restricted to primarily topical applications and show little activity against pathogens that produce life-threatening systemic infections. The morpholines (17) are a group of sterol biosynthesis inhibitors (SBI) which block two separate steps in sterol synthesis, C-14 sterol reduction (*ERG24*) and sterol Δ8→7 isomerization (*ERG2*). This group is used primarily in agricultural applications although amorolfine is under investigation for human topical use (18). The azoles (imidazole and triazoles) are the most widely employed SBI (19) and are used in both topical and systemic situations. These compounds inhibit the C-14 demethylation of lanosterol (*ERG11* gene product) resulting in the formation of C-14 methylsterols. As a substitute for ergosterol, these sterols produce membrane effects leading to reduced growth (20), decreased membrane fluidity (3), and reduced ability to form invasive mycelia (20), an important feature in fungal pathogenesis. The polyene group (21) of antifungals interacts selectively with membrane ergosterol and introduce channels through which essential cell constituents escape, resulting in cell death. Due to their hydrophobicity and metabolism, some polyenes, such as nystatin, are restricted to topical application. Others, such as amphotericin B, can be used systemically but produce serious side effects.

Although not recognized as a major pathogen (22), the yeast *Saccharomyces cerevisiae* has been used as a model system for the elucidation of the ergosterol pathway, and it has been possible in this organism to determine the essentiality of the genes responsible for some of the enzymatic steps. Yeast has the advantage of a defined life cycle and sexual reproduction, making haploid existence and genetic crosses routine. Progress using pathogenic fungi, such as *Candida albicans*, has been considerably slower and largely dependent on procedures and information derived from work with *S. cerevisiae*.

The review will focus on the latter part of the pathway, beginning with the synthesis of squalene, the precursor of lanosterol, which is the first sterol intermediate in the pathway (Fig. 1). Steps prior to squalene formation are important for pathway regulation, and early pathway intermediates are me-

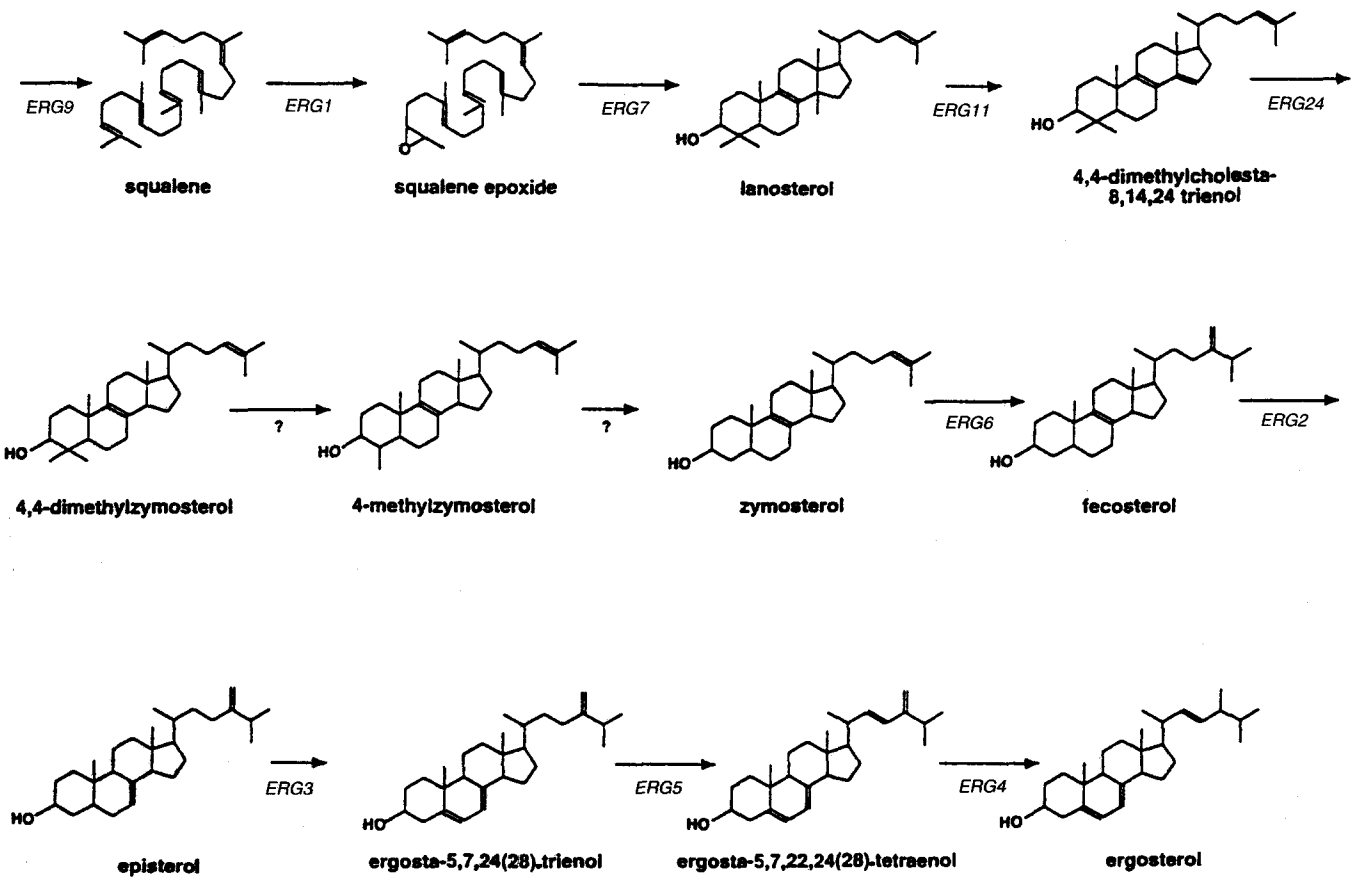

FIG. 1. The sterol biosynthetic pathway in *Saccharomyces cerevisiae* (adapted from Ref. 57).

tabolized to produce other essential cellular components (1). The genes responsible for coding nine of the eleven enzymes in the squalene to ergosterol part of the pathway have been cloned, and the essentiality of each for aerobic growth has been determined. For biosynthetic steps from lanosterol to ergosterol, essentiality was determined by gene disruption, followed by allelic replacement and growth under aerobic conditions. Blocks in the steps from squalene formation to lanosterol synthesis are essential because they do not allow the formation of any sterol molecule. Table 1 lists the eleven reactions from lanosterol formation to ergosterol and, where known, the genes involved, their essentiality for aerobic growth, their chromosomal location and drugs that inhibit the gene products. The genes specifying the enzymes responsible for two of the eleven steps have not been cloned. These include the genes encoding the enzymes responsible for the removal of the two bulky C-4 methyl groups and for desaturation of the side chain at the C-22 position (*ERG5*).

ERG9

Squalene, the first sterol precursor in ergosterol biosynthesis, is formed from two farnesyl diphosphate molecules by the enzyme squalene synthetase (farnesyl diphosphate farnesyl transferase). The substrate of this reaction, farnesyl diphosphate, serves as a beginning compound in the synthesis of several other important molecules that have isoprenoid components. Thus, the action of the *ERG9* gene product represents the first reaction in the branch committed to sterol synthesis. Two laboratories have reported the cloning of the *ERG9* gene (23,24). In both studies, *erg9* sterol auxotrophs containing a marker allowing the aerobic uptake of sterol were transformed with a wild-type yeast genomic library. Transformants capable of aerobic growth without ergosterol supplementation were selected. Plasmids containing the *ERG9* gene resulted in squalene synthase activity in *erg9* cells as well as in *Escherichia coli*. Characterization of the insert DNA indicated an open reading frame coding for a 444 amino acid protein with a molecular mass of approximately 51,700. This enzyme is highly conserved between yeast and humans (25). The *ERG9* gene has been mapped to chromosome 8.

ERG1

The product of the *ERG1* gene is an oxygen-requiring enzyme that converts squalene to 2,3-oxidosqualene, the immediate precursor of lanosterol. This enzyme is sensitive to allylamine inhibition, and this characteristic has been exploited to clone *ERG1* (26). An allylamine-resistant mutant (based on enzyme resistance) of *S. cerevisiae* was used to construct a library that was employed to transform the wild-type parental strain. Transformants were then isolated based on resistance to the drug. The plasmid containing the *erg1* allele was analyzed and found to contain an open reading frame encoding a 496 amino acid protein. The *ERG1* gene has been localized to chromosome 15.

ERG7

The *ERG7* gene encoding 2,3-oxidosqualene cyclase or lanosterol synthase has been cloned from both *C. albicans* (27) and, more recently, *S. cerevisiae* (28). A similar gene encoding the plant enzyme, cycloartenol synthase, which performs a parallel step in plant sterol synthesis, has also been cloned from *Arabidopsis thaliana* (29). In *S. cerevisiae*, polymerase chain reaction (PCR) amplification of yeast genomic DNA was performed using oligonucleotide primers derived from the conserved amino acid sequences from the *Candida* and *Arabidopsis ERG7* gene products. The PCR product was then employed to probe both cDNA and genomic libraries, but no full-length sequences were identified, possibly because the sequence is unstable in *E. coli*. Ultimately, two overlapping clones were utilized to reconstruct the entire coding sequence. The gene comprises a 2196bp open reading frame corresponding to a 732 amino acid protein. As is the case with the other genes preceding the formation of a sterol molecule, *ERG7* is required for aerobic viability. The *Candida ERG7* gene (27) was cloned by using a wild-type *C. albicans* library

TABLE 1
Cloned Genes in the Ergosterol Biosynthetic Pathway

Gene	Enzyme encoded	Essential for viability	Known enzyme inhibitors	Chromosomal location
ERG9	Squalene synthase	Yes	Squalestatin	8
ERG1	Squalene epoxidase	Yes	Allylamines	15
ERG7	Squalene cyclase	Yes	U1866A	8
ERG11	Lanosterol demethylase	Yes[a]	Azoles	8
ERG24	Δ14 Reductase	Yes[b]	Morpholines	?
ERG6	C-24 Methyltransferase	No		13
ERG2	C-8 Isomerase	No	Morpholines	13
ERG3	C-5 Desaturase	No		12
ERG4	Δ24 Reductase	No		7

[a]Suppressed by *erg3*.
[b]Suppressed by *fen1* and *fen2*.

to complement an *erg7* mutant of *S. cerevisiae*. *ERG7* has been mapped to chromosome 8 in *S. cerevisiae*.

ERG11

The product of the *ERG11* gene is a cytochrome P-450 demethylase which is responsible for the removal of the methyl group from the C-14 position. Several aerobically viable *erg11* mutants have been reported (30,31), but all have been found to be leaky and were accompanied by a second mutation in the *ERG3* gene whose product introduces a double bond at the C-5 position (C-5 desaturase) later in the pathway. The essentiality of the *ERG11* gene was in question until it was cloned and characterized by Kalb *et al.* (32,33) and found to be essential for aerobic growth. The cloning was accomplished by transforming yeast with a yeast genomic library in a high copy number plasmid and screening transformants for resistance to the azole, ketoconazole, a specific inhibitor of the C-14 demethylase. Subsequent analysis indicated a protein of 530 amino acids. The gene encoding the demethylase has been mapped to chromosome 8.

The suppression of *ERG11* essentiality by *erg3* mutants remained a question. Recently, Bard *et al.* (34) have shown that double disruptions of *ERG11* and *ERG3* are aerobically viable, indicating that the removal of the C-14 methyl group is not an essential step. The suppression of the *erg11* phenotype by *erg3* is explained by the hypothesis of Watson *et al.* (35). Since the enzymes of the sterol pathway show a high level of substrate infidelity, enzymes subsequent to a blocked step will continue to catalyze the available sterol intermediates. In this case, C-14 methyl sterols continue down the pathway to the C-5 desaturase which attempts to desaturate the C-5 position but is unable to complete the process. The result of this aborted effort is the formation of an intermediate, 14α-methyl-ergosta-8,24(28)-diene-3β,6α-diol, a sterol proposed to disrupt membrane structure and function resulting in cell death. This diol has been identified in *erg11* mutants of *C. albicans* and is tolerated by this organism (36,37). This difference may be the result of subtle variabilities in membrane structure or may reflect alternative mechanisms for esterification of toxic sterols in the two species.

ERG24

The product of the C-14 demethylase reaction, 4,4-dimethylcholesta-8,14,24-trienol, is reduced at the C-14 position to form 4,4-dimethylcholesta-8,24-dienol by the action of the product of the *ERG24* gene. The C-14 reductase is one of the two sites inhibited by the morpholine antibiotics, and this characteristic was employed by one group to clone *ERG24* (38). Using a strategy similar to that employed in the cloning of *ERG11*, *S. cerevisiae* was transformed with a yeast genomic library in a high copy number plasmid, and resulting transformants were screened for resistance to fenpropidin, a morpholine. Resistance was confirmed to be due to the overproduction of the C-14 reductase. Subsequent gene disruption and allele replacement resulted in strains that were unable to grow in the presence of oxygen. To address the issue of whether nonviability under these conditions is due to the accumulation of toxic sterol intermediate (primarily ignosterol, ergosta-8,14-dienol) or the lack of a sterol possessing an essential structural feature, aerobic growth was attempted in a genetic background allowing for uptake of exogenous sterols on a medium containing ergosterol. Growth did occur, arguing that ignosterol did not block aerobic growth.

Simultaneously, a second research group cloned the C-14 reductase using a clever alternative strategy (39). This group selected for a fenproprimorph-resistant mutant that carried two recessive mutations, *fen1* and *fen2*. Both the wild-type and the resistant mutant produce ergosterol when the drug is absent and ignosterol when it is present. The presence of the *fen1* and *fen2* mutations allow survival of cells producing only ignosterol. Nystatin-resistant isolates of a strain carrying *fen1* and *fen2* were generated by mutagenesis and screened for the accumulation of ignosterol. One such isolate was obtained. The *ERG24* gene was cloned by transforming the nystatin-resistant, ignosterol-producing, *fen1, fen2* strain with a wild-type yeast genomic library and by selecting an ergosterol-producing, nystatin-sensitive isolate. The plasmid conferring the desired phenotype was characterized, and a 1314bp open reading frame encoding a 438 amino acid protein of a molecular mass of 50,612 was deduced. This gene has yet to be mapped.

A third research group has recently reported the cloning and characterization of the *ERG24* gene (40). The approach used was similar to that employed by Marcireau *et al.* (38). Sequence analysis confirmed the conclusions of the previous reports. In addition, this study reported sequence similarities among *ERG24*, the *sts1*$^+$ gene of *Schizosaccharomyces pombe* (41) and the *YGL022* gene of *S. cerevisiae* (42). The latter two genes and their relationship to the ergosterol pathway are discussed in the *ERG4* section of this review.

ERG6

The product of the *ERG6* gene methylates the C-24 position of zymosterol to produce the 28 carbon sterol structure common to most fungi. C-24 methylation was considered to be an essential step in the synthesis of functional sterol (43,44). However, since only hormonal amounts of "essential" sterol were required, absolute proof of this hypothesis was difficult. The *ERG6* gene was ultimately cloned by complementation using an *erg6* mutant (45). Cloning using the *erg6* strain presented technical difficulties since cell membrane function was significantly affected by the presence of unmethylated sterol, resulting in low transformation rates and diminished mating efficiencies. Significant protocol alterations were required to successfully transform *erg6* with a yeast genomic library and select for clones that were insensitive to cycloheximide (a permeability defect in *erg6* results in increased sensitivity to this drug). Restoration of wild-type cycloheximide resistance was an effective initial screen for *erg6* complementation.

Transformants were then assayed for ergosterol production and nystatin sensitivity. Two deletion-substitutions of the *ERG6* gene were constructed on a plasmid used to replace the wild-type *ERG6* gene by transformation in which the *LEU2* gene inserted into the *ERG6* gene provided a selectable marker. These disrupted strains were viable. A subsequent report (46) has indicated that gene *SED6*, which suppressed a mutant form of *ERD2*, a gene involved in protein retrieval from endoplasmic reticulum, is identical to the *ERG6* gene. The *ERG6* gene has been localized on chromosome 13.

ERG2

The Δ8→7 isomerase, the product of the *ERG2* gene, is one of the targets of the morpholine antibiotics (47). Based on the efficacy of these drugs, it was suggested that this step may be essential. Using the same protocol as was used with *ERG6*, *erg2* mutants were transformed with a yeast genomic library and screened for cycloheximide resistance (48). Sequence analysis of functional plasmid inserts conferring ergosterol synthesis indicated an open reading frame encoding a 222 amino acid protein. Disruption of the coding sequence did not affect viability, indicating the gene is not essential (49). The *ERG2* gene has also been mapped to chromosome 13.

ERG3

The C-5 desaturase, the product of the *ERG3* gene, converts episterol [ergosta-7,24(28)-dienol] to ergosta-5,7,24(8)-trienol. Based on feeding experiments, Parks and co-workers (50–52) concluded that only sterols containing a C-5 unsaturation or the capability of undergoing this alteration could provide the essential sterol function. The *ERG3* gene was cloned (53) using a protocol for transformation, selection and verification identical to that employed for *ERG6* (45) and *ERG2* (48). Sequencing of the *ERG3* gene indicated a 365 amino acid protein. The essentiality of *ERG3* was determined by deletion and substitution, and strains carrying the allele containing the deletion and disruption are viable. The *ERG3* gene is located on yeast chromosome 12.

ERG4

The *ERG4* gene provides the enzyme which reduces the double bond at C-24(28), the final step in ergosterol biosynthesis. Direct cloning of this gene has not been possible using the protocols employed in cloning the genes operating earlier in the pathway. The sterols accumulated in *erg4* mutants are similar in structure to ergosterol, and the effects of sterol substitution are insufficient to distinguish mutant and wild-type, based on permeability or antibiotic sensitivity differences. Recently, the sequence for *ERG24* was shown (40) to have similarity to the sequences reported for the *sts1*$^+$ gene of *S. pombe* (41), the *YGL022* gene of *S. cerevisiae* (42) and the chicken nuclear lamin B receptor gene (54). Based on the accumulation of C-24(28) sterols, both *sts1*$^+$ and *YGL022* were determined to contain defects in the C-24(28) reductase (*ERG4*). In addition, a disruption of *YGL022* was shown to be allelic to an *erg4* mutant. The authors thus concluded that *YGL022* is *ERG4* and that the reductase is not essential for viability. Figure 2 shows the amino acid sequences of the *ERG24* and *ERG4* gene products. *ERG4* has been localized to chromosome 7.

THE REMAINING GENES

The remaining two steps not yet cloned in the ergosterol biosynthetic include the *ERG5* gene and the C-4 demethylase gene. The latter gene is interesting since no mutants have been detected using the standard polyene resistance selection procedure. This might mean that the inability to demethylate may result in the accumulation of sterol intermediates that are unacceptable for functional inclusion in the membrane or that the resulting sterols may not possess the essential structural features to provide the essential cell cycle function. The process of C-4 demethylation is complex and involves three separate enzymes—an oxidase, a decarboxylase, and a 3-keto reductase. Little work has been done on the yeast enzymes although the counterpart reactions in the cholesterol pathway have been described (55,56).

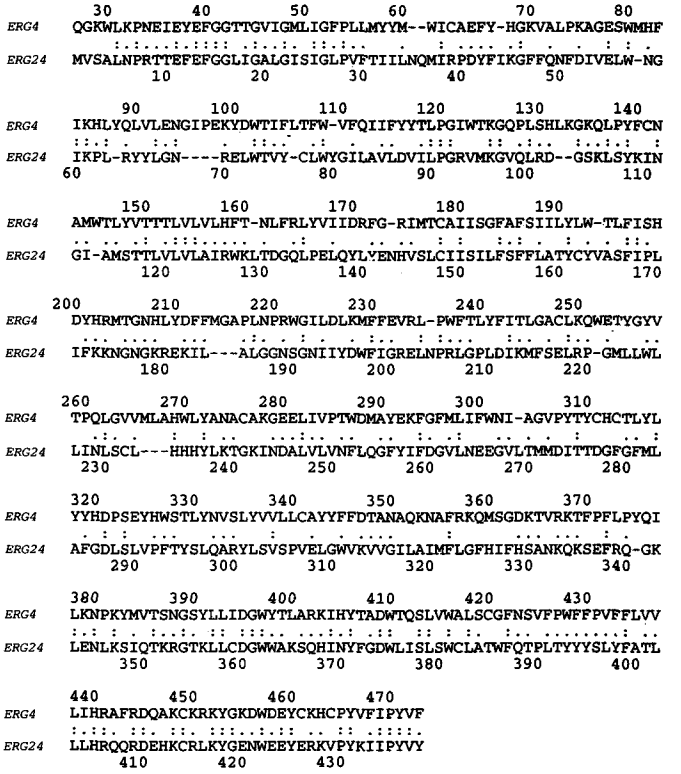

FIG. 2. The amino acid sequences of the *ERG4* and *ERG24* genes of *Saccharomyces cerevisiae*. Single dots represent amino acid similarity and double dots represent amino acid identity.

ACKNOWLEDGMENTS

Various aspects of the research summarized in the review were supported in part by an NIH grant IR15GM45959-01, a grant from Eli Lilly & Co. and an American Cyanamid contract, all to M.B. We thank Mark Goebl for providing the figure containing the sequences for *ERG24* and *ERG4*.

Biochemical and Physiological Effects of Sterol Alterations in Yeast—A Review[1]

Leo W. Parks*, Steven J. Smith and James H. Crowley

Department of Microbiology, North Carolina State University, Raleigh, North Carolina 27695-7915

ABSTRACT: Considerable progress has been made in the selection and characterization of mutants that are defective in the synthesis of ergosterol in the yeast, *Saccharomyces cerevisiae*. Mutations in nearly every step of the yeast sterol biosynthetic pathway have been induced and selected. These mutants have been used to elucidate the sequential order of steps in sterol synthesis, to study the mode of action of antifungal agents and to determine the method of resistance of some pathogenic fungi, and to answer questions on the role of sterols in general cell biology. Physiological examination of ergosterol null mutants, lacking all biochemical activity attributed to the particular gene, supports a role for ergosterol in a number of critical functions in the organism. Among the physiological functions attributed to ergosterol are sparking and bulking requirements, involvement in amino acid and pyrimidine transport, resistance to antifungal agents and certain cations, and a requirement for respiratory activity. Those genetic null alleles discussed in this review are *erg24*, lacking the ability to reduce the Δ^{14} double bond; *erg6*, unable to methylate C-24; and *erg3*, defective in the C-5 desaturase. The different biochemical activities that are disrupted in the ergosterol mutants support a role for ergosterol in a number of critical functions in yeast.

Lipids 30, 227–230 (1995).

Considerable research is aimed toward understanding the roles of sterols in the physiology and biochemistry of the cell. Yeast is ideally suited for this work because of its ease of culture, well-defined genetic and molecular biological procedures, and the wealth of biochemical data that is available on these organisms. Ten years ago, experiments were performed that indicated that there were multiple roles for sterols in yeast (1). Prior to that, it was generally assumed that sterols in fungi merely served passive roles in their constituent membranes to buffer the membrane's physical properties in response to environmental changes. Working with the assumptions that if different functions existed they would likely have different quantitative and qualitative requirement for the sterols and that ergosterol served as a "consensus" sterol, it was established that at least four growth-dependent functions for sterols must exist. The inability to define the biochemical and physiological components of these functions has been a continuing challenge in this field. Here the status of the studies on sterol functions will be reviewed, particularly with regard to developments with the *ERG6*, *ERG24*, and *ERG3* structural genes.

ERG6

ERG6 is the structural gene for the sterol methyltransferase. In yeast, zymosterol is the preferred substrate with the formation of fecosterol at the expense of *S*-adenosylmethionine. In respirationally adapting cells we have found small amounts of 4α-methyl fecosterol in our cultures (2). The *erg6* mutants have been relatively easy to obtain and, in fact, are the most abundant class of ergosterol mutants that have been isolated. However, these were also a source of enormous frustration to us in our early experiments. Working with a haploid strain that had a tryptophan marker for genetic purposes, a wide variety of procedures were attempted to select for nystatin-resistant mutants that were defective in sterol methyltransferase, but these attempts were without success. Many *erg3* mutants were isolated, blocked in the C-5 desaturase, which other researches found difficult to obtain. It is clear now why such difficulties were experienced thanks to the work of Gaber *et al.* (3). These authors found that mutants defective in sterol transmethylation had a sixfold reduction in tryptophan uptake. Thus, *erg6* mutants could not be selected in a tryptophan auxotroph because of their extremely poor growth. Impaired tryptophan uptake also contributed to the incorrect mapping assignment of *ERG6* being linked to *TRP1* (4). Since tryptophan is transported by two permease systems, each of relatively low specificity (5,6), the absence of methylated sterols may have a more general effect than altering one of the tryptophan uptake mechanisms. These results explain in part the discrepancies in results obtained by different laboratories where different genetic constructions are used.

Additional transport defects in *erg6* mutants are suggested by recent work from Trumbly's laboratory (7). There the

ERG6 structural gene was inadvertently selected in screenings for revertants to mutants that had hypersensitivity to certain cations, especially Li^+ and Na^+. It is now known that a gene originally identified as *LISI* is in fact *ERG6*. Previous work from Bard's laboratory (8) suggested that sterol mutants had enhanced sensitivity to cations.

Brefeldin A, which disassembles the Golgi structures and inhibits protein movement to the plasma membrane, has been used extensively in mammalian cell cultures. However, wild-type yeast are insensitive to it. The *erg6* mutants are sensitive to Brefeldin A and have been used to study the secretory process (9–11).

The *erg6* mutants also have decreased mating frequency (3). This reduction in zygote formation is consistent with our observations that sterols other than ergosterol reduce mating frequency (12). With several sterols other than ergosterol, we found that mated pairs became adherent but failed to undergo cytoplasmic fusion.

A most intriguing effect of *ERG6* has been found in mutants that have a defect in the secretory pathway. The trafficking of newly synthesized proteins that are destined for the vacuole, plasma membrane, or secretion in eukaryotic cells are sequentially passed through a series of compartments. Specifically targeted transport vesicles mediate the movement of the proteins with high precision and efficiency between the compartments. Some of the components of this secretory pathway have been defined genetically and biochemically (13). Newly synthesized proteins that are destined for the secretory pathway are inserted initially into the endoplasmic reticulum (ER). Subsequently they are transported to the Golgi and then partitioned to their appropriate destination. In the vesicularly mediated transport to the Golgi, some luminal proteins of the ER enter the transport vesicle, that buds from the ER, and are moved along with proteins that are destined for functions beyond the ER. These ER luminal proteins are returned to the ER following modification by Golgi specific enzymes (14). *ERD2* is a structural gene in yeast that encodes a receptor responsible for the retrieval of the ER proteins from the Golgi (15); mutants lacking this gene are unable to divide. A number of suppressors of *erd2*Δ strains have been isolated. One of these, *SED6*, is a weak multicopy suppressor and is effective when introduced into *erd2*Δ strains. Recently (16), following sequencing of *SED6*, it was found to be identical to *ERG6*. The role of the *ERG6* as a methyltransferase or some other function in permitting the replication of *erd2*Δ cells has not been determined.

Cells that are depleted of the *ERD2*-designated protein (Erd2p) accumulate large amounts of membranes that are unlike the transport vesicles, ER- or Golgi-like structures that are formed in other secretory-restricted strains (13). It is interesting that such Erd2p-depleted cells also abundantly accumulate lipid droplets. We have shown previously (4) that the cellular fraction most enriched with the sterol methyltransferase is the microdroplets of lipids, known as the floating lipid layer, that accumulate at the top of gradients when cells are fractionated (17).

Although the ERG6-designated protein, Erg6p, or its transmethylated sterol products appear to be involved in a variety of cellular activities, mutants lacking Erg6p are viable aerobically. Based on conclusions obtained by Atkinson (18), the transmethylation of zymosterol by *S*-adenosylmethionine is found to be very costly to the cell, occurring at an overall metabolic expense of from 12 to 14 ATP equivalents (19). It is highly unlikely that such an expensive reaction would be retained in the evolution of the organism, unless it offered a substantial selection advantage to organisms having a functional ERG6.

ERG24

The biosynthetic pathways for ergosterol and cholesterol include a $\Delta^{8,14}$-sterol intermediate as a consequence of the demethylation of lanosterol (20,21). Generally, the Δ^{14}-bond is reduced by the enzyme Δ^{14}-sterol reductase (22), forming 4,4-dimethylcholesta-8,14-dienol before the removal of the C-4 methyl groups or modifications of the sterol's side chain. We observed growth inhibition and the accumulation of ignosterol (ergosta-8,14-dien-3ß-ol) when yeast cells were treated with 15-azasterol (15-aza-24-methylene-D-homocholestadien-3ß-ol) (23,24). It is interesting that yeast cells growing on respiratory substrates were much more sensitive to 15-azasterol than cells growing on glucose (25). Fungal cells exposed to the morpholine antifungal agent, fenpropimorph, also accumulate ignosterol (26), and the antifungal activity has been attributed to the production of ignosterol (27,28). We have isolated mutants that are resistant to fenpropimorph (28), and we used them to clone and sequence the structural gene, *ERG24*, for the Δ^{14}-sterol reductase (29).

Fenpropimorph treatment results in a decrease in the level of membrane ergosterol and the accumulation of ignosterol and its derivatives. Consequences of the sterol alterations are most likely decreased capacity of the organisms to maintain normal membrane processes. It has been observed that the incorporation of 24-methylene-ignosterol into membranes results in increased membrane disorder and a concomitant decrease in the ability to accumulate glucose (30). We have found that fenpropimorph treatment of cells also affects directly the uptake of the pyrimidine bases, uracil and cytosine (31); however, the inhibition of uracil, and cytosine uptake differs dependent on the endogenous sterol produced (Fig. 1).

We have previously isolated mutants that are resistant to fenpropimorph (28), and these were used to clone the recessive *fen1* and *fen2* suppressors of *erg24*. We incorporated the *ura3* gene into our stocks so that we might use the *URA3*-containing YCp50 plasmid-based library for cloning *FEN1* and *FEN2*. We observed, however, that our strains became more resistant to the growth inhibitory effects of fenpropimorph, when made prototrophic for uracil by transformation. Cytosine, which is taken up by a different mechanism than is uracil (32,33), can rescue cells that have impaired uracil uptake as can high concentrations of uracil.

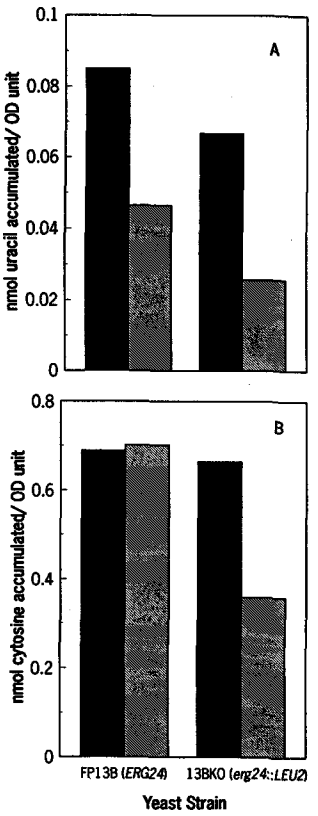

FIG. 1. Effect of fenpropimorph on the uptake of uracil and cytosine by *Saccharomyces cerevisiae*. Strains FP13B (*ERG24*) and 13BKO (*erg24::LEU2*), which synthesize ergosterol and ignosterol, respectively, were grown to exponential phase, filtered, resuspended in fresh medium with or without the addition of fenpropimorph, and incubated for 3 h. The uptake of radiolabeled uracil (A) and cytosine (B) was measured as described by Crowley et al. (31). Black bar, - Fenpropimorph; striped bar + Fenpropimorph.

ERG3

ERG3 is the structural gene for the sterol C-5 desaturase, which appears to function as a mixed-function oxidase (34). Working with strains of yeast that were defective in that desaturation, we found that cholestanol, lanosterol, or ergosta-7,22-dienol could satisfy the bulk of the required sterol but that a sterol with Δ^5-unsaturation was required for growth (35–37,38). When the *ERG3* gene was cloned and disrupted, Arthington *et al.* (39) found that their disrupted strains grew, despite their inability to synthesize Δ^5-sterols. The principal differences between the strains used by the Arthington group and our laboratory were that our strains had heme deficiencies which were included to permit the efficient uptake of exogenous sterols (40, 41). We found that insertionally activated mutants of *ERG3* did not grow without "sparking" levels of Δ^5-sterols in heme-deficient cells, and they did not grow on defined medium using respiratory substrates, such as glycerol and ethanol (38).

Although there is considerable circumstantial evidence in support of roles for sterols in the respiratory metabolism of cells, involvement of sterols at a specifically defined biochemical site has not been established. Toward that end, our laboratory is studying the effect of specific sterol deficiencies on respiratory development in strains of yeast. As a part of that study, we sought to determine which features of ergosterol might be essentially involved in synthesis or maintenance of respiratory competency. For that we took a genetic approach.

We reasoned that, as in our previous work (1), ergosterol could most likely satisfy all of the principal sterol functions in yeast. Yeast growing on ergosterol can grow respirationally or fermentatively. Yet, we assumed that if there were structural features of sterols that specifically did not permit respiration, we should be able to deduce them by differences between mutants that were selected on glucose as opposed to glycerol or ethanol. We undertook an extensive selection of mutants that were resistant to polyene antifungal agents on glucose or glycerol. A summary of the results is shown in Table 1. In total, 600 polyene-resistant mutants were selected, 300 on glucose and 300 on glycerol, and were characterized by sterol analysis. A wide variety of yeast mutant types were found on glucose. All of the mutants selected on glycerol as the carbon and energy source produced some Δ^5-sterols. Of the 300 selected, 297 have sterols that display the typical absorption spectrum of the $\Delta^{5,7}$-sterols. The remaining three have some $\Delta^{5,8}$-sterols. Most of the mutants produce the Δ^5-

TABLE 1
Isolation of *erg* Mutants on Fermentative and Respiratory Carbon Sources[a,b]

Media[c]	W303-1A	JC530-4b	x2180-1A
YPG + Nystatin	All mutants made some $\Delta^{5,7}$-sterol, often in addition to Δ^8-sterol.	All mutants made some $\Delta^{5,7}$-sterol, usually as $\Delta^{5,7,22,24(25)}$-sterol.	48 of 50 mutants made $\Delta^{5,7}$-sterol. Other two made $\Delta^{5,8,22}$-sterol or zymo.
YPG + Filipin	All mutants made some $\Delta^{5,7}$-sterol, often in addition to Δ^8-sterol.	All mutants made some $\Delta^{5,7}$-sterol, usually as $\Delta^{5,7,22,24(25)}$- or $\Delta^{24(28)}$-sterol.	49 of 50 mutants made $\Delta^{5,7}$-sterol. $\Delta^{5,8,22}$-, $\Delta^{7,22}$-, zymo made by leaky mutant.
YPD + Nystatin	11 mutants had no $\Delta^{5,7}$-sterol, only $\Delta^{5,8}$ or Δ^8: *erg2* or *erg6*. Rest are leaky *erg2, erg3, erg6*.	*erg2, erg3, erg4, erg6* equally found.	Found *erg2, erg3, erg4, erg5, erg6*. *erg6* is predominant mutant species.
YPD + Filipin	13 to 15 are *erg4* or *erg6*, rest are *erg2* or *erg3*, most make predominantly Δ^8-sterols.	Most mutants examined are *erg5* (37 of 50), rest are *erg2, erg3, erg4* and *erg6*.	Wide range of mutants as above.

[a]Mutagenesis performed following the procedure of Lewis *et al.* (42).
[b]Strains used: W303-1A (Mata *leu2 his3 ura3 trp1 can1-100 ade2*), JC530-4b (Mata *leu2 his4 ura3*), x2180-1A (Mata *SUC2 cup1 gal2*).
[c]YPG: 0.5% yeast extract, 1.0% peptone and 2.0% glycerol; YPD: 0.5% yeast extract, 1.0% peptone and 2.0% dextrose.

sterols in combination with other alterations in sterol biosynthesis, indicating substantial leakiness in the mutants. There were marked differences in the ratios of different sterols in the different mutants. We realize that these experiments are only presumptive of the roles for sterol features on respiration, but they do not provide an interesting opportunity to speculate on the importance of the principal ring features as being important in respiratory development.

CONCLUSIONS

This review emphasizes the varied functions in which sterols participate in the physiology of the yeast cell. As the tools of biophysics, biochemistry, genetics, and molecular biology are increasingly more effectively applied to this field, a convergence of understanding is emerging. Researchers, looking at different aspects of cell physiology, are finding sterols involved in structural, regulatory, and developmental roles. With the abundance of data that is accumulating, a greater appreciation is required for the differences in strains, culture conditions and techniques that are being used in the various laboratories. Explanations for seemingly disparate conclusions can provide an even greater depth of insight into the roles of sterols in the general economy of the cell.

ACKNOWLEDGMENTS

The authors express their appreciation to Dr. R.J. Trumbly for providing the information on *lis1* in advance of its publication. Special thanks are given to Dr. W.D. Nes and Dr. E. Parish for organizing the symposium on sterols at which this paper was originally presented. The original research cited in this paper was conducted with the support of the National Institutes of Health (DK37222) and the North Carolina Agricultural Research Service.

Identification of the Active Site of Vertebrate Oxidosqualene Cyclase[1]

Ikuro Abe and Glenn D. Prestwich*

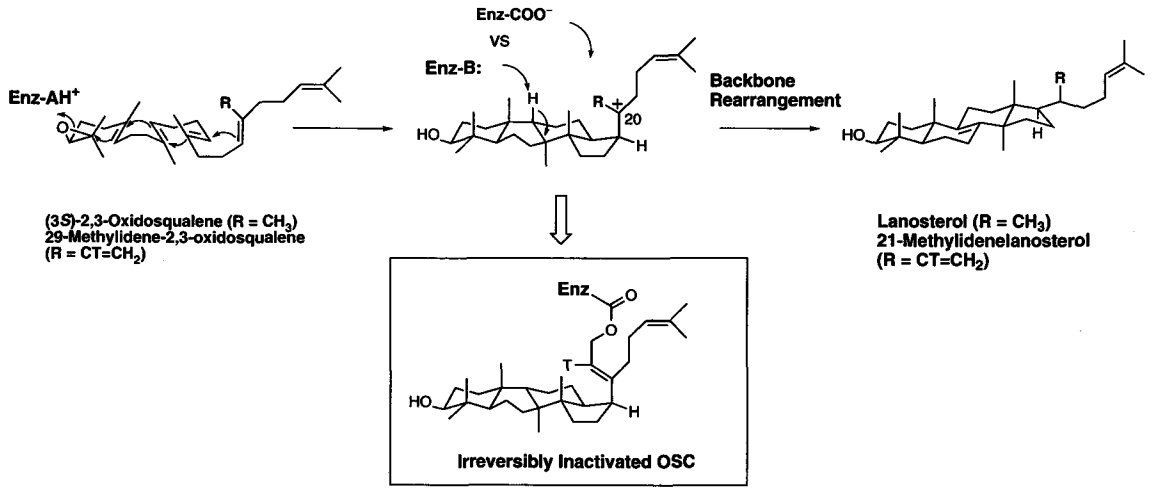
Department of Chemistry, University at Stony Brook, Stony Brook, New York 11794-3400

ABSTRACT: Active site mapping of rat liver oxidosqualene cyclase (OSC), a 78 kDa membrane-bound enzyme, was carried out using the mechanism-based irreversible inhibitor, [^{3}H]29-methylidene-2,3-oxidosqualene. The amino acid sequence of the radiolabeled CNBr peptide fragment showed unexpectedly high similarity to the yeast OSC, plant OSC, and bacterial squalene cyclases. Further, radio analysis established that the two adjacent Asp residues in the highly conserved region (*Asp-Asp*-Thr-Ala-Glu-Ala, or DDTAEA) were equally labeled by the irreversible inhibitor. This result provided the first information on the structural details of the active site of OSC, and showed for the first time the ancient lineage of this vertebrate enzyme to ancestral eukaryotic and prokaryotic cyclases. Interestingly, the covalently-modified DDXX(D/E) sequence of rat liver OSC showed surprising similarity to the putative allylic diphosphate binding site sequence of other terpene cyclases and prenyl transferases. The Asp-rich motif may act as a point charge to stabilize incipient cationic charge.

Lipids 30, 231–234 (1995).

The enzymatic cyclization of oxidosqualenes is the most remarkable step in the biosynthesis of sterols and triterpenes (1). In a single step, an acyclic polyene is converted by a specific enzyme to either a tetracyclic or pentacyclic triterpene. In the case of lanosterol formation, (3*S*)-oxidosqualene first adopts a prechair–boat–chair conformation. Then protonation of the epoxide initiates a cascade of ring-forming reactions and backbone rearrangements that proceed through rigidly held carbocationic intermediates (2–6). Several oxidosqualene cyclases (OSC) (EC 5.4.99.7) have been purified to homogeneity from vertebrate (7–9), plant (10–13), and yeast sources (14). Recently, three OSC enzymes have been cloned and sequenced from two fungal sources, *Saccharomyces cerevisiae* (15,16) and *Candida albicans* (17–19) and, from one plant, *Arabidoposis thaliana* (20). The predicted molecular masses ranged from 80 to 90 kDa, and the cDNA sequences predicted proteins with significant sequence similarity. In addition, sequence comparisons of these cyclases with bacterial squalene cyclases (SC) revealed an existence of a highly-conserved repetitive motif rich in aromatic amino acids (the QW motif) (21,22).

Recent work from our laboratories on active site mapping of rat liver OSC using 29-methylidene-2,3-oxidosqualene (29-MOS), the first mechanism-based irreversible inactivator of vertebrate OSC, will be summarized in this paper. 29-MOS was first prepared in racemic form and showed potent inhibition of OSC. An IC_{50} value of 0.5 μM, an apparent K_i value of 4.4 μM, a k_{inact} value of 221 min^{-1}, and a partition ratio of 3.8 (inactivations per turnover) were obtained for pig liver OSC (23). Incubation of 0.1 μM 29-MOS with pig liver OSC gave a polycyclic product in 30% yield; however, at [29-MOS] > K_i, complete inactivation precluded isolation of this product (23). A new synthesis of the enantiomerically-enriched substrate, [^{3}H](3*S*)-29-MOS, by the Sharpless asymmetric dihydroxylation reaction (24–26) was achieved recently (27). Several other 26- and 29-functionalized 2,3-oxidosqualene derivatives were found to be slightly less active than 29-MOS (28).



Vertebrate OSC enzymes can be efficiently and specifically labeled with tritium-labeled 29-MOS (8). For a typical affinity labeling experiment, enzyme preparations were first incubated with [^{3}H]29-MOS (1.0 μM, 2.3 Ci/mmol) for 15 min at 37°C. Next, the proteins were separated by denaturing polyacrylamide gel electrophoresis (SDS–PAGE), and the covalently-modified protein bands in fluorophore-enhanced, dried gels were visualized on X-ray film by fluorescence autoradiography. For each enzyme source, a single radiolabeled protein band was observed having a molecular mass between 70 and 80 kDa (rat, 78 kDa; pig, 75 kDa; dog, 73 kDa; and human, 73 kDa). The proposed mechanism of inhibition by 29-MOS involves initial cyclization to the 21-methylidene-protosterol cation as proposed for lanosterol formation. However, we have postulated that instead of backbone rearrangement, this allylic cation can be trapped by an active-site nucleophile, resulting in irreversible inactivation of the enzyme (Scheme 1). Moreover, this hypothesis also predicts that the structures of the released and enzyme-bound tetracyclic products are different; 21-methylidene lanosterol should be released, while the covalent moiety attached to the enzyme

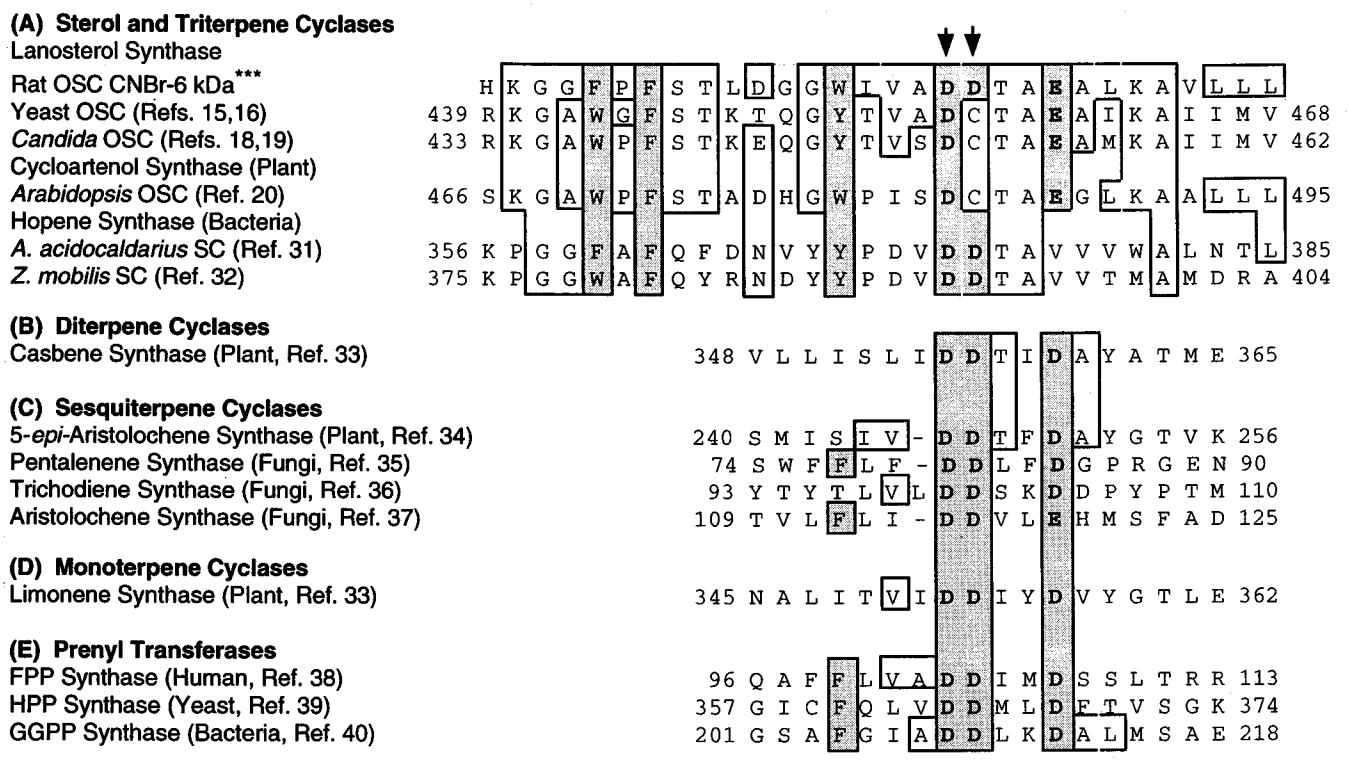
should retain the unrearranged protosterol skeleton. Verification of these structures is in progress.

In contrast, yeast and plant OSC enzymes were not labeled even under forcing conditions, and [^{3}H]29-MOS was recovered unchanged by chromatography (8). Because 29-hydroxy-2,3-oxidosqualene is quantitatively converted to 21-hydroxylanosterol by yeast OSC (29), it seemed most likely that 29-MOS would be accepted as a substrate. The initially formed 21-methylidene protosterol cation could be stabilized by the enzyme, preventing backbone rearrangement to the cyclization products. In this case, instead of covalent bond formation, the stabilization would probably be attained by an electrostatic interaction. As a result, 29-MOS appears to act as a slow tight-binding inhibitor; and an IC_{50} value of 1.5 μM, an apparent K_i value of 1.5 μM, and a k_{inact} value of 0.088 min^{-1} were obtained for yeast OSC (8).

In order to localize the 29-MOS binding site region of rat liver OSC, purified enzyme was labeled with [^{3}H]29-MOS and then selectively cleaved adjacent to Met residues with CNBr (30). A single radioactive 6 kDa peptide fragment was separated by Tricine SDS–PAGE. After electrophoretic transfer to a polyvinylidene difluoride membrane, the labeled peptide was sequenced by Edman degradation (30). The sequence of the first 30 amino acids of the peptide showed unexpectedly high similarity to the other eukaryotic sterol and terpene cyclases: 50% identity with Arg^{439}–Val^{468} of yeast OSC (15,16), 50% identity with Arg^{433}–Val^{462} of *C. albicans* OSC (18,19), 63% identity with Ser^{466}–Leu^{495} of plant *A. thaliana* OSC (cycloartenol synthase) (20), and to the bacterial SC enzymes, 33% identity with Lys^{356}–Leu^{384} of *Alicyclobacillus* (formerly *Bacillus*) *acidocaldarius* SC (31), 27% identity with Arg^{375}–Ala^{404} of *Zymomonas mobilis* SC (32) (Fig. 1). This result provides the first information on the structural details of the active site of OSC and demonstrates the ancient lineage of this vertebrate enzyme with respect to the ancestral eukaryotic and prokaryotic cyclases.

Furthermore, radioanalysis clearly established that the two adjacent Asp residues in the highly-conserved region (*Asp*-Thr-Ala-Glu-Ala, or DDTAEA) were equally labeled by the irreversible inhibitor (30). The initially formed 21-methylidene-protosterol cation would be trapped by nucleophilic attack by the carboxyl group of one of the two adjacent Asp residues, resulting in ester bond formation. The two Asp residues appear to be equally accessible to the methylidene-extended protosterol cation. In the case of yeast or plant OSC enzymes, the appropriate nucleophilic residues seem to either be absent or not to have access to the allylic cation. Indeed, each of these enzymes has a Cys residue in the second position, giving a characteristic DCTAEA motif. Recently, rat liver OSC was cloned and sequenced in our laboratory (Abe, I., and Prestwich, G.D., unpublished data). According to the deduced amino acid sequence of this cDNA, the 29-MOS binding site has the DCTAEA sequence instead of DDTAEA. Isozymes of this enzyme with the DDTAEA sequence may exist, or there may be sequencing anomalies associated with a lipid-modified amino acid. We are exploring these two possibilities.

Interestingly, the covalently-modified DDTAEA sequence of rat liver OSC showed surprising similarity to the known consensus sequence, Asp-Asp-Xaa-Xaa-Asp (the "DDXXD" motif) found in diterpene cyclases (33), sesquiterpene cyclases (34–37), and monoterpene cyclases (33), as well as in several prenyl transferases (38–40) (Fig. 1). Each of these enzymes uses an allylic diphosphate as a substrate and divalent metal ions as a co-factor. Thus, this aspartate-rich domain has been implicated in catalyzing the ionization of the allylic diphosphate to the reactive allylic cation, presumably by coordination *via* an Mg^{2+}-diphosphate bridge. Recent site-directed mutagenesis experiments of the conserved aspartate residues of farnesyl–diphosphate synthase suggest that the first Asp residue in this domain is important in catalysis (41–43). The high degree of sequence conservation of the 29-MOS binding site in triterpene and sterol cyclases supports a catalytic or structural function for this domain. Stabilization of tertiary or allylic carbocations may be the true raison d'être for the DDXX(D/E) motif. We present this hypothesis in



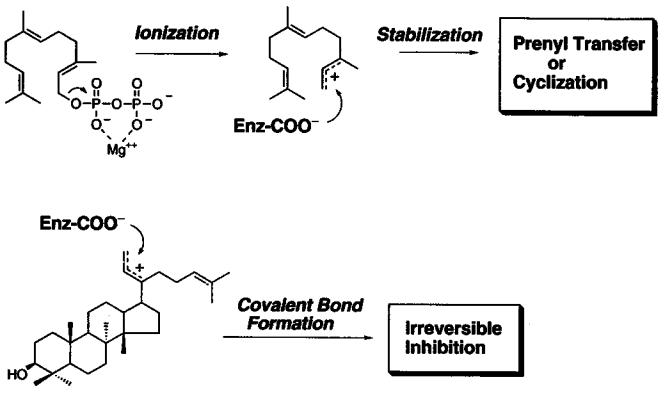


FIG. 1. Comparison of the DDXX(D/E) motif in the predicted amino acid sequences of terpene biosynthetic enzymes. OSC, oxidosqualene cyclase; SC, squalene cyclase.

SCHEME 2

Scheme 2, and we suggest that rather than assisting the departure of the pyrophosphate, the Asp-rich motif may act as a point charge to stabilize incipient cationic charge. For transferases and other cyclases, this corresponds to stabilization of the transition state to a high-energy intermediate cation at the initiation of the reaction, or perhaps during cyclization. For OSC, the Asp-rich motif would stabilize a "stopping point" in the cyclization pathway, i.e., after tetracycle formation but prior to backbone rearrangement. Very recently, Poralla *et al.* (44) reported that a point mutation of the first Asp residue of the DDTAVV motif of bacterial SC (*A. acidocaldarius*) can cause almost complete loss of the cyclase activity. Additional single mutations in cyclases will provide further tests for this hypothesis. Finally, it should be noted that the existence of such a consensus sequence in the terpene and sterol biogenesis enzymes is very interesting, considering the molecular evolution of these enzymes.

ACKNOWLEDGMENTS

The authors are indebted to T. Fischer at the Center of Analysis and Synthesis of Macromolecules (Stony Brook) for Edman peptide sequencing and Dr. X.-y. Xiao for synthesis of the [^{3}H]29-MOS used in this study. This work was supported by the Center for Biotechnology/New York State Science and Technology Foundation, Sandoz Research Institute and the National Institutes of Health (GM 44836).

2,3-Oxidosqualene Cyclase: From Azasqualenes to New Site-Directed Inhibitors[1]

Luigi Cattel*, Maurizio Ceruti, Gianni Balliano, Franca Viola, Giorgio Grosa, Flavio Rocco and Paola Brusa

Istituto di Chimica Farmaceutica Applicata, Facoltà di Farmacia, 10125 Torino, Italy

ABSTRACT: 2,3-Oxidosqualene cyclases (OSC) are enzymes which convert 2,3-oxidosqualene (OS) into polycyclic triterpenoids such as lanosterol, cycloartenol, and α- and β-amyrin. Our interest in the study of OSC is the development of new OSC inhibitors for potential use as hypocholesterolemic, antifungal, or phytotoxic drugs. In particular, we describe the biological activity and the mechanism of a series of acyclic azasqualene derivatives mimicking the C-2, C-8, and C-20 carbonium ions formed during OS cyclization. Some of these carbonium ion analogues are very promising as specific hypocholesterolemic agents. The toxicity, the biodistribution, and the pharmacokinetics of different azasqualene derivatives in mice are also presented. In order to obtain new, site-directed irreversible inhibitors of OSC, a series of squalene derivatives containing functional groups that can link covalently to an active-site thiol group was designed. Among these compounds, squalene maleimide was the most active toward mammalian OSC, whereas squalene Ellman behaved as an irreversible inhibitor of OSC from yeast.

Lipids 30, 235–246 (1995).

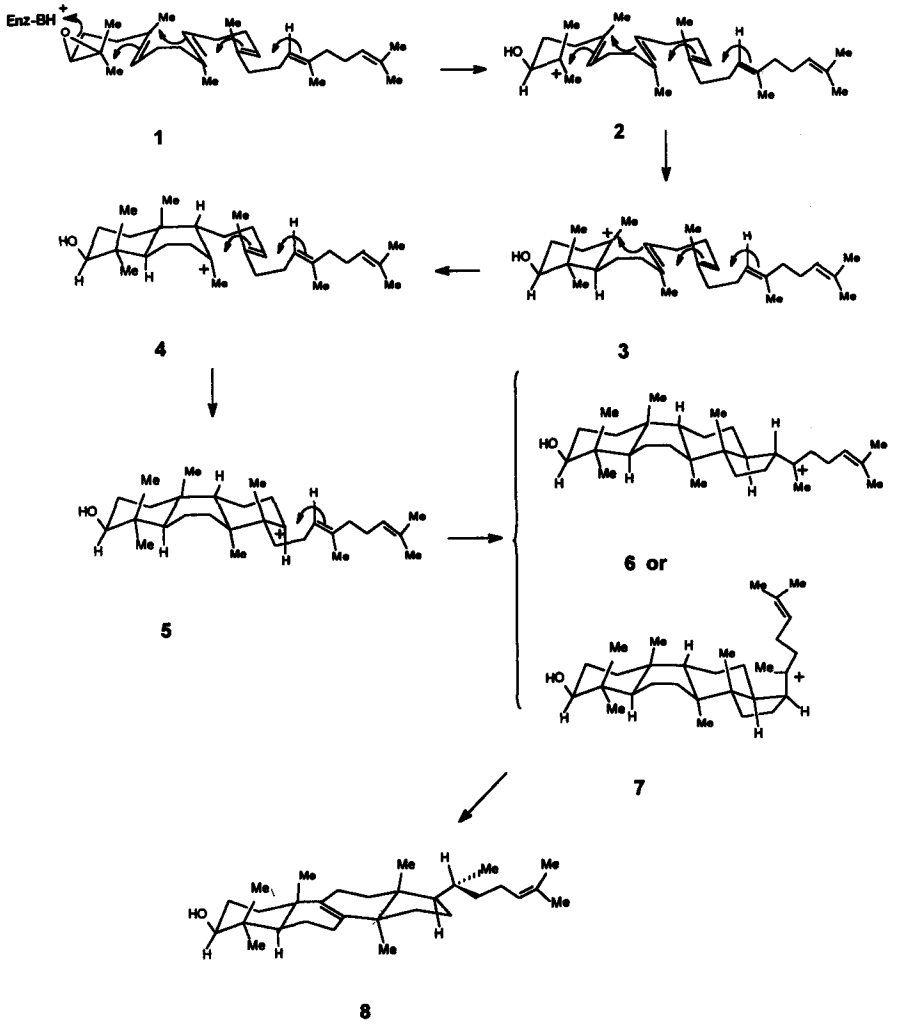
2,3-Oxidosqualene cyclases (OSC) are key enzymes in the biosynthesis of animal, plant, and fungal sterols. They catalyze the conversion of (*3S*)-2,3-oxidosqualene **1** to lanosterol **8** (Scheme 1) in mammals and fungi and to cycloartenol in algae and higher plants (1–7). Moreover, OSC are responsible for the formation of a variety of tetra- or pentacyclic triterpenoids found in higher plants (8,9). In some bacteria and protozoa, squalene can be directly cyclized to tetrahymanol-type pentacyclic triterpenoids (7).

The enzymatic cyclization of 2,3-oxidosqualene (OS) **1** starts with an initial protonation of the oxirane ring, which is accomplished by a suitable electrophilic residue present at the active site of the enzyme to give a C-2 carbonium ion intermediate **2**, followed by cyclization to a series of discrete, conformationally rigid carbonium ion intermediates such as the C-10 monocyclic intermediate **3**, the C-8 bicyclic **4**, the C-13 tricyclic **5**, and the C-20 tetracyclic carbonium ion **6** or **7** (10–19) (Scheme 1). These intermediates, which are also called high-energy intermediates (HEI) (10,20), undergo further rearrangement to form lanosterol **8** in animals and yeasts or cycloartenol in higher plants.

Our interest in the study of OSC is the development of new inhibitors for potential use as hypocholesterolemic, antifungal, or phytoxic agents (15,21). Inhibition of OSC has constituted an attractive approach for the design and synthesis of drugs, as this step is beyond the synthesis of other triterpenoid intermediates, such as dolichol, ubiquinone, and farnesylated proteins, which have important physiological functions including those related to cell division (22).

A general strategy for the design of new inhibitors of OSC has been to mimic the previously described carbonium ion intermediates by replacing the positively charged carbonium ion with a nitrogen (protonated at physiological pH) (23–27). These inhibitors are being thought of as analogues of the enzyme-bound HEI (10).

Several laboratories have synthesized cyclic aza derivatives (Scheme 2) with a nitrogen corresponding to the C-10 HEI, such as in **9**, **10**, and analogues, or to the C-8 HEI, such as the azadecalin derivatives **11** and **12** (27–32). These mono- and bicyclic derivatives were shown to be potent inhibitors of OSC, whereas the tricyclic ones, such as **13**, showed only modest inhibition of OSC *in vitro* (31). It is worth pointing out that some uncharged species, such as the piperidine amide **14**, the decalin amide **15**, or the thioamide derivative **16**, are also potent inhibitors of OSC (33,34). Finally, a series of sulfur-containing oxidosqualene analogues **17** and **18** (Scheme 3) showed significant inhibition of the mammalian OSC (28).



Our strategy has been to design acyclic aza squalenoid derivatives **21–23** (Scheme 4) possessing a nitrogen atom corresponding to the carbonium ions or HEIs **2, 4,** and **7** arising from cyclization of OS **1**. We believe that these acyclic compounds are conformationally more flexible than the cyclic ones, and thus they should be less likely to interfere with

[1]Based on a paper presented at the symposium on the "Regulation of Biosynthesis and Function of Isopentenoids," Atlanta, Georgia, May 1994.

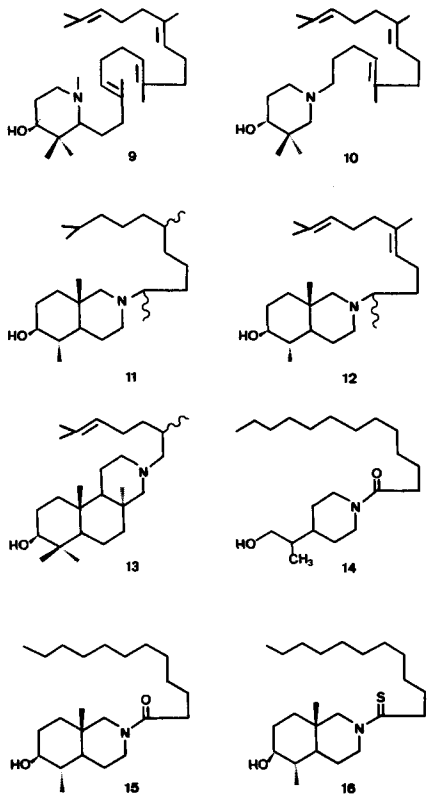


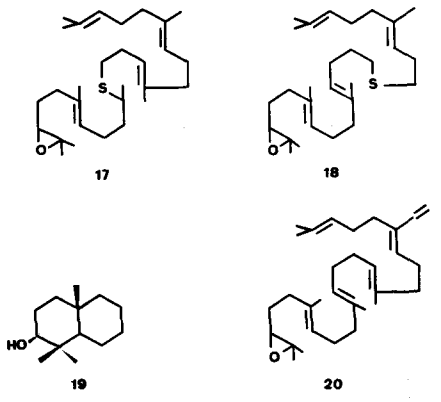
SCHEME 1

other sterol biosynthetic enzymes, such as the sterol $\Delta^8 \rightarrow \Delta^7$ isomerase or sterol Δ^{14} reductase, which are sometimes inhibited by the cyclic inhibitors (32–37). Some of these inhibitors can be considered as product state analogues, like the known OSC inhibitor 4,4,10β-trimethyl-*trans*-decal-3β-ol **19** (Scheme 3) (35).

Detailed kinetic studies with microsomal or partially solubilized OSC indicated that both the acyclic and the cyclic aza derivatives apparently behaved as noncompetitive inhibitors (38–40). It has been postulated (31) that cyclic inhibitors such as the aza tricyclic compounds mimicking HEI with structures very different from those of substrates or products could be slow-binding inhibitors. So far only some noncharged inhibitors, such as the 19-oxa vinylether analogue of OS or the bicyclic amide **15**, were shown to be competitive inhibitors of OSC (41). Usually, such kinetic studies are difficult to carry out with the OSC membrane-bound enzymes associated with the microsomal fraction, or solubilized and partially purified OSC, both of which can be considered highly heterogeneous.

The first mechanism-based irreversible inhibition of OSC was recently reported by Xiao and Prestwich (42). 29-Methylidene-2,3-oxidosqualene **20** (Scheme 3) was a very potent inactivator of pig liver OSC, showing an IC_{50} (the concentration of inhibitor which reduces the enzymatic conversion by 50%) value of 0.5 μM, an apparent K_i of 4.4 μM, a $k_{inactiv}$ of 221 min^{-1}, and a partition ratio of 3.8. By affinity labeling experiments, it was shown that **20** specifically labeled vertebrate OSC, whereas neither yeast or plant OSC was labeled (43). Covalently-modified peptide fragments were successively isolated from purified rat liver OSC and sequenced. The labeled peptide contained a DDTAE motif characterized by the presence of two adjacent aspartate residues (44).

The synthesis of new, site-directed irreversible inhibitors is, in our view, a very interesting task as it provides new tools for preparing potent therapeutic agents, as well as for modifying the active site, to gain mechanistic insights into the mode of action of the enzyme. We are particularly interested in the design of specific thiol modifying agents with a squalene-type structure, as several authors have demonstrated an irreversible inhibition of OSC from different sources by some thiol reagents such as *p*-chloromercuribenzenesulfonic acid

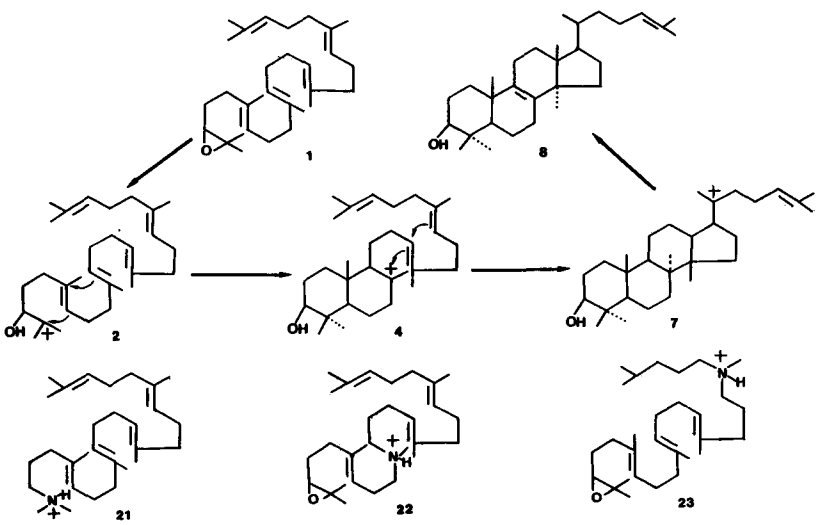


SCHEME 2

and *N*-ethylmaleimide in hog liver, yeast, and pea seedlings cyclase (45–49). Similar results were reported by Poralla for squalene–hopene cyclase from *Bacillus acidocaldarius* (50).

MATERIALS AND METHODS

IC_{50} values on OS–lanosterol cyclase activity were determined in microsomal preparations from rat liver, pig liver, *Saccharomyces cerevisiae* and *Candida albicans* and on partially purified OS cyclase of pig liver. IC_{50} values on squalene epoxidase activity were determined in microsomal preparations from rat and pig liver.



SCHEME 3

Microsomes of rat and pig liver and of *S. cerevisiae* were prepared according to the methods previously described (38,41,51,52). *Candida albicans* microsomes were kindly provided by LEPETIT (Gerenzano, VR, Italy).

Pig liver OSC was purified according to the method previously described (38).

Assay of mammalian oxidosqualene cyclase activity. The substrate and the insoluble inhibitors were added to the test tubes as organic solutions in $CHCl_3$ in the presence of 0.05% (wt/vol) Tween 80, and the solvent was evaporated under nitrogen before addition of the aqueous components of the mixture. OSC activity was determined by incubating the microsomal suspension (5 mg protein for rat liver or 1 mg for pig liver) or the solubilized enzyme preparation (250 µL, 0.1 mg protein) for 30 min at 45°C with [3-^{3}H](*R,S*)-OS (100,000 dpm) diluted with (*R,S*)-OS (50 nmol), 0.1 M K/K phosphate

SCHEME 4

buffer, pH 8, containing 1 mM EDTA, Tween 80 (final concentration, 0.05% wt/vol), the inhibitor (when present) and 0.05% Emulphogene for solubilized enzyme (final volume, 1 mL). The reaction was stopped, and the amount of lanosterol was determined as previously described (41).

IC_{50} values were determined at 50 μM substrate in the presence of different concentrations of the inhibitors (38).

Assay of yeast oxidosqualene cyclase activity. The substrate OS, detergent and inhibitors, when present, were added to the test tubes as organic solutions. After evaporation of the solvent under N_2, the products were emulsified by stirring vigorously with a minimum of buffer. When not otherwise indicated, the reaction mixture contained (in a volume of 0.5 mL): [3-^{3}H](*R,S*)-OS (100,000 dpm) diluted with (*R,S*)-OS (25 nmol), Tween 80, 0.01% (wt/vol), 0.5 mM dithiothreitol, 0.1 M phosphate buffer, pH 7.1, and 1.5 mg microsomal protein. The reaction mixture was incubated for 30 min at 35°C in a shaking water-bath. Boiled microsomes were used as a blank. The reaction was stopped by adding 1 mL of KOH 15% (wt/vol) in methanol. Tubes were capped and heated at 80°C for 30 min. The nonsaponifiable lipids were extracted (51) and fractionated together with authentic samples of OS and lanosterol by thin-layer chromatography (TLC) on silica gel plates developed with CH_2Cl_2. Areas corresponding to OS and lanosterol were visualized under ultraviolet light with berberine. Fractions were scraped off and counted for radioactivity in a Beckman (Fullerton, CA) LS 5000 liquid scintillator (53).

Isotope counting and activity calculations were done as described (51).

Assay of mammalian squalene epoxidase activity. Squalene epoxidase activity was determined in rat and pig liver microsomes in the presence of supernatant fraction S_{100} and of the OSC inhibitor, 3β-(β-dimethylaminoethoxy)androst-5-en-17-one (U-14226A).

The substrate and the insoluble inhibitors were added to the test tubes as organic solutions in $CHCl_3$, in the presence of 0.05% (wt/vol) Tween 80, and the solvent was evaporated under nitrogen before addition of the aqueous components of the mixture. The reaction mixture contained (in the final volume of 1 mL): [^{3}H]squalene (20,000 dpm) diluted with squalene (20 nmol), Tween-80 (final concentration, 0.05% wt/vol), 0.1 M K/K phosphate buffer, pH 7.4, containing 1 mM EDTA, microsomes (5 mg protein), S_{100} (10 mg protein), U-14226A (50 μM), $NADP^+$ (2 mM), glucose-6-P (5 mM), glucose-6-P dehydrogenase (1 unit), and $MgCl_2 \cdot 6H_2O$ (5 mM). Incubations lasted 30 min at 37°C. The reaction was stopped by the addition of 1 mL of 10% ethanolic KOH followed by saponification for 30 min at 80°C. Extraction and chromatographic procedures similar to those of the OSC assay were used. After developing the TLC plate in CH_2Cl_2, the areas corresponding to authentic squalene and OS were scraped off and the fractions counted for radioactivity in a Beckman LS 5000 liquid scintillator. The enzymatic activity was expressed as nanomoles of OS formed per hour (52).

Inhibition of cholesterol biosynthesis in 3T3 fibroblast and in HEP G2 hepatoma cell cultures. Cells derived from semi-confluent cultures were seeded at about 5×10^5 cells in 17-mm wells in 1 mL of Dulbecco's modified Eagle's medium containing 10% of lipid-free fetal calf serum and were grown for 36 h at 37°C in a humidified incubator under 5% CO_2. After 4 h of preincubation in the presence or absence of inhibitors, [^{14}C]acetate (1 μCi, 0.018 μmol) was added and 2 h later the medium was removed and the cells hydrolyzed with 0.1 N KOH for 30 min. The hydrolysate was saponified with 6% methanolic KOH for 30 min at 80°C. The nonsaponifiable lipids were extracted with light petroleum hydrocarbon and fractionated by TLC using CH_2Cl_2 as developing solvent. The chromatographic plates were analyzed with a Packard (Meriden, CT) radioscanner system 200, and the counts associated with each lipid fraction were measured and expressed as percent of total counts (54).

Time-dependent inactivation: general procedure. Time-dependent inhibition was determined at 37°C by adding the inhibitors to the enzymatic solution of partially purified OSC of pig liver in the absence of substrate. Residual activity was determined under the same conditions as previously described, at 45°C for 30 min after lowering the inhibitor concentration 40 fold; aliquots of 25 μL were withdrawn at time intervals from 30 s to 60 min and transferred to test tubes containing the labeled OS (25 μM) and Tween-80 (0.5 mg/mL) in 950 μL of phosphate buffer. The concentrations of inhibitors obtained after dilution did not inhibit OSC without preincubation.

LD_{50} assay. Female Balb/c mice, one-month-old, were purchased from Charles River Italia (Milano, Italy). They were acclimatized for one week before the start of the experiment.

Increasing amounts of 2-aza-2,3-dihydrosqualene **21**, its HCl salt, 2-aza-2,3-dihydrosqualene alcohol **26** and 2-aza-2,3-dihydrosqualene epoxide **24** were intraperitoneally, intravenously and per os injected into groups of five animals, and the experiments were repeated two or three times. The LD_{50} was calculated from the number of dead mice after seven days. A control group was always set up by injecting the animals with an identical amount of the solution used to prepare the samples: phosphate buffer 0.1 M, pH 7.2, with methanol 25% (vol/vol). At the end of the experiment, the mice were autopsied to assess tissue damage (55).

Pharmacokinetic and biodistribution studies on 2-aza-2,3-dihydrosqualene (HCl salt). The compound was previously labeled with ^{3}H by total synthesis to a specific activity of 1.1×10^{-4} mCi/mol. The labeled compound was used as tracer to monitor the circulatory clearance of the tested drug.

The mice (22 g) were intravenously treated with 2.5 μCi of the tracer. The test doses, including the mass of radiolabeled compound, were 1.5 or 761.5 μg of 2-aza-2,3-dihydrosqualene (HCl salt). The samples were diluted, as described above, to a final volume of 100 μL. Blood samples of 100 μL were drawn from the right retroorbital plexus of groups of five animals at various time points (0, 1, 3, 5, 6, 7, 8, 10, 15, 20 and 30 min, and 1 and 24 h). Capillary Pasteur and Eppendorf vials used for sample collection were washed

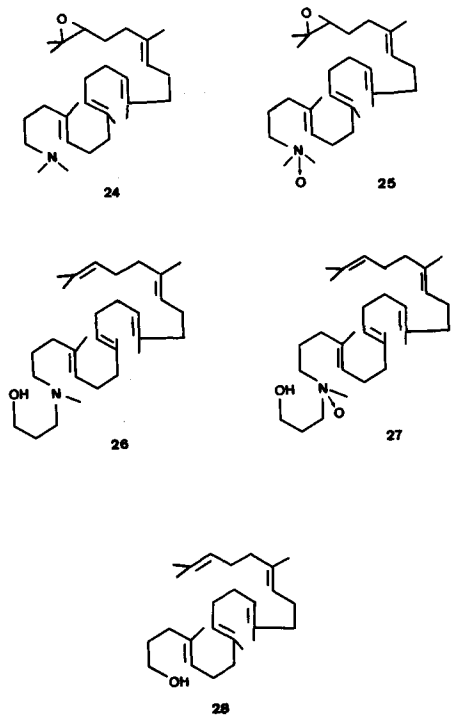
in a heparin solution the day before use. Because the animals underwent no more than four drawings, the different groups were overlapped to sample the chosen time range. The blood samples were centrifuged at 10,000 rpm for 5 min (J2-21 Beckman). The plasma was fractionated in 20-μL (amount usually recovered from 50 μL of blood) samples and directly counted in a β-counter (LS 5000 TD Beckman). The radioactivity measured was correlated to the total blood volume, which was assumed to be 10% of body weight.

The pharmacokinetic parameters and slopes were derived using a least-square regression algorithm with a weighting function $1/(y + \bar{y})^2$ (Sigma Plot 4.0 software; Jandel, Erkrath, Germany). Each point of the slope was the mean of seven drawings and is represented as the concentration in μg/mL plotted against time expressed in minutes. The values were obtained adopting a one-compartment phamacokinetic model: $C = C_0^{-kt}$. The plasma samples not used in this experiment were frozen at −80°C for further use in the experiments described below.

Other groups of five animals were similarly injected; the principal organs (liver, kidney, diaphragm, brain, muscle, spleen hearth, and gastrointestinal tract) were removed at different times (0, 3, 5, 7, 10, 15, 20 and 30 min, and 1 and 24 h). The organs were washed twice in physiological solution, wiped, and weighted; amounts of 10–100 mg were prepared and treated with 1 mL of NCS (tissue solubilizer; Amersham, Buckinghamshire, United Kingdom) by stirring overnight at 50°C. Thereafter, and upon addition of acetic acid, 0.034% with respect to the solubilizer volume, the samples were β-counted. The results were plotted as histograms and recorded as radioactivity per organ vs. time expressed in minutes. Mean values for five animals are shown in the graphs (55).

High-performance liquid chromatography (HPLC) and TLC on plasma samples. A Lichrosfer RP 60 Select B (Merck, Darmstadt, Germany) (5 μm) was used with an HPLC Merck Hitachi LC 6000 instrument. Absorbance was monitored at 220 nm. Methanol, (96%), MilliQ water (3%), and isopropylamine (1%) were used as eluent. The samples drawn at different timepoints were diluted with methanol/water (50:50, vol/vol), and peaks were identified by comparison with reference compounds. The eluted fractions were successively chromatographed by TLC (Kieselgel 60 F254, 0.2 mm), using methanol (99.8%) and isopropylamine (0.2%) as solvent. The plates were then radiomonitored with a radioscanner (System 200 Imaging, Canberra Packard). Another set of plasma samples was treated as follows to extract the lipophilic components. Aliquots of 100 μL of plasma were stirred in 200 μL of 12% methanolic KOH and 700 μL 0.1 M phosphate buffer, pH 7.2, at 80°C for 30 min. Lipids were extracted with 3 × 1 mL of light petroleum hydrocarbon and then, after evaporation under vacuum, resuspended in methanol prior to TLC. TLC slabs were eluted as described above.

To monitor the drug biodistribution in different blood components, red cells were precipitated and separately β-counted after solubilization. The plasma was treated with trichloroacetic acid (50% wt/vol) at 4°C for 5 min. After centrifugation at 4000 rpm for 10 min, the pellet of plasma protein was separated, and the samples were extracted as described above. The lipophilic fraction was fractionated by TLC (55).



Metabolic studies on urine and excrements. Mice were maintained in metabolic cages (Jencon) with water feeding for 24 h. For urine drawings after 24 h, one mouse per cage was used. Otherwise two mice were necessary to obtain sufficient amounts of sample. Urine was sampled for the following time periods: 0–2, 2–4, 4–7, 7–24, and 0–24 h. Feces was collected 24 h after injection to obtain suitable amounts.

Urine samples after dilution with water (1:1, vol/vol) and filtration (0.2 μm Millipore; Watford, Hertfordshire, United Kingdom) were adjusted to pH 5 with 0.1 M acetate buffer and then stirred at 37°C for 24 h in the presence of glucuronidase sulfatase (1000 U/mL of urine; Boehringer, Mannheim, Germany). The samples were then centrifuged 2000 rpm for 15 min, and the pH was adjusted to 8 with 3 N NaOH. Lipids were extracted with ethyl acetate, and the solvent was evaporated prior to HPLC or TLC analysis. Feces were treated as described (55). Briefly, aliquots of 100 mg were taken up in water, homogenized, and the supernatants centrifuged at 12,000 rpm for 30 min (1-5 50B Beckman). After filtration (0.2 μm), the supernatants were diluted with methanol and extracted prior to TLC (55).

RESULTS AND DISCUSSION

Acyclic azasqualenes. Historically, the first acyclic azasqualene, synthesized in our laboratory, was 2-aza-2,3-dihydrosqualene **21** (Scheme 4) and a series of derivatives, which mimicked the first C-2 carbonium ion or transition state arising from the protonation of the epoxide ring (15,21,24,25,51, 56). These compounds were potent inhibitors of OSC from animals, yeasts, and higher plants, as well as being inhibitors of squalene epoxidase, an enzyme that transforms squalene to OS (6). Thus, the azasqualene derivatives, such as the model compound 2-aza-2,3-dihydrosqualene **21**, did not act specifically on the target enzyme OSC. Moreover, they also inhibited the different OSC of animals, fungi, and higher plants.

We recently found that the introduction of a polar group (epoxy, hydroxy) helped to suppress inhibitory activity on squalene epoxidase without impairing inhibitory potency toward OSC (54) (Scheme 5). By comparing the activity of 2-aza-2,3-dihydrosqualene **21**, the 22,23-epoxy derivative **24**, the corresponding *N*-oxide **25**, azasqualene alcohol **26**, the *N*-oxide derivative **27**, and squalene alcohol **28** on squalene epoxidase from rat liver microsomes, we found that at a concentration of 10 μM, the aza derivatives bearing an epoxy or hydroxy functionality were poor inhibitors (Table 1). In 3T3 fibroblasts, at the lowest concentration (1 μM), azasqualene alcohol **26** and its *N*-oxide derivative **27** were found to be, together with azasqualene **21**, the most active compounds as shown by the suppression of cholesterol biosynthesis by 74 and 90%, respectively (Fig. 1). Moreover, the two compounds, **26** and **27**, proved to be the most specific inhibitors of OSC, as they did not affect squalene epoxidase. We suggest that the

SCHEME 5

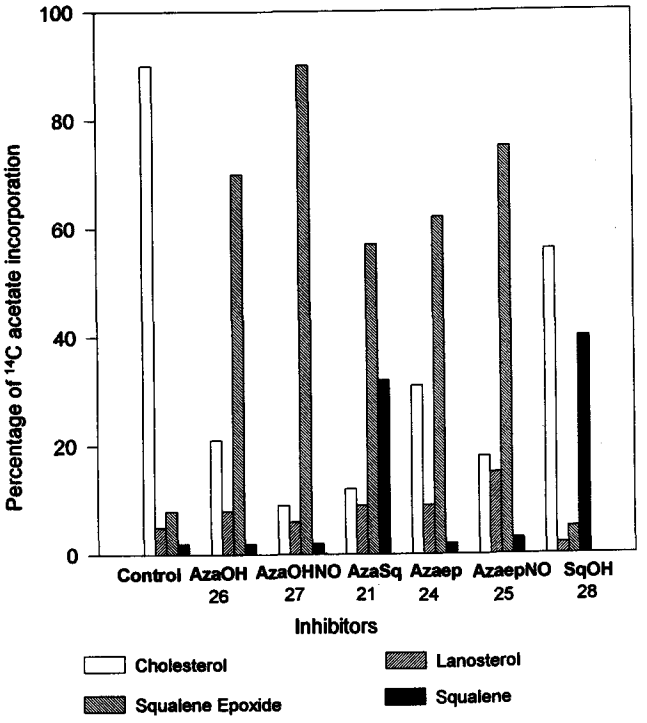


FIG. 1. Incorporation of [^{14}C]acetate into nonsaponifiable lipids by various squalene derivatives at 1 μM concentration. AzaOH, azasqualene alcohol; AzaOHNO, azasqualene alcohol N-oxide; AzaSq, 2-aza-2,3-dihydrosqualene; Azaep, 22,23-epoxy-2-aza-2,3-dihydrosqualene; AzaepNO, 22,23-epoxy-2-aza-2,3-dihydrosqualene N-oxide; SqOH, squalene alcohol.

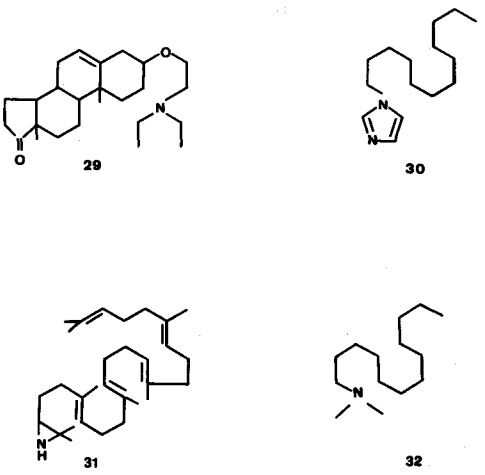
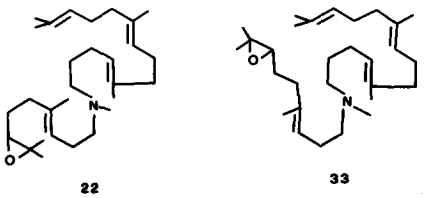


introduction in the structure of 2-aza-2,3-dihydrosqualene **21** of a polar function, such as 3-hydroxypropyl or epoxy, may impair hydrophobic interactions at the active site of squalene epoxidase. On the other hand, the 22,23-epoxyazasqualene derivatives **24** and **25** were as effective as the azasqualene model **21** on OSC from *S. cerevisiae* and *C. albicans* or on cycloartenol and β-amyrin OSC from maize and peas.

Very different compounds, such as U-18666A **29**, *N*-dodecylimidazole **30**, 2,3-iminosqualene **31**, and *N,N*-dimethyldodecylamine **32**, are equally active against higher plant, animal, and yeast OSC (Scheme 6) (15,39,56). Consequently, we suggest that the inhibitors that are able to mimic the high-energy carbonium ion arising from the opening of the epoxidic ring of OS do not strictly need a geometrically correct folding of the squalene skeleton.



The subsequent step in our strategy was to mimic the C-8 carbonium ion, which is transiently formed during OS cyclization, by synthesizing the two geometrical isomers (*6E*) **22** and (*6Z*)-10-aza-10,11-dihydrosqualene-2,3-epoxide **33** (52) (Scheme 7). As expected, only isomer (*6E*), the carbonium ion analogue corresponding to the natural all *E* OS, was active in all biological systems tested: the IC_{50} values varied from 3–5 μM in yeast (*S. cerevisiae* and *C. albicans*) to 5 μM in animal OSC (Table 2). Moreover, both isomers *E* and *Z*, as opposed to 2-aza-2,3-dihydrosqualene **21**, were inactive against squalene epoxidase from rat liver at the higher concentrations tested.

TABLE 1
Inhibition of Squalene Epoxidase in Rat Liver Microsomes

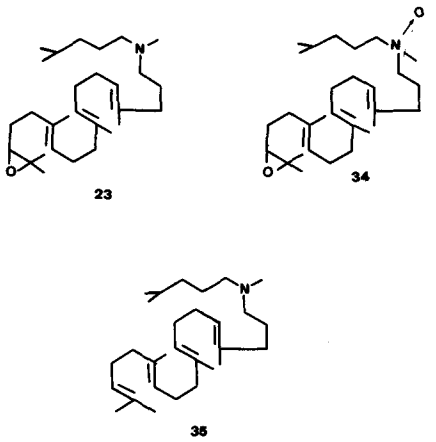
Azasqualene (**21**)	10	70
Azasqualene (**24**)	10	8
Azasqualene epoxide *N*-oxide (**25**)	10	14
Azasqualene alcohol (**26**)	10	2
Azasqualene alcohol *N*-oxide (**27**)	10	13
*Tris*norsqualene alcohol (**28**)	10	40

SCHEME 6



22 33

SCHEME 7

The *in vivo* results obtained by studying the activity of the two isomers in 3T3 fibroblast cell cultures confirmed the selectivity of (*6E*)-10-azasqualene-2,3-epoxide **22** (Viola, F., unpublished data). Indeed, by comparing the incorporation of radioactivity from [2-^{14}C]acetate into the different sterol fractions after preincubation in the presence or absence of inhibitors, it was observed that there was a selective inhibition of OSC by isomer (*6E*), whereas isomer (*6Z*) was practically inactive. The inhibition of cholesterol was dose-dependent: at 0.5 μM it was 60% of the control and at 2 μM the biosynthesis of cholesterol was totally inhibited. At the same time, a correspondent accumulation of OS and 2,3;22,23-dioxidosqualene was observed. Similarly, in the nonsaponifiable lipid fractions from *S. cerevisiae* (57), isomer (*6E*) at 10 μM totally inhibited cholesterol biosynthesis, causing a corresponding dose-dependent accumulation of radioactivity in OS (87.5% of the total label). The main effect of the (*6Z*) isomer was a significant accumulation of the label in the fraction comigrating in TLC with lanosterol. In contrast, (*6E*)-10-azasqualene-2,3-epoxide **22** failed to inhibit OSC from maize, whereas the azadecaline and the 2-aza-2,3-dihydrosqualene derivatives proved to be potent inhibitors (Rahier, A., personal communication).

Thus, the noncyclic inhibitors, that are analogues of the C-8 HEI, must possess the *all-trans* squalenoid geometry of the natural substrate. Moreover, the pro C-8 HEI inhibitor **22** appeared to be more selective than the C-2 HEI azasqualene-type inhibitors such as **21**, as it was able to inhibit OSC from animals and yeasts, whereas it did not inhibit higher plant OSC (Rahier, A., personal communication).

The next step in our program was the synthesis of acyclic azasqualenes mimicking the C-20 carbonium ion intermediates, such as 19-aza-18,19,22,23-tetrahydrosqualene-2,3-epoxide **23**, its *N*-oxide **34**, and 19-aza-18,19,22,23-tetrahydrosqualene **35** (58) (Scheme 8). We assayed the inhibition caused by these compounds *in vitro* on partially purified OSC from pig liver, and on OSC associated with microsomes from rat and pig liver, and from *S. cerevisiae* and *C. albicans*.

23 34 35

SCHEME 8

The most active compounds, 19-azasqualene-2,3-epoxide **23** and its *N*-oxide **34** showed *in vitro* an inhibitory activity on animal OSC similar to that found for the parent compound 2-aza-2,3-dihydrosqualene **21** and the corresponding *N*-oxide (Table 3). The presence of an epoxide ring is essential for activity, as 19-azasqualene **35** was not active under the same conditions. The two 19-azasqualene-2,3-epoxide derivatives **23** and **34** were not effective inhibitors of OSC from yeast microsomes or from higher plants, such as cycloartenol OSC or β-amyrin OSC (Rahier, A., personal communication), and they did not inhibit animal squalene epoxidase.

In Hep G2 hepatoma cultures, incubation with [2-^{14}C]-acetate in the presence of inhibitor **23** caused a decrease in the radioactivity in the cholesterol fraction (IC_{50} = 0.2 μM), whereas an accumulation of the label in the fractions corresponding to OS and 2,3;22,23-dioxidosqualene was observed. Consequently, 19-azasqualene-2,3-epoxide **23** is a much more

TABLE 2
IC_{50} Values (μM) of Inhibition of Microsomal 2,3-Oxidosqualene Cyclase by (6*E*-22) and (6*Z*)-10-Azasqualene-2,3-epoxide (33)[a]

Microsomes	Isomer *E*	Isomer *Z*
Rat liver[b]	4.8	>20
Pig liver[b]	5	ND
Saccharomyces cerevisiae[c]	5	>100
Candida albicans[d]	3	>100

[a]The values are means of two different experiments; ND, not determined; IC_{50}, the concentration of inhibitor which reduces the enzymatic conversion by 50%.
[b]Microsomal protein concentration was 1 mg/mL for pig liver and 5 mg/mL for rat liver.
[c]Microsomal protein concentration was 2 mg/mL.
[d]Microsomal protein concentration was 3 mg/mL.

TABLE 3
IC_{50} Values (μM) of Inhibition of 2,3-Oxidosqualene Cyclase by 19-Azasqualene-2,3-epoxide (23) and 19-Azasqualene-2,3-epoxide *N*-oxide (34)[a]

	Compounds	
Enzymatic assay[a]	**23**	**35**
Partially purified pig enzyme	1.7	7
Rat liver[b]	7.5	ND
Pig liver[b]	1.5	ND
Saccharomyces cerevisiae[c]	35	100
Candida albicans[c]	22	55

[a]The values are means of two different experiments. Abbreviations as in Table 2.
[b]Microsomal protein concentration was 1 mg/mL for pig liver and 5 mg/mL for rat liver.
[c]Microsomal protein concentration was 3 mg/mL.

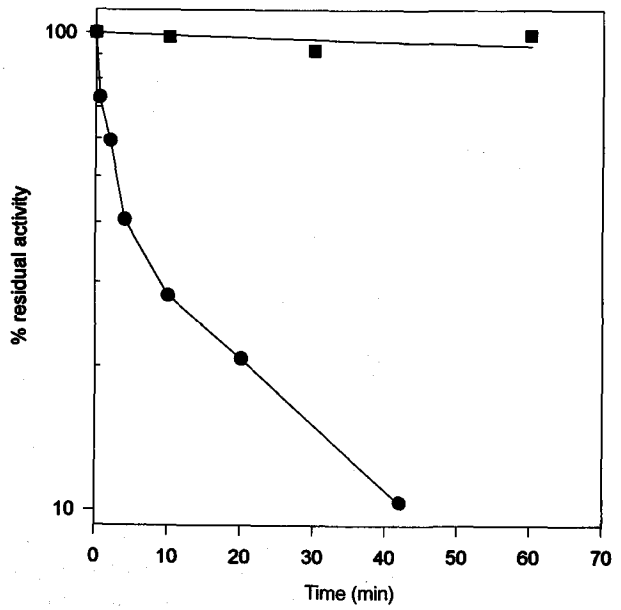


FIG. 2. Time-dependent inhibition of 2,3-oxidosqualene cyclase (OSC) by 19-azasqualene-2,3-epoxide **23** (5 μM) (●) and 19-azasqualene **35** (50 μM) (■). OSC was preincubated at 37°C in phosphate buffer in the presence of the inhibitors. At intervals, 25 μL were withdrawn and diluted to 1 mL of phosphate buffer containing the substrate 2,3-oxidosqualene. The enzymatic activity was determined as % of the activity obtained after preincubation in the absence of inhibitors.

selective inhibitor than the corresponding 10-azasqualene-2,3-epoxide **22** and 2-aza-2,3-dihydrosqualene **21**, because it inhibited mainly mammalian OSC rather than yeast or higher plant OSC.

Surprisingly, 19-azasqualene-2,3-epoxide **23** was also able to inactivate OSC from pig liver in a time-dependent manner (Viola, F., unpublished data); the inactivation was very effective. The inhibitor, at a concentration of 10 μM, caused the loss of 50% of the enzymatic activity after 1 min of preincubation (Fig. 2). By contrast, 19-azasqualene **35** was ineffective at the higher concentrations tested (50 μM). When the enzyme, preincubated with compound **23**, was passed after the preincubation through a membrane anion exchange cartridge, the activity was not restored.

We could speculate that 19-azasqualene-2,3-epoxide **23**, in order to inhibit OSC, must be first recognized by the enzyme through the epoxide ring and then correctly folded or cyclized to obtain the conformation that best mimics the C-20 carbonium ion. At this point, this postulated intermediate could covalently link to the enzyme, acting as a site-directed inhibitor, or it could be strictly associated with the enzyme as a tight-binding inhibitor. In order to test this, we assayed (*6E*)-10-aza-10,11-dihydrosqualene-2,3-epoxide **22** as a time-dependent inhibitor. We found that **22** was also a pseudo-irreversible inhibitor of OSC, as it was able to inhibit 50% of the enzymatic activity after a few minutes of preincubation, whereas isomer (*6Z*) **33** was found to be inactive. Therefore, it appears that the azasqualenes with the correct all *E* geometry, bearing an epoxide terminal ring and a nitrogen corresponding to the C-8 or C-20 intermediates, act as irreversible inhibitors.

Thus, we can make the following conclusions in regard to the azasqualene derivatives: (i) All the azasqualenes designed could mimic the corresponding HEI formed by cyclization of OS, as shown by their good inhibitory activity. This can be considered indirect evidence of the known isoprenic rule which postulates the formation of a series of conformationally rigid carbonium ion intermediates (from C-2 to C-20). (ii) A progressive selectivity was shown in regard to the inhibition of OSC going from C-2 to pro C-8 and pro C-20 HEI azasqualene analogues. This could also mean that the OSC active site complementary to the C-8 and C-20 HEI differs considerably in mammalian, yeast, and higher plant enzymes. (iii) The inhibitory efficacy of azasqualenes appears to be related to their relative conformational flexibility, which allows these compounds to bind to the OSC in their ground state and then trigger a rapid conformational change at the active site of the enzyme. This step seems necessary to obtain a strict interaction with the cyclic carbonium ion formed during the cyclization of OS.

Initial pre-clinical studies with 2-aza-2,3-dihydrosqualene. We initially compared the toxicity of different azasqualene derivatives in mice (Table 4) upon administering different amounts of the dugs by the intravenous, the intraperitoneal, and the oral route (55).

The LD_{50} of 2-aza-2,3-dihydrosqualene **21** and of its HCl salt following intravenous injection was calculated to be 38 mg/kg mouse; with up to 34 mg/kg no pathological lesions were observed. At the highest dose (60 mg/kg mouse), death of the animals occurred quickly with widespread hemorrhage of intestine, kidney, spleen, and lung. After intraperitoneal injection, the LD_{50} of the **21** HCl salt was 80 mg/kg mouse; the LD_{50} after per os administration was approximately 800 mg/kg. 2-Aza-2,3-dihydrosqualene-22,23-epoxide **24** proved to be nontoxic; after intraperitoneal administration of the drug, death did not occur up to doses of 2 g/kg mouse.

Pharmacokinetic analysis of the **21** HCl salt upon intravenous injection revealed that the plasma disappearance could be described by a monoexponential function with a mean half-life of 5.62 min (Fig. 3). The distribution of the drug indicated that after 30 min, most of HCl salt of com-

[a]Concentrations are expressed in mg/kg mouse. iv, intravenous; n.t., not toxic; ip, intraperitoneally; po, per os; LD_{50}, standard deviations were less than 2.9%, and are not reported.

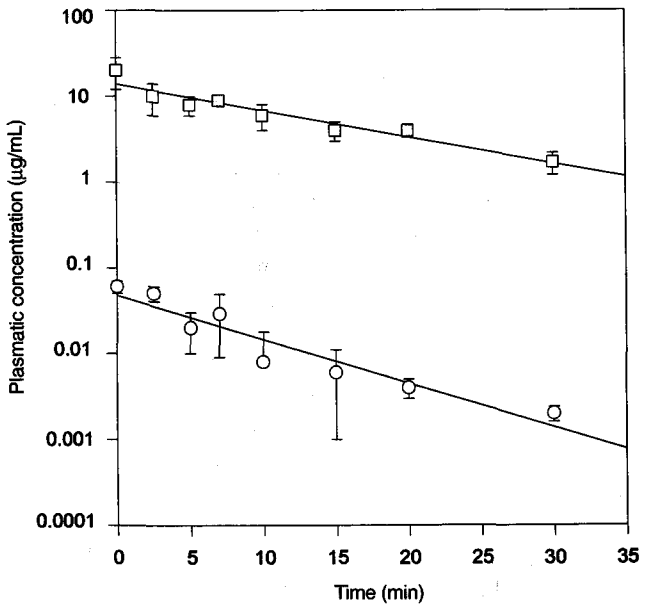

FIG. 3. Plasma clearance: Balb/c mice were injected intravenously with radiolabeled 2-aza-2,3-dihydrosqualene **21** (HCl salt) at different doses. Geometric mean (points) and SD (bars) of results, obtained in seven drawings, are reported; ○, 1.5 µg; □, 761.5 µg.

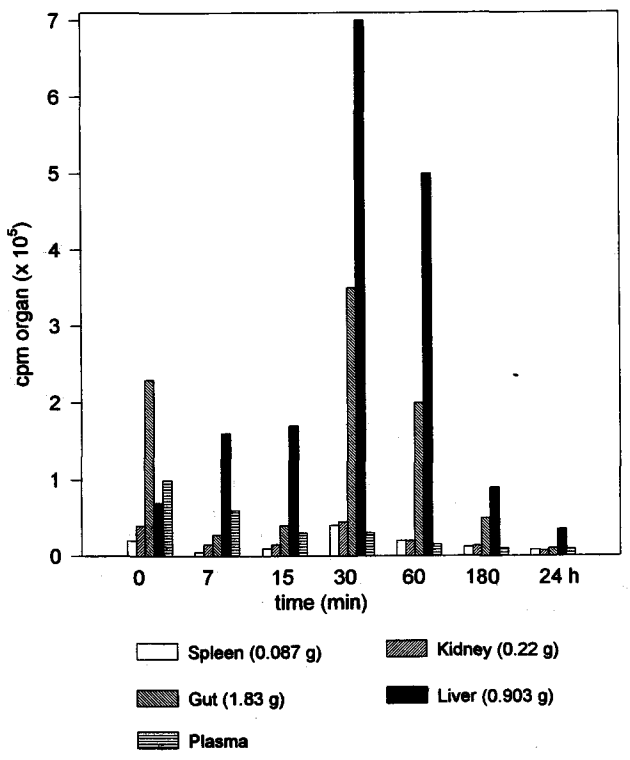
pound **21** was present in the liver and in the gut, while the remainder (less than 10%) was in the plasma and in the other tissues (Fig. 4).



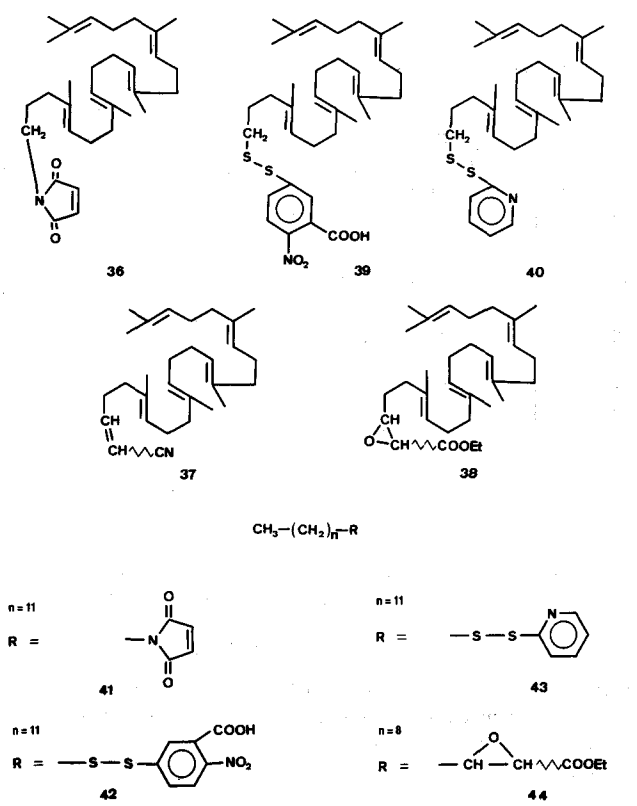


FIG. 4. Biodistribution of 2-aza-2,3-dihydrosqualene **21** (HCl salt) in Balb/c mice; means of five animals are shown. SD values were less than ±10%.

Thus, 2-aza-2,3-dihydrosqualene **21** HCl salt was characterized by a short plasma half-life, a high apparent volume of distribution, and an elevated total clearance. Moreover, this compound was mainly concentrated in the liver and in the gut, and also associated, to a significant extent, with red blood cells and plasma proteins. Plasma, urine, and feces showed the presence of a single metabolite identified as 2-aza-2,3-dihydrosqualene *N*-oxide, previously found (59) after incubation of **21** with rat liver microsomes. This compound has shown high cholesterol-inhibiting activity in animal cells (60). The observed metabolism of **21** may contribute to the hepatic elimination of the parent drug, and eventually also from the enterohepatic circulation. The high concentration of the **21** HCl salt in liver and gut, its recovery in feces accompanied by its *N*-oxide metabolite, and the low concentration of the drug in extrahepatic tissues suggest hepatic extraction and enterohepatic shunt.

According to this view, lovastatin, simvastatin, and pravastatin, which often are the drugs of choice in the treatment of familiar hypercholesterolemia (61–64), appear pharmacokinetically related to 2-aza-2,3-dihydrosqualene **21**.

Squalene derivatives as thiol-modifying agents. In order to obtain further insight into the mechanism of OS cyclization in different OSC enzymes, a series of squalene derivatives was designed that could covalently link to an active-site thiol group.

The following types of potential irreversible inhibitors of

[a]The concentration of the inhibitors was 200 μM. Values are the means of two independent determinations which differed less than 5%.

OSC carrying a squalenoid or dodecyl skeleton (Scheme 9) were synthesized (65): (i) Michael-type inhibitors such as squalene maleimide **36** and the α,β-unsaturated nitrile **37**; (ii) Calpain-type (66) oxirane inhibitors such as **38**: in some proteases these compounds would be attacked after protonation of the epoxide group by a suitable nucleophilic thiol group of the enzyme; (iii) Ellman-type squalenoid inhibitors such as the 2-nitro-5-dithiobenzoic derivative **39** (squalene Ellman) and the 2-dithiopyridyl derivative **40**.

By comparing the activity of the squalene **36–40** and dodecyl **41–44** derivatives, we found that the maleimido derivatives **36** and **41** were the most active inhibitors of mammalian OSC, followed by the Ellman-type compounds **39** and **42**. THe α,β-unsaturated nitrile **37** and the oxirane derivatives **38** and **44** showed little or no activity (Table 5). By evaluating the time-dependent inactivation of these compounds following their incubation with the mammalian enzyme, we found that only the maleimide derivatives were effective as irreversible inhibitors. In particular, we found that the substrate OS was not able to protect the enzyme from inactivation by *N*-dodecylmaleimide, but partially protected the enzyme after incubation for up to 90 min with 50 μM of squalene maleimide **36** (Fig. 5). The degree of substrate protection was statistically significant (15–25%) and was also obtained at 250 and 500 μM concentration of the inhibitor. Similar results had previously been obtained by Schuber. The competitive inhibitor 20-oxa-22,23-dihydrosqualene-2,3-epoxide (41) was not able to protect the enzyme by *N*-ethylmaleimide inactivation (47).

Surprisingly, the squalene Ellman derivative **39** (3-carboxy-4-nitrophenyldithio-1,1′,2-*tris*-norsqualene; CNDT-squalene) did not behave as a time-dependent irreversible inhibitor of liver OSC. In contrast, this compound was found to be an irreversible inhibitor of OSC from *S. cerevisiae* with an apparent binding constant K_i = 1.21 mM and an inactivation rate constant at saturation $k_{app.max.}$ = 0.220 min^{-1} (67).

In Figure 6 is shown the time-dependent inactivation of yeast OSC after pre-incubation with CNDT-squalene **39** at

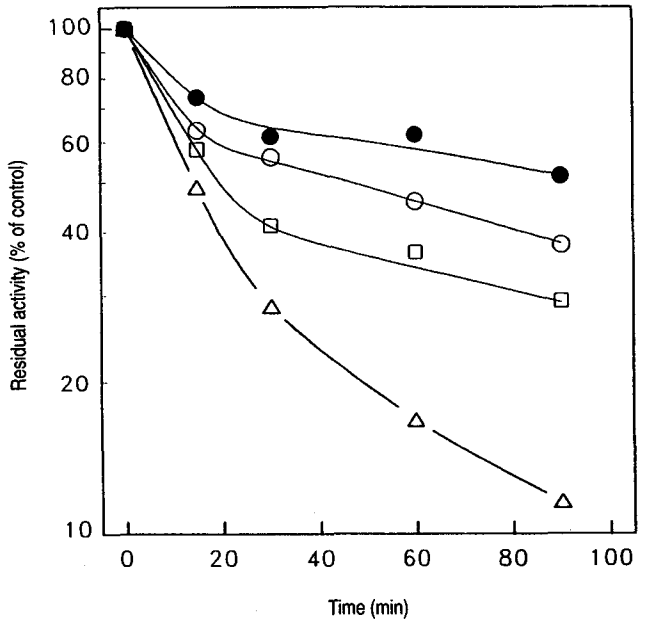

FIG. 5. Time-dependent inhibition of 2,3-oxidosqualene cyclase (OSC) with different concentrations of squalene maleimide **36**. Residual activity (expressed as % of controls without inhibitor) was determined after preincubation of solubilized OSC for increasing time periods (15–90 min) with squalene maleimide 50 μM (○), 100 μM (□), and 200 μM (△). The black circles indicate the residual activity after preincubation of 50 μM inhibitor in the presence of 500 μM of 2,3-oxidosqualene.

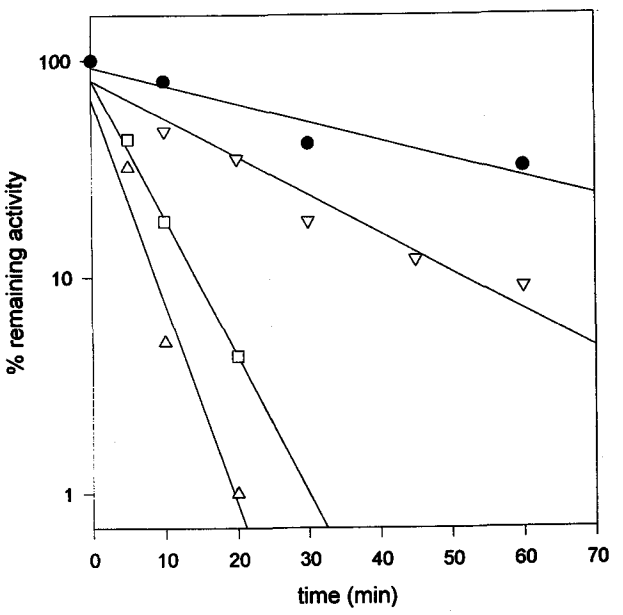

FIG. 6. Time-dependent activation of yeast 2,3-oxidosqualene cyclase by 3-carboxy-4-nitrophenyldithio-1,1′-2-*tris*-norsqualene **39**. The enzyme solubilized from microsomes with Nonidet P-40 (Sigma, Milano, Italy) was incubated (0.3 mg protein/mL, 0.1 M K/Na phosphate buffer, pH 7.1, containing 1 mg/mL Nonidet P-40) at 35°C with 0.0 (●), 0.1 (▽), 0.5 (□), and 1 mM (△) reagent. At time intervals, 50-μL aliquots were withdrawn and diluted with 450 μL 0.1 M K/Na phosphate buffer, pH 7.1, containing 0.5 mg/mL Nonidet P-40, 0.2 mg/mL Tween 80, [^{3}H]2,3-oxidosqualene (50,000 dpm) and 2,3-oxidosqualene (25 μM). The mixture was then incubated for 30 min at 35°C to determine the residual activity, which is expressed as % of control (no reagent).

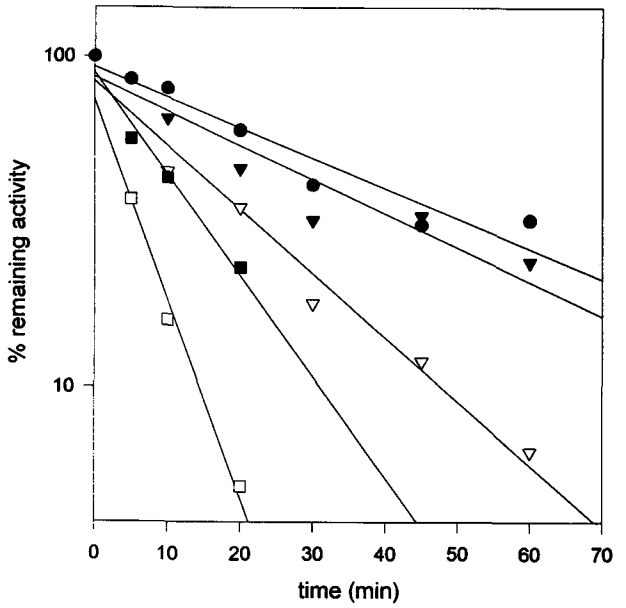

FIG. 7. Protection by 2,3-oxidosqualene (substrate) against 3-carboxy-4-nitrophenyldithio-1,1′-2-*tris*-norsqualene (CNDT)-squalene **39** inactivation of yeast 2,3-oxidosqualene cyclase. Experiments were carried out as described in the legend to Figure 6. CNDT-squalene concentrations were 0.0 (●), 0.1 (▼), and 0.5 mM (■) in experiments with substrate (0.5 mM) as a protecting agent, and 0.1 (▽) and 0.5 mM (□) in experiments with no substrate present.

different concentrations (0.1, 0.5, and 1 mM). The inactivation was reversed by tenfold dilution of the enzyme or by direct reduction of the thiol reagent with dithiothreitol or mercaptoethanol (both ineffective on OSC). In order to localize the thiol groups involved in the inactivation of OSC, substrate protection experiments were performed in the presence of inactivator. Substrate, at a saturating concentration, clearly protected the yeast OSC against inactivation (Fig. 7).

By contrast, the Ellman's reagent 5,5′-dithio-*bis*-(2-nitrobenzoic) acid (DTNB) (68) proved to be effective as a time-dependent inactivator, but failed to be affected by the presence of the substrate. These results were confirmed by following photometrically the release of TNB (thionitrobenzoate) from CNDT-squalene or DTNB in the presence or in the absence of the substrate. While the release of TNB from DTNB was not affected by saturating concentrations of the substrate, there was a significant reduction of TNB release from CNDT-squalene **39** under the same conditions. Replacement of the squalene moiety by a dodecyl residue also made the inhibition less specific and less active. The squalene group of **39** seems to act as a carrier able to lead the modifying agent into the active site of the enzyme.

Much more work will be necessary to arrive at a definitive view on the role of the single amino acid residues in the overall enzymatic catalysis leading to the cyclization of squalene 2,3-epoxide to tetracyclic or pentacyclic triterpenes. At the moment, on the basis of our experiments, we can postulate the existence of a set of thiol groups outside and inside the OSC active site (in animals and yeasts). The latter can potentially interfere with each step of OS transformation, namely, the initial protonation, the cyclization, the following rearrangement, and the final abstraction of a proton leading to the final product.

In conclusion, our strategy of designing reversible HEI analogue inhibitors (acyclic azasqualene derivatives) or irreversible squalene-derived thiol reagents, as squalene maleimide or squalene Ellman derivatives, has been useful in obtaining further insights into the mechanism of OS cyclization as well as the design of specific hypocholesterolemic or antifungal agents.

Side-Chain Oxysterol Regulation of 3-Hydroxy-3-methylglutaryl Coenzyme A Reductase Activity[1]

Edward J. Parish*, Sarawanee C. Parish and Shengrong Li
Department of Chemistry, Auburn University, Auburn, Alabama 36849

ABSTRACT: Side-chain oxysterols are known to be potent inhibitors of 3-hydroxy-3-methylglutaryl CoA reductase, a key regulatory enzyme in the biosynthesis of sterols. Structural variations in the side-chain oxysterols influence enzyme inhibition. Under certain conditions, biological systems have been induced to produce side-chain oxysterols, adding support to the hypothesis that oxysterols may be natural regulators of sterol biosynthesis in the intact cell. Specific inhibition of sterol biosynthesis is of interest as it may prove useful in the prevention or reversal of various cardiovascular disease states, as well as in the control of normal and abnormal cell growth.
Lipids 30, 247–251 (1995).

Sterol biosynthesis in mammalian systems has been intensely studied for several decades (1–3). Interest in the cholesterol pathway has increased following clinical observations that the incidence of cardiovascular disease is greater in individuals with levels of serum cholesterol higher than average (4). More recently, the results of numerous clinical studies have indicated that lowering serum cholesterol levels may reduce the risk of coronary heart disease (5) and even promote the regression of atherosclerotic lesions (6,7). Serum cholesterol levels can sometimes be controlled by restricting the dietary intake of cholesterol and fat. However, with a significant number of patients, this approach does not result in the lowering of serum cholesterol concentrations. This makes the development of other approaches to reduce serum cholesterol levels an important goal of cardiovascular research.

A direct approach to this problem has been the development of inhibitors of cholesterol or sterol biosynthesis. A key regulatory enzyme of cholesterol biosynthesis is 3-hydroxy-3-methylglutaryl CoA (HMG–CoA) reductase (EC 1.1.134) which catalyzes the reductive deacylation of HMG–CoA to yield mevalonate (Scheme 1) (8,9). The addition of highly purified cholesterol to cultured cells does not affect the activity of HMG–CoA reductase or the rate of sterol biosynthesis (10,11). However, various oxysterols have been shown to be potent suppressors of HMG–CoA reductase activity resulting in marked reductions of sterol biosynthesis (12). These observations led Kandutsch and co-workers (12,13) to hypothesize that oxysterols, rather than cholesterol, may function as the natural regulators of HMG–CoA reductase activity and sterol biosynthesis.

SCHEME 1

Oxysterols, i.e., sterols bearing a second oxygen function in addition to that at carbon-3, have been demonstrated to possess diverse biological activities (8,14–16). These include cytotoxicity, atherogenicity, carcinogenicity, mutagenicity, hypocholesterolemia, and various effects on certain enzymes. In addition, several oxysterols have been isolated from drugs used in folk medicine for the treatment of cancer (17–19). Other studies have shown that several oxysterols have significant activity in inhibiting DNA synthesis in cultured cells (20,21). Oxysterols having the second oxygen function in the side-chain region of the sterol structure are termed side-chain oxysterols.

An important property of many oxysterols is their ability to inhibit HMG–CoA reductase activity in cultured mammalian cells (8,14,22). This suppression of activity has been found to vary over a wide range depending on the structural features of the oxysterol. As a general trend, inhibitory activity increases as the distance between carbon-3 and the second oxygen group becomes greater. Sterols with an additional oxygen function in ring D and the side chain have been shown to have the highest activity. An intact side chain is a requirement for potent activity; a decrease in the length of the (isooctyl) side chain results in decreased activity (23). Another structure–activity relationship has been noted between inhibitory activity and the extent to which the second oxygen function is sterically hindered. In general, axial hydroxyl groups are more hindered and exert lower activities than the less hindered equatorial conformation (8,23,24). Steric hindrance from other parts of the steroid molecule can result in diminished activity (i.e., effect of carbon-14 alkyl substituents

on the carbon-15 hydroxyl group) (25). It has been suggested that oxygen functions in conformationally flexible positions, such as those in ring D and in the side chain, and produces steroids with greater inhibitory activity due to increased effectiveness of hydrogen bonding or hydrophilic interactions with receptor molecules (16).

THE OXYSTEROL REGULATION HYPOTHESIS

The experimental evidence summarized here suggests a regulatory mechanism which, by analogy to steroid hormone receptors and bacterial induction–repression systems, requires a binding protein to recognize oxysterols and mediate subsequent cellular events. There is evidence for the existence of a specific cytosolic receptor protein for oxysterols (23,26). After the activities of a number of sterols were evaluated, a good correlation was found between the actions of certain oxysterols on HMG–CoA reductase in L cells and their affinity for an oxysterol binding protein (23) Moreover, the actions of oxysterols which depress the rate of cholesterol biosynthesis from lanosterol and possibly inhibit the 14-demethylation of lanosterol are also postulated to exert their actions by an oxysterol binding protein (22,27,28).

The side-chain oxysterol most frequently utilized in the study of HMG–CoA reductase regulation is cholest-5-ene-3β,25-diol (25-hydroxycholesterol). This oxysterol is a potent inhibitor of enzymatic activity ($IC_{50} < 1$ μM) (10,12,13, 24). Repression of the synthesis of immunoprecipitable HMG–CoA reductase by this oxysterol has been demonstrated by Faust *et al.* (29) in a Chinese hamster ovary (CHO)-derived compactin-resistant cell (UT-1) line that overproduces the enzyme and by Sinensky *et al.* (30) in CHO cells. Luskey *et al.* (31) have shown that the level of mRNA for the reductase in UT-1 cells is reduced in the presence of the oxysterol. Similar results were obtained by Kandutsch *et al.* (10,12) in wild-type CHO cells (see also Ref. 24). Based on this, Kandutsch *et al.* (32) proposed a model for the regulation of HMG–CoA reductase activity by oxysterols. The oxysterol binds to a cellular protein, and the resultant oxysterol–protein complex then acts to repress transcription of the gene for reductase production. In support of this model, several investigators (23,24,26,33) isolated a protein which exhibits high affinity and low capacity for 25-hydroxycholesterol and other oxysterols which are known to inhibit reductase activity. Although 25-hydroxycholesterol has been isolated from cells, there is no direct evidence that this oxysterol functions as the natural regulator of cholesterol biosynthesis (34). This model (Fig. 1) was in direct contrast to the prevailing view that cholesterol, accumulating in cells after endocytosis of low density lipoprotein (containing cholesteryl esters), is the regulatory messenger molecule (35).

THE DIOXIDOSQUALENE PATHWAY

Side-chain oxysterols are known to be products of primary metabolism in mammalian systems. Derivatives of cholesterol hydroxylated in the 25- or 26-positions are produced in liver during bile acid biosynthesis and side-chain hydroxylation at the 20α- and 22*R*-positions in the initial step of the conversion of cholesterol to steroid hormones in endocrine organs (36–38). Another mode of oxysterol biosynthesis has been described which utilizes the isopentenoid pathway to

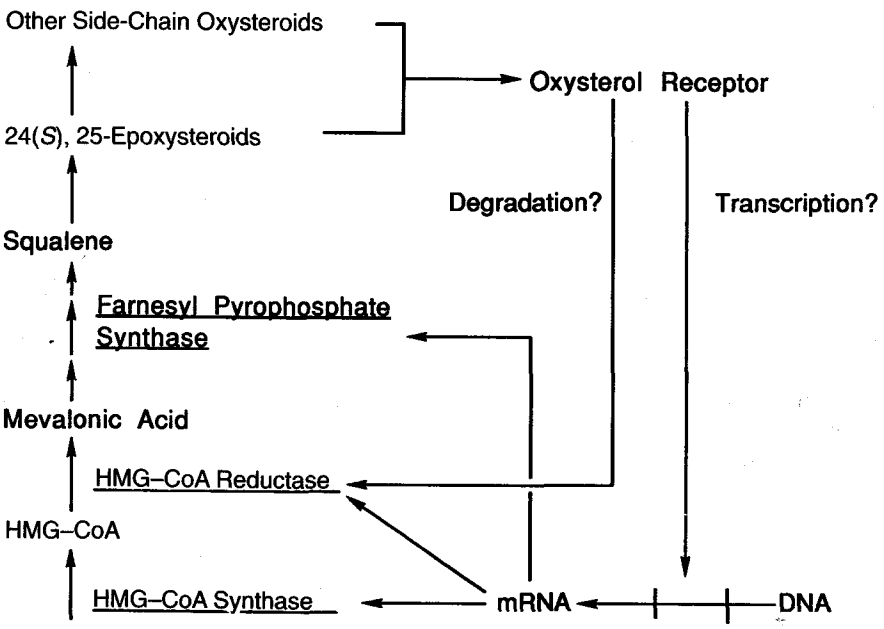

FIG. 1. Kandutsch model for the oxysterol regulation of sterol biosynthesis, adapted from References 44 and 45. HMG–CoA, 3-hydroxy-3-methylglutaryl CoA.

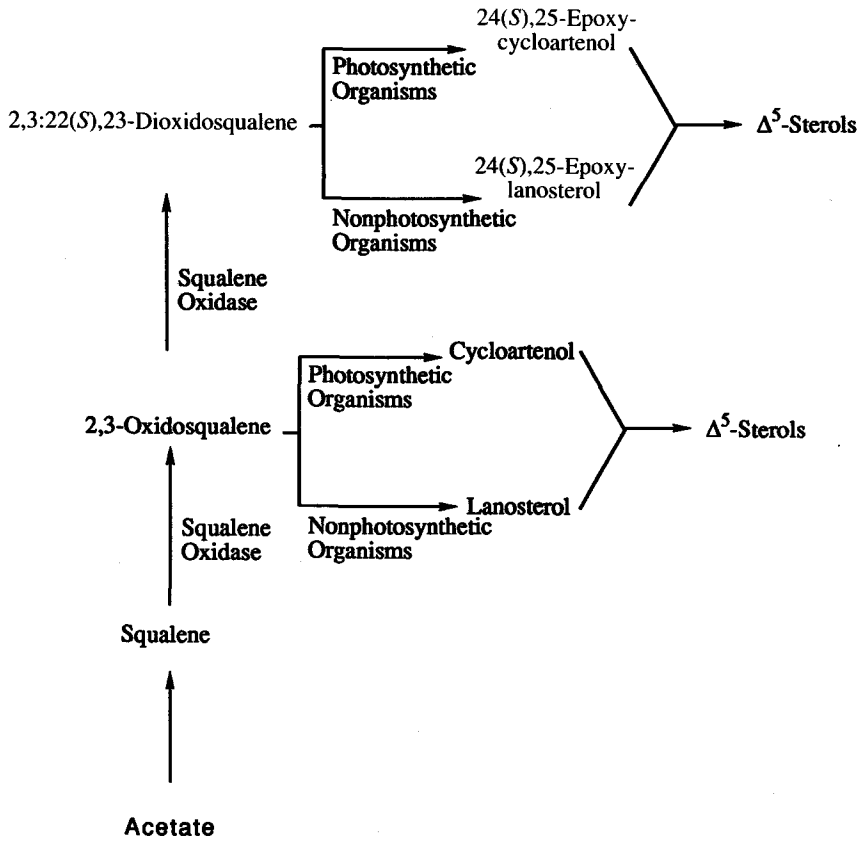

FIG. 2. The biosynthesis of sterols and side-chain oxysterols in plants, animals and microorganisms.

produce side-chain derivatives of cholesterol and lanosterol (Fig. 2) (39,40). Such compounds are derived from squalene 2,3-epoxide by the introduction of a second oxygen function to form 2,3,22,23-dioxidosqualene prior to cyclization. Thus, this intermediate has been shown to form 24(*S*),25-epoxylanosterol, 24(*S*),25-epoxycholesterol, and 25-hydroxycholesterol in mammalian systems (40–43). 24(*S*),25-Epoxycholesterol has been isolated from cultured mouse L cells, Chinese hamster lung fibroblasts, and human liver (34). These oxygenated side-chain derivatives proved to be potent inhibitors of HMG–CoA reductase and sterol biosynthesis, and they possess a high affinity for the oxysterol binding protein (34,40–43). These results add further support to the hypothesis that oxysterols may be natural regulators of cholesterol biosynthesis in mammalian cells (9,12). The dioxidosqualene pathway has recently been reviewed (44,45), as has its occurrence in plants, animals, and microorganisms (46,47), and its evolution (48).

REGULATION OF HMG–CoA REDUCTASE

A key regulatory step in overall sterol biosynthesis is catalyzed by HMG–CoA reductase; therefore, much of the effort toward the development of inhibitors of sterol biosynthesis has focused on this enzyme (3,49,50).

Oxysterols are significant inhibitors of the HMG–CoA reductase found in plant tissues (51–53). However, in intact animal cells, oxysterols are potent inhibitors of reductase activity (8,11,12,23), which requires intact cells and active protein synthesis (54). This effect has recently been attributed to a decrease in the rate of HMG–CoA reductase synthesis (29,30,55) and under some (29,56), but not all (57), conditions to an increase in the rate of enzyme degradation. Side-chain oxysterols, which are products of primary metabolism, are among the most potent inhibitors of enzymatic activity. This high activity would be consistent with their proposed role as natural regulators of cholesterol biosynthesis in mammalian systems.

The inhibitory activity of side-chain oxysterols can vary in different cell lines. In this report we have combined the results from different studies and organized the results according to the type of cell line.

The inhibition of HMG–CoA reductase in L cells (a subline of NCTC clone 929 mouse fibroblasts) by a number of side-chain oxysterols is presented in Table 1, based on published reports (23,34,58). In general, sterols with an intact isooctyl side-chain and a 3β-hydroxyl group showed more potent inhibitory activity (23,34). Also, sterols with a 3-ketone group showed generally somewhat less activity than those with a 3β-hydroxyl group (23). It is known that 3-keto sterols with a sat-

urated A ring are efficiently reduced in L cell cultures to the alcohols while Δ^4-3-ketones are not reduced and accumulate as the conjugated ketones exhibiting less activity (23).

Table 2 presents the results of inhibition studies done on primary cultures of fetal mouse liver cells (34). Although the overall values for reductase inhibition are somewhat lower than those reported for L cells (Table 1), the general trends in inhibitory activity remain similar. Side-chain oxysterols with intact iso-octyl side chains exhibit the greatest inhibition. The most potent oxysterol in these series was 25-hydroxycholesterol.

The effect of side-chain oxysterols on the reductase found in rat intestinal epithelial cells (IEC-6, CRL 1592) are presented in Table 3 (42,59). In these studies, lanost-8-ene-3β,25-diol was the most potent inhibitor of enzymatic activity. Chemical oxidation to the 3-keto derivative resulted in a significant reduction in reductase activity (42). The authors also reported that dioxidosqualene was cyclized to 24(*S*),25-epoxylanost-8-en-3β-ol and metabolized to 24(*S*),25-epoxycholesterol in this cell line (42).

[a]Data from References 44 and 59.

In other recent studies, (25*R*)-5α-cholest-8(14)-ene-3β,26-diol-15-one was found to be a potent inhibitor of reductase in CHO–K1 cells (60). At a concentration of 0.1 μM, this oxysterol caused a 50% reduction in enzymatic activity. Its potency was indistinguishable from that of its analog lacking the carbon-26 hydroxyl group, 3β-hydroxy-5α-cholest-8(14)-en-15-one. Interestingly, 3β-hydroxy-5α-cholest-8(14)-en-15-one and (25*R*)-cholest-5-ene-3β,26-diol (both potent inhibitors of reductase) have been found to show synergism in the reduction of the levels of reductase activity in CHO-K1 cells (1). When equimolar concentrations of both inhibitors were added together, synergistic reduction of enzyme activity was observed at total oxysterol concentrations of 0.1, 0.2 and 0.5 μM. A maximal synergistic effect in lowering reductase activity (28% greater than that predicted) was observed at 0.1 μM total oxysterol concentration.

CONCLUSIONS

Summarized in this review are studies on the side-chain oxysterol mediated repression of HMG–CoA reductase activity in various mammalian cell lines. These studies have provided much useful information concerning the possible role of side-chain oxysterols as natural regulators of reductase activity and, thus, sterol biosynthesis. The studies have also contributed to our basic understanding of regression of cholesterol biosynthesis in general. Continued basic research in this area should provide further leads for the development of new approaches for the control of cholesterol biosynthesis and the reduction of serum cholesterol levels.

Growth of *Cucurbita maxima* L. Plants in the Presence of the Cycloartenol Synthase Inhibitor U18666A[1]

Gregeory P. Fenner* and Ibrahim Raphiou

Crop Science Department, North Carolina State University, Raleigh, North Carolina 27695

ABSTRACT: Squash, like other Cucurbitaceae, have unique sterol profiles that offer an excellent opportunity to examine the relationship between sterol biosynthesis and plant growth. To determine the effect of sterol biosynthesis inhibition on squash growth, Cucurbita maxima seedlings with and without cotyledons were subjected to increasing concentrations of the cycloartenol synthase (EC 5.4.99.8) inhibitor 3ß-(2-diethylaminoethoxy)androstenone (U18666A). Inhibition of shoot growth was concentration-dependent (from 0, 2, 5, 10, and 20 µM); plants with intact cotyledons grew to 26.4, 23.7, 21.6, 20.0, and 15.6 cm, respectively, at the above inhibitor concentrations, compared to 25.5, 19.4, 17.0, 12.0, and 1.1 cm for plants with severed cotyledons. In plants with severed cotyledons, 10 and 20 µM U18666A caused rapid necrosis of the first two, newly emerged, primary leaves, and halted new leaf formation. Secondary root formation was initially affected at all inhibitor concentrations regardless of whether cotyledons were present or not. Vegetative tissue showed a decrease in the accumulation of the major squash sterol, 7,22-stigmastadienol, accompanied by increased accumulation of minor sterol components. Sterol profiles in cotyledons were unaltered. The data show that sterols are crucial for maintaining plant growth and viability, but do not address the cotyledonary effect on growth with respect to sterol biosynthesis.

Lipids 30, 253–256 (1995).

Inhibitors of plant sterol biosynthesis may be used to determine the importance of sterols in plant growth and development. It is not clear which step in the sterol biosynthetic pathway should be targeted in designing compounds for plant growth regulation. Plant growth can be reduced by hydroxymethylglutaryl CoA (HMG–CoA) reductase (EC 1.1.1.34) inhibitors such as mevinolin (1). However, since HMG–CoA reductase is also involved in the synthesis of other isopentenoids (phytohormones, etc.), further investigations are needed to define the nature of the inhibitory effect. Plants grown in the presence of inhibitors affecting cytochrome-P450-dependent sterol 14α-demethylation show reduced seed germination, reduced plant growth and reduced growth of cells in culture (2,3). Some attention has been given to the design of transition state inhibitors that mimic high-energy intermediates produced during sterol biosynthesis, for example, during C-24 transmethylation and Δ8–Δ7sterol isomerization (4). The inhibition of squalene has been proposed to be a favored target site for inhibition (5). The rationale is that inhibiting this step in sterol biosynthesis should not affect the synthesis of other isopentenoids, as would HMG–CoA reductase inhibitors, or the accumulation of sterol intermediates caused by inhibitors of 14α-demethylation. More thorough reviews on these types of inhibitors and their modes of action have been published (6–8).

As part of our long-range goal of determining the physiological significance of sterols in plant growth, we utilized a well-defined sterol containing plant, zucchini squash *Cucurbita maxima* L., in our experimentation on the effect of the inhibitor 3ß-(2-diethylaminoethoxy)androstenone (U18666A) on whole plant growth. This inhibitor, developed clinically as a hypocholesterolemic agent, has been shown to inhibit squalene cyclization in microsomal preparations from both pea and yeast (5). Bach and Lichtenthaler (9) also showed that it could reduce root growth in radish seedlings. Though sterol transport in plants is questionable, we further asked whether intact cotyledons would have any effect on growth of the plant when new sterol synthesis is inhibited. This forethought is based on the fact that squash have the α/ß duality that is partitioned between vegetative and cotyledonary tissue, respectively (10–13). In this article we report the effect of U18666A on sterol biosynthesis and growth on whole squash plants, and the unexpectedly positive effect of intact cotyledons on sustaining plant growth in the presence of the inhibitor.

MATERIALS AND METHODS

Cucurbita maxima L. (Fordhook zucchini) seeds were purchased from Burpee Seed Company (Warminster, PA). Seeds were sown between germination paper and placed in

Hoagland's nutrient solution for four days in a darkened growth chamber. At this time, cotyledons were imbibed, and uniform seedlings were selected. Plants were divided into 25-mL test tubes (three plants per tube × two replicates × two experiments). The test tubes were wrapped in foil, and plants were grown in a plant growth chamber at 23.8°C on a 16/8 h day/night cycle. U18666A was purchased from BIOMOL Research Laboratories (Plymouth Meeting, PA) and dissolved in water to produce a 2 mM stock solution. Aliquots were added to Hoagland's to give the following inhibitor concentrations: control (Hoagland's), 2, 5, 10, and 20 μM U18666A. After the first true leaves emerged, cotyledons were removed with a razor from half of the seedlings. From each set of seedlings, three plants per test tube (50 mL) were grown for four weeks using the inhibitor treatments described above.

In a separate study, seedlings with and without cotyledons were grown for two weeks in inhibitor-free Hoagland's medium, and then transferred to 10 μM inhibitor solutions. These plants were then grown for an additional two weeks to test the inhibitor's effect on growth after leaves were established. Finally, to determine the effect of secondary root formation on shoot growth under our experimental conditions, secondary roots from plants grown for one week were severed with a razor, and the primary roots were coated with lanolin to prevent nutrient uptake by the exposed vascular bundles. These plants were grown for an additional three weeks in inhibitor-free Hoagland's medium.

At harvest, plant height, petiole length, and leaf width were measured for each treatment from plants grown with and without cotyledons. Prior to drying and sterol extraction, cotyledons were removed from the set of plants where cotyledons remained intact during the growth period; thus sterols from these plants and their cotyledons were analyzed separately.

Plant material was oven-dried at 80°C for 48 h, weighed, ground with a mortar and pestle, and then extracted with 15 mL of warm chloroform/methanol (2:1, vol/vol) in a water bath. The mixture was filtered through Whatman No. 1 filter paper, and an organic phase was produced by partitioning the filtrate against 2 mL of 1% NaCl, followed by vortexing and spinning at 2,000 rpm. After discarding the aqueous phase, volumes were adjusted with chloroform, an aliquot was removed, and total lipid was determined gravimetrically. Samples were dried under nitrogen and then refluxed with KOH/MeOH/H_2O (20:60:40, wt/vol/vol) containing 0.2% pyrogallol. After cooling, the mixture was extracted three times with diethyl ether, and the ether extracts were pooled and dried under nitrogen. Total sterol fractions were recovered by alumina chromatography using published methods, except that toluene was substituted for benzene (14). Trimethylsilyl ether (TMSE) derivatives of sterols (15) were identified and quantified by gas chromatography (GC) with cholesterol TMSE as an internal standard. The instrument consisted of a Varian 3500 Gas Chromatograph (Sugarland, TX) equipped for flame-ionization detection (FID), and a Varian 8100 autosampler. Data were processed using a Varian Star workstation. Sterols were analyzed on a Supelco (Bellefonte, PA) fused silica SPB-1 capillary column, 30 m × 0.32 mm i.d., 0.25 μ film thickness, under the following conditions: oven temperature, 230°C isothermal; injection port, 280°C; detector, 300°C; split ratio, 18:1; average linear carrier gas velocity (helium), 76.5 cm/s; column head pressure, 33 psi.

RESULTS

Plant growth in the presence of U18666A was inhibited in a concentration-dependent manner (Table 1). Also shown in Table 1 is the effect that cotyledons had on sustaining growth in the presence of the inhibitor. The effect on petiole length and leaf width is most evident. As compared to total plant height, which included root and shoot lengths (much of which was established during germination and prior to introduction of the inhibitor), measurement of petiole length and leaf width showed very well the effect the inhibitor has on leaf formation and growth. The cotyledons had a positive effect on sustaining plant viability. Plants grown in the presence of the inhibitor had more intensely green leaves than did controls.

To test the effect of the inhibitor on growth after leaves had been established, plants with and without cotyledons were grown in inhibitor-free nutrient solution after the initial germination period for up to two weeks. During that growth period, leaves were fully expanded and growth was normal. When plants were subsequently placed in 10 μM inhibitor solution and grown for an additional two weeks, plants with cotyledons grew to 24 cm and those without cotyledons to 22.5 cm, compared to 26.4 and 25.7 cm for controls with and without cotyledons, respectively. In both cases, and especially where cotyledons were severed, leaves began to exhibit necrosis.

Sterol synthesis was altered both qualitatively and quantitatively. Most noticeable was the reduction in the accumulation of 7,22-stigmastadienol and 7-stigmastenol, which are normally the only two predominant sterols in squash vegetative tissue (10). This reduction was accompanied by an in-

crease in the levels of other components, especially the 24-methyl sterols, 7-ergostenol, and gramisterol. The changes in individual components and in total sterols that were seen on a dry weight basis are listed in Table 2. Similar results had previously been obtained with celery cells grown in the presence of the 14α-demethylase inhibitor paclobutrazol (2,16). While the synthesis of the two 24α-sterols, 7,22-stigmastadienol and 7-stigmastenol, is apparently decreased, the synthesis of the 24ß-sterol, 7,25-stigmastadienol, seems unaffected. We did not, however, attempt to determine the amount of 7,22,25-stigmastatrienol (24ß) in 7,22-stigmastadienol, which are known to co-elute under these GC conditions. The accumulation of squalene or 2,3-oxidosqualene was not observed in any of the inhibited plants.

We further noted that the changes in sterol composition that coincided with reduced growth were most pronounced in plants in which cotyledons were allowed to remain and growth inhibition was more gradual. In plants without cotyledons at 10 and 20 μM inhibitor concentrations, there was virtually no new tissue growth after germination. However, the data for the latter treatments could be somewhat misleading, especially in regard to the high levels of 7,22-stigmastadienol observed (Table 2), which are likely due to accumulation of this sterol prior to introduction of the seedlings into the inhibitor solution, after which lack of dry matter production resulted in what appears to be increased 7,22-stigmastadienol.

The percentage of each major sterol relative to total sterol found in the cotyledons was qualitatively unchanged (data not shown). The sterol profile is also in agreement with previous data (10), although no efforts were made to determine the amount of the other major cotyledon sterol, 7,22,25-stigmastatrienol.

The initial impact of the inhibitor was on the root system. Regardless of the presence or absence of cotyledons, secondary root growth was inhibited at all inhibitor concentrations. However, when plants had their secondary roots removed and then were grown in inhibitor-free media, we observed that growth for these plants was similar to that of plants whose root systems had remained intact. Thus, it is unlikely that reduced absorption alone was responsible for the diminished growth seen in response to the sterol synthesis inhibitor.

DISCUSSION

It is known that cotyledons function as storage reserves for developing young seedlings, and that early removal of cotyledons from germinated seeds affects growth (17,18). However, the cotyledon effect we observed in regard to sterol synthesis and plant viability is not easily explained. In our experiments on plants on which cotyledons were allowed to remain intact during the growth period, cotyledons were not senesced. The observation that sterol profiles in cotyledons were unaffected by the inhibitor was somewhat expected and may suggest that the sterols in these organs are preformed during seed maturation.

If we assume that intact cotyledons result in an overall greater nourishment for the axis, the presence or absence of cotyledons on control plants should also have resulted in a greater difference in growth of the controls like that seen in inhibited plants (with and without cotyledons), but this was not the case. One explanation for this could be that in inhibited plants on which cotyledons remained intact, the cotyledons may be acting as a sink for the inhibitor, thus reducing its effectiveness. The fact that cotyledons imbibe and expand does not rule out the possibility of inhibitor accumulation in these organs. That inhibition of sterol biosynthesis is involved is further shown by the decreased growth of plants grown for two weeks on inhibitor-free media followed by two weeks on 10 μM inhibitor, regardless of whether the cotyledons were present or not.

Our data do not differentiate between the qualitative and quantitative requirements for sterols to maintain plant growth. The reduction in the amount of total sterol accompanied by

the qualitative changes suggests that in plants, as with yeast, both micro- and macrorequirements are being met by different sterols (19). It is currently well accepted that sterols are required for membrane synthesis and function. Thus the data presented here could be taken to mean that lack of sterol synthesis precludes cell maturity resulting in the inability of the cells to divide or grow. Given that cells in whole plants are under strict hormonal controls relative to both growth and differentiation, it appears that lack of sterol synthesis negates the effect of such signals. Observed lack of secondary root growth even at low inhibitor concentrations suggests that sterols are themselves involved in differentiation, or at least that the lack of sterol and/or membrane synthesis coincides with the inhibition of secondary root formation. Radish seedlings that had been inhibited for sterol synthesis likewise exhibited reduced secondary root formation (9). At these same inhibitor concentrations, however, leaf tissue seems to be able to grow and expand which is likely to be due to an inhibitor gradient in the vascular tissue, while roots are directly exposed. At higher inhibitor concentrations, the damage to the shoots would be expected to be more pronounced, as was observed.

Since no direct sterol transport mechanisms have been proven to exist in plants, an interesting question arises as to the different effects the inhibitor may have on the biosynthesis of 24α- vs. ß-sterols in these plants. This question is raised by data showing that in vegetative tissue the amounts of the 24α-isomers, 7,22-stigmastadienol and 7-stigmastenol, decrease while the amount of 7,25-stigmastadienol is unaffected. Thus for cucurbits, determining the timing of biosynthesis or the organ specific requirements for a given sterol or structural analogue would be significant in determining target sites for sterol inhibition, which may be true for other plant groups as well. It has been shown that the timing of synthesis of certain sterols is correlated to plant developmental events and that different plant parts may contain different kinds and amounts of sterols (10,20–22).

In the current study, it appears that the inhibitor may have had secondary effects in addition to inhibiting cycloartenol synthase (EC 5.4.99.8). The accumulation of 24-methylsterols and 24-methyl-sterol precursors implies that the second C-24 alkylation step might be affected to a lesser degree. Regardless, inhibitors such as U18666A are invaluable since their modifying effects of sterol biosynthesis in plants allows us to gain insights into the roles of these sterols in plant cellular processes. The effects of U18666A we observed on suspension cultures provide us with a direct tool to further study its effect on cell division, growth and membrane composition.

Biosynthesis and Distribution of Insect-Molting Hormones in Plants—A Review[1]

John H. Adler[a,*] and Robert J. Grebenok[b]

[a]Department of Biological Sciences, Michigan Technological University, Houghton, Michigan 49931 and [b]Department of Plant Science, University of Arizona, Tucson, Arizona 85721

ABSTRACT: Insect-molting hormones, phytoecdysteroids, have been reported to occur in over 100 plant families. Plants, unlike insects, are capable of the biosynthesis of ecdysteroids from mevalonic acid, and in several cases the biosynthesis of phytoecdysteroids was also demonstrated to proceed *via* sterols. *Spinacia oleracea* (spinach) biosynthesizes polypodine B and 20-hydroxyecdysone, which is the predominant insect-molting hormone found in plant species. The onset of ecdysteroid production in spinach requires the appropriate ontogenetic development within the plant, which is related to leaf development. In spinach, lathosterol is the biosynthetic precursor to ecdysone and 20-hydroxyecdysone. Phosphorylated ecdysteroid intermediates, particularly ecdysone-3-phosphate, are required during biosynthesis. Polyphosphorylated forms of ecdysteroids are putative regulatory components of the pathway. During spinach development, the 20-hydroxyecdysone is transported from the sites of biosynthesis to the apical regions. An analysis of the physiological data available suggests that different species may synthesize ecdysteroids in various organs and distribute these ecdysteroids to other sites. Annual plants appear to concentrate ecdysteroids in the apical regions, including flowers and seeds. Perennial plants may recycle their ecdysteroids between their deciduous and their perennial organs over the growing season. Further investigations of ecdysteroid biosynthesis and physiology within plants will be required before an acceptable system can be designed to test phytoecdysteroid effectiveness *in vivo* against insect herbivory.

Lipids 30, 257–262 (1995).

The insect-molting hormone, 20-hydroxyecdysone, was first discovered in plants in 1966 and was shown to be structurally identical to the molting hormone isolated from insects (1). Since then over 100 phytoecdysteroid structures have been identified in plants, with 20-hydroxyecdysone being the most common one reported (2,3). The biological activity of some phytoecdysteroids has been tested by a variety of insect bioassays, with many of these structures demonstrating molting hormone activity (4–7). The compounds have been found in various plant structures of both annuals and perennials, including bark and rhizomes (2). Recent studies have demonstrated that active biosynthesis of phytoecdysteroids takes place in young developing tissues (8–11). Transport of ecdysteroids from the site of biosynthesis to other organs has been reported (9,12,13) as well as the apparent cycling of ecdysteroid from deciduous organs in herbaceous perennials (14–17). Ecdysteroids appear to be transported to the growing portions of the plant from their biosynthetic sources. A multiplicity of ecdysteroid conjugates have been observed in plants (2), with recent reports suggesting that phosphorylated conjugates may also be involved in the regulation of ecdysteroid metabolism in spinach (11). The presence of ecdysteroids and their conjugates in plants has been suggested to be a factor which may alter development of nonphytoecdysteroid-adapted insect species (6,7). Hence these compounds may potentially prove useful to control insect herbivory on agriculturally important plants.

PLANT BIOSYNTHETIC STUDIES

The biochemistry of insect-molting hormone has been extensively studied in insects and has been reviewed (18). Insects and all other arthropods require sterols in their diet due to their inability to endogenously cyclize squalene to the requisite sterols needed for membrane function and hormone production, such as insect-molting hormone (19,20). Plants, however, possess a complete sterol biosynthetic pathway, and many are capable of insect-molting hormone biosynthesis. Recent studies on plant ecdysteroid production have shown an active and highly controlled biosynthetic pathway early in plant development as demonstrated by the incorporation of [2-^{14}C]mevalonic acid (MVA) (9–11). The seeds of *Spinacia oleracea*, spinach, and other chenopod plants (Chenopodiaceae) have high levels of ecdysteroid; spinach has 100 μg/g fresh weight and *Chenopodium album* 36–80 μg/g fresh weight (8,21). As the seeds germinate, the level of ecdysteroid decreases on a gram fresh weight basis due to expansion and growth of the plant and the apparent low level of phytoecdysteroid biosynthesis during this stage of development (8). However, in spinach the level of ecdysteroid was never lower than 13 μg/g fresh weight. This is well within the

concentration range of phytoecdysteroid dietary intake reported to interfere with the development of susceptible insects (7). An increase in biosynthesis of ecdysteroids occurs in developing spinach plants between days 11 and 20 as demonstrated by [2-^{14}C]MVA incorporation (9) into first leaves. Onset of biosynthesis eventually produces a ratio of ecdysteroid to sterol of 10:1 on a μg/g fresh weight basis as compared to a prior ratio of 1:1 (8,9). In spinach, the flow of sterol into ecdysteroid on a μg/g fresh weight basis is thus a major sink for carbon entering the triterpenoid pathway *via* squalene. Roots are also thought to be a site of biosynthesis in chenopods, since spinach was shown to contain 30 μg/g fresh weight ecdysteroids (Grebenok, R.J., unpublished data), *C. album* fluctuating levels of ecdysteroid (22), and *Kochia scoparia* 14 μg/g of ecdysteroids in these tissues (23). Radiolabel incorporation studies with isolated root systems have not been reported.

Evidence to date suggests that the biosynthesis of ecdysteroids in spinach proceeds as illustrated in Figure 1. The most frequently reported phytoecdysteroid is 20-hydroxyecdysone (2) which possesses a reduced side chain at C-24 (Fig. 1). Many plants have also been reported to possess C-24 alkylated ecdysteroids (for a review, see Ref. 2), and these presumably are biosynthesized from C-24 alkylated sterols. Spinach possesses exclusively Δ^7-sterols which are also found in related chenopods (24) and in some other plant families (25). The C-24 reduced Δ^7-sterol, lathosterol, is a logical precursor available for the biosynthesis of a C-24 reduced side-chain ecdysteroid. Lathosterol conversion to ecdysteroid has clearly been demonstrated by the precursor product relationships reported between the two (10). Particularly compelling evidence for this relationship is seen during ontogeny of the plant (10). When young leaves are newly emerging from the apical meristem, they are incapable of converting [2-^{14}C]MVA to ecdysteroid. In these tissues, the C-24 alkyl sterols are radiolabeled by [2-^{14}C]MVA; however, lathosterol could not be isolated, and ^{14}C label from [2-^{14}C]MVA was not associated with lathosterol, although lathosterol carrier was added (10). Thus, lathosterol biosynthesis in spinach is apparently coordinately regulated with ecdysteroid biosynthesis. Whether such coordinate regulation of C-24 reduction takes place in other plants is yet to be determined. This is important since the majority of plants are known to produce 24-alkylsterols with a C-5(6) double bond, and many of these have been shown to contain small amounts of cholesterol. In species also producing ecdysteroids, the question of whether cholesterol or lathosterol is the preferred substrate for ecdysteroid biosynthesis remains open since both lathosterol and cholesterol could be biosynthesized in such plants. Both cholesterol and lathosterol have been reported to occur in *C. album* and *C. quinoa* (Table 1). Interestingly, [4-^{14}C]cholesterol can be converted to ecdysteroids in spinach when excised leaves are incubated for a prolonged time (10). Whether this is an alternate route or a scavenging pathway, or whether cholesterol can be converted to lathosterol, is yet unknown. The sterol and ecdysteroid compositions of several chenopods are presented in Table 1.

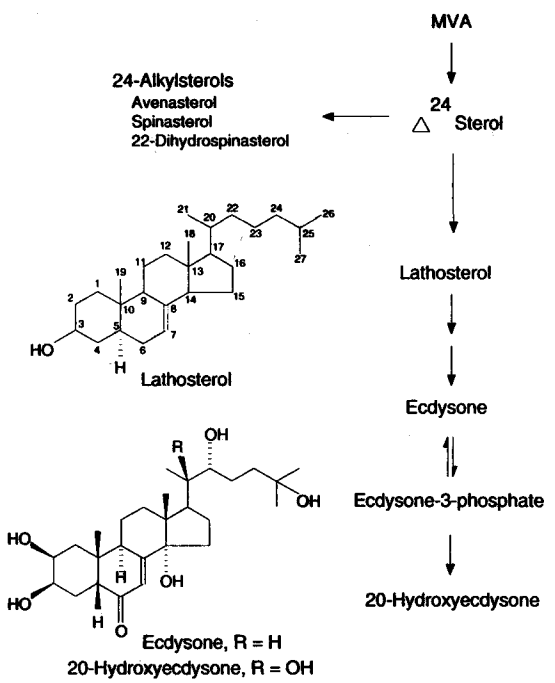

FIG. 1. Biosynthesis of spinach ecdysteroids. The metabolism of mevalonic acid (MVA) proceeds to both 24-alkysterols, lathosterol and subsequently to 20-hydroxyecdysone in intact excised spinach leaves. Ecdysone and ecdysone-3-phosphate are endogenously biosynthesized and metabolized to 20-hydroxyecdysone.

Conversion of a sterol to ecdysteroid requires several structural modifications. Among these are the inversion of the A/B ring juncture, addition of the 6-ketone group, and hydroxylation of the sterol nucleus and side chain. The steps in the bioconversion of sterols to ecdysteroids in plants have been studied only to a limited extent (18). The mechanism of A/B ring juncture inversion in plants is putatively different from that in insects (26). The hydroxylation steps are presumably mediated by cytochrome P-450 monooxygenases as they are in insects (27–29). Recent evidence suggests that phosphate conjugates are important in the processing or targeting of sterols and ecdysteroids in ecdysteroid biosynthesis in spinach. In insects, ecdysteroids are phosphorylated for excretion of the parent ecdysteroid from the insect gut (30,31). In plants, the phosphorylated ecdysteroids appear to be involved in the biosynthetic pathway (11). Spinach endogenously biosynthesizes radiolabeled ecdysone, ecdysone-3-phosphate, and 20-hydroxyecdysone from [2-^{14}C]MVA (11). Incorporation of [22,23-^{3}H]ecdysone and [^{14}C]ecdysone-3-phosphate (biosynthesized from [2-^{14}C]MVA, isolated and purified from spinach) into spinach leaves actively biosynthesizing ecdysteroids produces radiolabeled ecdysone-3-phosphate and 20-hydroxyecdysone from [^{3}H]ecdysone and radiolabeled 20-hydroxyecdysone from [^{14}C]ecdysone-3-phosphate. The production of ecdysone-3-phosphate is a coordinately regulated biosynthetic step in ecdysteroid metabolism in spinach. This is consistent with the lack of production

of ecdysone-3-phosphate in young leaves that are unable to biosynthesize ecdysteroids even when [22,23-^{3}H]ecdysone is provided as a precursor (11). These data, in conjunction with the apparent production of ecdysteroid polyphosphates for the regulation of the ecdysteroid biosynthetic pathway, suggest a new and different role for steroid phosphates in plants compared to insects.

REGULATION OF BIOSYNTHESIS

Onset of ecdysteroid biosynthesis appears to be developmentally controlled with ontogeny, yet a regulatory mechanism for the maintenance of a balanced flow of carbon into ecdysteroids must also exist. Studies designed to investigate the metabolic fate of putative ecdysteroid intermediates in spinach revealed an apparent feedback inhibition of ecdysteroid biosynthesis through the production of ecdysteroid polyphosphates (Fig. 2). When either of the putative intermediates, 2-deoxy-20-hydroxyecdysone or 22,25-dideoxyecdysone, were incubated with spinach leaves actively biosynthesizing ecdysteroids, and this incubation was followed 12 h later by exposure to [2-^{14}C]MVA, a time course of ecdysteroid regulation emerged (11,32). Incubation with either compound caused the disappearance of all 20-hydroxyecdysone mass within the excised leaves and cessation of incorporation of [2-^{14}C]MVA into lathosterol and 20-hydroxyecdysone 24-h post-MVA exposure. Similar incubations with 20-hydroxyecdysone and ecdysone (Fig. 2A) demonstrated depressed incorporation of [2-^{14}C]MVA into 20-hydroxyecdysone, but did not cause the disappearance of 20-hydroxyecdysone mass (11,32). Subsequent analysis revealed that, in the cases where 20-hydroxyecdysone disappeared from the polyalcohol fraction, the 20-hydroxyecdysone had been converted to a polyphosphate. The 20-hydroxyecdysone could be freed from this conjugate by treatment with wheat germ acid phosphatase or human seminal acid phosphatase [EC 3.1.3.2] (11,32). Based on chromatographic evidence, the 20-hydroxyecdysone polyphosphate required a minimal conjugation with four orthophosphates to provide the correct retention values from reverse-phase high-performance liquid chromatography (HPLC). In addition, the 2-deoxy-20-hydroxyecdysone was also polyphosphorylated and was liberated by acid phosphatase treatment from the corresponding incubation with 2-deoxy-20-hydroxyecdysone. At 36-h post-[2-^{14}C]MVA incubation, the endogenous biosynthesis of 20-hydroxyecdysone from [2-^{14}C]MVA appeared to be recovering from the cessation of biosynthesis observed at 24 h. At 36 h, free 20-hydroxyecdysone mass could be isolated from the leaves (11,32), and little 20-hydroxyecdysone polyphosphate was freed by acid phosphatase treatment. The presence of polyphosphorylated ecdysteroids appears to affect the regulation of [2-^{14}C]MVA incorporation into ecdysteroids. High levels of polyphosphorylated ecdysteroids inhibit incorporation, whereas when no polyphosphorylated ecdysteroids can be detected, [2-^{14}C]MVA is incorporated into ecdysteroid end product (Fig. 2). Interestingly, when ecdysone was incubated,

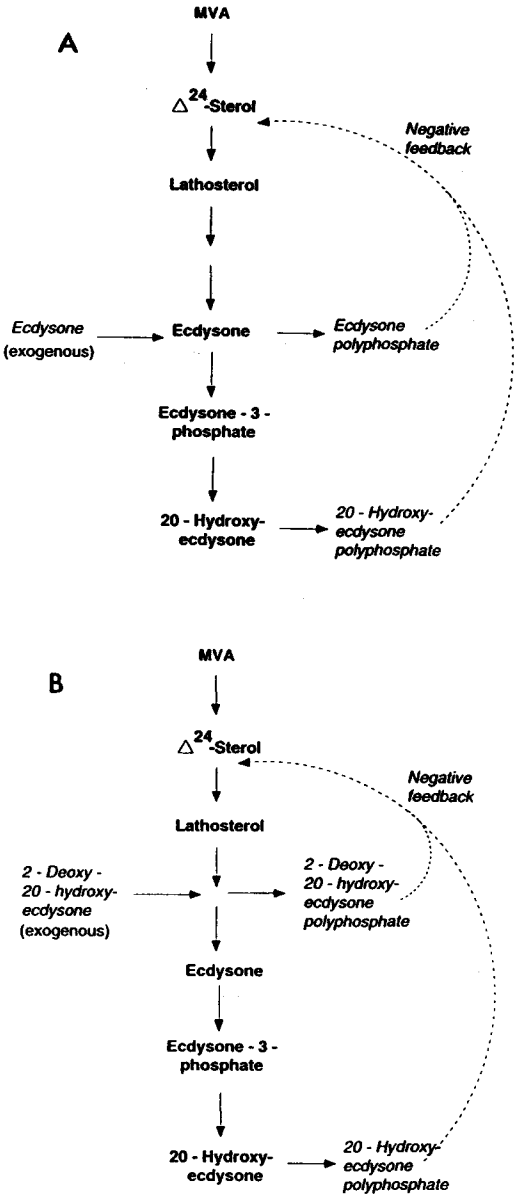

FIG. 2. The metabolism and proposed regulation of the ecdysteroid pathway in spinach. The incorporation of intermediate ecdysteroids—A, ecdysone and B, 2-deoxy-20-hydroxyecdysone—results in the formation of various polyphosphates of the ecdysteroids indicated. The incorporation of MVA into lathosterol and ecdysteroids is also diminished. The polyphosphates are proposed to act through negative feedback to regulate biosynthesis of ecdysteroids. See Figure 1 for abbreviation.

[2-^{14}C]MVA incorporation into 20-hydroxyecdysone was lower, and both free ecdysone and polyphosphorylated ecdysone were observed as well as free 20-hydroxyecdysone (11,32; Fig. 2A). This would suggest that the concentration of ecdysteroid polyphosphate may be sensed as a means to monitor 20-hydroxyecdysone buildup in cells.

The regulation of ecdysteroid biosynthesis *via* ecdysteroid polyphosphates within intact leaves may be essential in controlling ecdysteroid carbon flow within the intact plant. The phytoecdysteroid in spinach appears to be actively transported from the sites of biosynthesis to a sink. Although very young apical spinach leaves show no biosynthesis of ecdysteroid, they show high levels of ecdysteroid (8–10). In intact plants, leaves subtending the very young apical leaves incorporated [2-^{14}C]MVA into ecdysteroids (10). This ^{14}C-labeled ecdysteroid from the subtending leaves appeared in the very young apical leaves over time (9). No [^{14}C]MVA or ^{14}C-labeled sterol was observed in these young apical leaves over the same time course (9). This suggests that ecdysteroid is transported from the sites of biosynthesis, the subtending leaves, to the apical leaves, which act as a sink. Roots may potentially act as a similar sink. Although no data on ecdysteroid biosynthesis in roots is available, spinach roots contain ecdysteroids at levels of about 30 μg/g fresh weight (Grebenok, R.J., unpublished data). Fluctuating levels of ecdysteroids in root tissues have been reported in *C. album* during development (22).

PHYTOECDYSTEROID DISTRIBUTION

The apical-most leaves of spinach contain the highest ecdysteroid levels on a μg/g fresh weight basis (9). During ontogeny of any leaf, the ecdysteroid levels are very high (500–800 μg/g) early in development due to transport, are lower during the stage of active ecdysteroid biosynthesis (100–200 μg/g fresh weight) in that leaf, and are lowest in mature leaves (<100 μg/g fresh weight). Similarly high ecdysteroid levels in the growing tips of plants have been reported in four species of *Chenopodium* (21). Growing tips of *Chenopodium* spp. contain 600–3400 ng ecdysone equivalent per mg dry weight as determined by radioimmunoassay (assuming 90% of plant mass is water, this converts to approximately 60–340 μg/g fresh weight). These chenopods have been reported to possess high levels in the flowers (100–260 μg/g fresh weight), fruits (250–800 μg/g fresh weight), and seeds (250–360 μg/g fresh weight). In the flower organs of *C. album*, the anthers contain four to five times the level of ecdysteroid (500 μg/g fresh weight) reported in the other flower parts. Pollen itself has a low level of ecdysteroid, i.e., <3% of the amount reported for intact anthers. Thus, the anthers, which encase the pollen during development, contain high levels of ecdysteroid whereas the pollen does not. Since individual pollen grains in this wind-pollinated species have a small chance of fertilizing an ovule, these released pollen grains do not need much protection from herbivory. However, since production of pollen grains represents a large investment in energy for the plant, protection of these developing structures by the surrounding anther tissues is an evolutionarily logical defense strategy (21). Interestingly, the three chenopod species which contain little, if any, ecdysteroids in their growing tips (0–3 μg/g fresh weight) produce small amounts of pollen and are presumably insect pollinated (21).

Spinach contains a high level of ecdysteroid (90 μg/g fresh weight) in its fruits, and essentially all (95%) of this ecdysteroid is present in the seed itself (one seed per fruit) with only a small amount present in the fruit walls (8). A related chenopod, *K. scoparia,* also contains 20-hydroxyecdysone

and polypodine B as well as other phytoecdysteroids (23). However, the *Kochia* levels are low compared to those in *C. album* and spinach. *Kochia* contains 20-hydroxyecdysone and polypodine B at the following levels (μg/g fresh weight): leaves, 4–10; roots, 14; seeds, 3; and flower, 5. Interestingly, the distinct concentration gradient seen for ecdysteroids in *C. album* and *S. oleracea* is not observed in the aerial portions of *K. scoparia* (23). *Kochia scoparia* contains the highest levels of ecdysteroids in roots and in the lower and middle leaves of the mature plant. Since *Kochia* is also known to possess other defense compounds including saponins, alkaloids, and phenolic acids (Ref. 23 and refs. therein), ecdysteroids may not be the first line of defense produced by the plant against insects. However, ecdysteroids may serve this function in *C. album* and *S. oleracea*, and thus the distribution within the plant tissues is different.

Ecdysteroids have also been reported to be present in callus and organ tissue cultures of plants known to produce ecdysteroids. A concentration gradient of phytoecdysteroids in the aerial portion of *Ajuga reptans* (13) (Lamiaceae) is similar to the one observed in *S. oleracea* (9) and *C. album* (21). This gradient is most pronounced in wild plants examined in the spring and is less pronounced in plants harvested in summer (33). Plants grown in a greenhouse also maintain a distinct gradient similar to plants collected in the spring in the wild (33). In all cases, the roots of *Ajuga* maintain a high concentration of phytoecdysteroids (1500–3110 μg/g dry weight or 150–311 μg/g fresh weight). The six phytoecdysteroids produced varied in composition depending upon the organ examined and upon growth conditions. Through many subcultures, micropropagated plants of *A. reptans* derived from runners did not vary substantially in total phytoecdysteroids in the aerial parts (33). The roots of micropropagated plants always maintained high levels of phytoecdysteroids (33). When two morphologically different callus culture lines (33) derived from leaves or roots of *A. reptans* were examined, no phytoecdysteroids were found with a lower level of detection of 5 ppm dry weight or 0.5 μg/g fresh weight. The capacity to produce phytoecdysteroids would appear to reside with differentiated cells organized within distinct tissues of *A. reptans*. Phytoecdysteroid production has, however, been reported for some callus cultures of *Achyranthes* spp. (34) (Amaranthaceae), *Trianthema portulacastrum* (35) (Portulacaceae), *Ajuga turkestanica* (36), and hairy root cultures of *A. reptans* var. *atropurpurea* transformed with *Agrobacterium rhizogenes* (37). Analysis of phytoecdysteroid production in *in vitro* root and shoot cultures of *A. reptans* demonstrates that roots are capable of ecdysteroid biosynthesis independent of the shoots (13,38). Similar analyses on shoot cultures devoid of roots demonstrated that shoots did not biosynthesize phytoecdysteroids. The perennial *Serratula tinctoria* (Asteraceae) contains ecdysteroids in leaves, roots, and flowers at 2.6, 8.4, and 12 mg/g dry weight (or 260, 840, and 1200 μg/g fresh weight), respectively. Callus and cell cultures of this plant contain 0.10–0.03 and 0.08 mg/g dry weight (or 100–30 and 8 μg/g fresh weight), respectively, depending upon culture conditions (39). Thus, individual species appear to express their capacity for phytoecdysteroid biosynthesis in different organs, and the state of tissue organization within the plants appears to influence this expression.

Perennial plants appear to accumulate ecdysteroids over many years of growth, whereas annuals bring only the ecdysteroids present in the embryo to the new plant. The high levels of ecdysteroid reported in the fern rhizome *Polypodium vulgare*, 2% dry weight (40) (Polypodiaceae), *Lychnis chalcedonica* root, 0.3% dry weight (17) (Caryophyllaceae), *Serratula tinctoria* root, 1% dry weight (39), and *Rhaponticum carthamoides* (15) (Asteraceae) reflect the accumulation of ecdysteroids in these perennial structures over years. A general pattern of ecdysteroid distribution within plants is emerging, however. The early growth of either newly flushed woody or herbaceous perennials, such as *Taxus* (12) (Taxaceae), *Rhaponticum* (15), *Leuzea* (14) (Asteraceae), *Lychnis* (17), *Serratula* (41), and *Ajuga* (38), contain high levels of ecdysteroids on an ecdysteroid per plant mass basis. With the onset of flowering, *Rhaponticum* and *Serratula* possess high levels in the developing influorescences, and this allows for specific floral parts and seeds and/or fruits to accumulate high levels of phytoecdysteroids. The accumulation in the influorescences is also observed in certain annual plants. *Spinacia* (9) accumulates ecdysteroids in the seed embryo, *C. album* accumulates ecdysteroids in the anthers (21) and intermediate levels are observed to accumulate in flower and seed of *K. scoparia* (23). In annual plants, there appear to be two distinct organs for ecdysteroid biosynthesis, the roots *Kochia* (23) and the leaves *Spinacia* (9); presumably this is also the case for perennial plants. Several plants maintain high levels in the roots *Kochia, Ajuga, Serratula,* and *Rhaponticum* throughout their growth, whereas the levels in the leaves may fluctuate with ontogeny. Trafficking of ecdysteroid within the plant during development is supported by transport of endogenously biosynthesized ecdysteroid observed in *Spinacia* (9) and the shift in ecdysteroid mass profiles observed within perennial plants (12,14,15,17).

CONCLUSION

Ecdysteroids accumulate in various plant organs, including fruits, seeds, flowers, anthers, leaves, and roots, during various phases of their growth. Phytoecdysteroid biosynthesis is dynamic with a specific ontogenetic onset and feedback regulation as demonstrated in *Spinacia* leaves. The herbaceous perennial *Ajuga* biosynthesizes and maintains high levels of ecdysteroids in roots. Other herbaceous perennials accumulate ecdysteroids in root stocks and distribute ecdysteroids to growing aerial structures during ontogeny. These perennials also increase the total ecdysteroid content per plant over many years. However, *Spinacia* and *C. album*, both annuals, produce an increasing concentration gradient of ecdysteroids toward the apex of the plant. Annuals must flower and set seed to maintain their life strategy as species, and seeds carry ecdysteroids forward to developing seedlings. Phytoecdys-

teroids have been suggested to serve as a defense against non-phytoecdysteroid-adapted insects and nematodes (3). Proof of this putative function will require an ability to genetically or physiologically manipulate plant phytoecdysteroid content, to test various hypotheses related to this proposed role.

Sterol Metabolism in the Tobacco Hornworm, *Manduca sexta*—A Review[1]

James A. Svoboda* and Gunter F. Weirich

Insect Neurobiology & Hormone Laboratory, ARS, USDA, Beltsville, Maryland 20705

ABSTRACT: A number of intermediates involved in the dealkylation and conversion of the major C_{28} and C_{29} phytosterols to cholesterol in insects were first isolated and identified in studies with the tobacco hornworm, *Manduca sexta,* carried out in our laboratory. We also investigated the effects of a variety of known sterol metabolism inhibitors in *Manduca,* particularly those affecting the Δ^{24}-sterol reductase enzyme, and synthesized and tested a number of new inhibitors as well. In-depth studies of ecdysteroids in *Manduca* during embryogenesis and during pupal–adult development provided new information on molting hormone content, biosynthesis, and metabolism. In addition, this insect has been utilized in the study of three specific enzyme systems of ecdysteroid metabolism, namely 20-monooxygenase, 3-epimerase, and phosphotransferase, which are critical to activation and deactivation of molting hormones in insects.

Lipids 30, 263–267 (1995).

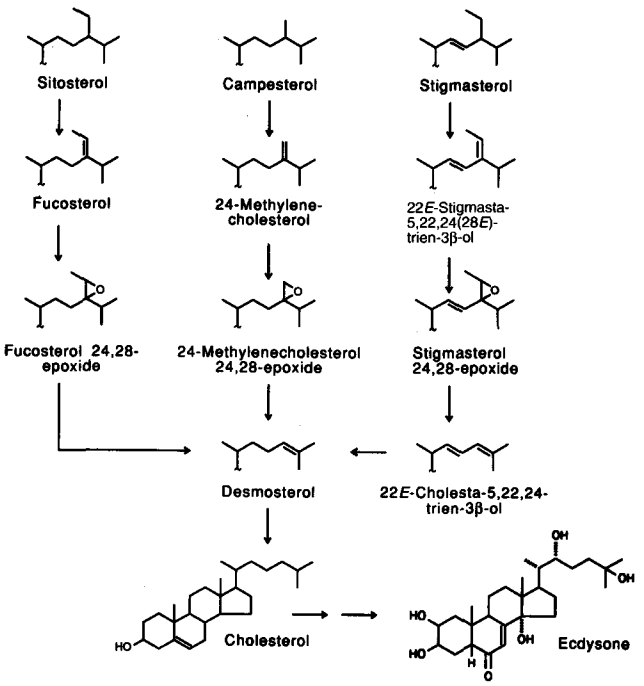
The tobacco hornworm, *Manduca sexta*, has been one of the primary experimental insects utilized in our studies on the elucidation of the pathways of sterol metabolism in insects and is widely used in many laboratories throughout the world for basic studies in virtually every area of insect physiology and biochemistry. This species is particularly useful because a satisfactory artificial agar-based diet is available for rearing and can be modified for metabolic studies. *Manduca sexta* grows quite rapidly, is relatively large, and yields mature larvae which weigh 10 g each about 15 d after egg hatching.

Interest in research on sterol utilization and metabolism in insects was stimulated by the discovery that insects, unlike vertebrates and plants, are unable to biosynthesize the tetracyclic steroid skeleton (1). Sterols are essential as structural components of membranes of insect cells and tissues, as precursors of the ecdysteroids (the only functional steroid hormones yet known in insects), and perhaps as components of other, as yet unknown physiological systems (2). Thus, insects require an exogenous or dietary source of sterol to support normal growth, development, and reproduction. With only a few known exceptions, like the dietary requirement of a Δ^7-sterol in *Drosophila pachea* (3) and a beetle, *Xyleborus ferrugineus* (4), cholesterol will satisfy the dietary need for sterols in insects. However, phytophagous insects often encounter little or no cholesterol in their food plants, and most species have adapted by converting C_{28} and C_{29} phytosterols to cholesterol *via* dealkylation of these phytosterols at C-24 (5). Most phytophagous insects can produce sufficient cholesterol in this manner to satisfy their needs. There are a number of interesting variations in the dealkylation process in certain species, and some phytophagous species totally lack the capability to dealkylate (6).

In addition to sections on the utilization and metabolism of neutral sterols with special emphasis on dealkylation mechanisms, this review will include an outline of ecdysteroid (molting hormone) metabolism in *Manduca*. However, this is not intended as a comprehensive coverage of the topic as we will concentrate on ecdysteroid research done with *Manduca* in our laboratory. For a more thorough coverage of ecdysteroid biosynthesis and metabolism, the reader is referred to several recent reviews by Rees (7), Thompson *et al.* (8), and by Grieneisen (9).

Some of the unique features of sterol metabolism in insects offer potential targets for insect control. Disruption of the conversion of phytosterols to cholesterol, the conversion of cholesterol to the ecdysteroids, or other processes in ecdysteroid metabolism and function would inhibit normal insect development in the early larval instars, which is highly desirable for management of many pest species. Therefore, studies on the effect of inhibitors of steroid metabolism done in *Manduca* will also be included in this review.

DEALKYLATION OF C_{28} AND C_{29} PHYTOSTEROLS



The dealkylation of ergosterol to form 22-dehydrocholesterol in the German cockroach, *Blattella germanica*, was the first conclusive proof of dealkylation of a phytosterol in an insect (10). Later studies with the same insect provided the first unequivocal proof of the dealkylation and conversion of a C_{29} phytosterol to cholesterol in an insect (11). In metabolic studies with the tobacco hornworm, a variety of dietary C_{28} and C_{29} phytosterols were shown to be converted efficiently to cholesterol. Highly purified sitosterol, campesterol, stigmas-

SCHEME 1

terol, brassicasterol, 22,23-dihydrobrassicasterol, 24-methylenecholesterol, and fucosterol were dealkylated when fed to hornworms, and cholesterol was the major metabolite in each case (12,13). Thus, ethyl, methyl, methylene, and ethylidene groups could all be dealkylated from C-24, and, when present, the Δ^{22}-bond was reduced (Scheme 1).

The first identification of a dealkylation intermediate was accomplished in studies with *Manduca*. Desmosterol ($\Delta^{5,24}$-cholestadienol) was isolated and identified as the terminal intermediate in the conversion of [^{3}H]sitosterol to [^{3}H]cholesterol (12). Desmosterol was subsequently shown to be a common intermediate in the conversion of a variety of C_{28} and C_{29} phytosterols to cholesterol in *Manduca* (13). The Δ^{24}-sterol reductase, the enzyme catalyzing the conversion of desmosterol to cholesterol, was demonstrated in *Manduca* midgut tissue *in vitro* with microsomal preparations, which efficiently converted [^{14}C]desmosterol to cholesterol (14). The midgut microsomal preparation provided the first *in vitro* system for the study of specific sterol conversions in insects and proved useful for studying both normal sterol metabolism and the effects of inhibitors on the 24-reductase enzyme.

The conversion of sitosterol to cholesterol in *Manduca* proceeds *via* fucosterol (24-ethylidenecholesterol) as the initial intermediate (15). In an analogous pathway, [^{3}H]campesterol is converted to [^{3}H]cholesterol with [^{3}H]24-methylenecholesterol as the expected intermediate (16). Similarly, 24-methylenecholesterol is an intermediate in the conversion of dihydrobrassicasterol, the 24*S*-methyl isomer of campesterol, to cholesterol in this insect (16), although 24*S*-methyl isomers are not as efficiently converted to cholesterol as are 24*R*-alkyl sterols.

In contrast to the results with *Manduca*, the omnivorous German cockroach is unable to reduce the Δ^{22}-bond of ergosterol and, presumably, other Δ^{22}-sterols (10). A new sterol, 22*E*-cholesta-5,22,24-trien-3ß-ol, was identified as another intermediate in the conversion of [^{3}H]stigmasterol to cholesterol in the hornworm and in several other species (17). In addition, we established that the Δ^{22}-bond is reduced before the Δ^{24}-bond and that the hornworm can reduce the Δ^{22}-bond only if the Δ^{24}-bond is present. The conversion of 22*E*-cholesta-5,22,24-trien-3ß-ol to desmosterol and cholesterol was also accomplished *in vitro* with the microsomal preparation from hornworm midgut, which, apparently in addition to Δ^{24}-reductase, also has Δ^{22}-reductase activity (17). Stigmasta-5,22*E*,24(28*E*)-trien-3ß-ol was isolated from another lepidopteran, *Spodoptera littoralis*, as a metabolite of stigmasterol, indicating that the stigmasterol dealkylation pathway starts with a conversion analogous to the sitosterol–fucosterol conversion (18). The involvement of epoxides as intermediates following fucosterol and 24-methylenecholesterol in the dealkylation pathway was first demonstrated in the silkworm, *Bombyx mori* (19,20). Studies with *S. littoralis* also showed an epoxide, stigmasterol-24,28-epoxide, as an intermediate in stigmasterol dealkylation (18). The fucosterol 24,28-epoxide lyase enzyme from *Manduca* midgut was shown to have a great preference for 24*R*,28*R* over 24*S*,28*S*-diastereomeric forms of the epoxides (21).

INHIBITORS OF STEROL METABOLISM IN *MANDUCA SEXTA*

The discovery that desmosterol was the terminal intermediate in the dealkylation and conversion of phytosterol to cholesterol prompted us to test the effects of certain hypocholesterolemic agents developed by pharmaceutical firms. These drugs were known to inhibit the Δ^{24}-sterol reductase in vertebrates, where desmosterol is the terminal intermediate in the *de novo* biosynthesis of cholesterol. We first tested triparanol and a number of azasteroids, including 22,25-diazacholesterol (Fig. 1), and found them to inhibit both the Δ^{24}-reductase and larval development in *Manduca* and in other species when fed in a diet containing dietary phytosterols such as sitosterol (22). These inhibitors were also useful for the identification of desmosterol as a common intermediate in the metabolism of C_{28} and C_{29} phytosterols to cholesterol (13), and for the isolation of other intermediates of phytosterol dealkylation in the hornworm and other insects and nematodes (23). Some azasteroids also disrupt other aspects of steroid metabolism, as indicated by the observation that in certain species cholesterol does not reverse the effects of the inhibitor. Through structure–activity relationship studies, it was possible to design and synthesize simpler, more active azasteroids such as 25-azacholestane and 25-azacoprostane, which were over 200 times as active as the azasterols of our original work (24). In some species, including *Manduca*, 25-azacholestane and 25-azacoprostane were inhibitory at dietary concentrations of 1 ppm or less.

Because inhibitors with a complete steroid nucleus would be expensive to synthesize and could present regulatory prob-

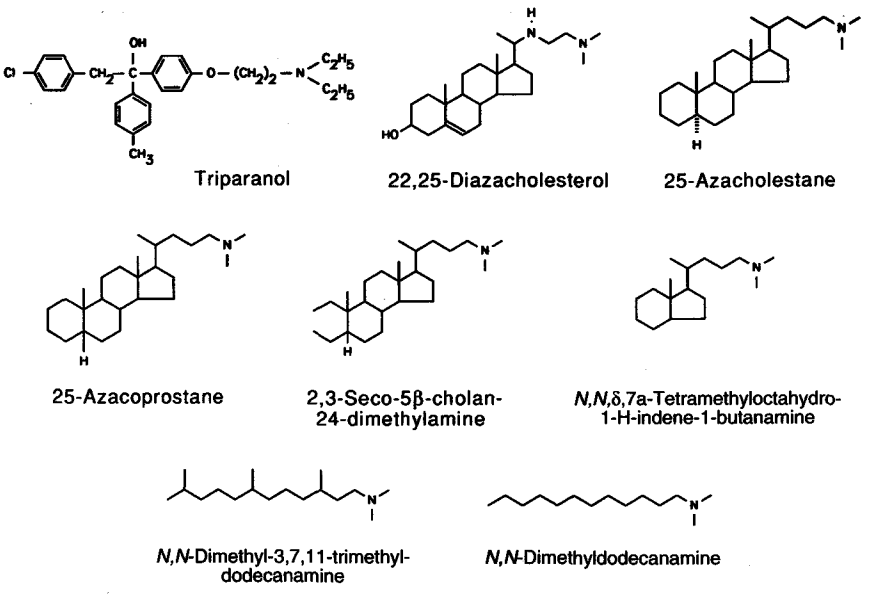

FIG. 1. Representative Δ^{24}-sterol reductase inhibitors.

lems if used as control agents, we attempted to develop non-steroidal compounds that might have the same types of activity as the azasteroids. By opening the A ring, we found that the intact steroid nucleus was not necessary and that even a simple bicyclic compound with the C and D rings and a 25-aza side chain had effects similar to the intact azasteroids. Indeed, simple branched- and straight-chain amines, such as *N,N*-dimethyldodecanamine also inhibited the Δ^{24}-reductase and larval development in *Manduca* and in other species, but at a lower level of activity than the best of the azasteroids (25). Interestingly, all of these Δ^{24}-reductase inhibitors have a dimethylamine functional group. These latter branched- and straight-chain amines were very inexpensive and available in large quantities, and had low vertebrate toxicity. Although these compounds were not suitable for use against phytophagous insects because of their phytotoxicity, they have shown promise for use against other arthropods and certain nematodes (23). Also, these inhibitors have served as valuable tools in our sterol metabolism and endocrinological studies, particularly in our search for new intermediates of dealkylation, as certain intermediates accumulate when later steps in the metabolic pathway are blocked (23).

ECDYSTEROIDS IN *MANDUCA SEXTA*

Although cholesterol has been known to be a precursor of ecdysone since 1963 (26), even before the structure of ecdysone was known, the pathway from cholesterol to ecdysone is still not entirely clear (9). 7-Dehydrocholesterol was first implicated as the primary intermediate between cholesterol and ecdysteroids in *Calliphora stygia* (27). The prothoracic glands are the major site of ecdysteroid biosynthesis in larval insects, and in *Manduca* these glands were found to contain relatively high levels of 7-dehydrocholesterol (9).

Manduca sexta was one of the first insect species from which both ecdysone and 20-hydroxyecdysone were isolated and identified (Fig. 2) (28). 20-Hydroxyecdysone is the most active molting hormone in most larval insects. Both ecdysteroids occur at fairly high titers in seven-day-old *Manduca* pupae. Much smaller quantities of a more polar ecdysteroid, later shown to be 20,26-dihydroxyecdysone, are also present but had a much lower level of biological activity (29). 20,26-Dihydroxyecdysone becomes much more prominent five days later in pupal–adult development, exceeding the levels of ecdysone and 20-hydroxyecdysone. The observed increase in the proportion of 20,26-dihydroxyecdysone lends support to the conclusion that 26-hydroxylation is a mechanism of deactivation. Lesser amounts of 3-epiecdysone, 3-epi-20-hydroxyecdysone and 3-epi-20,26-dihydroxyecdysone were also present in this later developmental stage, and they too are believed to be inactivation products (30). 3-Epiecdysone and 3-epi-20-hydroxyecdysone were initially isolated from hornworm meconium, the metabolic waste products discharged at adult emergence (31). In a complementary study, an enzyme system from *Manduca* midgut was discovered that converted ecdysone to 3-epiecdysone (32).

26-Hydroxyecdysone was first isolated and identified as the major ecdysteroid in tobacco hornworm eggs (33). *Manduca sexta* eggs appear to be unique in this respect. [^{14}C]Cholesterol was injected into late pupae to study ecdysteroid metabolism during the 96-h embryonic development of *Manduca* (34). Samples of eggs were collected at six time intervals after oviposition and the ^{14}C-labeled ecdysteroids were examined in detail. The total ecdysteroid content was quite constant throughout embryonic development (~40 μg/g), and considerable metabolism occurred during this period even though there was little or no *de novo* biosynthesis. In newly laid eggs, 26-hydroxyecdysone-26-phosphate (26E26P) was

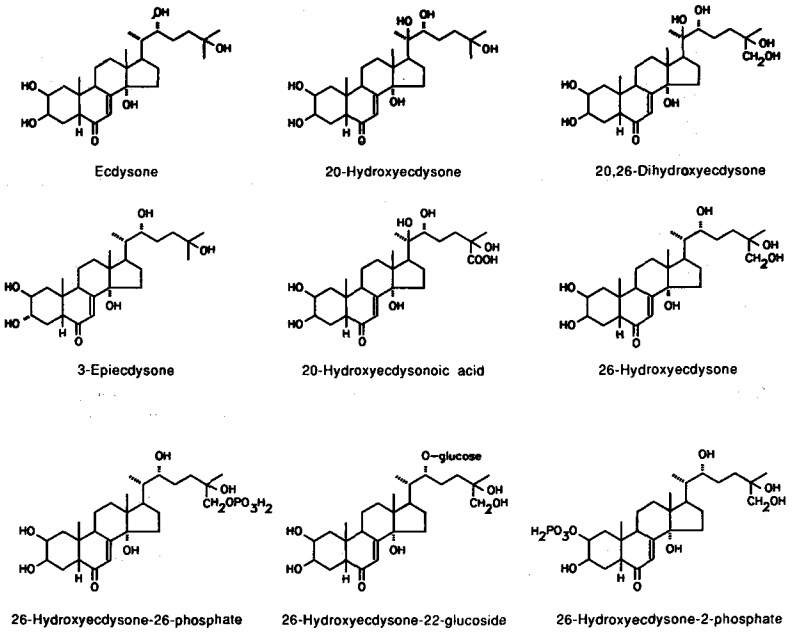

FIG. 2. Representative ecdysteroids.

the major ecdysteroid. Little ecdysone or 20-hydroxyecdysone was detected throughout embryogenesis. The 26E26P was hydrolyzed, and the 26-hydroxyecdysone was metabolized along several pathways, including glucosylation, epimerization, and oxidation to acids, all of which are presumed to be inactivation processes. Conjugates (phosphates and glucosides) constituted the major ecdysteroids throughout embryonic development. The most abundant ecdysteroid isolated from newly emerged first instar larvae was 26-hydroxyecdysone 22-glucoside. The results of these metabolic studies with [^{14}C]cholesterol closely paralleled the results of another study on ecdysteroid metabolism in *Manduca* embryos, in which identification and quantification were based on radioimmunoassay with two different antisera specific for different regions of the ecdysteroid molecule (35).

In another study, newly molted fifth-instar male *Manduca* larvae were injected with [^{14}C]cholesterol and analyzed for their ^{14}C-labeled ecdysteroids at five time intervals between 0 and 16 d after pupation (36). *De novo* biosynthesis of ecdysteroids occurred during the first four days following pupation. The total ecdysteroid levels increased from about 2.5 to 6.5 μg/g, which is much lower than the titers found in *Manduca* eggs. Ecdysteroid metabolism throughout pupal–adult development was characterized by hydroxylation, oxidation, epimerization, and phosphorylation. Concentrations of specific ecdysteroids varied throughout pupal–adult development, but the major metabolites were 3-epi-20-hydroxyecdysonoic acid and phosphoconjugates of 3-epi-20-hydroxyecdysone and 3-epi-20,26-dihydroxyecdysone. Thus, inactivation of ecdysteroids during pupal–adult development in *Manduca* is accomplished by oxidation and epimerization leading to 3-epiecdysteroid acid, as well as by phosphorylation leading to 3-epiecdysteroid phosphates. Interestingly, a considerable amount of ecdysteroids was synthesized during the first four days of pupal–adult development, whereas little or no *de novo* biosynthesis occurred during embryogenesis.

Our laboratory has used *M. sexta* for extensive *in vitro* studies of three specific enzyme systems involved in ecdysteroid metabolism: 20-monooxygenase (EC 1.14.99.22), 3-epimerase, and phosphotransferase (37). Two different ecdysone 20-monooxygenases have been discovered in the midgut, one located in the mitochondria, the other in the microsomes (38,39). These enzymes convert ecdysone to 20-hydroxyecdysone and therefore represent a molting hormone activating enzyme system. Ecdysone 20-monooxygenases are cytochrome P450-dependent enzymes, require oxygen and NADPH as a hydrogen donor, and are inhibited by carbon monoxide. High activity has been found in late fifth-instar larvae and early prepupae, coinciding with or slightly preceding the major increase in hemolymph 20-hydroxyecdysone titer. The interaction between the mitochondrial and the microsomal 20-monooxygenase systems and their contribution to the ecdysteroid balance of the hornworm are not fully understood.

Inactivation of ecdysteroids through 3-epimerization of ecdysone occurs *via* a two-step reaction, an oxidation to 3-dehydroecdysteroids followed by a stereospecific reduction to 3α-hydroxyecdysteroids. Enzymes for these conversions are located in the midgut cytosol (40,41). The first step is catalyzed by ecdysone oxidase (EC 1.1.3.16), the second step by 3-oxoecdysteroid 3α-reductase. The midgut cytosol also contains another enzyme, 3-oxoecdysteroid 3β-reductase, that converts the intermediate (3-dehydroecdysteroid) back to the 3β-hydroxyecdysteroid. Thus, the total amount of ecdysteroid converted to the 3-epimer depends on the balance between the two competing enzymatic reactions.

As mentioned before, another means of inactivation of ecdysteroids involves formation of phosphoconjugates. These have been found in larval, pupal, and pharate adult stages of

development in various species (8). Phosphotransferases in midgut cytosol preparations from *Manduca* have been shown to convert ecdysone to four different phosphoconjugates, and 3-epiecdysone to two phosphoconjugates (42).

The intent of this brief review is to summarize primarily our laboratory's research related to sterol metabolism in *Manduca.* Much of the information presently available on steroid metabolism in insects was initially obtained in studies with this species. Certainly, much has been accomplished using other species as well, but *Manduca* continues to be a major experimental animal for many studies on insect physiology and biochemistry, including those related to new approaches to insect control. For example, much of the initial work on ecdysone agonists, such as RH-5849 (1,2-dibenzoyl-1-*tert*-butylhydrazine), was done with the hornworm (43). Currently, a related benzoylhydrazine (RH-5992) that is very effective against Lepidoptera is being developed commercially (44). Related research on insect sterol metabolism with other species has been described in several recent reviews (e.g., Refs. 6,7,9,45). Continued basic research in these areas of insect steroid biochemistry may provide further leads for the development of new control technology. For example, isolation of specific enzymes involved in steroid metabolism and cloning of the corresponding genes could provide invaluable new tools for researchers in this area. This has been and continues to be an exciting and fruitful area of research in insect biochemistry.

Quantitation of Steryl Ferulate and *p*-Coumarate Esters from Corn and Rice[1]

Robert A. Norton*
USDA, ARS, NCAUR,
Mycotoxin Research, Peoria, Illinois 61604

ABSTRACT: The principal steryl ferulate and *p*-coumarate esters of different fractions from processed corn brans and corn oils, unrefined and refined, and from rice bran and rice bran oil were quantified by high-performance liquid chromatography. The results show that hexane-extracted corn oils yield more than five times the amount of esters compared to expeller processed oils. The yields of esters from bran and related products ranged from 0.07 to 0.54 mg/g of bran. Unrefined corn oils had levels from 0.18 to 8.6 mg/g for oil from hexane-extracted bran. By comparison, rice bran had ester levels of 3.4 mg/g of bran, and rice bran oil had levels of 15.7 mg/g of oil. The predominant esters from corn were sitostanyl and campestanyl ferulate, and sitostanyl and campestanyl *p*-coumarate. The principal esters from rice bran were cycloartenyl, 24-methylenecycloartanyl, and campesteryl ferulate. Rice bran oils had low levels of 24-methylenecycloartanyl but high levels of cyclobranol esters. The data presented provide a direct comparison of steryl ferulate and *p*-coumarate levels in the two cereals, and will aid in selecting the most suitable sources for the isolation of these compounds from corn products.
Lipids 30, 269–274 (1995).

Sterols esterified to cinnamic acid and its derivatives (CAD) are found in cereals and other plant families (1,2). The ferulates of cyclic dimethyl and desmethyl sterols occur in rice (3) and are collectively termed γ-oryzanol. Ferulate and *p*-coumarate esters of desmethyl sterols are found in corn, rye, wheat, and triticale (1). Two aspects of steryl CAD esters in corn and related cereals are of interest, namely the possible involvement of these compounds in the susceptibility, or resistance, of preharvest corn to pathogens and whether these compounds might have effects similar to those of rice bran oil or γ-oryzanol on certain types of hypercholesterolemia.

No specific function for these compounds in the plant has been demonstrated, however, one possibility is that they may affect the response of the seed to pathogens, either positively or negatively. The compounds are localized in corn kernels in the inner pericarp and aleurone layer (1), and ferulic acid, the principal compound esterified to the sterols, has been shown to inhibit growth and aflatoxin production in *Aspergillus flavus* (4,5), which is the primary source of aflatoxin contamination in preharvest corn (6). It was anticipated that hydrolysis of the ester by infecting fungi would release inhibitory levels of ferulic acid within the region of the kernel in which they occur. Recent evidence indicates that steryl CAD esters increase the amount of aflatoxin produced by *A. flavus* grown on a synthetic medium but did inhibit spore germination of *Scerlotinia sclerotiorum*, which is not a pathogen of corn but is a pathogen in other plants (R. Norton, and P. Dowd, unpublished data).

Rice bran oil has been reported in a number of studies to be effective in lowering blood cholesterol in some types of hypercholesterolemia, and γ-oryzanol has been suggested as the active factor (7). Similar studies have not been reported on this ester fraction from cereals other than rice. The levels of steryl CAD esters from intact whole corn were low compared with those from rice bran oil, i.e., about 46 μg/g for corn kernels (1) vs. 3500 μg/g for rice bran (8). Localization of the esters in the pericarp and aleurone layers indicated that bran could be a more efficient source of these compounds than whole corn and a recent report showed that one corn bran product contained about twice the level of the steryl CAD as did whole corn, and it contained at least 16 identifiable steryl esters (9). Even a doubling of the concentration of esters by using bran would still give a low yield for corn compared to rice. Because the pericarp and aleurone layers comprise most of the bran fraction, but make up only about 5% of the kernel (10), a yield of 20 times the kernel level would seem to be the upper limit, i.e., about 900 μg/g of bran. To determine which corn products might be the best source for these compounds, it would be helpful to obtain enough of the 16 or more minor constituents of bran for testing against corn pathogens as well as for testing their efficacy in the treatment of hypercholesterolemia.

In the studies reported here, we analyzed different bran fractions for composition and yield of steryl CAD esters and compared these to data obtained on unrefined and refined corn oils. The composition and levels of esters in rice bran and rice bran oil have been reported by others (7,8,11), but samples of

these products were also included in the present study to permit direct comparisons of data obtained by the same analytical methods. Nothing is known to date about the biosynthesis of these compounds. It would also be of interest to know whether esters from different parts of the corn kernel have similar ester levels and compositions. The specific ester compositions of the fractions would be important for evaluating the physiological effects of these compounds from corn in comparison to those from rice.

MATERIALS AND METHODS

Corn bran fractions designated raw bran, bran duster thrus, bran after duster, finished bran, fine high-fiber corn bran (No. 97800), standard corn bran (No. 96530), and ultra-high fiber corn bran (No. 99030) were obtained from Illinois Cereal Mills (Paris, IL). Corn oil processing intermediates designated expeller cake, crude corn oil (expeller extracted), and crude corn oil (hexane-extracted) were obtained from Lauhoff Grain Co. (Danville, IL). Commercial oils and rice bran from the following manufacturers were obtained from local health food stores: Spectrum Naturals, Inc. (Petaluma, CA); Select Origins Inc. (Southampton, NY); California Naturals (The California Olive Oil Corp., Salem, MA); BioSan (New Dimensions Distributors, Fountain Hills, AZ); NOW Foods (Glendale Heights, IL); Hain Pure Food Corp. (Los Angeles, CA); Mazola corn oil (CPC International Inc., Englewood Cliffs, NJ). γ-Oryzanol (as γ-Oryzanol), was purchased from CTC Organics (Atlanta, GA).

Extractions. Aliquots of bran and expeller cake were weighed and dried at 100°C to constant weight to determine percent moisture. Duplicate samples equivalent to 50 g of dry weight were mixed with 250 mL hexane, allowed to set, and extracted twice overnight in the dark. The samples were filtered through a Büchner funnel with filter paper, and the cake was rinsed twice with 125 mL of hexane. The combined extracts were evaporated under reduced pressure at 40°C and stored at −20°C along with the commercial oils prior to use.

Sample preparation. Free fatty acids were removed from samples by adding 3 mL of 1,2-dichloroethane (Sigma, St. Louis, MO) to a 1-g sample of the oil obtained by hexane extraction of bran or the oil obtained from the manufacturer. Next, 1.5 mL of a saturated aqueous solution of Na_2CO_3 (40%, wt/vol) was added to the diluted sample and mixed thoroughly. After centrifuging the mixture on a laboratory centrifuge for several minutes, the organic layer was pipetted off. The aqueous phase was extracted with an additional 3 mL of 1,2-dichloroethane, and the combined organic phases were evaporated to dryness with a stream of N_2 at ambient temperature (12). The dry extract was redissolved in 1 mL of hexane/Et_2O (9:1, vol/vol). A silica gel column was prepared by adding 10 g of silica gel (63–200 μm mesh; Alltech Associates, Deerfield, IL) made up in hexane/Et_2O (9:1, vol/vol) to a 50-mL glass column (28 × 100 mm; Kontes Glass, Flex-Column, Vineland, NJ). The sample was pipetted onto the column and eluted with Solvent Systems S_1, i.e., 50 mL hexane/Et_2O (9:1, vol/vol); S_2, i.e., 30 mL hexane/Et_2O (7:3, vol/vol); and then S_3, i.e., 50 mL hexane/Et_2O (5:5, vol/vol). The final 10 mL of S_2 and the entire volume of S_3 were collected as 10-mL fractions. The fractions were evaporated under reduced pressure and brought up to 1 mL with 2-propanol. The presence or absence of ferulates and *p*-coumarates in the column eluates was monitored by measuring absorption at 327 nm, using a Beckman DU 60 spectrophotometer (Beckman Instruments, Fullerton, CA). Triglycerides, sterol fatty acid esters, and fatty acids were eluted in S_1 and in the first 20 mL of S_2. Steryl CAD was eluted in the last 10 mL of S_2 and S_3. Sterols were not removed, but these were eluted ahead of the steryl CAD esters and did not absorb at the wavelength used for monitoring esters. Examination of all fractions eluted from the silica gel column showed that no appreciable amounts of esters were lost due to premature elution or due to incomplete elution.

High-performance liquid chromatography (HPLC). The steryl CAD mixture obtained was analyzed by HPLC using a C18 reversed-phase (5 μm, 300 Å, Deltabond ODS; Keystone Scientific, Bellefonte, PA) column (4.6 × 250 mm) and acetonitrile/*n*-butanol/acetic acid/water (82:3:2:13, by vol) as solvent system at a flow rate of 1.2 mL/min at ambient temperature. The effluent was monitored using a diode-array detector at 325 nm. Corn components were identified spectroscopically and by their retention times relative to sitostanyl ferulate, and were quantified as previously reported (9). Rice and γ-oryzanol compounds were identified by mass spectrometry using authentic sterols standards as described (9). For each type of sample, each HPLC peak that was included in the calculations was further examined to verify that the respective spectra reasonably matched those of the major ferulate and *p*-coumarates. For corn samples, these were sitostanyl ferulate and sitostanyl *p*-coumarate; for rice, it was cycloartenyl ferulate. Some of the refined corn oils had retention times close to those of *p*-coumarate and ferulate of the crude oils, but the spectra were atypical, and thus those peaks were not included in the calculations. The yield of oil per unit of extracted source material is unknown for the commercial or process oils; therefore yields for bran samples are not given. Each bran sample was extracted twice, and two silica gel column preparations made for one of the extracts to assess within-sample reproducibility for the cleanup procedure. Quantitation and composition data are the averages of duplicate extraction analyses and of the single sample analysis. Two of each of the commercial oil samples (identified by source in the tables) were prepared and analyzed, and the averages are given. The average coefficient of variation (CV) within samples for the composition of the major components was 1.4% for sitostanyl ferulate, 2.4% for campestanyl ferulate, and 12.2% for sitosteryl *p*-coumarate. The average CV for the composition between samples was 1.9, 5.2, and 13.7%, respectively. The average CV for the quantitation within samples (oil basis) was 5.8, 5.5% between samples, and 3.0% for the amount of oil extracted.

RESULTS AND DISCUSSION

Analysis. Use of the Deltabond column gave better resolution of the esters in less time than the column used in previous work (9). The flexibility of the column is illustrated in Figure 1, showing that γ-oryzanol chromatographed with increasing amounts of water in the mobile phase. Similar results were obtained with the ester fraction from corn. Peak numbers 2, 3, 4, and 9 (17.5%) showed increasing resolution as the amount of water was increased; however, peak number 6 (12.5%) was gradually lost under these conditions. For samples of this ester composition, 12.5–15% water seemed optimal as all peaks can be seen at least as shoulders. Water at 13% gave the best resolution for corn esters; a typical chromatogram is shown in Figure 2. Three other C_{18} columns all gave results similar to those in Figure 1 using the base solvent system and run times from 30–70 min. However, there was better separation of peak numbers 8 and 9. Peak numbers 2, 3, and 4 appeared to be ferulates with an unidentified steryl portion. The Deltabond column offers considerable flexibility because a higher percentage of water can be used without substantially lengthening run times.

Composition and level of esters. The results of the analyses for corn materials are given in Table 1, and for rice in Table 2. Representative structures are shown in Scheme 1. Sample R, ConAgra corn bran flour, had been kept for over two years in a −20°C freezer; thus some deterioration may have occurred over time. A previous examination of this sample had given a value of 93.3 μg steryl CAD esters per gram of bran (9). The unrefined corn oils I and W were from the same manufacturer but had different labels on the bottles, similarly for samples U and V.

As is shown in Table 1, significant differences in the yields of esters from different brans and bran processing fractions were seen both on the basis of the amounts of esters per unit of bran as well as for the related yield for oil. The composi-

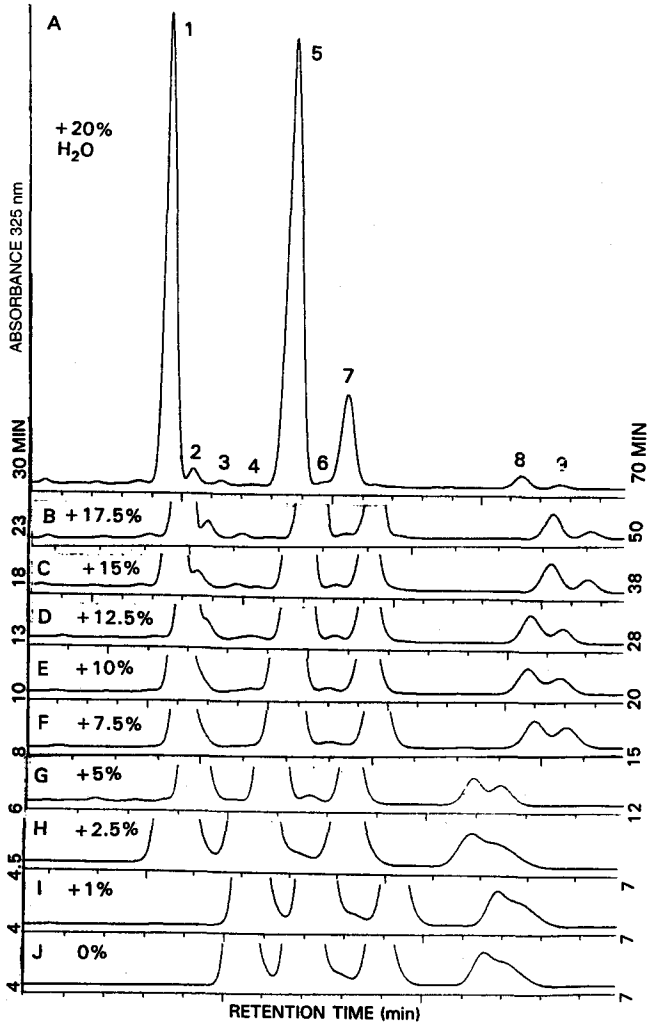

FIG. 1. Effect of increasing water concentration on the separation of γ-oryzanol components on a Deltabond C18 high-performance liquid chromatography column (Keystone Scientific, Bellefonte, PA) using acetonitrile/*n*-butanol/acetic acid/water (94:3:2:1, by vol) with additional water as shown. Detector wavelength, 325 nm. Peak 1, cycloartenyl ferulate; peaks 2, 3, 4, and 9, ferulates, sterol identity unknown; peak 5, 24-methylenecycloartanyl ferulate; peak 6, cyclobranyl ferulate; peak 7, campesteryl ferulate; peak 8, sitostanyl ferulate; not shown (off scale), cycloartanyl ferulate.

tions of the different corn brans showed little variation except for samples G, H, and R which showed lower levels of campestanyl ferulate and corresponding increases in sitostanyl ferulate levels. There was an increase in the percentage of *p*-coumarates in the expeller cake; however, the unrefined corn oils, both expeller and hexane-extracted, were similar to the brans. The higher level of esters in the bran duster thrus fraction may be the result of an enrichment of this fraction in aleurone fragments which, since this layer is quite fragile by itself, would not be retained in the bran after duster fraction except as a part of a larger pericarp fragment. If the contribution of the endosperm to this fraction could be corrected for, the yield would be considerably higher. It was interesting that expeller cake had a significant level of esters.

SCHEME 1

The only previous study on the steryl CAD composition of different seed fractions was that of Seitz (1); however, the ester levels of the germ were not determined in that study. The presence of substantial amounts of esters in unrefined corn oils, both expeller and hexane-extracted, and in the cake remaining after expeller extraction, indicates that steryl CAD esters also occur in the germ as corn oil is extracted from the germ fraction of corn. Steryl ferulate esters have been found in corn germ oil (13) but their levels were not reported. Compared to bran and unrefined corn oils, the refined oils, samples S and T, contained only traces of the two major stanyl esters. Refined oils, such as S and T, are processed through several steps (including degumming, caustic refining, bleaching and deodorization), which apparently remove most of the esters. From 50–90% of the γ-oryzanol is removed in refining rice bran oil (7,11). Samples I/W and U/V showed that oils from the same source were similar in content but not identical.

Of particular interest is the effect of the method of extraction on the yield of esters from corn (Table 1). Samples J and K were from the same processor but were extracted by the expeller method for K, and by hexane extraction for J. Moreover, the amount of esters isolated in the latter case was 553% greater. The levels found in expeller oils from samples I and W were similar to those of K, but two other expeller oils (U,V) were considerably lower. The effect of the extraction method showed a similar pattern in rice bran oils (Table 2). No commercial sample of unrefined rice bran oil identified as hexane-extracted was available, but bran extracted by us in the laboratory (N) showed a similar 530% higher level over that of the highest commercial oil examined (M). The other sample (L) had apparently been subject to additional refining steps. There was a marked difference in the levels of two components in the rice bran oils vs. γ-oryzanol and rice bran freshly extracted: cyclobranol was present only in trace amounts in γ-oryzanol and bran; however, its level was markedly higher in the rice bran oils examined. The level of 24-methylenecycloartanyl ferulate in the oils decreased proportionately (Table 2). The apparent health benefits of γ-oryzanol have led to increasing interest examining the steps in rice bran oil refining which affect the levels of γ-oryzanol (11), and in alternate processing modes which would retain these components in the finished oil product (14). The values reported here for rice bran and for the oil extracted from it are similar to the γ-oryzanol levels previously reported for rice bran and oil (8,11). The total ester levels of the two commercial oils were also similar to levels previously reported (7,15). Tables 1 and 2 show that the level of steryl ferulate esters in the oil from rice bran was lower than the level in oil from some types of corn bran; however, because of the much higher oil content of rice bran, the yield of esters on a bran basis would be six to eight times higher.

The effect of rice bran, rice bran oil, and γ-oryzanol on cholesterol metabolism has been the subject of several studies which have recently been reviewed (7). Similar studies seem not to have been carried out on the effect of nonrice steryl CAD esters on cholesterol uptake or serum cholesterol levels. As shown in Table 1, ferulate ester of sitostanol accounts for 65–85% of the ester fraction in oil from corn bran. Sitostanol has been reported to be as effective as sitosterol, at 10-fold lower levels, in lowering serum cholesterol in hypercholesterolemic patients (16), and it was suggested that low-dose sitostanol might be a useful hypolipidemic agent for the treatment of mild hypercholesterolemia. Fatty acid esters of cholesterol and of plant sterols are known to be hydrolyzed in the course of fat digestion (17,18). The effectiveness of plant sterols in lowering blood cholesterol levels is thought to result from their ability to displace free cholesterol from intestinal micelles (18). Rukmini and Raghuram (19) reported that cycloartenol is as effective as γ-oryzanol in lowering serum cholesterol in rats, which would be consistent with the idea that cycloartenyl ferulate is hydrolyzed and that the released sterol has an effect similar to that of the sterol taken up in the diet. Sitostanol has a further advantage in that it is not appreciably taken up into the bloodstream (16,20). The limited solubility of sitostanol in fats, however, has made it difficult to administer it (21), and it is only when plant sterols are suspended in lipids that they can be administered at a dose high enough to be effective (18,21). A recent report has shown that the effectiveness of sitostanol was markedly increased when the sterol was administered as a fatty acid ester with the dietary fat (21). Given the high percentage of sitostanol esters in the steryl CAD ester fraction of corn bran oil and the levels of esters comparable to or higher than the ester levels in

rice bran oil, it would seem that further studies on the effect of these compounds on blood cholesterol levels would be needed. The approaches presented in this paper should prove helpful in screening cereals for sterol esters of cinnamic acid derivatives and in selecting the appropriate corn fraction or oil for the isolation of steryl ferulate and *p*-coumarate esters or for feeding studies with crude preparations.

EDITORIAL

This month, *Lipids* contains a series of papers that originated from an AOCS symposium on isopentenoid metabolism and function. The range of topics runs from overviews of the complexities of this class of compounds in plants and animals, to new thoughts on its importance and pharmacologic manipulation derived from molecular biology approaches. A number of the articles also contain new primary data from the authors, producing a group of contrasting and interrelated articles that we hope will be thought-provoking for our readers. Portions of future issues will occasionally be devoted to thematic works such as these, in order to continue the tradition of *Lipids* being a forum for the latest ideas in lipid research.

As the needs and interests of our readership have evolved over the past twenty-nine years, *Lipids* has responded by altering its format and content. Recently, we have received an increasing number of comments on the format of our references. Titles have never been included in the references of *Lipids* papers, because this was the traditional format for the chemical literature and a major interest at *Lipids* has always been lipid chemistry. These days, however, many of our readers and contributors are from the biomedical disciplines and are used to having access to the titles of referenced papers. This allows readers to quickly decide whether a particular article referred to by our authors would be of interest to them, and has a positive impact on their impression of an article's (and, by extension, a journal's) utility to them. Therefore, we will be adding the titles to the references of articles published in *Lipids,* while keeping all other aspects of the reference format the same. We hope that this addition will be particularly helpful for the review articles that will be published on a regular basis in *Lipids.*

Again, *Lipids* appreciates comments and suggestions from the lipid research community, in addition to your submitted manuscripts!

Mechanisms of Free Radical Oxidation of Unsaturated Lipids

Ned A. Porter*, Sarah E. Caldwell and Karen A. Mills
Department of Chemistry, Duke University, Durham, North Carolina 27708

ABSTRACT: The primary products formed from the autoxidation of lipids can be understood based upon a mechanism that involves five different reaction types. These reactions are: reaction of a carbon radical and molecular oxygen, atom transfer of a hydrogen from substrate to the chain carrying peroxyl, fragmentation of the chain carrying peroxyl to give oxygen and a carbon radical, rearrangement of the peroxyl, and cyclization of the peroxyl. The mechanism of these primary reaction steps has been the focus of extensive research over the past fifty years, and the current level of understanding of these transformations is the subject of this review.
Lipids 30, 277–290 (1995).

The study of the spontaneous reaction of molecular oxygen with lipids has been of interest for centuries. Lavoisier (1) was interested in the combustion and the low temperature oxidation of fats and oils, and such reactions are the basis of elemental analysis, a critical development in the birth of the science of organic chemistry. In the past fifty years, interest in the processes responsible for the deterioration of manufactured goods, such as rubber and waxes (2,3), has stimulated the study of autoxidation, the spontaneous free radical reaction of organic compounds with oxygen (4). In more recent years, this process has received renewed attention because of its probable role in destructive biological processes (5). In living systems, autoxidation of lipids, known as lipid peroxidation (6,7), has been implicated in DNA and protein modification, radiation damage, aging and age pigment formation, modification of membrane structure, tumor initiation, and in the deposition of arterial plaque associated with low-density lipoprotein modification (6–13). For these reasons, lipid peroxidation is a subject of continuing interest to the scientific community.

PROPAGATION STEPS IN FREE RADICAL CHAIN OXIDATION

Autoxidation is a free radical chain process consisting of chain initiation, propagation, and termination steps (Fig. 1). The key event in initiation is the formation of a lipid radical, R·. This can occur by thermal or photochemical homolytic cleavage of an RH bond or by hydrogen atom abstraction from R-H by an initiator free radical. The propagation step normally begins with the addition of molecular oxygen to R· and the second step of propagation, the rate-limiting step, is abstraction of a hydrogen atom from RH by peroxyl radical ROO· to generate ROOH and another radical R·.

The rate constant k_p for the rate-limiting step of propagation depends primarily on the strength of the C-H bond being broken. The bond dissociation energy of an allylic hydrogen is approximately 10 kcal/mol greater than that of a bisallylic hydrogen (14). As a result, reasonable rates for the autoxidation of monoenes, such as methyl oleate, can only be achieved at elevated temperatures, while the autoxidation of dienes, such as methyl linoleate, occurs readily at room temperature (Scheme 1).

Propagation steps observed in autoxidation may be more complicated than the simple transfer and additions steps shown in Figure 1. In general, propagation steps observed in free radical chain processes include radical coupling with oxygen, atom or group transfer, fragmentation, rearrangement, and cyclization (Fig. 2). All five of these types of reactions have been observed in the autoxidation process (15).

Molecular oxygen is a ground state triplet having two unpaired electrons; consequently, molecular oxygen is a diradical, and reaction with an organic free radical [Fig. 2(a)] is es-

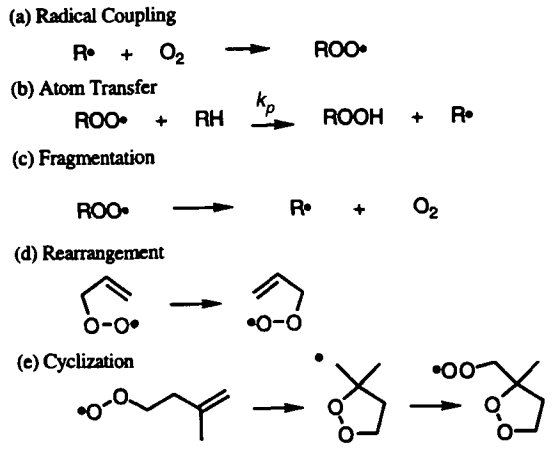

FIG. 2. Propagation reactions in autoxidation.

sentially a radical–radical coupling process (16). Molecular oxygen reacts with the carbon-centered free radical at or near the diffusion controlled rate of approximately 10^9 $M^{-1}s^{-1}$.

Peroxyl radicals abstract hydrogen from organic substrates in a reaction classified as an atom transfer reaction [Fig 2(b)]. At oxygen pressure above 100 torr (17), the rate of oxidation is given by Equation 1 where k_p and k_t are the propagation and termination rate constants, respectively, while R_i is the rate of radical initiation.

$$-dO_2/dt = k_p[\text{R-H}]R_i^{1/2}/2k_t^{1/2} \quad [1]$$

The β-fragmentation reaction of peroxyl radicals, which is the reverse reaction of the oxygen coupling to an organic free radical, is the third type of general process that occurs in the autoxidation propagation sequence [Fig. 2(c)]. This reaction is known to occur when *R* is a stabilized radical such as in the dienylperoxyl radical (see Fig. 14 later in the text) derived from methyl linoleate. Additionally, the first step of the proposed [2,3] allylperoxyl rearrangement mechanism [Fig. 2(d)], has been suggested to be a β-fragmentation of an allylperoxyl to give an allyl radical-dioxygen caged pair.

Peroxyl radicals undergo cyclization reactions, essentially an intramolecular radical addition, to yield five- and six-membered rings [Fig. 2(e)]. Radical cyclization was first proposed to occur in the autoxidation of polyisoprenoids (6). The radical formed in the kinetically favored 5-*exo* cyclization adds a second molecule of oxygen to yield a new peroxyl radical (5). Peroxyl radical cyclization is an important process in the autoxidation of fatty acids or esters having three or more double bonds.

AUTOXIDATION OF MONOENE LIPIDS

Studies of the autoxidation of methyl oleate date back to 1943 in work reported by Farmer and Sutton (18). These workers suggested that the products of oleate oxidation consist of a mixture of allylic hydroperoxides substituted at the C_8 and C_{11} of the eighteen carbon chain. Later, Farmer, Koch and Sutton (19) proposed a free radical chain mechanism involving intermediates **1** and **2** (Fig. 3). They postulated that there would be equal probability for the hydroperoxy group to appear at positions 8, 9, 10, and 11, and for the olefin to remain at the original position (Δ9–10) or to appear at the two adjacent C-C bonds (Δ8–9 and Δ10–11). Thus, it was suggested that autoxidation of methyl oleate yielded four hydroperoxides **3**–**6**. This was supported by work performed by Bickford *et al.* (20) in 1948 and Ross *et al.* (21) in 1946, in which the position of substitution of the hydroperoxy groups was established at C_8, C_9, C_{10}, and C_{11}. The products were confirmed

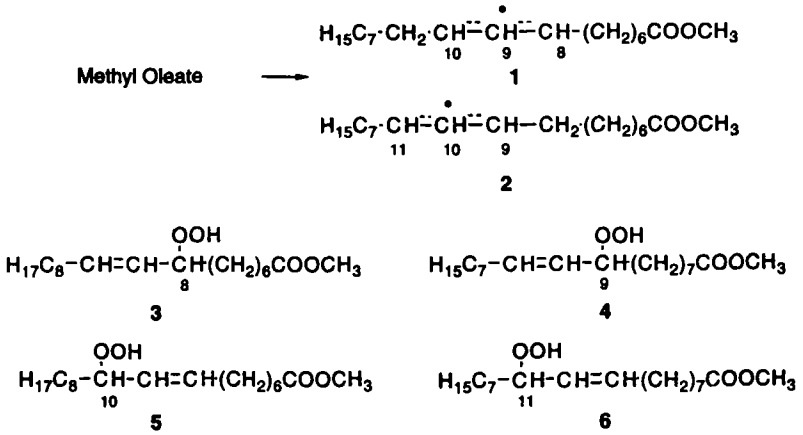

FIG. 3. Oleate product distribution postulated by Farmer, Koch, and Sutton (Ref. 19).

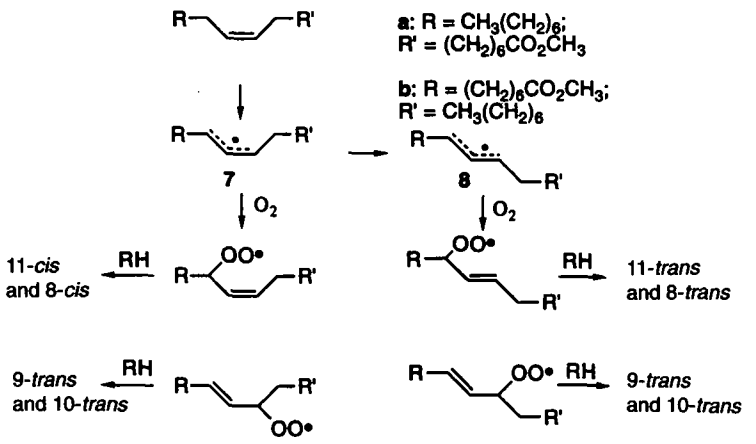

FIG. 4. Proposed methyl oleate autoxidation mechanism, Frankel *et al.* (Ref. 24).

by conversion of the oleate hydroperoxides to the corresponding keto stearic acids.

Prior to 1977, mixtures of oleate allylic hydroperoxides were not fully characterized due to a lack of appropriate analytical techniques (22). That year, Frankel *et al.* (23) reported a structural investigation of methyl oleate autoxidation products using gas chromatography/mass spectrometry (GC/MS). Oleate hydroperoxides were reduced and silylated followed by hydrogenation of the olefin. The resulting trimethylsilyl ethers of the saturated hydroxy esters have good gas chromatographic properties and produce characteristic fragments. This approach provided a direct, reliable method for analysis of regioisomeric oleate hydroperoxides. The 8- and 11-hydroxy isomers were consistently present in higher abundance than the 9- and 10-hydroxy isomers. The difference between these pairs is greatest when the autoxidation was carried out at 40°C, and it decreased when the reaction was run at 80°C.

In 1984, ^{13}C nuclear magnetic resonance (NMR) was used to determine the *cis/trans* geometry of all eight *cis* and *trans* allylic 8-, 9-, 10-, and 11-oleate hydroperoxides (24). The method, along with GC/MS, revealed that autoxidation of methyl oleate occurs symmetrically about the double bond. At 25°C, percentages of the 8-hydroperoxide, 26.4% (*cis/trans* = 14.1:12.3), closely parallel the 11-hydroperoxide, 26.6% (*cis/trans* = 13.7:12.9), and the 9-hydroperoxide, 24.2% (*cis/trans* = 1.1:23.1), is similar to the 10-hydroperoxide, 22.8% (*cis/trans* = 1.1:21.7), in both yield and *cis/trans* ratio.

The distribution of oleate oxidation products was explained by the mechanism outlined in Figure 4. Hydrogen atom abstraction from the 11 position was proposed to lead to delocalized radical **7a** that isomerizes, particularly at elevated temperatures, to give the isomeric allyl radical **8a**. Reaction of the allyl radical **7a** with molecular oxygen was proposed to generate to the 11-*cis* and 9-*trans* oleate hydroperoxides, and reaction of **8a** was proposed to generate the 11-*trans* and 9-*trans* oleate hydroperoxides. Also, hydrogen atom abstraction from carbon 8 was proposed to form delocalized radical **7b** that would isomerize to allyl radical **8b**. Addition of molecular oxygen to **7b** and **8b** was expected to generate the 8-*cis*, 8-*trans* and 10-*trans* oleate hydroperoxides (25).

The direct allyl radical isomerization shown in Figure 4 seems unlikely, since, under normal oxygen pressures, the allyl radical would be trapped with molecular oxygen at the diffusion controlled rate of 10^9 $M^{-1}s^{-1}$, making the allylperoxyl radical the main chain-carrying radical. Because of this, an alternative mechanism was proposed for the formation of products that involves competing peroxyl rearrangement and H-atom abstraction (5). This mechanism, outlined in Figure 5, involves hydrogen atom abstraction at the 8 and 11 positions of methyl oleate to give two allylic radicals **9** and **10**. Due to the symmetry of the oleate autoxidation, only the top portion of Figure 5, with hydrogen atom abstraction from position 11, is discussed here. Addition of O_2 to allyl radical **9** gives rise to two peroxyl radicals, 11-*cis*, **11**, and 9-*trans*, **12.** These peroxyl radicals interconvert *via* a [2,3] allylperoxyl rearrangement. The 11-*trans* peroxyl radical, **13**, is formed by [2,3] allylperoxyl rearrangement of the 9-*trans* peroxyl radical, **12**. Hydroperoxides **14–16** result from these peroxyl radicals undergoing hydrogen atom abstraction from methyl oleate, RH.

Due to the symmetry of the system, similar chemistry occurs for allyl radical **10**, giving hydroperoxides **17–19**. If this mechanism is operative, the product distribution would be dependent upon the hydrogen atom donating ability of the medium. In the presence of a "good" hydrogen atom donor (a compound with a C-H bond of low dissociation energy) the "kinetic" allylperoxyl radicals, **11**, **12**, and their C_8 and C_{10} equivalents, would be trapped prior to [2,3] rearrangement and formation of **16** and **19**. The product distribution would therefore consist of hydroperoxides **14**, **15**, **17**, and **18** with no thermodynamic products **16** and **19** being formed.

The results of a recent study support the mechanism presented in Figure 5 (26). The alcohols that result from reduction of hydroperoxides **14–19** separate by normal-phase high-pressure liquid chromatography (HPLC), and a complete analysis of the products can be achieved using ultraviolet detection at 205 nm. Most methyl oleate or oleic acid obtained commercially is contaminated with linoleate. Linoleate is

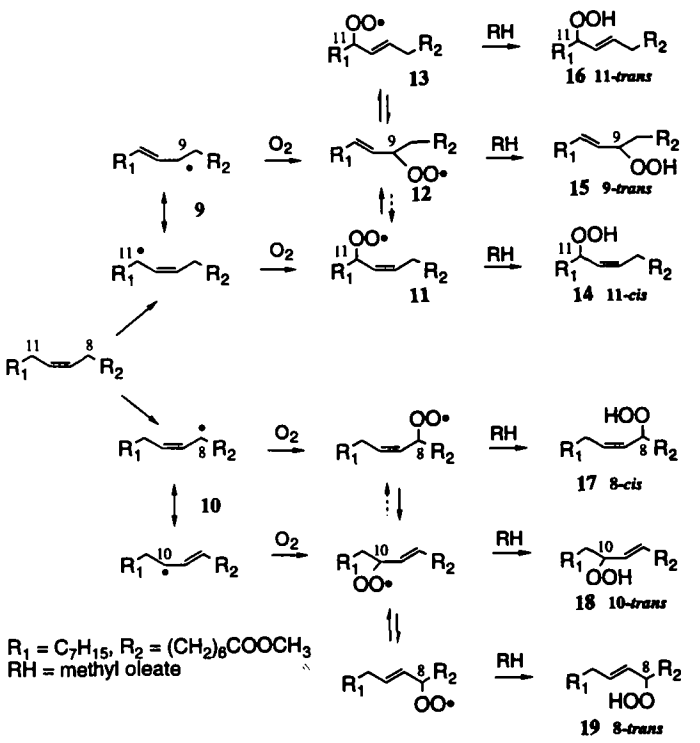

FIG. 5. Proposed mechanism for oleate autoxidation, Porter (Ref. 5).

substantially more oxidizable than oleate, and autoxidation therefore provides substantial quantities of the linoleate hydroperoxides. Due to the excellent chromophore of these conjugated diene hydroperoxides (and alcohols), the linoleate products create a severe problem for analysis of the oleates. In the studies of mechanism reported (26), quantitative data were obtained from oleate samples that had been recycled through autoxidation more than five times. Autoxidation of 1.8 M methyl oleate in benzene at 30°C gives a product distribution as follows: **14**, 11-*cis*, 13%; **15**, 9-*trans*, 21%; **16**, 11-*trans*, 16%; **17**, 8-*cis*, 13%; **18**, 10-*trans*, 21% ; **19**, 8-*trans*, 16%; 10-*cis*, 1%; 9-*cis*, 1%.

If the mechanism in Figure 5 is correct, increasing amounts of "kinetic" 11-*cis* and 9-*trans* hydroperoxides and decreasing amounts of "thermodynamic" 11-*trans* hydroperoxide will form as the concentration of hydrogen atom donors in the medium is increased. If autoxidations are carried out on solutions with starting oleate in the concentration range of 0.3 to 3.0 M, hydroperoxide product distribution is dependent on the concentration of starting oleate. At high starting oleate concentration, more of the "kinetic" products are formed; at low starting oleate concentration, the product mixture contains more "thermodynamic" products.

Courtneidge and Bush (27–29) have demonstrated that *tert*-butyl hydroperoxide-loaded autoxidation reactions are successful in suppressing rearrangements of allylperoxyl radicals, and this approach has been used in oleate autoxidation (26). Hydrogen atoms exchange rapidly between peroxyl radicals. The autoxidation of oleate in the presence of excess *tert*-butyl hydroperoxide, therefore, transfers the chain from oleate peroxyl radicals to *tert*-butyl peroxyl radicals [Equation 2 (Refs. 30–33)].

$$ROO\cdot + (CH_3)_3COOH \xrightarrow{k_p = 2{,}500\ M^{-1}s^{-1},\ 30°C} ROOH + (CH_3)_3COO\cdot \quad [2]$$

Under cooxidation conditions of 4.0 M *tert*-butyl hydroperoxide and 1.8 M oleate (30°C), only the 11-*cis*, 9-*trans*, 10-*trans*, and 8-*cis* oleate hydroperoxides are produced, and no 11- or 8-*trans* hydroperoxides are obtained. The ratio of the 11-*cis*/9-*trans* products is 1:1.2, as is that of the 8-*cis*/10-*trans* compounds. Autoxidations of oleate in the presence of *tert*-butyl hydroperoxide displayed a substantial acceleration compared to oxidations carried out in the absence of the cooxidant. The increase in the rate of oxidation is explained by a reduction in the termination rate of chain carrying *tert*-butyl peroxyl radicals compared to oleate peroxyl radicals (34,35).

The results from the cooxidation of oleate and *tert*-butyl hydroperoxide support the mechanism of oleate autoxidation proposed in Figure 5. According to Figure 5, the initially-formed carbon radical, **9**, has two resonance forms, corresponding to Δ9–10 *cisoid* and Δ10–11 *transoid* geometry. Addition of oxygen leads to the 11-*cis* and 9-*trans* peroxyl radicals, and subsequent hydrogen atom abstraction yields the 11-*cis* and 9-*trans* hydroperoxides **14** and **15**. Similar chemistry after H-atom abstraction at C_8 provides the 8-*cis* and 10-*trans* hydroperoxides. Indeed, these four hydroperoxides are the only products formed in the hydroperoxide-loaded autoxidations. Hydroperoxides are excellent hydrogen atom donors, and the data suggest that, in the presence of hydroperoxide, the product mixture is under kinetic control. The ini-

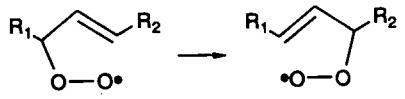

FIG. 6. [2,3] Allylperoxyl rearrangement.

tially-formed peroxyl radicals are directed to the "kinetic" hydroperoxides as a result.

Rearrangements of allyl peroxyls. As shown in Figure 6, allylperoxyl radicals undergo [2,3] rearrangements in which the oxygen atoms, the two component, migrate across the allylic backbone, the three component (6,36–39). A rearrangement of this type is proposed in oleate oxidation to account for the distribution of products formed. Such rearrangements may also be involved in the rearrangement of allylic hydroperoxides. The free radical nature of the hydroperoxide rearrangement is supported by the observation that the rearrangement is catalyzed by free radical initiators or light, and the rearrangement is inhibited by phenolic antioxidants (40). The rearrangement occurs most rapidly in nonpolar aprotic solvents using dilute solutions of hydroperoxide. In concentrated solutions, hydroperoxides form dimers, and hydrogen atom abstraction to form allylperoxyl radicals occurs readily from hydroperoxide monomers but not hydroperoxide dimers (41).

Despite the fact that [2,3] allylperoxyl rearrangements have been known since the late 1950s, the mechanism is still open to debate (6). In 1958, Schenck *et al.* (42,43) reported on the rearrangement of cholesterol hydroperoxides in which the tertiary hydroperoxide 5α-hydroperoxy-3ß-hydroxycholest-6-ene, **20**, slowly rearranges to its secondary allylic isomer, **21**, with complete retention of the α configuration (Fig. 7).

Over twenty years later, Smith (44) showed that compound **21** undergoes a slower epimerization to the 7β-hydroperoxide, **22**. In 1989, Beckwith, Davies, and co-workers (45,46) performed the cholesterol allylperoxyl rearrangement under $(^{18}O)_2$ and observed no ^{18}O incorporation in the 7α-hydroperoxy-3β-hydroxycholest-5-ene, **21**, whereas the epimerization of this product to 7β-hydroperoxy-3β-hydroxycholest-5-ene, **22**, involves 73–83% ^{18}O incorporation. They (45,46) suggested that the rearrangement of **20** to **21** involves a concerted [2,3] allylperoxyl rearrangement, whereas the second rearrangement of **21** to **22** proceeds through a dissociative mechanism.

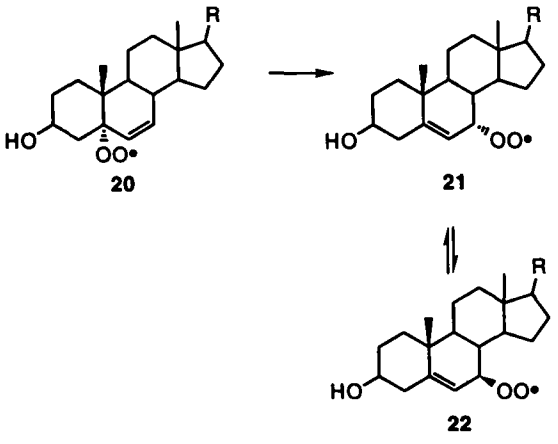

FIG. 7. Cholesterol [2,3] allylperoxyl rearrangement.

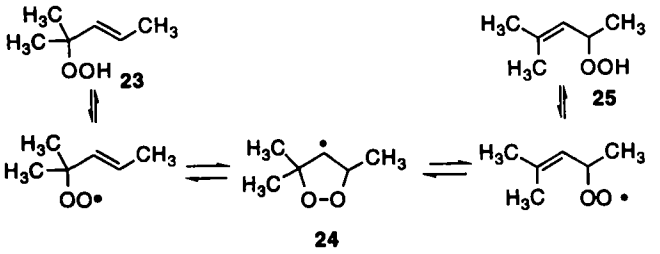

FIG. 8. Cyclization mechanism of [2,3] allylperoxyl rearrangement.

Work on acyclic systems was first reported by Brill (47,48) in 1965. It was observed that either *trans*-2-hydroperoxy-2-methyl-3-pentene, **23**, or its allylic isomer *trans*-2-hydroperoxy-4-methyl-3-pentene, **25**, isomerizes to an equilibrium mixture containing approximately equal quantities of each hydroperoxide **23** and **25** in hexane or carbon tetrachloride at 40°C (Fig. 8). Brill (47,48) concluded that the rearrangement was a free radical intramolecular process occurring *via* a five-membered cyclic intermediate (dioxolanyl radical **24**).

As shown in Figure 9, three mechanisms have been most often suggested for allylperoxyl rearrangement (44–49). The first consists of a stepwise process involving a dioxolanyl radical intermediate like **24**. Another viable mechanism consists of a concerted mechanism involving a five-membered ring peroxide transition state. Finally, an alternate stepwise process has also been suggested in which the peroxyl radical undergoes β-fragmentation to give an allyl radical and molecular O_2. In a follow up step, O_2 recombines at either end of the allyl radical to convert it to the rearranged peroxyl radical or to revert to the starting peroxyl radical.

In later work, Brill (41) provided convincing evidence to call into question the legitimacy of dioxolanyl radical **24** (41). The free radical rearrangement of pinocarvyl hydroperoxide was performed, and there was no evidence for an expected rearrangement of the putative intermediate dioxolanyl radical.

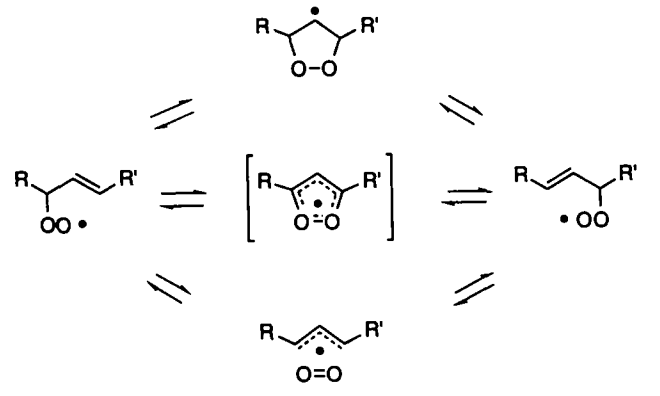

FIG. 9. Possible mechanisms of allylperoxyl rearrangement.

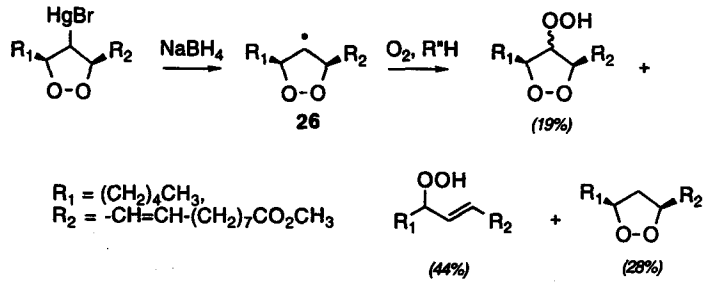

FIG. 10. Oxygen entrapment of the proposed dioxolanyl radical intermediate.

If the dioxolanyl radical is an intermediate along the rearrangement pathway, it would be expected to be trapped to form a cyclic peroxide–hydroperoxide in the presence of oxygen while structural rearrangement would be expected in the absence of oxygen. The data suggest that the dioxolanyl radical is not involved in the [2,3] allylperoxyl rearrangement mechanism.

A later study of an authentic localized dioxolanyl radical demonstrated that it could be trapped with molecular oxygen (49). The postulated intermediate **26** was obtained by the $NaBH_4$ reduction of a mercuric bromide precursor, and the radical was successfully trapped with O_2 to generate a cyclic peroxide–hydroperoxide (Fig. 10). These products are not formed in the rearrangement of the corresponding allylic hydroperoxide. This experiment therefore supports the notion that a dioxolanyl radical is not a discrete intermediate in the rearrangement.

Recent theoretical investigations failed to find the concerted transition state proposed for the rearrangement (50). These calculations were performed at the unrestricted Hartree-Fock and Moeller-Plesset levels using the simple allylperoxyl radical **27** (Fig. 11). Attempts to locate the concerted transition state structure revealed a dioxolanyl radical, **28**, close in energy to the allylperoxyl radical. Radical **28** has a barrier to formation in excess of 40 kcal/mol, which is unreasonably large for a free radical propagation step. The calculations also reveal that β-fragmentation to the allyl radical–dioxygen intermediate, **29**, requires only 22 kcal/mol; therefore, the calculations suggest that the [2,3] allylperoxyl

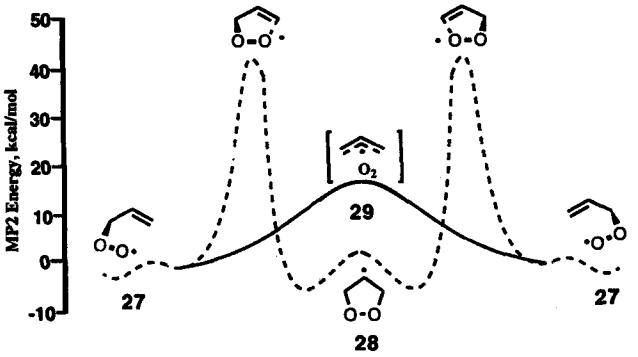

FIG. 11. Theoretical investigations of the allylperoxyl rearrangement.

rearrangement proceeds by this lower energy β-fragmentation process. Hence, the mechanism consistent with experiment and theory involves an allyl radical–triplet dioxygen solvent caged pair, **29** (Fig. 11).

The stereochemical course of the allylperoxyl rearrangement was studied with hydroperoxides derived from oleic acid (51). The rearrangement is highly stereoselective, and the 11-*trans* hydroperoxide rearrangement product derived from the 9-*trans* hydroperoxide has the opposite configuration from the starting hydroperoxide (Fig. 12). As an example of the stereoselectivity of the rearrangement, *(R)*-9-*trans* with an enantiomeric excess >99% rearranges at 22°C to yield a mixture of *(R)*-9-*trans* and *(S)*-11-*trans* with an enantiomeric excess in the latter compound of 97.2% ± 0.5 at the

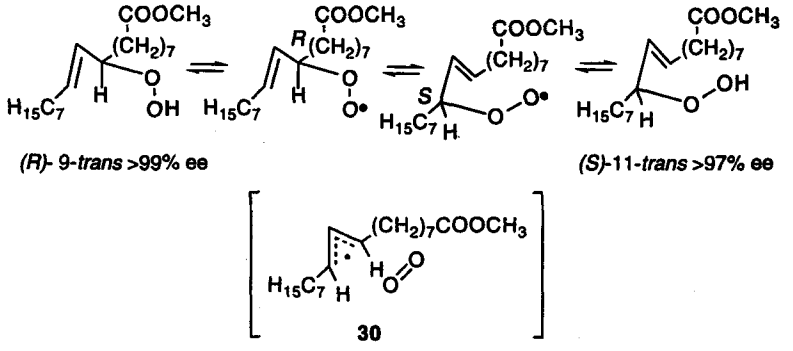

FIG. 12. Stereoselectivity of the *trans* allylperoxyl rearrangement; ee, enantiomeric excess.

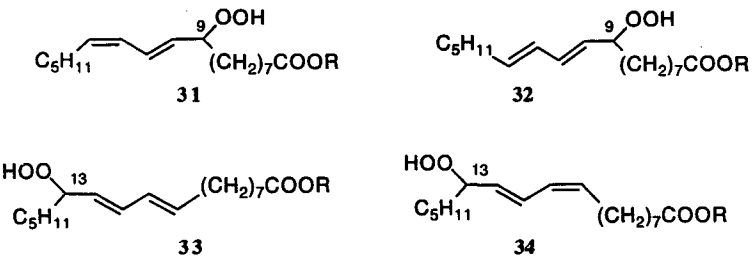
time where 9*R*/11*S* = 1.7. The stereoselectivity is shown experimentally to be dependent on temperature with an enantiomeric excess of 97% at 22°C and 94% at 50°C.

The stereoselectivity of the rearrangement is consistent with a concerted mechanism *via* an envelope-like transition state that results in transfer of chirality across the allyl system or with a mechanism involving a very tight allyl–oxygen pair, **30**, which collapses with predominant retention of configuration. One anticipates that study of the rearrangement under an $(^{18}O)_2$ atmosphere would distinguish between the concerted and stepwise mechanisms. The rearrangement proceeds with little incorporation of atmospheric oxygen at room temperature in viscous solvents. At higher temperatures, studies of the rearrangement under oxygen-18 in solvents of different viscosity provide mechanistic insights.

In short, it has been reported that incorporation of labelled oxygen from the atmosphere occurs but that this incorporation is solvent viscosity- and temperature-dependent, as is the stereoselectivity of the rearrangement (52,53). In more viscous solvents and at lower temperatures, less atmospheric oxygen is incorporated in the product of rearrangement, and the rearrangement is more stereoselective. In octadecane at 60°C, for example, the rearrangement of a *trans* alkene derived from methyl oleate gives product with over 96% enantiomeric excess and with incorporation of ~2% atmospheric oxygen. In hexane, substantially more atmospheric oxygen is incorporated, and a corresponding decrease in stereoselectivity is observed.

We conclude that the simplest mechanism for the rearrangement consistent with the experimental results and theoretical investigations involves the allyl–radical dioxygen caged pair **30** that collapses at a diffusion-controlled rate with stereochemical memory. It should be noted that the caged pair might have substantial charge-transfer character. However, a full-fledged allyl–superoxide ion pair seems unlikely in hydrocarbon solvents and would not provide a mechanism for escape that is solvent viscosity-dependent. The results rule out a bridged species as an intermediate in the rearrangement. Allyl radicals that diffuse into solution incorporate $(^{18}O)_2$ with racemization of configuration. This gives evidence of a planar allyl radical intermediate that escapes from the initial solvent cage. The pair collapse (^{16}O) product apparently forms with a high degree of stereoselectivity compared to other known radical pair reactions. The stereochemical-oxygen labeling studies indicate that solvent viscosity affects the partitioning between escape and collapse of the allyl radical–dioxygen caged pair. An increase in solvent viscosity results in a decrease in escape product and a corresponding increase in pair collapse product.



The studies of the [3,2] rearrangement of oleate hydroperoxides (52,53) have a bearing on the mechanism proposed in Figure 5 for oleate autoxidation. Rearrangements of this type are proposed to account for the distribution of products formed in oleate autoxidation, and studies of oleate hydroperoxide rearrangement provide data that are in general agreement with the mechanism proposed in Figure 5. Thus, reaction of the 11-*cis* oleate hydroperoxide, **14**, with free radical initiators gives an allyl peroxyl intermediate **11** that rearranges to the peroxyls **12** and **13.** These peroxyls are ultimately converted to the *trans* hydroperoxides, **15** and **16**. Consistent with the mechanism, *cis* allyl peroxyl radicals rearrange to the related *trans* peroxyl radicals, but the reverse reaction is not observed.

AUTOXIDATION OF DIENE LIPIDS

The autoxidation of methyl linoleate has been extensively studied (6,54,55), and the four major products of this reaction are the hydroperoxides **31–34** (56–58). These conjugated diene hydroperoxides result from oxygen addition at either the 9 or the 13 position of the eighteen carbon chain. Two of the products have *cis, trans* geometry in the conjugated diene unit while the other two display *trans, trans* geometry (Scheme 2).

A mechanism for the formation of the four major products (54–58) of methyl linoleate autoxidation has been elucidated and is outlined in Figure 13. In the first step, hydrogen atom abstraction from C-11 of methyl linoleate leads to the pentadienyl radical **35**. Subsequent oxygen addition to **35** generates one of two *trans, cis* peroxyl radicals, **36** or **37**, either of which has three possible options. Unlike the analogous transformation catalyzed by lipoxygenase enzymes (59), both C-11 hydrogens are removed, and oxygen reacts equally on both faces of the intermediate pentadienyl. Considering just the 13-substituted radical **36**, hydrogen atom abstraction from a donor such as another linoleate generates 13-*cis*, *trans* hydroperoxide **34**, which is the kinetic product.

The other two options involve β-fragmentation of the intermediate peroxyl radical. Nonproductive β-fragmentation

SCHEME 2

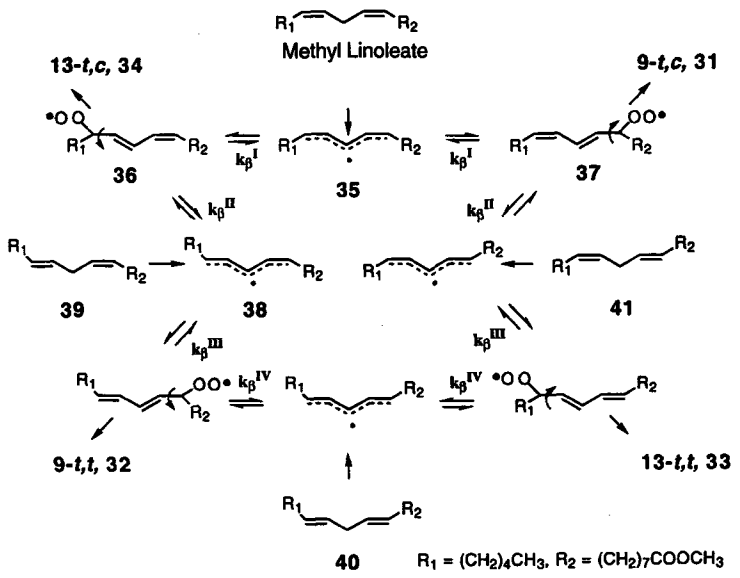


FIG. 13. Proposed mechanism of the autoxidation of octadecadienoates.

gives the original pentadienyl radical **35**. Alternatively, if bond rotation about C12–C13 precedes β-fragmentation, then a new pentadienyl radical **38** is formed.

This radical has *trans* rather than *cis* geometry about the partial double bond Δ-12,13. Oxygen addition at C-9 then leads to a peroxyl radical that gives the 9-*trans*, *trans* hydroperoxide **32**, the thermodynamic product. As can be seen from Figure 13, the same processes can occur with the initially formed 9-substituted peroxyl radical **37.** Autoxidation product ratios are therefore determined by the competition between hydrogen atom abstraction to give the *cis, trans* kinetic products and β-fragmentation to give the *trans, trans* thermodynamic products.

In-depth studies by Chan *et al.* (54) have established that the rearrangement of dienylperoxyl radicals derived from linoleate proceeds by a β-fragmentation mechanism. This was determined through investigations of the thermal rearrangement of the diene hydroperoxide **34** derived from methyl linoleate using an ^{18}O label (Fig. 14). It was demonstrated that ^{18}O-labeled dienyl hydroperoxides undergo rearrangement with incorporation of atmospheric oxygen into the rearrangement products **36** and **37**, giving evidence in support of a β-fragmentation mechanism involving pentadienyl radical intermediate **38**. The rearrangement has been studied in viscous solvents, such as heptadecane, and the products show complete atmospheric oxygen incorporation, unlike the oleates where a cage recombination mechanism has been sug-

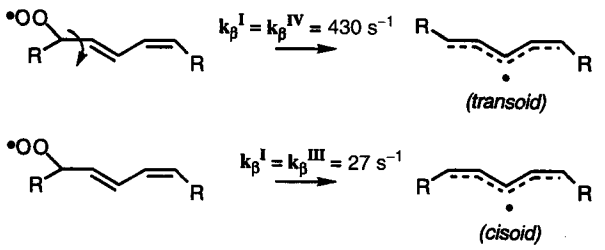

FIG. 15. Dienylperoxyl fragmentation rate constants.

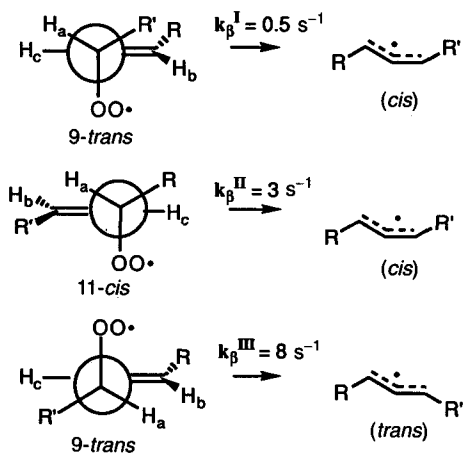
gested (52,53,56,60; Caldwell, S.E., and Porter, N.A., submitted for publication).

As shown in Figure 13, the autoxidation of methyl linoleate and the three isomeric methyl 9,12-octadecadienoates, **39–41,** has been investigated (56,61,62). In the absence of cyclohexadiene (an excellent hydrogen atom donor), the product distribution of diene hydroperoxides **31–34** is similar for each diene precursor, with the thermodynamic *trans, trans* products dominating the product mixture (Table 1). At higher concentrations of cyclohexadiene (i.e., 3.0 M), the product distribution changes to reflect the stereochemistry of the starting diene with the kinetic product distribution being obtained.

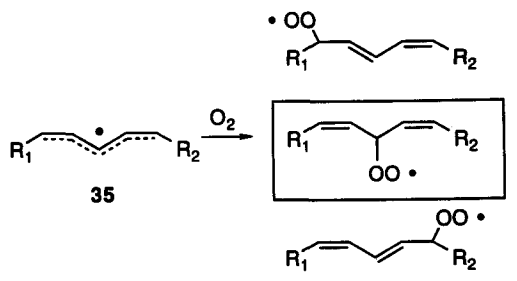
A steady-state successive approximation computer analysis was conducted to determine the fragmentation rate constants, k_β^I, k_β^{II}, k_β^{III}, and k_β^{IV} (56,61,62). This approach allows the product distribution to be calculated for each of the dienoate precursors as a function of cyclohexadiene concentration for various values of $k_\beta^{I–IV}$. Through this analysis, it was determined that $k_\beta^I = k_\beta^{III} = 27\ s^{-1}$ and $k_\beta^{II} = k_\beta^{IV} = 430\ s^{-1}$. These rate constants reveal that β-fragmentation of dienylperoxyl radicals leading to *transoid* centers occurs sixteen times faster than fragmentations of peroxyl radicals leading to *cisoid* centers (Fig. 15).



At high concentrations of cyclohexadiene, the product distribution reflects the initial partitioning of oxygen to the ends of the pentadienyl radical. Reaction at the *transoid* end of the pentadienyl radical is twofold that of reaction at the *cisoid* end of the radical. These results are consistent with electron paramagnetic studies that suggest a higher spin density at *transoid* pentadienyl termini (63).

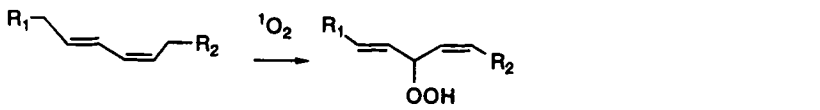
It is of interest to compare the fragmentation rate constants for linoleate with those determined for oleate. The oleate β-fragmentation rate constants are shown in Figure 16 with the allylperoxyl radicals represented as Newman projections. Three different fragmentation reactions occur in the oleate system: (i) fragmentation of the 9- (or 10-) *trans* allylperoxyl radical to generate the *cisoid* allyl radical (k_β^I); (ii) fragmentation of the 11- (or 8-) *cis* allylperoxyl radical to generate a cisoid allyl radical (k_β^{II}); (iii) fragmentation of the 9- (or 10-) *trans* allylperoxyl radical to generate the *transoid* allyl radical (k_β^{III}).

β-Fragmentation of the 9-*trans* allylperoxyl radical can generate either a *transoid* or *cisoid* radical. β-Fragmentation of the 9-*trans* allylperoxyl radical leading to a *transoid* allyl radical is sixteen times faster than β-fragmentation to a *cisoid* allyl radical (8 vs. 0.5 s^{-1}). On the other hand, fragmentation of a *cis* allyl peroxyl radical generates only a *cisoid* allyl radical, and the rate constant for this process is 3 s^{-1}.



In the linoleate system studied earlier, fragmentation to a *transoid* terminus was also found to occur sixteen times faster than fragmentation to the *cisoid* terminus. Substantial allylic 1–3 strain apparently attends fragmentation processes leading to *cisoid* allyl radicals as the sp^3 hybridized carbon bearing the peroxyl oxygen is converted to an sp^2 hybridized atom of the delocalized carbon radical. It has been suggested that this allylic strain (64) accounts for the rate differences observed for the different fragmentation processes. The peroxyl fragmentation rate constants for oleate are about twenty to fifty times smaller than the corresponding rate constants for fragmentation of linoleate peroxyl radicals. Since product oleate allyl radicals are less stabilized than the linoleate pentadienyl radicals, propagation and fragmentation rate constants in the oleate system are therefore smaller than for linoleate.

One question that arises in the mechanism of linoleate autoxidation is that bisallylic hydroperoxides resulting from oxygen addition to the central carbon of pentadienyl radicals (such as **35**) are not normally observed in autoxidation reactions. An exhaustive analysis of methyl linoleate autoxidation products failed to reveal the presence of a bisallylic prod-



R = C_7H_{15}; R' = $(CH_2)_7CO_2CH_3$

FIG. 16. Fragmentation rate constants for oleate peroxyls.

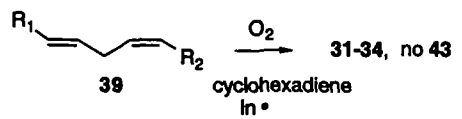
42 43 $R_1 = (CH_2)_4CH_3$, $R_2 = (CH_2)_7COOCH_3$

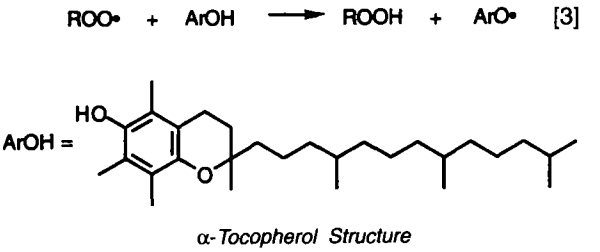
SCHEME 4



uct, although minor products resulting from abstraction of a singly allylic hydrogen atom at C-8 or C-14 of methyl linoleate were detected (Scheme 3) (65).

The failure to detect bisallylic products is puzzling, because the central carbon has the highest odd electron density in the pentadienyl radical (14). It has been suggested that oxygen attack at the central carbon does occur, but subsequent rearrangement to conjugated diene products (*via* β-fragmentation or [2,3] rearrangement) is rapid (6). This hypothesis was tested by means of a study of the radical rearrangement of an independently generated bisallylic hydroperoxide.

The bisallylic hydroperoxide **43** was prepared by singlet oxygenation of the diene **42** (Scheme 4). The hydroperoxide could be separated and purified from the complex mixture of products resulting from the singlet oxygen reaction. The bisallylic compound, **43**, itself proved to be surprisingly stable, even when concentrated samples were stored at room temperature.



Since the *cis*-9,*trans*-2-bisallylic 11-bisallylic hydroperoxide **43** has been characterized, attempts were made to determine if it is present in the "kinetic" product mixture formed by autoxidation of the appropriate linoleate isomer, **39**. Autoxidation of **39** was carried out at 30 °C in benzene or 1.4 M cyclohexadiene in benzene, initiated by di-*t*-butyl hyponitrite. Autoxidation products were purified by HPLC and analyzed by ^{1}H NMR and HPLC/MS. As expected, the major products of the reaction were the conjugated dienyl hydroperoxides **31–34.** Also detected were minor products resulting from abstraction of a singly allylic hydrogen at C-8 or C-14. However, there was no evidence of the bisallylic product. The results obtained in these autoxidation experiments are therefore consistent with the hypothesis that bisallylic products are not formed as products of lipid autoxidation because oxygen addition to the central carbon of the pentadienyl radical does not occur (Scheme 5) (Caldwell, S.E., and Porter, N.A., unpublished results).

Tocopherol mediated autoxidation. Phenolic antioxidants react with peroxyl radicals to generate a hydroperoxide product and relatively unreactive phenoxyl radical (Refs. 66–70;

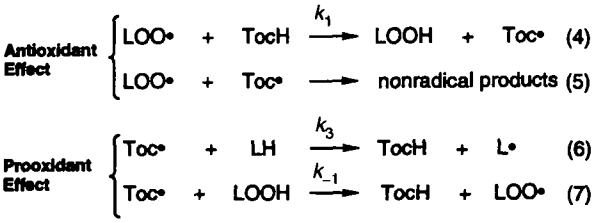
$R_1 = (CH_2)_4CH_3$, $R_2 = (CH_2)_7COOCH_3$

SCHEME 5

Equation 3). The most effective chain-breaking antioxidant among the phenolic antioxidants is α-tocopherol, the biologically active component of vitamin E (71). α-Tocopherol, present in cell membranes and edible oils, protects polyunsaturated lipids and fatty acids from peroxidation.

It is generally accepted (67–71) that α-tocopherol inhibits lipid peroxidation by hydrogen atom abstraction from the OH group by a peroxyl radical, LOO• (Eq. 4 in Fig. 17). Hydrogen atom abstraction occurs with a rate constant of $k_1 = 10^6$ $M^{-1}s^{-1}$, about four orders of magnitude faster than the propagation rates for hydrogen atom transfer from hydrocarbons to peroxyl radicals. The products of this H-atom transfer are a tocopherol radical, Toc• and a lipid hydroperoxide. The tocopherol radical can subsequently undergo chain termination reactions with peroxyl radicals in solution (Ref. 72; Eq. 5 in Fig. 17). Reactions 4 and 5 intercept and destroy the chain carrying peroxyl radicals, explaining the antioxidant effect of α-tocopherol.

Several research groups have demonstrated that α-tocopherol in high concentration acts as a prooxidant (73,74) during the autoxidation of polyunsaturated fatty acids by trapping out the kinetic peroxyl radicals and, as a result, altering the stereochemistry of the hydroperoxide products formed (75,76). It is proposed that the tocopherol radicals participate in the prooxidant effect through hydrogen atom abstraction (Eq. 6 in Fig. 17) and the chain-transfer reaction [Eq. 7 in Fig. 17). The rate constant k_{-1} was calculated to be approximately seven orders of magnitude less than k_1, the reverse of Equa-



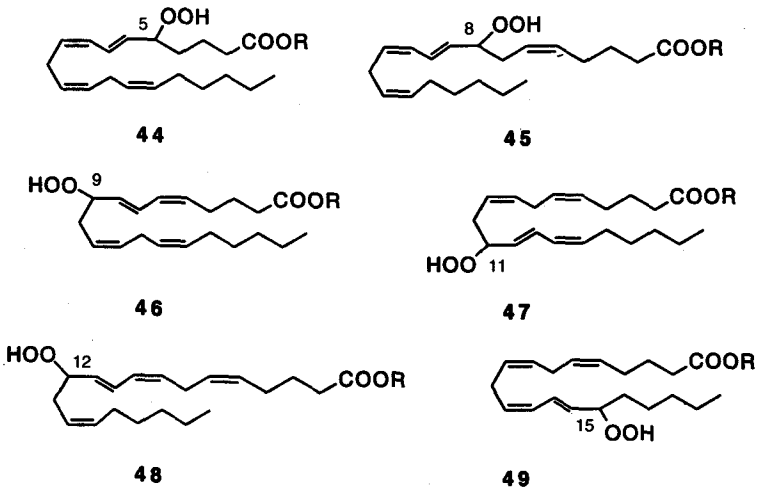


FIG. 17. Antioxidant/prooxidant properties of α-tocopherol.

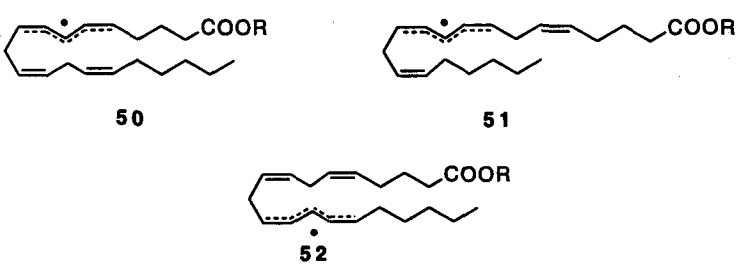
SCHEME 6

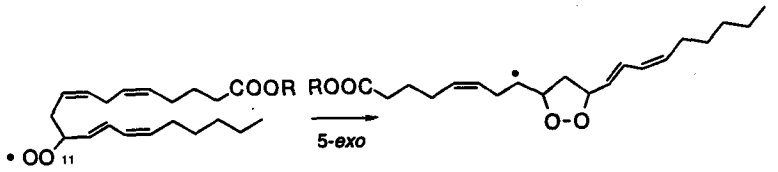
tion 4 (in Fig. 17). Reaction 6 generates another lipid free radical to propagate the chain explaining the ability of α-tocopherol to act as a prooxidant.

The rate constant k_3 was determined to be 1.8×10^{-2} $M^{-1}s^{-1}$ for hydrogen atom abstraction from methyl linoleate by the tocopherol radical (77). This reaction generates a linoleate pentadienyl radical, thus propagating the chain. Autoxidation of methyl linoleate in the presence of the excellent hydrogen atom donor α-tocopherol has been shown to change the product stereochemistry so that the kinetic product distribution is obtained. The ratio of the kinetic *trans, cis* product to the thermodynamic *trans, trans* product is >75:1 in the presence of α-tocopherol and 0.2:1 in the absence of α-tocopherol under otherwise comparable conditions. It is notable that phenols, which have historically been thought to prevent autoxidations, actually provide the kinetic product distribution for linoleate in a phenoxy-mediated reaction.



POLYENE AUTOXIDATION

Arachidonic (20:4) and linolenic acid (18:3) autoxidation have been investigated extensively as have pentaenoic and hexaenoic fatty acids (57,78). The free radical initiated oxygenation reaction of arachidonate illustrates the types of products that are generated in polyene autoxidation (57,79–81). The product mixtures in the autoxidation of this acid or its esters are extremely complex. Six simple hydroperoxide products, **44–49**, have been isolated, and these compounds all have *trans-cis* diene geometry. The alcohols formed from these hydroperoxides by reduction can be separated by HPLC, and this allows for extensive investigation of the mechanism of autoxidation (80,81). Smaller amounts of *trans-trans* diene products can be isolated, particularly the 15-*trans-trans* compound (Scheme 6).



Cyclic peroxide products have also been isolated in the autoxidation of arachidonate and other triene or tetraene fatty acids. To simplify the product mixture of cyclic peroxide products, specific hydroperoxides have been used as precursors to particular peroxyl radicals. For example, O'Connor, Mihelich, and Coleman (82) have investigated the cyclization reactions of the 9-hydroperoxide from γ-linolenate, and they found several cyclic peroxide compounds and proved the structure of these compounds.

For arachidonate, there are three centers at C-7, C-10, and C-13 that have carbons flanked by two double bonds. These carbons are analogous to the C-11 carbon of linoleate and are readily attacked by chain-carrying peroxyl radicals. Thus three pentadienyl radicals are formed as intermediates in arachidonate autoxidation, and these three pentadienyl radicals, **50–52**, all have *cis-trans-trans-cis* geometry by analogy to the pentadienyl radical formed from autoxidation of linoleate.

Oxygen addition occurs at either end of the three pentadi-

SCHEME 7

SCHEME 8

enyl radicals giving six peroxyl free radicals having *trans-cis* diene geometry. Hydrogen atom abstraction by these peroxyl radicals gives the six primary *trans-cis* diene products, **44–49** (Scheme 7).

Scission reactions of these peroxyl radicals are also possible, as is the case for linoleate peroxyl radicals. This scission reaction is a unimolecular process, but radical cyclization, another unimolecular pathway, apparently occurs with a faster rate constant. Consequently, few *trans-trans* products, which are formed by a fragmentation readdition pathway, are observed in arachidonate oxidation. Four of the six peroxyl radicals have isolated double bonds placed such that a 5-*exo* cyclization can occur. These four peroxyl radicals have oxygen substitution at positions C-8, C-9, C-11, and C-12 on the carbon chain. The 5-*exo* cyclizations are relatively facile (83,84) occurring with rate constants on the order of $k_c \sim 10^3\ s^{-1}$ (57). The peroxyl radicals substituted at positions C-5 and C-15 have no such double bond and no cyclization products are observed from these radicals (Scheme 8).

Since four different peroxyl radicals can give cyclic products and since multiple products are possible after cyclization, *vide infra*, many different products form in the autoxidation of arachidonate. Hydroperoxides serve as precursors to specific peroxyl radicals as described earlier, and the chemistry of peroxyl radicals generated in this manner is easier to study than is the case when random autoxidation is used. From one peroxyl radical, several products are formed other than the simple hydroperoxide. Monocyclic peroxides, bicyclic peroxides (85,86) and epoxy alcohols, all formed as several stereoisomers, give rise to literally hundreds of different products in the autoxidation of arachidonates. Other polyene structures may give more or less complicated product mixtures, depending on the number of double bonds in the system. At least three double bonds are required for radical cyclization pathways to exist, and the more double bonds present, the more complex will be the mixture of products.

Peroxyl radical cyclization has been discussed extensively elsewhere (5,6), and products formed from such cyclization of lipid radicals have been isolated from natural sources. Indeed, such cyclization products formed from lipid peroxidation (isoprostanes) may be natural markers of *in vivo* lipid peroxidation. We note also that peroxyl radical cyclization has been used to provide information about the [3,2] allylperoxyl rearrangement. Davies and Davison (46) performed kinetic studies on the [2,3] allylperoxyl rearrangement and found that the rearrangement occurs faster in cyclic as opposed to acyclic systems, but they were not able to quantify the rearrangement rates (46). Using the *tert*-butyl hydroperoxide loaded method, Courtneidge has estimated the rate constant for the [2,3] allylperoxyl rearrangement (Fig. 18). In this study, Courtneidge and Bush (27–29) converted the tertiary allylic hydroperoxide **53**, under azo-*bis*-isobutyryl nitrile initiation, to hydroperoxy cyclic peroxides: hydroperoxydioxane **56** (59%) and hydroperoxydioxolane **57** (41%). Applying the "radical clock" concept, Courtneidge's results, along with the estimate for 5-*exo* peroxyl radical closure of approximately $8 \times 10^2\ s^{-1}$ at 30°C (57), suggest that the 6-*exo* cyclization of **54** to **57** and the [2,3] allylperoxyl rearrangement of **54** to **55** have rate constants of approximately $10\ s^{-1}$ at 30°C.

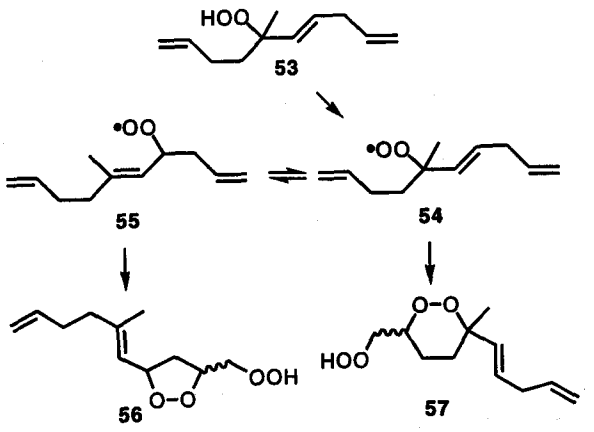


FIG. 18. Free radical initiated conversion of allylic hydroperoxide.

CONCLUSIONS AND PROSPECTS

This review has focused on the primary reactions that occur in the autoxidation of unsaturated fatty acids and esters. The reaction types that are observed in these fundamental transformations are relatively well understood. Hydrogen atom transfer to generate carbon free radicals from the lipid substrate, oxygen coupling to those radicals, peroxyl radical fragmentation and cyclization, and peroxyl radical hydrogen atom abstraction are the important reaction types that have been established in lipid peroxidation. While this review has dealt principally with unsaturated fatty acids and esters, similar mechanisms apply to the autoxidation of other unsaturated natural products, such as steroids (see Refs. 44–46).

Reaction product mixtures of autoxidized lipids are usually very complicated because many products can be formed as a result of these few important propagation reactions. Furthermore, the products of autoxidation, hydroperoxides and cyclic peroxides are themselves very reactive species, and

secondary products form from the decomposition of the primary peroxide oxidation products. The nature of these secondary products and the mechanisms of their formation are beyond the scope of this review.

Recent lipid autoxidation research efforts have focused on peroxidation in aggregates, including particles such as low-density lipoproteins (12,13,87–92). The importance of tocopherol mediated autoxidation and particle size on the course of autoxidation in aggregates has recently been the subject of intensive investigation. These factors can have dramatic consequences for the kinetics of autoxidation (93–97) and are presumably important not only for lipoproteins but also in the autoxidation of aggregates in foodstuffs or in the environment. The unraveling of the dynamics of such processes and how they affect the kinetics and products of autoxidation of these aggregate lipid forms should provide a new understanding of this age-old phenomenon.

ABSTRACT: The gastrointestinal handling and metabolism of [1-^{13}C]palmitic acid given as the free fatty acid was examined *in six* healthy women by measuring the excretion of ^{13}C-label in stool and in breath as $^{13}CO_2$. The gastrointestinal handling of [1-^{13}C]palmitic acid was compared with the apparent absorption of dietary lipid by measuring lipid losses in stool. The variation both within and between subjects was determined by repeating the study in the same individuals on separate occasions. The time course for excretion of label in stool over the five-day study period followed a common pattern, with most of the label excreted over the first two days of the stool collection. ^{13}C-Label excreted in stool over the five-day study period was 14.3 ± 9.8% of that administered and on repeating the trial was 31.6 ± 24.7% (not significantly different due to variability); there was poor agreement within subjects. Lipid excreted in stool expressed as a percentage of ingested lipid was 5.2 ± 4.4% in Trial 1 and 5.9 ± 4.0% in Trial 2, and was the same in each individual on repeating the trial. There was no clear relationship between the excretion of ^{13}C-label and lipid in stool (Trial 1: $R = -0.43$, $P > 0.40$; Trial 2: $R = -0.02$, $P > 0.97$). On the first occasion, 22.0 ± 4.5% of the administered label was excreted on breath over the 15-h study period and on repeating the trial was 15.8 ± 9.5% (not significantly different) with poor repeatability in a given individual. There was an inverse relationship between the proportion of ^{13}C-label excreted in stool and that excreted on breath in Trial 1 ($R = -0.80$, $P > 0.06$) with a weaker association observed in Trial 2 ($R = -0.49$, $P > 0.32$). Correcting for differences in the apparent absorption of label reduced the variability in its excretion in breath observed between subjects, particularly in Trial 2. It is concluded that although there are differences in the gastrointestinal handling of [1-^{13}C]palmitic acid both within and between healthy adults, the postprandial oxidation of absorbed substrate was similar. The assumptions underlying these observations need to be examined by characterizing the nature of ^{13}C-label in stool.
Lipids 30, 291–298 (1995).

The factors that determine the gastrointestinal handling of dietary triglycerides (triacylglycerols) and fatty acids and the subsequent metabolic fate in normal, healthy adults are not well understood. Measurements of gross fecal lipid losses made during balance studies in healthy adults (1,2), supported by *in vitro* digestion studies (3,4), have led to the general belief that the apparent absorption of dietary lipid is very efficient, with over 96% of the ingested dietary lipid normally absorbed. Such an approach assumes that all dietary fatty acids are handled equally across the gastrointestinal tract and fails to take into account the contribution made by endogenous losses and bacteria in stool to fecal lipid (5). Balance studies (6,7) and a study using ^{14}C-labelled fatty acids in the rat (8), suggest that both the chain length and degree of unsaturation of fatty acids, as well as the composition and stereospecific structure of triglycerides, may alter the apparent absorption of dietary lipids. Similar observations have been demonstrated in the few balance studies in healthy adults (9,10) and in both children (11) and adults with steatorrhoea (12). Further studies are needed to more precisely define the gastrointestinal handling and metabolic fate of fatty acids in normal health and disease in humans. One approach is to employ orally administered substrates labelled with ^{13}C.

From the rate and time course of excretion of ^{13}C-label in stool and breath $^{13}CO_2$, it is possible to assess the extent to which the labelled substrate is digested, absorbed, and subsequently oxidized by the body. Technical difficulties and the effort associated with the sample preparation and purification of CO_2 prior to analysis have previously limited attempts to measure the excretion of ^{13}C-label in stool. There has been only one published study where the proportion of label excreted in the stool was determined following the ingestion of [1-^{13}C]labelled fatty acids in healthy adults (13). Jones and co-workers (13) demonstrated that different [1-^{13}C]-labelled fatty acids were not handled by the body in the same way. [1-^{13}C]Stearic acid was relatively poorly absorbed by comparison to [1-^{13}C]oleic and linoleic acids, and the proportion of label recovered in the stool varied markedly between subjects (8–35%). However, there was no information on the repeatability of these observations in order to examine the within-subject variation.

We have developed a simplified approach to measure the excretion of ^{13}C in stool using innovative technology in isotope ratio mass spectrometry (14). The aim of the present study was to examine the gastrointestinal handling and me-

tabolism of [1-^{13}C]palmitic acid in a group of healthy women by measuring the excretion of ^{13}C-label in stool and on breath as $^{13}CO_2$. We were particularly interested in examining the gastrointestinal handling and metabolism of ^{13}C-labelled palmitic acid administered as the free acid. Palmitic acid is the most predominant long-chain saturated fatty acid in the United Kingdom diet (15) present in the form of mixed triglycerides. We have studied the gastrointestinal handling of [1-^{13}C]palmitic acid administered as the free acid, because it is free palmitic acid that is released from mixed triglycerides following digestion in the small intestine. The gastrointestinal handling of the [1-^{13}C]palmitic acid was compared to the apparent absorption of dietary lipid by measuring lipid in stool, but no relationship was observed. The variation within and between subjects was also examined by repeating the study in the same individuals on a separate occasion.

MATERIALS AND METHODS

Subjects. Six normal, healthy women, aged 21–30 yr, participated in the study. The subjects were members of staff at the University of Southampton. Informed consent was obtained, and the study protocol was approved by the Ethical Committee of Southampton and South West Hampshire Health Commission.

Study protocol. Each subject completed two trials separated by an interval of at least two months. After an overnight fast, the subjects consumed [1-^{13}C]palmitic acid at a dose of 10 mg/kg body weight (99% Atom Percent Excess; Tracer Technologies Inc., Somerville, MA) as part of a controlled standard test meal consisting of 120 g white bread, 100 g orange juice, and 10 g butter (1667 kJ). Butter, which consists predominantly of esterified palmitic acid (16), was used as a vehicle to administer the [1-^{13}C]palmitic acid. Breath samples were collected into breath collection bags (Quintron, Milwaukee, WI) before consuming the test meal to provide a measure of baseline ^{13}C-excretion on breath, and were then collected at hourly intervals for a period of 10 h, and again at 15 h in both trials. Specimen breath samples were transferred into evacuated gas sample containers (Exetainers; Labco, High Wycombe, United Kingdom) for analysis in duplicate. All the subjects were rested for the duration of the tests and were given constant supervision at the Clinical Nutrition and Metabolism Unit at Southampton General Hospital. No additional food or liquids were permitted during the initial 10-h period except for bottled mineral water. After 10 h the subjects consumed a meal without any foods naturally enriched in ^{13}C.

A baseline stool sample was collected on the day before the breath test study period to measure baseline ^{13}C-excretion. Thereafter, all stools passed were collected for five days following administration of the label. Carmine markers were taken with the test meal and at the end of the study to denote the five-day period. Stools were collected separately into polyethylene bags and immediately frozen. The Gompertz and Sammons modification (10) of the method of Van de Kamer *et al.* (17) was employed to measure lipid in stools passed on each day of the study period.

The subjects were instructed to avoid consuming naturally ^{13}C-enriched foods (e.g., corn or maize products, cane sugar) for at least two days prior to and during each five-day study period. None of the animal source protein foods consumed, e.g., eggs, meat, were from animals that consumed a corn-based diet. The same pre-selected diet was consumed throughout both trials to limit any effect that diet may have on the metabolism of [1-^{13}C]palmitic acid. This was achieved by recording the weighed food intake in Trial 1 and repeating the same diet in Trial 2. Within the group, the average contributions made by saturated, polyunsaturated, and monounsaturated fats to dietary energy were 9.3 ± 1.6, 3.4 ± 1.1 and 7.4 ± 1.4%, respectively. The food record from both trials were coded according to the McCance and Widdowson food tables (18) and analyzed using a computerized food composition database (Compeat 4; Lifeline Nutritional Services Ltd., London, United Kingdom).

In addition, the influence of the test meal on ^{13}C-enrichment on breath $^{13}CO_2$ was examined in a third trial on each subject by having the subject consume the same test meal without [1-^{13}C]palmitic acid.

Breath and stool sample analyses. Stools were weighed and homogenized with distilled water, and aliquots were then freeze-dried overnight (Genevac, Ipswich, United Kingdom) to a constant weight. Samples of freeze-dried stool (5 mg) were weighed into tin capsules (Elemental Microanalysis, Okehampton, United Kingdom) for analysis in duplicate. Enrichment of ^{13}C in breath as $^{13}CO_2$ and in stool was analyzed by continuous flow isotope ratio mass spectrometry (ANCA system; Europa Scientific Ltd., Crewe, United Kingdom). The analytical precision for mass spectrometric analyses of reference CO_2 gas and sugar beet calculated from ten samples were (SD) 0.06‰ and 0.03‰, respectively.

Measurement of ^{13}C-enrichment in breath $^{13}CO_2$ and stool. The ^{13}C-enrichment of samples of breath $^{13}CO_2$ and stool was expressed as the per mil relative difference from the reference standard Pee Dee Belemnite limestone (PDB) as defined by Craig ($^{13}C_{PDB}$, ‰) (19). The proportion of administered ^{13}C-label in stool was calculated according to the formula presented by Schoeller and co-workers (20). The enrichment of ^{13}C in each sample is calculated from the increase in the ratio of $^{13}CO_2$ to $^{12}CO_2$ as measured by continuous flow isotope ratio mass spectrometry. This sample ratio is compared with that obtained from a working reference standard, being 5% CO_2 and beet sugar for samples of breath and stool, respectively. The results are then expressed as the "del per mil" (parts per thousand) difference between the $^{13}CO_2/^{12}CO_2$ ratios of the samples and the reference standard. Whole body CO_2 excretion was measured by indirect calorimetry (Deltatrac; Datex Instrumentarium Corporation, Helsinki, Finland) at the same time points as the breath sampling. The proportion of ^{13}C-label excreted in breath $^{13}CO_2$ was expressed as a percent of administered ^{13}C-label calculated from the area under the curve over the 15-h study period.

Measurement of the natural ^{13}C-abundance of the test meal. A test meal was homogenized with 100 g of distilled water, and six aliquots were freeze-dried to a constant weight. Samples from each aliquot of the freeze-dried meal were weighed into tin capsules for analysis in duplicate for enrichment of ^{13}C by isotope ratio mass spectrometry. The natural ^{13}C-abundance of the test meal from duplicate analyses of six separate aliquots of homogenized test meal was −25.5 ± 0.07‰.

Presentation of results and statistical analysis. The results are reported as means ± SD. Statistical comparisons between the data were performed using the paired *t*-test. Differences between means were considered statistically significant where $P < 0.05$. Associations between variables were tested by the Pearson product moment correlation coefficient (R).

RESULTS

Analytical precision. In the present study the average SD for duplicate analyses of breath from all time points was small (less than 0.13‰). Greater variation was observed from duplicate analyses of stool samples collected from all the subjects over the study period (SD 0.85‰). On a separate occasion, the daily variation of ^{13}C-abundance in stools collected over five days was determined within the same individuals consuming no ^{13}C-label or ^{13}C naturally enriched foods. The SD within each individual was no greater than 0.6‰.

Background variation of ^{13}C on breath as $^{13}CO_2$ after an unlabelled test meal. The background variation of ^{13}C on breath was examined in all the subjects by collecting breath samples before consuming an unlabelled test meal, and then at hourly intervals for 10 h, and again at 15 h. Within the group, the pre-meal abundance of ^{13}C on breath was −26.6 ± 0.43‰. There was no detectable increase in the average postprandial excretion of ^{13}C on breath over the 15-h study period (−25.9 ± 0.33, not significantly different from baseline values). The between-subject ^{13}C-variation on breath from all time points was small (average SD 0.41‰). The within subject variation of ^{13}C on breath had an SD of less than 0.63‰.

Excretion of ^{13}C and lipid in stool. Within the group, the baseline abundance of ^{13}C in stool was −26.2 ± 0.75‰ in the first trial. All subjects passed stools on each day of the five-day study period. The greatest levels of enrichment in stool were observed over the first two days of the study period (Fig. 1). The peak enrichment of ^{13}C-label in stool was −15.0 ± 8.3‰. Thereafter the level of ^{13}C-enrichment declined, and after five days the enrichment of ^{13}C in stool was comparable to baseline values. However, there was one exception in the first trial where the enrichment of ^{13}C in stool in subject 3 increased by day five as no label was passed in stool on days two, three, and four of the study period.

On repeating the trial, the baseline abundance of ^{13}C in stool (−25.7 ± 0.50‰), the time course, and peak enrichment (−19.7 ± 73‰) were similar to those in Trial 1. However, much greater variability in the second trial compared to Trial 1 resulted from subject 6, having an exceptionally high level of enrichment of ^{13}C in stool (166.2‰) on the first stool passed.

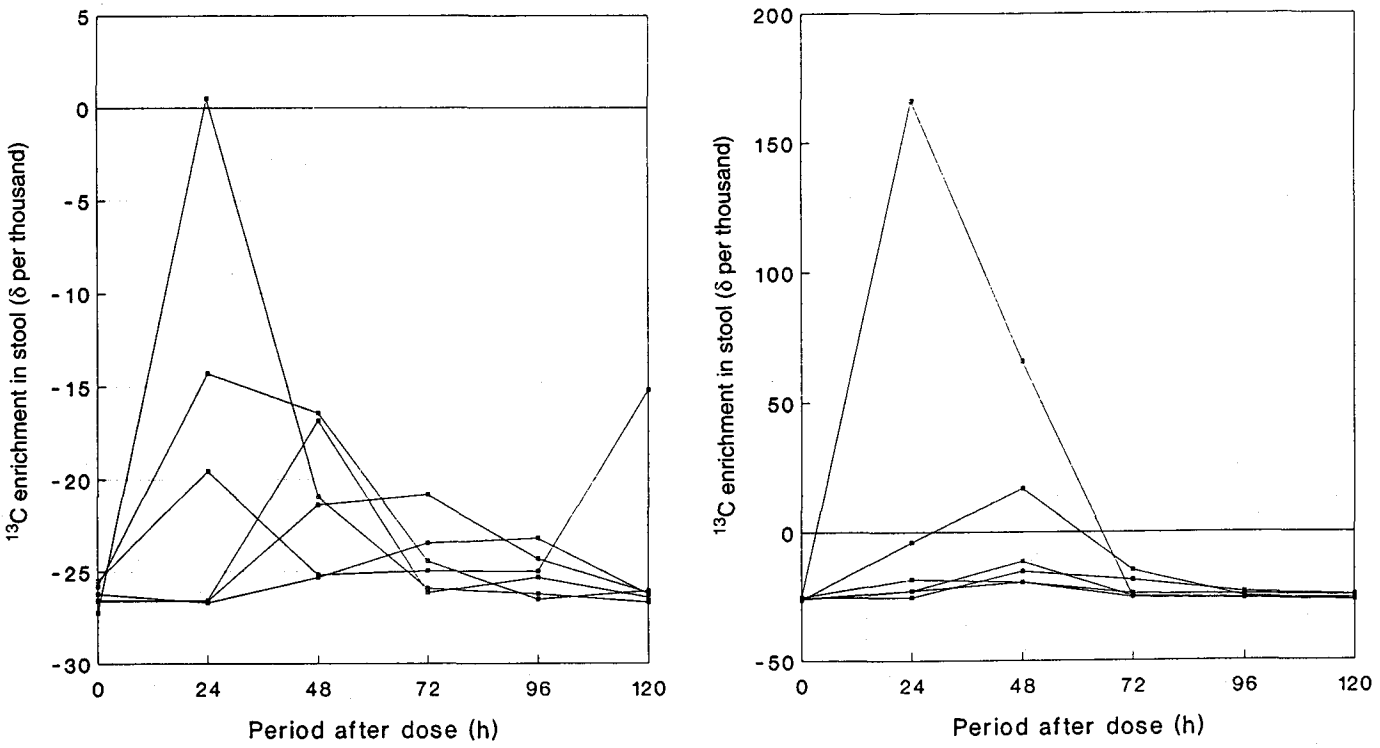

FIG. 1. Time courses for the ^{13}C-enrichment in stool over the five-day study period in six healthy women in Trials 1 and 2. The y-axis is different as one subject in the second Trial had a high enrichment of ^{13}C in the first stool passed.

TABLE 1
The Excretion of Lipid in Stool (% lipid ingested) and the Proportions of ^{13}C-Label Excreted in Stool and on Breath as $^{13}CO_2$ and Retained Within the Body Pools Following Orally Administered [1-^{13}C]Palmitic Acid in Six Healthy Women[a]

Subject number	Stool ^{13}C (% admin[b] ^{13}C)		Stool lipid (% lipid ingested)		Breath $^{13}CO_2$ (% admin ^{13}C)		Body pools (% absorbed ^{13}C)		Breath $^{13}CO_2$ (% absorbed ^{13}C)	
	Trial 1	Trial 2	Trial 1	Trial 2	Trial 1	Trial 2	Trial 1	Trial 2	Trial 1	Trial 2

[a]No correction factor has been used to account for the retention of $^{13}CO_2$ in the body pools.
[b]admin, Administered.

In the first trial ^{13}C-label excreted in stool over the five-day study period was 14.3 ± 9.8% of that administered with a fourfold difference between subjects (Table 1). On repeating the trial the ^{13}C-label excreted in stool over the five days was 31.6 ± 24.7% of that administered, with a ninefold difference between subjects. The ^{13}C-label excreted in stool was not significantly different between the trials. There was very poor repeatability in the amount of ^{13}C-label excreted in stool expressed as a proportion of that administered within a given individual.

In the first trial the average dietary intake of lipid over the 5-d study period was 63.6 ± 8.6 g/g, and, on repeating, the trial was 58.9 ± 8.8 g/d (not significantly different). The excretion of lipid in stool was 3.2 ± 2.2 g/d in Trial 1. On repeating the trial, lipid excreted in stool was similar to that observed in the first trial (3.4 ± 2.9 g/d, not significantly different). When expressed as a percentage of that ingested, the excretion of lipid in stool was 5.2 ± 4.4% in Trial 1 and 5.9 ± 4.0% in Trial 2 (not significantly different; Table 1). Within each individual, the excretion of lipid was similar on both occasions even for subject 1, who had a relatively high value for lipid in stool. In both trials there was no relationship between the excretion of ^{13}C-label and lipid in stool (Trial 1: R = –0.43, $P > 0.40$; Trial 2: R = –0.02, $P > 0.97$; Fig. 2).

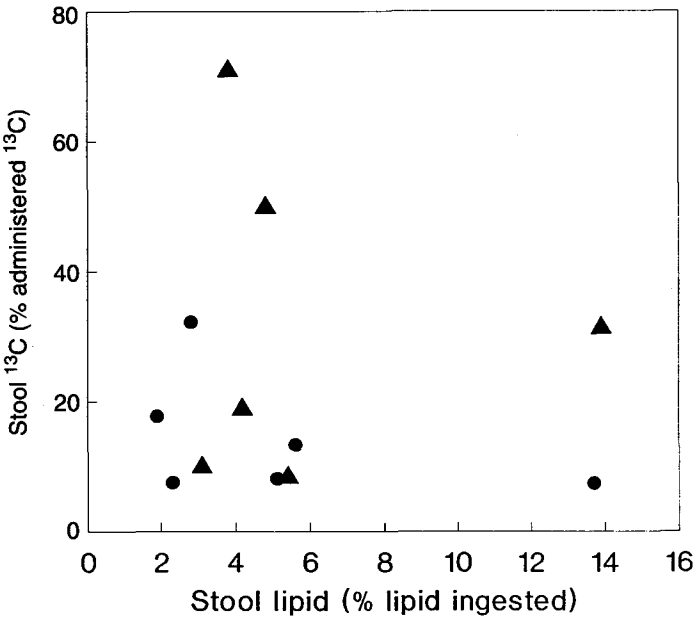

FIG. 2. Stool lipid (% lipid ingested) vs. ^{13}C in stool (% dose administered) in six healthy women in Trials 1 (●) and 2 (▲) (Trial 1: R = –0.43, $P > 0.40$; Trial 2; R = –0.02, $P > 0.97$).

Breath $^{13}CO_2$ excretion measurements. Within the group, the baseline ^{13}C-abundance on breath prior to consuming the test meal was –25.9 ± 0.6‰ in Trial 1. All the subjects exhibited a similar time-course pattern for the excretion of ^{13}C-label on breath over the 15-h study period (Fig. 3). The peak excretion of ^{13}C-label on breath occurred at 6 h (range 4–9 h) after administering the ^{13}C-labelled test meal. The enrichment of ^{13}C on breath at peak excretion was –15.3 ± 2.2‰. At the end of the 15-h study period, the enrichment of ^{13}C on breath had almost returned to the level of baseline ^{13}C-abundance (–22.4 ± 2.0‰). Consuming a test meal 10 h after administering the ^{13}C-label did not increase the excretion of ^{13}C-label on breath as $^{13}CO_2$.

On repeating the trial, the baseline ^{13}C-abundance on breath (–28.0 ± 0.9‰), the time at which peak excretion of ^{13}C-label occurred on breath (6.5 h; 5–8 h), and the time course for excretion of ^{13}C-label on breath over the 15-h study period were similar to Trial 1 (Fig. 3). The enrichment of ^{13}C on breath at peak excretion was less than that observed in Trial 1 (–21.0 ± 2.8‰; $P < 0.01$). The enrichment of ^{13}C on breath at the end of the 15-h study period was closer to baseline ^{13}C-abundance in Trial 2 (–26.0 ± 0.7‰) than that observed in the first trial.

In the first trial, the peak excretion of label on breath when expressed as a proportion of administered ^{13}C was 2.7 ± 0.5%. Over the 15-h study period the excretion of ^{13}C on breath was 22.0 ± 4.5% of that administered (Table 1). On repeating the trial, both the peak excretion of label (1.8 ± 1.0%) and excretion of label on breath over the 15-h study period

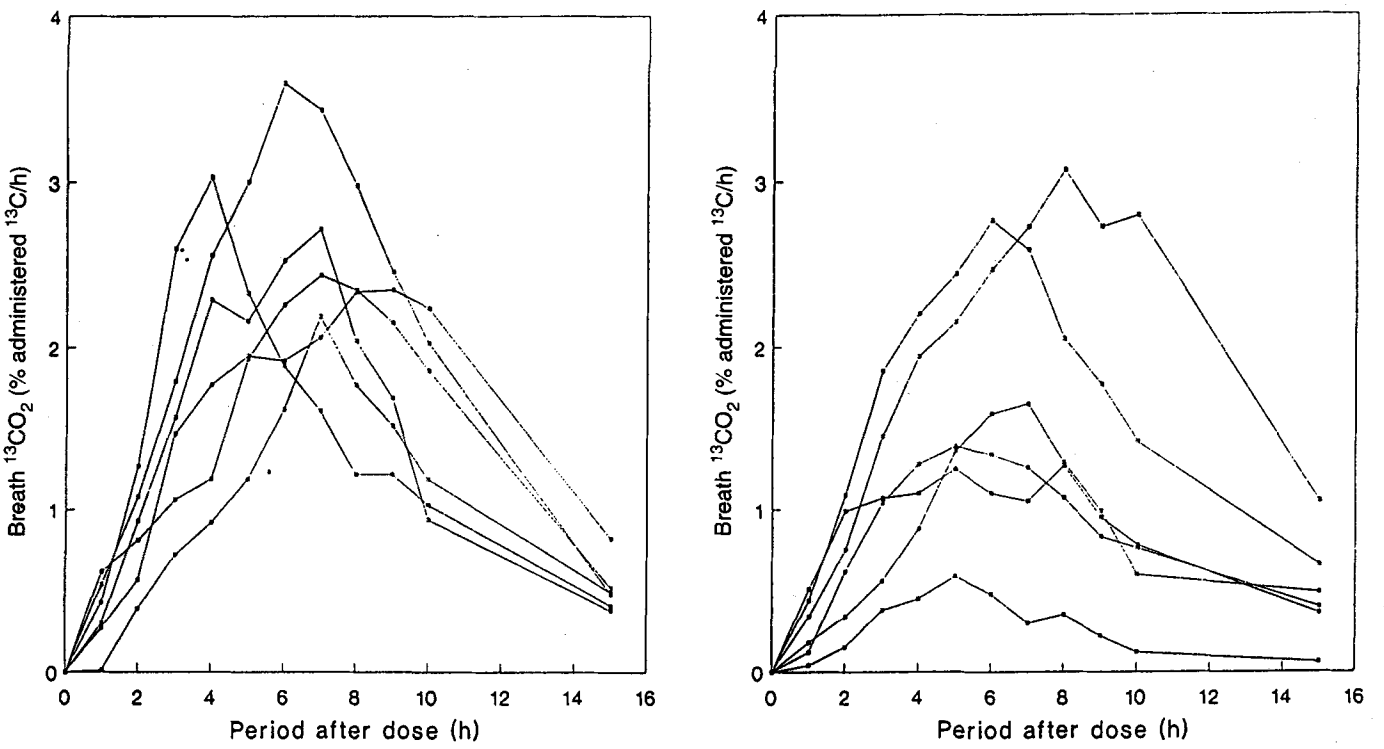

FIG. 3. Time courses for the excretion of ^{13}C on breath as $^{13}CO_2$ over 15 h following oral administration of [1-^{13}C]palmitic acid in six healthy women in Trials 1 (left) and 2 (right).

(15.8 ± 9.5%) tended to be less than that observed in Trial 1 (not significantly different). There was poor repeatability in the amount of ^{13}C-label excreted on breath expressed as a proportion of that administered within a given individual.

There was an inverse relationship between the proportion of ^{13}C-label excreted in stool and that excreted on breath in Trial 1 ($R = -0.80$, $P > 0.06$), with a weaker association observed in Trial 2 ($R = -0.49$, $P > 0.32$; Fig. 4).

Excretion of absorbed ^{13}C on breath as $^{13}CO_2$. The apparent absorption of ^{13}C-label was determined from the difference between label administered and that excreted in stool. The proportion of label excreted on breath $^{13}CO_2$ was then expressed as a proportion of label that was apparently absorbed. Correcting the excretion of ^{13}C-label on breath for differences in apparent absorption reduced the differences between subjects in Trial 1 (2-fold to 1.4-fold difference). Within the group, the amount of ^{13}C-label excreted on breath over the 15-h study period was 25.2 ± 3.0% of that absorbed in Trial 1 (Table 1). On repeating the trial the recovery of absorbed label on breath was 22.6 ± 11.0% (not significantly different to Trial 1). A much greater reduction in the differences between subjects was observed in Trial 2 (ninefold to threefold difference).

^{13}C-label retained within the body pools. The proportion of absorbed label which was not excreted on breath was expressed as retained ^{13}C-label. Within the group, the proportion of absorbed label that was not excreted on breath was 74.9 ± 3.0% in Trial 1 (Table 1). On repeating the trial the proportion of retained ^{13}C-label was similar to Trial 1 (77.4 ± 11.0%). Comparable values were observed between the same subjects on both occasions.

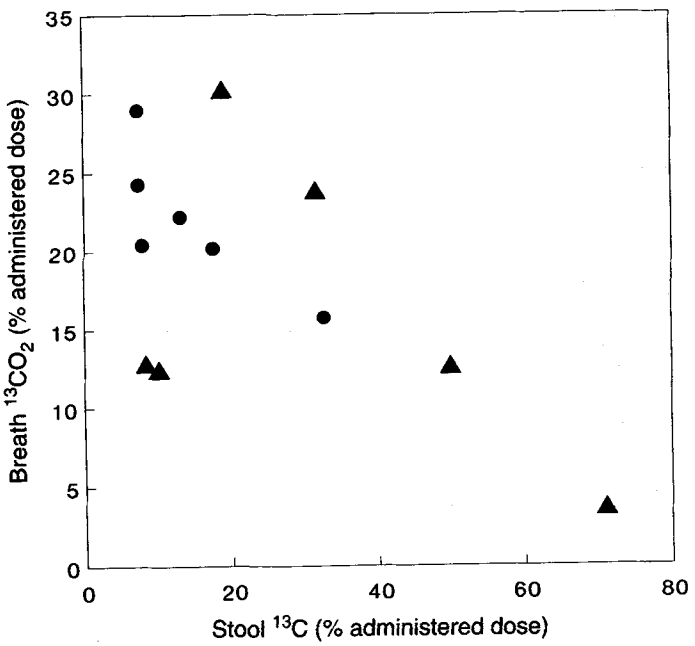

FIG. 4. ^{13}C-Label in stool (% dose administered) vs. ^{13}C-label on breath as $^{13}CO_2$ (% dose administered) in six healthy women in Trials 1 (●) and 2 (▲) (Trial 1: $R = -0.80$, $P > 0.06$; Trial 2: $R = -0.49$, $P > 0.32$).

DISCUSSION

The present investigation was designed to examine the gastrointestinal handling and metabolism of [1-^{13}C]palmitic acid given orally as the free fatty acid in healthy women. From the rate and time course of the excretion of ^{13}C-label in stool and on breath as $^{13}CO_2$, we have determined the extent to which the labelled substrate was apparently absorbed and subsequently oxidized by the body. To our knowledge, this investigation represents the first time that the gastrointestinal handling of [1-^{13}C]palmitic acid has been studied and compared with the handling of dietary lipid in healthy individuals.

Gastrointestinal handling and metabolic fate of [1-^{13}C]palmitic acid. The proportion of ^{13}C-label excreted in stool ranged from 7.4–32.4% within the group and reflected marked differences between healthy subjects in the gastrointestinal handling of [1-^{13}C]palmitic acid. It is not known whether the ^{13}C-label measured in stool is present in the same form as that ingested, i.e., as ^{13}C-labelled palmitic acid. The observed differences between subjects in the gastrointestinal handling of [1-^{13}C]palmitic may be partly accounted for by differences in the nature of label in stool. Further studies are needed to characterize the form of label in stool if the gastrointestinal handling of ^{13}C-labelled substrates are to be interpreted correctly. Assuming that ^{13}C-label excreted in stool is ^{13}C-labelled palmitic acid, the apparent absorption of label would have ranged from 67.6 to 92.6%. The time course for the excretion of label in stool over the five days followed a common pattern, with most of the label excreted in stool over the first two days of the study period.

These results in healthy women are generally similar to those reported for [1-^{13}C]stearic acid by Jones *et al.* (13) in healthy men, and are consistent with those observed from animal studies using ^{14}C-labelled saturated and unsaturated fatty acids (9). Taken together, these observations would suggest that long-chain [1-^{13}C]-labelled saturated fatty acids are not absorbed as well as [1-^{13}C]-labelled unsaturated fatty acids, and that there are wide differences between subjects in the apparent absorption of saturated fatty acids (when ingested as the free fatty acid).

The extent to which the [1-^{13}C]palmitic acid label, administered as the free acid, is handled within the body in the same way as palmitic acid derived by hydrolysis from mixed triglycerides in the diet is not known. At present it is assumed that the [1-^{13}C]-labelled free palmitic acid behaves in the same way as free fatty acids derived from hydrolysis within the lumen of the small intestine. Under normal circumstances, palmitic acid is consumed in the diet in the form of mixed triglycerides predominantly esterified in the *sn*-1 and *sn*-2 positions (16). Hydrolysis of dietary triglycerides by pancreatic lipase and other enzymes, such as carboxyl ester hydrolase in the intestinal lumen, forms 2-monoacylglycerols and fatty acids (2). The products of digestion are absorbed following solubilization with bile salts into mixed micelles. While the 2-monoacylglycerol products of hydrolysis are a well-absorbed form of most fatty acids, it is possible that free fatty acids from the *sn*-1 position may not form mixed micelles as readily as the 2-monoacylglycerol (21). The differences observed in the apparent absorption of [1-^{13}C]palmitic acid between subjects could be attributable to poor solubilization of the fatty acid into micelles. A proportion of the free fatty acids may have formed insoluble soaps with divalent cations in the gastrointestinal tract and may have been excreted in stool (22). Further studies using ^{13}C-labelled mixed triglycerides are required to determine whether the labelled free fatty acid used in the present study is handled in the same manner as a labelled fatty acid esterified into triglycerides at either the *sn*-1 or *sn*-2 positions.

Lipid excreted in stool showed a greater apparent absorption of dietary lipid compared to the gastrointestinal handling of [1-^{13}C]palmitic acid. Differences in the gastrointestinal handling of [1-^{13}C]palmitic acid and lipid were evident from the poor association observed between ^{13}C-label and lipid in stool. This would suggest that [1-^{13}C]palmitic acid was not handled in the same way as lipid in the diet. It may be that the ^{13}C-labelled palmitic acid used in the present study is not a representative form of dietary fatty acids in general, yet is the most frequently occurring fatty acid in terms of its apparent absorption. Alternatively, it could be that the presentation of ^{13}C-labelled palmitic acid to the absorptive site may not be the same as palmitic acid normally hydrolyzed from dietary triglycerides in the gastrointestinal tract. A previous study has shown that emulsified deuterated triglycerides have an apparent absorption above 90% when heated to a temperature of 80°C or above (23), which is similar to that observed in the present study for the apparent absorption of dietary lipid. The [1-^{13}C]palmitic acid label was administered in a form (added to butter) which is different than that for dietary lipid, which is often heated or contains emulsifiers. It could be that part of the discrepancy observed between the apparent absorption of the ^{13}C-labelled palmitic acid and dietary lipid could be attributable to differences in the form of the ingested lipids vs. administered label.

Oxidation of the absorbed ^{13}C-labelled palmitic acid was examined by measuring the excretion of ^{13}C-label on breath as $^{13}CO_2$. It has been shown that the most significant factor which can influence the sensitivity and precision of measurements of ^{13}C on breath as $^{13}CO_2$ is the normal variability of baseline ^{13}C-to-^{12}C ratio (24). In the present study, the between-subject variation in baseline ^{13}C-abundance on breath in Trials 1 and 2, although small, was -25.9 ± 0.6‰ and -28.0 ± 0.9‰, respectively, in healthy women who excluded foods with a high natural ^{13}C-enrichment. The between-subject differences in baseline ^{13}C-abundance values demonstrate the importance of measuring baseline levels in studies examining the excretion of label on breath as $^{13}CO_2$. The proportion of administered ^{13}C-label excreted on breath over the 15-h period ranged from 15.7 to 29.0%. There was a smaller difference between subjects in the proportion of administered ^{13}C-label excreted on breath compared to the variability observed in the gastrointestinal handling of the ^{13}C-labelled palmitic acid. Correcting for differences in the apparent ab-

sorption of label reduced the between-subject variability in oxidation. This would suggest that, once absorbed, the metabolic fate of the label, in particular the oxidation of absorbed substrate, was similar (approximately 20–25%).

On average, the proportion of ^{13}C-label excreted on breath could be underestimated by 13.3% if expressed directly as ^{13}C-label administered rather than as ^{13}C-label made available through absorption. The proportion of ^{13}C-label unaccounted for (not recovered as either stool over 5 d or breath over 15 h) ranged from 69 to 78%. The extent of further oxidation of the label following retention within the body pools after the 15-h study period was not determined. However, limited observations in the same group of individuals demonstrated that the excretion of ^{13}C-label on breath remained at baseline levels after a 24-h study period. Furthermore, not all of the CO_2 generated from the label would have been excreted as breath $^{13}CO_2$. A proportion of the $^{13}CO_2$ formed from oxidation of the labelled substrate is not directly excreted on breath but may be retained in the body pools or excreted *via* urine, skin (25), and stool (26). The body pools are believed to consist of a central, rapidly turning-over, vascular pool which includes CO_2 in the circulation, a peripheral rapidly turning-over pool including organs with a high perfusion rate (heart, brain, liver), and a more slowly turning-over pool which includes muscle, adipose tissue, and bone (27). Previous studies have either presented uncorrected data (28) or have employed correction factors to more accurately predict the extent of oxidation of labelled substrates (29,30). Exactly how much of the CO_2 is retained in the body pools remains unresolved, with estimates ranging from less than 10 to 50% (27). There is a wide range in the reported values for retention of CO_2 in the body pools arising from differences in the type and duration of experiments, and whether the subjects were fasted or fed over the study periods. The values reported in the present study for the oxidation of absorbed label have not been corrected for the retention of $^{13}CO_2$ in the body pools and, as such, are underestimates. Preliminary results of studies from our group have shown that over 24 h, 69% of an intravenous dose of $NaH^{13}CO_3$ could be excreted on breath in the same group of individuals (31). Applying this correction factor to the values in the present study would result in approximately 36.5% of the absorbed label being oxidized as opposed to 25.2%.

These results would suggest that approximately a third of the absorbed [1-^{13}C]palmitic acid was oxidized over the 15-h study period. The values observed are much greater than those reported for the long-chain saturated fatty acid, [1-^{13}C]stearic acid, where only 3% of the absorbed stearic acid was oxidized over the postprandial study period of 9 h (29). It appears that the metabolic fate of [1-^{13}C]stearic acid differs markedly from the observations made for [1-^{13}C]-palmitic acid in the present study despite similarities in the design of the study and in apparent absorption.

Within subject variation in the gastrointestinal handling and metabolic fate of [1-^{13}C]palmitic acid. On repeating the trial to examine within-subject differences, there was a greater range in the gastrointestinal handling of [1-^{13}C]-palmitic acid compared to the first trial. The excretion of ^{13}C-label in stool ranged from 8.3 to 71.0% with poor agreement within each subject. Assuming that ^{13}C-label excreted in stool is ^{13}C-labelled palmitic acid, the apparent absorption of label would have ranged from 29.0 to 91.7%. The greatest difference within a given subject between trials was observed in subject 6, with an apparent absorption of 92% in the first trial and 29% on repeating the trial. This would suggest that, within a given individual single measurement using [1-^{13}C]palmitic acid, label should be interpreted with caution owing to the variability in apparent absorption.

The time course for the excretion of label in stool over the five days followed a similar pattern to that observed in the first trial, with most of the label excreted in stool over the first two days of the study period. In contrast, the lipid excreted in stool was similar to that observed in the first trial, with good agreement within each subject. This would suggest that, on repeating the trial, the apparent absorption of dietary lipid still remained greater than the apparent absorption of [1-^{13}C]-palmitic acid, with no relationship between the two variables.

In the second trial, differences in the proportion of administered ^{13}C that was excreted on breath between subjects were much greater than that observed in the first trial (3.5–23.7%), with poor repeatability within a given individual. There were smaller differences between subjects in the proportion of administered label excreted on breath as compared to the variability in the gastrointestinal handling of labelled substrate, which was similar to that observed in the first trial. Those subjects with the lowest enrichment of ^{13}C on breath tended to exhibit the highest enrichment of ^{13}C in stool.

Although there were greater differences between subjects in the gastrointestinal handling of [1-^{13}C]palmitic acid in the second trial compared to the first trial, the oxidation of absorbed label was similar. On average, the proportion of label excreted on breath could be underestimated by approximately 31% if expressed directly as ^{13}C-label administered rather than as ^{13}C-label made available through absorption. Taken with the observations from the first trial, the effect of correcting for differences in the gastrointestinal handling of label appeared to be small when considered as a group. However, for a given individual, differences in the apparent absorption could markedly alter the interpretation of label excreted on breath. This would suggest that there is a need to account for the amount of ^{13}C-label in stool where a more objective, quantitative approach to examine gastrointestinal handling and metabolism of substrates is required.

In conclusion, the present study has examined the gastrointestinal handling and metabolism of [1-^{13}C]palmitic acid in six healthy women. There were greater differences in the gastrointestinal handling of [1-^{13}C]palmitic acid, both within and between subjects, than the post prandial oxidation of absorbed label. Taken together with the observations by Jones *et al.* (29), it appears that the metabolic fate of [1-^{13}C]-labelled long-chain saturated fatty acids differs markedly despite similarities in apparent absorption. Assuming that the

^{13}C-label excreted in stool is ^{13}C-labelled palmitic acid, the gastrointestinal handling of [1-^{13}C]palmitic acid was different from that observed from dietary lipid in general. The assumption that the ^{13}C-label in stool reflects dietary residue needs to be examined by characterizing the nature of label in stool.

Dietary Fat Alters the Distribution of Cholesterol Between Vesicles and Micelles in Hamster Bile

ABSTRACT: The type of dietary fat strongly affects the incidence of gallstones in the hamster model of cholesterol cholelithiasis. The present study was designed to determine whether dietary fats could affect gallstone formation by altering the microstructure (vesicular/micellar ratio) of cholesterol in bile. Golden Syrian hamsters from Sasco (Omaha, NE) or Charles River (Wilmington, MA) were fed nutritionally adequate semipurified diets to which were added: (i) 4.0% butterfat without added cholesterol; (ii) 1.2% palmitic acid plus 0.3% cholesterol; or (iii) 4.0% safflower oil plus 0.3% cholesterol. Gallstone incidence and the percentage of cholesterol in vesicles and micelles were determined after two- or six-week feeding periods. Three out of ten Sasco hamsters fed the 1.2% palmitic acid diet for two weeks had cholesterol stones, while none of the eight Charles River animals had stones. In the Sasco hamsters, a significant proportion of the biliary cholesterol was found in void volume vesicles (28.8%) and small vesicles (17.1%); Charles River hamsters had negligible proportions (1.1%) of cholesterol in void volume vesicles and 15.4% in small vesicles. Cholesterol gallstones were most abundant in Sasco hamsters fed 1.2% palmitic acid for six weeks (nine out of ten animals); the mean cholesterol saturation index of the bile was 1.27. A significant proportion of the biliary cholesterol was eluted in the void volume vesicles (21.4%) and in small vesicles (15.0%). Five of the eight identically treated Charles River hamsters had cholesterol stones; the cholesterol saturation index averaged 1.36, and the biliary cholesterol was present in void volume vesicles (31.3%) and small vesicles (14.3%). Vesicles were not detected in the bile of hamsters fed cholesterol-free diets, and none of these animals developed cholesterol gallstones. Safflower oil diets inhibited stone formation even though the cholesterol saturation index was above unity. After six weeks, biliary cholesterol transported in void volume vesicles was highest for Sasco hamsters (13.3%) as compared to Charles River animals (6.9%), but total cholesterol transported in void volume vesicles plus small vesicles was similar in both groups (33.5% vs. 26.2%), respectively. These results suggest that in both strains of hamsters dietary fat influences gallstone formation by modulating the vesicular/micellar distribution of biliary cholesterol. Apparently, the presence of cholesterol/phospholipid vesicles in bile is associated with cholesterol gallstone formation.

Lipids 30, 299–305 (1995).

Animal models of cholesterol cholelithiasis have enabled investigators to study certain aspects of the pathogenesis and course of this important human disease (1–7). In the hamster model, cholesterol cholelithiasis was found to be a function of age, gender, genetic background, composition of the lithogenic diet, and duration of the feeding period (1,2,5).

The animal model developed in our laboratory employed young male golden Syrian hamsters from Sasco, Inc. (Omaha, NE), which were fed nutritionally adequate semipurified diets (SPD) for six weeks. The diets contained 4% butterfat and 0.3% cholesterol. At the end of that period, cholesterol gallstones were present in 50–80% of the animals. Stone incidence was strongly dependent on the type and percentage of fat, in the diet. Thus, substitution of safflower oil for butterfat resulted in a significant decrease in gallstone incidence (6). Butterfat is high in palmitic acid, whereas safflower oil contains more than 75% linoleic acid. Nevertheless, with either fat, the cholesterol saturation index (CSI) of the bile exceeded unity (6). The reason for the observed difference in the incidence of gallstones remained unclear.

In previous studies it was found that human bile was frequently supersaturated with cholesterol but that stones or cholesterol crystals were not necessarily present (8–11). This unexpected result was ascribed to the presence of cholesterol–phospholipid vesicles in bile (12,13). Although such vesicles are inherently unstable and eventually deposit cholesterol crystals, they can persist for hours or days (12,13). It was originally hypothesized that cholesterol was solubilized in bile in the form of cholesterol–phospholipid–bile acid mixed micelles (13). However, studies by Sömjen and Gilat (14,15) and Pattinson *et al.* (16,17) identified large cholesterol–phospholipid vesicles in both hepatic and gallbladder bile. Such metastable vesicles increased cholesterol solubility in bile; they were converted to micelles in the presence of bile

acids. An explanation for the prolonged persistence of vesicles in bile is under intensive study.

We have reported that the presence of cholesterol stones or crystals in gallbladder bile is associated with the presence of relatively large proportions of vesicular cholesterol carriers (18). Other investigators (19) reported differences in cholesterol gallstone incidence from those reported by us (5). These differences were probably due to experimental variables such as animal source, composition of the lithogenic diet, and duration of feeding. The present experiments were undertaken to further investigate the cholesterol carriers in hamster bile in the presence or absence of biliary cholesterol crystals and stones. We hypothesized that differences in cholelithiasis were due to differences in the relative proportions of these cholesterol carriers. Hamsters from two sources [Sasco; and Charles River (Wilmington, MA)] were studied as previous work indicated that stone incidence in these animals differed significantly (5). It was found that the source of the hamsters, the feeding period, and the type of dietary fat affected gallstone incidence and that there was a distinct correlation between the increase of the vesicular/micellar ratio in bile and the development of cholesterol cholelithiasis.

MATERIALS AND METHODS

Animals and diets. Male golden Syrian hamsters (*Mesocricetus auratus*), four weeks of age, weighing between 60 and 70 g, were purchased from either Sasco, Inc. or from Charles River Breeding Laboratories and fed rodent chow for 4–6 d prior to the start of the experiment. Animals from each supplier were randomized into 7–10 animals/group and fed the following for either two or six weeks: (i) SPD plus 4% butterfat (0% cholesterol) (groups 1, 4, 7, 10); (ii) SPD plus 1.2% palmitic acid plus 0.3% cholesterol (groups 2, 5, 8, 11); or (iii) SPD plus 4.0% safflower oil plus 0.3% cholesterol (groups 3, 6, 9, 12). Food intake was monitored throughout the experiment. All animals were fasted 24 h prior to sacrifice to ensure maximum quantities of bile. Animals were anesthetized with 20 mg of ketamine hydrochloride (Aveco Co., Inc., Fort Dodge, IA). Blood was withdrawn *via* cardiac puncture. The gallbladder was visualized, and bile was removed using a Hamilton syringe. The bile was immediately examined under polarized light microscopy for the presence of cholesterol stones and crystals. Bile samples (20–50 μL per animal) from animals in the same group were pooled to obtain adequate quantities (>200 μL) for analysis and centrifuged at 2000 × *g* for 20 min. The supernatant, minimum volume 200 μL, was recovered and equilibrated with 0.25 μCi radiolabeled 1-palmitoyl-2-[1-^{14}C]oleoyl-*sn*-glycero-3-phosphocholine (53 mCi/mmol; Amersham Corp., Arlington Heights, IL) and 0.25 μCi of [1α,2α(n)-^{3}H]cholesterol (45.6 Ci/mmol) (NEN Research Products, Boston, MA) for 60 min at 37°C.

Column chromatography. Cholesterol carriers in bile (vesicles, micelles) were separated on Sepharose CL-4B-200 (Pharmacia, Piscataway, NJ) using the procedure of Pattinson (16,17), with some modifications. Sepharose was equilibrated with buffer (see below) in a 20 × 1.5-cm Pharmacia column. These methods have been described in detail (18). The elution pattern was similar to that described by Pattinson; vesicles were eluted in the void volume (fractions 20–30), followed by small vesicles (fractions 30–45) and micelles (fractions 45–80) (Figs. 1–3). A total of 90 fractions (500 μL each) was collected in 1.5 mL microfuge tubes using an LKB fraction collector. An aliquot from each sample (100 μL) was counted in Aquasol-2 (NEN Research Products) using a Beckman (Palo Alto, CA) 3801 liquid scintillation system. The percentages of cholesterol and phospholipids were determined from the radiolabeled cholesterol and phospholipid present in each sample. All samples were counted for 10 min. Corrections for background and quenching were made using appropriate blanks and standards.

Analytical procedures for biliary lipids. An aliquot of the fresh bile used for column chromatography was analyzed for biliary lipids [determined as described earlier (6)]. The concentration of total lipids in bile was used to calculate the CSI (20).

Statistical analyses. Differences in gallstone incidence between groups were determined using chi-square.

RESULTS

Gallstone incidence at sacrifice is summarized in Table 1. Stone incidence was always higher in Sasco than in Charles River animals. In the absence of exogenous cholesterol, neither Sasco nor Charles River hamsters developed cholelithiasis. Under the conditions employed, dietary palmitic acid (1.2%) gave the highest incidence of gallstones. Sasco hamsters fed palmitic acid had cholesterol gallstones after two weeks (30%, group 2); lithiasis increased significantly to 90% after six weeks (group 5). Charles River hamsters fed the identical diet did not have stones after two weeks (group 8); cholesterol gallstones were detected after six weeks (63%, group 11). Dietary safflower oil significantly reduced the incidence of stones in both Sasco (groups 3 and 6) and Charles River hamsters (groups 9 and 12). Gallstones were present only in Sasco animals fed safflower oil plus 0.3% cholesterol for six weeks (22%, group 6); stones were completely absent from the other safflower oil-fed hamsters (groups 3, 9 and 12).

The biliary lipid composition is also summarized in Table 1. Analyses were performed on the same pooled samples of bile which were used for the chromatographic separation of vesicles and micelles. The CSI of all Sasco hamsters fed cholesterol for either two or six weeks exceeded 1.0 (groups 2, 3, 5, and 6). The bile of Sasco animals fed butterfat diets without cholesterol (groups 1 and 4) was nonlithogenic. In contrast, the bile of Charles River hamsters fed the SPD with either palmitic acid or safflower oil plus cholesterol was lithogenic only after six weeks (groups 11 and 12, CSI = 1.36 and 1.13, respectively). The total lipid concentration (g/dL) tended to be higher in Sasco hamsters compared to Charles River animals fed identical diets (groups 1–6 vs. 7–12, respectively).

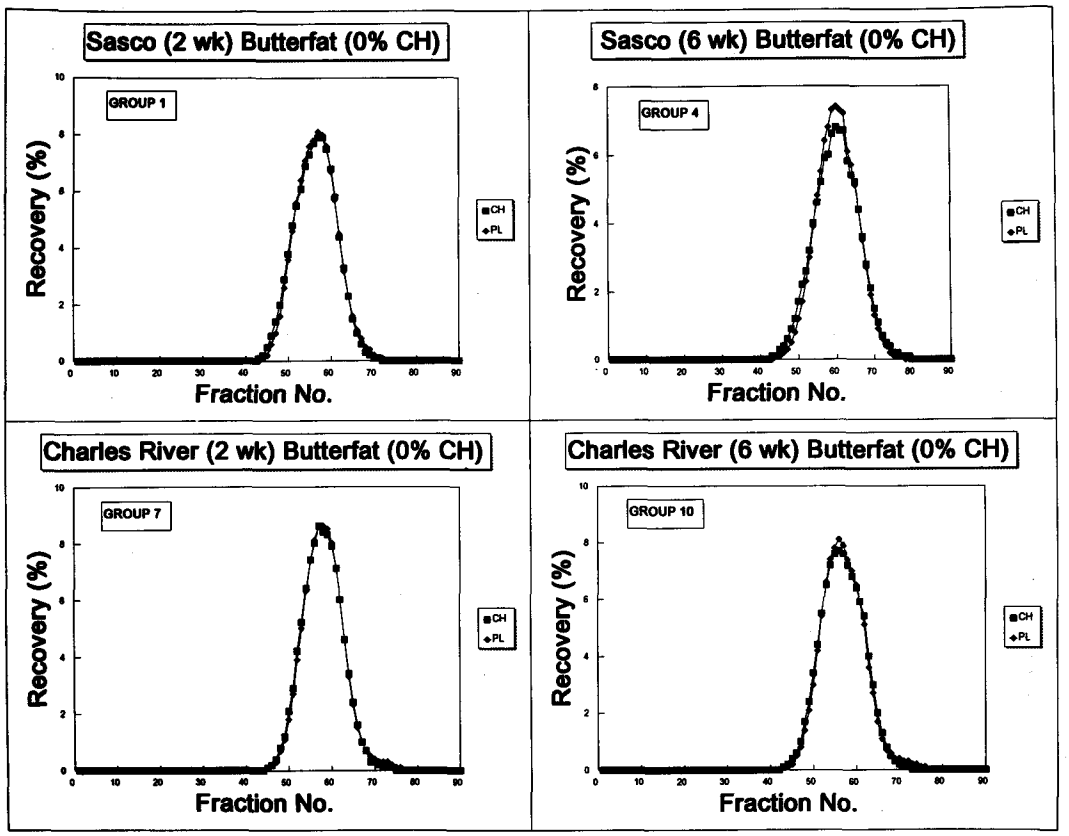

FIG. 1. Gel filtration chromatography of hamster gallbladder bile using Sepharose CL-4B-200 (Pharmacia, Piscataway, NJ). The elution profiles show % recovery of [^{3}H]cholesterol (CH) (■) and [^{14}C]phosphatidylcholine PL (◆). The groups fed 4.0% butterfat + 0% cholesterol are Sasco hamsters (Sasco, Inc., Omaha, NE) (2 wk), group 1; Sasco (6 wk), group 4; Charles River hamsters (Charles River, Wilmington, MA) (2 wk), group 7; Charles River (6 wk), group 10. See experimental section for details of diets, feeding conditions, and chromatography. PL, phospholipids.

The distribution of cholesterol in void volume vesicles, small vesicles, and micelles is summarized in Table 2 and in Figures 1–3. Quantitation was made by determination of ^{3}H and ^{14}C in each fraction. In all experiments in which cholesterol carriers were isolated, the recovery of the radiolabeled cholesterol and phospholipid averaged 90% or better. The cholesterol/phospholipid ratio in the void volume vesicles, small vesicles, and micelles is summarized in Table 2. This ratio was highest for void volume vesicles (range 1.83–2.92), followed by small vesicles (range 0.92–1.90). Small vesicles were detected in the bile of all groups fed 0.3% cholesterol (except Charles River animals fed 4% safflower oil plus 0.3% cholesterol for two weeks, group 9, Table 2). In both Sasco and Charles River animals fed butterfat without cholesterol for either two or six weeks, only micellar cholesterol carriers were present in bile (Table 2 and Fig. 1; groups 1, 4, 7, and 10). The highest amount of cholesterol in void volume vesicles was detected in the bile of Sasco hamsters fed 1.2% palmitic acid plus 0.3% cholesterol for two weeks (28.8%, group 2, Fig. 2). Group 2 was also the only group with cholesterol gallstones at the end of two weeks. However, after six weeks of feeding, both Sasco and Charles River hamsters had a significant proportion of the biliary cholesterol in vesicular form (group 5, 21.4%; group 11, 31.3%). Some Sasco hamsters fed the safflower oil diet for six weeks had cholesterol gallstones (22%). These animals had 13.3% of the biliary cholesterol in void volume vesicles and 20.2% in small vesicles (Table 2, and Fig. 3).

DISCUSSION

The experiments presented here examined whether lithogenic diets produced cholesterol/phospholipid vesicles which nucleated to form cholesterol stones. We separated large vesicles, small vesicles and micelles from gallbladder bile by gel filtration chromatography. The procedure was essentially that of Pattinson (17). Gel filtration was chosen instead of density gradient ultracentrifugation to preserve the metastable vesicles as separations could be carried out in a shorter time (4 vs. 48 h) using smaller quantities (200 μL) of bile. The sizes of the void volume vesicles, small vesicles, and micelles were reported by Pattinson (17) using electron microscopy of the various gel filtration column fractions.

Earlier hamster models of cholesterol cholelithiasis presented problems which made the interpretation of the results difficult. The hamster model developed by Christensen *et al.*

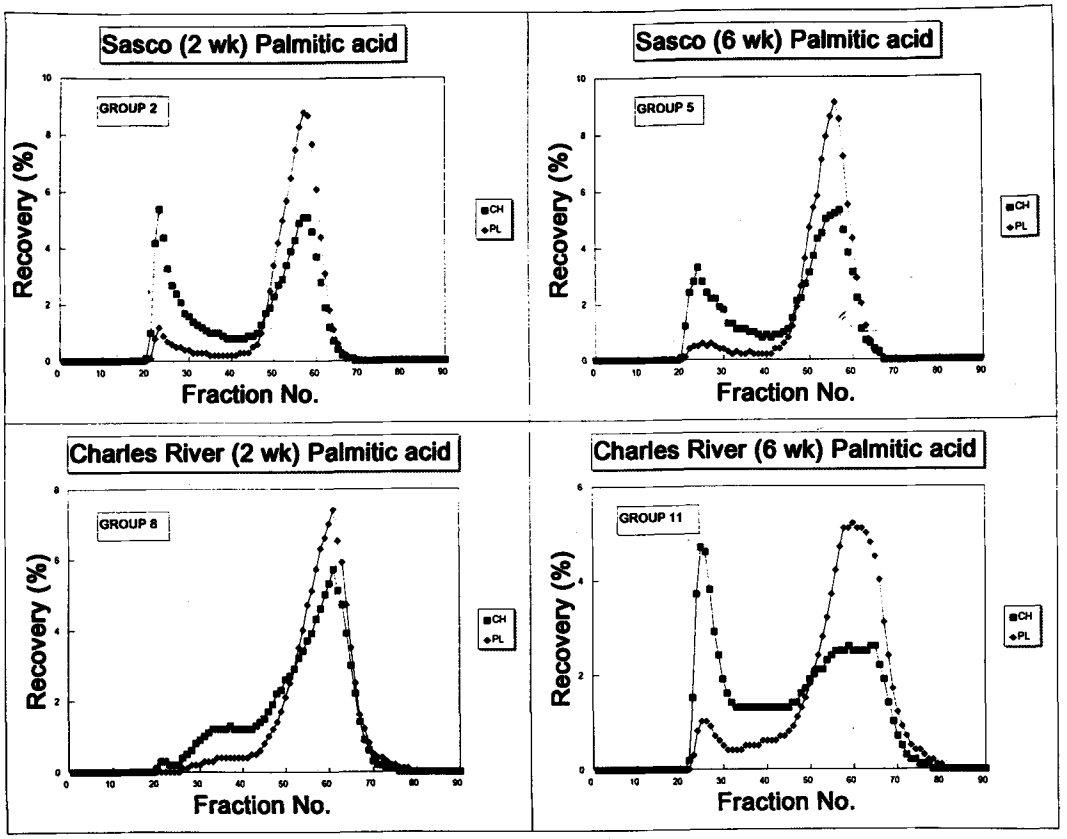

FIG. 2. Gel filtration chromatography of hamster gallbladder bile using Sepharose CL-4B-200. The elution profiles show % recovery of [^{3}H]cholesterol (■) and [^{14}C]phosphatidylcholine (◆). The groups fed 1.2% palmitic acid and 0.3% cholesterol are Sasco (2 wk), group 2; Sasco (6 wk), group 5; Charles River (2 wk), group 8; Charles River (6 wk), group 11. See experimental section for details of diets, feeding conditions, and chromatography. See Figure 1 for abbreviations and source locations.

(2) used diets which lacked essential fatty acids; consequently, even though gallstones formed, many of the hamsters became ill, lost weight, developed diarrhea, and died prematurely. Another hamster model (21) used a chow diet plus cholesterol and estrogen to induce cholesterol gallstones; bile acid therapy prevented stones in these animals. This model could not be duplicated in other laboratories (22). Our laboratory developed a reproducible hamster model of cholesterol cholelithiasis (3–6). In our model, male Sasco hamsters were fed nutritionally adequate SPD supplemented with 0.3% cholesterol to form stones; compounds were added to the diet to study gallstone prevention (7). On the standard lithogenic diet (5), gallstone incidence, after a six-week feeding period, was 50–80%; in all cases, the CSI of the bile exceeded unity. Our studies revealed that gallstone incidence varied significantly with the source of the hamster, e.g., Sasco vs. Charles River (5), even when the CSI in gallbladder bile was above 1.0. We attempted to elucidate dietary factors that affected stone incidence and found that changing the source of fats or fatty acids affected cholelithiasis (23). The CSI of the bile of all animals fed these fats exceeded unity even in the absence of stones.

The "stability" of cholesterol in supersaturated bile which contained neither crystals nor stones, was found to be related to the presence of vesicular rather than micellar cholesterol (14,15). Vesicles, which were rich in cholesterol and phospholipid but contained little bile acids, have now been characterized and identified in human bile (14,15,24–28) and in model bile (29–31). We designed the present study to discover a relationship between certain experimental variables and the distribution of biliary cholesterol between vesicles and micelles. We compared hamsters from two sources (Sasco and Charles River) with different responses to the lithogenic diet. We found that dietary cholesterol was essential for lithogenesis. We also studied the effect of a diet containing safflower oil because with this regimen the bile becomes supersaturated, but few gallstones formed. We used an established procedure to isolate void volume vesicles, small vesicles, and micelles (17), but made some modifications necessary for using hamster bile instead of human bile. These changes were mandated in the hamster model by the small amount of bile (only 20–50 μL/animal) obtainable for analysis. A minimum of 200 μL of bile was needed to obtain adequate separation and quantitation of vesicles and micelles. Statistical analyses were limited because the bile samples were pooled. An additional study of ours using three groups of hamsters (10–12 animals/group) fed 1.2% palmitic acid plus 0.3% cholesterol for six weeks showed similar proportions of void volume vesicles (26.9–34.9%), small vesicles

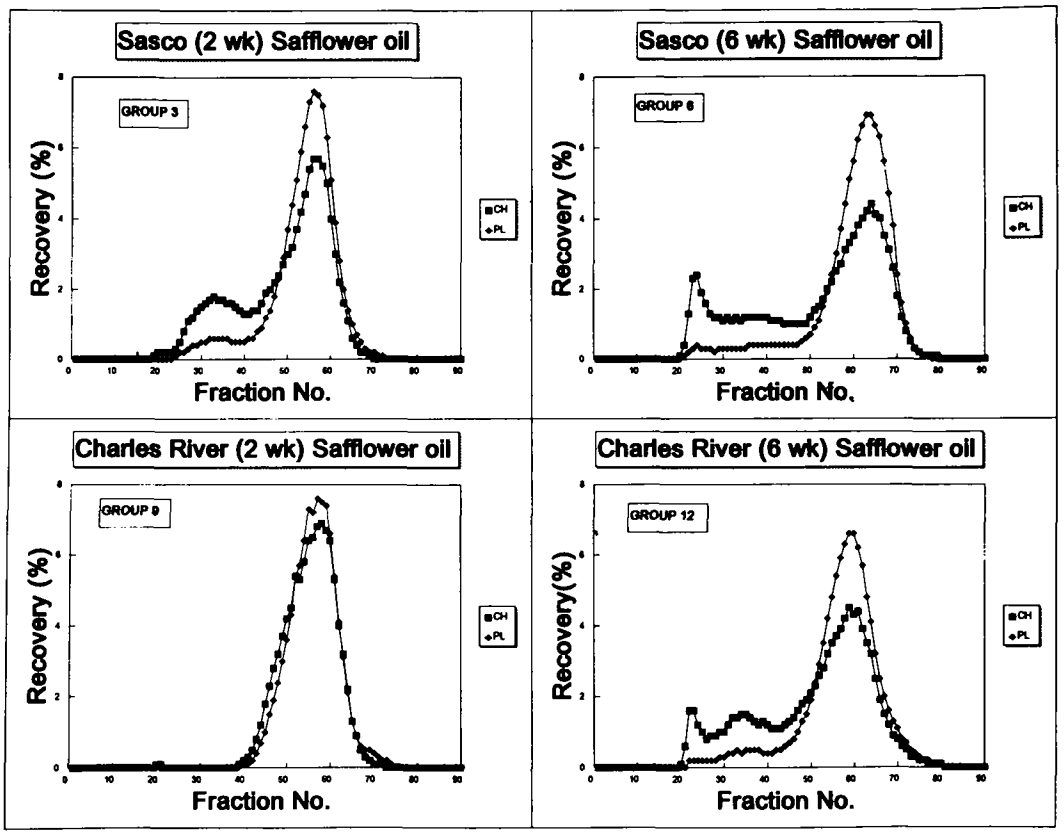

FIG. 3. Gel filtration chromatography of hamster gallbladder bile using Sepharose CL-4B-200. The elution profiles show % recovery of [^{3}H]cholesterol (■) and [^{14}C]phosphatidylcholine (◆). The groups fed 4% safflower oil and 0.3% cholesterol are Sasco (2 wk), group 3; Sasco (6 wk), group 6; Charles River (2 wk), group 9; Charles River (6 wk), group 12. See experimental section for details of diets, feeding conditions, and chromatography. Abbreviations and source locations as in Figure 1.

(12.3–19.0%), and micelles (46.1–59.1%) (18). These results suggest that the analyses of cholesterol carriers are reproducible from experiment to experiment for biles treated under identical experimental conditions. We used the column elution buffer (6 mM sodium taurocholate) described by Pattinson (17). This concentration was at best an estimate. If this amount of bile acid were too low, one might expect to see vesicle formation. No void volume vesicles were detected in four of the twelve groups studied, suggesting that the bile acid concentration used in our eluting buffer was appropriate to maintain the integrity of the void volume vesicles, small vesicles, and micelles. In addition, if the bile acid concentration were too high, one might expect some conversion of vesicles to micelles. In several groups (2, 5, and 11), the total void volume vesicles plus small vesicles exceeded 30%. Our methods allow semi-quantitative comparison between groups; the absolute quantitation of vesicles/micelles may not be possible with current methodology. A similar conclusion was reported by other investigators using human bile (32).

The results presented in Tables 1 and 2 and Figures 1–3 clearly show that void volume vesicles and small vesicles were present in bile from most animals on lithogenic diets but were not present in biles of animals given nonlithogenic diets containing no exogenous cholesterol. The latter groups (1, 4, 7, and 10) carried cholesterol only in the micellar fraction. In the groups fed 1.2% palmitic acid (groups 2, 5, and 11), animals that had cholesterol gallstones retained a significant portion of the biliary cholesterol in void volume vesicles and small vesicles. Charles River hamsters fed the palmitic acid diet for two weeks did not develop gallstones; this was the only group fed palmitic acid which had few (only 1.1%) void volume vesicles in the bile. We postulate that vesicle formation may be the initial event in formation of cholesterol crystals and cholesterol stones in this model. The presence of vesicular cholesterol in the bile of gallstone patients has been reported (17). The ratio of cholesterol/phospholipid in human bile was highest in void volume vesicles, followed by small vesicles and micelles (16,17). A similar trend was observed for these particles in our hamsters. It has been suggested that a high cholesterol/phospholipid ratio would accelerate nucleation with subsequent crystal formation (25). Interestingly, we found the highest cholesterol/phospholipid ratio in animals receiving safflower oil plus cholesterol (group 6, 2.83; group 12, 2.92). We found that the cholesterol/phospholipid ratio did not correlate with changes in total lipids; a similar finding was reported for human bile (16,17). For example, in Sasco hamsters, group 2, fed SPD + 1.2% palmitic acid + 0.3% cholesterol, total lipids were higher compared to group

TABLE 1
Gallstones and Biliary Lipids at Sacrifice[a]

8	Charles River	2 wk	SPD + 1.2% palmitic acid + 0.3% cholesterol	0/8	0/8	125.1	25.3	7.7	8.4	0.90
9	Charles River	2 wk	SPD + 4% safflower oil + 0.3% cholesterol	0/8	0/8	129.8	24.5	7.0	8.5	0.81
10	Charles River	6 wk	SPD + 4% butterfat + 0% cholesterol	0/7	0/7	88.5	9.4	2.3	5.2	0.65
11	Charles River	6 wk	SPD + 1.2% palmitic acid + 0.3% cholesterol	5/8[c]	6/8[c]	79.5	19.1	8.2	5.7	1.36
12	Charles River	6 wk	SPD + 4% safflower oil + 0.3% cholesterol	0/8	0/8	109.9	24.2	9.2	7.6	1.13

[a]Animals were fed the semipurified diets (SPD) for either two or six weeks. See Experimental section for details. Sources: Sasco, Omaha, NE; Charles River, Wilmington, MA. [b]Differs significantly from groups 1, 3, 4, and 6, $P < 0.01$ by chi-square. [c]Differs significantly from groups 7–9, 10, and 12, $P < 0.01$ by chi-square.

6, fed SPD + 4% safflower oil + 0.3% cholesterol (12.6 vs. 10.5 g/dL, respectively), yet the cholesterol/phospholipid ratio in vesicles was higher in group 6 vs. group 2 (2.83 vs. 2.61, respectively). We reported earlier (18) that vesicles were present in hamster bile in animals fed 4% butterfat + 0.3% cholesterol for six weeks. However, only micelles were found when either 1.2% palmitic acid or 4% safflower oil were fed without exogenous cholesterol (Cohen, B.I., and Mosbach, E.H., unpublished data).

Cholesterol gallstone formation is affected by factors other than percent vesicles and micelles in bile. Recent studies showed that specific proteins in bile were associated with the vesicular fraction and presumably affected the nucleation of cholesterol (33–37). However, the limited quantities of hamster bile available have precluded such studies to date. Biliary phospholipids have also been implicated in the stability of cholesterol vesicles in bile (37,38). It was suggested that dietary changes in the fatty acid composition of biliary phosphatidycholines could affect vesicle stability (37–39). To date, we have not characterized individual phosphatidylcholine species under the conditions studied in the present experiments.

In summary, we report the composition of the cholesterol carriers in bile obtained from Sasco and Charles River hamsters fed nutritionally adequate lithogenic or nonlithogenic diets for two or six weeks. The presence of cholesterol gallstones and cholesterol crystals was correlated in both strains of hamsters with the proportions of void volume vesicles and small vesicles in bile.

Cholesteryl Ester Transfer Protein Inhibition in Hypercholesterolemic Hamsters: Kinetics of Apoprotein Changes

Steven H. Zuckerman* and Glenn F. Evans

Division of Cardiovascular Research, Lilly Research Labs, Indianapolis, Indiana 46285

ABSTRACT: Inhibition of cholesteryl ester transfer protein (CETP) activity in hypercholesterolemic hamsters results in elevated high-density lipoprotein (HDL) cholesterol, an increase in HDL size, and the appearance of apolipoprotein E (apo E)-rich, apo A-I-poor particles. The present study has focused on the kinetics of apoprotein redistribution among the HDL particles and the relative increase in HDL-associated apo E and CETP in hypercholesterolemic hamsters, following inhibition of transfer activity using the monoclonal antibody, TP2. A 60% inhibition in CETP activity was observed 24 h after antibody injection and was associated with an increase in HDL cholesterol and HDL size. Increased amounts of apo E were associated with these HDL particles and remained in this fraction throughout the duration of the study. In contrast, while CETP was also detected on large HDL particles, this distribution shifted back toward the pretreatment pattern by 14 d. The dynamic changes in apoprotein distribution may represent a compensatory physiologic response following disruption of reverse cholesterol transport.
Lipids 30, 307–311 (1995).

Cholesteryl ester transfer protein (CETP), a 74 kD hydrophobic glycoprotein, mediates the transfer of cholesterol ester from high-density lipoprotein (HDL) to acceptor apoprotein B-containing lipoproteins and a reciprocal transfer of triglycerides to HDL (1,2). The role of CETP in the process of reverse cholesterol transport has been suggested through studies of CETP-deficient families (3,4), in rabbits or hamsters in which CETP activity has been inhibited (5–7), and in murine CETP transgenic models (8,9). CETP deficiency in humans is associated with the accumulation of large apoprotein E (apo E) containing HDL particles, HDL_c, increased amounts of HDL cholesterol, decreased low-density lipoprotein (LDL) and very low density lipoprotein (VLDL) cholesterol, and increased heterogeneity in LDL particle size (3,4,10–12). In addition to the appearance of apo A-I-poor, apo E-rich large HDL, the ratio of HDL_2 to HDL_3 particles was increased in subjects homozygous for the splicing defect in intron 14 of the CETP gene (3,11).

While CETP deficiency is associated with increased HDL and a less atherogenic profile, the consequences of increased CETP activity have been investigated in transgenic mice. C57BL/6 mice expressing either the human or simian CETP gene demonstrate a decrease in HDL cholesterol following transgene induction (8,9) and develop arterial lipid lesions when maintained on a cholesterol-rich diet (9). Increased CETP has also been observed clinically in some patients presenting with dyslipidemia (13,14), nephrotic syndrome (15), and following probucol therapy (16). Serum cholesterol and lipoprotein profiles reflect the increase in CETP activity by an overall decrease in HDL cholesterol and a shift in the ratio of HDL_2 to HDL_3, with an increase in the amount of the smaller HDL_{3b} particles (17).

The inverse relationship between CETP and HDL levels in both human and in animal models suggests that pharmacologic inhibition of CETP synthesis or activity may mitigate the progression of atherosclerosis. This approach, however, requires verification in small animal models that are amenable to drug discovery. Syrian golden hamsters, in contrast to mice and rats, have a significant portion of serum cholesterol associated with the LDL fraction (18–20). Hypercholesterolemia in this model results in an increase in LDL and VLDL cholesterol and a 2–3-fold increase in plasma CETP activity (18–22). Inhibition of CETP activity in normocholesterolemic and hypercholesterolemic hamsters by subcutaneous injection of the CETP-neutralizing monoclonal antibody TP2 (23) results in increased HDL cholesterol, and in hypercholesterolemic animals, the association of apo E and CETP with larger HDL species (7). However, whether these apoprotein changes occur early following inhibition of CETP activity and what the duration is of these effects relative to the return of serum transfer activity were questions which required further investigation.

In the present study, these two questions which related to the kinetics of apoprotein redistribution onto larger HDL particles, have been investigated. In addition to this shift in apo E and CETP, the inhibition of transfer activity results in a significant increase in the amount of apo E and CETP on the HDL particle. Apoprotein changes were observed 24 h after

the initial TP2 injection and were still apparent at 14 d, a point at which the cholesterol profile resembled the immunoglobulin control. Therefore, accumulation of apo E-rich, apo A-I-poor HDL in CETP-deficient hypercholesterolemic hamsters represents an early response to inhibition of transfer activity, and these particles persist at a time point at which transfer activity and serum cholesterol profiles approach the pattern seen in control hamsters.

METHODS

Hamster model and CETP assay. Male Syrian hamsters between 120–175 g (Charles River Laboratories, Portage, MI) were maintained on a cholesterol-rich diet (Purina 5001 rodent chow, supplemented with 10% saturated coconut oil and 0.12% cholesterol) for a minimum of one week prior to use. Hypercholesterolemic hamsters, with serum cholesterols greater than 200 mg/dl, were injected subcutaneously at days 0 and 4 with either 12.5 mg/kg of TP2 monoclonal antibody or a control IgG (Cappel, West Chester, PA). An ascites preparation of TP2 antibody (23) was obtained by injection of pristane primed Balb/c mice with the TP2 hybridoma cell line (provided by Dr. Allan Tall, Columbia University, NY). At designated intervals, serum was obtained by retroorbital bleeding. Preparation of [^{3}H]-cholesterol ester-labeled HDL and CETP transfer assays were performed using minor modifications (7) of previously described procedures (13,24).

Serum lipoprotein and electrophoretic analysis. Changes in HDL, LDL, and VLDL were evaluated by fast-performance liquid chromatography (FPLC) (Pharmacia, Bromma, Sweden) analysis using tandem Superose 6 columns (Pharmacia) (25) with cholesterol determined on the fractions as described previously (7). FPLC fractions 20–40, including the LDL and HDL peaks, were electrophoresed on denaturing 10–20% gradient gels, and electroblotted onto nitrocellulose using semiwet blotting conditions (ABN Polyblot; American Bionetics, Inc. Emeryville, CA). Nitrocellulose blots were probed with polyclonal goat antisera against human apo E (Chemicon, Temecula, CA) or with TP2, and immunoreactive bands were detected by enhanced chemiluminescence (ECL) (Amersham Intl., Buckinghamshire, England) as previously described (7). Film (Hyperfilm-ECL; Amersham) was exposed to the chemiluminescent signal under conditions which resulted in a linear film exposure. Bands were quantitated by densitometry and expressed as integrated optical density (IOD) units using a Truvel scanner and Visage software (Bio Image Products, Ann Arbor, MI).

RESULTS

The injection of 12.5 mg/kg of TP2, a concentration of antibody that results in maximal inhibition of CETP activity in hypercholesterolemic hamsters (7), induced a significant shift in the lipoprotein profile when compared to the IgG control. An increase in both HDL size and cholesterol content was apparent 24 h after injection, was maximal between days 4–9, and was less significant by day 11 (Fig. 1). Concomitant with

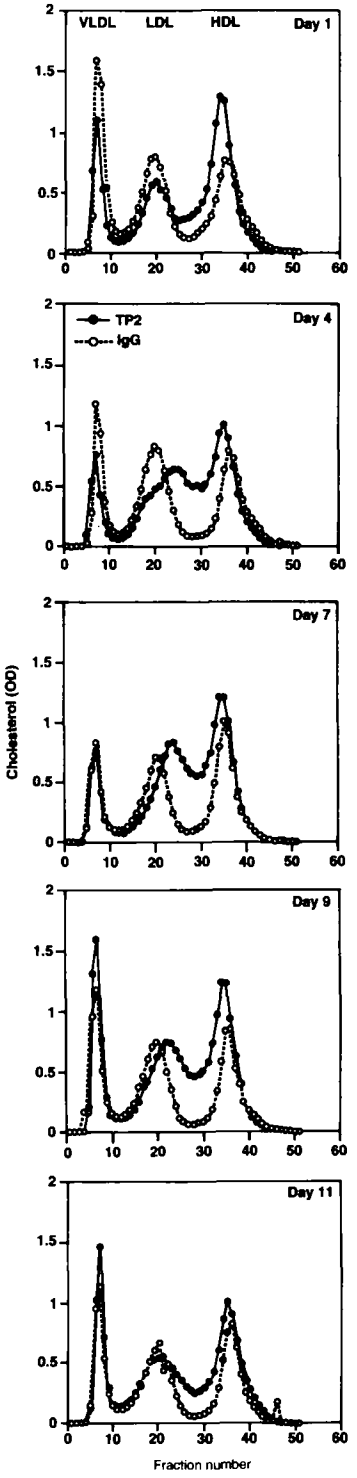

FIG. 1. Effect of cholesteryl ester transfer protein (CETP) inhibition on serum lipoprotein cholesterol profiles. Hamsters injected with TP2 or an IgG (Cappel, West Chester, PA) control were bled at days 1, 4, 7, 9, and 11; 250 mL sera pools (six animals per group) were subjected to fast-performance liquid chromatography on tandem linked Superose 6 columns (Pharmacia, Bromma, Sweden). Resulting fractions were monitored for total cholesterol; very low density lipoprotein (VLDL), low-density lipoprotein (LDL), and high-density lipoprotein (HDL) peaks were identified using purified lipoprotein standards. CETP activity was inhibited: 60%, day 9; 30%, day 11. Reduction in transfer activity relative to day 0 was significant by a two-tailed Student's *t*-test for all points evaluated ($P < 0.001$); OD, optical density.

the increase in HDL cholesterol, there was a reduction in VLDL and LDL cholesterol which was also detected at 24 h. While the reduction in VLDL and LDL cholesterol during the earlier time points was reproducible, the increase in VLDL cholesterol 9 and 11 d after TP2 injection was more variable.

In addition to the increase in HDL cholesterol, there was a significant shift in the distribution and amount of apo E on the lipoproteins. Apo E in the hypercholesterolemic hamster was primarily localized to the ascending shoulder of the HDL peak on FPLC, with the greatest concentration of apo E occurring between fractions 30–32 (Fig. 2A). Inhibition of CETP activity resulted in both a significant shift in apo E distribution to larger lipoprotein particles between fractions 22–30 and in the amount detected. These qualitative and quantitative effects on apo E were apparent by 24 h, the earliest time point evaluated (Table 1). The shift in apo E to larger particles was still apparent at days 11 and 14. While some shift in apo E relative to day 0 was also apparent in IgG-treated hamsters (Fig. 2B), these effects were less marked with most of the apo E detected between fractions 28–30.

TABLE 1
Quantitative Changes in apo E and CETP in TP2-Treated Hamsters

Days[a]	Apo E (IOD)[b]	CETP (IOD)[c]
0	0.15	0.227
1	0.61	12.80
4	5.61	11.47

[a]Days post-injection of 12.5 mg/kg of TP2.
[b]Integrated optical density (IOD), units were based on the peak fraction containing the greatest amount of apoprotein E (apo E). This represented fraction 30 from the day 0 pool and 26 at both the day 1 and day 4 pools.
[c]IOD units were based on the peak cholesteryl ester transfer protein (CETP)-containing fractions, which was fraction, 30 for the day 0 pool and 28 at both the day 1 and day 4 pools. Sixteen-second and fifteen-minute exposures were scanned for apo E and CETP, respectively. These exposures were determined to be within the linear adsorption range.

The profile for CETP was then evaluated to determine whether the apoprotein changes observed following CETP inhibition were unique to apo E (Fig. 3). The untreated day 0 hypercholesterolemic hamsters had maximal CETP detected by immunoblot between fractions 30–34. Twenty-four hours after the initial TP2 injection, there was both an increase in

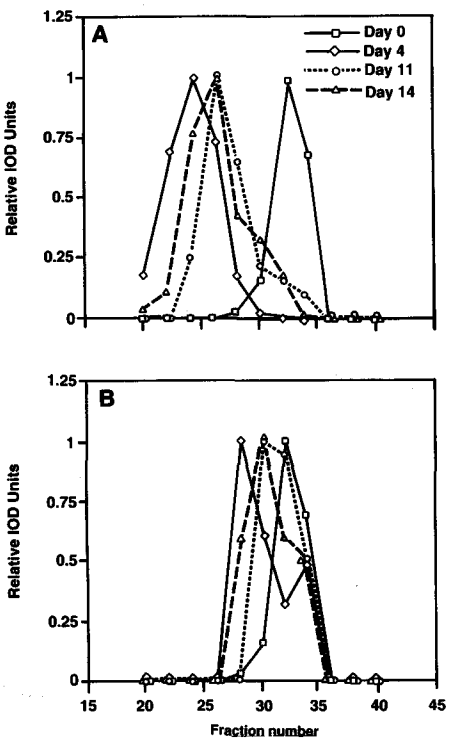

FIG. 2. Kinetics of apoprotein E (apo E) shift in TP2- or IgG-treated hamsters. Sera from hypercholesterolemic hamsters 0, 4, 11, and 14 d after the initial TP2 (A) or IgG (B) injection were run on fast-performance liquid chromatography, appropriate fractions were electrophoresed, and immunoreactive apo E was detected by enhanced chemiluminescence. Immunoblots were scanned by densitometry, the maximal adsorption of the peak fraction was normalized to one integrated optical density (IOD) unit, and the apo E band from the other fractions on the same immunoblot were expressed relative to the peak fraction. See Figure 1 for company sources.

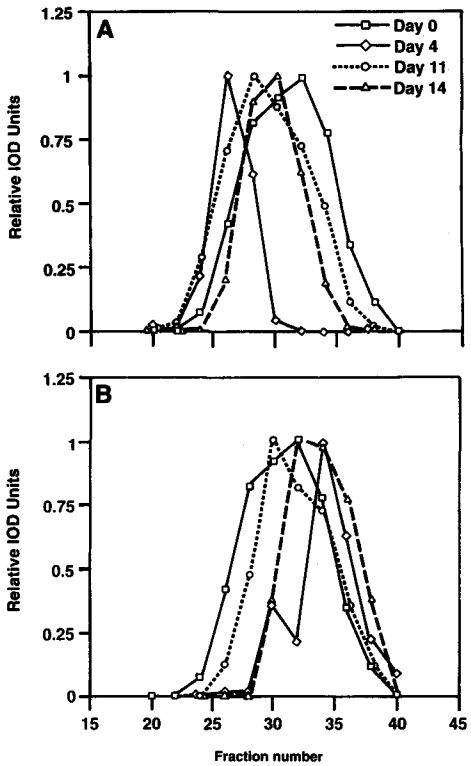

FIG. 3. Kinetics of cholesteryl ester transfer protein (CETP) shift in TP2- or IgG-treated hamsters. Nitrocellulose filters from the TP2- or IgG-injected hypercholesterolemic hamsters (A and B, respectively) were reprobed for CETP, and the resulting bands were quantitated by densitometry. The peak fraction at each time point was normalized to 1 IOD unit, and the CETP band from the other fractions on the same immunoblot was expressed relative to the peak fraction. See Figure 1 for company sources. See Figure 2 for abbreviation.

immunodetected CETP and a shift toward larger particles with maximal immunoreactivity localized to fractions 26–28 (Table 1). A similar profile was observed at 96 h with no further increases in CETP detected. However, in contrast to the persistence of apo E on larger particles, the CETP profile across the fractions by day 14 was similar to the day 0 pattern. A slight shift in immunodetected CETP was also detected in the IgG-treated controls, but this did not vary more than two fractions from the day 0 peak at fraction 32 (Fig. 3B). While quantitative changes in apoproteins were apparent by 24 h and showed no further increase for CETP at 4 d, apo E continued to increase. As with apo E, the increase in CETP appeared to be associated with lipoprotein particles which were intermediate in size between the LDL and HDL peaks. Therefore, while the accumulation of cholesterol-containing lipoprotein particles continued to increase during the first 7 d following CETP inhibition, the shifts in apo E and CETP distribution were apparent by 24 h. Expression of the IOD in the peak fraction in terms of cholesterol composition demonstrated a 17-fold increase in the amount of apo E when comparing day 0 to day 4, and a 26-fold increase in CETP. In a second series of hypercholesterolemic hamsters, normalization of the IOD-to-cholesterol content revealed a 23-fold increase in apo E between days 0 and 4 (data not shown). Therefore, inhibition of transfer activity in hypercholesterolemic hamsters was associated with both qualitative changes in lipoprotein size as well as significant quantitative changes in both apo E and CETP content. However, the relative distribution of apo E and CETP on these large HDL particles throughout the 14-d time course suggested distinct patterns of expression.

DISCUSSION

The lipoprotein changes associated with CETP deficiency have been well characterized following studies of patients with homozygous and heterozygous mutations of the CETP gene (3,4,10–12). The increase in HDL cholesterol and the appearance of larger HDL particles with a shift toward an increase in the HDL_2/HDL_3 ratio would suggest a lipoprotein profile less prone toward atherosclerosis. Clearly, the lipoprotein profile in CETP-deficient patients suggests that pharmacologic inhibition of CETP activity in humans may represent a therapeutic approach for increasing HDL cholesterol.

Inhibition of CETP activity in normocholesterolemic rabbits (5,6) and hypercholesterolemic hamsters (7) with monoclonal or polyclonal antibodies has been reported to increase HDL cholesterol. Studies in normocholesterolemic rabbits infused with a polyclonal CETP antiserum reported that while elevations in HDL cholesterol were observed, the only apoprotein change was an association of serum amyloid A protein with HDL (5). In rabbits injected with a neutralizing monoclonal antibody, TP1 had increased HDL cholesterol ester, a reduction in HDL triglyceride, a decrease in the clearance rate of [3H]cholesteryl ester-labeled HDL, and yet there was no significant change in HDL protein (6). This decrease in the clearance of cholesteryl ester-labeled HDL was consistent with the lower catabolic rates reported for apo A-I particles in CETP-deficient patients (26).

In previous studies, the inhibition of CETP activity in hamsters was associated with an increase in HDL cholesterol, the accumulation of large HDL and, in hypercholesterolemic animals, a shift in the distribution of both apo E and CETP onto larger HDL particles 7 d after *in vivo* neutralization of CETP (7). In the present study, the changes in apoprotein distribution were evaluated 24 h post-antibody injection and were followed throughout the entire two-week duration of the experiment. Inhibition of transfer activity resulted in an increase in apo E-containing lipoproteins with a size distribution between the HDL and LDL peaks. The increase in apo E was apparent by 24 h as was the shift to larger particles. This distribution of apo E persisted throughout the entire time course and was still evident when CETP activity and cholesterol profiles were similar to untreated or IgG-injected hamsters. Increased amounts of CETP were also detected in hamsters in which CETP had been inhibited and the distribution was toward larger HDL particles, as seen with apo E. However, in contrast to apo E, as transfer activity approached pretreatment levels by day 14, the distribution of CETP across the lipoprotein fractions also returned toward normal. In addition to the shifts in apo E and CETP to larger lipoproteins, the amount of these apoproteins increased more than 15-fold by day 4 when compared to the day 0 peak fraction.

The appearance of large apo E particles was previously reported in CETP-deficient subjects (3,4), although this was not apparent in the earlier rabbit studies. The increase in CETP activity associated with acceptor particles containing apo E (27) suggests that apo E may play a role in facilitating cholesteryl ester transfer when a significant fraction of CETP activity has been inhibited.

In vitro studies with CETP-neutralizing monoclonal antibodies have demonstrated an increase in apo A-IV and the appearance of apo E on larger HDL particles (28). Additional *in vitro* studies with Fab fragments also demonstrated that TP2 increased the binding of CETP to plasma lipoproteins and phospholipid vesicles (29). The relationship between the increased appearance and shift in CETP distribution *in vivo* and the effects of TP2 on CETP–lipoprotein association *in vitro* remains to be determined. In summary, the hypercholesterolemic hamster offers investigators a small animal model in which changes in lipoprotein profile, apoprotein distribution, and lesion regression can be monitored following inhibition of CETP activity by antibodies or by smaller molecular weight entities.

Uptake by Macrophages of Low-Density Lipoprotein Damaged by Nitrogen Dioxide in Air

Kiyomi Kikugawa*, Masatoshi Beppu and Yutaka Okamoto

Tokyo College of Pharmacy, 1432-1 Horinouchi, Hachioji, Tokyo 192-03, Japan

ABSTRACT: In order to know whether nitrogen dioxide, an environmental and endogenous free radical toxin, can participate in the formation of atherosclerotic lesions, damage to low-density lipoprotein (LDL) by nitrogen dioxide and uptake of the damaged LDL by macrophages were investigated. A solution of LDL at pH 7.5 was exposed to an atmosphere of nitrogen dioxide (70 ppm) in air at 37°C for 5 or 10 h. Lipid oxidation was induced by the exposure as assessed by the formation of thiobarbituric acid reactive substances. Apolipoprotein B was covalently cross-linked *via* nondisulfide bonds. Fluorescence analysis showed that tryptophan residues were extensively decreased, and amino acid analysis indicated that the contents of histidine, lysine, and tyrosine residues were decreased by 30–40, 10–20, and 20–30%, respectively. Binding of LDL to thioglycolate-induced mouse peritoneal macrophages was markedly increased by the exposure as observed by the binding of mouse erythrocytes coated with LDL. The activity of LDL to convert macrophages into lipid-laden foam cells was also increased by the exposure. Modification of lysine residues of apo B with lipid oxidation products formed by the exposure may be responsible for the uptake by macrophages. The results suggest the possibility that exposure of LDL *in vivo* to nitrogen dioxide participates in the formation of atherosclerotic lesions.

Lipids 30, 313–320 (1995).

There are several lines of evidence showing that oxidative changes of low-density lipoprotein (LDL) are associated with the formation of atherosclerotic lesions (1–5). LDL can be oxidized by endothelial cells, smooth muscle cells, macrophages, and cupric ion. Macrophages take up oxidized LDL more efficiently than normal LDL through the scavenger receptor. The excessive uptake of the oxidized LDL results in accumulation of oxidized cholesterol esters within the cells and converts the cells into lipid-laden foam cells. The conversion of macrophages into foam cells has been considered to be a possible early event in the formation of atherosclerotic lesions.

Nitrogen dioxide is a free radical toxin in polluted urban air (usually at 0.02–0.2 ppm) and in fresh smog (up to 100 ppm) (6). Inhalation of exogenous nitrogen dioxide has been suggested to cause pulmonary edema, pulmonary fibrosis, bronchitis (7–9), and cancer (10,11). Diffusion of exogenous nitrogen dioxide through an alveolar membrane to blood is possible because exposure of rats to nitrogen dioxide in air significantly damages the components of red blood cells (12). Nitrogen dioxide is also formed endogenously from nitrogen monoxide, which is synthesized by endothelial cells and plays an important physiological role as an endothelial-derived relaxing factor (13). Thus, nitrogen monoxide can react with oxygen to form nitrogen dioxide (Eq. 1) (14), and with superoxide to form peroxynitrite which, in turn, produces nitrogen dioxide by protonation (pKa = 6.8) (Eq. 2) (15,16).

$$2NO + O_2 \rightarrow 2NO_2 \qquad [1]$$

$$\begin{aligned} &\qquad\qquad + H^+ \\ &NO + O_2^- \rightarrow ONOO^- \rightarrow ONOOH \\ &ONOOH + O_2^- + H^+ \rightarrow NO_2 + O_2 + H_2O \end{aligned} \qquad [2]$$

Several reactions of biomolecules with nitrogen dioxide have been demonstrated. Exposure of polyunsaturated fatty acids to nitrogen dioxide in air gives many compounds, including lipid oxidation products (17–23). Exposure of tyrosine results in the formation of 3-nitrotyrosine and dityrosine, and exposure of tryptophan results in the breakdown of its indole ring (24). Reaction of cysteine with nitrogen dioxide gives certain highly reactive radical species (25).

In the present study, we investigated damage to LDL by exposure to nitrogen dioxide in air and the subsequent binding and uptake of the damaged LDL by macrophages. It was found that LDL was damaged extensively by exposure to nitrogen dioxide, and the damaged LDL readily bound to macrophages and converted the cells into lipid-laden foam cells. From a toxicological point of view, the present results may have significant implications for the formation of atherosclerotic lesions.

MATERIALS AND METHODS

Materials. Nitrogen dioxide in air was obtained from Nippon Sanso Ltd. (Tokyo, Japan). The concentration of nitrogen dioxide was determined each time according to the method of Saltzman (26,27) using a conversion coefficient of NO_2^-/NO_2 of 0.84, where the measured nitrite concentrations were divided by 0.84 to convert to the nitrogen dioxide concentrations. Thus, nitrogen dioxide in air was bubbled into 10 mL of a solution containing sulfanilic acid, *N*-(1-naphthyl)ethylenediamine and acetic acid placed in a tube (15 mm i.d. × 105 mm) at a rate of 10 mL/min for 10 min. The solution was kept at room temperature for 15 min, and its absorbance at 545 nm was measured. The concentration of nitrite was determined by comparing the absorbance with that of the solution (10 mL) containing 0.375 μmole sodium nitrite. The concentration of nitrogen dioxide in air used in the present experiments was found to be 70 ppm.

Thiobarbituric acid (TBA) and butylated hydroxytoluene (BHT) were obtained from Wako Pure Chemical Industries (Osaka, Japan). 3-Nitrotyrosine was obtained from Sigma Chemical Company (St. Louis, MO). Dityrosine was prepared as previously reported (28).

Analysis. Ultraviolet absorption spectra were measured on a Hitachi (Tokyo, Japan) U-2000 double beam spectrophotometer. Fluorescence spectra were measured on a Hitachi (Tokyo, Japan) 650-40 fluorescence spectrophotometer. The instrument was standardized with 0.1 μM quinine sulfate in 0.1 N sulfuric acid to give a fluorescence intensity of 100 at a maximum excitation/emission of 350/450 nm.

The TBA assay was performed by the colorimetric procedure according to the method of Ohkawa *et al.* (29) with modification (30). Briefly, a mixture of 0.80 mL of water containing sample, 50 μL of 0.8% BHT in glacial acetic acid, 0.20 mL of 8.1% SDS solution, 1.50 mL of 20% acetic acid solution adjusted to pH 3.5 with 10 N NaOH, and 1.50 mL of 0.8% TBA solution was kept at 5°C for 60 min and then heated at 100°C for 60 min. After cooling, the mixture was extracted with 1.0 mL of water and 5.0 mL of 1-butanol/pyridine (15:1, vol/vol). The absorbance at 532 nm of the organic phase (5.8 mL) was measured. The amount of thiobarbituric acid reactive substances (TBARS) was determined by the molar absorbance coefficient of the 1:2 malonaldehyde/TBA adduct, $\varepsilon = 156{,}000$. The amount of red pigment reflects not only malonaldehyde but alkenals and alkadienals, which are generated during lipid oxidation (30).

The concentration of proteins was determined by the Lowry method (31), using bovine serum albumin as a reference standard. SDS–polyacrylamide gel electrophoresis (PAGE) was performed using a 3.5% gel according to the method of Maguire *et al.* (32). The sample was treated with the sample buffer containing 40 mM dithiothreitol at 37°C for 1 h before electrophoresis, in order to destroy disulfide bonds in proteins. Protein bands were visualized by Coomassie blue.

Amino acid analysis was carried out on a Hitachi L-8500 high-performance amino acid analyzer equipped with a No. 2620 ion exchanger column (4.6 mm i.d. × 80 mm). The sample was hydrolyzed in 6 M HCl containing 4% thioglycolic acid at 110°C for 24 h under vacuum, and the mixture was evaporated to dryness. For the analysis of cysteine plus cystine and methionine, the sample was oxidized with performic acid in the usual manner prior to the hydrolysis. The column was eluted stepwise with sodium citrate buffer systems at pH 3.3, 4.0, 4.9, and alkaline pH, which are generally used for the analysis of amino acids and amino sugars. Common amino acids and 3-nitrotyrosine were detected by ninhydrin coloration at 570 nm (for most amino acids) and 440 nm (for proline), and fluorescent dityrosine was detected by fluorescence at 285/410 nm. 3-Nitrotyrosine and dityrosine appeared at retention times of 57 and 67 min, respectively.

LDL. Blood from a healthy human donor was collected into a citrate–phosphate–dextrose solution. Plasma was obtained by centrifugation and stored at −20°C for use within seven days. LDL was obtained from the plasma by preparative ultracentrifugation according to the method of Hatch and Lees (33) as described previously (34). In brief, aliquots of 6.5 mL of plasma mixed with EDTA at 1 mM were measured into ultracentrifuge tubes, and 3.25 mL of the density 1.006 solution was layered over the surface. The tubes were centrifuged at 31,000 × *g* and 16°C for 30 min. The bottom 6.5 mL layer was again overlaid with 3.25 mL of the density 1.006 solution, and the tubes were centrifuged at 115,000 × *g* for 6 h. Into the bottom 6.5 mL layer was mixed 3.25 mL of the density of 1.182 solution, and the tubes were centrifuged at 115,000 × *g* for 8 h. The top 2 mL layers from two tubes were combined and mixed with diisopropylfluorophosphate at 1 mM and sodium azide at 0.01% and finally with 4 mL of the density 1.182 solution. The density 1.006 solution (2.0 mL) was layered over the surface. The tube was centrifuged at 115,000 × *g* for 6 h. The 3–4 mL layer at the top of the higher density solution was collected. The LDL fraction was dialyzed at 4°C against phosphate buffered saline (PBS) containing 10 mM sodium phosphate buffer (pH 7.4) and 0.14 M sodium chloride, which had been freed from dissolved oxygen by purging with nitrogen gas. The fraction showed a single protein band in SDS–PAGE. Twenty milliliters of LDL solution in the buffer containing 23 mg protein were obtained and stored at 4°C for use within a day.

Macrophages. Macrophages were obtained from the peritoneal cavity of 7 to 15 week-old ddY male mice four days after intraperitoneal injection of 2–3 mL of 3% thioglycolate medium (Difco Laboratories, Detroit, MI). The peritoneal exudate cells obtained were washed twice with Hanks' balanced salt solution by centrifugation at 80 × *g* and 4°C for 10 min. The cells were then resuspended in Roswell Park Memorial Institute (RPMI) 1640 medium supplemented with 20 mM HEPES (pH 7.2), 50 units/mL penicillin and 50 μg/mL streptomycin (RPMI–HEPES medium) at 0.85×10^6 cells/mL.

Oxidation of LDL with cupric ion. LDL was oxidized as previously described (35,36). LDL (2 mg protein) in 3 mL of PBS was incubated with and without 5 μM cupric sulfate at 37°C for 24 h. The reaction was stopped by addition of 0.05

mM BHT. The mixture was dialyzed against PBS free from oxygen, and centrifuged to remove a small amount of precipitate.

Exposure of LDL to nitrogen dioxide. Into an L-shaped tube (content: 34 mL, 10 mm i.d. × 100 mm) was placed 5 mL of a solution of LDL (0.5 mg protein/mL) in 0.1 M phosphate buffer (pH 7.5), which had been prepared by dialyzing the LDL preparation against the buffer. Nitrogen dioxide in air was blown over the surface of the solution slightly swirled at a flow rate of 15 mL/min at 37°C for 5 and 10 h. As a control, purified air was similarly blown over the surface of the LDL solution. After dialysis against saline, the LDL solution was centrifuged to remove a small amount of precipitate.

The TBA assay was performed before and after dialysis. Fluorescence of the solution was measured, and SDS–PAGE of the solution was performed after dialysis. For the analysis of amino acid composition, the apolipoprotein B (apo B) fraction was isolated by delipidation according to the method previously reported (36). In brief, to one volume of the LDL solution, one volume of cold methanol and two volumes of cold chloroform were added. The mixture was shaken well and then centrifuged at 550 × *g* for 10 min. The aqueous layer and the turbid interphase were collected and combined, and dialyzed against water. The solution was lyophilized to obtain the apo B fraction. The fraction was dissolved into 0.3–0.6 mL of 1% SDS solution, and the aliquot containing 500 μg of protein was hydrolyzed and evaporated. The residue was redissolved into 0.50 mL of 0.02 M hydrochloric acid, and 10 and 100 μL of the solution were used for the analysis of common amino acids and dityrosine, respectively.

Erythrocytes coated with LDL samples. Blood was collected from ddY mice by cardiac puncture using acid citrate–dextrose preservative solution, and erythrocytes were centrifuged down, washed three times with Dulbecco's PBS (DPBS) without Ca^{2+} and Mg^{2+} (Ca^{2+}, Mg^{2+}-free DPBS) for removal of the buffy coats and plasma, and resuspended in isotonic saline to make a 4% cell suspension.

Coating of erythrocytes with LDL samples was performed as follows: A 4% erythrocyte suspension was mixed with an equal volume of a solution of the LDL sample (20 μg protein/mL) and incubated at 37°C for 15 min with occasional mixing. The mixture was centrifuged at 170 × *g* and 4°C for 15 min. The cell pellet was washed twice with the same buffer at 5°C by the centrifugation, and resuspended in RPMI–HEPES medium to make a 2% cell suspension. This operation was done on the day the coated erythrocytes were used. In this procedure, cupric ion-oxidized LDL samples were effectively adherent to the erythrocytes (1–3 ng LDL protein/10^6 cells) (37).

Binding of erythrocytes coated with LDL samples to macrophages. A 0.2 mL aliquot of the macrophage suspension was loaded onto a round cover glass (18-mm diameter). After incubation at 37°C for 1 h in a CO_2 incubator (5% CO_2/95% air), nonadherent cells were removed by washing three times with Ca^{2+}, Mg^{2+}-free DPBS, and adherent cell monolayers were subjected to the binding assay.

The suspension of erythrocytes coated with LDL sample (200 μL) was loaded on the macrophage monolayer. After incubation at 37°C for 1 h in a CO_2 incubator, nonadhering erythrocytes were removed by gentle washing with DPBS, and the cells were fixed with 1.25% glutaraldehyde in Ca^{2+}, Mg^{2+}-free DPBS. The number of the macrophages binding three or more erythrocytes on their surface was scored for the random fields of the cover glass under phase-contrast microscopy. At least 200 macrophages were examined for binding of coated erythrocytes, and the percentage of macrophages binding three or more erythrocytes were determined. The results were expressed as the mean ± SD of the triplicate experiments.

Foam cell formation. A 0.14 mL aliquot of the macrophage suspension was loaded onto a round cover glass (16-mm diameter). After incubation at 37°C for 1 h in a CO_2 incubator, nonadherent cells were removed by washing three times with Ca^{2+}, Mg^{2+}-free DPBS. The monolayer was placed in a well of a plastic 24-well plate (Corning), and to this was added 0.5 mL of RPMI 1640 medium containing LDL (100 μg protein/mL) and 5% fetal calf serum. The monolayer was incubated at 37°C for 24 h in a CO_2 incubator. After washing gently with Ca^{2+}, Mg^{2+}-free DPBS, the cells were fixed with 10% formalin for 60 min and washed with water. The oil droplets in the foam cells were stained by incubation with an Oil-red-O staining solution at 40–45°C for 30 min. After washing with water, the monolayer was subjected to the counter staining using Mayer's hematoxylin solution. After washing with water, the number of the macrophages containing oil droplets stained red was scored for the random fields of the cover glass under microscopy. At least 200 macrophages were examined. The results were expressed as the mean ± SD of the triplicate experiments.

RESULTS

Nitrogen dioxide-induced LDL damage. A surface of the solution of LDL at pH 7.5 and 37°C was exposed to nitrogen dioxide (70 ppm) in air for 5 and 10 h. As a control, a surface of the solution of LDL was similarly exposed to air. Extent of lipid oxidation was assessed by the formation of TBARS. While the amount of TBARS in the LDL solution was increased only slightly by the control air-exposure, it was extensively increased by the nitrogen dioxide exposure (Fig. 1). It has been clearly demonstrated that methyl linoleate and linolenate are oxidized into their hydroperoxide forms by exposure to nitrogen dioxide under the similar conditions (23), so TBARS provides an index of increased lipid oxidation of LDL particles. Hence, the results indicate that the lipid fraction of LDL particles was extensively oxidized by the nitrogen dioxide exposure. Substantial amount (70%) of TBARS disappeared after dialysis of the solution, probably because of loss of water-soluble low-molecular weight TBARS that were not bound to the LDL particles (data not shown).

The characteristic fluorescence due to tryptophan residues with maxima at 285/345 nm was decreased by both control

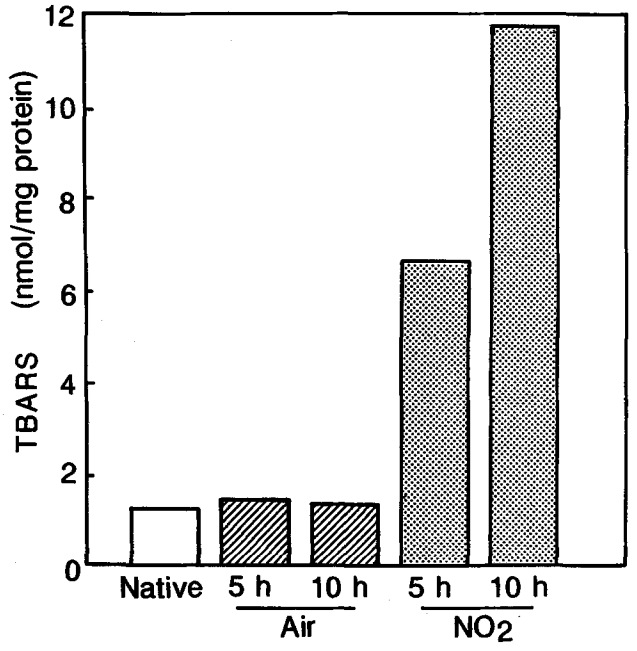

FIG. 1. The thiobarbituric acid reactive substances (TBARS) in the non-dialyzed low-density lipoprotein solution exposed to air and nitrogen dioxide (70 ppm) in air.

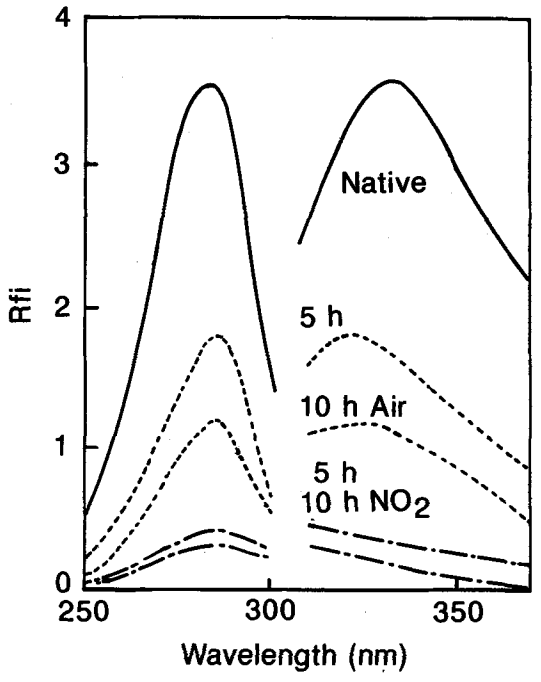

FIG. 2. Fluorescence spectra of the low-density lipoprotein solution, not exposed (—), exposed to air (---), and exposed to nitrogen dioxide (70 ppm) in air (–·–). Fluorescence spectra of the dialyzed solution containing 1 mg/mL protein were measured, and expressed as relative fluorescence intensity (Rfi) against 0.1 μM quinine sulfate in 0.1 N sulfuric acid.

air and nitrogen dioxide exposure, but the extent of the decrease by the nitrogen dioxide exposure was much greater than that by the air exposure (Fig. 2). SDS–PAGE was performed in the presence of dithiothreitol in order to detect apo B protein covalently cross-linked by nondisulfide bonds (Fig.

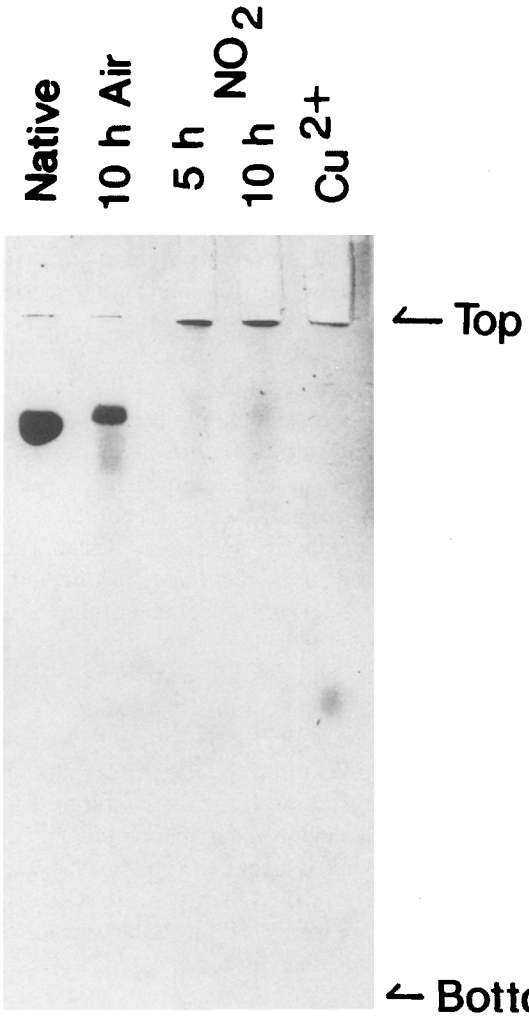

FIG. 3. Sodium dodecyl sulfate–polyacrylamide gel electrophoresis under reduced conditions of the dialyzed low-density lipoprotein solution exposed to air and to nitrogen dioxide (70 ppm) in air. An aliquot containing 20 μg protein was subjected to the electrophoresis in the presence of dithiothreitol.

3). Apo B from LDL exposed to nitrogen dioxide was extensively cross-linked by nondisulfide covalent bonds, whereas apo B from LDL exposed to air was not. In contrast, apo B from the cupric ion-oxidized LDL was fragmented, as has been reported previously (38).

The apo B fractions obtained by delipidation of native LDL, LDL exposed to air, and LDL exposed to nitrogen dioxide in air were hydrolyzed and subjected to amino acid analysis to detect common amino acids and 3-nitrotyrosine by ninhydrin coloration and to detect dityrosine by fluorescence. The results of amino acid analysis are summarized in Table 1. In the apo B fractions from LDL exposed to air for 5 and 10 h, only histidine residues were significantly decreased as compared with the histidine content of the apo B fraction of native LDL. While the amount of tryptophan residues of apo B is too low to be detected by amino acid analysis, the residues may be partially destroyed, as observed by the fluorescence analysis (Fig. 2). Hence, histidine and tryptophan residues of apo B may be damaged by the air exposure. In the

[a]Amino acid residues calculated per mol apo B with 5000 residues.

[b]From Reference 39. Values underlined indicate those significantly decreased from those of native LDL.

apo B fractions from LDL exposed to nitrogen dioxide for 5 and 10 h, histidine, lysine, and tyrosine residues were decreased. Histidine residues were decreased by 30–40%, lysine residues by 10–20%, and tyrosine residues by 20–30%. Tryptophan residues must be extensively destroyed because fluorescence due to tryptophan residues was diminished (Fig. 2). Hence, histidine, lysine, tyrosine, and tryptophan residues of apo B were found to be susceptible to the nitrogen dioxide exposure. It is interesting to note that 3-nitrotyrosine and dityrosine were not detectable in the apo B fractions from LDL exposed to nitrogen dioxide, whereas they are detectable in bovine serum albumin and α-crystallin exposed to nitrogen dioxide (24).

Macrophage adhesion of LDL exposed to nitrogen dioxide. The ability of LDL exposed to nitrogen dioxide to bind to the monolayer of thioglycolate-induced mouse peritoneal macrophages was examined. The binding ability of LDL to macrophages was measured by observing the binding of erythrocytes coated with LDL to macrophages microscopically (37). Figure 4 shows that the percentage of macrophages binding erythrocytes coated with native LDL was less than 20%, and the percent macrophage adhesion of the control LDL exposed to air for 5 and 10 h was about 33%. The percent macrophage adhesion increased with increasing exposure of LDL to nitrogen dioxide. The percent macrophage adhesion of LDL exposed to nitrogen dioxide for 5 h was 50%, and that of LDL exposed to nitrogen dioxide for 10 h was 83%. The latter value was comparable to that (73%) of the cupric ion-oxidized LDL, which is known to bind effectively to macrophages (35,36).

Furthermore, the number of erythrocytes coated with LDL exposed to nitrogen dioxide for 5 and 10 h that bound to one macrophage cell was much larger than that of erythrocytes coated with the control LDL exposed to air (data not shown). Hence, LDL exposed to nitrogen dioxide showed a high ability to bind to macrophages.

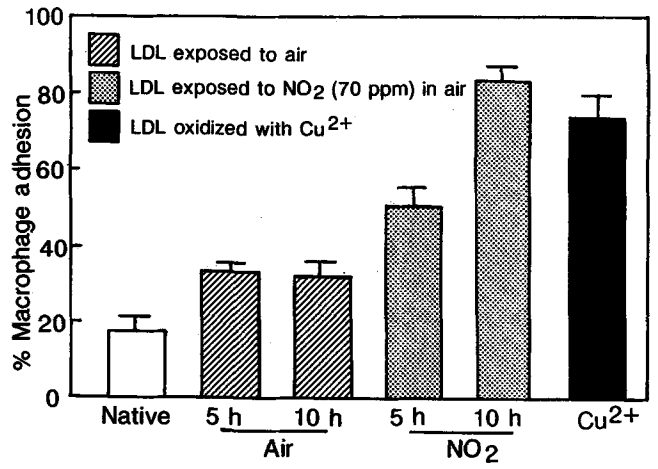

FIG. 4. Macrophage adhesion of mouse erythrocytes coated with low-density lipoprotein (LDL) exposed to air, exposed to nitrogen dioxide (70 ppm) in air, or oxidized with cupric ion. Thioglycolate-induced mouse peritoneal macrophages were used. The mean ± SD of percentage of cells with adherent erythrocytes in three experiments are shown.

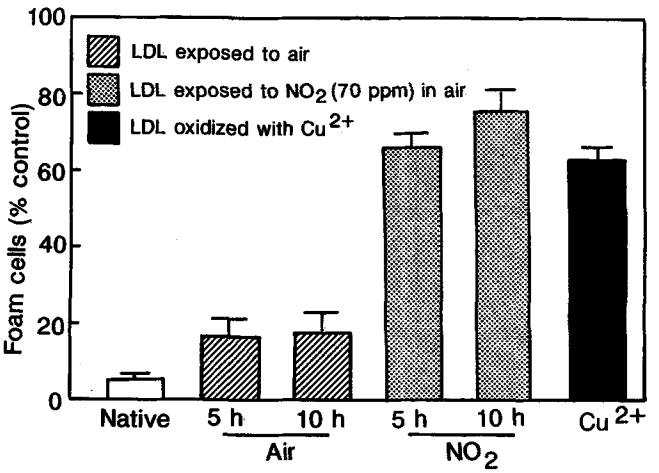

FIG. 5. Conversion of mouse peritoneal macrophages into lipid-laden foam cells by low-density lipoprotein (LDL) exposed to air, exposed to nitrogen dioxide (70 ppm) in air, or oxidized with cupric ion. The mean percentage of foam cells ± SD of three experiments are shown.

Conversion of macrophages into foam cells by LDL exposed to nitrogen dioxide. The ability of LDL exposed to nitrogen dioxide to convert thioglycolate-induced mouse peritoneal macrophages into lipid-laden foam cells was examined. Figure 5 shows that only 5% of the total macrophages were converted into foam cells in the presence of native LDL. The control LDL exposed to air for 5 and 10 h converted about 20% of the cells into foam cells. The LDL exposed to nitrogen dioxide for 5 and 10 h, however, converted a greater proportion of macrophages into foam cells. The ability of LDL exposed to nitrogen dioxide to convert macrophages into foam cells was comparable to that (65%) of the cupric ion-oxidized LDL. Hence, the ability of LDL to convert macrophages into foam cells was increased by the nitrogen dioxide exposure.

DISCUSSION

Plasma lipoprotein LDL is believed to play an important role in the formation of atherosclerotic lesions. Oxidation of LDL appears to increase its uptake into macrophages of the arterial wall and may thus convert macrophages into lipid-laden foam cells rich in oxidized cholesterol esters. This process has been considered to be a possible early event in the formation of atherosclerotic lesions (1–3). Oxidation of LDL *in vitro* by cupric ion has been characterized by the decrease in polyunsaturated fatty acids and the generation of lipid hydroperoxides and aldehydes (40). Apo B is fragmented (38) and becomes fluorescent by interaction with aldehydes generated during lipid oxidation (35,40). Lysine residues of apo B are modified by their interactions with lipid oxidation products (35,41,42). A decreased number of unaltered tryptophan residues has also been shown (43). The modification of lysine residues of apo B (42,44–48) has been considered to be the alteration of oxidized LDL that is responsible for their enhanced uptake by macrophages. On the basis of experiments conducted with cultured cells, it has been suggested that a number of oxidants are involved in damaging LDL. Superoxide (49), the products of lipoxygenase (50), and certain radical species generated by interaction of nitrogen monoxide with superoxide (51) have been suggested as possible oxidants.

In the present experiment, it was found that exposure of LDL to nitrogen dioxide (70 ppm) in air resulted in lipid oxidation as assessed by TBARS, apo B cross-linking by nondisulfide covalent bonds, and marked decreases of histidine, lysine, tyrosine, and tryptophan residues of apo B. Our present findings suggest that modification of apo B is derived not only from the reaction with secondary lipid oxidation products but also from the direct reaction with nitrogen dioxide.

Control exposure of LDL to air alone resulted in the loss of histidine and tryptophan residues of apo B. Although this exposure only slightly increased TBARS, lipid oxidation may have been induced because histidine and tryptophan residues of apo B, which are known to react readily with lipid oxidation products (35,42,43), were damaged. It has been shown that modification of delipidated apo B with lipid hydroperoxides or their aldehyde degradation products causes the loss of histidine, lysine, and tryptophan residues (42). The loss of histidine, lysine, and tryptophan in apo B of LDL exposed to nitrogen dioxide may be due to the increased lipid oxidation induced by nitrogen dioxide in air. This idea is supported by the fact that nitrogen dioxide in air at these low concentrations readily initiates lipid oxidation of polyunsaturated fatty acids (23). Nondisulfide cross-links produced in apo B by the nitrogen dioxide exposure may be due to the reaction of ly-

sine residues of apo B, with aldehydes resulting from lipid oxidation, as has been demonstrated previously (52).

It has been shown that exposure of proteins to nitrogen dioxide in air results in the loss of tyrosine and tryptophan residues of the proteins (24). The decrease of tyrosine residues in proteins exposed to nitrogen dioxide may be due to its radical attack to generate tyrosine phenoxy radical, which in turn is converted into 3-nitrotyrosine and dityrosine. The decrease of tryptophan residues may also be due to the radical reactions of nitrogen dioxide. The decrease in tyrosine residues of apo B induced by exposure to nitrogen dioxide may be due to the radical attack of nitrogen dioxide to form tyrosine phenoxy radical, but because we did not detect 3-nitrotyrosine and dityrosine in the treated apo B, the intermediary phenoxy radical may be converted into other species by interaction with lipid radicals being generated simultaneously.

The ability of LDL to bind to macrophages was assayed by a newly devised method using erythrocytes, where the binding of LDL to macrophages was microscopically observed as the binding of erythrocytes coated with LDL (37). LDL exposed to nitrogen dioxide greatly increased erythrocyte binding to macrophages. Furthermore, LDL exposed to nitrogen dioxide acquired the ability to convert macrophages into lipid-laden foam cells. The results indicate that LDL exposed to nitrogen dioxide was recognized and readily taken up by macrophages and converted the cells into lipid-laden foam cells. The recognition site for macrophage uptake of LDL exposed to nitrogen dioxide may be the modified lysine residues of apo B with aldehydes generated by lipid oxidation, similar to that seen with cupric ion-oxidized LDL (42,44–48). Scavenger receptors of macrophages may play a role in the uptake of LDL exposed to nitrogen dioxide.

In conclusion, nitrogen dioxide in air can cause damage to apo B of LDL, making the lipoprotein susceptible to the uptake by macrophages. Environmental and endogenous nitrogen dioxide may be one of possible oxidants for the formation of atherosclerotic lesions.

Antioxidant Activity of Thiocholesterol on Copper-Induced Oxidation of Low-Density Lipoprotein

Mitsuo Tanaka* and Mitsuo Nakagawa

Showa College of Pharmaceutical Sciences, Tokyo 194, Japan

ABSTRACT: The effect of thiocholesterol (SH-Chol) on the copper-induced *in vitro* oxidation of low-density lipoprotein (LDL; $1.019 < d < 1.063$) was investigated. Among the antioxidants tested, including cysteine, glutathione, 2-mercaptoethanol, dithiothreitol, probucol, thiopalmitic acid, and SH-Chol, SH-Chol was the most effective antioxidant in copper-induced LDL oxidation. Also, SH-Chol completely inhibited the formation of oxysterols, i.e., 7-hydroxycholesterol and 7-ketocholesterol, in LDL particles and reduced 1,1-diphenyl-2-picrylhydrazyl used as stable free-radical model. Moreover, SH-Chol suppressed the degradation of endogenous α-tocopherol in LDL particles. These findings indicate that SH-Chol acts as antioxidant in the oxidative damage of LDL *in vitro* and as a free-radical scavenger in lipid peroxidation.

Lipids 30, 321–325 (1995).

The oxidative modification of low-density lipoprotein (LDL) is believed to be related to foam cell formation *via* uptake by macrophage scavenger receptors and may play an important role in atherosclerotic processes (1–5). Oxidative modification of lipids can be catalyzed by small amounts of transition metal ions such as Cu^{2+} and Fe^{2+} as well as macrophages, smooth muscle, and endothelial cells (6–10). Since these metals, even in the absence of cells, mimic cell-induced changes in the lipoprotein (9,10), the transition metal ion-induced modifications of LDL and peroxidation of LDL-lipids is believed to be a useful model system for the study of atherogenesis (11,12). In addition, heavy metals such as mercury and cadmium also are capable of inducing lipid peroxidation (13,14). The enhanced lipid peroxidation may be related to the toxicities of these metals (15).

On the other hand, the presence of water-soluble and sulfur-containing antioxidants such as glutathione, 2-mercaptopropionylglycine and N-acetylcysteine can prevent free radical-mediated oxygen damage *in vivo* and *in vitro* (16–19). Similarly, besides the water-soluble, sulfur-containing antioxidants, we reported recently that thiopalmitic acid (SH-Pal), a lipid-soluble, sulfur-containing compound, acts as an antioxidant and free-radical scavenger on microsomal lipid peroxidation of rat liver (20). Another lipid-soluble, sulfur-containing compound thiocholesterol (SH-Chol) has been reported to protect against mercury and lead poisoning in mice (21,22).

Therefore, in this paper, we investigated whether SH-Chol and SH-Pal, as well as the water-soluble antioxidants mentioned above, can protect against the copper-induced oxidation of LDL *in vitro.*

MATERIALS AND METHODS

Chemicals. SH-Chol, 7-ketocholesterol (7-Keto Chol), α-tocopherol, probucol (4,4′-(isopropylidenedithio)*bis*[2,6-di-*tert*-butylphenol]), glutathione, dithiothreitol, 2-mercaptoethanol, and 1,1-diphenyl-2-picrylhydrazyl (DPPH) were purchased from Sigma Chemical Company (St. Louis, MO). Thioacetic acid, palmitoyl chloride, propylamine, and anhydrous pyridine were from Aldrich Chemical Co. (Milwaukee, WI). 7-Hydroxycholesterol (7-OH Chol) was obtained from Midorijugi Co. (Tokyo, Japan). Thiobarbituric acid (TBA) was from Wako Pure Chemical Industries (Tokyo, Japan). All other chemicals used were of analytical grade.

Synthesis. SH-Pal was prepared by the method of Shin and Quinn (23) as described previously by (20). The SH-Pal synthesized was characterized by nuclear magnetic resonance (NMR; JEOL JNM-EX90, Tokyo, Japan) and infrared (IR; JASCO IR-700, Tokyo, Japan) spectroscopy and by gas chromatography/mass spectrometry (GC/MS; Hewlett-Packard HP5890A, Palo Alto, CA). The purity of SH-Pal was about 90%.

Preparation of lipoprotein. LDL was isolated from fresh normal human plasma by ultracentrifugation as described previously (24). Serum (4.0 mL) was added to ultracentrifuge tubes, and a $d = 1.006$ g/mL solution (2.0 mL) was layered

over the surface. The tube was capped and centrifuged in a Hitachi 65P ultracentrifuge (Hitachi Co., Tokyo, Japan) at 20,000 rpm for 30 min at 4°C. The upper layer (2.0 mL) containing chylomicrons was removed, and a d = 1.006 g/mL solution (2.0 mL) was layered over the surface. The tube was centrifuged at 40,000 rpm for 16 h at 4°C. The upper layer (2.0 mL) containing very low density lipoprotein (VLDL) was removed, and a d = 1.182 g/mL solution (2.0 mL) (final d = 1.063 g/mL) was added and mixed. Then, the mixture was centrifuged at 40,000 rpm for 20 h at 4°C. The upper layer (1.0 mL) containing LDL was removed through the side of the tube with a needle and syringe. The LDL preparation obtained was dialyzed exhaustively against 0.15 M NaCl/0.02M tris(hydroxy-methyl)aminomethane–HCl (Tris–HCl) buffer (pH 7.4) containing 0.02% EDTA at 4°C for 24 h. The LDL preparation containing EDTA was used within 2 wk. Prior to the LDL oxidation experiment, the EDTA was removed from the EDTA–LDL preparation by dialyzing against 0.1 5M NaCl/0.02M Tris–HCl buffer (pH 7.4) and sterilized by filtration (0.45 μm). The LDL preparation obtained was used within 24 h after EDTA removal. Oxidized LDL was prepared by incubation of LDL (200 μg protein/mL 0.15 M NaCl/0.02 M Tris–HCl buffer, pH 7.4) with 10 μM $CuSO_4$.

Assay of lipid peroxidation products. The formation of thiobarbituric acid reactive substances (TBARS) was used as an indicator of lipid peroxidation. The lipid peroxide content of oxidized LDL was measured by a modified method of the TBARS assay as described previously (25). TBARS values are expressed as malondialdehyde equivalents using 1,1,3,3-tetramethoxypropane as a standard.

Measurement of sterols. The content of sterols (oxysterol and SH-Chol) in LDL was determined by capillary GC/MS as we have described previously (26). The sterols in LDL were extracted with hexane/isopropanol (3:1, vol/vol), and the organic phase was evaporated to dryness under nitrogen. The extracts were dissolved in a small volume of toluene and injected directly into the capillary gas chromatograph/mass spectrometer.

Determination of α-tocopherol. The determination of α-tocopherol content was carried out by high-performance liquid chromatography (HPLC; Hitachi D-6100) with fluorometric detector according to partially modified procedures of the method of Bieri *et al.* (27). All samples for HPLC analysis were extracted with hexane/isopropanol (3:1, vol/vol). The organic phase was evaporated to dryness under nitrogen. The extracts were dissolved in a small volume of ethanol and then applied to the HPLC instrument equipped with Inertsil ODS-2 column (5 mm × 150 mm; Gasukuro Kogyo Co., Tokyo, Japan).

Reduction of DPPH. The reduction of DPPH free radical was measured by the method of Uchiyama *et al.* (28). Reaction mixtures (final volume 5.0 mL) contained 1.0 mL of 0.5 mM DPPH–ethanol solution, 2.0 mL of ethanol, and 2.0 mL of 0.1 M sodium acetate buffer (pH 5.5). In the case of the addition of SH-Chol, α-tocopherol, and cysteine to the reaction mixture, SH-Chol and α-tocopherol were added in 2.0 mL of ethanol, and cysteine was added in 2.0 mL of acetate buffer (pH 5.5). The incubation was carried out at 37°C for 30 min. The reduction of DPPH free radicals was measured with the optical density at 517 nm.

Determination of enzyme protein content. The protein content was determined by the method of Lowry *et al.* (29) using crystalline bovine serum albumin as a standard.

Statistical evaluation. All data were expressed as the mean ± SD. Statistical analysis was performed using a one-way analysis of variance and Scheffe's method for multiple comparisons.

RESULTS AND DISCUSSION

In order to investigate the protective potencies of various antioxidants on copper-induced oxidation of LDL, LDL with 10 μM $CuSO_4$ was incubated with cysteine (100 μM), glutathione (100 μM), 2-mercaptoethanol (100 μM), dithiothreitol (100 μM), probucol (50 μM), SH-Pal (90 μM), and SH-Chol (30 μM). As shown in Figure 1, under the present experimental conditions, cysteine, 2-mercaptoethanol, dithiothreitol, probucol, SH-Pal, and SH-Chol protected against

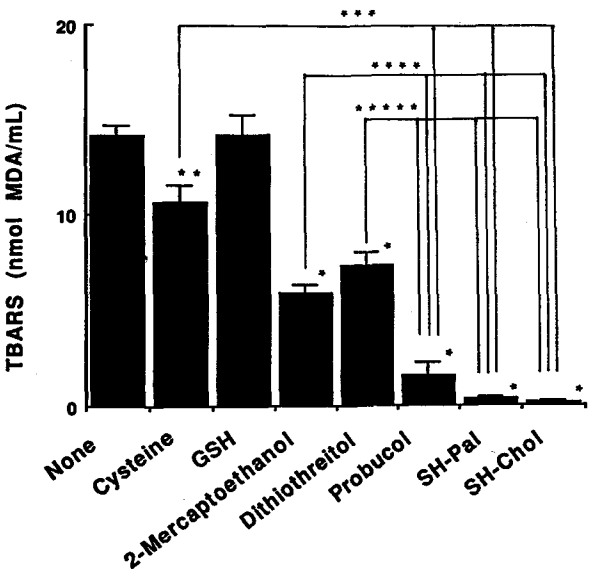

FIG. 1. Effect of various antioxidants on the copper-catalyzed oxidation of low-density lipoprotein (LDL). The incubation mixture contained LDL (200 μg/mL), 10 μM $CuSO_4$, and 0.15 M NaCl/0.02 M Tris-HCl buffer (pH 7.4) in a total volume of 1.0 mL. Probucol, thiocholesterol (SH-Chol), and thiopalmitic acid (SH-Pal) in the standard incubation mixture were added as ethanol solution (10 μL). Incubations were carried out at 37°C for 4 h. The values are the means ± SD of three separate experiments (triplicates for each experiment) done on the same LDL sample. Antioxidant concentrations: cysteine (100 μM); glutathione (GSH) (100 μM); 2-mercaptoethanol (100 μM); dithiothreitol (100 μM); probucol (50 μM); SH-Pal (90 μM); SH-Chol (30 μM). $^{*}P < 0.001$; $^{**}P < 0.01$ from the value obtained by addition of Cu^{2+} alone; $^{***}P < 0.001$ from cysteine; $^{****}P < 0.01$ from 2-mercaptoethanol; $^{*****}P < 0.001$ from dithiothreitol all by one-way analysis of variance with Scheffe's test. TBARS, thiobarbituric acid reactive substances; MDA, malondialdehyde.

copper-induced oxidation of LDL as measured by the amount of TBARS. Upon addition of 100 μM of probucol, SH-Pal, and SH-Chol to the Cu^{2+}–LDL incubation medium, the amount of TBARS generated was scarcely detectable (data not shown). Accordingly, the protective action of cysteine, 2-mercaptoethanol, and dithiothreitol was significantly lower than that of probucol, SH-Pal, and SH-Chol (vs. cysteine and dithiothreitol, $P < 0.001$, vs. 2-mercaptoethanol, $P < 0.01$, respectively), which are lipid-soluble antioxidants. Notably, SH-Chol appears to be the most effective antioxidant during copper-induced oxidation of LDL. The antioxidant action may be partly due to the protection from copper attack on the LDL by the association between LDL and SH-Chol rather than the direct interaction between copper and SH-Chol.

We next investigated the effect of SH-Chol concentration on copper-induced oxidation of LDL *in vitro*. As shown in Table 1, when LDL was incubated with 10 μM $CuSO_4$ at 37°C for 4 h, the oxidative modification of LDL was significantly increased. Upon addition of increasing amounts of SH-Chol to the incubation medium, the oxidation of LDL was effectively suppressed. In particular, upon addition of over 60 μM SH-Chol, TBARS were below the control level. However, when SH-Chol (60 μM) was added to the medium at the end of incubation period, the suppressive action of SH-Chol on LDL oxidation was no longer observed, demonstrating that SH-Chol did not interfere with the measurement of TBARS.

We next investigated the time-course of LDL oxidation by copper ions *in vitro*. As shown in Figure 2, the time-course of LDL oxidation showed an initial lag phase of 1 h, followed by a propagation phase over the next 1 h. The addition of SH-Chol (15 μM) at 0 h (Fig. 2a) or at 0 and 1 h (Fig. 2b) delayed the onset of the propagation phase. The addition of SH-Chol at 0 and 2 h (Fig. 2c) was less effective than its addition at 0 and 1 h (Fig. 2b), presumably because SH-Chol reacts with the lipid peroxyl radicals already formed in LDL and present in the incubation medium. In fact, as shown in Table 2,

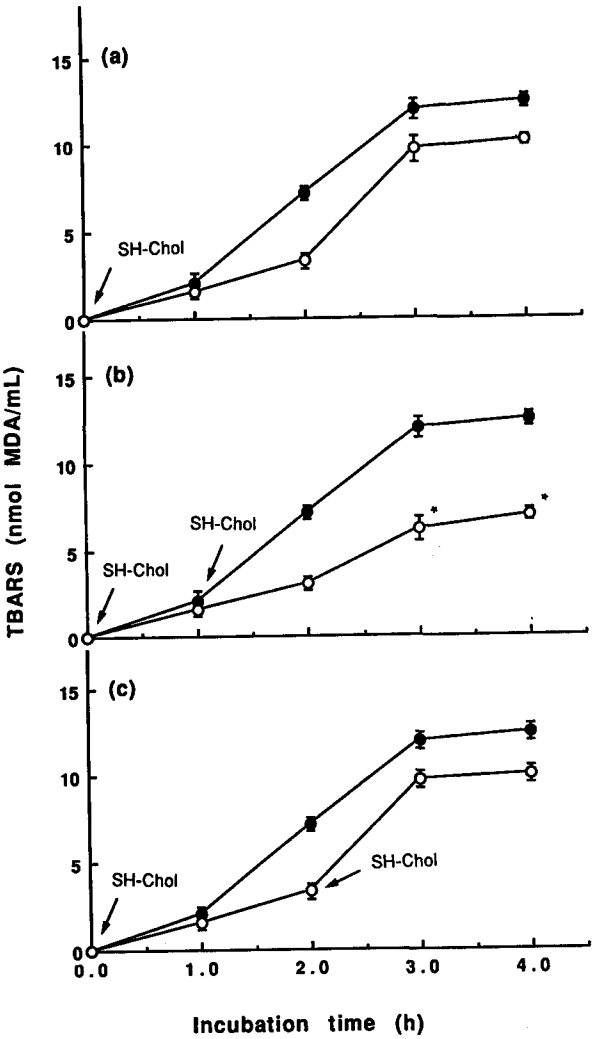

FIG. 2. Effect of SH-Chol on the formation of TBARS during copper-catalyzed oxidation of LDL. LDL (200 μg/mL) was incubated with 10 μM $CuSO_4$ at 37°C. SH-Chol (15 μM) was added to the incubation medium at 0 h (a), 0 and 1 h after incubation (b), or 0 and 2 h after incubation (c). The values are the means ± SD of three separate experiments (triplicates for each experiment) done on the same LDL sample. *$P < 0.05$ from the value obtained by addition of SH-Chol at 0 (a), and at 0 and 2 h (c) by analysis of variance, Scheffe's test. ○, +SH-Chol; ●, –SH-Chol. See Figure 1 for abbreviations.

TABLE 1
Effect of Thiocholesterol (SH-Chol) on Copper-Catalyzed Oxidation of Low-Density Lipoprotein (LDL)[a]

Addition	TBARS (nmol MDA/mL)
None	0.65 ± 0.10
Cu^{2+}	13.25 ± 0.78
Cu^{2+} + 15 μM SH-Chol	10.19 ± 0.76
Cu^{2+} + 30 μM SH-Chol	1.05 ± 0.35[b]
Cu^{2+} + 60 μM SH-Chol	0.45 ± 0.05[b]
Cu^{2+} + 120 μM SH-Chol	0.40 ± 0.01[b]
Cu^{2+} + 30 μm SH-Chol added at the end of incubation	13.10 ± 0.52

[a]LDL (200 μg protein/mL) was incubated with 10 μM $CuSO_4$ at 37°C for 4 h in the presence or absence of SH-Chol. Thiobarbituric acid reactive substances (TBARS) contents of samples were determined as described in the Materials and Methods section. The values are the means ± SD of three separate experiments (triplicates for each experiment) done on the same LDL sample.

[b]$P < 0.001$ from the value obtained by addition of Cu^{2+} alone by analysis of variance, Scheffe's test.

DPPH, which is a typical model compound of the stable free radical, was reduced by SH-Chol, as well as by α-tocopherol and cysteine, which are typical free-radical scavengers (30). The results suggest that the antioxidant effect of SH-Chol on copper-induced oxidation of LDL may partly be due to its radical scavenging action. In addition to acting as the radical scavenger, one of the mechanisms of its inhibitory action on the initiation process of lipid peroxidation may be the formation of a Cu–SH-Chol complex as indicated by Steinrauf *et al.* (21), who have reported that the thiosterols form methylmercuric ion–thiosterol complexes.

Recently, it has been reported that the copper-induced oxidation of cholesterol present in LDL particles forms a variety

TABLE 2
Reduction of α,α-Diphenyl-β-Picrylhydrazyl[a]

Test compound	D517 nm
Tocopherol (10 μM)	0.198 ± 0.01
Tocopherol (20 μM)	0.420 ± 0.03
Cysteine (20 μM)	0.199 ± 0.01
Cysteine (40 μM)	0.415 ± 0.02
SH-Chol (20 μM)	0.187 ± 0.02
SH-Chol (40 μM)	0.397 ± 0.04

of toxic products, notably 7-OH Chol, 7-Keto Chol, 5β, 6β-epoxycholesterol, and 25-hydroxycholesterol (31). Thus, we next investigated whether SH-Chol is able to prevent the formation of oxysterols by copper-induced oxidation of LDL. As shown in Figure 3, 7-OH and 7-Keto Chol were rapidly produced by copper-induced oxidation of LDL as previously reported by us (26). However, upon addition of 30 μM SH-Chol to the incubation medium, the formation of both oxysterols was completely inhibited. At the same time, under the present experimental conditions, we have confirmed that although the amount of SH-Chol has progressively decreased the incubation, SH-Chol is not oxidized to 7-OH and 7-Keto SH-Chol (data not shown). However, we have not yet investigated other potential oxidation products of SH-Chol. In any event, the results suggest that SH-Chol can prevent the formation of oxysterols by copper-induced oxidation of LDL and that the protective action of SH-Chol on formation of oxysterols may be due to the competition between low-density lipoprotein–cholesterol and SH-Chol in this copper-induced oxidation system.

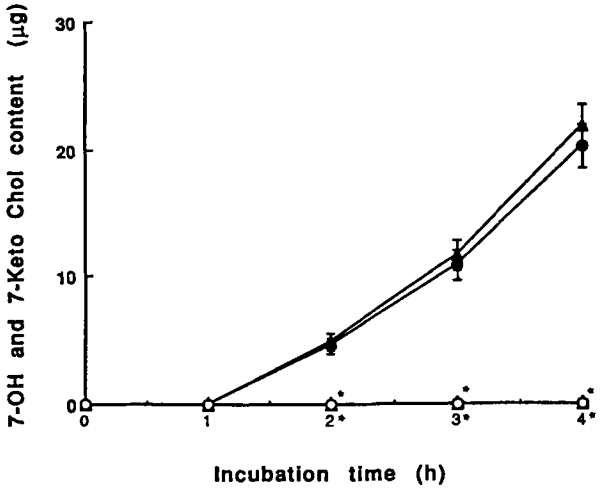

FIG. 3. Effect of thiocholesterol (SH-Chol) on 7-hydroxycholesterol (7-OH Chol) and 7-ketocholesterol (7-Keto Chol) formation during copper-catalyzed oxidation of low-density lipoprotein (LDL). LDL (200 μg/mL) was incubated with 10 μM $CuSO_4$ at 37°C in the presence or absence of SH-Chol (30 μM). Oxysterol concentrations were determined as described in the Materials and Methods section. The values are the means ± SD of three separate experiments (triplicates for each experiment) done on the same LDL sample. *$P < 0.001$ from the value obtained by addition of Cu^{2+} alone by one-way analysis of variance, Scheffe's test. ▲, –SH-Chol (7-Keto Chol); △, +SH-Chol (7-Keto Chol); ●, -SH-Chol (7-OH Chol); O, +Sh-Chol (7-OH Chol).

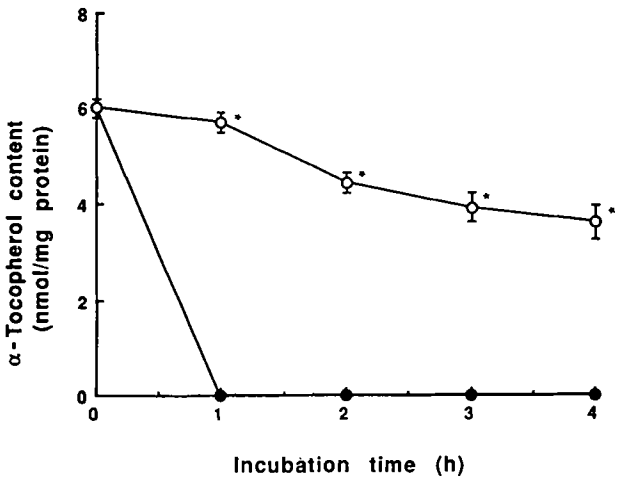

FIG. 4. Low-density lipoprotein (LDL) α-tocopherol content during copper-catalyzed oxidation of LDL in the presence or absence of thiocholesterol (SH-Chol). The incubation conditions were the same as in the experiments described in Figure 3 except for the use of 60 μM of SH-Chol. The values are the means ± SD of three separate experiments (triplicates for each experiment) done on the same LDL sample. *$P < 0.001$ from the value obtained by addition of Cu^{2+} alone by analysis of variance, Scheffe's test. O, +SH-Chol; ●, –SH-Chol.

It has been shown that the protective effects of ascorbate and probucol on LDL oxidation *in vitro* are more effective than those of α-tocopherol (32,33) and that ascorbate preserves the endogenous α-tocopherol in LDL particles during LDL oxidation *in vitro,* whereas probucol fails to preserve it (34). Therefore, we next investigated the effect of SH-Chol on the endogenous α-tocopherol content in LDL particles during copper-induced oxidation of LDL. As shown in Figure 4, when LDL was incubated with 10 μM $CuSO_4$ at 37°C for 1 h, endogenous α-tocopherol was decreased below levels of detection (<0.01 nmol/mg protein). However, addition of SH-Chol (60 μM) to the medium prior to incubation preserved approximately 60% of the initial level of α-tocopherol in LDL particles up to 4 h of incubation. Since the protective action of SH-Chol on copper-induced oxidation of LDL *in vitro* is similar to that of ascorbate (34), the protective action of SH-Chol on copper-induced oxidation of LDL likely results in the preservation of endogenous α-tocopherol in LDL particles.

The results described here suggest that SH-Chol acts as an antioxidant during the copper-induced oxidation of LDL, that the antioxidant action of SH-Chol is partly a function of its radical scavenging action, and that by reacting with lipid radicals, SH-Chol also protects α-tocopherol in LDL particles.

Experiments are in progress to study the antioxidant action and other effects of SH-Chol *in vivo.*

ABSTRACT: The mechanism of the self-assembly of the lamellar structure of natural stratum corneum lipids (SCL) has been a subject of considerable interest. We have examined this question by using a synthetic pseudo-ceramide (sphingolipid E, SLE) which was analogous to the naturally occurring ceramide type 2. The thermotropic properties and the structural characteristics of SLE, together with other main components of SCL, fatty acids, and cholesterol, were investigated by differential scanning calorimetry and X-ray analysis. A mixture of SLE and stearic acid was in a stable α-form having a lamellar structure, which is very similar to that of natural SCL. However, lipid mixtures in which stearic acid were replaced by oleic acid did not form lamellar structures, and existed in the crystalline states. This indicates that the stable bilayer formation of the natural SCL is strongly dependent on the molecular fatty acid structure. Moreover, incorporation of cholesterol (0–50%) into equimolar mixtures of SLE/stearic acid and of SLE/oleic acid caused a marked decrease of melting entropies, while the aggregation states of both systems were not changed. This effect of cholesterol can be attributed to the disorder of the molecular packing. These results suggest that the hydrophobic interactions between the SCL are important for bilayer formation as are the hydrophilic interactions between the polar groups.
Lipids 30, 327–332 (1995)

The stratum corneum lipids (SCL) which exist in the intercellular space of the stratum corneum are known to provide an epidermal barrier against water loss as well as protection against environmental, chemical, and biological stress (1–3). It is established now that the SCL, which consist of ceramides, fatty acids, cholesterol, and cholesteryl esters, retain water in the stratum corneum by forming lamellar structures (4,5). Elias (3,6) suggested that the presence of ceramides and sphingolipids is the basis for the structural organization of SCL in bilayers. Wertz and Downing (7) determined the structures and the composition of the ceramides. Wertz *et al.* (8) showed that ceramides could take part in the bilayer formation, and that fatty acids were essential for this to occur (9). Imokawa and co-workers (4,10–12) reported that ceramides play an important role in the water-retaining properties of stratum corneum. Furthermore, they found that a synthetic pseudo-ceramide, named sphingolipid E (SLE), which had a molecular structure analogous to that of the naturally-occurring ceramide type 2 (7), exhibited water-retaining properties similar to those of the natural lipids (12).

The dermatological properties of the SCL and their interactions with ceramides are under active investigation (13–18). Although the ceramides have apparent importance in the structure and function of SCL, relatively little effort has been directed toward elucidating their structure–function relationships. Studying the physicochemical properties of SLE in a model SCL mixture would greatly facilitate our understanding of the behavior of natural ceramides.

Our preliminary study (19) of the thermotropic phase behavior of the pseudo-ceramide SLE suggested that SLE showed polymorphism, as was reported for natural SCL (9,13,17,20). Moreover, we examined the aggregation structures of the equimolar mixtures of SLE/cholesterol; SLE/stearic acid; and SLE/cholesteryl isostearate (a cholesteryl ester of methyl-branched octadecanoic acid), and we found that only the equimolar mixture of SLE and stearic acid formed a stable lamellar structure (19,21). In addition, the equimolar mixture of SLE and cholesterol was in liquid-crystalline state when it was prepared, whereas the liquid-crystalline state was unstable and changed to a rigid-crystalline state in a few days. These results suggest that the interaction between ceramides and fatty acids is important for the bilayer formation of natural SCL. The effect of cholesterol on the thermotropic behavior of SLE is also a subject of considerable interest.

In the present study, we report the detailed thermotropic behavior of an SLE/stearic acid system to clarify the role of fatty acid in the self-assembly of natural SCL. Furthermore, we focus on the hydrophobic interactions between these lipids. The thermotropic properties and the structural characteristics of SLE in mixtures of stearic acid, oleic acid, and cholesterol were investigated using differential scanning calorimetry (DSC) and X-ray diffraction.

MATERIALS AND METHODS

Materials. The pseudo-ceramide *N*-(3-hexadecyloxy-2-hydroxypropyl)-*N*-2-hydroxyethyl hexadecanamide, SLE, was obtained from Kao Co. (Tokyo, Japan), and the purity was greater than 99% as measured by high-performance liquid chromatographic analysis (Scheme 1). Stearic acid, oleic acid, and cholesterol of reagent-grade were purchased from Wako Pure Chemical Industry (Osaka, Japan). The compounds were dried *in vacuo* and were used without further purification. The water content of all lipids was checked by Karl Fischer's method and were found to be less than 0.1%.

SCHEME 1

Preparation of samples. The lipids containing SLE (5–10 g) were weighed into glass test tubes with a Teflon-sealed screw cap and were melted at 90–100°C to ensure homogeneous mixing. Then, the samples were cooled to 25°C and maintained at that temperature for seven days or more, after which the DSC and X-ray measurements were started.

DSC. DSC analyses were carried out on a DSC-100 instrument (Seiko Instrument & Electronics Ltd., Tokyo, Japan). The lipid mixture (10–20 mg) was put into a silver DSC pan (Seiko). The pan was sealed and placed in the DSC cell along with a vacant reference pan. Then the sample was heated from 20 to 100°C at 2°C/min. The melting point (T_m) was determined by extrapolation to the baseline of the most rapid rise in the excess heat capacity curve as a function of temperature. The melting enthalpy (ΔH_m) was determined by integrating the area under the curve from a plot of the excess heat capacity as a function of temperature. The melting entropy (ΔS_m) was calculated from Equation 1:

$$\Delta S_m = \Delta H_m / T_m \quad [1]$$

X-Ray diffraction. The aggregation structure of the lipids was identified by powder X-ray diffraction with a wide-angle diffractometer, XD-7A (Shimadzu Co., Kyoto, Japan). Cu-Kα radiation ($\lambda = 1.54$ Å) was used in X-ray diffractometries. The lipid mixtures were placed on the X-ray diffraction glass plate in a sample holder, and then studied at 25°C.

RESULTS

Interaction of SLE and fatty acids. In Figure 1, representative DSC curves of SLE/stearic acid mixtures are given. On the basis of calorimetric scans, it is clear that stearic acid at concentrations as low as 30% has a marked effect on the thermotropic behavior of SLE (Fig. 1, curves A–F). As the stearic

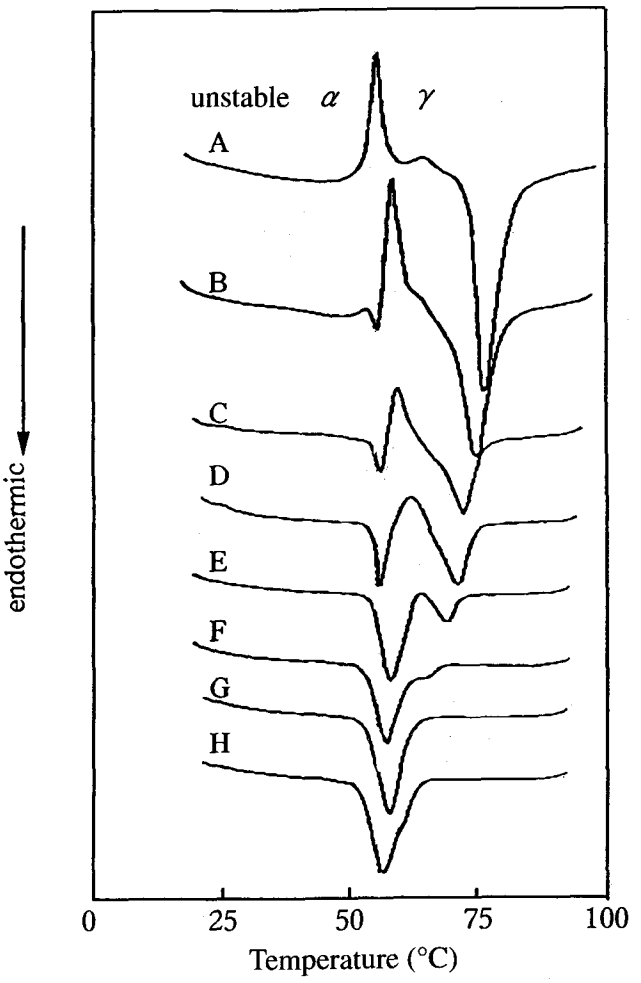

FIG. 1. Differential scanning calorimetry curves of sphingolipid E/stearic acid mixtures with weight fraction of stearic acid being: (A) 0, (B) 0.05, (C) 0.10, (D) 0.15, (E) 0.20, (F) 0.30, (G) 0.40, and (H) 0.50.

acid content was increased, the endothermic peak at around 75°C (γ-crystal to liquid) decreased and shifted to a lower temperature (Fig. 1, curves A–F), and then disappeared when the weight fraction of stearic acid was 0.4 or more (Fig. 1, curves G and H).

The exothermic peak of pure SLE at around 50°C, which may be attributed to a close packing of hydrocarbon chains of SLE molecules (19), was decreased as the stearic acid content increased. Concurrently, a new endothermic peak at around 50°C appeared. The DSC curves of the SLE/stearic acid mixture containing 40% stearic acid showed only one broad endothermic transition at around 50°C (Fig. 1, curve G). Further, this mixture showed a strong single peak at 4.1 Å in the X-ray diffraction (Fig. 2), indicating that the lipid mixture was in the α-form at 25°C.

The T_ms and the ΔH_ms of the SLE/stearic acid system were plotted against mole fraction of stearic acid (Fig. 3). Figure 3 clearly shows that the aggregation of SLE and stearic acid changes the state of SLE from the γ-form to the α-form. To clarify the effect of unsaturation between SLE and fatty acid, the thermotropic behavior and the aggregation structure of the

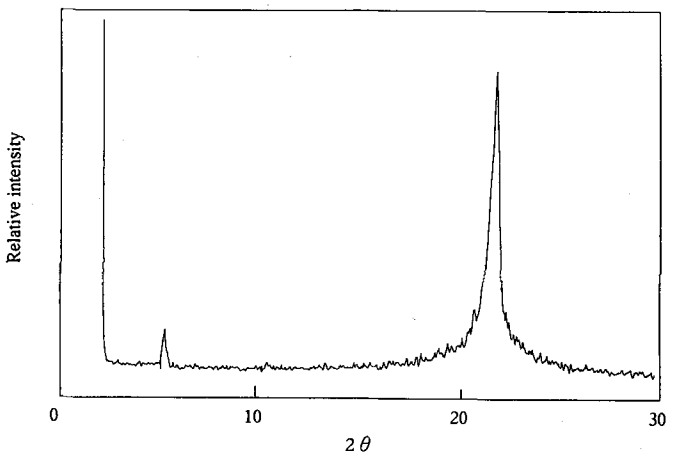

FIG. 2. X-Ray diffraction pattern at 25°C of sphingolipid E/stearic acid mixture with weight fraction of stearic acid being 0.40.

SLE/oleic acid system were examined. The DSC curves and the X-ray diffraction patterns are shown in Figure 4 and Figure 5, respectively.

As shown in Figure 4, all DSC curves of the SLE/oleic acid mixtures (weight fraction of oleic acid = 0.1–0.5) showed a single endothermic peak at higher temperatures than the melting points of SLE/stearic acid mixtures. Figure 6 clearly shows the states of the mixtures to be γ-crystal. In this system, the temperature of phase transition (γ-crystal to liquid) was shifted to the lower temperature, and the ΔH_m (Fig. 6) decreased when the oleic acid content was increased. From the X-ray diffraction patterns, the stable lamellar structure was not observed in the SLE/oleic acid mixtures containing 10–50% oleic acid.

Interaction of cholesterol and equimolar mixture of SLE and fatty acids. Changes in the T_m and ΔH_m of SLE/fatty acid (1:1 mole ratio)/cholesterol system were shown in Table 1, and the calculated ΔS_ms were plotted as a function of cholesterol content in Figure 7. Incorporation of cholesterol into the equimolar mixtures of SLE/stearic acid and SLE/oleic acid caused a marked decrease of the phase transition enthalpy and the ΔS_m. It can be seen that the extent of the entropy decrease of the SLE/stearic acid/cholesterol system was larger than that of the SLE/oleic acid/cholesterol system in the range of 22–53 mol% (20–50 wt%) cholesterol (Fig. 7 and Table 1). On the other hand, based on the X-ray data, the incorporation of cholesterol did not change the aggregation states of either system when the mole fraction of cholesterol was 53 mol% (50 wt%) or less. The typical X-ray patterns of the SLE/fatty acid/cholesterol mixtures with 20 wt% of cholesterol (SLE/fatty acid/cholesterol = 54:26:20 weight ratio) showed that the stearic acid mixture was in α-form and the oleic acid mixture in γ-form (Fig. 8).

DISCUSSION

Pure SLE exists as the monoclinic γ-crystal (22–26) in which the methylene chains are packed in a parallel fashion. In the γ-form, four strong diffraction peaks (4.24, 4.13, 3.78, and 3.62 Å) are observed in X-ray diffraction in the short-spacing region (19). The γ-crystal of SLE undergoes an endothermic transition at around 75°C to form an isotropic liquid. Upon cooling, the melted SLE undergoes a state change from a supercooled liquid to a lamellar α-form at around 50°C. In the α-form, a strong single peak is observed (19,20). The characteristic X-ray diffraction pattern of the α-form indicates that the alkyl chains are hexagonally packed and rotating within

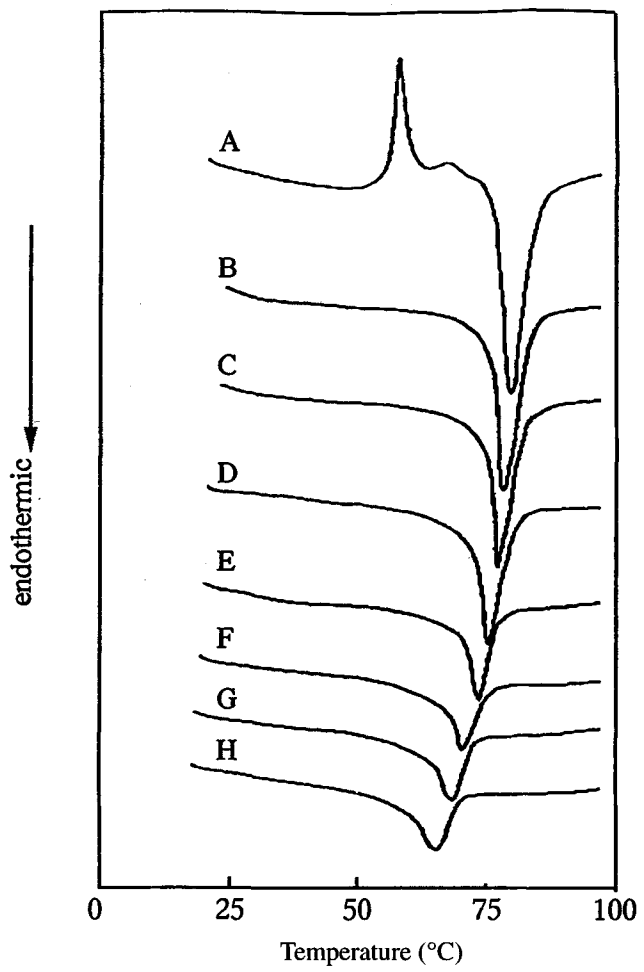

FIG. 4. Differential scanning calorimetry curves of sphingolipid E/oleic acid mixtures with weight fraction of oleic acid being: (A) 0, (B) 0.05, (C) 0.10, (D) 0.15, (E) 0.20, (F) 0.30, (G) 0.40, and (H) 0.50.

lamellar planes (27,28). However, the α-form of SLE is metastable and changes to the monoclinic γ-crystal upon long-term storage (19). The results from the present study show that fatty acids having long hydrocarbon chains affect the thermotropic properties (Figs. 1 and 4) and the aggregation structure (Figs. 2 and 5) of the synthetic pseudo-ceramide. The thermotropic behavior is similar to that observed in the glucosyl-ceramide and phospholipid system (20). The difference in the thermotropic behavior and the stable states of the SLE/stearic acid system and of the SLE/oleic acid system clearly shows that hydrophobic interactions between the lipid molecules are as important for determining the aggregation state as are the hydrophilic interactions (9,13,19,20).

Investigation of the monolayer behavior at the air–water interface of ceramides having various hydrophobic moieties showed that the aggregation structure of the condensed state

is dependent on the nature of the hydrophobic part of the molecules, and that the *cis* double bond in the fatty acid reduces the packing to limit the lateral interactions of polar groups (18). In a study of the thermotropic behavior of glucosyl-ceramide and phospholipids, it was found that the intermolecular interaction among the glycosphingolipid and phospholipid molecules is strongly dependent on the acyl chain of the phospholipid (20). Our present data are consistent with these observations. Therefore, changes in the structure of the hydrophobic part of fatty acid would be anticipated to affect the molecular packing and/or the mobility of the pseudo-ceramide and fatty acid mixture. In the α-form, the interaction between lipids is relatively small, since the mobility of the lipid molecule in the α-form is larger than that in the crystalline state (27,28). For the formation of the stable α-form, it is believed that strong hydrophilic interaction; such as hydrogen bonding between the hydrophilic portions of the lipids, would be necessary. Since oleic acid has a *cis* double bond at the center of the molecule, close packing of oleic acid with an SLE molecule bearing two straight hydrocarbon chains would be less likely than stearic acid. The decrease in the molecular packing should limit the lateral interaction of the polar group (18). Therefore, oleic acid cannot be accommodated in the α-form, but forms the γ-crystalline with SLE molecule.

On the other hand, it was observed that the incorporation of cholesterol into SLE/fatty acid system decreased the melting entropy of the lipids (Fig. 7) without any phase transition (Figs. 2, 6, and 8). The lipid molecules change their aggregation state from the α-form and/or γ-crystalline to the isotropic liquid by melting. Therefore, the magnitude of the ΔS_m associated with the T_m should reflect the degree of disorder of the molecular packing. Thus, the decrease of the ΔS_m in the SLE/stearic acid/cholesterol system and in the SLE/oleic acid/cholesterol system (Table 1 and Fig. 7) by the incorporation of cholesterol can be attributed to the disorder in molecular packing. Cholesterol, a major component of almost all biological membranes, seems to generally play an architectural role, reducing the flexibility of the hydrocarbon chains of lipids and stiffening the membranes. This stiffening effect, well-known as the cholesterolic effect, is accompanied by a reduction in the surface area occupied by the lipid mixture and by a decrease in permeability (29). Additionally, cholesterol broadens or eliminates the gel-to-liquid-crystalline phase transition of phospholipids containing straight acyl chains (29), but this mechanism is not clear. Wiedmann and Salmon (13) examined the effect of cholesterol on the thermotropic phase transition of the hydrated natural hydroxyceramides. They reported that cholesterol caused a broadening of the phase transition at relatively low levels as well as a decrease in the peak transition temperature. In the SLE/stearic acid system and in the SLE/oleic acid system, the incorporation of cholesterol enhanced the mobility of the lipids and decreased the ΔS_m. This behavior is close to that of the several natural systems mentioned above. Moreover, the extent of the decrease of ΔS_m in the SLE/stearic acid/cholesterol system was larger than that in the SLE/oleic acid/cholesterol system when cholesterol content was 20–50%. We are not able to explain this phase behavior at the present time.

In conclusion, this study showed that an anhydrous mixture of the pseudo-ceramide and stearic acid formed a stable lamellar structure, and that the difference of the hydrocarbon

chain of fatty acid affected the molecular packing of the artificial SCL. Moreover, it was noted that incorporation of cholesterol into the pseudo-ceramide/fatty acid system gave rise to a marked decrease of ΔS_m without any phase transition. Further studies on the phase behavior and dynamic aspects of the artificial SCL in an aqueous system are needed to explain the effects of cholesterol and fatty acid unsaturation that we have discussed.

ABSTRACT: The occurrence of glycosphingolipids with unique carbohydrate structures in different species of cestode, Platyhelminth, which had been shown previously, prompted us to study the molecular species of the monohexosylceramides (cerebrosides) in the pseudophyllidean cestode, *Spirometra erinacei*. The purpose of the study was to obtain a basis for future investigations of the physiological role of glycolipids in parasitism. Cerebrosides were isolated from *S. erinacei* at two growth stages, i.e., from the larval form (plerocercoid) and from the adult tapeworms (intestinal form). The cerebrosides were separated into four subfractions by silica gel column chromatography, and their constituents were analyzed by gas–liquid chromatography, gas chromatography/mass spectrometry, and high-performance liquid chromatography/mass spectrometry. The hexoses of the cerebrosides consisted primarily of galactose in both growth stages, while only a small amount of glucose was detected. The ceramides were composed of sphinganine (d18:0) and phytosphingosine (t18:0) as sphingoid bases, and of nonhydroxy fatty acids ranging from C_{16} to C_{30} and hydroxy stearic acid (18h:0). The cerebrosides of adult tapeworms contained more 18h:0 than those of plerocercoids. The combination of hexoses and ceramides in the cerebroside molecules was slightly different in the two growth stages: the glucocerebrosides of plerocercoids contained only d18:0-nonhydroxy fatty acids in their ceramide moieties, whereas those of adult tapeworms contained varying ceramide moieties. Our data indicate that the molecular species of glycolipids present were essentially homeostatic throughout growth in spite of the entirely different environmental conditions, although there were slight differences in the hexose distribution in the two growth stages. *Lipids 30,* 333–337 (1995).

Glycosphingolipids are located on the outer surface of the plasma membrane of most living organisms and are known to participate in various important events occurring on the cell surface (1,2). In parasites, glycosphingolipids may also be involved in processes essential for parasite survival, such as mediation of the host-parasite interaction and in host immune response. Recent structural analyses of parasitic helminth glycosphingolipids have revealed some species-characteristic glycolipid differences and differences in immunological antigenicity (for reviews, see Refs. 3 and 4). The findings point toward a possible biological role of glycosphingolipids in parasitism.

We recently isolated a fucosylated glycosphingolipid (SEGLx) with a novel carbohydrate structure from plerocercoids of *Spirometra erinacei* (5). This prompted us to study in more detail the distribution of glycosphingolipids in this parasite. In the present study, we determined the molecular species of the cerebrosides in two growth stages of *S. erinacei*, i.e., in the larval (plerocercoids) and in the adult forms. Although the compositional heterogeneity of cerebrosides in different cestode species has been reported (6–11), the cerebrosides of *S. erinacei* have not been characterized so far. Based on the present findings, we will discuss differences in cerebroside compositions at different growth stages, species differences, and their relationship with putative precursors of SEGLx.

MATERIALS AND METHODS

Collection of plerocercoids and adult worms. Plerocercoids of *S. erinacei* were collected from snakes, *Elaphe quadrivirgata*, in Japan. The plerocercoids were quickly removed from the muscle and subcutaneous tissues of snakes, and washed thoroughly with 0.8% NaCl. Adult tapeworms were obtained from cats infected with plerocercoids for 20 d. Tapeworms were collected from the cat intestines and washed with 0.8% NaCl. Totals of approximately 200 g of plerocercoids and 150 g of adult tapeworms were used in the present investigation.

Extraction and purification of glycolipids. Plerocercoids and tapeworms were extracted with 20 vol of chloroform/methanol (2:1, vol/vol), followed by 10 vol of chloroform/methanol/water (1.0:1.0:0.1, by vol). The filtrates were combined and concentrated to dryness in a rotary evaporator. Following removal of nonlipid contaminants by repetitive ex-

traction with chloroform/methanol (2:1, vol/vol), the material soluble in this solvent (total lipids) amounted to 4.0 g from plerocercoids and 2.3 g from adult cestodes.

Total lipids were subsequently chromatographed on a column of DEAE-Toyopearl (Tosoh Co., Tokyo, Japan), acetate form, and neutral glycolipids were separated from acidic lipids as described (12). Neutral glycolipids were further fractionated by Iatrobeads (6RS-8060 1 × 90 cm; Iatron Laboratories, Tokyo, Japan) column chromatography, using a linear gradient solvent system, comprising 5 column vol of chloroform/methanol (98:2, vol/vol) to chloroform/methanol/water (60:40:5, by vol), at the flow rate of 2 mL/min. The resultant cerebroside fraction was purified by high-performance liquid chromatography (HPLC) (Model CCPS; Tosoh Co.) on a column of ODS 80TM (4.6 × 150 mm; Tosoh Co.). It was confirmed that the isolated cerebrosides did not contain any other glycolipids on thin-layer chromatography (TLC).

Analytical methods. Purified glycolipids were methanolyzed with 5% methanolic HCl at 100°C for 3 h. Fatty acid methyl esters were extracted from the methanolysate using *n*-hexane. The resultant methanolic phases were dried under a stream of nitrogen and the residue trimethylsilylated with pyridine/hexamethyldisilazane/trimethylchlorosilane (10:2:1, by vol). The trimethylsilyl (TMS) derivatives of carbohydrates were subsequently analyzed by gas–liquid chromatography (GLC) on a SPB-1 fused-silica capillary column (0.32 mm × 30 m; Supelco Inc., Bellefonte, PA). The column temperature was programmed from 60 to 190°C at the rate of 20°C/min, held at 190°C for 1 min, and then elevated to 260°C at the rate of 10°C/min.

Fatty acid methyl esters were analyzed by GLC on the same column as above. The column temperature was programmed from 50 to 200°C at the rate of 20°C/min, and then elevated to 300°C at the rate of 10°C/min. For determination of sphingoid bases of glycolipids, the material was hydrolyzed with aqueous methanolic HCl at 85°C for 3 h (13). After removal of fatty acid methyl esters, sphingoid bases in the methanolic phase were extracted using diethyl ether under strongly alkaline conditions, and then analyzed as TMS derivatives by GLC, as described above. The column temperature was programmed from 50 to 240°C at the rate of 20°C/min, and then raised to 260°C at the rate of 2°C/min.

Gas chromatography/mass spectrometry (GC/MS) was performed with a Shimadzu QP-1100EX apparatus (Shimadzu, Kyoto, Japan) on a HiCap CBP1 fused-silica capillary column (0.33 mm × 25 m; Shimadzu), with He as the carrier gas, which was applied at the flow rate of 1 mL/min. MS was carried out at an electron energy of 70 eV and an ion source temperature of 250°C.

Fast atom bombardment mass spectrometry (FAB–MS). Negative-ion FAB–MS of cerebrosides was performed using a JMS-HX110 double focusing mass spectrometer equipped with an FAB ion source and a JMA-DA5000 data system (JEOL, Tokyo, Japan), with triethanolamine as the matrix (14). The accelerating voltage was set at 8.0 kV and the primary beam for bombardment at 6.0 kV Xe^0.

Micro HPLC/FAB–MS analysis. Micro HPLC/FAB–MS was performed using a newly developed system, as described previously (14). Briefly, cerebrosides isolated from *S. erinacei* were injected onto a column (Develosil ODS-5, 0.3 mm × 150 mm; Nomura Chemical Co., Aichi, Japan) and separated by elution with 10% *n*-hexane in methanol containing 0.9% glycerol, which was used as the matrix, at the flow rate of 6 μL/min. Liquid nitrogen was introduced into the trap of the oil diffusion pump in order to keep the vacuum as high as possible. Mass chromatography was performed for the detection of the ions from *m/z* 300 to 1,500 at intervals of 5 s.

RESULTS AND DISCUSSION

Composition of glycosphingolipids. A total of 48 mg of cerebrosides was extracted from 200 g of plerocercoids, while 150 g of adult tapeworms provided 24 mg of cerebrosides. Figure 1 shows that cerebrosides from both plerocercoids and adult worms were separated into four fractions, represented by single bands, on TLC. The relative contents of L1, L2, L3, and L4, which were determined by TLC–densitometry, were 1:4:1:0.3 (plerocercoids), while those of A1, A2, A3, and A4 were 1:9:17:3 (adult tapeworms). The results show that the third fraction (A3), followed by the fourth fraction (A4), increased most conspicuously with growth.

GLC analysis of the hexose composition of the cerebrosides showed that L1 consisted of galactose (69%) and glu-

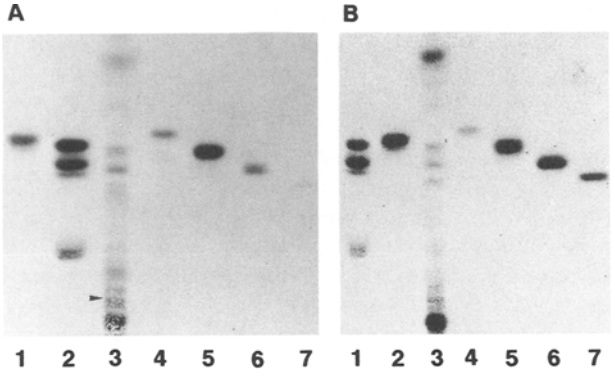

FIG. 1. Thin-layer chromatography of isolated cerebrosides of *Spirometra erinacei*. A. Plerocercoids. Lane 1, authentic glucosylceramide from human Gaucher's spleen; lane 2, authentic galactosylceramide and sulfatide from bovine brain; lane 3, total glycolipids of plerocercoids; lanes 4, 5, 6, and 7, purified cerebroside subfractions L1, L2, L3, and L4, respectively. B. Adult tapeworms. Lane 1, galactosylceramide and sulfatide from bovine brain; lane 2, glucosylceramide from human Gaucher's spleen; lane 3, total glycolipids of adult tapeworms; lanes 4, 5, 6, and 7, purified cerebroside subfractions A1, A2, A3, and A4, respectively. The arrowhead indicates SEGLx, a recently discovered glycosphingolipid (Ref. 5). Glycolipids were developed on a silica gel HPTLC plate (Merck, Darmstadt, Germany) with chloroform/methanol/water (65:25:4, by vol), and visualized by spraying with orcinol/H_2SO_4 reagent followed by heating.

cose (31%), whereas L2–L4 contained galactose only (Table 1). The subfractions of the cerebrosides from adult tapeworms (A1–A4) contained small amounts of glucose (range, 7–13%) in addition to galactose (range, 87–93%) (Table 2). Thus, the distributions of glucose and galactose in the four subfractions were found to be slightly different between plerocercoids and adult tapeworms. In previous studies, cerebrosides obtained from *S. mansonoides* tegument (6) and *Taenia crassiceps* metacestodes (7) were found to contain galactose as the only sugar component, while those of *Echinococcus multilocularis* metacestodes (8) were comprised mainly of galactose, with glucose constituting 9% of the cerebroside hexose.

Sphingoid bases consisted of two components, sphinganine (d18:0) and phytosphingosine (t18:0). Compositional analysis revealed that the distribution of the two components was almost identical in plerocercoids and the adult form (Tables 1 and 2): L1 and A1 consisted of only d18:0, while L4 and A4 contained large amounts of t18:0 (79 and 67%, respectively). Based on these results and those of previous studies indicating that galactosylceramides of *S. mansonoides* contained d18:0 and t18:0 but not d18:1 (6), we suspect that cerebrosides from *Spirometra* species contain only saturated sphingoid bases. This is in contrast to cerebrosides from *E. multilocularis* (8), *T. crassiceps* (7), and *Metroliasthes coturnix* (11), which contain detectable amounts of d18:1.

The fatty acid composition of *S. erinacei* cerebrosides was comprised of nonhydroxy fatty acids, ranging from C_{16} to C_{30}, and hydroxy stearic acid (18h:0) (Tables 1 and 2). Plerocercoid glycolipids L1 and L2 and adult tapeworm glycolipids A1 and A2 contained only nonhydroxy fatty acids, including components longer than C_{26}. On the other hand, plerocercoid L3 and adult tapeworm A3 contained both nonhydroxy and hydroxy fatty acids, nonhydroxy components consisting of short-chain components such as C_{16} and C_{18}, while 18h:0 amounted to nearly half the total. Plerocercoid L4 and adult tapeworm A4 contained mainly 18h:0, together with 18:0 as the other major species present. Although the overall distribution of cerebroside fatty acids was similar in plerocercoids and adult tapeworms, the abundance of long-chain monounsaturated components, such as 28:1 and 30:1 in plerocercoids, and that of the hydroxy component (18h:0) in adult forms, were notable. The results of previous studies indicated that cerebrosides from *E. multilocularis* (8), *M. coturnix* (11), and *T. crassiceps* (7) contain straight-chain fatty acids that are longer than those of *S. erinacei* found in the present study. The composition of hydroxy fatty acids, however, differed with the species. For example, *E. multilocularis* and *M. coturnix* cerebrosides contained long-chain 2-hydroxy components such as C_{24}, C_{26}, and C_{28} (8,11), whereas the glycolipid in *T. crassiceps* lacked hydroxy components (7).

Ceramide species of cerebrosides. To examine the combination of sphingoid bases and fatty acids composing ceramide moieties, the whole molecules of cerebroside subfractions were analyzed by MS. Negative-ion FAB–MS spectra of glycolipids showed major pseudo-molecular ions ($[M - H]^-$) at *m/z* 728, 840, and 866 (L1 and A1), 700, 728, 744, and 882 or 884 (L2 and A2), 716, and 744 (L3 and A3), and 728, 744, and 760 (L4 and A4), identical spectra being obtained for plerocercoids and adult tapeworms (Fig. 2).

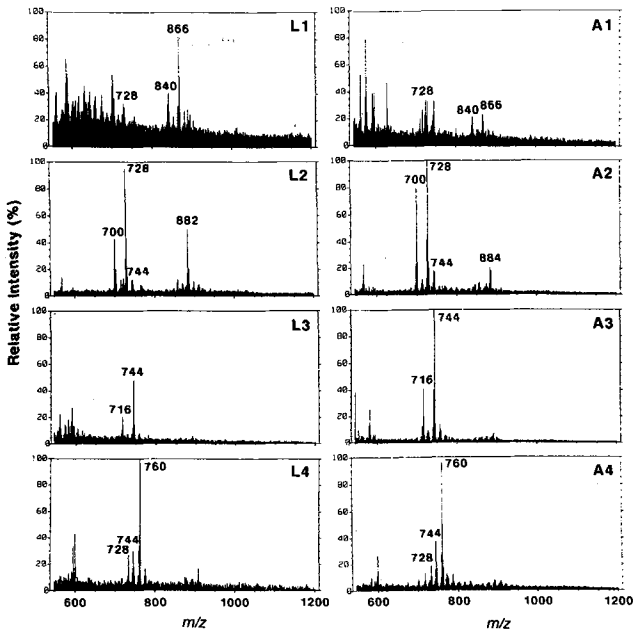

FIG. 2. Negative-ion fast atom bombardment mass spectrometry spectra of cerebroside subfractions from plerocercoids and adult tapeworms. L, plerocercoids; A, adult tapeworms.

Based on the HPLC/FAB–MS spectra (Fig. 2) and the analytical data for sphingoid bases and fatty acids (Tables 1 and 2), the major molecular species of ceramides were determined (Table 3). Selected peaks representing pseudo-molecular ions, such as *m/z* 700, 716, 728, 744, 760, 840, 866, 882, and 884, were also observed in the mass chromatograms obtained on micro HPLC/FAB–MS (data not shown), thus confirming the ceramide species shown in Table 3. In addition, the relative abundances of the respective molecular species determined by FAB–MS reflected those obtained on chemical analysis of ceramide moieties.

Considering the combination of ceramide species and the hexose composition, cerebroside molecules were slightly different between the two growth stages: glucocerebrosides of plerocercoids contained d18:0 and nonhydroxy fatty acids as ceramide constituents, whereas those of adult tapeworms contained various ceramide species, such as d18:0- or t18:0-linked to hydroxy or nonhydroxy fatty acids. These findings suggest that glucose can combine with not only the d18:0 but also the t18:0 sphingoid base in adult tapeworms.

700		d18:0–16:0		
716			t18:0–16:0	
728	d18:0–18:0	d18:0–18:0		d18:0–18:0
744		t18:0–18:0	d18:0–18h:0	t18:0–18:0
			t18:0–18:0	t18:0–18:0
760				t18:0–18h:0
840	d18:0–26:0			
866	d18:0–28:1			
882		t18:0–28:1 (L2)		
884		t18:0–28:0 (A2)		

The results of the present study demonstrate that the composition of *S. erinacei* cerebrosides is different from those of other cestode species. For example, *S. mansonoides* (6), a species taxonomically close to *S. erinacei*, contains three major cerebroside species, t18:0-18:0, d18:0-18h:0, and t18:0-18h:0. On the other hand, *M. coturnix* cerebroside contains d20:0 and t20:0 sphingoid bases, and longer chain hydroxy fatty acids (24h:0 and 26h:0) (11). The composition of *E. multilocularis* cerebroside fatty acids is different, since these acids include hydroxylated components ranging from C_{16} to C_{28} (8). In contrast to these cestode species, cerebrosides from *T. crassiceps* lack hydroxy fatty acids (7). We suggest that the distribution of cerebrosides in each of the various cestodes studies is an inherent property of that species, since the composition is not essentially different between *S. erinacei* plerocercoids and adults, although they are found in radically different hosts.

In summary, the cerebrosides from plerocercoids and the adult form of *S. erinacei* were separable into four subfractions. The different TLC mobilities were mainly due to differences in ceramide species. It should be noted that the two growth stages had essentially the same cerebroside constituents in spite of the entirely different environmental conditions; there were measurable differences in the quantitative distributions of the four cerebroside subfractions, i.e., in their hexose, fatty acid and sphingoid base substituents. These findings show that the glycolipids were homeostatically maintained as plasma membrane components throughout the lifecycle of this parasite, although slight modification of ceramide constituents may occur. In addition, the composition of sphingoid bases and fatty acids corresponded to that of SEGLx, a novel fucosylated glycosphingolipid that was recently reported by our group (5). This suggests that cerebrosides represent possible biosynthetic precursors of SEGLx.

ACKNOWLEDGMENTS

We wish to thank Dr. T. Udagawa for his encouragement throughout the course of this work. We also thank Dr. A. Suzuki (Tokyo Metropolitan Institute of Medical Science) for his interest in the study, and T. Taketomi (Shinshu University) for the gift of the standard fatty acids, 27:0 and 28:0. This work was supported in part by a Sasagawa Scientific Research Grant from the Japan Science Society, and by a Grant-in-Aid from the Ministry of Education, Science and Culture of Japan.

ABSTRACT: The major ether-type lipid structures of *Sulfolobus acidocaldarius* (ATCC33909) were composed of caldarchaeol and calditoglycerocaldarchaeol. However, the characterization by nuclear magnetic resonance spectroscopy and mass spectrometry showed that the structure of calditol in calditoglycerocaldarchaeol is not nonitol, 2-(1′,2′,3′-trihydroxypropyl)1,2,3,4,5,6-hexahydroxyhexane, but 2-hydroxymethyl-1-(2,3-dihydroxypropoxy)2,3,4,5-cyclopentanetetraol with an ether linkage in the molecule. Such an intermolecular ether linkage was resistant to BCl_3 treatment, but nonresistant to 57% HI degradation treatment conducted at 100°C for 60 h, producing 2-hydroxymethyl-1,2,3,4,5-cyclopentanepentaol from calditol as reaction product. Further, it was confirmed that the structure of calditol is essentially a derivative of glycerol, and hydrocarbon chains were conjugated to the glycerol-like site in the structure. The calditol with an ether linkage in the molecule suggested an important role regarding the properties of heat-resistance and acid-resistance observed in *Sulfolobales*.
Lipids 30, 339–344 (1995).

The membranes of thermoacidophilic archaebacteria are monolayers based on two types of cyclic tetraether core lipids in which two polyols are linked together through two C_{40} isoprenoid chains (1–4). In one core type the hydrophilic portions were two glycerol units; the core has been termed caldarchaeol. The other type displayed hydrophilic portions of glycerol and calditol, and could be called calditoglycerocaldarchaeol according to Nishihara *et al.* (5). It was reported by De Rosa *et al.* (6) that the structure of calditol from calditoglycerocaldarchaeol of *Sulfolobus solfataricus* was nonitol, 2-(1′,2′,3′-trihydroxypropyl)-1,2,3,4,5,6-hexahydroxyhexane (hereafter, calditoglycerocaldarchaeol with the structure of nonitol will be described as nonitoglycerocaldarchaeol). Because no such nonitoglycerocaldarchaeol has been found in *Halobacteria* and *Methanobacteria* of *Archaea,* the presence of nonitoglycerocaldarchaeol in bacterial lipids has been considered as a specific taxonomic marker for *Sulfolobales* (7–10).

We have isolated several species of sulfur-dependent, extremely thermophilic archaebacteria from different hot springs in Japan and have investigated the structure of their bacterial lipids (A. Sugai, I. Fukuda and T. Itoh, unpublished data), comparing them with the type strains of *Sulfolobaceae.* From these experimental results, both caldarchaeol and calditoglycerocaldarchaeol were detected from *S. acidocaldarius* (ATCC33909), *Acidianus brierleyi* (IFO15269), *Metallosphaera sedula* (IFO15509), and our strains. In all these strains, calditoglycerocaldarchaeol was a major core component which constituted about 80% of all cores. However, the results of fast atom bombardment mass spectrometry (FAB–MS) analysis for calditoglycerocaldarchaeol prepared from these strains were not in agreement with those of the calculated molecular mass of nonitoglycerocaldarchaeol. From this finding it could be presumed that the structure of calditol obtained from our calditoglycerocaldarchaeol was different from the nonitol in nonitoglycerocaldarchaeol from *S. solfataricus.* On the other hand, in the early works of archaebacterial lipids, it was reported by Langworthy *et al.* (11) that the structure of calditol might be cyclic–polyol linked *via* an ether linkage to glycerol in *S. acidocaldarius.* In this paper we investigated the structure of calditol from calditoglycerocaldarchaeol in *S. acidocaldarius,* and we report that the structure of calditol obtained in our experiments is that of a new type polyol which was postulated by Langworthy *et al* (11).

MATERIALS AND METHODS

Materials. Chloroform and methanol were distilled before use. All other chemicals and solvents were of analytical grade.

Organisms and culture conditions. Sulfolobus acidocaldarius (ATCC33909) was obtained from the American Type Culture Collection (ATCC, Rockville, MD), and the cells were grown at 75°C, pH 2.5 in 5-L medium consisting of inorganic salts [$CaCl_2 \cdot 2H_2O$, 0.4 g; $MgSO_4 \cdot 7H_2O$, 1.25 g; KH_2PO_4, 1.4 g; $(NH_4)_2SO_4$, 6.5 g], supplemented with 5 g of yeast extract and 10 g of sucrose. The cultures were aerobically grown for 60 h.

Lipid extraction. Total lipids were extracted from harvested cells with neutral solvents as follows: Cells were harvested from the culture medium by centrifugation, washed twice with 20 mL of distilled water, and suspended in 10 mL of methanol. After the addition of 5-mL chloroform, the mixture was sonicated for 20 min and centrifuged. The supernatant was then transferred to a recovery flask. The precipitated cells were suspended in 30 mL of chloroform/methanol/water (1:2:0.5, by vol) and sonicated for 20 min. Each suspension was centrifuged, and the supernatant was combined with that previously obtained. The extraction was repeated three times. All supernatants were dried using a rotary evaporator at 40°C. Residual lipids were dissolved by adding 5 mL of chloroform/methanol (2:1, vol/vol) and 0.5 mL of water with thorough mixing. Methanol was then added to the mixture until the solution was clear. The mixture was used for lipid analysis as a crude total lipid.

Thin-layer chromatography (TLC). TLC was performed with silica gel 60 high-performance thin-layer chromatography (HPTLC) plates (0.25 mm; Merck, Darmstadt, Germany) which were activated at 120°C for 2 h before use. The TLC of polar lipids was conducted on activated plates that had been dipped in 3% H_3BO_3–methanol, and developed using chloroform/methanol/0.2% CaCl (55:45:7, by vol, solvent system A). The core lipids, including calditoglycerocaldarchaeol, were chromatographed on activated plates in chloroform/ethanol (9:1, vol/vol, solvent system B). Acetylated core lipids and nonitol were developed on activated plates in chloroform/ethyl acetate (9:1, vol/vol, solvent system C). Lipid spots on TLC plates were detected by spraying the Dittmer reagent (12) for phospholipids, and both reagents, for all lipids. After spraying with both reagents, all lipids were visualized as charred spots after heating at 160°C for 10 min. Preparative TLC for the purification of the lipids or their degradation products were also chromatographed on HPTLC plates with the same solvents.

Preparation of core lipids. Total bacterial lipids (10 mg) were heated under reflux in 1.5 mL of 5% methanolic–HCl in a stoppered reaction tube for 2 h to release the polar head groups from the intact lipids. The core lipids were obtained from the organic phase after partition between chloroform and water. The core lipids were chromatographed on a silica gel column (i.d. 15 mm × 300 mm) with Iatrobeads 6RS-8060 (Iatron, Tokyo, Japan). The column was eluted stepwise with solvents of increasing polarity from chloroform to chloroform/methanol at 9:1 (vol/vol), 4:1 (vol/vol), and 2:1 (vol/vol). Chloroform/methanol (4:1, vol/vol) eluted calditoglycerocaldarchaeol, which was further purified by preparative TLC with solvent B.

Preparation of calditol. The following procedure is a modification of the method of Nishihara and Koga (13). Calditoglycerocaldarchaeol (100 mg) was treated with 2 mL of BCl_3/chloroform (1:1, vol/vol) at room temperature for 3 h. The reaction solution was dried under a stream of nitrogen, and borate was removed by the repeated addition of methanol followed by drying. The residue was chromatographed on an Iatrobeads column (i.d. 5 mm × 50 mm) which was then eluted stepwise with solvents of increasing polarity from chloroform to chloroform/methanol at 2:1 (vol/vol), 3:2 (vol/vol) and 1:1 (vol/vol). The calditol fraction was eluted with chloroform/methanol (3:2, vol/vol).

Cleavage of the ether bond in calditol. Calditol (1 mg) was treated with 57% HI (0.5 mL) at 100°C for 72 h. After neutralizing the HI reaction mixtures with Amberlite CG-400I (OH^- form; Tokyo Organic Chemical Industries, Ltd., Tokyo, Japan), the solution was filtered through glass wool and dried *in vacuo*. Following acetylation, the residual products were purified by column chromatography over Iatrobeads. Chloroform eluted the acetylated degradation products of calditol.

Periodate oxidation of calditoglycerocaldarchaeol. Calditoglycerocaldarchaeol (1 mg) was dissolved in 0.5 mL of chloroform, and 1.2 mL of methanol and 0.5 mL of 0.2M sodium metaperiodate were then added. The mixture was oxidized for 6 h at room temperature. After excess reagent was destroyed with glycerol, the oxidation products were recovered by extraction with chloroform (1 mL) and dried under a nitrogen stream. The residue was dissolved in 0.5 mL of chloroform, and 2 mL of methanol and 0.5 mL of 0.25M sodium borohydride were added. The reduction was performed for 15 h at room temperature. Excess borohydride was destroyed with 1M HCl. After drying, the reduction products were acetylated, and examined with gas chromatography/MS.

Methylation of calditol. The methylation of calditol was performed using the modified method of Ionel and Francisc (14) as follows: Calditol (1 mg) was dried under vacuum and methylated in a mixture of dimethyl sulfoxide (0.5 mL), CH_3I (0.1 mL), and NaOH (100 mg) powder under sonication for 10 min. The methylated calditol was then extracted with chloroform/water (1:1, vol/vol) under cooling, and purified by preparative TLC with solvent C.

Acetylation of calditol. A sample (10 mg) was dried under vacuum, and acetylated with 3 mL of acetic anhydride/pyridine (2:1, vol/vol) at 60°C for 12 h. After being cooled, the acetylated products were dried under a stream of nitrogen, and then purified by preparative TLC in the same manner as methylated calditol.

Trimethylsilation of calditol. The trimethylsilation of calditol was done using the mixture of pyridine/1,1,1,3,3,3-hexamethyldisilazane/trimethylchlorosilane (5:1:1, by vol) at

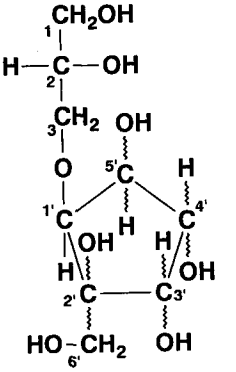
100°C for 40 min. After cooling, the trimethylsilated calditol was extracted with chloroform/water (1:1, vol/vol).

MS analysis. Negative and positive FAB–MS of calditol was obtained using a JMS-AX505H (JEOL, Tokyo, Japan) instrument with a matrix of glycerol, and for acetylated calditol, 3-nitrobenzylalcohol (NBA), or a mixture of NBA and NaI was used as the matrix. GC/MS was performed on a glass packed column (3% OV-101, i.d. 3 mm × 1 m; GL Sciences, Tokyo, Japan) at a temperature increasing from 100 to 250°C at a rate of 8°C/min and 40 mL/min of isobutane chemical ionization reagent gas using a JMS-DX300 (JEOL) instrument.

Nuclear magnetic resonance spectroscopy (NMR) analysis. ^{1}H and ^{13}C NMR proton decoupled spectra were obtained using a Varian VXR-300 (Varian Instruments, Ltd., Palo Alto, CA) at 300 and 75 MHz, respectively. Calditol and acetylated calditol were dissolved in dimethyl sulfoxide (DMSO) or DMSO-d_6. Chemical shifts were given in ppm relative to tetramethylsilane as the internal standard. Analysis of the multiplicities of the peaks found in the ^{13}C NMR spectra of calditol and acetylated calditol were achieved using the distortionless enhancement by polarization transfer (DEPT) technique, which discriminates between methine, methyl, and methylene spins.

RESULTS

NMR data for calditol. The ^{1}H NMR spectrum of calditol showed the presence of seven hydroxyl groups. Their proton resonances could be seen at 4.18 ppm (triplet), 4.45 ppm (doublet), 4.46 ppm (triplet), 4.55 ppm (singlet and doublet), 4.65 ppm (doublet), and 5.01 ppm (doublet). These chemical shifts disappeared by adding DMSO-d_6. Also, the ^{13}C NMR spectrum of calditol obtained using the DEPT technique showed nine carbons at 61.83 ppm (methylene), 63.26 ppm (methylene), 70.43 ppm (methine), 72.54 ppm (methylene), 75.32 ppm (methine), 76.10 ppm (methine), 79.92 ppm (single), 81.54 ppm (methine), and 91.35 ppm (methine). The number of carbons was the same as in nonitol. Detailed information on the structure could not obtained from ^{1}H NMR of the intact calditol, as no assignments could be made, due to the ambiguous separations of the ^{1}H chemical shifts in a high magnetic field.



NMR data for acetylated calditol. In fully acetylated calditol, each of the seven ^{13}C chemical shifts of the methyl and carbonyl resonances derived from the acetyl groups was observed at 20.21–21.68 ppm and 168.81–170.17 ppm, respectively. No ^{1}H chemical shifts from hydroxy groups were observed in acetylated calditol. These results showed that all seven hydroxy groups observed in intact calditol were fully acetylated. In the region from 58.61 to 86.07 ppm, nine ^{13}C signals, due to the skeletal carbons of acetylated calditol, could be seen as the same number of skeletal carbons of intact calditol.

The ^{13}C NMR chemical shifts of individual carbons and ^{1}H NMR chemical shifts of protons in acetylated calditol are shown in Table 1. The postulated calditol structure is shown in Scheme 1. Assignments of ^{1}H to ^{13}C were made by the ^{1}H-detected multiple quantum coherence spectrum technique (Fig. 1A). The skeletal structure of acetylated calditol was confirmed by the ^{1}H-detected multiple-bond heteronuclear multiple quantum coherence (HMBC) spectrum technique in which the relationship between a proton and 2–3 carbon bonds from the proton, $^2J_{CH}$ and $^3J_{CH}$, were observed. The results of HMBC are shown in Figure 1B: long-range coupling of ^{1}H and ^{13}C of acetylated calditol was observed from H-1 to C-2, H-2 to C-1, H-3 to C-1, C-2 and C-1′, H-1′ to C-3, C-2′, C-3′, and C-5′, H-3′ to C-1′ and C-5′, H-4′ to C-5′, H-5′ to C-1′, and C-4′, H-6′ to C-2′ and C-3′. The ^{1}H-^{1}H correlation spectroscopy showed cross peaks from H-1 to H-3 and H-1′ to H-3′, but no cross peak was observed between H-3 and H-1′ (data not shown). No linkages of the acetyl group to C-3 and C-1′ were observed by long-range selective proton decoupling and HMBC. Because neither C-3 nor C-1′ is hydroxylated, an ether linkage would appear to be present between these carbons, based on the C-3 and C-1′ in acetylated calditol being moved downfield (see Table 1).

TABLE 1
^{13}C Nuclear Magnetic Resonance Spectroscopy (NMR) Chemical Shifts and ^{1}H NMR Chemical Shifts for Acetylated Calditol[a]

Carbon number	^{13}C NMR δ_C	^{1}H NMR δ_H

SCHEME 1

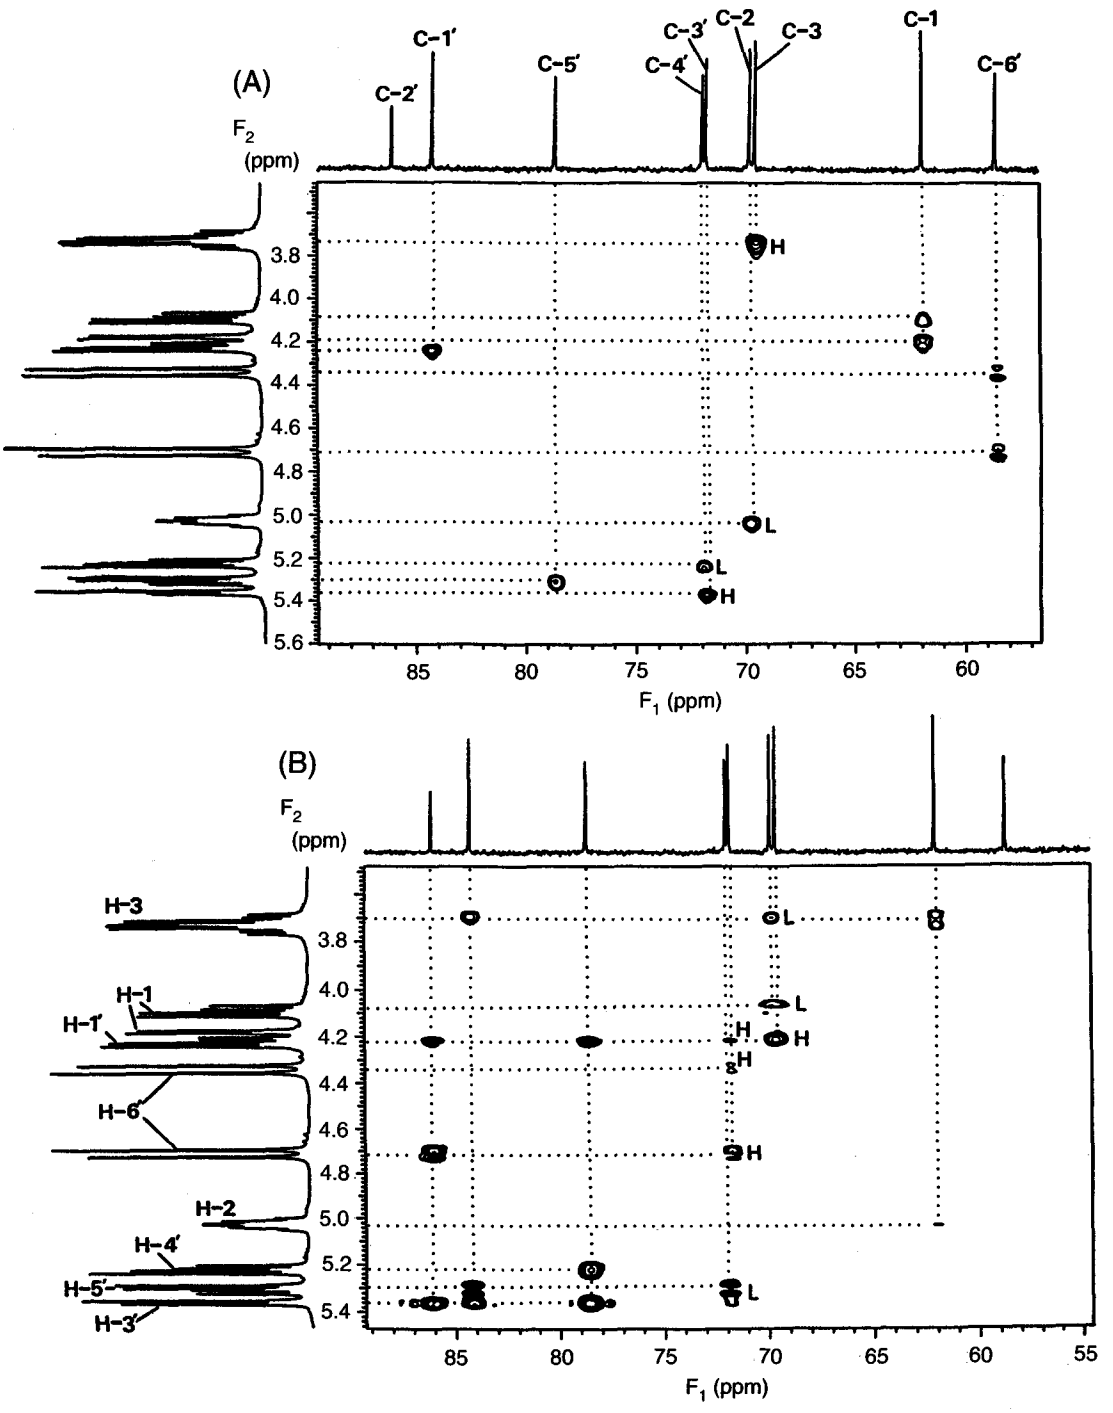

FIG. 1. (A) ^{1}H-Detected multiple-bond heteronuclear multiple quantum coherence spectrum and (B) ^{1}H-detected multiple quantum coherence spectrum of acetylated calditol. The axis of F_2 corresponds to ^{1}H nuclear magnetic resonance (NMR) chemical shifts and the axis of F_1 corresponds to ^{13}C NMR chemical shifts. "H" indicates a high magnetic field and "L" indicates a low magnetic field.

Nuclear Overhauser effects (NOE) were detected between H-1′ and H-5′ ($J_{H1'\text{-}H5'}$ = 5.25 Hz), H-3′ and H-4′ ($J_{H3'\text{-}H4'}$ = 5.25 Hz), respectively, indicating a *cis* relationship between these two protons. The existence of NOE between H-4′ and H-5′ ($J_{H4'\text{-}H5'}$ = 8.33 Hz) could not be examined, as those ^{1}H NMR chemical shifts were close to each other. H-1′ and C-6′ appeared to be in a *cis* conformation, because NOE was observed between H-1′ and H-6′. Based on NMR, the structure of calditol appeared to be **1**, 2-hydroxymethyl-1-(2,3-dihydroxypropoxy)-2,3,4,5-cyclopentanetetraol.

The mass spectra data of calditol. Negative FAB–MS of calditol showed a peak at *m/z* 253 [(M – H)$^-$; 100%], *m/z* 507 [(2M – H)$^-$; 56], *m/z* 761 [(3M – H)$^-$; 6] and *m/z* 1015 [(4M – H)$^-$; 2]. Positive FAB–MS showed a peak at *m/z* 255 [(M + H)$^+$; 100%], *m/z* 347 [(M + glycerol + H)$^+$; 16] and *m/z* 439 [(M + 2-glycerol + H)$^+$; 5]. In these FAB–MS spectra, a num-

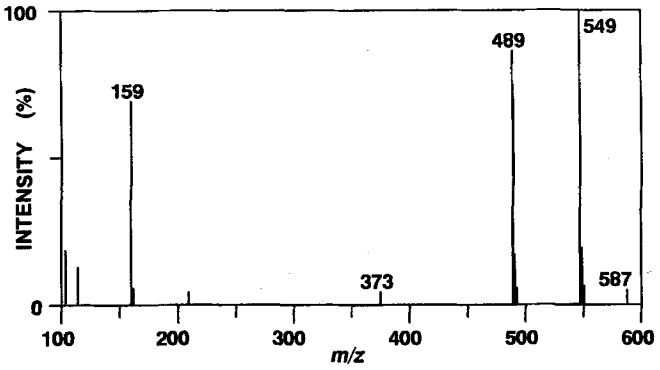

FIG. 2. Gas chromatography/mass spectrometry [chemical ionization (CI)] spectrum of acetylated calditol.

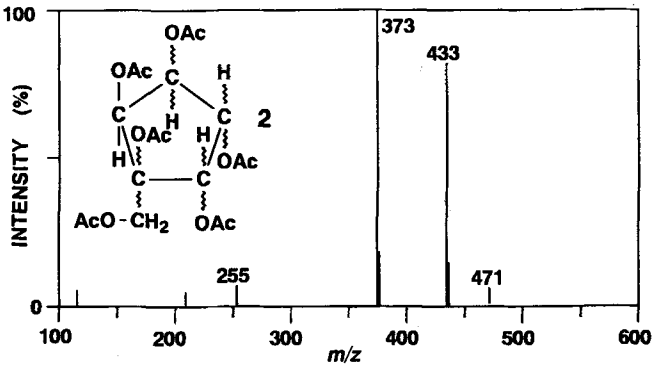

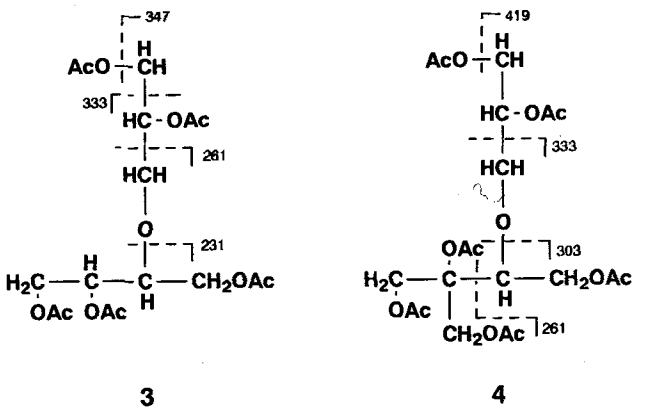

FIG. 3. Gas chromatography/mass spectrometry (CI) spectrum of the acetylated hydroiodic acid degradation product of calditol. A satisfactory conclusion could not be drawn from nuclear magnetic resonance.

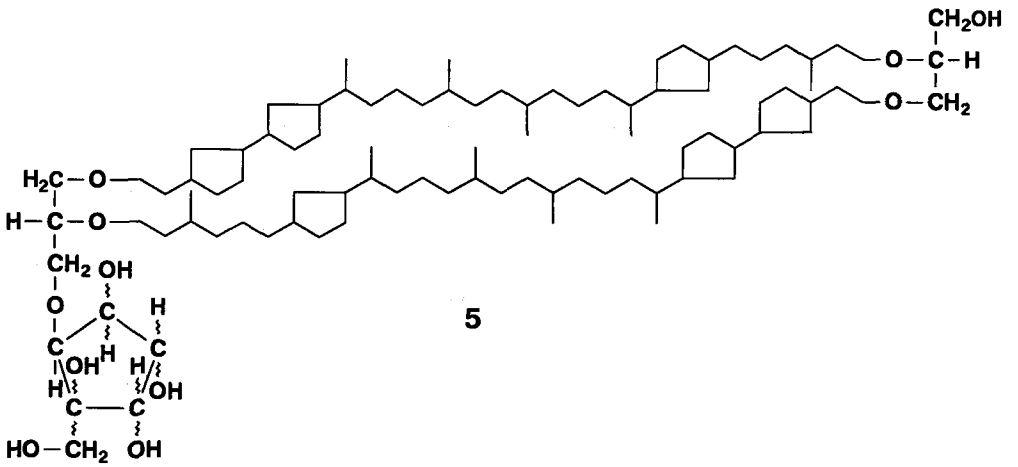
ber of noncovalent cluster peaks were observed, but showed strong molecular ion peaks corresponding to the postulated molecular formula $C_9H_{18}O_8$; 254.

GC/MS of acetylated calditol showed a peak at *m/z* 549 as a molecular ion peak (Fig. 2), and methylated calditol and trimethylsilated calditol showed parent peaks at *m/z* 353 and *m/z* 759, respectively (data not shown). The molecular peaks of these calditol derivatives observed by GC/MS were confirmed by positive FAB–MS spectra. These results supported the estimated structure of calditol as determined by NMR, as these derivatives possessed seven acetyl, seven methyl, and seven trimethylsilyl groups, respectively.

The degradation of calditol. An attempt was made to cleave the intermolecular ether linkage to confirm the structure of calditol. After BCl_3 treatment of calditol was done under the general conditions (2,8), the products were acetylated and examined by GC/MS. From these results, only acetylated calditol was detected on GC/MS, so this linkage could not be cleaved using the BCl_3 method. The cleavage was accomplished by heating at 100°C for 60 h with 57% HI. The degradation products of calditol by 57% HI treatment were acetylated and analyzed by GC/MS. Acetylated 1,2-dihydroxy-3-iodopropane was not detected as a degradation product, but a peak corresponding to acetylated 1-hydroxymethyl-1,2,3,4,5-cyclopentanpentaol was obtained, and the mass spectrum gave peaks for $(M + K)^+$ at *m/z* 471, the protonated molecule, $(M + H)^+$ at *m/z* 433, and a peak at *m/z* 373 due to the loss of one acetyl group from structure **2** in Figure 3.

The structure of calditoglycerocaldarchaeol. Periodate oxidation of calditoglycerocaldarchaeol was carried out to confirm the conjugated sites of the hydrocarbon chains to calditol in calditoglycerocaldarchaeol, and, after reducing, the polyol moiety was recovered by BCl_3 treatment. The polyols were acetylated and examined with GC/MS. The result showed that the glycerol portion of calditoglycerocaldarchaeol was not decomposed and was detected quantitatively, though no calditol was detected because of complete cleavage. Two major peaks were observed on the gas chromatogram of the calditol degradation products. The proportions of the two peaks, A and B, were 0.6:0.4. The GC/MS of A and B were as follows: A, *m/z*



SCHEME 2

406 (M + H; 7%), 347(100), 333(1), 303(2), 261(6), 231(11), 159(61); and (B), *m/z* 478 (M + H; 9%), 419(100), 333(5), 303(7), 261(3), and 159(73). This result suggested that structures A and B were **3** and **4**, respectively, as shown in Scheme 2. Because both structures showed that the glycerol-like portion of calditol had not been oxidized, it seems most likely that the C_{40} isoprenoid chains had been conjugated to C-1 and C-2. From these results, the structure of calditoglycerocaldarchaeol was deduced to be that indicated in Scheme 3. Also, the molecular ion peaks (producing plural molecular ions by the number of cyclopentane rings in alkyl chains), *m/z* 1456 and *m/z* 1452, on negative FAB–MS of calditoglycerocaldarchaeol prepared from *S. acidocaldarius*, suggested the structure of **5**.

DISCUSSION

In the present work, we have described the structural elucidation of calditol from the core lipid of *S. acidocaldarius*. The existence of an ether linkage in the calditol molecule was determined by NMR data. The intermolecular ether linkage of calditol was resistant to BCl_3 treatment, but nonresistant to HI degradation treatment. The HI degradation procedure produced 1-hydroxymethyl-1,2,3,4,5-cyclopentanepentaol from

SCHEME 3

calditol. This resistance was presumably due to the existence of a steric hindrance by hydroxy groups in the polyol. The structure of calditol was determined as heptanol, **1**, 2-hydroxymethyl-1-(2,3-dihydroxypropoxy)-2,3,4,5-cyclopentanetetraol. However, respective NOE observed in between H-1′ and H-2′, H-1′ and H-6′, were very weak, so we could not completely exclude the possibility that no NOE were presented in them. If the existence of those NOE are in error, all orientations of H-2′, H-3′, H-4′, and C-6′ on the cyclopentane ring of calditol should be contrary to **1**. To confirm this structure, it would be necessary to examine the chemical structure of calditol by X-ray diffraction studies.

The stereochemical structure of the glycerol moiety of calditol was not unambiguously established by the values of $J_{H1\text{-}H2}$ (6.45 Hz) and $J_{H2\text{-}H3}$ (4.50 Hz), and the NOE data. But, if the 2,3-dihydroxypropyl group of calditol is assumed to be present instead of glycerol, hydrocarbon chains should bond to the *sn*-2,3 configuration of the glycerol moiety through ether linkages, as can he seen in other archaebacterial lipid cores (8). In any case, the structure obtained in our experiments shows that calditol from *S. acidocaldarius* is not just a peculiar polyol, as was the previously published nonitol from *S. solfataricus,* but is essentially a derivative of glycerol. Also, our structure of calditoglycerocaldarchaeol, **5**, as shown in Scheme 3, is a stable form of glycolipid since a hexose-like compound is conjugated with glycerol through an ether linkage.

In a historical note, the structure of calditol was shown by Langworthy *et al.* (11) to be the cyclic–polyol linked *via* an ether linkage to glycerol, and the note indicated six free hydroxy groups in the structure of calditoglycerocaldarchaeol. Our presented structures **1** and **5** were neither nonitol nor nonitoglycerocaldarchaeol, respectively, but satisfied the results reported by Langworthy *et al.* (11). This structure may be one of the factors attributable to the properties of heat-resistance and acid-resistance observed in *Sulfolobales*.

Role of Cyclic Adenosine Monophosphate in Phospholipid Synthesis in *Mycobacterium smegmatis* ATCC 607

Harpinder Kaur and G.K. Khuller*

Department of Biochemistry, Postgraduate Institute of Medical Education and Research, Chandigarh-160012, India

ABSTRACT: The present study was undertaken to examine the influence of intracellular levels of cyclic AMP on phospholipid synthesis in *Mycobacterium smegmatis* ATCC 607. The cyclic AMP levels were modulated by growing cells in the presence of activator (forskolin) and inhibitor (atropine) of adenylate cyclase, the synthesizing enzyme of cyclic AMP. Forskolin-grown cells exhibited a 1.4-fold increase in the level of cAMP while a similar decrease (1.8-fold) was seen with atropine-grown cells. These altered levels of cAMP in turn affected the total content, composition and synthesis of phospholipids. Total phospholipid content increased and decreased in cells grown in the presence of forskolin and atropine, respectively. These observations were further supported by alterations in [^{14}C]acetate incorporation as well as in activities of glycerol kinase and glycerol-3-phosphate acyltransferase, the key enzymes of phospholipid synthesis. Protein phosphorylation mechanism seems to be involved in phospholipid metabolism as the activities of protein kinase increased and decreased in cells grown in forskolin or atropine cells. Our results demonstrate a correlation between phospholipid synthesis and intracellular levels of cAMP in *M. smegmatis*.
Lipids 30, 345–349 (1995).

Cyclic AMP participates in cellular function both in prokaryotic and eukaryotic organisms (1,2). Cyclic AMP in different mycobacterial species is present in large amounts in cells and culture fluid as reported earlier (3). Much of the evidence of cAMP involvement in regulation of various processes is based on the methods involving manipulation of its intracellular levels (4). In *Mycobacterium smegmatis*, this nucleotide has been shown to enhance the incorporation of [^{14}C]acetate into lipids when the cells were incubated with dibutryl-cAMP (5) or forskolin (6) while in *M. phlei*, no relationship was observed between the changes in phospholipid composition and cAMP (7). However, no systematic study has been carried out to demonstrate whether a correlation exists between intracellular levels of cAMP and lipid biosynthesis in mycobacteria. Therefore, the present study has been carried out with forskolin and atropine, activator/inhibitor of adenylate cyclase to find out the relationship between cAMP and lipid biosynthesis in *M. smegmatis* ATCC 607. Further, preliminary experiments were also carried out to determine the role of cyclic AMP-dependent protein phosphorylation in relation to phospholipid metabolism.

MATERIALS AND METHODS

[1-^{14}C]Glycerol-3-phosphate (specific activity 4.75 mCi/mmol^{-1}, [^{3}H]ATP (specific activity 13.5 Ci/mmol), [^{3}H]adenosine 3′,5′-cyclic monophosphate (specific activity 2000 mCi/mmol), [γ-^{32}P]ATP (specific activity 3000 Ci/mmol), and [1-^{14}C]acetate (specific activity 56.2 mCi/mmol) were purchased from Bhabha Atomic Research Centre (Bombay, India). [^{3}H]Glycerol (specific activity 2.5 Ci/mmol) was obtained from Amersham (Buckinghamshire, United Kingdom). Atropine, forskolin, cyclic AMP-dependent protein kinase inhibitor (catalogue number P-5015) and acetyl CoA were obtained from Sigma (St. Louis, MO). Other chemicals used were of analytical grade.

Organism and growth conditions. Mycobacterium smegmatis ATCC 607 (M. 607) obtained from NTCC (London, United Kingdom) was grown in modified Youman's medium as a static culture at 37°C (8). Cells were harvested in their mid log-phase and processed for different studies.

Determination of optimum concentration of atropine and forskolin. Mid log-phase cells were incubated with different concentrations of atropine (2 to 10 mM) and forskolin (1–7 μM) in Krebs Ringer buffer (KRB) (pH 7.2) for 3 h at 37°C. The cells were collected by centrifugation at 4°C, and a homogenate for adenylate cyclase assay was prepared by sonicating the cells at 4°C in 40 mM Tris-HCl buffer (pH 7.5). The homogenate was centrifuged at 5,000 × *g* for 20 min to remove cell debris, and the supernatant was used for enzyme assay. The activity of adenylate cyclase was assayed by the method of Salomon *et al.* (9).

Extraction and estimation of intracellular cAMP. Cells (0.3–0.5 g wet weight) were suspended in hot 0.1N HCl, and the suspension was kept in a boiling water bath for 10 min. Each sample was chilled, centrifuged at 12,000 × *g* for 10 min

at 4°C, and pH of the supernatant was adjusted to 7.0. The supernatant was again centrifuged at 12,000 × *g* for 10 min to remove precipitated material (10). Intracellular cAMP was then measured by the method of Takeda *et al.* (11).

Quantitation of lipids. Lipids were extracted by the method of Folch *et al.* (12). Phospholipids were quantitated by the method of Marinetti (13). Total phospholipids were separated from total lipids by thin-layer chromatography in acetone while individual phospholipids were separated by one-dimensional thin-layer chromatography on silica gel H (14) impregnated with 0.18% ammonium sulfate in chloroform/methanol/7N ammonia (65:25:4, by vol) as developing solvent. The respective fractions were scraped off and transferred into vials containing a toluene-based scintillation fluid for radioactivity determination.

Uptake studies. Cells grown in the presence of optimum concentration of atropine (6 mM) or forskolin (5 μM) were harvested and suspended in KRB (pH 7.2). [^{14}C]Acetate (25 μCi/100 mL) pulse was given for different time intervals ranging from 15 to 90 min. After appropriate incubation, cells were filtered and lipids were extracted.

Fatty acid synthesis. Fatty acid synthesis by intact cells was studied according to the method of Buttke and Ingram (15). [^{14}C]Acetate was added to the control, forskolin, and atropine grown cultures, at a concentration of 10 μCi/g cells/15 mL KRB buffer and incubated at 37°C for 60 min. The cells were filtered, washed with normal saline and lipids were extracted by the Folch procedure (12). Transesterification of lipids was done using 2% H_2SO_4 in methanol by the method of Silbert *et al.* (16). The methyl esters were extracted with pentane and concentrated under vacuum prior to analysis. Radioactivity was counted using a toluene-based scintillation fluid.

Enzyme assays. The homogenate for adenylate cyclase, phosphodiesterase and glycerol-3-phosphate acyltransferase was prepared by sonicating cells at 4°C in 40 mM Tris-HCl buffer (pH 7.5). For glycerol kinase, the cells were homogenized in 10 mM Tris-HCl buffer (pH 8.0) with 250 mM sucrose. The homogenate for protein kinase activity assay was prepared in 50 mM-Tris maleate buffer (pH 7.0). The homogenates were centrifuged at 5,000 × *g* for 20 min to remove cell debris, and the resulting supernatants were used for enzyme assays.

The activities of adenylate cyclase and phosphodiesterase were measured according to the methods of Salomon *et al.* (9) and Aboud and Burger (17), respectively. For the activity of acyltransferase, the assay system used was of Okuyama *et al.* (18), and the filter paper disc method of Goldfine (19), as modified by van den Bosch and Vagelos (20), was employed. The activity of glycerol kinase was determined by the method of Kasinathan *et al.* (21). The activity of protein kinase was measured as described by Banerjee and Sarkar (22).

RESULTS

The role of cAMP in phospholipid synthesis of *M. smegmatis* was examined by modulating its intracellular cAMP levels with the help of forskolin and atropine. These compounds alter the activity of adenylate cyclase and thus increase or decrease the cAMP levels in the cell.

Initially, the optimum concentrations of both forskolin and atropine were determined by measuring the activity of adenylate cyclase in the presence of different concentrations of either atropine (0–10 mM) or forskolin (0–7 μM) in the assay mixture. The activity of adenylate cyclase increased with increasing concentration of forskolin while the reverse was observed in case of atropine (Table 1). Maximum increase (56%) and decrease (48%) in adenylate cyclase activity was observed at 5 μM of forskolin or 6 mM of atropine, respectively. Therefore, these concentrations were used for further studies.

After determining the optimum concentration, cells were grown in the presence of these concentrations, and the growth was monitored. No significant change in the growth pattern of *M. smegmatis* was observed with optimum concentration of forskolin (5 μM) and atropine (6 mM). To examine the effect of cAMP on phospholipid synthesis, levels of intracellular cAMP were determined in cells grown in the presence of these compounds. Increased levels of cyclic AMP (40%) was exhibited in forskolin grown cells while a decrease (44%) was observed in atropine-grown cells (Table 2). These altered levels of cyclic AMP were probably due to the effect of these compounds on adenylate cyclase as the activity of this enzyme increased (60%) and decreased (45%) respectively in cells grown with forskolin or atropine (Table 2). However, the activity of phosphodiesterase remained largely unaltered by either treatment.

The effect of altered levels of cAMP on phospholipids of *M. smegmatis* was examined (Table 3). It was found that total content of phospholipids increased in forskolin-grown cells while a decrease was observed in atropine-grown cells. On examining the individual phospholipid components, significant increases in phosphatidylinositol mannosides (PIMs) and cardiolipin (CL) were observed in cells grown with forskolin while all the phospholipid components (PIMs, phos-

phatidylethanolamine and CL) decreased in atropine-grown cells. These changes in the phospholipids were further confirmed by examining the rate of incorporation of [^{14}C]acetate into phospholipids and total lipids (Fig. 1). A net stimulation in the rate was observed in forskolin-grown cells as compared to control cells while the rate was decreased in the atropine-grown cells.

The levels of phospholipids in cells change only when the activity of either synthesizing or degradative enzymes are altered. The activities of glycerol kinase and glycerol-3-phosphate acyltransferase, the key enzymes of phospholipid synthesis, increased and decreased in forskolin and atropine-grown cells, respectively (Table 4). Further, the activity of glycerol-3-phosphate acyltransferase depends upon the synthesis of fatty acids. Therefore, *in vivo* fatty acid synthesis was monitored, and it was found to increase (34%) in forskolin-grown cells and decrease (46%) in atropine-grown cells (Table 5).

In order to study the mechanism of action of cAMP, the phosphorylating capacity of *M. smegmatis* was examined. A crude mycobacterial cell extract phosphorylated histone, indicating the presence of protein kinase activity (Table 6). On addition of different amounts of cAMP to the assay mixture, the activity of protein kinase increased with increasing concentration of cyclic AMP. There was maximum activation at 2 μM, indicating the presence of cAMP-dependent protein kinase in *M. smegmatis* (Fig. 2). The protein kinase activity was completely inhibited in the presence of specific cAMP-dependent protein kinase inhibitor (20–60 μg/μL), further indicating its presence in *M. smegmatis*. The phosphorylating activity of forskolin- and atropine-grown cells was increased and decreased, respectively, compared to controls (Table 7), which may be due to the increased and decreased intracellular levels of cAMP in these cells (Table 2).

DISCUSSION

In prokaryotes, the role of cyclic AMP in the synthesis of inducible enzymes is well established but its effect on the regulation of phospholipid metabolism is not known. In this study, the influence of cyclic AMP on phospholipid synthesis was determined by modulating the intracellular levels of cAMP in *M. smegmatis*. Cells grown with forskolin and atropine exhibited increased and decreased levels of cAMP, respectively (Table 2). The raised levels of cAMP in forskolin-grown cells was due to the activation of adenylate cyclase by forskolin (Table 2) which is known to bind the catalytic subunit of the enzyme (23). Atropine decreased the activity of adenylate cyclase (Table 2), but its mechanism is unknown. Forskolin has been shown to increase the cAMP levels in human platelets (24) while atropine decreased its levels in *Neurospora crassa* (4).

Forskolin, which increased the cAMP levels, further enhanced the total content and synthesis of phospholipids while the opposite was seen with atropine, which lowered the levels of cAMP (Table 3). These results show a direct correlation between intracellular cAMP and phospholipid synthesis in *M. smegmatis* similar to the observations in *M. gypseum*

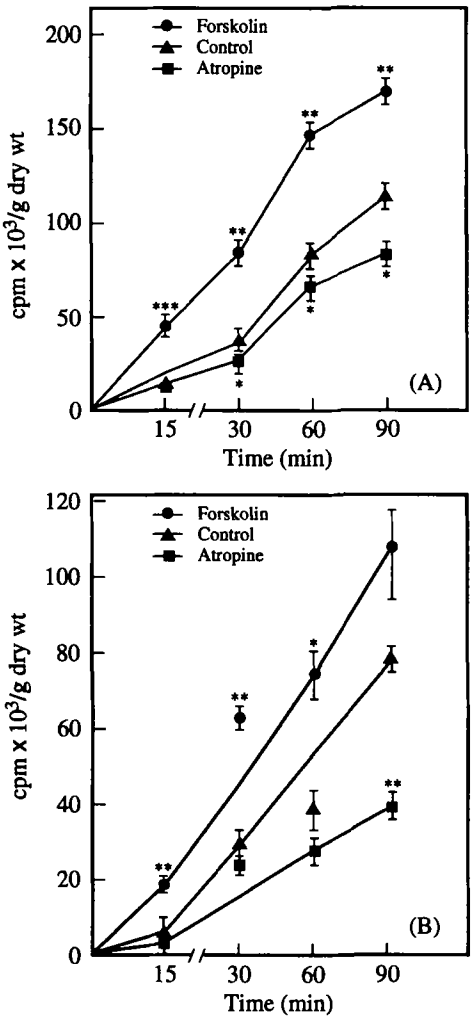

FIG. 1. Incorporation of [^{14}C]acetate into total lipids (A) and phospholipids (B) extracted from control cells (▲), forskolin (●), atropine (■) grown cells. After suspending the cells in Krebs Ringer buffer, [^{14}C]acetate (25 μCi/100 mL buffer) was added, and aliquots were taken at different time intervals ranging from 0–90 min. Lipids were extracted, and the radioactivity incorporated into lipids was counted as described in the Materials and Methods section. The values are mean ± SD of three different batches. [c]$P < 0.001$.

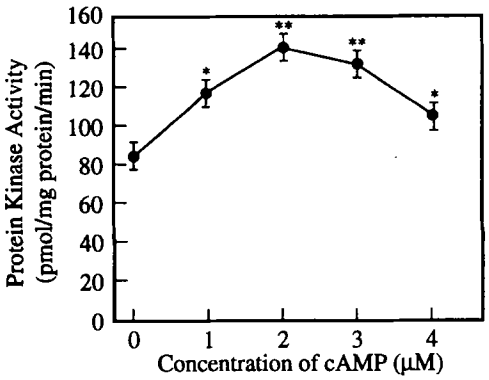

FIG. 2. Effect of cAMP on protein kinase activity in cell extracts of *Mycobacterium smegmatis*. Protein kinase activity was measured by comparing the transfer of [^{32}P]phosphate from [γ-^{32}P]ATP to histone in the presence of different concentration of cAMP. Assay was carried out in 50 mM Tris-maleate buffer (pH 7.0), containing 20 mM $MgCl_2$, 0.25 mg histone, 150 μM [γ-^{32}P]ATP, 10 mM DTT, 2.5 mg/mL bovine serum albumin, and an appropriate amount of enzyme preparation. Values are mean ± SD of four different batches. Asterisk denotes values that are significantly different from control (without cAMP). *$P < 0.05$, **$P < 0.01$ based on Student's *t*-test.

(25). The earlier report (5) that dibutryl cAMP increased the incorporation of [^{14}C]acetate into lipids of *M. smegmatis* further supports our observations with forskolin.

The increased and decreased activities of glycerol kinase and glycerol-3-phosphate acyltransferase in forskolin- and atropine-grown cells (Table 4) also correlates with the altered synthesis of phospholipids in these cells. We observed that

the activity of these enzymes depended on cAMP, which is consistent with earlier reports (24,26). Further, the activity of glycerol-3-phosphate acyltransferase depends upon the synthesis of fatty acids, which also was found to exhibit increases or decreases in cells grown in forskolin or atropine (Table 5). These results are in agreement with the earlier observation (3) that dibutryl cAMP increased the incorporation of [^{14}C]acetate into fatty acids by *M. smegmatis*. Thus, the increased or decreased synthesis of fatty acids in response to the altered levels of cAMP may ultimately be responsible for the altered synthesis of phospholipids.

In eukaryotes, action of cAMP is mainly mediated through cAMP-dependent protein kinase (27). As *M. smegmatis* is believed to lack cAMP receptor protein (28), the possibility of the presence of protein kinase in this organism was examined. A crude extract of the mycobacteria was found to possess protein kinase activity by its phosphorylation of histone (Table 6). This has also been demonstrated in other bacterial species (29). The addition of exogenous cAMP enhanced the protein kinase activity, indicating that at least some of the protein kinase present in *M. smegmatis* is cAMP-dependent. Similar findings were reported earlier for *Escherichia coli* (30), *Streptococci* (31), and *Saccharomyces cerevisiae* (32). Increased or decreased activity of protein kinase in cells grown in forskolin or atropine, respectively (Table 6), is probably due to the altered expression of the protein in mycobacteria, and this aspect warrants further study.

In summary, we can conclude from the present results that phospholipid biosynthesis in *M. smegmatis* is influenced by cyclic AMP and that its effects are probably mediated through protein kinases.

[a]Laboratoire de Biologie et Physiologie Végétale, Université de Reims, 51062 Reims Cedex, France and [b]Laboratoire de Cryptogamie-Phytopathologie, Université des Sciences et Technologies de Lille, 59655 Villeneuve d'Ascq Cedex, France

ABSTRACT: An extracellular lipase (EC 3.1.1.3) from the fungus *Botrytis cinerea* has been purified to homogeneity and characterized. The purification included ammonium sulfate fractionation and sequential column chromatography. The purification of the preparation was 31-fold and recovery yield was 21%. The purified enzyme was associated with esterase activity according to activity staining on polyacrylamide gel. The molecular weight was determined as 60 kDa on sodium dodecyl sulfate–polyacrylamide gel electrophoresis and estimated at 72 kDa using gel filtration, which suggests that the enzyme may be a monomer. The isoelectric point was 6.5, and optimal activity was obtained at 38°C and pH 6.0. This lipase showed a high specificity for synthetic substrates containing long-chain unsaturated fatty acids using umbelliferone esters. The effect of β-cyclodextrin on the hydrolysis of olive oil has been studied. The specific activity was 25 μmole/min/mg in the absence of β-cyclodextrin and 132 μmole/min/mg in its presence.
Lipids 30, 351–356 (1995).

Lipases (EC 3.1.1.3, glycerol ester hydrolase) are recognized as being important industrial enzymes. Their potential for industrial application was reviewed in 1989 (1). These enzymes are able to hydrolyze acylglycerols in aqueous medium and catalyze the synthesis of esters in organic medium (2,3). In the first group, lipases hydrolyze fats and oils by breaking the fatty acyl ester bonds of triacylglycerols (TGs). Lipases can be specific to the nature of the fatty acid on the glycerol backbone. Some are known to show preference for saturated fatty acids (4), while others preferred unsaturated fatty acids with a *cis*-double bond at the 9-position (palmitoleic, oleic, linoleic and linolenic acids) (5,6).

Lipases are produced by animals, plants, and microorganisms. To date, the majority of lipases used for biotechnological purposes have been isolated from fungi (7,8). Filamentous fungi are preferred sources of lipases, as they produce extracellular enzymes. The most productive species belong to the genera *Geotrichum*, *Aspergillus*, *Rhizopus*, *Mucor*, and *Penicillium* (9).

Botrytis cinerea is a ubiquitous pathogen, causing a serious disease in wine grapes *(Vitis vinifera).* It has the ability to produce a lipase. This enzyme, which is released into the culture medium, hydrolyzes the esters of unsaturated long-chain fatty acids. We used a sensitive fluorimetric method for measuring lipase activity using various esters of umbelliferone (UMB) (10).

In this paper, the purification and properties of an inducible extracellular lipase from *B. cinerea* are reported.

MATERIALS AND METHODS

Materials. UMB, fatty acid chlorides, Concanavalin A-Sepharose, methyl-α-D-mannopyranoside, bovine serum albumin, molecular weight markers for SDS–polyacrylamide gel electrophoresis (PAGE) (SDS6-H and SDS7) and for gel permeation were obtained from Sigma Chemical Co. (St. Louis, MO). Octyl-Sepharose CL-4B and Sephacryl S-200 were purchased from Pharmacia Fine Chemicals (Uppsala, Sweden). Bio-Beads SM-2, silver stain kit, isoelectric focusing standards, and reagents for PAGE were obtained from Bio-Rad Laboratories (Richmond, CA). Tetrahydrofuran, pyridine, diethyl ether, ethylene glycol monomethyl ether (EMMEG), and other solvents were of chromatographic grade.

Lipase production. Botrytis cinerea was isolated from grapevines. The fungus was grown in 25/200-mm tubes containing 15 mL culture medium. The medium contained, per liter of distilled water, was: aspartic acid, 1.99 g; dextrose, 1 g; KH_2PO_4, 0.8 g; $CaHPO_4$, H_2O, 0.2 g; $MgSO_4$, $7H_2O$, 0.5 g; $MnSO_4$, $5H_2O$, 0.01 g; $CuSO_4$, $5H_2O$, 0.005 g; $FeSO_4$, $7H_2O$, 0.0001 g; methyl oleate, 3 g; and taurocholic acid, 0.6 g. The medium was adjusted to pH 5.5. Inoculum was prepared from seven day-old mycelial mats, broken by shaking with glass beads in 60 mL sterile water. Inocula of 2 mL were transferred to 1-L conical flasks containing 200 mL culture medium and incubated on an orbital shaker at 120 rpm. Cultures were harvested after seven days' growth at 23°C in darkness, at which time extracellular lipase activity was maximal.

Lipase purification. Culture fluid containing extracellular enzymes was separated from mycelia by filtration. Proteins

were precipitated from the culture filtrate with ammonium sulfate (51% saturation). The solution was constantly stirred at 4°C during the addition of ammonium sulfate. After standing 10 h at 4°C, the precipitate was collected by centrifugation at 30,000 × *g* for 20 min, dissolved in 10 mM phosphate buffer pH 7.0 (buffer A) and dialyzed against the same buffer overnight. After dialysis, ammonium sulfate was added to make the final 1 M concentration. The dialyzate was placed on an Octyl-Sepharose CL-4B column (11.5 × 1 cm) which had been equilibrated with buffer B (buffer A + 1 M ammonium sulfate). The column was washed with buffer B, then with buffer A, and finally with buffer C (buffer A + 0.3% polyoxyethylene 10-tridecyl ether, Emulphogene BC-720; Sigma). This is a nonionic detergent very similar to Triton X-100, but nonabsorbing at 280 nm (11). The lipase activity was found in the fraction eluted with buffer C. The passage on Bio-Beads SM-2 (column, 4 × 1 cm) allowed a partial removal of the detergent. The active fraction was applied to Concanavalin A-Sepharose column (4 × 1 cm) equilibrated with buffer A. The column was washed sequentially with buffer A, buffer A containing 0.1 M, then with 0.5 M methyl-α-D-mannopyranoside. Lipase was eluted with buffer A containing 0.1 M methyl-α-D-mannopyranoside, and the eluate was dialyzed against buffer A. The active fraction was concentrated by ultrafiltration (ultrafree-MC PTGC, 10 kDa cut-off; Millipore, Bedford, MA). The enzyme fraction was submitted to a Sephacryl S-200 column (98 × 1.5 cm) previously equilibrated with buffer A. All steps were performed at room temperature (20–25°C), and all the protein elution profiles were recorded spectrophotometrically at 280 nm.

Lipase assay. Lipase activity was assayed by a fluorimetric method (10) using umbelliferyl oleate as a standard substrate. The reaction mixture contained 20 µL of umbelliferyl oleate solution (4 mM) in EMMEG in a total volume of 1 mL of hydrochloride Tris–maleate buffer (0.05 M, pH 6.0). At time zero, enzyme fraction was added to this mixture, and the fluorescence emission (470 nm) was recorded over 2 min (F-1200 fluorescence spectrophotometer; Hitachi Instruments, Tokyo, Japan) at an excitation wavelength (320 nm) corresponding to the absorption peak of UMB. The reaction was carried out at 38°C. This method can be carried out quickly, in two to three minutes.

Lipolytic activity was also quantitated by a titrimetric assay using emulsion olive oil as substrate. Composition of the reaction mixture was 3 mL 0.1 M citrate/Na_2HPO_4, buffer pH 6.0, 16.5 mM $CaCl_2$ and 0.11 mM sodium taurocholate, 5 mL deionized water, 1 mL olive oil emulsion (50% vol/vol olive oil), and 1 mL of the enzyme preparation appropriately diluted with 0.1 M citrate/Na_2HPO_4 buffer. Incubations were carried out at 38°C. After 60 min, the reaction was stopped by the addition of 10 mL an ethanol/acetone mixture (1:1, vol/vol). The liberated fatty acids were titrated with 50 mM KOH. A unit of lipase specific activity was defined as the release of one micromole of fatty acid per min and per mg under the assay conditions.

The course of triolein (0.1 mL triolein in 5 mL reaction mixture as described above) hydrolysis by the lipase was followed by thin-layer chromatography (TLC). Diethyl ether was added to stop the reaction and to extract the products. Samples were taken to run TLC on plates (0.2 mm) of silica 60 F_{254} (E. Merck, Darmstadt, Germany). Development was with a hexane/diethyl ether/glacial acetic acid mixture (78:20:4, by vol). Spots were revealed with primulin and identified by comparison of their migration rates with those of known standards (Sigma).

Effects of metal ions, pH, and temperature on lipase activity. To determine the effects of metal ions on lipase activity, the enzyme was incubated in Tris–maleate buffer containing the agents to be tested. Reagents were added to an enzyme solution, and the enzyme activity was measured after 30 min pre-incubation at 38°C. The following buffers (50 mM) were used for the determination of the pH dependence on the enzyme activity: sodium citrate–phosphate (pH 4, 5, 6, 7); Tris–maleate (pH 6, 7, 8); Tris–HCl (pH 7, 8, 9); glycine–NaOH (pH 9, 10). The effect of pH on enzyme activity was analyzed after pre-incubation in buffered solutions for 30 min at 38°C. Corrections were made to compare lipolytic activities at different pH values as the fluorescent intensity of UMB varies with pH. The optimum temperature for enzyme activity was determined by incubation of the reaction mixture at different temperatures. The enzyme solution was pre-incubated for 30 min to various temperatures (5–60°C).

Substrate specificity of lipase activity. The specificity of the lipase for laurate, myristate, palmitate, stearate, oleate, and linoleate was calculated from the initial rate of hydrolysis of the respective umbelliferyl esters (80 µM). Fatty acid esters were synthesized according to the method in Reference 10.

Molecular weight determination. Native molecular weight was estimated by chromatography on a Sephacryl S-200 column (98 × 1.5 cm). The following proteins were used as standard markers: phosphorylase a (97.4 kDa), bovine serum albumin (66 kDa), ovalbumin (45 kDa), and carbonic anhydrase (29 kDa). The void volume was determined with blue Dextran 2000. Molecular weight of the purified lipase was also determined by SDS–PAGE according to the method of Laemmli (12) and resolved in 7.5–15% linear gradient polyacrylamide gel. The run was carried out at 24 mA. Proteins were detected in gels by silver staining (13). The molecular weight of the lipase was determined by reference to the mobilities of known molecular mass from SDS standards (Sigma).

Isoelectric point (pI) determination. Isoelectric focusing was performed on 5% polyacrylamide gels. A vertical minigel system with 8 × 7 cm cell format was utilized (Mini Protean; Bio-Rad) according to the method of Robertson *et al.* (14). Electrophoresis was carried out at 4°C for 1.5 h at 200 V constant voltage, then increased to 400 V constant voltage for an additional 1.5 h. Proteins were detected with silver stain. The pI of the lipase was estimated by comparison of its mobility to those of standard proteins (IEF; Bio-Rad) included on gel.

Activity staining. Native PAGE was performed on an 8% gel, and the esterase activity was identified by staining with

50 mg Fast blue RR salt, 30 mg α-naphthyl acetate in 2 mL acetone/water (1:1, vol/vol) and 80 mL Tris–maleate (0.1 M) at pH 6.4 (15).

Protein determination. Protein concentrations were determined according to Bradford (16) using the Bio-Rad protein assay kit. Bovine serum albumin was used as the standard in the assay.

RESULTS AND DISCUSSION

Enzyme purification. Botrytis cinerea produced an inducible extracellular lipase in a medium containing methyl oleate as inducer. Many lipases are considered to be inducible enzymes, their synthesis being promoted by their substrates, products of their hydrolysis, or substrate analogs. Dextrose (1 g/L) must be present in the culture medium in order to start the growth; a higher concentration results in a lower lipase production. When methyl oleate was not added, the activity was not detectable. Shaking improves the production of the lipase, probably because of the better oxygenation of the culture medium, and also results in a higher release of the lipase. Due to the great dilution of enzymes in the medium, a preliminary protein concentration was necessary. The lipase was precipitated from the culture supernatant at 51% ammonium sulfate saturation with 30% of total proteins. Chromatography of lipase on Octyl Sepharose is shown in Figure 1. There were strong hydrophobic interactions between the enzyme and the gel matrix which could be broken only by addition of detergent. Total lipase activity is eluted with 0.3% Emulphogene BC-720. Other detergents were assayed but, due to tailing and poor recovery of activity, Triton X-100 and sodium deoxycholate were discarded. Fractions 46–52 were pooled and, after passage on Bio-Beads SM-2, applied to the Concanavalin A-Sepharose column. The lipase activity was associated with the peak of proteins eluted by 0.1 M methyl-α-D-mannopyranoside (Fig. 2). This result suggests the glycosylation of the lipase. A glycosylation level of 5–10% appears to be fairly typical of fungal lipases (17). Fractions 21–24 were pooled, dialyzed, concentrated, and applied to a Sephacryl S-200 column. The complete purification achieved is shown in Table 1. A sixfold purification with 51% recovery of activity was obtained with the Octyl-Sepharose column. The purification protocol (Table 1) resulted in a 31-fold purification with a 21% recovery of total activity. This preparation is stable for at least several months at –20°C.

The purified lipase was homogeneous as shown by SDS–PAGE (Fig. 3) and IEF (Fig. 4). A single band was also detectable by esterase activity stain on polyacrylamide gel.

Enzyme characterization. The molecular weight of the lipase, calculated by SDS–PAGE, was 60 kDa (Fig. 3). The native molecular weight of the lipase was estimated by gel filtration through Sephacryl S-200 and was found to be 72 kDa. The lipase, therefore, consists of a single polypeptide chain. Most fungal extracellular lipases are monomers having molecular weights ranging from 30 to 64 kDa. The molecular mass was 30.3 kDa for *R. delemar* (18), 56 kDa for *P. simplicissimum* (19), and 64 kDa for *G. candidum* (5). The lipase from *Neurospora crassa* is a dimer with 27 kDa molecular weight subunits (20) and those from *Pythium ultimum* (6), a tetramer with 68 kDa subunits.

The molecular mass of the lipase, determined by gel filtration, was 12 kDa larger than that found by SDS–PAGE. This larger molecular weight may be an overestimate of the true mass, as gel filtration has been shown to overestimate the mass of another lipase (21). An initial attempt by using the gel filtration at the first step of the purification process was abandoned because of a tendency of the lipase to aggregate as a broad fraction on the column. Aggregation of lipases occurs often with mammalian (22) and microbial lipases (23). Lipases can also associate with glycosylated impurities present in the extract, leading to the formation of high-molecular weight aggregates.

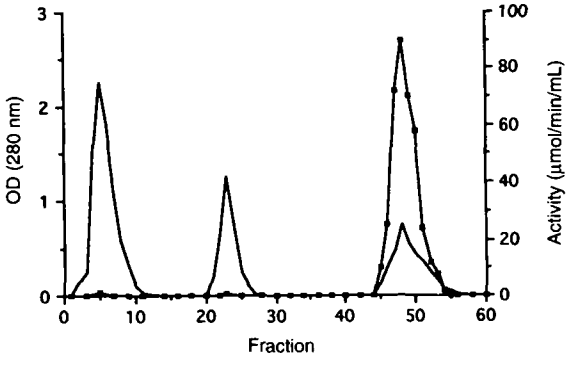

FIG. 1. Chromatography on Octyl-Sepharose (Pharmacia, Uppsala, Sweden). The enzyme solution after ammonium sulfate precipitation was loaded onto an Octyl-Sepharose column (11.5 × 1 cm). Protein (–) was measured by absorbance (OD) at 280 nm, and 3-mL fractions were collected. Lipase activity (–■–) starting at fraction 32, that eluted with detergent (0.3% Emulphogene BC-720; Sigma, St. Louis, MO) was measured spectrofluorimetrically as described in the Materials and Methods section.

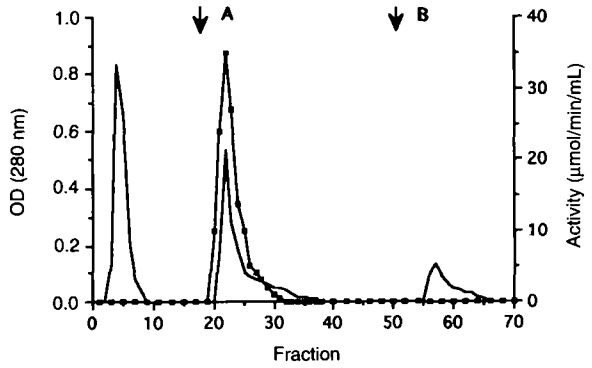

FIG. 2. Chromatography on Concanavalin A-Sepharose (Sigma, St. Louis, MO). Active fractions from the Octyl-Sepharose (Pharmacia, Uppsala, Sweden) column were applied on the column (4 × 1 cm). Elution conditions are given in the Materials and Methods section; 1-mL fractions were collected. Bound proteins were eluted with buffer containing 0.1 M methyl-α-D-mannopyranoside (A) and 0.5 M methyl-α-D-mannopyranoside (B). Shown are lipase activity (–■–) and protein (–).

TABLE 1
Purification of *Botrytis cinerea* Extracellular Lipase

Steps	Protein (mg)	Activity[a] (μmol UMB/min)	Specific activity[a] (μmol UMB/min/mg)	Yield (%)	Purification factor
Culture filtrate	15.5	1271	82	100	1
$(NH_4)_2SO_4$ precipitation	4.7	799	170	62.9	2.1
Octyl Sepharose CL-4B[b]	1.3	647.4	498	51	6.1
Con A Sepharose[c]	0.36	475.2	1320	37.4	18
Sephacryl S200[b]	0.106	272.8	2574	21.5	31.4

[a]Lipase activity was assayed by a fluorimetric method using umbelliferyl oleate as a standard substrate. Activity is defined as micromoles of umbelliferone (UMB) released per min at 38°C and per mg protein for specific activity. Details regarding the activity determinations are given in the Materials and Methods section.
[b]From Pharmacia Fine Chemicals, Uppsala, Sweden.
[c]Concanavalin-A Sepharose, from Sigma Chemical Co., St. Louis, MO.

The pI, determined by isoelectric focusing of the lipase in polyacrylamide gel was found to be about 6.5 (Fig. 4). pI of lipases from *R. delemar* (18), *G. candidum* (17), and *P. simplicissimum* (19) were 8.6, 4.0–4.7, and 4.1, respectively.

Effects of temperature, pH, and metal ions on lipase activity. Lipase activity is temperature-sensitive. Maximum activity occurred at 38°C, with 75% of the value exhibited between 32–40°C. The enzyme was completely inactivated above 60°C. The lipase proved to be quite stable at room temperature. After 48 h at room temperature, 98% of the initial activity remains in the control.

The pH dependence of the activity of the *B. cinerea* lipase was observed over the pH range 4.5–9.0, but the optimum pH was 6.0. The enzyme exhibited 70% or more of maximal activity between pH 5.5 and 6.5. The fact that the lipase is maximally active near its pI value may indicate that the binding of this enzyme to its hydrophobic substrate is best when its net charge is zero. Most of extracellular fungal lipases have acidic or neutral pH optima, and very few are alkaline lipases.

Actions of some cations were studied on lipase activity. Neither Ca^{2+} (5, 10, and 30 mM), Mg^{2+} (10, 50, and 100 mM), Na^+ (0.1, 0.5, and 1 M), nor K^+ (0.1, 0.5, and 1 M) had an effect on the action of the enzyme. Calcium ions are

The isoelectric point values of the standard proteins are indicated in the left margin: lentil lectin (8.2), (8.0), (7.8); human hemoglobine C (7.5); human hemoglobine A (7.1); human carbonic anhydrase (6.5); bovine carbonic anhydrase (6.0); β-lactoglobulin B (5.1); and phycocyanin (4.6).

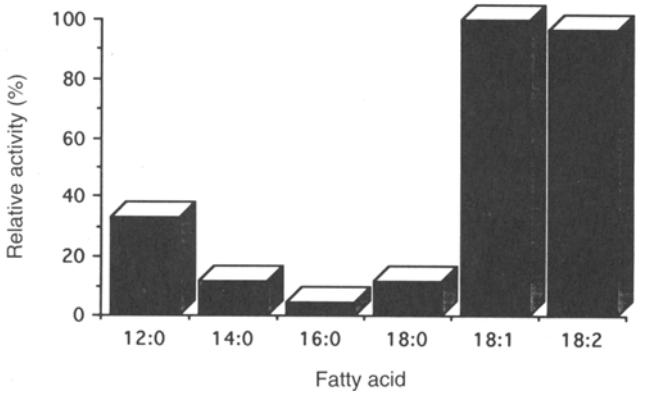

FIG. 5. Substrate specificity of lipase activity. Activities are expressed relative to that of the most active substrate.

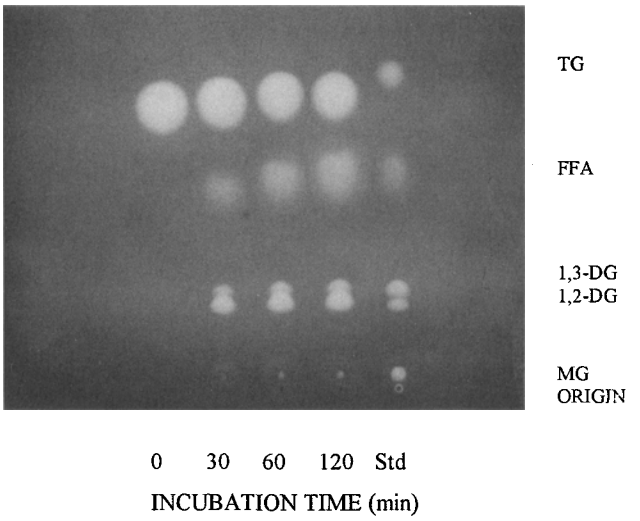

FIG. 6. Thin-layer chromatography of products of triolein hydrolysis by extracellular lipase from *Botrytis cinerea*. The reaction conditions are given in the Materials and Methods section. TG, triacylglycerol; 1,3-DG, 1,3-diacylglycerol; 1,2-DG, 1,2-diacylglycerol; FFA, free fatty acid; MG, monoacylglycerol.

known to increase lipase activity (24) by acting directly on the enzyme (25). They also can reduce the solubility of fatty acids generated during hydrolysis (26), which can be a major problem when using titrimetric methods. This problem was avoided by the fluorimetric method.

Substrate specificity of lipase activity. A comparison of the lipase activities toward different fatty acid ester substrates demonstrated important differences. The best hydrolysis rates were obtained with the oleic acid and linoleic acid esters (Fig. 5). The rate of hydrolysis for lauric acid ester is 33% of oleic acid ester, while it is only 12% for stearic acid and 5% for palmitic acid esters. In the C18 series, the presence of double bonds seems to enhance apparent lipase activity. We can then say that this lipase is very specific for the esters of unsaturated fatty acids. In the series of saturated fatty acids tested, maximum activity was found for C12. Gargouri *et al.* (27) demonstrated that enzyme activity toward triglycerides may reflect the dependence of the enzyme on appropriate surface tension and viscosity, which vary with fatty acid chain length and the number of double bonds, but does not show real substrate specificity.

TABLE 2
Effect of β-cyclodextrin on the Activity of the Extracellular Lipase from *Botrytis cinerea*

β-Cyclodextrin content[a]	Activity[b] (U/mg protein)	Relative activities[c]
Control (none)	25.03 ± 4.49[d]	100
0.5% (wt/vol)	71.85 ± 5.96[e]	287
1% (wt/vol)	93.24 ± 12.88[f]	372
1.5% (wt/vol)	132.60 ± 9.66[g]	530

[a]β-Cyclodextrin was added to the reaction mixture before activity determination.
[b]Each value is the mean ± SD of four determinations. One unit is defined as one micromole of fatty acid release per min from emulsified olive oil at 38°C and pH 6.0. Details regarding the activity determinations are given in the Materials and Methods section. Significance was assessed by Student's *t*-test: $P < 0.01$ between d and e, and $P < 0.05$ between e and f and f and g.
[c]Values were calculated relative to the control (without additive) using mean.

Use of a fluorimetric method is convenient for the rapid detection of lipases. In order to confirm that we measured a true lipase activity rather than a general esterase one, we checked the hydrolysis of olive oil. The specific activity of the purified enzyme was 25 µmole/min/mg. The lipase from *B. cinerea* is able to hydrolyze soluble esters (characteristic of esterases) as well as long-chain TG (natural substrate of lipases).

The effect of β-cyclodextrin (cycloamylose) on the activity of the lipase was studied using olive oil as substrate. A marked stimulation of the activity was observed by the addition of β-cyclodextrin to the assay mixture (Table 2). Optimal lipase activity (132 µmole/min/mg) was found with a concentration of 1.5% (wt/vol). The β-cyclodextrin was insoluble up to this concentration. The use of cyclodextrin in enzymology is known to enhance the solubility of hydrophobic compounds in water (28).

Positional specificity. Figure 6 shows a thin-layer chromatogram of the enzyme reaction products obtained after various reaction times (30, 60, and 120 min) with triolein as the substrate. The chromatoplate showed that 1,2 (2,3)-diolein was formed in larger quantities than 1,3-diolein. These results indicate that the enzyme hydrolyzes 1- and 3-positioned ester bonds in preference to 2-positioned ester bonds. This specificity is typical of the fungal lipases studied previously (6). The production rate of monoglycerides was lower than that of diacylglycerides.

These results are the first report of the purification and the characterization of an extracellular lipase from the fungus *B. cinerea*. Further work will generate information about the amino acid composition, *N*-terminal amino acid sequence, and the neutral sugar content of the lipase.

Induction of Geranyl Pyrophosphate Pyrophosphatase Activity by Cholesterol-Suppressive Isoprenoids

Gary L. Case, Lei He, Huanbiao Mo and Charles E. Elson*

Department of Nutritional Sciences, University of Wisconsin, Madison, Wisconsin 53706

ABSTRACT: Diets supplemented (1 mmol/kg) with thymol, carvacrol, and ß-ionone significantly decreased the serum cholesterol levels of cockerels. These mevalonate-derived end products of plant secondary metabolism (isoprenoids) had no impact on two cytosolic prenyl alcohol (and ethanol) dehydrogenase activities; each treatment increased microsomal geranyl pyrophosphate pyrophosphatase activity by greater than twofold. The structural diversity of the isoprenoids which suppress cholesterol synthesis may be reconciled by their ability to increase pyrophosphatase activity, thus leading to the production of the endogenous, post-transcriptional regulator of 3-hydroxy-3-methylglutaryl coenzyme A reductase activity.
Lipids 30, 357–359 (1995).

Mevalonate-derived end products of plant secondary metabolism (isoprenoids) have a cholesterol-lowering effect and a tumor-suppressive action. Both actions may be coupled to the suppression of mevalonate synthesis (1,2). Diverse isoprenoids, including cyclic monoterpenes (3), ß-carotene (4), the tocotrienols (5), farnesyl-pyrophosphate (PP) analogues (6), and farnesol (7), down-regulate microsomal 3-hydroxy-3-methylglutaryl CoA (HMG–CoA) reductase activity by a post-transcriptional action. Mevalonic acid (8) and prenyl-PP containing one (9) to four (7) isoprene units similarly down-regulate HMG–CoA reductase activity. The regulatory actions triggered by the isoprenoids (3–7) reflect those of the physiological, mevalonate-derived nonsterol regulatory agent which acts post-transcriptionally to down-regulate HMG–CoA reductase activity (8).

A microbiological screen (10) of diverse isoprenoids revealed the potent mevalonate-suppressive activities of ß-ionone, carvacrol (2-methyl-5-isopropylphenol), and thymol (2-isopropyl-5-methylphenol) (unreported data). In a follow-up study we found that diets supplemented with 0.5–1.3 mmol/kg ß-ionone, an end-ring analog of ß-carotene, suppressed HMG reductase activities in livers of White Leghorn cockerels and pullets by 45–70% (11).

Abbreviations: HMG–CoA, 3-hydroxy-3-methylglutaryl CoA; PP, pyrophosphate.

Our experiments draw on reports that cells incubated with saturating concentrations of mevalonic acid accumulate α,ω-prenyl dicarboxylic acids (12). Following the hydrolysis of prenyl-PP intermediates by a microsomal phosphatase (13), cytosolic dehydrogenase and microsomal monooxygenase activities catalyze the formation of prenyl aldehydes, α-prenoic acids, ω- and ω3 hydroxy–α-prenoic acids and α,ω-prenyl dicarboxylic acids (9,12–16). We recently reported that pentobarbital, an inducer of the microsomal P450 monooxygenase activity that catalyzes the formation of ω- and ω3 hydroxy–α-prenoic acids, totally reverses the isoprenoid-mediated suppression of HMG–CoA reductase activity (11). This finding and the postulation by Watson and colleagues that changes in the post isopentenyl-PP isopentenoids individually or in combination define the regulatory signal molecule pool (9,12,14,15) are compatible with the recent report that farnesol induces the degradation of HMG–CoA reductase in permeablized cells (7). Correll *et al.* (7) further report that the induction of protein degradation by farnesyl-PP, the putative regulator identified by Bradfute and Simoni (6), is inhibited by NaF (7). We suggest that the cyclic monoterpenes (3), ß-carotene (4), and the tocotrienols (5) that lower HMG–CoA reductase activity divert a key phosphorylated intermediate of sterol synthesis toward the synthesis of the physiological regulatory agent. These considerations led us to examine the impact of dietary isoprenoids on the reactions preceding the formation of the ω- and ω3 hydroxy–α-prenoic acids.

METHODS

Four groups (n = 8) of White Leghorn cockerels, 126 g, were fed a growing ration (control) or the same ration supplemented with 1 mmol/kg diet of one of the aforementioned isoprenoids [all from Aldrich Chemical Co. (Milwaukee, WI)]. Serum cholesterol levels and three hepatic enzyme activities, microsomal prenyl-PP pyrophosphatase and cytosolic prenyl alcohol and ethanol dehydrogenases were measured following a 21-d feeding period. Body weight gains were not influenced by the treatments. Serum cholesterol levels were measured with diagnostic kits (Sigma Chemical Co., St. Louis, MO). Enzyme activity assays were conducted using concentrations of substrates that were determined experimentally to

be saturating. Microsomal prenyl-PP pyrophosphatase activity was determined by measuring the conversion of [1-^{3}H]-geranyl-PP to ^{3}H-geraniol, using a method adapted from those previously described by Christophe and Popják (13) and Croteau and Karp (17). The incubation mixture contained 50 mM Tris (pH 7.4), 100 µM geranyl-PP (Sigma), 0.03 µCi [1-^{3}H]-geranyl-PP (American Radiolabeled Chemicals, Inc., St. Louis, MO) and approximately 400 mg of microsomal protein. The reaction was carried out in a 200 µL volume at 37°C for 20 min. At the end of the incubation period, geraniol was extracted with 1 mL of hexane and counted by liquid scintillation. Results were corrected for small amounts of radioactivity extracted from heat-inactivated tissue blank samples and for geraniol extraction efficiency (90%). Reaction rates were linear with incubation time and amount of tissue extract employed. Prenyl alcohol and ethanol dehydrogenase activities were determined spectrophotometrically at 30°C by following the initial rate of reduction of NAD^+ at 340 nm. The reaction mixture contained 50 mM Tris buffer (pH 7.4), 2 mM NAD^+, 5 mM geraniol, farnesol, or ethanol, and approximately 50 µg of cytosolic protein in a total volume of 1 mL.

RESULTS AND DISCUSSION

Cockerels fed diets supplemented (1 mmol/kg diet) with carvacrol ($P < 0.005$), thymol ($P < 0.05$), or ß-ionone ($P < 0.001$) had a reduced serum cholesterol level as compared to the controls; differences between treatment groups were not significant (Table 1). The isoprenoid-mediated depression of serum cholesterol concentration ranged from 9 to 18%. Under the conditions employed in this study, that is, birds fed an isoprenoid-supplemented, cholesterol-free diet, a 5% suppression of HMG–CoA reductase activity was associated with a 2% decrease in serum cholesterol ($P < 0.004$) (18).

Microsomal geranyl-PP pyrophosphatase activities in livers of birds fed carvacrol ($P < 0.01$), thymol ($P < 0.005$), and ß-ionone ($P < 0.005$) were >2.2-fold greater than the control activity (Table 1). The induction of microsomal prenyl-PP pyrophosphatase activity may represent a key common site of action for the diverse plant isoprenoids that alter cholesterol metabolism in animals. Although this activity diverts prenyl-PPs from the sterologenic pathway, the diversion is not of sufficient magnitude to suppress the incorporation of mevalonate into cholesterol (5,6,19). More likely this activity increases the intracellular concentration of the post isopentenyl-PP metabolite(s) that accelerates the degradation of HMG–CoA reductase (6,7,9,12,14,15). The finding that the farnesol-induced degradation of HMG–CoA reductase, unlike that of farnesyl-PP (7) and farnesyl acetate (6), occurred with no apparent lag time led Correll *et al.* (7) to suggest that farnesol has a more direct role in enzyme degradation.

It should be noted that none of the studies leading to the identification of farnesol as the physiological regulator of HMG–CoA reductase activity (5–7) employed an inhibitor of the prenyl dehydrogenase activity. It remains possible that an inhibitor targeted to the constitutive prenyl alcohol dehydrogenases (Table 1) might potentiate or attenuate the HMG–CoA reductase-suppressive action of farnesol depending on whether farnesol or a farnesol metabolite proves to be the physiological regulator.

Human liver prenyl alcohol dehydrogenase exists in multiple forms with Kms for geraniol and farnesol ranging from 0.2 to 73 and <0.1 to 3 µM, respectively (16). Keung (16) has suggested that genetic determinants of the prenyl alcohol de-

TABLE 1
Effect of Feeding Carvacrol, Thymol, or ß-Ionone on Serum Cholesterol and Hepatic Ethanol and Prenyl Alcohol Dehydrogenase and Geranyl-Pyrophosphate Pyrophosphatase Activities[a]

hydrogenase isozymes influence the disposition of products diverted from the sterologenic pathway; differences in prenyl alcohol dehydrogenase isozyme characteristics thus may contribute to differences in serum cholesterol levels among various populations.

This study, to our knowledge, is the first to show the induction of a prenyl-PP pyrophosphatase activity. The disparity between this activity and the prenyl alcohol dehydrogenase activities is consistent with our suggestion that the microsomal prenyl-PP pyrophosphatase reaction is more important in the synthesis of a physiological regulator of HMG–CoA reductase activity.

Effects of Pregnenolone-16α-carbonitrile on the Metabolism of Cholesterol in Rat Liver Microsomes

Dagny Ståhlberg*

Department of Medicine, Karolinska Institutet at Huddinge University Hospital, Stockholm, Sweden

ABSTRACT: The effects of pregnenolone-16α-carbonitrile (PCN) on hepatic metabolism of cholesterol were studied in rat liver microsomes in order to clarify the underlying mechanisms of the PCN-induced biliary hypersecretion of cholesterol. Male Sprague-Dawley rats were fed a diet supplemented with 0.05% of PCN for one week. The microsomal activity of 3-hydroxy-3-methylglutaryl coenzyme A reductase, regulating cholesterol biosynthesis, decreased from 577 ± 46 (SEM) to 367 ± 38 pmol/min/mg protein compared to the controls. Cholesterol 7α-hydroxylase activity, governing bile acid synthesis, was 9.0 ± 1.1 pmol/min/mg protein in the treated group and 34.8 ± 7.4 pmol/min/mg protein in the controls, a reduction of 74% ($P < 0.01$). The acyl CoA:cholesterol acyltransferase (ACAT) activity, catalyzing the esterification of cholesterol, remained unchanged, as did the levels of total and free cholesterol in liver homogenates and microsomes. The results of this study provide evidence that the increase in biliary cholesterol secretion during PCN treatment is not caused by a change in ACAT activity, but can be explained by a decreased catabolism of cholesterol to bile acids.

Lipids 30, 361–364 (1995).

Pregnenolone-16α-carbonitrile (PCN) is a potent catatoxic steroid which is known to induce hepatic microsomal mixed-function oxygenases, thereby making the liver more resistant to various toxic drugs. Previous studies with rats have shown that PCN also increases the rate of bile secretion and causes bile to be saturated with cholesterol because of an increased cholesterol secretion and an unchanged or decreased output of bile acids and phospholipids (1,2). The enhanced rate of bile flow could be explained by increased bile salt-independent bile flow through induction of the activity of canalicular membrane Na^+K^+-dependent adenosine triphosphatase (1–3). The mechanism of the enhanced biliary secretion of cholesterol during PCN treatment has not been fully explained, but it may be due to effects of PCN on the hepatic metabolism of cholesterol—increased hepatic synthesis, decreased catabolism to bile acids and reduced cholesteryl ester formation. Thus, the activity of cholesterol 7α-hydroxylase, the rate-limiting enzyme for bile acid formation, has been shown to decrease slightly in rats treated with PCN (4,5).

Nervi *et al.* (6) and Stone *et al.* (7) have previously studied the interrelationship between hepatic cholesterol esterification and biliary cholesterol output in rats, and they demonstrated that an inhibition of the acyl CoA:cholesterol acyltransferase (ACAT) activity was associated with increased biliary cholesterol secretion. The effect of PCN on ACAT activity has not previously been studied, but Turley and Dietschy (2) found an increase in cholesteryl esters when female rats were fed a diet containing PCN.

The present work aimed at studying further the mechanism of the previously reported PCN-induced hypersecretion of cholesterol in rats. The activities of 3-hydroxy-3-methylglutaryl CoA (HMG–CoA) reductase, cholesterol 7α-hydroxylase, and ACAT, the three key enzymes in the regulation of the hepatic cholesterol synthesis and metabolism, were simultaneously determined in male Sprague-Dawley rats treated with 0.05% PCN added to the food. In addition, the concentrations of free and esterified cholesterol in liver homogenates and microsomes were measured.

MATERIALS AND METHODS

Materials. Deuterium-labeled cholesterol was obtained from Larodan Fine Chemicals (Malmö, Sweden). Deuterium-labeled 7α-hydroxycholesterol was synthesized as described previously (8). [3-^{14}C]HMG–CoA (specific activity 19 mCi/mmol), [1-^{14}C]oleoyl coenzyme A (specific activity 57.8 mCi/mmol) and [1,2,6,7-^{3}H]cholesteryl oleate (specific activity 82.7 Ci/mmol) were obtained from New England Nuclear Corp. (Boston, MA). DL-[2-^{3}H]mevalonic acid (specific activity 125 mCi/mmol) was obtained from Radiochemical Centre (Amersham, England). Unlabeled mevalonic acid lactone, cholesteryl oleate, NADP, NADPH, EDTA, dithiothreitol (DTT), glucose-6-phosphatate, glucose-6-phosphate dehydrogenase, and human serum albumin were purchased from Sigma Chemical Co. (St. Louis, MO). PCN was obtained from Upjohn Co. (Kalamazoo, MI).

Experimental design. Two groups of six male rats of the Sprague-Dawley strain, weighing about 170 g, were used. Both groups had free access to water and a crushed commercial standard diet. In one of the groups the food was supplemented with 0.05% (w/w) of PCN. The other group served as controls. After one week of treatment, the animals in both groups were killed, the livers were immediately removed, weighed, cut into two pieces and put in cold buffer solutions. The weight of the rats was recorded immediately before the initial feeding of the experimental diet and again on the day of the experiment.

Preparation of liver microsomes. An aliquot of the liver was minced and homogenized with a loose-fitting Teflon pestle in nine volumes of a 50 mM TRIS–HCl buffer, pH 7.4, containing 0.3 M sucrose, 10 mM DTT, 10 mM EDTA, and 50 mM NaCl. The homogenate was centrifuged at 20,000 × *g* for 15 min. The supernatant solution was centrifuged at 100,000 × *g* for 60 min. Half of the microsomal fraction prepared was resuspended in the homogenizing medium and recentrifuged at 100,000 × *g* for 60 min. This fraction was then suspended in a 20 mM imidazole buffer, pH 7.4, containing 10 mM DTT in a volume corresponding to that of the 20,000 × *g* supernatant, and used for the assay of HMG–CoA reductase. Half of the original microsomal fraction was recentrifuged at 100,000 × *g* in a homogenizing medium lacking DTT. The resulting fraction was suspended in a 0.1 M phosphate buffer, pH 7.4, containing 1 mM EDTA and used for the assay of cholesterol 7α-hydroxylase activity.

The other piece of the liver was minced and homogenized in 50 mM TRIS–HCl buffer, pH 7.4, containing 0.3 M sucrose and 1 mM EDTA, as described above. The homogenate was centrifuged at 20,000 × *g* for 15 min. The supernatant solution was centrifuged at 100,000 × *g* for 60 min. The pellet obtained was resuspended in 0.1 M phosphate buffer, pH 7.4, containing 1 mM EDTA, and used for assay of the ACAT activity.

The microsomal and the liver homogenate contents of protein were determined by the method of Lowry *et al.* (9).

Assay of HMG–CoA reductase activity. The HMG–CoA reductase activity was assayed essentially as described (10). The microsomal fraction, 40 μL, was preincubated for 15 min at 37°C in a total volume of 0.2 mL containing 100 mM phosphate buffer, pH 7.4, 10 mM imidazole buffer, pH 7.4, 5 mM DTT, 10 mM EDTA, 3 mM NADP, 12 mM glucose-6-phosphatase, and 1 unit of glucose-6-phosphate dehydrogenase. The HMG–CoA reductase assay was then initiated with the addition of 90 nmol of [3-^{14}C]HMG–CoA (0.5 μCi) dissolved in 25 μL of distilled water. The incubation was run for 15 min and was stopped by the addition of 25 μL of 6 M HCl. Tritium-labeled mevalonic acid (0.01 μCi) was added as an internal standard together with 3 mg of unlabeled mevalonic acid lactone, and the incubation mixture was allowed to stand overnight at room temperature for complete lactonization. The incubation mixture was then subjected to thin-layer chromatography using toluene/acetone (1:1, vol/vol) as the developing solvent. The zone containing mevalonic acid lactone was visualized with iodine vapor and scraped off, and the radioactivity was counted. Corrections for losses were made based on the internal standard.

Assay of cholesterol 7α-hydroxylase activity. The standard assay system consisted of 1.0 mL of the microsomal fraction, 0.1 M phosphate buffer, pH 7.4, containing 1 mM EDTA and 1 mM NADPH. The enzyme assay was carried out in duplicate for 15 min at 37°C according to the method of Björkhem and Kallner (8) where the product 7α-hydroxycholesterol was analyzed by gas chromatography/mass spectrometry. Each set of experiments also included two assays in which the mass of 7α-hydroxycholesterol was determined in the incubation mixture extracted at zero time. The amount of 7α-hydroxycholesterol formed during an incubation was estimated by subtracting the amount present at zero time from the amount present at the end of the incubation period and was expressed as pmol/min/mg protein.

Assay of ACAT enzyme activity. The ACAT activity was assayed both in the absence and presence of exogenous cholesterol as described previously (11). The assay system contained 0.1 mL of the microsomal preparation and 1 mg of fatty acid free bovine serum albumin in 0.1 M phosphate buffer, pH 7.4, containing 1 mM EDTA, to give a final volume of 1.0 mL. The mixture was preincubated for 5 min at 37°C or for 30 min at 37°C after the addition of 50 nmol of unlabeled cholesterol dissolved in 600 μg of Triton. The reaction was initiated by addition of 25 nmol (1.45 μCi) of [1-^{14}C]oleoyl CoA. After 4 min the assay was stopped by the addition of 10 mL chloroform/methanol (2:1, vol/vol). Tritium-labeled cholesteryl oleate (0.01 μCi) was added as an internal standard to estimate recovery followed by 1 mL 0.9% (wt/vol) NaCl.The chloroform phase was collected and evaporated to dryness under N_2. The residue was resuspended in chloroform/methanol (2:1, vol/vol) and subjected to thin-layer chromatography together with unlabeled cholesteryl oleate as marker. The chromatogram was developed in hexane/ethyl acetate (95:5, vol/vol). The cholesteryl oleate zone was visualized with iodine vapor, scraped into a vial, and counted.

Determination of liver cholesterol. The concentrations of total cholesterol in the liver homogenates and the microsomal fractions were determined by isotope dilution–mass spectrometry after addition of deuterium-labeled cholesterol as an internal standard as described previously (12) with modifications (13). Free cholesterol was determined by the same method, but without the hydrolysis step. The concentration of esterified cholesterol was calculated as the difference between total and free cholesterol in the same sample.

Statistical analysis. Data are presented as means ± SEM (standard error of the mean). The significance of differences was evaluated by Student's *t*-test.

RESULTS

The PCN-treated rats consumed the same quantity of food as the control group and tolerated the treatment well. The weight gain of the rats during the treatment period with PCN did not

TABLE 1
Effects of Pregnenolone-16α-Carbonitrile (PCN) Treatment on Body and Liver Weight

	Number of rats	Weight gain (g)	Liver weight (g)
Controls	6	52 ± 2	10.5 ± 0.3
PCN treatment	6	52 ± 3	13.2 ± 0.5[a]

[a]Significantly different from the controls; $P < 0.001$.

differ from that of the controls. Treatment with PCN significantly increased the liver weight by 25% (Table 1). The protein content in the liver microsomes increased slightly in the treated rats as compared to the controls (1.97 ± 0.13 and 1.65 ± 0.20 mg/mL, respectively), but the difference did not reach statistical significance. The protein content in liver homogenate was about the same in the treated group and in the controls.

The activity of HMG–CoA reductase was about 35% lower in the group of rats treated with PCN compared to the controls (367 ± 38 and 577 ± 46 pmol/min/mg protein, respectively) (Table 2). The activity of cholesterol 7α-hydroxylase was 34.8 ± 7.4 pmol/min/mg protein in the controls and 9.0 ± 1.1 pmol/min/mg protein in the treated group, a decrease of nearly 75%. The ACAT activity, determined without exogenous cholesterol added, remained unchanged in the rats treated with PCN. When exogenous cholesterol was added to the assay system, the ACAT activity increased sevenfold in the controls, as well as in the PCN-treated rats (Table 2). The concentrations of free and esterified cholesterol in the liver homogenates and the microsomes were not significantly changed in the PCN-treated rats (Table 3).

DISCUSSION

The effects of PCN on the three key enzymes, regulating the hepatic cholesterol metabolism, were studied in male Sprague-Dawley rats. From previous studies it is known that PCN stimulates the rate of bile secretion and increases biliary cholesterol output (1–3). In the present study, when the rats were fed a diet containing 0.05% PCN, the weight of the liver increased by 25%, a well-known effect of PCN treatment (1–3,5), and explained by a proliferation of the smooth-surfaced endoplasmic reticulum in the hepatocytes (4,14). In the present study, the concentration of microsomal protein showed a tendency to increase.

The activity of HMG–CoA reductase, regulating the synthesis of cholesterol in the liver, decreased by about 35%, and the activity of cholesterol 7α-hydroxylase, the rate-limiting enzyme in bile acid formation, was reduced by about 75%. Honohan and Parkinson (5) found an increased total cholesterol turnover, as well as a slight inhibition of cholesterol 7α-hydroxylase, in rats treated with PCN.

The activity of ACAT, determined both without and with exogenous cholesterol added, was not affected by PCN treatment, and, in accordance with this, the levels of cholesteryl esters in liver homogenates and microsomes remained unchanged compared to the control group. In contrast, Turley and Dietschy (2) found an increase in the amount of liver cholesteryl esters when female Sprague-Dawley rats were treated with PCN at the same dietary level as that used in this study. There is no apparent explanation of the different results obtained in the present study and in that of Turley and Dietschy (2). But one contributing factor might be that different sexes of rats were used (15).

TABLE 3
The Concentrations of Total and Esterified Cholesterol (nmol/mg protein) in Liver Homogenates and Microsomes in Controls and in PCN-Treated Rats[a]

	Liver homogenates		Microsomes	
	Total cholesterol	Esterified cholesterol	Total cholesterol	Esterified cholesterol
Controls	34.4 ± 2.2	6.2 ± 1.2	55.5 ± 8.2	8.5 ± 2.3
PCN-treated	35.6 ± 4.2	7.8 ± 1.8	51.3 ± 5.1	9.1 ± 1.0

[a]Values are means ± SEM of six determinations. None of the differences were statistically significant. Abbreviation as in Table 1.

The liver is the main organ through which cholesterol is cleared from the body either unchanged or after conversion to bile acids (16). An imbalance between the excretion of cholesterol and bile acids may cause an excess of cholesterol in bile, as has been reported for PCN-treated rats. Such an imbalance may theoretically be due to one of several factors, e.g., an enhanced synthesis of cholesterol (HMG–CoA reductase activity) in the liver; a decreased catabolism of cholesterol to bile acids as reflected in a decreased activity of cholesterol 7α-hydroxylase; a reduced esterification rate of cholesterol (ACAT activity) in the liver, leading to a decreased storage of cholesterol in the liver as cholesteryl esters. We did not find that PCN affected the esterification rate or storage of cholesterol in the liver; nor did we find that PCN stimulated the HMG–CoA reductase activity; rather the HMG–CoA reductase activity was reduced. The most pronounced effect of PCN was a marked decrease in the conversion of cholesterol to 7α-hydroxycholesterol. Decreased cholesterol 7α-hydroxylase activity in PCN-treated rats has previously been demonstrated by Einarsson and Gustafsson (4) and Honohan and Parkinson (5).

The results of this study, together with evidence from other laboratories, support the conclusion that the increased biliary cholesterol output during PCN treatment of rats is not regulated by the rate of cholesterol esterification, but may be related to the pronounced decrease in the rate of cholesterol 7α-hydroxylation.

Fatty Acid Composition of Erythrocyte, Platelet, and Serum Lipids in Strict Vegans

Jyrki J. Ågren*, Marja-Leena Törmälä, Mikko T. Nenonen and Osmo O. Hänninen

Department of Physiology, University of Kuopio, 70211 Kuopio, Finland

ABSTRACT: The fatty acid composition of erythrocytes, platelets, and serum lipids was compared between subjects who had been eating a strict uncooked vegan diet ("living food") for years and omnivore controls. The vegan diet contains equal amounts of fat but more monounsaturated and polyunsaturated and less saturated fatty acids than the mixed diet of the control group. In vegans, the proportion of linoleic acid was greater in all lipid fractions studied. Also, the levels of other n-6 fatty acids were greater, with the exception of arachidonic acid levels, which were similar in most fractions. In erythrocytes, platelets and serum phospholipid fractions, this increase was mainly at the expense of the n-3 fatty acids. The proportions of eicosapentaenoic and docosahexaenoic acid were only 29–36% and 49–52% of those in controls, respectively. In vegans the ratio of n-3 to n-6 fatty acids was only about half that in omnivores. In addition to the lower levels of n-3 fatty acids, the proportions of palmitic and stearic acids were lower in serum cholesteryl esters, triglycerides and free fatty acids of vegans. The proportion of oleic acid was slightly lower only in serum cholesteryl esters and erythrocyte phosphatidylserine. The results show that, in the long term, the vegan diet has little effect on the proportions of oleic and arachidonic acids, whereas the levels of n-3 fatty acids are depressed to very low levels with prolonged consumption of the high linoleic and oleic acid components of this diet. *Lipids 30,* 365–369 (1995).

In numerous studies the fatty acid composition of different blood lipid components has been measured to assess the quality of dietary fat or to clarify the effects of dietary fat modification or fatty acid supplementation. It is well known that the amounts of several fatty acids in blood lipids reflect, to some extent, their dietary intake (1–4). However, there is little firm information about the long-term effects of different dietary combinations of saturated, monounsaturated and n-6 and n-3 fatty acids on plasma and membrane lipids. In addition, methodological problems may complicate the interpretation of some published data.

One possible way to elucidate the relations between dietary fatty acid intake and the fatty acid composition of blood lipids is to study the subjects, such as vegetarians, who follow a special lifestyle diet. Vegetarian diets are known to have positive effects on weight, blood pressure and coronary artery disease (5). It should be noted that in addition to the nutrient content of their diet, other aspects of the lifestyles of vegans may contribute to these positive health effects. The fatty acid composition is one feature of the diet which is clearly different in vegetarian and omnivore diets. The intake of linoleic acid is high in many vegetarian diets, and this has been clearly shown to increase its proportion in platelet phospholipids (PL) (6) and in plasma phosphatidylcholine (PC), erythrocytes and adipose tissue (7), when vegans have been compared to omnivore controls. The only significant difference in the major fatty acids of serum lipids was the lower level of arachidonic acid in cholesterol esters and phospholipids of vegans in the study of Phinney *et al.* (8). Melchert *et al.* (9) found only small differences in arachidonic acid concentrations, but the proportion of linoleic acid was greater, whereas the proportions of oleic and docosahexaenoic acids were lower in vegans than in omnivores. Unfortunately, dietary data were included in one only of these reports (6).

In the present study, fatty acids of blood lipids were analyzed from subjects who had consumed a vegan diet ("living food") for many years. "Living food" is a strict uncooked vegan diet, rich in lactobacilli, which contains no animal products or added salt. The amounts of cholesterol and saturated fatty acids are very low in this diet. Monounsaturated fatty acids constitute about half and polyunsaturated fatty acids, mainly linoleic acid, almost one-third of the fatty acids available in the diet (10). The subjects have participated in a special course where the preparation of the diet has been taught and the recommended weekly schedule learned.

EXPERIMENTAL PROCEDURES

Originally twelve "living food" consumers and twelve control subjects with a normal mixed diet volunteered to participate in this study. Two subjects of the vegan group were found not to be following strictly to the diet. The rest were requested to come to give a blood sample for fatty acid analyses. Blood samples were obtained from nine vegans and eleven controls. One subject of the vegan group was excluded from the final results due to very exceptional fatty acid pro-

[c] Dietary records were obtained from seven subjects in control group.
[d] Estimated on the basis of fish consumption questionnaire.

files: the proportions of several fatty acids differed by 4–5 standard deviations from the mean values. The vegans included had followed the "living food" diet for at least two years (mean time 7.3 yr).

Subjects kept food records for seven days using household measures. About six months elapsed between the blood sampling and recording the food intake. Therefore they were asked to complete another questionnaire to clarify if any changes, especially in fat intake, had occurred during this period. No changes were observed, emphasizing the stability of their diet. In addition, subjects of the control group filled in a separate questionnaire concerning their consumption of fish. This showed a frequency of 2.0 ± 0.9 fish meals per week (mean ± SD), providing about 0.4 g of n-3 fatty acids per day. Nutrients were analyzed using the software system developed at the Finnish Social Insurance Institute (Helsinki, Finland). The food and nutrition database currently comprises about 1400 food items and 200 nutrients. The composition of some special food items of the living food diet was analyzed and added to the database. The anthropometric data and the intake of basic nutrients, fatty acids and cholesterol are presented in Table 1. The database contains information of total linolenic acid. Therefore, linolenic acid is used instead of α-linolenic acid when dietary intake data is discussed.

The fasting blood samples were collected, and erythrocytes, platelets, and plasma separated as described earlier (11). Lipids from erythrocyte membranes, platelets, and serum samples were extracted by the method of Folch *et al.* (12). Erythrocyte phospholipids were separated by thin-layer chromatography (TLC) (Empore™ TLC; 3M, St. Paul, MN). Serum lipids were separated in a single aminopropyl solid-phase glass column (13). Fatty acid methyl esters were prepared with 14% BF_3–methanol and were analyzed with a Carlo Erba Vega 6130 gas chromatograph (Carlo Erba Instruments, Milan, Italy) equipped with a 25 m × 0.32 i.d. fused silica capillary column (NB-351; HNU-Nordion Ltd., Helsinki, Finland).

The Mann-Whitney U-test was used to statistically compare the differences between the groups.

RESULTS

The anthropometric data in Table 1 shows that vegans are leaner than control subjects despite their equal energy intake. One possible reason for this is that all the nutrients present in this uncooked diet are not utilized as efficiently as in the normal diet. There could also be some underreporting of energy intakes in controls, especially in two subjects with reported energy intakes below 5 MJ/d. However, the fatty acid distribution of controls was very close to the mean distribution for Finnish women. There was no significant difference in total fat intake between the groups, but the vegan diet contained considerably less saturated and more monounsaturated and polyunsaturated fatty acids. The sources of dietary fat were quite different in these groups. Vegans do not use milk products or meat, and the fat is derived mostly from seeds, nuts and avocado. The cholesterol intake of controls was much higher than that of vegans. The small amount of cholesterol found in the vegan diet originated predominantly from egg containing pastry eaten by one subject.

The differences between vegans and their controls in the fatty acid composition of erythrocyte and platelet lipids (Table 2) and serum phospholipids (Table 3) were very similar. The proportions of all n-6 fatty acids were greater in vegans, with the exception of the unchanged levels of arachidonic acid found in most fractions. Its proportion was significantly greater only in erythrocyte phosphatidylserine (PS) of vegans. The greatest difference between the groups was seen in the amount of linoleic acid, but, in relative terms, even greater differences were observed in the minor fractions of long-chain n-6 fatty acids.

The proportion of n-3 fatty acids was much lower in the serum lipids and cell membranes obtained from the vegans. In erythrocytes, platelets, and serum cholesteryl esters (CE) and PL the proportions of eicosapentaenoic acid (20:5n-3) and docosahexaenoic acid (22:6n-3) were only 29–36 and 49–52%, respectively, of those of controls. The proportions of docosapentaenoic acid (22:5n-3) were only slightly lower in vegans. The ratio of n-3 to n-6 fatty acids in vegans was about half of that in omnivores. Only small differences were found in the amounts of saturated and monounsaturated fatty acids in erythrocytes and platelets, as well as in serum PL. The proportion of nervonic acid (24:1n-9) was greater in total erythrocyte lipids of vegans. In erythrocyte PC there was more stearic acid and less palmitic acid in vegans than in the control group. In serum PL the proportion of palmitic acid was also slightly lower in vegans.

TABLE 2
The Fatty Acid Composition of Erythrocyte Membrane Total, Phosphatidylethanolamine (PE), Phosphatidylcholine (PC) and Phosphatidylserine (PS), and Platelet Lipids in Vegans (n = 8) and Controls (n = 11) (mol%, mean ± SD)

The serum PL fraction followed the same pattern as erythrocyte and platelet lipids. In the other fractions, the proportion of linoleic acid was also much greater in vegans than in controls [60.6 ± 3.8 compared to 53.7 ± 4.6% for CE, 27.5 ± 5.5 compared to 17.2 ± 5.2% for triglycerides (TG) and 22.4 ± 5.1 compared to 12.6 ± 2.7% for free fatty acids (FFA)] (Table 3). The amounts of n-3 fatty acids were lower in vegans. The greatest difference was seen in serum TG, where the ratio of n-3 to n-6 fatty acids was 0.23 in omnivores and only 0.07 in vegans. In addition to differences in the polyunsaturated fatty acids, the proportions of palmitic and stearic acids were much lower in serum TG (19.4 ± 2.4 compared to 25.0 ± 4.5% and 2.7 ± 0.8 compared to 3.8 ± 1.0%, respectively), and in FFA (22.9 ± 2.3 compared to 29.0 ± 1.9% and 11.9 ± 0.4 compared to 16.2 ± 4.6%, respectively), and also slightly lower in serum CE of vegans. The only significant difference in monounsaturated fatty acids was the lower level of oleic acid in CE of vegans (15.9 ± 2.2 compared to 18.3 ± 2.0%).

The total amount of fatty acids in serum CE, TG and PL of vegans were lower (15–36%) than in the control group, but the differences were not statistically significant. The total amounts of serum FFA were similar in both groups (0.38 mmol/L).

DISCUSSION

The high linoleic acid intake of vegans was reflected in all the lipid fractions studied. Similar findings have also been reported in other studies with vegans and vegetarians (6,7,9), with one exception (8). The effects of the vegetarian diet on other fatty acids have been much more variable. The short-term increase of linoleic acid intake has been shown to increase its amount in serum CE and erythrocyte membranes at the expense of oleic acid (14). In the present study, the proportion of oleic acid was lower only in serum CE of vegans. In the other fractions, the increased n-6 fatty acid content was compensated mainly *via* lowered amounts of n-3 fatty acids in membranes and saturated fatty acids in serum TG and FFA. It seems that the high intake of oleic acid combined with the very low intake of long-chain n-3 fatty acids in vegans leads to the substitution of n-3 fatty acids by n-6 fatty acids instead of oleic acid, especially in PL. Similar trends have also been observed in earlier studies (6,7,9). It seems that with vegetarian diets, which have a higher linoleic/oleic acid ratio than that of the present study, oleic acid is more easily replaced by linoleic acid. However, limited dietary data makes the comparison difficult.

The proportions of n-3 fatty acids vary greatly in different membranes and PL, and these characteristics partly determine the possible extent to which they can be modified by diet. The relative differences between the groups were, however, very similar in erythrocytes, platelets, and serum PL where in vegans the ratio of n-3 to n-6 fatty acids was about half of that in omnivores. In serum cholesterol esters of vegans, this ratio was 40% and in TG 30% of that in omnivores. Thus, the very low intake of long-chain n-3 fatty acids in vegans was most clearly seen in these fractions which are more dependent on daily dietary supplementation than membrane PL. The selec-

tive deacylation–reacylation of PL probably maintains higher levels of n-3 fatty acids than would be expected on the basis of dietary data. However, the proportions of eicosapentaenoic and docosahexaenoic acids in erythrocyte and platelet lipids of vegans were much lower than in omnivores. They were also clearly lower than we have found in subjects consuming an otherwise usual mixed diet but not consuming any fish products (Ågren, J., unpublished data). This is probably caused by the higher intake of linoleic acid in vegans leading to a decreased incorporation and desaturation of α-linolenic acid. These results indicate that with very low intakes of long-chain n-3 fatty acids their amounts in membrane lipids are more easily altered by other dietary fatty acids, especially n-6 fatty acids, than with intakes obtained from usual mixed diet.

The mean intake of linolenic acid was higher in vegans than in omnivores. This difference was not seen in plasma lipids. This may be caused by the greater linoleic acid intake of vegans causing displacement of α-linolenic acid. It is also possible that the calculated total linolenic acid intake contains more γ-linolenic acid in vegans. The variation between subjects was also much greater in vegans. However, the amount of linolenic acid in the diet of vegans correlated with the proportion of α-linolenic acid in serum TG, CE, and PL, and also in erythrocyte phosphatidylethanolamine and PS (r = 0.71–0.77, $P < 0.05$ in all). This is in accordance with the results of Chan *et al.* (15), who also found increased levels of eicosapentaenoic and docosapentaenoic acids in individuals with increased α-linolenic acid intakes. Mantzioris *et al.* (16) have also shown that the proportions of long-chain n-3 fatty acids are increased in plasma lipids by a high α-linolenic acid intake. In the present study, the α-linolenic acid intake or its ratio to linoleic acid did not show any correlation with longer chain n-3 fatty acids. In fact, the lowest levels of long-chain n-3 fatty acids were found in those vegans having the greatest linolenic acid intakes and levels in serum and membrane lipids. If there really was a negative correlation, it would imply that dietary α-linolenic acid intake should accompany some factor preventing its elongation but not affecting linoleic acid metabolism. This does not seem very probable. It should be noted that quite high α-linolenic acid intakes are needed to increase the amounts of long-chain n-3 fatty acids, and the effect on docosahexaenoic acid seems to be very small (15,16). It is obvious that not much preformed long-chain n-3 fatty acids are needed to obscure the effect of α-linolenic acid. It is possible that the differences in the low intake of preformed long-chain n-3 fatty acids between vegans overshadow the effect of dietary α-linolenic acid. Small amounts of long-chain n-3 fatty acids could be derived from the seaweed products commonly included in the vegan diet. Whatever the reason, these results show the weak ability of α-linolenic acid to increase the amount of longer chain n-3 fatty acids when compared to direct intake of these fatty acids.

The proportion of nervonic acid in erythrocytes was significantly greater in vegans, the same trend also being observed in platelets. Nervonic acid is located almost exclusively in the sphingomyelin fraction of membrane lipids. The proportions of other sphingomyelin derived fatty acids, such

as behenic acid (20:0) and lignoceric acid (24:0), were similar in both groups. This indicates that there are differences in the fatty acid composition of sphingomyelin between vegans and omnivores. This might be some compensatory change, e.g., to maintain membrane physical properties.

There has been considerable controversy about the influence of a vegetarian diet on levels of arachidonic acid. The high linoleic acid intake may interfere with arachidonic acid metabolism by competition for esterification and by suppressing desaturases (17). The small amount of arachidonic acid present in a vegetarian diet may also decrease its amount in serum and membrane lipids (8). It could be speculated that a vegetarian diet could alleviate the symptoms of rheumatoid arthritis by depressing the eicosanoid production from arachidonic acid. The reported data of arachidonic acid level in vegetarians is, however, inconsistent, showing lower (6,8), higher (7), and similar (7,9) levels as in the omnivore controls in different lipid fractions. In the present study, the proportions of other long-chain n-6 fatty acids were generally greater in vegans, but arachidonic acid level differed only in erythrocyte PS, where it was greater in vegans. It is obvious that all vegetarian diets do not necessarily decrease the arachidonic acid content in serum and membrane lipids. It could be speculated that even the small increase in the amount of long-chain n-3 fatty acids in a vegetarian diet would decrease the amount of arachidonic acid in membranes. This could be of importance if a lowered level of arachidonic acid metabolism is desirable. The increase of 22-carbon n-6 fatty acids in vegans is probably a compensatory mechanism in response to the low levels of docosahexaenoic acid. Docosahexaenoic acid is necessary for normal development of the nervous system. However, the possible significance of low plasma and tissue levels of docosahexaenoic acid to changes in the health of adults is not known.

It could be concluded that similar kinds of differences as those found in the erythrocytes and platelet membranes are also present in the membranes of other tissues. This may cause alterations in membrane properties. It could be argued that vegan diet changes the eicosanoid formation due to lowered n-3 fatty acid levels. It is also possible that the characteristic membrane fatty acid composition of vegans could influence the activity of membrane enzymes and receptors as well as physical properties of the membrane itself. At present, little is known about the relationships between fatty acid composition and membrane function, and no direct conclusions can be made.

In addition to fatty acid intake, there are also many other differences in nutrient intakes between strict vegan and omnivore diets. Differences in the vitamin and trace element intakes might also have effects on lipid composition. However, the differences found in the fatty acid profiles between these groups were quite consistent with the dietary intakes of fatty acids. Thus, it is apparent that differences in the fatty acid intakes are the main cause for the observed differences in plasma and membrane lipids of vegans and omnivore controls.

NOTE: *Lipids* is now italicizing all mathematical variables. This may not have been clear in January 1995 "Guide to Authors."

AVAILABILITY OF FISH OIL TEST MATERIALS

The Fish Oil Test Materials Program is a cooperative effort of the National Institutes of Health (NIH) and the National Oceanic and Atmospheric Administration/Department of Commerce (NOAA/DOC). This program provides a long-term, consistent supply of quality-assured/quality-controlled test materials to researchers that facilitates the evaluation of ω-3 fatty acids in health and disease.

Current test materials available, in both capsules and bulk, include: (i) vacuum deodorized menhaden oil; (ii) ethyl esters of olive, corn, and safflower oils; (iii) commercial preparations of corn, olive, and safflower oil; (iv) n-3 ethyl ester concentrates; (v) EPA ethyl ester; and (vi) DHA ethyl ester.

To qualify to receive the fish oil test materials from the Program, the researcher must fill out an application. The applicant must: (i) have peer-reviewed research indicating the need for the requested materials, and (ii) submit a cor-

(continued on next page)

rectly completed application form and a signed waiver of liability. *The awarded materials are provided free of charge (researchers will pay shipping costs).*

Investigators may obtain further information and an application form from Fish Oil Test Materials Program, NIAAA, National Institutes of Health, 12501 Washington Ave., Flow Building, Room 2, Rockville, MD 20852 (Phone: Beth Aurecchia, 301-443-9643; Fax: 301-594-0035).

Leukotriene B_4 Stimulation of an Early Elevation of Phosphatidic Acid Mass in Human Neutrophils

Jen-sie Tou* and Thao Dola

Department of Biochemistry, Tulane Medical School, New Orleans, Louisiana 70112

ABSTRACT: The signal transduction pathway of leukotriene B_4 involves phospholipase D activation in cytochalasin B-primed neutrophils, but leukotriene B_4 stimulation of increased phosphatidic acid mass in neutrophils has not been demonstrated. Employing the NIH Image program, we have examined the effect of leukotriene B_4 on phosphatidic acid mass in human neutrophils incubated with or without cytochalasin B. Our results show that 0.15 μM leukotriene B_4 without cytochalasin B was capable of increasing phosphatidic acid mass in neutrophils by 2-fold after 5 s, 2.5-fold after 1 min, and 2-fold after 5 min incubation. Leukotriene B_3, leukotriene B_4, and leukotriene B_5 were equipotent stimuli for phosphatidic acid mass elevation. Leukotriene B_4 induced phosphatidylethanol formation at the expense of phosphatidic acid in cells preincubated with 0.25–1% ethanol, indicating phospholipase D activation. Cytochalasin B enhanced leukotriene B_4 stimulation of phosphatidic acid mass elevation and phosphatidylethanol formation. There were no measurable changes in 1,2-diglyceride mass after 5 s, but a 1.7-fold increase occurred after 1 min and declined thereafter. Leukotriene B_4 stimulation of [^{3}H]glycerol incorporation into phosphatidic acid, diglyceride and phosphatidylinositol was detectable after a 1-min incubation, suggesting increased *de novo* synthesis of these lipids. These results suggest that leukotriene B_4 stimulation of phospholipase D activity contributes to part of the early increased phosphatidic acid mass and that combined actions of stimulated phospholipases C and D, and *de novo* phosphatidic acid synthesis contribute to the total increased phosphatidic acid mass.
Lipids 30, 373–381 (1995).

Leukotriene B_4 (LTB_4) is a potent agonist for neutrophil chemotaxis (1). It also stimulates neutrophil metabolism. Its signal transduction pathway in neutrophils involves activation of phospholipases A_2 (2,3) and C (4), but LTB_4 stimulation of phospholipase D activity has been shown to require priming neutrophils by cytochalasin B (5). The products of phospholipid hydrolysis and their metabolites in turn serve as second messengers to amplify neutrophil metabolism. Activation of phospholipase A_2 leads to the synthesis of platelet-activating factor (PAF), which is an agonist for neutrophil chemotaxis and aggregation (6). Activation of phospholipase C results in the production of inositol 1,4,5-trisphosphate [Ins(1,4,5)P_3] and 1,2-diglyceride (DG). [Ins(1,4,5)P_3] raises cytosolic Ca^{+2} levels (7). Although DG is a protein kinase C activator, LTB_4 has not been shown to increase protein kinase C activity in neutrophils. This could be due to a rapid metabolism of DG to phosphatidic acid (PtdOH) and triglyceride (TG). LTB_4 has been shown to enhance ^{32}P-PtdOH formation in human neutrophils prelabeled with ^{32}Pi (8). It has also been demonstrated to induce [^{3}H]alkyl-PtdOH production in cytochalasin B primed rabbit peritoneal neutrophils, which were prelabeled with 1-*O*-[^{3}H]octadecyl-*sn*-glycero-3-phosphocholine (5). However, increased PtdOH mass in neutrophils challenged with LTB_4 has not been demonstrated. In intact neutrophils, PtdOH can be formed from phosphorylation of DG by a DG kinase or from the hydrolysis of choline glycerophospholipid by a phospholipase D in the presence of cytochalasin B. In addition, it can also be derived from *de novo* synthesis. Indeed, LTB_4 has been shown to promote the incorporation of palmitic, but not arachidonic, acid into PtdOH (9).

In the present studies, we demonstrate that LTB_4 without the priming effect of cytochalasin B is capable of inducing a prompt (5 s) but transient (5 min) elevation of PtdOH mass in human neutrophils. Cytochalasin B enhanced PtdOH mass elevation induced by LTB_4. Our results suggest that LTB_4 stimulation of phospholipase D activity contributes to the prompt increase in PtdOH mass, and that combined actions of stimulated phospholipases C and D and *de novo* PtdOH synthesis contribute to the total increased PtdOH mass.

MATERIALS AND METHODS

Materials. Commercial sources of the reagents used are: PtdOH prepared from egg yolk lecithin, fatty acid-free bovine serum albumin (BSA), and LTB_4 from Sigma (St. Louis, MO); leukotriene B_3 (LTB_3), leukotriene B_5 (LTB_5), and 12-

epi-leukotriene B_4 (12-*epi*-LTB_4) from Cayman (Ann Arbor, MI); phosphatidylethanol (PtdEt) from Avanti Polar-Lipids (Alabaster, AL); Merck silica gel 60 plastic-backed plates from VWR (Philadelphia, PA); [1,2,3-^{3}H]glycerol (40 Ci/mmol) from Du Pont–New England Nuclear (Boston, MA); cytochalasin B from Aldrich (Milwaukee, WI); silica gel H glass plates from Analtech (Newark, DE). The sources of reagents for DG mass determinations were the same as previously described (10).

Preparation of human neutrophils. Neutrophils were isolated from heparinized peripheral blood from healthy volunteers as previously described (9). Cells were suspended in Dulbecco's balanced salt solution (11), pH 7.4, supplemented with 5 mM glucose at a concentration of 2×10^7 cells/mL. Cell counts were made in a hemocytometer, and cell viability was measured by Trypan blue exclusion. Cell preparations contained more than 95% neutrophils.

Incubation of neutrophils. LTB_4 or (other leukotrienes in ethanol) was evaporated at room temperature under vacuum by a rotary evaporator and suspended in Dulbecco's balance salt solution containing 4.0 mg of BSA per mL. Each incubation tube contained, in a final volume of 2 mL, 0.4 mg of BSA, 0–15 μM LTB_4, 0–1% ethanol ± 10 μg cytochalasin B (or equivalent amounts of dimethylsulfoxide), and 2×10^7 cells. Unless otherwise indicated, each experiment was started by a 10-min preincubation of cell suspensions at 37°C with 0–1% ethanol ± 10 μg cytochalasin B, and then incubations were started by adding LTB_4 or other leukotrienes to each tube. After 5 s–10 min at 37°C, incubations were stopped by adding 5 mL of methanol to each tube. Total lipids were extracted according to the original method of Bligh and Dyer (12). The chloroform layer was evaporated under vacuum by a rotary evaporator. The dried lipid residue was redissolved in chloroform/methanol (2:1, vol/vol) containing 0.01% butylated hydroxytoluene.

Thin-layer chromatography (TLC) of PtdOH. PtdOH was resolved from other lipids by a two-step one-dimensional TLC on plastic-backed silica gel 60 plates (20 × 20 cm). The plates were not treated with potassium oxalate. Each lipid extract from 2×10^7 cells was dissolved in 25 μL chloroform/methanol (2:1, vol/vol), and 18 μL (1.44×10^7 cell equivalents) was applied to the plate (20 × 10 cm) as a 1-cm streak. PtdOH standards from egg yolk lecithin in the range of 129–1290 pmoles were applied to the same plate as the lipid extracts. A total of 12 samples can be applied to one plate. One PtdOH standard (1290 pmoles) was applied as a 1-cm streak on a separate plate (5 × 10 cm). Both plates were first developed in ethyl acetate/acetic acid/isooctane (36:8:20, by vol) as described by Mallows and Bolton (13). After drying in a hood for one hour, the plate with PtdOH standard only was stained with iodine, and the PtdOH area was marked to serve as a guide for PtdOH mobility on the sample plate. In the first solvent system, PtdOH moved as a wide band with an R_f value of 0.61. The sample plate was cut at 0.5-cm above the PtdOH standard. It was then turned 180° and developed in the second solvent system consisting of chloroform/methanol/28% ammonia (50:20:4, by vol) until the solvent moved to the sample origin of the plate. PtdOH appeared as a narrow band and was well separated from other lipids.

For PtdEt determination from cells without cytochalasin B, lipid extracts from duplicate incubations were combined, and each lipid sample from 2.88×10^7 cell equivalents was applied to the TLC plate as a 1-cm streak. PtdEt standards in the range of 129–1290 pmoles were applied to the same plate. PtdEt was separated from other lipids in chloroform/methanol/acetic acid (45:5:5, by vol) as described by Olson *et al.* (14).

Quantitation of PtdOH and PtdEt. After drying in a hood for 30 min, the chromatogram was stained with iodine vapor for 5 min and then sprayed with 10% cupric sulfate in 8% phosphoric acid (15). It was then heated in a 100°C oven for 20 min and for 10 additional min at 120°C. The bands of PtdOH and PtdEt were scanned on a DeskScan II and analyzed on a Macintosh LCII computer using the public domain NIH Image 1.56b18 program (written by Wayne Rasband at the U.S. National Institutes of Health and available from the Internet by anonymous ftp from zippy.nimh.nih.gov or on floppy disk from NTIS, Springfield, VA; part number PB93-504868). The mass amounts of PtdOH and PtdEt were expressed as pmoles ± SEM per 10^7 cells from three separate experiments.

Recovery of PtdOH extracted in neutral solvents by the method of Bligh and Dyer (12). PtdOH standards in the range of 129–1290 pmoles in 5 mL chloroform were added to tubes containing 5 mL methanol, 2.5 mL chloroform, and 2 mL incubation buffer or 2 mL incubation buffer containing 2×10^7 neutrophils. After 20 min at room temperature, the mixture was partitioned with 2.5 mL each of chloroform and water. The chloroform layer was evaporated under vacuum by a rotary evaporator. The dried lipid residue was redissolved in chloroform/methanol (2:1, vol/vol) containing 0.01% butylated hydroxytoluene. PtdOH was resolved by the two-step one-dimensional TLC, scanned and quantitated as described above.

DG mass determination. DG levels in total lipid extracts from cells incubated with or without 0.15 mM LTB_4 were determined by using *Escherichia coli* DG kinase to convert DG into PtdOH (16). DG mass was expressed as pmoles ± SEM per 10^7 cells from three separate experiments.

Incorporation of [^{3}H]glycerol into lipids. Each incubation tube contained, in a volume of 2 mL, 0.4 mg BSA, 10 mCi (1.1 mM) of [1,2,3-^{3}H]glycerol, ±0.15 μM LTB_4, and 2×10^7 cells. Incubation tubes and cells were kept separately at 37°C for 5 min, and then incubations were started by adding 1 mL of cells (2×10^7) to each tube. After 1–10 min at 37°C, incubations were stopped by adding 5 mL of methanol to each tube containing 2 mL incubation mixture. Total lipids were extracted according to the method of Bligh and Dyer (12). The lipid residue from 2×10^7 cells in each tube was dissolved in 50 μL chloroform/methanol (2:1, vol/vol) containing 0.01% butylated hydroxytoluene, and each 15 μL representing 6×10^6 cell equivalents was used for resolution of

phospholipids or neutral glycerolipids. Phospholipids were separated by two-dimensional TLC, and neutral glycerolipids were separated by one-dimensional TLC on silica gel H glass plates (17). The radioactivity of each lipid was counted by liquid scintillation spectrometry and expressed as dpm ± SEM per 6×10^6 cells from three experiments.

RESULTS

TLC of neutrophil lipid extracts and PtdOH standards. PtdOH in lipid extracts was separated from other lipids by a two-step one-dimensional TLC system. Figure 1A demonstrates two chromatograms scanned with DeskScan II. The left chromatogram shows that in the first solvent PtdOH standard and PtdOH in a lipid extract from 2×10^7 cells moved as a wide band with an R_f value of 0.61. However, after developing in the second solvent both PtdOH standard and PtdOH in the lipid extract appeared as a narrow band (right chromatogram). For PtdOH mass measurement, a standard curve was constructed on the same plate as the lipid extracts. The intensity of PtdOH was greatly enhanced when only the PtdOH areas were scanned. Figure 1B is a representative chromatogram demonstrating the effect of LTB_4 on PtdOH mass in neutrophils preincubated with cytochalasin B and different concentrations of ethanol.

PtdOH can be quantitatively recovered from neutrophils under the experimental conditions. The recovery of PtdOH extracted in neutral solvents by the method of Bligh and Dyer (12) was examined. The results shown in Figure 2 indicate that the recovery for PtdOH standards varied with the amounts of PtdOH in each tube. An average of PtdOH recovery was 50% for 129 pmoles, and it reached 90% for 1290 pmoles. Also shown in Figure 2 is that a quantitative recovery of PtdOH was achieved at all concentrations tested if PtdOH standards were extracted together with 2×10^7 cells. The results indicate that PtdOH was quantitatively recovered from neutrophils under the experimental conditions.

We found that staining the chromatogram in iodine vapor enhanced the intensity of lipids charred with $CuSO_4/H_3PO_4$ by twofold (data not shown), thereby enhancing the sensitivity of lipid analysis by using the NIH Image program. This method measured PtdOH from egg yolk lecithin with a linear range of 129–1290 pmoles. Although the values of PtdOH determined by the present method was 25–30% lower than those

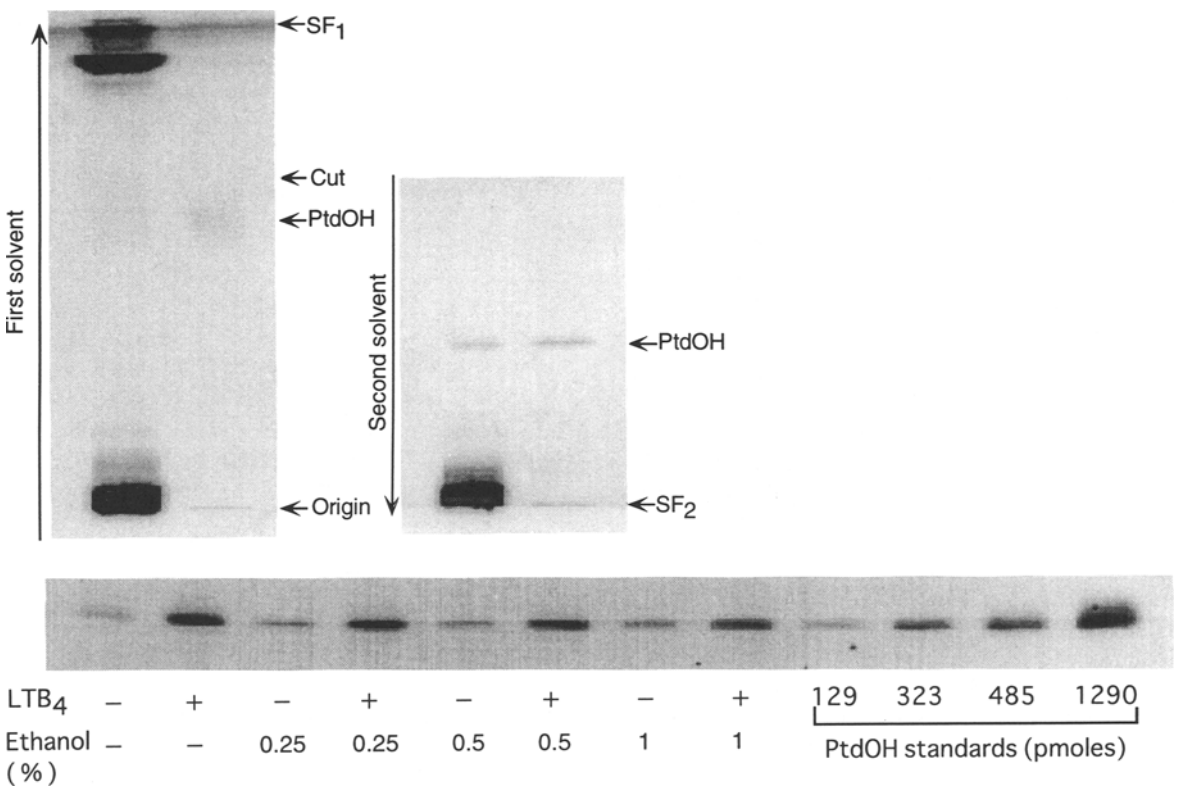

FIG. 1. Thin-layer chromatography (TLC) of neutrophil lipid extracts and phosphatidic acid (PtdOH) standards. A. PtdOH in neutrophils was separated from other lipids by a two-step one-dimensional TLC. Neutrophil lipid extract from 2×10^7 cells and a PtdOH standard (1290 pmoles) were each applied to two TLC plates. One of the plates (left) was only developed in the first solvent. The chromatograms were charred and scanned as described in the Materials and Methods section. B. Lipid extracts (each from 1.44×10^7 cells) were from cytochalasin B-primed neutrophils incubated with 0.15 μM leukotriene B_4 (LTB_4) for 1 min in the presence of 0–1% ethanol. PtdOH in neutrophil extracts and PtdOH standards were applied to the same plate. After the two-step one-dimensional TLC, the plate was charred, and only the PtdOH areas were scanned with DeskScanII as described in the Materials and Methods section.

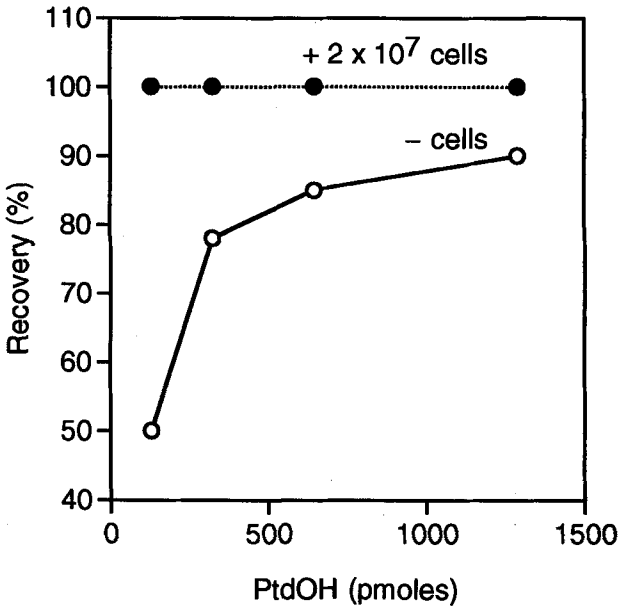

FIG. 2. Recovery of PtdOH extracted in neutral solvents by the method of Bligh and Dyer (Ref. 12). PtdOH standards in the range of 129–1290 pmoles in 5 mL chloroform were added to tubes containing 5 mL methanol, 2.5 mL chloroform, and 2 mL incubation buffer or 2 mL incubation buffer containing 2×10^7 neutrophils. Lipids were extracted in neutral solvents by the method of Bligh and Dyer (Ref. 12), and PtdOH was separated and quantitated as described in the Materials and Methods section. Data expressed are average values from two experiments. Abbreviations as in Figure 1.

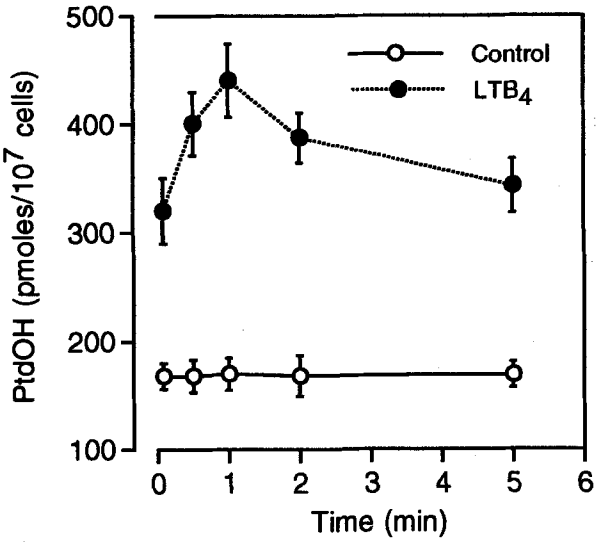

FIG. 3. Time course of LTB_4 effect on PtdOH mass. Each incubation tube contained, in a final volume of 2 mL, 0.4 mg of bovine serum albumin (BSA) ± 0.15 μM LTB_4, and 2×10^7 neutrophils. Neutrophils were preincubated for 10 min at 37°C, then incubations were started by adding 0.15 μM LTB_4 or BSA to each tube. After 5 to 10 min at 37°C, incubations were stopped by adding 5 mL methanol to each tube. Lipids were extracted, and PtdOH was separated and quantitated as described in the Materials and Methods section. Data are expressed as pmoles ± SEM per 10^7 cells from three separate experiments. Abbreviations as in Figure 1.

determined by phosphate analysis (10), the extent of LTB_4 stimulation of PtdOH mass increase was similar. The lower values obtained by the present method may reflect a lower degree of unsaturation of neutrophil PtdOH than that of the PtdOH standards, as unsaturated lipids are more sensitive to both iodine staining and to $CuSO_4/H_3PO_4$ charring than saturated lipids.

LTB_4 elicits a prompt rise in PtdOH mass. Figure 3 depicts the time course of PtdOH mass increase in neutrophils challenged with 0.15 μM LTB_4 without cytochalasin B. The PtdOH mass (pmoles per 10^7 cells) increased from 168 ± 12 to 320 ± 30 after 5 s, reaching a maximum of 440 ± 34 after 1 min. It declined to 343 ± 25 after 5 min and returned to basal levels after a 10-min incubation (data not shown).

*LTB_3 and LTB_5, but not 12-*epi*-LTB_4 increase PtdOH mass.* The specificity of LTB_4 stimulation of PtdOH mass increase was examined by incubating neutrophils with 0.24 μM LTB_3, LTB_4, LTB_5, or 12-*epi*-LTB_4 for 1 min. PtdOH content was measured after separating PtdOH from other lipids by the two-step one-dimensional TLC. The results summarized in Table 1 show that LTB_3, LTB_4, and LTB_5 were equally active in stimulation of PtdOH mass increase under the experimental conditions. However, the structural analog 12-*epi*-LTB_4 was ineffective on PtdOH mass elevation.

LTB_4 stimulation of PtdOH mass elevation is concentration-dependent. Figure 4 shows LTB_4 stimulation of PtdOH mass elevation in a concentration-dependent manner. The basal levels of PtdOH mass were 182 ± 12 pmoles per 10^7 cells. Incubation of neutrophils with 0.015 μM LTB_4 for 1 min increased PtdOH mass by 1.7-fold. PtdOH mass increase reached a maximum of 2.5-fold at 0.15 μM LTB_4. The effects of LTB_4 concentrations lower than 0.015 μM were not examined.

Activation of phospholipase D contributes to part of the early PtdOH mass elevation. The prompt rise in PtdOH mass induced by LTB_4 suggests phospholipase D activation. In neutrophils, phospholipase D catalyzes the hydrolysis of choline glycerophospholipid, generating PtdOH and choline

TABLE 1
Effect of LTB_3 and LTB_5 on Phosphatidic Acid (PtdOH) Mass[a]

Leukotrienes (0.24 μM)	PtdOH (pmoles/10^7cells)
None	178 ± 15
LTB_4	435 ± 36
12-*epi*-LTB_4	195 ± 16
LTB_3	471 ± 42
LTB_5	444 ± 29

[a]Each incubation tube contained, in a final volume of 2 mL, 0.4 mg bovine serum albumin ± 0.24 μM leukotriene, and 2×10^7 neutrophils. Cells were preincubated for 10 min at 37°C; then incubations were started by adding leukotriene B_3 (LTB_3), leukotriene B_4 (LTB_4), or leukotriene B_5 (LTB_5) to each tube. After 1 min at 37°C, PtdOH was extracted, separated, and quantitated as described in the Materials and Methods section. Data are expressed as pmoles ± SEM per 10^7 cells from three separate experiments.

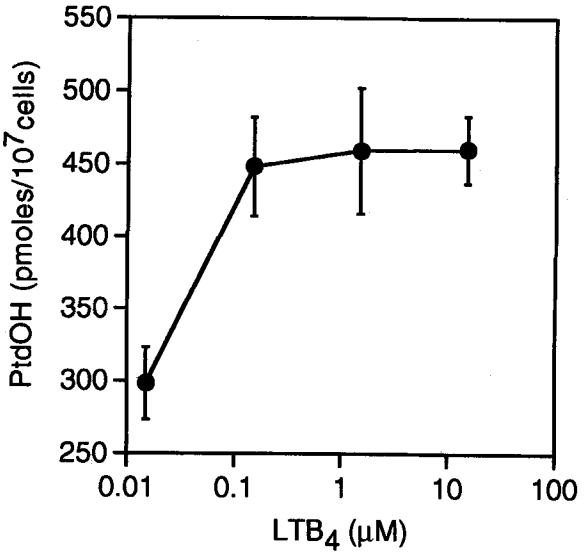

FIG. 4. Effect of LTB_4 concentration on PtdOH mass elevation. The incubation conditions and the abbreviations are the same as those in Figure 1, except that incubations were started by adding 0.015–15 μM LTB_4 or bovine serum albumin. After 1 min at 37°C, incubations were stopped by adding 5 mL methanol to each tube. Lipids were extracted, and PtdOH was separated and quantitated as described in the Materials and Methods section. Data are expressed as pmoles ± SEM per 10^7 cells from three separate experiments. The basal levels of PtdOH mass in neutrophils were 182 ± 12 pmoles per 10^7 cells.

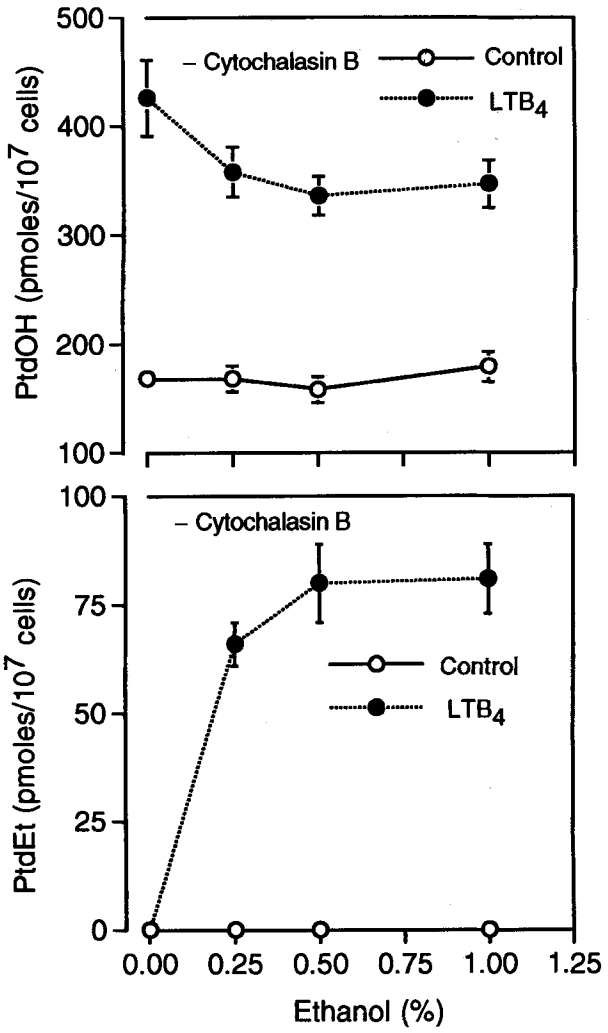

FIG. 5. Effect of LTB_4 on PtdOH and phosphatidylethanolamine (PtdEt) production in neutrophils without cytochalasin B. The incubation conditions (and abbreviations) were the same as those in Figure 1, except that cells were preincubated with 0–1% ethanol for 10 min at 37°C. Each tube was then further incubated with 0.15 μM LTB_4 for 1 min. PtdOH and PtdEt were extracted, separated, and quantitated as described in the Materials and Methods section. Data are expressed as pmoles ± SEM per 10^7 cells from three separate experiments.

(18,19). This enzyme also catalyzes the transfer of the phosphatidyl group to ethanol, propanol, or butanol, forming PtdEt or other phosphatidylalcohols (20). PtdEt is more metabolically stable than PtdOH and has been used for assay of phospholipase D activity in intact cells. It required the priming effect of cytochalasin B for the stimulation of phospholipase D by chemotactic peptide in human neutrophils (17) and by LTB_4 in rabbit peritoneal neutrophils (5). In the present study, the effect of LTB_4 on the changes in the mass amounts of PtdOH and PtdEt in cells with or without cytochalasin B was measured.

Figure 5 shows that 0.5–1% ethanol induced a maximum reduction in PtdOH mass elevation by 19% in cells incubated with 0.15 μM LTB_4 without cytochalasin B. It also demonstrates that decreased PtdOH mass paralleled with increased PtdEt formation. Because 1% ethanol had no effect on phospholipase C activity in human neutrophils (21), these results suggest that LTB_4 activation of phospholipase D contributes to part of the early increase in PtdOH mass induced by LTB_4 without cytochalasin B.

As demonstrated in Figure 6, LTB_4 induced a greater increase in PtdOH mass in cells primed with cytochalasin B than in primed cells without cytochalasin B (Fig. 5). In cytochalasin B-primed cells, ethanol (0.25–1%) inhibition of PtdOH mass elevation and stimulation of PtdEt formation were more pronounced than in cells without cytochalasin B, indicating that cytochalasin B enhanced the expression of phospholipase D activity in neutrophils (5,18,22).

DG mass elevation contributes to part of the increased PtdOH mass. LTB_4 has been shown to induce Ins(1,4,5) P_3 formation, indicating phospholipase C activation (4). Part of the DG derived from phospholipase C action is expected to be phosphorylated to form PtdOH by DG kinase. If the prompt PtdOH mass elevation is partly derived from increased DG mass, an increased DG mass is expected to occur after a 5 s challenge of cells with 0.15 μM LTB_4. However, Figure 7 shows that there was no measurable increase in DG mass after 5 s, a time in which a twofold increase in PtdOH was demonstrated (Fig. 1). DG mass was increased by 1.7-fold after 1 min; then it declined to basal levels (93 ± 7 pmoles per 10^7 cells) after 10 min. The results shown in Figure 7 suggest that increased DG mass may contribute to part

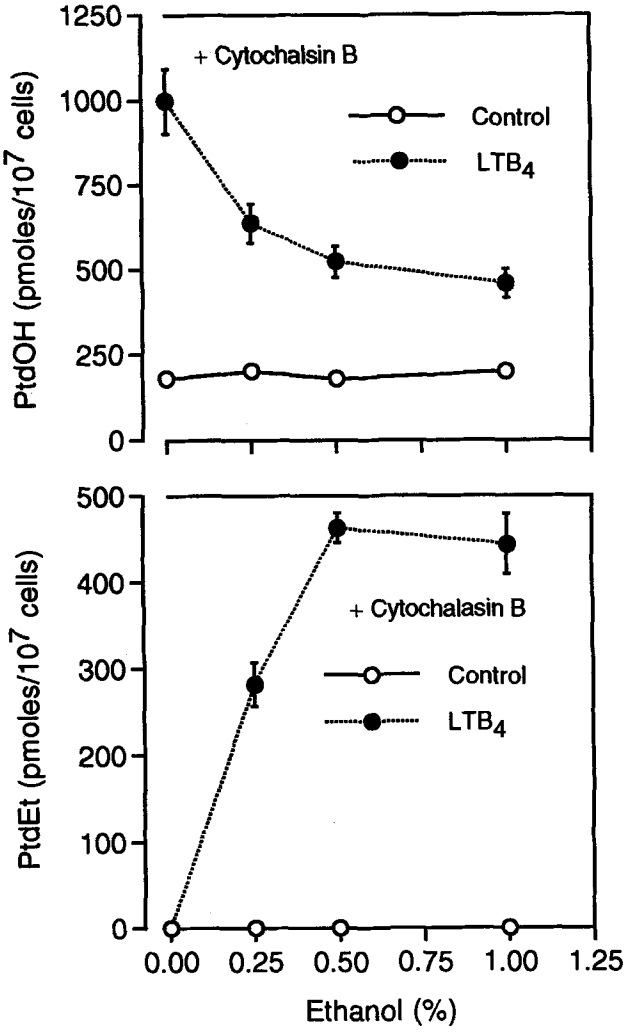

FIG. 6. Effect of LTB_4 on PtdOH and PtdEt production in neutrophils preincubated with cytochalasin B. The incubation conditions were the same as those in Figure 1, except that cells were preincubated for 10 min at 37°C with 0–1% ethanol and 10 μg cytochalasin B or equivalent amount of dimethylsulfoxide. The tubes were then further incubated with 0.15 μM LTB_4 for 1 min. PtdOH and PtdEt were separated and quantitated as described in the Materials and Methods section. Data are expressed as pmoles ± SEM per 10^7 cells from three separate experiments. Abbreviations as in Figures 1 and 5.

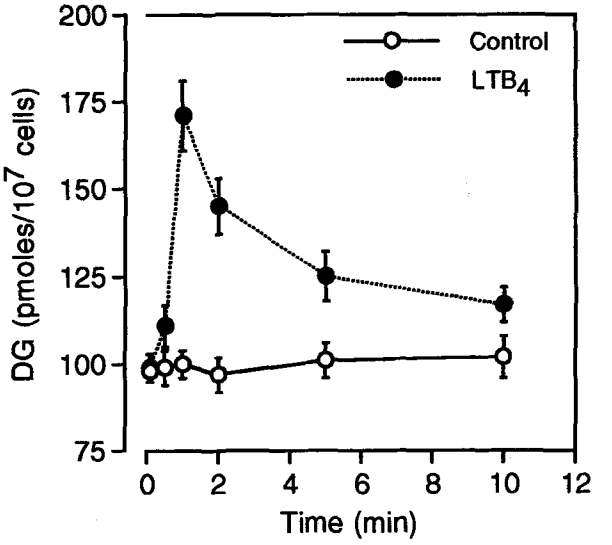

FIG. 7. Time course of LTB_4 effect on 1,2-diglyceride (DG) mass. The incubation conditions (and abbreviations) were the same as those in Figure 1. Total DG mass was measured by using *Escherichia coli* DG kinase as described in the Materials and Methods section. DG mass is expressed as pmoles ± SEM per 10^7 cells from three separate experiments.

of the PtdOH accumulation induced by LTB_4 after 1-min incubation.

LTB_4 stimulates de novo *PtdOH synthesis.* The effect of LTB_4 on *de novo* PtdOH synthesis was examined by measuring [^{3}H]glycerol incorporation into glycerolipids. Due to the low incorporation rate of exogenous [^{3}H]glycerol into PtdOH during 5–30 s of incubation, glycerol incorporation into phospholipids was measured after 1–10 min incubation. Figure 8 demonstrates LTB_4 stimulation of glycerol incorporation into PtdOH, DG, and phosphatidylinositol (PtdIns), suggesting increased *de novo* synthesis of these glycerolipids. LTB_4 induced a twofold increase in glycerol incorporation into PtdOH, DG, and PtdIns during 1–2-min incubations. The increased glycerol incorporation into PtdOH and DG started to decline after longer periods of incubation, but a twofold increase in PtdIns radioactivity remained even after a 10-min incubation. Phosphate analysis (10) could not detect the changes in PtdIns mass during the neutrophil–LTB_4 interaction. The changes in the radioactivity of choline glycerophospholipid (CGPL), ethanolamine glycerophospholipid (EGPL), and TG were insignificant.

DISCUSSION

The present study presents a convenient method for the separation of PtdOH from neutrophil lipid extract. Bocckino *et al.* (23) developed a two-step one-dimensional TLC for separation of PtdOH from hepatocyte extracts. However, it had a longer developing time than the present method for PtdOH separation. In the present method, prestaining the developed chromatogram with iodine enhanced the intensity of PtdOH charred with $CuSO_4/H_3PO_4$ twofold. PtdOH mass can be quantitatively measured on the NIH Image program. Under the experimental conditions, a 100% recovery of PtdOH from neutrophils could be achieved. By using this method, the present study has demonstrated that LTB_4 is capable of inducing a prompt (5 s) but transient (5 min) PtdOH mass accumulation in human neutrophils without the priming effect of cytochalasin B. Phospholipase D activation appears to contribute to part of the early increased PtdOH mass, as evidenced by PtdEt formation at the expense of PtdOH. Cytochalasin B enhanced PtdOH mass elevation induced by LTB_4. As cytochalasin B had no effect on phospholipase C activity (4,22), the results obtained by measuring the mass amounts of PtdOH and PtdEt support the finding that cytocha-

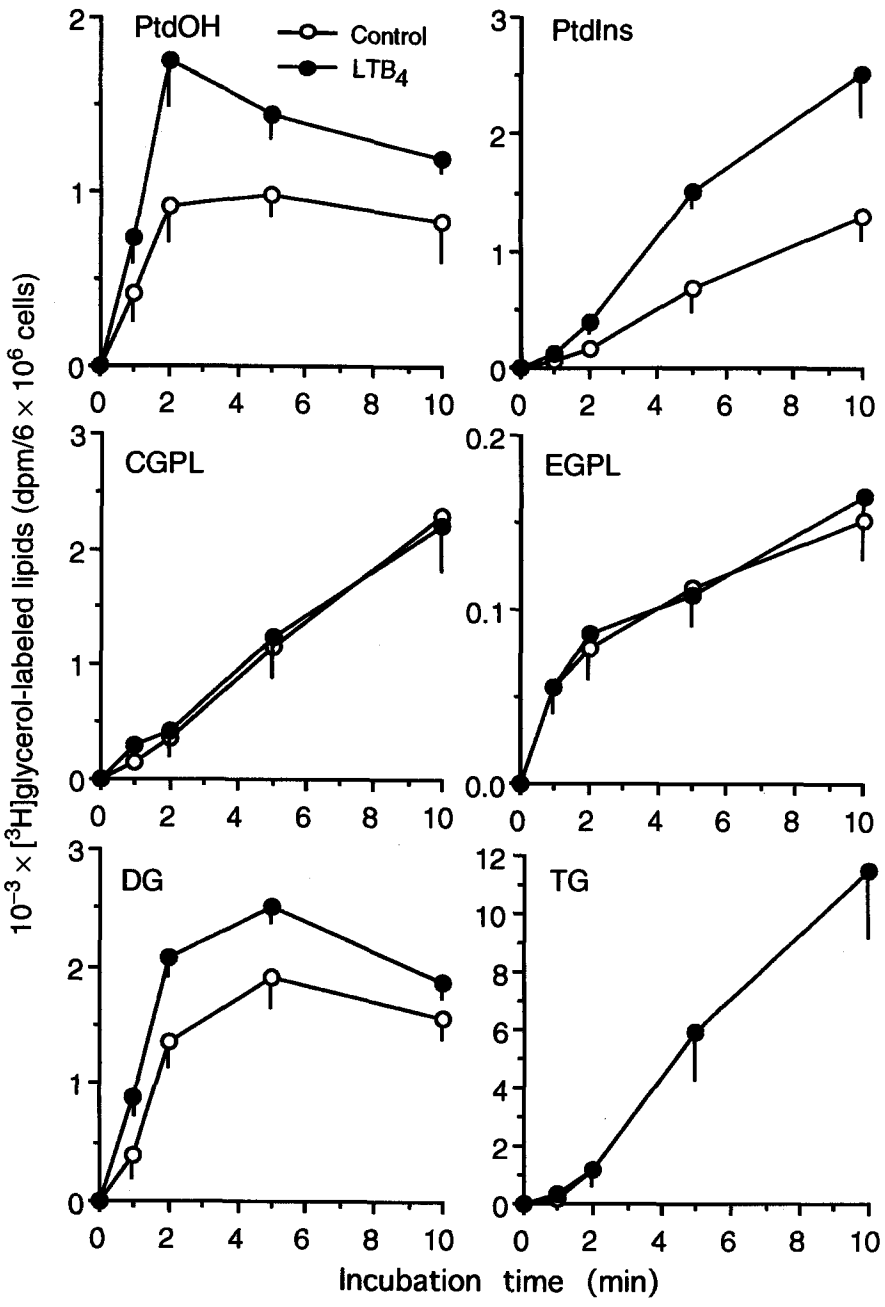

FIG. 8. Time course of LTB_4 effect on [^{3}H]glycerol incorporation into glycerolipids. Incubation conditions, lipid extraction and separation, and radioactivity measurements were described in the Materials and Methods section. The radioactivity of each lipid was expressed as dpm ± SEM per 6×10^6 cells from three experiments. Abbreviations as in Figures 1 and 7. PtdIns, phosphatidylinositol; CGPL, choline glycerophospholipid; EGPL, ethanolamine phospholipid; TG, triglyceride.

lasin B enhanced the expression of phospholipase D activity in human neutrophils (18,22) and in rabbit peritoneal neutrophils (5). The mechanism of cytochalasin B potentiation of phospholipase D activity in agonist-activated neutrophils is not well understood. Phospholipase D in neutrophils requires Ca^{2+} and small molecular weight GTP-binding protein for activity (24,25). It has been hypothesized that cytochalasin B may facilitate the availability of Ca^{2+} to phospholipase D (22).

Because LTB_4 has been shown to stimulate Ins(1,4,5) P_3 generation without cytochalasin B (4), part of the increased PtdOH mass may be derived from phospholipase C activation producing DG, which is subsequently phosphorylated to form

PtdOH. Although the changes in DG mass after 5 s were undetectable during the neutrophil–LTB_4 interaction, it is possible that the enzymatic method for DG mass determination is unable to detect the early small changes in DG mass.

The effect of LTB_4 is stereospecific because the structural analog 12-*epi*-LTB_4 had no effect on PtdOH levels. However, LTB_3, LTB_4, and LTB_5 were equipotent stimuli for PtdOH mass elevation. The effect of these leukotrienes on the changes in PtdOH mass appears to be at variance with their effects on chemotaxis and degranulation. A recent study (26) showed that LTB_3 was as active as LTB_4 in inducing neutrophil chemotaxis and lysozyme release from cytochalasin B-treated neutrophils. However, LTB_5 was shown to be a weaker stimulus of chemotaxis (26,27) and of lysozyme release (26) than LTB_4.

LTB_4 stimulation of glycerol incorporation into PtdOH, DG, and PtdIns suggests increased *de novo* synthesis of these lipids. Our earlier study (9), showing LTB_4 stimulation of palmitic, but not arachidonic, acid incorporation into PtdOH also suggests increased PtdOH synthesis. Enhanced PtdIns synthesis by LTB_4 may serve to replenish this molecule after its conversion to phosphatidylinositol 4,5-bisphosphate, which undergoes increased hydrolysis by phospholipase C (4) and increased transformation into phosphatidylinositol 3,4,5-triphosphate (28).

The function of PtdOH accumulation during the neutrophil–LTB_4 interaction deserves further study. Studies using cytochalasin B-treated neutrophils have demonstrated the association of degranulation (5,19) and superoxide anion production (29,30) with the formation of phospholipase D-derived PtdOH, which is a mixture of diacyl and alkylacyl species. However, PtdOH alone does not seem to be sufficient or necessary for initiating superoxide generation (31,32). The synergy of diacyl-PtdOH and diacylglycerol appears to be important in a cell-free system for NADPH oxidase activation (33). A recent study using neutrophils adherent to fibrinogen has shown that diradylglycerol (a mixture of diacylglycerol and alkylacylglycerol) derived from phospholipase D activation plays an important role in degranulation and oxidant release (34). In cell-free systems of other tissues, diacyl-PtdOH has been shown to induce protein phosphorylation (35) and activation of phosphatidylinositol 4-phosphate [PtdIns(4)P] 5-kinase (36,37). LTB_4 has been shown to promote phosphorylation of a 64-kD protein (38) and activation of a PtdIns(4)P 5-kinase (39) in neutrophils. It remains to be established whether the prompt rise in PtdOH mass induced by LTB_4 in these cells plays a role in these events.

Diabetes and Proteolysis: Effects on Carnitine Palmitoyltransferase-I and Malonyl-CoA Binding

Khosrow Kashfi[1] Lauren Cagen and George A. Cook*

Department of Pharmacology, College of Medicine, University of Tennessee-Memphis, The Health Science Center, Memphis, Tennessee 38163

ABSTRACT: Malonyl-CoA binding and malonyl-CoA inhibition of carnitine palmitoyltransferase-I (CPT-I) were measured in hepatic mitochondria from normal and diabetic rats and in protease-treated mitochondria from fed rats to test the hypothesis that proteolysis represents a mechanism by which diabetes produces changes in the sensitivity of CPT-I to inhibition by malonyl-CoA. As in diabetes, protease treatment increased the apparent K_i values for malonyl-CoA. Palmitoyl-CoA greatly diminished malonyl-CoA specific binding in the mitochondrial system being studied, suggesting strong competition at the malonyl-CoA binding site. Proteolysis decreased capacity for specific binding of malonyl-CoA by 60–80%, but it had no effect on binding affinity. In contrast, the decreased specific binding of malonyl-CoA seen in the diabetic state is accompanied by increased binding affinity. Furthermore, observed K_d values differed from K_i values by a factor of 10 or more, suggesting that measured K_d and K_i may represent different ligand–protein complexes. These data suggest that alterations in inhibition of CPT-I by malonyl-CoA occurring in the diabetic state may involve mechanisms other than simple proteolytic removal of malonyl-CoA binding sites.

Lipids 30, 383–388 (1995).

Carnitine palmitoyltransferase (CPT; EC 2.3.1.21) is generally recognized as the most important regulatory enzyme in the hepatic mitochondrial fatty acid oxidation pathway. Two forms of CPT exist in mitochondria. CPT-I, located in the mitochondrial outer membrane, is inhibited by malonyl-CoA in concentrations that occur within the cytoplasm (1,2). CPT-II is located in the mitochondrial inner membrane and is insensitive to this inhibitor (1,2). The activity of CPT-I increases, and its sensitivity to inhibition by malonyl-CoA is diminished during fasting and diabetes (3–8). The most significant change that occurs with the onset of diabetes (7,8) or during a fasting period (9,10) is a 10-fold increase in the apparent K_i for malonyl-CoA.

The results of treating intact mitochondria and mitochondrial outer membranes with proteases led Murthy and Pande (1) to propose that the malonyl-CoA binding site of CPT-I faces the cytosol, while its catalytic site faces the intermembrane space. We recently evaluated the effects of proteases on the sensitivity of CPT-I to a variety of inhibitors (11,12). Sensitivity to most of these was not affected, suggesting that they act at the palmitoyl-CoA binding site facing the intermembrane space, but sensitivity to malonyl-CoA and 4-hydroxyphenylglyoxylate (HPG) was lost after protease treatment, suggesting that these act at a site facing the external medium. HPG is also the only inhibitor yet reported whose inhibitory potency is altered, like that of malonyl-CoA, by fasting and diabetes (13).

Since both protease treatment and diabetes reduce the sensitivity of CPT-I to inhibition by malonyl-CoA, and since proteolysis is enhanced in diabetes, we have previously proposed that proteolysis may be a mechanism by which diabetes alters the normal control of hepatic fatty acid oxidation (12). Similar proteolytic mechanisms have been found to occur in other metabolic pathways (14,15). The present study was conducted to compare the effect of diabetes with effects of protease treatment on both binding of [^{14}C]malonyl-CoA to intact mitochondria and malonyl-CoA inhibition of hepatic CPT-I since previous studies of malonyl-CoA binding to intact mitochondria (16,17) and mitochondrial outer membranes (18,19) have linked malonyl-CoA binding closely to malonyl-CoA inhibition of CPT-I.

EXPERIMENTAL PROCEDURES

Animals. Male Sprague-Dawley rats (200–250 g) obtained from Harlan Industries (Indianapolis, IN) were fed on Purina rat chow (Ralston Purina Co., Richmond, IN) and water *ad libitum.* On the day of the experiment, rats were killed by decapitation, and livers were removed rapidly for preparation of mitochondria. Ketotic diabetic rats used in some experiments were produced by injecting rats with 150 mg of streptozotocin/kg of body weight into the tail vein (20) and were used 48 h after the injection. This high dose of streptozotocin

was used to produce rats that were highly ketotic [urine ketone bodies ≥80 mg/mL and urine glucose levels ≥2000 mg/mL using Multistix® (Miles, Inc. Elkhart, IN)].

Isolation and protease treatment of mitochondria. Intact mitochondria were isolated by the method of Johnson and Lardy (21), with the modifications previously published (9), except that the isolation medium contained 210 mM mannitol, 70 mM sucrose, 0.1 mM EDTA, and 10 mM Tris/HCl (pH 7.4). In some experiments, mitochondria (5 mg protein/mL) were incubated at 37°C in isolation medium with subtilisin BPN′ (5 μg/mL). After incubation (2 to 20 min), the proteolytic activity was quenched by addition of 0.2 vol of bovine serum albumin (BSA) followed by addition of 40 mL of ice-cold isolation medium. Mitochondria were subsequently sedimented by centrifugation at 5600 × *g* for 10 min and then resuspended in isolation medium to a concentration of 20 mg protein per mL. In some initial experiments, 0.2 mM phenylmethylsulfonyl urea was added to the buffer after quenching, but it was found that the washing procedure with BSA was sufficient to prevent further proteolysis of the mitochondria. Protein was determined by a biuret reaction (22). The effects of the proteases papain, trypsin, and subtilisin BPN′ to decrease activity and malonyl-CoA sensitivity of CPT-I have been shown previously to be caused by proteolytic action since heating the proteases at 100°C for 10 min before use or addition of specific protease inhibitors prevented alterations of CPT-I (11,12). Also, increased effects of proteases were associated with increased incubation time and increased protease concentration but were decreased not only by protease inhibitors, but by specific inhibitors of CPT-I and by addition of BSA (11,12). Furthermore, the use of a specific chromogenic protease assay has been useful in correlating protease activity with alterations in CPT-I (12).

CPT. The method of Bremer (4) was used, modified as reported previously (7). Each assay contained, in a total volume of 1 mL, 82 mM sucrose, 70 mM KCl, 70 mM imidazole, 1 μg of antimycin A, 1 mM EGTA, 2 mg BSA, 40 μM palmitoyl-CoA, and 0.5 mM L-carnitine (0.4 mCi/mmol of L-[methyl-^{3}H]carnitine).

Binding of [2-^{14}C]malonyl-CoA. Malonyl-CoA binding experiments were performed in 1.5-mL plastic stoppered centrifuge tubes. The binding cocktail for incubations at 0°C contained, in a total volume of 1 mL, 82 mM sucrose, 70 mM KCl, 70 mM imidazole, 1 μg of antimycin A, and 1 mM EGTA. The pH was adjusted to 7.0 using HCl and KCl, to maintain equal ionic strength, according to Ellis and Morrison (23). Albumin was omitted from the binding cocktail since it had been shown to influence malonyl-CoA binding (24). The concentration of [^{14}C]malonyl-CoA (51 mCi/mmol) was usually varied from 5 to 660 nM, although higher concentrations were used in some initial experiments to show saturation of malonyl-CoA binding sites (Fig. 1). Experiments were started by addition of mitochondria (1 mg protein per mL). Equilibrium was reached within 120 min at 0°C with all treatments (Fig. 2), and incubations were terminated by centrifugation for 2 min at 12,000 × *g* using an Eppendorf micro-centrifuge at 0–4°C. Supernatant solution was aspirated, and the walls of the tubes were dried with tissue paper. The mitochondrial pellets were solubilized with 0.5 mL of 10% Triton X-100 at 37°C and transferred to scintillation vials. Radioactivity in the pellet and supernate was measured by scintillation spectrometry. Nonspecific binding was estimated by inclusion of 250 nmol unlabeled malonyl-CoA in the incubation medium (4 μmol unlabeled malonyl-CoA were used when the concentration of labeled ligand exceeded 660 nM). Nonspecific binding was proportional to the con-

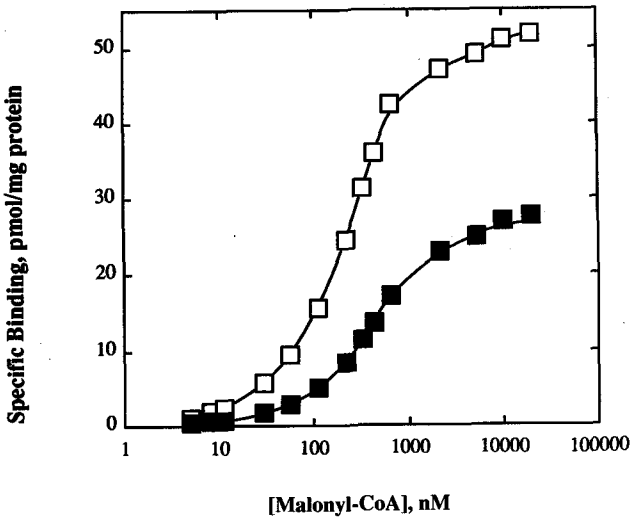

FIG. 1. Saturation binding curve represented as specific binding as a function of the log of malonyl-CoA concentration. Specific binding of [^{14}C]malonyl-CoA was measured at 0°C in control (□) and protease-treated (■) intact hepatic mitochondria as described in the Materials and Methods section.

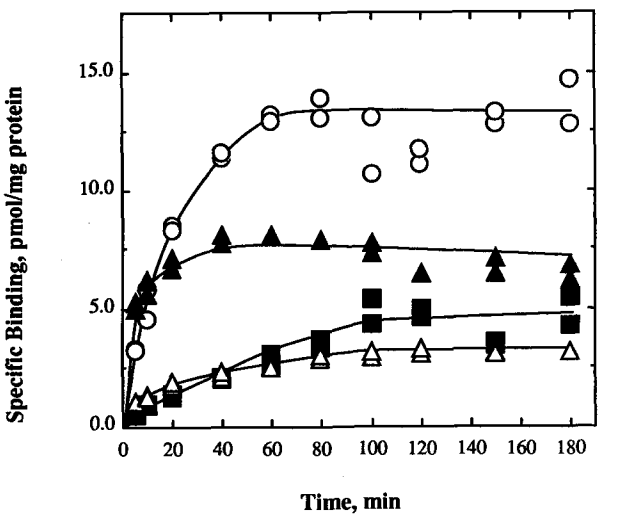

FIG. 2. Equilibrium time course for different mitochondrial treatments. Specific binding was measured as a function of time at 0°C in control (○), diabetic (▲), protease-treated (■), and control plus 5 μM palmitoyl-CoA (△) using intact hepatic mitochondria that had been incubated with [^{14}C]malonyl-CoA as described in the Materials and Methods section.

centration of labeled malonyl-CoA and was nonsaturable (data not shown); specific binding was calculated by subtracting nonspecific binding from total binding at each concentration of ligand.

Analysis of [2-^{14}C]malonyl-CoA binding data. The binding data were plotted according to Scatchard (25). This plot gave a curve which was upward concave in shape. Two possible biological interpretations of these data are possible: (i) multiple binding sites exist with unchanging and different affinities; and (ii) negative cooperativity exists, such that the affinity of the overall binding population decreases with increasing occupancy of the binding sites (26). In order to distinguish between these two possibilities, "infinite dilution" experiments were carried out according to De Meyts *et al.* (27). Mitochondria (1 mg protein per mL) were incubated with [2-^{14}C]malonyl-CoA at 0°C for 120 min. After centrifugation at 12,000 × *g*, the mitochondrial pellet was resuspended in 1 mL of binding cocktail without added malonyl-CoA, and 100 µL was removed for determination of "zero time" binding. Additional 100 µL aliquots were diluted in 10 mL of cocktail at 0°C with or without a 100-fold excess of unlabeled malonyl-CoA. At various times, the suspensions were centrifuged, and bound radioactivity was determined as described above. From a plot of malonyl-CoA bound vs. time elapsed after dilution (Fig. 3), it was concluded that negative cooperativity did not exist since the presence of an excess of unlabeled ligand did not affect the rate of dissociation of the labeled ligand. Infinite dilution experiments were also carried out for nonspecific binding. Nonspecific binding represented only a small fraction of the total radioactivity bound, and dissociation was much more rapid so that the dissociation rates observed in the infinite dilution experiments were not affected by nonspecific binding.

After establishing that the Scatchard plots represented multiple binding sites, estimates of binding parameters were obtained using the computer programs EBDA (28) and LIGAND (29,30). The analysis of the data fitted the two-site models ($P < 0.05$) better than the one-site ($P \geq 0.1$) model when residual sums of squares were compared. Hence, all parameters reported here are for a two-site model. These data clearly suggest that malonyl-CoA binds to more than one site in mitochondrial membranes, although binding data alone cannot indicate the nature of the proteins involved.

Materials. Palmitoyl-CoA, imidazole, BSA, malonyl-CoA, EGTA, Subtilisin BPN′ (Catalogue # P 4789), and streptozotocin were purchased from Sigma Chemical Co. (St. Louis, MO). L-[methyl-^{3}H]Carnitine hydrochloride and [2-^{14}C]malonyl-CoA were obtained from Amersham Corporation (Arlington Heights, IL).

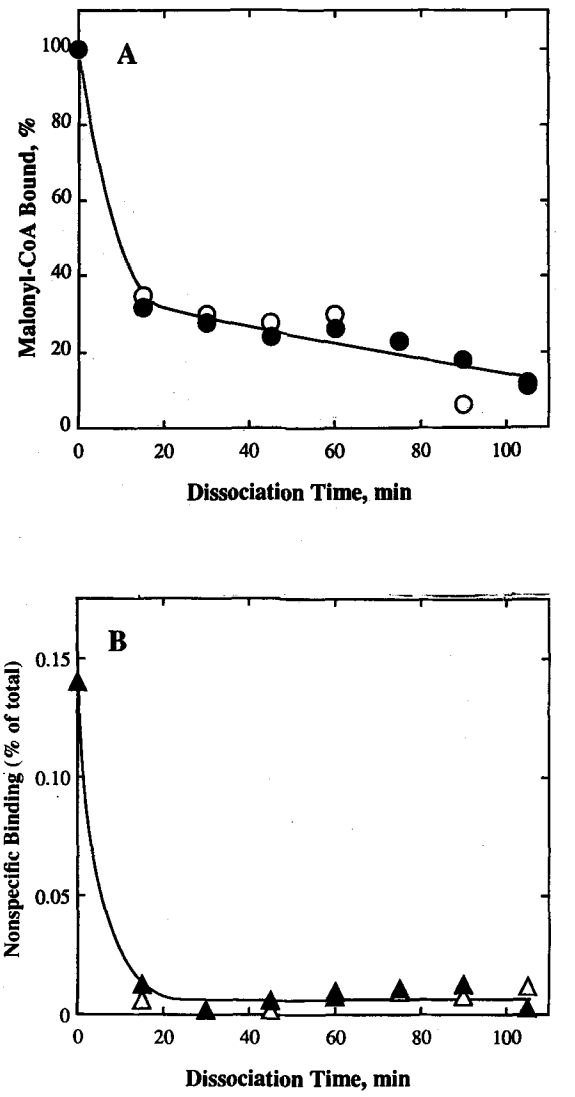

FIG. 3. Dissociation of bound [^{14}C]malonyl-CoA from mitochondria. A. [^{14}C]Malonyl-CoA and intact hepatic mitochondria were first incubated at 0°C for 120 min to allow binding equilibrium to be reached, then mitochondria were centrifuged and diluted with (●) or without (○) a 100-fold excess of unlabeled malonyl-CoA to allow dissociation of malonyl-CoA. Labeled malonyl-CoA remaining bound was measured at the times indicated. B. Dissociation of nonspecific binding. Conditions were identical with A; ▲, with; △, without.

RESULTS

Effects of protease treatment on the apparent K_i for malonyl-CoA. We previously presented data indicating that limited proteolysis of the intact hepatic mitochondria resulted in altered kinetic properties of CPT-I as indicated by changes in the shapes of Dixon (31) plots, suggesting that positive cooperativity was lost as a result of protease treatment (12). Therefore, we wanted to find out what effect proteolysis would have on the apparent K_i for malonyl-CoA after exposure of the intact mitochondria to protease for different time periods. We used the low concentration end of the Dixon plots (1–5 µM) to estimate apparent K_i values for malonyl-CoA. At these concentrations, graphs were linear and a direct estimation of apparent K_i could be made. The calculated apparent K_i values for malonyl-CoA are presented in Figure 4. The data indicate that exposure of intact hepatic mitochondria to the protease greatly increases the apparent K_i values for mal-

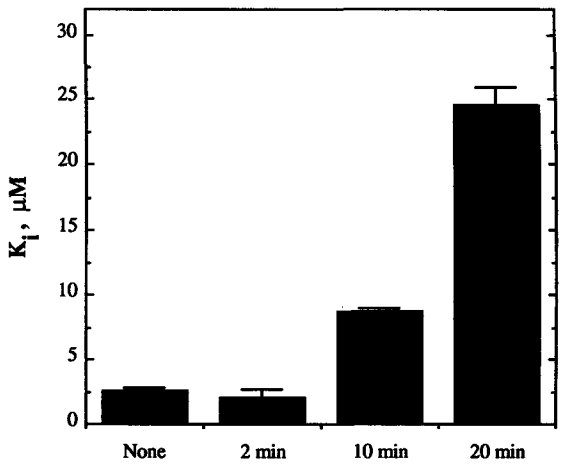

FIG. 4. Effects of proteolysis on the apparent K_i of carnitine palmitoyltransferase-I for malonyl-CoA. K_i values were determined from Dixon plots (Ref. 31) that were constructed for control and protease-treated intact mitochondria using 5 concentrations of malonyl-CoA at each of three concentrations of palmitoyl-CoA at the conditions indicated in the figure. Results are means ± SEM for three different preparations of mitochondria.

onyl-CoA in a manner dependent on the extent of proteolysis and similar to effects seen with the onset of diabetes (6–8).

Effect of protease treatment on specific binding of [2-^{14}C]malonyl-CoA to hepatic mitochondria. Since protease treatment and diabetes both increase the apparent K_i values for malonyl-CoA, we wanted to determine whether proteolysis would alter malonyl-CoA binding to intact hepatic mitochondria to suggest a mechanism for the effects of diabetes. The time course of specific association of [2-^{14}C]malonyl-CoA with intact rat hepatic mitochondria at 0°C, with or without prior treatment with protease for 20 min, is shown in Figure 2. Equilibrium was achieved within 120 min. Treatment with protease for 20 min reduced the extent of [2-^{14}C]malonyl-CoA binding (Figs. 1 and 5). Analysis of the binding data for control mitochondria by LIGAND was consistent with a two-site model (Table 1). High affinity sites (K_d = 63 nM) represented 26% of the total binding capacity; the remainder reflected low affinity (K_d = 257 nM) sites. Dissociation of bound [2-^{14}C]malonyl-CoA was biphasic whether net dissociation was initiated by dilution or by addition of excess unlabeled ligand (Fig. 3). This is consistent with a model composed of two independent classes of binding site. Under conditions of the experiment, about one-third of the ligand was bound to slowly dissociating sites. Treatment with protease removed 79% of the high-affinity sites and 62% of the low affinity sites with no significant change in the apparent affinity of the surviving sites.

Binding of [2-^{14}C]malonyl-CoA to mitochondria from diabetic rats. Similar to the effects of protease treatment, streptozotocin-induced diabetes reduced the number of high- and low-affinity binding sites (by 58 and 56%, respectively) for [2-^{14}C]malonyl-CoA in hepatic mitochondria (Figs. 5 and 6; Table 1); however, in contrast to protease treatment, the apparent affinities of the remaining sites were significantly enhanced in hepatic mitochondria from diabetic rats. Palmitoyl-CoA was added in some experiments to show the effects of competition of malonyl-CoA and palmitoyl-CoA, indicating that malonyl-CoA is binding specifically and competitively to an acyl-CoA binding enzyme. Addition of palmitoyl-CoA increased both dissociation constants for malonyl-CoA, suggesting that both sites are related to CPT function.

TABLE 1
Malonyl-CoA Binding Parameters for Binding to Intact Hepatic Mitochondria[a]

Treatment	K_{d1} (nM)	K_{d2} (nM)	N_1 (pmol/mg)	N_2 (pmol/mg)
Control	63 ± 13	257 ± 20	19 ± 3	52 ± 5
Protease	47 ± 4	366 ± 50	4 ± 0.2[b]	20 ± 4[b]
Diabetic	18 ± 2[b]	170 ± 14[b]	8 ± 0.6[b]	29 ± 4[b]
Control + 5 μM palmitoyl-CoA	102 ± 1[b]	2321 ± 124[b]	6 ± 4	91 ± 12

[a]Malonyl-CoA binding was measured under the conditions described in the Materials and Methods section. Protease treatment was carried out using the protease subtilisin BPN' at 5 μg/mL for 20 min. Diabetic rats were produced by streptozotocin injection and were ketotic. N_1 and N_2 represent numbers of high- and low-affinity binding sites for malonyl-CoA, respectively. Results are mean ± SEM for three different preparations of mitochondria.
[b]Significantly different from control values ($P < 0.05$).

DISCUSSION

The effects of proteolysis on the apparent K_i values for malonyl-CoA raised the possibility that endogenous proteolysis of hepatic mitochondrial CPT-I might be a mechanism for changing the apparent K_i values for malonyl-CoA in such states as fasting and diabetes, where proteolysis is most

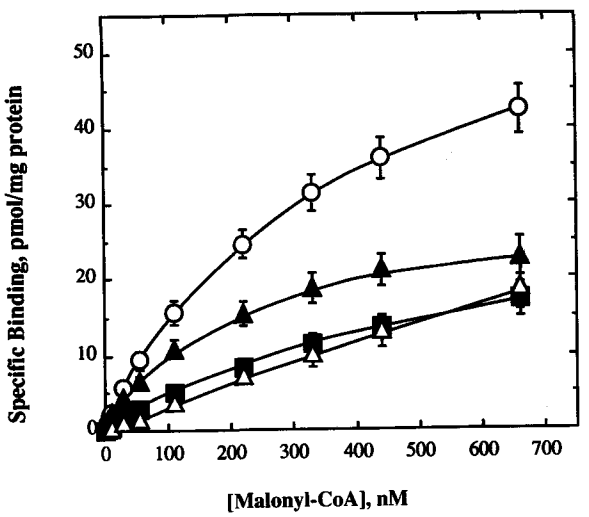

FIG. 5. Specific binding of malonyl-CoA in normal, diabetic, and protease-treated mitochondria. Specific binding of [^{14}C]malonyl-CoA was measured at 0°C in control (○), diabetic (▲), protease-treated (□), and control mitochondria plus 5 μM palmitoyl-CoA (△) as described in the Materials and Methods section. Results are means ± SEM for three different preparations of mitochondria.

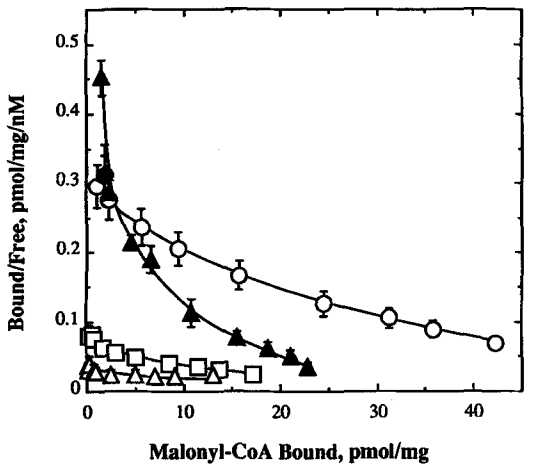

FIG. 6. Scatchard analysis of the binding data. Scatchard analysis of the binding data was carried out as described in the Materials and Methods section. The symbols refer to control (○), diabetic (▲), protease-treated (□), and control in the presence of 5 μM palmitoyl-CoA (△). Results are means ± SEM for three different preparations of mitochondria.

prevalent. There are a number of reports which indicate that isovalerylcarnitine, a product of L-leucine catabolism, activates the endogenous protease calpain II and modulates the effects of calpstatin, an endogenous inhibitor of calpain II, suggesting a possible mechanism for initiation of proteolysis during starvation or diabetes (14,15). The binding data we obtained from diabetic animals showing a significant decrease in the number of both the high- and low-affinity binding sites is comparable to the effects of protease treatment of intact normal mitochondria and further suggests that proteolysis may be a mechanism for changes observed during diabetes. However, the change in binding affinity with diabetes, but not with proteolysis, suggests that the proteolytic removal of malonyl-CoA binding sites is not sufficient to account for all the effects of diabetes on CPT-I. The increasing affinity for malonyl-CoA during diabetes is paradoxical. It suggests the binding of malonyl-CoA during the diabetic state may be unrelated or somehow dissociated from malonyl-CoA inhibition. This further suggests that the effects of diabetes are more complex than previously expected. We have recently found that diabetes increases CPT-I mRNA 15-fold, suggesting greatly increased rates of transcription (data not shown).

Proteolytic treatment of intact hepatic mitochondria increased the apparent K_i for malonyl-CoA as a function of treatment time; however, there were no changes in the dissociation constants for malonyl-CoA binding to intact hepatic mitochondria. This suggests that the apparent K_i for malonyl-CoA and the K_d values for malonyl-CoA binding do not represent the same dissociation constants. One would expect these two values to be identical since the K_i value for a competitive inhibitor is the equilibrium constant for the dissociation of the enzyme-inhibitor complex. The only effect of proteolysis is to decrease the number of binding sites. This suggests that the K_d values measured here relate to the enzyme remaining after protease treatment and that the protease eliminates malonyl-CoA binding completely without altering binding characteristics. Since the K_i is changed but the K_d is not, it is possible that the K_i is for an association involving malonyl-CoA, CPT-I that is unaltered by protease treatment, and an auxillary protein binding malonyl-CoA that is digested by the protease. Recent data have indicated that it may be possible to discriminate two components of liver CPT-I, a catalytic component and a regulatory component that binds malonyl-CoA (32–34). If this hypothesis is correct, then our present data suggests that K_{d1} and K_{d2} represent dissociation constants of separate complexes formed by malonyl-CoA binding to the binding protein (the regulatory component) and to the catalytic component, while K_i represents a more complex dissociation constant of a ternary complex comprising malonyl-CoA, the regulatory binding component, and the catalytic component of CPT-I.

In light of the known effects of diabetes to decrease malonyl-CoA inhibition by increasing the apparent K_i value for malonyl-CoA (7,8), the binding parameters measured for [2-^{14}C]malonyl-CoA to the hepatic mitochondria from diabetic animals were surprising. That numbers of both the high- and the low-affinity binding sites were significantly reduced is easily understood. However, the fact that both K_d values decreased during diabetes, which is exactly opposite to the effect on apparent K_i values, again suggests that K_i and K_d values do not represent the same dissociation constants for CPT-I. Diabetes may act to dissociate malonyl-CoA binding and malonyl-CoA inhibition of CPT-I. Using isolated mitochondrial outer membranes, it was reported that diabetes increased the number of high-affinity binding sites while increasing the high-affinity dissociation constant and decreasing both the number and affinity of the low-affinity sites (18). Our data are contrary to these findings, possibly because: (i) the protocols that these authors used (18) included BSA, which interferes with malonyl-CoA binding (24); (ii) binding was conducted for only 20 min, which our data indicates is too short a time period to reach binding equilibrium; (iii) their binding medium was at pH 6.8, a condition which favors tighter binding (24); (iv) the membranes were washed twice with their binding medium, and significant amounts of malonyl-CoA could have been lost in washing; and (v) no corrections were made for nonspecific binding.

The primary structure of CPT-I has recently been deduced from the sequence of a cDNA which suggests that CPT-I has a single membrane-spanning region (35). When our previous work on proteolytic effects on CPT-I (11,12) and that of Murthy and Pande (1) are considered when examining the deduced sequence, it becomes apparent that most of the CPT-I protein, containing the active site, must lie inside the mitochondrial outer membrane but that approximately 100 amino acid residues at the N-terminal end lies outside that membrane in the cytosolic space. It is this N-terminal region which may be susceptible to attack by endogenous proteases or to proteases added *in vitro*, and when this region is removed or damaged by proteases, CPT-I loses its ability to be inhibited by malonyl-CoA. Alternatively, proteases may act on a puta-

tive regulatory protein. Recent work on the kinetics of CPT-I has shown that this enzyme has two independent binding sites for inhibitors, with malonyl-CoA preferring a noncatalytic site located outside the mitochondrial outer membrane (36). Whether this site resides on the catalytic protein or on a regulatory subunit remains to be resolved; however, the data presented here suggest that the changes in malonyl-CoA sensitivity of CPT-I that occur in diabetic animals may be due to mechanisms other than simple proteolytic removal of malonyl-CoA binding sites.

ABSTRACT: The concentration-dependent effects of two different synthetic phospholipids on cell proliferation and phosphatidylcholine biosynthesis were compared in Madin-Darby canine kidney (MDCK) cells. The alkyllysophospholipid 1-*O*-octadecyl-2-*O*-methyl-*sn*-glycero-3-phosphocholine and the alkylphosphocholine, hexadecylphosphocholine, inhibited cell proliferation with half-inhibitory concentrations (IC_{50}) of 75 and 135 μmol/L, respectively. The agents also inhibited phosphatidylcholine biosynthesis in confluent and proliferating MDCK cells. The IC_{50} of 1-*O*-octadecyl-2-*O*-methyl-*sn*-glycero-3-phosphocholine was 40 μmol/L in confluent cells and 20 μmol/L in proliferating cells, whereas the IC_{50} of hexadecylphosphocholine was higher in both experimental systems (67 μmol/L in confluent cells and 40 μmol/L in proliferating cells). Further experiments revealed that the effect of both agents on phosphatidylcholine biosynthesis was reversible and that the inhibition was mediated by translocation of the rate-limiting enzyme of this pathway, CTP:phosphocholine cytidylyltransferase (EC 2.7.7.15), from membranes to the cytosol, where it is inactive. The present findings suggest that the inhibition of phosphatidylcholine biosynthesis by both synthetic phospholipids might be related, in part, to their antiproliferative effects.

Lipids 30, 389–393 (1995).

Alkyllysophospholipids have been shown to possess antineoplastic properties *in vitro* and *in vivo* (for a review, see Ref. 1). A number of hypotheses have been brought forth to explain their mechanism(s) of action (2,3). One proposed mechanism is the perturbation of reacylation of lysophospholipids that is mediated by lysophosphatidylcholine:acyl-CoA transferase (4). It was shown that the alkyllysophospholipid 1-*O*-octadecyl-2-*O*-methyl-*sn*-glycero-3-phosphocholine (ET-18-OCH_3) inhibits the incorporation of unsaturated fatty acids into phosphatidylcholine in HL60 cells (4). However, in other studies a correlation between the inhibition of cell proliferation and the effect on incorporation of fatty acids into phospholipids could not be demonstrated (5,6).

SCHEME 1

Alkylphosphocholines, another class of synthetic phospholipids, are effective antineoplastic agents which have been used as anticancer drugs against skin metastases of human breast carcinoma (7). We have previously shown that alkylphosphocholines inhibit the biosynthesis of phosphatidylcholine by disturbing the translocation process of the rate-limiting enzyme, CTP: phosphocholine cytidylyltransferase (EC 2.7.7.15), and that this inhibition correlates with the antiproliferative effect of these agents (8–10).

In the present study, we compared the effects of ET-18-OCH_3 and hexadecylphosphocholine (HePC) (Scheme 1) on cell proliferation and phosphatidylcholine biosynthesis in Madin-Darby canine kidney (MDCK) cells. ET-18-OCH_3 inhibited cell proliferation and phosphatidylcholine biosynthesis, and the inhibitory effects of ET-18-OCH_3 were stronger as compared with the effects of HePC. However, the cytotoxicity of ET-18-OCH_3 in our experimental system was also quite high. From our results, we conclude that the influence of HePC on phosphatidylcholine biosynthesis is more specific because inhibition of phosphatidylcholine biosynthesis by HePC clearly preceded cell death.

EXPERIMENTAL PROCEDURES

Materials. ET-18-OCH_3 was obtained from Novabiochem (Bad Soden, Germany), and HePC was synthesized as de-

scribed previously (11). [*Methyl*-^{3}H]choline chloride (2.8–3.1 TBq/mmol) was from Amersham (Braunschweig, Germany). Silica gel 60 high-performance thin-layer chromatography (HPTLC) plates, solvents, and reagents (reagent grade) were purchased from E. Merck (Darmstadt, Germany) and Fluka (Neu-Ulm, Germany). The bicinchoninic acid (BCA) kit for protein determination was obtained from Pierce (Weiskirchen, Germany). 12-*O*-tetradecanoylphorbol-13-acetate (TPA), choline, phosphocholine, and CDP-choline were from Sigma (München, Germany). For quantification of radioactivity a Berthold (Wildbad, Germany) LB 2821 HR thin-layer chromatography scanner was used.

Cell culture. MDCK cells were grown in plastic culture dishes (Nunc, Denmark) containing Dulbecco's minimal essential medium supplemented with 10% calf serum, 0.56 g/L L-glutamine, 100,000 IU penicillin, and 0.1 g/L streptomycin. Media and culture reagents were obtained from Gibco (Berlin, Germany), and penicillin and streptomycin from Boehringer (Mannheim, Germany). Confluent cells were subcultured every three days after detaching the cells with a 0.1% trypsin/0.02% EDTA solution.

Cytotoxicity assay. Cytotoxicity of the different synthetic phospholipids to MDCK cells was estimated according to Culvenor *et al.* (12) by measurement of the alkaline phosphatase activity of the cells. Confluent cells were incubated for 6 h with medium containing different concentrations of ET-18-OCH_3 and HePC or no additional supplements as controls. The cells were centrifuged at 1000 × *g* for 10 min, and the supernatant was discarded. The reaction mixture [containing 20% diethanolamine, 2 µmol/L $MgCl_2$, 2 µmol/L *p*-nitrophenylphosphate, and 10% Triton X-100 (Aldrich, Steinheim, Germany)] was added. After 1 h at 37°C, the reaction was stopped with 0.5 mol/L NaOH. The amount of *p*-nitrophenolate was determined photometrically at 410 nm.

Cell proliferation assay. Proliferating MDCK cells (approximately 20,000 cells/cm^2) were incubated with medium containing different concentrations of ET-18-OCH_3 and HePC or no additional supplements as controls. After 16 h, the proliferation rate was determined by the crystal violet assay as described (13) and compared with that of control cells. Cells were fixed by treatment with 1% glutaraldehyde for 15 min, stained for 30 min in 0.1% crystal violet solution, then washed with deionized water for 15 min. Crystal violet absorbed by cell nuclei was solubilized with 0.2% Triton X-100, and the amount released was quantitated photometrically at 590 nm.

Measurement of phosphatidylcholine biosynthesis. Confluent (72 h after plating) and proliferating (24 h after plating) MDCK cells were incubated for 6 h with pulse medium (1 µCi/mL [*methyl*-^{3}H]-choline) which was supplemented with ET-18-OCH_3 or HePC in concentrations of 0, 10, 50, 100, or 200 µmol/L. After incubation, cells were washed two times with ice-cold phosphate-buffered saline (PBS) (pH 7.2) and harvested with a cell lifter (Costar, Cambridge, MA), followed by modified lipid extraction according to Bligh and Dyer (14). After lyophilization of the cells, 50 µL methanol, 25 µL chloroform, and 20 µL water were added. Samples were stirred for 2 min on a vortex mixer and centrifuged at 13,000 × *g* for 10 min. Phase separation was accomplished by addition of 25 µL chloroform and 25 µL water. The suspension and centrifugation steps were repeated. Then 10 µL of the chloroform phases were taken for scintillation counting, and 15 µL were applied to silica gel 60 HPTLC plates using a HPTLC applicator (Linomat III; Camag, Berlin, Germany). Lipids were separated according to Touchstone *et al.* (15) using the solvent chloroform/methanol/triethylamine/water (30:35:34:8, by vol). Radioactivity was quantified by radioscanning. Phospholipids were identified by calibrating the scanner with known standards. Approximately 95% of the radioactivity co-chromatographed with the phosphatidylcholine standard.

For determination of phosphatidylcholine biosynthesis under stimulating conditions, cells were simultaneously treated with 5 nmol/L TPA plus 50 µmol/L ET-18-OCH_3, and 5 nmol/L TPA plus 50 µmol/L HePC.

Reversibility of the inhibitory effect of both synthetic phospholipids was investigated using a different protocol. In these experiments, cells were preincubated for 6 h with medium, containing 50 µmol/L ET-18-OCH_3 or 50 µmol/L HePC. The cells were washed two times with warmed culture medium, and labeling was initiated by adding pulse medium (1 µCi/mL [*methyl*-^{3}H]choline) without additional supplements. After 1, 2, and 6 h, cells were collected, and incorporation of [*methyl*-^{3}H]choline into phosphatidylcholine was measured as described previously. Phosphatidylcholine biosynthesis under control conditions was determined using cells which had been preincubated and labeled with medium containing no additional supplements. Furthermore, phosphatidylcholine biosynthesis under inhibitory conditions was measured using cells which had been preincubated and labeled with medium containing 50 µmol/L ET-18-OCH_3 or 50 µmol/L HePC.

Digitonin-mediated release of cytidylyltransferase from MDCK cells. The release of cytidylyltransferase from MDCK cells was measured according to Pelech *et al.* (16). Cells were incubated for 4 h in 35-mm dishes with medium containing the appropriate supplements (as described for the labeling experiments), then washed twice with 1 mL ice-cold PBS. Digitonin-mediated release of cytidylyltransferase was performed as described earlier (17). The distribution of cytidylyltransferase activity between cytosol and membranes was calculated from the data for each dish.

CTP:phosphocholine cytidylyltransferase assay. The enzyme activity was measured by a modified method of Sohal and Cornell (18) as described (17), using liposomes (400 µmol/L phosphatidylcholine and 400 µmol/L oleic acid) and 10 µL of enzyme preparation in a final volume of 55 µL. One unit of enzyme activity is defined as 1 nmol of CDP-choline formed per minute.

Other procedures. Cellular protein was determined in each sample of the radiolabeling experiments by the BCA assay (19), using bovine serum albumin as a standard. Statistical comparisons were made in these studies with Student's *t*-test.

RESULTS

We first determined the cytotoxicity of ET-18-OCH_3 and HePC in MDCK cells. As shown in Figure 1, a dose-dependent increase of the cytotoxic effect was seen for both substances. However, at concentrations of 50 µmol/L or less the synthetic phospholipids did not show any cytotoxicity (viability >95%).

Cell proliferation was also inhibited by ET-18-OCH_3 and HePC. Whereas ET-18-OCH_3 had a half-inhibitory concentration (IC_{50}) of 75 µmol/L, HePC was less inhibitory with an IC_{50} of 135 µmol/L (Fig. 2). Nevertheless, the antiproliferative effect of HePC seemed to be more specific because the cells were still viable when cell proliferation was totally abolished.

The incorporation of [*methyl*-^{3}H]choline into phosphatidylcholine in MDCK cells treated with different concentrations of ET-18-OCH_3 was investigated and compared with the effect of the alkylphosphocholine, HePC. In confluent, nonproliferating cells, the IC_{50} of ET-18-OCH_3 was 40 µmol/L compared with an IC_{50} of HePC of 67 µmol/L (Fig. 2). In a second set of experiments, we used proliferating cells 24 h after plating the cells at a density of 20,000 cells/cm^2. Under these conditions, the cells had a doubling-time of about 24 h (data not shown). Proliferating cells appeared to be more sensitive than confluent cells and revealed IC_{50} levels of 20 µmol/L (ET-18-OCH_3) and 40 µmol/L (HePC) when incorporation of [*methyl*-^{3}H]-choline into phosphatidylcholine was measured (Fig. 3).

Recently, we found that phorbol ester-stimulated phosphatidylcholine biosynthesis is antagonized by simultaneous treatment with HePC (8). Therefore, we compared the effects of 50 µmol/L ET-18-OCH_3 and 50 µmol/L HePC on phorbol ester-stimulated phosphatidylcholine biosynthesis in MDCK cells. Phorbol ester treatment stimulated [*methyl*-^{3}H]choline incorporation into phosphatidylcholine by 600 ± 50% as compared with nontreated controls. This stimulation of phosphatidylcholine biosynthesis was completely antagonized by both synthetic phospholipids. Incorporation of [*methyl*-^{3}H]choline into phosphatidylcholine was 25 ± 5% and 50 ± 6% as compared with controls when cells were incubated with TPA plus ET-18-OCH_3 or with TPA plus HePC, respectively.

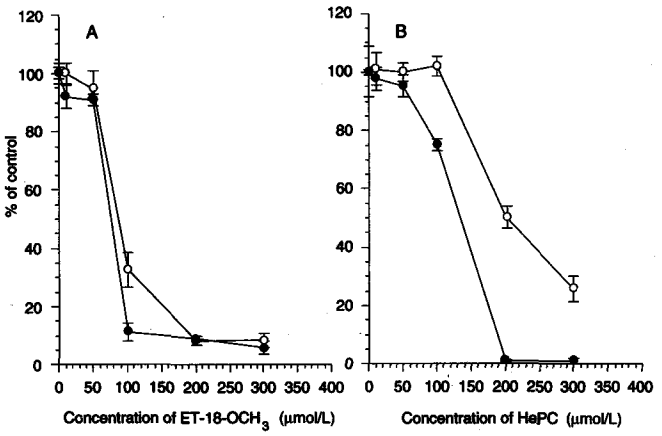

FIG. 2. Concentration-dependent effects of ET-18-OCH_3 and HePC on phosphatidylcholine biosynthesis in confluent MDCK cells. After 72 h, confluent MDCK cells were incubated for 6 h with pulse medium containing 2.5 µCi/mL [*methyl*-^{3}H]choline and different concentrations of ET-18-OCH_3 (A) and HePC (B). After 6 h of labeling, the incorporation of radioactivity into phosphatidylcholine was determined as described in the Experimental Procedures section. Values are given in % of controls ± SD (n = 3). The incorporation of [*methyl*-^{3}H]choline into phosphatidylcholine in control cells was 480 ± 33 dpm/µg cellular protein. Abbreviations as in Figure 1. IC_{50}, half-inhibitory concentration.

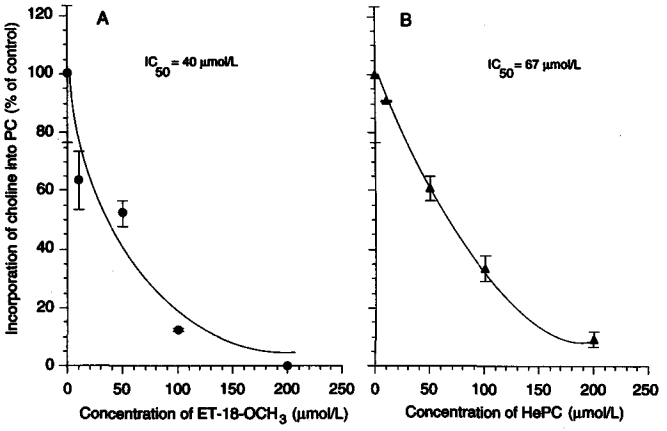

FIG. 1. Cytotoxicity and antiproliferative effect of 1-*O*-octadecyl-2-*O*-methyl-*sn*-glycero-3-phosphocholine (ET-18-OCH_3) and hexadecylphosphocholine (HePC). After incubation of confluent Madin-Darby canine kidney (MDCK) cells for 6 h with the indicated concentrations of ET-18-OCH_3 (A) or HePC (B), the cytotoxicity (○) was measured as described in the Experimental Procedures section. Proliferating MDCK cells were incubated with different concentrations of ET-18-OCH_3 (A) or HePC (B). After 16 h, the proliferation rate (●) was determined by crystal violet assay as described in the Experimental Procedures section. Values are given in % of controls ± SD (n = 4).

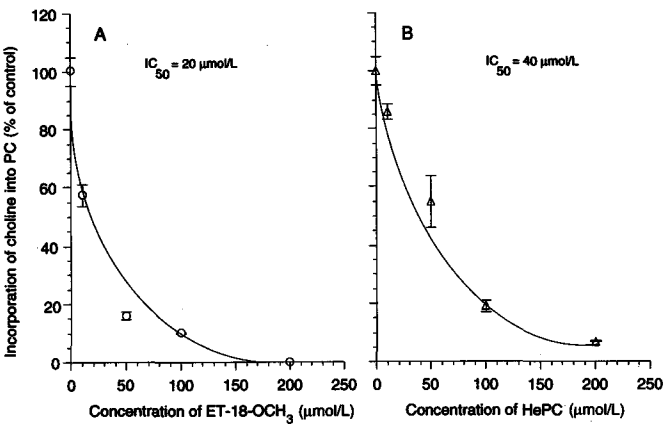

FIG. 3. Concentration-dependent effects of ET-18-OCH_3 and HePC on phosphatidylcholine biosynthesis in proliferating MDCK cells. After 24 h, proliferating MDCK cells were incubated for 6 h with pulse medium containing 2.5 µCi/mL [*methyl*-^{3}H]choline and different concentrations of ET-18-OCH_3 (A) and HePC (B). After 6 h of labeling, the incorporation of radioactivity into phosphatidylcholine was determined as described in the Experimental Procedures section. Values are given in % of controls ± SD (n = 3). The incorporation of [*methyl*-^{3}H]choline into phosphatidylcholine in control cells was 480 ± 33 dpm/µg cellular protein. Abbreviations as in Figure 2.

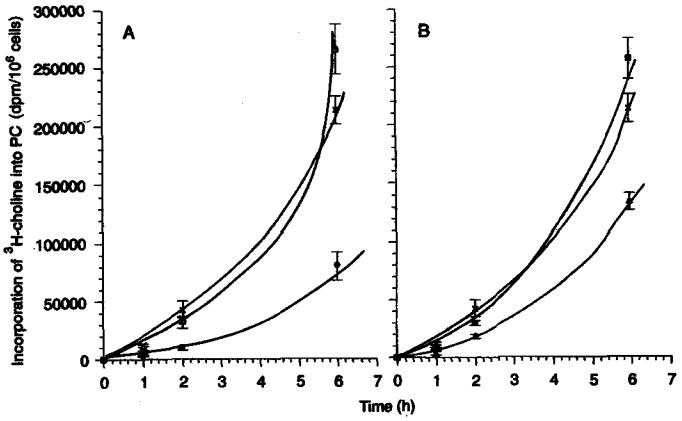

FIG. 4. Reversibility of the effect of ET-18-OCH_3 and HePC on phosphatidylcholine biosynthesis. Cells were preincubated with 50 μmol/L ET-18-OCH_3 (□, A), 50 μmol/L HePC (■, B) or without supplements (×, A, B) for 6 h. Then the medium was replaced by pulse medium containing 1 μCi/mL [*methyl*-^{3}H]choline. The cells were incubated for 1 h, 2 h or 6 h. Incorporation of radioactivity into phosphatidylcholine was determined as described in the Experimental Procedures section. Furthermore, phosphatidylcholine biosynthesis under inhibitory conditions was measured using cells which had been preincubated and labeled with medium containing 50 μmol/L ET-18-OCH3 (●, A) or 50 μmol/L HePC (▲, B). Values are given in dpm/10^6 cells ± SD (n = 3). Abbreviations as in Figure 2.

We also showed that the inhibition of phosphatidylcholine biosynthesis by ET-18-OCH_3 and HePC was reversible (Fig. 4). Six hours after removal of ET-18-OCH_3 and HePC from the medium, incorporation of [*methyl*-^{3}H]choline into phosphatidylcholine continued and exceeded the level of non-treated controls.

It has been accepted that phosphatidylcholine biosynthesis is regulated by translocation of the rate-limiting enzyme (CTP:phosphocholine cytidylyltransferase) from the cytosol to membranes where the enzyme becomes active (20). In order to investigate the effect of ET-18-OCH_3 and HePC on the localization of cytidylyltransferase, we permeabilized cells with digitonin and measured the enzyme activity in the digitonin supernatant and in the remaining cell ghosts. When cells were incubated for 4 h with 50 μmol/L ET-18-OCH_3, the amount of membrane-bound cytidylyltransferase was decreased by 60% as compared with controls (Table 1). Addition of 50 μmol/L HePC to the medium caused a 50% decrease of membrane-bound cytidylyltransferase which is nearly the same as reported previously (17).

We also measured the influence of both synthetic phospholipids on liposome-activated cytidylyltransferase *in vitro*. For this purpose, we prepared liposomes (100 μmol/L oleic acid/100 μmol/L phosphatidylcholine) which contained 50 μmol/L of ET-18-OCH_3 or HePC. Whereas liposome-activated cytidylyltransferase was inhibited by addition of HePC by 38.1 ± 3.7% as compared with controls, cytidylyltransferase activity was not significantly affected by ET-18-OCH_3 in this *in vitro* system. Cytidylyltransferase activity in the presence of ET-18-OCH_3 was 110 ± 18% as compared with controls.

DISCUSSION

Recently, we showed that alkylphosphocholines, such as HePC, inhibit cell proliferation (9) and phosphatidylcholine biosynthesis (9,21). Both cell proliferation and phosphatidylcholine biosynthesis were stimulated by tumor-promoting phorbol esters, such as TPA, while the TPA-induced effects were counteracted by HePC (8,10). We therefore suggested that a link exists between the anti-proliferative effect of HePC and its inhibitory properties on phosphatidylcholine biosynthesis. In the present study, we investigated the effect of the alkyllysophospholipid ET-18-OCH_3 on cell proliferation and phosphatidylcholine biosynthesis and compared its effects with those of the alkylphosphocholine, HePC. This was done to further elucidate the mechanisms that might account for the antineoplastic action of the different synthetic phospholipids. Up to now various mechanisms of action, including the disturbance of phospholipid metabolism (3), effects on membrane cholesterol (22), activation of macrophages (23), and inhibition of cellular enzymes, such as protein kinase C (10, 24,25) and (Na^+-K^+)-activated adenosine triphosphatase (24), have been proposed. It was also reported that ET-18-OCH_3 acts as an activator of protein kinase C in HL-60 cells (26).

TABLE 1
Influence of ET-18-OCH_3 and HePC on the Distribution of Cytidylyltransferase in MDCK Cells[a]

	Control		ET-18-OCH_3		HePC	
	Cytosol (%)	Membrane (%)	Cytosol (%)	Membrane (%)	Cytosol (%)	Membrane (%)
3 min of digitonin	59.4 ± 3.0	40.6 ± 2.5	82.9 ± 12.9	17.1 ± 3.1[b]	79.6 ± 1.0	20.4 ± 0.7[b]

[a]The translocation of cytidylyltransferase in Madin-Darby canine kidney (MDCK) cells was measured by digitonin-mediated release of cytosolic cytidylyltransferase. Cells were incubated for 4 h with medium containing either 50 μmol/L 1-*O*-octadecyl-2-*O*-methyl-*sn*-glycero-3-phosphocholine (ET-18-OCH_3), 50 μmol/L hexadecylphosphocholine (HePC), or no supplements as a control. After incubation, cytidylyltransferase activity was measured in supernatants obtained after 3 min of digitonin treatment and in the cell ghost homogenates as described in the Experimental Procedures section. The distribution of cytosolic and membrane-bound cytidylyltransferase activity was calculated in % for each dish (n = 3). The total activity of control cells was 1.2 ± 0.2 nmol/min per 10^6 cells. The total activity was not influenced by treatment of the cells with ET-18-OCH_3 or HePC.
[b]Different from controls with $P < 0.001$.

Our data show that ET-18-OCH_3 is a potent inhibitor of cell proliferation (IC_{50} 75 μmol/L). The agent also inhibited phosphatidylcholine synthesis in confluent MDCK cells (IC_{50} 40 μmol/L), which is in agreement with what was found in an earlier study using leukemic cells (27). Furthermore, we demonstrated that proliferating cells were more susceptible to inhibition than confluent cells (IC_{50} 20 μmol/L for inhibition of phosphatidylcholine biosynthesis). At concentrations >50 μmol/L, ET-18-OCH_3 also showed nonspecific, cytotoxic effects. For example, there was a strong correlation between cytotoxicity and inhibition of phosphatidylcholine biosynthesis ($r = 0.993$).

The situation was somewhat different when cells were treated with HePC. Concerning cell proliferation (IC_{50} 135 μmol/L) and phosphatidylcholine biosynthesis (IC_{50} 67 μmol/L), the IC_{50}-values of HePC were higher as compared with ET-18-OCH_3. However, the effect of HePC on phosphatidylcholine biosynthesis was more specific as there was only a weak correlation between cytotoxicity and inhibition of phosphatidylcholine biosynthesis ($r = 0.736$). The effect of both agents on phosphatidylcholine biosynthesis was reversible, which confirmed our assumption that this effect is not simply due to cell death.

In cells treated with ET-18-OCH_3 or HePC, the inhibition of choline incorporation into phosphatidylcholine was accompanied by an accumulation of radiolabel in the phosphocholine pool (data not shown), indicating that CTP:phosphocholine cytidylyltransferase is the target of the synthetic phospholipids. In order to investigate the mechanism underlying the inhibition of phosphatidylcholine biosynthesis in more detail, the effect of both synthetic phospholipids on the translocation of CTP:phosphocholine cytidylyltransferase was measured. Both agents inhibited translocation of cytidylyltransferase to membranes and, thereby, its activation. Cytidylyltransferase is known to be affected by the lipid composition of cellular membranes (28,29). In a recent study, evidence has been provided that the binding of this enzyme to membranes is modulated by the ratio of bilayer- to nonbilayer-forming lipids (30). We therefore suggest that both synthetic phospholipids disturb the physical properties of the membrane bilayer and, finally, the binding of cytidylyltransferase to membranes.

In conclusion, both types of antiproliferative agents inhibit phosphatidylcholine biosynthesis by disturbing the translocation of the rate-limiting enzyme of this metabolic pathway, CTP:phosphocholine cytidylyltransferase. Therefore, we suggest a link between the regulation of phosphatidylcholine biosynthesis by cytidylyltransferase and the proliferative properties of cells. In this context, evidence has been provided that cytidylyltransferase is translocated to the nuclear envelope in HeLa cells under stimulatory conditions (31).

Iron-Catalyzed Reaction Products of α-Tocopherol with Methyl 13(*S*)-Hydroperoxy-9(*Z*),11(*E*)-octadecadienoate

Ryo Yamauchi*, Norio Yamamoto and Koji Kato

Department of Food Science, Faculty of Agriculture, Gifu University, Gifu 501-11 Japan

ABSTRACT: α-Tocopherol was reacted with methyl 13(*S*)-hydroperoxy-9(*Z*),11(*E*)-octadecadienoate in the presence of an iron-chelate, Fe(III)-acetylacetonate, at 37°C in benzene. The reaction was carried out either aerobically or anaerobically. The main products of α-tocopherol under air were isolated and identified as two stereoisomers of 4a,5-epoxy-8a-hydroperoxy-α-tocopherone, four stereoisomers of methyl 9-(8a-dioxy-α-tocopherone)-12,13-epoxy-10(*E*)-octadecenoate, four stereoisomers of methyl 11-(8a-dioxy-α-tocopherone)-12,13-epoxy-9(*Z*)-octadecenoate, two stereoisomers of methyl 13(*S*)-(8a-dioxy-α-tocopherone)-9(*Z*),11(*E*)-octadecadienoate, and α-tocopherol dimer. Besides the 8a-(lipid-peroxy)-α-tocopherones, two stereoisomers of methyl 11-(α-tocopheroxy)-12(*S*),13(*S*)-epoxy-9(*E*)-octadecenoate, two stereoisomers of methyl 9-(α-tocopheroxy)-12(*S*),13(*S*)-epoxy-10(*E*)-octadecenoate, and two isomers of methyl (α-tocopheroxy)-octadecadienoate were obtained under nitrogen atmosphere. The results indicate that the peroxyl radicals from lipid hydroperoxides prefer to react with the 8a-carbon radical of α-tocopherol and the carbon-centered radicals react with the phenoxyl radical of α-tocopherol.

Lipids 30, 395–404 (1995).

The primary products of lipid peroxidation are hydroperoxides, which can dissociate into free radicals. Lipid hydroperoxides are fairly stable at physiological temperatures, and a major role of transition metals is to catalyze their decomposition (1,2). Transition metal ions catalyze homolysis of lipid hydroperoxides that are cleaved to alkylperoxyl radicals by metal ions in the oxidized state, such as Fe(III), whereas reduced metal ions, such as Fe(II), lead to alkoxyl radicals. The free radicals produced in these processes are believed to stimulate the chain reaction of lipid peroxidation by abstracting further hydrogen atoms. α-Tocopherol (TOH), an antioxidant in foods and living cells, can trap such free radicals to stop lipid peroxidation and converts them to nonradical products (3).

Free radical reactions of TOH take place *via* the α-tocopheroxyl radical as intermediate (4,5). If a suitable free radical is present, a nonradical product may be formed from the coupling of the free radical with α-tocopheroxyl radical. The reaction products of TOH with lipid-peroxyl radicals have been reported to be 8a-(lipid-peroxy)-α-tocopherones (6–10). TOH also traps alkyl and alkoxyl radicals to give alkylated products (11–13). In our previous study (11), we characterized isomeric 6-*O*-(lipid-alkyl)-α-tocopherols as the reaction products of TOH with the alkyl radicals of methyl linoleate. It has been reported that the iron-catalyzed decomposition of lipid hydroperoxides under anaerobic conditions yielded epoxyalkyl radicals which, in turn, reacted with α-tocopheroxyl radical to form 6-*O*-epoxyalkyl-α-tocopherols (12,13). However, the reaction products of TOH during metal-catalyzed decomposition of lipid hydroperoxides, especially under aerobic conditions, are still unknown.

In this study, we have isolated and characterized the reaction products of TOH with free radicals formed by iron-catalyzed decomposition of methyl 13(*S*)-hydroperoxy-9(*Z*),11(*E*)-octadecadienoate (13-MLOOH) under air or nitrogen atmosphere. A reaction mechanism of TOH with free radicals from 13-MLOOH is discussed based on the reaction products observed.

MATERIALS AND METHODS

Materials. RRR-TOH was purchased from Sigma Chemical Co. (St. Louis, MO) and purified by reversed-phase high-performance liquid chromatography (HPLC) using methanol. 13(*S*)-Hydroperoxy-9(*Z*),11(*E*)-octadecadienoate (13-LOOH) was prepared by oxidation of linoleic acid (99% purity; Wako Pure Chemical Industries, Osaka, Japan) with soybean lipoxygenase-1 (Sigma) (14). The 13-LOOH was converted to its methyl ester with diazomethane in diethyl ether and purified by silica-gel column chromatography using a mixture

of hexane/diethyl ether. The purity of 13-MLOOH was checked by normal-phase HPLC after reduction (15). The purity of 13-MLOOH was about 90% of the total MLOOH, the remainder being the 9-isomer. Fe(III) acetylacetonate [Fe(III)AA] was purchased from Dojindo Laboratories (Kumamoto, Japan). All solvents were distilled in an all-glass still before use.

Apparatus. HPLC was performed using a Jasco Trirotar pump and a Model GP-A40 gradient programmer (Japan Spectroscopic Co., Tokyo, Japan). A Jasco Model 875-ultraviolet (UV) detector or a Model 820-FP spectrofluorometer was used as the detector. ^{1}H (270.17 MHz) and ^{13}C (67.9 MHz) nuclear magnetic resonance (NMR) spectra were recorded at 25°C on a JEOL (Tokyo, Japan) JNM-GX-270 FT NMR spectrometer using $CDCl_3$ as solvent and tetramethylsilane as internal standard. Mass spectra (MS) were obtained on a GCMS QP-1000 instrument (Shimadzu Co., Kyoto, Japan) operated in the electron impact mode (70 eV). Samples were introduced *via* the direct inlet probe. Gas chromatography/mass spectrometry (GC/MS) was done on the same instrument equipped with a Shimadzu Hicap CBP-1 capillary column (25 m × 0.2 mm), and the temperature was programmed from 230 to 290°C (4°C/min). Helium was used as carrier gas at a flow rate of 0.8 mL/min. UV spectra were measured with a Jasco Ubest-30 spectrophotometer. Infrared (IR) spectra of samples in liquid film were measured on a Jasco A-302 IR spectrometer. Specific rotations were determined with a Union PM-201 automatic digital polarimeter (Union Gikken, Osaka, Japan). Circular dichroism (CD) measurements of the optical isomers of the compounds were performed with a Jasco J-600 spectropolarimeter.

Reaction procedure. 13-MLOOH (2.0 g, 6.1 mmol) and TOH (0.53 g, 1.2 mmol) were dissolved in 600 mL of benzene. Fe(III)AA (0.43 g, 1.2 mmol) was then added to the reaction mixture and incubated at 37°C for 20 h under air. When the reaction was carried out under anaerobic conditions, nitrogen was bubbled through the reaction mixture. After the reaction was complete, the solvent was removed *in vacuo*. The oily residue was dissolved in hexane (10 mL), applied onto a silica gel column (20 g). The products were separated from the Fe(III)AA catalyst by rapid elution with 100 mL of hexane/diethyl ether (1:1, vol/vol) by applying reduced pressure to the column outlet. The solvent of the eluent was removed *in vacuo*, and oily products were obtained. The products were dissolved in ethanol and analyzed by reversed-phase HPLC. Reversed-phase HPLC was done with a μBondasphere 5μC_{18} column (3.9 × 150 mm; Nihon Waters Co., Tokyo, Japan) developed with methanol/ethanol (3:2, vol/vol) at a flow rate of 1.0 mL/min. The eluent was monitored by an absorbance at 240 nm. For isolation of the reaction products, a WakoSil 5C18 column (1.0 × 300 cm; Wako) was developed with the same solvent at 5.0 mL/min. The dimer in the column was eluted using ethanol as the solvent. Normal-phase HPLC was done with a Bio-Sil D 90-10 column (1.0 × 250 mm; Bio-Rad Laboratories, Tokyo, Japan) developed with hexane/2-propanol (100:0.3 or 100:0.5, vol/vol) at a flow rate of 5.0 mL/min. The compounds isolated were dissolved in ethanol and stored at −20°C until analysis.

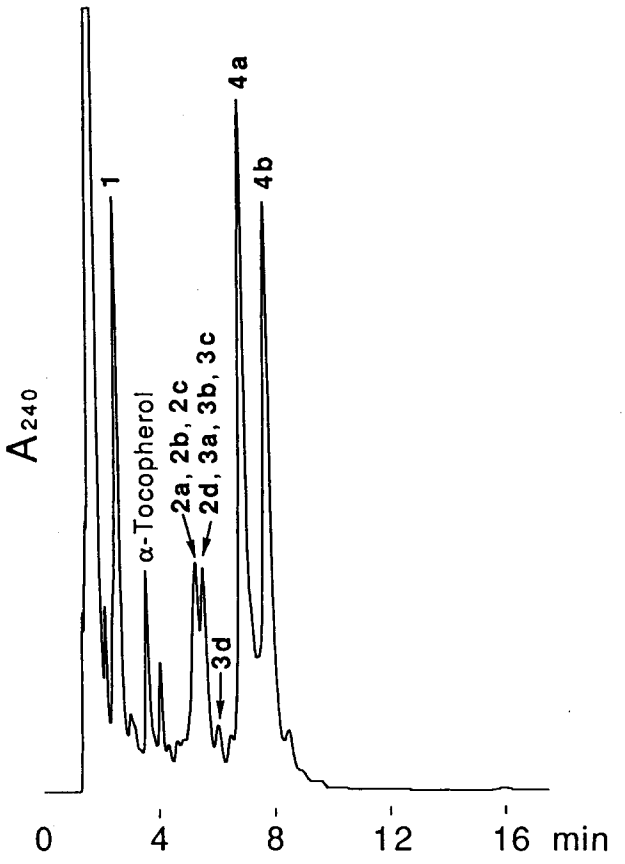
A mixture of 13-MLOOH (10 mM), TOH (2 mM), and Fe(III)AA (2 mM) in benzene was incubated at 37°C under air. At regular intervals, aliquots of the sample solution were withdrawn, passed through a Sep-Pak silica cartridge (Waters, Millford, MA) using 3 mL of hexane/diethyl ether (1:1, vol/vol), and the eluent was dried, *in vacuo*. The residue was dissolved in ethanol and injected into the HPLC. A μBondasphere 5μC_8 column (3.9 × 150 mm) was developed with a 15-min linear gradient of acetonitrile/methanol/water (60:35:5, by vol) to acetonitrile/2-propanol/hexane (35:50:15, by vol) at a flow rate of 1.0 mL/min (11). The amounts of TOH were calculated from the peak area by monitoring the fluorescence (ex. 295 nm, em. 340 nm). The amounts of reaction products were calculated from the peak areas by monitoring elutions at 240 nm. α-Tocopheryl acetate was used as the internal standard.

Derivatization. The compounds isolated (*ca.* 2 mg) were dissolved in 1 mL of methanol/ethanol (2:1, vol/vol) and reduced with sodium borohydride at 4°C for 2 h, extracted with diethyl ether, converted to the corresponding trimethylsilyl ethers, and then analyzed by GC/MS. Furthermore, the methyl epoxyhydroxyoctadecenoates in the reduced compounds were separated by normal-phase HPLC using a Bio-Sil D 90-10 column (1 × 25 cm) and hexane/2-propanol (100:4, vol/vol) at 5 mL/min. The eluent was monitored by absorbance at 203 nm. The *R* and *S* configurations of the hydroxy group were determined by CD spectroscopy in methanol (8).

RESULTS

Reaction products under aerobic conditions. Transition metal ions are effective in catalyzing free radical reactions in the presence of hydroperoxides and TOH (12,13). Figure 1 shows the Fe(III)AA-catalyzed reaction products of TOH with 13-MLOOH under air. Six peaks that appeared to be the reaction products of TOH were collected by preparative reversed-phase HPLC. The dimer fraction was eluted from the column with ethanol, obtained as a yellow oil (**5**, 50.7 mg yield), and identified by the HPLC behavior with that of the authentic sample as the spirodiene dimer of TOH (16). Each peak was further separated by normal-phase HPLC using hexane/2-propanol (100:0.5, vol/vol) as eluate. Thus, compounds **1a**, **1b**, **2a**, **2b**, **2c**, **3a**, **3c**, **3d**, **4a**, and **4b** were obtained, and **2d** and **3b** were obtained as a mixture. The structures of compounds **1–4** were determined as described below (Scheme 1).

Compounds **1a** and **1b** were obtained as colorless oils (yields: **1a**, 15.8 mg; **1b**, 13.3 mg). Their structures were shown to be a pair of diastereoisomers of 4a,5-epoxy-8a-hydroperoxy-α-tocopherone as reported by Matsuo *et al.* (7). **1a**: UV (ethanol) λ_{max} 248 nm (ε 6000); IR (film) ν_{max} 3360, 2930, 1680, 1460, 1380, 1260, 1230, 1140, 1090, 1060, 950 cm^{-1}; MS *m/z* 445 ($[M - HO_2]^+$, 4%), 430 (1), 428 (1), 419



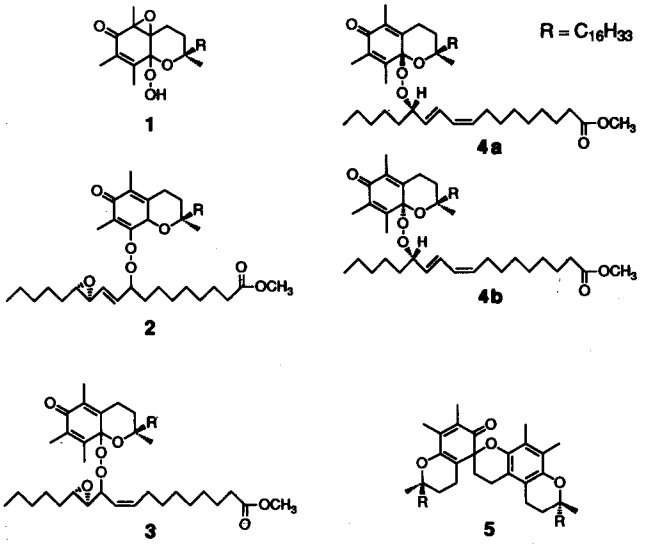


FIG. 1. Reversed-phase high-performance liquid chromatography (HPLC) of the products of the Fe(III) acetylacetone-catalyzed reaction of methyl 13(*S*)-hydroperoxy-9(*Z*),11(*E*)-octadecadienoate and α-tocopherol under air for 20 h. HPLC was done with a μBondasphere 5μC_{18} (Nihon Waters Co., Tokyo, Japan) column (3.9 × 150 mm) which was developed with methanol/ethanol (3:2, vol/vol) at 1.0 mL/min.

SCHEME 1

(2), 417 (2), 416 (3), 205 (3), 165 (8), 43 (100). ^{1}H NMR ($CDCl_3$) δ 0.84–0.88 (*m*, 12H), 1.09–1.96 (*m*, 23H), 1.32 (*s*, 3H), 1.48 (*s*, 3H), 1.82 and 1.83 (*s*, 3H), 1.89 and 1.90 (*s*, 3H), 2.09 (*m*, 1H), 2.52 (*m*, 1H), 7.49 (*s*, 1H); $[\alpha]_D^{25}$ + 81 (c 0.41, ethanol). **1b**: UV (ethanol) λ_{max} 247 (ε 5900), IR (film) ν_{max} 3360, 2930, 1680, 1460, 1380, 1260, 1230, 1140, 1090, 1060, 950 cm^{-1}; MS *m/z* 445 ($[M - HO_2]^+$, 4%), 430 (1), 428 (3), 419 (3), 417 (2), 416 (3), 205 (3), 165 (6), 43 (100); ^{1}H NMR ($CDCl_3$) δ 0.83–0.88 (*m*, 12H), 1.08–1.90 (*m*, 23H), 1.46 (*s*, 3H), 1.49 (*s*, 3H) 1.82 and 1.83 (*s*, 3H), 1.90 (*s*, 3H), 2.01 (*m*, 1H), 2.56 (*m*, 1H), 7.54 (*s*, 1H); $[\alpha]_D^{25}$ – 82 (c 0.28, ethanol). It is obvious that the configurations of the epoxy and hydroperoxy groups in **1** are responsible for the structural difference between **1a** and **1b**. However, the stereochemistry of **1a** and **1b** remains to be assigned.

Compounds **2** and **3** were obtained as colorless oils (yields: **2a**, 15.8 mg; **2b**, 13.3 mg; **2c**, 15.3 mg; **3a**, 5.9 mg; a mixture of **2d** and **3b**, 15.0 mg; **3c**, 7.2 mg; **3d**, 6.3 mg). Each compound gave a positive peroxide test (17). UV spectra of these compounds showed the same absorption maximum at 241 nm in ethanol (**2a**, ε 11500; **2b**, ε 12900; **2c**, ε 13000; **3a**, ε 10800; a mixture of **2d** and **3b**, ε 12200; **3c**, ε 12200; **3d**, 11700), indicating the presence of a dienone structure (6).

Compounds **2** and **3** were reduced with sodium borohydride, and the products were identified by GC/MS as trimethylsilyl derivatives. Compounds **2a**, **2b**, and **2c** gave two major peaks that were identified to be methyl 12,13-epoxy-9-hydroxy-10-octadecenoate trimethylsilyl ether (18): MS *m/z* 398 (M^+, 1%), 383 ($[M - 15]^+$, 2), 327 (3), 259 (α-cleavage of the 9-trimethylsilyloxy group, 16), 241 (α-cleavage of the 9-trimethylsilyloxy group, 70), 103 (23), 99 (100), 73 (85); and TOH trimethylsilyl ether (9): MS *m/z* 502 (M^+, 100%), 237 (56%), 73 (79%). Compounds **3a**, **3c**, and **3d** gave methyl 12,13-epoxy-11-hydroxy-9-octadecenoate trimethylsilyl ether (18): MS *m/z* 383 ($[M - 15]^+$, 1%), 327 (2), 285 (α-cleavage of the 11-trimethylsilyloxy group, 80), 163 (6), 155 (12), 135 (16), 129 (21), 73 (100); and TOH trimethylsilyl ether. A mixture of compounds **2d** and **3b** gave trimethylsilyl ethers of methyl 12,13-epoxy-9-hydroxy-10-octadecenoate, methyl 12,13-epoxy-11-hydroxy-9-octadecenoate and TOH. The results indicate that compounds **2a**, **2b**, **2c**, and **2d** consist of methyl 12,13-epoxy-9-hydroxy-10-octadecenoate moiety and TOH moiety in the molecule; and **3a**, **3b**, **3c**, and **4**, methyl 12,13-epoxy-11-hydroxy-9-octadecenoate moiety and TOH moiety, respectively.

The configurations of the hydroxy group of methyl 12,13-epoxy-9-hydroxy-10-octadecenoates from compounds **2a–2d** were determined by CD measurement. Methyl 12,13-epoxy-9-hydroxy-10-octadecenoate from compounds **2c** and **2d** showed a positive Cotton effect and those from compounds **2a** and **2b** showed a negative Cotton effect, respectively. Therefore, the hydroxy group of methyl 12,13-epoxy-9-hydroxy-10-octadecenoate from compounds **2c** and **2d** is assumed to be in the *S* configuration, and that from **2a** and **2b** is in the *R* configuration (9). The methyl 12,13-epoxy-11-hydroxy-9-octadecenoates from compounds **3a**, **3b**, **3c** and **3d** did not show a clear Cotton effect.

[a]Shifts in parts per million downfield relative to tetramethylsilane. Multiplicity: *s*, singlet; *d*, doublet; *t*, triplet; *q*, quartet; *m*, multiplet; *br*, broad.

[b]The numbering systems used are the standard numbering systems for the fatty acid chains and the α-tocopoherol moiety: H_l, the hydrogen atom in the fatty acid moiety; H_t, the hydrogen atom in the α-tocopherol moiety.

The ^{1}H NMR spectra of the compounds were consistent with those expected for methyl 9-(8a-dioxy-α-tocopherone)-12(*S*),13(*S*)-epoxy-10(*E*)-octadecenoates and methyl 11-(8a-dioxy-α-tocopherone)-12(*S*),13(*S*)-epoxy-9(*Z*)-octadecenoates (Tables 1 and 2). In particular, the geometrical relationship between the compounds can be established by interpretation of the spectra. Since the 8a-peroxy group of the tocopherone moiety to the 2-methyl group of the tocopherone is *trans* or *cis*, shielding (**2b**, δ 1.06; **2c**, δ 1.07; **3b**, δ 1.08; **3c**, δ 1.07) or deshielding (**2a**, δ 1.32; **2d**, δ 1.31; **3a**, δ 1.38; **3d**, δ 1.34) of the 2-methyl group is observed (9). On the *erythro–threo* isomerism of *vic*-epoxyhydroxy compounds, the

[a]Shifts in parts per million downfield relative to tetramethylsilane.

[b]The numbering systems used are the standard numbering systems for the fatty acid chains and the α-tocopoherol moiety: C_l, the carbon atom in the fatty acid moiety; C_t, the carbon atom in the α-tocopherol moiety.

[c]Number of carbon in parentheses.

coupling constants of the *erythro* isomers are smaller than those of the *threo* isomers (13,19). From a consideration of the coupling constants between the protons at C-11 and C-12 of the fatty acid moiety in **3a** (J = 6.1 Hz), **3b** (J = 5.3 Hz), **3c** (J = 5.8 Hz) and **3d** (J = 5.2 Hz), **3a**, **3b**, **3c**, and **3d** appear to be the *threo, erythro, threo* and *erythro* isomers, respectively (Table 2). The magnitude of the olefinic coupling constants (J = 15.5–15.7 Hz in Table 1 and J = 10.6–10.9 Hz in Table 2) was typical of *trans* and *cis* olefins, respectively (20). The coupling constant between the protons at C-12 and C-13 of the fatty acid moiety (J = 1.9–2.4 Hz) was a characteristic of *trans* epoxides (13). The ^{13}C NMR spectra of the compounds show two carbonyls (δ 174.3 and 185.4–185.5), a carbon atom bearing two oxy substituents (δ 97.1–97.6), a secondary ether (δ 80.0–80.7 or 83.6–84.2), a tertiary carbon (δ 76.4–77.0) two epoxy carbons (δ 55.2–58.0 and 58.2–60.6), and a methoxy carbon (δ 51.4–51.5) (Tables 3 and 4).

From these results and other spectral data, the structures of compounds **2** and **3** were identified as stereoisomers of methyl 9-(8a-dioxy-α-tocopherone)-12(*S*),13(*S*)-epoxy-10(*E*)-octadecenoate and methyl 11-(8a-dioxy-α-tocopherone)-12(*S*),13(*S*)-epoxy-9(*Z*)-octadecenoate, respectively. The stereochemistry of each compound was assumed as follows: **2a**, methyl 9(*R*)-[8a(*R*)-dioxy-α-tocopherone]-12(*S*),13(*S*)-epoxy-10(*E*)-octadecenoate; IR (film) ν_{max} 2930, 1740, 1640, 1460, 1380, 1085, 965, 920 cm^{-1}; MS *m/z* 445 (3%), 430 (7), 417 (3), 219 (2), 205 (3), 203 (7), 165 (12), 137 (8), 43 (100); $[\alpha]_D^{25}$ + 13 (c 0.53, ethanol). **2b**, methyl 9(*R*)-[8a(*S*)-dioxy-α-tocopherone]-12(*S*),13(*S*)-epoxy-10(*E*)-octadecenoate: IR (film) ν_{max} 2930, 1740, 1640, 1460, 1380, 1080, 965, 920 cm^{-1}; MS *m/z* 445 (3%), 430 (11), 417 (2), 219 (2), 205 (3), 203 (7), 165 (15), 137 (8), 43 (100); $[\alpha]_D^{25}$ +28 (c 0.34, ethanol). **2c**, methyl 9(*S*)-[8a(*S*)-dioxy-α-tocopherone]-12(*S*),13(*S*)-epoxy-10(*E*)-octadecenoate: IR (film) ν_{max} 2930, 1740, 1640, 1460, 1380, 1085, 965, 920 cm^{-1}; MS *m/z* 445 (2%), 430 (9), 417 (2), 219 (2), 205 (4), 203 (7), 165 (14), 137 (10), 43 (100); $[\alpha]_D^{25}$ – 13 (c 0.36, ethanol). **3a**, methyl 11(*S*)-[8a(*R*)-dioxy-α-tocopherone]-12(*S*),13(*S*)-epoxy-9(*Z*)-octadecenoate: IR (film)

[a]Shifts in parts per million downfield relative to tetramethylsilane.

[b]The numbering systems used are the standard numbering systems for the fatty acid chains and the α-tocopoherol moiety: C_l, the carbon atom in the fatty acid moiety; C_t, the carbon atom in the α-tocopherol moiety.

[c]Number of carbons in parentheses.

ν_{max} 2930, 1740, 1640, 1460, 1380, 1085, 920 cm^{-1}; MS *m/z* 445 (6%), 430 (10), 417 (3), 219 (2), 205 (5), 203 (12), 165 (17), 137 (9), 43 (100); $[\alpha]_D^{25}$ +14 (c 0.21, ethanol). A mixture of methyl 9(*S*)-[8a(*R*)-dioxy-α-tocopherone]-12(*S*), 13(*S*)-epoxy-10(*E*)-octadecenoate (**2d**) and methyl 11(*R*)-[8a(*S*)-dioxy-α-tocopherone]-12(*S*),13(*S*)-epoxy-9(*Z*)-octadecenoate (**3b**) [the ratio of 9(*S*)- and 11(*R*)-isomers was about 2:1 based on the ^{1}H NMR signals]: IR (film) ν_{max} 2930, 1740, 1640, 1460, 1380, 1085, 965, 920 cm^{-1}; MS *m/z* 445 (6%), 430 (10), 417 (3), 219 (2), 205 (5), 203 (12), 165 (17), 137 (9), 43 (100); $[\alpha]_D^{25}$ − 31 (c 0.44, ethanol). **3c**, methyl 11(*S*)-[8a(*S*)-dioxy-α-tocopherone]-12(*S*),13(*S*)-epoxy-9(*Z*)-octadecenoate: IR (film) ν_{max} 2930, 1740, 1640, 1460, 1380, 1085, 920 cm^{-1}: MS *m/z* 445 (5%), 430 (13), 417 (3), 219 (2), 205 (4), 203 (12), 165 (20), 137 (8), 43 (100); $[\alpha]_D^{25}$ + 14 (c 0.14, ethanol). **3d**, methyl 11(*R*)-[8a(*R*)-dioxy-α-tocopherone]-12(*S*),13(*S*)-epoxy-9(*Z*)-octadecenoate: IR (film) ν_{max} 2930, 1740, 1640, 1460, 1380, 1085, 920 cm^{-1}; MS *m/z* 445 (5%), 430 (11), 417 (3), 219 (2), 205 (5), 203 (12), 165 (18), 137 (8), 43 (100); $[\alpha]_D^{25}$ − 38 (c 0.25, ethanol).

Compounds **4a** and **4b** were obtained as colorless oils (yields: **4a**, 54.8 mg; **4b**, 59.1 mg). After reduction and trimethylsilylation, each compound gave two major peaks corresponding to trimethylsilyl derivatives of methyl 13-hydroxy-9,11-octadecadienoate and TOH by the GC/MS analysis (9). The structures were identified by comparison with those of authentic samples as reported previously (11): compound **4a** was methyl 13(*S*)-[8a(*S*)-dioxy-α-tocopherone]-9(*Z*),11(*E*)-octadecadienoate and **4b** was methyl 13(*S*)-[8a(*R*)-dioxy-α-tocopherone]-9(*Z*),11(*E*)-octadecadienoate.

TOH was reacted with 13-MLOOH in the presence of Fe(III)AA in benzene under air. Figure 2 shows the results of TOH decay and the formation of the reaction products of

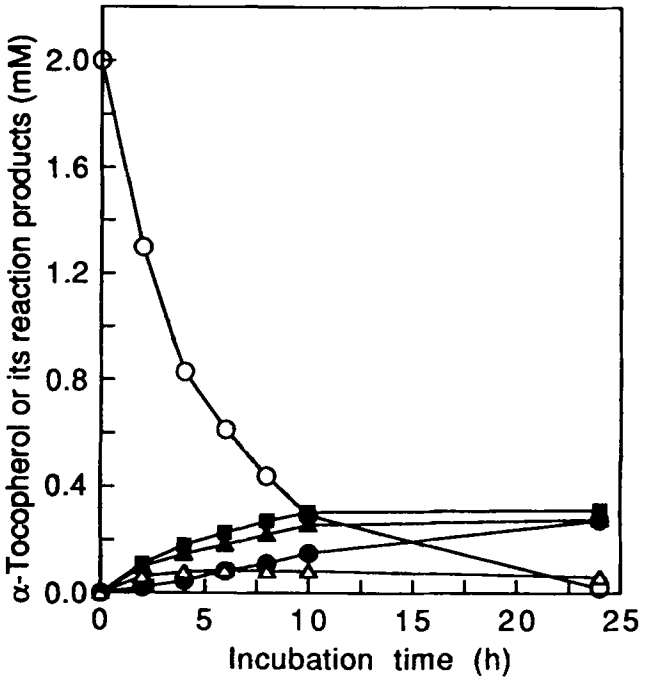

FIG. 2. Reaction of α-tocopherol during the Fe(III) acetylacetone-catalyzed [Fe(III)AA] decomposition of methyl 13(*S*)-hydroperoxy-9(*Z*),11(*E*)-octadecadienoate (13-MLOOH) under air. A reaction mixture containing 10 mM 13-MLOOH, 2.0 mM α-tocopherol and 2.0 mM Fe(III)AA in benzene was incubated at 37°C under air. Residual amounts of α-tocopherol (○) and the reaction products, compound **1** (●), compounds **2** and **3** (▲), compound **4** (■) and α-tocopherol dimer (△), in the reaction mixture are shown.

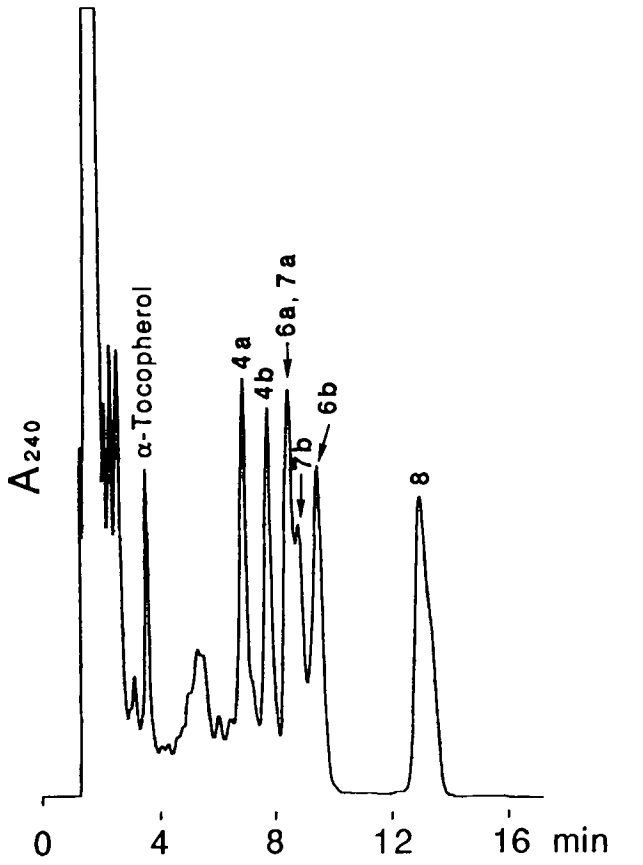

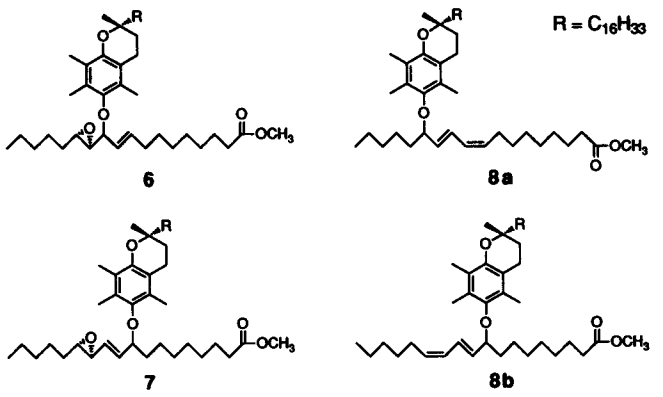

FIG. 3. Reversed-phase high-performance liquid chromatography (HPLC) of the products of the Fe(III)AA-catalyzed reaction of 13-MLOOH and α-tocopherol under nitrogen atmosphere for 20 h. HPLC was done with a μBondasphere 5μC_{18} column (3.9 × 150 mm) developed with methanol/ethanol (3:2, vol/vol) at 1.0 mL/min. Abbreviations and company location as in Figures 1 and 2.

TOH during the reaction. 8a-Epoxyalkylperoxy-α-tocopherones (**2** and **3**), 8a-alkylperoxy-α-tocopherones (**4**), and TOH dimer (**5**) formed initially, and then 4a,5-epoxy-8a-hydroperoxy-α-tocopherones (**1**) accumulated with the decrease of TOH. Compounds **1–5** accounted for 50% of the consumed TOH in the 10-h reaction mixture, and the rest were unknown products.

Reaction products under anaerobic conditions. Figure 3 shows the Fe(III)-catalyzed reaction products of TOH with 13-MLOOH under nitrogen atmosphere. Six peaks that appeared to be the reaction products of TOH were detected on the chromatogram. Peaks corresponding to compounds **4a** and **4b** were already obtained under the aerobic conditions as described previously. Each peak was collected by preparative reversed-phase HPLC. A peak containing compounds **6a** and **7a** were further separated by normal-phase HPLC using hexane/2-propanol (100:0.3, vol/vol), and **6a** and **7a** were eluted in that order. Thus, compounds **5–8** were obtained as colorless oils (yields: **6a**, 65.4 mg; **6b**, 103.9 mg; **7a**, 87.5 mg; **7b**, 47.3 mg; **8**, 27.9 mg), and their structures were identified as follows (Scheme 2).

The spectral data of **6a** and **6b** were consistent with those expected for methyl 11-(α-tocopheroxy)-12(*S*),13(*S*)-epoxy-9(*E*)-octadecenoates (13). Compounds **6a** and **6b** had the IR absorption at 970 cm^{-1} due to a *trans* double bond. The ^1H NMR spectra have signals at δ 2.57–3.03 due to methin protons on epoxy rings and the coupling constants (J = 2.2–2.4 Hz) show that the configuration of the epoxy groups is *trans* (13). From the coupling constants between the protons at C-11 (δ 3.81–3.87) and C-12 (δ 2.91–3.03) of the fatty acid moiety in **6a** (J = 6.2 Hz) and **6b** (J = 5.7 Hz), **6a** and **6b** appear to be the *threo-* and *erythro-*(α-tocopheroxy)-epoxides (13,19). Thus, the stereochemistry of **6a** and **6b** was assumed as follows: **6a**, methyl 11(*R*)-(α-tocopheroxy)-12(*S*),13(*S*)-epoxy-9(*E*)-octadecenoate: UV (ethanol) λ_{max} 282 (sh ε 2000), 289 nm (2300); IR (film) ν_{max} 2930, 1740, 1460, 1380, 1250, 1085, 970, 905 cm^{-1}; MS *m/z* 430 (62%), 205 (8), 203 (6), 189 (3), 177 (4), 175 (3), 165 (77), 151 (8), 121 (10), 43 (100); ^1H NMR ($CDCl_3$) δ 0.83–0.89 (*m*, 15H), 1.04–2.15 (*m*, 43H), 1.21 (*s*, 3H), 2.05 (*s*, 3H), 2.10 (*s*, 3H), 2.15 (*s*, 3H), 2.29 (*t*,J = 7.5 Hz, 2H), 2.54 (*t*,J = 6.4 Hz, 2H), 2.78 (*dt*,J = 2.2, 5.7 Hz, 1H), 3.03 (*dd*,J = 2.4, 6.2 Hz, 1H), 3.66 (*s*, 3H), 3.81 (*t*,J = 6.4 Hz, 1H), 5.52–5.56 (*m*, 2H); ^{13}C NMR ($CDCl_3$) δ 11.9, 12.9, 13.8, 14.0, 19.7, 19.8, 20.8, 21.1, 22.6 (2 atoms), 22.7, 23.8, 24.5, 24.8, 25.0, 25.7, 28.0, 28.8, 28.9, 29.1 (2 atoms), 31.5, 31.6, 31.7, 32.3, 32.7, 32.8, 34.1, 37.3, 37.5 (3 atoms), 39.4, 40.1, 51.4, 56.0, 60.5, 74.6, 84.6, 117.3,

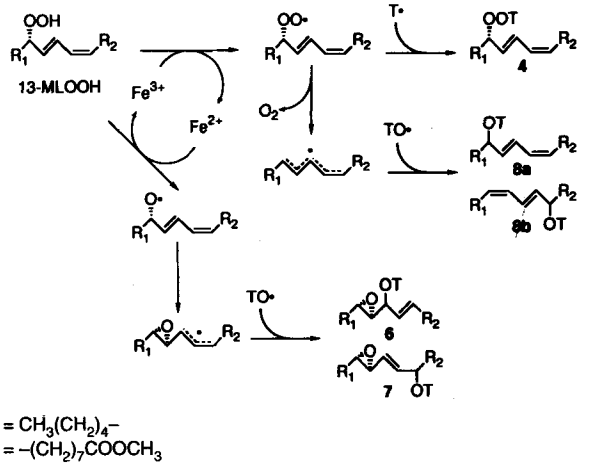
Compounds **7a** and **7b** were identified as stereoisomers of methyl 9-(α-tocopheroxy)-12(*S*),13(*S*)-epoxy-10(*E*)-octadecenoate from their spectral data. **7a**: UV (ethanol) λ_{max} 282 (sh ε 2060), 290 nm (2340); IR (film) ν_{max} 2930, 1740, 1460, 1380, 1250, 1085, 965, 885 cm^{-1}; MS *m/z* 430 (91%), 205 (9), 203 (7), 189 (3), 177 (4), 175 (3), 165 (92), 151 (11), 121 (11), 43 (100); ^1H NMR ($CDCl_3$) δ 0.83–0.91 (*m*, 15H), 1.07–2.11 (*m*, 43H), 1.22 (*s*, 3H), 2.06 (*s*, 6H), 2.11 (*s*, 3H), 2.29 (*t,J* = 7.5 Hz, 2H), 2.54 (*t,J* = 6.3 Hz, 2H), 2.65 (*dt,J* = 2.1, 5.2 Hz, 1H), 3.01 (*dd,J* = 1.9, 7.1 Hz, 1H), 3.66 (*s*, 3H), 4.04 (*dt,J* = 5.5, 7.9 Hz, 1H), 5.20 (*dd,J* = 7.2, 15.5 Hz, 1H), 5.89 (*dd,J* = 8.1, 15.6 Hz, 1H); ^{13}C NMR ($CDCl_3$) δ 11.9, 13.2, 14.0 (2 atoms), 19.7, 19.8, 20.8, 21.1, 22.6 (2 atoms), 22.7, 23.8, 24.5, 24.8, 24.9, 25.3, 25.5, 28.0, 29.1, 29.2, 29.5, 31.5, 31.6, 31.9, 32.7, 32.8, 34.0, 34.9, 37.3, 37.4, 37.5 (2 atoms), 39.4, 40.0, 51.4, 57.6, 60.5, 74.6, 82.8, 117.3, 122.6, 126.2, 128.1, 130.3, 134.2, 146.8, 147.4, 174.2; $[\alpha]_D^{25}$ + 9 (c 0.88, ethanol). **7b**: UV (ethanol) λ_{max} 282 (sh ε 2110), 290 nm (2400); IR (film) ν_{max} 2930, 1740, 1460, 1380, 1250, 1085, 965, 885 cm^{-1}; MS *m/z* 430 (92%), 205 (11), 203 (7), 189 (3), 177 (4), 175 (3), 165 (100), 151 (13), 121 (11), 43 (98); ^1H NMR ($CDDl_3$) δ 0.83–0.92 (*m*, 15H), 1.04–2.10 (*m*, 43H), 1.22 (*s*, 3H), 2.06 (*s*, 6H), 2.10 (*s*, 3H), 2.30 (*t,J* = 7.5 Hz, 2H), 2.54 (*t,J* = 6.7 Hz, 2H), 2.63 (*dt,J* = 2.2, 5.4 Hz, 1H), 3.01 (*dd,J* = 2.2, 7.9 Hz, 1H), 3.66 (*s*, 3H), 4.01 (*dt,J* = 5.4, 8.0 Hz, 1H), 5.07 (*dd,J* = 7.9, 15.7 Hz, 1H), 5.89 (*dd,J* = 8.1, 15.6 Hz, 1H); ^{13}C NMR ($CDDl_3$) δ 11.9, 13.2, 14.0 (2 atoms), 19.7, 19.8, 20.8, 21.1, 22.6 (2 atoms), 22.7, 23.7, 24.5, 24.8, 24.9, 25.3, 25.6, 28.0, 29.1, 29.2, 29.5, 31.5, 31.6, 32.0, 32.7, 32.8, 34.1, 34.9, 37.3, 37.5 (3 atoms), 39.4, 40.1, 51.4, 57.9, 60.4, 74.7, 83.0, 117.3, 122.6, 126.3, 128.2, 131.1, 134.5, 146.7, 147.4, 174.3; $[\alpha]_D^{25}$ – 27 (c 0.95, ethanol). It is obvious that the configuration of the α-tocopheroxy group in **7** is responsible for the structural difference between **7a** and **7b**. Furthermore, the CD spectra of **7a** and **7b** in ethanol showed a positive and a negative Cotton effect, respectively, indicating that these compounds are optical isomers (data not shown). However, the stereochemistry of **7a** and **7b** could not be assigned.

Compound **8** was identified by comparison of the HPLC behavior with those of authentic samples as reported previously (11). Compound **8** contained methyl 13-(α-tocopheroxy)-9(*Z*),11(*E*)-octadecadienoate (**8a**) and methyl 9-(α-tocopheroxy)-10(*E*),12(*Z*)-octadecadienoate (**8b**). We did not study the time course experiment under nitrogen atmosphere, because contamination with air in the reaction system could not be prevented.



DISCUSSION

TOH reacts with a variety of free radicals and forms various reaction products. In the present study, we have isolated and characterized the reaction products of TOH with 13-MLOOH in the presence of Fe(III)AA. The main products under air were 8a-(lipid-peroxy)-α-tocopherones (**2–4**) in addition to 4a,5-epoxy-8a-hydroperoxy-α-tocopherones (**1**) and TOH dimer (**5**). Gruger and Tappel (21) and Igarashi *et al.* (22) reported that α-tocopheryl quinone was formed during the Fe(III)-catalyzed reactions between TOH and MLOOH. Gardner *et al.* (12) also obtained α-tocopheryl quinone as the Fe(III)-catalyzed reaction products of LOOH and TOH in the presence of air. The formation of α-tocopheryl quinone is undoubtedly due to hydrolysis of the 8a-(lipid-peroxy)-α-tocopherones. The 8a-(lipid-peroxy)-α-tocopherones are unstable in acid (23), and the chromatographic separation or the acidic condition may result in the formation of α-tocopheryl quinone. The reaction products under nitrogen atmosphere were almost the same as those reported by Kaneko and Matsuo (13) and Gardner (24). The main products were the addition compounds of α-tocopheroxyl radical with the epoxyalkyl radicals (**6** and **7**). In addition to these 6-*O*-epoxyalkyl-α-tocopherones, we also detected 8a-(lipid-peroxy)-α-tocopherones (**4**) and 6-*O*-alkyl-α-tocopherols (**8**).

The Fe(III)AA-catalyzed decomposition of 13-MLOOH and the reaction with TOH in homogeneous solution at sufficient oxygen pressure are illustrated in Scheme 3. The first reaction would be iron-dependent free radical formation by being oxidized 13-MLOOH to a peroxyl radical or reduced to an alkoxyl radical (1,2). It is also likely that the Fe(III)AA reacts very readily with TOH to give Fe(II)AA and α-toco-

SCHEME 3

SCHEME 4

pheroxyl radical (12). This assertion is supported by the observation of significant amounts of TOH dimer (**5**) derived from the bimolecular self-reaction of α-tocopheroxyl radical, consistent with the presence of a high concentration of α-tocopheroxyl radical (25). Furthermore, TOH can trap the peroxyl radical by hydrogen-atom transfer, giving a hydroperoxide and an α-tocopheroxyl radical (3). The alkoxyl radical which was produced by the Fe(II)AA-catalyzed decomposition of 13-MLOOH then adds to the adjacent double bond to form the carbon-centered 12,13-epoxyalkyl radical (26–28). In the presence of oxygen, the epoxyalkyl radical reacts with molecular oxygen to form peroxyl radicals. Coupling of oxygen to the carbon-centered radical occurs at a diffusion-controlled rate at ambient oxygen concentration (29). The α-tocopheroxyl radical reacts rapidly and irreversibly with these peroxyl radicals to form stable products (11). In the present study, the 13(*S*)-peroxyl radical reacted with α-tocopheroxyl radical to form methyl 13(*S*)-(8a-dioxy-α-tocopherone)-9(*Z*),11(*E*)-octadecadienoates (**4**); the 12,13-epoxy-9-peroxyl and the 12,13-epoxy-11-peroxyl radicals reacted with α-tocopheroxyl radical to form methyl 9-(8a-dioxy-α-tocopherone)-12(*S*),13(*S*)-epoxy-10(*E*)-octadecenoates (**2**) and methyl 11-(8a-dioxy-α-tocopherone)-12(*S*),13(*S*)-epoxy-9(*Z*)-octadecenoates (**3**), respectively.

There may be another pathway for the reaction of α-tocopheroxyl radical. The pathway is thought to be the formation of 4a,5-epoxy-8a-hydroperoxy-α-tocopherone (**1**) by peroxyl-radical dependent epoxidation of α-tocopheroxyl radical and oxygen addition to the 8a-position followed by hydrogen addition (7,30). However, this reaction pathway is still unclear.

All the epoxyalkyl radicals produced are expected to react very rapidly with oxygen. When the oxygen pressure is lowered, the epoxyalkyl radical can directly react with the phenoxyl radical of TOH (12,13,28). Scheme 4 shows the Fe(III)AA-catalyzed reaction mechanisms of α-tocopheroxyl radical with 13-MLOOH under anaerobic conditions. The carbon-centered 12,13-epoxyalkyl radicals from 13-MLOOH could attack the α-tocopheroxyl radical to form the 6-*O*-epoxyalkyl-α-tocopherols (**6** and **7**) under nitrogen atmosphere. In addition, radical elimination of the peroxyl radical may result in the formation of an alkyl radical and oxygen (31). The formation of the carbon-centered alkyl radical is substantiated by the finding that the isomerization of methyl linoleate hydroperoxides is accompanied by the exchange of the oxygen atoms of the hydroperoxy group with atmospheric oxygen (32). The alkyl radical produced then reacted with α-tocopheroxyl radical to form 6-*O*-alkyl-α-tocopherols (**8**) (11). Although the 6-*O*-alkyl-α-tocopherol was produced in low yields, the elimination reaction of peroxyl radicals might occur under the anaerobic conditions.

The reaction products obtained in the present study indicate that peroxyl and oxygen radicals prefer to react with the 8a-carbon radical of TOH; whereas, the phenoxyl radical of TOH appears to react with carbon radicals of fatty acids.

ACKNOWLEDGMENTS

We thank H. Inoue for recording the NMR spectra. This study was supported in part by the Asahi Breweries Foundation, Tokyo, Japan.

Oxidized Cholesterol Modulates Age-Related Change in Lipid Metabolism in Rats

Kyoichi Osada, Takehiro Kodama, Satoshi Noda, Koji Yamada and Michihiro Sugano*

Laboratory of Food Science, Kyushu University, School of Agriculture, Fukuoka 812, Japan

ABSTRACT: For three weeks, male Sprague-Dawley rats at either four weeks (young) or eight months (adult) of age were pair-fed one of the purified diets free of or containing either 0.2% of oxidized cholesterol mixture (cholesterol oxidation products) or 0.2% of cholesterol. Although the food intake was similar, dietary oxidized cholesterol lowered body weight gain in young rats, but did not increase relative liver weight, in contrast to the enlargement seen with dietary cholesterol. Oxidized cholesterol, compared to cholesterol, tended to reduce the activity of hepatic 3-hydroxy-3-methylglutaryl CoA reductase and cholesterol 7α-hydroxylase, particularly the latter in aged rats, and prevented the rise in the concentration of liver cholesterol at both ages. It also tended to increase the activity of hepatic Δ6 desaturase, particularly in young rats. Moreover, oxidized cholesterol in relation to cholesterol influenced liver and serum lipid concentrations in different ways, and increased lipid peroxidation at both ages. The ratio of splenic $CD4^+/CD8^+$ T-lymphocytes increased with age, but the influence of cholesterol and oxidized cholesterol was comparable. Thus, oxidized cholesterol may specifically disturb growth and age-related changes in the lipid metabolism in rats.

Lipids 30, 405–413 (1995).

Lipid oxidation products are present in varying amounts in processed foods. It is well understood that these oxidized lipids show various undesirable effects, such as the acceleration of the atherogenic process (1). Among oxidized lipids, cholesterol autoxidation products (oxidized cholesterol) have received much attention in recent years with respect to their diverse biological activities: carcinogenicity (2), cytotoxicity (3), mutagenicity (4), and inhibition of sterogenesis (5). However, these observations are based exclusively on the *in vitro* studies and have not been studied in depth with respect to the situation *in vivo*. Substantial amounts of oxidized cholesterol are detected in a variety of foods of animal origin exposed to oxidizing conditions (6–10). We have reported previously that oxidized cholesterol in the diet was absorbed in detectable amounts, around 30% of that ingested (11), and disturbed cholesterol and linoleic acid metabolism (12).

In addition to these observations, Emanuel *et al.* (13) showed that increased dietary oxidized cholesterol led to increased concentrations in human serum, and Cho *et al.* (14) reported that oxidized cholesterol disturbs the biosynthesis of cholesterol in chicks. However, the effect of oxidized cholesterol on the aging process was not mentioned, despite the possibility that the changes associated with aging are promoted by lipid peroxidation (15). Therefore, it is of interest to know the effect of dietary oxidized cholesterol on this metabolic process, particularly in relation to the modification of lipid metabolism.

Choi *et al.* (16) showed the reduction of the key enzymes in cholesterol metabolism in aged rats. The age-related change in cholesterol metabolism in rats has been shown to be largely completed by the age of 8–9 mon, the additional changes after that being rather marginal (17). Therefore, we studied the effect of oxidized cholesterol on the metabolism of cholesterol and fatty acid using young (four-week-old) and adult (eight-month-old) rats to determine age-related differences using a pair-feeding protocol.

Recently, Hobbs *et al.* (18) suggested that gradual age-associated shifts in the subset composition of the splenic $CD4^+$ cell pool underlie progressive changes in the patterns of cytokine gene expression by this cell group. However, the relationship among diets, aging, and splenic T-cell subsets has not been fully explored. Therefore, the interaction of oxidized cholesterol and aging on T-cell subsets was also studied.

MATERIALS AND METHODS

Materials. 3-Hydroxy-3-methyl[1-^{14}C]glutaryl CoA (55 mCi/mmol) was obtained from Amersham International plc (Buckinghamshire, United Kingdom). [1-^{14}C]Linoleic acid (53 mCi/mmol) and [4-^{14}C]cholesterol (51 mCi/mmol) were the products of New England Nuclear (Boston, MA). Radioactive cholesterol and linoleic acid were purified by thin-layer chromatography prior to use. All reagents used were analytical grade.

Animals and diets. Young (four-week-old) and adult (eight-month-old) male Sprague-Dawley rats obtained from Seiwa Experimental Animals (Fukuoka, Japan) were housed individually in a room with controlled temperature and light

(20–23°C and lights on from 0800 to 2000). After acclimation for four days, the rats were divided into groups of six each and fed one of the cholesterol-free, cholesterol-added, or oxidized cholesterol-added diets. The cholesterol-free and cholesterol-added groups were fed diets at the level consumed by the oxidized cholesterol group. After three weeks, rats were decapitated at night (0100). Feces were collected for two days beginning 10 d before killing, and then lyophilized. Experimental diets were prepared according to the formula recommended by the American Institute of Nutrition (19), and contained (wt%): casein, 20; safflower oil (Rinoru Oil Co., Nagoya, Japan), 5; mineral mixture, 3.5; vitamin mixture, 1.0; choline bitartrate, 0.2; DL-methionine, 0.3; cellulose, 5.0; corn starch, 15; sodium cholate, 0.05; and sucrose to 100. Cholesterol (0.2%) and the oxidized cholesterol mixture (0.2%) were added at the expense of sucrose. Food was changed daily, and food intake and weight gain were recorded.

Preparation of oxidized cholesterol mixture (cholesterol oxidation products). Cholesterol (300 g) was heated in an electric oven at 150°C for 12 h. Heated cholesterol was dissolved in *n*-hexane, applied on a silicic acid column (Silica gel 60, 70–230 mesh; E. Merck, Darmstadt, Germany; 100 ϕ mm × 800 mm) and fractionated by successive elution with 1 L each of *n*-hexane, diethyl ether, and methanol. An aliquot of the polar fraction eluted by methanol was dried in a rotary evaporator and finally *in vacuo*. The composition of the oxidized cholesterol mixture is shown in Table 1. The preparation contained more than 90% as oxidized cholesterol.

Analyses. The activities of 3-hydroxy-3-methylglutaryl (HMG)–CoA reductase, cholesterol 7α-hydroxylase, and Δ6 desaturase in liver microsomes were measured by the methods of Shapiro *et al.* (20), Van Cantfort *et al.* (21), and Svensson (22), respectively. Microsomal protein was determined by the method of Lowry *et al.* (23). Serum and liver lipids were extracted, and cholesterol, triglyceride, and phospholipid were measured (24). The fatty acid composition of liver phosphatidylcholine (PC) and phosphatidylethanolamine (PE) was analyzed by gas–liquid chromatography (GLC) (25). Fecal neutral and acidic steroids were also analyzed by GLC using 5α-cholestane (Sigma Chemical Co., St. Louis, MO) and 23-nor-deoxycholic acid (Steraloids Inc., Wilton, NH) as internal standards, respectively (26). During the feeding period, blood was withdrawn from the tail vein on days 0, 5, 10, and 15, and serum cholesterol was determined enzymatically (Cholesterol C Test, Wako Pure Chemicals Co., Osaka, Japan). Liver and blood lipoperoxides were measured by the method of Yagi and co-workers (27,28) as thiobarbituric acid (TBA) reactive substances. Oxidized cholesterol contents of liver and serum were measured by capillary GLC on fused silica capillary ULBON HR-1 column (Shinwa Chemical Industries, Ltd., Kyoto, Japan) under the conditions described previously (10). The serum glutamic pyruvic transaminase (GPT) activity also was measured by the enzymatic method (GPT-UV Test; Wako Pure Chemicals Co.).

Separation of spleen lymphocytes analysis of $CD4^+$ and $CD8^+$ cells. Lymphocytes were squeezed out into the RPMI 1640 medium from isolated spleen using glass slides. After incubating the cells at 37°C for 30 min to remove fibroblasts, 5 mL of the cell suspension was layered on 4 mL of Lymphocyte-Rat (Cedarlane, Hornby, United Kingdom) and centrifuged at 1,500 × *g* for 30 min. The lymphocyte band at the interface was recovered, and the cells were rinsed three times with the RPMI 1640 medium. The lymphocytes were resuspended in the phosphate-buffered saline (PBS; pH 7.5) containing 10% fetal bovine serum (FBS; Gibco, Grand Island, NY). The cell concentration was then adjusted to 1×10^6 cells/100 μL, and 5 μL of either fluorescein-labeled mouse anti-rat CD4 or phycoerythrin-labeled mouse anti-rat CD8 (Serotec Ltd., Kidlington, Oxford, United Kingdom) were added. After incubation for 30 min at 4°C, lymphocytes were rinsed three times with PBS containing 10% FBS and then centrifuged at 1,200 rpm for 5 min. The stained lymphocytes were fixed with 2% paraformaldehyde and applied to flow cytometry (EPICS PLOFILE II; Coulter Electronics Ltd., Luto, Beds, United Kingdom).

Statistical analysis. Data were analyzed by Student's *t*-test (29) and Duncan's new multiple-range test (30) to determine the exact nature of the differences among the groups. The interaction of the age and sterol was evaluated by two-way analysis of variance (31).

TABLE 1
Composition of Cholesterol Oxidation Products

Components	Wt%
7α-Hydroxycholesterol	6.0
Cholesterol	8.0
7β-Hydroxycholesterol	13.3
5β-Epoxycholesterol	3.9
5α-Epoxycholesterol	14.2
Cholestanetriol	3.3
7-Ketocholesterol	26.7
25-Hydroxycholesterol	1.7
Unknown steroids[a]	18.5
Total oxidized cholesterol	92.0

[a]Composed of more than 20 components.

RESULTS

Growth and liver weight. Although the food intake was adjusted to be the same by pair-feeding, weight gain in young, but not in adult rats fed oxidized cholesterol was significantly lower than in the other two groups (Table 2). Oxidized cholesterol, in contrast to cholesterol, did not increase relative liver weight in both ages.

Concentration of serum and liver lipids. The time course of the changes in serum cholesterol concentrations is shown in Figure 1. In young rats, the serum cholesterol levels were significantly higher in the cholesterol group than in the cholesterol-free and oxidized cholesterol groups throughout the feeding periods. In contrast, the levels were similar among the groups in adult rats, although the oxidized cholesterol group showed a slightly lower level than other groups.

TABLE 2
Effect of Dietary Cholesterol and Oxidized Cholesterol on Growth Parameters in Young and Adult Rats[a]

[a]Data are presented as means ± SE for six rats in each group; B.W., body weight.
[b]Data were analyzed by two-way analysis of variance (ANOVA). When the *f* value for the age or sterol effect was significant ($P < 0.05$), the differences between means were inspected by Duncan's multiple range test.
[c,d]Values without a common superscript letter are significantly different at $P < 0.05$. *Significantly different from the corresponding value in adult age rats at $P < 0.05$. NS, not significant.

As shown in Figure 2, when the diet containing oxidized cholesterol was fed, the concentration of liver cholesterol was significantly lower than when cholesterol was fed at both ages, and it was as low as that in the cholesterol-free group. The same response was observed in the concentration of serum cholesterol in young, but not in adult, rats. The concentration of liver triglyceride remained unchanged after feeding oxidized cholesterol and tended to be lower than in the cholesterol-free diet, particularly in young rats. There was no significant difference in the serum triglyceride concentration at either age. On the other hand, oxidized cholesterol tended to increase the liver phospholipid concentration in young rats compared to cholesterol. Both cholesterol and oxidized cholesterol increased serum phospholipid in young rats, while decreasing it in adult rats.

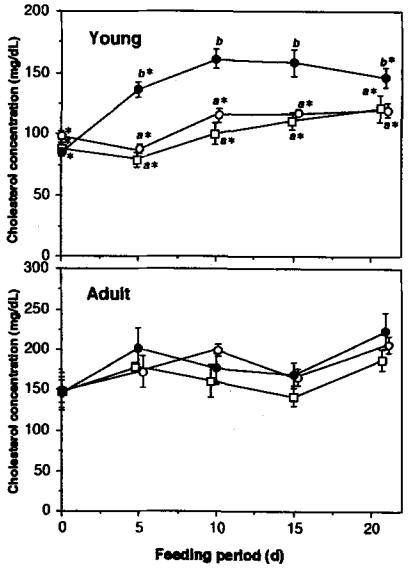

FIG. 1. Time course of the effect of dietary cholesterol and oxidized cholesterol on the concentration of serum cholesterol in young and adult rats. Data are presented as means ± SE for six rats in each group. ○, Cholesterol-free; ●, cholesterol; □, oxidized cholesterol. [a,b]Values in the same age group without a common letter are significantly different at $P < 0.05$. *Significantly different from the corresponding value in adult rats at $P < 0.05$.

Key enzyme activities of liver microsomes. Figure 3 shows the specific activities of HMG–CoA reductase, cholesterol 7α-hydroxylase, and Δ6 desaturase of liver microsomes. In young rats, the HMG–CoA reductase activity was significantly lower in the cholesterol group than in the cholesterol-free group, but this was not the case in adult rats. Oxidized cholesterol tended to reduce the reductase activity more than cholesterol in both ages, particularly in adult rats. Although dietary cholesterol tended to increase cholesterol 7α-hydroxylase activity, oxidized cholesterol reduced it in both age groups. There was a tendency to decrease the activity of Δ6 desaturase when cholesterol was fed compared to the cholesterol-free diet, particularly in young rats, whereas no such reduction was observed in the oxidized cholesterol group. The desaturase activities were higher in the oxidized cholesterol groups than in the cholesterol-free groups for both age groups, although they were not statistically significant.

Fatty acid compositions of liver phospholipids. As shown in Table 3, the significant diet-dependent difference was observed in the fatty acid composition of liver phospholipids. Dietary cholesterol increased the proportion of oleic and linoleic acids in PC and PE both in young and adult rats, whereas the proportion of arachidonic acid tended to decrease except for PE of young rats. As a result, the ratio of linoleic acid to its metabolites, (20:3n-6 + 20:4n-6)/18:2n-6, was significantly decreased in cholesterol-fed rats as compared to

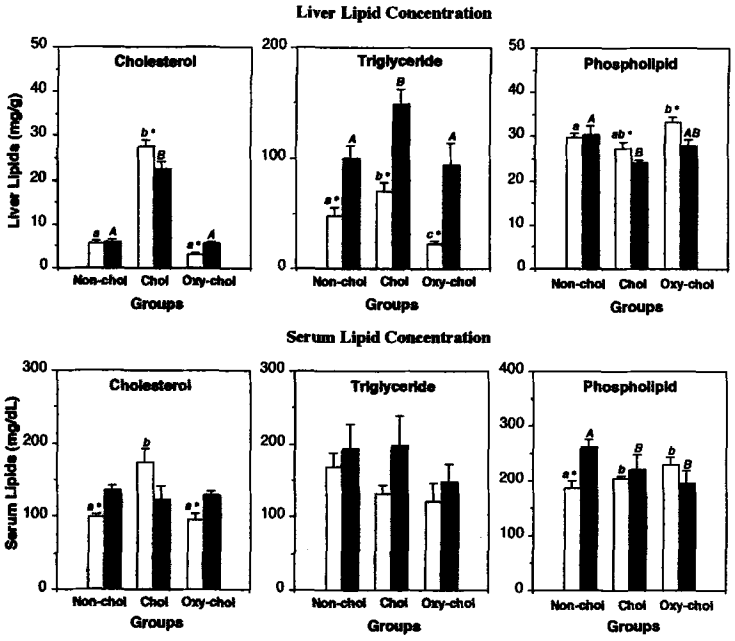

FIG. 2. Effect of dietary cholesterol and oxidized cholesterol on liver and serum lipid concentrations in young and adult rats. Data are presented as means ± SE for six rats in each group. □, Young; ■, adult. Data were analyzed by two-way analysis of variance. When the *f* value for the age or sterol effect was significant ($P < 0.05$), the differences between means were inspected by Duncan's multiple range test. ^{a,b,c,A,B}Values without a common letter are significantly different at $P < 0.05$. *Significantly different from the corresponding value in adult rats at $P < 0.05$. Non-chol, cholesterol-free; Chol, cholesterol; Oxy-chol, oxidized cholesterol; NS, not significant. Analysis of variance: A = significant effect of age; S = significant effect of sterol; A × S = significant effect of interaction. Following significant difference was observed: liver cholesterol, S and A × S; liver triglyceride, A and S; liver phospholipid, A and S. Serum cholesterol, S and A × S, serum phospholipid, A and S.

those fed the cholesterol-free diet. In contrast, the ratio was significantly higher in the oxidized cholesterol group than in the cholesterol-free group, except for PC of young rats.

Fecal steroid excretion. As summarized in Table 4, there was no significant difference in the weight of dried feces among the same age groups. The excretion of total neutral steroid was at a similar level between the cholesterol and oxidized cholesterol groups in the respective age groups, and it was significantly higher than in the cholesterol-free group. The effect of oxidized cholesterol on the composition of fecal neutral steroids differed from that of cholesterol, and oxidized cholesterol significantly raised the excretion of coprostanol in young rats. Cholesterol significantly increased the excretion of acidic steroids as compared to the cholesterol-free group

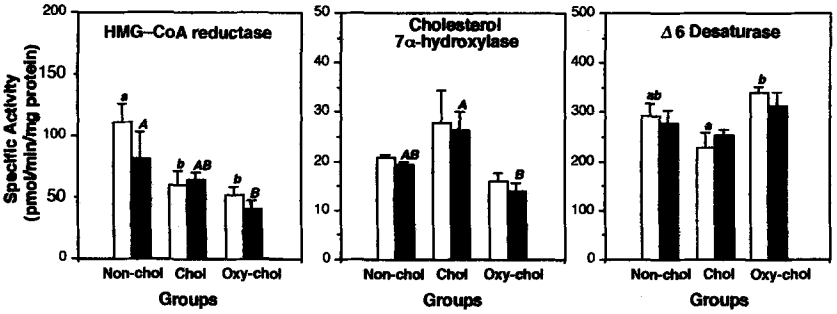

FIG. 3. Effect of dietary cholesterol and oxidized cholesterol on the activities of key enzymes in cholesterol metabolism and fatty acid desaturation in young and adult rats. Data are presented as means ± SE for six rats in each group. □, Young; ■, adult. Data were analyzed by two-way analysis of variance. When the *f* value for the age or sterol effect was significant ($P < 0.05$), the differences between means were inspected by Duncan's multiple range test. ^{a,b,A,B}Values without a common superscript letter are significantly different at $P < 0.05$. Abbreviations as in Figure 2. The following significant difference was observed: 3-hydroxy-3-methylglutaryl (HMG)-CoA reductase, S; cholesterol 7α-hydroxylase, S; Δ6 desaturase, S.

[a]Data are presented as means ± SE for six rats in each group.
[b]Data were analyzed by two-way analysis of variance (ANOVA). When the *f* value for the age or sterol effect was significant ($P < 0.05$), the differences between means were inspected by Duncan's multiple range test.
[c–e,g–i]Values in the same age group without a common superscript letter are significantly different at $P < 0.05$. *Significantly different from the corresponding value in adult age rats at $P < 0.05$. NS, not significant.

in young rats, but it was not the case for oxidized cholesterol. The composition of acidic steroids was also modified by dietary oxidized cholesterol, as characterized by the different changes in the ratios of primary to secondary bile acids, particularly in young rats.

Contents of oxidized cholesterols in serum and liver. Table 5 shows the contents of various oxidized cholesterol in serum and in liver. In both young and adult rats, dietary oxidized cholesterol elevated the level of each oxidized cholesterol in serum. The concentration of 7α-hydroxycholesterol, 5β-epoxycholesterol, and unknown steroids was higher in adult rats than in young rats. 5β- and 5α-Epoxycholesterols, cholestanetriol, and 7-ketocholesterol were detected only in rats fed oxidized cholesterol. 7α- and 7β-Hydroxycholesterols were detected even in rats that were not fed oxidized cholesterol. Similar results were observed in the liver.

TBA value of blood and liver. The blood TBA value was higher in the oxidized cholesterol groups than in the cholesterol-free groups for both ages, but particularly in adult rats (Fig. 4), whereas the value of the cholesterol groups was comparable to the cholesterol-free groups. In contrast, there was no increase in liver TBA value after feeding with oxidized cholesterol, while cholesterol significantly reduced the liver TBA value.

Effect of oxidized cholesterols on $CD4^+$ and $CD8^+$ splenic T-cell subsets. The percentage of $CD4^+$ and $CD8^+$ cells in splenic lymphocytes of rats fed different diets is summarized in Table 6. The proportion of $CD4^+$ increased, whereas that of $CD8^+$ decreased with age. As a result, the ratio of $CD4^+/CD8^+$ increased in adult rats. Although the results were not significant, dietary cholesterol tended to lower the ratio in adult rats, while oxidized cholesterol did not influence it.

DISCUSSION

This study was designed to elucidate how oxidized cholesterol influences the changes in lipid metabolism during aging. Care was taken to rule out the possible toxic effect of oxidized cholesterol, and it was given at a 0.2% level under the pair-feeding protocol. Despite pair-feeding, oxidized cholesterol reduced weight gain in young, but not in adult, rats. Kandutsch *et al.* (32) found that dietary 25-hydroxycholesterol or 7-ketocholesterol causes a loss of body weight in mature mice (eight-week-old), and both weight loss and suppression of growth in immature mice (four-week-old). Thus, oxidized cholesterol exerted a greater influence on growth parameters of young rats whose homeostatic ability is not fully matured. Furthermore, oxidized cholesterol did not increase liver

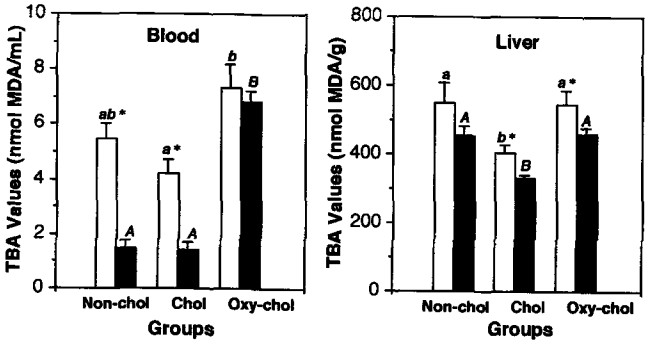

FIG. 4. Effect of dietary cholesterol and oxidized cholesterol on blood and liver thiobarbituric acid (TBA) values in young and adult rats. Data are presented as means ± SE for six rats in each group. □, Young; ■, adult. Data were analyzed by two-way analysis of variance. When the *f* value for age or sterol effect was significant ($P < 0.05$), the differences between means were inspected by Duncan's multiple range test. ^{a,b,A,B}Values without a common superscript letter are significantly different at $P < 0.05$. *Significantly different from the corresponding value in adult rats at $P < 0.05$. Abbreviations as in Figure 2. The following significant difference was observed: blood TBA, A, S and A × S; liver TBA, A and S. MDA, malondialdehyde.

weight, in contrast to cholesterol, and slightly increased the serum GPT level in adult, but not in young, rats (cholesterol-free, 19.2 ± 1.6; cholesterol, 20.9 ± 0.8; oxidized cholesterol, 23.9 ± 1.2 IU/L; the difference between two extremes was significant, $P < 0.05$). 7-Ketocholesterol at a dietary level of 0.5% appears to have toxic effects as indicated by the reduction of body and liver weights after 66 h feeding (33). Therefore, oxidized cholesterol exhibits potent toxicity toward hepatocytes and could impair liver function, particularly in adults. Oxidized cholesterol shows strong cytotoxicity (3) and inhibition of cell growth (34) *in vitro*.

[a]Data are presented as means ± SE for six rats in each group.
[b]Data were analyzed by two-way ANOVA. When the *f* value for the age or sterol effect was significant ($P < 0.05$), the differences between means were inspected by Duncan's multiple range test. Abbreviations as in Table 3.
^{c,d}Values in the same age group without a common superscript letter are significantly different at $P < 0.05$. *Significantly different from the corresponding value in adult age rats at $P < 0.05$.

The activity of hepatic HMG–CoA reductase was lower in adult rats than in young rats, as reported previously (35,36). The depressive effect on HMG–CoA reductase activity was more marked in the rats fed oxidized cholesterol, especially in adults under the conditions of these experiments. Various oxidized cholesterols have been shown to be potent inhibitors of sterol biosynthesis *in vitro* (5). Similarly, 7-ketocholesterol or 24(S),25-epoxycholesterol lowered HMG–CoA reductase activity after short-term feeding (33,37), although Kandutsch *et al.* (32) reported that dietary 25-hydroxycholesterol or 7-ketocholesterol did not depress hepatic cholesterol synthesis. However, the decrease of HMG–CoA reductase activity by oxidized cholesterol as observed in these studies could be modified by the development of tolerance to oxidized cholesterol when it is fed for a relatively long time. A possible explanation of these diverse observations is the report of Vargas *et al.* (38) that the oxidized cholesterol mixture is a potent inhibitor of hepatic HMG–CoA reductase after 14 days of feeding. Therefore, oxidized cholesterol may accelerate the impairment of hepatic cholesterol synthesis associated with aging. The depression of cholesterol synthesis could, in turn, lead to the reduction of the liver cholesterol level, particularly in young rats, in spite of the different response of the reductase activity as observed in the present study. Young animals fed oxidized cholesterol also tended to have lower concentrations of esterified cholesterol in liver compared to those fed a cholesterol-free diet. The amount of cholesterol ester in livers of rats fed cholesterol was also significantly higher than those fed a cholesterol-free diet (cholesterol-free, 3.38 ± 0.49; cholesterol, 23.8 ± 1.6; oxidized cholesterol, 1.38 ± 0.28 mg/g liver; the difference between cholesterol and other two groups was significant, $P < 0.05$). Oxidized cholesterol may cause the reduction of liver acyl-CoA:cholesterol *O*-acyltransferase (ACAT) activity in young but not in adult rats, although Smith and Johnson (39) reported a stimulation of ACAT activity by oxidized cholesterols. It is also known that short-term 7-ketocholesterol feeding increases hepatic microsomal esterified cholesterol content (33). Thus, oxidized cholesterol may disturb cholesterol homeostasis, such as biosynthesis and esterification, in ways that contribute to the aging of tissues. Elucidation of the effect of oxidized cholesterol on ACAT and cholesterol ester hydrolase *in vivo* deserves further study.

Choi *et al.* (35) found that the activity of cholesterol 7α-hydroxylase was low in adult rats as compared to young rats. It was also found that the excretion of fecal acidic steroids changes in the course of the aging process in some species (40,41). These findings are consistent with the present results, and reduction in activity of cholesterol 7α-hydroxylase by feeding of oxidized cholesterol in both age groups. The hydroxylase activity has been reported to be inhibited by various oxidized cholesterol *in vivo* (42). Thus, oxidized cholesterol may worsen the reduction of cholesterol 7α-hydroxylase activity with aging, and disturb cholesterol catabolism. The change in the composition of fecal acidic steroids at least partly indicates the differential effects of oxidized cholesterol on enzymes involved in bile acid conversion as compared to cholesterol. In

addition, oxidized cholesterol may interfere with the microbial conversion of bile acids in the large intestine.

On the other hand, the activity of hepatic Δ6 desaturase tended to be higher in the rats fed oxidized cholesterol than in those fed cholesterol, as reported previously (12). This difference was significant in young rats, although it is well known that dietary cholesterol decreases the desaturase activity (43). Consequently, the desaturation index [(20:3n-6 + 20:4n-6)/18:2n-6] significantly increased in liver phospholipids of rats fed oxidized cholesterol compared to cholesterol both in young and adult rats. Therefore, oxidized cholesterol may alter the production of eicosanoids, as the supply of free substrate is one determinant of eicosanoid production (44,45).

The TBA values of blood were higher in rats fed oxidized cholesterol than in the other groups of rats of both ages, but this was not the case in the liver. It is, however, at least plausible that peroxidized cholesterol may promote peroxidation of fatty acids.

Dietary oxidized cholesterol influenced the concentration of triglyceride and phospholipid in the liver and serum, especially in the liver of adult rats. The same tendency has been observed in plasma, but not in liver, of the chicks fed oxidized cholesterol (14). Although it is understood that hepatic triglyceride concentration increases with age (17), it significantly decreased when rats were fed oxidized cholesterol. This may be one specific effect of oxidized cholesterol.

T-cells were characterized by the cell surface markers CD4 and CD8, which bind to nonpolymorphic regions of MHC classes II and I, respectively (46). $CD4^+$ T-cells act as helper/inducers and $CD8^+$ T-cells as cytotoxic/suppressors. The percentage of $CD4^+$ cells in spleen lymphocytes increased and that of $CD8^+$ cells decreased with age, suggesting the promotion of immunoglobulin production. However, as oxidized cholesterol compared to cholesterol did not lower the $CD4^+/CD8^+$ ratio in adult rats, it seems unlikely that oxidized cholesterol influences the depression of immunoglobulin production found with age (in contrast to cholesterol). More detailed studies on this observation are required.

In conclusion, the present study demonstrated diverse undesirable effects of dietary oxidized cholesterol on growth and lipid metabolism in young and adult rats. In contrast to cholesterol, oxidized cholesterol did not modify the splenic T-lymphocyte subsets. Therefore, dietary oxidized cholesterol appears to worsen various parameters of homeostasis, irrespective of the age of the animals. In this context, studies are required to elucidate the gender-dependence of the effects of oxidized cholesterol, as there are considerable differences in lipid metabolism between male and female rats. An attempt to study the effects of oxidized cholesterol over a greater portion of natural life span would also be valuable

Dietary Fats Rich in Saturated Fatty Acids (12:0, 14:0, and 16:0) Enhance Gallstone Formation Relative to Monounsaturated Fat (18:1) in Cholesterol-Fed Hamsters

Satya S. Jonnalagadda, Elke A. Trautwein[1] and K.C. Hayes*

Foster Biomedical Research Laboratory, Brandeis University, Waltham, Massachusetts 02254

ABSTRACT: To test the possibility that dietary palmitic acid (16:0) may be lithogenic, different fats were blended to exchange 18:1 in olive oil with either 16:0 in palm stearin, 12:0 + 14:0 in coconut oil, or 14:0 + 16:0 in butterfat. Dietary 18:2 was held constant at 1.2% energy (en) (with extra safflower oil as needed) in these four purified diets containing low fat (11% of total energy) and 0.4% cholesterol. A fifth, high-fat diet provided 40% of the total energy as the 16:0-rich blend. All hamsters fed the low-fat, 16:0-rich blend for six weeks developed cholesterol gallstones (8/8). Although the gallstone incidence was lower for the 12:0 + 14:0-rich diet (5/8), the severity of stone formation in affected hamsters was equal to that in the low-fat, 16:0-rich group. Mucin accumulation in gallbladder bile was often associated with cholesterol gallstones in diets containing 16:0, but was minimal in 18:1-rich and 12:0 + 14:0-rich groups. Neither the lithogenic index (all >1.0), plasma lipids, nor liver cholesterol was a selective predictor of stone formation. The high-fat, 16:0-rich diet actually decreased cholesterol stone incidence (3/8) and severity, but yielded a high incidence of pigment stones (5/8). Thus, saturated fat and 16:0 *per se* were not responsible for the exaggerated lithogenesis. Because the antilithogenic 18:1-rich diet also normalized the 18:2 intake (1.2% en) relative to previous butter diets (0.3% en), the potential importance of essential fatty acids (EFA) deficiency in the model was tested in a second study by feeding graded amounts of 18:2 (0.3, 0.6, 0.9, and 1.2% en) as safflower oil in four low-fat, butter-rich diets (11% en as fat) without alleviating gallstone incidence or severity. These studies indicate that substitution of 18:1 for saturated fatty acids in low-fat diets reduces gallstone formation without affecting the lithogenic index. Furthermore, intake of 18:2 at or below the EFA requirement does not appear to be a major factor in this model.

Lipids 30, 415–424 (1995).

Abbreviations: ACAT, acyl cholesterol acyl transferase; ANOVA, analysis of variance; apo B, apolipoprotein B; apo E, apolipoprotein E; CE, cholesteryl ester; EFA, essential fatty acid; en, energy; HDL, high-density lipoprotein; HI, hydrophobicity index; HPLC, high-performance liquid chromatography; LDL, low-density lipoprotein; LDLr, low density lipoprotein receptor; LI, lithogenic index; PUFA, polyunsaturated fatty acids; TC, total cholesterol.

The roles of dietary cholesterol and the type of dietary fat as etiologic agents for cholesterol gallstones have received considerable attention but remain unresolved (1). Most successful models of cholelithiasis depend on the feeding of excessive cholesterol, but the type of fat also influences bile cholesterol concentration and bile acid composition (2–4). The impact of fat saturation on gallstone development in any species is not clear, although one study in men suggested that polyunsaturated fatty acid (PUFA) increased the excretion of biliary cholesterol while decreasing the mole percent of bile acids (5). On the other hand, epidemiological evidence suggests that consumption of PUFA may protect against gallstones in women (6).

Purified diets containing butterfat (4–5%) and 0.3–0.4% cholesterol are especially lithogenic in hamsters (7–9). Substitution of olive oil for butterfat prevented stone formation completely, whereas palmitic acid added to the diet enhanced cholesterol gallstone formation (8). However, previous studies that compared dietary fats during gallstone induction have not always controlled for multiple changes in individual dietary fatty acids, even though evidence indicated that 16:0 might be most lithogenic.

In the present study, all fatty acids were controlled (equalized between diets) in order to test whether substitution of a dietary monounsaturated fatty acid (18:1) for specific saturated fatty acids (12:0, 14:0, 16:0) in coconut oil, butterfat, and palm stearin would alter the incidence of cholesterol cholelithiasis in the hamster. The dietary 18:2 (from safflower oil) was kept constant in all four diets at 1.2% energy (en). In addition, the effect of a high-16:0 intake was examined to assess the quantitative importance of that specific saturated fatty acid on gallstones.

In a second investigation, graded amounts of 18:2 (0.3, 0.6, 0.9, and 1.2% en) were added to the low-fat, butter diet (11% en) to reexamine the possible protective influence of PUFA originally noted in the essential fatty acid (EFA)-deficient model of Dam (10).

MATERIALS AND METHODS

Animals and diets. Male golden Syrian hamsters (*Mesocricetus auratus*, Lakeview strain), approximately 20 days old,

weighing 50–60 g were obtained from Charles River Laboratories, (Kingston, NY). The animals were randomly assigned to five groups (in Experiment 1, n = 8; Experiment 2, n = 12) and fed purified diets for six weeks. The purified diets were made by blending different fats to exchange olive oil (18:1-rich) with either palm stearin (16:0-rich), coconut oil (12:0 + 14:0-rich), or butterfat (14:0 + 16:0-rich). Dietary 18:2 was kept constant at 1.2% en (with extra safflower oil as needed) in these purified diets, in which fat supplied 11% of the total calories; and cholesterol was added at 0.4%. A fifth diet contained the 16:0-rich blend at 40% total energy (Tables 1 and 2). In the second experiment graded amounts of 18:2-rich safflower oil (0.3, 0.6, 0.9, and 1.2% en) were blended into the low-fat, gallstone-inducing butter diet (11% en) (Table 3) to examine the impact of the transition from a subnormal to adequate intake of EFAs.

The hamsters were housed in groups of four per cage and kept in a temperature-controlled environment with a 12-h light–dark cycle (lights on 1800 h). The diets were fed *ad libitum* (25 g wet weight per hamster daily), and the daily food intake was monitored. Water was provided *ad libitum*. Body weights were monitored on a weekly basis. All protocols and procedures were approved by the Brandeis University Animal Care and Use Committee.

Plasma lipid analysis. Blood samples were drawn from animals fasted overnight (18 h), at baseline, and at the end of six weeks. Blood samples were collected under light anesthesia, into an EDTA-wetted syringe by cardiac puncture, and plasma was separated by centrifugation at 12,000 × *g* for 15 min. Plasma total cholesterol (TC), high-density lipoprotein (HDL)-cholesterol (HDL-C), and triglycerides were determined by enzymatic assays (Sigma kit 352 for cholesterol and 336 for triglycerides; Sigma Chemical, St. Louis, MO). HDL-cholesterol was assayed following Mg^{2+}-phosphotungstate precipitation of lipoproteins containing apolipoprotein B (apo B) and apo E using the HDL-cholesterol Reagent Set® (Boehringer Diagnostics, Indianapolis, IN), according to the procedure described by Weingard and Daggy (11).

Necropsy and gallstone evaluation. After six weeks, hamsters were exsanguinated under anesthesia, and the liver, cecum, and small intestine were excised, blotted, and weighed. A portion of the liver was taken and frozen for hepatic cholesterol analysis. Gallbladder bile was aspirated, weighed, and analyzed for biliary lipids and bile acids. The gallbladder was dissected from the liver, opened under a dissecting microscope, and examined for gallstones under regular and polarized light microscopy (12).

A gallstone score (0–10) was generated by one of us (KCH, blinded) based on gradations in gallstone formation as well as number and size of stones. Low scores (for cholesterol stones) were represented by a cloudy mucin gel with cholesterol crystals (sludge), whereas the highest score was characterized by a gallbladder distended with numerous, 0.5–2.0 mm rounded almost pure-white stones that essentially displaced bile. Parallel scores for pigment stones ranged from a greenish, inspissated gel to numerous large, well-formed, pleomorphic green-brown to black stones, again completely filling the gallbladder. Occasionally distinct mixtures of the two types are observed, and occasionally cholesterol is deposited around a pigmented nucleus. Pigment stones often

[a]Diets were fed as starch gels, prepared by withholding 6 g cornstarch per 100 g mix from the formulation and premixing it with 80 mL of simmering water to form a gel to which the remaining ingredients were added.
[b]The composition of the Hayes-Cathcart vitamin mix and Ausman-Hayes mineral mix was detailed previously (Ref. 12).

form in hamster bile (especially when fed purified diets) that is not supersaturated with cholesterol, whereas cholesterol stones never do.

Bile analysis and bile acid pool size. Gallbladder bile lipids were isolated using a modified Folch extraction (13). A 10 μL aliquot of gallbladder bile was extracted with 3 mL chloroform/methanol (2:1, vol/vol) and 0.75 mL of 1.12% KCl solution. Biliary cholesterol, in an aliquot of the evaporated chloroform layer redissolved in isopropanol, was measured using the enzymatic Wako free cholesterol C kit (Wako Chemicals, Richmond, VA). Biliary phospholipid was measured using the Wako phospholipids B kit. Biliary bile acid concentration was determined as conjugated bile acids using an isocratic high-performance liquid chromatography (HPLC) procedure adapted from Rossi *et al.* (14), as described previously (15).

Bile acid pool size. This was determined as the sum of bile acids in gallbladder bile and small intestine. Small intestines were homogenized completely (Tissuemizer; Tekmar, Cinncinati, OH), and 100 mg of homogenate was ground with anhydrous sodium sulfate prior to extraction with 6 mL of chloroform/methanol (2:1, vol/vol) and 1.5 mL of 1.12% KCl solution. An aliquot from the methanol phase was then assayed for bile acids. Total gallbladder bile acids was determined as the biliary bile acid concentration times the volume of bile collected from the gallbladder.

The lithogenic index (LI) was calculated based on the relative molar ratios of lipid components and total lipid concentration using a computerized version of cholesterol solubility (16). The hydrophobicity index (HI) for individual bile samples was determined using the procedure of Heuman (17).

Hepatic cholesterol analysis. Hepatic cholesterol was extracted by grinding a 100 mg portion of liver with anhydrous sodium sulfate and by extracting three times with chloroform/methanol (2:1, vol/vol). The liquid phase was evaporated to dryness and redissolved in chloroform. An aliquot was evaporated and redissolved in isopropanol for analysis of free cholesterol using HPLC (18). TC was determined enzymatically using the Sigma total cholesterol kit. Esterified cholesterol was calculated as the difference between the TC and free cholesterol.

Fecal bile acid and cholesterol excretion. In the first study, feces were collected over a three-day period from all hamsters. Fecal bile acids were analyzed by using a modified method of Suckling *et al.* (19). The feces were oven-dried overnight and pulverized before hydrolysis. A 0.1 g fecal sample was hydrolyzed in 10 M NaOH at 110°C overnight. An aliquot of the hydrolysate was evaporated and extracted with 3 mL of chloroform/methanol (2:1, vol/vol) and 0.75 mL of 1.12% KCl. An aliquot from the methanol/KCl layer was evaporated under nitrogen and redissolved in a mixture of calf serum/saline (1:1, vol/vol), and bile acid concentration was determined using the enzymatic Sigma bile acid kit (Kit 450-A). Cholesterol was determined in an aliquot of the chloroform layer using the Sigma TC kit.

Statistical analysis. Statistical differences for the low-fat diet comparisons in both Experiments 1 and 2 were calculated using a one-way analysis of variance (ANOVA) followed by Scheffe's F-test utilizing the SuperANOVA statistical software package (Abacus Concepts, Inc., Berkeley, CA). The difference between the low-fat and high-fat 16:0-rich diets (Experiment 1) was calculated using a Student's *t*-test (Statview 512$^+$; Brain Power Inc., Calabasas, CA).

RESULTS

Experiment 1

Plasma cholesterol and triglycerides. After six weeks of feeding purified diets rich in specific saturated or monounsaturated fatty acids in the presence of a high cholesterol intake, body and organ weights were normal and equal (Table 4), but the baseline plasma TC (150 ± 40 mg/dL) had more than doubled (Table 5). However, no significant differences were observed between low-fat treatment groups or between the low-

[a]Values are mean ± SD (n = 8).
[b,c]Means in a row sharing a common superscript are significantly different ($P < 0.05$) using analysis of variance and Scheffe's F-test.
[d]HDL-C, high-density lipoprotein-cholesterol.
[e]TG, triglycerides.
[x]Significantly different by Student's *t*-test ($P < 0.05$).

16:0 and high-16:0 intakes. Plasma HDL-C in the 12:0 + 14:0 group at six weeks was significantly higher than that in either the 18:1 group or the 14:0 + 16:0 group. The percent HDL-C (HDL-C/TC) in these groups tended to reflect the absolute amount of HDL-C. The plasma triglyceride concentration also increased significantly compared to the baseline value (157 ± 28), but no significant differences were observed between treatment groups, even though the high-fat, 16:0-rich diet tended to decrease triglyceride values.

Liver cholesterol. Livers from hamsters fed the high-fat, 16:0-rich diet (40% en as fat) weighed more than livers from the low-fat, 16:0-rich diet (Table 4), even though the TC and esterified cholesterol concentrations were significantly lower. By contrast, the 18:1-rich diet significantly increased hepatic cholesterol compared to other treatment groups. Free cholesterol was constant (about 4 mg/g) in all groups (Table 5).

Biliary lipids. When biliary lipid composition was expressed as molar ratios, the mol% bile acids was unaffected by the specific saturated fatty acid exchanges, whereas the mol% cholesterol was significantly lower in the 14:0 + 16:0 group. The biliary lipid composition was not altered by the low-fat vs. high-fat 16:0-rich diet comparison. The total biliary lipids concentration did not differ between treatment groups. The LI was highest in the 12:0 + 14:0 diet (3.8) and lowest in the 14:0 + 16:0 diet (1.6) (Table 6).

Bile acid profile. The total bile acid concentration (mM) was not affected by exchanging specific saturated fatty acids for 18:1 (Table 6). Neither the absolute concentration nor relative distribution of individual bile acids was remarkable except for glycocholate in the low-fat groups (Table 7), which was significantly higher in the 14:0 + 16:0 than the 12:0 + 14:0 and 18:1 diet groups. Taurochenodeoxycholate was the predominant bile acid in gallbladder bile and was unaffected by dietary treatments. Both taurocholate and glycocholate exhibited higher concentrations in the high-fat, 16:0-rich diet compared to the low-fat, 16:0-rich group. Total cholate was lowest in the 12:0 + 14:0 group, and total secondary bile acids were highest in this group, whereas total chenodeoxycholate

[c]Significantly different by Student's *t*-test ($P < 0.05$).

was lowest in the 18:1 group. The primary-to-secondary bile acid ratio was significantly higher during 14:0 + 16:0 than during 12:0 + 14:0 consumption and during high-fat, 16:0-rich intake than during low-fat, 16:0-rich consumption. However, the glycine-to-taurine ratio in the 12:0 + 14:0 group was significantly higher than the 14:0 + 16:0 group. The HI, a measure of the hydrophobic–hydrophilic balance among bile acids, was lowest in the high-fat, 16:0-rich diet group compared to the low-fat, 16:0-rich group. The HI was highest in the 12:0 + 14:0 diet group compared to the other low-fat groups (Table 7).

Gallstone incidence. Examination of gallbladders revealed striking differences in gallstone incidence between specific saturated fatty acid treatments (Table 6). Hamsters fed the low-fat, 16:0-rich diet proved to be the most susceptible, with eight of eight hamsters developing cholesterol gallstones. Hamsters fed the 18:1-rich diet proved least susceptible, with only one of eight hamsters developing gallstones. The 14:0 + 16:0 and the high-fat, 16:0-rich diets each produced cholesterol gallstones in three of eight hamsters, while the 12:0 + 14:0 diet generated stones in five of eight hamsters. However, both the low-fat, 16:0-rich and the 12:0 + 14:0 diets produced equally severe cholesterol gallstone scores. Mucin accumulation in gallbladder bile was often associated with cholesterol gallstones in diets containing 16:0 but was minimal in the 18:1-rich and 12:0 + 14:0 groups. When present, the thick, gel-like mucus was typically loaded with cholesterol crystals. No pigment stones were found in the low-fat, 16:0-rich diet group, while five of eight hamsters in the high-fat, 16:0-rich group developed pigment stones. The latter were observed in various stages of development, usually in bile without cholesterol crystals or stones. The early stage was characterized by cigar-shaped clumps or granules of inspissated mucin gel of yellow-green to amber coloration. The larger ones (0.2–0.5 mm) resembled jelly beans in shape and gooey consistency. Other more advanced forms represented glistening dark green-brown flakes of dried mucus, soft and somewhat pliable, often curled at the edges. The most mature stones were brownish-to-greenish black granules (up to 1.0 mm) with an irregular, pleomorphic configuration and a hard, friable, gritty texture.

Bile acid pool size. The bile acid pool size did not differ significantly among treatment groups although it tended to be smallest in the 18:1-rich group (Table 8).

Fecal bile acid and cholesterol excretion. Fecal bile acid excretion was lowest in the 18:1-rich group and significantly lower than the low-fat, 16:0-rich group. Fecal cholesterol excretion was significantly elevated in the high-fat, 16:0-rich diet group compared to the low-fat, 16:0-rich group, while no significant differences were observed between the low-fat treatments (Table 8).

Experiment 2

Plasma cholesterol and triglycerides. After six weeks of the purified diets containing graded amounts of 18:2, averages for body and organ weights were unaffected by dietary 18:2: total body, 128 g; liver, 6.5 g; cecum, 1.28 g; small intestine, 2.12 g. By six weeks, all four purified diets containing graded amounts of 18:2 elevated the plasma lipids above baseline, to an average TC of 424 mg/dL and TG of 444 mg/dL. No meaningful differences were observed.

Liver cholesterol and biliary lipids. The average hepatic cholesterol concentration [63 mg/g, 93% cholesteryl ester (CE)] was elevated equally by all diets, i.e., increasing the dietary 18:2 level had no effect. Adding graded amounts of 18:2 in the low-fat butter diet produced no significant differences

in biliary lipids or the LI, although the latter tended to decrease based on a tendency toward higher bile acids relative to bilary cholesterol associated with a slight rise in the cholate-to-cheno ratio (Tables 9 and 10). The glycine-to-taurine ratio was not affected, and the HI was similar in all treatment groups (Table 10).

Gallstone incidence. The amount of 18:2 in these low-fat diets did not modulate gallstone incidence, as 60–75%

of hamsters from each group developed cholesterol stones. However, the severity of cholesterol stone formation tended to decrease as the % en from 18:2 increased (Table 10).

DISCUSSION

Syrian hamsters are commonly used to study diet-induced cholelithiasis. Traditionally, induction of gallstones in hamsters utilized the EFA-deficient diet described by Dam (10) or diets containing a modest amount of butterfat with or without added cholesterol (3,20). Although a high intake of dietary cholesterol in a low-fat diet represents an anomaly from the practical, dietary point of view for humans, this manipulation definitely contributes to supersaturation of gallbladder bile and gallstone formation in the hamster model. In fact, a low level of dietary fat seems to be an important requirement for optimal stone formation (21). The secondary contribution of dietary fatty acids in this situation is less well-defined. Previous research has shown that certain dietary fats (7–10), and even specific fatty acids (22), alter lithogenesis. However, the reason for these associations is unclear.

The objective of our experiments was to determine whether varying the concentration of specific dietary fatty acids (as natural triglycerides) would alter bile lithogenicity and whether the absolute intake of the main fatty acid in question (16:0) would influence gallstone incidence. Accordingly, the different dietary treatments varied the intake of specific saturated and monounsaturated fatty acids, while safflower oil was added as necessary to assure an equal and adequate intake of 18:2 (EFA) at 1.2% en. The results reveal that (i) the monounsaturated fatty acid (18:1), as compared to the three saturated fatty acids (12:0,14:0,16:0), protects against gallstone formation in the cholesterol-fed hamster while increasing hepatic CEs and reducing bile acid excretion (synthesis); (ii) among the saturated fatty acids, 16:0 tended to be more lithogenic than 12:0 or 14:0, but specifically increasing 16:0 by higher fat intake reduced cholesterol gallstone formation; and (iii) the lithogenic effect of a low-fat diet rich in saturated fatty acids was not attributable to EFA deficiency since supplementation with EFAs (as safflower oil) did not alter lithogenicity.

Dietary fatty acids (as natural triglycerides) presumably influence all three major criteria involved in gallstone formation, i.e., cholesterol supersaturation of gallbladder bile, bile stasis due to reduced motility of the gallbladder, as well as nucleation and cholesterol crystal growth in the gallbladder (23). Biliary cholesterol supersaturation typically results from hypersecretion of cholesterol, hyposecretion of bile salts, or a combination of both. In the present study, the hepatic cholesterol concentration was elevated in all groups, but was highest in the group with the least stones (18:1-rich diet) and lowest in the two 16:0-groups (Experiment 1). Thus, hepatic cholesterol accumulation reflected the high dietary cholesterol content, but dietary monounsaturated fat exacerbated this effect, in keeping with previous data from cholesterol-fed hamsters (24). However, these fatty acids have minimal differential impact on hepatic cholesterol in the absence of dietary cholesterol (Hayes, K., and Dictenberg, J., unpublished data).

The increase in hepatic esterified cholesterol concentration with the 18:1-rich diet may reflect enhanced acyl cholesterol acyl transferase (ACAT) activity (24–26), which has been related to an increase in the hepatic low-density lipoprotein (LDL) receptor activity in cholesterol-fed hamsters (27). Saturated fatty acids reportedly suppressed LDL receptor activity and decreased the mass of hepatic CEs (27–29). One might anticipate that accumulation of hepatic cholesterol in the 18:1-rich diet group would increase biliary cholesterol secretion leading to supersaturated bile (LI greater than 1.0) and gallstones, or, conversely, that the lower hepatic cholesterol during 16:0 intake might reflect enhanced biliary cholesterol excretion and lead to gallstones. However, despite a relatively high LI in the 18:1-rich diet group, the incidence of gallstones was lowest in this group; and the high-fat, 16:0-rich diet (with no change in LI) actually decreased the incidence of stones while depressing the HI, suggesting that a low level of dietary fat is critical to gallstone formation and that higher concentrations of fat may actually be protective. These data confirm the lack of a specific relationship between elevated hepatic cholesterol concentration, biliary cholesterol saturation, and stone formation (15,30–32). Interestingly, although hamsters fed the low-fat, 16:0-rich diet were arguably the most severely afflicted with gallstones, those fed the low-fat, 14:0 + 16:0 diet, which is consistently lithogenic (7,15), had a slightly lower gallstone incidence and much lower severity of cholesterol stones than those fed the 12:0 + 14:0 diet. Coupled with the protective effect of added 16:0 in the high-fat, 16:0-rich diet, the inference is that 16:0 *per se* was not the initiating factor, but rather some aspect of its metabolism as the major fatty acid in a low-fat diet.

The cholate-to-cheno ratio tended to be lower in the two highly lithogenic diets (12:0 + 14:0 and low-fat, 16:0-rich diets) than in the other three diets, linking a low-cholate, high-chenodeoxycholate profile with stone formation. In general the primary bile acid profile was such that the lowest 18:1 intake (12:0 + 14:0-rich diet) resulted in the lowest total cholate and highest concentration of secondary bile acids, whereas high intake of 18:1 tended to assure a larger cholate pool and reduced cholesterol gallstones, even though bile acid synthesis and excretion were reduced. Thus, a low cholate/cheno ratio appears to be lithogenic for hamsters; and LDL receptor (LDL_r) activity, enhanced by 18:1 in the cholesterol-fed hamster (27), may be connected to the synthesis of cholate (1). A decrease in the cholate-to-cheno ratio has been observed previously in hamsters under a variety of gallstone-inducing dietary conditions (20,32–34), and the associated elevation in HI (33) has been hypothesized to depress 12 α-hydroxylase activity (32), which is essential for cholate synthesis (35).

Fecal bile acid and cholesterol excretion were highest in the 16:0-rich diet groups and were surprisingly greater ($P < 0.05$) than excretion of bile acids (and therefore synthesis) in the 18:1-rich group. However, despite these differences, the

similar LI and HI in these two groups imply that neither the bile lipid molar ratios nor bile acid profile per se was the definitive factor in the striking discrepancy in gallstone incidence between the two diets. The data also contrast with the increased susceptibility to cholesterol gallstones typically associated with a reduced bile acid pool. The high hepatic cholesteryl ester content associated with 18:1 intake would further suggest that the tendency of 18:1 to lower plasma cholesterol in these hypercholesterolemic hamsters, possibly by enhanced ACAT and LDL_r activities (24,26,27), does not promote sterol excretion but rather enhances cholesteryl ester deposition in tissues, which in itself may not be desirable.

Because a 5% butter diet is limited in EFA, it was unclear whether the lithogenic potential of butter was due to its saturated fatty acids or relative lack of either 18:2 or 18:1. Feeding graded amounts of 18:2 from the low level in 5% butter (0.3% en) to a level in excess of the EFA requirement (>1.0% en) under these lithogenic circumstances (Experiment 2) did not affect the incidence of cholesterol gallstones. Thus, marginal EFA depletion in the hamster fed butterfat and cholesterol does not appear to be an issue. However, adding 18:2 did seem to decrease pigment granules, at the highest 18:2 intake (1.2% en 18:2) and tended to cause progressive reduction in the LI.

In summary, the type and amount of dietary fatty acids impact cholesterol gallstone formation in hamsters, especially related to whether the fats (fatty acids) are consumed in high-fat or low-fat diets.

ACKNOWLEDGMENTS

The authors thank Andrzej Pronczuk for assisting with the formulation of the diets and for the fatty acid analysis of the diets.

ABSTRACT: Male Syrian hamsters and male CD-1 mice were fed diets supplemented with ethyl esters of oleic, linoleic, arachidonic, and eicosapentaenoic acids (1.1–1.5%, w/w) for 3–4 wk. Plasma and serum triglycerides were significantly higher in the arachidonic acid-supplemented animals compared to those in the other supplementation groups. Changes in serum insulin and glucose levels did not appear to be related to the changes in circulating triglycerides observed in the arachidonic acid-supplemented group. These data indicate that dietary arachidonic acid elevates circulating triglyceride levels compared to other unsaturated fatty acids in hamsters and mice by unknown mechanisms.

Lipids 30, 425–429 (1995).

Dietary polyunsaturated fatty acids (PUFA) are a group of heterogenous fatty acids which can possess dramatically diverse biological effects (1). Recent evidence demonstrates that dietary arachidonic acid (AA; 20:4n-6) possesses effects which are diametrically opposed to those observed with n-3 PUFA, and these effects appear to be related to the ability of dietary AA to alter tissue AA content and to abrogate the effects of n-3 PUFA (2–5).

One unequivocal effect of n-3 PUFAs, and in particular eicosapentaenoic acid (EPA; 20:5n-3), is their ability to lower circulating triglyceride levels (6). This is in comparison to n-6 PUFA derived from vegetable oils, i.e., linoleic acid (LA; 18:2n-6), which are relatively weak hypotriglyceridemic agents (6–9). However, the effects of dietary AA (desaturation and elongation product of LA) on circulating triglycerides remain unclear. Recently, it was reported that dietary AA may elevate plasma triglycerides, an effect which is opposite that of EPA (10). Based on the recent evidence for the opposing effects of dietary AA and EPA on circulating triglyceride levels and the limited research on the effects of dietary AA (3–5), these studies were designed to compare the effect that dietary AA has on circulating triglycerides with that of other dietary unsaturated fatty acids.

METHODS

Animals. Male Golden Syrian hamsters (~90 g) (Charles River, Wilmington, MA) or CD-1 male mice (~30 g) (HSD, Indianapolis, IN) were used in these studies. All animals were randomly divided and housed (hamsters: one per cage; mice: four per cage) on a 12-h dark/light cycle. All animals were fed standard laboratory pellet diets for one week, after which time they were fed experimental diets for three to four weeks as described previously (3,4). All animal procedures were approved by the University of Tennessee Animal Care and Use Committee (Knoxville, TN) and were in accord with the *NIH Guide for the Care and Use of Laboratory Animals (NRC 1985).*

Diets and experimental groups. The diets and experimental groups have been previously described in detail as part of larger studies (3,4) and, therefore, will only be briefly summarized. In Study 1, 24 male Syrian hamsters were randomly divided into four dietary groups (Table 1) (3). In the second study (Study 2), 49 male CD-1 mice were randomly divided into four dietary groups [n = 13: oleic acid (OA; 18:1n-9) group; n = 12: EPA, AA + EPA, and AA groups] (Table 1) (4). The animals in each study were fed identical diets [10% (w/w) fat] supplemented with various unsaturated fatty acid ethyl esters (1.1–1.5%, w/w), *viz.* OA, LA, AA, and EPA. Preparation and treatment of the diets are described elsewhere (3,4). Fatty acid analyses of the diets are presented in Tables 2 and 3 (3,4).

Triglyceride analysis. Animals were fasted overnight prior to blood collection. For hamster plasma triglycerides (Study 1), whole blood was drawn by cardiac puncture (nine parts blood and one part 38 g/L trisodium citrate) and centrifuged at 650 × *g* for 4 min. An aliquot of the plasma was analyzed for triglyceride content by the enzymatic measurement of triglyceride-derived glycerol (11) using the triglyceride analysis kit from Sigma (St. Louis, MO). The accuracy of the kit was validated using tripalmitin and glycerol standards. The coefficient of variation for multiple analyses performed on the same sample was 2%. For mouse serum triglycerides (Study 2), whole blood was drawn by cardiac

puncture and collected in tubes containing a gel clot activator (Bectin Dickison, Rutherford, NJ). Serum was isolated according to the manufacturer's instructions, and serum triglycerides were analyzed as stated previously.

Serum insulin and glucose. Serum insulin concentrations were determined by double antibody radioimmunoassay analysis (ICN Biomedical Inc., Costa Mesa, CA). Intra-assay coefficient of variation was 2.7%. Serum glucose concentrations were determined by the highly specific glucose oxidase method using an analysis kit from Sigma in which glucose oxidase and peroxidase, coupled with chromatogenic oxygen acceptor, are quantitated colorimetrically (12). The coefficient of variation for multiple analyses performed on the same sample was 3.4%.

Statistical analysis. The effects of dietary treatments were determined by analysis of variance. Comparisons between individual dietary groups were made using Fisher's protected least significance method using the Stat.View 512+ statistical package (Brain Power, Calabasas, CA).

RESULTS

Weight gain and food intake were not significantly different among the different dietary groups in each respective study (Table 4).

Circulating triglyceride levels. Plasma triglyceride levels in hamsters fed the diet containing AA were 32 and 49% higher ($P < 0.05$) compared to animals in the LA and in the EPA dietary groups, respectively, and the difference approached significance ($P < 0.055$) compared to the OA group (Fig. 1). Similarly, serum triglyceride levels in mice fed the diet containing AA (devoid of EPA) were 24 and 30% higher ($P < 0.05$) compared to the OA and EPA group, respectively (Fig. 2). The serum triglyceride level in the AA + EPA group was not significantly different from the triglyceride level of any of the other dietary groups.

TABLE 4
Effects of Dietary Unsaturated Fatty Acids on Animal Weight Gain[a]

	Dietary groups			
	OA	EPA	AA + EPA	AA
Study 1	22.9 ± 3.6	21.7 ± 1.6	23.9 ± 1.7	22.1 ± 2.3
Study 2	21.5 ± 0.8	22.3 ± 2.0	22.6 ± 0.9	20.1 ± 1.6

[a]All data are expressed as mean ± SEM for six experimental values in Study 1 and 12–13 experimental values in Study 2. Weight gain of animals were reported as grams of weight gain/hamster/three weeks in Study 1 and grams of weight gain/four mice/four weeks in Study 2. Weight gains were not significantly different among dietary groups in each respective study. Abbreviations as in Table 1.

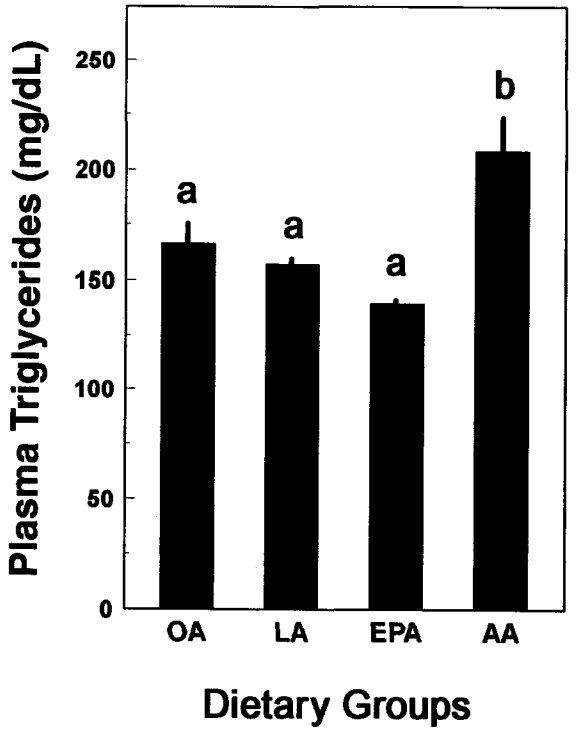

FIG. 1. The effect of dietary unsaturated fatty acids on plasma triglyceride levels in hamsters. Hamster diets were supplemented with one of the following unsaturated fatty acid ethyl esters: oleic acid (OA); linoleic acid (LA); eicosapentaenoic acid (EPA); arachidonic acid (AA). Plasma triglyceride levels were determined after three weeks on experimental diets. Data was pooled in each dietary group (n = 6) to generate means ± SEM. The AA group was significantly different from the LA and EPA groups at $P < 0.05$ and from the OA group at $P < 0.055$.

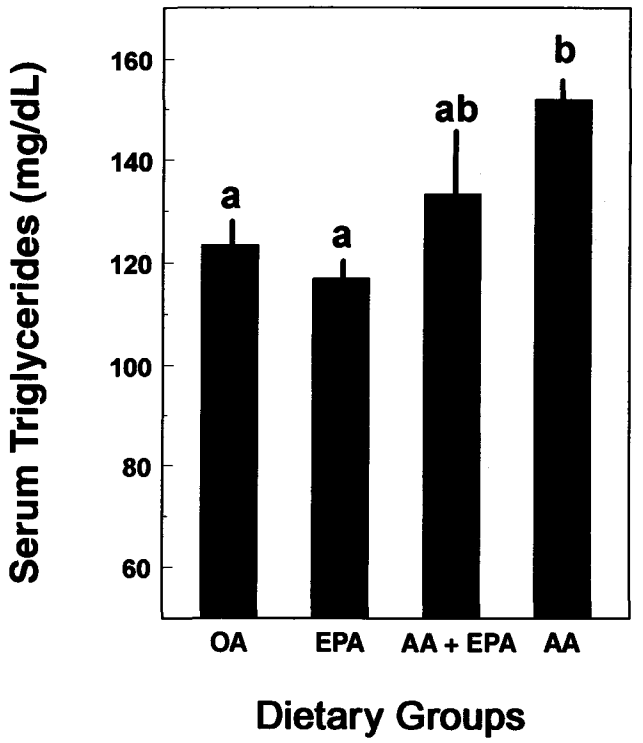

FIG. 2. The effect of dietary unsaturated fatty acids on serum triglyceride levels in mice. Diets were supplemented with the following unsaturated fatty acid ethyl esters: OA, EPA, AA. Data was pooled in each dietary group (n = 12 or 13) to generate means ± SEM. Values with different letters are significantly different at $P < 0.05$. Abbreviations as in Figure 1.

Serum insulin and glucose levels in mice (Study 2). Serum insulin levels were not significantly different among the different dietary groups (Table 5). Serum glucose levels in the AA group were not significantly different from the other dietary groups (Table 5), but those of the EPA and the AA + EPA dietary groups were significantly lower than those of the OA group.

DISCUSSION

A novel finding in this study was that the plasma triglyceride concentration was highest in the AA group compared to the other treatment groups. We observed statistically significant differences in the AA group compared to the LA and EPA groups ($P < 0.05$) and the OA group ($P < 0.055$) (Study 1). Our findings are supported by a study reporting that plasma triglycerides were 87% higher in streptozotocin-induced diabetic rats whose diets were supplemented with AA as compared with streptozotocin-treated controls (10). These more recent results are in contrast to an earlier study reporting that dietary AA did not appear to affect plasma triglyceride levels (13).

If dietary AA elevates plasma triglycerides and dietary n-3 PUFA are known to be hypotriglyceridemic, then the combination of AA and EPA (AA + EPA, Study 2) could nullify these divergent effects. We had previously established that an antithetic relationship existed between AA and EPA with regard to tissue fatty acid composition and eicosanoid production *in vitro* and *in vivo* (3,4). Therefore, a follow-up experiment was designed, in part, to further elucidate the relationship between dietary AA and circulating triglycerides and to explore the opposing effects that AA and EPA may have on circulating triglycerides.

The results observed in the first study were reproduced in the second study, where the AA-supplemented group (AA group, Study 2) had a significantly higher serum triglyceride concentration compared to the OA and EPA groups. The results from the two studies presented here suggest that dietary arachidonate possesses a triglyceride-elevating effect. When

AA and EPA were included in the diet concomitantly (AA + EPA, Study 2), the triglyceride level in this group was midway between the triglyceride levels of the AA group and the EPA group, providing supporting (but not conclusive) evidence that AA and EPA may have opposing effects.

The effects of LA and EPA on plasma triglyceride levels, compared to those of OA (Fig. 1), were consistent with what has been reported in the literature (8,9,14). We observed that increasing chain length and unsaturation of dietary fatty acids resulted in a weak but progressive decline in plasma triglyceride concentrations, with the EPA group having the lowest value. However, although these changes were not statistically significant, they were also not surprising. Dietary LA possesses weak, but inconsistent, hypotriglyceridemic activity compared to saturated fatty acids and monosaturated fatty acids (7,15). n-3 PUFA, on the other hand, are very effective in lowering plasma triglyceride concentrations at dietary levels higher than those used in this study (6,16). When EPA was included in the diets (EPA group), the level of triglycerides were not different from the OA group, but the effect of EPA on triglyceride levels reflected similar quantitative and qualitative changes previously observed using the same animal model under similar experimental conditions (17). Therefore, our results are most likely due to the dietary level of n-3 PUFA used in the study (1.1%, w/w).

It has been reported that long-chain n-3 PUFA are poor substrates for β-oxidation, and that these PUFA, especially EPA, enhance mitochondrial and peroxisomal β-oxidation, suggesting n-3 PUFA may be affecting fatty acid availability for triglyceride synthesis (17–20). Dietary AA is also a poor substrate for β-oxidation (21), but recent evidence demonstrated that dietary AA has effects on β-oxidation which are in opposition to those observed with n-3 PUFA (22). It was reported that β-oxidation was significantly lower in AA-fed animals compared to animals consuming n-3 PUFA or OA-enriched diets. The authors suggested that the lower rates of fatty acid oxidation observed in the AA group favor triglyceride synthesis (22). However, dietary AA does not appear to significantly alter hepatic triglyceride secretion rates or plasma triglyceride fractional catabolic rates in rats (13), but some of the effects of AA on triglyceride secretion are difficult to interpret because of inconsistent results and the supraphysiological levels of AA used (1–20 mM) (23,24).

With respect to triglyceride synthesis, AA has been shown to be a potent modulator of lipogenesis by repressing the expression of a number of lipogenic genes (25–30); however, AA has also been shown to have contrasting effects on the activity of lipogenic enzymes such as glycerol-3-phosphate dehydrogenase (28,31,32). While all common PUFA have been shown to inhibit the expression of lipogenic genes, not all PUFA have hypotriglyceridemic properties. Therefore, further studies are required to more fully appreciate the relationship between dietary PUFA, circulating triglyceride levels, and expression of lipogenic genes.

Serum insulin levels were not different among the dietary groups (Study 2), indicating that dietary AA has little effect on circulating insulin levels. Serum insulin levels have been shown to be negatively correlated with AA content of muscle phospholipids in patients undergoing coronary artery surgery, but dietary AA intakes in these individuals were not reported (33). Similarly, dietary AA did not alter serum glucose levels (OA group vs. AA group). AA has been shown to reduce the responsiveness of the GLUT4 transporter to insulin in cultured 3T3-L1 adipocytes (34). However, in these same cells, AA had no effect on the maximal rate of glucose uptake as AA regulated GLUT4 and GLUT1 by altering their gene transcription and mRNA stability in opposite directions. In comparison, dietary fish oil supplementation, at a level of 20% of calories, improves insulin sensitivity in rats fed high-fat diets (59% of calories). However, serum insulin levels (Study 2) were not altered by EPA supplementation (3% of calories), and these results are consistent with those observed with non-diabetic healthy individuals fed diets containing fish oils (35,36). Although insulin levels remained unchanged, we nevertheless observed lower glucose levels in the EPA-containing groups. It has been reported that fish oil feeding improves insulin sensitivity in rats, possibly accounting for the observed results (37).

In summary, we observed that circulating triglyceride levels were elevated in hamsters and mice whose diets were supplemented with AA compared to animals whose diets were supplemented with OA, LA, or EPA, and these differences could not be explained by differences in circulating insulin or glucose levels. Although research evaluating the effects of dietary AA on lipid metabolism is limited, a review of the literature emphasizes the uncertainty of these effects, and this and other studies suggest that AA and n-3 PUFA could have effects which are in opposition (3–5,10,35). Our data and the data of Collier and Collier (10) provide the first evidence suggesting that dietary AA may elevate circulating triglyceride levels compared to other unsaturated fatty acids; however, the mechanisms responsible for these effects remain unclear.

Reduction of Hyperlipidemia in Hepatoma-Bearing Rats by Dietary Fish Oil

Masashi Kawasaki, Kazumi Yagasaki *, Yutaka Miura and Ryuhei Funabiki

Department of Applied Biological Science, Tokyo Noko University, Fuchu, Tokyo 183, Japan

ABSTRACT: The effect of dietary fish oil on serum lipid levels was studied by comparing it with dietary corn oil in Donryu rats subcutaneously implanted with an ascites hepatoma cell line (AH109A). The hepatoma-bearing rats exhibited hyperlipidemia charactarized by a rise in both serum cholesterol and triglyceride levels. Increased cholesterogenesis in the host liver and decreased steroid excretion into feces are suggested to be responsible for the hepatoma-induced hypercholesterolemia, and increased fatty acid mobilization from peripheral adipose tissues and decreased triglyceride clearance from the blood circulation are considered causes for the hepatoma-induced hypertriglyceridemia. Dietary fish oil reduced the hyperlipidemia in these animals, suppressed the hepatoma-induced increase in hepatic cholesterogenesis and fatty acid mobilization from adipose tissue. Dietary fish oil also tended to increase fatty acid oxidation in the liver. Such diverse effects of fish oil may lead to the reduction of the hepatoma-induced hyperlipidemia. These results suggest that studies on dietary fish oil may be warranted in patients with cancer-related hyperlipidemia.
Lipids 30, 431–436 (1995).

Various cancers affect serum lipoprotein profiles in humans (1,2). Hepatoma also induces abnormal serum lipid metabolism in humans (3,4) and in animals (5,6). Rats subcutaneously implanted with an ascites hepatoma line of AH109A cells show a notable decrease in high-density lipoprotein (HDL) fraction and an enormous increase in the very low density lipoprotein (VLDL) plus low-density lipoprotein (LDL) fraction (5) and a resultant hypertriglyceridemia (7) during growth of the hepatoma. Thus, AH109A-bearing rats provide us with an endogenously hyperlipidemic animal model that is quite distinct from the cholesterol (Ch)-loaded animals that have been widely used as an exogenously hypercholesterolemic model. Dietary fish oil (FO), rich in n-3 polyunsaturated fatty acids, has been well documented to suppress the levels of serum lipids, such as triglyceride (TG), phospholipid (PL), Ch, and nonesterified fatty acid (NEFA) in rats (8–13) and in hyperlipidemic patients (14). The present study examined the effect of dietary FO on serum lipids and various parameters related to lipid metabolism in both normal and hepatoma-bearing rats. Corn oil (CO), which is rich in n-6 linoleate, was employed as the control oil.

Abbreviations: ANOVA, analysis of variance; Ch, cholesterol; CO, corn oil; FA, fatty acid; FO, fish oil; HDL, high-density lipoprotein; HSL, hormone-sensitive lipase; HTGL, hepatic triglyceride lipase; LDL, low-density lipoprotein; LPL, lipoprotein lipase; NEFA, nonesterified fatty acid; PL, phospholipid; TG, triglyceride; VLDL, very low density lipoprotein.

MATERIALS AND METHODS

Animals and diets. Male Donryu rats (three weeks of age; NRC Haruna, Gunma, Japan) were individually housed in stainless-steel cages with wire bottoms and kept on a stock pellet diet (CE-2; CLEA Japan, Tokyo) in an air-conditioned room with a temperature of 22 ± 2°C, a relative humidity of 60 ± 5%, and an 8:00 a.m. to 8:00 p.m. light cycle. On the fourth day of the stock pellet feeding, rats with equal body weights were divided into two groups and for 23 d were fed a basal diet containing 20% casein (Oriental Yeast Co., Tokyo, Japan), 10% CO (Hayashi Chemicals Co., Tokyo, Japan), or FO (San-omega EPA-S18GA; the generous gift of NOF Corporation, Tokyo, Japan), 46.3% α-corn starch (Nihon Nosan Kogyo Co., Yokohama, Japan), 17% sucrose (Nissin Sugar Manufacturing Co., Tokyo, Japan), 3.5% mineral mixture (AIN composition; Nihon Nosan Kogyo Co.), 1% vitamin mixture (AIN composition; Nihon Nosan Kogyo Co.), 0.2% choline bitartrate (Wako Pure Chemical Industries, Osaka, Japan), and 2% cellulose powder (Oriental Yeast Co.). The FO contained 0.3% vitamin E, so the CO diet was also supplemented with extra vitamin E (Riken E Oil 800; Riken Vitamin Co., Tokyo, Japan) in order to make the vitamin E content of both diets equal (350 mg/kg diet). No side effects have been noted at this dose of vitamin E in rats (15). The fatty acid (FA) composition of each oil is shown in Table 1. There was no Ch in CO, and 0.5% in FO, whereas the β-sitosterol content was 0.3% in CO with none in FO. Thus, the CO diet contained 0.03% β-sitosterol, whereas the FO diet contained 0.05% Ch. An enzymatic assay employed for the determination of fecal neutral sterols reacts with both Ch and β-sitosterol (38.4% of Ch). After feeding the experimental diets for 23 d, rats of either the CO group or the FO group were again divided into two groups with equal body weights. Half the rats of each oil group received a subcutaneous implantation of 5×10^5 AH109A cells (provided by SRL, Tokyo, Japan) in the back to produce a solid hepatoma (5), and the other half

received only a sham injection of phosphate-buffered saline (0.5 mL/rat) and were designated as normal rats (day 0). Rats of each group were kept for a further 14 d on the same test diets. Water and each diet were available at all times. Animals were deprived of their diet at 9:00 a.m. on day 14, but allowed free access to water until killing (which was performed 4 h later by decapitation). Blood was collected and left to clot at room temperature to obtain serum. The liver, epididymal adipose tissue, cardiac muscle, gastrocnemius, and solid hepatoma were quickly removed, washed with cold 0.9% NaCl, and blotted on filter paper. Aliquots of these tissues were frozen in liquid nitrogen and stored at −70°C until analyzed.

Lipid analyses. Total lipids were extracted according to the procedure of Folch *et al.* (16) from the liver and solid hepatoma. After portions of the chloroform phase had been dried under nitrogen, Ch (17), TG (18), and PL (19) were determined as previously described (20). The serum TG and PL levels were also determined as described previously. The serum NEFA level was measured by the method of Kushiro *et al.* (21). The serum lipoproteins were separated into HDL and VLDL + LDL fractions by the precipitation method (5). The total Ch of unfractionated serum (T-Ch) and HDL (HDL–Ch) were determined by an enzymatic method using a cholesterol C-test kit (Wako Pure Chemical Industries), and the difference between T-Ch and HDL-Ch was regarded as (VLDL + LDL)-Ch.

Measurement of tissue lipolytic activities. Lipoprotein lipase (LPL) was extracted from epididymal adipose tissue, cardiac muscle, and gastrocnemius by the method of Noguchi *et al.* (22); the tissues weighing 300 mg were homogenized in 0.2 M Tris-HCl buffer (pH 8.5) containing 10 U/mL of sodium heparin (Wako Pure Chemical Industries). Hepatic TG lipase (HTGL) was also extracted from the liver and the solid hepatoma in the same way. Lipase (LPL and HTGL) activities were then estimated as described previously (23,24). Briefly, 0.1 mL of the abovementioned enzyme source was mixed with 0.1 mL of substrate solution (arabic gum-emulsified Tris-HCl buffer, 0.2 M and pH 8.0, containing rat serum to supply adequate apolipoprotein C-II as an LPL activator for LPL, and 0.1 M and pH 8.5 for HTGL) containing 925 Bq (55,500 dpm)/μmol/assay of [carboxyl-^{14}C]triolein (original specific radioactivity, 4.1 GBq/mmol; NEN Research Products, Boston, MA). The mixture was incubated at 37°C for one hour, followed by the extraction and counting of hydrolyzed [^{14}C]oleic acid. Hormone-sensitive lipase (HSL) activity in adipose tissue was also determined. From epididymal adipose tissue, HSL was extracted with two volumes of 0.2 M phosphate buffer (pH 7.0) by homogenization (25). The enzyme suspension (0.1 mL) previously incubated with 1 M NaCl for 10 min was mixed with 0.1 mL of substrate solution (arabic gum-emulsified 0.2 M phosphate buffer, pH 7.0) containing 925 Bq/μmol/assay of [carboxyl-^{14}C]triolein and the mixture was incubated at 30°C for one hour. At the end of the incubation period, hydrolyzed [^{14}C]oleic acid was extracted, and radioactivity was counted after adding Insta-Gel (Packard Instrument Co., Inc., Meriden, CT). One unit of lipase activity was defined as 1 μmol of FA released per hour.

Hepatic FA oxidation. FA oxidation was estimated using liver slices (26). Liver slices weighing 200 mg were placed in 2 mL of Krebs-Ringer phosphate buffer (pH 7.4) containing 37 kBq/μmol/assay of [1-^{14}C]palmitic acid (original specific radioactivity 310 MBq/mmol; NEN Research Products). Each tube was gassed with 100% O_2, connected with a rubber tube (18 mm i.d.) to a counting vial which held circular filter paper (No. 131, 24 mm in diameter; Toyo Roshi Co., Tokyo, Japan), saturated with 100 μL of Protosol (NEN Research Products), and incubated at 37°C for two hours. The incubation was terminated with 1 mL of 8% $HClO_4$ *via* the rubber tube with a needle, and thereafter each tube was incubated for another hour to absorb $^{14}CO_2$ to Protosol. The residual layer was extracted twice with petroleum ether to remove traces of [^{14}C]palmitic acid, and an aliquot of the aqueous phase was counted (acid-soluble oxidation products: ketone bodies). Radioactivity was measured after adding Insta-Gel.

Hepatic lipid syntheses. Total FAs and Ch syntheses were measured using liver slices (26,27). Liver slices weighing 100–120 mg were placed in 1 mL of Krebs-Ringer phosphate buffer (pH 7.4) containing 37 kBq/μmol/assay of [1-^{14}C]-acetic acid (sodium salt, original specific radioactivity 2.04 GBq/mmol; Amersham International plc, Buckinghamshire, United Kingdom). Each tube was gassed with 100% O_2, stoppered tightly with a screw cap, and incubated at 37°C for two hours. At the end of the incubation period, 1 mL of 15% ethanolic KOH was added, and the mixture was saponified at 75°C for two hours. Nonsaponifiable lipids were extracted three times with petroleum ether, and digitonin-precipitable sterols were formed, isolated, washed, dissolved in methanol, and counted after addition of a toluene-based scintillator. The residual aqueous layer was acidified to pH 2 with concentrated HCl, and total FAs were extracted three times with petroleum ether. Pooled extracts were dried under nitrogen, dissolved in chloroform, and washed twice with water. The chloroform layer was quantitatively transferred to a scintillation vial, dried, and counted as mentioned previously.

Fecal steroid excretion. Feces were collected for two days before sacrifice (days 12–14). Neutral sterols and bile acids

[c,d]Values not sharing a common letter are significantly different at $P < 0.05$ by Duncan's multiple-range test.
[e,f]Values not sharing a common letter are significantly different at $P < 0.05$ by Student's *t*-test.

were extracted from dried and ground feces after saponification according to the procedure of Yamanaka *et al.* (28). Fecal 3β-hydroxy neutral sterols and 3α-hydroxy bile acids were determined by enzymatic methods (29), using commercial kits as described previously (30).

Statistical analysis. Results were expressed as mean ± standard error. Statistical analysis was carried out by two-way analysis of variance (ANOVA) followed by Duncan's multiple-range test (31). In some cases (Table 2), Student's *t*-test was employed after one-way ANOVA. The correlation coefficient was determined by least square analysis.

RESULTS

Both food intake and body weight gain during the 23 d of preliminary feeding were almost the same between the CO and FO diet groups (data not shown). Table 2 shows food intake, body weight gain, liver and solid hepatoma weights, and lipid contents in the liver and hepatoma 14 d after AH109A implantation [hepatoma-bearing (H) groups] or phosphate-buffered saline injection [normal (N) groups]. Food intake, body weight gain, and liver weight were reduced by bearing hepatoma (N-CO vs. H-CO), but FO as compared with CO had no significant effects on these parameters in either the normal (N-CO vs. N-FO) or the hepatoma-bearing (H-CO vs. H-FO) state. Feeding the FO diet did not influence hepatoma weight, although a slight (11%) decrease was seen (H-CO vs. H-FO). The liver TG content was decreased by both bearing hepatoma (N-CO vs. H-CO) and feeding FO (N-CO vs. N-FO), whereas the liver PL and Ch contents were not affected by either diet or hepatoma. The hepatoma PL content was increased, but the TG and Ch contents were not affected by feeding FO (H-CO vs. H-FO).

Changes in the serum lipid levels are illustrated in Figure 1. The serum TG, PL, NEFA, T-Ch, and (VLDL + LDL)-Ch levels were significantly higher in the hepatoma-bearing rats than in the normal rats, irrespective of dietary oils (N-CO vs.

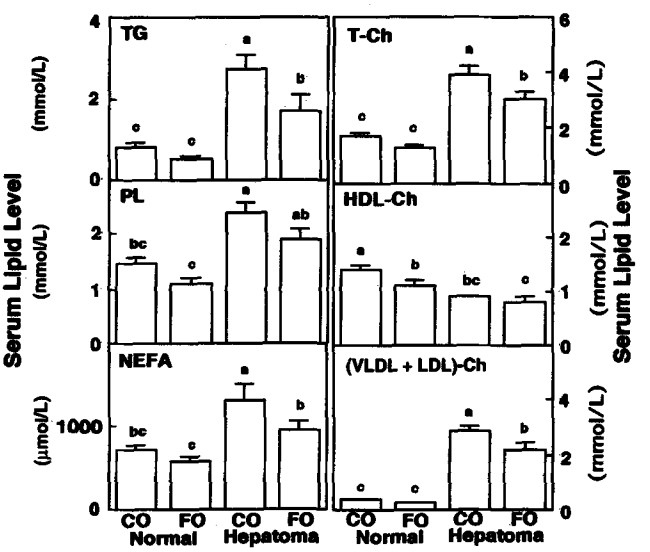

FIG. 1. Effects of types of dietary oils on serum lipid levels in normal and in hepatoma-bearing rats. Each value represents the mean of six rats. Vertical bars indicate standard errors. When the F value for either hepatoma state (S) effect, dietary oil (O) effect, or both interaction (S × O) was significant at $P < 0.05$, the means were inspected by Duncan's multiple-range test. Values not sharing a common letter are significantly different at $P < 0.05$. The F values for S and O of triglyceride (TG), phospholipid (PL), nonesterified fatty acid (NEFA), total cholesterol (T-Ch), total cholesterol of high-density lipoprotein (HDL-Ch) and (VLDL + LDL)-Ch (the difference between T-Ch and HDL-Ch) level were all significant at $P < 0.05$. CO, corn oil; FO, fish oil.

H-CO, N-FO vs. H-FO). The reductive effect of FO on these lipid levels was weak in the normal state (N-CO vs. N-FO). However, FO, as compared with CO, significantly suppressed the serum TG, NEFA, T-Ch, and (VLDL + LDL)-Ch levels but did not significantly suppress the PL level in the hepatoma-bearing state (H-CO vs. H-FO). Conversely, the serum HDL-Ch level was significantly lower in the hepatoma-bearing state than in the normal state, irrespective of dietary oils (N-CO vs. H-CO, N-FO vs. H-FO). In the normal state, FO more than CO significantly decreased HDL-Ch level (N-CO vs. N-FO), although FO did not further decrease the HDL-Ch level in the hepatoma-bearing state (H-CO vs. H-FO).

Table 3 shows activities of LPL, HTGL, and HSL in adipose tissue and in other tissues. The LPL activity in adipose tissue, cardiac muscle, and gastrocnemius, and the HTGL activity in the liver were notably lower in the hepatoma-bearing state than in the normal state (N-CO vs. H-CO, N-FO vs. H-FO). Dietary FO, as compared with CO, had no significant influence on these lipase activities in either the normal or the hepatoma-bearing state, except for the LPL activity of adipose tissue in the normal state that was significantly enhanced by feeding dietary FO (N-CO vs. N-FO). When LPL activity was expressed as U per whole tissue, the enzyme activity in adipose tissue was also lower in the hepatoma-bearing state than in the normal state. However, the stimulatory action of FO on LPL activity weakened, especially in the normal state. The HTGL activity in hepatoma was unaffected by dietary FO (H-CO vs. H-FO). In contrast to the LPL activity, the adipose tissue HSL activity was significantly enhanced by bearing hepatoma (N-CO vs. H-CO). Dietary FO showed no significant effect on the HSL activity in comparison with dietary CO in the normal and in the hepatoma-bearing states (N-CO vs. N-FO, H-CO vs. H-FO).

FA oxidation and lipid (FA and Ch) syntheses by host liver slices are shown in Table 4. The production of $^{14}CO_2$ was unchanged among the four groups. However, the production of [^{14}C]ketone bodies and, hence, total FA oxidation in the hepatoma-bearing state, were significantly higher than in the normal state (N-CO vs. H-CO, N-FO vs. H-CO). Dietary FO showed no significant enhancement in the production of [^{14}C]ketone bodies and total FA oxidation in both the normal and the hepatoma-bearing states, although slight increases (18–20%) were observed (N-CO vs. N-FO, H-CO vs. H-FO). Neither hepatoma nor dietary FO affected FA synthesis by liver slices. On the other hand, the hepatic Ch synthesis was significantly stimulated by hepatoma implantation (N-CO vs. H-CO), and this rise in the hepatoma-bearing state was suppressed by dietary FO when compared with dietary CO (H-CO vs. H-FO).

Fecal steroid excretion is also shown in Table 4. Dry weight of feces was significantly lower in the hepatoma-bearing state than in the normal state (N-CO vs. H-CO, N-FO vs. H-FO). Excretion of both neutral sterols and bile acids was reduced by bearing tumor (N-CO vs. H-CO). Dietary FO as compared with CO showed no significant effect on their excretion, except for neutral sterols in the normal state where dietary FO significantly suppressed their excretion into feces (N-CO vs. N-FO).

DISCUSSION

Donryu rats receiving a subcutaneous implantation of ascites hepatoma line of AH109A cells exhibited hyperlipidemia, and dietary FO as compared with CO was demonstrated to reduce the hyperlipidemia in these animals. The HDL-Ch level was decreased slightly but significantly by hepatoma implantation, but dietary FO did not further accelerate the hepatoma-induced reduction of the HDL-Ch level despite the fact that FO decreased the serum level of this antiatherogenic lipoprotein in the normal state. The hypocholesterolemic and hy-

potriglyceridemic actions of FO were prominent in the tumor-bearing state than in the tumor-free state (Fig. 1). The ingestion of FO may, therefore, possibly have a similar effect in patients with cancer-related hyperlipidemia.

The present results show that at least two factors, hepatic cholesterogenesis and fecal steroid excretion, are responsible for the induction of hypercholesterolemia by AH109A implantation. The Ch synthesis by liver slices from the hepatoma-bearing rats was threefold greater than those from the normal rats (Table 4). This finding is in good agreement with our previous results showing cholesterogenesis *in vivo* from ^3H_2O in the liver of hepatoma-bearing rats was twice that in the liver of normal rats (32). Another factor, fecal steroid excretion, was reduced by hepatoma bearing. Dietary FO suppressed the hepatoma-induced enhancement of host liver cholesterogenesis, while the oil demonstrated no influence on the hepatoma-induced reduction of steroid excretion. The CO and FO used here are actually in the TG form, and there was little neutral 3β-hydroxysterols in both oils and, hence, diets, i.e., less than 0.05% in both diets. In rats fed Ch-enriched (0.5%) diets, β-sitosterol was reported to increase fecal excretion of neutral sterols at the dietary level of 0.5% or more (33). In the present study, such small amounts (less than 0.05%) of dietary neutral sterols, Ch and β-sitosterol, are therefore unlikely to be responsible for the results. The hypocholesterolemic effect of dietary FO in the hepatoma-bearing state may thus mainly be due to its inhibitory action on hepatic cholesterogenesis.

Increased FA mobilization from peripheral adipose tissue and decreased TG clearance from the blood circulation are likely to contribute to the hepatoma-induced hypertriglyceridemia. The serum NEFA level was elevated in hepatoma-bearing rats (Fig. 1), as has been reported in rats (13) and in cancer patients (34). The high level of serum NEFA in the hepatoma-bearing state coincides with the rise in adipose tissue HSL activity (Table 3). There was a positive correlation between the serum NEFA and TG levels ($r = 0.84$, $P < 0.01$, $n = 12$ in N-CO and H-CO groups). The rise in the serum NEFA level would augment a supply of fatty acyl-CoA to be esterified to PL as well as TG, and hence formation and secretion of VLDL from the liver, although a portion of the increased fatty acyl-CoA might be rapidly oxidized in the livers of the hepatoma-bearing rats (Table 4). Tissue LPL and HTGL activities decreased in the hepatoma-bearing state, possibly leading to a reduced clearance of serum TG and, hence, to hypertriglyceridemia. The reduction of LPL activity is also observed in animals bearing some other tumors (22,35). Dietary FO suppressed FA mobilization and tended to enhance FA oxidation in the livers of hepatoma-bearing rats. The hypotriglyceridemic action of dietary FO is suggested to be a result of integration of these diverse effects in the animals.

Intriguing questions arise from these results: Why do the HDL level, LPL activity, and fecal steroid excretion decrease in the hepatoma-bearing state, and why does cholesterogenesis increase in the host liver of hepatoma-bearing rats? Further studies are needed to answer these questions and to clarify the exact mechanisms involved in the action of FO.

ABSTRACT: Previous studies indicate a suppressive influence of fish oils on rodent malaria. The present work was carried out to study (i) the dose–effect relation between dietary fish oils and lethality of primary malaria infection in mice; (ii) the modifying influence of vitamin E; and (iii) the effect of previous fish oil feeding on parasitemia and lethality of a rechallenge infection. For two or four weeks, groups of weanling male mice were fed a standard laboratory diet or one of eight purified diets containing various amounts of fish oil (providing 6–21% of energy). The diets were prepared with and without vitamin E. After the two- or four-week feeding period, the mice were injected intraperitoneally with *Plasmodium yoelii yoelii*-infected erythrocytes. Six months after the primary infection (four months after discontinuing fish oil feeding), the surviving mice were again injected intraperitoneally with parasitized red blood cells (or even better—erythrocytes, erythrocytes are used elsewhere). Primary malaria infection was lethal in mice fed standard diet alone or with fish oil and vitamin E added. In contrast, feeding a fish oil-based diet without vitamin E improved survival to at least 70% if the mice had been fed these diets for four weeks. Protection against malaria did not seem to be related to the fish oil dose used. Regardless of the previous fish oil dose, all the mice surviving the primary infection survived the rechallenge infection with low parasitaemias. The results suggest that the prooxidant nature of highly unsaturated fatty acids in fish oils may beneficially influence malaria infection, and may also increase the resistance against reinfection for some time after discontinuing fish oil intake.

Lipids 30, 437–441 (1995).

Malaria is a serious global threat to human health. The need for effective forms of treatment and prophylaxis against the disease is of great interest. The situation is worsening with increasing parasite and mosquito vector adaptation to drugs and insecticides (1). The suppressive action of a vitamin E-deficient n–3 fatty acid diet on plasmodium infection in mice has been known since 1957 (2–4). Vitamin E reversed the suppressive action of fish oils, suggesting increased lipid peroxidation as a mechanism behind the effect. Cream rich in saturated fatty acids, and olive oil rich in monounsaturated fatty acids had no effect on survival or on parasitemia.The protection against malaria rechallenge by a 5% menhaden oil (MO)-enriched vitamin E-deficient diet was reported in abstract form by Ager *et al.* (5). The authors observed that once mice were cured of malaria by feeding this prooxidant diet, the animals were largely protected against malarial rechallenge.

The long-chain polyunsaturated n-3 fatty acids (PUFAs), e.g., eicosapentaenoic acid (EPA, 20:5n-3) and docosahexaenoic acid (DHA, 22:6n-3), are important components of the phospholipids in cell membranes. Intake of fish oil rich in n-3 fatty acids results in increased amounts of these fatty acids in plasma and in cell membranes. When exposed to oxygen, PUFAs easily give away one hydrogen atom, thereby forming free radicals which may start a free radical chain reaction. Vitamin E in cell membranes stops the peroxidation of long- chain highly unsaturated fatty acids (6).

The purpose of the present work was to study (i) the dose–effect relation between dietary fish oils and lethality of primary malaria infection in mice; ii) the modifying influence of vitamin E; and iii) the effect of previous fish oil feeding on parasitemia and lethality of a rechallenge infection.

MATERIALS AND METHODS

Groups of 15 weanling, three-week-old male outbred CD-1 Swiss albino mice were fed one of eight purified diets (Table 1) or a Purina Chow (Formulab Chow 5008^{R}, Ralston Purina Co., St. Louis, MO) for two or four weeks. The fat in the purified diets was either MO 4 g/100 g plus corn oil 1 g/100 g [diet MO], or the diets containing different amounts of EPAX fish oil concentrate (2.4 or 8 g/100 g) plus corn oil (0.5,1.0, or 2.0 g/100 g). MO contained 9.1% w/w DHA and 11.0% EPA, obtained from National Marine Fisheries service (U.S. Department of Commerce, Charleston, SC). The fish oil triglyceride EPAX 3000 contained 11.4% DHA and 17.8% EPA, and was from Pronova Biocare A/S (Sandefjord, Nor-

[a]AIN-76 salt mix without selenium, diet supplemented with 0.1 mg selenium per kg as sodium selenite.
[b]AIN-76A vitamin mix without vitamin E (VE) diet also contained 20 mg para-aminobenzoic acid per kg.
[c]Added as d-alpha-tocopheryl acetate (equivalent to 0.0035 g of d-alpha-tocopherol).
[d]MO (menhaden oil) contained 11.0% eicosapentaenoic acid (EPA) and 9.1% docosahexaenoic acid (DHA) as triglyceride, supplied by National Marine Fisheries Service, U.S. Department of Commerce (Charleston, SC).
[e]Stripped of vitamin E.
[f]EPAX contained 11.43% EPA and 17.81% DHA as triglyceride, supplied by Pronova A/S (Sandefjord, Norway).
[g]DL-methionine.
[h]Added as choline dihydrogen citrate.

way). The purified diets were prepared with and without d-alpha tocopherylacetate, referred to as vitamin E, to obtain eight purified diets (Table 1). The antioxidant tertiary butylhydroquinone (200 ppm) was added to the diets to prevent lipid peroxidation, and the diets were stored at 4°C.

Protein, carbohydrate, and fat provided 20, 69, and 11% of energy in the MO and the 4% EPAX diets. Corresponding energy distribution in the 2% EPAX diets was 20, 74, and 6 and 19, 60, and 21% in the 8% EPAX diets. Energy densities (MJ/100 g) were 1.70 (MO and 4% EPAX diets), 1.65 (2% EPAX diets), and 1.81 (8% EPAX diets). The mice were kept in metal-topped plastic cages and had free access to their diets and drinking water. The room housing the mice was maintained at 24°C and 66% relative humidity with a 12-h light/dark cycle. Mice were maintained according to the National Research Council's guide for the care and use of laboratory animals at the Center for Tropical Parasitic Diseases, Department of Microbiology and Immunology, University of Miami, (Miami, FL).

After two or four weeks, ten of the mice in each group were injected intraperitoneally with 5×10^4 red blood cells parasitized with *Plasmodium yoelii yoelii* (primary infection study). At the same time five of the mice in each group were killed, and plasma was saved for vitamin E analyses. Plasma vitamin E concentrations were analyzed by high-performance liquid chromatography using the procedure of Bieri *et al.* (7).

Previous experience has demonstrated that 60 days postinfection is sufficient to judge the parasitemia and survival of infected mice (3). At that time, samples of tail blood were examined for parasites with a light microscope by the following procedure: we examined 100 erythrocytes if parasitemia was 10–100%, 200 erythrocytes if parasitemia was 5–10%, 2,000 erythrocytes if parasitemia was 0.5–5% (until ten parasites were found), 2,000–20,000 erythrocytes if parasitemia was 0.01–0.45% (until one parasite was found), and 20,000 erythrocytes without a parasite before the mouse was considered free of parasites.

The mice were maintained on the fish oil diets for another eight weeks; then the fish oil supplementation was stopped and the diet changed to a standard Chow diet for four months (Formulab Chow 5008^R, Ralston Purina Co.) Still on the standard Chow diet, the mice surviving after the primary infection were again reinjected intraperitoneally with 5×10^4 red blood cells parasitized with *P. yoelii yoelii* (Rechallenge trial). The chloroquine sensitive *P. yoelii yoelii* was originally obtained from Dr. Richard Jacobs in 1973 and has been routinely passed through *Anopheles stephensi* in the laboratory of Dr. Arba L. Ager (Miami, FL) to maintain viable gametocytes.The origin of this CS line is described in detail by Rane and Kinnamon (8).

Statistics. Biochemical and parasitemia data were analyzed by analysis of variance and Duncan's multiple range test (9). The survival data were analyzed by the Wilcoxon rank test (10). For analysis of vitamin E data, we used Student's *t*-test to estimate the difference between means.

RESULTS

Primary infection. To evaluate the dose–effect of fish oils on the survival rate following a primary infection with malaria, mice were pre-fed Chow or vitamin E-deficient diets with various concentrations of fish oils. Primary malaria infection was lethal in mice fed Chow or fish oil diets with vitamin E (Table 2). In contrast, feeding fish oil minus vitamin E improved survival to at least 70% in all mice fed fish oil diets for four weeks. Increasing the fish oil dose above 2% did not seem to increase protection. A shorter pre-feeding interval (two weeks) was generally less effective than four weeks of prefeeding, but the global difference was not statisistically significant. Table 3 shows the serum vitamin E concentration after the primary feeding period. Groups fed vitamin E-deficient fish oil diets had appreciably lower values ($P < 0.05$) than groups fed Chow, or fish oil diets supplemented with vitamin E.

Rechallenge survival and parasitemia. Prefeeding Chow

TABLE 2
Total Sixty-Day Survival of Mice in Malaria Primary Infection[a]

Diet	Vitamin E (% of diet)	Two weeks prefeeding (survivors/total)	Four weeks prefeeding (survivors/total)
Chow		0/10	0/10
4% Menhaden oil[b]	0	4/10	8/10

	Control	0/10	45 ± 6

[a]Mice surviving the primary infection reported in Table 3 were fed fish oil diets (see Materials and Methods section) for two months, and then Chow diet for four months. The animals were then again injected intraperitoneally with *Plasmodium yoelii yoelii*-infected erythrocytes. Control mice were fed Chow.
[b]Menhaden oil contained 11% EPA and 9% DHA.
[c]EPAX contained 18% EPA and 12% DHA.

offered no protection against malaria (Table 4). In contrast, all the surviving animals from the primary infection survived a malaria parasite rechallenge after six months. Whereas Chow prefeeding resulted in a high parasitemia, all the fish oil groups had low parasitemias of 0.1–0.4%. All of the mice that had, previously received fish oil were free of parasites by day 13 after infection. The survival and parasitemia in the rechallenge infection seemed to be independent of the dose of fish oil fed during the primary infection.

DISCUSSION

This study confirms a preliminary report of the protective effect of vitamin E-deficient, fish oil-enriched diets on parasitemia and survival during reinfection after a primary *P. yoelii yoelii* infection in mice (5). In addition, the present work demonstrates that the antimalarial effect of fish oil can persist even four months after stopping the fish oil diet, and that the effect was not clearly dose-related in the range studied (i.e., 2–8%). The present results do not, however, elucidate the mechanisms involved in the persistent malaria-protective influence of fish oils.

The lipid composition of the cell membranes reflects dietary fatty acids (11). Moreover, cell membranes of the malaria parasite are greatly influenced by the diet of the host. Conceivably, membranes formed with a surplus of PUFA and a lack of vitamin E may be more susceptible to lipid peroxidation than cell membranes formed under conditions with less PUFA available and more vitamin E. In this context, PUFA of fish oil are especially peroxidation-prone in the absence of vitamin E. It would appear, therefore, that lipid peroxidation is at least partly involved in the observed effects. This suggestion is supported by the fact that vitamin E abolished the protective influence of fish oils in the primary infection trial. Thus, the protective effect of fish oils apparently is not caused by the intact fatty acids of fish oil *per se*. Whether vitamin E supplementation can also modify a rechallenge infection was not investigated in this study.

The course of the malaria infection requires a rapid regeneration of parasites with a high degree of plasmodial membrane biosynthesis. It was demonstrated in mice at a late stage of infection that the phospholipid content of *Plasmodium vinckeii* parasitized mouse erythrocytes was elevated more than fourfold compared to uninfected cells, with a relative increase in the ratio of unsaturated-to-saturated fatty acids in the phospholipids (12). Most of this increase could be attrib-

uted to the presence of parasite membranes. There was also a decrease in the vitamin E content of the infected erythrocytes that would act synergistically to increase the parasite membrane susceptibility to peroxidative damage.

In vitro studies have demonstrated that increasing concentrations of DHA have an increasing parasitolytic effect on a Chloroquine-sensitive Tanzanian parasite strain (F 32) of *Plasmodium falciparum* (13). Full growth inhibition was obtained with 0.05 mM or higher DHA concentrations in the medium. *Plasmodium falciparum* is the parasite that causes the most lethal type of malaria in humans.

The strong inhibition of malaria parasite multiplication by fish oil, or *in vitro* by pure ν–3 fatty acids, may have some similarities to the inhibiting effect of PUFA on the growth of human hepatoma cells (14,15). In these latter studies, it was suggested that the growth inhibitory effect depended on lipid peroxidation as there was a parallel formation of thiobarbituric acid reactive substances, an index of PUFA peroxidation. Furthermore, PUFA-induced growth inhibition was strongly antagonized by the antioxidant vitamin E. Also, increasing the albumin concentration prevented growth inhibition by PUFA and the appearance of thiobarbituric acid reactive substances. Although it is well known that albumin is a carrier of fatty acids, its role to protect against growth inhibition by PUFAs may also relate to its extracellular antioxidant effects (16).

Related to the hypothesis that lipid oxidation *in vivo* can affect the clinical expression of malaria are the findings that grossly undernourished nomads from sub-Saharan districts developed severe malaria when they were refed with relief grain and cereals which are high in vitamin E and protein, i.e., making a favorable situation for the malaria parasite (17). Moreover, refeeding with grain exacerbated latent malaria in undernourished adults and precipitated severe cerebral malaria in young undernourished children (18). As one would hope that refeeding would eventually increase the resistance against infectious and parasitic diseases, some of these unexpected findings could be attributed to the antioxidant influence of vitamin E protecting the parasites or to increased ability to carry on protein synthesis by the parasites, brought about by feeding relief grain with its several nutrients. Interestingly, infants from Papua New Guinea with riboflavin deficiency had lower malaria parasite densities than infants with normal riboflavin status (19). This finding is consistent with results from rodent malaria studies (20), and with the idea that both parasite and host nutrition can be closely interrelated.

The severity and duration of malaria attacks depend on many factors, including the nutritional status of the host and the virulence of the infective strain. The most important modifying factor, however, is the development of resistance in the infected individual. It is well known that a child surviving to the age of 5–6 years in areas with very high transmission of *P. falciparum* will have achieved a high degree of resistance to the lethal effects of the infection. Specific malaria antibodies have been demonstrated in *P. yoelii yoelii* infections in rodents (21). Similar findings have been made in simian and in human malaria. It remains to be established, however, to what extent immunological resistance was part of the protection against the rechallenge infection observed in the present study. Our study demonstrates that the malaria protection in the rechallenge infection after four months on a standard laboratory diet is independent of dietary fish oil concentration in the primary feeding period if the dose is above 2%. It seems likely that the erythrocyte concentration of n-3 fatty acids would be very low after four months without fish oil in the diets (11). In contrast, standard antimalarial therapy is associated with substantially depressed antibody levels (22), and the widespread use of antimalarials has not been associated with protection against rechallenge infection.

The present diet study in mice supports the contention that there is a connection between the severity of a malaria infection and the state of nutrition. It would appear that a nontoxic nutritional approach with n-3 fatty acid supplements could beneficially influence the course of malaria infection and increase the resistance against a reinfection. Further research is necessary to support this suggestion and to determine the mechanism of this effect of fish oil.

ACKNOWLEDGMENTS

The experimental work of the study was performed at the Center of Tropical Parasitic Diseases (Miami, FL) under the guidance of Dr. Arba L. Ager. We also thank Dr. Orville A. Levander, Vitamin and Mineral Nutrition Laboratory (Beltsville, MD), for scientific support with the planning and performance of the study. This work was supported by Pronova Biocare A/S (Sandefjord, Norway).

Dietary Deficiency of Docosahexaenoic Acid Impairs Vision at Low Light Intensities in Juvenile Herring (*Clupea harengus* L.)

Michael V. Bell[a,*], Robert S. Batty[b], James R. Dick[a], Karen Fretwell[b,1], Juan Carlos Navarro[a,2] and John R. Sargent[a]

ABSTRACT: In the retina of herring (*Clupea harengus* L.), rods are recruited from about 8 wk after hatching, and from this time there is a linear relationship between the number of rods in the photoreceptor cell population and the content of di22:6n-3 molecular species of phospholipids. Juvenile herring were reared from four weeks' post-hatching for 15 wk on either *Artemia* nauplii deficient in 22:6n-3 or on enriched *Artemia* nauplii containing 4.3% 22:6n-3. The visual performance of the fish was then determined at three light intensities (0.01, 0.1, and 1.0 lux) by observing their frequency of striking at live *Artemia* nauplii using infrared video recording. Herring reared on the diet containing no 22:6n-3 were less active predators, especially at the lowest light intensity where very few strikes were observed. The eyes of these fish contained greatly reduced levels of di22:6n-3 molecular species of total phospholipid, 2.1% vs. 12.0% in fish supplemented with 22:6n-3. The contribution of saturated and monounsaturated fatty acids in the molecular species of phosphatidylethanolamine (PE), phosphatidylserine (PS), and phosphatidylcholine (PC) was virtually unchanged, while 20:5n-3 and 22:5n-3 largely replaced 22:6n-3. There was an almost complete disappearance of di22:6n-3 PC, while the amounts of di22:6n-3 PE and PS fell by 18.1 and 20.6% to 2.7 and 7.6%, respectively. The dipolyunsaturated molecular species di20:5n-3, 20:5n-3/22:5n-3, and di22:5n-3 made up a substantial part of the deficit. We conclude that a dietary deficiency of 22:6n-3 during the period early in rod development impairs visual performance such that the fish can no longer feed at low light intensities.

Lipids 30, 443–449 (1995).

In terrestrial vertebrates, docosahexaenoic acid (22:6n-3) is concentrated in neural tissue, especially in retina and brain (1,2) and testes (3), and this is the case also in marine vertebrates, including fish, even though fish tissues in general are richer in 22:6n-3 than mammalian tissues. Vertebrate retinae contain large amounts of di-docosahexaenoyl (22:6n-3/22:6n-3) glycerophospholipid which is concentrated in rod outer segment membranes (1,4,5). However, the concentration of 22:6n-3 in the retina of fish is particularly impressive, e.g., in cod (*Gadus morhua*) 71.8% of phosphatidylethanolamine (PE), 59.7% of phosphatidylserine (PS), and 29.3% of phosphatidylcholine (PC) occurs as 22:6n-3/22:6n-3 molecular species (6). The amounts in the retina of herring are slightly lower, equivalent to 30.6% of total glycerophospholipid in adult fish (7). Therefore, there is strong circumstantial evidence that 22:6n-3 is essential for neural function.

Docosahexaenoic acid (22:6n-3) is an essential fatty acid in carnivorous species of fish and other animals which appear to have lost the Δ5 desaturase and cannot therefore elongate and desaturate dietary precursor C_{18} polyunsaturated fatty acids (PUFA) to C_{20} PUFA (8–10). It is now believed that the final step in the formation of 22:6n-3 in mammals involves Δ6 desaturation of 24:5n-3 and subsequent chain-shortening of 24:6n-3 (11), and the same pathway probably operates in fish. Furthermore, in some species the ability to synthesize 22:6n-3 from dietary precursors at times of high demand during neural development may be inadequate, and 22:6n-3 deficiency at this time causes impairment of visual and cognitive abilities in young animals (12,13). Recent evidence suggests this is also the case in human infants, especially preterm infants, and that such deficiencies lead to visual and cognitive subperformance (14–16). This has led to the recommendation in the United Kingdom that infant formula feeds should contain 22:6n-3 (17).

Induction of 22:6n-3 deficiency in experimental animals is difficult since 22:6n-3 is retained avidly in neural tissues (12,13), and experiments to test visual and behavioral subper-

formance are difficult to devise, especially with a view to separating effects on vision (performance of retina) and cognition (performance of brain) (18). The free-swimming larvae of marine fish offer a number of advantages over fetal mammals for studies on the effects of 22:6n-3 deficiency. Their small size and rapid growth from first-feeding mean that they have a very large demand for 22:6n-3 which must be met directly from the diet, and deficiencies of 22:6n-3 are thus easy to induce. At hatching, the larvae of many species of marine fish have almost pure cone retinae with rods appearing later in development. In herring larvae, significant numbers of rods are recruited to the photoreceptor cell population progressively from about 8 wk after hatching (length 2.5 cm) to maturity (length 25–30 cm) to give a rod/cone ratio of 15–20:1 (19). The length of the fish is a good indicator of rod development (19). It has been shown that the amount of di22:6n-3 PE, PS, and PC in herring eyes correlates with the proportion of rods in the photoreceptor population and that the pure cone retina of larvae contains about half the amount of di22:6n-3 phospholipid in adult retina (7). The present study sought to reduce the content of di22:6n-3 phospholipid in the eyes of young herring by feeding a diet lacking 22:6n-3 and to determine whether this affected the visual performance of the fish as measured by their ability to detect and strike at prey at different light intensities chosen specifically to test cone vision and rod (scotopic) vision.

MATERIALS AND METHODS

Experimental animals. Spring spawning herring were caught in the Firth of Clyde, Scotland. The mixed progeny from artificially fertilized eggs from twelve females and six males were reared in 450-L tanks containing seawater with a salinity of 30 to 32‰. Ambient seawater temperatures were used and rose from 8.5 ± 0.4°C during the embryo stage to 13.1 ± 0.7°C during the last week of the experiment. Larvae were fed initially from eight days' post-hatching on nauplii of *Artemia* sp. (AF grade; Artemia Systems, Baasrode, Belgium). After 20 days' feeding on this diet, larvae were transferred to the experimental diets which consisted of two strains of San Francisco Bay *Artemia* nauplii with relatively high or low n-3 fatty acid contents, the former supplemented with n-3 PUFA to provide 4.3% of fatty acids as 22:6n-3 and the latter supplemented with coconut oil giving no 22:6n-3 (Table 1, see Ref. 20 for details). Two replicate tanks of larvae were fed on each of these diets for a further 102 d before sampling.

Chemicals and solvents. Phospholipase C from *Bacillus cereus* was purchased from Boehringer Corporation (London) Ltd. (Lewes, East Sussex, England). Oxalyl chloride and anthracene-9-carboxylic acid were supplied by Aldrich Chemical Co. (Gillingham, Dorset, England). All other chemicals and biochemicals were purchased from Sigma (Poole, Dorset, England), and solvents of high-performance liquid chromatography (HPLC) grade were obtained from Rathburn Chemicals (Walkerburn, Peeblesshire, Scotland).

Measurement of visual performance. Twenty fish were sampled at random from each tank, and their feeding behavior recorded in tanks 59 cm in diameter using an infrared video recording system with strobed infrared illumination (21). Infrared illumination was provided by a tungsten halogen bulb and infrared transmitting filter with a sharp cut-off at 700 nm which is outside the reported range of spectral sensitivity for larval and adult herring (22,23) or of any other marine fish species (24). Diffuse visible light was provided by a tungsten halogen lamp through a fiber-optic light guide fitted with neutral density filters and reflected off a white background 2 m above the tanks. The light intensity was measured at the water surface with an EEL micro photometer (Evans Electroselenium Ltd., Halstead, Essex, United Kingdom). Three replicate five-minute experiments were performed with groups of 20 fish from each tank. Three visible light intensities of 0.01, 0.1, and 1 photopic lux (equivalent to 50, 500, and 5000 $\mu W \cdot m^{-2}$) were used with different randomly chosen groups of 20 fish. In order to ensure complete adaptation to the low light intensities used, the fish were first dark-adapted by keeping them in complete darkness overnight. They were not fed during this time (approximately 16 h), and their guts were empty at the start of the experiment. They were then adapted to the experimental light intensity for 30 min before introducing prey (*Artemia* sp. nauplii at a density of 1000 L^{-1}) and commencing video recording. The larvae were returned to their rearing tanks after the behavior experiments. Subsequent frame-by-frame analysis of the video recordings (20 ms intervals) revealed the total number of strikes made at prey per fish per minute. The single camera recording system allowed analysis in only two dimensions, and therefore successful and unsuccessful feeding strikes could not be distinguished reliably.

Lipid extraction and analysis. Twenty herring larvae were anaesthetized in 0.02% (wt/vol) ethyl 3-aminobenzoate methane sulphonate (MS222), their lengths measured, and their eyes removed. The eyes and carcases were immediately frozen in liquid nitrogen and subsequently stored at −70°C. Total lipids were extracted from the eyes of individual fish by sonication in 2 mL of chloroform/methanol 2:1 (vol/vol) containing 0.01% (wt/vol) butylated hydroxytoluene as antioxidant and a Folch extract prepared as previously described (25). Samples were stored at −20°C under nitrogen between

preparative procedures. The fatty acid composition of total eye lipid of five fish matched for size from each tank was determined by gas–liquid chromatography of fatty acid methyl esters using a Packard 436 gas chromatograph fitted with a fused silica capillary column (50 m x 0.25 mm) coated with FFAP phase (S.G.E., Milton Keynes, United Kingdom) using hydrogen as carrier gas (26).

Molecular species analysis. To determine the di22:6n-3 content of total phospholipid, neutral lipid was removed by thin-layer chromatography (TLC) on high-performance TLC (HPTLC) silica gel 60 plates (Merck, Darmstadt, Germany) in hexane/diethyl ether/acetic acid (70:30:1, vol/vol/vol) and the phospholipid remaining on the origin scraped from the HPTLC plate. The glycerophospholipid was hydrolyzed with phospholipase C (*B. cereus*) [Boehringer Corporation (London) Ltd.] and the 9-anthroyl derivatives prepared as described previously (7,27). The eyes from ten fish matched for size from each tank were analyzed.

PC, PE, and PS were prepared from 100 μg of total lipid by HPTLC in methyl acetate/propan-2-ol/chloroform/methanol/0.25% (wt/vol) aq. KCl (25:25:25:10:9, by vol) (28). The edges of the bands were visualized with iodine, and the remaining sample scraped from the plate before hydrolyzing with phospholipase C as before. The eyes from two fish matched for size (4.0 cm) from each tank were analyzed. Molecular species were separated by HPLC on an Ultrasphere C18 column (25 x 0.46 cm, 5 μm particle size) (Beckman Instruments U.K. Ltd., High Wycombe, United Kingdom) using isocratic elution with acetoni-trile/propan-2-ol, 7:3 (vol/vol) at a flow rate of 1.0 mL/min and methanol/propan-2-ol, 4:1 (vol/vol) at a flow rate of 1.0 mL/min to separate any unresolved peaks. Peaks were detected using a Waters (Watford, United Kingdom) 470 scanning fluorescence detector (excitation 360 nm, emission 460 nm) and quantified with a Shimadzu CR3A recording integrator (Tokyo, Japan). Peaks were identified with reference to standard lipids and samples of known composition (6,7,29).

Data analysis. The behavioral data and the total di22:6n-3 phospholipid content were analyzed with a SAS statistical package by repeated measures multivariate two-way analysis of variance (ANOVA). The molecular species composition of individual lipid classes was analyzed by one-way ANOVA.

RESULTS

At the end of the experimental period, there was no significant difference ($P = 0.3366$) in the size of fish fed the two diets or those used in the behavior experiments. Lengths ranged from 2.5–4.9 cm with mean sizes in the replicate tanks of 3.48 ± 0.60 cm and 3.68 ± 0.41 cm for the 22:6n-3-supplemented fish and 3.68 ± 0.37 cm and 3.87 ± 0.58 cm for the 22:6n-3-deficient fish.

The threshold light intensity for visual feeding by dark-adapted adult herring is 0.01 lux (30). At this light intensity, there was a significant difference in the behavior of the fish reared on the two dietary regimes (ANOVA, $P = 0.0044$). Fish reared on the 22:6n-3-supplemented diet fed well, but almost none of the fish reared on the diet lacking 22:6n-3 attacked the prey (Fig. 1). At a light intensity of 0.1 lux, the threshold for larvae (23) before rods develop in the retina, the fish deficient in 22:6n-3 still fed less well, but the difference between dietary treatments was similar to that between replicate tanks and was no longer significant. There was little difference in feeding performance between fish reared on the two diets at 1 lux.

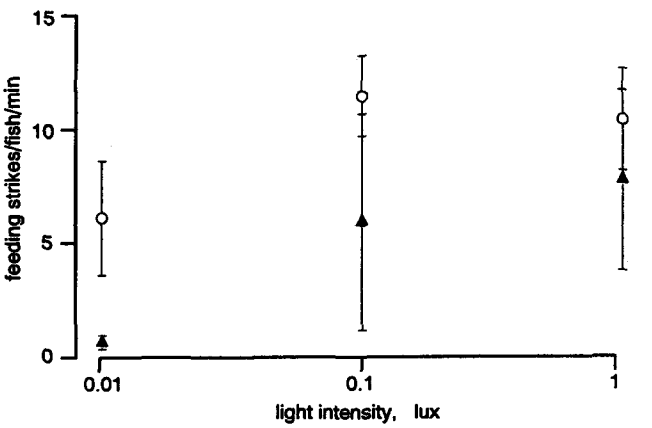

FIG. 1. The effect of light intensity on feeding behavior of herring larvae reared on diets either supplemented with 22:6n-3 (O) or lacking 22:6n-3 (▲). *Symbols represent means ± 95% confidence intervals (n = 6) for* three replicate behavior experiments for each of two rearing groups on each dietary treatment.

Fatty acid and molecular species analysis of the lipids from the eyes of fish from the replicate tanks showed only small differences in composition, none of which were significant ($P > 0.05$). Therefore, in the following presentation, the data for replicate tanks has been combined. Fish reared on the diet lacking 22:6n-3 showed a large decrease in the 22:6n-3 content of total lipid from eyes with concomitant increases in

[a]Significantly different from the 22:6n-3-supplemented fish at [a]$P < 0.0001$, [b]$P < 0.001$, [c]$P < 0.01$. Data are means ± 1 SD of eyes from four fish (two from each replicate tank) matched for size; trace = <0.1%. The order of fatty acids does not imply any stereospecificity on the glycerol. The n-9 and n-7 isomers of monounsaturated fatty acid (MUFA) were not resolved. 20:4 Fatty acid was the n-6 isomer and 22:5 the n-3 isomer. Molecular species containing 18:2n-6 could not be resolved from those containing 22:5n-3. However, 22:5n-3 was two to three times more abundant than 18:2n-6 in both dietary groups (4.0 ± 0.4% vs. 1.8 ± 0.3% and 7.6 ± 0.4% vs. 2.6 ± 0.3% in the 22:6n-3-supplemented and -deficient fish, respectively). PUFA, polyunsaturated fatty acid; SFA, saturated fatty acid.

20:5n-3 and 22:5n-3 ($P < 0.0001$, all cases) (Table 2). The total glycerophospholipids from eyes of fish on the diet lacking 22:6n-3 had only 17.6% of the di22:6n-3 content of control fish ($P < 0.0001$) (Table 2). The amounts of 18:1, 18:2n-6 and 20:4n-6 were slightly but significantly ($P < 0.0001$) elevated in the eyes of the 22:6n-3-deficient fish (Table 2).

The changes in the n-3 PUFA composition of the lipid from eyes were reflected in large changes in the molecular species of PC, PE, and PS (Table 3). In the diPUFA class of molecular species, di22:6 PC fell from 5.0 to 0.3%, di22:6 PE from 20.8 to 2.7%, and di22:6 PS from 28.2 to 7.6% (Table 3). There was little change in the amounts of 20:5/22:6 and 22:5/22:6 in all three lipid classes, while increases in 20:5/20:5, 20:5/22:5, and 22:5/22:5, particularly in PE and PS, redressed part of the balance. However, the total diPUFA species were decreased in all three lipids classes (Table 3). These changes are summarized in Figure 2.

The other PUFA-containing molecular species, i.e., saturated fatty acid (SFA)/PUFA and monounsaturated fatty acid (MUFA)/PUFA species, followed the same patterns as above with 16:0/20:5, 18:1/20:5, and 18:0/20:5 being elevated in each phospholipid class from the 22:6n-3-deficient fish and 16:0/22:6, 18:1/22:6, and 18:0/22:6 being decreased (Table 3). Although all molecular species containing 22:5n-3 were also elevated, the differences were less marked, and only the changes in 16:0/22:5 and 18:0/22:5 PC and in 18:1/22:5 and 18:0/22:5 PE and PS were significant (Table 3). All arachidonyl-containing molecular species were also elevated in all three phospholipid classes from the 22:6n-3-deficient fish (Table 3), but most changes were small and not significant. In contrast to the marked changes in PUFA-containing molecular species, there was virtually no change in those molecular species containing only SFA and MUFA (Table 3).

The selectivity of particular lipid classes for particular molecular species followed well-established trends found in other studies (6,7,29). Thus, in PC, 16:0/PUFA species were

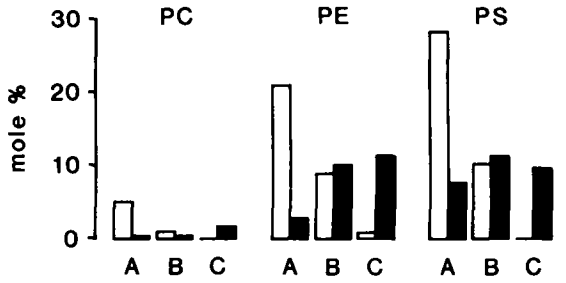

FIG. 2. The dipolyunsaturated fatty acid molecular species composition of phosphatidylcholine (PC), phosphatidylethanolamine (PE), and phosphatidylserine (PS) from the eyes of juvenile herring fed on diets supplemented with (open bar) or deficient in (filled bars) 22:6n-3. A = 22:6/22:6, B = 20:5/22:6 + 22:5/22:6, C = 20:5/20:5 + 20:5/22:5 + 22:5/22:5.

abundant with low amounts of diPUFA species and a large amount of 16:0/18:1 (Table 3). In PE, 16:0/PUFA species were less prominent, while 18:1/PUFA species were 10–14% more abundant than in PC and diPUFA species contributed 26.0–30.5% (Table 3). PS contained the largest percentage of diPUFA species (28.7–38.4%) in both dietary groups, and in this phospholipid the decrease of 18:0/22:6 was balanced almost completely by an increase in 18:0/22:5 in the fish fed the 22:6n-3-deficient diet.

DISCUSSION

Adult herring have good scotopic vision and feed visually at any time whenever both suitable prey and adequate illumination are available. The present study emphasizes the essential role of 22:6n-3 in the visual process by showing that it is possible to induce a dietary deficiency of 22:6n-3 in predatory, visual feeding fish, so that their ability to feed at low (natural) light intensities is impaired. Though not tested here, predator evasion behavior could also be affected. Late larval and juvenile stages of herring are susceptible to predation by other fish and develop the ability to respond to visual looming stimuli typical of such attacks at the same time as rods appear in the retina (31). A reduction in the ability to detect attacks by predators would markedly decrease the likelihood of survival. The size of the eyes precluded routine preparation of retinas. In adult herring, about 70% of the total phospholipid from eyes was found in retina, and about half the remainder was in the iris muscle which contained half the amount of 22:6n-3 of retina (Bell, M.V., and J.R. Dick, unpublished observations). Retinal phospholipids are therefore the major pool of 22:6n-3 in whole eyes, and even assuming total depletion of 22:6n-3 in all other ocular tissues, the deficit of 22:6n-3 induced in retina in this study would have been substantial.

Herring (22,23) and most other species of marine fish (24) are unable to detect ultraviolet or infrared light; their spectral sensitivity is similar to humans. Herring are totally dependent on photopic vision at first feeding and can only use vision to attack prey at light intensities above 0.1 lux (23). Rods do not occur in significant numbers in herring retinae until eight weeks after hatching when larvae are about 2.5 cm in length and the retinomotor responses of adult fish only develop after this time (19). Adult herring are completely light adapted at 1 lux but are dark adapted, and therefore dependent on scotopic vision, at 0.01 lux (19), the threshold for visual feeding by adults (30). Since rods are recruited to the photoreceptor population from about eight weeks' post-hatching whereas cones are present at hatching, a deficiency of 22:6n-3 during development would be expected to produce a larger effect on scotopic vision than on cone vision. The result found here is consistent with that interpretation. It was not possible to determine in this study whether the decreased proportion of 22:6n-3 in ocular phospholipids was due to decreased amounts in rod outer segment membranes, to a reduced length of the outer segment leading to smaller amounts of outer segment membrane, or to a reduced number of rod cells. The latter two possibilities would also be consistent with a lower sensory threshold. The fact that a substantial part of the deficit of di22:6n-3 molecular species was compensated by increases in molecular species containing 20:5n-3 and 22:5n-3, especially in PE and PS, suggests that the amounts of outer segment membrane were similar in the eyes of both groups of fish. Preliminary microscopic examination of retinas showed rod cells and retinomotor responses present in fish fed on both dietary regimes (Batty, R., and R. Harvey, personal observations). A much more detailed study of retinas in a further experiment would be necessary to eliminate the possibility that a deficiency of 22:6n-3 has an effect on rod development *per se*.

Docosahexaenoic acid is present in a variety of other cell membranes in fish and especially in excitable membranes, including synapses. It is probable therefore that 22:6n-3 was depleted in all other tissues with possible deleterious effects on their functions. This experiment measured the ability of fish to perform a task (feed) at three different light intensities, the lower two chosen to select for vision using cones or rods. Subperformance in consummatory behavior can be due either to a reduced ability to perform the task or to changes in motivational status (or an interaction of the two). A change in motivational status under the more demanding sensory conditions of low light intensity would necessitate light, affecting another neural function directly. Herring larvae become more active in the presence of prey at light intensities below the feeding threshold even though they cannot feed. They are motivated by chemical and mechanical stimulation, but light (vision) is necessary for successful encounter and capture (32). We find it difficult to accept that fish with functioning vision at all light intensities, deprived of food and therefore hungry, might be poorly motivated to feed at low, but natural, light intensities. Difficulties in interpretation are inherent in studies of this nature where the primary events of vision in the retina are closely coupled with signal transduction and processing in the brain where other factors may then modulate responses. Since the 22:6n-3-deficient fish were able to see at higher light intensities, their cone cells and the downstream signal processing from those cells were functional. We believe the

probable lesion in this study lay in the retina since light intensities were specifically chosen which represented the visual threshold for larvae (cones only) and adults (rods and cones). The effect was specific for the lowest light intensity, suggesting impaired scotopic vision either by interrupting the primary events of photon capture by the photoreceptor membranes in rod cells or by the subsequent neural processing of the signal from the rod cells.

Herring, in common with marine fish in general, are unable to synthesise 22:6n-3 from shorter chain C_{18} or C_{20} n-3 PUFA at rates sufficient to meet their requirements. The 22:6n-3-deficient diet also lacked 22:5n-3 and contained only 2.9% 20:5n-3 compared to 11.6% 20:5n-3 in the 22:6n-3-supplemented diet. Consequently, the amounts of 22:5n-3 in the phospholipids from the eyes of the fish reared on the 22:6n-3-deficient diet are notable in that they indicate that herring are able to elongate 20:5n-3 to 22:5n-3, but appear unable to complete the final desaturation step to form 22:6n-3.

The present study has implications for the husbandry of farmed fish and possibly also for natural fish populations. Docosahexaenoic acid is largely absent from marine diatoms; dinoflagellates and prymnesiophytes represent the only substantive source of this fatty acid in marine phytoplankton (33). It is unclear how the species composition and timing of phytoplankton blooms may vary from year to year to influence the amount of 22:6n-3 available (directly and indirectly) to larval marine fish, but amounts of n-3 PUFA in phytoplankton do vary spatially and temporally (34–36). The dietary deprivation of 22:6n-3 in this study was total, and it is very unlikely that this would occur in nature. However, it is unknown whether suboptimal lipid nutrition during early development could ultimately affect recruitment to adult stocks. In herring, rod cells are recruited to the photoreceptor population relatively late in development (19). More recent investigations of other species have shown that rods begin to appear much earlier in development at the first-feeding stage (37) but are very few in number. An adequate dietary supply of 22:6n-3 is probably essential for the survival of marine fish larvae at all stages of development. In mariculture, the supply of adequate amounts of 22:6n-3 to first-feeding larvae is a continuing problem.

Since the fish on the 22:6n-3-deficient diet had impaired vision, the diPUFA molecular species containing 20:5n-3 and 22:5n-3 were unable to replace di22:6n-3 phospholipids functionally in the visual process. At present, the molecular basis for the essentiality of 22:6n-3 in biological processes is not understood. Recent molecular modeling studies have suggested that 22:6n-3-containing glycerophospholipids do not perturb bilayer packing (38,39) as had previously been thought. Furthermore, the favored angle-iron conformation adopted by 22:6n-3 shows the smallest coefficient of thermal expansion of any fatty acid (40), making these lipids particularly suited to control bilayer volume. Finally, it has been proposed that 22:6n-3-containing glycerophospholipids, and especially di22:6n-3 molecular species, provide a highly structured liquid–crystalline membrane which can accommodate the rapid conformational changes in rhodopsin associated with the light-transducing process (41,42). In recombinant bovine rod outer segment membranes, an equimolar mixture of PE and PC containing 50 mole % docosahexaenoyl chains resulted in optimal photochemical function of rhodopsin (43). It was interesting in the present study to find that PS retained 22:6n-3- containing molecular species, and especially di22:6n-3, better than PE even though the % of PS (8.1%) in total phospholipid of the eye is much less than that of PE (26.5%) (44). The total diPUFA molecular species was highest in PS from both dietary groups and the amounts of 20:5/22:5, 22:5/22:6, and 22:5/22:5, as well as 22:6/22:6, were higher in PS than in PE from the eyes of the 22:6n-3-deficient fish. Few studies have been carried out on the physical–chemical properties of PS since it is a minor component of most membranes. However, Hubbell (45) suggested that the asymmetric distribution of PS in the disc membrane was caused by interaction with rhodopsin.

Irrespective of its precise mode of action, 22:6n-3 appears to have a unique role in vertebrate rod function. Clearly, any explanation of the particular role of 22:6n-3 in the visual process must encompass the unusual prominence of di22:6n-3 molecular species of both PS and PE. Experiments, such as the present one, establish that marine fish larvae offer particular advantages for dietary intervention studies on the role of this fatty acid in vertebrate vision.

ACKNOWLEDGMENT

We thank R. Harvey for carrying out microscopic examination of retinas.

Eicosanoid Generating Capacities of Different Tissues from the Rainbow Trout, *Oncorhynchus mykiss*

John Knight, Jason W. Holland, Linda A. Bowden, Katrina Halliday and Andrew F. Rowley*

School of Biological Sciences, University of Wales, Swansea, Singleton Park, Swansea, SA2 8PP, United Kingdom

ABSTRACT: The eicosanoid generating potential of the brain, gills, skin, ovary, muscle, eye, liver, spleen, heart, and alimentary canal in the rainbow trout, *Oncorhynchus mykiss*, was examined. All the organs/tissues examined synthesized the 12-lipoxygenase products, 12-hydroxyeicosatetraenoic acid (12-HETE), and 12-hydroxyeicosapentaenoic acid (12-HEPE), implying the widespread nature of this enzyme in trout. Both prostaglandin E and LTC were also found in variable amounts in the organs, with the greatest amount of PGE found in the gill. Leukotriene (LT) B_4 and LTB_5 were found in supernatants from calcium ionophore-challenged brain, skin, ovary, liver, spleen, and heart, but the lipoxins A_4 and A_5 were only present in brain, ovary, and spleen in relatively small amounts. As lipoxins have previously been shown to be synthesized by macrophages in rainbow trout [Pettitt *et al., J. Biol. Chem. 266,* 8720–8726 (1991)], and related cells (microglial cells) are found in the brain of mammals, the localization of macrophage-like cells in trout brain was investigated immunocytochemically. Monoclonal antibodies specific for trout leucocytes failed to identify any microglial-like cells in sections of the brain, although microvessels containing immuno-positive reaction products were observed. A number of distinct lipoxygenase products were found in supernatants of ionophore-challenged gill, including 14-hydroxydocosahexaenoic acid, 12-HETE, and 12-HEPE, and a large number of dihydroxy fatty acid derivatives with conjugated triene chromophores. One of these products was tentatively identified as 8(*R*),15(*S*)-dihydroxyeicosatetraenoic acid, a dual 12- and 15-lipoxygenase product, but apparently no LTB_4 was generated by this tissue.

Lipids 30, 451–458 (1995).

The biosynthesis and role of eicosanoids, such as leukotrienes (LT), lipoxins (LX), and prostaglandins (PG) have been extensively studied in mammals. In particular, LTB_4 and PGE_2 have been shown to play important roles in inflammation and immune regulation (1,2), whereas PGs, in general, are also involved in homeostatic and reproductive processes (3).

Despite this wealth of information on eicosanoids in mammals, significantly less is known of the generating capacity of tissues in other animals, including fish. Fish tissues, unlike their mammalian counterparts, often contain relatively large amounts of eicosapentaenoic acid (EPA; 20:5n-3) and docosahexaenoic acid (DHA; 22:6n-3) as well as the arachidonic acid (AA; 20:4n-6) characteristic of mammalian tissues (4). As all of these fatty acids can act as substrates for eicosanoid generation (5), fish have been reported to generate a plethora of lipoxygenase products including LXA_4 and LTB_4 and the equivalent 5-series compounds derived from EPA (6,7) and cyclooxygenase products of the 2- and 3-series derived from AA and EPA, respectively (8). The tissue most commonly studied in fish is blood (6–10), although the eicosanoid-generating capacity of the gills (5,11–14), skin (15), gonads (16–18), heart (19), and kidney (20) have also been examined. To date, however, no study has attempted to define which eicosanoids are synthesized by an extensive range of tissues/organs in a single species of fish.

Therefore, this study was undertaken to compare the eicosanoid-generating ability of a wide range of tissues/organs (gill, heart, spleen, alimentary canal, eye, skin, muscle, liver, ovary, and brain) in the rainbow trout, *Oncorhynchus mykiss.*

MATERIALS AND METHODS

Fish. Rainbow trout (*O. mykiss*), typically between 120–500 g, were used in this study and purchased from local fish farms. They were maintained as described previously (6,7).

Preparation of tissues for calcium ionophore challenge. Fish were killed by overdose in ethyl aminobenzoate (0.05 $g.L^{-1}$) and exsanguinated *via* the caudal vessel. The main body cavity was exposed, and the alimentary canal removed intact and placed in a large beaker containing ice-cold Ca/Mg-free Hank's balanced salt solution (HBSS). The liver

and any associated fat was excised from the alimentary canal and a number of pyloria caeca (*ca.* 5–8) were removed from the intestine and cut into small (0.5-mm long) pieces. The esophagus, stomach, and small and large intestine were isolated, and small pieces (*ca.* 1-cm long) were washed thoroughly in Ca/Mg-free HBSS to remove all gut contents. Portions of ovary and spleen were also excised and placed in Ca/Mg-free HBSS.

The thoracic region of the fish was exposed, and *ca.* 500 μL of ice-cold Ca/Mg-free HBSS was injected into the ventricle of the heart. This procedure invariably restarted the heart beating, flushing out any residual blood from the other chambers of the heart and gills. The heart was then excised, and a gill arch removed and gill filaments cut into small fragments and washed free of contaminating blood by centrifugation (1000 × *g*, 10 min at 4°C). The eyes were excised using a small pair of scissors and connective tissue and surrounding muscle removed, while the brain was removed from the cranium intact and placed in cold Ca/Mg-free HBSS. Finally, an area of integument was washed with distilled water to remove any mucus, and a small rectangular area was scored out with a scalpel. This was subsequently peeled away from the underlying musculature and cleaned to remove fragments of muscle. A small amount of muscle from below this area was also excised using a sterile scalpel.

All organs/tissues were weighed, and soft tissues (brain, spleen, and ovary) teased through a fine mesh into 5 mL of ice-cold Ca/Mg-free HBSS to obtain cell suspensions. The remaining, more consolidated tissues were cut into small pieces (1–2 mm^3) in Ca/Mg-free HBSS. All samples were transferred into plastic centrifuge tubes and centrifuged at 2800 × *g* for 5 min at 4°C, and the pellets resuspended in 5 mL of Ca/Mg-containing (0.26 $g.L^{-1}CaCl_2 \cdot 2H_2O$, 0.41 $g.L^{-1}$ $MgSO_4 \cdot 7H_2O$) HBSS, and the samples challenged with 5 μM calcium ionophore, A23187 (Sigma Chemical Co. Ltd., Poole, United Kingdom) for 20 min at 18°C. Supernatants were obtained following centrifugation (2800 × *g*, 5 min, 4°C) to remove cell debris, and were either stored at −70°C or extracted immediately for reverse-phase high-performance liquid chromatographic (RP-HPLC) analysis.

Eicosanoid analysis. PGE and LTC were quantified by enzyme immunoassay (EIA), and all other lipoxygenase products were separated by RP-HPLC. For EIA, supernatants from ionophore-challenged tissues were tested with commercially-available EIA kits (Cascade Biochem Ltd., Reading, United Kingdom; and Cayman Chemicals, Ann Arbor, MI) as directed in the protocols supplied. For PGE_2, the sensitivity of the assay was 20 $pg.mL^{-1}$ with 100% cross-reactivity with PGE_3, and for LTC_4 the sensitivity was 10 $pg.mL^{-1}$ with 100% cross-reactivity with LTC_5 and <0.01% cross-reactivity with $LTB_{4/5}$.

Samples for RP-HPLC analysis were Sep-Pak extracted, as described previously (6,7), after the addition of 100 ng of PGB_2 (Sigma Chemical Co. Ltd.) as an internal standard. Separation was achieved using an Ultrasphere C_{18} ODS column (250 × 4.6 mm; Beckman Instruments, High Wycombe, United Kingdom) and a linear gradient changing from either 100% water/methanol/acetonitrile/acetic acid (45:30:25:0.05, by vol, pH 5.7) to 100% methanol over 40 min with a flow rate of 0.6 mL min^{-1} or water/methanol/acetic acid (35:65:0.05, by vol, pH 5.7) to 100% methanol over 40 min with flow rates of either 0.6 or 0.8 mL min^{-1}. The eluted compounds were detected with either a Beckman 167 dual wavelength detector or a Waters 991 diode array detector (Waters Chromatography, Northwich, Cheshire, United Kingdom). Identification of products generated was by characteristic peak absorption spectra, co-chromatography with authentic standards [LXA_4, 11-*trans*-LXA_4, LXA_5, LTB_4, LTB_5, 6-*trans*-12-*epi*-LTB_4, 6-*trans*-LTB_4, 8(*R*),15(*S*)DiHETE, 5(*S*), 6(*R*)DiHETE, 5(*S*),12(*S*)DiHETE, 5-HETE, 12-HETE, and 12-HEPE (HETE = hydroxyeicosatetraenoic acid; HEPE = hydroxyeicosapentaenoic acid) Cascade Biochem Ltd., Reading, United Kingdom] or by reference to previous gas chromatography/mass spectrometry studies (6,7). Quantification of the principal products formed was by reference to the internal standard (PGB_2) using published extinction coefficients.

Effect of captopril, nordihydroguiaretic acid (NDGA), esculetin, MK886, and exogenous fatty acids on lipoxygenase product generation by trout gill. To investigate the mechanism of eicosanoid generation in trout gill further, either homogenates or chopped gill tissue were incubated in the presence of the lipoxygenase inhibitors, esculetin, and NDGA (1–100 μM), or the LTA hydrolase inhibitor, captopril (10–200 μM), or the 5-lipoxygenase activating protein (FLAP) inhibitor, MK886 (10–1000 ng mL^{-1}). Additionally, gill homogenates were incubated with exogenous AA, EPA, or DHA (25–150 μM) for 10 min at 18°C. Gill homogenates were prepared by removal of gill arches from the filaments and subsequent homogenization of *ca.* 0.3 g of filament in 4 mL of ice-cold Ca/Mg-containing HBSS. The supernatants were used immediately following centrifugation (10,000 × *g* for 5 min). Product generation was assessed by RP-HPLC.

Immunocytochemical analysis of trout brain. As previous studies have reported the presence of leucocytes in the brain of both mammals (21) and fish (22) and the generation of eicosanoids by these or related cells in mammalian brain (23), the distribution of leucocyte-like cells in the brain of *O. mykiss* was determined using monoclonal antibodies, 21F11 and 21G6, which have been shown to cross-react with all trout leucocytes but not with thrombocytes (platelet equivalents of fish) and erythrocytes (24). Monoclonal antibodies were produced using a standard methodology (25) by fusion of NS1 myeloma cells with splenocytes from mice immunized with formalin-fixed [1% formalin in phosphate-buffered saline (PBS)] purified trout macrophages. Following initial dilution of the hydridomas, these were screened for their specificity by ELISA and immunocytochemistry using monolayers of peripheral blood leucocytes as detailed previously (24). Selected hybridomas were cloned down by limiting dilution, rescreened and selected clones grown in RPMI 1640 containing 10% fetal calf serum, 2 mM L-glutamine, 100 $iu.mL^{-1}$ penicillin, and 0.1 $mg.mL^{-1}$ streptomycin and stored at −70°C prior to use.

Trout brains were excised and washed free of any contaminating blood with Ca/Mg-free HBSS and fixed in ice-cold 4% Baker's formol-calcium, pH 7.0, for 12–24 h. Dehydrated material was embedded in Paraplast histological wax and sections (*ca.* 10-μm thick) cut and attached to glass slides. Sections of brain were rehydrated and incubated in 3% H_2O_2 in PBS for 30 min to inactivate endogenous peroxidase. Following extensive washing (× 3 in PBS), sections were incubated in blocking solution (10% normal goat serum, 3% bovine serum albumin, 0.1 M ammonium chloride, 0.05% Tween-20, 0.1 M glycine in PBS) for 30 min at room temperature (RT). Subsequently, they were incubated in a hybridoma supernatant (21F11 or 21G6) blocking solution mixture (1:1 ratio) for 60 min at RT, washed in PBS (×3), and incubated in goat antimouse Ig antiserum conjugated to peroxidase (1:1000 dilution in blocking solution) for 60 min at RT, washed in PBS (×3), and incubated in the dark in 0.05% diaminobenzidine tetrahydrochloride and 0.01% H_2O_2 in PBS for 15 min. Finally, sections were rinsed in PBS (×3), and some counterstained with Cole's haematoxylin (4 min) prior to mounting in a water-soluble mountant. As controls, additional sections of brain were incubated in the absence of both primary and secondary antibodies or with primary or secondary antibodies alone followed by the stages described here.

Statistical analyses. All quantitative results are expressed as a mean ± SD or SE and, where appropriate, compared using Student's *t*-test for related samples.

RESULTS

All organs/tissues examined were found to generate 12-HETE, 12-HEPE, PGE, and LTC immunoreactive material (Table 1). The greatest amount of PGE immunoreactive material was found in the brain and this organ also generated LXA_4 and LXA_5 in significant amounts (Fig. 1 and Table 1). As previous studies have reported LX generation in mononuclear phagocytes both in mammals and fish (6,7,26), and microglial cells in mammalian brain are derived from monocytes, the presence of such cells in the brain of rainbow trout was investigated using monoclonal antibodies (21F11 and 21G6). No cells were observed in histological sections of the brain with the characteristic stellate appearance of microglial cells, and the immunoperoxidase-positive staining was limited to capillary-like vessels containing 21F11/21G6$^+$ material (Fig. 2).

Despite the highly vascularized nature of the gills, no LXs were found in the supernatants of ionophore-challenged material (Table 1). However, gills were found to yield the largest amount of LTC-immunoreactive material of all tissues examined, as well as significant levels of monohydroxy fatty acids, 12-HETE and 12-HEPE (Fig. 3 and Table 1). One further product with a long retention time and a λmax of 235 nm, characteristic of conjugated diene-containing fatty acid derivatives, was also observed in the ionophore-challenged gill (Fig. 3). Incubation of gill homogenates with exogenous DHA caused a dose-dependent increase in this product but had no significant effect on 12-HETE and 12-HEPE generation (Fig. 4), suggesting that it is probably 14-hydroxy-4,7,10,13,16,19-docosahexaenoic acid (14-HDHE), previously shown to be synthesized in fish gill by the action of 12-lipoxygenase activity on this substrate (5,12). The generation of this compound and the other monohydroxy fatty acids, 12-HETE and 12-HEPE, was inhibited by the specific lipoxygenase inhibitors, esculetin (IC_{50} 7.5 μM) and NDGA (IC_{50} 5.0 μM). A variable number of di-HETEs/di-HEPEs with conjugated trienes and λmax 268–275 nm were also found in supernatants of ionophore-challenged gill, and some of these were apparently only found in gill (Figs. 3 and 5). The most abundant of these compounds had a retention time of *ca.* 22 min and had a λmax of 275 nm (peak 8 on Fig. 3), but failed to co-chromatograph with any of the authentic standards employed. The second largest peak had a retention time of 19.5 min, a λmax of 268 nm, and co-chromatographed with authentic 8(*R*),15(*S*)di-HETE (Figs. 3 and 5). Furthermore, the online ultraviolet scans of the material under this peak (peak 6) were also similar to authentic 8(*R*),15(*S*)di-HETE in terms

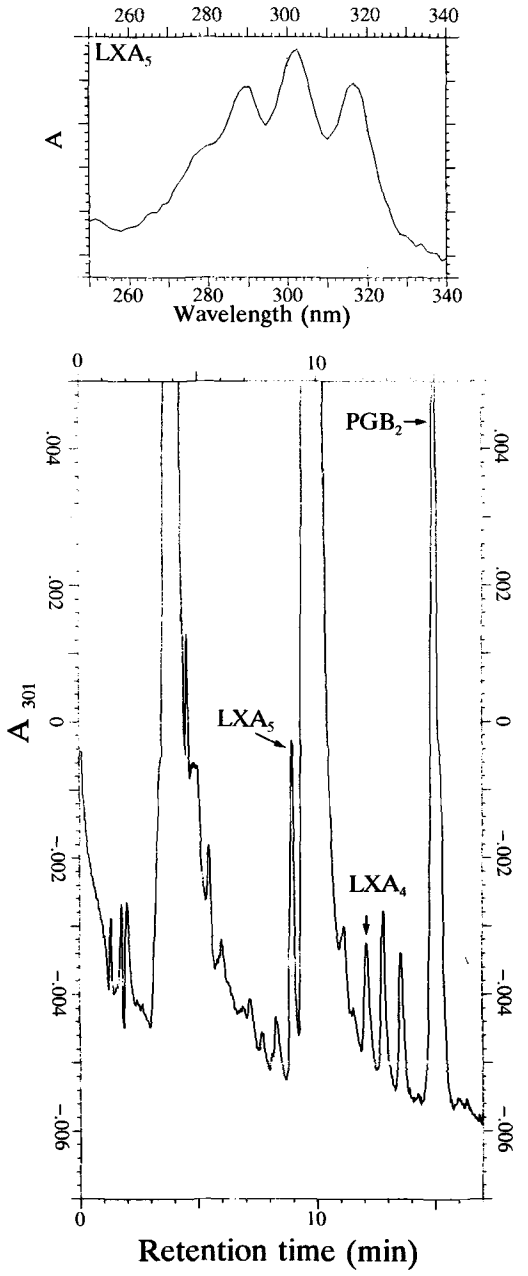

FIG. 1. Reverse-phase high-performance liquid chromatographic chromatogram demonstrating the generation of LXA_4 and LXA_5 by rainbow trout brain challenged with calcium ionophore. Upper inset shows the ultraviolet scan of the material under the peak identified as LXA_5 revealing the characteristic conjugated chromophore with a λmax of 301 nm and shoulders at 289 and 317 nm. The large unlabelled peak with a retention time of *ca.* 10 min is a contaminant from the incubation procedure and is not a product of brain tissue, and the peak with a retention time of *ca.* 4 min represents the solvent front. PG, prostaglandin.

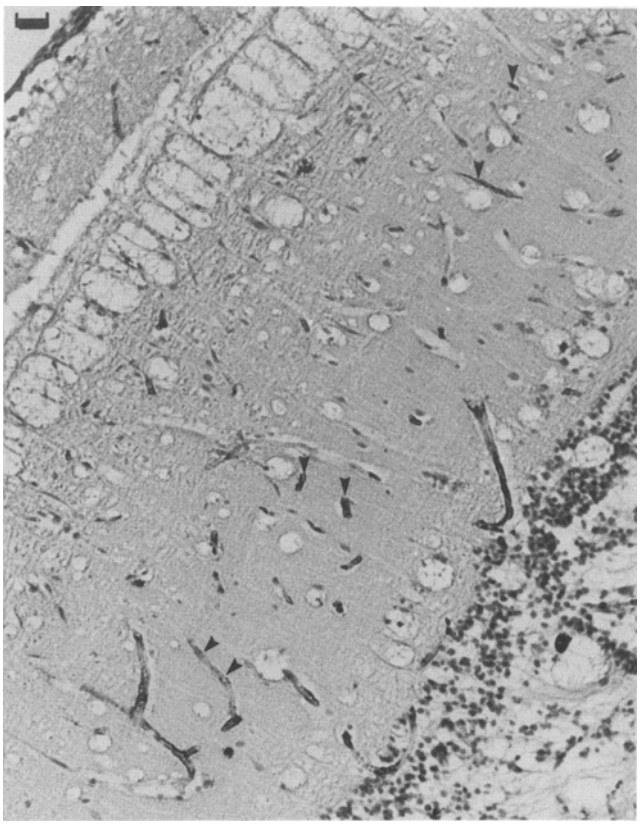

FIG. 2. Section through the optic lobe region of trout brain showing the immunocytochemical localization of $21G6^+$ material in vessels (unlabelled arrows). Scale bar = 25 μm.

of λmax, position of shoulders, and overall slope (Fig. 5). One further main peak had a retention time of 21 min and, although the material under the peak co-chromatographed with LTB_4 in the two gradient solvent systems employed (see Materials and Methods section) its λmax was *ca.* 272 nm, which is different from the ultraviolet profile of authentic LTB_4 that has a λmax of 270 nm. Furthermore, the production of this material was relatively insensitive to captopril (an LTA_4 hydrolase inhibitor, see Ref. 27) at all concentrations tested and the FLAP inhibitor, MK-886. Finally, there were also a number of smaller peaks (e.g., peaks 2 and 5 in Fig. 3) apparently containing di-HETEs/di-HEPEs, but these were not present in all gill samples examined and so were not investigated further.

Of the remaining tissues examined, only ovary and spleen generated LXs, while the skin, ovary, liver, spleen, heart, and alimentary canal produced LTB_4 and LTB_5. The amounts of LTB_4 and LTB_5 synthesized by different regions of the alimentary canal (esophagus, stomach, pyloric caeca, anterior, and posterior intestine) were all similar, whereas in the case of LTC, significantly more product was generated by the stomach than the pyloric caeca and the posterior intestine ($P < 0.05$; Fig. 6). The levels of PGE-immunoreactive material also differed within the regions of the alimentary canal tested with the pyloric caeca, and the anterior and posterior intestine generating statistically significant ($P < 0.005$) more product than the esophagus and stomach. No similar distinct trend was observed for 12-HETE and 12-HEPE, although the anterior intestine was found to synthesize significantly less 12-HETE than the posterior intestine ($P < 0.05$).

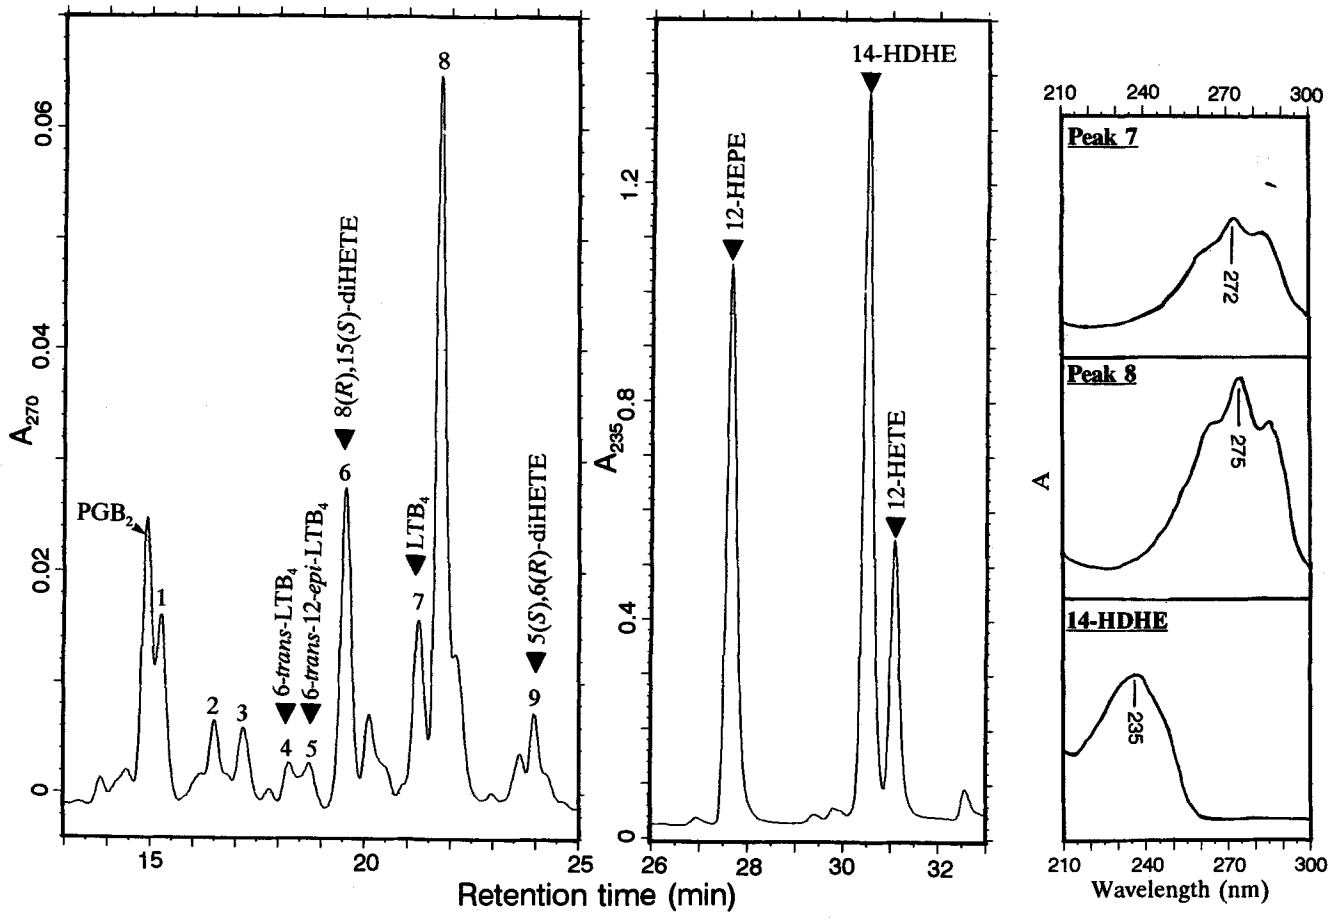

FIG. 3. Representative reverse-phase high-performance liquid chromatographic chromatogram showing the products generated by trout gill after challenge with calcium ionophore, A23187. Peaks labelled 1–9 all contain material with conjugated triene chromophores. The retention times of authentic di-HETEs/LTB_4 (indicated by the position of the arrow heads) are shown for comparison. Insets show ultraviolet scans of material under some of the main peaks. LT, leukotriene; HETE, hydroxyeicosatetraenoic acid; HEPE, hydroxyeicosapentaenoic acid; HDHE, hydroxydocosahexaenoic acid.

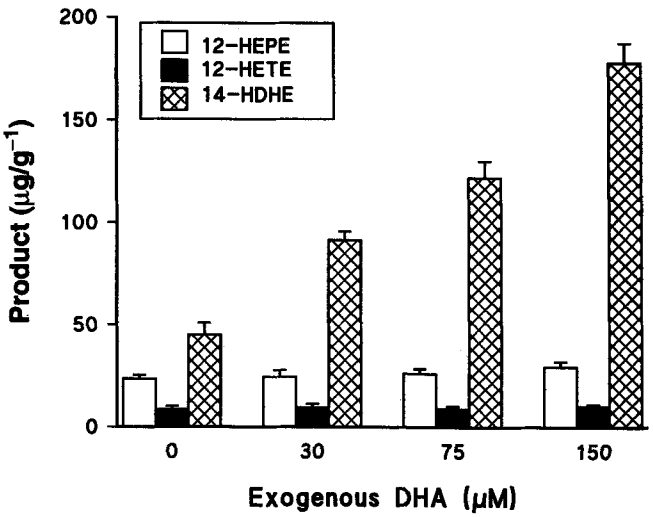

FIG. 4. Effect of exogenous docosahexaenoic acid (DHA) on the generation of 12-HETE, 12-HEPE, and material tentatively identified as 14-HDHE by trout gill homogenate. Homogenates were incubated for 10 min at 18°C in the presence of 0, 30, 75, or 150 μM DHA, and the eicosanoids generated were Sep-Pak extracted, separated, and quantified by reverse-phase high-performance liquid chromatography. Values are means ± SE, n = 3. Abbreviations as in Figure 3.

DISCUSSION

All of the organs/tissues examined in the present study generated the 12-lipoxygenase products, 12-HEPE and 12-HETE, implying that this enzyme is widely distributed in rainbow trout. Previous studies have also reported the preponderance of 12-lipoxygenase products in both the gills (11,12) and in the blood cells (6,7,9,24) of a range of fish, and this enzyme has been partially purified from trout gill (11) and its substrate specificity determined (5). German *et al.* (5) showed, using kinetic analysis of 12-lipoxygenase toward AA and DHA, that this enzyme displays a lack of substrate specificity. Hence, in gill, at least, both 12-HETE and 12-HEPE, as well as the equivalent product from DHA, 14-HDHE, are synthesized. The ability of gill to produce monohydroxy derivatives of AA, EPA, and DHA differs from that of other fish tissues. For example, trout leucocytes, although displaying a prominent 12-lipoxygenase activity and DHA in their phospholipids, do not yield appreciable amounts of 14-HDHE upon calcium ionophore challenge (6,7). This may suggest some diversity in the 12-lipoxygenase activity of gill and other tissues, such as blood. A similar situation is also apparent in

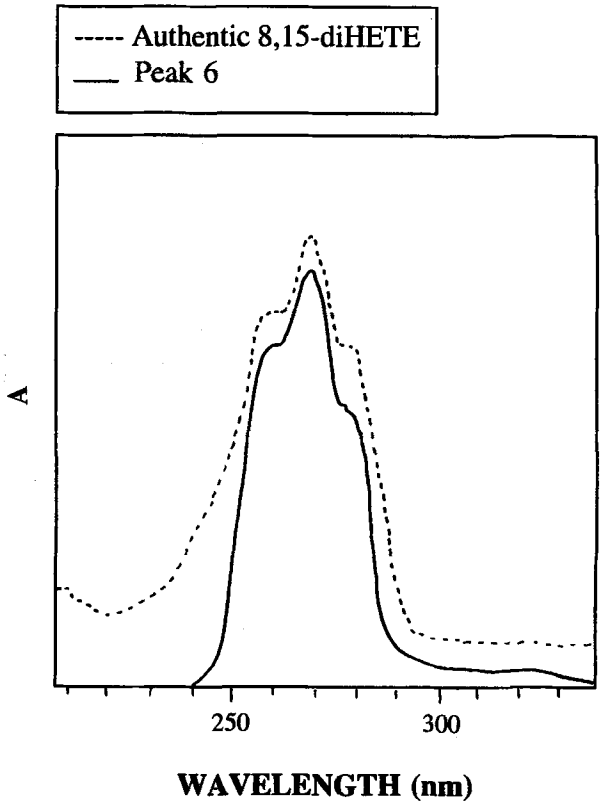

FIG. 5. On-line ultraviolet scans of authentic 8(*R*),15(*S*)-diHETE and material under peak 6 both separated by reverse-phase high-performance liquid chromatography. These have a λmax of 268 nm and shoulders at *ca.* 258 and 278 nm. Abbreviation as in Figure 3.

mammals with "platelet" and "leucocyte" types of 12-lipoxygenase (28).

Although the identification of 14-HDHE in trout gills is tentative in the absence of commercially available standards, previous studies using gas chromatography/mass spectrometry have verified its presence in this tissue (5). More recently, Bell *et al.* (12) have identified this same compound in Atlantic salmon (*Salmo salar*) gills based on relative retention times during RP-HPLC and ^{14}C DHA incubation. None of these reports, including the present study on fish gills, have shown the generation of 11-HDHE as found in human platelets following incubation with exogenous DHA (29). Aveldaño and Sprecher (29) hypothesized that as the ratio of 14-HDHE to 11-HDHE generated by these platelets varied depending on the concentration of exogenous fatty acid precursor, implying the presence of two forms of lipoxygenase with different affinities for DHA. Incubation of trout gill in the present study with varying concentrations of DHA did not result in the generation of any additional peaks in the region of the chromatograph of the other HETEs/HEPEs that could have been 11-HDHE.

Previous studies have revealed the propensity of fish leucocytes to yield LXs (7,24) and that the biosynthesis of LXA_4 in trout macrophages occurs by the synthetic collaboration of 5- and 12-lipoxygenase activity found in this cell type (30). The only tissues/organs that generated LXs in the present study were the ovary, spleen, and brain (Table 1). It is possible that this biosynthesis was due to the contamination of these organs with leucocytes; however, other highly vascularized organs such as gills, liver, and heart were found to lack the ability to generate LXs at levels above the detection limit of RP-HPLC. As microglial cells are derived from monocytes, these cells are potential candidates as the source of LXs in trout brain. Therefore, immunocytochemical studies were carried out using monoclonal antibodies raised against trout macrophages that also react with all of the leucocyte types. These antibodies failed to demonstrate any immunoreactive microglial cells in all of the regions of brain examined. In another species of fish, the tilapia (*Oreochromis mossambicus*), abundant macrophages and lymphocytes that react with an anti-CD45-like monoclonal antibody have been found in the central nervous system particularly in myelinated fiber tracts (22), suggesting the potential for large populations of leucocytes with eicosanoid-generating ability in the central nervous system of fish. Furthermore, astroglial cells from the rainbow trout, *O. mykiss*, generate a range of 5- and 12-lipoxygenase products upon calcium ionophore challenge, including $LTB_{4/5}$, 12-HETE, and 12-HEPE (31), although the capacity of these cells to synthesize lipoxins was not determined. Finally, it is pertinent to note that LX generation has also been reported in mammalian brain (32,33) and that ischemia (32) and HIV infection (33) enhance the generation of these compounds.

Rainbow trout gill displayed a different profile of di-HETE/di-HEPE generation than the other tissues examined. Although a peak was found in RP-HPLC chromatograms that co-eluted with authentic LTB_4 in two solvent systems, specific inhibitors failed to modify the production of this material, implying that this compound was not present. Caution should be exercised in such a conclusion, however, as the specificity and efficacy of these inhibitors have not been reported in fish. Furthermore, initial studies with the LTA hydrolase inhibitor, captopril, used in the present study, have shown that the biosynthesis of lipoxygenase products other than $LTB_{4/5}$ in trout leucocytes is also inhibited (Lloyd-Evans, P., unpublished observations), perhaps suggesting a lack of selectivity in the action of this compound. Other studies with the gills from rainbow trout (11) and Atlantic salmon (12) have failed to detect $LTB_{4/5}$ generation although LTB_4 has been identified as a major lipoxygenase product in killifish (*Fundulus heteroclitus*) gills (34). It should be pointed out, however, that this identification of LTB_4 in killifish gills was only based on RP-HPLC and detection of ^{14}C AA-labelled products without co-chromatography with authentic standards or mass spectrometry. The limited generation of material that co-chromatographs with authentic LTB_4 in the present study and its proximity to other material in chromatograms (e.g., peak 8 in Fig. 3) would also make it difficult to confirm the identity of the compound(s) produced using gas chromatography/mass spectrometry. What is clear, however, is that even if LTB_4 and LTB_5 are generated by rain-

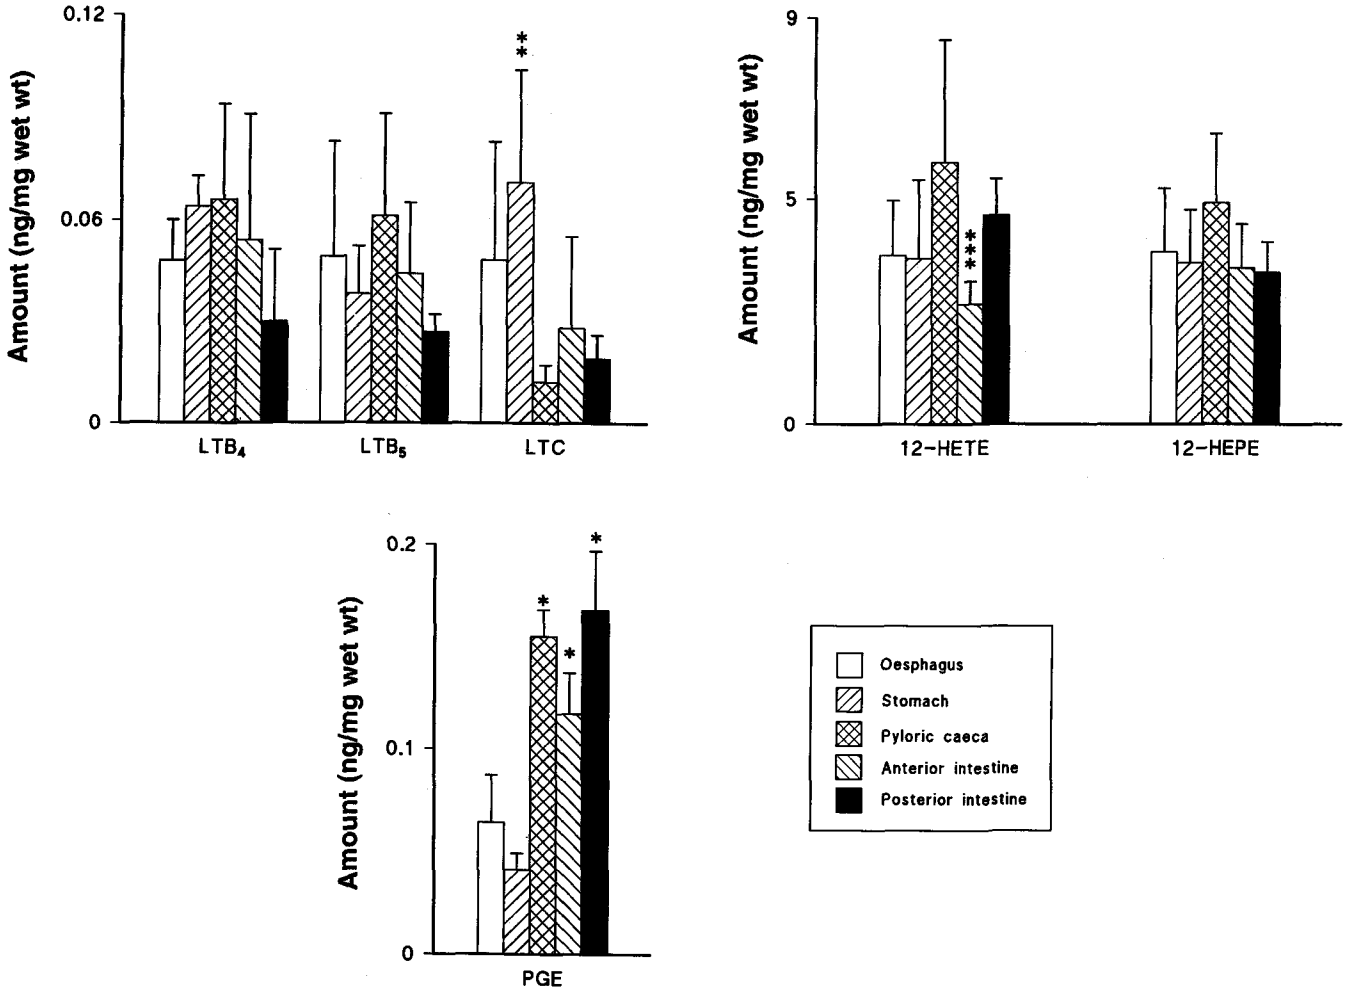

FIG. 6. Generation of various eicosanoids by different regions of the alimentary canal of the rainbow trout, *Oncorhynchus mykiss*. Tissues were incubated with 5 μM calcium ionophore, A23187, for 10 min at 18°C, and the reaction was terminated by centrifugation. Supernatants were used without extraction for enzyme immunoassay analysis of LTC and PGE levels, and for reverse-phase high-performance liquid chromatography, samples were Sep-Pak extracted following the addition of PGB_2 (100 ng) as an internal standard. Values are means ± SD, n = 3–5. $^*P < 0.005$ compared with values for esophagus and stomach, $^{**}P < 0.05$ compared with values for pyloric caeca and posterior intestine, and $^{***}P < 0.05$ compared with values for the posterior intestine. Abbreviations as in Figures 1 and 3.

bow trout gill, they are very minor components and are therefore unlikely to be of physiological consequence.

The gills of rainbow trout do generate appreciable amounts of LTC-immunoreactive material, implying the presence of 5-lipoxygenase and LTC synthase activity in this tissue. Furthermore, LTC_4, LTD_4, and LTE_4 have been convincingly identified in gills from the eel, *Anguilla rostata* (13). Other 5-lipoxygenase products, such as 5(*S*)-HETE, were not observed in ionophore-challenged supernatants of trout gill in the present study and, similarly, other trout tissues that have been shown to contain 5-lipoxygenase activity, including blood, do not synthesize appreciable amounts of 5-HETE in comparison to 12-HETE and 12-HEPE (6,7). The only di-HETE tentatively identified in the present study by RP-HPLC was 8(*R*),15(*S*)-diHETE, a dual 12- and 15-lipoxygenase product previously observed in crude gill homogenates of trout as the major dihydroxy metabolite of exogenous AA (11). Its potential finding in intact gill material from endogenous stores of AA adds weight to the suggestion of German and Berger (11) that it may be of physiological importance. Clearly, a large number of potential mono- and di-hydroxy metabolites of AA and EPA can be produced by fish gills as a result of the 5-,12- and 15-lipoxygenase activities present. It should be of interest to examine the biological significance of some of these lipoxygenase metabolites in fish gills as both cyclooxygenase and lipoxygenase products, including PGE_2, LTC_4, LTD_4, and LTE_4 appear to play a role in the regulation of ion transport in the gills of the killifish, *F. heteroclitus* (34).

ABSTRACT: Fatty acids from total lipids of the gorgonian *Leptogorgia piccola* (white and yellow morphs), collected from the same area at two different periods with regard to the average water temperature, were studied. More than fifty fatty acids were identified as methyl esters and *N*-acyl pyrrolidides by gas chromatography and gas chromatography/mass spectrometry. Three new, branched-chain unsaturated fatty acids were identified in addition to the unusual 7-methyl-6-hexadecenoic acid, namely 10-methyl-6-hexadecenoic, 7,9-dimethyl-6-hexadecenoic, and 10-methyl-6,9-heptadecadienoic acids. Also 6,9-heptadecadienoic acid was identified. The fatty acid patterns of specimens harvested in colder waters were quite different from those harvested in warmer waters in that the former contained high amounts of methylene-interrupted polyunsaturated acids, including tetracosapolyenoic acids, especially 6,9,12,15,18-24:5 (up to 15.8% of the total acid mixture) and 6,9,12,15,18,21-24:6 (up to 5.3%). Arachidonic acid was, nevertheless, a major component in all the fatty acid mixtures studied (13.6–20.5%). Based on gas chromatography/Fourier transform infrared experiments, the double bonds were assigned the (*Z*) configuration. Several fatty aldehydes and their dimethyl acetals were also detected, of which the most abundant was octadecanal.
Lipids 30, 459–466 (1995).

Marine invertebrates, such as sponges and gorgonians, are known to contain many unusual metabolites, especially terpenoids, sterols, and fatty acids. We recently described the sterol composition of nine Senegalese gorgonians (Cnidaria, Octocorallia) including *Leptogorgia piccola* (1), which also contained four novel terpenoid secondary metabolites (2). The fatty acid composition of several classes of marine invertebrates, including Cnidaria, have been reviewed (3–5). The fatty acid composition of an unidentified sublittoral Caribbean gorgonian was reported first, revealing low amounts of polyunsaturated fatty acids (PUFAs) (6). Fatty acids from some Octocorallia species have also been identified, including gorgonians *Plumarella longispina* and *Paragorgia arborea*, which contained high amounts of 6,9,12,15,18,21-24:6 and 6,9,12,15,18-24:5 acids (7). Eicosapentaenoic acid (5,8,11,14,17-20:5) was the major component of the former organism, and 5,8,11,14-20:4 (arachidonic acid) was that of the latter. These icosapolyenoic acids are known to possess remarkable pharmacological effects in higher animals. They are membrane phospholipid components and important prostaglandin precursors. An interesting finding was the occurrence of arachidonic acid as a major fatty acid (>20%) in lipids of the gorgonian *Plexaura homomalla* (8), which also contains some prostaglandin derivatives accounting for 1.8% of its dry weight (9).

We have investigated gorgonians as part of our continuing research on lipids from Cnidaria (10). This report details the fatty acid composition of total lipids from *L. piccola*. These Senegalese gorgonians were encountered as two color morphs (white and yellow) in the same area, but mixed colonies have never been observed (11). As a first step in this study, lipids from specimens harvested during the cool season (November to April) were investigated. Fatty acids were determined by their gas chromatography (GC) retention behavior on either nonpolar or polar columns (by comparison with commercially available standards) and by GC/mass spectrometry (GC/MS) studies for the most prominent GC peaks. In order to investigate whether water temperature had effects on fatty acid composition, additional specimens of *L. piccola*, collected at the beginning of the hot season (June), were studied. In Senegal, the cool season corresponds to a period of important upwelling characterized by cold and saline water (averaging 16–20°C). The hot season usually begins with a rapid warming of seawater (more than 25°C) (12,13). These latter samples were studied in more detail, using GC/MS to elucidate the structure of several unusual minor fatty acids encountered in colder water samples. Surprising differences between the two harvests were observed concerning relative abundance of dif-

ferent PUFA. Several interesting branched short-chain unsaturated fatty acids were identified and are described in this paper.

EXPERIMENTAL PROCEDURES

Gorgonian material and lipid extraction. Both morphs (white and yellow) of *L. piccola* were collected by hand (scuba diving) 20 km off Dakar (Senegal) at an average depth of 30 m, first from November 1989 to April 1990 (colder water) and then in June 1992 (warm water). Total lipids of the colder water gorgonian samples were extracted by the Bligh and Dyer method (14). The chloroform layer was filtered and evaporated under vacuum at room temperature, yielding a lipid residue which was saponified with 2N ethanolic potassium hydroxide. The unsaponifiable matter was separated, and the remaining aqueous fraction acidified. Fatty acids were recovered by *n*-hexane extractions and converted into methyl esters using BF_3/methanol (15). Crude fatty acid methyl esters (FAME) were purified by thin-layer chromatography (TLC) on Kieselgel 60 0.5-mm thick precoated plates (Macherey-Nagel, Doren, Germany) by development with benzene/methanol (98:2, vol/vol). The gorgonian samples from warmer water were ground in a Waring blender (Bioblock-Scientific, Strasbourg-Illkirch, France) and steeped twice in dichloromethane/methanol (1:1, vol/vol) for 24 h (room temperature). Combined crude total lipids were saponified as above and converted into FAME by refluxing with 2% methanolic hydrogen chloride (40 min). To determine double-bond positions and methyl branching, FAME were converted into *N*-acyl pyrrolidides by treatment with pyrrolidine/acetic acid (10:1, vol/vol) under reflux (2 h). Pyrrolidides were purified by TLC on 0.5-mm silica gel layers using hexane/diethyl ether (1:2, vol/vol) as developing solvent. FAME mixtures were hydrogenated by stirring (4 h) at ambient pressure and temperature in methanol in the presence of catalytic amounts of platinum (IV) oxide (Adam's catalyst). Many of the fatty acids reported here were simply identified by comparing their GC mobilities as methyl esters with those of known natural mixtures (salmon oil lipids) and by co-injection with commercial standards. Capillary GC analysis of a hydrogenated aliquot also provided useful information for detection and identification of unsaturated acids.

Gas–liquid chromatography. Analytical GC was carried out on a Carlo-Erba 4130 apparatus (Milano, Italy) with a flame-ionization detector linked to a Spectra Physics model 4270 numerical integrator (St. Albans, United Kingdom) for data collection. GC analyses were performed on two types of fused silica capillary columns: a polar Carbowax-20M (50 m × 0.32 mm i.d., 0.40 μm phase thickness) and a nonpolar OV-1 (25 m × 0.32 mm i.d., 0.40 μm phase thickness) (A.M.L.-chromato, Limoges, France). Oven temperature was 195°C for the former column and 180°C for the latter. Common FAME were identified by comparison of their retention behavior on either column (equivalent chain length, ECL) with those of authentic standards (Sigma Chemical Co., St. Louis, MO) or salmon oil FAME that had been studied previously (16), and confirmed by GC/MS experiments.

GC/MS. For the gorgonian specimens harvested from November to April, combined GC/MS was performed on a Girdel 30 gas chromatograph linked to a Ribermag R-10-10B mass spectrometer and coupled with a Sidar computer. The GC column was a 25 m × 0.32 mm i.d. fused silica capillary column coated with OV-1 (0.40 μm phase thickness). FAME were analyzed from 180 to 300°C at 3°C/min and pyrrolidide derivatives from 220 to 300°C at 3°C/min (carrier gas, helium; ion source, 180°C; ionizing voltage, 70eV). For the gorgonian specimens harvested in June, combined GC/MS was performed on a Hewlett-Packard HP-5890 chromatograph linked to an HP 9000/345 integrator (Palo Alto, CA). The GC column was a 30 m × 0.32 mm i.d. fused silica capillary column coated with DB-1 (0.25 μm phase thickness). The carrier gas was helium. Column temperature was programmed from 180 to 310°C, at 3°C/min, for both derivatives (FAME and pyrrolidides).

Gas chromatography/Fourier transform infrared (GC/FTIR). For specimens harvested in June, GC/FTIR spectra of the FAME were recorded with a 20S×B Nicolet spectrometer (Madison, WI) interfaced with a 5300 Mega Carlo Erba FID chromatograph equipped with a fused silica capillary (DB-1, 60 m × 0.32 mm i.d., 0.25 μm phase thickness; J&W Scientific, Folson, CA). Oven temperature was programmed from 70 to 130°C (15°C/min) and from 130 to 290°C (4°C/min). The carrier gas was helium. Light-pipe temperature was maintained at 293°C.

RESULTS

As determined by the Bligh and Dyer procedure for the colder water specimens (dry weight), the white morph yielded 2.1% of total lipids, and the yellow morph (dry weight) yielded 1.9%. As determined by the dichloromethane/methanol extraction procedure for the warmer water specimens (dry weight), the white morph yielded 8.4% of total lipids, and the yellow morph yielded 4.9%.

The fatty acid composition of the two morphs of *L. piccola* (at two different sampling periods) is given in Table 1. More than fifty fatty acids were identified in gorgonian lipids, most being present in the four samples studied.

Colder water specimens contained 21.5% (white morph) and 26.9% (yellow morph) of saturated fatty acids, whereas warmer water specimens contained 51.3 and 53.4%, respectively. On the contrary, colder water specimens contained 66.3% (white morph) and 55.9% (yellow morph) of PUFAs, whereas warmer water specimens contained 25.3 and 29.1, respectively. The partial *m/z* 113 ion monitoring GC/MS chromatogram of fatty acid pyrrolidides is presented in Figure 1.

Mass spectral data of selected fatty acid pyrrolidides are as follows: *10-Methyl-6-hexadecenoic acid pyrrolidide* **4**. MS *m/z* (rel. intensity): 321 (M^+, 1.3), 306 (0.3), 292 (0.1), 278 (0.4), 264 (0.3), 250 (0.5), 236 (1.1), 222 (0.3), 208 (4.2), 196
