[a]Acyl-CoA:cholesterol acyltransferase was assayed using 150 µg microsomal protein incubated with [9,10-^{3}H]oleoyl CoA for 5 min. Activity was measured using the cholesterol endogenous to the microsomes and in the presence of saturating amounts of exogenous cholesterol added as cholesterol:phosphatidylcholine liposomes as described in the Materials and Methods section. 3-Hydroxy-3-methylglutaryl (HMG)–CoA reductase activity was measured by incubation of 100 µg of protein with 3-hydroxy-3-methyl[3-^{14}C]-CoA for 15 min. Neutral cholesteryl ester hydrolase activity was estimated by incubating 50 µg microsomal protein with cholesteryl [9,10-^{3}H]oleate for 45 min. The results are the means ± SEM for six animals except where indicated by the number in parentheses. Significant differences from control values (*b,c,d*), between treatments (*e,f*) and between treatments and treatments plus 24 h on control diet (*g,h,i*) were determined using Student's *t*-test. $^{b,g}P < 0.05$. $^{e}P < 0.02$. $^{c,h}P < 0.01$. $^{d,f,i}P < 0.001$.

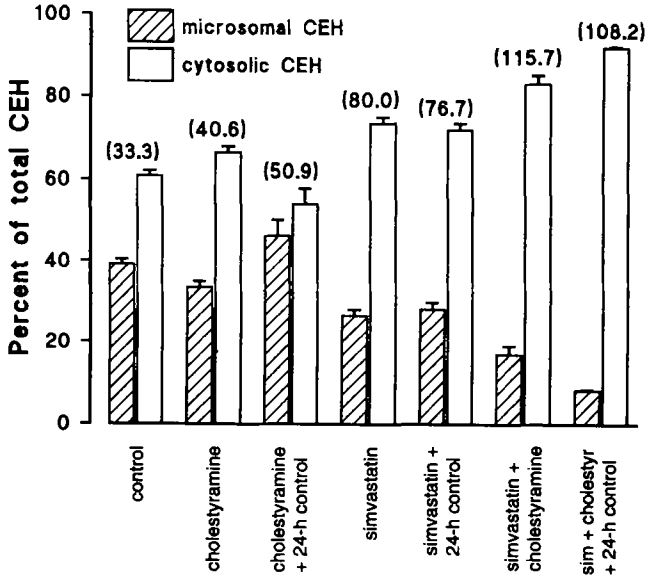

FIG. 1. Histogram showing the relative proportions of the total cholesteryl ester hydrolase (CEH) activity in the cytosolic and in the microsomal fractions of the livers (nmol/min/total liver) following drug treatment. Cytosolic CEH activity was calculated making allowance for the activity of the inhibitory protein of CEH in the appropriate cytosols; sim, simvastatin; cholestyr, cholestyramine.

TABLE 5
The Effects of Treatment with Simvastatin and Cholestyramine, Alone and in Combination, on the Microsomal Contents of Cholesterol and Cholesteryl Esters[a]

Treatment	Cholesterol (C) (μg/mg protein)	Cholesteryl esters (CE) (μg/mg protein)	Ratio CE/C
Control (8)	31.8 ± 0.9	19.6 ± 0.6	0.60 ± 0.02
Cholestyramine (6)	24.1 ± 0.7[d]	16.2 ± 0.7[c]	0.67 ± 0.02
Cholestyramine + 24-h control diet (6)	21.6 ± 0.7[d]	13.6 ± 0.4[d]	0.63 ± 0.01
Simvastatin (6)	27.6 ± 1.1[b]	13.0 ± 0.5[d]	0.47 ± 0.02[d]
Simvastatin + 24-h control diet (6)	33.4 ± 0.7[e]	20.4 ± 0.7[f]	0.61 ± 0.02
Simvastatin + cholestyramine (10)	26.6 ± 0.9[d]	16.1 ± 0.6[d]	0.61 ± 0.01
Simvastatin + cholestyramine + 24-h control diet (10)	26.1 ± 0.5[d]	23.0 ± 0.7[c,f]	0.88 ± 0.03[d]

[a]Cholesterol and cholesteryl esters were determined by means of a fluorometric assay on the extracted microsomal lipids in ethanolic solution. The results are the means ± SEM for the number of animals given in parentheses. Significant differences from control values (*b,c,d*) and between treatments and treatments plus 24 h on control diet (*e,f*) were determined using Student's *t*-test. [b]$P < 0.05$. [c,e]$P < 0.01$. [d,f]$P < 0.001$.

significantly lowered (−17%, $P < 0.001$). Withdrawal of the drugs led, within 24 h, to an increase in the cholesterol level in the whole liver (+16%) but reversed the increase in plasma free cholesterol (to 24% below control) without affecting microsomal levels. In contrast, hepatic and microsomal CE content was significantly increased (+77 and +18%, respectively) following reversion to the normal diet, and this was reflected in a decrease (−35%) in the CE of the plasma.

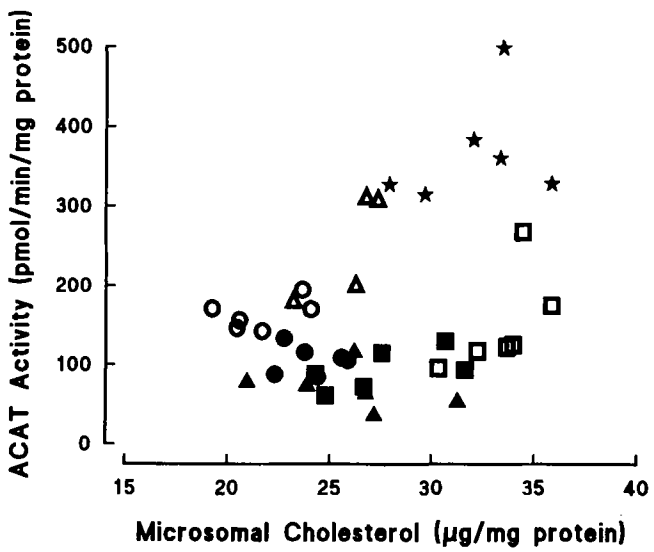

FIG. 2. Scatter diagram relating acyl-CoA:cholesterol acyltransferase (ACAT) activities to microsomal contents of cholesterol. Controls (★), and animals treated with simvastatin (□,■), cholestyramine (○,●) and a combination of the two drugs (△,▲). Open symbols represent drug treatments, filled symbols represent drug-treated animals refed control diet for 24 h.

Feeding both drugs had major effects on the activities of the enzymes of cholesterol metabolism. HMG–CoA reductase was higher (4.2-fold), and ACAT activity, measured both with and without exogenous cholesterol, was significantly reduced (−73 and −81%, respectively, $P < 0.001$), both effects being greater than was observed with simvastatin alone (Table 4). Refeeding control diet for 24 h returned HMG–CoA reductase activities to that of the controls and markedly increased ACAT activities (3.5-fold), which nevertheless remained substantially below control levels. The data in Figure 2 indicates that the enhanced ACAT activity, following drug withdrawal, occurred through a combination of nonsubstrate modulation of enzyme activity, together with an increase in substrate availability.

Cytosolic CEH was dramatically increased (5.9-fold) by this combined drug treatment (Table 3), and this was correlated with a significant reduction (−21%, $P < 0.01$) in the activity of the cytosolic inhibitory protein. Microsomal CEH was also increased, although to a lesser extent (1.4-fold, Table 4), as was emphasized in Figure 1. Withdrawal of the drugs reduced microsomal CEH to below control values, but cytosolic CEH remained substantially elevated (3.8-fold). Allowance for the effect of the cytosolic inhibitor of CEH activity made a quantitative difference but did not alter the relative effects of the drugs (Table 3). It did, however, emphasize that the relative proportions of cytosolic to microsomal activity were markedly higher in the refed animals compared with the drug-treated animals (9.4:1 and 5.1:1, respectively, Fig. 1).

DISCUSSION

The results obtained in the present investigation confirm that the effects of the cholesterol-lowering drugs simvastatin and cholestyramine, alone and in combination, on hepatic cholesterol metabolism are much more complex than simply the inhibition of HMG–CoA reductase with a secondary increase in LDL receptors (4). They clearly cause major variations in the hepatic activities of ACAT and the neutral CEHs which lead to changes in the levels of cholesterol, CEs, and TAG, both in the liver and the plasma of these animals. Moreover, it is clear both from previously published results (44–46) and from the data presented here that the variations in CEH activity, arising from the different dietary conditions, may have an equal importance with ACAT in maintaining intracellular cholesterol levels.

Cholestyramine administration, by promoting fecal loss of bile salts (28,29), creates a cellular need for free cholesterol to replace cholesterol utilized for bile salt synthesis (30) which is apparently met by induction of microsomal HMG–CoA reductase activity (30–32; Table 4) and by inhibition of its degradation (47). However, our data indicate that this free cholesterol requirement also could be partially met by a decrease in CE formation, through a reduction in ACAT activity (Table 4), or an increase in CE hydrolysis, *via* enhancement of CEH activity (Table 4). The significant variation in ACAT was in agreement with previous results (12), whereas the significant increase in cytosolic, but not microsomal, CEH activity contrasted with previous reports (12,48). The change in ACAT appeared to occur partially from a decline in the amount of microsomal cholesterol (Table 5) and partially from a decline in either the amount, or the activity, of the enzyme as indicated by the 50% loss of activity in the presence of saturating concentrations of cholesterol (Table 4). Consideration of the scatter diagram relating ACAT activity to microsomal cholesterol content (Fig. 2) also would suggest that increases in the amount or activity of the enzyme, rather than substrate availability, was the explanation for the enhanced ACAT activity observed when simvastatin was withdrawn. The net result of these changes in enzyme activity was a significant decrease in microsomal cholesterol and CE content although the total hepatic content of these sterols was unaltered. However, at the present stage, it is not possible to apportion these effects between the various enzymes involved.

The major reason for the variation between our results and those previously published (12) in relation to CEH activity arises from the different conditions that were used in the assay. The hepatic cytosol contains a protein inhibitor of this enzyme activity (34) for which allowance can be made by performing the assay with small (50 μg) amounts of protein. Stone *et al.* (12) employed much larger quantities of cytosolic protein, and under the conditions of their assay, it can be assumed that less than 10% of the CEH activity was measurable. Hence, variations in this enzyme activity, due to dietary manipulation, could not be observed.

Simvastatin administration also stimulates the induction of HMG–CoA reductase (47) but, at the same time, leads to a decrease in the activity of ACAT, thus allowing unesterified cholesterol to enter the free cholesterol pool (Table 4). A reduction in hepatic ACAT activity in rats due to simvastatin has not been reported previously, although such a reduction has been proposed to explain a selective decrease in hepatic CE content (23), and lovastatin has been shown to inhibit ACAT activity in intestinal cells (18,21). Microsomal cholesterol was, however, only reduced by 14% below controls, suggesting that the decline (–75%) in ACAT activity was only partially due to decreased substrate availability and was predominantly due to a nonsubstrate modulation of enzyme activity. This interpretation was supported by the 53% decrease in ACAT activity observed in the presence of saturating concentrations of cholesterol. Perhaps more significantly in this situation, both microsomal and cytosolic CEH activities were substantially increased (Tables 3 and 4). The combined effect of reduced ACAT and increased CEH was a significant decline in both total and microsomal CE. Nevertheless, in spite of these compensatory variations in HMG–CoA reductase, ACAT, and CEH, hepatic cholesterol content was still markedly reduced below control values. This may result from increased disposal of cholesterol *via* the biliary route since administration of an HMG–CoA reductase inhibitor, both with (49) and without (50) the addition of a second drug (AOMA, a copolymer of maleic acid and an α-olefin of 18 carbon chains; Monsanto, St. Louis, MO) to block intestinal cholesterol absorption, prompted an increased output of cholesterol to bile. Moreover, since increased biliary cholesterol secretion also has been reported to occur when ACAT activity was inhibited by progesterone (51,52), the reduction in ACAT observed in the present investigation would also be consistent with increased biliary sterol excretion.

The rapid decline in HMG–CoA reductase activity following withdrawal of the simvastatin correlates with the known short half life of this enzyme (47). However, simvastatin is eliminated from the plasma even more quickly (5), and hence, one effect of withdrawal of the drug is a large overshoot in cholesterol production (33). This expanded pool of newly synthesized cholesterol can enrich the hepatic microsomal membrane fraction, part of which can be esterified by ACAT, as indicated by the increased enzyme activity in this fraction (Table 4). Moreover, since the total ACAT activity, measured under saturating substrate conditions, was unaltered, it can be inferred that the observed enhancement of ACAT activity was solely due to the increased substrate availability (Fig. 2) rather than any change in other factors capable of modulating enzyme activity, such as covalent modification (53) or variation in the amount of enzyme protein. Since total ACAT activity was not increased, there appeared to be a limit to the proportion of the excess cholesterol that could be converted to the ester, and this was further constrained by the high CEH activity, which showed negligible response to withdrawal of simvastatin. The inability to further increase the hepatic stores of CEs could help to explain the marked in-

crease in the rate of biliary sterol secretion reported by Bilhartz *et al.* (33).

The marked induction of HMG–CoA reductase activity which results from the diet containing simvastatin and cholestyramine (7,8,30–32) was confirmed by the data presented here. The reduction in ACAT activity following this treatment, which was even greater than that observed in response to the individual drugs, ensured that newly synthesized cholesterol arising from the induced HMG–CoA reductase was not converted to the ester. This strategy was supported by the greater than fivefold increase in cytosolic CEH activity, the net result of which should have been increased free cholesterol levels in the cell. However, in spite of these changes in ACAT and CEH, hepatic cholesterol and CE remained at the same level as in untreated animals, and microsomal CE was only slightly reduced. Major changes had, nevertheless, occurred in the levels of plasma cholesterol, which were substantially elevated, suggesting that increased export of cholesterol to the plasma may have contributed to this maintenance of intracellular sterol levels. A rise in serum cholesterol levels has been observed in rats fed lovastatin for seven days (50), and an increase in high-density lipoprotein (HDL) cholesterol was reported in rats in which hepatic ACAT activity had been inhibited (54). In contrast, Mitchell *et al.* (55) reported a reduction in plasma cholesterol in rats fed this drug combination. The difference between our results and those of Mitchell *et al.* (55) could be explained by the fact that their animals were fasted overnight, a period when they normally would be consuming the bulk of their food, whereas the animals in our study and in that reported in (50) had access to food up to the time of slaughter.

Nevertheless, both Mitchell *et al.* (55) and ourselves observed a fall in plasma TG. They attributed this partly to decreased secretion of VLDL, arising from a decline in the hepatic content of mRNA species coding for apo-B, and partly to upregulation of the B/E receptor, leading to increased clearance. Interestingly, a fall in plasma TAG was also recorded (54) when hepatic ACAT was inhibited, and others have shown that inhibition of ACAT selectively decreased the plasma content of apo-B containing lipoproteins and shifted the distribution of cholesterol to HDL (56). Thus, the fact that ACAT activity was inhibited by both simvastatin and cholestyramine also would support the suggestion of reduced TAG secretion.

As expected, HMG–CoA reductase activity was reduced to control levels following withdrawal of the drugs but, in contrast to the situation with simvastatin alone, total ACAT activity, i.e., measured with saturating substrate, was markedly increased. In these animals, ACAT would have esterified a greater proportion of the expanded pool of free cholesterol, and this, together with the reduced CEH activity present in the microsomal fraction, resulted in a significant increase in microsomal CEs. Nevertheless, the data indicate that, although cytosolic CEH activity remained substantially elevated, there was an accumulation of both cholesterol and CE in the liver. This correlated with significant reductions in the plasma level of these sterols, which could arise from either decreased secretion of lipoproteins and/or increased clearance from the circulation. The increase in the plasma levels of TAG after drug withdrawal would argue against a further reduction in VLDL secretion, particularly as there was an accumulation of hepatic CEs, which have been implicated as a requirement for VLDL secretion (51). Increased clearance is the more likely cause, arising from an upregulation of HDL receptors, since cholesterol loading of cells, that can utilize HDL particles, has been shown to have such effects on plasma sterol levels (57). Furthermore, although this drug combination has been shown to decrease hepatic TAG lipase activity, it resulted in increased levels of the mRNA species coding from this lipase (58). A rapid rise in hepatic TAG lipase levels on drug withdrawal also could contribute to the lowered plasma sterol levels observed.

The cause of the variations in enzyme activity are unknown at present, although available evidence would argue against direct action of the drugs on the enzymes. Cholestyramine remains in the gut and does not enter the circulation, and although the lactone form of simvastatin has been reported to directly inhibit intestinal ACAT, *in vitro*, the open β-hydroxy acid form of the drug was ineffective (27). Since the lactone is rapidly converted into the hydroxy acid in both rat plasma (5) and liver (59–61), it is unlikely that much of the lactone form exists within the circulation.

The results presented here are important since they demonstrate that manipulation of cholesterol synthesis in the rat hepatocyte has major effects on all of the enzymes involved in hepatic cholesterol metabolism, not just on the rate-determining enzyme of cholesterol synthesis. Whether such changes also occur in humans is a subject worthy of investigation.

ACKNOWLEDGMENTS

The authors would like to acknowledge the generous donation of simvastatin by Dr. M. Mark (Karl Thomae GMBH, Biberach, Germany). Financial support was supplied by the Scottish Office Agriculture and Fisheries Department.

Proteolytic Susceptibility of Platelet Low Density Lipoprotein Receptor[1]

Javier Pedreño* and Rosa Fernández

Department of Biochemistry, Hospital Universitario Son Dureta, Palma de Mallorca, Spain

ABSTRACT: In order to further characterize low density lipoprotein (LDL)-platelet interaction, we investigated the effect of protease pretreatment of human platelets on the subsequent binding of iodinated LDL (^{125}I-LDL). Our results showed that the platelet LDL receptor had a proteolytic susceptibility different from that of both classical LDL receptors and the fibrinogen receptor. Platelet pretreatment with chymotrypsin, trypsin, and pronase (at 50 μg/mL) had no effect on ^{125}I-LDL binding, whereas fibroblast ^{125}I-LDL binding was markedly reduced. Mild proteolytic digestion, however (up to 1 mg/mL), was helpful in characterizing the platelet LDL receptor. Scatchard analysis showed that chymotrypsin did not modify LDL binding characteristics, whereas trypsin and pronase altered maximal number of binding sites (B_{max}) without variation in dissociation constant. Trypsin increased B_{max} approximately twofold (2156 ± 327 binding sites on control platelets vs. 5246 ± 296 on treated platelets, $P < 0.001$, mean ± SEM, n = 5), but pronase decreased B_{max} about 50% (2017 ± 275 control vs. 1153 ± 195 treated, $P < 0.001$). A minimum of 30 min preincubation was required to detect significant effects, and apparent equilibrium was reached by 60 min. Maximal increase in platelet LDL binding sites induced by trypsin was observed at a protein concentration of 1 mg/mL at 37°C, whereas at 4°C no effect was found. In contrast, maximal pronase-inhibitory effect also was observed at 37°C but at higher protein concentration (10 mg/mL). Aprotinin, phenylmethylsulfonylfluoride, and soybean trypsin inhibitor were capable of fully blocking both the stimulation and the inhibition of platelet LDL binding induced by trypsin and pronase, respectively. Platelet pretreatment with both chymotrypsin and pronase (0.5 mg/mL) activated fibrinogen binding sites to a similar extent as ADP (100 μM). Furthermore, LDL (at a protein concentration of 0.3 mg/mL) increased by 81 ± 6% the binding of fibrinogen to both protease- and ADP-stimulated platelets, but was unable to activate fibrinogen binding sites in unstimulated platelets. Overall, the results suggest that platelet LDL receptor presents a different proteolytic susceptibility in comparison with both "classical" LDL receptor and fibrinogen receptor.

Lipids 30, 927–933 (1995).

Abbreviations: B_{max}, maximal number of binding sites; GP, glycoprotein; ^{125}I-LDL, iodinated low density lipoprotein; K_D, dissociation constant; LDL, low density lipoprotein; PMSF, phenylmethylsulfonylfluoride; STI, soybean trypsin inhibitor.

It is well known that proteolytic enzymes are implicated in a multitude of important physiological processes, including the functional activation or inactivation of proteins (1). Proteolytic enzymes have been used to characterize platelet receptors, and several studies have shown that a protease-specific mechanism is involved in their proteolytic susceptibility (2–7). Pretreating platelets with either chymotrypsin or pronase can activate the inducible fibrinogen receptor *via* proteolysis of glycoprotein (GP) IIB (2,3), increasing the binding of protein C (4), or causing the inhibition of U46619 binding to thromboxane receptors (5). In contrast, pretreating platelets with trypsin induces the functional activation of thrombin receptors (6) and inhibits the binding of α_2-adrenergic agents (7). However, data on the effect of proteases on the platelet low density lipoprotein (LDL) receptor have not yet been published. Several characteristics indicate that this lipoprotein receptor could be different from the "classical" LDL receptor of nucleated cells (8). A 140 kDa LDL-binding protein has been purified (9,10) from platelet membranes, suggesting that it could be related to the fibrinogen receptor (10), but several differences have been described between fibrinogen and LDL binding characteristics (8). Previous studies from our laboratory also have confirmed differences between platelet and classical LDL receptors (11), and that both native and oxidized LDL particles are recognized with the same apparent affinity by this new lipoprotein receptor (12). In order to further characterize platelet LDL receptors, we investigated their susceptibility to proteolytic digestion and the effect of platelet protease pretreatment on the LDL-platelet interaction.

EXPERIMENTAL PROCEDURES

Materials. α-Chymotrypsin, sucrose, and EDTA were purchased from E. Merck (Darmstadt, Germany); Iodo-Gen, trypsin inhibitor (type I-S: from soybean), pronase, aprotinin, and phenylmethylsulfonylfluoride (PMSF) were supplied by Sigma Chemical Co. (St. Louis, MO); fibrinogen was from Kabi (Stockholm, Sweden); TPCK-trypsin was from Biochrom KG (Berlin, Germany); and Na^{125}I was purchased from New England Nuclear (Boston, MA).

Isolation of lipoproteins and fibrinogen. Human LDL (d = 1.019–1.063 g/mL) were obtained from pooled sera of nor-

mocholesterolemic volunteers and isolated by sequential ultracentrifugation (13) in a T 2060 Centrikon ultracentrifuge (Kontron Instruments, Milan, Italy). The protein content was determined by the procedure of Bradford (14) using bovine serum albumin as the standard. The apoprotein composition of LDL and its specific mobility were routinely assessed by the procedure previously reported (11). Isolated LDL was dialyzed against buffer A (150 mM NaCl, 20 mM Tris, and 0.3 mM EDTA; pH 7.4) and filtered through a Millipore (Barcelona, Spain) filter (0.22 μm) before use. Human fibrinogen was purified by chromatography on gelatine-Sepharose 4B (Pharmacia Biotech Europe GmbH, Barcelona, Spain). The clottability of this fibrinogen was between 93 to 96%. As judged by SDS–PAGE after reduction with 5% (vol/vol) β-mercaptoethanol, no contaminating protein was detectable and a typical distribution of Aα, Bβ, and ψ chains and absence of any degradation products was revealed. The protein migrated in nonreducing conditions as a single band on SDS–PAGE with an estimated M_r of 330,000.

Iodination of proteins. Both LDL and fibrinogen were labeled with ^{125}I by the Iodo-Gen method (15) and dialyzed as indicated for unlabeled lipoprotein. The final specific radioactivity of iodinated LDL (^{125}I-LDL) was 2.0 ± 0.1 Bq/ng protein. The purity of ^{125}I-LDL was assessed by gel filtration in a fast protein liquid chromatography device (Pharmacia LKB, Uppsala, Sweden) as previously described (11). The specific radioactivity of ^{125}I-fibrinogen was of 3.5 ± 1.2 Bq/ng of protein. The purity of labeled fibrinogen was evaluated by both SDS–PAGE and by its clottability. All labeled proteins were used immediately.

Platelets. Human platelets were isolated from freshly drawn citrated (sodium citrate 3.8%) blood of healthy volunteers. Platelet-rich plasma was obtained by centrifugation at 300 × *g* for 10 min at room temperature. The platelet pellet was sedimented at 900 × *g* for 6 min at room temperature and then resuspended and adjusted to give a platelet count of 10^{12} platelets per liter in a volume of incubation buffer (0.15 M NaCl, 20 mM Tris, 2 mM $MgCl_2$, 2 mM $CaCl_2$, and 1 mM EDTA; pH 7.45) for LDL binding assays, and in a volume of Tyrode's buffer (0.14 M NaCl, 2.7 mM KCl, 2 mM $CaCl_2$, 2 mM $MgCl_2$ 12 mM $NaHCO_3$, 0.4 mM NaH_2PO_4, 5.5 mM glucose, 10 mM HEPES, pH 7.45) for fibrinogen binding assays.

Pretreatment of washed human platelets with proteolytic enzymes. Suspensions of washed platelets (0.4 mL) were preincubated with proteases (up to 1 mg/mL) in the absence and presence of different protease inhibitors [PMSF 0.5 mM = 10 μL in ethanol; aprotinin or soybean trypsin inhibitor (STI), 5 μM in buffer] for 1 h at 37, 22, and 4°C, following the procedure previously described (2). Control (untreated) platelet suspensions also were incubated under the same conditions. The effect of ethanol on both platelet LDL and fibrinogen binding was assessed by control experiments without PMSF. Finally, in order to inhibit proteolysis at the end of the incubation period in the samples without protease inhibitors, PMSF (0.5 mM = 10 μL in ethanol) and aprotinin (5 μM) were added to the incubation mixture. Platelets were then recovered by centrifugation at 1,600 × *g* for 15 min at room temperature and the final volume adjusted to give a platelet count of 10^{12} platelets per liter with incubation buffer (for LDL binding) or Tyrode's buffer (for fibrinogen binding), both containing bovine serum albumin (5 g/L).

Ligand-binding assays. ^{125}I-LDL binding (0.05 mg of protein/mL) to control and protease-pretreated platelets was determined following the procedure previously described (11,12). Nonspecific binding was defined as binding not displaced by a 20-fold excess of unlabeled LDL. After incubation for 25 min, aliquots (0.2 mL) were removed, layered onto 0.8 mL of 20% sucrose in incubation buffer in Eppendorf tubes, and centrifuged at room temperature for 3 min at 16,000 × *g*. The platelet pellet was then recovered by cutting off the tips of the tubes and counted for radioactivity.

Platelet ^{125}I-fibrinogen binding (100 nM) was determined following the procedure previously reported (2). Washed human platelets were incubated with labeled fibrinogen for 5 min at room temperature, and nonspecific binding was obtained in the presence of a 40-fold excess of unlabeled fibrinogen. Finally, specific high-affinity platelet fibrinogen binding was determined as described above for LDL.

Cultured human skin fibroblasts were grown and maintained in a humidified 5% CO_2 incubator at 37°C in 75-cm^2 flasks, and high-affinity binding was measured following the procedure previously described (16). Briefly, fibroblasts were seeded at 5 × 10^4 in 35-mm culture wells and grown in minimal essential medium containing 10% (vol/vol) fetal calf serum, 100 U/mL penicillin, 100 μg/mL streptomycin, 24 mmol/L $NaHCO_3$, 1 mmol/L pyruvate, and 2 mmol/L L-glutamine. The growth medium was replaced every three days. At confluence, the medium was removed, and the cells were incubated in lipoprotein-deficient serum [2 mL fresh medium containing 5% (vol/vol) lipoprotein-deficient serum instead of fetal calf serum) for 24 h prior to the experiment. The effect of proteases on ^{125}I-LDL binding to human fibroblast was determined following the procedure previously reported by Kovanen *et al.* (17). Calculation of bound lipoprotein was based on the specific activity of labeled LDL, and the results expressed as nanograms of protein bound per 10^8 platelets and as nanograms of protein bound per milligram of total cell protein for fibroblasts. Specific binding was evaluated mathematically by Scatchard analysis (18) to determine the number of binding sites and the dissociation constant by using the KINETIC/EBDA/LIGAND program (19).

Statistical analysis. Results are expressed as mean ± SEM. Differences between means were compared by Student's *t*-test, with $P < 0.05$ considered significant.

RESULTS

Table 1 shows the effect of pretreatment with proteases at varying concentrations on platelet and fibroblast LDL receptors. Under our experimental conditions, platelet pretreatment up to 50 μg/mL with chymotrypsin, pronase, or trypsin had no effect on ^{125}I-LDL binding, and similar values of bound

[a]Iodinated low density lipoprotein (^{125}I-LDL) binding (0.05 mg/mL) to control and pretreated platelets and fibroblasts was determined as described in the Experimental Procedures section. Specific high-affinity binding is expressed as nanograms of ^{125}I-LDL bound per milligram of total cell protein for fibroblast and as nanograms of ^{125}I-LDL bound per 10^8 platelets. Results are mean ± SEM of three independent experiments.

LDL were obtained in control and protease-treated platelets. In contrast, at the same concentration, ^{125}I-LDL binding to human fibroblasts was reduced to 70 ± 10% of control (mean ± SEM, n = 3). However, proteolytic digestion (up to 1 mg/mL) was useful to characterize the platelet LDL receptor (Fig. 1). In these experimental conditions, chymotrypsin pretreatment did not exert any significant effect on ^{125}I-LDL binding; however, in a dose-dependent manner, both trypsin and pronase pretreatment increased and decreased the platelet ^{125}I-LDL binding to 140 ± 20 and 50% ± 11% of control (mean ± SEM, n = 7), respectively. Maximal effects of trypsin and pronase were observed at protein concentrations of 1 and 10 mg/mL, respectively.

Figure 2 shows saturation curves of ^{125}I-LDL binding to protease-treated and control platelets. Scatchard analysis of

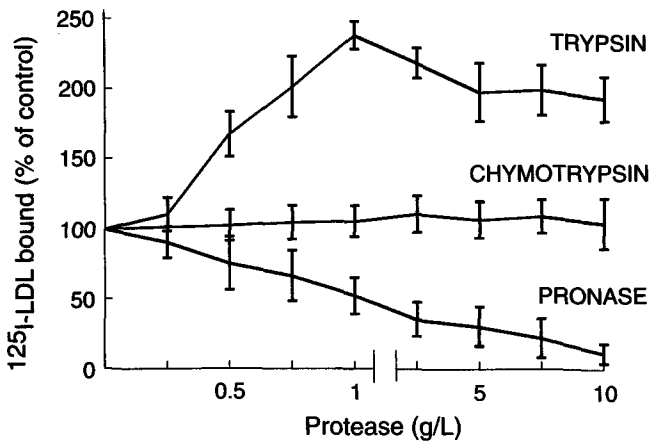

FIG. 1. Effect of proteolytic digestion on platelet low density lipoprotein (LDL) receptor. ^{125}I-LDL binding (0.05 mg/mL) to protease-pretreated platelets was determined as described in the Experimental Procedures section. Results are mean ± SEM of seven independent experiments performed in duplicate.

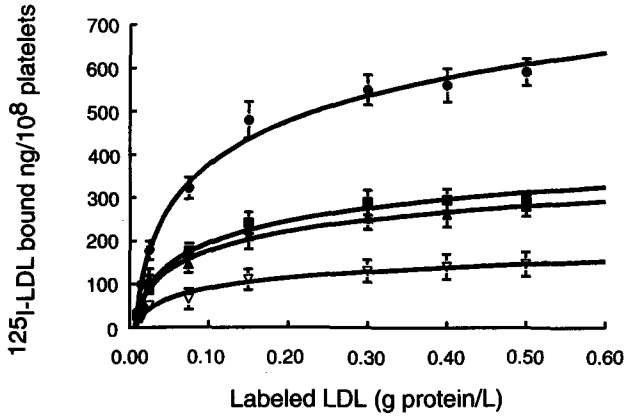

FIG. 2. Saturation curves of ^{125}I-LDL binding to treated pronase (▽), chymotrypsin (▲), trypsin (●), and control (■) platelets. Experimental procedures were carried out as described in the Experimental Procedures section. Platelets (0.4 mL) were preincubated with trypsin, chymotrypsin, and pronase (at a protein concentration of 1 mg/mL) for 1 h at 37°C. Control-unpretreated platelets were also incubated under the same conditions. Afterwards, platelets were recovered by centrifugation and specifically bound ^{125}I-LDL was determined as described in the Experimental Procedures section. Each point is mean ± SEM of five duplicate independent experiments. See Figure 1 for abbreviations.

binding data (Fig. 3) obtained with chymotrypsin-treated platelets showed binding characteristics similar to those of untreated platelets [maximal number of binding sites (B_{max}) = 1967 ± 256 binding sites with a dissociation constant (K_D) of 28 ± 9 nM, and B_{max} = 2119 ± 318 binding sites with a K_D of 31 ± 12 nM, respectively; mean ± SEM, n = 5]. Nevertheless, trypsin-treated platelets showed functional alterations in binding characteristics; B_{max} increased approximately twofold (2156 ± 327 binding sites vs. 5246 ± 296 binding sites, $P < 0.001$, mean ± SEM, n = 5), whereas K_D remained unaltered (31.4 ± 7.8 nM vs. 41.2 ± 10.1 nM, mean ± SEM, n = 5). Binding data obtained with pronase-pretreated platelets showed the opposite effects on B_{max} values, which decreased about 50% (2017 ± 275 binding sites vs. 1153 ±

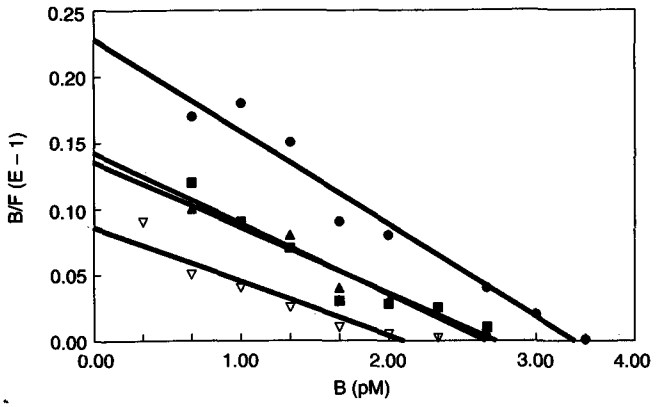

FIG. 3. Scatchard plots of the saturation curves of ^{125}I-LDL binding to treated pronase (▽), chymotrypsin (▲), trypsin (●), and control (■) platelets. See Figure 1 for abbreviation.

195 binding sites), but again with no change in K_D values were found (36 ± 9 nM vs. 33 ± 6 nM, mean ± SEM, n = 5).

The stimulatory effect on ^{125}I-LDL binding induced by trypsin was temperature-dependent. On preincubating at 22 and 37°C, trypsin increased the binding of LDL about 60 ± 15 and 140 ± 20% of control, respectively, whereas at 4°C trypsin was unable to modify platelet LDL binding (Fig. 4B). A minimal preincubation period of 30 min was necessary to observe significant effects, maximal effect being reached after incubation for 60 min at 37°C (Fig. 4A). These results would indicate that both the temperature and time effects relate to protease activity and have nothing to do with LDL-binding isotherms.

Specificity of the proteolytic effect was assessed using trypsin inhibitors (Table 2). Both the trypsin stimulatory and pronase inhibitory effects were fully blocked by 0.5 mM PMSF and 5 μM aprotinin or 5 μM STI. Protease inhibitors at varying protein concentrations were unable to displace the ^{125}I-LDL bound to protease-treated platelets, and inhibition required the addition of trypsin inhibitors prior to the proteolytic enzymes, suggesting that this inhibition was not due to displacement of ^{125}I-LDL bound to its receptor.

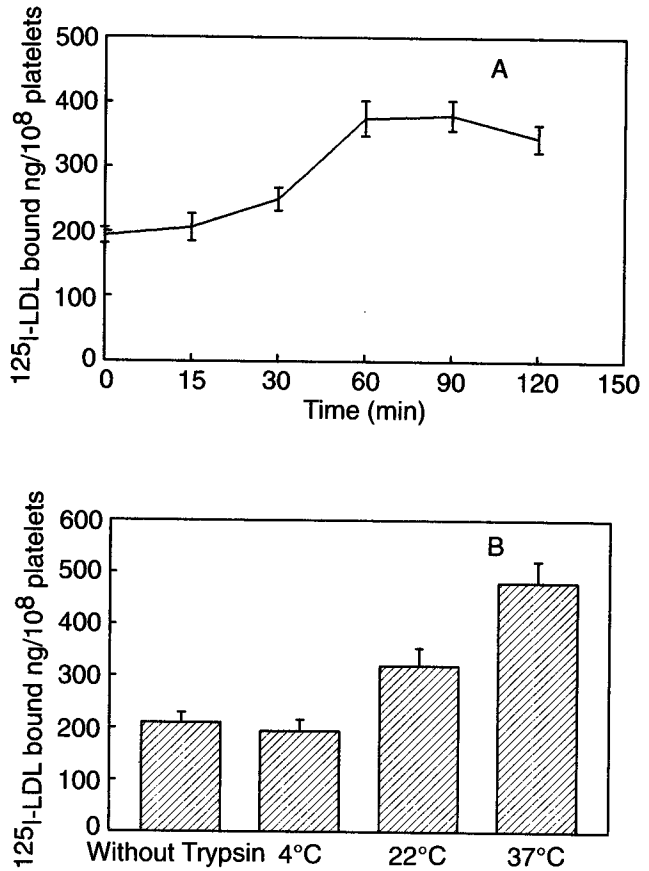

FIG. 4. Effect of time (A) and temperature (B) on the effect of trypsin platelet (1 mg/mL) pretreatment of platelets on subsequent binding of ^{125}I-LDL (0.05 g/L). Results represent mean ± SEM of three independent experiments performed in duplicate. See Figure 1 for abbreviation.

TABLE 2
Effect of Trypsin Inhibitors on the Stimulatory Effect Induced by Trypsin[a]

Addition	Trypsin (mg/mL) None	0.1	0.5	1.0	2.0
None	98 ± 6	110 ± 9	156 ± 12	228 ± 13	211 ± 14
PMSF and aprotinin	96 ± 8	99 ± 10	102 ± 9	98 ± 7	104 ± 10
STI	99 ± 12	104 ± 9	102 ± 11	108 ± 9	99 ± 11

[a]Platelets were preincubated with varying concentrations of trypsin for 1 h at 37°C in the presence and absence of phenylmethylsulfonylfluoride (PMSF) (0.5 mM), aprotinin (5 μM), and soybean trypsin inhibitor (STI) (5 μM). Specifically bound ^{125}I-LDL (ng of protein/10^8 platelets) was measured as described in the Experimental Procedures section. Values are mean ± SEM of three independent experiments. Similar results were obtained for inhibitory effect of pronase.

The effect of chymotrypsin pretreatment of platelets on ^{125}I-fibrinogen (100 nM) binding to unstimulated platelets in the presence and absence of LDL is shown in Figure 5. Figure 5 also shows the effect of LDL on ^{125}I-fibrinogen binding both to unstimulated and ADP-stimulated platelets. Under our experimental conditions, both platelet chymotrypsin (0.5 mg/mL) and pronase (results not shown) activated fibrinogen binding sites in a similar manner to ADP (16 ± 3 ng of ^{125}I-fibrinogen bound/10^8 platelets vs. 12 ± 3 ng of ^{125}I-fibrinogen bound/10^8 platelets). Furthermore, LDL at a protein concentration of 0.3 mg/mL increased ^{125}I-fibrinogen binding to both chymotrypsin-treated and ADP-stimulated platelets (29 ± 2 ng of ^{125}I-fibrinogen bound/10^8 platelets vs. 24 ± 2 ng of ^{125}I-fibrinogen bound/10^8 platelets, respectively). In contrast, LDL at the same protein concentration was unable to activate fibrinogen receptors in unstimulated platelets. These results suggest that LDL increases fibrinogen binding to proteolytically- and ADP-stimulated platelets, whereas in unstimulated

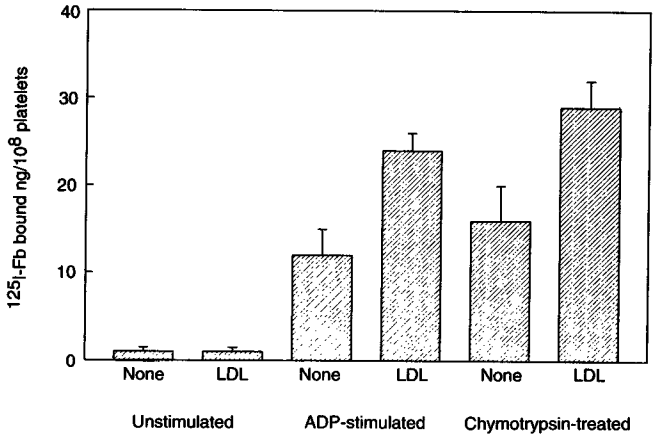

FIG. 5. Effect of LDL (0.3 mg/mL) on ^{125}I-fibrinogen (^{125}I-Fb) binding to chymotrypsin-treated, ADP-stimulated, and unstimulated platelets. Specific high-affinity binding of ^{125}I-fibrinogen (100 nM) in the presence of LDL was determined as indicated in the Experimental Procedures section. Values represent mean ± SEM of four independent experiments performed in triplicate.

platelets this lipoprotein particle is unable to activate GPIIB-IIIA complex.

Finally, it is well known that trypsin at a protein concentration above 1.5 μg/mL induces platelet aggregation (6). Under our experimental conditions, binding of ^{125}I-fibrinogen to trypsin-treated platelets was impracticable both using Tyrode's and incubation buffer, suggesting that a different mechanism *via* GPIIB-IIIA is involved in both LDL and fibrinogen binding to human intact platelets.

DISCUSSION

Plasma cholesterol has been considered as a systemic risk factor for thrombus formation on ruptured atherosclerotic plaques (20). LDL-platelet interactions may explain the increased thrombogenicity described in atheromatous plaques of hypercholesterolemic rabbits (21), the initial step in the modulation of this process being the binding of LDL to a specific platelet receptor (22).

Since the first descriptions of the existence of specific, high-affinity, and saturable binding sites for LDL in platelets, evidence has been presented indicating that these binding sites could be different from the "classical" LDL receptor of nucleated cells (8–12). In fact, Koller (23) first reported that three platelet membrane proteins of 156, 130, and 115 kDa bound LDL specifically. Further studies identified platelet membrane glycoprotein IIB-IIIA complex (the inducible fibrinogen receptor) as responsible for platelet–LDL interactions (10). We have demonstrated that a monoclonal anti-LDL receptor (IgG-C7) was unable to block binding of LDL to control platelets (11). Our most recent findings revealed that the platelet LDL receptor, in contrast to the "classical" LDL receptor of human fibroblasts, does not mediate an endocytotic response and recognizes both native and oxidized LDL particles with the same apparent affinity (12). These data strengthen the hypothesis that platelet LDL receptor differs from "classical" LDL receptor, but on the basis of LDL binding characteristics, several conflicting results concerning the implication of GP IIB-IIIA complex on platelet LDL binding have been presented (8). Nevertheless, GP IV or CD-36, a GP resistant to proteolytic digestion, appears to be involved in the binding of oxidized LDL particles to both monocyte-derived macrophages and platelets, and it has been suggested that this GP could be a new lipoprotein receptor (24,25). Since our previous results found that the platelet LDL receptor binds both oxidized and native LDL particles with the same apparent affinity (12), and implicated a GP resistant to proteolytic digestion in the binding of oxidized LDL, we have attempted to characterize the effect of several proteases on the platelet LDL receptor, and the functional consequences of this effect.

In this study, we have demonstrated that protease treatment, prior to incubation with ^{125}I-LDL, totally abolished fibroblast LDL binding but did not alter platelet LDL binding. In addition, the platelet LDL receptor was resistant to chymotrypsin treatment (up to 10 mg/mL); however, mild pronase treatment (1 mg/mL) was able to reduce platelet LDL binding approximately fifty percent, and more extensive proteolytic digestion (10 mg/mL) caused total inhibition of the binding. Taken together, these data suggest that a different type of cell-surface protein receptor is involved in the binding of LDL to human platelets, and are in agreement with our previous results (11,12).

Treating platelets with chymotrypsin and pronase up to 1 mg/mL produces neither platelet shape change nor aggregation (2). In contrast, 1 μg/mL trypsin induces platelet shape change and aggregation at higher concentrations (26). When we preincubated platelets with trypsin (up to 1 mg/mL) in the presence of 1 mM EDTA, both platelet shape and aggregation were prevented (results not shown), whereas in the absence of EDTA, trypsin caused a complete aggregation. Our results also found increased LDL binding sites when human platelets were treated with trypsin in the presence of EDTA (1 mM). Enhanced lipoprotein binding by platelets after mild trypsin treatment has not been previously reported; however, a stimulatory effect on high density lipoprotein binding to peripheral blood lymphocytes has been described (27). In the present study, our data show that mild trypsin treatment (1 mg/mL) increases platelet LDL binding without changes in dissociation constant and that this stimulatory effect is dependent upon dose, time, and temperature. Moreover, a minimal preincubation period of 30 min is necessary to find significant effects, suggesting that protease effect is caused by proteolysis and not by platelet activation.

Specificity of the effect of proteases on ^{125}I-LDL binding to platelets was assessed in the presence and absence of protease inhibitors. Equimolar concentrations of several protease inhibitors such as STI, aprotinin, and PMSF, led to a total reduction of the proteolytic effect. The effect of protease inhibitors was principally the result of a noncompetitive interaction with the proteases, and cannot be attributed to a competitive inhibitory mechanism.

Finally, it is well known that the GPIIB-IIIA complex is unable to bind fibrinogen unless platelets are activated by agonists such as ADP or proteolytic enzymes, such as chymotrypsin and pronase (2). Conversion of platelet membrane GPIIB and GPIIIA from the latent state to a GPIIB-IIIA complex is a calcium-dependent process. Therefore, the binding of fibrinogen requires this divalent ion and chelating agents cause the dissociation of the complex, fully inhibiting both fibrinogen binding and platelet aggregation (28). It has recently been demonstrated that LDL increases the exposure of fibrinogen receptors instead of inducing inhibition in intact resting platelets (29). The authors postulated that GPIIB-IIIA probably assumes a different conformation in experimental conditions which allow the binding of LDL, and in intact platelets GPIIB-IIIA complex is unable to bind LDL. The results of this study show that chymotrypsin–pretreatment did not alter LDL binding characteristics, whereas it can activate fibrinogen receptors. Moreover, in agreement with van Willigen *et al.* (29), our data demonstrate that activation of fibrinogen binding sites induced by ADP was enhanced in the presence of LDL, and in a similar manner this lipoprotein particle

increased the binding of fibrinogen to protease-treated platelets. In contrast, when platelet aggregation was prevented (incubation buffer containing EDTA), LDL binding was increased by trypsin-pretreatment, whereas fibrinogen binding was unrealizable. All the results indicate that the platelet LDL receptor has a different proteolytic susceptibility compared to both "classical" LDL receptors and fibrinogen receptors, suggesting that the binding of LDL to intact platelets could be related to GP other than GPIIB-IIIA.

A characteristic feature of platelet membrane GP (30,31) is their susceptibility to proteolysis caused by moderate trypsin concentrations (1 mg/mL). GP IV or CD-36, however, has been found to exhibit extensive resistance to proteolytic digestion (32). It has been reported that in both platelets and monocyte-derived macrophages, GP IV-bound oxidized LDL particles with high affinity (24,25). These data, combined with our previous results, suggest that a GP resistant to proteolytic digestion, such as GP IV, could be related to the binding of lipoproteins to intact platelets. The significance of this potential platelet LDL receptor regulation mechanism involving proteolysis needs to be explored in further studies.

Effects of Randomization of Partially Hydrogenated Corn Oil on Fatty Acid and Cholesterol Absorption, and Tissue Lipid Levels in Rats

Tamiho Koga[a,*], Takako Yamato[a], Ikuo Ikeda[b] and Michihiro Sugano[c]

[a]Department of Food and Nutrition, Nakamura Gakuen University, Jonan-ku, Fukuoka 814-01, [b]Laboratory of Nutrition Chemistry and [c]Laboratory of Food Science, Kyushu University School of Agriculture, Higashi-ku, Fukuoka 812-81, Japan

ABSTRACT: Randomization of partially hydrogenated corn oil containing approximately 45% of *trans* octadecenoic acid only slightly, but not significantly, increased the lymphatic fatty acid absorption in rats. No effect of randomization was observed on cholesterol absorption. When rats were fed these fats at the 8.8% level (with 1.2% safflower oil) for three weeks, the concentrations of serum cholesterol, and serum and liver phospholipid were significantly higher in randomized fat than in control fat, which was composed of 9% high-oleic safflower oil and 1% palm oil. Liver cholesterol tended to be higher in randomized fat. In contrast, nonrandomized fat was not hyperlipidemic compared to control fat. Although the fatty acid composition of liver phospholipids suggested a possible interference of *trans* fatty acid with the metabolism of linoleic acid to arachidonic acid, there was no effect of randomization. In the two hydrogenated fat groups, *trans* octadecenoic acid was incorporated and distributed similarly in adipose tissue triacylglycerol. These observations indicated that randomization of partially hydrogenated fat is not beneficial to various lipid parameters in rats.
Lipids 30, 935–940 (1995).

The nutritional and physiological functions of dietary fat depend on the structure of triacylglycerol, i.e., the positions of fatty acids esterified in the glycerol skeleton. In classical studies on the effect of the difference in the positional distribution of fatty acids in the triacylglycerol molecule, linoleic acid esterified at position-2 of glycerol was more hypocholesterolemic than that at position-3 (1,2). More recently, Kritchevsky (3) reviewed that the atherogenic propensity of dietary peanut oil in rabbits disappeared when it was interesterified. Sugano *et al.* (4) observed in rats a slight but insignificant reduction of the cholesterol-elevating nature of palm oil after randomization. Similar results were also reported for randomized palm oil (5), lard (6), peanut oil (7), and fish oil (7). In the case of a mixture of coconut oil and palm oil, chemical randomization improved the absorption of long-chain saturated fatty acids (8).

Trans fatty acids have been suspected to be hypercholesterolemic and to disturb lipoprotein metabolism (9–12). Since the use of partially hydrogenated vegetable oils is still increasing in various areas of commercial food processing, it is of interest to know whether the randomization could modify possible untoward effects of *trans* fat. Considering the positional specificity of pancreatic lipase toward triacylglycerol and the efficient micellar solubility of 2-monoacylglycerol, a lipase hydrolysis product, the difference in the positional distribution of fatty acid in the triacylglycerol molecule may influence their intestinal absorption and metabolic fates (8,13).

In this context, it is reasonable to understand the effect of randomization of *trans* fat on its intestinal absorption efficiency. In the study reported here, we examined the effect of interesterification of partially hydrogenated corn oil (PHC) containing a high level of *trans* fatty acid, exclusive of *trans* octadecenoic acid on intestinal absorption of fatty acid and cholesterol in lymph-cannulated rats. The effect of positional fatty acid randomization on lipid metabolism was also studied.

MATERIALS AND METHODS

Fat sources. PHC and its randomized product were a gift from Dr. I. Niiya (The Japan Institute of Oils and Fats, Other Foods Inspection, Tokyo, Japan). For randomization, PHC was interesterified in the presence of sodium–methoxide catalyst (0.5 wt%) at 80°C for 30 min. The purified interesterified fat contained more than 98% of triacylglycerol and <2% remained as mono- and diacylglycerols. The composition and distribution of fatty acids of the fat preparations are shown in Table 1. The interesterification did not change the fatty acid composition of triacylglycerol, but changed the fatty acid positional distribution to a more evenly randomized structure as compared to the fatty acid composition of total and the 2-position of triacylglycerol measured after pancreatic lipase hydrolysis (14). In brief, to approximately 10 mg of fat samples was added 1 mL of Tris buffer, pH 8.0, containing 8 mg of porcine pancreatic lipase (Wako Pure Chemicals, Osaka, Japan), and the mixture was vigorously shaken at 40°C for 30 min. Lipids were then extracted with a 2:1 chloroform–methanol mixture, and 2-monoacylglycerol was separated by thin-layer chromatography.

Fat absorption experiment. Male Sprague-Dawley rats (Seiwa Experimental Animals, Fukuoka, Japan) weighing 390 g on average were given *ad libitum* a commercial nonpurified diet (Type NMF; Oriental Yeast Co., Tokyo, Japan) and drinking water. Under Nembutal anesthesia, rats were subjected to cannulation of the left thoracic lymphatic channel, and an indwelling catheter was placed in the stomach. A solution containing 139 mM glucose and 85 mM NaCl was infused continuously until the end of lymph collection at a rate of 3 mL/h through the gastric tube (15). After surgery, animals were placed in restraining cages in a warm recovery room and allowed free access to drinking the isosmotic infusion solution. The next morning, after collection of lymph for 2 h as a control period, each animal was administered 3 mL of a test emulsion through the gastric tube, and the lymph was collected for 24 h, beginning at 1000 hours. The 3-mL test emulsion contained 200 mg of sodium taurocholate, 50 mg of fatty acid-free albumin (Miles Scientific, ICN Immuno Biologicals, Lisle, IL), 1 mCi of [^{14}C] cholesterol (60 mCi/mmol; NEN Research Products, Boston, MA), 25 mg of cholesterol, and 200 mg of fats. The emulsions were prepared by sonication prior to administration. The lymph was collected in a tube containing EDTA at 3-h intervals during the first 9 h after administration of a test emulsion and at a single collection 9–24 h after the emulsion.

Feeding experiment. Male Sprague-Dawley rats five-weeks-old (Seiwa Experimental Animals) were housed individually in a temperature (20–22°C) and light (lights on 0600 to 1800 hours) controlled room. The animals were fed AIN-type purified diets (16) *ad libitum* for three weeks after three days of acclimatization. The diet composition is given in Table 2 together with the fatty acid composition of dietary fat. High-oleic safflower oil served as a control fat, and the content of oleic acid was made equal to that of total octadecenoic acids in hydrogenated fats by mixing with palm oil. By this manipulation, the linoleic acid content was also comparable among three dietary fats. Food intake and body weight were recorded every other day. Feces were collected for two days during the end of third week. After three weeks, rats were killed by decapitation without fasting, and blood collected. Tissues were immediately excised, blotted, and weighed.

[a]Other ingredients were vitamin mixture AIN-76, 1.0; mineral mixture AIN-76, 3.5; choline bitartrate, 0.2; cellulose, 5.0; corn starch, 15.0; and sucrose, 45.3. See Table 1 for other abbreviations.

Lipid analyses. Lymph lipids were extracted by the method of Folch *et al.* (17). Pentadecenoic acid (Aldrich, Milwaukee, WI) was added as an internal standard, and the fatty acid composition was measured by gas–liquid chromatography (18). The fatty acid recovery rate was calculated by subtracting the fatty acid amount in the blank lymph (3–6 mg fatty acids/mL) from that in the lymph collected after the administration of a test emulsion. An aliquot of the lymph was transferred to a scintillation vial, and 10 mL of Aquasol II (NEN Research Products) was added. The radioactivity was measured using a liquid scintillation counter (LSC-1200; Aloka, Tokyo, Japan). Serum and liver lipids were extracted (17), and the concentrations of cholesterol, triacylglycerol, and phospholipids were measured (19). Liver phospholipids were separated into their constituents by thin-layer chromatography (20), and the fatty acid composition and phosphorus content (21) were measured. Fecal lipid contents were measured by the method A of Kamer *et al.* (22). The fatty acid composition of fecal lipids was measured on the chloroform-methanol extract.

Statistical analysis. Student's *t*-test (for the absorption study) and Duncan's multiple range test (for the feeding study) (23) were used to determine the statistical difference between groups in absorption and feeding studies, respectively.

RESULTS

Effects of randomization on fatty acid and cholesterol absorption. The lymph flow rate was comparable between randomized and nonrandomized fats (data not shown). As shown in Figure 1, lymphatic absorption of fatty acid was largely unaltered by the randomization of hydrogenated fat administered (Fig. 1A), but it tended to be slightly higher with the randomized fat than in the nonrandomized fat, particularly 9 h after the administration of the fat emulsion. No effect on choles-

terol absorption was observed (Fig. 1B). Lymph collected periodically showed no significant differences in the fatty acid compositions between two types of fats at any time intervals (data not shown).

Effects of randomization on lipid metabolism. In this experiment, we could directly compare the effect of the difference in the geometry of dietary octadecenoic acids (between the control fat and two hydrogenated fats) and the distribution of fatty acid in the triacylglycerol molecule (between two hydrogenated fats) as well.

Food intake and weight gain were comparable among the groups, but the weight of some tissues differed depending on the fat source (Table 3). Thus, relative weight of liver was significantly higher and that of heart significantly lower in rats fed hydrogenated fats than in those fed control fat, high-oleic safflower oil. However, there was no difference in weight between these tissues and two hydrogenated fat groups. Weights of kidney, spleen, and epididymal adipose tissue were all comparable among three groups.

TABLE 3
Effects of Randomization of Partially Hydrogenated Corn Oil on Growth Parameters and Tissue Weights[a]

Parameter	Dietary group

Epididymal adipose tissue	1.59 ± 0.29	1.73 ± 0.12	1.67 ± 0.28

[a]Values are means ± SE of eight rats. See Table 2 for abbreviations.
[b,c]Values with different superscript letters are significantly different at $P < 0.05$.

The concentrations of serum and liver lipids are summarized in Table 4. There was a trend toward increasing serum lipids after randomization, and serum cholesterol and phospholipid were significantly higher in animals receiving randomized fat than in the control fat group, with the nonrandomized fat group being intermediate. The concentrations of liver lipids were again highest in the randomized fat group, and liver phospholipid was significantly higher compared to the control group. However, there was no change in the fatty acid composition of liver phospholipid (data not shown).

The data shown in Table 5 indicate that the fatty acid composition and distribution in adipose tissue triacylglycerol were the same between the two hydrogenated fat groups. Thus, the proportion of *trans*-octadecenoic acid was not different in total and 2-position of triacylglycerol. Table 6 shows that feeding *trans* fats resulted in a significant reduction of arachidonic acid and a significant increase in linoleic acid in

[a]Values are means ± SE of eight rats. See Table 2 for abbreviations.
[b,c, d,e]Values with different letters are significantly different at $P < 0.05$, respectively.

liver phosphatidylcholine. Linoleic acid was also increased in phosphatidylethanolamine. Thus, the ratio of (20:3n-6 + 20:4n-6)/18:2n-6, an index for linoleic acid desaturation, was significantly lower in the two hydrogenated fat groups. The proportion of docosapentaenoic acid (22:5n-6) decreased significantly on feeding hydrogenated fats. In addition to these changes, there was a significant difference in the proportion of stearic and palmitoleic acids. In liver triacylglycerol, palmitic and palmitoleic acids were significantly higher in rats fed hydrogenated fats than in those fed high-oleic safflower oil.

Rats fed hydrogenated fats excreted more lipids in their feces (0.26 ± 0.04 and 0.22 ± 0.03 g/d for nonrandomized and randomized fats, respectively) than did rats fed high-oleic safflower oil (0.13 ± 0.04 g/d, different from the two hydrogenated fat groups at $P < 0.05$). There was, however, no significant difference in the fecal lipid level between the two hydrogenated fat groups. Feeding hydrogenated fats resulted in a significant reduction of the proportion of palmitic and stearic acids in feces, while increasing *trans* octadecenoic acid (Table 7). The same level of *t*-18:1 was found in rats fed hydrogenated fats. A small amount of *t*-18:1 was also detected in rats fed no *trans* fatty acid, the control group.

DISCUSSION

The studies on the effects of glyceride structure on absorption and metabolism have mainly been focused on structured triacylglycerols composed of medium-chain fatty acids and polyunsaturated fatty acids (24–27), and more detailed studies are still required for understanding this issue (28). The experimental procedure used to study fatty acid absorption may not be physiological, and there is some limitation to the interpretation of the results. However, the observation that the net absorption rate of triacylglycerol was quantitative and that of cholesterol was around 50% supports the usefulness of the current procedure (15,29). Vahouny *et al.* (30) established this procedure after a systemic examination of the experimental conditions.

In the present study, the fatty acid absorption was largely uninfluenced by randomization. However, the apparent absorption rate of *trans* fatty acid seemed to be slightly lower

than in *cis* fatty acid (93.1 ± 6.8 vs. 94.8 ± 5.2% for PHC and 89.2 ± 8.2 vs. 93.6 ± 4.7% for randomized PHC) as observed for the free fatty acids (31). Because of a less specific positional distribution of fatty acids in triacylglycerol in PHC used in the present study, the effects of randomization on lipid absorption were rather marginal. Thus, the lymphatic fatty acid absorption was largely unmodified after randomization, although it tended to be slightly higher in randomized fat (96.8 ± 9.0 vs. 104 ± 12%). A more distinct improvement of fat absorption has been reported in randomized saturated fat (8). The metabolic significance of this small difference is not known, but the cumulative effect may not be insignificant. Once absorbed, some degree of rearrangement of the positional distribution of fatty acid has been observed when long-chain saturated fatty acids were given as triacylglycerol (3,27) while the randomization did not influence cholesterol absorption.

The fatty acid composition of adipose tissue was similar between two hydrogenated fat groups and reflected the composition of lymph lipids. However, the proportion of palmitic acid in the 2-position of adipose triacylglycerol in rats fed *trans* monoene was significantly higher than in those fed *cis* monoene, despite the same dietary level of palmitic acid. In contrast, the proportion of palmitic acid in whole triacylglycerol was not different among dietary fats. This observation, together with a significant increase in palmitoleic acid at the 2-position, suggests a change in the molecular species of adipose tissue triacylglycerol due to feeding *trans* fatty acid. The implications of this structural change are not clear, but it appears that not all fatty acids are released from and/or incorporated into the adipose tissue at the same rate (32).

The fatty acid composition data of liver phospholipids indicated a considerable interference by *trans* acid with the metabolic pathway leading from linoleic acid to arachidonic acid, in agreement with previous observation (33). However, this change may not influence eicosanoid production as indicated by Zevenbergen and Hademan (34), who showed that in rats 2 energy % linoleic acid is sufficient to prevent effects of dietary *trans* fatty acids on eicosanoid production. The proportion of docosapentaenoic acid (n-6) also decreased after feeding hydrogenated fats. This pentane can accumulate when dietary supply of n-3 polyunsaturated fatty acids is deficit (35). Since the proportion of docosahexaenoic acid (n-3) was not influenced by the type of dietary fats, the reduction of the pentane acid suggests a diverse effect of *cis* and *trans* monoenes on n-3 polyunsaturated fatty acid metabolism.

Although the present study failed to show a clear-cut effect of randomization of *trans* acid-containing fat on fatty acid absorption, it increased serum cholesterol significantly and, to a lesser extent, liver cholesterol as well. Thus, there is a possibility that a marginal increase in intestinal fatty acid absorption cumulatively influences lipid metabolism. In contrast, nonrandomized fat was not hypercholesterolemic as reported previously (33). The increase in liver weight after feeding partially hydrogenated fats may, in part, be attributed to an accumulation of triacylglycerol and phospholipid (Table 4). Thus, the randomization may have an undesirable effect on lipid metabolism. The reduction of heart weight by dietary *trans* fats has not been observed before, and at present it is difficult to explain the observed effect of *trans* fat.

Holman and co-workers (36) indicated that about 4% energy of linoleic acid is required for prevention of disturbance by *trans* fatty acid of polyunsaturated fatty acid composition in tissue phospholipids. Although 2% energy was shown to be enough in other studies (33,34), our rats may have been marginally essential fatty acid-deficient. Hence, the results of tissue weights, cholesterol levels, and phospholipid fatty acids may need to be evaluated in light of this possibility.

In conclusion, our results did not support the idea that randomization of PHC leads to beneficial effect on various lipid parameters, but rather that it enhances the hypercholesterolemic propensityof dietary *trans* fatty acids. There may be cumulative untoward effects when randomized fat was consumed regularly. Since randomization simultaneously causes changes in the distribution of fatty acids other than *trans* fatty acids, particularly palmitic acid, it is difficult to attribute the observed effect entirely to changes in the positional distribution of a single fatty acid.

Erythrocyte Fatty Acids of Term Infants Fed Either Breast Milk, Standard Formula, or Formula Supplemented with Long-Chain Polyunsaturates

Maria Makrides, Mark A. Neumann, Karen Simmer and Robert A. Gibson*

Department of Paediatrics & Child Health, Flinders Medical Centre, Bedford Park (Adelaide), South Australia 5042, Australia

ABSTRACT: The purpose of our study was to assess whether a supplement of fish oil (FO) and evening primrose oil (EPO) for formula-fed infants was capable of avoiding reductions in erythrocyte docosahexaenoic acid (DHA, 22:6n-3) and arachidonic acid (AA, 20:4n-6) associated with standard formula feeding. Healthy, term infants, whose mothers chose to formula feed, were randomized to either a placebo or supplemented formula for their first 30 wk of life. A reference group of beast-fed infants also was enrolled. Erythrocyte fatty acids were measured by capillary gas chromatography on day 5 and in weeks 6, 16, and 30. Supplementation of formula with 0.36% of total fatty acids as DHA resulted in erythrocyte DHA being maintained at or above breast-fed levels for the entire 30-wk study period, and breast feeding (0.21% DHA) resulted in a modest fall in erythrocyte DHA relative to baseline (day 5) values. The level of erythrocyte DHA in placebo formula-fed infants was halved by week 16. AA levels decreased in all infants in the first six weeks, but the levels in breast- and placebo formula-fed infants increased with age and returned to approximate baseline (day 5) values by 16 and 30 wk of age, respectively. Erythrocyte AA in FO + EPO-supplemented infants remained low and below breast- and placebo formula-fed levels. Our data suggest that dietary supplementation with DHA at 0.36% total fatty acids results in erythrocyte DHA levels above those found in breast-fed infants. EPO supplementation was not effective at maintaining erythrocyte AA when given with FO.

Lipids 30, 941–948 (1995).

Recent studies have postulated that the n-3 long-chain polyunsaturated fatty acid (LCPUFA), docosahexaenoic acid (DHA, 22:6n-3), may be important in the development of optimal neural function in preterm infants. Preterm infants fed diets containing n-3 LCPUFA [breast milk or formulas supplemented with fish oils (FO)] are reported to have improved neural maturation as assessed by electroretinograms, visual evoked potential acuity, and behavioral acuity measures compared with infants fed standard, unsupplemented formula (1–3). However, despite such observations, scientists and clinicians have been hesitant to recommend the addition of FO to infant formulas. Most FO, specifically those that have become routine in clinical trials, contain more eicosapentaenoic acid (EPA, 20:5n-3; ≈15% of total fatty acids) than DHA (≈11% total fatty acids), and have negligible n-6 fatty acids. In contrast, breast milk has more DHA than EPA and also contains n-6 LCPUFA such as arachidonic acid (AA, 20:4n-6). Preterm infants fed FO-supplemented formula have increased erythrocyte levels of EPA and reduced AA relative to infants fed standard formula (4,5) and breast milk (5). Such decreases in AA status of FO-supplemented formula-fed preterm infants have been associated with poorer growth compared with standard formula-fed infants (6).

EPA is the precursor to the three-series eicosanoids, which may suppress some effects of the two-series eicosanoids originating from AA. Although this may be beneficial in certain pathological instances, such as chronic inflammatory or thrombotic conditions, concerns persist about limiting the activity of AA-derived eicosanoids in infancy. For example, in preterm studies, bleeding times of FO-supplemented formula-fed infants are reported to be longer than those for infants fed human milk or unsupplemented formulas at 35–37 wk postconceptional age (5). Although all bleeding times were reported to be within accepted clinical norms, concerns still persist, especially considering the predisposition of preterm infants to intracranial bleeding.

However, most infants are born at term, and most recent research attention has focused on the dietary requirements of the healthy infant. We (7) and others (8,9) have reported that breast-fed term infants have better neural responses than infants fed formula, and postulated that DHA may be associated with these observations, as higher levels of DHA in the erythrocytes of breast-fed infants are associated with improved visual measures (7). The aim of this study was to assess n-3 LCPUFA supplementation of formula for term infants on erythrocyte fatty acid status and visual evoked potential acuity. Data on visual acuity are reported elsewhere (10), and detailed fatty acid results are reported here. We assessed whether FO together with evening primrose oil (EPO) was capable of increasing erythrocyte DHA of formula-fed infants to approximate breast-fed infant levels, without a con-

comitant reduction in erythrocyte AA, over the first 30 wk of infancy. At the time our study was commended, AA was not available for use as a supplement for infant formula, and therefore, we decided to use EPO, which contains γ-linolenic acid (GLA, 18:3n-6), a metabolic precursor of AA, that by-passes the supposed rate-limiting δ6 desaturase enzyme; it was hypothesized that GLA would prevent a fall in erythrocyte AA.

METHODS

Subjects. Women giving birth to healthy, term (37–42 wk gestation) infants at Flinders Medical Centre (Bedford Park, Australia) were eligible for entry into the study. Only women who had no known history of lipid metabolism disorders and insulin-dependent diabetes, and had babies with appropriate weight for gestation were approached to enter the study. Written informed consent was obtained following guidelines stipulated by the Committee on Clinical Investigations (Ethics). The mother's decision to breast or formula feed was not influenced, as enrollment to the study was after she had made her feeding choice.

Dietary treatment. Mothers who intended to formula feed their infants were randomly assigned either a placebo or supplemented formula. Mothers and assessment staff were unaware of the formula type (10). The supplement used was a 1:1 microencapsulated blend of FO + EPO in vacuum sealed sachets, supplied by Scotia Pharmaecuticals (Guildford, United Kingdom). The base formula was donated by Nestle Australia (Sydney, Australia) and was similar in nutrient composition to commercial "Nan," an infant formula (Nestle Australia), except that the fat blend was purely of vegetable origin (10). Mothers in the supplemented group were asked to add the contents of one sachet to 200 mL of formula, and mothers in the placebo group were instructed to add an extra amount of placebo powder to 210 mL of formula (10). The fatty acid compositions of the two study formulas were analyzed before the study and intermittently throughout the study period. The composition was stable and is listed in Table 1. The limited supply of FO + EPO supplement resulted in a smaller number of infants being enrolled in this group.

Mothers who chose to breast feed were encouraged to do so for as long as possible. The predetermined definition of full breast feeding was no formula in the first 16 wk of life and a maximum of 120 mL formula/day from 16 to 30 wk of age. Mothers were telephoned on a weekly basis to inquire about feeding practice, and were offered support. Infants who did not meet the criteria for full breast feeding were excluded. Of 47 mothers recruited with an intent to breast feed, 24 were excluded.

Infants with feeding or settling problems were referred, when appropriate, to a dietitian, pediatrician, or lactation consultant. All mothers received nutrition advice according to National Health & Medical Research Council guidelines with the recommendation that solid foods be introduced between four and six months of age (11). The fatty acids contribution of solid foods was not quantified as common weaning foods contain negligible amounts of LCPUFA (12).

TABLE 1
Fatty Acid Composition of Infant Formulas and Breast Milk of Each Mother During Week 16 of Lactation (data expressed as mean % total fatty acids ± SD)

[a]The analysis of infant formula was checked before the commencement of the study and intermittently throughout the study period.
[b]Each analysis represents a pooled breast milk sample collected over seven consecutive days in week 16 of lactation from mothers of fully breast-fed infants.
[c]ND, not detected.

Erythrocyte fatty acid assessment. Blood samples were taken by heel-prick (200 μL) on day 5 (timed to coincide with the routine Guthrie test), 6 wk, 16, and 30 wk, into tubes containing lithium heparin. In the case where consent to participate in the study was attained after the Guthrie test and the mother did not wish a further blood test, no day 5 blood sample was available for analysis. Erythrocytes were separated from plasma, and lipids were extracted, methylated, and quantified following previously reported procedures (13).

Statistical analysis. All data are expressed as mean ± SD unless otherwise stated. Effects of diet and age (time) on erythrocyte fatty acids of fully breast-fed, placebo-, and supplemented formula-fed infants were determined by repeated measures analysis of variance (ANOVA). Significant differences due to either dietary grouping or age were subsequently identified by least significant difference. However, differences in erythrocyte linoleic acid (LA, 18:2n-6), AA, 22:5n-3, and DHA were already established between infants who were breast-fed and those who received formula by day 5 of life (see Table 2). It was decided not to correct/normalize these differences as they were probably dietary-induced and, hence, important. Further, the correction of baseline (day 5) variation, either by expressing the fatty acid data as change from day 5 or including the day 5 values as a constant covariate in the repeated measures ANOVA, would have resulted in the loss of a degree of freedom in the time series (14). Hence, it would not be possible to statistically test for differences between day 5 and 6 wk within each dietary group. This was pertinent, as large shifts in fatty acids, such as AA, LA, DHA, and EPA, occurred in the first six weeks of life and were often related to dietary grouping.

TABLE 2
Day 5 Infant Erythrocyte Fatty Acids (data expressed as mean % total fatty acids ± SD)[a]

Fatty acid	Intend to breast feed (n = 34)	Intend to formula feed (n = 24)
Total saturated	44.82 ± 2.23	44.41 ± 3.20

[a]Values without common superscripts indicate significant differences at $P < 0.05$.

Thirteen infants had missing day 5 blood samples because they were enrolled after the routine Guthrie blood test, which would have excluded them from the analysis as they had incomplete sets of serial data. In all these cases, consent to participate in the study was obtained on day 5 or 6 after the routine Guthrie test, and mothers did not wish that extra blood be taken from their babies. As this was a random occurrence at the beginning of the study before any dietary treatment had been administered (five breast-fed infants, eight formula-fed infants), it was rationalized that these missing values could be replaced by the appropriate day 5 erythrocyte fatty acid means (listed in Table 2). Frequency distributions for each erythrocyte fatty acid were checked before and after replacement of missing values, and little change was noted in the variance. Further, the repeated measured ANOVA on each erythrocyte fatty acid was performed both with and without the missing values replaced, and again, little difference was noted. All analyses were completed using SPSS for Windows 6.0 (SPSS Inc., Chicago, IL).

RESULTS

The subjects are described in Table 3. Infants from all groups were of similar gestation, weight, length, and head circumference at birth. A total of 13 subjects were enrolled into the supplemented-formula group as only a limited supply of EPO + FO supplement was available. The data presented here are from infants with complete sets of serial fatty acid measures (21/23 fully breast-fed infants; 18/19 placebo formula-fed infants; 12/13 supplemented formula-fed infants; Table 4). All four missing values were a result of incomplete blood analysis at 30 wk.

Erythrocyte n-3 fatty acids. There was a modest reduction in DHA in breast-fed infants that achieved statistical significance at 30 wk of age (Fig. 1 and Table 4). In contrast, DHA levels in placebo formula-fed infants rapidly declined for 16 wk (53% decrease), slowing thereafter so that an apparent further decline (9%) at 30 wk did not reach statistical significance. Supplementation of infant formula with FO (0.36% total fatty acids as DHA) resulted in DHA levels being elevated above those of breast-fed infants at 16 and 30 wk (Fig. 1 and Table 4).

TABLE 3
Description of Subjects

Parameter	Fully breast-fed	Placebo formula-fed	Supplemented formula-fed
n	23	19	13
Gestation (wk ± SD)	39.8 ± 1.1	39.6 ± 1.2	39.1 ± 1.7
Male/female ratio	9:14	8:11	9:4
Apgar at 5 min (score ± SD)	9.5 ± 0.5	9.3 ± 0.6	9.1 ± 0.8
Birth weight (g ± SD)	3589 ± 360	3650 ± 416	3288 ± 525
Birth length (cm ± SD)	51.0 ± 1.9	51.2 ± 2.1	50.2 ± 2.8
Birth head circumference (cm ± SD)	35.1 ± 1.0	35.2 ± 1.2	34.4 ± 2.2

Although erythrocyte EPA in breast- and placebo formula-fed infants significantly increased between day 5 and 16 wk, EPA levels remained below 0.4% of total fatty acids for the whole of the study's period (Fig. 2 and Table 4). Such results were in direct contrast to those observed for infants fed the FO + EPO supplement, where there was a tenfold rise in EPA levels between day 5 and week 30 (Fig. 2 and Table 4), with a maximum EPA level of ≈2% of total fatty acids. Erythrocyte 22:5n-3 increased in all infants with age, but was greatest in FO + EPO-supplemented formula-fed infants (Table 4). α-Linolenic acid (ALA, 18:3n-3) accounted for ≈0.20% of total fatty acids in all dietary groups at all assessment ages.

Erythrocyte n-6 fatty acids. A decrease in AA between day 5 and week 6 was observed in all infants (12% in fully breast-fed infants, 20% in placebo formula-fed infants, and 28% in supplemented formula-fed infants; Fig. 3 and Table 4). Thereafter, both the breast and placebo formula groups demonstrated significant shifts toward baseline levels, so that breast-fed infants attained day 5 levels by 16 wk and there was no difference in the level of AA between breasts and placebo formula-fed infants at 30 wk. Erythrocyte AA in the supplemented formula group remained below that of infants fed either breast milk or placebo formula at all time points except day 5.

Erythrocyte LA increased in all dietary groups from a day 5 level of 5–6% to 8–12% of total fatty acids at week 6 (Fig. 4 and Table 4). LA was greatest in placebo formula-fed infants, rather than in the breast and supplemented formula groups at 6, 16, and 30 wk. Between 16 and 30 wk of age, there was a modest, but significant, increase in the level of erythrocyte LA in all infants, and that was independent of their dietary grouping.

All infants demonstrated significant reductions in 22:4n-6 and 22:5n-6 with age, but were most pronounced in the FO +

[d]Superscripts a,b, and c indicate significant differences between dietary groups at each assessment age. Superscripts 1, 2, 3 and 4 indicate significant differences between assessment ages for each dietary group.ND, not detected <0.05% total fatty acid. NS, not significant-no repeated measures analysis of variance.

EPO formula group (Table 4). This contributed to the fact that the level of both 22-C n-6 (22:4 and 22:5) fatty acids were reduced in supplemented formula-fed infants relative to the breast milk and placebo formula-fed groups at 6, 16, and 30 wk (Table 4).

The level of GLA in erythrocytes was <0.08% of total fatty acids in all dietary groups. In fact, no complete cases were available for the repeated measures ANOVA, highlighting the negligible accumulation of GLA in erythrocytes. Conversely, dihomo-γ-linoleic acid (DGLA) accounted for ≈2% of total erythrocyte fatty acids. DGLA modestly decreased between day 5 and 6 wk with all dietary groups having similar levels at 6 wk. Breast-fed infants demonstrated further declines with age and had lower levels of DGLA at 30 wk compared to both supplemented and placebo formula groups (Table 4).

DISCUSSION

The primary aim of our study was to assess the efficacy of prolonged fish oil (DHA) supplementation on the erythrocyte fatty acid profiles of formula-fed term infants. Infant formula with 0.36% DHA resulted in erythrocyte DHA above breast-fed levels at 16 and 30 wk of age. From this point of view, it is interesting to note that the average level of DHA in the milk of Australian mothers has apparently declined from 0.32 to 0.21% total fatty acids over the last decade (15). Furthermore, the current breast milk level of 0.21% resulted in a decrease in erythrocyte DHA over the 30-wk study period, suggesting that a dietary level of 0.21% DHA may not be enough to maintain baseline (day 5) levels. This raises an important issue regarding the definition of optimal or ideal DHA requirements and whether these are best represented by DHA content of breast milk or the level required to match and maintain DHA at birth. For example, as breast milk DHA is largely dependent on the DHA content of the maternal diet (16), it could be argued that such a variable benchmark is inappropriate for use as a dietary requirement. Similarly, infant DHA status at birth also may be affected by maternal diet, although there have been few investigations on the effect of diet in pregnancy on infant erythrocyte fatty acids. Presuming that

day 5 erythrocyte DHA levels of infants initially breast-fed reflect an ideal intake of DHA, our data would suggest that dietary supplementation of the order of 0.30% DHA would be necessary to maintain this level throughout the first 30 wk of life.

The decline in erythrocyte DHA of placebo formula-fed infants was one of the most notable shifts in fatty acid status observed. Given the postulated importance of DHA, it is natural to question why this reduction was so profound, even though DHA was not supplied in the diets of placebo for-

mula-fed infants. Other LCPUFA, such as AA, that also were not supplied in the formula demonstrated a reduction that was eightfold smaller than for DHA. These findings may, in part, be explained by the regulation of LCPUFA biosynthesis. For example, in the n-3 metabolic pathway, it is proposed that there are two substrates for the δ6 desaturase, namely 18:3n-3 (→ 18:4n-3) and 24:5n-3 (→ 24:6n-3) (17,18). As the δ6 desaturase is often referred to as the rate-limiting enzyme in PUFA biosynthesis, it is interesting to speculate that DHA synthesis is limited by competitive inhibition of a δ6 desaturase by at least four substrates, 18:3n-3, 24:5n-3, 18:2n-6, and 18:1n-9. This therefore implies that synthesis of DHA from ALA is impeded not only by two rate-limiting steps, but also by the presence of low levels of substrate (ALA) and large amounts of LA (18:2n-6) in infant formulas. Indeed, a recent study investigating the effect of dietary LA on the conversion of ALA and LA to their respective LCPUFA demonstrated that the conversion of ALA to DHA was approximately halved by high dietary LA (19). A feeding study in which the dietary LA/ALA ratio of adults was lowered from 18:1 to 0.6:1 increased levels of EPA in plasma and neutrophils, but failed to show significant differences in DHA status (20). However, whatever the rate of DHA synthesis in standard formula-fed infants, it is clearly inadequate to match the erythrocyte levels of DHA seen in breast-fed infants.

Supplementation of formula with FO + EPO also resulted in notable increases in erythrocyte EPA and 22:5n-3 in these infants compared to values seen in infants fed either breast milk or placebo formula. Furthermore, the proportion of erythrocyte 22:5n-3 remained greater than the proportion of erythrocyte EPA, although the supplemented formula contributed more dietary EPA (0.58% total fatty acids) than 22:5n-3 (0.07% total fatty acids). Similar effects also were observed in the erythrocyte lipids of FO-supplemented formula-fed preterm infants (5), suggesting either a preference for the accumulation of 22:5n-3 over EPA in erythrocyte membranes or a slow conversion of 22:5n-3 to DHA. This would further add support for the presence of a limiting δ6 desaturase at this point in the metabolic pathway (17).

Following a rapid decline in erythrocyte AA levels during the first six weeks, placebo formula-fed infants demonstrated a significant trend toward the accumulation of AA between 6 and 30 wk, despite having no direct dietary source. Erythrocyte levels of AA in preterm infants fed unsupplemented formula containing only C_{18} precursors showed a similar trend at similar post-conceptional ages (4). These data collectively suggest a developing capacity for the infant to synthesize and accumulate erythrocyte AA with age. Although infants have been postulated to have a reduced capacity to synthesize LCPUFA from precursors such as LA and ALA, there has been little direct evidence except for differences in LCPUFA status between breast- and formula-fed infants at fixed postnatal ages. Our data suggest that there is indeed a limited capacity of the infant to produce AA, which is most pronounced in the first weeks after birth, but that by four months of age the formula-fed infant may have sufficient capacity to match AA levels of breast-fed infants from precursors. If this is established for all LCPUFA by metabolic studies (19,21), it will provide direct biochemical evidence in support of a conditional essentiality of LCPUFA in early post-natal life. If such a temporal essentiality is established, it may mean that infant formulas containing only LA and ALA can never be nutritionally complete regardless of the ratio of fatty acid substrates (22,23). Finally, it is interesting to speculate that variations in AA status between breast- and formula-fed infants may be partly explained by the timing of these trials (22,24,25).

The aim of adding EPO (containing GLA) to the supplemented formula was to provide a metabolic precursor of AA in an attempt to avoid the reduction in AA status associated with FO feeding (4,5). However, EPO treatment did not appear to maintain AA status as the proportion of erythrocyte AA in the FO + EPO-supplemented formula infants at 16 wk was similar to those of preterm infant fed FO formula (without EPO) at their equivalent follow-up (57 wk post-conceptional age) (5). So, despite the possible metabolic mechanisms working for the conservation of erythrocyte AA status, the addition of GLA did not significantly influence its maintenance in the presence of FO.

Our results show that GLA does not accumulate in erythrocyte membranes (Table 1). DGLA was the only n-6 LCPUFA in FO + EPO-supplemented infants not to decline below levels observed in either breast- or placebo formula-fed infants. Other studies that have used comparable daily doses of GLA (in the form of either EPO or blackcurrant seed oil) to supplement the diets of nursing mothers have demonstrated increases in both GLA and DGLA of total plasma and breast milk lipids (26). This study (26) was done in the absence of FO, but there are other reports that FO feeding in adults results in a reduction of DGLA status (27), although the FO dose used was 20-fold greater than that fed to the FO + EPO-supplemented infants. If FO, even in small doses, is inhibitory to the accumulation of DGLA, then it would appear that supplementation with GLA was as able to reverse this reduction.

At six weeks, the increase in LA observed in all dietary groups could be accounted for (within 1% of total fatty acids) by the changes observed in all 20- and 22-C PUFA. Although competition between LA and n-3 LCPUFA for incorporation into membranes is widely accepted and documented in both adult (28) and infant studies (7,29), interactions between LA and n-6 LCPUFA are less well investigated. Data from this study suggest that 22% of the variance in erythrocyte AA at six weeks can be attributed to the level of erythrocyte LA. It is therefore tempting to speculate that part of the reduction in AA levels was related to the early rise in LA that also occurred during this time. Although such inferences are difficult to make because both erythrocyte LA and AA levels may be affected by a multitude of other fatty acids, studies comparing the erythrocyte fatty acid status of breast- and standard formula-fed infants also have reported paradoxical reductions in AA levels in the face of high LA (reviewed in Ref. 22).

To summarize, the most pertinent changes observed in erythrocyte fatty acid status were in DHA, EPA, AA, and LA, as well as the interactions between them. DHA in breast and FO + EPO supplemented formula infants were maintained near or above day 5 levels for the 30-wk study period, whereas erythrocyte DHA in placebo formula-fed infants halved by week 16. The synthesis of DHA from ALA in placebo formula-fed infants is probably impeded by the presence of two rate-limiting δ6 desaturase steps in the metabolic pathway, as well as competitive inhibition by the large amount of LA, which is also a substrate for the δ6 desaturase enzyme(s). AA decreased in all infants in the first six weeks of life, and this reduction was most pronounced in FO + EPO-supplemented formula-fed infants. However, erythrocyte AA was similar to day 5 levels by week 30 in both the breast- and placebo formula-fed groups, suggesting a developing capacity to synthesize and incorporate AA. On the other hand, AA in FO + EPO-supplemented formula-fed infants remained at the six-week level, and part of this observation may be accounted for by the presence of EPA and DHA in the supplemented formula, which is a well-known competitor of AA for incorporation into membranes.

ABSTRACT: Chondrocytes are imbedded in an avascular, highly charged extracellular matrix which could form a barrier to the transfer of dietary essential fatty acids (EFA) to chondrocytes. A study was designed to assess the composition of immature and mature joint cartilage with respect to essential and nonessential fatty acids relevant to EFA deficiency. Cartilage and muscle samples were obtained from human fetus, infant and adult cadavers, and from fetal and mature sheep. Lipid extracts were prepared and the fatty acid composition determined. In human and sheep joint cartilage, linoleic acid (LA; 18:2n-6) content was lower, and n-9 eicosatrienoic acid (ETrA; 20:3n-9) and arachidonic acid (AA; 20:4n-6) were higher in fetuses compared to mature subjects. An intermediate pattern was seen in infant cartilage. n-3 Fatty acids tended to be higher in fetal than in mature cartilage in humans and in sheep. In human muscle (and in other noncartilaginous comparison tissues), similar differences between fetuses and adults were seen in LA and AA, but not in ETrA. In fetal sheep muscle, very low LA, reduced AA and raised ETrA levels compared to mature sheep muscle were seen. However, although the pattern is characteristic of EFA deficiency, the abundance of n-6 EFA in liver and spleen of human fetuses and of n-3 EFA in liver and spleen of fetal sheep suggests that placental transfer of EFA is not likely to be limiting. During fetal development, the metabolism of fatty acids is distinctive and differs between the species. ETrA appears to be a readily measurable component of some tissues at certain stages of development when its presence in tissues does not indicate EFA deficiency.

Lipids 30, 949–953 91995).

The 20-carbon n-6 fatty acid, arachidonic acid (AA; 20:4n-6), is an important component of structural phospholipids and is a precursor for the eicosanoid mediators of cell metabolism, platelet-vascular homeostasis, and inflammation. However, mammals are unable to introduce double bonds into the n-6 position of long-chain fatty acids, and the essential cellular requirements for AA are normally met by ingestion of its 18-carbon precursor linoleic acid (LA; 18:2n-6) (reviewed in Ref. 1). Once ingested, LA is desaturated and elongated to AA. Thus, LA is a dietary essential fatty acid (EFA). By contrast, the 18-carbon n-9 fatty acid, oleic acid (OA; 18:1n-9), can be synthesized endogenously (2). In the presence of dietary sufficiency of LA, the desaturation and elongation of OA to the 20-carbon n-9 fatty acid, eicosatrienoic acid (ETrA; 20:3n-9), are inhibited by substrate competition between OA and LA. However, if tissues are deprived of LA, either through dietary insufficiency or diminished uptake of LA, then the level of ETrA increases (3). For this reason, the ratio of ETrA to AA in plasma has been used as a biochemical marker for EFA deficiency, which is associated with accumulation of ETrA and depletion of AA and LA (4). n-3 Fatty acids also are essential dietary components, and their presence in tissues can be used as an index of EFA.

ETrA is normally either undetectable or found at very low levels in tissues and plasma. Recently, Adkisson and coworkers (5) reported that immature hyaline cartilage in humans and in certain other vertebrates (6) has a fatty acid profile similar to that seen in other tissues in EFA deficiency; i.e., they reported that cartilage has relatively high levels of ETrA and low levels of n-6 fatty acids. These authors argued that, because cartilage is avascular with a highly charged extracellular matrix, chondrocytes may be deprived of n-6 EFAs relative to cells in other tissues. n-6 Eicosanoids have been shown to have important effects on the metabolism of chondrocytes cultured *in vitro* (7). The level of eicosanoid precursor, AA, within chondrocytes, and the level of ETrA, which can inhibit the metabolism of M to eicosanoids (8), will be critical determinants of the extent of eicosanoid synthesis by chondrocytes. Furthermore, the level of these fatty acids also may influence the effects on cartilage of antiarthritic drugs which can inhibit eicosanoid synthesis (9). The present study was designed to analyze the fatty acid composition of human and sheep articular cartilage at different stages of maturity.

METHODS

Human cadaver specimens. Cartilage was taken from cadavers of fetuses (death *in utero*), infants [sudden infant death

syndrome (SIDS)], and adults without a known history of inflammatory disease. Ten nonmacerated fetuses were studied; mean duration of gestation 25 wk, range 18–38 wk. Six SIDS cadavers were studied; mean age 6 mon, range 1–8 mon. Details of the fourteen adult cadavers studied are shown in Table 1. In fetuses and infants, the entire femoral head was excised and stored at −70°C prior to extraction of lipids from the sample. Full thickness cartilage specimens were obtained as shavings from the articular surfaces of 13 knees (femoral condyles and tibial plateau) from 13 adults and of 10 shoulders (glenoid cavity and head of humerus) from 10 adults. In joints where there was evidence of degenerative change, cartilage was taken from both macroscopically degenerate and macroscopically normal cartilage, which were processed and assayed separately. Skeletal muscle samples were taken from psoas major or quadriceps muscle. Liver and spleen samples were also taken in adults and fetuses.

Sheep specimens. Cartilage (elbow and stifle joints) and skeletal muscle samples were obtained from sheep fetuses and nonarthritic mature wethers shortly after slaughter. Liver and spleen samples from two of the fetal sheep also were analyzed.

Determination of arthritic status of joints. Knee and shoulder joints of adult cadavers were examined macroscopically for evidence of osteoarthritis and graded for severity (10). Initially, India-ink staining also was used to highlight osteoarthritic areas as the ink adheres to areas of cartilage fibrillation but not to healthy cartilage.

Fatty acid analyses. Cartilage shavings from knees or shoulders of adults or from the femoral head of fetuses or infant cadavers were rinsed thoroughly in normal saline to remove adherent body fluids. The tissues were then homogenized using a power homogenizer with a rotating blade (Ultra-Tarrax Type TP18/10; Janke-Kunkel, Staufen, Germany).

TABLE 1
Clinical Details of Cadavers

Age (yr)	Sex	Principle diagnoses	Status of joints[a]

85	F	Subarachnoid hemorrhage	++,
87	M	Cholelithiasis, septicemia	–
90	M	Pituitary tumor	+

[a]+,–, Arthritic and nonarthritic joints sampled; –, no degeneration; +, evidence of minor degenerative changes; ++, more advanced degenerative change in some areas, no full thickness cartilage loss; and +++, advanced degenerative disease with full thickness cartilage loss in some areas. In arthritic joints, samples were taken from macroscopically arthritic and normal regions and analyzed separately for fatty acid composition.

Lipids were extracted from tissue with chloroform/methanol, and extracts were evaporated to dryness under nitrogen. The samples were methylated in 1% H_2SO_4 in methanol at 70°C for three hours. When cooled, the resulting methyl esters were extracted into *n*-heptane and transferred to vials containing anhydrous Na_2SO_4 as the dehydrating agent. Fatty acid methyl esters were separated and quantified using a Hewlett-Packard (Avondale, PA) 5880 gas chromatograph equipped with a 50-m capillary column (0.33 mm i.d.) coated with BPX-70 (0.25 μm film thickness; SGE Pty. Ltd., Victoria, Australia). The injector temperature was set at 250°C and the detector (flame-ionization) temperature at 300°C. The initial oven temperature was 140°C and was programmed to rise to 220°C at 5°C/min. Helium was used as the carrier gas at a velocity of 35 cm/s. Fatty acid methyl esters were identified based on the retention time relative to authentic lipid standards obtained from Nu-Chek-Prep Inc. (Elysian, MN). Standards included saturated fatty acids C_6–C_{24} and unsaturated fatty acids $C_{14:1}$–$C_{22:6}$. Correction factors were not required for any of the fatty acids detected in the tissue samples. Reproducibility (coefficient of variation) was <1% for the major peaks (>5% total fatty acids) and <5% for minor peaks.

Statistics. The difference in fatty acid composition of the sample groups was examined by Student's *t*-test.

RESULTS

Human samples (Tables 2–4). Levels of fatty acids in adult cartilage were not significantly different between arthritic and nonarthritic joints and between arthritic and nonarthritic areas of cartilage from arthritic joints. Data obtained from different cartilage samples of individual joints were, therefore, pooled to yield mean values for individual joints, which have been used in comparisons between mature and immature articular cartilage.

There were significant differences ($P < 0.05$) between human adult and human fetal cadavers with regard to levels of LA and AA found in all of the tissues tested, i.e., cartilage, muscle, liver, and spleen. LA levels were higher in adults and, by contrast, AA levels were higher in fetuses. In infant cartilage, LA and AA levels were intermediate between those found in fetuses and adults. The levels of LA and AA in muscle were similar in infants and in adults.

A possible late age-related increase in AA as a percentage of fatty acids in cartilage was suggested by a comparison of the younger adult cadavers (6.4 ± 1.3, n = 3, age less than 40 yr) with those of advanced age (10.2 ± 2. 1, n = 10, age greater than 65 yr, $P = 0.015$). AA levels were similar in the muscle samples of the younger and older cadavers, and no differences were seen in the proportions of the other unsaturated fatty acids in muscle or cartilage (data not shown). No significant differences were found on comparison of fatty acids in cartilage samples from shoulders and knees (data not shown).

Mean ETrA was 2.0% of fatty acids in fetal cartilage, 1.5% in infant cartilage, and below the limit of detection (<0.1%) in adult articular cartilage ($P < 0.001$). There were no signifi-

cant differences between fetal and infant ETrA levels, which were both significantly different from adult levels. Differences in ETrA between adult and fetus were not significant in the other tissues studied.

In a similar manner to variations in AA, the levels of ETrA in cartilage varied inversely with levels of LA. This did not occur in muscle where the level of ETrA was not elevated in fetal or infant tissue. Despite the large variation in fetal, infant, and adult cartilage fatty acids, the aggregate amount of LA, AA, and ETrA was similar (range 18–20% of fatty acids). Total amounts of muscle LA, AA, and ETrA were greater in infants and adults (38–39%) than in fetal tissue (25%).

n-3 Fatty acids were higher in fetal cartilage than in infant or adult cartilage ($P < 0.01$), which were essentially similar in this respect. n-3 Fatty acids were found at similar levels in fetal and adult liver and were higher in adult than in fetal spleen ($P < 0.01$). Docosahexaenoic acid was the dominant n-3 fatty acid in all human tissues sampled.

Sheep samples (Table 5). ETrA was significantly higher in fetal cartilage and muscle, compared with adult tissues ($P < 0.001$). LA was significantly lower in fetal cartilage and muscle, compared with adult tissues ($P < 0.001$). AA was significantly higher in fetal, compared with adult cartilage ($P < 0.01$), but was significantly lower in fetal compared with adult muscle ($P < 0.01$). As seen in humans, the total amount of LA, AA, and ETrA was similar for fetal and mature sheep in cartilage (9–10% fatty acids), but not in muscle (fetuses 9.4%, wethers 27%). Total n-3 fatty acids were slightly higher in fetal than in mature cartilage ($P < 0.05$) and lower in the muscle of fetuses than in withers. Substantial amounts of n-3 fatty acids were found in fetal liver and spleen (18.8 and 12.6% of fatty acids, respectively). Thus, the overall pattern of fatty acids in fetal sheep tissues did not suggest EFA deprivation.

Relevant trace or minority fatty acids. In two of the six infant cartilage samples, 18:2n-9 was detected with levels of 1.9 and 3.1%. This fatty acid was not detected in any of the other infant cartilage samples, nor in any of the other human or sheep material analyzed. Small amounts of 22:3n-9 were found in various samples, but always less than 1% of total fatty acids. No 18:3n-9 was detected in any sample. Small amounts of 20:2n-6 were resolved, but were always less than 1% of fatty acids and typically less than 0.4%. No 18:3n-3 was detected in cartilage, and only trace amounts were found in other tissues (<0.2%).

[a]Mean ± SD. [b]Includes dimethyl acetal fatty acids. [c]Adult vs. fetus, $P < 0.01$.

from EFA deficiency in that the AA levels in all human fetal tissues sampled were significantly higher than in their adult counterparts. Furthermore, eicosapentaenoic acid levels were higher in fetal than in infant and in adult cartilage. The findings suggest a general alteration in EFA utilization in the fetus compared to adults rather than a cartilage-specific barrier to the transfer of EFA.

In fetal lamb cartilage, LA was lower but AA, ETrA, and total n-3 fatty acids were higher than in adult cartilage. In fetal lamb muscle, both LA and AA were lower and ETrA higher compared to mature sheep. This pattern in muscle, at least, more closely resembles EFA deficiency. However, the abundance of AA and n-3 fatty acids in fetal liver and spleen argues strongly against a state of EFA deprivation in sheep fetuses.

The observed differences between fetal and mature tissues in humans and sheep show that tissue fatty acid composition data obtained in fetal or immature animals cannot be taken as necessarily representative of the composition of their mature counterparts. The study of fatty acid composition in hyaline cartilage of ten-week-old chickens, fetal calves, and newborn pigs reported by Adkisson and co-workers (5) needs to be interpreted with this reservation in mind. In a very recent paper, Adkisson and co-workers have documented changes in fatty acid composition of articular cartilage of chicks fed test diets from age one-day to eight weeks (11). They observed changes in the content of saturated and unsaturated fatty acids (including EFA) within cartilage, which was influenced by the relative amounts of relevant fatty acids given in the diet. These latter findings, together with the present study, suggest that chondrocytes are not deprived of access to EFA because of their charged extracellular matrix, but rather that cartilage (like other tissues) has its own distinct pattern of fatty acid metabolism, of which ETrA accumulation, at certain stages of development is a manifestation.

The lower LA seen in the fetus may reflect, at least in part, different utilization of n-6 fatty acids during fetal life such that AA and ETrA accumulation is favored at the expense of LA. Compared to corresponding fetal samples, human infant cartilage and muscle exhibited substantially higher LA, which was similar to levels found in adult samples. Furthermore, LA content in infant cadavers appeared to be proportional to the age of the infant at the time of death (data not shown) although the size of the sample was too small to adequately assess the significance of difference in LA between infants. Notwithstanding, the change toward the adult pattern appears to occur soon after birth, suggesting that a change in LA metabolism occurs in early infancy.

Certain differences in fatty acid metabolism between fetuses and adults may be tissue-specific. Because femoral head specimens, which contain both articular cartilage and unossifed enchondral bone, were taken from both fetuses and infants, a putative metabolic difference between articular cartilage and enchondral bone could not fully explain the observed differences in fatty acid composition between fetal and infant femoral head cartilage. Furthermore, the fetal pattern of low LA and high AA relative to adult samples also was seen in liver and spleen.

In our analysis of material from cadavers without a history of clinically important arthritic disease during life, the presence of cartilage degeneration did not appear to influence the fatty acid composition of articular cartilage. However, it should be noted that one or more of the sampled joints of most subjects exhibited macroscopic and microscopic degenerative changes, and few entirely normal joints were studied, even in the younger adults. Notwithstanding, AA levels were lower in the younger adult cadavers than in those of advanced age. The weight-bearing status of the joints sampled (shoulder vs. knee) did not appear to influence their fatty acid composition.

For human articular cartilage, higher values of ETrA than AA and very low proportions of LA in "rapidly growing cartilage" have been reported (6). We have been unable to confirm this described dominance of ETrA over AA in either human or sheep fetus or in human infant hyaline cartilage, in which we have found AA to be increased compared to adult levels. The lower LA and raised ETrA in fetal compared to adult joint cartilage have been confirmed. It also was reported that ETrA was depleted in weight-bearing human articular cartilage after 25–30 yr (6). However, no comparison with nonweight-bearing joints, nor any data on the age of the younger subjects was provided, except for a statement that

the overall age range of subjects was 0–86 yr (6). In agreement with the present study, they found no difference in n-6 fatty acids in normal and osteoarthritic cadaver joints. By comparison, n-6 fatty acids in cartilage samples obtained at the time of joint replacement surgery were higher. The operative specimens are likely to contain significant amounts of fibrous tissue and fibrocartilage, which can replace hyaline cartilage in end-stage joint failure. Thus, the altered fatty acid composition in these samples could reflect the presence of tissue other than hyaline cartilage.

In summary, the fatty acid composition of articular cartilage does not suggest a tissue-specific reduced EFA state. The proportions of n-6 fatty acids in cartilage alter in association with maturation and aging, at least partly independently of joint degeneration.

Dietary Fish Oil and Cytochrome P-450 Monooxygenase Activity in Rat Liver and Kidney

Elena Valdes, Patricio Vega, Nicolas Avalos and Myriam Orellana*

Departamento de Bioquimica, Facultad de Medicina, Universidad de Chile, Casilla 70086, Santiago 7, Chile

ABSTRACT: Lauric acid hydroxylation and aminopyrine *N*-demethylation were studied in kidney and liver microsomes from rats treated with fish oil. Different doses of fish oil containing 20% eicosapentaenoic acid and 10% docosahexaenoic acid were provided daily to the rats for seven days. In all the groups studied, the lauric acid metabolism was higher in kidney microsomes and the aminopyrine metabolism in the liver microsomes. Although no effect on the renal cytochrome P-450 concentration was detectable, all four fish oil doses increased the hepatic concentration of cytochrome P-450 by a mean 27%. The higher fish oil doses used increased the renal and hepatic microsomal metabolism of aminopyrine. The lauric acid metabolism was increased by fish oil only in the liver. Fish oil, a known inducer of fatty acid peroxisomal β-oxidation, also induced microsomal activity. These results show that liver and kidney respond in different ways to dietary factors such as fish oil. In addition, our study would suggest that fish oil increased the activity of two different families of liver cytochrome P-450. The activity of kidney lauric acid 11- and 12-hydroxylation, however, was not modulated by fish oil.

Lipids 30, 955–958 (1995).

Microsomal cytochrome P-450 catalyzes the oxidative metabolism of a wide variety of lipophilic compounds, such as drugs, carcinogens, endogenous steroids (1), and fatty acids (2). Cytochrome P-450s are found predominantly in the liver, but are also present in many other tissues, such as the kidney.

Marine oils are rich in polyunsaturated fatty acids of n-3 family, especially eicosapentaenoic acid (20:5) (EPA) and docosahexaenoic acid (22:6) (DHA). There are several cytochrome P-450 isoenzymes from the family 4A that oxidize fatty acids. The CYP4A1 purified from liver of clofibrate-treated rats catalyzes the ω-hydroxylation of arachidonic and lauric acids (3). The physiological role of these isoenzymes P-450 has not been identified.

It has been reported that clofibrate and other peroxisomal proliferators simultaneously enhance the cellular content and activity of liver cytochrome P-450 (3). In previous studies with starved rats, we showed an increase in the microsomal lauric acid ω-hydroxylation, which was correlated with an increase in peroxisomal fatty acid β-oxidation in liver and in kidney (4,5).

The liver microsomal activity has been studied extensively. Meanwhile, our knowledge of both the constitutive and inducible content and activity of kidney cytochrome P-450 remains very limited. The levels of cytochrome P-450 in kidney previously have been shown to be much lower than those seen in liver, and the renal cortex presents the highest levels of cytochrome P-450 (6,7).

It has been reported that fish oil or diets enriched in EPA and DHA induce liver fatty acid microsomal and peroxisomal oxidation (8–11). The extent of the increase of microsomal activity or peroxisomal β-oxidation depends on the type of dietary fish oil (10). However, the effect of fish oil on kidney microsomal activity has not been reported.

In this work, we study the effect of fish oil consumption on microsomal lauric acid hydroxylation and aminopyrine *N*-demethylation to investigate the possible induction of the microsomal activity by this factor. We carried out a comparative study using liver and kidney microsomes in order to determine how these tissues respond to a diet enriched with polyunsaturated fatty acids EPA and DHA.

MATERIALS AND METHODS

Chemicals. Fish oil was provided by Maver Laboratory (Santiago, Chile). According to the manufacturers, the fish oil was encapsulated under vacuum using anerobic conditions. The capsules were stored at room temperature upon arrival and opened just prior to the rat gavages. The fish oil was a sardine oil concentrate containing 36.5% polyunsaturated fatty acids [20.4% EPA, 10.3% DHA, 1.4% linoleic, 0.8% linolenic, 1.6% octadecatetraenoic (18:4n-3), 0.4% eicosadienoic (20:2n-9), 1.1% arachidonic, and 0.5% docosatetraenoic acids (22:4n-6)]; 32.8% monounsaturated fatty acids [12.4% palmitoleic, 16% oleic, 2.5% eicosanoic (20:1n-9), and 1.9% cetoleic acids], and 30.7% saturated fatty acids (0.7% pentadecanoic, 20.1% palmitic, 1.0% heptadecanoic, 4.1% tetracosanoic, and 4.8% stearic acids). The corn oil used in our control rats was provided by Mazola (Inducoen, Santiago, Chile), and contained 60% total polyunsaturated fatty acids (57.7% linoleic and 2.3% linolenic acids); 26.1% of the mo-

nounsaturated oleic acid, and 13.6% saturated fatty acids (10.7% palmitic, 2.8% stearic, and 0.1% docosanoic acids). Lauric acid, aminopyrine, NADPH, isocitrate dehydrogenase, and sodium isocitrate were purchased from Sigma Chemical Co. (St. Louis, MO). (1-^{14}C] Lauric acid (56 mCi/mmol) was from Amersham (Arlington Heights, IL). All the other chemicals were obtained from commercial sources and were of the highest purity available.

Animals and treatments. Mature male Wistar rats (Charles River Breeding Laboratories, North Wilmington, MA) (weighing 200–250 g) were used throughout. Rats were fed for seven days with either pure corn oil or the fish oil described previously (0.5–7.5 g/kg body weight). The lowest fish oil dose used was comparable to that used clinically in Chile. The daily oil supplementation was given by gastric tube feeding, and an equivalent volume was applied to control and to treated rats (0.1–1.5 mL). All the animals had free access to standard pellets and water.

Microsomal activities. Microsomes from whole kidney or liver were prepared as described elsewhere (12). Decapsulated kidneys or livers of 3–5 rats were used for each microsomal sample. The total cytochrome P-450 content was measured as described by Omura and Sato (13). Sodium succinate was added to kidney microsome preparations to minimize hemoprotein interferences in light transmission, which become significant in tissues with low cytochrome P-450 content (14).

Lauric acid hydroxylation. This activity measurement was performed according to the method described previously (4). Lauric acid and its 11-hydroxy and 12-hydroxy derivatives were resolved by a reverse-phase high-performance liquid chromatographic technique as previously described (5).

Aminopyrine N-demethylation. The measurement of oxidative demethylation was performed according to the method described by Nash (15). The reaction mixture contained 10 mM aminopyrine, 50 mM buffer Tris–Cl, pH 7.5, 150 mM KCl, 10 mM $MgCl_2$, 8 mM sodium isocitrate, 0.25 IU/mL isocitrate dehydrogenase, 1 mM NADP, and 3.0 mg/mL of kidney microsomal protein. Incubations were performed at 37°C for a 20-min period (a range where the reaction was linear with time). Results are expressed as means ± SD, and the statistical significance of differences between mean values was assessed by analysis of variance (ANOVA) coupled with Student-Newman-Keuls test at the 5% level of significance.

RESULTS

Table 1 shows the different doses of fish oil provided to the rats daily for seven days, using 0.5 g/kg body weight initially and then increasing to 7.5 g/kg body weight. The body and kidney weight were not significantly altered by fish oil (220 ± 10 and 1.09 ± 0.10 g, respectively). The liver weight, however, increased about 20% in all the groups treated. The kidney microsomal protein was not significantly altered by fish oil (7.5 ± 0.81 mg/g kidney); in contrast, an increase of about 27% in liver microsomal protein was observed with all the doses used (Table 1). It is known that the kidney content of cytochrome P-450 is lower than that of the liver (6,7). In the control rats, the cytochrome P-450 concentration in kidney (0.98 ± 0.24 nmol/g wet weight) was one-fifth that found in liver (5.28 ± 0.60). Although no effect on the renal cytochrome P-450 concentration was detectable, all four fish oil doses increased the hepatic concentration of cytochrome P-450 by 27% (Table 1). Because the dietary fish oil also increased the liver size by 22%, all four doses of fish oil increased the total liver microsome P-450 content by about 55% (i.e., from 62.3 ± 18.1 nmol cytochrome P-450/liver to 101.95 ± 20.4 control and dose I values, respectively). Surprisingly, the effects on liver weight, the cytochrome P-450 concentration, and content did not increase with the fish oil dosage. There were no significant differences in the liver weight, microsomal protein, and cytochrome P-450 content between the fish oil doses I–IV, as assessed by ANOVA coupled with the Student-Newman-Keuls test.

TABLE 1
Effect of Different Doses of Fish Oil on the Liver Weight, Microsomal Protein, and Cytochrome P-450 Content

[d]Significantly different from control ($P < 0.05$) as assessed by analysis of variance coupled with Student-Newman-Keuls test.

The effect of fish oil on liver microsomal metabolism of lauric acid is shown in Table 2. Fish oil had no effects on renal microsome capacity to ω- and ωl-hydroxylate lauric acid, which remained at 0.38 ± 0.08 and 0.72 ± 0.10 nmol product/min/mg protein, respectively. In liver, however, a significant increase of about 43% was seen in the overall rate of

TABLE 3
Effect of Fish Oil on the Aminopyrine *N*-Demethylation Catalyzed by Rat Kidney and Liver Microsomes[a]

Group	(nmol product/min/mg protein)	
	Kidney	Liver
Control	0.06 ± 0.01	1.53 ± 0.21
Dose III	0.17 ± 0.02[b]	2.96 ± 0.13[b]
Dose IV	0.23 ± 0.05[b]	3.34 ± 0.36[b]

[a]Values are the means ± SD of at least five different experiments.
[b]Significantly different from control ($P < 0.05$) as assessed by analysis of variance coupled with Student-Newman-Keuls test.

lauric acid hydroxylation with the highest fish oil doses used (5 and 7.5 g/kg body weight). Only the effect of fish oil dose II was significantly different from doses III and IV. Because the fish oil also increased the amount of microsomal protein by an average of 27% (Table 1), the total hydroxylase activity in liver increased from a control value of 13.10 ± 1.44 nmol product/min/g liver to 19.23 ± 2.12, 15.20 ± 1.50, 24.63 ± 5.21, and 22.55 ± 5.24, with doses I, II, III, and IV, respectively. Thus, fish oils increased both the total cytochrome content and the total lauric acid hydroxylase activity in liver. In all the groups studied, the metabolite produced in a major proportion was the 12-hydroxy lauric acid (ω-derivative).

Aminopyrine *N*-demethylation was assayed in order to study the effect of fish oil on the activity of a different cytochrome P-450 family than CYP4A. Only fish oil doses III and IV were used in these studies. The renal metabolism of aminopyrine was lower than that of the hepatic tissue, the control group being about 4% of the liver values (Table 3). The metabolism of this exogenous substrate was significantly increased in both organs in rats treated with the higher doses of fish oil. The aminopyrine metabolism increased by about 3–4-fold in kidney and about 2-fold in liver in respect to the controls. There were significant differences between the effect of fish oil doses III and IV in both organs.

The liver and kidney microsomal turnover rates for aminopyrine and lauric acid was compared. In all the groups studied, the renal turnover rate of aminopyrine was lower than the hepatic one, being about 17% of the liver values in the control group (0.46 ± 0.07 and 2.65 ± 0.08 nmol product/min/nmol cytochrome P-450 for the kidney and liver values, respectively). In contrast, the kidney exhibited a higher metabolism of lauric acid. The turnover rate (nmol lauric acid product/min/nmol cytochrome P-450) in kidney (8.46 ± 2.01) was about threefold that in liver (2.48 ± 0.40).

DISCUSSION

In our studies, the liver and kidney respond in a different way to fish oil ingestion. Whereas the aminopyrine metabolism in both organs was increased by fish oil, the lauric acid metabolism increased only in the liver microsomes. Little is known about the fish oil effect on the kidney microsomal activity. In contrast to liver, kidney cytochrome P-450 is poorly induced by phenobarbital and clofibrate (16,17). Also, the response to peroxisome proliferators, such as di(ethylhexyl)pthalate, is different in liver and in kidney (18).

In relation to the effect of fish oil on the liver microsomal lauric acid metabolism, our results are similar to those obtained by Nilsson *et al.* (19). By feeding rats a diet with 20% fish oil (w/w) for one week, they obtained a more acute effect in increasing the liver lauric acid metabolism (about 2.5-fold compared to controls). The difference between our results and those reported by Nilsson *et al.* (19) might be attributed to the different fish oil origin or the doses ingested. Mounie *et al.* (20), by feeding rats a diet with a 6% fish oil content, reported an increased cytochrome P-450 content and bilirubin glucuronosyl transferase activity in liver.

Part of the clinical properties attributed to EPA (20:5n-3) are due to its structural similarity to arachidonic acid (20:4n-6) (21,22). Cytochrome P-450 participates in the metabolism of arachidonic acid, generating ω-derivates, epoxides, and others metabolites with biological activity (2,23). Several cytochrome P-450 isoenzymes involved in the metabolism of arachidonic acid have been purified in the rat liver and kidney (24). With the increasing interest in the health benefits of marine oils containing n-3 polyunsaturated fatty acids, it has been shown that EPA and DHA also can be metabolized by cytochrome P-450 *in vitro* (25). Urinary excretion of epoxides and diols derived from EPA during the fish oil ingestion by humans has been reported (26). In the microsomal metabolism of EPA, the participation of CYP4A family, specifically to metabolize fatty acids in the ω-position, is probable.

It is known that the levels and activities of cytochrome P-450 enzymes are affected by the diet (1,2). Our studies show that the liver and kidney respond in a different way to a dietary factor such as fish oil. The fish oil increased the lauric acid metabolism only in the liver. The aminopyrine metabolism, however, was induced in both organs. These results suggest that fish oil increases the activity of two different liver cytochrome P-450 families. The activity of kidney lauric acid 11- and 12-hydroxylase, however, was not modulated by this factor. More experimental work is needed to explore the biological significance of these selective changes.

ABSTRACT: The effect of age and peroxidative stress on the concentration of a deoxyguanosine malondialdehyde adduct (dG-MDA) in rat tissues was investigated. Vitamin E deficiency had no effect on the dG-MDA content of liver DNA in rats fed a diet containing 10% corn oil. When 2% cod liver oil was added to this diet, the dG-MDA content of liver DNA doubled in the positive controls fed a high level of vitamin E (100 ppm dl-α-tocopherol), and there was a further increase when vitamin E was deleted. Neither iron nitrilotriacetate administration nor choline deficiency had any effect on the dG-MDA content of liver DNA. Carbon tetrachloride had a lowering effect. The failure of iron or carbon tetrachloride administration and of vitamin E deficiency to increase liver dG-MDA is consistent with their failure in previous experiments to affect the urinary excretion of dG-MDA. In contrast, these forms of peroxidative stress produce large increments in the urinary excretion of MDA adducts with lysine, reflecting increased formation and degradation of MDA-modified proteins. DNA appears to be protected from modification by MDA produced at extranuclear sites. The frequency of dG-MDA in different tissues of 4-month-old rats varied markedly: brain >> liver > kidneys and testes. Higher concentrations of dG-MDA were found in the liver and kidneys, but not the testes, of 25-month-old rats. The determinants of the concentration of dG-MDA in DNA merit further investigation.
Lipids 30, 959–961 (1995).

In previous studies on the products of malondialdehyde (MDA) reactions *in vivo*, two Schiff's base adducts with lysine, one acetylated and the other unacetylated, were found to be the main forms of MDA excreted in human urine and in the urine of rats fed an MDA-free diet (1). These adducts reflect a reaction of MDA with the lysine residues of tissue and dietary proteins. Among several minor metabolites, a deoxyguanosine adduct with MDA (dG-MDA) was identified in urine (2) and in hydrolysates of rat liver DNA (3). Vitamin E deficiency, intraperitoneal administration of iron nitrilotriacetate (FeNTA), and oral administration of carbon tetrachloride resulted in marked increases in excretion of the lysine derivatives, signifying enhanced peroxidative modification of tissue proteins (1). In contrast, no effect was found on the excretion of dG-MDA (2).

In the present study, the effect of these treatments on the concentration of dG-MDA in rat liver DNA was investigated. In addition, the effect of choline deficiency, which gives rise to fluorescent pigments in the lipids of the nuclear membrane (4), was determined, as well as the dG-MDA content of DNA isolated from several tissues of young and old adult rats.

METHODS

Animal experiments: *Experiment 1.* Weanling rats were fed a vitamin E-deficient diet containing 10% molecular-distilled corn oil (1) with and without the addition of a high level of vitamin E (100 ppm dl-α-tocopherol). After six weeks, vitamin E depletion was confirmed using an autohemolysis test (81 vs. 17% in controls). The animals were euthanized and each liver was removed and frozen for dG-MDA analysis.

Experiment 2. This experiment was similar to Experiment 1, except that 2% cod liver oil, a source of highly oxidizable n-3 polyunsaturated fatty acids (PUFA), was added to the 10% corn oil diet to increase the peroxidative stress imposed on the animals.

Experiment 3. Two groups of five rats (weighing ~100 g) that had been fed a stock diet from weaning age were treated with FeNTA (9 mg Fe/kg) or an equivalent amount of NTA administered intraperitoneally. Another group was given 10 μL of CCl_4 by stomach intubation. The animals were sacrificed 48 h later.

Experiment 4. Two groups of six F-344 male rats (weighing ~150 g) were fed a choline-deficient diet with and without the addition of 0.8% choline (4). They were euthanized three days later, at which time a peak in peroxidation of the nuclear membrane lipids of choline-deficient animals has been documented using chemiluminescence and spin-trap measurements (5). Prolonged feeding of this diet produces a

100% incidence of putative preneoplastic hepatocyte nodules and a 50% incidence of hepatocellular carcinoma (4).

Experiment 5. The liver, kidneys, and testes from rats 4 vs. 25 months of age were analyzed to determine the relationship between aging and the dG-MDA content of DNA. The brain also was taken for analysis.

dG-MDA analysis. The procedures used for the isolation and hydrolysis of DNA and the determination of dG-MDA have been described previously (3). One-gram samples were used except in the case of brain, for which only 0.5-g samples were available. With the exception of the brain samples from the aged rats, clean fluorescence peaks were obtained for dG-MDA in the high-performance liquid chromatography chromatograms.

RESULTS AND DISCUSSION

The results of Experiments 1, 2, 3, and 4 are summarized in Table 1. Vitamin E depletion on the 10% distilled corn oil diet had no significant effect on the dG-MDA content of liver DNA. The excretion of total MDA, estimated by high-performance liquid chromatography as its thiobarbituric acid derivative, was higher in the vitamin E-deficient group (13.9 vs. 8.1 μg/24 h) ($P < 0.05$). This finding is in agreement with previous results (6). Adding 2% cod liver oil to the corn oil diet was associated with an increase in the dG-MDA content of hepatic DNA ($P = 0.02$). Neither FeNTA nor choline deficiency significantly affected dG-MDA content, and the hepatotoxic agent CCl_4 had a depressing effect.

The dG-MDA content of liver and kidney DNA, but not of testicular DNA, was higher in the 25-month-old rats than in the 4-month-old rats (Table 2). By far the highest concentration of dG-MDA was found in the brain. The yield of DNA from the brains of the old adults was too small and the analytical values too variable to provide a reliable estimate of their dG-MDA content.

The findings indicate that liver DNA is protected from modification by the increased amounts of MDA generated in vitamin E deficiency and by the administration of chemical catalysts of hepatic lipid peroxidation. Judging from the large increases in excretion of MDA adducts with lysine under the same conditions (1), DNA differs in this respect from tissue proteins. Both purified proteins and DNA react readily with MDA *in vitro*, but neither liver nor urine analysis has yielded consistent evidence of increased dG-MDA generation *in vivo* under the conditions of peroxidative stress imposed by these treatments. It is noteworthy that the increased fluorescence of nuclear membrane lipids caused by feeding a choline-deficient diet is not prevented by vitamin E or synthetic antioxidants, whereas it is completely prevented by choline and the free radical trapping agents *tert*-nitrosobutane and α-phenyl-*tert*-butylnitrone (5,7).

PUFA and vitamin E are concentrated in the mitochondria and endoplasmic reticulum of hepatocytes which, presumably, are therefore the main sites of MDA generation. These organelles contain aldehyde oxidases with a high affinity for MDA. Most of the MDA formed in hepatocytes appears to be either oxidized to CO_2 *in situ* or to react with proteins in the cytosol and extracellular fluids. These soluble proteins may constitute a defense barrier against modification of nuclear DNA by MDA and other aldehydes. Serum albumin reacts avidly with MDA *in vitro*, and most of the MDA in plasma is appears to be bound to albumin (8).

Although binding of MDA by soluble proteins may explain the prevention of DNA damage by MDA generated at extranuclear sites, it does not explain the apparent lack of increased MDA generation in the nucleus in vitamin E deficiency. The effect of vitamin E deficiency on its concentration in purified nuclei does not appear to have been investigated. It is also possible that the nuclear membrane is impermeable to the oxidants employed in this study.

If nuclear lipids are not vulnerable to lipid oxidants or a deficiency of antioxidants, some other explanation is necessary to explain the differences in the dG-MDA content of DNA among tissues and at different ages. No dG-MDA could be found in a commercial sample of calf thymus DNA (Sigma, St. Louis, MO) (data not shown). The increased values obtained for the dG-MDA content of liver DNA isolated from rats fed 2% cod liver oil suggests an effect of the concentration of highly oxidizable fatty acids of the n-3 series. In

a previous study (9), addition of cod liver oil to a corn oil-based diet produced an increase in fasting MDA excretion, whereas increments in corn oil in the diet had no effect. An effect of highly unsaturated fatty acids of the n-3 series on the dG-MDA content of brain DNA is suggested by the high concentrations of these acids and iron in the brain (9). The effect of the intake of highly unsaturated PUFA on the fatty acid composition and vitamin E content of nuclear membrane lipids, as well as on the binding of MDA, a confirmed mutagen in bacterial and mammalian cells (10), to DNA *in vivo* is worthy of further investigation.

ACKNOWLEDGMENTS

This work was supported by grants from the Natural Sciences and Engineering Research Council of Canada, the National Cancer Institute of Canada, and the Medical Research Council of Canada.. The authors are grateful for a gift of synthetic dG-MDA from Hiroshi Seto (Tokyo, Japan). Tissues from young and old adult rats were generously provided by George Roth, U.S. National Institute on Aging (Baltimore, MD).

Increased Formation and Degradation of Malondialdehyde-Modified Proteins Under Conditions of Peroxidative Stress

Haleh Mahmoodi, Mary Hadley[1], Yuan-Xun Chang[2] and Harold H. Draper*

Department of Nutritional Sciences, University of Guelph, Guelph, Ontario N1G 2W1, Canada

ABSTRACT: The effect of increased *in vivo* lipid peroxidation on excretion of the main urinary metabolites of malondialdehyde (MDA) was investigated. Peroxidative stress in the form of vitamin E deficiency or the administration of iron nitrilotriacetate or carbon tetrachloride was imposed on rats fed an MDA-free diet. Significant increases were observed in excretion of the lysine–MDA adduct ε-propenal lysine, its *N*-acetyl ester, and free MDA. Under the conditions imposed, the increments in excretion of the lysine adducts reflect increased peroxidative modification of tissue proteins *in vivo*. These adducts also were found to be the main forms of MDA excreted in human urine. Reacting ^{14}C-bovine serum albumin (BSA) with MDA resulted in its accelerated proteolysis *in vitro* by soluble enzyme preparations derived from human erythrocytes and rat liver mitochondria. The increments observed were similar to those reported for the hydrolysis of BSA following its exposure to hydroxyl radicals. The results show that lipid peroxidation *in vivo* results in peroxidative damage to tissue proteins and indicate that such proteins are subject to an accelerated rate of proteolysis.
Lipids 30, 963–966 (1995).

In studies on the reactions of malondialdehyde (MDA) *in vivo,* two Schiff's base adducts with lysine, one acetylated (1) and the other unacetylated (2), were found to comprise about 75% of the total malondialdehyde (MDA) excreted in the urine of rats fed an MDA-free diet. These compounds also constitute the main forms of MDA excreted in human urine. On normal diets, the amounts formed endogenously are augmented by release of the lysine adduct ε-propenal lysine (ε-PL) from food proteins in the course of digestion and its partial acetylation to form *N*-α-acetyl propenal lysine (APL) in the tissues (3).

In Part I of the present study, the effect of peroxidative stress on excretion of the two lysine adducts and free MDA was investigated in rats. In Part II the effect of reacting serum albumin with MDA on its rate of hydrolysis *in vitro* by a proteolytic enzyme from human red blood cells (RBC) and rat liver mitochondria was determined.

EXPERIMENTAL PROCEDURES

Part I. Two groups of six weanling rats of the Charles River strain were fed a vitamin E-deficient diet containing 10% molecular-distilled corn oil (4) for 10 wk. Vitamin E depletion was confirmed by an autohemolysis test (4). Controls received a supplement of 100 ppm dl-α-tocopherol. Urine was collected daily during the final week and frozen at –20°C.

In a second experiment, a group of six growing rats weighing ~150 g that had been fed a stock diet from weaning age were injected intraperitoneally with 9 mg Fe/kg as iron nitrilotriacetate (4). Controls were injected with an equivalent amount of nitrilotriacetate. Another group was treated with 10 μL CCl_4 by gastric intubation. Urine was collected under toluene for the following two days and frozen at –20°C. To avoid interference in the urinalysis by ε-PL released from dietary proteins in the course of digestion (3), the animals were switched to the MDA-free high vitamin E diet used in the first experiment two days prior to and during the collection period.

Urinalysis. Fifty-mL aliquots of urine were fractionated on a 2.3 x 45 cm AG-1 anion exchange column as described previously (1). The column was developed using a 0–2 M NaCl gradient and 5-mL fractions were collected. Every fifth fraction was analyzed for MDA by a spectrophotometric thiobarbituric acid (TBA) procedure (5). This procedure yields MDA values for urine that are indistinguishable from those obtained using a high-performance liquid chromatography (HPLC) procedure (5). The urine samples from each rat were chromatographed individually and a composite elution profile of MDA compounds was constructed for each treatment. The significance of group differences in the excretion of ε-PL, APL, and MDA was determined by analysis of variance of the data for their respective elution peaks and for those of their controls.

For comparative purposes, 24-h urine samples were collected from five adult humans and 50-mL aliquots were chromatographed by the same procedure. To minimize the excretion of lysine–MDA adducts of dietary origin, the subjects consumed a protein-free diet for 24 h prior to and during the collection.

Part II. Preparation of MDA-modified ^{14}C-bovine serum albumin (BSA). MDA was prepared fresh by acid hydrolysis of tetramethoxypropane (1N HCl for 40 min at 40°C); 0.5 mL of a 0.05 mM solution of MDA (1.9 μg) was incubated with 0.5 mL of a 7.6×10^4 mM solution of ^{14}C-labeled BSA (^{14}C-BSA, specific activity 30.1 μCi/mg, 16.6 μg; Sigma Chemical Co., St. Louis, MO) in 50 mM phosphate/citrate buffer, pH 4.3, at 37°C overnight. Unreacted MDA was removed by vacuum desiccation at 37°C for 16 h. Preliminary experiments showed that ≥99% of free MDA was removed under these conditions. The residue was taken up in buffer, and 10 μL aliquots were frozen at –70°C. MDA in the protein preparations was determined as the TBA derivative using an HPLC procedure that is specific for this compound (5). This procedure revealed that the unreacted ^{14}C-BSA contained 20 ppm MDA. The MDA-reacted ^{14}C-BSA used in the RBC and mitochondrial experiments contained 120 and 60 ppm MDA, respectively.

RBC assay. The enzyme was prepared from human RBC according to the procedure of Davies and Goldberg (6) for rabbit erythrocytes. The protein content was determined by the Lowry procedure and 60 μL of the enzyme preparation (~5 mg protein), 10 μL (0. 10 μg) of ^{14}C-BSA, and 80 μL of Hepes buffer, pH 7.8, were incubated at 37°C for up to 6 h. One volume of 20% trichloracetic acid (TCA) was added, and the mixture was kept on ice for 30 min. Intact proteins and large peptides were removed by centrifugation at 16,000 × *g* for 10 min. Radioactivity in the clear supernate was quantified by scintillation counting (Beckman LS 3810; Beckman Instruments, Mississauga, Ontario, Canada) using 10 mL of Ecolume cocktail (ICN Biochemicals, Inc., Mississauga, Ontario, Canada). The % recovery of radioactivity in the TCA-soluble fraction was calculated.

Rat liver mitochondria assay. The livers were homogenized using a Potter-Elvehjem Teflon homogenizer. Mitochondria were prepared according to Pedersen *et al.* (7) in a medium consisting of 0.07 M sucrose, 0.22 M D-mannitol, 0.002 M Hepes buffer, and 0.05% BSA. The enzyme was prepared and the assays carried out according to the procedures of Marcillat *et al.* (8). Sixty μL of the mitochondrial preparations (0.4 mg of protein), 10 μL of ^{14}C-BSA solution, and 60 μL of 50 mM Hepes buffer, pH 7.8, were incubated at 37°C for up to 6 h. Then 60 μL of a carrier solution of unlabelled BSA (4.5 mg) was added, followed by 190 μL of 20% TCA. The mixture was kept on ice for 30 min before centrifuging at 16,000 × *g* for 10 min. The recovery of radioactivity in the TCA-soluble fraction was used as a measure of proteolysis.

RESULTS

Part I. The elution profiles obtained for rat urine MDA and its conjugates are shown in Figure 1. They demonstrate that rats fed a vitamin E-deficient diet or dosed with Fe or CCl_4 excreted substantially larger amounts of ε-PL, APL, and free MDA than the controls. The enhanced excretion of free MDA reflects an increase in MDA production *in vivo* and the enhanced excretion of the lysine adducts a resulting increase in its reactions with tissue proteins. The elution profile for one 24-h sample of human urine is shown in Figure 2. It contains major peaks for APL and ε-PL and an unusually large peak for free MDA.

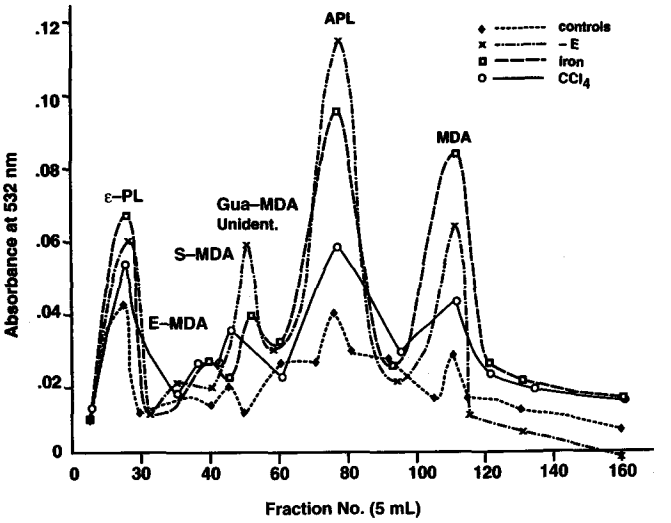

FIG. 1. Effect of vitamin E deficiency and iron or CCl_4 administration on the elution profile of malondialdehyde (MDA) metabolites obtained by anion exchange chromatography of rat urine. In addition to the lysine adducts and free MDA, the profile reflects the elution of minor amounts of adducts with ethanolamine (E–MDA), serine (S–MDA), guanine (Gua–MDA), and unidentified (Unident.) compounds. MDA was determined as the thiobarbituric derivative. In the interest of clarity, not all data points are shown. APL, *N*-α-acetyl propenal lysine; ε-PL, ε-propenal lysine.

Part II. RBC. There was a linear relationship between the amount of RBC protein used to hydrolyze ^{14}C-BSA (0–12.0

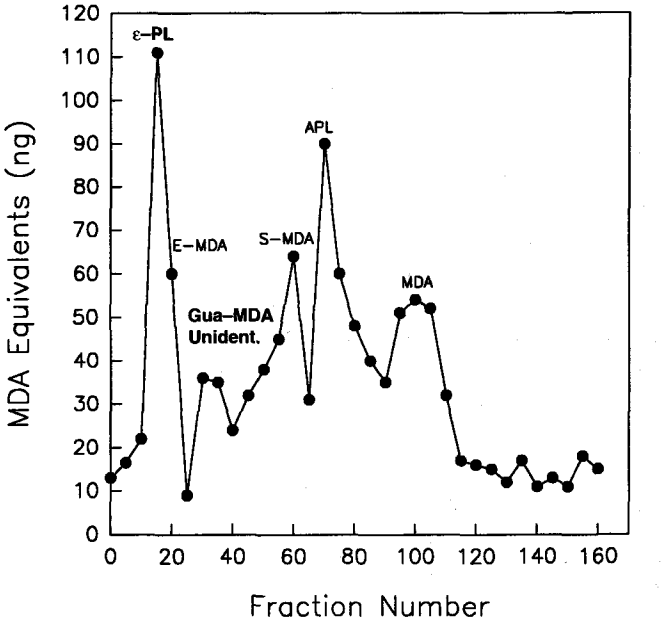

FIG. 2. Elution profile of MDA metabolites obtained by anion exchange chromatography of human urine. See Figure 1 for abbreviations.

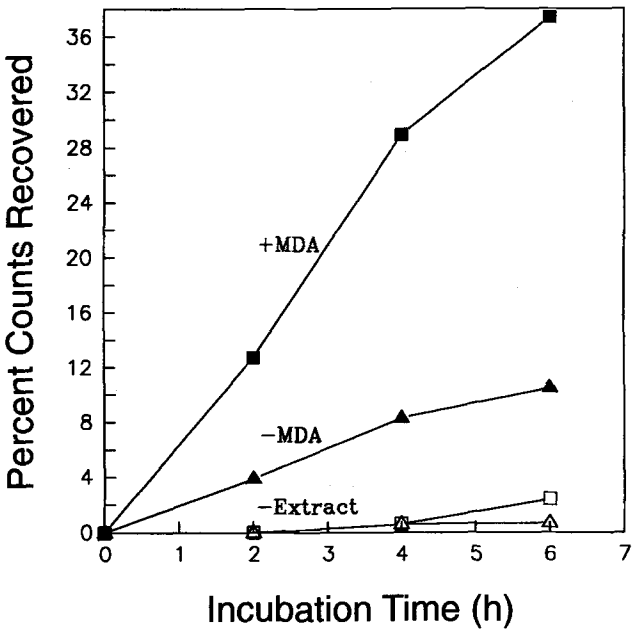

FIG. 3. Effect of reacting ^{14}C-bovine serum albumin with MDA on its rate of hydrolysis by the red blood cell enzyme. See Figure 1 for abbreviation.

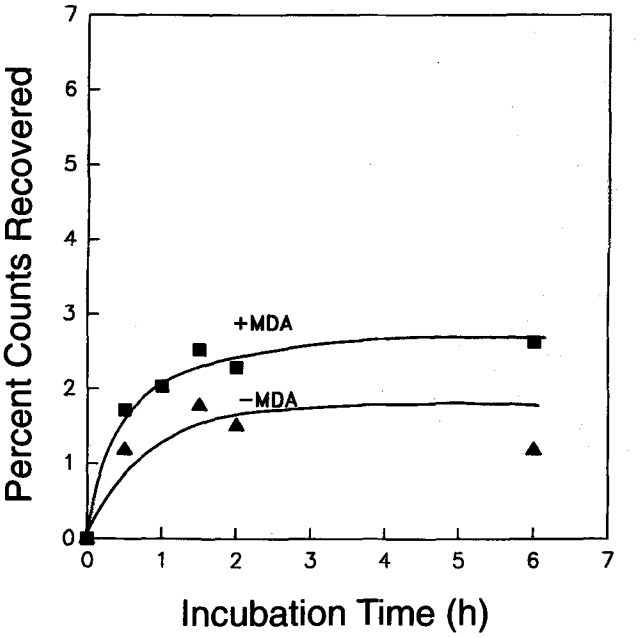

FIG. 4. Effect of reacting ^{14}C-bovine serum albumin with MDA on its rate of proteolysis by the mitochondrial enzyme. See Figure 1 for abbreviation.

mg) and the recovery of counts in the acid-soluble fraction. Five mg of protein was used for assay purposes. There was also a linear relationship between the amount of ^{14}C-BSA used (0–1. 0 μg) and the release of acid-soluble radioactivity (0–3,000 cdpm). The recovery of counts in the TCA fraction remained constant at 1.5% over the range of the assay.

The effect of reacting ^{14}C-BSA with MDA on its rate of hydrolysis by the RBC enzyme is illustrated in Figure 3. The release of counts from the reacted protein was threefold greater than that from the unreacted protein, a difference that was significant ($P < 0.0$ 1) using Student's *t*-test for paired values from five comparative assays. The release of counts in the enzyme blanks was nonsignificant ($P > 0.05$).

Liver mitochondrial assay. The recovery of acid-soluble counts increased linearly with increments in mitochondrial protein up to 0.2 mg, then reached a plateau. Assays were performed using 0.4 mg of protein. The yield of counts (0–300 cdpm) increased linearly with additions of up to 0.5 μg ^{14}C-BSA, and 0.10 μg was used in the assays. The fractional recovery of counts (1.2%) remained constant over the assay range (0–0.5 μg). The hydrolysis of MDA-modified ^{14}C-BSA proceeded at a rate approximately twice that of the unmodified protein (Fig. 4). This difference was found to be significant ($P < 0.01$) when the paired data from five comparative assays were analyzed. Degradation in the absence of the mitochondrial extract was negligible.

DISCUSSION

Normally, the main source of MDA in rat and human is the diet, from which it is absorbed primarily in the form of ε-PL (3). The excretion of free MDA and its lysine derivatives by rats fed a purified diet containing a nonperoxidizable fat (hydrogenated coconut oil) is only about 25% of that excreted on a stock diet of natural ingredients. However, the profile of MDA metabolites is similar, reflecting the predominant association of MDA with proteins in both the diet and the tissues. Neither the excretion of total MDA or of its lysine derivatives, therefore, is a useful indicator of *in vivo* lipid peroxidation, nor is the excretion of free MDA (9).

Free MDA (10), but not ε-PL (3), is mutagenic in bacterial and animal cells grown in culture. Administration of ε-PL to rats leads to marked increases in the excretion of ε-PL and APL, but not of free MDA, indicating that MDA is not a product of the metabolism of these compounds. MDA in food lipids therefore does not appear to pose a risk of mutagenicity in humans.

The reactivity of MDA with proteins has been known for many years. Crawford *et al.* (11) demonstrated in 1967 that MDA reacted with the lysine residues of *BSA in vitro.* The presence of 20 ppm MDA in a highly purified sample of ^{14}C-BSA may reflect a reaction with BSA *in vivo,* and the occurrence of ubiquitous reactions of MDA with tissue proteins is indicated by the predominance of lysine-MDA adducts in the urine of animals fed MDA-free diets (2). Most of the difference in values reported for the MDA content of animal tissues using TBA methods and methods for free MDA is attributable to hydrolysis of MDA from proteins during the TBA procedure (5). Serum albumin may have a physiological role as a scavenger for free MDA released into the circulation. No evidence was obtained in the present studies for the presence in urine of products of MDA reactions with amino acids other than lysine and the phospholipid base serine.

The clinical significance of the modification of tissue proteins by MDA, if any, is unknown. However, Haberland and co-workers (12) have shown that modification of 15% of the lysine residues of the apo-B100 moiety of plasma low-density lipoproteins by reactions with MDA impairs its recognition by the low-density lipoprotein receptor in human monocytes and macrophages and results in cholesterol deposition in the arterial walls. Reacting MDA with enzyme proteins *in vitro* has been reported by several investigators to result in inactivation, malfunction, or instability.

The responses of the RBC and liver enzymes to MDA-modified BSA observed in the present study are similar to those reported for their response to BSA modified by exposure to hydroxyl radical-generating systems (13). Although this similarity suggests that the protein damage caused by hydroxyl radicals may be mediated by initiation of lipid peroxidation, Davies and Goldberg (14) failed to find any evidence of increased lipid peroxidation in the course of their studies. The scavenger macroprotease may have a low specificity for the form of protein modification. Stadtman (15) demonstrated that oxidative damage to proteins in the presence of transition metal ions leads to the formation of carbonyl compounds and a concomitant susceptibility to degradation. Although MDA has been reported to cross-link proteins *in vitro* (16), there is no clear evidence that cross-linking occurs *in vivo* or that it results in protein cross-linking. Denaturing gel electrophoresis conducted on MDA-reacted BSA in the present study revealed no evidence of degradation. As postulated by Davies and Pacifici (17,18) to explain the accelerated proteolysis caused by hydroxyl radicals, MDA may alter the overall charge on proteins or expose previously hidden amino acid sequences that mark them for degradation.

ACKNOWLEDGMENTS

This work was supported by a grant from the Natural Sciences and Engineering Research Council of Canada. The helpful advice of Dr. Sanjiv Agarwal in the second part of these studies is appreciated.

Names of journals must be abbreviated according to *Chemical Abstracts Service Source Index* (CASSI), published by Chemical Abstracts Service, P.O. Box 3012, Columbus, OH 43210. These abbreviations are identical to those used in *Chemical Abstracts. These abbreviations are to be used exclusively.*

If it is necessary to refer to "unpublished data," "personal communication," "manuscript in preparation" or papers "submitted for publication," such citations should not be listed as references, but are to appear in the text, e.g., (Turner, E.H., and Smith, D.E., unpublished data). Authors must obtain written permission to cite the unpublished work of others, and copies of such correspondence must accompany the manuscript. Avoid the use of *et al.* in referring to authors: list all names.

NOTE: All titles in References section should be capitalized. See examples above.

NOTE: *Lipids* is now italicizing all mathematical variables. This may not have been clear in January 1995 "Guide to Authors."

AVAILABILITY OF PURIFIED OMEGA-3 FATTY ACIDS

Kilogram quantities of EPA and DHA ethyl ester capsules are available free of charge through the Fish Oil Test Materials Program, a joint effort of the National Oceanic and Atmospheric Administration and National Institutes of Health. These quality-assured and quality-controlled materials contain 94% EPA or 90% DHA. Ethyl esters of vegetable oils (olive, corn, and safflower) are available in capsule form as controls. Funded research projects studying the effect of

(continued on next page)

omega-3 fatty acids in health and disease, from all funding sources, are eligible to receive these capsules. For further information or to request a short application form, contact the Fish Oil Test Materials Program at 12501 Washington Ave., Rockville, MD 20852 (Phone: 301-443-9643; Fax: 301-594-0035).

Low-Fat Diets Do Not Lower Plasma Cholesterol Levels in Healthy Men Compared to High-Fat Diets with Similar Fatty Acid Composition at Constant Caloric Intake

Gary J. Nelson*, Perla C. Schmidt and Darshan S. Kelley

Western Human Nutrition Research Center, USDA, ARS, Presidio of San Francisco, California 94129

ABSTRACT: In most studies reporting the effects of high-fat (HF) and low-fat (LF) diets on human plasma fatty acids (FA) and lipoprotein levels, the design involved adding to the diet an oil that had an FA composition (FAC) very different from the FAC of the control diet. Thus, it is difficult to determine if simply reducing the fat content of the diet without changing the dietary FAC changes the tissue FAC or alters plasma lipid levels. In this study, we fed diets that contained either 22 or 39% of calories from fat, but had no differences in their FAC, for 50 d to a group (n = 11) of healthy men (20–35 y). Thus, the polyunsaturated/saturated ratios (1.0) of the diets were identical as were the n-3/n-6 ratio and the monounsaturated-to-total fat ratios. The diets contained (wt% of total fat) approximately 28% saturated FA, 33% monounsaturated *cis*-FA, 6% monounsaturated *trans*-FA, 22% n-6 polyunsaturated FA, and 7% n-3 polyunsaturated FA, and 4% other minor FA. The diets consisted of natural foods and were formulated to contain 16 en% protein, either 45 or 62 en% carbohydrate (CHO) and at least the recommended daily allowance for all micronutrients. Both diets contained 360 mg of cholesterol per day. All subjects were given the HF diet for 20 d, and then six were placed on the LF and the other five remained on the HF diet for 50 d. The two groups were crossed-over for the remaining 50 d of the study. The subjects' baseline total cholesterol level was 173 mg/dl, after 50 d on the HF diet it was 177 mg/dl and after 50 d on the LF diet, 173 mg/dl. The differences were not significant, and there were no significant changes in either the LDL or HDL cholesterol levels with either diet. Triglyceride levels, and consequently very low density lipoprotein levels, rose significantly on the LF, higher CHO diet compared to the levels found in the subjects on the HF diet (91.5 and 66.4 mg/dl respectively, $P < 0.002$). The linoleic acid content of the plasma, platelets, and red blood cells was significantly ($P < 0.05$) reduced in the LF diet compared to HF diet, without any obvious physiological effects. Hence, many earlier observations indicating reductions in plasma lipid levels when people are on LF diets may be due to changes in the FAC of the diet, not the reduction in fat calories.

Lipids 30, 969–976 (1995).

Abbreviations: AA, arachidonic acid; CHO, carbohydrate; FA, fatty acid; FAC, fatty acid composition; GLC, gas–liquid chromatography; HDL, high density lipoproteins; HF, high-fat; LDL, low density lipoproteins; LF, low-fat; VLDL, very low density lipoprotein.

It has been reported for more than forty years that dietary saturated fatty acids (FA) will raise blood cholesterol levels, and conversely, dietary polyunsaturated FA will lower blood cholesterol levels (1–4). Keys *et al.* (5) and Hegsted *et al.* (6) almost simultaneously published formulas based on epidemiological data from various sources showing that mean cholesterol levels (hence, cardiovascular disease rates) in different populations could be directly related to the mean fat consumption of the population. Both Keys *et al.* (5) and Hegsted *et al.* (6) went on to point out that saturated fat raised blood cholesterol almost twice as much (on a per gram of intake basis) than polyunsaturated FA lowered it. Both formulae were similar. Only the constants and coefficients were different between the Keys *et al.* (5) and Hegsted *et al.* (6) equations. Another important finding was that dietary cholesterol had a minor effect on blood cholesterol levels, about 2 mg/dl per 100 mg of dietary cholesterol. Dietary monounsaturated FA (mainly oleic acid) were neutral; i.e., they didn't raise or lower blood FA levels. Also Keys *et al.* (5) and Hegsted *et al.* (6) suggested that the saturated eighteen carbon FA, stearic acid, didn't raise blood cholesterol significantly, a point largely ignored until a few years ago when Bonanome and Grundy (7) reinvestigated this issue and reached the same conclusion, although it should be noted that Dougherty *et al.* (8) recently published a report indicating that stearic acid is hypercholesterolemic if fed for longer periods.

Along with our knowledge of the specific cholesterolemic effects of dietary FA, high-fat (HF) diets, regardless of their specific FA composition, were considered hypercholesterolemic and consequently deleterious to cardiovascular health (9–11). This concept was based on two ideas: (i) that HF diets lead to obesity more easily than high carbohydrate (CHO) diets (12), and (ii), that HF diets elevate blood cholesterol levels while low-fat (LF) diets lower blood cholesterol levels (9–11). The first hypothesis may well be right, but one has to eat excess calories (i.e., take in more calories than expended daily) to gain weight regardless of the character of the diet, HF, LF, etc. The second hypothesis remains to be proven (11,12).

In most studies reporting the effects of HF and LF diets on human plasma FA and lipoprotein levels, the design involved adding to the diet an oil that had a fatty acid composition (FAC) very different from the FAC of the control diet

(13–20). Thus, it is difficult to determine if simply reducing the fat content of the diet without changing the dietary FAC changes the tissue FAC or alters plasma lipid levels. Furthermore, people eat natural and processed food as complex mixtures that vary day to day and year to year. They rarely eat pure fats or oils, and certainly not continuously for weeks. In most previous studies (13–20) that have examined this issue, the FAC of the diet was changed markedly as well as the amount of calories from fat; thus, the experimental diets had different ratios of saturated and unsaturated FA in them. This confounds the interpretation of the results; one does not know if the changes observed are the result of changes in the caloric intake or changes in the type of FA in the diet. In an effort to clarify this point, we fed LF (22 en% fat) and HF (39 en% fat) diets to healthy volunteers for 50 d. The diets had FAC that were identical despite the intentional differences in the fat content in the diet.

MATERIALS AND METHODS

Materials. All natural foods were purchased at local food markets. FA standards were purchased from Nu-Chek-Prep (Elysian, MN). Organic solvents were obtained from Baxter Scientific, Burdick and Jackson Brand (McGaw Park, IL). The reagents for the enzymatic determination of plasma cholesterol and triglycerides were purchased from Sigma Diagnostics (St. Louis, MO).

Subjects. The volunteers were recruited from the West Coast, and consisted of men between the ages of 20 and 35. The physical characteristics of the eleven male volunteers (HNS-27) who completed the study were age (years), 32.9 ± 4.5; weight (kg), 72.9 ± 8.2; body mass index (kg/M^2), 23.1 ± 1.6; blood pressure systolic, 115.9 ± 9.5; blood pressure diastolic, 73.2 ± 7.8; smokers, none. Initially twelve volunteers were included in the study, but one was unable to complete the protocol. The volunteers were given complete physical examinations. Body weights had to be within −10 to +20 percent of ideal body weights using the Metropolitan Life Insurance Company tables (medium frame values from the 1983 edition). Evidence of existing illness or chronic disease was an exclusion criterion. Mild hypertension was not an exclusion criterion, but the group that was recruited tended to have blood pressures slightly below average for men in this age group. Smoking, excessive alcohol consumption, and evidence of narcotic abuse were also exclusionary.

Experimental design. All the volunteers were confined to the Nutrition Research Suite of the Western Human Nutrition Research Center (San Francisco, CA) for the duration of the study. As the subjects stay within the confines of the Nutrition Suite except for occasional supervised outings, they had no opportunity to consume any food except that provided by the Center. Thus, compliance with the protocol was, of necessity, 100%. In addition, all food intake was monitored, portions were weighed, and subjects were required to consume everything provided to them during their meals. (A rubber spatula was provided to ensure that all food was scraped from the plates and eaten.) Food spills were carefully monitored and recorded, and fluid intake, while *ad libitum,* was also measured precisely.

The protocol for this study was approved by the Institutional Review Boards of the University of California at Davis (Davis, CA) and the USDA (Washington, D.C.). A crossover design was used so that the subjects acted as their own controls. The subjects were fed a stabilization diet, containing 39% of calories from fat for 20 d. The HF diet had a macronutrient composition of 39 en% fat, 16 en% protein, and 45 en% CHO. On day 20 of the study, they were divided randomly into two groups: Group A remained on the HF diet (39% of calories from fat) for 50 d; Group B was placed on a LF diet (22% of calories from fat). The LF diet had a macronutrient composition of 22 en% fat, 16 en% protein, and 62 en% CHO. After 50 d, day 70 of the study, the groups switched diets for the remaining 50 d of the study. After 120 d, all the volunteers were discharged from the Nutrition Suite and returned to an *ad libitum* diet.

During the confinement period, there were blood draws on study days 2, 20, 45, 70, 95, and 120. As measured parameters on the intermediate blood draws (study days 45 and 95) showed insignificant differences from the endpoints (study days 70 and 120), only data obtained from the endpoint blood draws were used for statistical analysis. Statistical comparisons of the measured parameters were made using day 20 as the baseline values for each subject.

Diets. The diets consisted of natural foods. No dietary supplements were given. The macronutrient composition of the diets is given in Table 1. (A complete description of the diets, listing all the major and minor nutrients, is available upon request.) A seven-day menu cycle was used throughout the study. Proximate analysis was made on seven individual diet composite samples taken from each menu once during the study for both the stabilization diet and intervention diets. The results for the seven composite samples were averaged to find the actual composition of the diets. No alcohol was in-

cluded in these diets. The nutrient composition of the diets was calculated from a computerized nutrient data bank using the data from USDA Handbook 8 (21), and adjusted to provide at least the recommended daily allowance for known essential nutrients (22).

Table 2 gives the measured FAC of both diets. The ratios of all the major FA were intended to be held constant in these diets. Inspection of Table 2 indicates that all the major FA were very similar although the level of linoleic acid was slightly higher in the HF diet, 23% in the HF diet vs. 21% in the LF diet. As the diets consisted of only natural food, the initial FAC calculated from food composition tables matched very well with the analyses obtained on the actual diet. At the beginning of the study, each participant's caloric intake was estimated, and the caloric content of the meals was calculated to maintain current body weight. As the estimates were subjected to error, the participants were weighed every day, and the caloric value of their meals adjusted occasionally, if necessary, to maintain their weight within the limits of the study. Thus, the average weights of the participants did not vary significantly during the 120 d of the study. If all the intakes for each volunteer were averaged during the entire study, the mean energy intake was approximately 2800 Kcal/d.

Measurements. Blood was drawn between 7:00 and 8:00 a.m. after an overnight fast of at least 12 h. Blood was drawn into vacutainers with appropriate anticoagulants using a Teflon catheter (Angiocath; Desert Medical, Sandy, UT) for FA analysis, or syringes containing 1 mL of citrate solution for platelet studies. Platelet-rich plasma was prepared by low-speed centrifugation for 10 min at 100 × *g*. Platelet-poor plasma was prepared by respinning the blood after removal of the platelet-rich plasma for 15 min at 400 × *g*. Red cells for FA analyses were prepared from the residue by resuspending the cells in 10 mL of phosphate buffered saline and recentrifuging the cells at 400 × *g* for 15 min three times. The supernate was discarded. The red cells were frozen at −70°C until their lipids could be extracted.

Triglyceride and cholesterol determinations. Plasma was analyzed for triglycerides and cholesterol in a Cobas-Faras centrifugal analyzer (Roche Diagnostic Systems, Montclair, NJ) using automated enzymatic methods as described by McGowan *et al.* (23) and Allain *et al.* (24).

Lipid extraction and FA analysis. Tissues were extracted by the procedures described by Nelson (25,26) using chloroform/methanol (2:1, vol/vol). Samples were then transmethylated with methanolic HCl (7%, w/w) by procedures described elsewhere (26,27). When the total lipid extract was transmethylated, the impurities, extracted into the hexane phase after termination of the reaction, were removed by thin-layer chromatography as described by Nelson (25). Because the amount of material available from human platelets for FA analysis was limited FA methyl esters were obtained by direct transmethylation of the intact tissue without prior solvent extraction as described in an earlier publication (28). The conditions of the capillary gas–liquid chromatography (GLC) have been described previously (29). Briefly, the column was a 30 m × 0.025 mm fused quartz column coated with SP-2340 purchased from Supelco, Inc. (Bellefonte, PA). The GLC data were processed with Hewlett-Packard ChemStation software (Palo Alto, CA) running on a desktop computer. The gas chromatograph was a Hewlett-Packard Model 5890a. Data were reprocessed and combined using Excel 5.0 obtained from Microsoft Corporation (Bellevue, WA).

Statistical analysis. Lipid and FA data were analyzed with a single tailed, paired *t*-test, using SigmaStat (Jandel Scientific, San Rafael, CA) statistical program for IBM compatible computer. Analysis of variance statistical analyses were performed with a desktop computer using the PC SAS data system, version 6.08, obtained under license from the SAS Institute, PC-SAS, Version 6.08 (SAS PC Manual, Version 6.08, 1993; SAS Institute, Chapel Hill, NC). Both statistical treatments yielded essentially the same results. The power of this study to detect a significant difference at the $P < 0.05$ level was 90% with eleven subjects (n = 11) assuming a difference of 20% in the means of lipid parameters and a standard deviation of ±20% of the mean value.

RESULTS

The measured and theoretical values on the macronutrient composition of the LF and HF diets were extremely close (Table 1). The only significant difference between the fatty acid composition of the LF and HF diets was the slightly larger amount of arachidonic acid (AA) in the LF diet compared to the HF diet (Table 2). The linoleic acid content of the

HF diet was about 2% greater than the amount in the LF diet. This did not reach statistical significance, however, due to the large standard deviation between amounts in the individual menu plans in the seven-day menu rotation. This is a statistical quirk of the analysis. The difference in the amount of AA in the two diet regimes probably had little physiological significance.

The FAC of the subjects' plasma, red blood cells, and platelets are given in Tables 3 through 5. In each tissue, FAC remained similar on each diet. There is a small but constant elevation in the linoleic acid content of the blood from subjects consuming the HF diet. In the plasma and platelets, the linoleic acid content of the diet was significantly different at the $P < 0.05$ level, and equivalent to the amount of excess linoleic acid in the HF diet. Other differences were detected in the amount of specific FA in the plasma and platelets. These differences which were statistically significant usually involved FA that were present in small amounts. The physiological significance of these small differences, if any, is unknown. It also is possible that in several of these cases the statistical significance is artifactual.

In the red blood cell samples, the situation appears more complex. While plasma and platelet FA turn over rapidly in the body, 1–2 and 8–16 d, respectively, red cell FAC shows a consistency related to the 120-d turnover of the red cells in the circulation. During the 50-d intervention, we observed that the red cell linoleic acid level was reduced by the LF diet and increased by the HF diet, consistent with the difference in the FAC of the two diets. Besides this change in linoleic acid levels, red cells exhibited changes in stearate, α-linolenic acid, and dihomo-γ-linolenic acid, and AA. This suggests that the linoleic acid elongation and desaturation pathways were influenced by the amount of fat in the diet.

Table 6 lists the plasma cholesterol, triglycerides, high density lipoprotein (HDL)-cholesterol, and low density lipoprotein (LDL)-cholesterol levels before and after the subjects consumed the LF and HF diets. Also shown are their lipid values prior to the start of the study and after three weeks on the stabilization diet. Although the total cholesterol, HDL-cholesterol, and LDL-cholesterol levels are slightly increased when the subjects consumed the HF diet compared to the values obtained after they consumed the LF diet, the increase was not statistically significant.

The triglycerides' values did change significantly ($P < 0.002$), rising about 25 mg/dl when the subjects were consuming the LF diet compared to the period when they consumed the HF diet. Thus, although the cholesterol levels in the vari-

[a]See Tables 2 and 3 for abbreviations.

ous lipoprotein fractions were not altered significantly, there was a redistribution of the lipoprotein spectrum during the two diet periods. The increase in the plasma triglyceride level indicated an increase in the plasma very low density lipoprotein (VLDL) level and a decrease in both the plasma HDL and LDL levels. Thus, the total cholesterol level remained constant because the increase in plasma VLDL cholesterol compensated for the reduction in HDL-cholesterol and LDL-cholesterol. Because of individual variations, the standard deviation was large enough to prevent these values from reaching statistical significance.

DISCUSSION

It has almost been dogma for the last forty years in the field of dietary fat effects on blood lipids that HF diets will raise blood cholesterol levels while LF diets will lower blood cholesterol (1–4). A problem one encounters when examining the scientific basis for this concept is that the FAC of LF and HF diets was rarely the same. The Keys *et al.* (5) and Hegsted *et al.* (6) formulas for the effect of dietary fat on blood cholesterol levels were published thirty years ago. Those equations say nothing about the total percentage of fat calories in the diet, but they imply that HF diets will raise blood cholesterol because they relate grams of fat ingested to blood cholesterol level, positively for saturated FA, except stearic (7,8), and negatively for polyunsaturated fat (n-3 FA are ignored). Dietary cholesterol has only a small influence on blood cholesterol levels. If one uses the Keys equation (5) or the Hegsted equation (6) to calculate the change in blood cholesterol that one would expect with the protocol used in this study, there should have been an average difference between the HF and LF diets of −23 mg/dl. The subjects' LF diet cholesterol level was 173 mg, and should have risen to 196 mg/dl if the Keys *et al.* (5) and Hegsted *et al.* (6) equations were an appropriate explanation for the physiological response to changes in dietary fat intakers. The observed total cholesterol value when the participants consumed the HF was 177 mg/dl, not significantly different from the value obtained when they consumed the LF diet.

There are several possible reasons that the Keys *et al.* (5) and Hegsted *et al.* (6) equations do not hold in this particular experiment: (i) The equations were developed using large population data bases (11,20). Here the sample number is too small to detect the effect. This answer is unlikely and unsatisfactory because the conditions of this experiment were carefully controlled and the statistical power of the protocol was excellent.

(ii) The average cholesterol level in the subjects was considerably below that in the European and American populations used to develop the Keys *et al.* (5) and Hegsted *et al.* (6)

TABLE 6
High- and Low-Fat Diets, Blood Cholesterol, Triglycerides, and Lipoprotein Values

Period	Diet	Total cholesterol mean ± SD	Triglycerides mean ± SD	HDL-cholesterol mean ± SD	LDL-cholesterol mean ± SD
Entry	*Ad libitum*	176.3 ± 33.1	85.8 ± 28.4	46.3 ± 14.0	112.8 ± 26.8

Intervention	Low-fat	173.2 ± 27.3	91.5 ± 38.0	40.5 ± 12.4	114.5 ± 21.3
Intervention	High-fat	176.9 ± 32.9	66.4 ± 41.7	43.2 ± 13.4	119.5 ± 24.3
Paired *t*-test, *P* values[a]		0.425	0.002	0.258	0.238

[a]The *t*-test compares only the values at the end of the high- or low-fat diets with the values obtained at the end of the stabilization period, study day 20. Groups A and B values were taken at study day 70 and day 120, depending on the leg of the intervention diet for the each group; HDL, high density lipoprotein; LDL, low density lipoprotein.

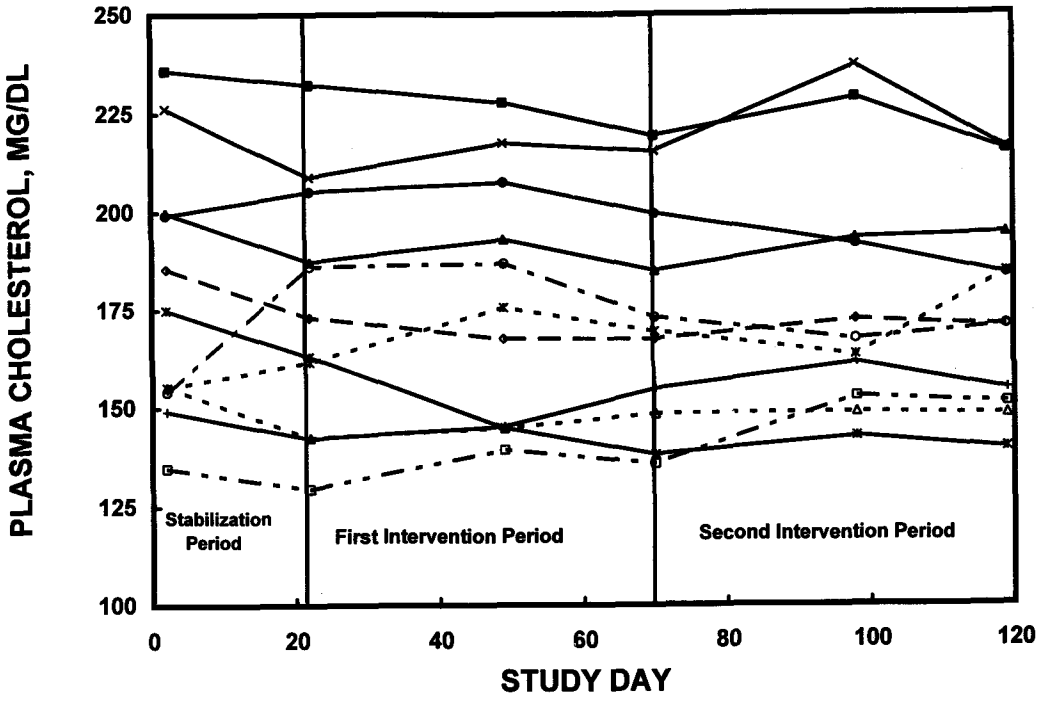

FIG. 1. The individual plasma total cholesterol values for the all participants during this study. The various study periods are shown on the figure. Separate symbols are used for each subject. Solid lines represent members of Group A who received the high-fat diet in the first intervention period while the dotted lines represent members of Group B who received the high-fat diet in the second intervention period.

equations, and it is impossible to lower blood cholesterol below a certain point by dietary manipulation alone (22). If subjects with higher mean cholesterol values were studied, the cholesterol levels would have dropped as predicted by the equations. We think not. The average cholesterol level of the group was 176 mg/dl on entry into the study. It was 177 mg/dl on the HF diet and 173 mg/dl on the LF diet. It did not go up or down on the intervention diets. Also, a blood cholesterol level of 177 mg/dl is not exceptionally low. It is above the mean level in Japan and several other non-European cultures (30,31) and about the level observed in vegetarians in the United States (32). Furthermore, if one looks at the plasma cholesterol levels of the individuals in this study, the values ranged from 133 to 240 mg/dl, yet none showed any significant drop from entry level on the LF diet nor any marked rise on the HF diet (Fig. 1).

(iii) The Keys *et al.* (5) and Hegsted *et al.* (6) equations were developed using data from populations which consumed diets in which the polyunsaturated/saturated ratio varied from 0.2 to 0.4, not the 1.0 found in the diets used in this study. If the P/S ratios in the diets used in this study were in the same range as that in the general American or European populations, the equations would have predicted the change in blood cholesterol level correctly. Perhaps, but that is just another way to restate our hypothesis: it is the ratio of the various FA in the diets that determines the changes in blood cholesterol levels upon changes in the dietary fat intake, not the percentage of calories from fat, either saturated or unsaturated. Hayes *et al.* (33–35) have suggested that if polyunsaturated fat in the diet makes up more than 6% of calories, it is not hypocholesterolemic. In this study, polyunsaturated fat accounted for 13% of calories in the HF diet and 7% of calories in the LF diet.

(iv) There are responders and nonresponders to dietary fat. This study only included nonresponders. That is highly unlikely as the subjects were randomly selected from the general population and were not selected on the basis of their cholesterol values nor tested for a response to dietary fat.

(v) The ratio of saturated to monounsaturated to polyunsaturated fat in the diet will determine the change in plasma cholesterol level in response to changes in dietary fat intakes, not the actual level of fat in the diet (i.e., the percentage amount of fat calories in the diet). We feel that this is the correct interpretation of the results from this study.

Obviously, if fat calories are significantly reduced in the diet, they must be replaced with another macronutrient, such as CHO. If the amount of CHO in the diet is increased, a temporary or perhaps permanent increase in the triglyceride levels in plasma will occur (36–39). While it is also possible that the observed increase in plasma triglycerides here, and also reported by many other investigators (37–39), was transient (40), a report by West *et al.* (41) suggests that high CHO diets induce a permanent elevation in plasma triglycerides and, consequently, in the VLDL levels in humans. It is still controversial whether increases in VLDL have any adverse health effects (42–44).

It also appears as if increased levels of saturated fat may cause an increase in HDL levels (12,45–47). But it is not clear whether this increase is due to the decrease in triglyceride levels found in low CHO diets, as there is an inverse relationship between plasma triglyceride levels and HDL levels (12). LDL-cholesterol levels, the cholesterol value most associated with heart disease risk (44), are unaffected by the percentage of fat calories in the diet. This has wide dietary implications for individuals trying to lower their plasma LDL levels as well as for health-care providers advising individuals on dietary modification as related to cardiovascular risk and health.

As the FAC of both intervention diets was held constant, there were few changes in the FAC of the three tissues examined here, plasma, platelets, and red cells. It was interesting, however, that the small difference (2%) between the linoleic acid content in the two diets was easily detectable in all of these tissues. This would seem to indicate that the tissue levels of essential fatty acids are determined primarily by diet and not by a homeostatic control in the tissue or organ. The other differences in the FAC between the tissue when the subjects consumed either the LF or HF diets may be due to small differences in the FAC of the two diets, or are artifacts of the analytical methods when FA are present in small amounts in the tissues. The differences observed in the FAC of the red cells, particularly dihomo-γ-linoleic and AA, may be real and related to the metabolism of linoleic acid. There is an inverse relationship between linoleic and AA levels in most tissues (48,49).

While we consider that the increased linoleic acid content of the plasma, platelets, and red blood cells reflects the 2% difference in the linoleic acid content between the LF and HF diets, this is only one possible explanation. Other factors that could account for the differences could be related to differences in metabolism between subjects consuming high CHO and LF diets vs. subjects consuming moderate CHO, HF diets. As this study did not have an isotopic tracer included in its design, there is no way in which this question can be answered definitively.

There are several caveats that must be attached to these results. This study involved only eleven subjects, between the ages of 20 and 37, who were all male, normal lipemic, and in excellent health who did not smoke or ingest alcohol (or other drugs) during this study. All environmental conditions were kept constant as the volunteers were confined to a metabolic unit for the duration of the study. Whether the results of this study can be extrapolated to free-living, hyperlipidemic subjects, other age groups or gender remains to be determined by further experiments. Still, it is apparent that one must be cautious in predicting changes in blood cholesterol from lowering total dietary fat intakes or applying the Keys *et al.* (5) and Hegsted *et al.* (6) equations to individuals when recommending dietary modifications with respect to fat intakes. The relationship of dietary fat intakes to blood cholesterol levels is very complex, so much of the information gleaned from human feeding studies using artificial mixtures of oils and diets must be viewed with skepticism when applied to individuals with dyslipoproteinemias.

ACKNOWLEDGMENTS

The authors wish to acknowledge the help of the staff at our Center. We are especially indebted to the Metabolic Research Unit staff, without whose help this study could not have been conducted, including the nursing staff who drew the blood and the dietetics staff who prepared the food. We also wish to thank the Bioanalytical Lab staff who did the plasma cholesterol and triglyceride analyses. We appreciate the help of Giovanni Bartolini with maintenance of the gas-chromatograph.

ABSTRACT: *The aim of this study was to investigate the effect* of the oxysterol 5α-cholestane-3β,5,6β-triol (triol) on the metabolism of linoleic acid (18:2n-6) to arachidonic acid (20:4n-6) and on the cell membrane fatty acid composition. Porcine kidney cells were incubated in medium with or without 10 μg/mL of triol for 24 h, then incubated for 1, 6, or 12 h in a medium which contained 50 μM of either [^{14}C]linoleic acid or unlabeled linoleic acid. The cellular uptake of [^{14}C]linoleic acid was significantly higher in the triol-treated cells than in control cells. After 1- and 6-h incubations despite the increase of [^{14}C]linoleic acid pool size in the triol-treated cells, neither total n-6 polyunsaturated fatty acids (PUFA) metabolites nor arachidonic acid were increased in the triol-treated cells as compared to the control cells, but trienoic acids accumulated to a greater extent in the triol-treated cells. Therefore, the ratios of n-6 PUFA metabolites vs. pool size of linoleic acid and of tetraenoic acids vs. dienoic acids were significantly decreased in triol-treated cells as compared to the control cells. The cellular fatty acid composition also showed that linoleic acid percentage was significantly increased while arachidonic acid percentage was significantly decreased in the triol-treated cells, and that the accumulation of trienoic acids (18:3n-6 + 20:3n-6) observed from the [^{14}C]linoleic acid experiment was due solely to increased 20:3n-6 content. This latter finding indicates that a decrease of elongase activity by triol is unlikely. Our results also showed that the triol-treated cells had a lower level of free cholesterol but higher levels of phospholipid and triol in their membranes, suggesting that triol displaced free cholesterol from the cell membrane.

Lipids 30, 977–985 (1995).

Oxysterols (OS) have attracted attention because of their possible role in atherogenesis (1–4) as well as their involvement in the feedback regulation of cholesterol biosynthesis (5). In humans, OS are derived from the diet primarily as products of cholesterol autoxidation (6). High concentrations of OS are formed in certain processed food (7,8), and they are easily absorbed and transported in the blood (2). OS also can be produced endogenously (1).

Previous studies have provided evidence that OS such as 25-hydroxycholesterol and triol possess inhibitory effects on membrane bound Na^+-K^+ ATPase and 5′-nucleotidase (9,10). Replacement of part of the cholesterol of erythrocyte membrane ghost by cholest-4-en-3-one was accompanied by an inhibition of Na^+-K^+ATPase activity of the erythrocyte membrane (11). The inhibitory effect was mainly related to the depletion of membrane cholesterol and/or the incorporation of these oxidation derivatives into the cell membrane which can affect the fluidity of the plasma membrane (12,13).

The microsomal acyl-CoA desaturases are integral enzymes located in the endoplasmic reticulum where these enzymes control polyunsaturated fatty acids (PUFA) synthesis (14). Earlier studies have suggested that alterations in the physical state of microsomal membranes could be correlated with changes in activity of acyl-CoA desaturases (15,16). The effect of fluidity on the desaturating enzymes implies the existence of a self-regulatory mechanism in the membrane (17). The existence of high affinity OS binding sites in microsomes which are distinct from the cytosolic binding protein was also reported by Hwang (18).

OS have been found in the aortic tissues and plasma of animals fed atherogenic diets in a significantly higher level than the control animals (19,20). In human aortic tissues, the OS levels also were correlated with the severity of atherosclerosis (21,22). Because OS can inhibit or modify the membrane-bound enzymes involved in PUFA metabolism and because high-affinity binding sites for OS exist in microsomes, the present study was conducted to assess the effect of triol on linoleic acid metabolism and the fatty acid composition of porcine kidney cells (LLC-PK).

MATERIALS AND METHODS

Materials. [1-^{14}C]Linoleic acid (specific activity 55 mCi/mmol) and [1-^{14}C]oleic acid (specific activity 56 mCi/mmol) were purchased from Amersham Corp. (Arlington Heights, IL). Bovine serum albumin (BSA) fraction V and 5α-cholestane-3β,5,6β-triol (triol) were purchased from Sigma (St. Louis, MO). Fatty acids and their methyl esters

and the thin-layer chromatographic reference standard mixtures, including phosphatidylcholine and the neutral lipids, were purchased from Nu-Chek-Prep (Elysian, MN). Coomassie blue G-250 based protein assay reagent was purchased from Pierce Co. (Rockford, IL). All other chemicals used in assays and tissue culture were purchased from Sigma. Solvents were reagent grade or high-performance liquid chromatography grade when required.

Cell culture. LLC-PK cells were purchased from American Type Culture Collection (ATCC; Rockville, MD), and stocks were frozen in liquid nitrogen. Cells were grown in M199 (Sigma) with 5% BCS (bovine calf serum, defined/supplemented) (HyClone Laboratories, Inc., Logan, UT) at 37°C in a 5% CO_2, humidified atmosphere. Cells were harvested using trypsin/EDTA (0.5 g trypsin, 0.2 g EDTA/L; Sigma). Medium containing triol was prepared by dissolving 0.5 g BSA (fraction V) (23) in 10 mL of M199, adjusting the pH to neutral, and adding 1 mg triol dissolved in 20 µL ethanol to make stock solution of 100 µg triol/mL. Then 90 mL of M199 were added to 10 mL of this stock solution to give 100 mL medium with 10 µg/mL of triol. The control medium was prepared similarly but with addition of BSA and ethanol without triol.

For an experiment, 60-mm diameter culture dishes were inoculated with 6.7×10^4 LLC-PK cells in 2 mL of medium. After 24 h of incubation, the medium was replaced with 2 mL of M199 with 5% BCS, antibiotic (100 units penicillin, 0.1 mg streptomycin, and 0.25 µg amphotericin B/mL, Sigma antibiotic antimycotic solution), and either 10 µg/mL triol or 0.02% ethanol for the control cells. After 24 h of incubation, the media were replaced with 2 mL of the appropriate media containing 100 nmol, 0.5 µCi/dish (50 µM) of [^{14}C]linoleate added as Na salt/BSA complex (1 µg fatty acid/11 µg BSA) (24).

In other experiments, the medium was enriched with 50 µM unlabeled linoleic acid as Na salt/BSA complex. After 1-, 6-, or 12-h incubations, the monolayers of the control and triol cells were washed gently with 2 mL of phosphate buffered saline, then harvested using trypsin/EDTA. The cells were collected in a test tube, and were pelleted by centrifugation. The supernatant was removed, 2 mL of methanol were added to the tube, the pellet was resuspended, and the tube was flushed with nitrogen.

Lipid analysis. The cellular lipids of the triol-treated and control cells were extracted according to the Folch method (25). The phospholipid fraction was separated from the neutral lipids on polysilicic acid gel impregnated glass fiber sheet (Gelman Science, Ann Arbor, MI) using as solvent system petroleum ether/diethyl ether/acetic acid (90:10:1, by vol). The phospholipids (PL) were transesterified using 14% BF_3 in methanol (Sigma) (26), and the fatty acid methyl esters were separated by gas–liquid chromatography as previously described (27). Butylated hydroxytoluene was added as antioxidant at a concentration of 0.005% (wt/vol) to all the solvents used for lipid extraction and chromatography. All operations were carried out under N_2.

The cellular fatty acid contents (expressed as µg/mg cell protein) were determined using heptadecanoic (17:0) acid as internal standard. The suspended cells in methanol were briefly sonicated (microprobe, output setting 60, 20 s, 4°C) in a Tekmar Sonic Disruptor (Model TM 50 T; Sonics and Materials Inc., Danbury, CT). Heptadecanoic acid was added to the methanolic cell suspension (10 µg in 10 µL $CHCl_3$). Two 100-µL aliquots were taken for protein determination using the microassay procedure following the instructions provided with the protein assay reagent kit (28), using albumin as standard. Cell lipids were then extracted, and the fatty acid methyl esters were prepared by methylation following saponification (29).

Fatty acids methyl esters were identified by comparing their relative retention times with those of authentic standards (Nu-Chek-Prep and Supelco, Bellefonte, PA). When 17:0 acid was used as internal standard, the fatty acid concentration as µg/mg cell protein was calculated relative to the internal standard peak (10 µg).

The cellular contents of PL, triol, and total as well as free cholesterol (FC) (as µg/mg cell protein) were determined as follows: The cells were incubated for 24 h with medium containing either triol (10 µg/mL) or ethanol for the control cells. The cells were collected, suspended in methanol, sonicated, and their protein content was determined as described above. One mL of this cell suspension in methanol was used to which 50 µg of 5α-cholestane (in 250 µL $CHCl_3$) was added as internal standard; then the cell lipid was extracted. The lipid residue was redissolved in exactly 10 mL $CHCl_3$, and two 1-mL aliquots were used for determining the total lipid phosphorus (30). The remaining lipid extract (8 mL) was dried under N_2 and derivatized to trimethylsilyl ether by addition of 500 µL of *N,N*-dimethylformamide (Fisher Scientific, Fair Lawn, NJ) and 500 µL of *bis*-trimethylsilyl-trifluoroacetamide (Supelco) and allowed to stand for 1 h at 60°C. The trimethylsilyl reagent was removed under a stream of nitrogen. The residue was redissolved in 50 µL isooctane, and 1–2 µL were analyzed by the gas-liquid chromatography as previously described (20). Quantitation of cholesterol and triol was accomplished by comparing their peak areas to that of the internal standard. The retention time of 5α-cholestane, cholesterol, and triol were 14.4, 18.34, and 21.87 min, respectively. For measuring the cellular total cholesterol content, the same procedure was followed but after saponification of the cell lipid with 2 M alcoholic KOH overnight at room temperature then extracting the unsaponifiable fraction, which was then silylated and injected into the gas chromatograph as described.

Conversion rate of linoleic acid to n-6 polyunsaturated acids. The cells were about 60% confluent when incubated in medium with or without triol for 24 h as described above. The medium was replaced with 2 mL of the same medium except that the fresh media contained 5% lipid-free BCS and 50 nmol/mL of [^{14}C]linoleic acid (100 nmol, 0.5 µCi/dish). After incubation at 37°C for 1, 6, or 12 h, the medium was removed. The cells were harvested, pelleted, and suspended in

methanol as described above. After sonication, two 100-μL aliquots were taken for protein determination (28), and another two 50-μL aliquots were used for measuring the total radioactivity. The total cellular uptake of linoleic acid as nmol/mg cell protein was calculated using the specific activity of linoleic acid (10,180 dpm/nmol). An additional 3.3 mL of methanol and 10 mL of $CHCl_3$ were added to the cell suspension, and lipids were extracted as described. Fatty acids from the extracted lipids were prepared by saponification with 2 M alcohol KOH and then methylation of free fatty acids (FFA) by 3 M methanolic HCl (Supelco) at 60°C for 1 h. The HCl/methanol was evaporated to dryness under N_2, and the methyl esters of linoleic, linolenic, arachidonic, and eicosapentaenoic acids as unlabeled carriers were added to each tube. The methyl esters were separated into dienes, trienes, tetraenes, and pentaenes, and the radioactivity in each band was measured as previously described (27). The percentage distribution of radioactivity in each band was determined, and the amounts (nmole) of labeled dienes, trienes, and tetraenes produced per mg cellular protein were calculated.

In order to measure the percentage distribution of the radioactivity between different lipid classes, the cell lipid was mixed with unlabeled carriers of standard PL and neutral lipids and separated into PL, FC, diglycerides, FFA, triglycerides (TG), and cholesteryl ester (CE) on silica gel G plates using the solvent system petroleum ether/diethyl ether/acetic acid (80:20:1, by vol). The bands were visualized by exposure to I_2 vapor, and the bands were each scraped from the plate and radioactivity was measured as described (27).

Statistical analysis. Results were expressed as means with their standard deviations. The statistical significance of difference between means was assessed by Student's *t*-test.

RESULTS

In this experiment we did not observe any significant change in the shape or viability of the cells when incubated with medium containing 10 μg triol/mL up to 24 h. The only difference was a slower growth rate of triol-treated cells as indicated by less cell protein as well as lower cell number/dish in the triol-treated cells (110 ± 5.4 μg protein/dish) than control cells (136 ± 4.1 μg protein/dish).

The fatty acid pattern of the cellular PL showed significant differences between the triol-treated and the control cells (Table 1). These differences were characterized by a substantial increase in linoleic acid (18:2n-6) and by decrease in arachidonic (20:4n-6) and docosatetraenoic (22:4n-6) acid percentages. Table 1 also shows that the ratios of total n-6 PUFA metabolites vs. total n-6 acids and 20:4n-6 vs. 18:2n-6 were significantly decreased in the triol-treated cells.

When the triol-treated and control cells were incubated with medium containing 50 μM [^{14}C]linoleic acid, the cellular uptake of this acid was significantly higher in the triol cells than in the control cells at 1-, 6-, and 12-h incubations (Fig. 1A). Table 2 shows that despite the increase of the pool size of linoleic acid in the triol-treated cells after 1- and 6-h incubations, a slight and nonsignificant increase was observed for its total n-6 PUFA metabolites (trienes + tetraenes) produced as nmol/mg cell protein in the triol-treated cells as compared to the control cells. This slight increase in total n-6 PUFA metabolites was the reflection of a significant increase in trienes produced as nmol/mg cell protein in the triol-treated cells. After 12-h incubation when the pool size of linoleic acid was increased to 318.9 nmol/mg cell protein in the triol-treated cells vs. 210.5 nmol/mg cell protein in the control cells, the n-6 PUFA metabolites (trienes + tetraenes), as well as tetraenes produced as nmol/mg cell protein, were increased in the triol cells (Table 2). The cellular protein contents of the control and triol-treated dishes were proportional to their cell counts in these dishes. In other words, the average protein content of the cells in the triol-treated dishes was about 19% less than the control dishes; the cell number in the triol-treated dishes was also about 20% less than the cell counts in the control dishes. Therefore, expressing our data of fatty acids or lipid contents per mg cellular protein or per cell number should give similar results.

When labeled dienes, trienes, and tetraenes produced by the triol or control cells, shown in Table 2 (as nmol/mg cell protein), were expressed as their relative percentages as shown in Figure 2, we found that the percentage of dienes was significantly increased while the percentages of tetraenes and total n-6 PUFA metabolites (trienes + tetraenes) were significantly decreased in the triol-treated cells. These changes are similar to those observed for the percentages of linoleic acid and its metabolites: 18:3n-6, 20:3n-6, 20:4n-6, and 22:4n-6 acids when the fatty acids of the cellular PL fraction of the triol and control cells were expressed as their relative percentages (Table 1).

[d]n-6 Metabolites are total n-6 acids other than 18:2n-6 acid.

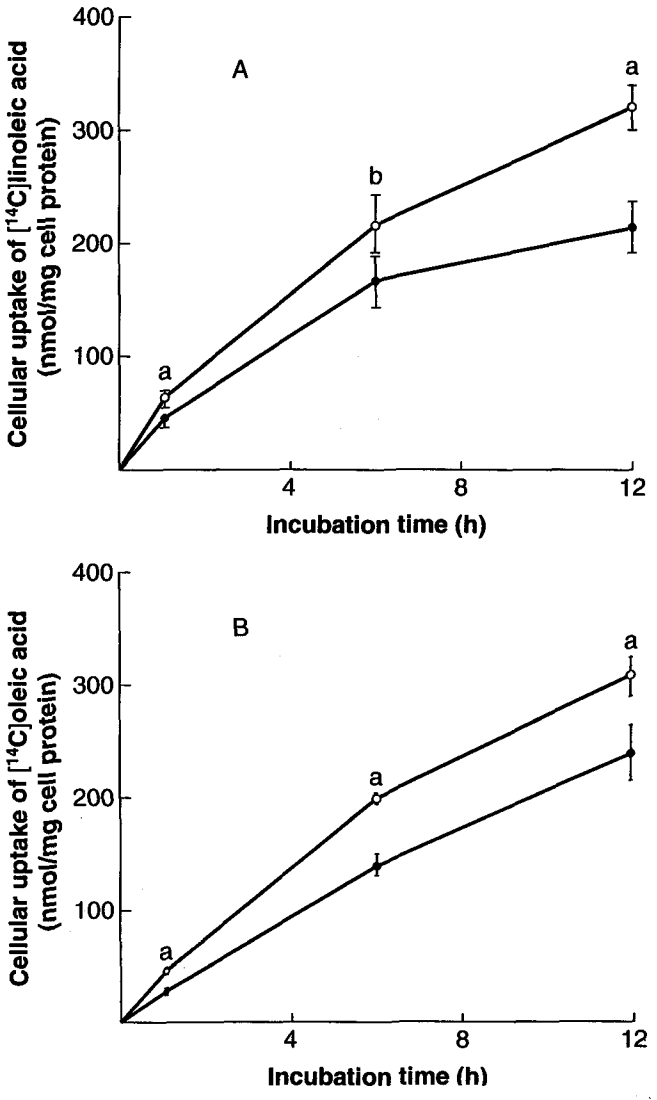

FIG. 1. A. Cellular linoleic acid uptake (as nmol/mg cell protein) by porcine kidney (LLC-PK) cells incubated in medium with (○) or without (●) cholestanetriol (10 μg/mL) for 24 h, then with medium containing 50 μM of [^{14}C]linoleic acid for 1, 6, and 12 h. a and b represent statistical differences at levels of $P < 0.001$ and $P < 0.02$, respectively, between control and triol cells. B. Cellular oleic acid uptake (as nmol/mg cell protein) by LLC-PK cells incubated in medium with (○) or without (●) cholestanetriol (10 μg/mL) for 24 h, then with medium containing 50 μM of [^{14}C]oleic acid for 1, 6, and 12 h. a Represents a statistical difference at a level of $P < 0.001$ as tested by Student's *t*-test.

Table 3 shows a significant increase in the cellular fatty acid concentration of palmitoleic (16:1n-7), stearic (18:0), and oleic (18:1n-9) acids (as μg/mg cell protein). The results in Table 3 also show significant increases in total n-6 acids, 18:2n-6, 20:3n-6, and 20:4n-6 concentrations, consistent with the results obtained in Table 2 when the triol and control cells were incubated with [^{14}C]linoleic acid for 12 h. A significant decrease of the ratios of total n-6 PUFA metabolites vs. total n-6 acids and of 20:4n-6 vs. 18:2n-6 also were observed. The cellular fatty acid contents in Table 3 also clarified that the increase of the trienes (as nmol/mg cell protein) observed in the [^{14}C]linoleic acid experiment (Table 2) was due to the accumulation of 20:3n-6 while 18:3n-6 was not increased from the levels of the control cells (Table 3).

Table 4 shows that the pool size of oleic acid in the triol-treated cells was significantly higher than in the control cells as a result of the increased uptake at 1-, 6-, and 12-h incubations (Fig. 1B). This increase in the pool size was accompanied by a significant increase of oleic acid (as nmol/mg cell protein) incorporated into both PL and TG of the triol-treated cells. No significant difference could be found between the number of nanomoles of oleic acid incorporated into FFA or CE of the triol-treated and control cells (Table 4). More than 85% of the total cellular oleic acid was incorporated into PL. The incorporation into TG did not exceed 10% of its pool size, indicating the selectivity of oleic acid esterification into PL.

Table 5 shows that when triol and control cells were incubated with [^{14}C]linoleic acid for 12 h, the pool size of the labeled fatty acids was significantly higher in the triol-treated cells. The labeled fatty acids incorporated into the PL and TG of the triol-treated cells also were significantly higher than in control cells and represented about 50 and 40% of the pool size of linoleic acid in both triol-treated and control cells, respectively. No significant difference was found between the number of nanomoles of labeled fatty acids incorporated into FFA or CE of triol and control cells (Table 5).

Since linoleic acid is metabolized to arachidonic acids in PK cells, we measured the numbers of nanomoles of dienes (18:2n-6) and tetraenes (20:4n-6 + 22:4n-6) incorporated into PL and TG per mg protein of the triol-treated and control cells. Table 6 shows that dienoic acids incorporated into either PL or TG were significantly higher in the triol-treated cells as compared to the control cells. Tetraenoic acids (mainly 20:4n-6) were slightly increased in the PL while significantly decreased in the TG of the triol-treated cells as compared to the control cells. These results agree with those previously reported (31) for arachidonic acid distribution under triol effect. In Table 5, the labeled fatty acids found in the FFA fraction in either triol or control cells did not exceed 0.5% of the pool size of linoleic acid. This indicates that the activation of linoleic acid to linoleoyl-CoA was not a rate-limiting step for linoleic acid conversion to arachidonic acid in either triol or control cells.

Our results in Table 7 show that triol decreased the levels of total as well as free cellular cholesterol (as μg/mg cell protein) in the triol-treated cells as compared to the control cells. It also shows that free triol was inserted into the cell membrane of the triol cells in a detectable level while it was absent from the control cells. Table 7 also shows that triol increased the cellular PL contents (as μg/mg cell protein).

DISCUSSION

The changes of the fatty acid percentage composition of the cellular PL in the triol-treated cells indicate that the conversion of linoleic acid to arachidonic acid was impaired in the

[a]Values are given as means ± standard deviation of eight incubations from two different experiments. Abbreviation as in Table 1.
[b]Porcine kidney (LLC-PK) cells were incubated in medium with (triol) or without (control) cholestanetriol (10 µg/mL) for 24 h, then with medium containing 50 µM [14C]linoleic acid for 1, 6, or 12 h.
[c]Statistical analysis was by Student's *t*-test.
[d]NS, not significant.

triol cells as evidenced by the decrease of the ratios total n-6 metabolites vs. total n-6 acids and 20:4n-6 vs. 18:2n-6 (32).

After 1- and 6-h incubations with [^{14}C]linoleic acid, despite the increase of linoleic acid pool size in the triol-treated cells, neither total n-6 metabolites nor arachidonic acid accumulation was increased while trienes did accumulate in the triol cells. The increased accumulation of labeled trienes in the triol-treated cells could be an indication of decreased Δ5 desaturase activity in the triol-treated cells. The increased accumulation of trienes in triol-treated cells was due to the accumulation of 20:3n-6 while 18:3n-6 was within the levels of the control cells. This rules out the possible inhibition of elongase enzyme by triol since no accumulation of 18:3n-6, the substrate for the elongase enzyme, was observed in the triol-treated cells. After 12-h incubation when the linoleic acid pool size in the triol-treated cells was increased 50%, dienes (18:2n-6) were increased 100%, trienes increased 65%, while arachidonic acid was increased only 18% as compared to the control cells.

Any change of arachidonic acid utilization for prostacyclin synthesis may alter its level under triol effect. We must mention here that LLC-PK cell line used in the present study lacks cyclooxygenase enzyme and does not produce prostaglandin. Triol also does not induce its effect through free radicals (33) which excludes any possible change of arachidonic acid due to oxidative alteration under triol effect.

Although linoleic acid uptake was increased in the triol-treated cells, the fatty acid percentage composition of cellular PL did not show any difference in the relative percentage of total n-6 acids between triol and control cells. Analysis of the fatty acids of total cellular lipids after 12-h incubation with 50 µM linoleic acid showed that the fatty acid concentrations (as µg/mg cell protein) of palmitoleic, stearic, and oleic acids were increased as well as total n-6 acids were increased in the triol cells. Indeed Peng *et al.* (34) found that triol was among the OS which enhanced the *de novo* synthesis of fatty acids by 42% in cultured cells. Palmitic acid (16:0) synthesized by the cells can be chain-elongated to stearic (18:0) then desaturased by Δ9 desaturase to oleic acid (18:1n-9).

The increased uptake of fatty acids by the triol-treated cells could be related to changes of the membrane-associated functions and properties (35). Proteins that have important cellular functions such as transporters, receptors, and enzymes are embedded in cholesterol–PL bilayer of the cell membrane. Any change of the lipid content of the bilayer may have a modulatory influence on the activities of these membrane proteins (36). The increase uptake of fatty acids might involve activation of an uptake mechanism caused by triol-induced changes in the plasma membrane (31).

The increased cellular uptake of oleic and linoleic acids in triol-treated cells affected their distributions between cellular lipids. In the present study, oleic acid incorporation was significantly increased into PL and TG of the triol-treated cells with a great selectivity of incorporation into PL, as previously observed by Seillan (31). Our results, however, are not in full agreement with those obtained by Seillan (31), who found that the percentage of oleic acid incorporated into PL was increased while in TG was decreased in the triol-treated cells. This discrepancy could be explained by the increased pool size of oleic acid in our study which makes oleic acid available for incorporation into both PL and TG fractions. In the study by Seillan (31), cellular uptake did not change; there-

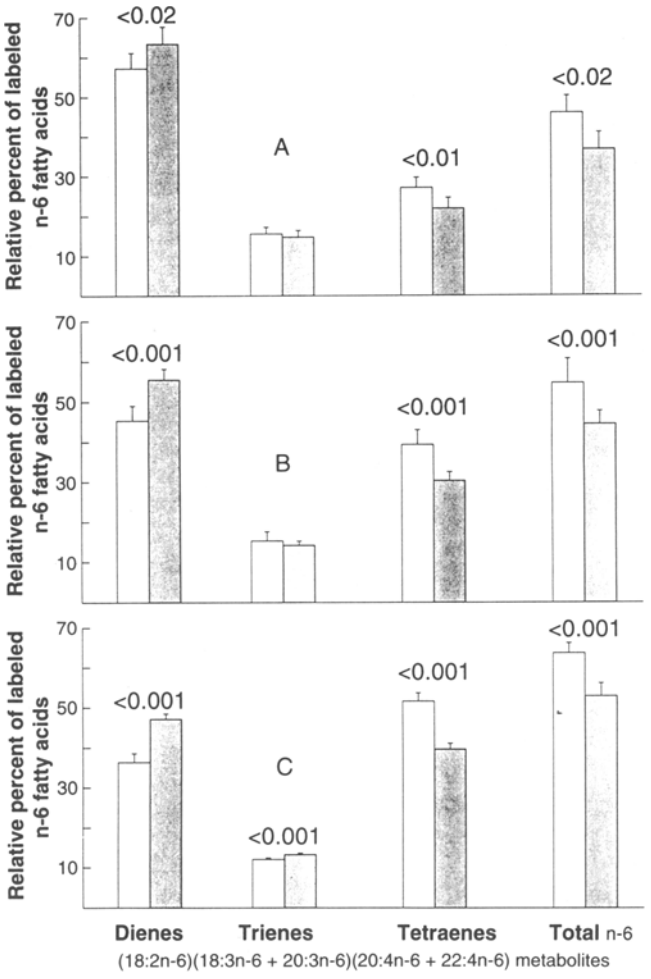

FIG. 2. Percent distribution of labeled dienes, trienes, and tetraenes and total n-6 metabolites (trienes + tetraenes) in porcine kidney cells incubated in medium with (■) or without (□) cholestanetriol (10 μg/mL) for 24 h, then with medium containing 5% lipid free bovine calf serum and 50 μM of [^{14}C]linoleic acid for one (A), six (B), or twelve (C) hours.

fore, oleic acid may be preferably incorporated into PL at the expense of oleic acid incorporation into TG. We used triol at concentration of 10 μg/mL medium while the maximum concentration Seillan (31) used was 4 μg/mL (31). When we used triol up to 5 μg/mL, we did not get any significant change in the cellular uptake of linoleic acid (data are not shown). This difference also may be attributed to the different sensitivity to triol between the artery cells used by Seillan (31) and the PK cells used in our study. It also indicates that triol is less cytotoxic to PK cells at the same level where it is highly toxic to the arterial cells. In our experiment we did not observe any significant change in the shape or viability of the cells when incubated with medium containing 10 μg triol/mL up to 24 h. The only difference was a slower growth rate of triol-treated cells as indicated by the less cell protein as well as cell number/dish in the triol cells than the control cells.

The decrease of total as well as FC in the triol-treated cells may have resulted from the inhibition of cholesterol synthesis in these cells (37). The decrease of the free cellular cholesterol and the increase of PL contents in the triol-treated

cells would result in a significant decrease in the cholesterol/PL ratio. The insertion of triol into the cellular membranes also can modify membrane fluidity (13) and consequently membrane-bound enzymes (10,11). OS have been found to strongly decrease the membrane fluidity of the cell membrane (38), as well as the internal cell membranes and lipid-containing organelles (13). A strong correlation also was found between their inhibitory effect on 3 hydroxy-3-methylglutaryl–CoA reductase and their decreasing effect on the membrane fluidity (39).

Cholesterol feeding which increases the level of oxysterols *in vivo* (19,20) has been shown to reduce the arachidonic acid percentage and the ratio 20:4n-6 vs. 18:2n-6 in plasma and liver lipids (40,41). Our results are in agreement with those reported by Kou *et al.* (42) who found that the percentage of linoleic acid was increased while arachidonic acid was decreased in the PL fractions of the platelets incubated with 25-hydroxycholesterol. If similar changes occur in aortic cells by triol or other oxysterols, one can speculate that our results may explain the elevation of linoleic acid and the decrease of arachidonic and docosatetraenoic (22:4n-6) acids percentages in the PL of the coronary arteries of cardiac sudden death patients as compared to the controls (43), considering that OS have been found in relatively higher levels in plasma (19,44) and aortic tissues (19) of atherosclerotic animals. These changes were related to the impaired metabolism or accumulation of linoleic acid in the coronary artery wall in cases of sudden cardiac death (43).

In conclusion, the present study showed that essential fatty acid metabolism is perturbed along with enhanced uptake of

[c]Not detectable.

linoleic acid in the triol cells. These changes disturbed the ratio between linoleic acid and its physiologically active metabolite arachidonic acid within the cellular membrane PL and affected their distribution between the cellular lipids.

Effects of Non-β-Oxidizable Sulfur-Substituted Fatty Acid Analogues on Synthesis and Secretion of Triacylglycerol and Cholesterol in Cultured Rat Hepatocytes

Jon Skorve[a,*], Arild C. Rustan[b] and Rolf K. Berge[a]

[a]Department of Clinical Biology, Division of Biochemistry, University of Bergen, Haukeland University Hospital, 5021 Bergen, Norway and [b]Department of Pharmacology, Institute of Pharmacy, University of Oslo, 0316 Oslo, Norway

ABSTRACT: The mechanisms behind the hypolipidemic effect of two sulfur-substituted fatty acid analogues, 3-thiadicarboxylic acid and tetradecylthioacetic acid, have been investigated in cultured hepatocytes. There was a dose-dependent reduction in incorporation of [^{3}H]water into triacylglycerol and diacylglycerol when tetradecylthioacetic acid was added to rat hepatocytes cultured in the presence of 200 μM oleic acid. Tetradecylthioacetic acid also increased the oxidation of [^{14}C]palmitic acid compared to oleic acid, inhibited the incorporation of radiolabeled precursors into diacylglycerol to a greater extent than into triacylglycerol, and reduced the secretion of triacylglycerol more than its synthesis. A stimulation, rather than a reduction, in glycerolipid synthesis and secretion by tetradecylthioacetic acid was observed when oleic acid was omitted from the culture medium. When 3-thiadicarboxylic acid was added to cultured hepatocytes, the effects on glycerolipid synthesis were generally similar to those observed with tetradecylthioacetic acid, but 3-thiadicarboxylic acid did not increase the oxidation of [^{14}C]palmitic acid. The two fatty acid analogues also had different effects on the synthesis and secretion of cholesterol and cholesteryl esters—3-thiadicarboxylic acid reduced the incorporation of [^{3}H]water into synthesized and secreted cholesterol and cholesteryl esters, whereas tetradecylthioacetic acid only reduced the secretion of cholesteryl esters without affecting its synthesis. It is concluded that tetradecylthioacetic acid increases the oxidation of fatty acids and reduces the synthesis and secretion of glycerolipids. 3-Thiadicarboxylic acid reduces the synthesis and secretion of both glycerolipids and cholesterol to approximately the same extent without a concomitant increase in the oxidation of fatty acids.
Lipids 30, 987–994 (1995).

Sulfur-substituted dicarboxylic and monocarboxylic fatty acid analogues can reduce the level of plasma triacylglycerol and cholesterol (1–3), but the mechanism is not fully understood. Feeding 3-thiadicarboxylic acid [HOOC-CH_2-S-$(CH_2)_{10}$-S-CH_2-COOH] to rats decreased plasma levels of free fatty acids, very low density lipoproteins triacylglycerol, low density lipoproteins triacylglycerol, and low density lipoprotein cholesterol levels. However, the composition of the various plasma lipoprotein fractions was essentially unchanged (4).

In the liver, 3-thiadicarboxylic acid increased the oxidation of of fatty acids while decreasing the level of triacylglycerol, and it also reduced the activities of several key enzymes in lipid metabolism, including phosphatidate phosphohydrolase and 3-hydroxy-3-methylglutaryl–CoA (HMG–CoA) reductase (3–5). 3-Thiadicarboxylic acid is also a potent peroxisome proliferator in rodents, increasing peroxisomal ß-oxidation up to tenfold (1).

The monocarboxylic acid, tetradecylthioacetic acid [CH_3-$(CH_2)_{13}$-S-CH_2-COOH] is structurally distinct from 3-thiadicarboxylic acid. This analogue has properties closely resembling normal fatty acids, except that it is unable to undergo β-oxidation (6). It is activated to its CoA-ester *in vitro* more readily than the dicarboxylic acid (7). 3-Thiadicarboxylic acid is far more polar than the monocarboxylic acid, and does not seem to be incorporated into glycerolipids. In contrast, tetradecylthioacetic acid is incorporated into triacylglycerols and phospholipids in rat liver (8), in isolated rat hepatocytes (9), and in hepatoma cells (10). In rat liver *in vivo*, most of the administered tetradecylthioacetic acid was found in the phospholipid fraction (11).

Despite structural differences, tetradecylthioacetic acid and 3-thiadicarboxylic acid have nearly the same hypolipidemic effects, but tetradecylthioacetic acid is less potent in decreasing the hepatic level of triacylglycerol and in inducing peroxisomal proliferation (1,2). The mode of action of these fatty acid analogues *in vivo* is presumed to involve decreased availability of fatty acids due to increased β-oxidation, as well as changes in the activities of key enzymes involved in triacylglycerol and cholesterol biosynthesis (4,5).

Primary cultures of rat hepatocytes are a well-characterized system for studying synthesis and secretion of lipoproteins and bile acids (12–14). We have, therefore, utilized these cells to study the *in vitro* effects of the non-β-oxidizable sulfur-substituted fatty acid analogues 3-thiadicarboxylic acid and tetradecylthioacetic acid on lipid metabolism. We have examined the incorporation of various labeled precursors into

synthesized and secreted lipids, as well as the oxidation of fatty acids in cultured hepatocytes.

MATERIALS AND METHODS

Chemicals. Arginine-free Dulbecco's modified Eagle's medium (DME) and gentamicin (10 mg/mL) were obtained from Flow Lab. (Irvine, Ayrshire, United Kingdom). The medium was supplemented with ornithine (0.5 mM), HEPES (20 mM), and $NaHCO_3$ (24 mM) from Sigma Chemical Co. (St. Louis, MO). [1,2,3-^{3}H]glycerol (200 Ci/mol), [^{3}H]water (18 Ci/mol), [1-^{14}C]palmitic acid (56 Ci/mol), and [1-^{14}C]oleic acid (58 Ci/mol) were obtained from New England Nuclear (Dreieich, Germany). Collagenase (type 1), bovine insulin, oleic acid, and bovine serum albumin (essentially fatty acid-free) were delivered by Sigma. Ultroser G (a serum substitute) was delivered by Gibco, Life Technologies Inc. (Gaithersburg, MD). Tissue culture dishes/flasks were supplied by Costar (Cambridge, MA). Thin-layer chromatography (TLC) plates (Silicagel F 1500) were purchased from Schleicher & Schuell (Dassel, Germany). All other chemicals and solvents were high-purity commercial materials.

Sulfur-substituted fatty acid analogus (3-thia fatty acids). Stock solutions (10 mM) of 3-thiadicarboxylic acid and tetradecylthioacetic acid were prepared as described earlier (15,16). The 3-thia fatty acids were dissolved in 0.1 mM NaOH at 50–60°C before addition to the culture medium.

Preparation of cultured hepatocytes. Hepatocytes were prepared according to Seglen (17), with some modifications (14). In short, the rats were anesthetized with barbiturate, and hepatocytes were isolated by collagenase perfusion, washed and plated in DME containing 20 mM HEPES, Ultroser G (2%), and gentamicin (50 μg/mL) at a density of 3×10^6 cells/dish or culture flask (1×10^6/mL). The culture medium was replaced after 6–7 h (2 mL/dish, identical medium as before). The cells were incubated at 37°C in air/CO_2 (19:1).

Measurement of cell-associated and secreted lipids. After overnight incubation (18 h), the culture medium was removed and the cells were rinsed twice with serum-free DME medium to remove unattached and damaged cells. The cells were then changed to DME containing glucose (25 mM), HEPES (20 mM), gentamicin (50 μg/mL), and the various isotopes and compounds indicated later and in legends to the figures and in the tables.

Incorporation of tritiated water. Two mL incubation medium with [^{3}H]water (3 mCi/mL), with or without oleic acid/bovine serum albumin (200 μM/80 μM) was added to hepatocytes cultured in plastic flasks (25 cm^2). Cells without oleic acid were incubated with 80 μM bovine serum albumin alone. The respective thia-fatty acids (from heated stock solutions) were then added to the culture medium, and the cells were incubated for periods up to 9 h.

Incorporation of glycerol. Two mL incubation medium (as described previously), containing [1,2,3-^{3}H]glycerol (5 μCi/ml, 25 μM), with or without oleic acid/bovine serum albumin (200 μM/80 μM), and the respective thia fatty acids were added to the cells. The cells were incubated for periods up to 1 h. In pulse-chase experiments, the cells were preincubated for 1 h in medium with oleic acid and 5 μCi/mL [^{3}H]glycerol (25 μM), as described previously. The medium was then changed and the cells chased for 2 h with the same incubation medium, which now contained 1 mM unlabelled glycerol and the respective thia fatty acids.

Harvesting of cells. The culture dishes were placed on ice after the incubation times indicated. The medium was collected, centrifuged at 2000 rpm for 5 min, and a cell-free aliquot was further treated as explained later. The cells were scraped off the culture dish with a rubber policeman into 2 mL phosphate buffered saline (NaCl/P_i), pH 7.4, containing NaCl (137 mM), KCl (2.7 mM), Na_2HPO_4 (8 mM) and KH_2PO_4 (1.5 mM). The culture dishes were washed once with 2 mL NaCl/P_i. The cell suspensions were centrifuged, and the cells were resuspended in 0.5 or 1.0 mL distilled water and frozen (–20°C). The protein content of each culture dish was determined using bovine serum albumin as standard (18).

Lipid extraction and TLC. The cell suspension was mixed with 20 vol of chloroform/methanol (2:1, vol/vol) (19), 4 vol of NaCl/P_i, pH 2.0, were added and the mixture was allowed to separate into two phases. The organic phase was dried under a stream of nitrogen at 45°C. Medium (1.0 mL) devoid of cellular debris was added to four volumes of chloroform/methanol (2:1, vol/vol) and 2% serum as lipid carrier. The water phase of the medium extract was reextracted once with four volumes of chloroform/methanol (2:1, vol/vol), and the combined organic phases were further treated in the same way as for the cells.

The residual lipid extract was redissolved in 200 μL hexane and separated by TLC using hexane/diethyl ether/acetic acid (80:20:1, by vol) as developing solvent. In other experiments, where it was important to separate diacylglycerol and unesterified cholesterol, hexane/diethyl ether/acetic acid (65:35:1, by vol) followed by hexane as a second developing solvent was used. The TLC foils were cut into scintillation vials and counted in a liquid scintillation spectrometer.

Fatty acid oxidation. Measurement of oxidation of palmitic acid to acid-soluble products (as a determination of the rate of β-oxidation) was performed as described later. Two mL DME medium, containing HEPES (20 mM), [1-^{14}C]palmitic acid (0.2–0.5 μCi/mL, 200 μM), and 200 μM oleic acid or 200 μM tetradecylthioacetic acid was added to cultured hepatocytes. Some cultures also contained 500 μM L-carnitine hydrochloride. The cells were incubated for 1 or 4 h; the medium was collected and centrifuged at 2000 rpm for 5 min. An aliquot (250 μL) was added to 100 μL 6% bovine serum albumin and precipitated with 1.0 mL ice-cold 1 M $HClO_4$. The mixture was centrifuged at 3500 rpm for 10 min, and samples of 500 μL of the supernatants were counted by liquid scintillation.

Statistical analysis. Data in figures are presented as mean ± SD of at least three culture dishes/flasks of hepatocytes, representative of two separate experiments. Statistical analysis was performed on data from three independent experiments

TABLE 1
Effects of 3-Thiadicarboxylic Acid and Tetradecylthioacetic Acid on Incorporation of [^{3}H]Water into Synthesized Lipids by Cultured Rat Hepatocytes[a]

Lipid classes	3-Thiadicarboxylic acid (50 μM)	Tetradecylthioacetic acid (50 μM)
	(% of control)	
Triacylglycerol	76 ± 5[b]	71 ± 7[b]
Diacylglycerol	71 ± 3[b]	44 ± 15[b]
Phospholipids	75 ± 11	83 ± 12
Free fatty acids	83 ± 15	87 ± 8
Cholesterol	60 ± 3[b]	76 ± 11[b]
Cholesteryl ester	52 ± 6[b]	100 ± 6

[a]The cells were incubated for 9 h in the presence of 3 mCi [^{3}H]water/mL, 80 μM bovine serum albumin, and 200 μM oleic acid. Incorporation of radioactivity was determined as described in the Materials and Methods section. Control values from cells incubated with 200 μM oleic acid (cpm/mg cell protein): triacylglycerol, 30700 ± 5200; diacylglycerol, 3350 ± 240; phospholipids, 7300 ± 1550; free fatty acids, 4900 ± 750; cholesterol, 3300 ± 30; and cholesteryl ester, 1110 ± 200. Data represents means ± SD from three independent experiments.

[b]$P < 0.05$ for difference between control cells and cells treated with fatty acid analogues.

when available (Tables 1 and 2). Differences were tested with the Mann-Whitney nonparametric test at 95% confidence interval. The counting efficiency for ^{3}H and ^{14}C was 65 and 92%, respectively, calculated by means of external standards, and quenching was similar in all experiments.

RESULTS

Incorporation of [^{3}H]water into synthesized and secreted lipids. The incorporation of [^{3}H]water into synthesized triacylglycerol, cholesterol, and cholesteryl ester was decreased after nine hours incubation with increasing concentrations of 3-thiadicarboxylic acid (Fig. 1). The strongest inhibitory effect of 3-thiadicarboxylic acid was on cholesterol and cholesteryl ester formation, with 40 and 48% (n = 3, $P < 0.05$) reduction, respectively, at 50 μM of the 3-thia fatty acid. 50 μM tetradecylthioacetic acid reduced [^{3}H]water incorporation into triacylglycerol and cholesterol with 30 and 24% (n = 3, $P < 0.05$), respectively, but no effect was observed on cholesteryl ester formation (Fig. 1, Table 1).

The incorporation of [^{3}H]water into synthesized diacylglycerol also was inhibited by the 3-thia fatty acids. The incorporation was reduced by 55% (n = 3, $P < 0.05$) by 50 μM tetradecylthioacetic acid and by 30% (n = 3, $P < 0.05$) by 50 μM 3-thiadicarboxylic acid compared to the control (Table 1). No inhibition of incorporation of [^{3}H]water into cell-associated monoacylglycerol was found (data not shown).

Increasing concentrations of both fatty acid analogues decreased incorporation of [^{3}H]water into secreted triacylglycerol and cholesteryl ester. 3-Thiadicarboxylic acid also reduced the incorporation into secreted unesterified cholesterol, an effect that was observed only at the highest concentration of tetradecylthioacetic acid examined (Fig. 1).

Incorporation of [^{3}H]glycerol into synthesized and secreted lipids. Tetradecylthioacetic acid (200 μM) and 3-thiadicarboxylic acid reduced the incorporation of tritium-labeled glycerol into cellular diacylglycerol after 1 h of incubation by 35 and 25% (n = 3, $P < 0.05$), respectively (Table 2). The incorporation of [^{3}H]glycerol into synthesized triacylglycerol was only marginally affected in the presence of tetradecylthioacetic acid as compared to control cells (Fig. 2A, Table 2).

In contrast, the incorporation of labeled glycerol into secreted triacylglycerol was significantly reduced by both 3-thia fatty acids (Fig. 2B). Tetradecylthioacetic acid (200 μm) decreased incorporation into secreted triacylglycerol by 50% (n = 3, $P < 0.05$), although 200 μM 3-thiadicarboxylic acid reduced this incorporation only with 37% (n = 3, $P < 0.05$) relative to control cells (Table 2). However, when the cells were labelled with [^{3}H]glycerol for one hour and then chased with unlabelled glycerol for two hours, the 3-thia fatty acids did not reduce the secretion of labelled triacylglycerol compared to control cells (Fig. 2C).

TABLE 2
Effects of 3-Thiadicarboxylic Acid and Tetradecylthioacetic Acid on Incorporation of [^{3}H]Glycerol into Synthesized and Secreted Lipids by Cultured Rat Hepatocytes[a]

Compounds added	Phospholipids synthesized	Diacylglycerol synthesized	Triacylglycerol	
			Synthesized	Secreted
	(% of control)

[a]The cells were incubated for 1 h in the presence of 5 μCi [^{3}H]glycerol/.mL, 80 μM bovine serum albumin, and 200 μM oleic acid. Control values from cells incubated with 200 μM oleic acid (cpm/mg cell protein): phospholipids, 34300 ± 5700; diacylglycerol, 3300 ± 280; triacylglycerol, 36200 ± 4900 and 3300 ± 420 for synthesized and secreted, respectively. Data represents means ± SD from three independent experiments.

[b]$P < 0.05$ for difference between control cells and cells treated with fatty acid analogues.

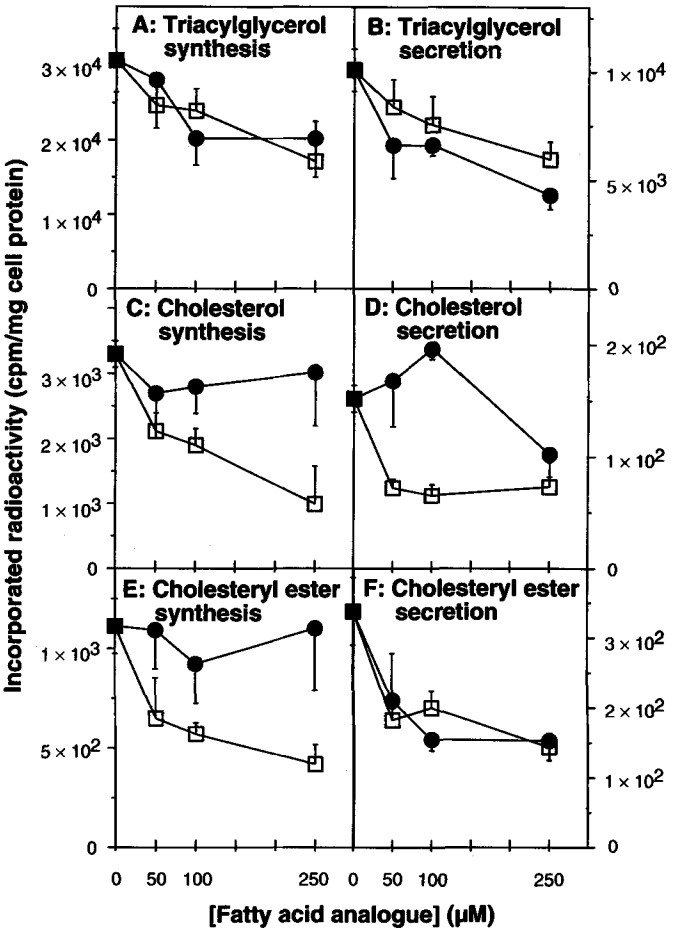

FIG. 1. Dose-dependent effects of 3-thiadicarboxylic acid (□) and tetradecylthioacetic acid (●) on incorporation of [^{3}H]water into synthesized (cell associated + secreted) and secreted lipids by cultured rat hepatocytes. A, Triacylglycerol synthesis; B, triacylglycerol secretion; C, cholesterol synthesis; D, cholesterol secretion; E, cholesteryl ester synthesis; and F, cholesteryl ester secretion. The cells were incubated for nine hours in the presence of 3 mCi [^{3}H]water/mL, 200 μM oleic acid/80 μM bovine serum albumin, and various concentrations of 3-thia fatty acid analogues. Data represent means ± SD for triplicate culture dishes.

Incorporation of labeled water and glycerol into synthesized and secreted lipids in the absence of oleic acid. In the absence of oleic acid, the incorporation of [^{3}H]water into synthesized glycerolipids was only marginally affected (Table 3). The same was observed for synthesized cholesterol and cholesteryl esters (data not shown). Thus, the inhibition of incorporation of [^{3}H]water into synthesized lipids by the sulfur-substituted fatty acids was most pronounced when oleic acid was added to the culture medium (Fig. 1, Table 3). It is also worth noting that, in the absence of oleic acid, the 3-thia fatty acids increased the incorporation of [^{3}H]water into secreted triacylglycerol and phospholipids when compared to no addition (Table 3).

Oxidation of [^{14}C]palmitic acid. The oxidation of [^{14}C]palmitic acid to acid-soluble products was increased nearly fivefold in cultured hepatocytes with increasing concentrations of tetradecylthioacetic acid in the presence of 200 μM oleic acid (Fig. 3). Tetradecylthioacetic acid increased the oxidation of [^{14}C]palmitic acid significantly more than oleic acid when these fatty acids were compared at equal concentrations (Fig. 4). 3-Thiadicarboxylic acid stimulated the fatty acid oxidation only slightly (Fig. 3). The rate of fatty acid oxidation was influenced by the addition of L-carnitine to the hepatocytes, but the relative stimulation by tetradecylthioacetic acid was similar irrespective of the addition of L-carnitine. None of the 3-thia fatty acids increased the peroxisomal fatty acyl–CoA oxidase activity when hepatocytes were incubated for up to 12 h (data not shown).

DISCUSSION

The hypolipidemic effects of non-β-oxidizable sulfur-substituted fatty acid analogues in rats *in vivo* are well documented (1–4). In this study we have demonstrated that these analogues also promoted lower synthesis and secretion of lipids in cultured rat hepatocytes (Fig. 1, Table 1). The two analogues had similar effects on the metabolism of triacylglycerol and phospholipids, although the metabolism of cholesterol was affected differently.

Using different radiolabeled precursors, the two 3-thia fatty acids showed variable effects on the synthesis of triacylglycerol and phospholipids (Tables 1 and 2). In hepatocytes labeled with [^{3}H]water, the synthesis and secretion of triacylglycerol were reduced to a similar extent (Fig. 1), and in experiments with [^{3}H]glycerol only secretion of triacylglycerol was significantly reduced (Fig. 2). It is possible that the different time of incubation, nine hours in experiments with [^{3}H]water and one hour in experiments with [^{3}H]glycerol, could be responsible for this discrepancy. In experiments where hepatocytes have been incubated with radiolabeled fatty acids for up to four hours, reduced secretion of triacylglycerol has been found without any significant effect on its synthesis (6,11).

It is noteworthy that the incorporation of labeled precursors into synthesized diacylglycerol was reduced to a greater extent than the incorporation into triacylglycerol and phospholipids, even in the short-term experiment with [^{3}H]glycerol (Tables 1 and 2). As the the sulfur-substituted fatty acids had only small effects on incorporation of [^{3}H]water into cellular monoacylglycerols (data not shown), these data suggest that 3-thia fatty acids decrease triacylglycerol synthesis by affecting some steps just prior to the formation of diacylglycerol. Reduced activity of phosphatidate phosphohydrolase has been shown to correlate with diminished triacylglycerol synthesis in some studies (20–22), and reduced triacylglycerol levels and phosphatidate phosphohydrolase activity previously have been found in livers from rats fed 3-thia fatty acids (3).

The effects of the fatty acid analogues have been studied in the presence of 200 μM oleic acid in the medium. It is well established that addition of up to 1 mM oleic acid to cultured hepatocytes stimulates synthesis and secretion of triacylglycerol, but the secretion of total apoproteinB is not stimulated

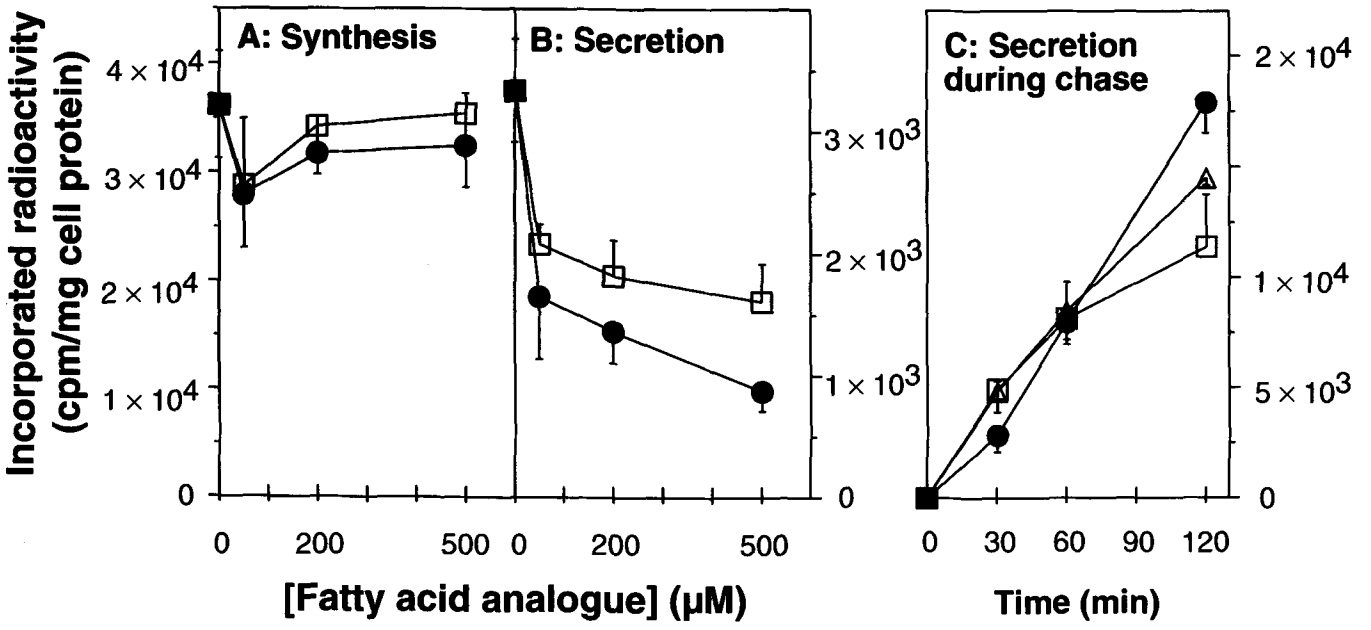

FIG. 2. Dose-dependent effects of 3-thiadicarboxylic acid (□) and tetradecylthioacetic acid (●) on incorporation of [^{3}H]glycerol into synthesized and secreted triacylglycerol by cultured rat hepatocytes. A, Triacylglycerol synthesis; B, triacylglycerol secretion; C, triacylglycerol secretion when hepatocytes were chased with 1 mM unlabelled glycerol. (△) Control cells. The cells were incubated for one hour in the presence of of 5 μCi [^{3}H]glycerol/mL (25 μM), 200 μM oleic acid/80 μM bovine serum albumin, and various concentrations of 3-thia fatty acid analogues. In C, 200 μM of 3-thia fatty acids were added. Data represent means ± SD for triplicate culture dishes.

TABLE 3
Incorporation of [^{3}H]Water into Synthesized and Secreted Glycerolipids with Different Combinations of Fatty Acids Added to Cultured Rat Hepatocytes[a]

Compounds added	Phospholipids		Triacylglycerol		Diacylglycerol
	Synthesized	Secreted	Synthesized	Secreted	Synthesized
			(% of control)		
Oleic acid	82 ± 19	164 ± 69	121 ± 16	185 ± 17	119 ± 7
3-Thiadicarboxylic acid	86 ± 18	425 ± 123	108 ±14	193 ± 35	95 ± 18
3-Thiadicarboxylic acid + oleic acid	43 ± 16	167 ± 57	67 ± 21	109 ± 14	52 ± 25
Tetradecylthioacetic acid	75 ± 8	457 ± 64	112 ± 15	155 ± 29	87 ± 10
Tetradecylthioacetic acid + oleic acid	53 ± 10	141 ± 75	80 ± 20	79 ± 11	46 ± 12

[a]The cells were incubated for 9 h in the presence of 3 mCI [^{3}H]water/mL and 80 μM bovine serum albumin. The various fatty acids were present in the following concentrations: oleic acid, 200 μM; 3-thiadicarboxylic acid, 250 μM; and tetradecylthioacetic acid, 250 μM. Incorporation of radioactivity was determined as described in the Materials and Methods section. Control values from cells incubated with 80 μM bovine serum albumin (cpm/mg cell protein): phospholipids, 8900 ± 1600, and 84 ± 35 for synthesized and secreted, respectively; triacylglycerol, 25300 ± 4500 and 5450 ± 1050 for synthesized and secreted, respectively; diacylglycerol, 2810 ± 640. Data represents means ± SD for triplicate culture flasks.

(23–27). The data in Table 3 suggest that the effects of 3-thia fatty acids on the lipid metabolism in hepatocytes are dependent on the presence of oleic acid in the medium. When hepatocytes were cultured in the absence of oleic acid, the fatty acid analogues rather stimulated the incorporation of [^{3}H]water into synthesized and secreted triacylglycerol (Table 3), mimicking the effect of oleic acid. It is possible that 3-thia fatty acids may have dual effects dependent on the actual fluxes of lipid metabolites. Without oleic acid in the medium, the flux of fatty acids into glycerolipids may be low. In this situation the fatty acid analogues act in the same way as ordinary fatty acids, increasing triacylglycerol synthesis and secretion. When the flux of fatty acids is increased due to the addition of oleic acid, the analogues may act by regulating rate-limiting enzymes. We have observed that the activity of lipogenic enzymes is decreased in the liver of rats treated with 3-thia fatty acids, and that this decrease is more pronounced when the rate of lipogenesis is high (4,28).

The effects of 3-thiadicarboxylic acid and tetradecyl-

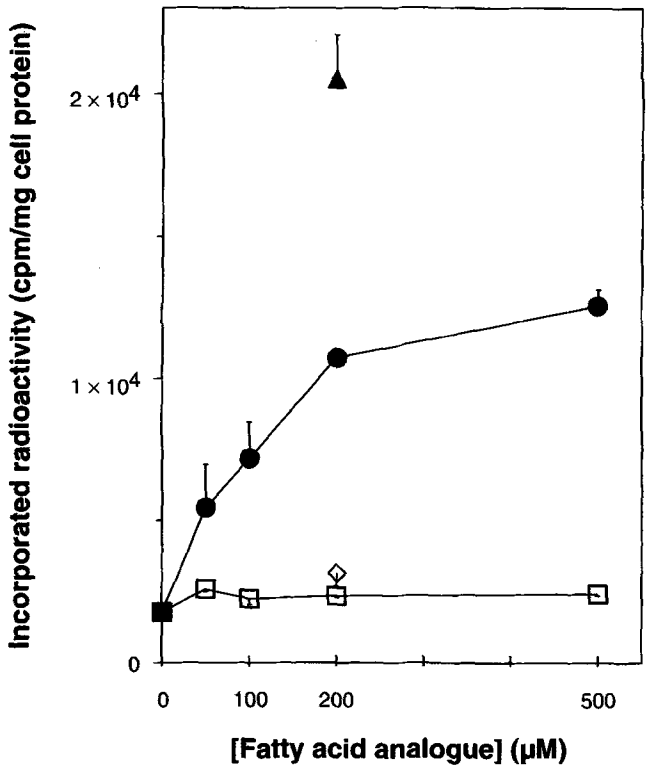

FIG. 3. Effects of fatty acid analogues on the oxidation of [^{14}C]palmitic acid to acid-soluble products by cultured rat hepatocytes. The cells were incubated for one hour with 0.2 μCi [^{14}C]palmitic acid, 200 μM, and 200 μM oleic acid in addition to tetradecylthioacetic acid (●); tetradecylthioacetic acid and 500 μM L-carnitine (▲); 3-thiadicarboxylic acid (□); 3-thiadicarboxylic acid and 500 μM L-carnitine (◇). Data represent means ± SD for triplicate culture dishes.

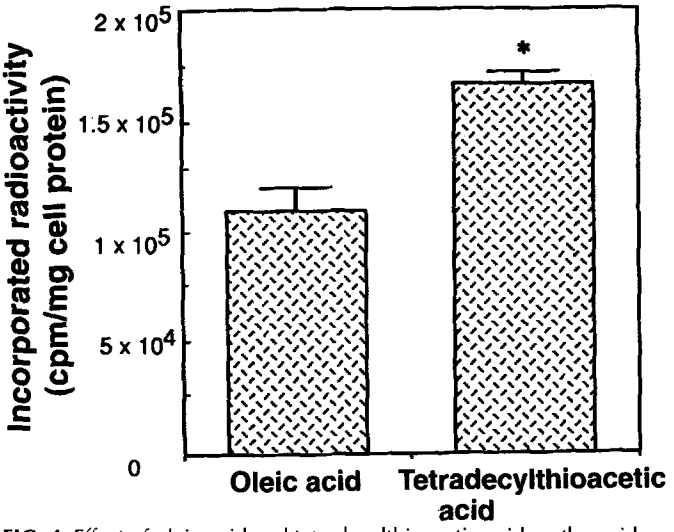

FIG. 4. Effect of oleic acid and tetradecylthioacetic acid on the oxidation of [^{14}C]palmitic acid to acid-soluble products by rat hepatocytes. The cells were incubated for four hours with 0.5 μCi [^{14}C]palmitic acid (200 μM) and L-carnitine (500 μM) in addition to either oleic acid (200 μM) or tetradecylthioacetic acid (200 μM). Data represent means ± SD of three independent experiments.*$P < 0.05$ for difference between cells incubated with oleic acid and tetradecylthioacetic acid.

thioacetic acid on cultured hepatocytes were similar in many aspects. However, some noteworthy exceptions with regard to β-oxidation of fatty acids and cholesterol metabolism merit further considerations.

Adding tetradecylthioacetic acid to cultured hepatocytes increased the oxidation of [^{14}C]palmitic acid compared to the addition of oleic acid (Fig. 4). This difference may be partly due to the non-β-oxidizability of tetradecylthioacetic acid (8–10), allowing it to compete with the available free fatty acids for esterification reactions (10). Compared to the addition of [^{14}C]palmitic acid and oleic acid, which both may be β-oxidized, relatively more [^{14}C]palmitic acid will be β-oxidized when tetradecylthioacetic acid and [^{14}C]palmitic acid are added together. Due to competition between tetradecylthioacetic acid and ordinary fatty acids, it is conceivable that when hepatocytes are cultured in the presence of this 3-thia fatty acid, ordinary fatty acids will be diverted into β-oxidation instead of esterification, especially into phospholipids (10). It also has been found that tetradecylthioacetic acid feeding rapidly decreases the level of malonyl–CoA in rat liver (29), which may further contribute to increased β-oxidation through the well-known regulation of carnitine palmitoyltransferase by malonyl–CoA (30,31). Previously, we have found an increased capacity for mitochondrial β-oxidation in liver of rats fed tetradecylthioacetic acid (2,3,5). The availability of ordinary fatty acids may therefore limit the synthesis of triacylglycerol in the hepatocytes.

The reduced output of triacylglycerol by tetradecylthioacetic acid may be related to the stimulation of fatty acid oxidation. It has been shown previously that inhibitors of fatty acid synthesis increased fatty acid oxidation and ketogenesis, accompanied by a decreased secretion of triacylglycerol (32,33). Recently, it has been found that the secretion of triacylglycerol from hepatocytes is less affected by tetradecylthioacetic acid when fatty acid oxidation is inhibited (6). 3-Thiadicarboxylic acid, however, did not significantly increase the oxidation of [^{14}C]palmitic acid when incubated with cultured hepatocytes (Fig. 4), in contrast to what has been observed in rat liver (4). Nevertheless, the secretion of triacylglycerol was reduced (Fig. 1), even after one hour of incubation (Fig. 2). This points to some possible differences in their mechanism of action.

The rate of secretion of triacylglycerol also was generally reduced to a greater extent with tetradecylthioacetic acid than with 3-thiadicarboxylic acid. This is seen in hepatocytes labelled with [^{3}H]water, with (Fig.1) and without oleic acid in the medium (Table 3), and also was observed with [^{3}H]glycerol (Fig. 2B) as radioactive precursor. When pulse-chase experiments were performed, none of the 3-thia fatty acids reduced the secretion of triacylglycerol (Fig. 2C), indicating that the fatty acid analogues do not affect the secretion process *per se*, but rather some step(s) prior to the complete assembly of lipoprotein particles.

Cholesterol synthesis and esterification were clearly inhibited by 3-thiadicarboxylic acid, whereas tetradecylthioacetic acid marginally affected the incorporation of [^{3}H]water into

cholesterol and cholesteryl ester (Fig. 1, Table 1). In rat liver *in vivo*, it has been observed that both fatty acid analogues inhibited the activity of the rate-limiting enzyme in the biosynthesis cholesterol, HMG–CoA reductase, although not to the same extent (4,11). It is thus likely that the inhibition of cholesterogenesis by 3-thiadicarboxylic acid is primarily due to reduced HMG–CoA reductase activity. This inhibition also may account for the cholesterol-lowering effect of the fatty acid analogue, as the incorporation of [^{3}H]water into secreted cholesterol and cholesteryl ester was reduced to the same extent as the synthesis (Fig. 1). The reason why tetradecylthioacetic acid inhibited HMG–CoA reductase *in vivo* (11), while no inhibition of cholesterogenesis was seen *in vitro*, is not obvious. In contrast to 3-thiadicarboxylic acid, this analogue decreased the secretion of cholesteryl ester without a concomitant reduction in its synthesis (Fig. 1).

The intracellular concentrations of 3-thia fatty acids in rat liver *in vivo* and in hepatocytes cultured *in vitro* are not known, but different effects of these fatty acid analogues *in vitro* and *in vivo* might possibly be related to differences in intracellular concentrations in these two situations. Apart from these considerations, it is noteworthy that even if the biological effects of the 3-thia fatty acids are very similar *in vivo*, the results obtained with regard to β-oxidation, triacylglycerol, and cholesterol metabolism when these fatty acids are added to hepatocytes *in vitro* seem to indicate that 3-thiadicarboxylic acid and tetradecylthioacetic acid may have different mechanisms of action.

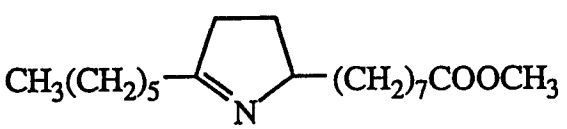
Enzymatic Hydrolysis of Long-Chain *N*-Heterocyclic Fatty Esters



Marcel S.F. Lie Ken Jie* and M.S.K. Syed-Rahmatullah

Department of Chemistry, The University of Hong Kong, Hong Kong

ABSTRACT: Incubation of a 1-pyrroline ester [viz. methyl 8-(5-hexyl-1-pyrroline-2-yl)octanoate, **1**] with bakers' yeast *(Saccharomyces cerevisiae)* gave the corresponding free fatty acid (**1a**, 52%). The C=N bond of the 1-pyrroline was not reduced by the yeast. Complete hydrolysis of compound **1** was successful using lipase of *Candida cylindracea* (CCL) or Lipolase *(Rhizomucor miehei)* under stirred or ultrasound condition. Fatty esters containing a pyrrolidine [viz. methyl 8-(*cis/trans*-5-hexyl-pyrrolidine-2-)octanoate, **2**] or *N*-methyl pyrrolidine [viz. methyl 8-(*cis*-5-hexyl-*N*-methyl-pyrrolidine-2-)octanoate, **3**] system in the alkyl chain were not hydrolyzed by either CCL or Lipolase, unless conducted in an ultrasonic bath. The hydrolytic activities of the enzymes appeared to be strongly affected by the stereochemistry of the *N*-heterocyclic ring system. Chemical hydrolysis of compounds **1–3** gave the corresponding fatty acid *N*-HCl salts.

Lipids 30, 995–999 (1995).

2,5-Dialkyl and 2,5-dialkenyl substituted 1-pyrrolines and pyrrolidines have been found to occur as venomous constituents of the fire ants *Solenopsis* and *Monomorium* species (1–3). These *N*-heterocyclic compounds possess antibacterial, antifungal, phytotoxic, insecticidal, haemolytic, and necrotoxic properties (4–8). However, long-chain fatty acids containing *N*-heterocyclic rings have not been found in nature. We have reported the synthesis of a novel 1-pyrroline fatty acid ester isomer, viz. methyl 8-(5-hexyl-1-pyrroline-2-yl)octanoate (**1**) from methyl *iso*-ricinoleate (9). This *N*-heterocyclic fatty ester and its derivatives are currently being investigated for their antifungal and antimicrobial properties for which the free acids are also required (Scheme 1).

Abbreviations: CCL, *Candida cylindracea*; HR–MS, high-resolution mass spectra; NMR, nuclear magnetic resonance spectroscopy.

Fatty esters containing the 1-pyrroline nucleus are readily transformed to the saturated *cis*- and *trans*-pyrrolidine (**2**) isomers by reduction of the C=N bond with sodium borohydride (9). *N*-Methylation and subsequent sodium borohydride reduction of compound **1** yields a mixture of *cis*- and *trans*-*N*-methyl pyrrolidine esters from which the *cis*-isomer (**3**) is separated by silica chromatography (10).

Bakers' yeast *(Saccharomyces cerevisiae)* is widely used for reducing carbonyl functions where the oxidoreductase of the yeast is activated. This yeast is also used for the hydrolysis of esters due to the presence of ester hydrolase (11). In most enzymatic reactions, mild and neutral pH media are employed. We have chosen bakers' yeast to investigate the hydrolyzing activity and the effect of the oxidoreductase toward the C=N bond of the 1-pyrroline ring system.

The lipases from *Candida cylindracea* (CCL) yeast and *Rhizomucor miehei* fungus (Lipolase™) show optimum hydrolytic activities when experiments are conducted at pH 7.0 in potassium phosphate buffer (12–14). Lipolase is a thermostable lipase and tolerates temperatures up to 60°C, while the optimum temperature in the case of CCL is 37–40°C.

In this paper we compare the results of the hydrolysis of *N*-heterocyclic fatty esters using bakers' yeast and various lipases in neutral media with those obtained by KOH hydrolysis followed by acidification with HCl. The physical properties of the free fatty acids are also compared to those of the corresponding *N*-HCl-salts obtained by chemical hydrolysis.

MATERIALS AND METHODS

The *N*-heterocyclic fatty esters, viz. methyl 8-(5-hexyl-1-pyrroline-2-yl)octanoate (**1**), methyl 8-(*cis/trans*-5-hexyl-pyrrolidine-2-)octanoate (**2**), and methyl 8-(*cis*-5-hexyl-*N*-methyl-pyrrolidine-2-)octanoate (**3**) were synthesized from methyl *iso*-ricinoleate according to procedures described elsewhere (9,10). Methyl 8-(5-hexyl-1*H*-pyrrole-2-)octanoate (**4**) was obtained by cyclodehydration reaction of methyl 9,12-dioxostearate as described elsewhere (15). Lipolase powder (one of the two forms of lipases from *R. miehei*, activity, 100 KLU/g) was a gift from Novo Nordisk A.S. (Hong Kong). One kilo lipase unit (KLU) corresponds to 1 μmol butyric acid formed from tributyrin per min under the conditions specified by the manufacturer. Lipase from CCL (also known

Copyright © 1995 by AOCS Press

as *C. rugosa*) (Type VII, activity 905 U/mg) and bakers' yeast (*S. cerevisiae*,YSC type II) were purchased from Sigma Chemical Co. (St. Louis, MO). One unit of lipase will hydrolyze 1.0 microequivalent of fatty acid from a triglyceride in 1 h at pH 7.2 at 37°C using olive oil as the substrate. Thin-layer and column chromatographic, infrared, ^{1}H and ^{13}C nuclear magnetic resonance (NMR) spectroscopic analyses were performed as described elsewhere (9). Gas–liquid chromatography was conducted on a Hewlett-Packard (Hewlett-Packard, Palto Alto, CA) model 5890 gas chromatograph fitted with a fused silica capillary column (30 m × 0.5 mm, Supelcowax™ 10 stationary phase, 1.0 μm film thickness; Supelco, Bellefonte, PA) using nitrogen (2 mL/min) as the carrier gas with temperature programmed from 160–240°C at a rate of 5°C/min. The injector and detector (flame-ionization) temperatures were maintained at 230 and 280°C, respectively. A Branson model 3200 (47 kHz) ultrasonic cleaning water bath (Branson Ultrasonic, Danbury, CT) was used for reactions under ultrasound conditions. High-resolution mass spectra (HR–MS) were recorded on a Finnigan Mat 95 mass spectrometer (Finnigan Mat Corp., San Jose, CA).

Enzymatic hydrolysis of the N*-heterocyclic fatty esters: (a) Hydrolysis of methyl 8-(5-hexyl-1-pyrroline-2-yl)-octanoate* (**1**) *using bakers' yeast* (S. cerevisiae). To a fermenting mixture of bakers' yeast (10 g), D-glucose (7.6 g), and water (170 mL) in a 250-mL round-bottomed flask at 30°C, 1-pyrroline fatty ester (**1**, 1.0 g, 3.24 mmol) was added and the mixture was stirred for 3 d. The mixture was extracted with diethyl ether (2 × 100 mL). The ethereal extract was washed with water (2 × 50 mL) and dried (Na_2SO_4). Evaporation of solvent under reduced pressure gave a crude product (0.9 g). Silica gel column chromatographic separation using a mixture of light petroleum (b.p. 40–60°C) and diethyl ether (1:1, vol/vol) gave the unreacted ester (0.4 g) followed by elution with dichloromethane to yield 1-pyrroline fatty acid (**1a**) (0.5 g, 52%). ^{1}H NMR ($CDCl_3$, δ): 0.88 (*t*, 3H, CH_3), 1.20–1.45 (*m*, 14H, CH_2), 1.45–1.80 (*m*, 6H, CH_2), 2.00–2.15 (*m*, 2H, ring-CH_2, 10-*H*), 2.27 (*t*, 2H, 2-*H*), 2.41 (*t*, 2H, CH_2, 13-*H*), 2.51 (*m*, 2H, ring-CH_2, 11-*H*), 4.03 (*m*, 1H, C*H*, 9-*H*) and 10.59 (*s*, 1H, COO*H*); ^{13}C NMR ($CDCl_3$, ppm): 14.04 (C-18), 22.51 (C-17), 25.32 (C-3), 26.24 (C-7), 26.45 (C-14), 27.92 (C-10), 29.06, 29.23, 29.29, 29.49, 31.49, 31.60 (C-16), 33.07 (C-2), 35.11 (C-13), 35.88 (C-11), 36.75 (C-8), 70.96 (C-9), 177.57 (C-12, *C*=N), and 180.39 (C-1, *C*OOH).

(b) Hydrolysis of methyl 8-(5-hexyl-pyrroline-2-yl)octanoate (**1**) *using lipase of CCL.* A mixture of 1-pyrroline ester (**1**, 0.2 g, 0.64 mmol), CCL lipase (40 mg), and potassium phosphate buffer (pH 7.0, 2 mL) was stirred at 40°C for 16 h. Diethyl ether (2 mL) was added. The mixture was centrifuged and the ethereal phase was separated. The aqueous phase was reextracted with diethyl ether (2 × 2 mL). The combined ethereal extract was washed with water and evaporated under a stream of nitrogen. An azeotropic mixture containing benzene/methanol/chloroform (1:1:1, by vol) (1 mL) was added, and the mixture was further evaporated under a stream of nitrogen to give 1-pyrroline fatty acid (**1a**) (0.19 g, 100%).

(c) Hydrolysis of methyl 8-(5-hexyl-pyrroline-2-yl)octanoate (**1**) *using Lipolase under silent or ultrasound condition.* A mixture of 1-pyrroline ester (**1**, 0.2 g, 0.64 mmol), Lipolase (40 mg), and potassium phosphate buffer (pH 7.0, 2 mL) was stirred at 60°C for 36 h. Isolation of the product yielded the corresponding free fatty acid **1a** (0.19 g, 100%). When the same reaction mixture was incubated in a Bransonic ultrasound cleaning bath for 3 h at a bath temperature of 57–60°C, isolation of the reaction product furnished the corresponding free fatty acid (100% yield).

*(d) Hydrolysis of methyl 8-(*cis/trans*-5-hexyl-pyrrolidine-2-)octanoate* (**2**) *using lipase of CCL or Lipolase under silent or ultrasound condition.* A mixture of compound **2** (0.2 g, 0.64 mmol), CCL lipase (100 mg), and potassium phosphate buffer (pH 7.0, 2 mL) was stirred at 40°C for 7 d. Extraction of the reaction mixture with diethyl ether (3 × 2 mL) gave unreacted starting ester **2** quantitatively. The same reaction was carried out using Lipolase (40 mg) as the biocatalyst at 55°C for 24 h. Isolation of the mixture gave unreacted ester **2** quantitatively.

A mixture of compound **2** (0.2 g, 0.64 mmol), Lipolase (50 mg), and potassium phosphate buffer (pH 7.0, 2 mL) in a screw-capped test tube was incubated in a Branson ultrasonic cleaning bath at 57–65°C for 48 h. The mixture was extracted with diethyl ether. Silica gel column chromatographic separation of the isolated product using a mixture of light petroleum and diethyl ether (1:1, vol/vol) (30 mL) followed by a mixture of dichloromethane and methanol (1:1, vol/vol) (50 mL) gave unhydrolyzed ester (80 mg) and 8-(*cis/trans*-5-hexyl-pyrrolidine-2-)octanoic acid (**2a**) (97 mg, 51%); ^{1}H NMR ($CDCl_3$, δ): 0.89 (*t*, 3H, CH_3), 1.20–1.60 (*m*, 22H, CH_2), 1.80 (*m*, 2H, ring CH_2 *trans*-isomer), 1.92 (*m*, 2H, ring CH_2 *cis*-isomer), 2.30 (*t*, 2H, 2-*H*), 2.90 (*s*, 1H, N-*H*), 2.90 (*m*, 2H, ring C-*H cis*-isomer), 3.12 (*m*, 2H, ring C-*H trans*-isomer), 3.66 (*s*, 3H, $COOCH_3$), and 10.2 (*s*, 1H, COO*H*).

*(e) Hydrolysis of methyl 8-(*cis*-5-hexyl-*N*-methyl-pyrrolidine-2-)octanoate* (**3**) *using Lipolase under stirred or ultrasound condition.* A mixture of compound **3**, Lipolase (40 mg), and phosphate buffer (pH 7.0, 2 mL) was stirred at 60°C for 24 h. Isolation of the reaction mixture gave unreacted starting ester **3** quantitatively.

A mixture of compound **3** (0.1 g, 0.31 mmol), Lipolase (20 mg), and potassium phosphate buffer (pH 7.0, 2 mL) in a screw-capped test tube was sonicated in a Branson ultrasonic cleaning bath for 24 h at 57–60°C. The mixture was extracted with diethyl ether. Silica gel column chromatographic separation of the isolated product using a mixture of light petroleum and diethyl ether (1:1, vol/vol) (30 mL) followed by a mixture of dichloromethane and methanol (1:1, vol/vol) (50 mL) gave unhydrolyzed ester (20 mg) and 8-(*cis*-5-hexyl-*N*-methylpyrrolidine-2-)octanoic acid (**3a**) (80 mg, 83%); ^{1}H NMR ($CDCl_3$, δ): 0.88 (*t*, 3H, CH_3), 1.20–1.40 (*m*, 18H, CH_2), 1.45–1.65 (*m*, 4H, CH_2), 1.70–1.90 (*m*, 4H, CH_2), 2.0 (*m*, 2H, C*H*, 9-*H*, 12-*H*), 2.20 (*t*, 2H, 2-*H*), 2.53 (*s*, 3H, N-CH_3), and 10.40 (*s*, 1H, COO*H*); ^{13}C NMR ($CDCl_3$, ppm): 14.06 (C-18), 22.55 (C-17), 25.93 (C-3), 26.82 (C-7), 26.97

(C-14), 27.95 (C-10, C-11), 29.25, 29.46, 29.83, 31.29 (C-8), 31.43 (C-13), 31.74 (C-16), 36.67, 37.70 (N-CH_3), 68.78 (C-9), 68.91 (C-12), and 179.29 (C-1, COOH).

(f) Hydrolysis of methyl 8-(5-hexyl-1H-pyrrole-2-)octanoate (**4**). A mixture of pyrrole ester (**4**) (0.1 g), potassium phosphate buffer (2 mL), and CCL of Lipolase (40 mg) was stirred at 40°C for 48 h. Isolation of the product gave 8-(5-hexyl-1*H*-pyrrole-2-) octanoic acid (**4a**) in 95% yield.

Chemical hydrolysis of N-*heterocyclic fatty esters: (a) Hydrolysis of methyl 8-(5-hexyl-1-pyrroline-2-yl)octanoate* (**1**). A mixture of compound **1** (0.2 g, 0.65 mmol) and ethanolic KOH (1 M, 1.2 mL) was stirred at 25°C for 2 h. The mixture was acidified with diluted HCl (6 M, 1 mL) and was extracted with dichloromethane (3 × 10 mL). The organic extract was washed with saturated aqueous NaCl (2 × 5 mL) and dried (Na_2SO_4). Evaporation of solvent gave the *N*-HCl salt of 8-(5-hexyl-1-pyrroline-2-yl)octanoic acid *N*-HCl salt (**1b**) (11 mg, 5%). ^{1}H NMR ($CDCl_3$, δ): 0.88 (*t*, 3H, CH_3), 1.20–1.50 (*m*, 14H, CH_2), 1.55–1.70 (*m*, 3H, CH_2, 10-*H*, N-*H*), 1.70–1.80 (*m*, 2H, ring-CH_2), 1.80–2.10 (*m*, 2H, CH_2, 8-*H*), 2.30 (*t*, 2H, 2-*H*), 2.50 (*m*, 2H, C*H*2, 14-*H*), 2.97 (*m*, 2H, CH_2, 13-*H*), 3.12 (*m*, 2H, CH_2, 11-*H*), 4.44 (*m*, 1H, C*H*, 9-*H*), and 9.46 (*s*, 1H, COO*H*); ^{13}C NMR ($CDCl_3$, ppm): 14.00 (C-18), 22.39 (C-17), 24.59 (C-3), 25.27 (C-7), 26.04 (C-14), 26.08 (C-10, ring CH_2), 28.65, 28.74, 28.93, 28.96, 32.01 (C-13), 33.92 (C-2), 34.04 (C-2), 34.12 (C-8), 36.47 (C-11, ring-CH_2), 67.22 (C-9, N*C*H), 178.18 (C-1, *C*OOH), and 195.41 (C-12, *C*=N^+).

*(b) Hydrolysis of methyl 8-(*cis/trans-*5-hexyl-pyrrolidine-2-)octanoate* (**2**). Compound **2** was hydrolyzed using ethanolic KOH by the same procedure as described above to yield *N*-HCl salt of 8-(*cis/trans*-5-hexyl-pyrrolidine-2-)octanoic acid (**2a**, 90%). ^{1}H NMR ($CDCl_3$, δ) 0.87 (*t*, CH_3, 3H), 1.20–1.1.50 (*m*, 14H, CH_2), 1.50–1.70 (*m*, 4H, CH_2), 1.70–1.90 (*m*, 2H, CH_2), 1.90–2.10 (*m*, 2H, CH_2), 2.10–2.25 (*m*, 2H, CH_2), 2.30 (*t*, 2H, CH_2), 3.48 (*m*, 2H, $^+NH_2$), 3.64 (*m*, 2H, C*H*, 9-*H*, 12-*H*, *trans*), and 10.60 (*s*, 1H, COO*H*); ^{13}C NMR ($CDCl_3$, ppm): 14.04 (C-18), 22.57 (C-17), 24.63 (C-3), 26.48 (C-7, *trans*), 26.59 (C-14, *trans*), 26.69 (C-7, *cis*), 26.83 (C-14, *trans*), 28.54, 28.57, 28.86, 28.93, 29.00, 29.03, 29.19, 30.3, 31.69 (C-16), 32.12 (C-10, *trans*), 32.24 (C-11, *trans*), 32.45 (C-10, *cis*), 32.61 (C-11, *cis*), 34.15 (C-2), 59.55 (C-9, *trans*), 59.64 (C-12, *trans*), 60.37 (C-9, *cis*), 60.46 (C-12, *cis*), and 178.42 (C-1, *C*OOH); HR–MS [*m/z* (relative intensity)]: M^+ = 297.2673 (calc. 297.2668, M^+-HCl); 154 (100), 194 (16.7), 198 (14.2), 212 (83.5), and 213 (10).

(c) Hydrolysis of methyl 8-(-cis-*5-hexyl-*N-*methyl-pyrrolidine-2-)octanoate* (**3**). Compound **3** was hydrolyzed using ethanolic KOH by the same procedure as described above to yield *N*-HCl salt of 8-(*cis*-5-hexyl-*N*-methyl-pyrrolidine-2-)-octanoic acid (**3b**, 92%). ^{1}H NMR ($CDCl_3$, δ): 0.88 (*t*, 3H, CH_3), 1.20–1.50 (*m*, 20H, CH_2), 1.55–1.70 (*m*, 2H, CH_2), 1.85–2.10 (*m*, 2H, CH_2), 2.15–2.25 (*m*, 2H, CH_2), 2.32 (*m*, 2H, 2-*H*), 2.82 (*s*, 3H, NCH_3), 3.05 (*s*, 1H, ^+NH) and 10.20 (*s*, 1H, COO*H*); ^{13}C NMR ($CDCl_3$, ppm): 14.03 (C-18), 22.51 (C-17), 24.71 (C-3), 26.43 (C-14), 26.62 (C-7), 27.26, 28.79, 28.82, 28.95, 29.80, 29.69, 31.61 (C-16), 34.33 (C-2), 36.87 (N-CH_3), 70.06 (C-9, C-12, 2C) and 177.78 (C-1, COO*H*). HR–MS [*m/z* (relative intensity)]: M^+ = 311.2818 (calc. 311.2824, M^+-HCl);168 (80), 226 (100), 227 (10.5).

(d) Hydrolysis of methyl 8-(5-hexyl-1H-pyrrole-2-)octanoate (**4**). Compound **4** was hydrolyzed using ethanolic KOH by the same procedure as described above to yield 8-(5-hexyl-1*H*-pyrrole-2-)octanoic acid (**4a**, 90%). ^{1}H NMR ($CDCl_3$, δ): 0.88 (*t*, 3H, CH_3), 1.20–1.50 (*m*, 14H, CH_2), 1.55–1.80 (*m*, 4H, CH_2), 2.30 (*t*, 2H, 2-*H*), 2.54 (*t*, 4H, CH_2, 8-*H*, 13-*H*), 5.76 (*d*, 2H, C*H*, 10-*H*, 11-*H*), 7.90 (*s*, *br*, 1H, N-*H*), and 10.40 (*s*, *COOH*); ^{13}C NMR ($CDCl_3$, ppm): 14.10 (C-18), 22.61 (C-17), 24.62 (C-3), 27.76 (C-8), 27.81 (C-13), 28.94, 29.03, 29.12, 29.15, 29.61, 29.69, 31.69 (C-16), 34.03 (C-2), 104.48 (C-10), 104.53 (C-11), 131.06 (C-9), 131.32 (C-12), and 180.10 (C-1, *C*OOH); IR (NaCl) 3200–3400 (s, N-*H*, CO*OH*), 1700 (*CO*OH), 1580 (C=C, pyrrole ring), 1420, 1200, and 770 (*CH*, pyrrole ring).

RESULTS AND DISCUSSION

The products obtained by enzymatic hydrolysis and by chemical means are summarized in Figure 1. Our initial attempts to obtain the pure fatty acids of compounds **1–3** for biological screening purposes by chemical hydrolysis of the corresponding methyl esters failed to afford the requisite free fatty acids due to the formation of the *N*-HCl salt in each case when the saponified product was acidified with dilute HCl. The HCl salt of the 1-pyrroline fatty acid was extremely water-soluble and difficult to isolate from aqueous solution by extraction with diethyl ether or dichloromethane. Repeated extraction with dichloromethane furnished only about 5% yield of the *N*-HCl salt of the 1-pyrroline fatty acid (**1a**). However, the HCl salts of compounds **2** and **3** were readily isolated by dichloromethane extraction in >90% yields. In view of the inability to produce *N*-heterocyclic fatty acids free from HCl by chemical hydrolysis, we considered enzymatic hydrolysis as a potential alternative method to the requisite free fatty acids.

Incubation of methyl 1-pyrroline ester (**1**) with bakers' yeast at 30°C for 3 d gave the corresponding 1-pyrroline fatty acid (**1a**) in 52% yield. Unhydrolyzed substrate was recovered in 38%. No reduction of the C=N bond of the 1-pyrroline system in compound **1** was observed, as the isolated product did not reveal the presence of any pyrrolidine derivatives. Reactions involving bakers' yeast involve cumbersome extraction procedures (11), which led us to concentrate on lipase-catalyzed reactions.

Incubation of methyl 1-pyrroline fatty ester (**1**) with CCL lipase in potassium phosphate buffer for 1 h at 40°C gave 52% of the corresponding fatty acid. The hydrolysis of compound **1** was complete, when the incubation period was extended to 16 h. Hydrolysis of compound **1** with Lipolase at 60°C required 36 h to complete. The reaction period using Lipolase was significantly reduced to 3 h, when the incuba-

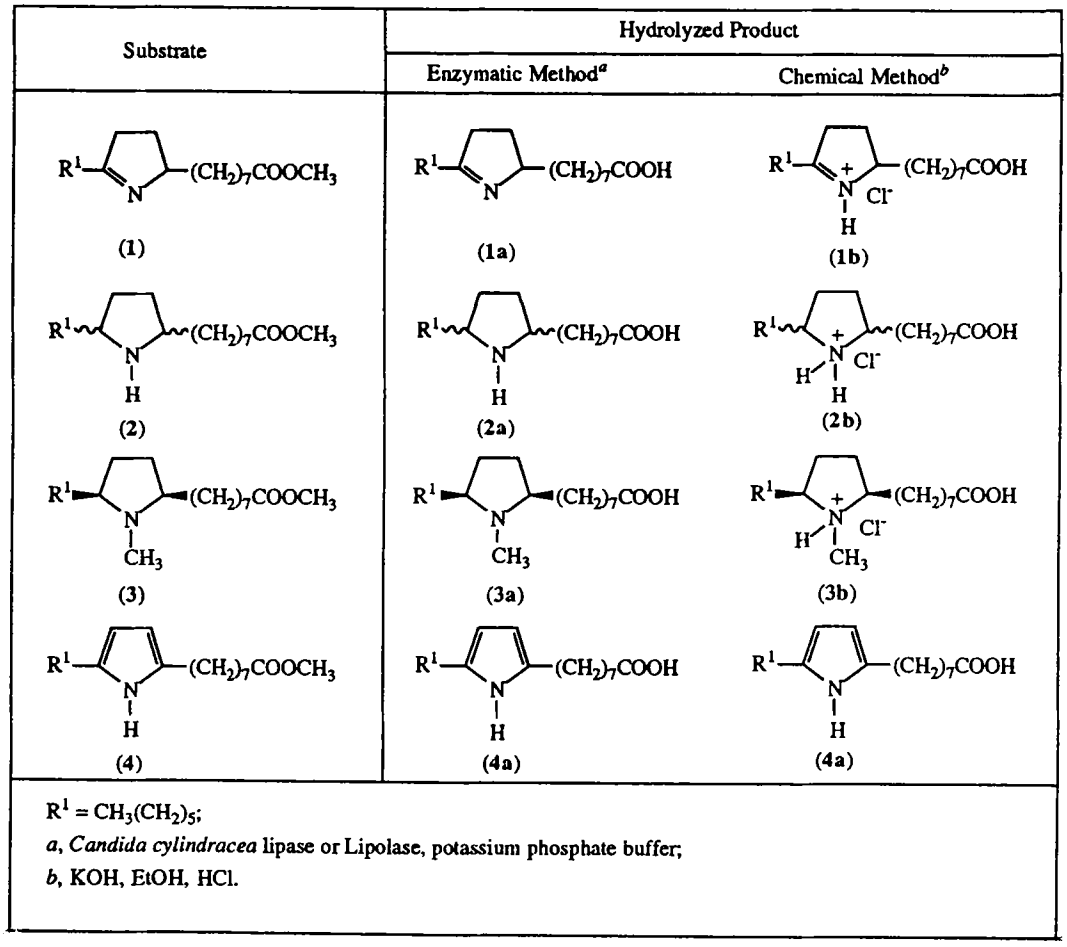

FIG. 1. Hydrolysis of *N*-heterocyclic fatty esters.

tion of compound **1** with Lipolase was carried out under ultrasound at a temperature of 57–65°C.

Attempts to hydrolyze pyrrolidine (**2**) and *N*-methyl pyrrolidine (**3**) methyl esters using CCL in potassium phosphate buffer were unsuccessful. Incubation of compound **2** for 7 d with a 2-fold amount of lipase showed no free acid product formation. From this result, it appears that the lipase of CCL is deactivated by the pyrrolidine, but not the 1-pyrroline system. Use of Lipolase to hydrolyze compound **2** at 55°C for 24 h also failed to produce the corresponding free fatty acid. However, when Lipolase-catalyzed hydrolysis of compound **2** was carried out under ultrasound at 57–65°C for 48 h, analysis of the isolated products showed the presence of the free acids (**2a**) in 51% yield, as assessed by the intensities of the carbonyl carbon signals of the ester (174.27 ppm) and acid (179.52 ppm) groups in the ^{13}C NMR spectrum of the product mixture. The hydrolysis of the *cis*-*N*-methyl pyrrolidine fatty ester (**3**) using Lipolase at 57–60°C under ultrasound condition was successful as 80% of the free acid (**3a**) was isolated after 24 h of incubation.

From these experimental results, it appears that the hydrolytic activities of CCL and Lipolase are not inhibited by the chemical nature of an *N*-heterocyclic system in the alkyl chain of the fatty esters under investigation, as the 1-pyrroline derivative is readily hydrolyzed. The resistance of the *cis*-*N*-pyrrolidine derivative to CCL and Lipolase hydrolysis reflects a stereochemical (*cis*-configuration) implication of the *N*-heterocyclic system on the enzymes, but which can be overcome by ultrasound treatment. As the 1-pyrroline system contains a planar C=N bond in its ring system, it seems that partial planarity of the ring system in the alkyl chain of a fatty ester does not cause any discriminating effects on the hydrolytic activities of such enzymes. To extend this concept to a planar *N*-heterocyclic system, we have carried out the lipase-catalyzed hydrolysis on methyl 8-(5-hexyl-1*H*-pyrrole-2-)octanoate (**4**), which contains a planar *N*-heteroaromatic system in the alkyl chain. Hydrolysis of compound **4** in the presence of CCL or Lipolase in potassium phosphate buffer at 40°C was complete in 24 h. Compound **4** was also hydrolyzed by KOH in ethanol, which on acidification with dilute HCl gave the corresponding free fatty acid (**4a**) only. No HCl-salt is formed in this case as the pyrrole ring is a heteroaromatic system.

While the saponification of methyl 1-pyrroline and pyrrolidine esters by chemical means (ethanolic KOH) is readily achieved, acidification with HCl of the saponified product

gives the *N*-HCl salts. Isolation of the *N*-HCl salt of 1-pyrroline fatty acid with dichloromethane gives a 5% yield. However, the isolation of the *N*-HCl salts of the pyrrolidine fatty acids derived from compounds **2** and **3** by solvent extraction was possible (>90% yield). The presence of chloride ions in these products was confirmed by the positive sodium fusion test (Lassaigne's test). The protonation of the nitrogen atom of the *N*-heterocyclic system caused a significant deshielding effect on the adjacent carbon atoms in the ^{13}C NMR spectra. In the case of the HCl-salt of the 1-pyrroline acid (**1b**), the protonated pyrroline nitrogen caused the carbon shift of the $C=N^+$ carbon atom to appear at 195.41 ppm, as compared to 177.07 ppm for the unprotonated 1-pyrroline carbon atom (C=N). The shifts of the methine proton (9-*H*) and carbon (9-C) nuclei of the 1-pyrroline system were also affected by the protonation of the nitrogen atom, as these signals appeared significantly more downfield than those observed for the unprotonated analogue (**1a**).

In the case of the protonated pyrrolidine (**2b**) and *N*-methyl pyrrolidine (**3b**) HCl-salts, the protonated nitrogen also caused a strong deshielding effect on the adjacent methine carbon and proton nuclei. The shifts of the *N*-methyl protons and methyl carbon atom of compound **3b** appeared at δ 2.82 and 36.87 ppm, respectively.

We conclude from this study that the hydrolytic activity of lipases from CCL and *R. miehei* (Lipolase) depends on the configuration of *N*-heterocyclic systems when present in the alkyl chain of the fatty esters. Planar and partially planar ring systems do not appear to affect the lipase activity much, but the *cis* or *trans* configuration of the ring system of 2,5-disubstituted pyrrolidines seems to cause a strong deactivation of the hydrolytic lipase activities. However, the inhibition can be overcome by conducting the reaction in ultrasound as demonstrated in these experiments.

ABSTRACT: A reliable method was needed to analyze molecular species of oxidized vegetable oils. In order to accomplish this goal, mono-, bis-, and tris-hydroperoxides (Mono-OOH, Bis-OOH, and Tris-OOH, respectively) of triacylglycerols formed during autoxidation and photosensitized oxidation of oils were determined by reversed-phase high-performance liquid chromatography in combination with chemiluminescence detection (CL-HPLC). Mono-OOH was the major species (96% of total hydroperoxides) in trioleoylglycerol [peroxide value (PV) 0.16 meq/kg], and Bis-OOH and Tris-OOH showed prolonged accumulation with photooxidation. This profile was confirmed in photooxidation of trilinoleoylglycerol and trilinolenoylglycerol. Soybean oil (PV 6 meq/kg) contained Mono-OOH oleoyl-linoleoyl-linoleoylglycerol as the main peroxidic molecular species (50% of total hydroperoxides). Mono-OOH trilinoleoylglycerol was the principal species (61% of total hydroperoxides) in safflower oil (PV 5 meq/kg), and Mono-OOH oleoyl-oleoyl-linoleoylglycerol was the representative species (66% of total hydroperoxides) in olive oil (PV 3 meq/kg). The CL-HPLC method, which is specific for the detection of hydroperoxides, should prove useful in studies of triacylglycerol oxidation in foods and vegetable oils.

Lipids 30, 1001–1006 (1995).

Oxidation of food lipids and edible oils causes undesirable tastes and rancid flavors (1–5). Ingestion of rancid oils has a deleterious effect, especially on immunocompetent cells in mammals (6). Therefore, it is important to detect peroxides present in the oil.

High-performance liquid chromatography (HPLC) is one of the most effective assays in the study of triacylglycerol oxidation (7–10). The HPLC method combined with chemiluminescence detection (CL-HPLC) has been established, and this method was applied to measure phospholipid hydroperoxides (11,12), squalene hydroperoxide (13), and α-tocopherol hydroperoxide (14) in biological tissues, as well as in several food models. This CL-HPLC method has an advantage of high sensitivity as to be able to detect picomoles of hydroperoxides in each lipid class. The postcolumn-chemiluminescence reaction is specific for the hydroperoxy group, and it enables the discrimination of the hydroperoxides from the corresponding hydroxy derivatives. The application of such a highly sensitive assay to the study of oxidation in food lipids would help to understand the susceptibility of hydroperoxidation and the efficiency of antioxidants in foods and vegetable oils.

This paper describes the CL-HPLC assay of triacylglycerol hydroperoxides and its application to characterize the hydroperoxides formed during autoxidation and photosensitized oxidation of vegetable oils.

MATERIALS AND METHODS

Materials. Trioleoylglycerol, trilinoleoylglycerol (LLL), and trilinolenoylglycerol (purity above 99%) were purchased from Nu-Chek-Prep, Inc. (Elysian, MN). Cytochrome *c* (from horse heart, type VI) was obtained from Sigma Chemical Co. (St. Louis, MO). Luminol (3-aminophthaloyl hydrazine), sodium borohydride, and methylene blue were from Wako Pure Chemical Co. (Osaka, Japan). *N,N*-Dimethyl-*p*-phenylenediamine dihydrochloride (DMPD) was purchased from Tokyo Kasei Kogyo Co. (Tokyo, Japan). Platinum (IV) oxide hydrate was from Aldrich Chemical Co. (Milwaukee, WI). Soybean, safflower, and olive oils were purchased from a local market. All solvents and other reagents were at the highest grade available.

Photooxidation of triacylglycerols. Photosensitized oxidation of trioleoylglycerol, LLL, and trilinolenoylglycerol was performed with a slight modification of our previously report method (12). Each triacylglycerol (500 mg) was dissolved in 30 mL of chloroform/methanol (1:1, vol/vol) containing 0.1 mM methylene blue as a photosensitizer. The reaction mixture was placed in a glass beaker (200 mL) and was photoirradiated at 10°C. The light source, a 500 W photoreflector

lamp (Toshiba Electronics Co., Tokyo, Japan), was held at a 50-cm distance above the surface of a reaction mixture. The photoirradiated mixture was passed through a silica column (Wako gel C-100; Wako Pure Chemical Co.) with methanol as an eluant to remove methylene blue. The methanol extract containing oxidized triacylglycerol was concentrated with a rotary evaporator, and its peroxide value (PV) was determined by potassium iodide reduction (15). The photooxidized triacylglycerol was redissolved in appropriate amounts of chloroform/methanol (2:1, vol/vol), and then analyzed by CL-HPLC with a sample injection volume of 5 to 20 μL.

Autoxidation of vegetable oils. Soybean, safflower, and olive oils were allowed to autoxidize in the dark at 25°C (6). The PV was determined by potassium iodide reduction (15). The autoxidized oil dissolved in appropriate amounts of chloroform/methanol (2:1, vol/vol) was analyzed by CL-HPLC, as in the case of photooxidized oils.

CL-HPLC. The CL-HPLC system used to determine triacylglycerol hydroperoxides was modified from that used previously (16). A reversed HPLC column, JASCO Finepak SIL C18-5 (5 μm, 250 × 4.6 mm; Japan Spectroscopic Co., Tokyo, Japan) fitted with JASCO Finepak SIL C18 T-P precolumn (5 μm, 50 × 4.6 mm), was employed. The mobile phase was methanol or a mixture of methanol/ethanol (5:1, vol/vol) and the flow rate was 1.1 mL/min. The column eluant was mixed at the post column with a chemiluminesence reagent consisting of cytochrome *c* (10 μ g/mL) and luminol (2 μ g/mL) in 50 mM borate buffer (pH 10.0). The chemiluminescence was measured with a CLD-100 detector (Tohoku Electronic Industries Co., Sendai, Japan). The hydroperoxide level was calibrated by known concentration of mono-, bis-, and tris-hydroperoxides (Mono-OOH, Bis-OOH, and Tris-OOH, respectively) of each triacylglycerol, except for vegetable oils, and was then expressed as picomol of hydroperoxide-0_2 (12). The concentration of triacylglycerol hydroperoxides in vegetable oils was estimated by using hydroperoxy LLL as a standard as most of the hydroperoxides formed during oxidation of vegetable oils were located on linoleic acid in triacylglycerols.

Mass spectrometry (MS). Triacylglycerol hydroperoxides isolated with preparative HPLC (Finepak SIL C18-5 and Finepak SIL C18 T-P guard column, ultraviolet detection at 210 or 234 nm) were analyzed by fast atom bombardment–MS (FAB–MS) using a JEOL JNM-HX-105 mass spectrometer (Tokyo, Japan) after reduction with sodium borohydride and hydrogenation with platinum (IV) oxide hydrate as a catalyst. The methyl esters of hydroxy fatty acids were obtained from triacylglycerol hydroperoxides after reduction, hydrogenation, and transmethylation, and then were characterized by gas–liquid chromatography (GLC) using a glass column (3 mm × 1 m) packed with Dexsil 300GC (GL Sciences, Tokyo, Japan). Constituent fatty acids of triacylglycerol molecular species separated with a reversed-phase HPLC also were determined by GLC. On the other hand, to confirm the presence of the hydroperoxy group in the molecule, oxidized oils and isolated triacylglycerol hydroperoxides were submitted to thin-layer chromatography (TLC) on a Kieselgel 60 plate (Merck, Darmstadt, Germany) with *n*-hexane/diethyl ether/acetic acid (60:40:1, by vol) as a mobile phase, and hydroperoxide detection was performed on TLC by spraying 1% DMPD in methanol solution (17).

RESULTS AND DISCUSSION

Trioleoylglycerol. Chemiluminescence chromatogram of trioleoylglycerol (PV 0.16 meq/kg) in CL-HPLC is shown in Figure 1. Two major chemiluminescence peaks of retention times (Rt) at 21.0 and 10.0 min were observed. The peak components were identified as Mono-OOH and Bis-OOH of trioleoylglycerol, respectively, from their structural characterization, as described later. Under such chromatographic conditions, unoxidized trioleoylglycerol appeared at Rt 56.0 min with ultraviolet detection at 210 nm. The chemiluminescence peaks ascribed to Mono-OOH and Bis-OOH of trioleoylglycerol completely disappeared from the chromatogram after reduction with sodium borohydride. Previously it was demonstrated that lipid hydroperoxide reduced to the corresponding hydroxy compound with sodium borohydride gave no chemiluminescence in the CL-HPLC (11,12).

Figure 2 shows the CL-HPLC chromatograms of photooxidized trioleoylglycerol. To characterize the chemiluminescence peaks, oxidized trioleoylglycerol (PV 3100 meq/kg) was analyzed by TLC, and it was confirmed to give four spots at R_f 0.57, 0.37, 0.19, and 0.13 after spraying with H_2SO_4 and heating. The three spots at R_f 0.37, 0.19, and 0.13 were identical with the compounds of chemiluminescence peaks 1, 2, and 3 in Figure 2, respectively, and the spot at R_f 0.57 was unoxidized trioleoylglycerol. Chemiluminescence com-

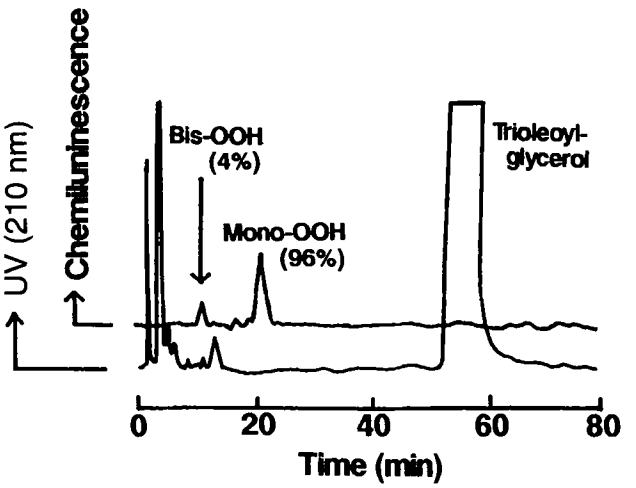

FIG. 1. High-performance liquid chromatography with chemiluminescence detection (CL-HPLC) of trioleoylglycerol (peroxide value 0.16 meq/kg). HPLC column was a Finepak SIL C18-5 (5 μm, 250 × 4.6 mm) connected with Finepak SIL C18 T-P pre-column (5 μm, 50 × 4.6 mm). The mobile phase was methanol and the flow rate was 1.1 mL/min. The chemiluminescence reagent was composed of cytochrome c and luminol. Mono-OOH, mono-hydroperoxides (retention time 21.0 min); Bis-OOH, bis-hydroperoxides (retention time 10.0 min); UV, ultraviolet.

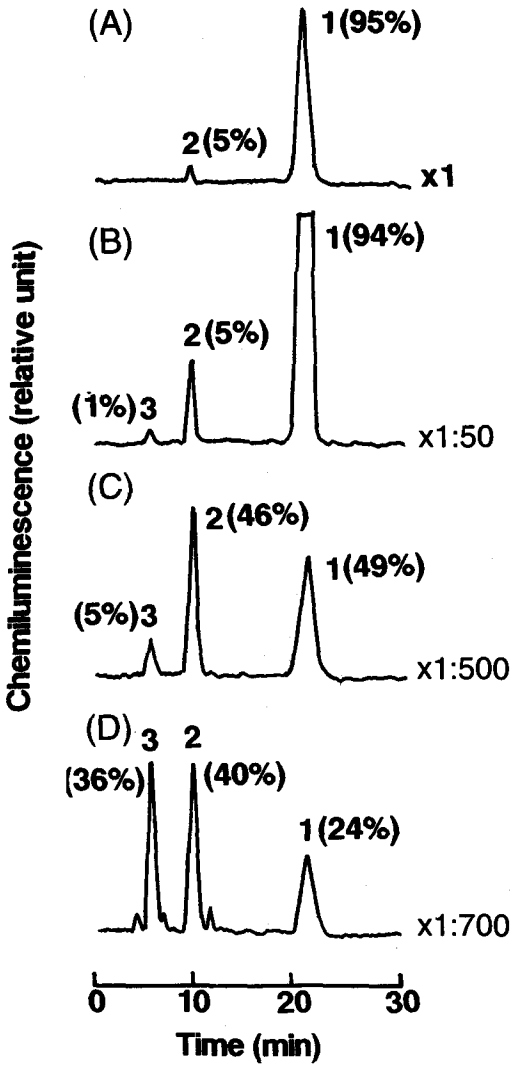

FIG. 2. CL-HPLC chromatograms of trioleoylglycerol photooxidized at 10°C for 0.5 h: A, peroxide value (PV) 4 meq/kg, 1 h; B, PV 330 meq/kg, 10 h; C, PV 3100 meq/kg and 20 h; D, PV 5000 meq/kg. Analytical conditions were the same as those given in Figure 1. Indications, ×1, ×1:50, ×1:500 and ×1:700, are the relative dilution ratios of oxidized oil. Peak 1, mono-hydroperoxides; peak 2, bis-hydroperoxides; peak 3, tris-hydroperoxides. Abbreviations as in Figure 1.

pounds of peaks 1, 2, and 3 gave a positive pink spot on a TLC plate when sprayed with DMPD reagent, which is specific for the hydroperoxy group. FAB–MS assay was conducted to further ascertain the structures. The reduced and hydrogenated compound of peak 1 component showed a molecular ion $[M + 1]^+$ at *m/z* 908 corresponding to monohydroxy tristearoylglycerol, thus indicating that the peak 1 compound was trioleoylglycerol Mono-OOH. Similarly, the compounds of peaks 2 and 3 gave $[M + 1]^+$ at *m/z* 924 and *m/z* 941, corresponding to bis- and tris-hydroxy tristearoylglycerols after reduction and hydrogenation, thus indicating that peak 2 and 3 compounds were Bis-OOH and Tris-OOH, respectively, of trioleoylglycerol.

Depending on the prolonged photooxidation periods, the PV increased, and the yield of chemiluminescence products ascribed to Mono-OOH (Rt 21.0 min), Bis-OOH (10.0 min), and Tris-OOH (6.0 min) grew (Fig. 2). As shown in Figure 3, Mono-OOH were predominant in the initial photooxidation stage of trioleoylglycerol (PV below 330 meq/kg), and a large accumulation of Bis-OOH and Tris-OOH were observed at further prolonged oxidation periods at PV above 2000 meq/kg.

LLL and trilinolenoylglycerol. The CL-HPLC chromatograms of photooxidized LLL revealed the formation of Mono-OOH, Bis-OOH, and Tris-OOH as chemiluminescence peaks (Fig. 4). The structural identification was performed in the same manner as in the case of trioleoylglycerol hydroperoxides. LLL Mono-OOH were predominant (97–98% of total hydroperoxides) at PV 120 and 480 meq/kg, although considerable concentrations of Bis-OOH and Tris-OOH appeared at PV 2400 meq/kg. In photooxidation of trilinolenoylglycerol, Mono-OOH (95% of total hydroperoxides) was a major product at PV 330 meq/kg, and Bis-OOH (17% of total hydroperoxides), but not Tris-OOH, was detected at PV 1700 meq/kg (Fig. 5). These observations were almost in agreement with those of Frankel *et al.* (8). The calibration curves of Mono-OOH formed during photooxidation of triacylglycerols were different in the chemiluminescence yield among three triacylglycerols, but a good proportional correlation ($r > 0.99$) was observed in each triacylglycerol between the accumulated hydroperoxides and the chemiluminescence yields (Fig. 6). The detection limit of LLL Mono-OOH was as low as 2 picomol under the present analytical conditions.

Vegetable oils. Figure 7 shows the CL-HPLC chromatograms of soybean oil (PV 6 meq/kg) and autoxidized soybean oil (PV 110 and 780 meq/kg). Only Mono-OOH was detected at PV 6 meq/kg, and the peroxidic molecular species con-

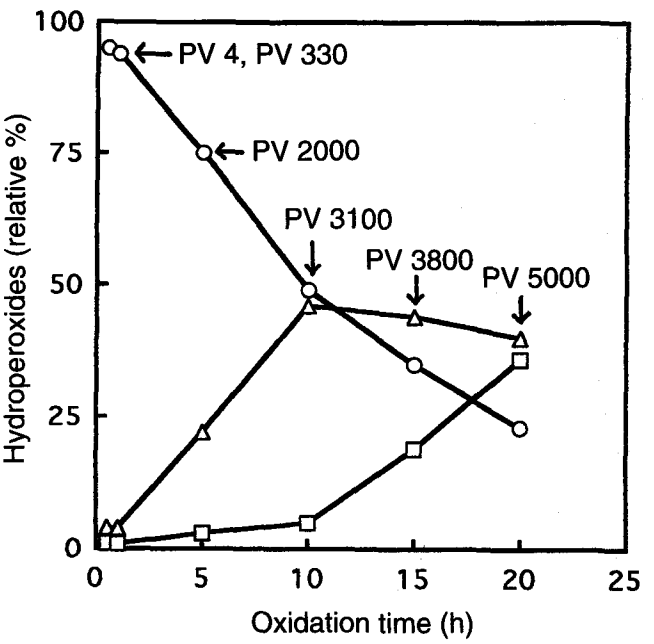

FIG. 3. Time course of mono- (○), bis- (△) and tris-hydroperoxides (□) formation during photooxidation of trioleoylglycerol as estimated by CL-HPLC. PV, peroxide value; other abbreviation as in Figure 1.

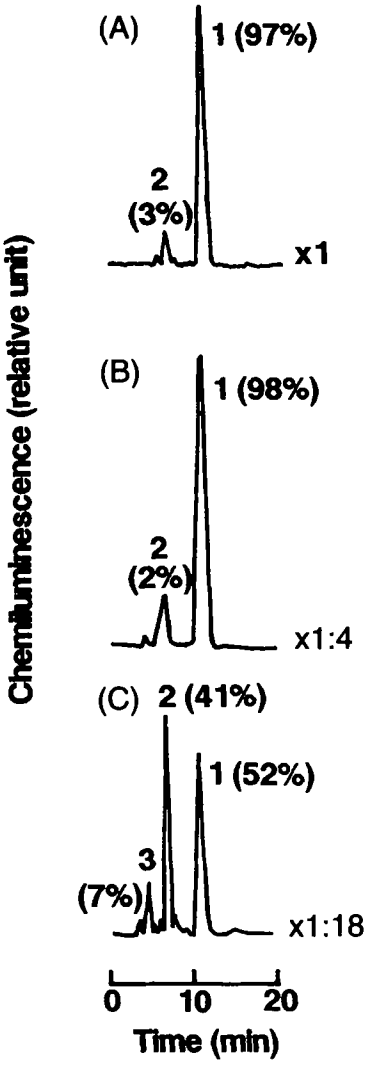

FIG. 4. CL-HPLC chromatograms of trilinoleoylglycerol photooxidized at 10°C for 5 min: A, PV 120 meq/kg, 30 min; B, PV 480 meq/kg and 5 h; C, PV 2400 meq/kg. The mobile phase was methanol/ethanol (5:1, vol/vol), and the flow rate was 1.1 mL/min. Other analytical conditions were the same as those given in Figure 1. Indications, ×1, ×1:4, and ×1:18, are the relative dilution ratios of oxidized oil. Peak 1, mono-hydroperoxides (retention time 11.0 min); peak 2, bis-hydroperoxides (6.8 min); peak 3, tris-hydroperoxides (4.8 min). Abbreviations as in Figures 1 and 3.

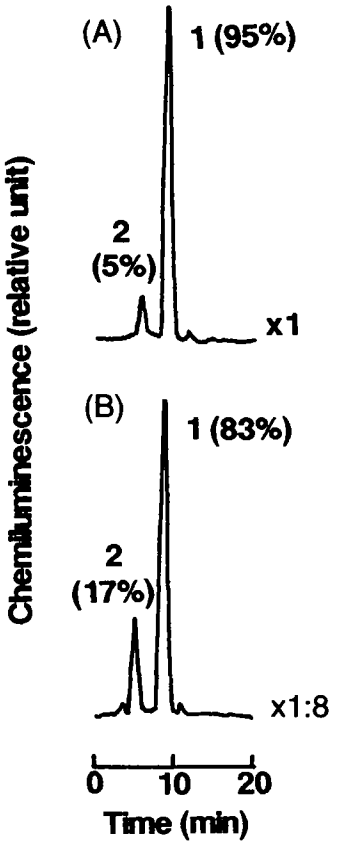

FIG. 5. CL-HPLC chromatograms of trilinolenoylglycerol photooxidized at 10°C for 5 min: A, PV 330 meq/kg and 30 min; B, PV 1700 meq/kg. Analytical conditions were the same as those given in Figure 4. Indications, ×1 and ×1:8, are the relative dilution ratios of oxidized oil. Peak 1, mono-hydroperoxides (retention time 7.9 min); peak 2, bis-hydroperoxides (5.8 min). Abbreviations as in Figures 1 and 3.

sisted of Mono-OOH of oleoyl-linoleoyl-linoleoylglycerol (OLL, 50%), LLL (28%), palmitoyl-linoleoyl-linoleoylglycerol (PLL), oleoyl-oleoyl-linoleoylglycerol (OOL, 20%), and palmitoyl-oleoyl-linoleoylglycerol (POL, 2%), which were characterized from their constituent fatty acids of the peak components analyzed by GLC. Bis-OOH at PV 110 and 780 meq/kg was 1 and 13% of the total hydroperoxides, respectively (Fig. 7). OLL Mono-OOH was the representative hydroperoxidic molecular species formed in the soybean oil autoxidation.

In safflower oil at PV 5 meq/kg, LLL Mono-OOH was predominant (61% of total hydroperoxides), followed by Mono-OOH of OLL (26%) and PLL (8%), and Bis-OOH was minor (5%), as shown in Figure 8A. In olive oil at PV 3 meq/kg, OOL Mono-OOH was the major one (66% of total hydroperoxides), followed by Mono-OOH of OLL (29%) and POL (4%). These results showed that the molecular species of Mono-OOH formed during oxidation of vegetable oils depended on their triacylglycerol composition. Bis-OOH was 1% of the total hydroperoxides in olive oil (Fig. 8B). Tris-OOH was not detected in either of the sample oils. A little quenching (negative peak) observed at Rt 7.6 min in the chemiluminescence chromatograms of safflower oil was due to α-tocopherol originally contained in the oils.

The present results demonstrate that the CL-HPLC is a useful tool for quantifying the molecular levels of hydroperoxides formed during the photooxidation and autoxidation of vegetable oils. The advantage of the CL-HPLC assay is being able to detect triacylglycerol hydroperoxides at lower concentrations such as PV 0.16–6.0 meq/kg. This high sensitivity may be very beneficial to the study of peroxidation and flavor changes in vegetable oils. A possible disadvantage is that excess amounts of α-tocopherol present in the oil might affect the chemiluminescent reaction of hydroperoxides, especially when the Rt are overlapped with each other. Fortu-

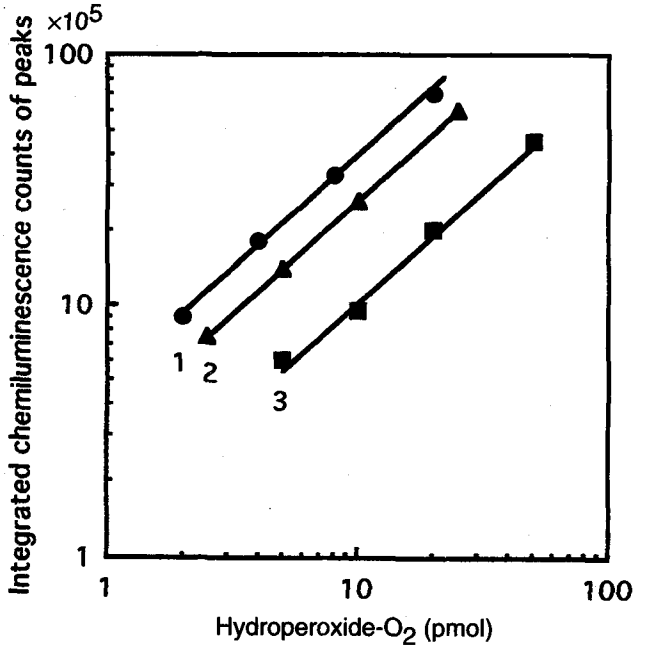

FIG. 6. Calibration curves of triacylglycerol mono-hydroperoxides as determined by CL-HPLC. Analytical conditions were the same as those given in Figure 4. 1, Trilinoleoylglycerol mono-hydroperoxides; 2, trilinolenoylglycerol mono-hydroperoxides; 3, trioleoylglycerol mono-hydroperoxides. Abbreviations as in Figure 1.

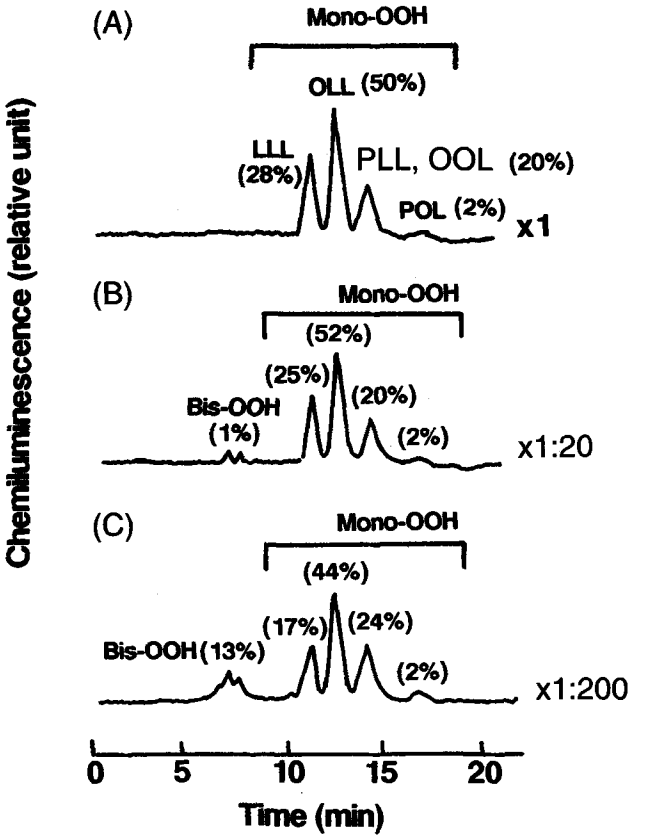

FIG. 7. CL-HPLC chromatograms of soybean oil (A, PV 6 meq/kg; B, PV 110 meq/kg; C, PV 780 meq/kg) autoxidized at 25°C. Analytical conditions were the same as those given in Figure 4. Indications, ×1, ×1:20, and ×1:200, are the relative dilution ratios of oxidized oil. LLL, OLL, PLL, OOL, and POL depicted the fatty acid combination in molecular species of triacylglycerol, with abbreviations of palmitic (P), oleic (O), and linoleic acids (L). Other abbreviations as in Figure 1.

nately, the α-tocopherol level, as generally present in commercial oils, did not cause such disturbance. The chemiluminescence reagent of a mixture of cytochrome *c* and luminol employed presently has very low reactivity to cyclic peroxides, such as epidioxides (18). Hydroperoxy cyclic peroxide has been reported to occur in oxidation of methyl linoleate (7,19) and methyl linolenate (20), but under the present analytical conditions with CL-HPLC, triacylglycerols containing such hydroperoxy cyclic peroxides were not detected at substantial levels in photooxidation of LLL and trilinolenoylglycerol. Porter *et al.* (21) reported that the rate of cyclization of initially formed peroxy radicals is in competition with H-abstraction; thus, the distribution of Mono-OOH vs. hydroperoxyepidioxide depends on the H-donating ability of the medium. Although Bis-OOH and Tris-OOH would be formed from the corresponding Mono-OOH and Bis-OOH, respectively (7,22), the principal peroxide would be Mono-OOH of triacylglycerols in vegetable oils, which are found commercially and are in PV lower than 6 meq/kg.

In Vitro Oxidation of Vitamins C and E, Cholesterol, and Thiols in Rat Brain Synaptosomes

G.T. Vatassery*

Research Service and the Geriatric Research Education and Clinical Center (GRECC), VA Medical Center, Minneapolis, Minnesota 55417, and Department of Psychiatry, University of Minnesota, Minneapolis, Minnesota 55455

ABSTRACT: Free radical-induced oxidation of vitamins C, E, sulfhydryl compounds, and cholesterol in brain synaptosomes from Fisher 344 rats was studied. The synaptosomes were incubated at 37°C with 2,2′-azo*bis*-(2-amidinopropane) dihydrochloride (AAPH), which undergoes thermal decomposition to yield free radicals. After incubation, the synaptosomes were sedimented, saponified, and extracted with hexane to isolate tocopherol and cholesterol. Ascorbate and tocopherol were assayed by liquid chromatography, cholesterol by gas chromatography, and total sulfhydryls by spectrophotometry. Under the *in vitro* conditions used in this study, the approximate order for the ease of oxidation of the various compounds was: ascorbate >> tocopherol > sulfhydryl compounds >>> cholesterol. However, tocopherol and sulfhydryl oxidation occurred even before all of the ascorbate had been consumed. Therefore, the fate of a specific antioxidant at a particular cellular location cannot be predicted with complete accuracy using the *in vitro* order for ease of oxidation shown here. Ascorbate may play a major role in protecting brain against oxidative damage because: (i) ascorbate concentration is high in brain, (ii) it can regenerate vitamin E from its radical oxidation product, and (iii) it is one of the first antioxidants to be consumed during oxidative reactions.
Lipids 30, 1007–1013 (1995).

Numerous studies have shown that cellular damage caused by oxidants may play a critical role in the incidence of pathological changes in a variety of diseases including cancer, heart disease, stroke, arthritis, and neurodegenerative diseases (1). Therefore, maintenance of the redox equilibrium of all compartments within a cell is important for prevention of oxidative damage in biological organisms. A number of endogenous compounds are involved in controlling the redox status of a cell. Vitamins C and E, as well as sulfhydryl groups in proteins, and low molecular weight compounds, such as glutathione, are known to play important roles in stabilizing the intra- and extracellular redox environment. As expected, biochemical and functional interactions occur among these antioxidant compounds. In 1968, Tappel (2) postulated that ascorbic acid can regenerate tocopherol from tocopheroxyl radical. The biochemical and nutritional interrelationship between vitamins C and E has been studied in detail by many investigators (see review, Ref. 3). To cite one example, using human platelets as biological cellular substrates, we have shown that ascorbic acid, glutathione, and synthetic antioxidants can prevent the oxidation of vitamin E under *in vitro* conditions (4). Thus, the functional and biochemical interrelationship between vitamins C and E have been well established.

The interactions between vitamins C and E and sulfhydryl compounds also have been studied by some investigators. Wefers and Sies (5) observed that the ascorbate-mediated protection of microsomal membranes is dependent upon the presence of vitamin E in membranes. In addition, they also found that in the presence of glutathione and ascorbate the antioxidant activity of vitamin E was maintained primarily by ascorbate. Willson (6) conducted pulse radiolysis experiments in pure chemical media and proposed that the sequence of reactions involved in the classical NADH oxidase action also may occur even when the intermediates involved are all free radicals. According to this scheme, single atoms of hydrogen are postulated to be shuttled from NADH to RS radical (derived from thiols such as glutathione) to ascorbate anion to tocopheroxyl radical to RO_2 radical (lipid peroxyl radical). This scheme suggests a functional linkage among vitamins C, E, and thiols. As far as we are aware, studies on the interrelationships between these endogenous antioxidants in subcellular fractions from mammalian brain are not available in the literature. This study was conducted to address this deficiency.

The temporal sequence of oxidation of the aforementioned antioxidants in human physiological fluids under *in vitro* conditions has been studied. Frei *et al.* (7) have reported that ascorbate prevents the peroxidation of lipids in human plasma and also spares α-tocopherol and bilirubin. When plasma was exposed to a constant flux of aqueous peroxyl radicals, the temporal order of antioxidant consumption was found to be ascorbate = plasma thiols > bilirubin > urate > α-tocopherol (7). Wayner *et al.* (8) found the relative contributions of plasma antioxidants toward the quenching of free radicals to be urate (35–65%), plasma proteins (10–50%), ascorbate (0–24%), and vitamin E (5–10%). Thus, the individual contributions toward antioxidant activity and the ease of oxida-

tion of the specific antioxidants are interrelated in a complex manner. Again, data on the relative oxidizabilities of these endogenous antioxidants in brain tissue are unavailable in the literature.

It is well known that brain is absolutely dependent upon oxygen supply for normal function. Therefore, biochemical interrelationships among the antioxidants in the brain are of special importance. Despite this, little, if any, information is available in the literature on the subject. Here we present the results of a study of the rate of disappearance of antioxidants such as vitamin E, vitamin C, and sulfhydryl compounds during *in vitro* oxidation of synaptosomes by the synthetic free radical generator 2,2′ azo*bis*-(2-amidinopropane) dihydrochloride (AAPH). The latter compound releases free radicals upon thermal decomposition. The concentrations of membrane cholesterol also were determined during the oxidative reactions.

MATERIALS AND METHODS

Chemicals. All chemicals used were of reagent-grade purity from standard sources. Solvents used for chromatography were high-performance liquid chromatography (HPLC) grade from Burdick and Jackson Laboratories, Inc. (Muskegon, MI). Other special chemicals used were purchased from the following sources: α-tocopherol, α-tocopherolquinone, and malonaldehyde tetramethyl acetal from Kodak Laboratory Chemicals (Rochester, NY); Ficoll (Type 400) from Sigma Chemical Co. (St. Louis, MO); AAPH from Polysciences, Inc. (Warrington, PA). Absolute ethanol was obtained from Midwest Solvents Company (Pekin, IL) and was redistilled prior to use. Most of the reagent-grade chemicals were from Sigma Chemical Co.

Biochemical assays. All experiments were repeated and confirmed with brain samples from separate animals on different days. Data from typical experiments are reported. The concentration of total protein was determined by the Lowry technique as modified by Markwell *et al.* (9). Lipid peroxidation *in vitro* was measured using an assay for thiobarbituric acid reactive substances (TBARS) as proposed by Asakawa and Matsushita (10). In brief, the following solutions were added to the samples: 0.1 mL $FeCl_3 6H_2O$ (0.27%, wt/vol), 1.5 mL glycine–HCl buffer (0.2 M, pH 3.6), 0.1 mL butylated hydroxytoluene (BHT) solution (0.22%, wt/vol in ethanol), 0.1 mL sodium dodecyl sulfate (5%, wt/vol), and 1.5 mL of 0.5% (wt/vol) thiobarbituric acid. The solution was mixed and then heated in a boiling water bath for 15–30 min. The sample tubes were cooled, 1 mL of glacial acetic acid and 2 mL of chloroform added, and the mixture was shaken and then centrifuged. The absorbance of the supernatant at 532 nm was measured. Standard curves for malonaldehyde were prepared using malonaldehyde tetramethyl acetal.

The concentrations of total sulfhydryl groups in the samples were determined by the method of Habeeb (11). The samples were dissolved in 0.08 M sodium phosphate buffer (pH 8.0) containing EDTA (0.5 mg/mL) and sodium dodecyl sulfate (2%) and then treated with 5,5′-dithio*bis* (2-nitrobenzoic acid). The absorbance of the solution was measured at 410 nm. Sulfhydryl concentrations were calculated using glutathione as the standard.

Determination of ascorbate by HPLC. All samples for ascorbate analyses were mixed with a solution containing metaphosphoric acid (5% final concentration, wt/vol), cysteine (0.2%, wt/vol), and EDTA (1 mM) and centrifuged at 1500 × *g* for 10 min. The supernatant containing the ascorbate was removed and kept at −70°C until analysis. Ascorbate was determined by HPLC with electrochemical detection by the method of Margolis (12). The chromatographic conditions were as follows: Aminex HPX 87H cation exchange column 300 × 7.8 mm (Bio-Rad Laboratories, Richmond, CA); eluent 5% acetonitrile in 0.1 M formic acid, flow rate 0.5 mL/min; detector Coulochem model 5100A (ESA Inc., Bedford, MA) with the D2 electrode of the 5011 analytical cell set at 0.6 V. The retention time for ascorbate was 11.2 min.

Chromatography of tocopherol, tocopherolquinone, and cholesterol. The method for determination of tocopherols and quinone by HPLC has been published (13). Briefly, 2-mL ethanol containing 0.025% (wt/vol) BHT and 0.1 mL of 30% (wt/vol) ascorbic acid were pipetted into tubes containing samples for tocopherol analyses. The mixture was saponified at 60°C for 30 min after the addition of 1 mL of 10% potassium hydroxide solution. Tubes were cooled and 2 mL of water was added followed by 2 mL of hexane containing 0.025% (wt/vol) BHT. Tocopherols and quinone were extracted into the hexane phase by vortexing for one minute. The hexane phase was separated out and evaporated under a stream of nitrogen. The residue was redissolved in mobile phase and analyzed by reverse-phase liquid chromatography using the following conditions: column, ultrasphere ODS, 5 microns, 4.6 × 150 mm (Beckman Instruments, Fullerton, CA); mobile phase, methanol/water (94.5:5.5, vol/vol), with 7.5 mM sodium dihydrogen phosphate (final concentration); flow rate, 2.7 mL/min. The tocopherols and tocopherolquinone were detected electrochemically using a Coulochem 5100 A instrument (ESA Inc.) equipped with 5011 analytical cell with detector 1 at a potential of −0.25 V and detector 2 at +0.55 V and 5021 conditioning cell at −0.75 V. The retention times for the various compounds were: tocol (internal standard), 4.2 min; α-tocopherolquinone, 5.2 min; and α-tocopherol 8.5 min.

One portion of the hexane extract was used for cholesterol determination. After evaporation of the solvent, trimethylsilyl ether derivatives of cholesterol were prepared using *bis*(trimethylsilyl)trifluoroacetamide and analyzed by a Hewlett-Packard (Avondale, PA) model 5880 gas chromatograph equipped with a flame-ionization detector and a capillary column (DB1 column, 30 m × 0.324 mm, film thickness 0.1 μm; temperature programming conditions: oven temperature initial 50°C, initial time 3 min, program rate 30°C per min, final value 230°C, second program rate 4°C per min, final temperature 310°C and kept at 310°C for 3 min). Under these conditions, the retention times of the internal standard cholestane and cholesterol were 17.43 and 21.40 min, respectively.

Preparation of subcellular fractions from rat brain. Four-month-old, male Fisher 344 rats (Harlan Sprague Dawley, Indianapolis, IN) were used. The subcellular fractions were isolated from cerebral hemispheres by standard centrifugation methods (14). The Ficoll solution used was purified by dialyzing a 40% (wt/vol) aqueous solution against water for three hours. The final Ficoll concentration was estimated by using a graph relating density and concentration. Brain tissue was homogenized in 10 vol of ice-cold isolation medium containing 0.32 M sucrose, 10 mM HEPES, and 1mM EDTA at pH 7.4, using a glass-glass homogenizer. The homogenate was centrifuged at 1300 × *g* for 3 min and the supernatant saved. The pellet was resuspended in 10 mL of the isolation medium, rehomogenized, and centrifuged at 1300 × *g* for 3 min. The pooled supernatants were centrifuged at 17,000 × *g* for 10 min to get the crude mitochondrial fraction. The resulting pellet was resuspended in 15 mL of isolation medium. Half of this suspension was layered over 11 mL of 7.5% (wt/vol) Ficoll medium, which had been layered over 11 mL of 10% (wt/vol) Ficoll medium. The tubes were centrifuged in a Beckman SW 28 rotor at 99,000 × *g* for 45 min. The fraction at the interface between the two Ficoll solutions was removed, diluted 1:5 (vol/vol) with isolation medium, and centrifuged for 10 min at 17,000 × *g* to isolate the synaptosomes. The purity of the synaptosomal fraction was tested by electron microscopy and also by estimating the activity of the marker enzyme sodium potassium ATPase (15). The activity of the ATPase was usually enriched threefold in synaptosomes compared with the crude homogenate.

Protocol for incubations. Synaptosomes were incubated in a medium (pH 7.4) simulating extracellular fluids or plasma and contained 135 mM NaCl, 5 mM KCl, 1 mM $MgCl_2$, 1 mM $CaCl_2$, 1 mM sodium phosphate, and 10 mM glucose. HEPES (4 mM) also was added for additional buffering capacity. After incubation, the tubes were placed on ice to stop the generation of free radicals. The reaction mixture was then centrifuged for 30 min at 17,000 rpm in a Sorvall SS 34 rotor (35,000 × *g*) to sediment the synaptosomes. The sedimented fractions were then analyzed for various components. In order to test whether the synaptosomal structural integrity is retained during incubations in the presence of AAPH, we estimated the release of lactate dehydrogenase into the medium using the method of Clark and Lai (16). Even when incubated in the presence of 10 mM AAPH for two hours, we could not detect any lactate dehydrogenase in the medium. Nearly all of the activity was accounted for in the pellet, indicating that no activity was lost during incubations.

A brief description of the experimental strategy follows: In every experiment a control sample was mixed with the medium and kept cold. The mixture was centrifuged and analyzed for the various components and the concentrations were used as the original basal levels for each component. The experimental and control tubes were incubated for varying lengths of time. After the lapse of specific times, the experimental and control tubes were removed and processed.

RESULTS

It was mentioned in the Materials and Methods section that incubations with AAPH did not cause release of lactate dehydrogenase into the medium. In addition, we also have found that only small amounts of protein and cholesterol were released into the medium during incubations with AAPH. The amounts released during incubations in the presence of AAPH were not significantly different from control tubes. Tocopherols, sulfhydryls, and ascorbate released into the medium were oxidized by AAPH if the latter was present in the medium. Therefore, it would not be possible to determine whether AAPH treatment results in the release of these compounds into the medium. The situation with ascorbate was even more complicated. Significant and measurable amounts of ascorbate were released into the medium when control synaptosomes were incubated without AAPH. The ascorbate released into the medium always was assayed separately. The total ascorbate was then calculated and the results used in the figures. The small amounts of tocopherol, protein, and cholesterol that were found in the supernatant could be due to the presence of fragments of membranes which were sucked up during the collection of the supernatants using pasteur pipettes. In any case, the observations that additional protein, lactate dehydrogenase, and cholesterol were not released into the medium when synaptosomes were incubated with AAPH suggest that treatment with AAPH did not result in any significant rupturing of synaptosomes.

The normal concentrations of ascorbate, α-tocopherol, total thiols, and cholesterol, as well as α-tocopherolquinone in synaptosomes are given in Table 1. It can be seen that there are substantial differences in the steady-state concentrations of the various antioxidants in the synaptosomes.

Among the different compounds studied, ascorbate and sulfhydryl compounds can be characterized as water-soluble antioxidants. The oxidations of ascorbate and total sulfhydryls in synaptosomal samples incubated in the presence or absence of 2 mM AAPH are shown in Figure 1. The oxidizability of ascorbate was considerably more than that of sulfhydryl compounds. In fact, a substantial percentage of ascorbate was oxidized even during incubations in the absence of AAPH. The oxidations of two lipid-soluble components, α-tocopherol and cholesterol, were compared. The re-

TABLE 1
Concentrations of Ascorbic Acid, Total Thiols, α-Tocopherol, and Cholesterol in Rat Brain Synaptosomes[a]

Component	Concentration (nmol/mg protein)
Ascorbic acid	5.5 ± 0.3[b]
Total thiols	92 ± 3
α-Tocopherol	0.43 ± 0.01
α-Tocopheroluinone	0.0035 ± 0.003
Cholesterol	377 ± 3

[a]Baseline levels of the different compounds were determined in rat brain synaptosomes isolated by centrifugation techniques.
[b]Mean ± SD (n = 3).

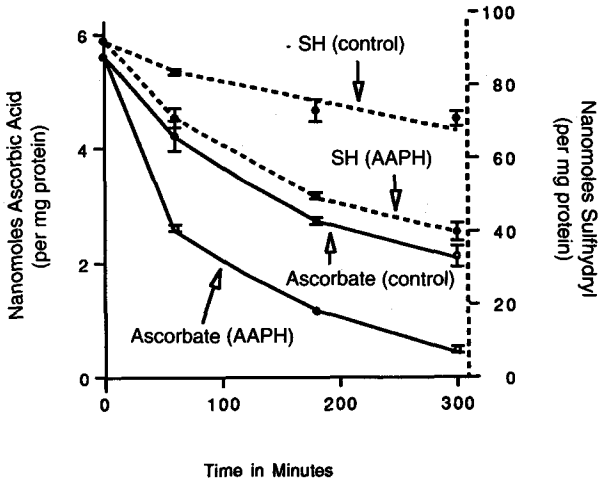

FIG. 1. Oxidation of ascorbic acid and total sulfhydryl compounds in rat brain synaptosomes induced by incubation at 37°C with the free radical generator (2,2′-azo*bis*-(2-amidinopropane) dihydrochloride (AAPH). Synaptosomes were isolated from rat cerebral hemispheres and incubated in isotonic media with 2 mM AAPH, and then ascorbate and sulfhydryl compounds were estimated. The individual incubation tubes contained 500 μg of total protein. Each point represents mean ± SD from quadruplicate assays. SH, thiols.

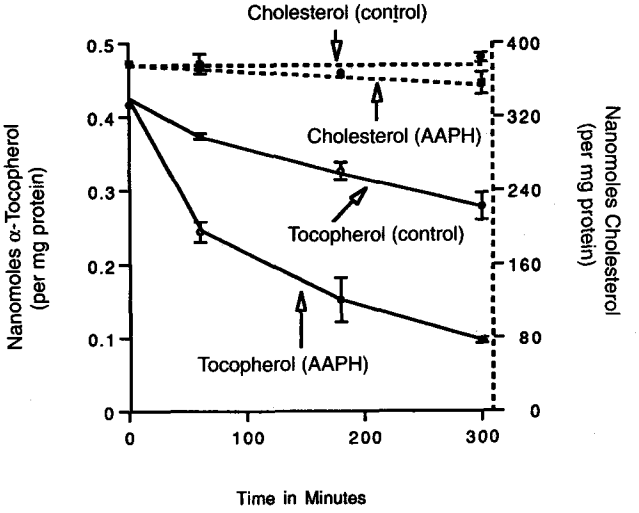

FIG. 2. Oxidation of α-tocopherol and cholesterol in rat brain synaptosomes induced by incubating at 37°C with the free radical generator AAPH. Synaptosomes were isolated from rat cerebral hemispheres and incubated in isotonic media with 2 mM AAPH, and then α-tocopherol and cholesterol concentrations were estimated. The individual incubation tubes contained 500 μg of total protein. Each point represents mean ± SD from quadruplicate assays. Abbreviations as in Figure 1.

sults (Fig. 2) show that cholesterol was very resistant to oxidation.

It can be seen from Figures 1 and 2 that the rates of oxidation of α-tocopherol and sulfhydryl compounds are quite similar. Therefore, the relationship between the rates of oxidation of these two components was studied in a single, separate experiment and the results are shown in Figure 3. The data show that when compared with oxidation of sulfhydryl compounds, a higher percentage of α-tocopherol tends to be oxidized.

Oxidations of the various compounds were followed in all experiments discussed here by determining the declines in concentration of the respective original compound. Tocopherolquinone is produced during the oxidation of tocopherol, and its rate of production was determined. The results (Fig. 4) show that production of α-tocopherolquinone paralleled the oxidation of α-tocopherol. Only a relatively small percent of the α-tocopherol oxidized was converted to tocopherolquinone. For example, at three hours of incubation, the conversion rate was 27.4 and 23% for control and AAPH-treated samples, respectively. The low yields of quinone must be due to the reaction of the tocopheroxyl radical with other substances.

Production of malondialdehyde as determined by the TBARS method is often used as a measure of lipid peroxidation. Even though this method is not very specific under *in vivo* conditions, TBARS do provide useful data on experimental induction of lipid peroxidation under *in vitro* conditions. The results of the measurements of TBARS during oxidation (Fig. 5) show that AAPH treatment is inducing lipid peroxidation. Thus, it can be concluded that incubations of

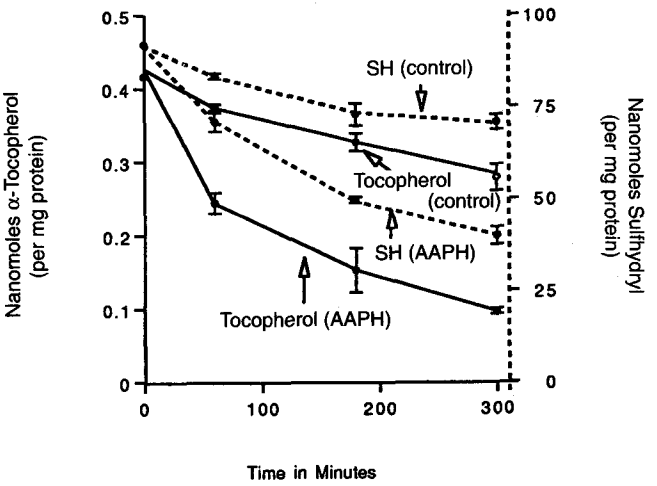

FIG. 3. Oxidation of α-tocopherol and total sulfhydryl compounds in rat brain synaptosomes. The oxidation was induced by incubating synaptosomes from rat cerebral hemispheres in isotonic media with the free radical generator AAPH (2 mM) at 37°C, and then ascorbate and sulfhydryl compounds were estimated. The individual incubation tubes contained 500 mg of total protein. Each point represents mean ± SD from quadruplicate assays. Abbreviations as in Figure 1.

synaptosomes with AAPH induce oxidations for the following reasons: (i) antioxidants such as ascorbate and tocopherol are consumed; (ii) tocopherolquinone, an oxidation product of tocopherol, is formed; and (iii) TBARS are formed.

The concentration of the oxidizing agent AAPH was 2 mM in all of the experiments described previously. The pattern of results obtained with 20 mM is nearly the same. However, if a higher concentration of AAPH (20 mM) is used as an oxi-

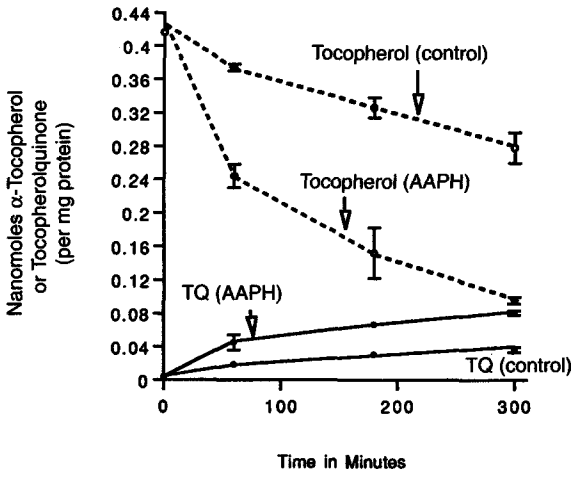

FIG. 4. Production of tocopherolquinone from synaptosomes upon incubations at 37°C with the free radical generator, AAPH. Synaptosomes were isolated from rat cerebral hemispheres and incubated in isotonic media with 2 mM AAPH, and then tocopherolquinone was estimated. The individual incubation tubes contained 500 μg of total protein. Each point represents mean ± SD from quadruplicate assays. Abbreviations as in Figure 1; *TQ, tocopherolquinone.*

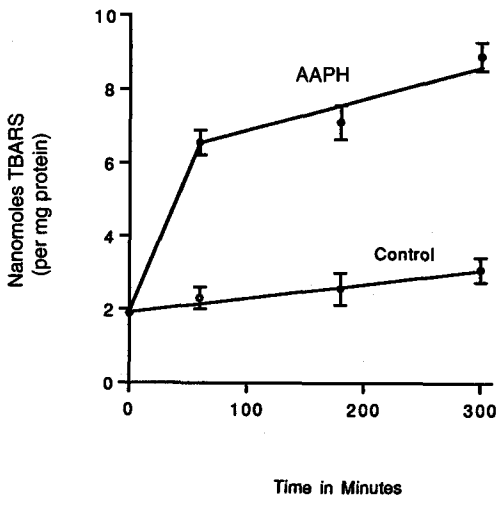

FIG. 5. Production of thiobarbituric acid reactive substances (TBARS) from synaptosomes upon incubations at 37°C with the free radical generator AAPH (2 mM). Synaptosomes were isolated from rat cerebral hemispheres and incubated for varying lengths of time. TBARS were estimated spectrophotometrically. The individual incubation tubes contained 500 mg of total protein. Each point represents mean ± SD from quadruplicate assays. Abbreviations as in Figure 1.

dant, cholesterol is oxidized (Fig. 6). As most of the α-tocopherol in the synaptosomes is oxidized before any of the cholesterol, it can be concluded that vitamin E is performing its role as a lipid-soluble antioxidant in preventing oxidation of cholesterol.

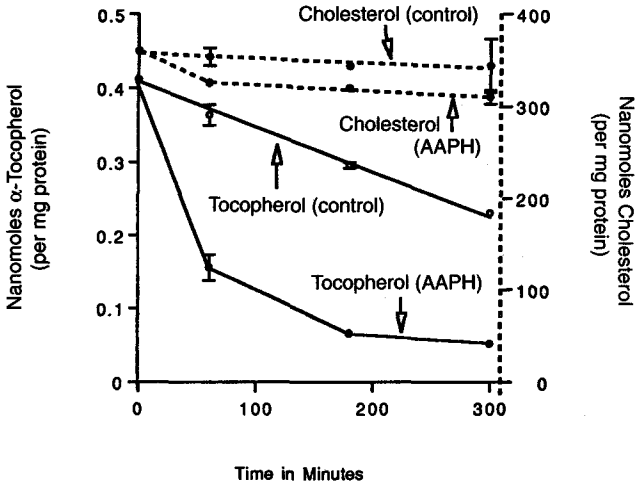

FIG. 6. Oxidations of cholesterol and α-tocopherol in rat brain synaptosomes incubated at 37°C with higher concentrations (20 mM) of the free radical generator, AAPH. Synaptosomes were isolated from rat cerebral hemispheres and incubated in isotonic media with AAPH, and then cholesterol and α-tocopherol were estimated. The individual incubation tubes contained 500 mg of total protein. Each point represents mean ± SD from quadruplicate assays.

DISCUSSION

Some investigators have suggested that compounds such as ascorbate, tocopherol, and thiols are consumed in a specific sequential order when a biological substrate like plasma is oxidized (7) . Even though compounds such as ascorbic acid are much more easily oxidized than sulfhydryl compounds, we did not find a strict sequential order of oxidation of various compounds. For example, tocopherol is being oxidized even when there is ascorbic acid remaining in the fraction. Buettner (17) has reported oxidation–reduction potentials for free radical redox couples derived from endogenous redox-active biological compounds. He has proposed that these redox potentials can be used like the classical listing of redox potentials for compounds in mitochondria, and that their order is based on the one-electron reduction potentials of the various species. Such thermodynamic tables of reactivity are indeed quite useful in predicting and understanding the behavior of the various components in biological systems. However, additional data from experiments with cells or subcellular organelles also are needed to assess the *in vivo* oxidizability of various compounds. Furthermore, as Buettner has pointed out, the redox sequence may also be changed by alterations of equilibria by various events. For example, changes in concentrations of the oxidized or reduced species result not only from removal of a component by diffusion or binding but also from enzymatic processes which replenish or utilize the component. Ultimately all of these factors are capable of changing the order of oxidation predicted solely on the basis of thermodynamic considerations. Nevertheless, a rough guide on the relative order of oxidizability of the various species can be obtained from studies using biological matrices, such as subcellular fractions.

As expected, the steady-state levels of the various compounds in synaptosomes are distinctly different from one another (Table 1). The very low levels of α-tocopherolquinone compared with that of α-tocopherol suggest that synaptosomes were not subjected to oxidation during the isolation procedure. The concentration of total thiols is much higher than those of tocopherol or ascorbate. The majority of total thiols (about 75%) are in proteins (data not shown). It is unknown how much of the protein-bound or unbound thiols are available for antioxidant protection. In addition to the steady-state concentrations of various antioxidants, the intracellular site of oxidation will play an important role in determining which antioxidant is of functional significance at a particular subcellular site.

A report dealing with a comparison of the rates of oxidation of vitamin E, protein sulfhydryls, and production of lipid peroxidation in rat liver microsomes was published by Scheschonka *et al.* (18). One part of their study involved oxidation of microsomes with AAPH. It is interesting to compare the results of Scheschonka *et al.* (18) with our data. In agreement with our data, they also have found that lipid peroxidation was preceded by the loss of most of the α-tocopherol. Their observation that α-tocopherol tended to get oxidized slightly faster than protein sulfhydryls is similar to ours. However, the ease of oxidation of these compounds in human plasma (7) is different from our observations, as well as those of Scheschonka *et al.* (18). One reason for this difference could be that plasma is much more homogeneous than subcellular fractions. In addition, antioxidants occur in specific compartments within the cell or subcellular fractions such as synaptosomes. Furthermore, mechanisms for the regeneration of antioxidants are available in the subcellular fractions and these are also compartmentalized. All of these factors would tend to make the utilization of antioxidants in plasma quite different from those of cells or subcellular structures.

The results from this study show that ascorbate is one of the first antioxidants undergoing substantial oxidation during oxidative stress of synaptosomes (Fig. 1). It is well known that among mammalian organs the brain contains one of the highest concentrations of ascorbic acid (19). Ascorbate is transported actively from blood to cerebrospinal fluid and into brain cells (20). This active transport system maintains the concentration of ascorbate in spinal fluid at a level four times that in plasma (20). In addition to being an antioxidant, ascorbate may serve other functions as well. Ascorbate is known to be a cofactor for several mono- and dioxygenases, and its mode of action is dependent on its ability to keep the metal cofactors, iron and copper, in the required reduced state (21). Thus, the reducing power of ascorbate is intimately involved with its mechanism of action as a cofactor. Ascorbate may play a major role in antioxidant protection of brain for at least three reasons. First, as mentioned previously, ascorbate concentrations are high in brain. Second, ascorbate can regenerate vitamin E, the major chain-breaking lipid-soluble antioxidant in biological membranes (2,3). Third, as shown by our data, ascorbate is one of the first components to be oxidized during challenge from an oxidant.

The interactions between thiols such as glutathione and vitamin E have been studied by a number of investigators. Tirmenstein and Reed (22) found that addition of glutathione to the incubation medium lowered the threshold level of α-tocopherol that was required for inhibition of lipid peroxidation. Studies of injury to hepatocytes caused by the chemicals adriamycin and ethacrynic acid have demonstrated that vitamin E protects against cellular damage by helping to maintain adequate levels of protein thiols (23). In experiments with homogeneous solutions, Niki *et al.* (24) found that glutathione can regenerate vitamin E from α-chromanoxyl radical. However, direct demonstrations of the reduction of tocopheroxyl radical by glutathione or other sulfhydryl compounds in cells or subcellular organelles have not been achieved so far. One report in the literature indicates that the presence of glutathione is associated with lower concentrations of tocopheroxyl radicals at steady state (25). Murphy *et al.* (26) found that protection of protein thiols was diminished in rat liver microsomes lacking vitamin E. Our data show that the oxidation of vitamin E is slightly faster than that of sulfhydryl compounds in synaptosomal fractions. This observation would be consistent with a protective role for vitamin E in preventing sulfhydryl oxidation.

One of the interesting findings in this study is that ascorbate which is confined to the cytoplasmic compartment of the synaptosome is utilized at a rapid rate in synaptosomes exposed to AAPH. This oxidation is induced by adding the water-soluble initiator AAPH into incubation medium. As significant amounts of ascorbate appear in the supernatant during incubation of synaptosomes without AAPH (see the Results section), it is possible that AAPH is oxidizing the ascorbate that is released into the medium. Other possibilities are that free radicals from AAPH cross the plasma membranes to initiate oxidation of ascorbate within the cytoplasm or radicals from AAPH induce an oxidative process in the membrane that is then transmitted to the cytoplasmic compartment within the synaptosomes. Which one of these processes is responsible for the oxidation of ascorbate cannot be decided using data from experiments in this report.

In conclusion, the results of our experiments show that an approximate order of the ease of oxidation of the various compounds within the synaptosomes is as follows: ascorbate >>α-tocopherol>sulfhydryls>>>cholesterol. It should be emphasized that smaller amounts of a component like α-tocopherol can be oxidized even when significant amounts of the more oxidizable ascorbate are still present in the synaptosome. Changes in concentrations of the various antioxidant components *via* removal by diffusion or compartmentation or replenishment by enzymatic means could substantially alter the observed order of oxidation under *in vivo* or *in vitro* conditions. Ascorbate may be one of the first antioxidants involved in the defense against oxidative damage within nerve cells, and α-tocopherol might be playing specific roles within the lipid bilayers of membranes. While assessing the antioxidant protection of the neuron, it is essential to examine the individual contributions as well as the interactions among the

various individual components of the antioxidant protective mechanisms.

ACKNOWLEDGMENTS

This study was supported by research funds from the Department of Veterans Affairs, Washington D.C., and from the National Institutes of Aging grant number RO1 AG 10528. The author wishes to thank W. Ed Smith and Hung T. Quach for expert technical assistance, and Dr. J.C.K. Lai for many helpful discussions.

Biodiscrimination of α-Tocopherol Stereoisomers During Intestinal Absorption

Chikako Kiyose[a,*], Riho Muramatsu[a], Yoko Fujiyama-Fujiwara[a], Tadahiko Ueda[b] and Osamu Igarashi[a]

[a]Institute of Environmental Science for Human Life, Ochanomizu University, Bukyo-ku, Tokyo 112, Japan and [b]Tokyo Metropolitan Research Laboratory of Public Health, Shijuku-ku Tokyo 169, Japan

ABSTRACT: Synthetic α-tocopherol (α-Toc) contains equal amounts of eight different stereoisomers, and the four stereoisomers with the 2*R* configuration are generally more active than their corresponding 2*S*-isomers. We investigated the biodiscrimination of α-Toc stereoisomers during intestinal absorption *in situ* and *in vitro*. Intestinal absorption of α-Toc stereoisomers was examined *in situ* in vitamin E-deficient rats with cannulated thoracic ducts. We found that the ratios of α-Toc stereoisomers in lymph of the all-*rac*-α-Toc group were the same as the administered α-Toc stereoisomers, and 2*R*-isomers occupied approximately 50% of absorbed α-Toc. The uptake of α-Toc stereoisomers also was measured using Caco-2 cells cultured on filter membranes. The concentration of *RRR*-α-Toc in Caco-2 cells was not significantly different from that of *SRR*-α-Toc. Therefore, the discrimination of α-Toc stereoisomers does not occur during absorption in small intestine, suggesting the liver as a source for the biodiscrimination.
Lipids 30, 1015–1018 (1995).

Synthetic α-tocopherol (α-Toc) contains equal amounts of eight different stereoisomers of α-Toc arising from three asymmetric carbons (2-position in the chroman ring and 4′- and 8′-position in side chain tail). Biological activities of all the stereoisomers of α-Toc were determined by rat resorption–gestation test as follows: *RRR* = 100%, *RRS* = 90%, *RSS* = 73%, *SSS* = 60%, *RSR* = 57%, *SRS* = 37%, *SRR* = 31%, *SSR* = 21% (1). This difference in biological activities in all the stereoisomers would suggest that their discrimination occurs in the absorption, uptake, and metabolism of each stereoisomer.

In 1987, Ingold and co-workers (2,3) had synthesized deuterium-substituted *RRR*- and *SRR*-α-Toc, in which the substituted numbers of deuterium were varied to distinguish them and to elucidate their absorption, transport, and biodiscrimination of *RRR*- and *SRR*-α-Toc. According to their results, the ratio of *RRR*-α-Toc to *SRR*-α-Toc in every tissue (except the liver) was higher than 1.0, suggesting that biodiscrimination occurs in the liver. In these studies, they used a gas chromatography/mass spectrometry-selected ion monitoring method for determining the isomers, because the simpler and less expensive analytical methods had not yet been developed.

In 1993, Ueda *et al.* (4) developed a new chiral high-performance liquid chromatography (HPLC) method to separate eight stereoisomers of α-Toc acetate into four peaks—the first peak was composed of the four 2*R*-isomers, the second peak of *SSS*- and *SSR*-α-Toc, the third peak of *SRR*-α-Toc, and the fourth peak of *SRS*-α-Toc. This HPLC method enabled us to resolve all-*rac*-α-Toc into 2*R*-isomers and three peaks of 2*S*-isomers. *RRR*- and *SRR*-α-Toc are completely separated into two peaks. This method is therefore convenient for elucidating the absorption, transport, and distribution of stereoisomers of α-Toc, especially in animal experiments.

We reported the distribution of α-Toc stereoisomers in the tissues of rats fed diets containing different levels of all-*rac*-α-Toc acetate using this HPLC method. The concentrations of 2*R*-isomers of α-Toc in the blood and tissues of the rats in the all-*rac*-α-Toc acetate groups were significantly higher than the concentration of the 2*S*-isomers. In most tissues, the level of 2*S*-isomers was in order of *SRS* > (*SSS* + *SSR*)/2 > *SRR* (5,6).

Absorption of α-Toc occurs in the presence of bile acids and fatty acids in small intestine. After uptake into intestinal mucosal cells, α-Toc is secreted into chylomicrons in lymph (3,7,8). Chylomicrons are catabolized in the circulation by the lipoprotein lipase, which formed the chylomicron remnants. After uptake of chylomicron remnants by the liver, α-Toc could be metabolized or secreted into very low density lipoprotein (VLDL). Traber *et al.* (9) elucidated the lipoprotein transport and biodiscrimination of two deuterium-labeled stereoisomers (*RRR*- and *SRR*-α-Toc) of α-Toc in healthy human subjects and concluded that no discrimination between the *RRR*- and *SRR*-α-Toc was observed during absorption and chylomicron secretion.

In the present study, we have investigated the biodiscrimination of α-Toc stereoisomers during intestinal absorption. Intestinal absorption of α-Toc stereoisomers was measured in rats with cannulated thoracic ducts, and the uptake of α-Toc stereoisomers was measured using the Caco-2 cells cultured on filter membranes as *in vitro* model.

MATERIALS AND METHODS

Materials. *RRR*-α-Toc acetate, all-*rac* (2*RS*,4′*RS*,8′*RS*)-α-Toc acetate and 2-*ambo*(2*RS*,4′*R*,8′*R*)-α-Tocs (free and acetate) were kindly donated by Eisai Co. Ltd. (Tokyo, Japan).

Animals. Male Sprague-Dawley strain rats (3 weeks of age) were purchased from Nippon Clea Co. (Tokyo, Japan). They were initially fed a commercial diet (CE-2; Nippon Clea Co.) for one week to allow them to adapt to the new environment. These rats were then fed a vitamin E-deficient diet (AIN-76; Eisai Co.) for eight weeks. The vitamin E-deficient diet was composed of 23.68% sucrose, 23.68% glucose, 18.95% vitamin-free casein, 14.21% corn starch, 4.74% filter paper, 3.32% mineral mixture, 0.95% vitamin mixture, 0.28% DL-methionine, 0.19% choline bitartrate, and 10% stripped corn oil. Animals were housed individually in cages at 22°C and 55% humidity, with a 12 h light/dark cycle. The feed and water were supplied *ad libitum.*

Lymphatic cannulation method. Lymphatic cannulation was carried out as described by Ikeda *et al.* (10). Under nembutal anesthesia, vitamin E-deficient rats were subjected to cannulation of the left thoracic lymphatic channel, and an indwelling catheter was placed in the stomach. Normal osmotic solution containing 139 mM glucose and 85 mM NaCl was infused continuously until the end of lymph collection at a rate of 3 mL/h through the gastric tube. After surgery, animals were placed in restraining cages (in the light) and allowed to drink water *ad libitum.* The next morning, after the collection of lymph for 2 h (blank lymph), each animal was administered 3 mL of a test emulsion through the gastric tube and the lymph was collected for a further 24 h. The 3 mL test emulsion contained 200 mg of sodium taurocholate, 50 mg of fatty acid-free albumin, and 200 mg of triolein with 100 mg of *RRR*-α-Toc acetate, all-*rac*-α-Toc acetate, or 2-*ambo*-α-Toc, respectively. The emulsions were prepared by sonication. The lymph was collected in a tube containing EDTA at 3 h intervals during the first 9 h after administration of the test emulsion, and then collected continuously from 9 to 24 h.

Preparation of Caco-2 cells. In recent years there has emerged a cell line that originates from human colon cancer cells, Caco-2. This cell line was established by Fogh *et al.* (11). Caco-2 cells were purchased from American Type Culture Collection (ATCC, Rockville, MD), and were grown in plastic flasks at 37°C in air and 5% CO_2 in minimum essential medium containing 10% fetal bovine serum. For subculture the medium was removed, and the cells were detached from the culture flasks with 0.25% trypsin and 0.02% EDTA. Cells were then suspended and seeded onto filters in dish (split ratio 1:2). After confluency cells, 10 mL of the culture medium containing free 2-*ambo*-α-Toc (final concentration 50 μM) dissolved in 10% bovine serum albumin solution was added to the dish (ϕ100 mm). After 6- and 24-h incubation, cells were washed by phosphate-buffered saline, scraped, and sonicated. Protein was measured by the method of Lowry *et al.* (12).

Measurement of α-Toc stereoisomers. The composition of α-Toc stereoisomers in lymph and cells was analyzed to modify the method of Ueda *et al.* (4). Ethanolic pyrogallol solution (6%) was added to each sample. After adding 60% KOH solution to each of the sample tubes, the contents were saponified with occasional shaking at 70°C for 30 min. After cooling in ice water, 1% NaCl solution was added to the saponified medium, and the medium was shaken vigorously with 10% ethyl acetate in hexane for 1 min. The mixture was centrifuged at 3000 rpm for 5 min. The upper layer was collected to extract all stereoisomers of α-Toc. Extracted α-Toc was acetylated by the dry pyridine and acetic anhydride at 50°C for 15 min. After cooling to room temperature, 1% NaCl solution was added and the whole medium was extracted with hexane. Then, hexane layer was collected and evaporated under a stream of nitrogen gas. The residue was dissolved in 98% methanol for the determination by HPLC. Analysis of the acetate of α-Toc stereoisomers was performed by HPLC. The HPLC instrumentation consisted of an LC Module 1 from Waters (Japan Millipore Ltd., Tokyo, Japan) and SK-25 column oven (Nihon Seimitsu Kagaku, Co., Ltd., Tokyo, Japan). The analysis of α-Toc stereoisomers was performed at 38°C using a Chiralpack OP(+) column (250 × 4.6 mm i.d., Daicel Chem. Ind., Tokyo, Japan). The mobile phase was methanol/water (98:2, vol/vol) at a flow rate of 0.48 mL/min. The detection wavelength for α-Toc acetate was 284 nm.

RESULTS

Biodiscrimination between α-Toc stereoisomers during lymphatic transport in rats. The lymphatic flow for 24 h was comparable in the three groups (Table 1). Lymphatic absorption of *RRR*-, all-*rac*-, and 2-*ambo*-α-Toc is shown in Table 2. Absorptions of each of the three forms of vitamin E were approximately 4–9% of that administered for 24 h, and differences between each groups were not significant. Ratios of α-Toc stereoisomers in lymph of all-*rac*-α-Toc group were equivalent, 2*R*-isomers were represented as approximately 50% of absorbed α-Toc (Table 3). Among 2*S*-isomers, amounts of (*SSS*- + *SSR*-)/2, *SRR*- and *SRS*-α-Toc were almost equal.

Moreover, the ratio of *RRR*-/*SRR*-α-Toc in lymph of the 2-*ambo*-α-Toc group was approximately 1.0 (Table 4). Therefore, biodiscrimination of α-Toc stereoisomers did not occur

during absorption in small intestine or during their release into the lymph.

Biodiscrimination of α-Toc stereoisomers in Caco-2 cells. Caco-2 cells were incubated with 2-*ambo*-α-Toc at 37°C for 6 or 24 h. Table 5 shows the concentrations of *RRR*- and *SRR*-α-Toc in Caco-2 cells. The concentration of *RRR*-α-Toc in Caco-2 cells was not significantly different from that of *SRR*-α-Toc. The ratio of *RRR*- and *SRR*-α-Toc in Caco-2 cells at 6 and 24 h was approximately 1:1. Therefore, no discrimination occurred during uptake of 2-*ambo*-α-Toc into Caco-2 cells.

DISCUSSION

We investigated the biodiscrimination of α-Toc stereoisomers during intestinal absorption *in situ* and *in vitro*. By cannulating the thoracic lymph duct, it is possible to obtain a more accurate measurement of the absorbed amount of α-Toc. Traber *et al.* (13) have reported that the absorption of α-Toc was approximately 65% when α-Toc acetate was administered during a slow continuous infusion of soybean oil into the duodenum in rats. In addition, Sugano *et al.* (14) have reported on the intestinal absorption of α-, β-, γ-, and δ-tocotrienol and α-toc in rats with cannulated thoracic ducts. The absorption of these compounds was 10–20% of that administered over 24 h. Absorption of α-Toc-3 was about two times higher than that of α-Toc. According to our results, the absorption of *RRR*-, all-*rac*-, and 2-*ambo*-α-Toc acetate were 4–9% of that administered over 24 h. The lower absorption of α-Toc observed in this study compared to that of Traber *et al.* (13) or Sugano (14) may be due to different methods of administering α-Toc, differences in the length of time the animals had to recover, and differences in the level of dose administered. Among α-Toc stereoisomers, no discrimination was observed during intestinal absorption *in situ*.

The use of cultured Caco-2 cells could allow investigation in detail on the absorptive process of α-Toc. We measured the discrimination of α-Toc stereoisomers using Caco-2 cells cultured on filters. The amounts of *RRR*- and *SRR*-α-Toc were almost equivalent for 6- or 24-h incubation on filters. These results suggested that the discrimination of α-Toc stereoisomers does not occur in small intestine *in vitro*.

We reported that biodiscrimination between α-Toc stereoisomers in rats occurs following intravenous administration (15). According to these results, we presumed that the intravenously administered 2*R*- and 2*S*-isomers were easily transported into the liver from the plasma, the 2*R*-isomers being preferentially released from the liver into the blood, whereas the 2*S*-isomers remained in the liver. Also, Sato *et al.* (16) have reported that two types of purified rat tocopherol-transfer proteins discriminated predominantly against α-Toc from among the α-, β-, γ-, and δ-Toc analogous during transfer between liposomes and mitochondria. Biodiscrimination does not take place in the intestine but at some other site, most likely the liver. Kayden and Traber (17) suggested that this tocopherol-transfer protein could preferentially transport *RRR*-α-Toc to the endoplasmic reticulum for secretion into VLDL during assembly.

In summary, α-Toc stereoisomers are taken up into the intestinal cells without the discrimination, then are secreted equally into chylomicrons and transported to the plasma. In the future, we plan to focus on the tocopherol-transfer pro-

teins in liver as for the biodiscrimination of α-Toc stereoisomers.

ACKNOWLEDGMENTS

We thank Dr. Kunio Ikeda, Kyusyu University School of Agriculture, for leading the lymphatic cannulation method, and Mie Kasuga for her assistance in the preparation of Caco-2 cell line.

Sesame Seed and Its Lignans Produce Marked Enhancement of Vitamin E Activity in Rats Fed a Low α-Tocopherol Diet

Kanae Yamashita*, Yoshie Iizuka, Tomoko Imai and Mitsuo Namiki

Department of Food and Nutrition, School of Life Studies, Sugiyama Jogakuen University, Nagoya 464, Japan

ABSTRACT: Three series of experiments demonstrated that sesame seed and its lignans cause significant elevation of α-tocopherol content in rats. In Experiment 1, 20% sesame seed (with a negligible amount of α-tocopherol) supplementing 10 (low), 50 (normal), or 250 (high) mg/kg α-tocopherol diets (protein and fat concentrations in diets were adjusted to 200 and 110 g/kg, respectively) all caused a significant increase of α-tocopherol in the blood and tissue of rats. In Experiment 2, groups of rats were fed five different diets: a vitamin E-free control diet, a low α-tocopherol diet, and three low α-tocopherol diets supplemented with 5, 10, and 15% sesame seed. Changes in lipid peroxides in liver, red blood cell hemolysis, and pyruvate kinase activity, as indices of vitamin E deficiency, were examined. These indices were high in the low α-tocopherol diet, whereas supplementation with even 5% sesame seed suppressed these indices completely and caused a significant increase of α-tocopherol content in the plasma and liver. In Experiment 3, two diets containing sesame lignan (sesaminol or sesamin) and low α-tocopherol were tested. Results in both of the sesame lignan-fed groups were comparable to those observed in the sesame seed-fed groups as shown in Experiment 2. These experiments indicate that sesame seed lignans enhance vitamin E activity in rats fed a low α-tocopherol diet and cause a marked increase in α-tocopherol concentration in the blood and tissue of rats fed an α-tocopherol-containing diet with sesame seed or its lignans.

Lipids 30, 1019–1028 (1995).

Sesame seed has long been used as a health food to prevent aging (1,2). However, there have been few detailed analytical studies clarifying such effects. Sesame seed is not only rich in oil (about 50%) and protein (about 20%), but also in characteristic lignans (such as sesamin and sesamolin). Sesame oil is known empirically to be highly stable against oxidative deterioration in cooking. It was found that its highly antioxidative properties appear to be related to its characteristic lignan components (3,4).

We examined the effect of sesame seed with highly antioxidative properties and as yet unclarified characteristics of lignans in senescence by using senescence-accelerated mouse developed by Takeda *et al.* (5) and have found that the advancement of senescence was apparently suppressed by the long-term feeding of sesame seed (6–8). It is to be noted that sesame seed contains only γ-tocopherol but the α-tocopherol content is negligible. γ-Tocopherol has exhibited a stronger antioxidative activity than α-tocopherol in *in vitro* tests, but its vitamin E activity is estimated to be only 6–16% that of α-tocopherol (9), indicating that sesame seed is likely a poor source of vitamin E. In this regard, we have recently found that sesame seed lignans and γ-tocopherol act synergistically to produce almost the same level of vitamin E activity as α-tocopherol in rats (10). This interesting synergism was observed in the treatment without α-tocopherol supplementation. However, previous studies have shown that α- and γ-tocopherol are both absorbed similarly from the intestine but that α-tocopherol is preferentially bound by the transporting protein in the liver, and most γ-tocopherol is excreted through the bile without combining with the transporting protein (11–15). Therefore, it appears to be of value to clarify whether or not sesame seed lignans act synergistically with α-tocopherol to produce higher vitamin E activity in rats fed a low α-tocopherol-containing diet. We found an enhanced vitamin E activity and marked increase of α-tocopherol concentration in the blood and tissue of rats fed a low α-tocopherol-containing diet with sesame seed or its lignans.

MATERIALS AND METHODS

*Materials.*The white sesame seed used (donated by the Shinsei Co., Aichi, Japan) was thoroughly washed, dried, and ground finely in a mixer. The seed from the same batch was used throughout this investigation. α-Tocopherol, γ-tocopherol, and vitamin E homologues used for biochemical analysis, as well as vitamin E-stripped corn oil, were gifts of the Eisai Co. (Tokyo, Japan). A vitamin E-free vitamin mixture (AIN-76A), including choline bitartrate and a mineral mixture, were made according to AIN-76 formulation (16) by Nihon Nosan Kogyo (Yokohama, Japan). Sesaminol (30% ethanol solution; 76.7% purity as solid) and sesamin (crystals, mixture of sesamin and episesamin) were donated by Takemoto Oil & Fat Co. (Aichi, Japan). Solvents used for chromatography were high-performance liquid chromatography (HPLC) grade from Katayama Chemicals Co., Ltd.

(Osaka, Japan). Thiobarbituric acid was purchased from Merck (Darmstadt, Germany). Reagents for the measurement of pyruvate kinase activity (EC 2.7.1.40) were all purchased from Boehringer Mannheim Yamanouchi (Tokyo, Japan). All other chemicals were of analytical grade.

Animals and diets. Three-week-old male Wistar strain rats (Japan SLC Inc., Shizuoka, Japan) were housed individually in stainless-steel wire-mesh cages at 24.5°C and 55% humidity, with a 12-h light/dark cycle. Rats were maintained in accordance with the Guidelines for Animal Experimentation of Nagoya University. Rats were allowed free access to a non-purified diet for 3–5 d and given an experimental diet for 8 wk. The concentration of tocopherol in diets was confirmed by assay immediately after formulation. Diets were stored at −20°C until used.

In Experiment 1, effects of sesame seed on α- and γ-tocopherol concentrations in plasma and tissue were evaluated in rats fed diets containing low (10 mg/kg diet), normal (50 mg/kg diet), or high (250 mg/kg diet) α-tocopherol with or without 20% sesame seed. Thirty rats were equally divided into six groups and fed the diets shown in Table 1 for 8 wk. In the sesame seed-containing diets, the final concentrations of protein, fat, and carbohydate were adjusted to almost the same as in each control diet by reducing the content of casein, stripped corn oil, and corn starch, estimated to be the concentrations of protein (20 g/100 g), fat (50 g/100 g), and residue (30 g/100 g, sugars and dietary fiber, mostly) present in sesame seed (17). Further, fat concentration was adjusted to 110 g/kg diet because 10 g stripped corn oil containing α-tocopherol was added to the 20% sesame seed-containing diets. After overnight food deprivation, the concentration of α- and γ-tocopherol in the plasma, red blood cells, liver, and kidney were determined.

In Experiment 2, we examined the concentrations of α- and γ-tocopherol and the vitamin E status in rats fed low α-tocopherol (10 mg/kg diet) diets supplemented with 0, 5, 10, or 15% sesame seed, and compared the vitamin E status with the control vitamin E-free diet. The composition of diets in Experiments 2 and 3 is shown in Table 2. Thirty rats were divided into five groups and fed the respective diets for 8 wk.

In Experiment 3, we examined the synergistic effect of sesame seed lignans with α-tocopherol by using two kinds of sesame seed lignan: sesaminol and sesamin (each 2 g/kg diet) instead of the sesame seed used in Experiment 2 (Table 2). Sesame seed contains substantial amounts of lignans such as sesamin and sesamolin (Fig. 1), but contains little sesaminol. Commercial sesame oil is of two types, roasted oil and raw salad oil. Raw salad oil is rich in sesaminol, which is formed from sesamolin during the refining process of the extracted oil (3,4). Sesaminol is a strong antioxidant in *in vitro* tests but sesamin is not. Thirty rats were subjected to five groups fed the following diets for 8 wk: (i) vitamin E-free, (ii) low α-tocopherol-containing (10 mg/kg diet), (iii) (low α-tocopherol + sesaminol)-containing, (iv) (low α-tocopherol + sesamin)-containing, or (v) normal α-tocopherol-containing (50 mg/kg diet) diet. In Experiments 2 and 3, we determined the lipid peroxidation in liver, oxidative hemolysis, plasma pyruvate kinase activity, and α- and γ-tocopherol concentrations in plasma and liver as indices of vitamin E status.

After overnight food deprivation, rats were anesthetized with Nembutal (pentobarbital Na), and blood samples were drawn from the heart using heparinized needles and syringes. The liver and kidneys were excised after the liver was perfused with physiological saline. A hemolysis test of red blood cells was conducted immediately after collection of blood samples. Plasma was prepared, and measurements of plasma pyruvate kinase activity were made within 7 h after killing the rats. The red blood cells were washed three times with isotonic 0.008 mol/L phosphate buffered saline. The final hematocrit of red blood cells was made up to about 50%. The remaining plasma, red blood cells, liver, and kidney were kept at −80°C until analysis.

Analysis of samples. Analytical procedures of samples were essentially the same as described by Yamashita *et al.* (10).

[c]In sesame-seed containing diets, stripped corn oil was reduced depending on the sasame seed lipid concentration, which was calculated to be 50 g/100 g.
[d]Roasted white sesame seed.
[e]α-Tocopherol (Toc) was added dissolving in stripped corn oil.
[f]γ-Toc in sesame seed. Sesame seed contain 23.5 mg/100 g γ-Toc and negligible amounts of α-Toc.
[g]30% Ethanol solution, 76.7% purity as solid.
[h]Crystals, mixture of sesamin and episesamin.

Lipid peroxides in the blood plasma were determined as thiobarbituric acid reacting substances by the fluorometric method of Yagi (18), and those in the liver and kidney by the thiobarbituric acid colorimetric method of Ohkawa *et al.* (19). α-Tocopherol and γ-tocopherol concentrations in the plasma, red blood cell, liver, and kidney were analyzed by HPLC according to the method of Ueda and Igarashi (20). Red blood cell suspension (0.4 mL) and 20% (wt/vol) homogenate of either liver or kidney (1 mL) were pipetted into 10 mL centrifuge tubes with caps and 6% ethanolic pyrogallol (1 mL) and an ethanolic solution of 2,2,5,7,8-pentamethyl-6-chromanol as an internal standard (1 mL) were added. A 60% KOH solution (0.2 mL) was added and saponified at 70°C for 30 min. After adding 1% NaCl solution (4.5 mL), the whole media were extracted with 10% ethylacetate in *n*-hexane (3 mL). After centrifuging, a portion of the hexane layer was evaporated, redissolved in *n*-hexane (200 μL), and injected into the HPLC system. Plasma was treated without saponification.

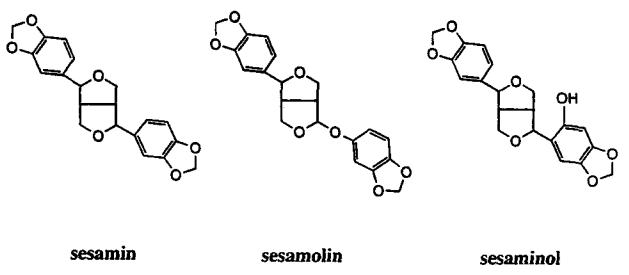

FIG. 1. Sesame seed lignans (sesamin and sesamolin) and related antioxidative compounds (sesaminol). The concentrations of these compounds are as follows: sesamin, 2.5–5.0 mg/g in sesame seed; sesamolin, 1.5–3.0 mg/g in sesame seed; sesaminol 5 μg/g in sesame seed; and 0.5–1.0 mg/g in refined raw sesame oil.

Oxidative hemolysis of red blood cells was measured using dialuric acid (21). Plasma pyruvate kinase activity was determined according to the method described by Gutmann and Bernt (22).

Statistical analysis. Data are expressed as means ± SEM. Experiment 1 was analyzed by two-way analysis of variance (ANOVA) to compare the effect of feeding sesame seed and the effect of dietary α-tocopherol concentration. Subsequently Student's *t*-test was performed to compare the effect

with and without sesame seed. Experiments 2 and 3 were analyzed by one-way ANOVA. When one-way ANOVA revealed $P < 0.05$, the data were further analyzed using Duncan's multiple comparison test (23). Differences were considered statistically significant at $P < 0.05$.

RESULTS

The diets exhibited no significant effect on the animal growth, but we observed significantly greater liver weights in rats fed sesame seed or sesame lignans in Experiments 1, 2, and 3. In Experiment 1, the liver weights in 20% sesame seed-fed groups were significantly higher in comparison with the respective control, 116% in low α-tocopherol, 109% normal α-tocopherol, and 126% high α-tocopherol-fed groups. The relative liver weight in Experiments 2 and 3 is shown in Figure 2. Differences in liver weight corresponded to sesame seed intake (between 5 and 15%). Although both sesamin and sesaminol caused significantly greater liver weight, it was found that sesamin showed a greater effect. The plasma concentrations of α- and γ-tocopherol in Experiment 1 are shown in Figure 3, indicating the level of α-tocopherol was higher in parallel with the dietary concentration of α-tocopherol. Further, sesame seed caused a significant increase in α-tocopherol in the plasma of rats fed diets with low, normal, and high concentrations of α-tocopherol. On the other hand, γ-tocopherol was detected only in the low α-tocopherol + sesame seed-fed groups, but not detected in the normal, as well as high, α-tocopherol-supplemented sesame seed-fed groups. This was invariably observed despite the fact that sesame seed contains about 25 mg/100 g γ-tocopherol and a negligible amount of α-tocopherol. The concentrations of α- and γ-tocopherol in the red blood cells, liver, and kidney in Experiment 1 are shown in Table 3. The concentrations of α-tocopherol in the liver and kidney were low as compared with values reported by other workers (24,25). Sesame seed caused a significantly higher concentration of α-tocopherol in the plasma and tissue of rats fed diets with three α-tocopherol levels (low, normal, or high), as seen in Figure 3. The γ-tocopherol concentrations in the red blood cells, liver, and kidney were detected only in the low α-tocopherol + sesame seed-fed group, and were not detected in the normal and high α-tocopherol with sesame seed fed groups, other than a very small quantity in the liver of rats fed the normal amount of α-tocopherol with sesame seed. In the low α-tocopherol + sesame seed-fed group, the combined concentrations of α-tocopherol and γ-tocopherol in the blood and tissue were almost the same as the concentrations of α-tocopherol in the normal α-tocopherol-fed group. These results may indicate that the supplementation of sesame seed caused an improvement of the vitamin E status of the low α-tocopherol-fed group.

In Experiment 2, we examined whether or not the vitamin E status of the low α-tocopherol-fed group was improved by sesame seed supplementation. We observed that the sesame seed-supplemented groups showed extremely low peroxide concentrations in liver, and even a 5% supplementation with sesame seed to the low α-tocopherol-containing diet almost completely suppressed the high concentration of lipid peroxide in rats fed the low α-tocopherol-containing diet (Fig. 4). Hemolysis and pyruvate kinase activity showed results paralleling peroxide concentrations. The results of Table 4 show that the low α-tocopherol-fed group gave a low concentration

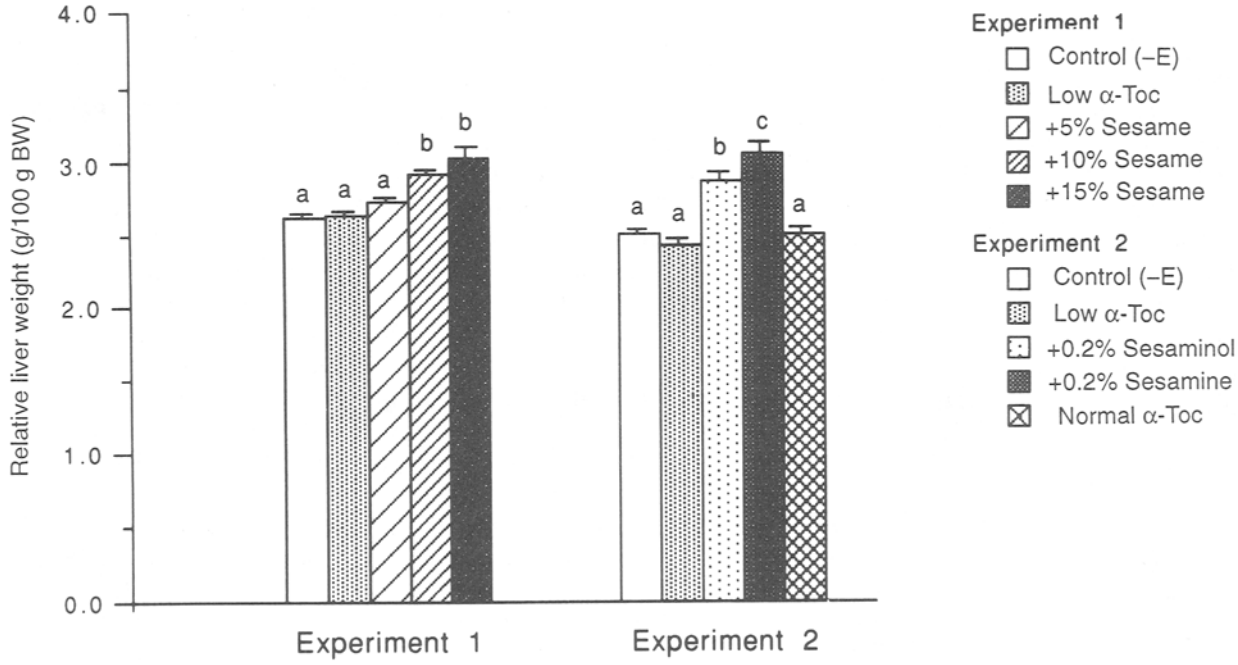

FIG. 2. Effect of sesame seed and its lignans on relative liver weight in rats fed low α-tocopherol (α-Toc) (10 mg/kg diet) diet supplemented with 5, 10, and 15% sesame seed (Experiment 2) or in rats fed low α-tocopherol (10 mg/kg diet) diet supplemented with 2 g sesaminol or sesamin/kg diet (Experiment 3) for 8 wk. Values are means ± SEM, n = 6. Values with different superscripts are significantly different, $P < 0.05$.

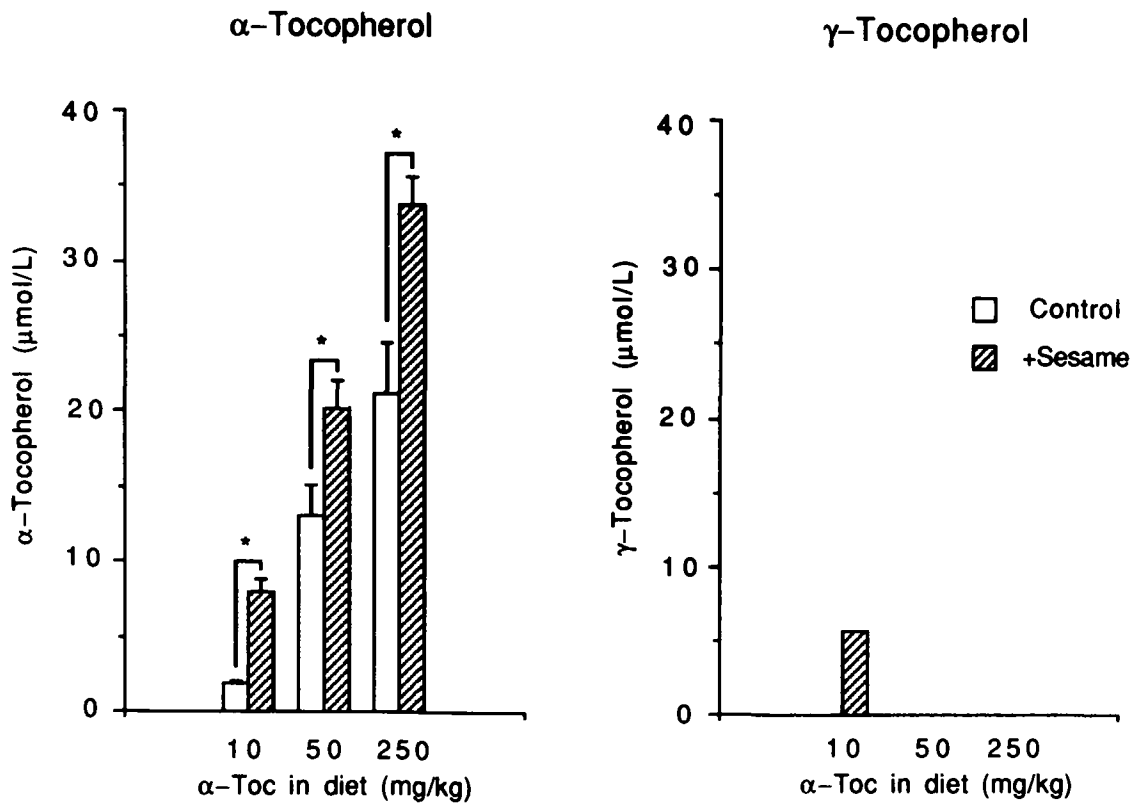

FIG. 3. Plasma α- and γ-tocopherol concentrations in rats fed low (10 mg/kg), normal (50 mg/kg), and high (250 mg/kg) α-tocopherol-containing diets with or without 20% sesame seed. Values are means ± SEM, n = 5. Data were analyzed by two-way analysis of variance. α- and γ-Tocopherol concentrations in plasma were significantly ($P < 0.01$) different among groups fed different concentrations of dietary α-tocopherol, between groups with and without sesame seed, and in their interactions; * shows significantly different, $P < 0.01$ by Student's *t*-test. See Figure 2 for abbreviation.

of α-tocopherol, though it was greater than in the vitamin E-free group; a 5% supplementation of sesame seed (negligible amounts of α-tocopherol) to the low α-tocopherol-containing diet caused significantly higher levels of α-tocopherol and γ-tocopherol. The effect to increase tocopherol level was marked with the 10% supplemented group, and no further increase was observed with the 15% supplemented group except in the α-tocopherol concentration in the liver. The total concentration of α-tocopherol and γ-tocopherol in the plasma and liver in the 10% sesame seed-supplemented group were

found to be nearly the same as that of α-tocopherol in the normal α-tocopherol-fed group in Experiment 1. Although we examined the supplementation effects of sesame seed using a 20% level in Experiment 1, supplementation with 5–10% sesame seed was shown to be sufficient to improve the deficient status of vitamin E in the low α-tocopherol-fed group as shown in Experiment 2.

Experiment 3 was performed using sesaminol and sesamin instead of the sesame seed used in Experiment 2. For the group fed the vitamin E-free diet and the low α-tocopherol-fed group, the results were shown to be essentially the same as in Experiment 2. As shown in Figure 5, hemolysis was nearly absent in the low α-tocopherol + sesaminol-, low α-tocopherol + sesamin-, and normal α-tocopherol-fed groups, in contrast to the high level found in the low α-tocopherol-fed group. Plasma and liver α-tocopherol concentrations in Experiment 3 are shown in Figure 6. They were low in the low α-tocopherol-fed group but slightly higher than in the vitamin E-free group. In the low α-tocopherol + sesaminol- and low α-tocopherol + sesamin-fed groups, significantly greater concentrations of α-tocopherol were found than in the low α-tocopherol diet with neither sesaminol or sesamin, although the concentration was higher in the sesaminol group than in the sesamin group, and lower in both than in the normal α-tocopherol-fed group. Thus it appears evident that both sesaminol and sesamin exhibit the effect of raising α-tocopherol concentrations *in vivo*, and that the antioxidant sesaminol is superior to sesamin (nonantioxidant).

DISCUSSION

We have demonstrated previously that rats fed a vitamin E-free diet supplemented with sesame seed, which contains γ-tocopherol only, exhibited a marked suppression of lipid peroxidation along with an increased γ-tocopherol concentra-

TABLE 4
Effect of Sesame Seed on Plasma and Liver Concentrations of α- and γ-Tocopherol in Rats Fed Low α-Tocopherol Diets Supplemented with 5, 10, and 15% Sesame Seed[a]

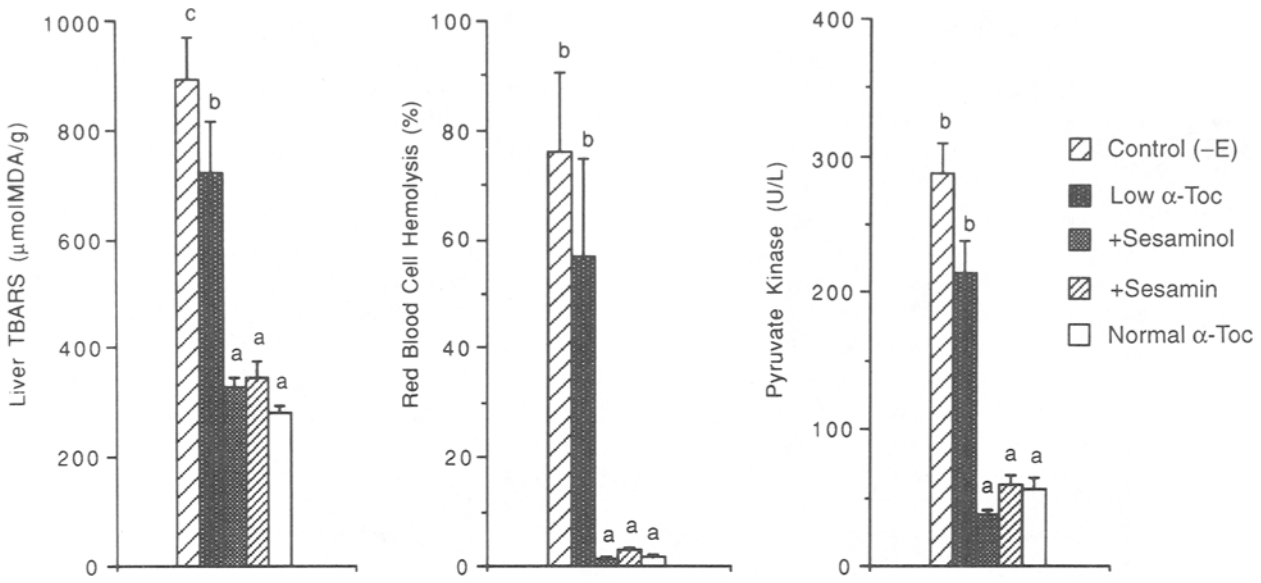

FIG. 5. Synergistic effect of sesame lignans with α-tocopherol *on* lipid peroxides in liver, red blood cell hemolysis, and plasma pyruvate kinase activity in rats fed low α-tocopherol (10 mg/kg diet) diet supplemented with 2 g sesaminol or sesamin/kg diet for 8 wk. Values are means ± SEM, n = 6. Values with different superscripts are significantly different, $P < 0.05$. See Figures 2 and 5 for abbreviations.

tion in the plasma and liver. This indicates that γ-tocopherol in the sesame seed exerts vitamin E activity equal to that of α-tocopherol through a synergistic interaction with sesame seed lignans (10). In the present work, we found that a low α-tocopherol-containing diet (10 mg/kg diet) was able to induce nearly the same vitamin E-deficient status as a γ-tocopherol-containing diet (50 mg/kg diet), and addition of sesame seed or sesame lignans to the low α-tocopherol-containing diet markedly suppressed lipid peroxidation, red blood cell hemolysis, and plasma pyruvate kinase activities, but caused an elevated level of α-tocopherol in blood and tissue (Figs. 4–6; Table 4). We believe that a marked increase of α-tocopherol concentration by sesame seed or sesame lignans *in vivo* is a significant finding since α-tocopherol is thought to be the most important component among its eight homologues in human nutrition (12) and an enhancement of vitamin E activity by other food components has not been reported except in the case of vitamin C (24,26,27), as will be discussed below.

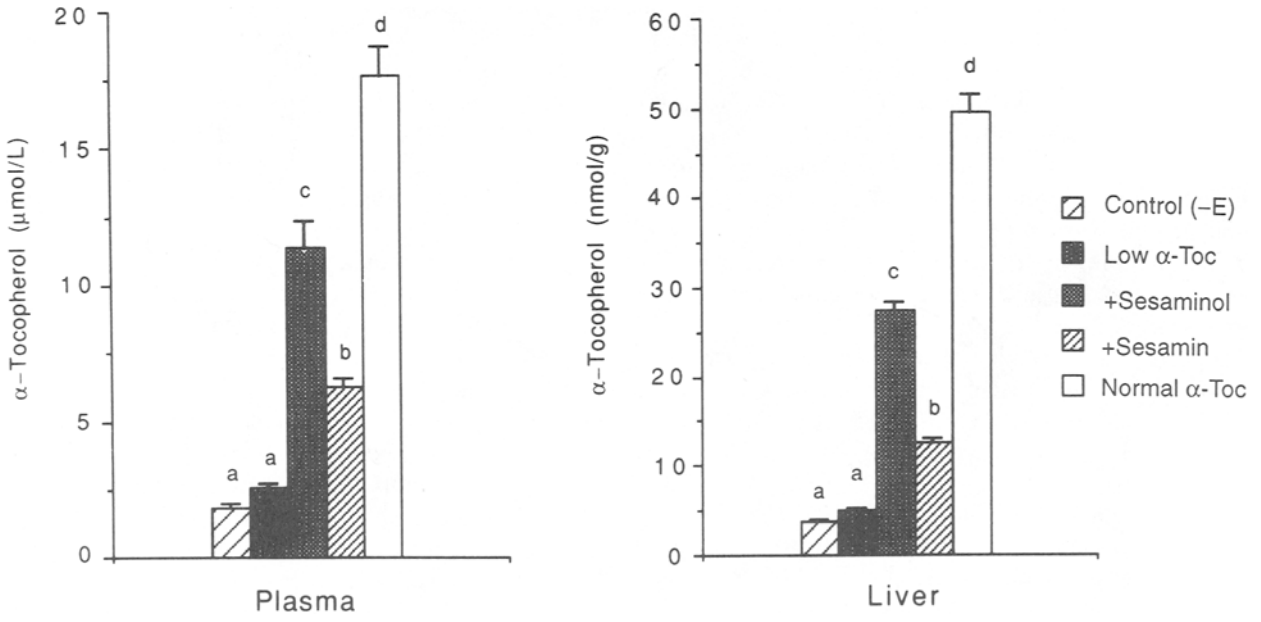

FIG. 6. Synergistic effect of sesame lignans with α-tocopherol on the plasma and liver concentrations of α-tocopherol in rats fed low α-tocopherol diet supplemented with 2 g sesaminol or sesamin/kg diet for 8 wk. Values are means ± SEM, n = 6. Values with different superscripts are significantly different, $P < 0.05$. See Figure 2 for abbreviation.

Concerning the mechanism of this synergistic effect of sesame lignans with α-tocopherol, three possible hypotheses can be put forward: (i) sesame lignan may enhance the binding activity of α-tocopherol with tocopherol-binding protein, (ii) sesame lignan may regenerate α-tocopherol from its oxidized product, and (iii) sesame lignan is a more effective antioxidant than α-tocopherol, protecting the α-tocopherol from oxidation.

Among eight structural forms of vitamin E, it is well known that α-tocopherol is the one found in the highest concentrations in human plasma and tissues, showing the highest biological activities. γ-Tocopherol is most abundant in the common edible vegetable oils, but its biological activity is estimated to be only 6 to 15% that of α-tocopherol. According to recent studies using various forms of vitamin E, it is shown that there is no discrimination between α- and γ-tocopherols during absorption, but following uptake by the liver only RRR-α-tocopherol is preferentially bound to tocopherol-binding protein and secreted in nascent very low density lipoprotein (VLDL) (12). Thus, it is suggested that discrimination between forms of tocopherol may occur on the hepatic tocopherol-binding protein. This was detected only in liver cytosol in rats (15). In our previous experiment, we observed that rats fed γ-tocopherol (50 mg/kg diet) showed very low concentrations of γ-tocopherol in plasma and liver, but it was increased significantly by the addition of sesame lignans to a diet containing the same amount of γ-tocopherol. These results indicate that the binding activity of γ-tocopherol to tocopherol-binding protein is weak, as previously reported by Sato *et al.* (13) and others (14,28,29). However, a possibility cannot be excluded that the presence of sesame lignans may enhance the binding activity of γ-tocopherol to the binding protein.

In Experiment 1, we found higher concentrations of α-tocopherol in the blood and tissues of rats fed diets containing α-tocopherol with sesame seed comparisons in rats fed diets containing only α-tocopherol. Interestingly γ-tocopherol was only detectable in the low α-tocopherol + sesame seed-fed group, but not in the normal or high α-tocopherol + sesame seed groups, despite the fact that the rats had ingested an equal amount of γ-tocopherol. These results may indicate that discrimination between α- and γ-tocopherols exists in rats fed the 20% sesame seed diets supplemented with α-tocopherol. As shown in Table 3, a very low concentration of γ-tocopherol was found only in the liver of rats fed the diet containing the normal α-tocopherol with sesame seed, but not in blood or other tissues. This indicates that γ-tocopherol barely exists in liver following uptake, but it cannot be transported to nascent VLDL due to discrimination of α- and γ-tocopherols by tocopherol-binding protein. These results suggest that the binding activity of tocopherol isomers with tocopherol-binding protein is strongly enhanced by the sesame lignans; but discrimination between α- and γ-tocopherols is given the highest priority.

The second and third possibilities involve antioxidative activity of sesame lignans. In this respect, sesaminol was shown to possess strong antioxidative activity both *in vitro* and *in vivo*. Sesaminol is mainly found in refined raw salad oil but only in small amounts in the sesame seed. Recently Katsuzaki *et al.* (30) reported that there are three new glucosides of sesaminol in defatted sesame cake, and antioxidative activity being generated by treatment with β-glucosidase. It is thus necessary to further investigate whether or not sesamolin, the second major lignan in sesame seed, can possibly be converted to sesaminol *in vivo*.

It is generally agreed that sesamin is not an antioxidant *in vitro*, but recently Asami *et al.* (31) reported that sesamin can be broken down and converted to an antioxidant in liver. Furthermore, we have observed that sesamin is able to almost completely suppress the high level of lipid peroxides in liver caused by a vitamin E-free diet (Yamashita, K., Iizuka, Y., and Namiki, M., unpublished observation). This suggests that sesamin may act as an antioxidant in the liver. The finding that sesaminol, a stronger antioxidant, is superior to sesamin may support these possibilities. There have been several reports indicating the synergistic effects of vitamins E and C (24,26,27), and it has been suggested that antioxidant vitamin C can regenerate vitamin E *in vivo* (24). Recently, we have compared the tocopherol-elevating effect of sesame lignans with that of vitamin C in rats fed a low α-tocopherol diet and found that the former exerted several times stronger activities in comparison to the latter (Yamashita, K., Iizuka, Y., and Namiki, M., unpublished observation: vitamin C increased α-tocopherol level from 1.60 ± 0.14 to 2.31 ± 0.09 μmol/L plasma, from 4.7 ± 0.26 to 7.66 ± 0.41 nmol/g wet liver compared to sesaminol from 2.56 ± 0.14 to 11.40 ± 1.02 μmol/L plasma, from 4.88 ± 0.32 to 27.44 ± 1.02 nmol/g wet liver). However, it is still not yet clear whether a marked increase in α-tocopherol concentration in rats fed diets containing α-tocopherol with sesame lignan can be explained by its possible regeneration from α-tocopherol radical by sesame lignan. Clarification of an antioxidative property of sesaminol is judged to be of great importance in its effect of increasing tocopherol content *in vivo*, because it is a strong antioxidant, and is superior to sesamin in increasing tocopherol levels.

Sesame seed or sesame lignans did not affect the body weight gain, but increased the liver weight. At present, however, it is not yet known whether or not the enlargement of liver weight caused by either sesame seed or its lignans is in favor of animal health, although Sugano *et al.* (32) and Hirose *et al.* (33) also have observed liver enlargement by feeding with sesamin. They reported neither specific histological changes nor accumulation of lipids detectable in the liver, and that the activities of glutamic-oxaloacetic transaminase (GOT EC 2.6.1.1) and glutamic-pyruvic transaminase (GPT EC 2.6.1.2) in serum and drug metabolizing enzymes in the liver all remained unchanged. Recently, several investigations have been reported concerning the physiological function of sesame lignans. For example, Shimizu *et al.* (34) reported that sesamin is a specific inhibitor of Δ5 desaturase, which catalyzes the desaturation of dihomo-γ-linolenic acid (20:3n-6) to yield arachidonic acid. In addition, sesamin exerted a

hypocholesterolemic activity through the inhibition of cholesterol absorption and synthesis (32,33). Furthermore, Akimoto *et al.* (35) reported that sesamin exhibits protective activities in liver injured by continuous inhalation of ethanol or by intraperitoneal administration of carbon tetrachloride. It is still not known whether these observations have any relevance to the enhancing effect on α-tocopherol levels we herewith report in this investigation.

In the present experiment, we have found that sesame seed and sesame lignans cause a high α-tocopherol concentration in plasma and tissues in rats. Based on the results of this investigation, we propose that one possible rationale for the consideration of sesame seed as a health food may exist in its enhancing effect on vitamin E activity. However, more thorough experiments are needed to clarify the nature of interactions between sesame lignans and tocopherol-binding protein.

ABSTRACT: Microcystin-LR is a liver tumor promoter in the okadaic acid class, a group of potent inhibitors of protein phosphatases 1 and 2A. Because of inhibition of protein phosphatases, microcystin-LR induces hyperphosphorylation of cellular proteins, including cytoskeletal proteins—cytokeratins 8 and 18—and causes morphological changes in mouse hepatocytes in primary culture. We studied the effects of carotenoids to antagonize microcystin-LR-induced morphological changes in hepatocytes. β-Carotene (100 nM to 100 μM) suppressed the morphological changes induced by 100 nM microcystin-LR in a dose-dependent manner. Other carotenoids tested exerted similar suppressive effects, although retinoids, such as all-*trans* retinol, all-*trans* retinoic acid, and 9-*cis* retinoic acid, were only weakly suppressive. The relative potency of the suppression correlated significantly with the number of conjugated double bonds in the *trans* configuration. β-Carotene strongly suppressed the hyperphosphorylation of cellular proteins induced by microcystin-LR without significant changes in the basal phosphorylation level. Other antioxidants, such as α-tocopherol, did not protect the cells against microcystin-LR. Taken together, the antagonistic effects of carotenoids against microcystin-LR are difficult to explain by their antioxidant or provitamin A activities. Suppression of the hyperphosphorylation of cellular proteins may be a novel mechanism by which carotenoids inhibit tumor promotion.
Lipids 30, 1029–1034 (1995).

Anticarcinogenic effects of carotenoids have been reported in studies using animal and cellular models and in several human intervention trials of carotenoids for cancer prevention (1–13). The anticarcinogenic actions of carotenoids are, at present, explained mainly by their antioxidative activities (as quenchers of singlet oxygen and free radical scavengers) or by their activities as provitamin A (1,2). However, some nonprovitamin A carotenoids also protect against carcinogenesis, and the radical scavenger activity of carotenoids does not always correlate with their anticarcinogenic effect (4,5,14). Therefore, biological mechanisms other than provitamin A activities or antioxidative effects may be operative in the suppression of cancer development by carotenoids.

In the process of multiple-step carcinogenesis, the promotion phase is the longest and can be retarded or even reversed by repeated applications of anti-tumor agents. Recently, okadaic acid class tumor promoters were reported to promote tumor formation in various organs by potently inhibiting protein phosphatases 1 and 2A (15–17). Microcystin-LR, a hepatotoxic compound produced by a planktonic cyanobacteria, is a liver tumor promoter of the okadaic acid class (17). Microcystin-LR strongly inhibits the activities of protein phosphatases 1 and 2A in hepatocytes (18), and subsequently induces various responses, such as protein hyperphosphorylation, morphological changes of hepatocytes (18), and tumor promotion (17). Schwartz *et al.* (19–21) reported that β-carotene induced expression of the cdc2 kinase (one of a cell cycle regulator), cyclins A and D, wild-type p53 and stress proteins; and also repressed expression of mutant p53, c-*Fos*, and *Raf*-1. They also found reduction of glutathione-S-transferase activity, superoxide dismutase activity, and the level of nonprotein sulfhydryls in the tumor cells by β-carotene (19,22). These modifications of intracellular signals by β-carotene may correlate with significant alterations in signal transductions, such as protein phosphorylation, in the tumor cells.

In the present study, we investigated whether carotenoids suppress the activities of okadaic acid class tumor promoters and found that carotenoids antagonized the morphological changes in mouse hepatocytes in primary culture induced by microcystin-LR. We also found that β-carotene suppressed the hyperphosphorylation of proteins induced by microcystin-LR in the hepatocytes.

EXPERIMENTAL PROCEDURES

Chemicals. A *dunariella* preparation containing (% by weight) 2% β-carotene, 0.3% 9-*cis* β-carotene (purity 86%, mainly contaminated with all-*trans* β-carotene), 0.2% astaxanthin, and 0.2% sulfated astaxanthin in liposomes was obtained from Kyowa Hakko Ltd. (Tokyo, Japan). The liposomes contained 61% glycerol, 5% esterified glycerol, 1%

lecithin, and 48 μM α-tocopherol. The *dunariella* β-carotene consisted of 50% all-*trans* and 50% 9-*cis* forms. The mean diameter of the mixed micelles in the emulsion was approximately 0.1 μm. All-*trans* β-carotene, lutein, lycopene, retinol, and all-*trans* retinoic acid were purchased from Sigma Chemical Co. (St. Louis, MO). 9-*Cis* retinoic acid was obtained from Kuraray Co. Ltd. (Okayama, Japan). Fucoxanthin and canthaxanthin were obtained from Roche Japan Ltd. (Tokyo, Japan). Microcystin-LR was a generous gift from Dr. Hirota Fujiki, Saitama Cancer Center Research Institute (Saitama, Japan). Okadaic acid was purchased from Wako Pure Chemical Co. (Osaka, Japan). ^{32}P-Orthophosphate was obtained from Amersham Co. (Buckinghamshire, United Kingdom).

Preparation of mouse primary culture hepatocytes. Eight-week-old male Balb/c mice were obtained from Chubu Kagaku Shizai Co. (Nagoya, Japan). Hepatocytes were isolated from mouse liver digested with collagenase; 1×10^5 cells/500 μL were inoculated on collagen-precoated 24-well plastic dishes to evaluate morphological changes, and 1×10^6 cells/mL were inoculated on collagen pretreated 6-well plastic dishes to analyze the phosphorylation of cellular proteins (18). The hepatocytes were cultured in William's E medium containing 5% fetal calf serum, 1 nM insulin, and 1 nM dexamethasone at 37°C in an atmosphere containing 5% CO_2.

Morphological observation of primary culture hepatocytes. After overnight culture of mouse hepatocytes, 100 nM microcystin-LR or 70 nM okadaic acid was added to the media and followed immediately by adding a test carotenoid or retinoid. The concentration of test compounds was as high as 50 μM for emulsified β-carotene, astaxanthin, or sulfated astaxanthin, and as high as 10 μM for other carotenoids or retinoids. Nonemulsified compounds were dissolved in a 1:1 solution of dimethylsulfoxide (DMSO) and tetrahydrofuran (THF). DMSO alone was added as a negative tumor promoter control, and DMSO/THF (1:1, vol/vol) or vehicle emulsion was added for each test. The final fractional volumes of the emulsion and DMSO + THF in the media were below 1 and 0.8%, respectively. After 3 h of incubation, a microphotograph of cells in each well was taken. Approximately 200 hepatocytes were counted on the microphotograph. The rate of suppression of morphological changes (%) was calculated by using the control being treated only with vehicle (100%) and treated only with tumor promoter (0%).

Measurement of phosphorylation of cellular proteins in primary culture hepatocytes. Mouse hepatocytes were preincubated in primary culture overnight in a phosphate-free Dulbecco's modified Eagle's medium with 1.85 MBq/mL ^{32}P-orthophosphate in each well. Then, 100 nM microcystin-LR was added, and incubation was continued for another 3 h in the presence or absence of β-carotene. The cells were scraped and solubilized in 200 μL of lysis buffer consisting of 50 mM 4-(2-hydroxyethyl)-l-piperazinediethanesulfonic acid (pH 7.4), 250 mM NaCl, 0.5% Nonidet P-40, and 1 mM phenylmethanesulfonyl fluoride (23). The lysate (20 μL) was subjected to 10% SDS–polyacrylamide gel electrophoresis according to the method of Laemmli (24), and phosphorylated proteins were detected by autoradiography. Densitometric measurement of each autoradiograph was performed using an image analyzer (GT6000; Epson, Tokyo, Japan).

Indirect immunofluorescence analysis of cytokeratin 18. Primary culture mouse hepatocytes (5×10^4 cells/0.5 mL/chamber) were plated in a 4-chamber glass slide (Nunc Inc., Naperville, IL) and treated with 100 nM microcystin-LR with or without 10 μM β-carotene for 2 h. After fixation with cooled acetone at −20°C, the cells were incubated with anti-cytokeratin 18 antibody (ImnoMAb™CK#18.04; IBL Research Products Co., Cambridge, MA) for 1 h at 30°C. After incubating for 30 min with an FTTC-conjugated second antibody, the slides were examined with a fluorescence microscope (Axioskop MC 100; Karl Zeiss, Okerkochen, Germany) (25).

RESULTS

Suppression of morphological changes of primary culture mouse hepatocytes. Within 3 h of incubation, morphological changes were observed in approximately 60% of the hepato-

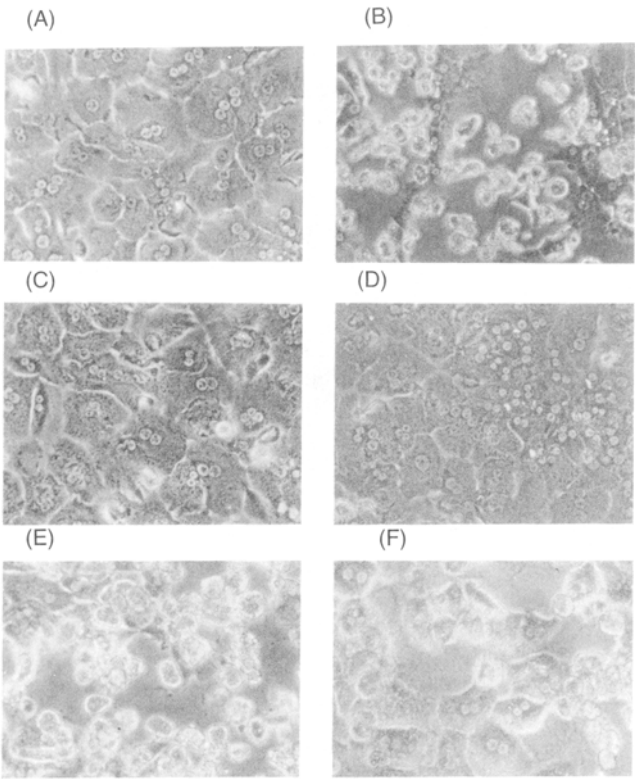

FIG. 1. β-Carotene or lutein protected the mouse primary culture hepatocytes from microcystin-LR-induced morphological changes (×152). After 3 h of incubation, morphological changes were observed in the hepatocytes treated with 100 nM microcystin-LR (B) or 70 nM okadaic acid (E). However, 10 μM β-carotene (C) and 10 μM lutein (D) with microcystin-LR or 10 μM β-carotene with okadaic acid (F) showed reduction of the morphological changes of the cells. (A) control (vehicle alone); (B) 100 nM microcystin-LR; (C) 10 μM β-carotene and 100 nM microcystin-LR; (D) 10 μM lutein and 100 nM microcystin-LR; (E) 70 nM okadaic acid; and (F) 10 μM β-carotene and 70 nM okadaic acid.

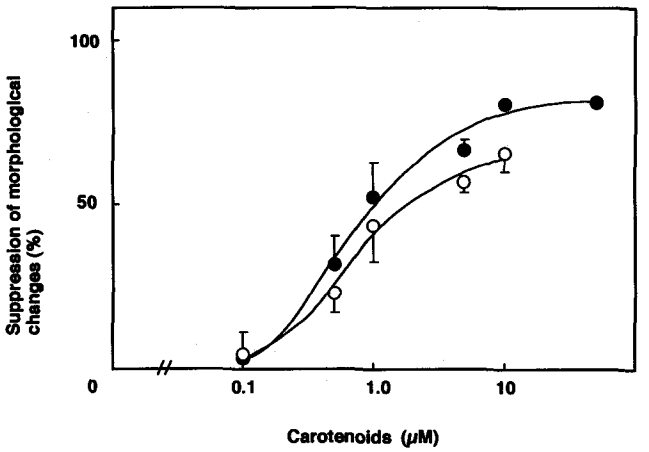

FIG. 2. Concentration dependence of the suppressive effect of carotenoids on microcystin-LR-induced morphological changes of mouse primary culture hepatocytes. The rates of suppression of morphological changes of hepatocytes induced by 100 nM microcystin-LR and the control were taken as 0 and 100%, respectively. Data represent the means ± SD of four determinations; ●, β-carotene, ○, lutein.

cytes treated with 100 nM microcystin-LR (Fig. 1B). Ten μM β-carotene or lutein reduced the effect of microcystin-LR on the morphology of the hepatocytes (Fig. 1C, 1D). β-Carotene also suppressed okadaic acid-induced morphological changes in the hepatocytes, although the effect was weaker than that on microcystin-LR-induced morphological changes (Fig. 1E, 1F). The vehicles of β-carotene or lutein alone did not have any effect on morphological changes of microcystin-LR-treated or nontreated hepatocytes (Fig. 1A).

β-Carotene and lutein dose-dependently suppressed microcystin-LR-induced morphological changes at concentrations from 100 nM to 10 μM (Fig. 2). When the extent of suppression of the morphologically changed hepatocytes, which were treated with 100 nM microcystin-LR alone and with solvent alone, were 0 and 100%, respectively, the 50% inhibitory doses (ID_{50}) of β-carotene and lutein were 0.9 and 2.1 μM, respectively (Fig. 2).

Other carotenoids also were observed to protect against morphological changes of the hepatocytes. With the suppressive activity of 10 μM *dunariella* β-carotene considered as 1.0, the relative potencies of suppression by other carotenoids and retinoids were calculated using the following equation: relative potency of suppression = [extent (%) of suppression of morphological changes with 10 μM carotenoid or retinoid]/[extent (%) of suppression of morphological changes with 10 μM *dunariella* β-carotene]. A significant correlation was observed between the number of the *trans*-conjugated double bonds of the compounds and the relative suppression of the morphological changes (Fig. 3). For example, the relative potencies of all-*trans* β-carotene, canthaxanthin, astaxanthin, and sulfated astaxanthin, which have 13 double bonds, were 1.07–1.17, and those of 9-*cis* β-carotene, which have nine conjugated double bonds in *trans* form, were 0.73, and lutein and α-carotene, which have ten conjugated double bonds, were 0.64–0.81.

Phosphorylation of cellular proteins in primary culture hepatocytes. Treatment with microcystin-LR for 3 h increased the phosphorylation of several proteins in the hepatocytes (Fig. 4, lane 2), and β-carotene particularly reduced the hyperphosphorylation of 55 and 49 kDa proteins (Fig. 4, lanes 3–5). However, hepatocytes treated with as much as 100 μM β-carotene alone did not show detectable changes in the level of protein phosphorylation as compared to the control (Fig. 4, lane 6). Densitometry of the 55 and 49 kDa bands revealed that β-carotene dose-dependently suppressed the hyperphos-

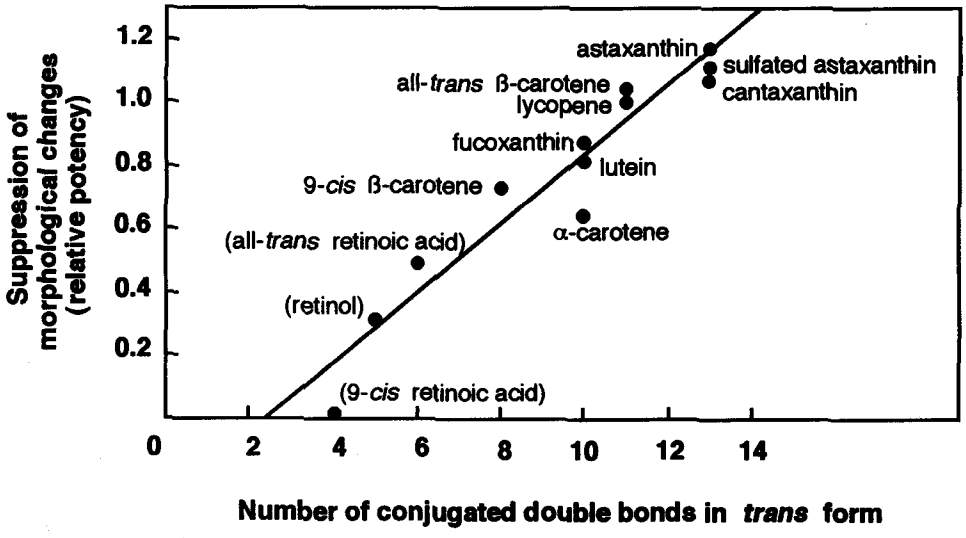

FIG. 3. Relative potency of suppression of 100 nM microcystin-LR-induced morphological changes of primary culture mouse hepatocytes by 10 μM carotenoids. See text for the definition of relative potency of suppression of morphological changes. The X axis represents the number of the *trans*-conjugated double bonds in each compound. Data represent the means of three determinations: $Y = 0.1086 \times -0.2583$, $r = 0.9589$, $P < 0.001$.

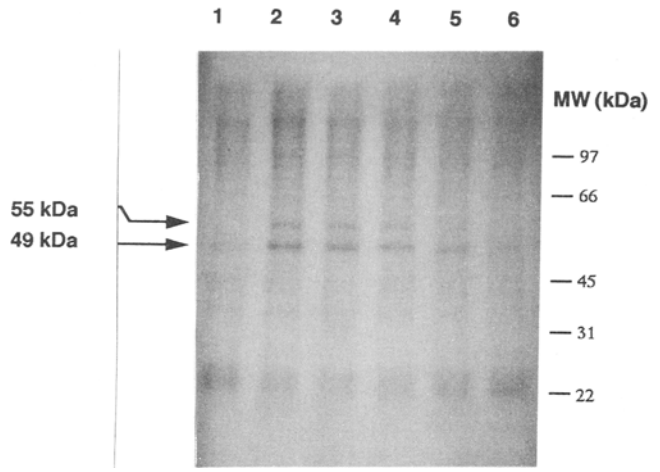

FIG. 4. Suppression by β-carotene of microcystin-LR-induced hyperphosphorylation of cellular proteins in primary cultured mouse hepatocytes. ^{32}P-labelled cellular proteins were separated by SDS–polyacrylamide gel electrophoresis and detected by autoradiography. Lane 1, control; lane 2, 100 nM microcystin-LR; lanes 3, 4, and 5, 1 μM, 10 μM, and 100 μM β-carotene, respectively, with 100 nM microcystin-LR; lane 6, 100 μM β-carotene alone.

phorylation of these proteins induced by 100 nM microcystin-LR (Fig. 5).

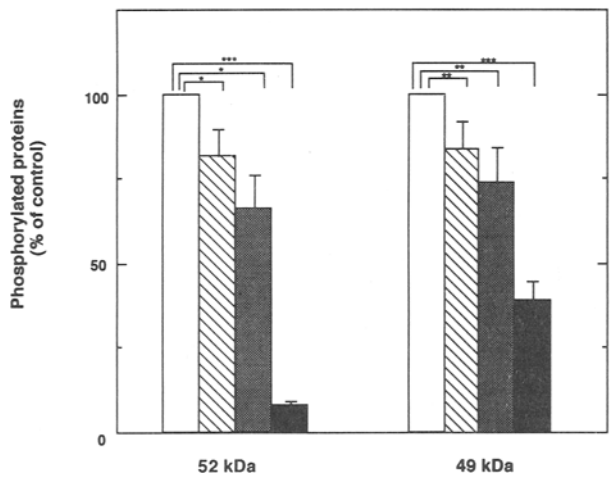

FIG. 5. Densitometric demonstration of the suppressive effect of β-carotene on hyperphosphorylation of 49 and 55 kDa proteins induced by microcystin-LR in primary cultured mouse hepatocytes. Density of the 100 nM microcystin-LR phosphorylated 49 and 54 kDa protein bands is 100% (white bar). One μM (striped bar), 10 μM (gray bar), 100 μM (black bar) β-carotene cotreated with 100 nM microcystin-LR showed reduction of the hyperphosphorylations of 49 and 55 kDa proteins dose-dependently. White bar, 100 nM microcystin-LR; striped bar, 1 μM β-carotene with 100 nM microcystin-LR; gray bar, 10 μM β-carotene with 100 nM microcystin-LR; and black bar, 100 μM β-carotene with 100 nM microcystin-LR. Data represent the means ± SD of four determinants: $^{*}P < 0.05$, $^{**}P < 0.01$, $^{***}P < 0.001$.

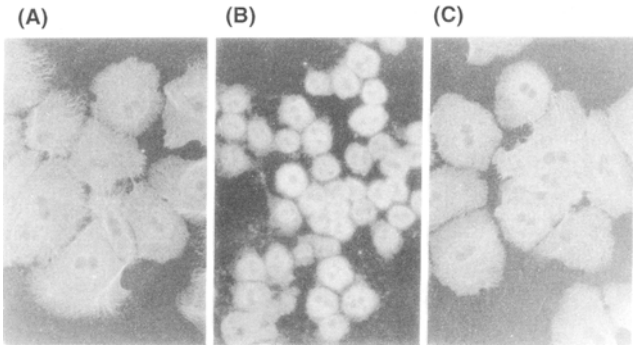

FIG. 6. Indirect immunofluorescence micrographs of cellular cytokeratin 18 in mouse primary cultured hepatocytes (×153). Cytokeratin 18 filaments in the hepatocytes (A) were retracted significantly by 100 nM Microcystin-LR (B). Cotreatment of 10 μM β-carotene protected the cytokeratin network against microcystin-LR (C). (A) Control; (B) 100 nM microcystin-LR; (C) 10 μM β-carotene with 100 nM microcystin-LR.

β-carotene protected the cytokeratin network in the hepatocytes from microcystin-induced disassembly (Fig. 6C).

DISCUSSION

In the present study, we have shown for the first time that several carotenoids antagonized okadaic acid class tumor promoters. Okadaic acid class tumor promoters are potent inhibitors of protein phosphatases 1 and 2A and induce hyperphosphorylation of cellular proteins (18,23,25–27). The intermediate filaments of cells are one of the targets of okadaic acid class tumor promoters, and hyperphosphorylation of the intermediate filaments causes the morphological changes of cells (25,26). All carotenoids tested herein protected mouse hepatocytes from the morphological changes induced by the tumor promoters and suppressed the tumor promoter-activated hyperphosphorylation of cytokeratins 8 and 18.

It was reported that cytokeratins 8 (55 kDa) and 18 (49 kDa), intermediate filaments of the primary cultured hepatocytes, are highly phosphorylated by microcystin-LR as compared to several other phosphorylated proteins in the hepatocytes (23). The 55 and 49 kDa bands appeared as major phosphorylated proteins after 3 h treatment with microcystin-LR (Fig. 4, lane 2); they were determined as cytokeratins 8 and 18, respectively, by immunoprecipitation (data not shown). The suppression of morphological changes of the hepatocytes by carotenoids may be a result of the marked reduction of cytokeratin hyperphosphorylation (Fig. 6). Phosphorylation of a specific subset of the many phosphorylation sites of these cytokeratins may disrupt the cellular cytokeratin network, thus resulting in morphological changes (23,28,29). β-Carotene may suppress hyperphosphorylation of the phosphorylation sites for the morphological changes of cells more specifically than other phosphorylation sites. Therefore, the suppression of the morphological changes seems more sensitive than the suppression of hyperphosphorylation of the other cellular proteins.

Suppression of hyperphosphorylation and the suppression of the morphological changes of the hepatocytes by

carotenoids are not clearly related to antioxidant or provitamin A activities . The emulsion of 10 μM β-carotene, astaxanthin, or esterified astaxanthin contained 48 μM α-tocopherol. However, the emulsion without carotenoids did not protect these cells against the morphological changes. Further, other carotenoids, such as canthaxanthin, which were dissolved in DMSO/THF (1:1, vol/vol) without α-tocopherol, also blocked the morphological changes of the hepatocytes, suggesting that α-tocopherol was not essential for the protective effect. α-Tocopherol is much more effective than β-carotene as an antioxidant for membrane lipids (30). Therefore, the antioxidant activity of β-carotene would not seem to play a significant role in its protection of the cells from the morphological changes caused by tumor promoters. In this study retinol, all-*trans* retinoic acid and 9-*cis* retinoic acid at the same concentrations as those of the carotenoids protected hepatocytes only weakly from morphological changes. These results indicated that suppression of morphological changes by carotenoids does not involve their conversion to retinoids.

Carotenoids strongly suppressed the microcystin-LR-induced morphological changes in primary culture mouse hepatocytes when added simultaneously with the tumor promoters. Carotenoids also suppressed the progression of morphological changes of the hepatocytes when β-carotene was added at 60 min after treatment with microcystin-LR (data not shown). These results indicated that carotenoids might not inhibit an uptake of microcystin-LR into the hepatocytes.

In the present study, we used 100 nM to 100 μM carotenoids. The concentration of β-carotene in human liver is reported to be 3–80 μmol/kg (28) (i.e., 3–80 μM if the specific gravity of the liver is estimated as L). Although it is hard to simply compare the intrahepatic concentrations of carotenoids between a human and a mouse or to estimate the real amount of β-carotene taken up by the hepatocytes in primary culture, the concentrations of carotenoids that suppressed the morphological changes may be within the physiological range.

Recently, it has been reported that β-carotene arrests tumor cells at G_0/G_1 or G_2 of the cell cycle (19,20,31,32) and that okadaic acid enhances cell cycling by inducing phosphorylation of cell cycle regulator proteins (33,34). Regulatory proteins of the cell cycle other than cyclins A and D, such as p53 and Rb antioncogene products, are also targets of okadaic acid class tumor promoters (35–37), and hyperphosphorylation of these antioncogene products is another important effect of this tumor promoter class. The β-carotene only affected the hyperphosphorylated intracellular proteins and did not reduce the basal protein phosphorylation levels of the control cells (Fig. 4). Therefore, the suppression of hyperphosphorylation of cellular proteins by the carotenoid might have some correlation with the arrest of the cell cycle.

Although the mechanisms by which carotenoids suppress the hyperphosphorylation of cellular proteins induced by microcystin-LR are not clearly understood and are now under investigation, the present results indicate further possibilities of the anticarcinogenic activities of carotenoids.

Dietary Menhaden Oil Enhances Mitomycin C Antitumor Activity Toward Human Mammary Carcinoma MX-1

Yu Shao, Lani Pardini and Ronald S. Pardini*

Allie M. Lee Laboratory for Cancer Research, Department of Biochemistry, University of Nevada, Reno, Nevada 89557

ABSTRACT: In the present study, we investigated the effects of high levels of dietary fish oil on the growth of MX-1 human mammary carcinoma and its response to mitomycin C (MC) treatment in athymic mice. We found that high levels of dietary fish oil (20% menhaden oil + 5% corn oil, w/w) compared to a control diet (5% corn oil, w/w) not only lowered the tumor growth rate, but also increased the tumor response to MC treatment. We also found that high levels of dietary fish oil significantly increased the activities of tumor xanthine oxidase and DT-diaphorase, which are proposed to be involved in the bioreductive activation of MC. Since menhaden oil is highly unsaturated, its intake caused a significant increase in the degree of fatty acid unsaturation in tumor membrane phospholipids. This alteration in tumor membrane phospholipids made the tumor more susceptible to oxidative stress, as indicated by the increased levels of both endogenous lipid peroxidation and protein oxidation after feeding the host animals the menhaden oil diet. In addition, the tumor antioxidant enzyme activities, catalase (CAT), superoxide dismutase (SOD), glutathione peroxidase (GPOx), and glutathione S-transferase peroxidase (GSTPx), were all significantly enhanced by feeding a diet high in fish oil. MC treatment caused further increases in tumor lipid peroxidation and protein oxidation, as well as in the activities of CAT, SOD, GPOx, and GSTPx, suggesting that MC causes oxidative stress in this tumor model which is exacerbated by feeding a diet high in menhaden oil. Thus, feeding a diet rich in menhaden oil decreased the growth of human mammary carcinoma MX-1, increased its responsiveness to MC, and increased its susceptibility to endogenous and MC-induced oxidative stress, and increased the tumor activities of two enzymes proposed to be involved in the bioactivation of MC, that is, DT-diaphorase and xanthine oxidase. These findings support a role of these two enzymes in the bioactivating of MC and indicate that the type of dietary fat may be important in tumor response to therapy.
Lipids 30, 1035–1045 (1995).

Fish oil, which contains high levels of n-3 long-chain polyunsaturated fatty acids (PUFAs), has been shown to suppress mammary gland tumorigenesis in rodent models (1–4). Several hypotheses have been proposed to explain how fish oil inhibits mammary tumorigenic processes, including inhibition and/or alteration of eicosanoid metabolism, induction of oxidative stress, and a deficiency in essential fatty acids in fish oil diets (1–4). The n-3 long-chain PUFAs contained in fish oil mainly are eicosapentaenoic acid (20:5, EPA) and docosahexaenoic acid (22:6, DHA), which contain five and six double bonds, respectively. When the PUFAs are presented in the diets, they are readily incorporated into tumor membrane phospholipids (1–4), resulting in an increase in the level of unsaturation of the membrane lipids. This makes the membrane more susceptible to peroxidation *in vitro* and *in vivo*, which leads to an increased accumulation of cytostatic and/or cytotoxic lipid peroxidation products, especially in the tumor (5,6).

Mitomycin C (MC), a quinone-containing antibiotic active in the treatment of solid tumors, undergoes both one-electron and two-electron reduction by the MC bioreductive activating enzymes (7–10). The two-electron reduction of MC forms a hydroquinone structure which can cross-link DNA, especially under hypoxic conditions. The one-electron reduction of MC results in the formation of the semiquinone free radical, which can interact with molecular oxygen to form toxic reactive oxygen species, such as superoxide, hydrogen peroxide, and hydroxy radical (•OH). The free radical dependent process could be critical to the antitumor activity of MC, for either DNA alkylation, DNA oxidation, or peroxidation of cellular membrane phospholipids (7–10).

It has been reported that high levels of dietary fat enhance the activities of a variety of enzymes, including those responsible for metabolizing xenobiotics (11–13). In a previous study (14), we found that MC bioreductive activating enzymes, including DT-diaphorase (DTD) and cytochrome b_5 reductase (CB5R) in human mammary carcinoma MX-1 heterotransplanted in the nude mice, were increased after feeding the host animals a high corn oil (CO) diet (25% CO, w/w). This would result in an increase in the formation of one-electron or two-electron reductive metabolites of MC in the tumor, increasing its antitumor effect through either increasing DNA cross-linking or production of toxic free radicals. In addition, we observed that feeding a high CO diet caused an

increased tumor response to MC treatment and increased oxidative stress after MC treatment, as indicated by elevated lipid peroxidation and enhanced antioxidant enzyme activities in the tumor.

In the present study, we determined the effect of feeding a diet high in fish (menhaden) oil [20% menhaden oil (MO) + 5% CO) on the growth, susceptibility to MC treatment, endogenous and MC-induced oxidative stress, and effect on MC-activating enzyme activities in human mammary carcinoma MX-1 grown in athymic mice.

MATERIALS AND METHODS

Materials. All chemicals were obtained from Sigma Chemical Co. (St. Louis, MO), unless otherwise indicated. The BCA total protein assay kit was obtained from Pierce Co. (Rockford, IL). Dietary components were purchased from Dyets Inc. (Bethlehem, PA).

Animals and diets. Forty-eight female adult athymic mice (female heterozygous BALB/c nu/+) were used in the present studies. The mice were housed under aseptic conditions (germ-free laminar-flow hood, sterilized cages, bedding, and water) at 27°C. Autoclaved laboratory mouse chow (Dyets Inc.) was fed *ad libitum* before the experimental diet was fed. The experimental diet was composed of the casein-based, semipurified AIN-76A diet (15,16) with some modifications according to Birt *et al.* (17), containing 20% MO + 5% CO (w/w) or 5% CO (w/w) (Table 1).

Tumor implantation and MC treatment. The animals were assigned randomly to the high-MO or low-CO diet, with 24 mice in each of the two experimental groups. Mice were fed their respective experimental diets for 20 d prior to tumor inoculation. A tumor fragment (1–2 mm^3) of human mammary carcinoma MX-1 was implanted subcutaneously on the right foreflank of each nude mouse. Tumor weights were recorded every 3–4 d and were estimated by the calculation based on the formula:

$$\text{tumor weight (mg)} = \frac{A \cdot B \cdot C}{2} \quad [1]$$

where A, B, and C represent the three perpendicular diameters of the tumor in millimeters (18). The percentage T/C ratio was calculated by the mean tumor weight of the treated group divided by the mean tumor weight of the control group (MC untreated) multiplied by 100 (18). All the mice were assigned to the following two experiments.

Experiment 1. Twelve mice in each dietary group with a total of 24 were used in this experiment. Ten days after tumor implantation, half of the mice in high MO and low CO groups (six animals in each group) were administrated with MC at the dosage of 0.5 mg/kg body weight, i.p., once a week for four consecutive weeks. Thirty days after tumor implantation, the animals in both dietary groups that did not receive MC treatment were sacrificed by cervical dislocation due to the large tumor volume. The remaining animals (MC treated) were kept on the experimental diets for another 30 d, and tumor volume and body weights were recorded as above. (Their tumors were too small to conduct biochemical testing.)

Experiment 2. Another 24 mice with 12 in each dietary group were used. Half (six animals) of the mice in each group received MC treatment 15 d after tumor implantation for three weeks, with the same dosage as in experiment 1. All the mice were sacrificed 24 h after the third MC treatment. Tumors were removed immediately, either homogenized in 3 mL of ice-cold 50 mM phosphate buffer (pH 7.0) for enzyme activities, lipid peroxidation, and protein oxidation assays, or kept in liquid N_2 for glutathione content and membrane phospholipid composition measurement. The homogenate was centrifugated at 10,000 × *g* for 30 min and the supernatant was retained for enzymatic assays.

Enzyme assays. DTD activity was measured as the dicumarol-sensitive reduction of 2,6-dichlorophenolindophenol, according to the method of Ernster (19) and modified by Benson *et al.* (20). Xanthine oxidase/dehydrogenase activities were assayed with the formation of uric acid from xanthine measured spectrophotometrically at 293 nm (21). Cytochrome C reductase (CCR) activity was measured according to the method of Masters *et al.* (22) and Yasukochi and Masters (23). Superoxide dismutase (SOD) activity was measured using the method described by Oberely and Spitz (24). Catalase (CAT) activity was determined by measuring the sample catalyzed disappearance of H_2O_2 spectrometrically at 240 nm (25). Glutathione peroxidase (GPOx) activity was measured in a coupled enzyme reaction with glutathione reductase (GR) (26). Glutathione S-transferase peroxidase (GSTPx) activity was measured similar to GPOx activity (27). GR activity was measured as described by Racker (28).

TABLE 1
Composition of Experimental Diets[a]

Ingredient (g)	Control (CO)	Menhaden oil (MO)
Corn oil (CO)	5	5
MO	0	20
Casein	20	24.6
DL-methionine	0.3	0.5
Cornstarch	15	9
Sucrose	50	29.1
Cellulose	5	6
AIN vitamin mix	1	1.2
AIN mineral mix	3.5	4.3
Choline bitartrate	0.2	0.3
Total weight	100	100
Caloric density (kcal/g)[b]	3.85	4.85
% of calories from fat	11.69	46.39
Unsaturation index	141	243
Daily diet consumed (g/mouse)[c]	4.36 ± 0.89	3.54 ± 0.80
Daily caloric intake (kcal/mouse)	16.79 ± 3.43	17.17 ± 3.88

[a]Formulated in accordance with the American Institute of Nutrition recommendation (15,16) and modified according to Birt *et al.* (17).
[b]Calculated as 4.0 kcal/g for starch, sucrose, and casein, and 9.0 kcal/g for corn oil and menhaden oil.
[c]Calculated daily by subtracting the amount of uneaten food from the amount of the food added the day before.

GST activity was determined by the method according to Mannervik and Guthenberg (29).

Lipid peroxidation. Malondialdehyde (MDA) was measured as an indication of lipid peroxidation by the method of Buege and Aust (30). Thiobarbituric acid [0.375% (wt/vol) with 15% trichloroacetic acid and 0.25 N HCl] was mixed with the test sample and heated in boiling water for 10 min. The precipitate was removed by centrifugation at 1000 × *g* for 10 min and the supernatant was removed for further analysis. Thiobarbituric reactive substances (TBARS) in the supernatant were measured spectrophotometrically at 535 nm.

Protein oxidation. Protein carbonyl groups were measured as an indication of protein oxidation by the method according to Levine *et al.* (31). Schiff's bases was also measured by this procedure. DNA was removed from the fraction by streptomycin precipitation. The remaining protein was precipitated and the pellet mixed with 10 mM 3,4-dinitrophenyl hydrazine (DNPH) for 1 h. Excess DNPH is removed with 1:1 ethanol/ethyl acetate mixture and the pellet is redissolved in 0.6 M guanidine in 20 mM potassium phosphate buffer, pH 6.3. Solution absorbance was then measured at 360–390 nm ($\varepsilon 360–390 = 22{,}000\ M^{-1}cm^{-1}$) to determine the protein carbonyl content. Control sample absorbance without DNPH was subtracted from the test absorbance.

Tumor glutathione (GSH) levels. Tumors were homogenized in 10% (vol/vol) perchloric acid containing 1 mM bathophenanthrolinedisulfonic acid. This acid extract was then spun at 15,000 × *g* for 15 min, and the supernatant derivatized and analyzed by HPLC by the method of Fariss and Reed (32). HPLC analysis was carried out using a Beckman 338 binary gradient system (Beckman Instruments, Palo Alto, CA) fitted with an a-Aminopropyl-Spherisorb column (Custom LC, Inc., Houston, TX).

Membrane lipid content. Tumor membrane lipid compositions were analyzed as previously described (18). Lipid was extracted from tumor membrane with chloroform/methanol (2:1, vol/vol). Fatty acid methyl esters were obtained by transesterification with borontrifluoride/methanol reagent. The methyl esters were analyzed by gas chromatography.

Statistical analysis. Data are expressed as means ± SD with n = 6 per group; differences in means were assessed by analysis of variance using the SAS general linear models program. Group means were considered to be significantly different at $P < 0.05$.

RESULTS

Tumor growth studies. Dietary intake of high levels of n-3 PUFAs has been reported to inhibit tumor growth and tumorigenesis in rodent models (1–4). In this study, we employed a diet high in n-3 PUFAs to evaluate its effects on tumor growth and responsiveness to MC chemotherapy. As shown in Table 2, the growth of human mammary carcinoma MX-1 was significantly inhibited in the animals fed a diet high in MO in Experiment 1. At the 30th day after tumor implantation, the average tumor weight in the high-MO group was 2016 ± 875 mg, whereas in the low-CO group it was 3500 ± 1050 mg (43% inhibition by MO). The treatment/control (T/C) ratios resulting from MC treatment were 1 for MO group and 10 for CO group with final mean tumor weights being 15 and 342 mg, respectively. Because 50 and 17% of the animals were clear of tumor at 30 d, the average tumor size of the remaining tumors at day 30 were 29 ± 10 mg for MO and 386 ± 102 mg for CO (Table 2). The MO-fed group possessed tenfold better response to MC compared to the CO-fed group. These T/C ratios were calculated by comparing the MC-treated group to its respective dietary control (see Materials and Methods section). If we compared the MO-fed MC-treated tumor to the CO control (dual effects from dietary MO feeding and MC treatment), the combined T/C ratio becomes 0.4. Thus feeding a 25% MO diet resulted in a dramatic reduction in tumor size following MC treatment compared to the 5% CO control. The animals

TABLE 2
Antineoplastic Activity of MC Against MX-1 After Different Diet Feeding

Dietary group	Treatment	Mean tumor weight (mg ± SD) (day 30)	T/C ratio day 30[a]	Combined T/C ratio day 30[b]	% Clear[c] Day 30	% Clear[c] Day 60	No. of animals used (N)	Net change in body weight between day 0 and day 30 (g ± SD)[d]

+ 20% menhaden oil)	MC	15 ± 17[e,g]			50	33	6	1.5 ± 0.3

[a]The percentage treatment/control ratio (T/C ratio) was calculated by taking the mean tumor weight of the mitomycin C (MC)-treated group divided by the mean tumor weight of the respective control (MC untreated) multiplied by 100. Other abbreviations as in Table 1.
[b]The combined T/C ratio accounts for the effect of diet and MC treatment and is calculated by taking the mean tumor weight of the MC-treated groups divided by the mean tumor weight of the CO control group multiplied by 100.
[c]Percent of animals free of visible or palpable tumor at the days indicated (the days after tumor implantation).
[d]Net change in body weight from day 0 (day of tumor implantation) to day 30 (day of termination of experiment).
[e]The average size of the tumors in mice that had visible or palpable tumors were 386 ± 102 mg in CO group and 29 ± 10 mg in MO group.
[f]Mean tumor weight is statistically different from the CO control group, $P < 0.05$.
[g]Mean tumor weight is statistically different from the CO+MC group, $P < 0.01$.

were maintained on the experimental diets for an additional 30 d following MC treatment, and observed for reoccurring tumor. In the low CO-fed group, the mouse free of tumor at day 30 experienced reoccurrence by the 60th day following tumor implantation. Of the three tumor-free mice in the MO group, only one appeared to have tumor regrowth, resulting in 2 out of 6 mice free of visible or palpable tumor (33% tumor-free) at the 60th day following tumor implantation. These data clearly indicate that the intake of high levels of MO not only significantly inhibited human mammary carcinoma MX-1 growth, but significantly enhanced the tumor responsiveness to MC treatment.

In Experiment 2, the same number of animals and same experimental diets were used. The only difference between these two experiments was that the time of the first MC treatment was postponed from the 10th day to the 15th day after tumor implantation in order to obtain large tumors to provide sufficient mass to measure tumor lipid peroxidation, protein oxidation, antioxidant enzyme activities, and MC-activating enzyme activities in the tumor. The results of this second study were similar to those from Experiment 1 (Table 2) in that the tumor growth was significantly suppressed by feeding MO diet and the tumor response to MC treatment was enhanced markedly by the MO diet. At the end of the second experiment (26 d after tumor implantation), the T/C ratios were 5 for MO group and 17 for CO group, indicating that the tumors from the MO-fed group were more sensitive to MC than the CO-fed group. There were no differences in host body weights between different dietary groups and MC treatment.

Tumor enzyme activities. Figure 1 shows the alterations of tumor MC bioreductive-activating enzyme activities by the different diets and MC treatment. In the present experiment, DTD activity was increased significantly by MO feeding ($P < 0.001$) and further increased by MC treatment ($P < 0.05$; Fig. 1A) compared to CO feeding. MC treatment had no effect on DTD activity in the CO group (Fig. 1A). CB5R activity was not affected by the diet alone. After MC treatment, CB5R activity was increased in the MO group (MO + MC group, $P < 0.01$; Fig. 1B) compared to the MO, CO + MC or CO groups. CCR activity was not altered by diet alone either, but was increased by MC treatment in both dietary groups ($P < 0.01$, Fig. 1C). A similar pattern was observed for xanthine dehydrogenase (XD) as CCR (Fig. 1D). Xanthine oxidase (XO) was significantly increased by feeding a diet high in MO ($P < 0.05$) and further increased by MC treatment (Fig. 1E) in both dietary groups. These results indicate that MO feeding and/or MC treatment changed tumor drug activating enzyme activities which are probably responsible for the enhanced antineoplastic effect of MC observed after feeding a high-MO diet.

Feeding MO which is rich in n-3 long-chain PUFAs will increase tumor membrane phospholipids (PLs) unsaturation by incorporating these highly unsaturated fatty acids into PLs (1–4). Figure 2 shows that dietary menhaden oil and MC treatment significantly altered tumor antioxidant enzyme activities. GPOx activity was increased by a high–n-3 PUFAs diet (MO, $P < 0.05$) and further increased by MC treatment ($P < 0.001$ in MO and $P < 0.05$ in CO). Similar changes were observed for GSTPx activity (Fig. 2C). Both tumor CAT and SOD activities were elevated after feeding MO and further elevated by MC treatment (Figs. 2E and 2F). As we observed in a previous study (14), GST activity was not changed by either dietary MO or MC treatment (Fig. 2B). GR activity was inhibited by MC treatment, but increased by feeding the high-MO diet ($P < 0.01$; Fig. 2D). These findings, along with tumor lipid peroxidation and protein oxidation data (discussed later), suggest that a high intake of n-3 PUFAs (MO in this study) causes an increase in endogenous oxidative stress in the tumor, presumably by changing the unsaturated fatty acid composition of tumor membrane lipids. This could be responsible for the observed suppressed tumor growth and enhanced the response to the prooxidant antitumor agents such as MC.

Tumor GSH. Tumor levels of GSH were measured after feeding the host animals with different diets, and the results are shown in Table 3. Tumor GSH levels were decreased by feeding the PUFA-rich MO diet ($P < 0.05$). Although the glutathione disulfide (GSSG) levels were not changed in the two different dietary groups, the GSH/GSSG ratio was significantly decreased in the MO group. These data indicate that feeding a diet rich in high levels of unsaturated PUFAs (such as MO) causes a decrease of GSH level in the tumor, which is consistent with increased tumor oxidative stress, and increased response to chemotherapy.

Lipid peroxidation and protein oxidation. The data in Figure 3 demonstrate that after feeding an MO-rich diet, a significant increase in tumor lipid peroxidation and protein oxidation occurred. MC treatment further increased both tumor lipid peroxidation and protein oxidation, similar to the responses of the antioxidant enzymes. Again, these results indicate that both dietary menhaden oil and MC treatment caused oxidative stress in this tumor model. These results are consistent with the observed decreased tumor growth and increased responsiveness to MC treatment.

Tumor fatty acid composition. As shown in Figure 4, tumor membrane PL fatty acid composition was changed by the different diets. There was a significant elevation of 18:1n-9, 18:2n-6, and 20:4n-6 fatty acids in the tumor membranes from the CO group, whereas in the tumor membranes from the MO group, there were significant increases of n-3 PUFAs such as 18:3n-3, 20:4n-3, 20:5n-3, 22:5n-3, and 22:6n-3. This change in the fatty acid pattern reflects an increased degree of unsaturation, with an unsaturation index of 208 in the MO-fed groups compared to 147 in the CO-fed groups, and, therefore, susceptibility to oxidative stress in the tumor lipid from the MO-fed group compared to the CO-fed group (Fig. 4).

DISCUSSION

Fish oil has been reported to inhibit mammary tumorigenesis in a variety of animal models, including carcinogen-induced rat and mouse models, transplantable mammary tumor mod-

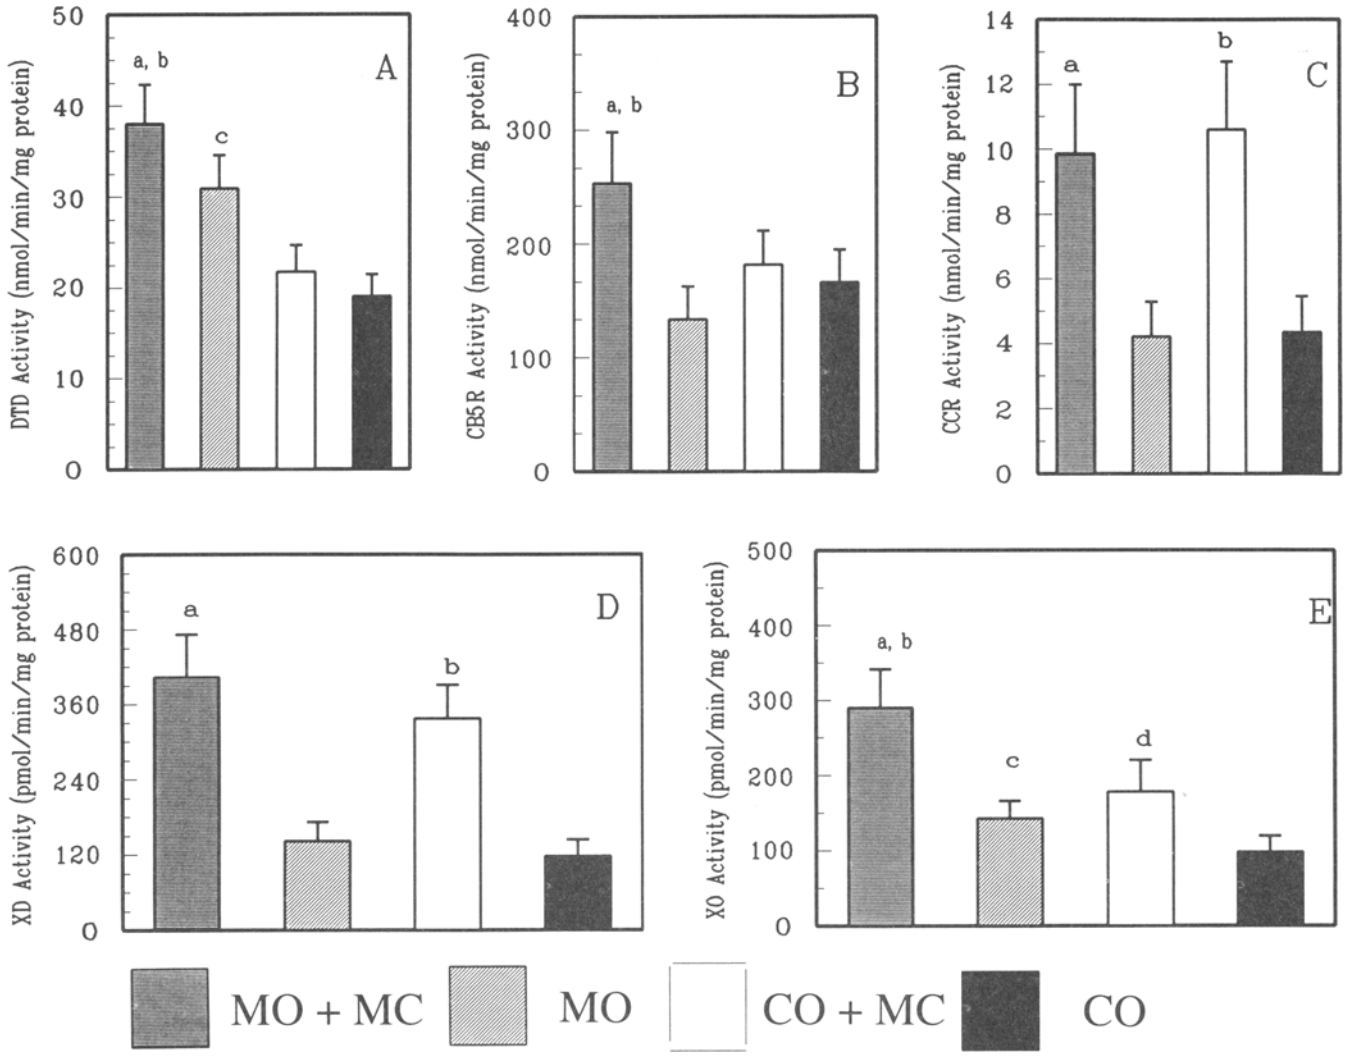

FIG. 1. Effects of feeding a diet high in menhaden oil (MO), or low in corn oil (CO) and mitomycin C (MC) treatment on tumor (A) DT-diaphorase (DTD), (B) cytochrome b_5 reductase (CB5R), (C) cytochrome C reductase (CCR), (D) xanthine dehydrogenase (XD), and (E) xanthine oxidase (XO) activities. Statistically significant differences were in (A) DTD activity between MO + MC and MO groups (a: $P < 0.05$), MO + MC and CO + MC groups (b: $P < 0.001$), and between MO and CO groups (c: $P < 0.001$); in (B) CB5R activity between MO + MC and MO groups (a: $P < 0.01$), between MO + MC and CO + MC groups (b: $P < 0.01$); (C) CCR activity between MO + MC and MO groups (a: $P < 0.01$) and between CO + MC and CO groups (b: $P < 0.01$); (D) in xanthine dehydrogenase activity between MO + MC and MO groups (a: $P < 0.01$) and between CO + MC and CO groups (b: $P < 0.01$); and (E) in xanthine oxidase activity between MO + MC and MO groups (a: $P < 0.01$), between MO + MC and CO + MC groups (b: $P < 0.01$), between MO and CO groups (c: $P < 0.05$), and between CO + MC and CO groups (d: $P < 0.05$).

els, or spontaneous mouse mammary tumor models (for review, see Refs. 1–4). Because fish oils are often deficient or marginal in the essential fatty acids, such as linoleic acid (18:2n-6), it is possible that the suppression of mammary tumorigenesis exerted by a high–fish oil diet may be due to insufficient amounts of linoleic acid. In fact, supplementation of fish oil diet with amounts of linoleic acid has been reported to block or partially block the inhibitory effects on mammary tumor development by a high–fish oil diet (33–36). In this study, we supplemented the high–fish oil diet with 5% corn oil, to provide essential fatty acid as recommended by the American Institute of Nutrition (15,16). We also observed a significant inhibitory effect on the growth of human mammary carcinoma by feeding a diet high in MO compared to a low-CO diet (Table 2). Thus, the inhibitory effect of MO on human mammary carcinoma growth in this study should not be due to the lack of sufficient essential fatty acids in the MO diet.

Previous studies have shown that dietary fat influences membrane structure and function (1–4) and have also demonstrated that membranes with a high unsaturation index are more sensitive to peroxidation (37–40). In this study, MO feeding resulted in a higher amount of n-3 PUFAs being incorporated into tumor membrane PLs with a decreased incorporation of arachidonic acid (20:4n-6; Fig. 4). These long-chain PUFAs significantly increased the degree of tumor membrane lipid unsaturation compared to the CO group, with a calculated unsaturation index of 208 and 147, respectively.

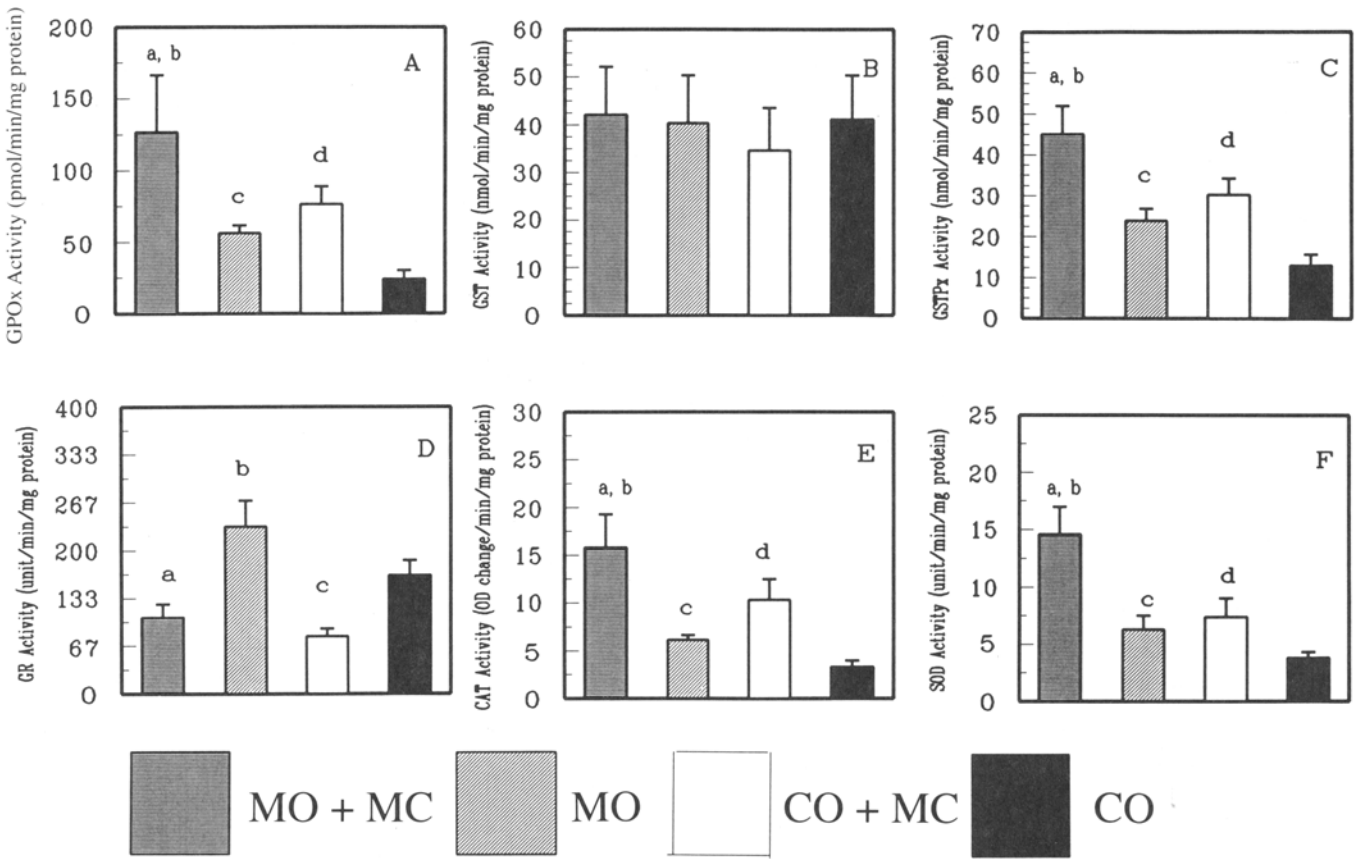

FIG. 2. Effects of feeding a diet high in MO, or low in CO and MC treatment on tumor (A) glutathione peroxidase (GPOx), (B) glutathione S-transferase (GST), (C) glutathione S-transferase peroxidase (GSTPx), (D) glutathione reductase (GR), (E) catalase (CAT), and (F) superoxide dismutase (SOD) activities. Statistically significant differences were (A) GPOx activity between MO + MC and MO groups (a: $P < 0.001$), between MO + MC and CO + MC groups (b: $P < 0.05$), between MO and CO groups (c: $P < 0.05$), and between CO + MC and CO groups (d: $P < 0.05$); (C) in GSTPx activity between MO + MC and MO groups (a: $P < 0.001$), between MO + MC and CO + MC groups (b: $P < 0.01$), between MO and CO groups (c: $P < 0.05$), and between CO + MC and CO groups (d: $P < 0.01$); (D) in GR activity between MO + MC and MO groups (a: $P < 0.01$), between MO and CO groups (b: $P < 0.01$), and between CO + MC and CO groups (c: $P < 0.01$); (E) in CAT activity between MO + MC and MO groups (a: $P < 0.001$), between MO + MC and CO + MC groups (b: $P < 0.01$), between MO and CO groups (c: $P < 0.05$), and between CO + MC and CO groups (d: $P < 0.01$); and (F) in SOD activity between MO + MC and MO groups (a: $P < 0.001$), between MO + MC and CO + MC groups (b: $P < 0.01$), between MO and CO groups (c: $P < 0.05$), and between CO + MC and CO groups (d: $P < 0.01$). Abbreviation as in Figure 1.

This increased level of unsaturation in the MO group increased the tumor lipid susceptibility to lipid peroxidation and subsequent endogeneous oxidative stress, as demonstrated by the following indicators of oxidative stress. (i) A significant elevation in the amounts of lipid peroxidation products (TBARS) and protein oxidation were observed in the tumor from the MO-fed group (Fig. 3). (ii) Antioxidant enzymes which participate in cellular protection against lipid peroxidation such as SOD, CAT, GPOx, and GSTPx were also activated by MO feeding (Fig. 2). (iii) Tumor GSH levels were

[b]Number of mice per group.
[c]$P < 0.05$, significant differences between CO and MO groups.

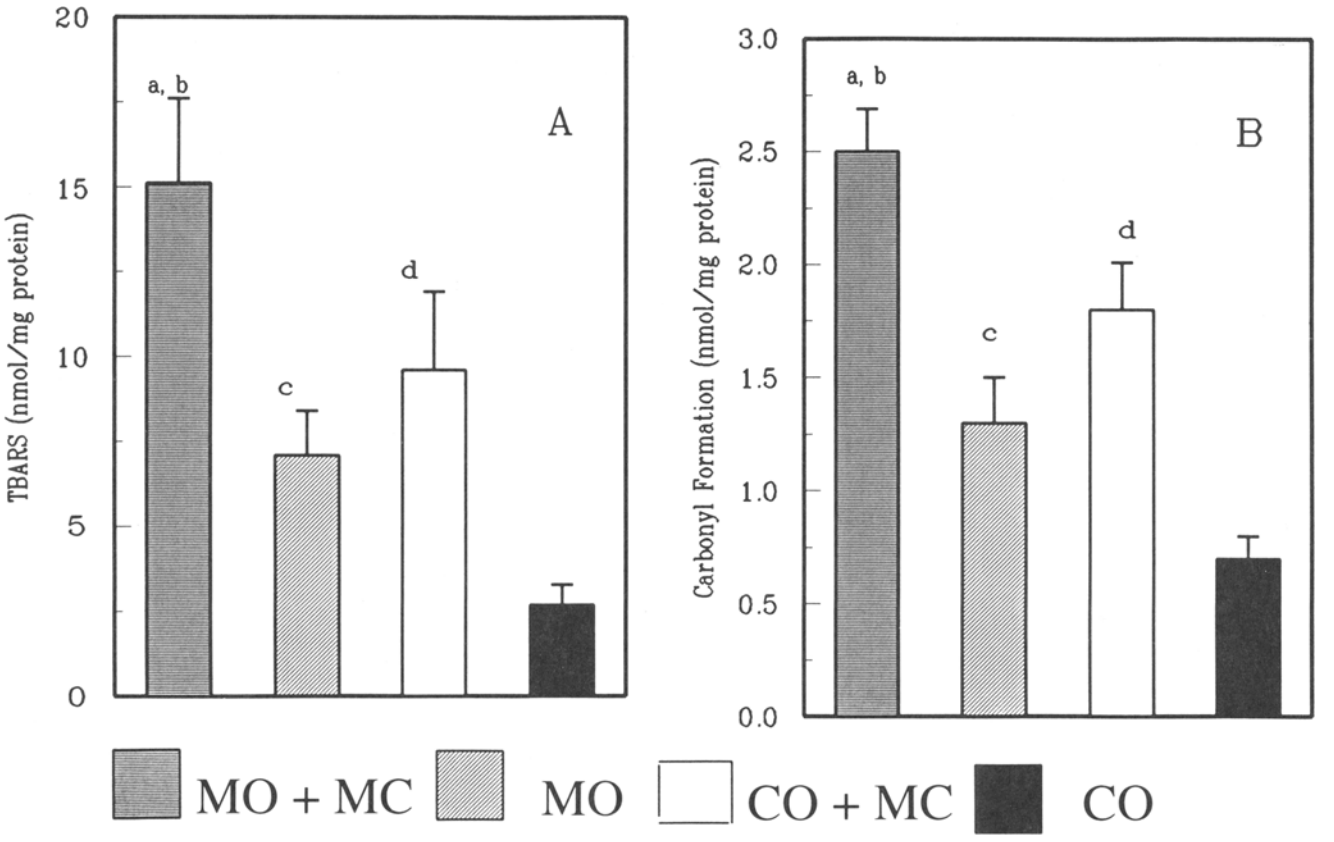

FIG. 3. Effects of feeding a diet high in MO, or low in CO and MC treatment on tumor (A) lipid peroxidation and (B) protein oxidation. Statistically significant differences were (A) in lipid peroxidation between MO + MC and MO groups (a: $P < 0.01$), between MO + MC and CO + MC groups (b: $P < 0.01$), between MO and CO groups (c: $P < 0.01$), and between CO + MC and CO groups (d: $P < 0.01$) and in (B) protein oxidation between MO + MC and MO groups (a: $P < 0.001$), between MO + MC and CO + MC groups (b: $P < 0.01$), between MO and CO groups (c: $P < 0.01$), and between CO + MC and CO groups (d: $P < 0.01$). Abbreviations as in Figure 1.

significantly decreased in the MO-fed group, indicating that high levels of dietary menhaden oil resulted in predisposing the tumors to oxidative stress. Although the mechanism by which oxidative stress inhibits tumor growth is not clear, lipid peroxidation products are reported to be capable of decreasing cell proliferation by damaging cell membranes, changing cellular structures, and inactivating cellular macromolecules such as key enzymes and other protein factors (41–44). However, under extreme oxidative conditions, lipid peroxidation may lead to cell death (45–48). Therefore, the observed inhibition of tumor growth by MO in this study may in part be attributed to the increased susceptibility of tumor cells to lipid peroxidation by altering the level of unsaturation of their membranes. This conclusion is consistent with the findings of Gonzalez *et al.* (5) who related the inhibition of tumor growth in animals fed fish oil to lipid peroxidation by preventing the fish oil inhibition of tumor growth by feeding high levels of α-tocopherol.

We previously reported that feeding a 25% CO diet also increased tumor oxidative stress as measured by increased tumor antioxidant enzyme activities and lipid peroxidation. However, contrary to findings reported here, in comparison to the 5% CO diet, the 25% CO diet enhanced human mammary carcinoma growth (14). The reason for this difference in tumor growth between the 25% CO (14) and 25% MO (Table 4) dietary regimes may be the difference in lipid peroxidation found in the tumors fed the different high-fat diets. Under certain conditions, metabolites of PUFA peroxidation actually activate cellular proliferation (49), whereas the cytotoxic effects of lipid peroxidation occur only under extreme oxidative conditions (45–48). The data in Table 4 indicate that lipid peroxidation in the tumors from animals fed 25% CO increased 25% over the 5% CO controls, whereas in the 5% CO + 20% MO groups, lipid peroxidation was increased 300%. Therefore, we speculate that the differences between stimulating tumor growth in the 25% CO diet and inhibiting tumor growth in the 5% CO + 20% MO diet is the extent of lipid peroxidation and production of toxic peroxidation byproducts. As reviewed by Esterbauer *et al.* (50), ω6 PUFAs, such as linoleic acid ($C_{18:2}$) and arachidonic acid ($C_{20:4}$), yield 4-hydroxynonenal (HNE), 4-hydroperoxynonenal, and 4,5-dihydroxydecenal, whereas the ω3 PUFAs, like docosahexaenoic acid ($C_{22:6}$), yield 4-hydroxyhexenal, 4-hydroperoxy hexenal, and 4,5-dihydroxy heptenal. The 4-hydroxy alkenals have widespread activity, including formation of cellular membrane bleb leading to cell death in Ehrlich ascites,

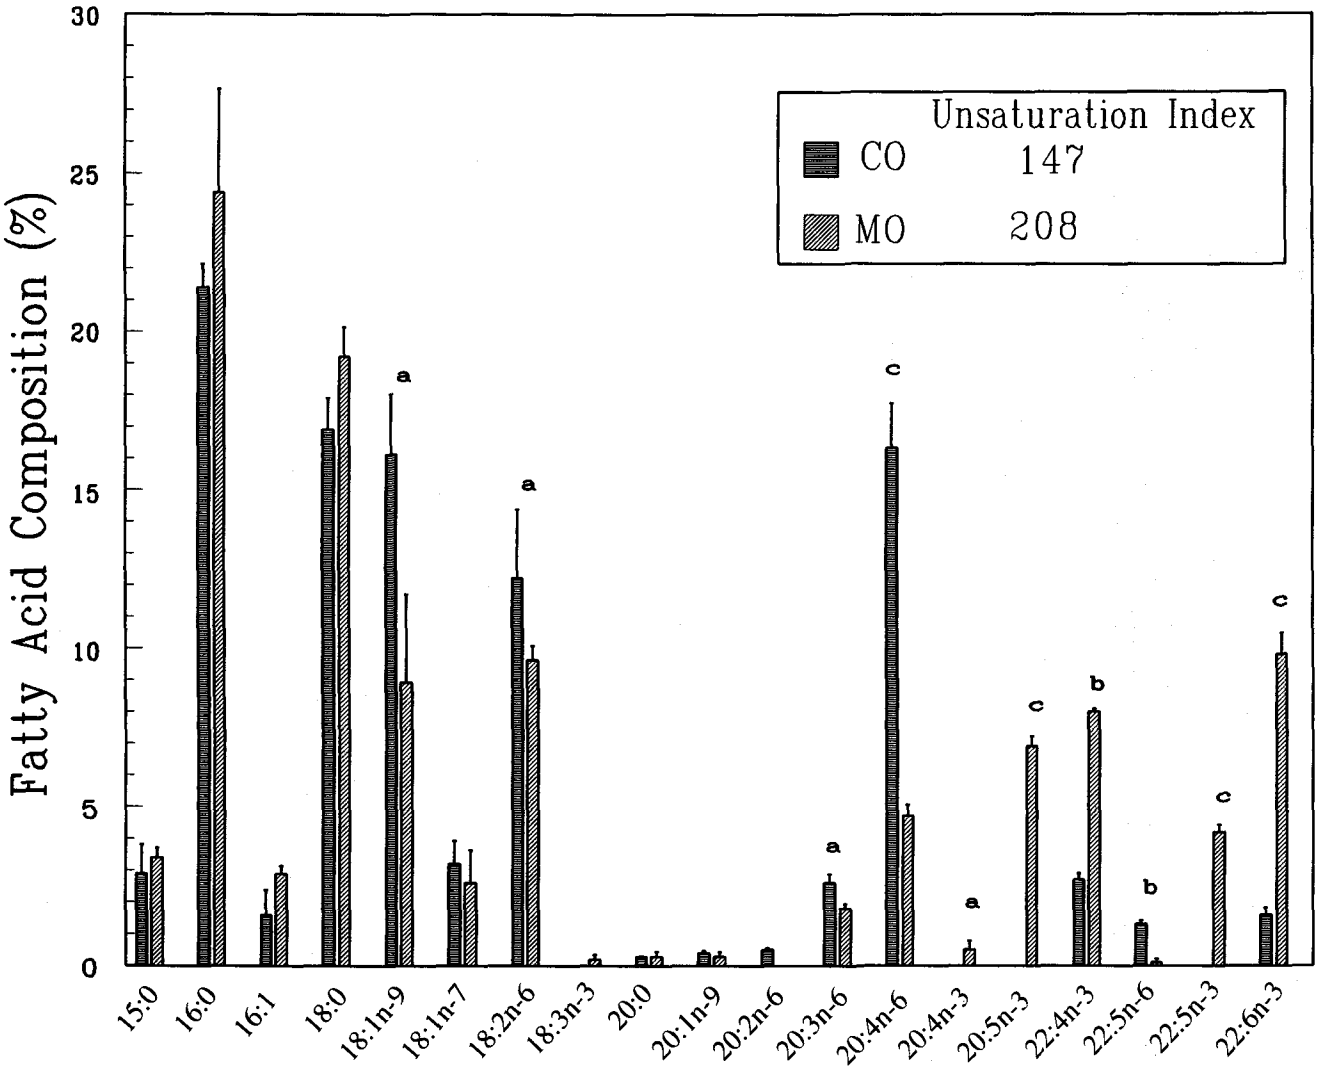

FIG. 4. Effects of feeding a diet high in MO and low in CO on tumor fatty acid compositions. Statistical differences between MO and CO groups were: a, $P < 0.05$; b, $P < 0.01$; and c, $P < 0.001$. The unsaturation index is calculated by multiplying the fatty acid percentage with the number of the double bond it has. Abbreviations as in Figure 1.

inhibition of glycolysis, respiration, depletion of GSH and protein thiols, protein syntheses, and DNA synthesis (51–56). Thus, the production of these toxic lipid peroxidation byproduct could account for the depressed tumor growth observed by MO feeding.

Based on the different fatty acid distribution in the tumor from the CO- and MO-fed groups (Fig. 4), we would expect different lipid peroxidation products to be formed in the tumors from each group. The extent to which these different products are formed in each tumor has not yet been determined, and therefore their contribution to the different growth patterns of tumor from the two groups is at present unknown. On the other hand, CO contains high amounts of n-6 PUFAs, which can enhance the synthesis of prostaglandins after incorporation into the cell membranes; and prostaglandins have been proved to stimulate tumor proliferation (1–4). In fact, the enhanced tumor growth by high–n-6 PUFA diets could be partially reversed by the treatment of indomethacin, a prostaglandin synthase inhibitor. However, n-3 PUFAs (such as MO) have been shown to inhibit prostaglandin synthesis by either directly inhibiting prostaglandin synthase or competing for the substrate binding site with arachidonic acid (which is the natural substrate for prostaglandin synthase to produce prostaglandins) (1–4). In this study, MO feeding resulted in a threefold decrease of arachidonic acid levels in the tumor cell membrane compared to the 5% CO (Fig. 4). The decreased arachidonic acid and increased incorporation of n-3 PUFAs in the tumor membranes of the MO-fed animals may affect the production of prostaglandins in the tumor cells.

The most interesting finding in this study is the relationship between dietary fat and tumor chemotherapy. In our earlier study (14), a high-CO diet (25% CO) significantly increased the tumor response to MC chemotherapy. We believed that this was due to activation of the MC metabolizing system by the high-fat diet, because some well-known MC bioreductive-activating enzyme activities such as DTD, CB5R, and

TABLE 4
Comparison Between the Effects of High–Corn Oil Diet (25%) and High–Menhaden Oil Diet[a]

	HCO	HCO + MC	MO	MO + MC
Tumor weight (mg) at day 30	4100 ± 1950	200 ± 69	2016 ± 875	15 ± 17
T/C ratio[b]		5		1
Combined T/C ratio[c]		5	0.37	
% of TBARS increase[d]	25	160	300	600
DT-diaphorase activity (nmol/min/mg)	16.2 ± 2.0	19.2 ± 2.9	30.9 ± 3.6	38.0 ± 4.3
Xanthine oxidase activity (pmol/min/mg)	130 ± 13	190 ± 14	143 ± 23	289 ± 52

[a]Data were collected from previous study (Ref. 14) and present study. HCO was the high–corn oil diet containing 25% corn oil in the diet; MO was the menhaden oil diet containing 20% menhaden oil + 5% corn oil.
[b]The percentage treatment/control ratio (T/C ratio) was calculated by the mean tumor weight of the MC-treated group divided by the mean tumor weight of the respective control group (MC untreated) multiplied by 100.
[c]The combined T/C ratio was calculated by the mean tumor weight of the MC-treated groups divided by the mean tumor weight of the HCO control group multiplied by 100.
[d]The data were obtained by the mean thiobarbituric acid reactive substances (TBARS) value in the respective dietary groups (HCO or MO) divided by the mean TBARS value from the low-fat (5% corn oil) control group mutiplied by 100.

XO/XD activities were enhanced by the high–CO diet. In the present study, human mammary carcinoma MX-1 was more sensitive to MC in the MO-fed group than in the control group (CO) (Table 2). MC treatment caused a significant depression in tumor growth compared to CO (Table 2) or 25% CO group (14) (Table 4). Tumor DTD and XO were also activated by dietary MO, but CB5R and XD activities were not increased (Fig. 1). These results indicate that feeding a high amount of dietary fat could alter the tumor susceptibility to MC treatment by enhancing certain drug activating enzyme systems directly in the tumor. A diet containing different fatty acids may have a different effect on various tumor enzymes. For example, we previously reported that feeding a high–CO diet (25% CO, w/w) increased the activities of CB5R and XD in addition to DTD and XO in human mammary carcinoma MX-1 (14); whereas in this study, the activities of CB5R and XD were not increased by high dietary MO. Since MO is associated with increased responsiveness to MC therapy, these findings tend to rule out the role of intratumor CB5R and XD in the MO-induced increased response to MC, although both enzyme activities were increased by treatment with MC. In this regard, the highest increase in MC-activating enzymes was XD, where treatment resulted in a threefold increase in tumor XD activity in MO-fed mice.

DTD catalyzes a two-electron reduction of MC resulting in the formation of the corresponding hydroquinone structure (10). Although it has been controversial, the role of DTD in the bioreductive activation of MC (57,58) has been clarified by using purified enzymes in cell-free systems. Metabolism of MC to DNA-reactive species by DTD is pH dependent in that it has been reported that the DNA cross-linking induced by MC increases as the intracellular pH is lowered. In addition, the bioreductive-activation of MC by DTD seems more efficient under aerobic conditions than under hypoxic conditions (for review, see Ref. 59). Both high levels of dietary CO (14) and MO increased endogeneous DTD activity in human mammary carcinoma MX-1, while increasing sensitivity to MC. Both diets support increased DTD activities following MC treatment, which support a major role for DTD in the bioreductive activation of MC in this model. XO activity was increased in tumors from the MO-fed group, and MC treatment further increased XO activity. These findings indicate that XO also plays a role in MC activation. We cannot rule out XD as a possible activation enzyme of MC, in that it was always activated following MC treatment on either the 25% CO diet (14) or the MO diet (Fig. 1). Under aerobic conditions, hydroquinone can be reoxidized to the semiquinone free radical or quinone structure with subsequent formation of superoxide, hydrogen peroxide, and hydroxy radical (7). This results in increased oxidative stress in the tumor which could contribute to the antineoplastic activity of MC. In fact, Pritsos *et al.* (60) reported that the toxicity of MC toward EMT-6 cells was decreased in a dose-dependent manner with increasing activity of SOD, a well-known free radical scavenge enzyme. In the present study, MC treatment caused significant levels of oxidative stress in the tumor from both MO and CO groups, as indicated by the increased antioxidant enzyme activities (SOD, CAT, GPOx, and GSTPx) and lipid peroxidation and protein oxidation. In addition, tumor GR was inhibited by MC treatment (Fig. 2D), which would be expected to increase tumor oxidative stress. This finding is consistent with the findings of others (61) that quinones can inhibit the activities of thiol containing enzymes. The role of inhibition of GR in the antitumor activity of MC requires further investigation, but is consistent with the decreased GSH levels in the tumors (Table 3). Collectively, these results indicate clearly that MC treatment caused oxidative stress in the tumor. As expected, the tumors from the MO-fed group were more susceptible to MC-induced oxidative stress because their membrane PLs were more unsaturated.

In summary, high intake of fats rich in long-chain n-3 PUFAs such as MO will increase the level of unsaturation in tumor membrane PLs. This results in tumor lipids possessing a high degree of unsaturation, which makes them more susceptible to endogenous and exogenous lipid peroxidation. When exogenous oxidative stress is induced by prooxidant drugs such as MC treatment, increased lipid peroxidation, protein oxidation, and increased responsiveness to MC

chemotherapy is observed. In addition, increased tumor activities of DTD and XO, two of the proposed MC bioreductive activating enzymes, resulted from feeding a high-MO diet, indicating that nutritional intervention involving this type of dietary fat may increase the therapeutic response to prooxidant therapy.

ABSTRACT: A phosphorus-31 nuclear magnetic resonance method has been developed for the determination of aquatic sediment phospholipid profiles that may be generally applied to all soils and deposits containing viable cellular material. A method of scrubbing chloroform/methanol extracts with potassium acid phosphate overcomes adverse signal broadening from the mineral component, permitting eleven sediment phospholipids to be determined at the quantitative level.
Lipids 30, 1047–1051 (1995).

Biomass can account for a significant fraction of sedimentary organic matter (1–3). Evaluation of biomass is coupled to understanding environmental interactions of organisms living in both aquatic sediments and terrestrial soils. The living cells constituting the biomass are the principal processors of both nutritive material and human-generated contaminants. These cells are defined by a cellular membrane composed of phospholipids, the profiles of which are characteristic of each cell (4). A profile of sediment phospholipids is representative of the aggregate living biomass community within a sediment and may closely reflect the ecological status of the community response to perturbation.

The methods used for determining biomass in sediments are numerous; however, none assess the profile of all living organisms present in sediments. A method has been developed that utilizes a phospholipid analysis for determining microbial biomass in sediments (5). The method is based upon the determination of lipid-bound phosphorus that is extracted using a modification of the Folch (6) extraction for total lipid.

The determination of lipid-bound phosphorus is based upon the concept that lysosomal activity released upon cell death rapidly hydrolyzes lipid-bound organic phosphate esters, converting oil-soluble organically-bound phosphate into water-soluble inorganic orthophosphate. Lipid-bound phosphorus, therefore, is a component only of living cells and, as such, a measure of viable biomass.

Lipid-bound phosphorus is almost exclusively contained in the polar head groups of cellular membrane phospholipids. These phospholipids can be profiled using phosphorus-31 nuclear magnetic resonance (^{31}P NMR) spectroscopy to obtain quantitative separation of the component phospholipids that are characteristic of the tissue from which they have been extracted (4,7,8). It follows that the aggregate cellular component of sediments similarly also could be analyzed to yield phospholipid profiles that are characteristic of a given sediment, reflecting its biological fingerprint.

^{31}P NMR phospholipid spectra obtained from clean fresh tissues are highly resolved and yield narrow ^{31}P signals in the range of 2–3 Hz line width at half-height (4,7,8). Spectra obtained from sediments, however, are broadened to the point of being unusable by the mineral component of sediments, principally iron, that broadens NMR signals through the physical–chemical mechanism of paramagnetic relaxation. We have eliminated this serious line-broadening artifact through extract scrubbing using EDTA in conjunction with potassium acid phosphate. The resulting well resolved ^{31}P NMR spectra can be integrated to produce a quantitative sediment phospholipid profile analysis.

Crude sediment total lipid extracts can be analyzed by ^{31}P NMR. This NMR method provides quantitative phospholipid profiles that may be used to fingerprint sediment types, monitor pollution, classify organisms, or provide insight into the fundamental properties of sediment biochemistry. The basic methodology is simple, requiring only common laboratory chemicals and equipment. The only unusual requirement is access to a high field (4.7 Tesla or greater) NMR spectrometer equipped to detect ^{31}P.

MATERIALS AND METHODS

Collection and extraction protocol. Samples (*ca.* 1 kg) consisting of the top 3 cm of sediment were collected during the fall of 1994 from the Milwaukee Harbor at the Center for Great Lakes Studies (Milwaukee, WI). To isolate the microbial community, sediments were passed through a 500 μm U.S. Standard soil sieve for removal of the macroinvertebrate fauna. Water content was analyzed using freeze-dried 2 g subsamples.

For phospholipid analysis, 40 g samples are stirred with 500–600 mL chloroform/methanol (2:1, vol/vol), using a large magnetic stirrer. After 10 min, stirring is stopped and the liquid phase examined for the presence of a second aque-

ous phase that may be found floating above the heavier chloroform phase. If a second aqueous phase is present, as may be the case with heavily hydrated samples, additional chloroform/methanol is added with stirring to take up this residual aqueous phase, so that only a single liquid phase is present. Failure to adequately dehydrate the sample will compromise the quantitative aspects of the analysis.

After 24 h of extraction with stirring, the extract is filtered through Schleicher & Schuell # 588 pre-pleated paper filters into a 1-L glass reagent bottle fitted with a screw-top Teflon-sealed cap. A volume of scrubbing reagent (0.2 M K–EDTA plus 0.2 M potassium acid phosphate, KH_2PO_4, pH 6.0) equivalent to 20% of the extract volume is added, the bottle capped, and the mixture stirred for 5 d at a rate sufficient to interdisperse the two liquid phases. After scrubbing, the mixture is placed into a separatory funnel and allowed to set for 24 h to thoroughly clear the bottom (chloroform) phase. The chloroform phase is recovered, evaporated to dryness at 40°C, and taken up in 30 mL chloroform/methanol. If needed, a small amount of water may be added along with the chloroform/methanol to dissolve residual K–EDTA carried over with the chloroform phase. The concentrated extract is placed into a separatory funnel, 6 mL 0.2 M K-EDTA added, the mixture shaken and allowed to separate. The chloroform phase is recovered and evaporated for NMR analysis.

^{31}P NMR phospholipid reagent. A chloroform–methanol–aqueous–Cs–EDTA phospholipid NMR reagent has been formulated for the analysis of phospholipids by ^{31}P NMR spectroscopy (4,7,8,9–11). The analytical medium consists of two reagents: (A) reagent-grade chloroform, containing 5% benzene-d_6 and an appropriate concentration of trimethylphosphate, a chemical-shift and quantification reference; (B) reagent-grade methanol containing 0.2 M aqueous Cs–EDTA, pH 6 (4:1, vol/vol). The final methanol reagent is prepared by dissolving 1 mL of the aqueous EDTA solution in 4 mL methanol.

For ^{31}P NMR analysis, the extract lipid sample is dissolved in 2 mL reagent A and transferred to a 10-mm NMR sample tube; 1 mL reagent B is added, and the combination mixed thoroughly. A small aqueous phase separates and is allowed to rise to the top of the sample (1 min). Ordinarily, there is no need to remove this small aqueous phase, which contains no detectable phospholipids, and its presence above the sample ensures that the proper equilibria are maintained and that the organic solvents will not evaporate significantly during the NMR analysis.

^{31}P NMR spectroscopy. The NMR spectrometer used in this investigation was a heteronuclear GE 500 NB system, operating at 202.4 MHz for ^{31}P. Spectrometer scan conditions used: pulse sequence, one pulse; pulse width, 18 μs (45° spin-flip angle); sweep width, 1,000 Hz; acquisition delay, 500 μs; free-induction decay size, 4,096 channels; interpulse delay, 500 μs; acquisition time, 2.05 s; number of acquisitions, 20,000–80,000. Additionally, a computer-generated exponential filter time-constant introducing 0.6 Hz line broadening was applied to reduce background noise. Each signal in the phospholipid spectral profile was quantified through digital integration and chemical-shift values computed (8). In areas of overlapping signals, such as in the immediate vicinity of 0.0 ppm chemical shift, digital spectral curve resolution techniques were applied that have been described (12). Proton broad-band decoupling also was applied routinely (0.25 watt).

Factors that limit the accuracy of ^{31}P NMR measurements (13–16), ^{31}P NMR spectral profile measurements (17), and NMR measurements of extracted phospholipids (7,8,10,11,18,19) have been discussed. In general, properly calibrated NMR spectra yield accurate quantitative data (9,10,14,18), with errors usually attributable to the formulation of inappropriate standards that deviate in matrix composition from those of the analytical samples in the nature and quantity of solutes, solvents, and for phosphates, counter cations, and pH.

RESULTS

Phosphate scrubbing. The ^{31}P NMR reagent developed for phospholipids, which performs well when applied to a wide variety of tissue extract (4,8) and synthetic samples (7,20,21), failed when it was applied to extracts of aquatic sediments. The top spectrum of Figure 1 shows the result of a ^{31}P NMR analysis of the harbor sediment sample prepared using the same procedures employed for the analysis of animal and plant tissue extracts. These procedures involve chloroform/methanol extraction followed by backwashing against 0.2 M aqueous K–EDTA, subsequent evaporation of the recovered chloroform phase, and analysis in the Cs–EDTA ^{31}P NMR reagent. (Analysis of the simple chloroform/methanol extract appropriately concentrated yields no detectable high-resolution NMR signal, whatsoever.) Only three broad phospholipid signals were detected, and the signal-to-noise ratio was very poor. With phosphate scrubbing, the same sediment specimen yields the bottom spectrum of Figure 1. Signal line widths were markedly narrowed and signal-to-noise greatly improved. Note that the broad features of the top spectrum were preserved in the bottom spectrum. The principal signal of the top spectrum corresponded in the bottom spectrum to the aggregate of the signals from phospholipids diphosphatidylglycerol, phosphatidylethanolamine, and sphingomyelin. The signal at 0.5 ppm corresponded to phosphatidylglycerol, while that at –0.8 ppm corresponded to the combination of alkylacylphosphatidylcholine and phosphatidylcholine. In the top spectrum an indication of the presence of lysophosphatidic acid and phosphatidylinositol also was discerned. Insofar as could be determined through curve resolution and integration (12), the relative areas of the signals in both spectra were equivalent, i.e., phosphate scrubbing did not appear to alter the relative amounts of the phospholipids present; it simply narrowed the respective signal widths. Such a property is consistent with the removal of paramagnetic impurities, principally iron, by phosphate scrubbing.

The assignments (Table 1) of both glycerol plasmalogen (GPLAS) and dimethylphosphatidylethanolamine (4,8) are tentative, principally because of the low amounts of these pres-

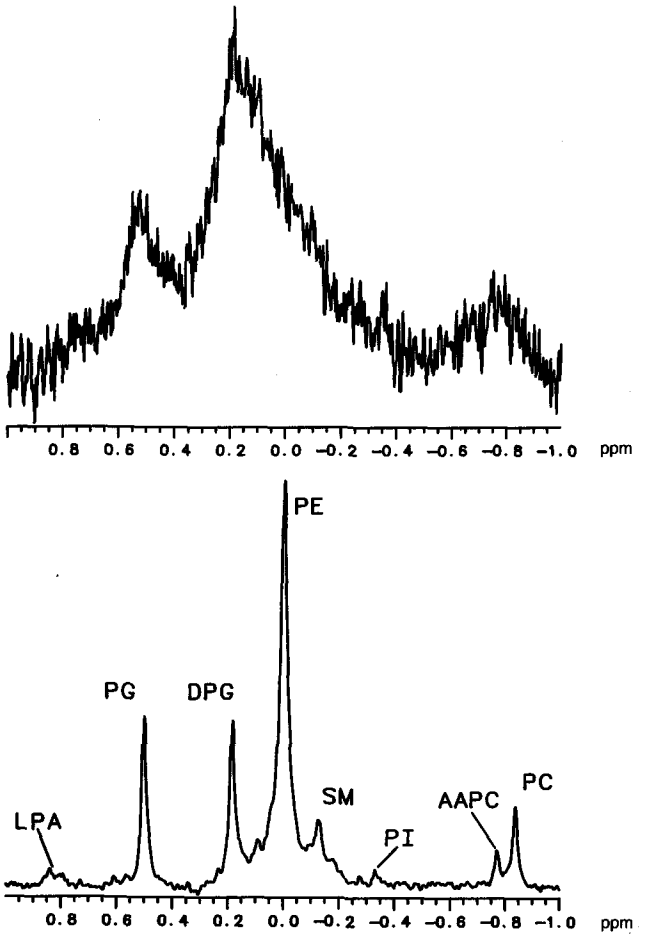

FIG. 1. Phosphorus-31 nuclear magnetic resonance spectral phospholipid profile of Milwaukee Harbor (Milwaukee, WI) sediment. The top spectrum was obtained from a sample that had not been scrubbed by phosphate, the bottom spectrum from a sample that had been scrubbed by phosphate: LPA, lysophosphatidic acid; PG, phosphatidylglycerol; DPG, diphosphatidylglycerol; PE, phosphatidylethanolamine; SM, sphingomyelin; PI, phosphatidylinositol; AAPC, alkylacylphosphatidylcholine; PC, phosphatidylcholine.

ent in this sediment. The assignment of GPLAS has an additional uncertainty, since it is not known whether our GPLAS reference samples are true plasmalogens, having the en-ol-ether functional group at the glycerol C_1 position, or the more recently discovered alkyl phospholipids, which have the simple alkyl ether at glycerol C_1.

Precision of the determination. The results from five replicate phospholipid profile determinations of the harbor sediment (Table 1) show a range of variation similar to those obtained with a series of pig lenses (10), which is about five times greater than errors obtained using synthetic laboratory solutions. This larger variability seen with cellular extracts is attributable to variation in the biological sample and can be overcome only through the use of replicate determinations. Standard deviations of the means range from a low of 3.3% for phosphatidylethanolamine to a high of 33.7% for dimethylphosphatidylethanolamine.

Water, oil, and phospholipid content of Milwaukee Harbor sediment specimens. The water content of the sediment samples was 67%. Extractable oil was 0.42% on a wet-weight basis and 1.28% on a dry-weight basis. The phospholipid content was 0.0021% on a wet-weight basis (0.0064% on a dry-weight basis), which corresponded to a phospholipid content in the isolated oil of 0.50%. This amount corresponded to 0.84 mg phospholipid. The number of millimoles phospholipid (assumed molecular weight 789) was 1.07.

DISCUSSION

Sediment specimens. Unlike the analysis of discrete tissue, such as the lens of the eye (10) or cells in tissue culture (22), the analysis of sediments is an analysis of a community. The phospholipid profiles, therefore, are representative of the cellular types that make up the sediment community, and they reflect the weight-fraction of each cell type present. The ^{31}P NMR analysis of sediment profiles biomass at the cellular grade of organization.

Extraction and phosphate scrubbing. After transport of sediment specimens from the field to the MR Laboratory at Midwestern University (Chicago, IL), a sieve is used to remove large debris. The sieving procedure has limitations as to just what is excluded and the degree of sample homogeneity. These limitations can be controlled by using large samples, by thoroughly mixing the sieved specimen, and by repeating the determinations. We have found with the sensitivity inherent in our older spectrometer, that, at the practical level, a 40 g wet-weight sample of sieved sediment is required. This corresponds to approximately 1 cm of sediment core section obtained using a benthos 3-inch diameter corer. Thinner core sample sections could be analyzed with a proportionately increased core diameter.

There must be only one liquid phase present during the initial chloroform/methanol extraction. Extractions carried out overnight with stirring are recommended, since these produce reasonably precise quantitative data (Table 1), although useful extractions can be carried out in about 10 min.

There was a considerable amount of ferromagnetic material in the sediment samples examined, as was evident by the accumulation of such material on the poles of the magnetic stir bars used to mix the samples during extraction. It is clear that iron was the principal element responsible for the NMR line broadening observed in unscrubbed phospholipid samples.

Filtration rates, though slow, were reasonable, even with finely divided samples. The extracts may be heavily pigmented (brown–black, harbor) or only lightly pigmented (light yellow, some river samples). The type or degree of pigmentation does not appear to have any effect on the phospholipid analysis and does not change during the phosphate scrubbing procedure.

Vigorous mixing is required during the phosphate–EDTA scrubbing step. The reaction is carried out using two immiscible liquid phases, with the phosphate being restricted to the

[a]LPA, lysophosphatidic acid; GPLAS, glycerol plasmalogen; PG, phosphatidylglycerol; DPG, diphosphatidylglycerol; EPLAS, ethanolamine plasmalogen; PE, phosphatidylethanolamine; SM, sphingomyelin; DIMEPE, dimethylphosphatidylethanolamine; PI, phosphatidylinositol; AAPC, alkylacylphosphatidylcholine; PC, phosphatidylcholine; ^{31}P NMR, phosphorus-31 nuclear magnetic resonance.

aqueous phase. The EDTA is found in both phases (20), with the bulk concentrated within the aqueous phase. We found that a minimum of 48 h was required for adequate phosphate scrubbing using the harbor sediment. Scrubbing beyond 6 d yielded no further improvement. The reaction probably is driven by the formation of iron phosphate that retains the sequestered iron within the aqueous phase. The EDTA, however, is essential to this process and probably serves as a chemical mediator, since it is capable of moving between the two liquid phases. The crystals that may form during phase separation pose no problem.

Some EDTA is carried within the chloroform phase and appears in the evaporated residue if this is taken to dryness. It can be taken up with the addition of a small amount of water in the transfer procedure for the second washing and is removed essentially completely in the second washing step.

After separation and evaporation to dryness following the second washing step, samples are dissolved in the chloroform–benzene–d_6 NMR reagent A for analysis. At this stage, concentrated samples are so heavily pigmented that they appear black.

Spectral characteristics. Usually the high-resolution phospholipid spectra, such as those shown in Figure 1, are superimposed upon a very broad featureless signal of low amplitude covering a spectral range of about 10 ppm. This signal cannot be reduced by further scrubbing and is characteristic of polymerized and cross-linked (hardened) phospholipids. This broad baseline deformity is easily corrected for accurate spectral integration.

The ^{31}P NMR method for phospholipids depends upon the detection of the phosphorus hetero atom found in the polar head group of each phospholipid. It does not depend upon the nature of the fatty-acid side chains, if these are over six carbon atoms long, or on the presence of double bonds in these side chains, or whether these double bonds are oxidized or otherwise chemically modified (except cross-linked) (8). Because of this property, the ^{31}P method is ideal for the analysis of phospholipids where biological and chemical processes may have altered the double bonds of the incorporated fats, and operations under nitrogen or argon gas are not required.

Sediment phospholipid content. By multiplying the total phospholipid content presented earlier by the mole % (or mole fraction) of each phospholipid in the sample's profile (Table 1), the quantity of each phospholipid in the profile may be calculated. The calculations presented for water, oil, and phospholipid content of Milwaukee Harbor sediment specimens assume that the average fatty-acid side chain is equivalent in molecular-fragment weight to stearoyl, i.e., C_{18} and saturated, and ignores the variations in the molecular-fragment weight of the of the polar head groups. The molecular weight of 789 corresponds to the distearoylphosphatidylcholine.

Phospholipid analysis. From the analytical point of view, the techniques described are designed to be as simple as possible. The idea is to minimize the number of separate chemical manipulations and, thereby, minimize errors. The data are presented as the mole-percent phosphorus present as a given generic species in the total phosphorus detected, which is the simplest and most straightforward manner of presenting the spectroscopic data (17). This method of presenting the data does not require exhaustive phospholipid extraction, only representative extraction, and it corrects internally for quantification errors developed during sample work-up.

The phospholipid profiles obtained contain all members of the broad class of phospholipid biochemicals, the familiar, as well as the new, the bizarre, and the previously unrecognized (4,8). Such an analytical strategy not only saves time, but, more importantly, it provides a total picture of the phospholipid component from which new, useful natural products may be obtained and from which insights into the operant biochemistry may be gleaned.

ABSTRACT: Excretion of malondialdehyde (MDA)-generating substances in the urine has been suggested as an indicator of *in vivo* lipid peroxidation. However, MDA in the urine also reflects the amount of lipid peroxidation products consumed in the diet. We determined MDA as the thiobarbituric acid (TBA)–MDA complex in urine of 19 healthy adults (10 male and 9 female) fed large quantities (3.6–4.1 g/kg body weight) of ground beef cooked at a low or a high temperature. Subjects ate a controlled diet with no alcohol or nutritional supplements. For 7 d they consumed ground beef cooked at 100°C for 20 min (low-temperature meat) followed by 7 d with meat fried at 250°C for 22 min (high-temperature meat). Prior to the study, subjects consumed their normal free choice diet with moderate amounts of meat. The concentration of MDA in urine at baseline was 2.1 ± 0.3 μmol TBA–MDA equivalents/day (mean ± SEM). After 7 d of low-temperature meat, urinary TBA–MDA equivalents increased to 23.1 ± 1.4 μmol/d. Urinary TBA–MDA equivalents were consistently lower (6.9–8.0 μmol/d) 1, 2, 3, and 7 d after subjects changed to high-temperature meat. After 7 d of treatment, 97% of the MDA-equivalents in the meat was recovered in 24–h urine samples. The low temperature meat had 3–4 times more MDA than did the high-temperature meat. These data indicate that the amount of meat eaten and the cooking procedures used can dramatically alter urinary MDA. Dietary sources of MDA must be controlled if urinary MDA is to be used as an indicator of oxidative stress.
Lipids 30, 1053–1056 (1995).

Malondialdehyde (MDA) is a by-product of the nonenzymatic peroxidation of polyunsaturated lipid, and excretion of substances in urine that can generate MDA has been suggested as a biomarker for *in vivo* lipid peroxidation (1). However, measurement of urinary MDA also includes the contribution from exogenous MDA-generating substances from dietary sources. Foods, especially meats, vary in the amount of MDA-equivalents present (2), and cooking methods can increase the MDA generation in meats (3). Increased urinary excretion of MDA-equivalents has been observed in human subjects ingesting large quantities of cooked meat or fish (4,5).

The extent to which diet influences total urinary MDA must be quantified before urinary MDA can be considered to be a reliable marker for *in vivo* lipid peroxidation. Lipid peroxidation can induce cell damage and contribute to various pathological conditions (6). Furthermore, several studies have suggested that MDA may be mutagenic (7), carcinogenic (8), or form adducts with DNA (9). However, the significance of these data is uncertain (10). The relative importance of consuming MDA-generating substances and any toxicity they might contribute is not clear.

A study designed to clarify the metabolic consequences of ingesting meat cooked at high or low temperatures offered the opportunity to investigate the urinary excretion of MDA-generating substances in adults fed such meats. Subjects were fed known amounts of ground beef cooked by two different methods. This study design allowed us to evaluate how the amount of meat and cooking method influenced urinary MDA under controlled conditions. We also assessed the balance between ingested and excreted MDA-equivalents to determine how quickly and completely dietary MDA was reflected in altered urinary excretion.

MATERIALS AND METHODS

Nineteen nonsmoking adults (10 male and 9 female), aged 27 to 62 yr and weighing 57 to 103 kg participated in a pre-study of self-selected diets and then in a larger controlled diet study concerning cooked meat during January and February of 1993. Volunteers were in good health as determined by a screening history, medical evaluation, and laboratory tests. They were taking no medications or vitamin/mineral supplements. Procedures for this study were approved by the Human Studies Review Committee of the United States Department of Agriculture (Beltsville, MD) and the Institutional Review Boards of Georgetown University School of Medicine (Washington, D.C.) and the National Cancer Institute (Bethesda, MD).

For 14 d preceding the study (self-selected period), subjects were instructed to eat their normal diets. Seven days before the controlled diet period, subjects collected a 24-h urine sample (baseline).

During the controlled diet period, subjects consumed breakfast and dinner from Monday through Friday at the Human Studies Facility of the Beltsville Human Nutrition Research Center (Beltsville, MD) under the supervision of a dietitian. Lunches and weekend meals were packaged and taken home. No other food was allowed. Diet soda, coffee or tea, and other noncaloric beverages were permitted. Weighed portions of the foods were adjusted to maintain body weight throughout the study. Subjects ate 3.6 to 4.1 g meat/kg body weight, all of which was eaten at the evening meal and served in combination with sauces during 7 d of rotating diets. At various times throughout the study, subjects collected 12- and 24-h urine samples.

During the first 7-d controlled diet period, all subjects consumed lean ground beef cooked at a low temperature. This was followed by a second 7-d period with meat cooked at a high temperature. The amount of high temperature cooked meat fed to each subject was decreased to compensate partially for its lower moisture content compared to the low-temperature cooked meat.

Freshly ground lean beef (15% fat) was purchased in large batches from the same local grocery store over several weeks. Meat was cooked within 30 h of purchase. The low-temperature meat was prepared in three batches by gently stirring ground beef in a pan heated to 100°C for 20 min until the meat was slightly browned. Then the meat was drained and held in a 90°C conventional oven for 20 min to reduce the moisture content, resulting in a total cooking weight loss of 35%.

The high-temperature meat was prepared from six batches of patties, 110–125 g, approximately 9 cm in diameter, and 1.5 cm thick. Patties were fried on a stainless-steel griddle for 11 min per side for a total of 22 min at 250°C with a total cooking weight loss of 45%. The cooked patties were broken up in a commercial food processor (Robot Coupe USA, Inc., Jackson, MS).

Samples of the two meat preparations were analyzed for moisture by drying to a constant dry weight at 60°C.

After cooking in batches, all meat for one cooking method was combined into a homogeneous mixture. Meat was aliquoted into bags for separate feeding days and immediately frozen at −15°C. For each day of the controlled diet, meat was defrosted overnight in a refrigerator and weighed out for individual subjects who microwaved their portion one to two minutes just before eating.

A single 12-h overnight urine collection was obtained the first 12 h (dinner to following breakfast) after beginning the low-temperature meat treatment. Two 12-h collections per day were obtained on days 1, 2, and 3 after beginning the high-temperature meat treatment; 24-h collections were obtained on day 7 for both treatments. The first 12-h urine collection period (overnight) began at the evening meal and continued until the first void of the following morning. The second 12-h collection period (day) was from breakfast until the evening meal. The 24-h samples covered a breakfast-to-breakfast period and thus represented urine from the second 12 h of one dose and the first 12 h of the next identical dose. Urine was collected in plastic containers and held on ice until delivery at the end of the collection period. Urine volume was estimated by weight (1 g = 1 mL urine), and then aliquots for analysis were immediately frozen at −20°C.

MDA was measured as thiobarbituric acid (TBA)–MDA equivalents, determined by the method of Halliwell and Chirico (11). This method separates the TBA–MDA complex by high-performance liquid chromatography with fluorescence detection. TBA–MDA equivalents are calculated from an acid hydrolyzed standard of 1,1,3,3-tetramethoxypropane that is carried through the same procedure. Ground beef samples were extracted for analysis by gently mixing with 10% trichloroacetic acid to prevent the release of catalytic iron (12).

Significance of differences among experimental time periods was analyzed by one-way analysis of variance and Duncan's multiple range test. Differences were considered significant at $P < 0.05$.

RESULTS

The concentration of MDA-generating substances in low-temperature cooked meat was three times higher than the value in high-temperature cooked meat (Table 1). When these concentrations were adjusted for moisture differences, the concentration of MDA in low-temperature meat was four times higher than that in meat cooked at a high temperature.

Table 2 presents the urinary excretion and percent recovery of measured MDA at various times throughout the study. After 7 d of dietary treatment, 97% as much MDA-generating substance was recovered in the 24-h urine samples as had been ingested that day. Fifty-five percent as much MDA as in the low-temperature meat was recovered in the urine during the first 12 h after ingestion, while 86–90% was recovered for the high-temperature cooked meat.

DISCUSSION

Our results demonstrate that cooking procedures can dramatically change the MDA content of meat, and this is reflected in the urinary excretion of MDA after consumption of such meat. Newburg and Concon (3) showed an approximately 30% increase in levels of MDA for ground beef cooked at a low temperature compared to meats cooked at a high temperature to the same degree of doneness. We demonstrated a 300–400% difference in the MDA content of meat for our cooking protocols comprising two extreme degrees of doneness. The final level of MDA was presumably a function of its formation and loss by volatilization (3). The gentle prolonged cooking used for the low-temperature meat apparently favored a large amount of MDA formation with minimal losses, whereas the extremely high temperature may have increased losses due to volatility or favored the formation of non-TBA reactive material through increased reactivity of MDA with the protein. These data suggest that cooked meats

TABLE 1
Percentage Dry Weight and Concentration of TBA–MDA Equivalents in Cooked Ground Beef Samples[a]

Cooking method	% Dry weight (g dry wt × 100) / (g cooked wt)	TBA–MDA equivalents (μg/g)	TBA–MDA equivalents (nmol/g)
Low temperature[b]	40.4, 40.5	13.4, 14.9	81.7, 90.8
High temperature[c]	56.7, 57.6	4.4, 5.0	27.0, 30.8

[a]All samples were analyzed in duplicate, and concentrations are reported on a cooked weight basis. TBA–MDA, thiobarbituric acid–malondialdehyde.
[b]Cooked at 100°C for 20 min, then held in 90°C oven for 20 min.
[c]Fried as patties at 250°C for 22 min.

warmed for long periods, such as during a buffet or in a cafeteria, may accumulate high concentrations of MDA-generating substances.

Several studies have demonstrated that MDA is a mutagen (7) and possible carcinogen (8). However, only a negligible fraction of the MDA in foods is absorbed in its free form. Most MDA in tissues such as meat is bound to protein as N-ε-(2-propenal) lysine (13). This compound is not mutagenic in the *Salmonella typhimurium* (Ames) test and does not appear to be a source of free MDA in tissues (10). Our analysis measures total MDA and could not distinguish between the free and bound forms. We analyzed the meat samples fed to our subjects for mutagenicity with the Ames test (14) (Sinha, R., and Knize, M., unpublished data) and did not detect revertants during testing of the low-temperature meat. On the other hand, the high-temperature meat produced 1020 revertants/g which may be due to heterocyclic aromatic amines, polycyclic aromatic hydrocarbons, or other pyrolysis products produced during prolonged cooking at a high temperature (15).

Our data indicate that almost as much MDA is excreted in 24 h as is consumed from the cooked meat, and 55–90% of that ingested is voided within the first 12 h. Jacobson *et al.* (4) observed a 50–60% recovery of MDA equivalents after 24 h in five subjects. Although these results suggest that most ingested MDA is readily excreted, more definitive studies (e.g., feeding MDA labeled with ^{14}C) are needed to verify that the amount excreted is a certain proportion of that ingested.

The urinary excretion of 2.1 μmol TBA–MDA equivalents/day observed during the free-living portion of our study is comparable to 1.45 μmol MDA equivalents/day for a 70 kg man calculated from the data of Jacobson *et al.* (4). During the free-living portion of our study, subjects consumed a mean of 131 g of cooked meat per day (data not shown). Assuming a meat consumption of 131 g/d and using the analytical data of Jacobson *et al.* (4) (2–4 μg MDA/g cooked chicken, pork, or beef), we estimate these subjects ingested 1.6–3.2 umol TBA–MDA equivalents/day, considerably less than that given during the controlled feeding period. This intake value corresponds well with our reported mean urinary excretion of 2.1 umol TBA–MDA equivalents/day. Thus, the feeding of a large quantity of meat provided high amounts of exogenous MDA-generating substances which apparently result in excretion of large quantities of TBA-reactive substances co-eluting with TBA–MDA. This variation in background MDA-generating substances in the diet would make assessment of endogenously produced MDA difficult without controlling for this factor.

TABLE 2
Urinary Excretion and Percent Recovery of TBA–MDA Equivalents Consumed in a Diet[a]

Diet	Collection period: 1st 12 h (overnight)	2nd 12 h (day)	24 h Total
		(μmol TBA–MDA equivalents)	
Self-selected	—	—	2.1 ± 0.3^{x}
Low-temperature meat[b]			
Day 1	13.0 ± 0.5^{x} (55 ± 2)[d]	—	—
7	—	—	23.1 ± 1.4^{z} (97 ± 4)
High-temperature meat[c]			
Day 1	6.4 ± 0.3^{y} (90 ± 5)	1.5 ± 0.1^{x} (21 ± 2)	$7.9 \pm 0.4^{y,e}$ (111 ± 6)
2	6.1 ± 0.3^{y} (86 ± 3)	1.7 ± 0.2^{x} (24 ± 3)	$7.8 \pm 0.4^{y,e}$ (109 ± 5)
3	6.2 ± 0.3^{y} (87 ± 4)	1.8 ± 0.2^{x} (25 ± 2)	$8.0 \pm 0.4^{y,e}$ (113 ± 6)
7	—	—	6.9 ± 0.3^{y} (97 ± 3)

[a]Values represent mean ± SEM; n = 19; values in same column with different lettered (x,y,z) superscripts differ significantly ($P < 0.05$). Samples were not collected at time points with missing data; see Table 1 for abbreviations.
[b]23.7 ± 0.7 μmol MDA equivalents consumed/day, analyzed as TBA–MDA equivalents.
[c]7.1 ± 0.2 μmol MDA equivalents consumed/day, analyzed as TBA–MDA equivalents.
[d]Numbers in parentheses represent excreted MDA-generating substances as the percentage of that consumed.
[e]Values were calculated by adding 1st and 2nd 12-h measurements.

Several workers have commented on the possible usefulness of urinary MDA measurement as a method for monitoring oxidative stress *in vivo* (1,16). Any condition thought to increase oxidative stress, such as dietary vitamin E deficiency (17), administration of pharmacological agents such as adriamycin (18) or carbon tetrachloride (19) or induction of diabetes by streptozotocin (20), is known to result in elevated urinary output of MDA-generating substances. Our results show that 24-h of a controlled intake could be sufficient to create a stable baseline of the urinary MDA excretion. If urinary "MDA" is to be used as an indicator of *in vivo* oxidative stress, however, dietary sources of MDA-generating substances must be controlled. Otherwise, dietary sources of MDA could easily mask any changes in urinary MDA-generating substances due to endogenously produced MDA.

Inhibition of Cholesterol Synthesis and Hepatic 3-Hydroxy-3-Methylglutaryl–CoA Reductase in Rats by Simvastatin and Pravastatin

M. Del Puppo, S. Rauli and M. Galli Kienle*

Department of Medical Chemistry and Biochemistry, University of Milan, 20133 Milan, Italy

ABSTRACT: In this communication we attempt to provide one possible explanation for the observed differences regarding kinetics and distribution between simvastatin and pravastatin. Rats treated with simvastatin or pravastatin exhibited a reduction in the incorporation of [2-^{14}C]acetate into liver cholesterol and displayed lower plasma mevalonate levels as compared to control animals. Moreover, both the total and dephosphorylated 3-hydroxy-3-methylglutaryl–CoA (HMG–CoA) reductase (EC 1.1.1.34) activities, particularly 1 h after treatment, were greatly reduced in liver microsomes obtained from simvastatin-treated as compared to control rats. During the same time frame, these parameters were actually elevated with pravastatin treatment. It is known that HMG–CoA reductase synthesis and activity increase following their competitive inhibition. Our results suggest that pravastatin, at 1 h following treatment, was no longer bound to the enzyme; however, it had entered the liver because its inhibitory effect on cholesterol synthesis was manifest at early times after administration. These data provide a plausible rationale for the earlier observation that activity of simvastatin persists longer in plasma than does that of pravastatin.
Lipids 30, 1057–1061 (1995).

Pravastatin and simvastatin are used in the therapy of hypercholesterolemia due to their inhibitory activity on 3-hydroxy-3-methylglutaryl–coenzyme A (HMG–CoA) reductase (EC 1.1.1.34), the key enzyme in cholesterol synthesis. According to previously reported data, the competitive inhibition of HMG–CoA reductase induces a decrease in the rate of cholesterol biosynthesis and is followed by an increase in low density lipoprotein receptors, enhancing the cellular uptake of cholesterol and lowering plasma low density lipoprotein cholesterol (1). An increase of HMG–CoA reductase concentration also follows the competitive inhibition of HMG–CoA reductase activity (2).

Differences between pravastatin and simvastatin in terms of their absorption, distribution, and excretion have been described. Simvastatin is more lipophilic and has been reported to diffuse through membranes, whereas pravastatin is internalized *via* an active transport mechanism (3–5). The different behavior of pravastatin has been ascribed to its hydrophilic nature, which derives mostly from an additional hydroxy group and from the open hydroxyacid chain instead of the lactonized one of simvastatin. The higher specificity for the liver observed for pravastatin relative to other tissues also has been related to these structural features (4). Kinetic data suggest that simvastatin's inhibitory activity may last longer than that of pravastatin because its main 6-hydroxylated metabolite, which is as active as the parent drug, reenters the liver through the enterohepatic circulation (6). In order to obtain direct evidence for the mechanism underlying this long-lasting effect, we have determined the *ex vivo* activity of HMG–CoA reductase in liver microsomes prepared from rats treated with a single dose of either simvastatin or pravastatin. *In vivo* incorporation of labelled acetate and plasma mevalonate levels were used as parameters to check the inhibition of the overall cholesterol synthesis in the treated rats.

The results show that overall cholesterol synthesis was inhibited by both drugs; both drugs reach the liver where they are active in inhibiting cholesterol synthesis. However, binding of simvastatin or its active metabolite to HMG–CoA reductase appears to last longer as compared to pravastatin, which may represent the rationale of the longer half-life of elimination observed for simvastatin as compared to pravastatin (7).

MATERIALS AND METHODS

Materials. All chemicals were of analytical grade. Pravastatin sodium salt (as Selectin) was obtained from Squibb S.p.A. (Rome, Italy), and simvastatin was from Merck Sharp & Dohme Research Lab. (Rahway, NJ). Sodium [2-^{14}C]acetate (56 mCi/mmol) was purchased from Amersham International (Amersham, Bucks, United Kingdom). NADP, glucose-6-phosphate, and glucose-6-phosphate dehydrogenase were obtained from Boehringer Mannheim GmbH (Mannheim, Germany). HMG–CoA and bovine serum albumin were purchased from Sigma Chemical Co. (St. Louis, MO). Scintillation fluids (Ultima Gold) were from Canberra Packard (Meriden, CT).

Animals. Male Sprague-Dawley rats (Charles River, Como, Italy) (180–200 g) were fed a normal rat chow with a

lighting cycle from 7.00 a.m. to 7.00 p.m. Drugs were given by gavage (20 mg/kg body weight) as solution of 6.5 mg/mL in water for pravastatin (Selectin—Squibb) or as suspension of 20 mg/mL in 0.5% tragacantha gum for simvastatin. Homogeneity of the preparation was tested by measuring pravastatin and simvastatin by gas chromatography/mass spectrometry. Rats were decapitated 1 or 4 h after oral administration (10 a.m.) of pravastatin or simvastatin. Sodium [2-^{14}C]acetate (4.5 μCi; 80 nmoles in 250 μL) was administered orally to the animals, by gavage, 45 min before the sacrifice. Control animals received the vehicle only. Untreated controls also were sacrified for the evaluation of *in vitro* binding experiments.

Blood was collected in tubes containing 4 mM EDTA, and the plasma obtained by centrifugation was stored at −20°C until analyzed for blood mevalonate determination. Livers were quickly removed and weighed. Part of the liver (1–2 g) was immediately frozen at −80°C for sterol radioactivity determination while the remaining was homogenized (1:2.5, wt/vol) in cold 0.3 M sucrose containing 50 mM NaF and 10 mM 2-mercaptoethanol, pH 7.4. The washed microsomal fraction (8) was suspended in 50 mM potassium buffer, pH 7.2, containing 0.3 M KCl, 1 mM EDTA, and 5 mM dithiothreitol. The final suspension contained 3–4 mg microsomal protein/mL determined according to Bradford (9).

HMG–CoA reductase assay. Total activity of the enzyme which is directly related to the amount of enzyme protein was determined as described previously in microsomes pretreated with a phosphoprotein phosphatase. Activity expressed by the enzyme in its dephosphorylated form also was measured in microsomes avoiding treatment with the phosphatase and maintaining the enzyme in the presence of NaF (10,11).

Plasma levels of mevalonate. Plasma mevalonate levels which reflect the overall cholesterol synthesis were determined by gas chromatography/mass spectrometry using selected ion monitoring and deuterated mevalonolactone as internal standard (12).

Cholesterol synthesis from [2-^{14}C]acetate. The liver tissue, stored frozen at −80°C, was homogenized with a glass homogenizer in ice-cold saline (1:2, wt/vol). Pellets obtained after treatment of liver homogenate (4 mL) with $HClO_4$ (480 μL) followed by centrifugation were extracted with chloroform/methanol (2:1, vol/vol) (3 × 4.5 mL) as described previously (13). Aliquots of the extract were counted to measure total lipid radioactivity. The lipid fraction was then saponified with 0.6 N NaOH in 94% ethanol at 60°C for 90 min, and the nonsaponifiable lipids were extracted with hexane. Aqueous phases were acidified and extracted with diethyl ether for the evaluation of incorporation of radioactivity into fatty acids. Residues were dissolved in 1 mL of ethyl acetate, and the incorporation of radioactivity into total and nonsaponifiable lipids and into fatty acids was determined counting 50 μL aliquots of the radioactive samples with a Packard liquid scintillation counter using Ultima Gold (Packard) as the scintillating mixture. Activity was expressed as % of the dose.

In vitro *binding of simvastatin and pravastatin.* Aliquots (5 mL) of liver homogenate (pool of three rat livers) in 0.3 M sucrose with 50 mM NaF and 10 mM 2-mercaptoethanol were added with 0.1 mL of either pravastatin or simvastatin, both as sodium salts, in sucrose buffer in order to obtain for both drugs two concentration levels (6 and 600 nM). Control samples were added with 0.1 mL of sucrose buffer. The suspensions were incubated at 37°C for 10 min. From each sample washed microsomes were then prepared and HMG–CoA reductase activity was measured as described above.

Statistical analysis. Statistical analysis was performed by multiple comparison using the Duncan test. Results are expressed as means ± SD.

RESULTS

The incorporation of sodium [2-^{14}C]acetate into unsaponifiable lipids (Fig. 1) confirms that both simvastatin and pravastatin inhibit the *in vivo* synthesis of cholesterol. Although not statistically significant, there is a suggestion that the inhibition caused by simvastatin was somewhat greater (94 and 81% at 1 and 4 h) than that caused by pravastatin (79 and 72% at 1 and 4 h). The synthesis of fatty acids from labelled acetate was not affected in treated animals relative to controls (data not shown), indicating that the effect of the drugs on cholesterol synthesis was specific.

Mevalonate plasma levels following simvastatin treatment were significantly lower than those of controls both 1 and 4 h after administration of the inhibitor (Fig. 2), whereas following pravastatin there was only a significant difference at 4 h ($P < 0.05$). Mevalonate levels were also significantly lower with simvastatin as compared to those with pravastatin.

Simvastatin lowered both the total and expressed activities of liver HMG–CoA reductase determined *ex vivo* (Fig. 3).

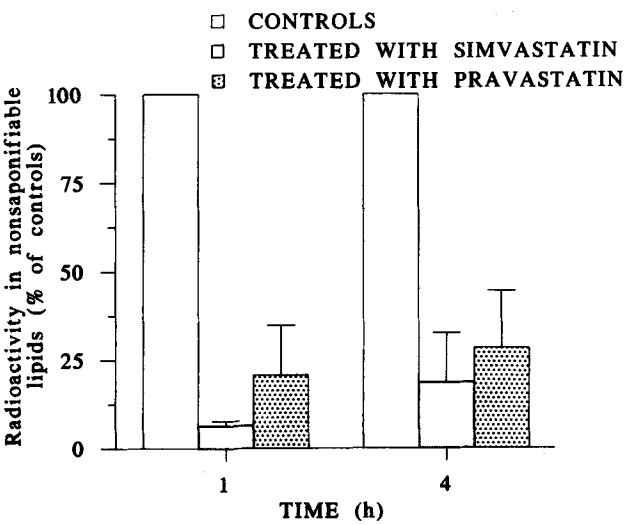

FIG. 1. Inhibition of *in vivo* [2-^{14}C]acetate incorporation into nonsaponifiable liver lipids. Livers of control animals and of rats treated with either simvastatin or pravastatin and [2-^{14}C]acetate were extracted as described in the text. Results are expressed as % of activity found in nonsaponifiable lipids of treated animals assuming 100% that of controls receiving only the vehicle of either simvastatin or pravastatin. Data are means ± SD of values obtained from four rats.

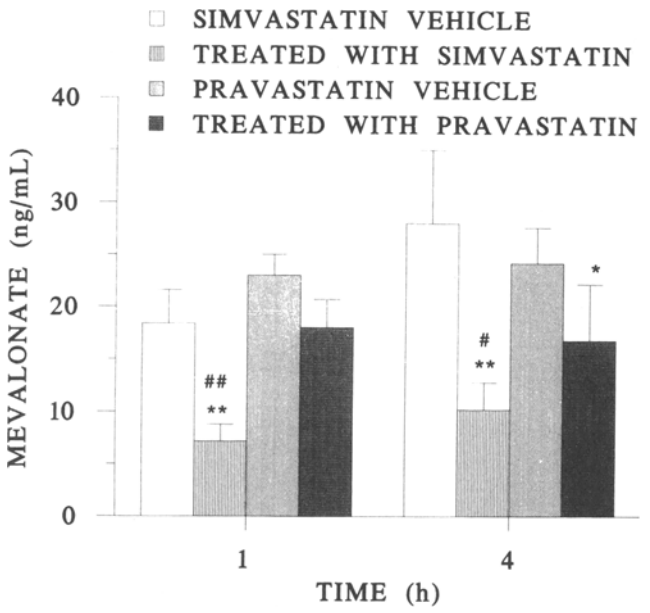

FIG. 2. Mevalonate plasma levels in rats treated with either simvastatin or pravastatin. Data represent mean ± SD of plasma mevalonate concentration (ng/mL) determined in four animals per group. $*P < 0.05$; $**$ $P < 0.01$ vs. control animals; # $P < 0.05$, ## $P < 0.01$ vs. animals treated with pravastatin at the same time.

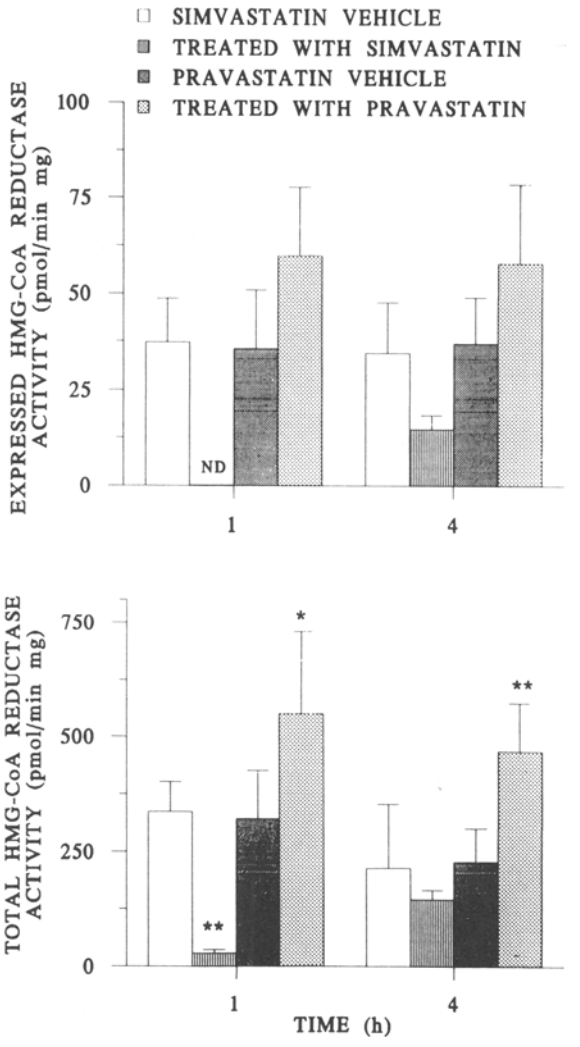

FIG. 3. Hepatic 3-hydroxy-3-methyglutaryl–CoA reductase activity (expressed and total). Activity was measured in the microsomal fractions prepared as described in the text from rats treated with either simvastatin or pravastatin. Results represent mean ± SD of four rats in each group. $*P < 0.05$; $**$ $P < 0.01$ vs. control animals; ND = not detectable.

One hour after treatment, the activity of the expressed dephosphorylated enzyme was below the limits of detection (<4 pmol mevalonic acid min^{-1} mg $protein^{-1}$). At 4 h HMG–CoA reductase activity reached approximately 50% of that of control animals. Nevertheless, due to high variability, statistical significance of the differences was not observed for the expressed form of HMG–CoA reductase. Total activity of the enzyme also was dramatically lowered by simvastatin; more than 90% inhibition of enzyme activity was seen 1 h after the administration of the drug (Fig. 3; $P < 0.01$). At 4 h the activity did not differ significantly from controls. In pravastatin-treated animals a completely different pattern was observed. Total enzyme activity, both 1 h and 4 h after drug administration, was twice that found in controls. There is a suggestion that the expressed form of HMG–CoA reductase also was higher in treated animals both at 1 and 4 h after treatment. Total activity of the enzyme in pravastatin-treated rats 15 and 30 min after treatment was instead 64 and 59% of that of controls, ensuring that lack of inhibition observed at longer times was not attributable to removal of the drug during the preparation of the microsomal fraction.

In order to further ensure that lack of inhibition observed with pravastatin at longer times was not attributable to removal of the drug during the preparation of the microsomal fraction, *in vitro* binding of the two drugs were carried out. Two concentration levels were tested, the higher corresponding to that previously described to occur in liver 2 h after treatment of rats with 25 mg/kg of the two drugs (4), a dose only slightly higher than that used here. Inhibition by pravastatin (Table 1) was lower than by simvastatin, as expected from the higher inhibition constant of the latter drug. Nevertheless, because enzyme inhibition was detectable even with the lower concentration of pravastatin, then pravastatin was not removed during the preparation of microsomes.

DISCUSSION

The marked decrease of labelled acetate incorporation into unsaponifiable lipids by treatment with pravastatin and simvastatin is in good agreement with previously reported data (4). The effect of these drugs on cholesterol biosynthesis was confirmed by mevalonate plasma levels which reflect the total body *in vivo* synthesis and supply an indirect evaluation of modifications of cholesterol synthesis (14,15). Despite the fact that pravastatin effect was significantly lower than that of simvastatin as far as mevalonate plasma levels are concerned, a conclusion about a different therapeutic effect of the two drugs could not be drawn because a single dose was ad-

TABLE 1
Inhibition of 3-Hydroxy-3-Methylglutaryl–CoA Reductase in Microsomes Prepared from Livers Incubated with Pravastatin and Simvastatin[a]

Drug concentration (nM)	Simvastatin		Pravastatin	
	Activity (pmol/min mg protein)	% Inhibition	Activity (pmol/min mg protein)	% Inhibition
0	53 ± 2		53 ± 2	
6	6.6 ± 0.3	88	32 ± 1	40
600	1.6 ± 0.2	97	20 ± 2	62

[a]Liver homogenate of untreated rats were incubated with the two drugs as described in the text. Microsomes isolated after incubation were used to evaluate the expressed enzyme activity as described. Values are expressed as means ± SE.

ministered and evaluation was carried out early after the administration.

In animals and humans it has been shown that pravastatin is actively transported into the liver while its uptake is less efficient in cells where active transport is deficient (5). Moreover it has been reported that pravastatin metabolites are not active as HMG–CoA reductase inhibitors. For the more lipophilic simvastatin, passive transport across membranes occurs, and its main hydroxylated metabolite is as active as the parent drug (6,16). Based on these observations and on the higher affinity of HMG–CoA reductase for simvastatin than for pravastatin, one should expect HMG–CoA reductase in the liver of animals treated with simvastatin to be inhibited for a longer period than in the liver of animals treated with pravastatin. In fact, expressed activity of HMG–CoA reductase in the livers of simvastatin-treated rats was found to be significantly lower than in controls both 1 and 4 h after treatment. With pravastatin, expressed activity was instead slightly higher than in controls. When total activity of the enzyme was measured, which reflects enzyme concentration, differences between simvastatin and pravastatin were even more striking. Both at 1 and 4 h after treatment, activity was dramatically lowered by simvastatin while with pravastatin there was a significant enhancement of the activity.

The increase of total activity of the enzyme observed in pravastatin-treated rats was not unexpected because the inhibition of enzyme activity is known to increase hepatic HMG–CoA reductase messenger RNA levels with the consequent increase of enzyme protein synthesis (2). On the other hand, the increase of the total amount of enzyme was not accompanied by a corresponding increase of overall cholesterol biosynthesis as evidenced by acetate incorporation and mevalonate plasma levels. This might be attributable, in part, to the fact that increase in the level of the enzyme in its active form is not significant.

Simvastatin, however, induced a decrease in the total and expressed activity of the enzyme, thus accounting for the more pronounced decrease observed for the overall synthesis with this drug as compared to pravastatin. Moreover, the inhibition of *ex vivo* HMG–CoA reductase activity strongly suggests that simvastatin is bound to the enzyme even 4 h after administration and therefore is associated with the enzyme in the microsomal fraction used to measure the activity. This is consistent with the inhibition constants reported by Ishida *et al.* (17) which are higher by an order of magnitude for pravastatin ($K_i = 2.3 \cdot 10^{-9}$) than for simvastatin ($K_i = 1.2 \cdot 10^{-10}$) and with the observation that the lipophilic portion of these compounds interacts with a lipophilic portion of the enzyme protein (18). Our explanation for the elevated HMG–CoA reductase activity in pravastatin-treated animals is that the drug is no longer present in the microsomes due to its clearance from the liver prior to harvesting. In fact, inhibition by pravastatin in microsomes prepared from a homogenate incubated in the presence of the drug and inhibition in *ex vivo* experiment at early times after treatment ensured that removal of the drug does not occur from liver after harvesting.

Differences observed here between the two drugs are consistent with the plasma decay curves reported by Morris *et al.* (7) in healthy subjects given a single oral dose of these drugs and represent a direct evidence for the previous hypothesis that the longer half-life of simvastatin is attributable to the higher affinity for HMG–CoA reductase of either the drug or its hydroxylated metabolite.

ACKNOWLEDGMENTS

This work was supported in part by grants of the Italian National Research Council (CNR) and MURST. We are grateful to Andrea Lorenzi for his technical assistance.

Names of journals must be abbreviated according to *Chemical Abstracts Service Source Index* (CASSI), published by Chemical Abstracts Service, P.O. Box 3012, Columbus, OH 43210. These abbreviations are identical to those used in *Chemical Abstracts. These abbreviations are to be used exclusively.*

If it is necessary to refer to "unpublished data," "personal communication," "manuscript in preparation" or papers "submitted for publication," such citations should not be listed as references, but are to appear in the text, e.g., (Turner, E.H., and Smith, D.E., unpublished data). Authors must obtain written permission to cite the unpublished work of others, and copies of such correspondence must accompany the manuscript. Avoid the use of *et al.* in referring to authors: list all names.

NOTE: All titles in References section should be capitalized. See examples above.

NOTE: *Lipids* is now italicizing all mathematical variables. This may not have been clear in January 1995 "Guide to Authors."

AVAILABILITY OF PURIFIED OMEGA-3 FATTY ACIDS

Kilogram quantities of EPA and DHA ethyl ester capsules are available free of charge through the Fish Oil Test Materials Program, a joint effort of the National Oceanic and Atmospheric Administration and National Institutes of Health. These quality-assured and quality-controlled materials contain 94% EPA or 90% DHA. Ethyl esters of vegetable oils (olive, corn, and safflower) are available in capsule form as controls. Funded research projects studying the effect of

(continued on next page)

omega-3 fatty acids in health and disease, from all funding sources, are eligible to receive these capsules. For further information or to request a short application form, contact the Fish Oil Test Materials Program at 12501 Washington Ave., Rockville, MD 20852 (Phone: 301-443-9643; Fax: 301-594-0035).

CALENDAR

February 1996
Fourth International Symposium on Hyphenated Techniques in Chromatography (HTC 4), Feb. 6–9, 1996, Saint John's Conference Center, Bruges, Belgium. Five workshops (hands-on training as well as tutorials) will be held Feb. 4–5. (1) Large volume injection: the next step in capillary gas chromatography for trace analysis; (2) Pre- and postcolumn techniques in HPLC for improved analyte isolation, derivatization, cleanup, separation, and detection; (3) Isotopically labeled compounds in hyphenated GC techniques; (4) Analytical tools for GC–MS (advanced modes of ion-trap spectrometry); (5) Biomedical applications of GC–MS. Purification and Characterization of a Cytochrome P450 Isozyme Catalyzing Lanosterol 14α-Demethylation (P450*14DM*) in Hamster Liver

Yoshio Sekigawa[a,1], Morio Fukuhara[a,*], Yoshiko Sonoda[b], and Yoshihiro Sato[b]

[a]Department of Pharmaceutical Sciences, National Institute of Public Health and [b]Department of Biochemistry, Kyoritsu College of Pharmacy, Tokyo 105, Japan

ABSTRACT: To characterize cholesterol synthesis in Syrian golden hamster, an isozyme of cytochrome P450, lanosterol 14α-demethylase (P450*14DM*), which catalyzes the initial step in the biosynthesis of cholesterol from lanosterol, was purified and its mode of induction by microsomal enzyme inducers was characterized. P450*450DM* was purified from hamster livers by chromatography using aminooctyl-Sepharose CL-4B, hydroxylapatite, DEAE-5PW, and CM-Sepharose CL-6B columns, to a specific content of 12.8 nmol/mg-protein. The purified protein displayed a single band on SDS–polyacrylamide gel electrophoresis with an apparent molecular weight of 52,000. The absorption spectra of the oxidized form of the purified protein showed a Soret peak at 417 nm in a low-spin state and a Soret peak of reduced CO-binding complex at 448 nm. In a reconstituted system, the purified protein catalyzed 14α-demethylation of 24,25-dihydrolanosterol (1.58 nmol/min/nmol-P450), although it did not show any activities toward testosterone and 7-ethoxyresorufin, marker substrates of other P450 families. Immunoblot analysis using an antibody against porcine P450*14DM*, which inhibited the activity of lanosterol 14α-demethylation in the hamster liver microsomes, demonstrated that the level of this isozyme protein was markedly decreased in dexamethasone-treated hamster livers. This was accompanied by a decrease in the enzyme activity. In contrast, the levels and the activity in the phenobarbital- and 3-methylcholanthrene-treated hamsters were almost equal to that in the untreated animals.

Lipids 30, 1067–1073 (1995).

It is well known that there are differences in hepatic cholesterol synthesis among mammalian species. Several studies disclosed significant quantitative differences in sterol balance among the species. For example, hepatic cholesterol metabolism differs between the rat and hamster. In general, activities of the rate-limiting enzyme in the biosynthesis of cholesterol (e.g., acyl-CoA/cholesterol acyltransferase and 3-hydroxy-3-methyl-glutaryl-CoA reductase) in the hamster are lower than in the rat (1). It has been reported that the hamster might offer a better animal model for examining human plasma lipoprotein profiles, lipoprotein metabolism, and liver cholesterol homeostasis than the rat (2–4).

In the metabolism of cholesterol, several steps are mediated by P450 isozymes. Marked species differences are known in mammalian cytochrome P450 (P450) involved in the activation of xenobiotics, including carcinogens. However, relatively few studies have been done on the species differences in P450 isozymes that metabolize endogenous substances, such as cholesterol, steroid hormones, and prostaglandins. Hamsters are known to have P450 isozymes with different properties from those of other animals (5–7). However, it is not fully known whether P450 isozymes in the hamster are similar to those of other species in metabolism of endogenous substances.

The initial step of cholesterol biosynthesis from lanosterol in yeast and mammals is the oxidative removal of the 14α-methyl group (C-32) from lanosterol, which is catalyzed by P450 enzyme, classified as P450*14DM* (P450 isozyme catalyzing lanosterol 14α-demethylation). The isozymes have been purified from yeast (8), rat liver (9,10), porcine liver (11), and human liver (12).

These earlier studies suggested that P450*14DM* in the hamster and other mammalian species might differ with respect to catalytic properties and regulation. However, little information is available on the mode of regulation of P450*14DM* in mammalian species or changes induced by xenobiotic treatment.

In the present study, we determined inducibility of P450*14DM* using immunoblot analysis and enzyme assay in Syrian golden hamsters treated with various inducers. We also purified P450*14DM* from Syrian golden hamster livers, characterized its spectral and catalytic properties, and tested its immunoreactivity with other P450 family proteins.

MATERIALS AND METHODS

Materials. Aminooctyl Sepharose CL-4B and CM Sepharose CL-6B were obtained from Pharmacia Fine Chemicals (Uppsala, Sweden). Hydroxylapatite and TSK-gel DEAE-5PW (150 × 21.5 mm i.d., particle size 13 μm) were obtained from Bio-Rad Laboratories (Richmond, CA) and Toso Co. (Tokyo, Japan), respectively. Emulgen 911 was a kind gift by Kao Co. (Tokyo, Japan). 24,25-Dihydrolanosterol (DHL) was prepared as described previously (11). Polyclonal antibodies against P450*14DM* protein were prepared as reported (12). Chemiluminescence reagent for Western blot was obtained from DuPont NEN (Boston, MA). The antibody to rat P450 2C11 was obtained from OXY gene (Dallas, TX). The antibodies to rat P450 2B1 and P450 4A1 were a kind gift from Dr. Omata, Department of Pharmacology, School of Medicine, Kurume University (Fukuoka, Japan). The antibodies to Syrian hamster P450 1A2, Chinese hamster P450 2A2, Syrian hamster P450 3A subfamilies, and porcine P450*14DM* were prepared in our laboratory. All other reagents used were of the highest quality available.

Treatment of animals and preparation of liver microsomes. Male Syrian golden hamsters and male Wistar rats (7–10 weeks old) were obtained from Nippon SLC (Hamamatsu, Japan). Animals were treated either with phenobarbital (60 mg/kg/d) for 4 d, 3-methylcholanthrene (25 mg/kg/d) for 3 d, or dexamethasone (100 mg/kg/d) for 3 d. These inducers were suspended in olive oil and injected intraperitoneally. Control animals received the vehicle only. Animals were killed one day after the last injection, and the livers were removed and homogenized in four volumes of 0.05 M Tris-HCl buffer (pH 7.4), containing 0.154 M KCl and 1 mM EDTA. The homogenates were centrifuged at 9,000 × *g* for 20 min, and then the supernatants were further centrifuged at 105,000 × *g* for 1 h to give microsomal pellets. The microsomes were resuspended in 0.05 M Tris-HCl buffer (pH 7.4), containing 0.154 M KCl, 1 mM EDTA, and 20% glycerol, and stored at −80°C until use.

*Purification of hamster P450*14DM. Hepatic microsomes from male Syrian golden hamsters treated with phenobarbital were suspended in 0.1 M potassium phosphate buffer (pH 7.4), which contained 20% glycerol, 1 mM EDTA, 1 mM DTT, and 0.7% cholic acid to produce final protein concentration of 2 mg/mL. The suspension was stirred gently for 60 min, and then centrifuged at 105,000 × *g* for 1 h. The supernatant was applied to an aminooctyl Sepharose CL-4B column (2.5 × 60 cm) previously equilibrated with 100 mM potassium phosphate buffer (pH 7.4), containing 20% glycerol, 0.7% cholic acid, 1 mM EDTA, and 1 mM DTT. The column was washed with two volumes of 10 mM potassium phosphate buffer (pH 7.4), containing 20% glycerol, 0.4% cholic acid, 1 mM EDTA, and 1 mM dithiothreitol (buffer A), and eluted with buffer A, containing 0.5% Emulgen 911. Eluted fractions were concentrated and dialyzed against 20 mM potassium phosphate buffer (pH 7.25), which contained 20% glycerol and 0.2% Emulgen 911 (buffer B). The resulting solution was applied to a hydroxylapatite column (5 × 5 cm) equilibrated with buffer B. The column was then washed with two volumes of buffer B with 60 mM and then with 90 mM potassium phosphate buffer (pH 7.25), containing 20% glycerol and 0.2% Emulgen 911, respectively. P450*14DM* was eluted with 200 mM potassium phosphate buffer (pH 7.25), which contained 20% glycerol and 0.2% Emulgen 911. Eluted fractions were concentrated and dialyzed against 5 mM potassium phosphate buffer (pH 7.4), containing 20% glycerol and 0.4% Emulgen 911 (buffer C). The solution was applied to a high-performance liquid chromatography equipped with a preparative DEAE-5PW column (21.5 × 150 mm i.d.) equilibrated with buffer C. After the pass through fraction was eluted, a 20–180 mM linear gradient of potassium phosphate buffer was applied. The fractions containing P450 showing immunoreactivity to anti-porcine P450*14DM* antibodies were concentrated and dialyzed with 20 mM potassium phosphate buffer (pH 6.5), containing 20% glycerol and 0.2% Emulgen 911 (buffer D). The resulting solution was applied to a CM Sepharose CL-6B column (1.5 × 5 cm) equilibrated with buffer D. The column was washed with buffer D, and successively eluted with buffer D, containing 60, 90, and 150 mM potassium phosphate to give a final P450*14DM* fraction.

Purification of NADPH-cytochrome c reductase. NADPH-cytochrome c reductase was purified from hamster livers, according to the procedure described by Yasukochi and Masters (13).

Gel electrophoresis and immunoblot analysis. SDS–polyacrylamide gel electrophoresis (PAGE) was performed according to the method of Laemmli (14), and separated proteins were visualized by silver staining. For immunoblot analysis, the separated proteins were transferred onto nitrocellulose membranes or polyvinylidene difluoride membranes, which were then developed using the antibodies raised against various P450 family proteins and detected by using the peroxidase–diaminobenzidine–tetrahydrochloride method (15) or by luminescence-monitored enzyme immunoassay (16).

*Characterization of the purified P450*14DM. The spectra of the purified P450*14DM* were measured by the method of Omura and Sato (17). The apparent molecular weight of the purified P450*14DM* was determined by SDS–PAGE with 10% acrylamide. The catalytic activities of the purified protein were determined using a reconstituted monooxygenase system consisting of the purified P450*14DM* (10–300 pmol), dilauroyl-L-α-phosphatidylcholine, NADPH-generating system, and NADPH-cytochrome c reductase (1 unit). The catalytic activity was measured toward DHL (23 μM of substrate concentration) (11), testosterone (0.25 mM) (18), and 7-ethoxyresorufin (0.3 mM) (19).

Assay of cholesterol synthesis from DHL using hepatic microsomes. The activity of DHL 14α-demethylation was determined by the amounts of cholesterol produced from DHL. Microsomes (2 μg protein) were incubated at 37°C for 30 min at the presence of [24,25-$^{3}H_{2}$]-24,25-DHL (0.37 kBq/mmol,

50 μM) and cofactors according to the method of Trzaskos *et al.* (20). Incubations were started by the addition of DHL. After incubation, methanol and potassium hydroxide were added to a final concentration of 50 and 10%, respectively. The mixture was heated at 70°C for 1 h, then extracted with dichloromethane, washed with water, and dried under nitrogen. The resulting residues were dissolved in 200 μL of dichloromethane, and were subjected to thin-layer chromatography. The band corresponding to cholesterol was collected, and the radioactivity was measured by a scintillation counter.

Protein assay. Protein contents were determined using Lowry's method (21) with bovine serum albumin as standard.

RESULTS

*Effect of anti-porcine P450*14DM *antibody (anti-P450*14DM*) on DHL 14α-demethylase activity in hamster livers.* To ascertain the affinity of the anti-P450*14DM* of pig (11) to hamster P450*14DM*, the inhibition of DHL 14α-demethylation activity of the hamster by the antibody was examined in the fractions containing hamster P450*14DM* obtained from the aminooctyl Sepharose CL-4B column. Anti-P450*14DM* inhibited DHL 14α-demethylation of hamster enzyme in a concentration-dependent manner (Fig. 1).

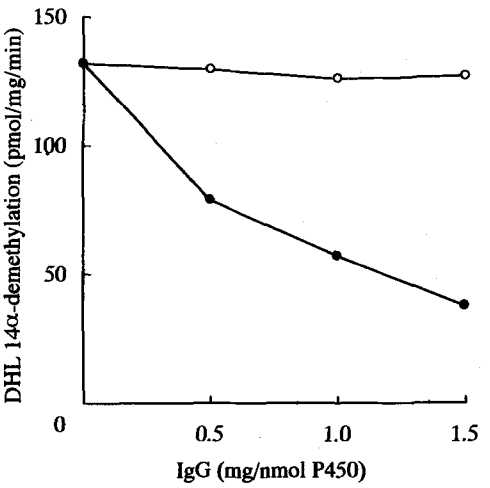

FIG. 1. Inhibitory effect of anti-porcine P450 isozyme catalyzing lanosterol 14α-dimethylation (P450*14DM*) antibody on 24,25-dihydrolanosterol (lanost-8-en-3β-ol) (DHL) 14α-demethylase activities in hamster hepatic microsomes. Hamster hepatic microsomes were incubated with the IgG from anti-sera containing antibodies against porcine P450*14DM* or from preimmune sera prior to the assay of DHL 14α-demethylase. Each point represents the mean of two determinations. (●), anti-porcine P450*14DM*; (○); preimmune sera.

*Purification of hamster P450*14DM. P450*14DM* was purified from hepatic microsomes of phenobarbital-treated hamsters, and a representative result of the purification of P450 is summarized in Table 1. Following solubilization with cholate and fractionation with aminooctyl Sepharose CL-4B column chromatography, the fraction containing P450*14DM* was further fractionated on a hydroxylapatite column. As shown in Figure 2, hydroxylapatite chromatography gave several peaks, which were examined by immunoblot analysis using anti-P450*14DM* (Fig. 3). Anti-P450*14DM* crossreacted strongly to the third fraction (HA-3), which was then collected. As shown in Figure 4, in the final purification step using CM-Sepharose CL-6B chromatography, three peaks were eluted from the column. DHL 14α-demethylase activity was detected in the second (CM-1) and the third (CM-2) fractions, and the former showed higher DHL 14α-demethylase activity than the latter (data not shown). The "CM-1" was collected and designated as P450*14DM* preparation. The specific P450 content of the final preparation was 12.8 nmol/mg-protein.

*Physicochemical and immunochemical properties of the purified hamster P450*14DM. The purified P450*14DM* demonstrated a single protein band upon SDS–PAGE and on immunoblot analysis using anti-P450*14DM*. The apparent molecular weight of P450*14DM* was estimated to be 52,000

TABLE 1
Purification of P450*14DM* from Hepatic Microsomes of Phenobarbital-Treated Hamster Livers[a]

Purification step	Protein (mg)	P450 Total (nmol)	P450 Specific recovery (nmol/mg)	P450 Specific recovery (%)	DHL 14α-demethylation (nmol/min/mg protein)

[a]P450*14DM*, P450 isozyme catalyzing lanosterol 14α-demethylation; DHL, 24,25-dihydrolanosterol (lanost-8-en-3β-ol).
[b]From Pharmacia (Uppsala, Sweden).
[c]From Toso (Tokyo, Japan).
[d]n.d., Not determined.

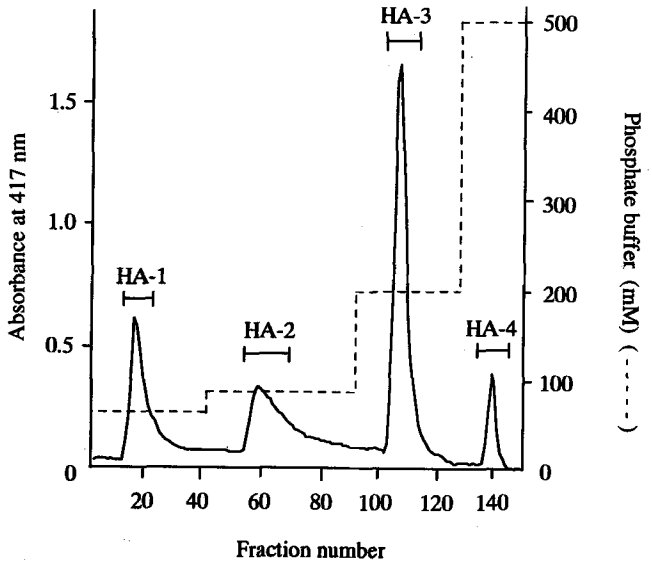

FIG. 2. Elution profile of the P450 fraction from hydroxylapatite column. P450 isozymes were separated on a hydroxylapatite column using a stepwise concentration of a potassium phosphate as described in the Materials and Methods section. One fraction contains 5 mL of eluate.

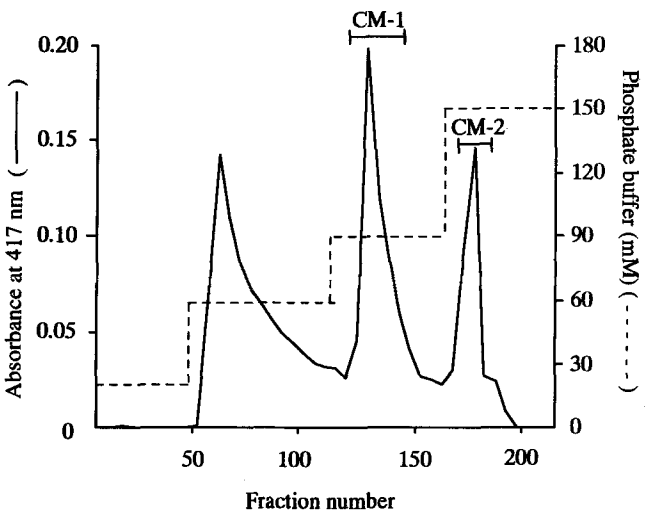

FIG. 4. Elution profile of P450 from CM Sepharose CL-6B (Pharmacia, Uppsala, Sweden). P450 isozymes were separated on a CM Sepharose CL-6B column using a stepwise concentration of potassium phosphate as described in the Materials and Methods section. One fraction contains 5 mL of eluate.

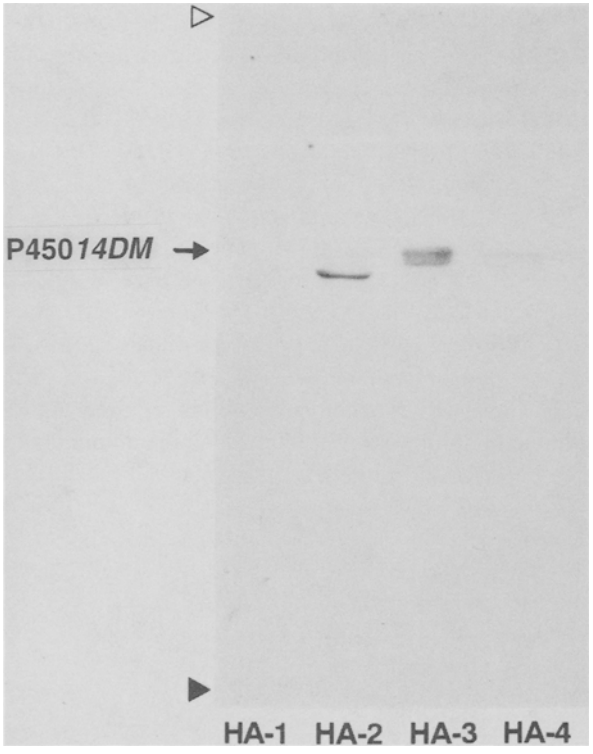

FIG. 3. Immunoblot analysis of the eluted fractions from hydroxylapatite column. Numbers of the individual samples corresponded to those of separated fractions displayed in Figure 2. Each sample (5 μg of protein) was submitted to SDS–polyacrylamide gel electrophoresis, transferred to polyvinylidene difluoride membranes and stained using the antibody against porcine P450*14DM* and peroxidase–diaminotetrahydrochloride.

(Fig. 5A). In immunoblot analysis, the antibody against P450*14DM* recognized two protein bands in hamster hepatic microsomes, and the purified enzyme corresponded to the band with a higher molecular weight (Fig. 5B).

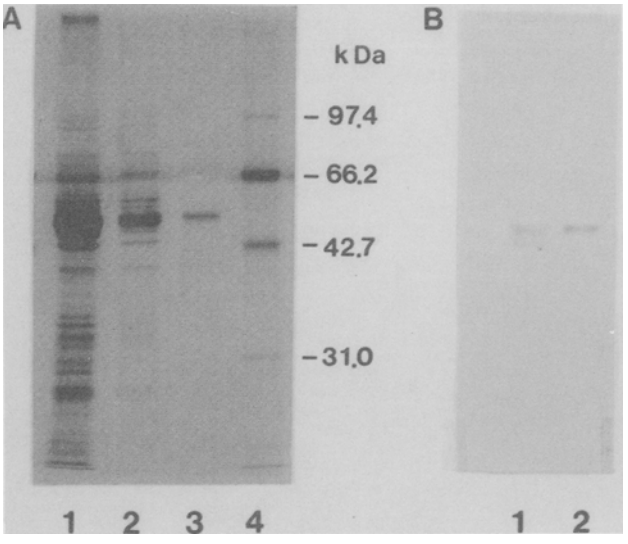

FIG. 5. SDS–polyacrylamide gel electrophoresis (PAGE) (A) and immunoblot analysis (B) of the purified P450*14DM* and hepatic microsomes of phenobarbital-treated hamsters. Panel A: hepatic microsomes from phenobarbital-treated hamsters (lane 1, 1 μg protein), solubilized hepatic microsomes from phenobarbital-treated hamsters (lane 2, 1 μg protein), purified P450*14DM* (lane 3, 0.05 μg protein), and molecular weight standard mixture (lane 4) were electrophoresed on 10% acrylamide gels and stained with silver. Panel B: microsomes from phenobarbital-treated hamster livers (lane 1, 20 μg protein) and purified P450*14DM* (lane 3, 1 μg protein) were submitted to SDS–PAGE, transferred to nitrocellulose membranes, and stained using the antibody against porcine P450*14DM* and peroxidase–diaminobenzidine–teterahydrochloride.

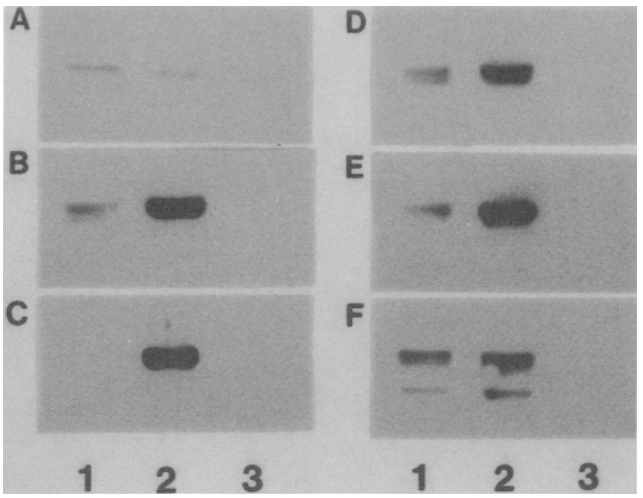

FIG. 6. Imunoblot analysis of the purified P450*14DM* using antibodies against P450 isozymes. P450 samples were submitted to SDS–PAGE, transferred to nitrocellulose membranes, and stained immunochemically using the antibody against Syrian hamster P450 1A2 (panel A), Chinese hamster P450 2A2 (panel B), rat P450 2B1 (panel C), rat P450 2C11 (panel D), Syrian hamster P450 3A (panel E), and rat P450 4A1 (panel F). Lanes 1 and 2 contain hepatic microsomes (5 μg protein) from untreated and phenobarbital-treated hamsters, respectively. Lane 3 contains purified P450*14DM* (0.1 μg protein) and peroxidase–luminol–hydrogen peroxide reaction. Abbreviations as in Figures 1 and 5.

To ascertain the homogeneity of the purified hamster P450*14DM*, we examined the crossreactivity of the protein with the antibodies against other P450 isozymes (P450 1A2, 2A2, 2B1, 2C11, 3A, and 4A1) by immunoblot analysis. As shown in Figure 6, the purified hamster P450*14DM* did not react with these antibodies.

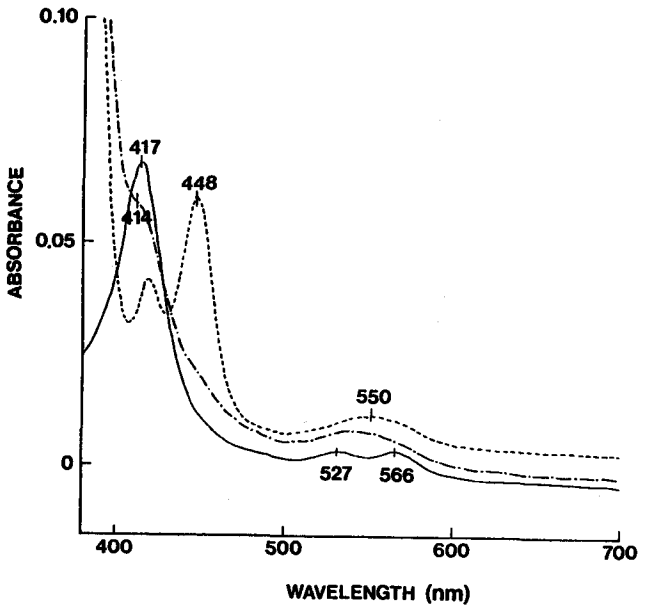

FIG. 7. Absolute spectra of the purified P450*14DM*. The concentration of P450*14DM* was 0.4 nmol/mL–0.1 M potassium phosphate buffer (pH 7.25) containing 20% glycerol. Oxidized, —; dithionite-reduced, –·–; reduced/CO-complex, ----. Abbreviation as in Figure 1.

TABLE 2
Effects of Various Xenobiotic Inducers upon Cholesterol Synthesis from DHL and Microsomal P450 Level

Inducers	Cholesterol synthesis from DHL[a] (pmol/min/mg protein)	P450 (nmol/mg protein)
Control (olive oil)	132 ± 5	0.907 ± 0.103
Phenobarbital	173 ± 16	1.591 ± 0.071[b]
3-Methylcholanthrene	122 ± 5	1.540 ± 0.078[b]
Dexamethasone	27 ± 1[b]	0.574 ± 0.037

[a]This activity represents DHL 14α-demethylation activity expressed as amounts of cholesterol converted from DHL per unit of microsomal protein. Data are expressed as means ± SE for three animals with statistical significance at [b]$P < 0.01$ vs. control (Student's *t*-test). Abbreviation as in Table 1.

The absolute spectra of the purified P450*14DM* showed that the oxidized form of this enzyme had a Soret band at 417 nm, the α bands at 527 and 566 nm (Fig. 7). This indicates that the P450*14DM* was of low-spin ferric P450. The difference absorption spectra of reduced CO-complex showed a maximum at 448 nm.

*Catalytic properties of purified P450*14DM. The catalytic activities of the purified P450*14DM* toward testosterone and 7-ethoxyresolfin were examined in a reconstituted system. The purified enzyme showed DHL 14α-demethylase activity (1.58 nmol/min/nmol-P450), but it did not show any detectable 7-ethoxyresorufin *O*-deethylase or testosterone hydroxylase activity.

*Effects of various xenobiotics upon P450*14DM *induction.* To determine the induction mode of P450*14DM*, hamsters were treated with phenobarbital, 3-methylcholanthrene, and dexamethasone and the level of P450*14DM* protein and the changes in the conversion activity of DHL to cholesterol in hepatic microsomes were determined instead of measuring DHL 14α-demethylase. DHL is known to be converted to its final product, cholesterol, when incubated with hepatic microsomes (20). To determine the activity of DHL 14α-demethylase using hepatic microsomes, the addition of two inhibitors in the reaction mixture that block the following reactions after DHL 14α-demethylation is required. As we did not have the inhibitors, we determined the amounts of cholesterol converted from DHL. As shown in Table 2, the conversion rate of DHL to cholesterol in hepatic microsomes decreased by treatment with dexamethasone, but it was not changed by treatment with phenobarbital with 3-methylcholanthrene. The level of P450*14DM* protein analyzed by immunoblotting in hepatic microsome was markedly decreased by treatment with dexamethasone (Fig. 8). These results show that conversion activity of DHL to cholesterol parallels protein levels of P450*14DM* in hepatic microsomes of hamster treated with inducers.

DISCUSSION

In the present study, we purified to apparent homogeneity P450*14DM* from phenobarbital-treated hamster livers. The purified protein was confirmed to be P450*14DM*, as it cross-

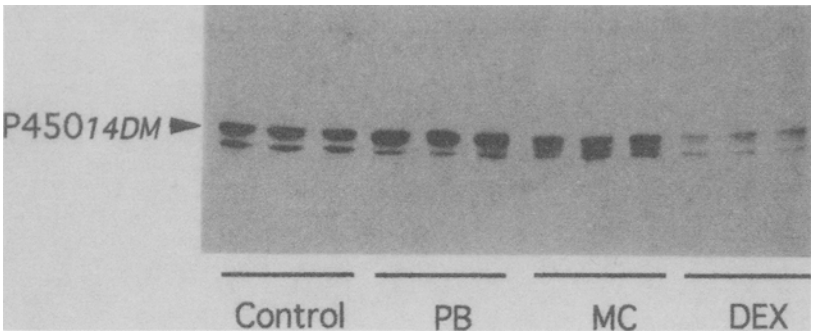

FIG. 8. Inducibility of P450*14DM* in hamster livers by phenobarbital, 3-methylcholanthrene, and dexamethasone. Immunoblot analysis was done on the hepatic microsomes from hamsters treated with phenobarbital (PB), 3-methylcholanthrene (MC), and dexamethasone (DEX). Each well contains 2 μg of microsomal protein with the exception of purified hamster P450*14DM*. The proteins, separated by SDS–PAGE, were transferred to polyvinylidene difluoride membranes, and stained using the antibody against porcine P450*14DM* and peroxidase–luminol–hydrogen peroxide reaction. Abbreviations as in Figures 1 and 5.

reacted with anti-P450*14DM* and showed a high DHL 14α-demethylase activity. As shown in Figure 1, anti-porcine P450*14DM* antibody (anti-P450*14DM*) dose-dependently inhibited the DHL 14α-demethylase activity in hamster hepatic microsomes. This indicates that hamster P450*14DM* is immunologically related to porcine P450*14DM* and that anti-P450*14DM* can be used to study hamster P450*14DM*.

In hamster livers, two bands were detected by immunoblot analysis using anti-P450*14DM*. The purified enzyme showing DHL 14α-demethylase activity corresponded to the upper band of the two in the hepatic microsomes of hamster (Fig. 5B). We also recognized two bands in the rat, and the lower band of the two did not show any DHL 14α-demethylase activity (10). P450*14DM* has been purified from hepatic microsomes of pig (11), human (12), and rat (10). Catalytic properties, including substrate specificity of the purified P450*14DM*, have not been fully characterized. We examined catalytic properties of hamster P450*14DM* toward the substrates other than DHL. However, it did not show any catalytic activities toward testosterone and 7-ethoxyresorufin that are specific to other P450 isozymes, such as P450 2A, P450 2B, and P450 3A (22). These suggest that substrate specificity of P450*14DM* might be very narrow.

As for the induction mode of P450*14DM* in the liver, induction of P450*14DM* by xenobiotic treatment was previously reported by measuring the changes in lanosterol 14α-demethylase activity in rat liver (20). In the present study, we examined the inducibility of P450*14DM* in hamster liver by immunoblot analysis using anti-P450*14DM* and by measuring the enzyme activity (Table 2). Of the inducers examined, dexamethasone-treatment markedly decreased the level of P450*14DM* in hepatic microsomal P450 and DHL 14α-demethylase activity. On the other hand, phenobarbital- and 3-methylcholanthrene-treatment did not affect the level of P450*14DM*. It is well established that, in rat liver, dexamethasone causes a significant increase in P450 content (23). However, we demonstrated that in the hamster, treatment with dexamethasone dramatically decreased the amounts of hepatic microsomal P450 and also the level of P450 3A subfamily protein (6). These findings indicated that in the hamster, dexamethasone may decrease most of P450 isozymes, including P450*14DM*.

Little information is available, so far, on the properties of hamster P450*14DM*. In the present study, we have characterized the physicochemical and catalytic properties of the purified P450*14DM* and demonstrated differences in the properties of P450*14DM* of the hamster from those of the rat, notably in the induction mode. Further studies on P450*14DM* of hamster livers with respect to the induction mechanism and cDNA structure are needed to explain species differences in cholesterol synthesis.

Multiple Forms of the Enzyme Glycerophosphodiesterase Are Present in Human Brain

Brian M. Ross[a,*], Allan L. Sherwin[b], and Stephen J. Kish[a]

[a]Human Neurochemical Pathology Laboratory, Clarke Institute of Psychiatry, Toronto, Canada and [b]Montreal Neurological Institute, Montreal, Canada

ABSTRACT: Brain levels of glycerophosphodiesters, including glycerophosphocholine (GPC) and glycerophosphoethanolamine (GPE), are altered in many human central nervous system disorders. Although much information is available on the enzymes responsible for the formation of these phospholipid metabolites, little information is known regarding their catabolism, by glycerophosphodiesterases, in human brain. In both autopsied and biopsied temporal cortex, a phosphocholine-producing glycerophosphodiesterase activity was observed. In the presence of 1 mM EDTA, the enzyme possessed a pH optimum of 9.0, while the addition of 5 mM zinc acetate shifted the pH optimum to 10.5. When assayed at pH 9.0 in the absence of zinc acetate, the K_m and V_{max} were 104 ± 2 μM and 77 ± 18 nmol/h/mg protein, respectively, while assaying at pH 10.5 in the presence of 5 mM zinc acetate yielded a K_m of 964 ± 56 μM, and a V_{max} of 534 ± 114 nmol/h/mg protein. Furthermore, whereas submillimolar concentrations of zinc acetate stimulated the activity of the enzyme in a dose-dependent manner when assayed at pH 10.5 (EC_{50} = 20.3 ± 3.0 μM), this did not result in a reciprocal inhibition of glycerophosphocholine phosphodiesterase (GPC PD) activity when assayed at a more acidic pH. This may suggest that human brain contains two phosphocholine-producing GPC PD activities, differentiable by their sensitivity to zinc ions. An activity capable of hydrolyzing GPE to form phosphoethanolamine could not be detected in either biopsied or autopsied brain. However, a choline/ethanolamine-producing glycerophosphodiesterase activity could be readily detected in biopsied, but not autopsied brain. This novel enzyme possessed a neutral pH optimum and was dependent upon divalent cations for activity. In conclusion, human brain contains at least two different glycerophosphodiesterases, a phosphocholine, and a choline/ethanolamine-producing activity, only one of which can be detected in autopsied tissue. The results of previous studies measuring brain glycerophosphodiesterase activity in degenerative brain conditions may need to be reevaluated in the light of these observations.

Lipids 30, 1075–1081 (1995).

Glycerophosphodiesters (GPD), for example, glycerophosphocholine (GPC) and glycerophosphoethanolamine (GPE), are abundant catabolites of brain membrane phosphoglycerides formed by the sequential actions of phospholipase A and lysophospholipase (1). Recent studies have shown altered brain GPD levels in several central nervous system disorders. For example, *in vivo* phosphorus-31 nuclear magnetic resonance spectroscopy studies suggest increased brain levels of GPD in schizophrenia (2), autism (3), and Alzheimer's disease (4). This is supported by the post mortem finding of increased GPC concentration in the brains of patients with Alzheimer's disease (5) and olivopontecerebellar atrophy (6). Although these changes have frequently been attributed to altered rates of phosphoglyceride breakdown in these disorders, they also may be explained by changed activity of the GPC catabolizing enzyme, GPC phosphodiesterase (GPC PD). Previous investigations of this enzyme in animal brain have show it to be a family of at least three different types, two of which catalyze the formation of glycerol and phosphocholine, while the other yields glycerol phosphate and choline as products (7–9). However, no enzyme capable of hydrolyzing GPE, another major brain GPD, has been identified. Furthermore, studies of these enzymes in human brain have not defined or characterized the forms which are present (5,10,11). Since GPC is also of considerable interest, due to its possible therapeutic potential in Alzheimer's disease (12), and its enhancement of choline acetyl transferase activity (13), it is now timely to investigate the enzyme responsible for its catabolism in human brain, and to examine the characteristics of the subtypes present.

MATERIALS AND METHODS

Materials. Glycerophospho[^{3}H]choline and glycerophospho-[^{14}C]ethanolamine were synthesized from 1,2-dipalmitoyl-*sn*-glycero-3-phospho-[methyl-1-^{3}H]choline and 1,2-dioleoyl-*sn*-glycero-3-phospho-[2-^{14}C]ethanolamine (Amersham, Oakville, Ontario, Canada), by alkaline alcoholysis (14). The identity of the synthesized compounds was confirmed as described (14). Radiochemical purity was greater than 98.5%, the remainder being composed of choline (ethanolamine) phosphate and choline (ethanolamine) as as-

sessed by thin-layer chromatography (TLC). The concentration, as deduced from the specific activity of the starting compounds, was confirmed by phosphate assay (15). TLC plates were purchased from Whatman (Chromatographic Specialties, Brockville, Toronto, Canada), and Dowex ion exchange resin from Biorad (Mississauga, Toronto, Canada). All other chemicals were purchased from Sigma Chemical Co. (St. Louis, MO), and were of the highest grade commercially available.

Brain tissue. Temporal cortices (Brodmann area 21) from the brains of four neurologically normal subjects of age 55 ± 14 yr (mean ± SEM) and post mortem interval 8 ± 1 h were used throughout this study. The brains had been frozen at autopsy and stored at −80°C. Biopsied temporal cortex, frozen immediately after surgical excision, was obtained from three individuals (age 25 ± 3 yr) who had undergone temporal lobectomy for epileptic seizures. The biopsied tissue was from nonepileptogenic regions as determined by depth recording electrography. All tissue was free of gross infarct and tumors, and autopsied tissue did not show any indication of neurodegenerative disease as assessed by neuropathological examination.

GPC PD assay. Brain tissue was dissected free of white matter and visible blood vessels, and sonicated for 15 s on ice using a Bonwell Biosonics sonicator (70% power) in 10 vol of 1 mM EDTA, 1 mM EGTA, and 50 mM HEPES/sodium hydroxide, pH 7.4. Aliquots containing 50 µg of protein were added to a buffer (total volume 200 µL) containing [^{3}H]-GPC (100,000–200,000 dpm), the exact reaction conditions for each experiment is described in the Results section. Boiled tissue homogenates were used as "blank" reactions; all samples were assayed in duplicate. The reaction was allowed to proceed for 45 min at 37°C before being terminated by the addition of 800 µL of chloroform/methanol (1:2). Phase separation was accomplished by the sequential addition of 200 µL chloroform and 200 µL water (16). The aqueous phase was removed, and the organic phase reextracted with 800 µL water. The combined aqueous phases were applied to 1 mL Dowex 50W-X8 (H^+) in a total volume of 4.7 mL. The columns were washed with 5 mL water to elute GPC, followed by 2 × 5 mL water to elute phosphocholine, and finally after washing with a further 5 mL water, choline was eluted with 3 mL of 3 M hydrochloric acid (14,17). Radioactivity in each fraction was determined by liquid scintillation spectroscopy. Elution volumes were determined using authentic radiolabelled standards. In some experiments, the aqueous phases were dried by vacuum centrifugation, resuspended in 30 µL water containing 200 µg GPC, 200 µg phosphocholine, and 40 µg choline, applied to silica gel TLC plates (Whatman LK5D), and developed in methanol/0.9% sodium chloride/30% ammonium hydroxide (70:50:5, by vol) (16). Compounds were visualized by staining with iodine vapor, scraped into 1 mL water and radioactively quantified. The TLC separation gave quantitatively similar results to the ion exchange method and, due to the lower reaction blanks when choline release was being investigated (approx. 800 dpm using ion exchange columns compared to 150 dpm using TLC), routinely was used to detect the production of free base. Similarly, when GPE was used as substrate, TLC separation was also used, with cold GPE (10 µg), phosphoethanolamine (10 µg), and ethanolamine (5 µg) being added as standards, the plate developed in methanol/0.5% sodium chloride/30% ammonium hydroxide (50:50:5), and the compounds visualized with ninhydrin.

Protein concentration was determined by the Biorad protein assay according to the manufacturers' instructions.

RESULTS

Phosphocholine-producing enzymes. The GPC PD activity of autopsied human temporal cortex catalyzed the hydrolysis of GPC to yield phosphocholine as the major product. The production of phosphocholine was linear with respect to time for at least one hour, and with respect to protein up to at least 150 µg homogenate protein (data not shown). The characteristics of GPC hydrolysis were dependent upon the ionic conditions used. Thus, in the presence of 1 mM EDTA or 5 mM calcium chloride, GPC PD activity exhibited a single pH optimum of 9.0, while the addition of 5 mM zinc acetate caused the pH

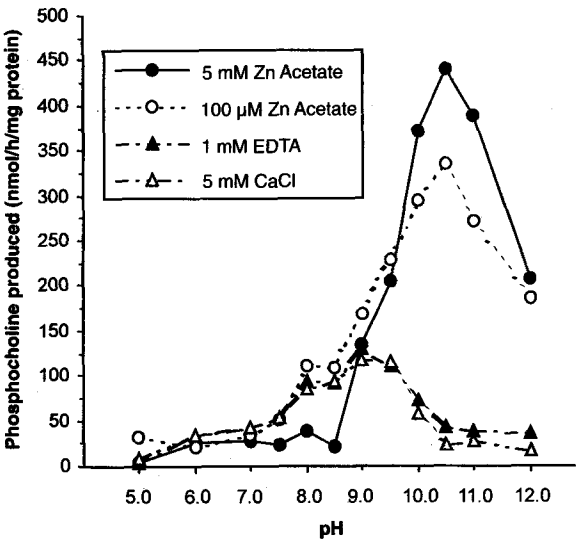

FIG. 1. Effect of assay pH upon the phosphocholine-producing glycerophosphocholine phosphodiesterase (GPC PD) activity of autopsied human brain. Activity was assayed using 5 mM [^{3}H]glycerophosphocholine as substrate under varying pH in the presence of 5 mM or 100 µM zinc acetate, 5 mM calcium chloride, or 1 mM EDTA as indicated. The assay buffer also contained 1 mM levamisole, and 12.5 µM EDTA, and 12.5 µM EGTA contributed by the homogenization buffer. The buffers used at each pH were: pH 5 and 6, 100 mM sodium acetate/acetic acid, pH 7–8, 100 mM HEPES/sodium hydroxide and pH 8.5–11, and 100 mM glycine/sodium hydroxide. Data represent the mean activity of three human temporal cortices analyzed in independent experiments. For reasons of clarity, error bars are not shown; average SEM was 14% as a percentage of mean activity. The rather high error values in this and other figures are not a consequence of high intra-assay variability, but are due to significantly different values of GPC PD activity being present in each brain. However, in all experiments, each brain examined yielded qualitatively similar results.

optimum to change to 10.5 (Fig. 1). Indeed, the addition of zinc acetate caused an approximately 10-fold stimulation of activity at pH 10.5. Furthermore, while the addition of 5 mM zinc acetate did not alter GPC PD activity when assayed at pH 9.0, it was inhibited markedly compared to zinc-free conditions at the slightly more acidic pH of 8.5. However, reducing the concentration of zinc acetate to 100 μM resulted in no inhibition relative to zinc-free conditions being observed at pH 8.5 (Fig. 1). To further investigate these two effects, namely zinc-mediated stimulation of GPC PD activity at pH 10.5, and zinc-mediated inhibition at pH 8.5, GPC PD activity was measured in the presence of varying concentrations of zinc acetate (Fig. 2). At pH 8.5, GPC PD activity was unaffected by zinc acetate concentrations below 1 mM, although higher concentrations caused inhibition, in agreement with Figure 1. In contrast, at pH 10.5, GPC hydrolysis was stimulated by zinc acetate in a dose-dependent manner (EC_{50} = 20.7 ± 3.0 μM; n = 3), with the highest activity occurring in the presence of 5 mM zinc acetate (Fig. 2).

Further investigations, in which the enzyme was assayed at either pH 8.5 in the presence of 1 mM EDTA, or pH 10.5 in the presence of 5 mM zinc acetate, showed that GPC hydrolysis exhibited Michaelis-Menton kinetics (Fig. 3), but with different K_m and V_{max} values under each condition: using 1 mM EDTA/pH 9.0 the K_m and V_{max} were 104 ± 2 μM and 77 ± 18 nmol/h/mg protein, respectively (by Eadie-Hofstee transformation), while in the presence of 5 mM zinc acetate/pH 10.5, K_m and V_{max} were 964 ± 56 μM and 534 ± 114 nmol/h/mg protein, respectively.

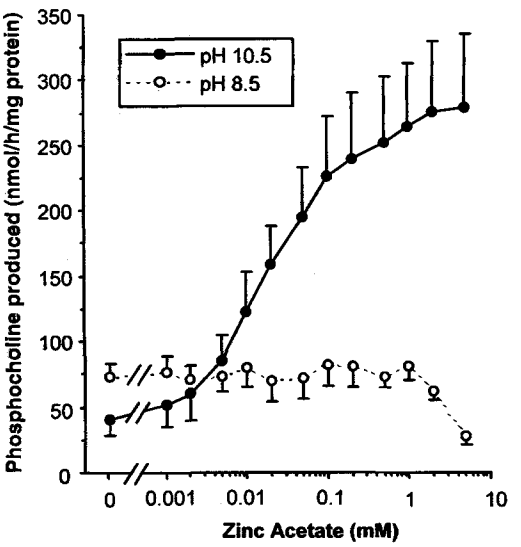

FIG. 2. Effect of zinc acetate concentration upon the phosphocholine-producing glycerophosphocholine phosphodiesterase activity of autopsied human brain. Activity was measured under a range of zinc acetate concentrations at pH 8.5 or 10.5 as indicated using 5 mM [^{3}H]glycerophosphocholine as substrate. The tissue preparations used in this experiment were homogenized in 50 mM HEPES/sodium hydroxide, pH 7.4 free of EDTA and EGTA. No chelating agents were added to the incubation buffer. Data represent the mean activity of three human temporal cortices analyzed in independent experiments; bars show the SEM.

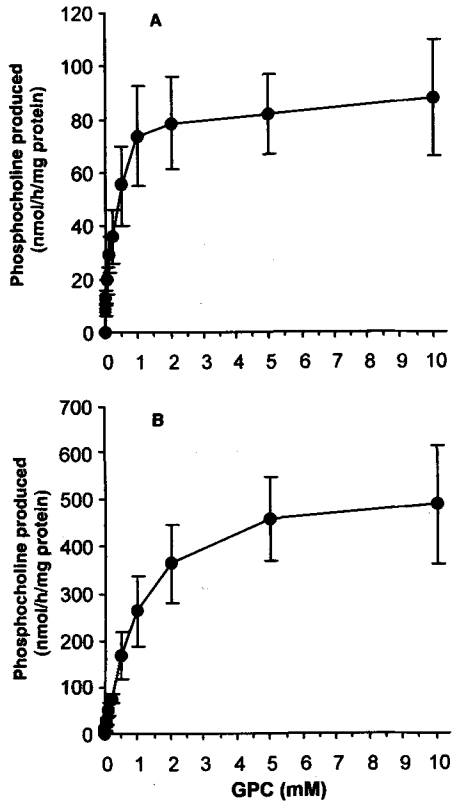

FIG. 3. Effect of substrate concentration upon the phosphocholine-producing GPC PD activity of autopsied human brain. GPC PD activity was measured in the presence of (A) 1 mM EDTA at pH 9.0, or (B) 5 mM zinc acetate at pH 10.5. The concentration of chelating agents contributed by the homogenization buffer were 12.5 μM EDTA and 12.5 μM EGTA. Data represent the mean activity of three human temporal cortices analyzed in independent experiments; bars show the SEM. See Figure 1 for abbreviation.

When assayed at pH 10.5, the enzyme was strongly activated in the presence of 5 mM cobalt chloride (1150 ± 108% of no additions), compared to 1400 ± 99% for zinc acetate (n = 3). However, 5 mM calcium chloride, sodium chloride, sodium acetate, or potassium chloride failed to activate the enzyme (data not shown), and 5 mM magnesium chloride caused only marginal activation (174 ± 27% of no additions; n = 3). In contrast, when assayed at pH 9.0, the rate of phosphocholine release was not altered by any of the aforementioned salts (data not shown).

The possibility that two phosphocholine-producing GPC PD activities were present in the preparation was investigated by pre-incubating the tissue homogenates with several compounds capable of covalently modifying amino acids (Table 1). Interestingly, acetic anhydride inhibited GPC PD activity by different degrees depending on whether GPC PD activity was assayed at pH 9.0 in the presence of EDTA (approximately 80% inhibition), or at pH 10.5 in the presence of 5 mM zinc acetate (approximately 25% inhibition). In contrast, when assayed at either pH 9.0 with 1 mM EDTA, or at pH 10.5 with 5 mM zinc acetate, the rate of phosphocholine release was unaffected by pre-incubation of tissue homogenates with bromophenacylbromide, *N*-ethylmaleimide,

TABLE 1
Effect of Amino-Modifying Compounds upon Phosphocholine-Producing GPC PD Activity in Autopsied Human Brain[a]

	Assay incubation conditions		
	0.5 mM GPC 1 mM EDTA pH 9.0	0.5 mM GPC 5 mM zinc acetate pH 10.5	5 mM GPC 5 mM zinc acetate pH 10.5
Bromophenacylbromide	112 ± 8	105 ± 2	113 ± 6
Diethylpyrocarbonate	33 ± 2	36 ± 2	45 ± 5
Phenylmethylsulphonylfluoride	116 ± 42	101 ± 3	94 ± 10
N-ethyl maleimide	105 ± 4	100 ± 5	107 ± 13
Acetic anhydride	22 ± 1	70 ± 1	75 ± 2

[a]Aliquots of temporal cortical homogenates were incubated at 37°C for 15 min in the presence of 10 mM modifier [dissolved in dimethylsulfoxide (DMSO); final DMSO concentration 4%]. The homogenates were then assayed for glycerophosphocholine phosphodiesterase (GPC PD) activity under the indicated reaction conditions. The concentration of modifier during the assay of GPC PD activity was 1 mM, due to the homogenates being diluted by assay buffer. The assay buffer also included 1 mM levamisole, 12.5 μM EDTA, and 12.5 μM EGTA contributed by the homogenization buffer. Results are expressed as mean percentage of activity in the presence of vehicle ± SEM for three brains analyzed in independent experiments. Control activity (i.e., pre-incubation in the presence of 4% DMSO) was 45 ± 14 for 0.5 mM GPC/1 mM EDTA/pH 9.0, 138 ± 38 nmol phosphocholine produced/h/mg protein for 0.5 mM GPC/5 mM zinc/pH 10.5, and 325 ± 39 nmol phosphocholine produced/h/mg protein for 5 mM GPC/5 mM zinc/pH 10.5.

and phenylmethylsulphonylfluoride (all at 10 mM concentration), while diethylpyrocarbonate inhibited both by approximately 65% (Table 1). The addition of 0.5 mM choline, phosphocholine, acetyl choline, 1-palmitoyl-*sn*-glycero-3-phosphocholine, 1,2-dipalmitoyl-*sn*-glycero-3-phosphocholine, or arachidonic acid to the assay buffer did not significantly affect GPC PD activity under either assay condition (data not shown).

When GPC was substituted by 0.5 mM ^{14}C-GPE, no release of phosphoethanolamine or ethanolamine could be detected at either pH 9.0 in the presence of 1 mM EDTA, or at pH 10.5 in the presence of zinc acetate. In addition, the rate of GPC hydrolysis was not altered by the inclusion of 0.5 mM cold GPE, glycerophoshoserine, and glycerol-3-phosphate (data not shown).

Choline-producing enzymes. When homogenates of autopsied human brain were assayed for GPC PD activity at pH 10.5 in the absence of levamisole (an alkaline phosphatase inhibitor) with 0.5 mM GPC as substrate, choline was formed at a rate of 18.9 ± 7.3 nmol/h/mg protein (data not shown). The inclusion of 1 mM levamisole reduced choline formation to negligible levels, while the rate of phosphocholine release was unaffected (data not shown). This indicated that the released choline was derived from the hydrolysis of phosphocholine by alkaline phosphatase, and was not due to the actions of a choline-forming GPC PD activity. However, even in the presence of levamisole, other experiments, using biopsied rather than autopsied tissue, did suggest the presence of a distinct choline-producing activity. Due to the limited availability of biopsied tissue, only a preliminary investigation of this enzyme could be carried out. The choline-producing GPC PD activity in biopsied tissue was most active at pH 7.0 compared to pH 6.0, 8.0, 9.0, or 10.0 (data not shown), and required the presence of either magnesium or calcium ions for activity (Table 2). Furthermore, the addition of 0.5 mM GPE (i.e., equimolar to GPC) to the assay inhibited choline formation by 45 ± 12% (n = 3). Interestingly, an activity hydrolyzing GPE to form ethanolamine also was detected in biopsied tissue. The ionic and pH sensitivities of GPE hydrolysis were the same as that for GPC hydrolysis, and proceeded at a slightly lower rate (Table 2).

Glycerophosphodiesterase activities in autopsied compared to biopsied human brain. The stability of each enzyme post mortem was investigated by comparing the activity in autopsied temporal cortex with that in temporal cortical biopsies (Table 3). When assayed at pH 9.0 in the presence of 1 mM EDTA, phosphocholine-producing GPC PD activity was approximately half as active in autopsied tissue as it was in biopsied, while at pH 10.5 plus 5 mM zinc acetate activity was similar in both autopsied and biopsied tissues. However, significant hydrolysis of either GPC or GPE to form the free base was only detected in biopsied brain (Table 3).

TABLE 2
Choline/Ethananolamine-Producing Glycerophosphodiesterase Activity in Biopsied Human Brain[a]

	Substrate	
Addition	GPC (nmol/h/mg protein)	GPE (nmol/h/mg protein)
1 mM EDTA	0.6 ± 0.1	<0.5
5 mM calcium chloride	6.4 ± 1.2	4.0 ± 2.5
5 mM magnesium chloride	11.9 ± 2.9	8.7 ± 2.6

[a]Homogenates of three biopsied human temporal cortices were assayed for glycerophosphodiesterase in the presence of 0.5 mM glycerophosphodiester, 100 mM HEPES/sodium hydroxide, pH 7.0, and the indicated addition. The assay buffer also contained 1 mM levamisole, 25 μM EDTA, and 25 μM EGTA contributed by the homogenization buffer. Activities are given in nmol choline or ethanolamine produced/h/mg protein and are the mean ± SEM of three brains analyzed in independent experiments. GPE, glycerophosphoethanolamine. See Table 1 for other abbreviation.

TABLE 3
Glycerophosphodiesterase Activity in Autopsied and Biopsied Human Brain[a]

Incubation conditions	Autopsied tissue		Biopsied tissue	
	Phosphobase	Base	Phosphobase	Base
5 mM GPC/5 mM zinc acetate/pH 10.5	528 ± 101	<2.0	641 ± 58	<2.0
0.5 mM GPC/5 mM zinc acetate/pH 10.5	231 ± 79	<2.0	209 ± 25	<2.0
0.5 mM GPC/1 mM EDTA/pH 9.0	76 ± 12	<2.0	162 ± 33	<2.0
0.5 mM GPC/5 mM magnesium chloride/pH 7.0	16.2 ± 11.3	<2.0	20.3 ± 6.4	12.2 ± 0.9
0.5 mM GPE/5 mM magnesium chloride/pH 7.0	<2.0	<2.0	<2.0	9.2 ± 0.7

[a]Homogenates of four autopsied, or three biopsied, human temporal cortices were assayed for glycerophosphodiesterase activity under the indicated reaction conditions. The assay buffer also included 1 mM levamisole, 12.5 μM EDTA, and 12.5 μM EGTA contributed by the homogenization buffer. Activities are given in nmol product/h/mg protein and are given as mean ± SEM. See Table 1 for abbreviation.

DISCUSSION

GPC is an abundant breakdown product of choline phosphoglyceride. GPC is hydrolyzed by GPC PD to yield products which can be used in the resynthesis of choline phosphoglyceride. As such, GPC levels are frequently quantified as a measure of membrane turnover (1–6). Previous studies of GPC PD have identified several subforms of the enzyme in animal brain (7–9). However, surprisingly little is known about the characteristics of the human brain enzyme.

Our data suggest that human brain contains at least two enzymes capable of hydrolyzing GPC, one which forms phosphocholine as a product, the other producing free choline. In contrast to the GPC PD activity of rat brain (7), the most active enzyme in human brain was that which yielded phosphocholine, rather than choline, in agreement with that observed previously by others (1). The presence or absence of zinc ions in the assay incubation medium resulted in different characteristics being observed for the enzyme in terms of its substrate affinity, sensitivity to inhibition by acetic anhydride, pH optimum, and post mortem stability. Most strikingly, in the absence of zinc ions, the enzyme possessed a pH optimum of 9.0, which shifted to 10.5 with the addition of zinc acetate (see Fig. 1). A possible explanation for these observations is that zinc ions switch the conformation of a single enzyme between two states, one having a more alkaline pH optimum than the other. However, in such a scenario, as the amount of enzyme possessing a pH optimum of 10.5 increases, the proportion of the other form must decrease in a reciprocal manner. Thus, since stimulation of activity at pH 10.5 is not accompanied by a corresponding decrease at pH 9.0 (Fig. 1), or at pH 8.5 (Fig. 2; inhibition is only observed at high zinc ion concentrations), the possibility has to be considered that two phosphocholine-producing GPC PD activities are present in human brain, a zinc-sensitive, and a zinc-insensitive form. Zinc-sensitive GPC PD (Zn-GPC PD) activities have been described in both rat and bovine brain, and in *Bacillus cereus*, all of which display the highly alkaline pH optimum of the human enzyme assayed in the presence of zinc ions (7,18,19). Previous studies of this enzyme have indicated that it is localized predominantly to myelin (7,11,19). However, the tissue used in the present investigation was largely free of white matter. This suggests a more widespread localization, and consequently more general role, for the enzyme, although the possibility that the small myelin content of grey matter contributes all of the activity detected cannot be excluded. Since, in the presence of zinc, GPC PD possesses an unusually alkaline pH optimum, it is unclear how active the enzyme is *in vivo*. However, the availability of zinc is unlikely to be a limiting factor, since zinc concentrations in human brain [reported to be between 30 and 90 μg/g dry weight which, assuming a 90% water content of brain tissue, correspond to molar concentrations of between 50 and 140 μM (20)] are well above the EC_{50} of zinc for stimulation of the enzyme. Our results also suggest the presence of a zinc-insensitive phosphocholine-producing GPC PD activity in human brain which is active in the presence of EDTA. Similar, though not identical, enzymes have been described by others. Thus, rat brain also contains an EDTA-insensitive GPC PD activity, although it differs from that in human brain in terms of both its pH optimum and requirement of calcium ions for maximal activity (21). Moreover, Kanfer and McCartney (7) reported that rat brain microsomes contained a second phosphocholine-producing GPC PD activity which differed in its affinity for GPC from that of Zn-GPC PD, although no information was obtained regarding its metal ion sensitivity. If two phosphocholine-producing enzymes are present in human brain, it is unclear as to the roles and relative importance of each enzyme in brain. It has been suggested that Zn-GPC PD is the most physiologically relevant form of the enzyme regarding the choline phosphoglyceride degradative pathway, although little direct evidence exists to support this notion (18). Neither enzyme would appear to be involved in the metabolism of GPE, since we could not detect the production of phosphoethanolamine when GPE was used as a substrate. Similarly, the addition of GPE to the GPC PD assay did not inhibit the release of phosphocholine. The failure of Zn-GPC PD to hydrolyze GPE has previously been observed in rat brain preparations (7).

To assess the stability of phosphocholine-producing GPC PD activity post mortem, we compared their activities in autopsied brain to that in biopsied tissue. When assayed at pH 10.5 in the presence of zinc ions, GPC PD activity was similar in both tissue groups, suggesting that this enzyme is stable

post mortem. However, when assayed in the absence of zinc ions, GPC PD activity in autopsied temporal cortex was approximately half that in biopsied tissue, further suggesting the presence of two phosphocholine-producing enzymes, each one possessing a different post mortem stability.

A third GPC PD activity was detected in human brain which yielded the free base, rather than the phosphobase, as a product. This enzyme, which required divalent cations for activity and possessed a neutral pH optimum, could only be detected in biopsied tissue, thereby precluding future studies of this enzyme in disease conditions which routinely utilize autopsied brain. The phosphoester bond being cleaved, as well as the neutral pH optimum of this enzyme, could suggest that the reaction is catalyzed by a phospholipase D like activity (22,23). However, this possibility seems less likely given that the phospholipase D activities of rat and canine brain are either insensitive to, or inhibited by, divalent cations (23,24), in contrast to human brain choline-producing GPC PD, which is dependent upon divalent cations for activity. No evidence was found for a human brain homologue of the alkaline pH optima, calcium-dependent GPC PD activity identified in rat brain (8). Although the activity of the choline-producing enzyme, under optimal assay conditions, was much lower than that of the phosphocholine-producing enzymes, the observation that GPE inhibits the release of choline from labelled GPC, and that the hydrolysis of GPE to ethanolamine possesses similar characteristics to GPC hydrolysis, suggests that the same enzyme metabolizes both GPC and GPE. Thus, among the activities identified in human brain, the choline/ethanolamine-producing enzyme is unique in its ability to hydrolyze GPE, and, to our knowledge, represents the first identification of such an enzyme in brain. Since the other activity(s) identified in human brain did not catalyze detectable hydrolysis of GPE, the levels of brain GPE may be highly dependent upon the activity of this enzyme. In addition, while the role that the choline/ethanolamine-producing enzyme plays in the metabolism of GPC is presently unclear, the observation that this enzyme is optimally active at near-physiological pH, compared to the alkaline pH optimum of the phosphocholine-producing enzyme, suggests that the choline/ethanolamine-producing activity may represent a significant route of GPC hydrolysis *in vivo*. Finally, while a GPE-hydrolyzing activity has previously been identified in rat kidney, this enzyme differed from that in human brain in terms of its cation requirements and pH optimum (25).

Our failure to find a choline-producing GPC PD activity in autopsied human brain is in agreement with that of Blusztajn and colleagues (1), but is in contrast to the findings of Kanfer and colleagues (10), in which choline formation is described. However, these authors did not attempt to exclude the possibility that choline was being formed as a secondary product *via* the breakdown of phosphocholine by alkaline phosphatase. It may, therefore, be prudent to include such an inhibitor in future studies of this enzyme.

Previously, GPC PD activity has been measured in Alzheimer's diseased brains, and in multiple sclerosis plaques (1,10,11). It is now apparent that in these investigations the enzyme was assayed under conditions in which the majority of the GPC PD activity is due to a metal ion-independent GPC PD activity. Since our results suggest the presence of a second, zinc-sensitive enzyme, it may be valuable to reassess the status of GPC PD in these disorders.

Regulation of Cholesterol Synthesis in Four Colonic Adenocarcinoma Cell Lines

Sonia R. Cerda, John Wilkinson IV, and Selwyn A. Broitman*

Boston University School of Medicine, Department of Microbiology and The Mallory Institute of Pathology, Boston City Hospital, Boston, Massachusetts 02118

ABSTRACT: Colon tumor cells, unlike normal human fibroblasts, exhibited an uncoupling of low density lipoprotein (LDL)-derived cholesterol from cellular growth, when endogenous cholesterol synthesis was inhibited by mevinolin, a hydroxymethylglutaryl–CoA reductase (HMG–CoAR) competitive inhibitor [Fabricant, M., and Broitman, S.A. (1990) *Cancer Res. 50,* 632–636]. Further evaluation of cholesterol metabolism was conducted in two undifferentiated (SW480, SW1417) and two differentiated (HT29, CACO2) colonic adenocarcinoma (adeno-CA) cell lines and an untransformed human fibroblast, AG1519A. Cells grown in monolayer culture to near subconfluency were used to assess endogenous cholesterol synthesis by ^{14}C-acetate incorporation, in response to the following treatments in lipoprotein-deficient serum (LPDS)-supplemented minimum essential medium (MEM): LPDS alone, LDL, mevinolin, mevinolin with LDL, and 25-hydroxy-cholesterol (25-OH-CH). Complete fetal bovine serum (FBS)-supplemented MEM was used as control. All colon tumor lines exhibited similarly high endogenous cholesterol synthesis in both FBS and LPDS relative to the fibroblasts which demonstrated low basal levels in FBS and maximal synthesis in LPDS. LDL treatment did not inhibit cholesterol synthesis in colon tumor cells, but suppressed that in the fibroblast by 70%. Sterol repression of cholesterol synthesis mediated by 25-OH-CH occurred in all cells. Mevinolin caused a reduction in cholesterol synthesis in the colonic cancer cell lines, which was not further decreased by concurrent addition of LDL. In contrast, in mevinolin-treated fibroblasts, LDL further inhibited cholesterol synthesis. When the effect of cell density on cholesterol synthesis regulation was evaluated under conditions of sparse density in SW480 and SW1417, results indicated that (i) basal rates of cholesterol synthesis were higher, (ii) LDL inhibited cholesterol synthesis more effectively, and (iii) mevinolin or 25-OH-CH had a more pronounced effect than in subconfluent cells. Evaluation of LDL receptor activity through ^{125}I-LDL binding and internalization studies demonstrated LDL receptor expression was reduced by 37% in normal density cells relative to the low density cultures. In contrast to cholesterol synthesis, exogenous LDL could inhibit LDL receptor activity at both densities. Thus subconfluent growing colonic adenoCA cell lines retain the capacity for sterol repression, but, in contrast to normal fibroblasts, exhibit a high endogenous cholesterol synthesis which LDL cannot regulate. *Lipids 30,* 1083–1092 (1995).

Cholesterol is required for growth of cells (1). This sterol may be obtained either by *de novo* synthesis from acetate, which is catalyzed by the enzyme 3-hydroxymethylglutaryl–CoA reductase (HMG–CoAR), or *via* uptake of exogenous cholesterol from the environment, primarily as low density lipoprotein (LDL) (2). A relationship between the neoplastic state and loss of feedback inhibition in cholesterol metabolism was first suggested by Siperstein *et al.* (3), who described a failure of dietary cholesterol to regulate *de novo* synthesis in hepatoma and prehepatoma cells. Rapidly proliferating cancer cells may have a higher cholesterol requirement for membrane or synthetic purposes; consequently, these increased demands for cholesterol can be met either by increasing endogenous synthesis (4,5) or uptake (6–13) of exogenous cholesterol as LDL, or both (14).

The rate-limiting step in the cholesterol biosynthetic pathway is catalyzed by HMG–CoAR (15). Increased activity of this enzyme increases its direct product, mevalonate, precursor to sterols and nonsterol isoprenoids, such as ubiquinone, dolichol, and isopentenyl tRNA, which are all necessary for cell growth (16). Mevalonate also incorporates into isoprenylated proteins (17), including such signal transduction participants as ras and other GTP binding proteins (18). An increase in the expression of HMG–CoAR has been described in certain tumors relative to normal tissue (19–21), indicating its importance in cellular growth control.

Cells grown in culture exhibit a preference for cholesterol *via* receptor-mediated uptake of LDL (22). Inhibition of cholesterol synthesis by compactin, a fungal metabolite known to competitively inhibit HMG–CoAR (23), renders growth of fibroblasts, Chinese hamster ovary, and raji lymphoma cells dependent on the LDL receptor (LDLR) (24). When the four lines used in these experiments were grown in lipoprotein-deficient serum (LPDS)-supplemented media in the presence of mevinolin (at a dose which inhibits growth by 50%), LDL was unable to reverse growth inhibition, in direct contrast to the human fibroblast, where growth was totally restored (25).

It has been demonstrated that small intestinal cells do not use exogenous LDL for growth when endogenous cholesterol synthesis is inhibited by mevinolin, though LDL receptors may be present and this lipoprotein internalized by the cells (26–28). However, discrepancies still exist as to whether or not intestinal cells preferentially use endogenous cholesterol for membrane synthesis (29). In order to further elucidate previous findings, we studied cholesterol metabolism in four colonic adenocarcinoma (adenoCA) cell lines, two of which (HT29, CACO2) differentiate *in vitro* under appropriate conditions to small intestinal cells (30,31). Results suggest a lack of regulation upon endogenous cholesterol synthesis by LDL in subconfluent growing colonic adenoCA cells, similar to the metabolism of a differentiated small intestinal cell phenotype.

MATERIALS AND METHODS

Cell culture. Four human colonic cancer cell lines, SW480, SW1417, HT29, and CACO2, were obtained from the American Type Culture Collection (Rockville, MD). Stock cultures were grown in monolayer in plastic 75 cm^2 flasks and incubated at 37°C in a 5% CO^2/95% air atmosphere. Culture medium consisted of Eagle's minimal essential medium (MEM) containing antibiotics (penicillin, 200 units/mL; streptomycin, 0.2 mg/mL), glutamine (0.2 mg/mL), and nonessential amino acids and nonessential vitamins both at 10 mL of 100X solution (GIBCO, Grand Island, NY), per 500 mL MEM and supplemented with 10% fetal bovine serum (FBS) (Sigma, St. Louis, MO). Cells were plated at a density of 10^6 cells per flask, and cultures divided weekly (1:19 or 1:20) using 0.05% trypsin/0.02% disodium EDTA. After removal of media, cells were rinsed with isotonic phosphate-buffered saline (PBS) (pH 7.4), and 4 mL of trypsin added. Flasks were incubated at 37°C until cells began to detach, after which 4–6 mL of fresh medium was added. Cells used in experiments are grown in plastic 35 mm^2 dishes. Normal human skin fibroblast cells (AG1519A), obtained from the Institute for Medical Research (Camden, NJ), were grown as monolayers in MEM supplemented with antibiotics, glutamine, nonessential amino acids, and 20% FBS. Stock cultures were plated at a density of 1×10^6 per 75 cm^2 flask and divided weekly (1:4) using trypsin/EDTA. Cell cultures were assayed for the presence of mycoplasma using the Gen-Prove Mycoplasma T.C. 11 Rapid Detection System (San Diego, CA).

Preparation of LPDS. Lipoproteins were removed from FBS by density gradient centrifugation (32). FBS was adjusted to a density of 1.21 g/mL with solid potassium bromide (64.4 g KBr per 200 mL FBS) and centrifuged for 48 h at 5°C at 244,000 $\times$ g_{max} (45,000 rpm in a 50.2ti rotor in a Beckman L8-70 ultracentrifuge; Beckman Instruments, Fullerton, CA). The top lipoprotein fraction (d < 1.21 g/mL) was removed, and the bottom lipoprotein-deficient fraction dialyzed extensively against 0.01% EDTA/double-distilled water (pH 8) and then PBS. The LPDS was sterilized by passage through a 0.22 μ filter.

Preparation of mevinolin. This reagent was kindly provided by A. Alberts of Merck Sharp & Dohme (Rahway, NJ) in the lactone form. Saponification was carried out by adding 0.1 mL absolute ethanol and 0.1 mL of 0.1 N NaOH to 4 mg of mevinolin and by heating at 50°C for two hours. Mevinolin was neutralized with 5% HCl to pH 7.3. Stock solutions (4 mg/mL) were prepared by bringing the volume to 1 mL with dimethyl sulfoxide and stored at –20°C. At the concentrations used, dimethyl sulfoxide was found to have no effect on cell growth. Mevinolin was diluted in MEM to the concentrations used in experiments. All the studies regarding the use of mevinolin were conducted at a 1 μM concentration as published by this laboratory (25).

Protein determinations. Proteins were determined by the bicinchoninic acid reagent method (Pierce Chemical Company, Rockford, IL). A standard curve was prepared using a stock bovine serum albumin standard in sample diluent. Samples and standard are mixed with the protein reagent and absorbance read at 562 nm by spectrophotometry.

Cholesterol synthesis assay. Cells were seeded in six-well (35 mm^2) dishes at 20,000 cells/well in triplicate per group studied per experiment, in MEM supplemented media with 10% (SW480, SW1417, and HT29) or 20% (CACO2 and AG1519A) FBS. All cells were grown to a subconfluent to confluent growth, termed normal density (≈80% of the plate was covered after day 5), except where specified as "LD," meaning low density or sparse growth (≈30% was covered, after day 3). After day 5 (day 3 for LD cultures), cells were then rinsed with Dulbecco's PBS and switched to a LPDS based medium (1 mL/well). After 24 to 48 h, the media was replaced with media containing 5 μCi/mL of 2-^{14}C-acetate (51 mCi/mmole NEN), and the following treatments: (i) FBS (ii) LPDS, the basal media for all subsequent treatments (each of which contain 10% LPDS), (iii) LDL (50 μg protein/mL), (iv) 25-OH-CH (25-OH-CH at 0.5 μg/mL + cholesterol at 16 μg/mL), (v) mevinolin at a 1 μM concentration, and (vi) mevinolin + LDL. After 24-h incubation, the medium was removed and saved; monolayers were harvested in 1 mL 0.1 N NaOH and pooled with their respective saved media to be saponified following the methodology of Brown *et al.* (32). Briefly, these mixtures were treated with 0.5 mL 50% KOH, 3 mL ethanol, and (1,2) ^{3}H-cholesterol (10^5 cpm, 50 Ci/mmole) as internal standard. After saponification at 80°C for two hours, unsaponifiable lipids were extracted three times with petroleum ether followed by two washes with NaOH. Samples were dried with nitrogen gas, resuspended in chloroform, spotted on silica gel "G" thin-layer chromatography plates, and separated using chloroform as a running solvent to isolate the ^{14}C-cholesterol with appropriate markers. This methodology discriminated 27C sterols from lanosterol and squalene, which had higher R_f values. Although this running system does not resolve cholesterol from other 27C sterols, gas chromatography analysis of the derivatized lipids from the scrapings showed a predominance of cholesterol with some desmosterol and 7α-dehydrocholesterol (data not shown). Cholesterol synthesis was evaluated as nanomoles of

acetate incorporated into cholesterol per mg cellular protein, and these values normalized to the LPDS control within each experiment. Results of challenge with various treatments were expressed as percentage of LPDS control. Data was analyzed by general linear model analysis of variance (ANOVA) to determine significant differences between groups.

^{125}I-LDL binding to colonic adenoCA cell lines. The ^{125}I-LDL binding assays were conducted using the following methodology adapted from Goldstein *et al.* (33). Cells were seeded at 2.5 and 15×10^4 cells per well in three wells each of six-well plates to generate contrasting conditions of normal, and low density within individual assay plates. After two days' growth in FBS-supplemented MEM, cells were washed with PBS and changed to media supplemented with 10% LPDS, which was prepared in-house from FBS (Sigma) to generate maximal responses in terms of receptor activity. After 24 h, the cells received treatments in LPDS-based MEM for a duration of 24 h. Following treatments, the cells were incubated in 1 mL LPDS/MEM with 5–10 μg/mL ^{125}I-LDL (Biomedical Technologies Inc., Stoughton, MA) for five hours. Within an experiment, two wells of a six-well dish are used to measure hot or total binding per treatment at either density state. To control for nonspecific binding, one well received 25- to 40-fold increase of cold LDL (125–200 μg/mL) above the level of the hot LDL in the media. One empty, cell-free, six-well plate was treated with media, washed, treated, and incubated just as the other groups, and used as a blank.

Surface binding. After incubation for five hours, a steady state is reached in which binding, internalization, and degradation of the lipoprotein are equilibrated (33). The cells were placed on an ice bed, and rinsed 5 times with 2 mL ice-cold tris-buffered saline (TBS)-A buffer (50 mM Tris/150 mM NaCl/2 mg/mL albumin at pH 7.4), once with ice-cold TBS buffer (TBS-A with no albumin), and finally incubated with 1.5 mL of dextran sulfate release buffer (50 mM NaCl/10 mM HEPES/4 mg/mL dextran sulfate at pH 7.4) for one hour at 4°C. Polyanionic macromolecules such as dextran sulfate or heparin sulfate cause LDL to be released from its receptor; thus the activity of the released tracer is a measurement of the surface binding capacity for the cells. Following this incubation, 750 μL aliquots were taken for gamma counting.

Internalization. The major count found in this assay represents the LDL that is internalized by the cells, which has not yet been degraded. In fibroblasts this will typically be 80–90% of the total cell associated radioactivity (33). To measure internalization, the cells are returned to the ice bed and washed two times with 2 mL TBS buffer. Then, the monolayers are dissolved in 1.5 mL hot 60°C NaOH (0.1N), and aliquots are taken for gamma counting (750 μL) and protein (20 μL) measurement.

RESULTS

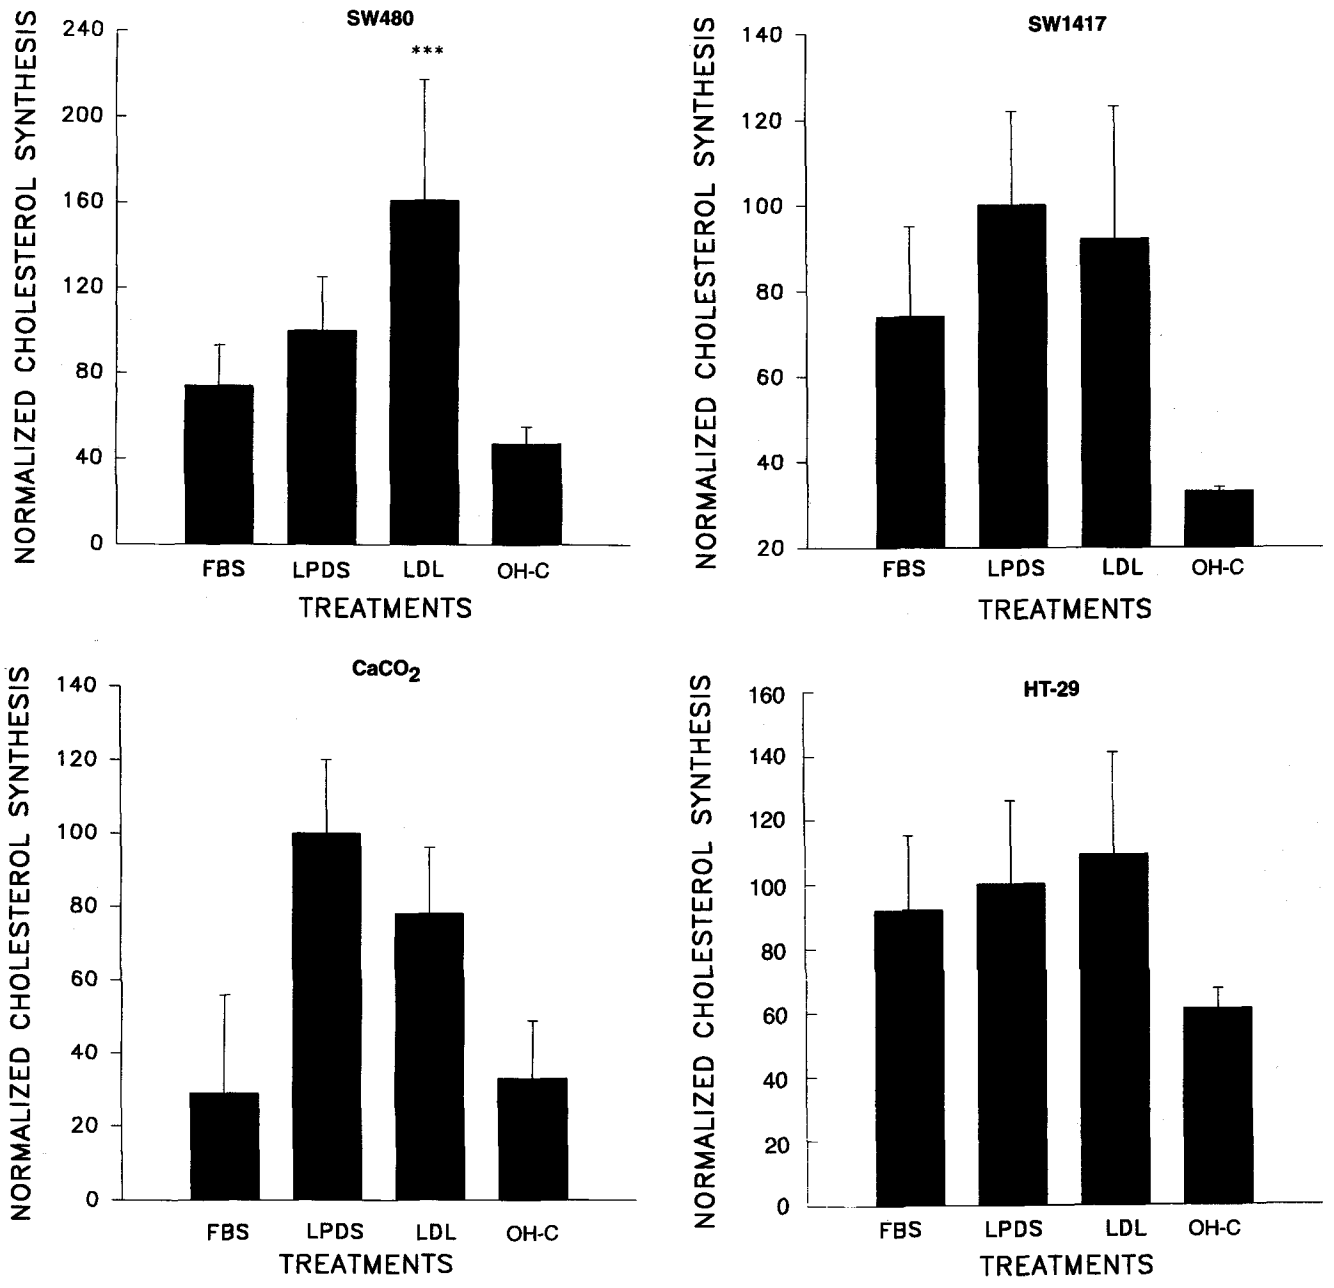
Colon tumor cells were evaluated for their ability to synthesize cholesterol in response to different sterol treatments. Cells were grown in culture to a subconfluent state to limit any growth-rate dependent effects of replication upon the results. At subconfluency, cells were deprived of exogenous sterols through culture for 24 h in LPDS-based MEM. Under these conditions, fibroblasts depend upon endogenous cholesterol synthesis for growth (2). Cells were then subjected to subsequent treatments. All data is normalized as a percentage of the individual experiments' LPDS control group.

FBS provides cells with a sterol-rich medium, generating a reference point to determine levels of endogenous synthesis under "normal" growth conditions. The colonic cell lines exhibited similarly high basal rates of cholesterol synthesis in both FBS- and LPDS-supplemented media. The fibroblast presented low basal levels of cholesterol synthesis when grown in FBS (Fig. 1A–E), suggesting an increased reliance upon endogenous synthesis in subconfluent colonic adenoCA cells.

LDL is the primary cholesterol source in man (2), and certain cells in culture preferentially derive this sterol from LDL in the serum of culture media, synthesizing cholesterol at a low rate (22). When colonic tumor cells grown in LPDS were treated with this lipoprotein, cholesterol synthesis was not suppressed (Fig. 1A–D), as occurs in the fibroblast (Fig. 1E), indicating an inability of this lipoprotein to regulate endogenous cholesterol synthesis.

Regulation by LDL of HMG–CoAR has been shown to occur both transcriptionally and post-transcriptionally *via* a putative oxysterol intermediate (16). In order to test if colonic tumor cells can demonstrate a functional sterol-mediated suppression of this enzyme, the ability of the oxysterol 25-OH-CH to repress cholesterol synthesis was tested. All cells were found to exhibit a decrease in cholesterol synthesis when treated with this oxysterol in LPDS (Fig. 1A–E), indicating that oxysterol regulatory mechanisms remained functional in these lines.

Most of the work in cholesterol metabolism in human fibroblasts has taken place at a confluent state (35–37) in order to avoid replication-dependent factors upon the results. However, alterations in confluency state can cause certain cultured colonic cell lines such as $CACO_2$ cells to differentiate and gain small bowel phenotypic characteristics. Therefore, we examined whether cell density had an effect on the ability of sterols to regulate cholesterol synthesis in two lines which are not known to differentiate in culture to a small bowel phenotype, the undifferentiated colonic adenocarcinomas SW480 and SW1417 (Fig. 2). The sterols in FBS and LDL were found to downregulate endogenous cholesterol synthesis in low density growing cells (≈30% of the dish is covered at three days), in direct contrast to subconfluent (≈80% of the dish was covered) cells. Additionally, the rates of *de novo* cholesterol synthesis (see Table 1) in cells cultured at lower densities were higher than at subconfluency, implying a greater demand for endogenously synthesized cholesterol in low density cells. However, while endogenous cholesterol synthesis was inhibited by LDL in normal fibroblasts at both low and normal densities of growth, colon tumor cells were



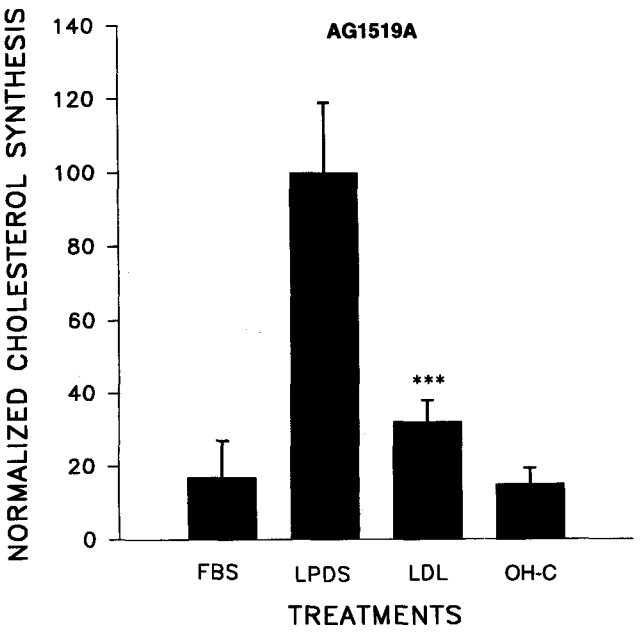


FIG. 1. A–E: (continued on next page).

only repressed by this sterol when growing at low density. It is of interest that control studies have shown the same effects at 1.5 h of treatment, even when the specific activity was diluted to one-third of the original values used in this study (data not shown).

LDLR activity was then analyzed in SW480 cells under these two density culture conditions. LDLR is reported as ng ^{125}I-LDL bound per mg cell protein, and the mean of three assays is depicted in Tables 2 and 3. The mean LDLR activity for these cells at both density states in LPDS-supplemented media is low (57 to 90 ng LDL/mg cell protein internalized count) relative to the fibroblast, which has a reported 100 and 600 ng/mg for surface and internalized activity, respectively (33). Thus, as previously speculated (25), this tumor cell line has a lowered LDLR activity relative to fibroblasts. This is consistent with an enhanced cholesterol synthesis rate in these cells, as strictly sterol-regulated genes, such as the receptor, would be repressed by such an increase in intracellular sterols. The LDLR activity between density states across all treatments was not statistically different by ANOVA (α 0.05). Cells were treated with LDL (5, 50, 300 μg/mL), or 25-OH-CH (3 μg/mL) in basal LPDS media to evaluate the effect of external sterols on LDLR activity. As seen in Table 2, addition of 5, 50, and 300 μg/mL LDL resulted in a diminution of LDLR activity at both density states. This difference was statistically significant at both densities between all treated groups and the LPDS controls within each density state (ANOVA $P <$ 0.01; Bonferoni control test for multiple comparisons). Addi-

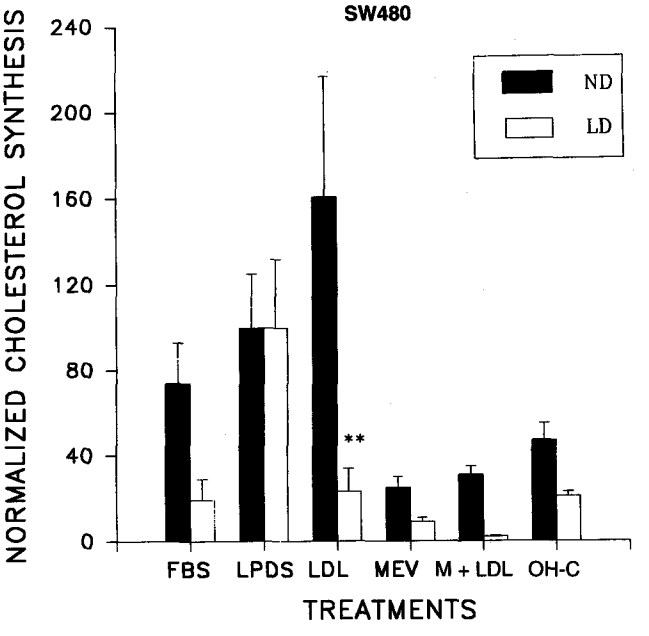

FIG. 1. A–E: Cellular cholesterol synthesis in four colonic adenocarcinoma cell lines ($CACO_2$, HT29, SW480, SW1417; American Type Culture Collection, Rockville, MD), and a normal human fibroblast AG1519A (Institute for Medical Research Camden, NJ). Cells were grown to subconfluency (80% of the plate was covered), incubated with ^{14}C-acetate, nonsaponifiable lipids were extracted and subjected to thin-layer chromatography as indicated in the Materials and Methods section. Nanomoles of acetate per mg cellular protein were determined per sample, and these values were normalized to the lipoprotein-deficient serum (LPDS) control within each experiment. Results of challenge with various treatments are expressed as percentage of LPDS control and depicted as bar graphs, where the filled area represents the mean of three different experiments carried out in triplicate. Open areas above the bars represent the standard deviation of the mean. Significance of findings was evaluated by general linear model analysis of variance comparing: low density lipoprotein (LDL) treatments with LPDS controls. FBS, Fetal bovine serum; OH-C, 25-hydroxy-cholesterol.

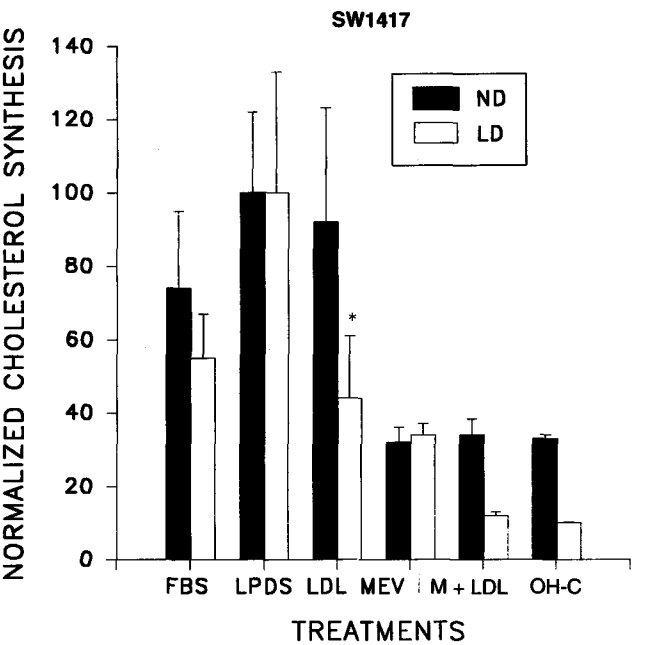

FIG. 2. A, B: Comparison of cellular cholesterol synthesis in two colonic adenocarcinoma cell lines between subconfluent and lower density culture conditions. SW480 and SW1417 cells were grown to a low density state (30% of the plate was covered), and treated as described for Figure 1. Results are expressed as indicated for Figure 1, except that filled bars represent subconfluent cultures [normal density (ND)] depicted in Figure 1 (C, D), and open bars represent cultures seeded and grown to sparser densities [low density (LD)]; Mev, mevinolin; M + LDL, mevinolin + LDL. See Figure 1 for other abbreviations and company sources.

tion of 25-OH-CH (3 μg/mL) caused significant ($P < 0.01$) inhibition of the LDLR activity vs. the LPDS control group.

In fibroblasts cultured in lipoprotein-deficient medium, inhibition of cholesterol synthesis with the HMG–CoAR inhibitor compactin renders their growth dependent upon LDL-derived cholesterol (24). To assess the effects of a similar HMG–CoAR inhibitor, mevinolin, upon cholesterol metabolism in colonic adenocarcinomas, we determined its impact upon cholesterol synthesis. In order to minimize differences in evaluating the effects of this inhibitor between the lines when analyzing results, the concentration of mevinolin remained the same for all the cells. As shown in Figure 3, mevinolin inhibited cholesterol synthesis in all lines.

This report is consistent with previous findings, where LDL did not reverse growth inhibition imposed by mevinolin (25). In the current study, when the four colonic adenoCA cell lines were grown in the presence of mevinolin, concurrent addition of LDL had no effect upon cholesterol synthesis in the tumor lines (Fig. 3). In contrast, LDL further inhibited cholesterol synthesis in the fibroblast. These effects also were evaluated in SW480 and SW1417 cells growing at low density (Fig. 2). These cells responded to simultaneous treatment with both mevinolin and LDL by further suppressing cholesterol synthesis, similar to the fibroblast. Additionally, cholesterol synthesis was inhibited to a greater extent by treatment

TABLE 1
Nanomoles of ^{14}C-Acetate Incorporated into Cholesterol per Milligram of Cellular Protein (in 24 h)[a]

	Treatment	SW1417	SW480	AG1519A
Low density	LPDS	13.5 ± 5.2	113.1 ± 43.6	17.1 ± 5.7
	LDL	4.2 ± 1.9	37.8 ± 6.4	4.8 ± 0.7
Normal density	LPDS	5.25 ± 2.2	7.35 ± 2.7	7.5 ± 1.9
	LDL	5.9 ± 1.5	12.15 ± 4.5	1.95 ± 0.45

[a]Cells were grown to a low density state (30% of the plate was covered), or 80% confluent and treated with lipoprotein-deficient serum (LPDS) or low density lipoprotein (LDL) 50 μg/mL (LDL) in the presence of ^{14}C-acetate. Nonsaponifiable lipids were extracted and subjected to thin-layer chromatography as indicated in the Materials and Methods section. Cholesterol synthesis is reported as nanomoles of acetate incorporated per mg cellular protein. Results are expressed as means ± SE of a representative of three experiments, n = 3. SW1417 and SW480 are colonic adenocarcinoma cell lines (American Type Culture Collection, Rockville, MD). AG1519A (Institute for Medical Research, Camden, NJ) is a normal human fibroblast.

[a]SW480 cells were cultured at normal and low density states, pretreated with LPDS-supplemented media for 24 h, then treated for 24 h with the LPDS-based media alone or supplemented with increasing concentrations of human LDL as indicated or with 25-hydroxy-cholesterol (25-OH-CH) (3 μg/mL). Cells were evaluated as described under methods for their ability to bind (surface activity) and internalize ^{125}I-LDL. Table 1 activity is reported as ng of radiolabeled LDL per mg cellular protein (mean and standard error of six measurements taken over three experiments). See Table 1 for company source and other abbreviations.

with mevinolin and 25-OH-CH as compared to normal density growing subconfluent cells (Fig. 2).

DISCUSSION

Stange and Dietschy (38) first demonstrated an independent regulation between LDL uptake and cholesterol synthesis in rat intestinal epithelium. This work and that of others (26–28,39) led to a proposed model for the compartmentalization of cholesterol metabolism and cellular growth in intestinal cells (40). The present study shows that colonic adenoCA cell lines exhibit different responses in cholesterol synthesis to treatment with: the sterols in FBS, LDL, mevinolin, and mevinolin + LDL. Our results demonstrate that in cultures supplemented with LDL at 50 μg/mL in LPDS-based medium, cholesterol synthesis was not found to be inhibited, as opposed to the fibroblast (Fig. 1). This unresponsiveness to LDL could reflect: (i) relative deficiency in LDLR expression or activity, (ii) an altered compartmentalization, trafficking, or storage of LDL-derived cholesterol into non-regulatory cellular pools, and (iii) a deregulation in the mechanisms by which sterols downregulate HMG–CoAR. The latter hypothesis was deemed unlikely because data indicated normal sterol regulatory function in these cells by 25-OH-CH mediated sterol repression (see Fig. 1A–E).

The inclusion of colonic tumor-derived cell lines into the

TABLE 3
LDLR Activity in SW480 Cells Cultured at Two Different Density Conditions in Response to Various Treatments[a]

[a]SW480 cells were cultured at normal and low density states, pretreated with LPDS supplemented media for 24 h, then treated for 24 h with the LPDS-based media alone or supplemented with increasing concentrations of human LDL as indicated or with 25-OH-CH (3 μg/mL). Cells were evaluated as described under methods for their ability to bind (surface activity) and internalize ^{125}I-LDL. Activity is reported as percentage of LPDS control for each experiment (mean and standard error of six measurements taken over three experiments). See Tables 1 (also for company source) and 2 for abbreviations.

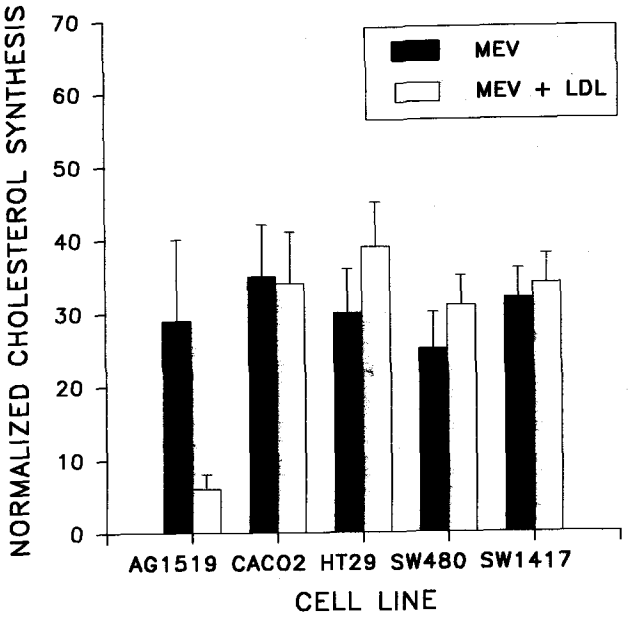

FIG. 3. Cholesterol synthesis in cell lines treated with mevinolin (MEV) or mevinolin and LDL. Cells were cultured as described for Figure 1 and treated with 1 μM mevinolin with (solid bars) or without (open bars) concurrent addition of 50 μg/mL of human LDL. Results are expressed as percentage of LPDS control as described for Figures 1 and 2. See Figure 1 (for company sources also) and 2 for abbreviations.

development of models designed to help elucidate intestinal cholesterol metabolism necessitates embracing the full spectrum of phenotypic characteristics evidenced by such lines. Cholesterol dynamics for a given tumor cell reflect its current state of (i) differentiation which includes not only "poorly vs. well" differentiated characteristics but also the differences between large vs. small bowel phenotypes, and (ii) cellular density in monolayer culture which may or may not affect such differentiation. The colonic adenoCA cell lines HT-29 and $CACO_2$ have shown altered regulation of cholesterol metabolism with the state of differentiation (colonic vs. small intestinal) and confluency (28,41,42). When the adenoCA subline HT-29G is undifferentiated, acyl cholesterol acyl transferase (ACAT) activity was found to be absent (43). Consequently, LDL cannot be directed to this enzyme to be stored as cholesterol esters, or used for lipoprotein synthesis as has been hypothesized in small intestinal cells (39); this could have great impact upon the lipoprotein's ability to affect HMG–CoAR. Mevinolin is known to suppress esterification of exogenous, but not endogenous, cholesterol in enterocytes (see Ref. 58). This suggests an effect of mevinolin on the ACAT substrate pool. The inability of LDL to inhibit synthesis may, therefore, be linked to the ability of a cell to turn ACAT on for storage or lipoprotein synthesis. The latter could reflect a differentiation of the colonic adenoCA cell to a small intestinal phenotype.

The correlation of a decrease in serum cholesterol levels with an increased incidence of colorectal cancer has been the focus of many epidemiologic studies (44–47). Normal human (48) and murine (49) colonic epithelium have been shown to be LDLR positive by immunohistochemistry. Expression of the LDLR was found to vary in different portions of the small and large intestine (37,48,49), which may be imposed by the current state of differentiation (40), and growth (41,50,51) of these cells. In fact, immunohistochemical studies from this laboratory have shown that LDLR expression in human normal and neoplastic colon increases with the degree of differentiation of the tissue (48). Other authors found a high proportion of tumors and surrounding normal mucosa to be negative (52) for LDLR (68% of the cases studied); however, no correlation between LDLR expression and serum cholesterol levels, histological grading, or Duke's stage was found.

Consequently, we investigated the state of cellular density and its effect on LDL regulation of endogenous cholesterol synthesis *in vitro* and found a positive correlation. After three days of culture, LDL was capable of inhibiting cholesterol synthesis in cells growing at low density. In contrast, subconfluent cells cultured for five days did not show this regulation (Fig. 2). We cannot dismiss the fact that the incorporation of ^{14}C-acetate into cholesterol is not a direct measurement of cholesterol synthesis, since differences in intracellular acetate uptake, acetate pools, or activation of acetate to acetyl CoA can occur. Thus, rates of sterol synthesis based on this assay could be regarded as estimates only. Therefore, we conducted a parallel experiment in SW480 cells cultured at the two density states of growth, utilizing ^{14}C-acetate vs. ^{14}C-octanoate as a source of acetyl CoA. Cells preferentially utilize this medium-chain fatty acid as a source of acetyl CoA, *via* its rapid intramitochondrial oxidation, avoiding some of the problems discussed above (53). Results showed that the cells exhibited similar responses to the different treatments when either label was used (data not shown). Nevertheless, since intestinal cells have been reported to prefer ^{14}C-acetate as a source of acetyl CoA to synthesize cholesterol (53), we used ^{14}C-acetate and not ^{14}C-octanoate for our experiments. While it is known that contact inhibited vascular endothelial cells bind LDL with high affinity, without affecting cholesterol metabolism (54), LDLR decrease in number as fibroblasts reach confluency (55). Our results demonstrate that in contrast to the fibroblast, colonic cells exhibited no downregulation of cholesterol synthesis by LDL at subconfluency (Table 1). This variation of cellular density with lipoprotein metabolism also has been shown by many others in intestinal cells in culture (28,40,41) and in neoplastic cells (56,57).

To determine if the culture density-dependent ability of LDL to inhibit cholesterol synthesis was due to a variation in LDLR activity which was concurrently cell density-dependent, the ability of these cultured cell lines to bind and internalize LDL at normal and low densities was assessed. The LDLR activity of LPDS control cultures was 57.3 (normal density) and 89.8 (low density) ng ^{125}I-LDL internalized/mg cell protein. These were not statistically different by ANOVA under even nonstringent conditions ($\alpha = 0.05$; $n = 6$). It is unlikely, should subsequent testing determine an actual difference between these groups, that a 36% decrease in activity from low to normal density should confer an LDL unresponsive phenotype in terms of cholesterol synthesis inhibition. Evidence exists for phenotypic change in terms of cholesterol metabolism with changing growth and differentiation states in colonic adenoCA cells. The observed inability of LDL pretreatment to reduce cholesterol synthesis in four colonic adenoCA cell lines cultured at normal density is similar to observations reported by Villiard *et al.* (58) for HT29 cells in stationary vs. exponential phase. This group also found LDLR activity to be more responsive vs. control under exponential (approximately 85%) than stationary (10%) conditions with a dramatic difference in the differentiated "G-" phenotype (58). This contrasts with our findings, which are supportive of a partially independent regulation of the two sterol controlled genes as suggested previously by others (28,38,40). Under conditions where synthesis of C27 sterols was unaffected by LDL in normal density SW480 cells, LDL pretreatment (5 μg/mL) caused LDLR expression to be reduced to 50 and 34% of the control LPDS treatments in normal and low density cells, respectively. Pretreatment with increased amounts of LDL or 25-OH-CH confirmed that exogenous sterols can be internalized and can cause inhibition of LDLR activity. Although specific degradation of LDL particles was not assessed, the ability of LDL to downregulate its own receptor's activity at each density state is strong evidence that such degradation is taking place even at normal densities where cells are not responsive to cholesterol synthesis inhibition by LDL.

In the fibroblast, the activity of HMG–CoAR and of overall sterol synthesis is regulated according to the rate of cell growth and proliferation (2). However, regulation of the LDLR and HMG–CoAR may not always directly relate to replication, as cell density (59), and standard culture conditions (51) may affect the results. The rates of *de novo* cholesterol synthesis (see Table 1) in cells growing at lower densities were higher than in the subconfluent cells, possibly due to a greater degree of proliferation in the lower density cells. Our laboratory is currently investigating the correlation of LDLR with growth and proliferation in these tumor cells (34).

Treatment of various colonic tumor cell lines with the competitive inhibitor of HMG–CoAR, mevinolin, reduced cholesterol production from acetate in all cells; however, cells cultured at low density were more inhibited by mevinolin treatment than those grown to subconfluence (Fig. 2). Similarly, enhancement of inhibitory action was noted in cells tested at low density relative to subconfluency with other inhibitors (Fig. 2) as 25-OH-CH (nonreceptor-dependent repressor of transcription and enhancer of protein degradation), or LDL (receptor-dependent repressor of transcription and enhancer of protein degradation). These findings are consistent with a possible flux of acetate (and thus mevalonate) toward nonsterol isoprenoids which may be in higher demand in these cells. Inhibitors would thus impact more strongly on cholesterol production. In fact, LDL and mevinolin combined as a treatment in the lower density cells resulted in enhanced inhibition of cholesterol synthesis (Fig. 2) compared to subconfluent densities.

Despite these responses in terms of cholesterol synthetic ability, under these treatments growth is not restored by LDL in intestinal cells inhibited by mevinolin (25,26,28). It is suggested that concurrent treatment with LDL and mevinolin can result in inhibition of HMG–CoAR in such a way that cellular levels of nonsterol mevalonate-derived products may be affected, thereby causing alterations in growth in tumor cells as compared to fibroblasts. This is of considerable interest as the expression of HMG–CoAR is high in tumors of colonic origin (19), and this may affect the expression of active membrane-bound ras oncogene, also found to be high in colon tumors (60–62). Recent work accomplished using a human lung adenoCA cell line has produced similar findings (63); LDL did not reverse a growth inhibition imposed by mevinolin when cells were grown in LPDS. These authors found a high proportion (40%) of HMG–CoAR activity devoted to the generation of nonsterol products in the lung cancer cells, as compared to the 15–20% seen in the fibroblast. Inhibitors of mevalonate synthesis, such as mevinolin, also have proven to inhibit tumor growth in various animal models (64,65). Thus, this inability to utilize exogenous sterol sources for growth in human cells of intestinal origin under conditions of mevalonate inhibition may be of therapeutic significance.

ACKNOWLEDGMENTS

Studies discussed have been supported in part by a research grant CN-95 from the American Cancer Society, and by a training grant T32 CA 09423 and research grant R01 CA57684 from the National Cancer Institute or the National Institutes of Health. The authors acknowledge the helpful suggestions of Dr. Herbert Kupchik. Functional and Ultrastructural Effects of Essential Fatty Acid Deficiency in Kidney Epithelial Cells

Lynn L. Stoll* and Arthur A. Spector

Departments of Anesthesia and Biochemistry, University of Iowa, Iowa City, Iowa 52242

ABSTRACT: Madin-Darby canine kidney (MDCK) epithelial cells were grown in culture medium supplemented with 1% fetal bovine serum (FBS) to provide a cell culture model of essential fatty acid deficiency (EFAD). 5,8,11-Eicosatrienoic acid (20:3n-9) accumulated in cellular phospholipids, and arachidonic acid (20:4) decreased. A large increase in cellular cholesterol/phospholipid ratio was observed. Hemicyst formation was greatly reduced from normal levels in the EFAD–MDCK cells. Scanning and transmission electron microscopy revealed that EFAD–MDCK were much flatter than their normal counterparts. They had much less dense surface microvilli, mitochondria and other organelles were very sparse, except in the perinuclear area, and much of the peripheral cytoplasm was amorphous. The EFAD was rapidly reversed by the addition of as little as 10 μM linoleic or arachidonic acid to the medium. Cells supplemented with 10% FBS, the usual culture condition, displayed borderline EFAD, with intermediate levels of 20:3n-9 and 20:4 and hemicyst formation. These studies suggest that EFAD reduces water and electrolyte transport in renal tubular epithelium.

Lipids 30, 1093–1103 (1995).

Essential fatty acid deficiency (EFAD) is known to produce metabolic and functional disturbances in a wide variety of cells and tissues. These disturbances include a decrease in macrophage leukotriene production (1) and acetylated low density lipoprotein receptor activity (2), impaired intestinal fat absorption (3), decreased Ca^{2+}-ATPase activity in submandibular gland microsomes (4), and decreased growth, cessation of beating, and impaired oxidative phosphorylation in cardiac myocytes (5).

Impaired renal function has long been recognized as one of the hallmarks of EFAD (6). The condition has been extensively characterized in animal models, with the accumulation of 5,8,11-eicosatrienoic acid (20:3n-9) and an increase in the ratio of fatty acid trienes/tetraenes considered diagnostic (6,7). EFAD in the rat produces a salt-sensitive hypertension with a combined defect in both sodium and water excretion which is related to prostaglandin depletion (8). Administration of 0.5 g/d of linoleic acid to these essential fatty acid-deficient rats normalized sodium and water excretion and returned urinary prostaglandin E output to normal within 3–4 d. Strandvik *et al.* (9) have shown that EFAD can be found in patients with cystic fibrosis and may contribute to the pathophysiology of the disease, as intravenous administration of essential fatty acids normalized the increased glomerular filtration rate found in these patients (10). EFAD also has been found in chronic hemodialysis patients, where it is associated with erythrocyte fragility, skin problems, and other clinical abnormalities (11).

Laposata *et al.* (12) have reported the development and characterization of a tissue culture model system for EFAD derived from the $HSDM_1C_1$ mouse fibrosarcoma cell line. These authors showed that the phenotypic modulation observed in this line can be reversed by the addition of arachidonic acid, but not by any other fatty acid that was tested (13). Although this line is useful for studies of cell growth and lipid metabolism, the mouse fibrosarcoma does not exhibit any characteristic physiological function. Madin-Darby canine kidney (MDCK) cells are widely used as an *in vitro* renal distal tubule model system for studying various aspects of renal function (14,15). We now report the development of a line of MDCK cells grown in medium supplemented with only 1% fetal bovine serum (FBS), which display many of the characteristics of EFAD seen in animal models. These include accumulation of eicosatrienoic acid (20:3n-9) and probably of its elongation product, docosatrienoic acid (22:3n-9), altered gross and ultrastructural morphology, growth inhibition, reduced transport function as indicated by decreased hemicyst formation, and changes in the cell phospholipid-to-cholesterol ratio, suggesting membrane abnormalities. Our results with this EFAD–MDCK cell culture model indicate that EFAD reduces water and electrolyte transport in the renal tubule, as indicated by decreased hemicyst formation.

MATERIALS AND METHODS

Cell culture. MDCK cells (ATCC CCL 34) were obtained from the American Type Culture Collection (Rockville, MD). Stock cultures were maintained in minimum essential medium (MEM) with Earle's Salts (GIBCO, Grand Island,

NY) supplemented with MEM Nonessential Amino Acids (GIBCO), MEM Vitamin Solution (GIBCO), HEPES (Sigma, St. Louis, MO), 2 mM L-glutamine (Sigma), 50 μg/mL gentamicin (Schering Corp., Kenilworth, NJ), and either 1, 10, or 20% HyClone Defined Fetal Bovine Serum (HyClone, Logan, UT). For electron microscopy studies, cells were grown in either 20% FBS or 1% FBS plus 19% delipidized FBS prepared according to the method of Rothblat *et al.* (16). The EFAD–MDCK subline had been adapted to growth in the medium containing 1% FBS plus 19% delipidized serum for at least three passages before being used for experiments. Cultures were grown at 37°C in a humidified atmosphere containing 5% CO_2. Stocks were subcultured weekly by trypsinization and reseeding at a 1:5 dilution for cells grown in 1% FBS, 1:10 for cells grown in 10% FBS, and 1:20 for cells grown in 20% FBS. Fatty acid-supplemented incubation media were prepared by adding the sodium salt of each fatty acid to medium containing 1% FBS (17).

Phospholipid fatty acyl composition. Confluent cell monolayers were washed three times with cold, phosphate-buffered saline solution (pH 7.4), and then harvested by scraping with a rubber policeman. The cells were pelleted by centrifugation; the cell pellet was resuspended in cold buffer and the cell lipids extracted with chloroform/methanol (2:1, vol/vol). Phospholipids were isolated by thin-layer chromatography on Silica Gel G plates (Alltech Associates, Deerfield, IL) using a solvent system of mixed hexanes/diethyl ether/acetic acid/methanol (170:40:4:4, by vol). The phospholipids were eluted from the gel with chloroform/methanol (1:1, vol/vol) and then saponified and methylated (17). Fatty acid methyl esters were separated by gas–liquid chromatography using a Hewlett-Packard (Avondale, PA) Model 5700 gas–liquid chromatograph with a 1.8 m glass column (2-mm i.d.) packed with 10% SP-2330 on 100/120 mesh Chromosorb W-AW (Supelco, Bellefonte, PA). Peak assignments were made by comparing retention times with those of fatty acid standards (Nu-Chek-Prep, Elysian, MN). Peak areas were determined with a Hewlett-Packard Model 3380-S integrator-recorder and are reported as weight percentages.

Mass spectrometry. Fatty acids were collected using a gas–liquid chromatograph equipped with a 9:1 stream splitter, with 90% of the effluent being diverted through Teflon tubing into CS_2. Approximately 1 μg of the collected fatty acid methyl ester was introduced into the solid inlet probe of a Nermag R10-10C mass spectrometer coupled to a Nermag Model 40 Data System (Delsi-Nermag, Paris, France). Conditions employed were a 25 m column of 5% phenyl methyl silicone, inner diameter 0.2 mm, film thickness 0.33 μm, temperature 220°C, and pressure 1 bar. Ionization was by electron impact at 70 eV.

Phospholipid classes. Individual phospholipid classes were separated from the chloroform/methanol extracts of the cell lipids by thin-layer chromatography, using boric acid-impregnated Silica Gel G plates and a solvent system of $CHCl_3/H_3OH/NH_4OH/H_2O$ (120:75:2:6, by vol) (18). Appropriate standards were cochromatographed on each plate. Phospholipids of each class were eluted from the gel with chloroform/methanol (1:1, vol/vol).

Processing of cells for scanning electron microscopy. MDCK and EFAD–MDCK cells were grown in Falcon P-35 plastic tissue culture dishes. Cells were fixed in 2.5% glutaraldehyde in 0.1 M sodium cacodylate buffer. After three buffer rinses over a 15-min period, the fixed cells were treated with freshly prepared 1% OsO_4 for 30 min. This was followed by a thorough rinsing with 5–10 changes of 0.1 M sodium cacodylate buffer. Cells were then treated with 1% tannic acid in 0.1 M cacodylate buffer for 1 h, followed by a rinse with glass-distilled water. The initial dehydration step was in 50% ethanol for 15 min; the cells were then stained overnight with 2.5% uranyl acetate in 75% ethanol. The following morning they were rinsed several times with 75% ethanol, and then dehydration was continued with 95% ethanol for 15 min and finally 100% ethanol. At each step, care was taken not to remove all of the fluid from the cells, so as to prevent drying and cracking of the monolayer. Sections of the plastic tissue culture dish with dehydrated cells were cut out and critical point dried, mounted on stubs, coated with gold in an Emscope SC-500 sputter coater (Ashford, Kent, England), and examined in a Jeol (Tokyo, Japan) 35C scanning electron microscope.

Processing of cells for transmission electron microscopy. Confluent cultures of both MDCK and EFAD–MDCK cells were fixed in 2.5% glutaraldehyde in 0.1 M sodium cacodylate buffer. After three buffer rinses over a 15-min period, the fixed cells were treated with freshly prepared 1% OsO_4 for 30 min; this was followed by two buffer rinses and one distilled water rinse. Cells were then stained for 5 min with 2.5% uranyl acetate. Cells were dehydrated with successive 10-min treatments in 25, 50, and 75% ethanol, followed by 20 min in 95% ethanol and 3 × 20 min in 100% ethanol. After dehydration, cells were infiltrated with Epon (Ted Pella, Inc., Redding, CA) (1:1 Epon/ethanol for 30–60 min, followed by 1 h in 100% Epon). Ultrathin sections were stained with 5% uranyl acetate for 10 min, rinsed well, stained with 0.5% lead citrate for 6–8 min, rinsed again, allowed to air-dry, and examined in a Hitachi (Toyko, Japan) H-600 transmission electron microscope.

Other determinations. Lipid phosphorous was determined by the method of Chalvardjian and Rudnicki (19). Proteins were measured by the Lees and Paxman modification of the Lowry procedure (20). Cholesterol content was determined according to the Manual of Laboratory Operations, Lipid Research Clinics Program (21).

RESULTS

Identification of 5,8,11-eicosatrienoic acid. 5,8,11-Eicosatrienoic acid (20:3n-9) accumulated in MDCK cell lipids under certain conditions, as identified by its elution on gas–liquid chromatograms (between 20:2n-6 and 20:3n-6) (Fig. 1) and by mass spectrometry (Fig. 2, top panel). The mass spectrum of the methyl ester contained a molecular ion with *m/z* 320, consistent with a structure of 20:3. Other ions

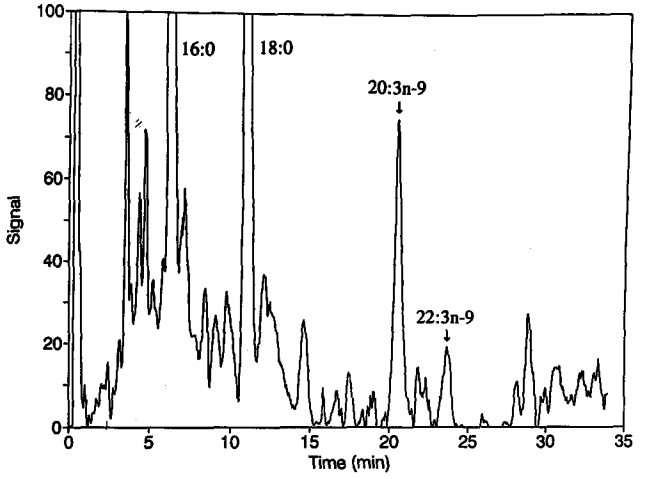

FIG. 1. Gas–liquid chromatogram, showing retention times and relative composition of 5,8,11-eicosatrienoic acid (20:3n-9), retention time 20.55 min, and putative 7,10,14-docosatrienoic acid (22:3n-9), retention time 23.72 min, in essential fatty acid deficiency–Madin-Darby canine kidney cells. Retention times for other fatty acids in this system: 20:2n-6, 19.45 min; 20:3n-6, 22.04 min; 20:4, 22.76 min; 24:0, 28.18; 24:1, 28.96.

consistent with this structure are m/z = 221, M − 99 (loss of C_7H_{15}); m/z = 219, M − 101 (loss of $C_5H_9O_2$); m/z = 161, $C_{12}H_{17}$; m/z = 147, $C_{11}H_{15}$; m/z = 135, $C_{10}H_{15}$; m/z = 120, C_9H_{12}; m/z = 106, C_8H_{10}; m/z = 80, C_6H_8; and m/z = 67, C_5H_7. This fragmentation pattern is identical to a mass spectrum obtained in a previous study of 20:3n-9 accumulation in 3T3-L1 and 3T3 cells (22).

A smaller peak which eluted on gas–liquid chromatography between 20:5n-3 and 22:4n-6 (Fig. 1) also was collected and analyzed by mass spectrometry. The mass spectrum from this fatty acid methyl ester revealed a molecular ion of m/z 348 (Fig. 2, bottom panel), consistent with a structure of 22:3, possibly the elongation product of 20:3n-9. Other observed ions that are consistent with the 22:3 structure are m/z = 317, M − 31 (loss of OCH_3); m/z = 249, M − 99 (loss of C_7H_{15}); m/z = 208, M − 140 (loss of $C_{10}H_{20}$); m/z = 192, M − 156 (loss of $C_9H_{16}O_2$); m/z = 163, $C_{12}H_{33}$; m/z = 149, $C_{11}H_{19}$; m/z = 135, $C_{10}H_{15}$; m/z = 121, C_9H_{13}; m/z = 107, C_8H_{11}; m/z = 94, C_7H_{10}; m/z = 87, $C_4H_7O_2$; m/z = 80, C_6H_8; m/z = 71, C_5H_{11}; and m/z = 67, C_5H_7. Further studies to unequivocally assign double bond locations were not performed.

Serum concentration and fatty acid composition. Experiments with MDCK cells grown in media supplemented with FBS in concentrations ranging from 0 to 20% indicate an inverse relationship between 20:3n-9 and arachidonic acid (20:4n-6) content in cell phospholipids (Table 1). In cells which had been grown for several passages in medium supplemented with delipidized serum only, the cell phospholipids contained 9.0 ± 0.39% 20:3n-9, with no detectable 20:4 or other n-6 polyunsaturated fatty acids, 18:2n-6 and 20:3n-6. We were unable to maintain MDCK cells under these conditions for more than six passages. However, addition of only 1% FBS along with 19% delipidized serum to the growth

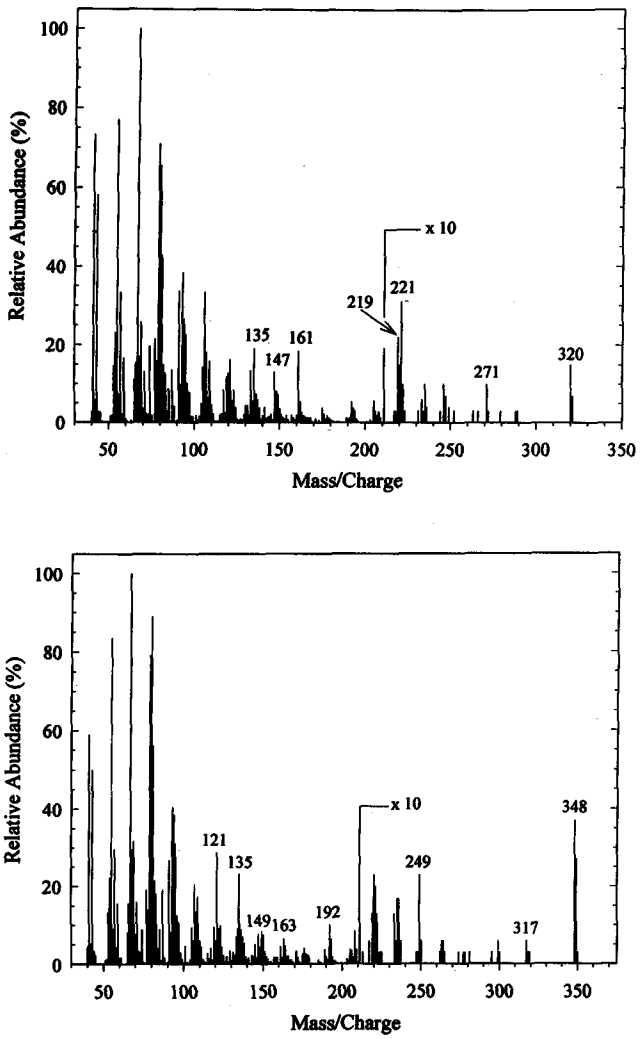

FIG. 2. Electron impact mass spectra of 5,8,11-eicosatrienoic acid (20:3n-9) (top panel) and a fatty acid suggested to be 7,10,13-docosatrienoic acid (bottom panel). Fatty acid methyl esters were isolated by collecting the effluent from the peaks using a gas–liquid chromatograph equipped with a 9:1 stream-splitter. These spectra are consistent with the structures of 20:3 and 22:3, respectively.

medium permitted maintenance up to 20 passages, with the phospholipid 20:3n-9 content ranging from 6–8% in several experiments, and the 20:4 content remaining at approximately 1%. Cells maintained under these conditions are clearly essential fatty acid-deficient by the traditional criterion of fatty acid triene/tetraene ratio = >1 (6), exhibiting a triene/tetraene ratio ranging from 3.1 to 10.9 in several experiments. The putative 22:3n-9 peak was detected only in cells grown in medium containing 5% or less FBS.

MDCK cells grown in a medium containing 10% FBS, the usual method of culture, contained approximately equal percentages of 20:3n-9 and 20:4 in phospholipids. The fatty acid triene/tetraene ratio, which is approximately 1, indicates that MDCK cells grown under ordinary culture conditions actually are in a state of borderline EFAD (6). A further increase in serum concentration above 10% substantially reduced the 20:3n-9 content, with a concomitant increase in

TABLE 1
Fatty Acid Composition of Cellular Phospholipids[a]

Fatty acid	Phospholipid fatty acid composition

[a]Madin-Darby canine kidney cells were grown for seven days in either serum-free medium or in medium supplemented with the indicated percentages of serum. After the lipids were extracted and the phospholipids isolated by thin-layer chromatography, the fatty acid composition of the phospholipids was determined by gas–liquid chromatography. Each value is the mean ± SEM of three separate cultures.
[b]Percent fetal bovine serum in culture medium.
[c]nd = Not detected.

20:4 content. Medium supplemented with 20% FBS produces a normal phospholipid fatty acid triene/tetraene ratio of approximately 0.5.

Culture morphology. Coincident with these fatty acid compositional changes was the observation of greatly enhanced hemicyst formation in cultures grown with 20% FBS supplementation as compared to cultures grown with lower percentages of FBS (Fig. 3). A hemicyst is a blister-like phenomenon formed when renal tubule epithelial cells grown on tissue culture plastic transport water and salt from the apical to the basolateral surface. This fluid is trapped under the cell layer, rather than being released through the tubule, causing the formation of groups of cells rising in domes above the plane of the cell surface. Loss of hemicyst formation is attributed to loss of transport function by the epithelium (23). EFAD–MDCK cultures grown with 1% FBS supplementation (Fig. 3, panel A) exhibited a virtual absence of hemicysts, with only one hemicyst observed in a total of 25 consecutive low-power fields examined. With 10% FBS supplementation, a total of nine hemicysts were observed in a series of 25 consecutive lower power fields examined. However, with cells grown with 20% supplementation, a mean of 31 ± 1.9 hemicysts were observed in each low-power field. Changes in gross morphology were also evident, with the EFAD–MDCK being flattened and spread compared to the cells grown in 10 or 20% FBS.

Fatty acid supplementation. The EFAD of EFAD–MDCK grown with 1% FBS supplementation was reversed within a single passage by the addition of either linoleic acid (18:2n-6), a precursor of arachidonic acid, or arachidonic acid

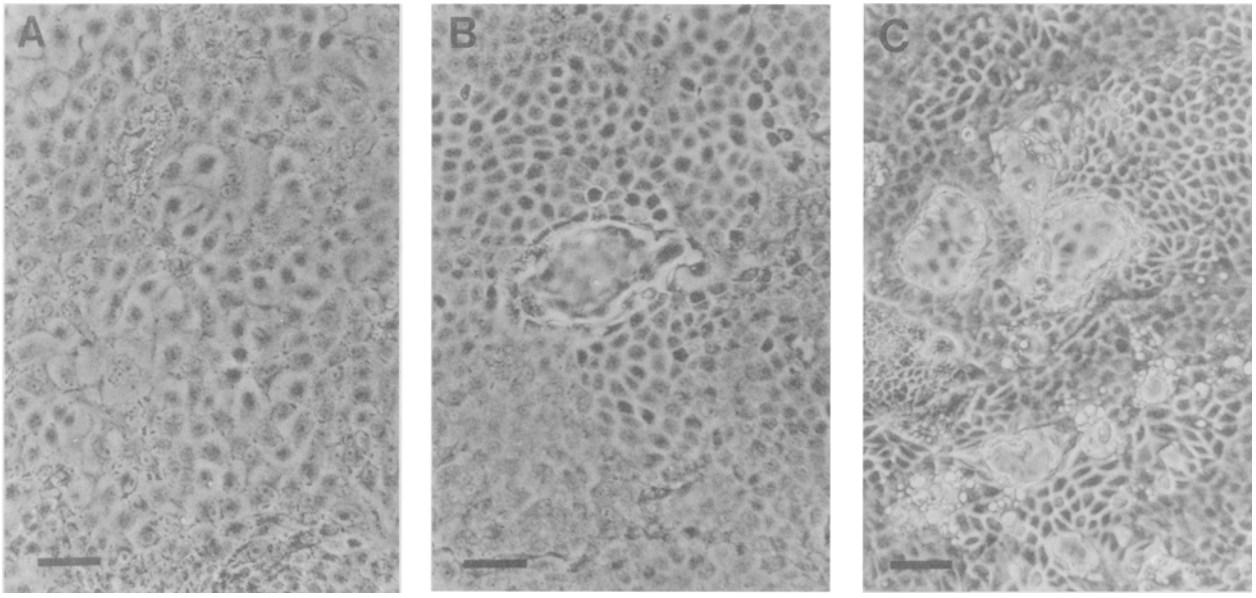

FIG. 3. Phase contrast photomicrographs of Madin-Darby canine kidney cells grown in medium supplemented with 1% (Panel A), 10% (Panel B), and 20% (Panel C) fetal bovine serum; bar = 100 μm.

TABLE 2
Effect of Increasing Concentrations of Supplemental 18:2 or 20:4 on the Phospholipid Fatty Acid Composition of Madin-Darby Canine Kidney Cells Grown in 1% Fetal Bovine Serum[a]

	Phospholipid fatty acid composition (%)						
		18:2[b]			20:4[c]		
Fatty acid	Control	10 μM	25 μM	50 μM	10 μM	25 μM	50 μM
16:0	12.2 ± 0.03[d]	13.3[e]	11.2	10.6	11.4	12.4	13.2
16:1	6.3 ± 0.41	4.7	2.8	2.4	4.1	3.4	2.6
18:0	17.4 ± 0.32	17.0	20.2	20.2	18.8	23.8	22.6
18:1	44.9 ± 0.78	38.2	32.4	27.4	42.8	37.6	25.2
18:2	<0.1	5.1	9.0	13.0	2.2	1.7	1.8
20:3n-9	4.6 ± 0.11	2.9	1.6	1.0	2.8	0.8	0.2
20:3n-6	0.3 ± 0.02	3.2	5.8	6.2	1.1	1.4	2.6
20:4	1.3 ± 0.12	3.8	9.4	11.2	7.8	11.8	22.2
22:4	0.3 ± 0.13	0.9	1.0	1.4	1.5	1.8	2.8

[a]Madin-Darby canine kidney cells were grown for seven days in medium containing 1% FBS (control) or in this medium supplemented with the indicated amounts of either linoleic (18:2) or arachidonic (20:4) acid.
[b]Media supplemented with linoleic acid.
[c]Media supplemented with arachidonic acid.

[e]Average of two determinations from separate cultures.

itself to the growth medium (Table 2). In this experiment, the ratio of 20:3n-9 to 20:4 in the phospholipids of control cells grown with 1% FBS supplementation was approximately three; this was reduced to <1 by the addition of as little as 10 μM of either 18:2 or 20:4. The phospholipid content of 20:3n-9 was reduced to 1% by supplementation with 50 μM linoleic acid, and virtually eliminated by supplementation with 50 μM arachidonic acid. In addition, the amounts of palmitoleic (16:1n-7) and oleic (18:1n-9) acids were substantially reduced by these treatments.

A generally similar, though less complete, reversion of the EFAD pattern occurred when confluent cultures of EFAD–MDCK were placed in medium containing 10 or 20% FBS or 10% horse serum. FBS is rich in arachidonic acid, and horse serum is rich in linoleic acid (24). Table 3 shows the alterations that take place in the phospholipid fatty acid composition at different times up to seven days after changing from 1% FBS supplementation to these media that contain a higher serum content. As early as 6 h after changing the culture medium, the phospholipid 20:4 content increased from 1% to 2.7 ± 0.17% with 10% FBS, and 3.2 ± 0.19% with 20% FBS. After seven days, 20:4 levels increased to 3.8 ± 0.23% with 10% FBS and 4.9 ± 0.21 with 20% FBS. However, 20:3n-9 decreased much more slowly. At seven days, 20:3n-9 levels decreased from an initial value of 6.8 ± 0.26% to 5.5 ± 0.22% in 10% FBS, and 3.6 ± 0.21% in 20% FBS.

Hemicyst formation. A significant number of hemicysts began to appear in cells three days after changing from 1 to 20% FBS supplementation, at which time 20:3n-9 and 20:4 contents were 5.0 ± 0.12 and 3.4 ± 0.22%, respectively. Seven days after adding 20% FBS-supplemented medium, hemicyst formation was equivalent to that seen in cells grown continuously with 20% FBS supplementation, suggesting that the presence of phospholipid 20:3n-9 does not itself inhibit hemicyst formation. Hemicyst formation also was rapidly induced by supplementation of the culture medium of EFAD–MDCK with 18:2 or 20:4, but not with 18:1 (Table 4). Before the fatty acids were added to confluent cultures of EFAD–MDCK, there were 2–3 hemicysts per 25 low-power fields. After 48 h this increased to 157 hemicysts per 25 fields in the 18:2-supplemented cells, and 73 per 25 fields in the 20:4-supplemented cultures. By contrast, supplementation with 10 μM 18:1 for 48 h had little effect.

Lipid composition. Determination of total lipid phosphorous and its distribution among different phospholipid classes revealed marked differences between the EFAD–MDCK and the MDCK cells grown with 10 or 20% FBS supplementation. There was a sharp reduction in the amount of total lipid phosphorous per mg cell protein in the EFAD–MDCK (Table 5). Furthermore, the relative amounts of the individual phospholipid classes differed (data not shown). Of the three major phospholipid classes analyzed, which accounted for 79–89% of the total phospholipids, only phosphatidylinositol increased in the EFAD–MDCK, both in absolute amount and especially in percentage (from 8 to 17%). Phosphatidylcholine decreased substantially both in absolute amount and in percentage (from 49 to 34%). Phosphatidylethanolamine declined in absolute amount, but remained a constant percentage of the total phospholipids (approximately 30%). In contrast to the total lipid phosphorous values, the total cholesterol content of the EFAD–MDCK cells was not significantly different from that of the MDCK cells grown with 10 or 20% FBS supplementation (Table 5). Therefore, the cholesterol/phospholipid molar ratio was significantly higher in the EFAD–MDCK cells compared to the two other groups.

Scanning electron microscopy. The morphological differences between EFAD–MDCK and normal MDCK cells observed by light microscopy (Fig. 3) were confirmed by scanning electron microscopy. Pairs of micrographs (Fig. 4, panels A vs. C, and B vs. D of MDCK and EFAD–MDCK at the same

TABLE 4
Hemicyst Formation in EFAD–MDCK Cells After 48 Hours of Fatty Acid Supplementation[a]

Supplement	Hemicyst formation (hemicysts/25 low-power fields)
None	3
18:1	5
18:2	157
20:4	73

[a]EFAD–MDCK (essential fatty acid deficient–Madine-Darby canine kidney) cells adapted to growth in medium containing 1% fetal bovine serum plus 19% delipidized serum were grown to confluence in T-25 flasks. This medium was removed and replaced with fresh medium containing no supplemental fatty acid or 10 μM 18:1, 18:2, or 20:4. After 48 h, total hemicysts were counted in five randomly selected low-power fields in each of five flasks, for a total of 25 fields examined.

TABLE 5
Lipid Phosphorous and Cholesterol Content of MDCK Cells Grown in 1, 10, and 20% Fetal Bovine Serum[a]

	Serum concentration of medium (nmol/mg protein)		
Cell lipid	1%	10%	20%
Total lipid phosphorus	225 ± 13	353 ± 15	382 ± 20
Cholesterol	78 ± 5.4	87 ± 4.0	87 ± 3.4
Cholesterol/phospholipid ratio	0.35	0.25	0.23

[a]MDCK cells were grown to confluence in 75 cm^2 flasks in medium containing 1, 10, or 20% serum. Lipid extracts were assayed for inorganic phosphorus and cholesterol as described in the Materials and Methods section. Values are expressed as mean ± SEM (n = 3).

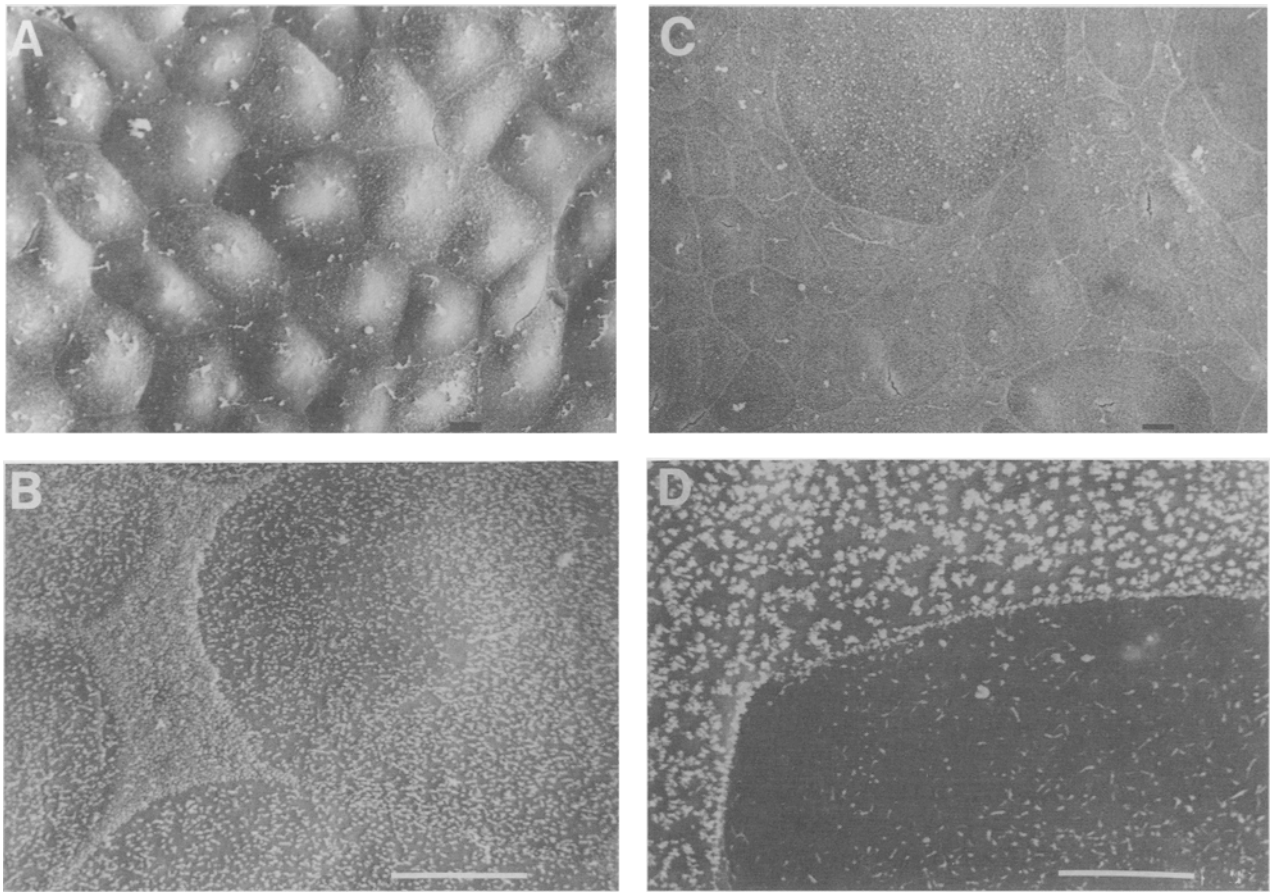

FIG. 4. Scanning electron micrographs (1,680×) of Madin-Darby canine kidney (MDCK) cells grown in 20% fetal bovine serum (FBS) (panels A and B) and essential fatty acid deficient (EFAD)–MDCK cells grown in 1% FBS (panels C and D). Panels A and C, low magnification; Panels B and D, high magnification; bar = 10 μm in all panels.

magnification show clearly that the EFAD–MDCK (C and D) are much flatter than their normal counterparts (A and B), and that individual EFAD–MDCK cells are spread out over a much larger surface area than MDCK cells. SEM also revealed that microvilli are much less dense in EFAD–MDCK than in MDCK, with a 5:1 ratio of MDCK/EFAD–MDCK microvillar density. This ratio was consistent for both the recently divided cells, with relatively sparse microvilli, and for the older cells in the cultures, with greater microvillar densities.

Transmission electron microscopy. Transmission electron microscopy revealed striking differences in the number and distribution of organelles, especially mitochondria. Figure 5 shows low-power micrographs of typical normal MDCK (panel A) and EFAD–MDCK (panels B and C). Panel A, photographed at 2,800×, shows the cytoplasm of the normal MDCK to be densely packed with organelles, which are dispersed more or less evenly, including at the cell periphery (indicated by arrowheads). By contrast, a micrograph of an EFAD–MDCK cell at the same magnification (panel B) shows fewer organelles, and these are for the most part clustered in the perinuclear area, with very few organelles found in the peripheral cytoplasm. Although individual EFAD–MDCK cells extend over a much larger surface area, much of the peripheral cytoplasm (panel C) is amorphous, almost completely lacking in organelles except for free ribosomes and cytoskeletal elements.

Figure 6 is a series of micrographs taken at higher magnification (8,400×) which show additional ultrastructural detail. Panels A and B show the perinuclear area (panel A) and the peripheral cytoplasm (panel B) of normal MDCK cells. These photomicrographs show numerous mitochondria and other organelles, both in the perinuclear area and at the periphery. Panels C and D show cytoplasmic details of EFAD–MDCK at the same magnification; panel C shows the perinuclear area, and panel D part of the peripheral cytoplasm. As seen also in Figure 5, organelles in the EFAD–MDCK are clustered around the nucleus, with much of the peripheral cytoplasm appearing amorphous. The mitochondria in the EFAD–MDCK appear on the average to be larger and more poorly organized than those in the MDCK, with few intact cristae.

DISCUSSION

These results demonstrate that a metabolic state corresponding to EFAD occurs in MDCK renal tubular epithelial cells

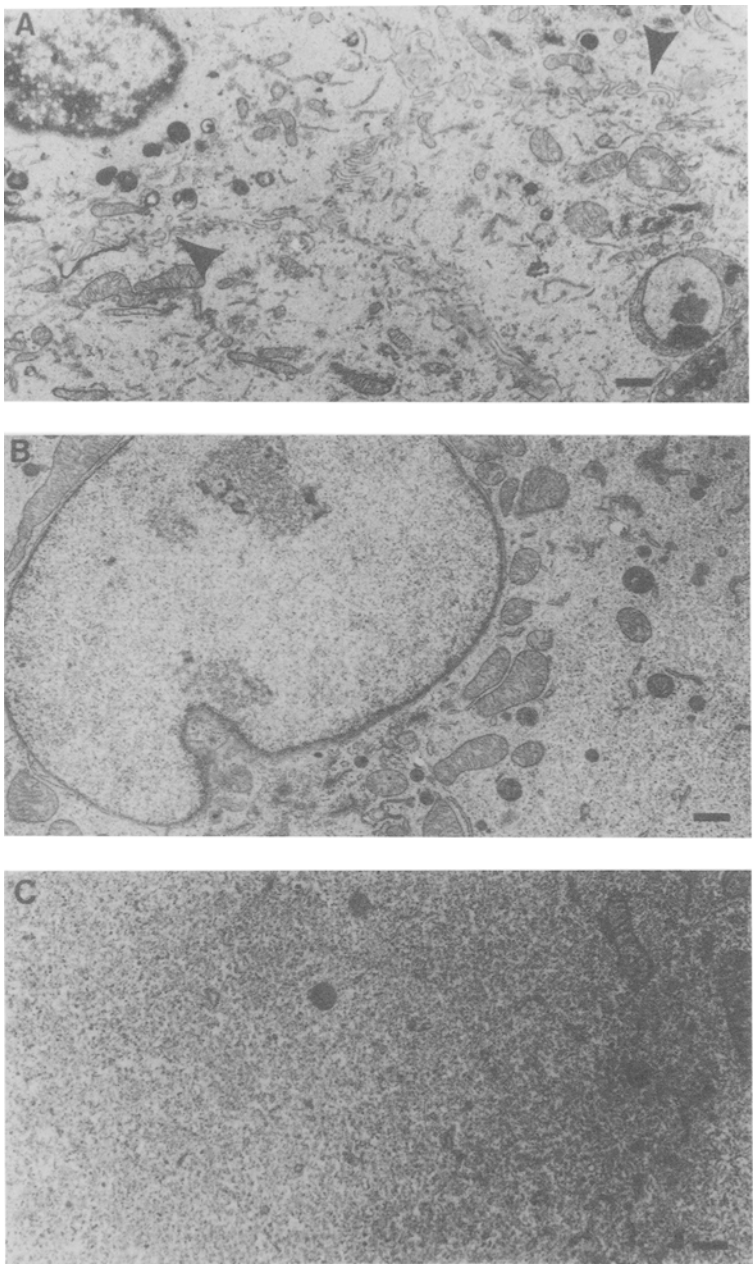

FIG. 5. Transmission electron micrographs (2,800×) of MDCK cells grown in 20% FBS (panel A) and EFAD–MDCK cells (panels B and C). Arrowheads indicate cell–cell boundaries; bar = 1 μm. Abbreviations as in Figure 4.

when they are grown in 1% FBS. This is associated with biochemical changes in phospholipid content and composition, ultrastructural changes as determined by electron microscopy, and functional disturbances as reflected by reduced hemicyst formation. Even when the medium contains 10% FBS, the usual culture condition, fatty acid compositional signs of EFAD are apparent. The finding of enhanced hemicyst formation in MDCK cells grown in medium supplemented with 20% FBS as compared to 10 or 1% supplementation is consistent with an earlier finding that substitution of 10% horse serum for FBS produces enhanced hemicyst formation (24). MDCK cells grown in horse serum, which contains over six times the amount of linoleic acid present in FBS, were found to have 0.8 ± 0.13% 20:3n-9 and 9.0 ± 0.47% 20:4 in their phospholipids (24). Thus MDCK cells grown in 10% horse serum, as opposed to those grown in a similar concentration of FBS, show no signs of EFAD. Hemicyst formation in MDCK cell cultures is an indication of active fluid transport (14,15). This phenomenon is sharply reduced in cells grown under conditions which produce EFAD. As relatively few hemicysts were observed when the medium contained 10% FBS, MDCK cells grown under these ordinary conditions

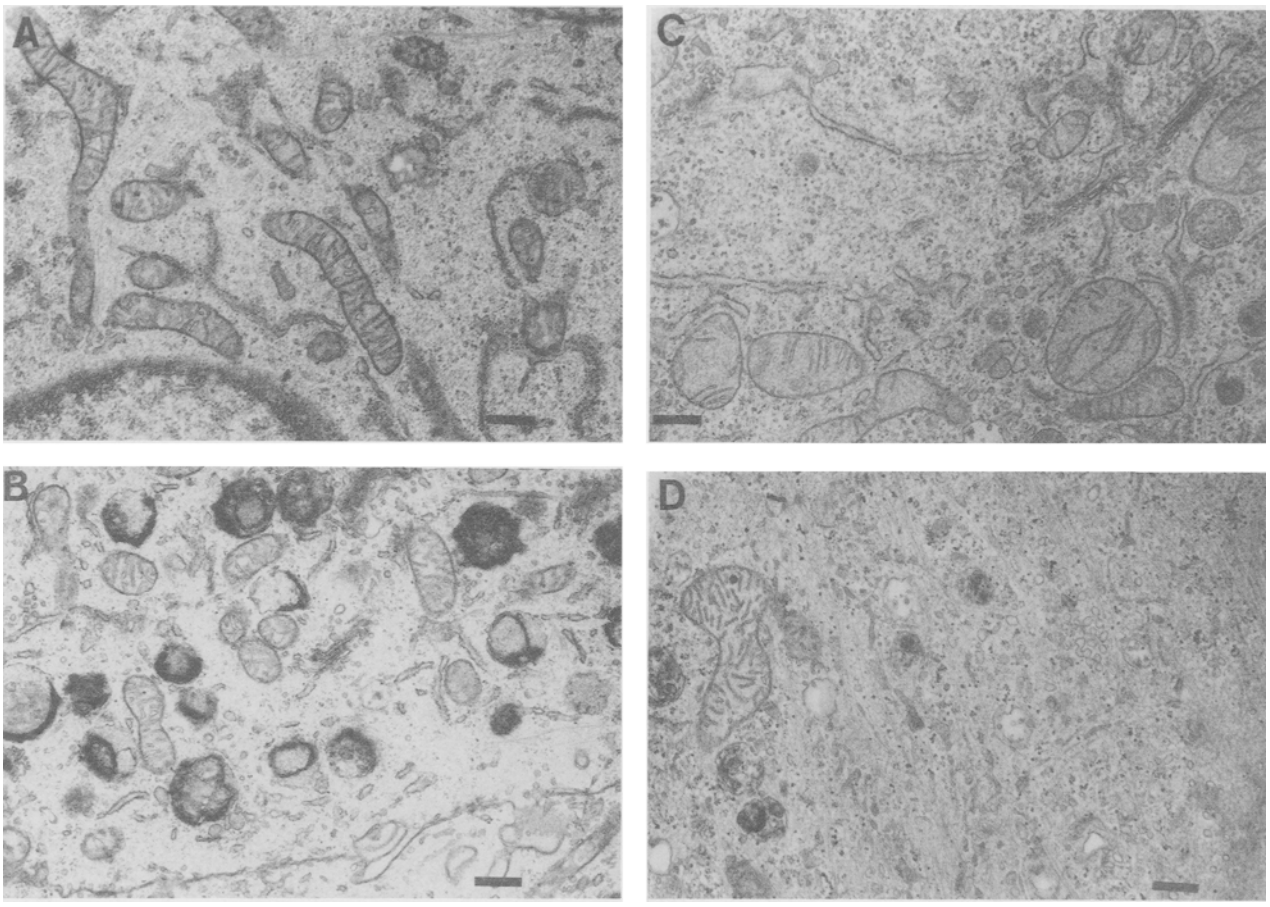

FIG. 6. Transmission electron micrographs (8,400×) of MDCK cells grown in 20% FBS (panels A and B) and EFAD–MDCK grown in 1% FBS (panels C and D). Panels A and C, perinuclear areas; panels B and D, peripheral cytoplasm; bar = 0.5 μm. Abbreviations as in Figure 4.

may not express the full transport potential of normal renal tubular epithelium.

In addition to 20:3n-9, a small amount of a fatty acid likely to be 22:3n-9 accumulates in the EFAD–MDCK lipids. This would be the elongation product of 20:3n-9, and it has been suggested to accumulate in certain cases of EFAD. Consistent with this finding, Dunham *et al.* (25) have reported large amounts of a fatty acid they also believed to be 22:3n-9 in the phospholipids (3.8%) and especially in the triglycerides (23.5%) of renal papillae from rats with long-term (60 wk) EFAD.

The observed ultrastructural differences between the normal MDCK and the EFAD–MDCK can be correlated with the biochemical differences we have found. The total cell lipids of EFAD–MDCK exhibit a large increase in cholesterol/phospholipid ratio compared to those of normal MDCK, caused by a decrease of approximately 50% in EFAD–MDCK cell phospholipids without any accompanying change in cholesterol content (Table 5). Cholesterol is usually found in large amounts in plasma membranes but not in intracellular membranes (26). For this reason, we anticipated that although the EFAD–MDCK plasma membrane probably was relatively unaffected, one or more intracellular membranous organelles whose membranes are composed primarily of phospholipids might be greatly reduced in size or number.

Transmission electron microscopy revealed that the number of such organelles was indeed greatly reduced. This was particularly evident in the peripheral cytoplasm, which was nearly amorphous except for cytoskeletal elements. A deficiency of mitochondria was particularly apparent. Several laboratories have reported mitochondrial dysfunction in studies of EFAD (5,27). This dysfunction has been suggested to result from differences in total number of mitochondria per cell, and possibly also from a functional impairment of these organelles. The present ultrastructural findings support these suggestions. In addition to the reduced numbers of mitochondria, the mitochondria in the EFAD–MDCK appear on the average to be larger and more poorly organized than those in the control MDCK cells, with few unbroken cristae. However, we did not pursue the quantitation of this finding. It is possible that the fragmentary cristae seen in the EFAD cells in Figure 6C is an artifact due to increased membrane fragility during the sectioning process, presumably due to altered membrane lipid composition. However, no such increased breakage is seen in other EFAD membrane structures in the same sections. Such "megamitochondria" also were observed

in rat hepatocytes from animals fed an essential fatty acid-deficient diet (27). Our findings are also consistent with the report by Christon *et al.* (28) of a decreased number of mitochondrial cristae in intestinal mucosal cells of rats fed a diet low in linoleic acid. Similarly, in studies of anterior pituitary phospholipids of rats fed an essential fatty acid-deficient diet, Alessio *et al.* (29) found that 20:4 levels in microsomal plus plasma membrane and nuclear fractions were unchanged compared to those from animals fed control diets, whereas they were decreased in both heavy and light mitochondrial fractions. These authors suggested the existence of a compensatory mechanism which may preferentially allow cells to conserve essential polyunsaturated fatty acids in discrete membrane fractions. It is possible that the reduced phospholipid content of the EFAD–MDCK may limit the capacity of mitochondria to divide. The large numbers of secondary lysosomes observed may also be related to a necessity to conserve membrane components by reprocessing.

The reduction in the density of microvilli on the EFAD–MDCK cell surface also may be related to a decrease in available membrane phospholipid. As the individual EFAD–MDCK have more surface area, there may be no significant reduction in the total number of microvilli per cell. Nevertheless, it seems likely that a cell with a severe fatty acid nutritional deficit might elaborate more, not fewer, microvilli to increase its absorptive surface area if it were not constrained from doing so. Such a phenomenon has been observed in intestinal epithelial cells in diabetic rats, which have a significantly greater surface area than corresponding cells in normal animals (30).

In conclusion, we have characterized an *in vitro* tissue culture model that may be useful for the study of EFAD in the renal distal tubule, using MDCK cells grown in medium supplemented with 1% FBS. The studies reported here show biochemical changes in the cells which are correlated with functional abnormalities and changes in gross and ultrastructural morphology. The abnormalities observed with this system correlate well with published data from animal models of this syndrome in terms of changes in fatty acid composition and transport function in the kidney. Our results also suggest that when MDCK cells are used as models of normal kidney function, the FBS concentration in their growth medium should be increased above the usual 10% level, or some horse serum should be included in the medium to supply additional linoleic acid and, thereby, ensure the presence of an adequate amount of essential fatty acids. Alternatively, supplemental linoleic acid may be added directly to the usual culture medium.

ACKNOWLEDGMENTS

This work was supported in part by Research Grant HL 49,264 from the National Heart, Lung and Blood Institute, National Institutes of Health. Electron microscopy was performed in the University of Iowa Central Electron Microscopy Facility, with the assistance of Dr. Kenneth C. Moore, and gas chromatography/mass spectrometry utilized the University of Iowa College of Medicine GC/MS facility. Technical assistance was provided by Tracy J. Timson.

ABSTRACT: The hypothesis that the essential oil from *Tagetes minuta* L. can interact with biological membranes was investigated by assessing its ability of perturbing the binding of a benzodiazepine [flunitrazepam (FNTZ)] to crude membranes from chick brains. The essential oil from *T. minuta* L. inhibited [^{3}H]FNTZ specific binding to chick brain membranes. These values were obtained from the analysis of the saturation curve for the kinetic parameters: dissociation equilibrium constant (K_d) = 2.47 ± 0.32 nM, maximal binding (B_{max}) = 556 ± 5 fmoles/mg protein, and Hill coefficient (n) = 1.00 ± 0.07 in the absence, and K_d = 6.73 ± 1.4 nM, B_{max} = 583 ± 69 fmoles/mg protein, and n = 1.02 ± 0.08 in the presence of 29 μg/mL of essential oil. The essential oil could self-aggregate with a critical micellar concentration (CMC) of 60 μg/mL. The marked increase in [^{3}H]FNTZ nonspecific binding starting at 60 μg of essence per mL was due to that phenomenon and revealed the ability of self-aggregated structures to interact with membranes. [^{3}H]FNTZ specific binding decrement as a function of essence concentration cannot be ascribed merely to oil's micelles ability of trapping the lipophilic radioligand molecules, because the discontinuous behavior that characterizes a monomer-aggregate phase transition was not shown. Oil's components might behave as competitive inhibitors or allosteric modulators of FNTZ specific binding. However, their ability to increase FNTZ nonspecific binding at concentrations below oil's CMC suggests that this effect may be due to oil's partitioning into the lipid bilayer. This latter phenomenon would induce an increment in membrane fluidity and a change on FNTZ binding site toward a lower affinity conformation. Therefore, the essential oil components can interact with brain membranes either as monomers, by partitioning into the lipid bilayer, or as self-aggregated structures, through an adsorption to the membrane surface.
Lipids 30, 1105–1110 (1995).

Tagetes minuta L. is a plant widely spread over the Argentinean territory. The composition of *T. minuta* L. essential oil has been described (1,2). Most of its components are terpene derivatives. Furthermore, some terpenes have been previously shown to affect membrane fluidity (3), and other terpenes behaved as γ-aminobutyric acid $(GABA)_A$ receptor complex inhibitors (4); the present essential oil could inhibit the development of fungus in culture through a mechanism that may involve instabilization of biological membranes (5).

Modifications in membrane organization can be transduced as changes in ionic permeabilities, in activities of membrane enzymes, in affinities of membrane receptors, etc. These could be due to changes in proteins' conformations exerted either directly, through the binding of a specific ligand, or indirectly, through phase transitions within lipidic domains (6,7).

$GABA_A$ is a supramolecular complex of several integral membrane proteins that includes three major binding sites—one for GABA, one for 1,4-benzodiazepines, and a third site for picrotoxine and barbiturates. Those sites are linked so that the binding of one of those ligands to its specific site can allosterically modulate the binding of another ligand to its own receptor (8–10). In addition, the sensitivity of the $GABA_A$-complex may fluctuate because of conformational constraints imposed by the lipid microenvironment (11).

As a lipophilic substance, the benzodiazepines (BZD) flunitrazepam (FNTZ) can partition into the hydrophobic domains of the membrane through nonspecific interactions (12) and increase membrane fluidity (13), as well as binding specifically to its receptor site at the $GABA_A$ receptor complex. Conversely, changes in membrane organization can modify FNTZ partition coefficient, as proven by the differences in FNTZ partition coefficient in model membranes above and below lipid phase transition temperature (García, D.A., and Perillo, M.A., unpublished data).

As both specific and nonspecific bindings of FNTZ were modulated by changes in membrane organization, it appeared that FNTZ would be a sensitive molecular probe for testing the ability of the essential oil to interact with biological membranes. Moreover, we also considered the possibility that not only the nonspecific, but also the specific, FNTZ binding were affected by the essence. Then, it would be justified to think of other possible effects of the essence, beyond the antifungic, such as its possible ability to be an antifeedant in insects, as well as an anxiolytic and/or anticonvulsant in vertebrates.

In the present paper, we assessed the ability of *T. minuta* essential oil of perturbing the *in vitro* binding of a BZD to crude membranes from chick brain.

MATERIALS AND METHODS

BZD [diazepam (DZ) and FNTZ] were obtained from Hoffman La Roche (Basle, Switzerland). [^{3}H]FNTZ was purchased from New England Nuclear Chemistry (E.I. DuPont de Nemours & Co., Inc., Boston, MA). Other drugs and solvents were of analytical grade. Plant material consisted of aerial parts of *T. minuta* L. collected in March from plants growing in the locality of Sesenta Curvas, Córdoba, Argentina. Voucher specimens have been deposited in the Botanical Garden Museum of Córdoba (herbarium CORD 79).

Extraction and characterization of the essential oil from T. minuta *L.* The oil was isolated from fresh plant material by hydrodistillation for three hours, using a homemade Clevenger-type apparatus (1,2,14). The very essential oil was used as the sample for gas chromatography (GC), and the ethyl acetate extract of an oil–water partition was used to find the composition of water-solubilized components of the essence. GC analysis was performed using a Shimadzu (Tokyo, Japan) GC-GA gas chromatograph equipped with a flame-ionization detector, a data handling system, and a fused-silica column (25 × 0.25 mm i.d.). Oven temperature was programmed from 70 to 200°C at a scanning rate of 40°C/min; the injector and detector were set at 280°C; the carrier gas was helium at a flow rate of 2 mL/min. The percent composition of the oil was computed from the GC peak areas (1,2). The GC/mass spectrometry unit consisted of a Hewlett-Packard (Avondale, PA) 5890 gas chromatograph equipped with an SE54 fused silica column (25 × 0.25 mm i.d.). The chromatograph was coupled to an HP5971A mass selective detector at 70 eV. The identity of the components was assigned by comparison of their retention indices and mass spectra with corresponding data of components of reference oils (1,2,14).

Effect of T. minuta *essential oil on the interaction of [^{3}H]flunitrazepam with brain membranes: incubation system.* The membrane receptor preparation was obtained as follows: whole brains from recently sacrificed chicks were dissected on ice and homogenized with 50 mM Tris–HCl pH 7.4 cold buffer (50 mL per gram of wet tissue); this suspension was centrifuged at 36,000 × *g* for 20 min at 40°C. The pellet was stored at −20°C, and it was resuspended in the same buffer immediately before use.

The incubation system contained (in 650 µL final volume) the membrane suspension at a final concentration of 1 mg protein/mL, Tris–HCL buffer containing (nonspecific) or not (total) DZ 9.2 µM (final concentration) and [^{3}H]FNTZ (specific activity 87 Ci/mmol) to reach final concentrations ranging from 0.7 to 16 nM (saturation curve) or a fixed concentration of 1 or 2 nM (other experiments). The essential oil from *T. minuta* L. was incorporated in 10 µL of an aqueous dispersion of a proper concentration. The samples were incubated at 4°C in the dark for 1 h, and then 200-µL aliquots were added to 2 mL of cold Tris–HCl buffer and immediately filtered through Whatman (Maidstone, England) GF/B filters. Those filters were rinsed with another 2 mL of cold buffer, dried in air, and placed in glass vials containing 2.5 mL of scintillation cocktail (Triton 30%, diphenyloxazole 0.3% in toluene); radioactivity was determined with a precision of 5% and a counting efficiency of 60% for tritium in a Rackbeta LKB 1224 scintillation spectrometer (Pharmacia Wallac OY, Turku, Finland). The whole filtration procedure was completed in 10 s. The filters used had been treated for 4 h at 4°C with isobutanol 4% (vol/vol) in water to minimize their capacity of adsorbing BZD. Protein concentrations were determined by a modified Lowry procedure (15).

Determination of the critical micellar concentration (CMC). Variable amounts of the essential oil (from 0 to 2.3 mg) were dispersed in 1 mL of water at room temperature; 10 µL of 3.3% (wt/vol) thymol blue methanolic solution were added, and the absorbance was measured at 720 nm with a Spectronic 21 spectrophotometer (Bausch & Lomb Inc., Rochester, NY). The CMC was determined as the concentration value corresponding to the interception with the abscissa axis of the asymptote to the curve of absorbance at 720 nm vs. essential oil concentration.

Statistical analysis. The saturation curves were adjusted to the following equation (16):

$$B = \frac{B_{max} \cdot F}{K_d + F} \qquad [1]$$

by a nonlinear regression analysis performed by a computed added least squares method (B and F were the bound and free [^{3}H]FNTZ concentrations, respectively, B_{max} = maximal binding, K_d = equilibrium dissociation constant). Comparisons among means were performed by a two-tailed Student's t-test; the propagation of errors was applied to compute the standard deviation of magnitudes calculated from two or more experimentally determined parameters (17).

RESULTS

The *T. minuta* L. essential oil was a complex mixture of mostly hydrophobic substances. Its density was 0.94 g/mL. Table 1 shows the composition of the essential oil and also that of its aqueous dispersion. The *cis* isomer of ocimene is the major component of the essential oil, representing 51.32% by weight of the total essence. A group of compounds that includes *t*-ocimene, dihydrotagetone, *c*-tagetone, *c*-ocimenone, *t*-ocimenone, and spathulenol represent 33.74%, with individual abundances ranging between 2 and 7.8%; fifteen other compounds with abundances of 1.48% or lower add 7% and, finally, 7.95% that corresponds to 20 chromatographic peaks remained unidentified. The highest concentrated compounds in the essential oil, although in different proportions, were also the major components found in the water phase. As expected, the relative proportion of hydrocarbon-type compounds decreased and that of the aldehydes, cetones, alco-

[a,b]The oil composition was determined by gas chromatography/mass spectrometry. Pinene: bicycle [3.1.1]hept-2-ene-2,6,6-trimethyl; ocimene, 1,3,6-octatriene-3,7,dimethyl; limonene, cyclohexene-1-methyl-4-(1-methylethenyl)-(R); terpinene, 1,3-cyclohexadiene-1-(methyl)-4-(1-methylethyl); terpinolene, cyclohexen-1-methyl-4-(1-methylethylidene); α-thujene, bicycle [3.1.0] hex-2-ene-2-methyl-5-(1-methylethyl)-(1R); α-copaene, tricycle [4.4.0.$0^{2,7}$]dec-3-ene-1,3-dimethyl-8-(1-methylethyl); *t*-elemene, cyclohexene-6-ethenyl-6-methyl-1-(1-methylethyl)-3-(1-methylethylidene)-(S); dihydrotagetone, 7-octen-4-one-2,6-dimethyl; tagetone, 5,7-octadien-4-one-2,6-dimethyl-(E); ocimenome, 2,5,7-octatrien-4-one-2,6-dimethyl; carvona, 2-cyclohexen-1-one-2-methyl-5-(1-methylethenyl)-(R); dihydrocarvona, cyclohexanone-2-methyl-5-(1-methylethenyl); linalool, 1,6-octadien-3-ol-3,7-dimethyl; limonene oxide, 1,2-epoxy-cyclohexene-1-methyl-4-(1-methylethenyl)-(R); borneol, bicycle-[2,2,1]-heptan-2-ol-1,7,7-trimethyl-(1S-Endo); carveol, 2-cyclohexen-1-ol-2-methyl-5-(1-methylethenyl); spathulenol, ^{1}H-cycloprop[e]azulen-7-ol-decahydro-1,1,7-trimethyl-4-methylene-1aR-(1aα,4aα-7aβ,7aα)].

hols, and oxides increased in the water phase compared with that of the total essential oil.

As shown in Table 2, in the presence of 29 μg/mL of *T. minuta* essential oil the specific binding of 1 nM [^{3}H]FNTZ to its receptor sites at chick brain membranes decreased significantly with respect to the control. However, the nonspecific binding increased as a function of the final oil concentration.

The absorbance at 720 nm (A_{720}) of thymol blue (Fig. 1a) and the nonspecific binding (Fig. 1b) were constant up to 60 μg of essence per mL of aqueous solution. Beyond this point, both parameters rose abruptly as a function of the essence concentration. Identical results were obtained when mixtures of [^{3}H]FNTZ with variable amounts of essential oil were filtrated through glass filters that had previously retained the same membrane suspension used in the nonspecific test tubes; however, with membrane-free filters, no radioactivity was recovered along the same range of essence concentrations (Fig. 1b). The specific binding of [^{3}H]FNTZ decreased as a function of the essence concentration (Fig. 1c), but, instead of what occurred with the parameters measured in Figure 1a and 1b, which showed discontinuous behavior, this decrement increased continuously, starting from the lowest essence concentration assayed.

Figure 2a shows that the specific binding of [^{3}H]FNTZ to membrane receptors increased as a function of free [^{3}H]FNTZ concentration in the incubation system, reaching a plateau at approximately 8 nM. In the presence of 29 μg of *T. minuta* essential oil, an inhibition of the binding was observed mainly at low [^{3}H]FNTZ; here, a plateau was reached at a radioligand concentration higher than in the absence of essence. From the nonlinear regression analysis of the saturation curves, the following values were determined for the binding parameters: $K_d = 2.47 \pm 0.32$ nM and $B_{max} = 556 \pm 5$ fmoles/mg protein, and $K_{d,e} = 6.73 \pm 1.4$ nM and $B_{max,e} = 583 \pm 69$ fmoles/mg protein in the absence and in the presence of the essential oil, respectively. The difference between K_d and

Binding of [^{3}H]FNTZ to Chick Brain Membranes as a Function of *Tagetes minuta* L. Essential Oil[a]

Essential oil concentration (μg/mL)	Binding of [^{3}H]FNTZ (fmol/mg protein)		
	Total	Nonspecific	Specific
0	110.3 ± 5.0	6.5 ± 0.5	103.5 ± 5.5
29	82.8 ± 3.4*	6.2 ± 0.3	76.6 ± 3.7*
145	95.4 ± 2.1*	12.3 ± 1.2*	83.1 ± 3.3*
273	102.1 ± 1.2	27.5 ± 1.4*	74.6 ± 2.6*

[a]The binding of 1 nM [^{3}H]flunitrazepam (FNTZ) to chick brain membranes was measured in the presence (nonspecific) or in the absence (total) of nonlabeled diazepam. Specific: results from the difference between total minus nonspecific. The experimental details are explained in the Materials and Methods section. The values shown correspond to the means of triplicate determination ± SEM; *significatively different ($P < 0.05$) with respect to the control (without essential oil).

$K_{d,e}$ was significant from the statistical point of view ($P < 0.01$). B_{max} and $B_{max,e}$ were not statistically different ($P > 0.1$). The Scatchard plot of the saturation curve obtained without the essential oil was linear, as described previously (18); the presence of the oil did not change this characteristic (Fig. 2a, inset). Hill coefficients were equal to unity in the presence (1.02 ± 0.08) and in the absence (1.00 ± 0.07) of the essential oil (not shown).

In the absence and in the presence (below CMC) of the essence, the nonspecific binding increased as a function of [^{3}H]FNTZ concentration (Fig. lb); in both cases the points were adjusted to straight lines passing through the origin, but the slope in the presence of essence was higher than in the absence of the essence (7.14 and 4.24 fmol/mg prot/nM, respectively).

DISCUSSION

The essential oil from *T. minuta* L. could inhibit the specific binding of [^{3}H]FNTZ to chick brain membranes (Fig. 1c, Fig. 2a, Table 2). Whether this effect was actually exerted at the membrane level was the question that arose.

The increase of A_{720} of thymol blue as a function of the essential oil concentration in an aqueous solution (Fig. 1a) could be interpreted on the basis of the spontaneous self-aggregation of the essence component molecules after a critical point of essence concentration in the aqueous phase was overcome (CMC). These self-aggregated structures constitute a new hydrophobic phase in the system where the dye, also hydrophobic, is more soluble than in water. This phenomenon was made evident by the abrupt increase of the dye absorbance beyond an essence concentration of 60 μg/mL. As BZD is also a high lipophilic substance, it could be preferentially partitioned into the mentioned structures as well. This mechanism can explain the discontinuous increment of [^{3}H]FNTZ nonspecific binding (Fig. lb). On the other hand, these structures are not big enough to be retained by clean glass filters, as suggested by the flatness of the plot of radioactivity vs. oil concentration (Fig. lb). However, the fact that these self-aggregated structures were retained by membrane-coated filters following a radioactivity pattern similar to that of nonspecific binding (Fig. lb) points out their high tendency to establish surface–surface interaction with biological membranes.

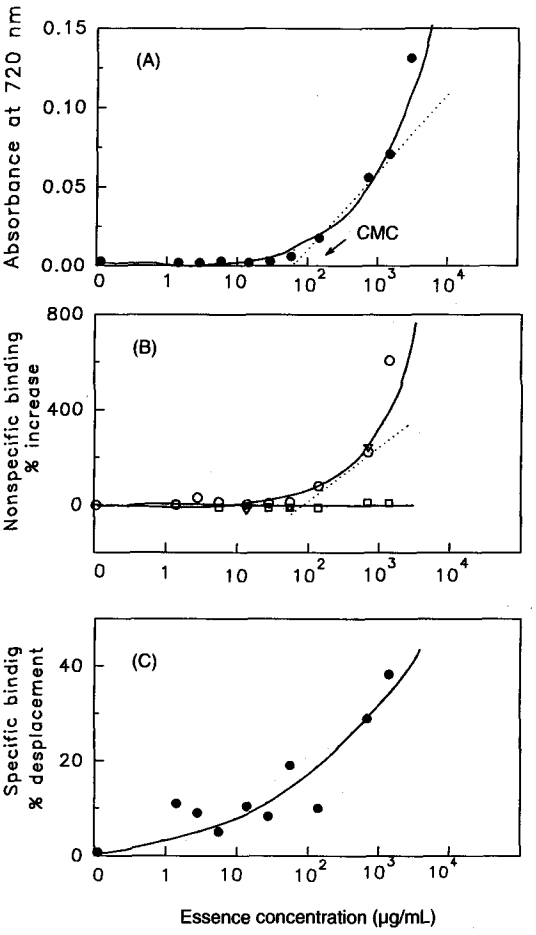

FIG. 1. Effect of *Tagetes minuta* L. essential oil concentration on the self-aggregation of its components and on the specific and nonspecific interaction of [^{3}H]flunitrazepam (FNTZ) with chick brain membranes. (A) Variation of thymol blue absorbance at 720 nm, CMC, critical micellar concentration; (B) ○, nonspecific binding of [^{3}H]FNTZ (2 nM) to chick brain membranes (the displacement agent was 10 μM diazepam); ▽, mixture of essential oil plus 2 nM [^{3}H]FNTZ filtrated through glass filters which had previously retained the same membrane suspension used in the nonspecific test tubes; □, mixtures of essential oil plus 2 nM [^{3}H]FNTZ filtered through membrane-free glass filters. (C) displacement percentages of [^{3}H]FNTZ (2 nM final concentration) specific binding with respect to the control without essence. Values are the mean ± SEM of triplicate determination; the values in (C) come from four experiments, each one in triplicate.

The specific binding of [^{3}H]FNTZ decreased as a function of the essence concentration (Table 2, Fig. 1c), and, contrary to what happened with the A_{720} of thymol blue and the nonspecific binding of [^{3}H]FNTZ, it did not show the discontinuous behavior typical of a phase transition process. In fact, the specific binding decreased continuously, starting from the lowest concentration tested (Fig. 1c).

The presence of self-aggregated structures might decrease the ligand effective concentration in the aqueous phase; consequently, this would induce an artificial decrement of the

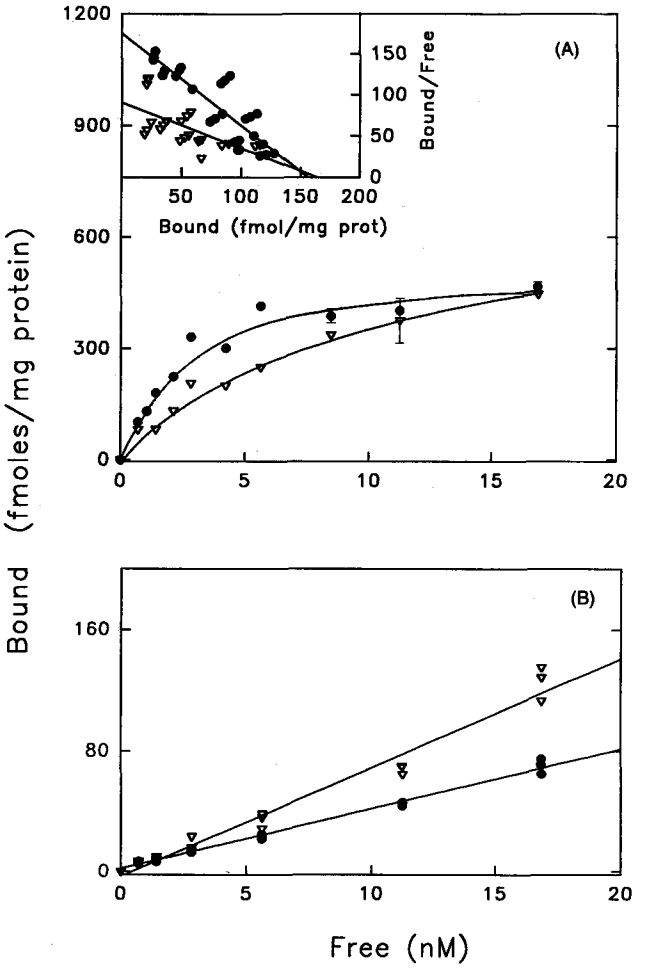

FIG. 2. Binding of [^{3}H]FNTZ to chick brain membranes as a function of [^{3}H]FNTZ concentration. (A) Saturation curves of the specific binding (total binding minus nonspecific binding) of [^{3}H]FNTZ; Inset: Scatchard plots of the saturation curves; (B) nonspecific binding of [^{3}H]FNTZ as a function of total [^{3}H]FNTZ concentration in the absence (●) or in the presence (▽) of 29 µg of essential oil from *Tagetes minuta* L. per mL of incubation system. Nonlabelled diazepam, 10 µM, was used in the nonspecific test tubes as the displacement agent. Points are the mean of three determinations; error bars represent the SEM values. Abbreviation as in Figure 1.

ligand specific binding that could be erroneously interpreted as true inhibition of the bindings This decrease in the specific binding, which would be higher at low ligand concentrations, could be overcome at higher ligand concentrations and might be misinterpreted as a competitive inhibition. However, this mechanism can only explain the decrement in specific binding observed over the essence CMC, but not the one observed below this concentration value.

From the regression analysis of the saturation curves shown in Figure 2a, it was found that, in the presence of 29 µg/mL of the essential oil, the affinity of the ligand binding decreased while the maximal binding remained constant, compared with the values obtained with control samples without essence. Because the essential oil concentration used in this experiment was well below the essence CMC value, the phenomenon of ligand trapping could not take place in the system. Therefore, that decrease in K_d cannot be ascribed to a mere artificial decrement in the free ligand concentration; on the contrary, it can be considered either a displacement of ligand from the receptor site at the membrane or an allosteric effect leading to a decrement of ligand-binding affinity.

If a competitive inhibitory mechanism takes place, the best candidates for the competitive agent may be found among the aldehydes and ketones because these were the essence components that were more concentrated in the aqueous phase (Table 1). In addition, these would probably be the molecules more capable of leaving any self-aggregated structure, establishing multiple chemical equilibria micelle ↔ water ↔ membrane, well displaced toward the right. On the other hand, the putative inhibitory agent(s) did not discriminate among the different BZD-receptor subtypes, as the Hill coefficient was not different from the unity in the presence of the essential oil (16,18). However, although not made evident by the saturation curve shape, an allosteric effect cannot be discarded, as the antagonistic effects on the $GABA_A$ receptor complex exerted by terpenoid epoxides have already been proven (4).

Much experimental evidence pointed out that changes in the membrane lipid microenvironment (19,20,21) play an important role in regulating ligand binding to BZD receptors. For that reason, oil-induced modifications in the general membrane properties that can cause a conformational change in one or more protomers of the $GABA_A$ complex and lead to a decrement in the affinity of the BZD receptor for FNTZ should also be considered.

The ability of oil's self-aggregated structures to interact with membranes has been demonstrated in this paper by the increment, as a function of oil concentration, of the radioactivity retained upon the filtration of [^{3}H]FNTZ–oil mixtures through membrane-coated filters only after an oil concentration threshold in the mixture (equivalent to oil's CMC) had been passed over (Fig. 1b). Moreover, the increment in [^{3}H]FNTZ nonspecific binding in the presence of essence concentrations lower than its CMC (nonassociated), with respect to essence-free samples, suggested the possibility that oil components could have partitioned into the lipid bilayer, increasing membrane fluidity. This conclusion is supported by the results we obtained with artificial membranes; we showed that the partitioning of FNTZ into the membrane from the aqueous media is favored by a lipid phase transition from a highly organized structure, the gel phase, to a less organized arrangement, the liquid crystalline phase (Perillo, M.A., and García, D.A., unpublished data).

An enhancement of [^{3}H]DZ binding by nonsaturated fatty acids was observed *in vitro* in membranes of most animal species, although an inhibition was shown in some fish species (21); it was claimed that this effect would not be merely a change in membrane fluidity. However, no comments had been made in relation to the behavior of nonspecific binding, and/or about the possible relationship among the effects observed and the self-aggregating properties of the

perturbing agents that (as shown here) may induce artificial effects in some conditions. For that reason, we believe that the approach used in the present paper may give new insights into the way some binding phenomena should he analyzed.

In conclusion, the essential oil from *T. minuta* can interact with biological membranes as demonstrated by its ability to perturb both [^{3}H]FNTZ specific binding (decrement in K_d at a concentration lower than oil's CMC) and [^{3}H]FNTZ non-specific binding (increment in [^{3}H]FNTZ partitioning at oil's concentration below CMC and, above oil's CMC, increment of the adsorption to the membrane of [^{3}H]FNTZ-containing oil's self-aggregated structures). Thus, essential oil-induced changes in membrane dynamics may explain oil's biological effects on fungus. The inhibitory effects demonstrated *"in vitro"* had a pharmacological correlate *"in vivo,"* as the oil exerted anxiogenic actions on rats (Martijena, I.D., García, D.A., Marín, R.H., Zygadlo, J.A., Molina, V.A., and Perillo, M.A., unpublished data). Experiments to investigate *in vitro* and *in vivo* effects of the individual major components of this essential oil are being carried out in order for their activities to be compared with that of the whole essence. Additivity, synergism, or antagonism among the activities of the different components could be demonstrated if the mixture equals, is more, or is less active, respectively, than either pure compound.

ABSTRACT: A study was performed to explore the effects of supplemental intake of various marine oils known to be part of the Eskimo diet. Healthy men and women (134) were randomly selected to consume 15 mL/d of oil from blubber of seal, cod liver, seal/cod liver, blubber of Minke whale, or no oil for ten weeks. Total cholesterol was unchanged in the oil groups, whereas high density lipoprotein cholesterol increased 7% in the seal/cod liver oil (CLO) group ($P < 0.05$) and 11% in the whale oil group ($P < 0.005$). Triacylglycerol was significantly reduced in the CLO group only. The concentration of prothrombin fragment 1 + 2 was reduced 25% ($P < 0.05$) after whale oil supplementation. No change in fibrinogen or factor VIIc was detected. Tumor necrosis factor generation in lipopolysaccharide (LPS)-stimulated blood was 30% reduced after whale oil ($P < 0.05$), but was unaffected by intake of seal or CLO. The LPS-induced tissue factor activity in monocytes was reduced to a significant degree only in the seal/CLO group (34%) and whale oil group (35%) ($P < 0.05$). The most dramatic change in thromboxane B_2 in LPS-stimulated blood was seen after whale oil intake with 44% reduction ($P < 0.01$). Supplementation of a regular diet with a combination of seal oil and CLO and especially with whale oil seems to have beneficial effects on several products thought to be associated with cardiovascular and thrombotic diseases.

Lipids 30, 1111–1118 (1995).

In 1978 Dyerberg *et al.* (1) suggested that the high content of n-3 polyunsaturated fatty acids present in the traditional Greenland Eskimo diet offers protection against atherosclerosis and thrombosis. This inspired a number of scientists throughout the world to carry out epidemiological studies on the importance of dietary intake of fish and fish oil and to explore the effects of n-3 polyunsaturated fatty acids (PUFA) on various important biological systems.

*To whom correspondence should be addressed.

Abbreviations: CLO, cod liver oil; CV, coefficient of variation; DHA, docosahexaenoic acid; EPA, eicosapentaenoic acid; FVIIc, factor VII coagulant activity; F1 + 2, prothrombin fragment 1 + 2; HDL, high density lipoprotein; LPS, lipopolysaccharide; PAF, platelet activating factor; PDGF, platelet derived growth factor; PUFA, polyunsaturated fatty acids; TF, tissue factor; TG, triacylglycerol; TNF, tumor necrosis factor; TxA, thromboxane A; TxB, thromboxane B.

Although several recent studies have shown that a large intake of n-3 fatty acids is beneficial with regard to lowering blood pressure (2), reducing triacylglycerols (3), and modulation of cell function and cell reactivity to external stimuli (4–7), the final conclusion depends on more controlled studies (8). One of the reasons for this is that when epidemiological data relating fish consumption to cardiovascular disease were corrected for covariants, the results were controversial (9,10). The putative role of n-3 fatty acids from fish oil on the development of coronary heart disease has been questioned (11).

Although the low death rate from coronary heart disease among the Eskimos of Greenland has been suggested to stem in large part from their consumption of fish, one should keep in mind that the daily diet of Eskimos living in the traditional way consists of substantial quantities of meat and fat (blubber) from seals and whales (12). The fat composition of seals and especially whales differs significantly from that of fish. (13). Hence, one may ask whether oil from these animals may be better candidates than fish oil in explaining the apparent protective effect of the Greenland Eskimo diet. So far no controlled studies pertinent to any effects of these oils have been performed.

In this study we have raised the question as to whether seal and whale oils are more effective than cod liver oil (CLO) in changing biological parameters that might be important in explaining low incidence of coronary heart disease, asthma, and psoriasis among Greenland Eskimos (14). In order to address this question, we have measured some related parameters that are probably associated with, or mediators of, inflammatory reactions, atherogenesis, and thrombus formation before and after ten weeks of daily dietary supplemention with oils from fish, seal, and whale. In addition to determining serum lipids, fatty acid, total cholesterol, high density lipoprotein (HDL) cholesterol, and triacylglycerol (TG) levels, we measured the coagulation factors fibrinogen and factor VII, both of which have been proposed to be risk factors in ischemic heart disease (15,16).

It has been established that monocytes play a central role in atherosclerosis through their adhesion to a damaged endothelium, thus inducing and sustaining atherosclerosis. In

the present study, the reactivity of monocytes in blood was examined by measuring lipopolysaccharide (LPS)-induced tumor necrosis factor (TNF)-α production and LPS-induced tissue factor (TF) activity in monocytes of whole blood *in vitro*. This test system is used since we have seen that LPS stimulation of whole blood is a sensitive way to measure the ability of cells to be activated under physiological conditions. Thus the cellular responsiveness to LPS is quite constant over time but varies considerably between individuals (17,18). The response of blood cells to LPS *in vitro* correlates well with the activation during physical exercise (19).

Thromboxane A_2 (TxA_2), which induces platelet aggregation and vasoconstriction, is a major metabolite of activated platelets. Its pathophysiological importance is essentially still unknown, although inhibitors of the synthesis of TxA_2 decreased cholesterol-induced atherosclerotic foam lesions in rabbits (20). In the present study, thromboxane B (TxB_2), the stable metabolite of TxA_2, was measured in LPS-stimulated blood.

MATERIALS AND METHODS

One hundred and thirty-four healthy Norwegians living in Tromsø (72 men and 62 women), median age 29 years and range 18–60, gave informed consent to supplement their usual diet with daily consumption of marine oils known to be part of the Greenland Eskimo diet. They were randomly selected to consume 15 mL/d of Harp seal blubber oil (n = 27), CLO (n = 26), oil from blubber of Minke whale (n = 26), seal blubber oil/CLO (n = 27), and no oil (controls, n = 28) for ten weeks. The seal oil/CLO was a 1:1 volume mixture of these two oils. The blubber of whale was obtained from the animals hunted for research purposes in Norway in 1992 which was approved by the International Whaling Commission (Histon Cambridge, United Kingdom). The groups were all run in parallel. The various groups consisted of 16 men and 12 women (median age 26 and range 18–56 in control group); 16 men and 11 women (median age 29 and range 21–60) in seal oil group; 13 men and 13 women in CLO group (median age 28 and range 19–54); 13 men and 14 women in seal/CLO group (median age 34 and range 21–57); and 14 men and 12 women in whale oil group (median age 26 and range 21–54). There were seven smokers in the control group and seal oil group, eight smokers in the seal/CLO and whale oil groups, and six smokers in the seal oil group. The participants were told not to change their regular diet during the study. None of them had been using supplements of n-3 fatty acids for four months prior to the study. After the study was finished, they conveyed how much of the oil they had consumed. None of the subjects were taking any chronic or acute medication (including aspirin) one month before or during the study. Prior to each blood sampling, the participants were not allowed to drink alcohol or perform any strenuous physical activity for 48 h.

The fatty acid composition of the oils was determined by gas–liquid chromatography using on-column injection and flame-ionization detector detection. The participants were not told which oil they were drinking, and the code was opened after completing analysis of the samples. The procedures followed were in accord with the Helsinki Declaration of 1975 as revised in 1983.

Twenty-five milliliters of venous blood was withdrawn from fasting subjects between 8:00 a.m. and 10:00 a.m. on three different days before the start of supplementation and ten weeks after. The blood samples in the syringe were immediately portioned into the following tubes: a 5-mL polycarbonate tube containing 10 U heparin/mL blood, tubes containing either 3.2% sodium citrate or 2% Na_2EDTA in a 9:1 blood/anticoagulant ratio, and serum glass tubes.

Citrated blood was centrifuged immediately at $1200 \times g$, plasma pipetted off, and stored at −80°C. EDTA blood was analyzed within two hours in a Coulter Counter (Luton, England), STKR for blood cell counts. Serum tubes were incubated at room temperature for two hours, centrifuged at $1200 \times g$ for 10 min and the resultant sera stored at −80°C. The samples were assayed in a bulk, i.e., samples from one individual were assayed in one series.

Stimulation of whole blood in vitro. Heparinized blood was divided into 1-mL aliquots in polycarbonate tubes and LPS (LPS, 026:B6; Difco, Detroit, MI) added to a final concentration of 5 ng/mL blood followed by incubation at 37°C in an incubator shaker (200 rpm) for 2 h. The LPS stimulation was stopped by adding 0.1 mL 2% Na_2EDTA per mL blood. Part of the LPS-stimulated blood was immediately centrifuged at $1200 \times g$ for 10 min, and the resultant plasma pipetted off and frozen in aliquots at −80°C for later quantitation of TNF-α and TxB_2. Another part of the stimulated blood was subjected to isolation of mononuclear cells on Lymphoprep (Nycomed, Oslo, Norway) as described earlier (21). The mononuclear cells were resuspended in 0.15 M NaCl and frozen at −80°C until testing for LPS induced TF activity in monocytes.

Determination of TNF-α. TNF-α produced and secreted in LPS-stimulated blood was measured using a commercially available DuPont Human tumor necrosis factor-alpha ELISA kit (DuPont, NEN Research Products, Boston, MA). In the range we used this assay, its intra-assay coefficient of variation (CV) was 2.3%.

Quantitation of TF activity. TF activity was measured in frozen and thawed monocyte-samples in a two-stage clotting assay based on the ability of TF to accelerate the activation of factor X by factor VIIa as described (22). The activities measured in the samples were expressed in milliunits of crude extract of TF prepared from human brain. A 1:5000 dilution of this standard gave a clotting time of 25 s in the assay system. The samples were diluted 100- to 500-fold just before testing. Platelets and lymphocytes did not affect the clotting time of this assay.

TxB_2 determination. TxB_2, the stable product of TxA_2, was measured in plasma of LPS-stimulated blood using a thromboxane B_2 (^3H) radioimmunoassay kit (NEN Research Products). In this method, separation of the antibody–antigen complexes from free antigen is achieved by adsorption of the free tracer onto activated charcoal. After centrifugation, the

supernatant containing the antibody–antigen complexes is decanted into a counting vial, and scintillation cocktail is added. The cross reactivity in this kit is 100% for TxB_2, whereas cross reactivities to related compounds are: PGD_2, 0.3%; PGE_2, 0.04%; PGF_2, 0.03%; 6-keto-PGF_1, <0.5%; and PGA_2, <0.05%.

Coagulation factors. Prothrombin fragment 1 + 2 (F1 + 2) was measured in citrated plasma using the Enzygnost F1 + 2 ELISA kit from Behring (Behringwerke AG, Marburg, Germany) according to the manufacturer's instructions. The test system has a lower detection limit of 0.02 nmol/l F1 + 2. In the range 0.12 to 6.7 nmol/L, the CV in the series (intra-assay CV) was found to be 6 to 9%. The reproducibility of F1 + 2 measurements in plasma was 88 to 110% according to the manufacturer.

Factor VII coagulant activity (FVIIc) was measured in a one-stage clotting assay utilizing factor VII-deficient plasma and a human brain thromboplastin reagent (23). Fibrinogen was quantitated according to the method described by Inada *et al.* (24).

Lipids in serum. Serum samples were analyzed for TG, cholesterol, and HDL-cholesterol using commercially available enzyme-kits from Boehringer (Mannheim, Germany), in combination with an RA-1000 automatic analyzer (Technion RA-1000; Bayer Norway, Hagan, Norway).

Fatty acids in serum. The fatty acids were extracted from serum by the method of Folch and co-workers (25) and analyzed by gas–liquid chromatography using on-column injection and flame-ionization detector detection.

Statistical analysis. Data are reported as mean ± standard error of mean. All the statistical data presented for serum lipids, fibrinogen, FVIIc, prothrombin F1 + 2, TNF-α, TF, and TxB_2 was analysed by using a two-way repeated measures analysis of variance. Statistical analysis of differences between the control and the various groups in fatty acid composition of serum after ten weeks' supplementation with marine oils were performed with Dunnett's *t*-test. A *P*-value less than 0.05 was considered significant.

RESULTS

Fatty acid composition of the marine oils and of serum from the volunteers after ten weeks' supplementation with various marine oils. Part of the fatty acid composition of the marine oils is given in Table 1. This table shows that fatty acid composition of Harp seal oil and CLO is relatively similar, whereas Minke whale oil contains less PUFA and a little more monounsaturated fatty acids than the two other oils.

Compared with the control group, there were small differences in the saturated fatty acids of serum after ten weeks' intake of oils in the various groups (Table 2). Relatively small differences also were seen in the monounsaturated fatty acids although the level of 20:1 was significantly higher in all groups compared to the control group except the seal oil group, whereas the 24:1 was significantly higher in all four groups. Noteworthy is the lower level of 18:1 which was only significant in the CLO and CLO/seal oil groups. Among the PUFA, there was a significantly lower level of 18:2 in the seal oil and CLO groups as compared to the control group. As expected from the fatty acid profile in the various oils, the difference from the control group was highest in 20:5 and 22:6. Thus, 20:5 was 223, 262, 295, and 126% higher, respectively, in the seal oil, CLO, seal/CLO, and whale oil groups, whereas a similar, although smaller, difference of 22:6 was found (71, 83, 102, and 41% in the same order). There was a trend (not significant) of higher 20:5 and 22:6 in the combined seal/CLO group than in the groups with either seal oil or CLO alone.

Serum lipids. Total cholesterol levels were not significantly altered in any of the groups after ten weeks' supplemental intake of marine oils (Table 3), whereas HDL-cholesterol increased 7% in the seal/CLO group ($P < 0.05$) and 11% in the whale oil group ($P < 0.005$). TG were significantly reduced (23%) in the CLO group only ($P < 0.05$).

Fibrinogen and FVIIc. Large-scale epidemiological studies have indicated that the plasma content of fibrinogen and FVIIc are powerful risk factors for ischemic cardiovascular disease (15,16). In the present study we found no effect on FVIIc levels or fibrinogen in any of the oil groups (Table 4).

[a]Statistical differences (Dunnett's *t*-test) between the control group and the various marine oil groups are indicated; CLO, cod liver oil.
[b]$P < 0.05$.

F1 + 2 in plasma. F1 + 2 is an activation peptide released after proteolysis of prothrombin by factor Xa (26). The occurrence of F1 + 2 in plasma has been shown to serve as a useful indication of coagulation activation *in vivo*. The results depicted in Table 4 show that the level of F1 + 2 was significantly reduced in the whale oil group (from 0.99 ± 0.08 to 0.74 ± 0.04, $P < 0.05$). No significant changes were observed in any of the other groups.

Generation of TNF-α and TF activity in monocytes of LPS-stimulated blood. Stimulation of whole blood with a low concentration of LPS (5 ng/mL) has been used as a method to test the reactivity of cells and platelets in blood. Measurements of TNF-α in plasma obtained from blood incubated for 2 h with LPS, before and after ten weeks of the different diet supplements, revealed a significantly reduced level in the whale oil group (Fig. 1). Thus, the TNF-α level was about 30% lower after the oil intake was started than before (from 2.3 ± 0.3 to 1.6 ± 0.2 ng/mL, $P < 0.05$). Although there also was a 17% reduction in TNF-α in the seal/CLO group, this was not statistically significant since there also was a 12% reduction in the control group.

The LPS-induced TF activity in monocytes of whole blood was significantly reduced in all groups, including the control group (Fig. 2), but to a different degree. Thus, the highest reduction in LPS-induced TF activity was found in the monocytes of the subjects in the seal/CLO group and the whale oil group, i.e., 34.4 and 34.9%, respectively ($P < 0.05$). The reduction in the seal oil group (11.5%) and CLO group (12.6%) was similar to that of the control group (14.2%).

Generation of TxB_2 in LPS-stimulated blood. LPS-stimulated blood generates TxB_2 mainly from the platelets (27). This product, appearing in LPS-stimulated blood, was reduced in all four groups after ten weeks of oil supplementation (Fig. 3). The reduction in TxB_2 production in the seal oil,

Serum Lipids Before and After Ten Weeks' Supplementation with Marine Oils (mean value ± SEM)[a]

	TG (mmol/L)		Tot-Chol (mmol/L)		HDL-Chol (mmol/L)	
	Before	After	Before	After	Before	After
Control (n = 28)	1.18 ± 0.12	1.20 ± 0.08	4.94 ± 0.23	4.75 ± 0.23	1.36 ± 0.09	1.36 ± 0.09
Seal (n = 27)	1.20 ± 0.10	1.06 ± 0.11	5.18 ± 0.22	5.04 ± 0.23	1.31 ± 0.04	1.37 ± 0.04
CLO (n = 26)	1.28 ± 0.16	0.98 ± 0.05[a]	5.29 ± 0.22	5.12 ± 0.22	1.25 ± 0.05	1.32 ± 0.07
Seal/CLO (n = 27)	1.29 ± 0.15	1.07 ± 0.11	5.30 ± 0.21	5.35 ± 0.21	1.36 ± 0.07	1.46 ± 0.08[a]
Whale (n = 26)	1.10 ± 0.08	1.02 ± 0.08	5.12 ± 0.21	5.18 ± 0.24	1.27 ± 0.06	1.41 ± 0.07[b]

[a]Compared to the changes in the control group, triacylglycerol (TG) was significantly reduced in the CLO group, $P < 0.05$, and HDL-Chol was significantly increased in the seal/CLO group[a] ($P < 0.05$) and whale oil group[b] ($P < 0.005$) (two-way analysis of variance). There were no significant differences between the various groups in base line values in any of the parameters. Tot-Chol = total cholesterol; HDL-Chol = high density lipoprotein-cholesterol. See Table 2 for other abbreviation.

TABLE 4
Coagulation Parameters Before and After Ten Weeks' Supplementation with Various Marine Oils (mean values ± SEM)[a]

Test parameter	Control (n = 28)		Seal oil (n = 27)		CLO (n = 26		CLO/seal oil (n = 27)		Whale oil (n = 26)	
	Before	After	Before	After	Before	After	Before	After	Before	After
FVIIc (U/mL)	1.08 ± 0.07	1.07 ± 0.07	1.23 ± 0.09	1.14 ± 0.08	1.16 ± 0.06	1.15 ± 0.10	1.21 ± 0.06	1.23 ± 0.07	1.20 ± 0.07	1.18 ± 0.06
Fibrinogen (g/L)	2.6 ± 0.1	2.4 ± 0.1	2.8 ± 0.2	2.6 ± 0.2	2.6 ± 0.1	2.4 ± 0.1	2.5 ± 0.1	2.4 ± 0.1	2.6 ± 0.1	2.3 ± 0.1
F1 + 2 (nmol/L)	0.85 ± 0.06	0.80 ± 0.05	0.85 ± 0.05	0.82 ± 0.05	0.85 ± 0.06	0.78 ± 0.06	0.85 ± 0.06	0.75 ± 0.04	0.99 ± 0.08	0.74 ± 0.04[b]

[a]FVIIc = Factor VII coagulant activity; F1 + 2 = prothrombin fragment 1 + 2; see Table 2 for other abbreviation.
[b]$P < 0.05$ (compared to the change in the control group).

CLO, seal oil/CLO, and whale oil groups was 35.8, 33.8, 28.0, and 43.7%, respectively. In the whale oil group, the TxB_2 was reduced from 16.7 ± 2.0 to 9.4 ± 1.6 ng/mL ($P < 0.01$).

DISCUSSION

The results of the present study show that supplementation of an otherwise-unrestricted diet with moderate amounts of certain oils from marine fat, known to be part of the Greenland Eskimo diet, is effective in reducing the reactivity of blood cells and reducing the activation of coagulation in a favorable nonthrombotic direction. Surprisingly, intake of seal oil or CLO alone had only a relatively small effect. In contrast, the whale blubber oil alone appears to be superior in this regard. Interestingly, seal oil and CLO in combination seemed to be more effective than either of the two oils taken separately.

Weak LPS stimulation of whole blood has been used in our laboratory for more than ten years as a model for the reactivity of blood cells (18). This whole blood system may be less sensitive to changes in diet than seen in regular cell cultures, as we failed to find any significant change in LPS-induced TF and TNF-α after eight weeks' supplementation with 4 g/d of eicosapentaenoic acid (EPA) + docosahexaenoic acid (DHA) (Østerud, B., unpublished data). However, we believe that this *ex vivo* system is more relevant to *in vivo* conditions than artificial cell culture systems in studying changes in blood cells as a consequence of marine oil supplementation in the diet.

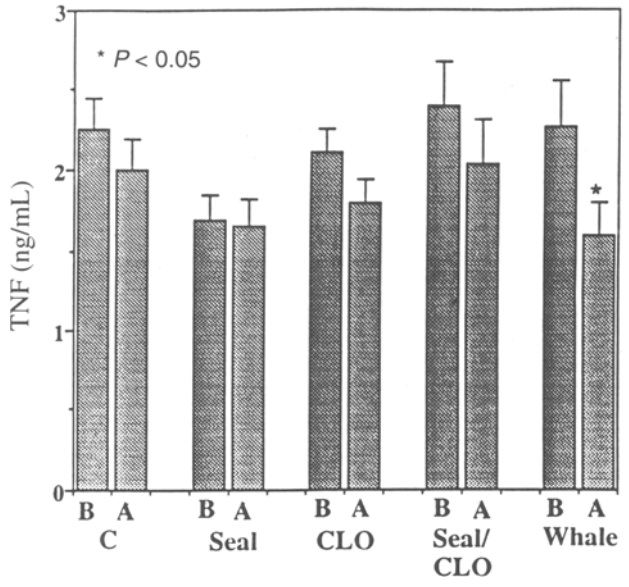

FIG. 1. Generation of tumor necrosis factor-α (TNF-α) by monocytes in lipopolysaccharide-stimulated whole blood before and after ten weeks' daily supplement with various marine oils. Values are means ± SEM. Compared to the change in the control group (C), only the change in TNF-α of the whale oil group was statistically significant ($P < 0.05$) (two-way analysis of variance). The TNF-α in the seal oil group was significantly lower in baseline than in all other groups. CLO = cod liver oil, B = before, A = after marine oil supplementation (n = 28 in control group, 27 in seal oil group, 26 in CLO group, 27 in seal/CLO group, and 26 in whale oil group).

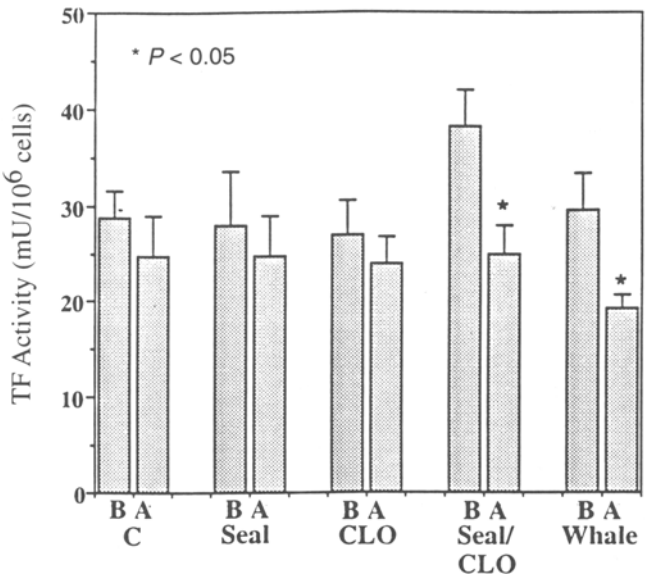

FIG. 2. Formation of tissue factor (TF) activity in monocytes in lipopolysaccharide-stimulated whole blood before and after ten weeks' daily supplement with various marine oils. Values are means ± SEM. Compared to the change of TF activity in the control group (C), the TF activity was significantly reduced in the seal/cod liver oil (CLO) group and the whale oil group (two-way analysis of variance). There was no significant difference in baseline values of the different groups (n = 28 in control group, 27 in seal oil group, 26 in CLO group, 27 in seal/CLO group, and 26 in whale oil group).

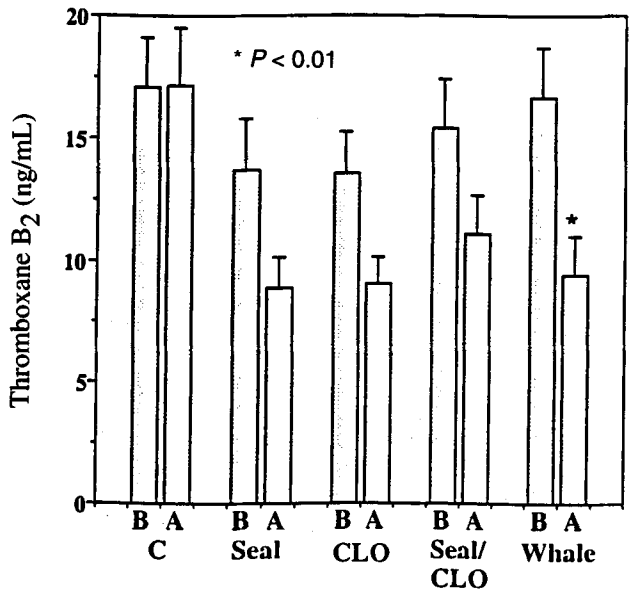

FIG. 3. Production of thromboxane B_2 (TxB_2) in lipopolysaccharide-stimulated whole blood before and after ten weeks' daily supplement with various marine oils. Values are means ± SEM. Compared to the control group (C), TxB_2 was significantly reduced only in the whale oil group (two-way analysis of variance). There was no significant difference in base line values between the different groups [n = 28 in control group, 27 in seal oil group, 26 on cod liver oil (CLO) group, and 27 in whale oil group].

The present study shows that supplementation of a regular diet with moderate amounts of whale oil reduced LPS-induced TNF-α and TF activity production in monocytes 30–40% on average, and TxB_2 production by about 44%. The smaller effect obtained by intake of seal oil or CLO alone (no significant change in TNF-α and TF activity vs. 30–35% reduction in TxB_2) may suggest that these oils lack factor(s) present in whale oil. Although the baseline values of TF are much higher in the seal/CLO group than in the other groups, the seal oil/CLO effect was also high in the subjects with low baseline TF activities. The large difference in baseline values of TF activity is caused by the great variation between individuals in responding to a low dose of LPS. Thus, a high responder will always have high values, whereas a low responder will have low values (18). TNF-α is believed to play a critical role as an early response cytokine in cellular activation and the propagation of the inflammatory response [for review, see Strieter *et al.* (28)]. Atherosclerosis is today suggested to reflect a defense system gone awry (29), and TNF-α may thereby be associated with the atherosclerotic process. Furthermore, tissue factor is the most potent trigger of blood coagulation, and its localization in macrophages in atherosclerotic plaques probably accounts for the instant thrombus formation following plaque rupture. Thus, downregulation of both TNF-α and TF production in monocytes/macrophages may be quite beneficial in the prevention of thrombosis and atherosclerosis. In this context, it is of interest finding that women produce 39% less TNF-α than men using the same whole blood test system (30) and that estrogen replacement for a year in postmenopausal women caused a 35% reduction in LPS-induced TNF-α (31).

A reduction in cellular activation products has been documented after dietary supplementation with relatively large amounts of PUFA, of which the n-3 fatty acids, EPA and DHA, have been suggested to be of crucial significance (4,5). The antiatherogenic effects of n-3 fatty acids have been suggested to be multifunctional (32). As seen in Table 1, the most striking difference between the fatty acid compositions of seal oil, CLO, and whale oil is that the content of n-3 fatty acids in the whale oil is only approximately 60–65% of that of seal oil and CLO. The amount of EPA (20:5n-3) in the whale oil is less than half of the amount found in CLO. In addition, there is approximately 55% monounsaturated fatty acids in the whale oil, which is 10% more than that of CLO and seal oil. It is therefore questionable whether the n-3 fatty acids alone in the whale oil can be responsible for the apparent beneficial effect of this oil.

The effect of different marine oils on the TG level in serum is quite noteworthy, since CLO appeared to be the only oil that caused a significant reduction. The reduction of TG by the CLO corresponds relatively well with the content of n-3 fatty acids in this oil and dose responses reported in the literature (33). The question arises as to why seal oil does not produce such an effect, since its fatty acid composition is very similar to that of CLO (Table 1). Since reduction in TG also has been documented using relatively pure EPA as a dietary supplement, it has been assumed that this fatty acid is the main component in CLO causing the reduction in TG (34). Based on the content of EPA in CLO, seal oil, and whale oil, one should have expected the reduction of TG in the seal oil group to be about 17% (instead of 12%) and about 11% (instead of 7%) in the whale oil group. This discrepancy in response is probably attributed to the localization of EPA in the TG molecule. Whereas EPA is mainly found in the 1- and 3-positions of seal oil TG, it is equally distributed in positions 2 and 3 in CLO (35). Thus EPA is about five times more likely to be found in position 2 of the TG in CLO as compared to those of seal oil.

The n-3 fatty acids may have low or no effect as cholesterol-lowering modulators (33). None of the oils used in our study appeared to have any effect on the total cholesterol concentration in serum. However, whale oil and the seal/CLO combination caused a small but significant increase in HDL-cholesterol. This observation may be relevant to the finding by Dyerberg *et al.* (36) that levels of low density lipoprotein-cholesterol were significantly lower and that levels of HDL-cholesterol were higher among Eskimos than among Danes.

Our data may indicate a reduction in the ongoing *in vivo* activation of blood coagulation, as judged by F1 + 2 levels in plasma, after marine oil supplementation. Interestingly, such an effect was not observed using either CLO, seal oil, or seal oil/CLO, but it was significant following the intake of whale oil (25% reduction). Since the F1 + 2 level reflects proteolysis of prothrombin by factor Xa, one may speculate that less factor Xa is generated after whale oil supplementation due to

reduced TF available for the interaction with factor VII. It also could reflect impaired prothrombinase complex formation due to reduced activation of the platelets *in vivo*.

FVII and fibrinogen have been claimed to be powerful risk factors for ischaemic cardiovascular diseases. In our study we did not observe any significant change in FVIIc and fibrinogen in plasma after any of the oil supplements. In the great majority of trials, plasma fibrinogen levels are not significantly affected by dietary fish oil, but in a couple of studies intake of fish oil concentrates resulted in a significant reduction of the plasma fibrinogen level (for review, see Ref. 37).

In conclusion, daily dietary supplementation with whale oil alone or seal/CLO in combination appeared to have the most pronounced effects on some selected biological parameters thought to play a role in cardiovascular disease. Although we did not perform any analysis of diet or dietary effect of supplementation, we are quite confident that the changes observed in our test model are caused by the oil supplementation. Pilot studies and an extensive experience with single individuals on various marine oils have all given results in accordance with the present study.

The difference in the effects of whale and seal oils argues against the position in TG as being of relevance to the superiority of whale oil, since the n-3 fatty acids are mainly in the 1- and 3-position of both these oils. However, the difference in effects of CLO and seal oil as compared to the beneficial effects by these oils in combination may indicate two things: (i) there are two (or more) essential factors needed and that whale oil contains both, but seal and fish oils contain one of each, or (ii) the beneficial component(s) of whale oil is unrelated to the beneficial components of CLO/seal oil in combination. The effect of whale oil is probably not mediated by n-3 fatty acids alone (or at all) as the content of these fatty acids is relatively low in whale oil and corresponds to an intake of only 1.8 g n-3 fatty acids per day. Our study may strongly indicate that in addition to n-3 fatty acids, there may be another component present in the Greenland Eskimo diet that might explain its apparent protective effect against atherosclerosis and thrombosis. As this is the first controlled study to survey a number of parameters potentially influenced by components of the Eskimo diet, we realize that more studies are required to clarify the role of oils from marine blubbers as a beneficial supplement to the diet in the prevention of coronary heart disease and thrombosis. Such studies are already in progress in our laboratory.

[a]Institute of Biochemistry, Biological Research Centre, Hungarian Academy of Sciences, H-6701 Szeged, Hungary, [b]Department of Preventive Medicine & Biometrics, School of Medicine, University of Colorado Health Sciences Centre, Denver, Colorado 80262, [c]Bay Zoltán Institute for Applied Research, Szeged, Hungary, [d]Department of Pathology & Cell Biology, Jefferson Medical College, Philadelphia, Pennsylvania 19107

ABSTRACT: Phospholipids from livers of carps (*Cyprinus carpio* L.) adapted to winter (5°C) and summer (25°C) temperatures were isolated, and the fatty acid composition of total phospholipids, as well as molecular species composition of diacyl phosphatidylcholines and ethanolamines, were determined. Order parameter of 5-doxyl stearic acid and steady-state fluorescence anisotropy of different anthroyloxy fatty acids—[2-,12(*N*-9-anthroyloxy)stearic acid and 16(*N*-9-anthroyloxy)palmitic acid—embedded in native and synthetic (16:0/16:0, 16:0/22:6, 18:0/22:6, 18:1/22:6, 20:4/20:4, 22:6/22:6 phosphatidylcholines and 16:0/18:1, 18:1/22:6 phosphatidylethanolamines) phospholipid vesicles was also determined between −30 and 30°C and 5 and 30°C, respectively. There is an accumulation of 1-monoenoic, 2-polyenoic diacyl phosphatidylcholine and ethanolamine with a concomitant reduction of 1-stearoyl,2-docosahexaenoyl species in the cold-adapted state. Despite a 30% accumulation of long-chain polyunsaturated fatty acids in phospholipids in cold, there is only a 5°C downshift in the solid-gel to liquid-crystalline phase transition temperature (−8 vs. −13°C). Vesicles from total phospholipids of cold-adapted fish proved to be more disordered in all segments than from the warm-adapted ones when assayed using 2,12-(*N*-9-anthroyloxy)stearic and 16-(*N*-9-anthroyloxy)palmitic acid. Vesicles made from purified phosphatidylcholines showed the same pattern, but they were more disordered than the corresponding total phospholipids. This could be modelled using mixed phospholipid vesicles made of synthetic 16:0/22:6 phosphatidylcholine (75%) and either 18:1/22:6 phosphatidylethanolamine (25%) vs. 16:0/18:1 phosphatidylethanolamine (25%) and comparison of the anisotropy parameters of 100% 16:0/22:6 and 100% 18:1/22:6 phosphatidylcholine vesicles. Mixing either 16:0/18:1 (25%) or 18:1/22:6 (25%) phosphatidylethanolamines to 18:0/22:6 (75%) phosphatidylcholine shifted down or up, respectively, the transition temperature of vesicles compared to 100% 18:0/22:6 vesicles assayed by electron spin resonance spectroscopy using 5-doxylstearic acid. It is concluded that it is not the gross amount of long-chain polyunsaturated fatty acids in phospholipids, but rather their specific combination with *cis* Δ9 monounsaturated fatty acids in the position *sn*-1, especially in phosphatidylethanolamines, that is important in determining the physical properties of biomembranes in relation to adaptational temperature.

Lipids 30, 1119–1126 (1995).

Temperature is one of the most important environmental factors affecting the physiological activity of poikilotherms, such as fish. The first targets of temperature changes are the biomembranes which exist in a so-called liquid-crystalline state at body temperature (1). Thus the temperature can be regarded as a membrane perturbant to which the cell must respond to establish a new equilibrium between the environment and the physicochemical properties of their membraneous structures in order to survive under the new conditions, a process called homeoviscous adaptation (2). Membranes are assemblies of lipids and proteins (1), and the lipid components are considered to be responsible for maintaining their proper physicochemical properties. The concept of involvement of lipids in thermoregulation processes is based on the fact that the melting point of unsaturated fatty acids decreases with increases in the number of the double bonds in the molecule. Accumulation of long-chain polyunsaturated fatty acids in fish when the environmental temperature decreases has often been reported (3–5), and it has also been observed that the ratio of unsaturated to saturated fatty acids is inversely related to the temperature to which the animals are adapted. However, neither the thermotropic phase transition (6) nor the surface area (7) is a linear function of the number of double bonds present in the phospholipid molecules. In both cases, the introduction of the first double-bond results in most spectacular change in these parameters. Moreover, accumulation of long-chain polyenoic fatty acids is not necessarily linked to reduced temperatures, as demonstrated recently for marine and freshwater fish or shrimp evolutionarily

adapted to the two temperature extremes (8,9). Furthermore, comparison of the order parameter of 5-doxylstearic acid (5-SASL) revealed only negligible differences between liver phospholipids of fish inhabiting either cold or warm seas for millions of years (6), suggesting that gross lipid unsaturation plays only a subordinate role in determining the overall fluidity of these structures, whereas characteristic differences were revealed in the structural organization of the bilayer (8–10). In this article, the composition and physical properties of phospholipids obtained from the livers of a freshwater fish (*Cyprinus carpio*), seasonally adapted to the two temperature extremes, is investigated. Hopefully the information obtained will contribute to a better understanding of the role that lipid components play in controlling membrane physical state and architecture in thermal adaptational processes.

MATERIALS AND METHODS

Animals. Fish (*Cyprinus carpio* L.), weighing 0.7–1.0 kg, were obtained from a local fish farm. The summer-adapted (SA) fish were collected at the end of the summer of 1993, when the water temperature was above 23°C for more than two months; and the winter-adapted (WA) fish were collected at the end of the winter of 1994 shortly after thawing. Livers of ten freshly killed animals were pooled for the analyses.

Extraction and analyses of lipids. Lipids were extracted according to Folch *et al.* (11). Phospholipids were separated by column chromatography on silicic acid, using chloroform to elute the neutral lipids and methanol to elute the polar lipids. Polar lipids were further separated into different subclasses by thin-layer chromatography on precoated silica gel plates (E. Merck, Darmstadt, Germany) according to Fine and Sprecher (12). Phosphatidylcholine(s) (PC) and phosphatidylethanolamine(s) (PE), after visualization by spraying with 0.5% 8-anilino-1-naphthalene sulfonic acid in 50% methanol, were eluted with chloroform/methanol (2:1, vol/vol) and stored in benzene containing 0.01% butylated hydroxytoluene at –20°C until further processing.

Fatty acid composition of total and individual phospholipids were determined using a Hitachi (Tokyo, Japan) Model 260-80 gas chromatograph equipped with dual flame-ionization detector after transmethylation in absolute methanol containing 5% HCl at 80°C for 2.5 h. Fatty acids were segregated on 10% free fatty acid phrase (Supelco, Bellefonte, PA) coated onto 100–120 mesh Supelcoport (Supelco). Quantitation was made using a data processor (Hitachi 260-80) connected to the gas chromatograph.

Molecular species determination of purified PC and PE were determined according to Takamura *et al.* (13). The diradylglycerols obtained by digestion with phospholipase C (*Bacillus cereus*) were converted to benzoyl derivatives, and the dinitroyl derivatives of diacylglycerols were separated into individual molecular species by high-performance liquid chromatography using a Hypersyl C_{18} column (250 × 4 mm i.d.). Acetonitrile and 2-propanol in a ratio of 80:20 served as mobile phase. Detection took place at 254 nm, and identification was made using authentic standards and on the basis of relative elution times given by Bell and Dick (14).

Spectroscopic techniques. Fluorescence anisotropy measurements were made on 250 μg phospholipids mixed with 10 μl of 1 μmol 2-(*N*-9-anthroxyloxy)stearic acid (2-AS), 12-(*N*-9-anthroloxy)stearic acid (12-AS), and 16-(*N*-9-antholoxy)palmitic acid (16-AP) (Molecular Probes Inc., Eugene, OR). This mixture of probes was evaporated onto the surface of a suitable test tube and suspended in Tris–HCl buffer, pH 7.4, according to Sen *et al.* (15). Measurement and calculation of steady-state fluorescence anisotropy (R_{ss}) were made according to Dey *et al.* (8). The SE of the determination was always less than 0.005.

Electron spin resonance (ESR) spectroscopy. Measurements were carried out by incorporating <1 mol% of 5-SASL (Sigma, St. Louis, MO) spin label into the phospholipid vesicles. The sample containing 1 mg of phospholipid was poured into sealed glass capillary (1 mm i.d.) and adjusted within a standard ESR tube under thermal regulation. Spectra were recorded from –30°C to 30°C using an ESC-106 ESR spectrometer (Brucker, Karlsruhe, Germany) under medium microwave power (10 mW) and low magnetic field modulation (1 mT). The outer hyperfine splitting ($2A_{max}$) of the spectra was used to characterize the membrane ordering state at a given temperature (16).

Determination of change-point temperatures. The procedure of Jones and Dey (17) was used to determine the thermotropic phase transition temperature of phospholipid vesicles. First, a straight line was fit to the data by least squares. Next, a model with a single change-point at an unknown location was fit by searching over the range of the data for the position of a change-point that minimized the sum of squares of residuals. A change-point is a point where the line suddenly changes slope, but the line is continuous. The model with a single break-point is tested statistically to determine if the break-point produces significant improvement in the fit to the data. The procedure is repeated by adding break-points until no significant improvement is obtained.

Chemicals. 1-Stearoyl, 2-docosahexaenoyl-, 1-palmitoyl, 2-docosahexaenoyl, 1-oleyl, 2-palmitoleyl, 1-oleoyl, 2-docosahexaenoyl PC, 1-palmitoyl, 2-oleyl-, 1-oleyl, and 2-docosahexaenoyl PE were from Avanti Polar Lipids, Inc. (Birmingham, AL). 2-AS, 12-AS, and 16-AP were from Molecular Probes, Inc. Acetonitrile and 2-propanol (high-performance liquid chromatography-grade) were products of Carlo Erba (Milan, Italy). All other reagents were of analytical grade.

RESULTS

WA carps accumulated 25% more long-chain polyunsaturated fatty acids (20:4n-6, 22:6n-3) in their total phospholipids at the cost of saturated palmitic and stearic acids, resulting in a drastic decrease in the ratio of saturated-to-unsaturated fatty acid (Table 1). Of the polyunsaturated fatty acids, 20:4n-6 gave the most sensitive response, showing an almost 100% accumulation. However, 22:6n-6 was less responsive. Accu-

[b]Ratio of saturated-to-unsaturated fatty acids.

mulation of 20:4n-6, which was not observed in a previous study (18), might be explained by possible abundance of linoleic acid in their natural food in this particular case, and a cold-induced activation of Δ6 and Δ5 desaturases. Choline and ethanolamine phosphoglycerides gave differential response with respect of accumulation of monounsaturated fatty acid. The level of 16:1 almost doubled in the former, and 18:1 increased by 50% in the latter. Cold-induced accumulation of oleic acid in ethanolamine phosphoglycerides has been reported in several cases (8).

About 16–20 different molecular species were identified from diacyl PE and diacyl PC, respectively (Table 2). Adaptation to winter temperatures brought about a reorganization of molecular species composition of both subclasses. 16:0/22:6, 16:0/18:1, and 18:0/22:6 (amounting to 58% of the total) were the major PC species in the SA fish. In the WA state, the level of 16:0/18:1 and 18:0/22:6 species decreased by almost 50%. 16:0/22:6 did not change at all in the course of the thermal adaptation. There was also a 75% decrease in the level of 16:0/16:0 PC. These changes were compensated for by an increase in the levels of 20:4/20:4 (75%), 18:1/20:5 (85%), 18:1/22:6 (55%), and 18:1/20:4 (52%). Altogether, the levels of 1-monounsaturated, 2-polyunsaturated species rose from 12 to 19%. 16:0/20:4 also increased in the WA fish livers. This resulted in a decrease in the ratio of the total saturated/unsaturated-to-monounsaturated/polyunsaturated PC from 6.6 to 3.3 (Table 2).

A major difference between diacyl PE and cholines from the SA and WA fish is the lower proportion of 16:0/18:1 in the latter. In general, however, the trend of the changes was similar to PC, but in addition to 18:0/22:6 and 16:0/18:1, levels of 16:0/22:6 and 18:0/20:4 also decreased from a total of 63.6 to 37.7%. There was a substantial increase in the levels of 1-monounsaturated, 2-polyunsaturated species from a total of 10.2 to 28.5%, with a concomitant 75% decrease in the

ratio of total saturated/unsaturated-to-total monounsaturated/polyunsaturated species from 8.1 to 2.2. Similarly, in PC, there was an increase also in the level of 16:0/20:4.

These differences in molecular composition of the major phospholipids are reflected in physical properties of phospholipid vesicles probed using ESR spectroscopic technique. Figure 1 compares the order parameters between −30C and 30°C of the phospholipid vesicles made from cold- and warm-adapted fish livers. As seen, there is a change of slope, representing a thermotropic phase transition from solid gel to a more fluid liquid-crystalline state, around −13 and −8°C in the case of probes from WA and SA fish, respectively. Thus, a reduction of 20°C in the ambient temperature brought about a 5°C downshift in the thermotropic phase transition temperature.

In another approach, steady-state fluorescence polarization, R_{ss}, of different anthroyloxy fatty acids (2-AS, 12-AS, and 16-AP), reporting the corresponding membrane segments, was determined. Figure 2 shows that the phospholipid vesicles made from livers of WA fish exhibited lower R_{ss} values, that is, they were more "fluid" at all segments, than those from the SA fish. Equal anisotropy values were measured in the C_2 segment at 5°C for the vesicles from the WA fish and at 25°C for those from the SA fish.

In further experiments, anisotropy parameters of vesicles made from isolated PC were compared. Again, PC vesicles from WA carp proved to be less ordered than those from SA carp (Fig. 3), but they were less ordered at almost each segment than the corresponding total phospholipids.

In an attempt to understand the role of phospholipid molecular species showing changes during thermal adaptation, model experiments on vesicles from synthetic phospholipids also were carried out using ESR spectroscopy and 5-SASL. First it seemed logical to decide whether the downshift of the transition temperature and the increased disorder seen with vesicles made either from total phospholipids or PC of WA fish can be related to the observed alterations in molecular

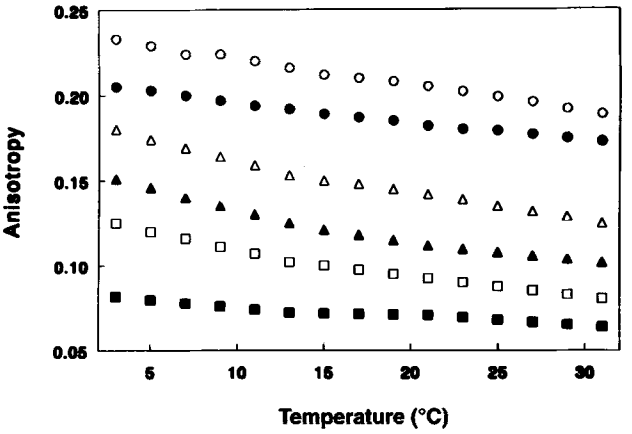

FIG. 2. Temperature dependency of fluorescence anisotropy of 2-(*N*-9-anthroloxy)stearic acid (2-AS), 12-(*N*-9-anthroyloxy)stearic acid (12-AS), and 16-(*N*-9-anthroyloxy)palmitic acid (16-AP) embedded in vesicles made from liver total phospholipids of carp adapted to summer (○, 2-AS; △, 12-AS; and □,16-AP) and winter (●, 2-AS; ▲, 12-AS; and ■,16-AP) temperatures.

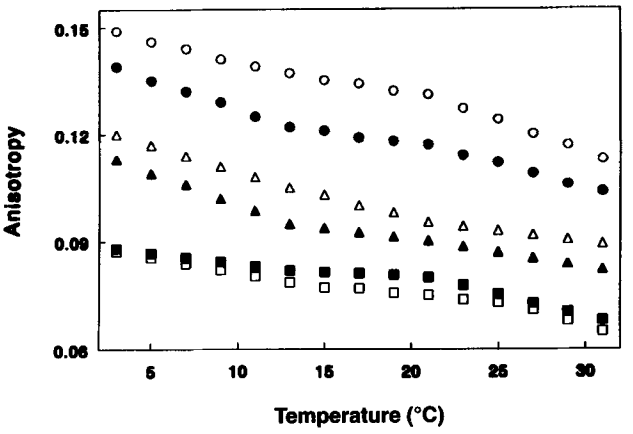

FIG. 3. Temperature dependency of fluorescence anisotropy of 2-AS, 12-AS, and 16-AP embedded in phosphatidylcholine vesicles made from livers of carp adapted to summer (●, 2-AS; ▲, 12-AS; and □, 16-AP) and winter (●, 2-AS; ▲, 12-AS; and ■, 16-AP) temperatures. Abbreviations as in Figure 2.

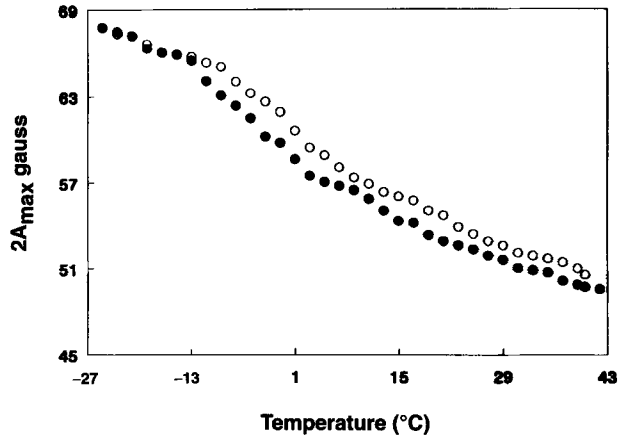

FIG. 1. Temperature dependency of outer hyperfine splitting, (2 A_{max}) of 5-doxylstearic acid in hydrated phospholipids obtained from livers of carp adapted to summer (○) and winter (●) temperatures.

species composition of PC and PE. Based on the data of Table 2, Figure 4 compares the melting temperature of 18:0/22:6 PC (100%) with ternary mixtures of synthetic PC. Vesicles made of 4% 16:0/16:0, 1% 20:4/20:4, and 94% 18:0/22:6 PC were selected to mimic the PC from SA fish, while vesicles made of 1% 16:0/16:0, 10% 20:4/20:4, and 89% 18:0/22:6 PC were selected to mimic the PC from WA fish. As seen in Figure 4, addition of 4% 16:0/16:0 PC along with 1% 20:4/20:4 PC did not significantly affect the transition temperature of 18:0/22:6 (100%) PC (−8.8 vs. −8.4°C). Increasing the amount of 20:4/20:4 PC with a concomitant reduction of the amount of 16:0/16:0 PC (from 2 to 10%, and from 4 to 1%, respectively) brought about an increase of this temperature from −8.4 to −6.2°C. The acyl chain order, reflected by the hyperfine splitting values, remained virtually unaffected in these combinations of PC.

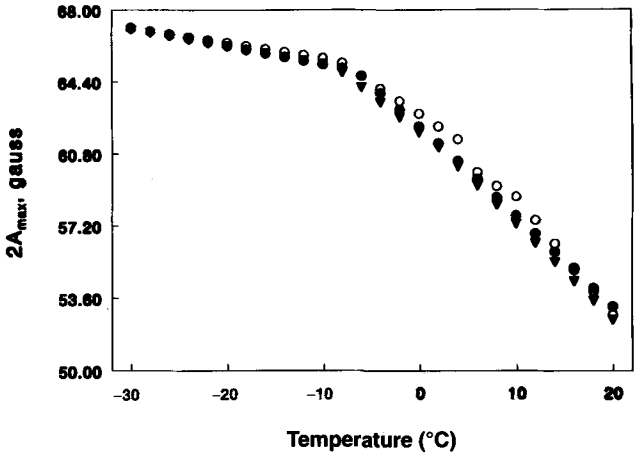

FIG. 4. Thermotropic phase transition temperature of 18:0/22:6 vesicles (▼) or in mixed phospholipid vesicles consisted of either 1% 16:0/16:0, 10% 20:4/20:4, and 89% 18:0/22:6 (●); or in 4% 16:0/16:0, 2% 20:4/20:4, and 94% 18:0/22:6 (○).

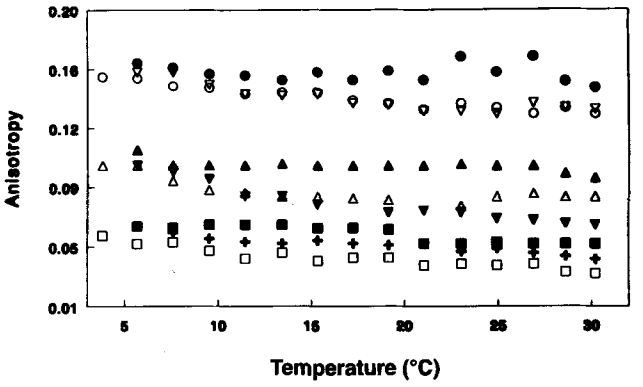

FIG. 5. Temperature dependency of fluorescence anisotropy of 2-AS, 12-AS, and 16-AP in 16:0/18:1 (▼, 2-AS; ▼, 12-AS; and +, 16-AP), 18:0/22:6 (○, 2-AS; △,12-AS; and □, 16-AP), and 22:6/22:6 (●, 2-AS; ▲, 12-AS; and ■, 16-AP) phosphatidylcholine vesicles. Abbreviations as in Figure 2.

In another series of experiments, fluorescence spectroscopy was used and anisotropy parameters of 16:0/18:1, 16:0/22:6, and 22:6/22:6 PC using 2-AS, 12-AS, and 16-AP were compared. Figure 5, in agreement with the data presented in Figure 4, shows that the R_{ss} values of these phospholipids were very close in the corresponding membrane segments. That is, introduction of 11 double bonds in PC molecules relative to 16:0/18:1 does not render the vesicles more disordered than a single Δ9 *cis* double bond in the *sn*-1 position. On the contrary, 22:6/22:6 PC were slightly more ordered at higher temperatures (above 25°C).

PC make 40–50% of the total phospholipids in the membranes (19–21), and thus, it can be expected that physical properties of these phospholipids, given the matrix of membranes, remain unaffected during thermal adaptation. Consequently, some other membrane lipid components might be involved in controlling acyl chain order in response of temperature changes. PE are the second most abundant phospholipids in membranes (19–21), comprising 20–30% of the total. As the total amounts of saturated/unsaturated and monounsaturated/polyunsaturated species showed the most characteristic changes in thermally adapted fish (Table 2), model experiments with binary mixtures of the representative molecular species of PE (16:0/18:1 and 18:1/22:6) and PC (18:0/22:6) were carried out using either ESR spectroscopy or fluorescence polarization techniques. In Figure 6, the thermotropic phase transition temperature of mixed vesicles consisting of either 18:0/22:6 PC (75%) and 18:1/22:6 PE (25%) or 18:0/22:6 PC (75%) and 16:0/18:1 PE is compared with 18:0/22:6 (100%) vesicles using ESR spectroscopy. It is evident that the presence of 18:1/22:6 PE in the model system reduced the transition temperature from −8.8 to −11°C. The acyl chain disorder also decreased, especially at lower temperatures. On the contrary, the presence of 16:0/18:1 shifted the phase transition to higher temperatures, from −8.8 to −3°C.

Figures 7 and 8 confirm and extend the observations

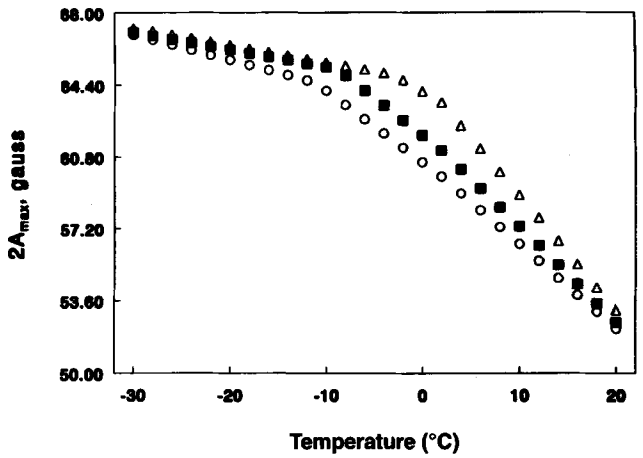

FIG. 6. Thermotropic phase transition temperatures of 18:0/22:6 phosphatidylcholine, 100% (■), 16:0/18:1 phosphatidylethanolamine, 25%; +18:0/22:6 phosphatidylcholine, 75% (▲); and 18:1/22:6 phosphatidylethanolamine, 25%; +18:0/22:6 phosphatidylcholine, 75% (●).

shown in Figure 6, that increased acyl chain disorder in the vesicles from WA fish is due to the observed accumulation of 1-monounsaturated, 2-polyunsaturated PE, and also PC species. In the model experiment shown in Figure 7, mixed vesicles consisting of 75% 16:0/22:6 PC and either 25% 16:0/18:1 (Fig. 7A) or 25% 18:1/22:6 PE (Fig. 7B) were tested. While 16:0/18:1 PE rendered the mixed vesicles more ordered in the uppermost segment, the 18:1/22:6 species increased the disorder (Fig. 7B) in comparison to the 16:0/22:6 (100%) vesicles. In the deeper layers, the ordering effect of 16:0/18:1 PE was reversed, and a slight fluidization was observed (Fig. 7A). The fact that 16:0/18:1 PE made the mixed vesicles more ordered in the C-2 segment explains the differences in anisotropy parameters of total phospholipids and purified PC (Fig. 2 vs. Fig. 3). This ordering effect of PE already has been described (22), and is attributed to interactions be-

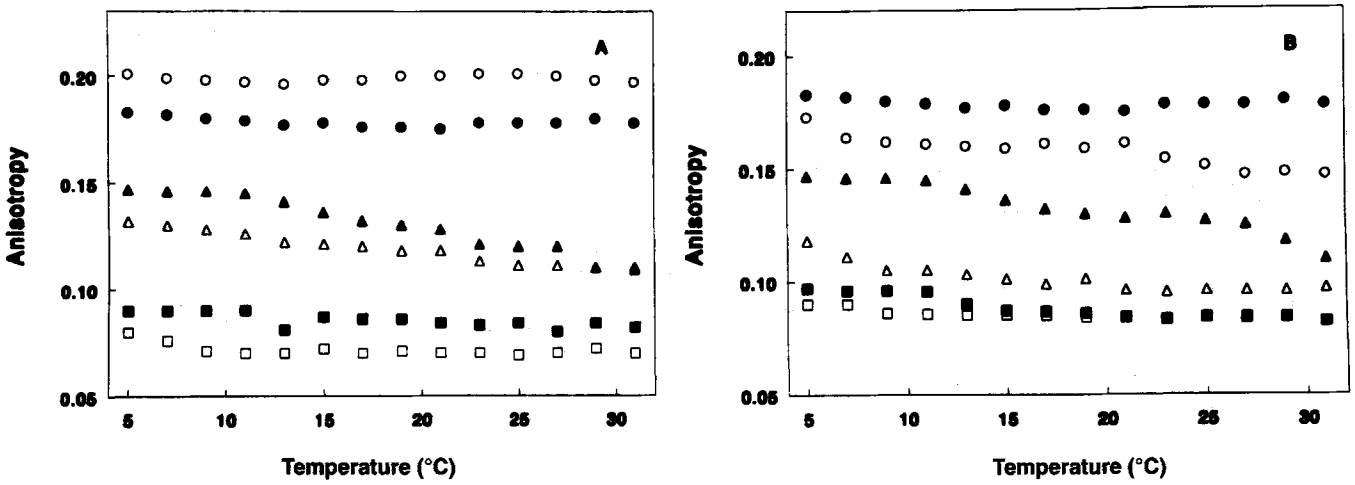

FIG. 7. Temperature dependency of fluorescence anisotropy of 2-AS, 12-AS, and 16-AP embedded either in A: 100% 16:0/22:6 phosphatidylcholine (●, 2-AS; ▲, 12-AS; and ■, 16-AP) or 75% 16:0/22:6 phosphatidylcholine and 25% 16:0/18:1 phosphatidylethanolamine (○, 2-AS; △, 12-AS; and □, 16-AP) or in B: 100% phosphatidylcholine (●, 2-AS; ▲, 12-AS; and ■, 16-AP) or 75% 16:0/22:6 phosphatidylcholine and 25% 18:1/22:6 phosphatidylethanolamine (○, 2-AS; △, 12-AS; and □, 16-AP). Abbreviations as in Figure 2.

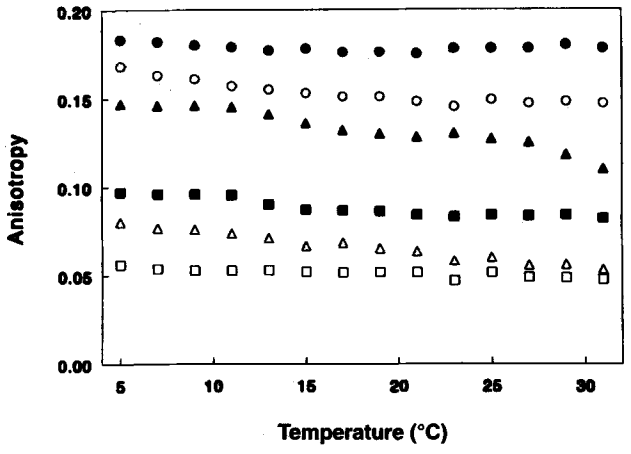

FIG. 8. Comparison of fluorescence anisotropy of 2-AS, 12-AS, and 16 AP embedded either in 100% 16:0/22:6 (●, 2-AS; ▲, 12-AS; and ■, 16-AP) or 100% 18:1/22:6 phosphatidylcholine (○, 2-AS, △, 12-AS; and □, 16-AP). Abbreviations as in Figure 2.

tween the positively charged amino N and the negatively charged phosphate ester groups of the adjacent phospholipid molecules. The presence of a *cis* double bond in the *sn*-1 position of PE may overcome these interactions with resulting increase of disorder in the hydrophobic region of the bilayer. In fact, mixing 18:1/22:6 PE with 16:0/22:6 PC resulted in a drastic fluidization in both the C_2 and C_{12} segment that is just beyond the position of the olefinic bond of oleic acid. A similar picture is seen when anisotropy parameters of 18:1/22:6 and 16:0/22:6 PC are compared, with the exception that vesicles made from 18:1/22:6 PC were more fluid in the C-16 segment than its 16:0/22:6 analog (Fig. 8). Using these model systems, the temperature-related changes in structural order of fatty acyl chains in phospholipid vesicles could be successfully modelled.

DISCUSSION

Besides temperature, the photoperiod, nutritional, and hormonal state of fish may affect metabolism of lipids and, hence, the composition of biomembranes. Although several lines of evidence show a compensation of the membrane ordering state for changes in the ambient temperature (23–27), little information is available about the alterations taking place at the structural level within the bilayer during thermal adaptation. It is also unclear how the individual phospholipid molecules participate in this process. The results presented in Figure 1 clearly show that the transition from a solid gel to a melted, liquid-crystalline state is shifted down by about 5°C in phospholipids in the livers of WA carps. This, and comparison of hyperfine splitting values of phospholipids from WA fish at 5°C and from warm-adapted fish at 11°C, indicate a roughly 25–30% compensation of the membrane ordering state for the temperature. Using fluorescent probes and a different approach, this compensation is 100% in each segment scanned.

Both the downshift of the transition temperature and the increase of the acyl chain disorder in the bilayer might be related to the observed changes in the molecular species composition of the major phospholipids, diacyl PC, and PE. The most important changes in molecular species composition of these phospholipids are a decrease in the level of 18:0/22:6 species and a concomitant increase in the levels of 1-monounsaturated, 2-polyunsaturated (18:1/22:6, 18:1/20:4) species during adaptation to winter temperatures (Table 2). Accumulation of 18:1/22:6 and, to some extent, 18:1/20:5 PE, also has been demonstrated for marine fish and shrimp inhabiting polar and subtropic waters (8,9) or brains of freshwater fish adapted to reduced temperatures (10). The thermotropic phase transition temperatures of 18:0/22:6 PC and 16:0/22:6 PC are rather close. Thus, accumulation of 16:0/22:6 PC to the cost of 18:0/22:6 species (Table 2) might not have been

responsible for the observed downshift of the thermotropic phase transition temperature of phospholipid vesicles. Moreover, model experiments made on vesicles of PC consisting of disaturated (having high phase transition temperatures, above 40°C) and polyunsaturated (having extremely low phase transition temperatures, below −40°C), as well as saturated/polyunsaturated PC species (having intermittent phase transition temperatures, around −10°C), revealed that these species in concentrations recorded in cold/warm-adapted livers (Table 2), do not participate in the control of membrane physical properties according to the temperature. Thus, such changes alone do not explain either the increased disorder in the fatty acyl chains or the downshift of the thermotropic phase transition temperature in the WA state. The noninvolvement of polyunsaturated fatty acids/phospholipid molecular species in controlling membrane physical state also is supported by the results of Stubbs and Kisielewski (28) on sarcoplasmic reticulum of rats fed either fish oil or vegetable oil. Despite the increase in the levels of long-chain polyunsaturated fatty acids in membranes of fish oil-fed group, the acyl chain disorder remained unchanged measured using diphenylhexatrione and trimethylammonium–diphenylhexatrione. Our study also did not reveal any effect of long-chain polyunsaturated fatty acids in the C_2, C_{12}, or C_{16} region of the vesicles made from livers of fish oil-fed rats compared to the vegetable oil-fed rats (9).

A characteristic difference between carp and rat liver phospholipids is the absence and cold-induced accumulation of 18:1/22:6 and 18:1/20:5 PE and PE in the latter. Figures 6, 7, and 8 clearly suggest a drastic disordering effect of 18:1/22:6 PE (Fig. 7B) and choline species (Fig. 8) in each segment of the bilayer. Previously we have shown that combination of rat liver PC (75%) with salmon liver PE (25%) rich in 18:1/20:5 and 18:1/22:6 species resulted in a considerable fluidization, compared with vesicles made from salmon liver PC (75%) and rat liver PE (25%) (9). In addition, 18:1/22:6 PE in contrast to 16:0/18:1 PE, shifts the thermotropic phase transition to lower temperatures (Fig. 7). Thus it can be proposed that increased disorder and lower transition temperatures of membranes of marine and freshwater fish, either evolutionary or seasonally-adapted to reduced temperatures, are at least partially due to an increase in the levels of 1-monounsaturated, 2-polyunsaturated PE species.

However, the technique used to incorporate the labels into the vesicles does not permit the differentiation between the outer and inner membrane leaflet. But, because PE are conic-shaped molecules (29), it is reasonable to speculate that most of them, similar to the native membranes, are enriched in the inner leaflet of the membrane to ensure the curvature of these structures. Considering this, the increase of fluidity in the inner leaflet of vesicles from the WA fish might have been considerable. However, native membranes might differ considerably in this respect and the fluidizing effect of 1-monoenoic, 2-polyenic PE species might be influenced by the presence of proteins and other membrane components. Increased disorder in the outer leaflet of the bilayer can be explained by accumulation of molecules like 18:1/22:6 PC. This can be an explanation of why PC vesicles from cold-adapted carps were more disordered than those from the warm-adapted specimens, and why the outer leaflet of hepatocyte plasma membranes of cold-exposed trout become more fluid than those of warm-exposed trout (30). Based on this, it can be proposed that "fine tuning" of the ratio of 1-saturated, 2-unsaturated, and that of the 1-monounsaturated, 2-polyunsaturated PE might be an important factor determining the molecular architecture of membranes in relation to thermal adaptation. However, we are aware that these experiments are oversimplifications of interactions taking place in native membranes at molecular and structural level because there are a large number of phospholipids present not considered in this study, in addition to cholesterol and proteins. Although more investigations are necessary to prove this, it has become evident from the results presented here that not the gross amounts of long-chain polyunsaturated fatty acids, but their specific pairing with monounsaturated fatty acids in the *sn-1* position might be an important factor in adjusting membrane architecture and physical properties to temperature in fish.

Composition of Phospholipids of White Muscle of Six Tuna Species

Isabel Medina*, Santiago P. Aubourg, and Ricardo Pérez Martín

Instituto de Investigaciones Marinas del CSIC, E-36208 Vigo, Spain

ABSTRACT: A comparative study of the phospholipids of white muscle of six of the commercially utilized tuna species, including quantitative analyses of phospholipid classes and studies of the acyl composition of the major components. Plasmalogen compounds also were identified and quantified. Choline and ethanolamine glycerophospholipids were the most abundant classes in all the samples, as well as the only molecules containing plasmalogens (16:0, 18:0, and 18:1 alkenyl-ether chains). The patterns of fatty acid distribution within each of the phospholipid classes showed general similarities in the species analyzed. However, ratios between certain saturated and polyunsaturated fatty acids in different phospholipid classes showed remarkable differences. The high content of n-3 polyunsaturated fatty acids in the principal phospholipids, such as the plasmalogens, and taking into account the fatty acids possible importance in human nutrition, indicates that the white muscle of tuna species may be a potentially important dietary item.

Lipids 30, 1127–1135 (1995).

Tuna processing is an industry of well-known economic importance in many countries, including Spain, supporting a significant market demand and playing an important role in the field of human nutrition as components of the Spanish diet (1). One of the most important aspects in the quality of marine foods concerns their lipid content and composition. Marine lipids are known for their highly unsaturated fatty acid composition (2,3), which makes them very prone to oxidative damage (4,5). On the other hand, these lipids are now the subject of a great deal of attention due to their high content of n-3 polyunsaturated fatty acids (PUFA), which have potential roles to play against certain diseases (6,7).

Several papers describing the lipid compositions of tuna fish and their alterations during frozen storage or thermal processing have been published (8–10). Most of the work carried out has been focused on the composition of the simpler lipid classes containing two types of primary products per mole, such as triacylglycerides (11–13), and literature data related to complex lipids (classes that contain three or more different primary products per mole), such as phospholipids (PL) and, especially, plasmalogens (PLA), are quite limited (14–16).

The PL composition of fish species that are consumed as foods has attracted a great deal of attention due to several characteristics: (i) they possess a highly unsaturated fatty acid composition which makes them especially vulnerable to damages during processing; (ii) some of the PL classes have been reported to possess antioxidant properties (17); and (iii) in contrast with triacylglycerides, the distribution of the PL classes with respect to their fatty acid composition is little influenced by external and internal factors, an aspect that may be relevant for species characterization purposes (18–21). Further, the abundance in n-3 PUFA of these PL may give the fish muscle a supplementary nutritional value.

The aim of the present work was to study the PL composition in several of the tuna species most widely consumed in Spain prior to processing. Different chromatographic techniques, such as high-performance liquid chromatography (HPLC), thin-layer chromatography (TLC), and gas chromatography (GC) have been combined to complete PL class identifications and quantification. The compositions of fatty acids and alkenyl ethers on the glycerol moieties were studied simultaneously using an acid derivatization procedure and subsequent analysis of the corresponding methyl esters and dimethylacetals (DMA) by GC. For identification purposes, GC coupled with mass spectrometry was employed.

MATERIALS AND METHODS

Raw material and lipid extraction. Six commercial tuna species were employed—big eye tuna (*Thunnus obesus*), bluefin (*T. thynnus*), bonito (*Sarda sarda*), frigate (*Auxis thazard*), skipjack (*Katsuwonus pelamis*), and yellowfin (*T. albacares*). The fish came from the Atlantic Ocean and were purchased at a commercial market. All fish except bonito were landed frozen. Bonito fish were caught and kept on ice for three days. After arrival at our laboratory, the bonito were frozen at −40°C, and all samples were stored at −20°C prior to analysis. Five individual fish for each species were used.

Fish were skinned, beheaded, and eviscerated, and the red muscle was removed. Lipids were extracted from the white muscle by the Bligh and Dyer method (22), and the muscle

content was determined gravimetrically as described by Herbes and Allen (23). All organic solvents employed were reagent grade (E. Merck, Darmstadt, Germany).

Free fatty acid determination. Free fatty acids were measured using the Lowry and Tinsley (24) method based on the formation of a complex with $(AcO)_2Cu$–pyridine (E. Merck).

Determination and purification of PL. Organic phosphorus was determined on total lipid extracts according to the Raheja *et al.* method (25) based on a complex formation with ammonium molybdate (E. Merck). Lipid extracts were subjected to TLC on 20 × 20 cm glass plates coated with Silica Gel 60W (0.8 mm) (E. Merck) and were developed twice in the same direction with $CHCl_3/CH_3OH/CH_3COOH$ (100:15:2, by vol). The polar fraction remained at the bottom and was recovered from the silica gel by elution with $CHCl_3/CH_3OH$ (2:1, vol/vol).

Fractionation of PL classes. Total PL extracts were resolved by high-performance TLC on 10 × 10 cm glass plates coated with silica gel 60W (0.25 mm) (E. Merck) and developed twice in the same direction in a solvent system of chloroform/methanol/ethyl acetate/isopropanol/KCl (0.25%) (30:9:25:6:18, by vol) (26). KCl and all organic solvents were reagent grade (E. Merck). Spots were visualized after spraying with cupric sulfate and subsequent heating at 160°C for 10 min. Individual PL classes were identified by comparison with PL standards (Matreya Inc., Pleasant Gap, PA). Optical densities of the charred spots were measured at 360 nm with a Shimadzu CS-910 dual-wavelength TLC scanner (Kyoto, Japan). In this way, sphingomyelin (SPH) and other minor PL classes, characterized by an essential saturated fatty acid composition, were quantified. Quantitation of other PL classes was not possible following this procedure as they showed highly unsaturated fatty acid composition, whereas the composition of the PL standards used was largely saturated (27). To determine the PLA content in choline and ethanolamine glycerophospholipids, elution on TLC plates (Silica Gel 60W, 20 × 20 cm, 0.25 mm) using the procedure described previously was performed. Spots corresponding to these classes, combining the diacyl and PLA forms [phosphatidylcholine (PC)–PLA, phosphatidylethanolamine (PE)–PLA], were scraped off and the lipid recovered for subsequent GC analysis.

Determination of PL fatty acid composition. To obtain the fatty acid composition of individual PL, a combination of HPLC and GC techniques was carried out. HPLC was performed with a Silica Gel 60 column (4.6 mm i.d × 25 cm.; Supelco, Inc., Bellefonte, PA), coupled with a Perkin Elmer Solvent Pump (Beaconsfield, Buckinghamshire, United Kingdom), a Perkin Elmer LC-65 UV variable wavelength detector set at 205 nm, and a Hewlett-Packard 8380A integrator (Wotingham, Berkshire, United Kingdom). The separation was achieved with an isocratic elution in a solvent mixture of $CH_3CN/CH_3OH/H_3PO_4$ (98:1:1, by vol). The flow rate was maintained at 1 mL/min. All solvents employed were of HPLC grade (E. Merck).

Polar lipids (150 μg) were injected into the HPLC system, and the PL classes were separated under the conditions described previously. The identity of peaks was verified using PL standards. Diacyl forms of phosphatidylinositol (PI), phosphatidylserine (PS), PE, PC, and lysophosphatidylcholine (LPC) were separated completely, whereas other minor complex classes and PLA eluted with the eluent front. As a result of this separation, purified diacyl forms corresponding to the PC, PE, PI, PS classes and the monoacyl LPC class were obtained, and were transmethylated to determine their acyl composition. To eliminate the excess of H_3PO_4 prior to the transmethylation, a washing step with an alkaline solution (6 % K_2CO_3) (E. Merck) was necessary.

Transmethylation of lipids. Purified diacyl PL classes coming from the above HPLC separation, and spots scraped from TLC plates containing both diacyl and alkenyl–acyl molecular species were converted into the corresponding fatty acid methyl esters (FAME) and DMA by the method of Lepage and Roy (28).

Quantification of PL classes. Transmethylated lipids containing mixtures of FAME and DMA were analyzed simultaneously by GC (Perkin Elmer 8700 chromatograph) employing a fused silica capillary column SP-2330 (0.25 mm i. d. × 30 m; Supelco Inc.), programmed from 145 to 190°C at 1.0°C/min, from 190 to 210°C at 5.0°C/min, and then followed by a hold for 13.5 min at 210°C. Nitrogen at 10 psig was the carrier gas, and a flame-ionization detector set at 250°C was used. A programmed temperature injector was used in the split mode (150:1) and heated from 45 to 275°C at 15°C/min.

Peaks were identified by comparison of their retention times with standard FAME mixtures (Supelco: PUFA No. 1 and No. 2; Larodan, Qualmix Fish). For quantitation purposes, peak areas were automatically integrated, and 19:0 fatty acid (Sigma, St. Louis, MO) was used as an internal standard.

Quantification of diacyl PL classes (PE, PC, PS, PI) and the monoacyl LPC was done knowing their respective fatty acid composition and the structure of the nonacyl moiety. The PLA content was obtained by doubling the molar percentage of total DMA in the mixture of DMA and FAME obtained after transmethylation of polar lipids, according to Visnaanathan *et al.* (29). Total contents corresponding to PC and PE were determined by combining the quantities of diacyl and PLA forms.

GC/mass spectrometry. A Hewlett-Packard model 5890 A chromatograph, equipped with on-column capillary injection, was used with a 5970 series mass selective detector. The separation was made using the same column and conditions described previously. Helium was used as carrier gas. The mass spectrometer was operated in the electron impact ionization mode (70 eV). The transfer line and ion source temperature were both 280°C. Mass spectra of the different peaks were checked in order to differentiate FAME from DMA. The structures of the DMA components were investigated.

RESULTS AND DISCUSSION

Lipid and PL content. The lipid content for each species was rather constant, as can be observed from the low standard deviations calculated for five individual samples (Table 1).

TABLE 1
Lipid and Phospholipid Contents[a] in White Muscle of Six Tuna Species

Tuna species	Lipid[b]	Phospholipid[c]
Bigeye	0.76 ± 0.29	35.78 ± 6.99
Bluefin	0.95 ± 0.48	26.41 ± 5.30
Bonito	1.94 ± 0.19	1.60 ± 0.16
Frigate	0.65 ± 0.20	37.81 ± 5.86
Skipjack	0.78 ± 0.22	28.54 ± 7.52
Yellowfin	0.57 ± 0.04	58.80 ± 7.56

[a]Results are expressed as mean ± standard deviation for five samples.
[b]Expressed as g/100 g wet muscle.
[c]Expressed as percent of total lipids.

Specimens corresponding to the bonito species showed the highest lipid content with results which confirmed those obtained for the other species. A great variability in the lipid content has been observed in migrating fish species, depending on both enviromental and endogenus factors (12,30–32).

On the other hand, possible decomposition of lipids during frozen storage of samples prior their acquisition also must be also considered (33,34). In order to clarify the extent of this reaction, the amounts of free fatty acids in all samples were calculated. Levels of free fatty acids were generally low, with values ranging between 0–5% of total lipid for all samples, the lowest values being those for bonito. The extent of lipid hydrolysis thus could not explain the low lipid content in respect to the bonito samples. Therefore, the lipid contents found must be considered as completely natural in these tunas, and data published for tuna species, such as skipjack or yellowfin (35,36), were very similar to those determined in this work.

All species except bonito showed high percentages of PL (Table 1). Because PL contain more of the highly unsaturated fatty acids than do triacylglycerols, the white muscle of these species could be considered an important dietary source of PUFA.

PL content in muscle has proven to be relatively constant according to their presence in cellular membranes (3); this fact has led to the hypothesis of an inverse ratio between lipid content and PL proportion in total lipids (37). The regression between the lipid and the PL content in the present study has demonstrated an inverse correlation (correlation coefficient = −0.751) probably related to the previously mentioned stability of PL content as opposed to the significant variations that may occur in the amount of simpler lipids in migrating fish species (3).

PL classes quantification. Table 2 shows the distribution of PL classes in each species. All species analyzed showed a similar qualitative and quantitative pattern of PL classes. In all cases, PC was the major class, followed by PE and LPC. PC and, secondly, PE usually have been measured as the main PL classes in fish species (11,38,39).

Minor classes such as phosphatidylglycerol and phosphatidic acid also could be identified. In fact, some authors have described the presence of both PL classes in very low proportions in a wide variety of fish tissues (40,41).

The levels of LPC ranged between 15–20% in all tuna species studied. Previous researchers have described the presence of lyso-PL forms in commercially available fresh tuna muscle and the increase in their content during storage at low temperatures (9,14). In fact, it has been accepted that enzymatic PL hydrolysis can occur slowly during frozen storage or in the muscle of several fish species when held on ice (42). At this point, it seems clear that a certain level of hydrolysis in PL has taken place in all samples during its storage prior to acquisition. However, the extent of that hydrolysis did not appear to be great as samples in which no free fatty acids (bonito) were detected showed proportions of LPC similar to those with higher levels (Table 2).

Other important differences have been recognized in PI and SPH contents among the species. Both PL have been found in several marine samples, although their concentrations vary depending on the tissue and organ considered (38,43).

PLA. Table 3 shows the PLA contents obtained in the different tuna species. Some papers have described the presence of alkenyl ethers in a wide variety of fish muscle (15,44). Levels of ether-linked PL in food have a particular interest from a dietary point of view, as its ingestion could contribute to the production of potent biochemical mediators (45). Further, the PLA content and composition have been shown to be relevant when studying changes in processed foods, as the content decreased as a result of thermal treatment (46). Both aspects may be important in this study, taking into account

[b]Long-chain alkenyl ethers.

that all species have shown high levels of PLA in the white muscle (Table 3).

The PLA proportion was found to have a wide range in the tuna species studied, but a simple relationship with the PL content could not be determined (Table 1). The comparison of both parameters in most of the species studied suggests that an inverse trend with respect to the PL concentration in muscle may exist, although the low PL content found in bonito is in disagreement with this possibility. In addition, some papers have proposed a possible mechanism of adaptation to lower temperatures in marine organisms which involves a decrease in the PLA content with respect to diacyl forms of PL (44,47).

Finally, an enzymatic hydrolysis of PLA in marine invertebrates has been described during frozen storage, although it occurs more slowly than for diacylphospholipids (48). Because no significant hydrolysis seems to take place in diacyl forms as a result of frozen storage, the extent of this reaction on PLA is likely to be insignificant.

From their mass spectra, DMA were identified as a result of the methanolysis of alkenyl ether chains corresponding to 16:0, 18:0, and 18:1n-9 fatty acids in accordance with previous results determined in *Euthynnus pelamis* (15,49). Other fatty chains, such as 17:0, 20:0, and 21:0, were detected as trace components.

Alkenyl ethers were found only as PC–PLA and PE–PLA forms for all the tuna species studied (Table 3). Both major PLA usually have been found in marine tissues in association with the major PL (3,36). As can be seen in Table 3, ethanolamine glycerophospholipids showed the largest concentration in PLA, reaching values to nearly 50% of the class.

With respect to the composition of the alkenyl ether chains, two different patterns were observed for each PLA class (Table 4). PC–PLA showed an important concentration in 16:0 (approximately 75%), whereas the levels of 18:0 and 18:1n-9 in PE–PLA were higher than those found in its homologue PC–PLA. This situation has been described previously for other marine organisms (50,51).

1-*O*-Alkyl-2-acylglycerophospholipids also have been found in some tissues of some marine organisms (3,14), but they were not detected at significant levels in this research.

Fatty acid composition. Fish PL are remarkable for their high content in PUFA, and substantial differences in their fatty acid composition could be found, depending on the muscle tissue or organism (3,39). Fatty acid compositions of the five major PL classes in six tuna species are shown in Tables 5–9. SPH was a minor class for all tuna species; it also showed a less complicated fatty acid composition with 16:0 (30–35%), 18:1n-9 (23–39%), and 24:1n-9 (12–15%) as major components, and low contents of PUFA (12% of 22:6n-3 approximately). This composition is similar to that obtained by Linares and Henderson (52) in trout muscle.

As can be inferred from Tables 5–9, the fatty acid composition exhibits certain discrepancies between classes and even between species. However, very characteristic patterns could be recognized between lipid classes originating in different samples. One of the most noteworthy was the preponderance of stearic acid over palmitic acid as the principal saturated acid in PE, and the high level of palmitic acid in PC. This distribution of 16:0 and 18:0 fatty acids seems to be a characteristic of the PL from a number of tissues (53), and it is difficult to reconcile with the hypothesis that both PL come from

the same diglyceride precursor (54). On the other hand, this finding is supported by the alkenyl ether composition data mentioned previously (abundance of 18:0 in PE–PLA and of 16:0 in PC–PLA).

The preference of 16:0 over 18:0 as a saturated acid is repeated among the PL classes with choline as the polar head group, such as SPH and LPC. On the contrary, PI shows the inverse situation with a great abundance of 18:0.

[a]Data are given in mol% as means and standard deviations for five different samples.

The major monoene, 18:1n-9, was found in similar proportions in all PL classes, although choline-type PLs presented higher levels. Other monoenes, like 20:1n-9 and a homologue in the elongation pathway, 24:1n-9, were found to be highly concentrated in PE, PI, and PS. This distribution was in agreement with previous results reported in the case of the white muscles of albacore tuna and cod (39,46).

With respect to PUFA, 20:5n-3 and 22:6n-3 were especially concentrated in PC and LPC with levels around 5–6 and 30–45% of each fatty acid, respectively. Relatively high con-

[a]Data are given in mol% as means and standard deviations for five different samples.

tents also were found in PE. Results obtained herein do not confirm the idea that PE should concentrate a higher PUFA content than any other PL class (18,38). PI and PS showed a more saturated composition with relatively low values of 22:6n-3 fatty acid (around 25 and 15%, respectively).

The high PUFA content found in LPC may be related to the enzymatic hydrolysis of PC occurring during storage at low temperatures. Some authors have found that this lipolysis takes place first with saturated fatty acids that are mainly esterified in *sn*-1 position of the PL moiety, and in a second step with PUFA (14,55,56). As a result, a high concentration in PUFA could be obtained in the remaining lysophospholipids. The findings obtained in this research were in accordance with that notion.

However, a different composition was found in LPC of frigate as compared to the other species—saturated fatty acids (16:0 and 18:0) showed high contents, while n-3 PUFA (20:5 and 22:6) were present in lower contents. The proportion of these acids in PC was not significantly different from other species; hence, reasons related to a partial hydrolysis of PC could not explain the low content found in LPC. More complex factors surely may be considered, such as diet, temperature, salinity, or even internal conditions (18).

From a nutritional point of view, the enzymatic hydrolysis occurring in all samples did not seriously affect the n-3-composition, as can be inferred from the comparison of fatty acid composition of PC and PE in samples which showed higher levels of LPC, such as skipjack and yellowfin in contrast with bonito or frigate.

Finally, special emphasis often is given to the n-3/n-6 PUFA ratio for marine and freshwater fish actually consumed by humans (37,57). As could be expected, all PL classes described in this work were characterized by high ratios of n-3 to n-6 polyenes. Special attention must be given to the fatty acid composition of PI. Recently, several authors (52,58,59) have reported that PI from some marine fish tissues is especially enriched in 20:4n-6. In our case, PI showed a lower n-3/n-6 ratio than other PL classes, but arachidonic acid was not the major PUFA in any tuna species. This situation already has been described in white muscle of cod (39), in contrast with previous reports.

A different situation could be observed in the relative contents of 20:5n-3 and 20:4n-6. In general, PE and PI showed a larger proportion of 20:4n-6 than that of 20:5n-3, and PC revealed the opposite (Tables 5, 6, and 8). Studies carried out on fish coming from Australian waters contained different relative contents of both acids, depending on the species (60,61). In addition, an important variation in the content of 20:4n-6 found in PC and LPC also was observed between the six tuna species (Tables 5 and 7). In these classes, bonito showed the highest values of the n-3/n-6 ratio.

The present research indicates that the PL of white muscle of fresh tuna species has a noteworthy nutritional value, supplying substantial amounts of PUFA and PLA. No significant differences were found in the distribution of the PL classes among the different tuna species studied. Furthermore, in terms of fatty acid and alkenyl ether compositions, PL classes showed some general similarities, although ratios between certain fatty acids were found to be different.

Symposium on Palm Oil and Its Components

The Palm Oil Research Institute of Malaysia (PORIM) has pursued a policy of supporting biological research involving the use of palm oil, its fractions (palm olein, palm stearin, etc.), or other components such as Vitamin E or tocotrienols. At the occasion of the International Palm Oil Congress held in Kuala Lumpur, Malaysia, in September 1993, PORIM invited its grantees to present their findings. The papers which follow represent the completed projects of some of the PORIM grantees. I would like to thank Dr. David Kritchevsky for facilitating the submission of these manuscripts and for helping in the review process, and Dr. Wolfgang Baumann, former Editor-in-Chief of *Lipids*, for his meticulous attention to assuring their optimal presentation.

Effect of Tocotrienols on the Growth of a Human Breast Cancer Cell Line in Culture[1]

Kalanithi Nesaretnam[a,*] Najla Guthrie[b], Ann F. Chambers[c], and Kenneth K. Carroll[b]

[a]Palm Oil Research Institute of Malaysia, Kuala Lumpur 50720, Malaysia, [b]University of Western Ontario, London, Ontario N6A 5Cl and [c]London Regional Cancer Research Centre, London, Ontario, N6A 4L6 Canada

ABSTRACT: The tocotrienol-rich fraction (TRF) of palm oil consists of tocotrienols and some α-tocopherol (α-T). Tocotrienols are a form of vitamin E having an unsaturated side-chain, rather than the saturated side-chain of the more common tocopherols. Because palm oil has been shown not to promote chemically-induced mammary carcinogenesis, we tested effects of TRF and α-T on the proliferation, growth, and plating efficiency (PE) of MDA-MB-435 estrogen-receptor-negative human breast cancer cells. TRF inhibited the proliferation of these cells with a concentration required to inhibit cell proliferation by 50% of 180 μg/mL, whereas α-T had no effect at concentrations up to 1000 μg/mL as measured by incorporation of [^{3}H]thymidine. The effects of TRF and α-T also were tested in longer-term growth experiments, using concentrations of 180 and 500 μg/mL. We found that TRF inhibited the growth of these cells by 50%, whereas α-T did not. Their effect on the ability of these cells to form colonies also was studied, and it was found that TRF inhibited PE, whereas α-T had no effect. These results suggest that the inhibition is due to the presence of tocotrienols in TRF rather than α-T.

Lipids 30, 1139–1143 (1995).

Earlier studies have shown that palm oil does not promote chemically-induced mammary tumors in rats like other dietary fats and oils (1–3). Furthermore, the growth of cells derived from a spontaneously arising mouse mammary tumor, when injected into animals pre-fed with various dietary lipids, was halved when 20% (of energy) palm oil was fed compared with 20% safflower oil, and was reduced to one-sixth in animals fed 5% palm oil (4). It has been suggested that this inhibition might be due to the fact that palm oil is not rich in linoleic acid, which has been shown to promote cancer in *in vivo* and *in vitro* studies (5–8). A second explanation may be found in the anticarcinogenic potential of palm oil's minor components, mainly its vitamin E tocotrienols, as recent studies have shown that palm oil stripped of the vitamin E fraction enhances tumorigenesis. It also was demonstrated that addition of the tocotrienol-rich fraction (TRF) isolated from palm oil to corn oil caused a delay in the appearance of tumors when compared with the corn oil control group (9). Tocotrienols also caused a delay in the onset of subcutaneous lymphoma by 2–4 wk in HRS/J hairless mice, a strain genetically susceptible to subcutaneous lymphoma (10). The life span of mice inoculated with transplanted tumor cells was increased with tocotrienols (11). An inhibition of tumor cell growth of Hela and p388 cells by tocotrienols in culture also has been reported (12). The two forms of vitamin E—tocopherol and tocotrienol—were tested for chemopreventive activity in two chemically-induced rat mammary tumor models. It was found that only the tocotrienol group had a statistically significant increase in tumor latency when mammary tumors were induced with 7,12-dimethylbenz(a)antracene (DMBA), and neither analogue modified latency when nitrosometylurea was used (13).

Tocotrienols account for about 70% of the vitamin E present in palm oil and have an unsaturated side-chain, whereas tocopherols have a saturated side-chain. Although tocotrienols are generally believed to be much less biologically active than tocopherols, they have been shown to have greater free radical scavenging properties as cell membrane constituents (14,15). It has been proposed that vitamin E act as scavenger of nitrite compounds, thus preventing the formation of cancer-promoting nitrosamines (16). Epidemiological data suggest that vitamin E and other antioxidants may decrease cancer incidence. Several studies have revealed that the subjects with the highest serum concentrations of vitamin E have a lower risk of certain cancers (17–20). In addition to this role as a free radical scavenger, high intakes of vitamin E also may enhance the body's immune response (21).

Our interest in tocotrienols was stimulated by observations that dietary palm oil only promotes chemically-induced carcinogenesis in rats when stripped of the TRF. In this study, we tested the effect of TRF isolated from palm oil in comparison with α-tocopherol (α-T) on the proliferation and growth of MDA-MB-435 human breast cancer cells.

MATERIALS AND METHODS

Materials. Tissue culture plastic ware, growth media, and serum for cell culturing were purchased from Gibco Laboratories (Burlington, Ontario, Canada). [^{3}H]Thymidine (6.7 Ci/mmol) was purchased from ICN (Irvine, CA). Scintiverse was purchased from Fisher Scientific (Nepean, Ontario, Canada). The TRF was obtained from the Palm Oil Research Institute of Malaysia (Kuala Lumpur, Malaysia). α-T was obtained from Sigma Chemical Co. (St. Louis, MO). The TRF and α-T were dissolved in dimethyl sulfoxide and diluted with culture medium. All other chemicals were purchased from Sigma Chemical Co.

Isolation of TRF. The extraction of TRF from palm oil is described by Sundram and Gapor (22) and was performed as follows: Palm fatty acid distillate was used as the starting material, and this was converted into methyl esters by esterification. The methyl esters were then removed by distillation, leaving behind a vitamin E concentrate. This was then concentrated by crystallization and passed through an ion exchange column, resulting in vitamin E that was 60–70% pure. Further purification of this preparation was achieved by washing and then drying the concentrate and passing it through a second molecular distillation stage. The final purity of the vitamin E preparation was 95–99% and its composition was: α-T, 32%; α-tocotrienol, 25%; γ-tocotrienol, 29%; and δ-tocotrienol, 14%. The structural formulae of the compounds are depicted in Figure 1.

	R1	R2	R3

γ-tocotrienol	H	CH_3	CH_3
δ-tocotrienol	H	H	CH_3

FIG. 1. Structures of α-tocopherol and tocotrienols.

Cell culture experiments. The human breast cancer cell line MDA-MB-435 was obtained from Dr. Janet Price (M.D. Anderson Hospital, Houston, TX) (23) and was cultured routinely in minimum essential medium supplemented with 10% fetal bovine serum in a 95% air/5% CO_2 incubator at 37°C. Stock cultures were seeded at a density of 2×10^5 and allowed to grow to 80–90% confluence in T-75 flasks. Culture media was changed every two to three days.

The proliferation assay was performed in a 96-well, flat-bottom plate at a plating density of 2×10^4 cells/well in a total volume of 200 μL of medium. The cells were incubated at 37°C for 48 h, with or without the test compounds. Fifty μL of the TRF was added at the following final concentrations: 1 mg/mL, 500 μg/mL, 250 μg/mL, 200 μg/mL, 180 μg/mL, 160 μg/mL, 140 μg/mL, 120 μg/mL, 60 μg/mL, and 30 μg/mL. Tocopherol controls at the same concentrations were carried out simultaneously. [^{3}H]Thymidine (0.5 μCi/well) was then added, and after 4 h the cells were trypsinized and harvested onto a glass fiber filter paper on a semi-automatic 12-well cell harvester (Skatron, Sterling, VA) for evaluation of thymidine incorporation into DNA. Radioactivity on the paper was counted using Scintiverse for 10 min in a liquid scintillation counter.

Plating efficiency (PE) was determined by seeding a known number of cells in 60- or 100-mm tissue culture dishes with or without a given concentration of either TRF or α-T and counting the colonies 14 d later. PE was calculated as the number of colonies divided by the number of cells seeded. Relative PE was calculated as experimental PE divided by control PE.

For growth experiments, the cells were plated at 1×10^4 cells/60 mm dish in 7 mL of medium. TRF was added at concentrations of 125 and 500 μg/mL. The same concentrations of α-T were used to make allowance for any effects due to tocopherols in the TRF. Dishes were incubated for 2, 4, 6, 8, and 10 d, after which the cells were trypsinized and counted with a hemocytometer.

Viability of cells was measured by the 3,(4,5-dimethylthiazole-2-yl)2,5diphenyltetrazolium bromide (MTT) assay as described by Hansen *et al.* (24). In this assay, MTT is converted to a blue formazan product by dehydrogenases that are active in living cells. The intensity of the blue color developed is a measure of cell viability. MDA-MB-435 cells (8×10^4/well) were seeded with various concentrations of TRF and α-T in a 96-well plate in a total volume of 200 μL of medium. MTT (25 μL of 5 mg/mL) was added to each well. After 3 h, 100 μL of extraction buffer consisting of 20% SDS dissolved in a 50% dimethyl formamide/50% water solution at pH 4.0 was added. The blue color formed was measured at 590 nm.

RESULTS

To investigate the effects of TRF and α-T on cell proliferation, we examined the incorporation of [^{3}H]thymidine into MDA-MB-435 cells in the presence of various concentrations of these substances after 48 h. At a concentration of 180 μg/mL,

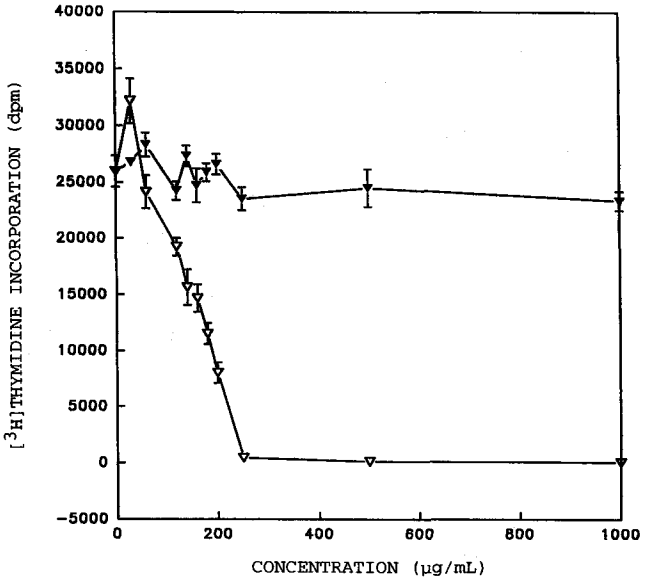

FIG. 2. Effects of α-tocopherol (α-T) (▼) and tocotrienol-rich fraction (TRF) (▽) on the proliferation of MDA-MB-435 cells. The cells were incubated with various concentrations of TRF or α-T (1 mg/mL or 30 µg/mL, respectively) for 48 h. [^{3}H]thymidine (0.5 µCi/well) was then added and the cells were harvested after 4 h to evaluate the incorporation of thymidine into DNA. Points are the average of mean values from three experiments ± SE.

TRF showed a 50% inhibitory effect (Fig. 2). At concentrations above 225 µg/mL, TRF completely inhibited the incorporation of [^{3}H]thymidine by MDA-MB-435 cells. However, there appeared to be a slight stimulation of thymidine incorporation by the cells at the lowest concentration (30 µg/mL) of TRF. In contrast, α-T did not show any inhibition of cell proliferation, even at the highest concentration of 1000 µg/mL.

Figure 3 shows the influence of TRF and α-T on the growth of the MDA-MB-435 cell line. Figure 3A shows the effect of TRF and α-T at a concentration 180 µg/mL on the cells. As shown earlier in the proliferation assay, TRF inhibited the growth of the cells to 50% of control values, and α-T did not. At a higher concentration of 500 µg/mL (Fig. 3B), TRF was shown to be extremely effective in producing complete growth suppression, whereas α-T had no effect.

The sensitivity of the human breast cancer cells to various concentrations of TRF or α-T was determined (Fig. 4). At 1000 µg/mL concentration of α-T, the PE of MDA-MB-435 cells was nearly identical to the control PE of the cells. At the same concentration of TRF, the PE of MDA-MB-435 cells was reduced by approximately three orders of magnitude.

The MTT assay uses the principle whereby cell growth or cell kill is indicated by the conversion or lack of conversion of the tetrazolium salt to the colored product, formazan, the concentration of which can be measured spectrophotometrically. As can be seen from Figure 5, the MDA-MB-435 cells incubated with various concentrations of α-T grew normally (no change in o.d. reading) and were comparable to the control cells, where there was no addition of α-T or TRF. The effect of various concentrations of TRF on the cells showed,

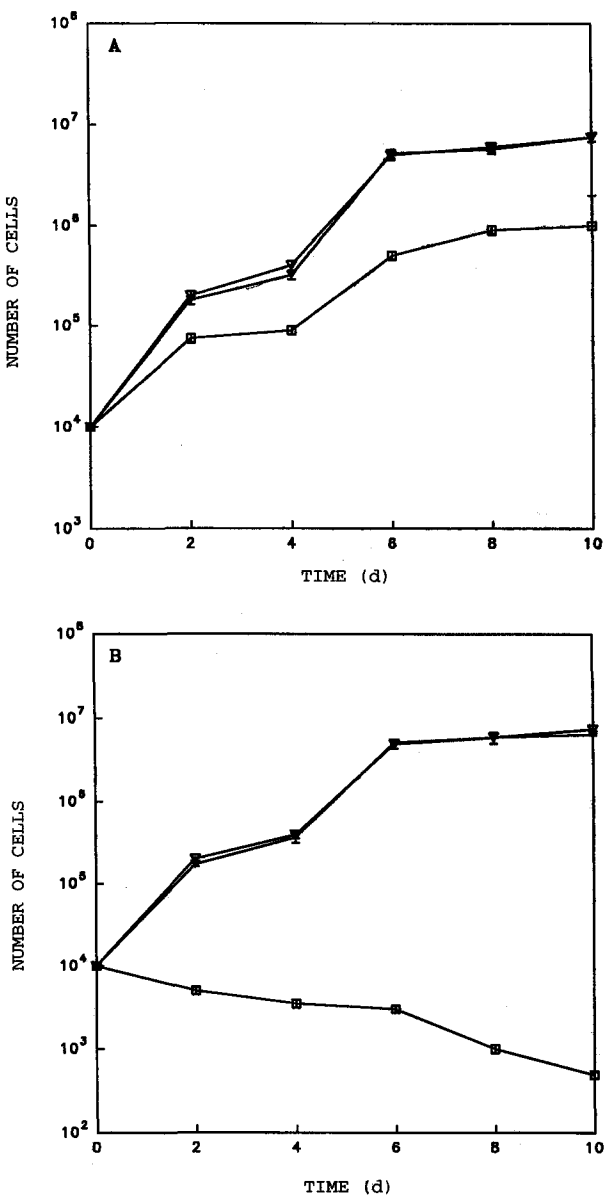

FIG. 3. Comparison of the inhibitory effects of α-tocopherol (α-T) (▼) and tocotrienol-rich fraction (TRF) (□) on MDA-MB-435 cell growth. TRF and α-T were added at concentrations of 180 (A) and 500 µg/mL (B). Neither TRF nor α-T was added to control cells (▽). Points are the average of mean values from three experiments ± SE.

however, that the cells were viable only up to 200 µg/mL; thereafter the o.d. curve dropped rapidly, indicating a substantial loss of cells.

DISCUSSION

As many dietary antioxidants have been shown to prevent cancer in animal studies, the potential activity of vitamin E (tocopherols and tocotrienols) is of interest. Although tocotrienols are known to possess a lower biological "vitamin E activity" than tocopherols (14,25), recent findings suggest that α-tocotrienol is a better antioxidant than α-T (15). In light of the fact that palm oil does not promote chemically-

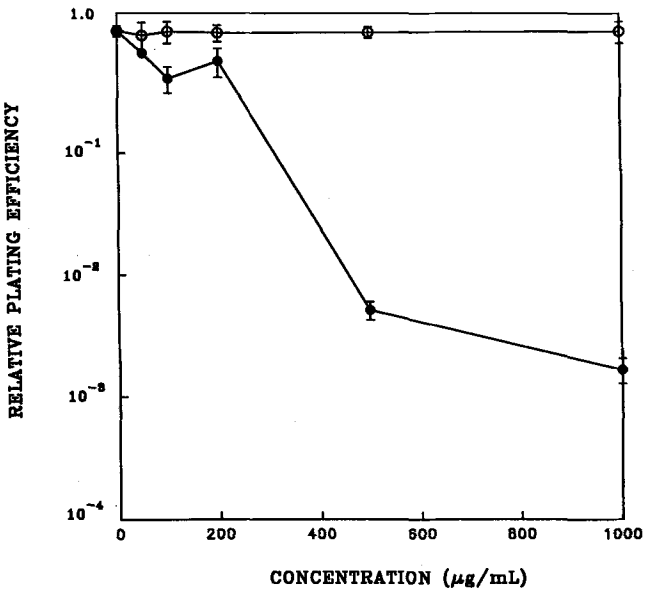

FIG. 4. Effect of tocotrienol-rich fraction (TRF) (●) and α-tocopherol (α-T) (○) on the plating efficiency (PE) of MDA-MB-435 cells relative to control PE without either compound. Cells were grown in 50- or 100-mm tissue culture dishes with or without a given concentration of either TRF or α-T. The colonies were counted 14 d later. Points are mean values ± SD.

induced mammary carcinogenesis when fed at a high level to rats in a semipurified diet, and this failure to promote appears to be due to the TRF of palm oil, we tested the effects of tocotrienols and α-T on human breast cancer cells in culture.

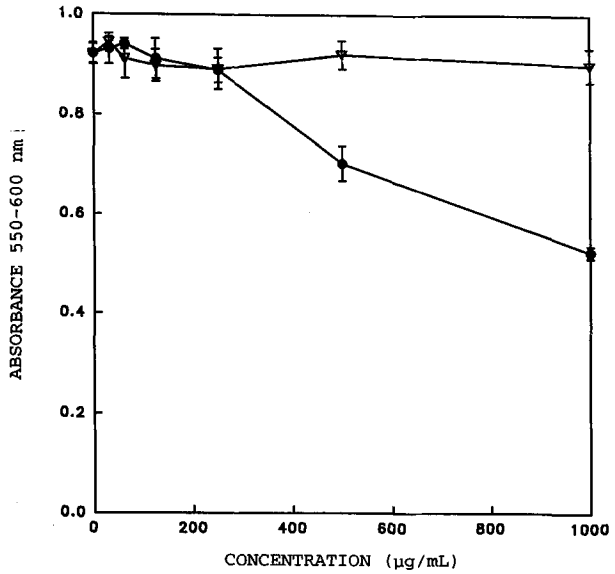

FIG. 5. Effect of tocotrienol-rich fraction (TRF) (●) and α-tocopherol (α-T) (▽) on the viability of MDA-MB-435 cells. MDA-MB-435 cells were incubated with various concentrations of TRF and α-T. 3,(4,5-Dimethylthiazol-2-yl)2,5-diphenyltetrazolium bromide (25 μL) was added, and after 3 h, 100 μL of SDS extraction buffer was added and o.d. measurements made at 570 nm. Points are the average of mean values from three experiments ± SE.

We found that TRF markedly inhibited the proliferation of MDA-MB-435 human breast cancer cells in culture, having a concentration required to inhibit cell proliferation by 50% of 180 μg/mL, whereas α-T had no effect at concentrations up to 1000 μg/mL. We also found that in testing the compounds on the growth of these cells over a period of ten days, TRF inhibited the growth by 50% at 180 μg/mL (Fig. 3A) and completely inhibited growth at 500 μg/mL (Fig. 3B). Also, these cells were viable in the presence of TRF at concentrations up to 200 μg/mL, and they were viable at all concentrations used for α-T (Fig. 5). The ability of the cells to form colonies was not altered with α-T, but TRF inhibited the PE (Fig. 4). Because TRF in palm oil is made up of 30% α-T and because in our study α-T appeared to have no effect at the same concentration, this inhibition is likely due to the presence of tocotrienols.

Our present results confirm the findings of Komiyama and Yamaoka (12), who showed growth inhibition of human and mouse tumor cells (H69, HeLa, and P388) when the cells were exposed to tocotrienols for 72 h *in vitro*. Tocopherols, on the other hand, showed no significant effect. Also, vitamin E (α-T) supplementation alone has been ineffective in inhibiting the development of mammary carcinomas in rats treated with carcinogenic chemicals (26–28). In addition, initiation of colon tumors induced by the carcinogen, dimethylhydrazine, and mammary tumors induced by DMBA, were increased by feeding diets deficient in vitamin E tocopherols (29,30). Horvath and Ip (31), however, presented evidence that α-T, although ineffective by itself, was able to potentiate the ability of selenium to inhibit the development of mammary carcinomas induced by DMBA in female rats fed a high-fat diet. Tocotrienols, on the other hand, have been shown to inhibit the increase in plasma γ-glutamyltranspeptidase activity, a recognized marker of early neoplasia in rats treated with the hepatocarcinogen, 2-acetylaminofluorene (32). Survival of mice receiving transplanted tumor cells was also increased if they were fed tocotrienol in a dose-responsive way (11).

The exact reasons for the higher sensitivity of the breast cancer cells to tocotrienols are unknown, but the following possibilities can be suggested: (i) Tocotrienols may more easily cross the cell membrane, and (ii) they may undergo slow degradation within the cell. These observations indicate that tocotrienols merit further investigation as possible agents for breast cancer prevention and/or treatment.

ABSTRACT: The oxidative susceptibilities of low density lipoproteins (LDL) isolated from rabbits fed high-fat atherogenic diets containing coconut, palm, or soybean oils were investigated. New Zealand white rabbits were fed atherogenic semisynthetic diets containing 0.5% cholesterol and either (i) 13% coconut oil and 2% corn oil (CNO), (ii) 15% refined, bleached, and deodorized palm olein (RBDPO), (iii) 15% crude palm olein (CPO), (iv) 15% soybean oil (SO), or (v) 15% refined, bleached, and deodorized palm olein without cholesterol supplementation [RBDPO(wc)], for a period of twelve weeks. Total fatty acid compositions of the plasma and LDL were found to be modulated (but not too drastically) by the nature of the dietary fats. Cholesterol supplementation significantly increased the plasma level of vitamin E and effectively altered the plasma composition of long-chain fatty acids in favor of increasing oleic acid. Oxidative susceptibilities of LDL samples were determined by Cu^{2+}-catalyzed oxidation which provide the lag times and lag-phase slopes. The plasma LDL from all palm oil diets [RBDPO, CPO, and RBDPO(wc)] were shown to be equally resistant to the oxidation, and the LDL from SO-fed rabbits were most susceptible, followed by the LDL from the CNO-fed rabbits. These results reflect a relationship between the oxidative susceptibility of LDL due to a combination of the levels of polyunsaturated fatty acids and vitamin E.

Lipids 30, 1145–1150 (1995).

Low density lipoprotein (LDL) has been identified as the principal proatherogenic lipoprotein (1,2). The accumulation of LDL-derived cholesterol in cells of the arterial wall is now widely believed to result from the chemical modification of LDL, especially the oxidatively modified LDL that has been detected in atherosclerotic lesions (3,4). Oxidized and mildly oxidized LDL, either wholly or the oxidized products leaving the particles, can have a number of deleterious effects, including chemotaxis for monocytes (5), inhibition of nitric oxide-mediated relaxation of coronary tone (6), and stimulation of inflammatory cell accumulation (7). Recognition and uncontrolled uptake of the oxidized LDL by macrophages lead to a chain of biochemical events which may result in the formation of foam cells, fatty streaks and, later, atherosclerosis.

Diet has been a major focus of research in relation to the environmental factors in cardiovascular disease. The development of atherosclerosis is an important aspect of cardiovascular disease and is influenced by plasma cholesterol levels (8). Plasma cholesterol levels are modulated by the amount and type of dietary fats and various micronutrients, such as tocotrienols (9,10). High levels of LDL-cholesterol are, however, not a sufficient condition for atherosclerosis, as the incidence of coronary heart disease among hypercholesterolemic individuals remains variable (11). This variation is a consequence of different biochemistry among individuals, of which modification and metabolism of LDL are probably important. Substantial and compelling evidence supports the hypothesis that oxidation of LDL plays an important role in atherogenesis (1,12). The inhibitory effect of antioxidants in the oxidation of human LDL is well documented (13), but there is still inadequate information on the influence of various fats with varying unsaturation on this process, or on the *in vivo* effects of antioxidants on LDL oxidation. The present paper examines the *ex vivo* oxidative susceptibilities of LDL derived from rabbits fed atherogenic diets containing palm oil as compared to diets containing coconut and soybean oils.

MATERIALS AND METHODS

Animals and diets. New Zealand white rabbits (six-month-old) were randomly divided into five groups and fed *ad libitum* semisynthetic diets (Table 1) containing 5% (w/w) commercial pellets, 95% (w/w) purified substances consisting of (i) 13% coconut oil plus 2% corn oil (CNO, n = 5), (ii) 15% refined, bleached and deodorized palm olein (RBDPO, n = 6), (iii) 15% crude palm olein (CPO, n = 4), or (iv) 15% soybean oil (SO, n = 6), all supplemented with cholesterol (5 g/kg), or

Choline dihydrogen citrate	2
Dietary fat	150

[a]Fifty grams of commercial-rabbit feed pellets, 950 g of a mixture of feed materials (from U.S. Biochemical Corp., Cleveland, OH) and dietary fats, and 5 g of cholesterol were blended and repelletized.

(v) RBDPO diet without supplementation of cholesterol [RBDPO(wc), n = 5]. All the synthetic diet components and cholesterol were purchased from United States Biochemical Corporation (Cleveland, OH). Blood samples were collected from overnight-fasted rabbits before and after a 12-wk dietary treatment.

Oxidation of LDL. LDL (density 1.019–1.063 g/mL) was isolated from plasma according to a modified method of Havel *et al.* (14), using sequential density ultracentrifugation in KBr solution at 4°C. The LDL was dialyzed at 4°C for 24 h against four changes of 50–100 vol of deoxygenated phosphate-buffered saline (0.01 M, pH 7.4). Dialyzed LDL samples were diluted with oxygen-saturated phosphate-buffered solution (0.01 M, pH 7.4) to 0.1 mg protein/mL and incubated at 37°C. Oxidation was initiated by addition of copper (II) chloride to a final concentration of 4.0 μM. Absorbance at 234 nm was continuously monitored by a U-200 Hitachi spectrophotometer (Tokyo, Japan) (15,16).

Analyses. Lipids from plasma and LDL were extracted by the method of Folch *et al.* (17). Plasma vitamin E content was analyzed by a modified method of Lang *et al.* (18) using normal-phase high-performance liquid chromatography equipped with a fluorescence detector. The plasma and LDL lipids were saponified with ethanolic potassium hydroxide containing 1 mg of butylated hydroxytoluene in vacuum-sealed tubes for 2 h at 100°C. After acidification, free fatty acids and methyl esters were extracted with hexane and methylated with boron trifluoride–methanol (19). The total fatty acid composition was analyzed using an HP5970A gas chromatograph (Hewlett-Packard, Avondale, PA) equipped with a 30-m 0.5-μm DB-23 capillary column from J&W Scientific (Folsom, CA).

Statistics. The Student's *t*-test was used for statistical evaluation of the results, and differences at $P < 0.05$ were considered significant.

RESULTS

The fatty acid compositions of various dietary fats in the diets are given in Table 2. The CNO-based diet is rich in saturated fatty acids (lauric, 12:0; and myristic, 14:0), the palm oil diets [RBDPO, CPO, and RBDPO(wc)] are rich in oleic (18:1) and palmitic (16:0) acids, and the SO diet is rich in polyunsaturated fatty acids, mainly linoleic acid (18:2). The compositions of intrinsic vitamin E components in the various diets are given in Table 3, with the palm and soybean oil diets having about the same total vitamin E content, whereas the coconut oil diet (CNO) has a slightly lower vitamin E content. Fatty acid profiles of the plasma and LDL derived from rabbits on the various diets are given in Tables 4 and 5. Substantial changes in the composition of long-chain fatty acids were observed. The levels of oleic acid for all rabbits on diets supplemented with cholesterol were seen to increase quite remarkably after a 12-wk dietary treatment, particularly in the palm oil groups (RBDPO and CPO), which showed significantly higher plasma and LDL oleic acid content than those from the CNO and SO groups. The SO-fed rabbits showed increases in linoleic acid levels in plasma and LDL which were about twofold higher than those found in other rabbits.

Supplementation with dietary cholesterol generally increased the yield of LDL which were required to carry out the oxidation experiments. The susceptibility of the LDL samples to Cu^{2+}-oxidation is reflected by the lag time and lag-phase slope observed in the plots of absorption at 234 nm vs. time (typical results are shown in Fig. 1). Data on lag times, lag-phase slopes, propagation phase, etc. are given in Table 6. LDL samples from palm oil groups were shown to have longer lag times than CNO and SO groups in the oxidation. As determined by the slope of the lag phase, the rates of oxidation of LDL derived from CNO and SO groups were shown to be about sixfold faster than LDL from the palm oil groups. However, during the propagation phase, the oxidation rate of the LDL from the SO group was about threefold higher than the other groups. The high absorption at the end of the oxidation for each sample of the SO group was indicative of a

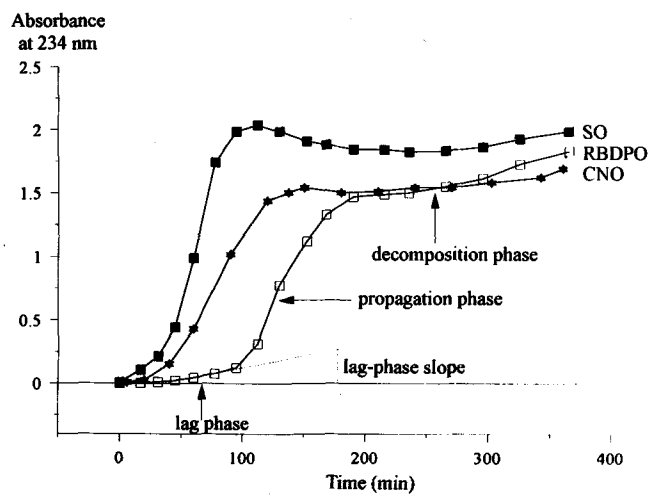

FIG. 1. Time course of absorption at 234 nm for the Cu^{2+}-catalyzed oxidation of low density lipoprotein isolated from the rabbits fed atherogenic diets containing coconut oil and corn oil (CNO); refined, bleached, and deodorized palm olein (RBDPO), and soybean (SO).

larger amount of conjugated dienes formed from the high content of polyunsaturated fatty acids (PUFA).

DISCUSSION

The dietary regimes used provided three diverse types of dietary fats, i.e., highly saturated (coconut), moderately saturated, and monounsaturated (palm), as well as highly polyunsaturated (soybean) fatty acids. The fatty acid distributions of the diets (Table 2) have undergone considerable modulation by the time they are incorporated into the LDL particles, so that their distribution in plasma only partially reflects the nature of fatty acids of the diets (Tables 4,5). The PUFA levels of the LDL particles increased noticeably with the SO-diet; those with the CNO and palm oil [i.e., RBDPO, CPO, and RBDPO(wc)] diets remained virtually unchanged. Despite the fact that the CNO diet contains mainly medium-chain fatty acids, the incorporation of these fatty acids in the LDL is minimal, a reflection of the different metabolic pathway for the handling of short- and medium- chain fatty acids as compared to the long-chain fatty acids.

TABLE 6
Effects of the Levels of Polyunsaturated Fatty Acids (PUFA) and Vitamin E on the Oxidative Susceptibility of Low Density Lipoproteins[a]

Dietary group	n	Lag time (min)	Lag-phase slope ($\times10^{-4}$/min)	Propagation-phase slope $\times10^{-3}$/min	Maximum absorbance at 234 nm	Vitamin E (μM)	PUFA (%)
CNO	5	56 ± 6^b	20.0 ± 9.0	15 ± 4	1.52 ± 0.35	38 ± 0.14^b	12.7 ± 2.4^b
RBDPO	6	111 ± 23^c	2.9 ± 0.9	19 ± 4	1.35 ± 0.08	41 ± 31^b	13.3 ± 2.7^b
CPO	4	103 ± 25^c	2.3 ± 1.3	15 ± 6	1.19 ± 0.02	59 ± 25^b	8.4 ± 2.1^b
SO	6	54 ± 17^b	18.0 ± 7.0	45 ± 4	2.18 ± 0.10	40 ± 16^b	22.4 ± 4.7^c
RBDPO(wc)	5	110 ± 8^c	3.5 ± 0.5	19 ± 5	1.26 ± 0.17	8.8 ± 3.7^c	10.7 ± 0.4^b

[a]Abbreviations as in Tables 2 and 3. Values are means ± SD. n, Number of rabbits in each dietary group. Lag-phase slope (absorbance unit/min) is the increase of absorbance at 234 nm with time during the lag phase. Propagation-phase slope (absorbance unit/min) is the increase of absorbance at 234 nm with time during the propagation phase.
[b,c]Means in the same column with different superscripts indicate differences are statistically significant ($P < 0.05$).

Although the actual initiation processes of the peroxidation of LDL are not precisely known, accumulated evidence indicates that the end products are from lipid peroxidation. Oxidation studies using *in vitro* experiments have suggested that the properties of LDL particles oxidized *in vitro* may be similar to those purported to arise *in vivo* (20). Oxidative stability of LDL particles can be conveniently studied using the Cu^{2+}-catalyzed oxidation established by Esterbauer *et al.* (16). The main targets of this oxidation are the PUFA (mainly linoleic, but also include, to a small extent, linolenic and arachidonic acids), and the formation of conjugated diene hydroperoxides (absorption at 234 nm) provides a kinetic profile containing lag, propagation, and decomposition phases (as shown in Fig. 1). It is noted that because this is a lipid peroxidation process, the inhibition of autoxidation in LDL can occur by antioxidants such as α-tocopherol, carotenoids, ubiquinol, etc. After the depletion of the antioxidants, a rapid oxidation occurs (propagation phase), and finally, a plateau is reached (decomposition phase) when the breakdown of peroxides occurs. The lag time (and also the lag-phase slope) which precedes the onset of rapid lipid autoxidation is important as it reflects the induction period of radical oxidation and is an indicator of the oxidative susceptibility of the LDL.

The results shown in Figure 1 and Table 6 provide comparisons of the lag times and lag-phase slopes for the oxidation of LDL resulting from the three dietary fats. The lag times and lag-phase slopes were reflective of the dietary fats, with the LDL from rabbits fed palm oil diets having the highest oxidative stability. Previous *in vitro* work (21) has indicated that increasing levels of antioxidants (vitamin E, ubiquinols, carotene, etc.) can effectively prolong lag times. The present data (CNO vs. CPO, $P < 0.1$) appear to support the observation that the vitamin E concentration is an important factor in determining the oxidative stability of LDL derived from rabbits fed with various types of dietary fats; LDL samples from rabbits supplemented with vitamin E or C are actually more stable than LDL obtained from rabbits deprived of these antioxidants in their diet (Goh, S.H., and Hew, N.F., unpublished data). However, there may be other antioxidant components, e.g., ubiquinols (Choo, Y.M., and Hazura, H., unpublished data), in palm oil which may be important but have not yet been considered. Tocotrienols may not be directly involved in the inhibition of oxidation as they are present in very low concentrations in LDL. Although α-tocopherol is selectively accumulated in the plasma and liver (22), the tocotrienols appear not to be, and apparently are excreted. However, tocotrienols are expected to remain as lipid antioxidants throughout the processes of ingestion, absorption, and transport in chylomicrons and very low density lipoproteins (VLDL). The plasma vitamin E level is generally low in normal rabbits but increased with cholesterol feeding, as noted in previous reports (22). This may be due to the cholesterol-induced increase in formation of various lipoproteins which are carriers of vitamin E. Vitamin E present in LDL is probably insufficient to effectively protect against oxidation of all the PUFA (23). Results from the CPO diet, which is unrefined liquid palm oil, are also noteworthy in that although the oil is rich in carotenes in addition to vitamin E (in contrast to RBD palm olein which lacks carotenes), the carotenes in the diet did not confer increased stability to the LDL. This is due to the fact that only small amounts of carotenes are found in the plasma (or LDL) and are metabolized rapidly to vitamin A.

Although many studies have focused on the oxidation of LDL, not much is known about the actual chemistry of oxidation of lipoproteins under *in vivo* conditions. Recent work (24) has indicated that without vitamin C, vitamin E is not only insufficient to protect LDL against oxidation, but may even be prooxidant under certain conditions. Other minor antioxidants, notably ubiquinols, are more effective antioxidants in aqueous lipid emulsions. Furthermore, there is considerable heterogeneity among lipoproteins, and recent evidence indicates that high density forms of LDL and lipoprotein(a) may be more atherogenic (25). The observed relationship between the oxidative stability of LDL and PUFA and vitamin E levels is very likely indicative of the presence of preformed or endogenous peroxides in the LDL. It is believed that oxidative damage of lipids in LDL may have occurred in its precursor particles (e.g., chylomicrons and VLDL), in which case the presence of the various types of dietary antioxidants will be beneficial.

Whereas levels of antioxidants may be an important factor in LDL oxidative stability, we have found that the degree of polyunsaturation of the LDL is also important. The propagation phase for the oxidation of LDL from SO-rabbits is much more rapid and is directly dependent on the LDL PUFA content. In terms of the degree of polyunsaturation, the CNO-diet (because corn oil was also added to provide essential fatty acids) has a slightly higher ratio of PUFA compared to palm oil diets if the medium- and short-chain (≤C12) fatty acids are neglected. The LDL from CNO rabbits show essentially similar lag- phase slopes for those of SO-rabbits, but much higher ones than those from the various palm oil diet groups. The shorter lag times and larger lag-phase slopes for LDL from rabbits fed coconut oil and SO diets are apparently the result of oxidative stress which is influenced by high PUFA content and low vitamin E levels. The tendency for rapid and extensive oxidation (highest absorbance) of LDL from the SO-diet would be theoretically an undesirable feature, as oxidized LDL has been demonstrated to be extensively taken up by macrophages. Present results support the previous report (26) that the monounsaturated oleic acid offers oxidative resistance to LDL similar to saturated fatty acids. The LDL of rabbits fed atherogenic (RBDPO) and nonatherogenic [RBDPO(wc)] palm oil diets show similar oxidative stability. Aside from the presence of similar vitamin E levels, this may be chiefly attributed to their unique fatty acid profiles, in that palmitic and oleic acids constituted about 75% of the total fatty acids.

Although coronary heart disease and atherosclerosis have generally been linked to excessive consumption of cholesterol and some saturated fats, the oxidative resistance of LDL and/or its protection are likely to be equally important factors for consideration in dietary recommendations. For example, epidemiological studies (27) have suggested that antioxidants in the plasma are associated with lower rates of cardiovascular disease. In many countries where relatively high fat/cholesterol diets are not correlated with high mortality from cardiovascular disease, there is usually a high consumption of vegetables and fruits which provides natural antioxidants. The "French paradox," an apparent compatibility of a high-fat diet with low incidence of coronary atherosclerosis, has been attributed to phenolic antioxidants from red wine (28) apart from a high consumption of fruits and vegetables. In view of the suggested importance of oxidative stability of LDL, adequate amounts of dietary antioxidants and a high monounsaturated fat diet with moderate amounts of saturated and polyunsaturated fat may be optimal.

Dietary Lipid Modification of Myocardial Eicosanoids Following Ischemia and Reperfusion in the Rat[1]

Mahinda Y. Abeywardena* and John S. Charnock

CSIRO, Division of Human Nutrition, Glenthorne Laboratory, O'Halloran Hill, SA 5158, Australia

ABSTRACT: Several different edible oils were compared for their ability to modify eicosanoid biosynthesis following experimentally-induced myocardial ischemia and reperfusion in the rat. Two types of palm oil [neutralized, bleached, and deodorized (NBDPO) and refined, bleached, and deodorized (RBDPO)] and partially hydrogenated soybean oil (SBO) were tested against a diet supplemented with sunflower seed oil (SSO) rich in n-6 polyunsaturated fatty acids (PUFA). Fish oil (FO) rich in n-3 PUFA, with its known cardioprotective actions, served as an internal reference point for the study. Test oils were fed as a 12% (w/w) supplement for nine months before the induction of myocardial ischemia and reperfusion. Palm oil diets exerted effects indistinguishable from the SBO group against cardiac arrhythmia, which occurred following alterations to coronary blood flow. Arrhythmic potentials, as expressed by a hierarchical scale (0–9) of arrhythmia score, were: SSO, 1.5 ± 0.5; FO, 0.9 ± 0.4; SBO, 3.1 ± 0.5*; NBDPO, 3.2 ± 0.5*; RBDPO, 3.3 ± 0.6*; *$P < 0.05$ vs. SSO. Following ischemia and reperfusion, both SSO and RBDPO groups tended to show an increase in myocardial prostacyclin, with the effect being more prominent in the RBDPO group (SSO, 10%; RBDPO, 25%). Thromboxane production was reduced in the FO group. Interestingly, cardiac muscle from both FO and palm oil groups displayed a reduced capacity to produce 12-hydroxyeicosatetraenoic acid SSO, 591.9 ± 95.8; SBO, 375.5 ± 48.9; NBDPO, 287.2 ± 64.7*; RBDPO, 230.9 ± 80.2**; FO, 203.7 ± 81.4** (ng/g dry wt, *$P < 0.05$, **$P < 0.01$). No clear relationship was seen between the availability of 20:4n-6 in myocardial phospholipids and eicosanoid profile. Data suggests that fatty acid composition of edible oils is not the only determinant of arrhythmic vulnerability and eicosanoid production.

Lipids 30, 1151–1156 (1995).

Although the influence of dietary fat on the pathogenesis of coronary heart disease has been recognized for several decades (1), direct evidence for the modification of arrhythmic vulnerability by dietary fatty acids has emerged only recently (2). For example, findings in this laboratory identify saturated animal fat as proarrhythmic, while either n-3 or n-6 polyunsaturated fatty acids (PUFA) possess cardioprotective actions in several whole animal models of sudden cardiac death (3,4). Interestingly, dietary monounsaturated fatty acids, such as olive oil, have been found to exert an effect similar to those of saturated fat following experimentally-induced myocardial ischemia and reperfusion (5). These observations therefore tend to implicate the fatty acid profile of edible oils and fats as a key determinant of arrhythmic vulnerability.

The biochemical basis for dietary lipid modification of arrhythmogenesis has not yet been identified with certainty as many factors influence cardiac rhythm, and because the immediate cause may vary with the type of arrhythmic stimulus (6,7). Nevertheless, changes in the myocardial production of eicosanoids are thought to be central to these effects as this group of lipid mediators represents a key regulatory mechanism in the cardiovascular system (7,8). Furthermore, their production is influenced by changes in the availability of precursor/inhibitor fatty acids in the cell (9). Therefore, changes in the composition of the myocardial membranes through dietary means may influence cardiovascular function due to modifications in the endogenous eicosanoid profile. Indeed, recent findings from this laboratory indicate that antiarrhythmic actions of dietary fish oil (FO) may be mediated through an eicosanoid-related mechanism (10).

In the present study, we have compared the effect of long-term (nine month) feeding of several different edible oils having variable fatty acid profiles on eicosanoid metabolism in rats after experimentally-induced brief regional myocardial ischemia and reperfusion. The experimental protocol employed in the present study also allowed an investigation of the vulnerability to and severity of cardiac arrhythmias, which originate in consequence to changes in coronary blood flow, to be made in these animals. A partially hydrogenated soybean oil (SBO) preparation and two different types of palm oils—refined, bleached, and deodorized (RBDPO); and neutralized, bleached, and deodorized (NBDPO)—were compared against sunflower seed oil (SSO) that was rich in linoleic acid (18:2n-6). A diet rich in n-3 PUFA of marine origin (MaxEPA, R.P. Scherer Holdings, Ltd., Melbourne, Australia) that has been reported to possess potent cardioprotec-

tive qualities (2–5) also was included as a positive control for the study.

MATERIALS AND METHODS

Animals and diets. Weanling male rats of the hooded Wistar type were maintained on standard rat chow for four weeks and then divided into five experimental groups (n = 18 per group) and fed different lipid-supplemented diets for nine months. The preparation and storage of various diets and the feeding protocol were as reported previously (11,12). In brief, standard rat diets (Milling Industries, Adelaide, Australia) were supplemented (12% w/w) with the respective dietary oil, which included SSO; NBDPO; RBDPO; SBO, and purified FO (MaxEPA® c.f.). Soybean oil was only partially hydrogenated to yield melting characteristics similar to that of palm oil. SSO was from Nuttelex Ltd. (Victoria, Australia), and palm oils and SBO were obtained from the Palm Oil Research Institute of Malaysia (Bandar Baru Bangi, Malaysia). Standard rat diet and the lipid-supplemented diets were routinely analyzed for the total fat content, peroxide value, and the fatty acid composition (11–13). In addition, each new batch of the standard rat diet was fully analyzed for protein, fat, fiber, and vitamin levels, as well as for major trace elements, by an independent laboratory (Australian Government Analytical Laboratory, Adelaide, Australia) in order to minimize batch variations. Animals were housed in stainless-steel wire cages with free access to food and water and cared for according to the National Health and Medical Research Council (Canberra, Australia) and CSIRO (Canberra, Australia) guidelines for experimentation in animals.

Lipid analyses. Lipids were extracted with chloroform/methanol (2:1, vol/vol, containing 0.01% butylated hydroxytoluene as antioxidant), and were purified as described previously (12,13). Fatty acid methyl esters were prepared by treatment with sodium methoxide and were further purified using silicic acid columns (Biosil A; BioRad Laboratories, Richmond, CA). A gas chromatograph (HP 5890), equipped with a 30-m long megabore column (i.d. 0.53 mm, DB-23; J & W Scientific, Folsom, CA) was used for the analysis of fatty acid methyl esters.

Myocardial ischemia and reperfusion. The procedure is similar to that previously described in detail (3). Overnight fasted animals were anesthetised with pentobarbitone sodium (60 mg/kg, i.p.) and artificially ventilated before thoracotomy and opening of the chest cavity. The heart was exteriorized and a loose silk ligature placed around the left anterior descending coronary artery (3,5). After a 15-min stabilization period, regional myocardial ischemia was induced (5 min) by tightening the ligature. Arrhythmias induced by reperfusion were assessed during a 10-min period after releasing the occlusion and restoring blood flow. Any survivors were killed by exanguination.

Arrhythmias were monitored by continuous recording of electrocardiogram and blood pressure and identified as ventricular premature beats (VPB), ventricular tachycardia (VT), or ventricular fibrillation as reported earlier (3,5). The severity of arrhythmia was assessed by computing an arrhythmia score (A.S.) which takes into account both the frequency and duration of various parameters of arrhythmia (3,14). At the end of the experiment, the heart was removed and perfused with buffer, and the underperfused region was estimated by dye exclusion of Evans blue dye. The nonischemic and ischemic regions of the heart were quickly frozen in liquid N_2 and stored at –80°C for biochemical and analytical studies.

Measurement of cyclooxygenase metabolites. Frozen myocardial tissue was pulverized using a precooled (in liquid N_2) stainless-steel mortar and pestle. The powdered tissue was divided into several portions and suspended in ice-cold calcium-free Tyrodes medium (mM: 138 NaCl, 2.4 KCl, 3.1 Na_2HPO_4, 1.2 KH_2PO_4, 0.5 $MgCl_2$, pH 7.4). The samples were washed several times to remove any residual contamination with blood and incubated at 37°C for 45 min in this medium containing 1 mM Ca^{++} (9). Samples were rapidly cooled on ice and centrifuged at the end of the incubation period. Aliquots of the supernatant were analyzed for the stable metabolites of prostacyclin (PGI_2; measured as 6-keto-prostaglandin $F_{1\alpha}$ and thromboxane A_2 (TxA_2; quantified as thromboxane B_2) by enzyme-immunoassay technique using kits purchased from the Caymen Chemical Co. (Ann Arbor, MI).

Measurement of lipoxygenase products. Powdered myocardial tissue was washed several times as described previously and finally incubated in a modified Tyrodes solution which contained, in addition to the aforementioned, L-cysteine (2 mmol/L) and increased Ca^{++} and Mg^{++} (2 mmol/L). After a 5-min preincubation period, the tissue suspensions were stimulated with ionophore, A23187 (0.5 μM), and incubated for a further 40 min. The reaction was terminated by cooling to 0°C and centrifugation. Supernatants were acidified (pH 3.5) with HCl before loading onto a C-18 Sep Pak (Waters-Millipore, Milford, MA) cartridge. The Sep Pak was washed with solutions of acetonitrile and water (25 and 20%, respectively) before the compounds of interests were eluted with acetonitrile. The solvent was removed under reduced pressure using a high-speed concentrator (Savant Speedvac SC100; Savant Instruments, Farmindale, NY), and samples were reconstituted in high-performance liquid chromatography-grade methanol. Recovery experiments using external standards showed a 65–70% efficiency of extraction. Dry weights of the tissue pellets were determined after extraction with 2 mL of acetone.

Lipoxygenase products were separated and quantified by high-performance liquid chromatography (Pharmacia-LKB, Bromma, Sweden) using a Brownlee (Applied Biosystems, Foster City, CA) Velosep C-18 reverse-phase analytical column (3.2 × 100 mm; 3 μm). The mobile phase consisted of 77.5% methanol and 0.1% trifluoroacetic acid with the flow rate maintained at 0.5 mL/min. Absorbance of the column eluent was continously monitored using two detectors in series, an LKB 2141 variable wavelength monitor set at 278 nm (for leukotrienes) and an LKB 2151 variable wavelength

monitor set at 235 nm for the detection of hydroxy fatty acids. Quantification was based upon peak areas relative to those of a standard mixture which contained prostaglandin B_2, leukotriene B_4, leukotriene C_4, and 5-, 12-, and 15-hydroxy-eicosatetraenoic acids. Data was collected and processed with the aid of a Nelson Analytical 920 interface and a Nelson 3000 series chromatography data system software package (PE Nelson, Cupertino, CA).

Statistics. The effects of different diets were compared against the SSO-supplemented diet, which was regarded as the reference point of the study. Data were analyzed using one-way analysis of variance followed by Tukey's test for multiple comparisons (15) between pairs at the 5% level or better.

RESULTS

Table 1 shows the major fatty acids of the experimental diets used in this study. It is clear that both the SSO and SBO diets are relatively rich in linoleic acid (43 and 59%, respectively) compared to the other three test diets, which contained low 18:2 levels (7–13%). Palm oil diets contained high proportions of palmitic (38%) and oleic (37%) acids, and no difference in fatty acid composition was evident between the NBDPO- and RBDPO-supplemented diets. The FO diet contained about 25% of total n-3 PUFA, with the two major fatty acids being eicosapentaenoic acid (EPA; 20:5n-3, 13%) and docosahexaenoic acid (22:6n-3, 9%). No *trans* fatty acid was detected in the SBO diet as the total *trans* fatty acid content of this SBO supplement was relatively small (<6%; data not shown).

All the diets were well accepted by the rats, as is evident from the consistent gains in body weights throughout the long-term (nine months) feeding period. The animals were healthy at the end of the pre-feeding period, and no obvious signs of any disease (e.g., yellow fat) were detected in major body organs at autopsy. The final body weights at the conclusion of the experiment were: SSO, 564.0 ± 8.5 g; SBO, 552.9 ± 7.4 g; NBDPO, 567.3 ± 5.9 g; RBDPO, 561.6 ± 7.1 g; and FO, 574.4 ± 8.1 g; n = 18 per group, $P > 0.05$.

TABLE 1
Major Fatty Acids[a] of Experimental Diets

	Diet[b]				
Fatty acid	SSO	SBO	NBDPO	RBDPO	FO
16:0	8.2	12.5	38.5	37.2	18.4
16:1	0.2	0.5	—	—	5.3
18:0	4.8	7.9	4.5	4.6	3.9
18:1n-9	22.0	25.2	36.3	37.0	14.6
18:2n-6	58.9	43.5	13.5	13.1	7.1
18:3n-3	0.9	2.8	0.8	0.7	1.4
20:1	—	—	—	—	4.3
20:5n-3	—	—	—	—	12.8
22:5n-3	—	—	—	—	1.8
22:6n-3	—	—	—	—	9.1

[a]Values are expressed as wt% and are the means of at least eight separate determinations.

[b]SSO, sunflower seed oil; SBO, partially hydrogenated soybean oil; NBDPO, neutralized, bleached, and deodorized palm oil; RBDPO, refined, bleached, and deodorized palm oil; and FO, fish oil.

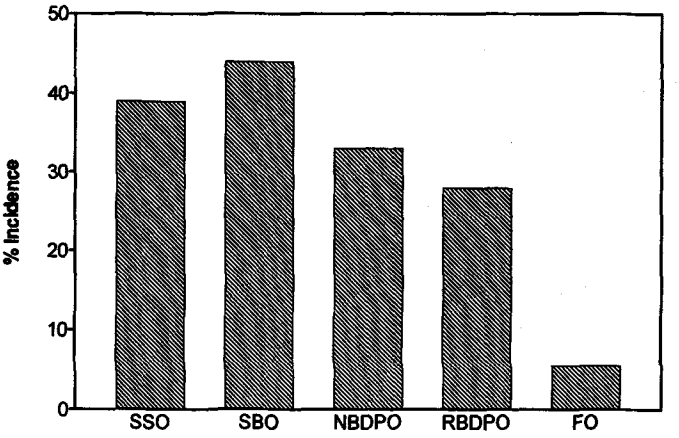

FIG. 1. Incidence (%) of ventricular tachycardia (VT) during experimentally-induced myocardial ischemia (5 min) in rats. Animals were fed different lipid supplemented diets for nine months before being subjected to regional myocardial ischemia and reperfusion as described in the text. SSO, sunflower seed oil; SBO, partially hydrogenated soybean oil; NBDPO, neutralized, bleached, and deodorized palm oil; RBDPO, refined, bleached, and deodorized palm oil; FO, fish oil; n = 18 per dietary group.

The effect of long-term feeding of different lipid supplements on various parameters of cardiac arrhythmia are presented in Figure 1 and in Table 2. As described in the Materials and Methods section, regional myocardial ischemia (5 min) was induced by ligating the left coronary artery followed by restoration of blood flow (reperfusion) for a 10-min period.

Figure 1 shows the % incidence of VT during ischemia where the protective effects of dietary n-3 PUFA can be seen. For example, in the reference group (SSO diet) 7 animals (7/18 or 39% incidence) displayed VT compared to only one animal (1/18) in the FO supplemented diet group. RBDPO and NBDPO groups showed 28 and 33% VT incidences, respectively, whereas in the SBO group 8/18 rats (44%) had developed tachycardia. However, these episodes of VT during this brief ischemic episode did not deteriorate into ventricular fibrillation in a majority of the animals, irrespective of the dietary group (data not shown).

The main parameters of cardiac arrhythmia following the restoration of blood flow (reperfusion) to the ischemic region are presented in Table 2. It is evident that only the NBDPO dietary group registered an increase in total VPB during the 10-min period compared to the SSO group ($P < 0.01$). As seen during the brief ischemic phase (Fig. 1), FO feeding resulted in the lowest incidence of VT among all groups. The mean duration of VT was also the lowest in the FO group, whereas NBDPO-fed rats displayed an increase relative to the linoleate rich SSO diet ($P < 0.05$ analysis of variance, Tukey's test; data not shown). Interestingly, the two palm oil preparations appeared to behave differently because, compared to the NBDPO group, RBDPO dietary rats showed a shorter duration of VT (26.8 s compared to 64.7 s for NBDPO). The A.S. were low in the SSO and FO groups compared to other three groups ($P < 0.05$ vs. SSO). No differences were evident in arrhythmic vulnerability between SBO and palm oil diet-fed animals.

TABLE 2
Effect of Various Lipid Supplements on Reperfusion-Induced (10 min) Arrhythmias[a]

Parameter[a]	Dietary group				
	SSO	SBO	NBDPO	RBDPO	FO
VPB/10 min	108 ± 45	298 ± 92	526 ± 111[b]	368 ± 96	94 ± 44
VT incidence (%)	7/18 (39%)	13/17 (76%)	12/17 (70%)	14/18 (77%)	4/18 (22%)
VF incidence (%)	2/18 (11%)	4/17 (23%)	6/17 (35%)	6/18 (33%)	1/18 (5%)
Total mortality[c]	1/18	2/18	1/18	2/18	0/18
A.S.	1.5 ± 0.5	3.1 ± 0.5[b]	3.2 ± 0.5[b]	3.3 ± 0.6[b]	0.9 ± 0.4

[a]For abbreviations Table 1; VPB, ventricular premature beat; VT, ventricular tachycardia; VF, ventricular fibrillation; A.S., arrhythmic score.
[b]Indicates significant difference at the 5% level (vs. SSO group, analysis of variance, Tukey's test).
[c]Including deaths for VF during the 5 min preceding ischemic period.

The major PUFA of cardiac membrane phospholipids which have been reported to affect eicosanoid production are presented in Table 3. Compared to the SSO diet, FO feeding led to an effective replacement of 18:2 (54% reduction), and palm oil diets showed a 26% reduction. However, despite this reduced level of 18:2 in palm oil-fed rats, the immediate elongation product of linoleic acid, i.e. arachidonic acid (AA 20:4n-6), was unaltered. Only the FO-fed animals demonstrated a significant reduction in this major fatty acid substrate for eicosanoids. The reduction in n-6 fatty acids in the myocardial phospholipids of FO-fed animals was offset by a considerable incorporation of n-3 PUFA (20:5, 22:5, and 22:6) which amounted to 24% of total fatty acids of myocardial membrane phospholipids. Nevertheless, the proportion of EPA in myocardial phospholipids remained low, being only 1.6% of total fatty acids, even after prolonged feeding of a diet rich (Table 1) in this long-chain PUFA.

Table 4 shows the release of PGI_2 and TxA_2 by homogenates of the ischemic/reperfused myocardium. The myocardial tissue from RBDPO-fed rats tended to have a greater capacity to produce PGI_2 following ischemia and reperfusion, than did the SSO group, although this difference did not achieve statistical significance. This possible increase in PGI_2 in the RBDPO group was not seen in the NBDPO group, despite both palm oil supplements containing an identical dietary fatty acid profile (Table 1). The production of TxA_2 was only affected by the n-3 PUFA-enriched diet. Therefore, the FO rats displayed a significant reduction in TxA_2 (51% reduction compared to the SSO group), which is not explained on the basis of reduction in membrane AA alone, which was approximately 15% lower in the FO group. These changes were reflected in the overall ratio of PGI_2/TxA_2, which was higher in both FO and RBDPO groups as compared to other dietary groups. There was no difference in PGI_2 production from the nonischemic region of the heart.

The production of lipoxygenase (LO) metabolites by cardiac muscle homogenates also was investigated in the present study. The major LO product of the heart was found to be 12-hydroxyeicosatetraenoic acid (12-HETE), which showed a significant response to dietary lipid supplementation (Fig. 2). The highest production of 12-HETE was associated with high linoleate diets (SSO 591.9 ± 95.8 ng/g dry wt; SBO, 375.5 ± 48.9 ng/g dry wt; $P > 0.05$), whereas both palm oil and FO feeding resulted in a lower production. As observed for PGI_2 production, homogenates from RBDPO-fed rats showed a tendency toward lower release of 12-HETE than did NBDPO. The % reductions relative to the SSO diet were: NBDPO (51%), RBDPO (61%), and FO (66%), but the differences between the two palm oil groups did not achieve statistical significance. In contrast to the AA-derived metabolites, no significant formation of LO products derived from EPA (e.g., hydroxyeicosapentaenoic acid) was observed possibly because of its low level of incorporation (only 1.6 vs. 17.3% for AA) into myocardial phospholipids. Similarly, the release of leukotriene

[b]$P < 0.05$ (vs. SSO, analysis of variance, Tukey's test).

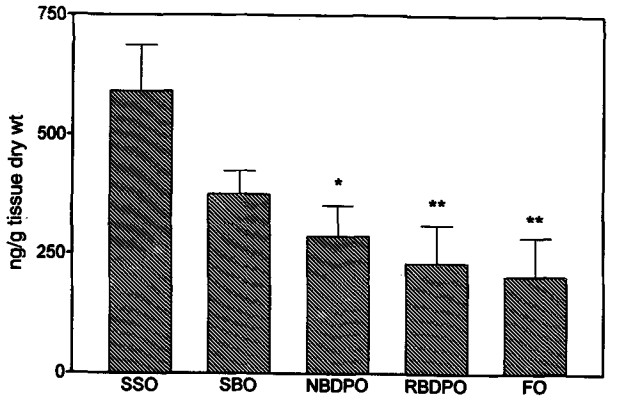

FIG. 2. Production of 12-hydroxyeicosatetraenoic acid by the ischemic/reperfused myocardium. Experimental conditions are described in detail in the Materials and Methods section. Values given are mean ± SEM; n = 15. Significant differences were assessed by analysis of variance followed by Tukey's post-hoc test for multiple comparisons (Ref. 15). $*P < 0.05$; $**P < 0.01$ vs. SSO. Abbreviations as in Figure 1.

B_4 or leukotrienes C_4/D_4 by the cardiac muscle was too low to be measured with accuracy using the assay methods employed in the present study.

Analysis of the vitamin E profile of different oil supplements showed SSO and palm oil preparations to be high in this antioxidant, whereas SBO contained no detectable level of α-tocopherol. Purified FO (MaxEPA®) preparation contained a high amount of α-tocopherol added by the manufacturer. The total vitamin E levels were: SSO, 557 ppm; SBO, not detected (<10 ppm); NBDPO, 637 ppm; RBDPO, 628 ppm; and FO, 958 ppm. Tocotrienols were only found in palm oils and amounted to about 75% of total tocopherols (data not shown).

DISCUSSION

The antiarrhythmic actions of dietary SSO and FO reported earlier (2,3) were confirmed in the present study. However, the effects of SBO, which contained a relatively high level of linoleic acid (18:2n-6; 43%), were indistinguishable from those of the diets rich in palm oils, which had only 13% of dietary linoleate. For example, the overall arrhythmic potential as expressed by the A.S. was not different between the SBO, NBDPO, and RBDPO groups. The two palm oil diets, however, appeared to exert differential effects on certain individual parameters of arrhythmia as well as on eicosanoid production. For example, both VPB and VT duration were greater following the NBDPO diet, despite this oil having a similar fatty acid profile to RBDPO. This suggests that the fatty acid profile of edible oils alone is not a predictor of arrhythmic vulnerability, and implies an important role for accompanying nonfatty acid constituents of dietary oils. The best candidates for such components are the endogenous antioxidants, as arrhythmogenesis has been reported to be influnced by both natural and synthetic antioxidants (16,17). In this context, it is worth noting that SBO used in the present study contained no α-tocopherol, whereas SSO and palm oils were high in this and other forms of vitamin E. Supporting evidence for the existence of a complex interaction between fatty acids and endogenous antioxidants in determining the overall arrhythmic vulnerability also arises from the recent observation that dietary olive oil, high in 18:1, failed to offer protection against arrhythmogenesis (5). Therefore, based on the fatty acid profile, palm oils with high 18:1 and low 18:2 levels could be expected to behave differently from linoleic acid-rich SBO. Nevertheless, no difference was evident in the relative arrhythmic potential of these dietary oils.

The fatty acid composition of cardiac membranes also tends to support this speculation because both SSO and SBO diets had similar effects on major PUFA (18:2; 20:4), but the two dietary treatments resulted in widely different physiological responses. Furthermore, and similar to our previous findings, the effects of dietary lipid supplements on the production of TxA_2 are also difficult to explain on the basis of precursor/inhibitor fatty acid availability alone (9,10,18). In the present study, FO feeding led to a considerably reduced capacity of the ischemic and reperfused myocardial tissue to produce TxA_2 and, in addition, limited the *in vitro* production of 12-HETE, a potent chemotactic and vasoactive agent which plays a pivotal role in the evolution of cardiac injury (19). Interestingly, this inhibitory action on 12-HETE production also was shared by palm oils.

The present findings also suggest that cardiac LO may have a broader substrate specificity in that it may be able to utilize both linoleic acid and AA as precursors for hydroxy fatty acids. Although EPA has been reported to be a preferred substrate for the LO enzyme complex (20), no end products of EPA metabolism were detected. This finding, however, can be explained on the basis of the availability of substrate fatty acid as the FO dietary animals showed negligible incorporation of EPA into the myocardial phospholipids. It appears that, in the rat myocardium, EPA is either poorly incorporated or further elongated and desaturated to yield docosahexaenoic acid (Tables 1,3).

The greater efficacy of RBDPO compared to NBDPO to limit the release of 12-HETE also suggests a modulatory role for minor constituents of dietary oils. However, tocopherols can be ruled out as a potential candidate, as both RBDPO and NBDPO contained comparable levels of this antioxidant. Trace metals (particularly selenium) offer an attractive explanation as recent reports indicate a potent modulatory role for selenium on the metabolism of eicosanoids (21). Another possible explanation, however, lies with the presence or absence of nontocopherol-type antioxidants in the two types of palm oil used in the present study. For example, several different polyphenol compounds (e.g., bioflavanoids) of plant origin have been shown to exert potent antioxidant actions and to modulate eicosanoid biosynthesis (22,23). In this regard, it is of interest to point out that increased aortic production of PGI_2 following olive oil feeding, compared to a high-oleic safflower oil diet, is reported to be mediated *via* polyphenol constituents of olive oil (24), which are known to be influenced by the refining process (25). Polyphenol antiox-

idants could lower the fatty acid hydroperoxide levels by inhibiting LO enzyme complex, thereby increasing PGI_2 synthesis through removal of the inhibitory effects of fatty acid hydroperoxide on prostacyclin synthetase (26). In the present study, RBDPO was found to exert trends toward both these effects—inhibition of 12-HETE formation and increase in PGI_2 synthesis. Therefore, it is conceivable that differences in the refining method (i.e., physical, RBDPO vs. chemical, NBDPO) may result in some biological differences between the two preparations of palm oils. Further studies are clearly warranted in this area.

ACKNOWLEDGMENTS

This study was supported in part by a grant from the Palm Oil Research Institute of Malaysia (PORIM). We thank A. Gapor (PORIM) for tocopherol analysis.

Plasma Lipids Are Affected Similarly by Dietary Lauric or Palmitic Acid in Gerbils and Monkeys[1]

Foster Biomedical Research Laboratory, Brandeis University, Waltham, Massachusetts 02254

ABSTRACT: To compare the relative impact of dietary lauric acid (12:0) and palmitic acid (16:0) on plasma lipids, two fat-sensitive species, Mongolian gerbils and cebus monkeys, were fed cholesterol-free, purified diets enriched with either 12:0-rich or 16:0-rich fats, while all other fatty acids were held constant by selective blending of up to five natural fats or oils. The two gerbil diets (40 en% from fat) allowed for an 8 en% exchange between 12:0 and 16:0, and the monkey diets (31 en% from fat) allowed for 6 en% exchange between these two fatty acids. Eight gerbils received the diets for eight weeks, and 12 cebus monkeys were fed each diet in a cross-over design for up to 22 wk. Both diets resulted in similar plasma cholesterol, triglyceride, and high density lipoprotein cholesterol concentrations within each species. Additionally, separation of cebus lipoproteins by discontinuous density-gradient ultracentrifugation failed to show any dietary differences in concentration or composition of the three major lipoprotein classes (d < 1.019, 1.019–1.055, and 1.055–1.168 g/mL). Thus, in two species sensitive to manipulations in dietary fat while consuming cholesterol-free diets, 16:0 was not hypercholesterolemic relative to 12:0.

Lipids 30, 1157–1161 (1995).

The ability of dietary saturated fat to raise plasma cholesterol has been appreciated for almost four decades (see Refs. 1–4 for recent reviews). More than thirty years ago, Keys *et al.* (5) proposed that the saturated fatty acids (12:0, 14:0, 16:0) were equally capable of raising cholesterol, while the saturated stearic acid (18:0) and monounsaturated oleic acid (18:1) were neutral. Hegsted *et al.* (6) concurred, in general, but initially found 14:0 to be substantially more cholesterolemic than either 12:0 or 16:0. However, subsequent experiments with synthetic triglycerides (7) led the latter investigators to the same conclusion as Keys *et al.* (5), although they included the small intake of 18:0 among the "saturates" pool. Numerous studies in the last decade have challenged the earlier notion that the C_{12}–C_{16} saturated fatty acids were equivalent with respect to their effects on serum cholesterol.

Although there is general agreement on the neutrality of 18:0 (7–11), considerable disagreement exists on the roles of lauric (12:0), myristic (14:0), and palmitic (16:0) acids in modulating plasma lipids. Studies in hamsters fed trilaurin-, trimyristin-, or tripalmitin-enriched diets revealed that all three (12:0, 14:0, and 16:0) were equivalent in terms of their cholesterol-raising ability (12). Denke and Grundy (13) reported that 16:0 was hypercholesterolemic relative to 12:0 in human subjects consuming liquid-formula diets containing a modified triglyceride enriched in 12:0, and both Doherty and Iacano (14) and Schwab *et al.* (15) observed similar cholesterol values when humans consumed natural fats and whole-food diets in which 12:0 was exchanged for 16:0.

Recent studies from this laboratory using normocholesterolemic hamsters (16), cebus and rhesus monkeys (17), and gerbils (18) consuming cholesterol-free diets, as well as collaborative studies in normocholesterolemic human subjects consuming whole-food diets providing about 200 mg cholesterol per day (19,20), suggest that if low density lipoprotein (LDL) receptor activity is not compromised, diets rich in 12:0 + 14:0 will increase plasma and LDL cholesterol, and 16:0 (similar to 18:1) can be quite neutral in its impact on plasma cholesterol. The latter interpretation is consistent with the initial "best" multiple regression equation of Hegsted *et al.* (6) that indicated 14:0 was four times more potent than 16:0 in its ability to raise the plasma cholesterol in men consuming whole-food diets containing natural fats. This contrasts with the situation in which LDL receptor activity would be impaired, as in hypercholesterolemic humans (21) or non-human primates fed dietary cholesterol (22,23), where 16:0 has been found to elevate plasma cholesterol. Re-analysis (24) of the original data reported by Hegsted *et al.* (6) confirmed this premise. In subjects consuming <300 mg/d cholesterol, 16:0 appeared neutral, whereas a hypercholesterolemic effect of 16:0 was observed in subjects consuming >400 mg/d cholesterol (24). More recently, Fielding *et al.* (25) have confirmed the dependence of "the saturated fat effect" on the presence of dietary cholesterol in normocholesterolemic subjects, including the possibility that ethnic background or lifestyle can influence the outcome. Furthermore, multiple regression analysis of accumulated data from normocholesterolemic cebus monkeys (24) and gerbils (18) implied that dietary 14:0 and 18:2 were the only two fatty acids to impact the plasma cholesterol concentration when LDL receptor activity was not impaired, i.e., when normal plasma cholesterol values exist at the time of intervention.

The current study was designed to address the question whether 12:0 *per se* contributes to the hypercholesterolemia previously observed during feeding of 12:0 + 14:0-rich diets to normocholesterolemic animals. Based on our regression data, indicating that only dietary 14:0 (cholesterol-raising) and 18:2 (cholesterol-lowering) induce measurable changes in plasma cholesterol, we reasoned that in the absence of cholesterol, dietary 12:0, like 16:0, should be neutral and their direct exchange should not perturb plasma lipids. The results agree with our prediction and further the notion originally proffered by Hegsted *et al.* (6) that the exceptional hypercholesterolemia observed by feeding 12:0 + 14:0-rich diets depends, in part, upon the presence of 14:0.

MATERIALS AND METHODS

Animals, diets, and study design. Twelve male cebus monkeys (*Cebus albifrons*)10–20 years old, and 16 male, eight-month-old Mongolian gerbils (*Meriones unguiculatus*; Tumblebrook Farm, West Brookfield, MA) were used in this study. The cebus monkeys had been fed purified diets from birth, and immediately prior to this investigation had been fed for eight weeks with a low-fat (20 en%), cholesterol-free diet containing equal amounts of saturated, monounsaturated, and polyunsaturated fatty acids. Mean (±SEM) plasma lipid values for the 12 monkeys at entry were: total cholesterol, 142 ± 10 mg/dL; and triglycerides, 89 ± 20 mg/dL.

The basal composition of the purified monkey diets was (g/kg dry weight): lactalbumin, 190; cornstarch, 256; sucrose, 255; cellulose, 100; fat, 143; mineral mix, 48; vitamin mix, 5; and choline chloride, 3. The composition of the Ausman–Hayes mineral and Newberne–Hayes vitamin mixes has been reported (17). For the 16:0-rich diet, the fat blend comprised (g/100 g fat): 55 g cholesterol-stripped milkfat, 20 g palm stearin, 15 g coconut oil, 5 g safflower oil, and 5 g olive oil. The 12:0-rich fat blend contained 55 g coconut oil and 45 g olive oil. The purified gerbil diets consisted of (g/kg dry weight): casein, 222; cornstarch, 230; glucose, 133; cellulose, 150; fat, 200 (same blends as the monkey diets); Ausman–Hayes mineral mix, 50; Hayes–Cathcart vitamin mix, 12; and choline chloride, 3. The fat represented approximately 31 en% in the monkey diet, and 41 en% in the gerbil diet.

Monkeys were housed individually, and gerbils were housed in groups of 3–4 per cage from four weeks of age. All animals were kept in a controlled environment with a 12-h light/dark cycle and had free access to water. Food was provided daily in a predetermined ration calculated to maintain constant body weight for the duration of the study. All protocols and procedures were approved by the Brandeis University Animal Care and Use Committee.

Animals were randomly assigned to either diet which differed solely in their source of fats and their fatty acid composition (Table 1), the latter verified by gas–liquid chromatography (26). Gerbils were fed their diets for eight weeks (eight gerbils/diet). For the monkeys a random cross-over design was employed, i.e., initially (phase 1) half of the cebus (n = 6) were assigned to each diet for an eight-week period. At the end of this period, diets were switched for another eight weeks. To ascertain any potential long-term effects of the diets on plasma lipids, feeding was continued for an additional 14 wk (phase 2: 22 wk total). Plasma lipid analyses were carried out at the end of eight (n = 12) weeks for the gerbils, whereas analyses in monkeys were carried out at 8 (n = 12) and 22 wk (n = 6).

TABLE 1
Fatty Acid Composition of Purified Diets as Fed to Cebus Monkeys and Gerbils[a]

	Percentage of total fatty acids	
Fatty acid	16:0-rich diet	12:0-rich diet
<12:0	5.6	6.6
12:0	12.2	32.9
14:0	10.3	9.7
16:0	35.9	11.2
18:0	5.7	1.2
18:1	22.3	31.4
18:2	6.2	6.2
18:3	0.1	0.1
Total sats	69.7	61.6
Total monos	22.3	31.4
Total polys	6.2	6.2
P/S	0.09	0.10

[a]Fatty acid profile represents a blend of fats and was generated by gas–liquid chromatographic analysis (see the Materials and Methods section). Sats, saturated fatty acids; monos, monounsaturated fatty acids; polys, polyunsaturated fatty acids; P/S, polyunsaturated/saturated fatty acid ratio.

Plasma lipid and lipoprotein determinations. Following an overnight fast (14–16 h), monkeys were sedated with an intramuscular injection of Ketamine HCl (10 mg/100 μL, Vetalar; Parke-Davis, Morris Plains, NJ) at a dose of 4–9 mg/kg body weight. Blood was obtained from the femoral (or saphenous) vein and placed into tubes containing an EDTA solution kept on ice. Blood samples (500 μL) were procured from gerbils by cardiac puncture following light anesthesia ($CO_2 + O_2$, 50:50 mixture) using a 30# needle and an EDTA-wetted insulin syringe. Plasma was isolated by centrifugation. Whole plasma and individual lipoprotein fractions were assayed enzymatically for their cholesterol and triglyceride content (kits Nos. 352 and 336, respectively; Sigma Diagnostics, St. Louis, MO). High density lipoprotein (HDL) cholesterol concentrations were determined in the supernatant of plasma samples following precipitation with phosphotungstic acid/Mg^{2+} (for monkeys: HDL cholesterol reagent, No. 352-4, Sigma Diagnostics; and for gerbils: HDL cholesterol Reagent Set, Boehringer Diagnostics, Indianapolis, IN). Lipoprotein phospholipids were determined using the Phospholipid B enzymatic kit (Wako Chemicals, Richmond, VA). Lipoprotein protein was determined using the Markwell modification of the procedure of Lowry (27).

Isolation of cebus lipoproteins. At the end of the 22-wk period, cebus plasma (from individual animals) was subjected to discontinuous density-gradient ultracentrifugation essentially as described by Chapman *et al.* (28), with the subsequent modification introduced by Goulinet and Chapman

(29). Gradients were prepared in Beckman Ultra-Clear tubes (Beckman Instruments, Palo Alto, CA) by succesively layering 2 mL of d = 1.24 g/mL solution, 3 mL plasma @ d = 1.21 g/mL, 2 mL of d = 1.063 g/mL solution, 2.5 mL d = 1.019 g/mL solution, and 2.5 mL of d = 1.006 g/mL solution. Tubes were spun at 35,000 rpm (max acceleration but no brake) for 48 h at 15°C in a Beckman SW 41 rotor using a Beckman L6-60 optima ultracentrifuge.

Immediately following centrifugation, lipoproteins were collected in thirty fractions using a Gilson precision pipette (Rainin Instruments Co., Woburn, MA), starting with a top fraction of 500 µL and subsequent 400 µL fractions. The cholesterol, triglyceride, phospholipid, and protein content of each fraction was determined. A blank salt gradient also was ultracentrifuged and identical fractions collected for measurement of densities using a µOsmette micro osmometer (Precision Systems Inc., Sudbury, MA).

Statistical analyses. All statistical analyses were performed using a Macintosh LC III computer (Apple Computer Inc., Cupertino, CA) with the Statview 512$^+$ (Brain Power Inc., Calabasca, CA) and Cricket Graph (Cricket Software Inc., Philadelphia, PA) statistical packages. The effects of the dietary fatty acids were assessed using Student's unpaired *t*-test (gerbils) or Student's paired *t*-test (monkeys). In all cases, statistical significance was set at $P < 0.05$.

RESULTS

After eight weeks of diets enriched with 12:0 or 16:0, gerbil and cebus body weights averaged 94 ± 2 g and 3.2 ± 0.06 kg, respectively. No significant difference was detected between dietary groups. Similarly, neither gerbils nor cebus monkeys exhibited significant dietary differences in their plasma cholesterol, triglycerides, or HDL-cholesterol concentration (Table 2), even though all total cholesterol values were elevated relative to typical basal values for these species (75 mg/dL for gerbils and 145 mg/dL for cebus). Extending the diet period to 22 wk in cebus monkeys still failed to elicit significant differences in plasma lipids between dietary fatty acid groups, although cholesterol values for both diets tended to be higher after 22 wk than at 8 wk, and there was a nonsignificant trend toward lower values in the 16:0 diet than in the 12:0 at 22 wk. As only six monkeys were extended to 22 wk on each diet, statistical analysis was not deemed appropriate between 8 and 22 wk.

TABLE 2
Plasma Lipids Concentration in Gerbils and Cebus Monkeys Fed Purified 12:0- or 16:0-Rich Diets for 8 or 22 Weeks[a]

Lipids[b] (mg/dL)	Diets			
	Gerbil		Cebus	
	12:0-Rich	16:0-Rich	12:0-Rich	16:0-Rich
Eight weeks				
TC	111 ± 10	106 ± 11	192 ± 10	200 ± 10
HDL-C[c]	81 ± 8	71 ± 6	116 ± 10	128 ± 8
TG	153 ± 38	163 ± 14	57 ± 3	78 ± 10
Twenty-two weeks				
TC	ND[d]	ND	227 ± 11	211 ± 16
HDL-C[c]	ND	ND	127 ± 11	133 ± 11
TG	ND	ND	76 ± 9	67 ± 7

[a]Values are mean ± SEM. Eight gerbils were fed each diet. For monkeys, the eight-week values are for all 12 animals fed each diet (mean of both diet rotations), while the 22-wk value is the mean from six animals per diet (values from the second rotation only).
[b]TC, total cholesterol; HDL-C, high density lipoprotein cholesterol; TG, triglycerides.
[c]HDL obtained by phosphotungstic acid–Mg precipitation (see the Materials and Methods section).
[d]ND, not determined.

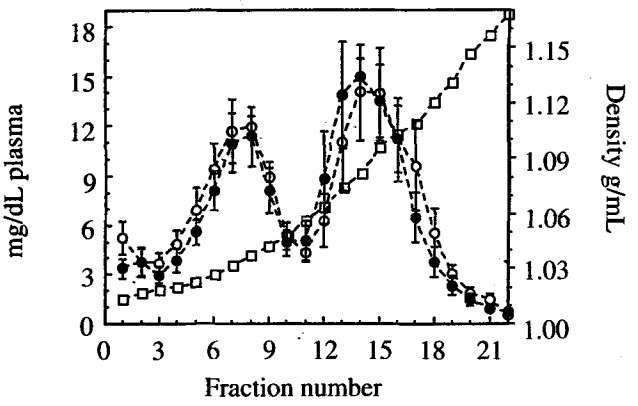

FIG. 1. Cholesterol and density distribution in cebus lipoproteins following density-gradient ultracentrifugation. The figure shows the cholesterol values (mean ± SEM) of six monkeys fed the 12:0-rich diet (○– – –○) and five monkeys (one sample of the 16:0-rich group was lost) fed the 16:0-rich diet (●– – –●). A blank salt gradient was used for measurment of densities (□– – –□).

Because similar plasma lipid concentrations do not necessarily mean that the lipoprotein distribution is the same, the cebus monkey lipoprotein classes were assessed across the entire density range after consuming either the 12:0-rich or 16:0-rich diets for 22 wk. Cebus lipoprotein cholesterol was distributed among three peaks with density less than 1.019, 1.019–1.055, and 1.055–1.168 g/mL (Fig. 1). The quantitative distribution and percent composition of lipoproteins in the three density classes were calculated with the result that dietary fatty acid treatment had no significant effect on any lipoprotein fraction (Table 3).

DISCUSSION

Our finding that dietary 12:0 and 16:0 exerted equivalent effects on plasma lipids is in agreement with previous reports in human subjects consuming whole-food diets (14,15), but disagrees with the conclusion of a study in humans consuming liquid-formula diets that found 16:0 to be more hypercholesterolemic than 12:0 (13). However, the latter study, as well as results from studies with liquid-formula diets in general, have been criticized because they may not reflect data obtained with solid-food diets (30). In addition, the 12:0 vs. 16:0 liquid formula comparison in humans (13) utilized modified triglyceride (monoacid) to incorporate a high level of 12:0 and was further biased by failure to equalize 14:0 and 18:2

TABLE 3
Effect of Dietary 12:0 and 16:0 for 22 Weeks on Cebus Lipoprotein Lipids and Protein Concentration and Lipoprotein Composition[a]

	Cholesterol (mg/dL plasma)	Triglyceride (mg/dL plasma)	Phospholipid (mg/dL plasma)	Protein (mg/dL plasma)
d < 1.019 g/mL density (fractions 1–3)				
12:0-Rich diet	15 ± 3	29 ± 8	15 ± 3	16 ± 11
	(22 ± 2)[b]	(37 ± 3)	(20 ± 1)	(21 ± 4)
16:0-Rich diet	12 ± 2	27 ± 9	13 ± 3	17 ± 6
	(17 ± 2)	(34 ± 7)	(18 ± 2)	(31 ± 8)
1.019 < d < 1.055 g/mL density (fractions 4–11)				
12:0-Rich	76 ± 7	25 ± 7	61 ± 7	84 ± 9
	(31 ± 1)	(10 ± 1)	(25 ± 1)	(35 ± 2)
16:0-Rich	68 ± 8	22 ± 3	57 ± 8	87 ± 11
	(29 ± 1)	(10 ± 1)	(24 ± 2)	(37 ± 3)
1.055 < d < 1.168 g/mL density (fractions 12–22)				
12:0-Rich	107 ± 6	35 ± 6	159 ± 17	324 ± 24
	(17 ± 1)	(5 ± 1)	(26 ± 2)	(52 ± 2)
16:0-Rich	102 ± 11	33 ± 2	182 ± 12	304 ± 35
	(16 ± 1)	(5 ± 0.5)	(30 ± 2)	(49 ± 3)

[a]Lipoproteins were isolated from the plasma of individual animals by discontinuous density gradient ultracentrifugation (see the Materials and Methods section). Values are the mean ± SEM for six monkeys fed the 12:0-rich diet and five monkeys fed the 16:0-rich diet (one sample of the 16:0-rich group was lost). No statistically significant differences were detected between dietary groups for any of the measured parameters.
[b]Values in parentheses denote % composition.

between diets (31,32). In humans fed transesterified triglycerides (33) or monoacid-enriched triglycerides (7), and in hamsters fed diets containing synthetic (monoacid) triglycerides and 0.12% (w/w) cholesterol (12), 12:0, 14:0, and 16:0 appeared to exert equal effects on plasma cholesterol. However, the hamster study cannot be compared directly with our results because 0.12% dietary cholesterol may have down-regulated LDL receptors sufficiently to cause all saturated fatty acids to appear to be equally cholesterol-elevating. In fact, in all three of these studies, the use of synthetic triglycerides may have distorted lipid metabolism and generated profiles for fatty acids that may not be easily extrapolated to the situation where those fatty acids are consumed as natural fats and oils (34,35).

The results of the current study also are consistent with a retrospective analysis of data from cebus monkeys fed numerous cholesterol-free diets (24), which was coupled with a reappraisal of the published data of Hegsted *et al.* (6). Both multiple regression analyses revealed that in normocholesterolemic subjects (humans or monkeys) consuming low-cholesterol diets, dietary 14:0 was the principal fatty acid associated with elevated plasma cholesterol. This observation was in accord with the original report of Hegsted *et al.* (6), in which 14:0 was assigned a fourfold higher cholesterol-elevating power than 16:0 in the "best" regression equation. In neither the Hegsted study (6) nor the monkey study (24) did multiple regression analysis identify a cholesterol-elevating role for 12:0 independent of 14:0. In a subsequent study with gerbils (18), incremental increases in dietary cholesterol confirmed the unique ability of a 16:0-rich fat to elicit progressive levels of cholesterolemia with increasing cholesterol intake. Thus, the cholesterol-raising potential of 16:0-rich fats appears to depend on the lipoprotein "setpoint" of the host at the time of challenge. As discussed elsewhere (35,36), the "setpoint" is highly dependent upon cholesterol intake and the 18:2 content of the diet, two factors greatly affecting LDL receptor activity (37).

In previous studies, diets rich in 12:0 + 14:0 were found to be hypercholesterolemic relative to 16:0-rich diets when formulated as part of cholesterol-free diets in gerbils (18) or three species of monkeys (17). The same result was obtained in normocholesterolemic human subjects consuming low-cholesterol (200 mg/d) diets (20). In order to ascertain the relative cholesterolemic impact of 12:0, the current diet exchanged 12:0 with 16:0 in the absence of cholesterol while maintaining a constant level of 14:0 and 18:2. Out of necessity to include adequate 12:0 while holding 14:0 constant in these two natural fat blends, substantial 14:0 (3–4 en%) was included as these two fatty acids normally occur together. Not surprisingly, the total cholesterol was elevated above basal values in both gerbils and cebus. However, relative to higher and lower consumption of 14:0-rich fat under similar circumstances, the present total cholesterol values were predictably intermediate to those previously obtained (17,18,24). Thus, the fact that 12:0 and 16:0 appeared similarly cholesterolemic implies that the more pronounced cholesterol elevation observed previously during feeding of 12:0 + 14:0-rich diets in comparison to 16:0-rich diets (6,17,20) may be attributed to the presence of 14:0 in those diets.

Coupled with our previous data (16,17,23,24,38–40), the current results suggest that 12:0 *per se* does not exert an independent cholesterol-elevating effect on plasma cholesterol in diets devoid of cholesterol [or in the case of human studies, diets with cholesterol intakes of <300 mg/d (24). In such situations, the presence of myristic acid (14:0), despite its low intake, would appear to dominate the cholesterolemic impact of saturated fatty acids on plasma cholesterol.

ACKNOWLEDGMENTS

This study was supported in part by the Palm Oil Research Institute of Malaysia, NIH grant HL49128, and by the Malaysian Palm Oil Development Council.

Palmolein and Groundnut Oil Have Comparable Effects on Blood Lipids and Platelet Aggregation in Healthy Indian Subjects[1]

Ghafoorunissa*, Vinodini Reddy, and B. Sesikaran
National Institute of Nutrition, Hyderabad - 500 007, India

ABSTRACT: Substitution of palmolein (POL) for groundnut oil (GNO) doubles saturated fatty acids and decreases by half the linoleic acid (18:2n-6) content of Indian diets. The effects of this substitution on selected parameters of cardiovascular risk and membrane functions were studied in middle-aged subjects. Both metabolic (short-term) and "in-home" (long-term) studies were conducted, and the subjects were crossed over from GNO to POL or vice versa. During both studies and in both sexes, blood pressure, plasma levels of total cholesterol and triglycerides and their distributions in various lipoprotein fractions were not altered. The lower 18:2n-6 and higher 16:0 intakes were reflected in fatty acid compositions of cholesteryl esters and triglycerides. However, the plasma and platelet phospholipid fatty acid patterns did not shift toward saturation. The observation that the levels of long-chain polyunsaturated fatty acids in phospholipids were similar at the end of GNO and POL regimens indicates that 18:2n-6 furnished during POL regimen may be sufficient to maintain the levels of arachidonic acid in cell membranes. Platelet aggregation, erythrocyte membrane fluidity, and activity of Na^+,K^+ ATPase, a membrane-bound enzyme, were essentially similar at the end of the two oil regimens. These results indicate that POL is comparable to GNO and may not induce hypercholesterolemia in Indian subjects consuming cereal-based diets containing 30% total fat calories and low cholesterol.
Lipids 30, 1163–1169 (1995).

Diets high in fats rich in saturated fatty acids (SFA) raise plasma cholesterol, and are atherogenic and thrombogenic (1). Lauric (12:0), myristic (14:0), and palmitic (16:0) acids constitute the bulk of dietary SFA. These three do not contribute equally to hypercholesterolemia or hyperaggregability, and further, their effects vary with dietary levels of cholesterol and unsaturated fatty acids (2,3). Dietary fat also affects lipid compositions of membranes—alters their fluidity—and activities of receptors and membrane-bound enzymes (4–6). All these changes have pathophysiological significance. In most foods, 16:0 is the major SFA (7) and among oils, palm oil and palmolein (POL) have the highest levels (8). Therefore, there has been a debate on whether increased consumption of palm oil or POL could increase the risk of cardiovascular diseases (8–10). Consequently, several experimental (11–14) and human studies (15,16) were published on the effects of palm oil and POL on plasma lipids, and a more recent review has critically examined this subject (17). The present study was carried out to investigate the effects of substitution of GNO with POL in the habitual diets of Indian subjects on plasma lipids, platelet aggregation, erythrocyte membrane fluidity, and activity of erythrocyte Na^+,K^+ ATPase.

MATERIALS AND METHODS

Subjects and study design. Two studies were conducted in subjects drawn from the Institute staff. Criteria for subject selection included normal blood chemistry and no history of diabetes. Age, body weight, height, and blood pressure were recorded, and body mass index (kg/m^2) was calculated. A cross-over experimental design was used to control within subject variability and the effects of sequence of oil supplementation. Study 1 was short-term (metabolic study) in 12 men and Study 2 was a longer term ("in-home" study) of 12 men and 12 women.

Study 1. Individual diet surveys were done before starting the study using a 24-h recall oral questionnaire (18), and the total intake of various nutrients was calculated using food composition tables (19). During the study, the subjects were maintained on diets consisting of traditional menus prepared in the metabolic unit. The amount and type of foods as well as the daily menus were the same for all the subjects throughout the study, and only the cereal intake was altered to ensure satiety. In the first phase, half the subjects received refined groundnut oil (GNO) for 8 wk, and the other half received re-

fined, bleached, and deodorized POL imported from Malaysia. After a washout period of 6 wk, in the second 8-wk phase they were switched to the other oil regimen. Body weight was monitored at weekly intervals.

Study 2. This was a study of 12 men and 12 women conducted using the subjects' own home-prepared foods. The oil was supplied at monthly intervals with instructions to use it as the only cooking (added) fat source. During the first phase of the study, half the families were supplied GNO and the rest POL for 16 wk. During each phase of the study, 24-h recall diet surveys were done twice, and the subjects' mean daily intakes of macronutrients and fatty acids were calculated. In order to monitor compliance, the subjects were requested to record the total number of meals and snacks taken outside. The dietitian collected these records at 10-d intervals. Body weight was monitored every month.

Blood pressure. Blood pressure measurements were made after 10–12 h fasting using a calibrated conventional mercury sphygmomanometer, with the subject lying down. Recordings were made in duplicate and consistent values were taken.

Blood sampling. Fasting blood samples were collected at pre-entry and at the end of each oil regimen after ensuring that the subjects did not take anti-inflammatory drugs during the previous two weeks. For platelet aggregation studies, blood was collected in 3.8% trisodium citrate solution (9:1, vol/vol). For analysis of plasma lipids and for preparing erythrocyte membranes and platelet pellet, blood was collected in EDTA (1 mg/mL).

Platelet aggregation. Citrated blood was diluted with normal saline (1:1, vol/vol), and collagen-induced (1–10 μg/mL) whole blood aggregation was measured by the impedance method of Cardinal and Flower (20) using a Whole Blood Aggregometer, Model 530 (Chrono-log, Havertown, PA). Platelet-rich plasma (PRP) was obtained by spinning the citrated blood at $120 \times g$ for 10 min. Platelet-poor plasma (PPP) was obtained by spinning blood at $1000 \times g$ for 15 min. PRP was diluted with autologous PPP to obtain 2.5×10^5 cells/μL, and aggregation was measured in 0.25 mL PRP with varying concentrations (1–20 μM) of ADP by turbidometry (21). The primary aggregation rate was calculated for each concentration of aggregating agent, and the estimated maximum response (EMR) and dose of aggregating agent required to bring about half maximum response (ED_{50}) were calculated. For whole blood aggregation, lag phase also was calculated.

Lipids and fatty acids. The blood collected in EDTA was spun to obtain PRP. Platelet pellet and PPP were obtained by spinning PRP at $1000 \times g$ for 15 min. The pellet was washed with saline and the cells were lysed. Cholesterol and triglycerides in various lipoproteins and fatty acid composition of plasma were analyzed in PPP.

Plasma total cholesterol was estimated by the method of Watson (22). Total triglycerides were determined by the method of Lowell and Dunn (23). Lipoproteins were separated by the dual precipitation method of Wilson and Spiger (24). Cholesterol was assayed in each of the lipoprotein fractions, and triglycerides were estimated in very low density lipoprotein (VLDL) fraction.

Lipids were extracted from both PPP and lysed platelets with chloroform/methanol (2:1, vol/vol) containing butylated hydroxytoluene and separated by thin-layer chromatography using hexane/diethylether/glacial acetic acid (73:25:2, by vol). The triglycerides, cholesteryl esters, and phospholipids were scraped into tubes and transmethylated as described earlier (25) along with 25 μg heptadecanoic acid (internal standard). The fatty acid methyl esters were analyzed by flame-ionization capillary gas–liquid chromatography using Perkin-Elmer 8500 Gas Chromatograph (Buckinghamshire, England) equipped with reintegration facility and GP 100 graphic printer. Supelco (Bellefonte, PA) fused silica SP™ 2330 capillary column 30 m × 0.25 mm id, 0.20 μm film thickness, was used. The column temperature was initially kept at 120°C for 8 min and then increased three times stepwise at 30°C/min to 150°C, at 10°C/min to 210°C and at 3°C/min to 235°C, then isothermally at 235°C for 10 min. The nitrogen pressure was maintained at 18 psi. Individual fatty acid methyl esters were identified by comparison of the retention times with authentic standards obtained from Nu-Chek-Prep (Elysian, MN) and Sigma Chemical (St. Louis, MO).

Erythrocyte membrane fluidity and Na^+,K^+ATPase activity. Erythrocyte membranes were prepared by the method of Hanahan and Ekholm (26). Membrane fluidity was monitored by measuring steady-state polarization of 1,6-diphenyl-1,3,5-hexatriene using a Hitachi 650-10S fluorescence spectrophotometer (Tokyo, Japan), and fluorescence anisotropy (rs) was calculated (27). Erythrocyte membrane protein was assayed by the method of Lowry *et al.* (28). Na^+,K^+ATPase activity was assayed according to Nakao *et al.* (29) using 200 μL (400–600 μg protein) erythrocyte membrane. Inorganic phosphate was estimated according to Fiske and Subbarow (30).

Statistical analysis. Results are given as mean ± standard error. The statistical significance between means (end of one oil period vs. end of second oil period) were analyzed using paired *t*-test; significant results were taken as $P < 0.05$. Two-way analysis of variance and "f" ratio test were used to evaluate the change in plasma total cholesterol between two oil periods vs. total cholesterol levels at pre-entry, and change in plasma triglycerides vs. body mass index at pre-entry. Unpaired *t*-test was done to compare the data between men and women.

RESULTS

The clinical characteristics of the subjects are given in Table 1. Men who volunteered for Study 2 were older and had higher plasma total cholesterol levels than subjects in Study 1. In Study 2, five subjects (three men and two women) had blood cholesterol values above 190 mg/dL, three of these subjects (two men and one woman) were also hypertensive; the medication for hypertension was not altered for these three subjects during the entire study.

TABLE 1
Clinical Description of the Subjects

Parameters before experiment	Study 1		Study 2			
	Men (n = 12)		Men (n = 12)		Women (n = 12)	
	Mean (SE)	Range	Mean (SE)	Range	Mean (SE)	Range
Age (years)	35 (1.1)	29–39	43 (1.6)	30–52	38 (1.3)	33–39

[a]Grams/person/day; values are mean ± SE; n = 12 in each group. [b]In five subjects only. [c]In six subjects only.

The average daily intakes of major food groups and macronutrients are presented in Table 2. In subjects of Study 1, the intake of various foods and total energy were higher during the study period as compared to the intakes on home (pre-entry) diets. In subjects of Study 2, the number of meals and snacks taken outside the home contributed less than 10% of the total number consumed during the 16-wk study period, and therefore the fat taken outside their homes was assumed not to have significantly contributed to the type of fat consumed. The total energy intake was lower in women than in men, but the percentage of total fat calories was similar.

The data on average daily intake of fatty acids during the two oil regimens is given in Table 3. In both the studies, use of POL provided twice as much 16:0 and half the quantity of linoleic acid (18:2n-6) than the GNO regimen. The ratios of polyunsaturated fatty acids (PUFA)/SFA and linoleic/α-linolenic acids (18:2n-6/18:3n-3) were low during the POL period.

In Study 1, five subjects gained weight during the study period (GNO = 3, POL = 2). In both studies, the mean body weights were similar at the end of the two oil regimens. Blood pressure, plasma total cholesterol, cholesterol in low density lipoprotein (LDL) and high density lipoprotein (HDL) fractions, as well as total and VLDL triglycerides, were not altered by the type of oil consumed in both studies and for both

TABLE 3
Average Daily Intake of Fatty Acids from the Total Diet (en%)[a]

Fatty acids	Study 1		Study 2	
	GNO	POL	GNO	POL

Diastolic	81 ± 3	77 ± 3	82 ± 2	82 ± 3	87 ± 3	86 ± 2
Blood lipids (mg/dL)						
Total cholesterol	150 ± 6.9	155 ± 8.7	182 ± 8.7	178 ± 5.7	168 ± 6.5	170 ± 3.9
LDL cholesterol	79 ± 4.5	71 ± 9.1	100 ± 7.1	104 ± 6.0	99 ± 6.7	98 ± 4.9
HDL cholesterol	34 ± 3.2	36 ± 3.8	33 ± 2.4	30 ± 2.3	29 ± 1.7	32 ± 1.5
Total triglycerides	90 ± 13.3	107 ± 21.8	81 ± 15.6	79 ± 12.0	74 ± 13.0	66 ± 5.5
VLDL triglycerides	55 ± 13	55 ± 15	42 ± 12.6	45 ± 9.5	36 ± 9.4	36 ± 3.9

[a]Values are mean ± SE; n = 12 in each group; paired *t*-test between oil periods—not significant; body mass index = weight (kg)/height^2 (m); HDL, high density lipoproteins; LDL, low density lipoproteins; VLDL, very low density lipoprotein. See Table 3 for other abbreviations.

sexes (Table 4). Whole blood aggregation in response to collagen (EMR, ED_{50}, and lag phase), as well as ADP-induced aggregation in PRP, were essentially similar at the end of the two oil regimens in both studies and for both sexes (Table 5). In Study 2, the basal values of EMR were higher in women than in men (Table 5), and erythrocyte membrane fluidity and Na^+,K^+ATPase activity were not altered by the type of oil consumed (Table 5).

The results of Study 1 on fatty acid composition of plasma lipids and platelet phospholipids are presented in Table 6. At the end of POL period, 18:2n-6 decreased in both triglycerides and cholesteryl esters and monounsaturated fatty acids (MUFA) increased in cholesteryl esters. Plasma and platelet phospholipid fatty acid compositions were essentially similar at the end of the two oil regimens. The results of Study 2 on fatty acid composition of plasma and platelet lipids (Table 7) show that in men, 18:2n-6 decreased in both triglycerides and cholesteryl esters, SFA increased in triglycerides, and MUFA increased in cholesteryl esters at the end of POL period. In women, these changes were small and did not achieve statistical significance. Plasma and platelet phospholipid fatty acid compositions were quite similar at the end of the two oil regimens for both sexes.

DISCUSSION

A substantial body of data indicates that dietary factors and genetic variability affect the risk of cardiovascular diseases (1). Among the dietary factors, SFA increase plasma cholesterol and platelet reactivity, and these changes in turn con-

[a]Values are mean ± SE; n = 12 in each group except where indicated in parentheses; LC, long chain; see Table 3 for other abbreviations; LC n-3 PUFA include 20:5, 22:5, and 22:6; SFA other than 16:0 and 18:0 include 20:0, 22:0, and 24:0; total MUFA—mainly 18:1; similar superscripts given to mean values indicate significant differences a = $P < 0.02$; b = $P < 0.01$ by paired *t*-test.

tribute to atherosclerosis and thrombosis (1). This study describes the effects of substituting GNO with POL in diets of middle-age Indian subjects on various parameters which increase the risk of cardiovascular diseases. Body weight can affect both blood pressure and serum lipids. Since the energy intakes and body weights were similar at the end of the two oil regimens, the results presented here can be attributed to differences in the type of oil consumed. In Study 1, body weights at pre-entry and at the end of each oil regimen were similar despite lower (~16%) total energy intakes at pre-entry. It is possible that the 24-h recall method has given underestimated values of energy intakes.

Substitution of POL for GNO doubles the 16:0 and reduces by half the 18:2n-6 content of cereal based diets containing about 30% total fat calories. Despite this, blood pressure, serum total cholesterol, and cholesterol distribution in various lipoproteins and total and VLDL triglycerides were not altered over 16 wk. It has been reported that 18:2n-6 reduces blood pressure in hypertensive but not in normotensive subjects (31). The lack of 18:2n-6 effect on blood pressure observed in this study may be because all the subjects (except three) were normotensive. Further, the observations made here suggest that increasing 16:0 up to about 12 en% does not raise blood pressure.

The effects of POL observed in this study are consistent with other studies showing that palm oil does not raise serum

[a]Values are mean ± SE; n = 12 in each group except where indicated in parentheses; see Table 3 and 6 for abbreviations; LC n-3 PUFA includes 20:5, 22:5, and 22:6; LC n-6 PUFA includes 20:3, 20:4, and 22:5; SFA other than 16:0 and 18:0 include 20:0, 22:0, and 24:0; total MUFA—mainly 18:1; similar superscripts given to mean values indicate significant differences a = $P < 0.01$; b = $P < 0.02$; c = $P < 0.05$ by paired *t*-test.

cholesterol (11–17). Some recent studies have reported that 16:0 has no effect on serum cholesterol in normocholesterolemic subjects consuming diets containing <300 mg cholesterol, whereas it raises serum cholesterol in hypercholesterolemic subjects consuming >400 mg cholesterol per day (3,32). However, the cholesterol intake in the subjects studied here was low (80 mg/d) and in 80% of the subjects the serum cholesterol levels at pre-entry were below 220 mg/dL. Further, the change in serum cholesterol at the end of POL period was not related to the cholesterol level at pre-entry. In normocholesterolemic subjects consuming diets low in 14:0 and cholesterol, the effects of 16:0 were found to be comparable to 18:1 on serum total cholesterol and LDL/HDL ratio (33). In the present study, the dietary 14:0 was low and 18:1 levels were similar during the two oil regimens. However, 18:2n-6 levels increased from 3.3 to 7 en% during POL and GNO regimens, respectively. It has been suggested that in healthy subjects, as long as the percent energy from 18:2n-6 exceeds 2.5, 16:0 does not raise serum cholesterol, whereas stressed populations have a threshold of 18:2n-6 near 5–6 en% (32). The lack of 18:2n-6 effect (i.e., no change in serum cholesterol despite increasing dietary 18:2n-6 by 3.7 en% observed here) appears to be the result of low 18:2n-6 threshold in these subjects.

The fatty acid composition of plasma and membrane lipids reflects the overall balance of fatty acid intakes and metabolic regulations. In men (but not in women), the lower 18:2n-6 and higher 16:0 intakes during POL regimen were reflected in the compositions of triglycerides and cholesteryl esters. The differences in the response to dietary fatty acids observed between sexes cannot be due to compliance since the subjects of both sexes (Study 2) were drawn from the same family and consumed the same meals. A higher proportion of 18:2n-6 in plasma triglycerides and erythrocyte membranes in Asian diabetics as compared to Europeans has been attributed to differences in dietary levels of 18:2n-6, but sex difference was not observed in the tissue response to dietary fatty acids (34).

Studies in which dairy fat consumption was increased indicate that the markers of high SFA intake are MUFA and eicosatrienoic acid (20:3n-9) in plasma and platelet phospholipids (35). The data presented here (Tables 6 and 7) show that the plasma and platelet phospholipid fatty acid compositions were essentially similar at the end of the two oil periods. However, the high SFA intake during POL regimen was reflected in the levels of MUFA in cholesteryl esters. It appears that about 3 en% 18:2n-6 may be sufficient to maintain membrane levels of arachidonic acid. This fatty acid being the predominant PUFA plays an important role in both eicosanoid and noneicosanoid functions of membranes (4,7).

The risk factors of cardiovascular disease, including high dietary SFA, may increase platelet aggregation which, in turn, participates in atherosclerosis and thrombosis (1). A positive relation has been shown between diet rich in SFA and *ex vivo* platelet aggregability to most agonists (35,36). It has been suggested that ED_{50} and EMR give a better description of platelet function than measurements made with a particular dose of agonist (21,37), and aggregation in whole blood using impedance is more sensitive to antiplatelet drugs than the measurement made in PRP (38). In the present study, the EMR and ED_{50} measurements were done in both PRP and whole blood, although in response to different aggregating agents. The data presented in Table 5 shows that substitution of GNO with POL does not affect the aggregability of platelets. This could be because the platelet arachidonic acid levels, which are known to be strong determinants of *in vitro* platelet reactivity were similar during the two oil regimens. Qureshi *et al.* (39) reported that dietary tocotrienols from palm oil (Palmvitee) reduce *ex vivo* thromboxane B_2 generation and platelet aggregation. It was subsequently reported that (40) tocotrienol-rich vitamin E from palm oil did not alter thromboxane A_2, prostacyclin I_2, and platelet aggregation. However, in the present study, we have not measured thromboxane A_2 and prostacyclin. The high EMR for collagen-induced whole blood aggregation (Table 5) in women indicates greater aggregability as compared to men, but ED_{50} and lag phase in whole blood and ED_{50} and EMR in PRP were similar for both genders. The reasons for this discrepancy are not clear.

The lipid composition and functions of erythrocyte membranes can be modified by the type of dietary fat (4,5). In the present study, although the fatty acid composition of erythrocyte membranes was not measured, fluidity and activity of Na^+,K^+ATPase, a membrane-bound enzyme, were determined. That POL did not affect these parameters suggests either that the fatty acid composition of erythrocytes was not altered or the magnitude of changes were not sufficient to alter these membrane functions.

This study assessed the effects of substitution of GNO with POL in cereal-based diets which contained low cholesterol and about 30% total fat calories on blood lipids, platelet aggregation, and erythrocyte membrane functions of normal Indian subjects. The failure to demonstrate changes in the above parameters in 12 men and 12 women during 8- or 16-wk cross-over periods for each fat suggests that POL is comparable to GNO and does not induce the adverse effects usually associated with dietary saturated fat. However, to draw definitive conclusions it will be necessary to extend these studies to a larger number of subjects with one or more risk factors (hyperinsulinemia, obesity, hypertension) for cardiovascular disease.

ABSTRACT: The cholesterol-suppressive actions of Palmvitee and γ-tocotrienol were assessed in hypercholesterolemic subjects after acclimation to the American Heart Association Step 1 dietary regimen for four and eight weeks, respectively. The four-week dietary regimen alone elicited a 5% decrease ($P < 0.05$) in the cholesterol level of the 36 subjects. Subjects continuing on the dietary regimen for a second four-week period experienced an additional 2% decrease in their cholesterol levels. Dietary assessments based on unanticipated recalls of 24-h food intake records suggest that significant reductions in energy and fat, predominantly in saturated fat, intakes are responsible. The subjects experienced significant Palmvitee- and γ-tocotrienol-mediated decreases in cholesterol. The group of subjects acclimated to the dietary regimen for four weeks responded to Palmvitee (a blend of tocols providing 40 mg α-tocopherol, 48 mg α-tocotrienol, 112 mg γ-tocotrienol, and 60 mg δ-tocotrienol/day for four weeks) with a 10% decrease in cholesterol ($P < 0.05$). Dietary assessments showed no further change in energy and fat intakes. α-Tocopherol attenuates the cholesterol-suppressive action of the tocotrienols. The second group of subjects, acclimated to the dietary regimen for eight weeks, received 200 mg γ-tocotrienol/d for four weeks. The cholesterol-suppressive potency of this α-tocopherol-free preparation was calculated to be equivalent to that of the mixture of tocotrienols (220 mg) used in the prior study. Cholesterol levels of the 16 subjects in the second group decreased 13% ($P < 0.05$) during the four-week trial. Plasma apolipoprotein B and *ex vivo* generation of thromboxane B_2 were similarly responsive to the tocotrienol preparations, whereas neither preparation had an impact on high density lipoprotein cholesterol and apolipoprotein A-I levels.

Lipids 30, 1171–1177 (1995).

The tocotrienols initiate post-transcriptional actions which lead to the down regulation of 3-hydroxy-3-methylglutaryl–CoA (HMG–CoA) reductase activity (1). Mevalonic acid, the product of this reaction, is generally considered to be the rate-limiting substrate for the synthesis of cholesterol. A decrease in serum cholesterol, a response consistent with the tocotrienol-mediated down-regulation of HMG–CoA reductase activity, is reported from some (2,3), but not all, human studies (4). We (2) and others (3,4) have reported the failure of some individual hypercholesterolemic subjects to respond to the tocotrienols. This variation could be anticipated, as the biological action of tocotrienols may limit their impact to those subjects who have an overproduction of cholesterol.

Excessive dietary intake of cholesterol overrides the biological action of the tocotrienols, but other confounding factors may be less apparent. Subjects receiving placebos often record modest decreases in blood lipids; these changes are attributed to subtle changes in dietary patterns. We recently confirmed (5) our preliminary finding (6) that α-tocopherol attenuates the impact of the tocotrienols on HMG–CoA reductase activity. This finding addresses another confounding factor. Tocotrienol preparations available for human tests (Palmvitee; BCP, AG; PORIM, Kuala Lumpur, Malaysia) are not standardized. Our review of the tocotrienol literature found that the studies showing a cholesterol-lowering action of the tocotrienols employed either a purified tocotrienol or Palmvitee preparations containing less than 20% tocopherol (5). The following study was designed to avoid the aforementioned confounding factors.

METHODS

Study population. Subjects were recruited from a hypercholesterolemic population (serum cholesterol > 5.7 mmol/L) screened at the University of Illinois, Chicago (Chicago, IL). Volunteers were excluded on the basis of weight (>150% of Metropolitan Life ideal weight), use of cholesterol-altering medication, an elevated serum glutamate-pyruvate or glutamate-oxaloacetate transaminase activity, an elevated blood urea nitrogen or glucose level, diabetes, or a history of a liver, renal, or hypertensive disease. Subject screening was accomplished during a three-week period. A fasting blood sample

was collected for cholesterol determination at the initial session following the determination of eligibility. Following blocking by gender and stratification according to low and high cholesterol levels as determined at screening, the subjects in each of the four subsets were randomized into an experimental (Palmvitee) group of 20 subjects (7.02 ± 0.99 mmol cholesterol/L) and a control (Placebo) group of 16 subjects (7.32 ± 0.84 mmol cholesterol/L). The groups were uniform in male/female distribution (45:55), age (40.6 ± 12.1 y), and body mass index (28.1 ± 4.9). All subjects signed an informed consent which was approved by the University of Illinois, Chicago Medical Center Institutional Review Board. The study was conducted under IND number 30906.

Experimental design. The 16-wk study consisted sequentially of Baseline, American Heart Association Diet (7,8), Palmvitee, and γ-Tocotrienol phases.

Baseline phase. On entry, the subjects met individually and in small group sessions with counselors. The individual sessions focused on 24-h recalls of food consumption, and the group sessions provided instructions for keeping three-day records of food intake (two weekdays, one weekend day). Subjects were encouraged to follow their typical dietary pattern and were instructed to keep food records for the terminal three days of this and the following phases. Subjects also received an unanticipated telephone call for a 24-h recall of food intake.

American Heart Association Step 1 Diet (AHA Diet) phase. Subjects met in small groups for discussions of the relationship between diet and cardiovascular risk factors and for instruction on the AHA Diet. Each subject received a copy of the *1988 AHA Diet, Patient Manual*, and the telephone number of a staff contact person.

Palmvitee phase. The subjects were continued on the AHA Diet during this phase; each subject consumed four 300 mg capsules daily. Subjects in the Placebo group received capsules containing 300 mg corn oil and ~0.25 mg α-tocopherol. Palmvitee subjects received capsules containing 235 mg palm olein, 10 mg α-tocopherol, 12 mg α-tocotrienol, 28 mg γ-tocotrienol, and 15 mg δ-tocotrienol (AG; PORIM, Kuala Lumpur, Malaysia).

γ-Tocotrienol phase. The 16 Placebo subjects were continued on the AHA Diet regimen for a final four weeks, during which each received four 300 mg capsules daily (each capsule contained 250 mg palmolein and 50 mg γ-tocotrienol). γ-Tocotrienol was isolated the tocotrienol-rich fraction of palm oil (AG; PORIM).

Analyses. Initial measures include the subjects' height, weight, blood pressure, history of significant diseases, medications, and alcohol use. Weights were recorded weekly. Venous blood samples were drawn at 7:00–9:00 a.m. following an overnight fast at the Baseline phase (week three represents data obtained at screening and at week four), and at weeks seven and eight (AHA Diet), 11 and 12 (Palmvitee), and 15 and 16 (γ-Tocotrienol) of the study. Processed samples were held at −72°C until analysis.

The study design provided control and treatment cholesterol values for each subject. Automated clinical laboratory procedures were used for cholesterol determinations at weeks 4, 8, 12, and 16. We found that the standard deviations for the paired differences were on the order of 51 ± 12% of the mean. At the termination of the study, we analyzed the samples according to the manual protocol. The standard deviations for the paired differences were on the order of 15 ± 3% of the mean (from Scheme 1). We then sent random coded samples to clinical laboratories at the University of Illinois and the University of Wisconsin for analyses. The results of these analyses proved to be more consistent with those obtained by the manual protocol. The manual and automated clinical procedures yielded similar values for the subjects with the relatively lower cholesterol levels. It should be noted that the latter clinical determinations were run with instruments at each setting calibrated against a single standard, whereas the ini-

Glucose (mmol/L)	36	5.97 ± 0.86	5.66 ± 0.77	1.63	NS

[a]LDL, low density lipoprotein; ApoB, apolipoprotein B; HDL, high density lipoprotein; ApoA-I, apolipoprotein A-I; NS, not significant. See Table 1 for other abbreviations.

tial analyses were conducted over a nine-month period with multiple standards. Alternatively, the extended incubation employed with the manual procedure might permit the more accurate determination of very elevated cholesterol levels.

The analyses of the coded samples were performed at Advanced Medical Research (Madison, WI). Serum cholesterol, high density lipoprotein (HDL) cholesterol, triglyceride, and glucose concentrations were estimated with reagent kits from Sigma Chemical Co. (St. Louis, MO). The incubation time for the cholesterol determinations was 10 min. Serum apoprotein A-I (ApoA-I), apolipoprotein B (ApoB), and thromboxane B_2 (TxB_2) concentrations were determined by radio immunoassay using kits from Sigma (ApoA-I, ApoB) and Chemicon International Chemicon International (El Segundo, CA) (TxB_2).

Diet records and 24-h recalls were analyzed (Nutrition Coordinating Center, University of Minnesota, Minneapolis, MN); if required, subjects were individually counseled to modify food intake to meet the goals of the AHA Diet or to maintain weight.

Statistical analyses. Treatment effects were evaluated by analysis of variance (SuperANOVA; Abacus Concepts, Berkeley, CA) and *t*-test (StatView; Abacus Concepts). *P* values shown on figures and in Tables 1 and 2 were obtained by two-tailed *t*-test of differences between means. We further evaluated the within group treatment effects on cholesterol (Fig. 7, shown later) using the paired, two-tailed *t*-test. Mean ± SD values are recorded in tables; mean ± SEM values are plotted on figures.

RESULTS

The intervention for all subjects during weeks 4–8 phase was the AHA diet. We first examined the subjects' response to the AHA diet instructions. Although somewhat limited from a quantitative standpoint, our analysis (Table 1) reveals that the subjects significantly decreased their reported intakes of energy (23%, $P < 0.01$), carbohydrate (19%, $P < 0.05$), fat and saturated fatty acids (40%, $P < 0.03$; and 38%, $P < 0.01$, respectively), and cholesterol (33%, $P < 0.04$). Concomitant with these changes, there were modest, but significant, decreases (Table 2) in cholesterol (5%, $P < 0.03$), the estimate (9) of low density lipoprotein (LDL) cholesterol (8%, $P < 0.05$), and ApoB (9%, $P < 0.01$). All subjects were continued on the AHA diet during weeks 8–12 phase of the study. Our analysis revealed no significant differences between the subjects reported intakes at weeks 4–8 and weeks 8–12. This design enabled us to evaluate the impact of an eight-week exposure to the AHA dietary regimen on blood parameters of 16 subjects (Placebo, Figs. 1–6). Our analyses of differences

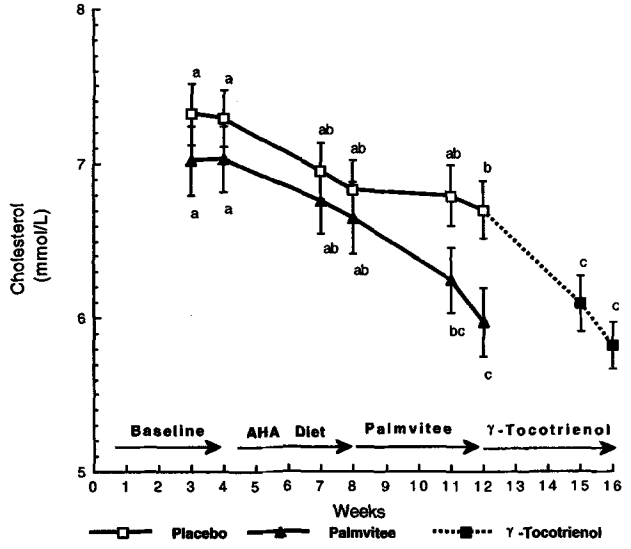

FIG. 1. Time-dependent impacts of American Heart Association Step 1 Diet (AHA) dietary regimen, Palmvitee (PORIM, Kuala Lumpur, Malaysia) and γ-Tocotrienol on serum cholesterol levels of hypercholesterolemic adult subjects. Differences between values on each plotted line which do not not share a letter are significant ($P < 0.05$).

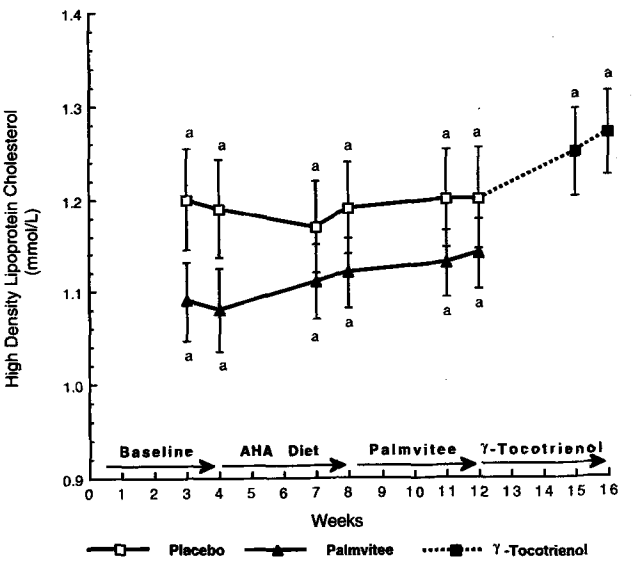

FIG. 3. Time-dependent impacts of AHA dietary regimen, Palmvitee, and γ-Tocotrienol on high density lipoprotein cholesterol levels of hypercholesterolemic adult subjects. Differences between values on each plotted line were not significant. Abbreviation and source as in Figure 1.

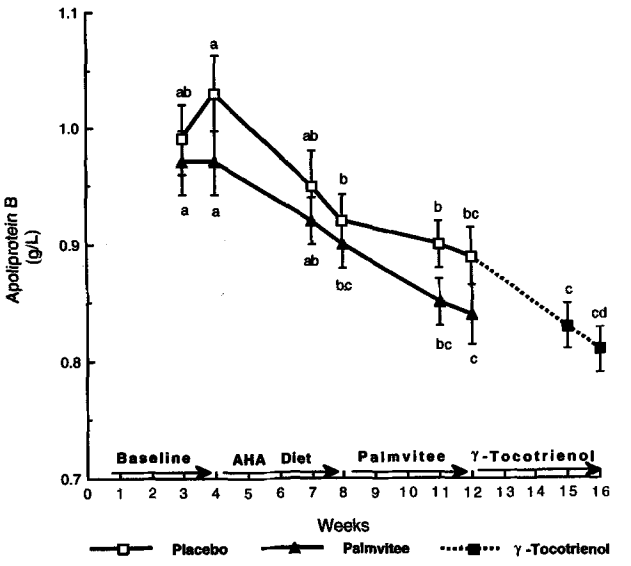

FIG. 2. Time-dependent impacts of AHA dietary regimen, Palmvitee, and γ-Tocotrienol on serum apolipoprotein B levels of hypercholesterolemic adult subjects. Differences between values on each plotted line which do not not share a letter are significant ($P < 0.05$). Abbreviation and company source as in Figure 1.

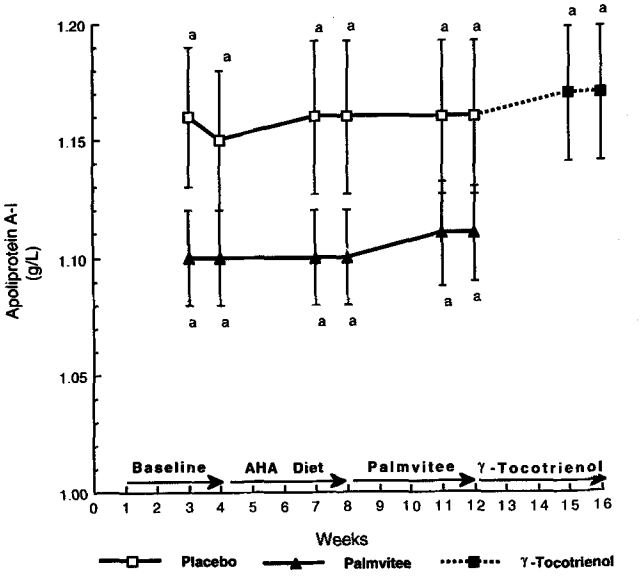

FIG. 4. Time-dependent impacts of AHA dietary regimen, Palmvitee, and γ-Tocotrienol on serum apolipoprotein A-I levels of hypercholesterolemic adult subjects. Differences between values on each plotted line were not significant. Abbreviation and company source as in Figure 1.

between Baseline (week four) and week 12 values reveal significant decreases in cholesterol (8%, $P < 0.05$, Fig. 1), LDL cholesterol (11%, $P < 0.05$), ApoB (13%, $P < 0.05$, Fig. 2), and glucose (9%, $P < 0.05$, Fig. 6). HDL cholesterol (Fig. 3), ApoA-I (Fig. 4), and triglyceride (Fig. 5) levels were not influenced by the dietary regimen. It should be noted that these subjects received 1.2 g corn oil in capsule form during weeks 8–12. In summary, the AHA diet proved to be effective in lowering the total cholesterol, LDL cholesterol (calculated, data not shown), ApoB, and glucose levels of this group of hypercholesterolemic subjects.

The cholesterol levels of the aforementioned 16 subjects decreased by 5 and 3% during the successive four-week exposures to the AHA dietary regimen. The cholesterol level of the remaining 20 subjects decreased by 5% during the first four-week exposure to the dietary regimen. These subjects re-

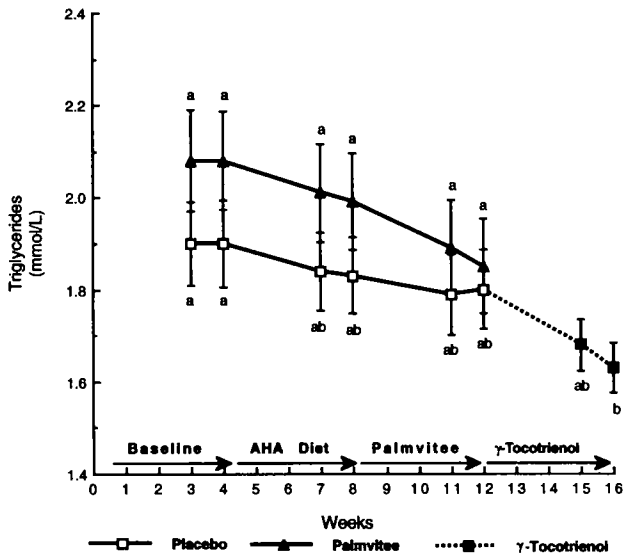

FIG. 5. Time-dependent impacts of AHA dietary regimen, Palmvitee, and γ-Tocotrienol on serum triglyceride levels of hypercholesterolemic adult subjects. Differences between values on each plotted line which do not share a letter are significant ($P < 0.05$). Abbreviation and company source as in Figure 1.

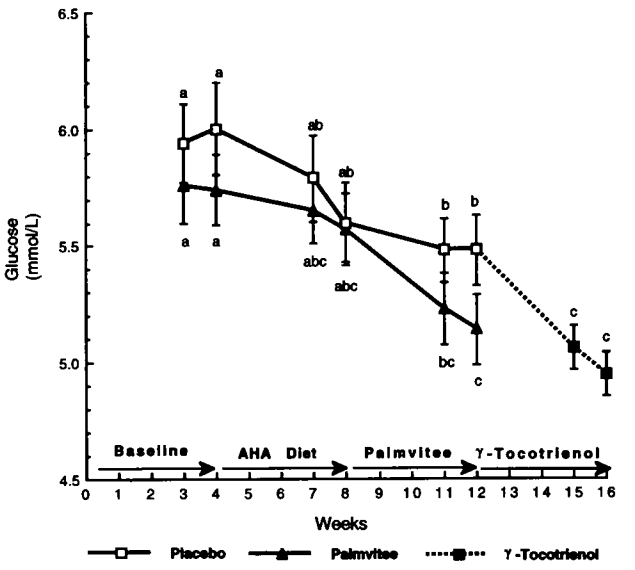

FIG. 6. Time-dependent impacts of AHA dietary regimen, Palmvitee, and γ-Tocotrienol on serum glucose levels of hypercholesterolemic adult subjects. Differences between values on each plotted line which do not share a letter are significant ($P < 0.05$). Abbreviation and company source as in Figure 1.

ceived Palmvitee, a tocotrienol-rich fraction of palm oil providing 40 mg α-tocopherol, 48 mg α-tocotrienol, 112 mg γ-tocotrienol, 60 mg δ-tocotrienol, and 1.14 g palm olein (0.6 g oleic acid, 0.15 g linoleic acid, and 0.4 g palmitic acid) during the second four-week exposure to the AHA diet. This combined regimen led to significant decreases in cholesterol (10%, $P < 0.05$), LDL cholesterol (13%, $P < 0.05$, calculated data not shown), and ApoB (7%, $P < 0.05$) levels during this four-week period (Figs. 1, 2). HDL cholesterol, ApoA-I, and triglyceride levels (Figs. 3–5) were not influenced by the combined regimen. Blood glucose at week 12 was 15% ($P < 0.05$) lower than the Baseline (week four) value (Fig. 6). In summary, the incremental response to Palmvitee likely accounted for 7% of the 10% decrease in cholesterol and associated decreases in LDL cholesterol and ApoB levels during this phase.

The tocol mixture in the Palmvitee supplement was comprised of 15% α-tocopherol and 85% tocotrienols. It has previously been noted that α-tocopherol attenuates the cholesterol-suppressive actions of the tocotrienols (5,6). Therefore, it was of interest to evaluate the impact of a tocopherol-free preparation of γ-tocotrienol on the cholesterol levels of the 16 Placebo subjects during a terminal four-week phase of the study. As shown on Figure 1, the cholesterol level of these subjects had plateaued during their second four-week exposure to AHA dietary regimen. The γ-tocotrienol supplement effected a significant 13% decrease in cholesterol (Fig. 1), with concomitant decreases in ApoB (Fig. 2) and LDL cholesterol (calculated, not shown) levels. The significant decrease in blood glucose during this period reflects that previously noted on the exposure of the other subjects to Palmvitee (Fig. 6). HDL cholesterol and ApoA-I levels remained stable (Figs. 3, 4). Finally, we note that the general decrease in triglycerides achieved statistical significance (Fig. 5). We postulate that this decrease reflects the long-range impact of the AHA dietary regimen.

We further evaluated the treatment effects on cholesterol levels using the paired *t*-test. We first calculated the difference between week 8 and week 4, week 12 and week 8, and week 16 and week 12 values for each individual (Scheme 1). The AHA diet-mediated decrease in cholesterol for the Placebo group during the first four-week exposure (–0.40 ± 0.07 mmol/L) was significantly greater than that during the second four-week exposure (–0.20 ± 0.03 mmol/L, $P < 0.005$). The decrease in cholesterol for the Palmvitee group during the four-week exposure to the AHA diet (–0.38 ± 0.05 mmol/L) equaled that observed in the Placebo group. This decrease, however, was significantly less than that observed when the subjects received Palmvitee (–0.68 ± 0.12, $P < 0.050$). This impact of tocotrienols is confirmed in the final comparison showing that the decrease in cholesterol during the γ-tocotrienol phase of the experiment (–0.87 ± 0.10 mmol/L) is significantly greater than that which occurred during the second four-week exposure to the AHA dietary regimen ($P < 0.001$).

Serum TxB_2 concentrations decreased significantly ($P < 0.05$) during the Palmvitee and γ-Tocotrienol phases of the study (Fig. 7).

DISCUSSION

The present study was designed to avoid the previously noted confounding factors which we believe underlie the failure of others (4) to demonstrate the cholesterol-suppressive action

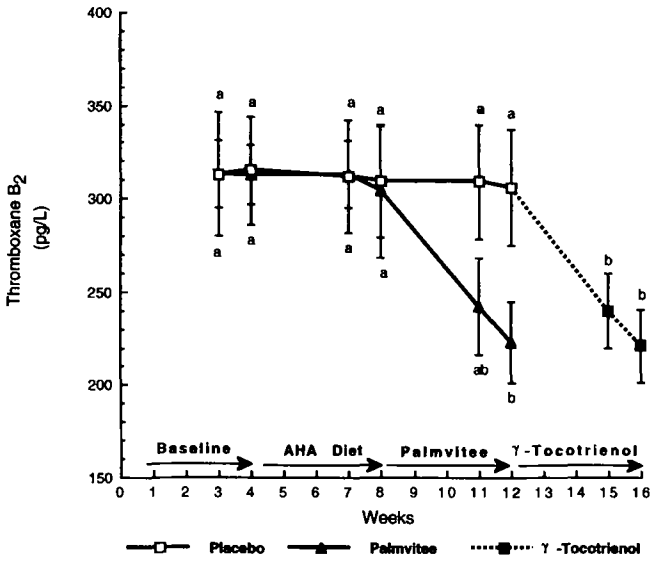

FIG. 7. Time-dependent impacts of AHA dietary regimen, Palmvitee, and γ-Tocotrienol on thromboxane B_2 concentrations in serum of hypercholesterolemic adult subjects. Differences between values on each plotted line which do not not share a letter are significant ($P < 0.05$). Abbreviation and company source as in Figure 1.

of the tocotrienols. Hypercholesterolemic subjects were first conditioned for four weeks to a dietary regimen patterned after the AHA Diet. During that acclimation period, energy intake, estimated from spontaneous diet recalls, decreased by 22%; the proportion of energy supplied by fat decreased from 34 to 30% and that provided by saturated fatty acids, from 12 to 9%. Cholesterol intake decreased from 123 to 106 mg/1000 kcal (Table 1). Four weeks' acclimation to the AHA Diet resulted in significant decreases in cholesterol (5%) and LDL cholesterol (8%) levels. The group of subjects continuing on the AHA Diet for another four weeks experienced an additional 2% decrease in these parameters. Cholesterol (Fig. 1) and LDL cholesterol after eight weeks' exposure to the AHA Diet were decreased by 7 and 10%, respectively.

As previously noted, this study was designed to segregate the impact of the dietary regimen from that of the tocotrienol supplements. Our analysis revealed no significant changes in dietary intakes during the Palmvitee phase of the study. Fat and saturated fatty acids provided 28 and 9%, respectively, of energy intake; cholesterol intake increased from 106 to 134 mg/1000 kcal. The cholesterol-suppressive action of Palmvitee achieved significance at four weeks (Fig. 1); this change is supported by concomitant and significant Palmvitee-induced changes in LDL cholesterol (not shown) and ApoB (Fig. 2).

The Palmvitee capsules provided 220 mg tocotrienols and 40 mg α-tocopherol. The *in vivo* cholesterol-lowering action of the tocotrienols is attenuated by α-tocopherol (5,6), and the tocotrienols differ significantly in their capacity to suppress cholesterol synthesis; γ-tocotrienol and δ-tocotrienol are approximately equipotent, whereas α-tocotrienol has a lower potency (10). These considerations led us to evaluate the cholesterol-suppressive action of a tocotrienol preparation free of α-tocopherol. This preparation provided 200 mg γ-tocotrienol, a quantity calculated to have the cholesterol-suppressive potency of the 220 mg mixture of tocotrienols in the Palmvitee. As shown on Figure 1, the decrease in serum cholesterol mediated by the tocopherol-free preparation reached significance at three weeks.

The significant tocotrienol-mediated decrease in serum cholesterol (Fig. 1) and ApoB (Fig. 2) (and LDL cholesterol) levels of hypercholesterolemic subjects were accomplished in the absence of a treatment-mediated impact on levels of HDL cholesterol (Fig. 3) and ApoA-I (Fig. 4). This response is at odds with that reported by by Wahlqvist *et al.* (4). They conducted a 26-week (six weeks run-in and 20 weeks experimental), rising-dose study with a Palmvitee preparation (23% α-tocotrienol, 31% γ-tocotrienol, 16% δ-tocotrienol, and 30% α-tocopherol). After the run-in period (unspecified dietary fat modification), 52 hypercholesterolemic subjects were randomly assigned to placebo (n = 26, 6.95 ± 1.58 mmol cholesterol/L) and rising-dose treatment (n = 26, 7.51 ± 1.94 mmol cholesterol/L) groups. Interpretation of the results of this study presents several problems, including that due to having a different number of subjects per group (17 to 44). The authors report that only four of the 17 subjects receiving Palmvitee from week 0 to week 16 experienced a fall in serum cholesterol. Tan *et al.* (3) reported that 14 of 15 hypercholesterolemic subjects receiving a similar preparation of Palmvitee (30% α-tocopherol) experienced a greater than 5% decrease in cholesterol. In our earlier study (2), cholesterol levels of 12–15 hypercholesterolemic subjects receiving a preparation of Palmvitee (20% α-tocopherol) decreased. As previously noted, the failure of some subjects to respond may indicate that the biological action of tocotrienols may be more complex than simply inhibiting HMG–CoA reductase.

We found significant tocotrienol-mediated decreases in serum TxB_2 (Fig. 7). This decrease, we postulate, is consistent with the finding that the tocotrienols in membrane redox systems have a major, but little appreciated, antioxidant capacity (11) that would be detected in this capacity-related *ex vivo* index of platelet cyclooxygenase activity. Whether this might reflect an additional cardiovascular benefit *in vivo* remains to be determined.

ABSTRACT: Antioxidants may have a role in the prevention of atherosclerosis. In the present trial, we investigated the antioxidant properties of Palm Vitee, a γ-tocotrienol-, and α-tocopherol enriched fraction of palm oil, in patients with carotid atherosclerosis. Serum lipids, fatty acid peroxides, platelet aggregation, and carotid artery stenosis were measured over an 18-month period in fifty patients with cerebrovascular disease. Change in stenosis was measured with duplex ultrasonography. Ultrasound scans were done at six months, twelve months, and yearly thereafter. Bilateral duplex ultrasonography revealed apparent carotid atherosclerotic regression in seven and progression in two of the 25 tocotrienol patients, while none of the control group exhibited regression and ten of 25 showed progression ($P < 0.002$). Serum thiobarbituric acid reactive substances, an *ex vivo* indicator of maximal platelet peroxidation, decreased in the treatment group from 1.08 ± 0.70 to 0.80 ± 0.55 μM/L ($P < 0.05$) after 12 mon, and in the placebo group, they increased nonsignificantly from 0.99 ± 0.80 to 1.26 ± 0.54 μM/L. Both tocotrienol and placebo groups displayed significantly attenuated collagen-induced platelet aggregation responses ($P < 0.05$) as compared with entry values. Serum total cholesterol, low density lipoprotein cholesterol, and triglyceride values remained unchanged in both groups, as did the plasma high density lipoprotein cholesterol values. These findings suggest that antioxidants, such as tocotrienols, may influence the course of carotid atherosclerosis.

Lipids 30, 1179–1183 (1995).

In recent years, evidence has linked processes involving oxygen-derived free radicals with the initiation and propagation of atherosclerosis. In particular, the oxidative modification of low density lipoproteins (LDL), with its ensuing sequelae of cytotoxic, thrombogenic, and chemotactic events, has emerged as a key step in promoting atherosclerosis (1–3). Antioxidants, especially vitamin E, have received considerable attention as potential antiatherogenic agents for over 40 years. A number of recent studies have demonstrated the ability of antioxidants to prevent *ex vivo* and *in vitro* LDL oxidation, and to potentially be able to ameliorate the development of atherosclerotic lesions (4–6). Epidemiological studies have linked the dietary intake of vitamin E and other antioxidants with a reduced risk of coronary heart disease (7,8), ischemic heart disease (9), ischemic stroke (10), coronary and total mortality (11), and with a decrease in carotid artery wall thickness (12). As the vitamin-rich distillate of palm oil [Palm Vitee; Palm Oil Research Institute of Malaysia (PORIM), Kuala Lumpur, Mayalsia] is enriched with several antioxidant members of the vitamin E family (tocopherols and tocotrienols), it seemed worthwhile to investigate its antioxidant effects in patients with cerebrovascular disease.

EXPERIMENTAL PROCEDURES

The study cohort consisted of 50 subjects (23 males and 27 females), ranging in ages 49–83 yr, with carotid artery atherosclerosis as determined by duplex carotid ultrasonography. Patient numbers 7 and 13, one from each group, dropped out and were excluded. They were replaced by patient numbers 51 and 52 in the analysis. Eligibility criteria included subjects less than 85 years of age who had either had a hemispheric transient ischemic attack, monocular blindness for less than 24 h, or a nondisabling hemispheric stroke within the previous year. Subjects had carotid artery stenosis ranging from 15 to 79%. Subjects having stenosis beyond 79% were referred to surgery. Forty-four percent of placebo and 60% of test subjects had more than 49% stenosis of the carotid artery. All patients continued to receive their current medical care, including antihypertensive, antidiabetic, and antiplatelet (usually aspirin) treatment, except that 3-hydroxy-3-methylglutaryl-CoA reductase inhibitors were discontinued.

At baseline, patients underwent standardized history, physical, and neurological examinations, an assessment of functional status, standardized laboratory tests, 12-lead electrocardiography, a chest X-ray, and duplex carotid ultrasonography. A synopsis of subject characteristics appear at baseline showing their similarity [Table 1; collagen-induced aggregation (Ω) was 17.3 for the antioxidant group, 15.5 for the placebo group; thrombin ATP release (μM/L) was 1.21 ± 1.1 and 1.02 ± 0.39 for the antioxidant and placebo groups, respectively].

Ultrasonography of the carotid arteries was done at baseline and repeated at six and twelve months, and annually thereafter. Degree of stenosis was graded as: 0–15%; 16–49%;

50–79%, and 80–99%. Ultrasound duplex measurements were done with an Acuson 128 XP ultrasonograph (Acuson Co., Mountain View, CA) equipped with a 5 or 7 MHz transducer. The transducer aperture was 38 mm. Subjects were examined in the supine position. Change from one category to the next was reckoned regression or progression; a change of two categories was considered marked regression or progression. All ultrasound studies were done by the same person, who was unaware of treatment assignments and results of earlier measurements. The artery of neurological involvement was used for study, in an attempt to more easily correlate the pathological and clinical changes.

Using a table of random numbers, patients were assigned to receive 300 mg capsules containing either 16 mg α-tocopherol, 40 mg γ- and α-tocotrienols, and 240 mg palm superolein, (Palm Vitee), or placebo (300 mg palm superolein). Palm superolein is a mixture of triglycerides with the predominant fatty acids being oleic, palmitic, and linoleic (6:4:1.51 ratio). Capsules containing placebo or palm oil fraction were provided by PORIM. Initial dosage of the palm oil antioxidants or placebo was four capsules daily. At the three- and six-month follow-up visits, the dosage was increased to five and six capsules daily, respectively, in an attempt to lower serum lipids. The dosage then remained at six capsules/day (240 mg tocotrienol) for the remainder of the study. Patients were blinded throughout the trial; none in either group reported side effects. Investigators also were blinded about treatment groups, except for the one who distributed the capsules.

During the baseline, 3-, 6-, 9-, 12-, and 18-month visits, venous blood was drawn after overnight fasting into EDTA and Vacutainer SST tubes (Becton Dickinson Co., Rutherford, NJ) with a sterile activator, stored at ambient temperature for five minutes, spun at ambient temperature at 3400 rpm, and either analyzed immediately or stored frozen overnight before analysis. Though samples were identified by name during analysis, the analyses were done in a laboratory separate from the outpatient clinic. A lipid profile was measured in each subject to control for dietary changes or medicinal usage compliance which might have affected stenosis. It included serum total cholesterol, LDL cholesterol (by difference) (13), and triglycerides for each visit using Reflotron methodology, which uses cholesterol esterase, oxidase, horseradish peroxidase, and 3,3′,5,5′-tetramethylbenzidine dye, which is quantitated by reflectance (Boehringer-Mannheim, Indianapolis, IN) and high density lipoprotein (HDL) cholesterol using the same chemistry with EDTA-treated plasma. Triglycerides were quantitated by reaction with an esterase, glycerol kinase, glycerol phosphate oxidase, and peroxidase in the presence of a dye [4-(4-dimethylaminophenyl)-5-methyl-2-(4-hydroxy-3,5-dimethyloxyphenol)-imidazole-dihydrochloride]. All analyses were done under amber light to reduce photooxidation. Fatty acid hydroperoxides were assayed according to Ohishi *et al.* (14). Cumene hydroperoxide was used as the standard. The serum level of thiobarbituric acid reactive substances (TBARS) was measured to quantitate malondialdehyde equivalent materials by the method of Mihara *et al.* (15). Serum levels of α-tocopherol were measured during baseline and at the 18-month visits by a high-performance liquid chromatography method of Bieri *et al.* (16) to monitor compliance. This method was not able to separate and detect measurable tocotrienols. Platelet aggregation in whole blood was measured with an impedance aggregometer (Chronolog Corp., Havertown, PA), using thrombin and collagen as agonists to initiate aggregation (17), measuring only the primary wave of aggregation after the reaction had proceeded for six minutes. These measurements were made on a background of aspirin, as all subjects were taking aspirin during the trial.

Subject compliance was monitored by pill counts and measurement of serum vitamin levels, as indicated with each data panel. Pill counts showed 95% compliance.

Statistics were performed using Student's *t*-test, the paired *t*-test, or the Mann-Whitney test. Available 3-, 6-, 9-, 12-, or 18-month data are presented.

RESULTS

Those patients being supplemented with tocopherol and tocotrienols for 18 mon approximately doubled their serum α-tocopherol levels compared to baseline (Table 2). Serum levels of tocotrienol were below the detection limits of our high-performance liquid chromatography system; hence, no tocotrienol data are presented.

The percentage change of carotid stenosis in patients by category differed in the groups receiving palm oil antioxidants and placebo after 12 mon of treatment. The data indicated (Table 3) that six (24%) of the subjects supplemented with antioxidants for 12 mon moved one category to a lesser apparent degree of stenosis; one (4%) improved two categories, suggesting marked regression. Only two from this group (8%) exhibited progression of carotid atherosclerosis. The remaining 64% manifested no change in disease state. In contrast, 24% of the placebo group appeared to progress, and 16% markedly progressed in carotid stenosis ($P < 0.002$; Mann-Whitney), while 50% of doppler studies from the placebo group remained unchanged. No one receiving the placebo showed carotid plaque regression. These data were little changed from the 6-month findings.

Data of the effect of the palm oil antioxidants vs. placebo in lowering serum lipid oxidation products are shown (in Table 2). Patients receiving antioxidants attenuated their generations of TBARS after 12 mon, with values decreasing from (mean ± SD) 1.08 ± 070 to 0.80 ± 0.55 μM/L ($P < 0.05$); whereas placebo subjects' values rose from 0.99 ± 0.80 to 1.26 ± 0.54 μM/L (nonsignificant). At baseline, a difference was seen in hydroperoxide levels, possibly attributed to cigarette smoking (Table 1). Although not significant, the fatty acid hydroperoxides increased in both groups, rising from 2.2 ± 1.26 at baseline to 3.6 ± 9.4 μM/L after 12 mon in the test group and 4.5 ± 6.4 to 3.6 ± 7.5 μM/L in the placebo group.

After 12 mon, both antioxidant supplement (16.9 ± 12.0 Ω to 12.0 ± 9.0 Ω; $P < 0.05$) and placebo (17.7 ± 12.9 Ω to 12.0 ± 7.8 Ω; $P < 0.02$) were associated with attenuation of collagen-induced platelet aggregation when compared with baseline. The platelet ATP response to thrombin did not change in the placebo group (1.02 ± 0.39 to 1.04 ± 0.73), but changed from 0.99 ± 0.46 to 1.24 ± 0.76 (nonsignificant) in the antioxidant group. The improvement seen in platelet aggregation may have resulted from improved compliance with respect to prescribed medication as a result of participation in the study. Because both groups used aspirin, and aspirin usage was monitored during the study, the decline seen in platelet aggregation was attributed to this cyclooxygenase inhibitor.

Treatment with the palm oil fraction providing 240 mg tocotrienols daily for 18 mon had no measurable effect on serum lipids (Table 4). Compared to baseline, serum total, LDL and HDL cholesterol, and triglyceride values remained virtually unchanged (nonsignificant) in test and in control groups over the observation periods.

DISCUSSION

The purpose of the present clinical study was to test the effect of tocotrienols in patients with carotid atherosclerosis. After extending the duration of the tocotrienol supplementation study to 18 mon, although we found no measurable improvement in blood lipids, we observed an apparently improved blood flow in the carotid arteries of six patients out of 25. Over a one-year period, in a population of hypercholesterolemic Eastern Finnish men, an inverse correlation was observed between plasma antioxidant levels (vitamin E, β-carotene, selenium) and the increase in carotid intima-media thickness (18). Similarly, in both men and women, an inverse

[a]Data expressed as number of subjects per category. MR, marked regression; R, regression; NC, no change; P, progression; MP, marked progression.

relationship was found between dietary antioxidant intake (α-tocopherol, ascorbic acid, β-carotene) and carotid artery wall thickness (12).

To date, the precise mechanism(s) responsible for plaque regression have not been fully elucidated and appear to be complex and multifactorial. Earlier work from this laboratory had documented the effective inhibition of platelet aggregation by antioxidants in hyperlipemic patients (19). After taking into account that one measure of the thrombogenicity of the blood was equally attenuated in both groups, and that the serum lipid profiles remained stable, it appears that the generation of serum TBARS data may provide a clue about the mode of action of tocotrienol. Elegant studies aptly support the theory that antioxidants curtail the levels of blood lipid peroxides, and blunt the formation of atherosclerotic lesions. Esterbauer *et al.* (4) demonstrated vitamin E to be very effective in preventing *in vitro* oxidation of LDL, and Carew *et al.* (5) showed that the antioxidant probucol inhibited the progression of atherosclerotic lesions in LDL receptor-deficient rabbits.

Throughout this trial, we have observed no change in serum lipid levels. To the contrary, Qureshi *et al.* (20,21) have reported a reduction in both serum total and LDL cholesterol in human hyperlipidemics and pigs supplemented with tocotrienol. Wahlquist *et al.* (22), however, observed a differential response to tocopherol and tocotrienol supplementation in human subjects without any change in serum lipids. In preliminary trials with a rat model, we had observed a hypolipidemic effect with γ-tocotrienol (23); in this regard, our results in rats did not predict the outcome in patients on uncontrolled diets who were taking a variety of medications. From the present data, it appears that a decrease in serum cholesterol was not a prerequisite in the six patients suggested to have improved carotid atherosclerosis. This impression is in contrast to coronary atherosclerosis, as we reported earlier (24). Cholesterol is, indeed, a poor predictor of carotid, compared to coronary, plaque thickness. Miettenen *et al.* (25) have reported that although no significant decrease in coronary risk was measured when clofibrate was given with probucol, no stroke cases were observed in this 1200-member study. Mao *et al.* (6) demonstrated that the attenuation of atherosclerotic lesions in Watanabe rabbits by a probucol analogue was not contingent on a concomitant reduction in serum cholesterol levels. Similarly, probucol reduced the incidence of atherosclerotic lesions in a group of Japanese hypercholesterolemic quail without altering their plasma total or lipoprotein cholesterol levels (26). These investigators attributed this effect to probucol's antioxidant properties. However, in view of the recent findings that probucol results in lowered HDL_{2b} levels in hypercholesterolemics (27), probucol use in atherosclerosis has been viewed with caution, and its manufacturer has recently indicated that this drug will be withdrawn from the U.S. market.

Our results highlight the need to investigate further roles of antioxidants such as tocotrienols in preventing, and possibly reversing, the natural course of carotid atherosclerosis.

Finally, two recent meta-analyses of randomized, controlled trials (28,29) found that lowering serum cholesterol through modified diets or medications did not reduce stroke mortality or morbidity in middle-aged men.

TABLE 4
Comparison of Response of Study Groups to 18-Month Antioxidant Supplementation on Serum Cholesterol Fractions and Triglycerides[a]

Serum moiety	Antioxidants						
(mM/L)	Baseline	3	6	9	12	18	*P*
Cholesterol	6.05 ± 0.03	6.01 ± 1.40	6.15 ± 1.57	6.10 ± 1.31	6.17 ± 1.63	6.20 ± 1.47	n.s.
LDL-chol.	4.24 ± 0.03	4.27 ± 1.36	4.39 ± 1.51	4.25 ± 1.08	4.39 ± 1.44	4.42 ± 1.19	n.s.
HDL-chol.	0.98 ± 0.01	1.01 ± 0.31	0.92 ± 0.22	0.98 ± 0.25	1.00 ± 0.34	1.08 ± 0.35	n.s.
Triglyceride[b]	5.67 ± 3.84	5.03 ± 3.09	7.08 ± 5.99	5.96 ± 5.09	5.45 ± 3.28	4.53 ± 2.48	n.s.
	Placebo						
Cholesterol	5.90 ± 0.16	5.86 ± 1.07	5.68 ± 1.39	6.03 ± 1.35	5.67 ± 1.32	5.92 ± 0.10	n.s.
LDL-chol.	4.19 ± 0.14	4.15 ± 1.14	4.00 ± 1.33	4.14 ± 1.52	4.01 ± 1.33	4.21 ± 0.88	n.s.
HDL-chol.	1.10 ± 0.01	1.12 ± 0.34	1.10 ± 0.27	1.10 ± 0.31	1.15 ± 0.32	1.04 ± 0.24	n.s.
Triglyceride[b]	4.71 ± 4.10	3.70 ± 1.53	4.92 ± 4.52	5.20 ± 5.16	3.85 ± 1.78	4.20 ± 1.76	n.s.

[a]LDL-chol., low density lipoprotein cholesterol; HDL-chol., high density lipoprotein cholesterol. Data expressed as mean ± SD; n.s., not significant.
[b]Average molecular weight 914 daltons.

ACKNOWLEDGMENT

The K.L. Jordan Research Group gratefully acknowledges the support in these studies of PORIM (Kuala Lumpur, Malaysia).

ANNOUNCEMENTS

CHANGE OF REFERENCE STYLE FOR *LIPIDS*

References should be used to quote published work as well as papers accepted for publication ("in press"). References are quoted in the text in numerical order (arabic numerals, in parentheses). **Titles of journal articles and chapter titles in multi-author books are to be included immediately preceding the name of journal or book.** When consecutive citations refer to the same journal, the source abbreviation should be given in each case (Avoid "*Ibid.*"). Each reference should refer only to one source. References are to be typed double-spaced on a separate page following the acknowledgments.

Literature citations *must* conform to the following format:

- For reference to journal articles:

  Turner, E.M., Miller, E., and Smith, D.E. (1975) Temperature and Diet Effects on Trout, *J. Biol. Chem. 250,* 108–115.

- For reference to books:

  Turner, E.H., and Smith, D.E. (1964) *Enzymes,* 2nd edn., pp. 565–567, Academic Press, New York.

- For reference to multi-author books:

  Turner, E.H. (1967) Temperature and Diet Effects on Trout, in *Comprehensive Biochemistry* (Florkin, E.M., and Stotz, E.M., eds.) Vol. 28, pp. 23–65, Elsevier, Amsterdam.

- For reference to theses:

  Turner, E.H. (1969) Fatty Acid Metabolism, Ph.D. Thesis, University of Wisconsin, Madison, pp. 12–14.

- Manuscripts accepted for publication should be listed as:

  Turner, E.H., Temperature and Diet Effects on Trout, *J. Biol. Chem.,* in press.

Names of journals must be abbreviated according to *Chemical Abstracts Service Source Index* (CASSI), published by Chemical Abstracts Service, P.O. Box 3012, Columbus, OH 43210. These abbreviations are identical to those used in *Chemical Abstracts. These abbreviations are to be used exclusively.*

If it is necessary to refer to "unpublished data," "personal communication," "manuscript in preparation" or papers "submitted for publication," such citations should not be listed as references, but are to appear in the text, e.g., (Turner, E.H., and Smith, D.E., unpublished data). Authors must obtain written permission to cite the unpublished work of others, and copies of such correspondence must accompany the manuscript. Avoid the use of *et al.* in referring to authors: list all names.

NOTE: All titles in References section should be capitalized. See examples above.

NOTE: *Lipids* is now italicizing all mathematical variables. This may not have been clear in January 1995 "Guide to Authors."

AVAILABILITY OF PURIFIED OMEGA-3 FATTY ACIDS

Kilogram quantities of EPA and DHA ethyl ester capsules are available free of charge through the Fish Oil Test Materials Program, a joint effort of the National Oceanic and Atmospheric Administration and National Institutes of Health. These quality-assured and quality-controlled materials contain 94% EPA or 90% DHA. Ethyl esters of vegetable oils (olive, corn, and safflower) are available in capsule form as controls. Funded research projects studying the effect of

(continued on next page)

omega-3 fatty acids in health and disease, from all funding sources, are eligible to receive these capsules. For further information or to request a short application form, contact the Fish Oil Test Materials Program at 12501 Washington Ave., Rockville, MD 20852 (Phone: 301-443-9643; Fax: 301-594-0035).

CALENDAR

February 1996
Fourth International Symposium on Hyphenated Techniques in Chromatography (HTC 4), Feb. 6–9, 1996, Saint John's Conference Center, Bruges, Belgium. Five workshops (hands-on training as well as tutorials) will be held Feb. 4–5. (1) Large volume injection: the next step in capillary gas chromatography for trace analysis; (2) Pre- and postcolumn techniques in HPLC for improved analyte isolation, derivatization, cleanup, separation, and detection; (3) Isotopically labeled compounds in hyphenated GC techniques; (4) Analytical tools for GC–MS (advanced modes of ion-trap spectrometry); (5) Biomedical applications of GC–MS. Information: Dr. Robert Smits, Congress Secretariat, Ordibo bvba, L. Henninckstraat, B-2610 Wilrijk (Antwerpen), Belgium [Phone/Fax: 32 (3)828.89.61].

May 1996
XVIth Washington International Spring Symposium on Frontiers in Bioactive Lipids—'96, May 6–9, 1996, Washington, D.C., USA. Information: Dr. Jack Y. Vanderhoek, Chair—Symposium '96, Dept. of Biochemistry and Molecular Biology, The George Washington University, 2300 Eye St., N.W. RN 5530, Washington DC 20037-2337 USA (Phone: 202-994-2929; Fax: 202-994-8974; E-mail: jyvdh@gwis2.circ.gwu.edu.). Deadline for submission of abstracts: February 1, 1996.

July 1996
European Thrombosis Research Organisation and the International Society for the Study of Fatty Acids and Lipids in cooperation with Summer University of Maastricht, July 10–12, 1996, University of Maastricht, The Netherlands, presents "Lipids, Membranes and Thrombosis (fundamental basis of cardiovascular disease and its prevention)." Information: Gerard Hornstra, Dept. of Human Biology, P.O. Box 616, 6200MD Maastricht, The Netherlands (Phone: +31-43-88 16 25; Fax: +31-43-67 09 76; E-mail: G. Hornstra @ HB.RuLimburg.NL).

July–August 1997
Fourth International Congress on Essential Fatty Acids and Eicosanoids, July 27–August 1, 1997, Edinburgh, Scotland. Information: Secretariat, c/o Meeting Makers, 50 George St., Glasgow G1 1QE, Scotland, United Kingdom.
